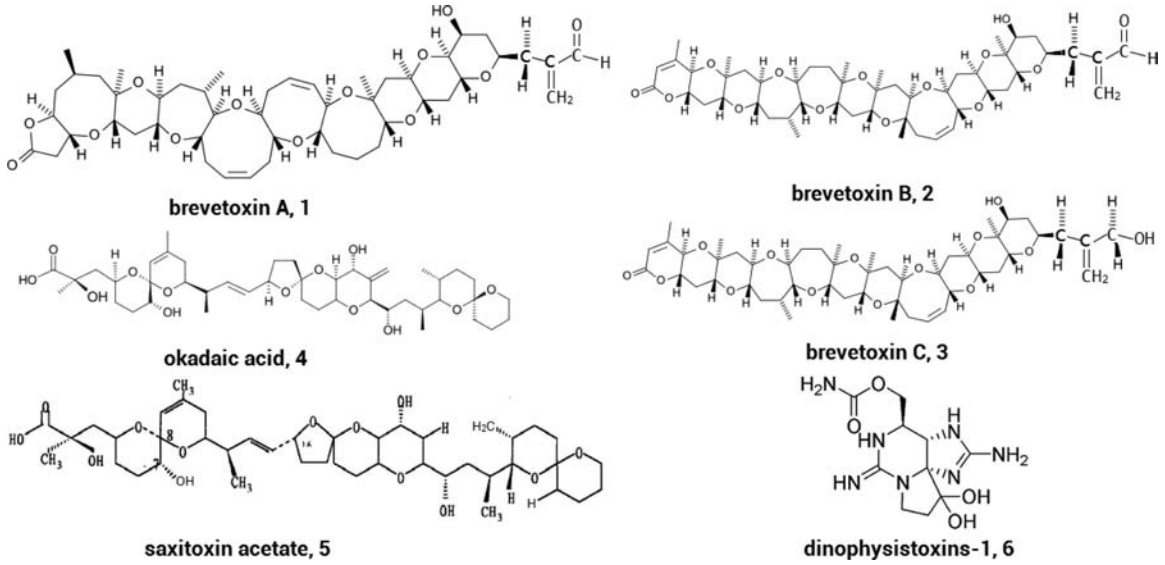

Figure 1. Chemical structures of different marine toxins: brevetoxin A, **1**; brevetoxin B, **2**; brevetoxin C, **3**; okadaic acid, **4**; saxitoxin acetate, **5**; dinophysistoxin-1, **6**.

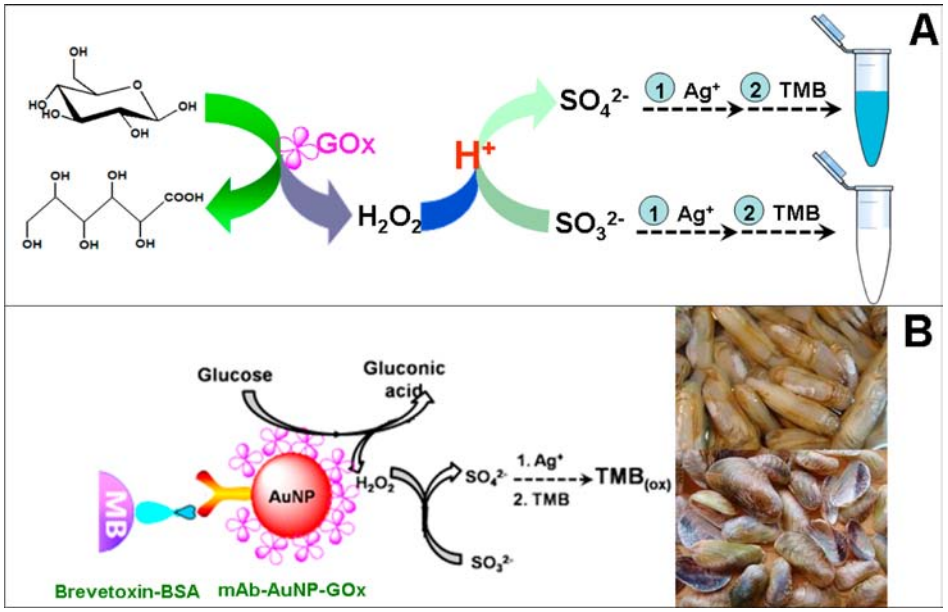

Figure 2. Schematic illustration of (A) GOx-mediated sulfite-to-sulfate chemical conversion for color development of the Ag(I)−TMB system and (B) Ag(I)−TMB-based colorimetric immunoassay by coupling with enzyme-controlled sulfite-to-sulfate chemical conversion.

MATERIALS AND METHODS

Safety. To avoid possible exposure and potential contamination, all tools and items in contact with marine toxins should be put into a 10 wt % bleach solution for 2−3 h before they are discarded because marine toxins are powerful hepatotoxins and carcinogens. Pure marine toxin standards were handled in a hood with great caution.

Materials and Reagent. Monoclonal mouse anti-brevetoxin antibody (mAb) and brevetoxin B−bovine serum albumin (brevetoxin−BSA) conjugate were gifted from the College of Chemistry of Soochow University (Suzhou, China). The standards including brevetoxins A, B, and C, **1**, **2**, and **3**, okadaic acid, **4**, saxitoxin acetate, **5**, and dinophysistoxin-1, **6** (Figure 1), were purchased from Express Technology Co., Ltd. (Beijing, China). GOx and $HAuCl_4{\cdot}4H_2O$ were purchased from Sigma-Aldrich (Shanghai, China). Silver nitrate ($AgNO_3$), TMB, and BSA were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Sodium sulfite (Na_2SO_3) and sodium sulfate (Na_2SO_4) were obtained from Fuchen Chemicals (Tianjin, China). The brevetoxin B ELISA kit was obtained from Abraxis LLC (Warminster, PA, USA). All other reagents were used as received without further purification. All water used was of Milli-Q ultrapure grade (Merck Millipore, Darmstadt, Germany). Different buffer solutions including pH 9.6 carbonate buffer, pH 7.0 phosphate-buffered saline (PBS, 0.5 mM), and pH 7.4 PBS were purchased from Sigma-Aldrich (Shanghai, China).

Food Samples and Extraction Procedure. A *Musculista senhousia* matrix (5.0 g, ground blank) was first milled with a small food mixer and then extracted with aqueous dimethyl sulfoxide (20 mL, 50%, w/v). After slight stirring for 60 min, the suspension was filtered with a nylon mesh (100 nm), no. 1 filter, and a GF/B filter (Whatman, Dassel, Germany) in turn. The extract color was a slight opalescent yellow. Finally, the solution for the calibration curve was prepared by spiking brevetoxin B standards into the diluted extract with various volumes.

Preparation of Brevetoxin−BSA-Conjugated Magnetic Bead and mAb/GOx-Labeled Gold Nanoparticle. Bevetoxin−BSA-

(Insets) Corresponding photographs.

conjugated magnetic bead was prepared similarly to our previous study.[27] Briefly, 3-aminopropyltriethoxysilane (30 μL, 98 wt %) was initially added into 1.0 mL of anhydrous ethanol containing 50 mg of magnetic beads (~100 nm) (Chemical GmbH, Berlin, Germany) for reaction for 6 h at room temperature under gentle shaking on a shaker. Following that, the aminated magnetic beads, collected by an external magnet, were suspended in 1.0 mL of 15 wt % glutaraldehyde and reacted for another 6 h. Afterward, the precipitate obtained by magnetic separation was placed into brevetoxin−BSA carbonate buffer (1.0 mL, 100 μg/mL, pH 9.6) and incubated for 6 h under the same conditions. Finally, the as-prepared brevetoxin−BSA-conjugated magnetic beads (brevetoxin−magnetic bead) were magnetically separated and stored in 1.0 mL of pH 7.4 PBS containing 1.0 wt % BSA and 0.1 wt % sodium azide for further use.

Gold nanoparticle (AuNP, ~16 nm) was synthesized and functionalized with mAb/GOx according to our previous work.[27] One microliter of 1.0 mg/mL mAb and 10 μL of 1.0 mg/mL GOx were simultaneously added into 1.0 mL of 0.24 μM gold colloids (pH 9.0). The resulting mixture was incubated for 12 h at 4 °C with slight shaking. Following that, the pellet (i.e., mAb−AuNP−GOx) obtained by centrifugation (14000 rpm, 20 min, 4 °C) was suspended in 1.0 mL of pH 7.4 PBS containing 1.0 wt % BSA and 0.1 wt % sodium azide.

Monitoring of GOx Activity Based on Sulfite-to-Sulfate Conversion with Ag(I)−TMB System. Figure 2A displays the detection principle of GOx activity based on sulfite-to-sulfate conversion with the Ag(I)−TMB system. The assay was carried out as follows: (i) 10 μL of GOx with different concentrations (from 0 to 500 μg/mL) was added into 50 μL of 0.5 mM PBS (pH 7.0) containing 4.0 mM glucose and incubated for 30 min at 37 °C; (ii) 20 μL of 2.0 mM nitric acid and 50 μL of 1.0 mM sodium sulfite were injected into the resulting solution and reacted for 2 min at room temperature; (iii) 50 μL of 2.0 mM silver nitrate was added into the mixture and reacted for 1 min at room temperature; and (iv) 100 μL of 1.0 mM TMB substrate solution (ethanol/buffer, 1:9, v/v) in pH 4.0 citrate acid−disodium hydrogen phosphate buffer was added and incubated for 30 min at room temperature. The resultant mixture was monitored on an SH-1000 microplate reader (Corona Electric Co., Ltd., Japan), and the absorbance was recorded at 652 nm.

Colorimetric Immunoassay toward Brevetoxin B Based on Enzyme-Controlled Sulfite-to-Sulfate Chemical Conversion with the Ag(I)−TMB System. Figure 2B gives the monitoring process of colorimetric immunoassay toward target brevetoxin B based on enzyme-controlled sulfite-to-sulfate chemical conversion with the Ag(I)−TMB system. Initially, 25 μL of brevetoxin B standard/sample and 50 μL of GOx−AuNP−mAb suspension ($C_{[Au]} \approx 0.24$ μM) were added in sequence to 25 μL of brevetoxin−magnetic bead suspension (6.0 mg/mL) in a 200 μL PCR tube and incubated for 60 min at 37 °C with gentle shaking. After that, the resulting suspension was collected by using an external cylindrical magnet, 10 mm in diameter and 10 mm in depth, to produce an inhomogeneous magnetic density, 0.2 T at the surface (Shanghai Da Xue Electromagnetic Devices Co., Ltd., China), and washed with the washing buffer. Fifty microliters of 4.0 mM glucose (pH 7.0, PBS) was added to the precipitate and incubated for 30 min at 37 °C. Following that, 20 μL of 2.0 mM nitric acid, 50 μL of 1.0 mM sodium sulfite, and 50 μL of 2.0 mM silver nitrate were injected into the mixture in turn as before. Finally, 100 μL of 1.0 mM TMB substrate solution was added and incubated for 30 min for color development. Meanwhile, the absorbance was registered and recorded at 652 nm on a plate reader.

RESULTS AND DISCUSSION

Design Strategy of Ag(I)−TMB System Based on Sulfite-to-Sulfate Chemical Conversion. To develop a user-friendly and sensitive colorimetric immunoassay, a stable and highly efficient color progression would be advantageous.

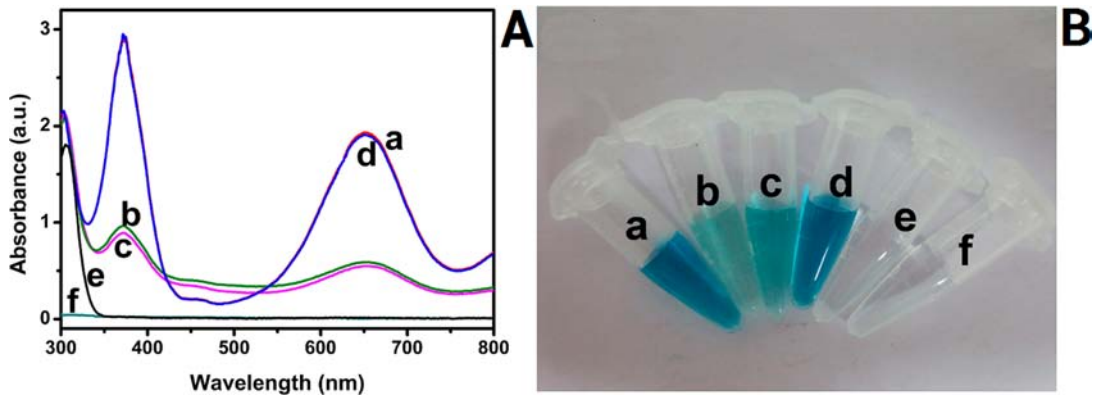

Figure 4. (A) UV−vis absorption spectra of (a) glucose + GOx + sulfite + silver(I) + TMB, (b) glucose + sulfite + silver(I) + TMB, (c) GOx + sulfite + silver(I) + TMB, (d) glucose + GOx + silver(I) + TMB, (e) glucose + GOx + sulfite + silver(I), and (f) glucose + GOx + sulfite + TMB, respectively; (B) corresponding photographs.

Typically, the peroxidase-based H_2O_2−TMB system has been widely used for ELISA development. However, most systems involve low sensitivity or poor visible color and thus are unfavorable for routine use. Recent papers have shown that TMB could be used as a selective and sensitive indicator for in situ quantification of Ag(I).[30,31] Addition of TMB into an Ag(I) aqueous solution could give rise to the oxidized form of TMB and Ag(0), thereby inducing a blue color and a strong characteristic absorption peak centered at 652 nm. As is well-known, silver sulfite is insoluble in water, whereas silver sulfate is slightly soluble. However, the sulfite can be oxidized to sulfate through hydrogen peroxide under acidic condition.[32] Thus, the sulfite can be used as an inhibitor of silver ion to control and tailor the color development of TMB at the visualization stage upon hydrogen peroxide introduction. Typically, hydrogen peroxide can be generated by glucose oxidase in the catalytic oxidation of β-D-glucose. In this case, H_2O_2-controlled chemical conversion of sulfite to sulfate can be utilized for quantitative monitoring of GOx activity in the presence of glucose. Figure 3A shows the UV−vis adsorption spectra of TMB solution in the absence and presence of 2.0 mM Ag(I). No characteristic absorption peak from 800 to 300 nm was observed at pure TMB solution (curve a). In contrast, two strong absorption peaks were simultaneously achieved after interaction of 1.0 mM TMB with 2.0 mM Ag(I) (curve b), which was ascribed to the oxidation of TMB by Ag(I). Moreover, the colorless TMB solution (Figure 3A, photograph a) exhibited an obvious blue color change in the presence of Ag(I) (Figure 3A, photograph b). Furthermore, we also investigated the dynamic response curve (absorbance vs reaction time) between TMB and Ag(I) (Figure 3A, left inset). The absorbance intensity rapidly increased with the increasing reaction time and tended to level off after 5 min. To ensure adequate reaction between Ag(I) and TMB, 30 min was used for the color development in this work. These results revealed that Ag(I) could oxidize TMB to the oxidized TMB to trigger a blue color and an absorption peak at 652 nm.

The second concern in our design was whether the sulfite-to-sulfate conversion could induce the progression of the Ag(I)−TMB system. To determine this point, sulfite and sulfate alone (2.0 mM) were added into the Ag(I)−TMB system, respectively. Ag(I) was initially incubated with sulfite/sulfate for 30 min at room temperature, and then TMB was added into the resulting solution. The resulting mixture was monitored using UV−vis absorption spectroscopy (Figure 3B). As seen from curve b, introduction of sulfate into the system did not appreciably change the characteristic peak or absorbance in comparison with the Ag(I)−TMB system alone (curve c). When the sulfite was added into the Ag(I)−TMB system, significantly, the absorbance largely decreased (curve a). This was attributed to the fact that the added sulfite initially reacted with Ag(I) to form the insoluble silver sulfite (Ag_2SO_3) and hindered the interaction of Ag(I) with TMB. The results revealed that the sulfite could hinder the progression of the Ag(I)−TMB system, whereas the sulfate had almost no effect on the colorimetric assay of the system. Therefore, the chemical conversion of sulfite to sulfate could trigger the continuance of the Ag(I)−TMB system with the colored product in the presence of sulfite.

The third important question arises as to whether hydrogen peroxide (H_2O_2) could cause the chemical conversion between sulfite and sulfate to complement the Ag(I)−TMB system. To demonstrate this, 50 μL of 1.0 mM sodium sulfite, 50 μL of 2.0 mM silver nitrate, and 100 μL of 1.0 mM TMB were added into acidic solution containing 1.0 mM H_2O_2 in turn. As shown from curve a in Figure 3C, the characteristic absorption peaks were almost the same as that of the Ag(I)−TMB system alone (Figure 3A, curve b). When 50 μL of 2.0 mM silver nitrate and 100 μL of 1.0 mM TMB were injected in sequence into 50 μL of 1.0 mM sodium sulfite, however, almost no absorption peaks were observed (Figure 3C, curve b). Meanwhile, the resulting mixture changed from blue to colorless (Figure 3C, insets). On the basis of the results in Figure 3, we deduced that the added H_2O_2 could convert the sulfite into the sulfate and relieve the inhibition effect of sulfite toward Ag(I), thereby resulting in increasing absorbance and colorimetric progression. Usually, H_2O_2 can be produced through glucose oxidase through the catalytic oxidation of glucose in the presence of oxygen. Therefore, the designed system could be utilized for monitoring the activity of GOx.

Control Tests for Ag(I)−TMB System with Sulfite-to-Sulfate Conversion. To further investigate that the Ag(I)−TMB system could be realized by GOx-triggered production of H_2O_2 accompanying the chemical conversion between sulfite and sulfate, several control tests were carried out under different conditions (Figure 4). As indicated from curve a, two strong absorption peaks at 652 and 372 nm appeared when glucose, sulfite, Ag(I), and TMB were added into GOx solution in sequence. Moreover, the absorbance at 652 nm increased with increasing GOx concentration. The reason might be most

J. Agric. Food Chem. 2015, 63, 1982−1989

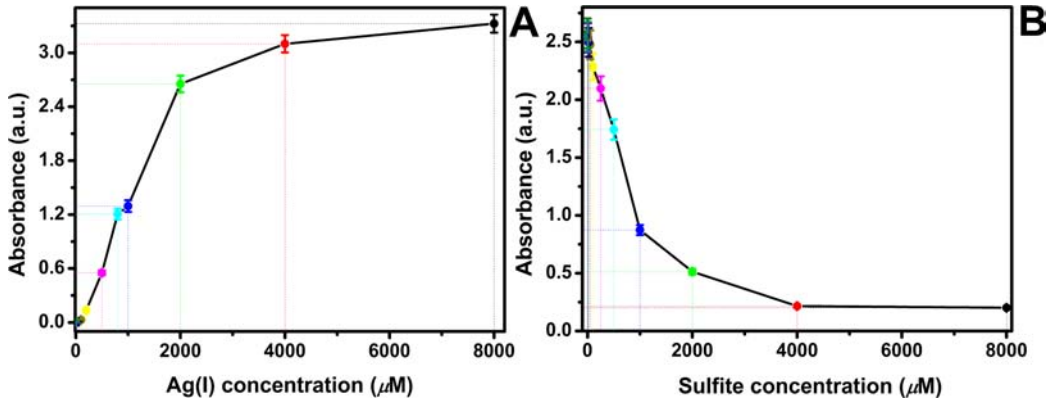

Figure 5. Effects of (A) silver(I) concentration and (B) sulfite concentration on the absorbance of the Ag(I)−TMB system by coupling with the sulfite-to-sulfate chemical conversion (1.0 mM TMB used in the case).

likely a consequence of the fact that Ag(I) could be released through the oxidizing reaction of enzymatic product toward sulfite to oxidize TMB into $TMB_{(ox)}$. When GOx (curve b) or glucose (curve c) was absent from the system, however, the absorbance greatly decreased and the color became light blue (Figure 4B, tubes b and c). The results indicated that glucose or GOx alone did not eliminate the inhibition effect of sulfite toward the Ag(I)−TMB system. However, the inhibition effect of the Ag(I)−TMB system could be relieved by sulfite regardless of the presence of glucose and GOx (Figure 4A, curve d, and Figure 4B, tube d). For comparison, we also monitored the effect of Ag(I) and TMB toward the designed system. As seen from curves e and f (Figure 4A), no absorption peak was achieved in the absence of Ag(I) or TMB even if glucose/GOx/sulfite simultaneously existed in the system. Furthermore, the resultant solution was colorless (Figure 4B, tubes e and f). These results further revealed that (i) the visible color mainly originated from the interaction between Ag(I) and TMB; (ii) sulfite could hinder the interaction of Ag(I) with TMB; (iii) H_2O_2 could oxidize sulfite to sulfate, which could not hinder the interaction between Ag(I) and TMB; and (iv) the colorimetric assay could be controlled by changing the GOx level. Such a cascade reaction could be used for monitoring enzymatic activity, which could be employed for colorimetric immunoassay development based on the change in the visible color by conjugating GOx with detection antibody.

Optimization of Assay Conditions. To achieve a good colorimetric immunoassay with high sensitivity for subsequent work, one important precondition was that the Ag(I)−TMB system should be highly efficient toward the sulfite-to-sulfate chemical conversion in the presence of low-concentration GOx. Actually, the system mainly consisted of three steps: (i) the added glucose was oxidized to gluconic acid and H_2O_2 by GOx; (ii) the produced H_2O_2 catalytically oxidized sulfite to sulfate under the acidic condition; and (iii) the generated sulfate triggered the colored product relative to the Ag(I)−TMB system. During this process, the sulfite (SO_3^{2-}) was used as an inhibitor of Ag(I) to hinder the color development of TMB owing to the formation of insoluble silver sulfite, which could be eliminated through the sulfate (SO_4^{2-}). To adequately complement the catalytic efficiency of GOx, the concentrations of sulfite, Ag(I), and TMB should be optimized. First, we investigated the effect of Ag(I) on the Ag(I)−TMB system. In this case, 1.0 mM TMB was used for color development on the basis of our previous work.[27] As shown in Figure 5A, the absorbance initially rapidly increased with increasing Ag(I) concentration and then tended to slow after 2.0 mM. To decrease the background signal and avoid excessive Ag(I), 2.0 mM Ag(I) was used for development of the colorimetric assay.

Normally, the free Ag(I) in the solution can trigger TMB to promote the change in the absorbance and color development. However, the colorimetric assay can be hindered in the presence of sulfite. By using 1.0 mM TMB and 2 mM Ag(I), we also investigated the effect of sulfite concentration on the colorimetric assay. As seen from Figure 5B, the absorbance decreased with the increase in sulfite concentration and reached a minimum value at 4.0 mM. However, we found that the absorbance (i.e., the slope for the plots) changed very quickly within the low-concentration range of 0−1.0 mM, suggesting that a slight decrease in the sulfite level induced a big increase in the absorbance. Considering the subsequent reaction between sulfite and H_2O_2 with high sensitivity, the high-concentration sulfite should not be preferable. Therefore, 1.0 mM sulfite was chosen as the inhibitor of Ag(I) to hinder color development in this work.

Monitoring for the Ag(I)−TMB System toward H_2O_2 and GOx. As is well-known, H_2O_2 can oxidize sulfite to sulfate under acidic conditions. To achieve a high sensitivity for development of the subsequent colorimetric immunoassay, the determination of low-concentration H_2O_2 with the system would be valuable. For this purpose, the Ag(I)−TMB system was utilized for the detection of H_2O_2 by using sulfite as the inhibitor. Experimental results indicated that the Ag(I)−TMB system could be used for monitoring of H_2O_2 concentration with a wide linear range (10 μM−1.0 mM) and a low detection limit (2.5 μM). The linear regression equation could be fitted to $y = 0.0016 \times C_{[H2O2]} + 0.8218$ (μM, $R^2 = 0.9976$). Furthermore, we also investigated the Ag(I)−TMB system for the detection of GOx by using glucose as the enzymatic substrate. H_2O_2 was obtained through GOx by the catalytic oxidation of glucose. The absorbance linearly increased with increasing GOx concentration within the range of 0.5−20 μg/mL. A detection limit of 0.1 μg/mL GOx could be achieved at the $3s_{blank}$ criterion. The linear regression equation could be fitted to $y = 0.0531 \times C_{[GOx]} + 0.7354$ (μg/mL, $R^2 = 0.9982$). Such a low detection limit provided a precondition for the development of a high-sensitivity colorimetric immunoassay.

Analytical Performance of the Ag(I)−TMB-Based Colorimetric Immunoassay. Figure 2 shows the fabrication process of the colorimetric immunoassay for the detection of brevetoxin B, used as a model, based on the Ag(I)−TMB system accompanying enzyme-triggered sulfite-to-sulfate chem-

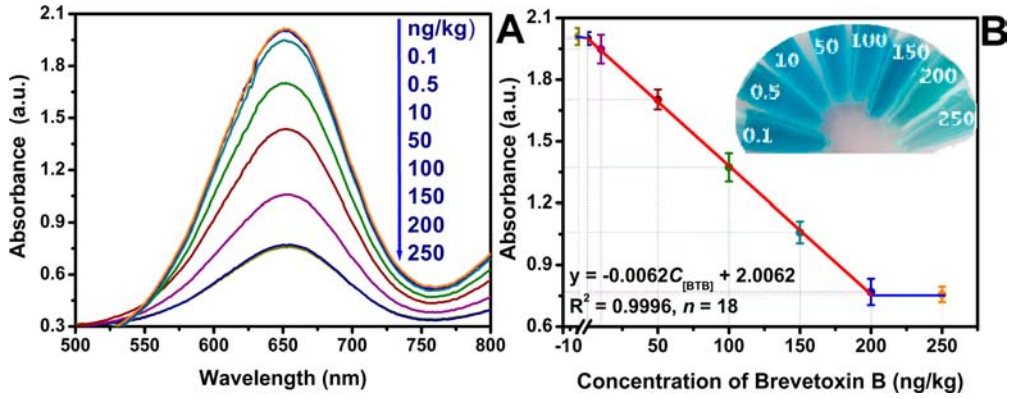

Figure 6. (A) Absorbance intensity; (B) calibration plots of Ag(I)−TMB-based colorimetric immunoassay by coupling with enzyme-mediated sulfite-to-sulfate chemical conversion toward different concentrations of BTB standards. (Inset) Corresponding photographs.

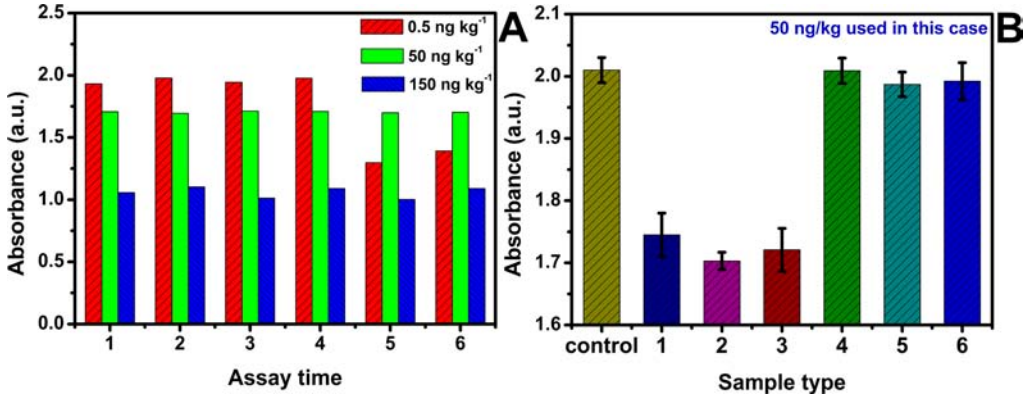

Figure 7. (A) Reproducibility; (B) specificity of the Ag(I)−TMB-based colorimetric immunoassay by coupling with enzyme-mediated sulfite-to-sulfate chemical conversion.

ical conversion. The assay was carried out on brevetoxin−magnetic bead by using mAb−AuNP−GOx as the detection antibody with a competitive-type immunoassay format. Brevetoxin−magnetic beads were prepared by covalent conjugation of brevetoxin−BSA onto the aminated magnetic bead with glutaraldehyde, whereas mAb−AuNP−GOx was synthesized on the basis of the interaction between gold nanoparticles and proteins. In the presence of target brevetoxin B, the analyte competed with the immobilized brevetoxin−BSA on magnetic beads for the labeled anti-brevetoxin B antibody on the AuNP. Accompanying the immunocomplex, the GOx catalyzed glucose into gluconic acid and H_2O_2, and the produced H_2O_2 could oxidize sulfite to sulfate under acidic condition, which could make Ag(I) oxidize TMB to TMB_{ox}, thus resulting in the change of the absorbance. As shown from Figure 6A, the absorbance decreased with increasing brevetoxin B concentration in the sample. A good linear dependence between the absorbance (au) and brevetoxin B level (ng/kg) could be acquired in the dynamic range from 0.5 to 200 ng/kg. The linear regression equation could be fitted to $y = -0.0062 \times C_{[\text{brevetoxin B}]} + 2.0062$ (ng/kg, $R^2 = 0.9996$, $n = 18$). The detection limit (LOD) was estimated to be 0.1 ng/kg (ppt) at the $3s_{blank}$ criterion, whereas the limit of quantification (LOQ) was calculated to be 0.3 ng/kg according to our previous method[29] (Figure 6B). To further clarify the merits of Ag(I)−TMB-based colorimetric immunoassay, the obtained LOD was compared with commercialized brevetoxin ELISA kits obtained from Abraxis LLC (LOD = 50 ng/kg) and other detection schemes (e.g., capillary electrophoresis-based immunoassay = 100 ng/kg,[33] competitive ELISA = 25 mg/kg,[34] LC-MS/MS = 12 μg/kg,[35] immunodipstick assay = 100 ng/kg,[36] glucometer-based immunoassay = 10 ng/kg).[37] Due to the legal limit of brevetoxin (≤80 μg of toxin per 100 g of shellfish tissue),[38,39] the Ag(I)−TMB-based colorimetric immunoassay could completely meet the requirement of brevetoxin B monitoring in seafood.

Next, we investigated the reproducibility and precision of the as-prepared brevetoxin−magnetic bead and mAb−AuNP−GOx by monitoring three brevetoxin B concentrations including 0.5, 50, and 150 ng/kg, respectively. Each sample concentration was determined six times. As seen from Figure 7A, the relative standard deviations (RSD) were 9.8, 6.9, and 7.5% ($n = 6$) for the above-mentioned target brevetoxin B, respectively. Therefore, the reproducibility and precision of the Ag(I)−TMB-based colorimetric immunoassay were acceptable.

Furthermore, the specificity and selectivity of the Ag(I)−TMB-based colorimetric immunoassay were also studied by spiking brevetoxin A, **1** (50 ng/kg), brevetoxin B, **2** (50 ng/kg), brevetoxin C, **3** (50 ng/kg), okadaic acid, **4** (50 ng/kg), saxitoxin acetate, **5** (50 ng/kg), and dinophysistoxin-1, **6** (50 ng/kg), into blank *M. senhousia* matrix. As shown in Figure 7B, the as-prepared brevetoxin−magnetic bead and mAb−AuNP−GOx displayed high cross-reactivity toward brevetoxins A and C, whereas no false compliant results were achieved for okadaic acid, saxitoxin acetate, and dinophysistoxin-1. The reason might be the fact that brevetoxins A and C had chemical structures similar to that of brevetoxin B.

Monitoring of *M. senhousia* Samples. The feasibility of applying the as-prepared brevetoxin−magnetic bead and mAb−AuNP−GOx to evaluate brevetoxin levels in a complex matrix was monitored. Initially, we spiked brevetoxin B standards at random concentrations into *M. senhousia* homogenate, followed by centrifugation and extraction. Finally, these samples were assayed by the Ag(I)−TMB-based colorimetric immunoassay and the commercialized Abraxis brevetoxin B ELISA kit, respectively. The content of brevetoxin B in these samples obtained by Ag(I)−TMB-based colorimetric immunoassay was calculated according to the above-fitted regression equation ($y = -0.0062 \times C_{[\text{brevetoxin B}]} + 2.0062$). The results are listed in Table 1. As seen from this table, all RSD values were <13%.

[a]Each sample was determined in triplicate, and the high-concentration BTB sample was assayed with an appropriate dilution. The linear regression equation for these usable mean data between two methods are as follows: $y = 1.024x - 3.2806$ ($R^2 = 0.9754$, $n = 30$; x axis, by Ag(I)−TMB-based colorimetric immunoassay; y axis, by BTB ELISA kit. [b]RSD for each sample was calculated according to the mean values obtained by two methods, and the statistical analysis method was described in our previous work.[40] [c]Not detected because the minimum concentration of BTB detectable by ELISA kit is 50 ng/kg.

Moreover, the slope and intercept of the regression equation between two methods ($y = 1.024x - 3.2806$) were close to ideal, 1 and 0, respectively, indicating these two methods had a good correlation for the determination of brevetoxin B in real samples.

In the present work, we for the first time systematically demonstrate the unconventional application of enzyme-triggered sulfite-to-sulfate chemical conversion in the colorimetric immunoassay through coupling with the Ag(I)−TMB system. During the signal transduction cascade, the inhibition effect of sulfite toward Ag(I) could be efficiently weakened by enzyme-catalyzed product (H_2O_2), thereby resulting in the development of the visible color and the change in the absorbance. Compared with traditional enzyme-based colorimetric immunoassays, our design should be feasible, sensitive, and specific. The system was capable of continuously carrying out all steps in ∼2.5 h for one sample, including incubation, washing, enzymatic reaction, and measurement. Although the system mainly focuses on target brevetoxin B, it can be easily extended to determine other small molecular biotoxins or low-abundant proteins. Importantly, the nanoparticle-based colorimetric immunoassay does not require sophisticated instrumentations and is well-suited for high-throughput biomedical sensing and application for other areas.

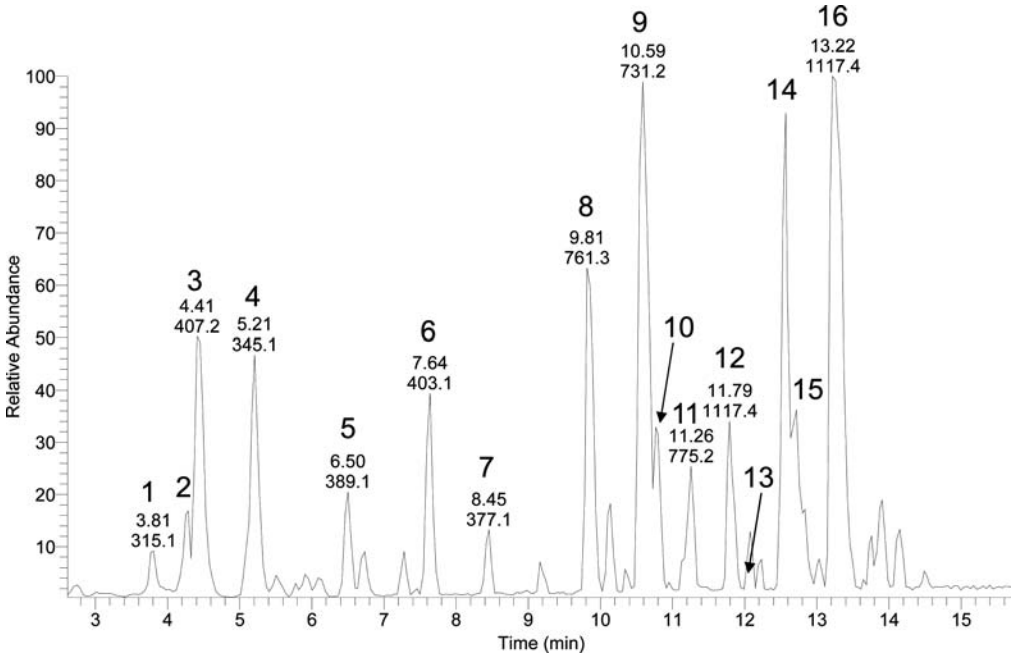

Figure 1. Negative ion chromatogram from LC−MS/MS analysis of an 80% aqueous methanol extract of Chemlali olive stones.

were purchased from Fisher Scientific (U.K.). Double distilled water used in the LC mobile phases was produced in-house. DPPH (2, 2-Diphenyl-1-picrylhydrazyl), 2,6-di*tert*-butyl-4-hydroxy-boxylic acid (BHT), 2,2′-azinobis (3-ethylbenzothiazoline-6-sulfonate) (ABTS), and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), were purchased from Sigma-Aldrich (Chemie Gmbh, Steinhein, Germany). Several phenolic standards were used for quantification purposes, namely hydroxytyrosol, tyrosol, nuezhenide, and oleuropein were supplied by Sigma-Aldrich (Chemie Gmbh, Steinhein, Germany).

Sample Preparation and Extraction. *Olea europaea* L. fruits (Chemlali cultivar) were obtained from in olive orchard in Sfax, Tunisia. Samples were collected in February 2012, when the black olives mature. Fruit (1000 g) were sampled randomly from the trees, olive stones (300 g) were prepared from fresh olives. The pulps were removed and the stones brushed. The stones were then abundantly rinsed by distilled water three times and dried at ambient temperature. After that the stones were crashed using a stainless steel hammer. The powder obtained was stored at −20 °C until analysis. Voucher material (ABM 2012) has been deposited at the laboratory.

Sample Extraction. The powder obtained (200 g) was extracted according to the method of Bouaziz et al.[4] An aqueous 80% methanol extract was made by adding 250 mL to 100 g of powder. This was left to stand under agitation for 24 h at 4 °C in the dark. Subsequently, the solution was filtered using GF/F filter paper and washed with 100 mL hexane, to remove oil. The extract was concentrated by evaporation to dryness at 40 °C and the residue obtained was stored in glass vials at 0 °C in the dark until LC−MS analysis. This extract was given the reference code BI-21470. The sample was rehydrated with 80% aqueous methanol and a 1 mL aliquot was placed in an LC−MS vial and 5 μL were injected onto the LC−MS.

LC−MS Analysis. LC−MS analyses were performed as described by Kite et al.,[21] on a Thermo Scientific System consisting of an Accela U-HPLC unit with a photodiode array detector and an LTQ Orbitrap XL mass spectrometer fitted with an electrospray source. Chromatography was performed on 5 μL sample injections onto a 150 × 3 mm^2 i.d., 3 um, Luna C18(2) column (Phenomenex) using a 400 μL/min linear mobile phase gradient of methanol/water/acetonitrile +1% formic acid changing from 0:90:10 to 90:0:10 over 20 min followed by an isocratic phase for 5 min and then a column wash phase and equilibrium of column for 3 min before the next injection. The ESI source of the mass spectrometer was operated in both positive and negative modes under the recommended manufacturers' conditions for the mobile phase parameters. The orbitrap mass analyzer was set to scan in range m/z 200−2000 at 30 000 resolutions in negative polarity, while the linear ion-trap analyzer performed MS^n analyses on the most abundant ions in both polarities using an ion isolation window of ±2 m/z and relative collision energy of 35%.

High-Performance Liquid Chromatography (HPLC). Quantification of individual phenolic compounds was carried out by HPLC analysis. It was performed on a Shimadzu apparatus composed of an LC-10ATvp pump and an SPD-10Avp detector. The columns used to analyze monomeric phenols were, respectively, a C-18 (4.6 × 250 mm^2) Shim-pack VP-ODS and a C-8 (4.6 × 250 mm^2) Shim-pack CLC. The temperature was maintained at 40 °C. The mobile phase was 0.2% acetic acid (pH 3.1) in water (A)/methanol (B) at a flow rate of 1.5 mL/min. The total running time was 55 min, and the gradient changed as follows: 95% A/5% B for 2 min, 75% A/25% B in 8 min, 60% A/40% B in 10 min, 50% A/50% B in 10 min, and 0% A/100% B in 10 min, maintained for 5 min, returned to initial conditions in 10 min; the total running time was 55 min.

Determination of Antioxidant Activity. *DPPH Radical Scavenging Assay.* The capacity to scavenge the free radical 2, 2-diphenyl-1-picrylhydrazyl (DPPH) was monitored according to the method described by Bouaziz et al.[4] The extract solution (0.25 mL) was mixed with 0.5 mL of methanolic solution containing DPPH radicals (6×10^{-6} M). The mixture was shaken vigorously and left to stand for 30 min at room temperature in the dark (until stable absorbance values were obtained). The reduction of the DPPH-radical was measured by continuous monitoring of the absorption decrease at 517 nm. DPPH scavenging effect was calculated as the percentage of DPPH discoloration using the following equation: % scavenging effect = $[(A_{DPPH} - A_E)/A_{DPPH}] \times 100$, where A_E is the absorbance of the solution when the sample extract is added at a particular level, and A_{DPPH} is the absorbance of the DPPH solution. The extract concentration providing 50% inhibition (IC_{50}) was calculated from the graph of scavenging effect percentage against extract concentration in the solution.

ABTS Assay. The free-radical scavenging capacity was measured using the ABTS decoloration method described by Re et al.[22] with some modifications. Briefly, ABTS was dissolved in water to get a 7 mM concentration. ABTS radical ($ABTS^{\cdot+}$) was produced by reacting this stock solution with a 2.45 mM $K_2S_2O_8$ solution and allowing the mixture to stand in the dark at room temperature for 12 to 16 h before use. The $ABTS^{\cdot+}$ solution was diluted with methanol to an absorbance

[a]See text for assignment criteria.

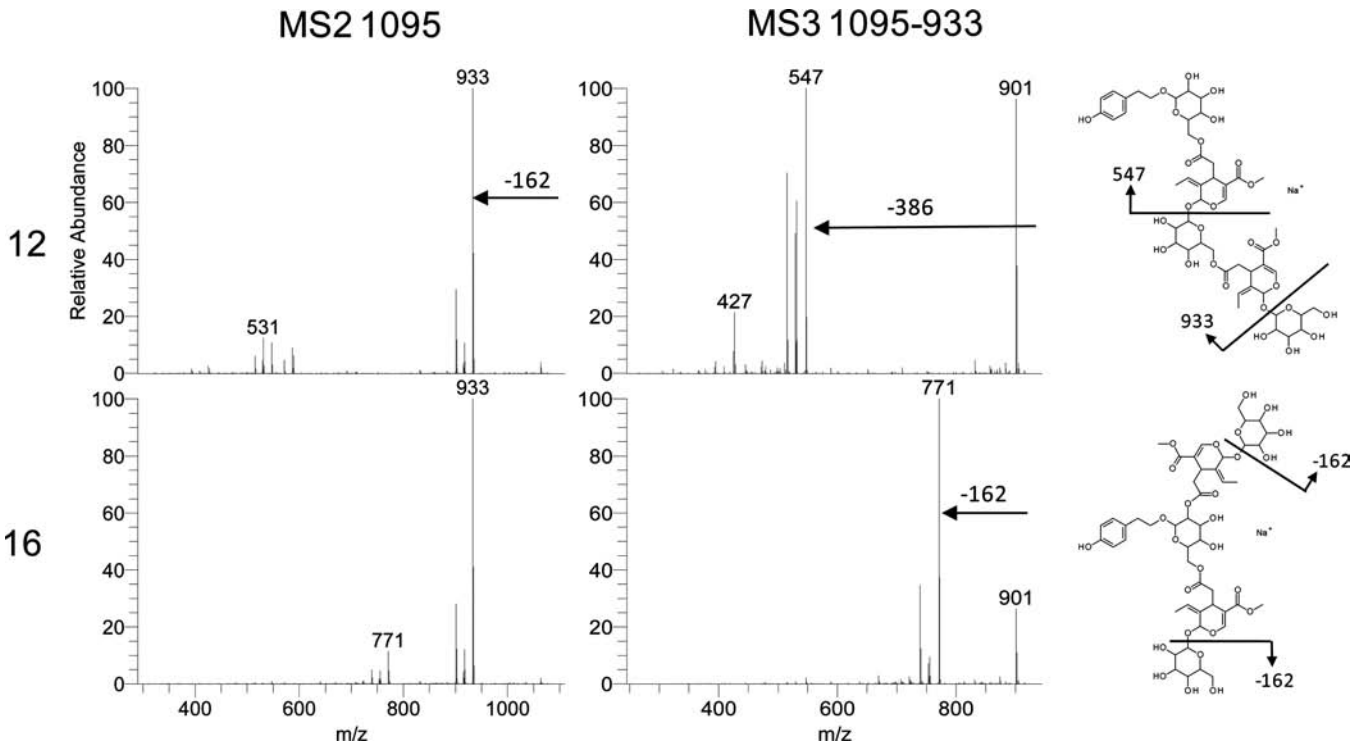

Figure 2. MS^n spectra of the sodiated molecules (m/z 1095) of compounds **12** and **16** rationalised against two possible condensation products of nuezhenide and 11-methyloleoside.

of 0.70 ± 0.02 at 730 nm. After the addition of 100 μL of sample, methanol as a blank, or Trolox standard to 2.9 mL of diluted $ABTS^{\cdot+}$ solution, absorbance readings were taken after 6 min. Methanolic solutions of known concentrations of Trolox were used for calibration. This standard curve was linear between 0.2 and 0.8 mM of Trolox (y = 0.6792x). The results were expressed in Trolox equivalent antioxidant capacity (TEAC; mM).

RESULTS AND DISCUSSION

Compound Assignment by LC−MS. LC−MS analysis of an aqueous 80% methanol extract (BI-21470) of the stone of *Olea europea* Chemali revealed the presence of numerous compounds, of which 12 of the main components were given tentative assignments (Figure 1; Table 1).

Compounds **9** and **16** produced the largest chromatographic peaks, both with photodiode array detection and negative ion mass spectrometry. Compound **9** generated a formate adduct, the formula of which was in accordance with the formate adduct of nuezhenide reported as the predominant phenol in olive stones.[12] The assignment of **9** to nuezhenide was supported by serial MS (m/z 731 → 685) that generated

DOI: 10.1021/acs.jafc.5b00353
J. Agric. Food Chem. 2015, 63, 1990−1995

fragments corresponding to the deprotonated molecules of the two subunits of nuezhenide, namely oleoside 11-methyl ester (at *m/z* 403) and 2-(4-hyroxyphenyl)ethanol 1-*O*-glucoside (= tyrosol 1-*O*-glucoside, salidroside, at *m/z* 299), and the spectrum matches that shown for nuezhenide by Silva et al.[18]

Compound **16**, of which an isomer was also present (**12**), generated a formate adduct (at *m/z* 1117) and its accurate mass suggested a formula that was greater than **9** by $C_{17}H_{22}O_{10}$, equivalent to the dehydrated residue of oleoside 11-methyl ester (386 Da). Therefore, **12** and **16** are possibly nuezhenide (**9**) with an additional oleoside 11-methyl ester moiety, as also concluded by Silva et al.[18] and as in oleonuezhenide and *iso*-oleonuezhenide reported from species of *Ligustrum*.[23,24] As also found by Silva et al.,[18] support of these assignments was difficult to obtain from the serial MS of the formate adducts of **12** or **16** (as neither generated high abundance ions), but in positive mode, sodiated **12** and **16** (at *m/z* 1095) lost 162 Da (hexosyl) upon MS2 to give a fragment at *m/z* 933 which upon MS^3 analysis lost a further 162 Da (hexosyl) in **16** and 386 Da in **12** (Figure 2). These data are in accordance with **16** being a condensation product of nuezhenide and oleoside 11-methyl ester with two terminal glucose moieties (as in oleonuezhenide) and **12** being a condensation product with one terminal glucose moiety (as in *iso*-oleonuezhenide). The subunits of nuezhenide (**9**), namely tyrosol 1-*O*-glucoside and oleoside 11-methyl ester, also occurred separately in the extract as accurate mass data assigned the corresponding formulas to **4** and **6**, respectively. Accordingly, **6** showed loss of 180 Da (glucose) from the deprotonated molecule while **4** showed loss of 120 Da (dehydrated tyrosol). Although the positions of glycosylation and hydroxylation of **4** cannot be determined, it seems most likely that **4** is tyrosol 1-*O*-glucoside (salidroside), given that this isomer occurs as the subunit of nuezhenide and salidroside is reported from olives.

Oleoside was assigned to peak **5**, eluting before its 11-methyl ester (**6**). This is the first report of oleoside from olive stones. No oleoside analogue of nuezhenide (**9**) could be detected, but a component (**11**) was present with a molecular formula suggesting it was a condensation product of oleoside and oleoside 11-methyl ester. The deprotonated molecule of **11** (at *m/z* 775) showed losses of 404 (oleoside 11-methyl ester) and 372 (dehydrated oleoside).

The molecular formulas of two isomers, **8** and **10**, suggested they could be methoxy derivatives of nuezhenide. The MS2 spectrum of deprotonated **10** showed a fragment at *m/z* 329, 30 Da greater than the tyrosol-1-*O*-glucosyl fragment in **9** suggesting the methoxy group was located on the phenylethanoid glycoside moiety. In the MS2 spectrum of **8**, the corresponding fragment was at *m/z* 315, but the deprotonated molecule did show direct losses of 168 Da (i.e., 30 greater than tyrosol) and 162 (hexosyl); the latter data again suggesting the methoxy group was located on the phenylethanoid glycoside moiety.

Only one very minor peak gave the deprotonated ion expected for oleuropein (**13**), a major phenolic component of olive oil.[25] Two other minor components were phenylethanoid glycosides, **1** and **2**. Compound **1** contained one more oxygen atom than **4** and the deprotonated molecule lost 162 (hexosyl) upon MS^2, so **1** is likely to be hydroxytyrosol glucoside. Three isomers of hydroxytyrosol glucoside have been reported in species of *Olea*.[26−28] Bianco et al.[29] found hydroxytyrosol-4′-*O*-glucoside to be the most abundant isomer in olive pulp, while other authors have identified hydroxytyrosol-1-*O*-glucoside in olive pulp.[28,29] The MS^2 spectrum of deprotonated **1** showed great similarity to that reported by De Nino et al.,[30] indicating that **1** was most likely hydroxytyrosol-1-*O*-glucoside.

Deprotonated **2** showed the loss of 162 Da (hexosyl) or 138 Da (tyrosol) and is likely to be a hexoside of **1** (i.e., a dihexoside of tyrosol) (Figure 3). This compound was identified for the first time in olive stones.

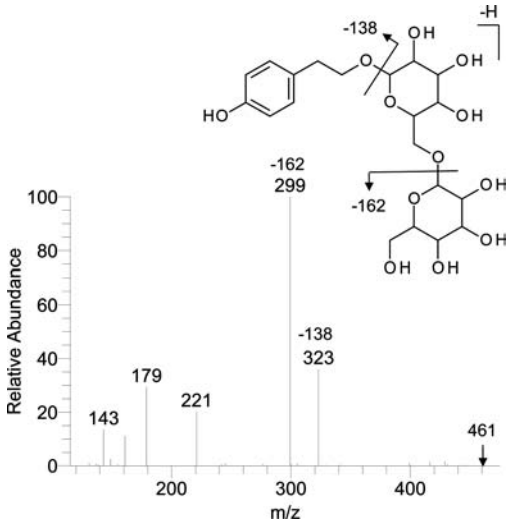

Figure 3. MS^3 (507 → 461) spectrum of the formate adduct of **2** (equivalent to the MS^2 spectrum of deprotonated **2**) rationalized against a possible structure.

Quantification of Phenolic Compunds. Six phenolic compounds were quantified in stones *Olea. europea* L. cv. Chemlali, such as hydroxytyrosol, tyrosol, nuezhenide, methoxy derivative of nuezhenide, nuezhenide-11-methyloleoside, and oleuropein as shown in Figure 4. The changes in the contents of the quantified phenolics in olives stones showed that nuezhenide presented the highest concentration (325.78 mg/100 g). This result is similar to the data previously reported by Servilli et al.[17] The second major compounds were methoxy derivative of nuezhenide and nuezhenide-11-methyloleoside which were quantified as nuezhenide equivalent given a concentration at 132.46 mg/100 g and 82.91 mg/100 g, respectively. Other minor phenolic compounds were detected, such as hydroxytyrosol (5.57 mg/100 g), tyrosol (9.81 mg/100 g), and oleuropein (5.21 mg/100 g).

Antioxidant Activity. Antioxidants have recently become a topic of increasing interest to health and food science researchers or medical experts. The antioxidant activities of the olives stones extract were measured (DPPH and ABTS) and compared to that of commercial synthetic antioxidants such as BHT (IC_{50} = 8.32 μg/mL, TEAC = 1.35 mM), are shown in Table 2. The lowest IC_{50} values indicated the highest free radical scavenging activity of the sample. Consequently, the olive stone extract showed a strong antioxidant activity and was the most effective with IC_{50} value 13.84 μg/mL and TEAC value 0.43 mM. This high antioxidant activity of the olive stone extract was attributed to its richness in phenolic content, especially in nuezhenide (325.78 mg/100g), methoxy derivative of nuezhenide (132.46), and nuezhenide-11-methyloleoside (82.91). In a previous study,[4] we compared the effect of phenolic compounds in preventing of radical scavenging. It is generally assumed that the ability to act as a hydrogen donor

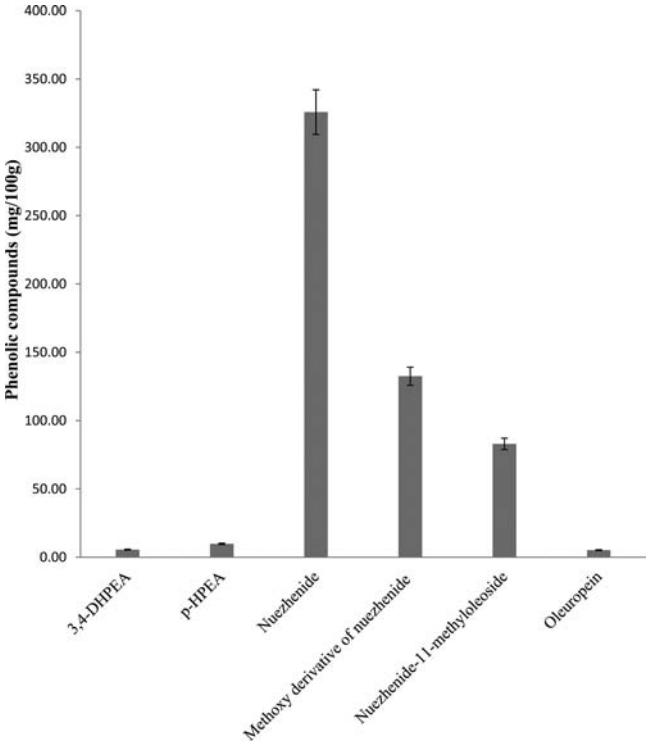

Figure 4. Composition of the phenolic compounds obtained from stones of Chemlali cultivar expressed in mg/100 g.

Table 2. Radical-Scavenging and ABTS Activities of Olives Stones Extract Compared to Those of BHT

	IC50 (μg/mL) (DPPH assay)	TEAC (mM) (ABTS assay)
olives stones	13.84 ± 0.26	0.436 ± 0.003
BHT	8.32 ± 0.05	1.35 ± 0.08

and the inhibition of oxidation are enhanced by increasing the number of hydroxyl groups in the phenol. The solubility and partitioning behavior of the phenols will also influence their reactive activity.[31,32]

In conclusion, a comprehensive knowledge of the phenolic composition of olive stones is fundamental to better understand the biochemical pathways in which they are involved and, ultimately, to shed more light on the physiology of olive trees.

To our knowledge, this is the first report on the characterization of secoiridoids based on oleoside detected in olive stones from the Chemlali cultivar. It showed that nuezhenide, methoxy derivative of nuezhenide, and nuezhenide-11-methyloleoside are the most abundant phenolic compounds in the Chemlali olive stone extract and may explain the high antioxidant activity of this extract. Therefore, this is of great interest for promoting the olive culture and better exploitation of olive fruits stones.

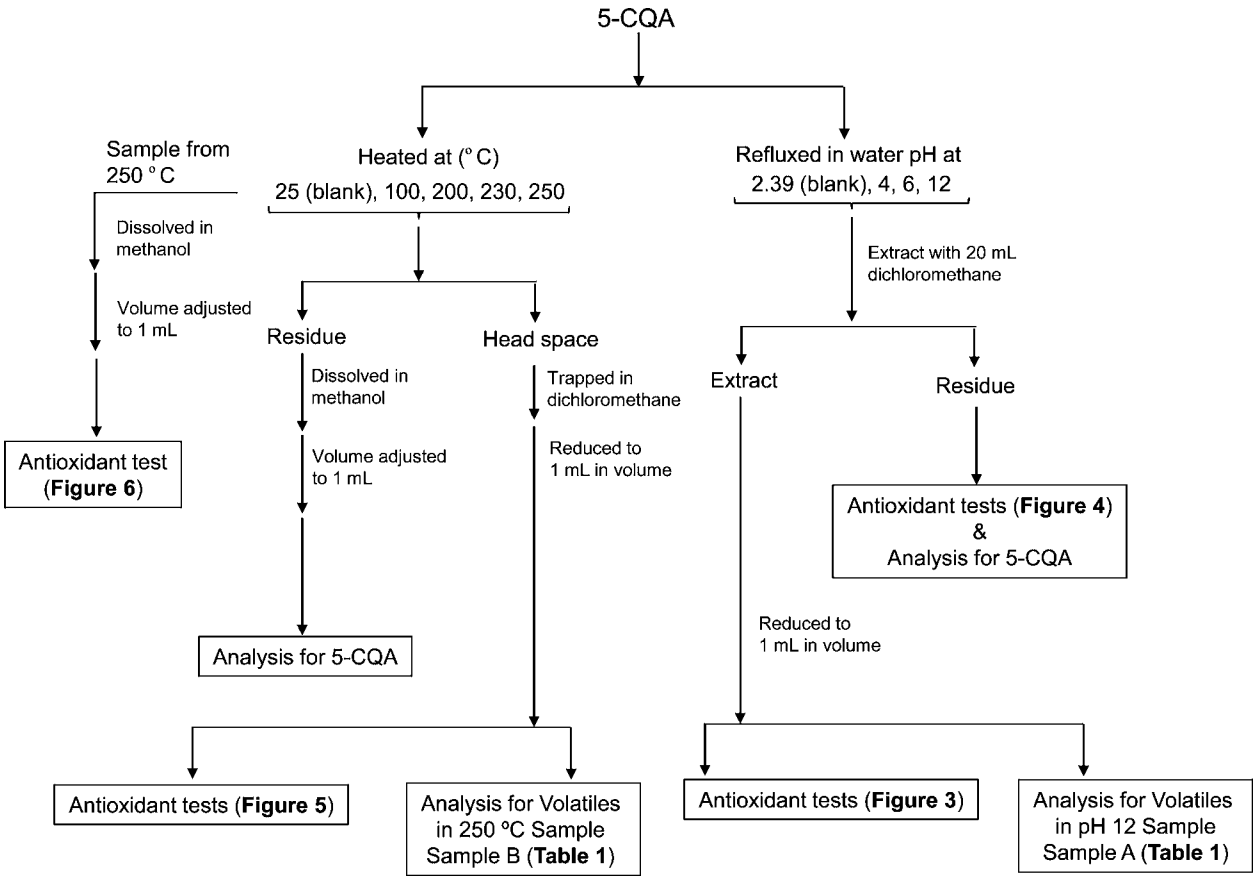

Figure 1. Experimental processes of sample preparations from 5-CQA.

(Sunbeam Products Inc., Boca Raton, FL, USA). Brewed coffee samples were cooled to room temperature in an ice bath. The pH of each brewed coffee sample was measured using a Corning 430 pH meter (Corning Inc., Corning, NY, USA). Because the color of the brewed coffee was too dark to measure the UV absorbance, the coffee samples were then diluted to 1/500, 1/1000, and 1/10000 with deionized water for the 1,1-diphenyl-2-picrylhydrazyl (DPPH) assay. The samples were also diluted to 1/10, 1/100, and 1/1000 with deionized water for the malonaldehyde−gas chromatography (MA-GC) assay. This was done to provide samples comparable to those used for the DPPH assay. Antioxidant assays were performed using 100 μL of each of the diluted samples.

Sample Preparation of Dichloromethane Extracts from Brewed Coffee for Antioxidant Assays. Brewed coffee VIa prepared above (500 mL) was extracted for 6 h with 150 mL of dichloromethane using a liquid−liquid continuous extractor at room temperature. After the extract was dried over anhydrous sodium sulfate, it was condensed to exactly 4 mL in volume by rotary evaporator, followed by purging with a purified nitrogen stream. The extracted sample was stored at 5 °C until analysis for volatile chemicals.

Preparation of 5-CQA Degradation Samples for Antioxidant Activities and Analysis. Two degradation methods were used to prepare 5-CQA degradation samples. The entire experimental processes are shown in Figure 1.

Degradation of 5-CQA in Aqueous Solution. An aqueous solution containing 5-CQA (mg/mL) was refluxed for 2 h in a 250 mL round-bottomed flask. The pH of the solution was adjusted to 4, 6, or 12 with 1 N sodium hydroxide solution. The pH of the original solution was 2.39 (blank sample). After the solution was cooled to room temperature, it was extracted for 3 h with 50 mL of dichloromethane using a liquid−liquid continuous extractor. The extract was dried over anhydrous sodium sulfate and then condensed to 1 mL in volume. The extract obtained from the sample refluxed at pH 12 was analyzed by GC, and the total volatiles were calculated to be 8.5 mg. The concentration of each chemical identified was calculated using a previously reported equation.[16] Residual aqueous solutions and dichloromethane extracts were stored at 5 °C for analysis and antioxidant assays.

Thermal Degradation of 5-CQA. Thermal degradation of 5-CQA and collection of products were conducted using a previously reported apparatus and method.[17] Briefly, the surfaces of 4 mm diameter glass beads were coated with 5-CQA (1 g) in a glass tube (250 mm × 40 mm i.d.). The sample tube was heated at 100, 200, 230, or 250 °C for 30 min while being purged with an air stream at 500 mL/min. The volatile degradation compounds were trapped in 200 mL of dichloromethane in an impinger (200 mm × 40 mm i.d.) cooled with ice-cooled brine water (−20 °C). After the dichloromethane solution was dried over anhydrous sodium sulfate, it was condensed to 1 mL in volume using a rotary flash evaporator followed by purging with a purified nitrogen stream. The samples were stored at 5 °C for analysis and antioxidant assays.

5-CQA (1 g) was heated at 250 °C for 30 min using the apparatus described above without purging with an air stream, then the heated sample was removed with 20 mL of methanol. The methanol solution was reduced to dryness by purging with a purified nitrogen stream. Approximately 800 mg of viscous brown liquid was obtained and stored at 5 °C until used for antioxidant assays and residual 5-CQA analysis by HPLC.

Determination of Antioxidant Activities of Samples. The antioxidant activities of the coffee samples were examined by two different assays, the DPPH assay and the MA-GC assay. Antioxidant activity was calculated using a previously reported method.[18]

The DPPH assay was conducted according to a previously reported method.[19] Briefly, a mixture containing a test sample (500 μL/mL) and 300 mM DPPH (500 μL) was incubated at room temperature for 30 min, and then the absorbance at 517 nm was measured using a Hewlett-Packard 8452A diode array spectrophotometer (Hewlett-Packard Co., Palo Alto, CA, USA). Butylated hydroxytoluene

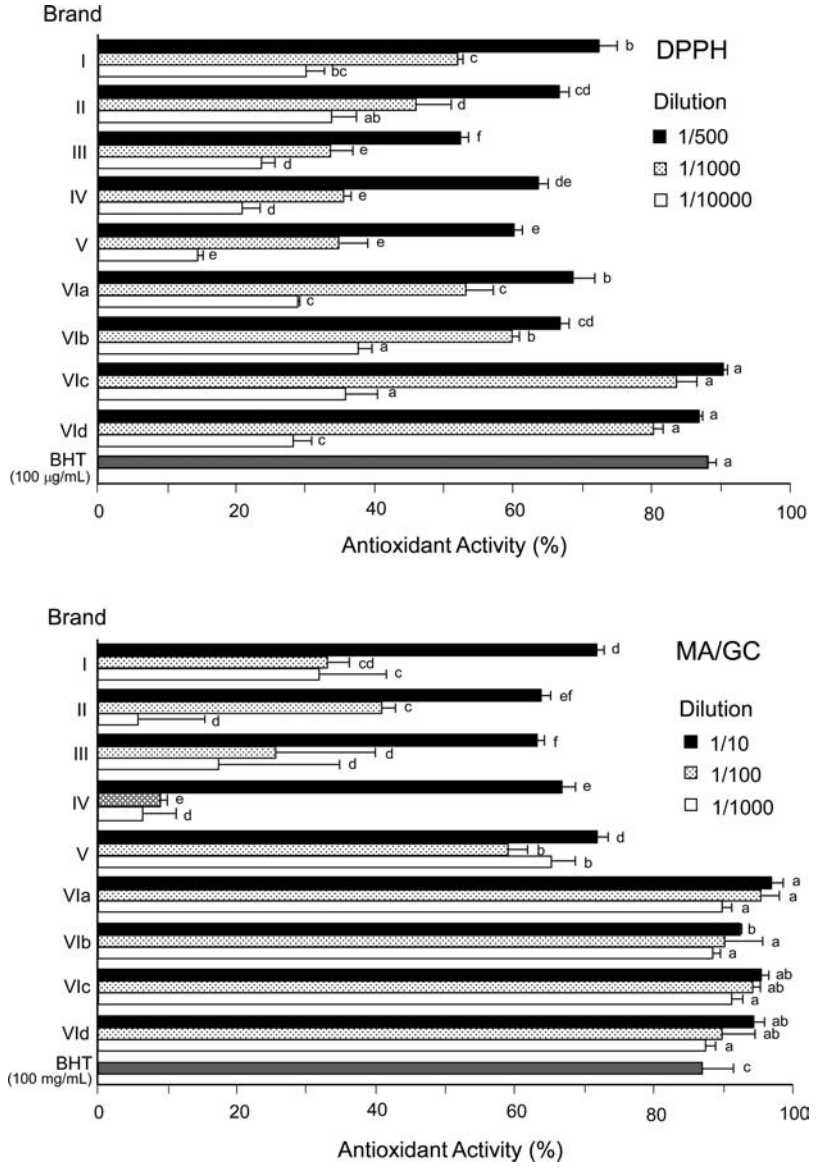

Figure 2. Results of antioxidant assays on six commercial coffee brands. Values are means ± SD (n = 3).

(BHT; 100 μg/mL) was used as a standard antioxidant to validate the assay.

The MA-GC assay was also performed according to a previously reported method.[17] Briefly, a test sample was added to an assay solution (5 mL) containing cod liver oil (10 μL) in a 20 mL test tube. After incubation of the sample at 37 °C for 18 h, the MA formed was analyzed as the 1-methylpyrazole derivative, using an Agilent Technologies 6890N GC equipped with a 30 m × 0.25 mm i.d. (d_f = 0.25 μm) DB-WAX fused-silica capillary column (Agilent Technologies Inc., Santa Clara, CA, USA) and a nitrogen−phosphorus detector. The GC oven temperature was programmed to increase from 70 to 120 °C at 4 °C/min. The injector and detector temperatures were 260 and 280 °C, respectively. The helium carrier gas flow rate was 1.4 mL/min. BHT (100 μg/mL) was used as a standard antioxidant and to validate the assay.

Analysis of Chemicals in Samples from 5-CQA Degradation Experiments. Chemicals in the 5-CQA samples were analyzed using gas chromatography (GC) and GC−mass spectrometry (GC-MS) for dichloromethane extracts (samples A and B) and liquid chromatography (LC)−MS for 5-CQA in the residual aqueous solution (refer to Figure 1). The experimental processes followed previously reported methods.[20] Briefly, the dichloromethane extracts from degradation samples were analyzed using an Agilent model 6890 GC equipped with a 60 m × 0.25 mm i.d. (d_f = 0.25 μm) DB-WAX bonded-phase fused-silica capillary column (J&W Scientific, Folsom, CA, USA) and a flame ionization detector (FID). The linear velocity of the helium carrier gas was 30 cm/s at a split ratio of 20:1. The injector and detector temperatures were 250 °C. The oven temperature was programmed to increase from 40 to 200 °C at 2 °C/min. The mass spectrum of each GC peak was obtained with an Agilent model 6890 GC interfaced to an Agilent 5971A mass selective detector (Foster City, CA, USA) at an MS ionization voltage of 70 eV. The GC conditions were the same as the ones used for GC-FID. Volatile chemicals were identified by comparison of the Kovats GC retention index I and the MS fragmentation pattern of each chemical with those of the authentic chemical. The identities of the chemicals were also confirmed using the National Institute of Standards MS library (AMDIS software, version 2.1).

Analysis of 5-CQA remaining in the residual aqueous samples from the experiments of 5-CQA degradation in an aqueous solution was performed according to a previously reported method.[7] An Agilent 1100 model HPLC system equipped with a Zorbax Eclipse XDB C-18 column (5 μm, 150 mm × 4.6 mm) and a multiple-wavelength detector was used. Mobile phases A and B were 10 mM citric acid and methanol, respectively. Identification of 5-CQA was confirmed

J. Agric. Food Chem. 2015, 63, 1996−2005

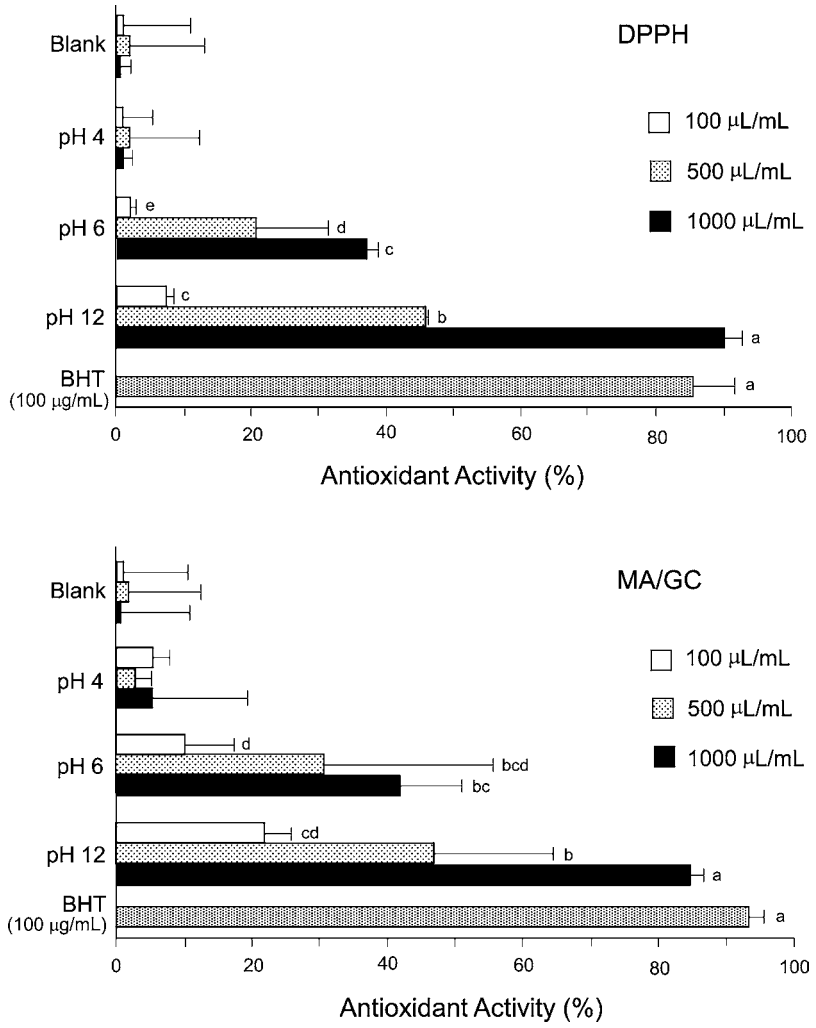

Figure 3. Results of antioxidant assays on dichloromethane extracts of the samples from 5-CQA refluxed in pH 4, 6, or 12 aqueous solution. Values are means ± SD (n = 3).

by an Agilent 1100 LC interfaced to an Applied Biosystems API 2000 MS/MS.

Statistical Analysis. Results were expressed as the mean ± standard deviation (n = 3). The values of antioxidant activities obtained in the present study were treated with an ANOVA analysis based on the SAS system, and the level of significance was determined using Duncan's multiple-range test at α = 0.05. Each experiment was repeated three times.

RESULTS AND DISCUSSION

Antioxidant Activity of Commercial Coffees Tested by DPPH and MA-GC Assays. The DPPH assay may be the most commonly and widely used in food and plant components because it is relatively simple. One of the drawbacks of this method is that the spectrophotometric absorption is interfered with by other components if a sample is dark in color, as in the case of coffee. Therefore, it is not possible to use this assay to examine the antioxidant activity of brewed coffee samples without diluting the samples. The MA-GC assay, on the other hand, is applicable to a dark-colored samples such as brewed coffee because it monitors the amount of MA by GC.

We previously reported that the total content of CQAs in commercial brands of coffee ranged from 5.26 ± 0.09 to 17.10 ± 0.34 mg/g.[7] The amount of 5-CQA was the greatest of the nine CQA isomers found, ranging from 2.13 to 7.06 mg/g in ground roasted coffee beans. 5-CQA comprised nearly 40% of the total CQAs in roasted coffee beans. It has also been reported that the lower the level of CQAs, the less acidic (higher pH) the resultant brewed coffees was.[21] In the present study, the pH of brewed coffee samples was 5.15 in brand I, 4.78 in brand II, 5.01 in brand III, 5.11 in brand IV, 5.06 in brand V, 5.49 in brand VIa, 5.57 in brand VIb, 5.64 in brand VIc, and 5.63 in brand VId. Therefore, 5-CQA was chosen to investigate the possible formation of antioxidants from degradation of chlorogenic acids in coffee during processing.

Figure 2 shows the results of the antioxidant assays on six commercial coffee brands. Values are means ± SD (n = 3). The antioxidant activity of BHT (standard antioxidant) was 88.05 ± 1.18% by the DPPH assay and 86.87 ± 4.38% by the MA-GC assay at the level of 100 μg/mL, indicating that these two antioxidant assays are valid in the present study. All brewed coffee samples exhibited dose-dependent antioxidant activity except for brand V in the MA-GC assay. The antioxidant activity of the brewed coffee samples ranged from 52.19 ± 1.18% (brand III) to 90.24 ± 0.67% (brand VIc) by DPPH assay and from 63.13 ± 1.01% (brand III) to 96.80 ± 1.68% (brand VIa) by MA-GC assay at the highest levels tested (1/500 dilution for the DPPH assay and 1/10 assay for the MA-GC assay). Generally, brand VI showed the most

J. Agric. Food Chem. 2015, 63, 1996−2005

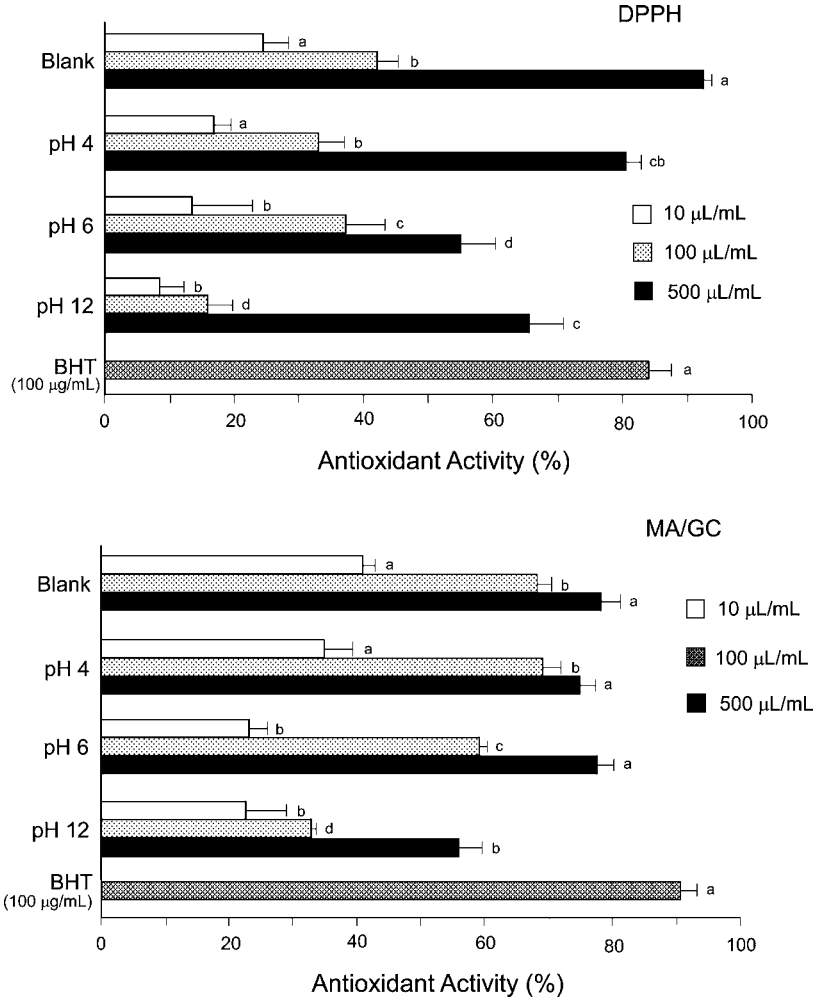

Figure 4. Results of antioxidant assays on residual aqueous solution samples from 5-CQA refluxed in pH 4, 6, or 12 aqueous solution. Values are means ± SD (n = 3).

potent antioxidant activity of the six brands tested in the present study at all levels. The average activity of the four brand VI products was 78.02% by DPPH assay and 94.66% by MA-GC assay.

Degradation Studies on 5-CQA. In this experiment, samples were prepared to simulate brewing processes and roasting processes. Figure 3 shows the results of the antioxidant assays on the dichloromethane extracts of the samples from 5-CQA refluxed in pH 4, 6, or 12 aqueous solution. A standard antioxidant, BHT, exhibited activities of 85.67 ± 6.58 and 93.35 ± 2.27% in DPPH and MA-GC assays, respectively, indicating that these assays are valid in the present study. Similar results were obtained from the two assays. The control samples did not show any appreciable antioxidant activity in either assay, suggesting that 5-CQA does not degrade or produce sufficient volatile antioxidants at the relatively acidic condition of pH 3.4. In fact, LC-MS analysis revealed only 8.46% of 5-CQA was degraded by reflux at this pH. On the other hand, 49.92% degradation was observed at pH 4, 63.59% degradation at pH 6, and 99.99% degradation at pH 12. The degradation of 5-CQA is obviously correlated with the antioxidant activity of the samples obtained from reflux. A dichloromethane extract from the 5-CQA solution refluxed at pH 12 exhibited potent antioxidant activities at the level of 1000 μL/mL (90.44 ± 2.48% in the DPPH assay and 84. 89 ± 1.35% in the MA-GC assay). These results suggest that some CQAs degrade into potent volatile antioxidants during the brewing process.

The extracts from 5-CQA refluxed at pH 6 exhibited moderate antioxidant activity at the level of 1000 μL/mL (37.99 ± 1.61 and 41.84 ± 9.21% in DPPH and MA-GC assays, respectively). Therefore, the commercial brewed coffees with a pH near 6 (brand VI) may produce volatile antioxidants during brewing and, consequently, have higher antioxidant activity than those with a pH near 5 because neither the samples from the control nor those with a pH of 4 showed appreciable antioxidant activity. These results suggest that chlorogenic acids degrade into some volatile antioxidants during brewing.

Figure 4 shows the results of the antioxidant assays on the residual aqueous solutions from the reflux experiments. The antioxidant activities of BHT at a level of 100 μg/mL were 84.01 ± 3/31 and 90.31 ± 2.61% in the DPPH and MA-GC assays, respectively, indicating that these assays are valid in the present study. All samples exhibited moderate (40−50%) or potent (>70%) dose-dependent antioxidant activities. The antioxidant activities at the highest levels (500 μL/mL) tested ranged from 54.78 ± 5.33% (pH 6 sample) to 92.10 ± 1.10% (blank) in the DPPH assay and from 55.70 ± 3.54% (pH 12 sample) to 78.03 ± 2.98% (blank) in the MA-GC assay. The low antioxidant activity of the samples with a high pH may be because the volatile antioxidants formed from 5-CQA were removed with the extraction.

DOI: 10.1021/jf5060563
J. Agric. Food Chem. 2015, 63, 1996−2005

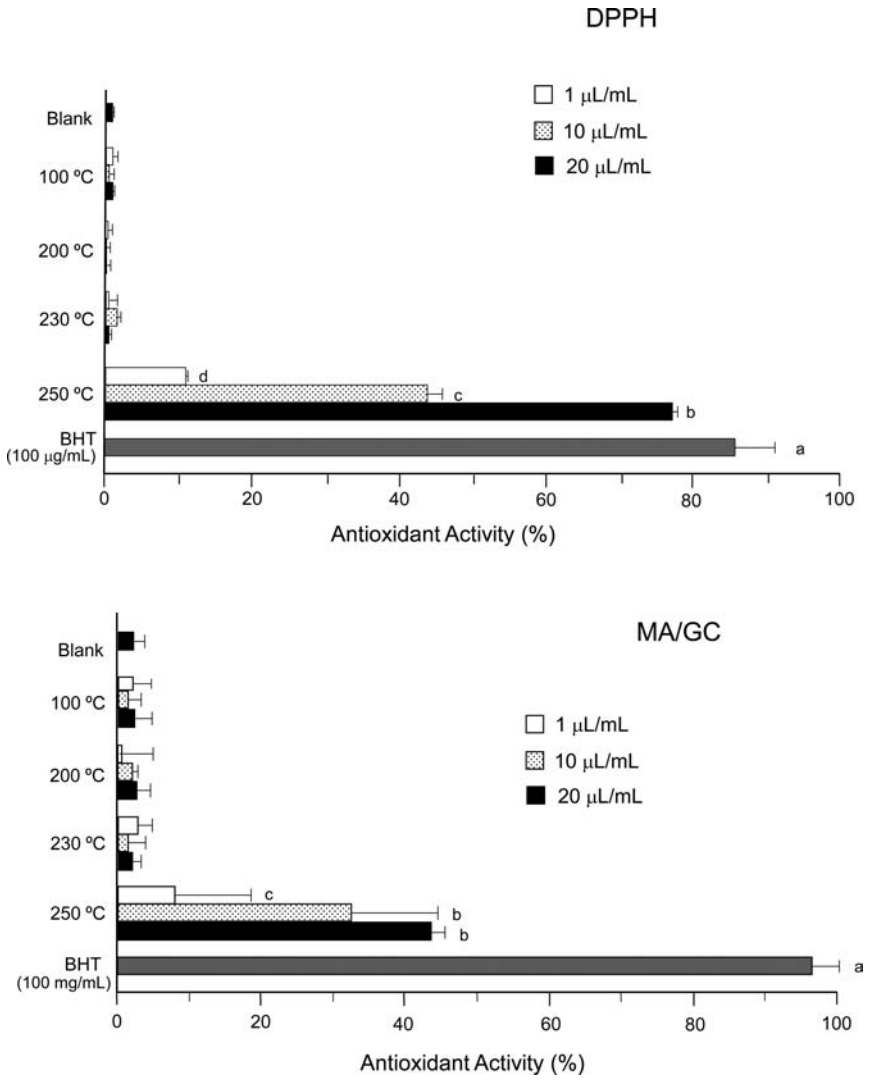

Figure 5. Results of antioxidant assays on the headspace samples trapped in dichloromethane from the thermal degradation of 5-CQA experiments at various temperatures. Values are means ± SD (n = 3).

Figure 5 shows the results of the antioxidant assays on the headspace samples trapped in dichloromethane from the experiments on the thermal degradation of 5-CQA. The antioxidant activities of BHT were 85.74 ± 5.42 and 96.32 ± 3.68% in the DPPH and MA-GC assays, respectively, indicating that these assays were valid in the present study. The samples from 5-CQA heated at 100, 200, and 230 °C for 30 min did not show any appreciable antioxidant activity in either the DPPH or MA-GC assay. On the other hand, when 5-CQA was heated at 250 °C, obvious formation of antioxidants was observed: 7.708 ± 0.72 and 43.46 ± 2.58% at the level of 20 μL/mL in the DPPH and MA-GC assays, respectively. The samples heated at 250 °C exhibited clear dose-dependent activity. Our previous study demonstrated that the amount of total CQAs decreases with increased roasting temperature.[14] In this study, we reported that roasting green coffee beans at 230 °C for 12 min (light roasting) decreased the total CQAs from 69.09 ± 2.36 to 32.09 ± 0.75 mg/g and decreased 5-CQA from 50.70 ± 1.61 to 15.11 ± 0.35 mg/g, whereas when they were heated at 250 °C for 21 min (French roasting), the total for CQAs was 0.34 ± 0.003 mg/g and that for 5-CQA was 0.16 ± 0.01 mg/g. These results indicate that CQAs, including 5-CQA, degrade under generally used roasting conditions, particularly in French roasts, and consequently increase antioxidant activity.

Figure 6 shows the results of the antioxidant tests on samples from unheated 5-CQA and from 5-CQA heated at 250 °C. BHT exhibited 93.25 ± 1.26 and 89.33 ± 3.77% at the level of 100 μg/mL in the DPPH and MA-GC assays, respectively, indicating that these assays are valid in this experiment. 5-CQA showed moderate antioxidant activities at the level of 100 μg/mL in both assays (44.41 ± 0.27%). The antioxidant activities of 5-CQA exhibited clear dose dependence and ranged from 5.18 ± 0.82% (1 μg/mL) to 50.69 ± 0.27% (20 μg/mL) in the DPPH assay and from 1.36 ± 0.54 to 44.41 ± 0.27% in the MA-GC assay. On the other hand, the sample from the heated 5-CQA exhibited potent antioxidant activities at 10 μg/mL (79.12 ± 2.49% in the DPPH assay and 70.88 ± 7.97% in the MA-GC assay). The same sample showed moderate antioxidant activities at 1 μg/mL (31.32 ± 1.10% in the DPPH assay and 43.96 ± 5.79% in the MA-GC assay), whereas 5-CQA did not show any appreciable antioxidant activity at the same level (5.18 ± 0.82% in the DPPH assay and 1.36 ± 0.54% in the MA-GC assay). These results clearly indicate that degradation of 5-CQA produced additional antioxidants. HPLC analysis of a

methanol solution of this sample confirmed that approximately 70% of 5-CAQ degraded into other chemicals.

Table 1 shows the compounds identified in the dichloromethane samples (refer to Figure 1). The amount of each compound identified was calculated according to a previously reported method.[20] Among the 29 compounds positively identified in sample A, acetone was found in the greatest amount (3060.0 μg/g), followed by 4-vinylphenol (1783.3 μg/g), benzoic acid (1269.1 μg/g), hexadecanoic acid (748 μg/g), octadecanoic acid (183.6 μg/g), 2-methoxy-4-vinylphenol (159.0 μg/g), and pyrocatechol (147.9 μg/g). All of these chemicals have been found in coffee except 4-vinylphenol.[22] It is interesting to note that 4-vinylphenol may have antioxidant activity, but it has not been reported in coffee. Only eight volatile compounds were isolated and identified in sample B. Pyrocatechol was found in the greatest concentration (2809.3 μg/g), followed by phenol (1275.0 μg/g), 2,5-dimethylfuran (259.3 μg/g), 2-methylcyclohexanone (107.1 μg/g), and 2-methoxy-4-vinylphenol (46.4 μg/g). All of these chemicals were reported in coffee except 2-methylcyclohexanone.[22] The compositional differences between the samples are due to the different preparation methods; sample A was prepared by direct extraction, whereas sample B was prepared from the headspace. Therefore, direct comparison of these samples is not appropriate. Three possible phenolic antioxidants (2-methoxy-4-vinylphenol, 4-vinylphenol, and pyrocatechol) were formed in relatively high concentrations in both samples A and B. Therefore, the antioxidant activity of these three phenolic chemicals identified in the present study along with caffeic acid and 4-ethylcatechol was examined. Caffeic acid and 4-ethylcatechol were examined because they were reported as chlorogenic degradation products in our previous study.[20] Figure 7 shows the proposed formation pathways of possible antioxidants formed from the caffeic acid that was formed from 5-CQA upon hydrolysis.[20]

Figure 8 shows the antioxidant activities of the major chemicals found in the samples obtained from the 5-CQA degradation experiments. BHT showed antioxidant activities (82.38 ± 0.49% in the DPPH assay and 85.23 ± 1.42% in the MA-GC assay) at a level of 100 μg/mL, indicating that the assays used in these experiments were valid. All chemicals tested exhibited dose-dependent antioxidant activity. Among them, 2-methoxy-4-vinylphenol showed the strongest antioxidant activities (98.63 ± 0.01% in the DPPH assay and 98.63 ± 2.18 in the MA-GC assay) at a level of 20 μg/mL. On the other hand, pyrocatechol had the most potent antioxidant activity (71.66 ± 0.01% in the DPPH assay and 76.57 ± 3.00% in the MA-GC assay) at a level of 10 μg/mL. All 5-CQA degradation products exhibited higher antioxidant activities than those of 5-CQA at all levels tested.

4-Vinylphenol, which has not been reported in coffee but was found in a sample from 5-CQA refluxed at pH 12 in relatively high concentration (1783.3 μg/g), exhibited antioxidant activity comparable to that of a standard antioxidant, BHT, with dose dependence. The antioxidant activity in 4-vinylphenol was 65.9 ± 0.81% in the DPPH assay and 85.23 ± 1.42% in the MA-GC assay at the level of 20 μg/mL. These results suggest that 4-vinylphenol forms from chlorogenic acids during brewing under low acidic conditions. The other chemicals formed in large quantities in this sample—acetone (3060.0 μg/mg) and benzoic acid (1269.1 μg/g)—did not show any appreciable antioxidant activity at the levels tested (1, 10, and 20 μg/mL).

[a]Kovats index on DB-WAX. [b]Amount <0.01 μg/g or not detected.

Also, 2,5-dimethylfuran (259.3 mg/g) and phenol (1275.0 mg/g) formed from 5-CQA heated at 250 °C in relatively high levels but, at the levels tested, did not show any appreciable antioxidant activity as other chemicals did. However, phenol exhibited moderate antioxidant activity (49.54 ± 4.21%) at an extremely high level (10 mg/mL) in the DPPH assay. A previous study demonstrated that unsubstituted furan inhibited hexanal oxidation by 80% at a 500 mg/mL level over 40 days,[23] suggesting that 2,5-dimethylfuran contributed to the antioxidant activity of a sample from heated 5-CQA.

The present study demonstrates that chlorogenic acids present in green coffee beans produce potent antioxidants under heat treatment, suggesting that the roasting conditions for coffee beans play an important role in the formation of antioxidants and the acidic condition of the brewed coffee.

[a]Not determined as concentration range did not exceed that of Dobberstein and Bunzel.[7] [b]Not determined due to lack of standard compound.

unprocessed corn grain samples were analyzed by reversed phase high-performance chromatography (RP-HPLC) with ultraviolet (UV) detection for the identification of 12 different cell wall-bound DFAs and TriFAs.

MATERIALS AND METHODS

Materials and Instrumentation. Standard compounds of 8-8(aryltetralin)-DFA, 8-8-DFA, 5-5-DFA, 8-*O*-4-DFA, 8-5-(benzofuran)-DFA, 8-5-DFA, 8-5(decarboxylated)-DFA, 5-5/8-*O*-4-TriFA, 8-8(aryltetralin)/8-*O*-4-TriFA, 8-*O*-4/8-*O*-4-TriFA were isolated as described by Jilek and Bunzel[8] and Bunzel et al.[13] The 5-5(methylated)-DFA (monomethylated 5-5-dehydrodiferulic acid) as internal standard[8] was kindly provided by Prof. Dr. John Ralph, University of Wisconsin, Madison, WI, USA.

An analytical phenyl-hexyl HPLC column (250 × 4.6 mm, 5 μm particle size) was purchased from Phenomenex (Germany). RP-HPLC was carried out with the following instrumentation for DFA and TriFA analysis: LC-20AT pumps, CTO-20AC column oven, SPD-M20A photodiode array detector (PDA), SIL-20AC autosampler, DGU-20A degasser, and CBM-20A communication bus module from Shimadzu, Japan. All solvents used were of HPLC grade, and water was distilled and deionized.

Sample Materials. A total of 63 DDGS samples were collected from 24 ethanol plants in the United States and European Union (EU), covering the following three parent grain origins: corn (*Z. mays*), wheat (*T. aestivum*), and a mix of cereals grains [wheat (*T. aestivum*), barley (*H. vulgare* L.), rye (*S. cereale*)], and triticale (a hybrid of wheat and rye). In addition, 11 unprocessed corn grain (*Z. mays*) samples were also collected. All samples have previously been characterized for contents of common constituents and NSP profiles in our laboratory.[2]

A total of 47 corn DDGS samples were collected from 21 different ethanol plants in the United States; 11 DDGS samples along with 11 unprocessed corn grain samples were sampled over 11 months with 1 sample every month from a plant in Nevada (P1); 5 samples were sampled over 1.5 months from a plant in Minnesota (P2); 5 samples were sampled over 20 days from another plant in Minnesota (P3); 5 samples were sampled over 20 days from a plant in Wisconsin (P4); 5 samples were sampled over 8 days from a plant in Iowa (P5); and 16 samples were supplied by a DDGS supplier in Iowa, representing samples from 7 plants in Minnesota, 4 plants in Iowa, 2 plants in Nevada, and 1 plant each in Illinois, Indiana, and Kentucky.

A total of 11 wheat DDGS samples were collected from 2 different ethanol plants in the EU, with 6 samples from a plant in the United Kingdom sampled over a period of approximately 3 months and 5 samples from a plant in France sampled over 20 days.

Finally, 5 DDGS samples of a mixed cereal grains were sampled over 20 days from a plant in Sweden. The parent grains used in the production of the mixed DDGS were wheat, triticale, barley, and rye; however, their individual proportions are unknown.

All 63 DDGS samples and 11 unprocessed corn grain samples were milled (0.5 mm) prior to analysis using a centrifugal mill (Retsch ZM200).

Pretreatment, Alkaline Hydrolysis, and Extraction of Phenolic Acids. Samples of 50, 175, or 200 mg were weighed out for corn DDGS, corn, and wheat and mixed-cereal DDGS, respectively. All samples were washed twice with 10 mL of 80% (v/v) ethanol and twice with 10 mL of acetone followed by centrifugation and removal of supernatant between and after extractions. The residues were dried under a fume hood. Saponification (5 mL of 2 mol/L NaOH) of the residues was carried out under nitrogen, protected from light, and under continuous stirring for 18 h, following a procedure described by Dobberstein and Bunzel.[7] Following acidification with 0.95 mL of concentrated HCl, 25 μg of 5-5(methylated)-DFA was added as internal standard for the quantification of DFAs and TriFAs. Extraction was carried out three times with 4 mL of diethyl ether. The diethyl ether extracts were dried under nitrogen and redissolved in 500 μL of THF/water (50:50 (v/v)) using ultra sonication and used directly for the determination of DFAs and TriFAs.

Phenyl-Hexyl RP-HPLC-PDA Analysis of DFAs and TriFAs. The procedure basically followed a protocol described by Dobberstein and Bunzel.[7] DFAs and TriFAs were analyzed using a Luna phenyl-hexyl column (250 mm × 4.6 mm i.d., 5 μm particle size, plus 3 mm × 4.6 mm i.d. guard column) and a ternary gradient made up of 1 mM aqueous trifluoroacetic acid (TFA), acetonitrile (ACN), and methanol (MeOH) at the flow rate of 1.0 mL/min. The sample (20 μL) was injected, and the separation was performed at 45 °C, with chromatograms monitored at 280 nm. The following gradients were used: eluent A, 1 mM aqueous TFA; eluent B, ACN/1 mM aqueous TFA [90:10 (v/v)]; eluent C, MeOH/1 mM aqueous TFA [90:10 (v/v)]. Separation of DFAs and TriFAs was carried out with initially 85% A, 15% B, and 0% C, linear over 15 min to 82% A, 18% B, and 0% C; linear over 5 min to 80% A, 20% B, and 0% C; linear over 5 min to 72% A, 25% B, and 3% C; linear over 5 min to 70% A, 25% B, and 5% C; linear over 10 min to 65% A, 30% B, and 5% C; held for 5 min; and linear over 10 min to 55% A, 45% B, and 5% C, following a rinsing and an equilibration step.

Identification of 8-8(Tetrahydrofuran)-DFA in DDGS Samples. Because no purified standard was available for the 8-8-(tetrahydrofuran)-DFA, the presence of this particular dimer was validated by its relative retention time and UV spectrum characteristics, as described by Dobberstein and Bunzel.[7] Furthermore, the elution order for the 8-8(tetrahydrofuran)-DFA was validated by screening for its mass (m/z 403 [M^{-1}]) using liquid chromatography−mass spectrometry, basically as described by Jilek and Bunzel.[8] Finally, gas chromatography−mass spectrometry of a silylated extract was exemplarily applied to validate the presence of the 8-8-(tetrahydrofur-

an)-DFA based on the mass spectral characteristics described by Schatz et al.[14]

Calculations and Statistical Analysis. The contents of DFAs and TriFAs were calculated relative to the area of the internal standard by using the correction factors reported by Dobberstein and Bunzel[7] (Table 1).

A one-way ANOVA was applied for comparison among means followed by Tukey's pairwise comparison with overall significance level at $P = 0.05$, using Minitab 16 (Minitab Inc.). The compositional data were analyzed by principal component analysis (PCA) with evenly spread seven-fold partial cross-validation after mean centering, and unit variance scaling, using Evince 2.5.5 software (UmBio AB), was performed as previously discussed.[15] PCA was used to detect correlations of DFAs and TriFAs with previously reported data on composition of common nutrients and NSPs from Pedersen et al.[2]

RESULTS

Detection of Ferulic Acid Dehydrodimers and Dehydrotrimers and Validation of Correction Factors. A chromatogram of the standard compounds of the DFAs and TriFAs monitored at 280 nm is shown in Figure 1, indicating an acceptable separation of eight dimers and four trimers. The 8-8(tetrahydrofuran)-DFA was not incorporated into the standard mix (see also Identification of 8-8(Tetrahydrofuran)-DFA in DDGS Samples) because a purified standard compound was not available. Because the concentration range of DFAs and TriFAs in the samples exceeded the ranges validated by Dobberstein and Bunzel,[7] increased concentration ranges of DFA and TriFA standards were analyzed for linear responses and are presented in Table 1. The linearity was validated by inspecting plots of the area on the *y*-axis versus analyte concentration on the *x*-axis, with observed correlation factors

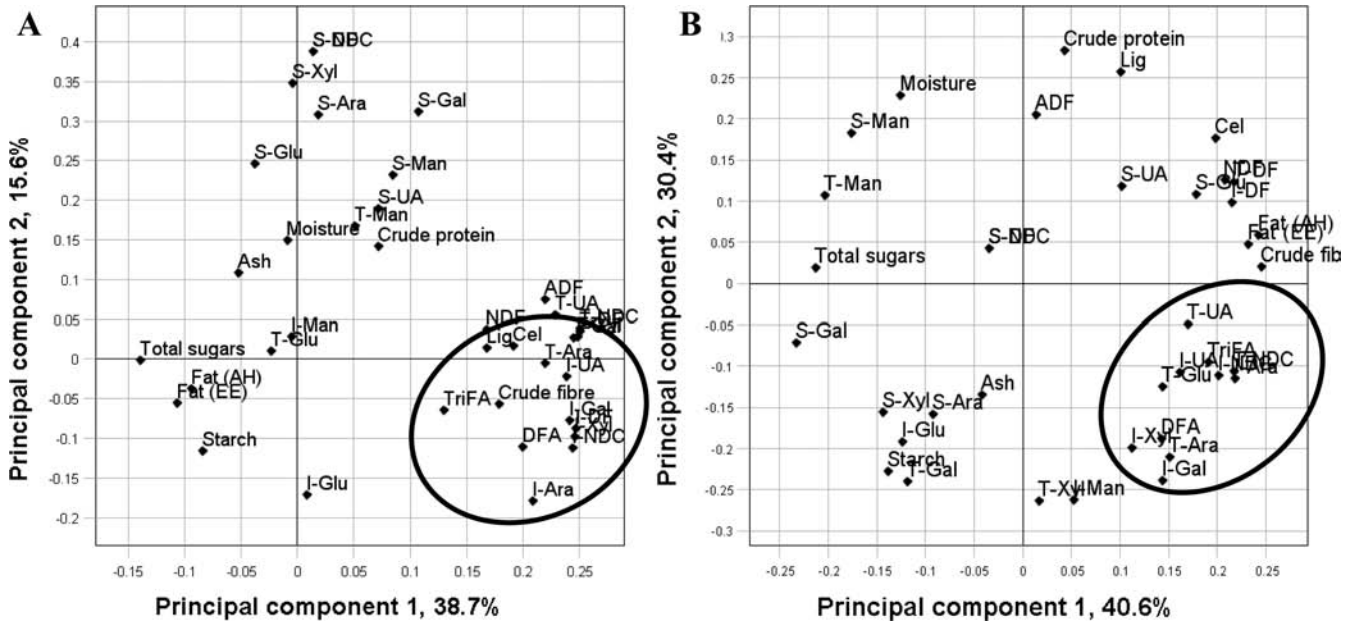

Figure 3. Loading plot of principal component analysis of corn DDGS (A) and wheat and mixed-cereal DDGS (B) constructed by combining DFA and TriFA profiles with additional compositional data from Pedersen et al. as model variables. ADF, acid detergent fiber; AH, acid hydrolysis; Ara, arabinose; Cel, cellulose; DF, dietary fiber; DFA, ferulic acid dehydrodimer; EE, ether extract; Gal, galactose; Glu, NCP-glucose; I, insoluble; Lig, Klason lignin; Man, mannose; NDC, nondigestible carbohydrates; NDF, neutral detergent fiber; S, soluble; T, total; TriFA, ferulic acid dehydrotrimer; Xyl, xylose.

ranging from 0.9839 to 0.9974 for the eight DFAs and TriFAs tested. Visual inspection of the graphs indicated a minor tendency toward curve flattening for the highest concentrations of the 8-5(decarboxylated)-DFA, which may lead to a slight underestimation of this particular dimer. Inspection of the graphs for the remaining DFAs and TriFAs indicated a consistent linear response between area and concentration of analyte measured in the samples.

Variation in Ferulic Acid Dehydrodimer and Dehydrotrimer Profiles in DDGS of Various Origins. A typical chromatogram of the analysis of alkaline extractable DFAs and TriFAs in DDGS is presented in Figure 2, demonstrating the suitability of this chromatographic method for DDGS samples. The results of the DFA and TriFA compositional analysis of the DDGS are listed in Table 2. The eight DFAs and the two TriFAs used to quantify the total content of DFA and TriFA were identified in all three DDGS origins. The dentity of these dimers and trimers was verified by comparison of relative retention times and comparison of the UV spectra with those of the isolated standard compounds. In addition, the 8-*O*-4/8-*O*-4-TriFA and the 8-5/8-*O*-4-TriFA were also identified by comparison to isolated standard compounds. However, because the amounts of these trimers were not sufficient for an appropriate validation, these TriFAs were not quantitated. Corn DDGS contained 5.3 and 5.9 times the content of total alkaline extractable DFAs than in wheat DDGS ($P < 0.001$) and mixed DDGS ($P < 0.001$), respectively. Similarly, the observed contents of total alkaline extractable TriFAs were 5.7 and 6.3 times greater in corn DDGS than in wheat DDGS ($P < 0.001$) and mixed-cereal DDGS ($P < 0.001$), respectively.

For corn DDGS the ∑8-5-DFA coupled dimers comprised the greatest proportion of the total DFA content, whereas for wheat and mixed-cereal DDGS the ∑8-8-DFA and ∑8-5-DFA coupled dimers contributed equally to the total DFA content. In corn DDGS the proportion of the 5-5-DFA was higher than in wheat ($P < 0.001$) and mixed-cereal DDGS ($P < 0.001$). Furthermore, corn DDGS contained a greater proportion for the ∑8-5-DFA coupled dimers than in wheat DDGS ($P = 0.024$). On the other hand, wheat and mixed-cereal DDGS contained a greater proportion of total DFA for the ∑8-8-DFA coupled dimers compared with corn DDGS ($P < 0.001$). No difference between the different DDGS origins was observed in contribution of the 8-*O*-4-DFA ($P = 0.481$) to the total DFA contents.

Independent of DDGS origin, higher amounts of 5-5,8-*O*-4-TriFA than 8-8,8-*O*-4-TriFA were observed. Both the 5-5,8-*O*-4-TriFA and 8-8,8-*O*-4-TriFA proportions were overall significantly different among the three DDGS origins ($P = 0.029$); however, the difference was not strong enough to be significant for pairwise comparisons among origins ($P \geq 0.09$).

The PCA loading plot illustrated with which compositional fractions of the DDGS (for DDGS composition see also Pedersen et al.[2]) the DFA and TriFA shared the highest correlation, presented for corn DDGS (Figure 3A) and wheat and mixed-cereal DDGS (Figure 3B). Both corn DDGS and wheat and mixed-cereal DDGS showed correlation of the total DFAs to the contents of insoluble xylose, insoluble uronic acids, and insoluble galactose. In addition, corn DDGS DFAs correlated to insoluble arabinose, insoluble dietary fiber, and crude fiber, whereas wheat and mixed-cereal DDGS further correlated to the total arabinose content. The TriFAs in corn DDGS correlated to Klason lignin, cellulose, neutral detergent fiber, and crude fiber, whereas the TriFAs in wheat and mixed-cereal DDGS correlated to total and insoluble uronic acids, insoluble arabinose, total and insoluble nondigestible carbohydrates, and cellulose (for principal component 1).

Analyses of corn DDGS samples from five different ethanol plants (P1, $N = 11$; P2, $N = 5$; P3, $N = 5$; P4, $N = 5$; P5, $N = 5$) revealed a greater content of total DFAs for P1 (4030 μg/g DM, $P < 0.001$) compared with P2 (3371 μg/g DM), P3 (3317

[a]Means in the same row that do not share a letter (b, c) are significantly different at $P < 0.05$. [b]Average corn-to-corn DDGS ratio.

μg/g DM), P4 (3292 μg/g DM), and P5 (3509 μg/g DM). However, the contents of total TriFAs were not different among the ethanol plants with an overall range of 426−504 μg/g DM (P = 0.12). The coefficient of variation (CV) ranged from 0.04 to 0.09 among the plants for the content of total DFAs with highest CVs for P1, whereas CVs of 0.01−0.02 was observed for the total TriFA contents among the ethanol plants.

Variation in Ferulic Acid Dehydrodimer and Dehydrotrimer Profile between Corn and Corresponding DDGS. The DFA and TriFA profiles of corn and corresponding DDGS, sampled simultaneously from the ethanol plant (P1) over a period of 11 months, are presented in Table 3. DDGS had a 3.6-fold increase in total DFA contents along with a 3.7-fold increase in total TriFA contents compared with corn. No difference in the proportions of ∑8-8-DFA (P = 0.773) and ∑8-5-DFA (P = 0.290) of total DFA and of 5-5,8-*O*-4-TriFA (P = 0.719) and 8-8,8-*O*-4-TriFA (P = 0.719) of total TriFAs was observed between corn and corresponding DDGS (Table 3).

DISCUSSION

Saponification with 2 mol/L NaOH at room temperature cleaves ester linkages. Thus, DFAs and TriFAs ester-linked to polymeric cell wall components were analyzed in this study. The applied chromatographic methodology allowed for separation and quantification of eight DFAs and two TriFAs, along with the identification of two additional TriFAs. Validation of the extended analyte concentration ranges (if compared to Dobberstein and Bunzel[7]) indicated that the 8-5(decarboxylated)-DFA might be slightly underestimated compared to the other DFAs. Because the 8-5-DFA, the 8-5(benzofuran)-DFA, and the 8-5(decarboxylated)-DFA presumably have the same precursor in vivo, the results of the 8-5-DFAs were reported as the sum of 8-5-coupled dimers.[6,8] Also, the contents of the 8-8-DFAs were reported as the sum of the 8-8-coupled dimers according to Dobberstein and Bunzel,[7] although it is likely that these three 8-8-DFAs occur as individual DFAs in vivo.[6]

Because only starch is removed during the fermentation process, the nutrient composition of DDGS is expected to partially reflect the composition of the parent grain.[2,16] The higher content of total DFAs and TriFAs observed in corn DDGS compared to wheat DDGS is in line with previous reports of the DFA and TriFA contents in corn and wheat insoluble fiber[7,17,18] and whole grain flours.[8] Also, the observed dominating proportion of the ∑8-5-DFAs (35% of total DFA) in corn DDGS is well in line with previous reports of 39%[8] and 42%[7] in corn, just as the proportion of the 8-*O*-4-DFA (18% of total) in corn DDGS is consistent with previous reports of 18%[8] and 17%[7] in corn. For corn DDGS the proportions of 5-5-DFA (27% of total) and the ∑8-8-DFAs (20% of total) were slightly different from previous reports on corn ranging from 18 to 19% and from 21 to 26% of total DFAs, respectively. For wheat DDGS the observed proportion of the ∑8-5-DFAs (31% of total) was lower than the previous reports of 49%[8] and 44%.[7] On the other hand, the observed proportions of the ∑8-8-DFAs (30% of total) and the 8-*O*-4-DFA (18% of total) in wheat DDGS were roughly comparable to previous reports ranging between 24 and 25% and between 15 and 16%, respectively.[7,8]

The 5-5,8-*O*-4-TriFA was the dominating TriFA in corn DDGS, just as reported for the parent grain.[7,8] Despite being dominant, the proportion of the 5-5,8-*O*-4-TriFA reported here is overestimated because a recent study quantitated five TriFAs in corn,[8] whereas only two were used for quantification in this study. As shown in Figure 2, at least two other trimers were identified in corn DDGS. The same consideration needs to be done for wheat DDGS, as the same study of Jilek and Bunzel[8] indicates an equal proportions of both the 5-5,8-*O*-4-TriFA and the 8-*O*-4,8-*O*-4-TriFA in wheat.

Arabinoxylan consists of a D-xylose backbone joined by β-1,4-linkages substituted with L-arabinose residues along the xylose chain. The arabinose substitution occurs randomly, allowing other substitutes such as D-glucuronic acid, acetyl groups, galactose, and feruloylated arabinose residues to be attached to the xylan backbone.[19] Evidence that DFAs are indeed attached to arabinoxylans has been reported for the 5-5-DFA by use of carbohydrases and mild acidic hydrolysis followed by structural characterization in bamboo and corn bran[20,21] and for the 8-*O*-4-DFA and 8-8-DFA from corn bran insoluble fiber.[22,23] The use of PCA multivariate data analysis based on the combination of DFA and TriFA profiles with compositional data previously reported[2] indicated a clear correlation between DFAs and TriFAs in the DDGS and the content of insoluble arabinoxylan (sum of anhydrous arabinose and xylose), uronic acids, insoluble galactose, and cellulose. In addition to pointing out that DFAs are attached to arabinoxylan as mentioned above, these results logically indicate a similar association for the TriFAs. The observed correlation of DFAs to insoluble galactose is in line with previous studies describing highly complex feruloylated heteroxylan side chains containing up to two galactose residues from corn bran.[24,25] The observed greater content of DFAs in DDGS from P1 is likely related to the higher content of insoluble arabinoxylan in DDGS from P1 than from P2−P5, as reported by Pedersen et al.[2]

The simultaneous sampling of both corn grains and corresponding DDGS over 11 months allowed for investigating

J. Agric. Food Chem. 2015, 63, 2006−2012

the potential changes in DFA and TriFA profiles after the fermentation and drying process. Although corn grains and DDGS were sampled simultaneously, it should be noted that due to practical challenges the samples did not originate from the same fermentation batch. Furthermore, it should be noted that the results may not be the same for all ethanol plants, emphasized by the variation in DFAs and TriFAs content from the 21 corn DDGS ethanol plants. The 3.6- and 3.7-fold increases in DFA and TriFA contents, respectively, in DDGS are in accordance with the 3.4-fold average increase in nutrients from the same set of samples reported by Pedersen et al.[2] and with previous studies reporting a similar nutrient increase in DDGS compared with the parent grain.[26,27]

Overall, the analysis of corn and DDGS indicated that the individual composition of DFAs and TriFAs is conserved, indicating that DFAs and TriFAs are basically not modified during ethanol fermentation and subsequent drying of DDGS. Previous characterization of NSP profiles of the samples led to the hypothesis that only arabinoxylan from corn endosperm, which comprises only a minor fraction of the total arabinoxylan, was modified during DDGS production.[2] Considering the latter and the fact that corn endosperm arabinoxylan contains markedly less feruloylated cross-linkages compared to corn bran heteroxylan,[28−30] the observed conservation of the DFA and TriFA patterns in corn DDGS is well in line. Because the major fraction of feruloylated arabinoxylan remains unmodified, the remaining arabinoxylan in DDGS is probably more complex than in the parent grain because the readily degradable arabinoxylan was modified during processing.

Large differences in enzymatic degradability were reported for corn- and wheat-based substrates,[31] with a markedly greater degradation potential for wheat than for corn. Furthermore, with regard to enzymatic degradation, corn DDGS[26] and especially corn bran have been described as recalcitrant substrates due to the highly complex structure of the arabinoxylan.[32−34] Especially the DFA and TriFA cross-links are suspected to play a major role in hindering the enzymatic degradation of cereal cell walls.[9−12] Thus, the results from this study on DFA and TriFA contents may indicate a generally higher potential for enzymatic degradation of wheat DDGS compared to corn DDGS. As a consequence of the difference in cell wall complexity, differences in digestibility, microbial fermentation, and resistance to fiber degrading enzymes may be observed when feeding either wheat DDGS or corn DDGS.

The use of DDGS in swine feed has been limited due to a reputation of having variable nutrient composition and protein quality, potentially high content of mycotoxins, and high fiber content. The high fiber content in DDGS is associated with nutritional challenges and negative effect on nutrient digestibility when fed in high quantities. To overcome the negative effects associated with high fiber content, studies have been performed to investigate the effects of adding fiber degrading enzymes to animal diets containing DDGS.[35−37] However, the results are inconclusive.

The results presented in this study may indicate that fiber-degrading enzymes applied for the degradation of DDGS need to be targeted toward highly complex substrates, especially when applied to diets high in corn DDGS.

In conclusion, the current study demonstrated a large variation in the content of DFAs and TriFAs between DDGS of three different origins. Corn DDGS contained 5.3 and 5.7 times greater content of total DFAs and TriFAs, respectively, compared with wheat DDGS. The contents of total DFA and TriFA correlated to the content of insoluble arabinoxylan, uronic acids, insoluble galactose, and cellulose in DDGS. A similar proportional profile of the individual DFAs and TriFAs was observed in both corn and corresponding DDGS, indicating that ferulic acid cross-links in the corn cell wall are presumably not modified during fermentation and DDGS processing. The results presented herein may add to the overall understanding and implication of compositional differences between DDGS sources in relation to animal nutrition and enzyme digestibility.

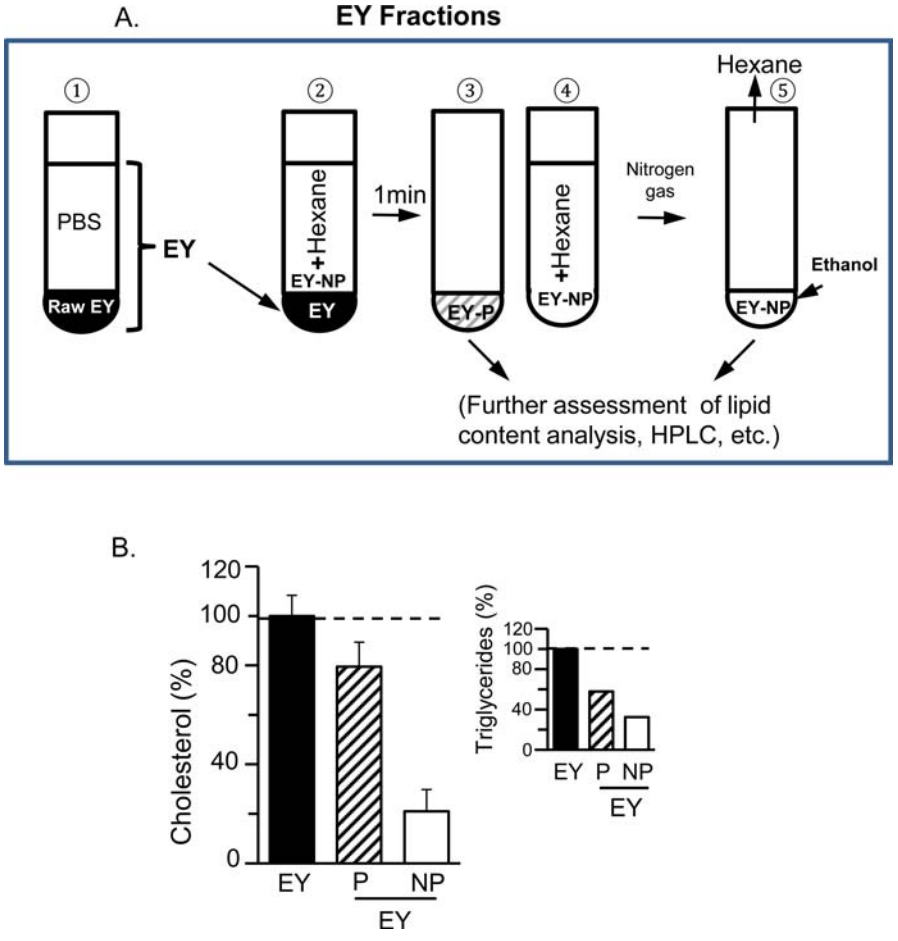

Figure 1. Delipidation of EY with hexane extraction moderately reduces its cholesterol and triglyceride content. (A) Schematic of EY extraction procedure. EY (~15 mL) was diluted with PBS to obtain 50 mL of whole EY solution (no. 1 tube). Then 1 mL of EY (black area in no. 2 tube) was extracted with hexane in a 10 mL glass tube. The remaining 1 mL fraction was termed polar "EY-P" (hatched area in no. 3 tube). Hexane phase was collected to another glass tube (no. 4 tube), evaporated by nitrogen gas, and then reconstituted in 1 mL of ethanol. This phase was termed nonpolar "EY-NP" (white area in no. 5 tube). For analysis of fatty acids and vitamins, EY-P fraction was additionally extracted as described in methods. (B) Cholesterol content in EY (black bars), EY-P (hatched bars), and EY-NP (white bars) fractions was measured in EY. Here and throughout study, we used EY obtained from different suppliers. Data (n = 5, mean ± SD) are shown as percent of esterified and nonesterified cholesterol in EY fractions (100%, dashed line). (B, low insert) Triglyceride content is shown as % of EY content (100%, n = 3, dashed line).

production and other mechanisms.[21−23] Vitamin E and polyphenols have been shown to inhibit NF-κB activation by disabling signaling cascades, counteracting ROS production as antioxidants, and through activation of redox-active transcription factors, e.g., nuclear factor (erythroid-derived 2)-like 2 (NRF2).[22]

Many dietary products have complex bioactive macro- and micronutrient composition. Recent research highlighted the anti-inflammatory[24] and pain-reducing[25] properties of egg yolk (EY). These effects have been attributed to specific lipid-soluble extracts[25] and water-soluble proteins.[24] EY contains an unique combination of vitamins A, D, E, carotenoids such as lutein and zeaxanthin, and phospholipids that can potentially diminish inflammation and oxidative stress.[26] However, the EY also contains cholesterol and fatty acids that can contribute to pro-inflammatory pathways.[27] The role of EY composition on the regulation of NF-κB has not been investigated. In this paper, we show that partial delipidation of the EY without changes to the EY's carotenoid/vitamin content, is sufficient to markedly reduce the activation of NF-κB and its target cytokines.

MATERIALS AND METHODS

Reagents and Supplies. We purchased reagents for cell culture from Invitrogen (Carlsbad, CA). Other reagents were acquired from Sigma-Aldrich (St. Louis, MO) unless otherwise indicated. Vectors were purchased: Cignal Lenti NFκB Reporter (GFP) Kit from SABiociences/Qiagen (Valencia, CA), mCherry constitutive expression vector from Genecopoeia (Rockville, MD). We bought four types of regular eggs from Sauder's egg (EY1), Kroger medium egg (EY2), Kroger large egg (EY3), and EggLand's Best egg (EY4). Cholesterol was purchased from MP Biomedicals (Santa Ana, CA).

EY Extraction. First, 15 mL of whole EY was diluted in 35 mL of phosphate buffered saline (PBS) (1:3.33, v/v). This solution was termed "EY". Hexane (4 mL) was added to 1 mL of EY and inverted vigorously by hand for 1 min. The hexane phase was removed and dried under nitrogen and then resuspended in 1 mL ethanol. The hexane extract of the EY was termed "Nonpolar, (EY-NP)" and the remaining phase was "Polar, (EY-P)" (Figure 1A). These EY, EY-NP, and EY-P extracts were used for cholesterol/cholesteryl ester quantification, triglyceride quantification, gas chromatography, high performance liquid chromatography (HPLC), and cell stimulation.

Cell Culture Studies. *Nfkb*-RE/GFP cell line was derived from murine 3T3-L1 preadipocyte clone stably transfected with lentiviral *Nfkb*-RE GFP reporter construct and control mCherry overexpression construct as described.[28] The *Nfkb*-RE/GFP cell line derivation

DOI: 10.1021/jf5056584
J. Agric. Food Chem. 2015, 63, 2013−2025

procedure and its characterization in the presence of pro- and anti-inflammatory mediators was described before.[28] *Nfkb*-RE/GFP cells were cultured in standard culture medium (high glucose DMEM containing 10% CS and 1% penicillin−streptomycin). Similar to the parent 3T3-L1 cell line, *Nfkb*-RE/GFP preadipocytes were capable of differentiation.[28] Differentiation was induced (day 0) in confluent preadipocytes using differentiation media I (DMI) containing 3-isobutyl-1-methylxanthine (0.5 mM), dexamethasone (1 μM), insulin (1.7 μM), 10% fetal bovine serum (FBS), and 1% penicillin−streptomycin in DMEM. Differentiation media II (DMII) contained 10% FBS, insulin (1.7 μM), and 1% penicillin−streptomycin in DMEM. Every 48 h post adipogenesis induction, cell media was replaced with DMII using standard protocol.[29] Prior to measuring fluorescence, cells were washed twice with PBS and lysed with an appropriate volume (i.e., 120 μL/well for 24-well plate, 150 μL/P60 dish) of RIPA buffer (Boston BioProducts, Ashland, MA) containing complete protease inhibitors (Roche Diagnostics Corporation, Indianapolis, IN). Cells were incubated on ice for 15 min, and then the plate was scratched using a tip to lyse residual cells. Cell lysate (80 μL/well) was transferred to a black 96-well plate (Fisher Scientific Company, Hanover, IL) to measure fluorescence at wavelengths Ex/Em 485/528 for GFP and then, at Ex/Em 587/640 for mCherry using Synergy H1 hybrid multimode microplate reader (BioTek, Winooski, VT). *Nfkb*-RE activation was calculated as ratio of GFP to mCherry control fluorescence (GFP/mCherry), or GFP/protein if mCherry fluorescence was below the detection limit. 3T3-L1 preadipocytes were cultured and differentiated under the same conditions as *Nfkb*-RE/GFP preadipocytes.

mRNA Analyses. The quantitative analysis of mRNA was performed using the nCounter mouse inflammation expression V2 Panel Kit (NanoString Technologies, Seattle, WA). NanoString's nCounter technology is based on direct detection of target molecules using color-coded molecular barcodes, providing a digital simultaneous quantification of the number of target molecules.[29] All data was normalized to six housekeeping genes quantified in the same samples. Total mRNA (100 ng in 5 μL) was hybridized overnight with nCounter Reporter (20 μL) probes in hybridization buffer and in excess of nCounter Capture probes (5 μL) at 65 °C for 16−20 h. The hybridization mixture containing target/probe complexes was allowed to bind to magnetic beads containing complementary sequences on the capture probe. After each target found a probe pair, excess probes were washed followed by a sequential binding to sequences on the reporter probe. Biotinylated capture probe-bound samples were immobilized and recovered on a streptavidin-coated cartridge. The abundance of specific target molecules was then quantified using the nCounter digital analyzer. Individual fluorescent barcodes and target molecules present in each sample were recorded with a CCD camera by performing a high-density scan (600 fields of view). Images were processed internally into a digital format and were normalized using the NanoString nSolver software analysis tool. Counts were normalized for all target RNAs in all samples based on the positive control RNA to account for differences in hybridization efficiency and posthybridization processing, including purification and immobilization of complexes. The average was normalized by background counts for each sample obtained from the average of the eight negative control counts. Subsequently, a normalization of mRNA content was performed based on six internal reference housekeeping genes *Cltc*, *Gapdh*, *Gusb*, *Hprt1*, *Pgk1*, and *Tubb* using nSolver Software (NanoString Technologies, Seattle, WA).

Protein Assay of Cell Lysates. The protein content was measured using a BCA kit (Thermo Fisher Scientific, Rockford, IL). The absorbance (562 nm) was measured using the Synergy H1 hybrid multimode microplate reader.

Lipid Content Analysis of EY Fractions. The EY, EY-P, and EY-NP fractions were prepared by hexane extract procedure as described above. To enable enzymatic reaction, EY-NP fraction was resuspended in 200 μL of chloroform and 300 μL of cholesterol assay buffer (from the Cholesterol Quantitation Kit) instead of 1 mL of ethanol. The suspension was mixed well by tapping and then sonicated to evaporate chloroform. Then 10 μL of EY-NP from this stock (in 300 μL cholesterol assay buffer) was diluted with DI water (to 33 μL) to achieve an original concentration in 1 mL EY. All EY fractions were then diluted in cholesterol assay buffer according to manufacturer's instruction and L-Type Triglyceride M Kit (Wako Diagnostics, Richmond, VA) was performed. The absorbance (650 nm) was measured using the Synergy H1 hybrid multimode microplate reader.

Cholesterol Enzymatic Kit (Wako Diagnostics) was performed according to the manufacturer's description. The absorbance (600 nm) was measured using the Synergy H1 hybrid multimode microplate reader.

For the cholesterol ester analysis, the EY and EY-NP fractions were prepared by hexane extract procedure as described above; however, EY-NP fraction was resuspended in 200 μL of cholesterol assay buffer (NP). Then 0.3 μL of EY, 0.5 μL of EY-P, and 10 μL of EY-NP were diluted with cholesterol assay buffer (total volume 50 μL). The cholesterol Quantification Kit was performed according to the manufacturer's description. The absorbance (570 nm) was measured using the Synergy H1 hybrid multimode microplate reader.

Fatty Acid Analysis. Total lipids were extracted from all EY fractions with 2:1 (v/v) chloroform:methanol and washed with 0.88% KCl.[30] Fatty acid methyl esters were prepared using 5% hydrochloric acid in methanol at 76 °C.[31] Analysis of fatty acid methyl esters was completed by gas chromatography with columns and conditions as previously described.[32] Retention times were compared to standards (Matreya, LLC, Pleasant Gap, PA, Supelco, Bellefonte, PA, and Nu-Check Prep Inc., Elysian, MN) and fatty acids were reported as percent of total identified fatty acids.

HPLC−Tandem Mass Spectrometry Analysis (HPLC/MS/MS). Prior to analysis, EY-P fractions were further extracted using hexane/ethanol/acetone/toluene (10:6:7:7, v/v/v/v, termed HEAT).[33] The EY-NP extracts and HEAT-extracted EY-P fractions were injected on a YMC C30 column (4.6 mm × 150 mm, 5um, Waters Corp.) and separated with a gradient solution 1 (80/18/2 MeOH/water/2% ammonium acetate) and solution 2 (78/20/2 MtBE/MeOH/2% ammonium acetate at 1.8 mL/min and 40 °C. Diode array spectra were collected with an Agilent 1260 diode-array detector with 60 mm path length flow cell (Agilent Technologies). Eluent was introduced to a QTrap 5500 (ABSciex, Concord, Canada) mass spectrometer via an atmospheric pressure chemical ionization (APCI) probe operated in positive ion mode. Multiple reaction monitoring (MRM) MS/MS transitions were used to detect vitamins and carotenoids. Lutein/zeaxanthin and retinol were quantified based on external standards.

Statistical Analysis. Data was shown as mean ± SD based on 3−4 independent experiments. Statistical comparison of groups was examined by both Student's *t* test and Mann−Whitney U test. Correlation analysis was performed using Pearson test. $P < 0.05$ was considered statistically significant.

RESULTS

Hexane Extraction Procedure Moderately Reduces Cholesterol and Triglycerides in EY Content. EY contains many lipophilic compounds that can potentially promote and suppress inflammation.[26,27] To assess how lipophilic compounds influence properties of whole EY, we performed a hexane extraction procedure on the EY (Figure 1A) and characterized the composition of the nonpolar (EY-NP) and polar (EY-P) fractions. To account for variability related to egg production, we performed experiments using EY obtained from four different suppliers. Due to the high level of amphipathic phospholipids in EY, the hexane extraction removed approximately 20% of total cholesterol from EY (100%) (Figure 1B). EY contained 65% free cholesterol (43% in EY-P and 22% in EY-NP fractions) and 35% cholesteryl ester (27% in EY-P and 8% in EY-NP fractions). Hexane extraction also removed 30% of triglycerides that were found in the EY (100%) (Figure 1B, insert). Thus, the majority of cholesterol was retained in the

DOI: 10.1021/jf5056584
J. Agric. Food Chem. 2015, 63, 2013−2025

EY-P fraction, while the EY-NP fraction contained only 20−30% of cholesterol and triglycerides content from the EY.

EY-P and EY-NP Fractions Have Similar Composition of Major Fatty Acids. Next we compared the composition of fatty acids in the EY, EY-P, and EY-NP fractions after their hydrolysis from complex lipids. The major fatty acids in all fractions were saturated palmitic (16:0), monounsaturated oleic (18:1), and polyunsaturated omega 6 linoleic (18:2) acids that comprised approximately 27%, 37%, and 19% of all fatty acids, in the EY, EY-P, or EY-NP fractions (Figure 2A−C). We found significant, but minor differences between different fractions (less than 2% compared to total fatty acid content) in the less abundant saturated (18:0, 14:0, 20:0), monounsaturated (16:1n7), and polyunsaturated (22:5n3) fatty acids. In the EY-P fraction, 22:5n3 was less than in EY (Figure 2D), while the content of saturated (18:0, 14:0) and monounsatured (16:1n7) fatty acids was greater in EY-P compared to EY-NP fractions. Overall, the relative composition of fatty acids was similar among the EY, EY-P, and EY-NP fractions.

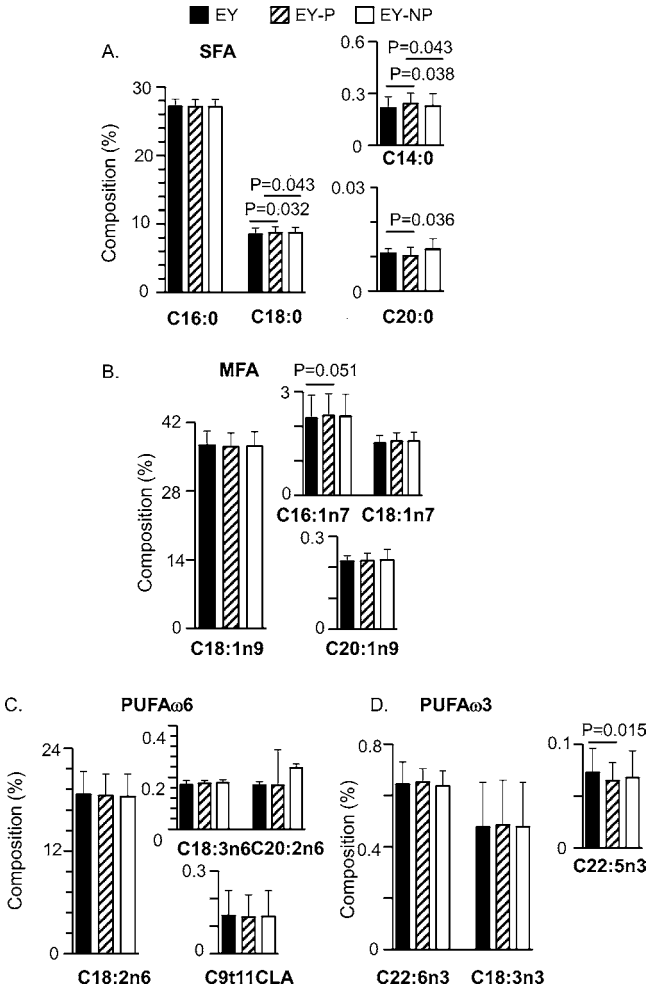

Figure 2. Low variability in fatty acid composition across EY fractions from different suppliers. Fatty acid composition was measured in EY (black bars), EY-P (hatched bars), and EY-NP (white bars) fractions (n = 4). Data are shown as mean ± SD % of distribution in whole FA in each fraction. P values were determined using Mann−Whitney U test. (A) Saturated fatty acids: C16:0, palmitic acid; C18:0, stearic acid. (A, upper insert) C14:0, myristic acid. (A, lower insert) C20:0, arachidic acid. (B) Monounsaturated fatty acids: vaccenic acid; C18:1n9, (B, upper insert) C16:1n7, palmitoleic acid; C18:1n7, oleic acid. (B, lower insert) C20:1n9, cetoleic acid. (C) Polyunsaturated ω6 fatty acids: C18:2n6, linoleic acid. (C, upper insert) C18:3n6, gamma linoleic acid; C20:2n6, eicosadienoic acid. (C, lower insert) Conjugated linoleic acid, C9t11CLA. (D) Polyunsaturated ω3 fatty acids: C22:6n3, docosahexaenoic acid; C18:3n3, alpha linolenic acid; (D, upper insert) C22:5n3, docosapentaenoic acid.

Lipophilic Vitamins and Carotenoids Were Retained Exclusively in EY-P Fraction. Simultaneous determination of vitamins E (α-tocopherol), D (D3), A (retinol and retinyl esters), and carotenoids (free and esterified lutein and zeaxanthin esters) was performed using HPLC/MS/MS. Carotenoids and retinol were quantified based on external standards. No detectable levels of lipophilic vitamins and carotenoids were found in the EY-NP fraction (Figure 3). All lipid soluble vitamins and carotenoids were found in the EY-P fraction, probably due to their interaction with phospholipids. The amounts of lutein and zeaxanthin were the most variable (∼25%) among the EY-P fractions from different EY suppliers (Figure 3A). The variability of retinol content in EY was less than 6% (Figure 3B). Vitamins E and D3 were not quantified but were detected in the EY-P fractions from all suppliers (Figure 3C). Thus, the EY-P fraction contained all lipophilic vitamins and carotenoids from the EY.

In summary: The EY-NP fraction contained 20−30% of cholesterol and triglycerides compared to EY (100%). The EY-P fraction contained 70−80% of cholesterol and triglycerides and all of the lipophilic vitamins and carotenoids seen in EY (100%).

EY-P Fraction Inhibits NF-κB Pathway in Adipocytes. *1. EY-P Fraction Inhibits the Activation of NF-κB and Its Target Genes in Adipocytes.* To assess whether similar composition of the EY and EY-P fractions exerted comparable activation of NF-κB, we performed reporter assays in the 3T3-L1-*Nfκb*-RE preadipocyte cell line. This reporter cell line was previously validated using both pro-inflammatory agents and anti-inflammatory antioxidants.[28] We compared *Nfκb*-RE activation in adipocytes stimulated with the EY, EY-P, and EY-NP fractions. Although both the EY and EY-P fractions contained carotenoids and vitamins, *Nfκb*-RE activation was suppressed only in adipocytes stimulated with the EY-P fractions. Compared to *Nfκb*-RE activation in nontreated adipocytes, stimulation with EY increased *Nfκb*-RE activation to 126%. In contrast, the EY-P fraction from the same EYs reduced *Nfκb*-RE activation (40%) compared to control adipocytes (Figure 4A). The suppression of *Nfκb*-RE activation by the EY-P fraction was seen in eggs from different suppliers. The variability of response to the EY, EY-P, and EY-NP fractions from EY obtained from different suppliers reached 33%, 20%, and 30%, respectively (data not shown). The suppression of *Nfκb*-RE activation by EY-P fraction occurs in a concentration-dependent manner (Figure 4B).

The inhibitory effect EY-P fraction on NF-κB target genes was further examined in the classical preadipocyte 3T3-L1 cell line. We stimulated differentiated 3T3-L1 preadipocytes with the EY, EY-P, and EY-NP. Then we simultaneously quantified expression of multiple genes in these cells. First, we analyzed the expression of classical NF-κB target genes such as MCP1 (CCL2). MCP1 was the most abundantly expressed cytokine in 3T3-L1 adipocytes followed by MCP3 (CCL7) and MCP2 (CCL8) (Figure 4C). In spite of differences in basal expression, all *Mcp* genes were markedly suppressed by the EY-P fraction. EY-P inhibited expression of *Mcp1* by 59% (Figure 4D), *Mcp2* by 61% (Figure 4E), and *Mcp3* by 49% (Figure 4F) compared

DOI: 10.1021/jf5056584
J. Agric. Food Chem. 2015, 63, 2013−2025

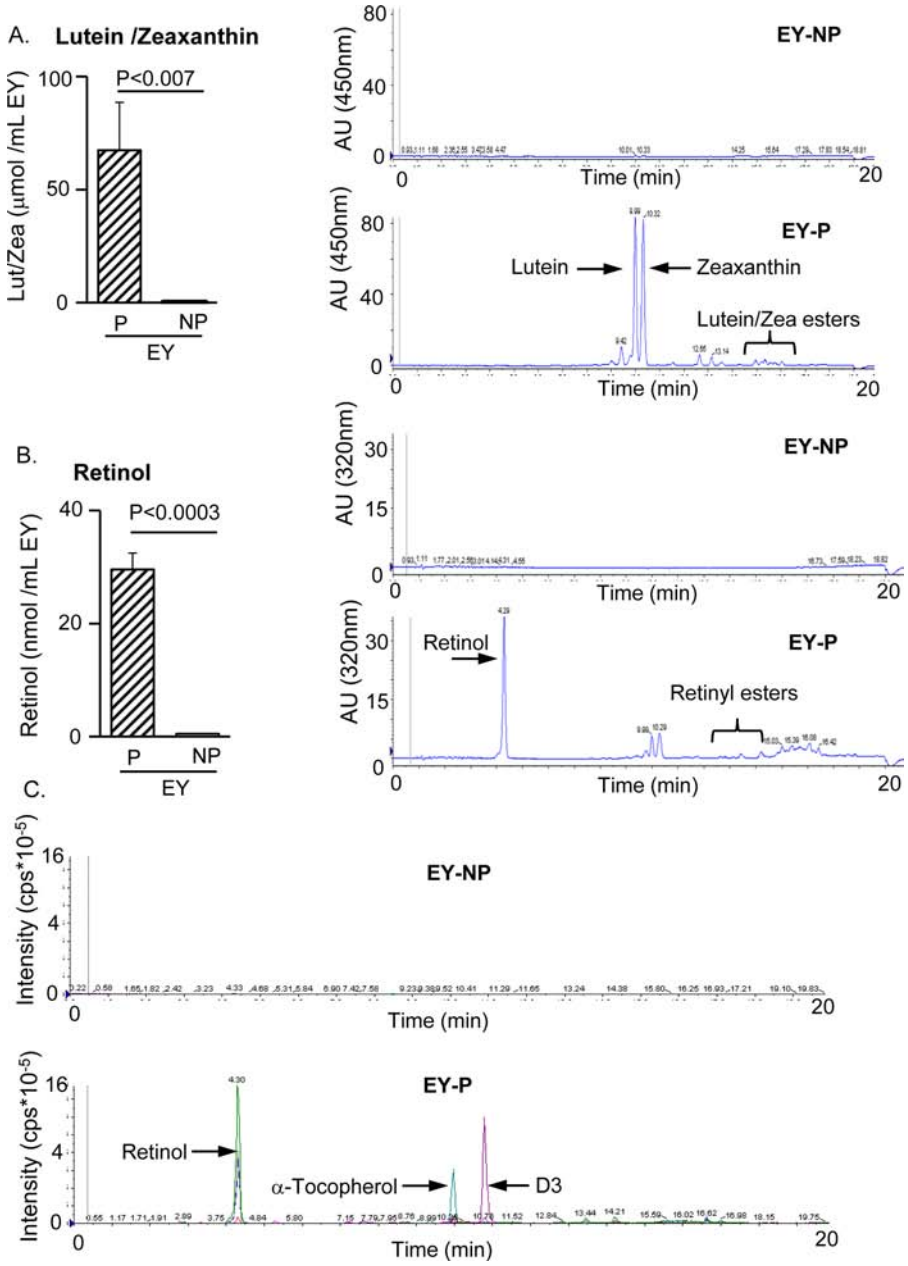

Figure 3. Vitamin and carotenoids are present in EY-P and absent in EY-NP fractions after hexane extraction. Same EY fractions (n = 4) that were examined for fatty acid composition (Figure 2) were analyzed for vitamin and carotenoids content using HPLC/MS/MS. (A) Concentrations of lutein/zeaxanthin in EY-P and EY-NP fractions. Inserts show one representative chromatogram for EY-NP (upper) and EY-P (lower) fractions. (B) Concentrations of retinol in EY-P and EY-NP fractions. Inserts show one representative chromatogram for EY-NP (upper) and EY-P (lower) fractions. (C) Representative chromatograms of EY-NP (upper insert) and EY-P (lower insert) fractions showed absence vitamins A, E, and D in EY-NP fraction.

to nonstimulated adipocytes. The EY and EY-NP fractions did not significantly influence expression of these genes.

We also explored the specificity of cytokine production in response to the EY fractions. All INFs (*Infa1*, 7 ± 3; *Infb1*, 51 ± 6; *Infg*, 7 ± 3 AU) were expressed at low levels in 3T3-L1 adipocytes. The EY fractions did not significantly influence expression of all *Infs* (data not shown). *Cxcl5* and *Cxcl1* cytokines are coregulated by NF-κB and STAT1 transcription factors,[3,14] whereas mitogene-inducible gene (Mig), interferon gamma-induced protein 10 (Ip10), and Rantes are coregulated by NF-κB, STAT1, and IRF transcription factors[11,34−37] (Figure 5A). Stimulation of 3T3-L1 adipocytes with the EY-P fraction markedly decreased expression of *Cxcl5* (Figure 5B) and *Cxcl1* (Figure 5C) to 9% and 22%, respectively, compared to nontreated control adipocytes. In contrast, all EY, EY-P and EY-NP fractions lead to a modest (less than 40%) reduction in expression of *Ip10* (Figure 5D), *Mig* (data not shown), or *Rantes* (Figure 5E) compared to the control. The reduction of *Ip10* and *Mig* expression was only significant in adipocytes stimulated with the EY-P fraction and *Rantes* only with the EY fraction compared to control adipocytes. None of the EY fractions significantly influenced the expression of other *Ccl* cytokines, *Tnfa*, and *Il6* (data not shown). Given that the EY-P fraction led to the most potent (10-fold) reduction in the expression of *Cxcl5*, which was known to be regulated by both STAT1 and NF-κB,[3,14,38] we also analyzed the expression of

DOI: 10.1021/jf5056584
J. Agric. Food Chem. 2015, 63, 2013−2025

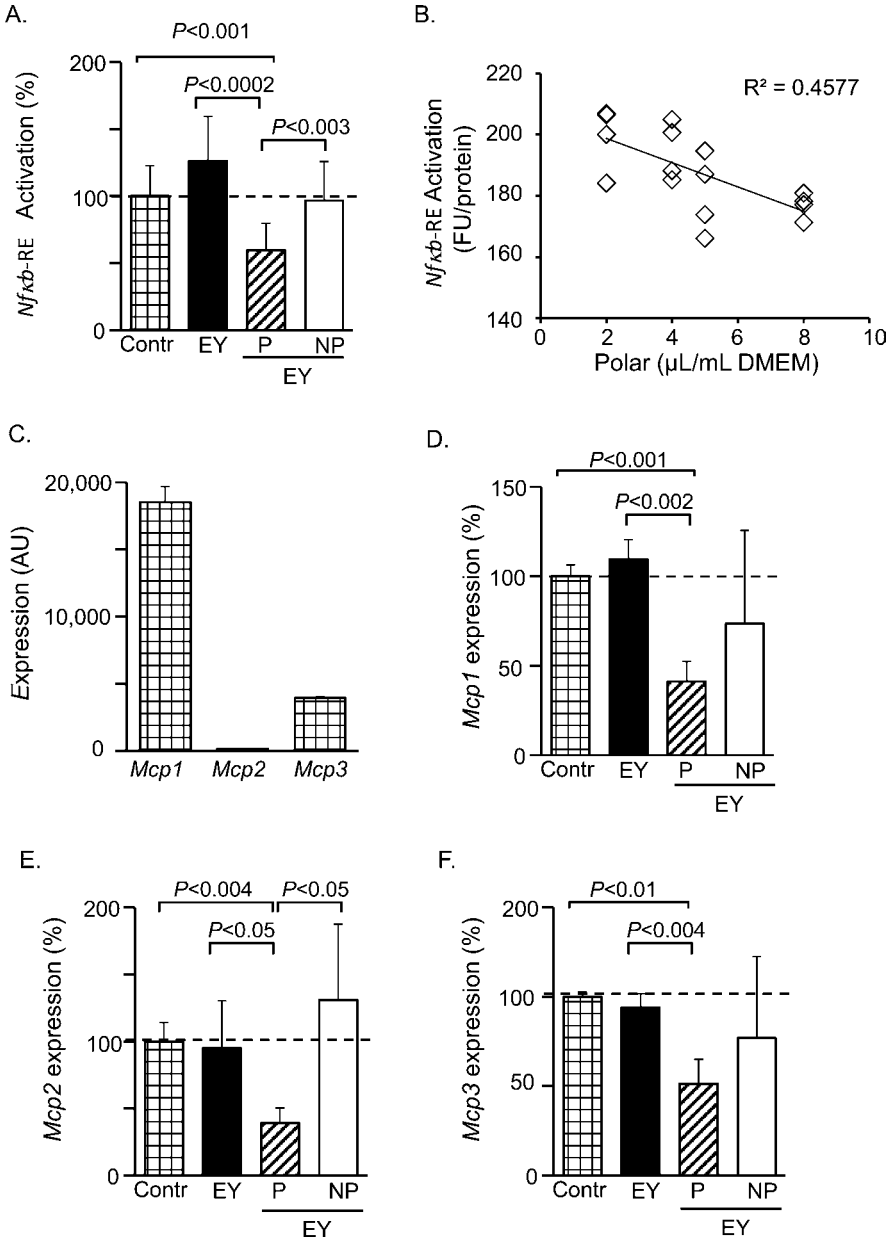

Figure 4. EY-P fractions inhibit NF-κB activity in *Nfκb*-RE/GFP and 3T3-L1 adipocytes. (A) *Nfκb*-RE/GFP preadipocytes were differentiated after 3 days and stimulated with identical concentrations of EY (black bar), EY-P (hatched bar), and EY-NP (white bar) EY fractions (5 μL EY fraction/mL DMII) for 24 h. Control, *Nfκb*-RE/GFP cells were maintained in DMII (Contr, gridded bar). Data is shown as mean ± SD, $n = 12$ for Control and EY or $n = 11$ for EY-P and EY-NP treated cells. The fluorescence/protein ratio was obtained from total cell lysates in RIPA buffer. Data are shown as a % of control fluorescence/protein ratio (100%, dashed line). (B) *Nfκb*-RE/GFP preadipocytes were differentiated for 3 days and stimulated with 2, 4, 5, and 8 μL EY-P/mL DMII. Data are shown as mean ± SD of fluorescence/protein ratio ($n = 4$). Correlation was examined by Pearson test, groups were compared using Mann−Whitney U test. (C) 3T3-L1 preadipocytes were differentiated for 4 days. The expression of *Mcp* gene family was measured using the nCounter data analysis system from NanoString Technologies. *Mcp* expression in 3T3-L1 adipocytes are shown as mean ± SD ($n = 3$). (D−F) 3T3-L1 preadipocytes were differentiated for 3 days and stimulated with EY (black bar), EY-P (hatched bar), and EY-NP (white bar) fractions (5 μL EY fraction/mL DMII) for 24 h. The expression of *Mcp1*, *Mcp2*, and *Mcp3* was shown as % of expression compared to in control adipocytes (gridded bar, 100%, dashed line) (mean ± SD, $n = 3$). Significance was examined using Mann−Whitney U test.

Stat1. We found a 10-fold reduction of *Stat1* expression in the presence of EY-P in adipocytes (Figure 5F). Thus, in spite of similar content of lipophilic vitamins in the EY-P and EY fractions, EY-P inhibited the activation of *Nfκb*-RE and expression of NF-κB target genes and *Stat1*, whereas EY and EY-NP exerted a similar level of NF-κB activation as nontreated adipocytes. The expression of genes that regulated apoptosis, such as *Bcl2l1* and *Fasl*, was not different in control compared to treated cells (Data are not shown).

2. Inhibition of NF-κB Activation by EY-P Fraction Is Associated with Selective Regulation of Tlr Receptors and Their Inhibitor Proteins. Among nine *Tlr* receptors, *Tlr2* was the most abundantly expressed receptor in 3T3-L1 adipocytes followed by *Tlr3* and *Tlr4* (Figure 6A). *Tlr2* expression was similar in nontreated adipocytes and adipocytes treated with EY-NP fraction (Figure 6B). EY moderately reduced expression of *Tlr2* (to 75%), whereas the EY-P fraction decreased *Tlr2* expression to 31% compared to control adipocytes. The

DOI: 10.1021/jf5056584
J. Agric. Food Chem. 2015, 63, 2013−2025

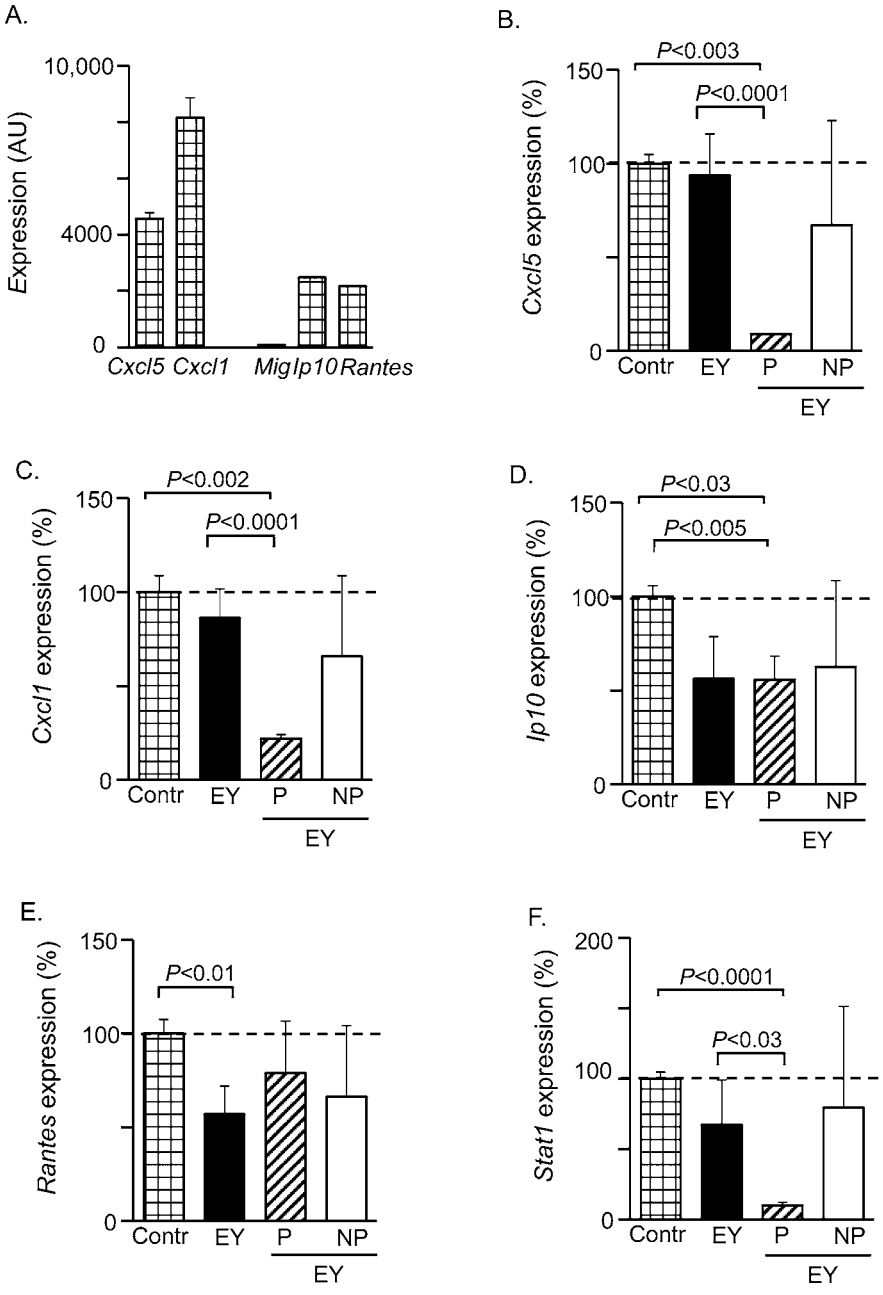

Figure 5. EY-P fractions suppress expression of NF-κB-regulated downstream genes in 3T3-L1 adipocytes. (A) The relative expression of *Cxcl5*, *Cxcl1*, *Mig*, *Ip10*, *Rantes*, and *Stat1* was measured by the nCounter data analysis system from NanoString Technologies using same samples that were described in Figure 4C. (B–F) Expression of *Cxcl5*, *Cxcl1*, *Mig*, *Ip10*, *Rantes*, and *Stat1* genes in same 3T3-L1 adipocytes described in Figure 4D–F.

expression of two other major, *Tlr3* and *Tlr4* receptors was not significantly affected by the treatment with any EY fractions (Figure 6C, D). However, the EY-P fraction significantly increased the expression of *Ly96* (to 224%) compared to control adipocytes (Figure 6E). The interaction of Ly96 with TLR4 prevents ligand binding to this receptor and the activation of NF-κB. The expression of an inhibitory adaptor protein, Tollip, was also increaed (to 145%) in EY-P fraction compared to control adipocytes. (Figure 6F). Therefore, decreased activation of NF-κB was associated with inhibited expression of *Tlr* either via direct inhibition of expression of *Tlr2* or indirectly via up-regulation of the expression of inhibitory *Ly96* and *Tollip* by the EY-P but not the EY-NP and EY fractions.

3. Dissimilar Regulation of Expression by EY-NP and EY-P Fractions Influence Proteins with Potential Binding Sites for Both SREBP and NFκB. To obtain a clue for specific regulation of *Tlr* and inhibitory *Ly96* and *Tollip* by the EY-P, but not the EY and EY-NP fractions, we analyzed the putative SREBP binding sites. This transcription factor has been established as a sensor of cholesterol/phospholipid ratio on the membranes or as factor activated by signaling cascades (e.g., insulin).[39] We found three potential high score SREBP binding sites in *Tlr2* (score 92–93) and two SREBP binding sites in *Tollip* (score 86) and one in *Ly96* (score 88). *Tlr2* and *Ly96* could be potentially regulated by NF-κB because they also contained five and two potential NF-κB binding sites, respectively. *Stat1* contains two SREBP and nine NF-κB binding sites. To examine the putative contribution of SREBP to dissimilar responses

J. Agric. Food Chem. 2015, 63, 2013–2025

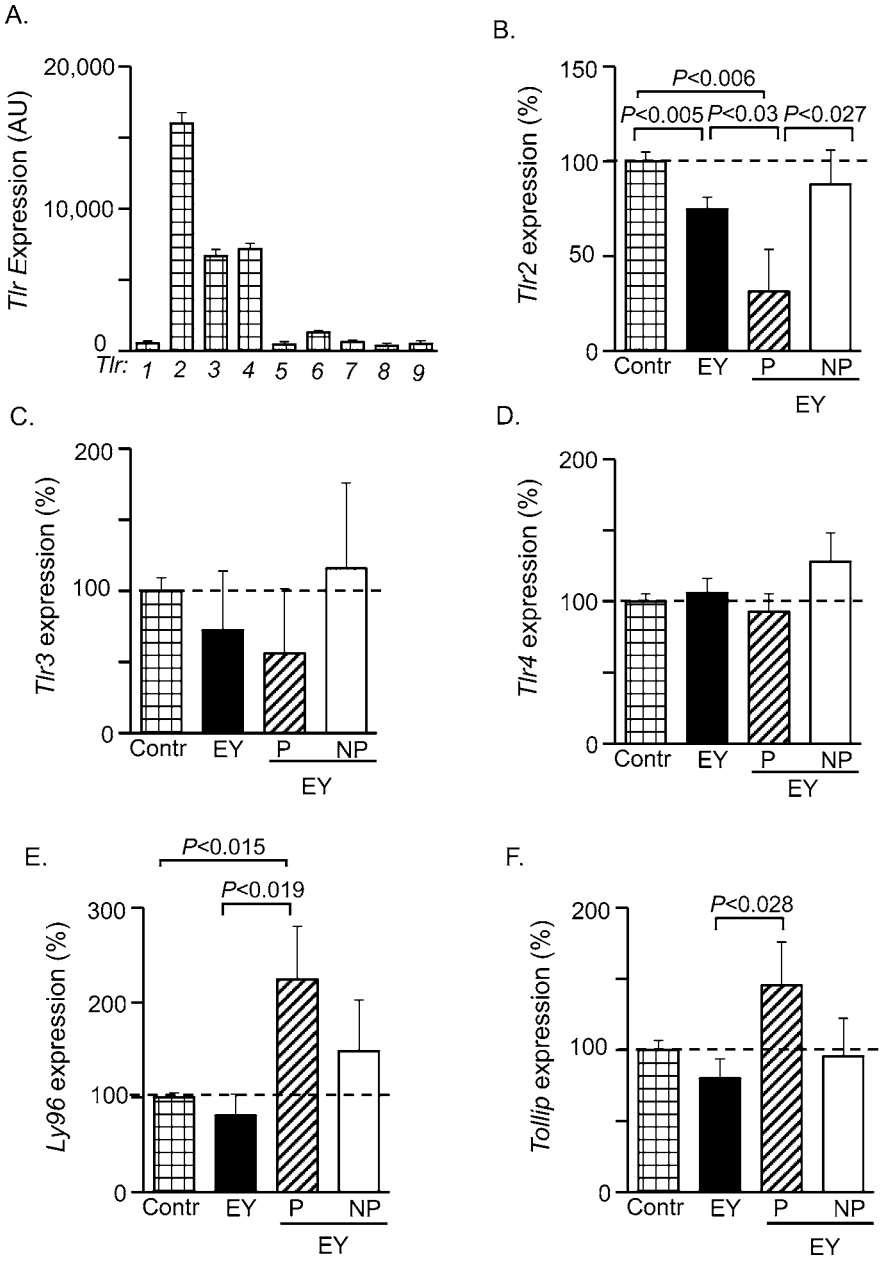

Figure 6. EY-P fractions inhibit expression of specific Toll-like (Tlr) receptors. (A) The relative expression of *Tlr1−9* was measured by NanoString using same samples that were described in Figure 4C. (B−D) Expression of *Tlr2*, *Tlr3*, and *Tlr4* genes as well as Ly96 (E) and Tollip in same 3T3-L1 adipocytes described in Figure 4D−F.

among the EY, EY-P, and EY-NP fractions, we examined the effect of SREBP inhibitor, fatostatin,[40] on NF-κB activation in *Nfkb*-RE/GFP preadipocyte cell line. Fatostatin significantly inhibited *Nfκb*-RE activation by 52% compared to the activation induced by the EY-NP fraction (Figure 7A). Thus, SREBP partially contributed to the activation of *Nfκb*-RE associated with the EY-NP fraction. Next we stimulated of *Nfkb*-RE/GFP preadipocytes with water-soluble cholesterol during differentiation. Cholesterol-induced concentration-dependent NF-κB activation reached 170% plateau compared to nonstimulated adipocytes (Figure 7B). Stimulations of *Nfkb*-RE/GFP preadipocytes with *all-trans* retinol (Figure 7C), lutein (Figure 7D), and α-tocopherol (Figure 7E) had the opposite effect. However, the significant concentration-dependent inhibition of NF-κB occurred only in the presence of *all-trans* retinol and lutein. Each of these compounds suppressed 30% of NF-κB activation compared to nonstimulated adipocytes.

DISCUSSION

Our data demonstrates that EY contains a mixture of compounds that can effectively suppress the key inflammatory transcription pathway of NF-κB in vitro; however, these effects were blunted in the presence of nonpolar cholesterol and TG. EY-P compounds efficiently inhibited:

(1) initiation of receptor-mediated signaling that leads to the activation of NF-κB pathway,
(2) binding of transcriptional complex to regulatory DNA sequences, and
(3) expression of target cytokines.

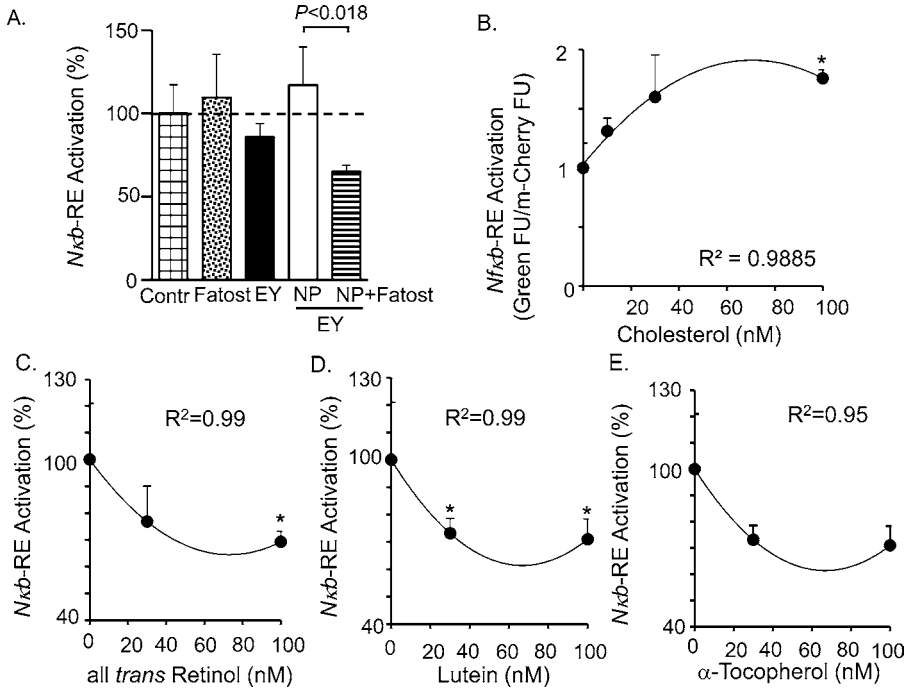

Figure 7. Fatostatin, retinol, and lutein suppressed EY-NP-induced NF-κB activation in *Nfκb*-RE/GFP adipocytes. (A) Control *Nfκb*-RE/GFP preadipocytes were differentiated for 4 days (Contr, gird bar). *Nfκb*-RE/GFP preadipocytes were differentiated for 3 days and stimulated for 24 h with 20 nM fatostatin (Fatost, dotted bars), EY (black bar), EY-NP (white bar), and EY-NP with fatostatin (20 nM, EY-NP+Fatost, bar with horizontal lines). Data are shown as % of control (100%, dashed line). Data (mean ± SD, n = 3) are shown as % of expression compared to in control adipocytes. *P*, Mann−Whitney U test. Different concentrations of cholesterol (B), *all-trans* retinol (C), lutein (D) and α-tocopherol (E) were added during the induction of *Nfκb*-RE/GFP preadipocyte differentiation and were replaced every 48 h. Differentiation continued for 5 days. Data are shown as GFP/mCherry ratio (n = 3). Correlation was examined by Pearson test. Groups were compared using Mann−Whitney U test. An asterisk indicates significant difference between control and cholesterol stimulated adipocytes.

The receptors regulating NF-κB in adipocytes exhibit a specific pattern. 3T3-L1 adipocytes expressed predominantly three *Tlr*s: *Tlr2* > *Tlr3* = *Tlr4*. EY-P fraction suppressed expression of *Tlr2*, whereas the expression of the seven other *Tlr*s remained unchanged. The inhibition of other TLRs was mediated via inhibitory adaptor protein, Tollip, and TLR4 inhibitor, Ly96. Polar lipids in the EY-P fraction induced expression of these inhibitory proteins. These changes in TLRs were associated with inhibition of NF-κB activation and the expression of NF-κB-dependent genes by EY-P compounds. Unexpectedly, EY supported NF-κB activation even though the EY and EY-P fractions shared similar content of vitamins, carotenoids, and fatty acids. Partial removal of nonpolar cholesterol and TG from the EY was required to reveal its inhibitory effects on the NF-κB pathway. Although these studies were performed in adipocytes, EY fractions expect to exert similar effects in other cells that are under NF-κB and SREBP transcriptional control such as mucosal epithelial cells exposed to EY-containing products such as mayonnaise. In other pathophysiological situations in vivo, EY can potentially have beneficial effects without delipidation.[41,42]

The inhibition of *Nfκb*-RE activation together with the suppressed expression of NF-κB-regulated cytokines and TLR2 receptor suggests that EY-P may exert anti-inflammatory properties. The association of anti-inflammatory properties with EY-P, but not EY fractions, appears to be independent of the variation in EY composition as the effects were seen using regular quality eggs from four different suppliers. The highest variability in composition was associated with the cholesterol content in the EY-NP fraction and lutein and zeaxanthin content in the EY-P fraction; however, all EY-P fractions inhibited expression of genes in the NF-κB cascade after partial delipidation. Although numerous studies showed that NF-κB pathways are regulated by fatty acids,[12] in our study similar fatty acid composition among the EY fractions suggest their unlikely role in dissimilar NF-κB activation. The mechanism by which cholesterol regulates NF-κB remains unclear. In macrophages, cholesterol mobilization to lipid rafts contributes to the activation of TLR.[43] Activation of NF-κB via TLR4 is blocked by mevinolin, suggesting that the activation of TLR4 may require binding of cholesterol or its metabolic precursors.[44] Decades of studies with statins, inhibitors of cholesterol synthesis, showed that anti-inflammatory effects of these pharmaceuticals depend on inhibition of NF-κB in a variety of tissues.[45−47] The regulation of cholesterol metabolism and fatty acid synthesis is controlled by a SREBP family of transcription factors. In adipocytes, SREBP is activated by insulin/JNK pathways[39] and glucose/JAK/STAT pathways,[48] which regulate differentiation, glycolytic pathways, fatty acid synthesis, and lipid droplet formation in adipocytes.[49] In our studies, all proteins participating in NF-κB activation cascade, TLR2, Tollip, and Ly96, had putative binding sites for SREBP. Given that detailed analysis of promoters was beyond the scope of our first study, we accessed the global impact of SREBP in the regulation of NF-κB by EY-NP fraction using its specific inhibitor fatostatin.[40] *Nfκb*-RE activation was significantly reduced by fatostatin compared to nontreated adipocytes, whereas cholesterol induced *Nfκb*-RE activation in a concentration-dependent manner. However, effects of fatostatin was less pronounced than that achieved by EY-P compounds.

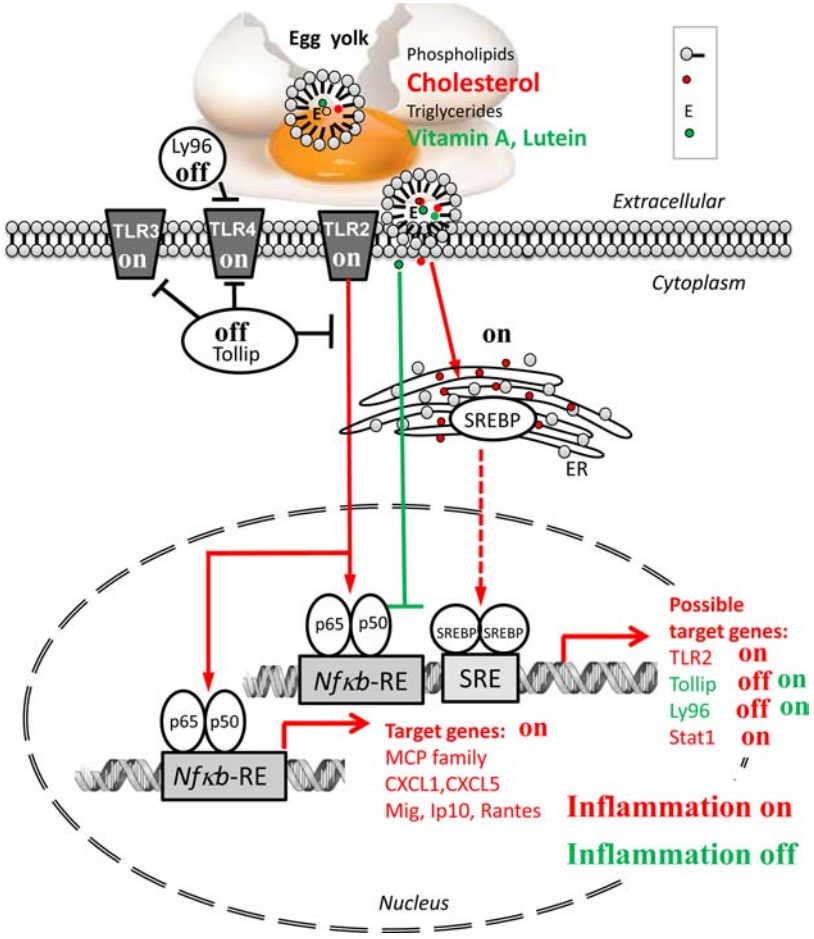

Figure 8. Hypothetical mechanism for EY-P-suppressed NF-κB activation in adipocytes. The major TLR on adipocytes are TLR2, TLR3, and TLR4. The inhibition of TLRs was mediated via inhibitory adaptor protein Tollip, while Ly96 inhibited TLR4 activation. TLR activation induces signaling cascade leading to translocation of NF-κB complex, for example, p50/p65 into nucleus and activation of activation of NF-κB-dependent genes (*MCP* family, *CXC* family, *Mig*, *Ip10*, *Rantes*, etc.). Cholesterol to phospholipid ratio in the endoplasmic reticulum (ER) membranes control activation of SREBP transcription factor, which coregulate genes involved in NF-κB activation (*Tlr2*, *Tollip*, *Ly96*, *Stat1*, etc.). EY and EY-NP fractions activate NF-κB through SREBP-dependent pathways and could be inhibited by SREBP inhibitor fatostatin. Partial delipidation EY (such as EY-P fraction, which is not shown in the schematics) alters phospholipid to cholesterol ratio and might prevent SREBP activation, resulted in the suppression of TLR2 and elevated expression of Tollip and Ly96 inhibitory proteins in adipocytes. Thus, partially delipidated EY-P fraction leads to the inhibition of NF-κB activation and its downstream inflammatory targets.

Vitamin A and lutein inhibited *Nfκb*-RE activation at low concentrations and could be potentially accounted for the inhibition mediated by EY-P fraction. Thus, partial delipidation of EY may lead first to the disruption of SREBP-dependent genes involved in NF-κB activation and then enable lutein and retinol to exert their potential anti-inflammatory effects (Figure 8).

A remaining question is why only partial delipidation was needed to improve the inhibition of NF-κB by the EY-P fraction? Although specific studies are needed to answer this question, a possible explanation can be found in the relationship between membrane composition and activation of SREBP. Recent studies showed that SREBP activation could be triggered by reduced phospholipid concentrations in the membranes.[50] After partial delipidation, the EY-P fraction has an increased ratio of phospholipid to cholesterol, which, possibly, prevents SREBP activation. The decrease in ratio of cholesterol to phospholipid could also improve the delivery of lipophilic vitamins and carotenoids to adipocytes.

Our study also revealed that partial delipidation of EY can influence inflammation via STAT1. This transcription factor is a critical mediator of interferon-mediated inflammation[51] and promotes a variety of diseases, including hepatitis[3] and type 1 diabetes in experimental animal models.[4] *Stat1* controls apoptosis in pancreatic β cells[52] via transcription of *Cxcl1* and *Cxcl2*. These cytokines promote neutrophil migration into pancreatic islets.[14] Insulin resistance in patients with obesity and hepatitis[3] were attributed to another STAT1-regulated cytokine, CXCL5. CXCL1 and CXCL5 are also NF-κB target genes.[14,38] The deficient NF-κB activation and *Stat1* in our studies markedly diminished expression of *Cxcl1* and *Cxcl5* expression (by 80% and 90% decrease in the presence of EY-P compared to control). It is unlikely that INF was the major regulator of *Stat1* in adipocytes because the expression of all *Inf* was very low in adipocytes and was not regulated by EY fractions (data not shown). Accordingly, the expression of INFγ-regulated *Ip10* and *Rantes* was only moderately regulated by EY fractions (Figure 5). Recent studies showed that CXCL5 could be another mechanism that leads to the activation activation of STAT1 in adipocytes.[53] Suppression of NF-κB activation and CXCL5 expression by EY-P fraction can also result in deficient *Stat1* expression. Regardless of these

J. Agric. Food Chem. 2015, 63, 2013−2025

speculative mechanisms, the results of our study suggest that regular EY contains compounds that can selectively regulate expression of inflammatory cytokines through two major transcriptional pathways, NF-κB and STAT1. Identification of these compounds and/or their mixtures can help to develop novel therapeutics and functional foods, which can potentially improve the treatment of metabolic diseases. Our data helps to recognize the pivotal role of lipophilic compounds in EY that can sensitize inflammatory pathways and disable anti-inflammatory effects of *all-trans* retinol and lutein associated with the EY-P fraction. We propose partial delipidation of EY as an efficient solution to improve beneficial effects of EY.

Analysis of Total Polyphenol Content (TPC). The TPC of tea extract was determined using the Folin−Ciocalteu method.[17,18] Results were expressed as milligrams of gallic acid equivalents per grams of leaves (GAE mg/g).

HPLC Analysis of Catechins Content. Catechins in white tea extract were identified and quantitated using a modified HPLC method.[19] A 20 μL aliquot of the standard (EGCG, ECG, EGC, and EC) solutions and sample extract was injected and analyzed two times using a Flexar HPLC (PerkinElmer Inc., Waltham, MA). The column used was a 250 mm × 4.6 mm i.d., 5 μm, Restek ultra C18 (Restek Corporation, Bellefonte, PA), with an elution flow rate of 1.5 mL/min, and a linear solvent gradient of A−B [(A, 10 mM KH_2PO_4 (pH 4.0); B, CH_3CN/H_2O (65%/35%)], as follows: 0 min, 20% B; 5 min, 20% B; 15 min, 30% B; 40 min, 60% B. The absorbance was measured at 280 nm. TotalChrome software program was used for data acquisition and processing. The catechins content of the white tea extract was expressed as a percentage by mass on a sample dry matter basis.

Nanoparticle Formulations. The white tea extract was encapsulated into polymeric NPs by using a nanoprecipitation method. Polycaprolactone (PCL) was dissolved in 3 mL of acetonitrile and added dropwise, under magnetic stirring (700 rpm), into a solution containing F-127 (0.5% w/v), alginate (0.1%, 0.5%, and 1.0% w/v), white tea extract, and water (2:2:1:5 v/v), to give a final polymer concentration of 6.0 mg/mL. The resulting colloidal suspension was evaporated under stirring (500 rpm) at room temperature for 1 h to remove the organic solvent. NPs were centrifuged at 10 000 rpm for 5 min and washed three times with water to remove the unencapsulated extract. A part of the NPs dispersion was lyophilized, and collected for other experiments.

Nanoparticle Characterization. *Scanning Electron Microscopy (SEM) Analysis.* Morphological examination of NPs was performed by analysis with a model 962 scanning electron microscope (Carl Zeiss Inc., Jena, Germany). A drop of the NPs aqueous suspension was placed on an aluminum stub and dried under a vacuum for 12 h. The

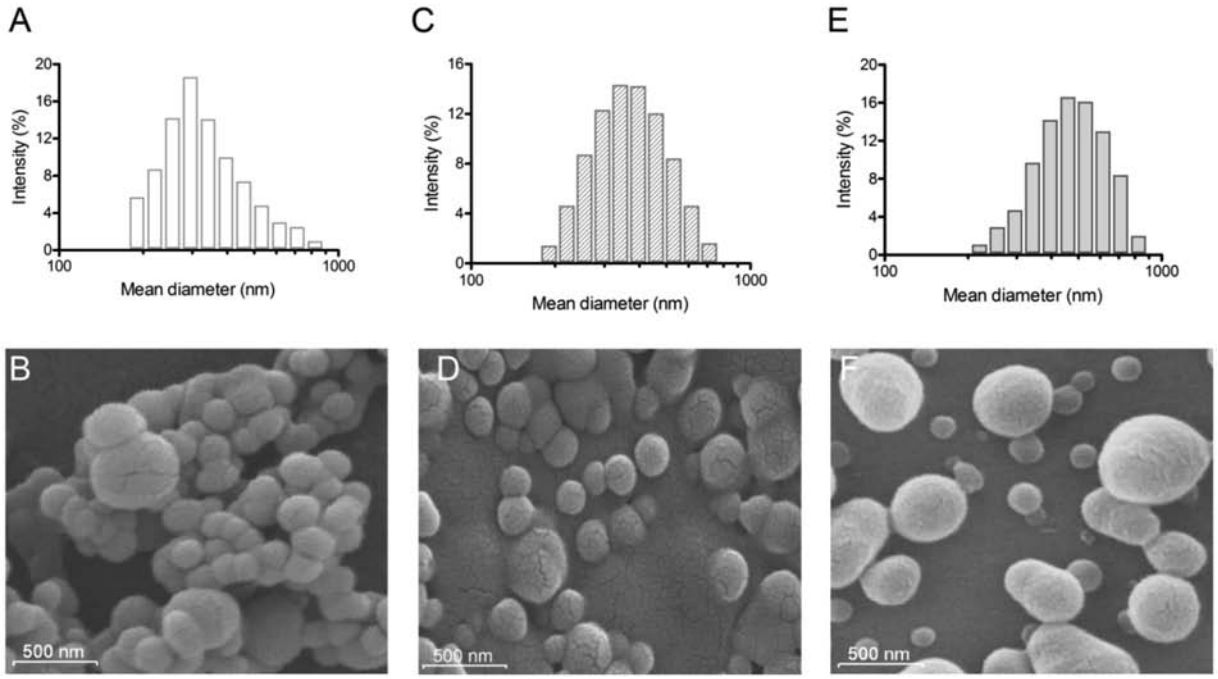

Figure 3. Particle size distributions and SEM images of white tea extract-loaded NPs prepared by using (A, B) 0.1%, (C, D) 0.5%, and (E, F) 1.0% of alginate (% w/v), respectively.

samples were analyzed at 20 kV acceleration voltage after gold sputtering, under an argon atmosphere.

Measurement of Particle Size (PS) and Polydispersity Index (PI). PS and PI were measured by using photon correlation spectroscopy with a Zetasizer Nano ZS (Malvern Instruments, Worcestershire, UK) at 25 °C, and a scattering angle of 90° after dilution of samples with Milli-Q water. Each sample was measured in triplicate.

Encapsulation Efficiency (EE%). The extract encapsulation capacity of NPs was evaluated in terms of both TPC and catechins content.

An aliquot of 1.0 mg of freeze-dried NPs was dissolved in 100 μL of acetonitrile and added to 100 μL of water. After centrifugation (10 000 rpm, 10 min), the supernatant was analyzed by using the Folin−Ciocalteu assay and the HPLC method previously reported. The EE% was calculated as the ratio between the amount of TPC and catechins encapsulated in NPs and their weight in the extract used for NPs preparation.

Fourier Transform Infrared Spectroscopy (FT-IR). The chemical composition of the white tea extract, PCL, alginate, tea extract-loaded NPs, tea extract/PCL, and tea extract/alginate blends was analyzed by FT-IR spectroscopic measurements by using a Bruker Vertex 70v spectrophotometer (Bruker Optik, Ettlingen, Germany) at a resolution of 4 cm^{-1} in KBr pellets, in the range 400−4000 cm^{-1}.

Release Kinetics of Polyphenols. A known amount of NPs (10 mg) suspended in 400 μL of distilled water or unencapsulated white tea extract (200 μL) was placed into dialysis bags and suspended in 20 mL of 0.1 M HCl (pH 1.2) for 2 h followed by PBS buffer solution (pH 7.4, 20 mL) for 5 h, to simulate gastric and intestinal fluids, respectively (37 ± 0.5 °C, 400 rpm). At defined time intervals, 1.0 mL of the supernatant was withdrawn and replaced with an equal volume of fresh medium to maintain a constant volume. The cumulative amount of TPC released was analyzed by using the Folin−Ciocalteu assay and expressed as % with respect to TPC into NPs.

Determination of Antioxidant Activity by the Scavenging of the Stable Radical DPPH•. The antioxidant activity by the scavenging of the stable free radical, DPPH•, was determined according to the methods previously reported.[20] The experiments were carried out on various concentrations of unencapsulated white tea extract (0.25−25 μg/mL) and white tea extract-loaded NPs (25−300 μg/mL).

Stability Studies. The stability of encapsulated white tea extract was evaluated by monitoring TPC and catechin contents during storage. Tea extract-loaded NPs (3.0 mg) in aqueous suspension (200 μL) and white tea extract were stored, under static conditions, at different temperatures (25 and 40 °C) for 30 days. Before analysis, the NPs were freeze-dried and then dissolved in 200 μL of acetonitrile.

The TPC and catechin content of NPs and white tea extract samples were then analyzed by using the Folin−Ciocalteu assay and HPLC method, respectively, as reported above.

Statistical Analysis. All data were expressed as the mean ± SD of three replications of the experiment. Statistical analysis was performed by one-way analysis of variance (ANOVA) and Student's t test. Significant difference was considered at $p < 0.05$.

RESULTS AND DISCUSSION

Preparation and Characterization of White Tea Extract. Tea leaves were extracted using water as solvent, chosen because of its high yield rate, low cost, safety, and accessibility in comparison with the organic solvents. The other extraction parameters (temperature, time, and the ratio of water-to-tea) were selected on the basis of their impact on the extraction process efficiency, previously investigated for the green tea.[21]

An average of 291.33 ± 6.11 mg of the extract was collected from 1.0 g of dry white tea leaves. In agreement with literature data,[22] TPC of tea extract, determined by Folin−Ciocalteu reagent assay, resulted in 87.29 ± 0.48 GAE mg/g, corresponding to 29.96 ± 0.63% of dry extract.

The major catechins in white tea extract were identified by a comparison of their retention times with those of standards at UV absorption spectra of 280 nm. Figure 2A and B shows the representative chromatogram of a standard mixture and white tea extract, respectively. As illustrated, the retention times for the studied catechins, EGC, EC, EGCG, and ECG, were 4.3, 10.5, 11.8, and 19.3 min, respectively. Moreover, the peak detected at 6.1 min in tea extract (Figure 2B) corresponds to caffeine.

DOI: 10.1021/jf505850q
J. Agric. Food Chem. 2015, 63, 2026−2032

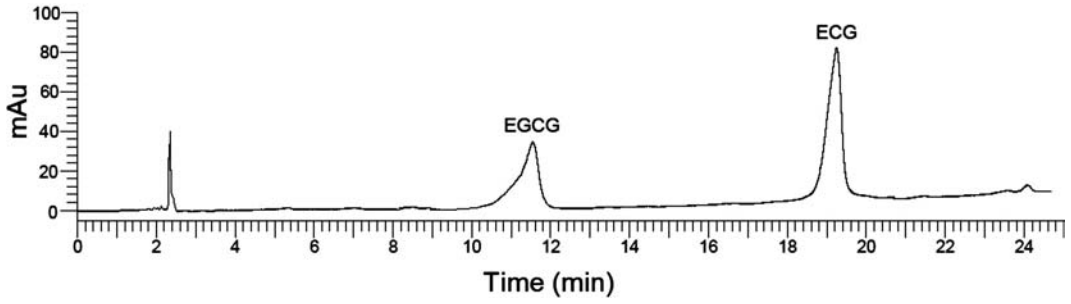

Figure 4. HPLC chromatogram of white tea extract-loaded NPs.

As expected, the tea extract was rich in catechins, predominantly in EGCG (31.31 ± 2.54 of mg/g dry white tea leaves), followed by ECG (6.87 ± 0.56 mg/g), EGC (2.70 ± 0.12 mg/g), and EC (1.46 ± 0.39 mg/g).

Formulation and Characterization of White Tea Extract-Loaded NPs. In this study, white tea extract was encapsulated into polymeric NPs by a nanoprecipitation technique using PCL and alginate as carrier materials. Among biodegradable polymers, PCL alone or in combination with many other polymers shows an excellent biocompatibility and great permeability, which make it a suitable candidate for controlled drug delivery.[23,24] In our previous studies, docetaxel-loaded NPs composed of block copolymers of poly(D,L-lactide-*co*-caprolactone) and poly(L-lactide-*co*-caprolactone-*co*-glycolide)[25] and resveratrol-loaded NPs based on PCL and poly-D,L-lactide-*co*-glycolic acid)−poly(ethylene glycol) blend were successfully prepared and explored for prostate cancer treatment.[26] However, the naturally occurring biopolymer alginate has been employed for the production of a broad spectrum of drug delivery micro- and nanosystems.[27,28] To optimize the NPs formulation conditions, different amounts of alginate (0.1%, 0.5%, and 1.0% w/v) were initially employed. Results demonstrated that the composition of NPs strongly influenced the size and distribution of NPs. In particular, as displayed in Figure 3, NPs obtained with alginate at lower concentration (0.1% w/v) are characterized by a mean particle size of about 300 nm with a wide distribution (PDI 0.397 ± 0.27) (Figure 3A and B). Conversely, by increasing the alginate concentration to 1.0% w/v, NPs showed a larger particle size distribution (560.80 ± 17.77 nm), probably due to the high viscosity of alginate solution that promoted a larger particle precipitation with a tendency to separate (Figure 3E and F). The optimal alginate concentration was found to be 0.5% w/v that produced NPs with spherical shape, a mean diameter of 380.80 ± 37.97 nm, and a unimodal distribution (PDI 0.15 ± 0.06) (Figure 3C and D). With regard to particle size and colloidal stability, these NPs were selected for the subsequent studies.

The TPC encapsulation efficiency, calculated by the Folin−Ciocalteu assay, was established as 24.07 ± 1.26%, corresponding to 24.24 ± 1.60 GAE μg/mg of NPs. However, the HPLC chromatograms of extract encapsulated into NPs revealed the presence only of the most abundant catechins EGCG and ECG (Figure 4). The amount of EGCG and ECG detected corresponds to encapsulation efficiency values of 30.62 ± 0.89% and 32.60 ± 5.39%, respectively. Additionally, the complete disappearance of the caffeine peak was observed in the chromatogram. We hypothesize that, during the encapsulation process, the caffeine can establish strong interactions with acidic groups of alginate in solution, contributing to a reduced incorporation into the polymer matrix and can be removed later during washing or freeze-drying steps.

The chemical interactions after encapsulation of tea extract into NPs were investigated by FT-IR spectroscopy, and the results are reported in Figure 5. According to the literature,[26,29]

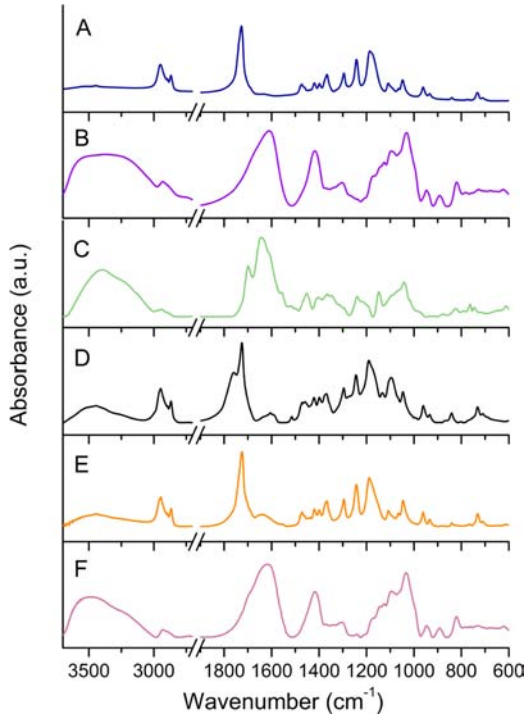

Figure 5. FTIR spectra of (A) pure PCL, (B) pure alginate, (C) white tea extract, (D) white tea extract-loaded NPs, (E) tea extract/PCL blend, and (F) tea extract/alginate blend.

for PCL, the bands at 2950−2865 cm^{-1} were assigned to CH_2 stretching. The peak at 1725 cm^{-1} represented C═O ester stretching, while peaks at 1293, 1240, and 1190 cm^{-1} corresponded to C−O and C−C, C−O−C, and O−C−O stretching, respectively. Sodium alginate showed a broad band at 3650−3000 cm^{-1} due to O−H stretching, the bands at 1620 and 1418 cm^{-1} were assigned to asymmetric and symmetric stretching peaks of carboxylate salt groups, respectively, and the bands around 1030 cm^{-1} were attributed to C−O−C stretching.[30] Most of the absorptions of white tea extract are well consistent with the data reported in the literature.[31] The broad band between 3650 and 3000 cm^{-1} was consistent with O−H stretching and with N−H stretching in primary and secondary amines, and amides. The bands between 2940 and 2860 cm^{-1} were assigned to C−H stretching of aliphatic

DOI: 10.1021/jf505850q
J. Agric. Food Chem. 2015, 63, 2026−2032

groups. The band at 1700 cm^{-1} represented the C═O vibrations. The strong band at 1640 cm^{-1} was due to the C═C vibration of aromatic structures, C═O stretching of primary amide, and carboxylic acids. Another broad band was noted between 1450 and 1360 cm^{-1} arising from the O−H, and C−O vibration stretching. The band at 1250 cm^{-1} is generally linked to C−H stretch and O−H deformation of carboxyl groups, and to the N−H of amide II.[32] The presence of the extract in NPs was confirmed by the broad band between 3650 and 3000 cm^{-1}, and the band at 1600 cm^{-1}, while the shifted peak at 1760 cm^{-1} indicated both the intermolecular and the hydrogen-bonding interactions between polymers and white tea extract. Meanwhile, the FTIR spectra of tea extract/PCL and tea extract/alginate in physical mixtures did not shown any significant shift, suggesting that the mentioned chemical interactions were most favored during the nanoprecipitation process.

Release Kinetics of Polyphenols. To assess the potential of prepared NPs for oral administration, we performed the in vitro release test at pH 1.2 for 2 h followed by pH 7.4 for 5 h, to reproduce the gastric and intestinal fluids, respectively.

As shown in Figure 6, in the case of free tea extract a rapid and complete dissolution of polyphenols within the first 2 h at

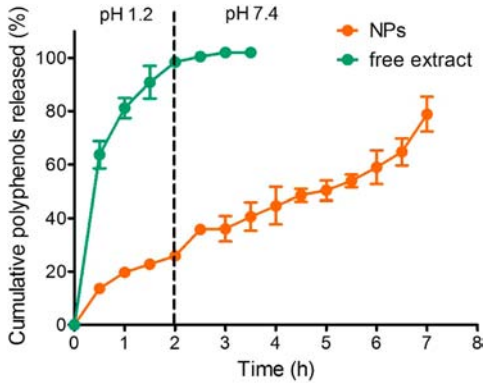

Figure 6. In vitro release profiles of polyphenols (TPC) from free white tea extract and from tea extract-loaded NPs in 0.1 M HCl (pH 1.2) for 2 h, followed by PBS (pH 7.4) for 5 h. Data are means ± SD, $n = 3$.

acidic pH was observed. In contrast, the tea extract-loaded NPs exhibited a controlled release in both tested conditions. In particular, NPs released about 20% of the encapsulated polyphenols in simulated gastric medium, and about 80% content within the subsequent 5 h at pH 7.4. This finding could be related to the low permeability of the water in the hydrophobic matrix of the NPs, due to the presence of PCL, and to the interaction of polyphenols−polymers that makes difficult the polyphenols' dissolution in water, thus retarding the release.[33] In addition, the presence of alginate promotes the formation of a gelatinous layer following the hydration, which can act as a polyphenols diffusion barrier.[34]

To assess the kinetics of polyphenols release from NPs, the in vitro release data were fitted to established mathematical models (zero-order $[Q = k_0 t]$, first order $[\ln\{100 - Q\} = \ln Q_0 - k_1 t]$, Higuchi $[Q = k_H t^{1/2}]$). Additionally, to better understand the release mechanism, the data were fitted to the Korsmeyer−Peppas exponential model $M_t/M_\infty = ktn$, where M_t/M_∞ is the fraction of polyphenols released after time t, k is a kinetic constant, and n is the release exponent that characterizes the different release mechanism.[35,36]

The correlation values (R^2) were used as an indicator of the best fitting of the models considered for loaded-NPs at different pH values. Comparison of the correlation coefficients identified the Higuchi model as that with the best fit of data at acidic pH (0.9918), while at pH 7.4 the release profile was consistent with zero-order kinetics (0.9840) (data not shown).

In simulated gastric conditions, the value of $n \leq 0.5$ revealed that the polyphenols' release follows a classical Fickian diffusion-controlled mechanism, which is assumed to be facilitated by the swelling of alginate, whereas for values $0.5 < n < 1$ found at pH 7.4, it is an indicator of both phenomena (drug diffusion in the hydrated matrix and polymer relaxation), which usually describes anomalous transport.[37]

DPPH• Inhibition. The polyphenolic composition of tea and especially the amount of catechins have aroused great interest because of their ability to scavenge free radicals, thereby inhibiting oxidative stress that is believed to be involved in several diseases.[38,39]

Free radical scavenging activities of unencapsulated white tea extract as a function of concentration are shown in Figure 7A.

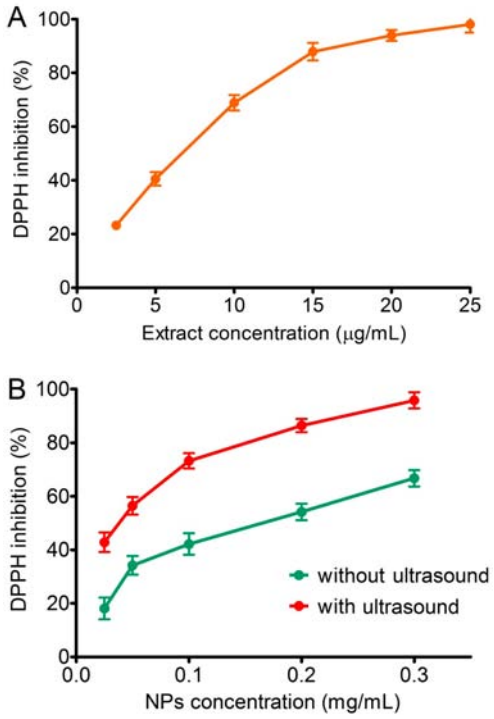

Figure 7. Comparison of DPPH• inhibition percentage of white tea extract (a) and tea extract-loaded NPs (b) at different concentrations, with and without ultrasound treatment. Data are means ± SD, $n = 3$.

The results indicated that the antioxidant activity of tea extract is concentration-dependent. This DPPH• inhibition percentage reached its maximum (98.07 ± 3.02%) at a concentration of 25 μg/mL white tea extract, with an IC_{50} value of 7.30 ± 0.27 μg/mL.

To prove the retention of antioxidant activity of tea extract after encapsulation, the DPPH• inhibition test was performed at different concentrations of tea extract-loaded NPs. As depicted in Figure 7B (without the ultrasound), only 60% of DPPH• inhibition was observed at higher concentration (0.3 mg/mL), with an IC_{50} value of 0.190 ± 0.16 mg/mL, probably

DOI: 10.1021/jf505850q
J. Agric. Food Chem. 2015, 63, 2026−2032

due to the slow release of loaded polyphenols. Because only the free polyphenols are able to show the activity toward DPPH•, to facilitate their release from NPs the test was then performed by incubation of the samples in an ultrasonic bath. As shown, a significant increase ($p < 0.05$) of DPPH• inhibition percentage at all tested concentrations was obtained, with an IC_{50} of 0.043 mg/mL, indicating that white tea extract maintained a good free radical scavenging activity after encapsulation into NPs.

Stability Studies. Several studies reported that polyphenols are subject to degradation by many environmental conditions, and temperature represents the dominant factor.[40,41] The catechin degradation involves different reactions (i.e., epimerization, oxidation, polymerization, etc.), and it was associated with a loss of catechins, mainly of EGCG, which appears to be susceptible to degradation during storage.[42,43]

In this study, the TPC and catechin retention of tea extract-loaded NPs and unencapsulated tea extract, stored at different temperature (25 and 40 °C), was monitored over 30 days. The results show that, overall, the polyphenols content was strongly influenced by the storage temperature (data not shown). The exposure of tea extract at 25 °C produced about 65% of TPC retention that significantly decreased to 43.7 ± 3.2% for the samples stored at 40 °C. However, the encapsulation of tea extract into NPs largely prevented its degradation with respect to free white tea extract, providing a TPC loss of 12.6% and 24% of the initial content with increasing storage temperature.

These results were also confirmed by HPLC analyses that revealed a significant reduction of EGCG concentration in the free white tea extract in comparison to the encapsulated extract (data not shown). The catechin content of loaded NPs, measured at 25 and 40 °C, was 1.3- and 1.7-fold higher than that in the free tea extract, respectively.

In summary, in this study the formulation of white tea extract into novel polymeric NPs for nutraceutical applications has been investigated. The results clearly demonstrated the effectiveness of the nanoencapsulation to control the white tea extract release in gastrointestinal fluids and to preserve the antioxidant activity of the polyphenols. Moreover, the encapsulation of the white tea extract into NPs significantly increased stability, thus preventing the losses of TPC and catechins over 30 days of storage. The application of this nanotechnology could offer interesting perspectives for the potential use of white tea extract as innovative nutraceuticals.

or functional food supplement in China commonly used for its antidepressant, anti-inflammatory, antibacterial, antithrombotic, hepatoprotective, and choleretic effects.[23−26] Genipin is also a natural water-soluble bifunctional cross-linking reagent, which reacts with amines in proteins spontaneously, thus producing a semiinterpenetrating protein network within the developed hydrogel system.[27] Recently, stable casein microgels were developed from the covalent cross-linking of casein micelles with genipin, which showed resistance to dissociating agents.[28]

Herein the effects of genipin cross-linking of the interfacial casein layer on the colloid structure behavior induced by pH and the lipase lipolysis profile of the nanoemulsions were investigated. The casein-stabilized nanoemulsions were prepared through high pressure homogenization. The physicochemical properties of the genipin cross-linked nanoemulsions under different reaction conditions, including particle size, polydispersity index (PDI), surface charge, and morphology, as well as their variation under different gastrointestinal (GI) pH environments, were characterized by dynamic light scattering (DLS), zeta potential measurement, and TEM. The effects of different amounts of bile salt extract (BE), genipin/casein mass ratio, and cross-linking time on the lipolysis of lipid droplets were systematically investigated through measuring the completeness of lipolysis. It has been previously reported that there was little difference in the rate and extent of in vitro lipid digestion in emulsions stabilized by unheated and heated β-lactoglobulin, indicating that disulfide cross-linking of the interfacial protein did not influence the lipolysis of the emulsions.[29] The results presented here show a different trend.

MATERIALS AND METHODS

Materials. Extra virgin olive oil obtained from Agrioil SpA (Italy) was selected as the oil phase. According to the composition table provided by the manufacturer, the lipid content was 91.6 g/100 mL, which contained 13 g of saturated fatty acid. There was no protein, cholesterol, carbohydrate, or metal elements in the oil. Bovine casein of technical grade (C7078), BE (porcine, B8631), lipase from porcine pancreas (activity ≥2.0 USP units/mg, Type II, L3126), and NaOH were purchased from Sigma Co. (St. Louis, MO). Genipin (purity >98%) was purchased from Linchuan Zhixin Biotechnology Co., Ltd. (Jiangxi, China). All other chemicals were of analytical grade.

Preparation of Nanoemulsions. Aqueous solutions of casein protein with a concentration of 0.5%, 1%, and 2% (w/w) were prepared by dispersing the dried powders in pH 7.0 buffer (10 mM PBS) at room temperature and adjusting the pH to be around pH 8.0 until the protein was fully hydrated. Then the pH of the casein solution was adjusted back to pH 7.0 and mixed overnight to enhance hydration of the protein prior to homogenization. Extra virgin olive oil with a final concentration of 10% (w/w) in the emulsion was used as core material. The oil (40 mL) and aqueous (360 mL) phases were premixed with a high speed homogenizer (Ultra-Turrax T25 IKA Works Inc., Wilmington, NC) equipped with a S25 N18 G rotor operated at 24 000 rpm for 1 min at room temperature. The coarse emulsion (400 mL) was finely dispersed with a high pressure homogenizer (High Pressure Homogenization, NS1001 L2K, Niro Soavi, Italy) with pressures of 90 MPa for five passes.

Cross-Linking the Casein Emulsified Nanoemulsions with Genipin. For preparation of genipin cross-linked casein-stabilized nanoemulsions with a casein concentration of 20 mg/mL, different amounts of genipin with concentrations of 4, 8, and 16 mg/mL were added to the nanoemulsion droplet suspension, forming different final genipin/casein mass ratios of 0, 1:20, 1:10, and 1:5, with a reaction time of 24 h at 37 °C. For the nanoemulsion with a casein concentration of 10 mg/mL, the genipin concentrations were 2, 4, and 8 mg/mL. In addition, the reaction mixture was incubated at 37 °C for different times of 0, 6, 12, and 24 h, with a genipin/casein mass ratio of 1:10.

Nanoemulsion Stability and Structure Behavior in Simulated GI pH Environments. Equal amounts of the casein-emulsified nanoemulsion and the genipin cross-linked casein-emulsified nanoemulsion were first diluted 50 times in pH 1.2 (0.1 N HCl), pH 6.0 (10 mM PBS), and pH 7.0 (10 mM PBS) solutions for 2 h, respectively, simulating the pH environments of the GI tract. The size distribution, surface charge, and morphology of the nanoparticles at these distinct pH conditions were characterized by DLS, zeta potential measurement, and TEM.

Characterization of the Nanoemulsions. The measurement of particle size, polydispersity index (PDI), and zeta potential of the casein-emulsified nanoemulsion and the genipin cross-linked casein-emulsified nanoemulsion were performed on a Zetasizer Nano-ZS (Malvern Instruments) on the basis of DLS techniques. To avoid multiple scattering effects, emulsions were first diluted 50 times with deionized water (or simulated GI solution) and stirred continuously before measurement to ensure that the samples were homogeneous. All measurements were made in triplicate at 25 ± 1 °C.

The morphology of the casein-emulsified nanoemulsion and the one cross-linked with genipin was characterized by a high-performance digital imaging TEM machine (JEOL H-7650, Hitachi High-Technologies Corp.). One drop of the suspension was stained with 2% (w/v) phosphotungstic acid, placed on a copper grid, and allowed to evaporate in air. Once evaporated, the samples were placed in the TEM machine for imaging. The accelerating voltage used was 100 kV, and the images were taken on a Gatan electron energy loss spectrometry system using a 6 eV energy slit.

In Vitro Intestinal Lipid Digestion Model. The extent of in vitro intestinal digestion of casein-emulsified nanoemulsions and their counterparts cross-linked by genipin was determined using the pH-Stat method.[6,30,31] To evaluate the effect of BE on in vitro intestinal digestion, nanoemulsion systems were incubated with BE solution with different concentrations to obtain samples with different BE/casein mass ratios. To evaluate the influence of cross-linking degree on the extent of in vitro intestinal digestion, genipin cross-linked nanoemulsions with different genipin/casein mass ratios and different cross-linking times were applied as the digestion samples. The basic procedure for the in vitro intestinal digestion: (i) A 10.0 mL amount of nanoemulsion sample (with or without genipin cross-linking) was placed in a glass beaker and incubated in a water bath at 37 °C for 10 min, and then the system was adjusted to pH 7 using HCl or NaOH solutions. (ii) A 10.0 mL amount of BE solution with different concentrations, 1.0 mL of $CaCl_2$ solution, and 1.0 mL of NaCl solution were added to the sample under continuous stirring, and the system was adjusted back to pH 7 if required. (iii) A 1.0 mL amount of freshly prepared lipase solution was added to above mixture. The lipase solution was the supernatant obtained through centrifuging (4000 rpm for 5 min in 4 °C) the lipase powder dispersion (60 mg/mL in pH 7 phosphate buffer), which was incubated in 37 °C for 10 min before application. (iv) Immediately after step iii, the pH of the mixture under digestion was monitored with a Thomas Scientific pH meter (Model 8025) and maintained at pH 7.0 by titrating the free fatty acid released from lipolysis with an appropriate volume of 0.1 M NaOH until the pH value remained unchanged for 5 min. The final ionic concentration of the digestion medium before titration was 20 mM $CaCl_2$ and 150 mM NaCl in 10 mM phosphate buffer. The final BE concentration of the digestion medium before titration was in the range of 1.14−9.09 mg/mL. The volume of NaOH solution added to the digested mixture was recorded, which represented the free fatty acid generated by lipolysis.

In the present study, a mouth or stomach stage in the in vitro digestion model was not included; however, the passage of nanoemulsions through these regions of the GI tract could influence the composition, size, and interfacial characteristics of lipid droplets. Hydrolysis of the interfacial casein protein after genipin cross-linking by proteases in the stomach and intestine is also possible. In future studies, it would be useful to use a more sophisticated in vitro

DOI: 10.1021/jf505724c
J. Agric. Food Chem. 2015, 63, 2033−2040

digestion model to examine the effects of these additional digestive stages on the nanoemulsion performance.

Statistical Analysis. Data were expressed as mean ± standard deviation (SD) of at least triplicates. The least significant difference (LSD) test and one-way analysis of variance (ANOVA) were used for multiple comparisons by SPSS 16.0. A difference was considered to be statistically significant if $p < 0.05$ and very significant if $p < 0.01$.

RESULTS AND DISCUSSION

Original Microstructure. Figure 1 shows the diameters of olive oil emulsion droplets stabilized with casein as a function of the total protein concentrations. The average droplet sizes of the casein-emulsified nanoemulsion with different protein concentrations were in a range from 206.7 ± 17.0 nm to 271.5 ± 23.1 nm with the surface charge around −55 mV (data not shown). The PDIs of the droplet suspension were less than 0.3, indicating that the nanoemulsion was homogeneously dispersed in the solution. Figure 1 shows that the droplet size decreased with the increase in casein concentration from 5 mg/mL to 20 mg/mL. Meanwhile, the PDI of the nanoemulsion suspension decreased sharply, which indicated that the homogeneity of the nanoemulsion suspension was enhanced at high casein concentration. At lower protein concentrations, less protein could be adsorbed at the oil−water interface; hence, less interfacial area was covered by the protein, leading to an increase in emulsion droplet size and suspension heterogeneity. At higher protein concentrations, the surface of the droplet was fully covered by the protein, making the nanoemulsion structure smaller. Due to electrostatic repulsion between the droplets, the particle size of the droplets remained constant with the increasing casein concentration.[32,33]

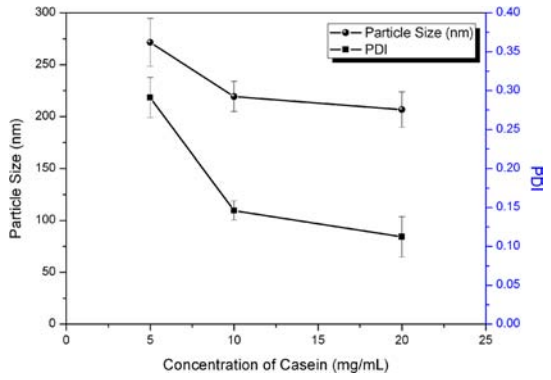

Figure 1. Average droplet size and PDI of the casein-emulsified nanoemulsion with different protein concentrations (5, 10, 20 mg/mL). Data were expressed as mean ± standard deviation (SD) of at least triplicates.

Genipin Cross-Linked Nanoemulsion Microstructure. Genipin covalently cross-linked the casein protein covering the surface of the olive oil nanoemulsion droplets spontaneously when genipin was added to the original suspension. The appearance of blue coloration in the reaction mixture was traditionally considered as rapid evidence that the cross-linking reaction was taking place.[27] The cross-linking reaction occurred by means of a complex mechanism.[34] A nucleophilic attack by the amino groups of casein protein on the olefinic carbon atom at C-3 in genipin occurred, followed by dihydropyran ring opening and attack by the secondary amino group on the newly formed aldehydo group. In the product, short chains of condensed genipin acted as cross-linking bridges. Figure 2 shows the droplet particle size and surface charge of the casein-emulsified nanoemulsion after cross-linking with genipin for 24 h as a function of different mass ratios between genipin and the protein (0, 1:20, 1:10, and 1:5). After cross-linking with genipin, the droplet size of the nanoemulsion with protein concentrations of either 10 or 20 mg/mL slightly increased compared with the nonmodified nanoemulsion (Figure 2A). This might be caused by the increased thickness of the interfacial protein layer due to the gelation of the casein adsorbed on the surface of oil droplet after intraparticle cross-linking, rather than interparticle association of the nanoemulsion droplets. It was reported previously that genipin could spontaneously cross-link casein to induce gelation of the protein.[28,35] The gelation rate increased significantly with the increase in genipin concentration and elevation of reaction temperature. Comparatively, no obvious changes in the droplet surface charge could be observed after cross-linking with genipin. The surface charge of casein-emulsified nanoemulsion droplets was in the range of −50 mV to −60 mV. Genipin cross-linked protein through its reaction with amino groups, with little impact on the carboxyl groups in the protein. Therefore, the surface charge of the nanoemulsion droplets was influenced little by genipin cross-linking.

Structure Stability of the Nanoemulsion and the Genipin Cross-Linked Nanoemulsion in Different Gastrointestinal pH Environments. Interfacial proteins impart emulsion stability by a combination of electrostatic and steric

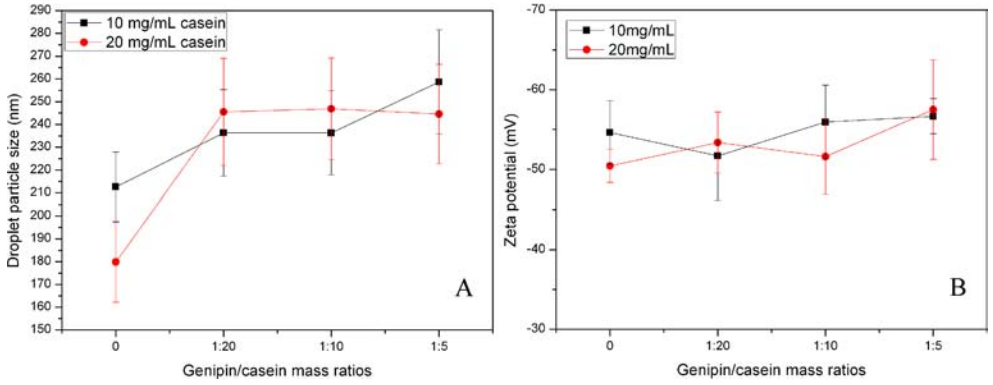

Figure 2. Droplet size (A) and surface charge (B) of the casein-emulsified nanoemulsion cross-linked with genipin under different genipin/casein mass ratios of 0, 1:20, 1:10, 1:5 (reaction at temperature of 37 °C for 24 h). Data were expressed as mean ± standard deviation (SD) of at least triplicates.

mechanisms.[32] The electrostatic effect of the emulsified protein on emulsion stability could be significantly influenced by the environmental pH conditions. Stability and structure behaviors of emulsions in the GI environment have received increasing attention because they impart not only the delivery profile of the nanoemulsion as drug or nutriceutical carriers but also the oil digestion rate and degree.[36,37] Figure 3A shows the droplet size of the casein-emulsified nanoemulsion with or without genipin cross-linking under simulated gastric acidic conditions. The droplet size of the nanoemulsion without genipin cross-linking increased significantly with prolonged incubation time under harsh gastric acidic conditions (pH 1.2). Similar phenomena were also reported in previous studies on the structure behaviors of protein-emulsified emulsions. Sarkar et al. found that β-lactoglobulin (β-lg)-stabilized emulsions underwent extensive droplet flocculation, with some coalescence, upon mixing with simulated gastric solution, which was primarily attributed to the acidic pH.[38] Golding et al. investigated the structure behavior of a protein-stabilized, negatively charged emulsion under simulated GI conditions and also found that incubation in a gastric pH environment resulted in emulsion flocculation.[9]

Interestingly, after cross-linking with genipin, the stability of casein protein-emulsified nanoemulsion was enhanced. Especially, with genipin/protein mass ratios of 1:10 and 1:5, the droplet size of the nanoemulsion was significantly ($p < 0.05$) or very significantly ($p < 0.01$) smaller than that of the non-cross-linked nanoemulsion at the same incubation time intervals. For the genipin cross-linked nanoemulsion with a genipin/protein mass ratio of 1:5, no changes in droplet size could be observed within the incubation time under the simulated gastric pH condition (pH 1.2). Under simulated intestinal pH environments, pH 6.0 for the duodenum and pH 7.0 for the proximal ileum, both the genipin cross-linked and non-cross-linked casein-emulsified nanoemulsions remained stable without changes in droplet size within the incubation time (Figure 3b,c).

Figure 4 shows the particle size distribution of the cross-linked nanoemulsion (genipin/protein mass ratio of 1:5) and the non-cross-linked nanoemulsion in a simulated gastric environment of pH 1.2 for 30 min. The droplet size distribution of the casein-emulsified nanoemulsion changed sharply (Figure 4a,b). Comparatively, no significant changes in the droplet size distribution of the genipin cross-linked nanoemulsions could be found under the same gastric pH condition for the same incubation time (Figure 4c,d). Similar phenomena were also found in a previous study where casein-stabilized emulsions enzymatically cross-linked by transglutaminase maintained colloid stability under gastric acidic conditions.[39] In the present study, the negative surface charge of the genipin cross-linked nanoemulsion droplets decreased in the same trend (data not shown) as that which occurred in the surface charge of the non-cross-linked nanoemulsion when it was incubated in the simulated gastric pH environment. Therefore, the significantly enhanced colloid stability of the genipin cross-linked nanoemulsion under strong acidic conditions might be mainly attributed to the amplified steric mechanics caused by gelation of the casein protein, rather than the electrostatic mechanics.

Morphology of the Nanoemulsions. TEM images of the nanoemulsion with stable structure were examined for the effects of genipin cross-linking on the morphology of the casein-emulsified nanoemulsion and its structure in a strong acidic environment. Figure 5 shows the morphology of the

Figure 3. emulsion with genipin. The droplet size of the genipin cross-linked nanoemulsion was similar to that of the original one in the TEM images (Figure 5A,B). These results were consistent with those obtained from the DLS results (Figure 2A). Compared with the casein-emulsified nanoemulsion droplets in Figure 5A, the genipin cross-linked ones in Figure 5B showed more compact microstructure with clearer and defined contour. After incubation in the pH 1.2 solution for 2 h, the genipin cross-linked nanoemulsion droplets were still stable and dispersed homogeneously (Figure 5C). It was consistent with the result in Figure 3A. Interestingly, the nanoemulsion droplets showed "core−shell" structure with a phantomlike shell and clear core, which might be caused by the swelling of the surface protein gelation film under strong acidic conditions.

Effects of Different BE/Protein Mass Ratios on Lipid Digestion of the Nanoemulsions and Genipin Cross-Linked Nanoemulsions. Figure 6 shows the volume of NaOH (0.1 M) consumed to neutralize the released free fatty

DOI: 10.1021/jf505724c
J. Agric. Food Chem. 2015, 63, 2033−2040

acid during in vitro intestinal digestion of the nanoemulsion lipid droplets with different BE/protein mass ratios ranging from 0, 1:4, 1:2, to 1:1. The amount of consumed NaOH increased with the increase of BE amount added to the nanoemulsion system, indicating that lipolysis was enhanced. The increased amount of casein covering the surface of the lipid droplets might be replaced by the elevated amount of BE, leading to a larger proportion of the drop surface ready for adsorption of lipase.[6,10] Therefore, an increased amount of free fatty acid was released from intestinal digestion of the lipid droplets in the system. Interestingly, cross-linking of the casein (10 and 20 mg/mL)-stabilized nanoemulsions with genipin significantly ($p < 0.05$) or very significantly ($p < 0.01$) decreased the amount of consumed NaOH compared with their non-cross-linking counterparts at the same BE/protein mass ratio, which indicated that lipolysis of the lipid droplets was effectively delayed. It was reported that the steric resistance between the interfacial layer and the bile salt played an important role in the displacement of the casein protein on the surface of lipid droplets.[13] One strategy that was applied in previous studies to enhance the steric resistance for inhibiting the displacement by bile salts was to associate casein protein on the nanoemulsion droplet surface with polysaccharides, which could further inhibit the absorption of the lipase.[17−19] In the present study, cross-linking of the droplet surface casein protein with genipin also formed a stable steric film that might resist the interfacial displacement by the bile salts to control the lipid digestion process, as it could retard the next action of lipase.

Effects of Different Genipin/Protein Mass Ratios on the Lipid Digestion of the Genipin Cross-Linked Nanoemulsion. Figure 7 shows that the amount of NaOH consumed to neutralize the released free fatty acid during lipid hydrolysis decreased with the increase in genipin/protein mass ratio in lipid nanoemulsions stabilized with 10 and 20 mg/mL casein protein, which indicated that the amount of released free acid decreased with the increase in genipin/protein mass ratio. The free fatty acid released from the cross-linked nanoemulsion (protein concentration of 10 mg/mL at genpin/protein mass ratios of 1:10 and 1:5, and protein concentration of 20 mg/mL at genpin/protein mass ratios of 1:20, 1:10, and 1:5) was very significantly ($p < 0.01$) less than that of their non-cross-linking counterparts. It was reported in a recent study that casein microgels were formed through cross-linking casein micelles with genipin, which were resistant to the presence of dissociating agents, did not dissociate at the air−solution interface, and formed solidlike interfaces rather than a viscoelastic gel.[28] In the present study, it has been revealed in the DLS results (Figure 2) that the increased genipin/protein mass ratios increased the thickness of the interfacial casein protein layer. This could also be caused by the formation of casein microgels on the O/W interface, which enhanced its resistance against bile salt displacement. Further, the lipolysis of the nanoemulsion lipid droplets was inhibited by retarding the following action of lipase. Therefore, the intestinal digestion of lipid could be effectively decreased and controlled through modulating genipin cross-linking degrees. The lipid digestion extent of the nanoemulsion droplet emulsified with 20 mg/mL casein was higher than that of the nanoemulsion droplet emulsified with 10 mg/mL casein, which was mainly related to the decrease in droplet size with the increase in casein concentration. It was reported that the extent of lipid digestion increased with the decrease in mean droplet diameter, which was attributed to the increase in lipid surface area exposed to pancreatic lipase with decreasing droplet size.[40]

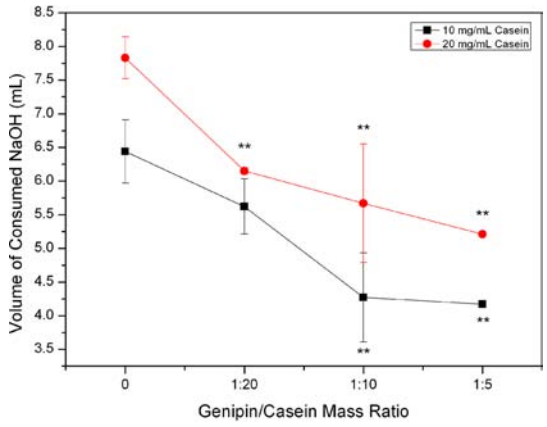

Figure 7. Extent of lipid digestion of the genipin cross-linked nanoemulsions stabilized with 10 and 20 mg/mL casein protein under different genipin/casein mass ratios. Data were expressed as mean ± standard deviation (SD) of at least triplicates. (The genipin cross-linking reaction took place for 12 h, and the BE/casein mass ratio was 1:2 for the in vitro intestinal digestion model. $^{**}p < 0.01$.)

Effects of Different Genipin Cross-Linking Time on the Lipid Digestion of the Genipin Cross-Linked Nanoemulsion. At the same genipin/protein mass ratio of 1:10, the cross-linking degree could also be adjusted through changing the cross-linking time. Figure 8 shows that the amount of NaOH consumed to neutralize the released fatty acid decreased with the increase in genipin cross-linking time during the 24 h testing. For the nanoemulsion droplets with a casein concentration of 10 mg/mL, intestinal digestion of the lipid droplets were very significantly ($p < 0.01$) decreased with the cross-linking times of 6, 12, and 24 h, compared with their counterpart digestion system with a cross-linking time of 0. The amounts of free fatty acid released from the digestion of the original nanoemulsion and the immediate mixture of the original nanoemulsion and genipin without cross-linking time were similar, indicating that the delay effect of genipin cross-

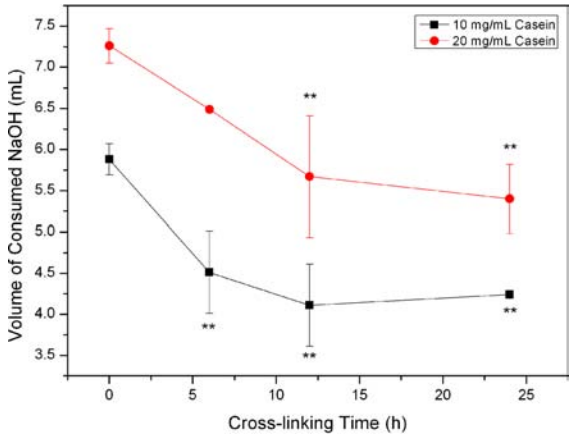

Figure 8. Extent of lipid digestion of the genipin cross-linked nanoemulsions stabilized with 10 and 20 mg/mL casein protein with different cross-linking times. Data were expressed as mean ± standard deviation (SD) of at least triplicates. (The genipin cross-linking reaction took place with a genipin/casein mass ratio of 1:10, and a BE/casein mass ratio was 1:2 for the in vitro digestion model. $^{**}p < 0.01$.)

DOI: 10.1021/jf505724c
J. Agric. Food Chem. 2015, 63, 2033−2040

linking on lipase digestion was mainly attributed to the casein layer's resistance against bile salt displacement rather than a direct influence on lipase activity. There was no significant difference between the lipid digestion extent of the genipin cross-linked nanoemulsion with cross-linking times of 12 and 24 h, which indicated that complete cross-linking of the droplet surface casein protein was achieved with a genipin cross-linking time of 12 h. In previous studies, it was found that the swelling rate of casein hydrogel cross-linked with genipin and the release rate of its loaded drug decreased with the increase in cross-linking degree, which meant that more compact net structure was formed with an enhanced genipin cross-linking degree.[35]

A green and effective method, cross-linking of the interfacial casein layer on the surface of nanoemulsion droplets with genipin, was successfully established to significantly enhance the stability of the nanoemulsions under GI pH conditions and delay the digestion of lipid in the droplets. The droplet size of the homogeneously dispersed (PDI < 0.3), casein-emulsified nanoemulsion was in the range of 206.7 ± 17.0 nm to 271.5 ± 23.1 nm, and its surface charge was around −55 mV. Droplet size and surface charge of the nanoemulsions decreased with the increase in protein concentration from 5 to 20 mg/mL. Genipin cross-linking slightly increased the nanoemulsion droplet size and did not change the surface charge. The stability of the nanoemulsion under a harsh gastric pH environment was enhanced significantly ($p < 0.05$) or very significantly ($p < 0.01$) with steady particle size after cross-linking with genipin under different genipin/casein mass ratios. The flocculation that normally occurred on the casein-emulsified nanoemulsion in a gastric environment was successfully prevented. Regular spherical droplets with a particle size of 200−300 nm were observed by TEM. The genipin cross-linked nanoemulsion droplets showed more compact microstructure with clear and defined contour. Incubated under gastric pH conditions, the genipin cross-linking nanoemulsion showed a "core−shell" structure that might be caused by the swelling of the surface protein film. Interestingly, the digestion extent of the lipid in the nanoemulsion droplets by lipase under simulated intestinal fluid conditions was delayed very significantly ($p < 0.01$) after cross-linking the interfacial casein layer with genipin, which was enhanced by the increase in genipin/casein mass ratio and cross-linking time. Further study of the detailed mechanism of the resistant effect of genipin cross-linked casein against bile salts displacement is in progress.

2. MATERIALS AND METHODS

2.1. Chemicals and Reagents. The standard compounds used were purchased from Fluka Sigma-Aldrich (St. Louis, MO, USA) [gallic acid, caffeic acid, p-coumaric acid, cinnamic acid, (−)-epicatechin, (+)-catechin, chlorogenic acid, ellagic acid, (−)-epicatechin gallate, kaempferol, kaempferol-3-*O*-*β*-D-glucuronide, kaempferol-3-glucoside, polydatin, penta-*O*-galloyl-*β*-D-glucose hydrate, apigenin, quinic acid, brevifolin, protocatechuic acid, isorhamnetin, (+)-taxifolin, eriodictyol, rutin, quercetin, homovanillic acid, and kaempferol glucuronide], Chromadex Inc. (USA) [procyanidin B1], and Extrasynthese [luteolin, (+)-aromadendrin, phloridzin, flavonomarein, and apigenin-7-*O*-glucoside]. DPPH, AAPH (2,2′-diazo-bis-amidine-propane-dihydrochloride), and Trolox (6-hydroxy-2,5,7,8-tetramethyl-chroman-2-carboxylic acid) were obtained from Sigma-Aldrich (St. Louis, MO, USA); acetonitrile, acetic acid, methanol, and formic acid (LC gradient) from Merck (Darmstadt, Germany), and methanol from Prolabo (Obregón, Mexico).

2.2. Samples. Two strawberry purée substrates (A and B) made with production surplus, grown in Huelva (Andalusia, Spain), were used as substrates of the fermentation process were analyzed and previously reported.[3] The principal cultivated varieties were Camarosa, Candonga, Festival, Ventana, Splendor, Honor, and Coral. They were provided by Hudisa Company (Lepe, Huelva, Spain). Substrate A corresponds to the 2011 harvest and B to the 2012 harvest. *Saccharomyces cerevisiae* (CET 13057 isolated from native strawberry yeast)[11] was used as a starter for the submerged fermentation process. The fermentation process was as follows: 3.6 L of strawberry purée was placed into the bioreactor and the conditions set (29 °C, 26.20 rad s^{-1}); the medium was saturated with oxygen only at the beginning of the fermentation process, before the inoculum was added [10% (w/v) glucose, 0.1% (w/v) $MgSO_4$, 0.2% (w/v) KH_2PO_4, 0.3% (w/v) $(NH_4)_2SO_4$, 0.4% (w/v) yeast extract, and 0.36% (w/v) bacteriological peptone]. At the moment when the inoculum was added, the initial samples were taken. The end of the fermentation process was established when the ferment reached alcoholic strengths of 3.02 and 1.8 for substrates A and B, respectively. The fermentation was carried out by batch, and a final sample was taken before the process continued with another fermentation cycle.

The pasteurization process consisted of heating the sample to 70−80 °C for 15 min and then rapidly cooling and freezing until analysis. Sample codes are shown in Table 1 and indicate: substrate named as A (more-concentrated purée) or B (less-concentrated purée); the cycles, referred to as 1, 2, 3, and 4; and finally the fermentation step I (initial), F (final), and P (pasteurized). Each cycle encompassed three analyzed samples.

Samples were analyzed in duplicate. In the case of substrate A, we studied four cycles, and with substrate B, three cycles. The fermented samples were supplied by the Department of Inorganic Chemistry and Chemical Engineering, Faculty of Science, University of Cordoba, Spain.

2.3. Sample Treatment. We followed a previously reported procedure[3,12] to extract nonanthocyanin polyphenol compounds from the samples.

2.4. Liquid Chromatography with Diode Array Detection (LC-DAD), Liquid Chromatography−Mass Spectrometry/Elec-

[a]The letter a indicates that identification of the compound was confirmed by the authentic standards.

trospray Ionization Tandem Mass Spectrometry (LC−MS/ESI−MS/MS), Multiple Reaction Monitoring (MRM) Analysis. *2.4.1. LC-DAD Analysis.* Chromatographic separation was performed using an LC Agilent Series 1100 system with a quaternary pump (Series 1100 G1311A), automatic injector (Series 1100 G1313A), and degasser (series 1100 G1379A). Detection took place using a UV−vis diode detector (Series 1100 G1379A) coupled to a Chemstation HP A.10.02 (HP/Agilent). The column used was a Merck LiChroCART 250−4 Superspher 100 RP-18 1.16056.0001. The method was a binary gradient and was the same as the one described and validated by Álvarez-Fernández et al.[3,12] Each sample was analyzed twice. Identification was achieved by matching the retention time and spectra of the peaks with the corresponding standards. Furthermore, samples were spiked with standards, where commercially available, to achieve complete identification. In accordance with the maximum absorbance of each compound, quantification was performed by external calibration at 280 nm, 320 nm, and 365 nm using the corresponding standards. Calibration curves were obtained by injecting standards diluted from five to eight different concentrations (R^2: 0.9949−0.9998). A duplicate was performed at each point of the calibration curve.

2.4.2. QTRAP Analysis. Mass analysis was performed using a PelkinElmer Series 200 HPLC system (Wellesley, USA) coupled to an Applied Biosystems QTRAP LC−MS/MS system (Foster City, USA) consisting of a hybrid triple quadrupole linear ion trap (QqQLIT) mass spectrometer equipped with an electrospray ion source. LC analyses were performed on a Merck LiChroCART 250−4 Superspher 100 RP-18 1.16056.0001 reversed-phase column. The flow rate was 400 μL min^{-1}. Chromatographic separation was performed using a binary gradient consisting of (A) water and (B) water/acetonitrile 20:80 (v/v). Both phases contained 0.1% formic acid (v/v). The elution gradient was the same as the one used in the LC-DAD analysis. The injection volume was 20 μL.

A MRM experiment was applied, where precursor ions and fragment ions were monitored at Q1 and Q3, respectively, using their corresponding standards.

For HPLC−ESI−MRM analyses, the mass spectrometer was set to the following optimized tune parameters: curtain gas 35 psi, ion spray voltage 4500 V, source temperature 350 °C, and source gas 60 psi. A dwell time was set at 50 ms for each transition.

2.4.3. High-Resolution Mass Spectrometry (HRMS). The experiments were performed using a Thermo Fisher Scientific (Bremen, Germany) LC system hybrid quadropole-orbitrap mass spectrometer (Q-OT-qIT). This benchtop UHPLC−MS/MS system combines quadropole precursor ion selection with high-resolution, accurate-mass spectrometer. Identification was performed according to mass spectra, exact mass, characteristic fragmentation, and retention time. Chromatographic separation was performed on a Phenomenex Luna

J. Agric. Food Chem. 2015, 63, 2041−2051

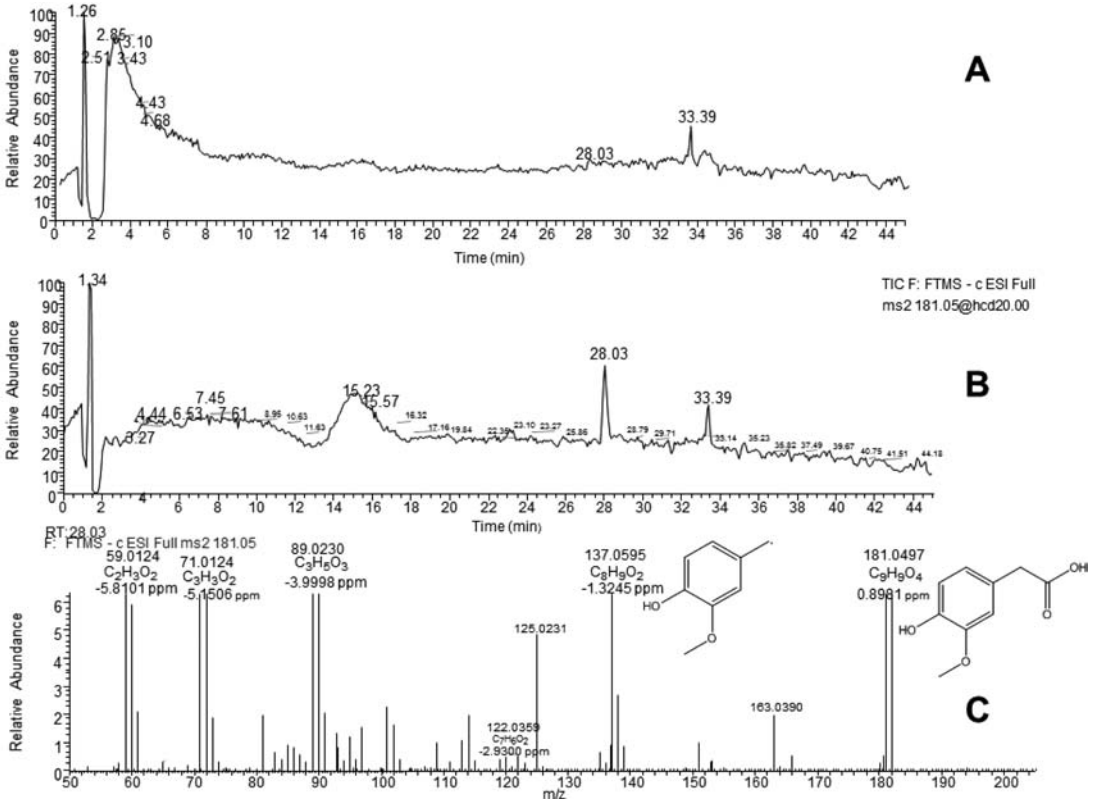

Figure 2. LC−MS/MS chromatogram of homovanillic acid. Panels A and B represent the TIC chromatogram of I and P steps of cycle three of substrate B, where the increase in signal is shown at 28.03 min after fermentation. Panel C represents the EPI chromatogram with the fragmentation pattern of a homovanillic acid isomer.

C18 (150 mm × 2.0 mm, 3 μm) column. The normalized collision energy of the high-collision-induced-dissociation (CID) cell was set at 20 eV. Twenty microliters of sample was injected, and the flow rate was 250 μL min^{-1}.

Identification in negative ionization mode using a binary gradient consisted of (A) water with 0.1% formic acid and (B) methanol with 0.1% formic acid 0.0−2.0 min 5% B, 2.0−40.0 min from 5−90% B, 40.0−42.0 min from 90−5% B, 42.0−45.0 5% B.

2.5. Antioxidant Activity. *2.5.1. ORAC Test.* The method used was as previously reported with the following modifications:[13] 100 μL of fluorescein (45 nM) and 50 μL of AAPH (15 mM) mixed with 50 μL of sample or Trolox. The reaction took place for a total time of 80 min. Fluorescence was assessed with a fluorometer (multidetector microplate Synergy HT, Biotek) with excitation, and emission wavelengths were 485 and 528 nm, respectively. Trolox was used as a calibration standard (0.5−9.5 μM). Fluorescein fluorescence readings were recorded every 5 min after addition of AAPH until they reached less than 5% of the initial reading. Results were calculated using the areas under the fluorescein decay curves between the blank and the sample and were expressed as micromols Trolox equivalents (TE) per gram of fresh weight. The reported values are the means of at least three experiments.

2.5.2. DPPH Method. Scavenging activity was also evaluated by DPPH using a slightly modified version of the literature method.[14] A 0.1 mL of sample in methanol (previously diluted 1:250) was added to 3.9 mL of DPPH methanolic solution (0.025 g L^{-1}) in a cuvette. Absorbance was recorded at 515 nm at the start time (when the sample was added) and 60 min later, when the reaction reached equilibrium. All measurements were the averages of at least three independent experiments, and methanol was used as the reference. To make the Trolox calibration curve, eight concentrations were used, which ranged from 0.9−0.12 mM. All values reported were recorded on a Hitachi UV-2800 spectrophotometer, thermostated with a Peltier system at 25 °C, and expressed as mmol of TE per kg of fresh weight.

2.6. Statistical Analysis. Statistical analyses were performed by means of Statistica software.[15] One-way analysis of variance (ANOVA) was used to test significant differences at the $p < 0.05$ level. Additionally, linear discriminant analysis (LDA) was tested to build a function to discriminate between the substrate (initial), fermented alcohol (final), and final pasteurized samples of all cycles and the two substrates A and B.

3. RESULTS AND DISCUSSION

3.1. Identification of Nonanthocyanin Phenolic Compounds. Sixty-six nonanthocyanin phenolic compounds and citric acid were identified in the strawberry purée and alcoholic-fermented samples. Figure 1 displays the LC−MS (QTrap) chromatogram, and Table 2 and 3 presents identification data. If standards were not available, identification was based on (I) retention time, (II) UV−vis spectra, (III) the deprotonated ion and mass spectra, (IV) accurate mass measurements, and (V) comparison with data reported in the literature.[16−34] When standards were available, identification was performed either by MRM or HRMS analysis.

As far as we know, 13 of these were identified for first time in strawberry and its derived alcoholic-fermented products: protocatechuic acid-4-*O*-β-hexoside (Peak 16), brevifolin carboxylic acid (Peak 35), ferulic acid glucuronide (Peak 2), dimer caffeic acid-*O*-hexoside (Peak 3), luteolin-3′-*O*-xyloside (Peak 27), isorhamnetin-3-*O*-glucoside (Peak 43), taxifolin-*O*-glucoside (Peak 34), (+)-aromadendrin rhamnoside (Peak 36), eriodictyol-7-*O*-glucoside (Peak 33), (+)-taxifolin, (+)-aromadendrin, eriodictyol, and homovanillic acid.

3.1.1. Hydroxybenzoic Acids and Derivatives. Peak 16 was tentatively identified as protocatechuic acid-4-*O*-β-hexoside. This compound exhibited a deprotonated [M-H]$^-$ ion at m/z

J. Agric. Food Chem. 2015, 63, 2041−2051

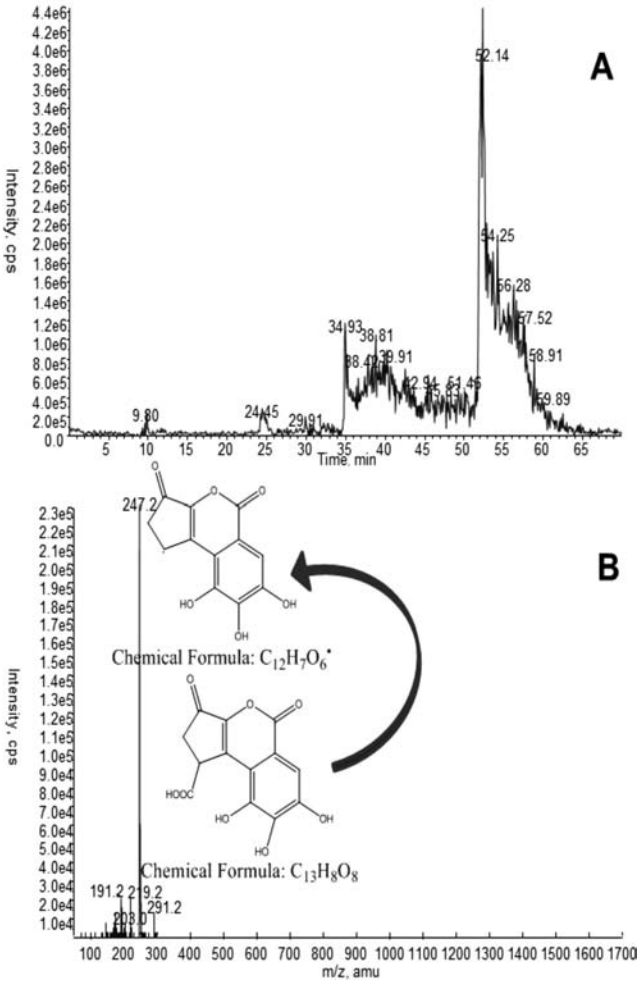

Figure 3. XIC and EPI chromatograms (A and B respectively) of brevifolin carboxylic acid and its fragmentation pattern.

315 and had MS/MS fragments at m/z 152 $[M\text{-}2H\text{-}162]^-$ (loss of glucose moiety) and 108 $[M\text{-}H\text{-}44]^-$ (loss of CO_2); it has been previously identified in artichoke.[18] Peak 26 was tentatively identified as 1-*O*-protocatechuic-*β*-xyloside. It presented a deprotonated ion at $[M\text{-}H]^-$ 285, and its fragmentation pattern was in accordance with the one reported in strawberry.[33] In our study, protocatechuic acid-4-*O*-*β*-hexoside was detected in strawberry (initial samples), in the alcoholic beverages (final sample) of both substrates, and in pasteurized samples of substrate A only.

3.1.2. Hydrolized Tannins. HHDP-Glucose (Peak 4) with pseudomolecular ion m/z 481 produced a fragment at m/z 301, which indicates the release of ellagic acid; this compound has been reported in strawberry before by Hanhineva et al.[25] Peak 28 had a pseudomolecular ion at m/z 951 and MS/MS fragmentation with m/z 907, 783, and 301. The fragmentation pattern and MW were in agreement with those reported before for Tris-galloyl-HHDP-hexose in *Fragaria vesca*.[20]

Peak 35 was tentatively identified as brevifolin carboxylic acid (Figure 3). This compound exhibited a deprotonated ion $[M\text{-}H]^-$ at m/z 291, and its fragmentation pattern had m/z 247, 203, which correspond to loss of carboxylic moieties. This compound was identified in all samples of substrate A. The results indicate the presence of this compound in strawberry and its alcoholic-fermented beverages. Brevifolin carboxylic acid has been reported before in pomegranate fruits,[22] but as far as we know, it has not yet been determined in strawberry.

3.1.3. Ellagic Acid and Derivatives. Peaks 18 and 52 were tentatively identified as methyl ellagic acid derivatives. Peak 18, with deprotonated $[M\text{-}H]^-$ ion 447 and fragmentation with MS/MS m/z 315, corresponds to the loss of pentoside residue, (132 Da), and m/z 301 resulted from the additional loss of a methyl group. This fragmentation pattern corresponds with methyl ellagic acid pentoside. Methyl ellagic derivatives have been reported before in strawberry.[32,20] The second peak, number 52, was tentatively identified as dimethyl ellagic acid pentoside with pseudomolecular ion $[M\text{-}H]^-$ 461, after loss of pentose moiety gave rise to m/z 315 and two fragments, m/z 300 and m/z 145, corresponding to ellagic acid. Many polyphenolic compounds occur naturally as metoxylated derivatives and exhibit a fragmentation pattern where loss of the methyl fragment from the pseudomolecular ion is common, which results in the production of the $[M\text{-}H\text{-}15]^-$ radical.[20]

3.1.4. Hydroxycinnamic Acids. Peak 2 was identified as ferulic acid glucuronide. This compound was detected only in the alcoholic fermented product (final samples of two substrates). It had a deprotonated $[M\text{-}H]^-$ ion 369 and exhibited a fragment with MS/MS m/z 193, which resulted from loss of a glucuronide moiety $[M\text{-}H\text{-}176]^-$. Peak 3 was tentatively identified as a dimer of caffeic acid-*O*-hexoside, described before in *Helichrysum obconicum*.[23] This compound had a pseudomolecular ion $[M\text{-}H]^-$ at 683 and a fragmentation pattern with two fragments, m/z 341 and 179, corresponding to caffeic acid hexoside and caffeic acid, respectively. This was detected only in substrate B, in the initial sample (strawberry) and alcoholic beverages (final samples).

3.1.5. Flavonols. Peak 27 was tentatively identified as luteolin-3′-xyloside with a deprotonated ion at m/z 417. After neutral loss of the sugar moiety $[M\text{-}H\text{-}132]^-$, it results in m/z 285 and 241 fragments, which are characteristic of luteolin aglycone. Peak 43 presented a pseudomolecular ion at m/z 955 and exhibited an MS/MS fragmentation pattern, which matched those attributed to isorhamnetin-3-*O*-glucoside in MassBank record PR040094[26] and ReSpect record PT204190.[31] It had a base peak, m/z 477, which gave rise to a fragment at m/z 301, characteristic of quercetin after cleavage of the molecule. This compound was present in all samples of the two substrates.

3.1.6. Dihydroflavonols. Peak 32 had an ion at 449 and was tentatively identified as (+)-aromadendrin hexoside, reported before in strawberry purée.[12] It presented a fragmentation pattern with base peak at m/z 431 $[M\text{-}H\text{-}18]^-$, which resulted from the dehydration process. Neutral loss of a hexose moiety $[M\text{-}H\text{-}162]^-$ gave rise to a fragment at m/z 287. The fragment at m/z 287 corresponded to (+)-aromadendrin aglycone.

Peak 36 was tentatively identified as (+)-aromadendrin rhamnoside in all samples of substrate A. This compound exhibited a deprotonated ion, $[M\text{-}H]^-$ 433, and presented a base peak at m/z 287, corresponding to (+)-aromadendrin aglycone and resulting from the loss of 146 Da, corresponding to dehydrated rhamnoside moiety. This compound has been described before in *Eucaliptus globulus*.[35]

Peak 34 was tentatively identified as taxifolin-*O*-glucoside in final and pasteurized samples of substrate A and initial and final samples of substrate B. It presented a pseudomolecular $[M\text{-}H]^-$ ion at 465 and MS/MS fragmentation with m/z 285, 151. The MW and fragmentation pattern were in accordance with those

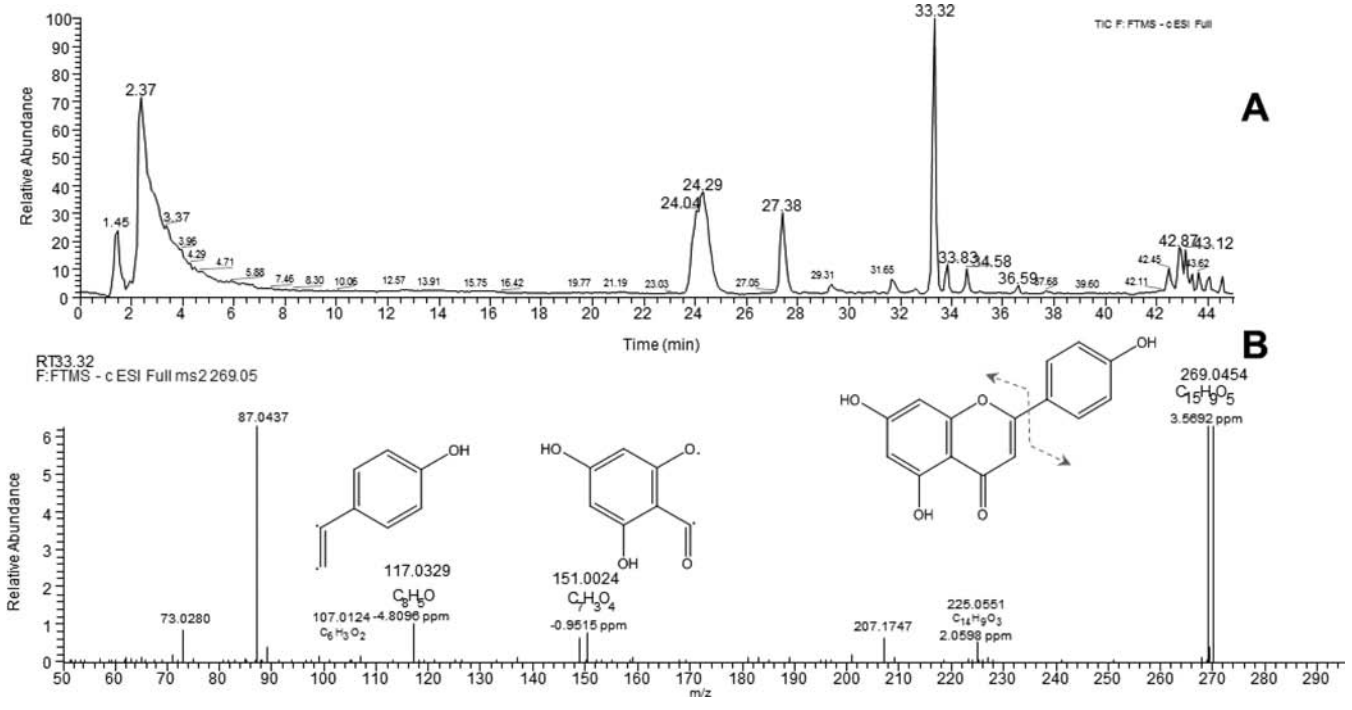

Figure 5. Mass chromatogram of apigenin. (A) TIC chromatogram and (B) EPI chromatogram with fragmentation pattern.

attributed to taxifolin-*O*-glucoside in grapes and red wine prepared from *Vitis vinifera*.[29]

3.1.7. Flavanones. Peak 33 was tentatively identified as eriodictyol-7-*O*-glucoside in all samples of substrate A and initial and final samples of substrate B. It exhibited a deprotonated $[M\text{-}H]^-$ ion at 449, which gave rise to m/z 287 $[M\text{-}H\text{-}162]^-$ by neutral loss, corresponding to sugar moiety (162 Da.). This ion corresponded to eriodictyol aglycone, and the presence of two fragments, m/z 151 and 135, characteristic of eriodictyol, confirmed this tentative identification.

3.1.8. Compounds Identified by HRMS. HRMS was used to confirm the identity of compounds with available standards (Figures 4 and 5). Eleven compounds were identified with standards by generating the molecular formula using accurate mass and matching with the isotopic pattern. The results are shown in Table 3. Three of these compounds, protocatechuic

[a]Mean values and standard deviation. Superscript a indicates a significant difference ($p < 0.05$) between the initial samples (I) and final samples (F) of the same substrate. Superscript b indicates a significant difference ($p < 0.05$) between the initial samples (I) and pasteurized samples (P) of the same substrate. Superscript c indicates a significant difference ($p < 0.05$) between the pasteurized samples (P) and final samples (F) of the same substrate, by ANOVA statistical test. Samples were determined in duplicate. nd, no data.

acid, *p*-hydroxybenzoic acid, and homovanillic acid (Figure 2), were detected in I, F, and P samples and have been reported before as human colonic metabolites of phenolic compounds.[36] Furthermore, increased concentrations of protocatechuic acid and *p*-hydroxybenzoic acid have been reported before due to yeast fermentation in Bokbunja.[37]

3.2. Quantitation of Nonanthocyanin Phenolic Compounds in Alcoholic Fermented Beverages. Nonanthocyanin phenolic compounds were quantified by external calibration with standards, in accordance with the validated LC-DAD method reported.[3] Tables 4 and 5 show the concentrations of the phenolic compounds, with significant increases and decreases after the alcoholic fermentation process ($p < 0.05$). (+)-Catechin content stands out with concentrations ranging from 86.4−144.3 mg kg fw^{-1}, and along with (−)-epicatechin gallate, galloyl-bis-HHDP-glucose, and *p*-coumaroyl glucose, it represents 70% of the total quantified compounds for the two substrates (Supporting Information). The concentration of *p*-coumaroyl glucose and the contents of the others compound listed above are in accordance with the results of gluconic-fermented products reported.[12]

In accordance with the report on sweet wine by Figueredo-González et al.,[38] the condensed tannins detected in ours samples was mainly dimer, specifically procyanidin B1 and appear in concentrations ranged between 14.8 and 28.0 mg kg fw^{-1} on average in initial samples for substrates A and B, respectively.

The most abundant compound was galloyl bis-HHDP-glucose. This compound was described as a monomer unit of two of the most abundant ellagitannis in strawberry, agrimoniin and sanguiin H-6,[39] and decreased during the alcoholic fermentation process (25−59%) in most of the cycles and for both substrates.

The concentration of monogalloyl glucose underwent a significant increase, which ranged from 20−36%, as a consequence of fermentation.

Homovanillic acid showed significant increases, 3.2−3.6% on average, for the two substrates, respectively. Authors such as Jaganath et al.[40] and Dall'Asta et al.[36] attributed the increment of this compound to be a consequence of the transformation of quercetin, rutin, and other quercetin glycosides; they detected this compound as a metabolite derived from human colonic fermentation after application of a diet rich in natural polyphenols. In contrast, in this study, we detected a slight decrease or increase in rutin and quercetin glycosides.

Another compound considered to be a metabolite, produced as a consequence of human colonic fermentation, is *p*-hydroxybenzoic acid.[36,41] It followed a similar pattern to homovanillic acid and underwent a significant increment in the majority of cycles, in both substrates, in a range of increase of 1.28−2.41%. Additionally, Vinjanen et al.[42] reported an increase in the content of *p*-hydroxybenzoic acid in yeast fermentation of lingonberries (*Vaccinium vitis-idaea*). It is known that many compounds, such as anthocyanins and phenolics, are stored in fruits in glycosidically bound form, and fermentation-effect-produced glycosidases can release aglycones of these compounds.

The effects of the pasteurization process were slight and scarce, and when they happened tended to decrease concentrations, for example, in the cases of phloridzin and kaempferol derivatives. Their concentrations experienced reductions in all cycles in amounts ranging from 2−13% for the two substrates.

3.3. LDA Analysis. Quantitated phenolic compounds were used as variables for statistical analysis, and grouping variables were initial (I), final (F), and pasteurized (P) steps. First, ANOVA pinpointed the variables that underwent significant change after the fermentation or pasteurization process, as shown in Tables 4 and 5. Second, 19 variables presenting significant differences were selected for discriminant analysis. Standard stepwise analysis included the whole set of 19 variables in the model, which achieved 98.8% correct

[a]Mean values and standard deviation. Superscript a indicates a significant difference ($p < 0.05$) between the initial samples (I) and final samples (F) of the same substrate. Superscript b indicates a significant difference ($p < 0.05$) between the initial samples (I) and pasteurized samples (P) of the same substrate. Superscript c indicates a significant difference ($p < 0.05$) between the pasteurized samples (P) and final samples (F) of the same substrate, by ANOVA statistical test. Samples were determined in duplicate. nd, no data.

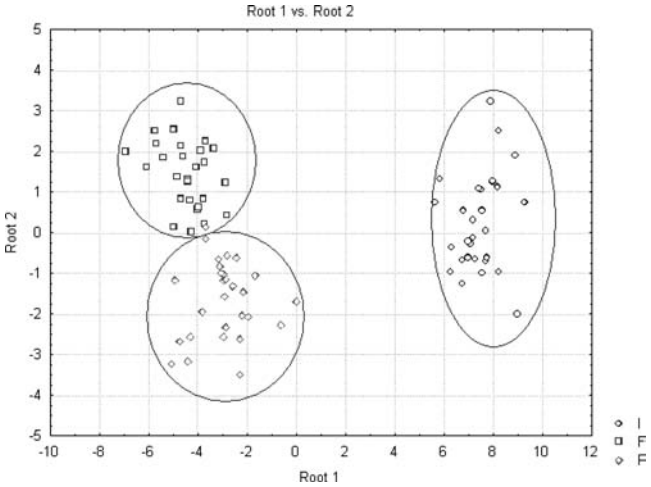

Figure 6. Scatterplot of canonical scores in discriminant analysis for two substrates and 19 variables with 98.8% of classification.

classification of samples. The only incorrectly classified sample was one pasteurized sample, classified as final. Figure 6 shows a scatterplot of the canonical roots obtained. As can be observed, F and P samples are closer than I (initial samples), which reflects the composition change produced by alcoholic fermentation.

3.4. Effect of Alcoholic Fermentation on Antioxidant Activity. Figure 7 displays the results of antioxidant activity determined by two methods, ORAC and DPPH, for the two substrates. The ORAC measurements revealed a significant decrease between initial and final samples for substrate B (17.6%). The same trend was observed between initial and pasteurized samples of the same substrate (15.2%). DPPH results show that only substrate A changed significantly and followed a similar trend to the ORAC data. A significant decrease was observed between initial and final samples (12.3%), and a decrease of and 13.9% between initial and pasteurized samples was observed. These results indicated that alcoholic fermentation caused antioxidant activity to decrease slightly; in contrast with reports on gluconic fermentation[12] and

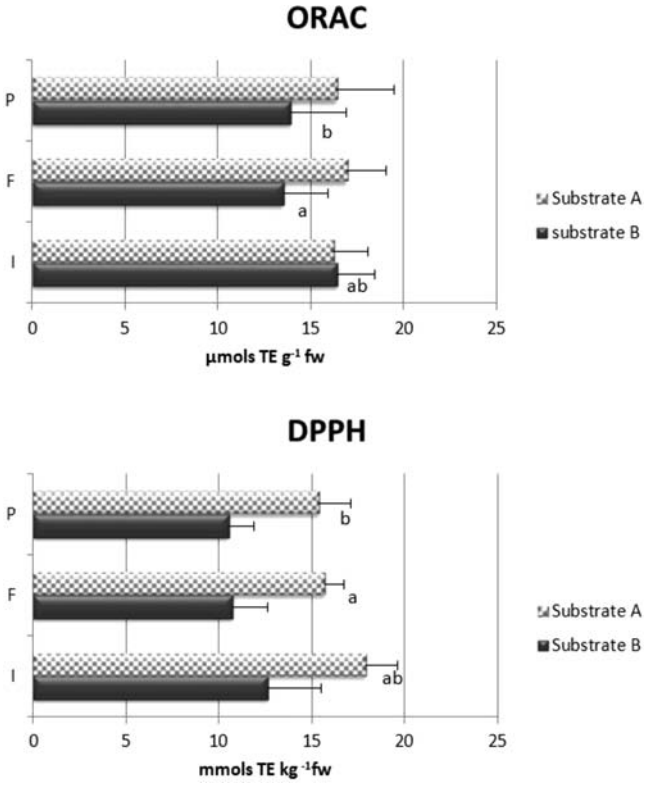

Figure 7. Bar representation of antioxidant activity by two methods, ORAC and DPPH, for the two substrates. Letters a, b, and c correspond to significant differences between I/F, I/P, and F/P samples, respectively.

alcoholic fermentation in mulberries,[43] no significant changes were detected. Apart from nonanthocyanin polyphenolic compounds, strawberry is a particularly rich source of anthocyanins,[44] which are outside the scope of this paper, which is focused on the identification of a large set of nonanthocyanin compounds. Indeed, the extracts for obtaining the nonanthocyanin fraction may present other compounds, which would account for a certain part of the antioxidant activity, which could also explain this average decrease.

3.5. Conclusions. Sixty-six compounds were identified by MS and HRMS. A total of 13 compounds was identified for the first time in strawberry and an alcoholic-fermented product: protocatechuic acid-4-*O*-*β*-hexoside, brevifolin carboxylic acid, ferulic acid glucuronide, dimer caffeic acid-*O*-hexoside, luteolin-3′-*O*-xyloside, isorhamnetin3-*O*-glucoside, taxifolin-*O*-glucoside, (+)-aromadendrin rhamnoside, eriodictyol-7-*O*-glucoside, (+)-taxifolin, (+)-aromadendrin, eriodictyol, and homovanillic acid.

LDA allows the correct classification of samples I, F, and P as alcoholic fermentation induces changes in phenolic composition, mainly related to the 19 compounds. Specifically, homovanillic acid and *p*-hydroxybenzoic acid increased significantly in almost every fermentation cycle.

and vegetables can be increased within the small intestine phase by coingesting them with lipids.[19−21] The bioaccessibility of curcumin can be increased in a similar manner using this approach.[4] This effect has been attributed to the ability of the lipid digestion products to form mixed micelles that solubilize and transport highly lipophilic components to the epithelium cells. An alternative strategy to improve the bioavailability of certain food components would be to incorporate efflux inhibitors, e.g., piperine (a constituent from black pepper) has been shown to act as an efflux inhibitor for curcumin.[22]

In the present study, we examined the possibility of developing excipient emulsions to increase the bioaccessibility of powdered curcumin. Crystalline forms of lipophilic bioactive agents usually have a much lower bioavailability than solubilized forms.[23] We therefore hypothesized that mixing powdered curcumin with an excipient emulsion would increase its bioaccessibility due to its ability to increase the solubility of curcumin in the intestinal fluids. The effect of incubation temperature and time on the transfer of curcumin into the excipient emulsion prior to ingestion was measured, as well as the bioaccessibility of curcumin after exposure to a simulated gastrointestinal tract (GIT). Two incubation temperatures (30 °C and 100 °C) were used to mimic conditions that curcumin might experience in food applications: (i) within ambient foods (such as salads); (ii) within cooked foods (such as curry sauces). The information obtained from this study may be useful for the design of excipient emulsions to increase the bioavailability and bioactivity of lipophilic nutraceuticals.

MATERIALS AND METHODS

Materials. Corn oil purchased from a local supermarket was used as an example of a digestible long chain triglyceride. The following chemicals were purchased from the Sigma Chemical Company (St. Louis, MO): curcumin (SLBH2403 V), mucin from porcine stomach (SLBH9969 V), pepsin from porcine gastric mucosa (SLBL1993 V), lipase from porcine pancreas pancreatin (SLBH6427 V), porcine bile extract (SLBK9078), Tween 80 (BCBG4438 V), and Nile Red (063 K3730 V). The supplier reported that the activity of the pepsin was around 250 units/mg, and the activity of the lipase was around 100−400 units/mg protein (using olive oil). All other chemicals were of analytical grade. Double distilled water was used to prepare all solutions and emulsions.

Excipient Emulsion Preparation. Initially, an aqueous phase was prepared by mixing 1% (w/w) Tween 80 with an aqueous buffer solution (10.0 mM phosphate-buffered saline (PBS), pH 6.5). Coarse oil-in-water emulsions were prepared by homogenizing 10% (w/w) corn oil with 90% (w/w) aqueous phase using a high-speed blender for 2 min (M133/1281-0, Biospec Products, Inc., ESGC, Switzerland). Fine emulsions were then obtained by passing the coarse emulsions through a microfluidizer (M110Y, Microfluidics, Newton, MA) with a 75 μm interaction chamber (F20Y) at an operational pressure of 9000 psi for five passes. The resulting excipient emulsions were stored in a refrigerator at 4 °C before use.

Preparation of Curcumin−Emulsion, Curcumin−Oil, and Curcumin−Buffer Mixtures. Curcumin (3 mg) was weighed into a beaker, and then excipient emulsion (10 mL) was added. The resulting mixtures were then incubated at either 30 °C or 100 °C for different times (ranging from 10 to 120 min for 30 °C and from 10 to 60 min for 100 °C). After incubation, selected samples were immediately placed in an ice−water bath and then used for the following experiments. In some experiments, the curcumin was mixed with bulk corn oil or with buffer (PBS) solution rather than an emulsion.

Curcumin Solubility in Mixtures. The solubility of curcumin in each mixture was measured spectrophotometrically based on the method of Ahmed, Li, McClements, and Xiao[4] with some modifications. Ten milliliters of mixture was collected and then centrifuged at 1750 rpm for 10 min at ambient temperature (CL10 centrifuge, Thermo, Scientific, Pittsburgh, PA) to remove non-dissolved (crystalline) curcumin. One milliliter of supernatant was then mixed with 5 mL of choloroform, vortexed, and centrifuged at 1750 rpm for 10 min at ambient temperature. The bottom layer containing the solubilized curcumin was collected, while the top layer was mixed with an additional 5 mL of chloroform and the same procedure was repeated. The two bottom chloroform layers were combined and diluted to an appreciate concentration to be analyzed by a UV−VIS spectrophotometer at 419 nm (Ultraspec 3000 pro, GE Health Sciences, Piscataway, NJ). A cuvette containing pure chloroform was used as a reference cell. The concentration of curcumin extracted from each mixture was calculated from a calibration curve of absorbance versus curcumin concentration in chloroform. The solubility of curcumin in each mixture was then calculated as the concentration of curcumin extracted from each mixture multiplied by the dilution factor.

Particle Characterization. The mean particle diameters (*Z*-average) and particle size distributions of the curcumin−emulsion mixtures after incubation at different temperatures were monitored using a dynamic light scattering instrument (Nano-ZS, Malvern Instruments Ltd., Worcestershire, UK). The electrical charge (ζ-potential) of the particles in these samples was measured using a microelectrophoresis instrument (Nano-ZS, Malvern Instruments Ltd.). Samples were diluted with buffer solution (10.0 mM PBS, pH 6.5) prior to measurements to avoid multiple scattering effects.

The mean particle diameter and particle size distribution of samples exposed to simulated gastrointestinal conditions was measured using static light scattering (Mastersizer 2000, Malvern Instruments Ltd.). Samples were diluted with appropriate buffer solutions (same pH as GIT phase) and stirred in the dispersion unit at a speed of 1200 rpm. The particle size is reported as the surface-weighted mean diameter (d_{32}).

Microstructural Analysis. The microstructure of samples was characterized using confocal scanning fluorescence microscopy (Nikon D-Eclipse C1 80i, Nikon, Melville, NY). Samples analyzed by confocal microscopy were dyed with Nile Red to highlight the location of the lipid phase. The Nile red was dissolved in absolute ethyl alcohol at a concentration (1 mg/mL). Then, before analysis, 2 mL emulsion samples were mixed with 0.1 mL of Nile Red solution (1 mg/mL ethanol) to dye the oil phase. All images were captured with a 10× eyepiece and a 60× objective lens (oil immersion). Changes in the properties of curcumin crystals in the mixtures were observed using a cross-polarized lens (C1 Digital Eclipse, Nikon, Tokyo, Japan).

Curcumin Oil-Solubility Characteristics. The temperature-dependence of the dissolution of crystalline curcumin into bulk corn oil was characterized by measuring the change in turbidity (600 nm) with temperature using a UV−visible spectrophotometer equipped with a temperature controller (Agilent Cary 200, Agilent, Santa Clara, CA). This method can be used to detect the presence of curcumin crystals in the oil phase and indirectly determine the solubility of curcumin in bulk corn oil. A weighed amount of curcumin (3 or 4 mg/mL) was dispersed in corn oil at ambient temperature, and then the mixture was heated from 25 to 100 °C and then cooled from 100 °C to 25 °C at a rate 1 °C/min with continuous stirring. In some experiments, the change in turbidity with time was measured at a fixed incubation temperature (30 °C or 100 °C) to determine the kinetics of isothermal dissolution.

Simulated Gastrointestinal Digestion. Powdered curcumin was mixed with excipient emulsion, corn oil, or buffer solution and then held at 30 °C for 30 min or 100 °C for 10 min. Each sample was passed through a three-step GIT model that consisted of mouth, gastric, and small intestine phases, which was slightly modified from the our previous study.[24]

Initial System. The initial systems were placed into a glass beaker in an incubator shaker at a rotation speed of 100 rpm for 15 min at 37 °C for preheating (Innova Incubator Shaker, Model 4080, New Brunswick Scientific, Edison, NJ). Three different initial systems were tested: (i) curcumin and excipient emulsion, (ii) curcumin, corn oil, and buffer

DOI: 10.1021/jf506149f
J. Agric. Food Chem. 2015, 63, 2052−2062

solution, or (iii) curcumin and buffer solution. The initial concentration of curcumin was the same in all systems, while the initial concentration of corn oil in systems i and ii were the same.

Mouth Phase. A simulated saliva fluid (SSF) containing 3 mg/mL mucin and various salts was prepared as described previously.[25] SSF was preheated to 37 °C and then mixed with the preheated curcumin mixture at a 1:1 mass ratio. The mixture was then adjusted to pH 6.8 and placed in an incubator shaker at 100 rpm and 37 °C for 10 min. This incubation time is longer than a food would normally spend in the mouth but was used to minimize sample-to-sample variations that might occur if very short times were used.

Stomach Phase. Simulated gastric fluid (SGF) was prepared by placing 2 g of NaCl and 7 mL of HCl into a container and then adding double distilled water to 1 L. The bolus sample from the mouth phase was then mixed with SGF containing 0.0032 g/mL pepsin preheated to 37 °C at a 1:1 mass ratio. The mixture was then adjusted to pH 2.5 and placed in a shaker at 100 rpm and 37 °C for 2 h to mimic stomach digestion. It should be noted that we did not include gastric lipase in the SGF because of the difficulty in obtaining a reliable and economically viable source of this digestive enzyme.[26] Gastric lipase typically promotes a limited amount of lipid digestion within the stomach phase and therefore its omission should only have a fairly modest impact on the gastrointestinal fate of the excipient emulsions.

Small Intestine Phase. Thirty milliliter chyme samples from the stomach phase were diluted with buffer solution (10 mM PBS, pH 6.5) to obtain a final corn oil concentration of 1.25%. The diluted chyme was then incubated in a water bath (37 °C) for 10 min, and then the solution was adjusted back to pH 7.0. Next, 3 mL of simulated intestinal fluid (containing 0.5 M $CaCl_2$ and 7.5 M NaCl) was added to 60 mL of digesta. Then, 7 mL bile extract, containing 375.0 mg of bile extract (pH 7.0, PBS), was added with stirring, and the pH was adjusted to 7.0. Finally, 5 mL of pancreatic suspension, containing 120 mg of lipase (pH 7.0, PBS), was added to the sample, and an automatic titration unit (Metrohm, USA Inc., Riverview, FL) was used to monitor the pH and control it to a fixed value (pH 7.0) by titrating 0.25 M NaOH solution into the reaction vessel for 2 h at 37 °C. The percentage of free fatty acids released in the sample was calculated from the number of moles of NaOH required to maintain neutral pH as described previously.[27] It should be noted that some of the free fatty acids may not be fully ionized at pH 7, and therefore the FFAs determined by the pH stat method are only the titrable ones.[28]

Curcumin Bioaccessibility. After in vitro digestion, 30 mL of raw digesta of each mixture was centrifuged (18000 rpm, Thermo Scientific, Waltham, MA) at 25 °C for 30 min. The clear supernatant was collected and assumed to be the "'micelle'" fraction in which the curcumin was solubilized. In some samples, a layer of nondigested oil was observed at the top of the samples, and it was removed from the micelle fraction. Aliquots of 5 mL of micelle fraction were mixed with 5 mL of chloroform, vortexed, and centrifuged at 1750 rpm for 10 min at ambient temperature. The bottom layer containing the solubilized curcumin was collected, while the top layer was mixed with an additional 5 mL of chloroform and the same procedure was repeated. The two collected chloroform layers were mixed together and then diluted to an appreciate concentration to be analyzed by a UV−vis spectrophotometer at 419 nm. The concentration of curcumin was calculated from the absorbance using a standard curve at a suitable dilution factor. The bioaccessibility of curcumin was calculated according to the following expression: BA% = 100 × c_M/c_D, where c_M and c_D are the curcumin concentrations in the mixed micelle phase and in the total digesta collected after the small intestine phase, respectively.

Statistical Analysis. All experiments were carried out on at least two freshly prepared samples. The results are expressed as means ± standard deviation (SD). Data was subjected to statistical analysis using SPSS software version 18.0. Differences were considered significant at $p < 0.05$.

RESULTS AND DISCUSSION

Effect of Incubation Temperature on Particle Characteristics. In this study, curcumin-containing samples were exposed to two different incubation temperatures to simulate different conditions that they might experience in food applications: (i) 30 °C for salads at ambient temperature; (ii) 100 °C for sauces at cooking temperatures. The mixture of curcumin and excipient emulsion was stirred to ensure homogeneity and then incubated at either 30 °C or 100 °C for different times. The mean particle diameter, particle size distribution, particle charge, and visual appearance of the different samples was then measured (Table 1, Figure 1a−c).

There were no appreciable changes in the characteristics of the droplets in the curcumin−emulsion mixtures during incubation at 30 °C for up to 120 min (Table 1 and Figure 1a). Indeed, there were no significant changes in the mean particle diameter, polydispersity index (PDI), or ζ-potential of the curcumin−emulsion mixtures when compared to the initial emulsions. The curcumin−emulsion systems were also stable to incubation at 100 °C from 10 to 30 min, with no significant changes in mean particle diameter, PDI, or ζ-potential. However, there was evidence of some droplet creaming in the curcumin−emulsion mixture after heating at 100 °C for 60 min (indicated by an arrow in Figure 1c). Moreover, there was a significant increase in the mean particle diameter and PDI for these emulsions (Figure 1b and Table 1). This effect may be due to droplet coalescence resulting from dehydration of the nonionic surfactant head groups at elevated temperatures.[29] There was no significant change in the magnitude of the electrical charge on the emulsion droplets when they were incubated at either 30 °C or 100 °C, which suggests that the interfacial composition remained relatively constant.

The microstructures of the curcumin−emulsion mixtures after heating at 30 °C and 100 °C for different times were recorded using confocal fluorescence microscopy (Figure 2a). There was little change in the microstructure of the mixed systems incubated at 30 °C for different times, confirming their high stability under these conditions. However, there was evidence of some larger oil droplets in the mixed systems after incubation at 100 °C for prolonged times, suggesting that some coalescence had occurred.

We also measured the amount of curcumin transferred into the excipient emulsions over time at different incubation temperatures. The amount of curcumin solubilized in the excipient emulsions depended on incubation temperature and time. There was a gradual increase in the amount of curcumin solubilized within the excipient emulsion for mixtures incubated at 30 °C (Table 1). On the other hand, there was a rapid increase in the amount of curcumin solubilized in the excipient emulsions during the first 10 min of incubation at 100 °C, followed by an appreciable decrease at longer incubation times. This decrease was attributed to the fact that droplet coalescence and oiling off occurred in the emulsions held at the higher temperature, which meant that some of the curcumin remained in the upper oil phase and was not therefore measured. Overall, the amount of curcumin solubilized within the excipient emulsions was considerable higher for the samples incubated at the higher holding temperatures. For example, the amount of curcumin solubilized in the emulsions was around 54 and 218 μg/mL after incubation for 60 min at 30 °C and 90 °C, respectively.

[a]Samples designated with different letters (a, b, c, d, e, f) were significantly different (Duncan, $p < 0.05$). The "initial" sample was the oil-in-water emulsion before adding curcumin and before incubation. ND = not determined.

The presence of curcumin crystals within the different mixtures after exposure to different incubation temperatures was observed using a crossed polarizer lens (Figure 2b). Some crystalline material was clearly observed in the curcumin−emulsion mixtures incubated at 30 °C from 10 to 120 min, which suggested that the curcumin crystals did not completely dissolve when held at this temperature in the presence of the excipient emulsion. Conversely, no crystals were observed in the curcumin−emulsion mixtures held at 100 °C at any incubation time, which indicated that curcumin crystals rapidly and completely dissolved within the emulsions at this elevated temperature. However, there was evidence of some large droplets in these samples after heating for prolonged times at 100 °C, again suggesting that droplet coalescence occurred.

Temperature Dependence of Curcumin Oil-Solubility. The dependence of the transfer of curcumin into the excipient emulsions on incubation temperature and time may be due to changes in its oil solubility with temperature.[30] We therefore used turbidity measurements to monitor the solubility of curcumin crystals in bulk corn oil at different temperatures. The principle of this method is that the turbidity of the curcumin−oil mixture is relatively high when curcumin crystals are present because they scatter light strongly, but it is relatively low when the crystals have melted or dissolved due to the decrease in light scattering.

The turbidity of curcumin in corn oil mixtures (3 mg/mL) decreased appreciably upon heating from 25 to 100 °C (Figure 3a) until it reached a value close to zero at 100 °C, indicating that the crystals had fully dissolved at this temperature. Upon cooling, the turbidity stayed low, suggesting that the curcumin remained dissolved within the oil. This may have occurred because curcumin was below its saturation temperature at the lower temperatures, or because of supersaturation/supercooling effects.[30] We therefore measured the change in turbidity with temperature for a curcumin−oil mixture containing a higher curcumin concentration (4 mg/mL). In this case, the turbidity still decreased appreciably with increasing temperature, but the final turbidity reached at high temperatures was considerably greater than that observed at the lower curcumin level. Indeed, the samples at the higher temperatures still appeared turbid, suggesting that not all of the curcumin crystals had dissolved. When this sample was cooled the turbidity remained relatively high and even increased slightly, which can be attributed to the fact that the solubility of curcumin decreases with decreasing temperature and the amount of curcumin present was above the saturation level. These results suggest that the solubility of curcumin in corn oil at ambient temperature was somewhere between 3 and 4 mg/mL, which is in agreement with the value of ≈3.2 ± 0.1 mg/mL reported previously.[4]

Information about the kinetics of curcumin dissolution at the two incubation temperatures was obtained by measuring changes in the turbidity of curcumin/oil mixtures (3 mg/mL) over time (Figure 3b). There was little change in the turbidity of the mixture held at 30 °C, suggesting that curcumin crystals only dissolved slowly at this temperature. On the other hand, the turbidity decreased rapidly in the mixture held at 100 °C, which indicated that the curcumin crystals rapidly dissolved in the corn oil at this elevated temperature. This knowledge may be important for developing effective processing operations for incorporating curcumin into food products.

Influence of Simulated Digestion on Particle Properties. In this section, we examined the influence of the excipient emulsions on the potential biological fate of curcumin using an

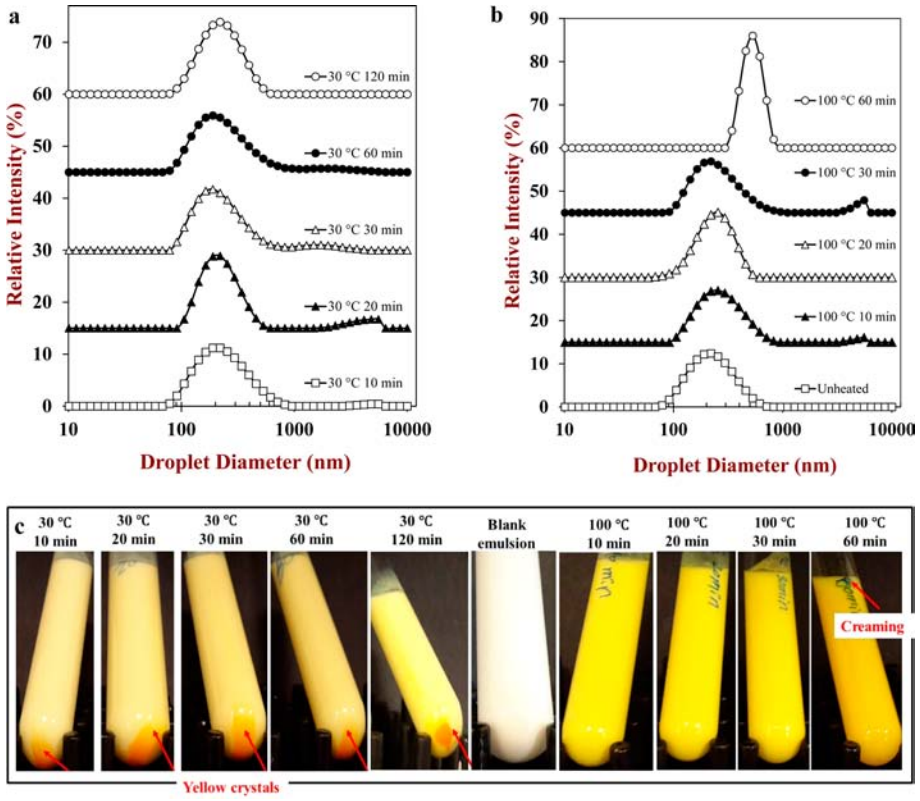

Figure 1. (a) Particle size distributions of mixtures of curcumin and excipient emulsion after incubation at 30 °C for different times. (b) Particle size distributions of mixtures of curcumin and excipient emulsion after incubation at 100 °C for different times. (c) Photographs of mixtures of curcumin and excipient emulsion after incubation at 30 and 100 °C. Note: yellow sediment (curcumin crystals) was observed at the bottom of the test tubes held at 30 °C, whereas a yellow oil layer was observed at the top of the test tubes after heating at 100 °C for 60 min (red arrows).

in vitro gastrointestinal tract (GIT) model that simulates the mouth, stomach, and small intestine phases. Curcumin−emulsion mixtures incubated at 30 °C for 30 min or at 100 °C for 10 min were selected for the GIT study to simulate ambient food applications (such as salad dressings) and cooking applications (such as curry sauces). These incubation times were selected because they led to excipient emulsions that were physically stable and that might simulate usage conditions. It should be noted that the amount of curcumin solubilized in the excipient emulsions at the higher temperature was not strongly dependent on incubation temperature. The results for the excipient emulsions were compared to curcumin−oil and curcumin−buffer mixtures that initially contained the same amount of curcumin. The particle size, microstructure, particle charge, and overall appearance of the different samples were then measured (Figures 4−6).

Particle Size and System Microstructure. The properties of the curcumin−emulsion mixture were evaluated at all stages of the GIT model, but the curcumin−oil mixture was only evaluated after incubation in the small intestine phase since reliable samples could not be obtained from the mouth or stomach phases. This was because the bulk oil tended to form a separate layer at the top of the mixtures, and therefore it was difficult to collect a representative sample. Similarly, the characteristics of the curcumin−buffer mixture were not determined in this series of experiments because it was difficult to collect reliable samples when there were only a few curcumin crystals present in a large volume of buffer solution.

In general, fairly similar trends were observed in the gastrointestinal behavior of curcumin−emulsion mixtures that had previously been incubated at either 30 °C or 100 °C, and so the results are discussed together. The mean particle diameter (d_{32}) determined by static light scattering remained relatively constant after exposure to the mouth and stomach phases but increased appreciably after exposure to the small intestine phase (Figure 4a). Examination of the full particle size distributions of these emulsions indicated that a large fraction of the droplets had fairly similar sizes to the initial emulsions after exposure to the mouth and stomach phases, which suggested that they were relatively stable to coalescence, presumably because they had a nonionic surfactant coating that was resistant to changes in pH, salt, and protease activity. Nevertheless, confocal microscopy images of the same samples indicated that extensive droplet flocculation occurred within the mouth and stomach phases (Figure 6), which may have been due to depletion or bridging flocculation promoted by mucin originating from the artificial saliva.[31] There appeared to be some dissociation of the flocs formed in the emulsions when they moved from the mouth to the stomach stage (Figure 6). This behavior is in agreement with previous studies[31] and may be caused by a number of factors including sample dilution, changes in solution composition, and/or mechanical agitation.[32,33]

The fact that the large particles observed in many of the samples by confocal microscopy were not observed by static light scattering suggests that the flocs dissociated upon dilution and stirring during sample preparation for the particle size analysis. This result highlights the importance of confirming light scattering measurements with microscopy measurements for this type of complex colloidal system.

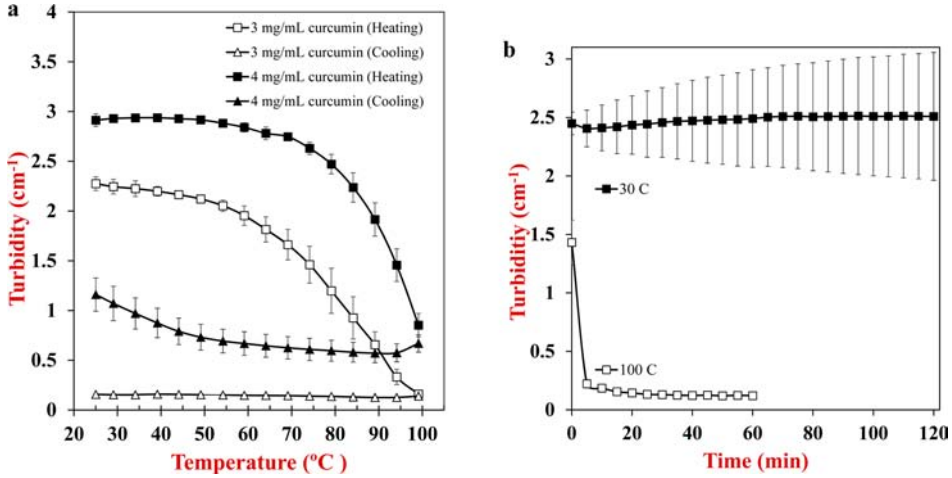

Figure 3. (a) Absorbance versus temperature profile of curcumin−corn oil mixtures (3 and 4 mg/mL). (b) Absorbance versus time profile of a curcumin−corn oil mixture (3 mg/mL) at different isothermal storage temperatures.

Light scattering measurements indicated that a population of relatively large particles was present in the curcumin−emulsion mixtures after exposure to the small intestine phase (Figure 5a and 5b), which was confirmed by confocal microcopy (Figure 6). It is difficult to identify the precise nature of these particles because the intestinal digesta may contain various types of colloidal species, including nondigested lipids, micelles, vesicles, liquid crystals, and insoluble matter (such as calcium soaps).

Light scattering (Figure 5) and confocal microscopy (Figure 6) indicated that there were much larger particles present in the curcumin−oil mixtures after exposure to the small intestine phase than in the curcumin−emulsion mixtures. A possible explanation for this effect is that the bulk corn oil was digested more slowly than the pre-emulsified corn oil (see later), and therefore there were some large nondigested lipid droplets present.

Electrical Characteristics. The electrical characteristics (ζ-potential) of the particles in emulsion−curcumin mixtures exposed to different incubation temperatures followed similar trends after passage through each stage of the simulated GIT (Figure 7), and so they will again be considered together. The particles in the initial curcumin−emulsion mixtures had

relatively low negative charges (≈−4 mV), which was due to the fact that a nonionic surfactant was used to coat the droplets. The particles became appreciably more negative after exposure to the mouth phase (≈−9 mV), which may have been due to association of anionic species (such as mucin) with the lipid droplet surfaces.[31] The particle charge became much less negative (≈−2 mV) after exposure to the stomach phase, which can be attributed to the relatively low pH and high ionic strength of the gastric fluids. Finally, the particle charge became highly negative (≈−47 mV) after exposure to the small intestinal fluids, which is probably due to the presence of various anionic constituents associated with this phase such as bile salts, phospholipids, and free fatty acids.[31] There were no significant differences between the electrical characteristics of the particles in the small intestine phase for the curcumin−emulsion and curcumin−oil mixtures at either incubation temperature. This effect can be attributed to the fact that the electrical characteristics were dominated by the presence of bile salts, phospholipids, and free fatty acids and were not strongly affected by sample microstructure.

Lipid Digestion. In this section, we used the pH stat method to determine the rate and extent of lipid digestion of curcumin−emulsion and curcumin−oil mixtures that had previously been incubated at either 30 °C or 100 °C. The volume of NaOH that had to be titrated into the samples to maintain a constant pH (7.0) was measured as a function of digestion time, and then the fraction of free fatty released from the mixture was calculated (Figure 8).

The initial incubation temperature (30 °C or 100 °C) had no effect on the rate and extent of lipid digestion for the curcumin−emulsion mixtures, which was probably due to the fact that the interfacial areas and compositions of the lipid droplets entering the small intestine phase were fairly similar (Figure 8). In these systems, there was a rapid increase in FFAs during the first 10 min, followed by a more gradual increase at longer times. Conversely, there was a much less steep increase in the FFAs released over time in the curcumin−oil mixtures for both incubation times (Figure 8). The origin of this effect can be attributed to the higher surface area of oil exposed to lipase for the emulsified corn oil than for the bulk corn oil. Indeed, the confocal microscopy images clearly highlighted that the fat droplets in the small intestine phase were much larger for the bulk oil than the emulsified oil (Figure 6). Additionally, the rate and extent of lipid digestion in the curcumin−oil mixture that had been incubated at 100 °C (56% FFAs released after 2 h) was higher than the one that had been incubated at

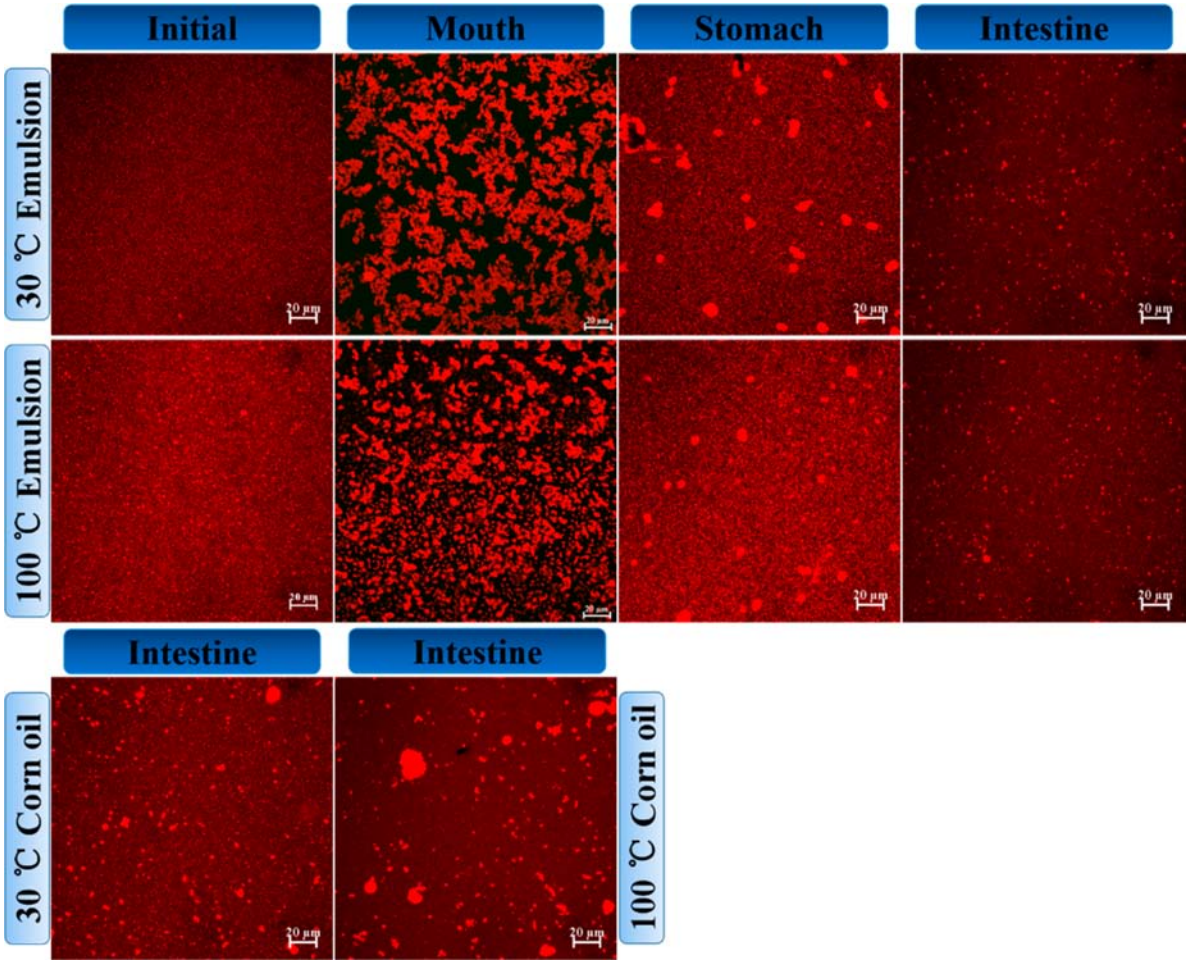

Figure 6. Influence of simulated gastrointestinal conditions on microstructure of curcumin−emulsion and curcumin−oil mixtures exposed to different incubation conditions (30 °C for 30 min or 100 °C for 10 min) determined by confocal fluorescence microscopy. The scale bars represent a length of 20 μm, and the red regions represent lipids.

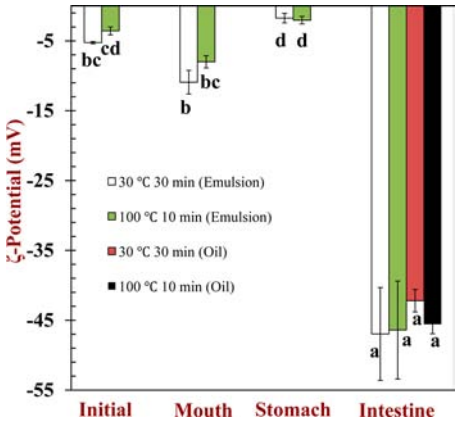

Figure 7. Influence of simulated gastrointestinal conditions on the particle charge of curcumin−emulsion and curcumin−oil mixtures exposed to different incubation conditions (30 °C for 30 min or 100 °C for 10 min). Samples designated with different letters (a, b, c) were significantly different (Duncan, $p < 0.05$).

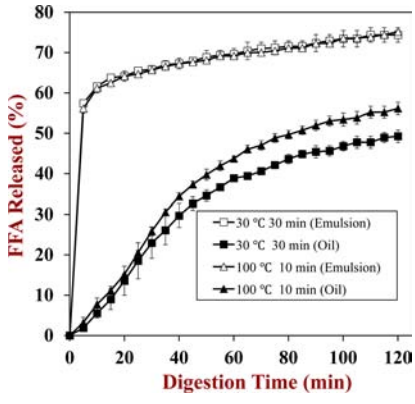

Figure 8. Influence of incubation temperature on the free fatty acids (FFA %) release profile for curcumin−emulsion and curcumin−oil mixtures exposed to different incubation conditions (30 °C for 30 min or 100 °C for 10 min).

30 °C (49% FFAs released after 2 h). The origin of this effect is unknown, but it may have been because the corn oil that had been incubated at the higher temperature was initially dispersed better in the water phase, i.e., formed smaller fat droplets (higher surface area).

Curcumin Solubilization and Mixed Micelle Properties. The characteristics of the particles in the mixed micelle phase formed after exposure of the samples to simulated small intestine conditions were measured, as well as the amount of curcumin solubilized within the mixed micelle phase (Table 2). It should be noted that the mixed micelle phase was collected by centrifugation, so that any large particles observed in the

small intestine digesta should have been removed. All of the mixed micelle samples contained highly negatively charged particles, which can be attributed to the fact that they consisted primarily of bile salts, phospholipids, and free fatty acids. The mean particle diameters in the micelle phase were around 100 to 200 nm, which suggests that they were probably vesicles since true micelles are much smaller than this (<10 nm). Surprisingly, the particles in the mixed micelle phase collected from digestion of the bulk oils were appreciably smaller than those collected from digestion of the emulsified oils (Table 2). There are a number of potential mechanisms that could account for this observation, such as differences in the rate and extent of lipid digestion, and the presence of nonionic surfactant in the emulsions. For both the curcumin−emulsion and curcumin−oil systems, there was no major difference between the size of the particles in samples that had been incubated at 30 °C or 100 °C.

The amount of curcumin present in the mixed micelle phase is a good indication of its bioaccessibility, i.e., the amount available for absorption. Overall, the concentration of curcumin measured in the mixed micelle phase was higher for the digested curcumin−emulsion mixtures that for the digested curcumin−oil mixtures (Table 2). This suggests that there was more efficient transfer of the curcumin into the mixed micelles for the emulsion than for the bulk oil. There are two major reasons for this phenomenon: (i) some of the bulk oil was not digested, and so some of the curcumin may have remained dissolved within this oil phase; (ii) more of the emulsified oil was digested, and so there will have been more mixed micelles available to solubilize the curcumin. The curcumin concentration in the mixed micelles obtained from digestion of the curcumin−emulsion mixture incubated at 100 °C was appreciably higher than that for the mixture incubated at 30 °C. This effect was probably due to the fact that a higher fraction of the crystalline curcumin was solubilized within the emulsion held at the higher incubation temperature. The amount of curcumin present within the mixed micelle phase resulting from digestion of the curcumin−oil mixture was also higher for the sample incubated at 100 °C than for the one incubated at 30 °C. This effect may again be due to the fact that a higher amount of curcumin was solubilized in the oil phase (rather than present as crystals) prior to digestion. In addition, there was a greater extent of lipid digestion in the bulk oil incubated at 100 °C, which may have resulted in greater curcumin release and solubilization.

Potential Mechanisms. The potential mechanisms responsible for the increase in bioaccessibility of curcumin by excipient emulsions are highlighted in Figure 9. Prior to ingestion, curcumin may be solubilized within the oil droplets when powdered curcumin is incubated with the emulsions. This may occur due to diffusion of curcumin molecules through the aqueous phase and occurs more rapidly for emulsifier oil than for bulk oil due to the higher surface area and shorter diffusion pathway. In addition, this process occurs more rapidly at higher temperatures due to the higher solubility of curcumin in the oil and water phases. After ingestion, curcumin may be solubilized within the mixed micelles resulting from digestion of the oil droplets. The transfer of curcumin into the mixed micelles may be more efficient for emulsified oil than for bulk oil due to the faster rate and greater extent of lipid digestion. Consequently, there are more mixed micelles available for the curcumin to the solubilized within.

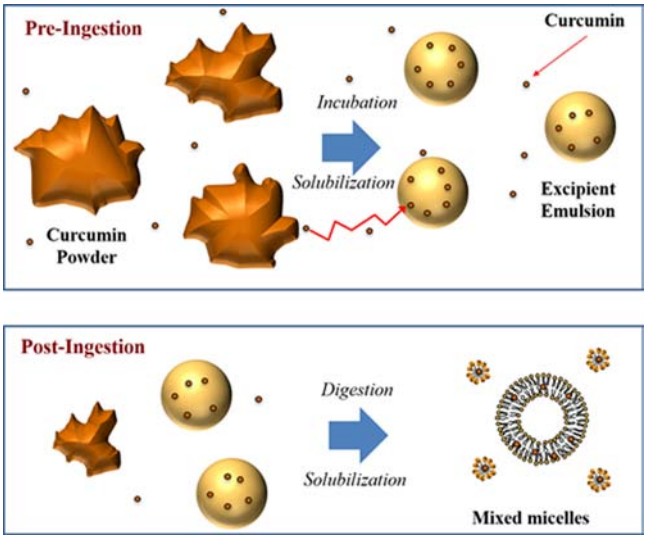

Figure 9. Schematic diagram of the preingestion and postingestion solubilization of curcumin in excipient emulsions. Prior to ingestion, curcumin may be solubilized in oil droplets when powdered curcumin is incubated with the emulsions. After ingestion, curcumin may be solubilized within the mixed micelles resulting from digestion of the oil droplets.

In summary, the present work has shown that excipient emulsions can be used to increase the bioaccessibility of powdered curcumin. We have shown that a greater amount of curcumin is transferred from the powder into the lipid droplets for curcumin−emulsion mixtures incubated at 100 °C than for those incubated at 30 °C. This effect was attributed to the fact that solubility of curcumin in the water and oil phases increases with increasing temperature, as well as the mass transport rate. It was shown that the curcumin concentration in the mixed micelle phase formed after exposure to a simulated gastrointestinal tract depended on the nature of the food matrix, decreasing in the following order: emulsified oil > bulk oil > buffer solution. This effect was attributed to the increased solubilization capacity of the small intestinal fluids when a

J. Agric. Food Chem. 2015, 63, 2052−2062

triglyceride oil is broken down into free fatty acids and monoglycerides that are incorporated into mixed micelles. In addition, the curcumin concentration in the mixed micelle phase was higher for curcumin−emulsion or curcumin−oil mixtures that had been incubated at 100 °C than for those that had been incubated at 30 °C, which was attributed to a greater solubilization of the curcumin into the oil phase prior to digestion. These results have important implications for designing food matrices to increase the oral bioavailability of lipophilic nutraceuticals and vitamins.

The experimental design was a randomized complete block with four replicate plots of each entry at each field site in the U.S. study and three replicate plots of each entry at each field site in the Brazil study. In the U.S. study, plots were four rows wide by 7.6 m long with 6 cm seed spacing and 76 cm row spacing. Each four row plot was separated from adjacent plots by two border rows of a commercially available nontransgenic soybean variety of similar maturity. In the Brazil study, plots were 10 rows wide by 10 m long with 10 cm seed spacing and 50 cm row spacing. In addition to DAS-81419-2 and the isoline, a total of five nontransgenic commercial varieties were used (DSR 75213-72, HiSOY 38C60, IL3503, Porter 75148, and Williams 82) in the U.S. study; three out of the five varieties were chosen at random and planted at each field site. In the Brazil study, the nontransgenic commercial variety CD 215 was planted at both field sites. Standard commercial agronomic practices (e.g., insect and weed control) were implemented at each field site (uniformly across the entire trial) to produce a commercially acceptable crop. Forage and seed samples were collected at the R3 (beginning pod) and R8 (full maturity) growth stages, respectively, and shipped to Covance Laboratories Inc. (Madison, Wisconsin) for compositional analysis. Samples were shipped frozen and were placed in freezer storage at the analytical laboratory where they remained until removal for preparation or analysis.

Compositional Analyses. At Covance Laboratories composition samples were cryogenically ground to a homogeneous state using a blender and liquid nitrogen prior to assay. Analytes in forage samples (9 total) included proximates (moisture, carbohydrates, ash, crude fat, and protein), fiber [acid detergent fiber (ADF) and neutral detergent fiber (NDF)], and minerals (calcium and phosphorus); seed analytes (80 total) included proximates (moisture, carbohydrates, ash, crude fat, and protein), fiber (ADF, NDF, crude fiber, and total dietary fiber), minerals (calcium, copper, iron, magnesium, manganese, phosphorus, potassium, selenium, sodium, and zinc), amino acids (alanine, arginine, aspartic acid, cystine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine, threonine, tryptophan, tyrosine, and valine), fatty acids (8:0 caprylic, 10:0 capric, 12:0 lauric, 14:0 myristic, 14:1 myristoleic, 15:0 pentadecanoic, 15:1 pentadecenoic, 16:0 palmitic, 16:1 palmitoleic, 17:0 heptadecanoic, 17:1 heptadecenoic, 18:0 stearic, 18:1 oleic, 18:2 linoleic, 18:3 linolenic, 18:3 γ-linolenic, 20:0 arachidic, 20:1 eicosenoic, 20:2 eicosadienoic, 20:3 eicosatrienoic, 20:4 arachidonic, and 22:0 behenic), vitamins [β-carotene, vitamin B_1 (thiamine hydrochloride), vitamin B_2 (riboflavin), vitamin B_3 (niacin), vitamin B_5 (pantothenic acid), vitamin B_6 (pyridoxine hydrochloride), vitamin B_9 (folic acid), vitamin C (ascorbic acid), tocopherols (α, β, γ, δ, total)], and bioactives (lectin, phytic acid, raffinose, stachyose, trypsin inhibitor, total daidzein equivalent, total genistein equivalent, and total glycitein equivalent). With the exception of crude fiber and selenium, samples were assayed using previously published methods.[23] Crude fiber was determined gravimetrically as the loss on ignition of dried residue remaining after digestion of the samples with 1.25% sulfuric acid and 1.25% sodium hydroxide solutions under specific conditions. Selenium samples were closed-vessel microwave digested with nitric acid (HNO_3) and water. After digestion, the solution was brought to a final volume with water. To normalize the organic contribution between samples and standards, a dilution was prepared for analysis that contained methanol. The selenium concentration was determined with Se^{78} using an inductively coupled plasma-mass spectrometer (ICP-MS) with a dynamic reaction cell (DRC) by comparing the counts generated by standard solutions.

Statistical Analysis. At Dow AgroSciences, analysis of variance (ANOVA) was conducted across field sites within the U.S. study and within the Brazil study using a mixed model where entry was considered a fixed effect and location, block within location, and location-by-entry were designated as random effects.[96] Paired contrasts were performed between DAS-81419-2 and the isoline using t tests, and a false-discovery rate adjustment was applied to the P-values to account for multiplicity.[97−99] Differences were considered significant at the 95% confidence level. Analytes were excluded from the statistical analysis if more than 50% of the results were less than the limit of

Figure 1. Site means for ADF and NDF in soybean forage. The shaded area represents the literature range and locations are represented by the following symbols: ○ = Richland, IA; × = Atlantic, IA; + = Carlyle, IL; Δ = Wyoming, IL; □ = Frankfort, IN;◇ = Fisk, MO; ● = La Plata, MO; ▲ = York, NE; ■ = Brunswick, NE; ◆ = Germansville, PA; # = Montividiu, Goiás; ∼ = Indianópolis, Minas Geráis. "Isoline" = near-isogenic nontransgenic line. Note that each nontransgenic commercial variety was included, on average, at only half of the field sites in the U.S. study, so the range of data for these entries is expected to be narrower than that of the isoline and DAS-81419-2 entries, which were present at all 10 sites.

quantitation (<LOQ); said analytes were excluded because data sets where most points are excluded or set to a given nominal value have substantially up-biased data or have improperly underestimated variability, respectively. No forage analytes were excluded, while seed analytes excluded from both the U.S. and Brazil studies were β-tocopherol, sodium, and the fatty acids 8:0 caprylic, 10:0 capric, 12:0 lauric, 14:1 myristoleic, 15:0 pentadecanoic, 15:1 pentadecenoic, 17:1 heptadecenoic, 18:3 γ-linolenic, 20:2 eicosadienoic, 20:3 eicosatrienoic, and 20:4 arachidonic. Additionally, β-carotene and the fatty acids 14:0 myristic, 16:1 palmitoleic, and 17:0 heptadecanoic were excluded from analysis of the U.S. data, and the mineral selenium was excluded from analysis of the Brazil data. The range of values observed in the nontransgenic commercial soybean varieties was included to put any statistically significant differences into context, and ranges for nontransgenic soybean in the literature were also compiled for further reference.[11,20,28,30,35,39,59,85,100−106]

RESULTS AND DISCUSSION

The composition of DAS-81419-2 soybean forage and seed was compared with that of the isoline at 10 field sites in the U.S.

DOI: 10.1021/jf505015y
J. Agric. Food Chem. 2015, 63, 2063−2073

and two field sites in Brazil. In addition to DAS-81419-2 and the isoline, the U.S. study included five commercially available nontransgenic soybean varieties, and the Brazil study included one commercially available nontransgenic soybean variety. Composition analytes evaluated in forage (9) included proximates, fiber, and minerals, while analytes evaluated in seed (80) included proximates, fiber, minerals, amino acids, fatty acids, vitamins, antinutrients, and bioactives. Of the 80 seed analytes, 18 were excluded from the statistical analysis of the U.S. and/or Brazil data sets because more than 50% of the results were <LOQ.

No statistically significant differences were detected between DAS-81419-2 and the isoline in both the U.S. and Brazil studies in all but one (16:0 palmitic acid) of the analytes included in the statistical analysis (Tables 1−7). Moreover, mean results for all analytes fell within the ranges observed in nontransgenic commercial reference varieties and/or the ranges of values for nontransgenic soybean in the literature. In the U.S. study only, a statistically significant difference was detected between the isoline and DAS-81419-2 soybean for 16:0 palmitic acid. Although statistically significant, the difference had no meaningful effect on nutritional value; the mean 16:0 palmitic acid content of DAS-81419-2 was only 4.5% higher than that of the isoline, and the entire range of values observed in DAS-81419-2 was encompassed by the range of values reported in the literature for nontransgenic soybean (Table 5). Furthermore, a difference for 16:0 palmitic acid was not observed in the Brazil study, where the DAS-81419-2 mean was actually slightly lower than the isoline.

While the composition of isoline and DAS-81419-2 soybean was similar both across and within field sites, results within each entry were highly variable across field sites; ADF and NDF in forage provide examples of this site to site variation (Figure 1). The lack of differences between the isoline and DAS-81419-2 coupled with the wide range of results across field sites in these studies indicates that environment has a substantial effect on crop composition and the effect of transgenesis is undetectable, as others have reported.[7,28,85,89,100,107−109]

CONCLUSIONS

On the basis of the absence of meaningful differences between the isoline and DAS-81419-2 soybean in studies that were conducted at multiple field sites in two countries, it is concluded that the composition of DAS-81419-2 soybean forage and seed is equivalent to that of nontransgenic soybean. The conclusion of this study is in concordance with 86 other published studies and over 100 regulatory submissions where compositional equivalence between the transgenic crop and nontransgenic crop was concluded.[7−92,110] Collectively, these results indicate that composition studies to detect unintended effects due to transgenesis with traits that are not expected to alter composition are of dubious value in assessing the safety of transgenic crops.

pigments, emulsifiers, and sweeteners a total of 18 types of food additives are permitted for use in specific foods, and the additives are prepared by extraction from natural sources or chemical synthesis, and the application and the amount of preservatives are regulated by Taiwan Food and Drug Administration (TFDA) "Standards for Specification, Scope, Application and Limitation of Food Additives List".[20] Items not included in the list are technically not permitted for use in processed foods.

In previous years, TFDA surveys of commercially available foods have found that illegal use of preservatives and addition of bleaching agents as food additives are very common in Taiwan.[21] It was also found that food additives and preservatives are added in amounts that exceed permissible limits for their use. Because the majority of the samples in the surveys of marketed foods by local government contained benzoic acid and sorbic acid, it is thus important to take a closer look at these two preservatives due to their popular use. These issues not only pose a risk to public health but also endanger the trade economy. Because of the growing concern regarding levels of preservatives in processed food exceeding their acceptable daily intake (ADI), preservative concentrations and estimated exposure of the population were subject to investigative examination. A survey of benzoic acid in foods in Finland identified fruit, berry juices, soft drinks, and semipreserved fish as the major sources of benzoic acid intake (40 mg/day, 13% of ADI),[22] and the 21st Australian TDS also estimated the dietary exposure to preservatives: benzoates and sorbates.[13]

The specific aims of this study include the following.

(1) To determine the concentrations of benzoic acid and sorbic acid in foods as consumed,
(2) To assess exposure and risk with regard to population groups of various ages,
(3) To identify which food pose the greatest exposure risk to consumers,
(4) To propose appropriate risk management options to protect consumers.

This study was deemed necessary, as dietary composition and intake patterns are distinctly different from Western countries where similar studies had been reported.

MATERIALS AND METHODS

Hazard Identification of Benzoic Acid. Repeated or prolonged exposure to benzoic acid can cause chronic health effects and damage to organs. Reproductive toxicity was observed in rats fed with benzoic acid at concentrations of 0.5 g/kg of body weight (BW)/day.[23] The use of benzoic acid with artificial food colors has also been linked to hyperactivity in children.[24] The Joint FAO/WHO Expert Committee on Food Additives (JECFA) has established an ADI of 0−5 mg/kg of BW/day for benzoic acid and benzoates. The no observed adverse effect level (NOAEL) was established at the highest experimental dose (500 mg/kg of BW/day) at which no adverse effects were observed based on long-term (lifetime) studies in rats. In establishing the ADI, a safety factor (SF) of 100 was applied to the NOAEL to take into account species differences and individual human variation.[25,26]

Hazard Identification of Sorbic Acid. Sorbic acid and potassium sorbate were practically nontoxic to rats and mice in acute oral toxicity studies.[27] They had a very low level of mammalian toxicity, even in chronic doses of up to 10% of the diet. They were found to be noncarcinogenic and nonmutagenic in vitro and in vivo.[28,29] However, oral toxicity studies showed that intake of sorbic acid may result in liver weight gain in 90 days.[30] The JECFA has established an ADI of 0−25 mg/kg of BW/day for sorbic acid and sorbates. The NOAEL was established at the highest experimental dose (2500 mg/kg of BW/day) at which no adverse effects were observed based on long-term (lifetime) studies in rats.[31] In establishing the ADI, a SF of 100 was applied to the dose level to take into account species differences and individual human variation.[32]

Core Food List for the Taiwan TDS. A large amount of food consumption data from the 2005−2008 Nutrition and Health Survey in Taiwan (NAHSIT) are available.[33] The sample population consisted of 6104 participants randomly selected from 48 counties. Information on dietary intake was collected by two nonconsecutive 24 h recalls in combination with a food frequency questionnaire. During the 24 h recall interviews, each respondent reported the quantity of all foods and beverages consumed during the preceding day. To construct the food list for the Taiwan TDS, 268431 raw data entries were first obtained from 6104 questionnaires and then consolidated into 11182 different food items which were grouped into 47 subcategories and 12 major categories on the basis of their nutrient content.[34,35] The number of food items selected from each subcategory for TDS was determined by the percentage of this subcategory in the total diet consumed. The second step involved determining which foods had the highest consumption rate (CR). The foods were ranked in the second step on the basis of percentage consumption, with 1% of the total diet being the cutoff rate. For example, the subcategory "rice and rice products" represented 10.4% of the amount of the total diet consumed daily; hence, the top 11 food items in this subcategory in descending order of CR were selected to represent this subcategory. In the third step, the amount of liquid food consumed was adjusted. The subcategories "ice and beverages" and "soup," where due to the large water content and relative uniformity of these food groups, the percentages of people consuming these groups (4.58 and 0.14%) instead of the percentages of amount consumed (29.80 and 10.72%) were used to keep the numbers of food items small. A total of 128 food items were selected from the 47 subcategories and 12 major categories to form a core list of food items to represent the total diet in Taiwan.

Food List for TDS of Preservatives. Not all food items contain preservatives. Only those containing high concentrations would have a significant contribution to health risk. Therefore, a food list specific to preservatives was constructed out of the core list of 128 items through the following adjustments: (1) Omitting from the core list the food items that were not likely to contain preservatives, such as fresh vegetables and fruits, (2) adding to the list the food items that were known to contain especially high levels of preservatives, including those known to frequently violate the preservative use regulations more than five times per year in the routine survey, and (3) adding to the list the food items that were legally permitted to contain preservatives. Thus, a preservative list of 97 food items from 47 subcategories and 12 major categories was established, which was not totally dependent upon levels of daily intake rate. These 97 items were used as the basis for purchasing food samples to be prepared for chemical analysis of food preservatives.

Purchasing of Food Samples and Preparation of Selected Foods. From this list of 97, one to three food products were selected for collection and preparation of samples for chemical analysis. A total of 239 food samples were obtained from 50 strategic sampling sites distributed among four cities and four counties in the northern, central, southern, and eastern parts of Taiwan. In each sampling site, food products were purchased from five wholesale stores, nine supermarkets, and 24 traditional wet markets. The purchased foods, food products, and food stuffs were combined, washed, cut, and cooked with flavoring agents according to standard recipes in the laboratory. For each item in the list of 97, at least eight products were purchased from the sampling sites, resulting in 2010 food products, which were used to prepare 239 food samples, including 46 cooked samples. These food samples were in turn used to prepare the 97 composite food samples for benzoic acid and sorbic acid analyses by mixing equal weights of food products collected from all sampling sites in two seasons. Each composite sample was homogenized and stored at −80 °C until analysis. All analyses were carried out from 2010 to 2011.

DOI: 10.1021/jf503987y
J. Agric. Food Chem. 2015, 63, 2074−2082

Table 1. Method Performance for Benzoic Acid and Sorbic Acid

analyte	matrix	LOQ (ppm)	recovery range (%)	RSD (%) (n = 5)	measurement uncertainty (ppm)	accreditation yes/no
benzoic acid	meat product	20	96.7 ± 1.90	1.76	250.0 ± 1.2	yes
sorbic acid	meat product	20	97.1 ± 1.07	1.26	250.0 ± 1.2	yes

Analysis of Preservatives. Analysis of food preservatives was conducted by first extracting benzoic acid and sorbic acid from 15 g of homogenized food matrix. Samples were extracted with 150 mL of 50% methanol by shaking for 30 min and then filtered. Deionized water was added to the filtrate to make up the volume to 250 mL, and the solution was filtered through a 0.45 μm membrane. The resulting extract was analyzed by high-performance liquid chromatography (HPLC) using a standard method (Chinese National Standards 10949-N6190). All chemicals used were of analytical reagent grade, and the solvents were of HPLC grade. HPLC was performed by the Hungkuang University Testing and Analysis Center for Food and Cosmetics. This center has been certified for microbial, chemical, and genetic analyses of foods and cosmetics under International Organization for Standardization (ISO) 17025 guidelines.[36] Chromatographic separation was performed using an Inertsil-ODS-2 (6 mm × 150 mm I.D.) analytical column, using methanol/acetonitrile/5 mM citric acid buffer (1:2:7, pH 4.0) as the mobile phase at a flow rate of 1 mL/min. A diode array detector was used for analyzing chromatographically separated analytes, and detection was carried out at a wavelength of 230 nm. This method simultaneously measures the concentrations of five food preservatives, namely, benzoic acid, sorbic acid, dehydroacetic acid, salicylic acid, and alkyl p-hydroxy benzoates at a limit of quantification (LOQ) of 0.02 g/kg. Thus, the detected concentration was labeled as "ND" (not detected) when it was lower than 0.02 g/kg. The analysis was performed in duplicate, using blank, control, and spiked samples for quality control. The target recovery rate was between 80 and 120%; however, in cases wherein the recovery rate was below 80% and above 120%, the samples were retested.

Estimation of Average Daily Dose (ADD) of Food Preservatives. The ADD of benzoic acid or sorbic acid was calculated on the basis of the daily food consumption rate (CR) and the concentration (C) of benzoic acid or sorbic acid in food. Thus, ADD of an analyte in the total diet from food item i for the specified age group j is calculated as follows:

$$\mathrm{ADD}_j = \sum_{i=1}^{n} \frac{C_i \times \mathrm{CR}_{ij}}{\mathrm{BW}_j} \quad (1)$$

where C_i is the concentration (mg/kg) of the analyte in food item i, CR_{ij} is the CR (g/person per day) of food item i by age group j, and BW_j is the average BW of age group j. The data for C in diet samples, BW of various age groups, and CRs were obtained from the NAHSIT. According to the recommendation of the WHO, when C is less than the LOD, the chemical is to be reported as nondetected (ND). When the ND rate is less than 60%, the data were replaced by $^1/_2$LOD, and C values below the LOQ but above the LOD were replaced by $^1/_2$LOQ. If the ND rate were over 60%, C values were assumed to be zero (ND).[37]

In this study, the exposure groups were classified according to sex (male and female) and age as in NAHSIT. A total of eight groups were classified by age and show the whole population. Eight groups included children of ages less than 1 year, 1−2 years, 3−6 years, 7−12 years, and 13−18 years; adults of ages 19−50 years and 51−65 years, and individuals above 66 years old. The CRs of the eight groups were estimated according to the 2005−2008 NAHSIT.[33]

In the NAHSIT have been given a unique coding for each food, each of the codes follow the nutritional content of different foods, food type, type of processing, and other related properties, to reclassification of all food into 230 food items. In the 47 subcategories (including 230 food items), the sum of the amount of 11182 available food intake records, we could get the total daily intake of all Taiwanese, and after conversion we could obtain the daily intake. The daily intake in the questionnaire was corrected by weighting to adjust the national daily intake data by the following steps: (1) The questionnaire weight was the total population in the layer/number of samples in the layer, (2) the individual food daily intake was multiplied by the questionnaire weight to obtain the national daily intake, and (3) national daily intake/number of the questionnaires in Taiwan and finally can get the food CR per person per day.

Distributions of CR and BW values were analyzed by Monte Carlo simulation techniques to obtain probabilistic parameters such as percentile values using the Crystal Ball software available from Decisioneering, Inc., Denver, Co., USA. Probabilistic distributions of CR were fitted to the 268431 raw data obtained from 6104 questionnaires. Distributions of the estimated BW of eight groups were fitted to the data obtained from 6104 participants. The selected log-normal distributions of CR and normal distributions of BW have optimal χ^2 fit and Kolmogorov−Smirnov (K−S) goodness-of-fit.

Hazard Index (HI, %ADI). The HI was calculated from the ADI and ADD according to the following equation:

$$\begin{aligned} \mathrm{HI}_j &= \sum_{i=1}^{n} \%\mathrm{ADI}_{ij} \\ &= \sum_{i=1}^{n} \frac{\mathrm{ADD}_{ij}}{\mathrm{ADI}_P} \times 100\% \\ &= \sum_{i=1}^{n} \frac{C_i \times \mathrm{CR}_{ij}}{\mathrm{BW}_j \times \mathrm{ADI}_P} \times 100\% \end{aligned} \quad (2)$$

where HI_j is the hazard index for age group j and ADI_p is the acceptable daily intake for chemical P. HI must be less than 100% to indicate that no harm would result from dietary exposure to the analyte in the lifetime of any consumer. ADI_P is generally accepted as an intrinsic property of the target chemical P. Toxicological and ADI data, as well as hazard characterization data for benzoic acid and sorbic acid, are collected from toxicological tests conducted on animals. ADI values of benzoic acid and sorbic acid used in this study were 5 mg/kg of BW/day and 25 mg/kg of BW/day,[31,39] respectively, as promulgated by the JECFA.

RESULTS AND DISCUSSION

Concentrations of Benzoic Acid and Sorbic Acid. Representative food samples, collected in the fall and winter of 2010 and in the spring and summer of 2011, were analyzed to determine the concentration of preservatives. The purchased food samples detection rates for benzoic acid and sorbic acid were approximately 30% and 22% respectively, of the total samples analyzed. The method performance for benzoic acid and sorbic acid show in Table 1. LOQ is 20 ppm and detected concentration lower than 20 ppm is labeled as "ND". In cases wherein the ND rate was greater than 60%, the concentration below the LOQ was assumed to be zero, and the concentrations of benzoic acid and sorbic acid were regarded as 0 mg/kg when calculating the daily intake.[35] LOD is 0.3 ppm considerably lower than that set by regulatory authorities in Taiwan. The analytical methods are in compliance with international standards for the analysis of food items in TDS requiring higher analytical sensitivities.[38]

Preservative concentrations in major categories show in Table 2. In the grains categories, 43 samples were analyzed. Frequency of detection is 44.2%, and mean concentration is 0.04 ppm in benzoic acid. Regulations pertaining to preservative use limit in Taiwan, the concentration of benzoic acid were 0.6 to 1.0 g/kg. In foods such as meats, sea urchins,

	sorbic acid	21	14.3	0.05 ± 0.16

caviar, peanut butter, cheese, candied fruits, dried fruits, and dried radish containing no less than 25% moisture, cooked beans, miso, seaweed sauce, fermented bean curds, pastry, sauces, jam, juice, margarine, tomato sauce, chili sauce, thick candy syrup, and flavored syrup, the maximum permissible concentration is set at 1.0 g/kg. For foods such as mullet roe, dried fish, dried shellfish, beverages, pickles, dried bean curd, and salted vegetables, the maximum permissible concentration is set at 0.6 g/kg.

Sorbic acid regulations limit concentration added in food were 0.5 to 2.0 g/kg. For minced fish surimi products, meat products, urchins, caviar, peanut butter, soy sauce preserved vegetables, and dried radish containing no less than 25% moisture, pickled vegetables, dried bean curd products, cheeses: not more than 2.0 g/kg calculated as sorbic acid. For cooked beans, soy sauces, miso, dried mullet roe, dried fish, and shellfish products, seaweed pastes, soybean curd cheeses, syrup-preserved fruits, dried fruits, cakes, and cookies (including steamed Chinese-styled ones), jams, juices, butter, cream, margarine, ketchup, chili sauces, fruit syrups, flavored syrups, and other sauces: not more than 1.0 g/kg calculated as sorbic acid. For noncarbonated beverages and carbonated beverages, the maximum permissible concentration is set at 0.5 g/kg.

In our studies, the use of benzoic acid and sorbic acid as preservatives is permitted for only 34 food items in Taiwan. Of the 239 food samples from two sampling seasons that were analyzed for preservatives, there are 90 food samples that have little bearing on the 34 mentioned even though the use of benzoic acid and sorbic acid as preservatives is permitted for only 34 food items and 46 out of the these 90 food samples (51%) were found to contain these preservatives. In addition, we found that the concentrations of benzoic acid in some samples of dried tofu, packaged dried tofu, bean pastes, and dried pickled radish were above the regulation limit. These findings suggest that the preservatives are widely distributed among foods other than the regulated 34 food items, making it imperative to regularly monitor the food industry in Taiwan.

ADD of Benzoic Acid and Sorbic Acid. The ADD of food additives benzoic acid and sorbic acid in each item was estimated by measuring the concentration of the target chemical in the food sample. The results obtained by multiplying the concentration by the amount of food consumed are shown in Table 3. To estimate the ADD of a target chemical consumed by a sex-specific and age-specific population using the equation of ADD, data on the BW and the CR in 12 major categories of food were required. The exposure groups were classified according to eight age groups of ages under 1 year, 1−2 years, 3−6 years, 7−12 years, 13−18 years, 19−50 years, 51−65 years, and over 66 years were estimated according to the 2005−2008 NAHSIT.[33] The food list for the TDS, which was derived from the CR, contained 97

[a]ADD: average daily dose of food preservatives (mg/kg bw/day).

DOI: 10.1021/jf503987y
J. Agric. Food Chem. 2015, 63, 2074−2082

items selected to represent the total diet in Taiwan that may contain benzoic acid and sorbic acid. Items containing benzoic acid and sorbic acid that are consumed by the eight age populations were selected according to three selection criteria: (1) high relative CR, (2) historical high level of occurrence of the analytes, and (3) items for which the use of the analytes is permissible. The food items in the TDS list represented 83% of the weight (g) of the total diet of general consumers in Taiwan.

At the 50th percentile, males aged 1−2 years had the highest ADD of benzoic acid, with exposure level reaching 2.4 mg/kg of BW/day. In this group, the participators in 97 food items constituted 97.8% of a total of 184 people in the group, meaning that only four people did not take in these food items during the 24 h recall interviews. Females aged 3−6 years had the highest 95th percentile ADD of benzoic acid, with exposure level reaching 2.9 mg/kg of BW/day. The level of exposure to sorbic acid was 0.1 (under 1 year old group) to 0.7 (3−6 years old group) mg/kg of BW/day. Even at the 95th percentile, the exposure did not exceed 0.7 mg/kg of BW/day (3−6 years old group).

HI (%ADI) of Benzoic Acid and Sorbic Acid. The HI values of benzoic acid and sorbic acid were calculated as a percentage of respective ADI, 5 and 25 mg/kg of BW/day, using eq 2. The ratio of ADD to ADI, taken as %ADI (Figures 1 and 2), represents different exposure populations for benzoic and ascorbic acid. HI of benzoic acid and sorbic acid were calculated with the 50th percentile and 95th percentile of the different exposure populations.

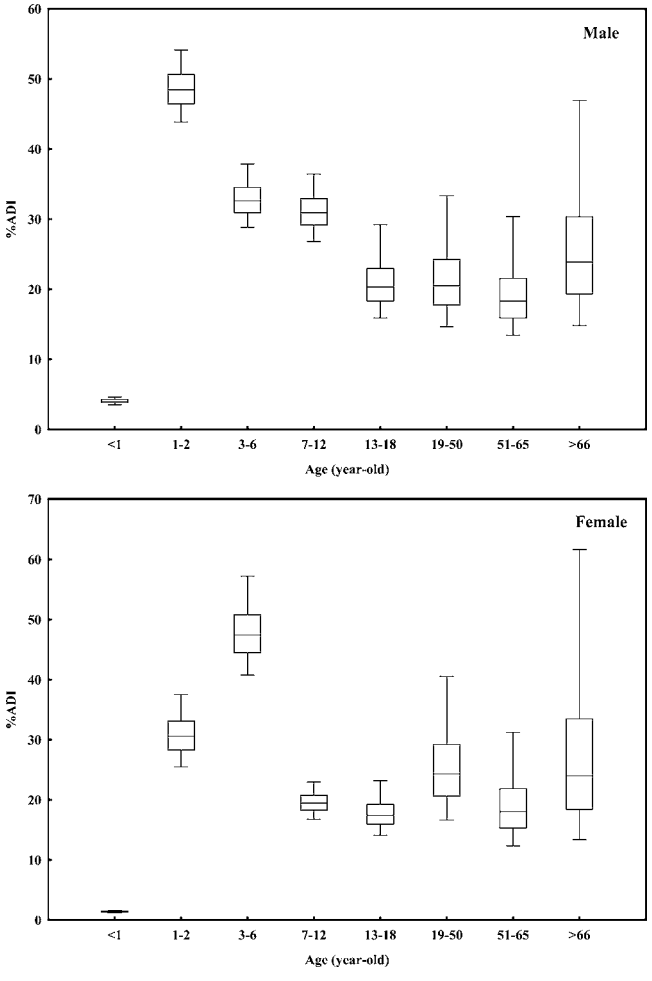

Figure 1. Food safety risk assessment hazard index (%ADI) of benzoic acid.

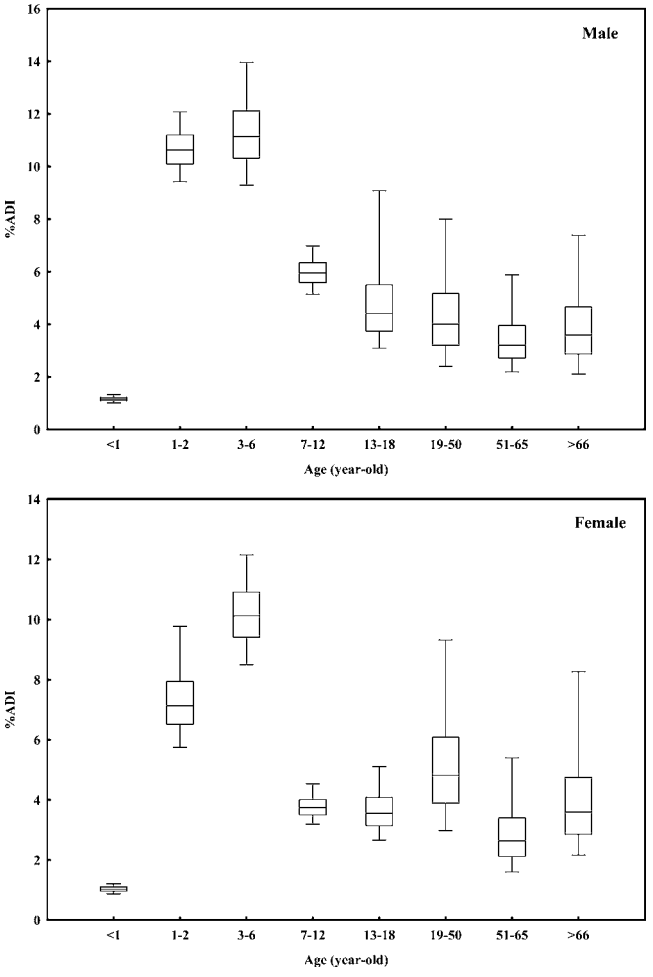

Figure 2. Food safety risk assessment hazard index (%ADI) of sorbic acid.

In Figure 1, the food safety risk assessment %ADI show males aged 1−2 years (48.5%) and females aged 3−6 years (47.4%) at the 50th percentile had the highest %ADI of benzoic acid, whereas males (11.2%) and females (10.1%) aged 3−6 years had the highest %ADI for sorbic acid at the 50th percentile shown in Figure 2. The values of HI for sorbic acid is generally lower than that for benzoic acid. HI of benzoic acid and sorbic acid are below the ADI. At the 95th percentile, the upper end of the intake distribution is still below the ADI; females over 66 years of age (61.7%) and males 3−6 years of age (14.0%) had the highest %ADI for benzoic acid and sorbic acid, respectively. These results indicate that there is a large margin of safety in the use of benzoic acid and sorbic acid as food preservatives in Taiwan.

In a study carried out in Belgium, the daily intake of benzoic acid in the male population exceeded the ADI (5 mg/kg of BW/day) at the 99th percentile, and the greatest contributor to the intake was soft drinks.[40] In our study, the ADD at the 99th percentile of men by all age groups did not exceed the ADI. In a study in Finland, fruit and berry juices, soft drinks, and semipreserved fish were identified as the major sources of benzoic acid intake, with the exposure level being 40 mg/day, or 13% ADI.[22] Comparing with the results of a 21st Australian

DOI: 10.1021/jf503987y
J. Agric. Food Chem. 2015, 63, 2074−2082

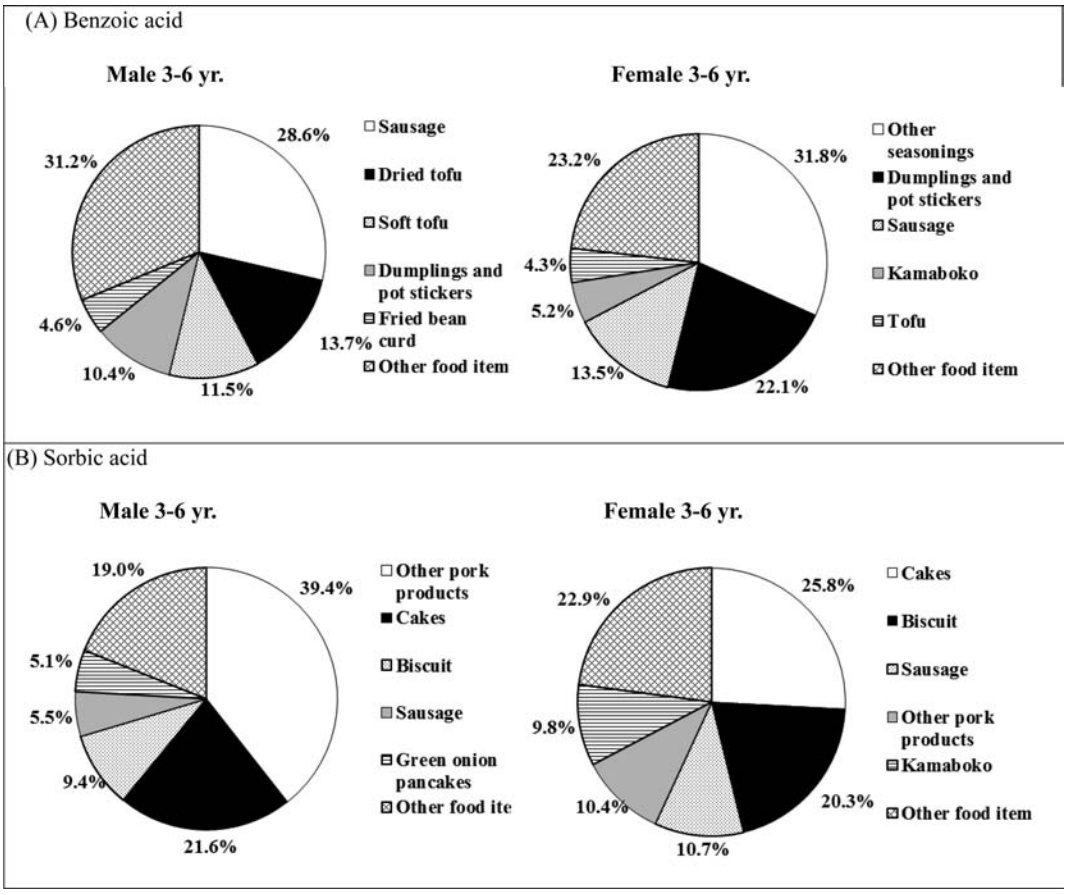

Figure 3. Exposure contributor of preservatives benzoic acid and sorbic acid for male and female aged 3−6 years old.

TDS,[13] the %ADI values for benzoic acid and sorbic acid of our study were slightly higher than those in Australia at 50th percentile, but lower at the 95th percentile. Although the eating habits in Taiwan are markedly different, the %ADI of benzoic acid and sorbic acid were nonetheless at very similar levels as in Australia. Although the results of the Australia study show that the mean estimated dietary exposure to benzoates was less than 50%ADI for all population groups assessed, the 95th percentile estimated dietary exposures to benzoates exceeded the ADI for young boys (approximately 140%) and young girls (approximately 120%) aged 2−5 years.[13] In the case of sorbates, the mean and 95th percentile estimated dietary exposure were less than or equal to 40%ADI for sorbates for all population groups assessed.

Our results indicate that the current exposure level to benzoic acid in foods in Taiwan is less than 60% of the ADI and hence not a hazard to public health. Combining the data for BW distribution and food CRs obtained in this study, we determined the HI for the Taiwanese population. The results indicate that in the 95th percentile, the exposure of the general population to benzoic acid is less than 60% of the ADI and hence not at a harmful level. Benzoic acid and sorbic acid are effective antimicrobials in acidic or slightly acidic foods. The temporary ADI was set at 5 mg/kg of BW by the European Scientific Committee on Food in 1994. The JECFA set an ADI of 5 mg/kg of BW in 1996, which was a confirmation of the evaluation in 1994. The 100-fold SF built into the ADI provides a significant margin of safety, which serves to reduce the likelihood of adverse effects on humans. As the %ADI is not over 100%, we assume that under the current exposure scenario, benzoic acid and sorbic acid pose no significant food safety risk in Taiwan. However, HIs even as high as 48.5%ADI (male 1−2 years group) at the 50th percentile, suggesting that regulatory actions must be implemented.[41]

HI (%ADI) Exposure Contributor for Benzoic Acid and Sorbic Acid. The intake of benzoic acid and sorbic acid through various food groups by various age groups is shown in Figures 3 and 4. According to the HI (%ADI) results, the 0−6 age sensitive population might have a higher risk of exposure to benzoic acid or sorbic acid. However, using adult food to estimate the infant (0−2 years old) dietary exposure would be an overestimation. Therefore, we focused on high-risk sensitive population aged 3−6 years and general population aged 19−50 years to explore further the exposure contributor of preservatives benzoic acid and sorbic acid (Figures 3 and 4). In 3−6 years population, the main HI contributors for benzoic acid were sausage (28.6%) for male and seasonings (31.8%) for female, respectively. The main HI contributors for sorbic acid were pork products (39.4%) for male and cakes (25.8%) for female, respectively. In the 19−50 years population, the main HI contributors for benzoic acid were dumplings and pot stickers (21.8%) for male and seasonings (34.5%) for female. The main HI contributors for sorbic acid were beef (29.5%) for male and cakes (23.7%) for female. Seasonings like tomato sauce, chili sauce, and soy sauce are added benzoic acid as a preservative to protect it from going bad. Dumpling and pot sticker skin were foods with high moisture that promotes growth of mold, yeast, and bacteria, whereas adding benzoic acid can inhibit them. Sorbic acid and its salts are used to protect cakes against mold spoilage and as inhibitors of

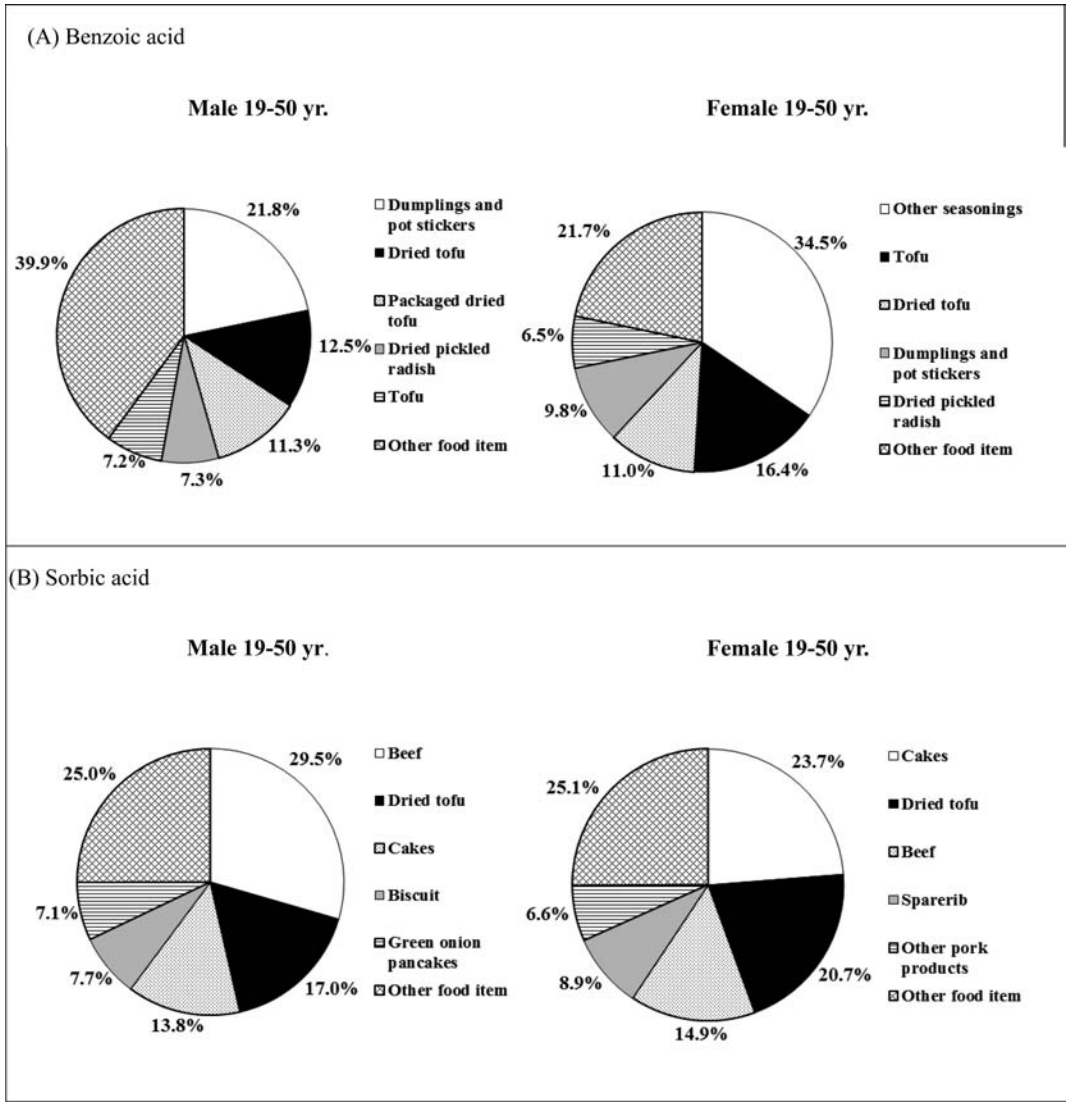

Figure 4. Exposure contributor of preservatives benzoic acid and sorbic acid for male and female aged 19−50 years old.

Clostridium botulinum in meat products in order to replace the use of nitrites, which produce carcinogenic nitrosamines.

In a study of dietary exposure to benzoic acid in secondary school students by Ma et al.,[15] the dietary exposures for average and high consumers of the school students from prepackaged beverages were 0.31 and 0.97 mg/kg BW per day, respectively. Both exposure levels were below the ADI established by JECFA. However, in the worst-case scenario where consumers had specific brand loyalty toward the fruit juice sample with the highest benzoic acid level detected in the study,[15] the general exposure in high consumers would exceed the ADI, leading to increased health risk.

In comparison, the major HI contributors for benzoic acid and sorbic acid in Australia were beverages (soft drinks) and fresh juices,[13] reflecting the vast difference in eating habits between the Orientals and the Caucasians. Likewise, in the Belgian study, the male group aged 15 years and older had a higher intake of benzoic acid than females due to a higher intake of soft drinks; their 99th percentile exposure exceed the ADI.[40] By conservative assessment of daily exposure, we found that seasoning, dumplings, and pot stickers were identified as the major sources of benzoic acid intake in Taiwan and hence require continuous monitoring.

Uncertainty Analysis. There are some methodological limitations and uncertainties in our study that need to be noted. First, Chinese foods are complex and dynamic, and it is very difficult to exactly match the food groups or items to be surveyed with the foods actually consumed. Second, foods analyzed in this survey were originally mapped to a wider range of foods described in the NAHSIT for a different research purpose, as the patterns of preservatives used in the mapped foods were assumed to be similar to the 97 food items analyzed, a kind of uncertainty inevitably was introduced. Third, it followed that the ADDs of preservatives were estimated with exposure factors associated with only these 97 items, introducing another kind of uncertainty. These uncertainties may cause underestimation. However, with our selection criteria, we believed that all the major sources of foodborne preservatives were covered. We also assessed the %ADI at the 95th percentile in order to avoid underestimation. In addition, the dietary exposures to benzoic acid and sorbic acid might have been overestimated in 1 year and 1−2 years because these groups are infants who consume mainly milk or baby food which are inherently different from adult food. Further studies will be conducted to examine this issue further. Finally, the one-day 24 h dietary recall records from the NAHSIT undoubtedly

DOI: 10.1021/jf503987y
J. Agric. Food Chem. 2015, 63, 2074−2082

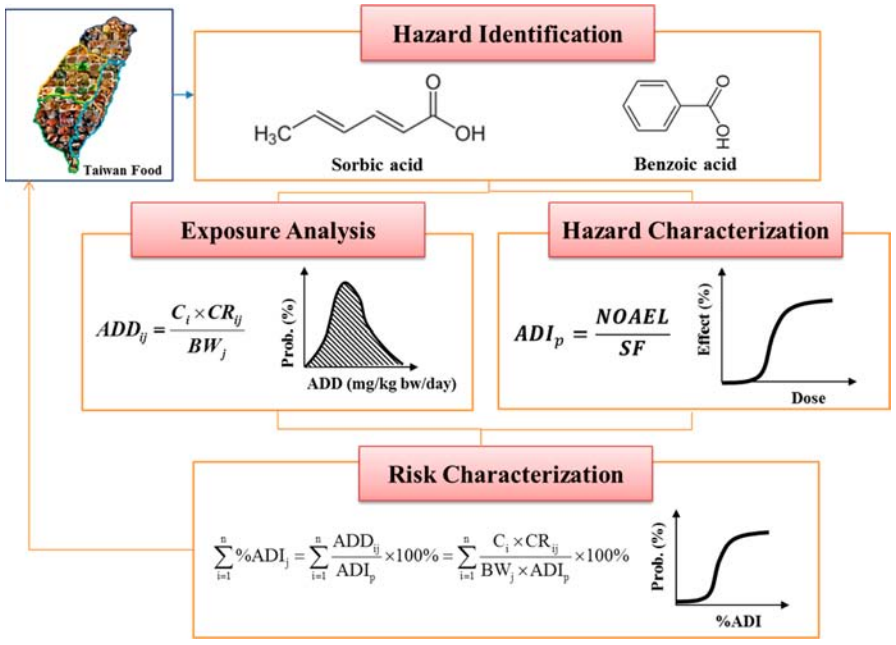

Figure 5. Flowchart of dietary exposure estimates for the food preservatives benzoic acid and sorbic acid in the total diet in Taiwan.

contained another kind of uncertainty due to individual differences in daily dietary practice. Our study therefore represents a preliminary attempt to construct a "market basket" for the total diet in Taiwan. To improve the accuracy of our estimates, future efforts are focused on minimizing the above-mentioned uncertainties and on validating the models and values of exposure factors in utilizing the data resources from NAHSIT, a major national research investment in Taiwan. In conclusion, the purpose of this study was to evaluate the HI (% ADI) of benzoic acid and sorbic acid through ingestion and thereby establish a model for total diet study on food additives in Taiwan by utilizing the existing data available from a national nutritional status survey, NAHSIT. The calculated 95th percentile ratios of ADD to ADI of benzoic acid and sorbic acid were less than 60%ADI, suggesting that the use of the two preservatives in food in Taiwan is within safe limits. This study provides a model for future work to address specific additives in specific foods as needed by food safety risk regulatory agencies.

In conclusion, this study demonstrated a dietary exposure estimates for the food preservatives benzoic acid and sorbic acid in the total diet in Taiwan (Figure 5). In hazard identification, related research in total diet study and the physical and chemical properties of preservatives benzoic acid and sorbic acid were collected. Then, in exposure analysis, ADD was estimated with Monte Carlo simulation. In hazard characterization, ADI, toxicological data (e.g., NOAEL) and SF of the preservatives from international institutions such as JECFA were analyzed. The dose−response profile was estimated according to the ADI by the JECFA. Lastly, in risk characterization, the probability distribution of the food safety risk was estimated and compared to ADI. In high-intake consumers, the highest HI of benzoic acid was 61.7%ADI for females aged over 66 years old. The highest HI of sorbic acid for male and female consumers aged 3−6 years old at the 95th percentile were 14.0%ADI and 12.2%ADI, respectively. These results indicate that the use of benzoic acid and sorbic acid as preservatives at the current level of use in the Taiwanese diet does not constitute a public health and safety concern, but the public is advised to maintain a varied and balanced diet so as to avoid excessive exposure of benzoic acid and sorbic acid from a small range of food items.

Funding

This TDS project was financed by the Taiwan Food and Drug Administration (TFDA), Department of Health (DOH), contract TFDA-TC-103.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

The data on related exposure factors, including BW and CR, were kindly provided by Dr. W. H. Pan, Principal Investigator of the National NAHSIT sponsored by the DOH (DOH94-FS-6-4). We thank our project manager at TFDA and the many food safety colleagues in Taiwan and TDS experts in China and elsewhere for their generous and professional help in completing this project. Without the help, we would not have been able to carry out this study. We would especially like to acknowledge the leadership and important contributions of coauthor DPHH, who has now honorably retired.

dithiothreitol (DTT), phenyl-methanesulfonil fluoride (PMSF), potassium hydrogen carbonate, hydrogen peroxide, and superoxide dismutase (SOD) bovine (EC 1.15.1.1) were from Sigma-Aldrich (St. Louis, MO, USA). *ortho*-Phosphoric acid 85% was obtained from Panreac (Barcelona, Spain). Methanol and acetonitrile were obtained from Merck (Darmstadt, Germany). Sodium chloride, ethyl acetate, hydrochloric acid, and formic acid were from BDH Prolabo (Dublin, Ireland). Standards were obtained from Extrasynthese (Genay, France). Dulbecco's Modified Eagle Medium (DMEM) + GlutaMAX^{TM-I}, heat-inactivated fetal bovine serum (FBS), phosphate-buffered saline (PBS), nonessential amino acids (NEAA), Pen Strep solution (Penicillin 5000 units/mL and Streptomycin 5000 mg/mL), fungizone (250 μg/mL amphotericin B), human transferrin (4 mg/mL), and trypsin-EDTA were purchased from Gibco, Invitrogen (Invitrogen, Paisley, U.K.). Human epithelial colorectal adenocarcinoma (Caco-2) cell line was acquired from American Type Culture Collection (ATCC) (LGC Standards S.L.U., Barcelona, Spain). Water was deionized using a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Samples. *E. plantagineum* bee pollen sample was provided by beekeepers in the Spanish Extremadura region in 2011. The botanical origin was assessed by Professor Paula B. Andrade (Laboratório de Farmacognosia, Faculdade de Farmácia da Universidade do Porto; voucher specimen EP-BP-032011). Bee pollen was stored protected from light under desiccating conditions to prevent alteration.

Extracts Preparation. Aliquots of 1 g of *E. plantagineum* bee pollen were accurately weighed, thoroughly mixed with 10 mL of methanol containing 0.5% HCl (v/v), sonicated for 1 h, and centrifuged at 4000 rpm for 10 min. The supernatant was decanted, and the residue was re-extracted by thoroughly mixing by vortexing for 2 min with 10 mL of methanol containing 0.5% HCl (v/v) and centrifuged at 4000 rpm for 10 min. The supernatants were pooled together, and the solvent was evaporated under reduced pressure at 30 °C. In order to obtain extracts enriched in phenolic compounds, a solid-phase extraction (SPE) procedure was performed using Chromabond C_{18} nonend-capped (NEC) columns (45 μm particle size, 60 Å pore size; 10 g sorbent mass/70 mL reservoir volume) from Macherey-Nagel (Düren, Germany). The residue was dissolved in 10 mL of water and applied to the SPE cartridge preconditioned with 20 mL of ethyl acetate, 20 mL of methanol, and 20 mL of water. The loaded cartridge was washed with 10 mL of water. A fraction containing noncolored phenolics was eluted with 100 mL of ethyl acetate (fraction I). A second fraction with anthocyanins (fraction II) was eluted with 40 mL of methanol. A combined extract was obtained by mixing ethyl acetate and methanol eluates (whole extract). The eluates were concentrated under reduced pressure, and the residues obtained were dissolved in 5 mL of methanol (final concentration of 200 mg/mL).

Acid Hydrolysis. A 1 mL amount of HCl 2 M was added to 2 mL of fraction II. The acid solution was heated at 100 °C for 30 min under reflux. The obtained anthocyanidins were recovered by SPE using a Chromabond C18 nonend-capped (NEC) column (45 μm particle size, 60 Å pore size; 1 g sorbent mass/6 mL reservoir volume) from Macherey-Nagel (Düren, Germany) previously conditioned with methanol and HCl, 2 M. Compounds were eluted with 20 mL of methanol. The solvent was evaporated under reduced pressure at 30 °C; the residue was dissolved in 2 mL of methanol, filtered through a 0.45 μm pore size filter, and injected for anthocyanidins identification.

HPLC-DAD Analysis. The extracts were analyzed on an analytical HPLC unit (Gilson) consisting of two pumps (321 model) and a Rheodyne injector (model 7125), connected to a diode array detector (Gilson 170 Diode Array detector). The HPLC was equipped with a Spherisorb ODS2 column (25.0 × 0.46 cm; 5 μm, particle diameter). Spectral data from all peaks were accumulated in the range 200−600 nm. The data were processed on a Unipoint Software system (Gilson Medical Electronics, Villiers le Bel, France). Peak purity was checked by the software contrast facilities.

Flavonols. The extracts were analyzed as described before.[4] Briefly, the mobile phase consisted of water−formic acid (1%) (A) and methanol (B). The following gradient was used: from 30% to 40% B (20 min), from 40% to 50% B (5 min), from 50% to 60% B (5 min), and from 60% to 80% B (2 min). The flow rate was 1 mL/min, and the injection volume was 20 μL. Phenolic compounds quantification was achieved by the absorbance recorded at 350 nm relative to external standards. Because standards of all identified kaempferol derivatives were not commercially available they were quantified as kaempferol-3-*O*-rutinoside, excepting kaempferol-3-*O*-glucoside, which was quantified as itself.

Anthocyanins. Colored phenolics were analyzed following a previously described method.[13] The mobile phase consisted of water/formic acid/acetonitrile (87:10:3, v/v/v; eluent A) and water/formic acid/acetonitrile (40:10:50, v/v/v; eluent B) using a gradient program as follows: from 10% to 25% B (10 min), from 25% to 31% B (5 min), from 31% to 40% B (5 min), from 40% to 50% B (10 min), from 50% to 100% B (10 min), and from 100% to 10% B (5 min). The flow rate was 0.8 mL/min, and the injection volume was 20 μL. Phenolic compounds in the extracts and in the hydrolyzed extracts were identified by comparing their retention times and UV−vis spectra with those of standards when commercially available and by comparison with the literature.[2] Quantification was performed at 500 nm. Delphinidin heterosides were quantified as delphinidin-3-*O*-glucoside; petunidin heterosides and malvidin-3-*O*-glucoside were quantified as malvidin-3-*O*-glucoside.

Caco-2 Culture Conditions and Treatments. Caco-2 cells were grown in DMEM+GlutaMAX^{TM-I} supplemented with 10% calf serum (FCS) heat-inactivated, 1% NEAA, 1% fungizone, 6 μg/mL transferrin, 1% penicillin, and 1% streptomycin, at 37 °C in 5% CO_2, until they reach 90% confluence. For cell treatments the culture medium was prepared without FCS. Cells were plated at 1.5×10^5 cells/mL using 200 μL/well of cell suspension in 96-well plates (viability assays), 1200 μL/well in 24-well plates (GSH, DCFA-DA), and 2.5 mL/well in 12-well plates (enzymes) and then incubated until they reached confluence.

Just before the assays, an aliquot of the extracts was evaporated under a nitrogen stream; the residue was dissolved in the same volume of culture medium without FCS and sterilized by filtration through a 0.22 mm size pore membrane. Five dilutions (1/2) were prepared, and cells were exposed for 24 h to the different concentrations of the extracts. In order to evaluate the antioxidant potential, cells were pre-exposed to the extracts for 24 h, then the extracts were removed, and cells were exposed to 150 μM *t*-BHP for 4 (DCFA-DA assay) or 6 h (other assays).

Viability Assays. The viability of cells was measured by the mitochondria-dependent reduction of MTT to formazan and by the release of the cytosolic enzyme lactate dehydrogenase (LDH) into culture medium by cells with disrupted cell membrane.

MTT Reduction. After cell treatment and removal of the culture medium, adherent cells were treated for 30 min with 0.5 mg/mL of MTT. The formazan crystals were then dissolved with DMSO and quantified by measuring the absorbance at 560 nm in a microplate reader (Multiskan ASCENT).[4,14] Results were expressed as percentage of control. Five independent experiments were performed in triplicate.

LDH Release. LDH was determined by adding pyruvate (124 μM) and NADH (154 μM) to the culture medium of treated cells and following the rate of oxidation of NADH at 340 nm during the conversion of pyruvate to lactate.[4,15] Results are expressed as percentage of control. Five independent experiments were performed in triplicate.

Reactive Species. The measurement of intracellular reactive species with DCFA-DA was performed using a previously described method,[16] with modifications. Cells were exposed to the extracts for 24 h, and the culture medium was removed. DCFA-DA (10 μM, dissolved in culture medium without phenol red) was added, and the cells were incubated with the probe for 30 min at 37 °C. The probe was removed, and *t*-BHP dissolved in culture medium without phenol red was added. Fluorescence (485 nm excitation, 528 nm emission) was read immediately and every 30 min, for 4 h, in a microplate spectrofluorimeter (Synergy HT, Bio-Tek Instruments Winooski, USA, operated by KC4 software). The plate was maintained at 37 °C between readings. Results are expressed as percent of control (without

DOI: 10.1021/jf505568h
J. Agric. Food Chem. 2015, 63, 2083−2091

t-BHP) and were normalized with the result at 0 min. Five independent assays were performed.

Glutathione. Total glutathione (GSHt) was measured by DTNB-glutathione reductase (GR) recycling assay, according to a previously described method.[17] Briefly, the culture medium was removed after cells treatment, and 250 μL of perchloric acid 5% was added to each well. Incubation was maintained for 10 min on ice in order to extract GSHt, and then the solution was collected and kept at −20 °C until analysis. A 250 μL amount of NaOH, 0.3 M, was added to the cells in each well to solubilize proteins for protein quantification.

GSHt was measured by following the increase of 5′-thio-2-nitrobenzoic acid (TNB) at 405 nm, resulting from the oxidation of GSH by DTNB (1.28 mM). The assay was performed after neutralizing perchloric acid with $KHCO_3$, 0.76 M, in the presence of GR (2.0 U/mL) and NADPH (0.21 mM), to recycle the glutathione disulfide GSSG increasing the detection limit. GSSG was measured after GSH derivatization by 2-vinilpyridine: 2-vinilpyridine (7.5 μL) was added to 150 μL of samples and mixed continuously in a shaker for 1 h at 4 °C. GSSG was then quantified as described above for GSHt. Five independent assays were performed.

Antioxidant Enzymes. The influence of the extracts on antioxidant enzymes activity was measured. After exposure to the extracts the culture medium was collected for extracellular SOD determination and the cells were lysed on ice for 30 min with 1% Triton X-100 in Tris-HCl 50 mM, pH = 8.0, containing 150 mM NaCl, 0.5 mM PMSF, and 1 mM DTT (for GPx analysis 0.5 mM of DTT was used). The lysates were centrifuged at 10 000 rpm for 10 min, at 4 °C, and the supernatants were collected for enzymatic and protein assays. Five independent assays were performed.

Glutathione Transferase (GST). GST activity was assayed according to a previously described method.[18] GSH (1 mM) was incubated at room temperature with 1-chloro-2,4-dinitrobenzene (CDNB, 1.5 mM), and the formation of the conjugate was monitored at 340 nm. GST activity was calculated by using an extinction coefficient of 9.6/mM/cm.

Glutathione Reductase (GR). GR activity was determined at room temperature, following the rate of oxidation of NADPH (0.5 mM) at 340 nm, during the reduction of GSSG (1.2 mM) to GSH.[19] GR activity was calculated by using an extinction coefficient of 6.22/mM/cm.

Glutathione Peroxidase (GPx). GPx activity was measured following a previously described method.[20] The activity was indirectly measured by a coupled assay of GSSG reduction under conditions in which GPx activity is rate limiting. The assay was performed at room temperature using *t*-BHP (150 μM) as substrate, GSH (1 mM) plus NADPH (0.15 mM), and GR (0.03 U/mL) to recycle the GSSG formed. The decrease of NADPH was measured at 340 nm. The enzyme activity was calculated by using an extinction coefficient of 6.22/mM/cm and expressed as mmol of NADPH oxidized/min/mg of protein.

Catalase. Catalase activity was measured at room temperature by monitoring the decomposition of H_2O_2 (10 mM) at 240 nm.[21] The enzyme activity was calculated by using an extinction coefficient of 39.4/M/cm.

Superoxide Dismutase (SOD). Extracellular SOD was assayed using a previously described method,[22] with modifications. A PMS (0.003 mM)−NADH (0.07 mM) system was used to generate superoxide radical ($O_2^{\bullet-}$). Subsequent reduction of NBT (0.03 mM) by $O_2^{\bullet-}$ was monitored at 560 nm. SOD activity was determined by interpolation of a calibration curve built under the same conditions with SOD bovine, with a concentration range of 0.025−0.25 U/mL.

In order to assess $O_2^{\bullet-}$ scavenging activity, an assay was performed incubating culture medium with the extracts but without cells and measuring NBT reduction as previously described. Four independent assays were performed. The results are expressed as percent of control and were compared with the ones obtained in the assay performed with cells.

Protein Quantification. Proteins were measured by the Bradford method using bovine serum albumin as reference.[23]

Statistical Analysis. Statistical analysis was performed using Graphpad Prism 6 Software (San Diego, CA, USA). Two Way ANOVA and Dunnets's test (LDH, MTT, DCFA-DA, and antioxidant enzymes) or Sidak's (GSHt, $O_2^{\bullet-}$), as posthoc test, were used to determine the statistical significance in comparison to control. Two-way ANOVA and Sidak's multiple comparisons test were used to compare between groups. Values of $p \leq 0.05$ were considered significant.

RESULTS AND DISCUSSION

Chemical Composition. The chemical composition of *E. plantagineum* bee pollen was determined after extraction of compounds with acidified methanol in order to recover both anthocyanins and noncolored phenolics. Anthocyanins are soluble in polar solvents but are instable in neutral or alkaline media, being usually extracted from plant materials with methanol containing an acid in small quantities to prevent alteration of acylated compounds.[24] The crude extract was fractioned by SPE using ethyl acetate (fraction I) and methanol (fraction II) as eluents. A whole extract was also characterized. Twelve phenolic compounds were identified, belonging to flavonols (seven compounds) and anthocyanins (five compounds).

Noncolored Phenolic Compounds. The identification of noncolored phenolics in fraction I, fraction II, and whole extract of *E. plantagineum* bee pollen was performed using the same chromatographic conditions of a previous study concerning a hydromethanolic extract of the same material.[4,5]

All of the determined noncolored phenolic compounds were derivatives of kaempferol (Figure 1A, Table 1). Fraction I (eluted with ethyl acetate) contained six compounds, while fraction II (collected with methanol, after ethyl acetate elution) and the whole extract contained all the identified compounds. Kaempferol-3-*O*-neohesperidoside was the major compound in all of the extracts, representing between 73.2% (Fraction I) and

[a]Values are expressed as mean ± standard deviation of three determinations. Different superscript letters in the same row mean statistically significant differences ($p < 0.05$ or higher).

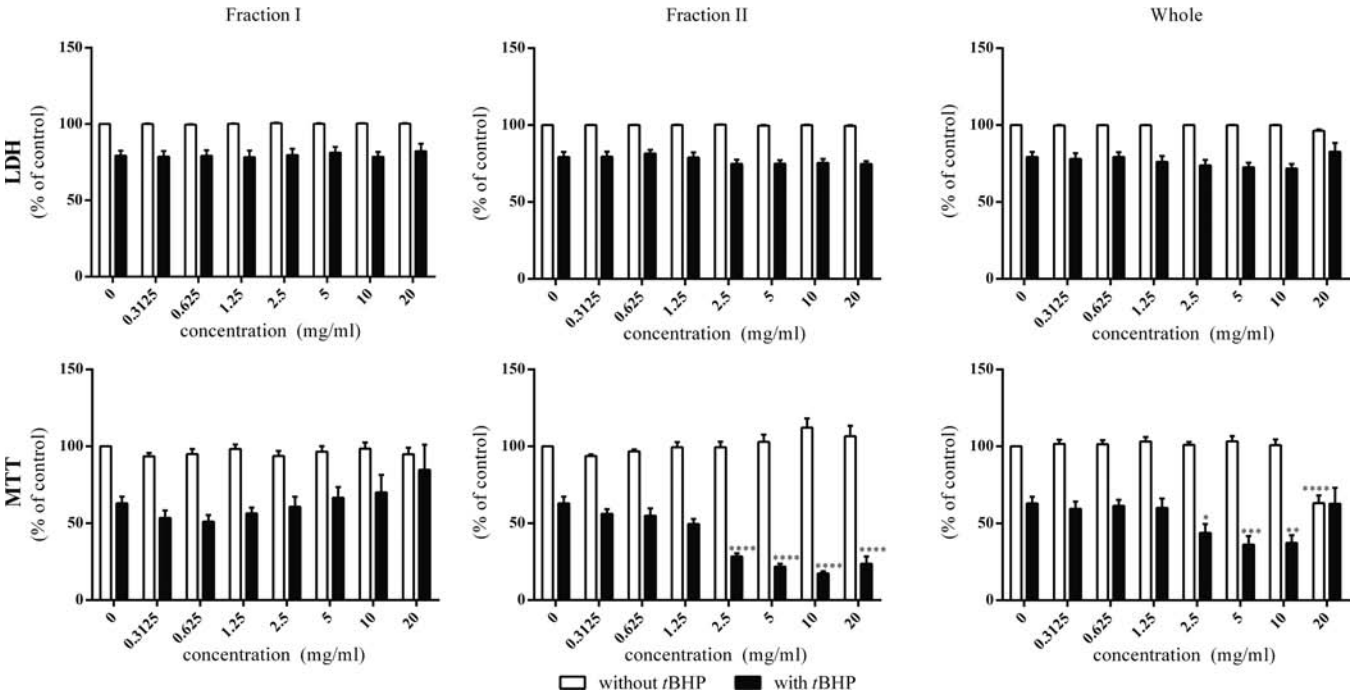

Figure 2. Viability of cells evaluated by LDH and MTT assays. Cells were treated with the extracts for 24 h or pretreated for 24 h with the extracts followed by 6 h treatment with 150 μM of *t*-BHP (without extract coincubation). Results are presented as mean ± standard error of the mean of five independent experiments performed in triplicate. *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, ****$p < 0.0001$ compared to the respective control (with or without *t*-BHP).

75.2% (whole extract) of the identified compounds. The total amount of flavonols was 5.6 times higher in fraction I than in fraction II, the amount in the whole extract approximately corresponding to the sum of flavonols present in both fractions (6.5 ± 2.0 g/kg) (Table 1). Fraction I contained higher relative amounts of compounds **2**, **5**, and **6 + 7** than fraction II, while compound **1** was absent. No statistical differences were found for the relative amounts of compounds **3** and **4** ($p > 0.05$).

Anthocyanins. As referred above, the dark blue color of *E. plantagineum* bee pollen was attributed to its anthocyanins.[2] Using SPE, a fraction containing almost all the anthocyanins present in the acidified methanolic extract was obtained (fraction II) by elution with methanol after eluting with ethyl acetate to remove some noncolored phenolic compounds.[13] The anthocyanins profile of fraction II can be seen in Figure 1B, being similar to the profile of the whole extract. In order to identify the compounds an acidic hydrolysis was performed and the obtained aglycones were identified by comparison with anthocyanidins standards. With the exceptions of delphinidin-3-*O*-glucoside and malvidin-3-*O*-glucoside, whose identity was confirmed with authentic standards, the complete identification of others heterosides present in the extracts was achieved taking into account what was described for this species[2] and further confirmed by our previous works with other matrices:[13] on using the same experimental conditions we obtained identical chromatograms in what concerns to order of elution and the

same UV spectra. Petunidin-3-*O*-rutinoside (compound **11**) was the major compound in fraction II and in the whole extract, this being the only anthocyanin found in fraction I (Table 1). This compound was quantified in the whole extract in higher quantity than its sum in fractions I and II. The total amount of identified anthocyanins corresponded to 0.313 mg/kg in fraction I, 32.6 mg/kg in fraction II, and 38.3 mg/kg in the whole extract, compound **11** representing 100.0%, 74.7%, and 77.3% of the total identified anthocyanins, respectively.

Cellular Viability. Before evaluating the antioxidant potential of the characterized extracts of *E. plantagineum* bee pollen its effects on the viability of Caco-2 cells under quiescent conditions were evaluated by LDH leakage and MTT reduction assays (Figure 2). No significant toxicity was observed in the concentration range from 0.31 to 20.0 mg/mL for fractions I and II. However, at the higher concentration tested, the whole extract caused a significant decrease in cellular viability, as assessed by the MTT assay ($p < 0.0001$, $n = 5$). This loss of cellular viability cannot be attributed to one class of phenolic compounds since neither fraction I (nearly free of anthocyanins) nor fraction II (containing 15% of total flavonols and anthocyanins) caused a significant loss in cell viability at this concentration. Rather the combined effects of anthocyanins with high amounts of flavonols may be responsible for the observed toxicity. Flavonoids can act as antioxidants in their reduced form, but when oxidized (to phenoxyl radicals or quinone/quinone methide intermediates), they can have pro-oxidant activities.[25] A pro-oxidant activity has been described for both classes of flavonoids present in *E. plantagineum* bee pollen. The flavonol compounds with a phenolic B ring like the kaempferol derivatives found in the extracts may act as pro-oxidants after oxidation by peroxidases/H_2O_2 to phenoxyl radicals, accompanied by GSH co-oxidation and oxygen activation, resulting in superoxide radical and H_2O_2 formation.[26] Also, a pro-oxidant effect of anthocyanidins in HL-60 cells was attributed to intracellular hydrogen peroxide production, triggering an apoptotic death program through oxidative stress.[27] This may explain why only in the MTT assay a significant loss of viability was observed.

As previously mentioned, oxidative stress can be induced in cells by *t*-BHP, which is metabolized by cytochrome P450, leading to the formation of toxic peroxyl and alkoxyl radicals that initiate lipid peroxidation, affect cell integrity, and form covalent bonds with cellular molecules, resulting in cell death.[9,28] The exposition of Caco-2 cells to 150 μM *t*-BHP for 6 h lead to a reduction of viability to 79.3 ± 3.2% of control in LDH leakage assay ($p < 0.0001$, $n = 5$) and 63.0 ± 0.3% in the MTT assay ($p < 0.001$; $n = 5$). The higher sensitivity of MTT in detecting *t*-BHP toxicity can be explained by the fact that its biotransformation by cytochrome P450 and GPx occurs mainly in the mitochondria.[10,12,27] The pretreatment of Caco-2 cells with the extracts did not prevent nor aggravate the toxicity of *t*-BHP as measured by the LDH leakage assay (Figure 2). However, the extracts containing anthocyanins (fraction II and the whole extract) significantly aggravated *t*-BHP toxicity as measured by the MTT assay, fraction II being more deleterious (Figure 2). When the cells were pretreated with this fraction a significant increase of cell death (compared to the control with *t*-BHP) was observed for extract concentrations higher than 1.25 mg/mL ($p < 0.0001$, $n = 5$), while with the whole extract the differences in cellular viability were only seen between 2.5 and 10 mg/mL ($p < 0.001$ or higher, $n = 5$). The additional cellular death, observed only in the MTT assay, may be a consequence of the depletion of cellular defenses of cells pre-exposed to anthocyanins, due to their ability to induce the production of reactive species.[27]

On the other hand, fraction I showed a tendency to protect Caco-2 cells from *t*-BHP-induced toxicity, directly dependent on its concentration, although the differences of cellular viability were not statistically significant (Figure 2). In cells pretreated with faction I at a concentration of 20 mg/mL the cellular viability measured by the MTT assay was increased to 84.7 ± 16.3% of control. Also, the pre-exposition to the whole extract at 20.0 mg/mL did not increase cellular death assessed by the MTT assay ($p > 0.05$, $n = 5$), which was nearly the same as in the cells exposed to *t*-BHP only, although at this concentration the whole extract induced cellular death by itself (Figure 2). It can be assumed that in insulted cells, the pre-exposition to flavonols may stimulate antioxidant defenses, which help to fight the subsequent oxidative stress induced by *t*-BHP. Probably, the pro-oxidant effects of anthocyanins do not prepare the cells for a subsequent insult, resulting in increased toxicity. As observed in the assay with the whole extract at 20 mg/mL, this toxicity can be counteracted by the defenses induced by flavonols, although they contribute to the overall oxidative stress observed in cells exposed to the extract.

The effects of *E. plantagineum* bee pollen in cellular viability greatly depend upon the cell line. In fact, a hydromethanolic extract of this material caused loss of macrophages viability at concentrations higher than 30 mg/mL,[4] but basophils showed decreased viability at 8 mg/mL.[7] Since macrophages are known to produce reactive species[29] and the gastrointestinal tract is constantly exposed to reactive oxygen, chlorine, and nitrogen species,[6] the sensitivity of the different cells lines can be explained by the oxidative stress induced by extract compounds and cellular ability to fight it.

Reactive Species. The levels of reactive species were measured by the DCFA-DA assay. The exposure of Caco-2 cells to 150 μM *t*-BHP lead to a significant increase of reactive species to 126.5 ± 1.4% of control after 30 min ($p < 0.0001$, $n = 5$), reaching a maximum of 133.7 ± 1.8% after 150 min and decreasing to 130.1 ± 2.9% after 240 min. Fraction I significantly decreased the levels of reactive species in a concentration- and time-dependent manner, this ability being reduced over time (Figure 3). The lower concentrations of fraction I and of the other extracts were more effective in reducing reactive species (Figure 3). For instance, pre-exposure to 1.25 mg/mL of fraction I reduced the level of reactive species induced by *t*-BHP to 111.6 ± 3.6% after 30 min ($p < 0.01$), but after 240 min the level of reactive species was 116.6 ± 4.2% ($p < 0.05$). On the other hand, the levels of reactive species were 122.4 ± 2.0% ($p > 0.05$) after 30 min and 137.7 ± 5.4% ($p > 0.05$) after 240 min, when the cells were pre-exposed to the extract at 20 mg/mL.

In cells pre-exposed to fraction II a more pronounced effect on the levels of reactive species induced by *t*-BHP was observed (Figure 3). All concentrations, excepting 20 mg/mL, lead to a significant decrease in the levels of reactive species during the 240 min evaluation ($p < 0.01$ or higher). It should be noted that the levels of reactive species were reduced to the levels attained in cells not exposed to *t*-BHP when the cells were pre-exposed to 1.25 mg/mL of fraction II (100.6 ± 4.5% after 30 min and 99.1 ± 3.8 after 240 min exposition to *t*-BHP). Although no statistical differences were seen for the concentration of 20 mg/mL, the levels of reactive species were lower than in cells not

J. Agric. Food Chem. 2015, 63, 2083−2091

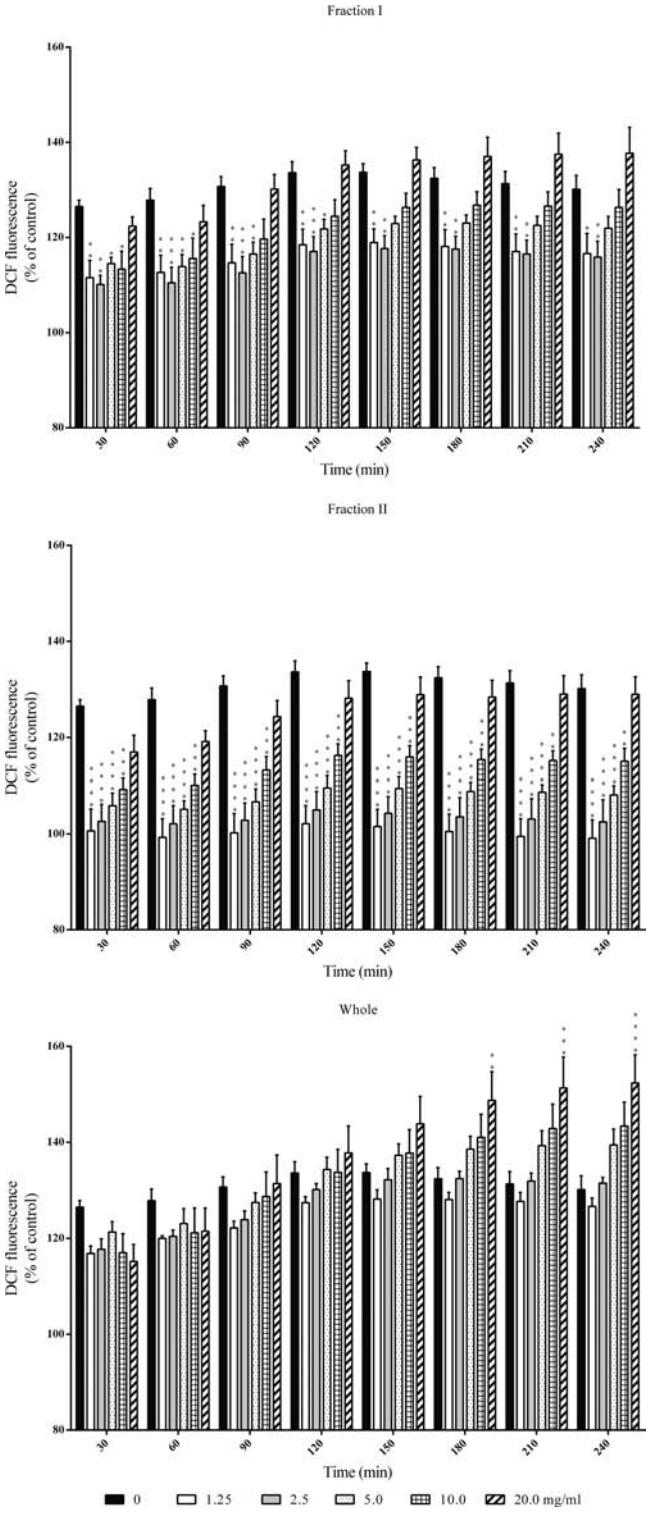

Figure 3. Time variation of reactive species in cells exposed to 150 μM *t*-BHP after pretreatment with the extracts for 24 h. Results are presented as mean ± standard error of the mean of five independent experiments. *p < 0.05, **p < 0.01, ***p < 0.001, ****p < 0.0001 compared to the control (with *t*-BHP).

pretreated with extract (116.9 ± 3.5 mg/mL after 30 min and 129.0 ± 3.7 mg/mL after 240 min).

Surprisingly, the whole extract, containing the compounds of both fractions, not only was unable to reduce the levels of reactive species induced by *t*-BHP but also further aggravated the oxidative stress after 180 min in cells pre-exposed to 20 mg/mL whole extract (Figure 3). At this concentration, the levels of reactive species reached 152.4 ± 5.9% after 240 min exposition to *t*-BHP (p < 0.0001). However, at the beginning of the measurements they were 115.2 ± 3.6% (p > 0.05), and for lower concentrations no statistical differences were seen (116.8 ± 1.5% after 30 min and 126.7 ± 1.7% after 240 min in cells pre-exposed to 1.25 mg/mL of whole extract). The whole extract was the one with higher variations in the levels of reactive species measured over time, this effect being detected earlier with higher concentrations. It showed a tendency to increase the levels of reactive species over time, with statistical differences being noticed, from the concentration of 2.5 mg/mL, while with the other extracts a significant increase was only seen at 20 mg/mL for fraction II and from 10 mg/mL for fraction I.

Although the levels of reactive species were measured without taking into account the viability of cells, a significant decrease in this parameter measured by the MTT assay was seen after 6 h exposure to *t*-BHP in cells pre-exposed to concentrations from 2.5 mg/mL of fraction II and from 2.5 to 10 mg/mL of the whole extract (Figure 2). Thus, the results may reflect the levels of reactive species in viable and inviable cells.

Fraction II, which showed the highest ability to aggravate the toxicity induced by *t*-BHP, was the one that reduced the levels of reactive species, measured with DCFH-DA, more pronouncedly (Figures 2 and 3). It is possible that reactive species produced during the pre-exposition to anthocyanins and other compounds present in fraction II have inactivated cytochrome P450, diminishing in this way the biotransformation of *t*-BHP and consequently the levels of reactive species. The inhibition of several cytochrome P450 isoforms activity by anthocyanins has already been described.[30,31] For instance, petunidin inhibited cytochrome P450 3A4 activity with an IC_{50} of 23 μM.[29] Flavonols (present in both fractions as well as in the whole extract) may also contribute to the inhibitory activity of these enzymes.[32] In cells pre-exposed to higher concentrations of fraction II cellular viability was adversely affected (as seen by the MTT assay) and the levels of reactive species induced by *t*-BHP were higher than in cells exposed to lower extract concentrations (Figures 2 and 3). It is possible that when cells with lower cytochrome P450 activity were exposed to *t*-BHP new radical species were generated by nonenzymatic reaction of *t*-BHP with iron, as demonstrated by Castilho and collaborators in an experiment using the iron chelator *o*-phenantroline with diminished toxicity of *t*-BHP.[33] This fact may also explain the increased toxicity observed with the whole extract, which can be due to the combined effects of anthocyanins and high amounts of flavonols in cytochrome P450 inhibition.

In addition to cytochrome P450 inhibition, the antioxidant ability of fractions I and II seen in this assay can be attributed to direct scavenging effect or metal chelating properties of the flavonoids absorbed by the cells previously to *t*-BHP exposure.[34,35]

Glutathione. The involvement of GSH in *t*-BHP detoxification is well known.[36] *t*-BHP acts as a substrate for cytosolic glutathione peroxidases, causing the oxidation of GSH to glutathione disulfide (GSSG). The activity of GR operating at the expense of NADPH and the release of GSSG into the extracellular medium maintains a steady state in intracellular levels of GSH.[37] In this work, the level of glutathione (reduced + oxidized; GSHt) was 22.88 ± 1.72 nmol/mg protein in

DOI: 10.1021/jf505568h
J. Agric. Food Chem. 2015, 63, 2083−2091

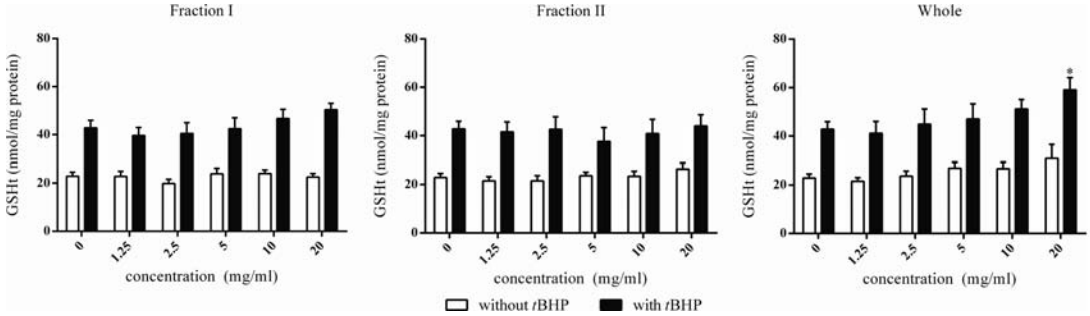

Figure 4. Glutathione levels in cells treated with the extracts for 24 h or pretreated for 24 h with the extracts followed by 6 h treatment with 150 μM of *t*-BHP (without extract coincubation). Results are presented as mean ± standard error of the mean of five independent experiments. *$p < 0.05$, compared to the respective control.

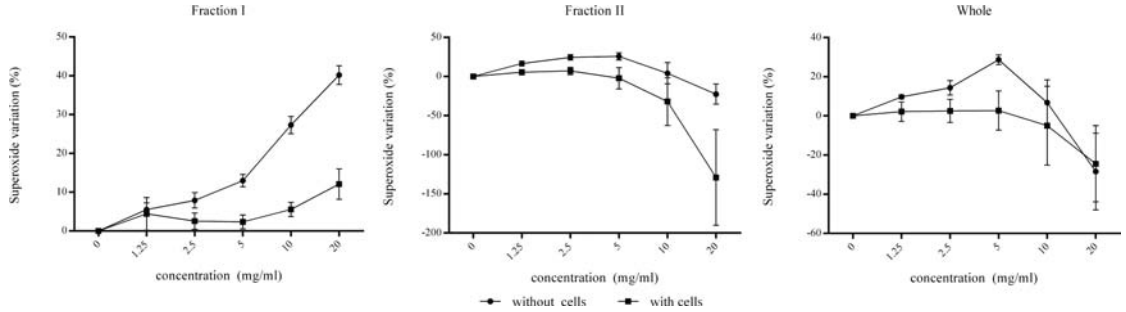

Figure 5. Effect of the extracts in superoxide levels. Superoxide was generated by the PMS/NADH system and monitored by the reduction of NBT in the presence of the extracts dissolved in culture medium and previously incubated for 24 h in a CO_2 incubator at 37 °C either with or without cells. Results are presented as mean ± standard error of the mean of four (without cells) or five (with cells) independent experiments.

quiescent cells and significantly increased to 42.84 ± 3.12 nmol/mg protein after 6 h exposure to 150 μM *t*-BHP ($p < 0.01$, $n = 5$). A further increase of GSHt levels was observed in cells previously exposed to 20 mg/mL of the whole extract ($p < 0.05$, $n = 5$) (Figure 4). It has been reported that the exposure of isolated hepatocytes to *t*-BHP leads to a rapid decrease of intracellular GSH levels.[9,38] However, similarly to the results found in this work, in Caco-2 cells an increase in GSH levels exposed to *t*-BHP has been observed.[39] The results may suggest an attempt of the cells to overcome the induced oxidative stress by increasing GSH, the main antioxidant involved in *t*-BHP detoxification.[38]

The increase of GSHt at the higher concentration of the whole extract (and less significantly at the higher concentration of fraction II and from 5 mg/mL of fraction I) may justify an inversion in the tendency of the extracts to aggravate the deleterious effects of *t*-BHP, although not accompanied by a significant reduction of the levels of reactive species seen with lower extract concentrations (Figures 2−4). The balance between antioxidant and pro-oxidant effects of the compounds present in the extracts may justify their dual behavior. It should be noted that the effects of flavonoids are not limited to antioxidant or pro-oxidant mechanisms, since these compounds can interfere with many cellular molecules and processes.[24,25]

In the assay conditions it was not possible to determine the intracellular levels of GSSG (below 0.38 nmol/mg protein). The low levels of GSSG (less than 1% of GSHt) can be explained by both its reduction to GSH by GR and its efflux from the cell.[37]

Antioxidant Enzymes. Since *t*-BHP detoxification involves its reduction by glutathione peroxidase (GPx) with concomitant oxidation of GSH to GSSG,[11] an attempt was made to quantify GPx and GR, the later being implicated in the recycling of GSSG back to GSH. In the assay conditions, the activity of GPx was below the detection limit of the method (<0.02 U/mg protein). GR activity in cells exposed to the extracts for 24 h was not statistically different from control (0.027 ± 0.001 U/mg protein) at the concentrations tested ($p > 0.05$; $n = 5$).

Mitochondrial GST may prevent lipid peroxidation in mitochondria by nonselenium glutathione-dependent peroxidase activity.[40] Because *t*-BHP is a known substrate for GST, the activity of this enzyme was determined, being of 0.101 ± 0.006 U/mg protein in control. GST activity in cells exposed to the extracts was not statistically different from the control ($p > 0.05$; $n = 5$). However, the noncolored phenolic extract showed a tendency to decrease GST activity, reaching 0.089 ± 0.006 U/mg protein at a concentration of 20 mg/mL fraction I.

Although *t*-BHP does not react with catalase,[11] the activity of this enzyme and of SOD was evaluated, due to their importance in the detoxification of H_2O_2 and superoxide that can be produced by a pro-oxidant effect of flavonoids, including flavonols and anthocyanins[26,27] and in the maintenance of the redox cellular status, in general. Catalase activity in control was 7.444 ± 1.012 U/mg protein. When the cells were exposed to *E. plantagineum* bee pollen extracts the enzyme activity varied between 5.998 ± 0.647 and 6.839 ± 0.829 U/mg protein. No statistical differences were seen for catalase activity ($p > 0.05$; $n = 5$).

The extracellular SOD is a copper−zinc isoform of SOD that contains a signal peptide that directs this isoform exclusively to extracellular spaces.[41] The activity of this enzyme in control was 0.100 ± 0.009 U/mg protein. Because the extracts exert a direct activity on superoxide, it was not possible to distinguish between the effects on SOD activity and the superoxide scavenging activity of the extracts. For this reason an assay was

DOI: 10.1021/jf505568h
J. Agric. Food Chem. 2015, 63, 2083−2091

performed using the extracts incubated in culture medium in the same conditions used to evaluate SOD activity but without cells. The results obtained for the variation of superoxide with or without the cells are presented in Figure 5. Fraction I demonstrated ability to decrease superoxide levels, but this ability was higher in the cell-free assay, indicating scavenging activity rather than induction of extracellular SOD. Significant differences from the control were observed from 2.5 mg/mL ($p < 0.01$; $n = 4$) in the cell-free assay and from 10 mg/mL ($p < 0.05$, $n = 5$) in the assay with cells. Comparing the two assays (with and without cells), they were significantly different from 5.0 mg/mL ($p < 0.0001$). This result can be explained by the inhibition of extracellular SOD, but it is possible that some compounds were absorbed or modified by the cells and were not available for superoxide scavenging. Considering fraction II and the whole extract, they exerted a slight scavenging activity (not statistically significant) for concentrations up to 5 mg/mL in the cell-free assay. This tendency was not observed in the assay with cells. At a concentration of 20 mg/mL a pro-oxidant effect was observed in both assays, although it was statistically significant only with fraction II in the assay with cells ($p < 0.001$).

The ability of fraction I to scavenge superoxide radicals may contribute to the tendency of this extract to protect Caco-2 cells from *t*-BHP-induced toxicity (Figures 2 and 5).

In conclusion, *E. plantagineum* bee pollen contains flavonoids that can interfere with many cellular processes. In Caco-2, a cell line that mimics the enterocytes of the small intestine, the oxidative stress induced by *t*-BHP was not efficiently counteracted by *E. plantagineum* bee pollen phenolic extracts, although the removal of anthocyanins from the extract not only ceased the pro-oxidant effects but also imparted a small protective effect. The cellular fate of *t*-BHP may explain the dual effect of the extracts: this short-chain analogue of lipid hydroperoxide is detoxified by GPx, but it can be bioactivated by cytochrome P450. Since a small increase in the levels of total glutathione was induced by the flavonols-rich extracts and flavonoids, in particular anthocyanins, are known inhibitors of cytochrome P450 enzymes, an antioxidant effect was expected. However, as in the presence of iron *t*-BHP can generate reactive species, which can be more deleterious than the ones generated by its biotransformation, the antioxidant potential of the compounds may be abrogated. The pro-oxidant effects seen with the extracts containing anthocyanins may also be explained by their ease in being themselves converted into radical species, although only the whole extract at the higher concentration tested significantly reduced the cellular viability.

Taking into account the obtained results, care should be taken in the consumption of high doses of *E. plantagineum* bee pollen. However, extracts with low recovery of anthocyanins prepared from this matrix can be protective in situations of oxidative stress.

[a]Note: $n = 3$ on day 10 for the white snakeroot group because one goat was necropsied on day 9. Means that are significantly different ($p < 0.05$) from others within the same group are indicated with superscript letters. Means that are significantly different from other groups on the same day are indicated with an asterisk (*).

which Angora goats were exposed to white snakeroot and 53 of the goats died in Central Texas.[10] Dosing studies with the plant collected from that site in Texas resulted in acute death from hepatic necrosis with no myotoxic lesions and established an LD_{50} of 5 mg/kg of fresh white snakeroot.[10] Spanish goats have been shown to be a good model to study the toxicity of the benzofuran-containing plant, rayless goldenrod (*Isocoma pluriflora*),[11,12] which is thought to contain the same toxin as white snakeroot. Recent research in our laboratory has focused on identifying the toxic component of white snakeroot and demonstrating its toxicity in a live animal model.

The purpose of this study was 4-fold: First, to determine if white snakeroot that contained known concentrations of tremetone, **1**, 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, was myotoxic in a goat model; second, to determine if a hexane extract of white snakeroot containing **1**, **2**, and **3**, adsorbed onto alfalfa at the same concentration as the white snakeroot plant material was toxic; third, to determine if the plant residue, following the hexane extraction of white snakeroot, that did not contain **1**, **2**, and **3**, was toxic; and fourth, to determine if the hexane extract recombined with the white snakeroot plant residue was toxic.

MATERIALS AND METHODS

Collection of Plant Material. The aerial parts of white snakeroot plants were collected from two locations near each other in Vermilion County, Illinois. The collection locations and GPS coordinates were: Interstate, 40°06.483′ N/87°40.866′ W, and Salt Fork, 40°05.536′ N/87°49.683′ W. The plants were collected in September while in early to full flower stages of growth. White snakeroot plants were identified by Dr. Stanley L. Welsh curator at the Stanley L. Welsh Herbarium at Brigham Young University, Provo, UT, and Dr. David S. Seigler, Professor, Department of Plant Biology, University of Illinois, Urbana−Champaign, Illinois. The current taxonomic classification for this plant is *Ageratina altissima* (L.) King & H. Rob. var. *altissima* as per the USDA, National Resources Conservation Service, Plant Database. Voucher specimens of white snakeroot, accession nos. 3555 and 3562 for the Salt Fork and the Interstate collections, respectively, were deposited in the Poisonous Plant Research Laboratory Herbarium, Logan, UT.

Preparation of Plant Material and Extracts. The white snakeroot from the Salt Fork and Interstate collections were air-dried at ambient temperature, mixed together in a ratio of approximately 0.40:0.60, and ground to pass through a 2.38 mm screen and mixed using a model 55 Mix-All, (Gehl Company, West Bend, WI).

Ground plant material (30 kg) was extensively extracted in 15 Soxhlet extractions of approximately 2 kg portions with *n*-hexane (50 h). The hexane extract from 8 of the extractions were concentrated to dryness by rotary evaporation, combined, and reconstituted to 4.0 L with dichloromethane and referred to as the hexane extract. The hexane extract was quantitatively adsorbed onto alfalfa (ratio of 1 mL hexane extract per 4 g alfalfa, which is equal to the hexane to plant ratio from which it was extracted) and allowed to dry overnight in a fume hood. The ground plant material extracted with *n*-hexane was recovered from the Soxhlet thimble, transferred to a paper bag, and dried in a fume hood for 24 h at ambient temperature to allow residual hexane to evaporate and is referred to as the extracted plant residue (=plant residue). The hexane extract and plant residue from seven Soxhlet extractions were quantitatively recombined and are referred to as the combined extract and residue (=extract+residue). The ground white snakeroot (=snakeroot), hexane extract, plant residue, and extract+residue, which were dosed to the snakeroot group, hexane extract group, plant residue group, and extract+residue

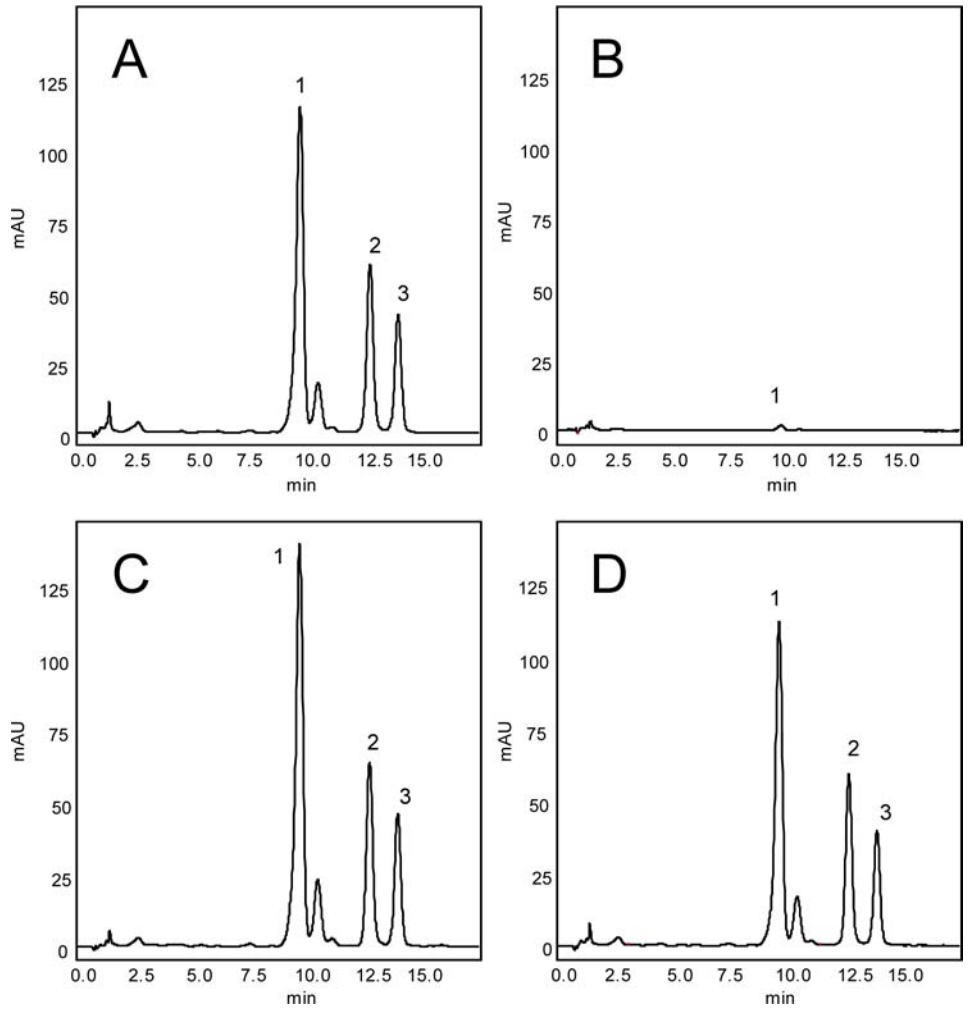

Figure 2. HPLC chromatograms from (A) white snakeroot plant material (white snakeroot); (B) white snakeroot plant material after extraction by hexane, (extracted plant residue); (C) white snakeroot hexane extract adsorbed onto alfalfa (hexane extract); (D) white snakeroot hexane extract adsorbed back onto extracted white snakeroot residue (combine extract and residue). Peak numbers refer to tremetone, **1**, 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, whose chemical structures are shown in Figure 1.

group, respectively, were analyzed for the benzofurans. It was confirmed that the snakeroot, hexane extract, and extract +residue contained the same benzofuran compounds and at nearly equal concentrations. The plant residue contained only trace amounts of the benzofurans in the same dosed mass.

HPLC Analysis. The analysis of tremetone, **1**, 6-acetyl-7-methoxy-2,2-dimethylchromene, 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, in snakeroot, hexane extract, plant residue, and extract+residue treatments was performed by HPLC as described previously.[2,13]

Dosing of Goats. Eighteen yearling Spanish goats in good body condition that weighed 29.1 ± 5.4 kg (mean ± SD) were selected from the same herd at the Poisonous Plant Research Laboratory. The goats were randomly divided into five groups with three or four animals per group (Table 1). The animals were trained to lead and to run for 5 min on a treadmill moving at 12 km/h on a 10% incline for 15 d before the start of the study. The day before the initial dosing, all animals were weighed, bled by jugular venipuncture, and exercised on a treadmill. The snakeroot, plant residue, hexane extract, and extract+residue groups were dosed with 1.67% body weight intraruminally via oral gavage, for 9 d. A negative control group was also dosed ground alfalfa hay via oral gavage at 1.67% of body weight. The dose was split and given twice per day at 9:00 AM and 9:00 PM. Throughout the duration of the study, the goats had access to water and long stem alfalfa hay *ad libitum*. One goat from the snakeroot group developed severe exercise intolerance, reluctance to move, and anorexia. The goat was euthanized on day 9. The rest of the goats were euthanized and necropsied during the morning of day 10.

Histological Analysis. At necropsy, samples of left lateral retroocular, tongue, masseter, superficial pectoral, triceps, intercostals, longissimus dorsi, semitendinosus, diaphragm, biceps femoris, biceps brachii, quadriceps femoris, gluteus medius, psoas major, adductor, and semimembranosus skeletal muscles were collected, attached to wooden tongue depressors, and fixed in 10% neutral buffered formalin. The heart was opened, cleaned with water, closely examined, fixed intact, and sectioned to examine portions of the right atrium, the right papillary muscle, the right ventricular free wall, the septum, the left atrium, the left papillary muscle, and the left ventricular free wall. Other tissues including brain, spinal cord, lung, liver, right and left kidneys, adrenal gland, urinary bladder, thyroid gland, mesenteric lymph node from the small intestine, esophagus, rumen omasum, abomasums, duodenum, pancreas, jejunum ileum, cecum, and colon were collected fixed, and prepared for

DOI: 10.1021/jf505614z
J. Agric. Food Chem. 2015, 63, 2092−2097

examination. Tissues were processed, sectioned, and stained using standard histologic techniques. Special stains of specific skeletal muscle, myocardium, and liver lesions included diastase-positive and diastase-resistant periodic acid-Schiff (PAS), Masson trichrome stain for collagen, and Congo red. Lesions were scored by distribution (percentage of tissue affected) and graded by the severity of lesion, (0 = none, 1 = minimal [loss of striation and hypereosinophilia], 2 = mild [sarcoplasmic clumping with myocyte swelling], 3 = moderate [sarcomere disruption with focal monocytic inflammation and mild nuclear proliferation], 4 = severe [extensive inflammation, regeneration with fibrosis]), by two pathologists who were "blinded" to the treatment groups. All animal work was done under veterinary supervision with the approval and supervision of the Utah State University Institutional Animal Care and Use Committee.

Exercise Tolerance. Goats were run on a treadmill (Horse Gym 2000 GmbH, Großsorheim, Germany) for 5 min to determine exercise tolerance. The treadmill was moving at 12 km/h on a 10% incline. If movement became labored and the goat was unable to keep pace before completion of the 5 min exercise period, as determined by an observer "blinded" to the treatment groups, then the treadmill was stopped and the animal was removed and considered to be exercise intolerant.

Serum Analyses. Serum biochemistries were analyzed as previously described.[12] Significant analytes that are reported herein include the activities of aspartate aminotransferase (AST), alanine aminotransferase (ALT), and creatine kinase (CK).

Statistical Analyses. Serum chemistry variables were analyzed using a mixed linear model approach (Proc Mixed in SAS 9.3). Serum variables were evaluated for normality, and all distributions were non-normal. Thus, a log transformation was performed before analysis; however, all means presented herein are untransformed values. The repeated measures model contained treatments, days and the day x treatment interaction, with animals as a random factor, and animals were nested within treatment groups. The appropriate covariance structure was determined using the lowest value of Akaike's information criteria (AIC) compared across models. Least square means were separated after a significant F test using the PDIFF option in SAS.

Subjective pathologic scores for each group were compared using an analysis of variance. Means that were significantly different were separated using Tukey's analysis ($p < 0.05$, SAS 9.3 Proc GLM).

RESULTS

The combined white snakeroot plant material from the Salt Fork and Interstate collections was analyzed by HPLC and found to contain 2.1 μg/mg, 0.72 μg/mg, 0.96 μg/mg, and 0.53 μg/mg of tremetone, **1**, 6-acetyl-7-methoxy-2,2-dimethylchromene, 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, respectively. These compounds were quantitatively extracted into hexane when the white snakeroot plant material was Soxhlet extracted with hexane, evaporated and resolublized in dichloromethane and quantitatively reabsorbed on the same amount of ground alfalfa or plant residue and dosed as hexane extract and extract+residue, respectively. Dosed extracts were analyzed for benzofuran content after applying the extracts resuspended in dichloromethane to the alfalfa or plant residue and dried overnight. The chromatograms showing the benzofurans in each treatment are shown in Figure 2. The amounts of the hexane extract and the dosed extract+residue material contained tremetone, **1**, and total benzofurans at the same dosages (35.1 and 60 mg/kg body weight, respectively) as the dosed snakeroot. The dosed plant residue contained only trace amounts of tremetone and the other benzofurans.

On day 5, one goat from the snakeroot group developed clinical signs of poisoning and was unable to run on the treadmill for 5 min. The condition of the goat became more severe and it was euthanized on day 9. A second and third goat from the snakeroot group developed the same clinical signs and became exercise intolerant on days 6 and 9. None of the goats from the plant residue, hexane extract, or extract+residue groups exhibited clinical signs of poisoning or became exercise intolerant.

The mean ± SD of serum enzyme activities of AST, ALT, and CK for each of the dosed groups are shown in Table 1. There were significant ($p < 0.05$) treatment by day interactions for AST, ALT, and CK. There were significant increases in the serum activities of AST, ALT, and CK on day 7 in the snakeroot dosed goats. Serum CK activities of the snakeroot dosed goats that were poisoned increased to between 2285 and 17704 U/L within 1 day of becoming exercise intolerant. There were no significant changes in CK, AST, and ALT activities of control, hexane extract, plant residue, and extract+residue dosed groups during the 10 days of the study.

Occasionally, skeletal muscle from goats in the control, hexane extract, plant residue, and extract+residue groups had rare myofiber swelling and edema. These lesions were also seen histologically as focal myocyte degeneration and necrosis (Figure 3A). The degeneration was characterized by myocyte swelling with loss of striation and rarely individual myocyte necrosis with focal inflammation. These lesions were small and rare involving small clusters of myocytes suggesting they were background changes. All but one of the snakeroot dosed goats had severe skeletal muscle myodegeneration and necrosis. This was evident grossly as many of the muscles of both the appendicular and axial skeleton were swollen with pale streaking. Histologically, these lesions were characterized as extensive Zenker's necrosis with loss of striation, swelling, coagulation and clumping of sarcomere proteins, focally extensive inflammation and phagocytosis of myocyte debris and focal regeneration (Figure 3B). The lesions were most severe in many of the large appendicular muscles including the biceps brachii, biceps femoris, semitendinosus, semimembranosus, quadriceps femoris, and gluteus medius. Fewer skeletal muscles of the axial skeleton were also affected with smaller, less severe lesions in the psoas major, longissimus dorsi, and intercostal skeletal muscles.

The livers from all dosed animals, including the control goats, had mild centrilobular hepatocyte swelling with occasional vacuolation. The vacuoles were clear with prominent margins suggestive of lipid accumulation. No additional liver lesions were identified in any of the groups including the snakeroot dosed goats. No significant histologic lesions were identified in the other sampled tissues from goats in either the treated or control groups.

DISCUSSION

White snakeroot is a potent myotoxin in most livestock species. It has caused sporadic cases of poisoning in livestock and humans since the early 1800s. The results from this study demonstrate for the first time that white snakeroot is a potent myotoxin in goats that affects both appendicular and axial

DOI: 10.1021/jf505614z
J. Agric. Food Chem. 2015, 63, 2092−2097

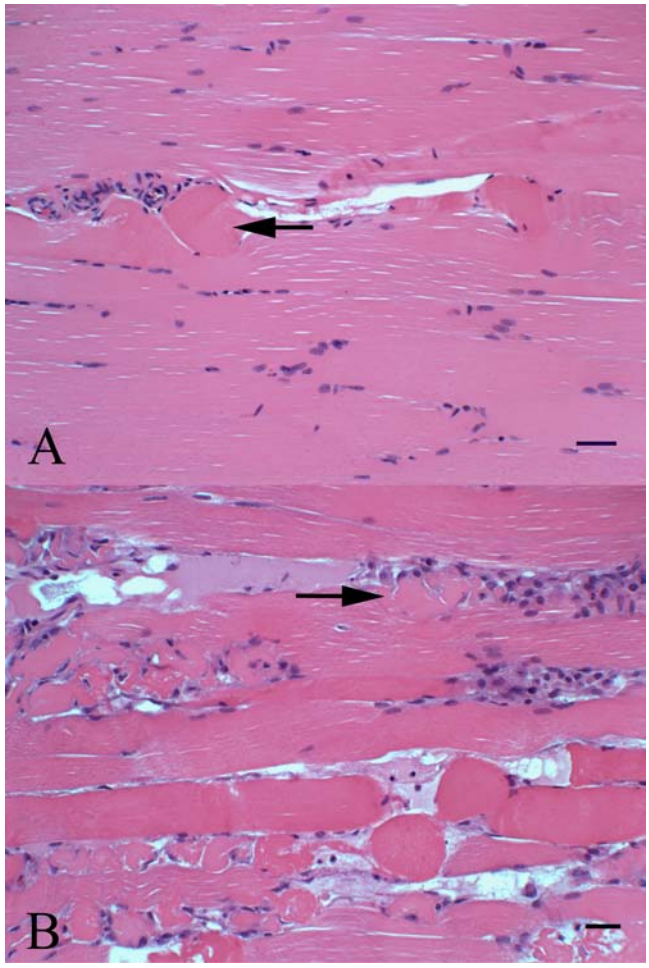

Figure 3. Photomicrograph of the skeletal muscle, quadriceps femoris from a goat from the (A) control group dosed with ground alfalfa; (B) white snakeroot dosed group that was treated with ground snakeroot, at 1.67% body weight for 9 d. Notice the rare myonecrosis and clumping of myocyte proteins (arrow) in part A. Such lesions never affected more than 1% of the myocytes in control animals. Also, notice the extensive myonecrosis, clumping of myocyte proteins (arrow) and focally extensive inflammation in Figure 3B. Such lesions were often severe and in some goats affected more than 60% of the myocytes. H&E, bar = 50 μm.

skeletal muscles in goats. The goats had severe skeletal muscle myodegeneration and necrosis and significant increases in serum activities (AST, ALT, and CK) of enzymes that can be used as indicators of muscle damage. The myotoxic lesions observed in this study are in contrast to the only reports of white snakeroot poisoning of goats in the literature,[10] in which a single fresh dose of white snakeroot from Texas was lethal to Angora goats within 24 to 48 h of dosing and was characterized by extensive para-acinar hepatic necrosis, and increases in serum LDH and SGOT (=AST) activities. The histological hepatic changes we observed appeared related mainly to increased lipid mobilization and metabolism. Similar hepatic changes in the control group suggest that it is not likely a toxic response but more likely associated with altered metabolism relating to the treatment (oral gavage and subsequent physiologic exercise). It may be that the chemical constituents of the white snakeroot from Texas are different from the white snakeroot from Illinois that was used in this study. The differences in the clinical disease produced by the two different populations of white snakeroot should be further investigated.

Previous dosing of goats with rayless goldenrod, which is thought to contain the same toxin as white snakeroot, caused lesions to develop mostly in the large appendicular muscles when orally gavaged at 2 and 3% body weight.[11] The rayless goldenrod dosed in that study contained tremetone, **1**, (0.53 μg/mg), dehydrotremetone, **3**, (1.34 μg/mg), and 3-oxyangeloyl-tremetone (2.39 μg/mg). The white snakeroot dosed in this study contained 2.1 μg/mg, 0.96 μg/mg, and 0.53 μg/mg of tremetone, **1**, 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, respectively. The goats dosed with rayless goldenrod at 3% body weight received a total dose of 60 mg total benzofurans/kg body weight, which was the same dosage of total benzofurans administered to the snakeroot, hexane extract, and extract+residue dosed goats in this study even though they were orally gavaged with plant material at 1.67% body weight. The goats in the snakeroot, hexane extract, and extract+residue dosed groups in this study received nearly 3.3 times more tremetone than the goats dosed with rayless goldenrod at 2% of BW. If tremetone, **1**, is the sole toxin in white snakeroot and rayless goldenrod then the goats dosed with hexane extract and extract+residue should have poisoned similar to the goats dosed dried snakeroot.

Tremetol has been commonly accepted as the toxin in white snakeroot. In fact, as recently as 1985 it was referred to as the toxin in white snakeroot.[14] When tremetone, **1**, was dosed orally or by injection into breast muscle of cockerels for 7 days, no signs of poisoning or distress were observed.[9] Bowen and co-workers[9] concluded that tremetone, **1**, was not the toxin in white snakeroot. Results of cell culture cytotoxicity studies led to the proposal that microsomally activated tremetone, **1**, was responsible for the toxicity of the plant;[8] however, it still has not been demonstrated in any animal model. The hexane extract and the extract+residue groups in this study were gavaged with the same dosages of tremetone, **1**, 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, as the snakeroot group. The hexane extract and extract+residue dosed groups did not develop clinical signs, exercise intolerance, serum enzyme changes, or histological lesions observed in the snakeroot dosed group. These results suggest that tremetone, **1**, and/or 6-hydroxytremetone, **2**, and dehydrotremetone, **3**, are not the singular toxin/toxins in white snakeroot. Consequently, there may be another compound or group of compounds that act either independently or synergistically with tremetone, **1**, or other benzofurans. The lack of toxicity observed in the extract+residue group further suggests that if another agent that acts singularly or synergistically with tremetone, **1**, and the other benzofurans is present in white snakeroot, this agent is modified and inactivated during the extraction-recombination process. However, since white snakeroot and rayless goldenrod both cause the same disease in livestock and both plants contain tremetone, **1**, and dehydrotremetone, **3**, it is possible that tremetone, **1**, (or a structurally related compound) is a marker for the active agent or that there is another compound that acts synergistically with one of the benzofurans.

In conclusion, the results from this study demonstrate for the first time that white snakeroot is a potent myotoxin in goats. The results also suggest that another compound besides tremetone, **1**, may have a significant role in producing trembles in livestock and milk sickness in humans.

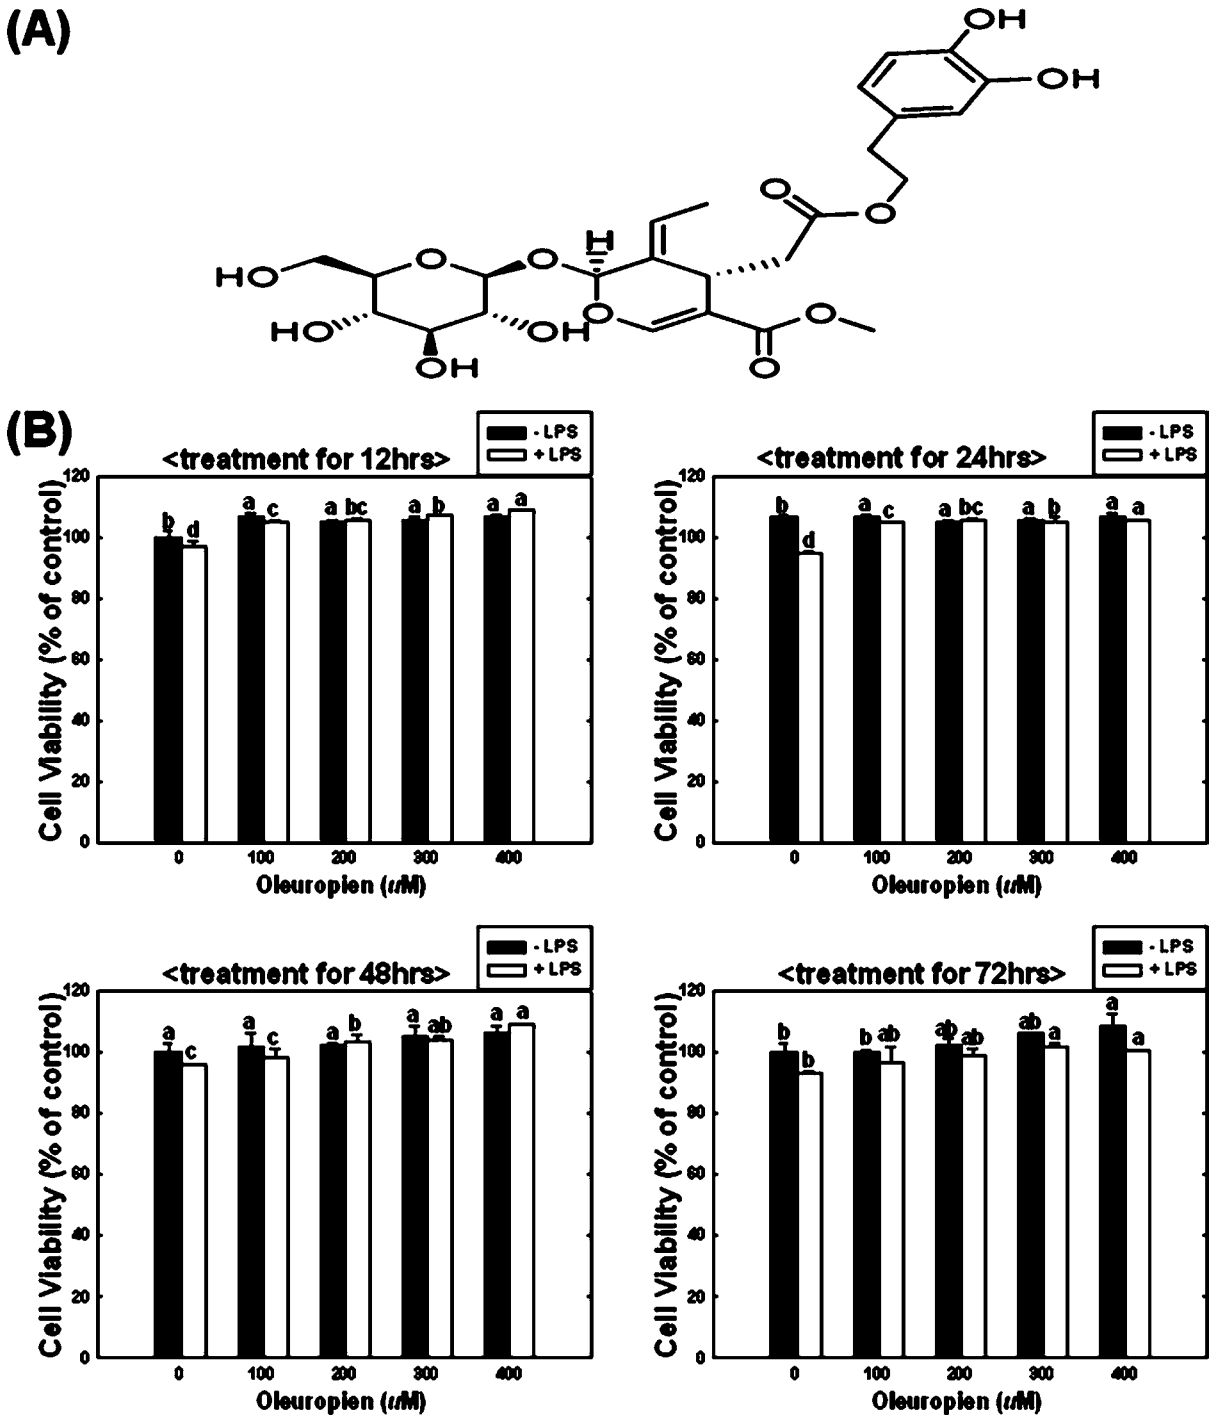

Figure 1. Chemical structure of oleuropein (A) and its effect on cell viability (B). RAW 264.7 cells (1 × 104/well) were treated with oleuropein (100−400 μg/mL) for 12, 24, 48, and 72 h. Cell viability was determined using the XTT assay (B). Data are presented as means with standard deviations of three replicates. Results were analyzed by ANOVA and Duncan's multiple range test ($p < 0.05$).

oleuropein on inflammatory responses and signaling in LPS-induced RAW 264.7 macrophages and a zebrafish model.

MATERIALS AND METHODS

Materials. Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), penicillin-streptomycin (P/S), and phosphate-buffered saline (PBS) were purchased from Gibco (Gaithersburg, MD). iNOS, COX-2, p65, p-IκB-α, IκB-α, p-ERK, ERK, p-p38, p38, p-JNK, JNK, and GAPDH monoclonal antibodies and secondary antibody were obtained from Cell Signaling Technology (Boston, MA). The enzyme immunoassay (EIA) kits for IL-1β and IL-6 were obtained from BioLegend (San Diego, CA). Maxime PT Premix KIT was purchased from iNtRON (Gyeonggi-do, Korea). iNOS, COX-2, IL-1β, IL-6, and GAPDH oligonucleotide primers were obtained from Bioneer (Seoul, Korea). Compound **2**, 3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2*H*-tetrazolium-5-carbox-anilide (XTT), was purchased from WEL GENE (Daegu, Korea). Oleuropein (>98.0%), TRIzol reagent, diaminofluorophore 4-amino-5-methylanino-2,7-difluorofluoroescein diacetate (DAF-FM DA), Griess reagent, and lipopolysaccharide (LPS) (*Escherichia coli, serotype 0111:04*) were obtained from Sigma Chemical Co. (St. Louis, MO).

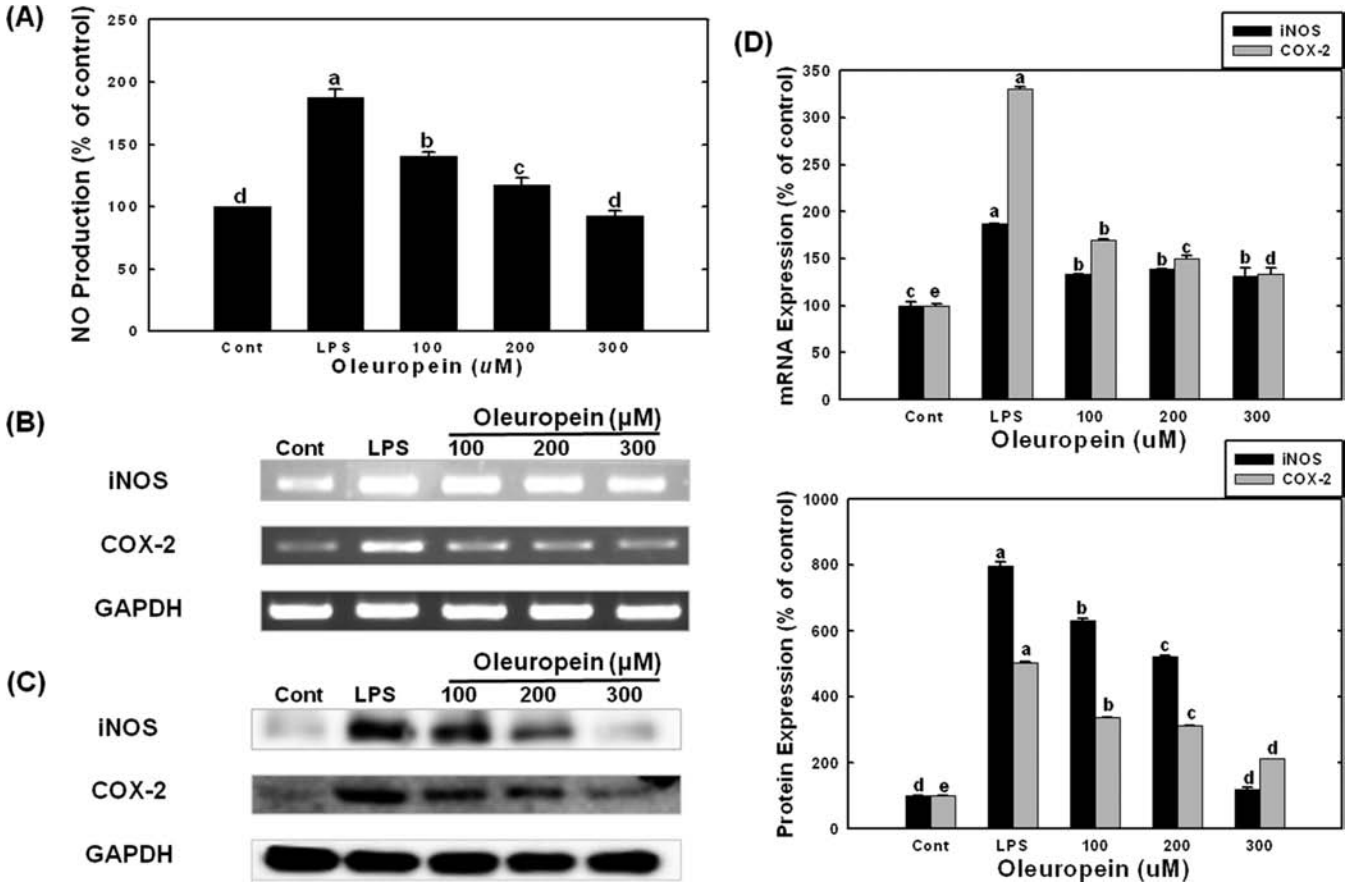

Figure 2. Inhibition by oleuropein of NO production and iNOS and COX-2 expression in LPS-stimulated RAW 264.7 cells. LPS-stimulated RAW 264.7 cells were treated with oleuropein (100, 200, or 300 μM) for 4 h, followed by oleuropein (100, 200, or 300 μM) and/or LPS for 24 h. Nitric oxide concentrations (A) in the culture media were determined by Griess assay. mRNA (B) and protein (C) levels were determined by RT-PCR and Western blot, respectively. The results were quantified using the ImageJ software (D). Data are presented as means with standard deviations of three replicates. Results were analyzed by ANOVA and Duncan's multiple range test ($p < 0.05$).

Cell Culture. RAW 264.7 macrophage cells (American Type Culture Collection, CL-173, and passage 5−7) were cultured in DMEM with 1.5 g/L sodium bicarbonate, 1% P/S, and 10% FBS at 37 °C and in a humidified chamber with a 5% CO_2 atmosphere. Cells were incubated with 100, 200, and 300 μM oleuropein, and then stimulated with LPS at 1 μg/mL for the indicated times.

XTT Assay. RAW 264.7 cells (~1×10^4 per well) were seeded in a 96-well plate and incubated in a CO_2 incubator at 37 °C for 12, 24, 48, and 72 h. Cells were treated with various concentrations (100−400 μg/mL) of oleuropein and incubated for 12, 24, 48, and 72 h, after which 2, 3-bis(2-methoxy-4-nitro-5-sulfophenyl)-2*H*-tetrazolium-5-carbox-anilide (XTT) was added to the culture medium. The cytotoxicity of oleuropein was determined on the basis of the absorbance at 450 and 690 nm measured using an ELISA plate reader.

Nitrite Determination in RAW 264.7. RAW 264.7 cells (~1×10^4 per well) were plated in 96-well plates, treated with various concentrations of oleuropein and then incubated with or without LPS (1 μg/mL) for 24 h. Nitrite levels, which reflect NO levels, in culture media were determined using the Griess reaction. Cell culture medium (100 μL) was mixed with 100 μL of Griess reagent and incubated at room temperature for 15 min. Absorbance was then measured at 540 nm using an ELISA reader. Nitrite levels in samples were determined using a standard sodium nitrite curve.

Enzyme-Linked Immunosorbent Assay (ELISA). RAW 264.7 cells were pretreated with various oleuropein concentrations for 1 h and then further stimulated with LPS (1 μg/mL) for 24 h. The supernatants were collected and stored at −80 °C until cytokine analysis. IL-1β and IL-6 levels in supernatants were determined using ELISA MAX Kits (BioLegend, San Diego, CA), according to the manufacturer's instructions.

RNA Isolation and Reverse Transcription Polymerase Chain Reaction. Total RNA was extracted using TRIzol (Invitrogen, Carlsbad, CA), and 1 μg of the total RNA was used to produce cDNA using an RT-PCR system. Amplification of the target genes was performed using specific oligonucleotide primers by PCR. The primers used were as follows: iNOS, forward (5′-CCCTTCCGAAGTTTCTGGCAGCAG-3′) and reverse (5′-GGCTGTCAGAGCCTCGTGGCTTTG-3′); COX-2, forward (5′-ATGCTCCTGCTTGAGTATGT-3′) and reverse (5′-CACTACATCCTGACCCACTT-3′); IL-6, forward (5′-CCATCTCTCCGTCTCTCACC-3′) and reverse (5′-AGACCGCTGCCTGTCTAAAA-3′); IL-1β, forward (5′-CAGGATGAGGACATGAGCACC-3′) and reverse (5′-CTCTGCACACTCAAACTCCAC-3′); GAPDH, forward (5′-AACTTTGGCATTGTGGAAGG-3′) and reverse (5′-ACACATTGGGGGTAGGAACA-3′). The PCR products were separated on 1.0% agarose gels, stained with ethidium bromide, and photographed. The expression levels were quantified by scanning using a gel documentation and analysis system (ImageJ, SAS).

Western Blot Analysis. RAW 264.7 cells were washed with PBS buffer, lysed with lysis buffer, and then centrifuged to remove cell debris. The total protein content of the supernatant was determined using the Bradford assay. Protein extracts (50 μg) were separated using SDS-PAGE and transferred to polyvinylidene fluoride membranes. The membranes were immunoblotted with primary antibodies specific for iNOS, COX-2, p65, p-IκB-α, IκB-α, p-ERK, ERK, p-p38, p38, p-JNK, JNK, and GAPDH overnight. Secondary antibodies conjugated to horseradish peroxidase (1:1000) were then applied for 1 h. The

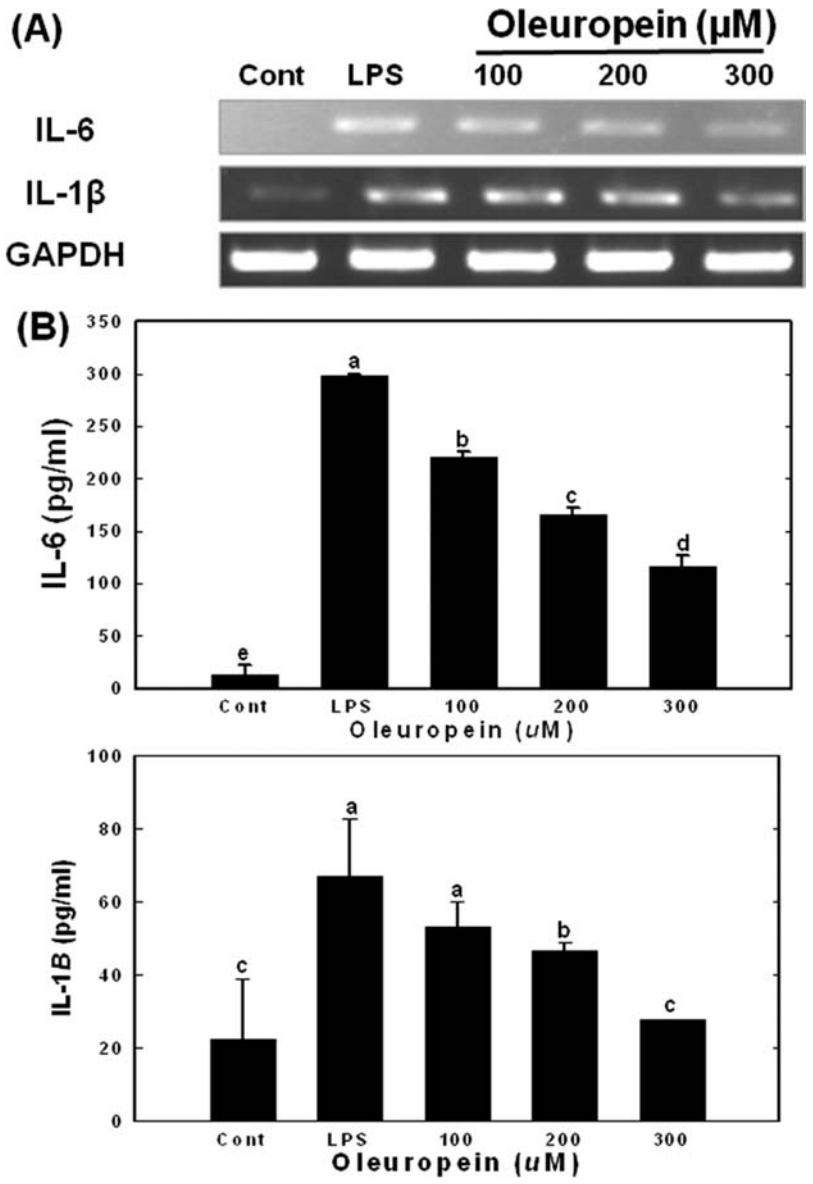

Figure 3. Effect of oleuropein on IL-6 and IL-1β mRNA and protein levels in LPS-stimulated RAW 264.7 cells. Cells were treated with oleuropein (100, 200, or 300 μM), followed by LPS. Cells were then incubated for a further 4 or 24 h. IL-6 and IL-1β mRNA levels were determined by RT-PCR and visualized on a gel. (A) Cytokine levels in culture media were determined using an enzyme immunoassay kit. (B) Data are presented as means with standard deviations of three replicates. Results were analyzed by ANOVA and Duncan's multiple range test ($p < 0.05$).

bands were visualized using enhanced chemiluminescence (ECL) and detected using the LAS imaging software (Fuji, New York, NY).

Nitrite Determination in Zebrafish. Synchronized zebrafish embryos were collected and rearranged using a pipet at 20 embryos/well in six-well plates containing 2 mL of egg water. After 7−9 h postfertilization (hpf), embryos were incubated with or without various concentrations of oleuropein for 1 h. Zebrafish were stimulated by LPS (5 μg/mL) for 24 h at 28.5 °C. The zebrafish embryos were then transferred into fresh embryo medium. NO levels in the inflammatory zebrafish model were measured using a fluorescent probe dye, diaminofluorophore 4-amino-5-methylanino-2,7-difluoro-fluoroescein diacetate (DAF-FM DA). Transformation of DAF-FM DA by NO generates highly fluorescent triazole derivatives. Following stimulation by LPS, the zebrafish larvae were transferred into 96-well plates and treated with DAF-FM DA solution (1 μM) for 1 h in the dark at 28.5 °C. After incubation, the zebrafish larvae were rinsed in fresh zebrafish embryo medium and anesthetized with tricaine methanesulfonate solution before observation. The fluorescence intensity of individual zebrafish larvae was quantified using an ECLIPSE E600 (Nikon, Tokyo, Japan).

Statistical Analysis. All experiments were performed in triplicate. The results were analyzed statistically using an analysis of variance (ANOVA) and Duncan's multiple range test. A p value < 0.05 was considered to indicate statistical significance (SAS Instititue, NC).

RESULTS AND DISCUSSION

Effect of Oleuropein on RAW 264.7 Cell Viability. There is the chemical structure of oleuropein in Figure 1A. Oleuropein was nontoxic to the RAW 264.7 cells at the indicated range of concentrations (Figure 1B) and also has no toxicity at serial time −12, 24, 48, and 72 h. No morphological changes in the cells were observed on the basis of microscopic analysis (data not shown). This result shows that oleuropein has no effect on cell apoptosis. Accordingly, all of the following experiments were performed using oleuropein concentrations of 100, 200, and 300 μM.

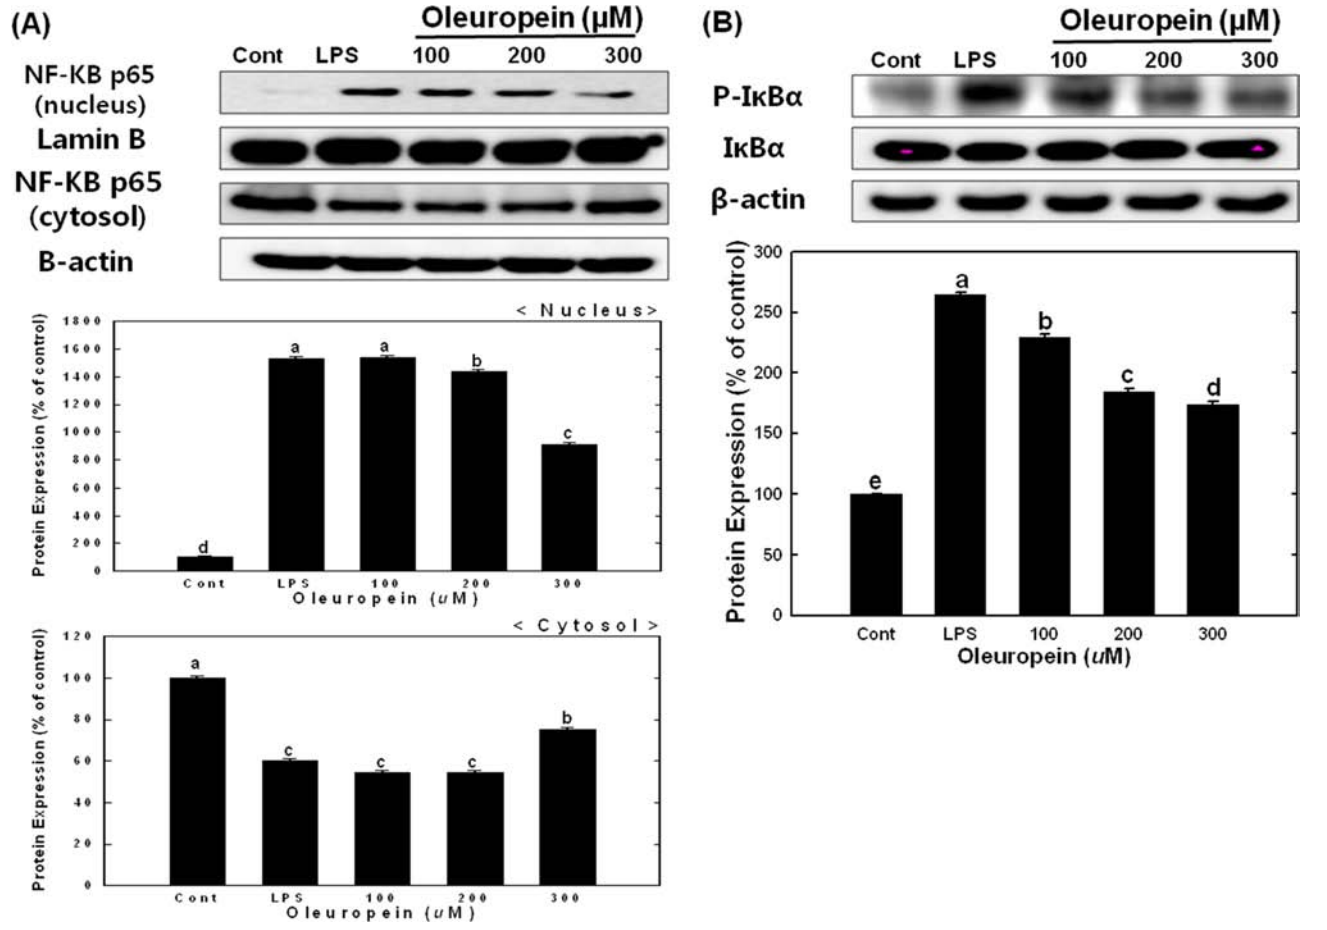

Figure 4. Effect of oleuropein on the phosphorylation of IκB-α and the nuclear translocation of NF-κB. Cells were pretreated with oleuropein (100, 200, or 300 μM) for 1 h and then with LPS (1 μg/mL) for 15 min. Protein levels were determined by Western blotting. NF-κb p65 levels in the cytosol and nucleus were quantified using the ImageJ software and normalized to Lamin B and β-actin, respectively. (A) The results were quantified using the ImageJ software and normalized to IκBα (B). Data are presented as means with standard deviations of three replicates. Results were analyzed by ANOVA and Duncan's multiple range test ($p < 0.05$).

Effect of Oleuropein on LPS-Induced NO Production and Expression of iNOS and COX-2. Overproduction of iNOS-mediated nitric oxide is a representative inflammatory reaction, and may be involved in other negative cellular physiologies such as mutagenesis, DNA damage, and the formation of *N*-nitrosoamine.[24−26] Cyclooxygenase-2 (COX-2), another inflammatory marker, is also associated with production of proinflammatory substances such as prostaglandins, and is upregulated during inflammation. In particular, COX-2-activated pathways, which are responsible for the conversion of arachidonic acid to prostaglandin and other eicosanoids, are of clinical importance as major targets for nonsteroid anti-inflammatory drugs such as aspirin, which is commonly used for inflammation and pain.[27] However, these drugs have several side effects such as gastrointestinal bleeding, swelling of skin tissue, and allergy. We examined the effect of oleuropein on LPS-induced NO production, a mediator of the inflammatory response. As shown in Figure 2A, the NO level in culture medium was reduced by oleuropein treatment in a dose-dependent manner. This decrease in NO production was due to the downregulation of iNOS, a major pro-inflammatory enzyme that produces NO, at the mRNA and protein levels (Figure 2B,C). In addition, COX-2 (also an inflammatory marker) mRNA and protein levels were decreased by oleuropein treatment in a dose-dependent manner (Figure 2B,C). Expression of iNOS and COX-2 in mRNA was reduced by 42% and 43%, respectively, and in protein levels was reduced by 72% and 45%, respectively, by 300 μM oleuropein (Figure 2D). Our data showed that oleuropein, an olive compound, decreased LPS-induced NO production dose-dependently by downregulating iNOS (Figure 2A,B), which is closely associated with the synthesis of NO and COX-2 expression. This result indicated that oleuropein could be a potential anti-inflammatory phytochemical. Recent studies identified various phytochemicals with anti-inflammatory effects. Resveratrol, EGCG, and tyrosol are also known to downregulate COX-2 and iNOS.[28−30]

Effect of Oleuropein on LPS-Induced IL-1β and IL-6 Release and Their mRNA Expressions. Inflammation generally involves the abnormal regulation of cytokines. Cytokines such as IL-6 and IL-1β are pro-inflammatory in vitro and in vivo.[31] Inflammation generally involves the abnormal regulation of cytokines. Cytokines such as IL-6 and IL-1β are pro-inflammatory in vitro and in vivo, and play important roles in the extent of inflammation and recruit other immune cells implicated in the pathogenesis of diverse inflammatory conditions, such as rheumatoid arthritis and septic shock.[32] We further examined the anti-inflammatory effect of oleuropein by assaying levels of pro-inflammatory cytokines. RT-PCR analysis showed that expression of IL-1β

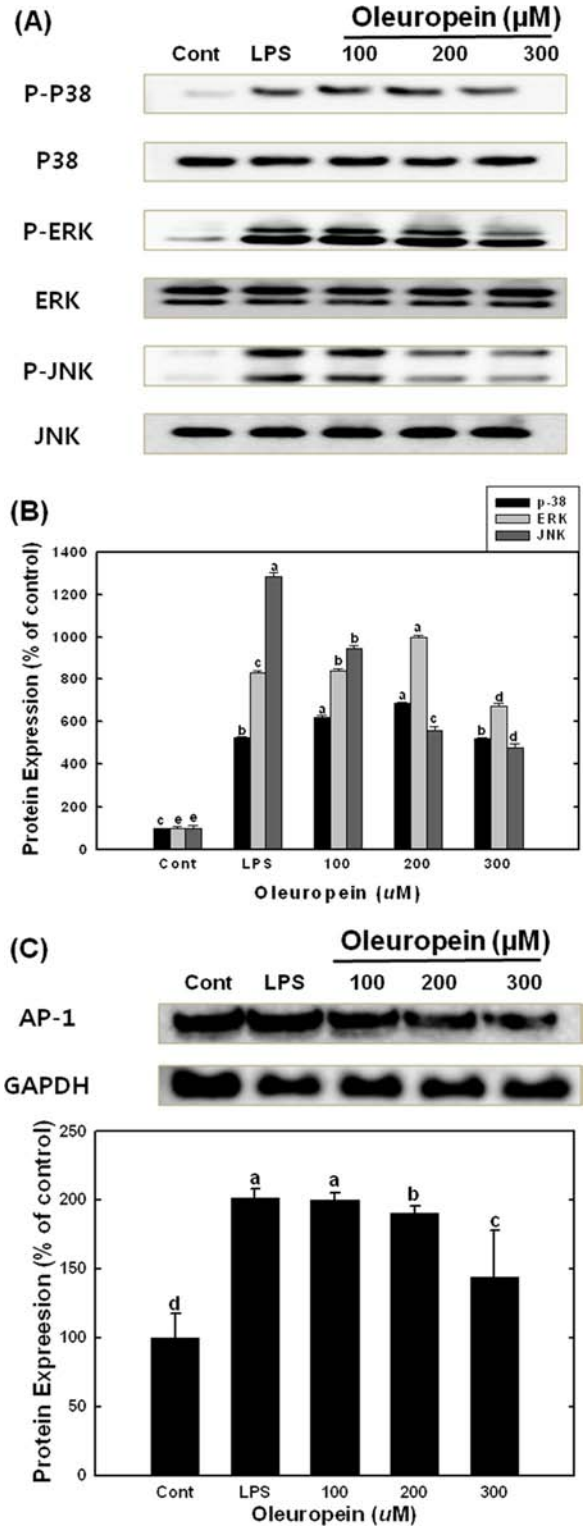

Figure 5. Inhibitory effect of oleuropein on LPS-induced activation of MAP kinases and AP-1 in RAW 264.7 cells. RAW 264.7 were pretreated with oleuropein (100, 200, or 300 μM) for 1 h and then with LPS (1 μg/mL) for 15 min. Total proteins (50 μg) were subjected to Western blotting (A and C). The protein levels were quantified using the ImageJ software, and those of the phosphorylated forms were normalized to total protein levels (B). The data of AP-1 were quantified using the ImageJ software and normalized to GAPDH (D). Data are presented as means with standard deviations of three replicates. Results were analyzed by ANOVA and Duncan's multiple range test ($p < 0.05$).

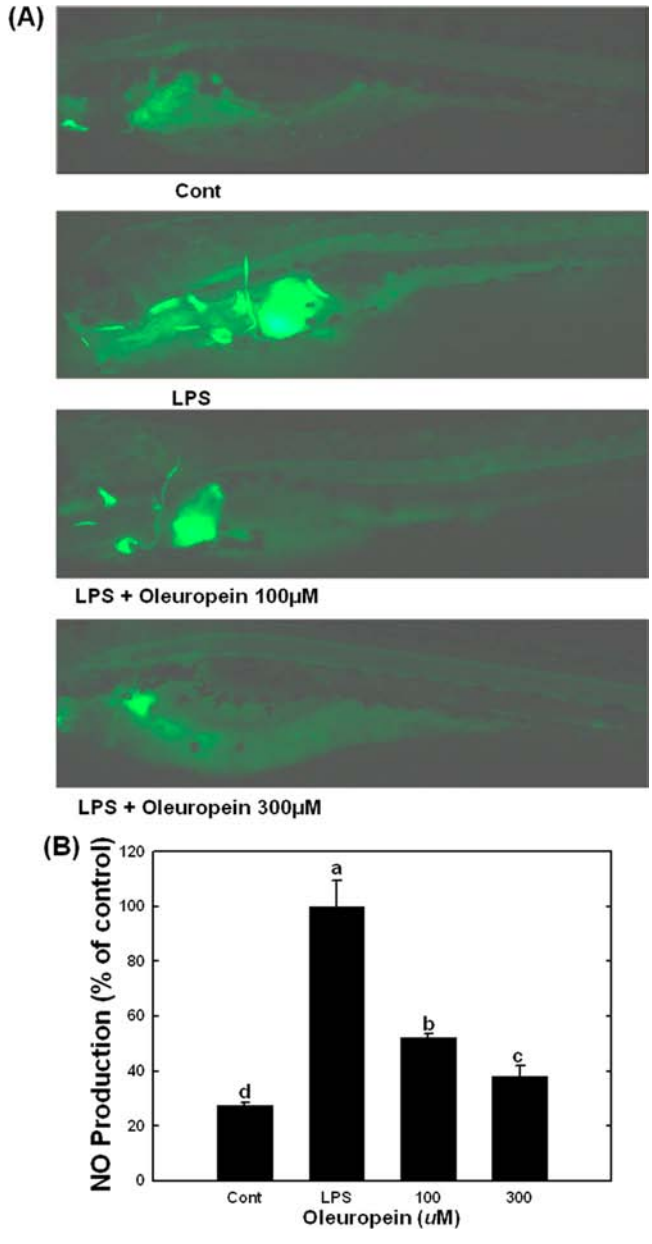

Figure 6. Effect of oleuropein on LPS-induced NO production in zebrafish embryo. Zebrafish embryos were pretreated with oleuropein for 1 h and then exposed to LPS (5 μg/mL) for 24 h (A). The NO level was measured after staining with DAF-FM-DA (A). The results were quantified using the ImageJ software. (B) Data are presented as means with standard deviations of three replicates. Results were analyzed by ANOVA and Duncan's multiple range test ($p < 0.05$).

and IL-6 (inflammatory cytokines) was reduced by oleuropein treatment (Figure 3A). Levels of these cytokines in culture medium were decreased by oleuropein treatment in a dose-dependent manner. IL-6 and IL-1β levels were decreased, respectively, compared with the LPS-induced group at 300 μM oleuropein (Figure 3B). In particular, IL-1β in the presence of 300 μM oleuropein was reduced to the level of the control (Figure 3B). Therefore, oleuropein suppressed the LPS-induced release of pro-inflammatory cytokines. Our results showed that LPS induced release of cytokines (Figure 3B) was effectively reduced by oleuropein treatment at the mRNA (Figure 3A). However, we did not explore whether other cytokines, such as TNF-α and IL-10, were also regulated by

DOI: 10.1021/jf505894b
J. Agric. Food Chem. 2015, 63, 2098−2105

oleuropein. Analysis of these cytokines would provide more information on the anti-inflammatory mechanism of oleuropein.

Effect of Oleuropein on LPS-Induced IκB Phosphorylation and NF-κB Translocation. Regulation of inflammatory cytokines and inflammatory responses is transcriptionally governed by NF-κb transcription factors. These transcription factors regulate inflammatory related genes in the nucleus, where they bind to the DNA of pro-inflammatory mediators to induce their transcription.[33,28] In addition, transcriptional activity of NF-κB is dependent on IκBα phosphorylation,[34] by which p65, a subunit of NF-κB, translocates into the nucleus to promote the expression of inflammatory genes including iNOS, COX-2, and cytokines such as IL-6 and IL-1β.[35,36] Our results showed that oleuropein-mediated inhibition of IκBα phosphorylation (Figure 4B) blocks the translocation of p65 from the cytosol to the nucleus (Figure 4A), suggesting that oleuropein exerts its anti-inflammatory effects by suppressing NK-κB, a major component of the TLR pathway. The nuclear NF-κB level increased significantly after LPS treatment compared with the normal control (Figure 4A). Oleuropein (300 μM) inhibited the translocation of p65, a subunit of NF-κB, into the nucleus by 40% compared with the LPS-induced control. However, lower concentrations of oleuropein exerted no significant effects on the translocation of p65 into the nucleus. Cytosolic NF-κB levels decreased with LPS treatment, but increased in the oleuropein-treated group (300 μM). This result was correlated with the nuclear NF-κB pattern, i.e., a reduction in the presence of oleuropein (300 μM) (Figure 4A). Translocation of NF-κB into the nucleus is associated with phosphorylation of IκB-α in the TLR4 pathway, a major inflammation pathway. Accordingly, we examined the phosphorylation of IκB-α, a mediator of NF-κB activation. Oleuropein inhibited IκB-α phosphorylation, suggesting that NF-κB translocation into the nucleus was inhibited by suppression of IκB-α phosphorylation (Figure 4B). Therefore, the inhibitory effect of oleuropein on LPS-induced inflammatory responses was due to the deactivation of NF-κb and IκB-α, major components in the TLR4 pathway.

Effect of Oleuropein on LPS-Induced Activation of Mitogen-Activated Protein (MAP) Kinase. MAP kinases are another signaling pathway that plays a critical role in inflammation through activation of NFκB.[17] This kinase family is composed of several subgroups, such as JNK, ERK, and p38. The activation of these kinase groups mediates various inflammatory responses in vitro and in vivo.[37−39] The inflammatory response can be activated through the MAP kinase pathway. Thus, we determined whether MAP kinase signaling is involved in oleuropein-mediated inhibition of LPS-induced inflammatory responses. MAP kinase plays a critical role in LPS-induced inflammation signaling at the transcriptional level. Since the MAP kinase pathway is phosphorylation-dependent, we examined the phosphorylation status of components of this pathway. Oleuropein significantly decreased LPS activated ERK and JNK by inhibiting their phosphorylation (Figure 5A). Phosphorylation of ERK and JNK induced by LPS was reduced by 20% and 62%, respectively, by 300 μM oleuropein (Figure 5B). However, phosphorylation of P38 induced by LPS, also a component of the MAP kinase pathway, was not decreased in the presence of oleuropein. Our data also showed that oleuropein decreased AP-1, downstream gene related with MAP kinase (Figure 5C). AP-1 is another inflammatory key gene by regulation NO.[18] Our results indicated that inhibition of ERK and JNK rather than p38 contributes to the anti-inflammatory effect of oleuropein in the LPS-induced inflammatory response. This result suggested that the anti-inflammatory effect of oleuropein might be due at least in part to the inhibition of ERK and JNK.

Effect of Oleuropein on LPS-Induced NO Production in Zebrafish Model. We used a zebrafish model to investigate the anti-inflammatory effect of oleuropein in vivo. Nitric oxide (NO) production in zebrafish was determined using a fluorescent probe dye. As shown in Figure 6A, the nitric oxide level in zebrafish was elevated after LPS treatment compared with the positive control. Therefore, LPS increased nitric oxide production in zebrafish, similar to that in RAW 264.7 cells. LPS-induced increases in NO production were significantly suppressed in the presence of oleuropein (Figure 6A). In particular, 300 μM oleuropein inhibited LPS-induced NO production in zebrafish by 62% compared with the LPS control group (Figure 6B). Our data showed that oleuropein effectively reduced LPS-induced NO production in zebrafish. This result was correlated with the in vitro cell culture data, suggesting that oleuropein exerts anti-inflammatory effects. To our knowledge, this is the first report of an anti-inflammatory effect of oleuropein in zebrafish. However, we did not explore the genetic regulation of inflammatory factors at the gene and protein levels. Thus, further studies on the inflammatory responses of zebrafish in the presence of oleuropein are required. Oleuropein is a relatively abundant phenolic compound in olive leaf compared with other components, such as tyrosol and hydroxytyrosol, which have been suggested to possess various biological activities; also, our data showed that oleuropein inhibited inflammatory responses in RAW 264.7 cells and zebrafish by suppressing NF-κB translocation and the MAP kinase pathway. Doses of oleuropein in the range 100−300 uM are very high so we think that concentrations were supraphysiological. Our study also provides information important for the development of anti-inflammatory agents containing oleuropein.

or branched chain. Several pathways for ester biosynthesis have been proposed, but conclusive evidence is lacking for some of the pathways. Precursors of straight-chain (SC) esters have been suggested to be formed from fatty acids by a combination of β-oxidation and lipoxygenase pathways,[11−13] and precursors of branched-chain (BC) esters have been suggested to be formed from the metabolic pathways associated with branched-chain amino acid (BCAA) formation[14−18] and via the recently proposed "citramalic acid pathway".[19] Identification of apple lines in the USDA Geneva *Malus* Germplasm Repository that differ markedly in the composition of their volatile profile should prove useful in the dissection of the various pathways of synthesis for ester precursors. Hypothetically, if the volatile profile data are of adequate quality and detail, statistical associations between classes of alcohols and/or esters should permit the selection of apple lines sufficiently divergent in their volatile profile to enable testing of proposed biochemical pathways.

The objective of this research was to investigate the diversity of volatile esters produced by ripe fruit from each line in the four-copy USDA Geneva *Malus* Core Collection and to use those data to investigate a hypothetical pathway implicated in the formation of odor-active esters. The information will serve to expand the GRIN system database and act as a resource for selection for volatile phenotype in breeding efforts.

MATERIALS AND METHODS

Plant Material. Apple fruit from 172 lines of the four-copy Geneva *Malus* Core Collection and an additional 12 Kazakhstan lines (all *M. sieversii*) were harvested on nine dates between August 24, 2005, and Oct 24, 2005, from the USDA Plant Genetic Resources Unit's *Malus* Germplasm Repository at Cornell University, Geneva, NY, USA. Several lines bore no fruit during the harvest season and so were omitted from the study. The 184 lines consisted of 39 taxa: 20 taxa were primary species (48 accessions), 8 were cultivated species (88 accessions), 9 were secondary species (12 accessions), 1 consisted of unidentified species (2 accessions), and 1 consisted of uncharacterized hybrid species (34 accessions). Harvest times were initially estimated on the basis of the GRIN harvest code, which classified lines relative to the timing for 'Delicious' maturation: (1) extreme early, >60 days before 'Delicious'; (2) very early, 50−60 days before 'Delicious'; (3) early, 30−50 days before 'Delicious'; (4) midearly, 20−30 days before 'Delicious'; (5) mid, 10 days before 'Delicious'; (6) midlate, same time as 'Delicious'; (7) late, 10 days later than 'Delicious'; (8) very late, 20−30 days later than 'Delicious'; (9) extremely late, >30 days later than 'Delicious'.

The harvested apples were packed and secured in a specialized corrugated cardboard box with polyurethane padding containing 7 cm diameter by 5 cm deep cylindrical cavities for individual apples to avoid bruising during shipping. The packed apples were shipped overnight to Michigan State University for evaluation. Samples for each of the 184 lines consisted of 3−50 fruits depending on fruit size and availability on the tree. On each occasion, fruit were held overnight in the laboratory to equilibrate to laboratory temperature (22 ± 1 °C) while covered with ventilated, black, 4 mil (0.1016 mm) thick plastic bags to avoid desiccation and responses to intermittent laboratory light before harvest maturity analysis. In addition to volatile profile, measurements included fresh weight, internal ethylene concentration (IEC), starch index, firmness, background color, and °Brix. Volatile compounds were analyzed after fruits were judged to be ripe according to IEC, starch index, °Brix, background color, and/or perceived intensity of aroma. If the fruit received were not yet ripening, they were re-sent at a later date or held for a short period to enable ripening to commence and re-evaluated.

Ten lines of apple fruit were also obtained from USDA Plant Genetic Resources Unit's *Malus* Germplasm Repository in the second season (2008) of the study based on ester composition determined during the first season. Lines were selected on the basis of their having high or low emission of esters derived from 2-methylbutan-1-ol or 2-methylbutanoate (2MB) relative to SC esters as described below. Handling was essentially the same as for the first year of the study except that the fruits were obtained on two separate dates: prior to the onset of the ethylene autocatalytic burst and after ripening was well advanced. Maturity and volatile analyses performed were the same as for the 184 lines in 2005. Additional analyses included the metabolites citramalic acid and the BCAAs isoleucine, leucine, and valine and the isoleucine precursor, threonine, as described subsequently. Four replicate fruits nearest the IEC median were used for volatile profile measurements, and two replicates (four fruits each) were used for metabolite analyses.

Measurement of IEC. The IEC was determined by withdrawing a 1 mL gas sample from the interior of the apples and subjecting the gas sample to GC (Carle series 400 AGC; Hach Co., Loveland, CO, USA) analysis as previously described.[20] Due to limitations on the interior gas space, the IEC could be accurately determined only on fruit with a mass >5 g. The ethylene detection limit was approximately 0.005 μL L^{-1}. The ethylene concentration was calculated relative to a certified standard (Matheson Gas Products Inc., Montgomeryville, PA, USA) containing 0.979 μL L^{-1} ethylene, 4.85% CO_2, and 1.95% O_2, balanced with N_2.

Measurement of Starch Index and °Brix. The starch index at harvest was determined by cutting fruit in half through the seed cavity along the plane perpendicular to the longitudinal axis. The cut flesh was dipped into an iodine solution containing 10 g of KI and 40 g of I_2 per 4 L of water. Color development was allowed to proceed for at least 1 min. Starch index (1−8) was determined by comparison to the Cornell Starch Chart.[21] °Brix was measured on a drop of juice expressed from the fruit cortex using a hand-held refractometer (Atago N1, Atago Co. Ltd., Tokyo, Japan).

Measurement of Firmness. Firmness was determined only on those lines with a fruit mass >20 g using a drill-stand-mounted Effegi penetrometer (FT-327; McCormick Fruit Tree Inc., Yakima, WA, USA) fitted with an 11 mm diameter probe. The penetrometer was calibrated at 53.4 N (12 lb) using a top-loading balance. Two skin disks (2−3 cm in diameter) and 3−5 mm of underlying cortex tissue were removed from opposite sides of each fruit. The penetrometer probe was pressed into the tissue of the cut surface to a depth of 8−9 mm in a single smooth motion requiring approximately 1 s. Data were recorded as pounds and converted to newtons by multiplying by 4.45 N/lb.

Measurement of Respiration. Respiration was measured as described by Sugimoto et al.,[19] using a 1 L Teflon chamber (Savillex Corp., Minnetonka, MN, USA) and a 20 min holding time at 20 °C. CO_2 concentration was measured on 0.1 mL gas samples withdrawn from a sampling port sealed with a Teflon-lined half-hole septum (Supelco Co., Bellefonte, PA, USA) using an insulin-type 0.5 mL plastic syringe. The gas sample was injected into an infrared gas analyzer (model 225-MK3; Analytical Development Co., Hoddesdon, UK) operated in a flow-through mode with N_2 as the carrier gas and a flow rate of 100 mL min^{-1}. The CO_2 concentration was calculated relative to the certified standard noted previously.

Measurement of Volatiles. For volatile measurement, a GC (HP-6890, Hewlett-Packard Co., Wilmington, DE, USA) was used in conjunction with a time-of-flight mass spectrometer (TOFMS) (Pegasus III, LECO Corp., St. Joseph, MI, USA). Fruit were placed in a 1-L Teflon container (Savillex Corp., Minnetonka, MN, USA) fitted with a gas-sampling port. The number of apples held in the container varied from 1 to 20 depending on the fruit size, and the analysis was performed on a minimum of 10 g of total fruit mass. Sampling ports were sealed with a Teflon-lined half-hole septum (Supelco Co., Bellefonte, PA, USA), and apples were incubated at 22 °C for 20 min. Headspace volatiles were sampled using a 1 cm long, solid-phase microextraction (SPME) fiber (65 μm PDMS-DVB, Supelco Co.) and a 3 min sorption period.[22] After sampling, the SPME fiber was immediately transferred to the GC for desorption and separation of volatiles. The injection port was operated in splitless mode and held isothermally at 230 °C; the desorption time was 2 min.

DOI: 10.1021/jf505523m
J. Agric. Food Chem. 2015, 63, 2106−2116

Desorbed volatiles were trapped on-column using a liquid nitrogen cryofocusing trap. Conditions of GC separation and TOFMS analysis were as previously described.[22] Identification of compounds was by comparison of the mass spectrum with authenticated reference standards and/or with spectra in the National Institute for Standard and Technology (NIST) mass spectrum library (version 05) when no standard was available. Volatile compound concentrations (nanomoles per liter) in the chamber headspace were quantified by calibration with a known concentration of an authenticated, high-purity, 72-component standard mixture of esters and alcohols as previously described.[22] Where no standard was available, quantization was by estimation of the instrument response factor based on the Kovats index for the compound of interest.[23]

Cluster Analysis for Volatiles. Hierarchical cluster analysis was performed on all of the esters detected in this study for all taxons using Cluster 3.0,[24] which was developed from the original program by Eisen et al.[25] and TreeView software.[25] The uncentered correlation and centroid linkage method was used.

Selection of Germplasm Lines for Metabolite Analysis. As noted above, *Malus* sp. lines from high and low 2MB/SC classes were selected for further characterization in season two. SC esters were defined as those having one, two, or four or more carbons arranged in a straight chain on both the alcohol and acid moieties of the ester. 2MB esters were those derived from 2-methylbutanoate or 2-methylbutan-1-ol and having either a branched or straight chain of any length for the complementary alcohol or acid moiety of the ester. The sum of the concentration (nanomoles per liter) of SC and 2MB esters were calculated for each of the 184 lines, and the ratio of 2MB/SC was determined. Selection of "high" and "low" 2MB/SC lines was based on the concentration of 2MB and SC ester concentrations in the chamber headspace and on the ratio of 2MB to SC esters. Selection required 2MB and SC ester emissions to exceed 3 nmol L^{-1}. In addition, high 2MB/SC lines had to have a 2MB/SC ester ratio >1, and low 2MB/SC esters had to have a ratio of <0.15. Fruit mass exceeded 85 g. Selected high 2MB/SC apple lines were 'Jonathan', 'PRI1312-6', 'PRI1176-1', 'Trent', and 'Nova Easygro', which had 2MB/SC ratios of 1.074, 1.180, 1.179, 1.679, and 1.958, respectively. Selected low 2MB/SC lines were 'Virginia Gold', 'Burgundy', 'PRI1850', 'Jonafree', and 'Cox's Orange Pippin', which had 2MB/SC ratios of 0.045, 0.073, 0.116, 0.103, and 0.119, respectively.

Apple lines identified as high and low 2MB/SC esters were shipped in the second season (2008) from the USDA *Malus* Germplasm Repository at the New York Agricultural Experiment Station in Geneva, NY, USA, to Michigan State University as previously described. Twenty fruits were acquired prior to the onset of ripening and after ripening had commenced. Ripening stage was determined on the basis of multiple indices of ripeness including IEC, °Brix, firmness, respiratory rate (CO_2 production), and starch index of the fruit, and the rate of ester synthesis (μmol kg^{-1} h^{-1}) was measured as previously described by Sugimoto et al.[19] IEC, °Brix, firmness, respiratory rate, and starch index averaged, respectively, 0.08 μL L^{-1}, 11.8%, 100.5 N, 27.7 mg kg^{-1} h^{-1}, and 2.0 for "unripe" fruit and 80.4 μL L^{-1}, 15.0%, 74.8 N, 43.6 mg kg^{-1} h^{-1}, and 6.9 for "ripe" fruit. The rates of volatile synthesis were used to calculate the 2MB/SC ratio, the ratio of the sum of 1-propanol- and propanoate-derived esters to SC esters (Prop/SC ratio), the ratio of the sum of 1-butanol- and butanoate-derived esters to SC esters (But/SC ratio), the ratio of the sum of 1-pentanol- and pentanoate-derived esters to SC esters (Pent/SC ratio), and the ratio of 2-methylbutan-1-ol to SC esters (2MBol/SC ratio).

Amino Acid Analysis. Apple tissue used for amino acid analyses was the epidermis and 2−3 mm of cortex removed with a manual rotary peeler (model 8, Goodell, Antrim, NH, USA). Upon collection, tissues were immediately frozen in liquid nitrogen and stored at −80 °C. There were two biological replicates, each consisting of pooled tissue samples from four fruits, and three technical replicates were analyzed per biological replicate. Approximately 5 g of the frozen apple tissue was ground into fine powder using a liquid N_2-cooled mortal and pestle. The ground tissue was divided into three technical replicates, each containing 0.5 g of tissue. The powdered tissue was transferred into 1 mL of preheated water, acetonitrile, and ethanol in 1:1:1 (v/v/v) ratio containing 10 μM deuterated methionine (Met-d_3) (Cambridge Isotope Laboratories Inc., Andover, MA, USA) as an internal standard, mixed vigorously, incubated at 70−80 °C for 5 min, and immediately transferred in ice. After centrifugation at 5000g_n for 10 min at 4 °C, the supernatant was filtered through a 0.22 μm filter (Millex GS, Millipore, Billerica, MA, USA). The cleared filtrate was diluted to one-fifth of its original concentration with water containing the internal standard and used for amino acid analysis.

The amino acids threonine, isoleucine, leucine, and valine (Sigma-Aldrich Corp., St. Louis, MO, USA) were dissolved in water containing 10 μM Met-d_3 to make individual stock solutions of 1 mM. A master mixture was created by mixing amino acids to a final concentration of 50 μM each. A series of six working standards ranging from 0.5 to 40 μM, each containing 10 μM Met-d_3, was prepared by serial dilutions from the 50 μM master mixture using water containing 10 μM Met-d_3. Amino acid samples were quantified by calibration curves obtained from the six working standards using linear regression, plotting amino acid concentration as a function of ratio of the amino acid peak area to the Met-d_3 peak area.

Amino acids were analyzed using a tandem mass spectrometer (Waters Quattro micro, Waters Inc., Milford, MA, USA) coupled to a high-pressure liquid chromatograph (LC-20AD HPLC, Shimadzu, Columbia, MD, USA) equipped with an autosampler (SIL-5000, Shimadzu). The 2.1 × 50 mm column was packed with a 2.7 μm diameter C18 stationary phase (Ascentis Express C18, Sigma-Aldrich) and held isothermally at 30 °C. Injection volume was 10 μL, and solvents used were 1 mM perfluoroheptanoic acid (mobile phase A) and acetonitrile (mobile phase B); the flow rate was held constant at 0.3 mL min^{-1}. The gradient program was as follows: 98% mobile phase A and 2% mobile phase B at start, 10% mobile phase B after 0.1 min, increasing to 25% mobile phase B at 0.5 min and held until 4 min, decreasing to 2% mobile phase B at 4.1 min for re-equilibration of the column. The total run time was 6 min. Mass spectra were acquired using electrospray ionization in positive ion mode (ESI+). The capillary voltage was 3.17 kV, the extractor voltage was 4 V, the rf lens was held at 0.3 V, the cone gas flow rate was 30 L h^{-1}, the desolvation gas flow rate was 400 L h^{-1}, the source temperature was 110 °C, and the desolvation temperature was 350 °C as described by Gu et al.[26] The data acquisition method was split into two functions, the first from 0 to 1.85 min and the second from 1.85 to 6.0 min. Ten multiple reaction monitoring (MRM) transitions were included in function 1 and 11 in function 2. Function number, collision energies, and masses of observed ions for each amino acid are were described by Sugimoto et al.[19] Data were collected and quantified with proprietary software (MassLynx 4.0 and QuanLynx; Waters).

Citramalic Acid Analysis. Approximately 5 g of frozen apple peel from each of the two four-fruit replicates was ground into fine powder using a liquid nitrogen cooled mortal and pestle. The ground tissue was divided into three technical replicates, each containing 0.5 g of tissue. The powdered tissue was transferred into 1 mL of preheated water, mixed vigorously, and incubated at 90−95 °C for 10 min. After centrifugation at 5000g_n for 5 min, the supernatant was filtered through a 0.22 μm filter (Millex GS, Millipore, Billerica, MA, USA), and the cleared filtrate diluted to one-tenth of its original concentration with water was used for analysis.

Citramalic acid (Sigma-Aldrich) was dissolved in water to make a stock solution of 1 mM. A master mixture (50 μM) was created for making standard dilutions. A series of five working standards ranging from 1 to 40 μM was prepared by serial dilutions from the 50 μM master mixture and used to create calibration curves.

Citramalic acid was analyzed using a mass spectrometer (Quattro Premier XE, Waters Corp., Milford, MA, USA) coupled to an ultraperformance liquid chromatograph (UPLC) (Acquity, Waters Corp.). The column (Thermo Betasil C18, 2.1 × 150 mm, 5 μm particles, Thermo Fisher Scientific Inc., Waltham, MA, USA) was held isothermally at 50 °C. The injection volume was 5 μL; solvents were 1 mM *N*,*N*-dimethylhexylammonium acetate (pH 7.7) in water (mobile phase A) and methanol (mobile phase B), and the flow rate was 0.4 mL min^{-1}. The gradient program was as follows: 80% mobile phase A and 20% mobile phase B at start, increasing to 75% mobile phase B

large	>100	77	1.09−782.2	11−17.5	3−8	24.0−109.0

[a]Fruit were classified into five categories based on the mass, and the number of accessions that belong to the category is shown. Maturity indices include internal ethylene content, °Brix, starch index (1−8), and firmness. Fruit were harvested on nine dates between Aug 24, 2005, and Oct 24, 2005, from the USDA Plant Genetic Resources Unit's *Malus* Germplasm Repository at Cornell University, Geneva, NY, USA. Internal ethylene and firmness measurements were possible only on fruit with weights greater than 5 and 10 g, respectively. nd, not determined.

after 3 min, and decreasing to 20% mobile phase B at 4 min for re-equilibration of the column. The total run time was 5 min. Mass spectra were acquired using electrospray ionization in negative ion mode. The capillary voltage was set at 3.25 kV, the cone gas flow rate was 40 L h^{-1}, the desolvation gas flow rate was 600 L h^{-1}, the source temperature was 120 °C, and the desolvation temperature was 350 °C. Data were collected and quantified with proprietary software (MassLynx 4.0 and QuanLynx; Waters).

RESULTS AND DISCUSSION

Fruit Characteristics. Fruit mass ranged from 0.3 to 342.3 g (Table 1; Supporting Information, Table S1). For evaluating the relationship between fruit size and other variables, the apple lines were assigned one of five fruit size categories (small, small−medium, medium, medium−large, and large) for comparison. Lines of *M.* × *domestica* used for commercial fruit production were all in the large fruit category. The cube root of fruit weight was correlated with °Brix, internal ethylene, and firmness (data not shown). On average, smaller fruit tended to have a higher °Brix (R^2 = 0.76), lower ethylene (R^2 = 0.86), and higher firmness (R^2 = 0.98) than larger fruit (Table 1). The lower IEC in smaller fruit may, in part, be related to enhanced diffusion characteristics associated with smaller fruit size.[27] A number of the early-maturing varieties had relatively high IEC compared to late ones. IECs for very early to midearly maturing varieties (GRIN harvest codes 2−4) were 128 μL L^{-1} on average, whereas mid to very late maturing varieties (GRIN harvest codes 5−8) were 80 μL L^{-1}. This finding was similar to that from previous studies.[28,29] Harada et al.[30] suggested that the rates of ethylene production in apple are influenced by genotype of 1-aminocyclopropane-1-carboxylate synthase. However, this genotypic relationship was not supported in subsequent studies.[29,31]

High ethylene production did not correlate with low firmness (R^2 = 0.020) and late maturation (based on harvest code) and did not correlate with high firmness (R^2 = 0.005). In our study, medium-sized fruit had a higher firmness than larger fruit, averaging 98 N compared to 70 N for large fruit. De Salvador et al.[32] reported that smaller fruit had a higher firmness than larger fruit in 'Golden Delicious' and 'Red Chief' apples. Vincent[33] suggested that firmness is correlated with fruit density and is partially related to the amount of air space in the flesh. Goffinet et al.[34] reported that fruit size is positively correlated with cortex cell number. The cell density of members of the Geneva *Malus* collection is not known.

When multiple harvests were taken, starch index declined over time (data not shown), although starch degradation remained incomplete for several lines. About 5% of the lines evaluated emitted high levels of volatiles and copious amounts of ethylene even when the starch index was <5 (Supporting Information, Table S1). These lines were members of *M.* × *domestica*, *M.* × *hybrid*, and *M. sieversii* taxa. In some cases, fruit with a starch index of ≤5 became mealy, greasy, and obviously overripe while retaining significant levels of starch. Successful commercial cultivars typically exhibit overripe symptoms only after starch conversion is essentially complete.[35−37]

Ester Abundance and Diversity. Ester diversity tended to increase with increasing fruit weight (Figure 1) and was linearly correlated with the cube root of fruit weight (R^2 = 0.64). Large fruit averaged 46 different esters per variety compared to small fruit, which averaged 10 ester types per variety. A total of 67 different esters including three with unsaturated alkyl groups were detected in the 184 lines evaluated (Table 2). Free acids and formate esters were occasionally detected but not quantified. Alcohol- and acid-derived moieties of the esters tended to be unevenly distributed. For instance, pentyl alcohol-derived esters were abundant only in combination with acetate, but not with longer chain acid moieties. Ester abundance tended to be greatest for esters containing alkyl and alkanoate moieties composed of two, three, four, and six carbons or branched moieties derived from 2-methylbutan-1-ol or 2-methylbutanoate. Esters derived from 2-methylpropan-1-ol, 2-methylpropanoate, methanol, pentanoate, 1-heptanol, heptanoate, 1-octanol, and octanoate were generally in low abundance and less frequently detected. Esters containing unsaturated subgroups were relatively rare, and of these, only acetate esters were detected (Table 2; Supporting Information, Table S1). To our knowledge, unsaturated esters have not been previously detected in the emanations of whole apple fruit.

The three esters most frequently detected in apples of the core collection were butyl acetate (179 lines), hexyl acetate (168 lines), and hexyl 2-methylbutanoate (164 lines). For ester classes segregated by the alkanoate group, acetate esters were most often found in greatest abundance. The three most abundant acetates, in decreasing order, were ethyl acetate, butyl acetate, and 2-methylbutyl acetate. Two of these esters, butyl acetate and 2-methylbutyl acetate, together with hexyl acetate (the fourth most abundant acetate ester in this study) are considered to be primary contributors to apple aroma.[38] For esters classed by the alkyl moiety, ethyl esters tended to be the most abundant, although butyl and hexyl esters, which were slightly less abundant, were found more frequently. Ethyl esters are frequently detected in high amounts in fruits well advanced in their ripening.[7]

The saturated esters detected were consistent with the type and number of esters previously characterized.[4,40,41] In addition, we tentatively identified five esters not previously

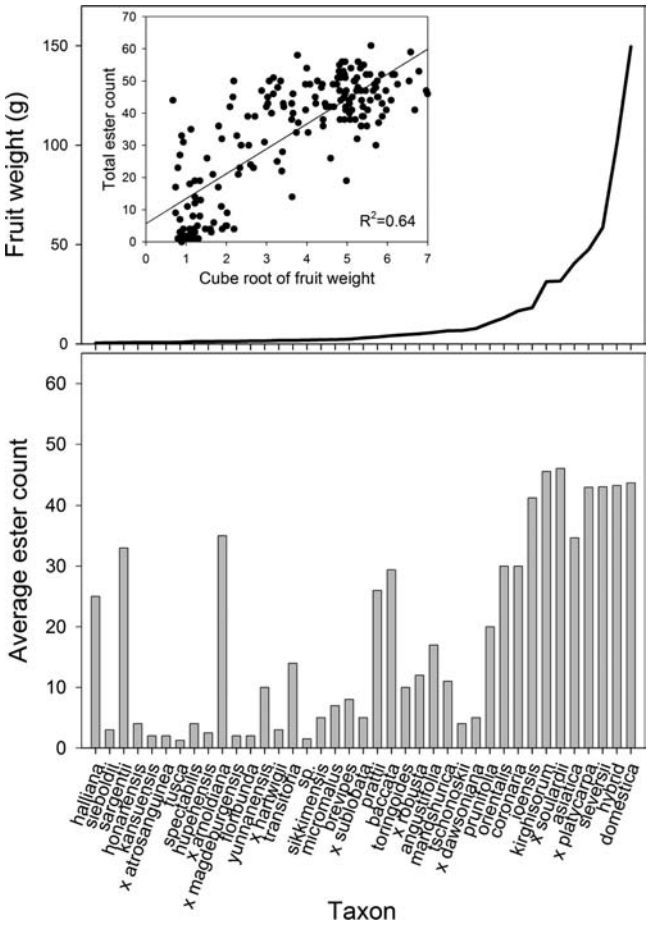

Figure 1. Ester count by taxon based on presence or absence of esters during ripening of the Geneva *Malus* four-copy core collection and the regression between ester count and the cube root of fruit weight. A total of 39 taxa including primary, cultivated, secondary, unidentified, and uncharacterized hybrid species[2] are listed in order by fruit weight ranging from small to large fruit. A total of 67 esters were detected, including 3 unsaturated esters.

reported: propyl 2-methylpropanote, 2-methylbutyl 2-methylpropanoate, heptyl butanoate, octyl 2-methylbutanoate, and methyl octanoate. Six esters (octyl butanoate, propyl pentanoate, pentyl pentanoate, propyl heptanoate, 2-methylpropyl octanoate, and pentyl octanoate) identified previously[4,39−41] were not detected in this study. The five previously unreported esters were found in several *M.* × *domestica* lines.

Cluster analysis of esters according to their alkyl and alkanoate groups across the 184 lines suggested that several classes of esters were more closely associated than others (Figure 2). Unsaturated esters did not cluster with any of the other ester types, which is suggestive of independent regulation. This is supported by what is known about the pathway of formation of the unsaturated C-6 aldehyde precursors,[42] which, as far as is known, would be exclusively via the lipoxygenase pathway.[43] Additionally, a seven-member alkanoate (acid) group (i.e., propanoate, 2-methylbutanoate, butanoate, 2-methylpropanoate, pentanoate, heptanoate, and hexanoate esters), clustered separately from a six-member alkyl ester group (i.e., propyl, 2-methylbutyl, butyl, 2-methylpropyl, pentyl, and hexyl esters). Interestingly, with the exception of heptyl esters, the members of these two clusters are acid and alcohol equivalents of the same carbon backbone. However, the separate clustering according to acid and alcohol precursors suggests differing metabolic regulation of corresponding acid and alcohol precursors for these ester classes. Ethyl and acetate esters clustered together, also, but this might reflect the very high quantity and frequency of ethyl acetate, which contains both ethyl and acetate moieties. Finally, methyl, heptyl, octyl, octanoate, and unsaturated esters clustered individually, suggesting distinct metabolic origins.

Within the alkanoate cluster, 2-methylbutanoate esters clustered with propanoate and butanoate esters. Similarly, Rowan et al.[44] also found a linkage between propanoate and 2-methylbutanoate esters in their evaluation of a diverse population of 240 breeding lines and suggested this and other cluster associations reveal underlying genetic linkages. 2-Methylbutanoate esters are derived from the pathway responsible for isoleucine formation.[16−19] Sugimoto et al.[19] proposed a novel entry point into the pathway for biosynthesis of isoleucine and 2-methylbutanoate (and 2-methylbutan-1-ol) esters by plants. The proposed pathway invoked the synthesis of citramalic acid from the α-keto acid pyruvate and acetyl-CoA in what they termed the "citramalic acid pathway". This pathway has been described in some bacteria and yeast[45−51] and has been implicated in the formation of acyl sugar esters in specialized organs in some Solanaceous plant species.[52] In *Saccharomyces cerevisiae*, the citramalic acid pathway has also been suggested to be present,[53] and citramalic acid synthase activity is evident in baker's yeast[54] and in *Saccharomyces carlsbergensis*.[55]

Sugimoto et al.[19] proposed the citramalic acid pathway would lead to the formation of α-ketobutyrate, elongating the carbon chain of pyruvate by one carbon. Data from bacteria, yeast, and plant studies suggest that α-ketobutyrate can be decarboxylated to yield propanoate and 1-propanol, which could be incorporated into esters. Furthermore, if the carbon backbone of α-ketobutyrate is further elongated by additional cycles of the three steps of the citramalic acid pathway, additional longer chain α-keto acids are formed.[52] For apple, this implies the pathway could also contribute to the formation of butyl, pentyl, and longer straight-chain esters (Figure 3).

Alcohols. Ester diversity is dependent on the diversity of the precursors apples synthesize, including alcohols.[56] In our study, alcohols differed between fruits of different size categories (Figure 4). Small fruit tended to produce methanol and unsaturated alcohols, whereas larger fruit tended to form BC alcohols and three- to six-carbon SC alcohols. The higher tendency of small apple lines to produce unsaturated six-carbon alcohols could be related to a higher peel/flesh ratio, which would mean a higher chloroplast content/flesh ratio. This is consistent with the observation that several LOX enzymes[57] and much of the fatty acid substrate[58] for the lipoxygenase pathway are mainly located in the chloroplasts/plastids.

All of the alcohols that we detected were similar to those reported previously.[4,7,39] In addition, the alcohols 2-butanol, 3-pentanol, 1-penten-3-ol, 2-methyl-2-propanol, and 2-penten-1-ol were also tentatively identified, but not quantified. The alcohols detected include some that have not been reported in apple fruit, but have been detected in other fruits, namely, 1-penten-3-ol and 2-methyl-2-propanol found in tangerine (*Citrus tangerina* Yu. Tanaka)[59] and 2-penten-1-ol found in yellow passion fruit (*Passiflora edulis* f. *flavicarpa*)[60] and kiwifruit (*Actinidia deliciosa* (A. Chev.) C.F. Liang et A.R. Ferguson).[61] On the other hand, 3-penten-2-ol, which has an apple-like

[a]Column and row headings refer, respectively, to the acid- and alcohol-derived subgroup of the ester (e.g., ethanol and acetic indicates the ester ethyl acetate). Nonparenthetical data are semiquantitative abundance data based on the sum of ester concentrations for all 184 lines (nmol L^{-1}). Data in parentheses indicate the percentage of the 184 lines producing that ester in detectable quantities. Details of ester complexity and abundance for individual lines can be found in the Supporting Information (Table S1). [b]2-Mpropanol, and 2-Mbutanol indicate 2-methylpropan-1-ol and 2-methylbutan-1-ol, respectively; 2-Mpropanoic and 2-Mbutanoic refer to 2-methylpropanoic and 2-methylbutanoic, respectively; nd, indicates not detected.

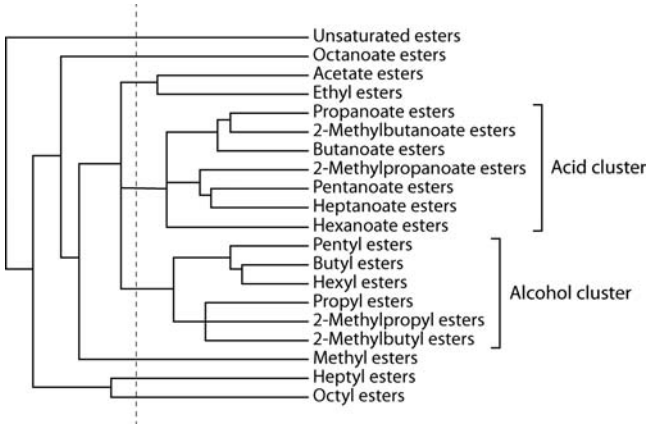

Figure 2. Cluster tree analysis of the esters classified according to alkyl (alcohol) and alkanoate (acid) groups across the four-copy core collection of the Geneva *Malus* Gerplasm Repository. Esters that comprise the alkyl or alkanoate classifications are found in Table 2. Vertical dashed line represents the threshold used for distinguishing clusters.

aroma and is found in 'Starkspur Golden' fruit,[62] was not detected.

Citramalic Acid and the Synthesis of Isoleucine and 2MB Esters. Of the 184 lines evaluated, 8 low and 11 high 2MB/SC lines were found. The lines having either high or low ratios for 2MB/SC esters did not associate with particular species or country of origin, suggesting that the capacity for differential synthesis of the 2MB and SC ester classes is quite ancient in *Malus*. For the 10 lines used for metabolite analysis, the 2MB/SC ratio for high 2MB/SC lines was, on average, 80-fold higher than for low 2MB/SC lines (Table 3). The low 2MB/SC ratios are similar in range to those previously reported for Italian cultivar 'Annurca', which produces primarily SC esters (96.8%) and little of the 2MB or other BC esters.[41] The extreme range in the ratios suggests that 2MB and SC esters are synthesized, at least in part, via differing pathways or are differentially regulated. As noted, ester formation is a function of precursor availability and the specificity of AAT,[63,64] and either of these options may be in play.

BC ester precursors have been proposed to be derived from BCAA degradation,[14,16,18,64] although this interpretation may be incomplete. Sugimoto et al.[19] noted that α-keto-β-methylvalerate, α-ketoisovalerate, and α-ketoisocaproate are precursors to isoleucine, valine, and leucine, respectively, and are also precursors to the BC alcohols and acids incorporated into esters. They found that isoleucine was not depleted, but rather accumulated during ripening in the 'Jonagold' apple, concomitant with the increase in 2MB ester production. They argued in this case an increase in the flux through the pathway, rather than isoleucine catabolism, was primarily responsible for the observed changes in 2MB esters during ripening.

In the current study, isoleucine levels did not differ between high and low 2MB/SC lines in unripe fruit (Table 3). However, upon ripening, isoleucine increased 4−30-fold for high 2MB/SC lines and declined slightly for low 2MB/SC lines. These data are therefore consistent with the suggestion that high 2MB ester production is linked to increased flux from α-ketobutyrate along both branches of the pathway to isoleucine and 2MB esters. Likely, there is an increase in the concentration of the key intermediate α-keto-β-methylvalerate as well, but this has not been determined in ripening apple to our knowledge. It should be noted that even the low 2MB/SC lines produced significant quantities of 2MB esters and that this production was accompanied by a decline in isoleucine of approximately 10 nmol g^{-1} on average. Thus, for some apple varieties, there does indeed appear to be a small depletion in the isoleucine pool. The decline in isoleucine in the low 2MB/SC lines might be sufficient to account for the amount of 2MB ester synthesized given that the rate of 2-methylbutan-1-ol emissions averaged 0.008 nmol g^{-1} h^{-1} and the 2MB ester production was >0.08 nmol g^{-1} h^{-1} for these fruits when ripe (Supporting Information, Table S2), such that in 5 days, a loss of approximately 11 nmol g^{-1} would accrue.

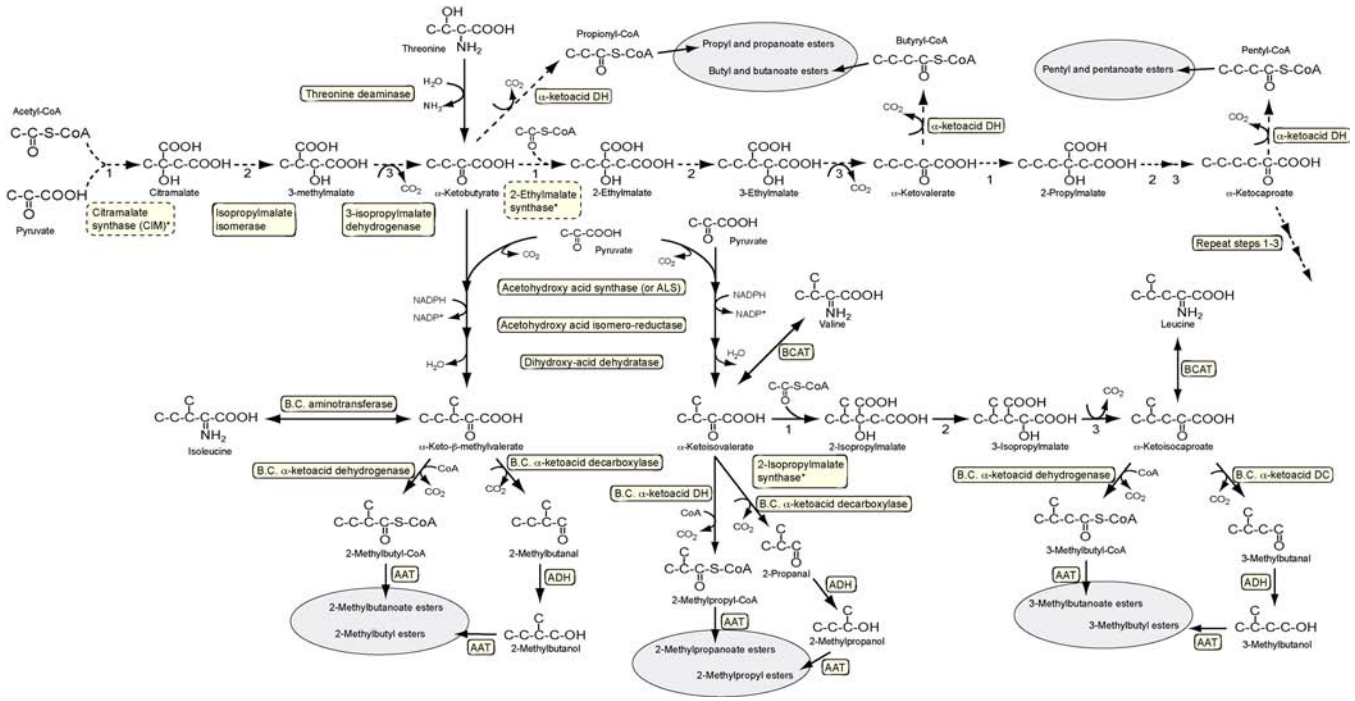

Figure 3. Putative (dashed lines) and demonstrated (solid lines) pathways and pathway elements involved in the biosynthesis of branched-chain amino acids, short, straight-chain fatty acids, and their related esters in plants as proposed by Sugimoto et al.[19] and Kroumova et al.[73] Threonine deaminase is feedback-inhibited by isoleucine, but stimulated by valine; acetohydroxy acid synthase [also known as acetolactate synthase (ALS)] is inhibited by valine and leucine; and 2-isopropylmalate synthase is inhibited by leucine. Hydrogens in carbon−hydrogen bonds are not shown. Reactions 2 and 3 in the putative pathway are considered to be catalyzed by isopropylmalate isomerase and 3-isopropylmalate dehydrogenase, respectively, per leucine biosynthesis.[52] The asterisk indicates similar reactions that may be catalyzed by the same or similar enzymes despite differing nomenclature (e.g., citramalate synthase, ethylmalate synthase, isopropylmalate synthase). BCAT, branched-chain amino transferase; DH, dehydrogenase; DC, decarboxylase; ADH, alcohol dehydrogenase; AAT, alcohol acyl-CoA transferase.

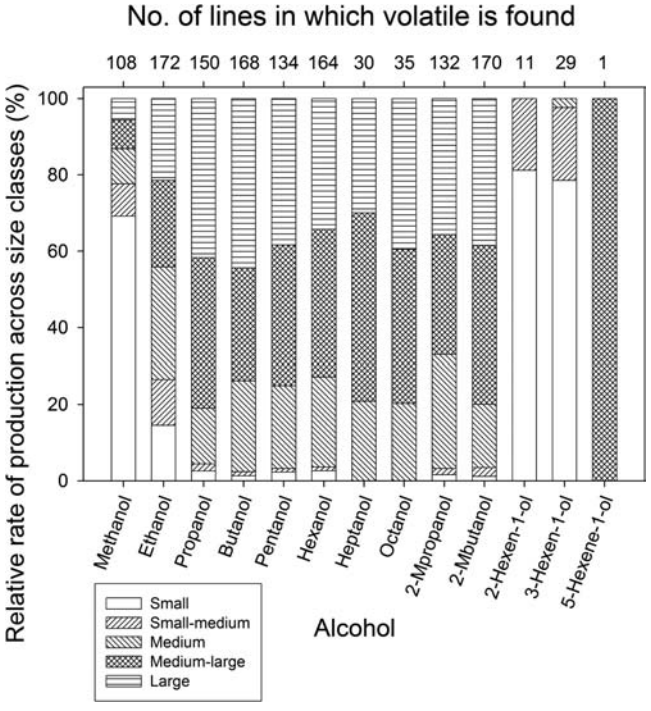

Figure 4. Relative rate of alcohol production across the Geneva *Malus* Core Collection and Kazakhstan apple (all *M. sieversii*) categorized by fruit weight ranging from small to large fruit. The numbers at the top indicate the number of lines in which the volatile is found.

In plants, isoleucine is synthesized from threonine via α-ketobutyrate.[65−68] In this study, the content of threonine was affected by stage of ripening and by 2MB/SC class (Table 3). The threonine content was similar for unripe fruit in low and high 2MB/SC lines, but declined with ripening only in low 2MB/SC lines. If threonine is required for the formation of isoleucine and 2MB esters, then one might expect a similar behavior for both lines as the production of 2MB esters increases with ripening. The approximate 50% reduction in threonine for low 2MB/SC lines upon ripening might suggest a facilitated conversion to α-ketobutyrate. A higher rate of α-ketobutyrate synthesis would be the expected result of lowered isoleucine levels, in that feedback inhibition of threonine deaminase by isoleucine would be lessened.[69,70] However, the lack of a similar reduction in threonine for the high 2MB/SC lines despite a many-fold higher flux in the formation of 2MB esters and accumulation in isoleucine suggests a different mechanism in the formation and/or regulation of this pathway in these lines. In high 2MB/SC lines, the greater rate of formation of 2MB esters was consistently associated with increased isoleucine content, which would not be anticipated in light of the aforementioned feedback inhibition of threonine deaminase by isoleucine. This paradox was also observed for 'Jonagold' apple fruit and led to the suggestion that a citramalic acid-dependent pathway may be functioning in some apple lines.[19]

In the citramalic acid pathway, acetyl-CoA and pyruvate are substrates for the formation of citramalic acid by citramalic acid synthase (CIM), which is a member of the 2-isopropylmalate synthase (IPMS) protein family (Figure 3). The subsequent

[a]2MB esters are represented by the sum of all esters derived from 2-methylbutanoate or 2-methylbutan-1-ol. SC esters are represented by the sum of all esters having 1, 2, or 4 or more carbons arranged in a straight chain on both the alcohol and acid moieties of the ester. Prop/SC ratio indicates the ratio of the sum of all esters derived from propanoate or 1-propanol to SC esters, and the 2MBol/SC ratio is the ratio of 2-methylbutan-1-ol to SC esters.

synthesis of α-ketobutyrate from citramalic acid would bypass threonine and thereby uncouple isoleucine formation from threonine metabolism and associated feedback mechanisms. If active, the citramalic acid pathway would yield increased isoleucine, 2-methylbutan-1-ol, and 2MB ester production concomitant with increased citramalic acid levels. Indeed, this is precisely what was observed in all five high 2MB/SC lines, but in none of the low 2MB/SC lines (Table 3). The extent of enhancement in citramalic acid ranged from approximately 20- to 100-fold in the high 2MB/SC lines. Hulme[71] also isolated citramalic acid from the peel of the mature apple fruit, and its concentration was shown to increase during ripening.[72] Hulme[71] proposed citramalic acid participated in the mitochondrial reactions of the TCA cycle, but no evidence has been forthcoming to support this hypothesis.

Kroumova and Wagner[52] inferred the existence of a fatty acid biosynthetic pathway involving one-carbon elongation from pyruvate through citramalic acid in the formation of sugar esters in some, but not all, members of the Solanaceae [e.g., tobacco (*Nicotiana tabacum*) and petunia (*Petunia* × *hybrida*)]. Kroumova et al.[73] and Kroumova and Wagner[52] noted that their proposed one-carbon elongation pathway for fatty acid biosynthesis would lead to the production of α-keto acids composed of chains of four, five, six, and seven carbons and longer. They noted that a series of straight- and branched-chain acids could be subsequently derived from this pathway via oxidative decarboxylation of the α-keto acids. In the proposed pathway, α-ketobutyrate would be expected to yield propanoic acid, which, in turn, would be activated by acyl acyl-CoA synthase to form propyl-CoA or reduced to form 1-propanol.[53,74−76] If the proposed pathway were preferentially active in the high 2MB/SC lines, then propyl and propanoate esters (Prop esters), butyl and butanoate esters (But esters), and pentyl and pentanoate esters (Pent esters) might also be expected to be elevated in these lines. This relationship was observed, in fact, with high 2MB/SC lines having a roughly 60-fold higher ratio of propyl and propanoate esters relative to SC esters (Prop/SC) than the low 2MB/SC lines (Table 3). Furthermore, there were elevated levels of synthesis of Prop, But, 2MB, and Pent esters and slightly lower synthesis rates of SC esters in the high 2MB/SC lines (Supporting Information, Table S2). Finally, it would be anticipated that enhanced

DOI: 10.1021/jf505523m
J. Agric. Food Chem. 2015, 63, 2106−2116

formation of 2-methylbutan-1-ol esters, which form the bulk of the 2MB esters, would be reflected in a larger pool of 2-methylbutan-1-ol. The ratio of 2-methylbutan-1-ol to SC esters (2MBol/SC) was on average 65-fold higher for the high 2MB/SC lines compared to the low 2MB/SC lines (Table 3), supporting this supposition and further supporting the suggestion that the elevated levels of citramalic acid may be linked with increased production of 2MB esters.

The two BCAAs leucine and valine were also affected by 2MB/SC class and by ripening. Valine, which is linked to the formation of esters derived from 2-methylpropan-1-ol and 2-methylpropanoate (2MP esters), declined approximately 50% during ripening in low 2MB/SC lines, but increased on average by approximately 40% in high 2MB/SC lines. This was true despite a decline in valine content for one line ('Jonathan'), with the end result that that valine levels averaged about 3-fold higher in ripe fruit of the high 2MB/SC lines compared to low 2MB/SC lines. Overall, 2MP ester production was quite low, averaging about $^{1}/_{20}$ that of 2MB esters. The rate of synthesis of 2MP esters (Supporting Information, Table S2) and the ratio of 2MP/SC esters (data not shown) were greater for high 2MB/SC ester lines compared to low 2MB/SC lines. This may suggest that the pathway for 2MP ester formation was influenced by regulatory changes associated with 2MB ester formation, which might be expected given that the pathways for 2MB and 2MP ester formation are quite similar.

Leucine levels were similar for unripe fruit in high and low 2MB/SC lines, increasing about 2-fold during ripening for the high 2MB/SC lines but remaining unchanged for the low 2-MB/SC lines. Interestingly, no esters derived from 3-methylbutan-1-ol or 3-methylbutanoate (3MB esters) were detected in any of the lines (Supporting Information, Table S1), which is in keeping with previously published analyses of apple esters.[5,77−79] The lack of 3MB esters may reflect substrate specificity limitations in AAT[80−87] or the enzymes responsible for BCAA dehydrogenase and decarboxylase reactions (Figure 3).

Collectively, the data demonstrate that the information on ester character for the four-copy core collection of the USDA Geneva *Malus* Germplasm Repository was useful in selecting appropriate apple lines for testing a pathway recently hypothesized to contribute to 2MB ester production. The data for 2MB, SC, Prop, But, and Pent ester synthesis, isoleucine and threonine levels, 2-methylbutan-1-ol production, and citramalic acid accumulation in this study all consistently support the hypothesis put forth by Sugimoto et al.[19] regarding the presence of the citramalic acid pathway in some apple lines. As yet, however, there has been no molecular characterization of the enzyme required for entry into the pathway, CIM, in any plant species to our knowledge.

The metabolite data related to 2MB ester formation suggest that the volatile profiles reported here for the members of the Geneva *Malus* collection may provide useful information in support of further physiological, biochemical, and molecular investigations. Likely, additional patterns could be identified for targeting biochemical pathways linked to ester synthesis. For instance, the ratio of esters derived from 1-hexanol to those derived from 1-butanol ranged from 0 to 10.8, and the ratio of 1-hexanol to 1-butanol ranged from 0 to 4.3, suggesting metabolite analysis might yield interesting new information regarding the formation of ester classes. Finally, our data have been supplied to the USDA GRIN system to expand on the phenotypic data available and are hoped to prove useful in breeding for flavor character in apple and, perhaps, other members of the Rosaceae family.

European Union[b]	0.6	0.4
Brazil – ANVISA[c]	1.0	0.2
safety interval-ANVISA[c**]	21 days	15 days

[a]IUPAC agrochemical information.[16] [b]U.S. Department of Agriculture.[66] [c]ANVISA, Brazilian Health Surveillance Agency.[67] *Not registered for rice production. **Safety interval between application of the pesticide and harvesting of rice grains in Brazil.

in an uncontrolled release of calcium from internal stores in the sarcoplasmic reticulum,[21] causing impaired regulation of muscle contraction and leading to feeding cessation, lethargy, paralysis, and eventual death of target organisms.[22] Its use provides good lepidoptera control;[23,24] it is a systemic insecticide that tends to be translocated long distances ascendingly[3] in the plant and is recommended for and widely used in irrigated rice crops by foliar application.[11,12] The insecticide moves within the foliar tissue, where it is protected from leaching while remaining available to chewing insects in both top and bottom surfaces of the leaves. This transfoliar activity associated with its insecticide potential, resistance, and photodegradation are the bases for efficient protection in the tomato plant. It is noteworthy that this insecticide presents low toxicity to nontarget organisms such as mammals, birds, fishes, and others,[25,26] a good option for pest control with low environmental impact. The anthranilicdiamide class has no cross-resistance with other insecticide chemical groups[27] and is an efficient alternative in the insecticide rotation.[28]

In rice crops the increasing application of pesticides directly on the organ of the plant that is used for consumption and in association with the fact that rice does not receive intensive industrial processing, the analysis of residues of insecticides on the grain becomes essential as a way to ensure food safety, due to the fact that insecticide residues can persist until the harvest stage, resulting in the contamination of the rice grain.[29−31]

However, pesticides may also affect human life due to pesticide buildup throughout the food chain may lead to an ecologic phenomenon called biomagnification, which is the bioaccumulation of a pesticide through an ecological food chain by transfer of residues from the diet into body tissues. The tissue concentration increases at each trophic level in the food web when there is efficient uptake and slow elimination.[32] However, knowledge pertaining to the long-term effects of pesticides in human health is still very restricted,[33] but indicates that its effects may be associated with several health problems.[34−37] The literature presents several studies related to pesticide residues in food; however, there is little information on the use of insecticides in rice fields and its persistence in the grains. It is important to analyze pesticide residues not only on the rice grain itself but also on rice subproducts such as rice bran, which can be used in whole rice[38] and animal feed.[39,40] Overall, the results of these studies show variation in the presence of pesticide residues in rice grain, likely due to environmental factors that can interact and interfere with the persistence of pesticides. The literature presents several hypotheses regarding what may influence the persistence of pesticides in food, and many such reasons are not fully understood due to the characteristics of the active ingredients,[41,42] the moment of application,[43] solar radiation, temperature,[44] and the persistence of pesticides in plants.[45−47]

Thus, studies analyzing pesticide residues in rice grain are pertinent and provide a better understanding of if and how

technologies used in commercial crops compromise grain quality. Another important issue may be related to the rate of pesticides applied to the aerial parts of plants; however, reports on the use of the recommended rate and double the recommended rate for the insecticide thiamethoxam have not been able to detect residues in polished rice grains.[46] However, it is important to analyze pesticide residues in rice as a whole because in a study with the insecticide thiamethoxam, the highest residue concentration was detected on the rice hull (62% of total detected), followed by rice bran (38% of total detected); no residues were detected on the polished rice grains.[48]

With regard to chlorantraniliprole in rice, residues were detected in polished rice grains varying with the applied rate [30 and 60 g active ingredient (ai) ha^{-1}]. The addition of a double rate of chlorantraniliprole presented the highest values of residues detected in polished rice grains, which was 85% higher than the recommended rate.[49]

The need for information regarding the persistence of pesticides in irrigated rice is relevant because of the nutritional and toxicological issues associated with rice consumption.[48] Therefore, it is necessary to study pesticide residues in rice grains to provide basic information for the use of thiamethoxam and chlorantraniliprole in pest management strategies for rice and grain quality.

The objective of this study was to analyze residues of the insecticides thiamethoxam and chlorantraniliprole in rice hull, bran, and polished grains when applied on the aerial part of the rice plants.

MATERIALS AND METHODS

The study was conducted in two stages; the first stage was conducted in the field and the second in the laboratory.

Experimental Procedures in the Field. The first phase of the experiment was conducted during the 2012 cropping season at Texas A&M Agrilife Research, David R. Wintermann Rice Research Station, near Eagle Lake, TX, USA. The rice was seeded on May 5, 2012, using the cultivar 'Presidio', with a seeding rate of 80 kg ha^{-1}. Each plot had seven rows spaced at 0.19 m from each other and measuring 4 m long. The management practices were conducted according to the technical recommendations for rice cultivation in Texas.[50]

Pesticide applications were performed at 5, 15, 25, and 35 days after flowering (DAF) using 1 and 2 times the recommended rate, that is, 30 g ai ha^{-1} of thiamethoxam and 30 g ai ha^{-1} of chlorantraniliprole (Table 1). Besides, two treatments using the insecticides recommended rate were applied sequentially at 5 and 25 DAF plus at 5, 25, and 35 DAF. Insecticide residues were analyzed in different sample fractions: rice hull, bran, and polished grains.

The applications were made with a CO_2 pressurized backpack sprayer calibrated to dispense a 205 L ha^{-1} spraying volume. The system was attached to a spray boom with three nozzles operating at 276 kPa. The experiment was conducted using a randomized complete block design with four replications.

For quantification of residues in grains, rice plants were harvested when the average moisture content in the grains reached 20%, based on Texas recommendations.[50] Rice harvest was performed 40 DAF from an area totaling 3.8 m^2 (4.0 × 0.95 m) in each plot. After grain harvest, a homogeneous sample of 2 kg was separated for each treatment. Subsequently, samples were cleaned and dried with forced air ventilation at 35 ± 2 °C until reaching an average moisture content of 13%. The samples were then stored at −20 °C during the 30 day period until extraction for pesticide residues.

Insecticide residues were analyzed using different fractions of rice samples including (1) rice hull, (2) rice bran, and (3) polished rice grains. These fractions were obtained by processing the samples in rice milling equipment (Zaccaria, model PAZ-1-DTA, Limeira, SP, Brazil).

Determination of the Pesticide Residues. The second stage of the study was conducted in the Department of Soil and Crop Sciences at Texas A&M University. Prior to chromatographic analysis, samples were extracted using an accelerated solvent extraction Dionex ASE 200 system (Dionex Co., Sunnyvalle, CA, USA), and afterward the samples were analyzed using ultrahigh-performance liquid chromatography–tandem mass spectrometry (UHPLC-MS/MS).

Sample Preparation for ASE. The sample preparation proceeded with 2 g of the matrix (rice hull, bran, or polished grains), 3 g of Chem tube hydromatrix (Agilent Technologies), and 2 g of Florisil (Acros Organics). Sample preparation was carried out in a 50 mL beaker, and the contents were mixed with a spatula to obtain a free-flowing powder. The cell size used was a 22 mL stainless steel cell, using two circular cellulose filters (size = 19.8 mm in diameter) at the low end of the cell. Fortification was done by adding appropriate volumes of solution to the samples, where they were equilibrated in the extraction in cells at room temperature for 10 min.

Optimization of ASE Conditions. Optimal extraction conditions demonstrating the highest chemical recoveries included were extraction temperatures of 75 °C for rice hull and 100 °C for rice bran and polished grains, pressure of 10.3 MPa, and solvent of acetonitrile (100%) determined from a previous experiment (unpublished data). The duration of static phase was 5 min, following 1 min of preheating and 5 min of equilibration. The solvent was collected in 60 mL vials with Teflon septa. Subsequently, each extraction cell containing the same sample went through another identical extraction cycle, and the solvent was collected in the same vial.

Optimization of Evaporation Conditions. The total extracted volume of 60 mL was transferred into 15 mL volumetric tubes 10 mL at a time for sample evaporation using a TurboVap LV Evaporator (Zymark Center, Hopkinton, MA, USA). Samples were evaporated at 45 °C to dryness using a gentle stream of nitrogen. Pesticides were resuspended in 2 mL of acetonitrile and shaken in a vortex mixer (Fisher Vortex Genie2, model G-560; Fisher Scientific, Bohemia, NY, USA) The samples were stored at 4 °C during the 2 h period to complete the preparation of all samples and begin analyses by chromatograph.

Chromatography Conditions. Analyses were performed using an UHPLC-MS/MS, model Acquity TQD (Waters Corp., Milford, MA, USA). Chromatographic separation was done with an ethylene-bridged hybrid (BEH) C_{18} column (50 × 2.1 mm; 1.7 μm) with controlled temperature of 30 °C and a 5 μL injection volume. Mobile phase was pumped from two solvent reservoirs consisting of 0.05% of formic acid in water (A) and acetonitrile (B) in an isocratic run (50 A/50 B) with a flow rate of 0.4 mL min^{-1}, and the estimated void time for this method is 0.3 min. The mass spectrometer was operated using electrospray ionization (ESI) in positive mode, capillary voltage at 2.2 kV, source and dissolution temperatures of 150 and 400 °C, and dissolution and cone gas flows of 800 and 50 L h^{-1}, respectively. Nitrogen (AOC, Bryan, TX, USA) was used as dissolution and cone gas and argon (AOC) as collision gas. The pesticides analyzed were

Table 3. Slope, Intercept, Determination Coefficient (r^2), Limits of Detection, and Limits of Quantification of Pesticides with the UHPLC-MS/MS Method

pesticide	slope	intercept	r^2	LOD (mg kg^{-1})	LOQ (mg kg^{-1})
thiamethoxam	5.2×10^{-3}	4.5×10^{-4}	0.998	0.00015	0.0005
chlorantraniliprole	3.9×10^{-3}	1.2×10^{-4}	0.996	0.00015	0.0005

confirmed using selected reaction monitoring (SRM) mode in which ionizations of the parent and one product were analyzed and monitored for each compound studied (Table 2).

Extraction Efficiency and Statistical Design. The efficiency of the extraction method was determined by sample fortification and analysis of quality control samples. Untreated rice samples were fortified to a concentration of 0.75 mg kg^{1}. The samples were then processed according to the extraction procedure previously described, and six repetitions of each sample were analyzed.

Limit of Detection (LOD) and Limit of Quantification (LOQ). The quantification was based on a seven-point calibration curve (0.0005, 0.001, 0.002, 0.01, 0.1, 0.5, and 1.0 mg kg^{-1}). A matrix effect was obtained by comparing each response generated from calibration standards, which were prepared in pure acetonitrile and in matrix extracts. ME (%) was calculated as follows: $(B/A) \times 100$, where B is a response of matrix-matched calibration standard and A is a slope of non-matrix-matched calibration standard. Matrix effect values between −20 and +20% are considered acceptable.[51]

LOD and LOQ were calculated according to the peak-to-peak noise method.[52] The baseline of the unfortified blank was magnified to obtain the instrument noise response and converted into a concentration estimate from the known concentration of the fortified extract. The LOD was estimated by multiplying the response of the method noise level by approximately 3 and then converting the total response into an estimated concentration. The LOQ was estimated by multiplying the response of method noise level by approximately 10 and then converting the total response into concentration.

Statistical Analysis. The experimental design was a completely randomized factorial arrangement with eight replications in laboratory. Data were subjected to analysis of variance, and means were compared using the Scott−Knott test ($p \leq 0.05$) using the SAS program (Statistical Analysis Systems, 9.2 software, SAS Institute Inc., Cary, NC, USA). The results plotted in the figure were determined by a 95% confidence interval.

RESULTS AND DISCUSSION

Recovery and Detection Limits. The standard calibration curves of thiamethoxam and chlorantraniliprole were constructed by plotting analyzed concentrations with the peak areas. Linearity of curves for each insecticide was achieved within the range from 5×10^{-4} to 1 mg kg^{-1} (Table 3). During the calibration step it was observed that thiamethoxam and chlorantraniliprole insecticides showed an increase or decrease effect in the detector response when the calibration solutions were prepared in matrix extracts or pure solvent. To assess the matrix effect of our extracts, the responses of calibration standard prepared in solvent and matrix extract were compared. In accordance with previously published works, soft matrix effects (suppression or enhancement of 0−20%) are negligible. Otherwise, if the pesticides suffer medium (suppression or enhancement of 20−50%) or strong (suppression or enhancement >50%) matrix effects, it is necessary to use certain calibration methods to overcome the influence of matrix. For hulls, grains, and bran extracts, thiamethoxam presented high suppression (−94, −34, and −88%, respectively). Moreover, for the same extracts chlorantraniliprole presented high suppression for hull (−75%) and bran (−59%). Otherwise, for grains the matrix effect for this pesticide was positive (31%). These results prove the importance of calculating the matrix effect.

The recovery study was conducted for hull, bran, and polished grains. Average recovery ranged from 89.6 to 109.7% with a relative standard deviation <0.05% (Figure 1).

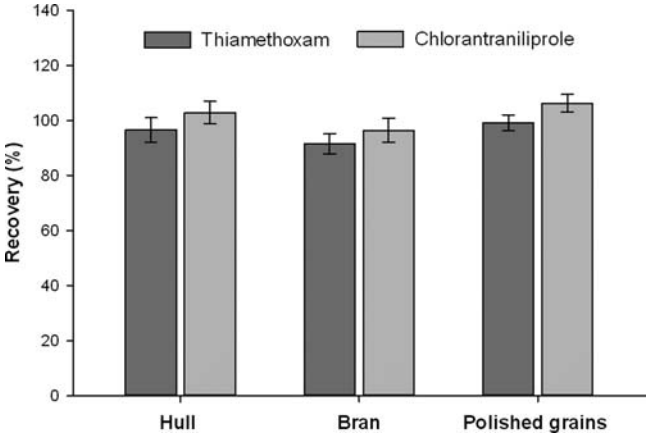

Figure 1. Recovery of thiamethoxam and chlorantraniliprole from rice hull, bran, and polished grains. Bars represent 95% confidence intervals.

Determination of Pesticide Residues in Rice Grains. Results showed thiamethoxam and chlorantraniliprole residues in rice hull, bran, and polished grains (Table 4).

Insecticide Thiamethoxam. For thiamethoxam, pesticide residues were quantified in rice hull for all analyzed treatments. The results showed that greater concentration of pesticides was observed for the sequential applications at 5, 25, and 35 DAF at the recommended rate (0.225 mg kg^{-1}); this result is 20% higher than the average of the other treatments. It is important to highlight that there was no difference regarding the recommended rate and the doubled rate.

The analysis carried out on the rice bran showed that for the insecticide thiamethoxam, the three-time sequential application using the recommended rate and the application at 35 DAF using the double rate resulted in the highest concentration of residues in rice bran. Treatments with applications at 5 and 15 DAF with the recommended rate and twice the rate had lower residues. This behavior may be related to the time between the applications of insecticides and the time of harvest, allowing the metabolism of these compounds,[41,46,53] which includes transformation of parent molecules into metabolites.[54]

Another hypothesis may be the hygroscopic behavior related to rice grains close to harvest,[55] which involves absorption and water loss to reach equilibrium with the relative moisture of the ambient air,[56] along with an increased rate of respiration of grain. This situation can facilitate penetration of insecticides into grain, associated with slow metabolism and translocation of assimilates in the rice plant.[57]

With respect to the analysis conducted in polished rice grains, residues of thiamethoxam insecticide were not detected for the applications using the recommended rate performed at 5 and 15 DAF. However, for all other treatments, residues were detected with the highest values for applications containing

twice the rate. Applications with double the recommended rate at 25 DAF resulted in greater concentrations of thiamethoxam residues when compared to sequential applications. This might be associated with a period of intense translocation of assimilates to the grain during rice grain filling.

In summary, the highest insecticide concentrations were observed in rice hull and rice bran, and the mean value detected in polished rice grains alone represents <1% of the total residue value detected on the sample (hull + bran + polished grain). Thus, the lipophilic composition of the hull and bran constituents may serve as a physical barrier to translocation of pesticides, lowering detected values in polished rice grains.[29] Similar tendencies in residue concentration were detected in rice hull, bran, and polished grains when several pesticides used in irrigated rice crops were studied, with results similar to the ones in this study when greater concentrations in hull and rice bran were detected.[48]

Experiments studying the dynamics and persistence of thiamethoxam from the chemical group of neonicotinoids did not show insecticide residues in polished rice grains.[46] Because of the relationship to dissipation and degradation of thiamethoxam in rice plants, about 40−60% of the initial residue dissipated 5 days after application, which after 15 days increased to 83−88%, regardless of the applied rate (33 or 66 g ai ha^{-1}). The calculated half-life values for thiamethoxam in rice plants were found to be 5.2 days for the 33 g ai ha^{-1} rate and 5.8 days for the double rate.[46]

Insecticide Chlorantraniliprole. Chlorantraniliprole residues were detected on the rice hull; it was noted that the applications using the recommended rate at 5−15 DAF resulted in lower pesticide concentrations. This demonstrated that applications made closer to rice flowering using the recommended rate, would favor dissipation or degradation of this insecticide. For other treatments, greater concentrations were quantified, especially for the treatment with three sequential applications that showed the highest value (0.707 mg kg^{-1}).

The literature presents several hypotheses that may influence the concentration of pesticide residues in the irrigated rice ecosystem. Many of the hypotheses are not fully understood because of the numerous factors involved. Some of the primary factors that can influence the persistence of pesticides are time of application, weather conditions, pesticide characteristics, and pesticide translocation within the plant.[58]

However, the adsorption or absorption of insecticides in rice grains, specifically in rice hulls, can be directly associated with the composition of the rice hull, which consists of >90% silica,[59] characterizing the rice hull polarity and contributing to the sequestration of pesticides in rice hull.

Chlorantraniliprole residues were detected on the rice bran, and the detected values are 22% higher than the value detected on the rice hull. The results showed that greater concentration of pesticides was observed for the sequential applications at 5, 25, and 35 DAF at recommended rates and for one application at 60 DAF with double the recommended rate.

These results may be related to the characteristics of the insecticide, highlighting that this insecticide presents greater lipophilic character; thus, distribution on these high lipid content matrices is reasonable.[48] This characteristic can be directly associated with increased quantification of residues in rice bran due to the fact that rice bran has a high lipid content.[60]

No residues for the 5 DAF applications with the recommended rate were detected on the polished rice grain. However, for all other treatments, residues were detected for chlorantraniliprole, with the highest values detected for applications containing double the recommended rate. Applications with double the recommended rate at 25 DAF resulted in greater concentrations of residues when compared to sequential applications. This might be associated with a period of intense translocation of assimilates to the grain during rice grain filling.

Chlorantraniliprole studies in rice plants demonstrated that there was a reduction of 98% of applied insecticide in 14 days after the application independent of the applied rate (30 or 60 g ai ha^{-1}).[49] In brown rice grains (processed grains with no polishing process), chlorantraniliprole residues were detected for the applications done at 21, 14, and 7 days before rice grain harvest for both of the applied rates. The highest values were detected for applications done 7 days before harvest (8 μg kg^{-1}, recommended rate; and 19 μg kg^{-1}, 2 times rate), showing that applications done near rice harvest had the highest residue concentration. In general, there were increases of 74 and 84% in residue concentrations for the applications made at 7 days before harvest in comparison to the application done 21 days before harvest, with the recommended rate and 2 times rate, respectively.[49]

Insecticide Residue Distribution. The distribution of residues throughout the rice grain is presented in Figure 2. The highest concentrations of thiamethoxam were observed in rice hulls, except for applications done at 35 DAF, for which the highest concentration was observed in rice bran.

DOI: 10.1021/jf5042504
J. Agric. Food Chem. 2015, 63, 2119−2126

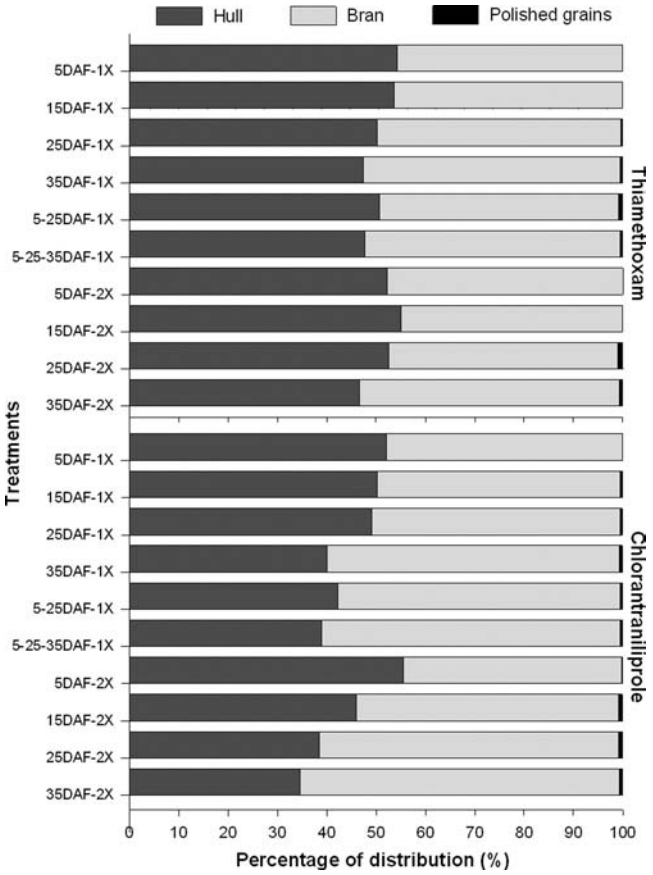

Figure 2. Percentage of thiamethoxam and chlorantraniliporle residues in rice hull, bran, and polished grains. Insecticides were applied at different timings after rice flowering using 1 and 2 times the recommended rate (30 g ai ha^{-1} recommended rate). DAF, days after flowering.

The highest concentrations in rice bran were found for the insecticide chlorantraniliprole, except for applications done at 5 DAF characterizing different behaviors between insecticides. A possible explanation could be that this pesticide is the most lipophilic compound; thus, its distribution on these high lipid content matrices is reasonable. The highest concentration of crude fat is in rice bran,[48] associated with higher concentrations of chlorantraniliprole. The rice hull and polished rice grains presented 96 and 97% less crude fat, respectively.[48]

The literature describes several factors that may influence how pesticide residues in plants may be affected by the time of application, application rate, weather conditions,[61] matrix chemical composition, pesticide lipophilicity, mode of action,[59] time of application, and weather conditions.[58] The correct pesticide residue distribution tendency on the rice grain is not clear; however, higher concentrations of pesticides have been detected on the rice hull and bran.[48]

For the rates applied in this study, the concentrations detected in polished rice grains were below the MRL set by Codex Alimentarius, the United States, the European Union, and the Brazilian Health Surveillance Agency (ANVISA). It is important to note that the MRLs are only for rice grain (Table 1).

It is important that management practices account for the limit of time between pesticide application and grain harvest. Overall, if the pesticides are applied according to good agricultural practices (GAP), MRLs are not exceeded; however, the misuse of these compounds is possible and may result in significant amounts of residues found in both food and the environment.[62,63] Corroborating this approach, there are no consolidated studies on concentrations of pesticide residues quantified in foods, especially those that exceed the maximum allowable limits for human consumption; the effects of accumulation of these compounds in humans are not yet known.[64,65]

In conclusion, the present study demonstrates that residues of thiamethoxam and chlorantraniliprole applied to rice were detected in hull, bran, and polished grains. Insecticide concentrations were higher in hull and bran, demonstrating the importance of evaluating the destination of a pesticide and its residues from the field to the final product.

elucidate the role of plant volatile diversity in ecology of this particular insect−plant interaction. The findings on alternative host plant species and the identification of behaviorally active volatile blends in relation to the development of control methods for pea moth are discussed.

MATERIALS AND METHODS

Insects. *C. nigricana* were collected as larvae from infested pea pods in pea fields near Ås in eastern Norway (59°67′N, 10°77′E). The cocoons formed by the larvae were kept over winter in sand substrate under outdoor conditions, and in the spring they were transferred to a cold climate chamber (4 ± 2 °C, 60−70% relative humidity [RH], 0:24 h L:D) as previously stipulated.[19] Approximately 4 weeks before the start of the experiments, the boxes containing the larval cocoons were transferred to Plexiglas cages (30 × 30 × 30 cm) placed in a climate chamber under warmer conditions (18 ± 2 °C, 60−70% RH, 18:6 h L:D) for eclosion. Emerging adults were allowed to mate and had access to 10% honey water solution and water until the start of experiments. Antennal recordings and wind tunnel tests were performed using five- to seven-day-old mated females. Virgin females and males were not tested, because their behavioral response to host plant odor was found to be very low in a preliminary study.[12] After the experiments, the females were dissected to verify their mating status, and only data on mated females were used in the analyses. In oviposition experiments, one male and one female of the same age (five to seven days old) were used.

Plants. As host plants for *C. nigricana*, we used the grain pea, *P. sativum* "Faust", and three other Fabaceae species that are common in the experimental area (Ås in eastern Norway): the broad bean, *Vicia fabae* "Threefold White", the bush vetch, *Vicia sepium*, and the sweet pea, *Lathyrus odoratus* "Old Spice Mixed". An experimental field of *P. sativum* (0.5 ha, square base) was established near Ås on May 6, 2013. On the same day, all four host species were sown in pots (diameter 20 cm) in Plantejord commercial substrate (Plantasjen Norge AS, Kolbotn, Norway). The pots were buried in the ground, and the plants were cultivated under field conditions in experimental cages (1.5 × 1 × 1.5 m, gauze pore size 500 μm) in a location close to the experimental pea field. For oviposition experiments and collection of volatiles, the potted plants were transferred from the field to the laboratory immediately before use.

Plant Phenology and Pea Moth Flight Activity in the Field. The phenology of the potted plants of the four Fabaceae species and the pea plants grown in the experimental field were recorded twice a week according to the BBCH scale, which uses a code to identify the phenological stage of a plant.[20] The flight of *C. nigricana* was assessed in the experimental pea field using E8E10-12AC commercial pheromone monitoring traps (Trifolio-M GmbH, Lahnau, Germany) that were placed in each corner of the field 3 m in from the edge. The trapped moths were counted twice a week during the entire flight period of *C. nigricana*.

Oviposition and Larval Performance. To test *C. nigricana* regarding host plant acceptance (oviposition) and host suitability (larval performance), we performed no-choice experiments and studied egg laying and larval development on the four selected plant species. Cylindrical plant cages (diameter 48 cm, height 65 cm, gauze pore size 500 μm) were placed in a climate chamber under approximately natural conditions for oviposition (18 ± 2 °C, 60−70% RH, 18:6 h L:D), and potted plants from the field (two flowers/plant) were placed individually in separate cages. A male and a female pea moth were kept in each cage for 3 days, and six such moth pairs were tested on each of the four plant species (n = 6). During the experiment, the moths had access to 10% honey water solution and water. The eggs deposited on the plants were counted daily during the three-day period. The plants bearing eggs were subsequently returned to the field, where the pots were again buried in the ground, and the plants were cultivated under field conditions in the field cages until the pods were fully mature. Harvested pods from each plant were placed on a metal net (mesh size 1.2 cm) mounted over a plastic box (15 × 15 × 5 cm) filled with moist sand to enable the late instar (L5) *C. nigricana* larvae to leave their pods, drop to the sand, and spin cocoons to overwinter. The cocoons were counted 4 weeks after pod harvest. To ensure unrestricted development during diapause, the boxes containing the cocoons were stored in an open greenhouse under outdoor conditions but protected against rain until the beginning of February 2014. At that time, the sand was moistened, and the boxes with the larval cocoons were transferred to a climate chamber (18 ± 2 °C, 60−70% RH, 18:6 h L:D) to allow eclosion. Eclosed adults were counted and sexed daily.

Volatile Collection and Chemical Analysis. Volatile compounds were collected from plants at full flowering,[20] using cut plant material from the field. Possible qualitative differences in the volatile profile of this cut material compared to intact plants were accepted in the experimental setup, based on strong behavioral responses to such cut material exhibited by pea moths in a previous study.[12] Headspace collection and analyses of volatile compounds were made according to previously reported protocols.[12] Batches of five aerations of each plant species were conducted for identification and quantification on combined gas chromatography and mass spectrometry (GC-MS). Volatile compounds were identified using Deconvolution Reporting Software (DRS, ver. A.02.00) (Agilent Technologies, Santa Clara, CA), which combines automatic MS deconvolution and identification software (AMDIS version 2.62, NIST), a MS library (NIST05 database), and GC-MS software (ChemStation ver. D.03.00) (Agilent Technologies). The AMDIS database contained 1187 volatile compounds, 240 of which connected to Kovats retention indices.[21] To obtain comparable retention times for all samples, the retention time was locked and referenced according to the internal standard heptyl acetate at 10.75 min using the ChemStation retention time-locking program. Peaks that were present in the chromatogram but were not identified by the DRS were manually interpreted using the NIST05 database. To ensure reliable identification, a match factor of ≥70 was employed.[22] Identification of compounds was verified by comparing mass spectra and Kovats indices with those obtained for synthetic standards on the same column. Enantiomers of chiral compounds were not available. Relative amounts of identified compounds were calculated by dividing the peak area (using the area from the total ion chromatogram) by the area of the internal standard heptyl acetate. The compounds α-pinene, (*Z*)-3-hexenal, and (*E*)-4,8-dimethyl-1,3,7-nonatriene were provided by Yngve H. Stenstrøm (Norwegian University of Life Sciences, Ås, Norway); all other compounds were acquired as standards from Aldrich, Fluka, and Chiron AS.

Electrophysiology. Antennal recordings were made by coupled gas chromatography−electroantennogram detection (GC-EAD) using a HP 6890N GC connected to an electroantennogram apparatus (Syntech, Hilversum, The Netherlands). The column used was a 30 m × 0.25 mm i.d, 0.25 μm, J & W Scientific DB-Wax (Agilent Technologies). After injection of a sample, the temperature was held at 40 °C for 0.5 min, subsequently raised 8.0 °C/min to 160 °C and then 25.0 °C/min to 230 °C, and thereafter held constant at 230 °C for 4.0 min. The total running time was 22.30 min. The effluent from the GC column was split at a ratio of 1:1 between the flame ionization detector (FID) and a pair of *C. nigricana* antennae. Preparation of antennae and connection to EAD were performed according to a previously reported protocol.[12] The antennal signal and the FID signal were amplified and recorded simultaneously using Syntech software. On the basis of the results of the first wind tunnel experiment, volatile collections from *L. odoratus* were selected as the most attractive alternative host plant odor. GC-EAD was performed using the headspace extracts of flowering *L. odoratus* and antennae from mated females (n = 6), and a compound was considered active if four of the six replicates induced an antennal response. The responses were verified by GC-EAD recordings obtained using synthetic standards. The following 17 compounds in headspace extracts were found to induce antennal responses in pea moth females and were tested as synthetic standards, using 10 ng of each compound being delivered to the antennae (n = 6), as described elsewhere:[13] (*Z*)-β-ocimene and (*E*)-β-ocimene (90% pure, mix of isomers *Z*/*E* 1:8), hexan-1-ol (98%), (*E*)-2-hexen-1-ol (96%), (Z)-3-hexenal (98%), (*E*)-2-hexenal (98%), octanal (98%),

[a]Compounds present in a given sample are denoted with an X. Detection threshold ~0.2 μg/100 g plant material. All compounds except those indicated in bold text were verified by comparison of Kovats retention index and mass spectra with synthetic standards. [b]RT, retention time. [c]RI, Kovats retention index, DB-Wax.

(*Z*)-3-hexenyl acetate (98%), (*Z*)-3-hexen-1-ol (98%), nonanal (95%), (±)-sabinene (75%), myrcene (90%), (±)-linalool (97%), (±)-β-caryophyllene (80%), phenylacetaldehyde (90%), (±)-citronellol (95%), and nerol (97%).

Wind Tunnel. The wind tunnel used in this study had a flight section of 67 × 88 × 200 cm and has been described previously.[23] The air flow through the tunnel was 30 cm/s, and inside the tunnel the light intensity was approximately 1000 lx, the temperature ranged from 20 to 22 °C, and the RH was 60−70%. An ultrasonic sprayer equipped with a conical nozzle (Sono-Tek corporation, Milton, NY) and connected to a model 102 syringe pump (CMA Microdialysis AB, Solna, Sweden) was used to introduce the volatiles in the tunnel as described previously.[12,13] *C. nigricana* females were placed individually in glass tubes (12.5 × 2.6 cm) and transferred to the room housing the wind tunnel 3 h before the start of the experiments. All wind tunnel tests were conducted 5 to 1 h before the scotophase, corresponding approximately to the natural period of highest pea moth activity. The tubes containing the female moths were placed separately in the downwind end of the tunnel, 30 cm above the floor and at a distance of 160 cm from the odor source, and then the moths were set free and allowed to respond to the odor for 6 min. The flight behavior of the females was observed during that time, and landings were recorded. The order of the tested treatments was randomized each experimental day.

Wind Tunnel Experiment 1. To assess the attraction of *C. nigricana* females to olfactory cues of different Fabaceae species without visual cues, we investigated the upwind orientation of mated females toward headspace extracts. Volatile collections from *P. sativum*, *V. fabae*, *V. sepium*, and *L. odoratus* were tested. For each plant species, 50 mated females were tested in five batches of 8−12 individuals, and each batch was tested on different days, with a total of 40−60 moths tested on each experimental day. All but one of the tested females responded (flight activation) to the headspace extract within the 6 min exposure period. On the basis of the recorded landing responses in this experiment, the headspace extract of flowering *L. odoratus* was selected as the most attractive alternative host plant odor for use in further analyses.

Wind Tunnel Experiment 2. The 17 compounds from flowering *L. odoratus* inducing antennal responses in mated *C. nigricana* were selected for a second wind tunnel experiment. In this experiment, five different blends of the mentioned compounds (denoted stimuli II_{WT}−VI_{WT}) were tested using the quantities and ratios identified in

DOI: 10.1021/jf505934q
J. Agric. Food Chem. 2015, 63, 2127−2136

flowering sweet pea plants by GC-MS analysis (Figure 4). The headspace extract of flowering *L. odoratus* (stimulus I_{WT}) was used as a control for natural odor. To identify the volatiles involved in attraction of pea moths, the 17-compound sweet pea flower mimic (stimulus II_{WT}) was split into a ten-compound blend (stimulus III_{WT}) and a seven-compound blend (stimulus IV_{WT}). The ten-compound blend contained the common sweet pea flower volatiles that were also emitted from flowering pea plants and the other Fabaceae species, whereas the seven-compound blend contained the more specific sweet pea flower volatiles that were not released by *P. sativum* (Table 1). Since substantial attraction of *C. nigricana* to a blend of (*Z*)-*β*-ocimene, (*E*)-*β*-ocimene, hexan-1-ol, and (*E*)-2-hexen-1-ol had been observed in wind tunnel and field tests in a previous study,[13] we also combined these four compounds with the sweet-pea-specific seven-compound blend to yield an 11-compound blend (stimulus V_{WT}). Furthermore, due to the dominance of (*Z*)- and (*E*)-*β*-ocimene in pea and sweet pea flowers, shown by GC-MS analyses in the present study and other investigations,[12,24−26] and the importance of these compounds in pea moth attraction,[13] we combined (*Z*)-*β*-ocimene and (*E*)-*β*-ocimene with the sweet-pea-specific seven-compound blend to obtain a nine-compound blend (stimulus VI_{WT}). For each odor stimulus, 50 mated females were tested in five batches of 8−12 individuals, and each batch was tested on different days, using a total of 40−60 moths on each experimental day. All but three of the tested females exhibited flight activation in response to the synthetic blends within the 6 min test period.

Field Experiment. To confirm attraction of mated female moths to the synthetic blends, we conducted a trapping experiment in 2013 in the experimental pea field near Ås. This square field was surrounded by birch forest (*Betula* spp.), with wheat (*Triticum aestivum*) and grassland in the immediate vicinity. The peas were sown on May 6, the first flower buds appeared on June 18, and the flowering period started on June 27. (*Z*)- and (*E*)-*β*-Ocimene were only available as a mixture of isomers at a ratio of 1:8, which corresponds approximately to the natural release of these compounds from pea flowers (12.6:110.0 ng/h (*Z*:*E*))[12] and sweet pea flowers (11.5:100.0 ng/h; GC-MS analyses in the present study). Therefore, the *β*-ocimenes were used at a *Z*:*E* ratio of 1:8 in all blends in the field, whereas all other synthetic compounds were present at a 1:1 ratio (Figure 5). The total load of active ingredients in each dispenser was always 9 mg. The blends were diluted in mineral oil and pipetted on dispensers consisting of 1 cm Parotisroll, size 5 cotton wicks (Roeko, Langenau, Germany) inserted into 1.5 mL Easy-Fit polypropylene microtubes (Treff, Degersheim, Switzerland). The dispensers were mounted in cardboard delta traps equipped with sticky yellow bottoms (16.5 × 18 × 13 cm) (Silvandersson Sweden AB, Knäred, Sweden). In the field, the traps were installed on metal stands (height 1.2 m, diameter 0.8 cm) above the vegetation. When the first flower buds appeared on the pea plants, the traps were placed in the borders of the field (3 m from the edge) 5 m apart. Trapped moths were counted and sexed twice a week over a period of 5 weeks (10 trap inspections) from calendar week (CW) 25 (18 June) until the end of the pea moth flight period (CW 31). The mating status of the moths caught in the traps was not investigated. On the basis of the results of the wind tunnel experiments, four field stimuli (II_F, III_F, IV_F, and VI_F) and a blank control (pure mineral oil) were tested (Figure 5). Stimulus V was not tested in the field experiment, because stimuli V and VI had induced similar responses in wind tunnel experiment 2 (Figure 4) and a preliminary field test. As natural flower control (stimulus I_F), detached flowers of *L. odoratus* were inserted separately in 1.5 mL polypropylene microtubes filled with water, and these tubes were then mounted in cardboard delta traps in the same manner as the dispensers containing the synthetic blends. The microtubes were furnished with fresh flowers and water refills daily. For each treatment, four traps were installed in the experimental field, one on each side (n = 4). The dispensers were replaced after 2.5 weeks, because preliminary tests had shown that they retain their attraction capacity for that length of time.[13] In addition to the kairomone traps containing the female attractants, pheromone traps were used in the field as described above. Neither pest infestation nor crop damage was recorded in this experiment, because the objective was to test attraction of *C. nigricana* to synthetic volatile blends in a natural setting, not to evaluate pest management efficacy.

Statistical Analysis. The data on proportion of landings in the wind tunnel and total number of moths trapped in the field experiment were subjected to Levene's test to evaluate variance homogeneity and, if necessary, were subsequently normalized using arcsine square root or log transformation. Differences between treatments were assessed by analysis of variance (ANOVA). Due to the factorial design of the field experiment, the interaction effects were evaluated in addition to the effects of individual factors. If significant *F*-values were obtained, treatment means were compared using Tukey's test.[27] Data recorded as repeated measures over time were analyzed by repeated measures ANOVA, considering dates of evaluation as repeated parameters and using AUC (area under the curve) estimates.[28] If ANOVA showed significant differences between treatments, Tukey's test was used for multiple comparisons. Individual ANOVAs were performed to identify particular time intervals in which treatment effects differed. In all analyses, a significance level of α = 0.05 was selected using SAS 9.2 (SAS Institute Inc., Cary, NC).

RESULTS AND DISCUSSION

Selection of Attractive Alternative Host Plant Species. Several studies have shown that *C. nigricana* can use a number of pea-related herbaceous legumes as host plants, although *P. sativum* is the preferred host.[9−11] However, to our knowledge, no previous investigations have compared different Fabaceae species with regard to the attraction and oviposition responses they induce in pea moth females or their suitability for development of pea moth larvae. Therefore, we compared the phenology, and particularly the flowering period, of four Fabaceae species that can serve as host plants for *C. nigricana*, which showed that the wild-growing bush vetch *V. sepium* flowered much earlier than the other three tested species (Figure 1). The cultivated pea *P. sativum* and the broad bean *V. fabae* flowered at approximately the same time, and the sweet pea *L. odoratus* flowered later (Figure 1). Even though these four Fabaceae species had different flowering periods, they were all in bloom during the period of pea moth flight activity (Figure 1). In this study, we compared the phenologies of four host plant species, all sown on the same day. These species probably exhibit shifts in phenology as a function of abiotic or biotic parameters, such as sowing date, climatic conditions, or pest infestation. Nevertheless, a general concurrence of host plant flowering and pea moth flight activity can be assumed for

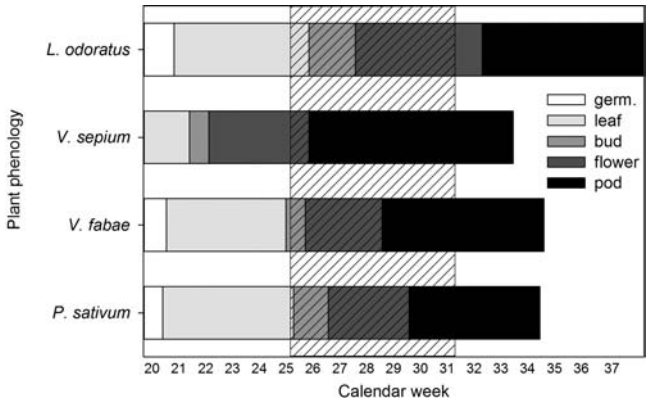

Figure 1. Phenology (germination, leaf, bud, flower, and pod stages) from sowing to harvest shown for the four tested host plant species *P. sativum*, "Faust", *V. fabae*, "Threefold White", *V. sepium*, and *L. odoratus*, "Old Spice Mixed". The diagonal shading indicates the period of pea moth flight activity in the experimental area.

J. Agric. Food Chem. 2015, 63, 2127−2136

the four species, as has previously been shown for *P. sativum*.[14,15,29−31] Such synchronization of the periods of host plant flowering and pea moth flight activity enables newly hatched larvae to penetrate emerging pods, in which they will have access to nutrition and be protected during development.

The wind tunnel experiments testing attraction of mated *C. nigricana* females to volatile collections of the four host species revealed significant differences (ANOVA: $F = 78.71_{3,16}$, $P < 0.001$) (Figure 2A). The landing response to headspace volatiles was markedly high for flowering *L. odoratus* (74%) and high for flowering *P. sativum* (56%) but was much lower for *V. sepium* (32%) and *V. fabae* (22%) (Figure 2A). There were also statistically significant differences in oviposition and larval performance on the four host species (ANOVA: $F_{eggs} = 21.48_{3,20}$, $F_{cocoons} = 15.79_{3,20}$, $F_{adults} = 33.00_{3,20}$, $P < 0.001$) (Figure 2B). Although mated females were more extensively attracted to *L. odoratus* than to *P. sativum* in the wind tunnel (Figure 2A), similar numbers of eggs were observed on both those host species in the oviposition experiments (9.7 and 10.5 eggs/plant, respectively) (Figure 2B). Moreover, for *L. odoratus* and *V. fabae*, there were similar numbers of eggs per plant (9.7 and 6.6) (Figure 2B) but higher upwind attraction of female moths to the former species than to the latter (Figure 2A). Also, there was similar attraction to *V. fabae* and *V. sepium* in the wind tunnel (Figure 2A), which did not correspond to the significantly lower number of eggs on *V. sepium* compared to *V. fabae* (0.8 versus 6.6) (Figure 2B). These discrepancies between attraction to a host plant odor (host location) and egg deposition on the plant (host acceptance) might be explained by specific behavioral decisions made during different steps of the host plant selection process.[32,33] However, both upwind orientation in the wind tunnel and oviposition in cage experiments showed that female moths preferred *P. sativum* and *L. odoratus* over *V. fabae* and *V. sepium*.

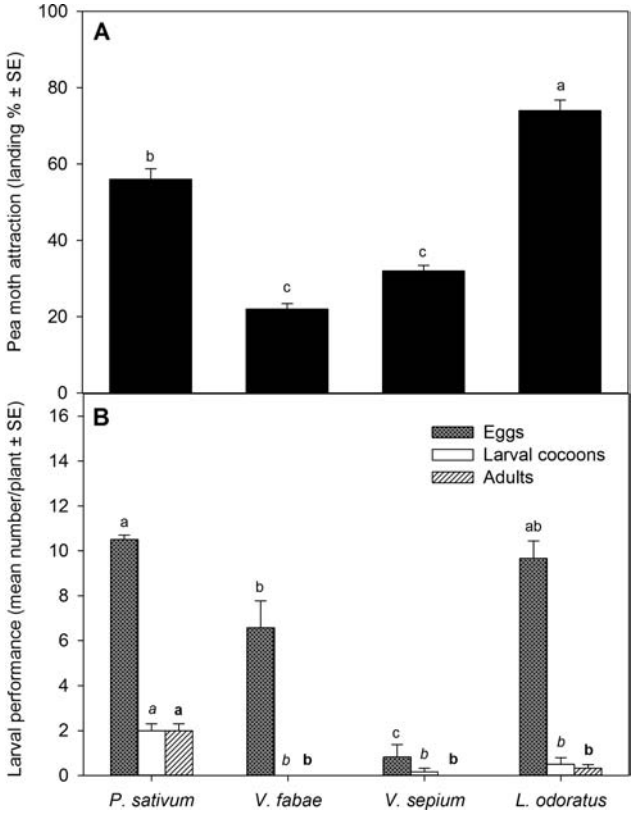

Figure 2. Attraction responses of mated *C. nigricana* females to headspace extracts from the four host plant species *P. sativum*, *V. fabae*, *V. sepium*, and *L. odoratus* recorded (A) in the wind tunnel, and (B) as oviposition and larval performance. The behavioral responses in the wind tunnel are presented as proportion (±SE) of female landings on the odor source ($n = 50$ for each plant species). Statistically significant differences are indicated by lower case letters (ANOVA, Tukey's test). Oviposition and larval performance are presented as mean number of eggs, larval cocoons, and emerging adults (±SE) on each plant ($n = 6$) of the four tested species. The four plant species were compared separately regarding phenological stages of *C. nigricana*: eggs (lower case letters), larval cocoons (lower case letters in italics), and adults (lower case letters in bold). Columns marked with the same letter indicate no statistically significant difference (ANOVA, Tukey's test).

Regarding larval performance on the four tested Fabaceae species, *P. sativum* appeared to be the most suitable host (Figure 2B). The highest mean numbers of cocoons and emerging adults per plant were found on *P. sativum* (both 2.0). By comparison, there were no or only low numbers of cocoons and adults on *L. odoratus* (0.5 cocoons, 0.3 adults), *V. sepium* (0.2 cocoons, 0 adults), and *V. fabae* (0 cocoons, 0 adults), indicating that those three species showed only limited or even no suitability as larval hosts (Figure 2B). For *P. sativum*, on average one larva survived on each developing pea pod, bearing in mind that the plants used in the experiments had two flowers each. The comparatively high number of eggs per pea plant and low survival of larvae (10.5 eggs compared to two cocoons and two emerging adults) might have been the result of the no-choice experimental design, which forced a female to lay her eggs on the only plant available. Consequently, the larvae might have cannibalized each other, because there were not enough seeds as a food source for all of them. An average infestation rate of one pea moth larva per pea pod has been observed in other studies.[14,15] Larger scale no-choice experiments (i.e., using more than one plant of the same species) and choice experiments using the four host species evaluated in the present study are needed to verify plant preferences. Also, a broader range of alternative host species should be tested to better elucidate the insect−plant interactions between the pea moth and Fabaceae species, as well as the underlying ecological mechanisms. However, the previously described high attractiveness and suitability of *P. sativum* for *C. nigricana*[10,11,14,15,29,30] were confirmed by the present study. In addition, the sweet pea *L. odoratus* was found to be highly attractive to *C. nigricana* females and moderately suitable for performance of larvae. The Mediterranean area and Asia Minor are the native habitat of wild pea and sweet pea, and there is evidence that both these species were originally short and bushy plants that had maroon-purple flowers and similar but stronger scents than they have today.[34,35] These similarities suggest coevolution of host plants and pest, which would explain why, like *P. sativum*, *L. odoratus* is highly attractive to *C. nigricana* as a host.

Identification of Volatiles Involved in Olfactory Host Recognition. We observed that the 17 compounds (*Z*)-*β*-ocimene, (*E*)-*β*-ocimene, hexan-1-ol, (*E*)-2-hexen-1-ol, (*Z*)-3-hexenal, (*E*)-2-hexenal, octanal, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexen-1-ol, nonanal, sabinene, myrcene, linalool, *β*-caryophyllene, phenylacetaldehyde, citronellol, and nerol were released from flowering sweet pea plants and induced antennal responses in pea moth females (Table 1; Figure 3). We did not determine which enantiomers of the chiral compounds sabinene, linalool, *β*-caryophyllene, and citronellol were produced by the plants, and therefore it is unclear whether

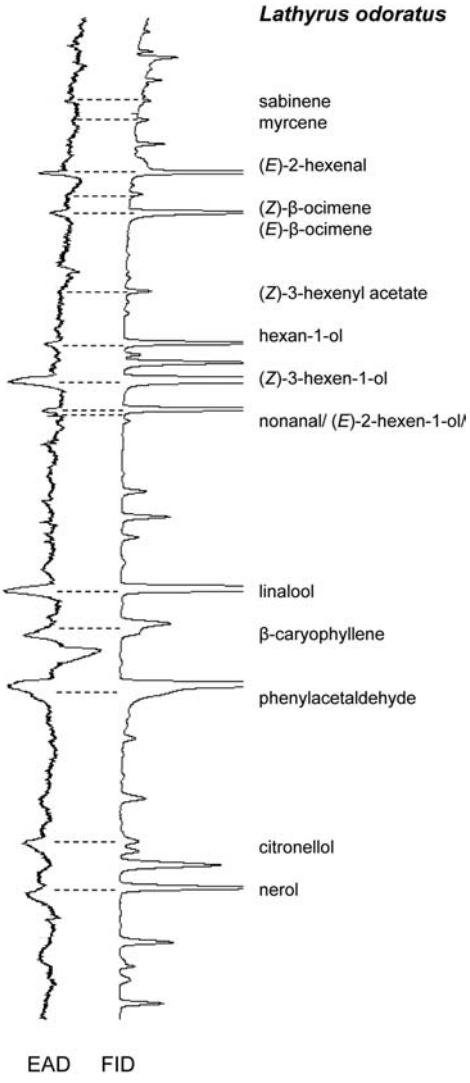

Figure 3. Example of simultaneously recorded GC-EAD analysis of volatiles from a flowering sweet pea plant (*L. odoratus*). The left trace represents the antennal responses (EAD) of a *C. nigricana* female, and the right trace shows the flame ionization detection responses (FID). (Z)-3-Hexenal and octanal were released from flowering sweet pea plants in small amounts (mean values 0.5 and 0.4 ng/h, respectively) and were not found in the headspace replicate used in the illustrated GC-EAD recording.

the correct enantiomers of those compounds were tested in subsequent experiments using synthetic standards. Notwithstanding, the behavioral responses recorded in further bioassays showed that the synthetics that were used were indeed active. (*Z*)-3-Hexenal and octanal were released in low and varying amounts (mean values 0.5 and 0.4 ng/h, respectively), and thus antennal responses to those two compounds were not recorded in all replicates (Figure 3). It can be mentioned that in previous studies,[12,13] (*Z*)-3-hexenal and octanal were found to be released from flowering *P. sativum* plants and elicit antennal responses in female *C. nigricana.* Figure 3 illustrates a typical example of antennal responses to sweet pea headspace extracts. Not all 17 compounds were found in all replicates (e.g., Figure 3, (*Z*)-3-hexenal and octanol are missing), and some compounds induced low antennal responses, such as sabinene, myrcene, and (*Z*)-3-hexenyl acetate. This highlights the natural variation in volatile emissions from *L. odoratus* plants and provides an indication of the plasticity necessary in odor detection by the moths.[3,5,18] Nonetheless, antennal responses to all 17 compounds were verified using synthetic standards, and therefore we included all 17 of the above-mentioned sweet pea volatiles in further behavioral assays. Odor profiles similar to those we recorded for flowering *L. odoratus* have been reported for other cultivars, including wild sweet pea, and showed (*E*)-*β*-ocimene and linalool as the predominant volatiles.[24−26,35] All 17 compounds we selected are ubiquitous volatiles in several plant species.[1,36] The ten compounds (*Z*)-*β*-ocimene, (*E*)-*β*-ocimene, hexan-1-ol, (*E*)-2-hexen-1-ol, (*Z*)-3-hexenal, (*E*)-2-hexenal, octanal, (*Z*)-3-hexenyl acetate, (*Z*)-3-hexen-1-ol, and nonanal were emitted by all four of the tested Fabaceae species (Table 1), whereas the other seven compounds (sabinene, myrcene, linalool, *β*-caryophyllene, phenylacetaldehyde, citronellol, and nerol) were released by flowering *L. odoratus* but not by flowering *P. sativum*.[12,24,25] Hence, *L. odoratus* headspace contained additional compounds that elicited antennal responses in female *C. nigricana* compared to those found in headspace extracts from all tested Fabaceae species. This finding suggests that *C. nigricana* has the physiological capacity to detect a broad range of compounds from the different host plants, as has previously been shown for the tortricid species *Lobesia botrana* and its two host plant species the wild-growing *Daphne gnidium* and the colonized *Vitis vinifera*.[18]

Behavioral Responses to Synthetic Blends in the Wind Tunnel and the Field. In the wind tunnel, the 17-compound synthetic mimic of flowering sweet pea (stimulus II_{WT}) caused marked attraction of mated *C. nigricana* females (66% landing) that was nearly as pronounced as that induced by the headspace extract of flowering *L. odoratus* (stimulus I_{WT}, 76% landing) (Figure 4). For the ten-compound blend containing the common volatiles of the flowering Fabaceae species (stimulus III_{WT}), the level of attraction was significantly lower (26% landing; $F = 30.98_{5,24}$, $P < 0.001$) when using natural quantities and the same ratios as found for *L. odoratus* (Figure 4). In a previous wind tunnel study,[12] testing of the same ten-compound blend, also in natural quantities but at ratios found for *P. sativum* "Avola", had resulted in 34% landing of *C. nigricana* females. Comparison of these responses in upwind orientation to the compounds found to be common to both hosts but released in species-specific ratios (i.e., 26% landing using the *L. odoratus*-specific ratio versus 34% landing using the *P. sativum*-specific ratio) suggests a certain plasticity in the host recognition behavior toward the ratio of behaviorally active volatiles.[3,5,18,37] However, attractiveness to females was substantially increased by combining sweet-pea-specific volatiles with the ten common volatiles (compare stimulus II_{WT} with stimuli III_{WT} and IV_{WT}) (Figure 4). Accordingly, the release of olfactory cues common to several host plant species cannot be the sole mechanism mediating host recognition in *C. nigricana.* No significant difference in attractiveness was found between the sweet-pea-specific seven-compound blend (stimulus IV_{WT}, 40% landing) and the ten-compound blend (stimulus III_{WT}, 26% landing; $F = 30.98_{5,24}$, $P = 0.069$) (Figure 4). However, combining stimulus IV_{WT} with either of two subsets of the ten common compounds (stimulus V_{WT} or VI_{WT}) resulted in increased attraction (64% and 62% landing, respectively; $F = 30.98_{5,24}$, $P < 0.001$) that was at nearly the same level as that elicited by the 17-compound sweet pea mimic (66% landing) and by the headspace of flowering *L. odoratus* (76% landing) (Figure 4). The importance of the

Figure 4. Behavioral responses of mated *C. nigricana* females to headspace extracts of flowering *L. odoratus* (stimulus I_{WT}) and blends of synthetic sweet pea flower volatiles (stimuli II_{WT}–VI_{WT}) in the wind tunnel. The release rates of the synthetic compounds correspond to the natural release rates (ng/h) of volatiles from flowering sweet pea plants. The responses are presented as proportion (±SE) of female landings on the odor source (n = 50 for each stimulus). Statistically significant differences are indicated by lower case letters (ANOVA, Tukey's test).

volatiles from the two subsets (i.e., (*Z*)-*β*-ocimene, (*E*)-*β*-ocimene, hexan-1-ol, and (*E*)-2-hexen-1-ol) for host location by mated *C. nigricana* females and for insect attraction in general has been shown in previous investigations[13,36,38] and was verified in the present study. Overall, the current wind tunnel results indicated that, in addition to common host plant volatiles, more species-specific compounds influence host recognition.[4,5] Moreover, our results indicate additive effects between common and more specific host plant volatiles, provided they are presented in the context of the correct blend, which agrees with earlier investigations and the hypothesis of ratio-specific odor recognition.[3−5,13,18,39,40]

We performed field studies using traps to confirm the wind tunnel findings in a natural setting. The trap catches recorded demonstrate that our synthetic host volatile blends had a significant impact on the behavior of pea moths despite the presence of a complex background odor. Moths in the field were attracted to the traps even though we tested 1:1 ratios of the synthetic host volatiles, rather than ratios corresponding to the natural release from the host plant as we had used in the wind tunnel experiments. We accepted this flaw in our experimental set up, because the varying evaporation of the single synthetics makes it difficult to achieve constant ratios corresponding to natural plant volatile emissions over time in a field experiment. However, the behavioral significance of our synthetic host volatile blends was apparent in the presence of a complex background odor in the field, which together with the findings of the wind tunnel experiments supports the coincidence detection theory.[3,4,6−8]

Only single *C. nigricana* males were caught in the kairomone traps (stimuli II_F, III_F, and VI_F) (Figure 5), whereas large numbers of males were attracted to the pheromone traps (Figure 6A), which demonstrates the importance of the floral host plant volatiles for attraction of females. The tested Fabaceae volatiles were attractive only to pea moth females in the field experiment, which is in contrast to other studies of species such as *C. pomonella* showing that both sexes were attracted to host plant volatiles tested in the field.[16,41] Other investigators have reported that *C. nigricana* starts mating at the emergence site and not on the host plant, and mated females subsequently migrate toward their host plants, often over long distances,[12] whereas *C. pomonella* males and females locate their host plants and then mate directly on the plants.[41,42] These differences in mating behavior of the two *Cydia* species might explain the selectivity of pea moth females we observed in relation to host plant volatiles. Detailed studies of sex and mating status of the pea moth in relation to moth migration and attractiveness of plant volatiles in a natural setting would help clarify the overall host location behavior of *C. nigricana*.

In our study, the most extensive attraction of females (total mean catch 35 females/trap) was induced by natural odor of sweet pea flowers (stimulus I_F) followed by the 17-compound

Figure 5. Overall trap captures (mean number ± SE/trap) of *C. nigricana* males and females responding to a natural sweet pea flower control (stimulus I_F, detached flowers of *L. odoratus* mounted in delta traps; $n = 4$) and to blends of synthetic sweet pea flower volatiles (stimuli II_F, III_F, VI_F, and VI_F; each $n = 4$). The captures were recorded in an experimental pea field in eastern Norway as a cumulative value of 10 trap inspections over a period of 5 weeks. Differences between stimuli over the entire experimental period are indicated by lower case letters (ANOVA, Tukey's test).

synthetic sweet pea mimic (stimulus II_F, mean catch 26.5 females/trap) (Figure 5). As in the wind tunnel test, a significantly lower level of attraction ($F = 90.60_{4,15}$, $P < 0.001$) was observed in the field experiment for the ten-compound blend containing the common volatiles (stimulus III_F, 11 females/trap) and the sweet-pea-specific seven-compound blend (stimulus IV_F, 8 females/trap). Combining stimulus IV_F with (*Z*)- and (*E*)-*β*-ocimene (stimulus VI_F) significantly increased attraction ($F = 90.60_{4,15}$, $P < 0.001$), with an additive effect (19.25 females/trap) (Figure 5). However, in the field the attraction to stimulus VI_F was not as pronounced as that elicited by the 17-compound sweet pea mimic (stimulus VI_F versus II_F; $F = 90.60_{4,15}$, $P = 0.008$) (Figure 5) as observed in the wind tunnel (stimuli VI_{WT} and II_{WT}) (Figure 4). The influence of complexity of vegetation on arthropod orientation in a natural setting, i.e., the effects of plant species diversity and corresponding plant volatile diversity in the field on arthropod behavior, and the impact of background odor in this context have been discussed[6−8,41,43] and demonstrated for the pea moth and pea plants in a natural setting in a previous study.[13] In the present investigation, phenological stage-specific emission of volatiles from the pea crop[12] may also have affected orientation of *C. nigricana* females toward the synthetic lures that were used in the field (compare trap catches for CW 26/27 with those for CW 27/28 to CW 29/30) (Figure 6B). However, trap catches in the field can also be influenced by the size of the insect population, and there are often unexpected differences in trap catches when examining a small population (e.g., CW 26/27) (Figure 6B). Thus, an effect of pea phenological stage-specific volatile emissions on female attraction to synthetic odor cues is difficult to discern in the results of our field experiment. Nonetheless, those experimental findings might suggest that insect orientation in a natural environment is influenced not only by diversity of plant volatiles related to the diversity of plant species in the surroundings of a pea field but possibly also affected by other potential differences in volatile emissions associated with factors such as host plant phenology.[6,7,44] Considering the overall chemical complexity that exists in a natural setting, the following scenario is plausible: for a herbivorous insect that is a specialist on specific Fabaceae species, being able to perceive combinations of common and more species-specific host plant volatiles, as well as the ratios between those compounds, represents a reliable mechanism for locating the most suitable host plants.[2−5]

In insects in general, allelochemicals such as plant volatiles are fundamental signals for plant−insect interaction, and hence in some cases such chemicals can be used to control insect pests by modifying their behavior. For example, attractant host plant volatiles provide tools for monitoring the occurrence and reproductive status of females, which is an essential element in pest management. This is particularly important when dealing

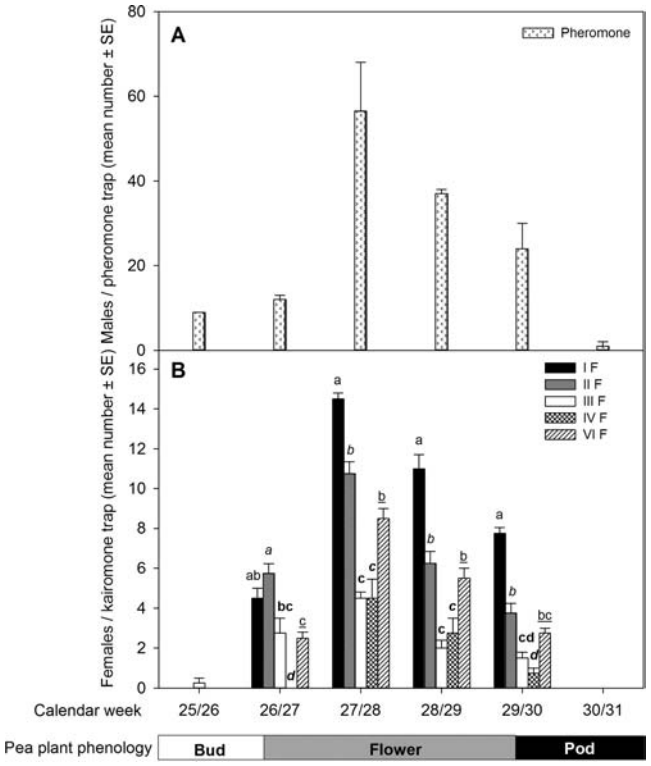

Figure 6. Weekly trap captures (mean number ± SE/trap) of *C. nigricana*: (A) males responding to sex pheromone (E8E10−12Ac), and (B) females responding to a natural sweet pea flower control (stimulus I_F, detached flowers of *L. odoratus*, mounted in delta traps, n = 4) and to blends of synthetic sweet pea flower volatiles (stimuli II_F, III_F, IV_F, and VI_F; each n = 4), shown together with the corresponding pea plant phenology. Observations were made in an experimental pea field in eastern Norway over a period of 5 weeks. Differences between stimuli for a particular (weekly) time interval are indicated by lower case letters (ANOVA, Tukey's test).

with pest species in which intraspecific communication is based on female-produced pheromones that attract only males, as is seen in the pea moth. Several methods aimed at controlling such pests have been developed by exploiting female attraction to volatile cues.[45−47] Flower volatiles are components of plant scents that are notably strong attractants for many different insects,[36,38] and synthetic floral attractants have been developed for several moth species.[48−50] Most such synthetics attracting female insects are based on volatiles that mimic a particular enticing host odor. An alternative approach is called "super-blending", which uses combinations of synthetic attractants that are not found in natural settings but represent various classes of volatile compounds regardless of the odor source (e.g., host or nonhost plants).[46,47] In the present study, a previously identified synthetic attractant for *C. nigricana* females[12,13] was improved by combining attractive flower volatiles from the main host plant *P. sativum* with those from an alternative host plant species, the sweet pea *L. odoratus*. In the long term, these results may serve as a basis for development of a kairomonal attractant that can be used to control *C. nigricana*. The efficiency of kairomones for pea moth control is being tested in an ongoing field study.

Cabernet Sauvignon, Durif, Mourvedre,[11] Schioppettino, and Vespolina, and in a white variety, Grüner Veltliner.[12] Schioppettino, Vespolina, and Grüner Veltliner are noted for their very "peppery" character and have correspondingly high concentrations of rotundone.[12] The concentration of rotundone in berries is extremely low at veraison but increases rapidly during ripening to reach maximal levels at harvest.[13] Studies of a range of varieties, including Shiraz, have shown that rotundone concentrations vary considerably between seasons and vineyard locations and even within vineyards, but as yet, there are no definitive data regarding the causal factors for this variation.[11−14]

In this paper, we describe the use of two different PGRs (Ethrel and NAA) to delay Shiraz berry ripening and how these treatments altered the profiles of a range of volatile flavor/aroma metabolites, the concentrations of rotundone and the sensorial properties of wine made from treated and control fruit.

MATERIALS AND METHODS

NAA and Ethrel Treatment of Field-Grown Shiraz Berries. *Vitis vinifera* L. cv Shiraz vines, on own roots, were grown on well-drained soil, with vertical shoot positioning trellising, at Hahndorf in the Adelaide Hills (−35°.02, 138°.84, elevation 400 m). Natural rainfall was supplemented by limited drip irrigation as required. Bunches were sprayed to runoff during the preveraison period with 50 mg/L NAA (Gibco BRL Life Technologies, Grand Island, NY) in 0.1% (v/v) Chemwet 1000 (Nufarm, Laverton North, VIC, Australia), (2-chloroethyl)phosphonic acid as Ethrel at 300 μL/L (Bayer Crop Science, East Hawthorn, VIC, Australia) in 0.1% (v/v) Chemwet 1000, or a 0.1% (v/v) Chemwet 1000 solution alone (control). Spray dates were as follows: for control and Ethrel, January 16, 2012 (8 days preveraison of control berries), and January 23, 2012 (1 day preveraison of control berries); for NAA treatment, January 23, 2012, and January 27, 2012 (3 days postveraison of control berries). Veraison was defined as the sample date previous to the first sample showing an increase in Brix value of more than two degrees per week. There was no precipitation during the 48 h period after each spray treatment. The trial was of a randomized triplicate design, and the sample size per replicate was 400 bunches (1200 bunches per treatment). Samples of 60 randomly harvested berries per replicate were taken throughout development (the sampling dates are indicated in Figure 2). Sampling was completed between 09:30 and 14:30 h. Berries were weighed, and total soluble solids (TSS) were measured for each of these replicates as described below. Anthocyanins were measured at two time points, February 14, 2012, and at harvest (which was different for each of the treatments), as described below. Minimum and maximum air temperatures (Figure S1 of the Supporting Information) for a site located near the vineyard (−35°.07, 138°.84) were obtained from the Australian Bureau of Meteorology (www.bom.gov.au).

Determination of Anthocyanin and Total Soluble Solid Levels. Frozen whole berries were ground to a powder using an IKA A11 basic analytical mill (IKA, Staufen, Germany). For the measurement of TSS (degrees Brix), 100 mg of berry powder was thawed on ice, the tissue was pelleted by centrifugation at 18000*g* for 5 min, and the supernatant was analyzed with an RFM710 digital refractometer (Bellingham Stanley, Tunbridge Wells, U.K.). For anthocyanin determination, 300 mg of a powdered sample was added to 1.5 mL of MeOH containing 1% (v/v) HCl. Anthocyanins were extracted at room temperature in the dark on a rotating mixer for 1 h. The tissue was pelleted by centrifugation at 18000*g* for 15 min and the supernatant retained. Depending on the developmental stage, the supernatant was diluted up to 20-fold with MeOH and 1% (v/v) HCl. Total anthocyanins were measured spectrophotometrically by reading the absorbance at 520 nm immediately following centrifugation. One-way ANOVA followed by Duncan's post hoc test was performed using IBM SPSS version 20 (IBM, Armonk, NY).

Small Scale Winemaking. Small scale winemaking was conducted by WIC Winemaking Services (Urrbrae, SA, Australia) using the following protocol. Control, Ethrel-treated, and NAA-treated fruit (20 kg for each of three replicates per treatment) were harvested at the times indicated in Figure 2. Harvested fruit was placed at 0 °C for 12 h, and the SO_2 concentrations were adjusted to 50 ppm during crushing and destemming. Yeast strain EC1118 (Lallemand, Edwardstown, SA, Australia) was added to a concentration of 200 ppm. The ferment was conducted on skins at 18−20 °C, and diammonium phosphate was added as required to a maximal concentration of 400 ppm. The cap was plunged 20 times twice daily. When the must reached 2°Baume, the must was pressed and then fermented to dryness, following which it was racked. SO_2 was added to a concentration of 60 ppm, and the wine was cold stabilized at 0 °C for 21 days. The wine was again racked, and SO_2 concentrations were adjusted to 80 ppm before being filtered and bottled with 30 × 60 Stelvin closures (Amcor, Hawthorn, VIC, Australia).

Sensory Analysis of Small Scale Wines. Detailed sensory profiles of all wines were generated by descriptive analysis (DA) conducted at the University of Adelaide sensory laboratory, which complies with international standards for the design of test rooms (ISO 8589:1988). The trained DA panel consisted of 12 members (eight female and four male, mean age of 36 years, ranging from 24 to 57) and underwent three 2 h training sessions, including evaluation of all wine samples before final assessment. The panel generated a standard list of vocabulary terms to profile the differences between the wines for appearance, aroma, palate, mouthfeel, and aftertaste. Reference standards (Table S2 of the Supporting Information) were developed to help clarify some of the aroma sensory attributes and ensure full agreement across assessors. The DA final assessment was conducted in triplicate in individual booths with panel members tasting up to 14 samples per day. Panelists received a sample volume of 30 mL served at 21 °C in 214 mL standardized tasting wine glasses (ISO 3591:1977). Each wine glass was covered with a watch glass to prevent headspace loss, and samples were poured immediately before being served to the assessor. Samples were blind-coded with random three-digit codes, and the order of sample assessment was randomized to account for first-order and carryover effects. Processed water crackers and water were consumed between samples to minimize carryover effects, and an interstimulus interval of at least 1 min was chosen as a suitable time between samples with a 5 min interval after flights of six wines. Panelists had access to and were encouraged to use all reference samples throughout final assessment. The experimental design was produced using the design generation package Design Express (Qi Statistics, Reading, U.K.). Attributes were rated on 0−15 line scales, with indented extreme end word anchors for each descriptive term. Data were recorded and stored using Fizz sensory data acquisition software (Biosystèmes, Couternon, France).

ANOVA was conducted to test the effects of Judge, Sample, Replicate, and all two-way interactions for each sensory attribute using a pseudomixed model with the Judge × Sample interaction as a denominator. IBM SPSS version 20 (IBM) was used for these analyses.

Nontargeted Headspace Volatile Analysis. SPME−GC−MS was used to analyze the volatile constituents of the wines produced from the control and treated fruit. Aliquots of the wines were analyzed at two different concentrations, 1:100 or 1:2 diluted with H_2O to a final volume of 10 mL. Three grams of NaCl was added to each SPME vial (20 mL) prior to sample addition.

The extraction and chromatographic conditions were identical to those described by Boss et al.[15] The identity of detected volatiles was determined by comparing mass spectra with those of authentic standards and spectral libraries. A laboratory-generated library (328 compounds) as well as the U.S. National Institute of Standards and Technology-11 (NIST-11) and the Wiley Registry 9th Edition mass spectral libraries were used for identification purposes. Compounds were considered positively identified after matching of both mass spectra and linear retention indices (LRI) with those of authentic samples. LRI was calculated from a compound's retention time relative to the retention of a series of *n*-alkanes (C_8−C_{26}). Other compounds

DOI: 10.1021/jf505491d
J. Agric. Food Chem. 2015, 63, 2137−2144

were tentatively identified on the basis of comparison with mass spectral libraries and published LRI, or comparisons with mass spectral libraries alone.

The components of the samples were quantified using Chemstation (Agilent, Forest Hill, VIC, Australia) relative to the relevant internal standard (d_{13}-hexanol, d_{11}-hexanoic acid, d_{16}-octanal, methyl nonanoate, or d_3-linalool) using the peak area of an extracted ion.

The effect of applying Ethrel and NAA to bunches on the concentration of volatiles in the headspace of the wines was analyzed by ANOVA using SPSS version 20 (IBM).

Synthesis of Rotundone and d_5-Rotundone. Guaiacwood essential oil was purchased from Auroma (Hallam, VIC, Australia). All reagents were purchased from commercial sources and used directly if no specific purification is mentioned.

The synthesis of rotundone (**4**) and d_5-rotundone (**5**) began with the synthesis of α-guaiene (**3**), which was prepared from guaiol (**1**) via acetylation and pyrolysis as described by Huang et al.[16] Rotundone (**4**) was then synthesized by one-step allylic oxidation of α-guaiene (**3**) by pyridinium dichromate (PDC) and *tert*-butyl hydroperoxide (TBHP) as described by Huang et al. (Figure 1).[17] d_5-Rotundone was synthesized by deuterium exchanged of rotundone with d_6-ethanol as described by Huang et al.[18]

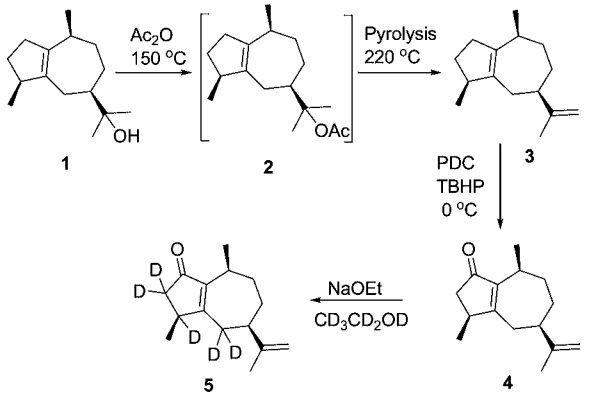

Figure 1. Synthesis of rotundone and d_5-rotundone from guaiol.

Rotundone Quantification. The method used for the extraction and analysis of rotundone was derived from ref 19. Styrene-divinylbenzene SPE cartridges (SDB-L, 500 mg/6 mL; Phenomenex, Lane Cove, NSW, Australia) were conditioned with a 10 mL *n*-pentane/ethyl acetate solvent (4:1), followed by 6 mL of methanol and then 6 mL of model wine (12% ethanol and 2 g/L potassium hydrogen tartrate, buffered to pH 3.2 with tartaric acid). A 100 mL aliquot of wine, containing 24 ng of d_5-rotundone in 100 μL of ethanol as an internal standard, was loaded onto the SPE cartridge. The cartridge was then washed with 10 mL of water followed by 2 mL of *n*-pentane and finally eluted with 10 mL of *n*-pentane/ethyl acetate solvent (9:1). This eluent was dried under a stream of N_2 and then redissolved in 1 mL of ethanol. The extract was added to a 20 mL amber SPME vial [Chromacol, Biolab (Aust) Ltd., Clayton, VIC, Australia] with 13 mL of aqueous tartrate buffer (2 g/L potassium hydrogen tartrate, buffered to pH 3.2 with tartaric acid) and analyzed by SPME−GC−MS.

SPME−GC−MS analysis was performed using an Agilent Technologies 7890A gas chromatograph coupled to a 5975C mass spectrometer with a MPS2 autosampler (Gerstel, Mülheim an der Ruhr, Germany). A polydimethylsiloxane/divinylbenzene 65 μm fiber (Supelco, Bellefonte, PA) was immersed in the sample for 60 min at 40 °C with agitation and then was desorbed in the inlet at 240 °C for 1 min in pulsed-splitless mode. A pressure pulse of 25.0 psi was applied for 30 s, and the flow was split with a total flow of 50 mL/min after 1 min. The fiber was cleaned for 4 min prior to extraction and also after desorption in a Gerstel fiber bake-out station at a temperature of 240 °C.

GC separation was performed on a 30 m ZB-Wax capillary column with an internal diameter of 0.25 mm and a film thickness of 0.25 μm (Phenomenex). Ultra High Purity Helium was used as a carrier gas with a constant flow rate of 1.0 mL/min. The oven temperature was initially held at 80 °C for 1 min and then increased to 220 °C at a rate of 3 °C/min, before being increased to 245 °C at a rate of 40 °C/min and then held at this final temperature for 10 min. The mass spectrometer transfer line was held at 250 °C. Selected ion monitoring (SIM) mode was used with ions at m/z 223 and 218 as the selected ions for quantification of d_5-rotundone and rotundone, respectively, and ions at m/z 147, 161, and 203 as the qualifying ions for rotundone and ions at m/z 147, 161, and 208 as the qualifying ions for d_5-rotundone (dwell time of 30 ms, electron impact of 70 eV). The analyses were performed in triplicate for each wine.

A Shiraz bag in box wine was selected for the preparation of the calibration curves as it was found to contain no rotundone by the preceding method. The wine was spiked in triplicate to give rotundone concentrations of 0, 1.2, 6, 12, 30, and 60 ng/L, and all samples were then analyzed as outlined above. The calibration was linear throughout the range with a correlation coefficient of 0.9996 and relative standard deviations of <5%. Using this method, the limit of detection for rotundone was 0.8 ng/L and the limit of quantification was 2.7 ng/L.

RESULTS

Both Ethrel and NAA Treatments Delay Shiraz Berry Ripening. The preveraison treatment of Shiraz berries with either Ethrel or NAA delayed the initiation of the phase of rapid increase in TSS and, by inference, sugar accumulation (Figure 2). After these differences in the onset of ripening, the rate of

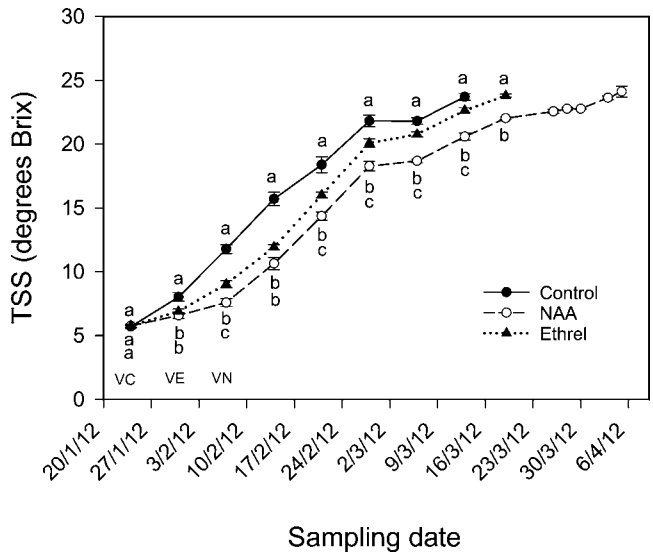

Figure 2. Effect of Ethrel and NAA treatments on total soluble solid (TSS) levels, measured as degrees Brix. All data represent means ± STERR (n = 3), and different letters denote significant differences between treatments at $p < 0.05$ using one-way ANOVA followed by Duncan's post hoc test. VC, VE, and VN indicate the time of veraison for control, Ethrel-treated, and NAA-treated fruit, respectively.

TSS increase was similar for all fruit, as can be seen from the similar slopes of the curves in Figure 2. At most of the time points after the first sampling, the TSS levels of all three treatments were significantly different ($p < 0.05$). The delay resulting from Ethrel treatment was less pronounced than that following NAA treatment. The fruit from all three treatments were harvested for winemaking at approximately the same mean TSS value [24.1°Brix for control, 24.0°Brix for Ethrel treatment, and 24.1°Brix for NAA treatment (ANOVA p =

DOI: 10.1021/jf505491d
J. Agric. Food Chem. 2015, 63, 2137−2144

0.961)]. The harvest of Ethrel- and NAA-treated fruit was delayed by 6 and 23 days, respectively. Despite the changes in ripening resulting from the treatments, the final mean berry weights for all three at harvest were similar [1.33 g/berry for control, 1.41 g/berry for Ethrel treatment, and 1.39 g/berry for NAA treatment (ANOVA $p = 0.583$)]. Anthocyanin accumulation was delayed by Ethrel and NAA treatments. Three weeks after veraison of the control fruit (February 14, 2012), control berries contained a significantly larger amount of anthocyanins than Ethrel- and NAA-treated fruit, which reflects the differences in soluble solid content. In contrast, the anthocyanin concentrations in berries of similar TSS levels (approximately 24°Brix) at harvest were not significantly different (Figure 3). There was also no significant difference

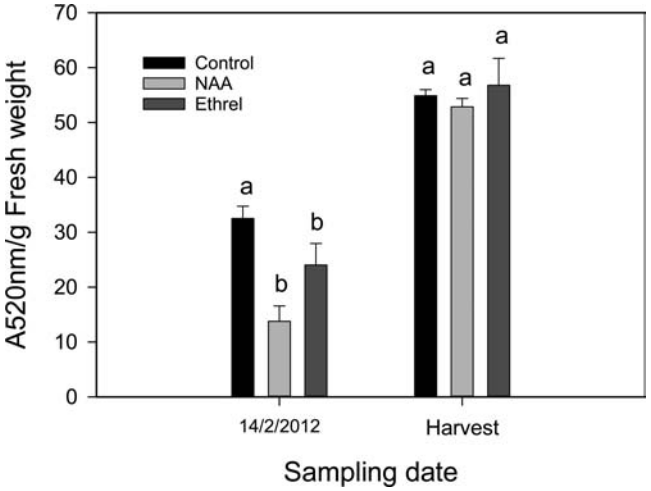

Figure 3. Effect of Ethrel and NAA treatments on anthocyanin accumulation (A_{520}). All data represent means ± STERR ($n = 3$), and different letters denote significant differences between treatments at $p < 0.05$ using one-way ANOVA followed by Duncan's post hoc test.

in titratable acidity at harvest [6.4 g/L for control, 6.7 g/L for NAA treatment, and 6.4 g/L for Ethrel treatment (ANOVA $p = 0.448$)]. From this, it appears that changes in both primary and secondary metabolism that occur during ripening were delayed by the preveraison application of Ethrel and, to a larger extent, NAA.

Wines were made from control, Ethrel-treated, and NAA-treated fruit for sensory and biochemical analysis. At the completion of winemaking, various basic measurements of the wine properties were taken. Small but statistically significant differences were observed in percent alcohol, acetic acid, pH, and titratable acidity (Table 1); these are unlikely to have an impact on the sensory properties of the wine.

Table 1. Measurements of Percent Alcohol, Acetic Acid, pH and T.A. of Wines at Bottling[a]

treatment	% alcohol (v/v)	acetic acid (g/L)	pH	T.A. (g/L of H^2T)
control	14.6 a	0.36 a	3.72 b	6.8 a

Ethrel	14.4 b	0.30 b	3.80 a	6.3 b

[a]Values represent means ($n = 3$), and different letters denote significant differences between treatments at $p < 0.05$ using one-way ANOVA followed by Duncan's post hoc test.

Descriptive Sensory Analysis of the Wine. Twenty-four wine sensory attributes were scored across the wines using a trained panel. Two were attributes related to appearance, and eight were related to odor. Eleven were palate characteristics, and three measured wine mouthfeel properties. Of these, significant differences were identified between the wines for the two appearance attributes, four aroma attributes, three palate attributes, and one mouthfeel attribute (Table 2). Those

Table 2. Sensory Attributes Found To Be Significantly Different amongs the Wines through Descriptive Analysis[a]

attribute	control	ethrel-treated	NAA-treated	p value
color	7.59 b	6.03 c	9.06 a	0.001
transparency	8.50 b	5.61 c	9.70 a	<0.001
dark fruit aroma	8.05 b	6.91 c	9.40 a	0.003

earthy/dusty flavor	2.18 b	2.97 ab	3.65 a	0.044
pepper flavor	4.41 b	4.58 b	7.59 a	<0.001
tannin quantity	8.89 a	8.00 ab	7.39 b	0.015

[a]Values represent means ($n = 3$), and different letters denote significant differences between treatments at $p < 0.05$ using one-way ANOVA followed by Duncan's post hoc test. The p value represents the "sample" effect (i.e., treatment) on the attribute.

attributes that were not significantly different because of the treatment of the fruit are listed in Table S3 of the Supporting Information. Wines produced from grapes treated with NAA were found to have more "color" and less "transparency" than those from the control and Ethrel-treated fruit (Table 2). Other sensory attributes more associated with the wines from the NAA-treated fruit included "dark fruit" and "pepper" aromas and "pepper" flavor on the palate (Table 2). It was also observed that scores for "red confection" odor and "red berry" flavor were significantly lower in the wine produced from NAA-treated grapes than in the wine from control and Ethrel-treated samples (Table 2). "Earthy/dusty" aroma and flavor were scored higher in the wines produced from the NAA treatment than in the control wines but were not significantly different from those of the wines from the Ethrel treatment (Table 2). In contrast, "tannin quantity" was found to be significantly lower in the wines from the NAA-treated fruit than in control wines but was not different from that of the wine from the Ethrel-treated bunches (Table 2). The Ethrel treatment also had a significant effect on wine attributes with significantly higher scores than the control and NAA wines for "red berry" flavor, but the lowest scores for wine "color", "transparency", and "dark fruit" aroma.

Analysis of Wine Volatiles. Significant differences were observed in the volatile profiles of the wines as determined using headspace SPME−GC−MS analysis. Of the 164 compounds quantified, eight were found in larger amounts in the headspace of the wines made from NAA-treated grapes compared to the control wines and 17 were more abundant in the control wines than in those made from the NAA-treated fruit (Table 3). No compounds were found in significantly greater concentrations in the wine from the Ethrel treatment compared with the other two treatments, but levels of two compounds (ethyl salicylate and hotrienol) were found to be lower in these wines than in wines from both the control and

[a]LRI (linear retention indices) calculated from retention of the compound relative to the retention of a series of *n*-alkanes (C_8–C_{26}). [b]Abbreviations: A, identity confirmed by matching mass spectra and LRI with that of authentic standards; B, tentative assignment based upon comparison with mass spectral libraries and published LRIs. [c]Values represent means ($n = 3$) of the areas under the peaks of a selected ion relative to the relevant internal standard. Different letters denote significant differences between treatments at $p < 0.05$ using one-way ANOVA followed by Duncan's post hoc test. [d]Compound quantified in the 1:100 dilution.

NAA-treated fruit (Table 3). However, the abundances of 18 compounds were lower in the wines produced from Ethrel-treated grapes than in those produced from control grapes (Table 3). The concentrations of 2-heptanol, 1-hexanol, and (Z)-3-hexen-1-ol were intermediate in the Ethrel treatment wines, being lowest after NAA treatment (Table 3).

Several compounds that are derived from the lipoxygenase pathway were present in lower abundances in the wines produced from NAA-treated grapes than in the control wines. These were 1-hexanol, (E)-3-hexen-1-ol, (Z)-3-hexen-1-ol, and the esters hexyl acetate, ethyl (Z)-3-hexenoate, ethyl (E)-2-hexenoate, and (Z)-3-hexenyl acetate, which have been shown to derive from C_6 alcohols and aldehydes produced by the lipoxygenase pathway.[20] Other lipid oxidation products with levels higher in control wines than in those produced from NAA-treated berries were 2-heptanol and 1-penten-3-ol. In general, the compounds that were significantly more abundant in the headspace of the control wines compared with those from the NAA treatment were less than 2-fold different, the exceptions being isoamyl isovalerate and (Z)-3-hexenyl acetate, with levels that were slightly more than 2-fold higher in the control wines than the NAA treatment wines.

Some aromatic compounds were more abundant in the wines from the NAA treatment than in the control wines. These were ethenyl benzene, ethyl salicylate, phenylethyl butyrate, and 1,1,6-trimethyl-1,2-dihydronaphthalene, the latter being derived from the degradation of carotenoids and the remainder from benzenoid metabolism. None of these compounds were more than 2-fold different in abundance between the wines.

The Concentration of Some Sesquiterpenes Is Elevated by NAA Treatment. Among the compounds found to be present at higher concentrations in the headspace of the wine from NAA-treated fruit were two sesquiterpenes tentatively identified as α-calacorene and cadalene. These volatile compounds were found in concentrations 4.7- and 2.4-fold higher, respectively, in the wines produced from the NAA-treated berries than in the control wines (Table 3). The compound responsible for pepper character in Shiraz wines has been identified as the sesquiterpene rotundone, which is sensorially active at very low concentrations.[11] Given that these two compounds had mass spectra typical of sesquiterpenes and that terpene synthase enzymes can make multiple products,[21] we decided to analyze the concentration of rotundone in the wines using a targeted analytical method. Rotundone could not be detected in the control wines, was present at low

DOI: 10.1021/jf505491d
J. Agric. Food Chem. 2015, 63, 2137–2144

concentrations (2 ± 0.4 ng/L) in the wine made from Ethrel-treated fruit, but was found at 14.5-fold higher concentrations (29 ± 1.6 ng/L) in the NAA treatment wines. The concentration found in the wine produced from NAA-treated fruit is above the odor threshold for rotundone, which was determined to be 16 ng/L in red wine, for those panelists sensitive to the compound.[11]

DISCUSSION

The results described above confirm previous studies showing that grape berry ripening and harvest can be delayed by the application of PGRs during the preveraison period of berry development. In this case, a considerable delay in harvest was achieved using NAA and a more modest delay when Ethrel was applied (Figure 2). On the basis of previous work,[3−6] Ethrel was applied earlier during berry development than NAA to achieve the desired, delaying effect. In a previous paper, it was shown that there is a likely explanation for the application of Ethrel (which releases ethylene) delaying ripening and harvest. It appears that ethylene can induce an increase in the level of biosynthesis and accumulation of the endogenous auxin indole-3-acetic acid (IAA) through the induction of putative IAA biosynthesis gene expression.[5] This increase in IAA concentration is a probable reason for the observed delay in ripening as the application of auxins has been shown to delay ripening.[8,9,22] NAA appears to be more efficacious than IAA in its ability to delay ripening. This may be due to it being a poor substrate for IAA-amino acid synthetases, the enzymes that inactivate IAA through conjugation,[2] thus increasing the longevity in the plant of any applied NAA. However, although it is less effective than NAA, it seems that an Ethrel-induced increase in IAA concentrations[5] could have occurred, and this was sufficient to delay the onset of ripening (Figure 2).

There were relatively few differences observed in the concentrations of headspace volatile compounds between the wines from control and NAA-treated grapes. Of the 164 compounds identified, only 25 were present in significantly different abundances (eight were higher in NAA wines, and 17 were higher in the control wines) (Table 3). In addition, the differences were mainly less than 2-fold. Four compounds, 2-heptanol, ethyl (*Z*)-3-hexenoate, ethyl (*E*)-2-hexenoate, and (*E*)-3-hexen-1-ol, have previously been found to be present at higher concentrations in control wine than in wine from ripening-delayed NAA-treated grapes, in Riesling, Shiraz, or both.[8,9] This indicates that NAA treatments affect the concentrations of some volatile compounds in a similar manner in different years and between different varieties. In contrast, levels of hexyl acetate and (*Z*)-3-hexenyl acetate, which were previously found to be at higher concentrations in wines made from NAA-treated Riesling grapes,[9] were higher in control wines in the current experiment (Table 3). Hexyl acetate was also at higher concentrations in NAA Shiraz wines compared to controls in a previous study.[8] These results indicate that NAA treatment and the subsequent delay in ripening significantly alter the abundances of relatively few of the measured volatile compounds. The changes in accumulation of some compounds in response to treatment with NAA seem to be consistent, but the concentrations of other compounds must be under more complex control as they vary independently.

Some compounds derived from the lipoxygenase pathway [1-hexanol, (*E*)-3-hexen-1-ol, (*Z*)-3-hexen-1-ol, and the esters hexyl acetate, ethyl (*Z*)-3-hexenoate, ethyl (*E*)-2-hexenoate, and (*Z*)-3-hexenyl acetate] were lower in the wines from NAA-treated fruit than in wines from control fruit (Table 3). The descriptors of all of these compounds are generally "green" for the alcohols and "green/fruity/apple" for the esters. However, green characters were not found to be significantly different among the wines. It is possible that these compounds are influencing the perception of "dark fruit" versus "red confection" in the wines; that is, larger amounts in the control wines make the fruit characteristics more "fresh" and "red" compared to those created by the smaller amounts in the wines from the NAA treatment where the fruit characters are described more as "cooked fruit" or "dark".

The increase in "pepper" aroma and flavor of the wine made from NAA-treated fruit was particularly noteworthy as it was observed during winemaking and was clearly distinguishable during the sensory testing (Table 2). The molecule responsible for "peppery" character in grapes has been identified as rotundone,[11] and its presence appears to be associated with the "pepper" aroma and flavor detected in the sensory analysis of the wines in this study. Although there were higher concentrations of rotundone in the wines made from Ethrel-treated grapes than in the control, the concentrations were not above the odor threshold in red wine,[11] and there was no significant difference in "pepper" character detected between the wines from control and Ethrel-treated grapes. The large increase in the level of rotundone in wine from NAA-treated grapes was detected sensorially (Table 3). Rotundone concentrations have been shown to vary considerably within a vineyard.[14] In the experiment described here, the sample replication in the field was maintained throughout winemaking, sensory analysis, and metabolite analysis, so the effects of any field variation can be tested by statistical analysis using ANOVA. While the effect of treatment on rotundone concentration was significant ($p = 0.002$), neither the effect of row ($p = 0.321$) nor the interaction of treatment and row ($p = 0.164$) was significant at the 0.05 level.

There are a number of possible explanations for the increased concentration of rotundone in wines from Ethrel-treated and, in particular, NAA-treated grapes. We have no evidence to indicate the mechanism involved in the increase in the concentration of rotundone, i.e., via an increased level of biosynthesis, a decreased level of catabolism, or a combination of both. As described above, it is feasible that auxins are the common factor in both NAA and Ethrel treatments because of the interaction of auxins and ethylene.[5,6] This may mean that there is a direct effect of auxins on rotundone metabolism that results in a sustained increase in its concentration and that the effect of NAA is greater than that for IAA because of the greater persistence of NAA in berries.

An alternative explanation is that the increased concentrations of rotundone, especially in wines made from NAA-treated grapes, were due to the delay in veraison. Certainly, the longer the delay in veraison, and therefore harvest, the greater the accumulation of rotundone. The increase in the level of rotundone could be caused by a lengthening of the period before veraison caused by the treatments. As rotundone appears to accumulate only after veraison,[13] an increase in the level of rotundone that was caused by a delay in ripening would have to result from an increase in the number of precursor molecules to rotundone during this period. The precursor for rotundone has been identified as α-guaiene, which can be converted to rotundone through oxidation.[17] Another possibility is that the delay in veraison means that ripening is occurring under different climatic conditions and that these conditions are more

DOI: 10.1021/jf505491d
J. Agric. Food Chem. 2015, 63, 2137−2144

favorable for rotundone accumulation. For example, some suggestions have been made that lower temperatures may result in increased pepper character (rotundone) accumulation.[10,13,14] There was no obvious change in the pattern of minimum and maximum temperatures during the period when rotundone accumulated (Figure S1 of the Supporting Information). Therefore, any effect of temperature on rotundone accumulation is quite subtle, or there are other factors that have a significant impact. One other parameter that differed between the control and NAA-treated fruit in particular was the length of time from veraison to harvest that was longer by approximately 8 days for NAA-treated fruit than for control fruit. As rotundone can be formed via the oxidation of α-guaiene,[17] it could be that the longer hang time of the NAA-treated fruit after harvest may have resulted in higher rotundone concentrations. Along with the increase in rotundone concentration, the concentrations of two other sesquiterpenes [α-calacorene and cadalene (Table 3)] were higher in wines from NAA-treated fruit, indicating that there may be a more general effect of the treatment on sesquiterpene metabolism.

Sensory analysis showed that although the wines from Ethrel-treated berries were quite similar to those from control berries there was a considerable difference between control and NAA wines as nine attributes were significantly different. The difference in rotundone concentrations can explain the differences observed in "pepper" aroma and flavor, but the other attributes are unlikely to be related to rotundone. Some of these differences could be related to changes in the levels of the volatile compounds measured (see above), but there may be other, undetected differences that influence aroma and flavor. Whatever the identity of the compounds, the difference in flavor and aroma is unlikely to be due to differences in sugar levels as there was no significant difference between the TSS values at harvest as determined by ANOVA.

In summary, both Ethrel and NAA treatments delayed the onset of berry ripening and harvest. NAA delayed ripening to a greater extent than Ethrel. Similarly, both treatments significantly altered wine volatile metabolite levels, but greater differences were induced by NAA treatment. NAA treatment, and to a lesser extent Ethrel treatment, also altered wine sensory character. Wines from NAA-treated fruit were notable for having higher scores for "pepper" aroma and flavor. Analysis by GC−MS showed that these wines had concentrations of rotundone above the sensory limit. The reason for an increased level of rotundone in the NAA wines is unknown but could arise from a direct effect of NAA on rotundone accumulation or be a result of the altered timing of the ripening phase affecting sesquiterpene metabolism.

stable) o/w emulsions on the adhesion and spreading of fat on the tongue was previously reported.[6] It was found that o/w emulsions stabilized with little protein had a stronger adhesion on the tongue (i.e., more stable against rinsing with saliva) compared to o/w emulsions stabilized with a high concentration of protein. It was hypothesized that this was due to difference in stability of the interfacial layer of the emulsion against rupture and thus creating coalescence of the oil droplets.[6]

Although the mentioned studies have indicated relations between o/w emulsion properties, such as viscosity, emulsifier type and content, and oral coatings, the mechanisms on how different macronutrients influence the deposition and clearance of oral oil coatings and how they relate to after-feel perception are still not understood. The aims of this study are to investigate the influence of (i) protein type, (ii) protein content, and (iii) viscosity of o/w emulsions on the clearance of oral oil coatings and after-feel sensory perception. The deposition and clearance of oral oil coatings from the tongue surface was determined using in vivo fluorescence measurements. The after-feel perception was determined using progressive profiling. To study the influence of protein emulsifier type on oil coatings, o/w emulsions stabilized with proteins differing in flocculation behavior when mixed with saliva were prepared. Lysozyme which forms irreversible agglomerates upon mixing with saliva and Na-caseinate, which is hypothesized to form no agglomerates upon mixing with saliva were used.[13] To study the influence of protein content on clearance and after-feel sensory perception of oral oil coatings, three concentrations of protein were used (all in excess to stabilize the water/oil interface). We hypothesize that excess protein has a blending effect with saliva, resulting in faster clearance of oil deposits from the tongue surface. To study the influence of viscosity of o/w emulsions on the clearance and after-feel sensory perception of oral oil coatings, three o/w emulsions stabilized with Na-caseinate were thickened with varying concentrations of xanthan gum. Emulsions stabilized with Na-caseinate were chosen to study the influence of viscosity, independently from other factors, to rule out possible effects of emulsifier−saliva biopolymers. Xanthan gum was chosen as it is commonly used as a thickener in various food liquid foods.

MATERIALS AND METHODS

Materials. Sunflower oil (Perfekt, purchased from local retailer), Na-caseinate (Excellion sodium caseinate S, DMV International, The Netherlands, typical protein content: 91%), lysozyme hydrochloride (The Protein Company, Belgium, protein content: >99%), sucrose (AH basic, purchased from local retailer), xanthan gum (Keltrol Advanced Performance, CP Kelco, Denmark), curcumin (7% w/w curcumin dissolved in propylene glycol and polysorbate; L-WS; Sensient, The Netherlands), NaOH (Merck, Germany), and tap water were used. All ingredients were food grade. Pig's tongues were obtained from the VION Food Group (The Netherlands).

Preparation and Characterization of o/w Emulsions. Table 1 shows the composition of all the o/w emulsions. All o/w emulsions were prepared in a food-grade environment. The oil phase of the o/w emulsions consisted of sunflower oil (10% (w/w)). The aqueous phase of the o/w emulsions consisted of protein solution (concentrations see Table 1) with 8% (w/w) sucrose. The aqueous phase was prepared by first dissolving sucrose in tap water and later dissolving either Na-caseinate or lysozyme at room temperature. The aqueous phase with dissolved lysozyme was brought to a pH of 6.9 by addition of 1 M NaOH. Protein concentration in the aqueous phase varied (0.2, 3.0, and 5.8% (w/w)). The 0.2% (w/w) protein concentration was chosen, as the lowest concentration, as it allows to prepare stable emulsions with low concentrations of "free-protein" in the aqueous phase, i.e., protein that is not adsorbed into the oil droplets surface. The 3.0% (w/w) protein concentration was chosen as the middle concentration, as it is a protein concentration common in dairy drinks. The 5.8% (w/w) protein concentration was chosen as the highest concentration, as it creates emulsions with high concentration of "free-protein" in the aqueous phase and has an equal difference of protein concentration between the emulsion with 3.0% as the emulsion with 0.2%.

Table 1. Overview of o/w Emulsions[a]

o/w emulsion	protein (% w/w)	xanthan gum (% w/w)	$d_{3,2}$ ± stdev (μm)	η ± stdev at 63 s^{-1} (mPas)
Na-caseinate	0.2	0	2.04 ± 0.20	1.7 ± 0.01
	3.0	0	1.45 ± 0.08	5.0 ± 0.05
	5.8	0	1.46 ± 0.05	9.0 ± 0.07
lysozyme	0.2	0	1.16 ± 0.24	2.2 ± 0.05
	3.0	0	1.21 ± 0.28	2.3 ± 0.05
	5.8	0	1.35 ± 0.19	3.5 ± 0.13
Na-caseinate	3.0	0.05	1.28 ± 0.10	13.8 ± 0.15
	3.0	0.20		49.9 ± 1.50
	3.0	0.50		143 ± 7.28

[a]All o/w emulsions contained 10% (w/w) oil and 8% (w/w) sucrose. o/w emulsions differed in type and concentration of protein used as emulsifier and xanthan gum concentration. $d_{3,2}$, droplet size (averages of measurements of 3−4 batches) and viscosity at a shear rate of 63 s^{-1} are shown.

The aqueous phase was then prehomogenized with the oil phase (sunflower oil) using an Ultra Turrax (IKA RW 20 Digital) at 4000 min^{-1} for 3 min and homogenized with a two-stage homogenizer (Niro-Soavi SpA, NS1001L2K) at pressures between 250 and 350 bar. All o/w emulsions had a neutral pH. The o/w emulsions thickened with xanthan gum were prepared from an o/w stock emulsion and mixed at a ratio of 1:1 with preprepared aqueous xanthan gum solutions. Xanthan gum solutions were prepared by heating water to 70 °C and adding the xanthan gum under agitation. The xanthan gum thickened o/w emulsions contained 10% (w/w) oil, 3% (w/w) Na-caseinate, and 8% (w/w) sucrose in the aqueous phase and varying concentrations of xanthan gum (see Table 1).

Emulsions were stored after preparation in a refrigerator at 4 °C and used for further studies no later than 3 days after preparation. Curcumin was added to the emulsions as a hydrophobic fluorescent dye prior to the in vivo measurements. Then 1 μL of 7% curcumin per gram of o/w emulsions was added under magnetic stirring immediately before testing.

Particle size distribution was determined by light scattering (Malvern Instruments, Goffin Meyvis) using a refractive index for sunflower oil of 1.469. Particle size of the different o/w emulsions was measured for every batch made for the fluorescence measurements. Sample was added to the light scattering measurement device until the obscuration reached 10%. $d_{3,2}$ was obtained as a measure of oil droplet size and averaged over measurements of 3−4 batches.

For every emulsion, the number of oil droplets was estimated by calculating: $number\ of\ oil\ droplets\ (N) = ((volume\ of\ oil)/((4/3) \times \pi \times r^3))$, where r is radius of the oil droplet. By knowing the number of oil droplets in each emulsion, the surface area of the emulsion can be estimated by calculating: $surface\ area\ of\ emulsion = N \times 4 \times \pi \times r^2$. On the basis of previous studies, we can estimate the amount of protein needed to cover the surface area of the emulsions.[14] We estimate that for the o/w emulsions with lower protein concentrations (0.2% w/w), about 1 mg/m^2 (Na-caseinate) to 1.5 mg/m^2 (lysozyme) of protein is adsorbed onto the surface of the oil droplets. For the higher protein concentrations used in our study (>2.25% (w/w)), we estimate that about 3.2 mg/m^2 of protein (Na-caseinate and lysozyme) is adsorbed onto the surface of the oil droplets.[14] This corresponds to a minimum protein concentration absorbed on the oil droplet interface of 0.05% (w/w) for low and 0.15% (w/w) for high protein concentrations. Therefore, all protein concentrations used in our study to emulsify the

DOI: 10.1021/jf505653t
J. Agric. Food Chem. 2015, 63, 2145−2153

o/w emulsions are assumed to be higher than the minimum protein concentration required to cover the oil droplet surface (see Table 1). All o/w emulsions used contained an excess of protein as emulsifier.

Flow curves of all o/w emulsions were determined in duplicate at 20 °C at shear rates ranging from 0.01 to 1000 s^{-1} using a rheometer (Anton Paar GmbH, Physica MCR 301) with a double gap geometry. All samples displayed shear thinning behavior. The viscosities at a shear rate of 63 s^{-1} (closest value in the range of the reported in-mouth shear rate (50−100 s^{-1})[15,16]) were extracted from the flow curves and are reported in Table 1.

Light microscopy (Carl Zeiss, Axioskop 2 Plus) was used to characterize the structure of the o/w emulsions before and after mixing with human saliva at a magnification of 40×. Saliva was collected according to reported procedure.[13] Unstimulated saliva was collected for 30 min in the same morning as the experiments from one healthy subject. First the subject rinsed her mouth with water and then collected the saliva with closed lips and expectorated into ice-chilled beakers.[13] Mixtures between o/w emulsions and saliva were prepared at room temperature at a ratio of 1:1 as in previous reports.[17,18]

In Vivo Fluorescence Measurements to Determine Oil Fraction Deposited on Tongue Surface. *Fluorescence Measurements and Calibration Curves.* The method used in the present study has been previously described in detail.[5] Fluorescence measurements were made with a single point measurement (Fluorolog Instruments SA Inc., Jobin Yvon Spex) at an excitation wavelength of 440 nm, an emission wavelength of 495 nm, with a slit width of 0.95 mm and a measurement time of 0.1s. A fluorescence remote read fiber optic probe was used to measure on tongue surfaces (in vivo for determination of oil fraction, and ex vivo for calibration curves). A plastic ring (diameter 16.9 mm, height 5 mm) was attached to the end of the probe to ensure that the distance between the probe and the tongue surface remained constant. The probe was put perpendicularly to the tongue surface and with slight pressure to avoid deformation of the papillae and the coating. For all measurements, the background (fluorescence intensity of the tongue surface without o/w emulsion) was measured first. The background measured immediately before the measurement of the o/w emulsion was subtracted afterwards from the o/w emulsion measurement.

To convert the fluorescence intensity measured on the subject's tongue surface to the oil fraction deposited on the tongue surface, i.e., mass of oil per area of tongue (mg/cm^2), calibration lines were made following the procedure described previously.[5] Briefly, calibrations were made with pieces of the middle part of the pig's anterior tongue at 37.5 °C. Oil in water emulsions at room temperature were spread on the surface of the pig's tongue (2 cm × 2 cm), and fluorescence intensity was measured. For each measurement, a fresh piece of tongue was used.[5] As the protein type and content affects the fluorescence intensity of curcumin, calibrations (fluorescent intensities vs oil fraction on tongue surface) were made for each of the nine o/w emulsions. Calibration lines consisted of six data points, for targeted oil fractions of 0.10 mg/cm^2 ($V_{emulsion}$ = 4 μL), 0.20 mg/cm^2 ($V_{emulsion}$ = 8 μL), 0.50 mg/cm^2 ($V_{emulsion}$ = 20 μL), 0.63 mg/cm^2 ($V_{emulsion}$ = 25 μL), 0.88 mg/cm^2 ($V_{emulsion}$ = 35 μL), and 1.0 mg/cm^2 ($V_{emulsion}$ = 40 μL). All calibration measurements were performed in triplicate and are shown in the Supporting Information.

Presentation of o/w Emulsions. Oil in water emulsions were presented to the subjects at room temperature in three blocks. Each block consisted of two sessions of about 1 h, during which each o/w emulsion was presented in triplicate. The o/w emulsions were presented in randomized order over subjects per block. During the first block, the o/w emulsions stabilized with 0.2, 3.0, and 5.8% (w/w) Na-caseinate were assessed. During the second block, the o/w emulsions stabilized with 0.2, 3.0, and 5.8% (w/w) lysozyme were assessed. Finally, during the third block, the o/w emulsions stabilized with 3% Na-caseinate and thickened with 0.05, 0.2, and 0.5% (w/w) xanthan gum were assessed.

Determination of Oil Fraction Deposited on Tongue Surface. Twenty untrained subjects (7 men, 13 women, mean age 23.4 ± 3.2 years) assessed the nine o/w emulsions in triplicate. Only subjects without tongue piercings and braces participated in the study. Participants gave informed written consent and received a financial compensation for their participation.

Subjects were asked to ingest 20 mL of the o/w emulsions and let it flow freely in the mouth for 30 s. Then subjects expectorated the o/w emulsions and the fluorescence intensity was measured on the front and back part of the anterior tongue at 0, 15, 30, 45, 60, 90, 120, and 180 s after expectoration. Before presentation of the next o/w emulsion, subjects cleaned their tongue with a tongue scraper and crackers were provided together with warm water (40 °C) and room temperature water to rinse the oral cavity. A break of approximately 5 min was made between measurements.

Determination of After-Feel Perception of Oral Coatings. During the fluorescence measurements, subjects performed progressive sensory profiling of after-feel attributes fatty film, sweetness, and creaminess at 0, 30, 60, 90, 120, and 180 s after expectorating the o/w emulsions. The definition of attributes and evaluation protocol were explained to the subjects (Table 2). The three attributes for the progressive profiling were chosen, as they have been shown to relate to the after-feel perception of o/w emulsions after expectoration.[5,9,10] A continuous 100 mm visual analogue scale was used anchored with "little" and "very" at a distance of 5 mm from the ends.

Table 2. Overview of After-Feel Attributes Assessed during Progressive Profiling at Different Times Points after Expectorating (0, 30, 60, 90, 120, and 180 s) of o/w Emulsions with Definitions and Evaluation Protocol

sensory attribute	definition	evaluation protocol
fatty film	sensation of feeling a layer of oil covering the mouth	slide the tongue against the palate and lips and slide the lips against each other
sweetness	degree of sweetness that lingers in the mouth	evaluate the sweetness perceived after expectoration
creaminess	degree of creaminess perceived in the mouth	slide the tongue against the palate and evaluate degree of creaminess

Statistical Data Analysis. SPSS Statistics version 19 was used for the statistical analysis. Descriptive statistics were used to obtain the mean and standard error (SE). Outliers ($z > 2$) were removed from the data. Fluorescence intensity data was normalized with a square root transformation. The effect of position of probe (within subject factor; front and back), o/w emulsion (within subject factor; 0.2, 3.0, and 5.8% lysozyme; 0.2, 3.0, and 5.8% Na-caseinate; 0.05, 0.2, and 0.5% xanthan), time (within subject factor; 0, 15, 30, 45, 60, 90, 120, and 180 s after expectoration) and interactions on oil fraction deposited on the tongue were tested by repeated-measures ANOVA. For the sensory data, a repeated-measures ANOVA was used to investigate the effect of o/w emulsion (within subject factor; 0.2, 3.0, and 5.8% lysozyme; 0.2, 3.0, and 5.8% Na-caseinate; 0.05, 0.2, and 0.5% xanthan) and time (within subject factor: 0, 30, 60, 90, 120, and 180 s after expectoration) and interactions on "fatty film", "sweetness", and "creaminess" intensity. A significance level of $p < 0.05$ was chosen.

RESULTS

Influence of Protein Type and Content on Oil Deposition on Tongue. *Microstructure of o/w Emulsions Stabilized with Na-Caseinate and Lysozyme before and after Mixing with Saliva.* Figure 1 shows the microstructure of 10% (w/w) o/w emulsions stabilized with different concentrations of Na-caseinate and lysozyme before and after mixing with human saliva. The 0.2% Na-caseinate o/w emulsion showed separate oil droplets (i.e., no aggregation) before and after mixing with human saliva. The o/w emulsions stabilized with 3.0 and 5.8% w/w Na-caseinate showed aggregation of the emulsion droplets. The size of the aggregates of the 3.0 and 5.8% w/w Na-caseinate emulsions seemed to decrease slightly

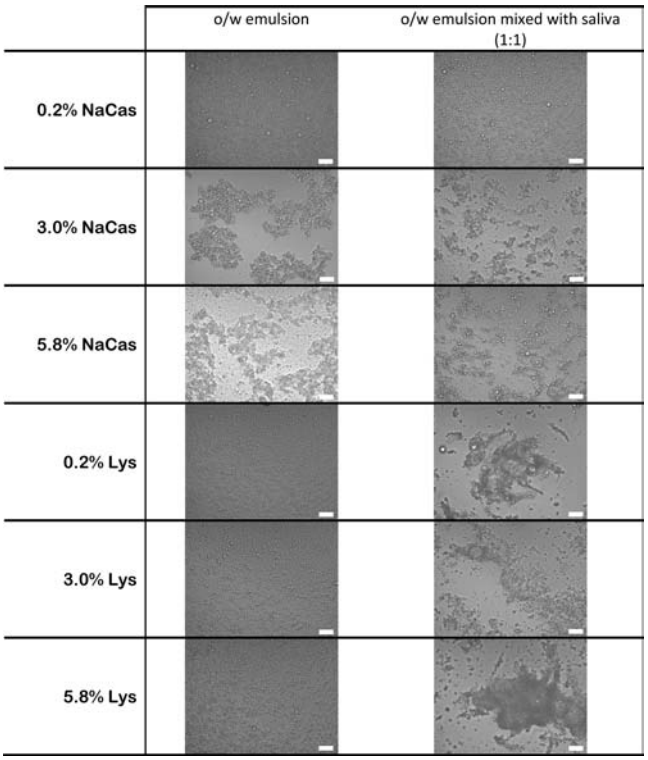

Figure 1. Light microscopy pictures. (left column) Images of 10% (w/w) o/w emulsions before mixing with human saliva and (right column) after mixing with human saliva at a ratio of o/w emulsion:saliva of 1:1. Scale bars represent 20 μm.

upon mixing with saliva. The o/w emulsions stabilized with Na-caseinate show no strong interaction with saliva because no considerable changes in the microstructure of the emulsions are observed comparing the microstructure before and after mixing with saliva. All lysozyme stabilized o/w emulsions (0.2, 3.0, and 5.8% (w/w) lysozyme) show individual, separate oil droplets before mixing with saliva. Oil in water emulsions stabilized with lysozyme revealed no flocculation at any of the lysozyme concentrations studied here. Upon mixing with saliva, agglomeration of lysozyme stabilized oil droplets was observed for all lysozyme concentrations.

Oil Deposition on Tongue Immediately after Expectoration of o/w Emulsions (t = 0 s). Figure 2 shows the oil fraction deposited on the tongue surface immediately after expectoration (t = 0 s) of the 10% (w/w) o/w emulsions stabilized with different concentrations of Na-caseinate and lysozyme at the front and back of the anterior tongue. Probe position had a significant main effect on oil fraction deposited on the tongue for emulsions stabilized by Na-caseinate as well as lysozyme (Na-caseinate, $F(1, 59) = 199$, $p < 0.001$; lysozyme, $F(1, 59) = 260$, $p < 0.001$). The oil fraction on the back part of the tongue was significantly higher than on the front part of the anterior tongue. No significant effect of Na-caseinate concentration on the oil fraction deposited on the tongue was found. With increasing lysozyme concentration, the oil fraction deposited on the tongue significantly decreased ($p < 0.05$).

Clearance of Oil Deposition on the Tongue after Expectoration. Time after expectoration had a significant main effect on oil fraction deposited on the tongue for o/w emulsions stabilized with Na-caseinate and lysozyme (Na-caseinate, $F(2.9, 176) = 412$, $p < 0.001$; lysozyme, $F(3.1, 184) = 207$, $p < 0.001$).

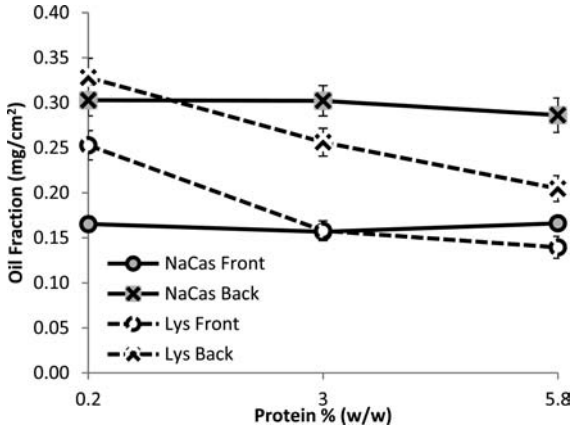

Figure 2. Oil fraction deposited on the front and back part of the anterior tongue immediately after expectoration (t = 0 s) as a function of protein concentration (% w/w) and type Na-caseinate (NaCas) and lysozyme (Lys). Each data point represents the average of n = 20 subjects and three replicates. Lines are drawn to guide the eye. Error bars represent standard error.

J. Agric. Food Chem. 2015, 63, 2145−2153

times after expectoration. Parts A and B of Figure 3 depict the relative oil content remaining on the tongue after expectoration, i.e., at time 0 s, the amount of oil on the tongue is 100% for all o/w emulsions. With increasing time, the relative oil content ($oil\ content(\%) = ((oil\ fraction_{t=x})/(oil\ fraction_{t=0s})) \times 100$ averaged over $n = 20$ subjects and three replicate measurements) decreases to lower percentages. Probe position had no influence on the oil clearance from o/w emulsions stabilized by Na-caseinate, showing no differences between the clearance rates of the oil deposited on the front vs back of the anterior part of tongue. In contrast, the probe position significantly affected the clearance rate of the o/w emulsion stabilized with 0.2% lysozyme from 30 s onward, and of the emulsion stabilized with 5.8% lysozyme from 60 s onward. For both cases, the oil deposited on the front part of the tongue was cleared faster, i.e., reached lower percentages of relative oil content after shorter time periods compared to the back part of the anterior tongue. The oil clearance from the o/w emulsion stabilized by 3% lysozyme was significantly different (front vs back) at time 90 s ($p = 0.06$) and 120s ($p = 0.03$).

Parts A and B of Figure 3 show that the oil deposited on the tongue of o/w emulsions stabilized with Na-caseinate had a faster clearance compared to o/w emulsions stabilized with lysozyme for both front and back parts of the tongue. These results were significant for the back part of the tongue from 30 s onward ($p < 0.05$). The o/w emulsions stabilized with lower concentrations of Na-caseinate (0.2% w/w) had a slower clearance of oil compared with the other two o/w emulsions stabilized with Na-caseinate (3.0 and 5.8% w/w). The concentration of lysozyme in the o/w emulsion did not affect the oil clearance from the tongue.

Influence of Protein Type and Content on After-Feel Perception of Oral Coatings. Figure 4 depicts the after-feel perception of 10% (w/w) o/w emulsions stabilized with different concentrations of Na-caseinate and lysozyme at different time points after expectorating the emulsions. Oil in water emulsions stabilized with Na-caseinate were perceived as significantly more intense for the after-feel attributes "fatty film", "sweetness", and "creaminess" ($p < 0.001$) than emulsions stabilized with lysozyme. The intensity of "fatty film" was significantly influenced by sample (i.e., 0.2, 3.0, and 5.8% lysozyme and 0.2, 3.0, and 5.8% Na-caseinate) [$F(2.6, 152) = 9.4$, $p < 0.001$], time [$F(2.6, 154) = 346$, $p < 0.001$] and sample × time [$F(8.2, 484) = 7.8$, $p < 0.001$]. Lysozyme concentration did not affect the perception of "fatty film" after-feel attributes of o/w emulsions stabilized with lysozyme. A trend was observed with higher concentration of Na-caseinate concentration, leading to higher "fatty film" after-feel perception. For the attribute "sweetness" the effects of sample (i.e., 0.2, 3.0, and 5.8% lysozyme and 0.2, 3.0, and 5.8% Na-caseinate) [$F(2.6, 157) = 21.5$], time [$F(2.1, 121) = 446$] and sample × time [$F(11.9, 702) = 7.8$] were significant at $p < 0.001$. The same was observed for the attribute "creaminess" (sample (i.e., 0.2, 3.0, and 5.8% lysozyme and 0.2, 3.0, and 5.8% Na-caseinate) [$F(3.6, 211) = 65.9$], time [$F(2.2, 127) = 464$, sample × time [$F(9.8, 577) = 13.5$]). The higher the concentration of Na-caseinate in the emulsion, the higher the perceived creaminess. No differences were found between the o/w emulsions stabilized with varying amounts of lysozyme.

Influence of Viscosity on Clearance of Oral Coatings. *Oil Deposition on Tongue Immediately after Expectoration (t = 0 s).* Figure 5 shows the oil fraction deposited on the front and back part of the anterior tongue immediately after

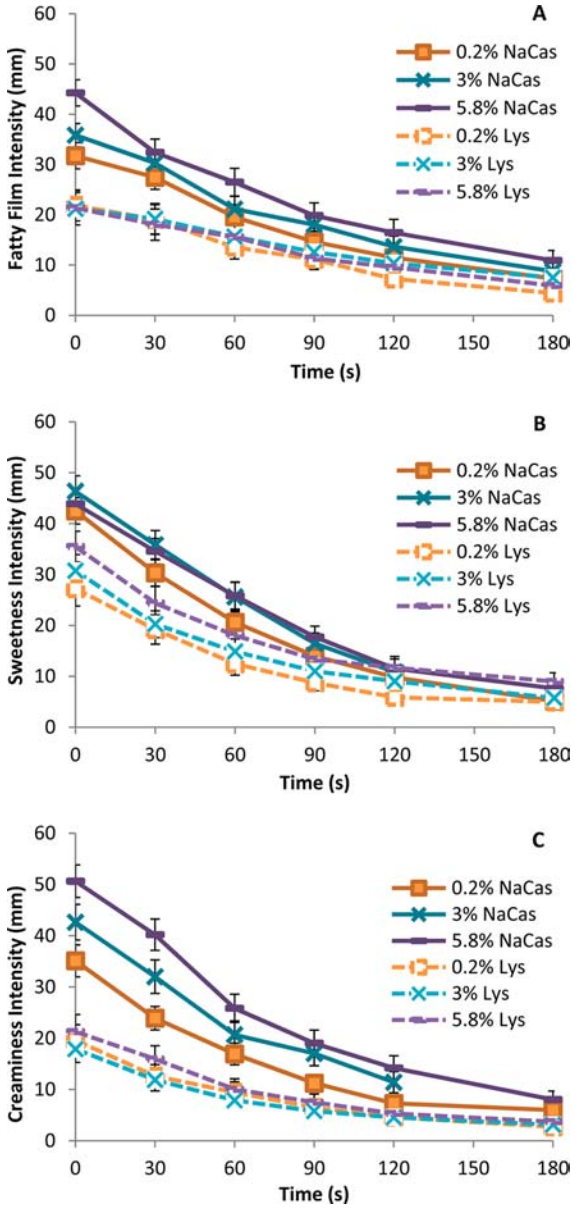

Figure 4. Intensity of after-feel attributes. Fatty film (A), sweetness (B), and creaminess (C) for 10% (w/w) emulsions differing in emulsifier type (Na-caseinate (NaCas) and lysozyme (Lys)) and content as a function of time after expectoration. expectoration ($t = 0$ s) of 10% (w/w) o/w emulsions stabilized with 3% (w/w) Na-caseinate differing in xanthan gum concentration. Sample (i.e., 0, 0.05, 0.2, and 0.5% xanthan gum) [$F(2.3, 133) = 137$, $p < 0.001$] and probe position [$F(1, 59) = 193$, $p < 0.001$] had a significant main effect on oil fraction deposited on the tongue for emulsions thickened with xanthan gum. Pairwise comparisons revealed no significant differences between o/w emulsions containing different concentrations of xanthan but only a significant difference between o/w emulsion without xanthan gum vs o/w emulsions with xanthan gum ($p < 0.001$). Immediately after expectoration of the o/w emulsions, the oil fraction deposited on the back part of the anterior tongue was significantly higher than on the front part of the tongue ($p < 0.001$). For both front and back part of the anterior tongue, the o/w emulsion with no xanthan

gum had a significantly higher oil fraction deposited on the tongue than o/w emulsions containing xanthan ($p < 0.001$).

Clearance of Oil Deposited on the Tongue of o/w Emulsions Varying in Viscosity. Figure 6 depicts the relative oil content deposited on the front and back of the anterior tongue for the 10% (w/w) o/w emulsions stabilized with 3% (w/w) Na-caseinate thickened with different xanthan gum concentrations as a function of time. Time had a significant effect on oil fraction deposited on the tongue surface [$F(2.3, 136) = 525$, $p < 0.001$]. The oil clearance was not significantly different for o/w emulsions differing in concentration of xanthan gum ($p = 0.082$). Probe position had no significant effect on the values of relative oil content ($p = 0.155$).

Figure 6. 13.45, $p < 0.001$], time [F(2.4, 140) = 387, $p < 0.001$], and sample × time [F(6.8, 398) = 3.3, $p < 0.05$] were significant. The emulsions with 0.5% xanthan and no xanthan were perceived significantly higher ($p < 0.05$) in "fatty film" intensity than the o/w emulsions thickened with 0.05 and 0.2% xanthan gum. The attribute "sweetness" was influenced by sample (i.e., 0, 0.05, 0.2, and 0.5% xanthan gum) [F(2.6, 153) = 38.1, $p < 0.001$], time [F(2.7, 161) = 382, $p < 0.001$], and sample × time [F(9.2, 543) = 7.0, $p < 0.001$]. The o/w emulsion with no xanthan was perceived as significantly sweeter ($p < 0.001$) than all other o/w emulsions. With increasing xanthan concentration, after-feel sweetness tended to decrease. The attribute "creaminess" was significantly influenced by sample (i.e., 0, 0.05, 0.2, and 0.5% xanthan gum) [F(2.6, 154) = 19.3 $p < 0.001$], time [F(2.5, 145) = 471, $p < 0.001$], and sample × time [F(8.2, 481) = 4.3, $p < 0.001$]. The o/w emulsion with 0.5% xanthan was perceived significantly creamier ($p < 0.05$) than all other o/w emulsions.

DISCUSSION

The aims of this study were to investigate the influence of (i) protein type, (ii) protein content, and (iii) viscosity of o/w emulsions on the oil fraction deposited on the tongue after expectoration of the samples and after-feel sensory perception.

The oil fraction deposited on the back part of the anterior tongue was by a factor of around 1.3−1.9 times higher compared with the oil fraction deposited on the front part of the anterior tongue for all o/w emulsion tested in this study. These results are in line with previous studies that showed that the coating deposition followed a similar spatial variation.[5,9] It has been suggested that the spatial variation in oil deposition on the tongue is due to differences in the morphology of the tongue and/or movement of the tongue while and after orally processing the samples.

Influence of Protein Type and Content on Clearance of Oral Oil Coatings. Light microscopy revealed the microstructure of the 10% (w/w) o/w emulsions stabilized with different concentrations of Na-caseinate and lysozyme before and after mixing with human saliva. All images were taken with o/w emulsions at neutral pH, at room temperature, and were mixed with the same batch of human saliva. The o/w emulsions stabilized with higher concentrations of Na-caseinate (3.0 and 5.8% w/w) showed aggregation likely due to depletion flocculation due to unadsorbed protein at high concentrations.[19] The flocculation properties of o/w emulsions stabilized with Na-caseinate were previously shown to be comparable to micelle induced depletion in surfactant-based systems.[19,20] As the unadsorbed protein concentration is increased, the flocculation is also expected to increase. This flocculation is weak and reversible.[19,20] The o/w emulsions stabilized with Na-caseinate showed very limited changes in the emulsion microstructure upon mixing with human saliva. No aggregation was observed upon mixing with human saliva for o/w emulsions stabilized by 0.2% Na-caseinate. This is in agreement with the hypothesis that negatively charged proteins result in negatively charged emulsion droplets, which do not interact with salivary biopolymers.[13]

The o/w emulsions stabilized with lysozyme showed no aggregation, even at higher concentrations (3.0 and 5.8% w/w). This is possibly due to the fact that lysozyme is a globular protein, and when in excess concentration to cover the oil droplets it can create multilayers of adsorbed protein around the emulsion droplet.[14] Lysozyme is known to form complexes with salivary proteins.[13] The complexes are formed by electrostatic interactions between the positively charged lysozyme and the negatively charged salivary biopolymers. The complex formation is responsible for the irreversible flocculation of the lysozyme emulsions.[13] Figure 1 shows that the lysozyme stabilized o/w emulsions (0.2, 3.0, and 5.8% lysozyme) used in this study formed large agglomerates upon mixing with saliva. In vivo fluorescence measurements showed that increasing the concentration of lysozyme led to smaller oil fractions deposited on the tongue immediately after expectoration of the o/w emulsion ($t = 0$ s, see Figure 2). It is possible that with higher concentrations of unadsorbed lysozyme more and larger agglomerates are formed upon mixing with saliva in the oral cavity. Previous studies found that starch granules were cleared faster from the tongue than xanthan gum.[11] They hypothesized that the larger starch granules might be too large to enter the voids between the papillae on the tongue and therefore were washed away easier.[11] As lysozyme forms aggregates, it is plausible that the aggregates were too large to enter the voids between the papillae during oral processing. When spitting out the o/w emulsions, it is likely that the formed complexes were spat out as well. On the other hand, there were no differences on oil fraction between the o/w emulsions stabilized with Na-caseinate. The depletion agglomerates of caseinate micelles are weak and reversible. It is likely that due to the constant stirring of the o/w emulsions prior to in mouth processing and to in mouth shear, these agglomerates were destroyed and thus did not have an effect on the oil deposition in mouth.

The oil coatings formed by lysozyme stabilized o/w emulsions had a slower oil clearance rate from the tongue than oil coatings formed by Na-caseinate stabilized o/w emulsions. Complex formation between salivary proteins and lysozyme can take place in the saliva fluid as well as with the mucous layer.[21] Complex formation with the mucous layer might slow down clearance. On the other hand, the coating formed by the Na-caseinate emulsions is likely to have no or very little binding with the mucous layer and as such, easier to be washed away by saliva and rubbing against palate.

No significant differences were found between the o/w emulsions stabilized with different concentrations of Na-caseinate. However, oil clearance tended to be slower at lower Na-caseinate concentrations. We hypothesized that excess protein has a blending effect with saliva, resulting in faster clearance of oil deposits from the tongue surface. The blending effect could be the underlying mechanism responsible for the observed trend. However, this effect depends on the behavior of the protein in mouth. In the case of the o/w emulsions stabilized with lysozyme, no trend was observed, indicating as dominant effect the behavior of the protein with saliva and to a lesser extent the concentration of protein in the emulsion.

The after-feel perception of lysozyme stabilized o/w emulsions was perceived as less intense compared to Na-caseinate stabilized o/w emulsions. As the clearance of the oil fraction deposited on the tongue for the o/w emulsions stabilized with lysozyme was slower than for o/w emulsions stabilized with Na-caseinate, the oil fraction deposited on tongue was larger at almost every measured time point (data not shown). It would be expected that the oil coatings left by the lysozyme stabilized o/w emulsions would be perceived as fattier and creamier because they effectively have more oil deposited on the tongue than Na-caseinate stabilized o/w

DOI: 10.1021/jf505653t
J. Agric. Food Chem. 2015, 63, 2145−2153

emulsions. It is known though that lysozyme provokes an astringent and dry sensation in the mouth,[8] which are sensations that are likely to reduce the intensity of the attributes "fatty film" and "creaminess". The flocculation of lysozyme stabilized o/w emulsions was found to have similarities to saliva flocculation observed by addition of tannins. The flocculation with proteins in saliva and mucous layer reduces the lubrication properties of saliva and increases friction in mouth, which leads to astringent and rough after-feel.[8] The after-feel sensations seem to be complex and not a sole function of the actual amount of oil deposited on the tongue.

Influence of Viscosity on Clearance of Oral Oil Coatings. A decrease in oil fraction deposited on the tongue immediately after expectoration of o/w emulsions when xanthan gum was present compared to o/w emulsions without xanthan was observed. This decrease was independent of xanthan concentration added to thicken the o/w emulsion. This suggests that the matrix created by xanthan is likely to capture the oil droplets and create a film which does not allow the oil droplets to enter the voids between the papillae and thus creating less oil deposition compared to emulsions without xanthan gum. Other studies have also shown that the addition of polysaccharides, such as guar gum, to emulsions reduces oil retention on the tongue surface.[8] Our results show that there is no significant difference in oil clearance dynamics depending on xanthan concentration. Furthermore, no influence on the fat clearance kinetics of different types of thickeners was found.[11]

It is interesting to note that "fatty film" perception was higher for o/w emulsions with the highest concentration of xanthan (0.5%). Physically, the oil deposition for both emulsions is very different with the emulsion with no xanthan having the highest oil fraction deposited on tongue. This suggests that xanthan gum might create a lubricating layer on the tongue, thereby decreasing the friction and increasing fatty after-feel. This lubrication effect is likely to dependent on the concentration of thickener. In accordance, "creaminess" was perceived as significantly higher for the 0.5% xanthan o/w emulsions compared to the o/w emulsions with lower concentrations of xanthan. All o/w emulsions with added xanthan were perceived as significantly less sweet compared with the 3% Na-caseinate stabilized o/w emulsion without xanthan. This was expected, as it is known that increasing viscosities in liquid foods can decrease taste perception.[22−24] Different explanations for taste suppression caused by thickeners were reported: kinetic and perceptual. Kinetic explanations suggest a reduction of the tastant release and diffusion rates in mouth due to the binding of tastants to the thickener or due to inhibition of the tastants transport due to the hydrocolloid chains.[25−27] Perceptual interactions were also demonstrated to contribute to the effect of taste perception due to texture differences caused by cross-modal interaction between tactile and taste signals.[28]

In conclusion, considerable differences were found in oil fraction deposited on the tongue and after-feel perception between o/w emulsions stabilized by Na-caseinate which do not aggregate under in mouth conditions and o/w emulsions stabilized by lysozyme which aggregate under in mouth conditions. The irreversible agglomeration of the o/w emulsions stabilized with lysozyme caused a slower oil clearance of the oral oil coating from the tongue compared to o/w emulsions stabilized with Na-caseinate. The increase of unadsorbed lysozyme in the o/w emulsion might have created larger agglomerates that were easier to expectorate, creating smaller depositions of oil immediately after expectoration than the Na-caseinate stabilized emulsions. The after-feel of o/w emulsions stabilized with Na-caseinate was perceived as creamier, fattier, and sweeter than the o/w emulsions stabilized with lysozyme. The addition of xanthan gum to Na-caseinate stabilized o/w emulsions decreased the deposition of oil on tongue although o/w emulsions with higher concentrations of xanthan had a similar or higher fatty and creamy after-feel perception than o/w emulsions without xanthan. We conclude that the after-feel perception of o/w emulsions is complex and that the physical deposited oil on the tongue contributes to it as well as factors such as the behavior of proteins in mouth and the presence of thickeners.

Ⓢ Supporting Information

The in vivo fluorescence results were translated into oil fraction by using calibration curves which relate fluorescence (relative fluorescence units (RFU)) to oil fraction (mass of oil per surface area of the tongue). Calibration lines for every sample measured by in vivo fluorescence in this study are included in the supporting information file. This material is available free of charge via the Internet at http://pubs.acs.org.

clusters.[25] MIL-101 has some advantages of large pore windows, mesoporous pores (2.9−3.4 nm), accessible coordinative unsaturated sites, and excellent chemical stability. These properties make it attractive in analytical applications, especially in chromatographic separation and sample pretreatment. MIL-101 has been explored as stationary phase for liquid chromatography.[26] In sample treatment, MIL-101 has been successfully used as sorbent to extract targets in aqueous samples.[27−29] Hasen et al. used MIL-101 to extract naproxen and clofibric acid from aqueous solution.[28] Hu et al. reported the application of MIL-101 packed microcolumn for the extraction of naproxen and its metabolite in urine samples.[29] The adsorption extraction with MIL-101 in nonpolar system is also attractive. In our previous work, MIL-101 was successfully used to clean up the extract of peanuts and a large mass of fat was separated.[3] Compared with conventional sorbents, MIL-101 shows better extraction efficiency in nonpolar solution. Thus, the MIL-101 could be potentially applied to the direct extraction of pesticides in vegetable oil and the sample preparation process can be effectively simplified and accelerated.

Herein, the dispersive microsolid-phase extraction (d-μ-SPE) based on MIL-101 was developed for extracting herbicides in vegetable oils. The herbicides were extracted directly with MIL-101 from diluted vegetable oils, and no further cleanup operation is needed. The fat remaining in sample solution was easily removed after centrifugation. The herbicides were separated and determined by HPLC. The operation is quick and simple, and the results are satisfactory.

MATERIAL AND METHODS

Chemicals. Fenuron, simeton, simazine, atraton, chlortoluron, secbumeton, and terbumeton were obtained from National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). Standard stock solutions for the herbicides (200 μg/mL) were prepared by dissolving 2.0 mg of the standard in 10.0 mL of acetonitrile. All of the stock standard solutions were stored in a refrigerator at 4 °C. Working and mixed working standard solutions were prepared by diluting stock standard solutions with acetonitrile. Chromatographic grade acetonitrile was purchased from Fisher Scientific Company (Pittsburgh, PA, USA). $Cr(NO_3)_3{\cdot}9H_2O$ (>99.0%) were purchased from XLong chemical Co., Ltd. (Guangdong, China). 1,4-Benzenedicarboxylic acid (H_2BDC, ≥98.5%) was purchased from Tianjin Guangfu Fine Chemical Research Institute (Tianjin, China). Hydrofluoric acid (HF, ≥40%) was purchased from Nanjing Chemical Reagent Co., Ltd. (Nanjing, China). Pure water was obtained with a Milli-Q water purification system (Millipore Co., USA). Primary secondary amine (PSA), C18, and graphitized carbon black (GCB) were purchased from Beijing Agela Technologies Inc. (Beijing, China). All of the other reagents (analytical-reagent grade) were purchased from Beijing Chemical Factory (Beijing, China).

Instruments. Chromatographic separation and determination of the herbicides were carried out on an Agilent 1100 series liquid chromatograph (Agilent Technologies Inc., USA) equipped with photodiode array detector (DAD) and quaternary gradient pump. Eclipse XDB-C18 column (3.5 μm, 4.6 mm × 150 mm, Agilent, USA) was used.

The KQ3200E ultrasonic cleaner was purchased from Kunshan Ultrasonic Instrument Co., Ltd. (Kunshan, China). The frequency and output power of the ultrasonic cleaner are 40 kHz and 150 W, respectively. An Allegra 64 R centrifuge was purchased from Beckman Coulter.

The X-ray diffraction (XRD) patterns were recorded on a Rigaku D/max-2550 diffractometer equipped with a graphite monochromator (Rigaku, Japan) and Cu Kα radiator (λ = 1.5418 Å). Transmission electron microscopic (TEM) characterization was performed on a Tecnai G2 F20 S-Twin (Philips, Holland). BET surface area was measured on an ASAP 2020 micropore physisorption analyzer (Micromeritics, Norcross, GA, USA) using nitrogen adsorption at 77 K. The synthesis and characterization of MIL-101 was consistent with our previous work.[3]

Sample Preparation. Vegetable oils were collected from local markets. Soybean oil (sample 1), corn oil (sample 2), sunflower oil (sample 3), and peanut oil (sample 4) were used. All samples were stored at room temperature.

Four fresh spiked samples containing triazine and phenylurea herbicides were prepared by adding the mixed working standard solution into the samples, shaking for 10 min, and standing for 1 h. The aged spiked sample of soybean oil was prepared by the method mentioned above except that the spiked soybean oil sample was kept in sealed bottle and stored for 1, 2, 3, and 4 weeks at 4 °C, respectively. In the "Analysis of Samples" section, four oil samples (sample 1−4) were used. The other experiments were performed with soybean oil sample (sample 1) only.

Extraction Procedure. *d-μ-SPE.* A 2 mL of vegetable oil sample was added into 25 mL centrifuge tube and diluted with 10 mL of *n*-hexane. Subsequently, 7 mg of MIL-101 was added into the tube and the ultrasonic extraction was carried out for 15 min. The mixture was centrifuged for 3 min at 8720*g*, and the supernatant was decanted. Then 0.5 mL of *n*-hexane was added into the tube and followed by the same procedure as mentioned above. The analytes were eluted from MIL-101 with 1.5 mL of methanol in an ultrasonic bath for 1 min. The mixture was centrifuged for 10 min at 8720*g*, and the supernatant was dried under nitrogen stream. The residue was dissolved in 200 μL of methanol. The resulting solution was filtered with 0.22 μm PTFE filter and referred to as analytical solution. Then 20 μL of the analytical solution was injected into the HPLC system.

QuEChERS Procedure. The quick, easy, cheap, effective, robust, and safe (QuEChERS) procedure was performed according to Sobhanzadeh et al.;[18] 2 mL of vegetable oil and 5 mL of water were added into a 25 mL centrifuge tube. Then, 7 mL of acetonitrile, 2.8 g of anhydrous magnesium sulfate, and 0.7 g of sodium chloride were added into the tube. The tube was vigorously shaken for 1 min. The mixture was centrifuged at 1395*g* for 1 min. The tube was horizontally stored in freezer at −20 °C for 2 h. Then the supernatant was transferred into a PTFE centrifuge tube containing 750 mg of anhydrous magnesium sulfate, 250 mg of PSA, 250 mg of C18 sorbent, and 250 mg of GCB. After shaking for 30 s, the mixture was centrifuged at 1395*g* for 1 min. The supernatant was evaporated to dryness and reconstituted in 200 μL of methanol. The resulting solution was filtered with 0.22 μm PTFE filter and referred to as analytical solution. Then 20 μL of the analytical solution was injected into the HPLC system.

HPLC Analysis. The HPLC analysis was conducted in gradient mode. Mobile phases A and B were water and acetonitrile, respectively. The gradient conditions are as follows: 0−8 min, 30−45% B; 8−10 min, 45% B; 10−15 min, 45−50% B; 15−19 min, 50−72% B. The column temperature was kept at 30 °C, and the flow rate of mobile phase was kept at 0.5 mL/min. Injection volume of analytical solution was 20 μL. The monitoring wavelengths were 244 nm for fenuron and chlortoluron and 222 nm for the other herbicides.

Statistics. The Student's *t*-test was applied to the evaluation of the reasonableness of the selected experimental parameters. The t is calculated from

$$t = \frac{x_1 - x_2}{S\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

$$S = \frac{(n_1 - 1)S_1^2 + (n_2 - 1)S_2^2}{n_1 + n_2 - 2}$$

where x_1 and x_2 are the mean recoveries obtained under two experimental conditions, n_1 and n_2 are the sample sizes, s_1 and s_2 are the standard deviations, and $(n_1 + n_2 - 2)$ is degree of freedom.

RESULTS AND DISCUSSION

Optimization of d-μ-SPE. In the study, some experimental parameters that affect the extraction efficiency were investigated

DOI: 10.1021/jf505760y
J. Agric. Food Chem. 2015, 63, 2154−2161

and optimized. All optimization experiments were carried out by analyzing the spiked soybean oil sample in triplicate.

Effect of Volume Ratio of n-Hexane to Oil Sample. The dilution has a significant effect on the extraction efficiency. In this work, vegetable oil sample was diluted with *n*-hexane. The results are shown in Figure 1. The recoveries of herbicides

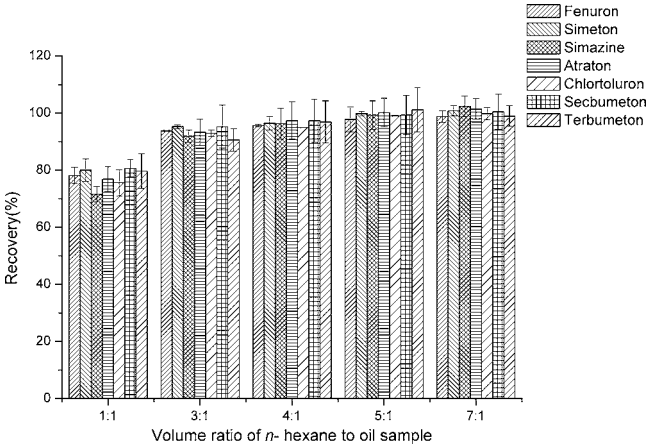

Figure 1. Effect of volume ratio of *n*-hexane to oil sample on recoveries of herbicides from soybean oil. Mass of MIL-101, 7 mg; extraction time, 15 min; centrifugation time, 3 min; eluting solvent, 1.5 mL of methanol; spiked concentration, 50 μg/L.

increase with the increase of the volume ratio of *n*-hexane to oil sample. The highest recoveries are obtained when the volume ratio is 5:1, and the recoveries change slightly with the further increase of the volume ratio. The reason could be that the viscosity of oil sample decreases with the increase of the volume of *n*-hexane, which is beneficial to the dispersion of sorbent and thus improvement of the extraction efficiency. In addition, the fat and other impurities are easily dissolved in nonpolar solvent (*n*-hexane). Consequently, the increase of *n*-hexane volume is beneficial to the removal of impurities. Therefore, the selected volume ratio of *n*-hexane to oil sample was 5:1.

Effect of Mass of MIL-101. The effect of mass of MIL-101 in the range of 0.5−12 mg on recoveries was investigated. The results shown in Figure 2 indicate that the recoveries of

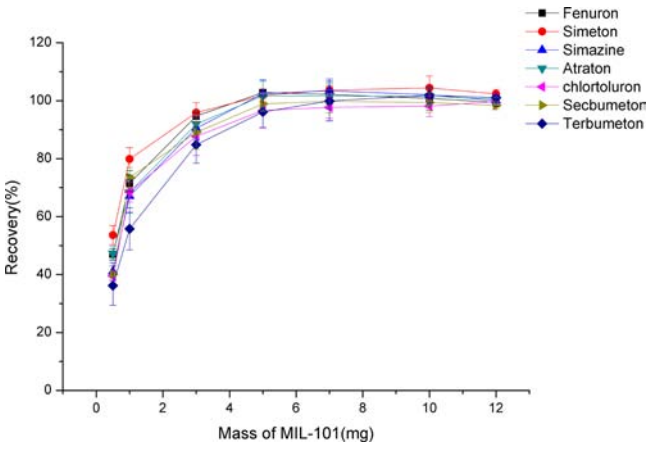

Figure 2. Effect of mass of MIL-101 on recoveries of herbicides from soybean oil. Volume ratio of *n*-hexane to oil sample, 5:1; extraction time, 15 min; centrifugation time, 3 min; eluting solvent, 1.5 mL of methanol; spiked concentration, 50 μg/L.

herbicides increase with the increase of mass of MIL-101 from 0.5 to 5 mg and change slightly when the mass of MIL-101 is more than 5 mg. To ensure sufficient extraction, 7 mg of MIL-101(Cr) was selected in the following experiments.

Effect of Extraction Time and Centrifugation Time. The effect of extraction time ranging from 1 to 30 min was investigated. The results are shown in Figure 3. The recoveries of

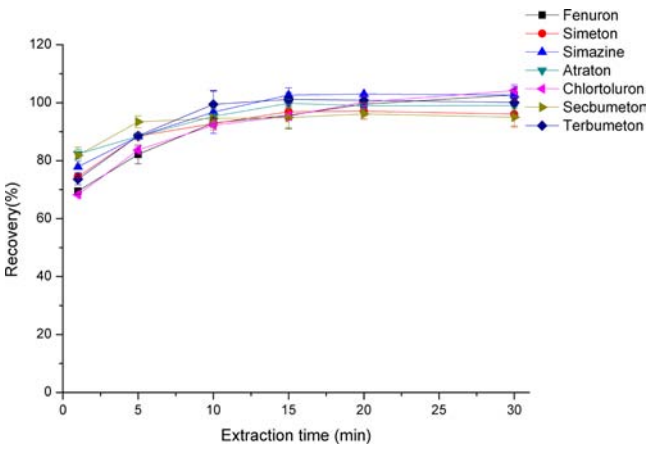

Figure 3. Effect of extraction time on recoveries of herbicides from soybean oil. Volume ratio of *n*-hexane to oil sample, 5:1; mass of MIL-101, 7 mg; centrifugation time, 3 min; eluting solvent, 1.5 mL of methanol; spiked concentration, 50 μg/L.

herbicides increase when extraction time increases from 1 to 15 min and change slightly with the further increase of extraction time. The recoveries increase rapidly within 10 min and increase slightly from 10 to 15 min. Therefore, the extraction time was selected as 15 min. The effect of centrifugation time was investigated in the range of 1−10 min. The effect of centrifugation time on the recoveries of herbicides is slight. The rapid separation of MIL-101 from sample solution may be due to the low density of sample solution. Therefore, 3 min was selected as centrifugation time.

Effect of Eluting Solvent and Elution Time. In this work, methanol and acetonitrile were used as eluting solvents in the volume range of 0.5−2 mL. The results shown in Figure 4 indicate that the recoveries of analytes increase with increasing

[a]The values in the table are mean recovery ± standard deviation (%, $n = 5$).

the volume of eluting solvent and change slightly when the volume of eluting solvent is larger than 1.5 mL. The recoveries obtained with methanol are slightly higher than those obtained with acetonitrile. As methanol is cheaper than acetonitrile, 1.5 mL of methanol was selected as eluting solvent. The eluting of analytes was carried out in ultrasonic bath. The effect of elution time ranging from 0.5 to 5 min was studied. There is no significant change in recoveries with the increase of elution time. So, 1 min of elution time was selected.

Statistical Analysis. To evaluate the reasonableness of the selected experimental parameters, the Student's t test was applied and the t values were calculated (the detailed information was listed in Supporting Information, Table 1). The results indicate that the difference between the selected value and the near value of the experimental parameters are significant ($P < 0.01$). So the selected experimental parameters should be reasonable.

Evaluation of the Present Method. *Analytical Performance.* The calibration curves were constructed by plotting the peak areas measured versus the concentrations of analytes in the spiked oil samples. The linear regression equations and correlation coefficients are listed in Table 1. The limits of detection (LODs) were calculated based on the signal-to-noise (S/N) ratio of 3. The LODs for triazine and phenylurea herbicides range from 0.585 to 1.04 μg/L.

Repeatability was evaluated by determining target analytes in spiked oil samples at spiked concentration of 50 μg/L. The intraday precision was obtained by analyzing a sample five times during a working day. The interday precision was obtained by analyzing the same sample over five working days.

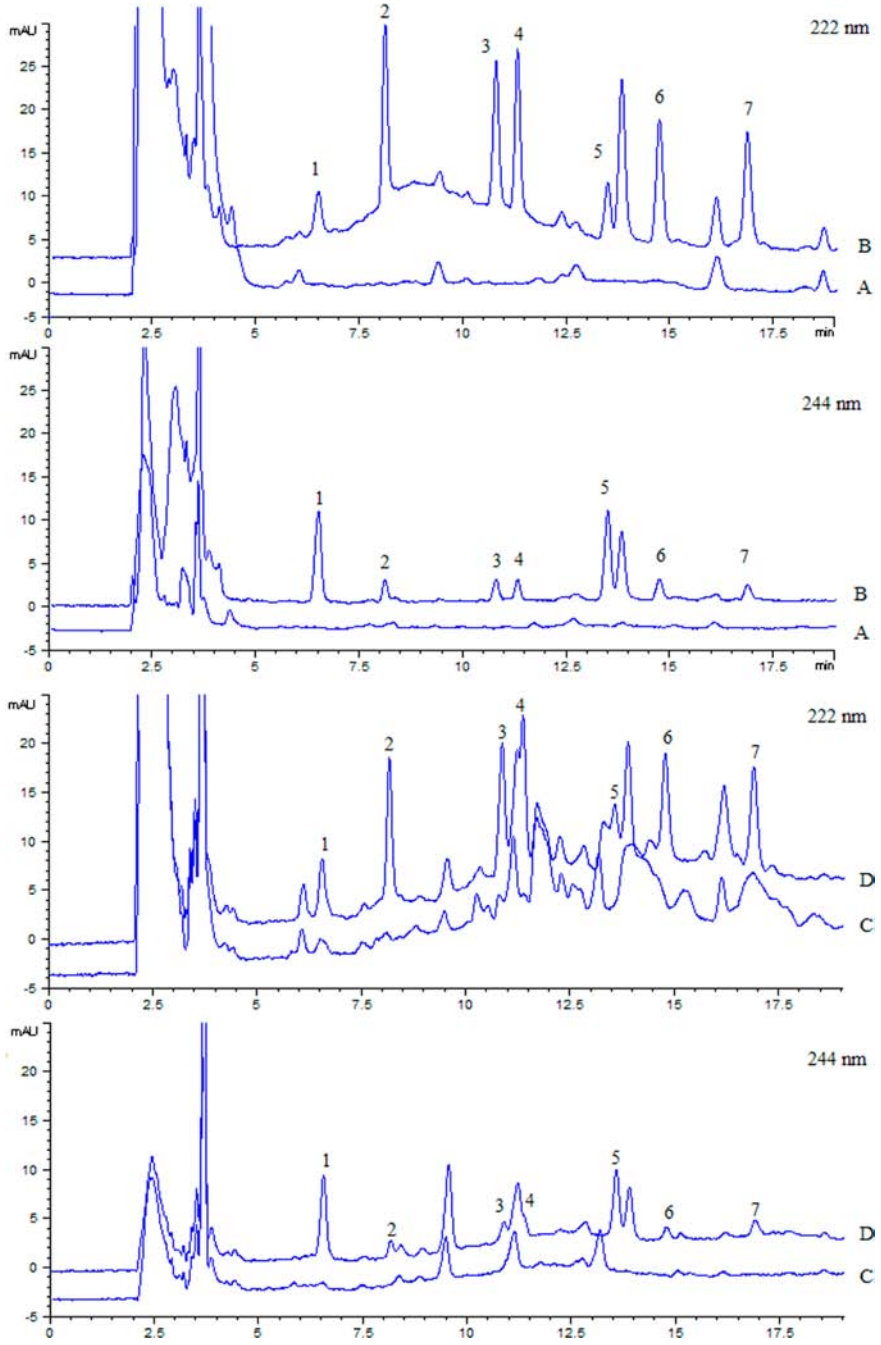

Figure 5. Chromatograms of extracts of soybean oil sample 1 (A) and spiked sample 1 (B) prepared by the d-μ-SPE method, and of soybean oil sample 1 (C) and spiked sample 1 (D) prepared by QuEChERS method. 1, fenuron; 2, simeton; 3, simazine; 4, atraton; 5, chlortoluron; 6, secbumeton; 7, terbumeton.

The results are listed in Table 2. The recoveries of intra- and interday range from 95.8 to 102%, with standard deviations ranging from 1.33 to 4.46%. The results indicate that the present method has good repeatability.

The long-term stability of the analytes in the sample was evaluated by analyzing one aged spiked sample of soybean oil. The recoveries of herbicides in aged spiked sample of soybean oil are listed in Table 3. It can be seen that the recoveries of herbicides range from 93.2 to 107%, with standard deviations ranging from 0.306 to 6.16%. It can be deduced that the herbicides in soybean oil are stable for at least 4 weeks.

Analysis of Samples. The target analytes were not found in vegetable oil samples. The practical applicability of the present method was evaluated by determining herbicides from four fresh spiked vegetable oils. The recoveries of herbicides in fresh spiked vegetable oil samples listed in Table 4 range from 87.3 to 104%, with standard deviations ranging from 0.562 to 7.79%. The results indicate that the present method provides satisfactory recoveries and acceptable precision at two concentration levels. The chromatograms of sample 1 and spiked sample 1 are shown in Figure 5.

Comparison with QuEChERS Method. For further evaluation, the present method was compared with QuEChERS method developed by Sobhanzadeh et al.[18] The chromatograms of the extracts obtained by QuEChERS method are shown in Figure 5. The resolutions of the peaks obtained by the present

DOI: 10.1021/jf505760y
J. Agric. Food Chem. 2015, 63, 2154−2161

method range from 2.04 to 24.6, and the selectivity ranges from 1.05 to 2.07. The resolutions of the peaks obtained by QuEChERS method range from 1.89 to 14.3, and the selectivity ranges from 1.04 to 1.42. In Figure 5, the chromatograms of the extracts obtained by QuEChERS method are much dirtier than those obtained by the present method. So the selectivity of the present method is higher than that of QuEChERS method. The high selectivity of the present method can be attributed to the reverse extraction way in which the analytes are adsorbed, while the fat and most of the interferents remain in sample solution. The large windows of MIL-101(Cr) make the introduction of the analytes into the cages easy.[3] The analytes were adsorbed on MIL-101 mainly by the coordination interaction between heteroatoms in analytes and the unsaturated metal sites, $\pi-\pi$ interaction between the analytes and terephthalic acid molecules of the framework, and the π-complexation between the π-electrons of analytes and Lewis acid sites in the pore of MIL-101. The analytes with log K_{ow} from 1.07 to 2.94 are relatively polar (the log K_{ow} was obtained from SciFinder scholar database). MOFs with open metal sites have great potential for enhancing adsorption of molecules with polarity.[30−32] The report by Huang and co-workers demonstrated that MIL-101 has high affinity to the volatile organic compounds containing heteroatom, especially the amines, and the surface of the MIL-101 is energetically heterogeneous.[31] Fu et al. also reported that the interaction between the open metal sites of MIL-101 and the polar analytes with electron-rich functional groups is very strong in nonpolar solvent.[32] The strong coordination interaction between the unsaturated metal sites of MIL-101 (electron acceptor) and the heteroatoms of analytes (electron donor) could have an important impact on the extraction process. Consequently, the herbicides in oil sample solution can be adsorbed effectively on MIL-101. Methanol, as a polar solvent, has strong dissolving ability toward analytes. Methanol, as a proton donor, could also chelate with the open metal sites of MIL-101 and weaken the interaction between MIL-101 and the analytes.[32] So the analytes can be easily eluted. The sensitivity of the method was evaluated by LODs. In Table 5, the LODs obtained by the present method are lower than those obtained by QuEChERS method. The accuracy was evaluated by the recovery of herbicides in spiked soybean oil samples. The results listed in Table 5 indicate that the two methods both provide acceptable accuracy. The comparison of the two methods on sample preparation process was also conducted and is shown in Table 5. Therefore, compared with QuEChERS method, the present method has some advantages in selectivity, sensitivity, sorbent and solvent consumption, operation procedure, and time consumption. So the present method is suitable to the extraction of herbicides in vegetable oils.

The present method was further compared with the reported methods for the determination of triazine and phenylurea herbicides in edible vegetable oils.[1,6,7,14,18−21,33−35] The results are shown in Table 5. The LODs obtained by the present method are lower than these obtained by most methods. The results indicate that the present method provides satisfactory sensitivity. In addition, compared with the other methods, the present method is quicker and simpler in terms of short extraction time and no additional cleanup step.

In the work, a d-μ-SPE method based on MIL-101 was developed for directly extracting triazine and phenylurea herbicides from diluted vegetable oils. A large mass of fat is easily separated. The experimental results indicated that the

present method has high selectivity, sensitivity, and accuracy. The present method is quick, simple, and effective, which shows great potential in the routine analysis of herbicides in vegetable oils. It would be an applicable method to extract contaminants in high-fat samples and also be a useful cleanup procedure for non- or low-fat samples by varying experimental parameters. The direct adsorption of analytes from oil samples is an attractive strategy to remove fat and improve method performance and MOFs are promising sorbents. It provides inspiration for the application of MOFs with unique structure and functions to the extraction of various contaminants in nonpolar system.

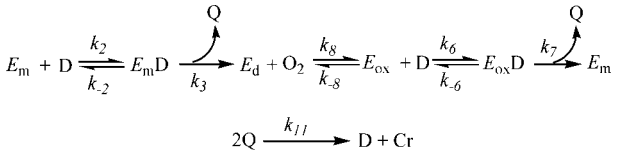

Figure 2. Action mechanism of tyrosinase on *o*-diphenols.

Considering the mechanism of action of the enzyme on monophenols and *o*-diphenols (Figures 1 and 2) and kinetic analysis of the two activities, the analytical expressions of the degrees of inhibition are obtained, and based on these, a test is proposed to differentiate a tyrosinase substrate other than L-tyrosine and L-dopa from an inhibitor of the enzyme. At the same time, the proper methodology is established to assay tyrosinase inhibition.

MATERIALS AND METHODS

Enzyme Source. Mushroom tyrosinase (3130 U/mg) was purchased from Sigma (Spain) and purified as previously described.[15] Protein content was determined by Bradford's method.[16]

Reagents. 4-*tert*-butylphenol (TBP), 4-*tert*-butylcatechol (TBC), L-dopa, L-tyrosine, sodium periodate, 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH), dimethylformamide (DMF), guaiacol, carvacrol, eugenol, isoeugenol, arbutin, benzoic acid, and cinnamic acid (see Figure 3) were purchased from Sigma. Stock solutions of substrates were prepared in 0.15 mM phosphoric acid to prevent auto-oxidation.

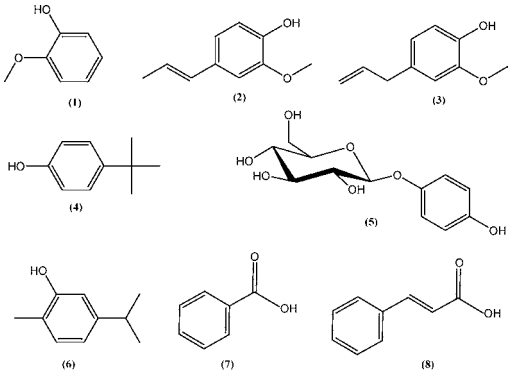

Figure 3. Chemical structures of the compounds studied. (1) Guaiacol, (2) isoeugenol, (3) eugenol, (4) 4-*tert*-butylphenol, (5) arbutin, (6) carvacrol, (7) benzoic acid, and (8) cinnamic acid.

Spectrophotometric Assays. Absorption spectra were recorded in a visible–ultraviolet PerkinElmer Lambda 35-spectrophotometer, online interfaced with a compatible PC 486DX microcomputer, with a 60 nm/s scanning speed controlled by the UV-Winlab software. The temperature was maintained at 25 °C using a Haake D16 circulating water bath with a heater/cooler and checked using a Cole–Palmer digital thermometer with a precision of 0.1 °C. Kinetic assays were also carried out with the above instruments by measuring the appearance of the products in the reaction medium. All the assays were carried out under saturating conditions of tyrosinase by molecular oxygen, 0.26 mM in the assay medium.[17] The activity on L-tyrosine and L-dopa was measured at 475 nm, which is the maximum absorption wavelength of dopachrome. The activity on TBC was followed at 410 nm.[18,19] The assays of activity in the presence of hydrogen peroxide were followed at wavelengths at which each generated product absorbed. All assays were made, unless otherwise stated, using 30 mM phosphate buffer pH 7.0.

Simulation Assays. The simulated progress curves were obtained by numerical solution of the nonlinear set of differential equations that describes the mechanisms corresponding to Figures 1, 2, 5, 6, 1SI, 4SI, and 2SI (see Supporting Information). The systems of differential equations were solved numerically for particular sets of values of the rate constants and of initial concentrations of the species involved in the reaction mechanism. The numerical integration used a fourth order Runge–Kutta method and the predictor-corrector Adams–Moulton algorithm, implemented on a PC-compatible computer program (WES).[20]

RESULTS AND DISCUSSION

Tyrosinase shows two enzymatic activities, the hydroxylation of L-tyrosine to L-dopa and the oxidation of the latter to *o*-dopaquinone. According to the mechanism shown in Figure 2, the formation and accumulation of dopachrome product is linear with time (data not shown). Figure 4 shows the tyrosinase activity on L-tyrosine: notice the apparition of a lag in the accumulation of dopachrome, curve a. At the same time, this lag decreased and was annulled when a certain amount of *o*-diphenol was added at the beginning of the reaction, curve b. The quantity of *o*-diphenol needed for the system to reach the steady state is given by $R = [D]_{ss}/[M]_{ss}$.[21] This equation establishes the quantity of *o*-diphenol [D] in the steady state $[D]_{ss}$ needed so that the monophenol concentration $[M]_{ss}$ reaches the steady state from $t = 0$. When more diphenol than needed was added to fulfill the relation R, a burst appeared at the beginning of the activity recording, curve c. In Figure 4, the inset shows the simulated progress curves a–c, obtained through numerical integration of the set of differential equations that describes the mechanism shown in Figure 1 (see Supporting Information).

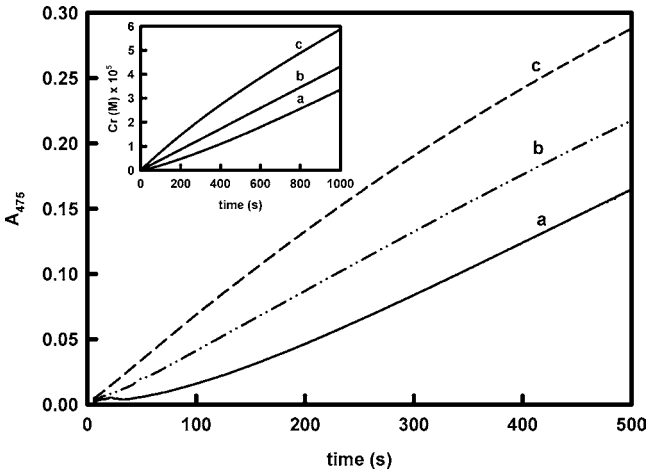

Figure 4. Relevance of the relation (R) between the *o*-diphenol, $[D]_{ss}$, and the monophenol, $[M]_{ss}$, in steady state ($R = [D]ss/[M]ss$). Dopachrome accumulation with time of using $[E]_0 = 8.0$ nM on L-tyrosine $[M]_0 = 0.25$ mM. (Curve a) L-dopa is not added at the beginning of the reaction $[D]_0 = 0$. (Curve b) L-dopa is added at the beginning of the reaction, $[D]_0 = 10.50$ μM, in order to fulfill the relation $R = 0.042$. (Curve c) More L-dopa than the required to fulfill the relation R is added, $[D]_0 = 28.75$ μM. (Inset) Simulated progress curves of the mechanism shown in Figure 1. The conditions were $[E]_0 = 22$ nM, $[E_{ox}]_0 = 0.3x[E]_0$, $[E_m]_0 = 0.7x[E]_0$, $[M]_0 = 0.25$ mM, (a) $[D]_0 = 0$, (b) $[D]_0 = 10.50$ μM, and (c) $[D]_0 = 28.75$ μM. The concentration of oxygen was 0.26 mM, and the rate constants were $k_1 = 2 \times 10^5$ M^{-1} s^{-1}, $k_{-1} = 10$ s^{-1}, $k_2 = 5 \times 10^6$ M^{-1} s^{-1}, $k_{-2} = 10$ s^{-1}, $k_3 = 900$ s^{-1}, $k_4 = 2 \times 10^4$ M^{-1} s^{-1}, $k_{-4} = 1$ s^{-1}, $k_5 = 5$ s^{-1}, $k_6 = 2.16 \times 10^5$ M^{-1} s^{-1}, $k_{-6} = 10$ s^{-1}, $k_7 = 108$ s^{-1}, $k_8 = 2.3 \times 10^8$ M^{-1} s^{-1}, $k_{-8} = 1.07 \times 10^3$ s^{-1}, and $k_{11} = 10$ s^{-1}.

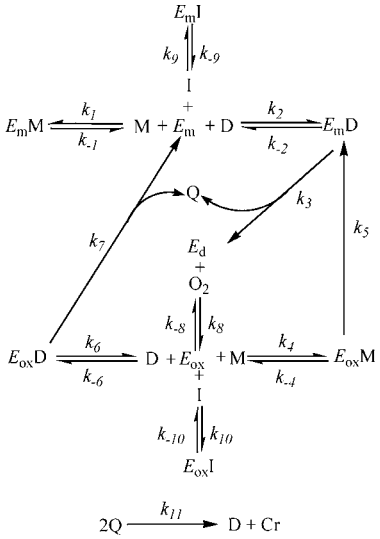

Figure 5. Action mechanism of tyrosinase on monophenols and *o*-diphenols in the presence of an inhibitor that binds to the enzymatic forms E_m and E_{ox}.

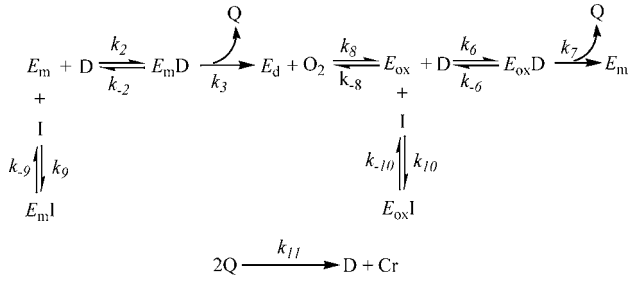

Figure 6. Action mechanism of tyrosinase on *o*-diphenols in the presence of an inhibitor that binds to the enzymatic forms E_m and E_{ox}.

The lag period observed at the beginning of the recording of the monophenolase activity of tyrosinase represents a substantial difficulty when making inhibitor assays.[22] It is essential to determine when the steady state is reached to measure the monophenolase activity. When an inhibitor is added to the reaction medium, the reaction rate of the enzyme decreases and so does the rate of accumulation of *o*-diphenol in the medium, and this means an increase in the lag period and the steady state is reached later, which therefore entails a longer measuring period. This has not usually been taken into account when studying the inhibition of the monophenolase activity, meaning that inexact values have been obtained for many studied inhibitors.[23−29]

We propose that to know whether the target molecules act as substrates or enzyme inhibitors, both the monophenolase and diphenolase activities must be studied. The monophenolase activity will be studied by adding the amount of *o*-diphenol necessary to avoid the lag period so that the steady state is reached from the beginning of the reaction.[22] In this case, the presence of an inhibitor in the medium will not involve an increase in the lag period, even though it will decrease the rate, so that the monophenolase activity can be measured from $t = 0$, both in the presence and absence of different concentrations of a target molecule.

In this work, we study two classic inhibitors of tyrosinase for comparative purposes (benzoic acid[30] and cinnamic acid) and investigate whether a group of target molecules (4-*tert*-

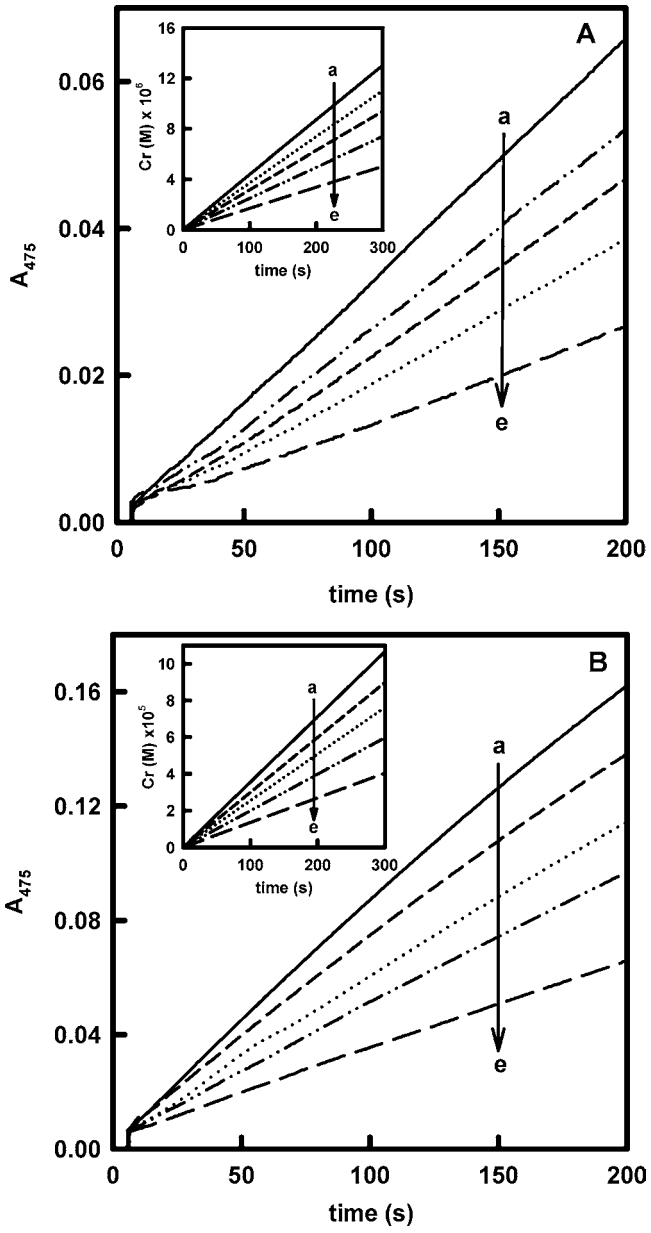

Figure 7. Action of benzoic acid on the diphenolase and monophenolase activities of tyrosinase. (A) Spectrophotometric recordings of the accumulation of dopachrome in the action of tyrosinase on L-tyrosine in the absence and presence of benzoic acid. The experimental conditions were $[M]_0 = 0.25$ mM, $[E]_0 = 7$ nM, $[D]_0 = 10.50$ μM, and the benzoic acid concentrations were (mM) (a) 0, (b) 0.15, (c) 0.35, (d) 0.70, and (e) 1.40. (A, inset) Simulated progress curves of the mechanism shown in Figure 5. The conditions were $[E]_0 = 22$ nM, $[E_{ox}]_0 = 0.3x[E]_0$, $[E_m]_0 = 0.7x[E]_0$, $[M]_0 = 0.25$ mM, and $[D]_0 = 10.50$ μM. The concentration of oxygen was 0.26 mM and the benzoic acid concentrations were the same as in part A. The rate constants were the same as in Figure 4 (inset) and $k_9 = 10^3$ M^{-1} s^{-1}, $k_{-9} = 4.1$ s^{-1}, $k_{10} = 10^4$ M^{-1} s^{-1}, and $k_{-10} = 4.1$ s^{-1}. (B) Records of the accumulation of dopachrome in the action of tyrosinase on L-dopa in the absence and presence of benzoic acid. The experimental conditions were $[D]_0 = 0.5$ mM, $[E]_0 = 5$ nM, and the benzoic acid concentrations were the same as in part A. (B, inset) Simulation of the mechanism shown in Figure 6. The conditions were $[E]_0 = 7.5$ nM, $[E_{ox}]_0 = 0.3x[E]_0$, $[E_m]_0 = 0.7x[E]_0$; $[D]_0 = 0.5$ mM. The concentration of oxygen was 0.26 mM and the concentrations of the inhibitor the same as in part B. The rate constants were the same as in part A (inset) and Figure 4 (inset).

butylphenol, eugenol, guaiacol, isoeugenol, carvacrol, and arbutin) act as tyrosinase substrates or inhibitors.

To determine whether a molecule of interest is a true substrate or an enzyme inhibitor, we must first ascertain if the enzyme reacts with the compound under study. In the case of target monophenols, this assay always shows no activity (data not shown), because monophenols, as described below, do not cause the chemical accumulation of *o*-diphenol in the medium.

Once this part of the test was completed, we determined the enzymatic activity on L-dopa in the presence and absence of a target molecule, measuring spectrophotometrically the accumulation of dopachrome at 475 nm. The concentration of L-dopa used was K_M^D. After this, measurements were made at different concentrations of the molecule of interest.

Table 2. Degree of Inhibition (i %) of the Monophenolase (i_M) and Diphenolase (i_D) Activities of Tyrosinase Obtained through Simulated Recordings by Numerical Integration of the Set of Differential Equations Corresponding to (a) the Mechanisms Shown in Figures 5 and 6, in Which Both Activities Are Shown in the Presence of Different Concentrations of an Inhibitor That Binds to the Enzymatic Species E_{ox} and E_m (Figure 7); (b) the Mechanisms Shown in Figures 1SI and 2SI Corresponding to the Tyrosinase Activity in the Presence of an Inhibitor That Binds to the Form E_{ox} in the Diphenolase Activity and E_{ox} and E_mM in the Monophenolase Activity (Figure 3SI)

	3.6	64.76 ± 0.49	58.74 ± 0.25
arbutin	0.3	33.02 ± 0.29	13.99 ± 0.04
	1.5	53.97 ± 0.76	27.59 ± 0.06

Similarly, the enzymatic activity on L-tyrosine was studied in the presence and absence of the target molecule, measuring the accumulation of dopachrome at 475 nm. The concentration of L-tyrosine used was K_M^M. Also, a concentration of L-dopa was added to fulfill $R = [D]_{ss}/[M]_{ss}$, reaching the steady state at t = 0.[31] After this, measurements were made at the same target molecule concentrations, as in the case of the diphenolase activity. To develop this kind of assay, it is not necessary to use concentrations of monophenol and *o*-diphenol similar to K_M, but the relations $[M]_0/K_M^M$ and $[D]_0/K_M^D$ must be the same.

Then, the degree of inhibition of the monophenolase (i_M) and diphenolase (i_D) activities were calculated and were compared. In cases where the inhibition degrees were the same ($i_M = i_D$), the molecule under study acted as an inhibitor. These mechanisms are described in Figures 5 and 6 and the results are shown in Table 2. The simulated progress curves obtained through numerical integration of the set of differential equations that describe the above mechanisms are shown in Figures 7A (inset) and 7B (inset). If the degree of inhibition differed ($i_M \neq i_D$), the molecule in question could either be an alternative substrate or an inhibitor (in which case it would

bind to any of the enzymatic forms of the diphenolase mechanism, and to one of the E_mM or E_{ox}M complexes of the monophenolase mechanism). Possible mechanisms involved are shown in Figures 1SI and 2SI and the results in Table 2. In Figure 3SI, the simulated progress curves obtained through numerical integration of the set of differential equations that describe these mechanisms are shown. In this case ($i_M \neq i_D$), two types of additional assays had to be undertaken to confirm if the target molecules were alternative substrates or inhibitors (see below).

Figure 7A shows the recordings of the monophenolase activity of tyrosinase on L-tyrosine at different concentrations of benzoic acid, obtained by adding a given amount of *o*-diphenol from t = 0 ($[D] = [D]_{ss}$), so as to satisfy the relation $R = [D]_{ss}/[M]_{ss}$, and Figure 7B shows the diphenolase activity of tyrosinase on L-dopa at the same concentrations of benzoic acid. The insets in Figure 7, show the simulated progress curves

monophenolase and diphenolase activities of tyrosinase in the presence of a competitive inhibitor (Figures 5 and 6)[30] (see Supporting Information).

Figure 8 depicts the kinetic recordings of the inhibition of the monophenolase and diphenolase activities by cinnamic acid. From the results obtained, both experimental and simulated, of the inhibition of the monophenolase and diphenolase activities (Figures 7, 8, and 3SI), the degrees of inhibition were calculated and are shown in Tables 1 and 2.

Note that the degrees of inhibition in both activities are the same, both for the experimental and simulated cases (Tables 1 and 2a), which agrees with eqs 4A and 8A (see the Appendix).

Investigating whether a phenol showing varying degrees of inhibition of the monophenolase and diphenolase activities is a tyrosinase substrate or inhibitor.

In cases in which the degree of inhibition of both activities was ($i_M \neq i_D$), two types of additional steps were made to confirm whether these molecules were alternative substrates or inhibitors. Guaiacol, isoeugenol, carvacrol, TBP, eugenol, and arbutin[6,32−38] showed this kind of behavior ($i_M \neq i_D$). Results are shown in Table 3. The recordings obtained with some of these molecules (TBP, isoeugenol, and guaiacol) are shown in Figure 9A−C.

Step 1. Measurement of the formation of the product originated in the oxidation of an *o*-diphenol by tyrosinase until total consumption of oxygen. To do this, TBC and L-dopa were chosen: in the case of TBC, the *o*-quinone, *o-tert*-butylquinone, is very stable and in the case of L-dopa dopachrome is formed, which is relatively stable. This step takes into account the stoichiometry of the mechanism shown in Figure 2. For TBC $1O_2$:2 *o*-quinone and for L-dopa $1O_2$:1 dopachrome. When all the oxygen is consumed in the absence or presence of an inhibitor and, bearing in mind the stoichiometries, when measuring the accumulation of *o-tert*-butylquinone, with ε = 1100 M^{-1} cm^{-1}, or dopachrome, with ε = 3600 M^{-1} cm^{-1},[18,19] the absorbances are constant. Figure 5SI depicts the simulated progress curves obtained through numerical integration of the set of differential equations that describe the mechanism shown in Figure 1SI. It can be seen that if the target molecule is an inhibitor, the level of concentration of the final product is always the same. If the phenols of interest are substrates, the level of concentration of the product is lower because the target molecules consume oxygen. The simulations of the mechanism shown in Figure 4SI show this behavior (Figure 5SI, inset). From the experimental point of view, to ensure that the observed variation in absorbance was due to the different coefficients of absorptivity of the *o*-quinones from the target compound and not to the interaction of this compound with the *o*-quinones of the TBC or the L-dopa, prior to this assay, the stability of these *o*-quinones was assayed. To test this, TBC or L-dopa substrates were oxidized with sodium periodate in deficiency to generate *o-tert*-butylquinone and dopachrome, respectively. Immediately after, the target phenols were added and the reaction of the *o*-quinones was observed. In cases in which there was not any variation in absorbance with time, the oxygen consumption step could be used to help identify whether the compound under study is an inhibitor or an alternative substrate.

In the reaction of dopachrome or *o-tert*-butylquinone with carvacrol or guaiacol (Figure 10), the variation of absorbance with time was evident. It was therefore not advisable to develop the oxygen consumption assay with these molecules. However, when the arbutin was studied, the absorbance did not change with time (Figure 11), and so, in this case, the test could be run as described in Step 1 (Figure 11, inset). The arbutin was seen to act as an alternative substrate of tyrosinase, because total absorbance decreases as the arbutin concentration increases (Figure 11, inset).

When the experiment described in Step 1 was applied to true inhibitors benzoic acid and cinnamic acid, oxygen consumption followed the typical substrate-dependent stoichiometry (reaching the same absorbance value as in the absence of the inhibitor). The apparent constant decreased when the inhibitor concentration increased, with both L-dopa (Figure 12A and inset) and TBC (data not shown).

Step 2. Deviations of the absorbance, after carrying out the oxidation with sodium periodate, indicated an interaction of the target molecule with the *o*-quinones of TBC and L-dopa, and it would not be possible to carry out the Step 1 correctly. In these cases, we assayed the target phenol with enzyme and hydrogen peroxide. It is known that hydrogen peroxide changes met-tyrosinase, which is not active on monophenols, into oxy-tyrosinase, which is active. When the target phenols in the presence of tyrosinase and hydrogen peroxide were assayed, we observed a variation in absorbance in repeated scans. After testing that this variation was not due to an attack of the hydrogen peroxide on the molecules under study, we could conclude that they are alternative substrates. This Step 2 was applied to isoeugenol and eugenol (Figure 13, recordings a and b, respectively), TBP (Figure 13, inset), arbutin, and carvacrol (Figure 14 recording a and b, respectively) and guaiacol (Figure 14, inset), measuring the increase of absorbance of the generated *o*-quinones. Note how arbutin that fulfilled Step 1 of the test also fulfilled Step 2. These findings confirm that all the studied molecules are tyrosinase substrates.

DOI: 10.1021/jf5051816
J. Agric. Food Chem. 2015, 63, 2162−2171

In conclusion, an experimental design is proposed that allows us to establish whether a phenol of interest is an alternative substrate or inhibitor of tyrosinase. The spectrophotometric method consists of several stages. If the results of the degree of inhibition of the monophenolase and diphenolase activities in the presence of the target molecule are the same, it can be deduced that this compound is an inhibitor. However, if the degrees of inhibition of both activities are different, it is still necessary to undertake Steps 1 and 2 to confirm that the target molecule is really an alternative substrate or a tyrosinase inhibitor. Also, a methodology is proposed to study the effect of inhibitors on the monophenolase activity experimentally by adding the *o*-diphenol necessary to reach the steady state at $t = 0$.

APPENDIX

Analytical Expressions for the Degrees of Inhibition of the Diphenolase and Monophenolase Activities of Tyrosinase

The rate of formation of dopachrome in the action of tyrosinase on *o*-diphenols is

$$V_0^{D(Cr)} = \frac{V_{max}^{D(Cr)}[D]_0}{K_M^D + [D]_0} \quad (1A)$$

In the presence of an inhibitor that binds to the enzymatic forms E_m and E_{ox} (Figure 7), it is

$$V_{0(i)}^{D(Cr)} = \frac{V_{max}^{D(Cr)}[D]_0}{K_M^D\left(1 + \frac{k_6K_{10} + k_2K_9}{k_2K_9K_{10}}[I]_0\right) + [D]_0} \quad (2A)$$

The degree of inhibition is given by

$$i_D = \frac{K_M^D\left(1 + \frac{k_6K_{10} + k_2K_9}{k_2K_9K_{10}}[I]_0\right) - K_M^D}{K_M^D\left(1 + \frac{k_6K_{10} + k_2K_9}{k_2K_9K_{10}}[I]_0\right) + [D]_0}100 \quad (3A)$$

Working at $[D]_0 = K_M^D$ and considering that $k_2 \gg k_6$ gives

$$i_D = \frac{[I]_0}{2K_{10} + [I]_0}100 \quad (4A)$$

A similar equation to eq 4A can be obtained for the monophenolase activity:

$$V_0^{M(Cr)} = \frac{V_{max}^{M(Cr)}[M]_0}{K_M^M + [M]_0} \quad (5A)$$

In the presence of an inhibitor that binds to the enzymatic forms E_m and E_{ox} (Figure 6), the rate of formation of dopachrome is

$$V_{0(i)}^{M(Cr)} = \frac{V_{max}^{M(Cr)}[M]_0}{K_M^M\left(1 + \frac{k_6K_{10} + k_2K_9}{k_2K_9K_{10}}[I]_0\right) + [M]_0} \quad (6A)$$

The degree of inhibition is given by

$$i_M = \frac{K_M^M\left(1 + \frac{k_6K_{10} + k_2K_9}{k_2K_9K_{10}}[I]_0\right) - K_M^M}{K_M^M\left(1 + \frac{k_6K_{10} + k_2K_9}{k_2K_9K_{10}}[I]_0\right) + [M]_0} \quad (7A)$$

Working at $[M]_0 = K_M^M$ and considering that $k_2 \gg k_6$ gives

$$i_M = \frac{[I]_0}{2K_{10} + [I]_0}100 \quad (8A)$$

Thus, eqs 4A and 8A show that, in the presence of the same concentration of inhibitor and the concentration of substrate corresponding to its respective K_M, the degrees of inhibition of the monophenolase and diphenolase activities of tyrosinase are similar.

be measured is bound between the capture antibody and the detection antibody.[17] By using a mouse mAb as a capture antibody and a rabbit polyclonal antibody (pAb) as the detected antibody, Chen et al. established a sandwich ELISA for detecting glycinin that showed high specificity for glycinin with a wider working range of 3−200 ng/mL and a limit of detection (LOD) of 1.63 ng/mL.[18]

Recently, as a developed technique based on ELISA method, immunochromatographic lateral flow test strips have been considered because they are inexpensive, rapid, portable, and extremely simple to operate. Immunochromatographic lateral flow test strips in the sandwich format have become a popular diagnostic tool for detecting high-molecular-mass analytes, such as viruses, bacteria, hormones, and parasite antigens.[19] However, these strips are not extensively used for the detection of food allergens, and there are no available lateral flow test strips for detecting glycinin. Therefore, in this study, we generated a pAb and a highly specific mAb against glycinin and developed a novel sandwich format lateral flow assay for the detection of glycinin in powdered milk.

MATERIALS AND METHODS

Materials and Apparatus. The following materials were used in this study: soybean β-conglycinin, agglutinin, trypsin inhibitor, peanut agglutinin (PNA), ovalbumin (OVA), casein, Freund's complete adjuvant (FCA), Freund's incomplete adjuvant (FIA), 3,3,5,5-tetramethylbenzidine (TMB), and mouse monoclonal antibody isotyping reagents, which were purchased from Sigma-Aldrich (St. Louis, MO, U.S.); PEG1500 was purchased from Roche (Mannheim, Germany); ELISA plates (96 wells) and other cell culture plastic wares were obtained from Costar (Cambridge, MA); goat antirabbit and goat antimouse IgG-horseradish peroxidase (HRP) were obtained from Abbkine (Redlands, CA); fetal bovine serum (FBS) was obtained from Hyclone (Logan, UT); Dulbecco's modified Eagle's medium (DMEM) was obtained from BRL-Gibco (Grand Island, NY); RPMI-1640, HAT, and HT medium were purchased from Invitrogen; nitrocellulose membrane, glass fiber, and absorbent pad were purchased from Millipore; and eight-week old female BALB/c mice and New Zealand White rabbits were obtained from the Laboratory Animal Center (Zhengzhou University, China) and were raised according to principles of the Henan Academy of Agricultural Sciences Animal Care and Use Committee. All other reagents and solvents were of analytical grade or higher.

The Model 450 Microplate Reader, electrophoresis cell vertical system, and semidry transfer cell used in this study were obtained from Bio-Rad (Richmond, CA). All water used was produced by a Milli-Q Academic Water Purification System (Millipore, Bedford, MA). The XYZ Biostrip Dispenser, CM 4000 Cutter, and TSR3000 membrane strip reader employed were purchased from Bio-Dot. The Multifuge X1R high-speed refrigerated centrifuge was purchased from Thermo Scientific (Osterode, Germany), and the FreeZone 2.5 Liter Benchtop Freeze-Dry System was purchased from LABCONCO (Kansas City, MO).

Glycinin Purification and Sample Protein Extraction. Soybeans and powdered milk were purchased at local supermarkets in Zhengzhou, China. Soybeans were ground to a fine powder and were passed through a 60 mesh sieve. The soybean powder was then defatted according to the method of Hei et al.[17] Soybean protein was then extracted by making a slurry with a 15-fold volume of water (adjusted to pH 9.0 with 2 N NaOH) under continuous agitation for 1 h, followed by centrifugation at 9000*g* for 30 min; the supernatant was then filtered through a 0.45 μm Millex GP filter (Millipore, Cork, Ireland). In accordance with a previous report,[20] 0.01 M $NaHSO_3$ was added to the soybean protein supernatant, and the pH was adjusted to 6.4 with 2 N HCl. The mixture was kept on ice overnight, and the precipitate was collected by refrigerated centrifugation at 6500*g* for 30 min at 4 °C. Crude extracts of glycinin were purified using Sepharose CL-6B (Sigma-Aldrich, St. Louis, MO), and the purified extracts were kept sealed after freeze-drying. The purity of the glycinin was estimated by high-performance liquid chromatography (HPLC) according to the method of García et al.[12] A Waters HPLC system (Milford, MA) equipped with a 600 Controller, In-Line Degasser AF, 2767 Sample Manager, and 2996 Photodiode Array Detector was used. The mobile phases employed were prepared with 0.1% (v/v) trifluoroacetic acid (TFA) in water (mobile phase A) and 0.1% (v/v) TFA in acetonitrile (ACN) (mobile phase B). Separation was performed with an reversed-phase (RP) perfusion column (POROS R2/H; 100 × 4.6 mm id) packed with cross-linked polystyrenedivinylbenzene beads (20 μm) from Perseptive Biosystems (Framingham, MA). The chromatographic method consisted of a linear binary gradient from 5 to 60% B over 5 min. The flow rate was 5 mL/min, the injection volume was 500 μL, and the detection was performed at 254 nm.

We procured commercially powdered milk without soybean included in the list of ingredients. Powdered milk was used in this study to evaluate glycinin recovery by the strip assay. The powdered milk was adulterated with different amounts of purified glycinin before being subjected to the defatting and protein extraction procedures described previously. The protein supernatants were analyzed either directly or following further dilution as required by the strip test.

Production of mAb against Glycinin. Three 8-week-old BALB/c female mice were immunized with purified glycinin. The first dose consisted of 50 μg of immunogen for subcutaneous injection as an emulsion of phosphate-buffered saline (PBS) and FCA. Three subsequent injections were administered at 3-week intervals with the same dosage of immunogen emulsified in FIA. Antisera samples were collected 4 weeks after the fourth immunization, and the samples were screened for antiglycinin activity by ELISA. The mouse with the highest antiglycinin activity received a fifth injection intraperitoneally. Three days later, the spleen of the injected mouse was removed for hybridoma production.

Hybridomas secreting antiglycinin antibodies were generated by standard methods.[21] Briefly, the spleen of the immunized mouse was removed, and the splenocytes were isolated and fused with NS0 cells using PEG1500. The fused cells were then distributed into 96-well culture plates in which mouse peritoneal macrophages were prepared on the day before fusion and were grown with the selective HAT medium. Ten days after fusion, the supernatants of hybridoma colonies were recovered and screened by indirect ELISA for the secretion of mAb binding to glycinin. Selected clones were subcloned by limiting dilution. Ascites fluids were produced in paraffin-primed BALB/c mice, and the mAb was then purified from the antiserum by ammonium sulfate precipitation. The subclass of the isotypes of the mAb was determined using mouse monoclonal antibody isotyping reagents. The measurement of monoclonal antibody affinity (Ka) was performed according to

DOI: 10.1021/jf5052128
J. Agric. Food Chem. 2015, 63, 2172−2178

the procedure described by Beatty et al.[22] The following formula was used to calculate Ka:

$$Ka = (n - 1)/2(n[Ab']t - [Ab]t)$$

$$n = [Ag]t/[Ag']t$$

where $[Ag]t$ and$[Ag']t$ represent two different concentrations of coating antigen and $[Ab]t$ and $[Ab']t$ represent the corresponding concentrations of mAb.

Indirect ELISA and Competitive Indirect ELISA. The antibody titer was monitored by indirect ELISA. Microplates were coated with 100 μL/well of purified glycinin (10 μg/mL) in 0.05 M carbonate-bicarbonate buffer (pH 9.6) and then were incubated at 37 °C for 2 h. After washing with PBST [PBS containing 0.05% Tween 20 (v/v), pH 7.4], the wells were blocked with 200 μL of 5% skim milk in PBST and then were incubated at 37 °C for 1 h. After another washing step, 100 μL/well of purified glycinin with 2-fold serially diluted antibody in blocking buffer was added and incubated for 15 min at 37 °C. Following the washing step, goat antimouse IgG-HRP conjugate (1:5000 in blocking buffer, 100 μL/well) was added and incubated for 30 min at 37 °C. The plates were washed again, and 100 μL/well of TMB in chromogen buffer was added; color development was terminated after 10 min with 2 mol/L H_2SO_4 (100 μL/well). The optical densities (ODs) were measured at 450 nm with a microplate reader. A competitive indirect ELISA was carried out to screen the antibody for antiglycinin activity. Microplates were coated as described previously, and 100 μL/well of glycinin serially diluted in PBS was then added with 100 μL/well of antibody and was incubated for 15 min at 37 °C. The following procedures were identical to those employed in indirect ELISA.

Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE) and Western Blot. The purified glycinin and isolated soybean protein were dissolved in PBS and were mixed with SDS sample buffer, and the samples were then loaded onto 5−12% polyacrylamide gradient gels. SDS-PAGE was performed at 90 V until the tracking dye migrated to the bottom edge of the gel. The gel was stained with 0.25% Coomassie Brilliant Blue R250.

The SDS-PAGE gels were transferred onto nitrocellulose membranes for 1.5 h at 15 V. The membranes were blocked with 5% skim milk in PBST at 4 °C overnight, and the membrane was incubated with antiglycinin mAb (1:5000) at room temperature for 1 h. After three PBST washes, the membrane was incubated with secondary antibodies (horseradish peroxidase-conjugated goat antimouse IgG 1:5000) at room temperature for 1 h, and 3-amino-9-ethylcarbozole (AEC) was used as a staining substrate.

Production of pAb against Glycinin. Two New Zealand White rabbits were used to produce pAb. Both rabbits were immunized subcutaneously with 200 μg of purified glycinin. The first subcutaneous injection was composed of an emulsion of PBS and FCA. Three subsequent injections were administered at 3-week intervals with the same dosage of immunogen emulsified in FIA. Four weeks after the fourth immunization, blood samples were collected directly from the heart and were screened for antiglycinin activity by ELISA. The antibody was purified from the antiserum by ammonium sulfate precipitation.

Preparation of Colloidal Gold-Labeled mAb. Colloidal gold with a mean diameter of 15 nm was produced by reduction of gold chloride with 1% sodium citrate (w/v), as described previously.[23] When preparing the colloidal gold-labeled mAb, the colloidal gold solution was adjusted to pH 9.0 with 0.2 mol/L sodium carbonate. The optimum ratio of mAb solution (1 mg/mL) to colloidal gold solution was determined according to a previous report.[24] Approximately 100 μL of mAb solution was added to 10 mL of the colloidal gold solution with constant stirring for 30 min. Then, 1 mL of 0.02 M sodium borate (pH 9.0) containing 10% bovine serum albumin (BSA) was added with stirring for 10 min to stabilize the conjugate. The colloidal gold-labeled antibody was washed three times with wash buffer (0.02 M sodium borate, pH 9.0; 1% BSA; and 0.1% sodium azide) by repeated centrifugation at 25 000*g* and 10 °C for 30 min. The precipitate was resuspended in 1 mL of wash buffer and was stored at 4 °C before use.

Fabrication of the Colloidal Gold Immunoassay Strip. The conjugation pad (7 mm × 300 mm) was prepared by dispensing a desired volume of colloidal gold-labeled mAb onto a glass fiber pad (Millipore) using an XYZ Biostrip Dispenser, followed by drying at 56 °C for 1 h before storage at 4 °C. Sample and absorbent pads were made from nonwoven material (Millipore). The sample pad (15 mm × 300 mm) was saturated with a buffer (pH 8.0) containing 20 mmol/L sodium borate, 2% (w/v) sucrose, 2% (w/v) BSA, and 0.1% (w/v) NaN_3, and the pad was then dried and stored as described previously. The nitrocellulose membrane (20 mm × 300 mm) was spotted using the same dispenser, with the optimal pAb and antimouse IgG antibodies applied in the test and control lines, leaving a 0.5 cm space between the two lines. After drying for 1 h at 40 °C, the membrane was blocked with 2% (w/v) BSA and then was dried, sealed, and stored under dry conditions. The absorbent pad was cut to dimensions of 20 mm × 300 mm. The sample pad, conjugate pad, blotted membrane, and absorption pad were assembled on a plastic backing support board (40 mm × 300 mm) sequentially with a 1−2 mm overlap. The master card was cut into 3 mm wide strips using a CM 4000 Cutter (Bio-Dot Irvine, CA, U.S.). The strips were then sealed in a plastic bag with desiccant gel and were stored at 4 °C.

Test Procedure and Principle. In the detection test, 100 μL of standard solution or sample extract is allowed to react with colloidal gold-labeled mAb. The mixture then moves upward on the nitrocellulose membrane chromatographically via capillary action. For a positive sample, glycinin binds to the mAb, forming a gold/antigen/antibody complex, which binds to pAb and forms a red color band in the test region. Higher amounts of glycinin in the sample result in a stronger test line color. The absence of this band suggests a negative result. To serve as a procedural control, a red band will always appear in the control region regardless of the presence of glycinin.

If both the test and control lines turn red, the sample is recorded as positive, indicating the presence of glycinin. If the control line but not the test line is colored, the sample is considered negative. If only the red test line appears, the strip is considered invalid, and the test should be repeated using a new strip.

Evaluation of the Lateral Flow Assay. The sensitivity of the test strips was determined by testing a series of diluted glycinin standard sample extracts in which various concentrations of purified glycinin, that is, 0, 50, 100, 200, 400, 800, 1600, 3200, 6400, and 12800 ng/mL, were used. Test lines were scanned with a Bio-Dot TSR3000 Membrane Strip Reader (BioDot, CA, U.S.). The assays were performed in triplicate using the test strip. The standard curve was constructed by

DOI: 10.1021/jf5052128
J. Agric. Food Chem. 2015, 63, 2172−2178

plotting the G/D × area (graph density × area) relative optical density (ROD) or G/peak-ROD values obtained from the standard samples against the logarithmic concentrations. The linearity of the analytes was assessed by the coefficient of determination (R^2), and the LOD was calculated from the regression equation.

To identify the specificity of the test strip, the soybean allergens (β-conglycinin, agglutinin, and trypsin inhibitor) and other food allergens (PNA, OVA, and casein) were tested at a concentration of 20 μg/mL.

To determine the accuracy of the test strip, powdered milk samples were spiked with purified glycinin at 3, 9, and 27 mg/kg; 100 g samples were defatted and mixed with 1500 mL water for protein extraction procedures and then were tested by the strip. The optical density of the test line was measured using the test strip reader, and sample values were calculated from the standard curve. Intra-assay precision was estimated using one batch of the test strips for replication analysis. For interassay precision, three batches of the test strips were used to detect the given samples. Precision was expressed as the coefficient of variation (CV, %).

RESULTS

Establishment of Hybridomas. The purity of glycinin was estimated to be 86.5% according to the HPLC analysis, which was sufficient for the immunization experiments. The BALB/c mouse immunized with purified glycinin with the highest titer (1:51 200) was selected for subsequent experiments for monoclonal antibody preparation.

Spleen cells from the mice immunized with glycinin were fused with NS0 myeloma cells, and the resulting hybridomas were selected in HAT medium. One or more growing hybridomas were observed in almost all wells after 7 days. The supernatants from each well were screened for antibodies against glycinin by direct ELISA using microtiter plates coated with glycinin. The cells from the wells showing the strongest response ($OD_{450\ nm}$ > 2.0) were tested again by competitive indirect ELISA for their ability to recognize free glycinin. Six selected hybridomas were screened and further cloned by limiting dilution. After culture and further screening, the most sensitive hybridomas (i.e., 2C3H5) were intraperitoneally injected into mice to produce ascites fluid, and the mAb was purified from the ascites fluid by ammonium sulfate precipitation.

Characterization of Antibody. The pAb from rabbit no. 2 was selected for further study because of its high titer of 1:1.024 × 10^6, which was the highest titer among the pAbs produced. The mAb 2C3H5 titer was 1:5.12 × 10^5, and the affinity constant (Ka) was 4.27 × 10^9 L/mol. The subtype of the mAb was identified as IgG1.

Western blot analysis was conducted to determine the polypeptide chains of glycinin that react with the mAb. Glycinin together with total soybean protein isolate was reacted with mAb 2C3H5. The results showed that there was a single band with a molecular weight of approximately 40 kDa, corresponding to the A3 acid polypeptide chain of glycinin (Figure 1A). The Western blot results indicated that the mAb reacted with the A3 acid polypeptide chain of glycinin specifically without cross-reaction with other polypeptide chains of glycinin or other soybean proteins.

Sensitivity of the Test Strip. The sensitivity of the test strip was determined by testing the series of diluted glycinin standard sample extracts. Test lines were scanned with a Bio-Dot TSR3000 Membrane Strip Reader. The G/D × area-ROD and G/peak-ROD values increased as the glycinin concentration in the samples increased, but they were saturated above 3200 ng/mL (Figure 2 and Table 1).

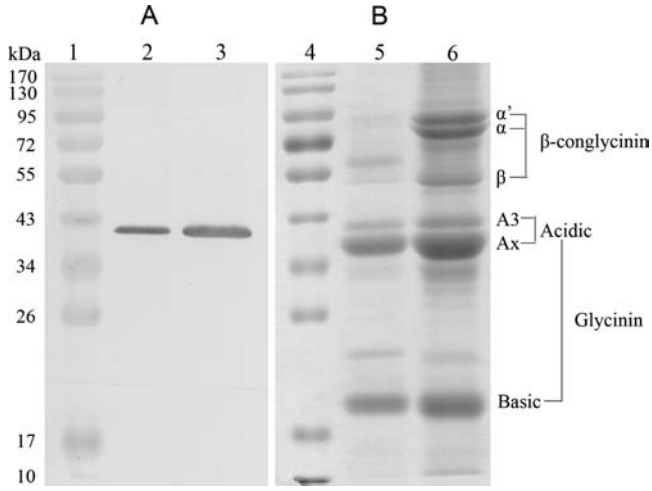

Figure 1. (A) Western blot analysis of mAb 2C3H5 with purified glycinin and soybean protein isolate. Lane 1, prestained protein marker; lane 2, purified glycinin; and lane 3, soybean protein isolate. (B) Protein profile of purified glycinin and isolated soybean protein determined by SDS-PAGE. Lane 4, prestained protein marker; lane 5, purified glycinin; and lane 6, isolated soybean protein. Subunits of β-conglycinin and polypeptide chains of glycinin are shown on the right (Ax indicates A1, A2, and A4).

The G/D × area and G/peak values of the ROD increased as the glycinin concentration in the samples increased. The concentration of standard glycinin and the G/D × area ROD produced a sigmoidal dose−response curve, which showed good linearity over the range of 50−3200 ng/mL. The standard curve was constructed by plotting the G/D × area-ROD percentage obtained from the standard samples against the logarithm concentrations (Figure 3). The LOD with the scanner was quantitatively defined as the amount of glycinin in the standard sample solution that caused a 10% increase in the G/D × area-ROD produced by the 0 ng/mL glycinin sample. Thus, a glycinin concentration of 46.1 ng/mL (equivalent to 0.69 mg/kg) was calculated to be the LOD for the test strip.

Specificity of the Test Strip. OVA, casein, PNA, soybean β-conglycinin, agglutinin, and trypsin inhibitor, each at a concentration of 20 μg/mL, were tested, and the color of the test line was the same as that of the negative control sample. The cross-reactivity results demonstrated that the test strip for glycinin was highly specific and showed negligible cross-reactivity with other food allergens (Figure 4).

Recovery of Glycinin in Powdered Milk Sample. To determine the accuracy of the test strips, powdered milk samples containing 3, 9, and 27 mg/kg of glycinin were tested. The test was performed in triplicate with a single batch of test strips. The optical density of the test line was measured using the test strip reader, and sample values were calculated from the standard curve. For intra-assay reproducibility, the recoveries ranged from 82.3 to 89.9%, with the highest coefficient of variation occurring at 5.29% (Table 2). For interassay reproducibility, three different batches of the test strips were used for triplicate measurements of the samples. Recoveries ranged from 80.5 to 87.7%, with the highest coefficient of variation occurring at 6.72%.

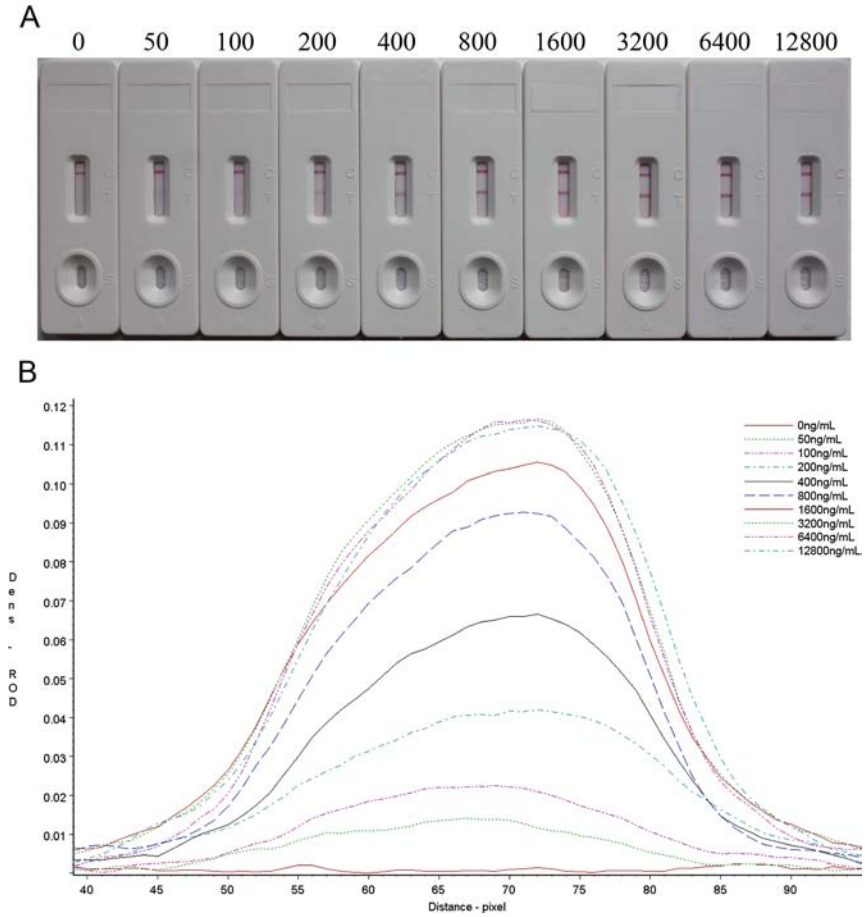

Figure 2. (A) Sample extracts added with glycinin standard solutions were tested using the test strips, and the test lines were identified with the naked eye. (B) Relative optical density (ROD) curves of the sample extracts. The extracts added with glycinin standard solutions at 0, 50, 100, 200, 400, 800, 1600, 3200, 6400, and 12 800 ng/mL were tested using the test strips. Test lines were scanned with a TSR3000 membrane strip reader.

Table 1. G/D × Area and G/Peak of the Relative Optical Density (ROD) of the Test Lines of the Sample Extracts Added with Glycinin Standard Solutions[a]

glycinin concentration (ng/mL)	G/D × area-ROD (pixel)	G/peak-ROD (pixel)
0	2.2518	0.0024
50	19.7731	0.0142
100	38.3656	0.0225
200	68.1175	0.042
400	93.8202	0.0666
800	128.8885	0.0927
1600	153.235	0.1055
3200	169.3604	0.1166
6400	169.0685	0.1163
12800	168.976	0.1147

[a]Sample extracts added to glycinin standard solutions were tested using the test strips, and the test lines were scanned with a TSR3000 Membrane Strip Reader. G/D × area-ROD: mean density value of the sampled line points multiplied by the area of the sampling window on the image. G/peak-ROD: peak value of the ROD points of the scanned line.

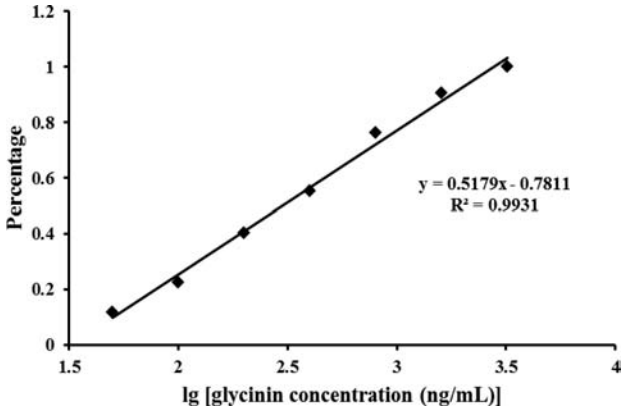

Figure 3. Standard curve for glycinin using test strip detection. The *x*-axis represents the logarithmic concentration. The *y*-axis represents the percentage of G/D × area-ROD of the standards divided by the G/D × area-ROD at saturation (3200 ng/mL). The linear regression correlation coefficient (R^2) is 0.9931.

DISCUSSION

Food allergies have become an important health problem in developed countries, affecting more than 1−2% of the population.[25] Undeclared allergens as contaminants in food products pose a major risk for sensitized persons. These issues are important because they could potentially have grave consequences for consumers and should be addressed by establishing reliable standards and methods for risk assessment.

Soybean allergy is of particular importance because soybeans are widely used in processed foods and therefore represent a particularly insidious source of hidden allergens.[26] To date,

Figure 4. Soybean β-conglycinin, agglutinin, trypsin inhibitor, PNA, OVA, and casein, each at a concentration of 20 μg/mL, were tested by test strip detection.

many ELISA methods have been developed for the detection of allergens using relatively inexpensive equipment and high-throughput screening. However, 2−3 h are required to perform such assays. In contrast, the immunochromatographic lateral flow test strip is a one-step assay that requires less professional personnel for the rapid identification of various analytes.

The key requirement for a successful immunochromatographic lateral flow test is the availability of antibodies with high specificity and the desired affinity.[27] In the present study, the monoclonal antibody prepared by the selected clone, 2C3H5, showed particularly high affinity for glycinin. The isotype of the mAb was identified as IgG1. The mAb 2C3H5 showed no cross-reactivity with other soybean allergens (soybean β-conglycinin, trypsin inhibitor, and agglutinin), resulting in a high specificity for glycinin.

Although some lateral flow assays designed for the determination of food allergens have been reported,[28−30] there has been no scientific report or sufficient validation of a lateral flow assay for detecting glycinin. In the present study, a novel immunochromatographic lateral flow test strip was developed using the sandwich format, which is applicable for target analytes with more than one epitope (high molecular mass analytes).[31] To evaluate the validity and reliability of the lateral flow test strip, sensitivity, specificity, and recovery studies were performed for the determination of glycinin in powdered milk. The results indicated that the lateral flow test strip was sensitive and reliable, and the lateral flow assay showed no reactivity toward other soybean allergens (β-conglycinin, agglutinin, and trypsin inhibitor) or other food allergens (PNA, OVA, and casein).

In conclusion, a high-affinity and specific mAb against glycinin was produced by immunizing mice with purified glycinin. Using the 2C3H5 mAb and rabbit pAb to develop the lateral flow test strip resulted in a highly sensitive test with an LOD of 0.69 mg/kg for glycinin, which is sufficient for the determination of glycinin in powdered milk. In addition, this lateral flow test strip can also be used to detect glycinin in other processed foods (e.g., cheese and sausage) when samples are appropriately extracted. Moreover, this effective method for detecting glycinin may be a valuable tool in identifying effective approaches for reducing the impact of glycinin.

DOI: 10.1021/jf5052128
J. Agric. Food Chem. 2015, 63, 2172−2178

Several studies have been carried out concerning the stability of olive oil under commercial and storage conditions using different types of packaging (see Table 1).[1,9−23] These studies conclude that the glass containers preserve the olive oils better than plastic bottles, because they provide greater protection against photo-oxidation and are impermeable to gases.[1−3] Other authors have concluded that the best container to package EVOO is the metal bottle, followed by the dark glass bottle.[10] From the revised works, only two papers have studied the effect of the Tetra-Brick package as a container to preserve the quality of EVOO.[1,20] Both studies concluded that the better package to preserve the EVOO is Tetra-Brick vs the metal container, at least during the time of study (6 and 9 months). It is important to take into account that these conclusions cannot be applied to any variety of EVOO, since different varieties have different behaviors under the same ambient conditions. As an example, it could be mentioned that Mendez et al.[1] did not show the variety used, while in the work of Samaniego-Sánchez et al.,[20] the variety used to carry out their study was *Picual*.

In this study, the stability of an EVOO from *Arbequina* olives over a long period of time (almost a year) according to container type and storage conditions is evaluated. This research was carried out by studying various quality-related parameters for olive oil.[24] To our knowledge, this is the first rigorous study assessing the stability of EVOO packaged in BB and in the more common package types (metal, glass, and PET) simulating household (Study 1) or supermarket storage of the oil (Study 2). And finally, as a second objective of this investigation, the results obtained with these physico-chemical analyses were for the first time compared with those for selected compounds present in the volatile fraction of EVOO as obtained in a single automatic analysis by headspace gas chromatography−ion mobility spectrometry (HS-GC-IMS).[25,26]

MATERIALS AND METHODS

Samples. Single-variety EVOO from *Arbequina* olives harvested in the 2012−2013 season was supplied by the firm *El Olivo Global* (Córdoba, Spain) and packaged in different types of containers that were all filled to the top in late January 2013 (month 0). The specific containers used were bag-in-box (BB, 5 L), metal bottle (M, 500 mL), dark glass bottle (DG, 500 mL), clear glass bottle (CG, 500 mL), and polyethylene bottle (PET, 500 mL). Notice that the different volume of BB with respect to the other types of containers is because a lower volume of commercial BB was not available. BB containers are usually used for packaging large amounts of olive oil. Although the initial volume of this container is 10 times higher than all others, it does not affect the comparison study, since BB prevents contact with air at all times, even after the package has been opened. A total of 30 different bottles (6 bottles of each one of the 5 types of containers) were filled for this study. All containers were exposed to alternating natural and fluorescent light to simulate supermarket storage conditions and household use of an olive oil package. The intensity of light was not controlled during the preservation of the samples. Also, all samples were stored at room temperature (approximately 23−25 °C) for 8 h each day over a period of 11 months. No temperature control was applied at any time during the rest of the day or at weekends. In addition, some samples were subjected to increased temperatures (above 30 °C) during the seventh month (August). In order to assess the effect of the container headspace and simulate typical domestic use of an olive oil bottle, a bottle of each container type was opened in February 2013 (month 1) and an amount of 50 g of oil withdrawn from each container at 2 month intervals (until December 2013) to create a substantial headspace. Once the sample was extracted of each container, the container was closed again and they were preserved, as mentioned above. This experiment was designated Study 1. Five bottles of each type of container were exposed to the experimental conditions of the study and a bottle of each container type was opened every 2 months and used to assess the stability of the oil on market shelves (Study 2). A schematic representation of the samples analyzed in this work is shown in Figure 1. All samples were filtered by gravity prior to analysis using filters of 85 g m^{-2} weight, 0.2 mm thickness, and 20−25 μm pore size supplied by FilterLab (Barcelona, Spain).

Reagents. The following chemicals were used in the physico-chemical analyses, all in analytical reagent grade except otherwise noted: acetic acid, chloroform, isooctane (spectrometric grade), and ethanol from JT Baker (Deventer, The Netherlands); sodium thiosulfate, potassium iodide, and potassium dichromate from Panreac (Barcelona, Spain); and soluble starch, diethyl ether, potassium hydroxide, and phenolphthalein from Sigma-Aldrich (St. Louis, MO, USA). All working-strength solutions used to assess oil quality were freshly prepared every 2 months.

The volatile compounds monitored, which had been identified by HS-GC-IMS in previous work,[27] were those possessing positive attributes or a rancid taste among those present or formed in EVOO, namely 2-penten-1-ol, hexyl acetate, 2-hexenal, 1-hexanol, 1-penten-3-one, 2-hexen-1-ol, hexanal, 2-heptenal, and 2-pentenal, all of which were purchased from Sigma-Aldrich and used to prepare stock solutions by dissolution in refined olive oil. All stock solutions were stored refrigerated at 4 °C prior to use.

Physico-chemical Analysis. Through EEC Regulation 2568/91[24] and EU Regulation 299/2013,[28] the International Olive Council and the European Community have defined the quality of olive oil in terms of physico-chemical parameters including free fatty acids, peroxide values and UV specific extinction coefficients (K_{232} and K_{270}).[24] These quality indices were evaluated in both oil batches at baseline and then at 2-month intervals. All parameters were determined at least in duplicate.

Direct Analysis of Volatile Compounds. Analyses for volatile compounds were carried out by HS-GC-IMS, using a FlavourSpec instrument from Gesellschaft für Analytische Sensorysteme mbH (G.A.S., Dortmund, Germany). For analysis, 1 g of sample was placed in a 20 mL vial that was then closed with magnetic caps. After 8 min incubation at 60 °C, 200 μL of sample headspace was automatically injected at 100 μL s^{-1} by means of a heated syringe at 80 °C inserted in a headspace autosampler from CTC Analytics (Zwingen, Switzerland) into the heated injector (80 °C) of the device. After injection, the carrier gas (N_2 from Abelló-Linde, Barcelona, Spain) was passed at 5 mL min^{-1} through the injector in order to drive the sample into the gas column, which was kept at 40 °C for timely separation. A 30 m long nonpolar gas chromatographic column from CS-Chromatographie Service GmbH (Dürem, Germany) packed with methyl, phenyl and vinyl silicone in a 94:5:1 proportion was used to separate the analytes. Then, the analytes were eluted in the isothermal mode and driven into the ionization chamber for ionization with a Tritium source (300 mBq < EURATOM allowed value) prior to spectrometric detection. The resulting ions were driven to the drift region via a shutter grid. The drift tube was 5 cm long and operated at a constant voltage of 400 V cm^{-1} and a temperature of 45 °C under a flow of N_2 (Abelló-Linde) at 250 mL min^{-1} as drift gas. Data were acquired in the positive ion mode. Each spectrum was the average of 32 scans obtained by using a grid pulse width of 100 μs, a repetition rate of 21 ms and a sampling frequency of 150 kHz. All samples were analyzed in triplicate. The procedure used to identify the volatile compounds by HS-GC-IMS is described in detail elsewhere.[27]

Data Analysis. Data were viewed and processed by using the software LAV v. 2.0.0 from G.A.S. One-way analysis of variance (ANOVA) using Tukey's test at the 5% significance level ($P \leq 0.05$) for all volatile compounds studied was done by using the software SPSS for Windows version 12.0 (SPSS, Inc., Chicago, USA) to identify variables exhibiting significant differences.

RESULTS AND DISCUSSION

The results obtained with classical analyses to assess the shelf life of EVOO under different storage conditions were compared

Table 1. State-of-the-Art about Studies of Stability of Olive Oil Samples

sample	type of package	storage conditions	storage time	study	conclusions	ref
four commercial samples of EVOO	clear PET bottles, PET bottle covered by A1 foil, glass bottle, tin and Tetra-brick	room temperature	6 mo.	influence of storage time on quality	Gradual loss of quality during storage, especially in plastic and glass bottles. The best containers for commercial packing of EVOO were tin and Tetra-brick.	(1)
EVOO (cv *Koroneiki*)	clear PET, clear PP, and clear glass bottles	22 °C with/without light incidence	12 mo.	effects of all three major packaging properties (oxygen permeability, light transmission rate, headspace volume) and storage temperature on the EVOO quality	The most appropriate material for olive oil packaging was glass, followed by PET and preferably a dark-colored container, stored in the dark, at temperatures less than or equal to 22ºC. Under such conditions the shelf life of extra virgin olive oil is 6 months.	(9)
EVOO (cvs *Picual*, *Hojiblanca*, and *Arbequina*)	0.5 mL dark and transparent glass bottles and tank	with/without headspace at 20 °C	12 mo.	evolution of the quality index of three EVOO varieties stored according to different packaging	The best packaging conditions for EVOO were deposits. *Arbequina* EVOO showed major changes throughout the storage period, while *Picual* EVOO was the most stable, and EVOO stored under nitrogen atmosphere could be packaged in glass bottles without appreciable quality changes.	(10)
EVOO (*Coratina* and *Oligliarola barese)*	clear and green glass bottles in light	light and dark, repeated opening of bottles and samplings	2 yrs	isomerization of 1,2-diacylglicerols to 1,3-diacyl-glycerols as a function of storage conditions	A significant increase in the 1,3-isomers took place during storage time, affected by the type of oil and the time.	(11)
EVOO	300 mL PET bottles	bottle with/ without oxygen scavenger (Amorsorb) in light and darkness at 20-22 °C	13 mo.	assessment the ability of active barrier PET bottles to preserve the quality of EVOO	The presence of a good oxygen scavenger dispersed in the PET bottles is useful to better preserve the original quality of EVOO.	(12)
EVVO (cvs *Bosana* and *Semidana*)	dark glass bottles	darkness at 20 °C with headspace	18 mo.	effect of extraction technology (traditional and with low oxidative stress technology) during storage	Free acidity, peroxide value, and K_{232} and K_{270} increased significantly during storage in both oils.	(13)
commercial Spanish EVOO	not reported	similar to conditions of market	12 mo.	stability of minor components with nutritional, antioxidant, and organoleptic properties	Higher market price is related to better quality and process control, giving a superior final product in terms of its content of minor components related to organoleptic properties.	(14)
seven samples of VOO (*Cornicabra*)	amber glass bottle	darkness at room temperature without headspace	21 mo.	evolution of major and minor components and oxidation indices	Quality indices PV, $K_{232,}$ and K_{270} increased linearly during the storage time studied. K_{232} was the first parameter that exceeded (8 weeks of storage) the established upper limit for EVOO.	(15)
EVOO (cv *Paragon)*	5 L containers	light and darkness at room temperature, and low temperature in the dark, with/ without headspace	12 mo.	how different storage conditions affect oil quality relative to that of fresh oil	EVOO stored at low temperature had characteristics similar to those of fresh olive oil, while oil stored in light conditions showed the largest departure from freshness. In the presence of oxygen, hexanal is a marker of storage in light conditions, free fatty acids in darkness, and acetic acid and pentanal at low temperatures. In the absence of oxygen, octane was the marker for storage in light conditions, whereas tyrosol and hexanol were markers for storage in the dark.	(16)

Table 1. continued

sample	type of package	storage conditions	storage time	study	conclusions	ref
four monovarietal Tunisian VOO (*Chemlali*, *Chétoui*, *El Hor*, and *Oueslati*)	not reported	accelerated oxidation conditions (50°C) in opened and closed bottles	8 mo.	changes in stability and antioxidant activity during long-term storage	A stronger and extended oxidation was observed in opened than in closed bottles throughout the storage period, with PV > 200 mequiv/kg.	(17)
EVOO (cv *Arbequina* and *Picual*)	glass flask	samples in closed flasks, irradiated with UV lamp	12 days	effects of UV radiation on the chemical and sensory characteristic of VOO	An abrupt decrease of the content in fatty acids and total phenols was observed during the irradiation time. Organic volatile compounds related to the rancid sensory attribute increased during the irradiation. *Arbequine* cv oil showed oxidation earlier than the *Picual* cv, which could be explained by the lower content in antioxidant in *Arbequine* against the *Picual*.	(18)
commercial EVOO (cv *Arbequina)*	amber glass bottle	darkness at ambient temperature	12 mo.	changes in lipid substrate in the phenolic fraction	An increase of oleic acid percentage was found in the fatty acid composition. Important losses of chlorophyll, carotenoids, and total phenol, secoiridoid derivatives, and 3,4-DHPEA-AC occur after the storage period. Lignans were the most stable phenolic compounds, and α-tocopheol disappeared after the storage period.	(19)
EVOO (cv *Picual*)	glass, PET, and Tetra-brick	stored at room (20 °C) and refrigerated (4 °C), darkness and no headspace	9 mo.	influence of factors affecting oxidation, such as time, storage temperature and the storage system, and their effect on EVOO quality	Storage of EVOO at low temperature offers a higher possibility for prolonged shelf life, in comparison to higher temperatures. The decrease of quality begins during the first month of storage. Oils placed in Tetra-brick were less altered than those packed in glass and plastic bottles.	(20)
EVOO (cv *Koroneiki*)	0.5 L tin containers	filtered and unfiltered oils, with/without nitrogen in the headspace; indoor conditions, 22 ± 5 °C; outdoor conditions, 0-20 °C (night-day) and 13-38 °C (night-day)	not reported	effects of olive oil storage indoors and outdoors	Increases in K_{232} and K_{270}, peroxides, total phenols and oxidative stability were very much reduced by inert headspace gas. Pattern of volatile compounds detected in olive oils stored indoors or outdoors showed subtle differences (3-pentenol, hexanal, and *trans*-2-hexenal).	(21)
EVOO (cv *Arbequina*)	transparent and amber glass bottles, PET, and tin containers	25 ± 1°C with and without illumination	6 mo.	effects of extraction system (pressure and centrifugation) and storage conditions (packaging material and illumination) on quality indices	Variations due to the extraction system were greater than those due to illumination conditions and package system. Glass and tin packages appear to be the most appropriate containers for maintaining the quality of olive oils, but this supposition is strongly dependent on the type of extraction.	(22)
EVOO (cv *Koroneiki)*	transparent glass and PVC bottle	stored at 28 °C, with different light intensities	10 mo.	effects of processing methods and commercial storage conditions (packing material and light intensities) on EVOO quality indexes	Oil exposed to daylight and artificial light attained maximum PV in the second or third month, while samples stored in darkness attained their maximum PV during the sixth month of storage. The rates of changes of PV, K_{232}, and K_{270} were affected similarly by the type of machinery, packing material, and light intensity. Samples packed in PVC showed higher PV than those packed in glass.	(23)

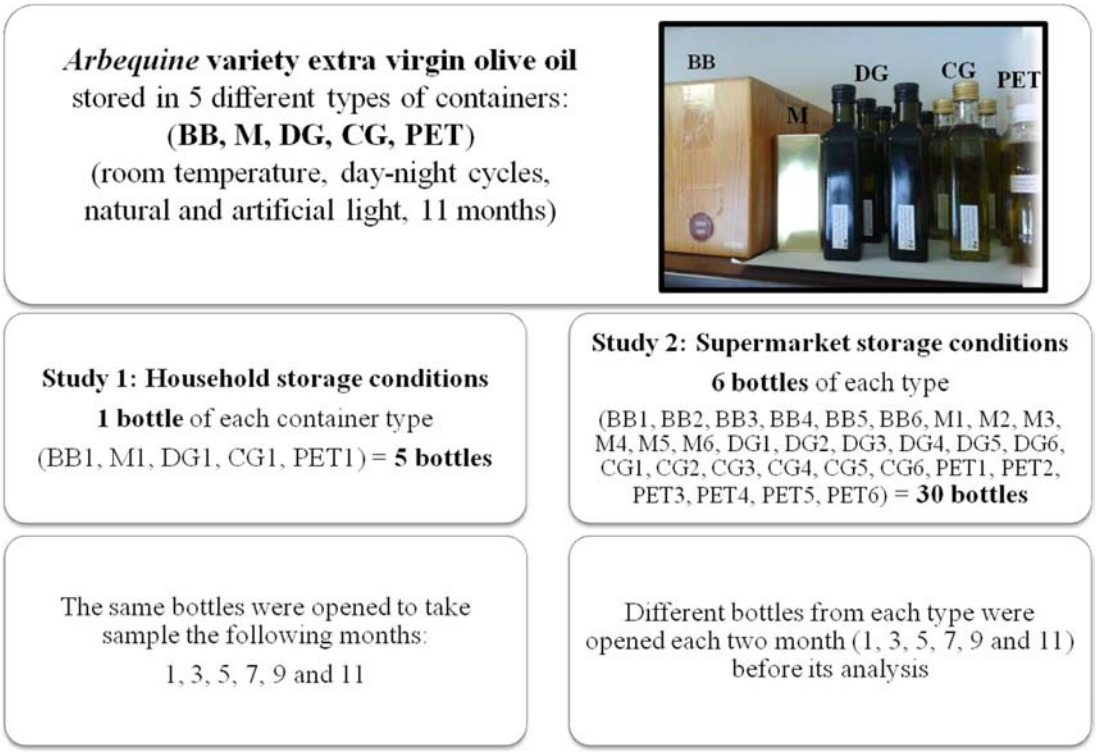

Figure 1. Schematic representation of the samples used in the shelf-life study.

with those obtained by HS-GC-IMS; this instrumental technique was used for the determination of some volatile compounds presented in olive oil samples. To this end, EVOO samples were stored in different types of packages and subjected to variable storage conditions in order to simulate household use (Study 1) and storage on supermarket shelves (Study 2).

Physico-chemical Analysis. Oil samples stored in different container types and conditions were subjected to baseline determinations of quality parameters including free acids, peroxide value and extinction coefficients (K_{232} and K_{270}). An increase in these parameters would indicate oxidation of the oil by effect of some storage condition or inappropriate processing of the oil. The initial values of all quality parameters (month 1) fell below the limits established by EU Regulation 1348/2013 for EVOO.[28] The results are discussed below.

Study 1: Simulation of Household Storage Conditions. Oil quality parameters were determined at 2 month intervals in order to assess the effect of the headspace created during consumption of EVOO samples in different types of containers. Acidity fell below the maximum acceptable levels established by the EEC regulations for EVOO (0.8% oleic acid) in all samples throughout the study. Also, storage for 11 months led to a slight increase in acidity in the five types of containers.

The initial peroxide values for the oils ranged from 10.4 to 15.8 mequiv of O_2/kg and were thus below the acceptable levels set by the EEC regulations (<20 mequiv of O_2/kg). As can be seen from Figure 2A, oxidation of the oil in DG, CG and PET after 5 months of storage was quite marked by effect of its high sensitivity to photo-oxidation; as a result, peroxide values exceeded the regulated limits for EVOO. In the containers where the oil was stored in the complete absence of light (viz., BB and M), the natural pigments in EVOO (chlorophylls) acted synergistically with phenolic antioxidants to inhibit auto-oxidation.[29] It should be borne in mind that when auto-oxidation starts it does not stop until all free radicals formed are inactivated.[30] Only the oil stored in BB retained EVOO grade at the end of the study period. On the other hand, as expected, the oil stored in PET exhibited the highest peroxide value as a result of the container material being the most permeable to oxygen and light,[1] and hence of its facilitating the formation and decomposition of hydroperoxides to volatile compounds responsible for the off-flavor of rancid oil.

The initial values of the coefficients K_{232} and K_{270} fell in the range 1.8−2.0 and 0.12−0.16, respectively, and hence below the legal limits for EVOO. Primary and secondary oxidation increased in the seventh month of storage (August, Figure 2B). Also, K_{232} exhibited a sharp increase in the containers exposed to high room temperatures that month; thereafter, however, K_{232} decreased gradually by effect of degradation into secondary products[23] in all samples except that stored in M. By contrast, K_{270} was not influenced by the high temperatures of August (see Figure 2C). At the end of the study, only the sample stored in BB had a K_{232} value below the acceptable limit for EVOO, and only those stored in BB, M, and DG had a K_{270} value under its limit. K_{270} peaked in the samples stored in transparent bottles.

Overall, the previous results are consistent with those of Pristouri et al.,[9] who found EVOO stored with a 200 mL headspace in clear PET bottles at 22 °C in the dark to lose its grade after 6 months. Based on our results, only the sample stored in BB retained its EVOO grade after 11 months. Therefore, BB was the best container type for storing EVOO under the influence of light and room temperature. Also, all traditional containers of commercial EVOO including glass and plastic bottles, which allow light to pass through, proved unsuitable for storing oil of this grade since, once the container was opened and the oil brought into contact with oxygen, the

J. Agric. Food Chem. 2015, 63, 2179−2188

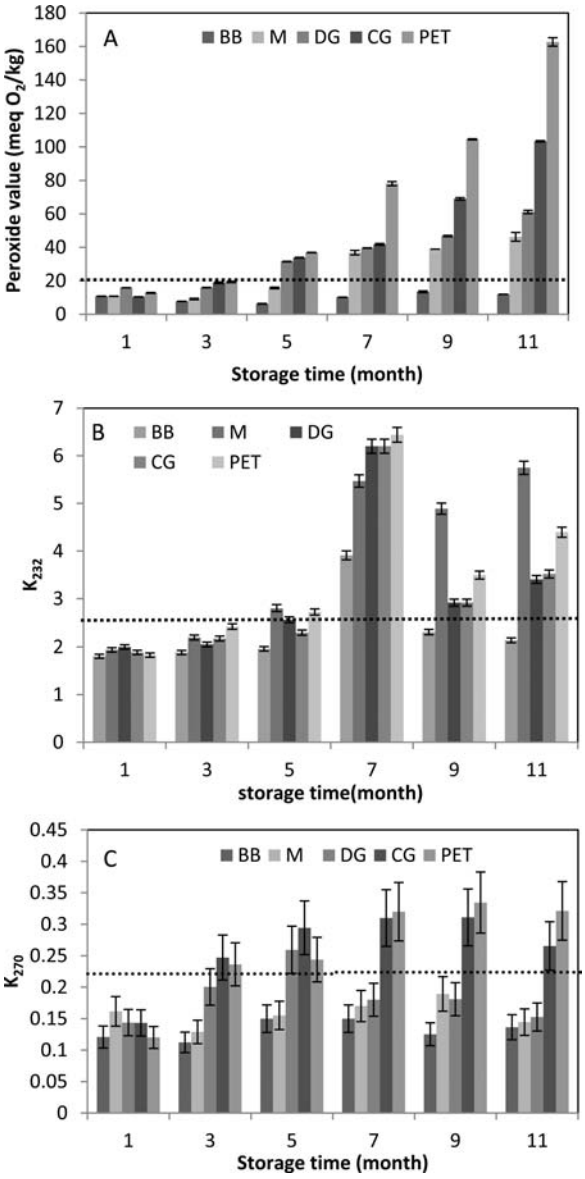

Figure 2. Variation of peroxide value (A), K_{232} (B), and K_{270} (C) in olive oil samples of the *Arbequine* variety held under household storage conditions in various types of containers. The dotted line sets the limit for EVOO grade according to ECC Regulation 2568/91.

oil degraded to an unacceptable extent after only 4 months. The sample stored in M, which is another typical container type for high-quality EVOO, lost its grade after 7 months (see Figure 2).

Study 2: Simulation of Supermarket Storage Conditions. In another experiment, we examined the variation of the target quality indices of EVOO from *Arbequina* olives over an 11-month period of storage in closed bottles under room temperature and light conditions in day/night cycles. The bottles were opened at 2-month intervals to withdraw oil samples for analysis. These conditions were intended to simulate storage of EVOO on a supermarket shelves. As expected, the oxidation rates were lower than those in the samples stored in containers with a headspace (Study 1).

Acidity increased slowly in all samples. The increase was somewhat greater in CG but all samples exhibited very similar values: 0.22−0.25% oleic acid. The peroxide value increased with storage time in all samples except that held in BB; also, only the oil stored in DG exceeded the acceptable limit for EVOO after 11 months—it should be noted, however, that this sample also exhibited the highest baseline peroxide value. The oil sample stored in PET exceeded only the accepted level for EVOO grade in the seventh and ninth months (see Figure 3A), possibly as a result of differences in surface area exposed to light and air between containers.

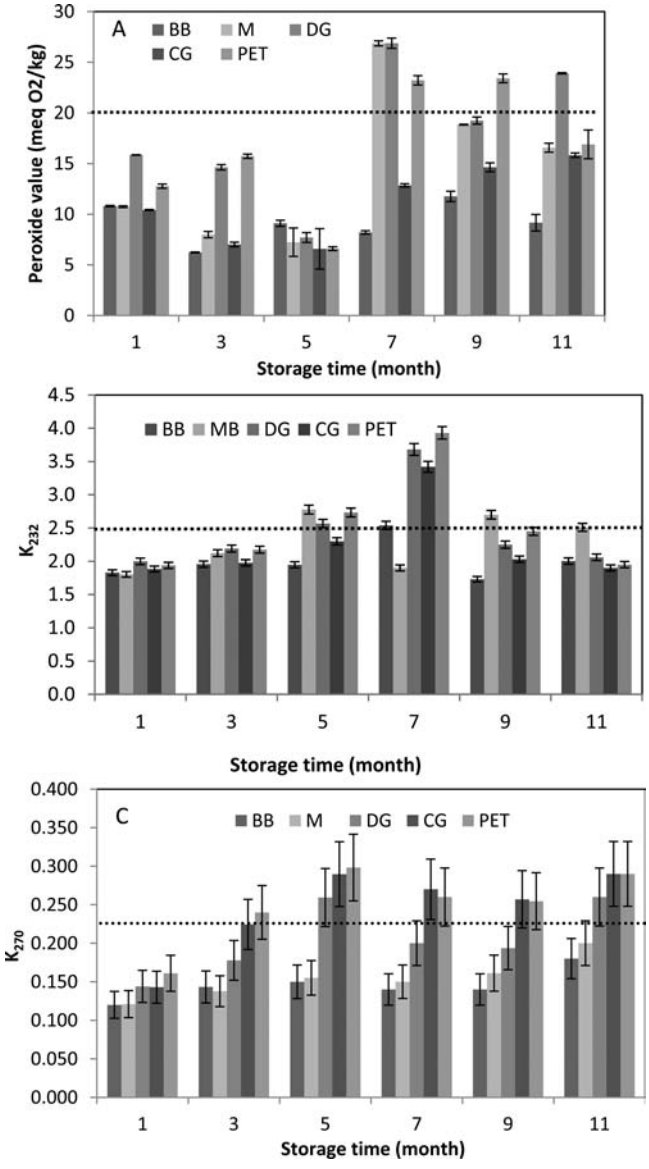

Figure 3. Variation of peroxide value (A), K_{232} (B), and K_{270} (C) in olive oil samples of the *Arbequine* variety held under supermarket storage conditions in various types of containers. The dotted line sets the limit for EVOO grade according to ECC Regulation 2568/91.

None the oil samples exceeded the K_{232} limits for EVOO grade ($\leq$2.5) at the end of the storage period (see Figure 3B). This parameter increased after 7 months but then decreased as in the samples stored with a headspace. These results are consistent with the low peroxide values obtained and hence with little primary oxidation. Also, they suggest that K_{232} was mainly influenced by the high temperatures reached in August owing to the absence of air conditioning in the storage room.

J. Agric. Food Chem. 2015, 63, 2179−2188

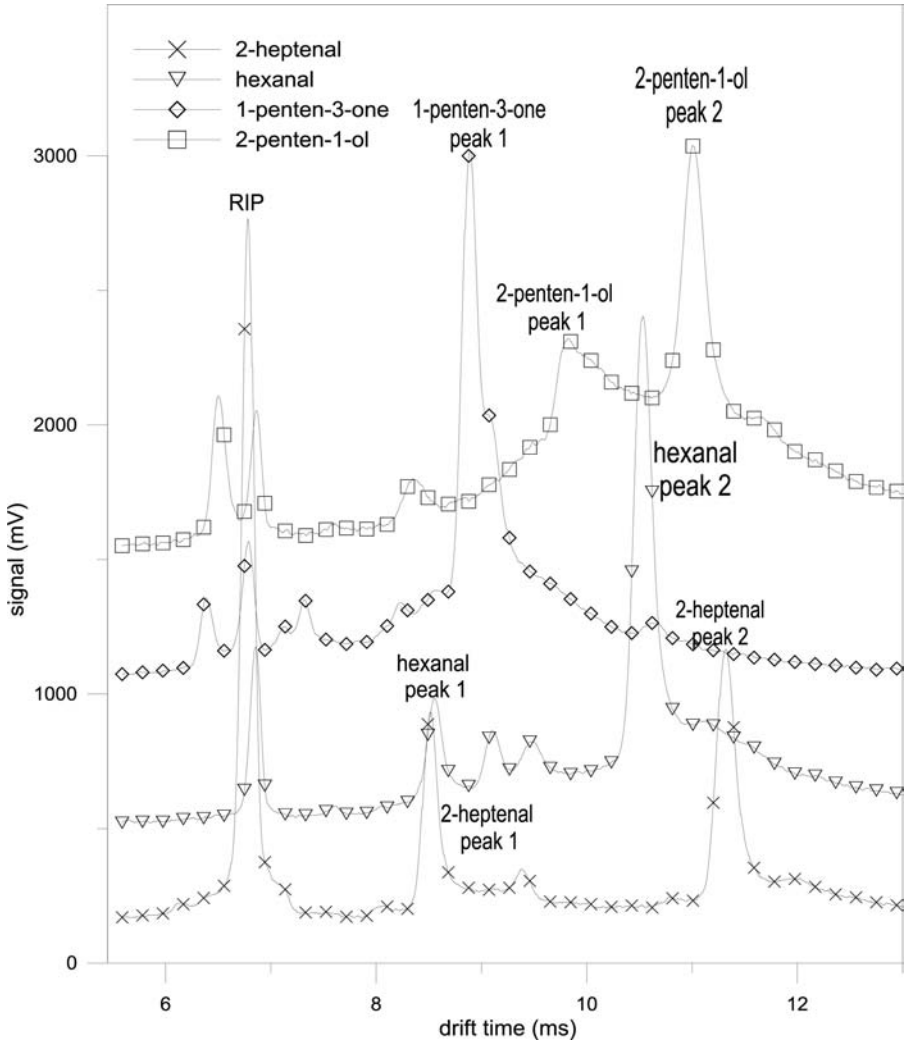

Figure 4. Ion mobility spectra from 2-heptenal, hexanal, 1-penten-3-one, and 2-penten-1-ol.

K_{270} behaved as expected (Figure 3C). Thus, the oil samples stored in CG, DG, and PET had K_{270} values above the accepted limit (0.22)—and suggestive of secondary oxidation—after 5 months that remained high through the end of the study. Consistent with previous results of Gutiérrez and Fernández,[31] K_{270} was the first quality index to exceed the legal limit for EVOO.

Based on the foregoing, the samples stored in BB and M retained EVOO grade for at least 11 months, whereas those held in the other types of containers lost it after only 5 months—as an exception, the DG samples seemingly remained intact for at least 9 months. The abnormal changes in some samples during the study can be ascribed to light and temperature having a different impact depending on the particular container.

Analysis of Volatile Compounds by HS-GC-IMS. HS-GC-IMS was used to determine the volatile fraction of the EVOO in order to evaluate the potential of this technique for assessing the shelf life of the oil. In this work, some major volatiles associated with positive and negative attributes of oil were determined at 1-month intervals in Study 1 and 2-month intervals in Study 2 to identify potential markers correlated with quality-related parameters for olive oil.

The aroma of olive oil has been attributed to aldehydes, alcohols, esters, hydrocarbons, and ketones among other compounds. The major volatiles in virgin olive oil are C6 and C5 compounds[16] that are enzymatically produced from polyunsaturated fatty acids via the so-called "lipoxygenase pathway". The main compounds with positive attributes examined in this study included 2-penten-1-ol, hexyl acetate, 2-hexenal, 1-hexanol, 1-penten-3-one, and 2-hexen-1-ol. Inappropriate storage of oil samples, however, can result in the production of volatiles conferring oil an off-flavor.[32,33] The volatile markers resulting from oxidation of virgin olive oil are mainly aldehydes. This led us to determine 2-pentenal, hexanal, 2-heptenal, and octanal, which are the main rancidity indicators according Solinas et al.[34]

Study 1: Simulation of Household Storage Conditions. As stated above, 5 bottles (one of each type) were opened in month 1 for analysis of the oil by HS-GC-IMS and the oil kept in its closed container for subsequent analysis on a monthly basis thereafter. The analytical results were subjected to ANOVA at the 0.05 significance level in order to identify those volatile compounds with a significant impact. Table S1 in the Supporting Information lists the mean values and standard deviations of the signal intensity for each compound as obtained by HS-GC-IMS. The compounds exhibiting significant differences in the ANOVA test were 2-heptenal, 2-penten-1-ol, hexanal, 1-penten-3-one, octanal, and 2-pentenal. Although 2-hexenal has been proposed as a marker of freshness

DOI: 10.1021/jf505415f
J. Agric. Food Chem. 2015, 63, 2179−2188

in EVOO,[4] the concentration of this compound failed to decrease with storage time in any container type here.

2-Heptenal has a typically rancid odor. This compound is present at increased concentrations in oxidized oil and is thus favored over hexanal or 2-pentenal as a marker for oil oxidation by some authors.[34] The ion mobility spectrum for 2-heptenal (Figure 4) exhibited two peaks, the first peak is known as protonated monomer and the second peak is a dimer ion with characteristics drift times. In some compounds (e.g., 1-penten-3-one), when the vapor concentration of the sample is high, only the dimer peak can be appreciated. As a general rule, it should be noted that the dimer ion is often formed with a decline in the intensity of the peak of the monomer ion and, the monomer peak can disappear from the spectrum or it cannot be distinguished from the background noise. Figure 5A shows the

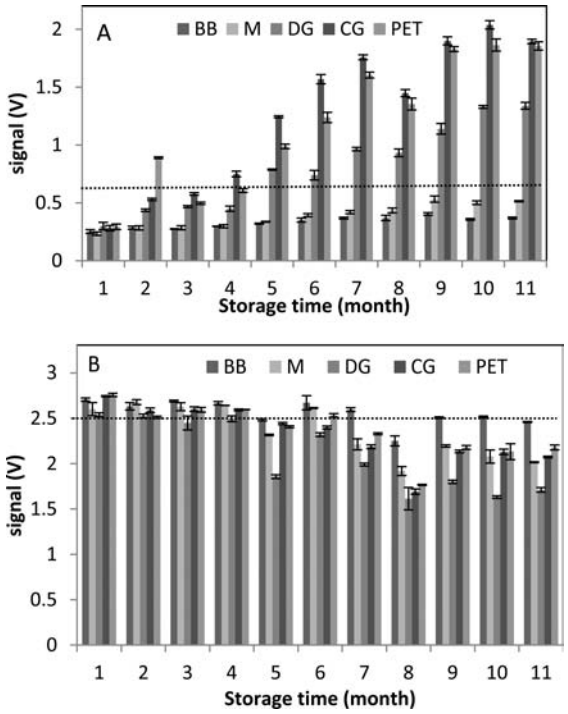

Figure 5. Variation of 2-heptenal (A) and 1-penten-3-one (B) in oils. Samples of the *Arbequine* variety held under household storage conditions in various types of containers.

temporal variation of the overall signal for 2-heptenal (peak 1, monomer ion + peak 2, dimer ion). The signal increased after the second month in the samples packaged in DG, CG, and PET, but particularly in those stored in the containers allowing light to pass through (viz., CG and PET). On the other hand, the signal for the oil stored in BB and M remained constant—as an exception, that for the sample stored in M increased slightly over the last 3 months. Formation of 2-heptenal was not altered by storage in BB because this package prevented contact of the oil with oxygen and also because the air chamber between the bag and the box isolated the oil from high temperatures. Based on the results, the increase in this compound was due to the effect of light mainly. The 2-heptenal concentration and the peroxide value were well correlated; in fact, as stated above, the formation and decomposition of hydroperoxides produces volatile compounds with rancid characteristics.

High-quality olive oil usually contains some hexanal, the concentration of which, however, can be increased by oxidative reactions. Hexanal is a product of the oxidation of linoleic acid occurring throughout the shelf life of olive oil. Like 2-heptenal, hexanal exhibited two IMS peaks (see Figure 4). The signal changed somewhat erratically. Thus, it initially increased for 5 months, and then leveled off for 3 months, and finally decreased through the rest of the study—particularly in PET. The changes in hexanal may be related to its contribution to oil flavor and off-flavor. A similar behavior was observed in 2-penten-1-ol.

1-Penten-3-one, which is present in quality olive oil, is responsible for green and spicy flavours in oil.[4] Figure 5B shows the temporal variation of this compound in EVOO stored in the different types of containers. As can be seen, its signal remained constant until the sixth month (July) in all samples and then decreased in all except that stored in BB. Also, the sample held in DG exhibited a more marked decrease in this compound than those stored in the other containers. The decrease may have resulted from the presence of oxygen in the containers and the high temperatures of month 7 (August).

2-Pentenal and octanal, which are also related to oil rancidity, exhibited significant differences in the ANOVA between samples, but no clear-cut variation in any container type.

The concentration of 2-heptenal was less markedly increased by storage in BB or M than in DG, CG or PET. The 1-penten-3-one content, were only preserved in the BB sample. The results for 2-heptenal (an aldehyde with negative connotations) and 1-penten-3-one (a ketone with favorable sensory attributes) confirm that the two can be used as markers for olive oil quality. A comparison between physico-chemical parameters and the intensity values of 1-penten-3-one and 2-heptenal compounds allowed establishing cutoff values. As peroxide values exceeded the regulated limits for EVOO after 5 months of storage, a cutoff value of 0.6 V for 2-heptenal and one of 2.5 V for 1-penten-3-one were established from the dotted lines of Figures 5A and 5B. Calibration curves for these compounds were run to find which values of concentration correspond to each intensity value corresponding to a concentration of 0.25 mg kg^{-1} for the aldehyde and 0.16 mg kg^{-1} for the ketone. Based on these cutoff values, the samples stored in containers allowing the passage of light lost their EVOO grade after 5 months and that stored in M after 7 months; also, the sample stored in BB retained its EVOO grade throughout. A similar conclusion can be drawn from the results of the physico-chemical analysis.

Study 2: Simulation of Supermarket Storage Conditions. As explained above, an aliquot from the sample stored in each type of container was withdrawn at 2-month intervals for analysis by HS-GC-IMS. The mean values and standard deviations of the IMS signal intensity for the target volatile compounds in each container, and the results of the ANOVA, are listed in Table S1 in the Supporting Information. The ANOVA revealed significant differences in 2-heptenal and 1-penten-3-one (i.e., the same compounds selected as markers from Study 1).

The signal for 2-heptenal (Figure 6A) increased in all containers except BB and M. In fact, all samples except that stored in BB exhibited an increase in this compound from the seventh month (August), probably as a result of the high prevailing temperatures and the little effect of this factor on the BB sample. Subsequently, the content of 2-heptenal decreased in all samples except those stored in CG and PET. The increase

DOI: 10.1021/jf505415f
J. Agric. Food Chem. 2015, 63, 2179−2188

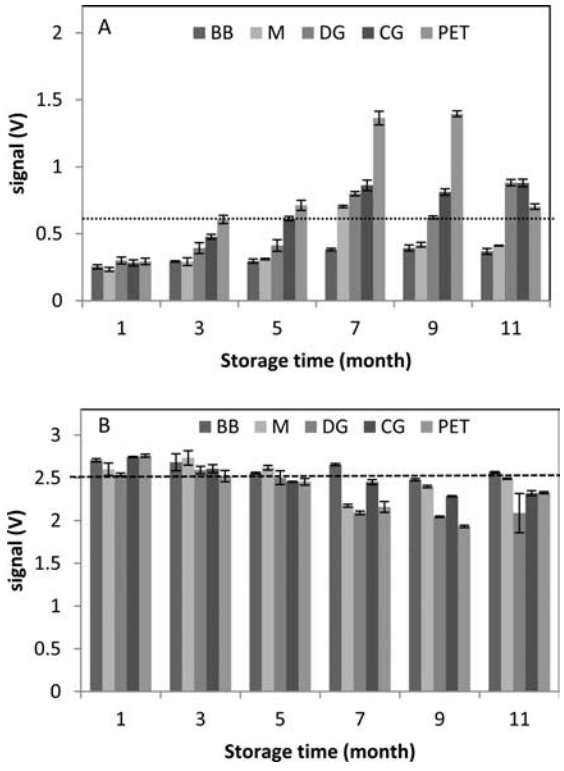

Figure 6. Variation of 2-heptenal (A) and 1-penten-3-one (B) in oils. Samples of the *Arbequine* variety held under supermarket storage conditions in various types of containers.

in 2-heptenal in the samples held in closed containers that were opened only once before analysis (Figure 6A) was less marked than that in the samples held under typical household storage conditions (Figure 5A). Therefore, the increased content of 2-heptenal was probably the main result of oxygen present in the bottles.

1-Penten-3-one (Figure 6B) decreased in all samples, but particularly in those allowing the passage of light: DG, CG, and PET. Also, all samples except those stored in BB and DG exhibited a sharp decline in this compound in the seventh month (August).

In conclusion, if a cutoff value of 0.6 V for 2-heptenal and one of 2.5 V for 1-penten-3-one are established from the dotted lines of Figure 6, panels A and B, then the only samples retaining EVOO grade at the end of the study were those stored in M and BB. On the other hand, the samples stored in completely transparent containers (CG and PET) lost their grade within 5 months, and that stored in DG within 7 months. The results obtained from the analysis of volatile compounds were similar to those of the physico-chemical analysis. Therefore, the HS-GC-IMS results for the studied volatile compounds confirm that 2-heptenal and 1-penten-3-one are two accurate markers of EVOO quality.

Advantages of HS-GC-IMS Method vs Others To Assess the Shelf Life of EVOO. Most existing methods for assessing shelf life in olive oil are classical methods (e.g., physico-chemical methods for determining quality-related parameters). These methods require large amounts of sample and solvents, and long processing times. The shelf life of EVOO has also been assessed by liquid (LC) or gas chromatography (GC). For example, fatty acids and diacylglycerols have been determined by GC with flame ionization detection[10,16] and antioxidants by LC.[25] Usually, these methods require dissolving the sample in an organic solvent or extracting the target compounds by using an effective method.[26]

HS-GC-IMS is also faster than physico-chemical analysis, and it uses less sample amount, does not needs solvents nor reagents, and is more environmentally friendly. The two methods provided similar results here. Thus, only the oil sample held in BB retained EVOO grade for at least 11 months under typical household storage conditions; by contrast, the sample held in M lost the extra grade after 7 months, and those stored in DG, CG, and PET after only 5 months. Among the samples stored under supermarket conditions, those held in BB and M retained their EVOO grade throughout; on the other hand, that stored in DG lost it after 7 months, and the others after 5 months, by effect of exposure to light and ambient temperature.

Based on the results of this study, and on previously reported data, the traditional containers for commercial EVOO (PET and glass) are unsuitable for storage on supermarket shelves. In fact, oil stored in these containers failed to retain its quality throughout its commercial lifetime in the presence of light. By contrast, oil stored in BB retained its EVOO grade throughout. Finally, it is important to mention that the variety used in this work (*Arbequine*) is more unstable than other varieties due to its low content of polyphenols.

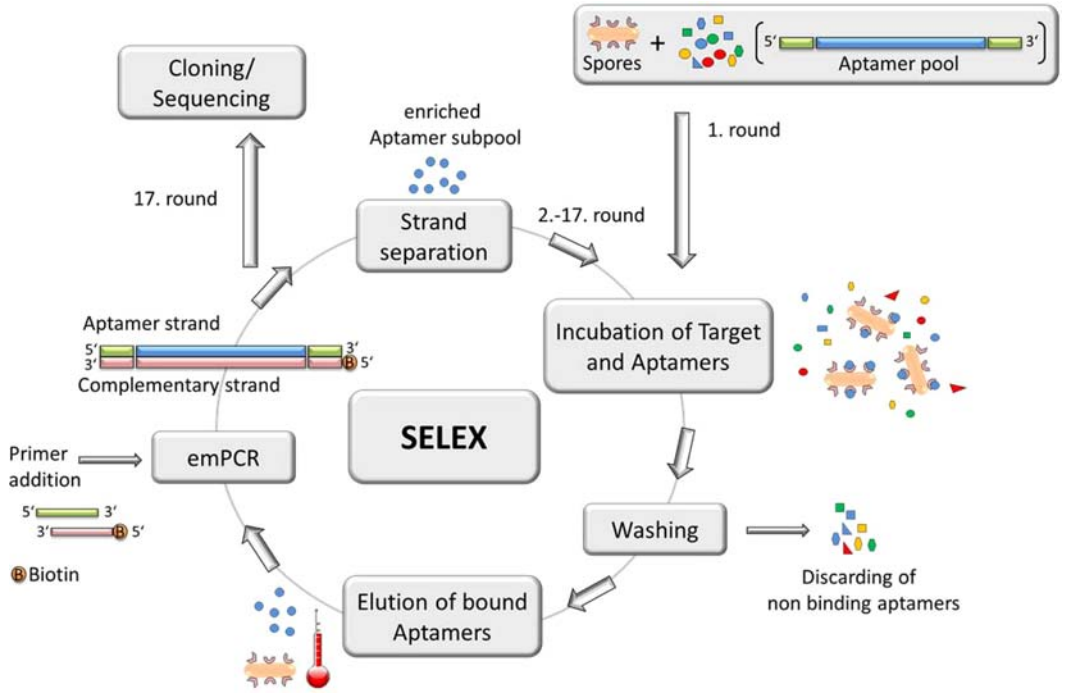

Figure 1. Schematic illustration of DNA aptamer selection for *Alicyclobacillus* spores by spore-SELEX in orange-juice-simulating buffer.

SELEX), and *Just-in-Time*-Selection (semiautomated two-step SELEX), but the field is still a part of current research, and further developments could be expected.[12,23,24]

Although aptamer amplification is established, common problems are (i) a preference for short DNA fragments during amplification and (ii) highly diverse aptamer pools which lead to undefined products by recombination of homologous template regions and formation of heteroduplexes.[25,26] Utilization of emulsion PCR (emPCR) provides significantly improved results, which are achieved by generating several different reaction compartments and a statistically ideal distribution of reaction compounds and templates.[27] To isolate single-stranded aptamers, the double-stranded nucleic acids have to be separated by utilization of a biotinylated reverse primer and streptavidin-coated magnetic beads.

In the present study, aptamers with an affinity to *Alicyclobacillus* spp. spores are selected in orange-juice-simulating buffer. The resulting aptamers are then used for selective trapping and enrichment of spores from orange juice, to supersede the classical time-consuming cultivation process. Hence, the aptamer-based trapping technique (e.g., magnetic separation) will help to accelerate the detection of these spores. The SELEX was verified by various techniques, including fluorescence-activated cell sorting (FACS), radioactive binding assays, and agarose gel electrophoresis (AGE). Aptamer characterization, including determination of dissociation constants (K_D values) and selectivity are performed by surface plasmon resonance (SPR) spectroscopy as well as fluorometric binding assay, flow cytometric binding assay, and fluorescence microscopy to validate the obtained results.

MATERIALS AND METHODS

Aptamer Selection. *Bacterial Strains.* For the spore-SELEX, *A. acidoterrestris* spores (DSM 2498, 10^8 cfu/mL; wild type, 10^8 cfu/mL) were received like all other spores from Lehrstuhl für Hygiene und Technologie der Milch, Tierärtzliche Fakultät, Ludwig-Maximilians-Universität (Munich, Germany), in paraformaldehyde (2%) and used as follows as SELEX targets: 1/1 v/v, final concentration 10^7 cfu/mL. The vegetative *Alicyclobacillus* cells used for counter selection during the first four SELEX rounds comprised ∼100 undefined wild *Alicyclobacillus* strains, obtained from Dr. B. Schütze, LADR GmbH (Geesthacht, Germany).

Aptamer Pool. The aptamer pool used for selection round one consists of the following sequence: 5′-CATCCGTCACACCTGCTC-$(N)_{40}$-GGTGTTGGCTCCCGTATC-3′ (Life Technologies GmbH, Darmstadt, Germany).

Aptamer Amplification and AGE. The emPCR was performed using the commercially available Micellula short DNA emulsion and purification kit (Roboklon GmbH, Berlin, Germany). The amplifications were carried out using biotinylated reverse primer for subsequent strand separation with the following sequences: 5′-CATCCGTC-ACACCTGCTC-3′ (forward primer, Life Technologies GmbH) and 5′-biotin-GATACGGGAGCCAACACC-3′ (reverse primer, Life Technologies GmbH). Aptamer amplification was carried out with 100 μL of aqueous phase in a 2 mL reaction tube as follows: 5 μL of DreamTaq-Polymerase (0.5 U/μL, Fisher Scientific GmbH, Schwerte, Germany), 10 μL of 10× DreamTaq buffer (Fisher Scientific GmbH), 8 μL of dNTPs (10 mM, Bioline GmbH, Luckenwalde, Germany), and 4 μL of each primer (100 μM, Life Technologies GmbH, Carlsbad, CA), and template was varied between 20 and 50 ng. After the aqueous phase was assembled, the oil-phase compounds were added to the reaction tube according to the manufacturer's protocol and mixed for 5 min at room temperature to create a homogeneous emulsion. Due to the volume of the reaction mixture, splitting into aliquots was necessary to perform a PCR under the following conditions: an initial denaturation step at 95 °C for 5 min, and subsequently 25 cycles of denaturation at 95 °C for 30 s, primer annealing at 56 °C for 30 s, and elongation at 72 °C for 30 s. Thereafter, a final elongation step at 72 °C for 5 min and finally a storage temperature of 4 °C followed. Afterward, the emulsion was broken according to the manufacturer's protocol, the oil phase was discarded, and the obtained emPCR products were purified using silica columns according to the protocol provided by the manufacturer. The emPCR products were analyzed by AGE.

Strand Separation. After the aptamer amplification, a strand separation step is mandatory to obtain again single-stranded DNA aptamers (subpool) for further selection rounds. Magnetic beads

DOI: 10.1021/jf505996m
J. Agric. Food Chem. 2015, 63, 2189−2197

(Dynabeads M-280 Streptavidin, Invitrogen Life Technologies GmbH, Carlsbad, CA) were incubated for 15 min under agitation with biotinylated emPCR products and the same volume of 2× binding-and-washing buffer (1 mM EDTA, 2 M NaCl, 10 mM Tris-HCl, pH 7.5). The supernatant was removed using a magnetic rack, and the beads were resuspended in 80 μL of ddH_2O before the tube was incubated 10 min at 95 °C for heat denaturation of double-stranded emPCR products. The heated supernatant was immediately centrifuged for 10 s at 10500*g*, and the tube was placed in a magnetic rack to agglomerate the magnetic beads at the bottom. The still-hot supernatant contained the desired aptamers, ready to be transferred into a new reaction tube.

General SELEX Protocol. To obtain aptamers with an affinity to *Alicyclobacillus* spores, the following SELEX protocol was used: 1 nmol of the corresponding aptamer pool (100 μM) was heated (5 min, 95 °C) in an orange-juice-simulating buffer (2 μM $CaCl_2$, 50 mM KCl, 2 μM $MgCl_2$, 40 mM Tris, pH 3.5), followed by immediately cooling (4 °C) to refold the aptamers and eliminate heteroduplexes. Afterward, a 20 μL aliquot of vegetative cells of *Alicyclobacillus* was added for counter selection. The mixture was incubated for 60 min at room temperature, followed by centrifugation (12 min at 10500*g*). The supernatant was refolded as described above and incubated for 60 min at room temperature with 20 μL of the SELEX target. Subsequently, the reaction mixture was centrifuged (12 min at 10500*g*), and the supernatant was removed. The resulting spore pellet was washed several times with 200 μL of 1× binding-and-washing buffer, centrifuged (12 min at 10500*g*), and resuspended in 35 μL of ddH_2O (Table 1). The obtained aptamer pool was heat eluted (5 min at 96 °C), and the hot supernatant was transferred to a new reaction tube. The obtained aptamers were amplified by emPCR followed by strand separation. For further SELEX rounds, 40 μL aliquots of each strand-separated aptamer pool (corresponding subpools) were used. A continuously rising stringency was achieved during the SELEX process by constantly increasing washing steps, decreasing target concentration and incubation times (Table 1). After 17 selection rounds, the final aptamer subpool was used for cloning and sequencing.

Table 1. Summary of SELEX Conditions To Increase Stringency during Selection Rounds

SELEX round	volume of spore mix (μL)	incubation time (min)	washing steps
1−4	20	60	1
5, 6	20	40	1
7	20	35	1
8	20	30	2
9	20	25	2
10	20	20	2
11	15	15	2
12, 13	15	15	3
14, 15	10	15	3
16, 17	10	10	3

Aptamer Cloning. The final aptamer subpool was ligated using a TOPO TA Cloning Kit (Life Technologies GmbH) and cloned into competent *Escherichia coli* cells XL1. Plasmid DNA was obtained and purified using the QIAprep Spin Miniprep Kit (Qiagen GmbH, Hilden, Germany). Ten aptamer candidates were sequenced by using the M13 universal primer (GATC-Biotech AG, Konstanz, Germany) (Table 2).

Determination of Aptamer Dissociation Constants (K_D) via SPR. *Spore Lysis.* Before immobilization of the target, the spores were fragmented using a TissueLyser (Qiagen GmbH). First, 40 μL of *Alicyclobacillus* spores (10^7 cfu/mL) and 250 mg of glass beads (0.5 mm diameter, Sigma-Aldrich-Chemie, Munich, Germany) were diluted with 360 μL of sodium acetate buffer (pH 5.0, Sierra Sensors GmbH, Hamburg, Germany), and the mixture was lysed twice (5 min, 30 Hz) at room temperature.

Sensor Chip Preparation. The resulting supernatant included the fragmented spores (10^6 cfu/mL) and was directly used for following immobilization and measurements using the SPR2 (Sierra Sensors GmbH). The HPA sensor chips (SPR-AS-HP, Sierra Sensors GmbH) are characterized by aliphatic hydrocarbon chains on the surface, and therefore highly hydrophobic interactions occur.[28,29] All SPR experiments were carried out at 25 °C with a flow rate of 25 μL/min using degassed orange-juice-simulating buffer containing 0.01% Tween 20. The HPA sensor chip was activated for 4 min by injecting a mixture (1/1 v/v) of isopropyl alcohol and sodium hydroxide (50 mM) on both channels. The chip was washed for 4 min by injecting the orange-juice-simulating buffer, and then the fragmented spores were injected for 8 min on channel 2. As a reference and to inhibit nonspecific interactions of injected aptamers with the chip surface, bovine serum albumin (BSA, 50 μg/mL, New England Biolabs GmbH, Frankfurt am Main, Germany) was immobilized by an injection for 8 min on both channels.

SPR Measurements. The K_D determinations were performed in orange-juice-simulating buffer as running buffer by injecting four different concentrations of pure aptamers (2.5, 5.0, 7.5, and 10.0 μM) for 6 min (Life Technologies GmbH). The obtained data were evaluated using AnalyserR2 (Sierra Sensors GmbH) and Scrubber (BioLogic Software Pty Ltd., Campbell, Australia) after subtraction of the reference signal from target signal. The sensor chip was regenerated by injecting regeneration buffer (100 mM hydrochloric acid) for 30 s after each aptamer injection. In addition, the orange-juice-simulating buffer was injected and used besides the BSA reference for a double-referenced calculation of dissociation constants.

Fluorescence Microscopy. To visualize the interactions between the spores and the aptamers, fluorescence microscopy was utilized. The visualization was carried out using a Cor2 fluorescence correlation spectroscope (Carl Zeiss AG, Oberkochen, Germany). Prior to the measurements, the aptamers were fluorescently labeled with Alexa488 by emPCR and strand separation using fluorescently labeled forward primer (5′-Alexa488-CATCCGTCACACCTGCTC-3′, Life Technologies GmbH) and biotinylated reverse primer. Subsequently, the aptamer concentration was determined using a Nanodrop ND-1000

spectrometer (Thermo Fisher Scientific Oy, Vantaa, Finland) and set to 5 ng/μL. To 190 μL of orange-juice-simulating buffer was added 30 μL of a labeled mix of all obtained aptamers, and this was then incubated with 30 μL of *Alicyclobacillus* spores (10^7 cfu/mL) for 1 h at room temperature under light exclusion. The mixture was centrifuged (12 min at 10500*g*), and the supernatant was discarded to remove excess aptamers. The resulting spore pellet was washed once with 100 μL of 1× binding-and-washing buffer and centrifuged (12 min at 10500*g*) anew, and the pellet was solved in 100 μL of ddH_2O. The analysis was carried out under the following conditions: argon laser (5 mW) with 25% output and 3% transmission, 40× lens, and wavelength 488 nm, which corresponds to the absorption maximum of the used fluorophore Alexa488.

Determination of Aptamer Selectivity via SPR. The aptamer selectivity was investigated using SPR2 by measuring the affinity of the obtained aptamers to different *Bacillus* spores as well as *Clostridium* spores (Table 3). For the following measurements, high-capacity amine chips (SPR-AS-HCA, Sierra Sensors GmbH) were used.

Table 3. Different *Alicyclobacillus*, *Bacillus*, and *Clostridium* Spores Used for Determination of Aptamer Selectivity via SPR

Sensor Chip Preparation. The sensor chips were activated for 4 min by injecting a mixture (1/1 v/v) of 100 mM *N*-hydroxysuccinimide (NHS, Sigma-Aldrich-Chemie) and 400 mM 1-ethyl-3-(3-(dimethylamino)propyl)carbodiimide (EDC, Applichem GmbH, Darmstadt, Germany) in PBS buffer. Afterward, a streptavidin solution (50 μg/mL, diluted in sodium acetate buffer, pH 5.0, Sierra Sensors GmbH) was immobilized by injecting for 6 min on both channels. Subsequently the sensor surface was blocked for 8 min by injecting ethanolamine (1 M, Sierra Sensors GmbH) on both channels. For the determination of selectivity, the aptamers were modified (5′-Biotin-TEG, Integrated DNA Technologies BVBA, Leuven, Belgium) and immobilized by injecting for approximately 8 min until a response signal of 200 RU (response unit) was obtained.

SPR Measurements. The aptamer selectivity was investigated in orange-juice-simulating buffer containing 0.01% Tween 20 as running buffer by injecting the spores listed in Table 3. The various spores were diluted to a concentration of 10^6 cfu/mL, fragmented as described above, and injected for 2 min. The sensor chip was regenerated by injecting regeneration buffer 2 (25 mM EDTA, 1% Tween 20, pH 12.0) for 30 s after each spore injection. In addition, the orange-juice-simulating buffer was injected for a referenced calculation of aptamer selectivity. The obtained data were evaluated as mentioned above.

RESULTS AND DISCUSSION

The occurrence of *Alicyclobacillus* spp. spores in juice is a major concern for fruit beverage industries due to the formation of an antiseptic and medicinal off-flavor by these microorganisms even after pasteurization. The endospores germinate under given conditions during the fruit juice production, especially in the course of the dilution of juice concentrates.[3] Prior to detection by various techniques, spores have to be enriched, typically by cultivation. Alternatives to the very time-consuming microbiological cultivation could be antibody-based or aptamer-based trapping and enrichment techniques. A prerequisite for aptamer applications is their selection using the so-called SELEX process.

Aptamer Selection. The specification of selection conditions, like buffer compositions and an increasing stringency during the selection process, is required to obtain aptamers with affinity to the target, i.e., the spores. The separation between aptamers with high affinity to spores, respectively vegetative cells, and aptamers with little or no affinity to spores, respectively vegetative cells, was achieved by centrifugation, which is common during cell- and spore-SELEX.[30,31] These particles accumulate by centrifugation due to the higher density of spores and vegetative cells and entrain the aptamers with an affinity for the corresponding target. In this work, defined *A. acidoterrestris* spores (DSM 2498, wild type, 1/1 v/v) were used as selection targets because these two strains seem to be representative for off-flavor production in fruit juices and are frequently abundant. To simulate the crucial conditions which influence aptamer secondary structures (ion composition: 2 μM Ca^{2+}, 50 mM K^+, 2 μM Mg^{2+}; pH 3.5), the used buffer compounds are, in terms of concentrations, as close as possible to orange juice. Especially the pH and the ionic bindings between cations and the DNA phosphate backbone have a huge impact on the secondary structure of aptamers and therefore on the binding properties.[32]

In addition, a continuously rising stringency during the SELEX process was achieved by constantly increasing washing steps, decreasing target concentration and incubation times (Table 1). Furthermore, a vegetative cell mix of ∼100 undefined *Alicyclcobacillus* spp. strains was used for a counter selection during selection rounds 1−4. The purpose of this approach was to generate aptamers selective to the spores of *Alicyclobacillus* spp., with little or no affinity to the vegetative cells. This strategy provides the opportunity to antagonize the enrichment of vegetative cells and therefore to inhibit false-positive results with the developed system.

The progress of aptamer selection was evaluated by various techniques to ensure the rising affinity toward the target during the SELEX process. After each SELEX round, the presence of aptamers was checked via agarose gel electrophoresis; furthermore, the increasing aptamer affinity was investigated via flow cytometric and radioactive binding assays (Supporting Information). After 17 SELEX rounds, the final aptamer subpool was ligated into plasmids, transferred into *E. coli* cells for isolation, and finally sequenced.

The 10 aptamers obtained with an affinity to *Alicyclobacillus* spores are listed in Table 2. Secondary structures are predicted using mfold V4.6 and shown for AliApt1, AliApt3, AliApt5, and AliApt9 in Figure 2.[33]

Aptamer Sequence Analysis. The secondary structure prediction was performed using mfold V4.6.[33] Taking into account the energy-minimization method, the secondary structure is calculated from a given primary structure, in which different characteristics of three-dimensional structures, such as hairpin structures, loops, or bubbles, are significant.[34] In addition, folding temperature and ion concentrations are

DOI: 10.1021/jf505996m
J. Agric. Food Chem. 2015, 63, 2189−2197

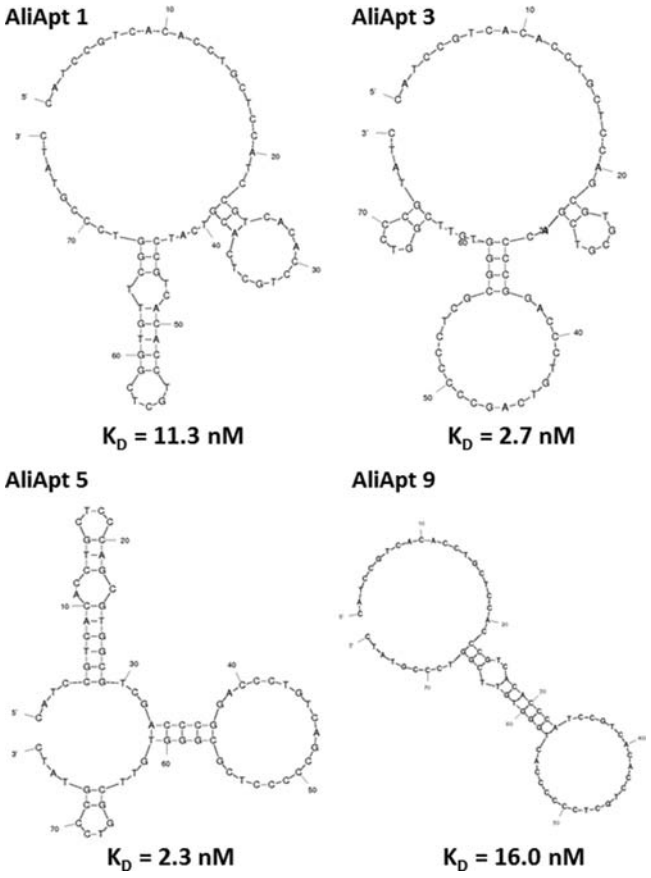

Figure 2. Secondary structural features with corresponding dissociation constants for AliApt1, AliApt3, AliApt5, and AliApt9, as predicted using mfold V4.6.

considered for calculation of the most energetically favorable secondary structure.[35] By comparison of the exemplary secondary structures (Figure 2), it could be noticed that homologous areas within similar structural features are observable. Furthermore, some characteristic structural features were unique in single secondary structures. The obtained aptamer sequences AliApt1−AliApt10 contain increasing numbers of cytosine repeats, which possibly form stable three-dimensional structures, called i-motifs.[36,37] These structural elements are very similar to guanosine quadruplexes and could be further investigated by NMR analysis. The high diversity of structural features led to the conclusion that the obtained aptamers presumably bind to various spore surface areas and not one defined spore coat. Further secondary aptamer structures are shown in the Supporting Information (Figure S3).

Determination of Aptamer Dissociation Constants (K_D) via SPR. To determine dissociation constants of the obtained aptamers to spores, several methods have been considered. For example, a flow system (quartz crystal microbalance, QCM) or immobilization-free techniques like microscale thermophoresis (MST) and isothermal titration calorimetry (ITC) have been previously used with cell lysates by Seidel et al. and Zhou et al., but suitable approaches for spores are not directly available.[38,39] Therefore, the well-established SPR technique was adapted to determine binding parameters of the obtained aptamers to the *Aliyclobacillus* spores.

In this context, we immobilized aptamers with different modifications on various sensor chip surfaces and injected spore suspensions without receiving evaluable data. It seems to be that the considerable differences in weights of the interacting partners and utilization of a flow system are responsible for steric hindrances and therefore non-evaluable data. Hence, like

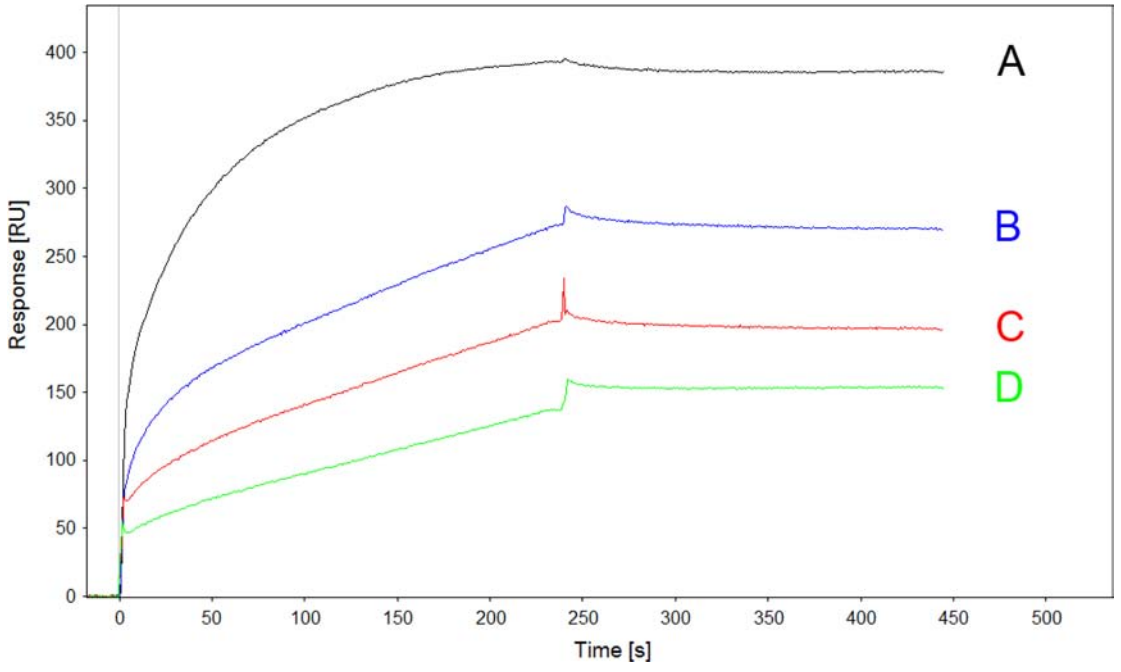

Figure 3. Overlay of AliApt3 sensorgrams with 360−840 pg immobilized spores fragments and several aptamer concentrations: (A) 10 μM, (B) 7.5 μM, (C) 5 μM, and (D) 2.5 μM. SPR measurements were carried out using orange-juice-simulating buffer (25 μL/min) to retain the secondary structures of aptamers. The double-referenced data are evaluated with AnalyserR2 (Sierra Sensors GmbH, Hamburg, Germany) and Scrubber (BioLogic Software Pty Ltd., Campbell, Australia).

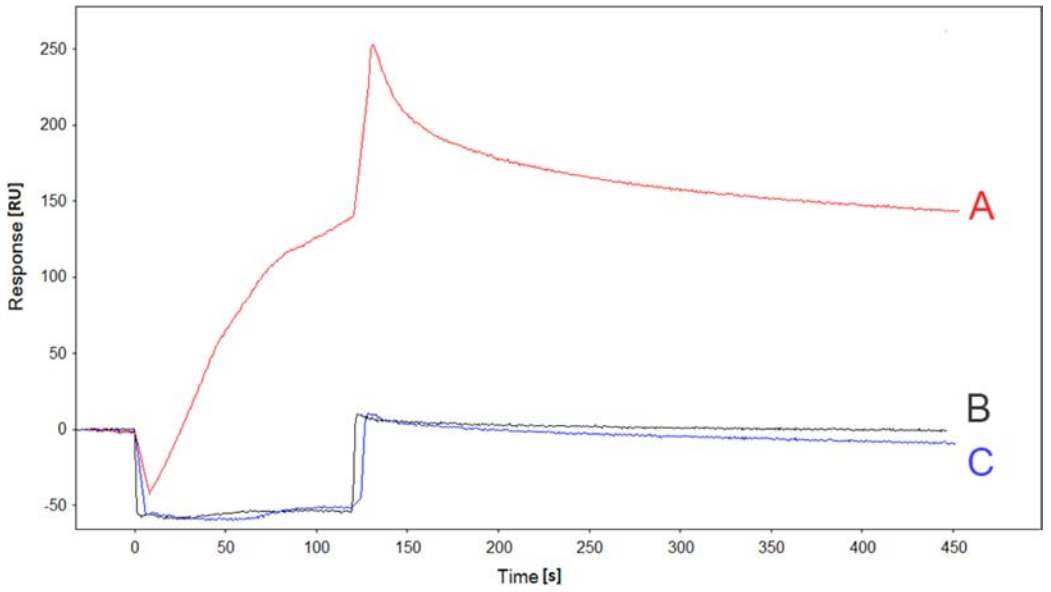

Figure 4. Exemplary SPR sensorgram overlay of spore lysate injections of (A) *A. acidoterrestris* as reference (DSM 2498, wild type, 10^7 cfu/mL), (B) *B. cereus* (wild type, 10^7 cfu/mL), and (C) *C. perfringens* (wild type, 10^7 cfu/mL), with immobilized streptavidin and 5′-biotin-TEG aptamer. SPR measurements were carried out using orange-juice-simulating buffer (25 μL/min) to retain the secondary structures of aptamers.

in the MST- and ITC-based techniques mentioned above, various methods using immobilized spores and spore lysates were investigated, whereby the utilization of a TissueLyser and glass beads enabled the preparation of an appropriate SPR sensor chip. In this context, the optimized parameters mentioned above (glass beads with several diameters, sodium acetate with different pH values, and the treatment time obviously) led to a suitable spores fragmentation degree for a subsequent immobilization on a sensor chip. In addition, several sensor chip surfaces (e.g., carboxylated dextran, carboxylated, aliphatic hydrocarbon chain) were examined, whereas the aliphatic hydrocarbon chains led to the most appropriate SPR sensorgrams with response signals of approximately 300−700 RU during immobilization. According to Karlsson one response unit corresponds roughly to 1 pg/mm^2 immobilized ligand on SPR sensor chips.[40] Considering the utilized sensor chip surface of 1.2 mm^2, a total weight of 360−840 pg of fragmented spores has been immobilized. Due to the high amount of immobilized ligands, it can be assumed that spore coat fragments have also been immobilized; therefore, the developed SPR immobilization method of spore lysate is applicable for determination of aptamer dissociation constants to *Alicyclobacillus* spores. The availability of spore coat fragments is a crucial prerequisite for SPR measurements due to the usage of whole spores during the SELEX process. It seems reasonable that the obtained aptamers possess an affinity to several coat compounds.

Furthermore, the developed surface regeneration procedure, including short contact times and minor chemical loads, is capable of being used for consecutive measurements without losses in response. Chip activity and stability were investigated by repeated injection of an aptamer (10 μM) and 50 subsequent regenerations (data not shown). The chip surface stability was decreased of approximately 10%, which is less than the recommended cutoff value of 20%.[41,42] In summary, the implemented spore immobilization procedure and regeneration fulfill the requirements of appropriate SPR measurements.

The aptamer dissociation constants were determined using orange-juice-simulating buffer to retain the secondary structures of aptamers and therefore the binding properties to the *Alicyclobacillus* spores under conditions which are comparable to those of orange juices. Here, the aptamers were injected on multiple SPR sensor chips for 6 min in rising concentrations (2.5, 5.0, 7.5, and 10.0 μM). To obtain double-referenced data, the RU signals of reference (BSA) and orange-juice-simulating buffer were subtracted. Examples of obtained sensorgram overlays of four different aptamer concentrations (2.5, 5, 7.5, and 10 μM) including the corresponding fits are shown in Figure 3. For calculation of dissociation constants, the obtained sensorgrams were fitted with a Langmuir 1:1 model, including a mass transport limitation factor, and separately calculated for each aptamer. Dixon's outliers were eliminated, and the averages of different SPR measurements were formed (Table 2). The obtained K_D values are in the low-nanomolar range (from 2.3 to 149.1 nM), which is quite comparable to those published for the aptamer for cells and proteins.[12,19,43]

Due to the mentioned SPR surface chip preparation using hydrophobic adsorption of spore lysates side effects like heterogeneous ligand sites, nonspecific binding, and charge-related attraction will influence binding kinetics of the injected aptamers. In contrast to a 1:1 interaction the obtained SPR sensorgrams for each aptamer injection reflect more a multivalent binding kinetic which explains the deviation of raw data and kinetic fits using a Langmuir 1:1 model including a mass transport limitation factor (Figure 3).

A binding model including all side effects of aptamer spore interactions on a heterogeneous surface, like a spore lysate, is currently not available, but use of a 1:1 model including a mass transport limitation factor seems to be a sufficient approach of the kinetic constants.

However, the obtained data, indicating a specific and concentration-dependent interaction of generated aptamers to the *Alicyclobacillus* spores, should be regarded with reservations based on the mentioned aspects. In addition, a fluorometric binding assay was performed by using fluorescently labeled

DOI: 10.1021/jf505996m
J. Agric. Food Chem. 2015, 63, 2189−2197

aptamers to confirm the assumed K_D values. Dissociation constants in a low-nanomolar range resulted from the fluorometric assay which supports the SPR measurements (data not shown).

Determination of Aptamer Selectivity via SPR. The determination of dissociation constants revealed four promising candidates with K_D values in the low-nanomolar range: AliApt1, AliApt3, AliApt5, and AliApt9 (Table 2). Selectivity is a crucial parameter for aptamer evaluation, as not only *Alicyclobacillus* spp. but also *Bacillus* spp. and *Clostridium* spp. occur as contaminants in fruit juice industry. Due to the high number of various endospores (Table 3) and the high price of SPR consumables, it was advantageous to develop a suitable aptamer immobilization method. In addition to the mentioned hindrances for SPR measurement of macromolecular analytes (e.g., flow system or/and different weights of interacting partners), the overall high densities of aptamers on sensor chip surfaces seem to be responsible for further steric hindrances and limitations toward evaluation of whole spore measurements. The utilization of biotin−streptavidin coupling and biotinylated aptamers with an appropriate spacer (triethylene glycol, TEG) enables SPR measurements of spore lysates by reducing the density and increasing the flexibility of the formed aptamer layer by concurrent reduction of target weight. This developed approach is completed by a suitable regeneration procedure, which was accomplished by regeneration buffer 2. In conclusion, the use of modified aptamers for immobilization and injection of spore lysate fulfills the requirements for the determination of aptamer selectivity via SPR.

To compare the obtained SPR data of different aptamers and various endospores, it was necessary to immobilize equal amounts of streptavidin and aptamers in terms of RU signals, respectively ligand densities, and inject similar spore concentrations. The spore suspensions were diluted to a concentration of 10^6 cfu/mL and lysed according to the above-mentioned protocol for fragmentation of *Alicyclobacillus* spp. in the context of sensor chip preparation. The lysate of *A. acidoterrestris* spores (DSM 2498, wild type), which were used as aptamer selection targets (1/1 v/v), was employed as reference and set as 100% aptamer affinity to the target to compare various species and strains (exemplary SPR sensorgram overlay in Figure 4).

The results of aptamer selectivity determination via SPR are stated in Table 4, where it can be seen that all four aptamers (AliApt 1, AliApt 3, AliApt 5, and AliApt 9) which have been immobilized show high affinities toward various *Alicyclobacillus* spp. and support the implemented K_D determinations. It should be noted that the four aptamers also possess a high affinity (76 to >100%) relative to SELEX target *Alicyclobacillus* spp. spores (DSM 2498 and a wild type) to two (AliApt 5 and AliApt 9), respectively three (AliApt 1 and AliApt 3), of the 12 different *Bacillus* spp. spores. In general, it seems that the investigated aptamers are more affine to spores of the genus *Alicyclobacillus* but also interact with several *Bacillus* and *Clostridium* spores (Table 4). The aptamer selectivity results gained via SPR were confirmed by fluorometric binding assay using fluorescently labeled aptamers (data not shown).

An explanation could be that the spore coats of *Alicyclobacillus*, *Bacillus*, and *Clostridium* are particularly similar, and therefore the selectivity of the generated aptamers is not sufficient enough to distinguish among the investigated genera. Due to the particularly high conformity in genome sequences of about 90% between *Alicyclobacillus* and *Bacillus*, it might be reasonable that the spore surfaces are highly similar, and therefore the generated aptamers possess an affinity to homologous spore surface proteins.[44,45] However, it is evident (Table 4) that the obtained aptamers are more affine to spores of *Alicyclobacillus* than to those of *Bacillus* and *Clostridium* and therefore usable for aptamer-based enrichment techniques. An extension toward a highly specific detection system could be achieved by combination with more specific molecular biological techniques, like real-time PCR or LAMP (loop-mediated isothermal amplification).[46]

Visualization of Binding Interactions via Fluorescence Microscopy. Interactions between generated aptamers and *Alicyclobacillus* spores were visualized using a fluorescence microscope. In addition, the orange-juice-simulating buffer containing only *Alicyclobacillus* spores was considered as well and used as a reference to exclude the intrinsic fluorescence of spores. As shown in Figure 5, the spores exhibit a fluorescence signal after incubation with fluorescently labeled aptamers, while spores by itself show no fluorescence signal under the chosen conditions. Thereby it was possible to visualize the interactions between the generated aptamers and *Alicyclobacillus* spore coat via fluorescence microscopy.

During the presented work, aptamers with an affinity to *Alicyclobacillus* spores were selected by spore-SELEX. The aptamer selection process was carried out in orange-juice-simulating buffer to obtain aptamers which are able to bind the mentioned spores under real conditions. Furthermore, the process was verified by various techniques (flow cytometric binding assay, AGE, and radioactive binding assay). The aptamer sequences gained after 17 selection rounds were compared in terms of their secondary structures. For characterization (determination of dissociations constants and aptamer selectivity), several SPR assays were developed, immobilizing spore lysates and modified aptamers, and were

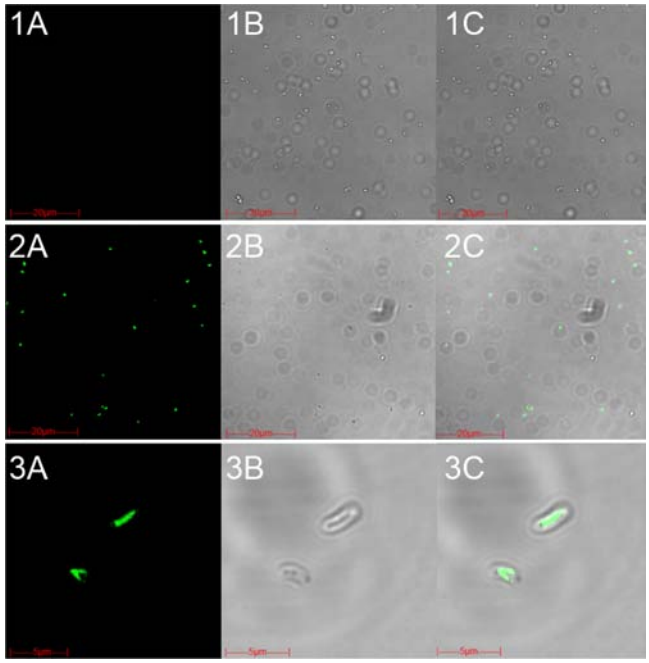

Figure 5. Fluorescence microscopy recordings of *A. acidoterrestris* spores in orange-juice-simulating buffer as blank sample (1A to 1C with 40× lens). Exemplary images of spores with prior incubation with a fluorescently labeled mix of obtained aptamers (2A to 2C with 40× lens; 3A to 3C with 100× lens). 1A to 3A show fluorescence images, 1B to 3B visual images, and 1C to 3C overlays of the fluorescence and visual images.

confirmed by fluorescence binding assays. Concerning K_D values and selectivity, suitable aptamers for corresponding enrichment techniques were obtained. Furthermore, the interactions between intact *Alicyclobacillus* spore coat and gained aptamer mix were visualized by fluorescence microscopy. To overcome microbiological plating methods, the gained aptamers could be integrated into aptamer-based techniques (e.g., magnetic separation) for the enrichment of *Alicyclobacillus* spores. Due to the lack of aptamer selectivity regarding differentiation of fruit-juice-related microbiological contaminants, the combination with further molecular biological techniques, like real-time PCR or LAMP, is necessary to increase sensitivity of the detection system.

In the future, the development and validation of an aptamer-based trapping and enrichment technique and the adaption to real orange juice samples will be integrated and compared to corresponding antibody-based systems. Furthermore, the development of different aptamer-based and rapid in-field applications, like lateral flow dipsticks/devices (LFDs), should be considered.[47] Also the replacement of antibodies in well-established techniques like enzyme-linked immunosorbent assay (ELISA) to develop a sensitive and easily applicable *Alicyclobacillus* spores detection system is conceivable.

they also exist in *E. ulmoides* in a large amount. It seems that plant flavonoids also act as antihypertension agents.

In the course of our continuous investigation into the bioactive components from important edible and medicinal plants in the Qinba Mountains,[16,17] we have carried out a phytochemical study on the leaves of *E. ulmoides*, on both sEH and potential NF-κB inhibition for sustainable utilization of bioresources. In this study, we report here the isolation and structure identification of 27 metabolites from the leaves of *E. ulmoides* as well as their biological functions, including inhibitory effects on sEH and NF-κB activity. On the basis of the mechanism of action of sEH, the work could highlight the group of natural compounds in *E. ulmoides* that are responsible for its cardiovascular effects. Therefore, this research might be helpful to better understand the potential contribution of these compounds to the pharmacological activities of *E. ulmoides* leaves and to lay a significant basis for the development and utilization of it as food and drug.

MATERIALS AND METHODS

General Experimental Procedures. UV spectra were obtained using a Thermo Scientific Evolution 300 UV−vis Spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded on 400 and 500 MHz NMR instruments (Bruker Daltonics Inc., Bremen, Germany). Chemical shifts are reported using solvent residual peak as the internal standard. ESI-MS spectra were carried out on a Thermo Fisher LTQ Fleet instrument spectrometer (Thermo Fisher Scientific Inc., MA, U.S.). Column chromatography (CC) was carried out on silica gel (90−150 μm) (Qingdao Marine Chemical Inc., Qingdao, China), Sephadex LH-20 (40−70 μm) (Amersham Pharmacia Biotech AB, Uppsala, Sweden), and Lichroprep RP-18 gel (40−63 μm; Merck, Darmstadt, Germany). GF_{254} plates (Qingdao Marine Chemical Inc., Qingdao, China) were used for thin-layer chromatography (TLC). Preparative TLC (PTLC) was carried out on silica-gel 60 GF_{254} (Qingdao Marine Chemical, Ltd., Qingdao, China); semipreparative HPLC (Waters Corp., USA) was carried out by a Thermo BDS Hypersil column (250 × 4.6 mm and 250 × 10 mm, 5 μm) (Thermo Fisher Scientific Inc., MA, USA).

Reagents. 3-Phenyl-cyano(6-methoxy-2-naphthalenyl)methyl ester-2-oxiraneacetic acid (PHOME), 12-[[(tricyclo[3.3.1.13,7]dec-1-ylamino)carbonyl]amino]-dodecanoic acid (AUDA), and purified recombinant sEH were purchased from Cayman (Cayman, Michigan, USA). The other chemical reagents and standard compounds were purchased from Sigma-Aldrich (St. Louis, MO, USA). AB-8 macroporous resin was purchased from the Chemical Plant of Nankai University (Tianjin, China) and was cross-linked polystyrene copolymer. All chemicals used (methanol, chloroform, ethyl acetate, petroleum ether, *n*-butanol, etc.) were purchased from Kelong (Chengdu, China). HPLC methanol was purchased from Tedia, Inc. (Fairfield, USA). Ultrapure water was made in our lab.

Plant Materials. The green leaves of *E. ulmoides* were collected from Lveyang county, Shaanxi Province of China on August 25, 2012. The plant was taxonomically identified by one of authors (K.J.Z.). A voucher specimen (LXY-01234) has been deposited at the Herbarium of College of Life Sciences, Northwest A&F University, PR China.

Extraction, Isolation, and Purification. The dried and powdered leaves of *E. ulmoides* (1 kg) were extracted with 50% methanol. All the filtrates were combined and concentrated under reduced pressure to give a crude extract. The crude extract was suspended in water and then extracted 3 times with *n*-butanol to obtain an aqueous layer and an *n*-butanol layer. The aqueous fraction was subjected to silica-gel CC and eluted with $CHCl_3$-MeOH with increasing polarities (5:1, 5:2, 5:3, and 5:5) to give four fractions (frs. 1−4).

Fr. 1 was separated by Sephadex LH-20 (LH-20, MeOH) to obtain three fractions (frs. 1-1 to 1-3). Fr. 1-1 was purified by PTLC ($CHCl_3$-MeOH, 5:1), then HPLC (20% MeOH, flow rate = 2 mL/min, λ = 254 nm) to yield **10** (15 mg, t_R = 18.6 min). Fr. 1-2 was separated by CC on LH-20 (MeOH) and RP-18 (20% MeOH) to give **21** (10 mg), and fr. 1-3 was purified by silica-gel CC ($CHCl_3$-MeOH, 9:1) to give **22** (21 mg). Fr. 2 was subjected to AB-8 macroporous-resin CC and sequentially eluted with water, 15% MeOH, and MeOH to provide three fractions (frs. 2-1 to 2-3). Fr. 2-1 was separated by CC on LH-20 (MeOH), RP-18 CC (20% MeOH), and then silica gel with ($CHCl_3$-MeOH 20:1) to afford **19** (13 mg). Fr. 2-2 was separated by LH-20 CC (MeOH) to yield two fractions (frs. 2-2-1 and 2-2-2). Fr. 2-2-1 was purified by RP-18 CC (40% MeOH), and then by HPLC (32% MeOH, flow rate = 2 mL/min, λ = 254 nm) to afford **16** (45 mg). Fr. 2-2-2 was submitted to silica-gel CC and eluted with $CHCl_3$-MeOH with increasing polarities (9:1−5:1) to give four fractions (frs. 2-2-2-1 to 2-2-2-4). Fr. 2-2-2-1 was separated by RP-18 CC (20% MeOH) and then by HPLC (30% MeOH, flow rate = 2 mL/min, λ = 254 nm) to obtain **11** (32 mg, t_R = 18.9 min). Fr. 2-2-2-2 was subjected to RP-18 CC using 20% to 30% MeOH and then purified by HPLC (30% MeOH, flow rate = 2 mL/min, λ = 254 nm) to afford **27** (11 mg, t_R = 15.6 min) and **15** (20 mg, t_R = 21.3 min). Fr. 3 was loaded to an AB-8 column and successively eluted with water, 15% MeOH, and MeOH to yield three fractions (frs. 3-1 to 3-3). Purification of fr. 3-2 by LH-20 CC (MeOH) and silica-gel CC ($CHCl_3$-MeOH, 3:1) yielded **20** (60 mg), and purification of fr. 3-3 by LH-20 CC (MeOH) and HPLC (40% MeOH; flow rate = 2 mL/min, λ = 254 nm) afforded **4** (76 mg, t_R = 14.0 min) and **3** (18 mg, t_R = 22.0 min).

The *n*-butanol fraction was separated by CC over AB-8 macroporous resin with water and then increasing concentrations of MeOH to provide five fractions: frs. A through E. Fr. C, eluted with 50% MeOH, was separated by silica-gel CC using EtOAc-MeOH (20:1−5:1) as eluent to afford five subfractions (Fr. C-1 to 5). Fr. C-2 was separated by silica-gel CC ($CHCl_3$-MeOH, 5:1), sephadex LH-20 CC (MeOH), and then RP-18 CC (30% MeOH) to give **2** (18 mg). Purification of fr. C-3 by LH-20 CC (MeOH) followed by HPLC (35% MeOH, flow rate = 2 mL/min) provided **7** (26 mg, t_R = 18.5 min). Fr. C-4 was purified successively by LH-20 CC (MeOH), silica-gel CC ($CHCl_3$-MeOH, 10:1), and RP-18 CC to give **23** (10 mg). Fr. D, eluted with 75% MeOH, was subjected to silica-gel CC with EtOAc-MeOH (20:1−5:1) to afford four subfractions: frs. D-1 to 4. Fr. D-1 was submitted to silica-gel CC ($CHCl_3$-MeOH, 12:1) to obtain three subfractions: frs. D-1-1 to D-1-3. Purification of fr. D-1-1 by LH-20 CC (MeOH) and RP-18 CC (40% MeOH) to yielded **12** (86 mg). Fr. D-1-2 was fractionated by LH-20 CC (MeOH) and RP-18 CC (40% MeOH) to afford **1** (21 mg) and **18** (13 mg). Fractionation of Fr. D-1-3 by LH-20 CC (MeOH) gave five subfractions (frs. D-1-3-1 to D-1-3-5). Further purification of frs. D-1-3-2 and D-1-3-3 by RP-18 CC (30% MeOH) afforded **14** (50 mg) and **8** (8 mg), respectively, whereas purification of fr. D-1-3-5 by LH-20 CC (MeOH) produced **9** (10 mg). Fr. D-2 was separated by silica-gel CC ($CHCl_3$-MeOH, 10:1) and LH-20 CC (MeOH) to furnish **6** (16 mg). Fr. D-3 was fractionated by silica-gel CC ($CHCl_3$-MeOH, 20:1−10:1) to give three subfractions (frs. D-3-1 to D-3-3), and purification of frs. D-3-1 and D-3-2 by RP-18 CC (30% MeOH) and LH-20 CC (MeOH) afforded **17** (7 mg) and **13** (10 mg), respectively. Fr. E, eluted with 100% MeOH, was fractionated by silica-gel CC using EtOAc-MeOH (30:1−10:1) to afford four subfractions (frs. E-1 to 4). Purification of Fr. E-1 by silica-gel CC ($CHCl_3$-MeOH, 15:1), LH-20 CC (MeOH), and RP-18 CC (30% MeOH) gave **5** (10 mg). Fr. E-2 was separated by LH-20 CC (MeOH) and silica-gel CC ($CHCl_3$-MeOH, 20:1) to obtain **24** (11 mg). Fractionation of fr. E-3 by silica-gel CC ($CHCl_3$-MeOH, 15:1) afforded two subfractions (frs. E-3-1 and E-3-2). Fr. E-3-1 was further purified by LH-20 CC (MeOH) and then silica-gel CC ($CHCl_3$-MeOH, 10:1) to afford **25** (17 mg), whereas purification of fr. E-3-2 by LH-20 CC (MeOH) gave **26** (18 mg).

sEH Inhibitory Activity. sEH inhibitory activity was determined using a hydrolysis reaction of PHOME in the presence of sEH enzyme. Briefly, 130 μL of sEH (62.5 ng/mL) in 25 mM Bis-Tris buffer (including 0.1% bovine serum albumin, pH 7.0) and 20 μL of ligands diluted in MeOH were mixed in 96-well plate. A 50 μL aliquot of PHOME (40 μM) in buffer was added as substrate. After starting the sEH reaction at 37 °C, products were measured using a Geniosmicroplate reader (Tecan, Mannedorf, Switzerland) during an hour at excitation and emission wavelengths of 320 and 465 nm, respectively. sEH inhibitory activity for each sample was calculated as follows:

$$\text{sEH inhibitory activity (\%)} = 100 - [(S_{60} - S_0)/(C_{60} - C_0)] \times 100$$

where C_{60} and S_{60} were the fluorescence of control and inhibitor after 60 min, S_0 and C_0 is the fluorescence of control and inhibitor at zero min.

Cell Viability Assay. Cell viability was evaluated by Cell-Counting Kit (CCK)-8 methods. Briefly, CCK-8 was added to the cell culture medium for 1 h. The supernatant was removed, and formazan crystals

[a]All compounds were examined in a set of experiments three times. [b]Statistical significance was determined by one-way analysis of variance followed by Dunnett's multiple comparison test, $P < 0.05$ versus control. [c]Data were expressed as mean ± SD of at least three experiments carried out in triplicate. [d]Positive control. [e]At 25 nM.

were dissolved in dimethyl sulfoxide (DMSO). Absorbance was measured at 450 nm. The percentage of dead cells was determined relative to the control group.

All compounds were tested for cytotoxic activity against HepG2 cell lines. All cell lines were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 mg/mL streptomycin at 37 °C with 5% CO_2. Each tested compound was dissolved with DMSO to obtain concentrations 0.1, 1, and 10 μM.

These were incubated with the cells for 72 h. The negative control received the same amount of DMSO (0.1% in the highest concentration). Doxorubicin (0.1−0.58 mg/mL) was used as a positive control. Cell viability was determined by reduction of the yellow dye 3-(4,5-dimethyl-2-thiazol)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) to a blue formazan product as described by Mosmann.[18]

NF-κB Inhibitory Activity Assay. Because NF-κB is essential for promoting inflammation-associated hepatic cancer, it is a potential target for prevention of hepatic cancer in chronic hepatic inflammatory diseases.[19] We examined the inhibitory effect of samples on NF-κB activated by TNF-α in hepatocellular carcinoma (HCC) cells such as HepG2 cells. The luciferase vector was first transfected into human hepatocarcinoma HepG2 cells. After a limited amount of time, the cells were lysed, and luciferin, the substrate of luciferase, was introduced into the cellular extract along with Mg^{2+} and an excess of ATP. Under these conditions, luciferase enzymes expressed by the reporter vector could catalyze the oxidative carboxylation of luciferin. Cells were seeded at 2×10^5 cells per well in 12-well plates and grown. After 24 h, cells were transfected with inducible NF-κB luciferase reporter and constitutively expressing Renilla reporter. After 24 h of transfection, the medium was changed to assay medium (Opti-MEM, 0.5% FBS, 0.1 mM NEAA, 1 mM sodium pyruvate, 100 units/mL penicillin, and 10 μg/mL streptomycin), and cells were pretreated for 1 h with vehicle (DMSO) and compounds, followed by 1 h of treatment with 10 ng/mL TNF-α for 20 h. Unstimulated cells were used as a negative control, and apigenin was used as a positive control. Dual luciferase assay was carried out 48 h after transfection, and promoter activity values are expressed as arbitrary units using a Renilla reporter for internal normalization.

Statistical Analysis. All data represent the mean ± SD of at least three independent experiments carried out in triplicate. Statistical significance is indicated as determined by one-way ANOVA followed by Dunnett's multiple comparison test, $P < 0.05$, using GraphPad Prism 6 (GraphPad Software Inc., San Diego, CA, USA).

RESULTS AND DISCUSSION

Extraction, Isolation, and Identification. *E. ulmoides* leaves were extracted with 50% methanol in water, and the crude methanol extract was fractionated into *n*-butanol and aqueous fractions by liquid−liquid separation. The *n*-butanol fraction was further subjected to column chromatography over AB-8 macroporous resin, silica gel, Sephadex LH-20, and finally semipreparative RP-HPLC to obtain 16 compounds: **1**, **2**, **5**−**9**, **12**−**14**, **17**, **18**, and **23**−**26**. Similarly, the water fraction was successively separated by multiple column chromatographies to yield 11 compounds: **3**, **4**, **10**, **11**, **15**, **16**, **19**−**22**, and **27** (Figure 1).

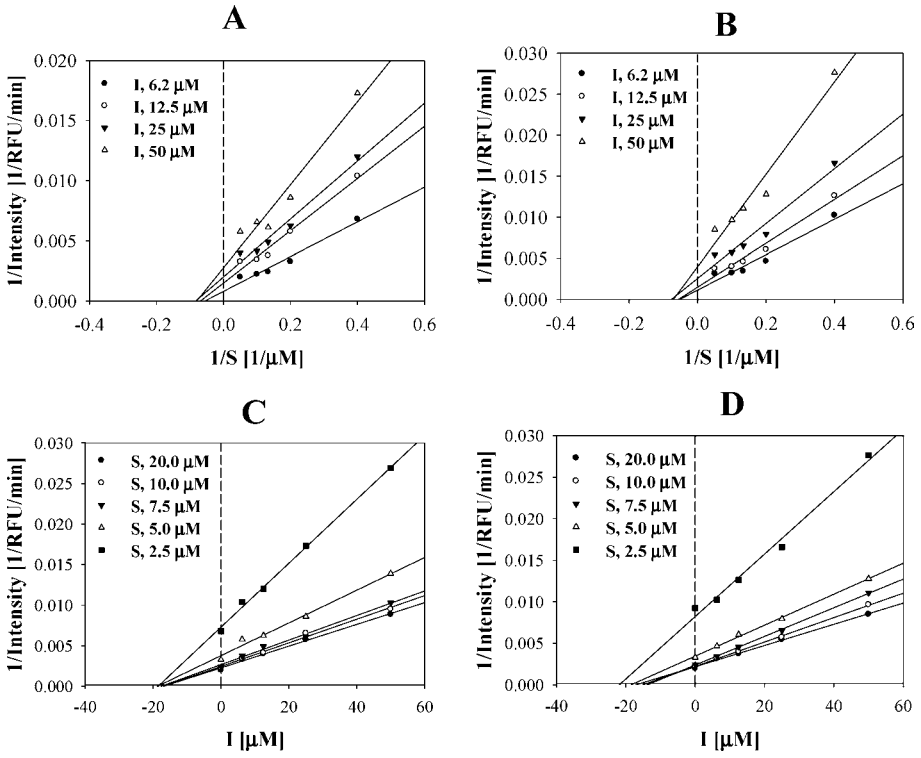

Figure 2. Study of binding mechanism between compounds **1** and **5** and sEH: (A and B) Lineweaver−Burk plots for the inhibition of compounds **1** and **5**, respectively, (C and D) Dixon plots for compound **1** and **5**, respectively. Data are the mean of three experiments carried out in triplicate and were determined by one-way analysis of variance followed by Dunnett's multiple comparison test, $P < 0.05$ versus control.

The structures of compounds **1**−**27** were characterized by ^{1}H and ^{13}C NMR, ESI-MS data, and comparison with published spectroscopic data. They were quercetin (**1**),[20] quercetin 3-glucoside (isoquercitrin, **2**), rutin (**3**),[21] quercetin 3-sambubioside (**4**),[22] kaempferol (**5**),[23] kaempferol 3-glucoside (astragalin, **6**),[21] kaempferol 3-rutinoside (**7**),[21] catechin-(7,8-bc)-4α-(3,4-dihydroxyphenyl)-dihydro-2(3H)-pyranone (**8**),[24,25] catechin-(5,6-bc)-4α,β-(3,4-dihydroxyphenyl)-dihydro-2(3H)-pyranone (**9**),[25] syringin (**10**),[26] 2,5-dimethoxy-3-glucopyranosyl cinnamic alcohol (**11**),[27] methyl caffeate (**12**),[28] erythro-guaiacylglycerol (**13**),[29] methyl chlorogenate (**14**),[30] sinenoside I (**15**),[31] liriodendrin (**16**),[32] syringaresinol 4′-O-glucopyranoside (**17**),[33] cyclo-olivil (**18**),[34] eucommiol (**19**),[35] eucommioside-I (**20**),[36] accubin (**21**),[37] asperuloside (**22**),[38] asperulosidic acid (**23**),[39] a mixture of blumenol C and 9-epi-blumenol C (**24**),[40] foliasalacioside B_1 (**25**),[41] foliasalacioside E_2 (**26**),[42] and icariside F_2 (**27**)[43] (Figure 1). Structure types of these compounds include flavonoids (**1**−**9**), phenylpropanoids (**10**−**14**), lignans (**15**−**18**), iridoids (**19**−**23**), and megastigmanes (**24**−**26**). Among these, compounds **11**, **26**, and **27** have been obtained from *E. ulmoides* for the first time.

Inhibitory Activity on sEH and Structure−Activity Relationships (SARs). sEH inhibitory activity of the isolated compounds (**1**−**27**) was evaluated using a fluorescent based on hydrolysis of the specific substrate PHOME in the presence of sEH enzyme. 12-(3-Adamantan-1-yl-ureido) dodecanoic acid (AUDA) was used as a positive control (50% inhibitory concentration, IC_{50} = 10.9 ± 1.2 nM). Compounds **1**−**27** were tested at 100 μM on sEH (Table 1). Isolated compounds **1**−**7** showed sEH inhibitory activity greater than 50% and were examined for further investigation at various concentrations for IC_{50}. IC_{50} was calculated using a dose-dependent response curve, as shown in Table 1. The results showed that compounds **1**−**7** displayed different inhibitory activity on sEH, with IC_{50} values of 22.5 ± 0.9−61.9 ± 1.5 μM. Among them, **1** and **5** showed strong inhibitory activity on sEH with IC_{50} values of 22.5 ± 0.9 and 31.3 ± 2.6 μM, respectively.

For the study of the binding mechanism between two compounds (**1** and **5**) and sEH, their activity was measured with different substrate and various inhibitor concentrations. As a result of this kinetic analysis, two compounds **1** and **5** were found to inhibit sEH activity in a noncompetitive manner because the different substrate concentrations resulted in a family of lines that did intersect on the x axis in a Lineweaver−Burk plot (Figure 2A,B) and on the negative x axis in Dixon plots (Figure 2C,D) with K_i values of 18.2 and 27.5 μM, respectively.

A structure−activity relationship (SAR) analysis of these tested compounds (**1**−**7**) is outlined as follows: (i) sEH inhibitory activity of flavonoid aglycones (**1** and **5**) is higher than that of their glycosides, e.g., **1** (IC_{50} = 22.5 ± 0.9 μM) vs **2**−**4** and **5** (IC_{50} = 31.3 ± 2.6 μM) vs **6** and **7**; (ii) for quercetin (**1**) or kaempferol (**5**), sEH inhibitory activity of monoglycosides is better than that of diglycosides, e.g., **2** (IC_{50} = 39.6 ± 1.4 μM) vs **4** (IC_{50} = 52.4 ± 1.5 μM) and **6** (IC_{50} = 49.8 ± 5.2 μM) vs **7**, indicating that an increase in the number of sugar at the C3 OH reduces their activity; (iii) the additional OH group at R_2 on the B ring of flavonoid aglycone enhances the activity, e.g., **1** > **5**; and (iv) the planar structures of the aglycones in the compounds tested seem to be essential because flavanonols **8** and **9**, bearing a nonconjugated moiety in the central C ring, had no activity. Taken together, it seems that the number of OH in the B ring of the tested compounds is able to increase sEH inhibitory activity, and the glycosylation of C3 OH is unfavorable to the activity. So far, the main inhibitors of sEH are urea and amides;[44] they were described as potent

DOI: 10.1021/acs.jafc.5b00055
J. Agric. Food Chem. 2015, 63, 2198−2205

and stable. However, their poor water-solubility and slow gastric absorption limit their use. In the future, good water-solubility, fast gastric absorption, and long duration of action would be the valuable direction to develop new sEH inhibitors. Flavonoids are less active than urea-based inhibitors, but their water-solubility, safety, and bioavailability are big advantages. In addition, wide distribution in natural resources give them great accessibility and promising prospects.

NF-κB Inhibition Activity in HepG2 cells. At a concentration of 10 μM, the MTT assay results indicated that compounds **1**−**27** showed little or no cytotoxic activities, suggesting that the leaves of this plant are safe (data not shown). Thus, all isolated compounds (**1**−**27**) were further tested for their ability to inhibit NF-κB by stimulation with TNF-α at various concentrations ranging from 0.1 to 10.0 μM, and IC_{50} values were calculated. As shown in Table 1, compounds **1**, **3**−**5**, **8**, **9**, **12**, **15**, **20**, **22**−**25**, and **27** showed marked NF-κB inhibitory activity, with IC_{50} values ranging from 15.14 ± 2.29 to 25.81 ± 2.33 μM, whereas compounds **6**, **16** both displayed weak inhibitory activities. Among the tested compounds, compounds **1**, **9**, **20**, and **27** turned out to be potent NF-κB inhibitors. Out of the flavonoid compounds (**1**−**9**), the best NF-κB inhibitors were compounds **1** and **9**, with similar IC_{50} data. In terms of the preliminary structure−activity relationship observations of **1**−**7**, glycosylation of the OH group at position C3 in quercetin (**1**) and kaempferol (**5**) caused a significant reducation of the NF-κB inhibitory effects (**1** vs **2** and **5** vs **7**), suggesting that the free C3 OH is important for enhanced activity (Table 1). In addition, although methyl caffeate (**12**) and methyl chlorogenate (**14**) both contained a caffeic acid moiety, **12**, bearing a small methyl group, was much more active than **14**, carrying a large bulky quinic acid group, in inhibiting potency. Because this is the only structural difference between the two compounds, it is very likely that this planar conformation is important for the binding of compound **12** to putative node proteins within the NF-κB signaling pathway.

Many plant flavonoids, such as quercetin (**1**), isoquercitrin (**2**), and kaempferol (**5**), found in many edible plants (e.g., tea, broccoli, and grapes), have been known as potential anti-inflammatory compounds through their inhibition of the expression of pro-inflammatory factors.[45−48] Quercetin (**1**) from lotus leaf (*Nelumbo nucifera*) has been shown to exhibit anti-inflammatory activities by inhibiting the JNK- and NF-κB-regulated pathways.[49] It has been reported that suppression of NF-kB by kaempferol (**5**) plays an important part in its anti-inflammatory activity.[48] Astragalin (**6**) has been reported to exert its anti-inflammatory effects, which are correlated with inhibition of TNF-α, interleukin-1 (IL-1), and interleukin-6 (IL-6) production, via inactivation of NF-κB.[50,51] Investigation of possible anti-inflammatory activity showed that isoquercitrin (**2**) may decrease the levels of prostaglandin E_2 produced by LPS-stimulated RAW264.7 cells.[52] Furthermore, methyl chlorogenate (**14**) is one of the main potent antioxidant components in the leaves of *Eriobotrya japonica*.[53] Compound **14** has been reported to be a potent suppressor of BHP-induced NF-κB activation in mouse liver, exhibiting its ability to downregulate NF-κB-dependent gene expression.[53] Jeong et al. have showed that accubin (**21**) suppressed the expression of TNF-α and IL-6 in Ag-stimulated rat basophilic leukemia (RBL)-2H3 mast cells. Because activator protein-1 binding activity was not affected, **21** was found to be a specific inhibitor of NF-κB activation in mast cells.[54] Moreover, recent studies revealed that flavonol glycosides such as isoquercitrin (**2**) and astragalin (**6**) with glycation inhibitory activity could be attributed to the antidiabetic action of *E. ulmoides* leaves.[21] However, in our experimental setup, flavonol glycoside (**2**), phenylpropanoids (**13** and **14**), lignan (**18**), and accubin (**21**) did not show discernible inhibitory effects on NF-κB in HepG2 cells with IC_{50} > 50 μM. Accordingly, flavonoids (except **2**) and iridoids (except **21**), megastigmanes, and **27** may be considered as the major anti-inflammatory components of the leaves of *E. ulmoides*. These results, in combination with our findings, further corroborate the anti-inflammatory effects of the compounds.

Crude extracts of *E. ulmoides* bark exhibit anti-inflammatory effects; thus, they may serve as a potential treatment for inflammatory diseases.[55,56] However, little is known about the anti-inflammatory actions of *E. ulmoides* leaves and its components. Recently, Luo et al.[57] identified two bioactive compounds, genipin and 4-(1,2-dimethoxyethyl)benzene-1,2-diol, from *E. ulmoides* leaves and showed that they had anti-inflammatory properties through inhibition of LPS-stimulated NO and TNF-α production. Methanolic extracts of *E. ulmoides* leaves were found to inhibit the growth of *Propionibacterium acnes*.[58] In addition, duzhong extracts also reduced the secretion of pro-inflammatory cytokines, such as TNF-α, IL-8, and IL-1β, in human monocytic THP-1 cells pretreated with heat-killed *P. acnes*.[58] To the best of our knowledge, this is the first report of sEH inhibitory and anti-inflammatory components in the leaves of *E. ulmoides*. In particluar, it has been believed that the anti-inflammatory properties of *E. ulmoides* should be ascribed to the combination of its various constituents and multiple targets, not limited solely to iridoids and/or flavonoids and a single target.

In conclusion, our findings demonstrate that the flavonoid components of the leaves of *E. ulmoides* are good sEH inhibitors (**1**, **5**) and that certain compounds (flavonoids **1** and **9**, iridoids **20** and **23**, megastigmane (**24**), and aromatic glycoside (**27**)) are potent inhibitors of the TNF-α-induced activation of NF-κB. Therefore, the fact that the extracts of *E. ulmoides* leaves are rich in phenolic compounds and iridoids might in part explain the use of this plant for the treatment of inflammatory or hypertensive conditions. This is the first report of the anti-inflammatory effects of components of *E. ulmoides* leaves by inhibiting both sEH and NF-κB. Additionally, the flavonoid components were at least revealed to be major components of the leaf agents with antihypertension activity through inhibition of sEH. Flavonoid, iridoid, and megastigmane components were verified as the key components responsible for NF-κB inhibition in our cell-based test system. This result is important for the development of *E. ulmoides* as an anti-inflammatory or antihypertensive functional food. Further studies should evaluate synergistic effects of the combination of these compounds in the treatment of inflammation or hypertension.

is strong evidence that this cross-linking between cell-wall polymers through ester-linked diferulates (DFAs) has an important role in maize resistance to corn borers.[29] Higher DFA deposition in diverse tissues and genotypic materials was found to be positively related with reduced corn borer damage.[30−33] Moreover, tall fescue transgenic plants with a modified level of cell-wall-esterified ferulates showed a reduction in cell-wall hydroxycinnamates and resulted in plants more susceptible to insect folivores, which imply a mechanical restriction to feeding or assimilation by these compounds.[34]

Most maize genotypes evaluated to date are limited to inbred lines with diverse genetic backgrounds and thereby maybe different defense mechanisms; therefore, experiments to provide direct evidence of the separate role of DFAs as a maize resistance mechanism against borers are needed. The genotypes developed in a previous selection program[35] maximize the differences in the DFA concentration in the main tissue that corn borer larvae use as feed and were used as model plant material to study the relationship between DFAs and corn borer resistance in maize. The objectives of the current work were (i) to field evaluate the severity of the damage in the DFA divergent maize populations under artificial corn borer infestations, (ii) to perform laboratory-feeding bioassays using the maize populations to evaluate the effects of plant endogenous DFA concentrations on larval growth, and (iii) to assess indirect effects of the selection program on the total amount of cell-wall material, mentioned as another pest-resistance-related trait.

MATERIALS AND METHODS

Chemicals. Methanol, high-performance liquid chromatography (HPLC)-grade methanol, acetone, acetonitrile, hydrochloric acid, ethyl acetate, and ethyl ether were purchased from Merck (Madrid, Spain). Sodium hydroxide and trifluoroacetic acid were purchased from Sigma-Aldrich Química (Madrid, Spain). Distilled water was purified with a Milli-Q system. Standards of FA and *p*-coumaric acid were purchased from Sigma-Aldrich Química (Madrid, Spain). DFA 5−5 was kindly provided by Dr. John T. Arnason, University of Ottawa, Ottawa, Ontario, Canada.

Field Evaluation Trials. Six maize populations were developed from a F_2 population derived from the inbred line cross CO125 and PB130. These two inbred lines were selected on the basis of their high (CO125) and low (PB130) DFA concentrations in stem pith tissue.[31] Divergent selection for total esterified DFA concentration (DFAT) in pith stalk tissues was conducted in the low (L) and high (H) directions for three generations to develop six populations (P1H, P2H, P3H, P1L, P2L, and P3L), following the procedure previously described by Barros-Rios et al.[35] Seed from P1L, P1H, P2L, P2H, P3H, and P3L was multiplied in a winter nursery in Chile (2009−2010) and evaluated in 2010 at two locations in Spain (Pontevedra, 42° 30′ N 8° 46′ W, and Zaragoza, 41° 44′ N, 0° 47′ W). The experimental design at both locations was a randomized complete block with three replicates. Plant density was approximately 60 000 plants ha^{-1}. Cultivation operations, fertilization, and weed control were carried out according to local practices and crop requirements. To accurately define the silking time of each genotype, plots were checked until 50% of plants were showing silks. At silking, 10 plants in each plot were artificially infested with the most abundant corn borer species at each location (MCB in Pontevedra and ECB in Zaragoza) by placing an egg mass between the shank of the main ear and the stem, as has been suggested by Butrón et al.[36] The rearing of MCB eggs and infestation methods followed standard procedures.[37] The eggs of ECB were purchased from the Research Centre of Poitou-Charentes (INRA, Luisignan, France). Plants were harvested at grain maturity. At harvest, the stem of infested plants was split longitudinally and the corn borer tunnel length was measured. Natural infestations by other borers in the studied area are low, and if any, these are not significant in comparison to the artificial infestations performed. Five non-infested plants were collected for DFA analysis 55 days after silking when internode elongation had ceased. The second and third elongated above-ground internodes from these plants were collected and frozen (−20 °C) for analysis. Each internode was dissected into pith and rind fractions, and subsequently, pith samples were lyophilized and ground through a 0.75 mm screen in a rotor mill.

Laboratory-Feeding Bioassays. Laboratory-reared MCB larvae were fed on pith stem tissues from the six maize populations evaluated. Single neonate larvae were initially weighed using a microbalance (Mettler-Toledo MT5) with ±1 μg accuracy and thereafter individually transferred to Petri dishes containing pith stem sections (±2 cm). Stem sections were obtained from four internodes below the main ear starting at silking time. A total of 60 larvae per population were used in the feeding experiments. Petri dishes were placed in a controlled environment room for 28 days at 26 °C with a photoperiod of 14:10 (L/D) h. Fresh pith stem tissues were replenished every 4 days to avoid tissue deterioration, and larval weight was recorded at 7, 14, 21, and 28 days.

Chemical Determinations. *Cell-Wall-Bound Phenolic Analyses.* Ester-bound ferulate (**1**), *p*-coumaric acid (**2**), and DFA extraction followed a procedure described by Santiago et al.,[28] with some minor modifications. Freeze-dried samples (500 mg) were extracted in 30 mL of 80% methanol and homogenized for 60 s with a Polytron mixer (Brinkman Instruments, Westbury, NY). Samples were extracted for 1 h in the dark and then centrifuged for 10 min at 1000*g*. Supernatant containing soluble phenolics was discarded, and the pellet with ester-bound phenolics was re-extracted twice with 20 mL of 80% methanol. The pellet was hydrolyzed with 20 mL of 2 N NaOH and shaken for 4 h in the dark under a nitrogen atmosphere. The hydrolysis reaction was stopped by adding 6 N HCl, and the pH was adjusted to 2.0. Samples were centrifuged as above, and the supernatant was collected. The pellet was washed twice with 10 mL of distilled water and centrifuged, and supernatants were combined, mixed, and extracted twice with ethyl acetate (50 and 35 mL each). The organic phase was dried using a Speed Vac for 6 h. The extracts were dissolved in 3 mL of HPLC-grade methanol and stored at −20 °C. All standards and samples were filtered through a 20 μm pore poly(tetrafluoroethylene) filter (Chromatographic Specialties, Brockville, Canada) before analysis.

HPLC analyses were performed on the basis of a previously described protocol,[31] with some minor modifications, using a 2690 Waters Separations Module (Waters, Milford, MA) equipped with a Waters 996 photodiode array detector and a Waters YMC ODSAM narrow-bore column (100 × 2 mm inner diameter, 3 μm particle size). Elution conditions with a mobile-phase system of acetonitrile (solvent A) and trifluoroacetic acid (0.05%) in water (pH 3.4) (solvent B) were as follows: initial conditions of 10:90 (A/B), changing to 30:70 in 3.5 min, then to 32:68 in 6.5 min, then to 100:0 in 4 min, and then to isocratic elution with 100:0 for 4.5 min, finally returning to the initial conditions in 3 min. The mobile-phase flow rate was 0.3 mL/min, and the total analysis time was 21.5 min. The sample injection volume was 4 μL, and the elution profiles were monitored online by ultraviolet (UV) absorbance at 325, 280, and 254 nm. Retention times were compared to those of freshly prepared standard solutions. Identities of FA dimers were confirmed by comparison to the authentic 5−5 standard or retention time and UV spectra previously published.[38] The DFAT concentration was calculated as the sum of three regioisomers of DFAs identified and quantified by this analytical procedure: 8−*O*−4-DFA (**3**), 5−5-DFA (**4**), and 8−5-DFA (**5** + **6**) (Figure 1B). The 8−5-DFA concentration was calculated as the sum of the 8−5-cyclic (or benzofuran)-DFA (**5**) and 8−5-non-cyclic (or open)-DFA (**6**) because the non-cyclic form is most likely formed during alkaline hydrolysis from the native cyclic form.[39]

Total Cell-Wall Content Analysis. The total amount of cell-wall material was isolated on the basis of a procedure previously described by Strack et al.,[40] with some minor modifications.[41] Pith samples (500 mg of dry matter) were homogenized in boiling ethanol (20 mL) and extracted for 15 min into an ultrasonic bath. After centrifugation (2700*g* for 10 min), the sediment was washed (stirring for 30 min)

J. Agric. Food Chem. 2015, 63, 2206−2214

with 20 mL of each of the following solvents in sequence: 30% methanol at 65 °C, methanol, acetone, ethyl acetate, and ethyl ether at room temperature, and dried at 60 °C to a constant weight.

Statistical Analysis. Combined analyses of variance over locations for cell-wall traits (compounds **1** and **2**, DFAT, and total amount of cell-wall material) and stem tunnel length were computed using the GLM procedure of SAS (version 6.12; SAS Institute, Inc., Cary, NC). The class variables were location, replication, and maize population. The analysis of variance for all traits was performed considering all factors as random effects, except populations. Means for the maize populations were compared using the Fisher protected least significant difference test (LSD; $p < 0.05$). In addition, the differences on larvae weight fed on the pith stem tissues obtained from the high and low DFAT populations (PHs and PLs, respectively) were compared using an orthogonal contrast.

To analyze the selection program efficiency, values of 3, 2, 1, −1, −2, and −3 were assigned to populations P3H, P2H, P1H, P1L, P2L, and P2L, respectively, and (1) simple linear regression analyses incorporating random effects in the model [environment and replication (environment)] were performed with the DFAT concentration as the dependent variable and population as the independent variable. Similar simple linear regression analyses were performed to determine (2) the relationships between tunnel length (dependent variable) and DFAT concentrations (independent variable), (3) the indirect response of selection for DFAs (DFAT as the independent variable) on hydroxycinnamate monomers and cell-wall concentration (dependent variables), and (4) the relationship between tunnel length (dependent variable) and hydroxycinnamate monomers and cell-wall concentration (independent variables). Variables included in the regression analyses were considered significant at the $p \leq 0.05$ level. All statistical analyses were performed using the SAS software package.[42]

RESULTS AND DISCUSSION

Response to Selection for Ester-Linked DFA Concentrations. For the cell-wall traits evaluated, the ferulate concentration (monomers and dimers with the exception of 5−5-DFA) differed significantly among the maize populations evaluated; the genotype × location interaction was not significant for any of the cell-wall traits evaluated (see Table S1 of the Supporting Information). After three generations of divergent selection, concentrations of compounds **3**, **5** + **6**, and DFAT, were 32, 23, and 31% higher in P3H than in P3L, respectively. Nevertheless, P2H had lower concentrations than expected for all DFAs evaluated. The reduction of DFAT in P2H was a "sawtooth" point in the selection program. Such "sawtooth" patterns have been previously observed for genetic gains in several agronomic traits during a selection program, usually associated with traits not 100% heritable.[43,44] The concentration of compound **1** was 25% higher in P3H than in P3L, and grouping of populations according to the LSD means that a comparison method followed a similar trend to that observed for DFAs (Table 1). Simple linear regression analysis equations showed significant and positive coefficients between compounds **3**, **5** + **6**, and DFAT concentrations and the maize populations (Figure 2A). After three generations of divergent selection, genetic gains were observed for compounds **3**, **5** + **6**, and DFAT (Figure 2A). Only the 8-coupled DFAs were significantly modified during the selection program. It appears that selection for the sum of all of the individual DFAs (DFAT) would be relatively efficient for 8-coupled DFA selection because these structures account for the largest proportion of the selection criteria (~80% of DFAT).

Mean comparisons and regression analyses showed that divergent selection was effective in altering the DFAT concentration in maize pith tissues and that it is possible to

modulate the concentration of DFAs at 0.017 g kg^{-1} of dry matter per cycle of selection (Table 1 and Figure 2A).

After 3 cycles of divergent selection, P3H had 31% higher DFAT than P3L. Current analytical results agree with those previously observed after preceding evaluations of two generations of divergent selection, where P2H had 21% higher DFAT content than P2L,[33] indicating that the DFAT concentration is a heritable trait that can be modified through classical breeding techniques. An unexpected reduction of DFAs was observed in P2H in both current and preceding evaluations.[31] The ongoing selection program provides unique genotypes to study the effect of selection on other quantitative traits and to validate candidate genes potentially involved in FA dimerization. Additional cycles of selection will clarify if the DFAT concentration reaches a plateau in any direction of selection, which would indicate the existence of an upper or lower threshold DFAT concentration that compromises the plant development or viability.

DFAs as a Plant Resistance Mechanism against Pest and Diseases. The relationship between cell-wall cross-linking and insect resistance was initially suggested by Fry.[45] Since then, diverse studies have pointed out the role of cell-wall

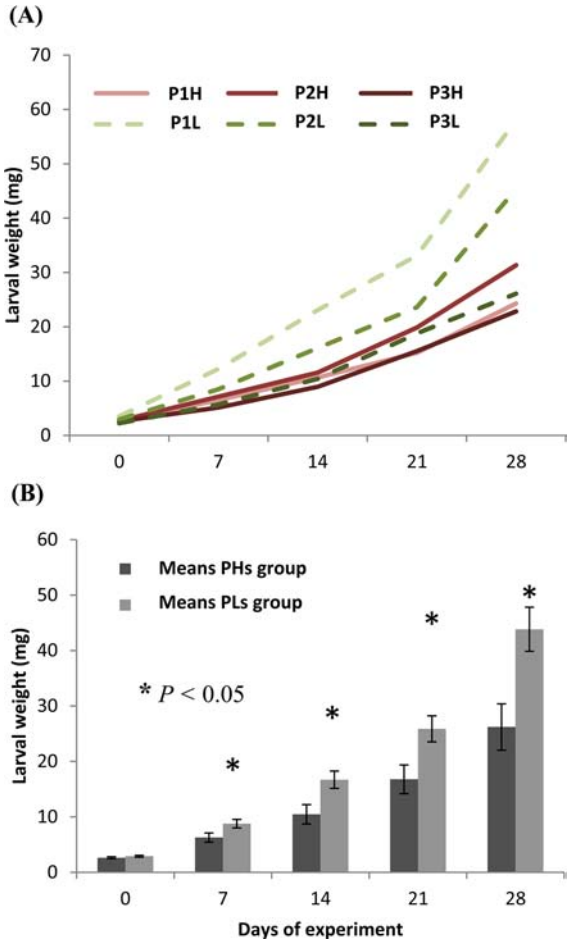

Figure 3. Laboratory-feeding bioassays with larvae fed on pith stem tissues from the six maize populations evaluated. (A) Weight (mg) of larvae fed on pith stem tissues from the six maize populations evaluated measured after 0, 7, 14, 21, and 28 days of experiment. (B) Orthogonal contrast for larval weight among high (P1H, P2H, and P3H) and low (P1L, P2L, and P3L) DFAT populations of corn hybrid CO125 × PB130 divergently selected for DFAT. Error bars are standard error of the means (N = 3). (∗) Probability level lower than 5%.

cross-linking through ferulates on resistance to stem borers in cotton (*Gossypium hirsutum*[46]) and armyworms in tall fescue (*Festuca arundinacea*[34]) as well as cereal beetles,[13] cereal aphids,[47,48] and cereal midges.[49,50] Cell-wall strengthening through FAs was also involved in the resistance to fungi, such as *Fusarium graminearum* and *Fusarium verticillioides* in maize,[51−53] *Clerotium rolfsii* in chickpea (*Cicer arietinum*[54]), and *Puccinia coronata* in smooth bromegrass (*Bromus inermis*[55]). The first study that observed negative correlations between the DFA concentration and damage caused by corn borer larvae was carried out by Bergvinson et al.[30] Subsequent experiments supported the relationship between DFAs and corn borer resistance in diverse and heterogeneous maize genotypes.[31,33,56,57]

Tissue toughness and hardness are two major mechanical defenses to herbivory of plants,[19,57] and several studies have shown a positive relationship between the DFA concentration and toughness of the tissues that corn borer larvae use as feed.[12,58] In the current trials under artificial infestation, the genotype × location interaction was not significant for the combined damage by both corn borer species as previously observed.[43] With the damage data combined across locations, borer stem tunneling was 29% lower in the P3H population than in P3L. The marked increase in tunnel length observed in P2H agreed with its unexpected low DFAT concentration (Table 1). The length of stem tunnels caused by corn borers showed a significant and negative regression coefficient with compounds **4**, **5** + **6**, and DFAT (Figure 2B). Similarly, Sampietro et al.[53] observed that compound **5** and DFAT were the best explanatory parameters for susceptibility to *F. verticillioides* in evaluations of 12 maize genotypes with different levels of resistance to this fungal pathogen.

Larvae weight obtained from laboratory-feeding bioassays showed significant differences between maize populations evaluated (Figure 3A). On the basis of significant orthogonal contrasts, larvae fed on PHs at 7, 14, 21, and 28 days had 29% (p = 0.03), 37% (p = 0.009), 35% (p = 0.01), and 40% (p = 0.003) lower weight, respectively, than larvae fed on PLs (Figure 3B). At these significant time points, P2H, which had an unexpected reduction of DFAs, showed a pattern closer to the maize populations with a low concentration of DFAs (panels A and B of Figure 3). In agreement with these results, significant negative correlations were found between the larvae weight and DFA concentration in the sheaths of six maize genotypes previously evaluated.[59] Furthermore, Buanafina and co-authors[46] showed that significantly reduced levels of these cell-wall ferulate monomers and dimers in tall fescue affected positively all measures of *Spodoptera frugiperda* (J. E. Smith) larval performance examined (pupal weight, duration of the larval stage, and growth rate).

Maize genotypes evaluated after the DFA selection program developed by our group showed, first, significant differences for the DFA concentration and, second, that these differences were significant and negatively correlated with the stem tunneling caused by corn borers. In addition, laboratory-feeding bioassays showed that corn borer larval performance was negatively associated with the level of DFAT in pith stem tissues that they were fed. From the point of view of resistance definitions, we demonstrate that DFAs have a role in plant resistance (as less tunnel length damage in the plant) and insect resistance (properly affecting borer development).

The concentration of compound **1** was the only cell-wall trait evaluated that showed significant differences among maize populations and significant and positive simple linear regression coefficients with the selection criterion (DFAs) (Table 1, Table S1 of the Supporting Informaton, and Figure 4A). As discussed above, the "sawtooth" pattern observed in P2H for DFA concentration might have also affected the deposition of FAs. The positive regression coefficient observed between ferulate monomers and dimers indicates that cell-wall ester-linked compound **1** was not significantly depleted by producing DFAs. These results agree with the hypothesis that a higher concentration of feruloylated arabinoxylan polymers present in the cell wall allows for compound **1** molecules to be placed in closer physical proximity, facilitating the ferulate dimerization reactions.[27]

The concentrations of compounds **1** and **2** and the total amount of cell-wall material were not significantly correlated with stem tunneling by corn borers (Figure 4B and Figure S1 of the Supporting Informaton). Most p-coumarate accretion occurs in tandem with lignification, making compound **2** accumulation a good indicator of lignin deposition.[60] Even though small amounts of compound **2** are esterified to arabinoxylans, most moieties are ester-linked to the γ position of the syringyl units of lignin.[38] Experimental observations

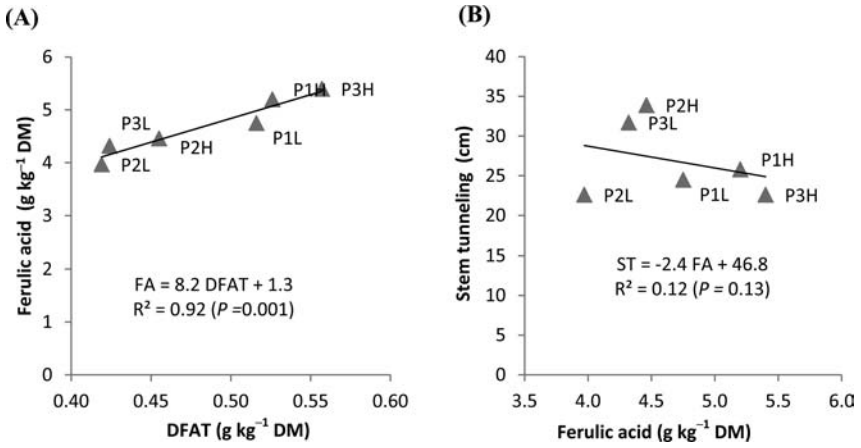

Figure 4. Relationships between FA, DFAs, and borer tunneling. Scatter plots and simple linear regression equations (N = 36) for (A) FA as a function of total ester-linked DFAs and (B) stem tunnel length (ST) by corn borers (in centimeters) as a function of FA (g kg^{-1} of dry matter).

suggest that substitution of sinapyl alcohol with compound **2** occurs prior to its incorporation into the lignin polymer and the presence of the ester linkage allows or facilitates the incorporation of sinapyl alcohol into the growing lignin polymer.[61,62] Maize populations evaluated in the current selection program showed no differences for the compound **2** concentration, and the regression analysis between compound **2** and DFAT showed non-significant regression coefficients (see Figure S1A of the Supporting Informaton). Current results agree with those previously observed after 2 cycles of divergent selection,[34] suggesting that compound **2** and, thereby, lignin deposition were not impaired during the selection program for DFAs. Conversely, some other approaches, such as the transgenic overexpression of a FA esterase gene (*faeA*) in tall fescue, significantly affect the concentration of other hydroxycinnamates, such as compound **2**.[46]

The total amount of cell-wall material has been considered a defense mechanism related with insect nutrition because elevated levels of indigestible cell-wall material increase the compactness of the diet to the point that insects are unable to ingest sufficient quantities of nutrients and water.[15,33,63] Additionally, the total amount of cell-wall material and cross-linking of cell-wall components through DFAs are physical barriers that herbivores must mechanically rupture through mastication to gain access to the cytoplasmic nutrients contained within feeding tissues.[57,46] Nevertheless, in the current evaluation, maize populations with the highest concentration of DFAs (P3Hs) were more resistant than P3Ls, despite having similar cell-wall contents (Table 1), suggesting that the stiffness conferred by DFAs rather than the total cell-wall content was critical for caterpillar deterrence.

As a summary, the results showed that the extent of cell-wall ester-linked DFA deposition in maize pith stem tissues can be genetically regulated through breeding. The concentration of FA monomers showed a significant and positive direct response to selection for DFAs; however, none of the cell-wall traits evaluated other than DFAs was significantly correlated with stem tunneling caused by corn borers. In addition, laboratory-feeding bioassays showed that corn borer larval performance was negatively associated with the level of DFAT in pith stem tissues that they were fed. These results suggest that cell-wall stiffness conferred by DFAs rather than the indigestibility of the cell-wall components is critical for corn borer larvae deterrence. Furthermore, this is the first report that demonstrates a direct relationship between DFA deposition in maize cell walls and corn borer resistance within the same genetic background, avoiding genotype-specific resistance mechanisms that may have biased the earlier works.

Overall, current results provide evidence to encourage further research to better understand the role of cell-wall cross-linking through ferulates as a common resistance mechanism against pests and diseases in grasses. Our results highlight the possibility of using conventional breeding to increase the concentration of DFAs and improve natural resistance in maize plants. Cross-linking of cell-wall polysaccharides through DFAs is a resistance factor that should be a candidate for inclusion as indirect selection criteria in Integrated Pest Management programs.

MATERIALS AND METHODS

Materials and Chemicals. Sephadex G-25, CM-Sepharose FF, phenyl-Sepharose HP, Superdex 75 16/60, preparative columns, and IEF calibration kit were purchased from GE Life sciences (Pittsburgh, PA, USA). Bovine fibrinogen and thrombin were purchased from the Tianjin Blood Institute (Tianjin, China). Human fibrinogen was purchased from Sigma Chemical Co. (St. Louis, MO, USA). Soybean trypsin inhibitor (SBTI), *N*-α-tosyl-L-phenylalanine chloromethyl ketone (TPCK), phenylmethanesulfonyl fluoride (PMSF), aprotinin, pepstatin, and low molecular weight SDS-PAGE Protein standard kit (ranging from 14.4 to 97.4 kDa) were purchased from Sangon (Shanghai, China).

Strain and Culture Conditions. *Cordyceps militaris* strain was stored on PDA slants. The mycelia were transferred from the slants to plate medium. The mycelia were inoculated aseptically into 250 mL shake flasks containing 50 mL of fermentation media composed of 2% sucrose and 5% soybean cake powder. Fermentation was carried out for 5 days at 23 °C, 180 rpm. The fermentation broth was centrifuged (10000 rpm, 10 min, 4 °C), and the supernatant was considered as the crude enzyme extract.

Enzyme Assay and Protein Determination. Fibrinolytic activity was determined by using the method of Astrup and Mullertz[22] with slight modifications. Fibrin plates were prepared as follows: fibrinogen (0.4%, w/v) dissolved in 5 mL of 100 mM barbital sodium−chlorhydric acid buffer, pH 7.8, was mixed with 5 mL of 0.5% (w/v) agarose solution along with 1 mL of thrombin solution (200 U/mL) and poured into Petri plates; after standing for 1 h at room temperature for clot formation, the plate was used to measure fibrinolytic activity. In brief, 10 μL of the enzyme solution was carefully placed on the fibrin plate and incubated at 37 °C for 6 h, and the diameter of the lytic circle was measured. The diameter was directly proportional to the potency of the fibrinolytic activity, and the unit of the enzyme activity was determined according to a calibration curve using urokinase as standard. The protein content was estimated by Lowry method[23] using bovine serum albumin as a standard. The carbohydrate content of the purified enzyme was quantified by anthrone colorimetric method using glucose as a standard.[24]

Purification of Fibrinolytic Enzyme. Crude sample was subjected to 0−20% saturation of $(NH_4)_2SO_4$ precipitation. The supernatant obtained by centrifugation (10000 rpm for 20 min at 4 °C) was buffer exchanged on a Sephadex G-25 column (1.6 cm × 50 cm) using 0.02 mol/L sodium phosphate buffer (pH 7.4). After buffer exchange, the enzyme solution was loaded onto a phenyl-Sepharose HP column (1.6 cm × 30 cm) which was earlier equilibrated with 0.02 mol/L sodium phosphate buffer (pH 7.4) containing 30% saturated $(NH_4)_2SO_4$. Bound proteins were eluted with a decreasing linear gradient of 30−0% $(NH_4)_2SO_4$ in 0.02 mol/L sodium phosphate buffer (pH 7.4). The active fractions were collected, buffer exchanged using 0.02 mol/L sodium phosphate buffer, pH 6.0, and loaded onto a cation exchange column CM-Sepharose FF (2.6 cm × 20 cm) which was previously equilibrated with the same buffer. Fractions exhibiting the most potent fibrinolytic activity were pooled and further purified on a Superdex 75 gel filtration column (1.6 cm × 60 cm) using 0.02 mol/L sodium phosphate buffer containing 0.3 mol/L NaCl (pH 6.0). Finally, the purified active fractions were pooled, lyophilized, and used for further characterization. All the purification steps were performed at 4 °C unless otherwise stated.

Determination of Molecular Weight and Isoelectric Point. The molecular weight of the purified enzyme was determined by SDS-PAGE (under reducing denaturing conditions) as described by Laemmli,[25] using a 12% polyacrylamide gel. Protein bands were visualized by staining the gel with Coomassie brilliant blue R-250. For calibration, an SDS-PAGE midrange molecular weight standard kit (Sangon Biotech, Shanghai, China) comprising rabbit phosphorylase B (97.4 kDa), bovine serum albumin (66.2 kDa), ovalbumin (42.7 kDa), bovine carbonic anhydrase (31.0 kDa), and chicken egg white lysozyme (14.4 kDa), was used.

The native molecular weight of the enzyme was determined by gel filtration chromatography using a Superdex 75 (1.6 cm × 60 cm) column in 20 mM phosphate buffer (pH 7.4) containing 300 mM NaCl. Gel filtration low molecular weight calibration kit comprising bovine serum albumin (67 kDa), ovalbumin (43 kDa), chymotrypsinogen A (25 kDa), and ribonuclease A (13.7 kDa), was used. The void volume of the column was determined by using blue dextran 2000.

The isoelectric point (p*I*) of the purified enzyme was determined by isoelectric focusing electrophoresis (IEF) using homogeneous polyacrylamide gels (7.5% polyacrylamide with 3% cross-linkage) containing carrier ampholytes (3−9).[26]

Q-TOF2 Tandem Mass Spectrometry Sequencing. To determine the partial amino acid sequence by Q-TOF2 tandem mass spectrometry, the purified enzyme was subjected to SDS-PAGE. Protein band was excised from the gel and submitted for amino acid sequencing using high performance liquid chromatography−electrospray tandem mass spectrometry (HPLC-ESI-MS/MS) at National Center for Biomedical Analysis, Military Academy of Medical Sciences (Beijing, China). Mass spectral sequencing was performed using a Q-TOF II mass analyzer (Q-TOF2, Micromass Ltd., Manchester, UK). Peptide sequencing was performed using a palladium-coated borosilicate electrospray needle (Protana, Denmark). The mass spectrometer was used in positive ion mode with a source temperature of 80 °C, and a potential of 800 V was applied to the nanospray probe. MS/MS spectra were transformed using MaxEnt3 (MassLynx, Micromass), and amino acid sequences were interpreted manually using PepSeq (BioLynx, Micromass).

Effects of Environmental Factors on Enzyme Activity. The optimal temperature of the purified enzyme was determined by measuring the activity at different temperatures (16−60 °C) in sodium barbital buffer (pH 7.4). The thermal stability of the enzyme was determined by incubating the enzyme at different temperatures (23−60 °C) for 0.5 h in sodium barbital buffer (pH 7.4), and the residual activities were assayed.

To determine the optimal pH of the purified fibrinolytic enzyme, the enzyme activity was assayed at 37 °C in different buffers within the range of pH 6.8−8.2. pH stability of the purified enzyme was determined by incubating the enzyme in different buffers ranging from pH 3−12 for 1 h, and the residual activities were assayed by fibrin plate method. The buffers used were: citrate−phosphate (pH 3.0−7.0), barbital sodium−chlorhydric acid buffer (pH 8.0−9.0), Na_2CO_3−$NaHCO_3$ (pH 9.5−10.5), and Na_2HPO_4−NaOH buffer (pH 11.0−12.0).

Effects of various factors such as (1) metal ions (Cu^{2+}, Co^{2+}, K^+, Fe^{3+}, Fe^{2+}, Ca^{2+}, Mg^{2+}, Mn^{2+}, Na^+, and Zn^{2+}) at a concentration of 5 mM at 37 °C for 18 h; (2) protease inhibitors such as pepstatin, PMSF (phenylmethyl sulfonyl fluoride), aprotinin, TPCK (*N*-α-tosyl-L-phenyl alanine chloromethyl ketone), SBTI (soybean trypsin inhibitor), Lys and metal chelator EDTA (ethylenediamine tetraacetic acid) at concentrations of 2.0 and 10 mM (2.5 and 10 mM in case of EDTA and Lys) at 37 °C for 10 min; (3) various protective agents and other reagents (5 mmol/L reduced glutathione, 5 mmol/L oxidized glutathione, 20 mmol/L cysteine, 0.5% β-mercaptoethanol, 1%, w/v, bovine serum albumin, 1% gelatin, 1% peptone), organic substances (10%, v/v, acetone, 10% glycerol), and denaturants (urea and SDS) at 37 °C for 4 h on the activity were determined as above.

Simulated Gastric and Blood Environment Effect on Enzyme Activity. To prepare simulated gastric juice solution, 10% HCl solution (pH 3.0) was first autoclaved (121 °C, 15 min), cooled down to 37 °C, and mixed with pepsin (1 g per 100 mL). Simulated blood solution (Clorox solution, commonly used for mammalian heart perfusion test) was prepared by dissolving 0.9 g NaCl, 0.042 g KCl, 0.024 g $CaCl_2$, 0.02 g $NaHCO_3$, and 0.2 g glucose into 100 mL deionized water and stored at 4 °C until further use.

The activity of the enzyme in simulated gastric juice and simulated blood was tested in six different combinations:

(1) 100 μL of water + 50 μL of purified enzyme;
(2) 50 μL of artificial gastric juice + 50 μL of broth + 50 μL of purified enzyme;
(3) 50 μL of artificial gastric juice + 50 μL of H_2O + 50 μL of purified enzyme;

DOI: 10.1021/jf505717e
J. Agric. Food Chem. 2015, 63, 2215−2224

(4) 50 μL of artificial gastric juice + 50 μL of 10% maltose + 50 μL of purified enzyme;
(5) 50 μL of artificial gastric juice + 25 μL of broth + 25 μL of 10% maltose + 50 μL of purified enzyme;
(6) 100 μL of Clorox solution + 50 μL of purified enzyme.

Simulated gastric and Clorox solutions were added to the purified enzyme separately and incubated at 37 °C for 4 h. The effect of simulated gastric juice in the presence of protein and carbohydrate was also evaluated. The residual activities were measured by standard fibrin plate method.

Storage Stability of Purified Enzyme. *1. Impact of Freeze−Thawing on Storage of the Purified Enzyme.* Purified fibrinolytic enzyme (0.151 mg/mL) was stored at −20 °C and −70 °C, and repeated freeze−thawing was carried out for 2, 4, 6, 8, 11, 13, 15, and 17 times and the residual enzyme activity was determined.

2. Effect of Stabilizers on Storage Stability of the Purified Enzyme. To appropriate volume of purified enzyme (0.066 mg/mL), an equal volume of different concentrations of glycerol and sucrose (5%, 10%, 15%, 20%) were added, mixed, and stored at 4 °C refrigerator for 1 week. The residual activity was measured by standard assay.

3. Long-Term Storage Stability of the Purified Enzyme. The purified enzyme (both in liquid (0.151 mg/mL) and lyophilized forms) was stored at different temperatures (25 °C, 4 °C, −20 °C, −80 °C) for 1 day, 2 days, 1, 2, 3, 4, and 7 weeks, and 1 year. The residual activities were determined.

Measurement of Thrombin Activity of the Purified Enzyme. Thrombin activity of the purified enzyme was measured as follows. First, 40 μL of different concentrations of fibrinogen (10, 20, 40, 80, and 100 mg/mL) was mixed with 10 μL of the enzyme (0.075 mg/mL), and then the clotting time was recorded. Bovine thrombin (500 U/mL) was used as a positive control.

Activation of Plasminogen (Plasminogen Activator Activity). Activation of plasminogen by the purified enzyme was analyzed by fibrin plate method. Fibrin plates were prepared as described earlier. Usually, commercially available fibrinogen contains traces of plasminogen, so the plasminogen-free plates were prepared by using similar method but were heated at 85 °C for 30 min to inactivate plasminogen. The presence of plasminogen activity was measured by difference in area of lytic zone in two different plates.

In Vitro Dissolution of Blood Clots by the Purified Enzyme. To 0.4890 g of blood clot, 500 μL (0.075 mg/mL) of enzyme solution was added and incubated at 37 °C for 6 h. Samples at different time intervals, 10, 20, 40, 60, 90, 120, 180, 240, 300, and 360 min, were centrifuged briefly at 3000 rpm for 30 s, the supernatant was transferred, and the residual clot weight was recorded. The clot was redissolved in the supernatant, and the reaction was continued for further dissolution. Finally the rate of clot dissolution was calculated as follows:

$$\text{clot dissolution rate} = [(\text{clot weight before dissolving} - \text{clot weight after dissolving}) / \text{clot weight before dissolving}] \times 100\%$$

Fibrin(ogen)olytic Activity of the Enzyme. *Human Blood Fibrinogen Degradation.* Fibrinogenolytic activity was measured by a modified fibrinogenolytic assay.[27] Fibrinogen (23 μL of 2% human fibrinogen in 0.05 mol/L Tris-HCl buffer (pH 7.6)) was mixed with the purified enzyme (23 μL of 0.075 mg/mL) and incubated at 37 °C for different time intervals (1 min, 5 min, 15 min, 25 min, 1 h, 1.5 h, 2 h, 4 h, and 24 h). After the indicated time intervals, aliquots were transferred onto ice and analyzed by SDS-PAGE to examine the cleavage patterns of the fibrinogen chains.

Fibrin Degradation. Fibrinolytic activity was measured by a modified fibrinolytic assay. To 23 μL of fibrinogen (2% human fibrinogen in 0.05 mol/L Tris-HCl buffer (pH 7.6)), 10 μL of thrombin was added. After coagulation, 23 μL of purified enzyme (0.075 mg/mL) was added and incubated at 37 °C for different time intervals (3 min, 6 min, 15 min, 25 min, 1 h, 1.5 h, 2 h, 4 h, and 24 h). After the indicated time intervals, aliquots were transferred onto ice and analyzed by SDS-PAGE to examine the cleavage pattern of the fibrin.

Analysis of In Vitro Fibrinolytic and Anticoagulant Effect. To study the fibrinolytic and anticoagulant effect in vitro, purified enzyme (0.075 mg/mL), fibrinogen (Fbg 10 mg/mL), and thrombin (Tb, 0.5 U/μL) were mixed in three ways as follows:

(1) Human fibrinogen + thrombin (clot formation time was recorded) + purified enzyme (clot dissolution time was recorded).
(2) Human fibrinogen (37 °C for 5 min) + purified enzyme and Tb mixture; subsequently incubated in 37 °C (time required for clot formation and complete dissolution was recorded).
(3) Human fibrinogen + purified enzyme (incubated at 37 °C water bath for 5 min) + Tb.

The samples were incubated at 37 °C, and the time required for clot formation and dissolution were recorded. The degradation patterns of the samples were analyzed by SDS-PAGE. Fibrinogen was used as control.

Proteolytic Effect of Purified Enzyme on Blood Proteins. The effect of purified enzyme on blood protein components was studied by incubating purified enzyme (23 μL) with equal volume of human serum albumin (HSA) (15 mg/mL), human immunoglobulin G (IgG), and human thrombin at 37 °C for 4 h. Samples were analyzed by electrophoresis.

RESULTS

Purification and Characterization of Fibrinolytic Enzyme. A submerged culture method was developed to prepare fibrinolytic enzyme. The fibrinolytic enzyme extract was first subjected to 20% ammonium sulfate precipitation. The precipitated materials were discarded, and after buffer exchange, the supernatant was subjected to hydrophobic interaction chromatography on phenyl sepharose FF column; the active fractions were pooled and further purified by cation exchange chromatography, followed by Superdex 75 gel filtration chromatography (Figure 1). An overall yield of 4.0% was obtained with 41.3-fold increase in purity. The specific activity of the purified enzyme was 1682 U/mg. A summary of purification steps is presented in Table 1.

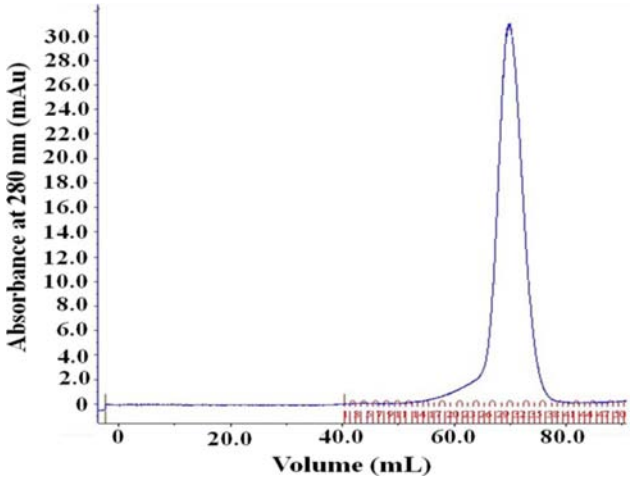

Figure 1. Purification of fibrinolytic enzyme from *Cordyceps militaris* by using Superdex 75 gel filtration chromatography column.

The purified fibrinolytic enzyme appeared to be a single homogeneous band on SDS-PAGE (Figure 2a). The molecular weight of the purified enzyme was determined under native and denatured conditions. Its molecular weight was determined to

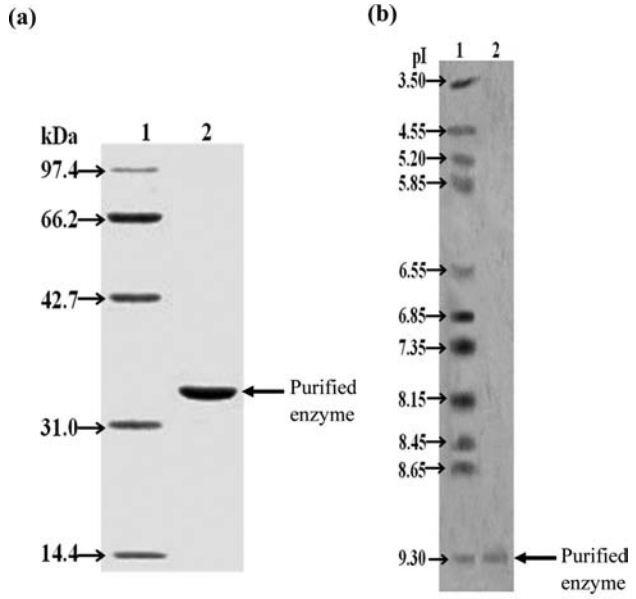

Figure 2. Analysis of the purified fibrinolytic enzyme. (a) SDS-PAGE under reducing denaturing conditions. Lane 1, molecular weight marker; lane 2, purified enzyme. (b) Isoelectric focusing (IEF). Lane 1, p*I* marker; lane 2, purified enzyme.

be 32 kDa by both gel filtration chromatography (data not shown) and SDS-PAGE (Figure 2a), indicating that the enzyme is monomeric in nature. The isoelectric point (p*I*) of the purified enzyme was determined to be 9.3 ± 0.2 (Figure 2b). The purified enzyme was found to be a glycoprotein as identified by Molish test with a carbohydrate content of 0.98% (w/v).

The partial amino acid sequences of the purified enzyme were determined by Q-TOF2 mass spectrometer. Three internal peptides were obtained and their amino acid sequences are APQALTVAAVGATWAR, EKNVGSTVNLLSYDGNK, and TDATSVLLDGYNVSAVNDLVAK. All the three peptides were analyzed using NCBI-BLAST database for sequence similarity with earlier reported fibrinolytic enzymes, and the results are summarized in Table 2.

Effects of Environmental Factors on Enzyme Activity. The optimal pH of the purified enzyme was 7.4 (Figure 3a) and exhibited stability at pH ranging from pH 6.0 to 11.0 (Figure 3b). The enzyme exhibited maximum activity at 37 °C (Figure 3c) and showed thermostability in the temperature range of 23−60 °C and was highly stable up to 47 °C, retaining >80% of its activity when incubated for 30 min (Figure 3d). Enzyme activity and thermostability decreased slowly above 50 °C.

Effect of various metal ions, protease inhibitors, and other reagents on fibrinolytic activity of the purified enzyme was also studied. The activity was strongly inhibited by Fe^{3+} (46.7%) but was not affected by Fe^{2+} (94.5%), however, the activity was enhanced by Ca^{2+} (131.9%) and Cu^{2+} (114.1%) at a concentration of 5 mM (Table 3). The enzyme activity was strongly inhibited by serine protease inhibitors and aspartic protease inhibitor but not by chymotrypsin inhibitor and metalloprotease inhibitor (Table 4). These results indicated that metal ion is not present in the active site of the enzyme and is not involved in enzyme activity.

The enzyme activity was inhibited by −SH group reactive agents, which indicated that the sulfhydryl group of the enzyme was necessary for its activity. BSA (80.5% activity) slightly inhibited the enzyme activity, while gelatin (120% activity) and peptone (127% activity) enhanced the enzyme activity (Table 5).

Stability Studies of the Purified Enzyme. The enzyme was found to be highly stable even after repeated cycles of freeze−thawing. This property is very useful during industrial

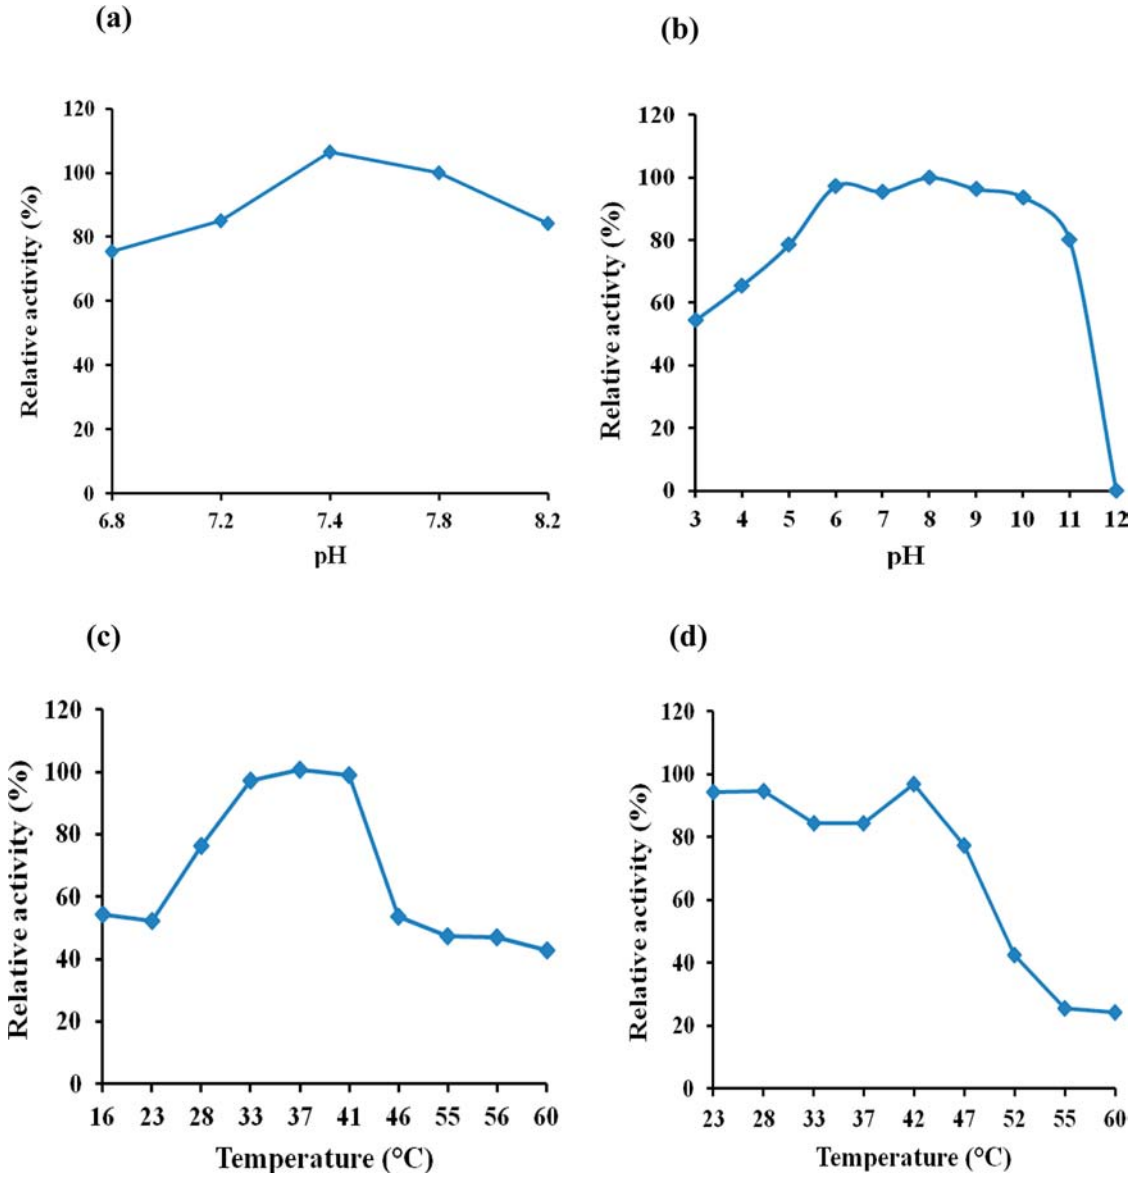

Figure 3. Effect of pH and temperature on fibrinolytic activity of the enzyme. (a) Optimal pH of the purified enzyme was checked at 37 °C in 20 mM of different buffers: citrate−phosphate (pH 3.0−7.0), barbital sodium−chlorhydric acid buffer (pH 8.0−9.0), Na_2CO_3−$NaHCO_3$ (pH 9.5−10.5), and Na_2HPO_4−NaOH buffer (pH 11.0−12.0). (b) For pH stability, the enzyme was incubated at 37 °C for 1 h over range of pH buffers and the residual activities were determined. (c) Optimal temperature of the purified enzyme was determined at different temperatures (16−60 °C) in sodium barbital buffer (pH 7.4). (d) For temperature stability, the enzyme was incubated at different temperatures (23−60 °C) for 0.5 h, in sodium barbital buffer (pH 7.4), and the residual activities were measured by standard fibrin plate method.

production and clinical applications of the enzyme. The effect of stabilizers such as glycerol and sucrose on storage stability of the purified enzyme was also investigated. The enzyme was stable for 1 week at 4 °C in the presence of 15% glycerol without any loss of activity (data not shown). Sucrose did not exhibit any protective role at the same experimental conditions as glycerol.

Stability of the purified enzyme both in liquid and lyophilized forms was studied. The enzyme was stable in liquid form up to 1 day at 25 and 4 °C, while in lyophilized form, the enzyme was stable after one month of storage at same temperature (25 and 4 °C), retaining 78% and 83% of its initial activity, respectively. Storage of both the forms at −20 °C and −80 °C did not result in loss of any activity up to one month.

The stability of the enzyme was further analyzed after 14 months of storage. The liquid form of enzyme was stable and

retained 56% and 76% of its activity when stored at −20 °C and −80 °C for 14 months. Meanwhile, the lyophilized form of enzyme was highly stable at 4 °C, −20 °C, and −80 °C for the same period of time and retained 62%, 83%, and 101% of its activity, respectively.

Simulated Gastric and Blood Environment Effect on Enzyme. As shown in Figure 4a, the enzyme lost its activity completely after 4 h of incubation in gastric juice (lane 3) and retained ∼60% of its relative activity in the presence of protein broth (lane 2) or protein broth and maltose (lane 5). Maltose did not show any protective effect (lane 4). The enzyme also tolerated simulated blood environment (Clorox solution); 60% of its relative activity was retained after 4 h of incubation. Therefore, the enzyme should be administered after a meal or intravenously; the loss of the enzyme activity after 4 h of incubation implied its possible advantage over the current fibrinolytic agents associated with bleeding due to excessive plasmin activity.

Determination of Thrombin-Like Activity of Purified Enzyme. The coagulation time required for clotting at different concentrations of human fibrinogen by bovine thrombin is 3−4 min. Thrombin specifically hydrolyzes Aα and Bβ subunits of fibrinogen and forms insoluble fibrin clot. The purified enzyme was unable to clot fibrinogen even at the highest concentrations of 100 mg/mL, indicating that the enzyme did not have thrombin-like activity but acts directly on fibrin clots (data not shown).

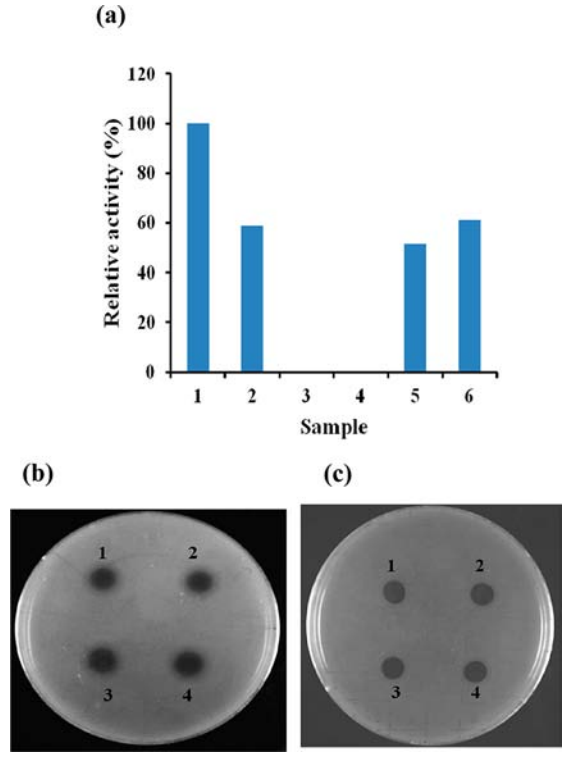

Figure 4. (a) Effect of simulated gastric and blood environments on purified enzyme. The activity of the enzyme in simulated gastric juice and simulated blood was tested in six different combinations. Lane 1, enzyme in water (control); lane 2, enzyme in artificial gastric juice and protein broth; lane 3, enzyme in artificial gastric juice; lane 4, enzyme in artificial gastric juice and maltose; lane 5, enzyme in artificial gastric juice, maltose and protein broth; lane 6, enzyme in Clorox solution. (b) Analysis of plasminogen activation by purified fibrinolytic enzyme on plasminogen-free fibrin plate and (c) activation of plasminogen by purified fibrinolytic enzyme on plasminogen-rich fibrin plate: 10 μL each of the purified enzyme was placed at four spots (1−4) on each plate and incubated at 37 °C for 6 h. Activity was quantified by measuring the area of lysis (1−4 circles) and compared between plasminogen-free and rich plates.

Activation of Plasminogen (Plasminogen Activator Activity). Plasminogen activator activity of the purified enzyme was examined. The purified enzyme did not act as plasminogen activator because the area of diameter of the lytic circle was almost similar in both plasminogen and plasminogen-free fibrin plates (Figure 4b,c).

In Vitro Dissolution of Blood Clots by the Purified Enzyme. The in vitro effect of purified enzyme on dissolution of blood clots, and its dissolution rate was measured at different time intervals (Table 6). The purified enzyme could dissolve the blood clots; the dissolution substantially increased at prolonged incubation time, and the clots completed disappeared within 6 h (Table 6).

Fibrin(ogen)olytic Activity of Purified Enzyme. The enzyme exhibited fibrin(ogen)olytic activity and the degradation patterns of fibrin(ogen) by the purified enzyme were analyzed by SDS-PAGE (Figure 5a,b). In control, fibrinogen was separated into Aα, Bβ, and γ chains. When fibrinogen was incubated with the purified enzyme, the Aα band disappeared first, followed by the Bβ and γ bands. This indicates that the enzyme degraded the Aα chain of fibrinogen first, followed by the Bβ and γ chains. The Aα chain was degraded within 5 min of incubation, while the Bβ and γ chains were degraded in 1 h

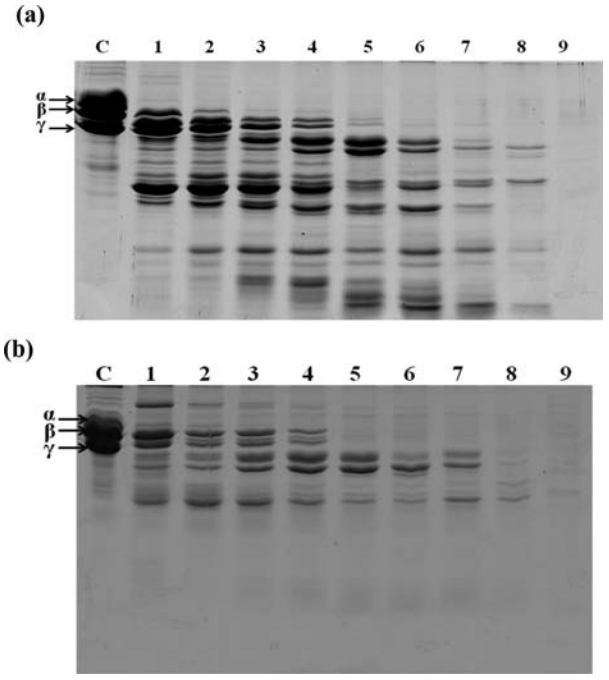

Figure 5. Analysis of cleavage pattern of fibrin(ogen) by purified enzyme. (a) SDS-PAGE analysis of reduced human fibrinogen after digestion by the purified enzyme; lane C, control; lanes 1−9, degradation pattern of fibrinogen at different time intervals of 1 min, 5 min, 15 min, 25 min, 1 h, 1.5 h, 2 h, 4 h, and 24 h, respectively. (b) SDS-PAGE analysis of reduced human fibrin after digestion by the purified enzyme; lane C, control; lanes 1−9, degradation pattern of fibrinogen at different time intervals of 3 min, 6 min, 15 min, 25 min, 1 h, 1.5 h, 2 h, 4 h, and 24 h, respectively.

after incubation (Figure 5a). This implies that the cleavage sites of Aα and Bβ chains were different from thrombin. The low molecular weight degradation products increased with incubation time.

The fibrin degradation pattern by the purified enzyme was also analyzed (Figure 5b). The fibrin α-chain was hydrolyzed within 3 min, followed by the γ−γ chain in 25 min of incubation. The β chain was hydrolyzed slowly and degraded completely in 1 h.

Analysis of in Vitro Fibrinolytic and Anticoagulant Effect. When fibrinogen and thrombin were premixed and then the enzyme was added, the time required for formation of clot was 9.75 s, and for dissolution it was 3 min 20 s. Although the clot was dissolved completely, the subunits of the fibrin were not degraded completely as shown in SDS-PAGE (Figure 6a); the α-subunit was degraded completely, while β and γ subunits were still visible.

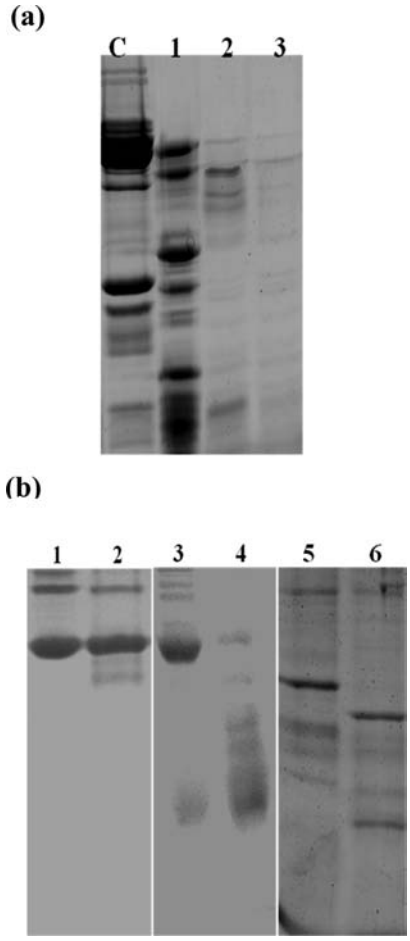

Figure 6. (a) In vitro fibrinogen degradation and anticoagulant effect of purified enzyme. Lane C, control; lane 1, Fbg and Tb were premixed and the enzyme was added after the formation of the fibrin clot (1st combination); lane 2, fibrinogen was first preactivated, then purified enzyme and thrombin mixture were added (2nd combination); lane 3, human fibrinogen was premixed with purified enzyme (3rd combination). (b) Effect of purified enzyme on blood proteins. Lanes 1, 3, and 5 represent positive controls of human serum albumin (HSA), human IgG, and human thrombin, respectively; lanes 2, 4, and 6 represent their respective degradation patterns by the enzyme.

When fibrinogen was first preactivated and then the purified enzyme and thrombin were added, it took 1 min 41 s for clot formation, which was much longer than the first combination (9.75 s). However, the newly formed fibrin clot was dissolved by the enzyme within a short period of 2 min 15 s, which was significantly shorter than first combination (3 min 20 s). The difference in time required for clot formation, and dissolution could be due to the fact that both processes might have occurred simultaneously in the system. Degree of degradation of each subunit of the fibrin between two reactions was further confirmed by SDS-PAGE (Figure 6a, lane 2). As shown in Figure 6a, lane 3, human fibrinogen subunit was thoroughly hydrolyzed; as a result, no observable large protein bands could be seen on the gel.

Effect of Purified Enzyme on Blood Plasma Proteins. The effect of purified enzyme on different blood plasma

DOI: 10.1021/jf505717e
J. Agric. Food Chem. 2015, 63, 2215−2224

proteins was studied. As shown in Figure 6b, human IgG and serum albumin were partially hydrolyzed by the enzyme. It also degraded human thrombin to some extent (Figure 6b).

DISCUSSION

In this study, a novel fibrinolytic enzyme from the mushroom, *Cordyceps militaris*, was produced by submerged culture fermentation. During fermentation, soybean cake was used as a major component of the culture medium, which is different from that of other reports.[29] The enzyme was purified to homogeneity by using combination of various chromatographic steps. The molecular weight of the purified enzyme was 32 kDa. The molecular weight of mushroom fibrinolyic enzymes are in the range of 17−100 kDa.[28] Our value is similar to the enzyme purified from *Pleurotus ostreatus* mycelia (32 kDa)[17] but is smaller than that of fibrinolytic enzyme from *Flammulina velutipes* (37 kDa) and *Cordyceps militaris* (52 kDa).[7,20] The molecular weight of the purified enzyme is not similar to any of the reported fibrinolytic enzymes from *Cordyceps* sp.[3,18,20,29] The isoelectric point (p*I*) of the purified enzyme was determined to be 9.3 ± 0.2, which is higher than the fibrinolytic enzymes from *Cordyceps militaris* (8.1) and *Rhizopus chinensis* 12 (8.5).[3,26] The partial amino acid sequences of the purified enzyme were determined by Q-TOF2 mass spectrometer. Peptides 1, 2, and 3 exhibited 94%, 93%, and 73% similarity with alkaline serine protease, Alp1, from *Cordyceps militaris* CM01, respectively (accession no. XP_006670629.1) (Table 2).

Mushroom fibrinolytic enzymes exhibited optimal activity in the range of pH 5.0−10.0.[28] The optimal pH of the purified enzyme for the fibrinolytic activity is 7.4, which is the physiological pH of humans. Its optimum pH is similar to fibrinolytic enzymes from fruiting bodies of *Cordyceps militaris* and *Tricholoma saponaceum*[15,20] but higher than that of *Flammulina velutipes*, *Armillaria mellea*, and *Schizophyllum commune* enzymes.[5,7,16] The enzyme exhibited maximal activity at 37 °C, which is the same as the enzyme purified from fruiting bodies of *Cordyceps militaris*[20] but higher than the enzyme purified from *Armillaria mellea*, *Flammulina velutipes*, and *Cordyceps militaris*.[7,16,18] Mushroom fibrinolytic enzymes have optimal activity at temperatures ranging from 20 to 60 °C.[28]

The enzyme activity was strongly inhibited by serine protease inhibitors and aspartic protease inhibitor but not by chymotrypsin inhibitor and metalloprotease inhibitor. Our results are similar to the fibrinolytic enzyme from *Cordyceps militaris*[20] but are in contrast to other fibrinolytic enzymes from fruiting bodies of Korean *Cordyceps militaris* where the enzyme activity was strongly inhibited by TPCK, EDTA, and metal ions.[3,18] Most fibrinolytic enzymes purified from mushrooms are inhibited by the metal chelator EDTA.[5,7,17,30] On the basis of their inhibitory specificities, mushroom fibrinolytic enzymes are classified into two groups, viz. serine proteases (those inhibited by PMSF, SBTI, aprotinin) and metalloproteases (those inhibited by EDTA). Therefore, the purified fibrinolytic enzyme from this study is a serine protease. SDS and urea strongly inhibited the enzyme activity, indicating that these reagents might have denatured the enzyme.

Glycerol and sucrose are used as thermoprotective agents for storage of proteins or enzymes. The cryoprotective effect of sucrose on stability of purified enzyme was found to be weaker than glycerol. Therefore, it is recommended to add 15% glycerol for improving its storage stability. Results from stability studies indicate that the liquid form of enzyme stored at 25 and 4 °C was stable only for a short time, and the rate of loss of activity of freeze-dried powder was less than that of solution form. The lyophilized powder of the enzyme can be stored for more than one year at −80 °C. After one year of storage at −20 °C, the enzyme was more stable in freeze-dried powder, retaining more than 80% of its activity as compared to the liquid enzyme solution where it lost about half of its activity. Therefore, it is recommended that the purified enzyme be lyophilized and stored in a deep freezer for long-term storage (more than one year). For the first time, stability of a purified fibrinolytic enzyme from mushrooms was studied and reported.

The enzyme retained 60% of its relative activity in the presence of an appropriate protein solution (broth) which acts as a protective agent. It also tolerated simulated blood environment (Clorox solution). Therefore, the enzyme should be administered after a meal or intravenously; the loss of the enzyme activity after 4 h of incubation implied its possible advantage over the current fibrinolytic agents associated with bleeding due to excessive plasmin activity. Fibrinolytic enzyme from fermented shrimp paste was resistant to the digestive enzymes, pepsin and trypsin; and tolerated in vitro physiological conditions of stomach and small intestine models for 1 h.[6]

Fibrinolytic enzymes degrade thrombus in two ways, either by degrading fibrin directly or by indirectly degrading fibrin through activation of plasminogen into plasmin.[5] The purified enzyme in this study did not act as plasminogen activator because the area of diameter of the lytic circle was almost similar in both plasminogen and plasminogen-free fibrin plates. In plasminogen-free plates, the lytic circles are not condensed and appeared slightly larger than the plasminogen plates. It is possible that pretreatment of fibrin plates at high temperature might have changed the fibrin structure, which resulted in less condensed lytic zone. These preliminary results indicate that *Cordyceps militaris* fibrinolytic enzyme is a plasmin-like protein, which can degrade fibrin directly, but not a plasminogen activator, which can participate in thrombolysis. These results are dissimilar to the earlier reported fibrinolytic enzymes from *Schizophyllum commune* and *Bacillus* sp., which exhibited enhanced activities in plasminogen rich plates.[5,9,10]

The purified enzyme could dissolve the blood clots; the dissolution substantially increased at prolonged incubation time, and the clots completely disappeared within 6 h (Table 6). Similar result was reported for fibrinolytic enzyme purified from *Bacillus subtilis* DC33.[9] Our study showed for the first time the presence of thrombolytic activity in mushroom fibrinolytic enzyme.

Degradation of fibrin(ogen) by purified enzyme was studied. Fibrinolytic enzymes from *Cordyceps militaris* and *Flammulina velutipes* also exhibited similar degradation patterns.[7,20] In addition, the enzyme can hydrolyze fibrin(ogen) chains more quickly than the fibrinolytic enzyme from fruiting bodies of Korean *Cordyceps militaris* (requires 4 h for complete degradation).[3] However, some fibrinolytic enzymes cannot hydrolyze all three chains of fibrin(ogen). It was reported that fibrinolytic enzyme from *Bacillus* sp. could hydrolyze only Bβ and γ-chains of fibrinogen.[10] Fibrinolytic enzymes from the mushrooms *Armillariella mellea* and *Tricholoma saponaceum* have been shown to hydrolyze Aα and Bβ chains of fibrinogen with equal efficiency, but γ-chain was resistant to hydrolysis.[14,15] It is noteworthy that the purified enzyme in this study can hydrolyze all three chains of fibrinogen more efficiently and quickly.

DOI: 10.1021/jf505717e
J. Agric. Food Chem. 2015, 63, 2215−2224

During in vitro fibrinolytic and anticoagulant studies when human fibrinogen was premixed with the purified enzyme, the enzyme degraded human fibrinogen. As a result, fibrinogen was not activated by thrombin, or even if activated it could no longer have the capacity to cross-link required for clot formation, which was further observed by electrophoresis (Figure 6a). As shown in Figure 6a, lane 3, human fibrinogen subunit was thoroughly hydrolyzed; as a result, no observable large protein bands could be seen on the gel. These results indicate that the purified enzyme could act as an anticoagulant as well as a fibrinolytic agent. It could suppress the formation of blood clots during coagulation process and has the potential to develop into a novel thrombolytic drug. The fibrinolytic enzyme from fermented shrimp paste also exhibited similar kinds of characteristics.[6]

Human IgG and serum albumin were partially hydrolyzed by the enzyme. IgG, the main human immunoglobulin, constitutes about 70% of human plasma globulin, which is the most important antibody in the primary immune response. Human serum albumin is the main component in the formation of the osmotic pressure of plasma gum and plays an important role in maintaining normal body fluid distribution, blood volume, and blood pressure. Thrombin is the most important clotting factor in the process of thrombosis. It also degraded human thrombin to some extent (Figure 6b). These results indicate that during normal fibrin clot formation, thrombin activity can also be inhibited and the enzyme can prevent thrombosis. Similar degradation was observed for the fibrinolytic enzyme from *Bacillus subtilis* DC33.[9] Therefore, the use of this enzyme for fibrinolytic therapy might cause some mild undesirable effects such as partial degradation of human IgG and serum albumin but can also prevent thrombosis by hydrolyzing thrombin. In contrast to the present results, the fibrinolytic enzyme purified from fermented shrimp paste, fruiting bodies of mushrooms *Armillariella mellea* and *Tricholoma saponaceum*, did not show any proteolytic effect on the blood proteins.[6,14,15]

To conclude, a 32 kDa novel fibrinolytic enzyme with specific activity of 1682 U/mg was purified from *Cordyceps militaris*. The optimal condition for this enzyme was at human physiological pH (7.4) and temperature (37 °C). As a plasmin-like protein, this enzyme could degrade fibrin directly and cleaved α-chains more efficiently than β- and γ-chains. It degraded thrombin, which indicates that it can act as an anticoagulant and prevent thrombosis. Intravascular thrombosis is one of the major reasons of cardiovascular diseases. Hence, the enzyme may be applied as a potential therapeutic agent for treating thrombosis.

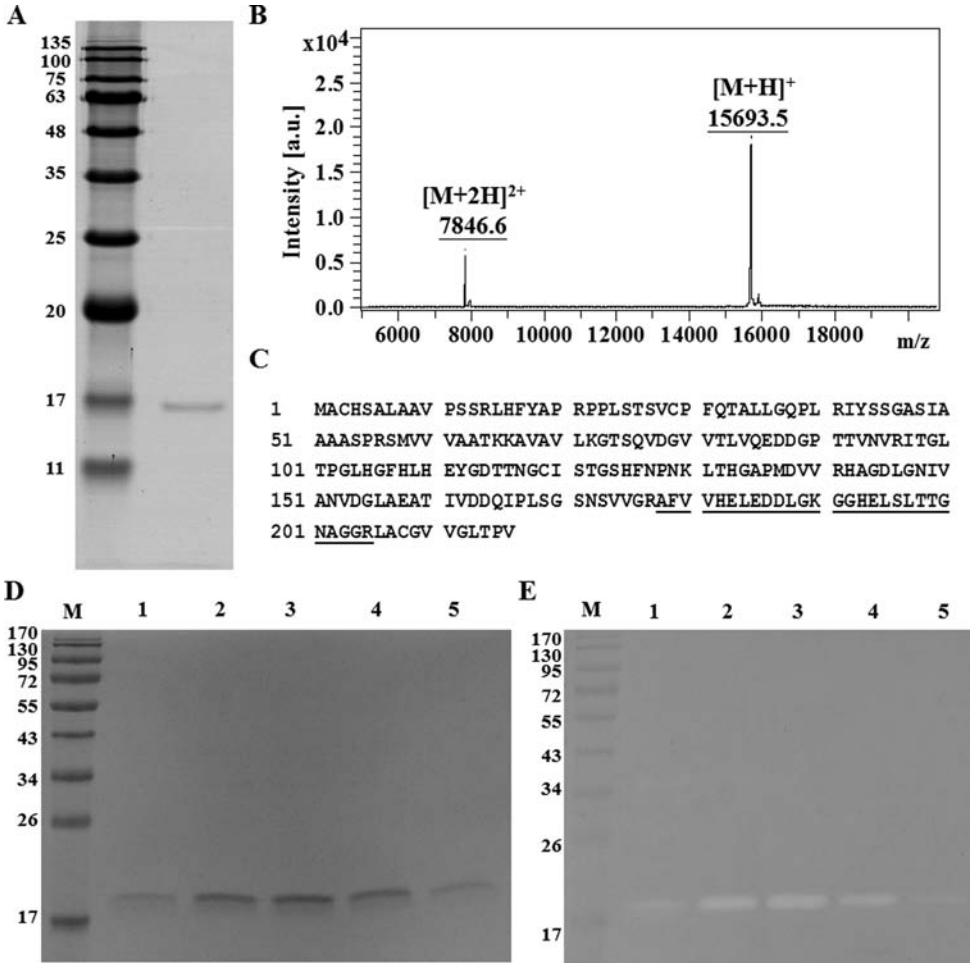

Figure 1. Purification and identification of SOD from *Piper betle* leaf (PBL). (A) Apparent homogeneity of the purified protein (right lane) detected by SDS-PAGE and Coomassie blue staining. Protein marker (left lane) with molecular mass (kD) is indicated. (B) MALDI-TOF analysis showing the purified protein with a molecular mass of 15.7 kDa. (C) The predicted sequence of Cu/Zn SOD from *Zantedeschia aethiopica*. The sequences of two adjacent tryptic peptides near the C-terminus are underlined. (D) and (E) Native gel examination of the five collected fractions from DEAE-cellulose chromatography by Coomassie staining (D) and zymography (E).

Purification of the PBL Protein of Interest. Unless otherwise indicated, the following protein purification protocol was performed at room temperature and initiated by homogenizing PBL in 3 volumes of buffer A (20 mM Tris/HCl, pH 7.0). The homogenate was filtrated with 4-layer cheesecloth and centrifuged at 13 000 rpm for 20 min at 4 °C, and the clear supernatant was filtrated again to remove insoluble residue on the surface of the supernatant. The proteins in the clear supernatant were fractionated with 80% ammonium sulfate and centrifuged to collect the precipitate. The precipitate was redissolved in buffer A and dialyzed against buffer A (50X volume) overnight. After repeating the dialysis step, the sample was loaded onto a DEAE-cellulose column pre-equilibrated with buffer A. The column was then washed with buffer A until the eluent was colorless, as judged with vision. The proteins in the column were eluted in the linear gradient with 1 M NaCl in buffer A, and the protein eluent was subjected to 15% SDS-PAGE (8 × 10 cm^2) at 110 V for 2 h. The fractions containing the protein of interest were pooled and diluted 5-fold with buffer A. The diluted sample was repeatedly subjected to the above-mentioned DEAE-cellulose chromatography to purify the protein of interest, except 0.2 M NaCl replaced the 1 M NaCl in the linear gradient. The molecular mass of the purified protein was determined in the linear mode using MALDI-TOF-TOF MS, as previously described.[13]

Protein Identification by nano-LC-Q-TOF-MS/MS. The protein band on the SDS-PAGE gel was excised, followed by in-gel digestion and peptide extraction according to the protocol previously described.[14] Analysis of the tryptic peptides was performed using an nano-LC-MS/MS system. The peptides were separated using an Ultimate 3000 LC RSLC nanoLC system (Dionex-Thermo Scientific, Chelmsford, MA, U.S.A.), and the mass spectrometry (MS) results were acquired with a quadrupole time-of-flight (Q-TOF) mass spectrometer (maXis impact, Bruker Daltonics Inc. Bremen, Germany). The sample was injected into a C_{18} trapping column (Acclaim PepMap100:100 μm × 2 cm, Dionex-Thermo Scientific, Chelmsford, MA, U.S.A.), connected with a C_{18} nano column (Acclaim PepMap RSLC, 75 μm × 15 cm, Dionex-Thermo Scientific, Chelmsford, MA, U.S.A.) to separate peptides. The mass spectrometer was operated by a captive spray source with a spray voltage of 1400 V, and the MS were acquired from 50 to 2000 m/z. The three most intense ions with charge states between 2 and 3 in each survey scan were selected for the MS/MS experiment. The MS/MS data were acquired from 50 to 2000 m/z. The peak list of MS spectra was processed by DataAnalysis v.4.1 software (Bruker Daltonics Inc. Bremen, Germany), and the extracted peak list was searched against the Swiss-Prot database (release 2011727) using MASCOT v.2.2.04 (Matrix Science, London, England).

SOD Zymography and Activity Assay. The following protocol for SOD zymography was conducted as described by Shukla et al.[15] with a slight modification. Gel electrophoresis is conducted exactly as the above-mentioned SDS-PAGE protocol, except the absence of SDS in the native gel. The native gel was then soaked twice in distilled water with gentle shaking for 30 min per time. The gel was

DOI: 10.1021/jf505753d
J. Agric. Food Chem. 2015, 63, 2225−2232

subsequently incubated in 0.28 mM nitro-blue tetrazolium (NBT) solution in the dark with gentle shaking for 20 min. The gel was then immersed in HEPES buffer (50 mM, pH 7.9) with 28 mM TEMED and 28 μM riboflavin and gentle shaken in the dark for 15 min. A white band on the gel gradually appeared after exposure to light.

Activity assay of SOD was conducted exactly as that suggested by the manufacturer. Reduction of WST-1 with superoxide anion, the product of xanthine oxidase-catalyzed reaction, was blocked in the presence of SOD. Absorbance at 450 nm was measured to determine the inhibition rate. In the experiment, 50- and 200-fold dilution for the crude extract and purified SOD, respectively, was used to perform activity assay. One unit/mL of activity was defined as 50% of inhibition rate calculated from the protocol in the kit.

Identifying the Mediator of SOD Dimerization by HPLC and LC-MS/MS. Areca nut or PBL alone was chewed in the oral cavity, and the oral extracts were then collected and centrifuged. The small-molecule components in the clear supernatant were filtrated using Microcon 3 concentrator, followed by HPLC analysis using a LiChroCART column (4 × 250 mm^2) (Merck & Co., Inc., Whitehouse Station, NJ). The mobile phases of ddH_2O and acetonitrile were used in a linear gradient at a flow rate of 1 mL/min, and 1.5 mL of eluent was manually collected in each tube. The LC-MS/MS analysis was conducted exactly as previously described.[13]

Measurement of Hydrogen Peroxide in the Oral Extract. (+)-Catechin (0.5 mM) and 3 μL oral extract, from different preparations were mixed in a 200 μL Tris/HCl (0.1M, pH 7.0) reaction solution. No additional peroxidase was required because peroxidase is present in both areca nuts and PBL. In the presence of hydrogen peroxide, peroxidase catalyzed catechin oxidation to form a product that exhibited absorbance at 475 nm and was measured spectrophotometrically.[13]

SDDC (a Cu/Zn SOD-specific inhibitor) was employed to evaluate whether SOD was responsible for production of hydrogen peroxide. It was conducted similarly except preincubation of catechin with 5-mM SDDC in Tris/HCl buffer for 5 min. After addition of the oral extract, absorbance at 475 nm was measured spectrophotometrically.

RESULTS

Identification of the Purified PBL Protein of Interest as Cu/Zn SOD. As depicted in Figure 1A, a functionally unknown protein in PBL was purified to apparent homogeneity using repetitive DEAE-cellulose chromatography. It appeared to be monomeric according to the results of SDS-PAGE (Figure 1A) with a 15.7-kDa molecular mass as determined by MALDI-TOF analysis (Figure 1B). The protein was identified as Cu/Zn SOD. Sequence identities were recognized in two adjacent tryptic peptides, both of which were mapped to the C-terminal region of Cu/Zn SOD from *Zantedeschia aethiopica*, as shown in Figure 1C. Zymography of the native gel clearly established the protein's SOD activity (Figure 1E). The pattern of Coomassie staining (Figure 1D) indicated that PBL SOD is monomeric at neutral pH. The process represented about 80-fold purification, obtained from comparison of specific activity between the crude extract (60 U/mg) and purified SOD (4700 U/mg).

SOD Dimerization in the Betel Nut Oral Extract. Zymography was used to examine the status of the SOD in the betel nut oral extract (BPS oral extract). Unexpectedly, the results showed nearly complete conversion of SOD monomer to the dimeric form in all 6 oral extracts (Figure 2A, arrowhead in lanes 1−6). Clearly, SOD was readily dimerized in the alkaline condition caused by slaked lime. Oral extract obtained after chewing PBL combined with areca nut in the absence of slaked lime (BP oral extract) induced SOD dimerization but to a much lesser extent than BPS oral extract (Figure 2A, lanes 7−9). The conversion was also observed using betel nut

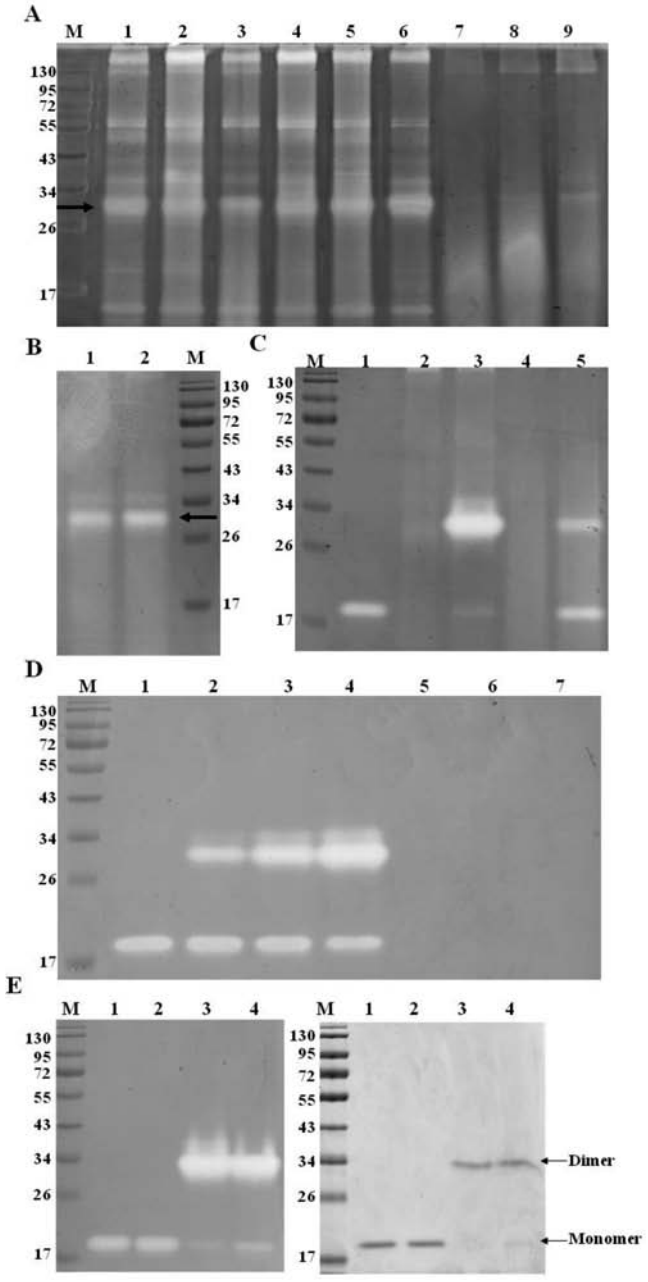

Figure 2. SOD dimerization induced by slaked lime. (A) Zymographic detection of SODs in the oral extract. The oral extract collected after chewing betel nut with slaked lime (BPS oral extract, lanes 1−6) or without slaked lime (BP oral extract, lanes 7−9). Equal volumes of BPS and BP oral extracts were analyzed, and the SOD dimer of interest is indicated by the arrowhead on the left. (B) The presence of SOD dimer in the betel nut homogenate. Betel nut was homogenized with Tris/HCl buffer (20 mM, pH 7.0) instead of oral chewing, and two doses of the homogenate (lanes 1 and 2) were used in a zymographic assay of SOD dimerization (arrowhead on the right). (C) The effect of BPS and BP oral extracts on SOD dimerization. Dimerization was assessed by mixing the purified SOD with a small amount of BPS (lane 3) or BP (lane 5) oral extract, as compared with an equal amount of enzyme alone (lane 1). Lanes 2 and 4 show BPS and BP oral extracts alone. (D) The effect of slaked lime on SOD dimerization. Slaked lime from a betel nut was dissolved in 10 mL ddH_2O and centrifuged, and the clear supernatant was used immediately. Increasing amounts of the supernatant were mixed with a given amount of SOD (lanes 2−4) to assess SOD dimerization, as compared with the enzyme control (lane 1). Lanes 5−7 show the

J. Agric. Food Chem. 2015, 63, 2225−2232

Figure 2. continued

supernatants alone corresponding to lanes 2−4, respectively. (E) The assessment of SOD dimerization was performed by separately mixing SOD with an equal volume of water (lane 1), 0.1 M Tris/HCl (pH 7, lane 2), 0.1 M Tris/HCl (pH 8.8, lane 3), or the slaked lime supernatant described above (lane 4). The left and right panels show zymography and Coomassie staining, respectively, with the monomer and dimer indicated.

homogenate (Figure 2B, arrowhead), which was derived from homogenizing the betel nut with neutral buffer rather than chewing betel nut in the oral cavity.

In the presence of a small amount of BPS oral extract with a lower SOD activity (lane 2 of Figure 2C), the purified SOD remarkably dimerized and possessed at least a 5-fold increase in activity (lane 3) as compared with an equal amount of the monomeric SOD with low activity at neutral pH (lane 1). The addition of a small amount BP oral extract exerted the same effect on SOD dimerization, although to a lesser extent (lane 5). The disappearance of the monomeric SOD in Figure 2A,B is believed to be due to SOD dimerization in the presence of slaked lime.

Next, the effect of slaked lime on SOD dimerization was studied. No dimerization was observed with SOD alone (Figure 2D, lane 1), but slaked lime induced SOD dimerization in a dose-dependent manner (Figure 2D, lanes 2−4). Usage of the supernatants, which contained even smaller amounts of slaked lime, resulted in no detectable SOD activity (lanes 5−7). BPS oral extract, which contains slaked lime, is alkaline (pH 8.9), and BP oral extract lacking slaked lime is acidic (pH 5.78). As shown in Figure 2E, the addition of alkaline solution to monomeric SOD induced SOD dimerization (lane 3 of both panels), mirroring the action of slaked lime (lane 4 of both panels), whereas the addition of neutral buffer had no effect (lane 2 of both panels).

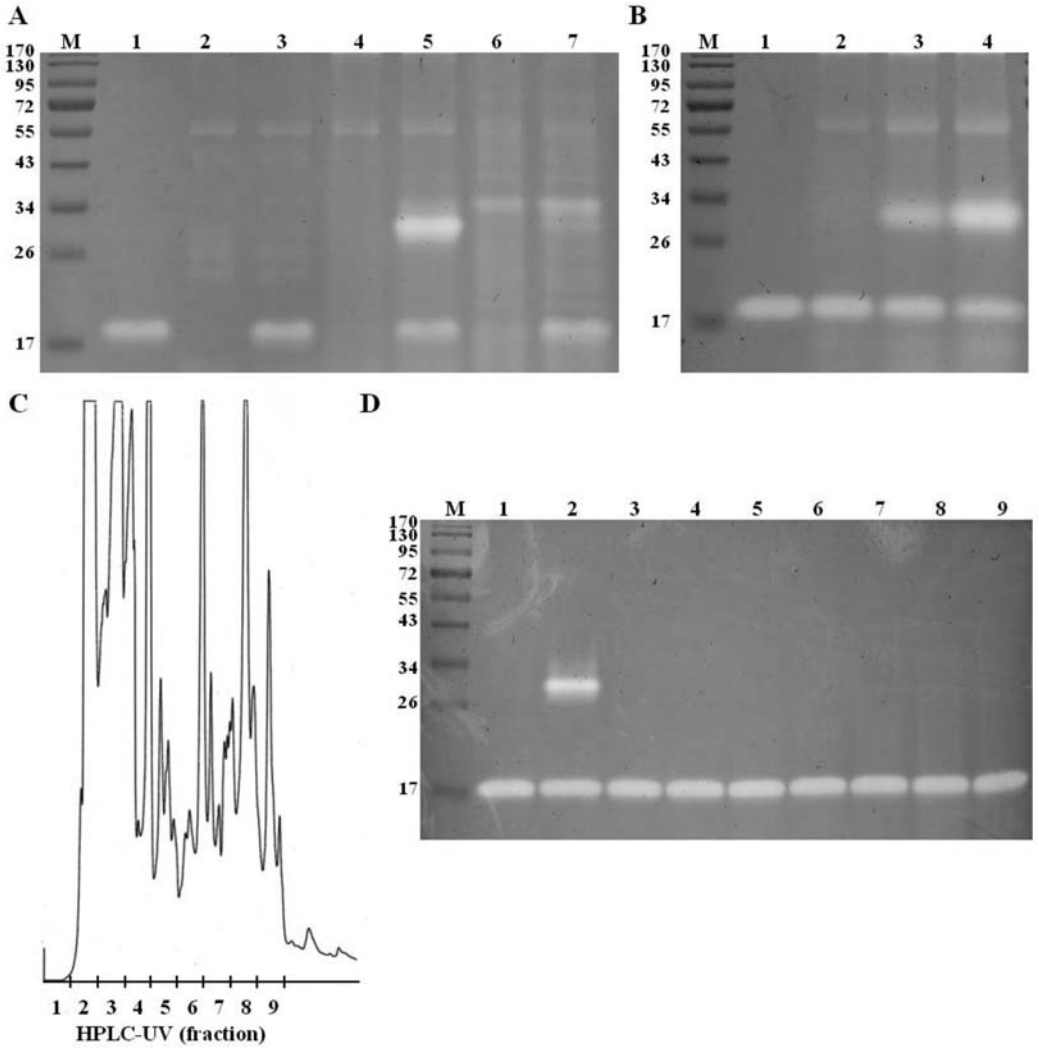

Figure 3. Mediator of SOD dimerization distinct from slaked lime. (A) The component in areca nut that mediates SOD dimerization. The assessment was performed by mixing SOD with saliva (lane 3), areca-nut (AN) oral extract (lane 5), or PBL oral extract (lane 7) and comparing with an equal amount of enzyme control (lane 1). Lanes 2, 4, and 6 show the controls for saliva and AN and PBL oral extracts, respectively. (B) The effect of AN oral extract on SOD dimerization. The effect of increasing amounts of AN oral extract (lanes 2−4) was compared with that of the enzyme control (lane 1). (C) HPLC chromatogram for small-molecule components in AN oral extract. The small-molecule components in AN oral extract were filtrated using Microcon 3, followed by HPLC analysis. The collected fraction for each time interval is shown at the bottom. (D) Each collected fraction, indicated at the top, was speed-vacuum-dried, and mixed with SOD to determine which fraction was able to mediate SOD dimerization.

J. Agric. Food Chem. 2015, 63, 2225−2232

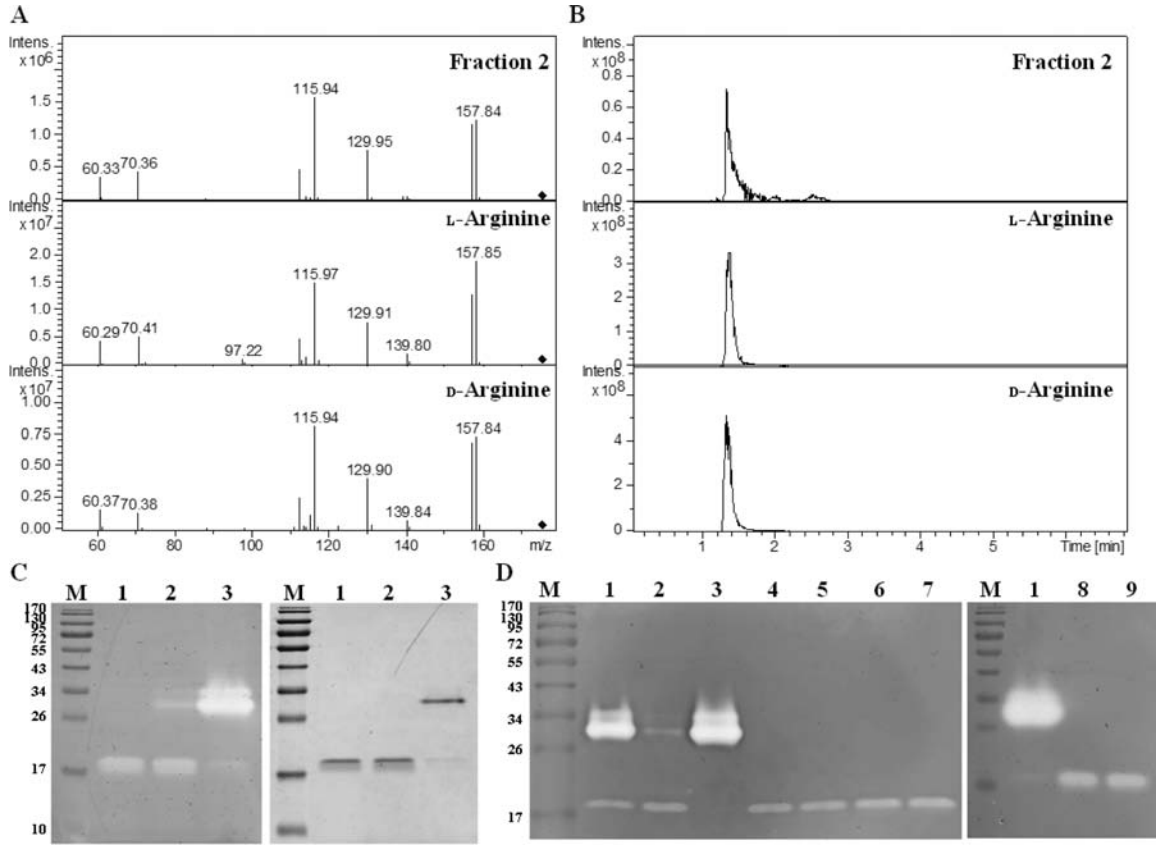

Figure 4. Identification of the mediator in areca nut as arginine. (A) and (B) MS/MS spectrum (A) and extracted ion chromatogram (EIC) (B) of the active component in fraction 2 (upper panel) compared with that of L- and D-arginine (middle and lower panels). (C) The effect of L-arginine on SOD dimerization. SOD dimerization was evaluated in the presence 10 and 20 mM L-arginine (lanes 2 and 3) by zymography (left panel) and Coomassie staining (right panel) and compared with that observed with an equal amount of enzyme control (lane 1). (D) The assessment was extended to D-arginine (lanes 2 and 3) and other basic amino acids, including lysine (lanes 4 and 5), histidine (lanes 6 and 7), and citrulline (lanes 8 and 9). A final concentration of 10 mM (lanes 2, 4, 6, and 8) and 20 mM (lanes 3, 5, 7, and 9) of each amino acid was used, as compared with 20 mM L-arginine (lane 1).

Contribution of Arginine in Areca Nut to SOD Dimerization. An additional component in areca nut distinct from slaked lime contributes to SOD dimerization. When oral extract obtained by chewing areca nut alone was added, dimerization was still observed, although to a less extent than that initiated by slaked lime (Figure 3A, lane 5 vs lane 4). No conversion was detected with the saliva control (lane 3 vs lane 2) or oral extract after chewing PBL alone (lane 7 vs lane 6). However, the oral extract after chewing areca nut alone in an acidic environment stimulated dimerization in a dose-dependent manner (Figure 3B), reminiscent of slaked lime. Furthermore, HPLC analysis revealed a complicated pattern with numerous components in the microcon-3 filtrate of the active oral extract (Figure 3C). The manually collected fractions were examined, and the ability to induce SOD dimerization was stringently restricted to fraction 2 (Figure 3D).

The MS/MS spectrum of the active component in fraction 2 with m/z 175 in the positive mode (Figure 4A, upper panel) was equivalent to that of L- and D-arginine (Figure 4A, middle and lower panels). As expected, the analysis of the extracted ion chromatogram (EIC) revealed the same retention time for the active component and both enatiomers of arginine (Figure 4B). As was observed for the enzyme control, 10 mM L-arginine exerted a faint effect that was insufficient to induce dimerization as examined by zymography and Coomassie staining (Figure 4C, lanes 1 and 2 in both panels). In contrast, a nearly complete conversion to the dimeric form occurred in the presence of 20 mM L-arginine (Figure 4C, lane 3 in both panels). Furthermore, D-arginine conferred a similar effect on SOD dimerization (Figure 4D, lanes 2 and 3 compared with Figure 4C, lanes 2 and 3). The absolute specificity of arginine in this process was also reflected in the fact that the other two basic amino acids histidine and lysine as well as arginine-analogous citrulline all lacked the ability to induce SOD dimerization (Figure 4D, lanes 4–9).

Production of Hydrogen Peroxide in the Betel Nut Oral Extract. The nearly complete dimerization of SOD in the presence of betel nut oral extract greatly increased its enzymatic activity, potentially resulting in the production of substantial amounts of hydrogen peroxide in the oral cavity. An absorbance increase in response to catechin was observed only with the BPS oral extract (left three bars of Figure 5A); very little change of absorbance occurred with the BP oral extract (middle three bars), clearly indicating the presence of hydrogen peroxide in the BPS oral extract. The increased absorbance was regenerated when hydrogen peroxide was produced in large quantities (right three bars), indicating little or no production of hydrogen peroxide in the BP oral extract.

To clarify the source of hydrogen peroxide, additional oral extracts were prepared by chewing PBL or areca nut in the presence of slaked lime and are referred to as PS and BS oral

DOI: 10.1021/jf505753d
J. Agric. Food Chem. 2015, 63, 2225−2232

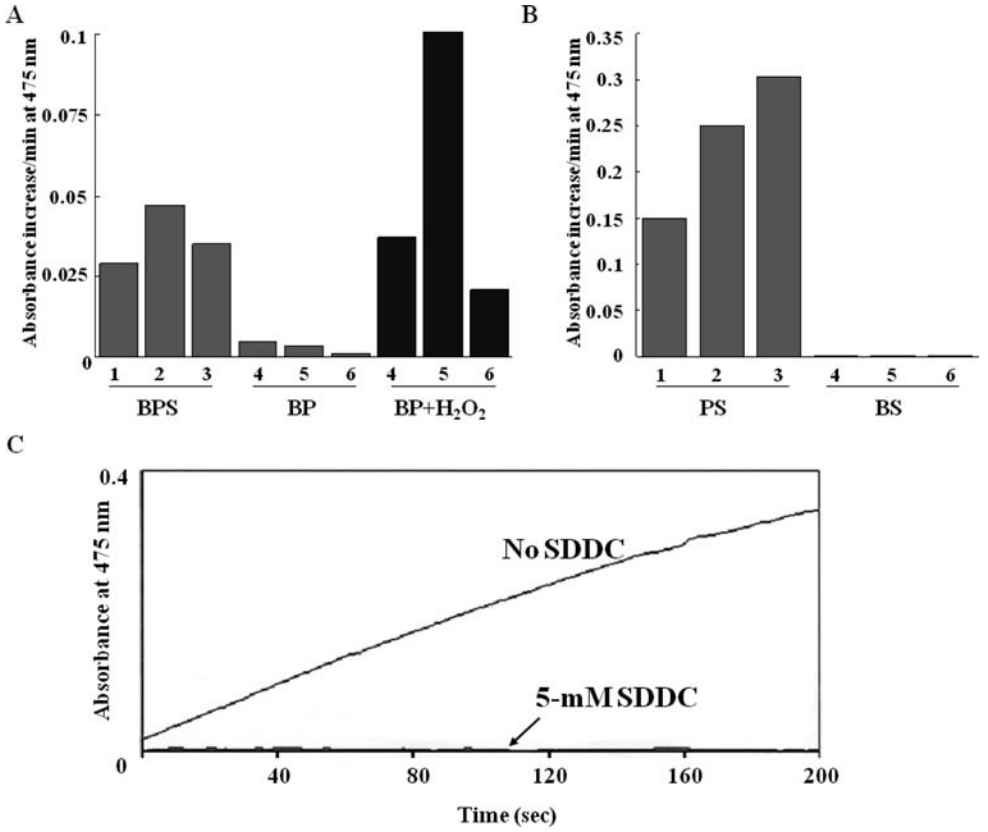

Figure 5. PBL as the source of hydrogen peroxide. (A) BPS and BP oral extracts (left and middle three bars) evaluated for their ability to oxidize catechin. Hydrogen peroxide was used as a control, demonstrating the extremely small amount of hydrogen peroxide in the BP oral extracts (right three bars). (B) PS and BS oral extracts (left and right three bars) were prepared to determine the source of hydrogen peroxide. (C) Continuity for hydrogen peroxide production in the PS oral extract. Formation of hydrogen peroxide immediately ceased in the presence of SDDC, an SOD inhibitor.

extracts, respectively. As depicted in Figure 5B, a significant change in absorbance was only detected when PS was present, i.e., the SOD in PBL was involved in the production of hydrogen peroxide. SOD may be the primary source for the generation of hydrogen peroxide, as supported by the fact that addition of SDDC immediately blocked the ability of PS oral extract to oxidize catechin (Figure 5C).

DISCUSSION

SOD dimerization and enhancement of enzymatic activity has been previously reported in other studies, using recombinant SOD of sweet potato.[16] Unlike other plant SODs, which exist in an equilibrium of monomers and dimers at neutral pH,[16,17] purified PBL SOD was entirely monomeric (Figure 1D,E) and existed in the same form within the cell. When chewing betel nut, the presence of slaked lime exerted two significant effects. First, in the presence of slaked lime, significantly more proteins were extracted compared with using oral extract from chewing betel nut alone (Figure 2A). The protein(s) were mainly derived from PBL rather than the areca nut, with trace amounts of proteins that included peroxidase as the major protein constituent.[13] Furthermore, the SOD of interest in the experiment was completely converted to the dimeric form in the presence of slaked lime, greatly enhancing its enzymatic activity in the oral cavity.

SOD dimerization was further augmented by arginine in the areca nut, i.e., arginine was a distinct mediator of SOD dimerization. The involvement of arginine in SOD dimerization was also reported by Klatt et al.[18] Furthermore, SOD dimerization in the BP oral extract (Figure 2C, lane 5) was most likely due to the presence of arginine in the areca nut. Previous experiments in animals and cell cultures have demonstrated that arginine plays a role in preventing toxicity such as that induced by free radicals[19,20] and may act through the synthesis of nitric oxide. These studies also revealed that arginine treatment alters the activities of antioxidant enzymes. Among them, the increased SOD activity[20] might be attributed to the formation of SOD dimers. Based on our results, the increased SOD activity may be independent of nitric oxide formation (Figure 4C). Despite the protective roles of arginine and SOD, the simultaneous presence of both components in the oral cavity resulted in harmful effects, such as the production of hydrogen peroxide as described below. The self-association of arginine molecules in aqueous solution demonstrated its striking ability to stabilize proteins and prevent protein aggregation.[21] Arginine monomers have been reported to hydrogen-bond to each other, forming a large cluster.[22] The charged amino acids on the surface of SOD may interact with arginine in a cluster and concomitantly link two molecules of SOD together.

Plant SODs play a defensive role by detoxifying superoxide radical to oxygen and hydrogen peroxide,[23] and numerous studies have demonstrated the protective role of plant Cu/Zn SODs against oxidative stress.[24,25] There is increasing evidence establishing hydrogen peroxide as a tumor promoter in carcinogenesis development.[26,27] In this study, PBL together

DOI: 10.1021/jf505753d
J. Agric. Food Chem. 2015, 63, 2225−2232

with the aid of slaked lime facilitated hydrogen peroxide production in the oral cavity (Figure 5A) in response to SOD. The antioxidants catechin and epicatechin in areca nut were in turn oxidized by hydrogen peroxide in the reaction catalyzed by peroxidases of both PBL and areca nut.[13] In this case, both antioxidants were completely consumed and undetectable in the BPS oral extract, as shown in the Supporting Information (Figure S1). In contrast, both antioxidants were still present in the BP oral extract due to the low concentration of hydrogen peroxide.

The hypothesis that hydrogen peroxide attacks and damages oral tissue is clearly supported by other reports, demonstrating hydrogen peroxide as a mediator of inflammation.[28,29] It was noteworthy that the formation of hydrogen peroxide in the oral cavity was immediately blocked by adding the inhibitor SDDC (Figure 5C), i.e., SOD activity was blocked and thus the production of H_2O_2 was prevented. This clearly indicates that hydrogen peroxide is continuously produced when betel nut is chewed uninterrupted, as is the case with most consumers. Nair et al. reported the effect of slaked lime on the production of reactive oxygen species (ROS) and its involvement in the development of oral cancer.[30,31] Taken together with our results, we conclude that slaked lime mediates the production of ROS, which is subsequently converted to hydrogen peroxide via SOD action. Therefore, we conclude that PBL SOD plays a role in oral carcinogenesis through the continuous formation of hydrogen peroxide in the oral cavity.

vitro, suggesting a method for the semisynthesis of brain-targeted flavan-3-ol metabolites.[7] Of the 12 enzymes tested, UGT1A9 was the most efficient, and this enabled us to generate 3′-*O*-methyl-EC-5-*O*-glucuronide to 50% overall yield.[7]

In the present study, we have extended the above approach, in combination with chemical methylation of C and EC with iodomethane, to generate authentic standards of the C and EC metabolites found in the plasma and brains of rats treated with GSPE. The structures of the metabolites were rigorously identified, and we present a robust, validated protocol for the measurement of the levels of these compounds in animal fluids.

MATERIALS AND METHODS

Materials. Uridine 5′-diphospho (UDP)-glucuronosyl transferase enzymes (recombinant or as mouse microsomes), buffers, and UDP-glucuronic acid were purchased from BD Biosciences (San Diego, CA). (−)-Epicatechin, (+)-catechin, DBU (1,8-diazabicyclo[5.4.0]-undec-7-ene), and iodomethane were from Sigma-Aldrich, St Louis, MO. 3′- and 4′-*O*-Methyl epicatechin were purchased from Nacalai USA, Inc. (San Diego, CA).

Chemical Methylation of C/EC. (Epi)catechin (1 g) was dissolved in 240 mL of dimethylformamide in a 1 L bottle, and the bottle was saturated with nitrogen gas for 5 min. DBU (14 mL) and iodomethane (300 mL) were then added and mixed well, and the solution was resaturated with nitrogen gas for 30 s. The bottle was capped and placed at 40 °C in the dark for 3 h. The reaction was then quenched by the addition of 400 mL of methanol with mixing. The solution was dried under nitrogen and resuspended in high-performance liquid chromatography (HPLC)-grade methanol for HPLC analysis and purification.

Large-Scale Purification of Methylated C/EC. Methylated (epi)catechins were purified on a large scale using a Biotage Isolera flash chromatography system equipped with a 10 g SNAP C18 cartridge at a flow rate of 18 mL/min, monitoring at 280 nm with a UV/vis detector. The sample in methanol was added to the column via a preloading concentrator disc. Solvent A was milli-Q water, and solvent B was HPLC-grade acetonitrile. The column was equilibrated at 5% B, and the gradient for elution was as follows: isocratic at 5% B for 12 column volumes (CVs) or 180 mL; from 5% B to 13% B in 48 CVs or 720 mL; from 13% B to 100% B in 4 CVs or 60 mL; then washed in 100% B for 20 CVs or 300 mL. Fractions were collected in 16 CV or 240 mL fractions.

Glucuronidation of EC and Methyl-C/EC and Purification of the Products. The glucuronidation reaction was performed at room temperature, and the mixture consisted of 210 μL of purified water, 40 μL of UGT Reaction Mix Solution A (containing UDP-glucuronic acid, BD Biosciences), 100 μL of UGT Reaction Mix Solution B (containing $MgCl_2$, Tris-HCl buffer, and alamethicin, BD Biosciences), 10 μL of 20 mM (epi)catechin derivative, and 120 μL of human UGT1A9 (for EC and methyl-EC) or pooled male mouse liver microsomes (5 mg protein per mL) (for C and methyl-C). After 6 h, an additional 40 μL of UGT Reaction Mix Solution A, 40 μL of Reaction Mix Solution B, 120 μL of UGT1A9 or mouse microsomes, and 10 μL of 20 mM (epi)catechin derivative were added. Then, at 12 h, a further 40 μL of UGT Reaction Mix Solution A and 120 μL of UGT1A9 or mouse microsomes were added. The reactions were stopped after 24 h by the addition of 400 μL of methanol containing 3% of 85% phosphoric acid. The solvent was removed under nitrogen gas, and the aqueous fractions were desalted using a Waters Sep-Pak Plus C18 cartridge. The cartridge was first washed with 10 mL of methanol, followed by 20 mL of water. The sample (5 mL) was loaded onto the cartridge, then washed twice with 5 mL of water, and finally eluted twice with 5 mL of methanol. The sample was dried under nitrogen and then resuspended in a small volume of methanol for HPLC purification. Product peaks were partially purified on the analytical HPLC, and the solvent was removed under nitrogen gas. The aqueous fractions were then acidified to 1% phosphoric acid final concentration and desalted using a Waters Sep-Pak Plus C18 cartridge. The methanol was dried under nitrogen, and the fractions were analyzed for comparison to products found in the plasma of mice/rats fed the monomer-enriched GSPE fraction. All samples were dissolved in 100 μL of acidified water and acetonitrile (4:1, v/v) and further analyzed by HPLC coupled to LC-TOF-MS (see below).

HPLC for Analysis and Purification of C/EC Metabolites. HPLC analysis and purification of (epi)catechin derivatives were performed on an Agilent HP1200 HPLC, monitoring at 280 nm. The HPLC with ChemStation software version B.02.01.SRI was equipped with a G1322A degasser, a G1311A quaternary pump, a G1367B autosampler, a G1316A thermostatic column compartment, and a G1315C diode array detector. A Varian Metasil 5 Basic C18 250 × 4.6 mm column was used for analytical and micropreparative HPLC on the Agilent HPLC system. Analytical and preparative HPLC were performed using the following gradient: isocratic at 5% B for 5 min; 5% B to 10% B in 5 min; 10% B to 17% B in 15 min; 17% B to 23% B in 5 min; then 23% B to 50% B in 35 min. Alternatively, a shorter method was used that retained the same gradient except that the last step gradient was from 23% B to 28% B in 5 min, reducing the run time by 30 min. Solvent A was 1% phosphoric acid in Milli-Q water, and solvent B was HPLC-grade acetonitrile. The flow rate was 1 mL/min.

Solid-Phase Extraction (SPE) of C and EC Metabolites from Rodent Plasma. Rodent plasma samples were obtained from a previous pharmacokinetic study using GSPE[4] that received approval from the Animal Care and Use Committee at Purdue University. Plasma aliquots from control animals (no GSPE) and treated animals (with GSPE) that were collected at sacrifice were thawed from −80 °C storage and quickly pooled separately at Purdue University. These control and GSPE plasma samples were then realiquoted into individual vials and refrozen at −80 °C until analysis. For target assessment purposes, typical plasma was diluted 5-fold with blank plasma to produce low-dose plasma. Blank, low, and normal plasma samples were then used for analytical validation at Purdue University, and a parallel set of samples was sent to the University of North Texas for cross-lab validation.

Samples of frozen plasma were thawed at room temperature, and 300 μL of acidified saline (9g of NaCl in 1 L of 0.1% v/v formic acid/H_2O) were added to 200 μL of plasma with vortex mixing. A SPE cartridge (30 mg Oasis HLB column, Waters Co, Milford, MA) was activated by addition of 1 mL of MeOH followed by 1 mL of DI H_2O, after which the plasma/saline mixture was loaded. The loaded SPE column was first washed with 1 mL of 1.5 M formic acid, followed by 1 mL of 95:5 v/v water/MeOH, and the eluate was discarded. Metabolites were then eluted with 2 mL of 0.1% v/v formic acid/MeOH.

Extraction recovery was assessed in a pilot experiment by spiking 10 μL of ethyl gallate stock solution (10 μM) into freshly thawed plasma samples prior to extraction and analysis. Extraction recovery was found to be 96.0 ± 3.1%. Following validation of recovery, ethyl gallate was used as a daily internal standard (10 μL of stock 10 μM solution) added to the eluates from solid-phase extraction prior to samples being dried under vacuum (<50 mmHg) at 37 °C. The residues were resuspended in 160 μL of 0.1% v/v formic acid/H_2O + 40 μL of 0.1% v/v formic acid/acetonitrile, sonicated for 10 s, vortex-mixed for 10 s, and then transferred to centrifuge tubes, which were centrifuged at 18 000*g* for 5 min to remove any particulates. The clear supernatants were carefully transferred to 300 μL HPLC vials for analysis.

The ability of this extraction method to account for potential matrix effects was assessed by comparing the response of individual metabolite standards in the presence or absence of blank plasma extracted matrix. Briefly, standards of C and its major metabolites in GSPE rodent plasma at 50, 100, and 500 nM were resuspended either in pure solvent (160 μL of 0.1% v/v formic acid/H_2O + 40 μL of 0.1% v/v formic acid/acetonitrile—Standard) or in resolubilized blank plasma extracted by SPE (Standard + Matrix). By comparison of response between standards injected with or without plasma matrix, an estimate of matrix effects was established by using the following equation: % matrix effect (% ME) = (peak area of standard with

matrix−peak area of pure standard)/(peak area of pure standard) × 100.[8]

NMR Analysis. NMR spectroscopy was performed using a Bruker Avance DRX 500 MHz spectrometer equipped with a cryoprobe. The metabolites were dissolved in CD_3OD (99.96% atom D; Sigma, St. Louis, MO) and then transferred to a 5 mm Shigemi tube (Wilmad Glass, Vineland, NJ).

HPLC/MS Analysis of C/EC Metabolites from Rodent Plasma. *(1). LC-TOF-MS for Unknown Metabolite Characterization.* Separation was achieved on an Agilent 1100 HPLC system using a Waters XBridge BEH shield RP-C18 XP (2.1 × 100 mm 2.5 μm) column following a 2 μm frit filter. The column and autosampler were maintained at 40 and 10 °C, respectively. Mobile phase A was 0.1% v/v formic acid/water and B was 0.1% v/v formic acid/acetonitrile. A linear gradient for elution was used at a constant flow rate of 0.26 mL/min. Initial conditions, 5% B; 0−12 min, 5−15% B; 12−18 min, hold at 15% B; 18−24 min, 15−40% B; 24−30 min, 40−50% B; 30−31 min, 50−5% B; 31−36 min, hold at 5% B to reset gradient. Injection volume was set to 10 μL. Mass spectra of flavan-3-ol metabolites were obtained using an Agilent 6200 time-of-flight (TOF) mass spectrometer, with negative mode electrospray ionization, using a mass range of 100−1000 *m/z* and an acquisition rate of 1.4 spectra/s. Source parameters were as follows: gas temperature = 350 °C, drying gas = 9 L/min, nebulizer pressure = 35 psi, capillary potential = 3500 V, fragmentor voltage = 145 V, skimmer voltage = 60 V, and OCT 1 RF Vpp = 250 V.

(2). LC-MS/MS for Metabolite Quantification. Separation was achieved on an Agilent 1200 HPLC system as described in the previous section, except for the gradient conditions as follows: initial conditions, 10% B; 0−9 min, 10−35% B; 9−10 min, 35−65% B; 10−12 min, 65−10% B; 12−16 min, hold at 10% B to reset gradient. Analytes were quantified using tandem mass spectrometry (MS/MS) with an Agilent 6460 triple quadrupole with electrospray ionization (ESI) in negative mode using selected reaction monitoring (SRM) mass transitions. Collision energy was 17 eV. Acquisition multiple reaction monitorings (MRMs) were as follows: C/E, 289 → 245 *m/z*; C/E glucuronide, 465 → 289 *m/z*; methyl C/E glucuronide, 479 → 303 *m/z*; ethyl gallate, 197 → 169 *m/z*. All mass transitions used a dwell time of 200 ms and a fragmentor voltage of 135 V. Source parameters were as follows: gas temperature = 350 °C, gas flow = 11 L/min, nebulizer pressure = 30 psi, sheath gas temperature = 350 °C, sheath gas flow = 11 L/min, capillary potential = 3500 V, and nozzle voltage = 1000 V. Intraday repeatability was assessed by extracting and analyzing pooled plasma *n* = 5 times. Interday reproducibility was determined across *n* = 5 days using aliquot pooled plasma. Repeatability and reproducibility were determined as relative coefficient of variation (% CV) as calculated by standard deviation/mean × 100. Limit of detection (LOD) was defined as signal-to-noise ratio (S/N) = 3, and limit of quantification (LOQ) was defined as S/N = 5. Both values were obtained by producing serial dilutions of parent nonmetabolized compounds and metabolites. Data are presented as mean ± standard deviation. S/N was calculated using MassHunter software using the peak-to-peak method.

(3). Second Site Validation. Samples were analyzed using a Waters Xevo-TQ mass spectrometer interfaced with a Waters Acquity ultra-performance liquid chromatography (UPLC) system. Sample preparation and LC parameters were according to the original protocol above. Mass spectrometry source parameters were as follows: ESI, negative mode; capillary voltage, 2 kV; source temperature, 150 °C; sheath gas flow, 800 L/h; desolvation temperature, 400 °C; cone voltage, 28 V. Acqusition MRMs were as follows: C/EC glucuronide, 456 → 289 *m/z*, collision energy 22; C/EC methyl glucuronide, 479 → 303 *m/z*, collision energy 22; ethyl gallate, 197 → 169 *m/z*, collision energy 16. Dwell time was 200 ms.

RESULTS AND DISCUSSION

Metabolites of Flavan-3-ols in Rat Plasma and Strategy for Generation of Standards. Multiple metabolites derived from the flavan-3-ols C (2,3-*trans*) and EC (2,3-*cis*) are found in mouse or rat plasma following the feeding of monomer-enriched GSPE. LC-MS analysis has indicated that these compounds are primarily glucuronides of C/EC or methyl-C/EC[4] (Figure 1A, B). One of the most abundant metabolites in plasma was previously identified by micro-NMR as 3′-*O*-methyl-EC-5-*O*-*β*-D-glucuronide (Figure 1C),[7] and we have developed a semisynthetic route to this compound.[7] Because of the low levels of the metabolites, as well as the need to develop a robust method for their quantitation, we decided to develop semisynthetic routes to the remaining compounds.

Our strategy for generation of standards of the other C/EC metabolites found in rat plasma was to (1) synthesize methyl derivatives of C and EC; (2) subject the (methylated) C and EC to enzymatic glucuronidation; (3) compare LC-MS mobility and fragmentation pattern of the synthetic compound to those of the metabolites in plasma; and (4) scale up the synthesis of compounds that match those in plasma and confirm their structures by NMR.

Methylation of C and EC. Although 3′-and 4′-*O*-methyl-EC are commercially available, they are expensive (synthetic 4′-

J. Agric. Food Chem. 2015, 63, 2233−2240

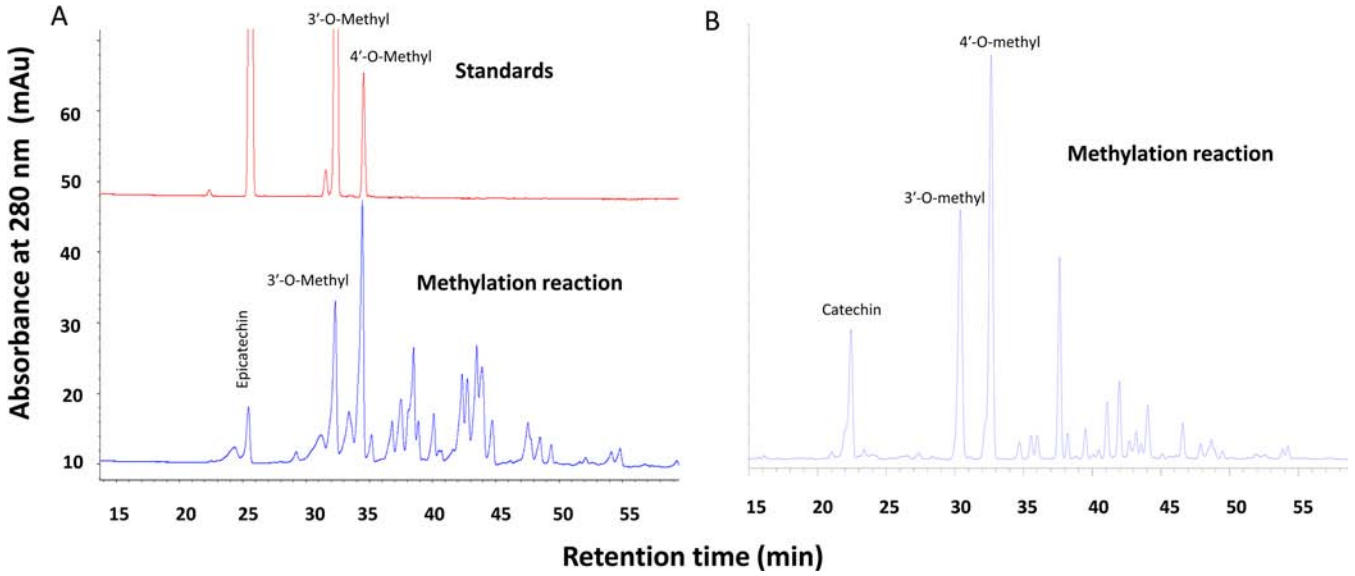

Figure 2. *O*-Methylation of epicatechin (A) and catechin (B) by reaction with iodomethane. HPLC traces show the multiple products formed, with the 3′- and 4′-*O*-methyl derivatives identified by comparison to authentic standards.

O-methyl-EC currently costs over 1 000 Euros per mg; tebubio, Le Perray-en-Yvelines, France). We have previously explored the methylation of EC using catechol-*O*-methyltransferase from porcine liver;[7] this leads predominantly to the 3′-*O*-methyl derivatives. Although this method was effective (and is a useful approach if it is desired to incorporate radiolabel in the methyl group through incubation with labeled methyl donor S-adenosyl-L-methionine), it is also relatively expensive, and we therefore investigated the cheaper alternative of chemical methylation of the core flavan-3-ols with iodomethane, using previously established procedures.[9] This approach leads to generation of multiple methylated products from both C and EC (Figure 2), with the more complex multimethylated products constituting a larger proportion of the reaction products with longer incubation times. However, because the different products and isomers can easily be separated by preparative HPLC, and because of the low cost of the starting materials, this method proved effective for generation of 3′- and 4′-*O*-monomethyl derivatives of both C and EC, suitable for subsequent glucuronidation. The methylated EC derivatives were authenticated by comparison to the commercial standards. Standards are not available for the methyl-C derivatives; identity was first inferred based on the retention times of the corresponding EC derivatives and subsequently confirmed (for the 3′-*O*-methyl derivative) by NMR of the resulting glucuronidated products (see below). Optimization of reaction conditions, particularly reaction time, resulted in maximum yields of 3′-*O*-methyl-C/EC of ∼20%. The methylated compounds were purified by chromatography using a Biotage Isolera system.

Glucuronidation of (Methyl)-C/EC and Matching of Synthetic Compounds to Metabolites in Plasma. Human recombinant glucuronosyltransferase UGT1A9, in the presence of UDP-glucuronic acid, converts EC to a number of products, the major one being the 3′-*O*-glucuronide (a compound not found in the plasma of rats or mice fed GSPE), with minor amounts of the 5-*O*-glucuronide (a minor metabolite in the plasma).[7] 3′-*O*-Methyl-EC is efficiently converted by UGT1A9 to 3′-*O*-methyl-EC-5-*O*-glucuronide (a major plasma metabolite). The other compounds in plasma appear to be derivatives of C. We therefore investigated conditions (reaction times, enzyme and substrate concentrations, and supplementation of reaction mixtures with additional enzyme/substrate) for the optimal glucuronidation of methylated and nonmethylated C by mammalian glucuronosyltransferases and UDP-glucuronic acid, as previously described for EC.[7] In contrast to EC, we found that pooled male mouse microsomes were more efficient at glucuronidation of C and its derivatives than was recombinant UGT1A9, resulting in two major products initially named CG14 and CG18 based on their approximate retention times by HPLC (Figure 1A in Supporting Information). CG14 and CG18 were further purified by preparative HPLC (Figure 1B in Supporting Information). Both compounds possessed a molecular ion of 465 and matched peaks in the plasma of rats fed GSPE: CG14 was a minor component (Figure 1C in Supporting Information), whereas CG18 corresponded to the second most abundant metabolite (Figure 1D in Supporting Information).

In a similar manner, glucuronidation of (presumed) 3′-*O*-methyl-C by mouse microsomes in the presence of UDP-glucuronic acid led to the formation of multiple products of which two, with retention times of 19 and 24 min and molecular ions of 479 (MCG19 and MCG24), matched metabolites in the rat plasma. Glucuronidation products of (presumed) 4′-*O*-methyl-C did not match any of the compounds found in plasma. Figure 3 summarizes the matches between the synthetic (methyl)-C's and plasma-derived metabolites and indicates the diagnostic major fragmentation products of the molecular ions.

Structural Characterization of C and EC Metabolites. We have previously reported the structural characterization of 3′-*O*-methyl-EC-5-*O*-glucuronide.[7] To elucidate the structures of CG14, CG18, MCG19, and MCG24, 2D NMR experiments using HSQC (heteronuclear single quantum coherence spectroscopy), HMBC (heteronuclear multiple bond correlation spectroscopy), and NOESY (nuclear Overhauser effect spectroscopy) were performed. The spectral data (chemical shifts) for the four compounds are shown in Table 1, and ^{1}H, HSQC, HMBC, and NOESY data are shown in Figures 2–8 in Supporting Information. The glucuronic acid moiety was

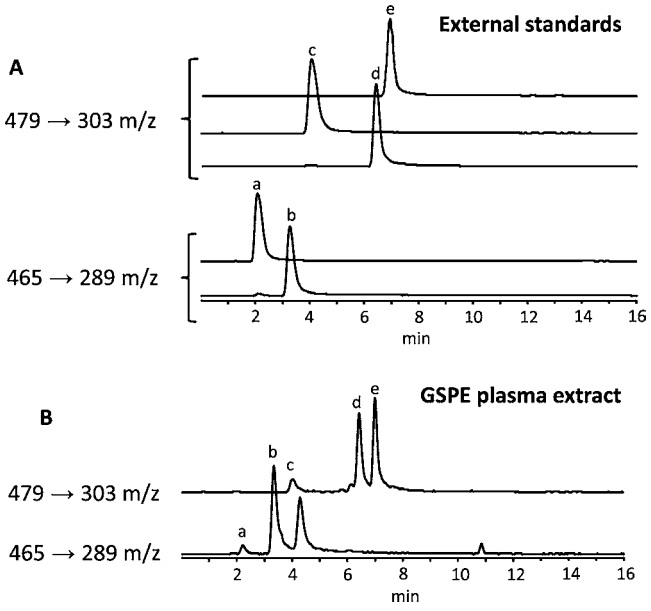

Figure 3. Chromatographic separation and identification of C/EC metabolites for each mass transition. Peak identification: (a) CG14, C-glucuronide; (b) CG18, C-glucuronide; (c) MCG24, 3′-*O*-methyl-C-glucuronide; (d) MCG19, 3′-*O*-methyl-C-glucuronide; (e) 3′-*O*-methyl-EC-5-*O*-glucuronide.

assigned to the 7 position on (+)-C for CG-14 and MCG-19 based on the presence of a HMBC cross-peak between the anomeric proton (H-1″) and C-7 (Figure 7 in Supporting Information). The assignment on CG-18 and MCG-24 was to the 5 position due to a HMBC cross-peak between H-1″ and C-5 (Figure 4 in Supporting Information). The methyl group was assigned to the 3′ position on MCG-19 and MCG-24 due to a NOESY cross-peak between H-2′ and the methoxy group, confirming the identity of the precursor as 3′-*O*-methyl-C (Figure 8 in Supporting Information). Figure 4 summarizes the structures of the four C metabolites, and its caption provides further description of how the positions of methylation and glucuronidation were assigned.

Several previous studies have reported the presence of PAC metabolites in blood plasma after feeding animals with PA preparations or foods rich in PACs.[10−13] The metabolites were partially identified as sulfonated, glucuronidated, and/or methylated derivatives of EC and C,[11,14−16] with most studies focusing on the EC derivatives. Definitive structures, particularly with respect to the position of glucuronidation, were not systematically assigned for many of the biologically relevant metabolites. The present systematic approach to the synthesis and identification of predominant plasma-derived metabolites of flavan-3-ols present in plasma of rodents dosed with GSPE provides a blueprint for the development of improved methods for the evaluation of bioavailability of plant polyphenols, as well as a source of standard target molecules for evaluating modes of action.

Cross-Validated Analytical Method for Determining Plasma Levels of C and EC Metabolites. LC-MS using an Agilent 6460 Triple Quadrupole system was selected as the analytical method to determine the levels of C and EC metabolites in samples of plasma from rats fed GSPE, due in part to the sensitive and selective nature of this method as well as the broad application of this method in the literature.[17−19] Initially, the linear dynamic range for each molecule (C, EC, two C-glucuronides, two methyl-C-glucuronides, and one methyl-EC-glucuronide) was determined for concentrations ranging over 4 orders of magnitude (pM−μM), with the lowest concentrations in the 250−650 pM range. The linear dynamic range was observed to be excellent (Table 2) and provides the ability to quantify these compounds across a range of concentrations typical in biological fluids and tissues. Metabolites were extracted from plasma by solid-phase extraction as described in Materials and Methods. Measurement of effects of matrix and plasma concentration (Table 1 in Supporting Information) and intraday and interday variability (Tables 2 and 3 in Supporting Information) revealed the method to be highly robust and efficient at limiting ion suppression or other matrix effects commonly reported, but rarely accounted for, in analysis of biological samples.[20−22] As expected, there was a greater matrix effect (ME) at lower concentrations. The % ME when measuring C ranged from −7.84% at 500 nM to −20.7% at 50 nM. The ME for MCG24 ranged from −13.5% at 500 nM to −23.0% at 50 nM. Finally, the ME for CG18 ranged from −13.1% at 500 nM to −15.7% at 50 nM. Because metabolites appear in rodent plasma at

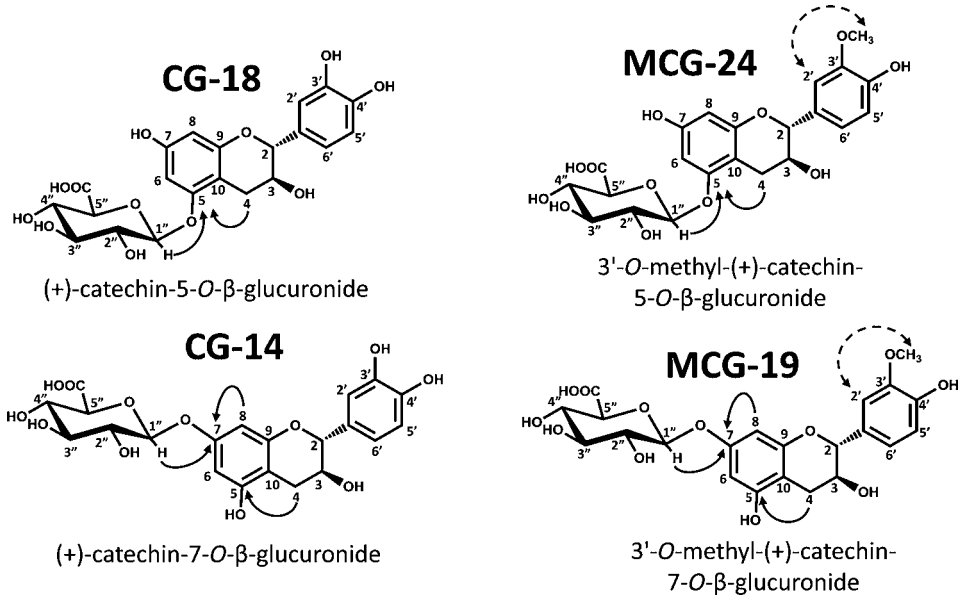

Figure 4. Structures assigned to CG14, CG18, MCG19, and MCG24. The glucuronic acid moiety was able to be assigned to the 7 position on (+)-catechin for CG-14 and MCG-19 based on the presence of a HMBC cross-peak between the anomeric proton (H-1″) and C-7. The chemical shift of C-7 was determined by a HMBC cross-peak between H-8 and C-7. Further support of this connectivity was provided by the absence of a cross-peak between H-1″ and C-5 (chemical shift determined by a cross-peak between H-4 and C-5). The assignment on CG-18 and MCG-24 was to the 5 position due to a HMBC cross-peak between H-1″ and C-5. The methyl group was assigned to the 3′ position on MCG-19 and MCG-24 due to a NOESY cross-peak between H-2′ and the methoxy group. HMBC is designated by a solid arrow, and NOESY is designated by a dashed arrow.

Table 2. Linear Dynamic Ranges for the Quantitation of (Methyl)catechin and (Methyl)epicatechin Glucuronides by LC-MS/MS

compound	range	regression line	linearity (R^2)	LOQ (S/N = 5) MOC	LOD (S/N = 3) MOC
C	5 nM−50 μM	$y = 7 \times 10^{09}x + 528.31$	0.9997	138.9 pmol	55.5 pmol
EC	5 nM−50 μM	$y = 7 \times 10^{09}x + 689.79$	0.9997	106.4 pmol	48.4 pmol
3′OMe-EC-5-*O*-glucr	250pM−2.5 μM	$y = 5 \times 10^{11}x - 3699.8$	0.9998	2.05 fmol	1.07 fmol
CG18	500pM−10 μM	$y = 4 \times 10^{11}x + 403.99$	0.9999	10.6 fmol	3.41 fmol
CG14	500pM−10 μM	$y = 6 \times 10^{11}x - 16601$	0.9998	3.68 fmol	1.2 fmol
MCG19	650pM−10 μM	$y = 2 \times 10^{11}x + 12580$	0.9990	5.80 fmol	2.80 fmol
MCG24	500pM−20 μM	$y = 4 \times 10^{11}x - 31920$	0.9994	4.70 fmol	1.03 fmol

∼300−400 nM after repeated dosing of GSPE, using the SPE procedure results in underestimating metabolites by ∼13%.

The Horwitz ratio (HorRat), a well-recognized normalized performance parameter that provides a measure of laboratory precision, was calculated for individual metabolites based on the equations described by Horwitz and Albert.[23] HorRat values ranging from 0.13 to 1.29 indicated the high reproducibility of this method. While lower values of the HorRat (0.13−0.21) do fall outside of the generally accepted range, it is important to note that these were for minor metabolites (C-7-*O*-glucuronide, 3′-*O*-Me-C-7-*O*-glucuronide, and 3′-*O*-Me-EC-7-*O*-glucuronide). Comparatively, values for major metabolites identified in this method, (C-5-*O*-glucuronide and 3′-*O*-Me-C-5-*O*-glucuronide) were 1.29 and 0.51, respectively. Overall these data are consistent with that of a highly reproducible analytical method.

Calculated LOD (defined as 3:1 signal/noise) ranged from 1.03 to 3.41 fmol on column for metabolites of C and EC compared to 55.5 and 48.4 pmol on column for the parent compounds C and EC, respectively. This suggests the potential for more efficient ionization of metabolites relative to parent compounds. These values translated to LOQs of 2.1−10.6 fmol on-column or ∼11−53 fmol per mL of plasma for metabolites.

Finally, the analyses were repeated at a second site, using the same column and separation parameters, but a different mass spectrometer (see Materials and Methods). The C and EC metabolites in the plasma were resolved by HPLC with very similar profiles to those recorded previously (compare Figure 9 in Supporting Information and Figure 3). Calibration with authentic standards resulted in absolute values and standard deviations that closely matched the results from the first site analyses, with the exception of MCG24 (3′-*O*-methyl-C-5-*O*-glucuronide), which was determined based on calibration with the corresponding 7-*O*-glucuronide (Table 4 in Supporting Information). It was observed that the C and EC metabolites were unstable in thawed plasma samples, as recently reported elsewhere,[24] such that reproducible results were only obtained if the samples were injected onto the HPLC within a few hours. Samples left at room temperature were almost totally degraded after 3 days.

Advantages and Disadvantages of the Present Approach. Alternative approaches for identifying metabolites of flavan-3-ols in biological fluids have either generated standard compounds by chemical synthesis[9] or attempted to identify the compounds directly from the fluids;[14−16,25] most of these previous approaches have only unequivocally identified a

DOI: 10.1021/jf505922b
J. Agric. Food Chem. 2015, 63, 2233−2240

subset of the metabolites present. A recent study has reported the chemical synthesis and full characterization of a complete range of EC glucuronides and sulfates.[24] Such compounds will be of great value for future studies on bioavailability, although their chemical synthesis is complex, requiring as a starting point the availability of a complete series of orthogonally protected EC derivatives.

The present study has combined a semisynthetic/biosynthetic scheme with matching of compounds to authentic metabolites. Although the glucuronosyl transferase enzymes are not completely regiospecific, their mammalian origin means that they can generate physiologically relevant metabolites, and the matching of synthetic compounds to plasma metabolites prior to final purification means that only those metabolites that are physiologically relevant are pursued. Furthermore, an enzymatic strategy has advantages for the facile introduction of radiolabel, for example, in the methyl (from S-adenosyl-L-methionine) or glucuronide (from UDP-glucuronic acid) moieties, should labeled compounds be required for mechanism of action studies or analytical internal standards. The limiting steps from a cost perspective are the price of the enzymes, which cannot be recycled, and the cost of UDP-glucuronic acid. Now that standards of all glucuronidated metabolites are available for subsequent identification of products, this problem could be circumvented by a total biological synthesis using recombinant enzymes expressed in *E. coli*, as we have previously shown for synthesis of flavonol and isoflavone glucosides.[26] It should be noted that the present work does not address the sulfated derivatives that also arise from mammalian metabolism of flavan-3-ols, particularly in humans.[27]

Table 1. List of Asteraceae Plant Essential Oils Tested

common name of essential oil	scientific name	source	part	country of origin
Artemisia afra	*Artemisia afra*	Jinarome	flowering plant	South Africa
Artemisia arborescens	*Artemisia arborescens*	Oshadhi	flowering plant	Morocco
chamomile blue	*Chamomilla matricaria*	Oshadhi	blossoms	Nepal
chamomile roman	*Anthemis nobilis*	Oshadhi	blossoms	France
chamomile wild	*Ormensis multicaulis*	Oshadhi	blossoms	Morocco
chrysantheme abs.	*Chrysanthemum morifolium*	Oshadhi	leaves	India
costus root	*Saussurea lappa*	Oshadhi	roots	India
davana	*Artemisia pallens*	Jinarome	leaves	India
elecampane roots	*Inula racemosa*	Oshadhi	roots	India
erigeron	*Coniza canadensis*	Oshadhi	flowering plant	Canada
Eriocephalus punctulatus	*Eriocephalus punctulatus*	Oshadhi	flowering plant	South Africa
Helichrysum bracteiferum	*Helichrysum bracteatum*	Oshadhi	blossoms	South Africa
helichrysum (Immortella)	*Helichrysum angustifolium*	Oshadhi	blossoms	Croatia
santolina	*Santolina chamaecyparissus*	Oshadhi	plant	Spain
tagetes extra-s	*Tagetes minuta*	Oshadhi	blossoms	Egypt
tarragon	*Artemisia dracunculus*	Oshadhi	plant	France

(90%) were purchased from Sigma-Aldrich (Milwaukee, WI, USA). Camphor (>97%), terpinen-4-ol (99%), γ-terpinene (97%), and *p*-cymene (95%) was purchased from Fluka (Buchs, Switzerland). β-Caryophyllene (>90%), (+)-α-pinene (95%), and β-pinene (94%) were obtained from Tokyo Kasei (Tokyo, Japan). Acetone (99.8%) was purchased from Merck. Dichlorvos (purity 98.6%) was purchased from Chem Service (West Chester, PA, USA), and deltamethrin (purity 96.8%) was supplied from Dongbu Farm Hannong (Seoul, Republic of Korea).

Insects. German cockroaches, *B. germanica*, were reared in plastic boxes (54.3 × 18.8 × 36.3 cm, $L \times W \times H$) without exposure to any insecticide. The cockroaches were supplied with water from a glass flask fitted with a cotton stopper and dried mouse food (Purina feed). The cockroaches were maintained at 25 ± 1 °C and 60% RH (relative humidity) under a 16:8 h light:dark cycle.

Gas Chromatography. Gas chromatography (GC) analysis of *Artemisia arborescens*, santolina, and tarragon oils was carried out using an Agilent 7890A (Agilent Technologies, Santa Clara, CA, USA), equipped with DB-1MS or HP-INNOWAX columns (30 m × 0.25 mm internal diameter [i.d.]; film thickness, 0.25 μm; J&W Scientific, Folsom, CA, USA) and a flame ionization detector (FID). Retention times of essential oil components were compared with those of authentic compounds. The oven temperature of the gas chromatograph was programmed as isothermal at 40 °C for 1 min, raised at a rate of 6 °C/min to 250 °C, and maintained at 250 °C for 4 min. Helium was used as the carrier gas at a flow rate of 1.5 mL/min. Retention indices were obtained in relation to a homologous series of *n*-alkanes (C_7−C_{20}; DB-1MS), (C_8−C_{22}; HP-INNOWAX) under the same gas chromatography operating conditions. Further identification of oil constituents was confirmed by increasing the integrated area by coinjection with oil and standard samples.

Gas Chromatography−Mass Spectrometry. Constituents of Asteraceae plant essential oils were also analyzed using a tandem gas chromatograph (Agilent 7890A) mass spectrometer (Agilent 5975C MSD) (GC-MS) (Agilent Technologies). A DB-5MS column (30 m × 0.25 mm i.d.; film thickness, 0.25 μm; J&W Scientific) was used, and the column oven temperature program was the same as used for GC-FID analysis. Helium was used as the carrier gas at a flow rate of 1.0 mL/min. The effluent of the column was introduced directly into the source of the MS via a transfer line (250 °C). Ionization was attained using electron impact (70 eV; source temperature, 230 °C). The scan range was 41−400 amu. Most components of the plant essential oils were tentatively confirmed by comparing the mass spectra of each peak with those of standard samples in the NIST MS library. NMR spectra were obtained on a Varian UI 500 NMR spectrometer (500 MHz for ^{1}H spectra and 125 MHz for ^{13}C spectra) at Korean Basic Science Institute using TMS as an internal standard.

Isolation and Identification of β-Thujone and Artemisia Ketone. To isolate β-thujone, 1 mL of *A. arborescens* oil was chromatographed on a SiO_2 column (Wakogel 200; Wako Pure Chemicals, Osaka, Japan) eluting with a diethyl ether−hexane gradient. β-Thujone and camphor coeluted with 10:90 (ether:hexane) solution. This mixture was rechromatographed on a 10% $AgNO_3$-impregnated SiO_2 column, and β-thujone eluted with 10% ether−hexane solution in 98.9% purity (395 mg). Artemisia ketone was isolated from santolina oil. Santolina oil (1 mL) was chromatographed on a SiO_2 column eluting with a diethyl ether−hexane gradient. Artemisia ketone (purity 80%) was isolated with 10:90 (ether: hexane) solution. To obtain pure artemisia ketone, the 10% ether fraction was rechromatographed on a SiO_2 column eluting with 1:99 ether:hexane. The purity of isolated artemisia ketone (245 mg) was 98.6%. Isolated β-thujone and artemisia ketone were subjected to NMR analysis and were used for bioassays.

Synthesis of β-Phellandrene. β-Phellandrene (purity 98.2%) was synthesized in the laboratory and was subjected to bioassay. The synthesis procedure and NMR data have been well documented in our previous study.[16]

Fumigant Toxicity Test. The fumigant toxicity of Asteraceae plant essential oils and their constituents was determined using a glass cylinder (diameter, 9.5 cm; height, 19 cm) with a wire sieve installed 9.5 cm above the bottom. Asteraceae plant essential oils or their components were applied to a paper disk (8 mm, Advantec). The treated paper disk was transferred to the bottom lid of the glass cylinder. The lid of the glass cylinder was sealed with Para-film to prevent the leakage of the oil or constituents (Pechiney Plastic Packaging Company, Chicago, IL, USA). Ten adult male or female German cockroaches were placed on the sieve, which prevented direct contact of the cockroaches with the test oils and constituents. Test cockroaches were maintained at 25 ± 1 °C and 60% RH. Mortality was determined 48 h after treatment. All treatments were replicated 4 times.

Contact Toxicity Test. The appropriate dose of Asteraceae plant essential oil or individual constituents was dissolved in acetone. Adult male and female German cockroaches were anesthetized using CO_2, and the oils or constituents in acetone were topically applied to the abdomen of adult male and female German cockroaches with a microapplicator (Burkard, U.K.). Control insects received only acetone (1 μL). Treated adults (10 adults/replication) were transferred to Petri dishes (diameter, 9.5 cm; height, 2 cm), which were maintained at 25 ± 1 °C and 60% RH. Mortality was determined 24 h after treatment. Each assay was replicated 5 times.

Acetylcholinesterase Inhibition. Crude protein was obtained from two adult male and female cockroaches. Adult cockroaches were soaked in 0.1 M Tris-HCl mixed with 0.02 M NaCl, 0.5% Triton X-100 (pH 7.8), and a protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO, USA), and then they were ground using a glass tissue grinder (Wheaton Industries Inc., Millville, NJ, USA) in ice. The ground

cockroach extract was centrifuged at 17000*g* for 15 min at 4 °C to eliminate insect tissue debris. The concentration of crude protein was measured by the Bradford protein assay using BSA as the standard protein. The AChE inhibition activity was evaluated using the modified Ellman method.[17] Test chemicals were dissolved in acetone to give a concentration of 100 mg/mL. Mixtures of 1 μL of test compound and 79 μL of crude cockroach protein were placed in 96-well microplates, which were incubated for 10 min at rt (room temperature). The control

received acetone only. 10 μL of acetylthiocholine iodide (ASChI, 10 mM) and 10 μL of 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB, 4 mM) were added to the mixtures of test compounds and crude protein. AChE activity was evaluated by estimating the initial velocity (V_0) for 20 min at 30 s intervals at 405 nm and rt using an iMark microplate absorbance reader (Bio-Rad, Hercules, CA, USA). The primary AChE inhibition assay was replicated at least 3 times. The percentage inhibition of each chemical was calculated according to the following formula:

$$\text{inhibn act. (\%)} = 100 - [(V_0 \text{ of chemical treatment} / V_0 \text{ of control treatment}) \times 100]$$

To determine the IC_{50} value of β-phellandrene, the following concentrations of β-phellandrene were used: 1, 0.5, 0.2, 0.1, and 0.05 mg/mL. All treatments were replicated 3 times at each concentration. The AChE inhibition activity was evaluated according to the formula described above, and the IC_{50} was determined by probit analysis.[18]

Statistical Analysis. Percentage mortality and primary AChE inhibition rates were transformed to arcsine square-root values for analysis of variance. Treatment mean values were compared and analyzed using Scheffé's test.[18] Mean (±SE) values of untransformed data are reported.

RESULTS AND DISCUSSION

Fumigant and Contact Toxicities of Plant Essential Oils. Fumigant and contact toxicities of 16 Asteraceae plant essential oils varied according to oil type and dose (Table 2). *Artemisia arborescens*, santolina, and tarragon essential oils exhibited 100% fumigant toxicity against male German cockroaches at 20 mg/filter paper. The fumigant toxicity of tarragon was 100% at 10 and 5 mg/filter paper, but declined to 90% at 2.5 mg/filter paper. Fumigant toxicities of *Artemisia arborescens*, and santolina were 60% and 22.5% at 10 mg/filter paper, respectively. Chamomile roman showed 85% mortality at 20 mg/filter paper, but declined to 22.5% at 10 mg/filter paper. Other oils showed moderate or weak fumigant toxicity against male German cockroaches. In a test with female German cockroaches, only tarragon showed potent fumigant toxicity at 20 mg/filter paper. Fumigant toxicities of tarragon against female German cockroaches were 100% and 50% at concentrations of 10 and 5 mg/filter paper, respectively. Other oils exhibited moderate or weak toxicity against female German cockroaches at 20 mg/filter paper. In contact toxicity tests, santolina and tarragon essential oils showed 100% insecticidal activity against adult male German cockroaches at 2 mg/♂ (Table 3). Insecticidal activities of tarragon and santolina were 100% and 86% at 1 mg/♂, but were reduced to 44% and 12% at 0.5 mg/♂, respectively. *Helichrysum bracteiferum*, helichrysum (Immortella), and chamomile wild exhibited 98%, 98%, and 96% mortality against male German cockroaches at 2 mg/♂, but declined to 30%, 50%, and 54% at 1 mg/♂, respectively. Contact toxicities of other oils against male German cockroaches were less than 85% at 2 mg/♂. In tests with female cockroaches, tarragon and santolina exhibited 100% and 70% mortality at 2 mg/♀,

respectively, while the other oils exhibited less than 55% mortality at 2 mg/♀. Many plant essential oils have been reported to exhibit fumigant or contact toxicity against German cockroaches.[8−10,12,13] Yeom et al.[8] reported that plant essential oils belonging to Apiaceae exhibited potent fumigant and contact toxicity against German cockroaches. Alzogaray et al.[19] and Yeom et al.[9] also investigated the insecticidal activities of plant essential oils belonging to Myrtaceae. However, fumigant and contact toxicities of the plant essential oils used in this study against German cockroaches have not been reported in any other study.

Chemical Constituents of Plant Essential Oils. The chemical compositions of *Artemisia arborescens*, santolina, and tarragon essential oils are shown in Table 4. The most abundant components of *Artemisia arborescens* were β-thujone (43.72%) followed by camphor (22.93%), β-myrcene (7.22%), sabinene (4.21%), terpinen-4-ol (3.03%), β-caryophyllene (2.56%), camphene (2.51%), α-pinene (2.33%), γ-terpinene (2.28), and *p*-cymene (2.09%). Artemisia ketone (31.20%), β-phellandrene (25.67%), β-myrcene (11.46%), sabinene (8.99%), and β-pinene (8.84%) were detected as the main constituents in santolina oil. Estragole (88.75%) was identified as the most abundant compound in tarragon oil followed by limonene (4.87%), *cis*-ocimene (3.02%), and α-pinene (1.46%). Chemical analyses of *Artemisia arborescens*, santolina, and tarragon essential oils have been reported previously in other studies.[20−22] While the main components of these oils were similar to those previous reports, there were some differences in minor components and composition quantities. Beyrouthy et al.[20] reported that β-thujone (68.5%), chamazulene (12.3%), terpinen-4-ol (1.5%), myrcene (1.1%), linalool and *cis*-thuyanol-4-ol (1%), α-thujone (0.9%), and sabinene (0.8%) were detected as the main components of *Artemisia arborescens.* Chamazulene, linalool, *cis*-thuyanol-4-ol, and α-thujone were not detected in our study. The difference of some oil components and composition amount could be attributed to the origin of *Artemisia arborescens.* Beyrouthy et al.[20] and we used *Artemisia arborescens* essential oils from Lebanon and Moroco, respectively. Artemisia ketone, camphor, and β-phellandrene were analyzed as the main compounds in santolina oil by Demirci et al.,[21] while camphor was not detected in our study. Arabhosseini et al.[22] analyzed the constituents of French tarragon oil and found estragole, methyl eugenol, ocimene, and sabinene as the main constituents. In our study, the amount of estragole was higher, and methyl eugenol and sabinene were not identified. Galambosi and Peura[23] suggested that constituents of plant essential oils differ widely according to production conditions such as harvesting date and storage time, as well as climatic or edaphic factors.

Isolation and Identification of β-Thujone and Artemisia Ketone. Based on ^{1}H- and ^{13}C NMR, DEPT, ^{1}H−^{1}H COSY, and HMQC, each signal of β-thujone was assigned as shown in Figure 1. β-Thujone: ^{13}C (ppm) 12.49 (C10, $-CH_3$), 14.71 (C6, $-CH_2$), 19.72 (C9, $-CH_3$), 19.79 (C8, $-CH_3$), 24.63 (C5, −CH), 27.42 (C1, -C), 32.30, (C7, −CH), 41.73 (C2, $-CH_2$), 45.41 (C4,-CH), 218.51 (C3, -C═O); ^{1}H (ppm) −0.04 (6a, 1H, dd, J = 5.5, 4), 0.59 (6b, 1H, tq, J = 7, 2), 1.00 (8, 3H, d, J = 7), 1.03 (10, 3H, d, J = 7), 1.44 (5, 7, 2H, m), 2.12 (2a, 1H, d, J = 18.5), 2.54 (2b, 1H, d, J = 18.5, 2), 2.71 (4, 1H, m). Chemical shift values of the proton at C6 of α-thujone and β-thujone were reported as 0.12 and −0.05 ppm, respectively.[24] ^{1}H NMR analysis of the isolated thujone showed only a chemical shift value at −0.05 ppm. Thus, the isolated thujone was determined

J. Agric. Food Chem. 2015, 63, 2241–2248

constituents from *Artemisia arborescens*, santolina, and tarragon essential oils are shown in Tables 5 and 6. Fumigant or contact toxicities of α-pinene, β-pinene, β-myrcene, *p*-cymene, limonene, γ-terpinene, and terpinen-4-ol were not tested in this study, because their toxicities to German cockroaches have been reported in our previous studies.[8,9] In a fumigant toxicity test, estragole was the most toxic component to adult males. Fumigant toxicities of estragole were 100% and 67.5% at 2.5 and 1.25 mg/filter paper, respectively. β-Thujone, β-phellandrene, and *cis*-ocimene showed 100%, 100%, and 82.5% fumigant toxicity against adult males at 20 mg/filter paper, but their activities were reduced to 90%, 20%, and 35% at 10 mg/filter paper, respectively. Other compounds showed weak activity. In tests with adult females, estragole exhibited 100% fumigant toxicity at 20 and 10 mg/filter paper, but its toxicity was reduced to 80% and 40% at 5 and 2.5 mg/filter paper, respectively. The fumigant toxicity of β-thujone was 100% at 20 mg/filter paper, but was reduced to 17.5% at 10 mg/filter paper. Other compounds showed moderate or weak toxicity at 20 mg/filter paper. In a contact toxicity test, only estragole exhibited potent activity against adult males. The contact toxicity of estragole was 100% at 1 and 0.5 mg/♂, but was reduced to 34% at 0.25 mg/♂. Artemisia ketone produced 74% mortality at 1 mg/♂, but the mortality decreased to 30% at 0.5 mg/♂. Other compounds exhibited moderate or weak contact toxicity. In a contact toxicity test with female German cockroaches, all test compounds showed moderate or weak toxicity at 1 mg/♀. However, fumigant or contact toxicity of all test compounds was weaker than that of conventional pesticides such as dichlorvos and deltamethrin (Tables 5 and 6). Insecticidal activities of phytochemicals from plant essential oils against German cockroaches have been reported in several studies.[8−10,13] Yeom et al.[8,9] reported fumigant and contact toxicities of constituents from Apiaceae and Myrtaceae plant essential oils. They found that carvone, 1,8-cineole, *trans*-dihydrocarvone, cumminaldehyde, *trans*-anethole, *p*-cymene, γ-terpinene, carvacrol, thymol, carveol, terpinen-4-ol, terpinolene, and α-terpinene demonstrated potent fumigant or contact toxicities against male and female German cockroaches. Philips et al.[10] and Philips and Appel[13] also tested fumigant and contract toxicities of phytochemicals from plant essential oils including carvacrol, 1,8-cineole, *trans*-cinnamaldehyde, citronellic acid, eugenol, geraniol, limonene, linalool, menthone, α-pinene, β-pinene, and thymol. In our study, estragole showed the most potent fumigant toxicity to male and female German cockroaches and contact toxicity to male German cockroaches. Estragole is the main constituent of basil oil, and its insecticidal activity against fruit flies (*Ceratitis capitata*, *Bactrocera dorsalis*, *Bactrocera cucurbitae*), maize weevil (*Sitophilus zeamais*), azuki bean weevil (*Callosobruchus chinensis*), rice weevil (*Sitophilus oryzae*), and cigarette beetle (*Lasioderma serricorne*) have been reported in several studies.[26−28] However, this is the first report on its fumigant and contact toxicity against adult German cockroaches. Many studies have identified β-thujone and β-phellandrene as components of plant essential oils.[20,21] However, there are few reports on their insecticidal activity because they are not commercially available.[29]

In this study, adult male German cockroaches were more susceptible than adult female German cockroaches to plant essential oils and their constituents. The weight of female German cockroaches (average weight of 20 females was 104.9 mg) was about twice that of the male German cockroaches (54.2 mg). This weight difference may be the main reason for the different susceptibility to test oils and their constituents. Lee et al.[30] also found that weight differences between male and female German cockroaches affected the insecticide susceptibility to synthetic insecticides such as organophosphates, carbamates, and pyrethroids.

Primary AChE Inhibition Assay and IC_{50} Determination. AChE inhibition by artemisia ketone, camphene, camphor, β-caryophyllene, estragole, *cis*-ocimene, and β-phellandrene was determined, since inhibition activities of the other constituents were reported in our previous study.[8,9] The primary inhibition activities of various isolated constituents against German cockroach acetylcholinesterase are summarized in Figure 2. β-Phellandrene gave the highest inhibition (81.28%), followed by *cis*-ocimene (44.10%) and estragole (25.04%) (Figure 2). Inhibition activities of the other compounds were less than 20%. In the primary inhibition assay, only β-phellandrene showed >50% inhibition. IC_{50} values of β-phellandrene against male and female acetylcholinesterase were 0.30 and 0.28 mg/mL, respectively (Table 7). Insect acetylcholinesterase inhibition activity of many phytochemicals has been investigated in several studies.[16,25,31−38] German cockroach AChE inhibition activity of phytochemicals from plant essential oils has also been studied by Yeom et al.[8,9] They reported that insecticidal activity of carvacrol and dihydrocarvone correlated with their ability to inhibit German cockroach acetylcholinesterase. However, there was no relationship between AChE inhibition and most other active compounds. In our study, only β-phellandrene showed potent AChE inhibition activity, while most of the other active compounds revealed moderate or weak inhibition activity. Seo et al.[25] reported that β-phellandrene exhibited potent AChE inhibition activity against Japanese termites. The results of our study and other research indicate that insecticidal activity of β-phellandrene correlates with its ability to inhibit AChE. Although the mode of action of phytochemicals from plant essential oils has been reported by some research groups to include AChE, a definitive mechanism has yet to be completely established.[8,9,16,25,31,39,40]

Our results indicate that Asteraceae plant essential oils and their components can be used as fumigants or spray-type control agents against German cockroaches. However, further studies including safety of the oils and their constituents to humans and nontarget organisms, formulations, and their modes of action are necessary for practical use of Asteraceae plant essential oils and their constituents as novel cockroach-control agents.

consuming ATP. The CK/PCr system is a buffer for short-term energy supply in tissues and cells with high and rapidly changing energy consumption, like skeletal and heart muscles (up to 94% of total body CR) and brain cells.[19] A male person weighing 70 kg has a total CR pool of approximately 120 g, from which 2% per day is nonenzymatically converted to creatinine at a constant rate. Creatinine is rapidly excreted via the kidneys into the urine. This daily loss of CR of about 2 g/day has to be replaced either endogenously by de novo synthesis or exogenously with the diet.[20]

Meat contains CR in amounts of 4 to 5 g/kg,[21] indicating that for nonvegetarians, approximately half of the daily requirement of creatine is covered by the diet. Vegetarians solely depend on the endogenous synthesis to replace excreted creatine. Concentrations of CR in serum and erythrocytes of subjects regularly consuming meat were significantly higher when compared to vegetarians (male subjects, serum 41 ± 19 vs 25 ± 19 μmol/L, erythrocytes 370 ± 72 μmol/L vs 270 ± 41 μmol/L).[22]

Studies point to an active transport of CR from plasma into erythrocytes, but the biological role of CR in erythrocytes remains enigmatic.[23] Dietary supplementation with large doses of CR is common, particularly for athletes, but scientific data pointing to ergogenic effects are still ambiguous.[24,25] In this context it is noteworthy that CR is intensively discussed in recent years as a therapeutic supplement for patients suffering from muscle, neuron, and brain disorders.[26−28] To date, however, no explanations of possible effects of CR on a molecular level have been provided.

Creatine shows structural analogy to aminoguanidine and arginine referring to the guanidine moiety (Figure 1). The reaction between MG and aminoguanidine or arginine, respectively, is well characterized. MG-H1 (methylglyoxal-derived hydroimidazolone 1, Figure 1) is a quantitatively important AGE, resulting from the reaction of MG with the guanidino side chain of peptide-bound arginine.[2] To the best of our knowledge, however, there are no studies investigating the reaction between MG and CR. We, therefore, hypothesized that CR should react with MG under physiological conditions to CR-specific dicarbonyl adducts similar to peptide-bound arginine.

Following incubation experiments in order to prove the carbonyl-trapping activity of CR, a hydromidazolone as a creatine-specific methylglyoxal adduct was isolated and quantified in urine samples of healthy volunteers. Considering the relatively high plasma levels of CR in comparison to MG, we postulate that CR, formed endogenously and/or applied via dietary sources, may constitute a "natural" trapping agent for MG in vivo.

MATERIALS AND METHODS

Chemicals and Materials. Creatine monohydrate was from Applichem (Darmstadt, Germany); creatinine was from Merck (Darmstadt, Germany); ammonium acetate was from Grüssing (Filsum, Germany); acetic acid was from Roth (Karlsruhe, Germany); ion-exchange material AG Resin 1-X8 was from Bio-Rad (Hercules, CA); *o*-phenylenediamine, silical gel (63−200 μm particle size), and methylglyoxal (40% solution in water) were from Sigma-Aldrich (Steinheim, Germany); HPLC gradient grade acetonitrile and methanol were from VWR Prolabo (Leuven, Belgium); and LC-MS grade acetonitrile was from Fisher (Loughborough, U.K.). All other chemicals were purchased from standard suppliers and were of the highest purity available. Water for preparation of buffers and solutions was obtained with a Purelab plus purification system (USFilter, Ransbach-Baumbach, Germany). Water for solutions used for LC-MS/MS analysis was distilled twice in the presence of potassium permanganate. Artificial urine was prepared according to the literature.[29]

Urine Samples. Eight healthy, nonvegetarian volunteers (age 21−25 years, 5 women and 3 men) and 7 healthy, vegetarian volunteers (age 21−23 years, 5 women and 2 men, 5 ovo-lacto-vegetarian and 2 vegan) had to collect their 24 h urine (8:00 a.m. until 8:00 a.m. the following day) for 1 day, and had to record a nutritional protocol. All participants were normoglycemic (fasting blood sugar ≤ 5.5 mmol/L) and were of normal body weigth (body mass index ≤ 25.0 kg/m^2).

In an orienting intervention study, one healthy, nonvegetarian volunteer (32 years, female) followed a controlled ovo-lacto-vegetarian diet for 7 days (wash-out period). At the last day (day 1 of the intervention study), 24 h urine was collected (8:00 a.m. until 8:00 a.m. the following day). Vegetarian diet was continued for a further 7 days (days 2−8), but additionally 2 g of creatine ("Creapure", creatine monohydrate, Olimp Laboratories, Dębica, Poland) was consumed daily after lunch (supplementation period). At the last day of the supplementation period (day 8), again 24 h urine was collected.

Isolation of *N*-(4-Methyl-5-oxo-1-imidazolin-2-yl)sarcosine (MG-HCr). 12.5 mmol of creatine monohydrate and 12.5 mmol of methylglyoxal in 125 mL of 0.1 M sodium phosphate buffer, pH 7.4, were incubated for 2 d at 60 °C. To remove nonreacted creatine via flash chromatography, the incubation mixture was dried in vacuo and the residue dissolved in 5 mL of a mixture of acetonitrile/methanol/water (6/4/2, v/v/v). This was applied to a glass column (dimensions 3.0 × 30 cm) filled with 70 g of silica gel with particle size 63−200 μm. Elution was performed with 1400 mL of a mixture of acetonitrile/methanol/water (6/4/2, v/v/v). The fractions were characterized by HPLC-UV-MS/MS, and fractions eluting between 140 and 460 mL containing a peak with the mass transition 186 → 87 were pooled. Solvents were removed under vacuum. To remove further byproducts, the residue was subjected to anion exchange chromatography. A column (2.5 × 8 cm) filled with AG Resin 1-X8 in acetate form was used and eluted with 300 mL each of 0.01, 0.05, 0.10, 0.15, and 0.20 M acetic acid. The fraction size was 10 mL, and a fraction collector (RediFrac, Pharmacia Biotech, Uppsala, Sweden) with a flow rate of 0.5 mL/min was used. Fractions eluting with 0.1 M acetic acid containing a peak with the mass transition 186 → 87 were pooled, dried under vacuum, washed with distilled water, dried by lyophilization, and characterized.

N-(4-Methyl-5-oxo-1-imidazolin-2-yl)sarcosine (MG-HCr): ESI-TOF-MS, positive mode, $[M+H^+]$ m/z 186.09; UV spectroscopy, λ_{max} (1.0 mM ammonium acetate, pH 5.5, acetonitrile/water, 75/25, v/v) 226 nm (log ε = 4.09); elemental analysis, $C_7H_{11}N_3O_3$ (MW = 185.18), calculated, C 45.40%, H 5.99%, N 22.69%, O 25.92%; found, C 41.65%, H 6.28%, N 20.11%; content = 88.6%, based on nitrogen (traces of acetate and methanol were visible in NMR spectra). Yield = 52 mg (molar yield = 2.0%).

Model Incubations under Physiological Conditions. Solutions of MG (10 mM) and CR (100 mM), respectively, in phosphate buffer (100 mM, pH 7.4) were prepared. Five milliliters of the CR solution was mixed with 5 mL of the MG solution in glass tubes, resulting in a 10-fold excess of CR. The mixtures were incubated at 37 °C, and aliquots were taken at defined times (0 h, 1 h, 2 h, 4 h, and 24 h). For the analysis of CR, creatinine, and MG-HCr, 200 μL aliquots were immediately frozen until analysis. For analysis of MG, aliquots of 500 μL were instantly used for derivatization and pipetted into vials containing 150 μL of phosphate buffer (500 mM, pH 6.5) and 150 μL of *o*-phenylenediamine solution (1% in phosphate buffer). Derivatization was done overnight for 16 h under exclusion of light.[30] The incubations were performed in triplicate. As control, MG was incubated in the absence of CR and CR in the absence of MG, respectively, to monitor stability of the compounds during the incubation.

Analysis of *N*-(4-Methyl-5-oxo-1-imidazolin-2-yl)sarcosine (MG-HCr), Creatine, and Creatinine in Model Incubations and Urine Samples by HPLC-ESI-DAD-MS/MS. The HPLC system consisted of a degasser, a pump, an autosampler, and a diode array

J. Agric. Food Chem. 2015, 63, 2249−2256

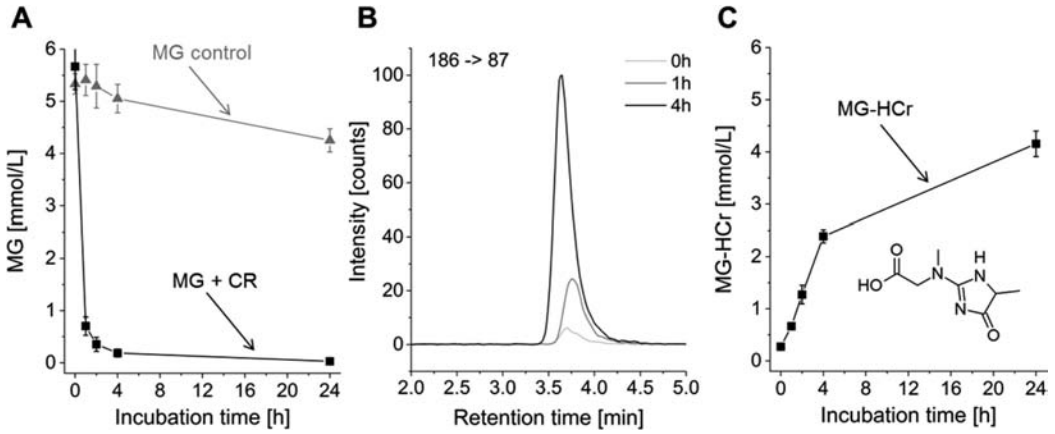

Figure 2. (A) Physiological model incubations of methylglyoxal in the presence of creatine and MG control sample. MG was analyzed after derivatization with *o*-phenylenediamine via RP-HPLC-UV.[30] Incubations were done in triplicate. (B) Formation of a new peak in the incubation of MG with CR with the transition 186 → 87 analyzed by HPLC-ESI-DAD-MS/MS. (C) MG-HCr concentration in the incubation of MG and CR. MG-HCr was quantitated via HPLC-ESI-DAD-MS/MS at UV = 226 nm.

detector, all from Agilent Technologies 1200 series (Boeblingen, Germany). For MS/MS measurements, a Triple Quad LC/MS 6410 from Agilent Technologies was used. For separation a column SeQuant ZIC-HILIC (3.5 μm, 100 Å, PEEK 150 × 2.1 mm; Merck KGaA, Darmstadt, Germany) was used. Elution was performed at 25 °C with a flow rate of 0.2 mL/min with the following starting conditions: 100% solvent A (1.0 mM ammonium acetate in water/acetonitrile 25:75, v/v, pH 5.5) and 0% solvent B (4.65 mM ammonium acetate in water/acetonitrile 70:30 v/v, pH 6.8). This solvent composition was held for 11 min (isocratic elution) followed by an increase of solvent B to 100% within 1 min and held for 8 min, followed by an equilibration at starting conditions for 11 min. Detection wavelengths were 214, 226, and 236 nm for CR, MG-HCr, and creatinine, respectively. For analysis of model incubations 1 μL and for analysis of urine samples 5 μL were injected into the HPLC system.

Single ion monitoring (SIM) was performed from 1 to 11 min in positive mode for *m*/*z* 186 with 200 ms dwell time, fragmentor voltage 115 V, gas temperature 350 °C, gas flow 11 mL/min, and nebulizer pressure 35 psi.

Product ion scans were recorded from 1 to 11 min with the precursor ions *m*/*z* 186 for MG-HCr, *m*/*z* 132 for creatine, and *m*/*z* 114 for creatinine, applying the conditions as described above. The ranges of product ions were set from *m*/*z* 50 to 200 with a scan time of 200 ms, a fragmentor voltage of 115 V, and collision energy of 25 eV.

Measurements of MG-HCr were performed using multiple reaction monitoring mode (MRM) in positive mode. The mass transition 186 → 87 was used for quantitation of MG-HCr with fragmentor voltage and collision energy of 115 V and 20 eV, respectively and a dwell time of 150 ms. For qualification purposes the mass transitions 186 → 140 and 186 → 69 were monitored.

In model incubations, MG-HCr was analyzed without further sample preparation except filtration (0.2 μm) and dilution (1:1000 with solvent A) as described above for the HPLC-ESI-DAD-MS/MS method. Identification of MG-HCr was realized via MS/MS detection and quantitation via UV detection (226 nm) with an external calibration using authentic MG-HCr reference material (see above).

Urine samples were centrifuged (4 °C, 10,000 rpm, 10 min), and 250 μL was deproteinized with 750 μL of acetonitrile at 4 °C for 20 min. After centrifugation (4 °C, 10,000 rpm, 10 min) and filtration (0.2 μm) the solution was employed to standard addition. Quantification via standard addition was necessary to avoid interference due to matrix effects. Urine samples of vegetarians were diluted 3 + 2 and urine samples of nonvegetarians 1 + 4 with 10 μL of MG-HCr standard solution and 10 or 30 μL of solvent A (1.0 mM ammonium acetate in water/acetonitrile 25:75, v/v, pH 5.5), respectively. For standard addition each urine was spiked with four ascending concentrations of MG-HCr resulting in 5 samples per urine including the nonspiked urine (instead of MG-HCr standard solution 10 μL of water was added). MG-HCr stock solution (35 mmol/L) was prepared from the above-described synthesized reference material. This solution was diluted to 0.70, 0.35, 0.18, and 0.07 μmol/L with water, respectively. Each was added to the urine samples. For analysis 5 μL of the spiked urine samples was injected into the HPLC-ESI-DAD-MS/MS. MG-HCr was detected via MS/MS and creatinine via UV at 236 nm. The quantitation of creatinine was realized via external calibration with commercially available reference material. Analysis of urine samples was done in duplicate.

The limits of detection (LOD) and quantification (LOQ) in urine were calculated as the concentrations of the analyte necessary to show a peak at a signal-to-noise ratio of 3 and 10, respectively. For determination of method precision, one urine sample was applied to replicate analysis on different days (n = 5). Recovery of MG-HCr was calculated from the slope of the recovery function after spiking a urine with ascending MG-HCr concentrations (resulting in the same MG-HCr levels as in the standard addition method) before sample workup (n = 5).

Quantitation of Methylglyoxal in Model Incubations by RP-HPLC with UV Detection. Analysis of MG in the model incubations was carried out as previously published.[30] Derivatization with *o*-phenylenediamine to the corresponding quinoxaline was realized immediately after withdrawal from the reaction mixture to scavenge the residual MG.

Mass Spectrometry. For mass spectrometric analyses, a PerSeptive Biosystems Mariner time-of-flight mass spectrometry instrument equipped with an electrospray ionization source (ESI-TOF-MS, Applied Biosystems, Stafford, TX, USA) working in the positive mode was used. Calibration of the mass scale was established using a mixture of bradykinin, angiotensin I, and neurotensin. After appropriate dilution with 1% formic acid in 50% acetonitrile, the sample was injected into the ESI source by a syringe pump at a flow rate of 5 L/min. Spray tip potential, nozzle potential, quadrupole RF voltage, and detector voltage were adjusted to 4812, 80, 1000, and 2400 V, respectively.

Ultraviolet (UV) Spectroscopy. Absorption spectra were recorded on a Specord S100 diode array spectrophotometer (Carl Zeiss, Jena, Germany) with a wavelength accuracy of ±1 nm. The compound was dissolved in 1.0 mM ammonium acetate, pH 5.5, in acetonitrile/water (75/25, v/v) at a concentration of 100 μM. The maxima and molar coefficient of extinction were calculated using quartz cuvettes 115-QS (Hellma, Müllheim, Germany) of 10.00 mm path length.

Nuclear Magnetic Resonance (NMR) Spectroscopy. ^{1}H and ^{13}C NMR spectra were recorded on an AVANCE III instrument (Bruker, Rheinstetten, Germany) at 400 and 100 MHz, respectively. Substances were resolved in 750 μL of deuterium oxide for analysis.

J. Agric. Food Chem. 2015, 63, 2249−2256

Assignments of ^{1}H and ^{13}C signals are based on $^{1}H-^{1}H$ COSY (correlation spectroscopy), HSQC (heteronuclear single quantum coherence), HMBC (heteronuclear multiple bond correlation), and DEPT (distortionless enhancement by polarization transfer) experiments. A NOESY (nuclear Overhauser enhancement spectroscopy) experiment for carbon−proton couplings and a HMBC (heteronuclear multiple bond correlation) experiment for nitrogen−proton couplings were performed in addition to the above-mentioned 2D experiments on a Bruker Avance III instrument at 600 MHz (^{1}H), 150 MHz (^{13}C), and 61 MHz (^{15}N). All chemical shifts are given in parts per million (ppm), those of protons relative to the internal HOD signal (4.80 ppm), those of carbon atoms relative to external standard tetramethylsilane, and those of nitrogen atoms relative to external standard urea.

Elemental Analysis. To know the purity of the isolated compound used as standard material, elemental analysis data were obtained on an Elementar Vario Micro Cube CHNS elemental analyzer (Hanau, Germany). The purity of the isolated compound was calculated as the percentage of nitrogen in the preparation divided by the theoretical percentage of nitrogen of the target substance and expressed in percent by weight.

Statistical Treatment. Comparisons of means between the daily urinary excretions of the different days were examined with Student's *t* test. *P* values ≤0.05 were considered significant (two-tailed) using OriginPro 8.6.

RESULTS AND DISCUSSION

Incubation of methylglyoxal in the presence of a 10-fold excess of creatine under physiological conditions resulted in a rapid decrease of the carbonyl compound (Figure 2 A). After 1 h of incubation at 37 °C, only 13% of the initial concentration could be detected as free MG, and after 24 h nearly complete derivatization of MG was observed. In control samples, MG and CR incubated individually remained stable (Figure 2 A). No creatinine formation was detectable using HPLC-DAD within 24 h. After prolonged incubation for 4 d, creatinine formation accounted for only 2% of the initial CR concentration (data not shown). Therefore, it can be concluded that reactive MG is quantitatively trapped by the guanidino compound CR.

From incubation mixtures containing equimolar amounts of MG and CR, the major reaction product was isolated by flash chromatography and semipreparative ion-exchange chromatography. For the isolated compound, a relative molecular mass M_r of 185.08 ($[M + H]^+$ m/z = 186.09) was determined via ESI-TOF-MS. This corresponds to the addition of one molecule of MG to one molecule of CR with the loss of one molecule of water and formation of a methylglyoxal-derived hydroimidazolone of creatine, namely, *N*-(4-methyl-5-oxo-1-imidazolin-2-yl)sarcosine (Figure 3). The supposed structure for MG-HCr was unequivocally confirmed with ^{1}H NMR and ^{13}C NMR experiments as well as two-dimensional NMR (Table 1 and Figure 3). In the ^{1}H NMR and ^{13}C NMR spectra (except for C-2 in ^{13}C NMR) all signals were doubled, indicating two dominating tautomeric forms in a ratio of 40:60 (A:B) based on proton intensities in the ^{1}H spectrum. The signals were assigned to the two tautomers each using the resonance in ^{1}H-^{1}H COSY and HMBC as well as the intensity relation in the ^{1}H experiment.

Results from ^{1}H NMR showed 4 different signals. The intensities indicated two methyl, one methylene, and one methine group. The singlets of one methyl group and the methylene group were assigned to C-8 and C-9 of the creatine backbone. The second methyl signal was split into a doublet and showed a vicinal coupling to the quartet of the methine

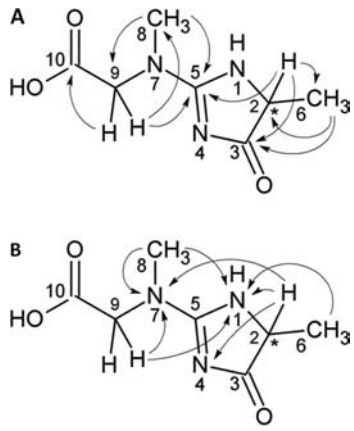

Figure 3. Structural formula of *N*-(4-methyl-5-oxo-1-imidazolin-2-yl)sarcosine (MG-HCr). Arrows indicate the relevant (A) carbon−proton or (B) nitrogen−proton long-range connectivities from HMBC spectra.

group. The $^{1}H,^{1}H$ COSY experiment showed only one resonance confirming the connection of the methyl group at C-6 and the methine H at C-2. In the ^{13}C NMR spectra, seven signals appeared, which were assigned to three quarternary, one methylene, and three methyl or methine carbon atoms by DEPT measurement. The HSQC experiment confirmed these results and allowed the interpretation of C-6 and C-8 as methyl groups, C-2 as methine group, and C-9 as methylene group. To confirm the position of the quarternary carbon atoms, a HMBC experiment was accomplished, which resulted in the assignment shown in Figure 3. The C-10 of the carboxyl group and the C-5 of the guanidino group are connected to the creatine backbone. By contrast, C-3 showed resonance with the protons of C-2 and C-6. Taking the resonance of C-2 and C-6 protons with C-5 into account, the hydroimidazolone substructure is highly likely. In consequence of the inflexible heterocyclic hydroimidazolone structure, the NOESY experiment showed only cross peaks of the protons of C-2 with C-6 and C-8 with C-9. An additional $^{1}H-^{15}N$ HMBC experiment resulted in cross peaks of the proton at C-2 with all nitrogen atoms N-1, N-4, and N-7, also verifying the heterocyclic hydroimidazolone structure.

As mentioned above, doubled signals indicating two tautomeric forms were observed. At present, the NMR data do not allow a definite assignment to two of five predictable tautomeric forms of the hydroimidazolone moiety (possible structures are shown in the Supporting Information). However, participation of all tautomers considering an enol at C-2/C-3 is implausible (compare structures **IV** and **V**, Supporting Information), because this would be indicated by the disappearance of the proton signal at C-2 due to a quantitative H−D exchange in the solvent D_2O. For the methylglyoxal-derived hydroimidazolone of arginine, two tautomers and the appearance of the keto-imine and the keto-amine structure in a ratio 2:1 were postulated as well, supported by NMR experiments.[31] This points to structures **I** and **II** (see Supporting Information). Although one report on X-ray analysis of the compound shown in Figure 3 can be found in the literature,[32] to the best of our knowledge, formation of MG-HCr as a specific reaction product from MG and creatine has not been described yet, although the reaction of guanidino moieties with oxoaldehydes is well-known.[33,34]

To further characterize the scavenging reaction between MG and CR, samples of different time points were analyzed with regard to the possible formation of MG-HCr. With proceeding incubation time, one peak at mass transition 186 → 87 increased in the chromatograms (Figure 2 B). This peak could be assigned to the compound MG-HCr by comparing retention time and fragmentation pattern of product ion scan of MG-HCr reference material (see Figure II in the Supporting Information). Quantitative data obtained for MG-HCr in the incubation mixtures via external calibration are shown in Figure 2 C. After 24 h, the concentration of MG-HCr in the incubation samples was quantitated with 4.2 ± 0.2 mmol/L (Figure 2 C). Initial MG concentration (t = 0 h) was 5.6 ± 0.4 mmol/L, indicating that 75% of MG had been reacted with CR to MG-HCr. Compared with the decrease in MG (Figure 2 A), the formation of MG-HCr (Figure 2 C) is somewhat delayed. This can be explained with the proposed reaction mechanism (Figure 4), in which the conversion to the hydroimidazolone in the last reaction step should be rate-determining.[35]

The fast and quantitative scavenging of MG by CR can be compared with the scavenging capacity of other guanidino compounds such as aminoguanidine[17] and acetylarginine.[35] At present, no studies have been performed to investigate a possible reaction between CR and MG under physiological conditions. The reaction between creatinine and reducing carbohydrates was studied regarding the taste modulating effects of the formed compounds in meat. From these reaction mixtures, a MG-derived creatinine compound was isolated and quantitated in urine after meat ingestion.[36,37]

Our results show that CR reacts with MG under physiological conditions resulting in MG-HCr as the main reaction product. The excellent trapping capacity of CR in vitro for the reactive oxoaldehyde MG points to a possible biological role of CR in vivo. As described in the Introduction, oral administration of aminoguanidine (AG) was found to suppress pathophysiological consequences of diabetes in animal experiments via dicarbonyl scavenging, but exhibited adverse side effects in human studies.[17,18] Plasma concentrations of AG

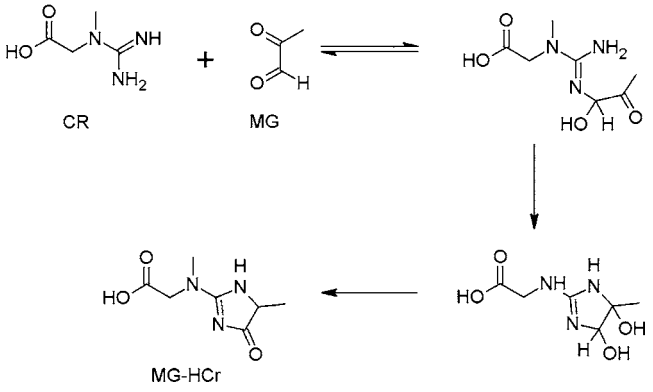

Figure 4. Proposed reaction mechanism for the reaction of creatine (CR) with methylglyoxal (MG) to *N*-(4-methyl-5-oxo-1-imidazolin-2-yl)sarcosine (MG-HCr) via the Schiff base and the dihydroxyimidazolidine. Formation of the hydroimidazolone of creatine should be rate determining.[35]

between 10 to 50 μmol/L were necessary to induce pharmacologically relevant effects.[38] In this context it is noteworthy that normal serum concentration of CR in men (nonvegetarian) is 41 ± 19 μmol/L.[22] Therefore, it can be hypothesized that naturally occurring CR may have MG trapping effects in vivo, leading to continuous formation and excretion of MG-HCr.

To support this hypothesis, a method was established for the quantitation of MG-HCr in urine samples of vegetarians and nonvegetarians, based on hydrophilic interaction chromatography (HILIC) to separate polar compounds.[21] Sensitive detection was realized via tandem mass spectrometry. SIM chromatograms were recorded at m/z 186, the pseudomolecular ion of MG-HCr ($[M + H]^+$). Using HILIC column material, it turned out that the retention time of MG-HCr was considerably dependent on the ionic milieu of the injected sample solution. For identification in urine samples, MG-HCr reference material was therefore dissolved in artificial urine,

DOI: 10.1021/jf505998z
J. Agric. Food Chem. 2015, 63, 2249−2256

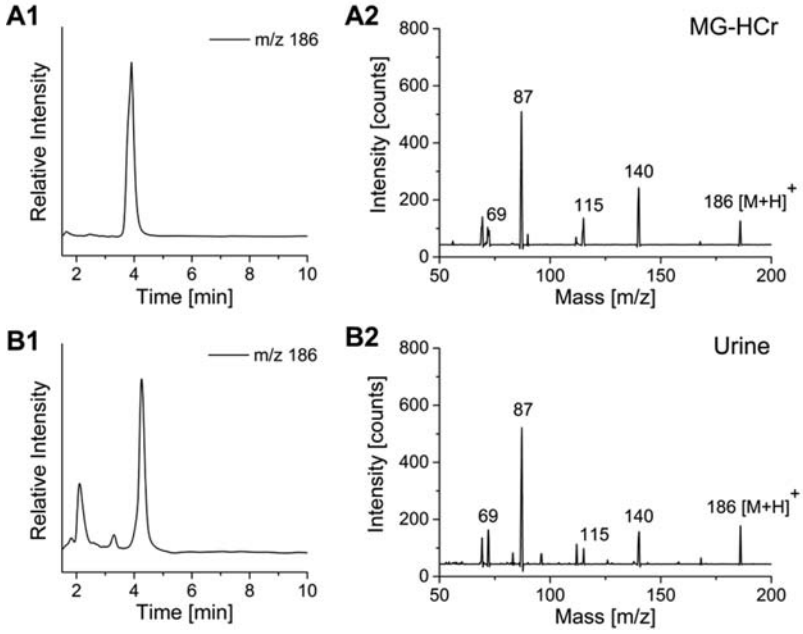

Figure 5. Identification of MG-HCr by HPLC-ESI-MS/MS. SIM chromatograms of the synthesized MG-HCr reference material in artificial urine[29] (A1) and a urine sample (B1) at m/z = 186, respectively. Product ion patterns after fragmentation of the peak at 3.9 min of the MG-HCr standard (A2) and the peak at 4.3 min of the urine sample (B2) with m/z = 186.

thus simulating the average composition of urine including salts, urea, and organic acids.[29] Assignment of the peak in the SIM chromatogram of a urine sample (Figure 5B1) to MG-HCr was confirmed first of all chromatographically by comparing the retention times of the target compound in artificial urine and urine (compare Figures 5A1 and 5B1). Retention time of the main peak in the chromatogram of the urine sample with m/z 186 (4.3 min in Figure 5 B1) differed slightly from that of the peak in the chromatogram of the MG-HCr reference material (3.9 min in Figure 5A1). Depending on the ionic milieu (artificial urine, dilution of the urine), retention time for MG-HCr could vary within 0.5 min on the applied HILIC column. The shifts in retention time of the peak in the urine samples were verified by standard addition (data not shown). Unequivocal identification was accomplished based on the corresponding mass spectra. In Figures 5A2 and 5B2, the product ion patterns after fragmentation (product ion scan) of the peak with m/z = 186 of a MG-HCr standard solution in artificial urine and of a urine sample are displayed, respectively. The two fragmentation patterns were identical and showed the same distinct signals (Figures 5A2 and 5B2). Thus, unambiguous identification of MG-HCr in urine was achieved.

With the applied chromatographic system, a sufficient retardation of the polar compound MG-HCr as well as separation from creatine and creatinine was possible (see Figure III, Supporting Information). Standard addition curves in the concentration range of 0.07−0.7 μmol/L showed linearity (R^2 > 0.99) for MG-HCr. The limit of detection (LOD) and limit of quantitation (LOQ) were calculated from the signal-to-noise ratio. LOD in urine was 0.01 μmol/L, and LOQ was 0.05 μmol/L. Method precision, expressed as relative standard deviation of replicate analysis of a urine sample (n = 5), was 8.6%. Repeated recovery experiments (n = 5), where urine samples were spiked before sample workup, showed a recovery of 81.6 ± 5.5%, calculated from the slope of the recovery function. The validation parameters of the standard addition method indicate a reliable method for accurate quantitation of MG-HCr in urine. The developed method should be easily transferred to other biological matrices as, for example, plasma.

Using this method, MG-HCr in 24 h urine samples of 15 healthy volunteers (7 vegetarians, 8 nonvegetarians) was analyzed. The participants followed their own individual diet and collected their 24 h urine for 1 day. Data for urinary excretion of MG-HCr are shown in Figure 6 A. Daily MG-HCr

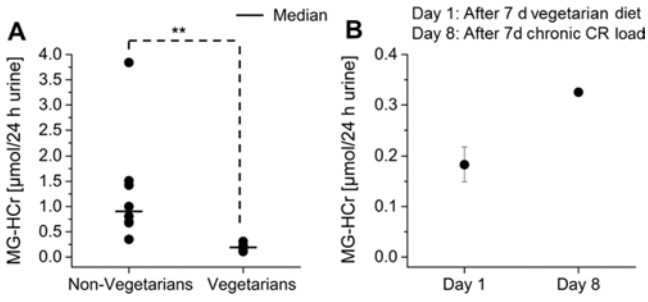

Figure 6. (A) 24 h urinary excretion of MG-HCr of 8 nonvegetarians and 7 vegetarians healthy volunteers. Comparisons of means were examined using Student's t test. **, P < 0.01 (significant). (B) Urinary excretion of MG-HCr into 24 h urine of 1 person (nonvegetarian) during a creatine intervention study. Day 1: after 7 days of vegetarian diet (wash-out period). Day 8: after 7 days of creatine supplementation (2 g daily after lunch). Error bars give the standard error of the mean (n = 2).

excretion of nonvegetarians ranged from 0.35 to 3.84 μmol/24 h urine (median: 0.90 μmol/24 h urine) and of vegetarians from 0.11 to 0.31 μmol/24 h urine (median: 0.19 μmol/24 h urine). The urinary excretion between nonvegetarians and vegetarians differed significantly (P < 0.01). Based on the dietary recordings and taking literature data of CR in food into account,[39−41] it turned out that the estimated intake of CR with the daily diet of the vegetarians was significantly lower when compared with the nonvegetarians (0−0.3 mmol/day vs 1.3−

DOI: 10.1021/jf505998z
J. Agric. Food Chem. 2015, 63, 2249−2256

12.2 mmol/day). Therefore, MG-HCr detectable in urine of vegetarians must be due to formation in vivo. The higher amount of creatine taken up with the daily diet of non-vegetarians should lead to higher plasma concentrations of the guanidino compound which may trap more MG and thus can induce an increased excretion of MG-HCr in urine samples of nonvegetarians.

To further strengthen this hypothesis, urinary excretion of one healthy volunteer (nonvegetarian) was measured after being for 7 days on a vegetarian diet (day 1, Figure 6 B). This wash-out period was followed by a supplementation period, in which for 7 days 2 g of CR per day was consumed after lunch. This amount of CR corresponds to an ingestion of about 500 g of meat.[21] After 7 days on a vegetarian diet, MG-HCr increased from 0.18 ± 0.03 μmol/24 h urine (day 1, Figure 6B), which is in the range of the vegetarians shown in Figure 6A, to 0.33 ± 0.01 μmol/24 h urine (day 8, Figure 6B). This significant increase of MG-HCr excretion following an oral load with creatine clearly demonstrates that trapping of MG in vivo can be increased by dietary means. On the other hand, however, it cannot be excluded that excretion of MG-HCr at least partly can result from an oral uptake of the reaction product with heated meat and subsequent renal excretion. At present, no data about the occurrence of MG-HCr in meat are available. Corresponding studies are currently underway in our laboratory.

In conclusion, with the identification of MG-HCr, the specific reaction product formed from MG and CR under physiological conditions, and its unambiguous quantitation in urine, we provide evidence for a new physiological role of creatine. Our results suggest that dietary intake of CR and resulting increased plasma concentrations may provide a natural "safety mechanism" for the trapping of highly reactive dicarbonyl compounds. This mechanism could be of special importance in situations in which the body has to deal with pathophysiologically increased amounts of dicarbonyl compounds ("carbonyl stress"), for instance in diabetic patients. Furthermore, our findings may shed light on the question why erythrocytes accumulate CR, but do not use the guanidino compound for their energy metabolism. As mentioned in the Introduction, concentrations of CR in erythrocytes are about 10-fold higher compared to blood serum, and subjects consuming meat have higher concentrations of CR in erythrocytes and serum compared to vegetarians.[22,23] Taking into account that erythrocytes produce energy solely by the glycolysis of glucose and lactic acid fermentation of the resulting pyruvate,[42] significant amounts of MG are continuously formed as byproduct, which have to be metabolized, in particular by the glyoxalase system. Additionally, the arginine residues of hemoglobin nonenzymatically trap MG via formation of MG-H1.[2] It is conceivable that CR may significantly contribute to the detoxification of MG in particular in erythrocytes. Acting this way, CR could retard the formation of advanced glycation end products (AGEs) and thus delay those long-term consequences of diabetes and aging, which are commonly attributed to AGE formation in vivo. As another aspect, CR may positively contribute to MG-linked neurological disorders.[13,14] If this hypothesis can be confirmed, dietary intake of CR via meat or supplements may constitute a so far overlooked nutritional benefit.

microfractionation coupled with microplate-based biochemical detection, also known as high-resolution bioassay,[10] and (ii) state-of-the-art high-performance liquid chromatography−solid-phase extraction−nuclear magnetic resonance spectroscopy (HPLC−SPE−NMR).[11−13] The combination of the two with high-resolution mass spectrometry, that is, high-resolution bioassay/HPLC−HRMS−SPE−NMR, has already proven successful for fast and efficient analysis of monoamine oxidase A inhibitors,[14] antioxidants,[15−17] α-amylase inhibitors,[4] and fungal plasma membrane H^+-ATPase inhibitors.[18] In this work, microplate-based high-resolution α-glucosidase profiling combined with HPLC−HRMS−SPE−NMR[19,20] have been used for identification of α-glucosidase inhibitors direct from crude extracts of a series of plants in order to investigate their potential use as future functional foods and/or to identify new T2D drug leads.

EXPERIMENTAL PROCEDURES

Chemicals. Analytical-grade methanol (99.9%), methanol-d_4, α-glucosidase type I (EC 3.2.1.20, from *Saccharomyces cerevisiae*, lyophilized powder), *p*-nitrophenyl α-D-glucopyranoside (≥99.9%), dimethyl sulfoxide (DMSO; ≥99.5%), sodium dihydrogen phosphate dihydrate, disodium hydrogen phosphate, sodium azide, acarbose, and quercetin were purchased from Sigma−Aldrich (St. Louis, MO). Analytical-grade ethyl acetate (99.8%) and acetonitrile (99.9%), as well as sodium hydroxide (35%), were purchased from VWR International (Radnor, PA), whereas formic acid (98−100%) was from Merck (Darmstadt, Germany). Water was purified by 0.22 μm membrane filtration and deionization (Millipore, Billerica, MA).

Plant Material. In total, 24 plants were bought in local stores in Denmark, Sweden, and Lebanon in March−April 2014 (Table 1). Fresh plant material was washed with tap water and sun-dried or oven-dried at 40 °C (Termaks, TS5410, Bergen, Norway) for 5 days. Dried material was ground in a mill, and the pulverized plant material was extracted with ethyl acetate and methanol by shaking on a Lab Dancer (IKA, Germany) for 3 min, followed by sonication at room temperature for 2 h. Details of amount of plant material and volume of extraction solvent are listed in Table S1 in Supporting Information. The extracts were passed through syringe filters with a pore size of 0.4 μM and subsequently evaporated to dryness by a stream of nitrogen gas. Percentage yields based on the dried starting materials are listed in Table S1 in Supporting Information. The dried extracts were kept at −18 °C until use.

Table 1. Names and Place of Purchase of Plant Species Included in This Work

family	plant species[a]	common name	purchased
Actinidiaceae	*Actinidia deliciosa*	kiwi	Denmark
Amaryllidaceae	*Allium ascalonicum*	shallot	Denmark
Amaryllidaceae	*Allium sativum*	garlic	Denmark
Apiaceae	*Cuminum cyminum*	cumin	Denmark
Apiaceae	*Foeniculum vulgare*	fennel	Denmark
Apiaceae	*Pimpinella anisum*	anise	Denmark
Brassicaceae	*Brassica juncea*	green mustard cabbage	Denmark
Compositae	*Gundelia tournefortii*	tumble thistle	Sweden
Compositae	*Scorzonera suberosa*	yemlik[b]	Denmark
Lamiaceae	*Thymus vulgaris*	thyme	Lebanon
Lauraceae	*Cinnamomum zeylanicum*	cinnamon	Denmark
Leguminosae	*Cassia angustifolia*	senna	Denmark
Leguminosae	*Glycine max*	soybean	Denmark
Leguminosae	*Glycyrrhiza glabra*	liquorice	Denmark
Leguminosae	*Lupinus albus*	white lupin	Lebanon
Leguminosae	*Tamarindus indica*	Indian date	Lebanon
Piperaceae	*Piper nigrum*	black pepper	Denmark
Polygonaceae	*Rheum palmatum*	Turkish rhubarb	Lebanon
Polygonaceae	*Rheum rhabarbarum*	rhubarb	Denmark
Polygonaceae	*Rumex acetosa*	sheep sorrel	Denmark
Ranunculaceae	*Nigella sativa*	black caraway	Denmark
Rhamnaceae	*Frangula alnus*	alder buckthorn	Denmark
Solanaceae	*Capsicum frutescens*	chili	Denmark
Urticaceae	*Urtica dioica*	stinging nettle	Denmark

[a]Purchased March−April 2014. [b]Turkish name.

α-Glucosidase Assay. A 0.1 M phosphate buffer was prepared by dissolving 2.65 g of $NaH_2PO_4{\cdot}2H_2O$, 4.70 g of Na_2HPO_4, and 0.10 g of NaN_3 in 500 mL of Milli-Q water and adjusting to pH 7.5 with 2 N sodium hydroxide. Enzyme solution was prepared by dissolving 1.3 mg of 15.8 units/mg α-glucosidase from *S. cerevisiae* in 10 mL of phosphate buffer, resulting in an enzyme activity of 2 units/mL. Substrate solution of 1.0 mM was prepared by dissolving 60.2 mg of *p*-nitrophenyl α-D-glucopyranoside (*p*-NPG) in 20 mL of phosphate buffer. The contents of all wells in the microplates were dissolved in 10 μL of DMSO, and 165 μL of phosphate buffer and 5 μL of α-glucosidase solution were added. After the samples were shaken for 2 min and preincubated at 28.1 °C for 10 min, 20 μL of 10 mM *p*-NPG solution was added to start the reaction. The absorbance was measured at 405 nm every 30 s for 35 min. Incubation and absorbance measurements were performed with a Multiscan FC microplate photometer with built-in shaker and incubator (Thermo Scientific, Waltham, MA). For data acquisition, SkanIt version 2.5.1 software (Thermo Scientific, Waltham, MA) was used. The absorbance readings for the samples were compared with a control, which consisted of the same materials except extract. The percentage of enzyme inhibition was calculated by

$$\%\ \text{inhibition} = \frac{\left(\text{slope}_{405}^{\text{control}} - \text{slope}_{405}^{\text{extract}}\right)}{\text{slope}_{405}^{\text{control}}} \times 100$$

Dilution series consisting of 10−16 dilutions of extracts dissolved in 0.1 M phosphate buffer were prepared for IC_{50} determination. Thus, 200 μL aliquots of each concentration in the dilution series were added to 96-well microplates in triplicate, and after evaporation overnight (Savant SPD121P concentrator coupled with a RVT400 refrigerated vapor trap and an OFP-400 oil free pump, Thermo Scientific, Waltham, MA), the α-glucosidase assay was performed by the method described above. Dose−response curves and IC_{50} values were obtained by use of GraphPad Prism (version 6.00.283).

HPLC Analysis. Dried extracts were redissolved in methanol and filtered (Q-Max RR 13 mm 0.45 μm Nylon, Frisenette, Denmark). HPLC analyses of the extracts were performed on an Agilent 1200 series chromatograph consisting of a G1311A quaternary pump, a G1322A degasser, a G1316A thermostated column compartment, a G1315C photodiode-array detector, a G1367C high-performance autosampler, and a G1364C fraction collector (Santa Clara, CA). Separations were performed with a Phenomenex Luna $C_{18}(2)$ column (150 × 4.6 mm i.d., 3 μm particle size, 100 Å pore size) maintained at 40 °C. HPLC solvent A consisted of water−acetonitrile 95:5 with 0.1% formic acid added, and solvent B consisted of acetonitrile−water 95:5 with 0.1% formic acid added. For all samples, 5 μL of extract was injected and separated by use of the following gradient elution profile at 0.5 mL/min: 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min, 0% B; 42 min, 0% B. The chromatograms were monitored at 210, 230, 254, 270, 310, and 360 nm. The chromatographic system was controlled by Agilent ChemStation revision B.03.02 software.

Removal of Tannins. Tannins were removed from methanol extracts of *C. zeylanicum* and *R. palmatum* by use of 500 mg Oasis HLB cartridges (Waters, Milford, MA). The extracts were dissolved in 5% aqueous methanol at a concentration of 50 mg/mL. The cartridges were preconditioned with 7 mL of methanol and subsequently equilibrated with 7 mL of Milli-Q water. Cartridges were loaded with 0.5 mL of extract, washed with 7 mL of 5% aqueous methanol, eluted with 7 mL of methanol, and re-equilibrated with 7 mL of water. This

DOI: 10.1021/jf506297k
J. Agric. Food Chem. 2015, 63, 2257−2263

procedure was performed repeatedly in series until the entire volume of the samples had been used. The methanol extracts were evaporated on a rotary evaporator, weighed, and stored at −18 °C until use.

High-Resolution α-Glucosidase Profiling. Methanol extracts of *R. palmatum* (201.3 mg/mL, injection volume 5 μL, fractionation of 5−35 min in 176 wells), *C. zeylanicum* (161.7 mg/mL, injection volume 20 μL, fractionation of 9−36 min in 176 wells), and *R. rhababarum* (14.4 mg/mL, injection volume 20 μL, fractionation of 2−33 min in 176 wells) were separated on a Phenomenex C_{18}(2) Luna column (150 × 4.6 mm, 3 μm, 40 °C, 0.5 mL/min) with the following elution gradient: 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min, 0% B; and 42 min, 0% B. Ethyl acetate extracts of *R. palmatum* (68.5 mg/mL, injection volume 2 μL, fractionation of 3−25 min in 176 wells) was separated under above conditions with the following elution gradient: 0 min, 20% B; 3 min, 20% B; 15 min, 80% B; 16 min, 100% B; 30 min, 100% B; 35 min. 20% B; and 41 min, 20% B. Ethyl acetate extracts of *A. ascalonicum* (68.5 mg/mL, injection volume 5 μL, fractionation of 9−36 min in 176 wells) and *C. zeylanicum* (36.1 mg/mL, injection volume 2 μL, fractionation of 3−25 min in 176 wells) were separated with the following elution gradient: 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min 0% B; and 42 min, 0% B. Microplates were evaporated to dryness under reduced pressure in a SPD121P Savant SpeedVac, and α-glucosidase inhibitory activity was assessed for each well as described above. Inhibition of α-glucosidase activity was plotted against chromatographic retention time to give a high-resolution biochromatogram.

HPLC−HRMS−SPE−NMR Analyses. HPLC−HRMS−SPE−NMR analyses of *A. ascalonicum*, *C. zeylanicum,* and *R. palmatum* were performed on a system consisting of an Agilent 1200 chromatograph comprising quaternary pump, degasser, thermostated column compartment, autosampler, and photodiode-array detector (Santa Clara, CA); a Bruker microTOF-Q II mass spectrometer (Bruker Daltonik, Bremen, Germany) equipped with an electrospray ionization (ESI) source and operated via a 1:99 flow splitter; a Knauer Smartline K120 pump for postcolumn dilution (Knauer, Berlin, Germany), a Spark Holland Prospekt 2 SPE unit (Spark Holland, Emmen, The Netherlands); a Gilson 215 liquid handler equipped with a 1 mm needle for automated filling of 1.7 mm NMR tubes, and a Bruker Avance III 600 MHz NMR spectrometer (^{1}H operating frequency 600.13 MHz) equipped with a Bruker SampleJet sample changer and a cryogenically cooled gradient inverse triple-resonance 1.7 mm TCI probe-head (Bruker Biospin, Rheinstetten, Germany). A solution of sodium formate clusters was injected in the beginning of each run to enable internal mass calibration. The HPLC eluate was diluted with Milli-Q water at a flow rate of 1.5 mL/min prior to trapping on 10 × 2 mm i.d. Resin GP [general purpose, 5−15 μm, spherical shape, poly(divinylbenzene) phase] SPE cartridges (Spark Holland, Emmen, The Netherlands), based on absorption thresholds at 254 nm. Before trapping, the cartridges were preconditioned with 500 μL of MeCN followed by 500 μL of H_2O. Thus, four analytes were trapped from ethyl acetate extract of *A. ascalonicum* peel (10 repetitive separations of 10 μL of a 51.64 mg/mL sample; elution profile 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min 0% B; and 42 min, 0% B). Eight analytes were trapped from ethyl acetate extract of *R. palmatum* root (10 repetitive separations of 5 μL of a 68.5 mg/mL sample; elution profile 0 min, 20% B; 3 min, 20% B; 15 min, 80% B; 16 min, 100% B; 30 min, 100% B; 35 min, 20% B; and 42 min, 20% B). Five peaks were trapped from ethyl acetate extract of *C. zeylanicum* bark (five repetitive separations of 10 μL of a 36.1 mg/mL sample; elution profile: 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min 0% B; and 42 min, 0% B). Loaded cartridges were dried with pressurized N_2 gas for 45 min and eluted with 30 μL of methanol-d_4 into 1.7 mm o.d. NMR tubes (Bruker Biospin, Karlsruhe, Germany) by use of a Gilson 215 liquid handler (Gilson, Middleton, WI). Separations were controlled by Bruker Hystar version 3.2 software, automated filling of NMR tubes was controlled by PrepGilsonST version 1.2 software, and automated NMR acquisition was controlled by Bruker IconNMR version 4.2 software.

NMR Experiments. All NMR spectra were recorded in methanol-d_4 at 300 K. ^{1}H chemical shifts were referenced to the residual solvent signal (δ 3.31). One-dimensional ^{1}H NMR spectra were acquired in automation (temperature equilibration to 300 K, optimization of lock parameters, gradient shimming, and setting of receiver gain) with 30° pulses, 3.66 s interpulse intervals, and 64K data points and multiplied with an exponential function corresponding to line broadening of 0.3 Hz prior to Fourier transform. Phase-sensitive double quantum filtered correlation spectroscopy (DQF-COSY) spectra were recorded using a gradient-based pulse sequence with a 20 ppm spectral width and 2k × 256 data points (processed with forward linear prediction to 1k data points). Multiplicity-edited heteronuclear single quantum coherence (HSQC) spectra were acquired with the following parameters: spectral width 20 ppm for ^{1}H and 165 ppm for ^{13}C, 2K × 256 data points (processed with forward linear prediction to 1K data points), and 2.0 s relaxation delay. Heteronuclear multiple-bond correlation (HMBC) spectra were optimized for $^nJ_{C,H}$ = 10 Hz and acquired with the following parameters: spectral width 20 ppm for ^{1}H and 222 ppm for ^{13}C, 2K × 128 data points (processed with forward linear prediction to 1K data points), and 1.5 s relaxation delay.

RESULTS AND DISCUSSION

This work aimed at identifying α-glucosidase inhibitors in plants by use of microplate-based high-resolution α-glucosidase inhibition profiling combined with HPLC−HRMS−SPE−NMR. Thus, a total of 24 different plants, primarily edible and well-known species, were purchased at local stores in Denmark, Sweden, and Lebanon (Table 1). The plants were distributed in 14 different families, with most species belonging to Leguminosae. The dried plant materials were extracted with methanol and ethyl acetate, and the crude extracts were assessed for α-glucosidase inhibitory activity. Table 2 lists IC_{50} values of methanol and ethyl acetate extracts of all samples. Six samples—methanol extracts of *C. zeylanicum*, *R. rhabarbarum* (peel), and *R. palmatum* (root) and ethyl acetate extracts of *C. zeylanicum*, *A. ascalonicum* (peel), and *R. palmatum* (root)—show IC_{50} values below 20 μg/mL. In comparison, the IC_{50} value of Acarbose reference standard is 0.47 ± 0.02 mg/mL. IC_{50} curves of these six extracts and Acarbose are shown in Figure S1 and high-resolution α-glucosidase inhibition profiles of methanol extracts of *C. zeylanicum* (bark), *R. rhabarbarum* (peel), and *R. palmatum* (root) are shown in Figures S2−S4, respectively, in Supporting Information. From the broad hump from approximately 8−30 min observed in the HPLC chromatograms in Figures S2−S4, it is evident that the methanol extracts of *C. zeylanicum* (bark), *R. rhabarbarum* (peel), and *R. palmatum* (root) contain tannins. It is also evident that this tannin hump is correlated with high α-glucosidase inhibition. Polyphenols, such as tannins, have been found to react with the α-glucosidase enzyme by accelerating the sedimentation of protein, which may cause the high level of inhibition,[21] that is, giving false-positive results. To investigate whether the methanol extracts of *C. zeylanicum* (bark) and *R. palmatum* (root) contain specific α-glucosidase inhibitors, tannins were removed by solid-phase extraction on Oasis HLB columns. The samples were subsequently assessed by analytical-scale HPLC to monitor the efficiency of tannin removal, and α-glucosidase inhibitory activities were measured for tannin-free samples. This showed IC_{50} values of 1.57 μg/mL for *C. zeylanicum* (bark) and 7.41 μg/mL for *R. palmatum* (root) (IC_{50} curves in Figure S5 in Supporting Information). Thus, the IC_{50} values were still below the inclusion criterion of 20 μg/mL chosen for this study, which indicated that tannin-free methanol extracts of *C. zeylanicum* (bark) and *R. palmatum* (root) must contain specific α-glucosidase inhibitors.

[a]Measured in triplicate. Acarbose standard IC_{50} = 0.47 ± 0.02 mg/mL. nd = not determined; that is, no significant inhibition above maximum possible concentration given in parentheses.

High-Resolution α-Glucosidase Inhibition Assay and HPLC−HRMS−SPE−NMR Analyses. Careful inspection of HPLC chromatograms of the tannin-free methanol extracts and ethyl acetate extracts of *C. zeylanicum* (bark) and *R. palmatum* (root) showed that the ethyl acetate extracts contained more or less the same analytes but with a flatter baseline of the chromatogram due to the absence of tannins. Thus, it was decided to perform high-resolution α-glucosidase inhibition assay/HPLC−HRMS−SPE−NMR analyses with ethyl acetate extracts of *A. ascalonicum* (peel), *R. palmatum* (root), and *C. zeylanicum* (bark). The α-glucosidase inhibition profiles of *A. ascalonicum* peel (Figure 1), *R. palmatum* root (Figure 3), and *C. zeylanicum* bark (Figure 4) allowed pinpointing of HPLC peaks correlated with bioactivity and thus allowed identification of the individual metabolites responsible for the activity by subsequent HPLC−HRMS−SPE−NMR analysis, as detailed below.

Allium ascalonicum. The high-resolution α-glucosidase inhibition profile of ethyl acetate extract of *A. ascalonicum* is shown below its corresponding HPLC chromatogram at 254 nm in Figure 1. The chromatogram shows several well-separated peaks but only four of these, peaks 1−4, are correlated with α-glucosidase inhibition in the inhibition profile. HPLC−HRMS−SPE−NMR analysis of peaks 1−4 allowed identification of the corresponding compounds **1**−**4** as

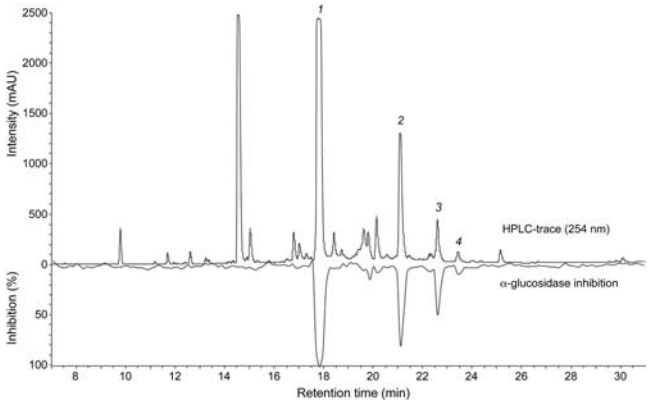

Figure 1. High-resolution α-glucosidase inhibition profile of ethyl acetate extract of *A. ascalonicum* peel with overlaid HPLC chromatogram at 254 nm. Peaks numbered 1−4 (corresponding to compounds **1**−**4**) correlated with α-glucosidase inhibition and were analyzed by HPLC−HRMS−SPE−NMR [Phenomenex C_{18}(2) Luna column, 150 × 4.6 mm, 3 μm, 40 °C, elution rate 0.5 mL/min; elution gradient 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min 0% B; and 42 min, 0% B; microfractionation from 7 to 31 min in 176 wells].

quercetin (**1**) as well as the dimer (**2**), trimer (**3**), and tetramer (**4**) of quercetin (see Figure 2).

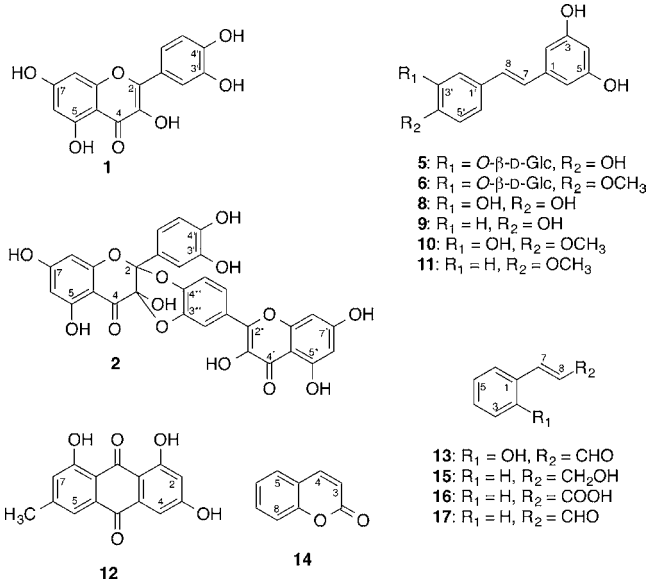

Figure 2. Structures of compounds identified in *A. ascalonicum*, *R. palmatum*, and *C. zeylanicum*.

HRMS of **1** and **2** showed *m*/*z* values of 303.0518 and 603.0760, in agreement with $[M + H]^+$ for molecules with the formulas $C_{15}H_{10}O_7$ and $C_{30}H_{18}O_{14}$, respectively. Comparison with ^{1}H NMR data from literature confirmed **1** to be quercetin[22] and **2** to be the dimer of quercetin formed by a Diels−Alder-related mechanism.[23,24] ^{1}H NMR data obtained in the HPLC−HRMS−SPE−NMR mode are given in Supporting Information Table S2.

HRMS analysis of **3** and **4** in negative-ion mode showed *m*/*z* values of 901.0862 and 1201.1154, in agreement with $[M - H]^-$ for molecules with the formulas $C_{45}H_{26}O_{21}$ and $C_{60}H_{34}O_{28}$, respectively. The ^{1}H NMR data acquired in HPLC−HRMS−SPE−NMR mode suggested the presence of a trimer and a tetramer, respectively, but the quality of the

DOI: 10.1021/jf506297k
J. Agric. Food Chem. 2015, 63, 2257−2263

spectra did not allow unambigous assignment of all ^{1}H resonances. Therefore, peaks 3 and 4 were isolated by preparative-scale HPLC (along with peaks 1 and 2) for NMR analysis. Furthermore, **1**−**4** were investigated by HPLC−ESI(−)−MS/MS with a range of collision energies to oberve daughter ions corresponding to neutral loss of the individual dioxane-linked quercetin monomers in a reverse Diels−Alder reaction (Q_{rDiAl}; m/z 300) (Supporting Information, Table S2). For both **2** and **3**, the main daughter ion was m/z 299, corresponding to $[Q_{rDiAl} - H]^-$, while for **3** a weak daughter ion of m/z 601 was also observed, corresponding to $[M - Q_{rDiAl}\text{-}H]^-$. The trimer (**3**) of quercetin has previously been reported from scales of *Allium cepa*,[23] but this is the first report on its α-glucosidase inhibitory activity. The fragmentation pattern of **4** showed the presence of an intense ion at 901 ($[M - Q_{rDiAl}\text{-}H]^-$) together with the daughter ions observed for **3**, that is, $[M - 2Q_{rDiAl} - H]^-$ and $[M - 3Q_{rDiAl} - 2H - H]^-$, corresponding to sequential loss of three quercetin moieties for **4**. Thus, **4** is a quercetin tetramer. Please refer to Supporting Information Figure S6 for the proposed ESI(−)-MS/MS fragmentation of **4**. Due to the complexity of the NMR spectra with increasing number of quercetin monomers, the NMR data of **3** and **4** did not allow unambiguous structural identification and full assignment of all NMR resonances of the quercetin trimer and tetramer. Thus, formation of the dioxane linkages in **3** and **4** via a Diels−Alder mechanism could occur via ether bond formation involving C-2 and C-3 on one quercetin and C-3′ and C-4′ on a second quercetin unit (i.e., C_2−O−$C_{3'}$ and C_3−O−$C_{4'}$ ether bonds) or the opposite (i.e., C_2−O−$C_{4'}$ and C_3−O−$C_{3'}$ ether bonds). We are awaiting access to ultra-high-field NMR facilities (>900 MHz) to conduct these structural studies, which will be published in an independent paper.

It has previously been shown that a wide range of 4-oxoflavonoids are present in onions, with quercetin monoglucosides and quercetin diglucosides accounting for 80% of the total flavonoids in the onion bulb.[25] It has, however, also been shown that autohydrolysis during storage, heating, and other kinds of processing cause degradation of quercetin monoglucosides and quercetin diglucosides into quercetin.[26,27] This is why the flavonoid content of onion scales, that is, the outer dry layer of onions, differs from the content of the onion bulb. The scales are rich in dimers and trimers of quercetin,[23] and these compounds are suggested to be formed by a Diels−Alder mechanism.[28] In recent years it has been shown that extracts of other *Allium* species have α-glucosidase inhibitory activity; for example, *N*-*p*-coumaroyltyramine in *Allium fistulosum*[29] and quercetin in *A. cepa*,[30] as well as a quercetin dimer,[31] are potent α-glucosidase inhibitors. In this work it was shown that the relative α-glucosidase inhibitory activities observed for the extract of scales of *A. ascalonicum* is **1** > **2** > **3** > **4** on the basis of the α-glucosidase inhibition profile. This correlates well with the intensity of the corresponding peaks, **1** > **2** > **3** > **4**, but further pharmacological characterization is needed for in-depth understanding of their mode of action. However, the current work shows the potential of scales of *A. ascalonicum*, a production side stream in the food industry, as a future functional food for management of T2D.

Rheum palmatum. The high-resolution α-glucosidase inhibition profile and corresponding HPLC chromatogram of ethyl acetate extract of *R. palmatum* are shown in Figure 3. The chromatogram shows more than 30 well-separated peaks, and eight of these are correlated with α-glucosidase inhibition. These peaks were numbered 5−12 and were subsequently

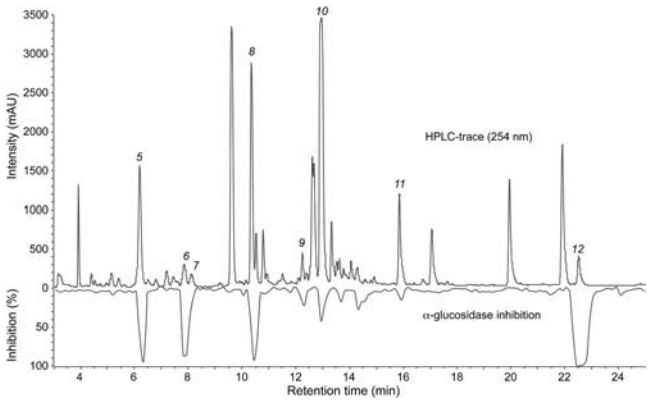

Figure 3. High-resolution α-glucosidase inhibition profile of ethyl acetate extract of *R. palmatum* with overlaid HPLC chromatogram at 254 nm. Peaks numbered 5−12 (corresponding to compounds **5**−**12**) correlated with α-glucosidase inhibition and were therefore analyzed by HPLC−HRMS−SPE−NMR. [Phenomenex C_{18}(2) Luna column, 150 × 4.6 mm, 3 μm, 40 °C, elution rate 0.5 mL/min; elution gradient 0 min, 20% B; 3 min, 20% B; 15 min, 80% B; 16 min, 100% B; 30 min, 100% B; 35 min, 20% B; and 36 min, 20% B; microfractionation from 3 to 25 min in 176 wells].

subjected to HPLC−HRMS−SPE−NMR analysis. HRMS and ^{1}H NMR data are given in Table S3 (Supporting Information), and this allowed identification of (*E*)-piceatannol 3′-*O*-β-D-glucopyranoside (**5**),[32] (*E*)-rhapontigenin 3′-*O*-β-D-glucopyranoside (**6**),[33] (*E*)-piceatannol (**8**),[34] (*E*)-resveratrol (**9**),[32] (*E*)-rhapontigenin (**10**),[32] desoxyrhapontigenin (**11**),[32] and emodin (**12**),[35] in agreement with NMR data from the cited papers. The structures of **5**, **6**, and **8**−**12** are shown in Figure 2. The amount and purity of the material eluted as peak 7 was too low to allow identification of the constituent(s) of this peak.

R. palmatum radix is an important ingredient in traditional Chinese medicine and is known to contain anthraquinones (hydroxyanthracenes), stilbenes, flavonoids, phenolic acids, tannins, and calcium oxalate.[32] *R. palmatum* radix is used as a laxative and has also been shown to contain two stilbene glucosides, 4′-*O*-methylpiceid and rhapontin, with α-glucosidase inhibitory activity.[36] This paper shows that *R. palmatum* contains several other analytes that also possess α-glucosidase inhibitory activity. However, the maximum allowed dose of *R. palmatum* is restricted to a dose providing 30 mg of hydroxyanthracene glycosides daily,[37] and use for more than 1−2 weeks requires medical supervision. Thus, a selective extraction protocol that omits the hydroxyanthracene glycosides is needed for prolonged use of *R. palmatum* root as a future functional food for type 2 diabetics.

Cinnamomum zeylanicum. As seen in Supporting Information Figure S2, the α-glucosidase inhibitory activity of methanol extract of cinnamon bark is correlated with the broad hump of tannins eluting at 10−30 min. The ethyl acetate extract is almost devoid of this tannin hump while maintaining α-glucosidase inhibitory activity (18.0 ± 0.6 μg/mL), albeit with a slightly higher IC_{50} value than for the methanol extract of cinnamon bark (9.0 ± 2.0 μg/mL).

The high-resolution biochromatogram of the ethyl acetate extract is shown in Figure 4, and it is clearly devoid of major peaks showing α-glucosidase inhibition. However, the areas around 18.5−19.5 and 21−23.5 min show repeatedly weak and broad inhibition profiles of up to 20% inhibition in separate experiments (data not shown). On the basis of HRMS and ^{1}H

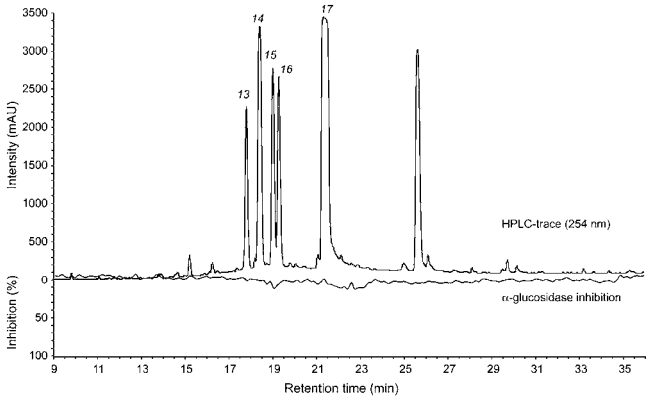

Figure 4. High-resolution α-glucosidase inhibition profile of ethyl acetate extract of *C. zeylanicum* with overlaid HPLC chromatogram at 254 nm. Peaks numbered 13−17 (corresponding to compounds **13**−**17**) were analyzed by HPLC−HRMS−SPE−NMR. [Phenomenex C_{18}(2) Luna column, 150 × 4.6 mm, 3 μm, 40 °C, elution rate 0.5 mL/min; elution gradient: 0 min, 0% B; 30 min, 100% B; 35 min, 100% B; 36 min, 0% B; and 42 min, 0% B; microfractionation from 9 to 36 min in 176 wells].

NMR data obtained in HPLC−HRMS−SPE−NMR mode (Table S4, Supporting Information), the compounds eluted as peaks 13−17 were assigned as (*E*)-2-hydroxycinnamaldehyde (**13**),[38] coumarin (**14**),[39] (*E*)-cinnamyl alcohol (**15**),[40] (*E*)-cinnamic acid (**16**),[41] and (*E*)-cinnamaldehyde (**17**).[42] Extract of cinnamon has previously been shown to inhibit α-glucosidase and lower postprandial glucose in diabetic rats,[43,44] but IC_{50} values of cinnamic acid (>5 mM)[45] and cinnamaldehyde (~225 μM)[46] against α-glucosidase are moderate to high. Thus, the observed α-glucosidase inhibitory effect of methanol as well as ethyl acetate extract of *C. zeylanicum* is likely to be a combined effect of tannins and one or more weak to moderate inhibitors.

In conclusion, quercetin (**1**) and its dimer (**2**), trimer (**3**), and tetramer (**4**) from *A. ascalonicum* as well as (*E*)-piceatannol 3′-*O*-β-D-glucopyranoside (**5**), (*E*)-rhapontigenin 3′-*O*-β-D-glucopyranoside (**6**), (*E*)-piceatannol (**8**), and emodin (**12**) from *R. palmatum* are responsible for the major α-glucosidase inhibitory activity of ethyl acetate extracts of the two plants. This shows that *A. ascalonicum* and *R. palmatum* hold potential as future functional foods, but further studies for investigation of optimal preparation procedures and seasonal variations, as well as in vivo activity and safety of optimized preparations, are needed.

mass spectrometry (LC/MS), we established the chemical profile of phytosterols in WB. Furthermore, the structure−activity relationship (SAR) of sterol oxides against the growth of human colon cancer cells was discussed on the basis of both purified and synthesized compounds **1**−**8** and **13**.

MATERIALS AND METHODS

Materials. Cholesterol, β-sitosterol, stigmasterol, and pregnenolone were purchased from Sigma (St. Louis, MO) or Thermo Fisher Scientific (Waltham, MA). Anhydrous reactions were carried out in oven-dried glassware under a nitrogen atmosphere unless otherwise noted. Analytical (250 μm thickness, 2−25 μm particle size) and preparative thin layer chromatography (TLC) plates (1000 μm thickness, 2−25 μm particle size) were purchased from Sigma (St. Louis, MO) and Sorbent Technologies (Atlanta, GA), respectively. Sephadex LH-20 was purchased from Sigma (St. Louis, MO). Medium pressure column chromatography was carried out over reverse phase silica gel (60 Å, Sigma, St. Louis, MO), equipped with LabAlliance Series I pump and Spectra/chrom fraction collector CF-2. LC/MS-grade solvents and other reagents were obtained from Thermo Fisher Scientific (Waltham, MA). HCT-116 and HT-29 human colon cancer cells were obtained from American Type Tissue Culture (Manassas, VA). McCoy's 5A medium was purchased from Thermo Fisher Scientific (Waltham, MA). Fetal bovine serum (FBS) and penicillin/streptomycin were purchased from Gemini Bio-Products (West Sacramento, CA). MTT (3-(4,5-dimethylthiaxol-2-yl)-2,5-diphenyltetrazolium bromide) was procured from Calbiochem-Novabiochem (San Diego, CA). Apoptag Plus Peroxydase *In Situ* Apoptosis Detection Kit was purchased from Millipore (Billerica, MA).

Preparation of Sterol-Enriched Fraction from WB. Eight fractions (F1−F8) were obtained from WB oil, as described in our previous study.[11] Briefly, wheat bran, provided by ConAgra Food Ingredients Company, was extracted by 95% ethanol at 40 °C for 24 h to give an ethanol extract. After evaporation, the ethanol residue was then suspended in water and partitioned with ethyl acetate (EA). After removal of EA in vacuo, the WB oil was obtained. The WB oil was subjected to column chromatography (CC) over a normal phase silica gel eluted with a mixture of hexane and EA, affording F1−F8, which are stored at −80 °C until analysis. Phytosterols could be detected in both F7 and F8. In order to avoid the analytical interference from ARs in F7, we enriched sterols from F8. Specifically, part of F8 (6.0 g) was subjected to reverse phase (RP) C_{18} silica gel medium pressure CC (30 mm × 360 mm, 60 Å) eluted with 50% methanol, methanol, and methanol containing 0.2% formic acid (FA). Sphingolipids remained in acidic methanol eluate. The neutral methanol fraction was further loaded on Sephadex LH-20 CC eluted with 50% ethanol and ethanol. The ethanol eluates were evaporated *in vacuo*, giving the sterol-enriched fraction (2.0 g).

Purification of Oxyphytosterols 1−4 from Sterol-Enriched Fraction and Their NMR Data. Repeated purification of the sterol-enriched fraction (1.0 g) by RP C_{18} silica gel medium pressure CC eluted with methanol, giving stigmast-4-en-6β-ol-3-one (**1**) (4 mg), stigmast-4,22-dien-6β-ol-3-one (**2**) (6 mg), stigmast-5-en-3β-ol-7-one (**3**) (8 mg), and stigmast-5,22-dien-3β-ol-7-one (**4**) (5 mg).

*Stigmast-4-en-6β-ol-3-one (**1**) as a White Solid.* ^{1}H NMR (700 MHz, Py-d5) δ 1.64 (1H, m, H-1a), 1.92 (1H, m, H-1b), 2.45 (1H, m, H-2a), 2.60 (1H, m, H-2b), 6.07 (1H, s, H-4), 4.57 (1H, m, H-6), 1.28 (1H, m, H-7a), 2.21 (1H, m, H-7b), 2.30 (1H, m, H-8), 0.91 (1H, m, H-9), 1.48 (2H, m, H-11), 1.17 (1H, m, H-12a), 2.04 (1H, m, H-12b), 1.02 (1H, m, H-14), 1.16 (1H, m, H-15a), 1.65 (1H, m, H-15b), 1.27 (1H, m, H-16a), 1.88 (1H, m, H-16b), 1.17 (1H, m, H-17), 0.74 (3H, s, H-18), 1.57 (3H, s, H-19), 1.43 (1H, m, H-20), 1.02 (3H, d, *J* = 6.6 Hz, H-21), 1.14 (1H, m, H-22a), 1.43 (1H, m, H-22b), 1.28 (2H, m, H-23), 1.02 (1H, m, H-24), 1.71 (1H, m, H-25), 0.89 (3H, d, *J* = 6.5 Hz, H-26), 0.91 (3H, d, *J* = 6.5 Hz, H-27), 1.32 (2H, m, H-28), and 0.92 (3H, t, *J* = 6.6 Hz, H-29); ^{13}C NMR (175 MHz, Py-d5) δ 37.9 (t, C-1), 35.4 (t, C-2), 200.1 (s, C-3), 126.3 (d, C-4), 170.3 (s, C-5), 70.3 (d, C-6), 40.1 (t, C-7), 30.7 (d, C-8), 54.5 (d, C-9), 38.9 (s, C-10), 21.7 (t, C-11), 40.4 (t, C-12), 43.2 (s, C-13), 56.7 (d, C-14), 25.0 (t, C-15), 29.0 (t, C-16), 56.6 (d, C-17), 12.5 (q, C-18), 20.0 (q, C-19), 36.8 (d, C-20), 19.4 (q, C-21), 34.6 (t, C-22), 26.9 (t, C-23), 46.5 (d, C-24), 30.0 (d, C-25), 19.6 (q, C-26), 20.4 (q, C-27), 23.9 (t, C-28), and 12.6 (q, C-29); positive ESIMS, *m*/*z* 429 $[M + H]^+$.

*Stigmast-4,22-dien-6β-ol-3-one (**2**) as a White Solid.* ^{1}H NMR (700 MHz, Py-d5) δ 6.07 (1H, s, H-6), 5.24 (1H, dd, *J* = 15.2, 8.8 Hz, H-22), 5.09 (1H, dd, *J* = 15.2, 8.8 Hz, H-23), 4.56 (1H, m, H-6), 2.61 (1H, m), 2.46 (1H, m), 2.28−2.18 (2H, m), 2.09 (1H, m), 2.01 (1H, m), 1.93 (1H, m), 1.78 (1H, m), 1.68−1.41 (5H, m), 1.37−1.0 (10H, m), 1.57 (3H, s, H-19), 1.12 (3H, d, *J* = 6.6 Hz, H-21), 0.94 (3H, t, *J* = 6.5 Hz, H-29), 0.92 (3H, d, *J* = 6.5 Hz, H-27), 0.89 (3H, d, *J* = 6.5 Hz, H-26), and 0.76 (3H, s, H-18); ^{13}C NMR (175 MHz, Py-d5) δ 200.1 (s, C-3), 170.3 (s, C-5),139.2 (d, C-22), 130.0 (d, C-23), 126.3 (d, C-4), 73.0 (d, C-6), 56.7, 56.5, 54.6, 51.9, 43.0, 41.2, 40.2, 40.1, 38.8, 37.9, 35.1, 32.6, 30.7, 29.7, 26.1, 25.0, 21.9, 21.7, 21.6, 20.0, 19.6, 13.0 (q, C-29), and 12.7 (q, C-18); positive ESIMS, *m*/*z* 427 $[M + H]^+$.

*7-Keto-β-sitosterol (**3**) as a White Solid.* ^{1}H NMR (600 MHz, CD_3OD + $CDCl_3$) δ 5.64 (1H, s, H-6), 3.56 (1H, m, H-3), 2.48−2.45 (1H, m), 2.40−2.32 (2H, m), 2.29−2.25 (1H, m), 2.06−2.03 (1H, m), 1.98−1.95 (1H, m), 1.90−1.88 (2H, m), 1.69−1.46 (6H, m), 1.37−1.00 (13H, m), 1.21 (3H, s, H-19), 0.93 (3H, d, *J* = 6.5 Hz, H-21), 0.85 (3H, t, *J* = 7.3 Hz, H-29), 0.83 (3H, d, *J* = 6.8 Hz, H-27), 0.81 (3H, d, *J* = 6.8 Hz, H-26), and 0.70 (3H, s, H-18); ^{13}C NMR (150 MHz, CD_3OD + $CDCl_3$) δ 204.5 (s, C-7), 168.7 (s, C-5), 126.2 (d, C-6), 70.9 (d, C-3), 55.8 (d, C-17), 51.1 (d, C-14), 51.1 (d, C-9), 46.9, 46.4, 44.1, 42.5, 39.7, 39.4, 37.3, 37.1, 34.9, 31.6, 30.1, 29.4, 27.2, 27.0, 23.9, 22.1, 20.2 (q, C-27), 19.5 (q, C-26), 19.4 (q, C-21), 17.7 (q, C-19), 12.4 (q, C-29), and 12.3 (q, C-18); positive ESIMS, *m*/*z* 429 $[M + H]^+$.

*7-Keto-stigmasterol (**4**) as a White Solid.* ^{1}H NMR (600 MHz, CD_3OD + $CDCl_3$) δ 5.63 (1H, s, H-6), 5.15 (1H, dd, *J* = 15.1, 8.7 Hz, H-23), 5.01 (1H, dd, *J* = 15.1, 8.7 Hz, H-22), 3.56 (1H, m, H-3), 2.48−2.45 (1H, m), 2.40−2.34 (1H, m), 2.31−2.24 (2H, m), 2.07−1.99 (2H, m), 1.97−1.94 (1H, m), 1.90−1.87 (1H, m), 1.75−1.71 (1H, m), 1.62−1.38 (7H, m), 1.34−1.10 (7H, m), 1.20 (3H, s, H-19), 1.01 (3H, d, *J* = 6.7 Hz, H-21), 0.83 (3H, d, *J* = 6.4 Hz, H-27), 0.79 (3H, t, *J* = 7.3 Hz, H-29), 0.78 (3H, d, *J* = 6.4 Hz, H-26), and 0.70 (3H, s, H-18); ^{13}C NMR (150 MHz, CD_3OD + $CDCl_3$) δ 204.4 (s, C-7), 168.5 (s, C-5), 139.0 (d, C-22), 130.3 (d, C-23), 126.1 (d, C-6), 70.6 (d, C-3), 55.6 (d, C-17), 52.2, 51.0, 50.9, 46.2, 43.8, 42.3, 41.1, 39.4, 39.3, 37.2, 32.7, 31.4, 29.8, 27.1, 26.1, 21.9, 21.8 (q, C-27), 21.4 (q, C-26), 19.4 (q, C-21), 17.7 (q, C-19), 12.6 (q, C-29), and 12.6 (q, C-18); positive ESIMS, *m*/*z* 427 $[M + H]^+$.

General Procedure A for the Synthesis of Sterol Acetates. A mixture of sterols (1.0 equiv), acetic anhydride (Ac_2O) (10.0 equiv), and pyridine (Py) (50.0 equiv) was incubated at 37 °C overnight. The solvent was removed *in vacuo*. The residue was reconstituted in ethyl acetate (EA), washed with water, dried over Na_2SO_4, and filtered. The filtration was evaporated off, and the residue was subjected to a short pad of Celite, eluting with a mixture of hexane/EA (20:1), to give sterol acetates.

General Procedure B for the Synthesis of 7-Ketosterol Acetates. Chromium trioxide (CrO_3) (15.0 equiv) was suspended in dry dichloromethane (DCM) and stirred for 30 min at −20 °C. 3,5-Dimethylpyrazole (15.0 equiv) was added in one portion, and the reaction mixture was stirred for 30 min at −20 °C. Sterol acetates (1.0 equiv) were added, and the mixture was stirred at −20 °C and allowed to warm up to room temperature (rt) overnight. EA was then added, and the brown suspension was filtered through Celite. The filtration was concentrated, and the residue was purified by CC or pre-TLC to give 7-ketosterol acetates.

General Procedure C for the Synthesis of 7-Ketosterols. LiOH (4.0 equiv) was added at rt to a stirred solution of 7-ketosterol acetates (1.0 equiv) in THF/MeOH/H_2O (3:1:1). The resulting mixture was stirred at rt for 2 h. The organic solvents were evaporated, and the residue was diluted with water, and extracted with EA. The organic layer was washed with water and brine, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was purified by pre-TLC to give 7-ketosterols.

J. Agric. Food Chem. 2015, 63, 2264−2276

General Procedure D for the Synthesis of 7β-Hydroxysterols. A suspension of 7-ketosterols (1.0 equiv) and cerium chloride heptahydrate (4.0 equiv) in methanol was stirred at 0 °C for 10 min. Sodium borohydride (2.5 equiv) was added to the suspension, and the mixture was stirred at rt for 4−18 h. The reaction solution was partitioned between water and EA. The organic layer was washed with water and brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by pre-TLC to give 7β-hydrolxysterols.

General Procedure E for the Synthesis of 3-*O*-(4-Acetoxyferuloyl)-oxysterols. *trans*-4-Acetoxy ferulic acid (1.1 equiv) and 7-oxysterols (1.0 equiv) were dissolved in dry DCM at 0 °C. DCC (3.0 equiv) and DMAP (2.5 equiv) were added, and the mixture was stirred at rt for 6 h. The solid that formed was filtered off, and the solution was washed with water, 10% HOAc, and again with water. The organic extracts were dried over Na_2SO_4 and concentrated *in vacuo*. The residue was purified by pre-TLC to give 3-*O*-(4-acetoxyferuloyl)-oxysterols.

General Procedure F for the Synthesis of Oxysterol Ferulates. 3-*O*-(4-Acetoxyferuloyl)-oxysterols (1.0 equiv) was dissolved in a mixture of DCM/MeOH (2:1, 3 mL). K_2CO_3 (0.2 equiv) was added, and the mixture was stirred at rt for 5 h. The reaction was quenched by adding a saturated aqueous NH_4Cl solution. The organic layers were separated, washed with water and brine, dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by pre-TLC (H/E = 3:1) to give oxysterol ferulates.

Synthesis of Sterol Oxides 3−8. *β-Sitosterol Acetate (**22**).* Procedure A was followed by using β-sitosterol (414 mg, 1.0 mmol), Ac_2O (0.94 mL, 10.0 mmol), and Py (4.07 mL, 50.0 mmol), giving the title compound (456 mg, yield: 100%) as a white solid: positive ESIMS, m/z 457 $[M + H]^+$.

*Stigmasterol Acetate (**23**).* Procedure A was followed by using stigmasterol (412 mg, 1.0 mmol), Ac_2O (0.94 mL, 10.0 mmol), and Py (4.07 mL, 50.0 mmol), giving the title compound (454 mg, yield: 100%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.39 (1H, d, J = 4.7 Hz, H-6), 5.16 (1H, dd, J = 15.1, 8.6 Hz, H-23), 5.03 (1H, dd, J = 15.1, 8.6 Hz, H-22), 4.62 (1H, m, H-3), 2.35−2.31 (2H, m), 2.10−1.95 (4H, m), 2.05 (3H, s, OAc-3), 1.90−1.85 (2H, m), 1.76−1.68 (1H, m), 1.62−1.39 (10H, m), 1.32−1.12 (5H, m), 1.11−0.92 (4H, m), 1.14 (3H, s, H-19), 1.13 (3H, d, J = 6.7 Hz, H-21), 0.86 (3H, d, J = 6.4 Hz, H-27), 0.82 (3H, t, J = 7.3 Hz, H-29), 0.81 (3H, d, J = 6.4 Hz, H-26), and 0.71 (3H, s, H-18); positive ESIMS, m/z 455 $[M + H]^+$.

*Cholesterol Acetate (**24**).* Procedure A was followed by using cholesterol (386 mg, 1.0 mmol), Ac_2O (0.94 mL, 10.0 mmol), and Py (4.07 mL, 50.0 mmol), giving the title compound (428 mg, yield: 100%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.36 (1H, d, J = 5.0 Hz, H-6), 4.59 (1H, m, H-3), 2.34−2.28 (2H, m), 2.04−1.93 (2H, m), 2.03 (3H, s, OAc-3), 1.88−1.78 (3H, m), 1.65−1.40 (8H, m), 1.38−1.20 (4H, m), 1.18−0.90 (9H, m), 1.02 (3H, s, H-19), 0.90 (3H, d, J = 6.5 Hz, H-21), 0.86 (3H, d, J = 6.6 Hz, H-27), 0.85 (3H, d, J = 6.6 Hz, H-26), and 0.66 (3H, s, H-18); positive ESIMS, m/z 429 $[M + H]^+$.

*7-Ketositosterol Acetate (**25**).* Procedure B was followed by using β-sitosterol acetate (**25**) (200 mg, 0.44 mmol), CrO_3 (658 mg, 6.58 mmol), and dimethylpyrazole (632 mg, 6.58 mmol) in dry DCM (20 mL). The resulting residue was purified by pre-TLC (H/E = 8:1) to give the title compound (138 mg, yield: 67%) as a white solid: positive ESIMS, m/z 471 $[M + H]^+$.

*7-Ketostigmasterol Acetate (**26**).* Procedure B was followed by using stigmasterol acetate (**26**) (454 mg, 1.0 mmol), CrO_3 (1.5 g, 15.0 mmol), and dimethylpyrazole (1.44 g, 15.0 mmol) in dry DCM (50 mL). The resulting residue was purified by CC (H/E = 15:1, 10:1, and 8:1) to give the title compound (269 mg, yield: 57%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.68 (1H, H-6), 5.16 (1H, dd, J = 15.1, 8.6 Hz, H-23), 5.01 (1H, dd, J = 15.1, 8.6 Hz, H-22), 4.70 (1H, m, H-3), 2.55−2.51 (1H, m), 2.47−2.42 (1H, m), 2.39−2.33 (1H, m), 2.24−2.20 (1H, m), 2.04−1.93 (4H, m), 2.03 (3H, s, OAc-3), 1.79−1.48 (7H, m), 1.41−1.10 (8H, m), 1.20 (3H, s, H-19), 1.01 (3H, d, J = 6.7 Hz, H-21), 0.83 (3H, d, J = 6.3 Hz, H-27), 0.79 (3H, t, J = 7.3 Hz, H-29), 0.78 (3H, d, J = 6.3 Hz, H-26), and 0.68 (3H, s, H-18); positive ESIMS, m/z 469 $[M + H]^+$.

*7-Ketocholesterol Acetate (**27**).* Procedure B was followed by using cholesterol acetate (**27**) (428 mg, 1.0 mmol), CrO_3 (1.5 g, 15.0 mmol), and dimethylpyrazole (1.44 g, 15.0 mmol) in dry DCM (50 mL). The resulting residue was purified by CC (H/E = 15:1, 10:1, and 8:1) to give the title compound (260 mg, yield: 60%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.69 (1H, s, H-6), 4.70 (1H, m, H-3), 2.55−2.51 (1H, m), 2.48−2.35 (2H, m), 2.26−2.18 (1H, m), 2.07−1.82 (4H, m), 2.06 (3H, s, OAc-3), 1.71−1.47 (5H, m), 1.40−0.99 (13H, m), 1.20 (3H, s, H-19), 0.91 (3H, d, J = 6.5 Hz, H-21), 0.86 (3H, d, J = 6.6 Hz, H-27), 0.85 (3H, d, J = 6.6 Hz, H-26), and 0.67 (3H, s, H-18); positive ESIMS, m/z 443 $[M + H]^+$.

*7-Ketositosterol (**3**).* Procedure C was followed by using 7-keto-β-sitosterol acetate (100 mg, 0.21 mmol) and LiOH (20 mg, 0.84 mmol) in THF/MeOH/H_2O (3:1:1, 5 mL). The resulting residue was purified by pre-TLC (H/E = 2:1) to give the title compound (**3**) (90 mg, yield: 100%).

*7-Ketostigmasterol (**4**).* Procedure C was followed by using 7-keto-stigmasterol acetate (181 mg, 0.39 mmol) and LiOH (37 mg, 1.55 mmol) in THF/MeOH/H_2O (3:1:1, 5 mL). The resulting residue was purified by pre-TLC (C/M = 20:1) to give the title compound (**4**) (166 mg, yield: 100%).

*7β-Hydroxysitosterol (**5**).* Procedure D was followed by using 7-keto-β-stigmasterol (**3**) (30 mg, 0.07 mmol), $CeCl_3{\cdot}7H_2O$ (104 mg, 0.28 mmol), and $NaBH_4$ (7 mg, 0.18 mmol) in MeOH (3 mL). The mixture was stirred at rt for 18 h. The residue was purified by pre-TLC (C/M = 20:1) to give the title compound (**5**) (17 mg, yield: 57%) as a white solid: ^{1}H NMR (600 MHz, CD_3OD + $CDCl_3$) δ 5.24 (1H, s, H-6), 3.72 (1H, d, J = 8.0 Hz, H-7), 3.41 (1H, m, H-3), 2.26−2.18 (2H, m), 2.04−2.02 (1H, m), 1.87−1.78 (4H, m), 1.70−1.66 (1H, m), 1.55−1.33 (6H, m), 1.32−0.99 (13H, m), 1.06 (3H, s, H-19), 0.94 (3H, d, J = 6.5 Hz, H-21), 0.86 (3H, t, J = 7.4 Hz, H-29), 0.84 (3H, d, J = 6.8 Hz, H-27), 0.83 (3H, d, J = 6.8 Hz, H-26), and 0.72 (3H, s, H-18); ^{13}C NMR (150 MHz, CD_3OD + $CDCl_3$) δ 144.0 (s, C-5), 127.4 (d, C-6), 73.7 (d, C-7), 72.1 (d, C-3), 57.7 (d, C-17), 56.8 (d, C-14), 50.0, 47.2, 44.0, 42.5, 41.2, 41.0, 38.2, 37.5, 37.4, 35.1, 32.2, 30.3, 29.6, 27.3, 27.1, 24.1, 22.2, 20.2 (q, C-27), 19.5 (q, C-26), 19.4 (q, C-21), 19.3 (q, C-19), 12.3 (q, C-29), and 12.3 (q, C-18); positive ESIMS, m/z 431 $[M + H]^+$.

*7β-Hydroxystigmasterol (**6**).* Procedure D was followed by using 7-keto-stigmasterol (**4**) (100 mg, 0.23 mmol), $CeCl_3{\cdot}7H_2O$ (350 mg, 0.94 mmol), and $NaBH_4$ (22 mg, 0.58 mmol) in MeOH (5 mL). The mixture was stirred at rt for 6 h. The residue was purified by pre-TLC (C/M = 20:1) to give the title compound (**6**) (50 mg, yield: 50%) as a white solid: ^{1}H NMR (600 MHz, CD_3OD + $CDCl_3$) δ 5.24 (1H, s, H-6), 5.16 (1H, dd, J = 15.1, 8.8 Hz, H-23), 5.03 (1H, dd, J = 15.1, 8.8 Hz, H-22), 3.71 (1H, d, J = 8.2 Hz, H-7), 3.42 (1H, m, H-3), 2.29−2.20 (2H, m), 2.06−1.99 (2H, m), 1.87−1.69 (4H, m), 1.58−1.36 (7H, m), 1.31−1.11 (9H, m), 1.06 (3H, s, H-19), 1.03 (3H, d, J = 6.7 Hz, H-21), 0.85 (3H, d, J = 6.3 Hz, H-27), 0.81 (3H, t, J = 7.1 Hz, H-29), 0.80 (3H, d, J = 6.3 Hz, H-26), and 0.73 (3H, s, H-18); ^{13}C NMR (150 MHz, CD_3OD+$CDCl_3$) δ 144.0 (s, C-5), 139.7 (d, C-22), 130.5 (d, C-23), 127.3 (d, C-6), 73.7 (d, C-7), 72.0 (d, C-3), 57.7 (d, C-17), 56.7, 52.7, 50.0, 43.8, 42.4, 41.8, 41.1, 40.8, 38.2, 37.5, 33.1, 32.2, 30.3, 27.3, 26.5, 22.2, 21.9 (q, C-27), 21.5 (q, C-26), 19.5 (q, C-21), 19.4 (q, C-19), 12.7 (q, C-29), and 12.6 (q, C-18); positive ESIMS, m/z 429 $[M + H]^+$.

*7-Ketocholesterol (**7**).* Procedure C was followed by using 7-keto-cholesterol acetate (260 mg, 0.61 mmol) and LiOH (59 mg, 2.44 mmol) in THF/MeOH/H_2O (3:1:1, 5 mL). The resulting residue was purified by pre-TLC ($CHCl_3$/MeOH = 15:1) to give the title compound (**7**) (223 mg, yield: 91%) as a white solid: ^{1}H NMR (600 MHz, CD_3OD + $CDCl_3$) δ 5.63 (1H, s, H-6), 3.55 (1H, m, H-3), 2.48−2.45 (1H, m), 2.41−2.35 (2H, m), 2.30−2.26 (1H, m), 2.06−2.04 (1H, m), 1.98−1.96 (1H, m), 1.90−1.87 (2H, m), 1.63−1.46 (5H, m), 1.39−0.99 (13H, m), 1.22 (3H, s, H-19), 0.94 (3H, d, J = 6.4 Hz, H-21), 0.87 (3H, d, J = 6.6 Hz, H-27), 0.86 (3H, d, J = 6.6 Hz, H-26), and 0.71 (3H, s, H-18); ^{13}C NMR (150 MHz, CD_3OD + $CDCl_3$) δ 204.5 (s, C-7), 168.8 (s, C-5), 126.3 (d, C-6), 71.0 (d, C-3), 56.1 (d,

C-17), 51.3 (d, C-14), 51.2 (d, C-9), 46.5, 44.2, 42.6, 40.6, 39.9, 39.5, 37.5, 37.3, 36.9, 31.7, 29.5, 29.0, 27.3, 24.9, 23.2 (q, C-27), 23.0 (q, C-26), 22.2, 19.4 (q, C-21), 17.1 (q, C-19), and 12.4 (q, C-18); positive ESIMS, m/z 401 $[M + H]^+$.

*7β-Hydroxycholesterol (**8**).* Procedure D was followed by using 7-keto-cholesterol (**7**) (100 mg, 0.26 mmol), $CeCl_3{\cdot}7H_2O$ (388 mg, 1.04 mmol), and $NaBH_4$ (25 mg, 0.65 mmol) in MeOH (8 mL). The mixture was stirred at rt for 4 h. The residue was purified by pre-TLC (C/M = 15:1) to give the title compound (**8**) (58 mg, yield: 58%) as a white solid: ^{1}H NMR (600 MHz, CD_3OD+$CDCl_3$) δ 5.24 (1H, s, H-6), 3.72 (1H, d, J = 8.2 Hz, H-7), 3.42 (1H, m, H-3), 2.27−2.18 (2H, m), 2.05−2.02 (1H, m), 1.89−1.78 (4H, m), 1.56−1.25 (10H, m), 1.18−0.99 (9H, m), 1.06 (3H, s, H-19), 0.93 (3H, d, J = 6.5 Hz, H-21), 0.87 (3H, d, J = 6.6 Hz, H-27), 0.86 (3H, d, J = 6.6 Hz, H-26), and 0.71 (3H, s, H-18); ^{13}C NMR (150 MHz, CD_3OD + $CDCl_3$) δ 143.9 (s, C-5), 127.3 (d, C-6), 73.6 (d, C-7), 72.0 (d, C-3), 57.6 (d, C-17), 56.9 (d, C-14), 49.9, 43.9, 42.4, 41.1, 40.9, 40.6, 38.2, 37.4, 37.3, 37.0, 32.2, 29.6, 29.0, 27.2, 24.9, 23.2 (q, C-27), 23.0 (q, C-26), 22.2, 19.5 (q, C-21), 19.4 (q, C-19), and 12.4 (q, C-18); positive ESIMS, m/z 403 $[M + H]^+$.

Synthesis of Sterol Ferulates 13 and 13a. *3-O-(4-Acetoxyferuloyl)-7β-hydroxycholesterol (**28**).* *trans*-4-Acetoxy ferulic acid was prepared followed procedure A by using *trans*-ferulic acid (582 mg, 3.0 mmol), Ac_2O (2.8 mL, 30.0 mmol), and Py (12 mL, 150 mmol). The mixture was incubated at 37 °C overnight. The organic solvent was removed *in vacuo* to give *trans*-4-acetoxy ferulic acid (700 mg, yield: 100%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 7.73 (1H, d, J = 15.9 Hz, H-1), 7.14 (1H, d, J = 8.1 Hz, H-6′), 7.12 (1H, s), 7.06 (1H, d, J = 8.1 Hz, H-6′), 6.39 (1H, d, J = 15.9 Hz, H-2), 3.87 (3H, s, OCH_3-3′), and 2.32 (3H, s, OAc-4′); positive ESIMS, m/z 237 $[M + H]^+$.

Procedure E was followed by using *trans*-4-acetoxy ferulic acid (20 mg, 0.08 mmol), 7β-hydroxycholesterol (31 mg, 0.08 mmol), DCC (50 mg, 0.24 mmol), and DMAP (24 mg, 0.2 mmol) in dry DCM (1 mL). The resulting residue was purified by pre-TLC (H/E = 4:1) to give the title compound (21 mg, yield: 42%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.34 (1H, s, H-6), 4.75 (1H, m, H-3), 3.86 (1H, d, J = 8.3 Hz, H-7), 2.48−2.32 (2H, m), 2.15−0.99 (24H, m), 1.06 (3H, s, H-19), 0.93 (3H, d, J = 6.5 Hz, H-21), 0.87 (3H, d, J = 6.5 Hz, H-27), 0.86 (3H, d, J = 6.5 Hz, H-26), 0.70 (3H, s, H-18), and 4-acetyl ferulate [7.62 (1H, d, J = 15.9 Hz, H-7′), 7.10 (1H, d, J = 8.1 Hz, H-6′), 7.09 (1H, s, H-2′), 7.04 (1H, d, J = 8.1 Hz, H-5′), 6.35 (1H, d, J = 15.9 Hz, H-8′), 3.85 (3H, s, OMe-3′), and 2.31 (3H, s, OAc-4′)]; positive ESIMS, m/z 621 $[M + H]^+$.

*3-O-(4-Acetoxyferuloyl)-7-ketocholesterol (**29**).* Procedure E was followed by using *trans*-4-acetoxy ferulic acid (18 mg, 0.075 mmol), 7-keto-cholesterol (20 mg, 0.05 mmol), DCC (31 mg, 0.15 mmol), and DMAP (16 mg, 0.13 mmol) in dry DCM (1 mL). The resulting residue was purified by pre-TLC (H/E = 4:1) to give the title compound (18 mg, yield: 58%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.72 (1H, s, H-6), 4.85 (1H, m, H-3), 2.64−2.61 (1H, m), 2.56−2.51 (1H, m), 2.42−2.38 (1H, m), 2.26−2.21 (1H, m), 2.08−1.98 (2H, m), 1.93−1.87 (1H, m), 1.77−1.74 (1H, m), 1.58−1.48 (5H, m), 1.37−0.99 (13H, m), 1.20 (3H, s, H-19), 0.92 (3H, d, J = 6.5 Hz, H-21), 0.85 (3H, d, J = 6.5 Hz, H-27), 0.84 (3H, d, J = 6.5 Hz, H-26), 0.68 (3H, s, H-18), and 4-acetyl ferulate [7.63 (1H, d, J = 15.9 Hz, H-7′), 7.10 (1H, d, J = 8.2 Hz, H-6′), 7.09 (1H, s, H-2′), 7.04 (1H, d, J = 8.2 Hz, H-5′), 7.35 (1H, d, J = 15.9 Hz, H-8′), 3.84 (3H, s, OMe-3′), and 2.31 (3H, s, OAc-4′)]; positive ESIMS, m/z 619 $[M + H]^+$.

*7-Ketocholesterol Ferulate (**13**).* Procedure F was followed by using 3-*O*-(4-acetoxyferuloyl)-7-ketocholesterol (15 mg, 0.024 mmol) and K_2CO_3 (0.52 mg, 0.0049 mmol) in DCM/MeOH (2:1, 3 mL). The residue was purified by pre-TLC (H/E = 3:1) to give the title compound **13** (10 mg, yield: 71%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.72 (1H, s, H-6), 4.84 (1H, m, H-3), 2.65−2.51 (2H, m), 2.44−2.37 (1H, m), 2.28−2.20 (1H, m), 2.10−1.85 (4H, m), 1.80−1.48 (3H, m), 1.40−1.20 (8H, m), 1.18−0.99 (6H, m), 1.23 (3H, s, H-19), 0.91 (3H, d, J = 6.5 Hz, H-21), 0.86 (3H, d, J = 6.5 Hz, H-27), 0.85 (3H, d, J = 6.5 Hz, H-26), 0.68 (3H, s, H-18), and ferulate moiety [7.60 (1H, d, J = 15.8 Hz, H-7′), 7.06 (1H, d, J = 8.2 Hz, H-6′), 7.02 (1H, s, H-2′), 6.90 (1H, d, J = 8.2 Hz, H-5′), 6.26 (1H, d, J = 15.8 Hz, H-8′), and 3.92 (3H, s, OMe-3′)]; ^{13}C NMR (150 MHz, $CDCl_3$) δ 202.0 (s, C-7), 164.0 (s, C-5), 126.7 (d, C-6), 72.1 (d, C-3), 54.8, 50.0, 49.8, 45.4, 43.1, 39.5, 38.7, 38.4, 37.9, 36.2, 36.1, 35.7, 28.5, 28.0, 27.5, 26.3, 23.8, 22.8 (q, C-27), 22.6 (q, C-26), 21.2, 18.9 (q, C-21), 17.3 (q, C-19), 12.0 (q, C-18), and ferulate moiety [166.4 (s, C═O, C-9′), 148.0 (s, C-4′), 146.8 (s, C-3′), 145.1 (d, C-7′), 126.9 (s, C-1′), 123.1 (d, C-6′), 115.4 (d, C-8′), 114.7 (d, C-5′), 109.3 (d, C-2′), and 55.9 (q, OMe-3′)]; positive ESIMS, m/z 577 $[M + H]^+$.

*7β-Hydroxycholesterol Ferulate (**13a**).* Procedure F was followed by using 3-*O*-(4-acetoxyferuloyl)-7β-hydroxycholesterol (21 mg, 0.034 mmol) and K_2CO_3 (1.0 mg, 0.0068 mmol) in DCM/MeOH (2:1, 3 mL). The residue was purified by pre-TLC (H/E = 3:1) to give the title compound **13a** (16 mg, yield: 80%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.34 (1H, s, H-6), 4.76 (1H, m, H-3), 3.87 (1H, d, J = 7.8 Hz, H-7), 2.48−2.37 (2H, m), 2.05−1.79 (5H, m), 1.70−1.22 (10H, m), 1.18−0.99 (9H, m), 1.09 (3H, s, H-19), 0.93 (3H, d, J = 6.5 Hz, H-21), 0.87 (3H, d, J = 6.5 Hz, H-27), 0.86 (3H, d, J = 6.5 Hz, H-26), 0.70 (3H, s, H-18), and ferulate moiety [7.60 (1H, d, J = 15.9 Hz, H-7′), 7.06 (1H, dd, J = 8.2, 1.6 Hz, H-6′), 7.03 (1H, d, J = 1.6 Hz, H-2′), 6.91 (1H, d, J = 8.2 Hz, H-5′), 6.27 (1H, d, J = 15.9 Hz, H-8′), and 3.92 (3H, s, OMe-3′)]; ^{13}C NMR (150 MHz, $CDCl_3$) δ 142.5 (s, C-5), 126.3 (d, C-6), 73.4 (d, C-7), 73.3 (d, C-3), 55.8 (d), 55.4 (d), 48.2, 42.9, 40.8, 39.6, 39.5, 37.8, 36.7, 36.6, 36.2, 35.7, 28.5, 28.0, 27.9, 26.4, 23.8, 22.8 (q, C-27), 22.6 (q, C-26), 21.0, 19.2 (q, C-19), 18.8 (q, C-19), 11.8 (q, C-18), and ferulate moiety [166.6 (s, C═O, C-9′), 147.9 (s, C-4′), 146.7 (s, C-3′), 144.7 (d, C-7′), 127.0 (s, C-1′), 123.1 (d, C-6′), 115.9 (d, C-8′), 114.7 (d, C-5′), 109.3 (d, C-2′), and 55.9 (q, OMe-3′)]; positive ESIMS, m/z 579 $[M + H]^+$.

Synthesis of Aza-oxysterols 7a and 8a. *Pregnenolone Acetate (**30**).* Procedure A was followed by using pregnenolone (1.58 g, 10.0 mmol) and Ac_2O (4.7 mL, 50.0 mmol) in Py (20 mL), giving the title compound (3.58 g, yield: 100%) as a white solid: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.35 (1H, m, H-6), 4.32 (1H, m, H-3), 2.58−2.52 (2H, m), 2.39−2.31 (1H, m), 2.23−2.12 (1H, m), 2.12 (3H, s, H-21), 2.04 (3H, s, OAc-3), 2.0−1.2 (16H, m), 1.37 (3H, s, H-19), and 0.64 (3H, s, H-18); positive ESIMS, m/z 359 $[M + H]^+$.

*20-Aza-cholesterol Acetate (**31**).* Pregnenolone acetate (358 mg, 1.0 mmol) was dissolved in 10 mL of methanol, and isopentylamine (522 mg, 6.0 mmol) was added. pH value of the solution was adjusted to around 6 by adding HOAc (1.0 mL). Then, 10 mL of THF and $NaBH_3CN$ (82 mg, 1.1 mmol) in methanol (2 mL) were added, and the reaction mixture was stirred under reflux overnight. After evaporation *in vacuo*, the resulted residue was resuspended in 10 mL of water, and the pH was adjusted to 8 by 10% Na_2CO_3 solution. The solution was extracted with DCM (10 mL × 3), washed with water (10 mL) and brine (10 mL), dried over Na_2SO_4, and concentrated under reduced pressure. The residue was purified by CC (H/E = 5:1; H/E/TEA = 5:1:0.1 and 3:1:0.1) to give the title compound (446 mg, yield: 85%) as a colorless gum: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.37 (1H, m, H-6), 4.60 (1H, m, H-3), 2.90−2.75 (1H, m, H-20), 2.38−2.28 (2H, m, H-23), 2.05 (3H, s, OAc-3), 2.02−1.92 (1H, m), 1.90−1.80 (2H, m), 1.75−1.41 (12H, m), 1.40−1.10 (8H, m), 1.01 (3H, s, H-19), 0.98−0.84 (9H, m, H-21, H-26 and H-27), and 0.73 (3H, s, H-18); positive ESIMS, m/z 430 $[M + H]^+$.

*7-Keto-20-aza-cholesterol Acetate (**32**).* Procedure B was followed by using 20-aza-cholesterol acetate (446 mg, 1.04 mmol), CrO_3 (1.56 g, 15.6 mmol), and dimethylpyrazole (1.50 g, 15.6 mmol) in dry DCM (50 mL). The mixture was stirred at rt for 6 h. After addition of EA, the mixture was filtered through a short pad of Celite eluted by a mixture of EA and TEA (30:1), and the filtration was concentrated *in vacuo*. The resulted residue was purified by CC (H/E = 5:1; H/E/TEA = 5:1:0.1 and 3:1:0.1) to give the title compound (314 mg, yield: 68%) as a yellow gum: ^{1}H NMR (600 MHz, $CDCl_3$) δ 5.70 (1H, m, H-6), 4.71 (1H, m, H-3), 2.98−2.80 (1H, m, H-20), 2.58−2.41 (2H, m, H-23), 2.30−2.10 (2H, m), 2.05 (3H, s, OAc-3), 2.02−1.20 (19H, m), 1.18 (3H, s, H-19), 0.98−0.84 (9H, m, H-21, H-26 and H-27), and 0.75 (3H, s, H-18); positive ESIMS, m/z 444 $[M + H]^+$.

*7-Keto-20-aza-cholesterol (**7a**).* Procedure C was followed by using 7-keto-20-aza-cholesterol acetate (314 mg, 0.71 mmol) and

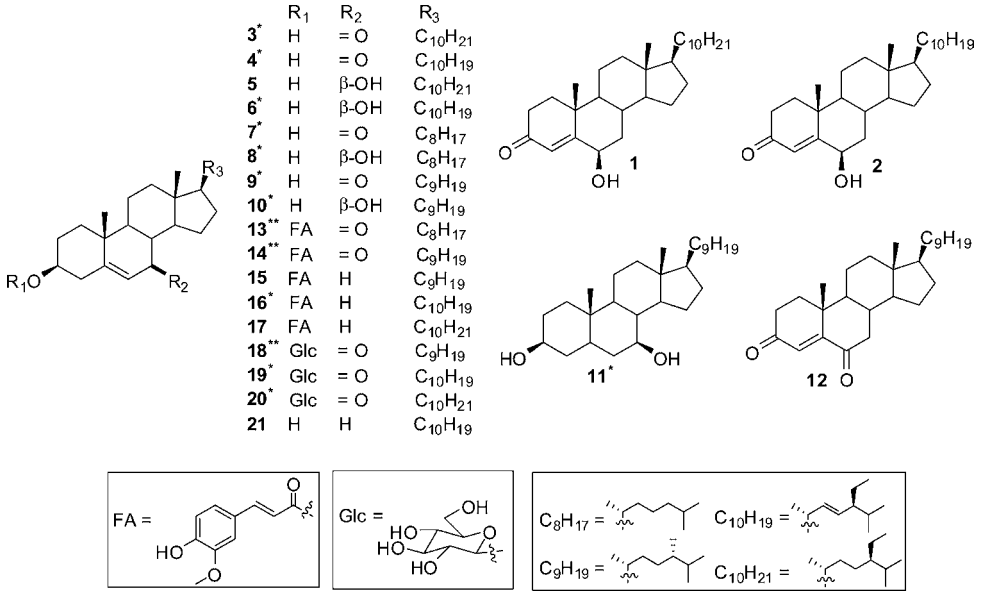

Figure 1. Structures of steroids **1**−**21** identified from wheat bran extract. *Reported in wheat bran for the first time. **New compounds.

LiOH (68 mg, 2.84 mmol) in THF/MeOH/H_2O (3:1:1, 5 mL). The mixture was stirred at rt for 1 h. After removal of the organic solvent, the residue was partitioned between water (5 mL) and DCM (5 mL). DCM extracts were washed with water and brine, dried over Na_2SO_4, and concentrated *in vacuo*. The residue was purified by CC (H/E/TEA = 5:1:0.5, 3:1:0.5, 2:1:0.5, and 1.5:1:0.5) to give the title compound (**7a**) (240 mg, yield: 85%) as a white solid: ^{1}H NMR (700 MHz, $CDCl_3$) δ 5.69 (1H, s, H-6), 3.67 (1H, m, H-3), 2.97−2.86 (1H, m, H-20), 2.53−2.49 (2H, m, H-23), 2.41−2.38 (1H, m), 2.25−2.21 (1H, m), 1.96−1.87 (2H, m), 1.85−1.77 (2H, m), 1.70−1.66 (2H, m), 1.64−1.58 (2H, m), 1.57−1.50 (1H, m), 1.45−1.21 (10H, m), 1.18 (3H, s, H-19), 0.94 (3H, d, J = 6.5 Hz, H-21), 0.93 (6H, d, J = 6.5 Hz, H-26/27), and 0.78 (3H, s, H-18); positive ESIMS, m/z 402 $[M + H]^+$.

*7β-Hydroxy-20-aza-cholesterol (**8a**).* Procedure D was followed by using 7-keto-20-aza-cholesterol (**7a**) (284 mg, 0.71 mmol), $CeCl_3 \cdot 7H_2O$ (1.59 g, 4.26 mmol), and $NaBH_4$ (108 mg, 2.84 mmol) in MeOH (10 mL) at −10 °C. The mixture was stirred at −10 °C for 5 min and quenched with water (1 mL). After removal of most of the organic solvent, the residue was partitioned between water (10 mL) and DCM (10 mL). DCM extracts were washed, dried, and concentrated. The resulted residue was purified by CC (H/E/TEA = 5:1:0.1, 2:1:0.1, 2:1:0.5, and 1:1:0.5) to give the title compound (**8a**) (100 mg, yield: 35%) as a white solid: ^{1}H NMR (700 MHz, $CDCl_3$) δ 5.27 (1H, s, H-6), 3.83 (1H, d, J = 8.1 Hz, H-7), 3.54 (1H, m, H-3), 2.99 (1H, m, H-20), 2.88 (1H, m, H-23a), 2.68 (1H, m, H-23b), 2.35−2.31 (1H, m), 2.28−2.22 (1H, m), 1.98−1.83 (5H, m), 1.66−1.57 (4H, m), 1.53−1.46 (4H, m), 1.42−1.30 (4H, m), 1.25−1.16 (4H, m), 1.16 (3H, s, H-19), 0.94 (3H, d, J = 6.7 Hz, H-21), 0.93 (3H, d, J = 6.5 Hz, H-27), 0.92 (3H, d, J = 6.5 Hz, H-26), and 0.73 (3H, s, H-18); ^{13}C NMR (175 MHz, $CDCl_3$) δ 143.5 (s, C-5), 125.6 (d, C-6), 73.3 (d, C-7), 71.3 (d, C-3), 63.2 (d, C-20), 55.2 (d, C-17), 48.1, 45.9, 43.5, 42.9, 41.7, 40.6, 37.7, 37.5, 37.0, 36.6, 31.5, 28.2, 26.7, 26.3, 22.6, 22.4 (q, C-26/27), 20.8 (q, C-21), 19.1 (q, C-19), and 12.7 (q, C-18); positive ESIMS, m/z 404 $[M + H]^+$.

LC/MS Analysis. LC/MS analysis was carried out with a Thermo-Finnigan Spectra System consisting of an Accela high speed MS pump, an Accela refrigerated autosampler, and an LCQ Fleet ion trap mass detector (Thermo Electron, San Jose, CA) incorporated with an electrospray ionization (ESI) interface. A Gemini-NX C_{18} column (150 mm × 3.0 mm i.d., 5 μm, Phenomenex) was used to analyze authentic sterol oxides and the sterol-enriched fraction with a flow rate of 0.3 mL/min. The binary mobile phase system consisted of water with 0.2% acetic acid (AA) as phase A and methanol with 0.2% AA as phase B. The column was eluted by a gradient progress (80 to 90% B from 0 to 10 min; 90 to 95% B from 10 to 20 min; 95−99% B from 20 to 30 min; 99−100% B from 30 to 45 min; 100% B from 45 to 65 min, and then 80% B from 65 to 70 min). The injection volume was 10 μL for each sample. The column temperature was maintained at 20 °C. To optimize the mass spectrometric parameters, each standard dissolved in methanol (10 μM) was infused in the ESI source by a syringe pump (flow rate 10 μL/min) and analyzed in positive ion mode. The optimized parameters for analysis of oxyphytosterols are capillary voltage 16 V, spray voltage 4.6 kV, tube lens offset 70 V, capillary temperature 260 °C, and sheath gas (nitrogen) flow rate 25 (arbitrary units). The structural information on compounds **1**−**21** were obtained by tandem mass spectrometry (MS/MS) through collision-induced dissociation (CID) with a relative collision energy setting of 35%. Data acquisition was performed with Xcalibur version 2.0 (Thermo Electron, San Jose, CA).

Nuclear Magnetic Resonance (NMR). ^{1}H, ^{13}C NMR, and two-dimensional (2-D) NMR spectra were recorded on a Bruker AVANCE 600 or 700 MHz spectrometer (Bruker Inc., Silberstreifen, Rheinstetten, Germany). Compounds were analyzed in $CDCl_3$, CD_3OD, or pyridine-d_5. Multiplicities are indicated by s (singlet), d (doublet), t (triplet), q (quartet), and br (broad). The ^{13}C NMR spectra are proton decoupled.

MTT Assay. Cell growth inhibition was determined by a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay.[21] Human colon cancer cells HCT-116 and HT-29 were plated in 96-well microtiter plates with 5000 cells/well and allowed to attach for 24 h at 37 °C. The test compounds in dimethyl sulfoxide (DMSO) were added to cell culture medium to the desired final concentrations (final DMSO concentrations for control and treatments were 0.1%). After the cells were cultured for 24 h, the medium was aspirated, and cells were treated with 200 μL fresh medium containing 2.41 mmol/L MTT. After incubation for 3 h at 37 °C, the medium containing MTT was aspirated, 100 μL of DMSO was added to solubilize the formazan precipitate, and plates were shaken gently for an hour at room temperature. Absorbance values were derived from the plate reading at 550 nm on a Biotek microtiter plate reader (Winooski, VT). The reading reflected the number of viable cells and was expressed as a percentage of viable cells in the control. Both HCT-116 and HT-29 cells were cultured in McCoy's 5A medium. All of the above media were supplemented with 10% fetal bovine serum, 1% penicillin/streptomycin, and 1% glutamine, and the cells were kept in a 37 °C incubator with 95% humidity and 5% CO_2.

Apoptotic Assay. The Cell Death Detection ELISA (enzyme-linked immunoabsorbant assay) Plus kit from Roche (Mannheim, Germany) was used. HCT-116 and HT-29 cells were seeded in 96-well plates at

3000 cells/well and incubated at 37 °C in 5% CO_2 incubator. After 24 h, fresh media supplemented with DMSO (control), **5**, **6**, **7**, or **8** (5, 10, 20, or 30 μM; final DMSO concentration for control and treatments was 0.1%) were added to the wells. After 48 h, the microplate was centrifuged for 10 min at 1200 rpm, and the supernatant was removed. Then, 200 μL of the lysis buffer was added in each well, and the microplate was incubated for 30 min at room temperature. The plate was then centrifuged for 10 min at 1200 rpm, and 20 μL of the supernatant was transferred to streptavidin-coated microwells. ELISA assay was performed according to manufacturer's instruction. Absorbance in each well was measured at 405 nm in absorbance units (AU), and the enrichment factor (EF) in small nucleosomes was calculated with the formula EF = $AU_{(treated)}/AU_{(DMSO)}$. The experiment was repeated independently to confirm the results.

Statistical Analysis. For simple comparisons between two groups, two-tailed Student's t-test was used. A p-value of less than 0.05 was considered statistically significant in all the tests.

RESULTS

Structural Elucidation of Oxyphytosterols 1−4. The chemical investigation on the sterol-enriched fraction yielded two unusual 3-ketophytosterols **1** and **2**, and two 7-ketophytosterols **3** and **4** (Figure 1). Compound **1** had a molecular formula of $C_{29}H_{48}O_2$ based on positive ESI-MS at m/z 411 $[M - H_2O + H]^+$ and NMR data. One tertiary proton adjacent to oxygen atom, one olefinic proton and six methyl groups in the ^{1}H NMR spectrum of **1**, and a ketone group, four double bond signals, and an oxygenated tertiary carbon in the ^{13}C NMR spectrum of **1**, suggested **1** is oxyphytosterol.[22]

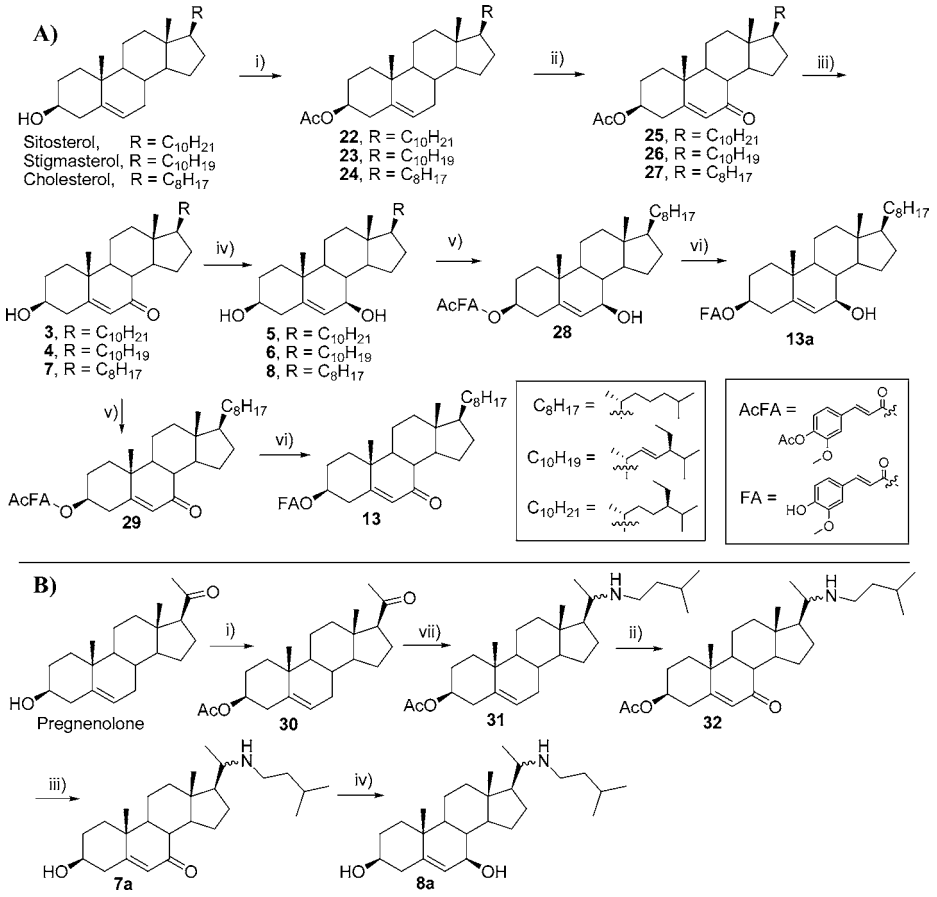

Figure 3. Synthesis of (A) sterol oxides **3**–**8** and oxysterol ferulates **13** and **13a**, and (B) 20-aza-oxysterols **7a** and **8a**. Reagents and conditions: (i) Ac_2O, Py, 37 °C, 18 h; (ii) CrO_3, 3,5-dimethylpyrazole, DCM, −20 °C to rt; (iii) LiOH, THF/MeOH/H_2O, rt; (iv) $CeCl_3{\cdot}7H_2O$, $NaBH_4$, MeOH; (v) 4-acetoxy ferulic acid, DCC, DMAP, DCM, 0 °C to rt, 18 h; (vi) K_2CO_3, DCM/MeOH, rt; (vii) isopentylamine, $NaBH_3CN$, HOAc, MeOH/THF, reflux, 18 h.

Heteronuclear multiple bond correlation (HMBC) established a partial structure of 4-en-6-ol-3-one in **1** (Figure 2). The fragment ion at m/z 253/393/429 $[M - 2H_2O - C_{10}H_{20} + H]^+$ in the MS^3 spectra of **1** (Table 1), corresponding to the loss of two water molecules followed by the cleavage of the side chain, further confirmed **1** as being stigmast-4-en-6β-ol-3-one, as previously described in extracts of wheat straw.[23]

Compound **2** possessed a molecular formula of $C_{29}H_{46}O_2$ based on positive ESI-MS at m/z 409 $[M - H_2O + H]^+$ and NMR data. Its ^1H and ^{13}C NMR data were very similar to those of **1** except for additional olefinic signals [δ_H 5.09 (1H, dd, J = 15.2, 8.8 Hz) and δ_H 5.24 (1H, dd, J = 15.2, 8.8 Hz); and δ_C 130.0 (d) and δ_C 139.2 (s)] in **2**, indicating **2** is stigmast-4,22-dien-6β-ol-3-one, as previously described in extracts of wheat straw.[23]

Compound **3** had the same molecular formula of $C_{29}H_{48}O_2$ to that of **1** based on positive ESI-MS at m/z 411 $[M - H_2O + H]^+$ and NMR data. The ^1H and ^{13}C NMR spectra of **3** were similar to those of **1**, suggesting **3** is also an oxyphytosterol. HMBC correlations established a partial structure of 5-en-3-ol-7-one in **3** (Figure 2). The fragment ion at m/z 253/393/429 $[M - 2H_2O - C_{10}H_{20} + H]^+$ in the MS^3 spectra of **3**, corresponding to the loss of two water molecules followed by the side chain, further confirmed **3** as being stigmast-5-en-3β-ol-7-one, namely 7-ketositosterol, as previously reported from marine sponges.[24] This is the first report of 7-ketositosterol **3** in WB.

Compound **4** had a molecular formula of $C_{29}H_{46}O_2$ based on positive ESI-MS at m/z 409 $[M - H_2O + H]^+$ and NMR data. Its ^1H and ^{13}C NMR data were very similar to those of **3** except for additional olefinic signals [δ_H 5.01 (1H, dd, J = 15.1, 8.7 Hz) and δ_H 5.15 (1H, dd, J = 15.1, 8.7 Hz); and δ_C 130.3 (d) and δ_C 139.0 (d)] in **4**, indicating **4** is an oxidation product of stigmasterol. Fragment ion at m/z 251/391/427 $[M - 2H_2O - C_{10}H_{20} + H]^+$ in the MS^3 spectra of **4** (Table 1), following the same fragmentation patterns as **3**, established **4** as being stigmast-5,22-dien-3β-ol-7-one, namely 7-ketostigmasterol, as previously described elsewhere.[25] This is the first report of 7-ketostigmasterol **4** in WB as well.

Synthesis of Sterol Oxides 3–8, Sterol Ferulates 13 and 13a, and Aza-oxysterols 7a and 8a. Sterol oxides **3**–**8** were synthesized in house in quantities, following the method of McCarthy with some modifications (Figure 3A).[26] Briefly, acetylation of sterols yielded sterol acetates **22**–**24**. The acetates were treated by the combination of chromium trioxide and dimethylpyrazole to give 7-ketosterol acetates **25**–**27**. After hydrolysis using lithium hydroxide, 7-ketosterols **3**, **4**, and **7** were obtained. Luche reduction of 7-ketosterols afforded 7β-hydroxysterols **5**, **6**, and **8**. Coupling reaction of 7-ketocholesterol **7** with 4-acetoxy ferulic acid utilizing *N*,*N*′-dicyclohexylcarbodiimide (DCC) and 4-dimethylaminopyridine (DMAP) followed by deacetylation yielded 7-ketocholesterol ferulate **13**. Likewise, 7β-hydroxycholesterol ferulate **13a** was obtained from 7β-hydroxycholesterol **8**. The synthesis of aza-

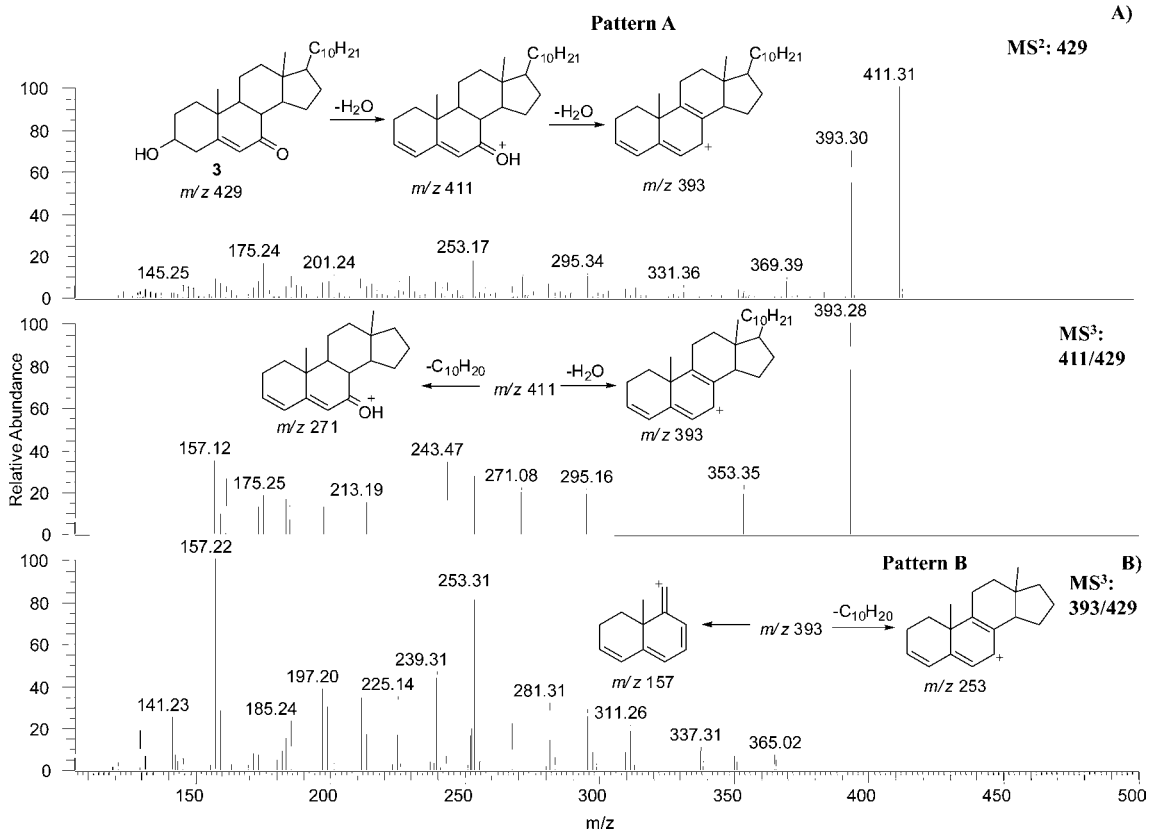

Figure 4. ESI/MS^n (n = 2−3) spectra and fragmentation patterns of compound **3**. (A) Fragmentation pattern A: loss of two water molecules from parent ion forms a stable resonance structure with the positive charge at the C-7 position in MS^2 spectra. (B) Fragmentation pattern B: cleavage of the side chain at the C17−C20 bond in the fragments obtained from pattern A via hydrogen shifts and inductive cleavages produces a typical daughter ion in MS^3 spectra.

oxysterols **7a** and **8a** was illustrated in Figure 3B. Reductive amination of pregnenolone acetate **30** with isopentylamine catalyzed by $NaBH_3(CN)$ in MeOH/THF at pH 6 produced 20-aza-cholesterol acetate **31**.[27] Oxidation of **31** by chromium trioxide followed by treatment with lithium hydroxide afforded 7-keto-20-aza-cholesterol **7a** with a yield of 60%. Luche reduction of **7a** gave 7β-hydroxyl-20-aza-cholesterol **8a** with a yield of 35%. This is the first report of synthesis for 7-keto-20-aza-cholesterol **7a** and 7β-hydroxy-20-aza-cholesterol **8a**.

Characterization of Synthetic Sterol Oxides 5−8, Sterol Ferulates 13 and 13a, and Aza-oxysterols 7a and 8a. Compound **5** was reduced from 7-ketositosterol **3**. Its molecular ion at m/z 431 $[M + H]^+$ is two mass units higher than that of **3**, indicating **5** is the reduction product of **3**. The appearance of one additional signal adjacent to oxygen atom [δ_H 3.72 (1H, d, J = 8.0 Hz) and δ_C 73.7 (d)] in **5** confirmed the conversion of the carbonyl group in **3** into the hydroxyl group in **5**. The fragment ion at m/z 241/395/431 $[M - 2H_2O - C_{10}H_{20} - CH_2 + H]^+$ in the MS^3 spectra of **5** (Table 1), corresponding to the loss of two water molecules followed by the side chain and one methyl group, further supported that **5** was stigmast-5-en-3β,7β-diol, namely, 7β-hydroxysitosterol, as previously reported in wheat flour.[18] Likewise, compound **6** was the product of the reduction of **4** and subsequently established as being stigmast-5,22-dien-3β,7β-diol, namely, 7β-hydroxystigmasterol, as previously reported elsewhere.[25]

Compound **7**, owning a molecular formula of $C_{27}H_{44}O_2$ based on positive ESI-MS at m/z 383 $[M - H_2O + H]^+$ and NMR data, was synthesized from cholesterol. Its ^{1}H and ^{13}C NMR data were very similar to those of **3**, suggesting **7** is an oxidation product of cholesterol. The fragment ion at m/z 253/365/401 $[M - 2H_2O - C_8H_{16} + H]^+$ in the MS^3 spectra of **7** (Table 1), in agreement with the loss of two water molecules followed by the side chain, provided **7** as cholest-5-en-3β-ol-7-one, namely, 7-ketocholesterol, as previously described in marine sponges.[24] Likewise, compound **8**, as the reduction product of **7**, was elucidated as being cholest-5-en-3β,7β-diol, namely 7β-hydroxycholesterol, as previously reported in marine sponges.[24]

Compound **13**, possessing a molecular formula of $C_{37}H_{52}O_5$ based on its positive ESI-MS at m/z 383 $[M - C_{10}H_{10}O_4 + H]^+$ and NMR data, was a ferulic acid conjugate of **7**. HMBC correlation between H-3 (δ_H 4.84) and the carbonyl group (C-9′) of ferulate (δ_C 166.4) established the linkage at C-3 between ferulate moiety and 7-ketocholesterol (Figure 2). The fragment ion at m/z 383/577 $[M - C_{10}H_{10}O_4 + H]^+$ in the MS^2 spectra of **13**, corresponding to the loss of a ferulic acid moiety, further confirmed **13** as being 7-ketocholesterol ferulate. Compound **13a** was synthesized by the coupling reaction of ferulic acid with **8**. Its NMR spectra were similar to those of **13** except for an additional oxygenated signal [δ_H 3.87 (1H, d, J = 7.8 Hz) and δ_C 73.4 (d)], coinciding **13a** being 7β-hydroxycholesterol ferulate.

Compound **7a**, having a molecular formula of $C_{26}H_{43}NO_2$ based on its positive ESI-MS at m/z 402 $[M + H]^+$ and NMR data, was synthesized from pregnenolone through four steps. The ^{1}H NMR spectra of **7a** was similar to that of 7-ketocholesterol **7**. The major difference is the appearance of

J. Agric. Food Chem. 2015, 63, 2264−2276

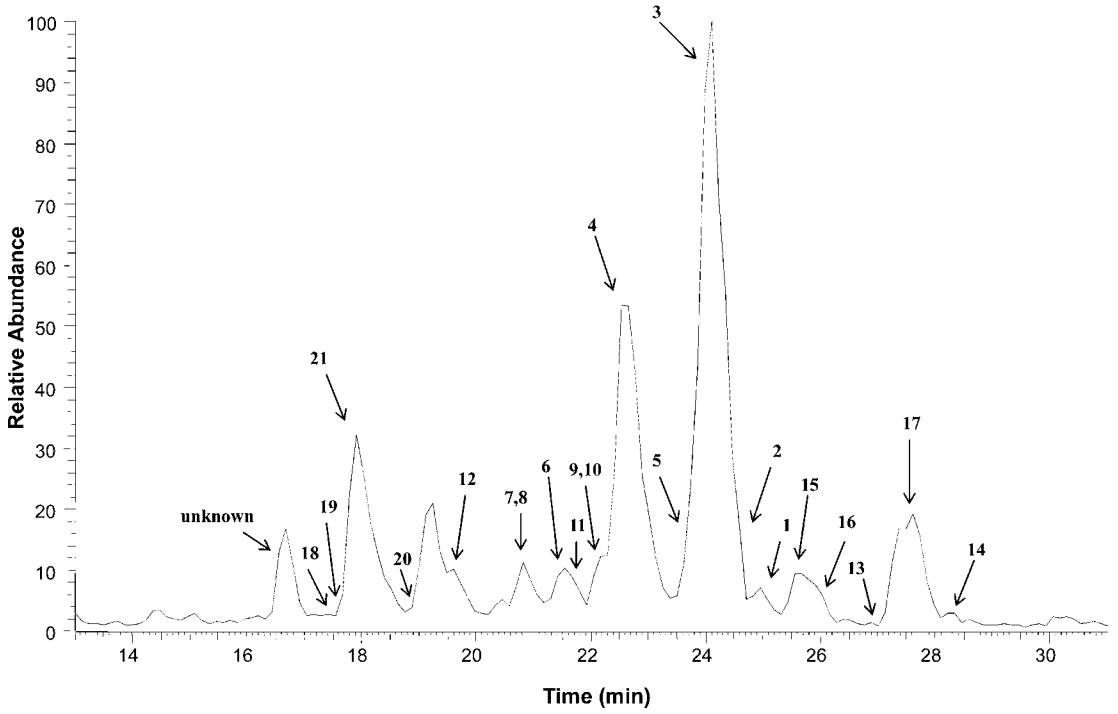

Figure 5. Chemical profile of steroids **1**–**21** in wheat bran extract generated from positive HPLC-ESI/MS^n (n = 2–3).

two multiplets at δ_H 2.97–2.86 (1H, m, H-20) and δ_H 2.53–2.49 (2H, m, H-23) in **7a** compared to those of **7**, indicating **7a** is 7-keto-20-aza-cholesterol. Compound **8a** was the reductive product of **7a**. The ^1H and ^{13}C NMR spectra of **8a** showed an additional oxygenated signal [δ_H 3.83 (1H, d, J = 8.1 Hz) and δ_C 73.3 (d)] compared to **7a**, suggesting **8a** is 7β-hydroxy-20-aza-cholesterol.

Fragmentation Patterns of Authentic Sterol Oxides. There are two major fragmentation patterns of the authentic 7-ketosterols **3**, **4**, and **7** (Table 1) under ESI positive ionization mode, as exemplified by compound **3** in Figure 4, pattern A): loss of two water molecules from parent ion forms a stable resonance structure with the positive charge at C-7 position in MS^2 spectra (Figure 4A), and pattern B): cleavage of the side chain at the C17–C20 bond in the fragments obtained from pattern A via hydrogen shifts and inductive cleavages produces a typical daughter ion in MS^3 spectra (Figure 4B). These fragmentation patterns are consistent with the conclusions that Jiang et al. reported previously.[28] The observation from 7β-hydroxysterols **5**, **6**, and **8** led to a characteristic fragmentation pattern C: the cleavage of the side chain followed by an additional methyl group in the fragments obtained from pattern A gives characteristic tertiary daughter ions in MS^3 spectra (Table 1).

Identification of Steroids 1–21 in WB by LC-ESI/MS^n Spectra. Oxyphytosterols **1**–**4** were isolated from WB extract and identified by NMR experiments. Sterol oxides **5**–**8** and **13** in WB were recognized by comparison of their retention times and tandem mass spectra with those of the synthetic standards (Table 1). Compounds **9**–**12** and **14**–**20** were tentatively elucidated in WB based on the analysis of their tandem mass spectra, referring to fragmentation patterns observed from known standards (Table 1 and Figure 4). Stigmasterol **21** was confirmed in WB by comparison with its commercial authentic standard.

As per the knowledge obtained above, compound **9** had two peak ions with loss of H_2O at m/z 397 $[M - H_2O + H]^+$ and 379 $[M - 2H_2O + H]^+$ in its MS^2 spectra (pattern A), and one daughter ion with loss of the alkyl side chain at m/z 253 $[M - 2H_2O - C_9H_{18} + H]^+$ in its MS^3 spectra (pattern B) (Table 1), indicating that **9** is campest-5-en-3β-ol-7-one, namely 7-ketocampesterol.[29] Compound **10**, with two peak ions at m/z 399 $[M - H_2O + H]^+$ and 381 $[M - 2H_2O + H]^+$ in its MS^2 spectra (pattern A), and one major daughter ion at m/z 241 $[M - 2H_2O - C_9H_{18} - CH_2 + H]^+$ in its MS^3 spectra (pattern C) (Table 1), was identified as campest-5-en-3β,7β-diol, namely, 7β-hydroxycampesterol.[29] Similarly, compound **11**, having two peak ions at m/z 395 $[M - H_2O + H]^+$ and 377 $[M - 2H_2O + H]^+$ in its MS^2 spectra (pattern A), and one tertiary ion at m/z 251 $[M - 2H_2O - C_9H_{18} + H]^+$ in its MS^3 spectra (pattern B), was proposed as ergost-4-en-3,6-dione, as reported previously in wheat straw.[30] Compound **12** owned two peak ions at m/z 401 $[M - H_2O + H]^+$ and 383 $[M - 2H_2O + H]^+$ in its MS^2 spectra (pattern A), and one daughter ion at m/z 243 $[M - 2H_2O - C_9H_{18} - CH_2 + H]^+$ in its MS^3 spectra (pattern C), and was tentatively suggested as ergostane-3β,7β-diol, as described previously elsewhere.[31]

Compound **14**, with a base peak at m/z 397 $[M - C_{10}H_{10}O_4 + H]^+$ in its MS^2 spectra and a major ion at m/z 379 $[M - C_{10}H_{10}O_4 - H_2O + H]^+$ in its MS^3 spectra, had similar fragmentation patterns (loss of ferulic acid moiety) as that of analogue **13** (Table 1), indicating **14** is a sterol ferulate. The molecular weight of **14** at m/z 591 $[M + H]^+$ was 14 mass units higher than that of **13**, suggesting that **14** is 7-ketocampesterol ferulate, which has never been reported before. In a similar manner, compounds **15**–**17**, with major peak ions at m/z 383 $[M - C_{10}H_{10}O_4 + H]^+$, 395 $[M - C_{10}H_{10}O_4 + H]^+$, and 397 $[M - C_{10}H_{10}O_4 + H]^+$ in their respective MS^2 spectra, corresponding to loss of ferulic acid moiety, were identified as campesterol ferulate **15**, stigmasterol ferulate **16**, and sitosterol ferulate **17**, respectively. Of these, campesterol ferulate **15** and

J. Agric. Food Chem. 2015, 63, 2264–2276

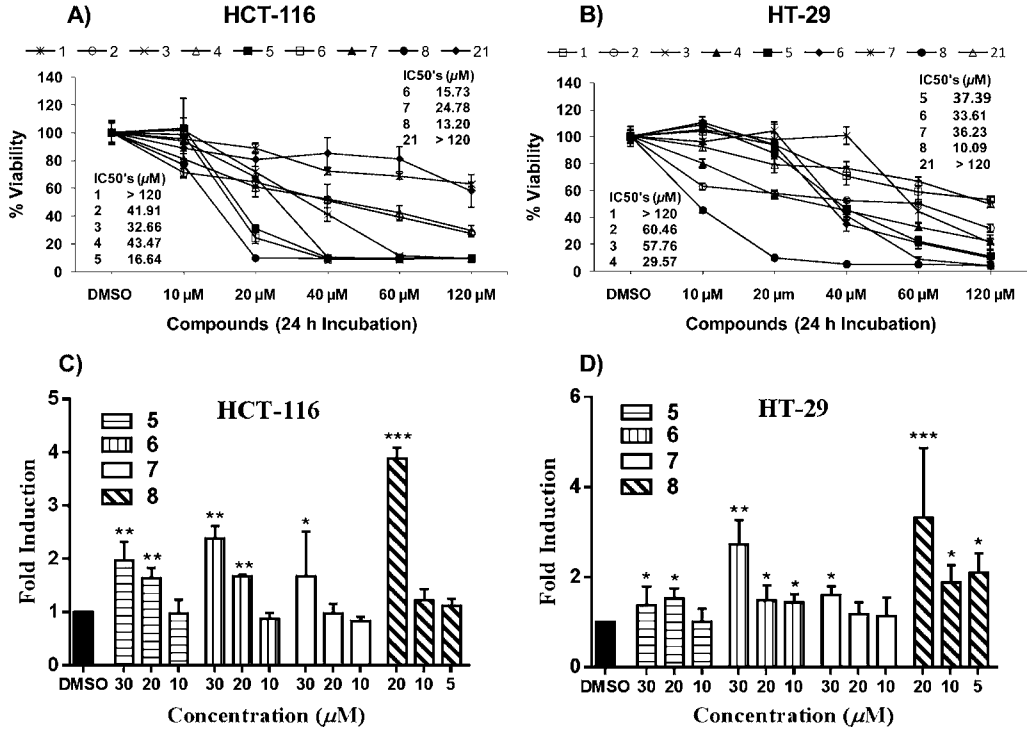

Figure 6. Growth inhibition of sterol oxides **1**–**8** and unoxidized stigmasterol **21** against human colon cancer cells HCT-116 (A) and HT-29 (B), and effects of sterol oxides **5**–**8** on the induction of apoptosis in human colon cancer cells HCT-116 (C) and HT-29 (D). MTT assays: cells were treated with 10, 20, 40, 60, and 120 μM concentrations of the test compounds for 24 h in the presence of 10% FBS and 1% streptomycin/penicillin at 37 °C. Bar, standard error (n = 6). ELISA assays: cells were incubated with test compounds or DMSO for 48 h, upon which a Roche Apoptosis kit was applied to the wells and apoptosis was quantified and expressed as fold induction against the DMSO control. Bar, standard error; *, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.0001$. All statistical tests are unpaired Student t-test, 2 tailed, compared to DMSO.

sitosterol ferulate **17** have been reported in WB previously,[19] whereas stigmasterol ferulate **16** was here described in WB for the first time. Peak ions at m/z 415 $[M - 162 + H]^+$ and 397 $[M - 180 + H]^+$ in MS^2 spectra of **18** corresponded to the loss of a hexanose. Moreover, peak ion at m/z 379 $[M - 180 - H_2O + H]^+$ in its MS^3 spectra, similar to the fragmentation of 7-ketocampesterol **9**, tentatively suggested that **18** is 3-*O*-glucopyranosyl-7-ketocampesterol, which has never been reported before. Compound **19**, bearing two peak ions at m/z 427 $[M - 162 + H]^+$ and 409 $[M - 180 + H]^+$ in its MS^2 spectra and one peak ion at m/z 391 $[M - 180 - H_2O + H]^+$ in its MS^3 spectra, was therefore proposed as 3-*O*-glucopyranosyl-7-ketostigmasterol, as reported previously in *Rosa laevigata*.[32] Similarly, parent ion at m/z 591 $[M + H]^+$ of **20** was 14 mass units higher than that of **18**, indicating that **20** is 3-*O*-glucopyranosyl-7-ketositosterol, as described previously in *Rosa laevigata*.[32]

Consequently, a total of 21 steroids **1**–**21** were identified and characterized from WB extract, using NMR experiments, chemical synthesis approaches, and LC-ESI/MS^n techniques, eventually leading to a comprehensive profile of steroids in WB, as shown in Figure 5. Among them, 7-ketositosterol **3** and 7-ketostigmasterol **4** were found to be the major oxyphytosterols in WB.

***In Vitro* Cytotoxic Activity.** Two human colon cancer cell lines HCT-116 and HT-29 were treated with eight sterol oxides **1**–**8** and the nonoxidized stigmasterol **21**, with concentrations ranging from 0 to 120 μM. Seven sterol oxides **2**–**8** were found to be active against the growth of both HCT-116 and HT-29 human colon cancer cells (Figure 6A,B). Nonoxidized stigmasterol was inactive in both cells (IC_{50} >120 μM, Figure 6A,B). Unusual 3-ketophytosterols **1** and **2** were less active than 7-ketophytosterols **3**, **4**, and **7** in both cancer cell lines, indicating an entity of 3-ol-5-en-7-one in the structure is more favorable for anticancer activity than a 6-ol-4-en-3-one. In HCT-116 cell lines, 7β-hydroxycholesterol **8** was found to be the most active compound with an IC_{50} value of 13.20 μM, followed by 7β-hydroxystigmasterol **6** (IC_{50}: 15.73 μM), 7β-hydroxylsitosterol **5** (IC_{50}: 16.64 μM), 7-ketocholesterol **7** (IC_{50}: 24.78 μM), 7-ketositosterol **3** (IC_{50}: 32.66 μM), and 7-ketostigmasterol **4** (IC_{50}: 43.47 μM) (Figure 6A). The reduction products **5**, **6**, and **8** showed 2-fold higher inhibitory effects than their respective 7-keto precursors **3**, **4**, and **7** (Figure 6A), suggesting that an entity of 5-en-3,7-diol in the structure greatly increases the activity compared to an partial structure of 3-ol-5-en-7-one. 7β-Hydroxycholesterol **8**, with eight carbons in the alkyl side chain, showed a better inhibitory effect than 7β-hydroxysterols **5** and **6**, both bearing 10 carbons in alkyl side chains, indicating that increasing the numbers of carbon in the alkyl side chain decreases the activity. In HT-29 cell lines, 7β-hydroxycholesterol **8** also showed the most potency with IC_{50} value of 10.09 μM (Figure 6B). Whereas the rest of the sterol oxides **2**–**7** showed moderate inhibitory effects, and IC_{50} values ranged from 29.57 to 60.46 μM (Figure 6B). Notably, the two major oxyphytosterols **3** and **4** found in WB exerted great antiproliferative property in both cancer cell lines, indicating that oxyphytosterols may contribute to the observed chemopreventive effects of WB.

We also measured the growth inhibitory effects of the ferulate conjugates of sterols, 7-ketocholesterol ferulate **13** and 7β-hydroxycholesterol ferulate **13a**. Our results indicated that they were inactive in both cell lines (IC_{50}'s > 60 μM),

DOI: 10.1021/jf506361r
J. Agric. Food Chem. 2015, 63, 2264–2276

indicating a free hydroxyl group at C-3β in both entities of 3-ol-5-en-7-one, and 5-en-3,7-diol plays a crucial role in the observed activity.

In order to increase the polarity of oxyphytosterols, we synthesized two aza-oxysterols **7a** and **8a** by introducing an −NH group into C-20 in the side chain of oxysterols **7** and **8**, respectively. In HT-29 cells, MTT assays showed that **7a** exerted a similar activity (IC_{50}: 35.33 μM) to that of **7** (IC_{50}: 36.23 μM), and the activity of **8a** was attenuated while still remaining active (IC_{50}: 54.26 μM), compared to **8** (IC_{50}: 10.09 μM). In HCT-116 cells, the activities of both aza-oxysterols **7a** and **8a** were decreased (IC_{50} > 60 μM for both) compared to oxysterols **7** and **8**.

Induction of Apoptosis in Colon Cancer Cells. Apoptosis is a mechanism often responsible for the induction of cell death in response to internal or external stress. In order to clarify whether oxyphytosterols exert antiproliferative properties via a pathway of apoptosis, we tested the four most active sterol oxides **5**−**8** for apoptotic effects in human colon cancer cells HCT-116 and HT-29. The results are summarized in Figure 6C,D. In HCT-116 cells, compounds **5**−**7** showed significant apoptotic effects at the concentration of 30 μM (Figure 6C), while compound **8** exerted significant apoptotic effect at an even low concentration (20 μM) compared to DMSO control. In particular, the induction of apoptosis by **8** was significantly superior to those of the remaining **5**−**7** at the same concentration (20 μM). In HT-29 cells, compound **8** was also found to be the most potent agent to induce apoptosis (Figure 6D). Compound **6** displayed a significant apoptotic effect at the concentration of 30 μM (Figure 6D). Compounds **5** and **7** showed more or less apoptotic effects at the concentration of 30 μM.

DISCUSSION

In the present study, we outlined a comprehensive chemical profile of steroids in WB. Notably, we observed that 17 (**1**−**14** and **18**−**20**) out of 21 steroids (**1**−**21**) in WB are sterol oxides. This suggests that WB or whole grain wheat may be a dietary source of oxyphytosterols.[33] Daily consumption of whole grain wheat or diet supplemented with WB allows oxyphytosterols to contribute to health effects of the whole grain. Interestingly, three oxidation products of cholesterol, **7**, **8**, and **13**, were also found in WB as minor components. This observation could be demonstrated by the fact that many plants contain cholesterol both in free and esterified forms.[34,35] In addition, it is worth emphasizing that most phytosterols are present in WB in oxidized form or ferulate conjugates in this study, and stigmasterol is the only free plant sterol detected in WB so far.

Phytosterols are liable to oxidation giving rise to a family of oxyphytosterols. Thus, oxyphytosterols are most often present in the proximity of their parent compounds phytosterols. The two main pathways elucidated for oxidation of sterols are enzymatic oxidations and nonenzymatic oxidations. Upon exposure to reactive oxygen and free radical species, or radiation, ring oxidation products are formed.[36,37] Side chain oxidation is believed to be due mainly to enzymatic reactions, the principal enzymes including cytochrome P450 monooxygenases, dehydrogenases, epoxidases, and hydroxylases.[36,37] Physiological effects of cholesterol oxidation products have been well-documented.[38] However, the biological data on oxyphytosterols is relatively scarce. Most reports available so far suggest that oxyphytosterols possess cytotoxic effects *in vitro* and *in vivo*, cholesterol- and lipid-lowering effects, antidiabetic properties, and anti-inflammatory activities.[39] The main barrier to progress in this area was the lack of availability of individual oxyphytosterols. In the present study, nine sterol oxides **1**−**8** and **13** obtained in quantities from direct purification or chemical synthesis enabled us to evaluate them for their antiproliferative properties. MTT assays showed that seven sterol oxides **2**−**8** exerted significant inhibitory effects against human colon cancer cells HCT-116 and HT-29, compared to the parent stigmasterol **21**. Our results demonstrated that sterol oxides in WB may greatly participate in the observed chemopreventative properties of the grain as an active ingredient.

It is known that phytosterols are hardly absorbed (<15%) in human and only low amounts circulate in plasma.[40] Absorption of phytosterols occurs under the same conditions as that of cholesterol and other lipids. Phytosterol solubilization into intestinal mixed micelles is a prerequisite to be absorbed from the lumen, due to their excessive hydrophobicity.[33] Concerning the relative higher polarity of oxyphytosterols than phytosterols, oxyphytosterols may be better absorbed than their nonoxidized counterparts. Studies on the *in vivo* absorption of oxidized phytosterols in rats found that oxyphytosterols may be better absorbed than their nonoxidized counterparts.[41,42] However, there is no study on the bioavailability of oxyphytosterols in humans. Whether or not oxyphytosterols are more bioavailable than phytosterols in humans is a topic of future study.

It has been previously reported that aza-sterols exerted great growth inhibitory effects against human colon cancer cells HT-29,[27,43] leading us to hypothesize that oxyphytosterols with a hydrophilic amino group on the side chain might have improved inhibitory potencies. In this study, we introduced an NH group into position C-20 on the side chain of oxysterols **7** and **8**, giving rise to 20-aza-oxysterols **7a** and **8a**, respectively. Our results showed that the polar aza-oxysterols **7a** and **8a** mostly retained the antiproliferative properties of their respective counterparts **7** and **8**, at least in human colon cancer cells HT-29. This finding led to a strategy to modify oxyphytosterols for better absorption and enhanced anticancer activity in the future study.

In conclusion, we purified four oxyphytosterols **1**−**4** from WB extract, synthesized five sterol oxides **5**−**8** and **13**, and identified a total of 21 steroids **1**−**21** in WB extract using LC-ESI/MS^n techniques based on analysis of their own tandem mass spectra or direct comparison with the authentic references. Among them, three sterol oxides **13**, **14**, and **18** are novel compounds, and 14 compounds **3**, **4**, **6**−**11**, **13**, **14**, **16**, and **18**−**20** were reported in WB for the first time. It is also the first report of the complete NMR data (^{1}H and ^{13}C NMR) for 3-ketophytosterols **1** and **2**. MTT assays showed that seven sterol oxides **2**−**8** exerted significant antiproliferative effects, with oxysterol **8** being the most active compound in both HCT-116 and HT-29 human colon cancer cells. ELISA assays demonstrated that sterol oxides **5**−**8** could induce cell death through apoptosis pathway. Study on SAR of sterol oxides revealed that (1) an entity of 3-ol-5-en-7-one in the structure is more favorable for anticancer activity than a partial structure of 6-ol-4-en-3-one; (2) an entity of 5-en-3,7-diol in the structure greatly increases the activity compared to 3-ol-5-en-7-one; (3) a free hydroxyl group at C-3β in an entity of 3-ol-5-en-7-one or 5-en-3,7-diol plays a crucial role in the observed activity; and (4) a lipophilic side chain of eight carbons in length yields the optimal activities.

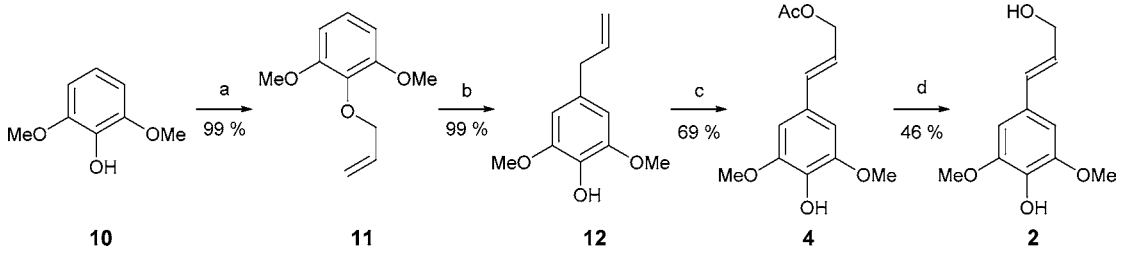

Figure 3. Synthesis of sinapyl acetate and sinapyl alcohol. Reaction conditions: (a) allyl bromide, K_2CO_3, *n*-Bu_4NI, DMF; (b) neat, under Ar, 200 °C; (c) Ag_2O, benzene, and then acetic acid/sodium acetate; (d) $LiAlH_4$, THF, −10 °C.

of phenols. The oxidative coupling of a syringyl-type phenol **7** by Ag_2O was reported to produce the *β-O*-4-coupled dimeric product **9** in 75% yield (Figure 2).[13] We expected that Ag_2O may be more suitable than HRP/peroxide to investigate the formation of *β-O*-4 structures by the oxidative coupling of syringyl-type monolignols.

MATERIALS AND METHODS

General. All chemicals were purchased from Wako (Osaka, Japan) and used as received without any purification. ^1H and ^{13}C NMR spectra were recorded with a Bruker AVANCE II 400 FT-NMR (400 MHz) or a Bruker AMX500 FT-NMR (500 MHz) spectrometer in $CDCl_3$ or acetone-d_6 with tetramethylsilane (TMS) as an internal standard. Chemical shifts (δ) and coupling constants are reported in δ values (ppm) and hertz, respectively. Assignments of *erythro* and *threo* isomers were made by the comparison of chemical shifts with the similar lignin model compounds. ESI-MS spectra were recorded on an 1100 LC-MSD spectrometer (Agilent Technology, Santa Clara, CA, USA). High-resolution ESI-ToF-MS was done with a Bruker micrOTOF. Biomimetic oxidations of sinapyl alcohol and sinapyl acetate were carried out at least twice during the isolation process of reaction products. The isolated yields of the reaction products were calculated on the basis of one set of reactions described below.

Synthesis of Sinapyl Alcohol and Sinapyl Acetate. Sinapyl alcohol, **2**, and sinapyl acetate, **4**, were synthesized from 2,6-dimethoxyphenol, **10**, as shown in Figure 3.[14]

*2-(Allyloxy)-1,3-dimethoxybenzene, **11**:* To a stirred solution of 2,6-dimethoxyphenol, **10** (5 g, 32.4 mmol), in *N*,*N*-dimethylformamide (DMF; 50 mL) under argon were added allyl bromide (98%, 3.5 mL, 38.9 mmol), potassium carbonate (6.72 g, 48.7 mmol), and tetra-*n*-butyl ammonium iodide (1.2 g, 3.24 mmol) at room temperature. The reaction mixture was kept at 50 °C for 3.5 h. The reaction mixture was filtered, diluted with ethyl acetate, washed with brine, dried over Na_2SO_4, and concentrated to dryness in vacuo. The product was purified on a silica gel column with ethyl acetate/hexane (1:4, v/v) to afford a syrup, **11** (6.0 g, 95%): ^1H NMR (400 MHz, $CDCl_3$) δ 3.85 (6H, s, OCH_3), 4.52 (2H, dt, J = 6.1, 1.1 Hz, $OCH_2CH{=}CH_2$), 5.18 (1H, ddt, J = 10.3, 1.6, 1.1 Hz, $OCH_2CH{=}CH_2$), 5.30 (1H, dq, J = 17.2, 1.6 Hz, $OCH_2CH{=}CH_2$), 6.12 (1H, ddt, J = 17.2, 10.3, 6.1 Hz, $-CH_2CH{=}CH_2$), 6.58 (2H, d, J = 8.4 Hz, C2,6-H), 6.99 (1H, t, J = 8.4 Hz, C1-H); ^{13}C NMR (400 MHz, $CDCl_3$) δ 56.1 (OCH_3), 74.1 ($OCH_2CH{=}CH_2$), 105.4 (C2,6), 117.6 ($OCH_2CH{=}CH_2$), 123.6 (C1), 134.6 ($OCH_2CH{=}CH_2$), 136.9 (C4), 153.8 (C3,5); ESI-MS (m/z) 217 ($[M + Na]^+$, 100); high-resolution ESI-ToF-MS, calculated for $C_{11}H_{14}NaO_3^+$, 217.0835, found 217.0839.

*4-Allyl-2,6-dimethoxyphenol, **12**:* Compound **11** (8 g, 41.2 mmol) was placed in a stainless steel autoclave and heated at 200 °C under stirring for 6 h. The product was purified on a silica gel column with ethyl acetate/hexane (1:4, v/v) to afford a syrup, **12** (8.0 g, 97%): ^1H NMR (400 MHz, $CDCl_3$) δ 3.31 (2H, br d, J = 6.7 Hz, α), 3.86 (6H, s, OCH_3), 5.04–5.12 (2H, m, γ), 5.95 (1H, ddt, J = 17.0, 10.0, 6.7 Hz, β), 6.41 (2H, s, C2,6-H); ^{13}C NMR (400 MHz, $CDCl_3$) δ 40.4 (α), 56.3 (OCH_3), 105.2 (C2,6), 115.8 (γ), 131.1 (C1), 133.0 (C4), 137.7 (β), 147.0 (C3, 5); ESI-MS (m/z) 217 ($[M + Na]^+$); high-resolution ESI-ToF-MS, calculated for $C_{11}H_{14}O_3Na^+$ 217.0835, found, 217.0843.

*(E)-3-(4-Hydroxy-3,5-dimethoxyphenyl)allyl acetate, **4**:* To a stirred solution of $AgNO_3$ (2.1 g, 12.4 mmol) in H_2O (12.4 mL) was

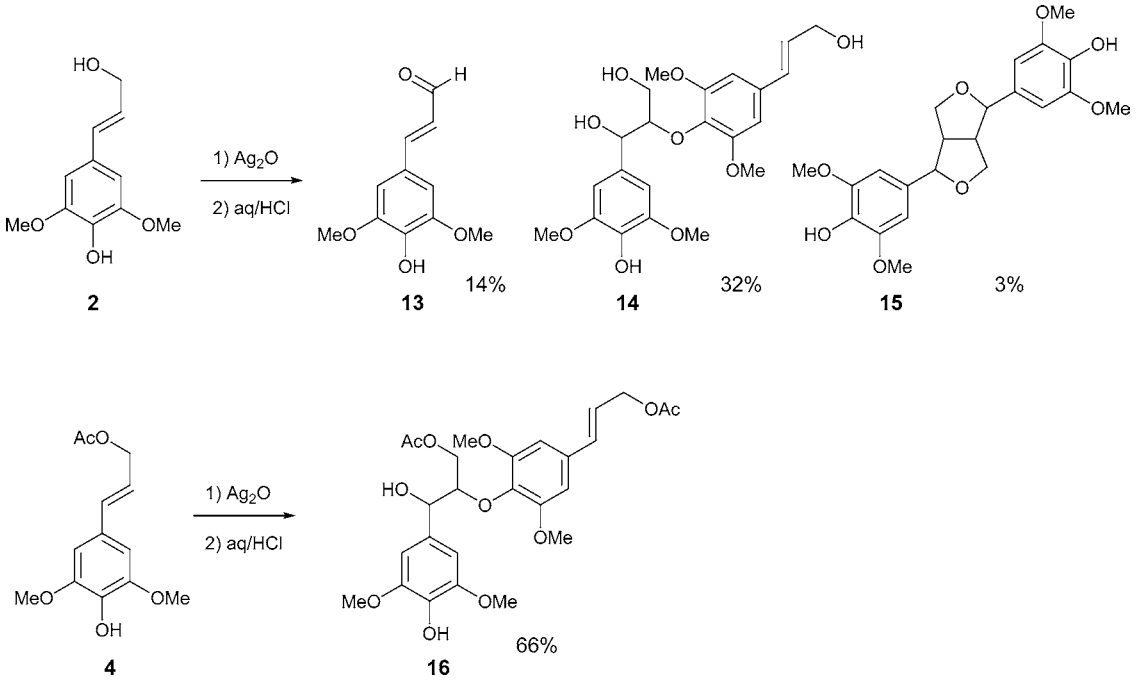

Figure 4. Ag_2O-mediated oxidative coupling of sinapyl alcohol and sinapyl acetate.

added dropwise aqueous NaOH (0.54 g, 13.5 mmol) solution in H_2O (4.9 mL) at room temperature. The reaction mixture was kept for 5 min; it was then filtered and dried under vacuum to afford Ag_2O. To a solution of compound **12** (1.0 g, 5.15 mmol) in benzene (20 mL) was added all of the freshly prepared Ag_2O at room temperature. The reaction mixture was kept for 30 min with vigorous stirring. The reaction mixture in benzene was filtered through Celite into a flask containing acetic acid (25 mL) and sodium acetate (2 g) at room temperature. The reaction mixture was kept for 30 min. The reaction mixture was filtered and concentrated to dryness in vacuo. The product was purified on a silica gel column with ethyl acetate/hexane (1:1, v/v) to afford a syrup (0.9 g, 69%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 2.10 (3H, s, $COCH_3$), 3.91 (6H, s, OCH_3), 4.71 (2H, dd, J = 6.6, 1.1 Hz, γ), 6.16 (1H, dt, J = 15.8, 6.6 Hz, β), 6.57 (1H, br d, J = 15.8 Hz, α), 6.64 (2H, s, C2,6-H); ^{13}C NMR (400 MHz, $CDCl_3$) δ 21.2 ($CO\underline{C}H_3$), 56.4 (OCH_3), 65.4 (γ), 103.6 (C2,6), 121.3 (β), 127.9 (C1), 134.8 (α), 135.2 (C4), 147.3 (C3,5), 171.1 ($COCH_3$); high-resolution ESI-TOF-MS, calculated for $C_{13}H_{16}O_5Na^+$ 275.0890, found 275.0899.

Sinapyl alcohol, 2: To a stirred suspension of lithium aluminum hydride (61 mg, 1.61 mmol) in dry THF (10 mL) at −10 °C under argon was added dropwise a solution of compound **4** (200 mg, 0.79 mmol) in dry THF (1.5 mL). The solution was kept at the same temperature for 1.5 h. To the reaction mixture was added ethyl acetate (0.5 mL) to stop the reaction, and wet THF (0.5 mL), cold water (4 mL), and CH_2Cl_2 (3 mL) were then added. The water phase was neutralized with a 10% $KHSO_4$ solution and extracted with CH_2Cl_2. The organic layer was dried with Na_2SO_4 and concentrated to 3 mL under vacuum. Hexane was added to the solution, and sinapyl alcohol, **2**, was crystallized in the cold to afford light yellow crystals (76 mg, 46%): ^{1}H NMR (400 MHz, $CDCl_3$) δ 3.90 (6H, s, OCH_3), 4.31 (2H, br s, γ), 6.24 (1H, dt, J = 15.8, 5.8 Hz, β), 6.52 (1H, br d, J = 15.8 Hz, α), 6.63 (2H, s, C2,6-H); ^{13}C NMR (400 MHz, $CDCl_3$) δ 56.3 (OCH_3), 63.8 (γ), 103.3 (C2,6), 126.6 (β), 128.2 (C1), 131.5 (α), 134.8 (C4), 147.1 (C3, 5).

Oxidative Coupling of Sinapyl Alcohol. To a stirred solution of compound **2** (100 mg, 0.476 mmol) in 1,4-dioxane (3 mL) under argon was added freshly prepared Ag_2O (111 mg, 0.479 mmol). The reaction mixture was kept for 1 h under vigorous stirring in the dark. The reaction mixture in 1,4-dioxane was filtered through Celite into a flask containing concentrated HCl (0.35 mL), H_2O (20 mL), and THF (10 mL) at room temperature. The reaction mixture was kept under stirring for 1.5 h and then neutralized by adding $NaHCO_3$. The reaction mixture was diluted with ethyl acetate, washed with brine, dried over Na_2SO_4, and concentrated to dryness in vacuo. The product was purified on a silica gel column with ethyl acetate/hexane (3:1, v/v) to afford five fractions. Sinapyl aldehyde, **13** (14 mg, 14%), was obtained from fraction 1. Both the *erythro* and *threo* isomers of syringyl glycerol-β-sinapyl alcohol, **14** (34 mg, 32%), and syringaresinol, **15** (<3 mg, 3%), were obtained from fraction 5 by thin layer chromatography (TLC) with methanol/CH_2Cl_2 (1:19, v/v). Sinapyl aldehyde, **13**: ^{1}H NMR (500 MHz, acetone-d_6) δ 3.92 (6H, s, OCH_3), 6.69 (2H, dd, J = 15.8, 7.7 Hz, β), 7.08 (2H, s, C2,6-H), 7.55(1H, d, J = 15.8 Hz, α), 9.64 (1H, d, J = 7.7 Hz, γ). Syringyl glycerol-β-sinapyl alcohol, **14**, chemical shifts and coupling constants were determined for *erythro* and *threo* mixtures: ^{1}H NMR (500 MHz, acetone-d_6) *erythro* δ 3.41 (1H, γ), 3.81 (OCH_3), 3.85 (1H, γ), 3.90 (OCH_3), 4.18 (1H, m, β), 4.24 (2H, br d, J = 5.2 Hz, γ'), 4.37 (1H, α-OH), 4.99 (1H, α), 6,39 (2H, dt, J = 15.9, 5.2 Hz, β'), 6.57 (1H, br d, J = 15.9 Hz, α'), 6.72 (2H, s, C2,6-H or C2′,6′-H), 6.82 (2H, s, C2,6-H or C2′,6′-H); *threo* δ 3.33 (1H, γ), 3.67 (1H, γ), 3.80 (OCH_3), 3.92 (OCH_3), 3.95 (1H, m, β), 4.99 (1H, α), 6.39 (2H, dt, J = 15.9, 5.2 Hz, β'), 6.56 (1H, br d, J = 15.9 Hz, α'), 6.77 (2H, s, C2,6-H or C2′,6′-H), 6.82 (2H, s, C2,6-H or C2′,6′-H); ^{13}C NMR (400 MHz, acetone-d_6) *erythro*/*threo* δ 56.7 (OCH_3), 61.0 (γ), 63.2 (γ'), 73.7 (α), 74.3 (α), 88.2 (β), 89.9 (β), 104.6, 104.7, 104.9, 105.6, 129.9, 131.0, 132.8, 132.5, 134.8, 136.2, 148.5, 154.1, 154.3; high-resolution ESI-TOF-MS m/z (M + Na)$^+$ calculated for $C_{22}H_{28}O_9Na^+$ 459.1626, found 459.1647. Syringresinol, **15**: ^{1}H NMR (500 MHz, acetone-d_6) δ 3.10 (2H, m, β) 3.82−3.85 (2H, m, γ), 3.84 (6H, s, OCH_3), 4.23 (2H, m, γ), 4.67 (2H, d, J = 3.8 Hz, α), 6.69 (4H, s, C2,6-H); ^{13}C NMR (500 MHz, acetone-d_6) δ 55.3 (β), 56.6 (OCH_3), 72.3 (γ), 86.8 (α), 104.4 (C2,6), 133.2 (C1), 136.2 (C4), 148.7 (C3,5); high-resolution ESI-TOF-MS m/z (M + Na)$^+$ calculated for $C_{22}H_{26}O_8Na^+$ 441.1520, found 441.1565.

Oxidative Coupling of Sinapyl Acetate. To a stirred solution of compound **4** (100 mg, 0.396 mmol) in 1,4-dioxane (3 mL) under argon was added freshly prepared Ag_2O (100 mg, 0.43 mmol). The reaction mixture was kept under vigorous stirring for 20 min in the dark. The reaction mixture in 1,4-dioxane was filtered through Celite into a flask containing concentrated HCl (0.35 mL), H_2O (20 mL), and THF (10 mL) at room temperature. The reaction mixture was

kept for 30 min under stirring and was then neutralized by adding $NaHCO_3$. The reaction mixture was diluted with ethyl acetate, washed with brine, dried over Na_2SO_4, and concentrated to dryness in vacuo. The product was purified on a silica gel column with ethyl acetate/hexane (2:1, v/v) to afford five fractions. Fraction 4 (18 mg, 18%) was mainly composed of *β-O*-4 oligomeric products, as was confirmed by the HSQC NMR spectra. The *β-O*-4-coupled dimers *erythro*-**16** (50 mg, 48%) and *threo*-**16** (19 mg, 18%) were obtained from fractions 2 and 3, respectively, by TLC with ethyl acetate/hexane/benzene (10:5:1, v/v/v).

*erythro-**16**:* ^{1}H NMR (500 MHz, acetone-d_6) δ 1.87 (3H, s, $COCH_3$), 2.04 (3H, s, $COCH_3$), 3.81 (6H, s, OCH_3), 3.91 (6H, s, OCH_3), 4.09 (1H, dd, J = 11.8, 3,3 Hz, γ), 4.36 (1H, m, γ), 4.53 (1H, m, β), 4.70 (2H, dd, J = 6.3, 1.0 Hz, γ'), 4.91 (1H, m, α), 6.36 (1H, dt, J = 15.9, 6.3 Hz, β'), 6.66 (1H, dt, J = 15.9 Hz, α'), 6.69 (2H, s, C2,6-H or C2′,6′-H), 6.86 (2H, s, C2,6-H or C2′,6′-H); ^{13}C NMR (400 MHz, acetone-d_6) δ 20.8 ($CO\underline{C}H_3$), 20.9 ($CO\underline{C}H_3$), 56.7 (OCH_3), 63.5 (γ), 65.4 (γ'), 73.1 (α), 84.5 (β), 104.6 (C2,6 or C2′,6′), 104.9 (C2,6 or C2′,6′), 124.4 (β'), 131.6 (C1, C1′, C4, or C4′), 133.5 (C1, C1′, C4, or C4′), 134.4 (α'), 136.0 (C1, C1′, C4, or C4′), 136.5 (C1, C1′, C4, or C4′), 148.6 (C3,5 or C3′,5′), 154.5 (C3,5 or C3′,5′), 170.9 ($\underline{C}OCH_3$); high-resolution ESI-TOF-MS m/z $(M + Na)^+$ calculated for $C_{26}H_{32}O_{11}Na^+$ 543.1837, found 543.1811.

Computational Calculations of Sinapyl Acetate and Sinapyl Alcohol Radicals. Computational calculations were conducted with Spartan ’08 Win (Wavefunction, Inc., Irvine, CA, USA). Conformational analyses of the radicals were performed with the standard conformer search program in Spartan ’08 using PM3 semiempirical calculations. The conformers obtained were further optimized at the UB3LYP/6-31G* level of theory to identify the lowest energy conformers. Single-point energy calculations of the conformers were performed at the same level to obtain electrostatic charges and spin densities based on natural population analysis. Solvent effects were added to the energy calculations using the POSTSOLVENT command based on the SM8 model in Spartan ’08.

RESULTS AND DISCUSSION

Synthesis of Sinapyl Acetate and Sinapyl Alcohol. Sinapyl acetate, **4**, and sinapyl alcohol, **2**, were synthesized from 2,6-dimethoxyphenol, **10**, by the reported procedure (Figure 3).[14] The allylation of compound **10** was performed with allyl bromide and potassium carbonate in dimethyl formaldehyde (DMF) to afford compound **11** in 99% yield. The Claisen rearrangement of compound **11** in a sealed tube under argon at 200 °C gave compound **12** in 99% yield.[15] Compound **12** was treated with freshly prepared Ag_2O in benzene, and the suspension was filtered through Celite to give a vinyl quinone methide intermediate. The benzene solution of the formed vinyl quinone methide was poured into acetic acid/sodium acetate to give sinapyl acetate, **4**, in 69% yield.[14] The acetyl group in compound **4** was removed by lithium aluminum hydride to give sinapyl alcohol, **2**, in 46% yield.

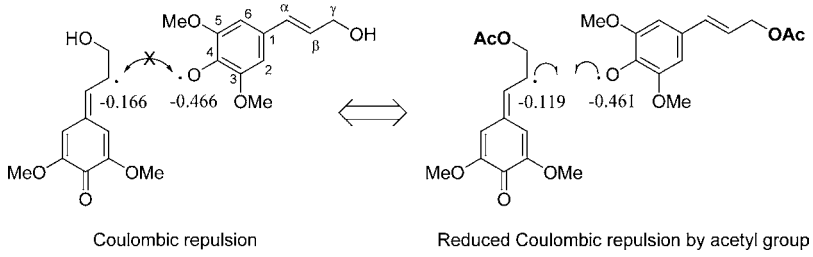

Figure 6. Reduced negative charges by acetyl group result in the high yield of β-*O*-4 products.

Oxidative Coupling of Sinapyl Alcohol and Sinapyl Acetate by Silver Oxide. The oxidative coupling of lignin-related monomers by Ag_2O was first carried out by Zanarotti.[13] The oxidation of a syringyl-type monomer, 2,6-dimethoxy-4-(prop-1-en-1-yl)phenol, **7**, in dry benzene or in dry methylene chloride quantitatively yielded quinone methide **8**, which was further hydrated with aqueous acid to produce the β-*O*-4-coupled dimeric product **9** (C−O-coupled dimer) in 75% yield (Figure 2).[13] Later, this procedure was applied to the oxidative coupling of a guaiacyl-type monomer, coniferyl alcohol.[16] The reaction products from coniferyl alcohol were different from those from the syringyl-type monomer. In methylene chloride, the β-5-coupled dimer was formed as a major product in 50% yield, whereas in a two-phase methylene chloride/water (1:1, v/v) solution, the β-β-coupled dimer was the major product in 25% yield.[16] Both the β-5 and β-β dimers were C−C-coupled products.

On the other hand, the oxidative coupling of sinapyl alcohol, **2**, a typical syringyl-type monomer, by Ag_2O has not been reported. Alternatively, $FeCl_3$ has been used for the oxidative coupling of sinapyl alcohol, **2** in 1,4-dioxane, which gave the β-*O*-4-coupled dimer **14** in 28% isolated yield.[17] In this investigation, sinapyl alcohol, **2**, was treated with Ag_2O in 1,4-dioxane, and the resultant quinone methide was further hydrated with aqueous hydrochloric acid (HCl)/tetrahydrofuran (THF) solution.[18] The Ag_2O oxidation of sinapyl alcohol, **2**, produced sinapyl aldehyde, **13**, in 14% yield, the β-*O*-4-coupled dimer **14** in 32% yield, the β-β-coupled dimer (syringaresinol, **15**) in 3% yield, and other unidentified oligomeric products (Figure 4). The yield of the β-*O*-4-coupled dimer from the Ag_2O oxidation of sinapyl alcohol was a little higher than the yield reported for $FeCl_3$ oxidation. The oxidative coupling of phenols by Ag_2O has been reported to preferentially form C−O-coupled products, whereas $FeCl_3$ leads to C−C-coupled products.[19]

We examined the Ag_2O-mediated oxidative coupling of the γ-acetylated monomer sinapyl acetate, **4**, to elucidate the effect of the γ-acetyl group on the oxidative coupling of sinapyl alcohol. The Ag_2O oxidation of sinapyl acetate, **4**, in benzene preferentially formed *erythro* and *threo* isomers of the β-*O*-4-coupled dimer, **16**, in 39% yield. In 1,4-dioxane, the selectivity for β-*O*-4-coupled products became even higher. The yield of the *erythro* and *threo* isomers of the β-*O*-4-coupled dimer was 66% (Figure 4). Oligomeric products with predominantly β-*O*-4 structures (Figure 5) were also obtained in 18% yield. However, nontraditional tetrahydrofuran-type β-β-coupled products[10] were not detected by the NMR analysis. These results showed that the Ag_2O-mediated oxidative coupling of sinapyl acetate preferentially formed β-*O*-4 linkages. The yield of the β-*O*-4-coupled products from sinapyl acetate was much higher than that from sinapyl alcohol. The oxidation of the hydroxyl group at the γ-position was completely prevented by the acetyl group in sinapyl acetate, which partially contributed to the high yield of β-*O*-4 products from sinapyl acetate.

Computational Calculations of Atomic Spin Densities and Charges of Sinapyl Radicals. To further understand the effect of the acetyl group at the γ-position in sinapyl acetate, computational calculations based on density functional theory (DFT) were performed. The atomic spin densities of phenoxy radicals derived from sinapyl acetate and sinapyl alcohol are shown in Table 1. The spin densities show that the unpaired electrons are mainly located at C1, C3, C5, Cβ, and O4 in both sinapyl acetate and sinapyl alcohol radicals. The spin densities of these radicals are the highest at O4, which is agreement with the reported data for sinapyl alcohol radical.[20] The C1, C3, and C5 sites are not considered to be important coupling sites in sinapyl alcohol radicals. Thus, the most reactive coupling sites

DOI: 10.1021/jf506111q
J. Agric. Food Chem. 2015, 63, 2277−2283

are Cβ and O4 in both sinapyl acetate and sinapyl alcohol radicals. The radical coupling at Cβ and Cβ produces β-β linkages, whereas coupling at Cβ and O4 produces β-O-4 linkages. The spin densities of carbon and oxygen atoms in sinapyl acetate and sinapyl alcohol radicals are quite similar to each other. The acetyl group at the γ-position did not significantly affect the localization of the unpaired electron in the sinapyl alcohol radical. These results indicate that the modification of the localization of the unpaired electron cannot explain the preferential formation of β-O-4-coupled products by the oxidative coupling of sinapyl acetate.

The charge density at each atom in monolignol radicals is also important for the coupling reaction of the radicals.[20] The electrostatic charges of all carbon and oxygen atoms in sinapyl acetate and sinapyl alcohol radicals are shown in Table 2. The solvent effects of water and 1,4-dioxane were also added to the calculation of the electrostatic charges. These data show that Cβ and O4 were negatively charged in the sinapyl alcohol and sinapyl acetate radicals. As the two radicals approach each other, their negative charges result in Coulombic repulsion between the Cβ and O4 positions.[20] The data show that the negative charge at the Oγ position in the sinapyl acetate radical was much smaller than that in the sinapyl alcohol radical. This result can be reasonably explained by the fact that acyl groups, such as the acetyl group, are electron-withdrawing groups. It is interesting to note that the electron-withdrawing effects of the acetyl group are active even at the Cβ position in the sinapyl acetate radical. The negative charge at Cβ in the sinapyl acetate radical was significantly smaller than that in the sinapyl alcohol radical. This tendency was more obvious when solvent effects were considered in the calculations. The differences in the electrostatic charges at Cβ between the sinapyl acetate and sinapyl alcohol radicals were 0.033 e in 1,4-dioxane and 0.052 e in water. These results suggest that the Coulombic repulsion between the Cβ and O4 positions was significantly reduced by the γ-acetyl group (Figure 6), which resulted in the high yield of β-O-4-coupled products from the oxidative coupling of sinapyl acetate.

In conclusion, compared to the biomimetic oxidative coupling of sinapyl alcohol, the biomimetic oxidative coupling of sinapyl acetate by silver oxide preferentially formed β-O-4-coupled products. Computational calculations showed that the γ-acetyl group significantly decreased the negative charge at Cβ in the sinapyl acetate radical. The Coulombic repulsion between Cβ and O4 seems to be reduced when two sinapyl acetate radicals approach each other. These results suggest that acylated monolignols preferentially couple at Cβ and O4, resulting in the high frequency of β-O-4 structures in highly acylated lignins.

genome allows the differentiation of even closely related genotypes.[6,22] For example, Ganopoulos et al.[23] were successful in discriminating 21 Greek sweet cherry cultivars by genotyping nine genic SNP loci. Moreover, a sufficient number of SNPs for varietal origin detection can be identified by analyzing relatively short DNA sequences. Reale et al.[24] did the first work describing SNP marker development for olive cultivar identification and identified 22 SNPs with only 3440 bp (base pair) of olive genic sequence. Thus, they observed a high frequency of SNP occurrence (1 SNP per 156 bp). Using a total of 11 markers, 8 of which were SNP derived, Reale et al.[24] discriminated 47 olive accessions. Following Reale et al.,[24] Consolandi et al.[25] used 17 SNP loci to differentiate 49 olive varieties that are commonly cultivated in the Mediterranean region and developed a SNP-based ligation detection assay for varietal origin detection. The efficiency of the SNP-based ligation detection assay was displayed on eight monovarietal olive oils from Italy, Spain, France, and Portugal.[1]

Restriction profile-based genotyping, either referred to as CAPS or PCR-RFLP (PCR-restriction fragment length polymorphism), has been successfully used in a number of DNA-based food authentication studies. Dooley et al.[26] were able to discriminate ten white fish species by using three PCR-RFLP assays that target a 464 bp region of the *Cytochrome b* gene. In addition, the reproducibility of the assays was displayed by an interlaboratory study that involves five different food control laboratories in the United Kingdom. Spaniolas et al.[27] described a single SNP-based PCR-RFLP assay that allows the discrimination of Arabica and Robusta coffee samples. Bazakos et al.[21] were first to display the effectiveness of a PCR-RFLP (restriction fragment length polymorphism) approach to identify the varietal origin of olive oils based on their SNP alleles. The authors were able to discriminate eight olive varieties using five SNPs and showed the usefulness of this approach on five Greek monovarietal olive oils.

Turkey is among the world's leading olive producers and ranks fourth with 1 676 000 tonnes (t) of total production, following Spain (7 875 000 t), Italy (3 022 886 t), and Greece (2 000 000 t).[28] According to statistics released by the International Olive Oil Council, Turkey ranked fifth in olive oil production in the harvest year 2011/2012 after Spain, Italy, Greece, and Syria.[29] Turkish olive cultivars such as Ayvalik, Memecik, Gemlik, and Nizip Yaglik are known for their oils with distinctive sensory features.[30] In a limited number of studies, DNA markers were used for the molecular characterization of Turkish olive cultivars.[31−34] However, there is no report on the use of molecular markers for establishing DNA barcodes of Turkish monovarietal olive oils. The aim of this work was to discriminate commonly cultivated Turkish olive varieties using the fewest possible SNP markers and to standardize SNP-based molecular assays that complement the shortcomings of conventional analytical approaches in resolving the traceability of premium monovarietal olive oils.

MATERIALS AND METHODS

Plant Material and Oil Samples. Leaf and oil samples of 17 commonly cultivated Turkish olive varieties were used in this study. Leaf samples of each olive variety were collected from three individual plants. Cultivar names and primary usage information are provided in Table 1. Leaf samples and filtered monovarietal oils produced by a laboratory-scale mill were obtained from the Olive Research Institute (Izmir, Turkey). Commercial olive oil samples were obtained from a retail market.

[a]Primary usage is indicated first for the varieties that have both uses.

DNA Isolation. DNA from the leaf tissue of three replicate plants was isolated from 200 mg of liquid nitrogen-frozen ground leaf tissue using a CTAB method.[35] For isolating DNA from monovarietal olive oil samples, Wizard Magnetic DNA Purification System for Food (Promega Corp., Madison, WI) was used according to the manufacturer's instructions. The concentration of DNA from leaf and oil samples was measured using a Qubit 2.0 Fluorometer (Life Technologies, Thermo Fisher Scientific Inc., Waltham, MA) with dsDNA BR Assay Kit (Life Technologies). DNA integrity was checked on a 1.5% agarose gel.

Primer Design, Sequencing, and SNP Identification. Primers that amplify targets from the *Cycloarthenol synthase* and *Lupeol synthase* genes were designed on the basis of the partial coding sequences Genbank Acc. No. AY847065 and AY847066, respectively (http://www.ncbi.nlm.nih.gov/genbank) (Table 2). The primer design process was carried out using Primer3 software.[36] The primers Cyc6-F and Lup1-F&R were previously reported by Bazakos et al.[21] (Table 2). Primers that target the *Anthocyanidin synthase* (Ant-F&R), *Calcium binding protein* (Cbp-F&R), and *Chalcone synthase* (Chs-F&R) genes were reported by Consolandi et al.[1] (Table 2).

Leaf DNA from the 17 olive varieties was used for dye-terminator sequencing reactions. Sequencing targets were amplified in 20 μL reaction mixtures containing 1X PCR buffer, 1.5 mM $MgCl_2$, 0.25 mM of each deoxyribonucleotide triphosphate (dNTP) (Promega Corp.), 1 U Taq polymerase, 0.25 μM of each primer, and 5 ng template DNA. Thermal cycling conditions consisted of one cycle of initial denaturation for 10 min at 94 °C, followed by 35 cycles of 94 °C for 30 s, 57 °C for 30 s, 72 °C for 45 s, with a final extension step of 10 min at 72 °C. For each olive variety, PCR reactions were performed in five replicates and combined during the purification step with the DNA Clean & Concentrator-5 Kit (Zymo Research, Irvine, CA). Purified PCR products were used as template in dye-terminator sequencing reactions, prepared using GenomeLab DTCS Quick Start Kit (Beckman Coulter, Brea, CA) according to the manufacturer's instructions. Sequencing reaction thermal cycling conditions were 30 cycles of 96 °C 20 s, 50 °C 20 s, 60 °C 4 min. The reaction mixture for each amplicon was then purified using ZR DNA Sequencing Clean-up Kit (Zymo Research), resuspended in 30 μL of sample loading solution (Beckman Coulter), and run on a Beckman CEQ8800 capillary electrophoresis device using the LFR-c method (injection voltage 2.0 kV for 10−15 s, separation temperature 60 °C, separation voltage 7.4 kV, separation time 45 min). Sequence peaks were visualized by Beckman CEQ8800 software version 8.0 (Beckman Coulter), and SNP detection was done by visual inspection of sequence peaks from different varieties.

[a]Unless indicated otherwise, primers were designed in this study. [b]Single asterisk indicates primers reported by Consolandi et al. (2008). Double asterisks indicate primers reported by Bazakos et al. (2012). Primers used in CAPS assays are given in italics. [c]Nucleotides in bold indicate SNP loci in motifs.

Design and Application of the CAPS Assays for SNP Genotyping. Sequences obtained by the dye-terminator method were analyzed with the NEBcutter Version 2.0 software (http://tools.neb.com/NEBcutter2/) (New England Biolabs Inc., Ipswich, MA) for the allelic variants of each SNP identified. SNPs with alleles that alter recognition motifs of restriction enzymes were selected for genotyping by a restriction digestion-based analysis.

Fragments that harbor SNP loci were amplified in 20 μL reaction mixtures containing 1X PCR buffer, 1.5 mM $MgCl_2$, 0.25 mM of each deoxyribonucleotide triphosphate (dNTP) (Promega Corp.), 1 U Taq polymerase, 0.25 μM of each primer, and 5 ng of olive leaf DNA or 5 ng of oil DNA stock solution as template. Thermal cycling conditions consisted of one cycle of initial denaturation for 10 min at 94 °C, followed by 40 cycles (35 cycles for leaf DNA) of 94 °C for 30 s, 57 °C for 30 s, 72 °C for 45 s, with a final extension step of 10 min at 72 °C. PCR products were directly subjected to restriction digestion without any purification step. Digestion reaction mixtures of the CAPS assays (Table 2) contained 20 μL of PCR product, 1 μL of restriction enzyme (New England Biolabs Inc.), and 2.5 μL of CutSmart reaction buffer (New England Biolabs Inc.) in a total volume of 25 μL. Reaction mixtures of the enzyme EagI involved NEBuffer 3.1 instead of the CutSmart buffer, and 0.25 μL of *S*-adenosylmethione was added to the BsgI reaction mixtures. Incubation temperature was constant (37 °C) for all enzymes, and incubation time was standardized as 6 h. Following the incubation step, digestion fragments were run on a Qiaxcel Advanced capillary electrophoresis system (Qiagen, Valencia, CA) using a Qiaxcel DNA High Resolution Kit (Qiagen). QX DNA Size Marker 25−500bp, v2.0 (Qiagen) was used as the size standard, and QX Alignment Marker 15 bp/600 bp (Qiagen) was used for aligning the size standard fragments. The high resolution run method OM800 was applied with a sample injection time of 20 s. QIAxcel ScreenGel Software (Qiagen) was used for the visualization of the digestion profiles. The six CAPS assays developed in this work were applied on the oil DNA of each olive variety in three replicates.

Statistical Analysis. The frequency of each SNP allele was determined by calculating the proportion of the occurrence of the allele to the total number of alleles at a given SNP locus. Probability of identity for individual SNP loci and the combined, multilocus probability of identity were calculated according to Paetkau et al.[37] Allelic error was calculated according to Pasqualone et al.[38]

RESULTS

SNP Identification by Sequencing. Five olive genes, *Anthocyanidin synthase* (*Ant*), *Calcium binding protein* (*Cbp*), *Chalcone synthase* (*Chs*), *Cycloarthenol synthase* (*Cyc*), and *Lupeol synthase* (*Lup*), were targeted for SNP identification by sequencing. Leaf genomic DNA from the 17 olive varieties (Table 1) was used as template for the dye-terminator sequencing reactions. Total lengths of the sequencing targets from *Cyc*, *Lup*, *Cbp*, *Chs*, and *Ant* genes were 1087 (six amplicons), 436 (three amplicons), 328 (one amplicon), 297 (one amplicon), and 274 bp (one amplicon), respectively (Table 2). Sequencing of these 12 PCR amplicons that spanned 2422 bp of coding sequence resulted in the identification of 17 SNPs, corresponding to a frequency of 1 SNP per 142.5 bp of coding sequence. Among these SNPs, five, one, two, six, and three SNPs were identified in the *Ant*, *Cbp*, *Chs*, *Cyc synthase*, and *Lup* sequences, respectively.

Design of CAPS Assays for SNP Genotyping. In order to develop a restriction digestion-based SNP genotyping strategy, sequences obtained from the five olive genes by dye-terminator method were analyzed to identify SNPs that reside in restriction enzyme recognition motifs. In the analysis, allelic variants were taken into account for each SNP, so that restriction enzymes with allele-dependent digestion patterns could be identified. As a result, allelic variants of 12 of the 17 SNP loci (71%) were found to alter restriction enzyme recognition motifs. CAPS assays were designed for each SNP

[a]Variety name Tekirdag Siyah Salamura is abbreviated as Tekirdag SS.

and applied on leaf DNA from three replicate plants for SNP verification (data not shown). The assays involved amplification of the PCR product that harbored the SNP, restriction digestion of the amplicon with the appropriate restriction enzyme, and visualization of the digestion pattern with capillary electrophoresis. Out of the 12 CAPS assays, a subset of six was sufficient to provide the discrimination power to distinguish 17 olive varieties. As a result, those six assays (Table 2) were used to establish an identification key for the monovarietal olive oils.

SNP1, identified in the *Lup* gene, had A and T variants. On the basis of SNP1 alleles, the olive varieties were separated into three groups (Table 3). A total of 5 varieties were homozygous for the A allele, 10 varieties were heterozygous carrying both A and T alleles, and 2 varieties were homozygous for the T allele. The T allele of SNP1 resulted in an intact HpyCH4III recognition motif, while the A allele disrupted the motif. As a result, genotypes homozygous for the T allele were distinguished by a homozygous digestion pattern with two restriction fragments, whereas genotypes homozygous for the A allele produced a single undigested fragment. Heterozygous genotypes yielded a three fragment digestion pattern with two digestion fragments and the undigested amplicon (Figures 2−4). SNP2, identified in the *Chs* sequence, separated the olive varieties into two groups. While 13 homozygous genotypes carried only the C allele, the remaining four genotypes were heterozygous and carried C and T alleles (Table 3). The C allele disrupted the recognition site for the restriction enzyme BsgI, leading to a single undigested fragment for homozygous genotypes. In contrast, heterozygous genotypes carried one copy of the intact BsgI restriction site and were distinguished by a three fragment digestion pattern in the capillary electropherograms (Figures 2−4). SNP3 was identified in the *Ant* sequence and allowed separation of olive varieties into two groups. Genotypes homozygous for SNP3 (seven varieties) carried only the C allele (Table 3) and were distinguished by a single undigested fragment. Whereas, due to the presence of the T allele, heterozygous genotypes (ten varieties) (Table 3) carried one copy of an intact HphI recognition motif and produced a three fragment HphI digestion pattern (Figures 2−5). SNP4 and SNP5 were both identified in sequences from the *Cyc* gene. Olive genotypes were either homozygous (TT) (12 varieties) or heterozygous (TC) (5 varieties) for the SNP4 locus (Table 3). Homozygous genotypes were distinguished by a homozygous Hpy166II digestion pattern with two restriction fragments. Because the C allele disrupted the recognition motif for the enzyme, heterozygous genotypes were identified by three fragments in their capillary electropherograms (Figures 3 and 4). SNP5 separated olive varieties into two groups of nine homozygous (CC) and eight heterozygous (TC) genotypes (Table 3). Homozygous genotypes (CC) displayed a homozygous digestion pattern with two HindIII digestion fragments in their capillary electropherograms. Heterozygous genotypes (TC) were distinguished by a three fragment digestion pattern including the two digestion fragments and the undigested amplicon (Figures 3 and 4). Olive varieties were either homozygous (GG) (12 varieties) or heterozygous (CG) (five varieties) for SNP6, identified in the *Cbp* gene (Table 3). Because the G allele disrupted the EagI recognition motif, homozygous genotypes displayed a single undigested fragment in their capillary electropherograms. Heterozygous genotypes carrying one copy of an intact EagI recognition site were characterized by a three fragment restriction pattern (Figure 4). Allelic frequencies of the six SNP loci used for the discrimination of the olive varieties are given in Table 4.

Fingerprinting Monovarietal Olive Oils Using SNP-Based CAPS Markers. Among the six SNPs used to design CAPS assays, combinations that involved two, three, four, or five SNPs were sufficient to discriminate the olive varieties (Figure 1). Therefore, variable sets of CAPS assays were applied to the oil DNA samples of the 17 varieties. SNP1-HpyCH4III assay was common in the discriminatory assay combinations for all varieties. However, different combinations of the remaining five assays (SNP2-BsgI, SNP3-HphI, SNP4-Hpy166II, SNP5-HindIII, and SNP6-EagI) were used for the identification of the olive varieties.

Only two SNPs were sufficient to discriminate Uslu, Mavi, and Sinop No:5 varieties. Discrimination of both Uslu and Sinop No:5 oils involved using the SNP1-HpyCH4III and SNP3-HphI assay combination (Figure 2). The SNP2-BsgI assay was used instead of SNP3-HphI for the discrimination of the Mavi variety (Figure 2). Identification of the varieties, Nizip Yaglik, Yun Celebi, and Cekiste, involved using three SNPs. A

common set of CAPS assays (SNP1-HpyCH4III, SNP2-BsgI, and SNP3-HphI) was used to discriminate the monovarietal oils of these varieties (Figure 2). The varieties Memecik, Ayvalik, Domat, and Saurani could be discriminated from the rest using four SNPs. Ayvalik, Domat, and Saurani oils were discriminated using an identical set of assays that included SNP1-HpyCH4III, SNP2-BsgI, SNP3-HphI, and SNP4-Hpy166II (Figure 3) whereas the SNP5-HindIII assay was required instead of SNP4-Hpy166II for the discrimination of Memecik oil (Figure 3). Among the 17 commonly cultivated Turkish olive varieties included in this work, two groups of cultivars were suggested as synonyms by the experts of the Olive Research Institute (Izmir, Turkey) based on long-term agromorphological observations. In agreement with these observations, the genotypes of the two groups of varieties were identical for all of the 17 SNPs identified in this study (data not shown). However, further detailed molecular genetic characterization would confirm whether the two groups of olive varieties are actually synonyms. The first group of varieties that are suggested as synonyms was Gemlik, Erdek, and Tekirdag Siyah Salamura. A combination of five CAPS assays (SNP1-HpyCH4III, SNP2-BsgI, SNP3-HphI, SNP4-Hpy166II, and SNP5-HindIII) allowed the discrimination of these three monovarietal oils from the rest of the collection (Figure 4). The second group of varieties suggested as synonyms was Kilis Yaglik and Tesbih Celebi. By using a set of five CAPS assays (SNP1-HpyCH4III, SNP2-BsgI, SNP3-HphI, SNP5-HindIII, and SNP6-EagI), the oils of these two varieties were discriminated from the rest of the monovarietal olive oils (Figure 4). Olive varieties Patos and Maras No:7 were also distinguished from the rest using five SNPs. Thus, a set of five assays (SNP1-HpyCH4III, SNP2-BsgI, SNP3-HphI, SNP4-

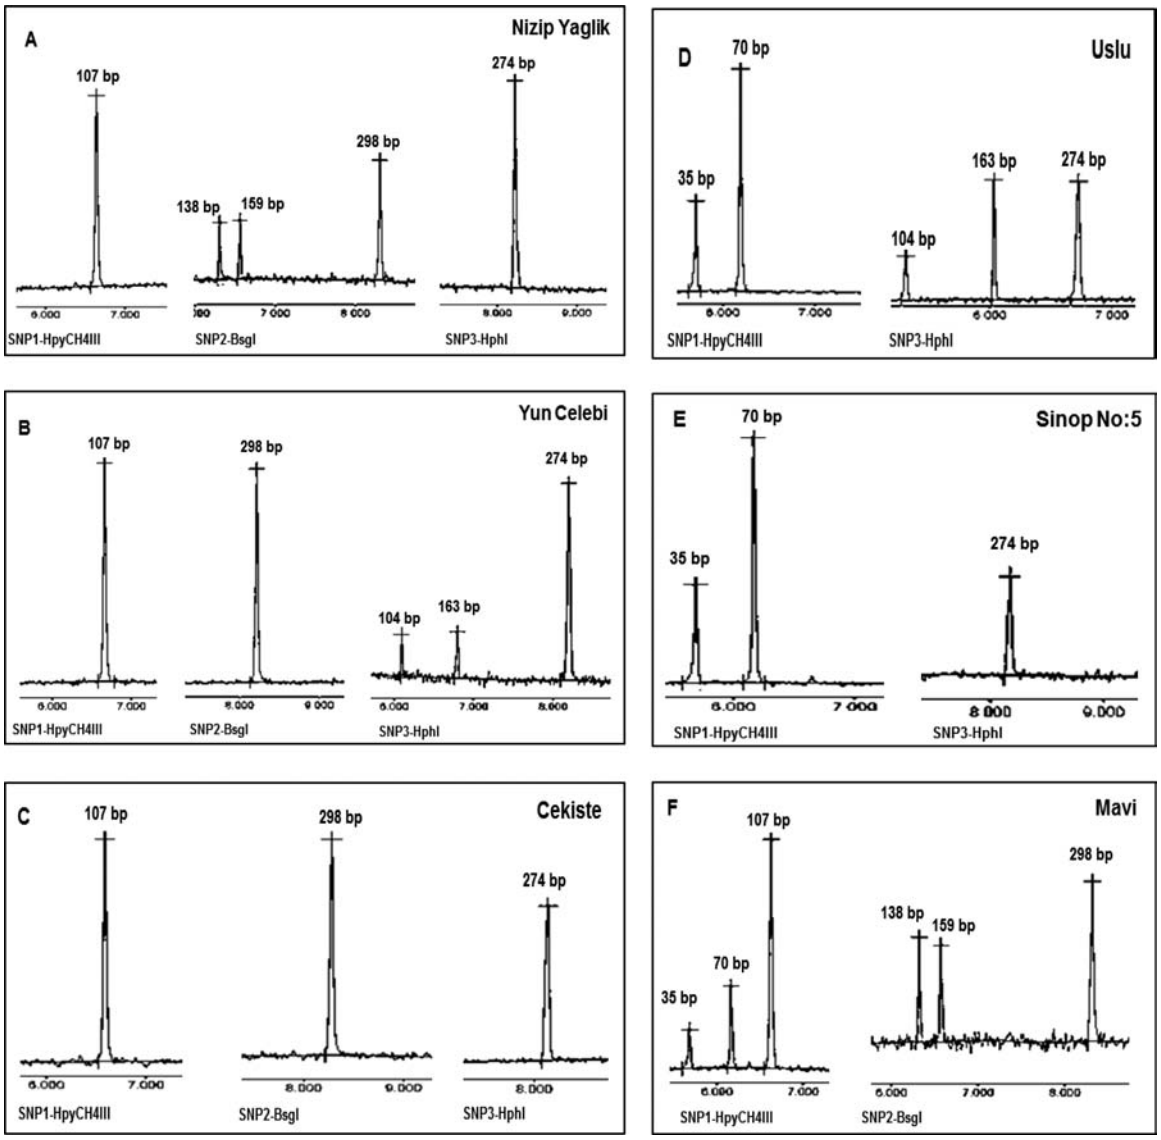

Figure 2. Electrophoretic patterns obtained by SNP-based CAPS assays for the monovarietal olive oils discriminated by two or three SNPs. Each capillary electropherogram displays the result of a SNP-based CAPS assay: A, Nizip Yaglik; B, Yun Celebi; C, Cekiste; D, Uslu; E, Sinop No:5; F, Mavi.

Hpy166II, and SNP5-HindIII) was used for the discrimination of Patos oil (Figure 4), while the SNP6-EagI assay was interchanged with the SNP4-Hpy166II assay for the discrimination of Maras No:7 oil (Figure 4).

Application of the SNP-Based CAPS Markers for Detecting Olive Oil Mixtures and Commercial Oil Samples. We tested the usefulness of our CAPS assays in identifying olive oil admixtures. For this purpose, we used oil from the Memecik and Uslu varieties, both of which are commonly cultivated in the South Aegean region of Turkey. We prepared admixtures of Memecik and Uslu oils at different ratios, extracted DNA from those admixtures, and applied the SNP3-HphI assay to determine if we could detect the contribution of DNA from the Uslu oil in the admixtures. When applied on the Memecik variety, the SNP3-HphI assay yielded a single, undigested fragment (Figure 3). Because Uslu was heterozygous for SNP3, application of the same assay yielded a three-fragment digestion pattern when applied on the oil of this variety (Figure 2). Therefore, any digestion fragment alongside the undigested band would be proof of an impurity in a Memecik oil sample. The olive oil samples prepared for the admixture detection assay contained 50%, 40%, 30%, 20%, and 10% of Uslu oil added to Memecik oil. In order to assess the limit of detecting olive oil admixtures confidently, SNP3-HphI assay was carried out in three replicates on each DNA sample. As a result of the analysis, we successfully detected Uslu oil contribution down to a limit of 20% (Figure 5). Because the admixture with 10% Uslu oil was detected only once out of the three replicate analyses, a 10% contribution by an undeclared variety was considered to be below the limit of detection of the CAPS analysis (data not shown).

We further tested the applicability of the SNP-based CAPS markers on two commercial olive oil samples. While sample no. 1 had its cultivar origin declared on the label as "Memecik", sample no. 2 was not labeled as a monovarietal product. A DNA concentration of approximately 2 ng/μL was measured by fluorometer for both of the commercial samples, which constituted a sufficient quantity of template DNA for further PCR amplifications. The entire set of six CAPS assays (Table 2) was applied on DNA from both samples in three replicates.

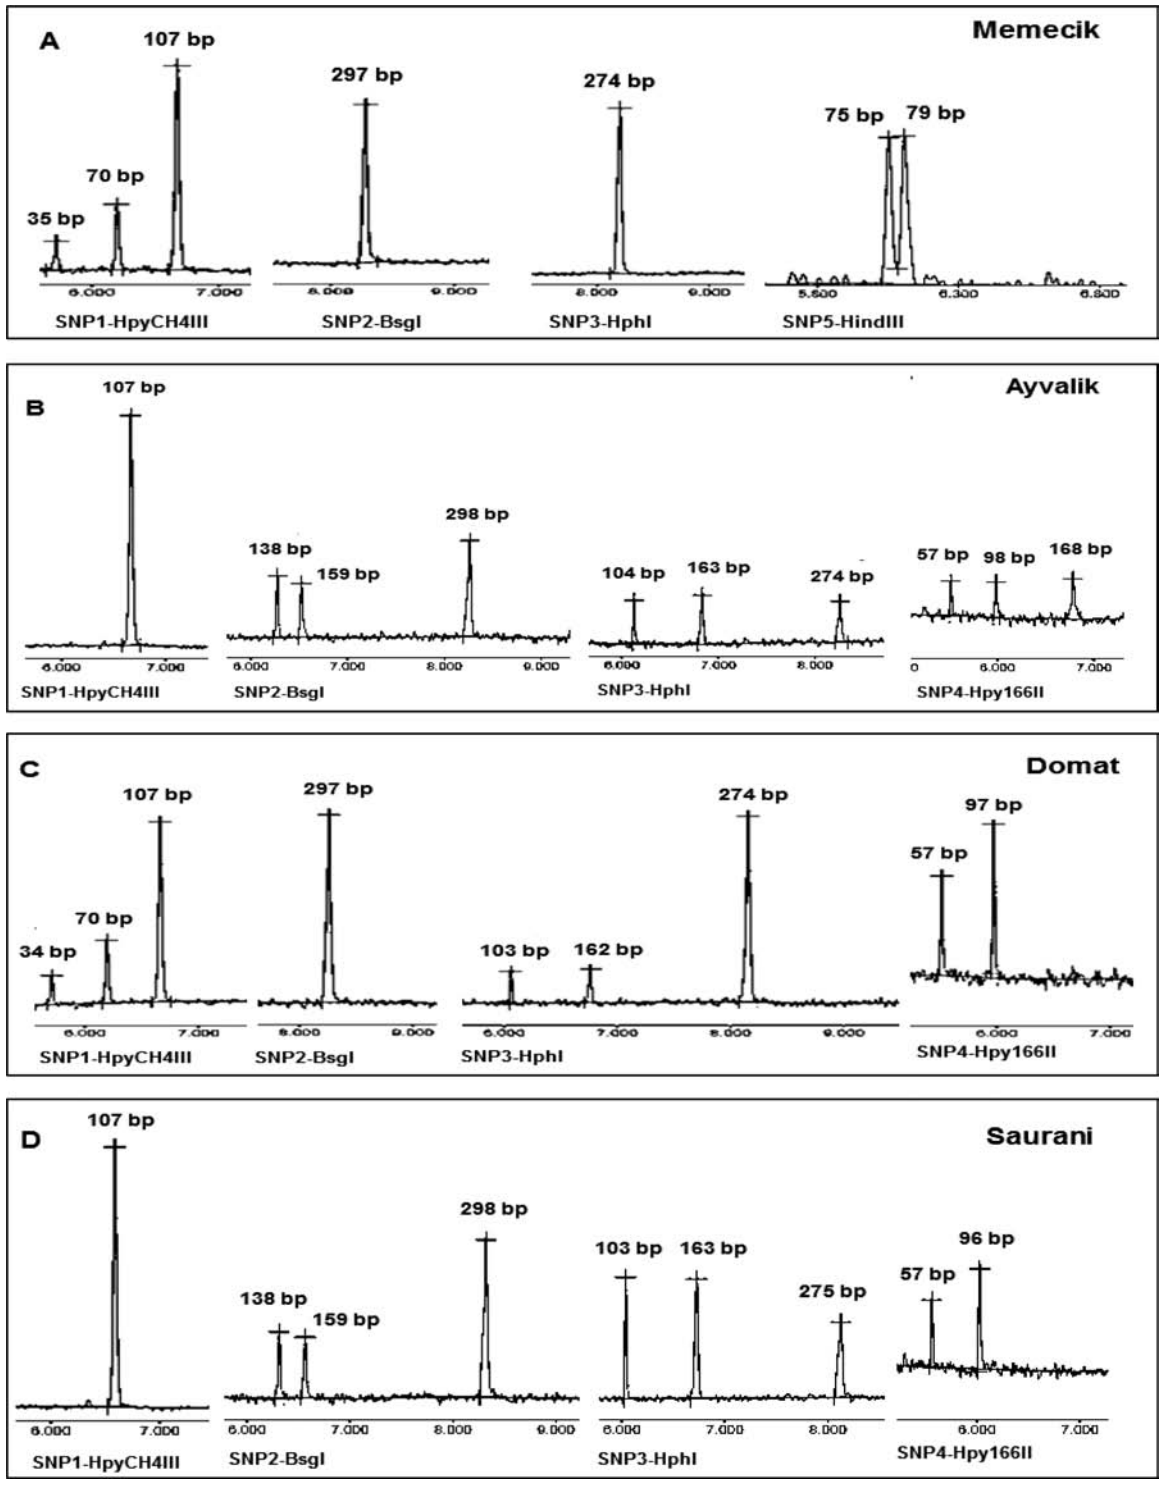

Figure 3. Electrophoretic patterns obtained by SNP-based CAPS assays for the monovarietal olive oils discriminated by four SNPs. Each capillary electropherogram displays the result of a SNP-based CAPS assay: A, Memecik; B, Ayvalik; C, Domat; D, Saurani.

For sample no. 1, the digestion profiles resulting from the six assays (Figure 6) were in agreement with the genotype of the Memecik variety (Table 2), and did not provide any evidence to suspect the declared varietal origin of the product. In case of sample no. 2, the digestion profiles obtained from the six assays (Figure 7) matched the combined SNP genotypes of none of the 17 varieties (Table 2). In addition, the result of the SNP2-BsgI assay (Figure 7) excluded the four varieties, Ayvalik, Nizip Yaglik, Mavi, and Saurani, as these varieties were heterozygous for this locus. As a result, it was concluded that either the cultivar origin of sample no. 2 was not represented in the set of 17 varieties or the product was a mixture of the oils from different varieties. The latter seemed to be a more viable explanation, because sample no. 2 was not declared as a monovarietal product on the label and the genotypes included in this work represent the most commonly cultivated Turkish olive varieties.

DISCUSSION

As an agro-food product with great economic value, virgin olive oil is an attractive target for adulteration and mislabeling. While olive oils with mislabeled cultivar origin do not constitute a health threat, traceability protocols to verify the authenticity of genuine products should be established to protect basic consumer rights. Several researchers reported that the chemical composition of oil extracted from the same olive variety is highly affected by climatic conditions,[9] agricultural practices,[10,11] time of harvest,[12] extraction procedure, and packaging and storage conditions.[13] In contrast, DNA-based assays are not influenced by compositional variations due to external effects. Therefore, either alone[21] or in combination with analytical chemistry methods,[2] DNA-based assays are increasingly used to authenticate monovarietal olive oils. The recovery of a sufficient quantity and quality of DNA is a key step in the success in

DNA-based olive oil authentication. Different authors recommend various commercial kits or in-house protocols.[1,16,17,39] When we compared different commercial kits and an in-house CTAB based protocol, we found that commercial kits are faster and more consistent in yielding amplifiable DNA from olive oil samples. While a DNA concentration that ranges between 100−200 ng/μL was obtained from olive leaf samples with the CTAB[35] method, the DNA extracted using the same method from oil samples was often below the limit of detection of the fluorometer. In contrast, commercial kits were consistent in yielding a DNA concentration of 2−4 ng/μL from the oil samples, with no visible sign of degradation on the agarose gel. Therefore, our experience suggests using food-specific commercial kits to ensure successful downstream applications.

We used SNP markers in our study as their abundance in the genome makes them ideal for identifying differences between closely related genotypes.[6] The SNP frequency we identified in olive coding sequences (1 SNP per 142.5 bp) was similar to the results of Reale et al.,[24] who reported a frequency of 1 SNP per 156 bp in the *Cycloarthenol synthase*, *Lupeol synthase*, and *Cu−Zn-superoxide dismutase* genic sequences. The high frequency of single nucleotide polymorphisms identified in olive coding sequences suggests that olive germplasm harbors a high level of genotypic diversity. Indeed, Belaj et al.[40] reported high genetic

DOI: 10.1021/acs.jafc.5b00090
J. Agric. Food Chem. 2015, 63, 2284−2295

diversity in both local olive germplasm and collections of cultivars representing different cultivation regions. Despite clonal propagation, a high genetic variability is not unexpected in olive because *Olea europaea* L. is an outcrossing species and interfertile with oleasters (wild olives).[40,41] Among the six SNPs used in the identification key, three were reported in previous work. SNP2, identified in the *Chalcone synthase* gene, was reported by Consolandi et al.[25] SNP5, identified in the *Cycloarthenol synthase* gene, was also reported by Consolandi et al.,[25] and Bazakos et al.[21] In addition, we found that the SNP in the *Calcium binding protein* gene, first described by Reale et al.,[24] was also polymorphic in Turkish germplasm and is referred to as SNP6 in this study. These results demonstrate that SNPs in olive coding sequences are conserved across the geography of olive distribution and can be useful for estimating ancestral alleles via phylogenetic analysis.

Restriction digestion-based SNP genotyping is a highly reproducible strategy, producing results that are not prone to variable interpretation in different hands. Very high reproducibility is due to the fact that genotyping is based on observing digestion patterns and does not involve any fluorescence signal intensity measurements or fragment size comparisons. In addition, there is no requirement for SNP-specific probe design or sophisticated equipment.[42] Regular PCR primers are sufficient for the application of SNP-based CAPS assays. Restriction enzymes recognizing a wide variety of sequence motifs are available, making restriction digestion-based SNP genotyping a highly feasible strategy. In this work, a high proportion (70%) of the identified SNPs were amenable to genotyping by CAPS strategy, and only six CAPS assays were sufficient to reach our aim of establishing an identification key for 17 monovarietal olive oils. According to long-term observation of agromorphological traits, two groups of varieties included in this work were suggested as synonyms by the experts of the Olive Research Institute (Izmir, Turkey). The first group of putative synonyms consisted of Gemlik, Erdek Yaglik, and Tekirdag Siyah Salamura, while the second group included Kilis Yaglik and Tesbih Celebi (personal communication). These varieties were included in our analysis in order to investigate if the DNA-based assay produced false positive results by identifying clones as distinct varieties. As a result, we found that the putative synonyms carried identical alleles for the 17 SNP loci identified in five genes, and they were grouped as indistinguishable varieties in the identification key (Figure 1). This result can be attributed to the fact that the SNP loci identified in this work reside in coding sequences. However, performing a detailed molecular genetic characterization involving markers from both coding and noncoding regions may result in distinguishing the putatively synonymous varieties.

When we applied SNP-based CAPS assays on monovarietal olive oils, we were able to obtain the expected digestion profiles. Indeed, SNP-based CAPS analysis proved highly reproducible, and produced identical banding patterns in all three replicate experiments. As a result, the allelic error was found to be 0.000 for the six SNP-based CAPS markers (Table 4). As expected for SNP markers due to their biallelic nature,[23] the multilocus probability of identity value of the SNP loci was moderately low (0.018). By following the identification key (Figure 1) introduced in this work, the cultivar origins of oils from the 17 Turkish olive varieties can be identified and authenticated. Given that the genotypes included in this work represent the most commonly cultivated olive varieties in Turkey, we expect that the variety-specific assay combinations would largely meet the expectations of the Turkish olive oil industry for authenticating high-economic value, premium monovarietal olive oils.

The ultimate goal of cultivar origin detection analyses is to determine if the origin of an oil sample is true to its labeling. Therefore, such an assay should enable the detection of undeclared impurities in a sample. Due to the fact that both the adulterant and the adulterated food commodity are extremely similar materials, the detection of mislabeled cultivar origin is a challenging task, making it attractive for unscrupulous manufacturers or vendors to gain profit from such fraudulent practice.[6,8] In addition, it is reasonable to expect that fruits of varieties cultivated in the same region are commonly processed together for oil extraction, leading to unintended mislabeling of cultivar origin. Thus, in addition to establishing a cultivar origin identification key, it was important for us to test the ability of our SNP-based CAPS assays to detect olive oil admixtures. The Memecik and Uslu varieties were specifically chosen for this kind of analysis as the oil of the Memecik variety is well-known for its sensory qualities and its area of cultivation (South Aegean region of Turkey) overlaps with that of Uslu. Therefore, we can expect that fruits of these two varieties are commonly used together for oil production. On the basis of our analysis, we could successfully detect a minimum of 20% Uslu oil mixed with Memecik oil (Figure 5). We consider this to be a good threshold of detection because, due to economic concerns, fraud generally involves much higher proportions of adulterants. However, it must be remembered that our method does not allow quantification of admixtures and that the use of different percent admixtures was solely to determine the threshold of detection.

To our knowledge, this is the first report that describes the utilization of SNP-based CAPS assays for the detection of admixtures of oils from different olive varieties. Moreover, this is the first time that SNP markers were applied on Turkish olive oils for establishing a varietal identification key and detecting olive oil admixtures. The applicability of the CAPS assays on commercial olive oil samples was also demonstrated. In addition to their use for addressing the authenticity issues of monovarietal olive oils, the CAPS assays introduced in this work will find several uses including olive tree certification, germplasm characterization, and preservation studies.

filling period,[20,21] collectively, might maintain normal yields. Salt concentrations above the tolerable threshold would compromise these adaptive processes and lead to lower productivity.[20] It is especially devastating when imposed at grain filling, since at this terminal phase of the lifecycle, the plant has fewer compensatory mechanisms to mitigate the buildup of salt in sensitive tissues.[9,20] The results are increased floret sterility, increased percentage of partially filled and unfilled grain, and lower yield.[3,8,17,22,23] Because of the multiplicity of factors that determine plant response to salinity the outcome may not always be predictable.

Rice growth environment also strongly dictates grain postharvest attributes since the grain is consumed whole with minimal processing.[3,24,25] Starch is the main grain reserve in rice accumulating up to 50−90% of dry weight with protein contributing 5−12% to the total.[26] Starch molecular composition and structure are the major quality determinants influencing grain visual, textural, nutritional, and taste attributes, but protein can also impact sensory properties.[15,26,27]

The effects of heat and drought on rice quality have been widely reported, but data on salinity are limited.[3] Some studies show that moderate to high concentrations (EC 4−8 dS/m^2) of salt reduce amylose[6,7,14] and modulate rice texture, pasting properties, and gel consistency.[6,14,28] These functional changes may be due to disruptions in the grain starch-to-storage protein ratio, amylose content, amylopectin glucan chain distribution, the lipids associated with amylose, starch granule crystallinity, and particle size distribution;[3,29−31] however, other than amylose content, most of these parameters have not been investigated.

Because of the importance of rice as a global commodity, and the potential threat of increasing soil salinity to rice production, a better understanding of how salinity affects rice quality and yield is needed. To work toward this goal we took a comprehensive view of how timing and severity of salinity stress can change some aspects of rice productivity and grain sensory quality. Plants were grown in a controlled greenhouse setting to eliminate extraneous, confounding factors.[3] Nipponbare was used, as it is the model rice ecotype, which should permit comparison with other published research.[32,33] Salinity (NaCl) was imposed at the seedling stage in one batch of rice, and at the reproductive stage in another as we anticipated differences in plant response with the differential timing of salt application.[3] This would also enable greater comparison and interpretability with the limited published data on salinity effects on grain quality, which usually adopt one approach, e.g., salt applied at the seedling stage[6,7] or during grain filling.[12,14] Two salt concentrations, EC 2 and 4 dS/m^2, were used to induce a mild and moderate salt stress rather than a nonagronomic "salt shock".[23] This was intended to allow us to examine plant adaptive responses that could be obscured by a rapid onset of senescence. Finally, we aimed to connect changes in grain sensory parameters to modifications occurring in the starch at the molecular level. Collectively these data could provide a nuanced overview of how grain parameters respond to salinity stress.

MATERIALS AND METHODS

Plant Growth Conditions. Rice (*Oryza sativa* L.) cv. Nipponbare were grown in a greenhouse in Davis, CA, from May to October 2013 in 5″ pots with a mixture of UC potting mix (1 peat moss: 1 coarse sand (v:v)) and perlite 9:1 (v:v) each containing Osmocote 17-7-12 controlled release fertilizer (B&T Grower Supply, Inc., Forest Hill, LA) flooded with water. Salt stress was imposed by adding either 20 or 40 mM NaCl to achieve EC values of 2 and 4 dS/m^2 either at 4-weeks after transplanting (V5 stages, ref 34), described here as Seedling EC2 and Seedling EC4, or at anthesis (R8 stage, ref 34), described here as Anthesis EC2 and Anthesis EC4. The control plants were grown without the addition of NaCl and were maintained at EC0. Once all filled seeds were hardened, the water was drained, and plants were kept in pots for another 7 days before the panicles were harvested. The EC was maintained at 2 and 4 (±15% variation) dS/m^2 until harvest (see Supporting Information Figure S1).

Plant Productivity and Seed Characteristics. The number of panicles per plant, 100-grain weight, total grain weight per plant, and seed fertility (expressed as number of fully filled seeds per 100 seeds) were calculated. To examine seed morphology in a high throughput manner, approximately 150 grains were placed on a scanner, and an image of 600 dpi was taken and then used as an input for WinSeedle (Regents Instrument Inc., Canada). Grain length, width, width-to-length ratio, perimeter, surface area, and volume were recorded.

Starch and Reducing Sugar Measurements. A half-gram of milled grains was homogenized to a fine powder using a Thomas Wiley Mini-Mill (Thomas Scientific, Swedesboro, NJ). Sugars were extracted from the grain by boiling 100 mg of milled flour samples three times in 80% (v/v) ethanol. Ethanol was removed by drying the soluble fraction in a speedvac, and the residue was reconstituted in 300 μL of water. Starch was analyzed from the ethanol-insoluble residue by digesting to glucose as previously described.[35] Reducing sugars in the reconstituted sample soluble fraction, as well as glucose digested from starch, were analyzed using 3,5-dinitrosalicylic acid.[36]

Starch Purification and Analysis. Starch was extracted as described in ref 37 except that 15 g of seeds was used. The samples were homogenized in a blender, and the homogenate was filtered through 4 layers of Miracloth. *Amylose* was assayed on 10 mg of purified starch using the Megazyme amylose/amylopectin determination kit (Wickson, Ireland).[36] *Amylopectin branch chain-length distribution* was analyzed by high-performance anion-exchange chromatography (HPAEC) as previously described.[38] *Thermal analyses* were done by differential scanning calorimetry (DSC), with the method modified from ref 39. Starch slurries with a water-to-starch ratio of 3:1 (∼15 mg) were hermetically sealed in a large volume stainless steel pan, and equilibrated overnight at room temperature prior to analysis. An empty stainless steel pan was used as a reference. The sample and reference pans were scanned from 30 to 120 °C at a heating rate of 10 °C/min. *Particle size analysis* was done as described in ref 40. *Pasting properties* of 8% (w/v) starch slurry was measured by AR1000-N Rheometer (TA Instrument, New Castle, DE). The temperature profile for the rheometer, which simulates the temperature profile of a Rapid Visco-Analyzer (RVA), was as follows: hold at 50 °C for 1 min, heat to 95 °C over 4.5 min, hold at 95 °C for 3 min, cool to 50 °C over 4.5 min, and finally hold at 50 °C for 1 min. The experiments were done in triplicate.

Total Protein and Nitrogen Content and SDS-PAGE Profile of Grain Flour. Protein and nitrogen (N) contents were assayed using the AOAC Kjeldahl method.[41] To analyze grains storage protein, 40 mg of flour was homogenized in 700 μL of sodium dodecyl sulfate−urea solution overnight and then centrifuged at 7000 *g* for 5 min.[42] Then, 5 μL of supernatant was loaded onto 10% (w/v) precast bis-tris sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) gel (Invitrogen, Carlsbad, CA) and subjected to electrophoresis. Coomassie Brilliant Blue R-250 (Bio-Rad, Hercules, CA) was used to stain the separated proteins, which were visualized using an AlphaImager (Alpha Innotech, San Leandro, CA). The density of each band was measured using ImageJ (NIH, Bethesda, MA).[43]

Statistical and Multivariate Analysis. A one-way analysis of variance (ANOVA) was used to determine statistically significant differences in means between treatments. A Tukey−Kramer post hoc test was calculated when statistical differences were observed. A minimum of 3, but typically 5−10, biological replicates were used. Differences were deemed to be statistically significant when $P \leq 0.05$. Partial-least squares discriminant analysis (PLS-DA) was done

RESULTS AND DISCUSSION

The aim of this work was to determine how salinity affects rice productivity and grain quality. These parameters both determine market value and acceptance of novel rice varieties.[14,27,45] Quality parameters encompass not only the physical appearance of the caryopsis, but also the biochemical composition of the grain, and most importantly the physicochemical properties of the endosperm protein and especially starch, as they are the major determinants of rice eating quality.[27] The study also aimed to investigate plants grown in the greenhouse settings where the EC was controlled (Supporting Information Figure S1) in order to achieve clear understanding of how salt impacts grain parameters.

Effect of Saline Soils on Yields and Grain Characteristics. *Plant Productivity.* Changes in rice agronomic yields were assessed by measuring grain weight, caryopsis fertility, and the number of panicles per plant (Table 1). Small and green unfilled caryopses were visible in all salt treatments except the Seedling EC2 (Figure 1). Decreases in fertility, total grain weight, and 100-grain weight were only statistically significant in the Anthesis EC4 treatment (Table 1). These results were similar to those in a study where EC 3.2 and 4.6 dS/m^2-treated rice led to reductions in grain weight.[16] Reductions of up to 98% in caryopsis weights[6,7,12] and increases in the fraction of unfilled spikelets[12] under high salt (5−8 dS/m^2) have been reported. The occurrence of unfilled seeds was suggested to be due to reduced activity of starch synthase and decreased translocation of soluble carbohydrate as a result of loss of Na^+/K^+ homeostasis in floral organs.[12] Pollen sterility and changes in floral structure may also have contributed to the floret sterility[21] in the Anthesis EC4 treatment. Conversely, Zeng et al. (2001) showed that total grain weight and grain fertility were enhanced when salinity (EC 1.8, 3.2, and 4.6 dS/m^2) was imposed at the booting stage.[16] However, unlike the present study, salinity stress was episodic, only imposed for 20 days after which soil EC was restored to control levels until harvest, perhaps accounting for the positive effects on productivity.[16]

Figure 1. Rice seeds from control and salinity-treated plants at harvest. There are 100 random seeds of each treatment shown. Several infertile unfilled seeds, as shown by green hull color, were seen in the Seedling 4 dS/m^2, and in the Anthesis treatments from both salt concentrations. The grains from these treatments were also smaller than those from the control and Seedling 2 dS/m^2 treatment (see Table 1).

Panicle numbers for the control and both anthesis treatments were not different, while it was enhanced (12%) in the Seedling EC2 treatment (Table 1). This has not been reported in any previous study, and thus requires further investigation to determine whether a mild stress had a stimulatory effect on floral primordia initiation. Since fertility, total grain weight, and 100-grain weight were not affected by the mild level of salt stress, this suggests an agronomically beneficial adaptive response of the plants. From a practical point of view, it should be possible to design experiments to determine the use of low quality irrigation water, or saline soils up to 2 dS/m^2 for rice irrigation purposes, as this treatment has minimal repercussions for rice growth in the greenhouse setting

Grain Characteristics. Grain physical appearance and dimensions are an important indicator of the marketability of rice as they are readily obvious to purchasers;[45] however, the length and shape of the rice kernels also affect kernel milling, cooking, and sensory properties.[46] Here, we showed that prolonged exposure to NaCl throughout development affected grain dimensions (Table 2). Seedling EC4 plants had lower grain volume compared to the control. This could indicate changes in cell number in the lemma and palea because the size of the outer glume greatly restricts the dimension of dehulled rice endosperms.[47] Seedling EC2 plants had increased grain length and surface area (Figure 1 and Table 2). This may be perceived negatively in some Asian markets.[15] On the contrary, a decrease in grain length of two indica rice cultivars has been reported for plants grown in a higher degree of salinity (EC 5−

[a]Values are means ± SEM. Means within each column with different superscripts and presented in bold are significantly different ($P \leq 0.05$) by Tukey's test ($n = 4$ for starch, sugar, and N content analyses; $n = 3$ for amylose content and particle size analyses).

6 dS/m^2),[6] again emphasizing that plant response is genotype and environment sensitive.

Grain Storage Product Composition. *Starch, Sugar, and Amylose Contents and Starch Particle Size Distribution.* The major grain carbohydrates are starch, sugars, and amylose. Starch dictates yield, while amylose content is one of the major properties determining rice sensory quality.[48] Differences in starch granule size also influence starch functionality,[49,50] and grain sugars could increase due to stress-induced starch breakdown and may influence taste.[51] Here we found no difference in reducing sugar content (Table 3). Interestingly, we found that the Seedling EC4 and the Anthesis EC2 treatments increased the percentage of starch in the rice flour (Table 3) as well as in each caryopsis (Supporting Information Table S1). These increases in starch content stand in sharp contrast to rice grown under stronger saline conditions (EC 4–8 dS/m^2) which reduced endosperm starch[6,14] even in greenhouse grown rice such as ours.[6] Salt enhances starch accumulation in tomato fruits by elevating ADP-glucose pyrophosphorylase (AGPase) activity, a key enzyme in starch biosynthesis.[52] In rice, expression level of the leaf large and small AGPase subunits also increased in response to salinity.[53] However, whether AGPase transcript level and enzyme activity increase in the endosperm in a similar way to that seen in tomato under salinity is worth determining.

Surprisingly, the percentage of amylose in starches from plants exposed to salinity, including those that had increased starch contents, did not differ from that of the control (Table 3). Reductions in amylose exposed to high salt concentration (EC 4–8 dS/m^2) at the reproductive stages have been reported;[6,14] however, in one study, salinity exposure at the seedling stage had to be as high as 6–8 dS/m^2 for amylose content to decrease.[7] The particle size distribution of starch grains was also not affected by salt stress (Supporting Information Table S2). Because salinity stress exposure was associated with increased starch content and no change in the percentage of amylose or starch granule size distribution, it is tempting to speculate that salinity may have altered some aspects of starch biosynthesis such as starch granule initiation and amylose biosynthesis.

Protein and N Content. Rice grain protein and N contents can be increased by salinity stress.[11] In this study, the protein and N content in the flour from the Anthesis EC4 treatment was significantly higher than that of the flours from other growth conditions (Table 3). SDS-PAGE profiles of these grains confirmed that the glutelin and prolamin contents were greatly enhanced (Figure 2). Similarly, six rice cultivars grown under 2.5 dS/m^2 salinity were found to have higher protein content with major contributions from glutelin.[11] When the protein content was expressed relative to starch content (data not shown), the starch:protein ratio of the Anthesis EC4 sample was lower compared to the control, thus potentially

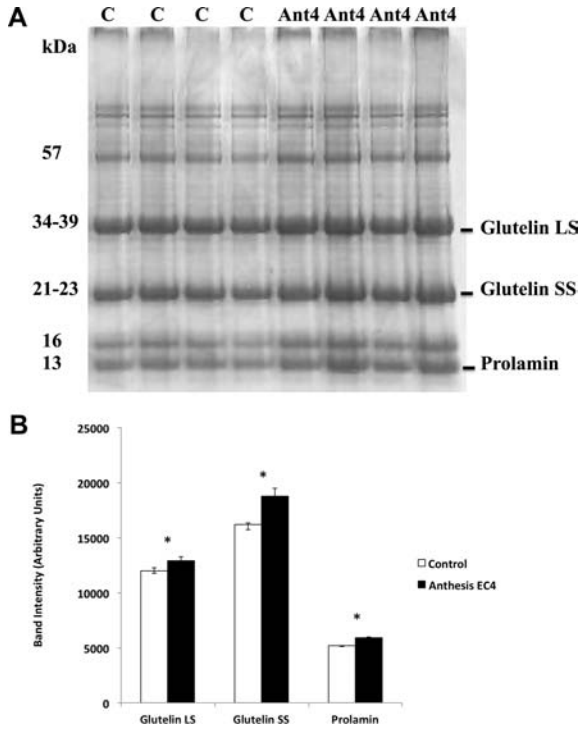

Figure 2. Analysis of grain storage proteins extracted from flour of Control and Anthesis EC4 treatments. (A) SDS-PAGE showing the bands of the glutelin large subunit (LS), glutelin small subunit (SS), and prolamin. (B) Densitometry plot showing the relative content of these rice storage proteins. affecting rice cooking and sensory properties.[54] Removing proteins from rice flours increases the water availability for starch and results in a less viscous product;[54] therefore, the Anthesis EC4 caryopsis, once cooked, might become firmer due to reduced water availability for starch granule swelling and glucan leaching. This high protein-induced hardness in cooked rice may be further amplified because caryopsis amylose content was unchanged (Table 3).[6] However, to determine this, the retrogradation property of the endosperm starch must also be considered.

When expressed on a mg per grain basis, caryopsis protein and starch levels in the Anthesis EC4 treatment were not different from the control (Supporting Information Table S1). The lack of congruency in protein expressed on an equal mass basis versus on a per grain basis suggests differences in reserve allocation and partitioning to the grain due to salinity. Moreover, while grain starch was enhanced in the Seedling EC4 and Anthesis EC2 treatments, the protein accumulation remained stable (Supporting Information Table S1). This

suggests that, under these two salinity conditions, starch and protein accumulation were differently regulated.

Starch Molecular Structure and Functionality. *Amylopectin Branch Chain-Length Distribution.* Amylopectin fine structure is an important contributor of starch functionality as its branch chain-length distribution is shown to relate to starch crystalline structure[55] and pasting properties.[56] There was no difference in distribution pattern of the branch chains of different degrees of polymerization among all treatment groups (Supporting Information Figure S2), suggesting no notable effect of salinity on the overall amylopectin chain-length profile. However, when the glucan chain lengths were categorized into discrete classes (A class, DP 6−12; B_1 class, DP 13−24; B_2 class, DP 25−36; and B_3 class, DP ≥ 37),[55] differences were found in the Anthesis EC4 treatment, which had a reduced proportion of the long chains (i.e., DP ≥ 37) (Figure 3).

Starch Gelatinization Properties. DSC enables the heat of gelatinization of a starch−water suspension to be observed as a well-defined endotherm peak.[57] Salt stress reduced both the peak and conclusion temperatures, while the temperature range was smallest in the Anthesis EC4 among others (Table 4). The enthalpy of the system nevertheless did not vary among all

DOI: 10.1021/jf503948p
J. Agric. Food Chem. 2015, 63, 2296−2304

treatments (Table 4). The DSC analysis also reveals the thermal behavior of the amylose−lipid complex melting, which can alter starch functionality.[58] There was no significant difference in the melting profiles of all treatments, except for the Anthesis EC4 treatment, where a significant reduction in onset temperature of melting was found (Supporting Information Table S3). This suggests only a slight difference in strength and amount of lipid complexes with amylose as a result of salinity, and is in agreement with the finding that amylose content was unchanged due to saline conditions in this study.

Starch Pasting Properties. The pasting behavior of a starch/water mixture is measured as a change in viscosity resistance of the mixture to controlled shear as the temperature is increased and decreased.[59] The rheometer-simulated RVA pasting profile showed that Anthesis EC4 starch formed a paste at slightly lower temperatures than the control starch (Table 5 and Figure 4), while the pasting temperatures of other treatments did not

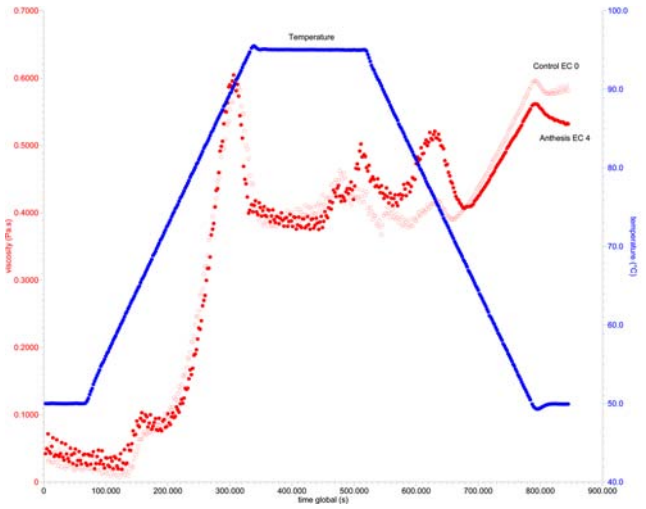

Figure 4. Pasting profiles of starches from Control and Anthesis 40 dS/m^2 NaCl-treated plants. An 8% (w/w) starch slurry was analyzed on the rheometer-simulated RVA platform. The temperature profile is shown in the figure.

deviate from that of the control sample. The same was shown in the study by Peiris et al.[7] with rice exposed to EC values ranging from 2 to 4 dS/m^2. The lower pasting temperature of the Anthesis EC4 starch may be explained by the diminished proportion of the long chains of amylopectin (Table 5), as these long chains could contribute to maintenance of starch granule integrity during the pasting process.[56] The peak viscosity and setback of most of the salt treatments were also lower than those of the control (Table 5), suggesting that the integrity of the gel network was compromised, thus reducing the occurrence of starch retrogradation.[60]

Multivariate Analysis. The PLS-DA algorithm is a supervised method that uses multiple linear regression analyses to identify maximum covariance between measured variables and treatments. In other words, the variation *within* groups is reduced in order to maximize differences *among* groups. The measured variables are summarized into a smaller number of variables called "scores" which then were plotted on the 2D-plots.[61] Here, PLS-DA was used to analyze the behavior of all variables measured in this study (Figure 5A), of the agronomic variables (Figure 5B), and of the grain composition and starch

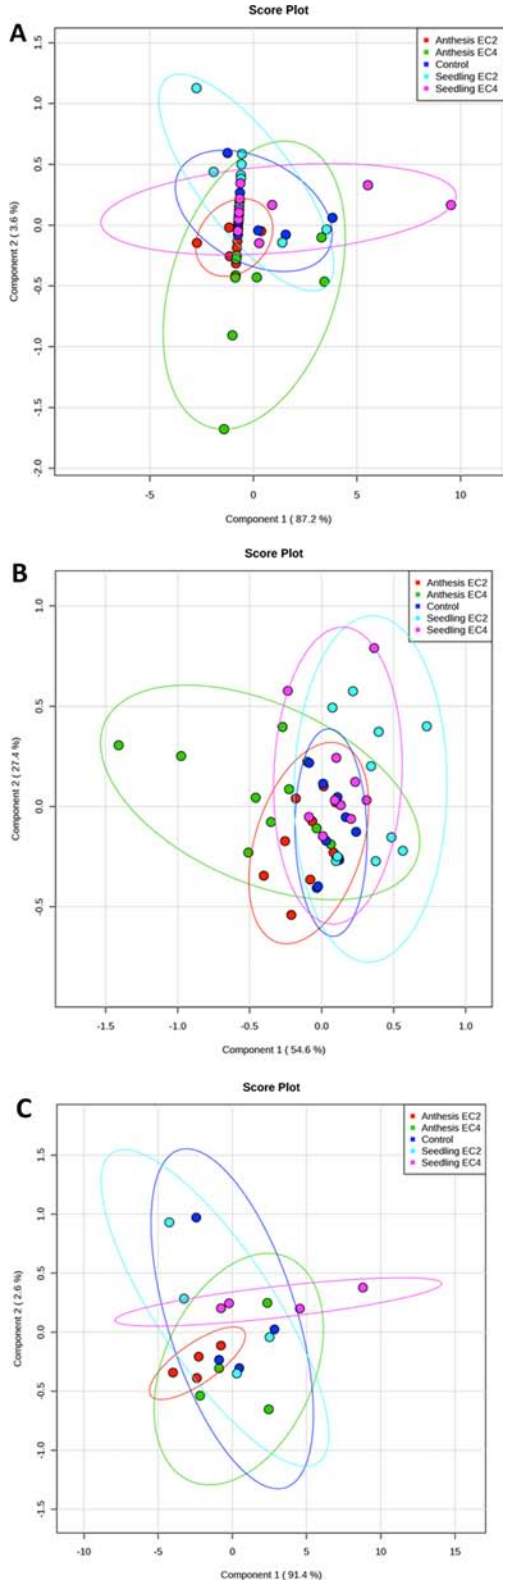

Figure 5. Partial-least squares discriminant analysis (PLS-DA) of measured variables. (A) PLS-DA plot of all variables in this study. (B) Agronomic yield and grain characteristic variables. (C) Grain composition and starch functionality variables. Each of the 3−10 replicates was individually plotted, and the samples were projected onto 2D-plots showing the first 2 principal components (PCs). Each PC captures maximum variation of the data set, where PC1 retains the most variation and PC2 captures the second most level of variation.[62] The confidence ellipses represent 95% confidence intervals of the data.

J. Agric. Food Chem. 2015, 63, 2296−2304

functionality variables (Figure 5C) in order to illustrate the separation between different groups of treatments. Although there were significant changes ($P < 0.05$) in the individual data sets of both agronomical and grain composition and starch functionality measurements, the multivariate analysis revealed that, when considered together, the variables behaved similarly among all the treatments as no distinct separation between treatment groups was observed (Figure 5A). Some separation could be seen between the Seedling EC2 Anthesis EC4 treatments when only the agronomical variables were taken into account (Figure 5B), but separation disappeared when grain composition and starch functionality parameters were simultaneously assessed (Figure 5C). Some separation between Anthesis EC2 and Seedling EC4 treatments however was observed when considering grain composition and starch functionality variables (Figure 5C). This implies that the impacts of different salinity levels applied at different developmental stages were not profound, at least in this greenhouse-based experimental setting in which other potential environmental variables were reduced.

This study aimed to understand and differentiate the prolonged and isolated effects at the grain filling stage of both mild and high salinity on the yield, and compositional and functionality components of rice grains. Overall, the changes were most pronounced in the high salinity treatment applied at the reproductive stages. Rice grown under both prolonged treatments seemed to have adapted to the salinity, but to different extents; that is, Seedling EC2 appeared to have morphological adaptation, while Seedling EC4 plants modulated their carbon flux to the developing kernels. Applying salt at Anthesis had a direct but opposite effect on grain filling process: Anthesis EC2 may have accelerated grain filling, resulting in higher starch accumulation, while Anthesis EC4 was compromised in its adaptability to the imposed salinity level, which was reflected in diminished agronomic yields and starch content. Although multivariate analysis of the data showed that the 2 and 4 dS/m^2 NaCl did not have profound effects on rice starch molecular composition regardless of the time of treatment application, there were still measurable changes in starch thermal and pasting properties, which were only limited to the most affected treatment (i e. Anthesis EC4). Overall, this study demonstrated the complexity of rice responses to timing and severity of salinity stress.

pomegranate seeds and almond have been studied by different researchers,[7−9] to the best of our knowledge, no investigation is available on the bioactive and physicochemical properties of those byproducts in detail and no investigation has been focused on the properties of extracts of walnut. Therefore, this study was aimed to investigate the physicochemical (crude fat, protein, fiber, mineral, phenolic, and fatty acid contents, volatile composition, and color properties), antimicrobial (against *Staphylococcus aureus*, *Listeria monocytogenes*, *Escherichia coli* O157:H7, and *Salmonella* Typhimurium), and bioactive (hydrolyzable tannin, total phenolic, and flavonoid contents) properties and volatile composition of those byproducts in detail. The results of the present study could provide information about where these byproducts could be used in the food industry to achieve economic gain.

MATERIALS AND METHODS

Materials. Oil byproducts obtained by cold pressing of grape, walnut, pomegranate, and almond seeds were provided from Oneva Food Co, Istanbul, Turkey, and were coded as GOB, WOB, POB, and AOB, respectively. Air-dried and powdered samples were subsequently transferred to the laboratory and stored in damp-proof plastic bags at room temperature until being analyzed.

Physicochemical Properties. *Determination of Color, Browning Index (BI), and Bulk Density.* The color properties of the byproducts were measured using a colorimeter (Konica Minolta, CR-400, Mississauga, ON, Canada), and the color values were expressed as *L* (whiteness/darkness), *a* (redness/greenness), and *b* (yellowness/blueness). BI analysis was carried out according to a method described by Palombo et al.[10] Briefly, absorbance values of the centrifuged clear filtrates were measured at 420 and 550 nm by spectrophotometer (8453E UV−vis spectroscopy system and Agilent, USA). Distilled water was used as the blank, and the BI, which was expressed as optical density/g dry solids, was calculated as

$$\text{browning index (BI)} = A_{420} - A_{520} \quad (1)$$

where A_{420} and A_{520} are absorbance values of the samples measured at 420 and 520 nm, respectively. Bulk density of the byproducts was determined according to method described by Chegini and Ghobadian.[11]

Determination of Dry Matter, Oil, Protein, Crude Fiber, and Ash Contents. Dry matter, ash, protein, crude fiber, and oil contents of the byproducts were determined according to the method reported by official procedures.[12] Dry matter contents of the samples were analyzed by drying at 105 °C for 4 h in a drying oven (FN 120, Nuve, Ankara, Turkey). Ash content was determined by incineration of the samples at 550 °C for 6 h, whereas protein content was tested using an automatic nitrogen analyzer (FP 528, Leco, USA), on the basis of the Dumas method. Total protein contents were calculated by multiplying the obtained nitrogen values by 6.25. Crude fiber contents of the samples were determined using an automatic fiber analyzer (ANKOM Technology Corp., Fairport, NY, USA). The oil contents of the byproducts was determined using a Soxhlet extraction system in which hexane were used as a solvent.

Determination of Water Activity and pH Values. A water activity meter (AquaLab, 2.0, USA) was used for determining the water activity of the samples. Samples were placed into plastic cups to cover the surface and transferred into the equipment. The results were measured at 25 °C. The pH of the sample was measured with a pH meter (WTW-Inolab, Weilheim, Germany) in a suspension of 10% (w/v) powder in distilled water at 25 °C.

Determination of Fatty Acid Composition. The fatty acid composition of the extracted oil samples was determined using fatty acid methyl ester (FAME) according to the method described by Yalcin et al.[13] To determine the fatty acid composition of the samples, the samples were subjected to an oil extraction procedure by hexane using a Soxhlet extraction system for 6 h. A GC (Agilent 6890, Agilent, USA) equipped with a FID and 100 × 0.25 mm i.d. HP-88 column was used. Injection block temperature was adjusted to 250 °C. The oven temperature was held at 103 °C for 1 min, heated to 170 °C at 6.5 °C/min and from 170 to 230 °C for 12 min at 2.5 °C/min, and then held at 230 °C for 5 min. Helium was used as a carrier gas with a flow rate 2 mL/min; the split rate was 1/50.

Determination of Mineral Composition. Mineral analysis of the samples was performed according to the method described by AOAC with some modifications.[14] Half a gram of the sample was weighed into Teflon microwave digestion vessel and incorporated with 5 mL of concentrated nitric acid and 1 mL of hydrogen peroxide. Vessels were covered and placed into a microwave oven. The initial oven temperature was adjusted to 25 °C, then heated to 90 °C for 5 min, from 90 to 120 °C at 6 °C/min, and from 120 to 150 °C at 6 °C/min, finally increased to 175 °C at 6 °C/min, and held at this temperature for 5 min. After the vessels cooled, clear digested samples were transferred to 50 mL volumetric flasks and diluted to the mark with deionized water. Minerals were determined using a PerkinElmer AAS 700 in flame mode. The following wavelengths and slit widths were used to quantify minerals: calcium, wavelength 422.7, slit, 0.7 H; sodium, wavelength 589.0, slit 0.2 H; iron, wavelength 248.3, slit 0.2 H; zinc, wavelength 213.9, slit 0.7 H; manganese, wavelength 279.5, slit 0.2 H; potassium, wavelength 766.5, slit 0.7 H; magnesium, wavelength 285.2, slit 0.7 H; copper, wavelength 324.8, slit 0.7 H.

Bioactive Properties. *Extraction Procedure.* Methanol was used for the extraction of the bioactive compounds from the byproducts. During the extraction process, 1 g of the sample was weighed into the test tube and mixed with 10 mL of methanol. The mixture was stirred by vortex and then by a shaker for 1 h at ambient temperature (Simsek Labor Teknik, Ankara, Turkey). Following the extraction process, the solution was centrifuged on a Universal 320 centrifuger (Hettich, Germany) at 5000g for 5 min, and the supernatants were filtered using a 0.45 μm filter (Sartorious Stedim Biotech, Gottingen, Germany). Obtained extracts were kept at −18 °C for further analysis.

Determination of Total Phenolic Content (TPC). TPC of the methanolic extracts was determined according to the modified method described by Singleton and Rossi.[15] TPC was determined at 760 nm by a spectrophotometer (Agilent 8453E UV−vis spectroscopy system) using Folin−Ciocalteu's phenol reagent. TPCs of the samples were calculated as milligrams of gallic acid equivalents (GAE) per 100 g of dried samples.

Determination of Total Flavonoid Content (TFC). TFC of the methanolic extracts was determined according to the method described by Zhinsen et al.[16] TFC was determined spectrophotometrically at 510 nm. The results were expressed as milligrams of catechin (CE) per 100 g of dried sample.

Determination of Total Hydrolyzable Tannin Content (HTC). The total HTC of the methanolic extracts was determined according to the method of Willis and Allen.[17] The absorbance of the samples was recorded at 550 nm, and the results were calculated as mg of tannic acid (TA) per 100 g of dried sample.

Determination of Phenolic Composition. The phenolic profile of the samples was determined according to the modified method described by Schieber et al.[18] using a HPLC system (Shimadzu, Kyoto, Japan) equipped with a DGU-20A5 degasser, an LC-20AT gradient pump, an SIL-20A autosampler, a CTO-10AS VP column oven, and an SPD-M20A diode array detection (DAD) system. The column used was a Luna, 5 μm, C18 100A (250 × 4.6 mm) from Phenomenex (Torrance, CA, USA). Column temperature was set to 25 °C. Mobile phase A was 2% (v/v) acetic acid prepared in double-distilled water; eluent B was 0.5% acetic acid in double-distilled water and acetonitrile (50:50, v/v). The gradient was as follows: from 90 to 55% of A within 40 min, from 55 to 0% of A within 5 min, and returning to the initial 90% A within 5 min. Between each analysis 15 min of equilibration treatment (90% of A) was performed. The flow rate was 1 mL/min, and the injection volume was 20 μL.

Antibacterial Activity. Antibacterial activity was assessed using the extracts of the byproducts prepared for determination of bioactive properties. Four bacterial strains were used to assess antibacterial activity of the extracts of oil byproducts, two Gram-positive (*Staphylococcus aureus* ATCC 25923 and *Listeria monocytogenes*

ATCC 19118) and two Gram-negative bacteria (*Escherichia coli* O157:H7 ATCC 33150 and *Salmonella enteric* subsp. *enteric* serovar Typhimurium ATCC 14028). All bacterial strains were activated twice in nutrient broth (Merck, Darmstadt, Germany), and inocula were prepared by 18 h culture in nutrient broth at 37 °C.

The agar diffusion method was used to determine the antibacterial effect on the basis of the method described by Özkan et al.[19] For this aim, autoclaved nutrient agar (Merck) was inoculated with each 18 h bacterial strain, targeting a final cell concentration of 10^6–10^7 CFU/mL at 43–45 °C and poured in Petri plates. After the solidification of agar, four wells were made in the agar using sterile cork pores (4 mm). A 50 μL of different concentrations (50%, 20% and 4% v:v in 95% ethanol) of the extracts was pipetted in each well. 95% ethanol was used as the negative control. Petri plates were incubated at 37 °C for 24h. The antibacterial activity was expressed as the mean of inhibition diameters (mm) produced by the extract minus that for the negative control.

Volatile Composition. The volatile profile of the oil byproducts was determined using a gas chromatography–mass spectrometry (Agilent 7890A GC system, Agilent Technologies, Avondale, AZ, USA) using a mass selective detector (Agilent Technologies) and DB-WAX column (60 m × 0.250 mm i.d.; film thickness, 0.25 μm). The oven temperature was adjusted to 40 °C for 10 min, then heated to 110 °C at 3 °C/min, from 110 to 150 °C at 4 °C/min, and from 150 to 210 °C at 10 °C/min, finally increased to 210 °C/min and held for 15 min. Helium was used as a carrier gas with a flow rate of 1.0 mL/min, and the voltage of the electron ionization detector was 70 eV. The compounds adsorbed by the SPME fiber (75 μm, 23 ga, carboxen/polydimethylsiloxane (CAR/PDMS)) (Supelco, Bellefonte, PA, USA) at 40 °C for 1 h were desorbed from the injection port for 15 min at 50 °C in the splitless mode. The compounds were identified by comparison with spectra from the libraries Flavor 2, NIST 05, and Wiley 7n. Analyses were conducted in duplicate.

Statistical Analysis. All of the results were expressed as the mean ± SD. ANOVA was performed to determine the differences among the samples using the SPSS Statistical Software Program (SPSS Statistics 17.0, Armonk, NY, USA). The Duncan multiple-comparison test was conducted to determine the differences between the parameters at the probability level of 0.05.

RESULTS AND DISCUSSION

Physicochemical Properties. *Physical Properties.* Color (L, a, b), BI, and bulk density values of the oil byproducts are shown in Table 1. As can be seen in Table 1, L, a, and b values of the byproducts were found between 42.01 and 68.39, between 5.71 and 12.72, and between 18.19 and 23.27, respectively. Color values of the WOB, POB, and GOB samples were very close to each other; however, those of AOB, especially L and a values, were quite different from the others. As known, the color of a certain food is one of the main factors affecting its consumer preference. Use of different additives may change color properties of foods. In this respect, these oil byproducts, if they are used, may affect foods' color. Color of the byproducts is related with pigments, carotenoids, and phenolic pigments (anthocyanins, flavonols, and proanthocyanins). Therefore, variation in type or amount of these compounds results in different color values. BI values of the byproducts analyzed in the present study changed between 0.042 and 0.520. Browning of the food and agricultural material and their byproducts occurs by the formation of some colored pigments due to enzymatic and nonenzymatic reaction and concentration changes The highest BI value belonged to WOB, whereas AOB had the lowest BI. In addition to color properties, bulk densities of the samples were also analyzed. Bulk density of the cold-pressed oil byproducts were found between 1.33 and 1.53. Because powder forms of these byproducts could be used for any aim, their bulk density values are also important in this respect. Among the samples, WOB had the lowest bulk density value, indicating that it can be compressed easily when compared with the others.

Some Chemical Properties. Chemical properties of the oil byproducts are presented in Table 2. pH and a_w values of the samples ranged from 4.25 to 6.14 and from 0.391 to 0.498, respectively. Dry matter contents of the byproducts were very close to each other and varied between 90.55 and 93.71%. Protein contents of the samples varied over a wide range, from 9.38 to 49.05%. Among the samples, AOB had the highest protein content followed by WOB, POB, and GOB, respectively. As seen from the results, WOB, POB, and AOB had significant amounts of protein; therefore, they might be used to enrich the protein content of different food products. Cam et al.[20] added pomegranate byproducts to ice cream and reported that ice cream samples enriched with byproducts had higher protein content than control ice cream. Enrichment of different food products with AOB could be preferred because it has high protein content and almond proteins can provide all essential amino acids except for methionine in quantities equal to or greater than recommended by the FAO.[21]

Oil Content and Fatty Acid Composition. Oil contents of the byproducts ranged from 4.82 to 12.57%. Except for GOB, the other seed byproducts had approximately 10% oil, indicating a relatively low cold-pressing yield, which can be considered as a general problem for cold press oil industry. The high oil content of the byproducts could lead to problems due to oxidation of oil, which might cause some problems during storage of the byproducts or food products enriched with them. However, as will be seen in subsequent sections, this problem might be prevented due to the high phenolic composition of the samples. The fatty acid composition of the oils extracted from the byproducts is presented in Table 3. As seen from Table 3, significant differences were observed among the fatty acid compositions of the oil byproducts. The dominant fatty acid of the oil extracted from GOB was found to be C18:2, followed by C18:1, C16:0, and C18:0, respectively. The saturated fatty acid content of the GOB was determined as 13.08%. Mono- and polyunsaturated fatty acid contents were found as 18.67 and 68.26%, respectively. Beveridge et al.[22] studied the fatty acid composition of oil extracted from different grape seed varieties with supercritical carbon dioxide extraction, and they revealed that saturated and mono- and polyunsaturated fatty acid compositions of the oils ranged between 11.21 and 13.85%, between 12.77 and 18.59%, and between 68.10 and 73.67%, respectively. As seen, our results were in accordance with the literature findings. The oil extracted from AOB contained the fatty acid types in decreasing order C18:1, C18:2, C16:0, C18:0, C18:3n6, and C14:0. The findings of the present study were in accordance with the previous study.[23] The fatty acid profile of POB oil is also presented in Table 3, and the most abundant fatty acid determined was C18:3n6, which was followed by C18:2, C18:1, C16:0, C18:0, C18:3n3, and C14:0, respectively. POB oil comprised saturated and mono- and polyunsaturated fatty acids in concentrations of 7.47, 6.48, and 86.25%, respectively. C18:3 was found as the dominant fatty acid in POB oil. The results of the present study were consistent with the findings of Fadavi et al.,[24] who reported that saturated and mono- and polyunsaturated fatty acid contents of the 25 different pomegranate seed oils varied between 4.8 and 26.8%, between 0.4 and 17.4%, and between 55.8 and 92.1%, respectively. C18:2 was determined as the dominant fatty acid in WOB oil when compared to the other fatty acid types, which was consistent with the study in which saturated and mono- and polyunsaturated fatty acid contents of walnut seed oil were reported to be 11.76, 15.28, and 72.96%, respectively.[23] As expected, slight differences

[a]Grape and walnut extracts did not show antibacterial activity against any of the bacteria. [b]Different lower case letters show differences between the studied extract concentration levels for each bacterial strain (n = 3). The results are expressed as the mean ± SD. [c]No inhibition zone was observed.

among the results of the present study and previous studies were observed for each byproduct oil, which might be resulted from genetic and environmental factors such as production year and growing location.[25] As known, consumption of vegetable oils is currently increasing due to their high polyunsaturated fatty acid content, which possesses a natural preventive role in cardiovascular diseases and promotes reduction of total and HDL cholesterol.[26] Therefore, enrichment of different foods with these oil byproducts could be suggested regarding their fatty acid composition, which also gains economic benefit as well as health benefit.

Crude Fiber Contents. The crude fiber contents of the byproducts varied between 5.87 and 45.83% as shown in Table 2. Among the byproducts analyzed in the present study, the highest crude fiber content was observed in GOB (45.83%), whereas POB, WOB, and AOB had crude fiber in concentrations of 25.10, 6.65, and 5.87%, respectively. As known, sufficient dietary fiber consumption could reduce the risk of cardiovascular disease, colon cancer, and obesity.[27] Hereby, consumption of the dietary fiber enriched products is very important for the health of people of all ages. Enrichment of the food products with GOB or POB should be suggested considering the beneficial effects of dietary fiber. Moreover, these byproducts can be used as a new source for the production of different dietary fiber types, which can provide important economic benefit because in recent years people tend to consume products with high fiber content. Chau and Huang[28] reported that products rich in dietary fibers have attracted attention as food ingredients and have encouraged researchers to search out new fiber sources.

Determination of Total Ash and Mineral Composition. Ash contents of the oil byproducts varied between 3.07 and 4.50%. AOB had the highest ash content followed by WOB, POB, and GOB, respectively. The mineral composition profile of the byproducts analyzed is summarized in Table 4. GOB was found to be a rich source of potassium (832.27 mg/100 g sample) and calcium (670.03 mg/100 g sample). AOB and WOB samples had significant amounts of potassium, calcium, phosphorus, sulfur, and magnesium. POB was rich in potassium, calcium, phosphorus, and sulfur. In general, all of the byproducts were rich in macroelements, namely, potassium, calcium, phosphorus, and magnesium, whereas these elements were all the most abundant minerals found in AOB. These byproducts also contained dietary trace minerals (iron, manganese, copper, and zinc) in different quantities. As known, calcium is required for bone growth, nerve and muscle functions, and protection against high blood pressure; phosphorus for bone growth, acid base balance, and structure of nucleic acids; magnesium also for bone growth and regular functions of nervous and muscular system; and potassium for regulation of blood pressure and muscular contraction. Among the trace elements, iron is required for use of oxygen in the body, building of blood cells, and structuring of hemoglobin and copper for absorption of iron, structuring of hemoglobin, and production of energy. For these reasons, people of all ages require these minerals to keep their healthy life and, in this respect, incorporation of the oil byproducts into different food products has the potential to improve their nutritional quality by enriching their mineral profile. For instance, if any AOB is incorporated to any food product in concentrations of 1%, it provides approximately 12.07 mg of potassium, 8.96 mg of calcium, 5.22 mg of phosphorus, and 2.56 mg of sulfur per 100 g of food to the person consuming this enriched food product. As seen, enrichment of the products with these byproducts can induce significant increase in mineral composition.

Antibacterial Activity. In this study, almond and pomegranate extracts showed antibacterial activity, whereas grape and walnut extracts showed no antibacterial activity against any pathogenic bacteria tested. Table 5 shows the antibacterial activity of AOB and POB as inhibition zone. As can be seen from the table, AOB showed no antibacterial activity on tested microorganisms except *L. monocytogenes* at the lowest concentration. It is also clear from the table that the antibacterial activity of the AOB and POB extracts was concentration dependent, and lower concentrations of the extracts exhibited weak or no antibacterial activity. AOB extract was more effective against Gram-positive bacteria (*L. monocytogenes* and *S. aureus*) than POB extract, whereas stronger antibacterial activity on Gram-negative *S.* Typhimurium and *E. coli* O157:H7 was exhibited by pomegranate. Baydar et al.[29] reported that grape bagasse extracts did not show antibacterial activity against 15 bacteria. They also stated that lower concentrations of grape seed extracts were ineffective. Hammer et al.[30] showed that sweet almond (*Prunus dulcis*) oil did not inhibit any organisms even at the highest concentration, which was 2.0% oil. De et al.[31] reported antimicrobial activity of pomegranate seeds against *Bacillus subtilis*, *E. coli*, and *Saccharomyces cerevisiae*. The peel extract has shown highest antimicrobial activity compared to other extracts, whereas the seed extracts exhibited variable antimicrobial activities to the bacteria except for *Bacillus coagulans*. It can be understood from the literature that the antimicrobial activity of plant extracts depends on several factors such as plant part, extraction method, solvent used, and extract concentration.

Bioactive Properties. *Total TPC, TFC, and HTC Contents.* Figure 1 represents TPC, TFC, and HTC values of the oil

byproduct extracts. TPC values of the samples varied from 5.21 to 801.89 mg GAE/100 g. TFC and HTC values of samples were found to be 71−216 mg CE/100 g and 364.97−2184.60 mg TA/100 g, respectively. Among the extracts, WOB extract had the highest TPC, TFC, and HTC levels.

Grape seeds have attracted considerable attention due to high abundance of bioactive compounds, especially various types of phenolics. It has been reported that grape seed contains higher levels of phenolics than skin and pulp.[32] As expected, TPC of GOB was found to be lower than those of their studies, probably caused by the cold-pressing process. The TPC value of GOB was also lower than that of the grape wine byproducts previously reported in the literature.[33] Growth environment of grape cultivars might also influence their TPC values. The TFC value of GOB was comparable with that of grape skin, whereas it was higher than that of the grape pulp as reported in the literature.

In the present study, considerable amounts of the bioactive compounds were found in the walnut waste obtained after cold press oil processing (Figure 1). It was reported that walnut bioactive compounds have antioxidant activity and potential beneficial health effects such as anti-inflammatory, antimutagenic, and antiatherogenic.[34] Almond HTC was reported to be 54.7 mg EA and 27.4 mg GA 100 g^{-1} for different almond varieties.[35] It was reported that tannins and other phenolic compounds found in almond could be beneficial for health due to their antioxidant and anti-inflammatory effects.[35]

Pomegranate seeds are byproducts of pomegranate fruits. In the present study, moderate levels of bioactive compounds were found in POB as compared to other byproducts (Figure 1). It can be concluded that byproducts analyzed in this study could be considered as valuable waste materials, which may have potential food applications due to the presence of high amounts of bioactive compounds.

Phenolic Profile of the Byproducts. Rather than TPC, distribution of the specific phenolics in a certain medium is very important due to balanced intake of essential materials into the body. Phenolic distribution may vary depending on several

[a]Different lower case letters show differences between the samples (n = 2). The results are expressed as the mean ± SD. Volatiles of the oil byproducts in concentrations <0.1% are not mentioned in the table. [b]nd, not detected.

factors such as plant origin, cultivar, harvesting time, and soil types. In this study, phenolic compositions of the cold press oil byproducts are presented in Table 6. As expected, distribution and ratios of phenolic compounds were variable and influenced from the origin of the byproducts. Epigallocatechin, gallocatechin, and epicatechin were the predominant phenolics in GOB (Table 6). Epicatechin was also found to be the most abundant phenolic compound in the grape seed extracts as reported by Baydar et al.[36] Gallocatechin was found to be the major phenolic among the AOB phenolics. Gallic acid, epigallocatechin, and *p*-coumaric acid were determined to be the other major phenolics detected in AOB (Table 6). Epicatechin had the highest level of phenolics in POB followed by *p*-coumaric acid, quercetin, and gallocatechin. There were slight differences between *p*-coumaric acid, quercetin, and gallocatechin contents of POB (Table 6). Gallocatechin was the highest phenolic in WOB, whereas epicatechin and quercetin were the other major phenolics found in WOB. WOB contained higher levels of catechin, chlorogenic acid, and resveratrol than the other byproducts (Table 6). Ellagitannins (ETs) have been reported to be the main phenolic compounds found in the seed of *Juglans regia*.[37] Gallotannins and ellagitannins, which are classified as hydrolyzable tannins, were also reported to be at high amounts in the walnut kernel.[38]

Volatile Composition. Approximately 35 different volatile compounds were identified in the oil byproducts. However, their concentrations >0.1% are shown in Table 7. As seen from Table 7, terpenes were found as the predominant volatile compounds of the byproducts. Terpenes were composed of 95% of the volatile compounds. Total terpene contents of AOB and POB were found to be similar ($p > 0.05$). Among the volatile compounds identified, limonene, which is a terpene, was found to be a major compound in all of the samples analyzed with amounts ranging from 90.2 to 93.7%. The highest limonene level was determined in POB and GOB, whereas the lowest was in WOB. Limonene is known as a natural and functional monoterpene. Limonene is considered as safe (GRAS) and used as a flavoring agent and food preservative.[39] Gerhäuser et al.[40] reported bactericidal, antioxidant, chemopreventative, and therapeutic activities of limonene. Therefore, the use of these byproducts that are rich in limonene in the different food products may be important for human health. In addition, the oil byproducts had myrcene and β-pinene compounds in concentrations that ranged between 1.22 and 1.56% and between 0.84 and 1.29%, respectively. *trans*-Limonene oxide is another volatile compound found in AOB and WOB with concentrations >1.0%. In addition, the percentage of citral in WOB was determined as 2.45%.

In conclusion, in the cold press edible oil industry, remarkable amounts of byproducts arise after production of the oil. Recovery of these products is important regarding economical gain. Determination of physicochemical and functional properties of the products is crucial to reveal their recovery potential in terms of economic and health aspects. In the present study, physicochemical and bioactive properties, fatty acid and mineral composition, antibacterial activity, and volatile profiles of the cold press oil byproducts of almond, walnut, grape seed, and pomegranate were determined. In general, the byproducts were found to possess significant amounts of protein and bioactive compounds including phenolic compounds, flavonoids, and tannins. GOB and POB had significant amounts of crude fiber, which gained them importance to be evaluated as new sources of dietary fiber. Extracts of almond and pomegranate showed considerable antibacterial activity against the pathogenic bacteria tested, indicating their antimicrobial potential, whereas grape and walnut did not have any inhibitory effect. Limonene was the most abundant volatile component of all the byproducts. In conclusion, this study revealed that pomegranate, walnut, grape seed, and almond cold press oil byproducts had valuable potentials and qualifications from different aspects to be used in different areas of the food industry for enrichment purposes of food materials.

chosen because it contains a high protein amount.[14] Macromolecules were purified following the preparative method proposed by Van Sluyter et al.[15] with some modifications. Ten liters of wine were treated with 4 g/L PVPP (Sigma-Aldrich, Milan, Italy) and 1.5 g/L charcoal (Sigma-Aldrich, Milan, Italy) for 24 h at 15 °C in order to remove most of the polyphenols. The wine was then filtered with GF/A filters (Whatman, Kent, U.K.) and finally at 0.45 μm with cellulose acetate membranes (Sartorius AG, Göttingen, Germany), and it was then brought to pH 3.0 with HCl. Aliquots of 5 L were loaded at 8 mL/min on a S-Sepharose column (5 × 14 cm) (Pharmacia, Uppsala, Sweden) previously equilibrated in trisodium citrate buffer 30 mM pH 3.0. After washing with two column volumes with the same buffer, proteins were eluted with a gradient of NaCl from 0 to 1 M. Both the flow through (containing the unbound material, i.e., mainly polysaccharides) and the pool of the eluted peaks (representing the total proteins) were ultrafiltered at 3 kDa with an Amicon 8400 apparatus (Sartorius), then dialyzed on regenerated cellulose membrane (3.5 kDa, Cellu-Sep) against water and finally freeze-dried. Five liters of the same wine were used for the purification of two main wine proteins (chitinase and the thaumatin-like protein VVTL1). In this case, the fractions obtained after cation exchange separation on S-Sepharose were diluted in 1.25 M ammonium sulfate and further purified by hydrophobic interaction chromatography (HIC) on a phenyl-sepharose HP column (GE-Healthcare) as follows. After washing the column with 1.25 M ammonium sulfate in 50 mM sodium citrate, pH 5.0, proteins were eluted with a 110 min linear gradient up to 100% 50 mM sodium citrate, pH 5.0. The peaks obtained with this second step were dialyzed against water (3.5 kDa MWCO) and freeze-dried. The purity and identity of the fractions were assessed by RP-HPLC[15] and SDS-PAGE.[16]

Aroma Extraction. Fermentative compounds and grape volatiles were extracted from a dry Moscato bianco wine (vintage 2011) produced in the Colli Euganei (Veneto, Italy) not previously treated with bentonite by using the method previously reported for wines and model wine solutions.[17] This type of wine was chosen because of its high content of primary aroma compounds. Aliquots of 500 mL were spiked with 4 mL of 1-heptanol (442 mg/L) as the internal standard, and extracted 3 × 50 mL with dichloromethane (Carlo Erba, Milano, Italy). Extraction was carried out under agitation for 15 min each time. The organic phase containing the aroma compounds was collected and washed 3 × 30 mL with 5% $NaHCO_3$ to remove the acidic compounds by salification and shift into aqueous phase. After dehydration with anhydrous sodium sulfate, dichloromethane was filtered on blue ribbon filters 589/3 (Whatman, U.K.). The extract was concentrated first using a Vigreux column and finally under nitrogen flow. This extract was then used for the reconstitution experiments in model wine solution.

Fifty milliliters of the clear supernatant of each reconstituted sample were used for the extraction of the aroma compounds remaining after bentonite treatment. The samples were spiked with 400 μL of 1-decanol 450 mg/L as the internal standard and extracted 3 × 15 mL with dichloromethane. After dehydration with anhydrous sodium sulfate and filtration as previously described, the extracts were concentrated with a Vigreux column (l = 40 cm) to approximately 3 mL and adjusted to 1 mL under nitrogen flow before GC/MS analysis.

Stability Test. The purified proteins were suspended at 100 mg/L in model wine (tartaric acid 5 g/L, ethanol 12%, pH 3.2) or in a ultrafiltered Manzoni bianco wine (3.5 kDa). Bentonite Nucleobent (EVER, Pramaggiore, Italy) was prepared at 5% (w/v) in water for 24 h, and then different amounts (5, 10, 15 g/hL, final concentrations) were added to the wine protein solution. After 1 h at room temperature, the solutions were filtered at 0.45 μm on cellulose acetate membrane (Sartorius). In order to assess the bentonite dose necessary to reach the protein stability, the protein solutions prepared in ultrafiltered wine were subjected to the heat test as reported by Pocock and Rankine.[18] Briefly, the samples were heated at 80 °C for 6 h, followed by incubation at 4 °C for 12 h; then, the turbidity was measured with a nefelometer (HACH). When the difference in the turbidity measured before and after the heating was less than 2 NTU the sample could be considered stable. For the samples prepared in model solution, the dose of bentonite necessary for stabilization was instead calculated as the amount able to reduce the protein content below 20 mg/L.

Determination of the Protein Content. The protein content was measured according to Vincenzi et al.[19] First, proteins were precipitated from 1 mL of wine with 10 μL of SDS 10% followed by 250 μL of KCl 1 M. The pellets were dissolved in 1 mL of distilled water and quantified by the Smith method,[20] using the BCA-200 protein assay kit (Pierce, Rockford, IL) according to the manufacturer instructions. The calibration curve was prepared by using serial dilution of bovine serum albumin (BSA, Sigma, Milan, Italy) in water.

Electrophoresis. Electrophoretic analyses were performed according to Laemmli.[21] Samples to be analyzed were dissolved in a 0.5 M Tris-HCl pH 6.8 buffer containing 15% (v/v) glycerol (Sigma-Aldrich, Milano, Italy), 1.5% (w/v) SDS (Bio-Rad laboratories, Segrate, Italy), and 4% β-mercaptoethanol (Sigma-Aldrich, Milano, Italy) and heated at 100 °C for 5 min before loading. For both fractions (bound and unbound material), 20 μg of lyophilized powder were loaded in each lane. Electrophoresis was performed in a Mini-Protean III apparatus (Bio-Rad, Hercules, CA) with T = 14% (acrylamide/N,N′ metylen-bis(acrylamide) 29:1; Fluka, Milan, Italy) gels. The molecular weight standard proteins were Broad Range Molecular Weight Markers (Bio-Rad, Hercules, CA). After electrophoresis, gels were stained for 18 h with colloidal Coomassie and then destained with water for 24 h. The Periodic Acid−Schiff (PAS) method was used to stain glycoproteins as described by Segrest and Jackson.[22]

Reconstitution Experiments. The concentrated extract was diluted in model wine to reach a concentration of the aroma compounds equal to that found in the original Moscato wine. Then, 10 g/hL of bentonite alone or 100 mg/L of proteins followed by 10 g/hL of bentonite were added to 55 mL of this solution. An additional experiment with 100 mg/L of proteins and 200 mg/L of the S-Sepharose unbound fraction followed by 10 g/hL bentonite was performed. Each experiment was done in triplicate.

The reconstituted samples were stored at 10 °C (in closed containers) for 12 h and centrifuged (5000g, 5 min, 15 °C), then 50 mL of clear supernatant was recovered and used for the aroma extraction. A second experiment was performed using four selected ethyl esters instead of the total aroma extract. Esters were ethyl hexanoate, octanoate, decanoate, and dodecanoate at 1167, 1102, 1035, and 1145 μg/L, respectively, dissolved in model wine. In this case, the treatments were performed as above, but adding the purified wine chitinase and thaumatin-like protein (TLP) separately (both at 100 mg/L) before treating the solution with 10 g/hL of bentonite. Each treatment was done in triplicate.

GC/MS Analysis. Gas chromatography/mass spectrometry (GC/MS) analysis was performed using a 6850 gas chromatography system (Agilent Technologies, Santa Clara, CA, US), equipped with a fused silica HP-INNOWax polyethylene glycol capillary column (30 m × 0.25 mm, 0.25 μm inner diameter) (Agilent Technologies, Santa Clara, CA, U.S.A.), coupled with HP 5975C mass spectrometer and 7693A automatic liquid sampler injector (Agilent Technologies, Santa Clara, CA, U.S.A.). Oven temperature program: 40 °C isothermal for 1 min, heating 2 °C/min until 160 °C, 3 °C/min until 230 °C, 230 °C isothermal for 15 min. Other experimental conditions: injector temperature, 230 °C; carrier gas, helium at flow rate of 1.2 mL/min; sample volume injected, 1 μL splitless injection; transfer line temperature, 250 °C; quadrupole temperature, 150 °C; mass range, m/z 35−550.

Compounds identification was performed by using the spectral libraries NIST Mass (rev08) Spectral Database and the homemade CRA-VIT database. For some compounds, the identification was confirmed on the basis of GC retention times of pure standards. For the other compounds the Kovats retention index on PEG stationary phase was calculated by using a standard mixture of C11−C32 aliphatic hydrocarbons. The concentration of compounds was calculated as μg/L of internal standard 1-decanol.

Statistical Analysis. Data were analyzed by XLSTAT program. Significance was determined at $P < 0.05$ or $P < 0.01$ by ANOVA followed by Fisher LSD comparison test.

RESULTS AND DISCUSSION

The distinct effect of bentonite and proteins on the removal of wine aroma compounds was first studied in wine model solution. Total wine proteins were extracted from a Manzoni Bianco wine, using a preparative procedure previously described.[15] The wine proteins bound to the cation exchange (SCE) resin were recovered as a whole, whereas the unbound material (flow through, FT) was collected separately. SDS-PAGE analysis followed by staining for proteins (Figure 1A)

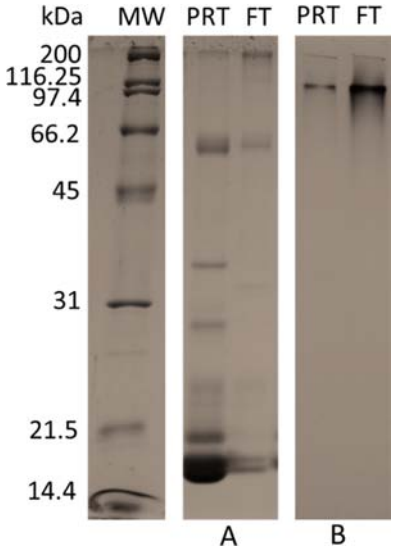

Figure 1. SDS-PAGE analysis of Manzoni Bianco wine molecules retained (PRT) or not retained (FT) on the cation exchange resin. The gels were stained with colloidal Coomassie (A) or Periodic Acid–Schiff (B). Standard molecular weight are reported on the left.

and sugars (Figure 1B) confirmed that FT was mainly composed of high molecular weight glycans, with only small contamination by two proteins of 65 and 18 kDa, which can be identified as the grape invertase and thaumatin-like protein, respectively—these latter components being similar to those retained by the SCE resin. On the contrary, the SCE bound material showed to be composed mainly of proteins. Nitrogen analysis confirmed that the protein content (as N × 6.25) in the SCE bound fraction was more than 70%, whereas that in the FT was about 10%, a percentage corresponding to that present in yeast mannoproteins.[23]

The protein concentration of 100 mg/L in the model solution was chosen for the experiments because this quantity falls in the typical range (20–250 mg/L) for white wines before bentonite treatment.[19,24]

Preliminary tests with increasing doses of bentonite (5, 10, and 15 g/hL) were performed to determine the amount necessary for stabilization. Different tests are available to assess wine stability and one of the most used is the heat test, in which the wine proteins are heat-denatured and the induced turbidity is measured by nephelometry. Since this test does not work in model wine,[25] the residual protein content after bentonite treatment was taken as the parameter to be considered for protein stability. The limit for stability was set at less than 20 mg/L of protein.[26] To reach this quantity, the dose of 10 g/hL of bentonite was necessary, which reduced the protein content to about 5 mg/L (Figure 2).

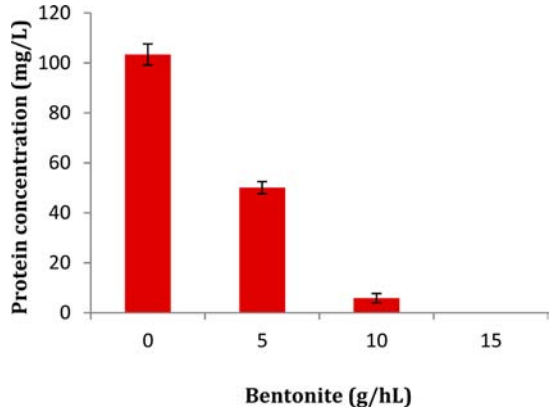

Figure 2. Protein concentration in model wine containing 100 mg/L of wine proteins and treated with increasing amount of bentonite.

Effect of Bentonite in the Presence of Total Wine Proteins and Aromas. Bentonite (10 g/hL) was then used to treat the model solution containing the wine aroma compounds, both in the presence and absence of added wine proteins. The use of such "reconstituted wine" allowed to study separately the direct effect of bentonite and that of the proteins removed by bentonite on the aroma composition. Differently from other papers, in which the effect of bentonite was studied only on selected molecules,[9,11] in these experiments all the volatile compounds extracted from an aromatic wine were examined, allowing to study the interactions among aroma molecules, bentonite, and proteins in a simple system. In addition, the use of a model solution allowed to exclude potential side interactions among the components of interest and other compounds present in wine. For example, polyphenols can modify the aroma volatility or bind to proteins,[27,28] thus potentially interfering in the interaction of proteins with aromas or bentonite. As a matter of fact, in our case, to completely remove 100 mg/L of wine proteins added to the ultrafiltered wine (containing all compounds with MW < 3000 Da), it was necessary to use at least the double of the bentonite needed to eliminate the same quantity of proteins from the model wine solution (data not shown).

Although it constitutes a simplification compared to the real wine, this approach allow to study in a direct way the interactions among aromas, bentonite, and proteins. In detail, the quantity of the different aroma compounds was determined in the model solutions before and after treatment with 10 g/L of bentonite, allowing to understand which are the aroma components directly removed by this treatment. Then, in order to establish the contribution of the phenomenon of protein removal by bentonite on aroma depletion, the same experiment was performed with the aroma solution containing 100 mg/L of added wine proteins. The average contents of fermentative (Table 1) and grape-deriving (Table 2) aroma compounds of the control sample (before the addition of bentonite) were compared to those remaining after treatment with bentonite alone and in the presence of added wine proteins.

In general, it can be observed that the treatment with bentonite resulted in a significant removal of various compounds, in particular ethyl esters and fatty acids (Table 1). For the ethyl esters, the longer was the hydrocarbon chain, the greater was the removal (Table 1), ranging from a loss of 20% for ethyl butanoate to 84% for ethyl dodecanoate. This relation between hydrocarbon chain length and rate of removal

would indicate an involvement of hydrophobicity in determining the interaction. However, because of the hydration of the inorganic cations on the exchange sites, the bentonite surface is recognized as hydrophilic, making the clay ineffective as sorbent for organic compounds.[29] It has, however, already been demonstrated by many authors that ethyl esters have high affinity for bentonite probably due to involvement of other weak forces, such as van der Waals attractions and hydrogen bonding. For example, Dif et al.[30] demonstrated that in aqueous solutions hydrophobic compounds tend to be "pushed" to the adsorbent surface of Na-bentonite.

The addition of proteins before the bentonite treatment did not cause statistically significant effects ($p < 0.05$) in the different aroma compounds content (data not shown). However, a general tendency toward an increased removal of the ethyl esters by bentonite could be observed when the wine proteins were present (Table 1). This additional ester removal was probably due to the fact that these aroma compounds were bound to the proteins, confirming a previous hypothesis.[7,31]

In the case of fatty acids (which are important precursors of aromatic esters), significant effect of bentonite was observed for the removal of decanoic and dodecanoic acids but not for octanoic acid, for which the electrostatic repulsion with the negative charge of bentonite may predominate on the interactions due to hydrophobicity. It has already been suggested that bentonite can interact with fatty acids in grape juices[31,32] thus explaining the increase of the fermentation time when bentonite is used before yeast inoculation.

As for ethyl esters, the presence of wine proteins increased the loss of the long chain fatty acids, in particular decanoic, although these differences were not statistically significant (Table 1).

The effect of addition to the samples of the S-Sepharose unbound fraction, which was mainly constituted by sugar-containing macromolecules (Figure 1) attributable to the yeast mannoproteins was also studied. Since mannoproteins can bind some wine aroma compounds (such as ethyl hexanoate, β-ionone, 1-hexanol, and isoamyl acetate[8,33,34]) and mannoprotein removal from wine by bentonite is low,[35] an improved retention of aroma compounds in wine during bentonite fining can be expected. However, the addition of this fraction showed no significant effects on the quantity of aroma compounds remaining in the solution after bentonite treatment (Table 1).

Considering the aroma compounds deriving from grapes, the overall effect of bentonite on monoterpenes was low and not significant ($p < 0.05$), with the exception of β-damascone (Table 2). These results seems not fully match with the literature, because losses of terpenols due to bentonite

treatments were previously observed.[12,36] However, in those experiments, bentonite doses higher than those used in this study (10 g/hL) were employed. For example in Albarino wine added with 60 g/hL of bentonite a loss of 13% of total terpenes was observed,[12] while in Falanghina treated with 80 g/hL of bentonite (but also with potassium caseinate, gelatin, silica gel, and charcoal), losses of total free and bound terpenols were found, corresponding to 23% in must and 31−36% in wine.[36]

When the wine proteins were added to the aroma solution before the treatment with bentonite, no effect on the terpenols or on the other aromas of grape origin was found (Table 2). These results suggest that wine proteins of grape origin have little or no effect on the depletion of grape-deriving aroma after bentonite fining. On the contrary, the addition of the sugar-containing S-Sepharose unbound fraction provoked, in combination with bentonite and wine proteins, a significant removal of few aromatic compounds, such as linalol and benzaldehyde. Because that chromatographic fraction was likely to comprise most of the mannoproteins, these results would indicate a certain effect of these yeast compounds on the aroma composition of bentonite-treated wines, confirming previous studies performed on wines aged on yeast lees.[8,33,34]

Effect of Bentonite in the Presence of Selected Ethyl Esters and Purified Wine TLP and Chitinase. Due to the importance of ethyl esters in determining the wine aroma, the effects of bentonite fining on four selected ethyl esters were studied in presence and absence of two individual proteins purified from wine. These proteins, a class IV chitinase and a thaumatin-like protein (VVTL1) have been described as the main components in wines.[37] When used alone, bentonite confirmed to have high affinity for the ethyl esters, with an effect which increased with the length of their carbon chain (from 20% of removal for hexanoate to 84% of removal for dodecanoate) (Figure 3). In this simplified system, the removal percentage was lower than in the previous experiment, especially for ethyl hexanoate and octanoate. This was probably due to the higher initial concentration of the esters in comparison to that of total wine aroma extract (from about the double for ethyl hexanoate to around 20-fold for ethyl dodecanoate). However, an effect of other compounds present in the wine extract could not be excluded. In any case, a reduction of the ethyl esters in wines treated with a relatively low bentonite dose can be expected.

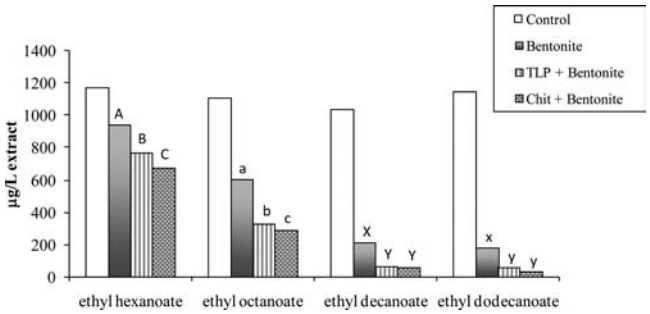

Figure 3. Mean content of ethyl esters found in the model wine treated with bentonite alone or in the presence of 100 mg/L of thaumatin-like protein or chitinase. Samples with different letters are significantly different ($p < 0.01$).

The two wine proteins, individually added at 100 mg/L before the treatment with bentonite, showed a synergistic effect with the clay, increasing significantly ($p < 0.01$) the amount of esters removed from the solution (Figure 3). The intensity of this effect was higher than that observed in the previous experiments, when total wine proteins and aroma were used (Table 1). The differences between the two experiments could be attributed to the higher initial concentration of the selected aroma molecules in the simplified model and/or to an interference caused by the other aroma compounds present in the more complex wine extract.

Compared to the bentonite alone, the additional removal increased from hexanoate to octanoate, then started to slowly decrease for the other two esters with longer chain. The maximum of this phenomenon was observed for ethyl octanoate in the presence of chitinase.

The more interesting results of this second experiment were the differences between the effect of the two proteins on the aroma removal. The mean value of ester depletion in the presence of chitinase was ever slightly higher than that observed when TLP was added, even though these differences were not statistically significant ($p < 0.01$). It has to be highlighted that for the esters tested the overall aroma removal in combination with bentonite almost ever reached values higher than 70%, thus potentially masking a possible difference between the two proteins. As a matter of fact, for ethyl hexanoate, for which the overall aroma removal was less intense (below 50%) the greater binding to chitinase in comparison with TLP became highly significant ($p < 0.01$).

An indication of the relative hydrophobicity of the two proteins can be roughly deduced from the elution order on the Phenyl Sepharose column (not showed). The conductivity of the solution at which the elution of chitinase starts (136 mS) is lower than that necessary to elute TLP (145−148 mS) thus highlighting the greater surface hydrophobicity of the former protein, confirming previous studies on wine proteins.[38] Considering the different affinity of chitinase and TLP for ethyl esters of varying length, the idea that hydrophobic forces are involved in the interactions between aroma compounds and proteins is further supported.

This study showed that in general bentonite has low effect on the loss of terpenes. Instead more evident effects were observed on ethyl esters: in addition, proteins showed synergistic effect with bentonite by increasing losses from ethyl octanoate to ethyl decanoate, as confirmed by a study on model wine solutions of the four esters. Contrarily to what it was expected from literature data,[8,33,34,35] the mannoprotein addition had no significant effect in reduction of ethyl esters, and only a small protective effect on some terpenols.

In conclusion, the data here reported confirm that the individual proteins of grape origin that can be found in wine can interact at least with the fermentative esters, thus contributing to the loss of aroma when those proteins are removed by bentonite fining. This conclusion supports previously reported hypotheses.[7] However, the described phenomena, which can be seen using a simple reconstituted system containing a single protein (grape TLP or chitinase) and a few esters, seem to have only small effects with a more complex system comprising the pools of the wine proteins and aroma compounds, indicating that the main responsible for the aroma losses after bentonite fining is the direct adsorption of the aroma molecules on the clay. This absorption, however, at least in the experimental condition here used, concerns mainly the fermentative aroma compounds, whereas those deriving from the grape are generally not affected. These results can be of great interest for the oenologist, because they suggest that bentonite fining could have a lower impact on the aroma quality when used before fermentation, which is when the fermentative aromas are still to be produced.

or different roasting grades, and the presence of defects on roasted coffee and to estimate the shelf life of packaged coffee.[33−39] Furthermore, the electronic nose system was applied on EC to determine the best time for packaging[40] of coffee grounds, to discriminate the coffee from different production countries and roasting degrees,[24] and to classify beans, grounds, and brew of commercial coffee blends.[41] Particularly, in this work, the authors reported that a correct distinction of the brews was not statistically significant.

On the basis of the above considerations, the purpose of this paper was to study the changes of the EC during extraction to obtain useful information for the better management of the brew quality. More specifically, the main objective was to use the electronic nose system to study the changes of the overall aromatic profile of EC, taking into account the extraction time and the grinding level of coffee powder as independent variables.

MATERIALS AND METHODS

Raw Materials and EC Preparation. Roasted coffee beans (medium-dark roasting: L^* = 21.50, a^* = 5.92) were supplied from ESSSE caffè S.p.A. (Anzola dell'Emilia, Bologna, Italy). The beans were ground by an automatic grinder with flat grinding blades (model Super Jolly coffee grinder for a grocery, Mazzer, Italy) having eight levels of grinding: 1 for the finest and 8 for the coarsest. Water "Leggera" (Gaudianello S.p.A., Italy) used for brew preparation was locally purchased. Table 1 reports the main physical and chemical characteristics of the water as specified on the label, except the pH value, which was experimentally measured. EC samples were prepared using an EC machine mod. V220 (Vibiemme, Italy) with filter holder monodose applied the following experimental conditions: 7.0 g of ground coffee, a 60 mm of holder filter diameter, pressure on the upper surface of ground coffee cake of 1500 g, water temperature of 92 °C, and 9 atm of relative pressure. According to scientific literature, these conditions may be considered as the most common for EC preparation.[7,8,11−13,42] Instead, the value of pressure was chosen on the basis of preliminary experiments in which different weights were used to press ground coffee.

bicarbonate (HCO^{3-}) (mg/L)	306
nitrate (NO^{3-}) (mg/L)	4

[a]Mean value of six samples measured in triplicate.

Experimental Design. EC samples were always prepared within 3 min from the grinding of beans, which was performed at three levels, 6, 6.5, and 7, corresponding to fine, fine−coarse, and coarse coffee grounds, respectively. The choice of these grinding levels was performed on the basis of preliminary experiments, in which the particle size distribution of the ESSSE caffè S.p.A. coffee grounds commonly used in the bars was determined. Once the variability of coffee grounds was defined, we did choose the grinding levels that enabled us to express the differences well in terms of particle size distribution commonly detectable in the bars. Then, the particle size distribution for each grinding level was described shaking 100 g of coffee grounds with four sieves (600, 400, 250, and 180 μm) until a constant weight. Table 2 shows the percentage of distribution of the particle sizes for each grinding level.

Table 2. Distribution (%) of Particle Size in Each Grinding Grade of Coffee Powder (Mean Values ± Standard Deviation)

	grinding grade		
particle size (μm)	6	6.5	7
>600	0.21 ± 0.11	0.68 ± 0.22	2.93 ± 0.53
400 < X < 600	5.69 ± 1.26	13.80 ± 0.82	33.87 ± 1.63
250 < X < 400	32.00 ± 4.89	47.15 ± 14.12	35.64 ± 1.88
180 < X < 250	52.60 ± 6.12	37.18 ± 14.10	26.42 ± 1.07
<180	9.52 ± 3.21	1.19 ± 1.02	1.15 ± 0.85

Each EC sample was divided into three fractions (F) collecting the brews obtained in the first 8 s (Ft1), from 9 to 16 s (Ft2), and from 17 to 24 s (Ft3) of extraction. These extraction times were chosen by dividing in three fractions the time necessary to prepare a regular coffee that is 25 s. The extraction times were measured using a digital timer. The regular EC of 25 mL, from each grinding level, was prepared measuring the volume of brew through a graduate cylinder. At least 20 replicates were performed for each espresso, obtaining a total of 240 samples.

Physical and Chemical Analyses. The pH of the samples was measured by a pH-meter model Basic 20 (Crison, Allen) previously calibrated with three buffers at pH 4.00, 7.00, and 9.00. Also, acidity was measured by titration of 25 mL of coffee brew at room temperature with 0.1 N NaOH until pH of 7.00.[43] The total solids content was measured gravimetrically by drying about 3 mL of EC at 105 °C until a constant weight.[44]

The caffeine content was measured using the method described by Skoog et al.,[45] with some modifications. Each EC brew (fractions and regular coffee) was previously filtered with 0.22 μm nylon filter (Olim Peak, Teknokroma Anlítica, Spain) and directly injected (injection volume = 20 μL) into a high-performance liquid chromatography (HPLC) binary pump (Waters model 1525, Milford, MA) equipped with a detector set at 254 nm (Waters model 2487, Milford, MA). Peak separation was achieved on a C_{18} column (Hibar 125-4 with LiChrospher 100, 5 μm) at 25 °C, using a mobile phase (v/v) of water (74%), methanol (25%), and acetic acid (1%) (J.T.Baker) previously seeped through a filter in cellulose acetate of 0.45 μm (VWR International, Radnor, PA) and submitted to an ultrasound pulse (Elmasonic S 60 H, Elma Schmidbauer GmbH, Germany) for 20 min to remove the air. The flow rate of pump was 0.9 mL/min. The concentration was calculated using the equation obtained by the linear regression of external caffeine standards at different concentrations (Sigma-Aldrich, St. Louis, MO), and the results were expressed as milligrams per milliliter.

Determination of the Aromatic Profile by the Electronic Nose System. The aromatic profile was characterized by an electronic nose system αFOX Sensor Array System 2000 (Alpha M.O.S., Toulouse, France) equipped with six metal oxide semiconductor sensors (T30/1, T70/2, P10/1, P10/2, P40/1, and PA/2) and an autosampler model HS 100 (Alpha M.O.S., Toulouse, France). The sensors measure the changes of the electrical resistance generated by the adsorption−desorption of the volatile organic compounds. Dry air with impurities specified as H_2O < 5 ppm, C_nH_m < 5 ppm, $O_2 + N_2$ > 99.95%, and O_2 = 20 ± 1% was used as carrier gas using a flow rate of 150 mL/min. A total of 1 mL of each coffee sample was placed in vials of 10 mL, sealed with a rubber stopper, and maintained in an oven at 87 °C in agitation at 300 rpm for 3 min before the injection of 500 μL. A flow rate of 150 mL/min was used for the analysis. The sensor responses were detected every 1 s for a total time, t, of 300 s (a total of 300 points for each sample). The response of the sensors was

[a]Different letters indicate statistically significant differences among grinding grade ($p < 0.05$, Tukey's test).

expressed as R_t/R_0, where R is the resistance of the sensor and the subscripts 0 and t refer to the initial value and each time t. After each analysis, the system was purged for 240 s with filtered air before a new injection to allow for re-establishment of the instrument baseline.

Statistical Analysis. For each grinding grade, significant differences among physicochemical parameters of the fractions and the regular coffee were determined by one-way analysis of variation (ANOVA). Tukey's test ($p < 0.05$) was used to highlight significant differences.

Principal component analysis (PCA) was performed on the data of the odor profile to discriminate the samples on the basis of their aromatic profile. The analysis was performed using as experimental data the values of maximum intensity detected by each sensor. Statistical analysis was performed using STATISTICA, version 10 (StatSoft. Inc., Tulsa, OK).

RESULTS AND DISCUSSION

Table 3 shows the main chemical attributes of the regular EC samples as well as each fraction of the brew collected as a function of the extraction time. The pH values of the regular coffee were not significantly different ($p > 0.05$), exhibiting values ranging between 4.983 ± 0.419 and 5.177 ± 0.021; these results were in accordance with the data reported from Parenti et al.[46] but slightly lower than the values reported from Andueza et al.[7] and Caporaso et al.,[47] who showed average values of ∼5.6 and ∼5.8, respectively.

Similar results were observed for titrable acidity for which only the samples obtained using a grinding level of 7 showed values significantly lower than the others. Moreover, taking into account the total solid content, no differences were observed ($p > 0.05$), stating that the three grinding grades did not affect this parameter for the regular EC samples. Our results showed values ranging between 44.342 ± 0.745 and 55.115 ± 4.747 mg/mL, which were in accordance with Parenti et al.,[46] who showed a total solid content of 59.48 mg/mL. However, a high variance in the total solids content of EC has been reported in the literature.[7,8,47]

Caffeine contents of the regular EC between 3.212 ± 0.267 and 4.179 ± 0.209 mg/mL were observed. These values were higher than those reported by Caporaso et al.[47] and Parenti et al.,[46] which showed values always lower than 2.44 mg/mL.

Although our results showed some discrepancies when compared to other authors, our findings may be considered within the natural variance of the chemical composition of EC brews. As well-known, the EC may be affected by several variables, such as roasting grade, mixture of roasted coffee varieties, water temperature, etc.[3−7] In addition, the volume of EC, which considerably affects the chemical composition of brew, is often highly variable among the scientific publications.[7,8,46,47]

However, from Table 3, the analysis of the changes in chemical attributes of the three fractions of EC showed structured variations. The pH values significantly increased as a function of the fraction of brew for each grinding grade. Of course, this result may be caused from the progressive reduction of organic acids still contained in the coffee grounds during the solid−liquid extraction. Moreover, in comparison to the pH values obtained from different grinding grades while keeping the same fraction constant, no significant differences ($p > 0.05$) were observed for the Ft1 samples, while a significant increase ($p < 0.05$) was observed for the second (Ft2) and third (Ft3) fractions of EC. These results were probably caused by a dilution effect because the increase of the grinding grade significantly affected the percolation rates with values of 1.66 ± 0.19, 2.89 ± 0.59, and 6.51 ± 0.26 mL/s when grinding levels of 6, 6.5, and 7 were used, respectively. More specifically, the increase of the percolation rate could be caused by the effect of the different particle size distributions (as reported in Table 2) on the microstructure of the coffee cake. A higher porosity and/or better percolation pathway, which are expected when increasing the grinding grade, could improve the extraction rate. However, because the pH values of the first fraction of EC samples were practically constant, it is possible to suppose that the major amount of organic acids was extracted in the first 8 s of percolation. Similar observations may be performed for titrable acidity, total solids, and caffeine contents, for which a progressive decrease was observed as a function of the coffee fractions and the grinding grade. Particularly, for caffeine content, the HPLC diagram of Ft1, Ft2, and Ft3 samples obtained using a grinding level of 6 is reported in Figure 1, showing the caffeine content decreasing as a function of the extraction time in the range of 5.231 and 0.749 mg/mL.

The study of the aromatic profile of each fraction of the EC and regular coffee obtained using different grinding grades is reported in Figures 2−5.

Figure 2 shows the loading plot of the sensors, which contributes to the discrimination of samples as well as the factor coordinates of the fractions of EC prepared with the three grinding grades. PC1 accounted for 98.77% of the variation of samples, while PC2 accounted for 1.01%, stating that the first two PCs allowed us to explain accurately the variation of the aroma profile of EC samples (99.78%). All of

the sensors have been significant for detecting differences in terms of odor compounds of EC samples. More specifically, the sensors T30/1, P10/2, PA/2, and T70/2 showed the highest contribution in the discrimination of the majority of samples with the exception of the sample 6-Ft1, which was better recognized by the sensors P10/1 and P40/1. Particularly, the sample 6-Ft1 was clearly separated from the other coffee fractions, stating that, during the first 8 s of percolation with the finest coffee grounds, a significantly different aromatic profile was developed. However, the samples 6-Ft2 and 6-Ft3 were

When the three fractions of ECs prepared with the grinding grade 6.5 were considered (6.5-Ft1, 6.5-Ft2, and 6.5-Ft3), a good discrimination was observed in the direction of the sensors T30/1, P10/2, and PA/2, which gave the most important contribution for detecting significant differences in the aroma profile of these samples. Similarly, the three fractions of the samples obtained from the coarse coffee grounds (7-Ft1, 7-Ft2, and 7-Ft3) were well-discriminated from the above three sensors. These results confirmed that there is a significant change in the type and/or amount of volatiles of EC during extraction. Moreover, significant differences were also observed among the three grinding grades used for preparing coffee brews. When the grinding grade was increased for each fraction of EC (Ft1, Ft2, and Ft3), the samples were well-discriminated, proving that the use of different grinding grades may significantly modify the aromatic profile of coffee brew. Again, it is reasonable to suppose that this result was caused by a different level of extraction as a consequence of the variation in the particle size distribution of coffee grounds. Particularly, the particle sizes become smaller as the solid−liquid surface becomes greater, and as previously reported, the percolation rate is lower. Of course, the greater solid−liquid surface could have increased the amount of volatiles extracted from coffee grounds. From Figure 2, it is possible to observe that the sample 6-Ft2 cannot be discriminated from the samples 6.5-Ft1 and 7-Ft1, stating that the coffee brew extracted from 9 to 16 s using the finest coffee grounds showed a similar aromatic profile to the brews obtained during the first 8 s of extraction with the medium−coarse and coarse coffee grounds. According to our results, Clarke[48] and Andueza et al.[7] reported that the coffee brews prepared with coarse coffee grounds showed the lowest aromatic profile. Bhurmiratana et al.[49] demonstrated that the grinding of roasted coffee beans increased the surface area and, consequently, influenced the release of aromatic compounds. Again, these results support the idea that different aromatic profiles of EC may be obtained when different grinding grades are used and/or when the extraction time is not constant.

With the aim to better compare the difference in aromatic profiles among the fractions of EC and regular coffee, Figures 3 and 4 show the results of principal component analysis (PCA) for samples prepared with grinding grades of 6 and 6.5, respectively. In all cases, PC1 accounted for more than 97% of the variance of the samples, while PC2 explained a maximum of 1.93%. Considering the samples prepared with a grinding grade of 6, a clear discrimination of each of the three fractions was observed (Figure 3). Again, these differences could be a result of a dilution effect because of the progressive reduction of the chemical substances and volatiles still contained in the coffee grounds, going forward with the extraction time of coffee brew. However, the regular coffee of 25 mL seems to have an aromatic profile comparable to the second fraction of the brew collected from 9 to 16 s of extraction. This is in accordance with the above results; particularly, by considering the flow rate of 1.66 mL/s, ∼15 s is the time necessary to obtain a regular coffee of 25 mL, which is in the range of time for obtaining an EC cup with all Ft1 and part of Ft2 samples. Probably, the dilution effect produced by the addition of Ft2 to Ft1 led the regular EC to have an aromatic profile similar to the Ft2 sample only. Similarly, Nicoli et al.[15] and Severini et al.[16] observed a progressive reduction of chemical and aromatic concentrations in the consecutive fractions of EC and moka coffee.

When grinding grades of 6.5 and 7 were used for EC preparation, a good discrimination was again observed among the three different fractions of the brew. Nevertheless, by considering PC1 axis, where the maximum variance explained resides, regular coffee appeared to be practically overlapped with the Ft1 sample when using a grinding grade of 6.5 (Figure 4), while the regular coffee was slightly separated when a grinding grade of 7 was used (data not shown). Again, considering the volume of brew of 28.858 ± 2.318 and 41.847 ± 1.701 mL (Table 3) measured for grinding grades 6.5-Ft1 and 7-Ft1, respectively, it is reasonable to suppose that these fractions showed similar and lower concentrations of odor compounds, respectively, when compared to the regular coffee (25 mL). Some studies supported our results, showing that the fine grade produced a low volume of coffee brew with respect to a coarse grinding level.[6,7] In addition, Clarke and Macrae[4] reported that the brews obtained with fine-ground coffee exhibited the highest extraction of soluble solids and volatile compounds, while Andueza et al.[7] found that the particle size is inversely related to the extraction of organic acids and the sensorial aromatic perception.

In Figure 5, the results of PCA obtained by analyzing the regular coffee only achieved from different grinding levels are shown. In this case, both the PCs had a significant contribution in the discrimination of samples, with PC1 accounting for 73.24% and PC2 accounting for 22.96%. The three types of regular coffee were well-distinguished, proving that different aromatic profiles were obtained by preparing a cup of coffee of 25 mL using coffee powder with different grinding levels; nevertheless, in comparison to the difference observed among

DOI: 10.1021/jf505691u
J. Agric. Food Chem. 2015, 63, 2321−2327

each fraction, the three types of regular coffee appeared to be nearest. According to the previous results, the regular coffee prepared with fine−coarse and coarse coffee grounds contain the entire Ft1 sample and only a small part of it, respectively, while using the fine coffee grounds, the regular coffee contains both fractions Ft1 and Ft2. Under this consideration, it can be stated that the regular coffee collected the majority of odor compounds.

Table 4 shows the maximum value of the responses of each sensor to the volatiles of EC samples. A reduction of the response of all sensors as a function of the fractions of EC brew was observed for each grinding grade. As reported from several authors, the reduction of the intensity of the response of the sensors may be related to the concentration of aromatic compounds.[37,50] Similarly, the reduction observed in Table 4 for EC samples may be related to a decrease of the volatile concentration in the brew because of the dilution effect discussed above. The maximum response observed for the Ft1 samples confirmed the hypothesis that the maximum extraction of odor molecules occurs during the first few seconds of the percolation process. For all grinding levels, the reduction of sensor intensity was more pronounced from Ft1 to Ft2, while the gap between Ft2 and Ft3 appeared practically negligible. For the regular EC (25 mL), only slight variations in the response of each sensor were observed, confirming the low differences in terms of the aromatic profile, as highlighted in Figure 5.

In conclusion, the chemical attributes and aromatic profiles of EC were proven to be significantly affected by the extraction time and grinding grade of coffee powder. Particularly, the majority of organic acids, solids, and caffeine contained in the coffee grounds was extracted during the first 8 s of percolation. Also, using the electronic nose system, it was possible to prove that both extraction time and grinding level significantly affect the overall aromatic profiles of EC samples; indeed, through PCA, a high discrimination was obtained among the brew fractions and grinding levels. This result highlights the importance of making more efforts on the control of these two variables in the bar with the aim to ensure a constant aromatic quality of EC served every day.

addition, no studies investigating this treatment on Tempranillo grapevines have been found. Tempranillo is the most cultivated red grape variety in Spain, accounting for around 21.5% of the total wine-growing surface in 2011. Moreover, it is the dominant red grape variety in Spanish aged wines. Therefore, improving its phenolic content would be of enological interest in order to enhance its aging potential. According to the literature, all the experiments conducted under vineyard conditions investigated the effect of direct applications of MeJ to clusters. Cluster application requires a previous defoliation in order to achieve correct distribution of the applied product. In contrast, foliar application is a costless and easier technique due to the fact that a previous defoliation is not required. Therefore, the aim of this paper was to evaluate the influence of MeJ foliar application to Tempranillo grapevines on grape and wine phenolic composition.

MATERIALS AND METHODS

Reagents and Standards. All solvents (methanol, acetonitrile, and formic acid) were of HPLC quality, and all chemicals were analytical grade (>99%) unless otherwise stated and were purchased from Panreac (Barcelona, Spain). Water was of Milli-Q quality (Millipore, Bedford, MA). Methyl jasmonate and Tween 80 were purchased from Sigma−Aldrich (Madrid, Spain). Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid) and DPPH radical (diphenyl-1-picrylhydracyl) were purchased from Fluka Chemie (Buchs, Switzerland). Folin−Ciocalteu reagent was purchased from Merck (Darmstadt, Germany). The following commercial standards were purchased from Sigma−Aldrich: (−)-epicatechin, (+)-catechin, rutin, quercetin, quercetin 3-*O*-glucoside, quercetin 3-*O*-galactoside, kaempferol, myricetin, piceatannol, *trans*-resveratrol, *trans*-piceid, gallic acid, protocatechuic acid, caffeic acid, *p*-coumaric acid, ferulic acid, and caftaric acid. Malvidin 3-*O*-glucoside was purchased from Extrasynthèse (Genay, France).

Plant Material, Foliar Treatments, and Vinification. The study was conducted in 2013 in the experimental vineyard of La Grajera, located in the northern region of La Rioja (Spain). Vines were grafted onto R-110 rootstock and the vineyard was managed under a conventional soil tillage management system. The soil was classified as Typic Calcixerept according to the American Soil Taxonomy. In 2013, the annual precipitation was 569.3 mm, and the average annual temperature was 17.7 °C. Methyl jasmonate (MeJ) was applied to Tempranillo (*Vitis vinifera* L.) grapevines. To carry out the treatments, aqueous solutions at a concentration of 10 mM MeJ were prepared with Tween 80 as wetting agent (0.1% v/v). Control plants were sprayed with aqueous solution of Tween 80 alone. The applications of MeJ and control were carried out twice, at veraison and 1 week later. For each application, 200 mL/plant were sprayed over leaves. Treatments were carried out in triplicate with three vines for each replicate and arranged in a randomized block design.

Grapes were harvested at their optimum technological maturity. From each treatment, about 150 berries were separated and frozen at −20 °C in order to determine their monomeric phenolic composition. Grapes were destemmed and crushed, and oenological parameters were determined in the musts.

The alcoholic fermentation was performed following the method described by Sampaio et al.[24] Grapes from each replicate (group of three plants) were elaborated separately. Three kilograms of pomace (must, seed, and skin) was introduced into 4 L glass bottles. Potassium metabisulfite was added to the samples to give a final total SO_2 concentration of 50 mg/L, and then the must was inoculated with commercial *Saccharomyces cerevisiae* strain Uvaferm VRB (Lallemand, St. Simon, France) (25 g/hL). The must was fermented at a controlled temperature of 25 °C. The end of the alcoholic fermentation was determined by measuring the reducing sugars. Wine enological parameters were then analyzed and aliquots of each wine were frozen and stored at −20 °C until analyses of monomeric phenolic compounds were carried out.

Enological Parameters of Musts and Wines. °Brix was determined by refractometry, pH, total acidity, malic acid, and potassium were determined in musts according to ECC official methods,[25] while tartaric acid was determined following the Rebelein method.[26] Wines were characterized by determining alcoholic degree, pH, total acidity, malic acid, lactic acid, volatile acidity, hue, color intensity (CI), and Folin−Ciocalteu index (FCI) according to ECC official methods[25] and tartaric acid by the Rebelein method.[26] Total phenolics were determined as total polyphenol index (TPI) by spectrophotometric absorbance at 280 nm after previous dilution of samples.[27] Total anthocyanins were determined by bleaching with sulfur dioxide,[27] and total tannins were determined following the method described by Ribéreau-Gayon et al.[28] Ionized anthocyanins were determined according to Glories,[29] and polymerization index was calculated according to Ruiz.[30]

Field treatments were performed in triplicate and a wine was made from each replicate, so the results of these enological parameters are the average of analyses of three samples (n = 3).

Determination of Total Antioxidant Activity in Wines. Total antioxidant activity in wines was determined according to the DPPH method, which evaluates the radical-scavenging activity of the sample.[31] The analysis was performed following the methodology described by Nixdorf and Hermosín-Gutiérrez.[32] Briefly, 100 μL of wine, previously diluted 5% (v/v) in methanol, were added to 2.9 mL of a 0.06 mM DPPH methanolic solution. The percentage absorbance decrease was measured after 25 min at 515 nm. Results were compared to a Trolox calibration curve set for the range of 0.10−0.80 mM. Results were expressed as millimoles of Trolox equivalents per liter of wine (mmol of TE/L).

Determination of Grape and Wine Low-Molecular-Weight Phenolic Compounds. *Extraction of Grape Phenolics.* Grape phenolic compounds were extracted according to the following method. About 50 g of each frozen grape sample was weighed and immersed into 50 mL of aqueous methanol solution (50% v/v), and the pH of the solvent was adjusted to pH 2 with formic acid (>96%). Grapes were then homogenized by Ultra-Turrax T-18 (IKA, Staufen, Germany) at high speed (18 000 rpm) for 1 min, producing a smooth paste. Then samples were macerated in an ultrasonic bath (JP Selecta, Barcelona, Spain) for 10 min and were centrifuged at 5000 rpm at 10 °C for 10 min. A second extraction of the resulting pellets was completed with the same volume of the solvent mixture (50 mL). The supernatants were combined and the volume was annotated. Each sample was transferred to vials and stored at −20 °C until HPLC analyses were carried out.

Sample Preparation for Analysis of Non-Anthocyanin Phenolic Compounds. Due to the fact that anthocyanins are present in high quantities in red grape and wine, other phenolic compounds might be masked during the chromatographic separation and identification. An extraction on PCX solid-phase extraction (SPE) cartridges (500 mg, 6 mL; Bond Elut Plexa, Agilent, Palo Alto, CA) containing a mixture of reverse-phase and cation-exchanger materials allowed the isolation of non-anthocyanin phenolic compounds. Cartridges were placed in the extraction system (Vac Elut 20 station from Varian, Palo Alto, CA). The separation was achieved following the method proposed by Castillo-Muñoz et al.[33] First, grape extracts (3 mL) were diluted with 9 mL of 0.1 N HCl. In the case of wine samples, 3 mL of wine were diluted with 3 mL of 0.1 N HCL. The PCX SPE cartridges were previously conditioned with 5 mL of methanol and 5 mL of water. Then diluted samples were passed through the PCX SPE cartridges and a washing step was carried out with 5 mL of 0.1 N HCl and 5 mL of water. The non-anthocyanin phenolic compound fraction was eluted with 3 × 5 mL of methanol. Adsorbed anthocyanins were removed by passing 2 × 5 mL of 2% ammonia in 80% methanol, then 3 × 5 mL of 2% hydrochloric acid in 80% methanol and finally 5 mL of water. The latter step also regenerates the cationic exchange sites for reuse of the cartridges. The non-anthocyanin phenolic compound fraction was dried in a rotary evaporator (35 °C) and resolved in 1.5 mL of 20% (v/v) aqueous methanol solution. The anthocyanin-free fraction was used to analyze non-anthocyanin phenolic compounds

DOI: 10.1021/jf5060672
J. Agric. Food Chem. 2015, 63, 2328−2337

(flavonols, hydroxycinnamic and hydroxybenzoic acids, stilbenes, and flavan-3-ols).

Analysis of Phenolic Compounds by HPLC-DAD. Phenolic compounds were analyzed by reverse-phase HPLC on an Agilent 1260 Infinity chromatograph, equipped with a diode-array detector (DAD) coupled to an Agilent Chem Station. Injection of samples was carried out after filtration (0.22 μm, Easyprep, Quebec, Canada). Separation was achieved on a LiCrospher 100 RP-18 reversed-phase column (250 × 4.0 mm; 5 μm packing; Agilent) with precolumn LiChrospher 100 RP-18 (4 × 4 mm; 5 μm packing; Agilent), both thermostated at 40 °C. A flow rate of 0.63 mL/min was established.

Chromatographic Conditions. Chromatographic conditions were based on Castillo-Muñoz et al.[34] In the case of anthocyanin analysis, 10 μL of sample (grape extract or wine) was injected. Eluents used were (A) acetonitrile/water/formic acid (3:88.5:8.5 v/v/v) and (B) acetonitrile/water/formic acid (50:41.5:8.5 v/v/v). The linear solvents' gradient for anthocyanin analysis was as follows: 0 min, 6% B; 15 min, 30% B; 30 min, 50% B; 35 min, 60% B; 38 min, 60% B; 46 min, 6% B. For analysis of non-anthocyanin phenolic compound fractions, the injection volume was 20 μL. Eluents were (A) acetonitrile/water/formic acid (3:88.5:8.5 v/v/v), (B) acetonitrile/water/formic acid (50:41.5:8.5 v/v/v), and (C) methanol/water/formic acid (90:1.5:8.5 v/v/v). The linear solvents' gradient for non-anthocyanin analysis was as follows: 0 min, 4% B and 0% C; 7 min, 4% B and 0% C; 38 min, 17% B and 13% C; 52 min, 30% B and 20% C; 52.5 min, 40% B and 30% C; 57 min, 50% B and 50% C; 58 min, 50% B and 50% C; 65 min, 4% B and 0% C.

Identification of phenolic compounds was carried out according to retention times of pure compounds and UV−vis data obtained from authentic standards and/or published in previous studies.[34,35] Phenolic compounds were quantified according to the DAD chromatograms recorded at 520 nm (anthocyanins), 360 nm (flavonols), 320 nm (hydroxybenzoic and hydroxycinnamic acids and stilbenes), and 280 nm (flavanols) and calibration graphs of the respective standards ($R^2 > 0.999$). When a standard was not available, quantification was made according to the calibration graph of the most similar compound. Hence, malvidin 3-*O*-glucoside was used for anthocyanins, quercetin 3-*O*-glucoside was used for flavonols, *trans*-caftaric acid was used for free hydroxycinnamic acids and the corresponding tartaric esters, catechin was used for procyanidins B1 and B2, epicatechin was used for epigallocatechin, and *trans*-piceid and *trans*-resveratrol were used for their respective *cis* isomers. Concentrations in grape samples were expressed as milligrams per weight of grape (mg/kg) while concentrations in wines were expressed as milligrams per liter of wine (mg/L).

Field treatments were performed in triplicate and a wine was made from each replicate, so results for phenolic compounds correspond to the average of analyses of three samples ($n = 3$).

Statistical Analysis. Statistical procedures were performed with SPSS version 21.0 statistical package for Windows (Chicago, IL). Data for the different determinations were processed by analysis of variance (ANOVA). Significant differences between means were determined by use of the Duncan test at $p \leq 0.05$.

RESULTS AND DISCUSSION

Enological Parameters. Results for grape enological parameters are summarized in Table 1. All samples presented normal values of these parameters for Tempranillo grapes from La Rioja.[36] No significant differences were found between control grapes and those from grapevines foliar treated with MeJ. Ruiz-García et al.[37] studied the application of MeJ at the same concentration as our study on clusters from different clones of Monastrell and observed that, in general, grapes from the MeJ treatment were very similar to the control grapes. Moreover, in a 2-year study in which Monastrell clusters were sprayed with the same dose of MeJ, the authors observed that the effect on total acidity, pH, and tartaric and malic acid content varied from one year to another.[22] The latter finding might suggest that the influence of MeJ application on grape physicochemical parameters could therefore depend on climatic conditions as well.

Table 1. Enological Parameters of Grape Berries from Control Grapevines and from Grapevines Treated with Methyl Jasmonate[a]

	control	MeJ-treated
weight of 100 berries (g)	232 ± 25 a	225 ± 5 a
°Brix	23.2 ± 0.8 a	22.3 ± 0.3 a
pH	3.30 ± 0.02 a	3.33 ± 0.04 a
total acidity[b] (g/L)	8.42 ± 0.19 a	8.53 ± 0.40 a
tartaric acid (g/L)	6.16 ± 0.11 a	6.23 ± 0.03 a
malic acid (g/L)	4.26 ± 0.36 a	4.40 ± 0.28 a
potassium (mg/L)	1635 ± 110 a	1583 ± 58 a

[a]Since the treatments were performed in triplicate, all parameters are listed with their standard deviation ($n = 3$). For each row, values with the same letters are not significantly different between the samples ($p \leq 0.05$). [b]As grams of tartaric acid per liter.

Physicochemical parameters of wines are shown in Table 2. All wines presented values within the usual ranges reported for young Tempranillo red wines from La Rioja region.[38] Significant differences between control wines and wines obtained from treated grapevines appeared to be related to phenolic composition. Control wines showed lower color intensity (CI) than wines from MeJ treatment. This result could be explained by a higher proportion of ionized anthocyanins in MeJ-treated wines than in control ones (Table 2). In this respect, this parameter is correlated with colored anthocyanin content. Moreover, the values obtained for Folin−Ciocalteu index (FCI) were higher in the case of wines from MeJ-treated grapevines than in control wines, suggesting that those wines had a greater phenolic content. In accordance with our results, Ruiz-García et al.[22] found that application of

Table 2. Enological Parameters and Total Antioxidant Activity of Control Wine and Wine Made from Grapevines Treated with Methyl Jasmonate[a]

	control	MeJ-treated
alcoholic degree (% v/v)	13.4 ± 0.6 a	12.7 ± 0.0 a

[a]Nomenclature abbreviations: glc, glucoside; acglc, acetylglucoside; cmglc, *trans-p*-coumaroylglucoside; cfglc, caffeoylglucoside. Since the treatments were performed in triplicate, all parameters are listed with their standard deviation ($n = 3$). For each row, values with different letters are significantly different between the samples ($p \leq 0.05$).

MeJ to Monastrell clusters led to wines with better chromatic characteristics [i.e., higher total anthocyanin content, total phenol index (TPI), and CI]. The same research group found that the application of MeJ together with another elicitor (benzothiadiazole) led to wines with higher TPI and CI.[39] Moreover, Fernández-Marín et al.[21] showed that application of MeJ to Syrah clusters resulted in darker wines with higher anthocyanin content at press moment, although no differences were found after bottling. On another note, our results showed that polymerization index in wine increased with the application of MeJ to grapevine (Table 2). This parameter measures the stability of anthocyanins against sulfur dioxide, providing information about anthocyanin polymerization and thus wine color stability.[30] In this respect, the results suggest that greater color stability could be found in wines made from grapevines treated with MeJ. For the remaining parameters, no significant differences were found between the samples. Indeed, no significant differences were observed regarding total antioxidant activity estimated by the DPPH assay. In contrast, Ruiz-García et al.[39] observed that wine antioxidant capacity, estimated by 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) assay, increased with application of a combination of MeJ and benzothiadiazole.

Effects of Methyl Jasmonate Foliar Application. *Anthocyanin Compounds.* The HPLC analysis identified 17 anthocyanins in grape samples (Table 3). The 3-*O*-glucosides (3-glc) of delphinidin, cyanidin, petunidin, peonidin, and malvidin were identified, together with their acetyl (3-acglc) and *trans-p*-coumaroyl (3-cmglc) derivatives. In addition, *cis-p*-coumaroyl (*cis*-3-cmglc) and caffeoyl derivatives (3-cfglc) of malvidin were also identified. The concentrations of individual anthocyanins found in all samples were within the ranges described for Tempranillo grapes in previous studies.[40,41] Thus, malvidin 3-*O*-glucoside and its derivatives were the dominant anthocyanin type in all samples, accounting for 40% of total anthocyanins. Nonacylated anthocyanins represented around 90% of all anthocyanins. Among acylated anthocyanins, *p*-coumaroyl derivatives were dominant (87% of all acylated anthocyanins), which is typical for this grape variety.[40]

Foliar application of MeJ to grapevine led to a significant enhancement of anthocyanin synthesis by the plant. Consequently, grapes from this treatment showed higher content of 3-*O*-glucosides of petunidin and peonidin and *trans-p*-coumaroyl derivatives of cyanidin and peonidin (Table 3). Total anthocyanin concentration, calculated as the sum of individual anthocyanin contents, was increased 23% due to foliar treatment. The improvement of anthocyanin content seems to be an expected outcome from MeJ application, as it has been reported in previous studies. In this respect, Ruiz-García et al.[22] observed that application of MeJ to Monastrell clusters led to increases of around 16% of total anthocyanin content. In a recent study, application of the same dose of MeJ to different clones of Monastrell also resulted in an increase of anthocyanin content in most of the clones.[37] Similar results were reported by Fernández-Marín et al.,[21] who treated clusters of Syrah with MeJ and found that total anthocyanin content

[a]Nomenclature abbreviations: glcU, glucuronide; gal, galactoside; glc, glucoside; rut, rutinoside. Since the treatments were performed in triplicate, all parameters are listed with their standard deviation ($n = 3$). For each row, values with different letters are significantly different between the samples ($p \leq 0.05$).

was increased 11% in comparison with control grapes. Moreover, induction of anthocyanin synthesis has also been observed in cell cultures of *V. vinifera* cv. Gamay Fréaux[20] and in studies in which MeJ was applied in combination with another elicitor, benzothiadiazole,[39] as well as in different works with other fruits such as raspberry[17] or apple.[18] Enhancement of anthocyanin synthesis seems to be explained by the accumulation of different enzymes involved in the phenylpropanoid pathway.[19] In this sense, it has been reported that grapevines may respond to MeJ application by activating gene expression of enzymes responsible for phenolic biosynthesis such as phenylalanine ammonia lyase, chalcone synthase, stilbene synthase, UDP-glucose:flavonoid-*O*-transferase, proteinase inhibitors, and chitinase, with subsequent accumulation of anthocyanins and stilbenes in grapevine cell cultures.[20]

Regarding wine analysis, in addition to the 17 anthocyanins found in grapes, two pyranoanthocyanins, vitisins A and B, were identified (Table 3). Formation of the latter compounds occurs during alcoholic fermentation by reaction of malvidin 3-*O*-glucoside with pyruvic acid (vitisin A) or with acetaldehyde (vitisin B).[42] Similarly to grape analysis, malvidin derivatives were the most abundant type of anthocyanin, and *p*-coumaroyl anthocyanins were the dominant acylated form.

Higher anthocyanin levels found in grapes from MeJ treatment were reflected in the corresponding wines (Table 3). Thus, wines made from treated grapevines exhibited higher content of 3-*O*-glucosides of delphinidin, petunidin, and peonidin and higher content of *trans*-*p*-coumaroyl 3-*O*-glucosides of cyanidin and peonidin, as well as vitisin B. Furthermore, total anthocyanin content in wines from MeJ treatment increased 24% with respect to control wine. The latter finding is partly in contrast with results obtained with spectrophotometric measurement of total anthocyanins in wine (Table 2). That measure revealed no significant differences between the samples even though a higher value (around 13%) was found in MeJ wines. Ruiz-García et al.[22] also observed discrepancies between HPLC and spectrophotometric analyses regarding anthocyanin concentration. These authors suggested that differences between the two analyses were explained by the analytical method. In any case, other analysis related to wine color (i.e., CI and ionized anthocyanin content) showed higher values for MeJ wines than for control wines. Moreover, results of individual analyses of wine anthocyanins are also in accordance with those obtained in the analysis of grapes (Table 3) showing a similar increase in total anthocyanin content. Ruiz-García et al.[22] also found that MeJ application improved wine total anthocyanin content determined by HPLC.

Anthocyanins play an important role in grape and wine quality since they are the main compounds responsible for red

[a]Since the treatments were performed in triplicate, all parameters are listed with their standard deviation ($n = 3$). For each row, values with the same letter are not significantly different between the samples ($p \leq 0.05$).

wine color. Wine color is the first feature perceived by the consumer, and consequently, improvements on this parameter may have a substantial impact on wine tasting and quality. Our results suggest that grape and wine anthocyanic composition of Tempranillo variety was improved following foliar treatment with MeJ, which could be of great enological importance.

Flavonol Compounds. Table 4 shows individual flavonol content of grape and wine samples. HPLC analysis indicated the presence of 14 flavonols in all samples. Derivatives of the two major forms in Tempranillo grape berries, myricetin and quercetin, were identified, accounting together for 85% of total flavonols. Derivatives of the other four flavonol structures naturally present in *V. vinifera* grape berries were also identified: laricitrin, kaempferol, isorhamnetin, and syringetin derivatives. Results indicated the presence of all 3-*O*-glucosides (3-glc), although 3-*O*-glucuronides (3-glcU) and 3-*O*-galactosides (3-gal) of myricetin, quercetin, and kaempferol were detected too. In addition, quercetin 3-*O*-rutinoside (3-rut) and isorhamnetin 3-*O*-galactoside (3-gal) were identified. There is little research on grape flavonols in comparison with anthocyanins. In this respect, flavonol levels in our study seemed to be in accordance with the scarce literature on this topic, which reports an important proportion of myricetin- and quercetin-type flavonols in Tempranillo grape berries.[43]

There were not significant differences between control grape samples and those from MeJ foliar treatment except for the content of isorhamnetin 3-*O*-glucoside, which was higher in samples from MeJ treatment (Table 4). Isorhamnetin-type flavonols are formed by gradual methoxylation of quercetin during grape ripening.[33] As can be seen from Table 3, peonidin 3-*O*-glucoside and its coumaroylated form were found in higher proportion in grapes from MeJ treatment. Therefore, results seem to suggest that MeJ application had a marked effect on the methoxylated forms of disubstituted flavonoids (i.e., peonidin and isorhamnetin). In this respect, flavonols are closely related to anthocyanins since they share a big part of their biosynthetic pathway. However, our results seem to indicate that MeJ application had less influence on flavonol compounds than on anthocyanin composition. In accordance with our study, Ruiz-García et al.[37] observed that flavonol content was normally unaffected by MeJ treatment. As well as this, although Ruiz-García et al.[22] reported an increase in grape anthocyanin content in the two years of their study, total flavonol content was improved only in the second year. Therefore, it appears that improvement of anthocyanin synthesis by MeJ application does not necessarily imply a significant induction of flavonol synthesis. Based then on the results, it seems as if MeJ application favors the activity of specific enzymes for anthocyanin synthesis [e.g., dihydroflavonol 4-reductase (DFR) or flavonoid 3-glucosyltransferase (UFGT)], while in contrast it does not significantly favor the activity of specific enzymes for flavonol synthesis [i.e., flavonol synthase (FLS)].

Regarding wine analysis, flavonol glycosides are hydrolyzed during fermentation, releasing their corresponding aglycons.[33,43] In this respect, the aglycons from six possible structures were identified: myricetin, quercetin, laricitrin, kaempferol, isorhamnetin, and syringetin (Table 4). Moreover, some glycosides that had been quantified in grape were not identified in wine (3-*O*-galactosides of myricetin, quercetin, kaempferol, and isorhamnetin, as well as quercetin 3-*O*-rutinoside and kaempferol 3-*O*-glucuronide). These compounds were present in small concentrations in grape samples. Consequently, their hydrolysis during vinification decreased their concentration in wine, making them undetectable. Moreover, Castillo-Muñoz et al.[33] stated that 3-*O*-glucosides of mono- and disubstituted flavonols (i.e., kaempferol, quercetin, and isorhamnetin) appeared to be easily hydrolyzed. Furthermore, in our study, syringetin 3-*O*-glucoside appeared to be the less hydrolyzed compound, which might be an expected outcome according to Hermosín-Gutiérrez et al.[43] As seen in grape analysis, myricetin- and quercetin-type flavonols were the dominant type of flavonols in wine samples, accounting for around 90% of all total flavonols, followed by laricitrin- and syringetin-type flavonols. In agreement with previous studies,[43] isorhamnetin- and kaempferol-type flavonols were minor compounds in wine.

In general, more significant differences for these compounds were observed between wine samples than between grape samples. Thus, wines obtained from grapevines treated with MeJ showed higher total flavonol content in comparison with control wines (Table 4). This result was probably due to differences in individual concentrations of quercetin 3-*O*-glucoside and free myricetin, which were quantitatively important in the wine samples, apart from kaempferol 3-*O*-glucoside. Moreover, as seen in grape analysis, isorhamnetin 3-*O*-glucoside was also found in a higher concentration in wines from MeJ treatment than in control ones. Since grape samples from control and MeJ treatment had shown similar flavonol levels, the slight differences occurring between wines might be

[a]Since the treatments were performed in triplicate, all parameters are listed with their standard deviation ($n = 3$). For each row, values with different letters are significantly different between the samples ($p \leq 0.05$).

attributed to higher flavonol extractability when MeJ was applied. Schwarz et al.[44] reported that prefermentation addition to the must of a flavonol compound, rutin, favored anthocyanin extraction during winemaking due to the formation of copigmentation complexes. On account of this, it could be hypothesized that grapes richer in anthocyanin compounds, such as those from MeJ treatment, may lead to wines richer not only in anthocyanins but also in flavonols. In contrast to our results, Ruiz-García et al.[22] found that MeJ application to Monastrell clusters had no influence on wine total flavonol content. However, the latter authors found that wine flavonol content increased with application of another elicitor, benzothiadiazole.[39]

Flavanol Compounds. Results of grape and wine flavanol analysis are shown in Table 5. Catechin was the major flavanol compound in grapes, followed by epicatechin. The results showed that MeJ foliar application did not affect flavanol synthesis since MeJ-treated grape samples exhibited similar flavanol levels to those found in control grape samples. There are only a few works in the literature that studied the influence of MeJ application on flavanol composition in grapes or in other fruits. Shafiq et al.[18] observed that preharvest MeJ application to red blush apples increased skin catechin and epicatechin content, although results depended upon the time of application. Ruiz-García et al.[22] found that skin proanthocyanidin content was increased by MeJ application, while on the other hand, there was barely any difference regarding seed tannin content between control and treated samples. Moreover, the latter research group stated that MeJ application could lead to different results depending on the treated clone.[37] In some clones, tannin synthesis might be favored at the expense of anthocyanin synthesis, while other clones could show the opposite behavior. In our study, Tempranillo grapes treated with MeJ have shown a significant enhancement of anthocyanin compounds while no differences have been observed in terms of flavanol composition.

As seen in grape analysis, catechin and epicatechin were the most abundant compounds in wines, accounting together for around 65% of the total flavanols identified (Table 5). Both wines showed a similar flavanol composition, suggesting that MeJ foliar application did not influence this group of flavonoids. Therefore, our results confirm those obtained from grape analysis, which showed no differences between control grapes and grapes from the foliar treatment. Similarly, Fernández-Marín et al.[21] did not observe any difference concerning total flavanol content between control wines and wines elaborated from Syrah clusters treated with MeJ. Moreover, Ruiz-García et al.[22] observed that the application of MeJ to Monastrell clusters led to an increase in the total amount of flavanols in the second year of the study, whereas no effect from MeJ application was noticed in the first year.

Non-Flavonoid Compounds. Non-flavonoid grape and wine composition is shown in Table 6. Gallic acid was the only hydroxybenzoic acid identified in grape samples. Hydroxycinnamic acids in grapes are esterified with tartaric acid.[45] *trans*-Caftaric and *trans*- + *cis*-coutaric acids were the dominant hydroxycinnamic acids. As for stilbenes, *trans*-piceid was the most abundant stilbene in grape samples, representing around 51% of total stilbene content.

Hydroxybenzoic and hydroxycinnamic acid content in grapes was independent of MeJ foliar application, since no differences were observed between the concentration found in control grapes and that found in grapes from treated grapevines (Table 6). In contrast, a marked increase in stilbene concentration was observed after MeJ foliar treatment. The synthesis of both piceid isomers was enhanced by this application: *trans*-piceid was 5.6-fold increased while the cis isomer was 3.3-fold increased. On the other hand, *trans*- and *cis*-resveratrol were not affected by MeJ foliar treatment. All the same, total stilbene content was 3-fold increased. Induction of stilbene formation seems to be an expected outcome, as it has been reported in several works. Ruiz-García et al.[37] observed that MeJ

DOI: 10.1021/jf5060672
J. Agric. Food Chem. 2015, 63, 2328−2337

application normally leads to an increase in stilbene concentration (up to 5-fold increase depending on the clone). Syrah clusters treated with MeJ were richer in different stilbenes than untreated clusters at the harvest moment.[21] Moreover, *trans*-resveratrol content increased at ripening in Barbera grapes treated by cumulative MeJ applications.[23] Apart from this, Belhadj et al.[20] observed an accumulation of total piceids (*trans*- and *cis*-piceids) in Gamay Fréaux cell suspensions treated with MeJ alone or in combination with sucrose. Furthermore, they found that different genes involved in the biosynthesis of polyphenols were upregulated by MeJ application. In a previous study conducted by the latter research group,[19] Cabernet Sauvignon leaves treated with MeJ showed an accumulation of enzymes responsible for stilbene formation (e.g., stilbene synthase). Therefore, our results confirm those previously reported for other grape varieties and obtained in different conditions. Elicitors may reduce the use of conventional fungicides by preventing the attack of certain pathogens through the induction of plant defense responses.[14,19] Accumulation of phytoalexins (e.g., stilbenes) is one of the plant responses to elicitor perception.[46] Thus, treated grapevines in our study seemed to activate the synthesis and accumulation of stilbene compounds. In contrast, the absence of significant differences regarding phenolic acids seems to be related to the different biosynthetic pathway of these compounds. Results suggest that MeJ application may favor the biosynthetic pathway of anthocyanins (also flavonols in a lesser extent) and stilbenes, while it seemed to have little effect on phenolic acid synthesis.

Concerning wine analysis, protocatechuic acid was identified together with gallic acid (Table 6). As expected, hydrolysis of the hydroxycinnamoyl tartaric acids during alcoholic fermentation released the corresponding free acids, enabling us to identify caffeic, *p*-coumaric, and ferulic acids. Still, *trans*-caftaric and *trans*- + *cis*-coutaric acids remained as the major hydroxycinnamic acid derivatives in the wine samples. As for stilbenes, like in grapes, *trans*-piceid was the major compound in wine, representing around 60% of total stilbene compounds. Moreover, the average *trans*-piceid/*trans*-resveratrol ratio decreased from 5.74 in grapes to 2.70 in wines, probably due to hydrolysis of *trans*-piceid to *trans*-resveratrol during the alcoholic fermentation.[46]

It was confirmed that samples from MeJ foliar treatment showed a higher concentration of total stilbenes and *trans*-piceid, while the effect on other non-flavonoid compounds was less evident. In particular, it could be of interest that wine made from treated grapevines showed a similar concentration of nonesterified hydroxycinnamic acids (caffeic, *p*-coumaric, and ferulic acids) to the control wine. These compounds are ethylphenol precursors, and therefore they could be involved in ethylphenol formation and subsequent wine alteration, especially during barrel aging.[47] This might be a noteworthy outcome, taking into account that Tempranillo grapes are normally used for producing aged wines.[48] Despite this fact, it should be also taken into account that hydroxycinnamic acids are also precursors in the formation of hydroxyphenyl pyranoanthocyanins, which are anthocyanin-derived pigments that contribute to wine color stability.[49] Regarding stilbenes, *trans*-piceid content was 3 times higher in wines from MeJ foliar treatment than in control wines. Moreover, total stilbene content was increased 163% in wines obtained from grapevines treated with MeJ in comparison with control wines. The increase in wine total stilbene concentration is in good agreement with previous works, which have shown that MeJ application in the vineyard could result in an improvement of wine stilbene content. In this respect, Fernández-Marín et al.[21] found that total stilbene content was increased in wine, both at press and bottle moments, with the application of MeJ to Syrah clusters. In recent years, research on stilbenes has become very popular due to their importance for human health.[50] Therefore, foliar application of MeJ to Tempranillo grapevines could be an interesting tool in order to enhance wine health-promoting properties.

Our results describe for the first time the effect of MeJ foliar application on the phenolic composition of Tempranillo grape and wine. Grape and wine phenolic content was increased in the samples from MeJ treatment in comparison with control samples. Anthocyanin content was increased in both grape and wine by MeJ application. Similarly, wine color-related parameters were also improved as a consequence of MeJ application. Apart from this, stilbene synthesis was enhanced by MeJ application, as stilbene content was increased in both grape and wine. The effect of MeJ application was less evident on flavonols, although total flavonol content was higher in wines from MeJ treatment than in control wines. For the remaining parameters, there were not significant differences between control and MeJ samples. It should be taken into account that foliar application does not require a previous defoliation, which, in contrast, is necessary when the application is carried out directly on clusters. Therefore, this paper has shown that foliar application of MeJ could be an easy and interesting viticultural practice in order to increase the phenolic content of grapes. Furthermore, it could improve as well the wine color and its health-promoting properties.

[a]Different letters indicate the statistical significance of difference at $p < 0.05$ for each estimated−measured pair. [b]IW, insoluble wheat; IR, insoluble rye; IO, insoluble oat; GT, green tea; RW, red wine; PJ, pomegranate juice; ESP, espresso.

(−)-epicatechin gallate, (−)-epigallocatechin gallate, chlorogenic acid, resveratrol, 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), iron(III) chloride, adenosine 5′-diphosphate sodium salt (ADP), methanol, chloroform, hexane, and ethanol were purchased from Sigma-Aldrich Chemie (Steinheim, Germany). L-(+)-Ascorbic acid, monopotassium phosphate, and glycine were purchased from Merck (Darmstadt, Germany). All solvents used were of analytical grade, unless otherwise stated. Water was purified through a Millipore Q-plus purification train (Millipore Corp., Bedford, MA, USA).

Grains and Beverages. All grain varieties used were purchased from a local market in Ankara, Turkey. Green tea, pomegranate juice, roasted coffee beans, and red wine were of food grade and purchased in Copenhagen, Denmark. Green tea was prepared by brewing 3 g of green tea with 100 mL of hot water for 15 min, and espresso was prepared in a kitchen-type coffee machine, Titanium Gaggia, at the seventh level of the dose control knob.

Preparation of the Insoluble Fractions of Grains. Ground whole grains were washed according to the procedure described by Çelik et al.[24] to remove water, alcohol, and lipid-soluble fractions. Washed grains were freeze-dried, ground with a ceramic mortar to obtain a fine powder, and passed through a sieve (Endecotts Test Sieve, London, UK) of 40 mesh size (425 μm). The final insoluble powder was tested and found to be free of soluble antioxidant compounds. It was kept under 4 °C prior to experiments.

Preparation of Liposomes. Liposomes were prepared with minor modifications[25] according to the method described by Tirmenstein et al.[26] Forty milligrams of phosphatidylcholine was dissolved in chloroform and evaporated to dryness under nitrogen flow. The phosphatidylcholine residue was subsequently rehydrated with 5 mL of 50 mM sodium phosphate buffer (PB) (pH 7.4) and vortexed. The suspension was sonicated at 100 W with 30 s intervals 10 times to yield a white homogeneous suspension of multilamellar liposomes. Between the intervals, the suspension was left to cool in an ice bath for at least 2 min. The sonicated suspension was centrifuged at 16000*g* for 30 min, and the supernatant containing the liposomes was collected. The liposomes were stored under 4 °C for 1 week before experimental studies to increase the level of lipid hydroperoxides (about 5−10% of the phosphatidylcholine). These will react with Fe^{3+} to produce free radicals.

Peroxidation of Liposomes. Liposomes prepared 1 week prior to measurement were pipetted into a 96-well transparent plate as 10 μL for each well and mixed with 50 μL of sample dilutions or standard solution (Trolox), whereas Milli-Q water was used as zero sample. Sample dilutions were prepared at 500, 100, 50, and 10 μM for pure antioxidant compounds, 1:500, 1:1000, 1:5000, and 1:10000 dilutions with water for beverages, and 10, 5, 1, and 0.5 mg/mL aqueous solutions for insoluble and whole grains. Mixtures of insoluble grains with beverages/pure antioxidant solutions were prepared by combining two different concentrations of grains (10 and 5 mg/mL) with two different concentrations of beverages (1:500, 1:1000) or pure solutions (500 and 100 μM) at a ratio of 1:1 to give 50 μL sample. Because aldehydes generated by lipid peroxidation can react with amines to produce fluorescent products, glycine was added to the reaction medium as glycine ascorbate buffer (GAB), which was prepared as 50 mM potassium phosphate buffer (PPB) with 100 mM glycine and 450 μM ascorbate at pH 7.4, for 120 μL per well. Background wells were made by pipetting GAB buffer instead of liposome and samples. Lipid peroxidation was initiated by introducing 20 μL of an oxidizing agent composed of 25 μM $FeCl_3$ in 50 mM PPB (pH 7.4) with 1 mM ADP.

The plate was inserted into the plate reader of a Tecan fluorometer immediately after addition of oxidizing agent. The lag phase before the onset of oxidation was measured for 4 h at 37 °C (excitation at 360 nm, emission at 460 nm) in 10 min intervals, and samples were analyzed in triplicate.

Inhibition of lipid oxidation was calculated by using the formula

$$\text{inhibition of lipid oxidation (\%)} = 100 - (\text{AUC}_{\text{sample}}/\text{AUC}_{\text{control}}) \times 100$$

where $\text{AUC}_{\text{sample}}$ is the area under the curve of sample containing antioxidant as measured in the well and $\text{AUC}_{\text{control}}$ is the area under the curve measured for the control well. To avoid differences originating from different starting levels of oxidation, all fluorescent values were subtracted from the lowest value, considering the lowest point as zero, and the AUC was calculated by the trapezoid rule.

Scavenging of Fremy's Salt Radical. The scavenging of Fremy's salt radical was determined with minor modifications according to the method described by Rødjter et al.[27] For insoluble and whole grains, 10, 15, or 20 mg of sample was mixed with 1 mL of Milli-Q water and 200 μL of a solution of Fremy's salt (1.64 mM) in 25% saturated sodium carbonate solution. For pure antioxidant solutions (10 μM) and beverages (1:1000 diluted) 100, 150, and 200 μL of sample was used instead of 10, 15, and 20 mg. Combinations of insoluble grains with beverages/pure antioxidant solutions were made in the ratio of 10 mg:100 μL, and then 100, 150, and 200 μL of sample from the prepared mixture was added into the reaction medium as described for beverages and pure solutions above. Six minutes after the mixing, ESR spectra were recorded with a MiniScope MS200 ESR spectrometer (Magnettech GmbH, Berlin, Germany). The measurements were carried out with the following settings: BO field, 3366.90 G; sweep

RESULTS AND DISCUSSION

Antioxidant Activity Measurement by ESR Spectroscopy Assay. Table 1 gives the relative decrease (%) in the intensity of measured and estimated ESR signal values for the mixtures of insoluble grains and beverages rich in antioxidants. The antioxidant activities of samples were determined as their ability to reduce the stable Fremy's salt radical as measured by ESR spectrometer. Diamagnetic reduction products are formed, which are ESR-invisible, when antioxidant compounds scavenge Fremy's salt radicals, leading to a decrease in the ESR signal.[27] The percentage decrease in the intensity of ESR signal was determined for insoluble grains, beverages, and pure antioxidant compounds separately, and the decrease in the ESR signal for combinations of grains with beverages/pure antioxidant solutions was calculated by using these data. At the same time, the experiments were performed for combinations of grains with beverages/pure antioxidant solutions. Estimated

[a]Different letters indicate the statistical significance of difference at $p < 0.05$ for each estimated−measured pair. [b]IW, insoluble wheat; IR, insoluble rye; IO, insoluble oat; CGA, chlorogenic acid; EC, epicatechin; ECG, epicatechin gallate; EGC, epigallocatechin; EGCG, epigallocatechin gallate.

data were obtained by summing the halves of the percentage decreases (%) in the intensities of ESR signals separately measured for the concentrations/dilutions of insoluble grains and beverages/pure antioxidant compounds, which were used to make 1:1 combination.

In general, an almost linear relationship was observed between the mixture volume added to the reaction medium and estimated/measured values of decrease in the ESR signals. The measured values of decrease in the intensity of ESR signals were significantly higher than the estimated ones for combinations of almost all insoluble grains with all beverages used, pointing toward a clear synergistic effect ($p < 0.05$). Among beverages, green tea showed the highest synergistic effect, whereas pomegranate juice showed the lowest one with all grain varieties. For insoluble grains the synergistic effect was highest for oat and lowest for wheat (Table 1).

Table 2 gives the relative decrease (%) in the intensity of measured and estimated ESR signal values for the mixtures of insoluble grains and pure antioxidants. It is clear from the results that replacing pure antioxidant solutions for antioxidant-rich beverages as the source of soluble antioxidants did not change the synergistic behavior observed between insoluble grains and soluble antioxidants. Particularly, the percentage decrease in the ESR signals measured with EC and EGCG was remarkably higher, pointing toward a stronger synergism. This result becomes meaningful, considering that EC and EGCG are the main antioxidants in green tea. Overall, the results suggested that both pure antioxidants and beverages rich in soluble antioxidants are effective synergistic agents of DF-bound antioxidants.

Prevention of Lipid Oxidation in Liposomes. The insoluble grains, beverages, and pure antioxidant solutions and combinations of insoluble grains with beverages/pure antioxidant solutions were also tested for their ability to inhibit lipid oxidation in a liposome system. Because liposomes allow investigations of both water and lipid-soluble antioxidants in the same system, it can be considered as a proper model of biological membranes.[28]

Table 3 gives estimated and measured inhibition of lipid oxidation (%) for different mixture combinations of insoluble grains with beverages rich in antioxidants. The potential inhibition of lipid oxidation values was estimated by summing the halves of the inhibition data (%) separately measured for the concentrations/dilutions of insoluble grains and pure antioxidant solutions/beverages, which were used to make a 1:1 combination. The inhibition of lipid oxidation measured for real combinations was significantly higher than those estimated for all beverage-insoluble grain combinations, showing a clear synergistic effect in agreement with the ESR assay results ($p < 0.05$). Espresso showed the highest synergistic effect among beverages, whereas oat was the most efficient synergist among insoluble grains. The combinations of insoluble grains with beverages had a slightly higher synergistic effect at low concentration of insoluble grains: the antioxidant activities of 5 mg−500 μM and 5 mg−100 μM combinations were higher than those of 10 mg−500 μM and 10 mg−100 μM combinations, respectively. The reason may most probably be the pro-oxidative behavior of insoluble grains in the liposome system due to the chain-carrying effect of DF phenolate groups.

In the liposome system, the antioxidant behavior of insoluble grains shifted to the pro-oxidant side, in contrast to the results obtained in the ESR assay, whereas the antioxidant role of beverages and pure antioxidant solutions remained the same (the results are not shown for single measurements of both insoluble and soluble antioxidants in the paper). The primary reason for this situation may be the metal ions, which are added to the liposomes from the fiber. Because ascorbate is present in the system, which is known to promote oxidation in the presence of metals, added metals from any source could explain the situation. In addition, it can be explained by the fact that the antioxidant activity depends not only on the chemical activity of the antioxidant molecules but also on the microenvironment of the reaction media.[29,30] Besides, the structure of antioxidants

J. Agric. Food Chem. 2015, 63, 2338−2343

such as ferulic acid bound in insoluble grains shows these to be more hydrophobic than the water-soluble antioxidants used, a difference that may restrict their interaction with the hydrophilic surfaces of liposomes. The DF phenolates may also create an environment for a chain-carrying effect due to the ease with which they form free radicals.[31]

Table 4 gives the estimated and measured inhibition of lipid oxidation (%) for different mixture combinations of insoluble grains with pure antioxidants. The combinations of insoluble grains with pure antioxidant solutions exerted the same synergistic behavior in liposome systems as for the insoluble grain−beverage combinations, low concentrations of insoluble grains causing a slightly higher synergistic effect. Among pure antioxidants, EC showed the highest synergetic effect, whereas CGA was the least effective with all insoluble grain types. It is a fact that ferulic acid is the dominant form of antioxidant bound to insoluble dietary fiber matrix. Its structural resemblance to CGA might be the reason for the pro-oxidant behavior of insoluble grains.

A proposed mechanism of the synergetic interaction between DF-bound antioxidants and soluble antioxidants is explained in Figure 1 for radical scavenging confirmed by ESR-based

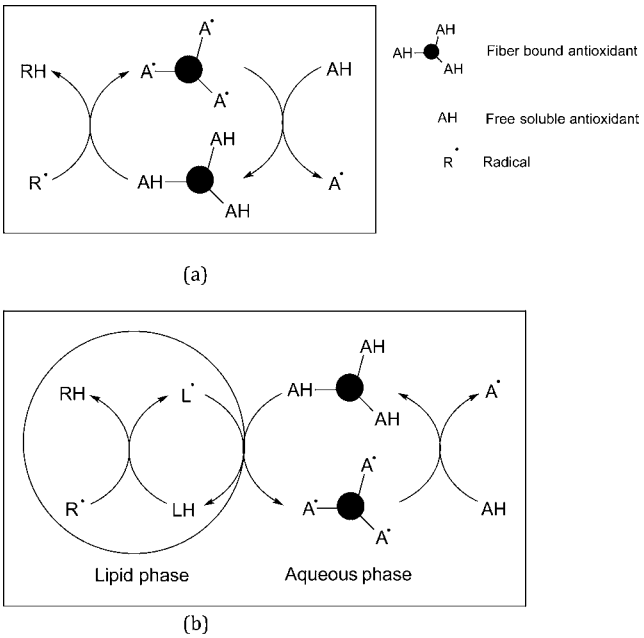

Figure 1. Synergistic antioxidant mechanism of dietary fiber bound antioxidants via regeneration by free soluble antioxidants: (a) radical scavenging confirmed by ESR-based Fremy's salt stable radical measurement; (b) inhibition of lipid oxidation in the liposome system confirmed by spectrophotometric measurement.

Fremy's salt stable radical measurement (a) and inhibition of lipid oxidation in a liposome system confirmed by spectrophotometric measurement (b). According to this proposal, in a medium containing stable radicals (i.e., Fremy's salt), an insoluble DF-bound antioxidant will scavenge a free radical, becoming an antioxidant radical itself. At this time, if soluble antioxidants exist in the medium, they will regenerate the DF-bound antioxidant, leading it to scavenge free radicals again. In the liposome system, an initiating factor (oxidizing agent in our experiment) will promote oxidation of the lipid phase, creating a lipid radical, which will revert to its original form via gaining one hydrogen from a DF-bound antioxidant, leading it to become a radical itself. At this point, if soluble antioxidants exist in the medium, they will regenerate the DF-bound antioxidant, leading it to exert its antioxidant effect against lipid oxidation.

If we want to adapt the proposed mechanism to the human GI tract, we should consider the metabolism of DF-bound antioxidants first. When we consume cereal products, the bound antioxidants, which exert their health effects already in the mouth, will part from the soluble fraction at the upper GI tract, bypass the digestion there, and reach the colon intact bound to the DF matrix. Then the colonic microbiota can start a slow and continuous release of bound antioxidants from the fiber matrix via fermentation. The antioxidants released will start to scavenge the radicals that are naturally found in the colon and create a healthy antioxidant environment there, at the expense of the antioxidants, which become radicals.

At this point, if free soluble antioxidants are available in the colon environment, they will react with the DF-bound antioxidant radicals to regenerate the bound antioxidant radicals and will help to maintain the healthy antioxidant environment created (soluble antioxidants will react with DF-bound antioxidants in any part of the GI tract as well). In this way, the advantage of soluble antioxidants will also increase and be prolonged in contrast to a sudden peak in plasma antioxidant capacity followed by rapid disappearance as normally seen.

As a result of the reaction between DF-bound antioxidants and soluble antioxidants, either synergistic or additive or antagonistic effects will occur. Within this framework, the potential synergistic effect has been investigated in the present study. According to the results, a clear synergism was observed between DF-bound antioxidants and frequently consumed beverages as well as pure antioxidant solutions tested at two different stages of oxidation. The synergistic effects of the materials tested differed due to the different stages of oxidation under investigation; that is, green tea showed the highest synergistic effect in the ESR assay, whereas espresso showed the highest synergistic effect in the liposome assay. In addition, synergetic effects of different combinations changed depending not only on the type of antioxidant compounds present and their concentration but also on the ratios at which they are mixed as mentioned in an earlier study of Zanfini et al.[32] For example, green tea catechins, which were found to be good synergists in this study, can also enhance lipid peroxidation and create an antagonistic effect.[33] However, the clear synergism demonstrated for green tea and its phenolic antioxidant with DF-bound antioxidants is also in good agreement with the result of other studies.[34]

In conclusion, the presence of the synergistic effect between DF-bound antioxidants and soluble antioxidants, which is evidenced by this study, is important because of its possibility to occur in the GI tract. The synergistic effect was demonstrated both for the capacity of the antioxidants as radical scavengers and for the formation of secondary lipid oxidation products. This work will constitute the basis for future studies exploring the synergistic behavior of DF-bound antioxidants with water-soluble antioxidants.

hyperaccumulative properties for several risk elements such as Cd, Hg, and Pb.[13] Whereas the Pb concentration in conventional plants is usually very low, Pb levels in PS growing on polluted areas can increase by up to 1.48[14] and 15.76 mg kg^{-1}.[15] Moreover, after cultivation in a 1 mmol L^{-1} Pb solution, an incredibly high Pb concentration of 203 g kg^{-1} was observed[16] under artificial conditions.

EU Directive 2002/32/EC[17] set the maximal permissible limits for Pb in green fodder at 30 mg kg^{-1}. However, even slightly increased levels of this metal in forage crops may negatively affect the health of both animal and human consumers because Pb is toxic to the organism, even when absorbed in small amounts. Recently, it has been demonstrated that the trace element toxicity of food is dependent on more than just their total concentration. With regard to the risk of feed intake, the bioaccesssibility and bioavailability of trace elements are crucial factors. Bioaccessibility (BAC) is theoretically the amount of substance that is soluble in the gastrointestinal environment, i.e., fraction that is released from the matrix into the gastrointestinal tract during the digestion process and, thus, becomes available for intestinal absorption and can enter the bloodstream.[18] Bioavailability (BAV) is the general term used to describe the absorption of a contaminant into the body of an exposed subject. Absolute bioavailability (ABAV) is the proportion of the contaminant in the administered dose that is absorbed into the test organism.

To evaluate bioaccessible fractions of contaminants, several *in vitro* approaches have been developed in attempts to mimic the effects of the digestion process in mammals. Generally, these approaches are commonly called simulated *in vitro* gastrointestinal extraction procedures. The physiologically based extraction test (PBET), an *in vitro* test system for predicting the bioavailability of metals from a solid matrix, is the most widely used to date. The PBET was designed primarily to evaluate the absolute risk element bioavailability from contaminated soil in the digestive tracts of children.[19] However, various modifications of this original technique have recently been made. With regard to risk element bioaccessibility in animal and human food, the PBET was previously used to determine bioaccessible portions of both essential and toxic elements in contaminated plant samples,[20,21] seaweed,[22] medicinal plants,[23] raw vegetables,[24] uncooked rice,[25] cooked vegetable soup,[26] walnuts,[27] and mussel tissue.[28] However, to the best of our knowledge, both the BAC and BAV of trace elements have never been evaluated simultaneously in any phyto hyperaccumulators, including *P. stratiotes*.

Because data concerning the total concentrations of both essential and risk elements in contaminated plant material provide little information about the possible nutritional values and toxic effects of this kind of forage, the PBET can be a useful tool in assessing the potential risk of its diet intake. Nevertheless, the results of *in vitro* procedures should always be accompanied and confirmed by *in vivo* trials. Therefore, the aims of this study were as follows: (i) to determine the potential bioaccessibility and real bioavailability of both essential and risk elements from *P. stratiotes* and (ii) to determine the effect of *P. stratiotes* biomass feed intake on the accumulation of elements in mammalian organisms. For this purpose, an *in vitro* PBET using artificial digestive solutions was conducted, followed by an *in vivo* feeding trial on laboratory rats. In the course of this experiment, essential (Cu, Fe, Mn, and Zn) and risk (Pb) element levels were determined within a simulated gastrointestinal tract and within several rat tissues (liver, kidney, muscle, bone, and intestinal wall).

MATERIALS AND METHODS

Chemicals. Nitric acid (65%, p.a. ISO, Merck), H_2O_2 (30%, TraceSelect, Fluka), an ASTASOL-CZ9098MN1 standard solution (Analytika, CR), ammonium dihydrogen phosphate GR (Merck), and certified reference material BRC 12-02-01 (bovine liver) were used in this study.

Apparatus. An MWS-3+ microwave digestion system (Berghof Products+Instruments) was equipped with Teflon digestion vessel DAP-60S.

An atomic absorption spectrometer with electrothermal atomization (ET-AAS, Varian AA 280Z) with graphite tube atomizer GTA 120 and a PSD 120 programmable sample dispenser was used. The inductively coupled plasma-atomic emission spectrometry (ICP-OES) (Varian VistaPro) instrument was equipped with a two-channel peristaltic pump, a Struman-Masters spray chamber, and a V-groove pneumatic nebulizer made of inert material.

***In Vitro* Evaluation of Bioaccessibility.** The PBET[20] was performed to assess bioaccessible portions of elements in the gastrointestinal tract as follows.

Gastric Solution (1 L volumetric flask). Pepsin (1.25 g), citric acid (0.5 g), malate (0.5 g), lactic acid (0.84 mL), and acetic acid (1 mL) were mixed with deionized water. The pH of the mixture was adjusted with concentrated HCl to 2.5 ± 0.05. Then 0.5 g of sample was mixed

DOI: 10.1021/jf5058099
J. Agric. Food Chem. 2015, 63, 2344−2354

in an 85 mL polypropylene bottle with 50 mL of the prepared gastric solution. The bottle was placed in a shaker bath at 37 °C and shaken for 1 h at 150 rpm. After centrifugation, a 5 mL aliquot was taken off and measured for element content.

Pancreatic Solution. Five milliliters of the fresh gastric solution was added to the remaining reaction mixture, and the pH was adjusted to 7 with a saturated $NaHCO_3$ solution. Later, 25 mg of pancreatin and 87.5 mg of bile salts were added. The sample was again shaken in the bath for 2 h and centrifuged, and the extract was then measured. The element contents in the extracts were determined by ICP-OES. Bioaccessible portions of Cu, Fe, Mn, Zn, and Pb were expressed as a percentage of total element concentration in both the control diet and *P. stratiotes* biomass.

***In Vivo* Evaluation of Bioavailability.** *Experimental Animals and Diet.* Adult male Wistar rats (*Rattus norvegicus*) were used as models for bioavailability evaluation. The animals were obtained from a commercial supplier (Institute of Physiology of the AS CR, Prague, Czech Republic) and randomly divided into two groups based on plant material intake: CO, commercial diet only (n = 6); PS, *P. stratiotes* intake (n = 9). The rats were placed separately into plastic metabolic cages (TecniPlast) and left to acclimatize for 7 days. They were kept in controlled conditions (temperature of 22 ± 2 °C, 12/12 h light/dark cycle), given commercial feed, and allowed to drink tap water *ad libitum*.

A complete feed mixture for SPF breeding rats was purchased from a commercial supplier (Velaz s.r.o.) and used as a control diet. The nutritional values, as declared by the manufacturer, are as follows: moisture, 12.5%; nitrogenous compounds, 24%; fiber, 4.4%; fat, 3.4%; ash, 6.8%; lysin, 14 g; methionine, 4.8 g; Ca, 11 g; P, 7.2 g; Na, 1.8 g; Cu, 20 mg; Se, 0.38 mg of dry weight. The PS-supplemented diet was prepared as follows. *P. stratiotes* specimens were cultivated in a Pb-enriched medium under greenhouse conditions.[29] Harvested biomass was dried. Dry mass was ground to a fine powder, and each single dose (25 mg) was then weighed and thoroughly mixed with 25 g of commercial feed. These batches were administered to rats daily for a period of 6 weeks. The PS biomass constituted approximately 0.1% of the feed ration. Data concerning feed consumption were recorded daily (see Table 3), whereas individual animal weight gains were recorded twice a week (Figure 1).

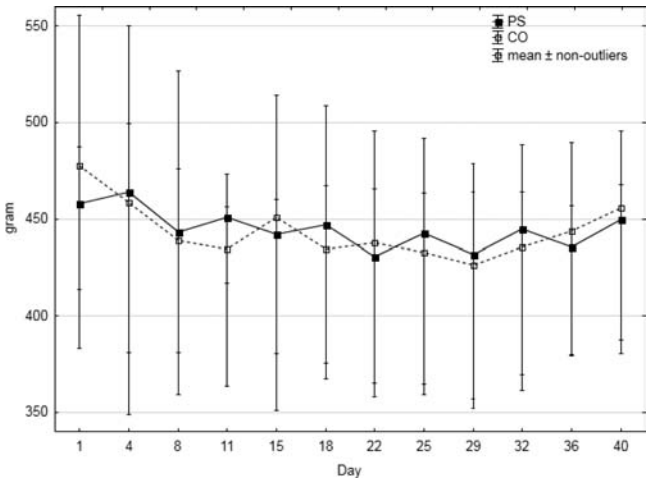

Figure 1. Weight gains of experimental animals.

All experiments with laboratory animals were conducted in compliance with the current laws of the Czech Republic (Act No. 246/1992 coll. on Protection Animals against Cruelty) and EC Directive 86/609/EEC. The experimental project was approved by the committee of the Ministry of Education, Youth and Sports, Czech Republic (approval code MSMT-31220/2014-7). Animal care was supervised by authorized personnel: Zuzana Čadková, Ph.D., recipient of the Central Commission for Animal Welfare Certificate CZ 02201.

Element Analysis of Rat Tissues. At the end of feeding trial, experimental animals were euthanized. Individual autopsies were conducted with Teflon instruments to obtain appropriate tissue samples (liver, kidney, testes, duodenal wall, femoral muscle, and bone) for element analyses. All tissues were weighed, properly washed in redistilled water, placed into Petri dishes, and stored at −20 °C until they underwent chemical analysis. Prior to element analysis, tissue samples (except bones) were freeze-dried and microwave digested in an acid-based mixture using the MWS-3+ microwave digestion system (Berghof Products+Instruments). The ET-AAS technique was used to determine element concentrations in all digested tissue samples of control groups, as well as in the liver, muscle, testes, and intestinal wall of PS-exposed groups.[30] The calibration curve for the measurement was prepared using the standard ASTASOL-CZ9098MN1 solution (Analytika). The evaluation of the obtained data was conducted using a standard addition method, and ammonium dihydrogen phosphate GR (Merck) was used as a matrix modifier. Samples with elevated Pb levels (kidneys and bones), along with the total element content in the PS biomass and in the control diet, were analyzed using ICP-OES (Varian VistaPro). Certified reference material BRC 12-02-01 (bovine liver) was simultaneously analyzed under the same conditions to assess analytical data quality (Table 2). Experimental data were adjusted

Table 2. Analytical Data Quality Assessment[a]

	CRM-BCR 12-02-01 certified value ($\mu g\ g^{-1}$) (mean ± SD)	CRM-BCR 12-02-01 determined value ($\mu g\ g^{-1}$) (mean ± SD)
Cu	26.3 ± 1.6	23.3 ± 3.0
Fe	495 ± 28	427 ± 51
Mn	7.6 ± 0.5	6.2 ± 0.5
Pb	0.71 ± 0.08	0.75 ± 0.09
Zn	162 ± 6.0	157 ± 5.5

[a]SD, standard deviation. CRM-BCR 12-02-01, certified reference material (bovine liver).

using the mean element concentrations in blanks (±3 standard deviations of blanks), which were prepared under the same conditions as were the tissue samples. Tissue samples were analyzed in two replicates, which were averaged for subsequent statistical processing. The relative element concentration in rat tissues was expressed in milligrams per kilogram of dry weight.

Total Element Levels in Rat Tissues. Total amounts of particular elements that accumulated in rat tissues (Table 3) were determined

Table 3. Total Feed Consumption and Element Intake during the *in Vivo* Trial[a]

	CO	PS
total feed consumption	1011[b]	992[c]
total Cu intake	0.023	0.022
total Fe intake	0.348	0.341
total Mn intake	0.114	0.112
total Zn intake	0.079	0.078
total Pb intake	0.002	0.037

[a]Mean values in grams per rat. [b]Total of 100% commercial diet for laboratory rodents ST1. [c]Total of 99.9% commercial diet for laboratory rodents ST1 + 0.1% of *P. stratiotes* dry mass.

using the element concentrations (milligrams per kilogram of fresh weight) together with the weight coefficient of individual rat tissues,[31] according to the following formula:

$$TEAT_{(mg)} = EC_{[mg\ (kg\ of\ FW^{-1})]} \times \text{animal weight}_{(kg)} \times SOWC \times 10^{-2}$$

where TEAT is the total element amount in tissue, EC the element concentration, FW the fresh weight, and SOWC the specific organ weight coefficient.[31]

DOI: 10.1021/jf5058099
J. Agric. Food Chem. 2015, 63, 2344−2354

Additionally, portions [$P_{(\%)}$] of the total Pb intake that accumulated in particular animal tissues were determined according to the folowing formula:

$$P_{(\%)} = \mathrm{TEAT}_{(mg)}/\mathrm{TI}_{(mg)} \times 100$$

where TI is the total intake.

Statistical Procedure. Data obtained from the *in vitro* PBET were assessed via Statistica version 12[32] using a Student's *t* test for dependent variables. Results of the *in vivo* feeding trial (differences in element tissue accumulations between animals from CO and PS groups) were analyzed using R version 3.1.1.[33] Because of the small number of animals used in our experiment (n = 15) and a significant number of potential interactions, we used separate tests for each monitored element. The basic *lme* model tested the general influence of a fixed effect "group" (CO vs PS) with control for a random effect "animal" with a nested factor "organ". The influence of individual animal variability was tested using AIC value comparison between a model that includes factor "animal" and a simplified model without this factor. In all cases (Cu, Fe, Mn, Pb, and Zn), AIC differences exceeded 50, favoring the simpler model. Finally, after factorial ANOVA with factors "group" and "organ", post hoc Tukey HSD tests were used to determine effect of diet (CO vs PS) on element concentrations in particular organs. An analogical approach was used for evaluation of differences in TAET values between PS and CO animals. To fit normality, data were log-transformed before applying the statistical models. However, to show the patterns more clearly, original values are presented in graphs and tables. The threshold for statistical significance was set at α = 0.05.

RESULTS

During the course of our experiment, the supplementing of daily feed rations with 0.1% PS dry mass did not significantly affect animal weight gains [*t* test, CO vs PS group (see Figure 1)]. The individual variance was mainly caused by nonuniform initial animal weights at the beginning of the experiment. Figure 1 shows that individual variation actually decreased during the feeding trial.

Total and Extracted Element Concentrations. Artificially cultivated *P. stratiotes* dry mass contained Fe, Mn, and Pb concentrations significantly higher than those of the control pellet feed. All three element concentrations were also significantly higher in the medium that simulated the gastric phase of PS digestion (pepsin extraction). In the artificial intestinal environment (pancreatin extraction), the PS digest showed significantly higher concentrations of all of the monitored elements, Cu, Fe, Mn, Zn, and Pb (Table 4).

***In Vitro* Bioaccessibility.** The PBET revealed that extraction of an element from PS biomass during the digestive process differs from that of conventional feed (Figures 2 and 3). In control feed, the BAC (%) of the majority of the monitored elements (Cu, Mn, Zn, and Pb) was higher (25−53%) in the gastric phase than in the intestinal fluid (9−20%). The most significant decrease was observed for Zn, a >5-fold decrease (from 53% in GP to 9% in IP). Fe BAC (%) from control feed showed a trend that was the opposite of those of previous elements. It was extremely low in GP (1%) and increased to 5% in a simulated intestinal environment. In PS biomass, the BAC (%) of all essential elements decreased significantly during the transition from the gastric phase (5−73%) to the intestinal phase (3−31%). As with control feed BAC, Fe BAC in PS was very low (5% in GP and 3% in IP), and Zn BAC dropped considerably (from 73 to 31%). Unlike control feed digestion, PS fed digestion exhibited almost twice the Pb BAC levels in the intestinal fluid (9%) as in the gastric phase (5%).

Table 4. Results (mean ± SD) of the *in Vitro* Experiment

	control feed (n = 3)	*P. stratiotes* (n = 3)	*t* test p value
	Total Element Concentration [mg (kg of DW)$^{-1}$]		
Cu	23 ± 5.3	25 ± 0.6	0.502
Fe	344 ± 24	991[a] ± 79	<0.001
Mn	113 ± 0.4	295[a] ± 25	<0.001
Zn	79 ± 6.5	73 ± 11	0.456
Pb	1.9 ± 0.4	14349[a] ± 1720	<0.001
	Element Concentration in the Gastric Phase (mg kg^{-1})		
Cu	5.5 ± 1.4	6.5 ± 0.2	0.307
Fe	3.7 ± 1.2	53[a] ± 1.4	<0.001
Mn	39 ± 9.4	122[a] ± 2.1	<0.001
Zn	40 ± 9.7	52 ± 0.3	0.103
Pb	0.5 ± 0.1	700[a] ± 19	<0.001
	Element Concentration in the Intestinal Phase (mg kg^{-1})		
Cu	4.4 ± 0.1	6.1[a] ± 0.2	<0.001
Fe	18 ± 1.6	32[a] ± 1.3	<0.001
Mn	16 ± 1.5	70[a] ± 2.4	<0.001
Zn	7.4 ± 0.7	22[a] ± 0.9	<0.001
Pb	0.2 ± 0.02	1319[a] ± 49	<0.001

[a]Significant differences (p < 0.001) between control feed and *P. stratiotes* biomass determined by a *t* test.

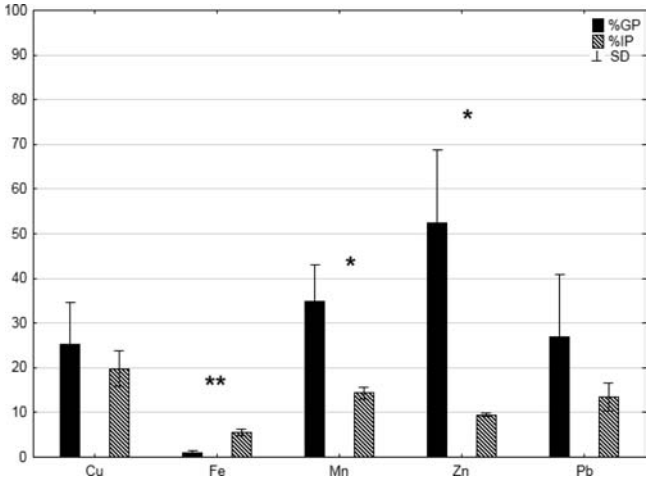

Figure 2. Control feed BAC (%) in gastric and intestinal phases of the PBET: GP, gastric phase; IP, intestinal phase; SD, standard deviation. Significant differences between GP and IP (*p < 0.05; **p < 0.01) determined by a pairwise *t* test.

***In Vivo* Bioavailability.** The accumulation of an element in rat tissues was expressed in two ways: (i) relative concentration in milligrams per kilogram of dry weight (DW) (Table 5) and (ii) total amount in milligrams (TEAT) (Figures 4A−F and 5). PS biomass intake affected element biokinetics in a rat. Supplementing the diet with Pb-loaded PS caused a significant increase in the total level of Pb accumulation (*lme*; F = 38.332; p < 0.0001). Compared to those of the CO group, the most intensive Pb growths were observed in bones (Tukey HSD test; p < 0.0001), kidneys (Tukey HSD test; p < 0.0001), and livers (Tukey HSD test; p < 0.0001). With regard to the Pb distribution in PS exposed animals (Table 6), the greatest portion of Pb accumulated in the skeleton (0.6%). Conversely, significantly lower (*lme*; F = 5.385; p < 0.05) Fe levels were observed in animals fed PS. Overall concentrations of Zn (*lme*; F = 3.94; p = 0.069), Mn (*lme*; F = 0.963; p = 0.344), and Cu (*lme*; F = 2.420; p = 0.144) were equal in both tested groups.

DOI: 10.1021/jf5058099
J. Agric. Food Chem. 2015, 63, 2344−2354

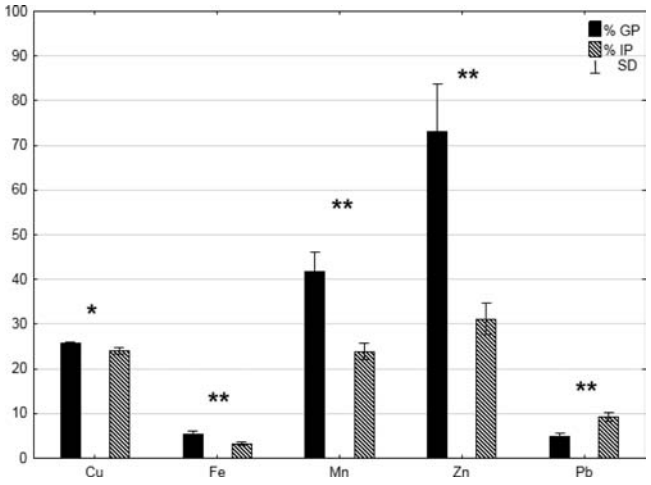

Figure 3. *P. stratiotes* biomass BAC (%) in gastric and intestinal phases of the PBET: GP, gastric phase; IP, intestinal phase; SD, standard deviation. Significant differences between GP and IP (*$p < 0.05$; **$p < 0.01$) determined by a pairwise t test.

Intestinal element levels were mainly influenced by diet because the intestinal walls of animals exposed to PS biomass had significantly smaller amounts of all monitored essential elements: Zn (Tukey HSD test; $p < 0.01$), Mn (Tukey HSD test; $p < 0.001$), Cu (Tukey HSD test; $p < 0.05$), and Fe (Tukey HSD test; $p < 0.0001$). With regard to TAET results, PS dietary intake reduced total Cu amounts in skeletons (Tukey HSD test; $p < 0.0001$) and increased Mn amounts in musculatures (Tukey HSD test; $p < 0.0001$). Zn levels in the testes of animals fed PS were considerably lower than in those of animals fed CO; however, the limit for statistical significance was not achieved (Tukey HSD test; $p = 0.09$).

DISCUSSION

***In Vitro* Bioaccessibility of Essential Elements.** In our experiment, the BAC (%) of Cu, Mn, and Zn in both analyzed types of feeds decreased significantly during the transition from the gastric phase to the intestinal phase. A similar trend can be found in the results of previous studies.[24,34] This decrease is most likely due to the fact that BAC of these elements correlates negatively with pH levels.[35] As with our results, previous study[20] concerning various leafy vegetables demonstrated the higher BAC of Mn and Zn in the gastric phase when compared to intestinal BAC. However, Cu BAC differs greatly between various matrices and extraction phases in several other works.[20,36,37] This variability may be related to Cu complexation with a wide spectrum of organic ligands that have various levels of degradability. On the basis of a high variability in previous *in vitro* BAC results summarized in Table 7, we can conclude that the identical microelements in different biological materials are bound to compounds with various grades of degradability for digestive enzymes. However, this presumption has to be verified through specific studies. Therefore, a particular extraction method as well as matrix characteristics should always be taken into account when assessing BAC. A generalization of this complex issue can lead to inaccuracy.

The behavior of iron in a simulated gastrointestinal tract differs considerably from that of Cu, Mn, and Zn. With regard to Fe in conventional plants, it usually has a very low BAC (only a few percent) under simulated stomach conditions; this is most likely due to the high content of phytates and phytosterols, which strongly bind Fe in an acidic environment. Subsequently, Fe BAC is enhanced in the artificial small intestine because Fe forms soluble complexes with chelating compounds, which are released in the intestinal juices during digestion. Because the most intensive nutrient absorption takes place in the small intestine, Fe BAC enhancement is crucial for sufficient Fe intake within the organism.

However, with regard to Fe extractability, a trend that is the opposite to that of a conventional plant was detected in phyto hyperaccumulators in a recent study[21] as well as in the experiment presented here. The reasons for this may be as follows. (1) Fe in hyperaccumulating plants may be bound to specific compounds, which have low solubility under intestinal conditions, or (2) elevated levels of risk elements in hyperaccumulating plants may reduce the extent of the transition of Fe from the gastrointestinal tract, which is due to antagonistic actions in intestinal fluids. Nevertheless, there is a lack of supporting information concerning this topic in the scientific literature, and the real reason for reduced Fe BAC from phyto hyperaccumulators under intestinal conditions must be elucidated. Even so, our current findings indicate that considerable consumption of these plant species could lead to a latent risk of severe Fe deficiency.

***In Vitro* Bioaccessibility of Pb.** Pb is generally considered to have a very low solubility. The main part of Pb in plant material is organically bound in the form of strong complexes

Table 5. Relative Element Concentrations[a] in Rat Tissues (milligrams per kilogram of dry weight)

(biomacromolecules), which are not dissociated even in a stomach environment.[27] Up to 99% of Pb can be insoluble because of chelation with polyphenols, phytosterols, or di- and monoacylglycerols.[38] When the Pb bioaccessible fractions from PS were compared to those from other biological materials (Table 7), considerably low levels (5−9%) were observed in our experiment. This may be due to relatively high polyphenol content in *P. stratiotes*, which was previously reported.[11,39]

According to previous studies,[21,24,40] Pb BAC is usually higher in the stomach than in the small intestine. This is due to the oxidation of elementary Pb forms at low pH levels. Pb dissolution in an acidic stomach environment is strongly pH-dependent[42] because the extent of dissolution is decreased by

65% when the stomach pH is increased from 1.3 to 2.5.[41] Under neutral-pH intestinal conditions, BAC can drop by around 70%. This is most likely due to reactions such as precipitation and re-adsorption, which are responsible for losses of soluble Pb.[35,43] Moreover, Pb can also be re-adsorbed on solid residues in chyme.[27]

The Pb BAC pattern of control feed in our experiment was in accordance with this presumption. On the contrary, Pb BAC from PS biomass under intestinal conditions was twice as high as that in an artificial stomach environment. Similar results regarding elevated intestinal BAC were observed in leafy and root vegetables and in mussels.[20,28] An enhanced Pb BAC level from PS in the small intestine poses a risk of excessive absorption into the exposed organism.

***In Vivo* Bioavailability of Essential Elements.** Total concentrations of essential elements detected in PS biomass are in good agreement with the previously defined metal composition of conventional plants.[44] The total Fe and Mn concentrations were significantly higher in PS biomass than in control feed. Moreover, simulated gastric as well as intestinal PS extracts exhibited higher concentrations of all essential elements when compared to those of the control feed. Regardless, there was no general elevation in tissue microelement concentrations detected in PS-fed animals. This is most likely due to two factors. First, essential element homeostasis in mammalian organisms allows a wide range of element intake without any marked effects. Second, the selected level of PS added to the diet (0.1%) was too low, and the experimental period (40 days) was too short to produce relevant changes.

In our experiment, the *in vivo* BAV was evaluated in two ways: (i) based on the final tissue Pb concentrations, which is actually one of standard methods for BAV evaluation, and (ii) based on total Pb amounts (TEAT), which were accumulated throughout the entire organ structure using the organ weight coefficient.[31] This represents a new and unique approach to BAV assessment. A principal advantage of this approach is the fact that it reflects individual weights of exposed animals. Moreover, our results showed that TEAT is able to detect differences in biokinetics of specific elements more sensitively than the conventional method.

Generally, animals fed PS biomass exhibited predominantly lower essential element levels in the tissues than did the control group (Figure 4A–F). Cu TEATs detected in the skeletons of PS animals were significantly lower than those in the CO group. This may be due to element interaction in the digestive tract, because a high intake of Fe, Zn, and/or Mn can interfere with Cu absorption and reduce the rate of transit of Cu through the intestinal wall.[45,46] The decreased Zn TEAT observed in the testes of PS-fed animals can pose a serious health problem because adequate Zn levels are crucial for an antioxidant defense of this organ. An interesting result of our study was that the intestinal wall of the animals exposed to PS biomass had significantly smaller amounts of all monitored essential elements. Such reduction most likely reflects some kind of imbalance in the absorption process. A suppressed transport of essential elements may be related to one of the following: (i) Pb competition for protein binding sites in the intestinal epithelium,[47] (ii) the inhibitory activities of *Pistia* tannins on digestive enzymes,[39] and (iii) reduced essential element absorption caused by the presence of phytic acids.[48,49]

***In Vivo* Bioavailability of Pb.** Despite extremely high total Pb concentrations in PS biomass and high Pb concentrations extracted into artificial gastrointestinal fluids, the BAV fractions of this element detected in rat bodies were rather low. After a 40 day feeding trial, <1% of the administered Pb dose was stored in monitored rat tissues (see Table 6). However,

[a]UDL, under the detection limit.

according to the current evaluations of the Joint FAO/WHO Expert Committee on Food Additives,[50] there is no safe threshold limit for Pb intake, and even a negligible portion of this toxic metal can produce harmful effects. With regard to Pb absolute bioavailability (ABAV), our findings are consistent with the results of soil-bound Pb ABAV based on bone and liver data.[51] A higher ABAV (approximately 3%) can be estimated on the basis of blood Pb values. Even though we did not determine blood Pb levels in our experiment, we could expect a pattern similar to those described in the study mentioned above. Blood Pb-based ABAV tends to be overestimated because blood Pb levels comprise also the Pb fractions, which are initially absorbed from the gut into the bloodstream but could eventually be excreted from the body through bile or urine.

The risk of Pb intoxication due to contaminated forage is usually low because the uptake of Pb from soil is limited in most terrestrial plants, including vegetables.[52] However, excessive Pb concentrations have often been detected in aquatic plants and weeds because many of these species have hyperaccumulative properties.[53−58] We detected elevated Pb concentrations in all monitored tissues of PS-fed animals, with the greatest increases observed in bones, kidneys, and livers. Therefore, the consumption of phyto hyperaccumulator biomass by both animals and humans can pose a serious toxic risk.

Pb levels in artificially cultivated PS biomass used in our experiment greatly exceeded the maximal allowable limit for animal feed in the European Union (10 mg of Pb kg^{-1}) and the United States (30 mg of Pb kg^{-1}). Therefore, this plant material could not be used as a single-component animal feed, and a low

DOI: 10.1021/jf5058099
J. Agric. Food Chem. 2015, 63, 2344−2354

level of supplementation (0.1%) was required in our experiment. However, with regard to the application of PS as animal feed, even the wild specimen *P. stratiotes*, which grows in some polluted areas, exhibits unacceptable Pb concentrations (15.76 mg kg^{-1}).[15] Therefore, potential forage plants that grow on polluted sites and artificially affected water bodies should be properly tested for risk element load before being processed for feeding purposes.

Comparison of BAC and BAV Results. A direct comparison of BAC and BAV results still remains questionable. The majority of previous studies focused on accidental dietary intake of soil-bound risk elements. Therefore, we are compelled to derive information from such studies. The partial correlations between *in vitro* BAC and *in vivo* BAV of soil-bound As, Cd, and Pb were previously demonstrated in young swine models.[42,59,60] However, when *in vitro* Pb BAC results were directly compared with *in vivo* BAV for swine, only two physiologically based extraction methods provided measurements that were within the accepted margin of error.[35]

We observed a similar trend in our experiment, wherein potential BAC fractions of particular elements differed from those determined in rat tissues. The results of the *in vitro* PBET indicated a high accessibility of all monitored elements form PS biomass; however, the supplementation level was most likely too low to cause significant effects in the *in vivo* model. With regard to human health risk assessment, an IVG method must always be correlated with an acceptable *in vivo* model.[61]

Because element (essential as well as toxic) absorption occurs primarily in the small intestine, there is a scientific basis for the relationship between intestinal BAC and potential BAV. Therefore, the determination of BAC in the intestinal compartment should be considered relevant for assessing the risk of element intake from the gastrointestinal tract. BAC determined in the stomach compartment results in a physiologically irrelevant relative BAV factor, which probably overestimates the actual fraction that is available for intestinal metal absorption.[62]

In summary, several important findings should be mentioned. BAC and BAV were compared in both conventional animal feed and phyto hyperaccumulator biomass for the first time. Using the *in vitro* PBET, we demonstrated that the digestive process of phyto hyperaccumulator biomass differed from that of conventional feed. *P. stratiotes* exhibited high concentrations of certain essential elements (Fe and Mn), and it could be potentially used in feedstuff. However, when this kind of plant grows in polluted areas, it can absorb extremely large amounts of risk elements. Therefore, consumption of such material poses a serious toxic risk. Additionally, our study revealed that high levels of risk elements (primarily Pb) in phyto hyperaccumulator biomass can affect essential element absorption from the gastrointestinal tract as well as element biokinetics inside an organism. The results of our experiment indicated heterogeneity between potential bioaccessibility determined *in vitro* and estimated bioavailability determined *in vivo*; this was because large bioaccessible fractions of elements from PS did not lead to elevated element concentrations in animal tissues. An important innovative aspect of this study is the application of a new method for ABAV evaluation based on the total element amount in specific organs or whole organ systems. Using TEAT, we were able to detect differences in element biokinetics between PS and CO groups more accurately. On the basis of the disparity between *in vitro* BAC and *in vivo* BAV in our study, we can recommend the following general approach. The PBET should be used primarily as a basic step for the identification of risk elements with high bioaccessibility in the digestive tract. Because *in vitro* methods are less expensive, less complicated, and less laborious than *in vivo* tests, this step allows us to specify potentially dangerous elements in animal fodder. Subsequently, once elements with high bioaccessibility are specified, only their bioavailability needs to be confirmed via more demanding *in vivo* trials.

have a higher rate than in Europe. Past studies about decreasing Cs accumulation in crops in Fukushima dominantly focused on the effect of K fertilization on Cs mobility in the soil−plant system.[4,26,27] However, more studies should set out to establish the elemental network to associate the Cs (and Sr) with other essential and nonessential elements, not only K and Ca, to clarify how regulatory mechanisms of Cs, Sr, and other elements interact, because the regulation in plants of a given ion uptake is decided by not only competitive ions but the balance of multiple ions.

In a previous study we concluded that the varietal effect of the genus *Amaranthus* brings about a significant difference in radiocesium uptake and transfer from soil.[28] In the present study we further present a phylogenetic analysis of interspecies difference in nutrient and trace element concentrations and establish the ionomic interactions between Cs, Sr, and other elements in amaranth shoots among 33 varieties of *Amaranthus* species.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. A field experiment was conducted in Iino located in the suburbs of Fukushima city (37°39 N, 140°32 E). The sites were 50.9 km northwest from the Fukushima 1 Nuclear Power Plant, and the field was cultivated in 2011. Soil type was gray lowland soil based on the classification of cultivated soils in Japan.[29] The contamination level of the soil by ^{134}Cs and ^{137}Cs was 2769 ± 141 Bq/kg (average ± SE). Thirty-three *Amaranthus* species were adopted including 10 local varieties (Table 1 in ref 28). All of the seeds were sown in vermiculite on June 30, 2012, and then transplanted to the field on July 14, 2012. The plot area was 120 m^2 (12 m × 10 m), and the soil was sampled for the chemical analysis before transplanting and the data for soil characteristics of the field are shown (Table 2 in ref 28). To avoid possible interaction between ions during radiocesium transport by root, only nitrogen fertilizer in the form of ammonium sulfate was applied at a rate of 100 kg N ha^{-1}, and the plants were then cultivated at a 15 cm depth. Twenty plants for each examined plant variety or species were transplanted at 70 cm × 50 cm planting density.

Sampling and Analysis. Plant samples were harvested on October 6, 2012, with three replications (two to three individuals in each replication) for each variety or species, and then the aboveground shoot was separated from the roots. Plant samples were dried at 70 °C for 1 week and then mercerized by a stainless grinder. After drying and milling, 50 mg shoot samples were digested with 2 mL of 61% HNO_3 (EL grade; Kanto Chemical, Tokyo) in a tube at 110 °C in a DigiPREP apparatus (SCP Science, Quebec, Canada) for 3 h, and 0.5 mL of hydrogen peroxide (semiconductor grade; Santoku Chemical, Tokyo, Japan) was added two times at a 30 min interval as an oxidant and heated at 110 °C until the solution became clear. After cooling to room temperature, tubes were filled to 15 mL with 2% HNO_3, and concentrations of 23 elements (P, K, Mg, Ca, Mn, Fe, Cu, Zn, B, Mo, Ni, Sr, Cr, Al, Ba, Cd, As, Na, Co, Se, Li, Rb, and Cs) in the digests were analyzed by an inductively coupled plasma mass spectrometer (ICP-MS) (Elan, DRC-e; PerkinElmer, Waltham, MA, USA). The ICP multielement standard solution IV (Merck, Tokyo, Japan) was used as standard for ionomic determination.

Statistical Analysis. To visualize the differences of the 23 mineral elements in 33 amaranthus varieties, descriptive statistics, one-way variance (ANOVA), correlation analysis, and principal component analysis (PCA) were performed using SPSS 18.0. For statistical differences between elemental compositions for the cultivars, ANOVA was conducted, and the ratio of variance between groups to variance within groups was used to estimate the variation caused by varieties. For correlation analysis Pearson correlation coefficients and Student's *t* test were applied to identify the significant correlations between mineral elements. A conservative *p* value limit of 0.001 was used to confirm whether the correlation is significant. The overall accumulations of 23 elements were profiled by PCA. The varimax with Kaiser normalization was used as rotation method.

RESULTS AND DISCUSSION

Statistics and Variation of Mineral Elements Contents in Amaranth Shoot among 33 Different Varieties. In this study, shoot element concentrations varied by 6 orders of magnitude from 0.073 μg g^{-1} for Cs to 34.15 mg g^{-1} for K, in the order K > Ca > P > Mg > Mn > Rb > Al > B > Fe > Na > Sr > Ba > Zn > Ni > Cu > Co > Cr > Cd > Li > As > Mo > Se > Cs (Figure 1). Cs accumulation was the lowest among 23 elements, which is probably related to the low available Cs concentration in soil and the high affinity of Cs to the clays.[8,11,30] The affinity of cations to clays in soil follows the order $Cs^+ > NH_4^+ > K^+ > Na^+ > Ca^{2+}$.[30]

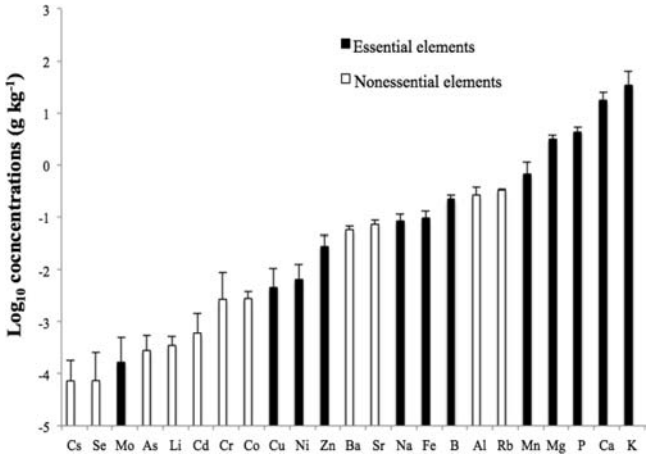

Figure 1. Average concentration of 23 mineral elements in shoots of 33 varieties of *Amaranthus* (n = 3 for each variety). Black columns represent the essential elements, and white columns represent nonessential elements. (Na is also regarded as an essential element in this research as Na is an indispensible part of growth of C4 plants including amaranths.)

The results of varietal difference contributed to the variation of elements, and descriptive statistics were presented in Table 1. Significant difference (p < 0.001) between different varieties was detected in all of the elements excluding Se. The relatively smaller phylogenetic variation in shoot Se was concordant with previous studies.[31,32] The remaining variation for a given element corresponding to differences besides species was likely caused by soil and climatic factors, sampling depth of field, or uneven distribution of trace elements in the field.[32] To quantify the varietal variance affecting each mineral element, the ratio of variance between groups to total variance was calculated and ranged from 53.64% for Se to 99.14% for Cr. Cr revealed the largest varietal variance, approaching 100%, and the largest ratio of maximum to minimum as well as CV (coefficient of variation, ratio of standard deviation of all cultivars to mean of all cultivars) was also observed in Cr. Although no metabolic activity involving Cr is known in plants, even within the same genotype there are differences in root exudates influencing the soil microbe community and element availability in the soil.[33,34] Environmental factors may also have important effects, such as the specific soil characteristics and uneven distribution of nonessential elements in the field. Whereas there is variation associated with genotypes across the entire elemental composition, the varied degree as measured by the ratio of

[a]Values reported are the partition of variance for the cultivar difference (ratio % of variance between groups to total variance); F values generated from the ANOVA with Tukey test; maximum (max), minimum (min), mean with the unit of μg g^{-1}; max/min (ratio) and standard deviation (SD) of elemental accumulation in shoot for mineral elements. [b]*, $P < 0.001$.

the maximum to the minimum concentration or by the CV is highly element dependent (Table 1; Figure 2). The CV in

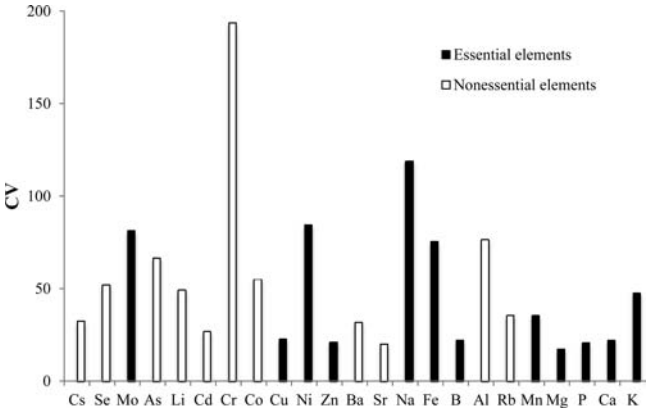

Figure 2. Relationship between mean concentration of elements in plants and their coefficients of variation (CV).

response to the variety effect increased in the order Mg < P < Sr < Zn < B < Ca < Cu < Cd < Ba < Cs < Mn < Rb < K < Li < Se < Co < As < Fe < Al < Mo < Ni < Na < Cr. The CV of macronutrients including P, K, Ca, and Mg varied <50%, whereas Na and Cr had CVs >100%. The pattern of CV of shoot minerals is consistent with the stability of limiting elements hypothesis: the CVs of Mg, Ca, P, B, Zn, and Cu (the essential elements) are <25%, whereas the CVs of As, Cr, Co, and Al were >50% and Cr approximated to 200%, becoming the most sensitive element of amaranths grown on the field subject to radionuclide contamination.

On the other hand, the CVs of seven elements (Mg, Ca, Mg, B, Sr, Zn, and Cu) were <25%, but only Sr belongs to nonessential elements. Both the CV and variety variance of Sr were higher than those for Cs, Ba, and Se. Meanwhile, variety difference of Cs was lower than all elements excluding Se. These results indicate that the amaranths are less sensitive to the accumulation of Cs and Sr than most other mineral elements to the species level. In contrast with Cs, the analogues K and Na showed relatively higher variety difference and CV. These results illustrate K and Na were unstably distributed in the shoot of different varieties of *Amaranthus*. Compared to the alkali metal elements, the variety diversity was more consistent for alkali earth metals and Ca, Mg, Sr, and Ba, which all showed relatively lower CV (<50%). The relatively stable intervarietal alterations for Cs and Sr within the *Amaranthus* genus coordinate with the larger range of investigations. According to meta-analysis for 27 plant species, it was concluded that the intervarietal variation at the ratio of the maximum to minimum of concentrations for a given crop species ranged from 1.0 to 6.3 for Cs and from 1.0 to 4.5 for Sr,[35] which is similar to the ratio within the genus of *Amaranthus* in this study and relatively lower than that of many other mineral elements. In conclusion, phylogenetic variation for Cs and Sr within genus was lower than the essential elements of their analogues, which suggests the essential elements of groups I and II in the periodic table are more sensitive to genetic difference than their alternative nonessential elements. Moreover, within the *Amaranthus* genus the lower interspecies difference of alkali earth metals (Ca, Mg, Sr, and Ba) than of some alkali metals (K and Na) suggests the elemental accumulation in shoot is independent of the mother rock composition of minerals. However, Ca and Mg have higher phylogenetic variation above family than K and Na.[32]

Among the 23 elements, the Rb concentration was higher than all elements excluding P, K, Ca, Mg, and Mn, but there is an unknown role for Rb in plant nutrition. As the analogue of

		17				25		17			
		20				26					

[a]Numbers represent the variety exhibited in Table1 of reference13. On the basis of ANOVA with Tukey's test, significantly highest/lowest varieties for each element were selected no more than three, and if there were over five varieties showing significant extreme values, the NS would be shown in this table. [b]Sig H means significantly highest and sig L, significantly lowest.

Cs, the Rb concentration was also relatively constant across species with lower CV and ratio of maximum to minimum concentration. This stable distribution in different varieties in amaranths was similar to Cs, but dissimilar to K, which coincides with the previous study that Rb concentration in the shoot mainly depends on soil chemical and physical properties, rather than variety difference.[31] In addition, Cs^+ and Rb^+ uptake are mediated by K transport systems because K^+, Rb^+, and Cs^+ have comparable physical−chemical characteristics owing to similar radii of their hydrated ions.[35,36]

Interactions between Mineral Elements. The homeostatic mechanisms that control the levels of different elements are reported interconnected, and certain interconnections could be detected across species.[20,37] The correlation analysis among elements in 33 varieties of *Amaranthus* was therefore investigated (Table 2).

In this study, positive correlations were identified between K, Na, and Li and Cs and Rb in the first group and between Mg, Ca, and Sr in the second group. Fe, Ni, Ba, Al, As, and Rb showed significant correlations with Cs, but among them only Fe and Ni are of essential role in plant nutrition, which suggested the Cs uptake was more readily affected by some nonessential elements. The absence of significant correlations between K and Cs coordinates with the previous study.[38,39] Whereas it has been reported that K and Cs enter root cells through the same molecular mechanisms and Cs uptake could be effectively strengthened in K-deficient solution,[40,41] the correlation between K and Cs was still insignificant. It has been proposed that the lack of this correlation is consistent with the constitutive expression of some selective K^+ transporters such as AKT1, which was unlikely to contribute significantly to Cs^+ uptake from the soil solutions with high concentration of Ba^{2+}, Ca^{2+}, or La^{3+},[42] and the expression of other proteins catalyzing the nonspecific absorption of Cs^+ and K^+ are regulated by varietal factors including the K^+ status of the plant.[41,43] The internal translocation rate of Cs is slower than that of K in rice shoot, and the distribution of Cs in grain and nonedible parts also diverges from that of K.[44] Therefore, the physiological reasons why K fertilization is against the transfer of Cs from soil to plant should separate from the transport inside the plant and associate with the block effect of K on Cs influx into root by cation exchanging from soil because K can occupy the absorption site of Cs in root.

Moreover, there was a recent report that Cs accumulation in yeast and plants could be specifically inhibited by the SNARE protein (Sec22p/SEC22) without interrupting K homeostasis in *Saccharomyces cerevisiae*, and the mechanism may be caused by raising nonselective cations storage to vacuole.[45] In the evaluation of taxonomic variation of shoot Cs concentration, it was speculated that the plants able to hyperaccumulate Cs, including amaranths, were all of halophytes with less selectivity to nonessential elements to meet their cation demands.[2] In addition, the partition of excessive quantities of cations in cell vacuole is an effective energy-efficient method for generating an osmotic potential for rapid cell expansion and growth.[46] Therefore, the interactions between Cs and its remarkably correlated cationic elements in vacuole are likely to be responsible for the higher Cs concentration in amaranths rather than only by cutting off the K supply.

In addition, among elements significantly correlated with Cs, As was the sole anion and displayed the highest coefficient with Cs (Table 2). It has been reported that *Athyrium yokoscense* not only displayed the highest TF (translocation factor) value of radiocesium (0.703) among 99 herbs grown on a radiocesium-contaminated field but also hyperaccumulated As from mine soil with elevated concentrations of As and heavy metallic ions.[47,48] These results indicate that the mutual promotion may exist for taking up As and Cs into plants. The findings from some previous studies may be helpful to explain the regulation of As on Cs that the significant decline in essential elements was associated with increasing As in rice grain.[49,50] Furthermore, Ba was the unique element showing a significantly negative association with Cs. This correlation probably resulted from the blocking of Ba^{2+} on the channel for Cs^+ xylem loading to aboveground tissues. The termed K^+-selective outward-rectifying channels (KORC) facilitate K^+ efflux from root cells and are permeable to Cs^+, but are inhibited by extracellular Ba^{2+} because the gene encoding the typical KORC is down-regulated by Ba^{2+} at millimolar concentrations.[51] This negative correlation between Ba and Cs also suggests the importance of long-distance transport for Cs accumulation in shoot of amaranths. In conclusion, the absence of correlations between K and Cs in amaranth shoot suggests that the competition between K and Cs mainly occurs in soils, and the negative correlation between Ba and Cs suggests that Ba is a key element to inhibit the internal Cs transport in shoot. As Ba^{2+} repressed Cs^+ translocation by obstructing the K transporters (AKT1) or pathway (KORC),[42,51] K availability in growth medium possibly played an important role in the interaction between Ba and Cs in the shoot.

Significant correlations between Ca, Mg, Mn, Zn, B, Ba, Cd, and Sr were detected, and all of the coefficients were positive. Compared with the relationship between K and Cs, the

relationship between Ca and Sr was much more pronounced (Ca presented the highest coefficient with Sr), which concurs with many previous findings in other plant species.[32,35,52] It has been reported that the interaction between Ca and Sr concentration in shoots is consistent with reduced transport selectivity due to a greater contribution of apoplastic movement of these elements in plants.[51] However, if the countermeasures to decrease Sr uptake are considered on the basis of this directly proportional correlation between Ca and Sr, the intake of Ca by humans may be compromised in varieties with low Sr accumulation. The positive correlation between Sr^{2+} and many bivalent ions possibly depends on the shared nonselective cation channels, including Ca^{2+}-ATPase, ZIP, and YSL family of transport proteins, in xylem transport.[23,53] Besides the bivalent cationic ions, B was the unique anion to significantly correlate with Sr. Bivalent cations are often transported in the xylem by complexation with organic acids,[23] but the relationship between B and Sr was little reported. It is probably related to the cation−anion balance, but the exact mechanism requires more studies.

Identification of Extreme Varieties. Because of the large genetic variance observed in a majority of elements and the fold-ranges of CVs for certain elements, potential candidate varieties for accumulating extremely high or low status of elements are prone to be identified. As shown in Table 3 (see the serial number of varieties in Table 1 of ref 13), varieties were identified with the significant highest value for all elements and significant lowest value for all elements excluding Fe, Al, and Na. Particularly some varieties showed the same extreme for more than one element with the significantly highest or lowest concentration, which relates to complicated elemental correlations. Variety 12 accumulated the significantly highest Cs, Mn, As, and Co in shoot. Variety 25 displayed the strongest resistance for Cs accumulation in shoot among 33 varieties, and it also restricted the As accumulation with the highest efficiency, which is possibly associated with the result that As was the element with the highest correlation coefficient with Cs. Therefore, the countermeasures to prevent As uptake may be also beneficial for Cs resistance, such as increasing P fertilization. Variety 17 showed extreme promotion for the accumulations of Cs, Fe, Ni, Al, Cr, and Mo and extreme inhibition for accumulations of Ca, Sr, Cd, Se, P, Rb, and B. Interestingly, Cs and Rb exhibited significant positive correlation, but in variety 17 the accumulations of Cs and Rb diverged. This result implies that although a positive correlation between Rb and Cs was demonstrated, the up-regulation on Rb^+ uptake may be still beneficial for restricting more Cs^+ influx into the shoot. The accumulation of Rb^+, rather than Cs^+, was remarkably high in amaranth shoot because it was ranked $K^+ > Rb^+ > Cs^+$, with a relative ratio of 468386:7818:1, which coincides with the previous study on the mobility of K, Cs, and Rb within the soil−ectomycorrhizal system.[37] In that study, the fungi showed a high preferential uptake of Rb and K compared with Cs, and it was reported that the mechanism of Cs uptake by fungi was similar to that of Rb, whereas the K uptake mechanism may be different. However, research on the relationship between Rb and Cs accumulation in shoot was quite scarce. On the basis of the inference from the extreme accumulation of variety 17, the much larger preference of amaranths on Rb may provide new insight into the regulation on Cs uptake. In addition, the significantly highest Cs and lowest Sr both appeared in variety 17. In the present study, Sr and Cs did not show significant correlation, which coordinates with a large proportion of past studies.[35,52] This specific accumulation in variety 17 probably resulted from the greatly different uptake mechanisms and functions of their analogous elements K and Ca. This result poses a challenge for the selection of low-accumulating varieties owing to the exhibition of low accumulation of one radionuclide but not necessarily of the other. Variety 17 may be a potential plant material for studying the relationship between Cs and Sr accumulation in shoots.

The significantly highest concentrations of Sr and Ca were both detected in variety 24, which showed the role of Ca on Sr accumulation in shoot again. The significantly highest concentrations of Sr and Cd were both detected in variety 28. The significantly lowest concentrations of Sr, Ba, and Zn were all observed in variety 3. All of the varieties, excluding variety 17, showed that the extreme accumulation for Sr must be associated with other bivalent cationic elements, and Ca was not the only choice.

Profiling the Ionome in 33 *Amaranthus* Varieties. PCA succeeded in reducing the number of variables by clustering the elements with close interactions into the novel principal component (PC) and explained their contributions to the genetic variance, respectively (Tables 4 and 5). A total of 23 elements of 33 varieties were subjected to PCA, and these 23 original variables were converted to a set of linearly uncorrelated 6 PCs that totally contributed 83.7% of total variance of elements among species (Table 4). The PC where the elements exposed the highest loading score can define the according elements. In this study, PC1 accounted for 23.2% of the highest total variance and was mainly affected by Ni, Al, Fe, Cr, Li, Mo, and Ca. Notably, PC2 explained 20.3% of total

variance and was dominantly incorporated by Sr and many of its significantly correlated elements, excluding Na. PC3 revealed 12.4% of the total variance and summed up the set of Cs and its significantly correlated elements, Rb, As, and Se.

In Table 5, the component score coefficient matrix of different varieties shows the relative accumulations of different elements in plants. The mean value of factor loading score is 0, and the positive value means the score is higher than the average level individual. It is noted that variety 12 not only accumulated the significantly highest Cs in shoot but also obtained the highest loading scores in PC3 and PC6 and the second lowest score in PC4. Besides variety 12, the variety with loading score of PC3 higher than 1 was detected only in varieties 4 and 5. On the other hand, variety 25 accumulated the lowest Cs and loading scores in PC3 among 33 varieties. Additionally, variety 17 exhibited the highest loading score in PC1 and higher than variety 13 at the second place in the ranking of loading score in PC1 by 1.4-fold. Variety 9 presented uniquely positive values in all PCs. Conversely, variety 3, with the lowest concentration of Sr in shoot, showed a negative loading score in all PCs, which means any of the loading scores in PCs was lower than the mean value.

PC3 is important with respect to Cs accumulation because it collected Cs and the significantly correlated elements As, Rb, and Se in the same set. Variety 12 obtained the highest loading score in both PC3 and PC6 dominated by positive Co and negative K quantification and the second lowest loading score in PC4 dominated by Ba and Zn quantifications. As a result, greater Cs deposited in the shoot of variety 12 may be achieved by increasing the absorption of Co, Cs, Rb, As, and other elements positively correlated with Cs and diminishing the K, Zn, and Ba, the potentially competitive or antagonistic ion flux into plants. It has been reported that a lack of K supply would result in the decrease of vacuolar K^+ concentrations and further lower osmotic potential,[23,37] which is beneficial for nonselective assimilation of minerals, especially for Rb^+ and Cs^+, owing to their chemical similarity. It could be speculated that K^+ starvation in the vacuole could probably push the flux of cations including Rb^+ and Cs^+ to vacuole to maintain the osmotic potential and limit the absorption of Ba^{2+} to be unobstructed in xylem transport, which is consistent with the loading score of variety 12 in PC3, PC4, and PC6.

Variety 17 revealed another similar mechanism for efficiently taking up Cs. It gained the highest loading score in PC1 that accounted for 23.2% of the highest total variance and was mainly affected by Ni, Al, Fe, Cr, Li, and Mo, among which Ni, Al, and Fe were significantly correlated with Cs. Meanwhile, the lowest loading score in PC2 and second lowest loading score in PC4 were achieved by variety 17. PC2 and PC4 were dominantly affected by B, Na, Ca, Mg, Sr, Ba, Zn, Cd, and Mn. These elements, excluding Na, were all significantly correlated with Sr and played an indicative role for Sr accumulation. There is no competitive relationship between monovalent ion and bivalent ion, so this pattern of elemental composition possibly derives from the regulation of plant on overall ionomic uptake. It was demonstrated that the inward-rectifying potassium channels (KIR) in the plasma membranes, also permeable for Cs^+, are inhibited by millimolar concentrations of Ba^{2+} and Ca^{2+}.[50] Although significant correlation was not detected between Cs^+ and any of the bivalent cations, the particular ionomic characteristic in variety 17 may be of importance to associate Cs and Sr. Varieties 12 and 17 both took up more Cs by promoting the influx of elements positively correlated with Cs into shoot, but the former decreased the K and Ba uptake and the latter inhibited the accumulation of Rb, Sr, and significantly correlated elements of Sr in shoot.

On the basis of these results, K fertilization may be a feasible countermeasure against radiocesium uptake in K-deficient soils in Fukushima, because grown under K deficiency the sudden K supply would inhibit the flux of Rb^+ and Cs^+ into root to a great degree and adequate K storage in vacuoles would limit the uploading of Ba^{2+} into xylem transport to maintain the Ba^{2+} concentration in shoot at millimole level to repress the upward transport of Cs^+.[35,39,51] In addition, vermiculates, zeolites, and bentonites may be splendid selections as well because many cations including K^+, Ca^{2+}, and Mg^{2+} are contained in them. The application of these minerals to achieve the radiocesium retention has been demonstrated successfully in some previous studies.[24,54−56] It was proved that manure application led to the inhibition of the upward translocation of Cs to soybean seed and improved the accumulation of Cd, Ba, Co, and Zn, which coordinates with the inference in this study.[17] In addition, because among elements the highest positive coefficient for Cs was detected between Cs and As and variety 33 accumulated

both the lowest Cs and As, the countermeasures to inhibit As uptake may be beneficial for resistance of Cs translocation to the shoot.

Correction to Fermentative Conditions Modulating Sweetness in Dry Wines: Genetics and Environmental Factors Influencing the Expression Level of the *Saccharomyces cerevisiae HSP12* Gene

Axel Marchal,* Philippe Marullo, Cécile Durand, Virginie Moine, and Denis Dubourdieu

J. Agric. Food Chem. **2015**, *63* (1), 304−311. DOI: 10.1021/jf504408t

There was a mistake in the caption of Figure 5A. The names of the yeast strains attributed to sweetness intensities were shuffled. The right attribution can be found in Figure 5 below.

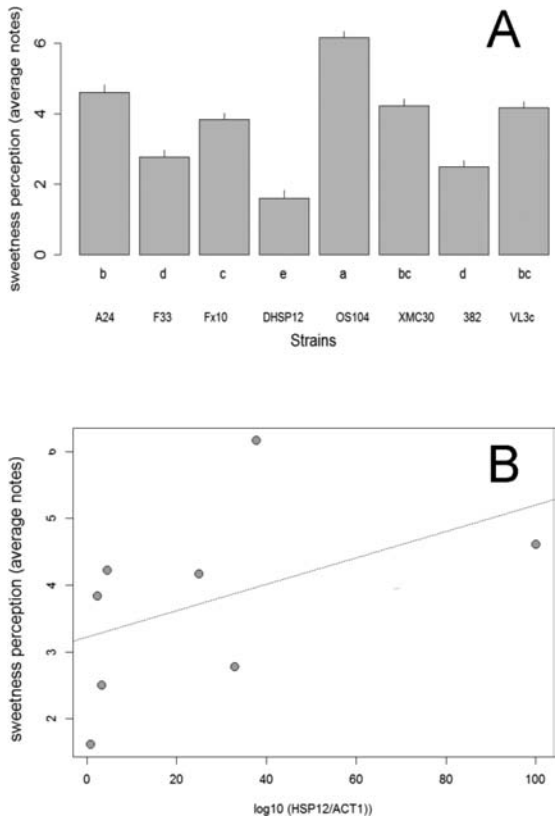

Figure 5. Wine in contact with lees obtained from different yeast strains showed marked difference in sweetness perception. (A) A wine without Hsp12p was obtained by fermenting a Merlot juice with Δ°hsp12. Yeast biomass of eight different strains was added to this wine, and aging on lees was carried out at 32 °C for 10 days. This biomass was collected from fermenting cells at 46 g/L of CO_2 produced. After wine centrifugation, a panel tasted the modalities, and the sweetness intensity was rated on a scale from 0 to 7. Error bars indicates the standard error of 17 notes. A two-way analysis of variance was used to estimate the strain effect ($Y = \mu + \text{strain}^i + \text{panel}^j + \varepsilon^{ij}$). The letters below the box plot indicate groups with a statistical difference according to the linear model used (Duncan test $\alpha = 0.05$). (B) Relationship between sweetness perception and expression level of *HSP12* (Kendall correlation test, $T = 22$, p value = 0.0601).

Correction to A Survey of Tremtone, Dehydrotremetone, and Structurally Related Compounds in *Isocoma* spp. (Goldenbush) in the Southwestern United States

Stephen T. Lee,* Daniel Cook, T. Zane Davis, Dale R. Gardner, Robert L. Johnson, and Clinton A. Stonecipher

J. Agric. Food Chem. **2015**, *63* (3), 872−879. DOI: 10.1021/jf505423h

Several of the values contained in the original version of Table 2 are incorrect due to a calculation error, and are corrected in the revised table by multiplying the previously published values by 8. Tremetone, **1**, and 7-isopentenyloxycoumarin, **5**, from the Red Rock, Mesa, Kingman, and Wickenburg Sites and 3-oxyangeloyltremetone, **3**, from the Tuba City Site have been corrected in the revised table and are greater by a factor of 8. The corrected table appears below.

Table 2. Concentrations of Tremetone, 1, Dehydrotremetone, 2, 3-Oxyangeloyltremetone, 3, 4-Hydroxy-3-(3-methyl-2-butenyl)acetophenone, 4, and 7-Isopentenyloxycoumarin, 5, in *Isocoma* spp. Field Collections[a]

intestinal mucosa and finally intracellularly, especially in the liver, first to H_2folate and subsequently to H_4folate.[9,12]

Immediately upon intracellular entrance, H_4folate participates in the biosynthesis of polyglutamate forms, usually up to five to seven residues, to be retained within cells and subcellular compartments. Polyglutamated folates are the preferred coenzymes involved in C1 metabolism. Chain elongation increases the anionic nature of folate coenzymes by providing α-carboxyl charges and decreases affinity for membrane carriers, thus impairing folate diffusion through hydrophobic barriers.[19] The polyglutamated H_4folate molecules accept C1 groups supplied from the catabolism of certain amino acids such as glycine, serine, and histidine or from the catabolism of purines. The C1 groups are donated enzymatically to be included in the nucleotide synthesis of DNA and RNA and in the methylation of homocysteine to methionine. After donation of their C1groups, the substituted folates regenerate to polyglutamate forms of H_4folate or H_2folate and are then ready to accept new C1 groups.[2,9,10]

OCCURRENCE IN FOOD

Plant foods are the major source of folate because they can synthesize folate. This biosynthesis route has already been explored for biofortification of tomato fruit and rice with 25- and 50-fold increases in folate content, respectively.[21,22] Other types of bioprocessing to enhance dietary folate are germination, sprouting, malting, or fermentation based on yeast or lactic acid bacteria (LAB) or both. Bioprocessing is commonly used for the manufacture of bread, yogurt, buttermilk, beer, and wine.[23−26] Good dietary sources of native folate include liver, legumes, green leafy vegetables, citrus fruit and juice, certain berries, cereals, and egg.[17] Mandatory or voluntary fortification with folic acid is also common mostly as prophylaxis against neural tube defects because women of fertile age throughout the world have difficulties meeting the daily folate recommendations during pregnancy and lactation.[27]

Most of the folate information in food databases originates from microbiological assays (MA), which give information only on the total folate content determined after deconjugation. During the past decades, chromatographic methods have been developed that can separate the different folate vitamers. Such studies have shown 5-CH_3-H_4folate to be the major native food folate form, followed by the formyl folates. Overall, unsubstituted folates are ranked as the third folate pool in diet. Table 1 gives an overview of deconjugated native folates in monoglutamate forms that have been determined in food using chromatographic methods, for example, high-performance liquid chromatography (HPLC) or ultrahigh-performance liquid chromatography (UHPLC). Only data based on HPLC and highly selective detectors such as mass spectrometry (MS) are displayed in Table 1.[22,25,28−34]

Dietary folates are divided into 5-CH_3-H_4folate, sum of formyl folates, and two individual unsubstituted folates, H_4folate and folic acid. H_2folate is not recorded because it is too labile to be determined. Folic acid is included as a stable degradation product of H_4folate and H_2folate. Baker's dry yeast is one of the richest dietary sources of folate, containing about 3 mg total folate/100 g, of which H_4folate constitutes ~25%.[28] Another rich dietary folate source is liver, where H_4folate occurs in similar proportions as 5-CH_3-H_4folate, and is thus the second most common group there.[29] Other good dietary sources of folate and H_4folate are legumes and green leafy vegetables such as spinach and cabbage, in which H_4folate constitutes about 10−20%.[30−33] Cereal fractions also contain H_4folate, usually below 10% (Table 1). Folic acid as a degradation product of H_4folate and H_2folate is occasionally but not regularly found in low concentrations, up to 25% of total folate in cereal fractions (whole grain flour, bran).[22,25,30,34] Apart from the "natural" presence of folic acid in certain foods, folic acid can also be added as a mandatory or voluntary food fortificant, especially to flours of wheat and corn, bread, fruit juices, and infant foods.

CHEMICAL PROPERTIES OF UNSUBSTITUTED FOLATES

Background information about chemical properties is essential to understand the stability and conversions of unsubstituted folates during food handling and analysis. All folates comprise a pteridine coupled via a carbon−nitrogen (C^9−N^{10}) bond to pABG, which in turn is coupled via an amide bond through its carboxyl moiety to the amino group of L-glutamic acid. The pteridine moiety of folates can exist in three oxidation states: fully oxidized (folic acid) or as the reduced 7,8-dihydrofolate (H_2folate) or 5,6,7,8-tetrahydrofolate (H_4folate). H_4folate is the coenzymatically active form of the vitamin that accepts, transfers, and donates C1 groups, attached either at the N^5 or N^{10} position or by bridging these positions.[9,35,36] The C1 groups also differ in their oxidation state, with folates existing as derivatives of formate (5-formyl-H_4folate, 10-formyl-H_4folate, 5,10-methenyl-H_4folate, and 5-formimino-H_4folate), methanol (5-methyl-H_4folate), or formaldehyde (5,10-methylene-H_4folate).[16] In addition to these structural variables, most naturally occurring folates exist as γ-linked polyglutamate conjugates, with chain lengths typically in the range of five to seven glutamate residues.[9] The chemical structures of unsubstituted folates are displayed in Figure 1.

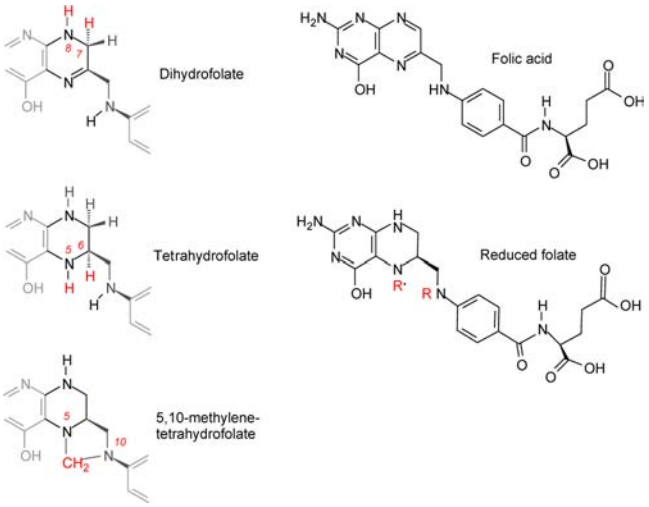

Figure 1. Structures of folic acid and the native monoglutamate folate forms.

Folates are ionogenic and amphoteric molecules, which exist in cationic, anionic, or zwitterionic form depending on pH. The pH ranges, in which the various ionizable groups of unsubstituted folates are predominantly (>50%) charged, are displayed in Figure 2.[37−41] Ionogenic groups of particular significance in the pH values relevant to foods and biological systems are the N^5 position of H_4folate (basic pK_a = 4.8) and the glutamate carboxyl groups (acidic α pK_a = 3.5; γ pK_a = 4.8). Folates undergo changes in ionic forms as a function of pH, which in part explains the pH dependency of folate solubility and the stability and behavior during chromatographic separation.[9,38−41]

Folates generally have minimum solubility in the mildly acidic pH range (e.g., pH 2−4), monocationic and neutral species predominating, whereas solubility generally increases in proportion to the pH above this range, mainly zwitterionic and anionic species. The solubility of folates in aqueous solutions is low due to the pteridine part. An increase in temperature and

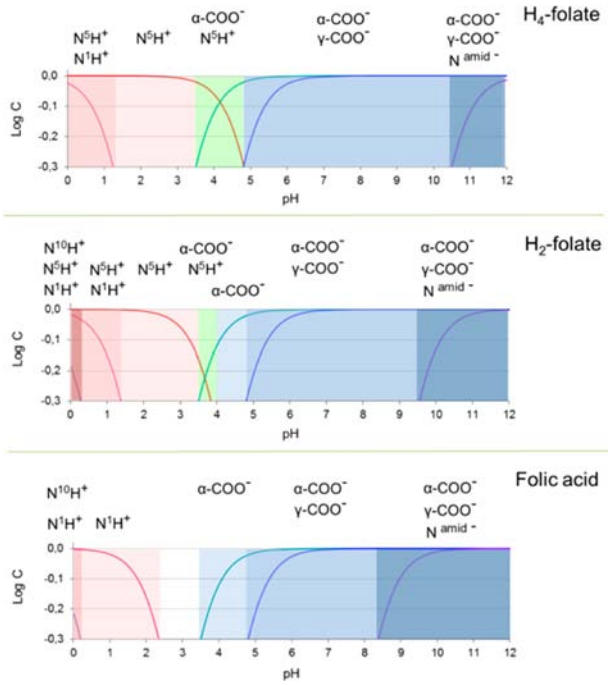

Figure 2. Ionized groups present in unsubstituted folates at different pH ranges and their pK_a values. pH ranges where they are predominantly charged, 50% or more, are displayed by color. pK_a values for each group are displayed where their log C curves cross the x-axis. For pK_a values displayed in a table, see Patring et al.[37]

the presence of ions from buffers or salts increase the solubility.[9,35,36]

UV light, air, and heating destroy the molecules by oxidation if not protected by antioxidants.[41] Early works show that the effect of pH on the stability of reduced unsubstituted folates is U-shaped with the highest stability observed between pH 1−2 and 8−12, whereas the stability is lowest between pH 4 and 6.[9,41−43] However, even at these favorable pH intervals, H_4folate and H_2folate are extremely unstable with half-lives of losses in bioactivity below 5 h.[9] Folic acid, the oxidized form, is much more stable than reduced unsubstituted folates. Its stability also depends on pH and it is stable under neutral and alkaline conditions, but less stable in acidic conditions (pH <5).[44−48] All three unsubstituted folates are sensitive to UV light. For more details on the stability of the unsubstituted folates, see Table 2.[36,43,46−54]

DEGRADATION BY AUTOXIDATION

All unsubstituted folates undergoing autoxidation are split in their C^9−N^{10} bond into biologically inactive products. Figure 3 gives an overview of the pathways and the major autoxidation products identified in the oxidation carried out in the presence of UV light, air, or oxygen *and in the absence of antioxidants*.[7,15,45,55,56] The major products are pABG and various substituted pterins, ultimately converted into pterins under release of formaldehyde. Classical work has shown that the oxidative degradation of solutions of H_4folate first produces a quinonoid isomer of H_2folate as intermediate. At acidic pH, this quinonoid is oxidized to pABG and 7,8-dihydropterin under release of formaldehyde. This dihydropterin is then further oxidized to pterins. At alkaline conditions, the quinonoid-H_2folate is converted to H_2folate, which is further oxidized to pABG and 6-formyltetrapterin, followed by the

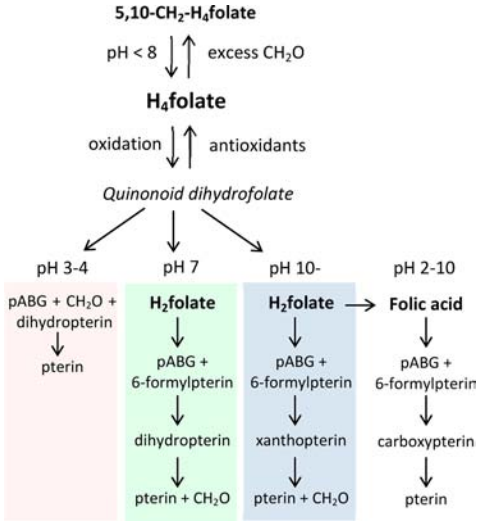

Figure 3. Pathways for interconversion between H_4folate and 5,10-CH_2-H_4folate and degradation of unsubstituted folates exposed to air at ambient temperature;[15,55,56] degradation of folic acid in the presence of light or UV irradiation.[44−46,48]

formation of xanthopterin and formaldehyde.[15,55,56]Irradiation of folic acid with UV light first produces pABG and pterine-6-carboxyaldehyde, which is converted to 6-carboxylic acid and finally to the decarboxylated 2-amino-4-hydroxypteridine.[45−48]

MECHANISMS OF AUTOXIDATION

The pH-dependent oxidation, affecting the rates and type of products, has drawn attention to the role of ionization and protonation of the zwitterion folate/folic acid as a mechanism.[15,38] Akhtar and co-workers studied the effect of pH in the pH range 2−10 on photodecomposition of folic acid.[46,47] According to their results folic acid exhibited best stability at highly alkaline pH 10.0, whereas its stability was lowest and susceptibility to photolysis was highest in the acidic range (pH 2−4). This clearly showed that photolysis of folic acid is a pH-dependent reaction and occurs more rapidly at low pH when folic acid exists predominantly as a neutral species. More recently, Martin et al. proposed a mechanism of photolysis of folic acid where UV radiation at 350−400 nm caused formation of pterin radicals, which were then oxidized to the known photoproduct 6-carboxypterin.[57]

According to early studies, steric hindrance is another phenomenon affecting the oxidative sensitivity of unsubstituted folates. H_4folates with substituents at the N^5 position, that is, 5-CH_3-H_4folate and 5-HCO-H_4folate, exhibit much higher stability than unsubstituted H_4folate. This suggests that the stabilization effect of the N^5 methyl group or the N^5 formyl group is, at least in part, due to steric hindrance in restricting the access of oxygen or other oxidants to the pteridine ring. The stabilizing effect of the substituent is presumably due to the effect of the one-carbon substituent in interfering with the formation of resonance forms involved in oxidative degradation.[15,55]

DEGRADATION PRODUCTS IN THE PRESENCE OF ANTIOXIDANTS

In the presence of antioxidants and while protected against UV light, the unsubstituted folates are protected against oxidation. Depending on the combination and concentration of antioxidants, pH, time, and temperature, the oxidation of H_4folates is either fully or partly prevented. Antioxidants decrease the rate of oxidative degradation, making it possible to detect even early biologically active oxidation products of H_4folate, such as H_2folate and folic acid. Hence, a mixture of these forms appears together with pABG and various pterins in foods during processing, cooking, storage, or analytical conditions (see Figure 3).[13,14,58]

Thiols, for example, 2-mercaptoethanol (MCE) and 2,3-dimercaptopropanol (BAL), were the first antioxidants to be shown to retard the oxidation of H_4folate.[59,60] In a classical work, Blakley[60] found BAL to be a better antioxidant than MCE. Later, the combination of thiols with ascorbate was found to be the most effective in protecting H_4folate. Wilson and Horne[58] were the first group to combine the use of ascorbate and MCE as antioxidants during food folate analysis. Today, combinations of 1−2% ascorbate with MCE or BAL are commonly used to stabilize H_4folate during determination by HPLC.

Although MCE is the most commonly used and inexpensive thiol in combination with ascorbic acid/ascorbate to protect H_4folate during food analysis, it is less effective and more toxic than other thiols such as BAL, 1,4-dithiothreitol (DTT), or 2-thiobarbituric acid (TBA).[22,61] Patring et al.[61] compared the combination of ascorbate (2%) and four different antioxidants (MCE, DTT, BAL, and TBA), all at 0.1%, on the stability of H_4folate solutions boiled for 1 h. BAL, DTT, and TBA were all capable of protecting >96% of H_4folate in three different buffers varying between pH 5.1 and 7.85. DTT was the most effective antioxidant in acetate buffer (pH 5), DTT and BAL were the most effective in phosphate buffer (pH 6.1), and BAL and TBA were the most effective in HEPES/CHES buffer, pH 7.85, whereas MCE was the least effective in all buffers compared to the other thiols (degradation range 7−12%). Recently, De Brouwer and co-workers found DTT in concentration of 0.5% to be as efficient as BAL when using phosphate buffer pH 7.2.[22] Thereby, these three antioxidants (BAL, DTT, and TBA) should be considered as more efficient and environmentally friendly substitutes for MCE in modern analytical methods for folate analysis, including AOAC methods.

H_4folate is easier to stabilize by proper combination of antioxidants than H_2folate because the initial/primary oxidation product of H_4folate is quinonoid-H_2folate, which can be reduced back to H_4folate by antioxidants.[35] This step is the only one that could be reversible in the oxidation chain of H_4folate, which means that once H_2folate has been formed, it is further oxidized to folic acid or to degradation products such as pABG and pterins (see Figure 3). Several studies have reported between 12 and 30% of folic acid formation from H_2folate under analytic conditions in the pH range 2.6−7.4.[13,14,58,62] As mentioned in a previous section (Occurrence in Food), H_2folate is usually not analyzed in foods due to its high instability. H_2folate seems to require much higher concentrations of antioxidants than H_4folate to be protected.[42,63]

MECHANISM OF ANTIOXIDANT PROTECTION AGAINST OXIDATION

Reducing agents such as ascorbic acids and thiols exert multiple protective effects on folates through their action as oxygen scavenger, reducing agent, and free radical scavenger. The degradation of unsubstituted folates via a free radical mechanism has been proposed by several groups.[15,55,56,64] Thomas et al.[48] suggested that singlet oxygen, probably

Table 2. Stability of Unsubstituted Folate According to the Literature

Folic Acid
At 20 °C and 65% relative humidity, solid folic acid has a decomposition rate of 1% per year.[54]
Extensive degradation of solutions of folic acid at room temperature is induced by sunlight, UV, or visible light. This photolysis increases in rate at pH <5.[46,47]
Solutions of folic acid are stable for up to 10 h at 100 °C in the pH range 5−12, light-protected and without antioxidants, but the stability decreases at pH values <5.[43]
H_2folate
H_2folate in powder is stable for up to 1 year if stored at −20 °C in oxygen-free sealed tubes.[36]
The extent of degradation of a stock solution of H_2folate in Tris buffer, at pH 7.3, containing 0.3 M MCE and stored at 0 °C, is only 2.3% in 10 h.[50]
H_2folate is oxidized 40 times faster at pH 4 than at pH 7. At pH 9.5, H_2folate appears to be relatively stable.[49]
Although H_2folate is relatively unstable at pH 4.0−7.0, addition of thiols and ascorbic acid appears to retard oxidation. MCE in concentration 5−10 mM is sufficient to prevent decomposition of H_2folate solutions.[50]
H_4folate
H_4folate is relatively stable dry in ampules at −20 °C[51]
The rate of degradation of an unprotected solution of H_4folate increases 5-fold from 0 °C to room temperature. Increasing the temperature from 23 to 37 °C increases the rate of decomposition another 5-fold.[51]
H_4folate in phosphate buffer (pH 7.5) loses half its activity in 40 min at 23 °C. MCE at a concentration of 0.01 M or bubbling with N_2 gas protects H_4folate for >90 min.[52]
H_4folate is stable in anaerobic conditions at room temperature.[36]
Aqueous solutions of H_4folate stored at room temperature undergo 90% degradation in 4 h, the lability being influenced by pH and the buffer.[42]
Aqueous solutions of H_4folate are rapidly degraded. After 5 min at room temperature, a 1 mM (6*R*,*S*)-H_4folate-3HCl solution is degraded by >10% in the presence of air. After 45 min, it is degraded by about 25%. Solutions should be made as concentrated as possible, in oxygen-free water, with lowest possible pH, and used immediately.[51]
At 100 °C, solutions of H_4folate have a half-life of 2.25 min.[53]

produced by electronically excited states of folic acid molecule, is the oxidant agent that starts the degradation reaction. Further support for free radical mechanisms is the finding that riboflavin (vitamin B_2) sensitizes the photodegradation of folic acid, leading to the deactivation of the vitamin.[45,47] In addition, transition metal ions such as Fe^{3+} or Cu^{2+}, recognized for their involvement in free radical mechanisms, have been found to catalyze the oxidation of H_4folate.[55]

INTERCONVERSIONS BETWEEN H_4FOLATE AND 5,10-METHYLENE-H_4FOLATE

H_4folate rapidly and reversibly condensates with formaldehyde (in ∼30-fold excess) in aqueous solutions at room temperature, forming 5,10-methylenetetrahydrofolate (5,10-CH_2-H_4folate (see Figure 3).[35,65] This is an example of interconversion reaction because it includes a reversible conversion between two bioactive folate vitamers. The N^5−N^{10}-bridged compound is found to be more stable against chemical oxidation than H_4folate, but its stability depends on an excess of formaldehyde.[11,35,65] Without excess of formaldehyde, the stability of 5,10-CH_2-H_4folate is strongly pH dependent; 5,10-CH_2-H_4folate appears to be completely stable at pH 9.5 or above, in either the presence or absence of antioxidants. As soon as the pH decreases to neutral pH, 5,10-CH_2-H_4folate dissociates rapidly, within 15 min, back to H_4folate and formaldehyde, and heating enhances the rate of the dissociation.[65,66]

5,10-CH_2-H_4folate is one of the C1 derivatives of H_4folate used for enzymatic methylation of uridinylate to thymidinylate, a key step for DNA synthesis. Hence 5,10-CH_2-H_4folate is a native folate form that could be present in intact living cells. Because 5,10-CH_2-H_4folate requires either alkaline pH (>8) or an excess of formaldehyde to remain stable, this form is not likely to occur in foods because the pH of food is generally neutral or slightly acidic. Hence, 5,10-CH_2-H_4folate most probably converts to H_4folate or its degradation products in food samples or both.

There is only one recorded condition in food analysis when formaldehyde can be formed in excess with potential to interconvert H_4folate into 5,10-CH_2-H_4folate. When Wilson and Horne[14] boiled aqueous solutions of H_4folate for 10 min in a buffer (pH 7.8) containing 2% sodium ascorbate, 5,10-CH_2-H_4folate was formed in a yield of 25%. The authors were able to show that heating of ascorbate led to its thermal degradation followed by the formation of formaldehyde, which converted H_4folate into 5,10-CH_2-H_4folate. This conversion did not occur *without heating*; neither did formation of formaldehyde. More recently, this interconversion was confirmed by de Brouwer et al. using HPLC and MS detection.[62] This emphasizes the need to combine thiols and ascorbate during heat extraction, which is also common practice today in folate determination. The inhibitory effect of adding thiols is a formation of hemithioacetal with formaldehyde, thereby preventing the reaction between formaldehyde and H_4folate.[58,66,67]

STABILITY OF UNSUBSTITUTED FOLATE IN THE FOOD CHAIN

Because H_4folate is the most vulnerable folate form, one could expect high losses of H_4folate in the food chain, especially after heat treatment such as thermal processing or cooking. Hence, the richest dietary sources of H_4folate should occur in raw foods with intact cell structure, where it may be bound and stabilized by proteins. A folate binding protein (FBP) is present in milk. By adding FBP to labile folate forms in model systems, H_4folate has been shown to become significantly stabilized.[68]

As soon as the cell integrity is compromised by freezing and thawing, mechanical stress, or thermal processing, H_4folate starts to oxidize unless protected by native antioxidants such as ascorbic acid or being bound to proteins and other cell constituents. Note that iron and copper ions leaking from process equipment or process water are pro-oxidative.[41]

Baker's yeast, in compressed or dried form, still contains viable cells and is therefore an example of a food ingredient with intact cell structure. It contains about 25% of its total

DOI: 10.1021/jf504987n
J. Agric. Food Chem. 2015, 63, 2367−2377

folate as H_4folate (Table 1). When dry baker's yeast was stored in room temperature during 45 days, H_4folate was stable. In contrast, compressed baker's yeast stored in a refrigerator (5 °C) lost 40% of H_4folate after 17 days. Drying of yeast reduced the content of H_4folate because the content of H_4folate was considerably higher in compressed baker's yeast prior to storage, but these differences reduced progressively with storage time.[28]

Cereal fractions contain about 10% of its folate as H_4folate. During breadmaking, yeast and fermentation could add further H_4folate. However, several studies indicate undetectable levels of H_4folate in bread; instead they often report the occurrence of folic acid, ranging from a few percent to 50% of total folate.[25,69,70] The breads in these studies were not made from folic acid fortified flours. Hence, the folic acid most probably originates from oxidation of unsubstituted reduced folates as well as from 5,10-CH_2-H_4folate during fermentation and oven baking.

Green vegetables are mostly blanched and frozen before being cooked and served. Their content of ascorbate and possibly other antioxidants could protect the H_4folate from being oxidized, but losses by leakage could occur. In one study by Stea and co-workers broccoli and green peas were investigated after different thermal processes.[71] Blanching did not reduce H_4folate, but, in general, these vegetables retained only up to half of their H_4folate after other thermal treatments, for example, steam cooking, microwaving, boiling, and reheating. In a recent study on the effects of industrial processing on folate content in green vegetables, Delchier et al. found leakage to be a major cause behind folate losses.[72]

Some losses of dietary folates by leakage and/or degradation seem inevitable in the food chain.[71,72] Therefore, it is of utmost importance to avoid further degradation and conversions of unsubstituted folates during the analytical procedure as outlined in the following section.

STABILIZATION DURING DIFFERENT STEPS OF THE ANALYTICAL PROCEDURE

Analytical techniques used to determine folate content are biological, such as microbiological and competitive-binding methods, or chemical, such as HPLC methods.[9,12,18,73] The microbiological assay (MA) utilizes the nutritional requirement of a microorganism (*Lactobacillus rhamnosus*), which exhibited high response to all bioactive folate forms in monoglutamic or diglutamic forms including biologically active interconversion products. Hence, MA gives the sum of all bioactive forms, that is, total folate.[9] There are standard methods assessed in collaborative studies established for microbiological assays, for fortified infant formula, for cereals, and for foodstuffs.[74−76] A disadvantage of the MA is the overall time needed for analysis, almost 2 days, during which the samples are kept at 37 °C, which emphasizes the need for optimal protection by antioxidants.

The competitive binding assay, using a folate-binding protein and a radiolabeled folate to compete with the folate to be determined, also gives total folate content. The Biacore method, certified by AOAC for folic acid determinations, uses a folate binding protein isolated from bovine milk and measures the amount of vitamin with plasma surface resonance technique.[77] However, the folate-binding protein does not have the same affinity to the various folate forms.[78,79] Therefore, these methods are appropriate only if it is possible to calibrate against the same form of folate as the one present in the sample, such as folic acid in fortified foods. They are less useful for food analysis with more complex matrices and several combinations of folate forms.

However, if the focus of interest is on the individual folate forms, chromatographic methods such as HPLC, UHPLC, or LC-MS, which separate and detect the different forms on the basis of their chemical properties, have to be used. Figure 4 gives a schematic overview of the analytical methods for folate determination in foods. All methods include the following steps: extraction, deconjugation, cleanup by filtration and centrifugation, and detection/quantification.[80] The chromatographic methods often include additional cleanup by affinity chromatography or solid phase extraction (SPE). It is beyond the scope of this paper to go into all analytical details about chromatography-based methods for determination of food folates. Instead, we refer to recent reviews.[12,18,30,62,73,81−83]

To obtain reliable analytical results, the stabilization of unsubstituted folates, especially H_4folate, is of great importance. In Table 3 we summarize the most crucial factors in the stabilization of unsubstituted folates during analytical procedure. As seen from Table 3, it is possible to efficiently stabilize unsubstituted folates by using the following protection strategies:

- protection from UV light, oxygen, and catalysts of free radical reactions such as iron and copper ions throughout the analytical procedure;
- avoidance of repeated freeze−thaw cycles of food samples, food extracts, and stock solutions;
- choice of lower temperature and shorter time for each analytical step everywhere it does not compromise the yield of folates;
- use of combination of two antioxidants, ascorbic acid/ascorbate and a thiol (BAL, DTT, or TBA).

Sampling, Storage, and Homogenization. To obtain reliable analytical results, good laboratory practice of sampling and storage of food samples is important, by protecting them from UV light, air, and high temperatures. Storage should preferably be carried out at −80 °C. Once the samples are homogenized, they should be dissolved in buffers of neutral pH containing two antioxidants, usually 1−2% ascorbic acid/ascorbate and a thiol to protect H_4folate from oxidative degradation.[58−61] Further storage after homogenization should be avoided because repeated freezing and thawing results in the degradation of H_4folate.[61]

Extraction and Deconjugation. Three major procedures are used to extract folate from the food matrix: heat treatment, enzymatic extraction, or a combination of heat and enzymatic treatments. Most studies use neutral pH during extraction and other enzyme treatments. Heat treatment is usually done by boiling in a water bath (100 °C for 10 min)[73,81] or heating (75 °C for 1 h),[80,85] when using HPLC methods, or by autoclave (120 °C/15 min), when applying MA.[74−76] The enzymatic extraction is commonly performed at 37 °C for 1−4 h by adding protease and/or amylase to the sample and terminating each enzyme treatment by boiling (5 min).[73,81] The combination of two antioxidants, ascorbic acid and thiol, is crucial during sample extraction to protect the labile H_4folate from oxidative degradation as well as to prevent interconversion of H_4folate into 5,10-CH_2-H_4folate caused by formaldehyde formed from ascorbic acid when heated.[14] Three thiols, BAL, TBA, and DTT, have been shown to be highly efficient for these purposes, whereas the most commonly used, MCE,

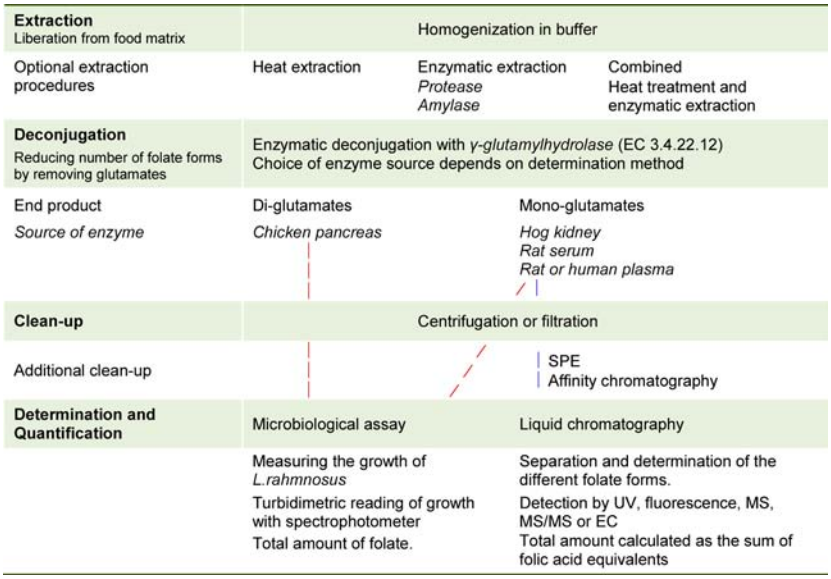

Figure 4. Schematic overview of analytical methods for folate determination in foods modified from refs 12, 18, 78, and 81.

appeared to be the least efficient.[61] Besides efficiency, the toxicity and environmental risks should also be considered when choosing thiol to stabilize H_4folate. From this point of view, the nontoxic TBA is the best choice followed by low-toxic DTT and BAL.[22,61]

To limit the amount of forms for determination, mono- or diglutamates are achieved by enzymatic deconjugation of the glutamate residues. Choice of conjugase (γ-glutamyl hydrolase) source depends on the method of determination used. For HPLC it is necessary to use a conjugase source, usually rat plasma, human plasma, or hog kidney conjugase with monoglutamates as the end product, whereas the bacteria in the MA can use the diglutamates produced by chicken pancreas as well.[86] The duration of deconjugation procedure usually varies from 2 to 3 h to overnight incubation at 37 °C, followed by inactivation by 5 min of boiling.[81] In addition to the mammal-based conjugase sources hitherto used, Diaz de la Garza's group recently evaluated two recombinant γ-glutamyl hydrolases from *Arabidopsis thaliana*.[87] These enzymes were far more efficient in hydrolyzing folate polyglutamates in plant food samples compared with rat plasma; in fact, the deconjugation time could be shortened to 0.5−1 h. Moreover, the recombinants also seemed to be less sensitive toward conjugase inhibitors present in certain plant extracts.[87] The repeated heating and relatively long time of incubation during deconjugation (overnight incubation is most common for MA) emphasize the need to optimize the antioxidative protection of H_4folate, as mentioned above for the extraction enzymes. Moreover, blanks need to be included for all enzymes added in the assay to subtract their endogenous folate content.

Storage of food extracts after heating and deconjugation should be avoided. Tamura and co-workers showed that storage at −70 °C for a few months caused considerable degradation of H_4folate (~60%) in food extracts.[88] Patring and co-workers also observed losses of native H_4folate in yeast extract stored at −22 °C for 4 weeks.[61] With 2% sodium ascorbate and 0.1% MCE the losses amounted to 53%, whereas the replacement of MCE with BAL reduced losses to only 19%. De Brouwer and co-workers reported stabilities of 63.7−77.7% for native H_4folate in rice extract stored at 4 °C for 36 h, whereas the stability was >95% when stored at −20 or −80 °C with one freeze−thaw cycle.[22,31] Van Daele and co-workers used 1% ascorbic acid and 0.5% DTT for stabilization of folates in standard solutions and potato extracts. They reported stability >90% for H_4folate solution when stored at 4 °C for 24 h in the autosampler or at −20 °C with three freeze−thaw cycles.[89]

Cleanup by SPE or Affinity Chromatography. Chromatographic methods are more sensitive to interfering substances and have higher demands on sample cleanup than MA. SPE can be used both to remove interfering substances and to concentrate the analyte. Affinity chromatography cleanup using folate-binding protein applied on columns can be used to increase sensitivity. However, different affinities to the various folate forms may easily lead to considerable losses of folate forms with low affinity.[18]

Folates are eluted by acidic buffers, and affinity chromatography causes the most pronounced acidification by operating close to pH 2 during the 10−20 min the elution takes. SPE-based cleanup procedures using strong-anion exchange (SAX) cartridges elute the folates by sodium acetate solution containing sodium chloride salt (5 or 10%) and ascorbic acid (1%), which keeps the pH close to 5. However, it is still important to use antioxidants in optimal amounts and UV light protection to prevent oxidation and degradation of reduced unsubstituted folates, especially if the samples are stored in a refrigerator or autosampler overnight until subjected into HPLC. For instance, Kirsch and co-workers[13] studied the stability of individual folate standards stored at 4 °C during 24 h in buffers of different pH values (2.6, 3.4, and 7.0) containing 0.1% ascorbic acid. The main interconversion products were presented for each folate form based on UHPLC-MS/MS analysis. H_4folate showed minor interconversion (<5%) into H_2folate and folic acid, whereas H_2folate showed degradation at acidic conditions and interconversion (12.7−16.7%) to folic acid.

Chromatographic Separation by HPLC and UHPLC. No antioxidants are present in the mobile phase during chromatographic separation, which makes folates unprotected against oxidation. Moreover, column temperatures might vary between 20 and 35 °C in HPLC[28,30] and 60 °C in UHPLC.[34,89] The extent to which acid-catalyzed oxidations of unsubstituted folates occur at this stage of analysis has received little attention

Table 3. Crucial Factors in the Stabilization of Unsubstituted Folates during All Steps of the Analytical Procedure[a]

factor	analytical steps	protection strategies
presence of oxygen	all	degass with nitrogen or argon
UV light	all	protect from UV light, e.g., by using yellow filter on lamps or yellow lamps
freeze–thaw cycle	storage of food samples	avoid multiple freeze–thaw cycles, no more than one
	storage of food *extracts* prior to analysis	avoid freeze–thaw step, use storage at 4 °C instead
presence of impurities	all	use reagents of high purity, avoid presence of pro-oxidative catalysts, e.g., copper and iron ions
		check the purity of folate standards and correct concentrations of stock solutions for purity[84]
temperature	storage of food *samples* prior sample pretreatment	as low a temperature as possible, −80 °C[22,34,88]
	storage of stock solutions	−80 °C
	extraction by heat treatment	as low a temperature as possible, e.g., 75 °C instead of 100 °C[61,85]
	storage of food *extracts* prior to analysis	4–6 °C
	separation on HPLC column	avoid using elevated column temperatures if possible[61,90]
	detection by UV followed by fluorescence	use UV-DAD detector with efficient cooling system
time	storage of samples and extracts	as short as possible
	extraction by heat treatment and/or enzymes	as short as possible
	deconjugation	as short as possible, avoid overnight incubation
	separation on the HPLC column	shorter retention times are preferable
oxidation	preparation of stock and working solutions, extraction and elution buffer.	use a combination of two antioxidants, ascorbic acid/ascorbate and TBA, for MA or ascorbic acid/ascorbate and BAL or DTT for HPLC methods
	all steps of sample pretreatment	make fresh working solutions on daily basis

[a]Only H_4folate and folic acid are considered, because there are no studies presenting data on H_2folate or the conversion product 5,10-CH_2-H_4folate in foods due obviously to their lack of stability as already discussed in the sections above.

over the years. Strandler and co-workers found a concentration-dependent stability of H_4folate under these conditions, pH around 3 and a temperature of 35 °C.[90] At a concentration of 5 μg/mL the losses of H_4folate were 20% after 30 min, whereas at a lower concentration of 0.5 μg/mL H_4folate was degraded completely after 10 min.[90] Usually the concentrations of H_4folate in injected standard and food extracts are in the range of 1–50 ng/mL, that is, much lower than those studied by Strandler and co-workers (for references, see Table 1). This indicates a considerable risk for losses of H_4folate during the passage of the chromatographic column, which can lead to deviations from linearity in the lower region of calibration curve and false-negative results for H_4folate. Therefore, special consideration should be given to the on-column stability of H_4folate in the development and optimization of new HPLC or UHPLC methods to determine folates in view of the concentration-dependent stability of H_4folate. Shorter retention time and lower column temperature are preferable to improve the on-column stability of H_4folate.

HPLC or UHPLC with Different Detectors. When using HPLC, the choice of calibrants becomes more crucial because only the forms that are used as calibrants can be identified in the sample. Due to interconversion and stability problems, there are limitations to which folate forms can be found in food extracts, and this has been reviewed in previous sections of this review. Determination can be made by using UV, fluorescence, MS, or electrochemical detection.[12,73,81,82] The reduced folates have native fluorescence of different intensities and wavelength maxima.[91] Folic acid does not fluorescence and is better determined with UV detection.[81] This means that a combination of UV and fluorescence detection at different excitation/emission wavelengths is necessary to quantify all folate forms. When using both detectors connected in sequence (UV detector followed by fluorescence detector), special attention should be paid to the stability of H_4folate during the passage of UV detector flow cell because of the high risk for degradation of H_4folate due to UV light and increased temperature in the flow cell. The stability check can be performed by comparing the fluorescence response for H_4folate with and without UV detector connected before the fluorescence detector. If the fluorescence response for H_4folate is lower without the UV detector, this indicates that there are losses of H_4folate in the UV detector flow cell. In such a case it is preferable to use split and connect detectors in parallel.

Higher specificity is achieved by using mass spectrometric detectors. Analytes are ionized, giving a specific mass to charge pattern, and folates can be determined in both positive and negative modes.[28] Quantification is usually performed with external calibration in HPLC methods when using UV and fluorescence detection. In methods with mass spectrometric detection the use of stable isotopes as internal standards, such as deuterium-labeled ($^2H_4$)[31]or ^{13}C-labeled ($^{13}C_5$) isotopes of folates,[22,89] can considerably improve the relative recovery, but it cannot affect the absolute recovery.[92] Although the *relative recovery* of H_4folate is about 100%, the *absolute recovery* may be much lower, about 37–70%,[22,30,33,34,89] which may lead to negative false results for H_4folate if concentrations in food samples are close to the limit of quantification. Moreover, the use of internal standards or external standards will not correct for oxidations or conversions into other bioactive folate forms during analysis, as recently discussed by Ringling and Rychlik,[30] for instance, when native 5,10-CH_2-H_4folate dissociates to

DOI: 10.1021/jf504987n
J. Agric. Food Chem. 2015, 63, 2367–2377

H_4folate and H_4folate is oxidized to H_2folate and folic acid. Hence, conversions and oxidations may cause some overestimations of H_4folate and folic acid because the changes are not exactly the same in the food matrix as in the standards.

It is important to consider that the bioactive unsubstituted folates analyzed in foods, H_4folate and folic acid, reflect the sum of oxidative and interconversion changes of H_4folate, H_2folate, and 5,10-CH_2H_4folate originally present in the intact cells of vegetable, animal, or microbiological origin such as yeast and LAB. In addition, folic acid in foods either depends on the oxidation of H_4folate or H_2folate or is a consequence of supplementation/fortification or both. Analysts monitoring folic acid content in fortified foods need to consider that parts of the analyzed folic acid could be due to oxidation of unsubstituted reduced folates or conversion from 5,10-CH_2-H_4folate to H_4folate and its further oxidation. Also worth mentioning is that the relatively stable folic acid in fortified foods might be underestimated due to photodecomposition if not protected from UV light during sample pretreatment. When it comes to UV light sensitivity, both oxidized and reduced folates are sensitive to degradation.

Table 1. Stages of Development of Tomato Fruits Exposed for Different Number of Days to High Temperature (DHT)

stage of development	description	DHT[a]
1	flowering	44
2	diam[b] ≤ 30 mm	36
3	diam ≤ 40 mm	27
4	diam ≤ 50 mm	22
5	diam ≤ 60 mm	16
6	green fruit fully developed	6

[a]DHT are mean values for each treatment, with a maximum variability of ±3 days. [b]Diameter.

replicates per treatment were randomly collected, each one constituted by ten fruits. After the physical parameters had been determined, fruits belonging to the same sample were cut into small pieces (using the whole fruit), powdered with liquid N_2, and kept at −80 °C until subsequent analysis.

For the extraction of vitamin C, samples were homogenized with EDTA (St. Louis, MO, USA), 0.05% (w/v), and dithiothreitol (Sigma-Aldrich, Steinheim, Germany). Vitamin C, measured as the sum of ascorbic acid and dehydroascorbic acid, was analyzed using liquid chromatography equipped with a triple quadrupole mass spectrometer detector (Agilent Series 1200, Santa Clara, CA, USA) according to the methodology developed by Fenoll et al.[10] For accurate quantification of the samples, the standard addition approach was performed. Ascorbic acid standard was purchased from Sigma-Aldrich (Sigma-Aldrich, Steinheim, Germany) (purity >99%).

Carotenoids were extracted according to the method of Böhm[11] with methanol/tetrahydrofuran (1/1, v/v) containing 0.1% BHT (Sigma-Aldrich, St. Louis, MO, USA) and using β-apo-8′-carotenal (Sigma-Aldrich, St. Louis, MO, USA) as internal standard. Carotenoids were determined using a Hewlett-Packard model 1100 HPLC system (Waldbronn, Germany) equipped with a photodiode array UV/vis detector. Separation was achieved in a 250 mm × 4.6 mm i.d., 3 μm Prontosil C_{30} column (Bischoff, Leonberg, Germany) with methanol (solvent A) and methyl *tert*-butyl ether (solvent B) as mobile phase. All the solvents (HPLC grade) were supplied by Fisher Chemical (Loughborough, U.K.). The gradient procedure was as follows: (1) initial conditions 15% solvent B and 85% solvent A, (2) a 10 min linear gradient to 15% solvent B, (3) a 20 min linear gradient to 90% solvent B. Elution was performed at a solvent flow rate of 1.3 mL/min with an injection volume of 20 μL and detection at 287 nm for phytoene, 347 nm for phytofluene, and 444 nm for other carotenoids and internal standard. Carotenoids in the samples were identified by comparison of retention times and UV−vis absorptions with those of the corresponding standard or with those reported in the literature. In addition, *cis* isomers were identified based on their absorption at near 330 or 360 nm and by the *Q* ratio, defined as the height ratio of the *cis* peak to the main absorption peak, as previously reported in the literature. The major compounds were identified using commercially available external standards of carotenoids (DHI LAB, Hoersholm, Denmark), except for phytoene and phytofluene, which were expressed as β-carotene equivalents.

The results were statistically analyzed using IBM SPSS Statistic 21 by analysis of variance (ANOVA) and Tukey's test for differences between means.

RESULTS AND DISCUSSION

Fruit mean weight and equatorial and longitudinal diameter decreased as a result of the increased temperature (32 °C) (Table 2). These weight and size losses were proportional to the period of exposure to the stress, except in the case of fruits exposed to high temperature from flowering (stage 1), which showed fruit weights and sizes similar to those of the control fruits. The results obtained at this first stage could have been due to the higher incidence of flower abortion as a feedback controlling mechanism to prevent an excessive sink/source ratio.[12] The reproductive process has previously been shown to be more sensitive to high temperature stress than vegetative growth. In addition, even within the different development stages of a fruit, certain stages are more sensitive. Thus, high temperature stress increased the tendency for younger flowers to abort due to shrunken pollen grain, failure of anther dehiscence, and an irregularly arranged endothecium and epidermis.[13] Therefore, the higher incidence of flower abortion caused by high temperatures would only affect trusses in development stage 1 (truss 6), leading to an increase in the mean weight of the remaining fruits, and thus compensating the weight loss resulting from temperature stress. In addition, the increased total soluble content in fruit from the stage 1 treatment (Table 2) could be explained as a concentration effect due to a decreased sink/source ratio. No treatment effect was observed in the fruit water content.

The Hunter parameter related to red (a^*) decreased as a result of high temperature in fruits subjected to the stress from the fully developed green fruit stage (6 DHT). Similarly, in a previous study, the redness of tomato decreased when fruits were ripened off-vine at 32 °C, as a result of the inhibition of lycopene synthesis.[8] In our study, the negative effect of high temperature on the red color diminished as the period of exposure to the stress increased. Moreover, in fruits grown 36 and 44 days under high temperature, the value of a^* increased above that obtained in control fruits.

The analysis of metabolites in control fruits was initially carried out separately in individual trusses (from 3 to 6). However, no differences between trusses were observed in any

J. Agric. Food Chem. 2015, 63, 2378−2382

of the studied metabolites (carotenoids and vitamin C), and so the results of the control treatment are presented as the mean values for the different trusses. The fact that no differences were observed between trusses in control plants can be attributed to (i) fruits from different trusses were collected from different plants, and therefore no modification of the sink/source ratio was influenced by previous harvest before sampling, and (ii) in the growth chamber, where the photoperiod remained unaltered throughout the growing period, differences between trusses are are much less likely to occur than in natural conditions.

The effect of high temperature on vitamin C concentration depended on the duration and timing of the stress (Figure 1).

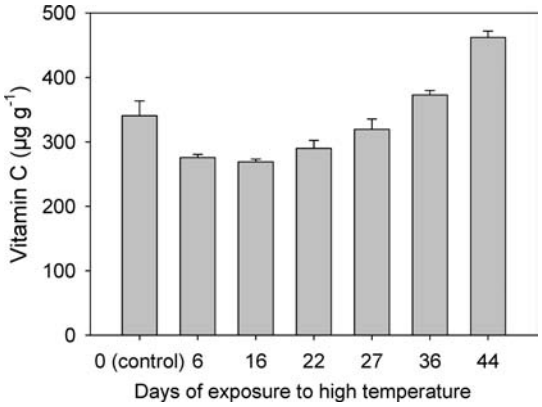

Figure 1. Vitamin C concentration in fruits exposed to temperature stress (32 °C) during increasing time periods. Bars are mean values ± SE (n = 6).

In fruits subjected to 32 °C from the advanced development stages (stage 6 and stage 5, equivalent to 6 and 16 DHT, respectively), vitamin C concentration decreased with regard to control fruits. The negative effect of high temperature on vitamin C decreased as the period of exposure to the stress increased. Thus, fruits grown at a high temperature for 36 days (from stage 4) showed a similar vitamin C content to control fruits. Moreover, increasing the exposure period up to 44 days led to an increase in the vitamin C concentration to above the values obtained in control fruits.

The stress caused by high temperatures leads to an alteration of the composition of the fruit through modifications at physiological, biochemical, and molecular levels. At plant level, the increased temperature changes the distribution of photoassimilates among plant organs, increasing biomass translocation to fruits at the expense of vegetative growth.[12] On the other hand, temperatures above the optimum values can directly alter metabolite synthesis/degradation processes. In particular, ascorbate accumulation is limited by high temperatures, which reduce ascorbate synthesis and/or favor ascorbate degradation through oxidation due to intensified ascorbate peroxidase and ascorbate oxidase activities and a depression of the enzyme dehydroascorbate reductase.[14]

The increase of vitamin C concentration observed after longer periods at high temperature suggests an adaptation of the plant metabolism to high temperature and/or a restoration of the ascorbate synthesis processes during the time intervals in which the temperature decreases along the photoperiod (night). Finally, the vitamin C content was higher in fruit exposed to a high temperature from flowering than in control fruits, probably due to a concentration effect as a result of a decreased sink/source ratio due to increased flower abortion. A concentration effect cannot be attributed to the lower fruit water content since no differences in this parameter were observed between treatments.

The carotenoids identified and quantified in the tomato samples by HPLC were phytoene, phytofluene, *all-trans*-lycopene, 13-*cis*-lycopene, 5-*cis*-lycopene, lutein, *all-trans*-γ-carotene, *all-trans*-β carotene, 9-*cis*-β-carotene, 13-*cis*-β-carotene, and violaxanthin (Figure 2). The increased temperature,

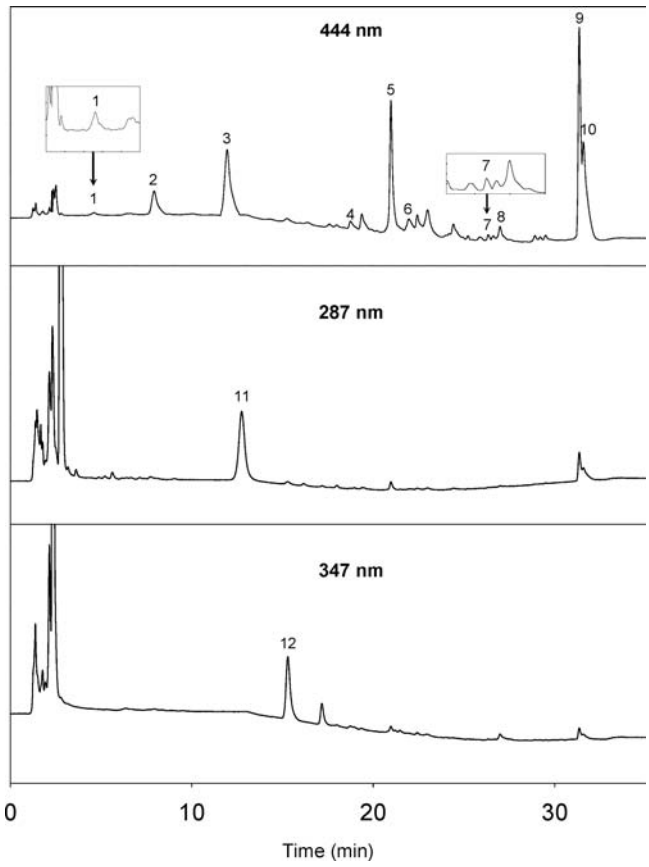

Figure 2. HPLC-DAD chromatogram of carotenoids in cv. Velasco recorded at 444, 287, and 347 nm. Peak identification: (1) violaxanthin, (2) lutein, (3) internal standard, (4) 13-*cis*-β-carotene, (5) *all-trans*-β-carotene, (6) 9-*cis*-β-carotene, (7) *all-trans*-γ-carotene, (8) 13-*cis*-lycopene, (9) *all-trans*-lycopene, (10) 5-*cis*-lycopene, (11) phytoene, and (12) phytofluene.

when imposed in the fully developed green fruit stage (stage 5), lowered the concentration of total lycopene (calculated as the sum of *all-trans*, 13-*cis*, and 5-*cis* lycopene isomers) in the mature fruit (Figure 3A). This decrease was accompanied by a decrease in the concentration of phytoene and phytofluene (precursors) and an increase in lutein (product) (Table 2 and Figure 4). At earlier stages, the inhibitory effect of temperature on the accumulation of lycopene and its precursors and the stimulatory effect on lutein decreased in proportion to the length of exposure to 32 °C. In the case of fruit subjected to high temperatures since flowering, the phytoene and lycopene concentrations reached higher levels than those observed in the control fruits. Unlike lycopene, the total β-carotene concentration (calculated as the sum of *all-trans*-, 9-*cis*-, and 13-*cis*-β-carotene isomers) was not affected by the temperature increase (Figure 3B). Furthermore, the concentrations of γ-carotene and

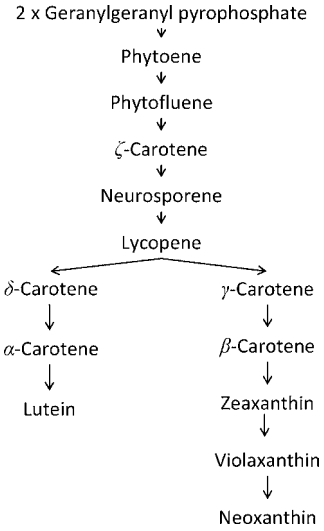

Figure 4. Summary of carotenoid biosynthesis.

violaxanthin decreased in proportion to the time of exposure to heat stress.

According Gautier et al.,[8] the enzyme phytoene synthase (PSY), responsible for the formation of phytoene from two molecules of geranylgeranyl diphosphate (GGPP), plays a key role in regulating the biosynthesis of carotenoids. PSY is inhibited by temperature increases, especially at the transcriptional level.[15,16] This inhibition could explain the observed decrease in the concentration of phytoene, phytofluene, and its product lycopene in fruits subjected to a high temperature for a short period (stage 5). Some authors suggest that the decrease in lycopene as a result of temperature increase may be due to a degradation of this compound toward the formation of β-carotene.[8] However, our results also suggest a degradation of lycopene toward the formation of lutein.

The feedback control mechanisms and metabolic channeling between each branch of the isoprenoid pathway play a key role in the final concentration of each compound.[17] Thus, the fact that the concentration of β-carotene was stable could be linked, on the one hand, to the increased degradation of lycopene and γ-carotene and, on the other, to the decreased catabolism of β-carotene into the formation of violaxanthin, which would also explain the observed decrease in the concentration of the latter compound.

An increasing time of exposure to temperature stress reduced the negative effect of temperature on the concentration of phytoene, phytofluene, lycopene, and lutein, suggesting, similarly to that observed in the case of vitamin C, an adaptation of the plant metabolism to high temperature and/or the restoration of carotenoid synthesis processes during the time intervals in which the temperature decreases along the photoperiod. The increase in the total carotenoid content observed in fruits from the stage 1 treatment (Table 3) could also be attributed to a concentration effect resulting from a lower sink/source ratio.

In addition to these metabolic changes in the isoprenoid biosynthesis route, temperature stress led to an increase in the concentration of the 13-*cis* isomer of β-carotene and lycopene. The formation of *cis* isomers from the *all-trans* form as a result of increased temperature has previously been described.[18] Different lycopene isomers were shown to have different stabilities (5-*cis* ≥ *all-trans* ≥ 9-*cis* ≥ 13-*cis* > 15-*cis* > 7-*cis* > 11-*cis*) due to their molecular energy.[19] Although the *cis* forms are more unstable, *cis*-lycopene isomers have been shown to be more bioavailable than *trans*-lycopene probably because of their shorter length and low tendency to form aggregates, which confers greater solubility.[20,21]

In conclusion, the effect of increased temperature on fruit development and on the concentrations of vitamin C and carotenoids depended closely on the development stage at which the stress was first imposed. In general, increased temperature negatively affected fruit weight and size propor-

tionally to the length of exposure. However, tomatoes subjected to the stress from the flowering stage showed similar weights and sizes to control fruits, due to a higher incidence of flower abortion and the subsequent weight increase in the remaining fruits. As regards nutritional quality, exposure to the increased temperature of 32 °C over a short period of time (beginning when fruit were in the last developing stages) caused a decrease of the concentration of vitamin C and lycopene but did not affect the β-carotene concentration. Changes in the concentrations of other carotenoids can be explained by possible metabolic channeling between the different isoprenoid biosynthetic pathway branches.

The negative effect of high temperature on vitamin C and lycopene diminished as the period of exposure to the stress increased, reaching values similar to those obtained in control fruits, or even higher if fruits were under temperature stress since flowering. These results show the ability of the tomato plants to adapt to temperature stress, being able to restore the concentrations of these metabolites after longer periods at high temperature. These results contribute to a better understanding of the effect of increased air temperature, as may be expected as a result of global warming, on the functional quality of tomato, allowing a more precise evaluation of temperature stress on the vitamin C and carotenoid concentrations of the fruit.

MATERIALS AND METHODS

Corn Cultivation, Experimental Design, and Sampling. Eight varieties were collected from the Canada−Saskatchewan Irrigation Diversification Centre, Agriculture and Agri-Food Canada (Outlook, SK, Canada; 51°30′ N, 107°03′ W). These varieties were Pioneer 2501 (P2501), Pioneer 39m26 (P39m26), Pioneer 7443 (P7443; Pioneer Hi-Bred International Inc., Johnston, IA, USA); Hyland 3083 (HL3083), Hyland Baxxos (HLBaxxos), Hyland R219 (HLR219), Hyland SR22 (HLSR22; Hyland Seeds, Blenheim, ON, Canada); and Silex BT (Pickseed Canada Inc., Nipawin, SK, Canada). This experiment was designed as a randomized complete block design. All of the varieties were arranged with four plots (blocks) with a total of 64 plots. The plot size was 6 m × 1.7 m with seeding rate of 600 kernels per plot on May 20, 2012. For the irrigated plots, irrigation was started at the end of July and ended in mid-September at 25 mm per week according to the practical standard. For the dry land plots, no irrigation was performed. The precipitation from seeding date to harvesting date was 192 mm. When the moisture content of corn forage of the entire plot reached 65−70%, the forage was ready for harvest. Harvests were carried out at the same time (September 28, 2012) with a kemper chopper (Champion 1200, Denmark) for all corn plots. Cutting height was set at 10 cm above the ground.

Agronomic Measurement. The numbers of corn plants in each plot, tassel initiation, and silk initiation were recorded during the experiment. On the harvesting day, the corn forages of the entire plot were chopped and weighed with a built-in scale in the chopper before unloading onto the ground. Approximately 500 g of fresh chopped plant from each plot was sealed in a plastic sample bag for the determination of DM according to AOAC Official Method 930.15.[18] In addition, chopped forage samples of around 1 kg for each treatment were collected, dried in a forced-air oven at 55 °C for 72 h, and ground through 1.0 mm screen (Retsch ZM-1; Brinkmann Instruments, Mississauga, ON, Canada) for further analyses.

Basic Chemical Profile with Near-Infrared Reflectance (NIR) Spectroscopy System. The air-dried forage samples were scanned using a NIR system (Foss InfraXact, Hilleroed, Denmark) at the University of Saskatchewan (SK, Canada) for measurements of DM, organic matter (OM), crude protein (CP), crude fiber (CF), and ether extract (EE) based on internal available calibration curves in the NIR system. Approximately 50 g of forage sample was used under the analysis model of plant (forage) material in NIR system. Spectra were collected in the visible (vis) and NIR regions in reflectance (ca. 1850−570 nm), within 60 s by a monochromator-based NIR system in triplicates. Both spectrophotometer operation and data acquisition were performed by ISIscan Software IS-2200 (FOSS Analytical, Hilleroed, Denmark).

Carbohydrate and Protein Molecular Structures by ATR-FT-MIR Spectroscopy. The spectral scans (within mid-IR region ca. 4000−800 cm^{-1}) of ground forage samples (0.5 mm) were performed using a JASCO FT/IR 4200 with ATR (JASCO Corp., Tokyo, Japan) at the University of Saskatchewan. In the present study, both protein- and carbohydrate-related molecular structures were revealed by 128 co-added scans at a resolution of 4 cm^{-1}. The parameters related to carbohydrate molecular structures included peak heights of total carbohydrate (CHO, peak baseline ca. 1198−800 cm^{-1}; three peaks fell into this region, named CHO first, second, and third peaks centered at 1154, 1103, and 1033 cm^{-1}, respectively), cellulosic compounds (CELC, peak baseline ca. 1290−1180 cm^{-1}) centered at 1240 cm^{-1}, and lignin (peak baseline ca. 1525−1490 cm^{-1}) centered at 1512 cm^{-1}. The protein spectral parameters involved protein amide I, amide II, and its secondary structures such as α-helix and β-sheet; all of the protein peaks were identified within the baseline ca. 1696−1488 cm^{-1} and the peaks centered at 1610, 1538, 1652, and 1629 cm^{-1}, respectively. More detailed information about peak identification can be found in previous publications.[19,20] Then the spectral analysis was carried out using OMNIC 7.2 software (Spectra Tech., Madison, WI, USA).

Principal Component Analysis (PCA). Multivariate spectral analyses−PCA was performed using Statistica 8.0 software (StatSoft Inc., Tulsa, OK, USA) within the NIR fingerprint spectra ca. 1850−570 nm on each corn variety to clarify whether there was any

molecular structural relationship between irrigated and nonwatered corn forages. The application of PCA in feedstuff molecular structure research has been described clearly by Yu,[21] which was also referred to in the current study.

Statistical Analysis. The treatment design was 8 × 2 factorial design with 8 corn forage varieties and 2 treatments (irrigation and nonirrigation). The experiment design was randomized complete block design (RCBD). The data of the agronomic measurements and basic chemical profile as well as carbohydrate and protein spectral data in corn forages were statistically analyzed using the Mixed Model procedure of SAS 9.2, and the model was

$$Y_{ijkl} = \mu + F_i + I_j + F_i \times I_j + B_k + e_{ijkl}$$

where Y_{ijkl} is the observation of the dependent variable *ijkl*; μ is the fixed effect of population mean of the variable; F_i is a fixed effect of corn forage variety (i = 8; P2501, P39m26, P7443, HL3085, HLBaxxos, HLR219, HLSR22, and Silex BT), I_j is a fixed effect of irrigation (j = 2; irrigation and dryland), $F_i \times I_j$ is a fixed effect of interaction between factor F at level i and factor I at level j; B_k is a random block effect; and e_{ijkl} is the random error associated with the observation *ijkl*.

The three assumptions of the RCBD were (1) residual errors are normally distributed; (2) there were common variances among the treatments; and (3) block effects are normally distributed. For normality tests, Proc Univariate of SAS with Normal Plot option was used. For the common variance, treatment ID against residue pattern was checked.

Multiple treatment comparisons were performed using the Tukey–Kramar test. Statistical significance was declared and detected at $P < 0.05$, whereas trends were declared at $P \leq 0.10$.

RESULTS AND DISCUSSION

Agronomic Characteristics. Table 1 shows the agronomic features of different varieties of corn forage response to irrigation. Forage plant number was significantly affected ($P < 0.05$) by the interaction of irrigation and variety. The number of HLSR22 plants grown with irrigation was at the highest level, whereas that of HL3085 (with or without irrigation) was at the lowest level. Most of our data fell into the optimum density range of 79,000−143,000 plants per hectare, which is considered to have maximum forage yields.[22,23] A significant difference (P = 0.0003) on DM content of corn forage was found between irrigation and no water use treatments. The plants grown with irrigation treatment had 4% more DM than those grown on dry land. Limited water supply in the growing stage leads to deficient water content in the soil, and this deficit strongly hinders nutrient uptake by the roots and delays physiological processes for the growth and development of plants.[24] Additionally, the drier soil may slow or even block rooting,[25] transpiration, photosynthetic rates, and nutrient transportation from roots to shoots.[26−28] A positive effect of irrigation on crop DM accumulation was also reported by numerous researchers previously.[11,26,29] Cultivar Pioneer had the greatest DM concentration with an average of 45.4%, followed by Hyland (39.5%) and Pickseed (37.5%). In regard to DM yield, it interacted ($P < 0.0001$) with irrigation regimen and corn variety. The DM yield of HLSR22 cultivated on irrigated land reached 20 tons (per hectare), which was at the highest level among treatments. Our result was in agreement with several studies[11,30,31] in which increased DM yield of forage was highly associated with higher level of irrigation. The timings of tassel initiation and silk initiation were also changed among corn varieties grown with and without water treatment. The interaction of irrigation and variety was significant, and the earliest tassel and silk initiations were found in P39m26 grown

in wetter plots, which were around 16 and 10 days prior to the latest one, HLSR22 cultivated on dry land. Such findings partially complied with previous results of NeSmith and Ritchie[32] and Abrecht and Carberry,[33] who reported that delays in crop phenology could be expected with severe water deficits.

Basic Chemical Profile Derived from NIR Spectral Analysis. The contents of OM, CP, CF, and EE in different varieties of corn forage grown with and without irrigation are shown in Table 2. Both growing conditions (irrigated or not; $P = 0.002$) and corn variety ($P = 0.001$) significantly affected OM content. Compared with corn grown on dry land, corn grown with water stress had 0.44% unit higher OM content, which partially corresponded to the recent result of Jahanzad et al.,[5] who found the ash content (=100 − OM) followed a declining trend as irrigation levels increased in two forage sorghum cultivars named Speedfeed and Pegah. Within three cultivars, Pioneer had a higher OM content than Hyland and Pickseed, and the latter two were similar to each other. Also, this result was not far from the observation reported by Abeysekara et al.[34] The concentration of CP plays an important role in forage quality and ruminant feed nutrition.[35] In the current research, the CP contents in different kinds of corn forage were strongly influenced by irrigation conditions ($P = 0.002$). A progressive rise in CP concentration was found in the corn forage grown on dry land. As for the effect of various irrigation regimens on CP accumulation in crops, previous studies showed inconsistent results. Some researchers reported an improved CP content in forage as water deficit intensified, which might result from nitrogen accumulation in drier soil,[7,36,37] the breakdown in plant protein molecules,[36] or the decrease in amino acids incorporated into protein,[38,39] which were also supported by our data. In contrast, certain increased levels of CP concentration in alfalfa were found in wetter cultivated spots.[40,41] Distinctively, Nielsen[11] found that the CP levels showed inconsistent variation from year to year (2001−2008) in soybean forages under four irrigation treatments.[11] The possible reasons for these controversial results might be partly associated with the precipitation conditions as well as nitrogen fertilizer supply as reviewed by Peyraud and Astigarraga.[42] Additionally, the CP concentrations varied ($P < 0.05$) among different cultivars. The averaged CP content of Pickseed was 10.5%, which was at the highest level, whereas that of Pioneer was at the lowest level (9.19%); an intermediate level (9.92%) was observed in the Hyland cultivar. The CP values in Pioneer and Hyland were much greater than those found in a very recent publication[34] in which these two cultivars had similar CP contents (averaged at 7.1% DM). This variation might be related to different growing years between two studies (2011 vs 2012) as discussed by Nielsen.[11] The variation might be also due to the analysis methods: NIR in this study versus wet chemical analysis. As for the carbohydrate composition like CF in the corn forages, there was a significant interaction between irrigation treatment and corn variety. Regardless of irrigated or dry plots, HLSR22 had the greatest the content of CF, whereas HLBaxxos grown on dry land had the lowest concentration. Compared with Hyland and Pickseed, which were similar to each other ($P = 0.36$), cultivar Pioneer had the lowest level of CF content. However, the average value for CF was only 12.1% DM, which was markedly lower than the value in the Dairy One Forage Database.[43] In this database, the ranges of CF content of crops accumulated from 2000 to 2013 are 18.3−23.7%. The possible reason for these inconsistent results might be related to the different growing conditions such as climate, fertilizer application, and water use or different biological stage of corn crops at harvesting time or different chemical analysis methods (NIR vs wet chemical analysis). Additionally, the EE content was highly affected by the interaction of corn variety and irrigation implementation. The average EE concentration in corn forages was 1.11% DM, and this value was slightly beyond the range of 1.4−1.8% DM reported by Abeysekara et al.,[34] who worked on the corn forages obtained from Pioneer and Hyland.

Spectral Characteristics of Corn Forage. Table 3 gives the carbohydrate and protein molecular structural characteristics for eight varieties of corn forage grown in both irrigated and dry plots. The CHO first peak (ca. 1154 cm^{-1}), second peak (ca. 1103 cm^{-1}), and third peak (ca. 1033 cm^{-1}) exhibited significant differences ($P < 0.05$) between corn forages cultivated on wet and dry lands. The CHO peak intensity of crops under irrigation treatment was approximately 1.1-fold that of the plants grown on dry land. No variation could be found among varieties or cultivars ($P > 0.05$). Irrigation treatment interacted with corn variety on mid-IR absorbance of cellulosic compounds (CELC), and the greatest and weakest intensities were observed on Silex BT grown with water stress (0.0082 IR unit) and HLBaxxos cultivated on dry plot (0.0061 IR unit), respectively. All of these chemical functional groups' spectral intensities are related to carbohydrate structure makeup. Our results indicated that irrigations implication and corn forage variety affected carbohydrate molecular structure makeup. The peak intensity of lignin was not altered by irrigation treatment ($P > 0.05$). Moreover, among three cultivars, Pickseed had the highest IR value on CELC and the lowest value on lignin, whereas Hyland displayed the opposite features and Pioneer was intermediate. There is no literature published on the effect of irrigation on spectral characteristics of corn forage, and therefore we did not have any data to compare with. However, our results indicated that carbohydrate structure makeup in corn variety differed and irrigation implication had a significant impact on carbohydrate structure makeup.

Studying the structure of proteins leads to an understanding of the components that make up a whole protein. An understanding of the structure of the whole protein is often vital to understanding its digestive behavior and nutritive quality. Protein secondary structures include mainly α-helix and β-sheet. The percentage of these two structures in protein secondary structures influences protein nutritive value because protein structure affects access to gastrointestinal digestive enzymes, which affect protein value. All of the protein spectral parameters were significantly influenced by both irrigation treatment and corn forage variety but without any interaction. The crops treated with water stress had 6.5−19.7% stronger peak intensities ($P < 0.05$) on protein amide I, amide II, α-helix, and β-sheet. These differences in FTIR spectral traits indicated that water use during growing period did influence structural conformations of corn forage, which might be highly related to nutritive values as shown in Table 2. Also, the protein structural features varied among corn varieties or cultivars. P3085 and HLR219 showed the highest amide I peak height, whereas P7443 exhibited the lowest peak height and the remaining five were in the middle. This might be one possible explanation of the variation in CP content (Table 2). If these eight varieties of corn forage were ranked on the basis of protein secondary structural profiles (α-helix and β-sheet), HL3085, HLR219, and HLSR22 showed the greatest values of α-helix; besides these

three varieties, P2501 and Silex BT were also at the greatest level for β-sheet intensity. Then, P39m26 exhibited the smallest peak intensity for both α-helix and β-sheet. Hyland had greater IR absorbance of amide I, α-helix, and β-sheet than Pioneer. Such results were not completely coincident with recent findings of Abeysekara et al.,[34] who reported that only protein amide II peak height significantly differed between Pioneer and Hyland. In fact, varieties P7443 and HLBaxxos were also used in their study. Even so, they displayed quite different profiles of protein structure. This interesting phenomenon might be attributed to different growing years between these two research studies (2011 vs 2012).

Peak height ratios of eight varieties of corn forage in irrigated and dry lands are presented in Table 4. Irrigation treatment and corn varieties interacted significantly to affect peak height ratios of CHO third peak to CELC, α-helix to β-sheet, and CHO third peak to amide I. Among different cultivars, the ratios of CHO third peak to lignin, CELC to lignin, and amide I to lignin as well as amide II to lignin showed a similar trend that Pickseed had much higher values ($P < 0.05$) than the other two cultivars ,which were not far from each other. Height ratio of amide I to amide II was remarkably modified ($P = 0.0002$) by irrigation treatment. Compared with the crops under water stress (1.42), corn forage on dry land had a smaller ratio value (1.39). These results implied that molecular structures in corn forages did not remain constant, and they could be altered by growing conditions such as irrigation implementation. Again, few studies were directed to the effect of different irrigation conditions on spectral ratio profiles of crops, so no results we can be referred to. However, as we discussed earlier, during the growing period, the plants need to take up nutrients and essential elements by ion transportation from soil to roots, from roots to stems, and from stems to leaves for their growth and development. Water is the best transmission medium for the whole process, so the soil water deficit could cause reduced transpiration, poor efficiency of nutrient transportation, and delayed cell elongation,[28,44,45] which might lead to a poor development of molecular conformation in the plants.

Additionally, although differences in peak intensity were statistically significant among treatments, the variation ranges were generally narrow. According to our knowledge, Fourier transform infrared (FTIR) spectroscopy has already been successfully applied to detect structural differences induced by transgenic modification,[46] heat treatment,[14,15] bioethanol processing,[16,17,47] and climate changes such as frost damage.[48] Then on the basis of our findings mentioned above, even small variations existed in structural makeup of corn forages grown on wet and dry soil could also be detected by this powerful and accurate spectroscopic technique.

Information on molecular structural makeup in forage in relation to nutrient availability is very limited or unknown. Future study is needed to see how structural changes and how structural makeup are affected by irrigation and corn variety and how structural changes affect nutrient utilization and availability. This is a novel research area in feed research.

Principal Component Analysis within the Near-Infrared Region (Figure 1). The detailed principal, variable selections, variable reduction, distance method, matrix method, principal components selection, and explanation of hierarchical cluster analysis and principal component analysis in feed structural research have been explained previously.[21] In the study, we used synchrotron-based FTIR microspectroscopy as an example. The main purpose of PCA and CLA analyses is to detect treatment differences based on structural spectral data at

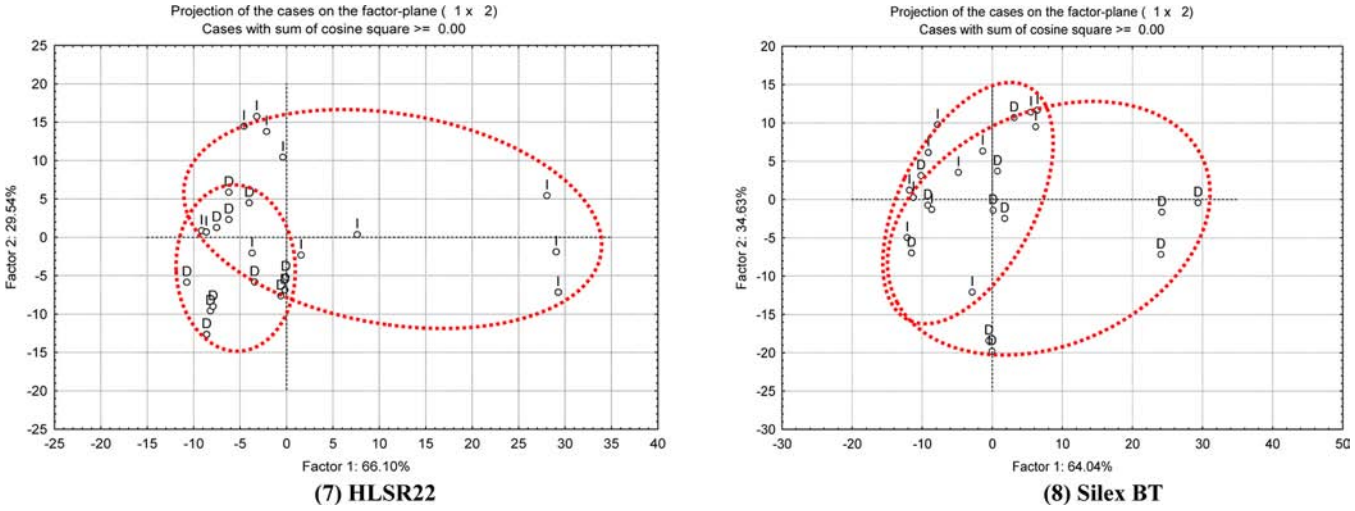

Figure 1. Principal component analysis within the NIR region (1842−570 nm) between irrigated (I) and dry (D) land corn forages.

fingerprint regions. If varieties form different clusters and groups, this indicated the structural difference between varieties.

NIR spectroscopy is performed on the basis of molecular information and combination vibrations, and every item should have its particular scanning spectrum within the detection region. In our study, to clarify whether irrigation treatment brings out any internal changes in molecular structural conformation, we selected all of the spectral data (ca. 1842−570 nm) of each corn variety obtained from the NIR system for PCA. For this multivariate analysis, the first and second principal components explained 45.83−67.12 and 23.31−41.13%, respectively, of the total variance in PCA figures. As can be seen from the figures, only for the varieties HL3085 and HLBaxxos could the structural makeup of the forage cultivated under water stress be almost distinguished from that grown on dry land. For the remaining six varieties, targeted plants from wet and dry experimental plots could not be grouped into separate ellipses owing to the produced heavy overlapping of groups. These results indicated that for most varieties, internal structural relationships in molecular makeup were exhibited between irrigated corn forage and that grown on dry land.

All of the results shown above might lead one to conclude that irrigation treatment was an influential factor in terms of agronomic measures and chemical compositions as well as molecular structural parameters over different kinds of corn forage. As for DM, OM, and CP contents as well as most spectral parameters, the well-watered plant was quite different from that cultivated on dry land. Moreover, water use interacted with corn variety on most agronomic features and CF and EE contents as well as some spectral data such as CELC peak intensity, peak ratios of CHO third peak to CELC, α-helix to β-sheet, and CHO third peak to amide I. Also, significant differences were often observed among three cultivars on these measured parameters. Multivariate results from PCA indicated some structural similarities existed between two treated corn forages with the exception of HL3085 and HLBaxxos. Further study on the optimum level of irrigation for corn forage cultivation might be helpful in semiarid regions such as western Canada.
