In conclusion, in the present study two different biolubricants were prepared from canola oil and canola biodiesel using Amberlite IR-120H for the epoxidation step and Amberlyst-15 for the simultaneous ring opening and esterification step. NMR and FT-IR spectral analyses confirmed the formation of products. Biolubricant from canola biodiesel has good low temperatue properties (−12 °C and −18 °C), kinematic viscosity (19 cSt at 100 °C), low friction and antiwear scar (95 μm), and high oxidative stability (76.3 h). Therefore, biolubricant derived from biodiesel can be used for low temperature and general application like automotive lubricants. However, canola oil biolubricant has a cloud point of −3 °C and pour point of −9 °C, kinematic viscosity measured at 373 K is 670 cSt, friction and antiwear scar (130 μm), and oxidative stability (56.1 h). As biolubricant from canola oil has high thermal stability (305 °C), and is highly viscous, even at high temperature, it can be used at high temperature, heavy load, and high speed operations such as

heavy machinery. This study shows that both the biolubricants are effective, attractive, renewable, and thus have good characteristics as industrial lubricants.

Table 1. List of Potato Species Used in This Study for Isolation of Patatins from Tubers

species	code of Gene Bank in Potato Research Institute Havlíčkův Brod	country of origin/geographic distribution
Solanum tuberosum L. cv. Desirée	EVIGEZ 07S0100243	Netherlands
Solanum andigenum Juz. & Bukasov	EVIGEZ 07S0300066	South America (Venezuela and Argentina)
Solanum goniocalyx Juz. & Bukasov	EVIGEZ 07S0300109	South America (Peru and Bolivia)
Solanum phureja Juz. & Bukasov	EVIGEZ 07S0300136	South America (Bolivia)
Solanum stenotomum Juz. & Bukasov	EVIGEZ 07S0300001	South America (Columbia and Argentina)

potato cultivars. Both groups showed similar values of the protein content, and three mass levels, 40.6, 41.8, and 42.9 kDa, of purified patatins were found by matrix-assisted laser desorption/ionization−mass spectrometry (MALDI−MS). The differences among these masses (~1.2 kDa) indicated a mass close to the molecular mass of patatin oligosaccharide, as mentioned above. However, the present study aiming at a detailed investigation of glycosylation profiles of patatins isolated from selected potato species showed the presence of more oligosaccharide structures. The data obtained by mass spectrometric analysis provided even evidence for differences in profiles of patatin *N*-glycans, and these results will be discussed.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. For this work, tubers from selected potato species (for details see Table 1) were donated by the Gene Bank of Potato Research Institute Havlíčkův Brod, Czech Republic. In both experimental years (2011 and 2012), analyzed tubers were obtained by the following approach of cultivation: Plant *in vitro* reproduction was made on Murashige and Skoog (MS) agar medium containing 30 g L^{-1} sucrose without growth hormones.[21] Rooted *in vitro* plants were transferred to *in vivo* conditions of the greenhouse. Each potato plant (in total, five plants from each species) was cultivated in a pot with 10 L of potting soil to ensure harmonic nutritive conditions for a complete growing season. Potting soil in pots was kept in appropriate humidity by daily watering. Potato plants were cultivated during both seasons under chemical control against *Phytophthora infestans* and insect pests. All conditions of plant cultivation were the same in both experimental years. Obtained tubers were flushed in water and cut first longitudinally into identical halves and then into thin slices (~2 mm). The slices were frozen to −80 °C, freeze-dried (−50 °C, 0.040 mbar, 48 h, freeze-dryer Alpha 1-4 LSC, Martin Christ, Germany), and homogenized using a laboratory mill. Freeze-dried potato tuber meal (5 g) was extracted in 25 mM Tris−HCl buffer (50 mL, pH 7.4) for 30 min at 4 °C. The mixture was centrifuged (4 °C at 3600*g* for 15 min), and the supernatant was filtered.

Purification of Patatins. Chromatographic purification of patatins was achieved with the following three steps modified according to the procedure reported previously:[20] (1) Ion-exchange chromatography was completed on DEAE 52-Cellulose Servacel (15 mL, Serva, Germany) with 90 mL of starting buffer (25 mM Tris−HCl at pH 7.4). After application of the protein extract (10 mL), the column was washed with 60 mL of starting buffer to remove unbound proteins, and isocratic elution of bound proteins was performed with 30 mL of elution buffer (25 mM Tris−HCl at pH 7.4 + 0.5 M NaCl). (2) Affinity chromatography was performed on Concanavalin A Sepharose 4B (10 mL, GE Healthcare, Little Chalfont, U.K.). The column was equilibrated with 60 mL of starting buffer (25 mM Tris−HCl at pH 7.4 + 0.5 M NaCl). Elution of bound patatins was performed with 20 mL of buffer consisting of 25 mM Tris−HCl at pH 7.4 + 0.5 M NaCl + 100 mM α-methyl-D-glucoside. (3) Desalting of patatin proteins was achieved using molecular weight cut-off (MWCO) filters (3 kDa) according to the protocol of the manufacturer (Millipore). The purity of patatins (~99%) was verified by a means of sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and Experion automated electrophoretic system (see Supplementary Figure 1 of the Supporting Information).

Release of *N*-Glycans from Patatins. Lyophilyzed powder of patatin protein (500 μg) was dissolved in 25 mM ammonium bicarbonate (100 μL) and deglycosylated with *N*-glycosidase A (0.2 mU, Roche) at 37 °C for 20 h. Alternatively, the samples were digested first with trypsin (20 μg) at 37 °C for 4 h. Then, the digest was kept in a water bath at 85 °C for 5 min. After cooling, N-linked oligosaccharides were released from peptides again enzymatically by treatment with PNGase A (37 °C, 20 h). The reaction samples were mixed frequently during incubation.

Solid-Phase Extractions on Carbon Clean Cartridges. Prior to an extraction, the carbon cartridge columns (Supelclean-ENVI Carb SPE cartridges, Sigma-Aldrich) were first washed with 100% acetonitrile (ACN), following deionized water (5 mL of each). Then, digest (100 μL) was applied to a column with wet carrier and left to permeate, and after approximately 10 min, the carrier was rinsed with 5 × 1000 μL of deionized water. After that, glycans were eluted with 40% ACN (3 × 800 μL) and collected into separate tubes without using any pressure. All glycan fractions were evaporated and derivatized according to the procedure as described below.

Phenylhydrazine (PHN) Labeling. The derivatization with PHN (Sigma-Aldrich) was achieved according to the method previously reported,[22,23] with modified conditions as described next.

For MALDI−MS analysis, on-target labeling approach was applied: the fractions with glycans were dissolved in 20 μL of deionized water, and 1 μL of a sample solution was spotted onto the pre-deposited matrix ATT/PHN·HCl (2-aza-2-thiothymine/phenylhydrazine hydrochloride in a molar ratio of 2:1).[24] When the spot was partially dried, 0.4 μL of derivatization reagent (10 μL of PHN in 50 μL of deionized water and 5 μL of ACN) was added. During this time, the target was kept at a temperature of 50 °C until the spot had dried. These conditions prevent smearing of the spot after adding PHN reagent solution; when the reaction time is sped up and after 3−5 min, the sample is ready for measurement.

For electrospray ionization (ESI)−MS analysis, *N*-glycan pools were reconstituted in the mixture consisting of deionized water (50 μL), PHN (1 μL), and ACN (3 μL). The tube with the reaction mixture was kept at a temperature of 60 °C for 30 min under vigorous mixing.

Exoglycosidase Digestions. Selected glycan fractions were subjected to α-mannosidase or β-*N*-acetylglucosaminidase (*Canavalia ensiformis*, Jack beans; Sigma) treatment at 37 °C according to the protocol supplied by the manufacturer. After each time of incubation (from 20 min to 4 h), 1 μL of digested mixture was spotted on the MALDI target, derivatized, and analyzed under the same conditions as the glycan pool before exoglycosidase treatment.

MS. MALDI−MS analysis was performed on the MALDI-TOF/TOF instrument (Ultraflex III, Bruker) operated in the positive reflectron mode, and for each sample spot, 1200 shots were summed. The spectra were acquired using the FlexControl software. Parent ions of interest were selected for LIFT (MS/MS) experiments. MS^n data were recorded on an Orbitrap ELITE instrument (Thermo Fisher Scientific, Waltham, MA) equipped with a Nanospray Flex Ion Source using direct infusion in 50% acetonitrile at a flow rate of 300 nL/min. The resolution of all MS^n spectra was 240 000 (at m/z 400). Automatic gain control (AGC) target value of 1×10^6 or 50 000 ions and maximum injection time of 200 or 5000 ms were set for all MS or MS^n measurements, respectively. Higher energy collisional dissociation (HCD) was used to generate MS^2 ions of glycans. In the case of the MS^3 fragmentation scheme, collision-induced dissociation (CID) at a relative energy of 40% was used to generate glycan fragments, from which one was further selected for HCD fragmentation at different

energies. The isolation window for all MS^n experiments was set to m/z 2. MS^n spectra were visualized and exported using Xcalibur Qual Browser (version 2.2, Thermo Fisher Scientific).

MS/MS spectra of *N*-glycans were interpreted manually. For the assignment of oligosaccharide fragment ions, the established nomenclature reported by Domon and Costello was followed.[25] The proposed oligosaccharide structures were derived from the single fragmentation patterns obtained for each precursor ions. For discrimination of single isomeric structures, previously reported rules were applied.[26]

Statistical Analysis. The MALDI measurements were repeated 3 times for each sample, and all experiments were repeated in triplicates for samples, with the exception of *S. tuberosum* L. (cv. Desirée). In the case of this cultivar, the experiments were repeated 5 times to confirm

RESULTS AND DISCUSSION

In this study, we examined *N*-glycans of patatins isolated from tubers of selected potato species from *Solanum* genus, as listed in Table 1. The selection of these potato groups was based on the knowledge reported recently that these types exhibit significant differences in the level of many tuber metabolites.[27] The oligosaccharides were released from purified patatins enzymatically with PNGase A, cleaned on carbon cartridges, and derivatized with PHN prior to mass spectrometric analysis. The principal method used for detection was highly sensitive MALDI−MS. This instrumental technique allows for the discrimination of different oligosaccharide classes. Besides, the abundance ratios of oligosaccharides can be calculated from a comparison of relative ion intensities corresponding to individual glycans. To confirm the type of cross-ring cleavages, additional MS/MS data were recorded on an Orbitrap ELITE instrument. The assignment of oligosaccharide types was based on monosaccharide composition, fragmentation patterns, exoglycosidase digestions, and knowledge of the glycan biosynthetic pathway in plants. Generally, only neutral oligosaccharides were detected and produced $[M + Na]^+$ ions when detected by MALDI−MS or Orbitrap when using a direct infusion. Most of the identified peaks showed 3-linked fucose at the GlcNAc of the reducing end (the resistance to PNGase F cleavage). The most abundant oligosaccharide in all samples was observed at *m/z* 1301.5 (Figure 1a), and its fragmentation pattern clearly corresponded to glycan with a composition of $Man_3(Xyl)GlcNAc_2(Fuc)$ (Figure 2a), the same structure as described previously in patatin isolated from potato tuber lipases.[19] This glycan was detected as only oligosaccharide in patatins isolated here from *S. tuberosum* cv. Desirée independently on the year of collection and from *Solanum goniocalyx* harvested in 2011 (Figure 1a). The glycoprotein obtained from *Solanum phureja* showed higher incidence of glycan at *m/z* 1139.4 (Figure 1b) and corresponded to the structure with composition $Man_2(Xyl)GlcNAc_2(Fuc)$ (Figure

DOI: 10.1021/acs.jafc.5b00426
J. Agric. Food Chem. 2015, 63, 3243−3250

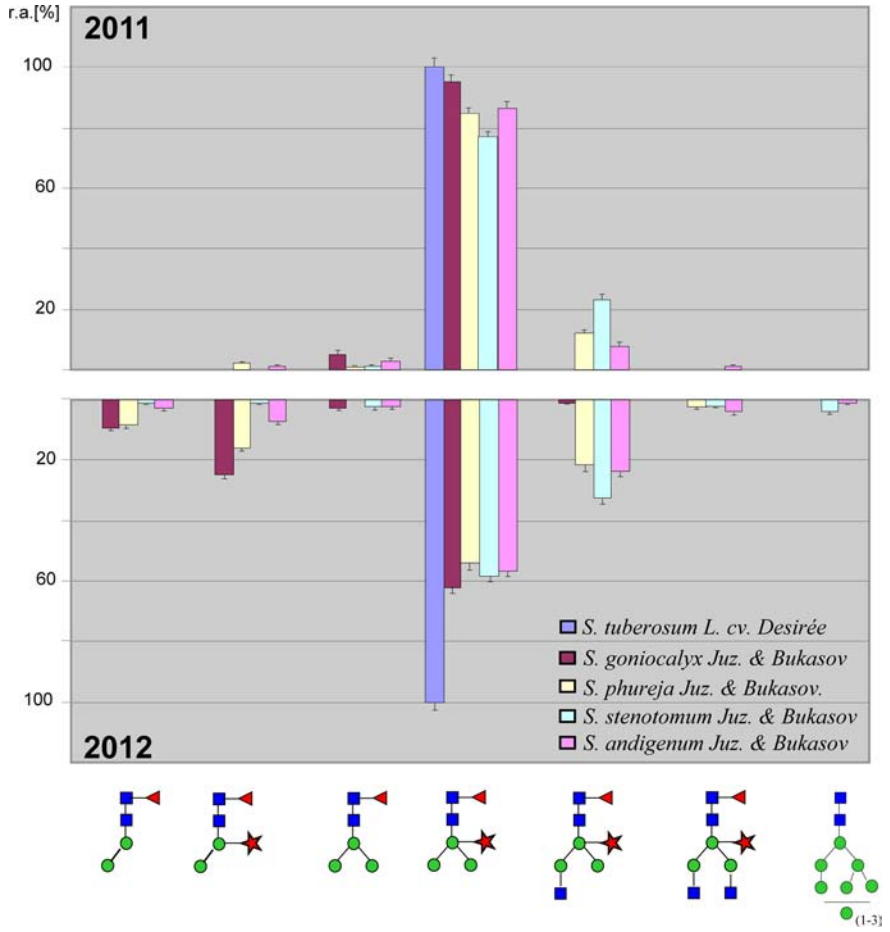

Figure 4. Schematic chart illustrating the occurrence of *N*-glycans detected by MALDI–MS in patatins isolated from five potato species (collected in years 2011 and 2012). The relative amounts of glycans calculated on the basis of their relative MS intensities as described in the Materials and Methods are presented as the mean ± standard deviation (SD) from at least three measurements.

2b). The peak with small intensity detected at m/z 1007.37 could be assigned to a glycan of similar structure as described above, however with no xylose linked on the core mannose (Figure 2c). The second highest peak in the spectra of most patatins was observed at m/z 1504.6 (e.g., panels b and c of Figure 1), and MS/MS data were supportive for the structure of the composition of $GlcNAcMan_3(Xyl)GlcNAc_2Fuc$ (Figure 3a). B and C fragment ions resulted from the loss of the chitobiose core, with m/z values detected at 1047.3 (B_4) or 1065 (C_4) or 844 (B_3) or 860 (C_3). Next the loss of 3-positioned hexose produced the fragment ions at m/z 682 (B_3/$Y_{3\beta}$) corresponding to the composition of the $GlcNAcMan_2Xyl$ residue (Figure 3a). Although two isomers could be possible for this glycan, according to the rules published previously,[23] only one isomer was detected: the preferential loss of 3-positioned hexose on the core mannose (m/z 682.21) was supportive for the prevalence of an isomer with GlcNAc moiety at the 6 position in mannose linked to the core mannose. Exoglycosidase treatment with β-*N*-acetylglucosaminidase confirmed the presence of the GlcNAc residue on the terminal end of oligosaccharides, and treatment with α-mannosidase produced glycans at m/z 1342.49, 1139.41, and 977.35 (e.g., see Supplementary Figure 2a of the Supporting Information). The parent ions of these products under MS/MS conditions produced the fragment ions supporting the attachment of the Xyl moiety on the core mannose (see panels a and b of Supplementary Figure 2 of the Supporting Information). Biantennary complex glycan detected at m/z 1707.6 was observed with lower abundance in some samples (e.g., panels b and c of Figure 1), and its precursor ions produced the fragment ions, indicating a structure with two GlcNAc residues at the non-reducing end (Figure 3b). The fragment ions recorded at m/z 682.2 (B_3/$Y_{3\alpha}$) were consistent with a loss of the GlcNAcMan residue from B_3 or C_3 ions and provided evidence for GlcNAc moieties on both mannoses linked at the core mannose.

In the MS/MS spectra of all detected glycans, the most dominant peak was associated with a loss of 282 mass units from each parent precursor ions (e.g., fragment ions detected at m/z 1019 in Figure 2a, fragment ions at m/z 1222 in Figure 3a, or ions at m/z 1425 in Figure 3b). The presence of these peaks in the MS/MS spectra of all detected glycans was not influenced by the type of monosaccharide residue(s) at the non-reducing end. Moreover, these fragment ions under MS^2 (Orbitrap) conditions produced the fragment ions as seen in the MS/MS spectra shown, e.g., in Figures 2 and 3 and provided again the support for cross-ring cleavages at the side from the reducing termini. On the basis of the above-mentioned facts, these dominant fragment ions could be explained by the loss of Fuc altogether with the cleavage $^{0,1}A$. The loss of the later mentioned residue from reducing termini ($^{0,1}A$-type cleavage) is commonly observed in the CID spectra of mammalian *N*-glycans when fucose on GlcNAc of the

DOI: 10.1021/acs.jafc.5b00426
J. Agric. Food Chem. 2015, 63, 3243–3250

reducing end is linked at the 6 position but never produced as major fragment ions.[23,28]

In the spectra of glycoproteins isolated from species *Solanum andigenum* and *Solanum stenotomum*, additional peaks appeared at m/z 1671.6 and 1833.7 (Figure 1c). Tandem mass spectra showed that these *N*-glycans had both antennae occupied with hexose residues only, and the fragmentation pattern was similar to that assigned to high-mannose structures as previously described.[28,29] Besides, sequential exoglycosidase treatment of the glycan pool with α-mannosidase caused the loss of hexose residue(s) and supported the structure with mannose residues on both antennae as depicted, e.g., in Figure 1c (m/z 1671 and 1833).

A lot of information regarding patatins as a glycoprotein with interesting properties was reported; however, most of this information is limited to only one type. The first report mentioning glycosylation pattern in patatin isolated from potato tubers was published more than 2 decades ago; two glycosylation sites at Asn60 and Asn90 were occupied with glycan of composition $Man_3(Xyl)GlcNAc_2(Fuc)$.[30] Although a few papers have studied the glycosylation of potato patatins, no evidence for the presence of other glycan structures has been reported up to now. Our present study provides evidence for the presence of other glycans in potato patatins, and the profile can differ with species level. The chart shown in Figure 4 illustrates identified *N*-glycans in the analyzed patatin samples. The major glycan structure found in all samples corresponded to the typical fucosylated plant glycan with xylose on the core mannose (m/z 1301). This glycan solely as one saccharide structure was found in *S. tuberosum* cv. Desirée (from both seasons) and *S. goniocalyx* (collected in 2011). It was reported previously that genotype (equally species and cultivar) is the predominant factor playing a role in the final expression of patatin proteins. However, the other factors, such as year, climate and soil conditions, fertilization, production system, and stress factors, represent also running factors with an ability to modify patatin proteins.[31] The patatin of *S. tuberosum* cv. Desirée did not show any significant change from one year to another. However, *N*-glycome profiles of other species altered with period. The most obvious change on this level was observed for *S. goniocalyx* (see Supplementary Figure 3a of the Supporting Information). This protein together with patatin of *S. phureja*, both collected in 2012, showed higher abundance of shorter glycans, $Man_2GlcNAc_2Fuc$ and $Man_2(Xyl)GlcNAc_2Fuc$. Whereas, in the samples from *S. stenotomum* and *S. andigenum* glycans with GlcNAc residue(s) on arm(s) were detected with higher intensity, $GlcNAc_{1-2}Man_3(Xyl)GlcNAc_2Fuc$. The above discussed species also showed the additional presence of high-mannose glycans with composition $Man_{7-9}GlcNAc_2$ glycans. These oligosaccharides have also never been described in patatins of potato tubers; on the other side, they are commonly found in mammals and not mentioned to be immunogenic.

Plants, among other properties, have great potentials as "biofactories" for the production of therapeutic proteins. Therefore, the number of plant recombinant proteins produced is increasing rapidly.[32] The immunogenicity of plant oligosaccharides in animals or humans is associated with the presence of an α(1,3)-fucose and a β(1,2)-xylose attached to the glycan core.[33] It was reported that the disappearance of sugar allergenic epitopes from plant oligosaccharides is offering a new possibility to produce safe proteins for therapeutic applications.[9] Although further studies are needed to follow carefully more conditions that may also influence the glycosylation profile and to provide better insight into biology of patatins, our data showed that the glycan profile of potato patatin among other factors alters with genotype/cultivar variability. The observed changes in profiles suggest that correct choice of species with careful monitoring of all conditions can enable the decrease of the presence of glycans with immunogenic sugar epitopes and potatoes as one of the most available and the low-cost crops can be used even more beneficially.

MATERIALS AND METHODS

Chemicals and Standards. All flavonoid standards used in the present study were purchased from Sigma-Aldrich Co. (St. Louis, MO). Methanol, formic acid, acetonitrile, and acetic acid (HPLC grade) were obtained from the Fisher Co. (Fairlawn, NJ). Deionized water (<18 MΩ resistance) was obtained from a Milli-Q Element water purification system (Millipore, Bedford, MA). Analytical-grade ethyl acetate was purchased from Beijing Chemical Reagent Plant (Beijing, China). All the other chemicals were purchased from Sigma-Aldrich Co. unless noted specially.

Plant Materials. *V. vinifera* L. cv. Cabernet Sauvignon grape berries from five commercial vineyards of the main wine-producing regions in China were obtained for the investigation of anthocyanin profile by HPLC–ESI-MS/MS (Table 1). All of the vineyards are located in a temperate continental arid climatic zone with the features of a cold–dry winter, abundant sunshine, and a big temperature difference between day and night. The Cabernet Sauvignon grapes collected at various developmental stages from Manasi of Xinjiang (XJM) in 2012 were used for quantitative polymerase chain reaction (PCR) analysis. The grape berries at commercial harvest from the same vineyard were used to separate *5GT* genes. The grape berry samples used for microsatellite analysis were collected in the years 2011 and 2012 from the five vineyards indicated in Table 2. Syrah and Chardonnay from Shang-Zhuang experimental station of China Agricultural University (Beijing, China) were taken as reference cultivars in the microsatellite analysis. The two cultivars were collected at harvest of the year 2013. To select representative grape samples, we performed the sampling according to the method described by Boulton et al.[16] Three 100-berry samples were selected at random from at least seven 10-cluster selections at similar positions on the 30 selected vines. The selected grape berries were washed, briefly dried, and then carried back to the laboratory under dry ice protection. The seeds were removed by hand. The skins were peeled and immediately put into liquid nitrogen and stored at −80 °C until further use.

Extraction and Analysis of Anthocyanins. The extraction of anthocyanins from grape skins was carried out according to the method of Liang et al.[17] Grape skin powder (0.5 g) was immersed in 10 mL of methanol containing 2% formic acid. This extraction was dispersed with the aid of ultrasonic vibration for 10 min and then shaken in the dark at 25 °C for 30 min at a rate of 150 rpm. The homogenate was centrifuged at 8000*g* for 20 min, and then the supernatant was collected. The residue was repeatedly extracted four times with the same solvent. The pooled extracts were evaporated to dryness by a rotary evaporator and finally redissolved in 10 mL of 10% ethanol solution (pH 3.7). The resulting suspensions were filtered through 0.22 μm filters (cellulose acetate and nitrocellulose, CAN) prior to HPLC–ESI-MS/MS analysis. For each sample, two independent extractions were performed.

HPLC–ESI-MS/MS experiments were carried out as reported in our previous work.[17] This analytical system used an Agilent 1200 series LC–MSD trap VL, equipped with a G1322A degasser, a G1312B bin pump, a G1367C HiP-ALS, a G1316B TCC, a G1314C VWD, and a Kromasil C18 column (250 × 4.6 mm, 5 μm). The compounds were eluted by using two solutions: (A) 6% (v/v) acetonitrile containing 2% (v/v) formic acid and (B) 54% acetonitrile containing 2% formic acid. The gradient was 10% B for 1 min, from 10 to 25% B for 17 min, isocratic 25% B for 2 min, from 25 to 40% for 10 min, from 40 to 70% for 5 min, and from 70 to 100% for 5 min, at a flow rate of 1.0 mL/min. The injection volumes were 30 μL, and the detection wavelength was 525 nm. The column temperature was 50 °C. MS conditions were as follows: ESI interface, positive ion model, 35 psi nebulizer pressure, 10 mL/min dry gas flow rate, 350 °C dry gas temperature, and scans at m/z 100–1000. All analyses were performed in duplicate. The identification and the peak assignment of anthocyanins were based on the comparison of their retention time (t_R), molecular ion, and products ions with those of the standards and the published data.[17−19] The concentration of each anthocyanin was expressed as the equivalent of malvidin 3-*O*-glucoside.

Microsatellite Analysis. The genomic DNA was separated using a DNeasy Plant Kit (Tiangen, Beijing, China) following the manufacturer's instructions. Samples were genotyped at six microsatellite loci proposed by the European project GENRES081 (http://www.eu-vitis.de/index.php): VVS2,[20] VVMD5 and VVMD7,[21] VVMD27,[22] and VrZAG62 and VrZAG79.[23] One primer of each pair was fluorescently labeled with the phosphoramidite dye. The 20 μL reaction system contained 50 ng of DNA, 1.0 U of Taq DNA polymerase (Takara), 1.5 mM Mg^{2+}, 200 μM of each dNTP, and 0.4 μM of each primer. The PCR reaction was performed at 94 °C for 5 min, 35 cycles at 94 °C for 30 s, 55 °C for 30 s, 72 °C for 90 s, and finally extension at 72 °C for 10 min and then cooling to 4 °C in a Techne TC-312 thermal cycler (UK). The separation and sizing of simple sequence repeat (SSR) alleles was completed on an ABI 3730XL DNA analyzer by Genewiz Biotechnology Co., Ltd. (Beijing, China). The data were analyzed with Gene-Marker software (Soft Genetics LLC, State College, PA). Allele sizes were adjusted to an exact number of bases using the algorithm as described by ref 24. SSR profiles were compared with a database (*Vitis* International Variety Catalogue (VIVC, http://www.vivc.de/index.php)) for cultivar identification.

Cloning of *5GT* Candidate Genes. Total RNA was separated from mature Cabernet Sauvignon grapes and the respective cDNA was synthesized using the method previously described.[25]

According to the nucleotide sequence (unpublished, communicated by Prof. Schwab) of the previously characterized functional *5GT-Cha*,[14] we used Cabernet Sauvignon genomic DNA as a template to amplify this gene (see primers for *Vv5GT1* in Table S1, Supporting Information). The PCR mixture (total volume 25 μL) contained 1 μL of DNA, 1 μL of each primer (20 μM), 12.5 μL of 2 × Taq PCR Master Mix (Tiangen, Beijing, China), and 9.5 μL of ddH_2O. Amplification was performed as described above. The PCR products were separated on 1.5% (w/v) agarose gel. The fragment was recovered and cloned into PMD19-T Easy vector (Takara, Japan) and subjected to sequence analysis. The resultant gene was designated as *Vv5GT1* (5-*O*-glucosyltransferase in *V. vinifera* L. Cabernet Sauvignon). Hausmann et al. found five candidate genes for 5GT in *Vitis* hybrid cv. Regent and suggested that one gene (gene 7) was the perfect candidate for anthocyanin 5GT through the investigation of their expression patterns.[26] The 5GT function of gene 7 was further confirmed by their subsequent study.[14] Here we used the 3′-RACE gene specific primers of the other four *Vitis 5GT* candidate genes (genes 5, 6, 8, and 9) to perform in-silico cloning in the database of Grape Genome Browse with the BLASTn program (http://www.genoscope.cns.fr/blat-server/cgi-bin/vitis/webBlat). The obtained sequences were blasted against the NCBI database (http://www.ncbi.nlm.nih.gov). The four in-silico sequences were taken as candidate *5GT* genes. Their specific primers were designed (Table S1, Supporting Information). The full-length cDNAs were obtained using the above Cabernet Sauvignon cDNA template by PCR amplification. The four PCR products all matched with their respective predicted sequences. They were named as *Vv5GT2* (grape genomic locus LOC100260432), *Vv5GT3* (LOC100265923), *Vv5GT4* (LOC100258380), and *Vv5GT5* (LOC100263517), respectively.

Sequence Analysis. Multiple sequence alignment was performed with ClustalX (http://www.clustal.org).[27] The phylogenetic tree was constructed using the neighbor–joining method in the MEGA4 package (http://www.megasoftware.net).[28] Bootstrap values (1000 replications) were performed to test the confidence of nodes.

Prokaryotic Expression and Purification of the Expressed Products. To determine whether these four candidate *Vv5GT*s are functional, we expressed these genes in *Escherichia coli* cells, respectively. Plasmids containing *Vv5GT* cDNAs were double-digested with *Xho*I and *BamH*I. The resulting DNA fragments were ligated with a pET-32a expression vector (Novagen, Madison, WI). The *E. coli* BL21 (DE3) with the recombinant plasmids was incubated into 500 mL of fresh Luria–Bertani medium containing 50 mg/L ampicillin and cultured at 37 °C until the optical density (OD_{600}) reached 0.6. Prokaryotic expression of the target genes was then induced by adding IPTG (isopropyl β-D-thiogalactoside) to a final concentration of 1 mM and further cultured overnight at 16 °C at a rate of 150 rpm. Cells were harvested by centrifugation, and the supernatant was discarded. The harvested cells were suspended in buffer A [50 mM NaH_2PO_4 (pH 8.0),

[a]YNSR, Shuori of Yunnan (28°34′ N and 98°47′ E); YNMLS, Meilishi of Yunnan (27°49′ N and 99°42′ E); SCMC, Mao County of Sichuan (32°0′ N and 103°42′ E); XJM, Manasi of Xinjiang (44°18′5 N and 86°13′ E); GSQL, Qilian of Gansu (99°84′ E and 39°14′ N).

300 mM NaCl, 10 mM imidazole] and proteinase inhibitors including 1 mg/mL leupeptin, 0.5 mg/mL lysozyme, 0.5 mM phenylmethanesulfonyl fluoride (PMSF), and 0.4% (m/v) Triton X-100. The cell suspension was disrupted by sonication for 15 min, and the resulting cell debris were removed by centrifugation followed by filtration with a 0.45 μm filter (Millipore). The target proteins were purified by Ni-NTA His Bind Resin (Novagen, Madison, WI). The column was washed with 5 mL of washing buffer containing buffer A and 3 M imidazole in a proportion of 150:1 (pH 8.0) and then with elution buffer containing buffer A and 3 M imidazole in a proportion of 15:1 (pH 8.0). The high-concentration fractions were collected and purified using a stirred cell (Millipore) with a regenerated cellulose membrane [molecular weight cutoff (MWCO) 3000 Da; Millipore]. All steps were conducted at 4 °C. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) was performed to estimate the relative purity of the recombinant proteins. The protein concentration was determined using the Bradford method.[29,30] Negative controls were carried out with *E. coli* BL21 (DE3) cells containing the empty expression vector pET-32a.

Enzyme Activity Assessment of Vv5GT Proteins. Six kinds of anthocyanidin 3-*O*-glucosides were respectively used as glycosyl acceptor. The reaction mixture (100 μL) was composed of 0.1 M potassium phosphate buffer (pH 8.0), purified recombinant protein (5 μL), 100 μM anthocyanidin 3-*O*-glucoside, and 2 mM UDP-glucose. The mixture was incubated in a 35 °C water bath for 30 min, and the reaction was terminated by adding an equal volume of methanol containing 1% (v/v) hydrochloric acid. Afterward, the reaction solution was filtered through 0.22 μm filters. The products were examined by means of HPLC−QQQ-MS/MS equipped with an Agilent series 1200 instrument and a Poroshell 120 EC-C18 column (150 × 2.1 mm, 2.7 μm, Agilent Technologies). The elution solution was composed of water (A) and acetonitrile/methanol (50:50, v/v, B), both with 0.1% formic acid. The elution gradient was from 10% to 46% B for 21 min, from 46% to 10% B 1 min later, with a flow rate at 0.4 mL/min; column cleanup and re-equilibration were at 90% A and 10% B for 5 min with a flow rate at 0.3 mL/min and a column temperature of 55 °C.

An Agilent 6410 QqQ instrument equipped with an electrospray ionization source was applied for identification and quantitation of the compounds. Spray voltage was set at 4 kV in positive mode, the source temperature was kept at 150 °C, gas temperature was 350 °C, gas flow was 12 L/h, and nebulizer pressure was 35 psi. The m/z^+ ions were selected as precursor ions of anthocyanins. SIM was used to find out the optimum fragmentor voltage. The target anthocyanins were detected under multiple reaction monitoring (MRM) mode. The catalytic activity of Vv5GT protein was assessed by the production of anthocyanidin diglucosides in the reaction system.

Biochemical Characterization of Vv5GT3. On the basis of the assessment of enzyme activity of various Vv5GT proteins, we found that only Vv5GT3 exhibited 5GT activity. To further understand the biochemical property of Vv5GT3, we altered some parameters of the above enzyme reaction protocols. In the reaction mixture using 60 μM peonidin 3-*O*-glucoside as glycosyl acceptor, the reaction was recorded from 0 to 23 h (Figure S3, Supporting Information); the amount of enzyme protein added was increased from 0 to 3.3 μg (Figure S4, Supporting Information); the reaction system was in the range of pH 6.5−10.0 (Figure S5a, Supporting Information), and the reaction temperature was set up from 25 to 45 °C (Figure S5b, Supporting Information). The K_m values were determined by varying the concentrations of cyanidin 3-*O*-glucoside (41.3−206.3 μM), delphinidin 3-*O*-glucoside (40.0−199.7 μM), malvidin 3-*O*-glucoside (37.8−189.1 μM), petunidin 3-*O*-glucoside (40.0−200.0 μM), pelargonidin 3-*O*-glucoside (38.8−194.2 μM), peonidin 3-*O*-glucoside (40.1−200.5 μM), quercetin 3-*O*-glucoside (861.4−4306.8 μM), delphinidin (118.1−590.5 μM), and quercetin (750.0−3750.0 μM), respectively, in the reaction mixture. The products were detected by HPLC−QQQ-MS/MS according to the above procedures, except that flavonols were identified in a negative ion mode. The K_m value was calculated from a double-reciprocal plot of initial velocity ($1/V$) against glycosyl acceptor concentration ($1/[S]$). The plot slope is K_m/V_{max}. All reactions were repeated in triplicate.

Subcellular Localization of Vv5GT3 Protein. The open reading frame of *Vv5GT3* was PCR-amplified, and the primers are listed in Table S1 (Supporting Information). Purified amplicon was digested with *BamH*I and *Hind*III and then fused to the upstream of the gene coding for green fluorescent protein (GFP) in the cauliflower mosaic virus 35S-EGFP-Ocs 3′ vector (*p*-EZS-NL vector, available online from https://deepgreen.dpb.carnegiescience.edu). Subcellular localization was conducted according to the protocol Zhu et al.[31]

Real-Time PCR. Quantitative real-time PCR was performed on a 7300 Real Time PCR System (Applied Biosystems) to investigate the expression pattern of *Vv5GT3* in developing Cabernet Sauvignon grape berries. *VvUbiquitin* (GenBank accession number AY684131) and *VvActin-7* (LOC100232866) were used as internal controls. The primers for real-time PCR are listed in Table S1 (Supporting Information). A total volume of 30 μL of reaction solution was composed of 15 μL of SYBR Premix Ex Taq and 0.5 μL of ROX reference dye (50×) (Takara), 13 μL of ddH_2O (TIANGEN), 0.5 μL of cDNA, and 1 μL of primer mixture (forward primer and reverse primer, 10 mM). For real-time PCR, the template cDNA was denatured at 95 °C for 30 s, followed by 40 cycles of amplification at 94 °C for 10 s and 60 °C for 31 s. The average cycle threshold (Ct) of *VvUbiquitin* and *VvActin-7* at each sampling point was determined, and their geomean value was used to calculate the transcript abundance of *Vv5GT3*, using the formula $2^{-\Delta Ct}$.[32] The mean and the standard derivation (SD) were estimated after $2^{-\Delta Ct}$ calculation.

RESULTS AND DISCUSSION

A total of 24 anthocyanins were detected in the skins of Cabernet Sauvignon grape berries. Among them, 20 anthocyandin 3-*O*-glucosides are commonly present in *V. vinifera* grapes. These anthocyanidin 3-*O*-glucosides include six individual anthocyanins, five acetylated anthocyanins, seven *p*-coumaroylated anthocyanins, and two caffeoylated anthocyanin (Table 1 and Figure 1a). Besides, four diglucosides of anthocyanidins were detected (Figure 1). The mass spectral data of peak 1 obtained with ESI-MS and ESI-MS/MS showed a molecular ion at m/z 627 ($[M]^+$) and two MS/MS fragment ions at m/z 465 ($[M - 162]^+$) and m/z 303 ($[M - 162 - 162]^+$), which were

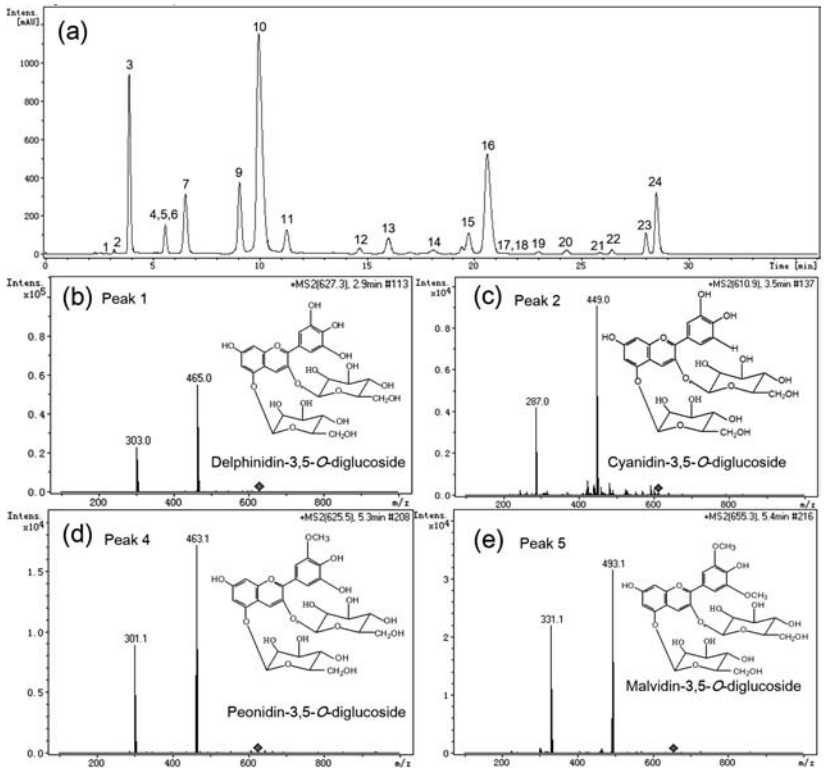

Figure 1. Detection of anthocyanidin 3,5-*O*-diglucosides in the skins of Cabernet Sauvignon grape berries from Deqin County of Yunnan Province in southwest China (28°34′ N and 98°47′ E). (a) Reverse-phase HPLC chromatogram of anthocyanins at 525 nm; the product ion mass spectra and chemical structures of (b) peak 1, (c) peak 2, (d) peak 4, and (e) peak 5. The compounds corresponding to the peak numbers are listed in Table 1.

compatible with a delphinidin-based structure linked to two hexose (m/z 162) units (Figure 1b). A similar fragmentation pattern was also reported previously.[19] So peak 1 was assigned as delphinidin 3,5-*O*-diglucoside. Similarly, peak 2 with a retention time of 3.50 min had a protonated ion of m/z 611 ($[M]^+$) and two fragment ions of m/z 449 ($[M - 162]^+$, cyanidin 3-*O*-glucoside) and m/z 287 ($[M - 162 - 162]^+$, cyanidin) by two successive losses of a hexose moiety. This compound was identified as cyanidin 3,5-*O*-diglucoside on the basis of fragmentation pattern and retention time (Figure 1c). Peak 4 had a molecular ion m/z 625, and two fragment ions of m/z 463 (peonidin 3-*O*-glucoside) and m/z 301 (peonidin), indicating that this compound is peonidin 3,5-*O*-diglucoside (Figure 1d); peak 5 with a retention time of 5.40 min had a protonated ion of m/z 655 ($[M]^+$) and two fragment ions of m/z 493 (malvidin 3-*O*-glucoside) and m/z 331 (malvidin), which correspond to malvidin 3,5-*O*-diglucoside (Figure 1e). Here, it needs to be noted that anthocyanidin 3,5-diglucoside has the identical molecular ion mass and fragmentation pattern with its 3,7-diglucoside, but they exhibit different retention times.[33−37] Previous study has found that malvidin 3,5-*O*-diglucoside elutes between delphinidin 3-*O*-glucoside and cyanidin 3-*O*-glucoside, whereas malvidin 3,7-*O*-diglucoside elutes between petunidin 3-*O*-glucoside and peonidin 3-*O*-glucoside,[34] which further demonstrates that peak 5 (Figure 1e) is malvidin 3,5-*O*-diglucoside. Moreover, in the present study, the identification of four anthocyanidin diglucosides was based on the analysis of *V. amurensis*, *Vitis davidii*, and *Vitis quinquangularis* grapes[17] with high levels of anthocyanidin 3,5-*O*-diglucosides, which also explains that these four compounds, corresponding to peaks 1, 2, 4, and 5, are 3,5-*O*-diglucosides of anthocyanidins, rather than 3,7-*O*-diglucosides. Additional investigation also revealed that the appearance of anthocyanidin 3,5-*O*-diglucoside in Cabernet Sauvignon grape berries is not an accident, and it has occurred in more than one wine-producing region in China (Table 1).

A few *V. vinifera* cultivars have been found to contain detectable anthocyandin 3,5-*O*-diglucosides.[3,15,38−41] However, so far no report has shown that anthocyanidin diglucosides are detected in Cabernet Sauvignon grapes, a *V. vinifera* cultivar widely planted in the wine-producing countries or regions of the world. Recent research also has demonstrated that *5GT* allele in this cultivar contains a three-base-pair deletion at nucleotide positions 901, 1182, and 1183, thus resulting in the loss of its function.[15] To test the real identity of the cultivar used in this study, we analyzed microsatellite DNA genotyping of the grapevines, using Syrah and Chardonnay cultivars as references. The obtained SSR loci were identical with microsatellite genotyping of Cabernet Sauvignon from grapevine SSR databases (http://www.vivc.de/index.php) (Table 2 and Figure S1, Supporting Information). Moreover, these grape samples from the five sampling vineyards all presented the same microsatellite profile. These facts demonstrate the authenticity of the Cabernet Sauvignon cultivar used in this study.

To explain why there are anthocyanidin 3,5-*O*-diglucosides in the Cabernet Sauvignon grapes grown in the wine-producing regions of China, we analyzed the DNA sequence of *Vv5GT1*, which was similar to the sequence of functional *5GT-Cha*.[14] The result showed that *Vv5GT1* had a nucleotide G deletion at position 902 when compared with the sequence of functional *5GT-Cha*. It is just this nucleotide deletion that caused a frameshift and a premature translation stop at codon 308 (TAA) at the C-terminus. That is, the deduced Vv5GT1 protein had a

The box indicates the plant secondary product glycosyltransferase motif (PSPG box).

158-amino acid deletion at the C-terminus. This deletion region contained a characteristic motif for plant secondary product glucosyltransferase (PSPG box).[42] It is thus suggested that the 158-amino acid deletion led to the loss of gene function. In addition, *Vv5GT1* was also found to have 7-bp substitution in comparison with the functional *5GT-Cha*.

J. Agric. Food Chem. 2015, 63, 3251−3260

In an effort to find the genes that encode 5GT in the Cabernet Sauvignon grape berries, the other four candidate *Vv5GT*s (*Vv5GT2*−*Vv5GT5*) were separated. Phylogenetic analysis revealed that each of these genes is related to the 5GT subfamily of glycosyltransferase genes (Figure 2a). The molecular masses of their predicted proteins were approximately 50.4, 55.4, 52.1, and 51.9 kDa, respectively, consisting of 457,497, 469, and 463 amino acids. All of these four proteins contained a 44-amino acid consensus sequence at the C-terminus (Figure 2b), called the PSPG box, which was highly conserved among plant glycosyltransferases.[42] More importantly, these four candidate *Vv5GT*s could be transcribed since they were obtained using cDNA template.

To assess the catalytic activities of the four prokaryotically expressed proteins, we have used six individual anthocyanin 3-*O*-glucosides as glycosyl acceptors. No product was detected for the Vv5GT2, Vv5GT4, and Vv5GT5 proteins. Therefore, these three proteins were not further studied. Among the identified *Vv5GT* genes, only Vv5GT3 was an enzymatically active protein.

The substrate specificity and biochemical properties of the recombinant Vv5GT3 protein were analyzed using a wide variety of flavonoids as glycosyl acceptors and using UDP-glucose or UDP-galactose as glycosyl donors. Vv5GT3 exhibited an apparent 5GT activity with respect to malvidin 3-*O*-glucoside (K_m = 91.87 μM) (Figure S2a, Supporting Information), peonidin 3-*O*-glucoside (K_m = 373.88 μM), cyanidin 3-*O*-glucoside (K_m = 111.29 μM), delphinidin 3-*O*-glucoside (K_m = 53.54 μM), petunidin 3-*O*-glucoside (K_m = 114.57 μM), and pelargonidin 3-*O*-glucoside (K_m = 206.98 μM), respectively. As shown in Figure 3a,b, Vv5GT3 converted malvidin 3-*O*-glucoside (*m*/*z* 493) into malvidin 3,5-*O*-diglucoside (*m*/*z* 655) through adding a glycosyl group (*m*/*z* 162). Here, we also noticed that the retention time and fragmentation pattern of the product from the reaction of Vv5GT3 and malvidin 3-*O*-glucoside (Figure 3b) completely corresponded to those of the standard malvidin 3,5-*O*-diglucoside (Figure 3a), suggesting that Vv5GT3 acts at the 5-position of malvidin 3-*O*-glucoside, rather than at the 7-position. Judging from K_m value, Vv5GT3 had a higher affinity for anthocyanidin 3-*O*-glucosides. In general, the concentration of anthocyanidin 3-*O*-glucoside in the berry skins of Cabernet Sauvignon was in the range of 100−3500 mmol/kg, which exceeds the K_m values of Vv5GT3 for these compounds (53.54−373.88 μmol/L). Additionally, Vv5GT3 also could convert quercetin 3-*O*-glucoside (*m*/*z* 463) into quercetin 3,5-*O*-dglucoside (*m*/*z* 625) (Figure 3c,d). However, this enzyme showed a relatively low affinity for quercetin 3-*O*-glucoside (K_m = 4.51 mM) (Figure S2b, Supporting Information), indicating that anthocyandin 3-*O*-glucosides should be the preferred glycosyl acceptors in the catalytic reaction of Vv5GT3. Surprisingly, this enzyme transferred the glucosyl group of UDPG to the 3-position of either anthocyanidins (such as cyanidin, delphinidin, and malvidin) or flavonols (such as quercetin, kaempferol, and myricetin), but their K_m values were very high (1.61 mM for delphinidin and 3.12 mM for quercetin) (Figure S2c,d, Supporting Information). Figure 3e,f present the production of quercetin 3-*O*-glucoside (*m*/*z* 463) in the reaction system using quercetin (*m*/*z* 301) as the glycosyl acceptor. Meanwhile, we also detected quercetin 3,5-*O*-diglucoside (*m*/*z* 625) with a very low level in this reaction system (Figure 3f). However, the recombinant Vv5GT3 was found not to use UDP-galactose as a glycosyl donor (data not shown). These results indicate that Vv5GT3 has the activities of both 3GT and 5GT

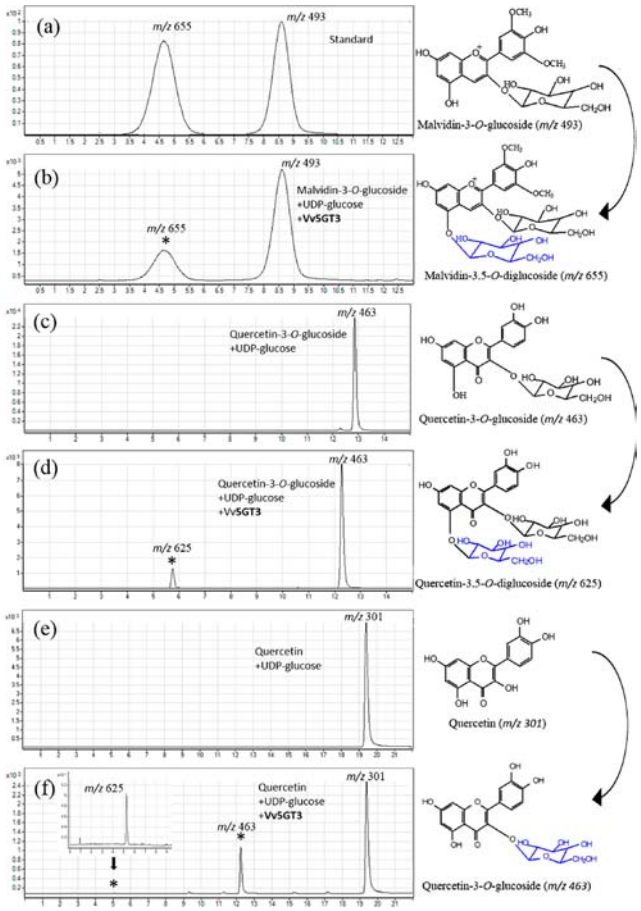

Figure 3. Enzymatic activity analyses of recombinant Vv5GT3 protein for glycosylation of malvidin 3-*O*-glucoside, quercetin 3-*O*-glucoside, and quercetin using HPLC−QQQ-MS/MS. (a) Authentic standards of malvidin 3-*O*-glucoside and malvidin 3,5-*O*-diglucoside. The product in the reaction systems containing (b) malvidin 3-*O*-glucoside, Vv5GT3, and UDP-glucose; (c) quercetin 3-*O*-glucoside + empty vector control + UDP-glucose; (d) quercetin 3-*O*-glucoside + Vv5GT3 + UDP-glucose; (e) quercetin + empty vector control + UDP-glucose; and (f) quercetin + Vv5GT3 + UDP-glucose. The asterisk indicates the product peak for each enzyme reaction.

and exhibits a broad substrate specificity. Such metabolic flexibility of Vv5GT3 might be one mechanism for producing the diversity of secondary plant metabolites.

To further understand the biochemical properties of Vv5GT3, we examined the effects of the reaction time course, enzyme amount, reaction temperature, and reaction system pH on the activity of Vv5GT3. TheVv5GT3 proteins continued to catalyze the glucosyltransfer reaction for about 11 h when incubated at 35 °C (Figure S3, Supporting Information), indicating that the enzyme is relatively stable and active. A linear relationship between the enzyme amount and the product concentration was also observed (Figure S4, Supporting Information). The highest catalytic activity of Vv5GT3 was around 35 °C and at pH 7.5−8.0 when we used peonidin 3-*O*-glucoside as the glycosyl acceptor (Figure S5a,b, Supporting Information).

Most of the anthocyanins accumulate in the vacuoles, and all structural genes involved in the anthocyanin biosynthesis are located on the endoplasmic reticulum membranes or in the cytoplasm, where the anthocyanins are directly produced.[43−45] To provide evidence regarding in vivo colocalization of the enzyme with its substrates, we examined the subcellular localization of

J. Agric. Food Chem. 2015, 63, 3251−3260

Vv5GT3 using transient expression of this gene fused with a *GFP* reporter gene in *Arabidopsis* protoplasts. The cytosol−nucleus double-localized PYR1 protein was taken as reference. GFP fluorescence was clearly observed in the cytoplasm (Figure 4), as we predicted.

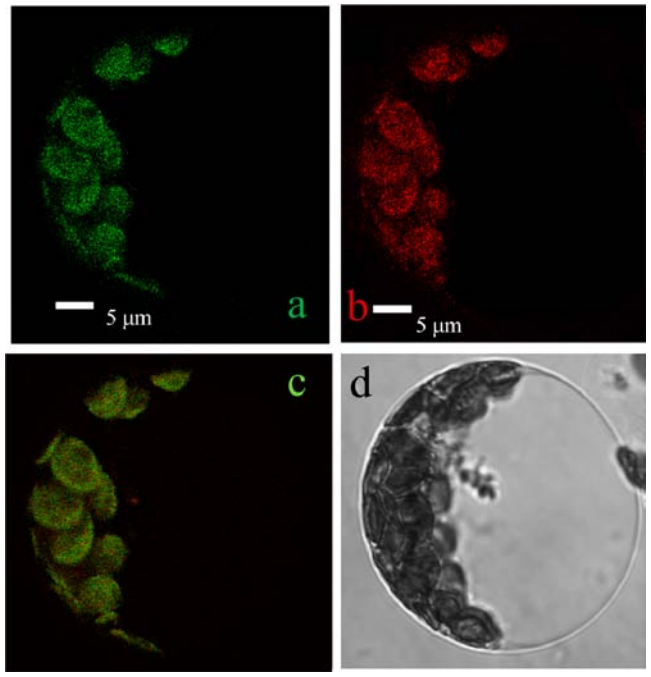

Figure 4. Confocal laser scanning microscopy of transiently expressed *Vv5GT3−GFP* fusions in *Arabidopsis* protoplasts. (a) Green fluorescent protein fluorescence of Vv5GT3−GFP. (b) Red fluorescent protein fluorescence of the nuclear−cytosol double-localized marker PYR1−RFP. (c) Merged image of parts a and b. (d) Light-microscopy image of intact protoplast. Bar: 5 μm.

Vv5GT3 was transcriptionally expressed during the development of Cabernet Sauvignon grape berries, and the relative expression amount was higher at preveraison than that at post-veraison (Figure 5). This may be related to the synthesis of flavonols, which occurs well before anthocyanin synthesis.

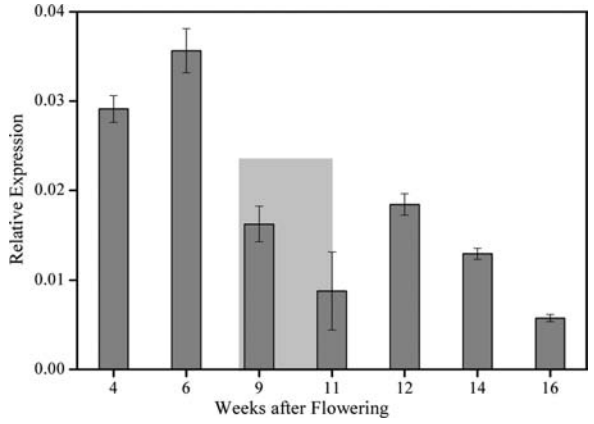

Figure 5. Relative expression levels of *Vv5GT3*. Expression analysis was performed on Cabernet Sauvignon grape berries at different development stages using quantitative real-time PCR (n = 3). The light gray background indicates the period of veraison from 10% to 100% of colored berries.

So far, most UGTs have been functionally characterized to be monofunctional. That is, 5GTs only can glycosylate flavonoid 3-*O*-glucosides but cannot take flavonoids like anthocyanidins, whereas 3GTs do not take anthocyanidin 5-*O*-glucoside as a glucosyl acceptor.[46] The present study showed a novel 5GT with catalytic activity at the 3-position of flavonoid. The following evidence could offer some explanations for this abnormal result. First, the primers cloning *Vv5GT3* are the same as gene 6 from the Regent cultivar,[26] and their nucleotide sequences have above 99% similarity. This gene 6 was found to be closely related to *5GT* genes in other plants based on the cluster analysis of sequences. Meanwhile, this gene can be transcribed in all the detected genotypes, independent of the existence of anthocyanidin 3,5-*O*-diglucoside.[26] Our study also revealed the occurrence of *Vv5GT3* transcription even in the early stage of Cabernet Sauvignon grape development, when grapes do not start to synthesize anthocyanins. It can be inferred that *Vv5GT3* might use the nonanthocyanins as glycosyl acceptors, such as flavonols. It may function to produce anthocyanidin diglucosides merely under a particular condition, such as under continental monsoon climate in the China's wine-producing regions. On the other hand, it should be completely possible to produce very low or trace levels of anthocyanidin diglucosides in *V. vinifera*, since there are *5GT*-like gene transcript and 3-*O*-anthocyanins existence in these cultivars. However, does the bifunctional property of *Vv5GT3* appear in other *V. vinifera* cultivars? Also, which catalytic activity of *Vv5GT3* is dominant in grape berries? Further study is under way.

In conclusion, we provided mass spectrometric and enzymatic evidence confirming the existence of anthocyanidin 3,5-*O*-diglucoside in *V. vinifera* L. Cabernet Sauvignon berries. This is the first report involving functional 5GT in Cabernet Sauvignon grapes. The identification of a new UGT with the activities of both 3GT and 5GT can be useful for better understanding anthocyanins' profile and their biosynthesis in *V. vinifera*. Our findings are also helpful for further investigations on the mechanism of the accumulation of anthocyanidin diglucosides in Cabernet Sauvignon berries in China's wine-producing regions.

of meat are well evaluated by LF-NMR measurements.[20,21] LF-NMR measurement is also a sensitive method for studying changes in water mobility and corresponding water populations in gel-like food matrixes such as cheese and tofu.[17,22] Different starch systems have been widely studied by LF-NMR. Tang et al. studied the molecular distribution of water in potato starch granules with LF-NMR, and they identified three proton fractions with different T_2 values, which were assigned to water molecules in different substructures of starch granules.[23,24] Bosmans et al. reported that there are three proton fractions in an unheated starch−gluten mixed system, and they used LF-NMR to study biopolymer dynamics, crumb firming, and several other physical properties of bread during its storage.[25−28] However, the soaking, steaming, and SSF processes of glutinous rice are currently not defined. In the present study, the soaking, steaming, and SSF processes of glutinous rice were studied by LF-NMR. On the basis of the intimate connection between proton dynamics and microstructure variations during SSF, we established a standardized SSF process of glutinous rice, which may aid in the real-time monitoring of other similar SSF processes of starch systems.

MATERIALS AND METHODS

Materials. Commercial glutinous rice from Jiangsu Province was obtained from a local market (approximately 77% amylopectin, 7.3% protein, and 13% water). The starter culture, sweet koji (Xiao Qu), was kindly provided by Suzhou Cereals, Oils and Foodstuffs Corporation (Suzhou, P. R. China). The starter culture contains *Rhizopus*, *Mucor*, and eight other strains of yeast. All other chemicals were of analytical grade and were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA).

Preparation of Fermented Glutinous Rice. Glutinous rice was rinsed several times with water to remove powders and soluble matters, and then it was soaked in deionized water at a ratio of 1:3 (w/w) for 6 h at 20 °C. The water was then discarded, and the soaked glutinous rice was steamed in a Midea WSYH26A electric saucepan at 100 °C (Midea Co., Ltd., Guangdong, China) for 20 min. Glutinous rice was then cooled by rinsing with cold sterile water and mixed with sweet koji (preground into powder) at a ratio of 1:100 (w/w; 700 g of dry glutinous rice to 7 g of sweet koji powder). The inoculated glutinous rice was placed into a bowl, the central part of which was hollowed out to guarantee the oxygen supply for the bottom part. The inoculated glutinous rice was then incubated at 30 °C with humidity of 90% in an incubator. The fermentation normally lasts approximately 36−48 h. However, the fermentation duration was prolonged to 54 h to obtain a full understanding of the alternations that occur in glutinous rice during SSF.

Reducing Sugar (RS) Analysis. Estimation of the total reducing sugars was performed by the 3,5-dinitrosalicvlic acid (DNS) method.[29] Samples (1 g) taken out at different fermentation times were homogenized with 50 mL of distilled water. The mixture was then incubated in a water bath at 50 °C for 20 min for better extraction of reducing sugars. After incubation, the mixture was centrifuged in a CT15RT centrifugal filter system (Techcomp Co., Ltd., Shanghai, China) at 8000*g* for 5 min to obtain a supernatant. The supernatant was then diluted with water to 100 mL. Aliquots (1 mL) of the supernatant were placed into test tubes, and 2 mL of DNS reagent was added. The mixture was boiled for 5 min and then cooled to room temperature. Absorbance of the samples was recorded at 540 nm using a Multiskan GO spectrophotometer (Thermo Fisher Scientific Co., Ltd., Waltham, MA, USA). All of the experiments were conducted in triplicate.

Determinations of Titrable Acidity (TA). Fermented glutinous samples (25 g) from different fermentation times were homogenized with 225 mL of distilled water and incubated for 30 min for better extraction of acidoids. The TA (°T, expressed as Thorner degree; °T × 0.009 = lactic acid %) of the different samples was measured according to the method of Cen et al.[30] All of the experiments were conducted in triplicate.

Determinations of Moisture Content (MC). Samples (10 g) were taken from the central part of the rice and placed into a BAO-80A high temperature drying oven (STIK Co., Ltd., Shanghai, China). The drying process was conducted at 105 °C, and the samples were dried to a constant weight. MC was defined as the ratio of the weight loss during drying and the original weight of each sample. All of the experiments were conducted in triplicate.

Deuterium Oxide (D_2O) Experiments. To distinguish between exchanging protons and nonexchanging protons, deuterium oxide (D_2O) experiments were performed based on the method of Bosmans with slight modifications.[25] Raw glutinous rice (2 g) was soaked in excess D_2O for 12 h and subsequently decanted to a Labconco freezone 12 L console freeze-dry system (Labconco Co., Ltd., Kansas City, MO) for vacuum freeze-drying at a temperature of −50 °C for 24 h. The samples were then rehydrated by excess D_2O. For steamed rice, the samples were vacuum freeze-dried and then rehydrated by D_2O. Both cycles were repeated three times. Control experiments were performed with water instead of D_2O to correct for the impact of the exchange method on the proton distribution of the sample.

Low-Field Nuclear Magnetic Resonance Measurements. A 22.4 MHz NMR analyzer PQ001 (Niumag Co., Ltd., Shanghai, China) was used to perform low-field nuclear magnetic resonance (LF-NMR) measurements. Approximately 2.5 g of different fermented glutinous rice samples was taken from the central part of the rice curd and placed into 15 mm NMR glass tubes. The tubes were then heated to 32 °C in a water bath for 5 min and inserted into the NMR-probe. T_2 relaxation times were measured using the Carr−Purcell−Meiboom−Gill (CPMG) sequence. The T_2 measurements were performed with a τ-value of 100 μs (time between 90° and 180° pulses). Data from 5000 echoes were acquired as 16 scan repetitions, and the repetition time between two successive scans was 5 s. The relaxation measurements were performed at 32 °C.

MultiExp Inv Analysis software (Niumag Co., Ltd., Shanghai, China) was employed for data analysis. The MultiExp Inv Analysis software performs distributed exponential curve fitting. A continuous distribution of exponentials for a CPMG experiment is defined by the following equation:

$$R_{\mathrm{mag}}(t) = \sum_{j=1}^{n} P_{2j} \exp\left(\frac{-t}{T_{2j}}\right) + e(t) \quad (1)$$

where R_{mag} is the residual magnetization as a function of acquisition time t, P_{2j} and T_{2j} are the spin−spin relaxation amplitude and time, respectively, of the jth component, and e is the residual error. For a better fit, multiexponential fitting analysis was performed on the relaxation data according to a modified inversion method of Xiao et al.[31] The relaxation time T_{2i} and its corresponding water population (area ratio) M_{2i} were recorded. Each cycle (testing and inversion) required less than 2 min, and 10 parallel samples of each fermentation time were measured.

Statistical Analysis. Statistical analyses were carried using with SPSS version 18.0. To evaluate the difference between means, one-way ANOVA was used followed by Duncan's test. The significance levels were defined as * ($p < 0.05$) and ** ($p < 0.01$). A principal component analysis (PCA) model was performed using Simca-P+ software (Umetrics AB) to identify cluster patterns. Sigmoid fitting was performed with Origin 8.1. An adjusted determination coefficient (Adj R^2) was used to evaluate the fitting degree with Adj R^2 defined as follows:

$$\text{Adj } R^2 = 1 - \frac{(n-1)(1-R^2)}{n-m} \quad (2)$$

where R^2 is the original determination coefficient and n and m are the numbers of sample and variables, respectively.

RESULTS AND DISCUSSION

LF-NMR Analysis of Raw, Soaked, and Steamed Glutinous Rice. The soaking and steaming pretreatments of glutinous rice are essential for further fermentation and sensory attributes of the final product. However, an in-depth understanding of the proton dynamics and interactions between water and macromolecules during soaking and steaming is still lacking. Figure 1 shows the relaxation time distribution curves of unsoaked glutinous rice (with 13% water content). Three proton fractions in raw glutinous rice were found in this study. As shown in Figure 1, T_{2b} was the fastest fraction, with a relaxation time of approximately 0.4 ms and accounted for more than 90% of the total signal. T_{21} was the intermediate fraction (approximately 5% of the total signal) with a relaxation time of approximately 5 ms, whereas T_{22} was the slowest and had the minimum fraction, with a relaxation time of approximately 25 ms (less than 1.5% of the total signal).

The interpretation and origin of the T_2 transverse relaxation of heterogeneous systems have been studied extensively. In general, multiexponential relaxation behavior of various food matrixes can be ascribed to different water fractions that exist in heterogeneous microstructures and protons of biopolymer.[13,15] Previous studies have shown that protons in starch systems can be differentiated into several distinct populations through their

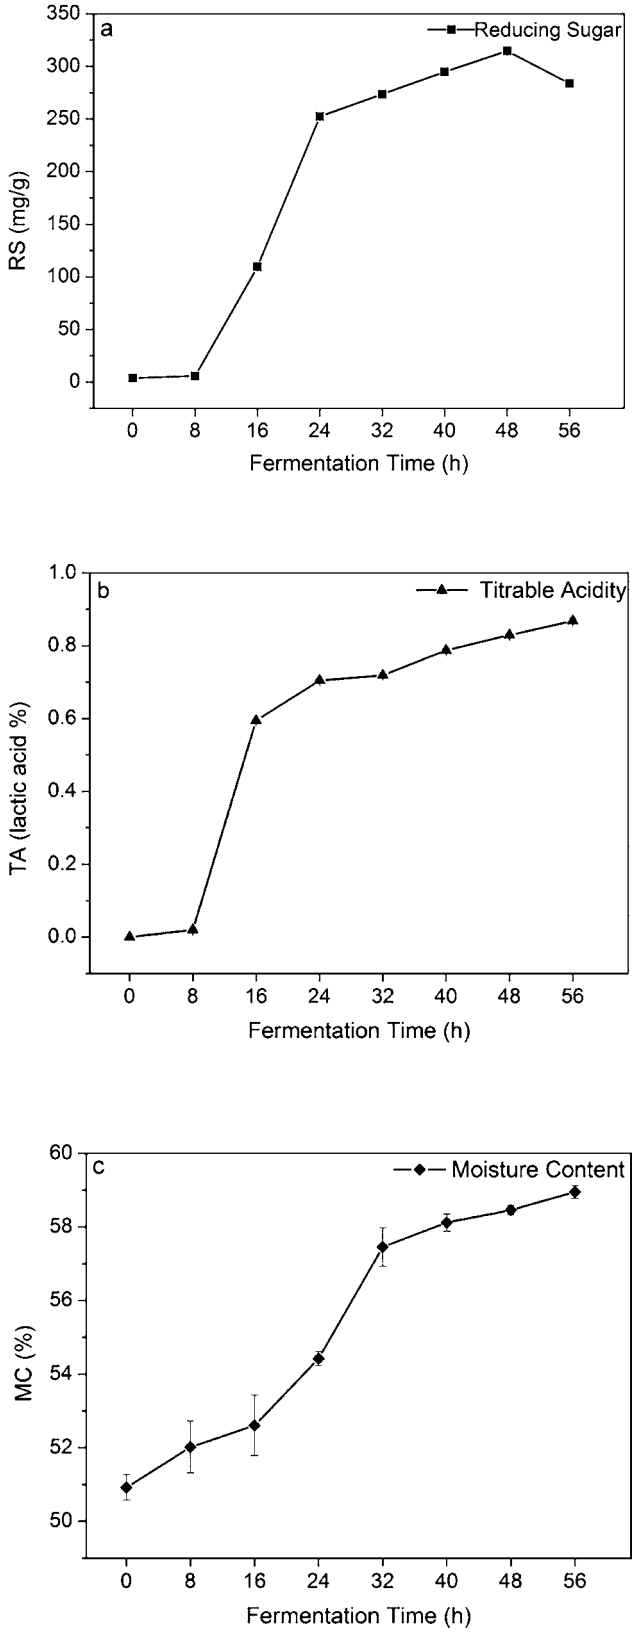

Figure 3. Variations of three traditional parameters during SSF: (a) total reducing sugar, (b) titrable acidity, (c) moisture content.

NMR relaxation behavior, which provides unique insight into the microstructure of the starch. Additionally, glutinous rice contains approximately 7.3% glutelin, which may also play a role in the formation of the microstructural network. The result

of the D_2O experiment using raw samples is shown in Figure 1. The T_{21} and T_{22} fractions nearly disappeared in the soaked rice–D_2O sample, indicating that the protons of these two fractions were exchangeable. T_{2b}, the fastest fraction of the CPMG sequence, contained both nonexchangeable and exchangeable protons, which corresponded well with the report of Bosmans et al.[25] On the basis of the D_2O experiment and a previous study of waxy starch models, it is reasonable to propose the origin of three proton fractions in raw glutinous rice.[25] The slowest exchangeable fraction, T_{22}, was ascribed to mobile bulk water existing in the extragranular space between the granules. In view of its small proportion and fast relaxation time, this water fraction should exist as a thin layer between closely packed granules and is influenced by the interaction between biopolymer and water molecules. By diffusion from the bulk to the biopolymer interface acting as a relaxation sink, the T_2 values of the T_{22} water fraction are controlled by diffusive exchange. The intermediate component T_{21} can be ascribed to intragranular confined water that is in slow exchange with outside water on the NMR measurement time scale of a few hundred milliseconds such as water in amorphous growth rings of the granule.[24] This fraction should also include exchangeable protons of amylopectin and glutelin, including sulfydryl, hydroxyl, and carboxyl protons. According to the D_2O experiment, the T_{2b} fraction contained both nonexchangeable protons and exchangeable protons. Thus, the fastest fraction, T_{2b}, can be assigned to the nonexchangeable protons of amylopectin and glutelin, which do not have extensive contact with water such as CH protons in amorphous parts of the granule.[25] In addition, the T_{2b} fraction should also include water molecules trapped within starch or glutelin, which is regarded as an integral part of these macromolecules. The relaxation time of these water molecules is controlled by a rapid chemical exchange with the protons of biopolymers. Meanwhile, these water molecules are in slow exchange with outside water molecules,[13,17] which can be exchanged by D_2O and were mainly responsible for the signal loss of T_{2b} in the D_2O experiment.

Horigane et al. studied the soaking process of rice using gradient echo magnetic resonance imaging and found that despite the different penetration routes, water could diffuse to nearly all parts of the rice.[32] However, imaging cannot provide detailed information about changes in the proton distributions in the granular substructures. Figure 1 presents the relaxation time distribution curves of raw glutinous rice after soaking (with moisture content of approximately 40%). Because the soaking of rice does not involve irreversible chemical changes, we postulate that the assignments of different fractions were similar to that of unsoaked rice. Four fractions were detected in the soaked sample. The slowest fraction should be superficial water of the sample. This assignment was confirmed by the fact that this fraction vanished after using a hot-air blower to dry the soaked sample for 30 s (data not shown). The populations of the other three fractions showed a dramatic change in the soaked sample compared to the unsoaked sample. As shown in Figure 1, after soaking, the signal amplitude and relaxation time of the T_{22} fraction increased, which indicated that more water existed in the interstitial space of the granules. Moreover, the T_{21} fraction became the major fraction, and the T_{2b} fraction lost nearly half of its signal. Thus, the changes in the proton distribution were caused by water penetration because the moisture content of the rice increased to approximately 40%. Soaking allowed more water to penetrate into the granules and interact with protons of the T_{2b} fraction, and some T_{2b} protons became more mobile. The increase in the T_{21} population implied that the water absorbed by the starch mainly existed in the substructure of the granules.

The gelatinization of starch occurs when the starch granule is heated with water, and it is a process where the granule loses its crystallinity and its internal structure turns amorphous.[33] After gelatinization, the starch forms a three-dimensional network microstructure, which can be characterized by numerous holes and meshes with different diameters.[34] The multiexponential fitting relaxation curve of the steamed glutinous rice is shown in Figure 2 (with moisture content of 51%). The steamed sample still presented three fractions (T'_{2b}, T'_{21}, and T'_{22}), which were named after the order that they appeared in the time scale. The T'_{21} and T'_{22} fractions consisted of exchangeable protons because they had a low intensity in the D_2O experiment. The T'_{2b} fraction maintained part of its signal after exchanging with D_2O, indicating that it contained both exchangeable and nonexchangeable protons. Thus, the T'_{2b} fraction can be assigned to integrated water and protons of biopolymers, which were in the inner space of the starch–glutelin gel framework. The T'_{2b} population increased and accounted for approximately 15% of the total signal, which presumably reflected the swollen and broken granules. As the sample was heated in excess water, water was absorbed into the starch–glutelin gel framework and became an integral part of the biopolymer during gelatinization. In addition, protons of the biopolymers were embedded in the gel framework by gelatinization and contributed to the increase in the T'_{2b} population. The T'_{21} fraction, which accounted for approximately 7% of the total signal, can be ascribed to the water present in the small meshes of the rice microstructure and exchangeable protons of biopolymers. The T'_{22} fraction can be assigned to bulk water located in large meshes and can be considered to be controlled by diffusive exchange. For some starch systems that contain amylose, the heating process would lead to the merging of the T'_{21} and T'_{22} fractions and result in only two peaks. Unlike those starch systems, steamed glutinous

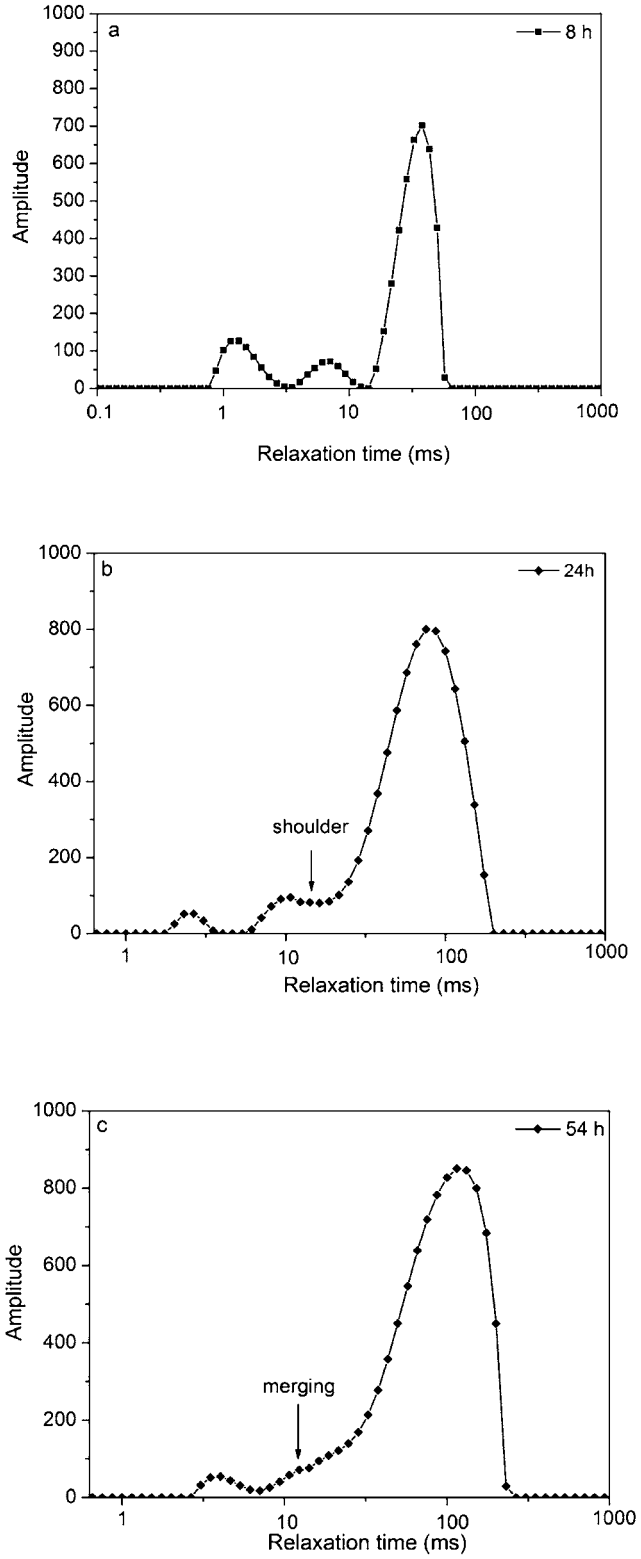

Figure 4. LF-NMR T_2 relaxation time distribution curves of samples at different fermentation times: (a) 8 h, (b) 24 h, (c) 54 h.

rice still presented three peaks, which was in accordance with the results derived from a waxy starch model.[25] Bosmans et al. suggested that the amylopectin has high swelling power and is disrupted more easily during heating. Heat-induced amylopectin gel forms a better developed three-dimensional network, microstructure with large meshes providing sufficient space for different proton fractions without averaging the diffusion.[25] The relaxation time of T'_{22} increased to approximately 51 ms, implying that the T'_{22} water was located in a more mobile microenvironment than in the raw and soaked samples due to the swelling and gelatinization effects of starch. Furthermore, more water was absorbed into the rice resulting in the T'_{22} fraction becoming the major fraction (accounted for approximately 78% of the total signal). Thus, the effects of soaking and steaming of glutinous rice is well reflected by the T_2 values, which provide detailed information about the proton dynamics during soaking and steaming.

Solid-State Fermentation of Glutinous Rice. The SSF of glutinous rice is a process by which starch is partially broken down and converted into reduced sugar (RS), alcohol, and other metabolites. During this process, filamentous fungi in koji are mainly responsible for generating hydrolases to convert starch to fermentable sugars for the subsequent ethanol fermentation performed by the yeast.[2] Figure 3a presents the changes of RS during fermentation. Because of the lag phase of fermentation, the RS remained at low levels (approximately 0.5 mg/g) in the first 8 h of fermentation before surging to more than 300 mg/g. After 48 h, the RS content decreased to 283 mg/g, indicating the start of the stationary phase. In addition to RS, microorganisms also produce organic acids such as lactic acid.[35] Figure 3b shows the variations of TA during SSF. In general, the TA presented similar tendency compared with RS, except that its surging point came earlier at approximately 8 h. Moisture content is another important parameter in SSF. Because of the metabolism of fungi and yeast, the MC of the glutinous rice increased from 50% to 57% during the fermentation period (Figure 3c). Compared to the LF-NMR measurements, the measurements of the three traditional parameters are time-consuming. In addition, the traditional parameters are unable to provide detailed information about biopolymer interactions, water dynamics, and microstructure changes during SSF.

The variation of the major fraction, T'_{22}, is shown in Table 1 and Figure 4. As mentioned previously, the T'_{22} fraction represents the water molecules that exist in large interstices or meshes of the microstructure of rice. During the first 8 h of fermentation, the T'_{22} relaxation time decreased significantly from 51 to 35 ms. We postulate that the decrease in T'_{22} relaxation was irrelevant to the changes of the microstructure because the effects of fermentation on rice should be insignificant considering the amount of water and metabolites (TA and RS) that they produced in the lag phase of fermentation. Starch retrogradation has been previously shown to result in a decrease of T_2 relaxation times in a starch system.[28] However, this assumption is not valid for the current conditions because the retrogradation of amylopectin belongs to the long-term retrogradation.[36] Thus, retrogradation did nearly not impact the T'_{22} relaxation time during the first 8 h of SSF. Considering the aforementioned facts, we propose that the decrease of T'_{22} relaxation time can be ascribed to the interactions between the water and macromolecules dissolved in the T'_{22} water. During the first 8 h, several macromolecules produced by microorganisms, such as maltodextrin, extracellular enzymes, and glutelin that were partially resolved by fungi, were dissolved and hydrated in the T'_{22} water fraction, which acted as a solution. The T'_{22} water molecules interacted with these macromolecules, leading to less mobility of the T'_{22} fraction and lower values of its relaxation time. After 8 h, the T'_{22} relaxation time presented an upward tendency, increasing

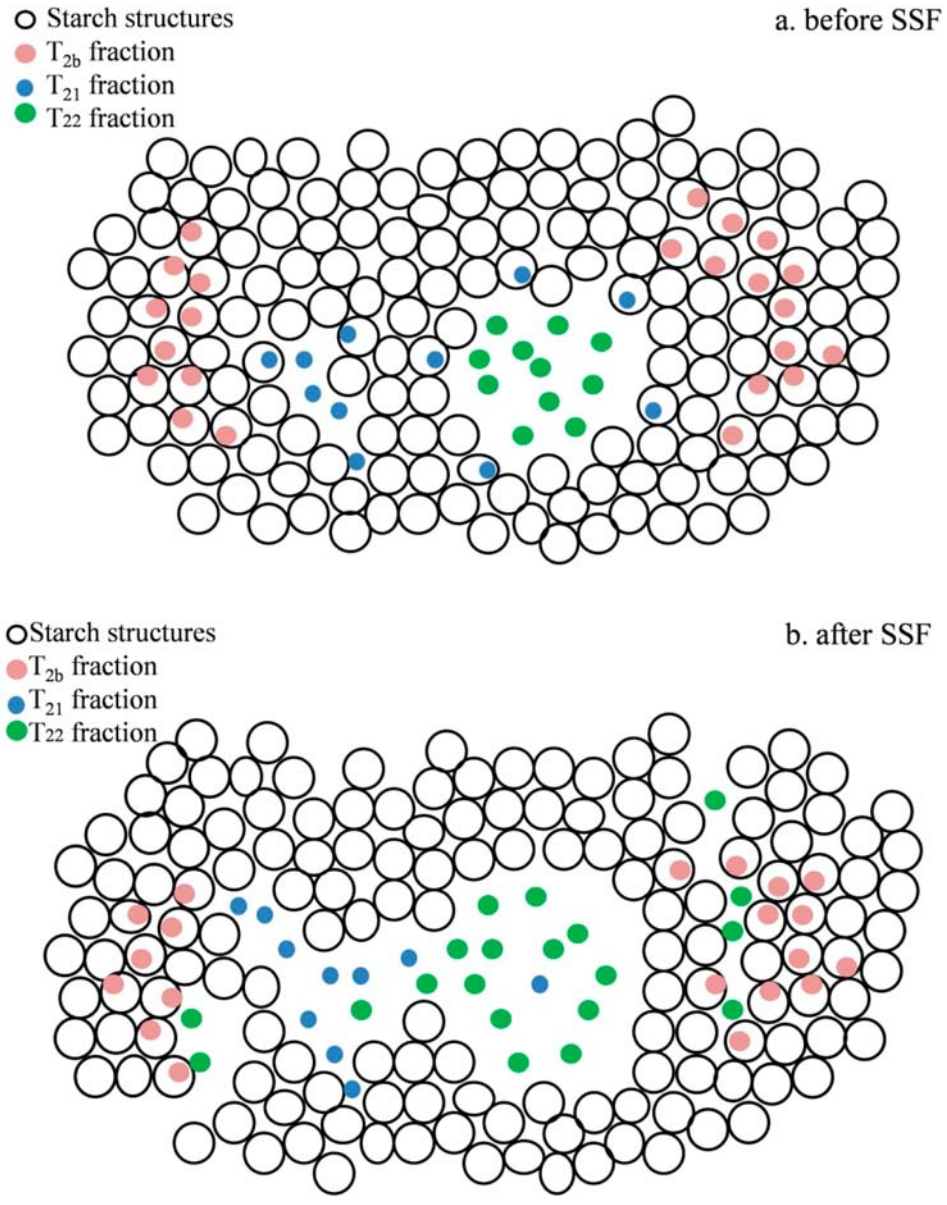

Figure 5. Simplified models to explain variations of the rice microstructure during SSF. Color-coded circles represent protons of different fractions: (a) before SSF, (b) after SSF.

from 35 to 113 ms, implying that the T'_{22} fraction was in a more mobile state. The significant influences of microorganisms on the microstructure of starch systems have been widely studied.[37,38] On the basis of variations in RS, TA, and MC, we speculate that the activities of fungi and yeast during fermentation lead to the change of microstructure and the increased T'_{22} relaxation time. To interpret the microstructure changes of glutinous rice, a simplified model was established. As shown in Figure 5, starch was consumed by microbial metabolism during fermentation, thus expanding the large interstices and meshes providing more space for the T'_{22} fraction. Moreover, the carbon dioxide produced by yeast may have also expanded the interstitial space of the microstructure.[38] Thus, we propose that these two factors increased the distance between the T'_{22} water molecules and the biopolymer interface, resulting in more mobile microenvironments in the T'_{22} fraction and higher values of its relaxation time. Although the MC of the sample increased by 7%, only the T'_{22} fraction population increased from 78% to 93% during SSF. This phenomenon indicated that the water produced by fermentation mainly diffused into the large meshes and became the T'_{22} water fraction, resulting in the increase of the T'_{22} population. As shown in Figure 4b, the rice microstructure became less homogeneous after fermentation because its peak broadened. This change also demonstrated the effects of fermentation on the microstructure of rice.

The intermediate fraction T'_{21} had a relaxation time that maintained an upward tendency. Although the lag phase of fermentation also influenced the T'_{21} fraction, which was reflected by the decrease in the relaxation time at 8 h, its impact was not as significant as that on the T'_{22} fraction because the relaxation time of the T'_{21} fraction at 16 h had exceeded its initial value. Similar to T'_{22} during fermentation, larger microenvironments were available for the T'_{21} fraction, leading to an increase of its relaxation time. Tang et al. found that the peak representing the intragranular water shifted to a longer

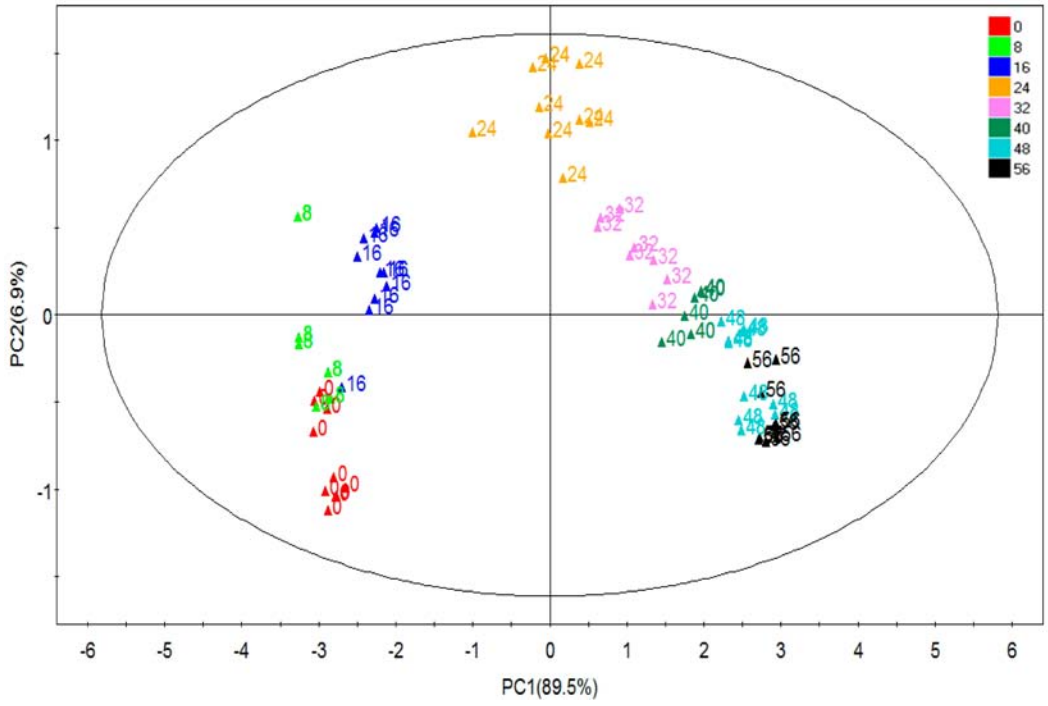

Figure 6. PCA plot obtained using distributed NMR T_2 relaxation data of all the samples (n = 80).

relaxation time during the acid hydrolysis of potato starch, and they ascribed the variation to an increased amount of water inside the granules.[24] However, the population of the T'_{21} fraction, which was different from that of the T'_{22} fraction, fluctuated during the first 24 h and then decreased slightly to approximately 5.6%. It was difficult to obtain detailed information on the variation of the T'_{21} population during fermentation because it was assigned to both water in the small meshes of the gel and exchangeable protons of biopolymers. Nevertheless, the T'_{21} population did not change considerably during fermentation. Moreover, the peaks of T'_{21} and T'_{22} were correlated with the fermentation time. After 24 h, there was a shoulder between the T'_{21} and T'_{22} fractions (Figure 4b). At 54 h, these two peaks completely merged into one (Figure 4c). Ideally, the distribution of proton relaxation times should be equivalent to the distribution of proton fractions in different microcompartments. However, the NMR signals of neighboring compartments can be averaged by the fast water diffusion between them. As a consequence, most water fractions in different microcompartments cannot be distinguished in time domain NMR, and the fractions can only be distinguished if their microstructural barriers exist because they can hinder the intercompartment water diffusion.[23] Thus, the independent signals of T'_{21} and T'_{22} fractions rely on the barriers that hinder the water exchange between them. The signals of the T'_{21} and T'_{22} water fractions were averaged by the fast diffusion between them, leading to the merging the T'_{21} and T'_{22} peaks. The diffusion averaging of the T'_{21} and T'_{22} fractions strongly indicated that the barriers between these two fractions were digested by fermentation, thereby reflecting the influence of SSF on the microstructure of rice (Figure 5b).

The T'_{2b} relaxation time increased from 0.8 to 3.6 ms, which may also be explained by the effects of SSF on the microstructure of rice. Before SSF, the strands of starch and protein network were well structured, thus preventing water molecules from penetrating in and interacting with the T'_{2b} fraction. Because of the activities of the microorganisms in fermentation, the structure of the starch and protein network may have been eroded by amylase and organic acid, allowing water to penetrate in and interact with the T'_{2b} fraction (Figure 5b). As more T'_{2b} protons associated with water penetrated into the fraction, the T'_{2b} population decreased from 15% to 1.3% along with increasing fermentation time.

LF-NMR provides unique insight into the soaking and SSF processes of glutinous rice. The variations of T_2 values during SSF can be ascribed to the microstructure changes of the rice. A PCA was performed using the T_2 parameters from different time intervals of the fermented samples to summarize the variation in the LF-NMR relaxation data. PC1 explained 89.5% of the variation in the data and clearly discriminated according to the different fermentation times (Figure 6). PC2 explained 6.9% of the variation in the data, which was considered to be largely due to the variation among replicates. There was a significant separation between the 16 and 24 h samples, indicating that the exponential phase of fermentation evaluated by LF-NMR began at approximately 16 h, which was 8 h later than suggested by the TA and RS measurements. It is reasonable that only metabolism proceeding to a certain extent may significantly change the microstructure. Thus, the microstructure changes were not significant until 24 h. The mixing of samples from 48 and 56 h implied that the sample microstructure did not change considerably during the stationary phase though fermentation. The mean values of the T_2 parameters were employed to establish mathematical models for SSF of glutinous rice. As shown in Figure 7, a cubic curve was the best fit for the relationship between the T'_{22} relaxation time and fermentation time. The relationships between the other parameters and fermentation time can be well explained by Boltzmann fitting, which is expressed by following equation:

DOI: 10.1021/acs.jafc.5b00769
J. Agric. Food Chem. 2015, 63, 3261−3270

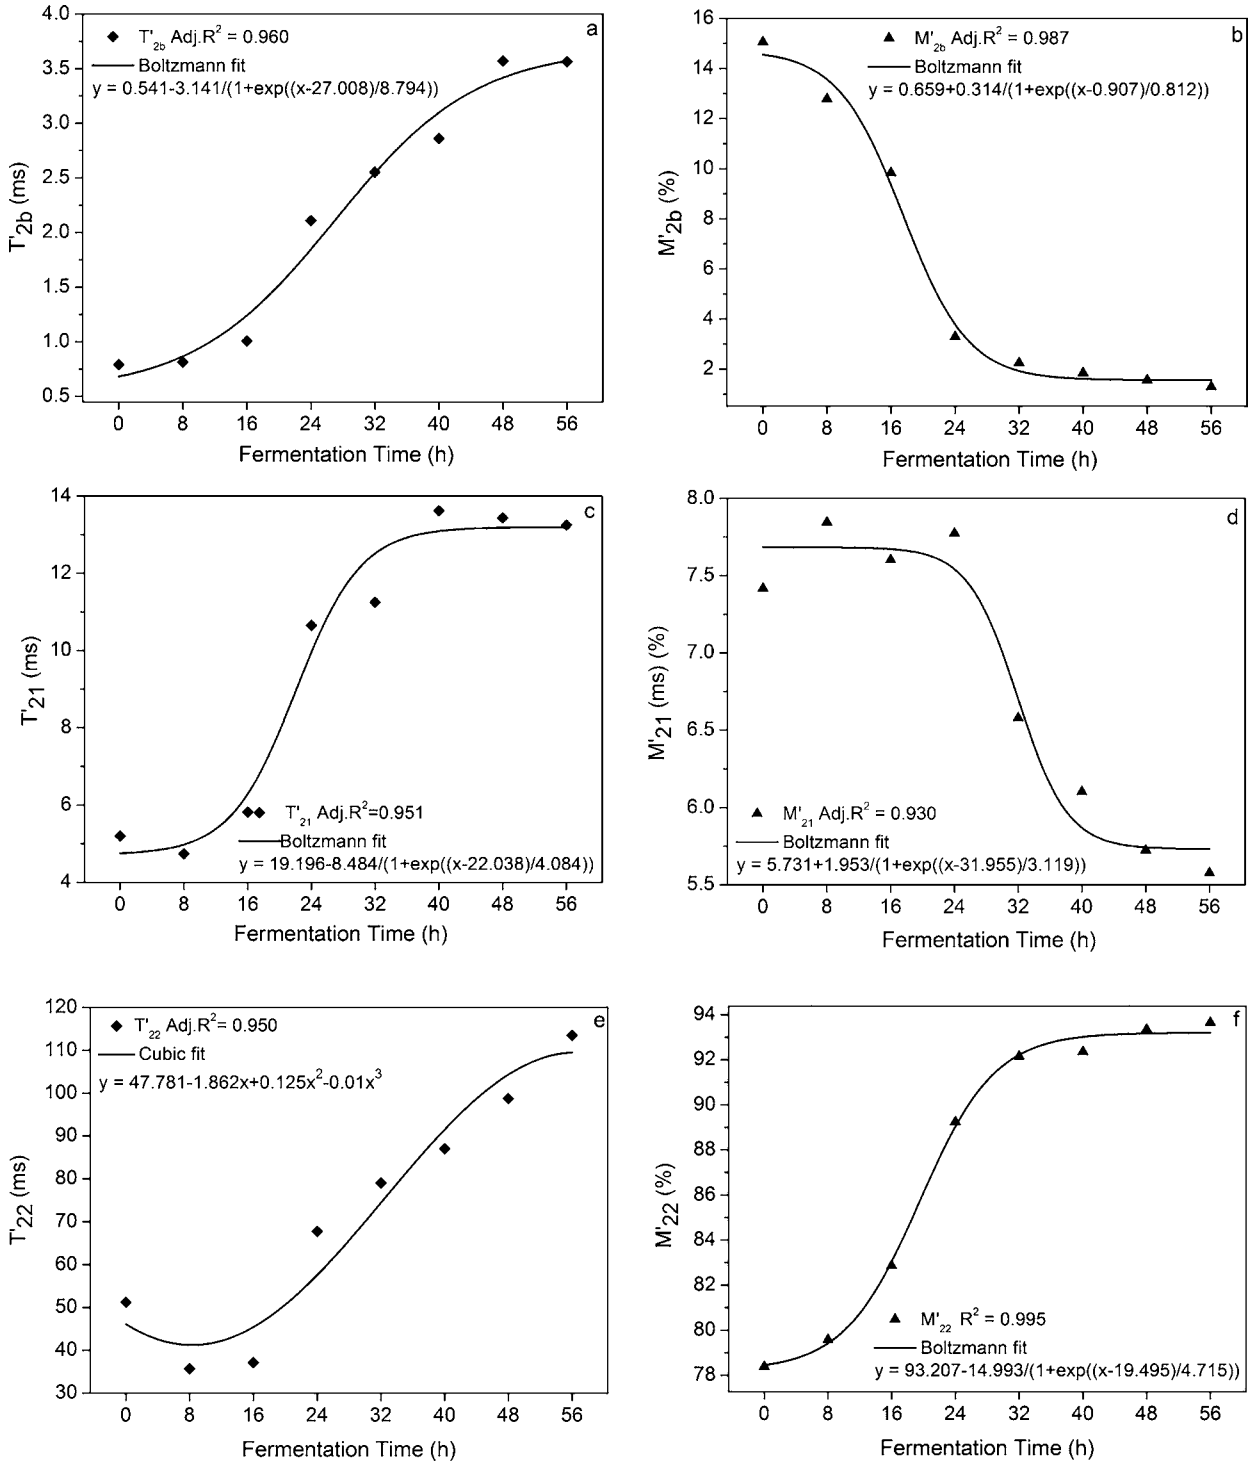

Figure 7. Fitting curves and equations of different T_2 parameters (n = 8) versus fermentation time: (a) T'_{2b}, (b) M'_{2b}, (c) T'_{21}, (d) M'_{21}, (e) T'_{22}, and (f) M'_{22}.

$$y = \frac{A_1 - A_2}{1 + e^{(X - X_0)/dx}} + A_2 \quad (3)$$

Interestingly, the fitting curves of the T_2 parameters were similar to the microbial growth curve. In conclusion, the present study demonstrated that the effects of SSF on glutinous rice can penetrate into the inner space and significantly change the microstructure rather than just affecting the surface. Thus, LF-NMR can be used to monitor the SSF of starch systems.

representing the deviation from ideality. These two coefficients are linked by the equation

$$K_i = \frac{y_i}{x_i} = \frac{\gamma_i \times P^0_{i(T)}}{P_T} \quad (3)$$

where x_i and y_i are molar fractions in the liquid and gas phases, respectively, $P^0_{i(T)}$ is the vapor pressure of pure component i at a given temperature T (Pa), and P_T is the total pressure (Pa).

Generally, K_i is measured at fixed temperature, pressure, and volume after the system reaches equilibrium. The most widely used methods for determining the partition coefficient can be divided into three groups: differential methods,[21−23] dynamic headspace methods,[24,25] and static methods.[26−33] No available methods are valid for complex matrices or for all aroma compounds regardless of their volatility. Moreover, some determination methods are technically difficult to implement or require external calibration.[34]

H_2S as a pure compound is very volatile, with a vapor pressure of 1698 kPa at 290 K.[35] Therefore, existing methods are not appropriate for the determination of its partition coefficient. Indeed, its very high volatility makes precise calibration and quantification by chromatographic methods very difficult, so the first step of this study was the development of a novel method that could be described as a "semistatic method" specifically to measure the partition coefficient of H_2S. The values of K_{H_2S} were first determined in water to validate the method and for comparison with published data. The method was then applied to synthetic media that simulated must, fermenting musts at different stages of fermentation, and wine. The effect of temperature on the partition coefficient of H_2S (K_{H_2S}) was also assessed. Finally, a model was established to calculate K_{H_2S} in enological conditions throughout alcoholic fermentation.

MATERIALS AND METHODS

Gas Standard. The H_2S standard gas was manufactured by Air Products SA (Paris, France): it consists of a gas cylinder of 3.074 Nm^3 at 162 bar with a precise H_2S concentration of 9.21% (i.e., 92 100 ppmV) in nitrogen.

H_2S standard gas was diluted with a binary gas dilutor LNI SONIMIX 6000C1 from LNI Schmidlin SA (Geneva, Switzerland), based on high-precision mass flow controllers and mechanical pressure regulators, with a glass dilution chamber and fluidics for perfect homogeneity. Air zero (99.9999% purity) for H_2S dilution was purchased from LINDE (Saint-Priest, France).

Dissolved H_2S Measurement. H_2S dissolved in liquid phases was assayed in situ using an amperometric microsensor purchased from AMT Analysenmesstechnik GmbH (Rostock, Germany). This H_2S probe allows precise and rapid measurement of the liquid concentrations of H_2S and total dissolved sulfides, without sampling and without reagents. The instrument consists of a box for reading and data treatment, linked to an amperometric microsensor covered with a membrane, and another separate probe for pH and temperature measurement. The probe is equipped with a type III microsensor for H_2S measurement in the range from 0.01 to 3 mg/L. The precision is better than 2% of the measured value, and the response time ($t_{90\%}$) is <200 ms.

Media Composition. A buffer solution was prepared containing 6 g/L of citric acid and 6 g/L of malic acid adjusted to pH 3.3 (with NaOH). For the model solution simulating a must, glucose was added to 220 g/L. For the model solution simulating a wine, the buffer solution was made up to 13.2% (v/v) ethanol. For the model solutions simulating musts at different stages of fermentation, the buffer solution was made up to (a) 175 g/L glucose and 2.7% (v/v) ethanol, (b) 132.5 g/L glucose and 5.3% (v/v) ethanol, or (c) 87.5 g/L glucose and 8% (v/v) ethanol. The resulting five media corresponded to 0, 20, 40, 60, and 100% progression of fermentation.

Determination of Gas−Liquid Partition Coefficients. The gas−liquid partition coefficient of H_2S was determined by a "semistatic" method: a gas phase for which the H_2S concentration was perfectly known and constant was continuously bubbled through the stirred liquid phase until the system was driven to equilibrium using the device shown in Figure 1. The concentration of H_2S in the liquid phase was continuously measured with the microsensor. A specially designed glass reactor with a total volume of 0.75 L (shown in Figure 1) was first filled with the liquid phase (500 mL) and regulated to the desired temperature (10, 15, 20, or 25 °C), within ±0.1 °C, by circulating water through the heating/cooling jacket fed by a cryostat Polystat cc1 (Huber, Offenburg, Germany). When the desired temperature was reached in the liquid phase, the gas supply to the reactor was opened with the lowest concentration of H_2S in the gas (H_2S_g; 112 ppmV at ambient temperature). All pipes connecting gas outside and inside the reactor were Sulfinert. Gas was sparged at 2000 NmL min^{-1} in the reactor through a stainless steel 316 L cylindrical porous distributor with a mean pore diameter of 0.5 μm. The liquid phase was stirred magnetically at 250 rpm. The concentration of H_2S in the liquid phase (H_2S_l) was recorded every minute for 20 min. Equilibrium was reached in the liquid phase after 15 min. The value of H_2S at equilibrium ($H_2S_l^*$) was calculated as the mean of five instantaneous values (one value per minute for 5 min after the first 15 min required to reach equilibrium). The procedure for measuring the equilibrium concentration of H_2S in the liquid phase was then repeated for four other values of H_2S_g: 135.4, 158.7, 205.4, and 263.7 ppmV of H_2S at ambient temperature. The H_2S concentrations in the gas studied were thus varied from 112 to 263.7 ppmV, which corresponds to a partial pressure from 1.13×10^{-2} to 2.67×10^{-2} kPa (respecting Henry's law, <200 kPa).[36] At the end of each measurement series (five values of H_2S_g), the reactor was drained. The reactor and the measuring probes (H_2S, pH, and temperature) were thoroughly rinsed with distilled water. The reactor was then refilled with fresh solution for a new set of measurements.

Each set of measurements was done in triplicate, except for media simulating 20, 40, and 60% progression of fermentation, which were measured in duplicate.

DOI: 10.1021/jf505733a
J. Agric. Food Chem. 2015, 63, 3271−3278

At equilibrium, the concentration of H_2S in the gas phase at the reactor inlet ($H_2S_{g(in)}$) was equal to the concentration of H_2S in the gas phase at the reactor outlet ($H_2S_{g(out)}$); in the liquid phase, the H_2S concentration reached an equilibrium (H_2S_l*). The partition coefficient was calculated using eq 2 with H_2S_l* = H_2S_l, assuming that, at low partial pressure (<200 kPa), the solubility of H_2S is strictly given by Henry's law.[36] Losses, which correspond to the amount of compound not accounted for by the measured concentrations of each phase, were not considered; losses were the results of leakage from the sample container, adsorption onto container surfaces, loss during sampling, and/or faulty measurement. Losses from leaks were easy to detect and repair because H_2S is very odorant. Losses due to adsorption onto container surfaces also were minimal because inert materials (Sulfinert tubes, glass, stainless steel 316L) were used. Also, in situ measurement of H_2S using a microsensor is associated with much smaller errors than all methods that involve sample collection, such as chromatography.

RESULTS AND DISCUSSION

Gas–Liquid Partition Coefficient of H_2S in Water. The method for determining the coefficient of gas–liquid partition was applied to distilled water at pH 3.3. It was assumed that the gas was at the temperature of the liquid during bubbling. The concentration values given by the gas dilutor (in ppmV) were systematically transformed to mg/L and adjusted for the temperature using the general equation

$$H_2S_g\ (g/m^3) = \frac{H_2S_g\ (ppmV) \times (1.2187 \times 10^{-2}) \times MW}{273.15 + T\ (°C)} \quad (4)$$

where H_2S_g (g/m^3) is the concentration of H_2S in gram per cubic meter of ambient air, H_2S_g (ppmV) is the volume of H_2S per 10^6 volumes of ambient air, MW is the molecular weight of the H_2S (34.01 g mol^{-1} for H_2S), and T (°C) is the ambient air temperature in degrees Celsius.

The corrected values of H_2S_g for the four studied temperatures are given in Table 1. H_2S_l* increased proportionally with the H_2S concentration in the gas whatever the temperature between 10 and 25 °C (Figure 2). The probe gave stable values of H_2S concentration at equilibrium in the liquid (H_2S_l*) for each set of H_2S gas concentrations (H_2S_g). This indicates that there was no accumulation of H_2S, the species to be assayed, in the environment of the sensor. Also, H_2S_l* increased linearly with H_2S_g such that Henry's law was respected whatever the partial pressure of H_2S in the gas input. As the relationship between H_2S_l* and H_2S_g at each temperature was linear, K_{H_2S} corresponded directly to the slope of each regression line (Figure 2). The ratio H_2S_g/H_2S_l* and the value of the gas–liquid partition coefficient of H_2S in water at pH 3.3 were calculated from these results for the four temperatures tested (Table 2). The H_2S_g/H_2S_l* ratio was almost independent of H_2S_g, indicating that even when the concentration of H_2S in the gas increases, the system stayed in the infinite dilution state and that Henry's law was respected. The value of K_{H_2S} obtained at 25 °C was compared with published values for water at the same temperature.

Table 1. Values of H_2S_g Corrected for the Temperature and Corresponding to the Values of H_2S_g at the Output of the Gas Dilutor

H_2S_g from gas dilutor: temperature (°C)	H_2S_g (mg/L) 112.0 ppmV	135.4 ppmV	158.7 ppmV	205.4 ppmV	263.7 ppmV
10	0.164	0.199	0.233	0.302	0.387
15	0.162	0.195	0.229	0.296	0.380
20	0.159	0.192	0.225	0.291	0.374
25	0.156	0.189	0.221	0.286	0.368

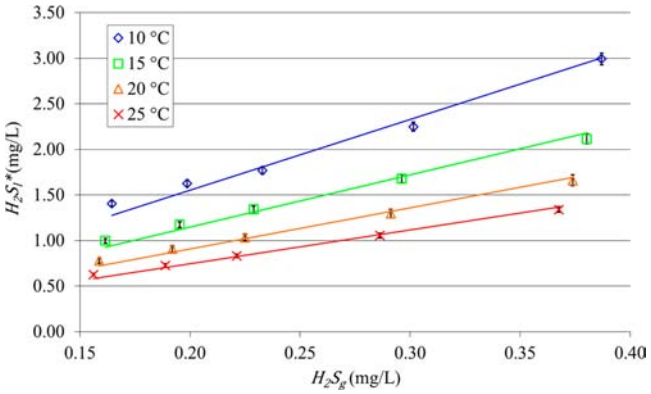

Figure 2. Changes in the H_2S concentration at equilibrium in water at pH 3.3 as a function of H_2S concentration in the gas phase, at 10, 15, 20, and 25 °C.

A compilation of published Henry's law data gives a value of k_H^{cp} = 0.1 mol kg^{-1} bar^{-1} for H_2S in water at 25 °C.[36−45] k_H^{cp} is defined as

$$k_H^{cp} = \frac{c_{l(i)}}{p_{g(i)}} \quad (5)$$

where c_l is the concentration of a species (i) in the liquid phase and $p_{g(i)}$ is the partial pressure of that species in the gas phase.

Henry's law constant can also be assimilated to the partition coefficient at infinite dilution of the species of interest expressed as the dimensionless ratio between its aqueous-phase concentration (c_l) and its gas-phase concentration (c_g)

$$k_H^{cc} = \frac{c_{l(i)}}{c_{g(i)}} = k_H^{cp} \times R \times T = \frac{1}{K_i} \quad (6)$$

where R is the gas constant and T is the temperature.

From eq 6, with R = 8.314 m^3·Pa mol^{-1} K^{-1} = 8.314 × 10^{-2} L·bar mol^{-1} K^{-1} and T = 25 °C = 298.15 K

$$K_{(H_2S)} = 1/(k_H^{cp} \times R \times T)$$
$$= 1/(0.1 \times (8.314 \times 10^{-2}) \times 298.15)$$
$$= 0.403$$

This value of 0.403 for K_{H_2S} obtained from the data in the literature differs substantially from the value of 0.265 that we obtained experimentally. This difference may be a consequence of these values of gas–liquid ratios not being determined at the same pH; indeed, the effect of the pH of the water is critical. Three ionic forms of H_2S coexist in the liquid phase (H_2S, HS^-, S^{2-}) with pK_1 = 6.97 and pK_2 = 12.90; their relative abundance depends of the pH (see Figure 3). At pH <5.0, H_2S is present in the form of an undissociated molecule, soluble in water. As the pH increases above pH 5.0, the concentration of the undissociated H_2S decreases, in a predictable manner, by dissociating to form the acid sulfide ion (HS^-); under alkaline conditions at pH >9.0, HS^- further dissociates, giving sulfide ions (S^{2-}). HS^- and S^{2-} are completely unable to partition

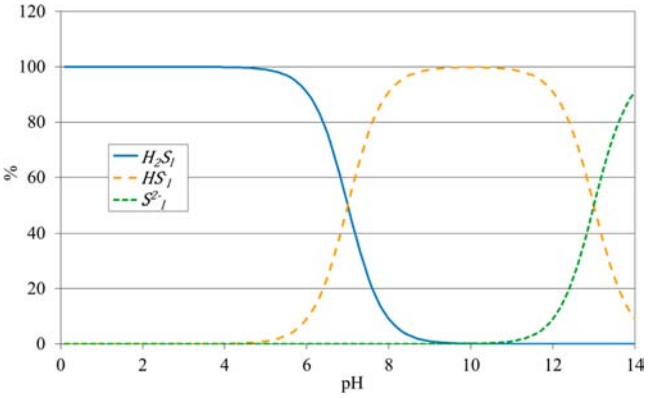

Figure 3. Changes in the equilibrium between the ionic species H_2S, HS^-, and S^{2-} as a function of pH.

from the water to the gas phase. Consequently, any H_2S in the gas phase coming into contact with an alkaline aqueous medium will, in addition to partitioning into the water, dissociate to the stable ionic species and continue to do so until the partitioning and dissociation reactions reach an equilibrium; this equilibrium state may or may not include the existence of H_2S in the gas phase. With knowledge about this phenomenon, $H_2S_l^*$ values observed experimentally at different pH values can be extrapolated. This approach is possible by using the concentration $H_2S_l^*$ at equilibrium in water at pH 3.3 and 25 °C and the proportion of the H_2S species in water according to the pH value:

$$H_2S^*_{l(pH_X)} = H_2S^*_{l(pH3.3)} \times H_2S_l\% \quad (7)$$

with

$$H_2S\% = \frac{10^{(-pH_X+pK_1)}}{[1 + 10^{(-pH_X+pK_1)}] + 10^{(pH_X-pK_2)}} \quad (8)$$

with $pK_1 = 6.97$ and $pK_2 = 12.90$.[39]

The K_{H_2S} for different pH values at 25 °C can then be calculated, on the assumption that H_2S_g is not affected by changes to the pH. Table 3 gives the results for calculated $H_2S_l^*$ and K_{H_2S} values in water for six values of pH in the range from 3.3 to 9.0 at 25 °C; Figure 4 shows the results of iterative

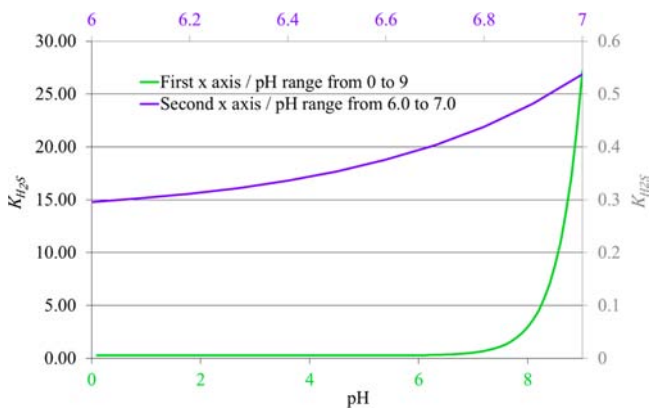

Figure 4. Changes in the K_{H_2S} value in water at 25 °C as a function of pH (first x axis for pH range from 0 to 9 and second x axis for pH range from 6 to 7. Results were obtained from iterative calculation step by step (0.1 pH unit).

calculation step by step (0.1 pH unit) of the changes in K_{H_2S} in water at 25 °C as a function of pH up to pH 9.0, the value at which <1% of H_2S is present in solution. By such calculations, K_{H_2S} was 0.403 (as reported in the literature) for the water at 25 °C when the pH was 6.7 (Figure 4), a pH consistent with that of distilled or deionized water. In all cases, published values fall within the range of K_{H_2S} values calculated from experimental results obtained at pH 3.3 and extrapolated.[36−45] These calculations and observations validate the experimental approach to measuring the partition coefficient of H_2S between liquid and gas. Therefore, this original semistatic method can be

applied to study changes to the H_2S gas−liquid partition coefficient (K_i) during winemaking fermentations.

GasLliquid Partition Coefficient of H_2S in Enological Conditions. Hydrogen sulfide is weakly acidic, and no reactivity has been described between H_2S and any of the species present in media simulating enological solutions (water, citric and malic acids, glucose, and ethanol) at the pH values and temperatures studied in this work. The effects of glucose and ethanol on K_{H_2S} were measured in model solutions simulating fermenting must at the beginning (22% w/v glucose and no ethanol) and end (no glucose and 13% v/v ethanol) of fermentation. As in water at pH 3.3, the H_2S concentration at equilibrium in the synthetic must (A) as in the synthetic wine (B) increased proportionally with the H_2S concentration in the gas at all temperatures considered between 10 and 25 °C (Figure 5). Thus, Henry's law was respected whatever the partial pressure of H_2S in the gas input, and the probe gave stable values of H_2S concentration at equilibrium (H_2S_l*) for each H_2S concentration in the gas (H_2S_g), indicating that there was no accumulation of H_2S around the sensor.

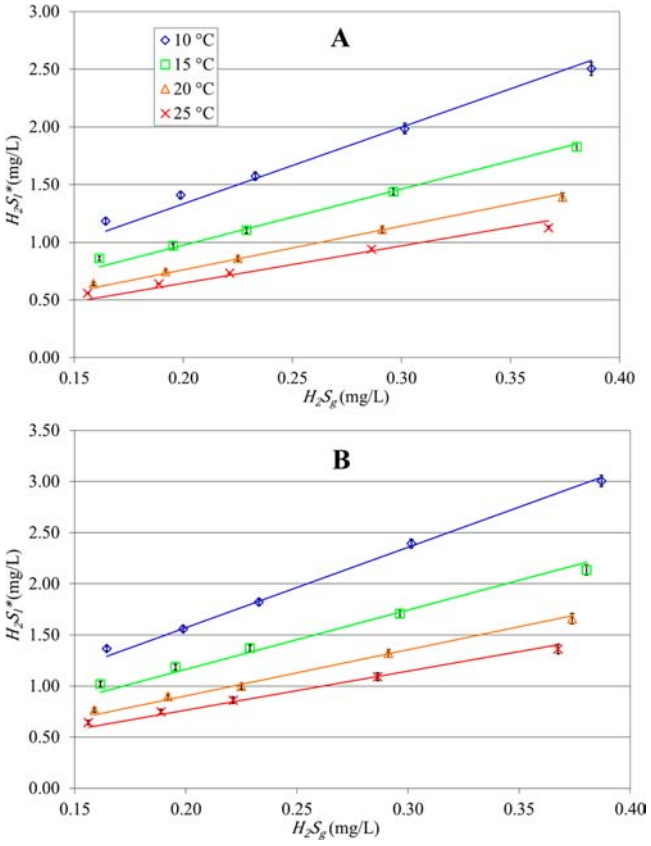

Figure 5. Changes in the H_2S concentration at equilibrium in synthetic must (A) and synthetic wine (B) as a function of the H_2S concentration in the gas phase, at 10, 15, 20, and 25 °C.

The partition coefficients of H_2S in both model solutions (Table 4) were different from those in aqueous solution (Table 2). The effects of the composition of the solution on the partitioning properties of volatile compounds were analyzed by calculating release ratios, expressed as

$$\%\, K_{H_2S_{m/w}} = \frac{K_{H_2S_m} - K_{H_2S_w}}{K_{H_2S_w}} \times 100 \quad (9)$$

where K_{H_2Sm} is the partition coefficient of H_2S in the model solution and K_{H_2Sw} is its partition coefficient in water at the same pH. A positive value indicates that the solute enhances release, whereas a negative value is associated with retention.

The presence of glucose in the model solution raised the partition coefficient of H_2S (Table 4), as observed for other volatile compounds with sucrose.[46,47] Indeed, in our conditions, simulating a grape must, the average (four studied temperatures) relative increase was 17%. However, the salting-out effect of glucose on H_2S was smaller than that observed on aromatic molecules (higher alcohols and esters) in the same enological simulating solutions.[48] The release of H_2S from glucose solution observed here resulted from a salting-out effect of glucose, which forms hydrogen bonds with water molecules, thereby decreasing the activity of the water, lowering the free water content and decreasing the solubility of aroma compounds.[49] Unlike glucose, the presence of 13% ethanol (a typical concentration in wines) did not substantially affect K_{H_2S} values (Table 4); the effect of ethanol on H_2S solubility was very much smaller than the salting-out effect caused by the presence of sugar.

Therefore, at constant temperature, changes in the value of K_{H_2S} during fermentation were mainly due to the decreasing sugar concentration (Figure 6). The gas−liquid partition not only depended on the composition of the liquid phase but was also strongly affected by the temperature (Figure 6). Indeed, the effect of temperature on K_{H_2S} was larger than that of the changes in matrix composition. However, the effect of temperature on the K_i of H_2S was as expected: the concentration ratio increased with the temperature.

Modeling of the Gas−Liquid Partitioning of H_2S during Winemaking Fermentations. The next objective of this work was to develop a model of the evolution of this partition coefficient (K_{H_2S}) between the gas and liquid phases during fermentation.

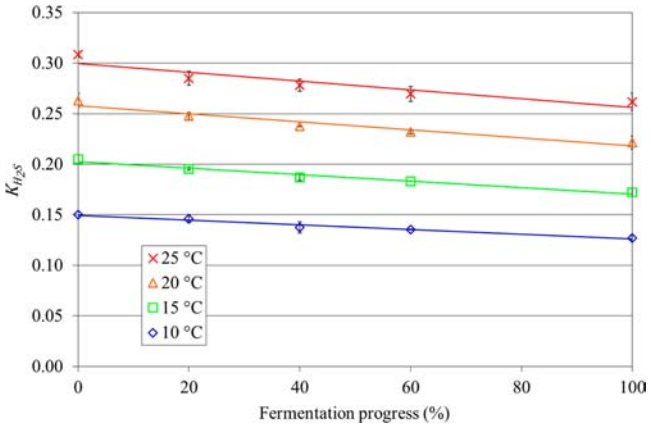

Figure 6. Changes in the K_{H_2S} as a function of the progress of fermentation at 10, 15, 20, and 25 °C.

A multiple linear regression method was chosen to describe the evolution of K_{H_2S} from characteristics of the liquid composition (glucose and ethanol concentrations) and the temperature. The general formula of the multiple linear model adopted was

$$K_{H_2S} = \beta_0 + \beta_1 \times [\text{glucose}] + \beta_2 \times [\text{ethanol}] + \beta_3 \times T + \varepsilon \quad (10)$$

where β_0 is the intercept (or constant), β_1, β_2, and β_3 are the coefficients corresponding to the effects of glucose concentration ([glucose] in g/L), ethanol concentration ([ethanol] in g/L), and temperature (T in °C), respectively, and ε is an independent $N(0,\sigma^2)$ error term.

Model parameters were determined simultaneously by multiple linear regression analysis (Excel software from Microsoft Pack Office Pro 2013) based on the values of K_{H_2S} obtained from all experiments including those in water: thus, all 60 values of measured K_{H_2S} were used to determine β_0–β_3 with the significance threshold set at 0.05. Estimated coefficients of the model parameters identified from eq 10 and test of significance are presented in Table 5. β_1 is of predictive value with a low P value (<0.05); the positive value of this parameter is consistent with the salting-out effect of sugar observed in the experiments. Conversely, the high P value (>0.05) of β_2 reflects the nonrepresentative effect of ethanol on H_2S solubilization. The strong effect of temperature on the K_{H_2S} was confirmed by the very low P value obtained for the β_3 parameter. The high value of β_3 itself reflects the predominant effect of temperature on the partition coefficient of H_2S. As ethanol had only a negligible effect, eq 10 can be written as

$$K_{H_2S} = 3.37 \times 10^{-2} + 1.35 \times 10^{-4} \times [\text{glucose}] + 9.43 \times 10^{-3} \times T \quad (11)$$

The adjusted R^2 (0.9644) indicates that the three variables combined predict >96% of the K_{H_2S} (Figure 7). The mean relative error between model prediction values and the experimentally measured values was calculated as follows:

$$\varepsilon = \frac{1}{n}\Sigma_{j=1}^{n}\frac{|K_{ij}^{\text{measured}} - K_{ij}^{\text{predicted}}|}{K_{ij}^{\text{measured}}} \times 100\% \quad (12)$$

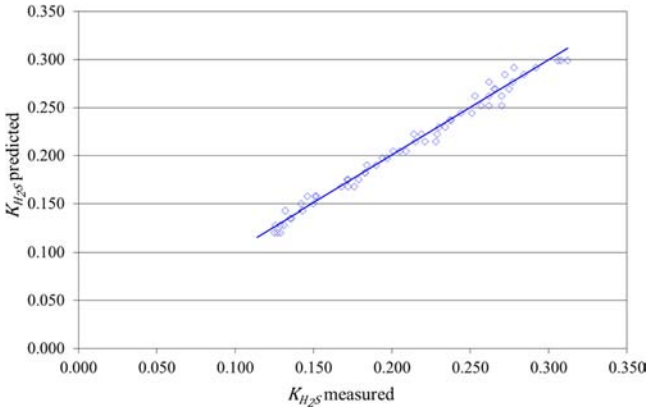

Figure 7. Comparison of measured K_{H_2S} (all media) and K_{H_2S} calculated from the model.

The average differences between experimental and predicted values of R^2 were <4%, demonstrating that H_2S gas–liquid partitioning was accurately predicted by the model based on the effects of modifications to the matrix and temperature.

Prediction of the partition coefficient of H_2S during fermentation will allow the calculation of the total production of this volatile compound from a single measurement (of its concentration in the gas or in the liquid phase). This will be particularly useful in cases of online monitoring of this extremely volatile compound in the fermentation gas, as described for carbonyl compounds but now possible for sulfur compounds with a flame photometric detector on the online monitoring system.[50] The ability to calculate total H_2S production and to differentiate between the amount remaining in the liquid and that lost in the CO_2 should help both improve our understanding of yeast metabolism and optimize fermentation control. Indeed, from a microbiological point of view, the total amount produced needs to be considered, whereas, from a technological point of view, the concentration remaining in the wine is more important. Minimizing the total amount of H_2S produced during fermentation and also the residual amounts after fermentation are important issues that may now soon be resolved.

Table 5. Estimated Coefficients of the Model Parameters Identified from Equation 10 by Multiple Linear Regression and Significance Testing

	coefficient	standard error	t stat	P value
β_0 (intercept)	3.37×10^{-2}	9.25×10^{-3}	3.6444	1.61×10^{-3}

increased bioavailability of (*Z*)-lycopenes caused by a better solubility in chylomicrons is often proposed to be the reason for this observation.[12] On the other hand, various processes during digestion are hypothesized to trigger the isomerization of lycopene and β-carotene.[13] Especially the gastric milieu is considered to be the main reason for the isomerization of carotenoids,[14] because a strong formation of (*Z*)-isomers at gastric pH as well as at elevated physiological temperatures was observed in several studies.[13,14] However, this cannot explain the dominant role of (*all-E*)-β-carotene in human plasma in the presence of only trace amounts of β-carotene isomers. Instead, enzymatic systems that could remove (*Z*)-isomers were discussed in the literature to form products such as (9*Z*)-retinoic acid.[7] Furthermore, the difference in the distribution of (*Z*)-lycopenes determined in various human tissues cannot be clarified by these hypotheses at all.[14]

Therefore, the physical and chemical quenching of carotenoids was investigated in detail, to identify possible mechanisms for the contradictory ratios of carotenoid (*Z*)-isomers in human plasma and tissues. The present work focused on the underlying isomerization processes and allowed insights to additional synergistic effects between lycopene and β-carotene.

MATERIALS AND METHODS

Chemicals. Chemicals with highest purities were obtained from Sigma-Aldrich (Taufkirchen, Germany) and Carl Roth GmbH (Karlsruhe, Germany) unless otherwise indicated. (15*Z*)-β-Carotene, (9*Z*)-β-carotene, (15*Z*)-lycopene, and (5*Z*)-lycopene were synthesized according to the literature.[15] Performed modifications were described in previous works.[16,17] (7*Z*,9*Z*)-Lycopene and (7*Z*)-lycopene were synthesized as well using the same Wittig strategy. In contrast to the literature, geraniol served as the educt for both these isomers.[15] Pure (*E*)-citral was generated after oxidation by activated manganese dioxide.[18] The following steps were more or less identical to the literature, with exception of the final Lindlar hydrogenation, where a ratio of Lindlar catalyst to Lindlar poison of 1:23000 (w:w) was used to accomplish an almost complete reaction. 11.0 mg of 7-*cis*-lycopene and 18.4 mg of (7*Z*,9*Z*)-lycopene were obtained with isomeric purities of 91% (7*Z*) and 83% (7*Z*,9*Z*). Standards were verified by 1D-, 2D-NMR spectra and HPLC−UV analyses. (*all-E*)-Lycopene was isolated from tomato paste according to the below described extraction method, followed by precipitation with methanol. Analytical parameters for identification and characterization as well as NMR data are summarized in Table S1 in the Supporting Information. 1,4-Dimethylnaphthalene-1,4-endoperoxide was synthesized according to Wasserman et al.[19] Peroxidase from horseradish (HRP) with an activity of about 150 U/mg was purchased as a lyophilized beige powder from Sigma-Aldrich (Taufkirchen, Germany). NMR solvents were purchased from ARMAR Chemicals (Döttingen, Switzerland) with a purity of 99.8 atom % D. Methanol and methyl *tert*-butyl ether as HPLC solvents were purchased from Sigma-Aldrich (HPLC grade ≥99.8%).

Fruit and Vegetable Samples. In this study, different fruits and vegetables were characterized for their content and isomeric composition of carotenoids. Samples of watermelon, papaya, persimmon, broccoli, eggplant, grapefruit, tomato, spinach, zucchini, and red pepper were purchased from local markets and food stores with different origins.

Preparation of Fruits and Vegetables. Fresh fruit and vegetable materials were homogenized at 0 °C with a mixer for 1 min under reduced light, if necessary with addition of water. Per sample between 15 and 30 g of the homogenate was frozen at −21 °C followed by lyophilization for 3 to 4 days. Dry plant materials were extracted overnight by addition of *n*-hexane/acetone/ethanol (50/25/25) containing 0.01% butylated hydroxytoluene performed on an orbital shaker (170 U/min). Saponification was performed for about 20 h at room temperature by addition of a methanolic potassium hydroxide solution (10%) to the filtrated extracts, thus allowing an effective separation of fatty compounds and chlorophylls. Alkaline extracts were washed 5 times with a 2% sodium chloride solution and were dried under an argon stream. Obtained precipitates were dissolved and diluted in mobile phase (methanol/methy *tert*-butyl ether, 50/50) followed by HPLC−UV analyses. This method was fully adopted from prior works.[16,17] Thermally induced or photoinduced isomerization processes were excluded during the whole preparation by working under reduced light and using aluminum foil or dark glassware. Temperature never exceeded 25 °C. Detailed investigations confirmed that the native isomeric composition was not influenced during storage and all steps of preparation.

Preparation of Human Plasma. A total of 15 human plasma samples of healthy donors between 22 and 35 years of age were obtained in cooperation with the university medical center Halle/Kröllwitz (Halle/Saale, Germany). All participants signed a written informed consent. Sample preparation was performed in compliance with the literature.[11] Plasma was obtained after centrifugation of blood samples for 10 min at 4 °C (2375 rpm, 454*g*). Separated plasma was stored on ice until preparation. 1 mL of plasma was diluted with 1 mL of doubly distilled water. Protein precipitation was performed by intensive shaking after addition of 2 mL of ethanol. Plasma carotenoids were extracted with 4 mL of *n*-hexane on a shaking device (Vortex) for 20 min. After centrifugation (15 min, 4500 rpm, 3400*g*) 3.8 mL of the organic layer was transferred to amber glassware vials and dried under an argon stream. For HPLC−UV analyses, the residues were dissolved in 200 μL of mobile phase (methanol/methyl *tert*-butyl ether, 50/50). All samples were prepared in duplicate.

Singlet Oxygen Assay. Transformation of (*all-E*)-lycopene and (*all-E*)-β-carotene was observed after treatment with various amounts of singlet oxygen, generated in situ, to gain a better understanding of chemical and physical isomerization processes. Concentration of singlet oxygen was referred to absolute amounts of carotenoids after incubation. First, separate incubations were performed with either lycopene or β-carotene as pure substances to investigate their individual isomerization processes. Then mixed incubations were used to determine possible synergistic effects between lycopene and β-carotene.

Singlet oxygen was generated in situ by thermal degradation of 1,4-dimethylnaphthalene-1,4-endoperoxide (DMNEP). This compound was synthesized according to Wasserman et al.,[19] followed by flash chromatography (silica gel 60; *n*-hexane/EtOAc, 7:3) to yield a mixture of educt and DMNEP (1:1). NMR experiments confirmed reproducible release ratios of molecular singlet oxygen during treatment at 40 °C for 20 min (about 37.7% of total applied amounts). For follow-up studies about 25 mg of DMNEP was diluted in 50 mL of *n*-hexane to yield an absolute concentration of 0.59 nmol/μL singlet oxygen or 0.059 nmol/μL for diluted solutions (1:10), respectively.

2.5 mg portions of lycopene and β-carotene were dissolved in 50 mL of hexane to final concentrations of 50 μg/mL. Aliquots (300 μL) were transferred to dark glass vials, and various volumes of DMNEP (0.059 nmol/mL, 0, 10, 25, 50, 100, 150, 200, 250 μL; 0.59 nmol/mL, 50, 100, 200, 500, 1000, 2200 μL) were added. For standardization, vials were filled up in each case to 2.5 mL with *n*-hexane. The resulting solutions were stirred for 20 min at 40 °C and were directly quenched on ice after treatment. After drying under an argon stream, residues were taken up in 400 μL of mobile phase (methanol/MTBE, 50/50) followed by HPLC−UV analyses.

H_2O_2/HRP and ABTS/H_2O_2/HRP Assay. Carotenoids were treated with H_2O_2 and horseradish peroxidase in model systems to simulate oxidative effects in vivo. Kinetics were analyzed by HPLC−UV and photometric measurements. Here, a protocol based on works of Özyürek et al. with some modifications was established.[20] First, 2.2 mg portions of carotenoid standards were dissolved in 4 mL of acetone to final concentrations of 0.55 mg/mL of lycopene and β-carotene, respectively. 5 mg of horseradish peroxidase (HRP, Sigma-Aldrich, ∼150 U/mg) was dissolved in 5 mL of H_2O/EtOH (1:1), resulting in HRP solution with 150 U/mL. 0.32 mM H_2O_2 solution was prepared

Table 1. Contents of β-Carotene and Lycopene and Their Isomeric Composition in Various Fruits and Vegetables and in Human Plasma, Expressed as Percentage of Total β-Carotene or Lycopene

	β-carotene				lycopene	
sample	content, μg/g FW	(*all-E*), %	(9Z), %	ratio (*all-E*)/(9Z)	content, μg/g FW	(*all-E*), %
broccoli	4.8	84.1	9.7	8.8	nd	
eggplant	0.4	85.4	7. 7	11.5	nd	
spinach	49.6	86.4	7.4	11.7	nd	
zucchini	1.6	84.0	8.4	10.1	nd	
pepper (red)	15.8	88.6	6.0	14.7	nd	
tomato	4.7	85.9	2.6	33.1	67.9	78.7
grapefruit (pink)	3.4	89.8	0.7	137.1	26.2	78.7
papaya	0.7	86.8	3.6	24.0	29.1	80.4
persimmon	0.2	76.0	3.8	20.0	3.2	79.9
watermelon	0.3	91.3	2.9	31.6	59.3	78.9
human plasma (n = 15)	1.0 nmol/mL	89.3	1.7	59.0	2.8 nmol/mL	37.3

from a 35% H_2O_2 solution (Sigma-Aldrich) by dilution in EtOH. Incubation solutions consisted of water (0.5 mL), ethanol (0.5, 0.4, 0.3, 0.2, 0.1, and 0 mL), and 0.1 mL of carotenoid solution. Various amounts of 0.32 mM H_2O_2 solution (0, 0.1, 0.2, 0.3, 0.4, and 0.5 mL) and constant levels of HRP solution (0.05 mL) in ethanol (150 U/mL) were also added to dark glass vials. The resulting solutions (final volume of always 1.15 mL) were shaken at room temperature for 30 min followed by photometric analyses with a Jasco UV/vis spectrophotometer V-530. Carotenoid concentrations were determined at 470 nm for lycopene and 450 nm for β-carotene. To analyze the isomeric composition the incubation solutions were extracted with dichloromethane (500 μL for two times) and dried under argon stream. Residues were taken up in 400 μL of mobile phase (methanol/MTBE, 50/50) followed by HPLC−UV analyses.

A similar model system was established to investigate quenching of radical species by carotenoids. 46.6 mg of 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) was dissolved in 20 mL of H_2O to a final concentration of 2.33 mg/mL (4.25 mM). First, 0.1 mL of ABTS solution was incubated with HRP (0.05 mL) and H_2O_2 (volumes as described before) after addition of H_2O (0.4 mL) and EtOH (volumes as described before) with a total volume of 1.05 mL for 30 min at room temperature. After formation of the green to blue colored radical ($ABTS^{\bullet+}$), 0.1 mL of carotenoid solution was added and shaken for an additional 10 min. Isomeric composition and degradation rates were analyzed after extraction and preparation as described above.

All described experiments were performed with pure lycopene and β-carotene standard solutions first. Subsequently, mixtures of both carotenoids were incubated in the model systems to determinate possible synergistic effects, maintaining the same concentration of total carotenoids to give comparable results to the single carotenoid incubation.

Analytical HPLC−UV and HPLC−DAD. Carotenoid profiles were determined for all samples by the following HPLC system. The HPLC apparatus (Jasco, Groß-Umstadt, Germany) consisted of a quaternary gradient pump (PU-2089 Plus) with degasser, a column oven (Jetstream Plus), an autosampler (AS-2055 Plus), and a UV detector (UV-2075 Plus) operating at a wavelength of 450 nm. For DAD analyses, a Jasco MD-2015 Plus detector was used. Chromatographic separations were performed on a stainless steel column packed with RP-C30 material (YMC carotenoid, 5 μm, 250 × 4.6 mm, YMC Europe, Dinslaken, Germany) connected to a C30 guard column (5 μm, 250 × 4.0 mm, YMC Europe, Dinslaken, Germany) using a flow rate of 0.65 mL min^{-1}. Chosen column temperature was 20 °C. The mobile phase used was methanol (solvent A) and methyl *tert*-butyl ether (solvent B). Samples were injected at 40% B (held for 5 min), and gradient was then changed to 83% B in 50 min. Afterward gradient changed to 100% B in 5 min (held for 10 min) and to 40% B in 5 min (held for 10 min). Retention time of the carotenoid isomers was checked with the authentic references where possible. Further identification and characterization was performed by HPLC−DAD and HPLC−MS/MS analyses, as described in previous works.[16,17] In particular, the Q ratios were calculated by division of the absorption at the subsidiary "(Z)-peak" by the absorption at the absorption maxima. Based on these spectral characteristics, further isomers were assigned according to data from the literature.[11,15,21,22] A representative chromatogram is given in Figure S1 in the Supporting Information to verify the applicability of the established method. Additionally, all data required for the identification or characterization of altogether 16 carotenoid isomers are summarized in Table S1 in the Supporting Information.

For all samples (model incubations and biological samples), the isomeric composition was calculated by integration of all identified lycopene and β-carotene peaks first. Then, the areas of the separate peaks were divided by the sum of all lycopene and β-carotene values to express them as the percentage of total lycopene and β-carotene concentrations. Absolute concentrations and ratios of β-carotene and lycopene were determined by external calibration using (*all-E*) standard compounds analyzed at 450 nm.

High Performance Liquid Chromatography Mass Spectrometry (LC−MS/MS). The HPLC apparatus (Jasco, Groß-Umstadt, Germany) consisted of a pump (PU-2080 Plus) with degasser and quaternary gradient mixer, a column oven (Jasco Jetstream II), and an autosampler (AS-2057 Plus). Mass spectrometric detection was conducted on an API 4000 QTrap LC-MS/MS system (Applied Biosystems/MDS Sciex, Concord, ON, Canada) equipped with an API source using an atmospheric pressure chemical ionization (APCI) interface in negative mode. Nitrogen was used as sheath and auxiliary gas. The optimized parameters for mass spectrometry of lycopene were Q1 536.7 amu, Q3 467.6 amu, DP −75 V, CE −27 eV, CXP −12 V. β-Carotene showed no fragmentation in Q3 (Q1 536.7 amu, DP −60 V). The analytical parameters with respect to the used column and temperature were as described above for the analytical HPLC−UV and HPLC−DAD.

Nuclear Magnetic Resonance Spectroscopy (NMR). ^1H and ^{13}C NMR spectra were recorded on a Varian Unity Inova 500 instrument operating at 500 MHz for ^1H and 125 MHz for ^{13}C and on a Varian VXR 400 spectrometer at 400 MHz for ^1H and 100 MHz for ^{13}C, respectively. $SiMe_4$ was used as a reference for calibrating the chemical shift.

Statistical Analysis. Analyses of carotenoid concentrations and isomeric composition were performed in duplicate for each sample and resulted in coefficients of variation less than 5% in fruits and vegetables. Mean variation coefficients for carotenoid concentrations in human plasma samples were below 10% (maximal coefficients of variation <20%). Determination of the isomeric composition in human plasma resulted in coefficients of variation less than 10% for all measured isomers with concentrations of more than 1.5%. Confidence intervals were calculated with a probability value of 95%.

RESULTS AND DISCUSSION

Identification of Carotenoid Isomers. Identification of various lycopene and β-carotene isomers was performed according to Heymann et al. by comparison of retention times on HPLC−UV using commercially available and independently synthesized references.[16,17] Additional LC/APCI-MS analyses and HPLC−DAD with Q ratio characterization was also used. The present synthesized (7Z)- and (7Z,9Z)-lycopene were added to the established analytical method. All representative data are summarized in Tables S2 and S3 in the Supporting Information. A total of 8 authentic reference standards verified the established analytical method as a powerful instrument for the determination of the carotenoid profile in model solutions and in biological samples, thus allowing a detailed description of isomerization processes in further experiments.

Carotenoid Profile of Various Fruits and Vegetables. First, various fruits and vegetables were analyzed for their carotenoid content as well as their isomeric lycopene and β-carotene composition. The results are summarized in Table 1. Tomatoes contained, with about 68 μg/g fresh weight, the highest lycopene concentration compared to the other analyzed food samples. This level was slightly higher than expected from the literature, where usually concentrations between 20 and 50 μg/g were reported.[4] In the present study, an almost complete array of lycopene isomers was determined in comparison to other works, which might explain the increased total concentration with respect to the literature. Moreover, the natural deviation between different tomato varieties has an impact on carotenoid biosynthesis, too.[23] Furthermore, about the half of all analyzed tomatoes were cultivated under field-grown conditions, which also has a great impact on the rate of lycopene biosynthesis.[16] All other results, e.g., determined in watermelons or pink grapefruits, complied with published data very well.[4,24] Contents of β-carotene showed no significant differences compared to data from comparable studies, e.g., analyses of spinach, zucchini, and eggplant resulted in concentrations of 49.55 μg/g, 1.60 μg/g, and 0.41 μg/g fresh weight, while O'Neill et al. determined 44.89 μg/g, 1.80 μg/g, and 0.50 μg/g fresh weight,[24] respectively. In contrast to the literature, the analysis of pepper led to considerably higher amounts of β-carotene (15.76 μg/g vs 4.8 μg/g).[24] Here, the high levels of β-carotene in pepper fruits might result naturally from the specific cultivation variety, but can be influenced also by many other factors, e.g., light, temperature, or humidity.

The determination of the isomeric pattern of unprocessed food samples resulted in ratios between 70 and 91% of the (*all-E*)-isomers, as apparent from Table 1. This reflects their predominant occurrence in nature, and has been reported in the literature before.[13,25] Mean concentrations of (*all-E*)-β-carotene and of (*all-E*)-lycopene of all analyzed food samples deviated only in a small range, e.g., for (*all-E*)-β-carotene between 84.0 and 91.3%. Only in persimmons lower levels of about 76% were observed. Additionally, (*all-E*)-lycopene was determined with concentrations from 78.7 to 80.4%. On the other hand, (*Z*)-isomers of β-carotene and lycopene accounted only for about 15% and 20%, respectively, as has been described in the literature before.[26,27] However, the present detailed studies on carotenoid isomers projected a significant difference in the observed (9Z)-β-carotene concentration between lycopene free and lycopene containing fruits and vegetables. While mean levels between 6.0 and 9.7% were determined in samples such as broccoli (9.7%), spinach (7.4%), or red pepper (6.0%), the (9Z)-β-carotene concentration never exceeded 4.0% in lycopene rich samples like tomato (2.6%), grapefruit (0.7%), or watermelon (2.9%). Thus, the (9Z)-β-carotene concentration allowed for a clear differentiation between lycopene free and lycopene containing samples, as shown in Figure 1.

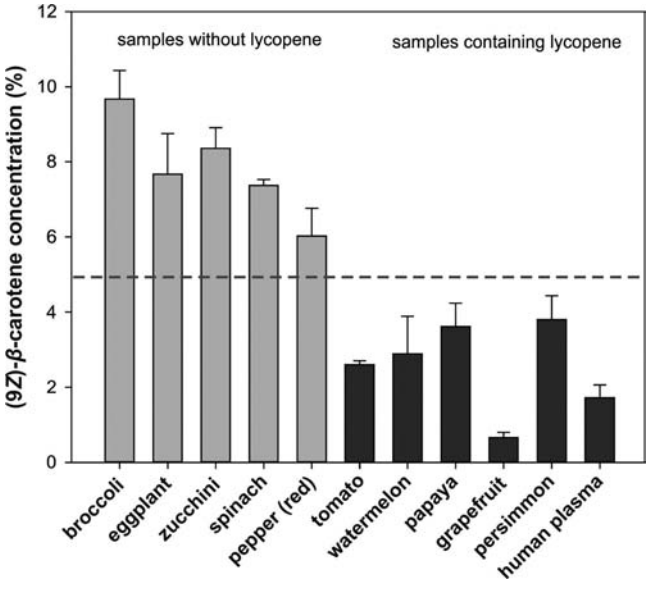

Figure 1. (9Z)-β-Carotene concentrations (expressed as percentage of total β-carotene) in lycopene free (gray bars) and lycopene containing (black bars) fruits and vegetables, and in human plasma samples.

Especially leafy green vegetables were reported for raised (*Z*)-isomer concentrations compared to others,[28] resulting in decreased (*all-E*)/(9Z) ratios (8.8 to 14.7, Table 1). Here, especially chlorophyll was proposed to act as a sensitizer that triggers the isomerization during photosynthesis.[29] Nevertheless, the isomerization process of β-carotene seems to be suppressed in the presence of lycopene. Our recent studies on the photoinduced isomerization process of carotenoids confirmed this observation. While energy-rich illumination resulted in significantly higher levels of (9Z)-β-carotene in field-grown spinach,[17] no difference in the isomeric β-carotene composition was observed between field- and greenhouse-grown tomato samples. As a consequence for the later, only the increased concentrations of (*Z*)-lycopenes led to a differentiation of light regimens during growing.[3,16] This means that, most likely, lycopene was able to minimize (i.e., quench) the photoinduced isomerization of (*all-E*)-β-carotene and thereby preserves its biological function as a vitamin-A precursor.[4]

Carotenoid Profile of Human Blood Plasma. The results of the analyses of plasma samples from 15 healthy subjects (age from 22 to 39) are also summarized in Table 1. Comparable to analyzed food samples, (*all-E*)-β-carotene dominated with a mean concentration of 89.3%, while (9Z)-β-carotene was determined at only 1.7%. (13Z)-β-Carotene represented the predominant (*Z*)-isomer with concentrations between 5.1 and 11.3%. These results completely complied with observations from the literature.[30,31] On the contrary, (*all-E*)-lycopene just occurred with a concentration of 37.3%, while (5Z)-lycopene was the dominant (*Z*)-isomer (29.8%) followed

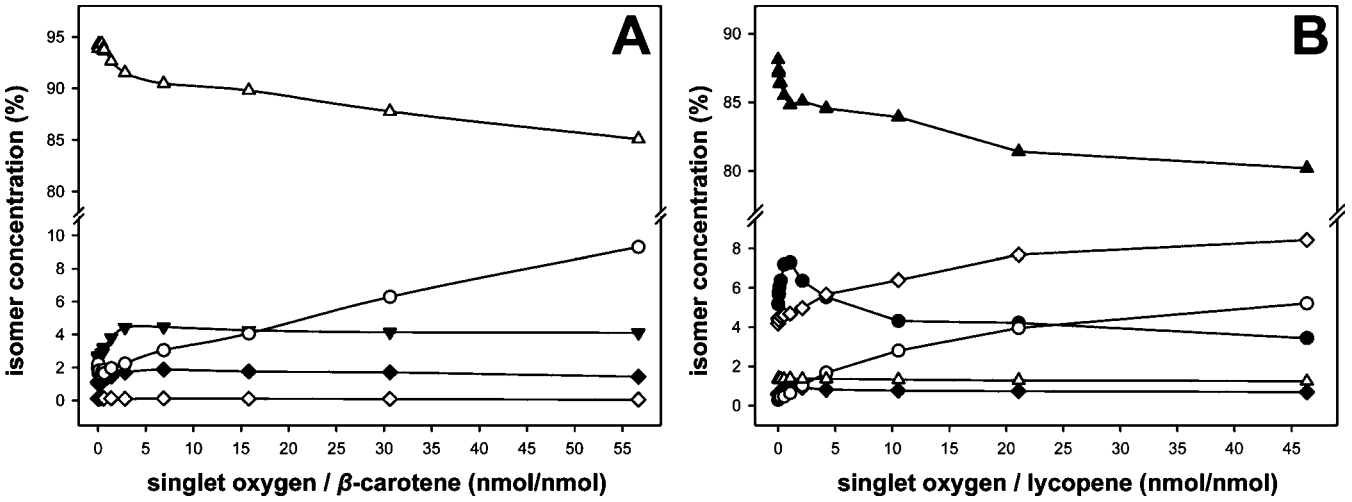

Figure 2. Concentrations of β-carotene (A) and lycopene (B) isomers during treatment with singlet oxygen of various concentrations, expressed as percentage of total β-carotene and lycopene (%). Kinetic products were formed especially at low levels, while thermodynamically controlled products dominated at high levels. A: (15*Z*)-β-carotene (◆), (13*Z*)-β-carotene (▼), (9*Z*,13*Z*)-β-carotene (◇), (*all-E*)-β-carotene (Δ), (9*Z*)-β-carotene (○). B: (15*Z*)-lycopene (◆), (13*Z*)-lycopene (●), (9*Z*)-lycopene (○), (7*Z*)-lycopene (Δ), (*all-E*)-lycopene (▲), (5*Z*)-lycopene (◇).

by (13*Z*) (14.1%), which was in line with the literature, too.[11,14,31]

Interestingly, the ratio of (*all-E*)- to (9*Z*)-β-carotene in human plasma was in the same range as for lycopene containing fruits (Figure 1). The chromatographic pattern of β-carotene was quite similar to lycopene containing fruits such as tomatoes or watermelon, characterized by very low levels of the (9*Z*)-isomer. This indicated that the suggested protective effect of lycopene on other carotenoids might be applicable for human plasma samples, too. Different from fruits, significantly higher amounts of (5*Z*)-lycopene were found in vivo.

Incubation of Lycopene and β-Carotene with Singlet Oxygen as Model System. The isomerization process during individual incubations of (*all-E*)-β-carotene (A) and (*all-E*)-lycopene (B) with singlet oxygen is illustrated in Figure 2. As expected from the literature, only physical quenching but no chemical quenching was observed during the reaction with singlet oxygen.[32]

The concentration of (*all-E*)-lycopene was degraded from initially 88.1% to 80.2%, while especially (9*Z*)-lycopene (from 0.3% to 5.2%) and (5*Z*)-lycopene (from 4.2% to 8.4%) were generated in high amounts. On the contrary, (7*Z*)- (1.4% to 1.2%) and (15*Z*)-lycopene (0.6% to 0.7%) just slightly changed at constant low levels during incubation. The isomerization process of (13*Z*)-lycopene was characterized by a strong increase (maximum of 7.3%) at singlet oxygen concentrations up to 1.05 nmol per nmol of lycopene, while it was degraded at higher singlet oxygen amounts to reach an equilibrium concentration of about 3.4%. In contrast, the formation of (5*Z*)- and (9*Z*)-lycopene showed almost linear increases with rising singlet oxygen concentrations. The remaining isomers showed no significant changes.

Comparable to lycopene the concentration of (*all-E*)-β-carotene was reduced from 94.2% to 85.1%. Only (9*Z*)-β-carotene (from 2.0% to 9.3%) significantly increased in an almost linear fashion. (13*Z*)-β-Carotene and (15*Z*)-β-carotene were formed only at low concentrations up to 2.8 nmol of singlet oxygen per nmol of β-carotene and reached subsequently equilibrium states at about 4.5% (13*Z*) and 1.9% (15*Z*). All other β-carotene isomers showed no significant changes.

These model systems illustrated defined processes during incubation of carotenoids with singlet oxygen. Obviously, the isomerization proceeded in two stages. In the first stage at low singlet oxygen concentrations, the isomerization progress was similar to thermally induced processes as described by Kuki et al., where mainly the kinetically controlled products such as (15*Z*)- and (13*Z*)-β-carotene as well as (15*Z*)- and (13*Z*)-lycopene were formed preferentially.[26,33] The second part of the reaction at high amounts of singlet oxygen (>10.5 nmol/nmol of β-carotene, >4.2 nmol/nmol of lycopene) was characterized by a dominant increase of the thermodynamic products like (9*Z*)-β-carotene and (5*Z*)-lycopene. These isomers are normally observed during high energy processing of foods, e.g., during high pressure sterilization or irradiation with UV light.[16,27,36] The results were in line with theoretical studies on the enthalpies of carotenoid isomers.[34,35] Accordingly, (9*Z*)-β-carotene has the highest rotational barrier to reisomerize to the (*all-E*) configuration compared to all other isomers ($\Delta E_r^{\ddagger}$ = 26.0 kcal/mol).[35] Thus, (9*Z*)-β-carotene is the most stable isomer that is only formed during high energetic stimulation. Rotational barriers for reisomerization of (13*Z*)-β-carotene ($\Delta E_r^{\ddagger}$ = 21.5 kcal/mol) and (15*Z*)-β-carotene ($\Delta E_r^{\ddagger}$ = 20.6 kcal/mol) are significantly lower, which explains equilibrium at high singlet oxygen concentrations, associated with their lower stabilities.[35] The same accounts for lycopene, where (13*Z*)- and (15*Z*)-lycopene were calculated to be the kinetically controlled products, whereas (9*Z*)- and especially (5*Z*)-lycopene represent the thermodynamically controlled products. Taken together, the present results illustrate that the energy input by singlet oxygen is located somewhere between thermal and photochemical excitation. Furthermore, the singlet oxygen induced isomerization of carotenoids is far more complex than illustrated in the literature so far, where only the complete transformation of (15*Z*)- and (13*Z*)-isomers to the (*all-E*)-configuration was reported for the interaction with singlet oxygen.[8,37]

The similar isomeric pattern in the single incubations changed abruptly in mixed β-carotene/lycopene reactions, where only lycopene displayed almost the same isomerization progress as shown before. Various ratios were chosen (38%, 56%, 64%, and 73% lycopene) with the total carotenoid

DOI: 10.1021/acs.jafc.5b00377
J. Agric. Food Chem. 2015, 63, 3279−3287

concentration maintained at the same level as used in the single carotenoid incubation. Specific formation rates of the 4 β-carotene isomers were calculated by linear fitting. In the case of (13*Z*) and (15*Z*) only the linear ranges at the start of the incubations were used for calculation to allow comparability. As depicted in Figure 3, the rates for (9*Z*) decreased with

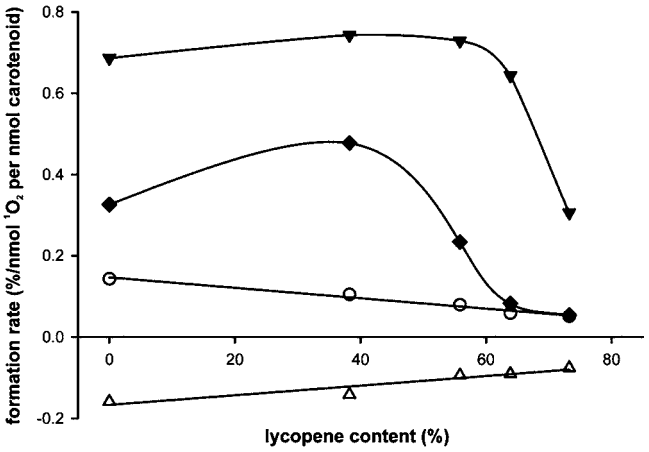

Figure 3. Formation rates of (*all-E*)- (Δ), (9*Z*)- (○), (13*Z*)- (▼), and (15*Z*)-β-carotene (◆) in β-carotene/lycopene reaction mixtures during quenching of singlet oxygen dependent on the lycopene content. Rates were calculated by linear regression during the linear formation progress of all isomers.

increasing lycopene concentrations from 0.143%/nmol of singlet oxygen per nmol of carotenoid (0% lycopene) to just 0.051%/nmol of singlet oxygen per nmol of carotenoid (73% lycopene), thus suppressing the formation to about one-third. The opposite effect was observed for the isomerization of (*all-E*)-β-carotene, where rates decreased from −0.1589 to −0.0757%/nmol of singlet oxygen per nmol of carotenoid. At lycopene contents of more than 50% the formation of (15*Z*)- and (13*Z*)-isomers was effectively suppressed, while smaller amounts of lycopene clearly led to increased formation compared to lycopene free systems. In line with the theoretical studies by Guo et al.,[35] lycopene reduces the potential energy levels during the physical quenching of singlet oxygen. Low-energy processes rather result in the formation of kinetically controlled products, i.e., (13*Z*) and (15*Z*)-β-carotene. Only very high amounts of lycopene significantly minimized the energy levels, leading to reduced formation of both isomers. In contrast, even small amounts of lycopene were able to suppress the formation of (9*Z*)-β-carotene with the highest activation energy within all mono-(*Z*)-isomers,[35] thus preventing the generation of this thermodynamic product at low energy levels.

These findings proved that lycopene was able to suppress the singlet oxygen induced isomerization of (*all-E*)-β-carotene probably as a result of its higher quenching activity.[2] Consequently, β-carotene is preserved in its (*all-E*) configuration and maintains its potential as a vitamin A precursor in vivo. Singlet oxygen naturally occurs in air, where it is generated during various reactions especially with oxygen and UV light.[38] The presence of sensitizers, such as chlorophyll during photosynthesis, or oxidation stress could also lead to singlet oxygen in vivo.[6] Unfortunately the determination of singlet oxygen concentrations is a technically challenging problem as reported by Kanofsky. Consequently, only quantum yields and lifetime experiments were described in the literature.[39] Thus, it is hard to assess if the used concentrations of singlet oxygen in our model systems might be applicable for biological systems.

Incubation with H_2O_2 and Horseradish Peroxidase (HRP). For simulation of reactions between carotenoids and reactive radical oxygen species first a model system of H_2O_2 and horseradish peroxidase (HRP) was used. In theory, carotenoid peroxides are formed from H_2O_2 that is enzymatically catalyzed by HRP. This reaction should result in a loss of total carotenoids as a measure for chemical quenching and decomposition. However, no relevant changes in extinction were found (data not shown). Amounts of carotenoids stayed at a constant level with the pattern of isomers nearly unchanged. Consequently neither chemical nor physical quenching was detected. It can only be speculated that the missing specificity of HRP to carotenoids was the reason for the lack in reactivity.

Incubation with H_2O_2 and Horseradish Peroxidase (HRP) and ABTS. Alternatively, the protective effect of lycopene on radical induced β-carotene isomerization was confirmed by experiments with ABTS radicals in the presence of hydrogen peroxide. In contrast to the reaction of carotenoids with singlet oxygen, the interaction with free radicals led to strong chemical quenching as reported in the literature.[40] This was evidenced by a strong degradation of both carotenoids. However, at high concentrations, lycopene was degraded completely, whereas loss of β-carotene was only partially. Figure 4 shows that, in β-carotene/lycopene mixed incubations

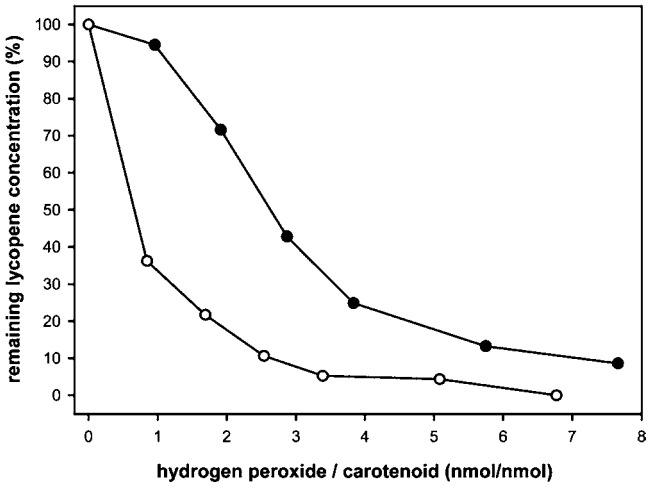

Figure 4. Degradation of lycopene in β-carotene/lycopene reaction mixtures during incubation with ATBS radicals and hydrogen peroxide. Values are expressed as remaining concentration of lycopene (%) compared to the initial concentration (β-carotene/lycopene ratio 4/1 (○) and 1/2 (●)).

(initial lycopene content 20%, see Figure 4 (○)), degradation of 54% of lycopene was already reached at 1.4 equiv of radical concentration, while at 2.8 equiv of lycopene was almost completely degraded. Parallel to degradation, lycopene showed also strong isomerization indicating physical quenching processes (data not shown). Higher lycopene proportions (initial lycopene content 67%, see Figure 4 (●)) shifted the degradation to higher radical concentrations. In contrast, even at 7.5 equiv of β-carotene degradation reached only 50%. This enabled us to study the effect of radicals on the physical quenching of lycopene in detail. The absolute degradation rates were calculated by comparison of the measured concentrations

DOI: 10.1021/acs.jafc.5b00377
J. Agric. Food Chem. 2015, 63, 3279−3287

to the initial starting carotenoid concentration during this study.

Figure 5A shows for single β-carotene reaction mixtures that increasing concentrations of ABTS radicals and hydrogen peroxide led to a strong degradation of (*all-E*)-β-carotene (from 95.4% to 70.8%) paralleled by considerable increases of (9*Z*)- (from 0.6% to 5.1%) and (13*Z*)-β-carotene (from 3.0% to 22.3%) by a factor of almost 10. (15*Z*)-β-Carotene concentration increased from 0.4% to 1.6%. The isomerization progress was immediately induced at low radical concentrations (★ at about 0.5 nmol of hydrogen peroxide per nmol of carotenoid). At high concentrations at about 6.0 nmol of hydrogen peroxide per nmol of carotenoid almost equilibrium states were reached for (*all-E*), (13*Z*), and (15*Z*), while (9*Z*) still increased in a linear fashion. A similar formation progress was described by Jeevarajan et al. and Gao et al., who both identified carotenoid radical cations and dications as precursors for the isomerization during radical quenching reactions.[41,42] In mixed lycopene/β-carotene incubations, the isomerization pattern of β-carotene changed significantly. Almost no degradation of (*all-E*)-β-carotene was observed as long as lycopene was still present at adequate concentrations, suppressing the isomerization of β-carotene at low hydrogen peroxide concentrations. Specifically, a mixed carotenoid solution with an initial lycopene content of 20% showed constant (*all-E*) levels up to concentrations of 1.7 nmol of hydrogen peroxide per nmol of carotenoid (Figure 5B). After that point (★) the strong isomerization coincided with the complete consumption of lycopene (see Figure 4 (○)), i.e., 79% of total lycopene was consumed at 2.5 nmol of hydrogen peroxide per nmol of carotenoid. From this point β-carotene (*Z*)-isomers quickly increased, comparable to the single incubations. A higher percentage of lycopene (67%, Figure 5C) moved the point of induction to even higher concentrations of hydrogen peroxide per carotenoid. In this system, 87% lycopene was degraded at concentrations of 5.8 nmol of hydrogen peroxide per nmol of carotenoid (Figure 4 (●)). This means that, only after complete oxidative breakdown of lycopene and thereby the loss of its high antioxidative quenching capacity, β-carotene (*Z*)-isomers are formed in significant amounts.

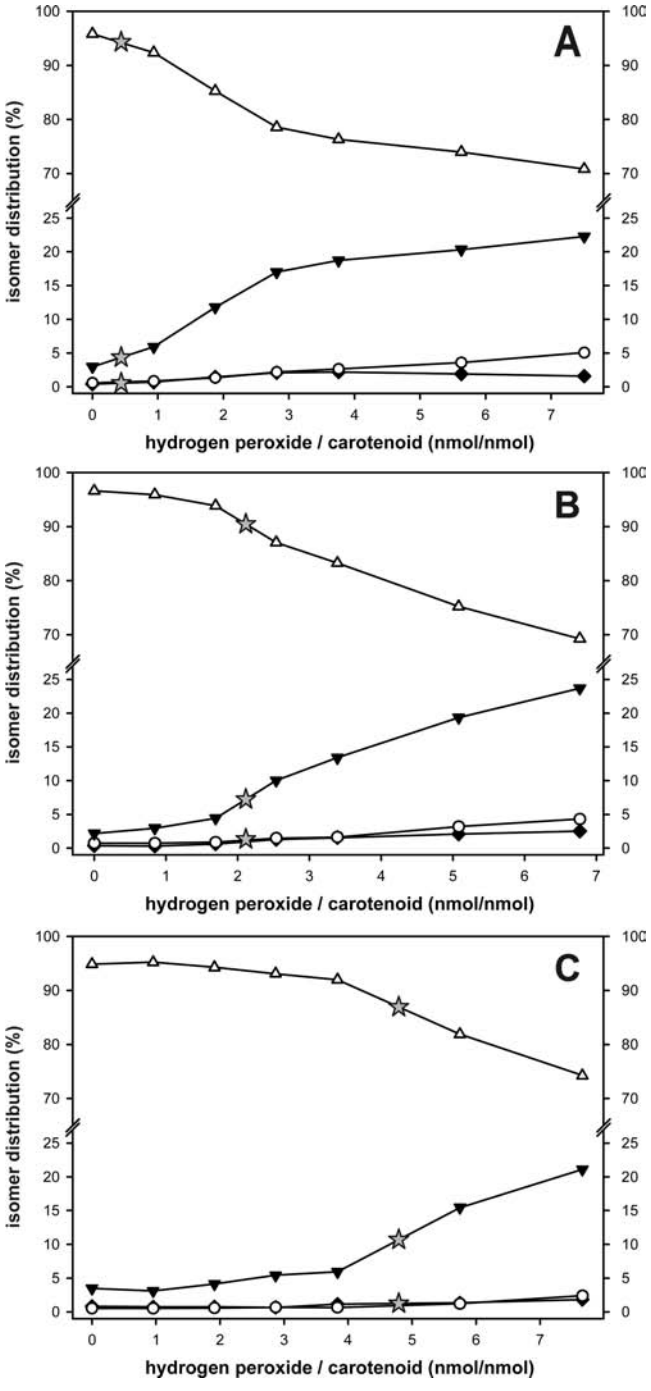

Figure 5. Isomerization progress during incubation of pure β-carotene (A) and in the presence of lycopene (B, 20%; C, 67%) with ATBS radicals and hydrogen peroxide. Gray stars indicate first observed significant changes in the isomeric pattern. (15*Z*)-β-Carotene (◆), (13*Z*)-β-carotene (▼), (*all-E*)-β-carotene (Δ), (9*Z*)-β-carotene (○).

The isomeric composition of β-carotene and lycopene in vivo is extensively discussed in the literature, because of the strong discrepancy in the (*Z*)-isomer concentrations. For a long time, the high content of (*Z*)-lycopene was related to a supposedly increased solubility and thus bioavailabilty of these compounds.[30,43] However, later studies disproved these results[44,45] and proposed isomerization processes during digestion to be the most plausible explanation for the differences in the isomeric pattern in vivo.[14] Indeed, under gastric pH the isomerization of lycopene was triggered to a much higher extent compared to the relatively stable β-carotene.[13] Furthermore, the supplementation of almost exclusively (*all-E*)-lycopene resulted in a strong increase of the (9*Z*)-lycopene plasma levels, which substantiated in vivo isomerization processes.[46] Moreover, thermal effects during digestion are suggested to explain the determined isomeric composition in vivo, too.[47] Various model systems showed that lycopene is more susceptible to thermal energy than β-carotene.[47] Additionally, the crystalline structure of the carotenoids in the food matrices was reported to have an enormous impact on the bioavailability and therefore on the isomerization in the gastric milieu, too. For example, lycopene is embedded in crystalline form in the chromoplasts of tomatoes, which effectively protects the configuration from external influences such as acids or thermal energy.[47,48] On the contrary, the liquid crystals in mango or papaya were shown to be transferred into the gastric micelles much more easily thus allowing an accelerated isomerization with respect to their thermodynamic characteristics.[34,49,50] On the other hand, (*all-E*)-lycopene was suggested to aggregate in the intestine to form crystals. This notion would lead to a reduced bioavailability and consequently

J. Agric. Food Chem. 2015, 63, 3279−3287

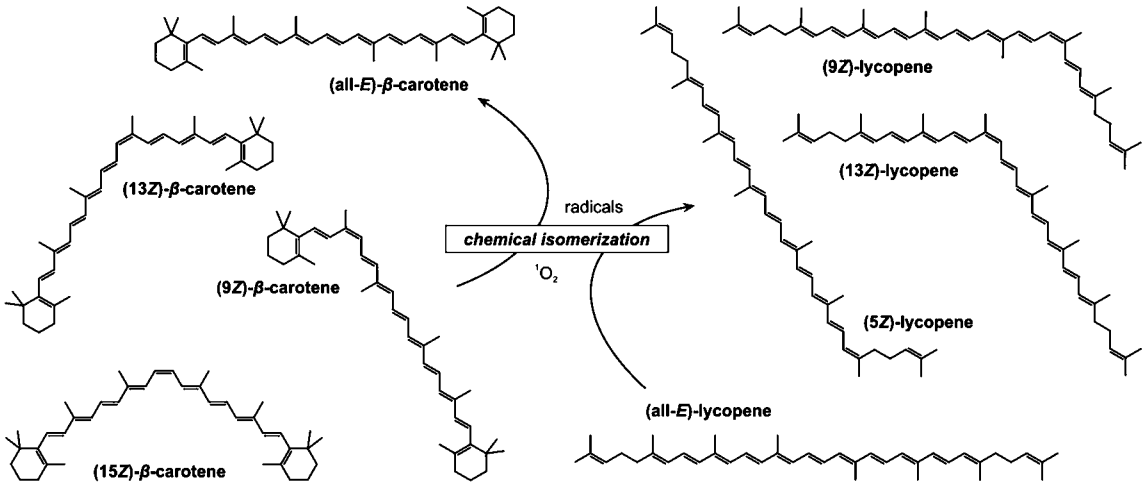

Figure 6. Lycopene effectively reduces or even inhibits the singlet oxygen or free radical induced isomerization of β-carotene.

to an accumulation of (Z)-isomers (with an assumed better solubility) in the human blood.[51]

Nevertheless, all known hypotheses are not able to explain the variable ratio of (Z)-lycopenes in various human organs and tissues, e.g., while about 80% of total lycopene was determined as (Z)-isomers in tissues of the lymph or prostata, only between 30 and 50% was isomerized in samples from the lung or serum.[31,43,52]

The present results strongly underpin the excellent quenching abilities of lycopene to explain these observations. All experiments clearly demonstrated that lycopene was able to reduce (singlet oxygen) or even to inhibit (radicals) the formation of (Z)-β-carotene isomers. It must be concluded that these findings are also true for in vivo systems. Here, oxidative stress in the form of singlet oxygen and radicals triggers the isomerization of carotenoids, as proposed earlier in the literature.[31,52] Lycopene acts as the effective quenching shield to protect other carotenoids against oxidative stress, i.e., β-carotene is preserved in its biologically active (all-E)-configuration, as illustrated in Figure 6.[4] During this process, lycopene gets highly isomerized and degraded. This rationale is also confirmed by studies of Stahl et al., who determined increased (9Z)-lycopene serum levels after consumption of processed tomato juice that contained only traces of this isomer.[31] Thus, the bioavailability theory to explain the different isomerization extent of specific carotenoids might be of minor relevance, if not of no relevance, to in vivo systems. In contrast, our lycopene protective theory is also capable of understanding the deviating (Z)-lycopene isomer concentrations found in specific human tissues, as different metabolic activities also entail different levels of oxidative stress.

In summary, our studies confirmed the outstanding quenching capabilities of lycopene in the reaction with radicals and activated oxygen species. This characteristic protects other carotenoids as β-carotene from degradation and isomerization, and explains the isomeric carotenoid patterns found in foods, but also in vivo.

DOPC reverse micelles improved the activity of α-tocopherol or trolox, a water-soluble analogue of α-tocopherol, at low concentrations (10 μM) but decreased their activity at higher concentrations (100 μM). Because lecithin is a mixture of different types of individual phospholipids, the objective of this study was to examine the impact of DOPC and DOPE both individually and in combination on the antioxidant activity of α-tocopherol or trolox. The experiments were conducted at PC and PE concentrations above and below their critical micelle concentrations to determine the impact of reverse micelles on the antioxidant activity of α-tocopherol and trolox. In addition to the investigation of the influence of association colloids formed by phospholipid, α-tocopherol regeneration by different types of phospholipids was also examined.

MATERIALS AND METHODS

Materials. Soybean oil was purchased from a local store and stored at −20 °C. Medium-chain triacylglycerols (MCT) were purchased from Sasol North America Inc. (Houston, TX, USA). 1,2-Dioleoyl-*sn*-glycero-3-phosphocholine (DOPC), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (DOPE), and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine-*N*-(7-nitro-2-1,3-benzoxadiazol-4-yl) (ammonium salt) (NBD-PE) were purchased from Avanti Polar Lipids, Inc. (Alabaster, AL, USA). Silicic acid, activated charcoal, α-tocopherol, α-tocopherol quinone, and trolox were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). All other reagents were of HPLC grade or purer. Distilled and deionized water was used in all experiments.

Preparation of Stripped Soybean Oil. To avoid the influence of the minor compounds such as tocopherols, phospholipids, free fatty acids, and mono- and diacylglycerols, which are originally in the commercial oil, stripped soybean oil (SSO) was prepared as described by Cui et al.[18] Briefly, a chromatographic column (3.0 cm diameter, 35 cm long) was used to isolate soybean oil triacylglycerols. Three layers were packed into the column sequentially. The bottom layer was packed with 22.5 g of silicic acid (washed with distilled and deionized water and activated at 110 °C for 24 h). Activated charcoal (5.6 g) was then used for the middle layer and another 22.5 g of silicic acid for the top layer. Commercial soybean oil (30 g) was mixed with 30 mL of hexane and the mixture was passed through the column using 270 mL of hexane for elution. The solvent was then removed by a vacuum rotary evaporator (Rotavapor R 110, Buchi, Flawil, Switzerland) at 38 °C, and the remaining solvent was evaporated by nitrogen flushing. The removal of polar lipids was verified by a thin layer chromatography method according to the Association of Official Analytical Chemists (AOAC).[20] HPLC analysis also detected no tocopherols in SSO (method described below). The water content decreased from about 250 ppm to about 20 ppm as determined by Karl Fischer analysis using a 831 KF Coulometer (Metrohm, Riverview, FL, USA).[21] Unless noted, SSO mentioned in the following experiments was a mixture of 25% stripped soybean oil and 75% MCT.

Sample Preparation. The experiment was separated to five parts. Part 1 included the addition of 20 or 1000 μM DOPC or DOPE into SSO. Part 2 included the addition of 20 or 1000 μM DOPC or DOPE to SSO containing100 μM α-tocopherol or trolox. Part 3 included the addition of 1000 μM DOPC or DOPE to the commercial soybean oil. Part 4 included the addition of 1000 μM DOPC or DOPE to SSO containing 0.95 μM NBD-PE and 0−100 μM α-tocopherol or trolox. Part 5 included the addition of 800 μM DOPC, DOPE, or ethanolamine to MCT or SSO containing 800 μM α-tocopherol quinone. According to the different parts, appropriate amounts of antioxidants (α-tocopherol, α-tocopherol quinone, or trolox) were dissolved in ethanol and then pipetted into empty beakers followed by removal of solvent by nitrogen flushing. SSO was then added, and the sample was magnetically stirred overnight. According to different experimental parts, the appropriate amounts of NBD-PE, DOPC, and/or DOPE in chloroform, individually or at different ratios, were pipetted into empty beakers, and chloroform was removed by nitrogen flushing. SSO containing antioxidants was added and magnetically stirred at room temperature for 5 h for NBD-PE fluorescence study or overnight for lipid oxidation studies. For the lipid oxidation studies, 1 mL samples were aliquoted into 10 mL headspace vials, sealed with aluminum caps with PTFE/silicone septa, and stored in the dark at 55 °C.

Measurement of Lipid Oxidation. At various sampling times, lipid oxidation was determined by monitoring lipid hydroperoxides and headspace hexanal formation. Lipid hydroperoxides were measured as primary oxidation products according to the method of Shantha and Decker.[22] In short, 2.8 mL of a mixture of methanol/butanol (2:1, v/v) was added to oil samples of known weight. Then 15 μL of 3.94 M ammonium thiocyanate and 15 μL of 0.072 M Fe^{2+} (ferrous sulfate) were added, and the solution was vortexed. After a 20 min reaction time, the absorbance was measured at 510 nm using a Genesys 20 spectrophotometer (ThermoSpectronic, Waltham, MA, USA). The concentration of lipid hydroperoxides was calculated from a cumene hydroperoxide standard curve ranging from 0.7 to 17 mM. Samples with hydroperoxide concentrations >17 mM were diluted with methanol/butanol (2:1, v/v) before measurements.

Headspace hexanal was measured as a secondary lipid oxidation products using a GC-17A Shimadzu gas chromatograph equipped with an AOC-5000 autosampler (Shimadzu, Kyoto, Japan) as described by Chen et al.[17] In short, a 30 m × 0.32 mm Equity DB-1 column with a 1 μm film thickness was used for separations. Oil samples (1 mL) in 10 mL headspace vials were heated at 55 °C for 8 min in the autosampler heating block. A 50/30 μm DVB/Carboxen/PDMS solid-phase microextraction (SPME) fiber needle was injected into the sample vial for 2 min to adsorb volatiles, and then the fiber was placed into the 250 °C injector port for 3 min at a split ratio of 1:5. The GC separations were 10 min at 65 °C for each sample. Helium was used as a carrier gas, with a total flow rate of 15.0 mL/min. A flame ionization detector at 250 °C was used to detect hexanal, and concentrations were determined from peak areas using a standard curve made from SSO containing known hexanal concentrations from 2 to 800 μM.

Fluorescence Measurement of SSO Containing Reverse Micelles and Antioxidants. The concentration of NBD-PE in SSO was varied to get appropriate fluorescence intensity with minimal self-quenching, and the optimal concentration of the probe was found to be 0.95 μM. The measurements were carried out as described by Kittipongpittaya et al.[23] Basically, the sample was transferred to a triangular Suprasil quartz cuvette (Sigma-Aldrich Co., St. Louis, MO, USA). The steady-state emission intensity of spectra, determined as the emission signal intensity (counts per second) measured by a photomultiplier, was recorded with a PTI spectrofluorometer (PTI, Ontario, Canada). The spectral bandwidths for both excitation and emission slits were set to 2 nm for excitation at 468 nm. The integration time was set to 1 s.

Determination of α-Tocopherol Concentration by HPLC. Oil samples (20−30 mg) were dissolved in 1 mL of isoproponal and 1 mL of methanol and then passed through a 0.2 μm filter (Fisher Scientific, Pittsburgh, PA, USA). Sample (20 μL) was then injected to a Shimadzu HPLC system equipped with a Beckman Ultrasphere C18 reversed phase column (150 mm × 4.6 mm, 5 μm). The mobile phase was isocratic methanol at a flow rate of 1 mL/min. A Waters 474 scanning fluorescent detector (Waters, Milford, MA, USA) was used to detect α-tocopherol at an excitation wavelength of 290 nm and an emission wavelength of 330 nm. Peak integration was performed using Shimadzu EZstart software (version 7.2). α-Tocopherol in the samples was identified and quantified by comparing their relative retention times and peak areas with those of authentic compounds.

Cyclic Voltammetry Measurements. Cyclic voltammetry measurements were performed according to the method described by Wilson and co-workers.[24] Briefly, a BASi model C-3 cell stand with a planar 1 mm diameter glassy carbon working electrode, a Ag/AgCl reference electrode, and a Pt wire auxiliary electrode was used. Tetrabutylammonium hexafluorophosphate (Bu_4NPF_6; 0.5 M) in dichloromethane was used as a salt bridge. DOPC, DOPE, and α-tocopherol (1 mM) were freshly dissolved in dichloromethane before measurements.

Statistical Analysis. All experiments used triplicate samples (three samples taken at each time point), and each experiment was repeated at least two times. Data were presented as the mean value ± standard deviation. Data results were analyzed by analysis of variance (ANOVA) using SPSS 17.0 (SPSS Inc., Chicago, IL, USA). The differences between mean values were compared using Duncan's multiple-range test with a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Impact of DOPC and DOPE on SSO Oxidation. There are two reasons for choosing 20 and 1000 μM DOPE in the first experiment. First, 20 and 1000 μM represent concentrations below and above the critical micelle concentration (CMC) for DOPE because the CMC for DOPE is 200 μM.[18] Second, these concentrations are within the range of what is found in refined commercial oils. In this experiment, we found that at 55 °C, DOPE had the same lag phase (4 days) as the stripped soybean oil control when its concentration (20 μM) was below its CMC (200 μM). On the other hand, when DOPE concentration (1000 μM) was above its CMC (200 μM), it had pro-oxidant activity with a lag phase of 2 days.

When 20 μM DOPC was added to the SSO at the same concentration as DOPE, the lag phase was also similar to the control. DOPC above its CMC (1000 μM) was pro-oxidative, which agrees with previous results.[17] Samples containing 1000 μM DOPE showed slower rates of lipid hydroperoxides and hexanal formation than DOPC, but both had the same lag phase. Lag phase is the most important indicator of oil quality because after the lag phase, the oil is rancid. This indicates that both DOPE and DOPC are pro-oxidative at concentrations above their CMCs, at which they form association colloids. This pro-oxidative activity of phospholipids caused by the formation of reverse micelles during storage at 55 °C agrees with our previous results using SSO stored at 37 and 45 °C.[17,18]

Impact of DOPC and DOPE on the Oxidation of SSO Containing α-Tocopherol or Trolox. There has been a lot of research done on the impact of phospholipids on bulk oil oxidation. However, no agreement has been made on their roles as studies report both antioxidative and pro-oxidative activity.[6,8,9,25] Our previous results showed that when DOPE is above its CMC, it is pro-oxidative, whereas DOPE below its CMC does not affect oxidation rates. However, those results were based on a SSO system, which was almost pure triacylglycerols. Here, we used a system consisting of SSO and 100 μM α-tocopherol or trolox, which enabled us to investigate on how DOPC and DOPE reverse micelles affect the ability of antioxidants to alter lipid oxidation in bulk oil.

In the case of α-tocopherol (Figure 2), the lag phases of hydroperoxides and hexanal formation in the presence and absence of 20 μM DOPC were 17 and 21 days, respectively. It was somewhat unexpected that 20 μM DOPC decreased the activity of α-tocopherol because 20 μM DOPC had no impact on lipid oxidation rates by itself (Figure 1A, 1B). A potential reason that 20 μM DOPC could be pro-oxidative is that this concentration was very close to the CMC of DOPC and addition of α-tocopherol could cause the formation of some pro-oxidative reverse micelles. In the presence of 1000 μM DOPC, where large amounts of reverse micelles were present, the hydroperoxides and hexanal formation lag phase reduced from 21 days (α-tocopherol only) to 12 days. DOPC reverse micelles themselves had pro-oxidant activity (Figure 1), which would be expected to diminish the antioxidant activity of α-tocopherol. In addition, it is worth noting that compared to

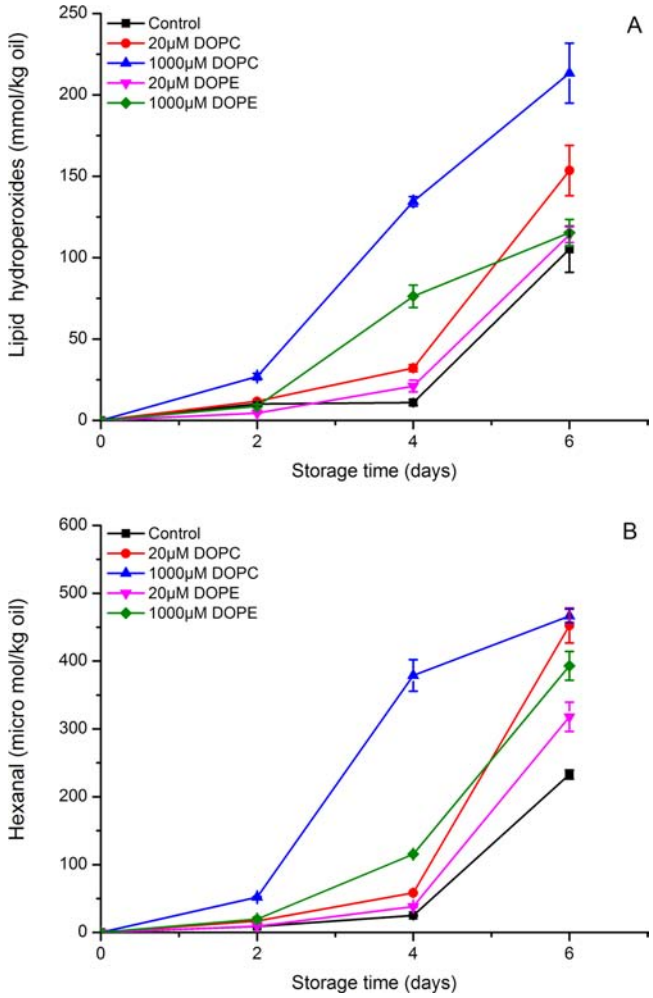

Figure 1. Formation of lipid hydroperoxides (A) and headspace hexanal (B) of SSO with 20 or 1000 μM DOPC or DOPE concentrations at 55 °C. Data points represent means (n = 3) ± standard deviations.

SSO alone, which had a lag phase of 4 days (Figure 1), the combination of 1000 μM DOPC and α-tocopherol still had a longer lag phase (12 days) and thus a net antioxidant effect.

As for DOPE, the activity of α-tocopherol was increased at DOPE concentrations both below (20 μM) and above (1000 μM) its CMC with antioxidant activity increasing with increasing DOPE concentrations as determined by both lipid hydroperoxides and headspace hexanal. This suggested that the ability of DOPE to increase the activity of α-tocopherol was independent from the presence of reverse micelles. The synergy seen between PE and α-tocopherol has been reported earlier,[8,9] but no clear mechanism was presented.

In the case of trolox (Figure 3), the lag phases of both hydroperoxides and hexanal formation in the presence and absence of 20 μM DOPC were the same, being 60 days. In the presence of reverse micelles formed by 1000 μM DOPC, the lag phase reduced from 60 days (trolox only) to 28 days for hydroperoxide formation and to 31 days for hexanal formation. This was as expected because of the pro-oxidative activity of DOPC reverse micelles. As for DOPE, the activity of trolox was increased at DOPE concentrations both below (20 μM) and above (1000 μM) the CMC with antioxidant activity increasing with increasing DOPE concentrations as determined by both lipid hydroperoxides and headspace hexanal. This again

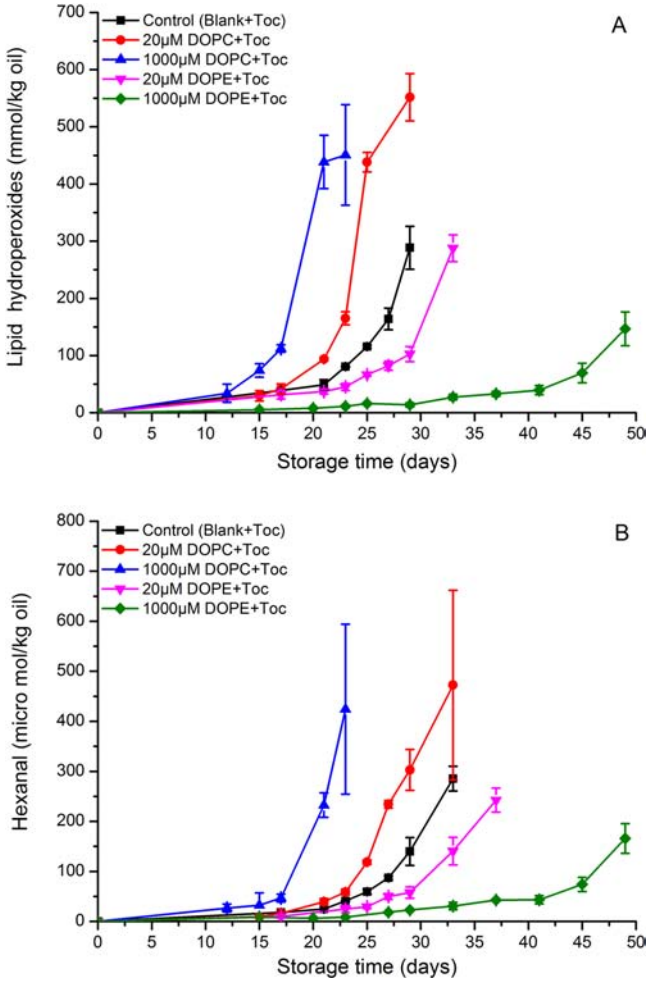

Figure 2. Formation of lipid hydroperoxides (A) and headspace hexanal (B) of SSO containing 100 μM α-tocopherol with addition of 20 or 1000 μM DOPC or DOPE at 55 °C. Data points represent means (n = 3) ± standard deviations.

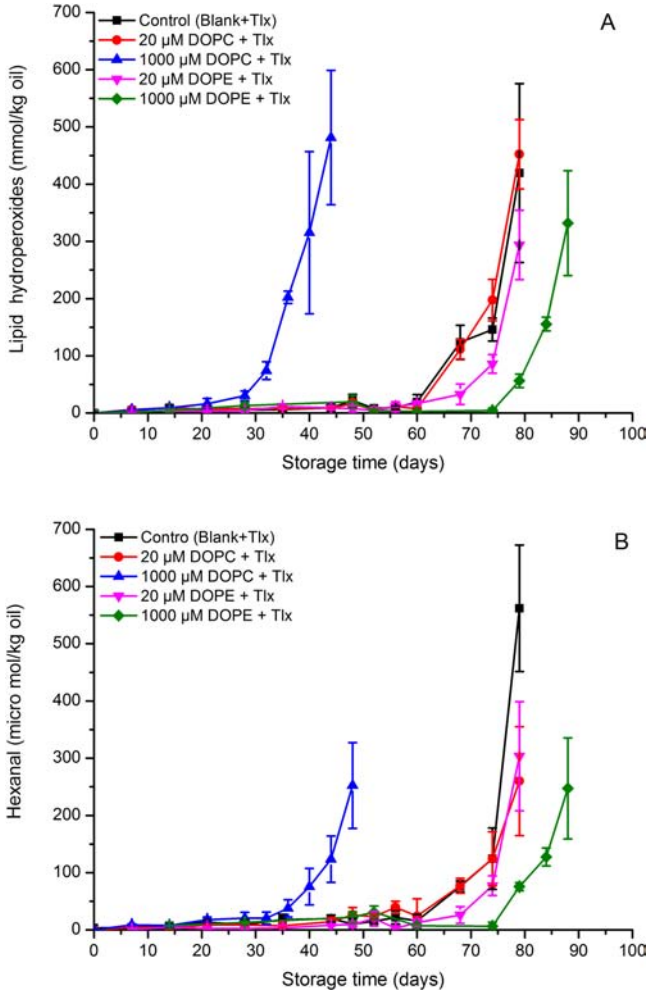

Figure 3. Formation of lipid hydroperoxides (A) and headspace hexanal (B) of SSO containing 100 μM trolox with addition of 20 or 1000 μM DOPC or DOPE at 55 °C. Data points represent means (n = 3) ± standard deviations.

suggested that DOPE was increasing the activity of trolox regardless of the presence of reverse micelles. In addition, the lag phases of all treatments with trolox were longer than those with α-tocopherol, which agreed with the antioxidant polar paradox theory.[26]

Impact of DOPC and DOPE Combinations on the Oxidation of SSO Containing α-Tocopherol. Previously, we reported that the combination of DOPC and DOPE at concentrations above their CMC could form mixed reverse micelles and was pro-oxidative in SSO.[18] Because PE was found to increase the activity of α-tocopherol, a further investigation on the combinations of these two phospholipids was carried out to see their overall impact on α-tocopherol. The lag phases of hexanal formation of different compositions of DOPC and DOPE above the CMC (1000 μM in total) with 100 μM α-tocopherol are shown in Figure 4. As the proportion of DOPE increased from 0 to 10, 30, 50, 60, and 100%, the corresponding lag phases increased from 17 to 21, 28, 28, 36, and 42 days, respectively. These different overall effects in hexanal lag phases with different DOPC/DOPE ratios were due to a combination of the pro-oxidative effect of the phospholipids reverse micelles and the ability of PE to increase the activity of α-tocopherol. This suggested that the addition of PE could improve the oxidative stability of refined soybean oil,

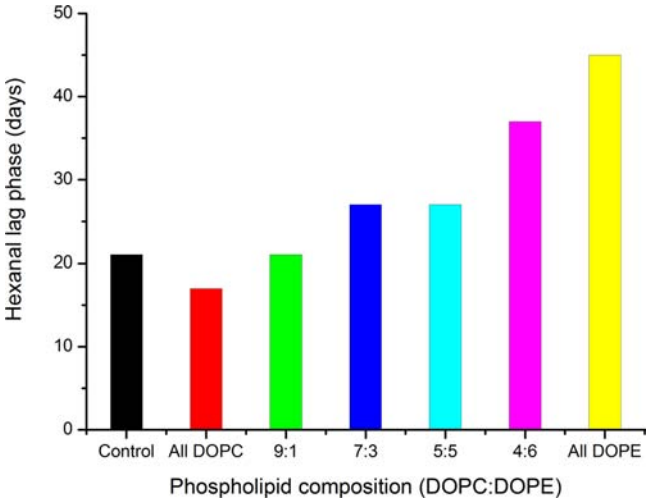

Figure 4. Headspace hexanal lag phases of SSO containing 100 μM α-tocopherol with addition of DOPC and DOPE at different ratios (1000 μM in total) at 55 °C.

which would naturally contain tocopherols. We tested this hypothesis with commercial soybean oil naturally containing

DOI: 10.1021/acs.jafc.5b00243
J. Agric. Food Chem. 2015, 63, 3288−3294

2000 μM (800 ppm) mixed tocopherols in which we added 1000 μM DOPC or DOPE (Figure 5). The control and the oil

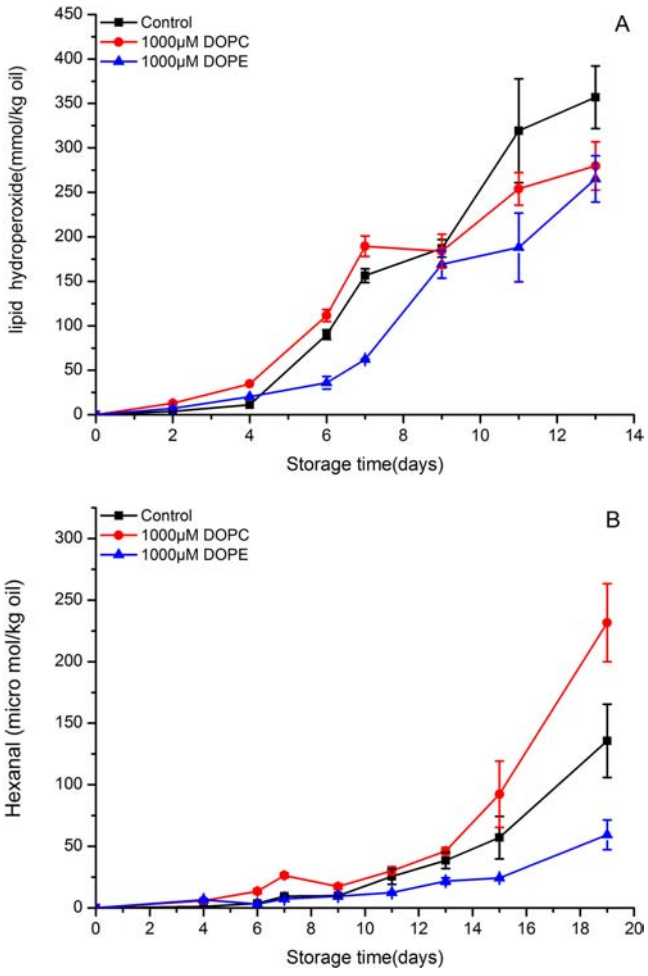

Figure 5. Formation of lipid hydroperoxides (A) and headspace hexanal (B) of commercial soybean oil with addition of 1000 μM DOPC or DOPE at 55 °C. Data points represent means (n = 3) ± standard deviations.

with the addition of DOPC had the same lipid hydroperoxides lag phase of 4 days and a hexanal lag phase of 9 days, whereas the oil with the addition of DOPE increased the lipid hydroperoxide lag phase to 6 days and the hexanal lag phase to 15 days.

Location of Antioxidants in the Presence of DOPE and DOPC Reverse Micelles. Physical locations of antioxidants in bulk oil can influence their antioxidant activities. NBD-PE was used to investigate whether or not DOPC and DOPE reverse micelles have an impact on antioxidant locations. NBD-PE is a surface-active phospholipid with a fluorophore group covalently attached to the headgroup of PE. This probe has been widely used in biological and model membranes as fluorescent analogues of native lipids, and the location of the probe in those models is believed to be at the interfacial region of the membrane.[27] In our experiments, 0.95 μM NBD-PE and 1000 μM DOPE or DOPC were added into bulk oil. With those concentrations, the ratio of fluorophore to surfactant was about 1:1000, which helped avoid probe aggregation and thus self-quenching effects.

When DOPC and DOPE reverse micelles were not present, the emission intensity of the probe decreased with increasing α-tocopherol concentration (data not shown), showing that α-tocopherol has the ability to quench the probe. On the other hand, when α-tocopherol is not present, the phospholipids alone (DOPC or DOPE) did not cause any changes of probe emission intensity (data not shown). In the presence of both DOPC and DOPE reverse micelles, increasing trolox concentration decreased the emission intensity of the NBD-PE probe (Figure 6), indicating that trolox was in close contact

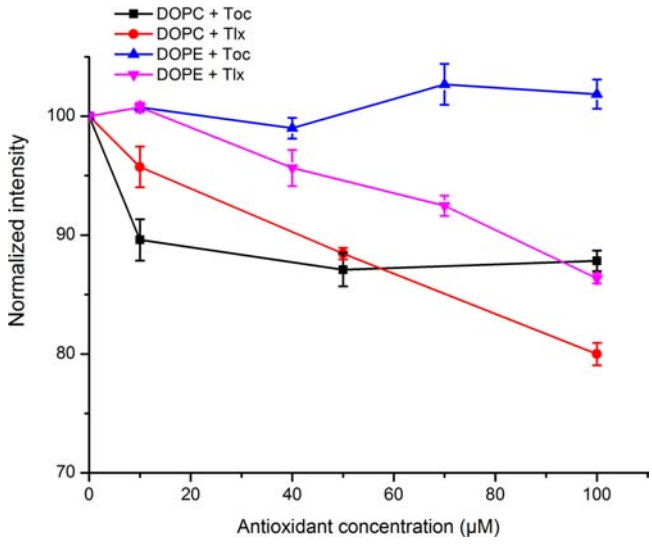

Figure 6. Normalized fluorescence intensity of NBD-PE in SSO with addition of 1000 μM DOPC or DOPE and different concentrations of α-tocopherol or trolox.

with the probe, thus quenching its fluorescence. However, the combination of DOPE reverse micelles and α-tocopherol did not cause a significant difference in NBD-PE emission intensity with increasing α-tocopherol concentrations. When the combination DOPC reverse micelles and α-tocopherol was present, the emission intensity of the probe decreased with the addition of α-tocopherol at first, but did not further decrease as α-tocopherol concentration increased from 10 to 100 μM. These results suggested that α-tocopherol did not accumulate in the DOPE reverse micelle but did accumulate in the DOPC reverse micelles. These data indicated that water-soluble trolox partitioned more readily into DOPE reverse micelles. Trolox also partitioned into DOPC reverse micelles, and at the concentration used in the antioxidant studies (100 μM), more trolox than α-tocopherol was in the reverse micelles. Because the micelle interface could be a major site of lipid oxidation reactions due to the presence of surface active hydroperoxides and water-soluble transition metals, the greater concentration of the antioxidant at the interface could explain why trolox was more effective than α-tocopherol. However, DOPE was found to increase the activity of α-tocopherol even though DOPE reverse micelles were not found to increase α-tocopherol concentrations at the micelle interface. This suggests that DOPE's ability to increase the activity of α-tocopherol was not due to changes in its physical location.

Effect of DOPE on α-Tocopherol Regeneration. Another potential mechanism by which DOPE could increase the activity of α-tocopherol would be through its ability to regenerate oxidized α-tocopherol back to its active, reduced

DOI: 10.1021/acs.jafc.5b00243
J. Agric. Food Chem. 2015, 63, 3288−3294

form. The hypothesis that phospholipids regenerate tocopherols was tested by monitoring the ability of DOPC, DOPE, and ethanolamine, the headgroup of PE, to react with α-tocopherol quinone, an oxidation product of α-tocopherol, in both MCT (Figure 7A) and SSO (Figure 7B) at 55 °C. In MCT (Figure 7A) where no lipid oxidation occurs, the treatments with DOPE and ethanolamine but not DOPC promoted the regeneration of α-tocopherol quinone to α-tocopherol, indicating that the ethanolamine headgroup of PE can reduce α-tocopherol quinone. In SSO (Figure 7B), only the treatment with DOPE and α-tocopherol quinone resulted in the formation of α-tocopherol. Also, the quantity of α-tocopherol regenerated by DOPE in SSO was smaller than that in MCT. This could be because in SSO, lipid oxidation was occurring, which could consume α-tocopherol once it was produced by DOPE and α-tocopherol quinone. This was confirmed by monitoring the hydroperoxide formation in SSO (Figure 7B, right *y* axis). DOPE with α-tocopherol quinone was still within the hydroperoxide lag phase after 8 days of storage, whereas all other treatments and the α-tocopherol quinone control had a lag phase of 2 or 4 days. This indicated that the newly produced α-tocopherol by DOPE and α-tocopherol quinone were being consumed to retard lipid oxidation in SSO, thus decreasing the accumulation of α-tocopherol compared to the nonoxidizing MCT.

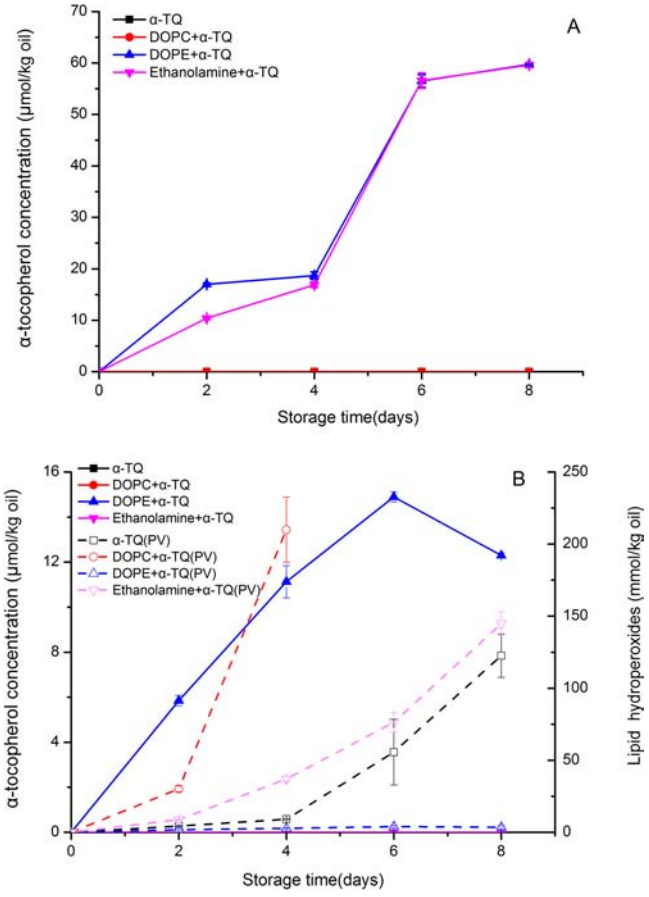

Figure 7. Formation of α-tocopherol (solid lines) by 800 μM DOPC, DOPE, or ethanolamine with 800 μM α-tocopherol quinone at 55 °C in MCT (A) and SSO (B); formation of lipid hydroperoxides (B, dashed lines) of SSO containing 800 μM DOPC, DOPE, or ethanolamine with 800 μM α-tocopherol quinone at 55 °C.

A potential mechanism by which DOPE could regenerate α-tocopherol quinone is by electron transfer. The potential for such an electron transfer reaction can be evaluated by measuring oxidation−reduction potentials via cyclic voltammetry.[28] Using this method, α-tocopherol exhibited an oxidation peak at about 600 mV, which was close to that reported in the literature.[29] However, there were no oxidation or reduction peaks detected for DOPC or DOPE (data not shown). This suggested that DOPE did not regenerate α-tocopherol through direct electron transfer. Recently, Doert et al.[10] also reported that α-tocopherol regeneration by primary amines can be explained by an ionic mechanism rather than by a radical mechanism. In their study, they found that a 1% addition of L-β,γ-dipalmitoyl-α-phosphatidylethanolamine (PE) and 1,2-dipalmitoylgycero-3-phosphoryl-L-serine (PS), but not L-β,γ-dipalmitoyl-α-phosphatidylcholine (PC) or L-β,γ-dipalmitoyl-α-inositol (PI), regenerated α-tocopherol quinone to α-tocopherol in toluene at 100 °C. In our case, this reaction was confirmed with about 10 times lower concentration of PE (0.07%) in both bulk oil and MCT at a much lower temperature (55 °C). The concentrations used in this study are much closer to concentrations expected in refined, commercial oils.

Conclusion. In this study, the impact of two types of phospholipids, DOPC and DOPE, both individually and in combinations on the antioxidant activity of α-tocopherol or trolox in bulk oil was investigated. It was found that DOPC reverse micelles decreased the antioxidant activity of α-tocopherol and trolox. DOPE reverse micelles did not cause changes in the physical location of α-tocopherol, but increased its antioxidant activity through regeneration of oxidized α-tocopherol by its primary amine headgroup. The addition of DOPE to commercial soybean oil inhibited lipid oxidation, whereas DOPC was ineffective. These results indicated that in bulk oils the primary amine headgroup of DOPE increased the antioxidant activity of α-tocopherol by regeneration of the α-tocopherol quinone. To get a better efficiency of natural antioxidants such as tocopherols in bulk oil, decreasing PC reverse micelles and increasing PE could help stabilize the food oils.

with the incidence of necrotizing enterocolitis in mice[24] and infants.[18−20] Bacterial strains were purchased from the American Type Culture Collection (ATCC, Manassas, VA, USA). Confirmation of bacterial identity was completed prior to the bacterial growth assays. Briefly, bacterial cultures were inoculated from frozen stock (12.5% glycerol, v/v) into brain−heart infusion (BHI; Difco, Franklin Lakes, NJ, USA) broth and incubated overnight aerobically with shaking at 200 rpm at 37 °C. Genomic DNA was isolated from stationary bacterial cultures. Briefly, a 1.8 mL aliquot was centrifuged at 10000*g* in a 2 mL centrifuge tube containing approximately 100 mg of 0.25 μm silicon beads (RPI Corp., Mount Prospect, IL, USA) for 1 min and the bacterial pellet was resuspended in nanopure water. The tubes were boiled for 5 min (additional kill step for pathogens) and were then centrifuged at 7000*g* for 5 min. The bacterial pellet was resuspended in nanopure water and vortexed at maximum speed for 10 min. The lysed bacterial cells were centrifuged at 12000*g* for 3 min, and the supernatant was frozen at −20 °C. An approximately 1400 bp amplicon of DNA was amplified from the crude DNA extract by 16S rRNA specific primers, 8F (5′-AGAGTTTGATCCTGGCTCAG-3′) and 1391R (5′-GACGGGCGGTGWGTRCA-3′).[25,26] The PCR reaction mixture contained 3 μL of target DNA, 5 μL of each primer (10 mM), and 25 μL of EconoTaq Plus 2X Master Mix (Lucigen Corp., Middleton, WI, USA). The PCR cycling parameters consisted of an initial step of 5 min at 95 °C, followed by 35 cycles (30 s at 95 °C, 60 s at 54 °C, and 2 min at 72 °C) and an extension step at 72 °C for 7 min. PCR products were purified using the Zymoclean DNA Clean & Concentrator Kit (Zymo Research Corp., Irvine, CA, USA) according to the manufacturer's instructions. Sanger sequencing was done with either primer (8F or 1391R) using an ABI 3730XL capillary sequencer (Life Technologies). The sequences were trimmed for quality and uploaded to the BLAST database (NCBI) to determine identity (>97% similarity). All strains were confirmed as the species indicated in Table 1.

Bacterial Growth Assays. Bacterial growth due to the addition of a carbohydrate was determined using a Bioscreen C (Growth Curves USA, Piscataway, NJ, USA). Bacterial cultures were inoculated from frozen stock (12.5% glycerol, v/v) into BHI broth and grown overnight aerobically with shaking at 200 rpm and 37 °C. A 1% (v/v) inoculum was passed into 5 mL of ZMB-1 broth,[27] a chemically defined medium allowing for carbohydrate utilization experiments, supplemented with 1% glucose and incubated overnight aerobically with shaking at 200 rpm at 37 °C. To prepare the bacterial inoculum for the Bioscreen C growth assay, bacterial cultures were centrifuged at 4000*g* for 10 min and washed twice with phosphate-buffered saline (PBS; MP Biomedicals, Santa Ana, CA, USA), pH 7.4. The washed bacterial pellets were resuspended in 5 mL of carbohydrate-free ZMB-1 broth. The final bacterial inoculum was prepared by transferring a 1% (v/v) volume of ZMB-1 suspended cells into a fresh aliquot of ZMB-1 broth. The honeycomb plate was prepared with each well containing a total of 300 μL: 225 μL of washed cells in ZMB-1 broth and 25 μL of 10% (w/v) sugar solution (Table 2), and 50 μL of mineral oil (to prevent evaporation). Plates were preincubated anaerobically (90% N_2, 5% CO_2, 5% H_2; Coy Laboratory Products, Grass Lake, MI, USA) for 1 h prior to the addition of mineral oil. Plates were incubated anaerobically for 24, 48, 72, or 96 h (varied by experiment). Optical density at 600 nm was measured at 30 min intervals, which were preceded by 30 s of shaking at maximum speed. Each carbohydrate was tested with a minimum of three independent replications.

Enrichment of Enterobacteriaceae Consortia. The following protocol was utilized to enrich and isolate Enterobacteriaceae from feces of weaned piglets (n = 10) aged 42 days. Fresh fecal samples (~1 g) were collected from piglets raised at the University of Illinois Swine

Table 2. Carbohydrate Substrates Supplemented as a Sole Carbon Source for Bacterial Growth Assays

carbohydrate source		abbreviation	purpose	supplier

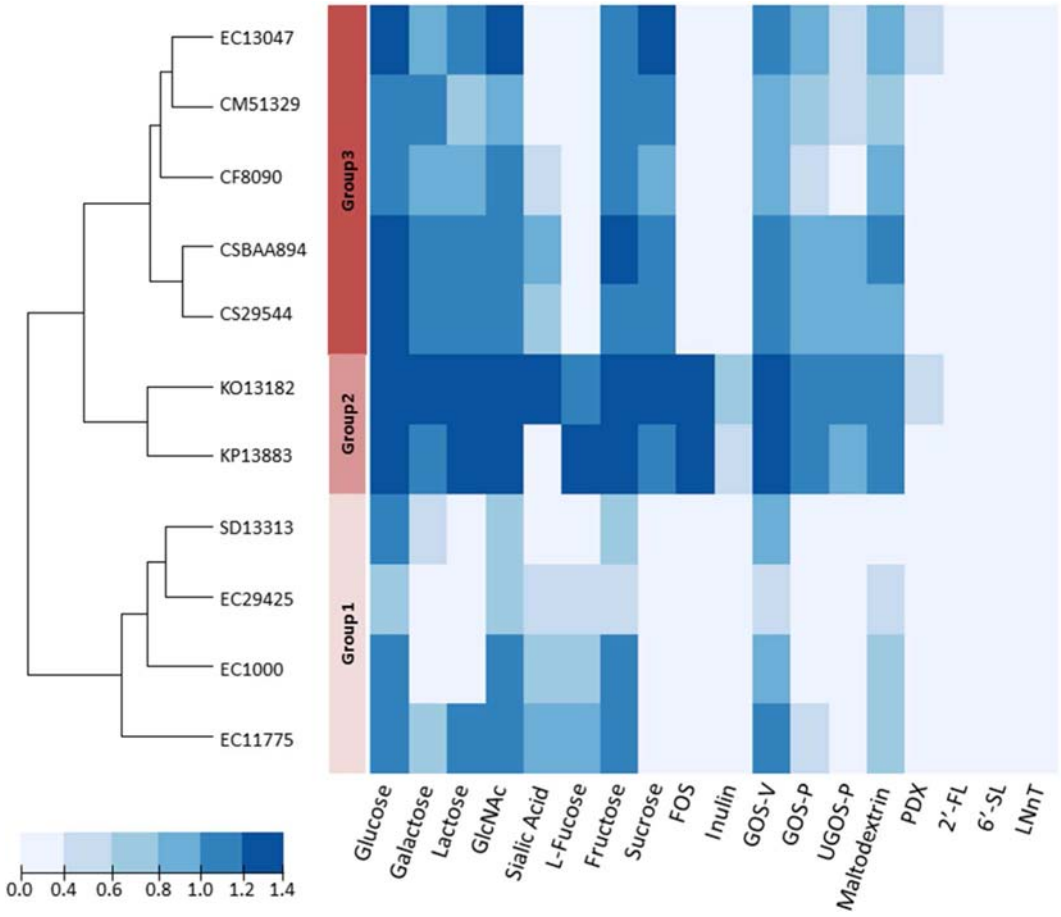

Figure 1. Maximal growth, OD 600 nm, achieved on 1% carbohydrate (glucose, galactose, lactose, *N*-acetylglucosamine (GlcNAc), *N*-acetylneuraminic acid (sialic acid), L-fucose, fructose, sucrose, sc-fructooligosacharides (FOS), inulin, galactooligosaccharides-vivinal (GOS-V), galactooligosaccharides-purimune (GOS-P), ultra-purified galactooligosaccharides-purimune (GOS-P), maltodextrin, polydextrose (PDX), 2′-fucosyllactose (2′-FL), 6′-siallyllactose (6′-SL), and lacto-*N*-neotetraose (LNnT)) in ZMB-1 media. No growth was observed in the absence of carbohydrates. Blank is corrected by subtraction of wells containing no cells and no carbohydrate. Dendrogram shows relatedness by pattern of growth. Average of three or more independent experiments.

Research Center. Samples were collected from their source (piglets) and stored on ice until use.

Enrichment of an Enterobacteriaceae consortium was performed as follows. Approximately 200 mg of feces was added to 2 mL (10-fold dilution) of prewarmed sterile buffered peptone water (BPW), pH 7.0. The fecal slurry was vortexed vigorously for complete homogenization. The BPW slurry was incubated overnight aerobically with shaking at 200 rpm and 37 °C. Following incubation the BPW fecal slurry was vortexed and set aside for 4 min to allow settling of the solid material. A 1 mL aliquot was combined with 9 mL (10-fold dilution) of Enterobacteriaceae Enrichment (EE) Broth (Oxoid, Basingstoke, UK) and incubated for 24 h aerobically with shaking at 200 rpm and 37 °C. A 5 mL aliquot of EE cultures was used for a Bioscreen C growth assay (procedure same as above). Upon completion of the Bioscreen C growth assay, 150 μL of cell suspension was centrifuged at 12000*g* for 3 min. A 100 μL aliquot was collected for HPLC analysis and stored at −20 °C. The remaining fermentate was pipetted off, and the cell pellets were frozen at −20 °C for archiving.

High-Performance Liquid Chromatography (HPLC). Selected fermentates from the in vitro growth assays were analyzed by HPLC using an Agilent Technologies 1260 Infinity HPLC (Agilent, Santa Clara, CA, USA) equipped with a refractive index detector using a Rezex ROA-Organic Acid H+ (8%) column (Phenomenex Inc., Torrance, CA, USA). The column was eluted with 0.005 N H_2SO_4 at a flow rate of 0.6 mL/min at 50 °C. Baseline samples were diluted 10-fold (20 μL of 10% sugar stock solution with 180 μL of ZMB-1), whereas fermentate samples were diluted 4-fold (50 μL of fermentate with 150 μL of water) prior to analysis.

Co-substrate Growth Assay. Bacterial growth resulting from the combination of a fermentable carbohydrate and an HMO was determined using a Bioscreen C as previously described. Washed cells were grown in ZMB-1 media supplemented with 1% (w/v) fermentable carbohydrate (Glu, Lac, or Mal) and 1% HMO (2′-FL, 6′-SL, or LNnT). Plates were incubated anaerobically for 48 or 72 h (varied by experiment). Each combination of carbohydrates was tested with three independent replications.

The impact to bacterial growth due to the presence or absence of HMOs was evaluated using a growth curve regression script written in MATLAB (version R2013a, The MathWorks, Natick, MA, USA) with the curve fitting toolbox. This script implements the modified logistic regression model, which provides a quantitative assessment of bacterial growth.[28] Additional heuristics were included in the modified logistic regression model to more accurately approximate the bacterial growth curves: (a) the death phase of the bacterial growth curve was not included in the regression, and (b) a threshold to detect cases where no growth occurred was set to an OD = 0.4 (600 nm). All regressions were judged by "goodness of fit" metrics, which were provided by the MATLAB curve fitting toolbox. Acceptable regression curves were selected on the basis of an $R^2 > 0.98$.

The growth curve was distilled into four calculable parameters: lag time (amount of time for bacteria to enter exponential growth phase), maximum specific growth rate (μ_{max}), doubling time (db time, also known as generation time), and delta OD (ΔOD, 600 nm). The lag

DOI: 10.1021/jf505721p
J. Agric. Food Chem. 2015, 63, 3295−3302

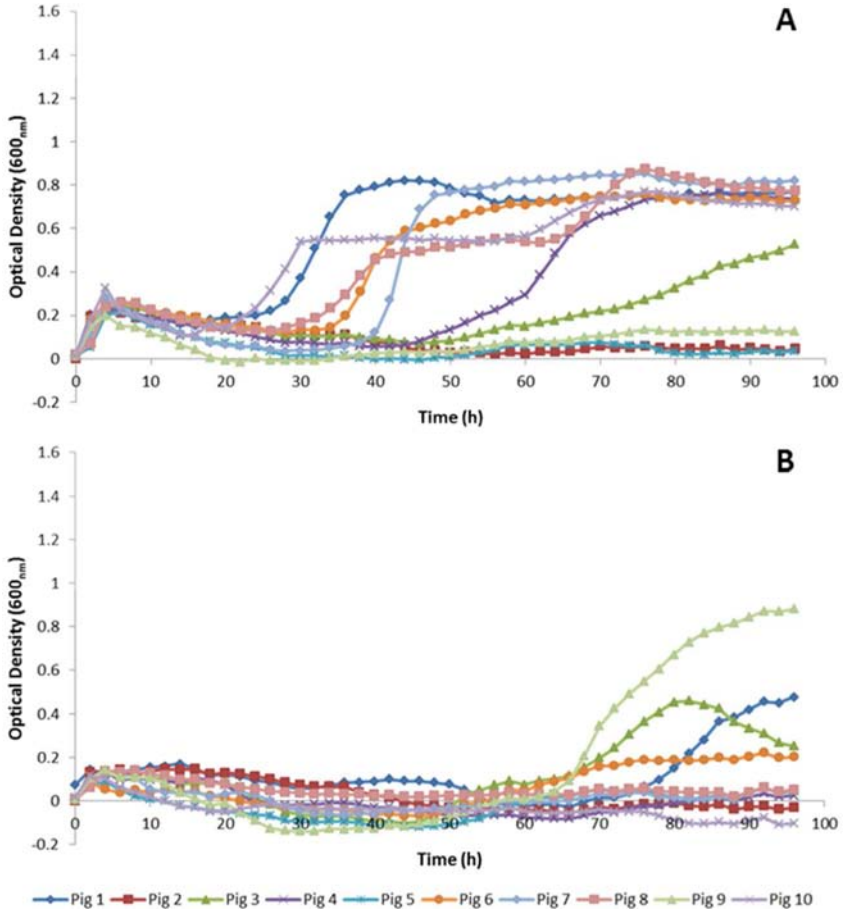

Figure 2. Growth curves of enriched piglet fecal Enterobacteriaceae consortia (n = 10), OD 600 nm, achieved at 96 h on 1% carbohydrate in ZMB-1 media: (A) ultra-purified purimune galactooligosaccharides (UGOS-P); (B) lacto-*N*-neotetraose (LNnT). Blank is corrected by subtraction of wells containing no cells and no carbohydrate. One independent Enterobacteriaceae consortia enriched per piglet.

time is defined as the x-intercept of the tangent line at the inflection point of the logistic regression curve (LRC) and is reported in hours. The maximum specific growth rate is defined as the slope of the tangent line at the inflection point of the LRC and is reported in hours^{-1}. The db time is mathematically related to the maximum specific growth rate and can be calculated using eq 1 (reported in hours):

$$\text{db time} = \frac{\ln(2)}{\mu_{\max}} \quad (1)$$

The ΔOD is calculated as the difference between the asymptote of the logistic curve (maximum OD) and the minimum OD and is reported as unit OD 600 nm.

Statistical Analysis. Statistical differences in bacterial growth parameters due to the presence/absence of HMO were determined using SAS (version 9.2, SAS Institute, Cary, NC, USA). Following satisfaction of the requirements of normality and homogeneity of variance, the bacterial parameters were evaluated using the generalized linear model (GLM). In cases when statistical significance was seen ($p < 0.05$), a post hoc mean separation was done using Dunnett's test. This test determines the statistical significance of the difference of each treatment (addition of HMO) to the control (fermentable sugar). Data visualized by heat map and dendrogram were conducted in R[29] using the gplots package.[30] The presented dendrogram (Figure 1) shows relatedness of organisms by their pattern of growth.

RESULTS

In Vitro Growth of Selected Carbohydrates. Nine pathogenic and two nonpathogenic Enterobacteriaceae strains (Table 1) were evaluated for their ability to grow in vitro using a selection of carbohydrates as a sole carbon source (Table 2). Preliminary experiments revealed that all tested Enterobacteriaceae were able to grow anaerobically in ZMB-1 supplemented with 1% glucose, whereas no growth was observed in the absence of a carbohydrate (data not shown). The resulting carbohydrate utilization data are displayed as a heat map (Figure 1). Interestingly, three distinct groups were identified on the basis of the observed patterns of growth and demonstrated significant overlap with phylogeny.[31] Group 1 is represented by the closely related *E. coli* strains and *Shigella dysenteriae*. Group 2 is represented by the two *Klebsiella* strains. Whereas the two *Cronobacter sakazakii* strains are grouped together, the other three strains, *Citrobacter freundii*, *Cronobacter muytjensii* and *Enterobacter cloacae*, in group 3 are not grouped according to phylogeny.

Bacterial strains that are represented by group 1 are EC1000, EC11775, EC29425, and SD13313. Their inability to utilize Suc and Lac (except EC11775) and weakened ability to grow in the presence of almost all carbohydrates tested are likely driving their clustering. Within the in vitro testing environment, these organisms were observed to grow on Glu, Fru, and GlcNAc; however, they did not grow in the presence of the tested prebiotics or HMOs.

The bacterial strains included in group 2 are KP13883 and KO13182. These two *Klebsiella* strains were strong utilizers of all carbohydrates tested except the HMOs. The unique ability

J. Agric. Food Chem. 2015, 63, 3295−3302

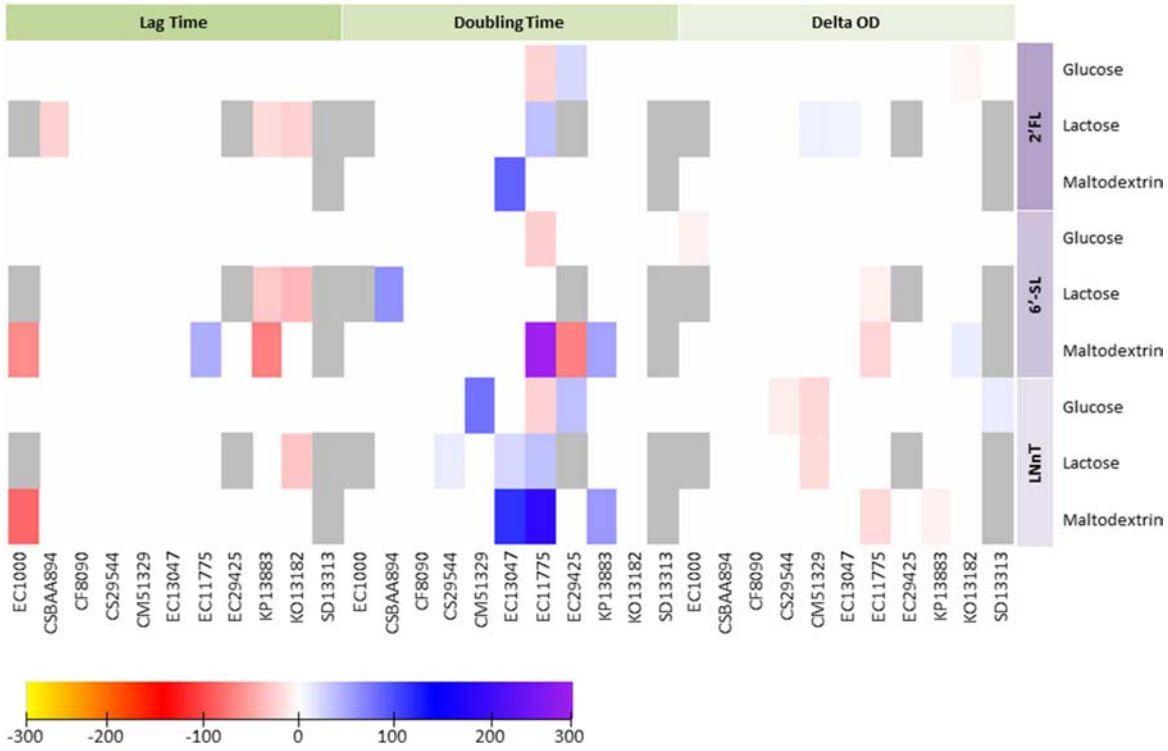

Figure 3. Statistically significant percent change in growth parameters determined from co-substrate bacterial growth. Bacterial cultures were grown in ZMB-1 with 1% fermentable carbohydrate (glucose, lactose, and maltodextrin) and 1% HMO (2′-fucosyllactose (2′-FL), 6′-sialyllactose (6′-SL), lacto-*N*-neotetraose (LNnT)). Heat map was generated on the basis of the percent change of either an increase or a decrease in the growth parameters of co-substrate wells compared to wells containing only the fermentable carbohydrate (ANOVA with Dunnett's mean separation). No growth was observed in the absence of carbohydrates. Blank is corrected by subtraction of wells containing no cells and no carbohydrate. Average of three independent experiments. Only organisms that were found to have a statistically significant percent change are shown. An organism's inability to grow in either lactose or maltodextrin is represented by gray boxes.

for KP13883 and KO13182 to utilize FOS and Inu for growth likely contributed to their clustering. Interestingly, only SA and PDX were differentially fermented between KP13883 and KO13182. Because KO13182 was observed to have a minimal increase in optical density in ZMB-1 supplemented with 1% LNnT (OD_{av} = 0.386), the bacterial growth curve was scrutinized. It was determined that an OD = 0.4 was an appropriate threshold because curves below this OD did not have a "characteristic" logistic curve with a distinct lag, exponential, or stationary phase. Additionally, the increase in OD occurred incrementally throughout the duration of the experiment (up to 96 h) until the maximum OD reading observed. We hypothesize that this small increase in growth was due to the presence of a small fraction of mono- or disaccharides in the LNnT we used. To test this hypothesis, the fermentate samples (n = 3) from KO13182 grown in ZMB-1 supplemented with 1% LNnT were analyzed by HPLC. The average percent decrease of LNnT detected in the fermentate as compared to the baseline (1% LNnT in ZMB-1) was 11.22 ± 0.29% (SEM) and was not considered significant.

Bacterial strains that are represented by group 3 are CSBAA894, CF8090, CS29544, CM51329, and EC13047. Interestingly, all five bacterial strains were unable to grow on L-fuc, fructooligosaccharides, and HMOs. Additionally, CF8090, CSBAA894, and CS29544 were observed to weakly grow on SA, whereas EC13047 and CM51329 were unable to utilize SA for growth. Conversely, these strains readily utilized Lac and Gal. Both CSBAA894 and CS29544 were observed to be GOS utilizers due to their ability to ferment the UGOS-P.

Enterobacteriaceae Consortia Growth. Enterobacteriaceae consortia were enriched from the feces of 42-day-old piglets (n = 10) who were weaned prior to fecal collection. These fecal consortia (PFEC) readily utilized Glu, Gal, Lac, GlcNAc, SA, and Mal for growth (data not shown). Interestingly, seven PFEC were capable of growing on UGOS-P with an extended lag time (Figure 2A), with three of the seven PFEC (4, 8, and 10) demonstrating multiphasic growth on UGOS-P. None of the PFEC grew when 2′-FL or 6′-SL (OD < 0.3) was supplemented as a sole carbon source. Conversely, three PFEC (1, 3, and 9) grew using 1% LNnT as a sole carbon source, albeit with a significant lag time (>60 h, Figure 2B). Subsequent HPLC analysis of the fermentate of all PFEC and two controls (EC29425 or no bacteria added) indicated that all of the PFEC, including the seven (piglets 2, 4, 5, 6, 7, 8, and 10) that did not show detectable growth (all OD < 0.25, Figure 2B), utilized at least some LNnT. More specifically, approximately 39 ± 8.8% of the LNnT disappeared from the fermentate of the seven PFEC that did not grow (OD < 0.25) on LNnT, and 62.8−97.7% of LNnT disappeared from the three PFEC that grew on LNnT (OD > 0.4). By contrast, the bacteria-free control (10.05 g/L) and EC29425 (9.4 g/L) showed no change in LNnT.

In Vitro Co-substrate Growth. Because HMOs are not the sole carbohydrates present in the diet of infants, we investigated the impact of providing various fermentable carbohydrates in combination with the HMOs on the growth of selected Enterobacteriaceae strains. Bacterial strains were grown in ZMB-1 supplemented with 1% of a fermentable

DOI: 10.1021/jf505721p
J. Agric. Food Chem. 2015, 63, 3295−3302

carbohydrate (Glu, Lac, or Mal) and compared to 1% fermentable carbohydrate + 1% HMO (2′-FL, 6′-SL, or LNnT). The impact on bacterial growth was evaluated by determination of the bacterial lag time, doubling time, and ΔOD and is presented in Figures S1−S3, respectively. To ease comparisons, the statistically significant percent of change between the experimental condition (addition of HMO) and control condition (fermentable carbohydrate) was illustrated using a heat map (Figure 3).

Combining individual HMOs with another fermentable carbohydrate affected lag time in only a few instances. The lag time for EC1000 was significantly decreased in the presence of Mal supplemented with 6′-SL and LNnT but not 2′-FL. Conversely, only Lac supplemented with 2′-FL caused a significant decrease in CSBAA894's lag time. Interestingly, both KP13883 and KO13182 had shorter ($p < 0.05$) lag times with all three HMOs in the presence of Lac, although it was more pronounced with 6′-SL ($p < 0.005$). Uniquely, EC11775 had a significantly increased lag time (6 h) when grown in the presence of Mal and 6′-SL.

The bacterial db time was differentially affected depending on the strain/carbohydrate combination. Several strains exhibited an increase in db time in the presence of an HMO. Specifically, the db time was significantly longer when an HMO was combined with Mal (EC13047:2′-FL and LNnT, EC11775 and KP13883:6′-SL and LNnT). Additionally, several strains (CS29544, EC13047, and EC11775) were significantly affected by the presence of LNnT in combination with Lac but to a lesser degree. Interestingly, only two strains (EC11775 and EC29425) had a significant decrease in db time. A significant decrease in db time for EC11775 was observed only when Glu was in combination with all three HMOs, whereas EC29425's db time decreased 69.7% when Mal was combined with 6′-SL. The largest percent change in db time was observed for EC11775 when Mal was combined with 6′-SL and LNnT (increases of 284 and 186%, respectively).

High-throughput experiments use the ΔOD to describe the magnitude of bacterial growth achieved over the course of a carbohydrate utilization experiment. It was observed that the ΔOD was differentially affected on the basis of the strain/carbohydrate combinations; however, the percent change was minimal (range from −25 to 10%). In general, the ΔOD was decreased in the presence of an HMO; however, no clear pattern was found. Interestingly, the ΔOD of CM51329 was significantly increased when Lac was in combination with 2′-FL. Conversely, when Glu and Lac were in combination with LNnT the ΔOD of CM51329 was significantly decreased.

DISCUSSION

Human milk oligosaccharides are believed to contribute to the health and development of the infant GI tract by multiple mechanisms. During the establishment of the intestinal microbiota,[2,11] HMOs function as prebiotics by selecting for certain *Bifidobacterium* and *Bacteroides* species. Although it has been assumed that HMOs do not support the growth of Enterobacteriaceae, which are thought to promote the inflammatory response that occurs during NEC, the ability of various members of this family to utilize individual HMOs has not been thoroughly examined. In this study, we assessed the ability of several Enterobacteriaceae strains and enriched piglet fecal Enterobacteriaceae consortia to utilize 2′-FL, 6′-SL, and LNnT as a sole carbohydrate for growth. Additionally, we examined the impact of adding glucose, lactose, and maltodextrin on HMO utilization by the various Enterobacteriaceae strains.

Several Enterobacteriaceae tested were able to readily utilize mono- or disaccharides (Glu, Gal, Lac, Fru, and Suc) for growth; however, growth on prebiotic carbohydrates (FOS, Inu, UGOS-P, Mal, and PDX) was lessened or absent (Figure 1). Utilization of prebiotics for growth may be limited due to an organisms' inability to transport larger carbohydrates (>3 monomers) intracellularly. Therefore, the presence of extracellular glycosidases may assist transportation by cleaving the prebiotics into mono- or disaccharides. The extracellular glycosidases from *Bifidobacterium bifidum* have been studied extensively. The extracellular lacto-*N*-biosidase allows for the intracellular transport of lacto-*N*-biose by removing the terminal galactose from type 1 HMOs.[13] We hypothesized that KP13883 and KO13182 likely possess several extracellular glycosidases due to their ability to use a wide range of prebiotics (FOS, Inu, UGOS-P, Mal, and PDX) tested regardless of chain length. On the basis of the inability of any of the selected Enterobacteriaceae to detectably grow when 2′-FL, 6′-SL, or LNnT was the sole carbon source, we also hypothesized that these organisms do not possess the appropriate HMO-specific transporter or extracellular enzymes necessary for catabolism. Our data do demonstrate the potential of cross-feeding, whereby commensal GI organisms could liberate monosaccharides from HMOs, thereby providing a substrate for pathogenic Enterobacteriaceae. Ng and collegues[32] demonstrated that *Salmonella enterica* subsp. *enterica* serovar Typhimurium and *Clostridium difficile* advantageously catabolize liberated muco-glycans in a *Bacteroides thetaiotaomicron* monoassociated mouse model. *Salmonella* Typhimurium and *C. difficile* were observed to have a growth advantage and induction of genes associated with the sialic acid (*nan*) operon when *B. thetaiotaomicron* was present.[32]

Analysis of the infant fecal microbiome in infants diagnosed with NEC detected a bloom in proteobacteria (>50% relative abundance) in the GI of infants diagnosed with NEC.[17−21] Interestingly, an analysis of an infants' GI metabolome pre-NEC and following diagnosis revealed a significant increase in carbohydrate utilization genes mapped to members of the Enterobacteriaceae family.[21] Although none of the selected Enterobacteriaceae were able to grow on the HMOs tested, it would be premature to assume that no Enterobacteriaceae strains are capable of utilizing HMOs for growth. Therefore, Enterobacteriaceae consortia were enriched with piglet feces, a rich source of Enterobacteriaceae, and evaluated for their ability to ferment selected carbohydrates including 2′-FL, 6′-SL, and LNnT. All PFEC tested were able to ferment HMO-associated mono- and disaccharides, whereas there was no detectable growth when 2′-FL or 6′-SL was supplied as a sole carbon source (data not shown). Conversely, all PFEC were observed to reduce LNnT detectably; however, not all PFEC had detectable growth (Figure 2B). Those PFEC that had detectable growth showed the largest reduction in LNnT (>63%); meanwhile, the other seven PFEC with no detectable growth converted only <40% of LNnT. Therefore, supplementation of preterm infant formula with LNnT may require further study. Additionally, seven PFEC were observed to utilize UGOS-P for growth (Figure 2B). Because galactooligosaccharides supplementation of infant formula did not cause a reduction in the incidence of NEC,[33] we conclude that supplementation poses no additional risk.

J. Agric. Food Chem. 2015, 63, 3295−3302

Considering that supplementation of HMOs in infant formula would likely be done in the presence of additional carbohydrates, we evaluated the impact of Enterobacteriaceae growth on Glu, Lac, and Mal in combination with HMOs. Although the inclusion of HMOs would likely not affect Glu utilization in vivo, Glu was included as a control. On the other hand, colonic lactose fermentation has been observed in premature infants.[34,35] Maltodextrin was also included because it is often added to infant formula. Because all included Enterobacteriaceae showed no detectable growth when 2′-FL, 6′-SL, or LNnT was provided as the sole carbon source, any change in growth was not attributed to direct fermentation of the tested HMOs. The resulting bacterial growth was analyzed using a logistic regression analysis to obtain the lag time, db time, and ΔOD. On the basis of these three parameters, two patterns can be used to determine the impact of growth in the presence of HMOs. A decrease in lag time and db time and an increase in ΔOD would indicate an environment that favors bacterial growth, whereas an increase in lag time and db time and a decrease in ΔOD would indicate an environment that disfavors growth. Interestingly, no strain/carbohydrate combination tested had a significant fold change in all three parameters that favored growth. Conversely, EC11775 was the only organism to have a significant fold change in all three parameters that did not favor growth. The combination of Mal and 6′-SL led to a significant increase in lag time (44%) and db time (284%) and a significant decrease in ΔOD (−23%). Hunt and colleagues[36] reported that pooled HMOs in combination with glucose and lactose resulted in an enhanced growth of *Staphylococcus epidermidis* and *Staphylococcus aureus* breast milk isolates. The two *Staphylococcus* species did not directly catabolize the pooled HMO fraction, but rather metabolized amino acids.[36] It appears that 6′-SL, an acidic HMO, may disturb EC11775's ability to grow on complex carbohydrates; however, the impact of 6′-SL on gene expression was not tested.

In conclusion, this study demonstrates that individual Enterobacteriaceae strains do not detectably grow in the presence of 2′-FL, 6′-SL, and LNnT, whereas three PFEC did have detectable growth when LNnT was added as a sole carbon source. Conversely, no PFEC had detectable growth on 2′-FL and 6′-SL. In addition, no Enterobacteriaceae strain had significantly enhanced growth in all three calculated bacterial growth parameters (lag time, db time, and ΔOD) when HMOs were combined with a fermentable carbohydrate. On the other hand, Mal in the presence of 6′-SL did not favor the growth of EC11775. Therefore, we conclude that supplementation of preterm infant formula with 2′-FL and 6′-SL should not lead to an increase in Enterobacteriaceae; however, supplementation with LNnT may require further exploration.

with a low level exposure to BPA.[2] Recent studies of the National Toxicology Program (NTP) and the U.S. Food and Drug Administration (FDA) pointed out the potential BPA effects on brain, behavior, and prostate gland in fetuses, infants, and young children.[15] Indeed, BPA can affect the hormone-mediated neurologic and behavioral development in early life.[15−19] In addition, high BPA exposure has been associated with heart disease, diabetes, abnormally high levels of liver enzymes, and alterations of the thyroid function.[20−22] For these reasons, BPA containing baby bottles have been banned in Europe since March 2011.[23] Diet remains the predominant source of exposure for both phthalates and BPA especially for infants, since these compounds have been found in breast milk and in baby formulas.[24−27] The present paper analyzes the presence of DEHP, DnBP, and BPA in infant formulas to assess possible neonatal exposure and to reduce the gap of knowledge in this field.

MATERIALS AND METHODS

Sampling. Fifty infant formula samples were collected at different neonatal nurseries in Naples 53 hospital during three months (May−July 2013). Liquid ready to use (n = 22) and powder (n = 28) milk samples were collected. Among them, there were seven special milk samples, that is, milks for infant with gastrointestinal problems (n = 3), rice milk formulas (n = 3), and a premature formula. Liquid samples were packed in polyethylene terephthalate (PET) and Tetrapak, whereas milk powders were contained in aluminum (Al) containers. The infant formula samples were collected in glass vials and were rapidly transferred to the laboratory of the Department of Agriculture, where analytical samples were obtained for the different procedures. All samples were labeled. For DEHP and DnBP analysis, aliquots (15 mL) of liquid milk were lyophilized and stored a −18 °C until analyses, whereas powder sample aliquots (1 g) were just stored in the dark. For BPA determination, aliquots (5 mL) of liquid milk were stored at −18 °C until analyses, whereas powder sample aliquots (2 g) were reconstituted with high-performance liquid chromatography (HPLC) water (15 mL), were split into 5 mL aliquots, and were stored at −18 °C until analyses. For each reconstituted vial, an additional 5 mL vial with HPLC water was stored at −18 °C as a negative control to avoid possible bias because of a contamination of HPLC water.

DEHP and DnBP. *Chemical Reagents.* Acetonitrile, n-hexane, acetone for organic trace analysis, and anhydrous Na_2SO_4 were supplied by Merck (Darmstadt, Germany). Florisil (60/100 mesh) was furnished by Supelco (Bellefonte, PA, U.S.), and Bondesil (PSA 40UM) was furnished by Varian (Palo Alto, CA, U.S.). Standard solutions of DEHP and DnBP were purchased from Sigma-Aldrich (St. Louis, MO, U.S.).

Instrumental Parameters. The analyses of phthalates (PAEs, phthalic acid esters) were carried out by a Shimadzu GC-17 (Shimadzu, Kyoto, Japan) capillary gas chromatography with a flame ionization detector (GC-FID) and an HP-5 (cross-linked 5% PHME siloxane, 30 m length, 0.32 i.d., 0.25 μm film thickness) glass-capillary column. Helium was used as the carrier, and a hydrogen/air mixture was used to sustain the flame. The volume of injection was 1 μL in splitless mode, and the injector and detector temperatures were 260 and 310 °C, respectively. The temperature program was 100 °C for 1 min, increase of 15 °C/min up to 280 °C, and retention of this temperature for 10 min.

DEHP and DnBP Measurement. Because of PAE ubiquity, any contact with plastic was avoided. All the glassware was thoroughly washed, was rinsed twice with acetone and n-hexane, was heated at 250 °C for 2 h, and finally was stored away from any environmental contamination. In accordance with the method by Cirillo et al.,[25] the lyophilized samples were (1) extracted three times with 15 mL of acetonitrile in an ultrasound bath for 15 min; (2) centrifuged at 2000 rpm for 10 min, and the acetonitrile layer was transferred to a separatory funnel; and (3) added with 10 mL of n-hexane saturated with acetonitrile, and the funnel was vigorously shaken for 5 min. The acetonitrile phase was transferred into a flask and was dried under vacuum at 55 °C. The extracts were reconstituted by 5 mL of n-hexane and were purified through a column containing 2 g of Florisil activated for 2 h at 200 °C, 0.5 g of Bondesil, and 1 g of anhydrous Na_2SO_4. The column was eluted three times with 10 mL of n-hexane/acetone mixture (100:5 v/v). The eluates were collected in a flask, were evaporated under vacuum at 40 °C, and were reconstituted with 1 mL of n-hexane for GC analysis. The calibration curves were obtained using standard solutions at 0.625, 1.250 and 2.500, 5.00 and 10.00 μg/mL for DEHP and at 0.312, 0.625, 1.250, 2.500, and 5.00 μg/mL for DnBP. The regression coefficients (R) were >0.99 for both contaminants. The PAE concentrations in the samples were obtained by comparing the relevant peak areas with calibration curve. Limits of detection (LODs) and quantification (LOQs) were evaluated as the mean blank value plus three blank standard deviations and LOQ was evaluated as 3 times the LOD. LODs and LOQs were 5.0 ng/g and 15.0 ng/g for DEHP and 7.5 ng/g and 22.5 ng/g for DnBP, respectively. A run without sample was carried out every six determinations to reduce the instrumental background due to contamination. Moreover, solvents used to wash the syringe were frequently replaced. The intra- and interday repeatabilities of the method were evaluated by injecting standard solutions at three different concentration levels (2.50, 5.00, and 10.00 μg/mL for DEHP and 1.25, 2.50, and 5.00 μg/mL for DnBP) five times during a day (intraday) and during five consecutive days (interday). The intraday repeatability ranged from 7.0 to 9.5% for DEHP and from 5.5 to 8.5% for DnBP, whereas interday repeatability varied from 6.0 to 8.5% for DEHP and from 4.5 to 6.5% for DnBP. Samples with DEHP and DnBP concentrations lower than LOD were used for recovery tests. Three liquid and three powder milk samples (each in triplicate) were spiked with standard solutions at concentration 2.0, 4.0, and 8.0 μg/mL for DEHP and 1.0, 2.0, and 4.0 μg/mL for DnBP and then were processed as milk samples. Recoveries were 98 ± 10% for DEHP and 98 ± 9% for DnBP. Because of the ubiquity of these compounds, a blank sample (only solvents) for each batch was analyzed, and the average concentration value was subtracted from PAE detected values.

Bisphenol A. *Chemical Reagents.* Acetonitrile, methanol, and water (HPLC grade) were supplied by Merck (Darmstadt, Germany). Solid-phase extraction cartridges (Bond Elut C18 SPE, 1 g/6 mL) were purchased from Agilent Technologies (Palo Alto, CA, U.S.). A BPA standard (purity ≥99%) was purchased from Sigma-Aldrich (St. Louis, MO, U.S.).

Instrumental Parameters. BPA detection was performed through an HPLC (LC-10AT VP Shimadzu, Kyoto, Japan) equipped with a fluorescence detector (Shimadzu RF-10A XL) and a reversed-phase column (Ascentis C18 Length × i.d.: 15 cm × 4.6 mm; particle size: 5 μm, Supelco, Bellefonte, PA). The column was kept at a constant temperature of 40 °C. The

DOI: 10.1021/jf505563k
J. Agric. Food Chem. 2015, 63, 3303−3310

mobile phase consisted of 60% of acidified water (1% of acetic acid), 35% of acetonitrile, and 5% of methanol. The flow rate of mobile phase was set at 0.950 mL/min (isocratic run). The fluorimetric detection was carried out at an excitation wavelength of 275 nm and an emission wavelength of 305 nm.

BPA Measurement. BPA measurement was performed by adapting the procedure by Sun et al.[9] An aliquot of each sample (5 mL) was inserted into a 250 mL glass round-bottom flask and was added with acetonitrile (20 mL). Flasks were placed onto a Heidolph Promax 2020 shaker for 25 min. The content of each flask was then filtered through a filter paper and was transferred into a separatory funnel. The flask was rinsed with 5 mL of acetonitrile, which was added to the funnel. Afterward, 35 mL of *n*-hexane was also added to the separatory funnel, and the resulting mixture was shaken for 25 min. The acetonitrile layer was removed from the funnel and was stored in a round-bottom flask, whereas the hexane layer was washed twice with acetonitrile (first with 15 mL, then with 10 mL) which was collected and added in the same round-bottom flask. The solvent was removed from the extract through a rotavapor, and then the flask was washed with 3 mL of a methanol:water (5:95 v/v) solution to be processed by solid-phase extraction (SPE). SPE cartridges were first conditioned with 5 mL of methanol and then with 5 mL of water. Later, the sample was loaded, and the elution was carried out at a flow rate of 3−4 mL/min using a Supelco Visiprep SPE vacuum manifold. The cartridges were then washed with 2 mL of a methanol:water solution (30:70 v/v) and were dried under 152 vacuum pump for 1 min. Finally, the BPA retained in the cartridge was eluted with 3 mL of a methanol:water (80:20 v/v) solution. The eluate was dried by a rotavapor, was dissolved with 1 mL of methanol, and finally was collected in an amber vial before the HPLC analysis. A calibration curve with a correlation coefficient of 0.998 was obtained by injecting standard solutions of BPA at concentrations of 10.0, 20.0, 30.0, 40.0, and 50.0 μg/L. An instrumental LOD equal to 0.003 μg/g dry weight (dw) was calculated using the standard deviation of the response (σ) and the slope of the calibration curve (S) according to the formula 3.3 σ/S. Similarly, an LOQ equal to 0.009 μg/g dw was calculated as 10 σ/S. Recovery percentages at three concentration levels were assessed on six samples (three liquid and three powder milk samples with BPA level below the LOD) by spiking each sample with BPA solutions in methanol at concentrations of 50.0, 100.0, and 1000.0 μg/L. The recoveries were 87 ± 3%. BPA quantification was performed comparing the peak areas obtained in the samples with the BPA standard calibration curve.

For each batch of samples, a blank sample was processed according to the procedures mentioned previously. A total of 16 blanks were analyzed, and all of them showed BPA concentrations well below the LOD value.

BPA Confirmation by LC MS/MS. Because BPA measurements could be affected by matrix-related interferences, a confirmation by Liquid Chromatography Tandem Mass Spectrometry (LC MS/MS) was carried out according to the Shao et al. method.[28]

Instrumental Parameters. Identification was carried out using an alliance 2695 (Waters, U.S.) liquid chromatography equipped with a Quattro Ultima Pt (Micromass, U.K.) tandem mass spectrometer and a symmetry C-18 column (150 mm × 2.1 mm i.d., 3.5 m). The temperature of the column oven was set at 40 °C, the flow rate was 0.2 mL/min, and the injection volume was 10 μL. Mobile phases consisted of methanol and water with 0.1% ammonia. The methanol was linearly increased from 10 to 55% in 10 min, then was increased to 85% in 10 min, was held for 7.5 min, and finally was brought back to 10% and was held for 15 min before the following injection. The mass spectrometer was operated in negative mode electrospray ionization in multiple-reaction monitoring (MRM) mode. The capillary voltage was 3.5 kV, the cone voltage was 70 V, and the multiplier voltage was 650 V. Nitrogen was used as nebulizing, desolvation, and cone gas. In particular, the nebulizing gas was adjusted to the maximum, whereas the flow of the desolvation gas and cone gas was set to 550 L/h and 80 L/h, respectively. The source temperature and the desolvation gas temperature were held at 100 and 300 °C, respectively. The RF lenses 1 and 2 were set at 50 and 0.5, the ion energy 1 and the ion energy 2 were both 0.5, the entrance and exit were zero, and the collision gradient was 3.2 eV. Ultra High Purity (UHP) argon was used as the collision gas for the tandem mass spectrometric analysis, and the pressure in the collision chamber was kept at 2.8×10^{-3} mbar. A calibration curve in the concentration range 1−100 ng/g was obtained by linear regression of the normalized (to the internal standard area) standard solution areas against BPA concentrations. The correlation coefficient was ≥0.999. The intra- and interday repeatabilities of the method were evaluated by injecting standard solutions at three different concentration levels (10, 50, and 100 ng/g) five times during a day (intraday) and during five consecutive days (interday). The intraday reproducibility ranged from 4.0 to 6.5%, while interday reproducibility varied from 4.5 to 6.2%.

Statistical Analysis. A power calculation was undertaken to determine an appropriate sample size for this study. On the basis of literature data,[29] considering DEHP as the most abundant phthalate in infant formula, a two-sided test power calculation was performed. Double of the range value was used as the sigma (0.780 μg/g dry weight). This power calculation indicated that 11 samples in each group would be necessary to detect a 15% difference in the DEHP concentration with a power of 80% at a 5% level of significance. Data distribution was assessed with the Shapiro Wilk's test. A two-sample t test was performed with SPSS 20.0 software (IBM) to assess the differences between DEHP, DnBP, and BPA concentrations in liquid and powder milks. Significance was set at $p < 0.05$. The concentrations below LOD were assumed to be equal to LOD.

Dietary Intake Assessment for Italian Infants (Age 0−4 Months). Daily intake was estimated as

$$\text{Intake} = (C \times V)/\text{BW}$$

where C is concentration, V is volume of milk per day, and BW is body weight. This equation was used to evaluate DEHP, DnBP, and BPA exposure of young children through artificial milk. Dietary exposure was calculated using the blueprint to the budget method (BM) model[30] in accordance with Food and Agriculture Organization of the United Nations/World Health Organization (FAO/WHO) and with the help of weight growth charts by WHO[31] and pediatric nutrition suggestions for our range of age. We considered two possible scenarios: (1) median concentrations of contaminants, infants with average weight to development at the 50th percentile or at the 97th percentile (according to the growth curve by WHO[31]) who introduce daily a medium quantity of milk (medium case); (2) maximum concentrations of contaminants, children who have grown at the 50th percentile or at the 97th percentile and introduce daily a higher quantity of milk (worst case).

J. Agric. Food Chem. 2015, 63, 3303−3310

RESULTS

Most milk samples showed detectable levels of DEHP (80%, 86% of liquid and 96% of powder milks), DnBP (90%, 82% of liquid milks and 96% of powder milks), and BPA (60%, 43% of liquids milks and 67% of powder milks) (Table 1). The average concentration of DEHP in all milk samples was 1.327 ± 0.724 μg/g dw, and in particular, it was 1.112 ± 0.716 μg/g dw in liquid milks and 1.496 ± 0.729 μg/g dw in powder milks. For DnBP, the average concentration in all milk samples was 0.354 ± 0.305 μg/g dw, namely, 0.384 ± 0.385 μg/g dw in liquid milks and 0.330 ± 0.229 μg/g dw in powder milks. The average concentration of BPA in all milk samples was 0.021 ± 0.022 μg/g dw; it was 0.019 ± 0.037 μg/g dw in liquid milks and 0.023 ± 0.028 μg/g dw in powder milks (Table 1). DEHP concentrations varied from 0.092 to 3.552 μg/g (median 1.136 μg/g), DnBP concentrations varied from 0.008 to 1.624 μg/g (median 0.244 μg/g), and BPA concentrations varied from 0.003 to 0.169 μg/g (median = 0.008 μg/g) (Table 1). Similar concentrations of the three analytes were found in liquid and powder milks, even though containers were of different types. DEHP, DnBP, and BPA concentrations in the HLPC water samples stored as negative controls for reconstituted powder milk were below the LODs.

The concentrations of DEHP, DnBP, and BPA in liquid and powder milks together with the type of packaging are reported in Tables 2 and 3, respectively. Estimates of dietary exposure to DEHP, DnBP, and BPA in the medium and worst cases are shown in Tables 4 and 5. The daily intake of DEHP in the medium case ranged from 19.34 to 24.85 μg/kg body weight (bw) day at the 50th percentile and from 17.54 to 21.14 μg/kg bw day at the 97th percentile. In the worst case, DEHP intake varied between 42.57 at 54.68 μg/kg bw day at the 50th percentile and 38.61 at 46.52 μg/kg bw day at the 97th percentile (Tables 4 and 5). Estimates of dietary exposure to DnBP in the medium case ranged from 4.15 μg/kg bw day to 5.34 μg/kg bw day at the 50th percentile and from 3.77 μg/kg bw day to 4.54 μg/kg bw day at the 97th percentile. In the worst case, the DnBP intake varied between 13.62 and 17.50 μg/kg bw day at the 50th percentile and between 12.35 and 14.89 μg/kg bw day at the 97th percentile (Tables 4 and 5). BPA intakes in the medium and worst cases are shown in Tables 4 and 5. In the medium case, values ranged from 0.14 to 0.17 μg/kg bw day at the 50th percentile and from 0.12 to 0.15 μg/kg bw day at the 97th percentile. In the worst case, the BPA intake varied between 0.99 and 1.27 μg/kg bw day at the 50th percentile and between 0.90 and 1.08 μg/kg bw day at the 97th percentile. Both in the medium and worst cases, the highest intake occurred at the 30th day of life because the amount of consumed milk starts increasing while the baby's weight is still pretty low. As for BPA, for both DnBP and DEHP, the higher values of intake occurred in children at 30 days of age (Tables 4 and 5).

DISCUSSION

Our data indicate the presence of DEPH, DnBP, and BPA in infant formulas. Data relevant to all contaminants showed a wide variability, but no significant differences between liquid and powder milks were found, even though samples were packed in different types of containers. This finding would suggest that DEHP, DnBP, and BPA contamination could arise from raw materials or from manufacturing processes rather than from different packaging. Phthalates, in particular, may

contaminate milk during the production or preparation of formulas. A main source of contamination results from migration of phthalates from products in contact with food during processing. Several studies concerned the migration of DEHP from the PVC tubing of the milking machine used in dairy farms.[32−34] PVC tubing contains up to 40% DEHP by weight. A Norwegian study showed a clear difference in DEHP levels between raw milk collected by hand milking (about 5 μg/

kg) and machine milking involving PVC tubing (30 μg/kg in milking chamber and 50 μg/kg in collection tank).[33]

Dietary Intake Assessment for Italian Infants (Age 0−4 Months). To assess postnatal exposure to phthalates and BPA, the estimation of daily dietary intake of these contaminants was carried out in 0−4 month old children, as milk is the only food introduced in this age group. Four possible nutrition scenarios were possible, namely, nutrition with infant powder, liquid formula, breast milk, or a combination of these, but we only considered artificially fed babies assuming liquid or powder formulas (or both). The European Food Safety Authority (EFSA) established a tolerable daily intake (TDI) of 50 μg/kg bw for DEHP and 10 μg/kg bw for DnBP.[35,36] As expected, the highest intakes of DEHP and DnBP were estimated among infants with growth at the 50th percentile, who have a lower body weight than those at the 97th percentile.

Daily intake of DEHP in the medium case varied between 20 and 25% and between 18 and 21% of TDI at 50th and 97th percentile, respectively. In the worst case, intake was also lower than TDI, except for the 50th percentile infants aged 30 and 45 days (Table 5).

Daily intake of DnBP in the medium case varied between 42 and 53% and between 38 and 45% of TDI at 50th and 97th percentile, respectively. In the worst case, instead, intake always exceeded TDI, up to 175%. Muller et al.[37] estimated for 0−6 month old Danish infants a daily intake via infant formulas of 9.8 μg/kg bw/day for DEHP and 16.4 μg/kg bw/day for DnBP.[37] Our values for DEHP intake were higher than Muller's both in the medium and in the worst cases, whereas DnBP intake levels were lower in the medium case and similar in the worst case. Our estimates of DEHP and DnBP daily intake were higher than those reported by MAFF[29] for infants 0−3 months old, that is, 13 μg/kg bw/day for DEHP and 2.4 μg/kg bw/day for DnBP. Our estimated BPA daily intakes were well below the temporary tolerable daily intake (t-TDI) established by EFSA in 2015 (4.0 μg/kg bw). In the medium case, our intake ranges were 3.5−4.3% and 3.0−3.8% of t-TDI for the 50th and 97th percentile respectively, which increased in the worst case to 25−31% and 23−28% of t-TDI for the 50th and 97th percentile, respectively. The results reported in the worst case are consistent with oral exposure data shown in Draft Scientific Opinion on the risks to public health related to the presence of bisphenol A (BPA) in foodstuff by EFSA.[38] Diet is the main source of exposure to BPA in infants aged 0−4 months.[38] Minor pathways of introduction could be the inhalation or ingestion of dust, dermal contact, and the mouthing of toys. Until a few years ago, babies could introduce BPA from polycarbonate baby bottles, especially when bottles were heated and reused multiple times.[2,7] The EU Regulation No. 321/2011 imposed not to use BPA in the manufacture of baby bottles, thus reducing exposure. In 2008, a report of the U.S. National Toxicology Program (NTP) provided daily exposure estimates for infants, children, and adults on the basis of realistic scenarios.[39] The highest daily exposure to BPA was estimated to occur in infants and children. Formula-fed infants (0−6 months of age) had estimated daily intakes of 1−11 μg/kg bw. In 2010, the FAO and WHO jointly held an Expert Meeting on BPA, whose final report was published in 2011.[40] The report identified 0−6 month infants fed with liquid formulas in polycarbonate bottles as the subpopulation with the highest dietary exposure to BPA, namely, 2.4 μg/kg bw per day

DOI: 10.1021/jf505563k
J. Agric. Food Chem. 2015, 63, 3303−3310

(average) and 4.5 μg BPA/kg bw per day (95th percentile). In 2012, a probabilistic exposure assessment using data from recent Canadian surveys suggested that daily exposure to BPA in children ranged from 0.083 μg/kg bw (0−1 month old) to 0.164 μg/kg bw (children 4−7 months of age).[41] Our data resemble those of Health Canada but are lower than those of NTP and FAO/WHO, probably because the problem of BPA migration from baby bottles in Europe has been solved. The different packages (Tetrapak, PET, and aluminum) represent a possible bias of the present study. However, the studied contaminants can be found not only in Tetrapak and PET but also in aluminum packages, as these are often internally coated with plastic derivatives.

Our data show a widespread contamination of infant formulas from the three investigated contaminants, either of environmental or process origin. Our findings demonstrate that infant formulas may represent a main source for the simultaneous exposure to DEHP, DnBP, and BPA in babies. This risk is particularly relevant for DEHP and DnBP because intake from formulated milk could exceed in the worst case the TDI from EFSA. In conclusion, potential hazards exist for infants fed with baby formula, as these endocrine disruptors show the highest toxicity in infant population. TDIs for the three investigated contaminants set by EFSA refers to adult and infant populations, indiscriminately, but since children and infants are developing individuals, providing a specific TDI could be worthwhile as TDIs intended to children would help the protection of the most vulnerable part of the population from a severe public health hazard.

Table 1. Abbreviations and Structural Formulas of Some Uncommon Chemicals

Abbreviation	Chemical name	Chemical structural formula
PEITC	Phenylethyl isothiocyenate	PEITC-GSH	S-(N-Phenylethylthiocarbamoyl)-glutathione	PEITC-CYS-CLY	S-(N-Phenylethylthiocarbamoyl)-cysteinylglycine	PEITC-CYS	S-(N-Phenylethylthiocarbamoyl)-cysteine	PEITC-NAC	N-Acetyl-S-(N-Phenylethylthiocarbamoyl)-cysteine	
■ ACTIVATION OF APOPTOSIS PATHWAYS

Apoptosis, a form of programmed cell death, is a pivotal defense against the occurrence of cancer and is essential for metazoans in maintaining tissue homeostasis. In principle, there are two alternative pathways that initiate apoptosis: one is mediated by mitochondria, referred to as the "intrinsic pathway";[25] the other is mediated by death receptors on the cell surface, referred to as the "extrinsic pathway".[26] In addition, a third apoptotic pathway, the "endoplasmic reticulum (ER) stress" pathway, has been described recently.[27] All of these mechanisms of apoptosis are associated with caspase activation damage sensing and proapoptotic signaling.

■ THE INTRINSIC (MITOCHONDRIAL) PATHWAY

Mitochondria have been shown to have a vital role in apoptotic signal transduction.[28,29] Emerging evidence suggests that PEITC can cause oxidative mitochondrial damage by enhancing the intracellular ROS to a toxic level.[30−32] Possible explanations for these findings are that (1) PEITC conjugates with GSH, and the conjugate compounds export from cancer cells;[33] (2) time-dependent ROS accumulation induced by PEITC could induce ROS-mediated lipid peroxidation of mitochondrial membrane, such as oxidation of cardiolipin,[30] followed by the loss of membrane integrity ($\Delta\Psi$m), and release apoptosis-inducing factor (AIF) as well as apoptogenic cytochrome *c*; (3) cytokines influx into the cytosol, and then activate caspase family members that are executionary arm of apoptotic

Table 2. Other Abbreviations Used

abbreviation	name
GSH	c-glutamate-cysteine-glycine
NAC	*N*-acetylcysteine
ΔΨm	membrane integrity
AIF	apoptosis-inducing factor
PTP	permeability transition pore
Bcl-2	B-cell leukemia/lymphoma-2
TRAIL	tumor necrosis factor-related apoptosis-inducing ligand
DR4	death receptor 4/TNF-related apoptosis-inducing ligand
DR5	death receptor 5/TNF-related apoptosis-inducing ligand
Fas L	Fas ligand
FADD	Fas-associated death domain
NF-κB	nuclear factor kappa B
PI3K	phosphatidylinositol 3 kinase
TLR3	toll-like receptor 3
JNK	Jun N-terminal kinase
MKK7	mitogen-activated protein kinase 7
MAPK	p38 mitogen-activated protein kinase
CDK	cyclin-dependent kinase
ATM/ATR	ataxia telangiectasia mutated/ataxia telangiectasia and Rad3-related
DMEs	drug metabolizing enzymes
GSTs	*S*-transferases
QR	quinonereductase
γGCS	γ-glutamyl cysteine-synthetase
HO-1	heme oxygenase1
NQO1	NAD(P)H quinone oxidoreductase1
MDR	multidrug resistance
DNM	daunomycin
VBL	vinblastine
ABCG2	breast cancer resistance protein
MRP-1	multidrug resistance associated protein-1
Pgp-1	P-glycoprotein-1
NPEITC	novel alkyne-tagged ITC

machinery.[34,35] The permeability transition pore (PTP) is an unselective voltage-dependent mitochondrial channel and is central to mitochondrial vital functions. PTP opening can dissipate the transmembrane inner potential, trigger matrix swelling, release cytochrome *c*, and subsequently elicit cell apoptosis.[36] Studies from our own laboratory have shown that cell apoptosis of MCF-7 induced by PEITC is associated with ROS-mediated PTP opening. Ca^{2+} can also open PTP, leading to the rapid loss of transmembrane inner potential.[37] Further studies are needed to define whether calcium overload contributes to PEITC-induced PTP activity.

The Bcl-2 (B-cell leukemia/lymphoma-2) family proteins include both antiapoptotic members (such as Bcl-2 and Bcl-xL) and proapoptotic members (such as Bax and Bid). They are distributed not only in the mitochondrial outer membrane but also in the cell membrane, ER, and nuclear membrane. Studies have found that Bcl-2 proteins reside upstream of irreversible cellular damage and focus the greatest efforts at the level of mitochondria.[38] PEITC can regulate intracellular location of proapoptotic proteins or antiapoptotic proteins promoting the release of cytochrome *c* from the mitochondria.[39] For example, PEITC induced apoptosis via downregulation of Bcl-2/XIAP and triggering the mitochondrial pathway in MCF-7 cells.[40] Similar results have shown that PEITC triggered apoptosis through promotion of Bax and Bid expression, leading to the decreased levels of ΔΨm and release of cytochrome *c*, and then activating the caspase-dependent cell death.[41,42] Moreover, in ovarian cancer OVCAR-3 cells, PEITC decreased the level of prosurvival Bcl-2 protein while simultaneously increasing the level of proapoptotic Bax protein, which in turn caused activation of caspase-9 and -3 leading to cell apoptosis.[43]

THE EXTRINSIC (RECEPTOR-MEDIATED) PATHWAY

The death receptor pathways for caspase activation are referred to as the extrinsic apoptosis pathways.[35] Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) has the unique activity of activating cell death exclusively in tumor cells. TRAIL can bind with two death receptors (DRs), DR4 (TRAIL-R1) and DR5 (TRAIL-R2), both of which are type I transmembrane proteins.[44,45] Studies have shown that PEITC can enhance TRAIL-induced apoptosis through downregulation of cell survival proteins and upregulation of the death receptors (DR4 and DR5). For example, in human oral cancer HN22 cells, PEITC activates p38 MAPK through increasing phospho-p38 MAPK. As p38 MAPK are the upstream targets of DR5, the function of DR5 regulating apoptosis induced by PEITC is strongly associated with the p38 MAPK pathway.[46] However, another study found that PEITC increased the expression of DR4 and DR5 by downregulating the phosphorylation of ERK 1/2, neither phospho-JNK nor phospho-p38 MAPK. One possible explanation for these contrary findings is that the different kind of cell types might have different pathway responses when cells are exposed to PEITC.[47] Previous studies have demonstrated that PEITC can enhance the intracellular ROS and induce apoptosis. And, a recent study demonstrated that PEITC enhanced TRAIL-induced apoptosis through the upregulation of DR5 receptors on the ROS-induced-p53.[48] Fas is another cell surface death receptor involved in the transduction of apoptotic signals in both normal and cancer cells. Fas ligand (Fas L) binding followed by Fas-receptor (Fas) oligomerization leads to formation of a death-inducing signal complex and recruitment of the adapter molecule Fas-associated death domain (FADD). FADD recruits and aggregates the pro form of caspase-8, leading to the activation of caspase-8, and then cleaved procaspase-3 and procaspase-9.[49] PEITC can sensitize the human bladder carcinoma cells leading to Fas-mediated apoptosis. The intracellular GSH out of the cells provides a potential mechanism for PEITC-induced apoptosis.[15] But the concise pathogenesis is still not clear.

THE "ENDOPLASMIC RETICULUM (ER) STRESS" PATHWAY

Recently, the "ER stress" pathway has been recognized as the third apoptotic pathway.[50] ER stress, induced by the accumulation of unfolded or malfolded proteins, activates various apoptotic pathways.[27]

Very recent studies demonstrated that PEITC induced cell apoptosis in a concentration-dependent, ROS/Ca^{2+}-independent manner.[51,52] Similar results showed that PEITC promoted Ca^{2+} movement by inducing phospholipase C-dependent Ca^{2+} release from endoplasmic reticulum and Ca^{2+} entry via store-operated Ca^{2+} channels in PEITC-treated human prostate cancer cells (PC3).[14,51] Moreover, the rapid increase of cytosolic Ca^{2+} may cause elevation of mitochondrial Ca^{2+} and decrease of Ca^{2+} in endoplasmic reticulum, and such imbalance of Ca^{2+} may trigger a variety of cascades leading to cell death.[53]

DOI: 10.1021/jf504627e
J. Agric. Food Chem. 2015, 63, 3311−3322

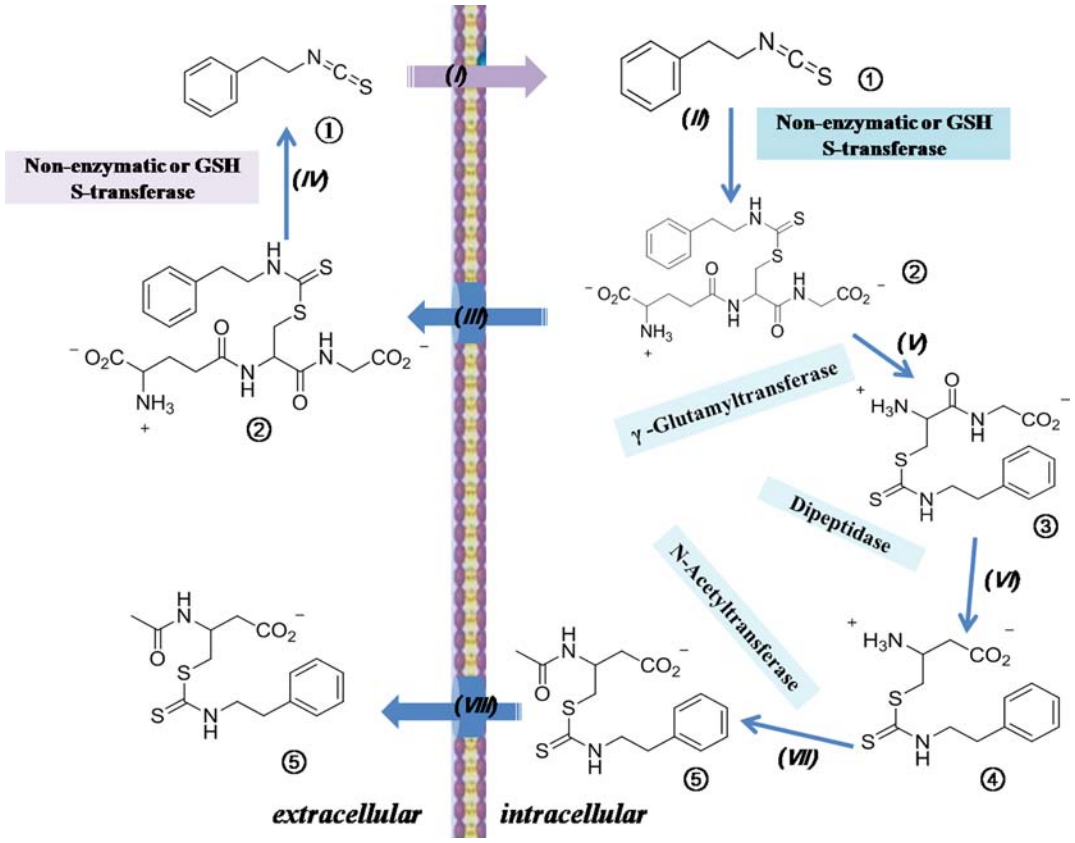

Figure 1. Metabolism of phenylethyl isothiocyanate by the mercapturic acid pathway. (I) PEITC (①) initially diffuses into cells and (II) and is rapidly conjugated to glutathione (GSH) via the action of glutathione *S*-transferases (GST). (III) The GSH conjugates (②) are exported from the cells via efflux pumps, and then (IV) the conjugates are hydrolyzed to the free PEITC, which is able to re-enter the cell. (V) But the intracellular PEITC−GSH is subsequently converted to the cysteinylglycine conjugate (③) by the action of γ-glutamyl transpeptidase and then (VI) converted to the cysteine conjugate (④) by the action of γ-glutamyl transpeptidase. (VII) Finally, the PEITC−cysteine conjugates are converted to NAC conjugates by the action of *N*-acetyltransferase and (VIII) excreted in the urine.

In addition to Ca^{2+} accumulation, inhibition of proteasomal activity and disruption of protein disulfide bond formation may trigger ER stress response. Various studies showed that PEITC significantly inhibited proteasome activities, including chymotrypsin-like, trypsin-like, and caspase-like, by inhibition of rapid accumulation of p53 and IκB nuclear factor-kappa B.[54,55] For example, PEITC can selectively induce degradation of α- or β-tubulin proteasome in different cancers, including non-small lung cancer A549 cells,[56] prostate cancer cells,[57] and breast cancer cells.[58] Interestingly, PEITC inhibits proteasome activity presumably through direct binding, suggesting that the proteasome, like tubulin, may serve as a molecular target of PEITC.

Taken together, the predominant apoptotic pathway targeted by PEITC may differ between cell types. The exact mechanism is difficult to determine because of the cross-talk between the different apoptotic pathways (Figure 2).

INHIBITION OF THE SURVIVAL PATHWAYS

The following section will summarize studies that investigated the effect of PEITC on survival pathways (Figure 3). Nuclear factor kappa B (NF-κB), phosphatidylinositol 3 kinase (PI3K), and p38 mitogen-activated protein kinase (MPKC) pathways are important for cell survival, proliferation, and differentiation.

THE NF-κB SURVIVAL PATHWAY

The NF-κB survival pathway plays a key role in cancer chemoprevention due to its involvement in tumor cell growth, proliferation, invasion, and survival.[59−61] NF-κB is sequestered in the cytoplasm in resting cells by combining with inhibitor proteins (IκB proteins). In response to stimulating factors, IκB was phosphorylated by the inhibitor of κB (IKK) kinase complex and further degraded, thus releasing active NF-κB dimers and allowing NF-κB to translocate to nucleus.[62] PEITC has been shown to have promising anti-inflammatory properties through the ubiquitous NF-κB signaling pathway.[16,63,64] For example, Xu et al. demonstrated the role of PEITC on NF-κB transcriptional activation and NF-κB-regulated gene expression in vitro.[59] A similar result showed that PEITC induced cell death by inhibition of NF-kB and EGFR activities in prostate cancer cells.[65] In these studies, PEITC exhibited its anti-inflammatory activity via the direct suppression of IκB kinase α/β (IKKα/β) phosphorylation, IκBα phosphorylation, and subsequent p65 NF-κB nuclear translocation.[66] Studies have demonstrated that Toll-like receptor 3 (TLR3) is one of the primary sensors of double stranded (ds) RNA and mediates NF-κB activation.[18] More recently, another study showed that PEITC could activate prosurvival NF-κB pathway by inhibiting TLR3 mediated IRF3 signaling.[67] However, the biochemical details of PEITC on IRF3 signaling are needed in further step.

Interestingly, PEITC and curcumin can exert their additive inhibitory effects on cell proliferation and ultimately lead to

DOI: 10.1021/jf504627e
J. Agric. Food Chem. 2015, 63, 3311−3322

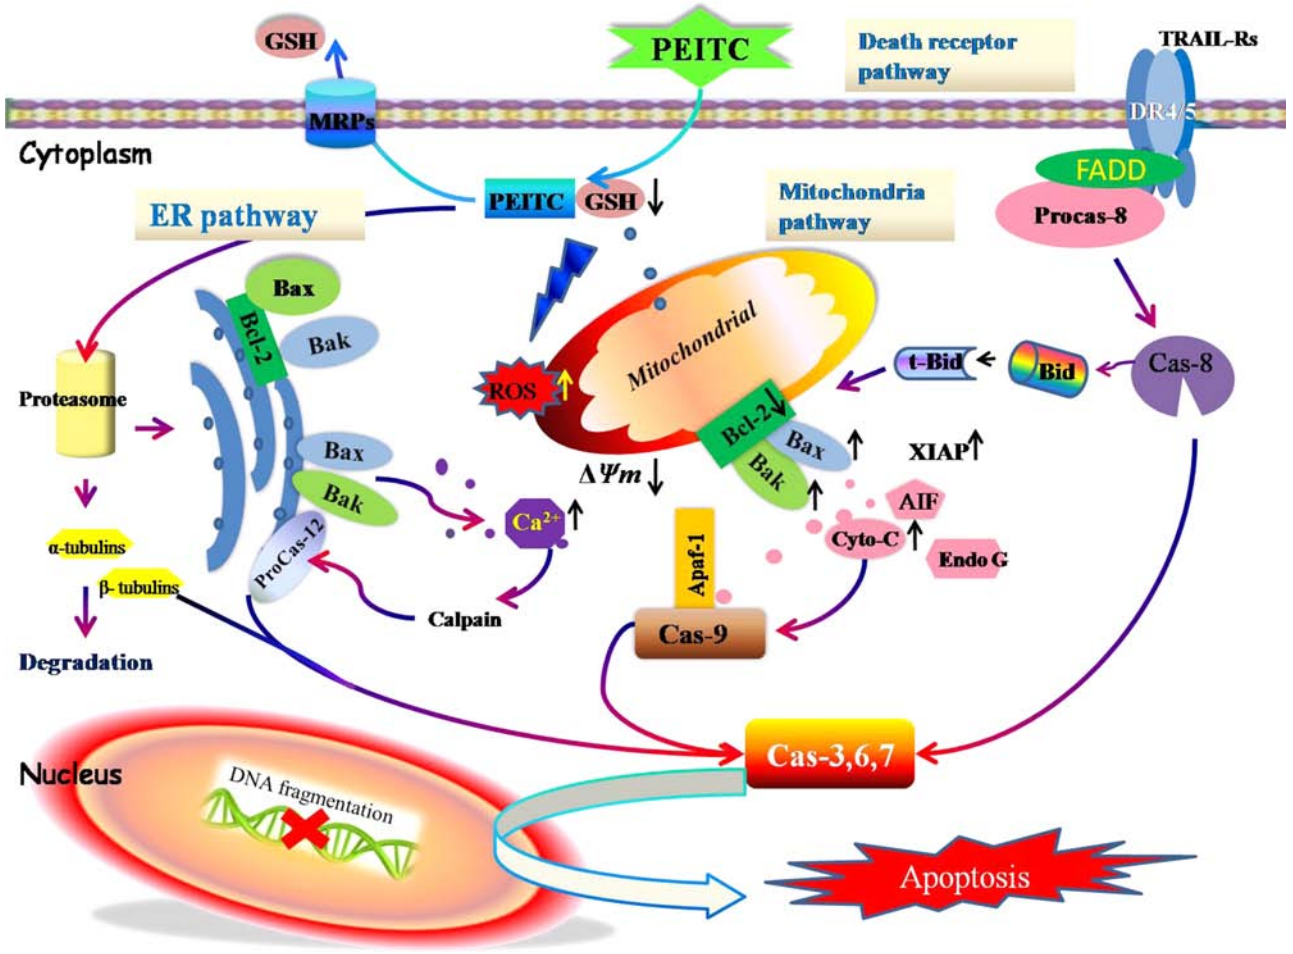

Figure 2. Signaling and molecular pathway of apoptosis in carcinoma cells. (1) In the mitochondrial pathway, PEITC-induced cell apoptosis interacts with the Bcl-2 family of proteins and then releases cytochrome *c*, AIF, and endo G, thereby forming the apoptosome which activates caspase-9 and is capable of proteolytically processing caspase-3 to induce apoptosis. (2) In the death receptor pathway, PEITC targets upregulation of death receptors which can interact with their ligands and recruit adaptor protein and initiator procaspases-8. Then, the active initiator caspase-8 activates the effector caspase-3 to induce apoptosis or to initiate degradation of Bid and to yield cytochrome *c* releasing from mitochondria. (3) In the ER pathway, PEITC induces cytoplasmic Ca^{2+} concentration, as a result of ER stress, resulting in the activation of caspase-12. Also, PEITC can induce degradation of proteasome, which may disrupt protein disulfide bond formation and trigger ER stress response.

programmed cell death of tumor cells by significant inhibition of NF-kB cell survival signal pathway and EGFR signaling pathway.[65] By contrast, others showed that MAPK/ERK signaling pathway, not NF-κB signaling pathway, was associated with apoptosis induced by PEITC plus cisplatin in HeLa cells.[68]

THE AKT SURVIVAL PATHWAY

Akt (also known as protein kinase B or PKB) comprises three closely related isoforms, Akt1, Akt2, and Akt3 (or PKB$\alpha/\beta/\gamma$ respectively).[69] It is a serine-threonine kinase intimately involved in the regulation of cell survival and is activated by recruitment to the cell membrane through PI3K.

Several research teams have demonstrated that PEITC can inhibit the PI3K/Akt signaling pathway and the downstream in recent years.[17,70] For example, PEITC inhibited ovarian tumor growth in vivo by suppressing the EGFR-AKT pathway.[71] Also, Xiao et al. demonstrated that PEITC treatment caused a decrease in survival of human umbilical vein endothelial cells by suppression of VEGF, downregulation of VEGF receptor 2 protein levels, and inactivation of prosurvival serine-threonine kinase Akt.[72] Very recent studies demonstrated that PEITC inhibited hypoxia-induced accumulation of HIF-1α and VEGF expression in human glioma cells, at least partly through the PI3K/AKT pathway.[73] Similar results showed that PEITC could target the Akt/JNK/Mcl-1 pathway. An in vivo study showed that the activity of the Akt is inhibited by PEITC, leading to Jun N-terminal kinase (JNK) activation, and culminating in Mcl-1 downregulation.[17] Moreover, PEITC can suppress the activating of Akt/mTOR, a downstream of Akt pathway.[74] Data from treatment of LNCaP and PC-3 cells with PEITC showed that levels of S2448-phosphorylated mTOR and phosphorylation of mTOR downstream target p70s6k (T389) decreased in both cell lines.[75]

THE MAPK SURVIVAL PATHWAY

Various studies have shown that PEITC can inhibit invasion and migration in cancer cells by MAPK (JNK, ERK1/2, and p38) pathways.[74,76] Indeed, in ovarian cancer cells, PEITC can inhibit Akt, ERK1/2 survival signaling, and c-Myc while simultaneously activating proapoptotic p38 and JNK1/2.[43] A similar result showed that PEITC exerted an inhibitory effect on the ERK1/2, mitogen-activated protein kinase 7 (MKK7), and MAP kinase3 (MEKK3) in human gastric cancer cells. Thus, suppressing MAPK pathways might be one of the

DOI: 10.1021/jf504627e
J. Agric. Food Chem. 2015, 63, 3311−3322

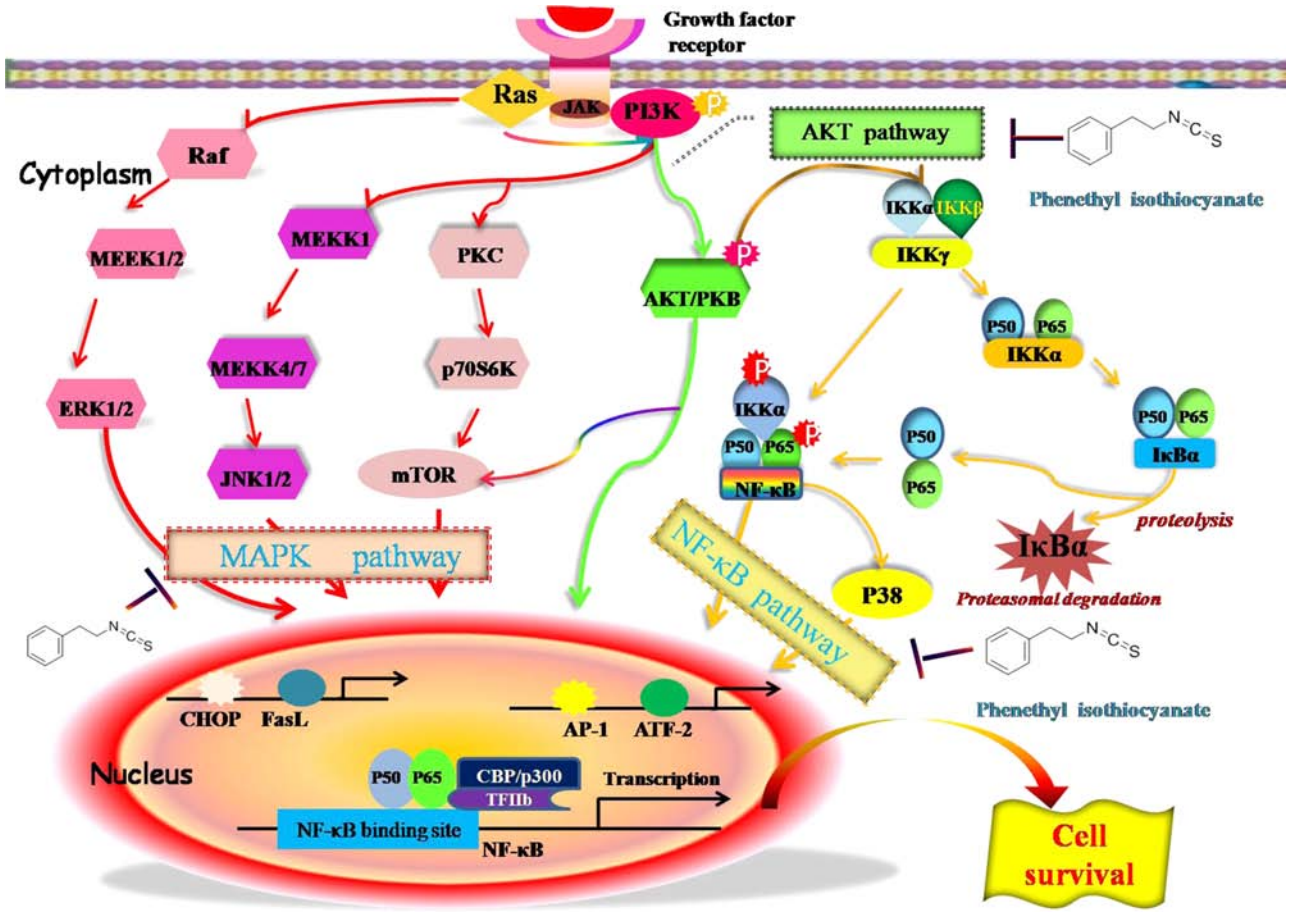

Figure 3. Regulation of survival signaling pathways by phenethyl isothiocyanate. Inactivation of survival pathways, including NF-κB, AKT, and MAPK pathways by PEITC, is considered as one important chemopreventive mechanism. (1) NF-κB is normally sequestrated by IκB which is subjected to phosphorylation by IκK. Phosphorylation of IκB by IκK increases degradation of IκB, and then the NF-κB translocates into the nucleus and activates the transcription of target genes involved in cell survival. PEITC has been shown to inhibit activation of NF-κB through inhibiting IκK. (2) PEITC can suppress the activating of AKT/PKB pathway and AKT/mTOR, a downstream of Akt pathway, by suppression of activating phosphorylations of Akt and mTOR. (3) MAPK signaling pathways such as ERK, JNK, and PKC can regulate the transcriptional activities of transcription factors that are induction of transcription of target genes. PEITC can downregulate the protein levels of MAPK pathways, such as ERK1/2, protein kinase C (PKC), and JNK1/2, and inhibit transcription survival genes.

mechanisms of migration and invasion of cancer cells inhibited by PEITC.[16]

Previous research has demonstrated that some agents inducing PKC activation can also stimulate MAPK, suggesting that there is a crosstalk between PKC and MAPK signaling pathway.[77,78] More recently, it has been shown that the functions of PEITC in migration and invasion of human gastric cancer AGS cells might be via inhibiting PKC/MAPK pathway by molecular targeting of PKC.[77] Similarly, in androgen-independent PC-3 cells, PEITC exhibited remarkable efficacy in sensitizing the cells to undergo cell death partly by modulating the activities of PKC.[79] Interestingly, some studies had demonstrated that upregulation of Nrf2/ARE-dependent gene expression by PEITC is likely mediated by the MAPK pathway.[78] Similar results have shown that PEITC inhibits the HIF-1α expression through inhibiting the MAPK signaling pathway.[73] As HIF-1 and Keap1/Nrf2 are involved in the expression of more than a hundred genes,[80,81] it is urgent to know whether cellular HIF-1α, Nrf2, and/or Keap1 proteins are direct targets of PEITCs. In conclusion, PEITC have the potential function to prevent invasion and metastasis in a wide range of tumor types by inhibition of the MAPK signaling pathway.

INDUCE OF CELL CYCLE ARREST

Cell cycle progression is a sequential process that directs dividing carcinoma cells through the G1, S, G2, and M phases.[82] The ability of PEITC to regulate the cell cycle and inhibit proliferation contributes to its chemopreventive capacity and is mediated through indirect targeting of cyclins, proteins responsible for the progression of the cell cycle, cyclin-dependent kinase (CDK) molecules, and their inhibitors (Figure 4).[83]

INDUCE OF G1/S PHASE CELL CYCLE ARREST

Recent studies have demonstrated the effect of PEITC on suppressing cell proliferation of cancer cells by causing G1/S phase cell cycle arrest in many cancers, such as human colorectal cancer,[84] oral squamous carcinoma,[42] and prostate cancer.[85] One possible explanation for these findings was that PEITC could lead to G0/G1 phase arrest by substantial reduction levels of cell cycle related proteins, such as CDC25A, CDK6, phospho-Rb, cyclin D, CDK2, and cyclin E proteins, but increase the expression of cyclin-dependent kinase inhibitors p15, p53, p27, and p21.[42] For example, in PC-3 cells, PEITC effectively blocked the G1-phase progression by

DOI: 10.1021/jf504627e
J. Agric. Food Chem. 2015, 63, 3311−3322

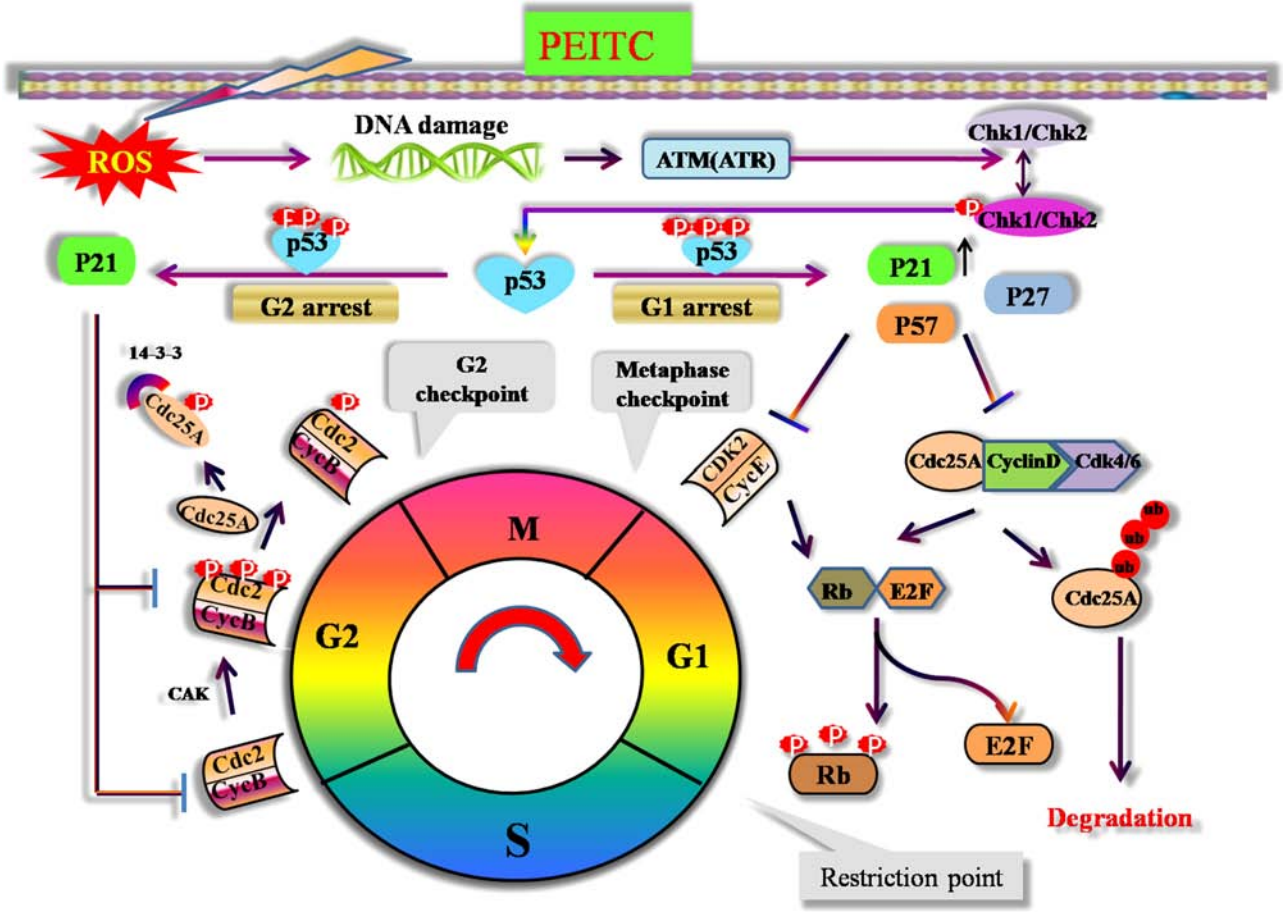

Figure 4. The proposed model of PEITC mechanisms of action for cell cycle arrest. The cell cycle is broadly divided into four phases (G1, S, G2, and M) culminating in cell duplication. Each phase of the cell cycle is regulated by a different complement of CDK−cyclin complexes. PEITC can lead to cell cycle arrest by direct reductions of the levels of cell cycle related proteins and indirect activation of the ATM/ATR pathway.

the combined activity of cyclin D1/CDK4, -6, and cyclin E/CDK2. In addition, decreasing phosphorylated Rb proteins activated the cell cycle progression.[85]

However, PEITC arrested the cells in the G1 phase by downregulation of cyclins through the activation of the p38 MAPK signaling pathway.[84] One possible explanation for these findings was that the p38MAPK stress kinase pathway was activated in response to DNA damage, and that the cell cycle checkpoint function was essential in cells with defective p53.[86] Moreover, several studies have demonstrated that the BAG family molecular chaperone regulator 3 (BAG3) belongs to a family of cochaperones and has been shown to play a relevant role in the survival, growth, and invasiveness of different tumor types.[87,88] Interestingly, a recent study found that PEITC promoted BAG3 silencing which sensitized EqS04b cells death and cell cycle arrest in G0/G1.[89]

■ INDUCTION OF G2/M PHASE CELL CYCLE ARREST

Furthermore, in a myeloma xenograft mouse model, PEITC caused G2/M cell cycle arrest by decreasing expression of key G2/M-regulating proteins including cyclin B1, p-cdc2, Cdc25C, p53, p27, and 14-3-3ε.[90] In vitro cell culture studies showed that PEITC induced time- and dose-dependent G2/M arrest by decline of cell cycle-related proteins, Cdk1 and Cdc25C.[91] Similarly, PEITC induced cell cycle arrest at the G2/M phase by inhibiting the levels of cell cycle regulatory proteins such as cyclin A and B1, while promoting the level of Chk1 and p53.[92] Another study found that the antiproliferative effects of PEITC in Caco-2 cells were attributed to the activation of the G2/M DNA damage checkpoint and sustained G2/M phase cell cycle arrest through upregulation of p21.[93] Several studies have demonstrated that the ataxia telangiectasia mutated/ataxia telangiectasia and Rad3-related (ATM/ATR) pathway plays important roles in maintaining genome integrity by triggering cell cycle arrest and DNA damage repair.[94,95] It indicated that the ATM/ATR pathway might be a therapeutic target in cancer therapy. Indeed, in oral cancer cells, PEITC induced G2/M phase arrest via a GSH redox stress and oxidative DNA damage-induced ATM-Chk2-p53-related pathway.[90]

A particularly interesting feature of PEITC was that PEITC-NAC, one of the metabolic products, had equal effectiveness with PEITC as an inhibitor of tumorgenesis by NNK while being less irritating and pungent than PEITC.[96−98] Therefore, PEITC-NAC, a prodrug of PEITC, has been introduced in a number of preclinical studies.[99] A recent study observed that PEITC-NAC had an effect on cell-cycle progression by downregulation of Cdk1 and cyclin B1 protein expression.[100] However, more detailed mechanism is needed to identify the chemopreventive activity and metabolic products of PEITC in humans.

■ INFLUENCE OF DMES

Drug metabolizing enzymes (DMEs) play central roles in xenobiotics (such as drugs) metabolism, elimination, and

DOI: 10.1021/jf504627e
J. Agric. Food Chem. 2015, 63, 3311−3322

detoxification in the human body. In general, DMEs protect or defend the body against the potential harmful insults from the environment.[101] PEITC has been attributed to its ability to disrupt multiple steps of the carcinogenic process: preventing genetic damage by the inhibition of carcinogen-activating phase I enzymes[102,103] and induction of carcinogen-detoxifying phase II enzymes.[10,15,104] Moreover, it could accumulate membrane drug transporters, such as MRP-1 and Pgp-1.[105]

INHIBITION OF PHASE I CYP DMES

PEITC could influence several CYP families by binding with their amino acid residues. Specifically, PEITC can activate or inhibit the expression of CYPs including CYP1A1, CYP1A2,[106] CYP2B1, CYP2E1,[107] CYP1A2, CYP2C9, CYP2D6, CYP2C19, CYP2B6, CYP2E1, CYP2A6, CYP3A4, and CYP3A5.[102,108] There can be many reasons behind the difference in their impacts. The main mechanism might be that PEITC could influence several CYP families by binding with their amino acid residues, and they had difference in binding affinity with the active group of PEITC. PEITC may react with α-amino groups in N-terminal residues and ξ-amino containing lysines through alkylation, thus forming thiourea.[109] Also, several recent studies have shown that PEITC reacts with the N-terminal of proline, and binds to hydroxyl group-containing residues of tyrosine.[110]

INDUCTION OF PHASE II DMES

The phase II metabolizing or conjugating enzymes consist of many superfamily of enzymes such as glutathione *S*-transferases (GSTs) and quinonereductase (QR).[101,111] PEITC was a substrate of GSTs, including Al-1, M1-1, M4-4, and P1-1. GSTs promote the thiol group of GSH to the electrophonic central carbon of the PEITC group to form dithiocarbamates (PEITC−GSH).[112] In animal models, treatment with PEITC resulted in an increase of NQO-1, GST, and UGT activities in the rat liver.[113] An earlier animal experiment had a similar result that PEITC could largely enhance UGT activities in liver.[114]

Nrf2, the key mediator of drug-induced changes in phase II metabolizing, can also be activated by ITCs.[115] When cells are exposed to oxidative stresses, chemicals, and UVR, Nrf2 dissociates from Keap1 and translocates into the nucleus, thereby activating ARE. PEITC can induce Nrf2-ARE-mediated phase II enzyme and its downstream gene expression, including γ-glutamyl cysteine-synthetase (γGCS), heme oxygenase1 (HO-1), and NAD(P)H quinone oxidoreductase1 (NQO1).[80,104] One of the mechanisms might be that PEITC induces the expression of ARE-mediated phase II enzymes via the c-Jun N-terminal kinase-1 (JNK1) and Nrf2-dependent pathways.[116]

REVERSE OF MULTIDRUG RESISTANCE

Multidrug resistance (MDR) is largely responsible for ineffective chemotherapy. P-glycoprotein/MDR1 (ABCB1) and MRP2 (ABCC2) are the uptake and efflux transporters of drugs. P-gp and MRP1 both transport a number of natural product chemotherapeutic agents, existing substrate preferences. Increased expression of P-gp, encoded by MDR1 gene, might account for MDR.[117,118] PEITC is effective in reducing and eliminating drug resistance including paclitaxel,[119] fludarabine,[31] metformin,[120] and cisplatin[68,121] in many types of tumor. The potential mechanism of PEITC reversing MDR might be inhibiting MRP1 by increasing the cellular accumulation of daunomycin (DNM) and vinblastine (VBL).[122,123] Moreover, breast cancer resistance protein (ABCG2) is an ATP-binding cassette transporter that plays an important role in drug absorption and disposition in the development of multidrug resistance in cancer cells. Studies have shown that PEITC is a substrate for BCRP and is a specific inhibitor of BCRP.[124]

On the other hand, the cellular accumulation or the drug-resistance effect of PEITC is regulated by multidrug resistance associated protein-1 (MRP-1) and P-glycoprotein-1 (Pgp-1). When the overexpression of MRP1 and P-gp cells is exposed to PEITC, the agent was rapidly exported, depending on accumulation in cells mainly in forms of GSH and cysteinylglycine conjugates.[105] In a word, PEITC can inhibit MDR proteins, but on the other hand, PEITC is regulated by these proteins.

Overall, this review summarized the work performed over the past 20+ years on PEITC absorption, metabolism, and cancer chemoprevention. Taken together, we have discussed the molecular signaling mechanisms of PEITC actions on some well-established mechanisms such as the following pathways: induction of apoptosis by intrinsic, extrinsic, and ER stress pathways; inhibition of the survival pathways, and cell cycle arrest; and reduction of the incidence of cancer by modulation of drug-metabolizing enzymes, including phase I and phase II. Recently, a novel alkyne-tagged ITC (NPEITC) was synthesized for the development of a "click" chemistry-based method to identify the protein targets for PEITC, which may pave the road for understanding the biological functions of PEITC as chemopreventive agents.[125] In addition to the well characterized effects on apoptosis, cell proliferation, and cell cycle, PEITCs can target angiogenesis, cell attachment,[126] and autophagic cell death.[9] Further investigation is required to answer whether normal dietary intake or pharmacological administration of PEITC is sufficient to modulate these pathways in vivo.

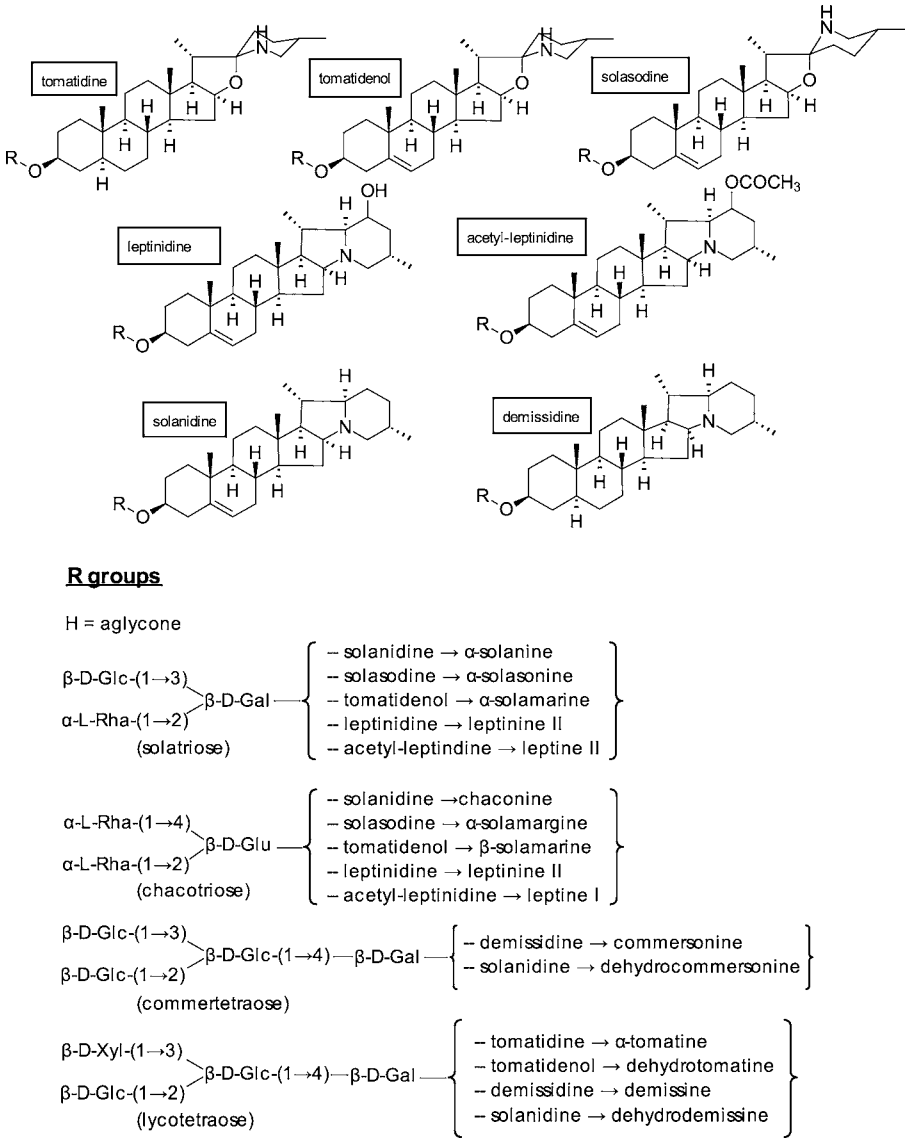

Figure 1. Structures of the aglycones and glycoalkaloids found in *Solanum*.[137,140,141]

combination, and as part of the diet against cancer cells and tumors. To help stimulate needed studies further, the main objective of this review is to unify the scattered information on the anticarcinogenic potential of the food-related glycoalkaloids. It should be noted that glycoalkaloids are reported to exhibit other beneficial as well as adverse effects in animals and humans. These aspects are beyond the scope of this review. They are comprehensively covered in our previous publications.[3−7]

CHEMISTRY AND PREVALENCE OF GLYCOALKALOIDS IN FOOD

Eggplants. *Solanum melongena* Linn. is an herbaceous plant with coarsely lobed leaves, white to purple flowers, and widely consumed fruit that can be eaten raw, cooked, or pickled.[8] The following selected studies show that eggplants contain several classes of bioactive compounds, including anthocyanidins, flavonoids, saponins, and glycoalkaloids. Individual or combinations of the bioactive compounds are probably responsible for the reported analgesic, antianaphylactic, anti-inflammatory, antioxidant, antipyretic, intraocular pressure reducing, central nervous system depressing, hypolipodemic, and hypotensive properties of eggplants, reviewed by Das and Barua and Sun et al.[8,9] We do not know whether eggplants also possess anticarcinogenic properties.

The fruits of the eggplant are one of the most widely consumed vegetables in the world, with the most popular species being Southeast Asia-domesticated *S. melongena* L.[10] These authors used liquid chromatography−mass spectrometry methods to compare the contents of the major eggplant glycoalkaloids (solamargine and solasonine) of *S. melongena* to the allied accession of the Africa-cultivated *S. aethiopicum* and *S. macrocarpon*. The results show that (a) fruits of *S. aethiopicum* and *S. melongena* contained (in mg/100 g fresh weight) 0.58−4.56 α-solamargine and 0.17−1.0 α-solasonine and (b) the corresponding much higher values for *S. macrocarpon* are 124−197 and 16−23, respectively, suggesting that this accession might not be safe for consumption. A related study of 10 eggplant lines and three allied species (*S. aethiopicum*, *S. integrifolium*, and *S. sodomaeum*) confirmed that the allied species had higher glycoalkaloid content than the widely consumed eggplants and that the glycoalkaloid content

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

generally increased during fruit development and ripening.[11] Bajaj et al.[12] used colorimetry to determine an average glycoalkaloid content of 21 eggplant varieties, whose concentrations (in mg/100 g fresh weightt) ranged from 6.25 to 20.5 or 3.3-fold variation from the lowest to the highest value. These authors also found that the crude protein content ranged from 0.77 to 3.63 (4.7-fold variation) and that high-glycoalkaloid eggplants tasted bitter. A British study used colorimetry to determine the average glycoalkaloid content of two eggplant samples of about 8 mg/100 g fresh weight.[13] Kintia and Shvets[14] isolated and characterized three steroidal saponins from seeds of Moldavian *S. melongena*. These compounds probably contribute to the observed bioactivities of eggplants. An Egyptian study[15] used colorimetry and thin-layer chromatography (TLC) to identify three glycoalkaloids (solamargine, solasonine, and solanine) in *S. melongena* fruit, whose concentrations varied with the harvesting season. These authors also found that fruit infected with *Botrytis cinerea* fungi contained the solanine hydrolysis product β-solanine. French scientists used colorimetry and TLC to determine the total glycoalkaloid and furastanol saponin content of six eggplant varieties, the concentrations of which (in mg/100 g fresh weight) ranged from 1.0 to 7.2 and 3.0 to 11.2, respectively.[16,17] Eanes et al.[18] developed an HPLC method for the separation and determination of the following eggplant glycoalkaloids: solamargine, solasonine, chaconine, and solanine and their aglycones, solasodine and solanidine. Extracts of *S. melongena* and *S. linnaeanum* were used to determine the method of recovery, limit of detection, and limit of quantification. In agreement with our studies with potato[19] and tomato[20] glycoalkaloids, grilling or boiling of eggplants did not result in significant changes in the total glycoalkaloid (solamargine plus solasonine) content.[21]

Potatoes. Nikolic et al.[22] describe a liquid−liquid system for the acid hydrolysis of potato glycoalkaloids from potato sprouts that yields 1.46 g of solanidine per 100 g of dried sprouts. Attoumbre et al.[23] describe a centrifugal partition chromatography procedure for the isolation of solanidine from glycoalkaloid hydrolysates of potato skins and sprout extracts. Kuo et al.[24] found that adding auxin phytohormones to cell culture tissues of the *Solanum lyratum* plant induced increases in the production of solanidine and solasodine levels, suggesting the availability of a new method for the production of steroidal alkaloids. Friedman and Levin[7] reviewed analytical methods for investigating potato glycoalkaloids and bioactive calystegine alkaloids. Figure 2 shows the glycoalkaloid content of fresh and processed potatoes.

Tomatoes. The glycoalkaloid known as tomatine consists of a mixture of two glycoalkaloids: α-tomatine and dehydrotomatine (Figure 1). In the present study, we will use the term tomatine for the 10:1 mixture. Both compounds are present in tomato fruit and leaves. Immature green tomatoes contain up to 500 mg of tomatine per kilogram of dry weight. The tomatine content of cherry tomatoes (grape tomatoes, minitomatoes) is several fold greater than that of larger size standard varieties. Because tomatine is largely degraded as the tomato ripens, the levels in red tomatoes are much lower, up to about 5 mg/kg. Consumers of high-tomatine green tomatoes and pickled green tomatoes consume high amounts of tomatine. A red tomato variant indigenous to the Andes mountains of Peru has a very high tomatine content, 500−5000 mg/kg dry wt.[25] These tomatoes are consumed without apparent acute toxic effects. Figure 3 lists the α-tomatine content of a small sampling of fresh and processed tomatoes.

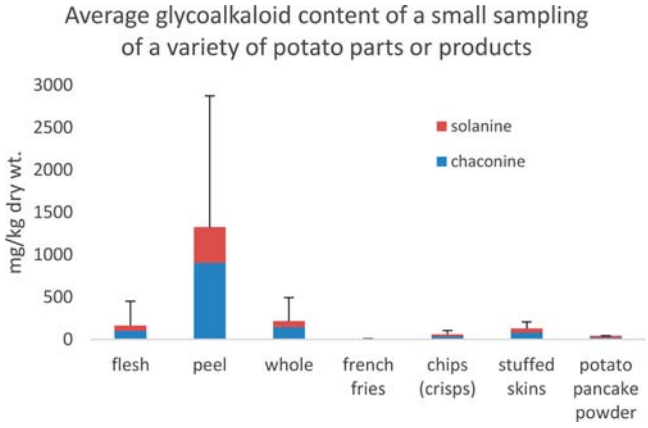

Figure 2. Makeup of total glycoalkaloids in a small sampling of a variety of potatoes and potato products. Due to the large standard deviations, ANOVA showed no statistical differences. Adapted from ref 6. Copyright 2006 American Chemical Society.

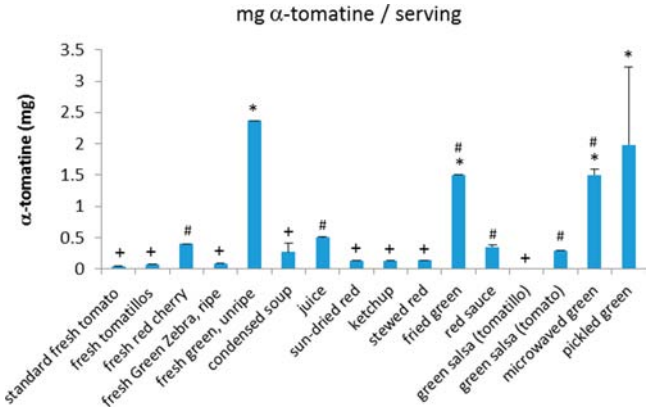

Figure 3. α-Tomatine content per serving of a variety of fresh and processed tomato (or tomatillo) products. Bars sharing the same symbol are not significantly different; $p < 0.05$. Adapted from ref 20. Copyright 1995 American Chemical Society.

The use of gene manipulation to introduce desirable traits into tomatoes, such as tolerance to stress and pesticides and resistance to phytopathogens, raises questions about the tomatine content of the transgenic tomatoes. Our results,[5] and those by other investigators,[26,27] indicate that tomatine levels of transgenic tomatoes were not significantly different from those observed in the standard varieties grown under the same field conditions. By contrast, a long-term (10 year) study revealed that organically grown tomatoes had higher average tomatine content than their standard counterparts, suggesting that soil composition and environmental conditions seem to affect the tomatine content in tomato.[28] The tomatine levels of tomatoes in both cropping systems ranged from 4.29 to 111.85 μg/g dry wt or a 26-fold variation from the highest to the lowest value. A related study found that the tomatidine content of 11 analyzed samples was higher in conventional tomatoes than that in organic tomatoes.[29] These results suggest the possibility of future anticancer and anticholesterol studies with selected high-tomatine and high-tomatidine red tomatoes.

We carried out studies designed to optimize the acid hydrolysis of the tetrasaccharide chain of tomatine to products

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

with three, two, one, and zero sugar groups.[30] A 20 min hydrolysis of tomatine in 1 N HCl at 100 °C was used for the formation of the trisaccharide β1-tomatine, the disaccharide γ-tomatine, and the monosaccharide δ-tomatine. Efforts to isolate the other theoretical possible trisaccharide, β2-tomatine, were unsuccessful, apparently because its xylose sugar is degraded during hydrolysis. A 70 min hydrolysis time achieved complete removal of the tetrasaccharide side chain to produce the aglycone tomatidine. Because tomatine was stable to acid hydrolysis at 37 °C, it may be stable in the acidic pH environment of the human gut. The hydrolysis products are formed by sequentially cleaving the sugars from lycotetraose (Figure 1).

With this background on the structures and composition of glycoalkaloids from eggplants, potatoes, and tomatoes and some of their hydrolysis products (metabolites), we will now briefly describe reported studies designed to determine the anticarcinogenic properties and mechanisms of action of the eggplant glycoalkaloids α-solamargine and α-solasonine, their common aglycone solasodine, the potato glycoalkaloids α-chaconine and α-solanine and hydrolysis products including the aglycone solanidine, and the tomato glycoalkaloids α-tomatine and hydrolysis products including aglycone tomatidine against cancer cells in culture (in vitro) and some animal and human tumors in vivo.

ANTICARCINOGENIC PROPERTIES OF EGGPLANT GLYCOALKALOIDS

Here, we briefly review mechanistic aspects associated with eggplant glycoalkaloids produced in some eggplant varieties. In addition to eggplants, numerous herbal and medicinal plants synthesize solamargine and solasonine. In fact, most of the anticancer studies mentioned below were done with glycoalkaloids isolated from these sources and not from eggplants. Because the glycoalkaloids from different plant sources are identical, we will also mention selected anticancer studies in cells, rodents, and human using glycoalkaloids from herbal and medicinal plants grown in different parts of the world. These include *S. incanum*,[31] *S. lycocarpum*,[32] and *S. nigrum*.[33]

Structural and Immune Effects in Apoptosis. Apoptosis is a genetically controlled (encoded), regulated, and conserved form of cell death, where the cell first undergoes nuclear and cytoplasm condensation with blebbing of the plasma membrane, DNA fragmentation, and breakdown of membrane-enclosed fragments known as apoptotic bodies, which are then engulfed rapidly by neighboring cells or macrophages.[34] The cell activity thus participates in its own destruction. In many cells, but apparently not with tomatine (see below), activation of caspases by eggplant glycoalkaloids may be the ultimate effector mechanism in apoptotic pathways. TNF exhibits antiproliferative effects against various cancer cell lines in vitro and in vivo.[34,35]

The trisaccharide solamargine and the corresponding mono- and diglycosides preferentially inhibited the uptake of tritiated thymidine by cancer cells relative to that by normal lymphocyte cells.[36] These results and the observed morphological changes in the cells indicate that the action against the cancer cells involves cell lysis. On the basis of a structure−activity and molecular modeling study, Chang et al.[37] concluded that the 2′-rhamnose moiety of solamargine [(22*S*,25*R*)-spiro-5-ene-3β-yl-α-L-rhamnopyranosyl-(1→2glu)-*O*-α-L-rhamnopyranosyl(1→4glu-β-D-glucopyranose)-solasodine] acts by penetrating the cell membrane by diffusion and then triggers death by apoptosis of human hepatoma Hep3B cells by changing the dihedral angle of the glycosidic bond, suggesting that the carbohydrate side chains of glycoalkaloids seem to govern the affinity to steroid human necrosis factor receptors and gene expression associated with carcinogenesis. A related study suggests that cells in the G(2)/M phases are highly susceptible to solamargine-mediated apoptosis and that parallel upregulation of tumor necrosis factor receptors TNFR-I or TNFR-II on the Hep3B cells may be an independent mechanism of solamargine-mediated apoptosis.[38]

Blankemeyer et al.[39] used a cell assay to measure the changes in membrane potentials of frog embryos induced by solamargine and solasonine. Experiments with solasonine at pH 6 and 8 suggest that the unprotonated form of solasonine is involved in the membrane potential effect and that the relative potencies of the two glycoalkaloids are similar for the observed frog embryo effects.

Solamargine and solasodine inhibit cell-mediated immune functions [(antibody-dependent cellular cytotoxicity (ADCC) and natural killer cell (NK)] activity of human peripheral mononuclear cells, possibly suggesting that enhancement of the immune system could contribute to apoptosis.[40] In vivo studies support this suggestion.[41] These authors found that groups of mice administered solasodine rhamnosyl glycosides one-half an hour after Sarcoma 180 inoculation caused total remission of the cancer, whereas mice treated with sarcoma but without the glycosides all died within 20 days. Moreover, 10 of 12 of cured mice were resistant to the reintroduction of terminal doses of cancer. Because, in addition to apoptosis, the glycosides stimulated lasting immunity against cancer similar to that observed with a vaccine containing *Corynbacterium parvum*, it seems that the stimulation of immunity contributed to the observed in vivo anticancer effects. It seems that solasodine glycosides could contribute to the management of diseases such as malignancy and also be used as a prevention therapy. Below, we mention the role of immunity in the bioactivity of glycoalkaloids.

Gastric Cancer Cells. Ding et al.[33] isolated six glycoalkaloids from *Solanum nigrum*. The following four induced cytotoxicity and apoptosis in the gastric cancer cell line MGC-803: solasonine, β1-solasonine, solamargine, and solanigroside P. The number and location of the α-L-rhamnose moiety and the type of sugar in the side chain as well as the presence of an OH group on the steroidal alkaloid backbone influenced relative potency. The suggested mechanism of apoptosis seems to be related to the recognized anticarcinogenic events: activation of caspase-3, cell cycle arrest, upregulation of the ratio of antiapoptotic Bax to Bcl-2 proteins, and downregulation of the mutant p53 gene.

Leukemia Cells. In an effort to define how solamargine mediates cytotoxicity via oncosis in human K562 leukemia and squamous cell carcinoma KB cells, Sun et al.[42] used the MTT assay to measure cytotoxicity and the release of lactate dehydrogenase (LDH) and the uptake of propidium iodide (PI) to determine leakage of cytoplasm content. Cytotoxicity and membrane disruption were triggered rapidly within minutes at the same rate by 10 μM solamargine, suggesting that apoptosis seems to be initiated by plasma membrane perturbation. These authors[34] also reported that exposure of the leukemia cells to 10 μM solamargine for 30 min induced a 7-fold increase in intracellular calcium concentration, down-expression of Bcl-2 and upregulation of Bax, caspase-3, and caspase-9 activities. These results and the observed decrease in

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

membrane potential and release of cytochrome c suggest that an induced lysosomal−mitochondrial death pathway is involved in the cytotoxicity. Because the cells do not show an early increase in reactive oxygen species (ROS) production before apoptosis, the lysosomal rupture does not seem to be associated with oxidative stress.

Liver Cancer Cells. Solamargine isolated from *Solanum nigrum* inhibited the growth and induced apoptosis of human hepatoma Hep G2 and SMMC-7721 cells lines via cell cycle arrest at G2/M phase and upregulation of caspase-3 expression, the so-called executioner caspase and mediator of DNA fragmentation and nuclear condensation, suggesting that the glycoalkaloid could be used to treat liver cancer.[43]

Lung Cancer Cells. Solamargine exhibited superior cytotoxicity in four human lung cancer cell lines, with IC_{50} values ranging from 3 to 7.2 μM, and increased binding of TNF-α and TNF-β to the lung cancer cells.[35] The glycoalkaloid induced release of cytochrome c, downregulation of anti-apoptotic Bcl-2 and Bcl-xL proteins, increase in caspase-3 activity, and DNA fragmentation.[35] These observations and the additional finding that TNF-resistant lung cancer cells became susceptible after exposure to solamargine suggest that the compound should be studied for its therapeutic value against human lung cancers.

Other investigators reported that the anticarcinogenic activity of solamargine is associated with the downregulation of HER-2 and upregulation of Fas and tumor necrosis factor receptor (TFNR) expression, which triggers the mitochondrial-mediated cell apoptosis pathway and sensitizes human lung cancer cell and A540 adenocarcinoma cells to chemotherapy, and that it potentiated the death of lung cancer H661 cells induced by the drugs herceptin and epirubicin[44,45] as well as the death of lung and breast cancer cells induced by the drug cisplatin.[46,47]

A detailed mechanistic study[48] revealed that solamargine inhibited growth and induced apoptosis of non-small-cell lung cancer cells in a time- and dose-dependent manner and increased phosphorylation of p38 mitogen-activated protein kinase (p38 MAPK) in a time-dependent manner. It also inhibited phosphorylation and protein expression of signal transducer and activator of transcription 3 (Stat3), which was abrogated by SB203580, a specific inhibitor of p38 MAPK, and induced protein expression of the p21 cyclin-dependent kinase inhibitors. Although silencing of Stat3 had no further effect, exogenous expression of Stat3 overcame the effect on cell proliferation. These results show that solamargine inhibits proliferation and induces apoptosis in lung cancer cells through p38 MAPK-mediated suppression of phosphorylation and protein expression of Stat3, followed by induction of Stat3's downstream effector, p21.

Osteosarcoma Cells. An investigation by Li et al.[49] on the role of the p53 gene in the proapoptotic action of solamargine in human U2OS cells using the microculture tetrazolium (MTT) and several other bioassays found that solamargine-induced apoptosis was associated with chromatin condensation, formation of apoptotic bodies, exposure of phosphatidylserine on the extracellular surface, increase in mRNA and protein levels of p53 and Bax (a proapoptotic protein), reduction in the expression of Bcl-2 (an antiapoptotic protein), loss of mitochondrial membrane potential, release of cytochrome c, and activation of caspase-3 and -9 enzymes. These results suggest that solamargine activates the mitochondria-mediated apoptotic pathway via both p53 transcription-dependent and -independent mechanisms. The authors conclude that the mechanism by which solamargine activates the p53 gene remains unclear.

Multiple Cancer Cell Lines. The Chinese medicinal herbs *Solanum incanum* and *Solanum nigrum* Linn. contain the steroidal glycoalkaloids solamargine, solanine, and solasonine. An ethanol extract of *S. nigrum* was found to inhibit the growth of MCF-7 breast cancer and to induce apoptosis of tumor cells.[50] Solanine isolated from this plant was found to inhibit tumors in the following cell lines (IC_{50} values in μg/mL): Hep G2 human carcinoma (14.5), SGC-7901 human gastric carcinoma (>50), and LS-174 human large intestine cancer cells (>50). The inhibitory action of solanine was accompanied by a decrease in the content of Bcl-2 protein in the Hep G2 cells. These data show that Hep G2 cells showed the greatest sensitivity to inhibition by solanine.

Munari et al.[32] evaluated the antiproliferative effects of solamargine and solasonine against the following tumor cell lines: murine melanoma (B16F10) and human colon carcinoma (HT29), breast adenocarcinoma (MCF-7), cervical adenocarcinoma (HeLa), hepatocellular liver carcinoma (Hep G2), and glioblastoma (MO59J, U343, and U251). Solamargine showed the most pronounced activity, with IC_{50} values ranging from 4.58 to 18.23 μg/mL. The lowest IC_{50} values (highest activities) were observed against Hep G2, with an IC_{50} value for solamargine of 4.58 and for solasonine of 6.01. These results show that the test substances behaved as broad-spectrum anticarcinogens.

Three solasodine glycoside derivatives prepared by trans-glycosylation exhibited strong cytotoxicity against four cancer cell lines, suggesting that they might serve as lead candidates for cancer chemotherapy.[51]

Multiple Drug Resistance. Multidrug resistance (MDR) is one of the major causes of the failure of conventional treatments of cancer. MDR is often associated with the expression of P-glycoprotein (P-gp), which acts as a drug efflux pump to transport intracellular drugs out of cells, thus imparting drug resistance to tumor cells.[52] These authors found that solamargine has broad-spectrum cytotoxic activity against multiple MDR cell lines (human myelogenous leukemia K562 cell line and its multidrug resistant counterpart K562/AO2) and that the P-gp−actin association pathway might be involved in the apoptosis, suggesting that the glycoalkaloid bypasses the MDR mechanism.

Enhancement of Cancer Drug Potencies. Solamargine synergistically enhanced the effects of cancer drugs including methotrexate, 5-florouracil, cisplatin,[46,47] and epirubicin[45,53] in several cancer cell lines, suggesting that it may have potential use in combination therapy for breast and lung cancers.

Mouse Cancers. A mixture of solasodine glycosides was effective in vivo against murine Sarcoma 180 (S180).[54] Mice in terminal stages of cancer became symptom free by a single dose. Because rhamnose inhibited the therapeutic effect, the authors suggest that the binding of glycosides to tumor cells may be mediated through the rhamnose carbohydrate of the trisaccharide side chain of solamargine.

Human Cancers. A 0.005% solasodine glycoside cream applied topically was effective in causing regression of human basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs) without adverse effect on the liver, kidneys, or blood system.[55] A solamargine-rich extract from *S. incanum* induced apoptosis in human SCC cells cells by upregulating the expression of TNFRs and Fas and downstream adaptors of TNF-α and Fas signaling pathways, triggering the mitochon-

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

drial apoptotic pathway, upregulating cytochrome c and Bax, and downregulating Bcl-X(L).[31] A once-daily application of a topical solamargine gel to the skin caused the disappearance of UVB-induced microinvasive SCCs in 27 of 30 hairless mice within 10 weeks. In addition, the gel cured 10 of 13 patients with actinic keratosis (AK) after 16 weeks. The authors suggest that the extract may be an ideal candidate for the treat of AK with minimal side effects on normal skin. Goldberg et al.[56] effectively treated cancer of the human penis, called Bowen's disease (in situ squamous cell carcinoma of the skin), with low concentrations of a mixture of solasodine glycosides and liquid nitrogen.

Punjabi et al.[57] evaluated, in a double-blind randomized study, the safety and efficacy of a cream containing a 0.005% mixture of solasodine glycosides (Zycure) for the treatment of basal cell carcinoma in humans (males, $n = 50$; females, $n = 44$) at 10 centers in the United Kingdom. The primary efficacy end point was histologically confirmed clearance of the basal cell carcinoma at the end of 8 week treatment. The results show that the treatment is a safe therapy for basal cell carcinoma, with a cure rate of 66% at 8 weeks and 78% at a 1 year follow-up.

In a related in vivo study, Tiossi et al.[58] used an extract of *Solanum lycocarpum* fruit containing 45% each of solamargine and solasonine to prepare a topical formulation and to optimize its penetration in vitro to porcine skin and in vivo to the skin of hairless mice. The results showed that pH 6.5 was optimal for delivery and penetration of skin in both animal models, suggesting that the formulation might be useful for topical therapy of skin disorders.

A review of the literature[59] concludes that there is insufficient evidence at present to make recommendations on the topical use of solasodine glycoalkaloids for skin cancers. Continued research on the efficacy of treatments is needed, including histologic confirmation of clearance, long-term follow-up, and comparison with surgical outcomes.

Solasodine. The aglycones solasodine and tomatidine isolated from the South African medicinal plant *Solanum aculeastrum* Dunal inhibited the growth of HeLa, MCF7, and HT29 cancer cell lines.[60] The IC_{50} value of the two compounds combined was lower (they were more active) than the value for solasodine but not for that of tomatidine.

ANTICARCINOGENIC PROPERTIES OF POTATO GLYCOALKALOIDS

Here, we will briefly describe reported anticarcinogenic properties and mechanisms of the bioactive potato compounds in cells (listed alphabetically) and laboratory animals.

***α*-Chaconine.** *Cervical, Liver, Hepatoma, and Stomach Cancer Cells.* Friedman et al.[2] describe methods for the isolation of large amounts of pure *α*-chaconine and *α*-solanine from Dejima potatoes and for the extraction and analysis of total glycoalkaloid content from five fresh potato varieties (Dejima, Jowon, Sumi, Toya, and Vora Valley). These compounds were then evaluated in experiments using a MTT assay to assess the anticarcinogenic effects of (a) the isolated pure glycoalkaloids separately, (b) artificial mixtures of the two glycoalkaloids, and (c) the total glycoalkaloids isolated from each of the five potato varieties. All samples tested reduced the number of the following human cell lines: cervical (HeLa), liver (Hep G2), lymphoma (U937), and stomach (AGS and KATO III) cancer cells and normal liver (Chang) cells. The results show that (a) the effects of the glycoalkaloids were concentration-dependent in the range of 0.1−10 μg/mL (0.117−11.7 nmol/mL), (b) *α*-chaconine was more active than *α*-solanine, (c) some mixtures exhibited synergistic effects, whereas others produced additive ones, (d) the different cancer cells varied in their susceptibilities to destruction, and (e) the destruction of normal liver cells was generally lower than that of liver cancer cells. The decreases in cell populations were also observed visually by phase contrast microscopy (Figure 4). This

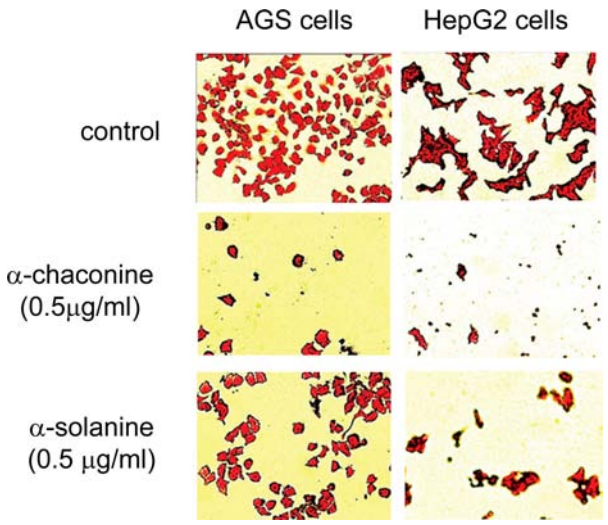

Figure 4. Morphological changes induced by glycoalkaloid treatments in Hep G2 and AGS cancer cells (×400 magnification). The cells were pretreated with either *α*-chaconine and *α*-solanine (0.5 μg/mL) for 48 h and stained with sulforhodanine B (0.4% w/v) for 30 min. Morphological alterations were recorded from phase-contrast microscopic observations. Adapted from ref 2. Copyright 2005 American Chemical Society.

study demonstrated for first the time the individual and synergistic anticancer properties of the two major glycoalkaloids present in all commercial potato varieties and processed potato products (chips, fries, skins).

Colon and Liver Cancer Cells. As part of an effort to improve plant-derived foods such as potatoes, eggplants, and tomatoes, the antiproliferative activities against human colon (HT29) and liver (Hep G2) cancer cells of a series of structurally related individual compounds were examined for the first time using a MTT assay.[1] The objective was to assess the roles of the carbohydrate side chain and aglycone part of *Solanum* glycosides in influencing inhibitory activities. Evaluations were carried out with four concentrations each (0.1, 1, 10, and 100 μg/mL) of the potato trisaccharide glycoalkaloids *α*-chaconine and *α*-solanine; the disaccharides *β*(1)-chaconine, *β*(2)-chaconine, and *β*(2)-solanine; the monosaccharide *γ*-chaconine and their common aglycone solanidine; the potato tetrasaccharide glycoalkaloid dehydrocommersonine; the potato aglycone demissidine; the tomato tetrasaccharide glycoalkaloid *α*-tomatine, the trisaccharide *β*1-tomatine, the disaccharide *γ*-tomatine, the monosaccharide *δ*-tomatine, and their common aglycone tomatidine; the eggplant glycoalkaloids *α*-solamargine and *α*-solasonine and their common aglycone solasodine; and the steroidal alkaloid jervine. All compounds were active in the assay, with the glycoalkaloids being the most active, and the hydrolysis products, less so. The effectiveness against the liver cells was greater than that against the colon cells. Potencies of *α*-tomatine and *α*-chaconine at a

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

concentration of 1 μg/mL against the liver carcinoma cells were higher than those observed with the anticancer drugs doxorubicin and camptothecin. This comprehensive report on anticarcinogenic potencies of a large number of glycoalkaloids and their hydrolysis products (metabolites) seems to have stimulated worldwide interest in the anticarcinogenic properties of potato and tomato glycoalkaloids and their mechanisms of action, as indicated by the numerous studies originating from different countries described below.

Colon Cancer Cells. α-Chaconine induced apoptosis of HT-29 human colon cancer cells in a time- and concentration-dependent manner.[61] The authors also showed that caspase-3 activity and the active form of caspase-3 were increased 12 h after α-chaconine treatment. In addition, caspase inhibitors prevented α-chaconine-induced apoptosis, whereas apoptosis was potentiated by an extracellular signal-regulated kinase (ERK) inhibitor. Results from the same study indicated that α-chaconine reduced the phosphorylation of ERK. It therefore seems that α-chaconine induces apoptosis of HT-29 cells through inhibition of ERK followed by activation of caspase-3.

Prostate Cancer Cells. Reddivari et al.[62] found that α-chaconine at 5 μg/mL and gallic acid at 15 μg/mL (a) exhibited potent antiproliferative properties and increased cyclin-dependent kinase inhibitor p27 levels in two prostate cancer cell lines, LNCaP and PC3, (b) induced poly[adenosine diphosphate (ADP)] ribose polymerase cleavage and caspase-dependent apoptosis in LNCaP cells and caspase-independent apoptosis through nuclear translocation of endonuclease G in both LNCaP and PC-3 cells, and (c) activated JNK, a response that played a major role in the induction of caspase-dependent apoptosis in LNCaP cells. These observations suggest that apoptosis induced by whole potato extracts in prostate cancer cell lines may be, in part, due to α-chaconine and gallic acid.

Inhibition of Angiogenesis of Bovine Aortic Endothelial Cells. In a study by Lu et al.,[63] α-chaconine inhibited the proliferation of bovine aortic endothelial cells (BAECs) in a dose-dependent manner, and nontoxic doses markedly suppressed cell migration, invasion, and tube formation. α-Chaconine also reduced the expression and activity of MMP-2, involved in angiogenesis (blood flow to cancer cells), and potently suppressed the phosphorylation of JNK, phosphatidylinositide-3 kinase (PI3K), and Akt, but it did not affect the phosphorylation of ERK and p38. Furthermore, the authors demonstrated that α-chaconine significantly increased the cytoplasmic level of inhibitors of IκBα and decreased nuclear factor κB (NF-κB), suggesting that it could inhibit NF-κB activity. It seems that α-chaconine inhibits migration, invasion, and tube formation of BAECs by reducing MMP-2 activity and JNK and PI3K/Akt signaling pathways and inhibiting NF-κB activity, suggesting its potential for use in antiangiogenic cancer therapy.

Reduction of Metastasis in Lung Carcinoma Cells. Metastasis is the spread of cancer cells from the initial or primary site of the disease to another part of the body. Shih et al.[64] found that α-chaconine (a) inhibited lung adenocarcinoma A549 cell invasion, migration, and phosphorylation of c-Jun N-terminal kinase (JNK) and Akt, (b) did not affect phosphorylation of extracellular signal regulating kinase (ERK) and p38, and (c) significantly decreased the nuclear level of NF-κB and the binding ability of NF-κB, suggesting that the inhibition of cell metastasis occurs by a reduction of matrix metalloproteinase-2 (MMP-2) and matrix metalloproteinase-9 (MMP-9) activities involving suppression of the phosphoinositide 3-kinase/Akt/NF-κB (PI3K/Akt/NF-κB) signaling pathway

α-Solanine. *Digestive System Cancer Cells.* Ji et al.[65] evaluated the effect of α-solanine isolated form the nightshade plant (*Solanum nigrum* Linn.) on the IC_{50} values of three digestive system tumor cell lines. The results show that (a) the IC_{50} values for the cell lines Hep G2, SGC-7901, and LS-174 were 14.47, >50, and >50 μg/mL, respectively, (b) the induced apoptosis rate in Hep G2 cells was 6.0, 14.4, 17.3, 18.9, and 32.2%, respectively, (c) cells in the G(2)/M phases of the cell cycle disappeared, whereas the number of cells in the S phase increased significantly for treated groups and the expression of Bcl-2 protein decreased. The target of solanine in inducing apoptosis in Hep G2 cells seems to be mediated by the inhibition of the expression of Bcl-2 protein.

Liver Cancer Cells. α-Solanine markedly increased in a dose-dependent manner the content of caspase-3 and concurrently decreased that of Bcl-2 in Hep G2 liver cancer cells. This observation suggests that α-solanine induces cell apoptosis by suppressing the activity of Bcl-2 and activating the caspase-3 protease.[66] Studies by Ji et al.[65] suggest that solanine-induced apoptosis in Hep G2 cells is turned on by reduction of the cell membrane potential, which opens ion channels that transport calcium ions down a concentration gradient, resulting in an increase in their concentration in the cell.

Pancreatic Cancer Cells In Vitro and In Vivo. Studies by Sun et al.[66] on the mechanism that may govern the anticarcinogenic activity of α-solanine in pancreatic cancer cells in vitro and in a nu/nu nude mouse model against human pancreatic cells show that the glycoalkaloid (a) inhibited the growth of the cancer cells through caspase-3-dependent mitochondrial apoptosis, (b) promoted the opening of the mitochondrial membrane permeability transition pore (MPTP) by downregulating the Bcl-2/Bax ratio, which resulted in the release of cytochrome c and Smac from the mitochondria into the cytosol to process the caspase-3 zymogen into its activated form, and (c) decreased the expression of tumor metastasis proteins, specifically MMP-2 and MMP-9, in the cells.

In a related study, Lv et al.[67] investigated the anticarcinogenic effect of α-solanine against human pancreatic cancer cells in vitro and in vivo. In vitro, α-solanine (a) inhibited the proliferation of PANC-1, sw1990, MIA PaCa-2 cells in a dose-dependent manner as well as cell migration and invasion at nontoxic doses; (b) suppressed the expression of MMP-2/9, extracellular inducer of matrix metalloproteinase CD44, eNOS, and E-cadherin in PANC-1 cells, (c) significantly decreased vascular endothelial growth factor (VEGF) expression and tube formation of endothelial cells, (d) suppressed phosphorylation of Akt, mTOR, and Stat3, and (e) enhanced phosphorylation of β-catenin and markedly decreased tran-nuclear translocation of NF-κB, β-catenin, and TCF-1. In vivo, administration of α-solanine (6 μg/g for 2 weeks) in a xenograft mouse model induced decreases in tumor volume and weight by 61 and 43%, respectively, as well as MMP-2/9, proliferating cell nuclear antigen (PCNA), and VEGF expression. These results indicate that the beneficial in vitro and in vivo effects seem to occur via the suppression of proliferation, angiogenesis, and metastasis. It seems that solanine might be an effective compound for the treatment of human pancreatic cancer.

Prostate Cancer Cells. An in vitro investigation of the effects of α-solanine on human androgen-independent prostate cancer cell line PC-3 showed that α-solanine suppressed the growth of the cells in a dose- and time-dependent manner and that the

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

cells were arrested in S phase.[68] The protein level of IκBα was increased and that of Bcl-2 was decreased at all tested concentrations (30, 40, and 50 μg/mL), suggesting that the antiprostate cancer effect occurred via inhibition of cell proliferation, arrest of the cells in S phase, induction of apoptosis, upregulation of the expression of IκBα, and downregulation of Bcl-2.

Shen et al.[69] investigated the mechanism involved in the suppression of human prostate cancer cell line (PC-3) metastasis by α-solanine. The results show that α-solanine reduces the viability of PC-3 cells. Treatment with a nontoxic dose markedly suppresses cell invasion and significantly elevates the expression of epithelial marker E-cadherin, and it concomitantly decreases the expression of mesenchymal marker vimentin, suggesting that the glycoalkaloid suppresses the epithelial−mesenchymal transition (EMT). The authors also showed that α-solanine reduces the mRNA level of MMP-2, MMP-9, and extracellular inducer of matrix metalloproteinase (EMMPRIN), but it increases the expression of reversion-inducing cysteine-rich protein with kazal motifs (RECK) and tissue inhibitor of metalloproteinase-1 (TIMP-1) and TIMP-2. In addition, it suppresses the phosphorylation of phosphatidylinositide-3 kinase (PI3K), Akt, and ERK. Furthermore, α-solanine downregulates oncogenic microRNA-21 (miR-21), upregulates tumor suppressor miR-138 expression and reduces ERK and PI3K/Akt signaling pathways, and regulates expression of miR-21 and miR-138. It seems that the inhibition of PC-3 cell invasion by α-solanine might, in part, result from blocking EMT and the expression of MMPs. These findings have therapeutic potential for suppressing invasion of prostate cancer cells.

Inhibition of Breast Cancer in Mice. Mohsenikia et al.[70] investigated α-solanine toxicity in vitro and in vivo and assessed its protective and therapeutic effects on a typical mouse model of breast cancer. The results show that α-solanine significantly suppressed the proliferation of mouse mammary carcinoma cells both in vitro and in vivo; at a concentration of 5 mg/kg, the tumor rate in the treated group was 0 compared with a 75% rate in the untreated controls. The average tumor size and weight were significantly lower in treated mice than that in corresponding controls. Moreover, α-solanine induced an increased in Bax protein expression in the breast tumor compared with that its respective control group and induced decreased expression of the antiapoptotic Bcl-2 protein and a decrease in proliferative and angiogenic parameters. These results demonstrate the chemoprotective and chemotherapeutic potential of α-solanine in a breast cancer model that operates through apoptosis induction and cell proliferation and angiogenesis inhibition.

Inhibition of Human Melanoma Cell Migration and Invasion. Lu et al.[71] examined the effect of α-solanine on the metastasis of melanoma cancer cells in vitro. The results show that α-solanine (a) inhibited proliferation of human melanoma cell line A2058 in a dose-dependent manner, (b) markedly suppressed cell migration and invasion and reduced the activity of MMP-2 and MMP-9, involved in the migration and invasion of cancer cells, at a nontoxic dose, (c) potently suppressed the phosphorylation of JNK, PI3K, and Akt but did not affect phosphorylation of extracellular signal regulating kinase (ERK), and (d) significantly decreased the nuclear level of NF-κB and inhibited NF-κB activity. Collectively, the results suggest that α-solanine inhibited migration and invasion of A2058 cells by reducing MMP-2/9 activities and inhibiting JNK and PI3K/Akt signaling pathways and NF-κB activity.

Disruption of Cell Membranes. Hep G2 cells treated with α-solanine showed typical signs of apoptosis associated with a lowered membrane potential of the mitochondria and an increased concentration of Ca^{2+}.[72] It seems that α-solanine opens up channels in the membrane by lowering the membrane potential that then leads to the transport of Ca^{2+} ions down their concentration gradient, resulting in an increase in the concentration of calcium ions in the cell and initiating the mechanism apoptosis.

Solanidine. *Solanidine and Solanidine Analogues.* Here, we will mention several aspects of solanidine biology and chemistry that may be relevant to the theme of the present review. A structure−function relationship study of the biological activities (cell cycle arrest, apoptosis) on human osteosarcoma 1547 cells revealed a correlation between the experimental and theoretical data that highlighted the importance of the heterosugar moiety and the 5,6 double bond in these activities.[73] Six synthetic solanidine analogues exhibited strong anticancer activities and multidrug resistance reversal effects in a hypodiploid population of HeLa murine lymphoma cells, suggesting that the modified solanidine skeleton is a suitable substrate for the design and synthesis of further innovative drug candidates with anticancer activities.[52]

Inhibition of Multidrug Resistance. Because intrinsic or acquired resistance of tumor cells to multiple cytotoxic drugs (multidrug resistance, MDR) is a major cause of failure of cancer chemotherapy, Lavie et al.[74] examined the ability of steroidal alkaloids of plant origin, namely, the *Veratrum* sp. alkaloid cyclopamine and the *Lycopersicon* sp. Aglycone (alkaloid) tomatidine, to act as chemosensitizers in multidrug-resistant NCI AdrR human adenocarcinoma. The results show that the alkaloids inhibited P-gp-mediated drug transport and multidrug resistance, suggesting that these plant-derived compounds may serve as chemosensitizers in combination chemotherapy with conventional cytotoxic drugs for treating multidrug-resistant cancer.

■ ANTICARCINOGENIC PROPERTIES OF THE TOMATO GLYCOALKALOID TOMATINE

Here, we will briefly mention results of reported studies on the anticarcinogenic potential of α-tomatine in vitro and in vivo.

Early Studies on the Inhibition of Multiple Cancer Cells. Lee et al.,[1] using the MTT in vitro assay, found that commercial tomatine is a strong inhibitor of growth for both human colon and liver cancer cell lines, as evidenced by the dose-dependent (0.1−100 μg/mL) inhibition of HT29 colon cancer cells at levels ranging from 38.0 to 81.5% and of human Hep G2 liver cancer cells from 46.3 to 89.2%. The anticarcinogenic activity against human liver cancer cells at a tomatine concentration of 1 μg/mL was higher than the activity observed with the commercial anticancer drug doxorubicin.

Friedman et al.[75] also investigated six green and three red tomatoes extracts for their ability to induce cell death in human cancer and normal cells using a microculture MTT assay. Compared to the untreated controls, the high-tomatine green tomato extracts strongly inhibited the following human cancer cell lines: breast (MCF-7), colon (HT-29), gastric (AGS), and hepatoma (liver) (Hep G2) as well as normal human liver cells (Chang). In another study, we discovered that the activity of α-tomatine generally decreases upon removal of one or more of the four carbohydrate groups of the lycotetraose side chain.[76]

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

For example, the activity of α-tomatine against the PC-3 prostate cancer cells was about 200 times greater than that of the aglycone tomatidine. Tomatidine is, however, active against the foodborne pathogen *Staphylococcus aureus*,[77] suggesting that the two bioactivities seem to be governed by different mechanisms.

Our systematic studies on the bioactivity of tomatine at microgram levels against multiple human cancer cells seems to have stimulated interest from a number of investigators mentioned below to explore the biomarkers and associated signaling pathways that may be associated with the anticarcinogenic effects of tomatine.

Leukemia Cells. α-Tomatine inhibited human leukemia MOLT-4 cells by activating cell cycle checkpoints without damaging single or double DNA strands in the cells.[78] The slowing of the cell cycle seems to involve caspase-independent cell death associated with an increase in the tumor suppressor protein p53 and the proapoptotic protein PUMA (p53 upregulated modulator of apoptosis) as well as other biomarkers associated with cell cycle regulation. A related study found that α-tomatine-mediated anticancer activity against human chronic myeloid leukemia cells in vitro and in a transplanted mouse tumor operated through cell cycle- and caspase-independent pathways.[79]

Prostate Cancer Cells. α-Tomatine inhibited PC-3 prostate cancer cells with an IC_{50} value of 1.67 μM.[80,81] Cytotoxicity occurred after an hour of treatment and was mainly due to induction of apoptosis, as evidenced by decreased mitochondrial membrane potential, increased nuclear condensation, polarization of F-actin potential, cell membrane permeability, cytochrome c expression, induction of activation of caspase-3, -8, and -9, inhibition of NF-κB nuclear translocation, and a decrease in NF-κB/p50 and NF-κBp65 in the nuclear fraction.

Suppression of NF-κB activation by α-tomatine in PC-3 prostate cancer cells seems to occur through the inhibition of IκBα kinase activity, leading to sequential suppression of IκBα phosphorylation, IκBα degradation, NF-κB/p65 phosphorylation, and NF-κB p50/p65 nuclear translocation.[82] As expected, α-tomatine also reduced TNF-α-induced activation of the prosurvival mediator Akt. Its inhibition of NF-κB activation was accompanied by significant reduction in the expression of NF-κB-dependent antiapoptotic (c-IAP1, c-IAP2, Bcl-2, Bcl-xL, XIAP, and survivin) proteins. It seems that NF-κB plays a role in prostate cancer and that agents that suppress its activation may inhibit development or progression of this malignancy.

Inhibition of Lung Cancer Cell Migration and Invasion. Shih et al.[83] found that α-tomatine (a) inhibited cell invasion, migration, and phosphorylation of Akt and extracellular signal-regulated kinase 1 and 2 (ERK1/2) in human lung adenocarcinoma A549 cells, (b) did not affect phosphorylation of JNK and p38, (c) decreased nuclear levels of NF-κB, c-Fos, and c-Jun, and (d) inhibited the binding abilities of NF-κB and activator protein-1 (AP-1). Metastasis inhibition occurs by reducing the effects of MMP-2, MMP-9, and uPA (urokinase-type-plasminogen activator) through the PI3K/Akt or ERK1/2 signaling pathway and inhibiting NF-κB or AP-1 binding activities.

A related study[84] confirmed that α-tomatine suppressed invasion and migration of human non-small-cell lung cancer NCI-H460 cells through inactivation of the FAK/PI3K/Akt signaling pathway and lowering the binding activity of NF-κB. Cytotoxicity occurred through inactivation of the signaling pathway and enhancement of IkBα protein expression to reduce NF-κB DNA binding activity, resulting in the downregulation of MMP-7 expression, inhibition of cell migration, and interference with the rearrangement of the actin cytoskeleton by decreasing the expression of the pFAK protein.

Inhibition of Fish and Mouse Tumors. Feeding 2000 ppm of tomatine and 224 ppm of the multiorgan carcinogen dibenzo[*a*,*l*]pyrene (DBP) to rainbow trout for 9 months resulted in a reduced incidence of liver and stomach tumors by 41.3 and 36.3%, respectively, as compared to the incidence of tumors observed with DBP alone.[85] This seems to be the first report on the inhibition of tumor growth by dietary α-tomatine.

Intraperitoneally (ip) administered α-tomatine (5−10 mg/kg) significantly attenuated the growth of androgen-independent PC-3 prostate cancer cells in mice.[82] Tumor suppression was associated with increased apoptosis and with reduced nuclear translocation of the p50 and p65 components of the NF-κB signaling pathway. It seems that α-tomatine can inhibit the growth of prostate cancer tumors in vivo without inducing overt toxicity.

An evaluation of the antitumor activity of α-tomatine against PC-3 cell tumors grown subcutaneously and orthotopically in mice showed that ip administration of α-tomatine significantly attenuates the growth of PC-3 cell tumors grown at both sites.[82] Analysis of tumor material indicates that the tumor-suppressing effects were accompanied by increased apoptosis and lower proliferation of tumor cells as well as reduced nuclear translocation of the p50 and p65 components of NF-κB.

Intraperitoneal-injected α-tomatine at 1 mg/kg slowed the growth of mammary carcinoma (Ehrlich tumors) in mice.[86] The combination of α-tomatine (1 mg/kg) and the cancer drug doxorubicin (2 mg/kg) acted synergistically and extended survival of the mice with the Ehrlich tumors. The activity against the tumors, which are derived from adenocarcinoma of the mammary gland, seems to involve the immune system in the inhibition of tumor progression. This suggestion seems plausible based on reports by other investigators that tomatine contributes to the protective immunity of rodents (see below).

Kim et al.[87] determined the effect of commercial α-tomatine on CT-26 colon cancer cells in vitro and in vivo in an intracutaneously transplanted mouse tumor. Cytotoxicity experiments showed that α-tomatine induces about 50% lysis of the cancer cells at 3.5 μM after 24 h treatment. Large proportions of cells were found to be in the Annexin V (+)/propidium iodide (+) phase of cell death, implying late-phase apoptotic/necrotic status. α-Tomatine induced cell death in CT-26 cancer cells through caspase-independent signaling pathways. This conclusion was supported by western blot analysis showing localization of apoptosis-inducing mitochondrial protein (AIF) in the nucleus, downregulation of the apoptosis inhibitor survivin, and failure to detect the active form of caspase-3, -8, and -9 produced by proteolytic cleavage in CT-26 cancer cells.

The ip-administered α-tomatine (5 mg/kg body weight) also markedly inhibited growth of the tumor without causing body and organ weight changes. It seems that the reduced tumor growth in the mice by 38% after 2 weeks was the result of increased caspase-independent apoptosis associated with increased nuclear translocation of AIF and decreased survivin expression in tumor tissues. It seems that α-tomatine in pure form and in tomatine-rich green tomatoes might prevent colon cancer.

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

In addition to the cited mechanistic aspects involving proapoptotic biomarkers and signaling pathways, it seems likely that tomatine–cholesterol interactions, tomatine-induced stimulation of the immune system, and disruption of cancer cell membranes might also contribute to the mechanisms that govern its anticarcinogenicity.

We will now briefly mention the possible scientific basis for these suggestions.

Stimulation of the Immune System. α-Tomatine can act as a powerful adjuvant to elicit an antigen-specific cell-mediated immune response to the circumsporozoite (CS) protein, a major pre-erythrocyte stage malaria vaccine candidate antigen, requiring both CD80 and CD86 costimulation to form antigen-specific cellular immunity.[88] Heal et al.[89] found that α-tomatine contributed to protective immunity elicited by a malaria vaccine candidate via $CD8^+$ T cell release of antigen-specific IFN-γ in a *Plasmodium berghei* (malaria) rodent model. It seems that stimulation of the immune system might also contribute the anticarcinogenic effects of α-tomatine.

α-Tomatine–Cholesterol Interactions in Breast and Leukemia Cancer Cells. Sucha et al.[90] observed that the inhibition of cell proliferation and viability of human breast adenocarcinoma MCF-7 cells in culture at concentrations of 6 and 9 μM was followed by a recovery of cells. The recovery was not caused by the biotransformation of α-tomatine in the cells but by a substantial decrease in the concentration of α-tomatine in the culture medium due to its binding with cholesterol. Additional experiments on the regulation of the mechanism of action of α-tomatine revealed a loss of ATP in α-tomatine-treated cells but no DNA damage, no changes in the levels of the proteins p53 and p21(WAF1/Cip1), and no apoptosis (neither activated caspase-8 and -9, sub-G1 peak, nor morphological signs). The authors suggest that these results support the conclusion that α-tomatine does not induce apoptosis in the MCF-7 cell line in culture.

Another study found that treatment of human myeloid leukemia HL-60 cells with α-tomatine resulted in growth inhibition and apoptosis in a concentration-dependent manner, that both events were partially abrogated by added cholesterol, and that α-tomatine inhibited the growth of HL-60 xenografts in vivo.[91] The authors suggest that interactions between α-tomatine and cell membrane-associated cholesterol might be involved in mediating the in vivo anticarcinogenic effect of α-tomatine. These results and the reported strong affinity of α-tomatine to cholesterol in an artificial cell membrane,[92] and to plasma cholesterol in vivo,[93−96] imply that the affinity of the glycoalkaloid to cancer cell membrane cholesterol might be a factor governing the mechanism of apoptosis.

Disruption of Cell Membranes. As part of an effort designed to establish the mechanism of action of glycoalkaloids in cells, frog embryos and frog skin were exposed to varying concentrations of α-tomatine and tomatidine.[97] α-Tomatine increased the fluorescence-measured membrane permeability of frog embryos by about 600% compared with control values; the corresponding value for tomatidine was about 150%. The glycoalkaloid also diminished sodium-active transport in frog skin by about 16% compared with control values, as estimated from the change in the interstitial short-circuit current. Tomatidine had no effect on frog skin. These observations suggest that the sugar side chain present in α-tomatine but not in tomatidine influences membrane permeability of cells. As these findings complement similar results with glycoalkaloids from potatoes[98,99] and eggplants,[39] it is likely that the disruption of cancer cell membranes associated with changes in ion flux and interstitial currents of the membranes may contribute to the anticarcinogenic mechanisms governing their action in animal and human cells in vitro and in vivo.

In a related study involving membrane potentials, Taveira et al.[100] found that tomatine-containing tomato leaf extracts and the isolated α-tomatine and tomatidine pure compounds at nontoxic concentrations preserved the mitochondria membrane potential, decreased reactive oxygen species of SY5Y glutamate-insulted neuronal cells, and interacted with nicotinic receptors. The authors suggest that this study provides novel insights into the neuroprotective effect of glutamate-induced neurotoxicity and demonstrates the low toxicity of both compounds.

■ DIETARY SIGNIFICANCE AND RESEARCH NEEDS

Overall, the cited studies seem to indicate that the molecular, signaling, biomarker, immunomodulating, cholesterol-chelating, and membrane-disruptive events at the cellular and molecular levels associated with apoptosis and cell migration and invasion might not be the same for the different cancer cell lines. They imply that both intrinsic and extrinsic proapoptosis pathways are involved and that α-tomatine may protect against the development and progression of several cancers (multiorgan protection). This is not surprising because, as mentioned earlier, carcinogenesis is a sequential multistage cellular process consisting of tumor initiation, promotion, and progression, characterized by dysregulation of multiple genes resulting in multiple adverse symptoms. Each stage involves signaling pathways and both the same and different associated biomarkers. The structurally different glycoalkaloids and their aglycones might impact the cancer cell components at different rates.

Antineoplastic glycoalkaloids complement and extend our knowledge of the mechanisms of alterations in the gene and/or protein levels of the Bcl-2 family members and other cell death mechanisms that are active in cancer cells following treatment with glycoalkaloids and numerous other natural compounds.[101,102] This overview is intended to stimulate interest in the use of both pure and food-containing glycoalkaloids at nontoxic levels to help protect against or ameliorate multiorgan carcinogenesis.

With respect to potatoes, unofficial worldwide guidelines recommend a guideline for total glycoalkaloid content of 20 mg/100 g fresh weight.[6,7] On the basis of the anticarcinogenic results discussed earlier, it seems that this level in commercial potatoes might help to protect against multiple cancers. Epidemiological studies are, however, needed to demonstrate this possibility. Guidelines for maximum glycoalkaloid content of eggplants and tomatoes have not been established.

Because, compared to the other glycoalkaloids, tomatine exhibits low toxicity in animals and humans, future experimental and epidemiological studies should concentrate on the tomato compounds.[4,25] Plant scientists are challenged to develop high-tomatine red tomatoes. High-tomatine red tomatoes will contain two anticarcinogenic compounds: the antioxidative red pigment lycopene and tomatine.[103] The potential payoff will be better human health.

Future studies need to address the following additional food and medical aspects:

- Determine whether in vitro anticarcinogenic effects of pure glycoalkaloids and glycoalkaloid-containing plant foods can be duplicated in humans.

DOI: 10.1021/acs.jafc.5b00818
J. Agric. Food Chem. 2015, 63, 3323−3337

- Determine how bioactivities vary depending on whether glycoalkaloids are tested or consumed in the free-state or as part of a mixture or a food.
- Determine, using epidemiology, the presumptive connection between glycoalkaloid consumption and lower risk of cancer in humans.
- Determine whether glycoalkaloid metabolites formed after absorption into the circulation possess anticarcinogenic properties.
- Validate, via dietary interventions, predicted anticarcinogenic properties based on mathematical modeling[104] or molecular interaction networks.[105]
- Define additive and synergistic effects of glycoalkaloids with other anticarcinogenic food-related plant foods and bioactive compounds, including pigmented rice brans and its anticarcinogenic constituent γ-oryzanol;[106−110] black and green teas and their anticarcinogenic epigallocatechin gallate (ECGC) and theaflavin constituents;[111−113] mushroom polysaccharides;[29,114] and multifunctional jujube fruit (Chinese dates) and jujube fruit and seed compounds jujuboside B and betulinic acid.[115−118] It seems that consumption of glycoalkaloid-containing food, pigmented rice, and teas with a high content of catechins and theaflavins might ameliorate carcinogensis[119−121] and that tea flavonoids might alleviate both cancer and infectious disease;[122] as noted above, lycopene- and tomatine-containing tomatoes might mitigate both carcinogenesis and cardiovascular disease. Combinations of food and bioactive food ingredients that act additively or synergistically will decrease the amounts needed for effective, safe, and tasty food formulations.
- Evaluate the efficacy of glycoalkaloids against multidrug-resistant cancers.
- Because inhibition of hedgehog signaling decreases tumor growth, determine whether inhibition of hedgehog signaling by tomatidine or tomatine can help to inhibit carcinogenesis.[123,124]
- Will α-tomatine, which is reported to inhibit the herpes simplex virus via insertion into the viral envelope, also inhibit the human papillomavirus that causes cervical cancer?[125,126]
- Encourage growers to produce tomatoes with a high content of tomatine using antisense RNA methods to suppress the genes that degrade tomatine. Create tomatine-containing potatoes.[127−130]
- Determine the anticarcinogenic potential of numerous glycoalkaloids present in tubers, leaves, and sprouts of uncultivated and wild-type potatoes.[131−137]
- Do glycoalkaloids contribute to the anticarcinogenic properties of anthocyanin-rich color-fleshed and high-antioxidant potatoes?[138,139]

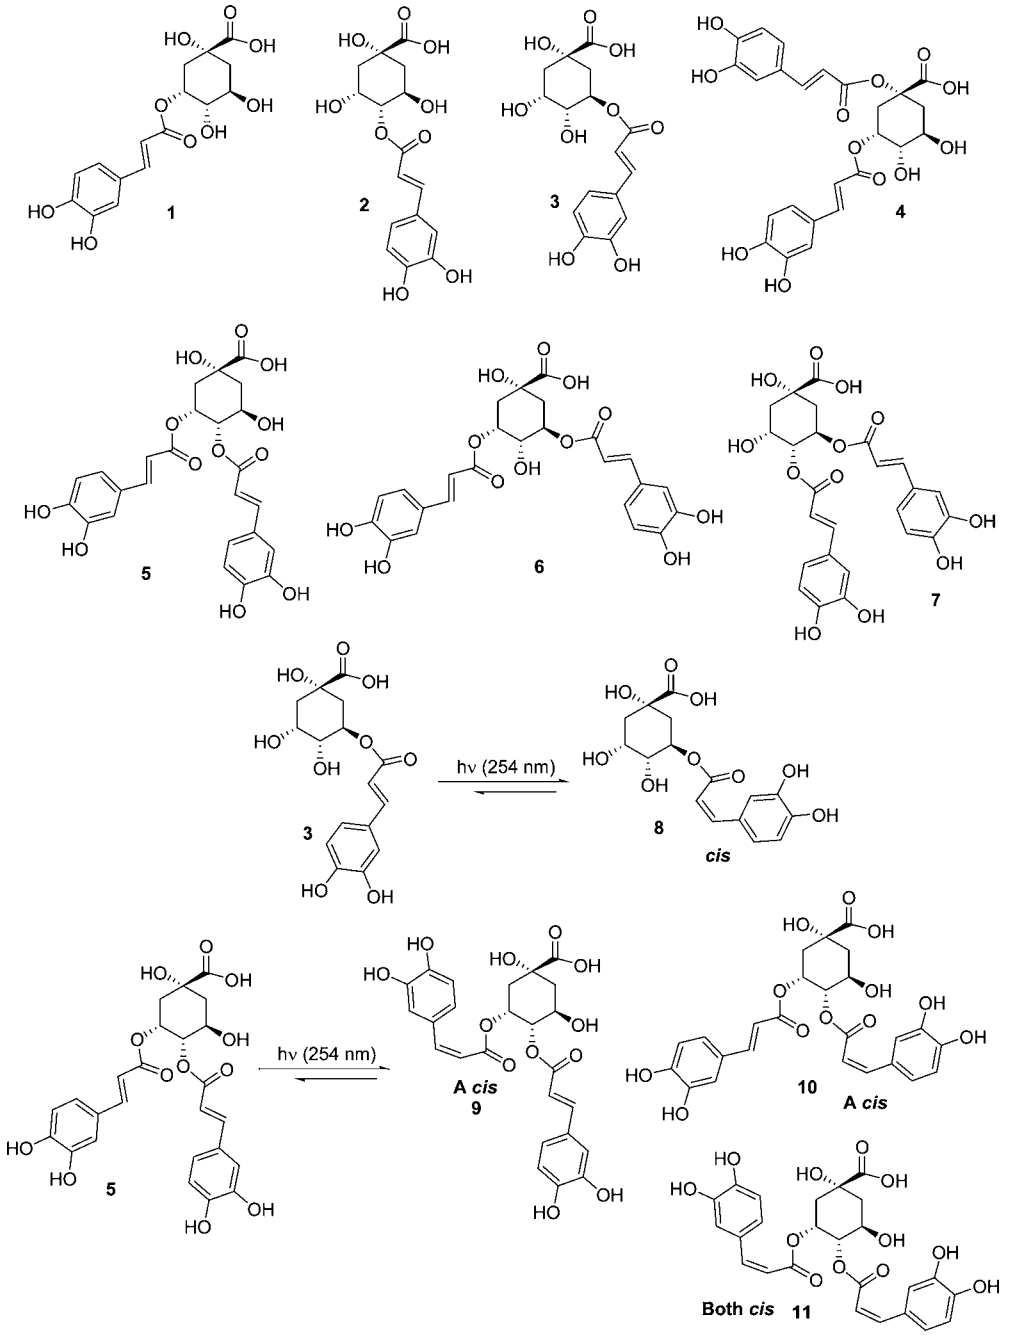

Figure 1. Representative structures of CGAs and *trans*−*cis* isomerization of 5-caffeoylquinic acid (**3**) and 3,4-dicaffeoylquinic acid (**5**).

optimized using 5-CQA (**3**) with a capillary temperature of 365 °C, a dry gas flow rate of 10 L/min, and a nebulizer pressure of 10 psi. High-resolution LC−MS was carried out using the same high-performance liquid chromatography (HPLC) equipped with a MicrOTOF focus mass spectrometer (Bruker Daltonics, Bremen, Germany) fitted with an electrospray ionization (ESI) source, and internal calibration was achieved with 10 mL of a 0.1 M sodium formate solution injected through a six-port valve prior to each chromatographic run. Calibration was carried out using the enhanced quadratic mode, and the mass error was below 5 ppm.

HPLC. Separation was achieved on a 150 × 3 mm inner diameter, 5 μm, diphenyl column, with a 5 × 3 mm inner diameter guard column of the same material (Varian, Darmstadt, Germany). Solvent A was water/formic acid (1000:0.005, v/v), and solvent B was methanol. Solvents were delivered at a total flow rate of 500 μL/min. The gradient profile was from 10 to 70% B linearly in 60 min, followed by 10 min isocratic, a return to 10% B at 90 min, and 10 min isocratic to re-equilibrate.[14]

Nuclear Magnetic Resonance (NMR). ^{1}H NMR spectra were acquired on a JEOL ECX-400 spectrometer operating at 400 MHz at room temperature in methanol-d_4 using a 5 mm probe.

UV Irradiation. The prepared samples of CGAs (0.5 mg/mL methanol) were placed in a photoreactor a LZC-4 V photoreactor (Luzchem, Ottawa, Canada) under a shortwave UV lamp and irradiated at 254 nm.

Statistical Analysis. Statistical analyses of the data were performed with the software package of IBM SPSS Statistics 20.0. The distribution of the data set was analyzed by descriptive statistics and the Kolmogorov−Smirnov test. The correlation studies were performed by Pearson's correlation for the Gaussian (normal) distributed data set (5-CQA, **3**), and Spearman correlation coefficient test was performed for the non-Gaussian data set (e.g., *cis*-5-CQA, **8**) (see the Table S1 of the Supporting Information). A value of $p < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Photochemistry of hydroxycinnamates have been investigated previously.[15−19] We have reported on numerous occasions that plant material exposed to UV light, in particular, leaf material of coffee leaves,[7] *S. rebaudiana*,[9] *L. sativa*,[10] *R. hirta*,[12] *I. paraguariensis*,[13] etc., contains small amounts of *cis*-caffeoyl and *cis*-feruloylquinic acids. We suggested that these plant constituents were obtained through a photochemical *trans*−*cis* isomerization induced by UV light and could show that, in model systems, such an isomerization indeed takes place.

To investigate this process further, we decided to establish the photostationary equilibrium of this reaction using the most common mono- and dicaffeoylquinic acids encountered in our diet. The photostationary equilibrium is defined as an equilibrium composition at which forward and backward rate constants of the photochemical reaction are equal. Hence, at which point, no further changes in concentrations of starting

material and product are observed. For this purpose, we irradiated 3-CQA (**1**), 4-CQA (**2**), 5-CQA (**3**), 3,4-diCQA (**5**), 3,5-diCQA (**6**), 4,5 diCQA (**7**), and 1,3-diCQA (**4**) in a photochemical reactor with irradiation at 254 nm and analyzed samples by LC–tandem MS at time intervals of 15 min. Two examples of the photoisomerization are shown in Figure 1. As a further experiment, dried leaf samples were irradiated at 254 nm for 15 min, showing after sample workup an increase of *cis*-5-CQA of 20%. Using a combination of retention times, UV spectra (the *cis* derivatives show an additional shoulder) and tandem MS data compounds were assigned as described previously.[7] Quantitation of *trans* and *cis* derivatives was carried out using integration of the extracted ion chromatograms at m/z 353 or 515, respectively. To validate this quantitation procedure, we additionally obtained ^{1}H NMR spectra from irradiated samples and integrated the olefinic protons of both *cis* and *trans* isomers, both being readily identified by their $^3J_{HCCH}$ coupling constant of 16.5 Hz for the *trans* isomer and 11.2 Hz for the *cis* isomers (Figure 2). Quantitation results for the relative amounts

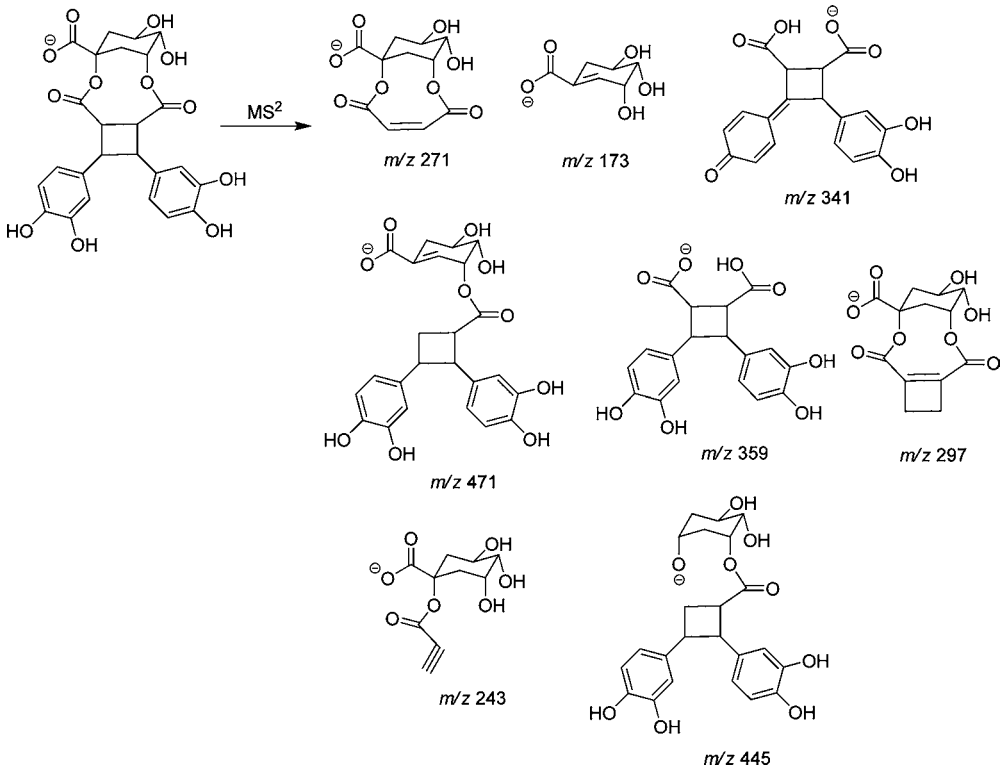

Figure 4. Fragmentation pattern of [2 + 2] cycloaddition products of 1,3-dicaffeoylquinic acids.

of *trans* versus *cis* isomers were found to be ±5% if NMR and LC−MS data were compared to one another. If, after three measurements, no further changes of the concentration of *trans* and *cis* isomers were observed, we assigned this equilibrium concentration to the photostationary equilibrium. It has to be noted that, for dicaffeoylquinic acids, three distinct isomeric *cis*-caffeoyl derivatives are produced as photoproducts, with the di-*cis* derivatives produced as a minor product. Interestingly, always one of two possible *cis* isomers is produced as a major product in the photoisomerization of dicaffeoylquinic acids, indicating preferential isomerization of one caffeoyl moiety over the other in a ratio of around 4:1. Currently, because tandem MS spectra of *cis* and *trans* derivatives are identical and NMR spectroscopic analysis suffers from extensive signal overlap, no clear assignment of regiochemistry was possible. Data are given in Table 1.

All compounds, except 1,3-diCQA (**4**, cynarin), showed exclusively *trans*−*cis* isomerization. 1,3-diCQA (**4**) in contrast showed, after irradiation, first the expected four geometric isomers and, after 30 min of irradiation at 254 nm, the appearance of four further reaction products, one of them a major product, at m/z 515. MS^2 spectra with 515 as a precursor ion revealed a base peak at 191, as expected for a quinic acid derivative.[6−10,12,13,20,21] No fragment ion at m/z 353 characteristic of a dicaffeoylquinic acid was observed.[20] Further fragments at m/z 271, 242, and 297 were observed (Figures 3−6).

These data indicate that a [2 + 2] photochemical cycloaddition reaction has taken place in cynarin, producing a cyclobutane diaryl diester of quinic acid. Such head-to-head photodimers of caffeic acid have been named truxinic acid. Of the theoretically possible eight isomeric cyclobutane derivatives, four isomeric structures were formed (Figures 3−6). The identity of the diaryl cyclobutane derivative was furthermore confirmed using, first, a hydrolysis experiment of the cynarin photoproduct. After base hydrolysis with aqueous NaOH, the LC−MS/MS analysis revealed two isomeric products at m/z 359 with fragment ions at m/z 341, 311, and 267.

For further structural anaylsis, the major photoproduct was isolated by preparative HPLC in an estimated purity of 85% and subjected to detailed NMR analysis. In the ^{1}H NMR spectra, the cyclobutane protons are observed as a higher order four-spin ABXY spectrum with chemical shifts at 2.56, 2.71, 3.21, and 3.35 ppm. Simulation of the higher order spectra revealed coupling constants of ^3J = 3.6, 5.1, 4.7, and 3.2 Hz, respectively. These data show that the major compound has a *cis* diaryl relationship and a *cis* diester relationship and must be assigned to either compound **3** or **8** (in Figure 5). The *cis* diaryl relationship appears to be a consequence of aromatic interactions in the lowest energy cynarin conformer.

The unique photochemical behavior of 1,3-diCQA (**4**) can be rationalized in terms of Schmidt's law.[22,23] Schmidt's law states that, in solid-state photochemical [2 + 2] cycloaddition, a critical distance between 32 and 40 pm of the two reacting olefinic chromophores must be reached to allow for formation of two new C−C σ bonds.[22−24]

Photochemical Mechanism and Fluorescence Spectra of CGAs. Zhu et al.[5] carried out a detailed investigation on the photochemistry of caffeic acid and 5-CQA (**3**). Their main conclusions were as follows. Hydroxycinnamic acids do not possess an accessible triplet state. Following irradiation, photoionization takes place, producing a hydroxycinnamic acid radical cation with a low quantum yield of around 0.02. Comments or experiments exploring the possibility of a singlet excited state were not carried out. Surprisingly, no fluorescence data of purified CGAs have been reported in the literature.

Because olefin *trans*−*cis* isomerization generally involves a triplet excited state as a key intermediate, the data by Zhu et al.[5] should actually not allow for an isomerization reaction. The possibility that photoisomerization proceeds via a long-lived radical cation intermediate should be ruled out because, in the

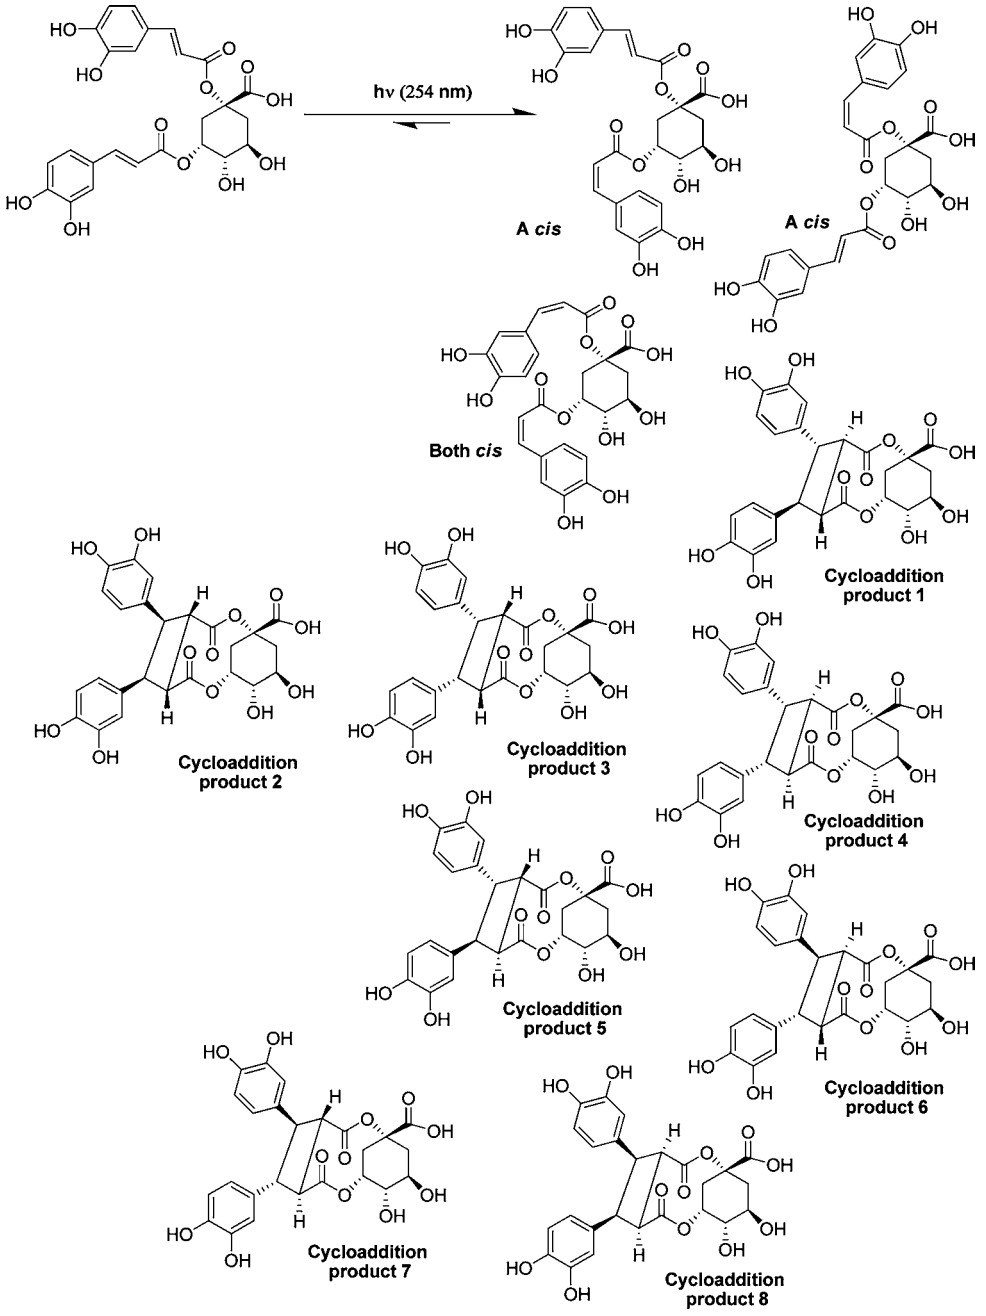

Figure 5. Formation of the photoisomerized [2 + 2] cycloaddition products of 1,3-dicaffeoylquinic acids.

model systems, it would be expected that side reactions with nucleophilic CGAs or with nucleophilic solvents form minor side products, which were never observed. To probe the presence of a radical cation, the photoisomerization was carried out in the presence of oxygen, and using LC−MS, CGAs quenched by O_2 were searched for in extracted ion chromatograms. However, no intermediates with m/z values of 385 and 537 could be detected. However, several other groups have demonstrated that *trans*−*cis* isomerization can occur as well from a singlet excited state.[25−27] To support this hypothesis, fluorescence spectra of all investigated CGAs were recorded. All mono- and dicaffeoylquinic acids displayed upon irradiation at 320 or 260 nm a weak fluorescence at 440 nm, supporting the presence of a singlet state (Figure 7).

***trans*−*cis* Isomerization in Agricultural Practice.** As a next step in our investigations, we decided to address the problem of whether the formation of *cis*-caffeoylquinic acids plays a role in agricultural practice. Furthermore, we wanted to investigate whether the formation of *cis*-caffeoylquinic acids would serve as a useful marker for UV exposure of plant tissues.

As an example, we used cultivation of *S. rebaudiana*, a plant cultivated mainly for its *ent*-kaurene-type terpenoids, better known as steviol glycosides, which are around 200 times sweeter than sucrose. We have recently reported on the presence of CGAs in *S. rebaudiana*. Within a European Union (EU) project (DIVAS), *S. rebaudiana* was cultivated in eight locations in the Mediterranean region of Europe over a period of 2 years using six different botanical varieties of *Stevia*. The leaves were harvested between 2 and 3 times annually from July to September, producing a total of 120 different samples of *S. rebaudiana* leaves. Agricultural parameters, including climatic conditions, are available through records of the nearest official weather station.

J. Agric. Food Chem. 2015, 63, 3338−3347

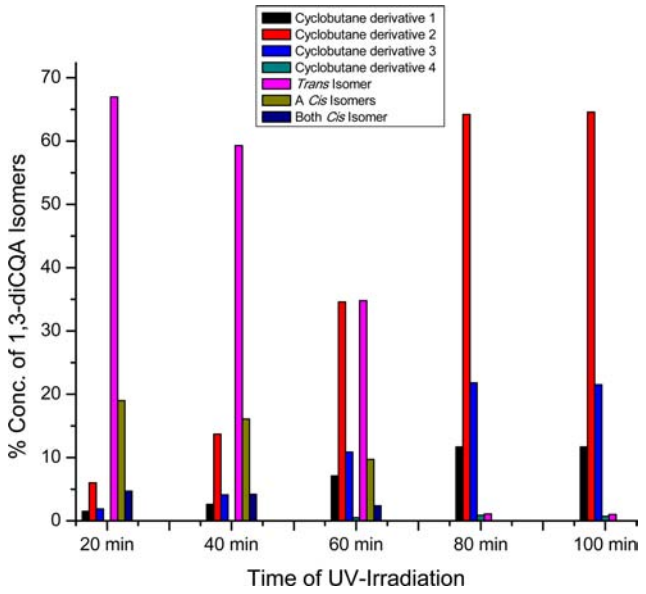

Figure 6. Concentrations of 1,3-dicaffeoylquinic acid isomers with time after UV irradiation.

For all 120 samples and an additional 30 samples of *Stevia* leaves obtained commercially, 5-CQA (**3**), *cis*-5-CQA, 3,4-diCQA (**5**), and two isomers of *cis*-3,4-diCQA were quantified in all samples. All further *cis*-CQA derivatives were present in the samples; however, for most data, their quantity was found to be below the limit of quantitation. A selection of data is shown in Table 2.

The first important question to be addressed involves the biosynthetic origin of the *cis*-CQA derivatives. For this purpose, initially, the statistical pattern and type of statistical distribution of the quantitative data were analyzed. Both 5-CQA (**3**) and 3,4-diCQA (**5**) concentrations show a Gaussian distribution profile over the 120 samples analyzed, as judged by the Kolmogorov–Smirnov test (Figure 8). In contrast, quantitative data for *cis*-5-CQA (**8**) and *cis*-3,4-diCQA were found to exhibit a non-Gaussian distribution.

For a large data set of quantitative data for three mono-CQA and four diCQA concentrations, we could recently show that concentrations of all CGA isomer concentrations in a plant correlate linearly with one another, pointing to a common stimulus of biosynthetic production in the plant. We applied this linearity test to this data set and observe that concentrations of 5-CQA (**3**) and *cis*-5-CQA (**8**) and concentrations of 3,4-diCQA (**5**) and their *cis* derivatives do not exhibit a linear concentration dependency. This points toward two distinct stimuli and pathways of their biosynthetic production.

In contrast, concentrations of the two *cis*-3,4-diCQA isomers and concentrations of *cis*-5-CQA and the *cis*-3,4-diCQA derivatives show a linear concentration dependency (see Figure S1 of the Supporting Information). This should be interpreted as all *cis*

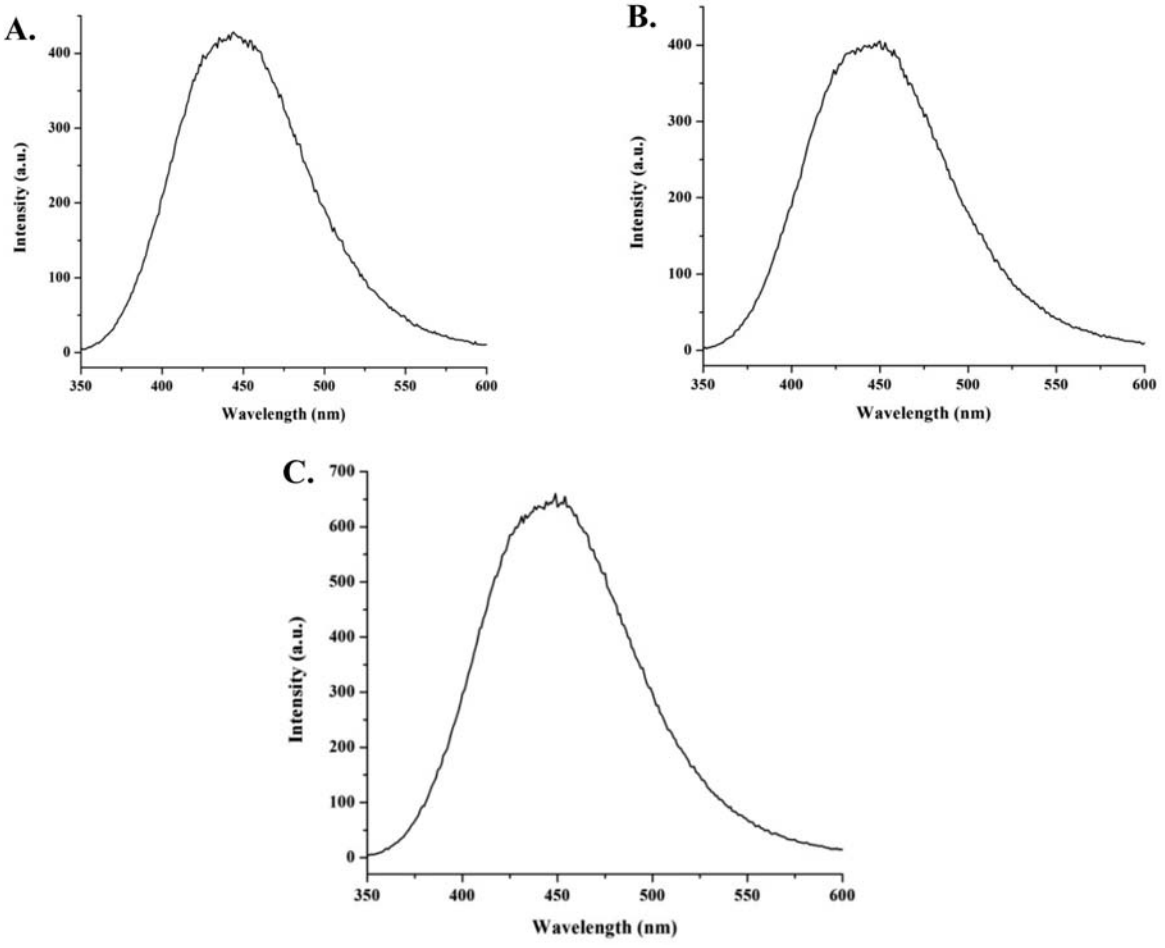

Figure 7. Fluorescence spectra of (A) 3-caffeoylquinic acid (**1**), (B) 4-caffeoylquinic acid (**2**), and (C) 5-caffeoylquinic acid (**3**) with excitation wavelength at 320 nm.

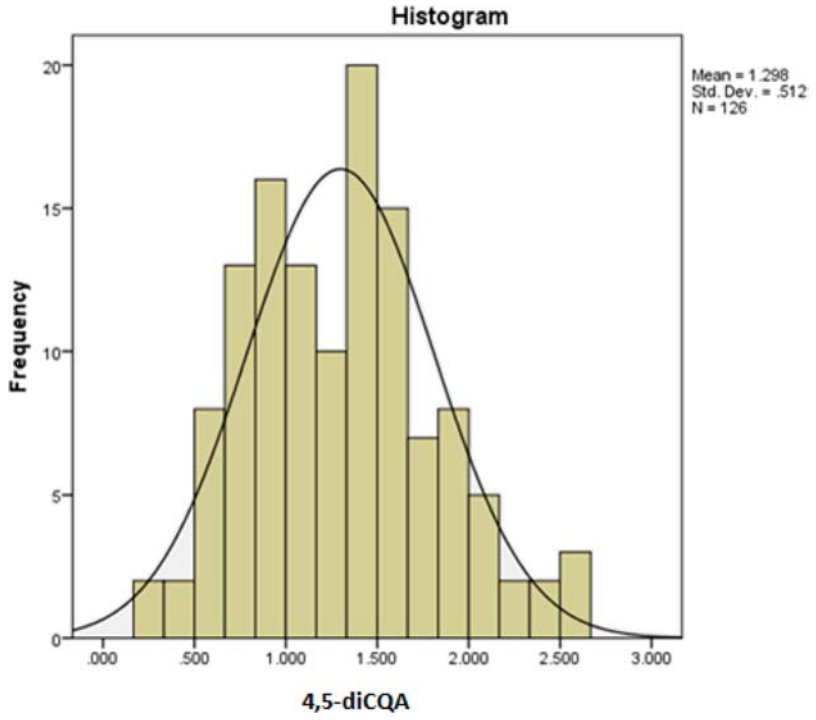

Figure 8. Histogram of 5-caffeoylquinic acid, showing the normal distribution of the data set.

derivatives sharing the same external stimulus for production. This stimulus is different from that of *trans*-CQA biosynthesis. We suggest that the stimulus of *cis*-CQA production is direct irradiation by UV light of exposed leaves.

To substantiate this hypothesis, we correlated available UV irradiation data with *cis*-CQA concentrations. As a first set of data, we looked at changes of *cis*-CQA concentrations in different harvests. For two set of samples, three harvests were carried out from June to September of crops grown at the same locations. For the last harvest in September, the number of sunshine hours affecting the plants was always considerably lower if compared to the two early harvests from June to August. Sunshine hours were available through the weather databases of the nearest airport weather station.[28,29] Representative data are shown in Figure 9, where, in two bar charts, the total *cis*-CQA concentration is given for three harvests in two different locations and, additionally, the ratio of *trans*-/*cis*-CQA concentrations at the three different harvests.

A more global picture including all available data was obtained by the log of *trans*-/*cis*-5-CQA concentrations against the number of sunshine hours in the month prior to sample collection for six locations, where, in 2010 and 2011, a total of 10 harvests were collected. The data plotted in this manner display a linear relationship with the quotient *trans*-/*cis*-5-CQA concentration clearly depending upon the number of sunshine hours 4 weeks prior to the harvest. The same observation can be made if correlating sunshine hours 2 weeks prior to the harvest with the quotient *trans*-/*cis*-5-CQA concentration. If longer periods prior to the harvest are taken into consideration, the difference in sunshine hours levels out and samples are more difficult to distinguish. The more sunshine hours the plant leaves were exposed to, the smaller the quotient and, therefore, the higher the relative amount of *cis*-5-CQA concentrations (Figure 10). It should as well be noted that the *trans*-/*cis*-5-CQA concentration does in no case exceed the theoretical maximum value, as determined in the measurement of the photostationary equilibrium values.

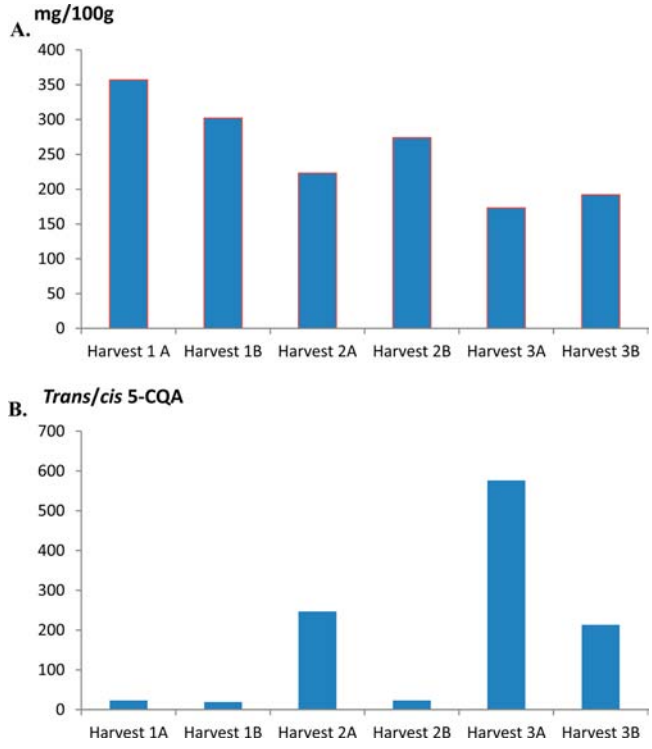

Figure 9. (A) Amount of 5-caffeoylquinic acid (**3**) (mg/100 g of dry leaves) and (B) *trans*/*cis* ratio from three harvests from location a (TCV) and location b (Amfilikeia) during 2011.

In conclusion, we have shown that all *trans*-CQAs investigated undergo photochemical *trans*−*cis* photoisomerization. The photostationary equilibrium for seven derivatives was determined for the first time. The only exception to this reaction

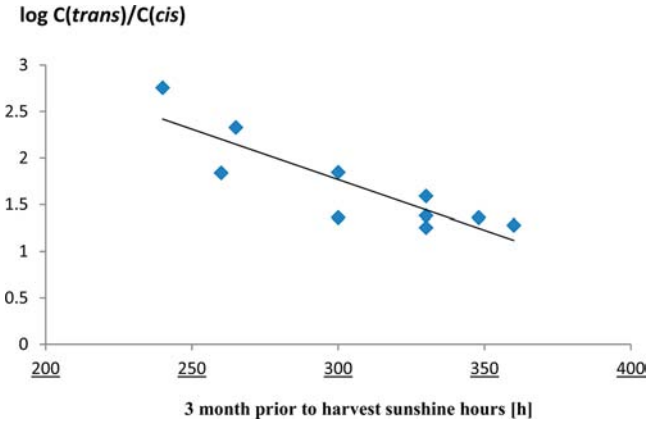

Figure 10. Plot of log $C(trans)/C(cis)$ against sunshine hours (prior to sample collection).

pathway was 1,3-diCQA (**4**, cynarin), which, following *trans*−*cis* photoisomerization, undergoes a [2 + 2] photocycloaddition to produce a diaryl cyclobutane derivative of quinic acid.

In a data set comprising 120 samples of *S. rebaudiana* grown in different locations, it could be convincingly demonstrated that the production of *cis*- and *trans*-CQA derivatives must follow two distinctly different pathways. The production of *cis* derivatives was shown to correlate with the number of sunshine hours, to which plant leaves were exposed in the month prior to harvest, suggesting that *cis*-CQA concentrations can serve as useful and promising markers of UV exposure of plant material in agricultural practice.

The measurement of the terpene patterns of a total of 40 cultivars in combination with sensory evaluations pointed out that sensory sensation such as sweet and nonbitter taste, sweetish, flowery, and nutty odor impressions correlate with a high popularity of the cultivars. As a marker for low popularity, the substances β-myrcene, β-caryophyllene, and humulene as well as a high content of total terpenoids were determined.[21]

In contrast to the roots, the terpene patterns of carrot leaves have hardly been studied. Habegger and Schnitzler[22,23] and Hampel et al.[24,25] studied the biosynthesis of VOCs in relation to the leaves and roots. No correlation of metabolite patterns between leaves and roots was found.

As monoterpenes are related to plant defense, Ibrahim[26] et al. studied the influence of temperature and exogenous limonene treatment on the headspace volatiles emitted from leaves. There are also only a few publications on the effects of VOCs of the leaves in the process of plant−herbivore interaction. For example Seljasen[27] determined an influence of *Psyllid* attack on the terpene pattern of the plant besides effects on the bitter compounds falcarindiol and 6-methoxymellein.

Regardless of the immense number of publications dealing with flavor compounds of carrots, no consensus about typical carrot volatile patterns exists. The lack of agreement in defining the essential chemical compounds of carrot aroma is depicted by analyzing 12 publications that give compilations of volatiles.[1,11,12,15,18,26,30−35] Altogether 124 different VOCs were reported. However, not a single compound out of the compilation of 124 is mentioned in all of the 12 papers coincidently. Consensus exists only in 11 out of 12 studies for five terpenoid compounds: sabinene, limonene, terpinolene, β-caryophyllene, and α-humulene. In addition frequently mentioned volatiles are the following: β-pinene (10×), α-pinene, γ-terpinene, and *p*-cymene (each 9×).

In summary it can be stated that the knowledge about VOC patterns of roots is present in particular in relation to the sensory quality, while leaves have been relatively unexamined. Especially the aspect of metabolic diversity in species is yet little-known. For carrot breeding approaches aiming to obtain good sensory properties in combination with high resistance to pests or diseases, knowledge of the usable biodiversity and the genotype−environment interactions (G × E) of VOCs is an important prerequisite.

In the present study for the first time 10 carrot cultivars, representing the main root colors white, yellow, red, orange, and purple and growing in a three-year field experiment, were analyzed with regard to the qualitative and quantitative composition of the VOCs of both roots and leaves. The influence of cultivar, harvest year, correlation between the VOCs, and the comparison between leaf and root metabolite patterns was examined using multivariate statistical methods.

MATERIALS AND METHODS

Chemicals. The reference substances hexanal, hexanol, limonene, γ-terpinene, humulene, and myristicine were purchased from Sigma-Aldrich Germany, Steinheim, Germany. The substances α-pinene, β-pinene, sabinene, β-myrcene, terpinolene, and β-caryophyllene were from Carl Roth Co KG, Karlsruhe, Germany. (*E*)-2-Hexenal was from Merck KGaA, Darmstadt, Germany, and bornyl acetate was delivered from CHEMOS GmbH, Regenstauf, Germany.

Plant Material. The leaves and roots of 10 carrot cultivars (*Daucus carota* L.) of different origin and color from a triennial field trial study at the experimental field station in Quedlinburg were included in the analysis. Cultivar specifications are given in Table 1. The seeds were sown (100 seeds/m) by a seed drill as plots in flat beds with two rows, each of them 3 m long and with a row distance of 45 cm by a seed drill. Plots were arranged in a randomized block design with four agronomical replications (biological replications). Chemical analyses were performed using 10 healthy and untouched marketable roots. Washed carrot leaves without the petioles as well as roots were sliced, immediately frozen with liquid nitrogen, and stored until analysis at −80 °C.

Volatile Analysis by Headspace SPME−Gas Chromatography. After thawing the plant material, samples were homogenized for 1 min in a 20% NaCl solution (leaves/NaCl solution = 1:10, w/v, and roots/NaCl solution = 1:1.5) in a Waring blender. The homogenate was filtered using gauze. For each sample, four 20 mL headspace vials each containing 4 g of solid NaCl for saturation were filled with a 10 mL aliquot of the supernatant and sealed with a magnetic crimp cap including a septum. For automated headspace SPME−GC, a 100 μm polydimethylsiloxane fiber (Supelco, Bellefonte, PA, USA) and a MPS2 autosampler (Gerstel, Mühlheim, Germany) were used. After an equilibration time of 10 min at 35 °C using the shaker (300 rpm) the fiber was exposed to the headspace for 15 min at 35 °C. Desorption was performed within 2 min in splitless mode and 3 min with split at 250 °C. An Agilent Technologies 6890 GC equipped with an HP-5 ms column (0.25 mm i.d., 30 m length, and 0.5 μm film thickness) and FID were used for separation and detection. Carrier gas was hydrogen using a flow rate of 1.1 mL min^{-1}. The temperature program was the following: 45 °C (5 min), from 45 to 210 °C at 3 °C min^{-1} and held 25.5 min at 210 °C. The volatiles were identified by parallel runs of selected samples on an identically equipped GC-MS by library search (NIST and MassFinder), retention indices, and coelution of authentic samples (except for germacrene). All samples were run with four agronomical replications.

Data Processing and Statistics. The commercial software ChromStat2.6 (Analyt, Müllheim, Germany) was used for raw data processing.[28,29] Data inputs for ChromStat 2.6 were raw data from the percentage reports (retention time/peak area data pairs) performed with the software package Chemstation (version Rev.B.02.01.-SR1 [260]) by Agilent. Using ChromStat2.6, the chromatograms were divided in up to 200 time intervals, each of which represented a peak (substance) occurring in at least one chromatogram of the analysis set. The peak detection threshold was set on the 10-fold value of noise. The values are given as raw data (peak area in counts), which also can be described as relative concentration because of the normalized sample preparation. The semiquantitation by the software ChromStat 2.6 was focused on 15 VOCs summarized in Table 2.

A primary data analysis of normality gave a non-Gaussian distribution for most of the VOCs (data not shown). Therefore, a nonparametric Kruskal−Wallis procedure using the software SY-

STAT13 (Systat Software, Inc., Chicago, IL, USA) was used to compare the VOC data of different cultivars for the single harvest years and additionally over the three years in summary. The Pearson correlation was performed with STATISTICA7.1. (StatSoft Europe GmbH, Hamburg, Germany). The heat map was constructed with the open source software Multi Experiment Viewer (MEV; http://www.tm4.org).

RESULTS AND DISCUSSION

Selection of Metabolite Targets. In this research the quantities of 15 compounds identified in both leaves and roots were used for further processing. The reasons to focus on the substances listed in Table 2 are the following. First, the selected VOCs are of high abundance in most of the samples, which is a result of the chosen volatile extraction method (HS-SPME). Second, these substances are identified by mass spectrometry (library search) and additional coelution of authentic reference substances. The only exception is germacrene, for which no reference was available. Third, the selection includes nine aroma compounds which are described in the literature as so-called "character impact compounds" (CIC) in carrot roots.[18] Additionally the compilation includes all of the mutual compounds published for carrots in the literature (from 11 studies) mentioned above. Finally, the substances listed in Table 2 are known to be involved in various biological activities that are of interest in plant genetics and breeding activities.

Cultivar and Harvest Year Affect the Contents of Volatile Metabolites. The data set of VOC patterns containing 10 cultivars, three harvest years, and four agronomical replications each is visualized by a heat map in Figure 1. Both qualitative and quantitative differences in VOC pattern were observed between cultivars as well as the harvest years. Qualitative differences are defined as values below the detection threshold of the SPME-GC-FID method used (7 counts) and are depicted as black spots in the heat map. For example, bornyl acetate (1BA) has never been detected in leaves over the three years in the cultivars 'White Satin', 'Yellowstone', 'Nutrired', 'Santa Cruz', 'Deep Purple', 'Pusa Kesar', and 'Anthonina', while in the remaining three cultivars low to medium levels were found. In roots hexanal (2H) is detected in only some samples of four cultivars at low concentrations ('Nutrired', 'Pusa Kesar', 'Santa Cruz', 'Nerac'). The compounds (*E*)-2-hexenal and 1-hexanol are exclusively present in the leaves only.

In general, the variability of metabolites seems to be determined by the cultivar especially in roots (Figure 1, Tables 3 and 4). Particularly the content of the monoterpenes *α*-pinene (2aP), sabinene (2Sa), *β*-pinene (2bP), *β*-myrcene (2bM), limonene (2L), and terpinene (2Te) decreases in the order white, yellow, red, orange, and purple. In contrast, the monoterpene terpinolene (2Te) shows high concentrations in roots of all cultivars. The most abundant VOC in leaves is *β*-myrcene (1bM), with a mean of 10 883 counts and a maximum of 30 884 counts (sample 9.1.3). In roots the highest concentration was found for the monoterpene terpinolene (2Te), with a mean of 15 331 counts and a maximum of 82 569 counts (sample 3.3.1). In general, the concentrations of VOCs were found in a similar concentration range in leaves and roots, although the sample preparation procedure for leaves works with a higher relation between tissue and NaCl solution by a factor of 6.67.

The statistical comparison of VOC patterns of the genotypes for the single harvest years and over the three years is summarized for both leaves and roots in Tables 3 and 4, respectively.

Leaves. The 10 cultivars show significant differences for 11 of the 15 leaf volatiles during the first year, differing from the compounds (*E*)-2-hexenal (1E2H), limonene (1L), *β*-caryophyllene (1bC), and humulene (1Hu) (Table 3). In the second harvest year the two VOCs *β*-caryophyllene (1bC) and humulene (1Hu) are not significantly different between the cultivars, whereas the third cultivation year was characterized by significant cultivar differences for all of the 15 VOCs. The statistical analysis for three years in summary shows nine significant metabolites.

The volatile bornyl acetate (1Ba) was detected in low to medium amounts in three out of the 10 cultivars (Figure 1). In all three years this compound was semiquantified only in the cultivar 'Nerac', while cv. 'Blanche', cv. 'BL 710015', and cv. 'Pusa Kesar' showed bornyl acetate only in the first year and not in all replicas. All other cultivars expressed no bornyl acetate. Thus, this compound seems to be a characteristic metabolite for discrimination of the mentioned cultivars. The partial expression in the cultivars 'Blanche', 'BL710015', and 'Pusa Kesar' suggests strong influences of the harvest year. Two of the compounds, hexanol (1Hol) and *β*-pinene (1bP), were not detectable in year 2, suggesting also an influence of the climatic conditions. The calculation over the whole period of three years gives no significances for six compounds (1aP, 1Sa, 1bM, 1L, 1gT, and 1Te), which suggests a stable expression independently from the environmental influences. In conclusion the VOC selection shows significant differences between the tested cultivars. A partially strong variation between the years suggests additional influences of the climatic conditions. On the other hand six VOCs (1aP, 1Sa, 1bM, 1L, 1gT, and 1Te) were expressed in equal relations between the cultivars over the three

J. Agric. Food Chem. 2015, 63, 3348−3356

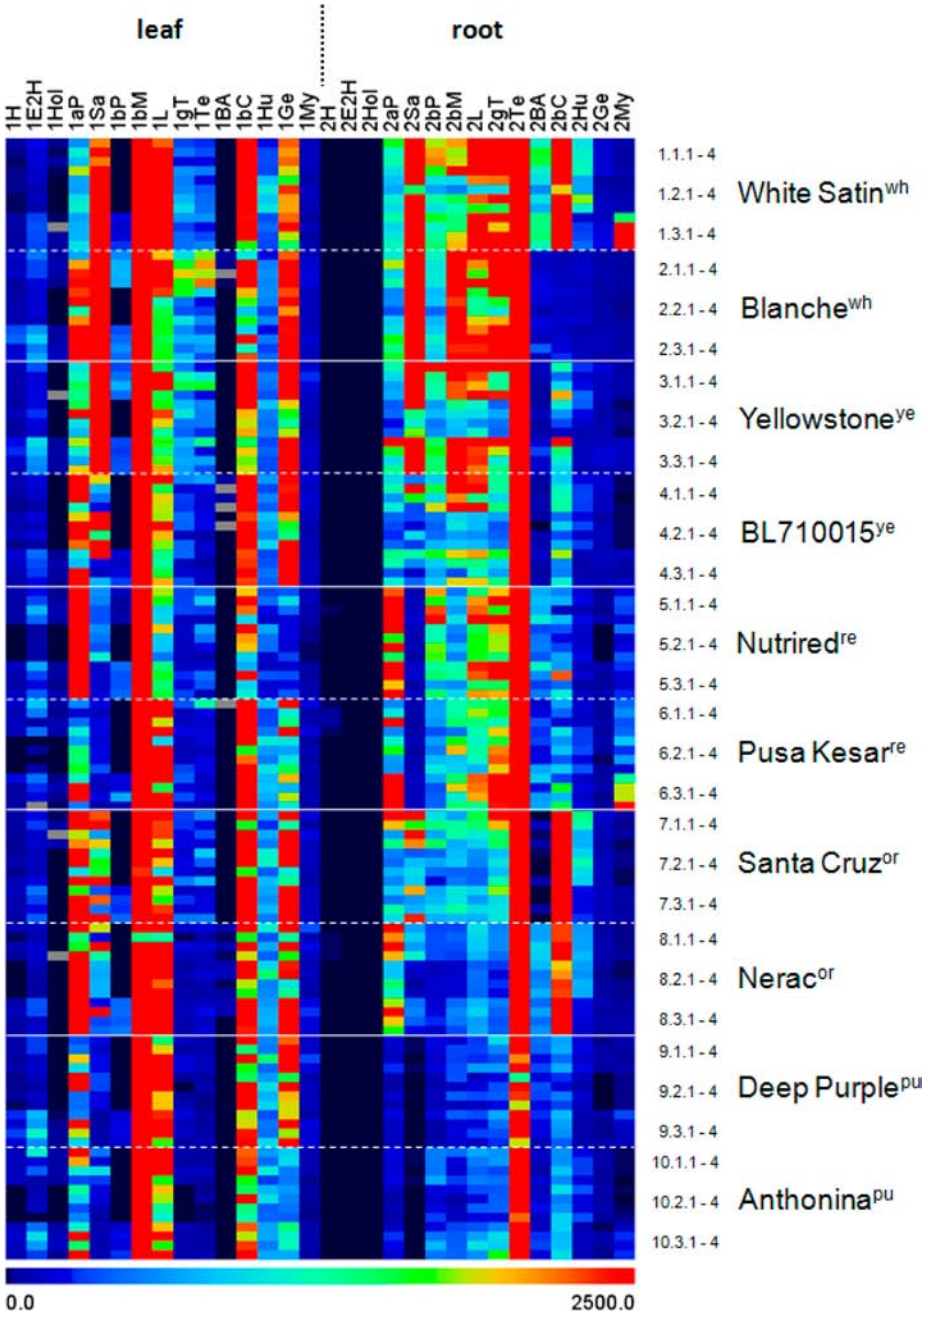

Figure 1. Heat map for 15 VOCs in leaves and roots separately, estimated for 10 cultivars, three harvest years, and four agronomical replications each. Color code for relative VOC concentrations in counts of peak area (color bar on bottom position): black = 0; red = 2500; gray = missing value. Sample code: "1.1.1−4" corresponds to "cultivar 1 (White Satin). harvest year 1. agronomical replications 1−4". Root color: ^{wh} is white; ^{ye} is yellow; ^{re} is red; ^{or} is orange; ^{pu} is purple.

years. It appears plausible that these six VOCs and bornyl acetate seem to be suitable for discrimination of carrot cultivars on the leaf metabolite level.

Roots. In contrast to leaves the VOCs (*E*)-2-hexenal and hexanol were not detected in root samples (Table 4). The root volatile hexanal (2H) showed a unique behavior because it was detected only in year 1 and exclusively for the cultivars 'Nutrired', 'Pusar Kesar', and 'Nerac'. The compound hexanal is discussed in the literature not only in association with plant defense[36] but also with stress responses.[36,37] The presence in the first year on one hand and the absence in the years 2 and 3 on the other hand suggests an association with the dryer and warmer climatic conditions in cultivation year 1.

Considering a year by year comparison, all of the 13 detected VOCs are significant between the tested cultivars. However, a statistical analysis of root volatiles based on the average of the three years showed differences between the cultivars for 10 of the 13 VOCs (Table 4). The high variation between the years with even qualitative differences for hexanal suggests influences of the environmental conditions similar to the discussion for leaf volatiles. The calculation for root VOCs over three cultivation years shows an equal relation in expression for 2Sa, 2BA, and 2bC, which can be interpreted as independence from the environmental conditions for these compounds. This seems to be suitable for discrimination of carrot cultivars on the basis

of the root metabolom. The occurrence of hexanal as a stress indicator should be tested in further experiments.

Correlation between Metbaolite Patterns and Root Color. The used cultivars are characterized by five different root colors: white, yellow, red, orange, and purple. Because especially the white and yellow cultivars 'White Satin', 'Blanche', 'Yellowstone', and 'BL71005' show a distinct increased level of the root compounds sabinene (2Sa), β-myrcene (2bM), limonene (2L), and γ-terpinene (2gT) (Figure 1), a correlation analysis was performed using the values for every cultivar as a mean of yearly and agronomical replications.

The cluster analysis of the leaf volatiles (Figure 2) results in two main clusters, with the cultivars 'Nerac' and 'Nutrired' in one and the remaining cultivars in a second cluster. The second cluster again is subdivided into two subclusters with the cultivars 'Blanche', 'Yellowstone', and 'White Satin' as one and the five others as a second group, respectively.

For the root volatiles (Figure 2) also two main clusters were specified but with different cultivars than in leaves. Cluster one contains the cultivars 'Santa Cruz' and 'Nerac', both with orange roots. The second cluster comprises the remaining eight cultivars. Similar to the leaf volatiles the second cluster is subdivided into two subclusters, one exactly the same as for leaves with the cultivars 'Blanche', 'Yellowstone', and 'White Satin'. The VOC patterns of roots partly correlate with the root color for orange, red, and purple carrots, whereas in leaves no clear correlation of VOC pattern and root color occurs. It is noteworthy that the two white cultivars 'White Satin' and 'Blanche' carry totally different patterns regarding the terpene acetate (2BA), the sesquiterpenes (2bC, 2Hu), and the phenylpropanoid myristicine in replica 3 (2My).

Correlations among the Volatile Compounds. A Pearson correlation analysis shows that 48 coefficients (out of 105 possible single correlations) with significant values exist between the individual compounds in leaves and 46 (out of 78) in roots, respectively (Table 5).

In leaves the three compounds hexanal (1H), (*E*)-2-hexenal (1E2H), and hexanol (1Hol) correlate among each other positively with high to medium values. High correlation coefficients occur for the pairs sabinene (1Sa) and γ-terpinene (1gT) (0.95), sabinene (1Sa) and terpinolene (1Te) (0.84), and terpinolene (1Te) and γ-terpinene (1gT) with a value of 0.82. The concentration of the phenylpropene myristicine (1My) correlates with 10 VOCs with significant positive values. The highest coefficient (0.85) occurs between myristicine (1My) and the sesquiterpene germacrene (1Ge) (Table5).

In roots the two lipoxygenase (LOX) products (*E*)-2-hexenal (2E2H) and hexanol (2Hol) were not detected, while hexanal (2H) was found sporadically in low concentrations only in three cultivars ('Nutrired', 'Pusa Kesar', and 'Nerac') (Figure 1). The highest correlation coefficient (0.94) occurs between the compounds limonene (2L) and terpinolene (2Te) (Table 5). Also in roots the compound myristicine (2My) is correlating positively with seven other volatiles.

Differences in Volatile Patterns between Leaf and Root. Earlier findings by Habegger and Schnitzler[22,24] and Hampel et al.[25] proved that the biosynthesis in leaves and roots may be independent from each other. To check the relation between the organs, a correlation was performed between the set of leaf and root VOCs, separately for every harvest year and also as the mean over three years. In contrast, the results in our study show that six out of the 13 VOCs correlate between leaves and roots over all years (Table 6).

Table 6. Pearson Correlation of Individual VOCs between Leaves and Roots[a]

	three years	year 1	year 2	year 3

[a]Pearson correlation coefficients are significant for values > 0.19, N = 120. "a" represents nonsignificant correlation coefficients for $p < 0.05$. n.d., not detectable.

Also Figure 1 indicates differences between the two plant organs. The most distinct difference was found for the three C6 compounds (green leaf compounds, LOX) hexanal (H), (*E*)-2-hexenal (E2H), and hexanol (Hol). While these compounds are present in leaves with highly abundant peaks, hexanal (2H) occurs in roots only in three cultivars ('Nutrired', 'Pusa Kesar', 'Nerac') in the first cultivation year. Positive correlations were found for the compounds α-pinene (aP), sabinene (Sa), γ-terpinene (gT), and terpinolene (T) for both the individual years and three-year average (Table 6). Correlations for either individual years or the mean of three years were evidenced for β-myrcene (bM), β-caryophyllene (bC), humulene (Hu), germacrene (Ge), and myristicine (My). Myristicine (My) generally is negatively correlated between the plant organs for three years and the single years 2 and 3. The overall level as well the variability is much higher in roots than in leaves for this compound (Figure 1). The closest correlation between leaves and roots occurs for the volatile sabinene (Sa), with high correlation coefficients in all years and the mean of three years.

Consequences for Metabolic Studies and Cultivar Breeding. The diversity of volatile patterns shows more noticeable differences in roots than in leaves (Figure 1). Between the cultivars both qualitative and quantitative differences in VOC pattern exist. A genotype−environment (G × E) interaction was evidenced for the VOC patterns. On the one hand for a number of VOCs the analyses showed a similar expression over the years (e.g., 1gT, 1aP, 1My, 1L, 2Hu, 2bP, 2Ba) and seem to indicate a discrimination of the cultivars. On the other hand a group of analyzed VOCs (e.g., 1bP, 1Hol, 2My, 2Hu) are highly influenced by environmental factors such as soil temperature and water availability determined as "harvest year".

The 10 analyzed cultivars belong to five different root color types. The root color depends on the proportion of the nonvolatile metabolites such as lycopene, carotene, lutene, and anthocyanins. Due to noticeable differences in root color, also an influence on metabolic patterns may be expected. Even if there are some quantitative differences between monoterpenes especially in roots (Figure 1), a correlation analysis based on 30 VOCs in leaves and roots indicates only a partial clustering regarding root color (Figure 2). In particular, the two white

DOI: 10.1021/acs.jafc.5b00704
J. Agric. Food Chem. 2015, 63, 3348−3356

cultivars 'White Satin' and 'Blanche' present completely different patterns regarding terpene acetate (2Ba), the sesquiterpenes (2bC, 2Hu, 2Ge), and the phenylpropanoid myristicine (2My). But these differences may be influenced by other factors such as breeding status because the very old cultivar 'Blanche' belongs to the so-called open pollinated cultivars, whereas 'White Satin' represents a modern F1 hybrid.

The 15 quantified VOCs are derived from three different biosynthetic pathways. The compounds hexanal (H), (*E*)-2-hexenal (E2H), and hexanol (Hol) are generated by the LOX pathway, whereas myristicin (My) is synthesized according to the phenylpropanoid pathway. The remaining VOCs are terpenoids (mono- and sesquiterpenes as well as one terpene acetate). In leaves the three LOX-derived compounds (1H, 1E2H, 1Hol) are highly positively correlated with each other. In roots this type of metabolites is not present or only sporadically detected, which may be a hint on the different ecological requirements of the two different plant organs regarding plant defense. As an example, the three mentioned compounds are known for an inhibiting effect on fungi such as *Botrytis cinerea*.[38,39] Some high correlation coefficients between monoterpenes are caused by the synthesis in the same pathway. For example the cyclic monoterpenes sabinene (1Sa), γ-terpinene (1gT), and terpinolene (1Te), which correlate highly in leaves, are synthesized via the α-terpinyl cation.[40] The same relationship exists between limonene (2L) and terpinolene (2Te), which correlate with a coefficient of 0.94 in roots. Interestingly, numerous correlations of the phenylpropanoid myristicine in leaves and roots to mono- and sesquiterpenes exist. In recent literature no connection of these two biosynthetic pathways has been established yet.

Habegger and Schnitzler[22,23] analyzed the essential oils extracted from leaves and roots separately to study correlations between the two plant organs and make predictions from the patterns of the leaf VOCs for the composition of the roots for plant breeding. The authors draw the conclusion that the metabolic patterns in both plant organs develop independently. The present study gives a more detailed picture. At least seven of the VOCs correlate between leaves and roots (over three years), six positively and one negatively (myristicine). It is known that this compound (My) is involved in the formation of bitter taste in carrots.[41] Therefore, the development of a new method to predict the bitter taste in carrot roots based on the analytical data of the leaves may be an important approach for early selection in breeding programs. The results obtained in this study give basic information for research and breeding regarding quality including flavor, resistance against diseases, and availability of VOCs in nutrition. Currently, our research activities are directed to reveal the genetic background of the described VOCs including candidate gene approaches, marker development, and genetic mapping.

although as the pH exceeds 10.2, hydrolysis of the ester on the benzene ring takes place.[11]

The anionic form of MS-M (4-methoxy-6-methyl-1,3,5-triazin-2-ylcarbamoyl)[(2-(methoxycarbonyl)phenylsulfonyl]-amidate **2** (Figure 1), however, is much less prone to hydrolysis than its neutral form,[12] and there are several reports of alkali or alkali earth metal salts of sulfonylurea compounds prepared by reaction of the corresponding *N*-protonated sulfonylureas with a solution of a corresponding base, such as alkali metal carbonates, alkali metal hydroxides, and alkaline earth metal hydroxides.[13−18] Ammonium and quaternary ammonium salts of sulfonylureas have also been synthesized by treating the corresponding *N*-protonated sulfonylurea with ammonia, ethanolamine, or ammonium salt solution.[14,19,20] We have not found evidence that these salts have been commercialized.

Another challenging problem with sulfonylureas is obtaining a stable liquid formulation.[21] During storage, sulfonylurea herbicides (in the form of concentrated formulations of dissolved active ingredients) precipitate out of solution and crystal growth takes place. In these cases, solubility limits effective application or use of concentrates of the active herbicide.

In 2011 we presented a strategy of converting a herbicide into an ionic liquid (IL, currently defined as a salt which melts below 100 °C[22]) and applied the approach to a variety of herbicides (e.g., 2,4-D, MCPA, triclopyr, cyhalofop, glyphosate, and dicamba).[23−30] These herbicidal ionic liquids (HILs) were comprised of an active compound in ionic form, possessed low melting points (below 100 °C[22]), and were designed with dual functionality where both cation and anion added to the beneficial properties of the salt. Such combinations of two active chemicals in a single entity demonstrated improved (or in a few cases simply the same) herbicidal activity, while the physicochemical properties were modified. The second actives (cations) were chosen from food or cosmetic grade antibacterial cations, antifungal cations, surfactants, etc. These herbicides possessed greatly reduced volatility, showed improved efficacy, and demonstrated lower water solubility resulting in reduced environmental mobility.

We noted that the MS-M anion (Figure 1) fits the normal design rules for choosing ions that will form HILs (asymmetric, charge delocalized[27]) and, therefore, hypothesized that a similar strategy could be employed for the conversion of MS-M into the HILs, to improve its stability and precipitation problems. Here we report a series of new MS-M IL herbicides where we have paired the MS-M anion with several cations of a second biological activity, including: additional biological activity (e.g., 4,4-dialkyl morpholinium[31]), antimicrobial activity (e.g., quaternary ammonium,[32,33] pyridinium,[34,35] and imidazolium,[35] with longer alkyl chain lengths), penetration enhancers (e.g., linear saturated long chain alkyl substituents, soya[32]), or herbicidal activity (pyperidinium and morpholinium cations with longer *N*-alkyl group substituents[31]). Greenhouse testing and field studies of the synthesized compounds were evaluated to establish their herbicidal activity.

MATERIALS AND METHODS

Materials. All materials were used as supplied unless otherwise noted. Deionized (DI) water was obtained from a commercial deionizer (Culligan, Northbrook, IL, USA) with a specific resistivity of 16.82 MΩ·cm at 25 °C. KOH and all solvents (methanol, DMSO, acetonitrile, acetone, isopropanol, ethyl acetate, chloroform, toluene, hexane) were purchased from Aldrich (European market, Poznan, Poland) and used without further purification. Galmet 20 SG was obtained from P.U.H. Chemirol (Chemirol Sp. z o.o., Mogilno, Poland) and contained 20% metsulfuron methyl (CAS 74223-64-6) and 5% dimethylamine (CAS 124-40-3) as active components.

Bis(2-hydroxyethyl)oleylmethylammonium chloride (Ethoquad O/12, purity 75%) was obtained from Akzo Nobel (Akzo Nobel Head Office, Amsterdam, Netherlands). 2-Hydroxyethyltrimethylammonium chloride (purity > 98%), 1-dodecylpyridinium chloride, hydrate (purity 98%), 1-butyl-3-methylimidazolium chloride (purity 98%), 4-methylmorpholine (purity 98%), 1-bromodecane (purity 98%), tetrabutylphosphonium chloride (purity 96%), and dimidium bromide indicator (purity 95%) were obtained from Sigma-Aldrich (Sigma-Aldrich, St. Louis, MO, USA). Compounds 1-methyl-1-propylpiperidinium chloride (purity 99%), 1-allyl-3-methylimidazolium chloride (purity 98%), 1-butyl-1-methylpyrrolidinium chloride (purity 99%), and trihexyltetradecylphosphonium chloride (purity > 95%) were received from Ionic Liquids Technologies GmbH (IoLiTec, Heilbronn, Germany).

4-Decyl-4-methylmorpholinium bromide was synthesized via quaternization reaction of 4-methylmorpholine and 1-bromodecane as follows. 100 mL of acetonitrile was placed into a 250 mL round-bottom flask equipped with a Teflon-coated stirring bar and a condenser. 4-Methylmorpholine (0.10 mol) and 1-bromodecane (0.11 mol) were added to the acetonitrile, and the reactants were stirred for 48 h at 60 °C. After 48 h the solvent was removed using a vacuum evaporator. After solvent removal, 200 mL of ethyl acetate was added to the residue and the product precipitated as a white solid. The product was carefully separated by vacuum filtration through a glass filter funnel, thoroughly washed with small portions of ethyl acetate (6 × 10 mL) to remove unreacted 1-bromodecane, and dried under reduced pressure at 50 °C for 24 h.

Methods. *Thermal Gravimetric Analysis (TGA).* Thermal gravimetric analysis was performed using a Mettler Toledo Star^e TGA/DSC1 unit (Leicester, UK) under nitrogen. Samples between 2 and 10 mg were placed in aluminum pans and heated from 30 to 450 °C at a heating rate of 10 °C/min.

Differential Scanning Calorimetry (DSC). Thermal transition temperatures were determined by DSC with a Mettler Toledo Star^e DSC1 (Leicester, UK) unit, under nitrogen. Samples between 5 and 15 mg were placed in aluminum pans and heated from 25 to 120 °C at a heating rate of 10 °C/min, cooled with an intracooler at a cooling rate of 10 °C/min to −100 °C, and then heated again to 120 °C.

Melting Point. The melting point for the compound **10** was obtained using a BÜCHI melting point apparatus B-540 (BÜCHI Labortechnik AG, Postfach, Switzerland). A sample of the test substance was placed into a glass capillary tube and then heated at a constant heating rate (3 °C/min). Melting was determined visually with an accuracy ±1 °C.

Nuclear Magnetic Resonance Spectroscopy (NMR). ^{1}H NMR spectra were recorded on a Mercury Gemini 300 spectrometer operating at 300 MHz. ^{13}C NMR spectra were obtained with the same instrument at 75 MHz. TMS was used as the internal standard.

Elemental Analyses (CHN). Elemental analyses were performed at the Adam Mickiewicz University, Poznan (Poland).

Water Content. The water content was determined using an Aquastar volumetric Karl Fischer titrator EMD Millipore (Billerica, MA, USA) with Composite 5 solution as the titrant and anhydrous methanol as the solvent.

Purity Assay by EN ISO 2871-1:2010. As an alternative measure of purity, an assay was performed by direct two-phase volumetric titration according to EN ISO 2871-1:2010.[36] The salts were titrated with a standard solution of sodium dodecyl sulfate ($Na[CH_3(CH_2)_{11}SO_4]$) in a water−chloroform ($H_2O-CHCl_3$) biphasic system (or water−methanol−chloroform in the case of compounds with limited solubility in water). The titration was conducted with the indicator (dimidium bromide). In a 50 mL volumetric flask, 0.1 g of the MSM salt was dissolved in water (or in a mixture of water and methanol). Then, a 10 mL sample was taken from the prepared solution and blended with 15 mL of chloroform and 5 mL of pre-mixed indicator. The resulting biphasic system was titrated with a 0.004 M sodium

DOI: 10.1021/jf505782p
J. Agric. Food Chem. 2015, 63, 3357−3366

dodecyl sulfate. After addition of a titrant increment, the sample was stirred vigorously for 15 min to allow reaction of the titrant with the analyzed compound and its extraction into the organic phase (chloroform). After 15 min, the two phases were separated and the color analyzed. This was repeated until the pink color disappeared from the chloroform lower phase at the equivalence point, and a one-drop excess of titrant formed a violet complex. The purity was calculated using equation 1:

$$\%\ \text{purity} = \frac{(V_K C_d V_d \text{MW}) \times 100}{m V_p \times 1000} \quad (1)$$

where % purity is the cationic content (% of available), V_K is the total volume of the prepared solution of analyzed substance in mL; C_d is the concentration of the titrant solution of sodium dodecyl sulfate, $Na[CH_3(CH_2)_{11}SO_4]$ in mol/L; V_d is the volume of the titrant solution in mL; MW is the molecular weight of the analyzed compound in g/mol; m is the mass of the tested sample in g; and V_p is the volume of titrated analyte in mL.

Solubility Measurements. The solubilities were determined via *Vogel's Textbook of Practical Organic Chemistry* protocol.[37] A sample of each HIL (0.1 g) was added to a certain volume of each solvent, and the samples were thermostated (MEMMERT Water Bath, model WNB 7, Schwabach, Germany) at 25 °C. Based on the volume of solvent used, 3 types of behavior were recorded: "soluble" applies to compounds which dissolved in 1 mL of solvent, "limited solubility" applies to compounds that dissolved in 3 mL of solvent, and "not soluble" applies to compounds which did not dissolve in 3 mL of solvent.

Statistics. A total of 5 experiments were statistically analyzed, including 2 greenhouse experiments (on *Chemopodium album* and *Brassica napus*) and 3 field experiments (field trials conducted in 2012 and 2013 in fields near Szczecinek and Szamotuly) on *Matricaria inodora, Viola arvensis, Polygonum convolvulus, Galeopsis tetrahit, Capsella bursa pastoris, P. rhoeas, Veronica persica, S. media*, and *Myosotis arvensis*. In order to study the effect of the applied plant protection product on the value of weed destruction, a statistical analysis for each greenhouse and each field experiment was carried out. Each experiment was performed in a completely randomized design with $r = 3$ or 4 replications in greenhouse experiments and $r = 4$ replications in all field trials. For each experiment the following number of groups (v, also called conditions) was used: $v = 7$ groups for greenhouse trials (six HILs, **6**–**8** and **10**–**12** and the Galmet 20 SG control) and $v = 6$ for field trials (five HILs, **6**–**8**, **10**, and **11** and the Galmet 20 SG control) to determine if there was a significant difference between the efficacy data collected under each condition. For each experiment, the degree of freedom (df) that indicates the total number of data points collected (n) and the number of groups being compared (v) is reported in the American Psychological Association (APA) format, $df = v - 1; n - v$. This means that for the greenhouse trials with seven groups being compared with each other and three replicates collected for each of the groups, there were a total of $n = 7 \times 3 = 21$ data points and, therefore, df = 6; 14. Similarly, for the greenhouse trials with seven groups being compared with each other but four replicates collected for each, df = 6; 21. For the field study, only six groups were compared with each other, with four replicates collected for each of the groups resulting in $n = 24$ data points and df = 5; 18.

The program package R (3.0.2) was used for the statistical calculations (R Development Core Team, 2013[38]). Only normally distributed data can be analyzed by analysis of variance (ANOVA). Here, the Shapiro–Wilk test was used first to test the null hypothesis that "the samples come from a normal distribution" against the alternative hypothesis "the samples do not come from a normal distribution". In the case of normal distribution, the Fligner–Killeen test of homogeneity of variances was used to test the null hypothesis that the variances in each of the groups–for each treatment in one trial–ere the same. Before performing the test, a "significance level" (or test's threshold value, α) of 0.01 was chosen, followed by calculation of a function of the observed sample results (p-value), and the null hypothesis was tested at the chosen α-level of 0.01. When the p-value obtained was more than the significance level (α), the tests suggested that the observed data were consistent with the assumption that the null hypothesis was true. Subsequently, to study differences between studied treatments, a one-way analysis of variance (ANOVA) was applied. When the p-value was less than 0.01, the null hypothesis that the data were normally distributed was rejected and the non-parametric Kruskal–Wallis (K–W) rank sum test that does not assume a normal distribution of the samples (unlike the analogous one-way ANOVA) was applied.

Both ANOVA and the non-parametric Kruskal–Wallis (K–W) rank sum test are statistical procedures used for comparing sample means. The results allow for comparison of many sample distributions using significance level α- and p-values; however, the null hypothesis in the case of ANOVA was different: "there is no relationship between the groups" against the alternative hypothesis "there is relationship between the groups". For quantification, the F score (also called F-statistic), equal to the ratio between the variance of the group means/the mean of the variances within the group, indicates how significant the effect of the independent variable is. For both ANOVA and the non-parametric Kruskal–Wallis tests, we reported significance level α-level, p-value, and F-score.

ANOVA (or K–W) tests indicate whether we have an overall difference between the groups but not which specific groups, differed. In order to compare the HILs Galmet 20 SG and determine which groups have significant differences, we computed a post hoc test (Tukey's post hoc test or Wilcoxon rank sum test). Post hoc tests were only run when statistically significant differences between HILs and Galmet 20 SG-treatments were found (i.e., ANOVA resulted in an overall significant difference in group means). As a quantitative result of post hoc tests, we report the Honest Significant Difference (HSD) which represents the minimum difference between two group means that must exist before the difference is to be considered statistically significant. The results of the statistical tests are shown by marking the individual value of each treatment by an appropriate letter.

Syntheses. *General Synthesis (Method A) of **3**–**10** and **12**.* In a 50 mL round-bottom flask equipped with a Teflon-coated magnetic stirring bar, 0.01 mol of the corresponding halide of the desired cation was dissolved in 10 mL of anhydrous methanol followed by adding an equimolar amount of potassium hydroxide dissolved in 5 mL of anhydrous methanol. The mixture was then stirred for 1 h at room temperature. The inorganic potassium halide byproduct precipitated as a white solid and was carefully separated by vacuum filtration through a glass filter funnel. The filtrate (the free base of the desired cation) was carefully transferred to a 50 mL round-bottom flask equipped with a Teflon-coated magnetic stirring bar followed by addition of a stoichiometric amount of MS-M (2-[(4-methoxy-6-methyl-1,3,5-triazin-2-yl)amino]oxomethyl]sulfamoylbenzoic acid methyl ester), which was added all at once. The mixture was then stirred for another 1 h at room temperature, and the solvent was removed using a rotary evaporator followed by adding 20 mL of acetone to the residue. After filtration and evaporation of the solvent from the filtrate, the products were dried under reduced pressure at 50 °C for 48 h.

The synthesized salts were dried under vacuum (10 mbar) at 50 °C for 48 h and stored over P_4O_{10}. The water contents of the dried salts were measured by Karl Fischer titration and found to be less than 500 ppm. The obtained salts were stable in air and in contact with water and tested organic solvents. NMR spectra descriptions, purity assays, and elemental analyses for compounds **3**–**10** and **12** are provided in the Supporting Information.

*General Synthesis (Method B) of **4**, **7**, and **11**.* In a 50 mL round-bottom flask equipped with a Teflon-coated magnetic stirring bar, 0.01 mol of the corresponding chloride of the desired cation was dissolved in 10 mL of water followed by adding an equimolar amount of the potassium salt of MS-M (2-[(4-methoxy-6-methyl-1,3,5-triazin-2-yl)amino]oxomethyl]sulfamoylbenzoic acid methyl ester) dissolved in 10 mL of water. The mixture was then stirred for 24 h at room temperature, and the water was removed using a rotary evaporator. Then, 20 mL of anhydrous acetone was added to the residue. After filtration and evaporation of the solvent from the filtrate, the products

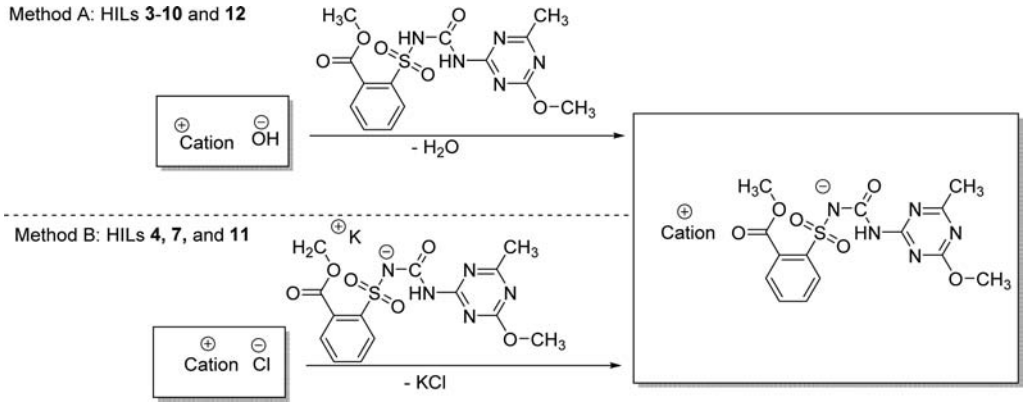
Scheme 1. Synthetic strategies to prepare MS-M-based salts: Method A (top)—acid base reaction with corresponding hydroxides (prepared from the appropriate halide salt if the hydroxide was not commercially available) and Method B (bottom)—metathesis.



were dried under reduced pressure at 50 °C for 48 h. NMR spectra descriptions, purity assays, and elemental analyses for compounds **4**, **7**, and **11** are provided in the Supporting Information.

Greenhouse and Field Trials. Common lambsquarters (*C. album*) and oilseed rape (*B. napus*) plants were grown in 0.5 L plastic pots filled with peat-based potting material under controlled environmental conditions: a temperature of 20 ± 2 °C, relative humidity of 60%, and photoperiod of 16/8 h day/night. The plants were thinned to five per pot 10 days after emergence and watered as needed.

Plants were treated at the 6–8 leaf growth stage, and a complete randomized design was used with four replicates for each treatment. HIL herbicides were mixed with deionized water ca. 24 h before application, and the plants were treated with the aqueous solution only once, at a 4 g ae/ha (active equivalents applied per hectare) rate. The applications were conducted using a moving sprayer (APORO, Poznan, Poland) with a TeeJet VP 110/02 flat-fan nozzle (TeeJet Technologies, Wheaton, IL, USA) capable of delivering 200 L/ha of spray solution at 0.2 MPa operating pressure. The sprayer was moved above the plants at a 40 cm distance and at a constant speed of 3.1 m/s. A control group of plants was treated with standard Galmet 20 SG herbicide at the same application rate. Untreated plants were used for comparison and included in all experiments. Efficacy was evaluated using the fresh weight reduction method 2 weeks after treatment (2 WAT). Data were expressed as percent of fresh weight reduction compared with untreated plants.

Field trials were carried out in two consecutive years, 2012 and 2013, at winter wheat fields located near Szczecinek (northwestern part of Poland) and Szamotuly (western part of Poland). Herbicide treatments were applied to plants as aqueous solutions prepared *ca.* 24 h before application, and the plants were treated at an 8 g ae/ha rate. Treatments were applied using a knapsack sprayer (APORO, Poznan, Poland) equipped with TeeJet DG110/02 VS flat-fan nozzles (TeeJet Technologies, Wheaton, IL, USA) capable of delivering 200 L/ha of spray solution at 0.3 MPa operating pressure. Weed control was evaluated visually 4 weeks after herbicide applications (4 WAT) using a scale of 0 (no effect) to 100% (complete weed destruction).

RESULTS/DISCUSSION

Synthesis of MS-M-Based Ionic Liquids. Ten MS-M-based salts (Table 1) were prepared utilizing structurally variable quaternary ammonium cations (bis(2-hydroxyethyl)-methyloleylammonium, 2-hydroxyethyltrimethylammonium), pyridinium (1-dodecylpyridinium), pyrrolidinium and piperidinium cations (1-butyl-1-methylpyrrolidinium and 1-methyl-1-propylpiperidinium), imidazolium cations with saturated and unsaturated side chains (1-allyl-3-methylimidazolium and 1-butyl-3-methylimidazolium), a morpholinium cation (4-decyl-4-methylmorpholinium), and structurally different phosphonium cations (trihexyltetradecylphosphonium and tetrabutylphosphonium). All of the target MS-M HILs (except **11**) were synthesized by direct reaction between the cation hydroxide and MS-M free acid (Scheme 1, Method A); when the hydroxide form of the cation was not commercially available it was obtained by ion exchange of the cation halide with KOH. Two of the HILs prepared by method A (**4** and **7**) and **11** were additionally synthesized by a metathesis route, i.e., reaction of the cation chloride with the potassium salt of MS-M (Scheme 1, Method B), to verify the possibility of using this method.

The compounds were all obtained in high yields (>90%), and 9 of the 10 compounds (**3**–**12**) were liquids at room temperature, while 1 (**10**) was a low-melting crystalline solid with a melting point of 62–64 °C. (This compound had a tendency to supercool when melted.) The structures of all compounds were confirmed by ^{1}H and ^{13}C NMR spectroscopy. Elemental analysis helped to validate the identity and purity of the synthesized compounds and all compounds were obtained with high purities (>95%), see Table 1. The detailed synthesis of the compounds and their characterization data are provided in the Results/Discussion.

Thermal Properties. Glass transitions were observed below 16 °C for all of the prepared HILs with no observed crystallization or melting events (except for **10** as discussed below) as commonly seen for similar alkylammonium and phosphonium ILs. Analysis of structure vs glass transition relationships revealed a known trend where the longer the alkyl chain substituent on the nitrogen or phosphorus the lower the glass transition of the resulting salt. The lowest glass transition temperature (T_g = −45 °C) was observed for the HIL with the bis(2-hydroxyethyl)methyloleylammonium cation **3**, which has the long unsaturated *N*-oleyl alkyl chain (C_{18} alkyl). The second lowest glass transition was found for trihexyltetradecylphosphonium **11** (T_g = −32 °C), which contains a C_{14} alkyl group, while cation **5**, 1-dodecylpyridinium with a C_{12} alkyl group, was exhibited (T_g = −18 °C).

Glass transitions for all other compounds except **10**, which was a crystalline low-melting solid, were similar and varied between 1 and 7 °C. The 4-decyl-4-methylmorpholinium solid salt **10** had a melting point of 62–64 °C (determined using a melting point apparatus) and the highest glass transition (T_g = 16 °C) of all of the compounds prepared. This HIL also exhibited supercooling behavior, where a melting transition was observed on first heating but could not be reproduced within

the design of the DSC experiment over several heating/cooling cycles.

Most of the investigated salts exhibited simple thermal decomposition behavior with a single decomposition step. However, cholinium salt **4** exhibited a three-step decomposition, and the tetrabutylphosphonium salt (**12**) had a two-step decomposition.

Generally, the HILs decomposed between 150 and 200 °C, with cholinium MS-M (**4**) and other aliphatic alkyl ammonium MS-M HILs (**6** and **9**) being the least thermally stable. HILs with morpholinium (**10**) and phosphonium (**11**, **12**) cations exhibited the highest thermal stability. Moreover, it was noticed that all unsubstituted aromatic HILs exhibited higher stabilities of ca. 20 °C, compared to aliphatic salts, varying from 182 (for imidazoliums **7** and **8**) to 195 °C (for pyridinum **5**).

From these results it could be concluded that the phosphonium salts were more thermally stable than their ammonium equivalents and that the aromatic HILs tend to be more stable than those aliphatic, although the latter also have high thermal stability. In general, the thermal stability for each group of salts was more dependent on the structure of the cation core than on the presence of or chain length of the *N*-alkyl substituents.

Solubilities. The solubilities of the prepared HILs were tested in ten solvents, varying from low polarity to high polarity with both protic and aprotic solvents studied, Table 2. The solvents chosen for study were selected in order of decreasing polarity expressed as the Snyder polarity index: water, 9.0; methanol, 6.6; DMSO, 6.5; acetonitrile, 6.2; acetone, 5.1; isopropanol, 4.3; ethyl acetate, 4.3; chloroform, 4.1; toluene, 2.3; hexane, 0.0.

Ionic liquids are generally miscible with liquids with medium to high dielectric constants and immiscible with apolar compounds.[39] Thus, as expected, all tested compounds were

[a]Snyder polarity index. [b]S: soluble. L: limited solubility. N: not soluble.

soluble in polar protic methanol and aprotic DMSO, though 1-allyl-3-methylimidazolium **7** had limited solubility in DMSO. Slightly less polar aprotic acetonitrile and acetone also dissolved all compounds albeit two, 1-butyl-3-methylimidazolium **8** and 4-decyl-4-methylmorpholinium **10**, demonstrated limited solubility in both acetonitrile and acetone, and HIL 2-hydroxyethyltrimethylammonium **4** was less soluble in acetone. Interestingly, only phosphonium HILs (**11**, **12**) and two of the ammonium HILs, bis(2-hydroxyethyl)methyloleylammonium **3** and 1-dodecylpyridinium **5**, were soluble in ethyl acetate. Isopropanol did not work as good as methanol, though it dissolved all HILs (some to the certain limits) except 2-hydroxyethyltrimethylammonium **4**. The chlorinated solvent, chloroform, even though of relatively low polarity, dissolved all HILs, although 1-butyl-3-methylimidazolium **8** and 4-decyl-4-methylmorpholinium **10** had limited solubilities. For nonpolar solvents, all tested compounds were insoluble in hexane and only bis(2-hydroxyethyl)methyloleylammonium **3** out of ammonium HILs and trihexyltetradecylphosphonium **11** were freely soluble in toluene. HILs with bis(2-hydroxyethyl)-methyloleylammonium **3** and the phosphonium cations, trihexyltetradecylphosphonium and tetrabutylphosphonium **11** and **12**, had solubility in almost all of the tested solvents.

Efficacy. Greenhouse tests were conducted using MS-M HILs **6**−**8** and **10**−**12**, and field trials were conducted with HILs **6**−**8** and **10** and **11**. Both types of trials were compared to the use of a commercial formulation of Galmet 20 SG and to control plants which were not treated.

Greenhouse Experiments. The HILs were studied for their herbicidal activity against dicotyledonous weeds (common lambsquarters and rapeseed) in a greenhouse. HILs **6**−**8** and **10**−**12** were selected for efficacy comparison against free MS-M as a commercial product Galmet 20 SG. The tests were conducted under controlled conditions of temperature 20 ± 2 °C, relative humidity 60%, and photoperiod 16/8 h day/night.

Common lambsquarters and rapeseed plants were separated into three groups: (1) those sprayed with the MS-M HILs (as aqueous solutions), (2) those sprayed with commercially available Galmet 20 SG (at the same application rate, 4 g ae/ha), and (3) those not sprayed (the control group). Two weeks after treatment (2 WAT), plants from four pots were selected from each group and their fresh weight was determined. The efficacy data is expressed as percent fresh weight reduction compared to untreated plants (see Methods and Materials for additional detail).

The HIL forms of MS-M applied to lambsquarters (*C. album*) showed a much higher activity that the Galmet 20 SG commercial herbicide, except for **6** whose activity was slightly lower than that of the reference herbicide. All HILs except **6** demonstrated at least twice the activity of commercial Galmet 20 SG, with **11** and **12** as much as 2.5 times more effective. On rapeseed, the herbicidal activities of HILs **6** and **7** were, respectively, 5% and 13% lower than that of Galmet 20 SG. HIL **11** demonstrated activity comparable to commercial analog, and HILs **8**, **10**, and **12** were substantially more effective (ca. 1.5 times greater activity).

Statistically, the HIL forms of MS-M applied to lambsquarters (*C. album*) showed significant differences in the mean effects of action for the tested substances in ANOVA. For HILs

Figure 2. Greenhouse efficacy of HILs **6**−**8** and **10**−**12** compared to Galmet 20 SG on lambsquarters.

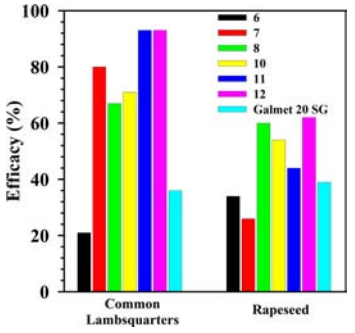

Figure 3. Greenhouse efficacy (measured as fresh weight reduction 2 weeks after treatment) of MS-M HILs **6** (black), **7** (red), **8** (green), **10** (yellow), **11** (blue), and **12** (fuschia) compared to Galmet 20 SG (aqua) on common lambsquarters and rapeseed at an application rate of 4 g ae/ha.

J. Agric. Food Chem. 2015, 63, 3357−3366

used on *C. album*, values of $F = 51.87$ and p-value = 0.000 were obtained, indicating a high significant difference between the treatment with HILs and commercial Galmet 20 SG, while for HILs used on *B. napus*, $F = 11.91$ and p-value = 0.000 (Table 3) the difference between the treatment with HILs and commercial Galmet 20 SG was significant but not that large. To determine which HILs among all the experiments had significant differences, post hoc comparisons using the Tukey HSD test ($\alpha = 0.05$) were conducted and indicated that the mean score for both *C. album* and *B. napus* treated with Galmet 20 SG was significantly lower than those plants treated with some of the HILs. The details are provided as follows.

On *C. album*, the mean value of Galmet 20 SG (36 ± 23) was significantly lower than the mean effects for all HILs except **6**. Specifically, the mean values of plants treated with HIL **11** (93 ± 23) and HIL **12** (94 ± 23) were the highest and significantly higher than the mean effects of action of HIL **8** (67 ± 23) and HIL **10** (71 ± 23).

On *B. napus*, Galmet 20 SG-treated plants gave a significantly lower mean effect (39 ± 9) than HIL **8** and HIL **12**. HIL **12** in this trial gave the highest mean effect on weed destruction (67 ± 9), which was significantly different than the mean effects of action of HILs **6**, 7, and **11**.

[a]Galmet 20 SG (% active metsulfuron-methyl − 20%) was used as the reference herbicide. [b]Analysis after Box-Cox transformation of data ($\lambda = 1.64$). [c]Treatment mean ± B gives lower and upper 95% confidence bounds (CI). [d]The same letter in the column means no statistical differences between treatments.

Field Trials. After greenhouse testing, HILs **6**−**8** and **10** and **11** were studied for their herbicidal activity in the field. The trials (a 2-year field investigation) were conducted in 2012 and 2013 in the winter wheat fields near Szczecinek (northwestern part of Poland) and Szamotuly (western part of Poland). The tests were conducted on a variety of weeds, particularly on mayweed (*M. inodora*), field pansy (*V. arvensis*), wild buckwheat (*P. convolvulus*), hemp nettle (*G. tetrahit*), shepherd's purse (*C. bursa pastoris*), field poppy (*P. rhoeas*), chickweed (*S. media*), field forget-me-not (*M. arvensis*), and persian speedwell (*V. persica*).

The herbicides were applied at a rate of 8 g ae/ha at the beginning of stem elongation, the end of tillering stage, or the BBCH (Biologische Bundesanstalt, Bundessortenamt and Chemische Industrie) 30 stage on the plant phenological development stage scale for cereals. All herbicidal treatments were conducted with an application rate of 8 g ae/ha. Weed control was evaluated visually 4 weeks after herbicide applications (4 WAT) using a scale of 0 (no effect) to 100% (complete weed destruction). The results are presented in Table 4.

Overall, the results were slightly different from the greenhouse data. In the field, the HILs tested and Galmet 20 SG were all 100% effective against *M. inodora*, *V. arvensis*, *P. convolvulus*, *G. tetrahit*, and *S. media*. The HILs were more effective that Galmet 20 SG for *C. bursa pastoris*, *P. rhoeas*, *V. persica*, and *M. arvensis*, demonstrating they can be used for weed control in winter wheat fields.

The efficacy of the HILs in greenhouse and field trials depended on species. On rapeseed the herbicidal activities of the HILs were only slightly higher than that of the commercial herbicide, while on lambsquarters (*C. album*) all but one of the HILs exhibited at least twice the activity of commercial Galmet 20 SG. In three field studies over 2 years (winter wheat fields), the herbicidal activity of the HILs again varied depending on the plant species but all tested HILs were at least as effective and in some cases more effective than the reference herbicide.

Statistically, for all field trials, the analyzed HILs **6**−**8**, **10**, and **11** demonstrated high efficiency (some as high as 100%) in plant reduction (Table 4). ANOVA test indicated significant differences in the mean effects of the action of the HILs used on *M. inodora*-2012[b] ($F = 4.364$; p-value = 0.0089), *V. arvensis*-2012[b] ($F = 4.687$; p-value = 0.0065), *P. rhoeas*-2013[c] ($F = 8.907$; p-value = 0.0002), and *V. persica*-2013[c] ($F = 13.15$; p-value = 0.0000), Table 4.

To determine which HILs in all of the experiments had significant differences, post hoc comparisons using the Tukey HSD test ($\alpha = 0.05$) were conducted similarly to those noted above for the greenhouse trials. The post hoc comparisons ($\alpha = 0.05$) indicated that the mean scores for *V. arvensis* treated with HIL **6** (90 ± 4) and HIL **11** (93 ± 4) were significantly different from the identical plants treated with Galmet 20 SG (81 ± 4, Table 4). The mean score for *P. rhoeas*-2013[c] treated with Galmet 20 SG (64 ± 5) was significantly lower than all HILs except HIL **11**; the identical situation occurred in the *V. persica*-2013[c] field trial. Although the mean values of the weed destruction for *M. inodora*-2012[b] treated with HILs **6**, **8**, and **11** were higher than in the case of Galmet 20 SG (90 ± 3), the differences were not statistically significant. For *M. inodora*-2012[b], the highest mean effect of action was observed for HIL **11** (95 ± 3), which was significantly different from the mean effects for HILs 7 and **10**.

P. rhoeas-2013[c] treated with HIL 7 (66 ± 5) and HIL **10** (68 ± 5) had mean scores significantly lower than the identical plant treated with HIL **6** (85 ± 5). The mean effect of action for HIL **10** (78 ± 5) used on *V. persica*-2013[c] was significantly higher than in the case of HILs 7 and **11**. While the Kruskal−Wallis tests used to analyze the other field experiments did not indicate significant differences between treatments, it is worth noting that in all cases HILs were 100% or almost 100% effective. Taken together, these results suggest that for some plants the efficacies of some of the HILs were significantly higher than Galmet 20 SG.

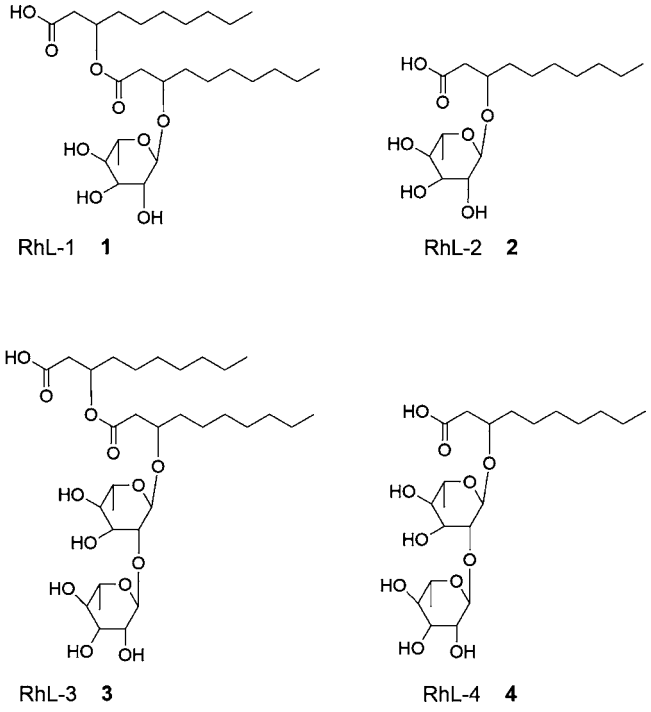

Figure 1. Representative molecular structures of four main groups of rhamnolipids, RhL-1−RhL-4.

the economic production of anti-zoospore chemicals and potentially valuable co-products from rhamnolipids.

MATERIALS AND METHODS

Materials. Ethanol, ethyl acetate, citric acid, sodium citrate, acetic acid, sodium bicarbonate, sodium hydroxide, sulfuric acid, sodium methoxide methanol solution (25%, w/w), cellulase (EC 3.2.1.4) from *Trichoderma reesei* [American Type Culture Collection (ATCC) 26921], and cellobiase from *Aspergillus niger* were purchased from Sigma-Aldrich (St. Louis, MO). Milli-Q water (Millipore, Billerica, MA) was used. V8 high-fiber 100% vegetable juice from Campbell Soup Company (Camden, NJ) was purchased from a local store. All other reagents were of analytical grade.

HPLC−MS Analysis. HPLC analysis was performed with the Hewlett-Packard LC1100 series equipment (Agilent Technologies, Santa Clara, CA). The column used was a 250 × 4.6 mm inner diameter, 5 μm, Supelcosil LC-18 (Supelco, Bellefonte, PA). The column temperature was controlled at 24 °C. Several mobile-phase solvents were used in this study for different sample groups. For clarity, they are described with the specific samples in later sections. The mobile phase flow rate used was always the same at 0.4 mL/min. All chromatographic peaks were confirmed to appear during the retention time period of 5−45 min. MS analysis was made with a Bruker Esquire-LC system. Compounds were ionized by electrospray ionization (ESI). The detection was made in the "smart mode" with the following conditions: gas flow pressure, 40 psi; gas flow rate, 8 mL/min; drying gas temperature, 365 °C; target m/z, 750; trap drive, 60%; compound stability, 75%; and under the wide-mode optimization.

Production and Purification of Rhamnolipids. Rhamnolipids were produced by *P. aeruginosa* fermentation. Inoculum was grown for 8 h in a 30 g/L tryptic soy broth (TSB) medium in a shaker operating at 34 °C and 250 rpm. A total of 10 mL inoculum was added to 90 mL of TSB solution and similarly grown for 18 h to prepare the preculture. The entire (100 mL) preculture was added to a 3 L fermentor (BIOFLO 110, New Brunswick Scientific, Edison, NJ) with 1 L of medium and agitated at 600 rpm with two six-blade turbines. The pH was maintained at 6.2 ± 0.1 by automatic addition of 1 N H_2SO_4 or NaOH. The dissolved oxygen concentration was kept at 10% (±3%) by controlled bubbling of pure oxygen; the temperature was controlled at 32.0 ± 0.1 °C. The fermentation medium contained 100 g/L glycerol, 6 g/L KH_2PO_4, 5.73 g/L NH_4Cl, 5 g/L yeast extract, 5 g/L peptone, 1.5 g/L NaCl, 0.9 g/L $MgSO_4{\cdot}7H_2O$, 0.1 g/L $FeSO_4{\cdot}7H_2O$, 0.03 g/L $CaCl_2{\cdot}2H_2O$, 0.03 g/L $MnCl_2{\cdot}4H_2O$, and 2 mL/L of a trace element solution. The trace element solution had 0.75 g/L $MnSO_4{\cdot}H_2O$, 0.75 g/L $ZnSO_4{\cdot}7H_2O$, 0.15 g/L H_3BO_3, 0.08 g/L $FeCl_3{\cdot}6H_2O$, 0.08 g/L $CoCl_2{\cdot}6H_2O$, 0.075 g/L $CuSO_4{\cdot}5H_2O$, and 0.05 g/L Na_2MoO_4.

The rhamnolipids produced in the fermentation broth were mainly RhL-1 and RhL-3. A glass chromatography column (600 × 50 mm inner diameter) was used for separation of RhL-1 and RhL-3. The height of silica gel in the column was about 500 mm. The mobile phase was a chloroform/methanol/water (100:23:3, v/v/v) mixture. The column was flushed with about 1.4 L mobile phase. The eluate was collected in 40 consecutive fractions of 25 mL. The 40 fractions were air-dried separately. RhL-1 was in the fractions 3−15, and RhL-3 was in the fractions 17−35, which was confirmed with HPLC−MS analysis.

Generation of Free Diacids from Rhamnolipids. Free diacids were generated in two steps: ethyl diacids were first formed and then hydrolyzed to free diacids, according to the route shown in Figure 2.

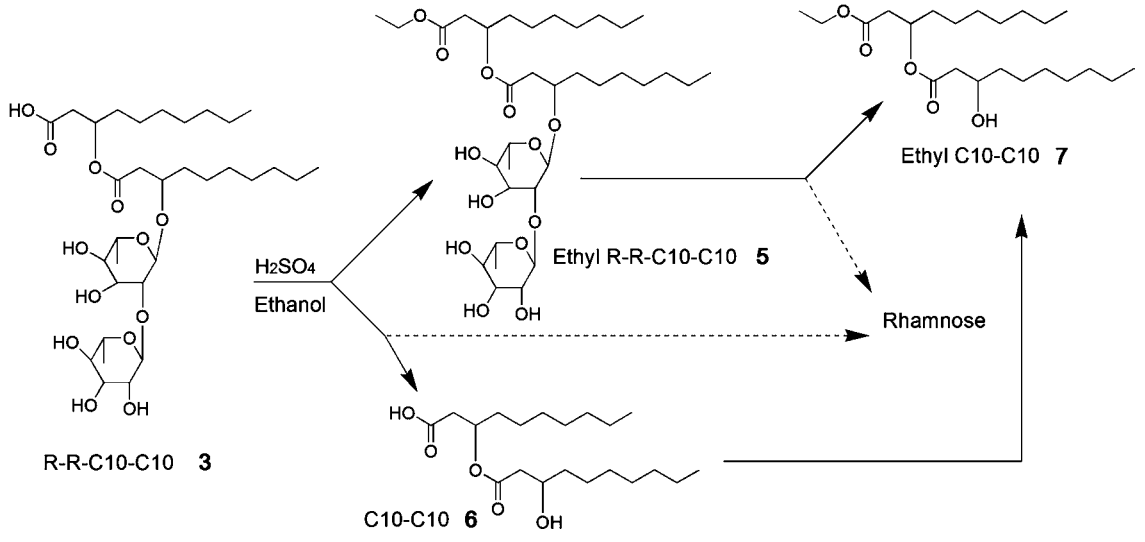

Figure 2. Reaction scheme for generating ethyl diacids from RhL-3, illustrated with R−R−C_{10}−C_{10} as the structural example.

DOI: 10.1021/acs.jafc.5b00033
J. Agric. Food Chem. 2015, 63, 3367−3376

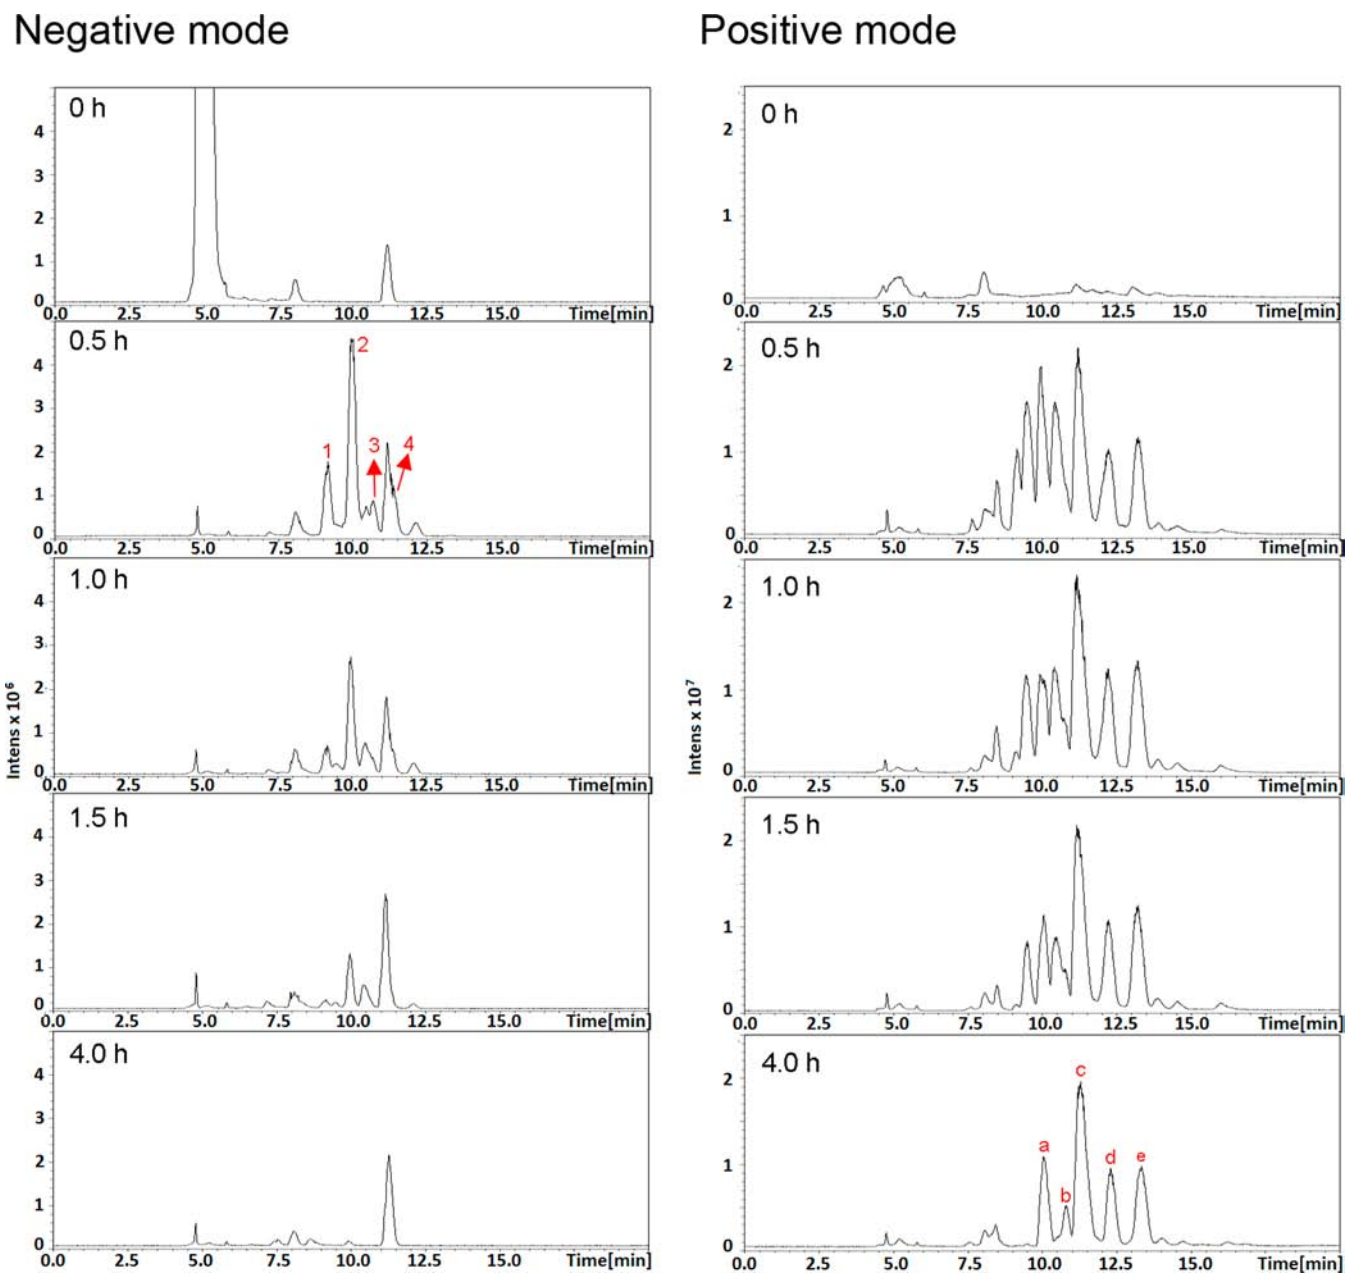

Figure 3. Total ion chromatograms from HPLC−MS analysis of samples during the generation of ethyl diacids from RhL-3.

For the production of ethyl diacids, 100 mg of RhL-3 and 5 mL of ethanol were charged into a 20 mL glass vial. Then, 0.2 mL of sulfuric acid was added dropwise. The mixture was reacted for 4 h in a 70 °C shaking water bath operating at 150 rpm. The reaction progress was followed by taking samples (typically 50 μL) at 0.5, 1.0, 1.5, 2.0, and 4.0 h. The sulfuric acid in these samples was neutralized by the addition of 100 μL of saturated aqueous solution of sodium bicarbonate. The neutralized samples were dried and extracted with ethyl acetate. The ethyl acetate phase was collected and dried, and the residue was redissolved in 95% methanol in water and then subjected to HPLC−MS analysis, which was performed with an isocratic flow (0.4 mL/min) of the following mobile phase: methanol/4 mM aqueous ammonium acetate (95:5).

Free diacids were then obtained in the second reaction step, by hydrolysis of the ethyl diacids with an aqueous sodium hydroxide solution. Typically, 2.5 mL of ethyl diacid solution (10 mg/mL in ethanol) was mixed with 1.5 mL of water. Then, 1 mL of sodium hydroxide stock solution (10 mg/mL in water) was added. The reaction mixture was shaken at 150 rpm and 25 °C for 2 h. The mixture was then neutralized with acetic acid, dried, and extracted with ethyl acetate to remove the remaining salt. The synthesized free diacids in the ethyl acetate extract were characterized by MS analysis with the following conditions: positive mode; gas flow pressure, 10 psi; gas flow rate, 8 mL/min; drying gas temperature, 310 °C; target m/z, 381; trap drive, 100%; compound stability, 100%; and under the normal-mode optimization.

Conversion of RhL-1 and RhL-3 to RhL-2 and RhL-4. A total of 100 mg of RhL-3 (or RhL-1) and 5 mL of aqueous NaOH solution (40 g/L) were reacted in a 20 mL glass vial for 4 h at 25 °C in a shaker operating at 150 rpm. Samples (50 μL each) were taken at 0.5, 1.0, 1.5, 2.0, and 4.0 h and neutralized with 50 μL of anhydrous acetic acid. The samples were dried and then dissolved with 40% methanol in water for HPLC−MS analysis. The mobile phase used for these samples was a gradient of (A) methanol and (B) 4 mM aqueous ammonium acetate according to the following: a 5 min isocratic hold at 40% A, a 20 min gradient to increase A from 40 to 95%, a 10 min isocratic hold at 95% A, a 15 min gradient to decrease A from 95 to 40%, and a 5 min isocratic hold at 40% A. The total run time was 55 min for each

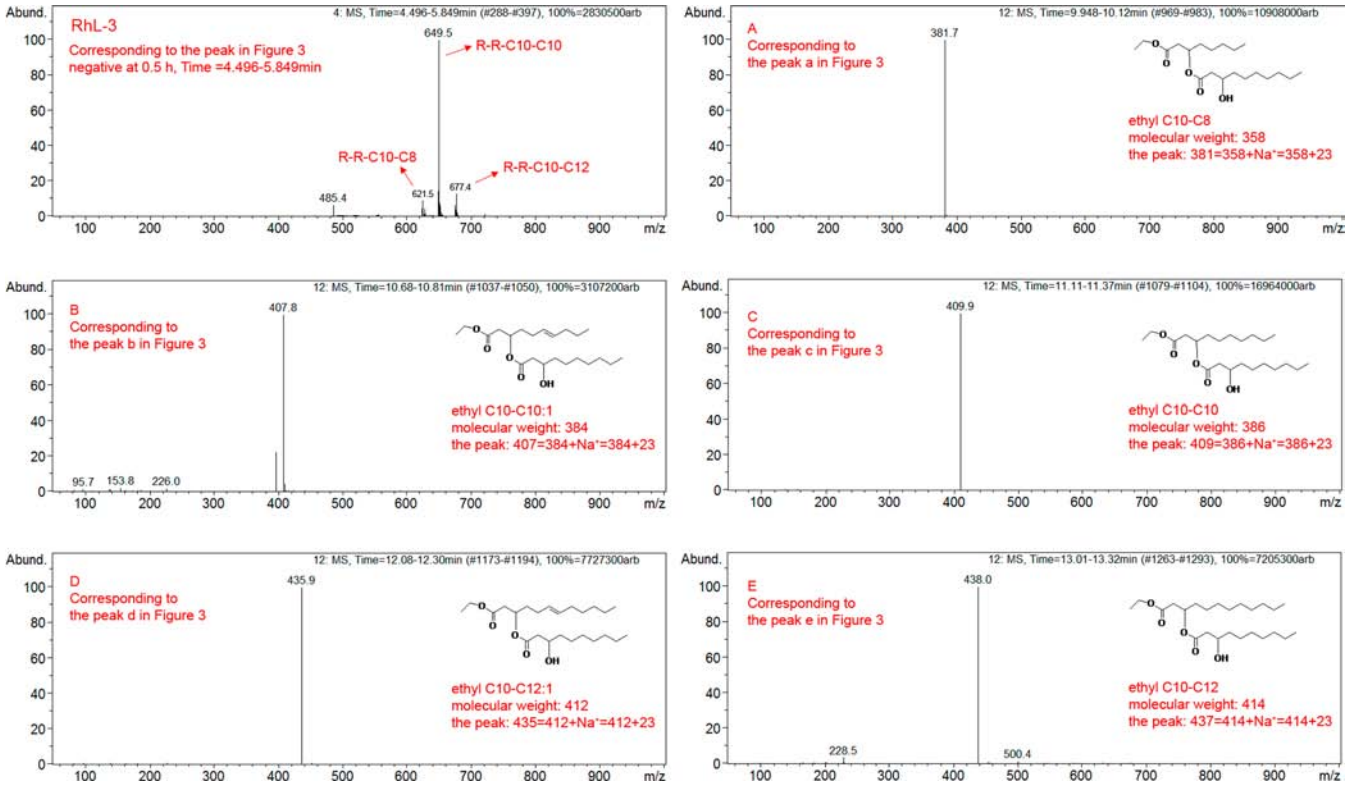

Figure 4. MS spectra for some isolated peaks shown in Figure 3, confirming the structures of the RhL-3 reactants and the five ethyl diacid products.

sample. MS analysis was in the negative mode, while other operating parameters were as described previously.

Enzymatic Conversion of RhL-3 to RhL-1. Into a 20 mL glass vial, 5 mL of RhL-3 solution (0.5 mg/mL in water) and 5 mL of enzyme solution (cellulase or cellobiase in 0.05 M citrate buffer at pH 4.8) were added. For cellulase, the concentration was 1 mg/mL (8.9 units/mL), assayed with cellulose as the substrate at pH 5.0 and 37 °C for 2 h of incubation time; 1.0 unit liberates 1.0 μmol/min glucose from cellulose. For cellobiase, the enzyme solution was prepared by adding 50 μL of cellobiase to 5 mL of citrate buffer. The reaction mixture was shaken at 150 rpm and 37 °C for 24 h. Samples (1 mL) were taken at 6 and 24 h. The samples were dried and redissolved in acetonitrile/water (40:60) for HPLC−MS analysis. The mobile phase used for these samples was a gradient of (A) acetonitrile and (B) 4 mM aqueous ammonium acetate according to the following: a 3 min isocratic hold at 40% A, a 17 min gradient to increase A from 40 to 95%, and a 10 min isocratic hold at 95% A. MS analysis was conducted in the negative mode as described previously.

Anti-zoospore Test. *P. sojae* was cultured on V8 juice agar. Zoospores were obtained by washing a 7-day-old plate culture with tap water, once every 30 min for a total of 6 h. Multiple 2 mL plastic tubes were used for the anti-zoospore test. Each tube was filled with 100 μL of rhamnolipid solution that had a concentration varying among 20, 40, 60, 80, 100, 120, 160, and 250 mg/L. A total of 50 μL of water and 50 μL of zoospore suspension were added to the tubes. The zoospore suspension had about 1×10^5 zoospores/mL as measured by counting with a hemocytometer under a light microscope coupled with a DP71 digital camera (Olympus America, Inc., Center Valley, PA). Immediately after the addition of zoospores, the tube was gently swirled for mixing for 5 s, followed by extraction of one drop of the mixture and placement on a glass slide for observation of zoospore motility under the microscope. The critical anti-zoospore concentration was defined in this study as the lowest rhamnolipid concentration at which the motility of all observed zoospores was stopped.

RESULTS AND DISCUSSION

Generation of Free Diacids from Rhamnolipids. There are several hypotheses as to why bacteria produce rhamnolipids.[19−21] None assumes that rhamnolipids are specifically produced to kill fungal zoospores.[19−21] The mechanism of the anti-zoospore effects of rhamnolipids is poorly understood. There have been no studies on the correlation of rhamnolipid molecular structures with their anti-zoospore effects. It was recognized at an early stage of this study that the structures of the diacid residue of RhL-1 and RhL-3 are somewhat similar to another class of biosurfactants, corynomycolic acids, which also have branched β-hydroxyl fatty acid structures.[22−24] On the other hand, other well-known biosurfactants, such as sophorolipids and surfactin, which have no strong anti-zoospore properties,[7] do not have the diacid structure. It was therefore hypothesized that, upon initial breakdown of rhamnolipids in natural environments, the free diacids generated may play a role in lysing zoospores (and/or other biological activities). If so, the anti-zoospore and/or other biological activities of the diacids may offer some longer term benefits to the rhamnolipid-producing bacteria, such as *P. aeruginosa*. Free diacids were therefore synthesized from rhamnolipids for the later anti-zoospore evaluation.

The reaction scheme for production of ethyl diacids from RhL3 precursors is shown in Figure 2. The total ion spectra from HPLC−MS analysis of the samples taken along the reaction of ethyl diacid production are shown in Figure 3. In the negative detection mode, RhL-3, with the free carboxyl group, is expected to give a strong signal. This is seen with the 0 h sample, as the large peak at the retention time of 4.5−5.5 min. The isolated mass spectrum for this large RhL-3 peak is given in Figure 4, showing three major structures: R−R−C_{10}−C_8, R−R−C_{10}−C_{10}, and R−R−C_{10}−C_{12}. In fact, five groups of

DOI: 10.1021/acs.jafc.5b00033
J. Agric. Food Chem. 2015, 63, 3367−3376

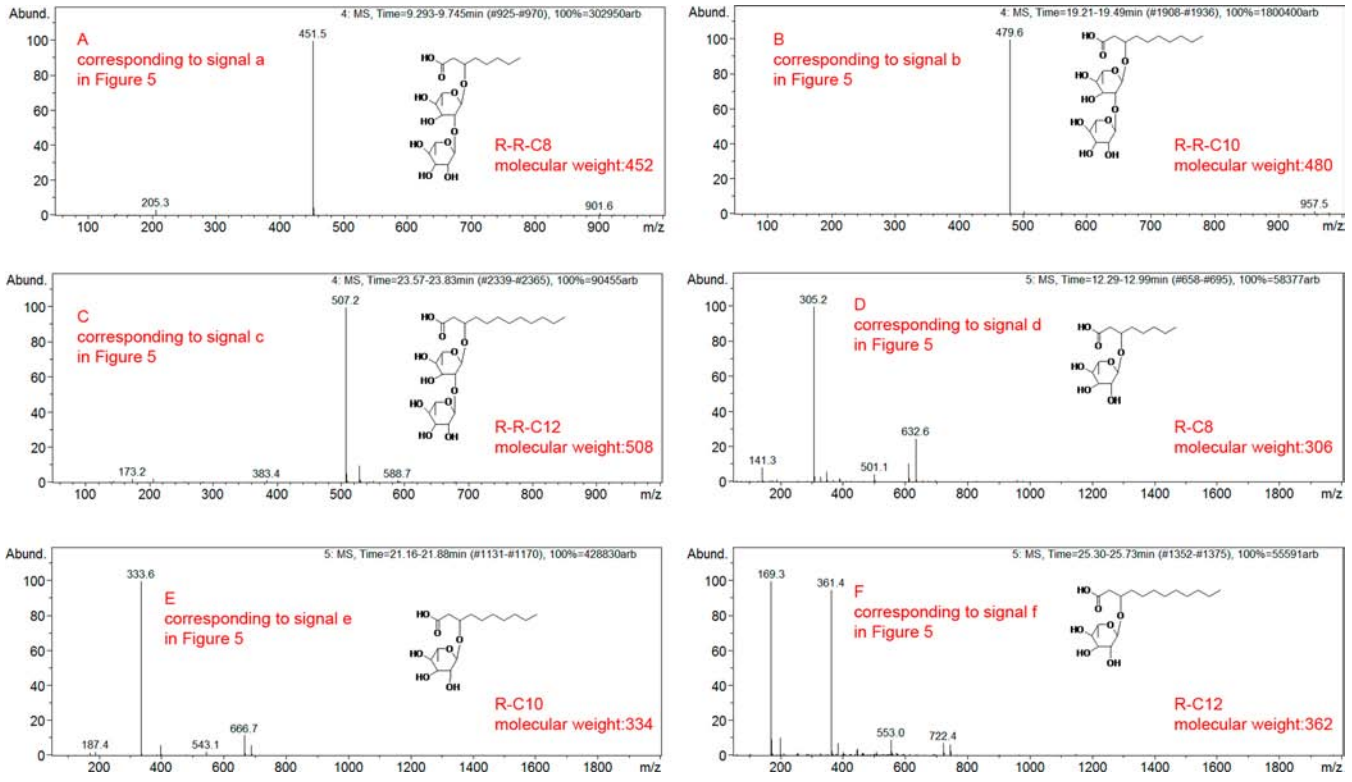

Figure 6. (A–F) MS spectra for the isolated product peaks, shown in Figure 5.

structures have been detected in RhL-3 produced in our laboratory, as given in Table 1. They are more clearly shown in Figures 5 and 7 in later sections. The two smaller groups of congeners are not apparent in this spectrum for the isolated peak.

In the negative-mode spectrum for the sample taken after 0.5 h of reaction, a group of new signals, labeled as 1–4 in Figure 3, appears in the retention time range of 8.5–11.5 min. According to their mass spectra, the new signals correspond to the ethylated rhamnolipids: (1) ethyl R–R–C_{10}–C_8, (2) ethyl R–R–C_{10}–C_{10}, (3) ethyl R–R–C_{10}–$C_{12:1}$, and (4) ethyl R–R–C_{10}–C_{12}. Among the five detectable structures in RhL-3, the group of R–R–C_{10}–$C_{10:1}$ and R–R–$C_{10:1}$–C_{10} is present in the smallest quantity; the ethylated rhamnolipid of this group is not seen in the negative-mode spectra in Figure 3.

The above four new peaks are seen to decrease in intensity with a longer reaction time and nearly disappear after 4.0 h. The results indicate that rhamnolipid ethylation is a fast reaction and the ethyl rhamnolipids formed are further converted to other products. These final products are more clearly seen in the positive-mode spectra in Figure 3. In the positive-mode spectrum for the 0 h sample, the signal of RhL-3 is much weaker than the signal in the negative-mode spectrum. However, more new peaks appear in the positive-mode spectrum for the 0.5 h sample. These peaks correspond to not only the ethyl rhamnolipids, which give strong signals at both negative and positive modes, but also the ethyl diacids formed by the reaction. For the 4.0 h sample, five peaks, labeled as a–e, remain in the positive-mode spectrum. These peaks are from the five synthesized ethyl diacids, as confirmed by the corresponding mass spectra shown in Figure 4 for the five isolated peaks.

Structures of the free diacids subsequently obtained by hydrolysis of the ethyl diacids with sodium hydroxide are summarized in Table 1. The synthesized free diacids were used in the later anti-zoospore study.

Besides ethyl diacids, rhamnose can be obtained as a byproduct. The production of rhamnose by sulfuric acid hydrolysis of rhamnolipids has been reported[25,26] and is not investigated in detail here. Currently, the commercial rhamnose is obtained through an extraction and hydrolysis process.[25,26] Rhamnose-containing materials are first extracted from plant materials, such as oak bark and citrus peels. Rhamnose is then produced by hydrolyzing these extracts. This labor-intensive process needs toxic, corrosive chemicals and produces undesirable waste products. The co-production of rhamnose from rhamnolipids represents an alternative route.

RhL-3 was used as the starting material to generate free diacid for easier tracking of the progress of reactions involving more manageable numbers of rhamnolipids and ethyl rhamnolipids. However, RhL-1 and RhL-3 have the same fatty acid residue (Table 1), and the diacids can be obtained from the mixture of RhL-1 and RhL-3. This process of generating diacids directly from the rhamnolipid mixture collected from fermentation, without the preceding chromatographic separation into RhL-1 and RhL-3, was also carried out in this study. The ethyl diacids obtained have the same final HPLC–MS positive-mode spectrum as that in Figure 3 (data not shown).

Generation of RhL-2 and RhL-4 from RhL-1 and RhL-3. RhL-2 and RhL-4, with one β-hydroxyalkanoic acid as the hydrophobic moiety, have been reported to be produced in the bacterial fermentation but typically make up very small fractions of the rhamnolipid mixtures.[17,18] In the rhamnolipids produced in our laboratory, the contents of RhL-2 and RhL-4 are very low, not observed in our MS analysis. RhL-1 and RhL-3, with two ester-linked β-hydroxyalkanoic acids as the hydrophobic moiety, are the most common groups of rhamnolipids. These

DOI: 10.1021/acs.jafc.5b00033
J. Agric. Food Chem. 2015, 63, 3367–3376

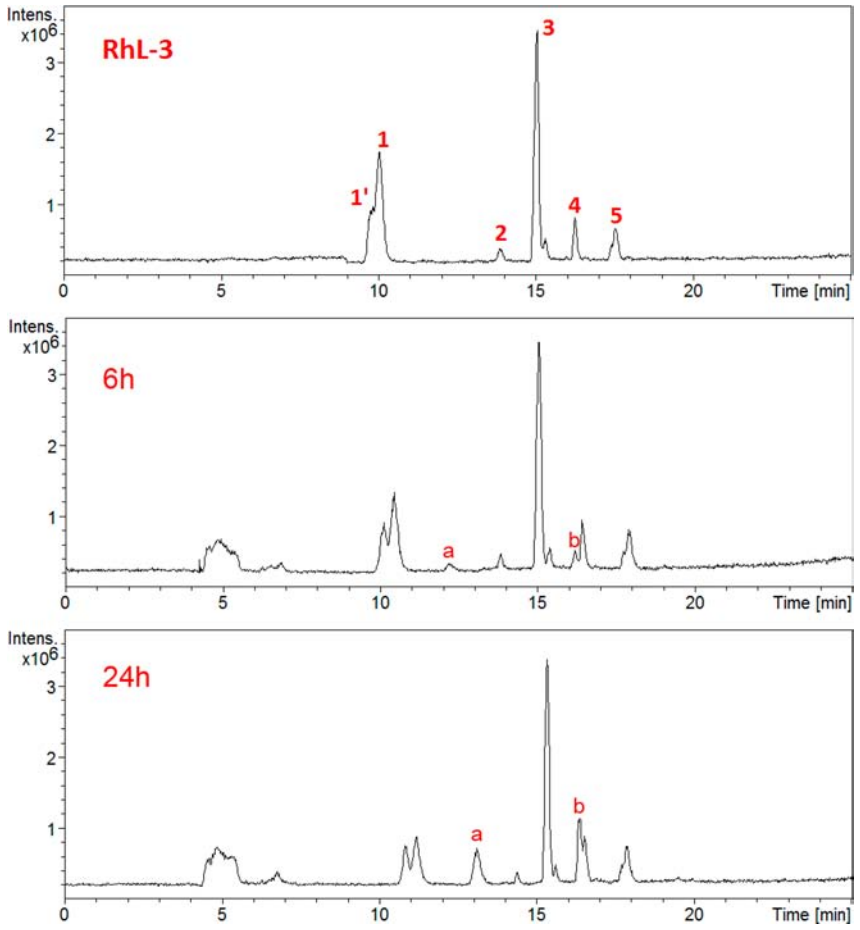

Figure 7. Total ion chromatograms from HPLC−MS analysis of samples from the cellobiase-catalyzed conversion of RhL-3 to RhL-1.

were the groups studied for rhamnose production and anti-zoospore effects in previous literature reports.[7,25] It was desirable to evaluate the anti-zoospore effect of RhL-2 and RhL-4, as compared to that of RhL-1 and RhL-3. The results might provide some insights into the potential importance of the unique diacid structure in rhamnolipids to the biological activities of the biosurfactants. In addition, if RhL-2 and RhL-4 would be found to have superior anti-zoospore property, there might be advantages to tailor the bacterial strain and fermentation conditions to produce RhL-2 and RhL-4, instead of RhL-1 and RhL-3. For example, RhL-2 and RhL-4 have smaller molecular weights than RhL-1 and RhL-3. The molar yield of RhL-2 and RhL-4 can be higher from the same amount of substrate.

RhL-1 and RhL-3 were hydrolyzed with sodium hydroxide to produce RhL-2 and RhL-4. The progress of the hydrolysis reaction is illustrated by the HPLC−MS results shown in Figure 5 for the samples taken at 0, 0.5, 1.0, 2.0, and 4.0 h. For the 0 h samples, the peaks numbered as 1−5 correspond to the five major structures in RhL-3 and those numbered as 6−10 correspond to the five structures in RhL-1. These structures are summarized in Table 1. As shown in Figure 5A, with increasing reaction time, peaks 1−5 of RhL-3 all decrease in intensity simultaneously and three new peaks, labeled as a−c, appear in the spectrum for the 4.0 h sample. The mass spectra corresponding to peaks a−c are shown in panels A−C of Figure 6, confirming that these new peaks formed are dirhamnolipids with the RhL-4 structure, i.e., R−R−C_8, R−R−C_{10}, and R−R−C_{12}. Similarly, three new peaks d−f are formed from hydrolysis of RhL-1, as shown in Figure 5B, and their corresponding mass spectra are shown in panels D−F of Figure 6, confirming that the new compounds produced are monorhamnolipids with the RhL-2 structure, i.e., R−C_8, R−C_{10}, and R−C_{12}. There are other possible RhL-2 and RhL-4 structures (i.e., R−$C_{10:1}$, R−$C_{12:1}$, R−R−$C_{10:1}$, and R−R−$C_{12:1}$) in addition to the three RhL-2 rhamnolipids formed from hydrolysis of RhL-1 and the three RhL-4 rhamnolipids from RhL-3. However, these structures are not seen in the product spectra. It should be noted that the broad signal appearing around 16−18 min of retention time in both panels A and B of Figure 5 (except for the 0 h starting reactants of RhL-3 and RhL-1) is from the sodium acetate present in the reaction mixture samples. The final reaction mixture required further purification techniques to collect only the RhL-2 and RhL-4 produced. Purification was performed by silica column chromatography, to remove the salt and hydroxyl fatty acids (see part 3 of the Supporting Information). The hydroxyl fatty acids collected were analyzed, and their structures were confirmed by MS (see part 3 of the Supporting Information). RhL-2 and RhL-4 thus produced were used in the later anti-zoospore tests. Industrial uses of the hydroxyl fatty acids obtainable from this simple base-catalyzed hydrolysis potentially improve the overall process economics of rhamnolipid production and applications.

Enzymatic Conversion of RhL-3 to RhL-1. Rhamnolipids mostly include RhL-1 and RhL-3, and the ratio of RhL-1/RhL-3 affects the rhamnolipid mixture physical properties. The monorhamnose RhL-1 is less hydrophilic than its dirhamnose

DOI: 10.1021/acs.jafc.5b00033
J. Agric. Food Chem. 2015, 63, 3367−3376

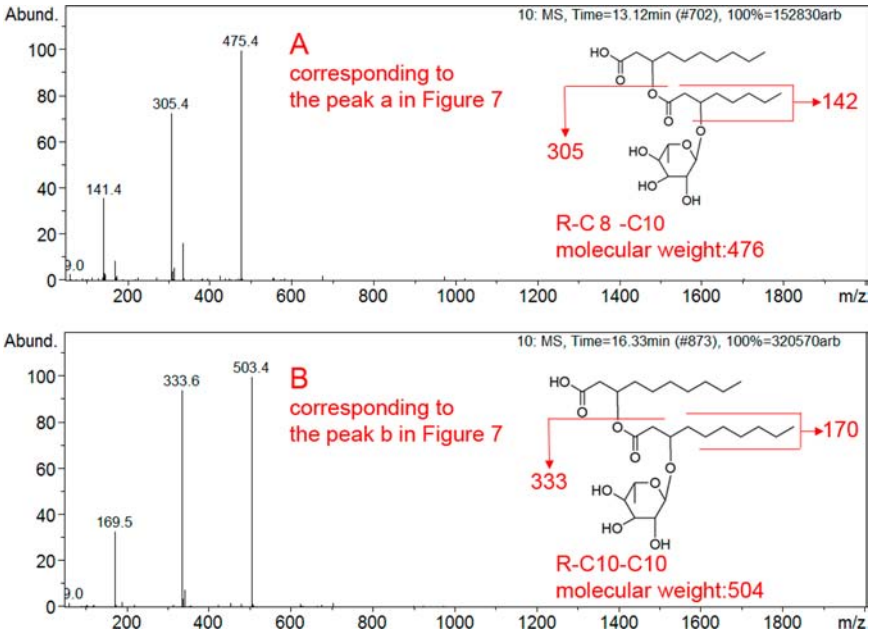

Figure 8. MS spectra for the isolated product peaks a and b in Figure 7.

RhL-3 counterpart with the same fatty acid residue. Accordingly, the critical micelle concentration (cmc) of RhL-1 is usually lower than that of RhL-3. For example, at pH 7, the cmc of RhL-1 is about 0.035 mM, while that of RhL-3 is about 0.110 mM.[23,27−29] These different properties might make different rhamnolipid mixtures more suitable for different applications. There are several ways to alter the ratio of RhL-1/RhL-3. This ratio varies with the fermentation conditions.[30,31] For example, mixtures of higher RhL-1 contents can be produced using vegetable oil as the carbon source in the fermentation.[31] The disadvantage is that the total yield of rhamnolipids also changes significantly with different fermentation substrates and/or conditions. A second approach is to first separate RhL-1 and RhL-3 and then blend them at different ratios, but the initial separation cost is high, usually relying on silica column chromatography. In current work, an enzymatic method was studied to convert RhL-3 to RhL-1. The enzymatic method not only suggests a way to tailor this ratio but also provides valuable information on the breakage of the glycosidic bond in RhL-3 *in vitro* with an enzyme as the catalyst. The latter is helpful to the understanding of the degradation of rhamnolipids in nature.

Both cellulase and cellobiase (β-glucosidase, EC 3.2.1.21) were tested for converting RhL-3 to RhL-1. No RhL-3 conversion could be detected with the cellulase alone. It is possible that the β-glucosidase activity was too low in the cellulase preparation used for this study. Note that β-glucosidase activity is mainly responsible for the intended hydrolysis of R−R disaccharide in RhL-3. On the other hand, RhL-3 hydrolysis was observed to take place with the cellobiase as the catalyst, as shown in Figure 7, in which RhL-3 rhamnolipids appear as a group of peaks 1 (and 1′)−5, similar to those in earlier figures. However, here, peak 1, which in earlier figures was described as the structure R−R−C_{10}−C_8 without differentiation of the order of the two fatty acid residues C_{10} and C_8, can clearly be seen to consist of two overlapping peaks. Peak 1′, which appears slightly earlier, has the structure of R−R−C_{10}−C_8, and the following peak 1 is R−R−C_8−C_{10}, as confirmed by MS analysis. With increasing reaction time, up to 24 h, the intensities of peaks 1 and 1′ are seen to clearly decrease but not the intensities of other peaks 2−5. Furthermore, two new peaks a and b appear and increase in intensity with the progress of reaction. The mass spectra for these new peaks a and b are shown in Figure 8, indicating that peak a is a combination of R−C_{10}−C_8 and R−C_8−C_{10} and peak b is R−C_{10}−C_{10}. According to the product peaks formed, R−R−C_{10}−C_8, R−R−C_8−C_{10}, and R−R−C_{10}−C_{10} were hydrolyzed by cellobiase to their corresponding monorhamnolipid counterparts, while no conversion was detected for R−R−C_{10}−$C_{12:1}$ and R−R−C_{10}−C_{12}. The conversions of R−R−C_8−C_{10} and R−R−C_{10}−C_8 appear to be the most significant, with the R−R−C_8−C_{10} conversion likely being faster. This is supported by two observations: the intensity of fragment R−C_8−C_{10} (m/z 305) is stronger than that of fragment R−C_{10}−C_8 (m/z 329) in Figure 8A, and peak 1 intensity decreases faster than peak 1′ intensity in Figure 7. It is possible that the enzymatic conversion is related to the fatty acid chain length. R−R−C_8−C_{10} and R−R−C_{10}−C_8 have the shortest chain length and are hydrolyzed the most. R−R−C_{10}−C_{10} is also hydrolyzed. The longest fatty acid chains in R−R−C_{10}−$C_{12:1}$ and R−R−C_{10}−C_{12} might have affected the affinity of these rhamnolipids for the active site of the enzyme. Cellobiase is supposed to act on the cellobiose released during enzymatic breakdown of cellulose. Rhamnose is not present in usual cellulose. The observed results of RhL-3 conversion with cellobiase suggest that the enzyme can also hydrolyze the dirhamnose residue of RhL-3 but not those with fatty acid residues longer than C_{10}−C_{10}.

Anti-zoospore Tests. RhL-1−RhL-4 and the synthesized diacids were investigated for their anti-zoospore effects. The results are shown in Table 2. RhL-1−RhL-4 have similar anti-zoospore effects, although RhL-1 appears to be most potent. This is inconsistent with the previous report that RhL-3 has better anti-zoospore property than RhL-1.[7,8] The discrepancies might arise from different choices for zoospores and different rhamnolipid compositions used in the various studies. More importantly, RhL-2 and RhL-4 are found to have anti-zoospore effects similar to RhL-1 and RhL-3. This finding sheds some

RhL-4	−	−	−	*	*	*	*	*
diacids (e.g., C_{10}−C_{10})	−	−	−	−	−	−	−	*

[a]"−", moving zoospores were observable; "*", all zoospores ceased moving; most were lysed.

light on the anti-zoospore mechanism of rhamnolipids. It does not support the hypothesis that the unique diacid structure of rhamnolipids plays a critical role in the anti-zoospore effect.

A wide range of cmc has been reported for rhamnolipid mixtures, because of the varying structures, e.g., 5−40 mg/L for RhL-1 and RhL-3 with two hydrophobic tails and around 200 mg/L for RhL-2 and RhL-4 with only one hydrophobic tail.[32] In this study, the critical anti-zoospore concentrations to stop movement of all zoospores for RhL-1−RhL-4 are found to be in the range of 20−40 mg/L (Table 2), which are much lower than the cmc of about 200 mg/L for RhL-2 and RhL-4. Therefore, while micelles might be present in the test solutions of RhL-1 and RhL-3 at their critical anti-zoospore concentrations, micelles were unlikely to be formed in the test solutions of RhL-2 and RhL-4 at those concentrations (30 and 40 mg/L). The finding implies that micelle formation and the associated solubilization of membrane lipids or other hydrophobic cell components are not an essential mechanism responsible for the anti-zoospore effect.

The diacids also exhibit the anti-zoospore effect (Table 2). The diacids are more effective against zoospores than most of the other biosurfactants tested in the literature;[7] more than 1000 mg/L of those biosurfactants (sophorolipids, trehalose lipid, and surfactin) are required to totally cease zoospore movement,[7] while approximately 125 mg/L diacids are required. Diacids are more hydrophobic and less soluble than RhL-1−RhL-4. The diacids make a clear solution in water at 100 mg/L but form a slightly white, turbid suspension at 1000 mg/L. The hydrophobicity of the diacids might affect their interactions with the surface of zoospores; the rhamnose residue in rhamnolipids lowers this hydrophobicity and significantly enhances the anti-zoospore effect of the biosurfactants. Overall, the results indicate that rhamnolipids are very effective against the zoospores of *P. sojae* and that, when applied to natural environments, the degradation intermediates, including RhL-2 and RhL-4 (which have lost one fatty acid residue) and the free diacids separated from the rhamnose residue, can continue to exert the anti-zoospore effect.

In summary, although RhL-1 and RhL-3 are produced in large quantities in *P. aeruginosa* fermentation, RhL-2 and RhL-4 and the free diacids can be synthesized from RhL-1 and RhL-3 using the methods developed in this study. Rhamnose, a valuable co-product, can be obtained from some of the conversion reactions developed. β-Hydroxy fatty acids can also be produced when generating RhL-2 and RhL-4 from RhL-1 and RhL-3. The possibility of adjusting the ratio of RhL-1/RhL-3 in the rhamnolipid mixture to better suit the specific application is further demonstrated using the cellobiase enzyme as a catalyst, and the enzyme is shown to have higher selectivity toward dirhamnolipids with shorter fatty acid chains. RhL-1−RhL-4 and the free diacids are all found to be very effective in damaging the zoospores of *P. sojae*, with RhL-1 being the most effective and the diacids the least effective among them. The results indicate that the combined structure of β-hydroxy fatty acid and sugar significantly enhances the anti-zoospore effect. This finding may be helpful to the further development of anti-zoospore chemicals. These results also indicate that, when applied to natural environments, the degradation intermediates, including the RhL-2 and RhL-4 that have lost one fatty acid residue (from RhL-1 and RhL-3) and the free diacids separated from the rhamnose residue, can all continue to exert the anti-zoospore effect.

and discovery of novel ametoctradin analogues and fungicides targeting the bc_1 complex.

MATERIALS AND METHODS

General Methods. Unless otherwise noted, all chemical reagents were commercially available from Acros Organics and/or Sigma-Aldrich and treated with standard methods before used. ^{1}H NMR spectra were recorded in $CDCl_3$ or DMSO-d_6 solution on a varian Mercury 600 or 400 MHz spectrometer. Chemical shifts were recorded in parts per million (ppm), with TMS as the internal reference. The following abbreviations were used to designate chemical shift multiplicities: *s* = singlet, *d* = doublet, *t* = triplet, *m* = multiplet, *br* = broad; MS spectra were determined with a Tracems2000 organic mass spectrometer, and signals were given in *m*/*z*. Melting points were measured on a Buchi B-545 melting point apparatus. Element analyses (EA) were measured on a Vario ELIII CHNSO elemental analyzer. The silica gel (200−300 mesh) for flash column chromatography was purchased from QingDao Marine Chemical Factory in China.

General Procedure for the Preparation of Intermediate 2.[18−20] Under a nitrogen atmosphere, THF (tetrahydrofuran, 30 mL) and anhydrous acetonitrile (25 mmol) was mixed and stirred for 5 min at −78 °C. BuLi (2.M) was added into the mixture and stirred for 1 h at −78 °C. Then, different substituent benzyl bromide was added dropwise slowly and then the mixture was stirred for 20 min and monitored by TLC detection. After 20 min, the reaction was complete. The resulting suspension was then diluted with water (15 mL) and extracted with ethyl acetate (2 × 25 mL). The combined organic extracts were washed with brine (2 × 25 mL), dried with Na_2SO_4, and concentrated, and the residue was purified by flash chromatography on silica gel to provide the desired product.

General Procedure for the Preparation of Intermediate 3.[18−20] A mixture of solid potassium methoxide (1.75g) and *o*-xylene (2.7 mL) was stirred and heated with reflux. When the mixture changed to light yellow, as monitored by HPLC detection, only 10% of **2** (total 10 mmol) and ester (total 20 mmol) were added in 5 min and then stirred for 15 min. The complete addition required another 10 min. The reaction mixture was refluxed 2.5 h and was allowed to warm room temperature. Water (3.3 mL) was added to the reaction mixture with pH equal to 5−6 adjusted by adding 20% hydrochloric acid. Then it was extracted with ethyl acetate (3 × 15 mL). The combined organic extracts were washed with brine 15 mL and dried with Na_2SO_4 to yield 2-propionyldecanonitrile.

General Procedure for the Preparation of the Title Compounds 4a ∼ z. A mixture of **3** (3 mmol), 1,2,4-triazol-3-amine (3 mmol), and *o*-xylene (2.5 mL) was quickly stirred, and then $ClSO_3H$ (0.6 mmol) was slowly added dropwise. The reactive temperature was heated to 160 °C under reflux for 12−16 h as monitored by TLC detection. The mixture was cooled to room temperature, and the product was precipitated in the form of colorless crystals. Water (5 mL) was added to the reaction mixture with pH equal to 8−9 adjusted by adding 20% triethylamine. Finally, the precipitate was purified by flash chromatography on silica gel to provide the desired product. Due to the complexity of reaction, the yield of some compound is lower than 10%. Our purpose was to obtain a certain compound to assay its activity. So, we did not to optimize the reaction condition to increase the yield.

5-Ethyl-6-octyl-1,2,4-triazolo[1,5-*a*]pyrimidin-7-amine (ametoctradin). Yield: 76%; mp 197.7−198.7 °C; ^{1}H NMR (600 MHz, d_6-DMSO) δ 8.33 (s, 1H), 7.71 (s, 2H), 2.74 (q, *J* = 7.2 Hz, 2H), 2.63−2.56 (m, 2H), 1.41 (d, *J* = 13.8 Hz, 4H), 1.33−1.19 (m, 11H), 0.86 (t, *J* = 6.6 Hz, 3H); MS: *m*/*z* = 275.33 (M+).

6-Octyl-5-(*p*-tolyl)-1,2,4-triazolo[1,5-*a*]pyrimidin-7-amine (4a). Yield: 10%; mp 156−158 °C; ^{1}H NMR (600 MHz, d_6-DMSO): δ 8.44 (s, 1H), 8.01 (s, 2H), 7.34 (d, *J* = 7.2 Hz, 2H), 7.28 (d, *J* = 7.2 Hz, 2H), 2.56 (s, 2H), 2.38 (s, 3H), 1.33 (s, 2H), 1.25 (d, *J* = 12.0 Hz, 2H), 1.23−1.16 (m, 2H), 1.08 (dd, *J* = 42.6, 6.0 Hz, 6H), 0.83 (t, *J* = 7.2 Hz, 3H); MS: *m*/*z* = 337.27 (M+). Anal. Calcd for $C_{20}H_{27}N_5$: C, 71.18; H, 8.06; N, 20.75. Found: C, 71.22; H, 8.102; N, 20.50.

6-Octyl-5-(3-(trifluoromethyl)phenyl)-1,2,4-triazolo-[1,5-*a*]pyrimidin-7-amine (4b). Yield: 11%; mp 130−131 °C; ^{1}H NMR (600 MHz, $CDCl_3$): δ 8.42 (s, 1H), 7.78 (s, 1H), 7.73 (dd, *J* = 15.6, 7.2 Hz, 2H), 7.62 (t, *J* = 7.8 Hz, 1H), 6.00 (s, 2H), 2.60−2.55 (m, 2H), 1.58−1.46 (m, 2H), 1.23 (dd, *J* = 25.2, 19.8 Hz, 10H), 0.86 (t, *J* = 67.2 Hz, 3H). Anal. Calcd for $C_{20}H_{24}F_3N_5$: C, 61.37; H, 6.18; N, 17.89. Found: C,61.35; H, 6.070; N, 18.01.

5-(3-Chlorophenyl)-6-octyl-1,2,4-triazolo[1,5-*a*]-pyrimidin-7-amine (4c). Yield: 7%; mp 154−155 °C; ^{1}H NMR (600 MHz, d6-DMSO): δ 8.47 (s, 1H), 8.12 (s, 2H), 7.58−7.47 (m, 3H), 7.42 (d, *J* = 7.2 Hz, 1H), 2.53 (d, *J* = 7.8 Hz, 1H), 1.39- 1.28 (m, 2H), 1.21 (dd, *J* = 13.8, 7.2 Hz, 2H), 1.17- 0.99 (m, 8H), 0.83 (t, *J* = 7.2 Hz, 3H); MS: *m*/*z* = 357.26 (M+). Anal. Calcd for $C_{19}H_{24}ClN_5$: C, 63.77; H, 6.76; N, 19.57. Found: C, 63.61; H, 6.783; N, 19.31.

5-Ethyl-6-propyl-1,2,4-triazolo[1,5-*a*]pyrimidin-7-amine (4d). Yield: 64%; mp 179−181 °C; ^{1}H NMR (400 MHz, d_6-DMSO): δ 8.34 (s, 1H), 7.74 (s, 2H), 2.75 (d, *J* = 7.2 Hz, 2H), 2.58 (s, 2H), 1.45 (s, 2H), 1.23 (t, *J* = 7.2 Hz, 3H), 0.98 (t, *J* = 6.8 Hz, 3H); MS: *m*/*z* = 205.06 (M+). Enzyme Assays. The preparation of succinate−cytochrome c reductase (SCR, mixture of respiratory complex II and bc_1 complex) from porcine heart was essentially as reported.[21] The activity of SCR was measured by monitoring the increase in absorbance of cytochrome c_1 at 550 nm, by using the extinction coefficient of 18.5 mM^{-1} cm^{-1}. The succinate−ubiquinone reductase (complex II) activity was measured by monitoring the decrease in absorbance of 2,6-dichlorophenolindophenol (DCIP) at 600 nm, by using the extinction coefficient of 21 mM^{-1} cm^{-1}. The reaction mixture may be scaled down to 1.8 mL with final concentrations of PBS (pH 7.4), 100 mM; EDTA, 0.3 mM; succinate, 20 mM; oxidized cytochrome c_1, 60 uM (or DCIP, 53 uM); and appropriate amounts of enzyme to start the reaction. The ubiquinol−cytochrome c_1 reductase (bc_1 complex) activity in catalyzing the oxidation of DBH_2 by cytochrome c_1 was assayed in 100 mM PBS (pH 7.4), 0.3 mM EDTA, 750 uM lauryl maltoside (*n*-dodecyl-β-D-maltoside), 20−120 uM DBH_2, 100 uM oxidized cytochrome c_1, and an appropriate amount of SCR. The preparation of DBH_2 from DB was carried out according to the procedure described in previous publications, and the concentration of DBH_2 was determined by measuring the absorbance difference between 288 and 320 nm by using an extinction coefficient of 4.14 mM^{-1} cm^{-1} for the calculation. For the steady-state studies, the reaction was carried out in the absence or presence of various concentrations of the inhibitor.[21]

Data Analysis. The concentrations at 50% inhibition (absolute IC_{50} values) for experiments with SCR were obtained from a nonlinear regression of the activity data according to a four parameter logistic model. The absolute IC_{50} was calculated according to eq 1.

$$y = \min + \frac{\max - \min}{1 + 10^{x - \log IC_{50}}} \quad (1)$$

Sigma Plot software 9.0 was used to determine all kinetic constants.

Computational Methods and Binding-Free-Energy Calculations. *Molecular Docking.* The three-dimensional (3D) structure of bc_1 complex was obtained from PDB database (PDB ID: 1PPJ, from bovine). The AutoDock 4.2 program[22] was applied to dock ametoctradin and its derivates into the Q_o and or Q_i site of the bc_1 complex. The Gasteiger charges were used for these inhibitors. To select the best set of docking parameters and to test the reliability of the docking results, the antimycin and stigmatellin were first docked into the Q_i and Q_o site, respectively. In the docking process, a conformational search was performed for the antimycin/stigmatellin molecule using the Solis and Wets local search method, and the Lamarckian genetic algorithm (LGA)[23,24] was applied for the conformational search of the binding complex of antimycin/stigmatellin with bc_1 complex. Among a series of docking parameters, the grid size was set to be 40 × 40 × 40, and the used grid space was the default value of 0.375 Å. The interaction energy that resulted from probing the cyt *b* with the antimycin/stigmatellin molecule was assessed by the standard AutoDock scoring function. Among a set of 100 candidates of the docked complex structures, the best one was first selected according to the interaction energy and was then compared with the conformation of antimycin/stigmatellin extracted from the crystal structure. By tuning the docking parameters, the final antimycin/stigmatellin-bc_1 complex was obtained, based on the smallest root-mean-square deviation (rmsd) of the docked conformation of antimycin/stigmatellin from its conformation in the crystal structure. The RMSD between the selected conformation and previously noted in the X-ray crystal structure is 0.84 for stigmatellin and 0.89 for antimycin (data not shown), confirming the reliability of docking parameters. The same docking parameters were adopted to perform molecular docking of other compounds.

Molecular Dynamics Simulations. All the complex structures derived from molecular docking were used as starting structures for further energy minimizations using the Sander module of the Amber8 program before the final binding structures were achieved. The Amber ff99 force field was used for amino acid and General Amber force field was used for ligands. For temperature regulation, the Langevin thermostat was used to maintain a temperature of 300 K. The bcc charges were used as the atomic charges for ligands. There are two stages for energy minimization. First, the ligand was minimized with the protein fixed. Second, the backbone atoms of the protein were fixed, and other atoms were relaxed. The final minimization was performed with both the ligand and the protein relaxed. In each step, the energy minimization was executed by using the steepest descent method for the first 1000 cycles, and the conjugated gradient method for the subsequent 3000 cycles, with a convergence criterion of 0.1 kcal mol^{-1} $Å^{-1}$. The atomic coordinates were saved every picosecond. Then, an additional 10 ns MD simulation was performed for ametoctradin-Q_o and ametoctradin-Q_i complex. In order to reduce the computational cost, only 20 ps MD simulations were performed for 12 newly synthesized analogues.

MM/PBSA Calculation. For ametoctradin-Q_o and ametoctradin-Q_i, 100 snapshots of the simulated structure within the

stable MD trajectory were selected and minimized to perform the MM/PBSA calculations (see below). For newly synthesized analogues, the last snapshot of the MD simulation was minimized to a convergence criterion of 0.1 kcal mol^{-1} Å^{-1}. Then, the ΔH calculation was performed on the minimized complex, as described elsewhere.[25,26]

In this method, the binding free energy of the protein−ligand complex (ΔG_{bind}) is obtained from the difference between the free energies of the protein−ligand complex (ΔG_{cpx}), the unbound receptor ($\triangle G_{rec}$), and the free ligand ($\triangle G_{lig}$) as follows:

$$\Delta G_{bind} = \triangle G_{cpx} - \triangle G_{rec} - \triangle G_{lig} \quad (2)$$

The binding free energy (ΔG_{bind}) can be evaluated as the sum of the changes in the molecular mechanical (MM) gas-phase binding energy (ΔE_{MM}), solvation free energy (ΔG_{sol}), and entropic contribution ($-T\Delta S$). The ΔE_{MM} was evaluated as a sum of electrostatic energy (ΔE_{ele}) and van der Waals interaction energy (ΔE_{vdw}).

$$\Delta G_{bind} = \Delta E_{MM} + \Delta G_{sol} - T\Delta S \quad (3)$$

$$\Delta E_{MM} = \Delta E_{ele} + \Delta E_{vdw} \quad (4)$$

The solvation free energy ΔG_{sol} was composed of two parts:

$$\Delta G_{sol} = \Delta G_{PB} + \Delta G_{np} \quad (5)$$

$$\Delta G_{np} = \gamma SASA + \beta \quad (6)$$

The electrostatic contribution to the solvation free energy (ΔG_{PB}) is evaluated by Poisson−Boltzmann (PB) methods. The nonpolar solvation energy, ΔG_{np}, can be estimated by an empirical relation of $\Delta G_{np} = \gamma SASA + \beta$, where SASA and is defined as the solvent-accessible surface area, and the solvation parameters γ and β were set to 0.00542 kcal·mol^{-1} Å^{-2} and 0.92 kcal·mol^{-1}, respectively. The dielectric constant for the molecule and surrounding solvent were set to 1 and 80, and the probe radius of the solvent was set to 1.4 Å.

The entropy contribution to the binding free energy can be divided into two parts: the solvation free entropy (ΔS_{solv}) and the conformational free entropy (ΔS_{conf}).

$$\Delta S_{sol} = \Delta S_{solv} + \Delta S_{conf} \quad (7)$$

The solvation free entropy is gained by the tendency of water molecules to minimize their contacts with hydrophobic groups in protein. The conformational free entropy is related to the change of the number of rotatable bonds during the binding process. The detailed computational procedure used to evaluate the entropy contribution ($-T\Delta S$) to the binding free energy was as previously described.[26]

RESULTS AND DISCUSSION

Synthetic Chemistry of the Title Compounds. As shown in Scheme 1, the target compounds **4a** ∼ **z** were smoothly prepared by a three-step synthetic route using bromide compound as starting materials. Compound **2**, resulting from the reaction of bromide compound with acetonitrile, underwent an elimination reaction with substituent ester to afford the key intermediates β-ketonitriles (**3**). By performing the cyclization reaction with 1,2,4-triazol-3-amine, compound **3** was successfully transformed into the corresponding substituted 1,2,4-triazolo[1,5-*a*]pyrimidine derivates **4a** ∼ **z**.

The structures of all synthesized compounds were characterized by element analyses, ^{1}H NMR, and GC-MS techniques. The crystal structure of ametoctradin was determined by X-ray diffraction analysis (CCDC 981965). As shown in Figure 2, the crystal structure showed that ametoctradin had an extended conformation.

Inhibition Effect against *bc*$_1$ Complex of Compounds 4a ∼ z. SCR is the mixture of respiratory complex II and the *bc*$_1$ complex (complex III), which was also deemed to form complex II−complex III supercomplexes.[27] Complex II (also

known as succinate-ubiquinone oxidoreductase, SQR) first passes electrons from succinate to ubiquinone, and then the cytochrome bc_1 complex passes electrons from reduced ubiquinone to cytochrome c_1. The activity of complex II in SCR was selectively determined using succinate and dichlorophenolindophenol (DCIP) as substrates, and the activity of only the cytochrome bc_1 complex in SCR was determined using decylubiquinol (DBH_2) and cytochrome c_1 as substrates, whereas the overall activity of SCR (both complex II and bc_1 complex) was determined using succinate and cytochrome c_1 as substrates.[28,29]

The results indicated that all of the compounds exhibited no effect on the activity of complex II (data not shown) but markedly inhibited the activities of the bc_1 complex and SCR. As shown in Table 1, some compounds showed very high percent inhibition, such as **4a** (82%), **4q** (92.8%), **4o** (94.3%), **4m** (84.1%), against porcine SCR. To reduce the time and workload of the biological assay, the IC_{50} values of some compounds were not determined when its percent inhibition was less than 50%. Among the **26** newly synthesized compounds, **4a** was identified as the most potent inhibitor with a IC_{50} value of 0.12 μM against SCR from porcine heart mitochondria (Table 1), which indicated that the potency of **4a** against porcine SCR is nearly twice as much as ametoctradin (0.3 μM). In addition, when R^1 was $-CH_2(CH_2)_6CH_3$ and or substituent $-CH_2Ph$, the inhibitor always displayed much higher potency against porcine SCR, such as compound **4a**, **4c**, **4m**, **4o**, and **4q**. Remarkably, 2-substituent and or 3-substituent benzyl derivatives in R^1 displayed lower antifungal activity compared with the 4-substituent. These results indicated that the substituent on R^1 will affect the bioactive conformation of inhibitors, which would lead to different binding free energy of a ligand toward the protein and would be discussed in the following section.

Binding Mode of Ametoctradin. Although ametoctradin has been known as inhibitor of cytochrome bc_1 complex for many years, its detailed binding mode is still unknown so far. Many existing studies have shown that molecular docking is a very powerful technique to predict the binding mode of ligands;[30−34] therefore, the AutoDock4.2 program was integrated with the molecular dynamic simulations and MM/PBSA calculation to uncover the detailed binding mode of ametoctradin.

Before docking, sequence alignment of cytochrome bc_1 complex from different species was performed (the data were included in the Supporting Information). The bovine cytochrome b (1PPJ)[35] showed about 50.92% sequence identity with yeast (3CX5),[36] 74.67% with chicken (1BCC),[11] 49.08% with *Rhodobacter capsulates* (1ZRT),[37] and 48.02% with *Paracoccus denitrificans* (2YIU).[38] In addition, the residues around the Q_o-site region are highly conserved. Up to now, most crystal structures of inhibitor-bound bc_1 complex are from vertebrate heart, such as bovine and chicken. Previously, we used the bovine bc_1 complex (PDB ID: 1PPJ) as the receptor model to study the binding mode of some new Q_o-site inhibitors, which successfully guided the design of a series of new subnanomolar, even picomolar, Q_o site inhibitors of bc_1 complex.[39,40] Hence, the bovine PDB crystal structure (1PPJ) was selected herein as receptor model.

As mentioned before, there are two binding sites in the cytochromore bc_1 complex, a quinone reduction site near the negative side of the membrane (Q_i site) and a quinol oxidation

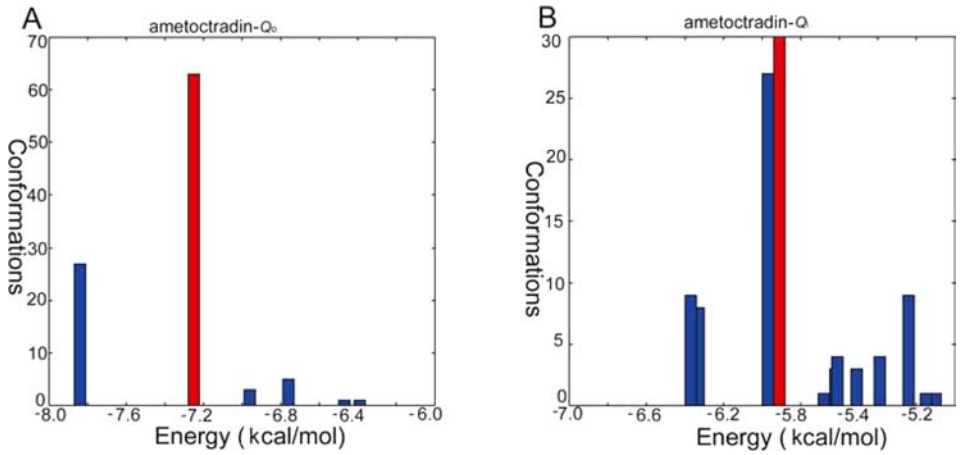

Figure 3. Binding energy of ametoctradin with bc_1 complex in Q_o (A) and Q_i (B) site. The red and blue histogram means the right and wrong binding mode, respectively. The figure was directly obtained from AutoDock cluster analysis with default parameters. Based on our knowledge, the 1,2,4-triazolo[1,5-*a*]pyrimidine ring in ametoctradin should locate into the $Q_{o/i}$-site, and then this binding mode cluster was defined as right. On the contrary, it was defined as wrong when 1,2,4-triazolo[1,5-*a*]pyrimidine ring pointed to other position in $Q_{o/i}$-site, such as the entrance of $Q_{o/i}$-site.

Table 2. Binding Free Energy of Ametoctradin in the Q_o and Q_i site (kcal/mol)

	AutoDock binding energy	ΔE_{ele}[a]	ΔE_{VDW}[a]	ΔE_{np}[a]	ΔE_{pol}[a]	ΔH_{PB}[a]
ametoctradin-Q_i	−6.0	−15.49	−38.97	−5.16	38.50	−21.11
ametoctradin-Q_o	−7.0	−18.27	−46.23	−5.10	45.15	−24.46

[a]Obtained from 10 ns MD simulation.

site close to the positive side of the membrane (Q_o site). Then, we, respectively, docked ametoctradin into the Q_o and Q_i sites, and obtained two ametoctradin-bound complexes, ametoctradin−Q_o and ametoctradin−Q_i complex (Figure 1S, Supporting Information). As shown in Figure 3, the Q_o site binding energy of ametoctradin (about −7.0 kcal/mol) was more favorable than the Q_i site binding energy (about −6.0 kcal/mol), showing that ametoctradin might be a Q_o site inhibitor. Then, we performed 10 ns molecular dynamics (MD) simulations for ametoctradin−Q_o and ametoctradin−Q_i complex (Figure 2S, Supporting Information), and the 100 snapshots obtained from the last 1 ns of each complex were used to calculate the binding free energy using MM/PBSA module. As shown in Table 2, the binding energies (ΔH) of ametoctradin−Q_o and ametoctradin−Q_i are −24.46 and −21.11 kcal/mol, respectively. It is necessary to point out that, if we prolonged the simulation time (e.g., 12 ns), ametoctradin would leave from the ametoctradin−Q_i complex, whereas the ametoctradin−Q_o complex remains very stable (data not shown). On the basis of these results, we proposed that ametoctradin should bind into the Q_o site of bc_1 complex.[41]

It is very interesting to compare the MD-simulated ametoctradin−Q_o complex with the existing crystal structures of Q_o site inhibitor-bound bc_1 complex. According to the reported crystal structures of Q_o site inhibitor-bound bc_1 complex,[4] the E271 and F274 would always form an H-bond and hydrophobic interaction with the inhibitor, indicating that both residues played an important role in the binding of Q_o site inhibitors.[39,40,42] For example, stigmatellin forms an H-bond with E271 and H161 and hydrophobic interaction with F274 (PDB code: 1PPJ)[35] (Figure 4A). As shown in Figure 4B, the amine group of ametoctradin also formed an H-bond with E271, and the aliphatic chain of ametoctradin formed a hydrophobic interaction with F274, F128, I146, L149, and L294 when binding into the Q_o site. As we knew, the long

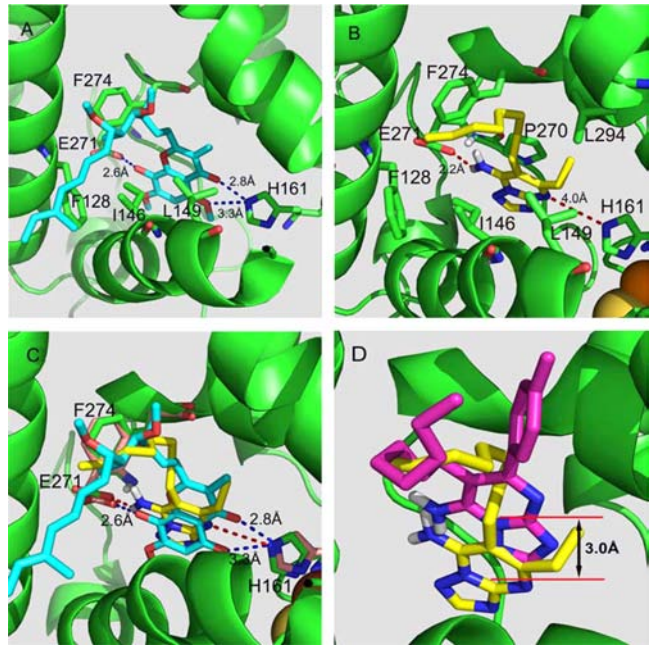

Figure 4. (A) Binding mode of stigmatellin in the Q_o site. The blue line represents the H-bond distance between stigmatellin and residue. (B) Binding mode of ametoctradin in the Q_o site. The red line represents the H-bond distance between ametoctradin and residue. (C) The overlay of ametoctradin and stigmatellin in the Q_o site. For clarity, only the key residues were shown. aliphatic substituent in antimycin and stigmatellin adopted an extended conformation in the crystal complex structure (PDB code: 1PPJ). Therefore, it was reasonable that the octyl group in ametoctradin also took on an extended conformation, and

DOI: 10.1021/acs.jafc.5b00228
J. Agric. Food Chem. 2015, 63, 3377−3386

then 1,2,4-triazolo[1,5-*a*]pyrimidine ring in ametoctradin formed a hydrophobic interaction with P270. However, the distance between ametoctradin and H161 is 4.0 Å, which could account for the reason why ametoctradin (IC_{50} = 0.3 μM) has lower binding affinity than stigmatellin (IC_{50} = 2.4 nM for bc_1 complex from bovine heart) (Figure 4C,D).[43,44]

As we know,[45] the G143A mutation showed a nearly killing effect upon all of strobilurin inhibitors, whereas ametoctradin did not show cross-resistance to strobilurin fungicides.[16,17] The resistance mechanism for G143A mutation was that residue A143 would create steric hindrance between the methoxyacrylamide moiety of inhibitor and cytochrome *b*.[44,46] Schiffer et al.[47,48] had pointed out that the residue mutation would lead to less effect upon ligand activity with longer distance between ligand and residue. Therefore, we monitored the distance between ametoctradin with G143. As shown in Figure 5A, the closest distance between Gly143 and ametoctradin was about 4.2 Å, while it decreased to 3.6 Å with azoxystrobin (1SQB). The binding free energy of azoxystrobin upon G143A mutant and wild type bc_1 complex were, respectively, −23.59 kcal/mol and −26.74 kcal/mol (IC_{50} = 21 nM toward wild type bc_1 complex from yeast; IC_{50} = 1394 nM toward G143A mutant bc_1 form yeast[44]), which accounted for the resistance mechanism of G143A mutation to azoxystrobin. On the contrary, the closest distance between Gly143 in wide type bc_1 complex and ametoctradin was about 4.2 Å, while the closest distance between A143 in mutant bc_1 complex and ametoctradin decreased to 3.7 Å (Figure 5B). As a result, the binding free energy of ametoctradin upon G143A mutant and wild type bc_1 complex were −25.61 kcal/mol and −21.68 kcal/mol, respectively, which means G143A mutation increased the binding affinity of ametoctradin. These results showed that the established binding mode of ametoctradin should be reasonable.

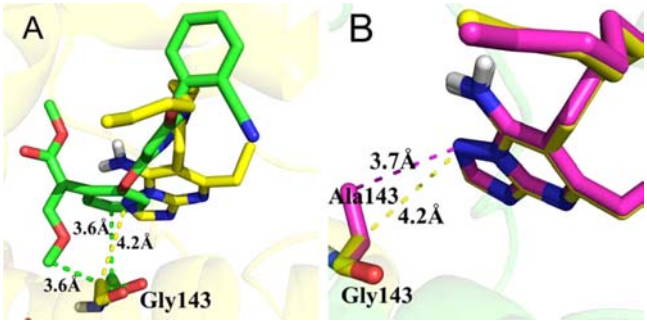

Figure 5. (A) Binding mode overlay between ametoctradin (yellow sticks) and azoxystrobin (PDB code 1SQB, green sticks). (B) The binding mode overlay of ametoctradin with wide type bc_1 complex (yellow stick) and G143A mutation (magenta stick). For clarity, only Gly143 or Ala143 was shown as a stick.

Binding-Free-Energy Calculation. In order to further confirm the binding mode of ametoctradin and understand the structure−activity relationships of ametoctradin analogues at the atomic level, we carried out molecular docking for 12 newly synthesized analogues with determined IC_{50} values and calculated their binding free energies using MM/PBSA method for the resulted analogue−Q_o and analogue−Q_i complex (Table 3), respectively.

For the analogue−Q_o complex, the correlation coefficients (R^2) between the experimental binding free energies (ΔG_{exp}, derived from the experimental binding affinities) and the calculated energy terms are 0.20 for enthalpy contribution (ΔH) and 0.64 for entropy compensation ($-T\Delta S$). Although these individual correlations are very low, the overall calculated binding free energies (ΔG_{cal}) correlated very well (R^2 = 0.96) with the experimental binding free energies (ΔG_{exp}) (Figure 6).

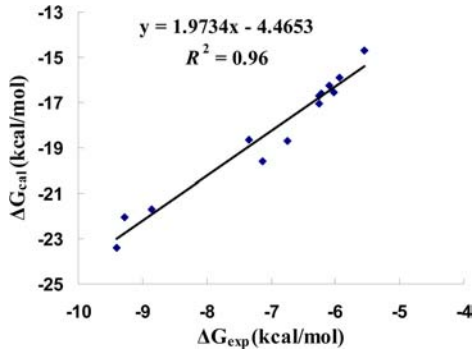

Figure 6. Correlation between the ΔG_{cal} and ΔG_{exp}.

However, for the analogue−Q_i complex, when the compounds were docked into the Q_i site, the corresponding R^2 values between ΔG_{exp} and the calculated energy terms were decreased to 0.06 for ΔH, 0.21 for $-T\Delta S$, and 0.0047 for ΔG_{cal}, respectively. Therefore, these molecular docking and binding free energy calculation results further confirmed that ametoctradin and its analogues should binding to the Q_o site of bc_1 complex.

It is very interesting to analyze the contribution of the individual energy terms. Although the enthalpy contribution (ΔH) always reflects the direct interaction between ligand and receptor, and plays an important role in the binding of ligand, the binding free energy arises from a more complex interplay between the enthalpy (ΔH) and entropy ($-T\Delta S$) terms. For the composition of enthalpy (ΔH) term, the ΔE_{VDW} (ranging from −43.83 to 49.27 kcal/mol) and the ΔE_{pol} (ranging from 31.25 to 45.10 kcal/mol) are two largest components of the binding free energy for each complex (Table 1S, Supporting Information). For the analogues bearing R^1 = $-CH_2(CH_2)_6CH_3$, their entropy term($-T\Delta S$, ranging from 8.59 to 11.67 kcal/mol) is lower than that of other compounds, but their binding affinity is higher than that of other compounds, such as **4a** (IC_{50} = 0.12 μM) and **4c** (IC_{50} = 0.15 μM). These result indicated that the R^1 group has an important role in the entropy compensation, which is a critical aspect for the binding of ametoctradin and its analogues.

The mode of ametoctradin−Q_o complex is shown in Figure 4B. As shown in Figure 4B, the octyl (R^1 group) of ametoctradin pointed to the outside of the Q_o pocket, whereas its ethyl (R^2) group inserted inside the Q_o pocket. As a result, when R^2 was a bulky group, such as substituted phenyl (4-CH_3−Ph, 3-CF_3−Ph, and 3-Cl-Ph), the compound (**4a**, **4b**, and **4c**) would move up about 3.0 Å compared to ametoctradin (Figure 4D) due to steric clash. It should be pointed out that this movement will lead to an entropy compensation, which is favorable to the binding of inhibitors.

In summary, a series of novel 1,2,4-triazolo[1,5-*a*]pyrimidine derivates **4a** ∼ **z** were designed and synthesized using ametoctradin as a lead compound. The in vitro assay indicated that compound **4a**, 6-octyl-5-*p*-tolyl-1,2,4-triazolo[1,5-*a*]-pyrimidine-7-amine, is a new inhibitor of bc_1 complex with higher binding affinity (IC_{50} = 0.12 μM) against porcine bc_1 complex than ametoctradin (IC_{50} = 0.30 μM). In addition, the results of molecular docking, molecular dynamics simulations, and MM/PBSA calculations strongly supported that ametoctradin and its analogues should bind to the Q_o site rather than the Q_i site of cytochrome bc_1 complex. Inside the Q_o pocket, ametoctradin and its analogues formed an H-bond with E721 and hydrophobic interactions with F274, F128, I146, L149, and L294.

On the basis of the results obtained from the present study, the following guidance for the future inhibitor design could be proposed: (1) 1,2,4-triazolo[1,5-*a*]pyrimidine should be substituted to form an H-bond with H161, a key residue for the binding of inhibitor; (2) Introduction of a bulky and hydrophobic group onto R^2 position is favorable to the binding due to their contribution to the entropy compensation.

shoots were cut into cylinders of 1 cm height and a mean diameter of 5 mm.

Dry Matter (DM) Content. Vine shoots were dried in a convictive oven at 105 °C for 48 h for the measurement of the DM content. The DM of Syrah, Cabernet Sauvignon, Cabernet Franc, and Tempranillo vine shoots was found to be 60, 65, 57, and 69%, respectively.

Solid−Liquid Extraction. The solid−liquid extraction process of polyphenols from cylindrical vine shoots was performed with a solid/liquid ratio of 1:20 (w/v).[8] After β-CD aqueous extraction at different concentration, time, and temperature combinations, extracts were centrifuged at 5000 rpm for 15 min. β-CD aqueous concentrations were prepared by dissolving the required weight of β-CD in the specific water volume in a 50 °C water bath under stirring.

Total Polyphenol Content (PC). The total PC was determined by the Folin−Ciocalteu colorimetric assay.[11] A total of 1 mL of Folin−Ciocalteu reagent (10-fold diluted) was mixed to 200 μL of extract. Then, 800 μL of sodium carbonate (75 g/L) was added. The mixture was incubated for 10 min at 60 °C and then 10 min at room temperature. The absorbance was measured at 750 nm by the ultraviolet/visible (UV/vis) spectrophotometer (UV- 9200, BioTECH Engineering Management, U.K.). The calibration curve was drawn with GA. PC was expressed as milligrams of gallic acid equivalent (GAE) per gram of DM.

Antioxidant Capacity (AC). The AC of vine shoot extracts was measured by means of the DPPH assay.[12] A total of 50 μL of vine shoot extracts or standard (Trolox) was added to 1.45 mL of DPPH radical (0.06 mM). After an incubation of 30 min at room temperature, the absorbance was measured at 515 nm. The DPPH value of the extracts was expressed in micromolar Trolox equivalent per milliliter (μMTE).

HPLC. The HPLC analyses were conducted for the identification and quantification of polyphenols from vine shoot extracts.[13] The HPLC−diode array detection (DAD) analyses of polyphenols were carried out with a HPLC system (Waters Alliance, Milford, MA) equipped with a quaternary Waters e2695 pump. A UV−vis photodiode array spectrophotometer Waters 2998 was used, with the control system and data collection Empower 3 software. HPLC analyses of polyphenols were carried out on a Discovery C_{18}, 5 μm, 250 × 4.6 mm, column (Supleco, Bellefonte, PA) with a C_{18}, Supelguard Discovery 18, 20 × 4 mm, 5 μm, precolumn (Supelco, Bellefonte, PA) at 30 °C. Separation of 100 μL of cane extract was performed at a flow rate of 0.5 mL min^{-1}. Mobile phase A consisting of 0.1% (v/v) formic acid in water and mobile phase B consisting of 100% acetonitrile were used. The elution profile had the following proportions (v/v) of solvent B: 5 min, 15−20%; 45 min, 20−44.5%; 1 min, 100%; kept at 100% of B for 9 min; and followed by 5 min of stabilization at 15%. Spectrophotometric detection was performed at 280 nm.

Experimental Design. The optimization of the β-CD-assisted extraction process of polyphenol from vine shoots was conducted by RSM. The independent variables were β-CD concentration, time, and temperature. They were coded at five levels (−α, −1, 0, 1, and +α), in a central composite design (2^3 + star) of 20 experiments, including six center points. Table 1 (first four columns) shows the central composite design with the range of variables and their coded values. Two responses were studied: PC and AC. Data analyses were carried out using STATGRAPHICS Plus 4.0 for Windows and were fitted to a second-degree regression equation of the form

$$Y = a_0 + \sum_{n=1}^{3} a_n X_n + \sum_{n=1}^{3} a_{nn} X_n^2 + \sum_{n=1}^{2} \sum_{m=n+1}^{3} a_{nm} X_n X_m \quad (1)$$

where Y is the response, a_0, a_n, a_m, and a_{nm} are the constant, linear, quadratic, and two factor interaction coefficients, respectively.

Statistical Analysis. Each extraction process was repeated on three different vine shoot samples. Means and standard deviations (error bars in the figures) of data were calculated. Variance analyses (ANOVA) and least significant difference (LSD) test were performed by STATGRAPHICS Centurion XV (StatPoint Technologies, Inc.).

RESULTS AND DISCUSSION

Experimental Design and Statistics. The effect of time, temperature, and β-CD concentration (β) on polyphenol extraction from vine shoots was studied. The RSM design was conceived taking into consideration the solubility limitation of β-CD at concentrations above 50 mg/mL[10] and temperature limitation because of the possible heat degradation/oxidation of polyphenols. RSM is a statistical and mathematical method employed for the development, improvement, and optimization of extraction processes.[14] Table 1 shows the experimental design and combinations of the coded variables with their responses (PC and AC). Total PC ranged from 0.36 to 2.48 mg

DOI: 10.1021/acs.jafc.5b00672
J. Agric. Food Chem. 2015, 63, 3387−3393

of GAE/g of DM, while AC was between 800.96 and 1740.37 μMTE.

The relation between the responses and the experimental parameters (β, t, and T) was demonstrated by statistical analyses to fit second-order polynomial equations shown in Table 2. The analyses of the predicted values, calculated from the regression equations, showed a high correlation with experimental values and resulted in the calculation of the coefficients of determination (R^2), which were shown to have high levels of adequacy (Table 2).

Effect of the Time, Temperature, and β-CD Concentration on PC. According to the pareto chart (Figure 1a) and the response surface plot (Figure 1b), time, temperature and β-CD concentration have linear positive effects on polyphenol extraction from vine shoots. No quadratic effects were observed nor interaction between the parameters. Excluding insignificant parameters, the regression equation becomes

$$\mathrm{PC} = -2.0886 + 0.0116057\beta + 0.196472t + 0.0461738T \quad (2)$$

The positive effect of t, T, and β was expected. The temperature augments molecular diffusion; it decreases solvent viscosity, enhancing the solute solubilization and diminishing surface tension.[15] CDs are likely to form, within their lipophilic cavities and through non-covalent forces, inclusion complexes with hydrophobic polyphenols, increasing thus their water solubility.[16,17] Time comes immediately after the temperature factor in terms of its significance (Figure 1a). It plays an important role in the diffusion process, which is a relatively slow operation of three steps: (1) internal diffusion of the solvent, (2) solubilization of the target molecule, and (3) diffusion of the solubilized molecules to the surface of the particle.[18] The significant positive effect of time is therefore expected for polyphenol extraction from vine shoots.

Effect of the Time, Temperature, and β-CD Concentration on AC. Similar to PC, AC is positively affected by the time, temperature, and β-CD concentration (Figure 2a). As shown in Figure 2b, the increase in the β-CD concentration and time of the extraction process linearly augments AC up to 1740.37 μMTE. The temporary locking of polyphenols within CD cavities stabilizes host molecules from oxidation, light, and heat degradation,[16] which probably gave linear positive effects for t, T, and β. Excluding insignificant parameters, the regression equation becomes

$$\mathrm{AC} = -812.072 + 25.3102\beta + 198.619t + 24.1344T - 4.893\beta t \quad (3)$$

Comparing the significance of the studied parameters, it can be noticed that the effect of time was more significant for extracting higher PCs but had less effect on their AC. This might be due to the oxidation phenomena that is likely to occur when subjecting polyphenols to high temperatures (>50 °C) for long durations. In contrast, the β-CD concentration played a more important role for conserving the AC of polyphenols than enhancing their quantity (PC) (Figures 1a and 2a).

Multiple Response Optimization. Figure 3 shows the overlay plots for PC and AC at 66.6 °C (optimal temperature). As marked by the black dot, the optimal conditions for the maximization of PC are 46.8 mg/mL β-CD for 6.2 h, while those for AC are 46.8 mg/mL β-CD for 0.7 h. These are the quantitative and qualitative optimums, respectively. However, for industrial applications of vine-shoot-derived polyphenols, it

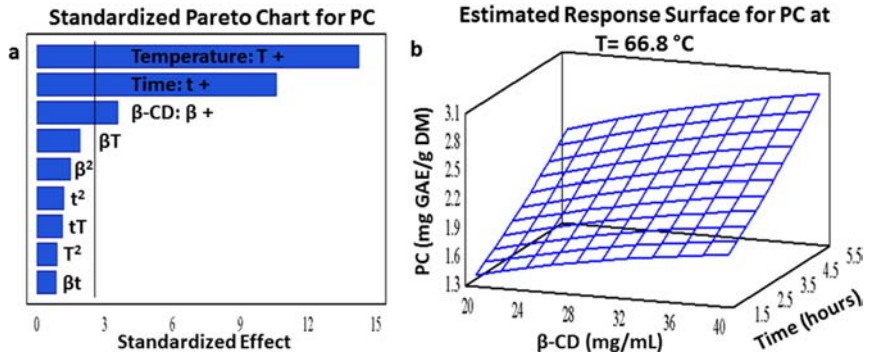

Figure 1. (a) Standardized pareto chart and (b) estimated response surface for PC.

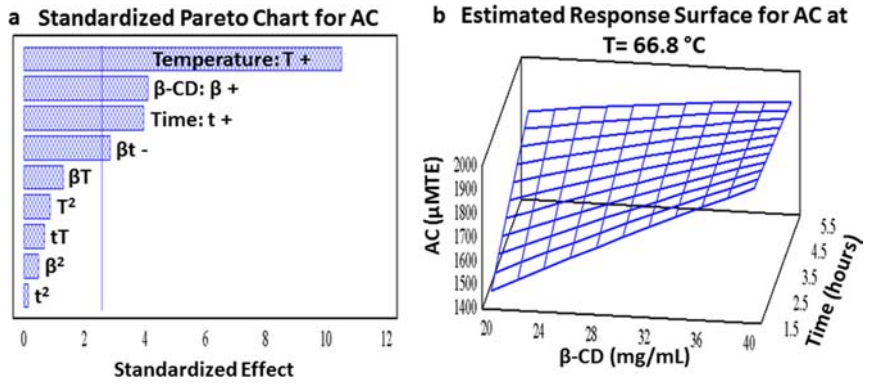

Figure 2. (a) Standardized pareto chart and (b) estimated response surface for AC.

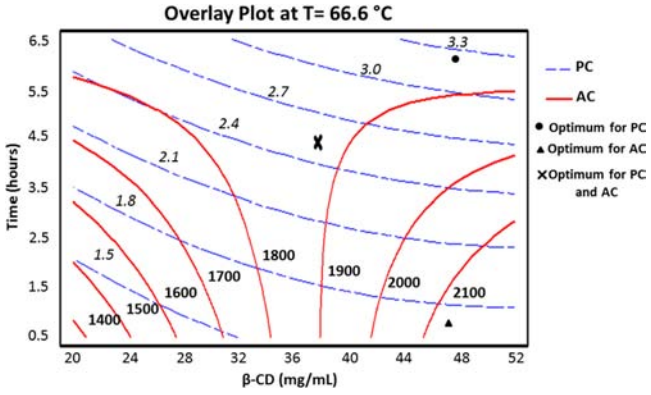

Figure 3. Superposition plots of PC and AC. The optimums for (●) PC, (▲) AC and (×) both responses are also shown.

is important to maintain the AC of the molecules through the extraction process. The simultaneous maximization of the polyphenol quantity (PC) and their quality (AC) is therefore primordial. Moreover, the optimization of the process is likely to diminish its cost. The simultaneous optimum for both responses was obtained with 37.7 mg/mL β-CD for 4.4 h at 66.6 °C. It permitted the decrease in β-CD consumption (from 46.8 to 37.7 mg/mL), thus reducing the overall cost of the process. The suggested multiple optimum is therefore an economic choice for industrial purposes that decreases the time and β-CD consumption, maintaining a high AC of concentrated polyphenol extracts. To verify the exactitude of the model, the optimal conditions for the optimization of both of the responses (PC and AC) were repeated. The extraction process of polyphenols from Syrah vine shoots was conducted at 66.6 °C for 4.4 h with a 37.7 mg/mL aqueous β-CD solvent. Experimental results were compared to those predicted by the model. As shown in Table 3, the difference of the values

Table 3. Predicted and Experimental Results of PC and AC at the Multiple Optimum Conditions (66.6 °C, 4.4 h, and 37.7 mg/mL β-CD)

multiple optimum	predicted	experimental	mean absolute error
PC (mg of GAE/g of DM)	2.5	2.45	0.14
AC (μMTE)	1881.3	1864	48.7

obtained by experimentation and model prediction are within the range of the mean absolute error, suggesting a good agreement of the model with experimental results.

Consequently, 66.6 °C and 37.7 mg/mL aqueous CD seem to be adequate optimal conditions for the maximization of both PC and AC. In the studied domain, all of the quadratatic effects (t^2, T^2, and β^2) of the parameters were insignificant. Time, temperature, and β-CD concentration had positive linear impacts on PC and AC (Figures 1a and 2a). The β-CD concentration in water is an experimental condition limited by its solubility and economic impact. Similarly, the temperature elevation is governed by the oxidation and/or degradation phenomena that it causes to polyphenols and also by its energy consumption that affects the overall cost of the process. Because of all of the aforementioned reasons, the linear extrapolation of the time parameter was possible because it was suspected to further increase PC and AC. Figure 4 shows PC and AC as a function of long periods of time (from 5 to 54 h) at 66.6 °C and 37.7 mg/mL β-CD. The highest PC and AC, 5.8 mg of GAE/g of DM and 3147 μMTE, respectively, were reached after 48 h of extraction. Beyond this time, PC

DOI: 10.1021/acs.jafc.5b00672
J. Agric. Food Chem. 2015, 63, 3387−3393

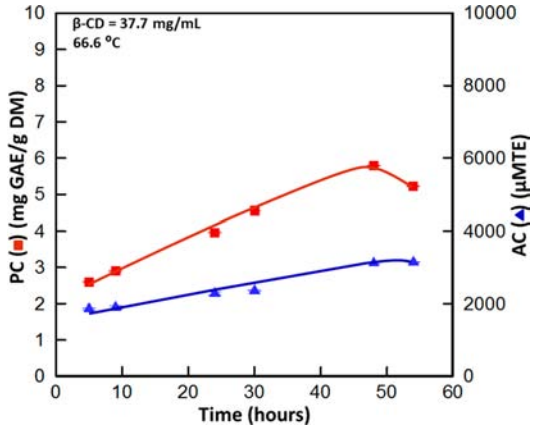

Figure 4. PC and AC as a function of time at 66.6 °C and 37.7 mg/mL β-CD.

diminishes, probably because of polyphenol degradation caused by exposure to a relatively high temperature for a long period of time.

The linear extrapolation of time permitted the amelioration of PC and AC by 2.3 and 1.7 times, respectively, enabling the obtainment of the highest concentration of bioactive polyphenols (5.8 mg of GAE/g of DM) with β-CD-assisted extraction (37.7 mg/mL) after 48 h at 66.6 °C.

β-CD and Organic Solvent Extraction. The efficiency of β-CD in the extraction of antioxidant polyphenols has been evaluated in comparison to organic solvent extraction with 50% ethanol/water, shown to be the optimal ethanolic mixture compared to 0, 25, and 75% ethanol/water in terms of polyphenol extraction from vine shoots.[8]

As shown in Figure 5, a PC of 2.6 mg of GAE/g of DM was reached after 0.5 h of extraction with 50% ethanol/water, while

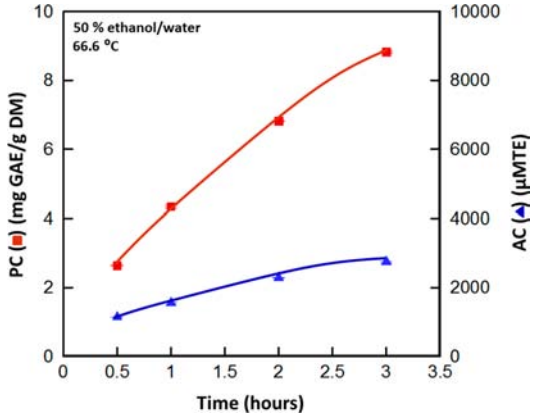

Figure 5. PC and AC as a function of time at 66.6 °C and 50% ethanol/water.

it took 5 h with β-CD (37.7 mg/mL) (Figure 4) and 10 h with pure water (data not shown) to attain the same phenolic yield. Ethanol is likely to enhance the polyphenol extraction process because it acts on both the solvent properties and the matrix. It influences the polarity of the solvent and its capacity to solubilize lipophilic polyphenols. Moreover, ethanol can chemically and biophysically alter biological membranes by affecting cell permeability.[19] The faster kinetics of polyphenol extraction with ethanol is therefore expected because it affects membrane permeability and, thus, facilitates molecular diffusion. With regard to the AC of the extracted molecules, a comparison was performed between polyphenols obtained by ethanol extraction and those by β-CD (37.7 mg/mL). For the same polyphenol yield (2.6 mg of GAE/g of DM), AC of 1000 μMTE was found with water, AC of 1100 μMTE was found with ethanol, and AC of 1864 μMTE was obtained with β-CD. The oxidation or degradation phenomena affecting polyphenol AC was more likely to occure in water and ethanol/water mixtures than with β-CD-containing solvent. This observation was maintained with higher polyphenol yields. For 5.8 mg of GAE/g of DM, AC of 2000 μMTE was found with ethanol compared to AC of 3146 μMTE obtained with β-CD. After 48 h of extraction at 66.6 °C with 50% ethanol/water mixture, PC of 24 mg of GAE/g of DM and AC of 6000 μMTE were obtained (data not shown). In comparison to β-CD, AC was only ameliorated 1.9 times, even when PC was 4.13 times higher. The negative effect of the ethanol and temperature combination on the polyphenol AC was highlighted within 48 h of extraction. Better antioxidant power and stability were reported for polyphenols encapsuled with CD compared to methanol extract.[20] The difference of AC among ethanol and β-CD extracts might result from (1) the difference in the composition and diversity of the extracted polyphenols and (2) the encapsulation role of β-CD in the protection of polyphenol from possible degradation by oxidation, heat, and UV light.[21] The identification and quantification of polyphenols from β-CD- and hydroethanolic-assisted extractions were conducted by HPLC. Both extracts had the same initial total PC of 5.8 mg of GAE/g of DM but different antioxidant activities (Table 4). As shown in Table 4, GA, HBA, FA, and TCA were identified in the β-CD extract obtained at the following conditions (37.7 mg/mL, 48 h, and 66.6 °C). Higher concentrations of polyphenols were identified in β-CD compared to the hydroethanolic extract. For instance, FA and HBA were by far better extracted with β-CD-containing solvent compared to 50% ethanol (Table 4). The higher yield of polyphenols and their improved diversity could be the reason for the enhanced AC activity observed with the β-CD extracts (3146 μMTE) compared to the hydroethanolic extracts (2000 μMTE).

With regard to the lower price of β-CD compared to ethanol and the higher quantity of ethanol used per experiment (7.8 g of ethanol equivalent to 50% ethanol/water mixture versus 0.754 g of β-CD equivalent to 37.7 mg/mL taken at the optimal conditions), it is more economic for industrial purposes to use β-CD. The importance of this latter is not limited to the extraction process because polyphenol encapsulation by β-CD

Tempranillo	1463 d				66 a	2300.2 c	7000 d	7.5 b

[a]nd corresponds to non-detectable. GA, gallic acid; HBA, 4-hydroxybenzoic acid; FA, ferulic acid; TCA, *trans*-cinnamic acid; PA, protocatechuic acid; R, resveratrol; AC, antioxydant capacity; and PC, polyphenol content. Different letters (a, b, and c) indicate significant statistical difference between means.

heightens their stability, masks their unpleasant taste, and improves their bioavailability and half-life.[21] Therefore, their removal is unnecessary, as is the case for organic solvents, after the extraction process, especially when they will be expected to be used in industrial applications. In comparison to organic solvent (50% ethanol), β-CD-assisted extraction was shown to be an efficient method in terms of antioxidant polyphenol extraction from vine shoots.

Comparison of Vine Shoot Cultivars. β-CD-assisted extraction of polyphenols was conducted on three other vine shoot cultivars proposed by a local viticulture for the valorization of their shoots: Cabernet Sauvignon, Cabernet Franc, and Tempranillo. The comparison was realized using the optimal conditions found with Syrah (β-CD, 37.7 mg/mL; *T*, 66.6 °C; and *t*, 48 h). Different diversities and quantities of polyphenols were identified among the extracts (Table 5). For example, in Tempranillo cultivar, three polyphenols were identified: GA, PA, and R. Among all of the studied vine shoots, Tempranillo had the highest concentration of R (2300.2 μg/g of DM), Cabernet Franc had the highest concentrations of GA (2162 μg/g of DM), and Syrah had the highest concentrations of FA (17.6 μg/g of DM) and HBA (6.5 μg/g of DM). All cultivars had the same PA content (73.2 μg/g of DM). No correlation was shown between the identified molecules and the antiradical capacities of the extract AC. However, all vine shoot cultivars were shown to be a rich source of highly antioxidant polyphenols. GA, PA, FA, TCA, HBA, and R were found by many authors in vine shoot extracts.[1,22,23] Our study focused on the differences between Syrah, Cabernet Sauvignon, Cabernet Franc, and Tempranillo cultivars in terms of their AC, PC, and diversity. All in all, we have clearly shown that β-CD-assisted extraction is an environmentally friendly process for the extraction of polyphenols with a high radical-scavenging capacity. At an industrial scale and compared to organic solvent, β-CDs are cheaper and safer for several applications and processes. This type of natural antioxidant molecule extraction is quite efficient in terms of quantity and quality of the polyphenols extracted from vine shoots. However, a potential co-extraction of phytochemicals is likely to occur when using β-CDs. Future studies on the identification and characterization of these phytochemicals is essential to consider this process as GRAS.

Table 1. Analyzed Compounds Associated with Oxidized Aroma, Their Odor Descriptors and Odor Thresholds

compound	odor descriptor	odor threshold (μg/L)
(*E*)-2-alkenals		
(*E*)-2-heptenal	soapy, fatty	4.6[a,9]
(*E*)-2-hexenal	green apple	4[a,9]
(*E*)-2-nonenal	green, fatty, sawdust	0.17[a,14]
(*E*)-2-octenal	fatty, nutty	3[a,9]
Strecker aldehydes		
methional	cooked potato-like	0.5[b,7]
2-methylpropanal	malty	6[b,9]
3-methylbutanal	malty	4.6[b,2]
2-phenylacetaldehyde	honey, floral	1[b,9]
furans		
furaneol	caramel	37[b,15]
homofuraneol	caramel	10[b,15]
sotolon	curry, seasoning	15[b,12]
aldehydes		
benzaldehyde	bitter almond-like	2000[a,16]
furfural	sweet, bread	14 100[b,17]
hexanal	grassy, green	20[a,16]
5-methylfurfural	sweet, bitter almond	2000[a,16]
alcohols		
maltol	caramel	5000[b,18]
methionol	cooked potato-like	1000[b,17]
eugenol	clove-like	6[b,17]

[a]Odor detection threshold determined in water. [b]Odor detection threshold determined in model wine (10% aqueous ethanol, 7 g/L glycerol, pH 3.2).

techniques were described: a HPLC and UPLC method[21,22] and a liquid−liquid extraction followed by GC-MS analysis.[23] In another paper, analysis of sotolon together with furaneol and maltol was performed via GC-MS after isolation of the volatiles via SPE.[24]

The aim of this work was to develop a highly sensitive GC-MS/MS method which allows simultaneous quantitation of 18 compounds involved in wine oxidation in a single run. This required quantifying a number of compounds which are present in trace quantities including (*E*)-2-alkenals, various Strecker aldehydes (methional, 2-phenylacetaldehyde, 3-methylbutanal, 2-methylpropanal), methionol, eugenol, maltol, as well as furans (sotolon, furaneol, homofuraneol). The comprehensive method was validated in an oxidized red, white, and model wine, and its application was demonstrated through the analysis of a 14 year old white wine which was stored under five different closures to study the effects of the formation of these flavor compounds.

MATERIALS AND METHODS

Chemicals. 3-Hydroxy-4,5-dimethyl-2(5*H*)-furanone (sotolon) (≥99%), 4-hydroxy-2,5-dimethyl-3(2*H*)-furanone (furaneol) (≥98%), 2-phenylacetaldehyde (≥95%), furfural (≥98%), 5-methylfurfural (≥98%), hexanal (≥97%), (*E*)-2-hexenal (≥95%), (*E*)-2-heptenal (≥97%), (*E*)-2-octenal (≥94%), (*E*)-2-nonenal (≥93%), 3-(methylthio)-propanal (methional) (98%), 3-(methylthio)-propanol (methionol) (≥98%), 3-methylbutanal (97%), 2-methylpropanal (98%), 4-allyl-2-methoxyphenol (eugenol) (≥98%), benzaldehyde (≥99%), and 3-hydroxy-2-methyl-4*H*-pyran-4-one (maltol) (≥99%) were supplied by Sigma-Aldrich (Castle Hill, NSW, Australia). *O*-(2,3,4,5,6-Pentafluorobenzyl)hydroxylamine hydrochloride (≥99%), used as a derivatization reagent, was also purchased from Sigma-Aldrich. d_4-Furfural was purchased from CDN Isotopes (SciVac PTY. Ltd., Hornsby, NSW, Australia). 2-Phenyl-d_5-acetaldehyde was prepared from 2-phenyl-d_5-ethanol using the method for *formyl*, α-[$^{13}C_2$]-2-phenylacetaldehyde.[25] d_5-Benzaldehyde was present as a byproduct (5%) in the 2-phenyl-d_5-acetaldehyde sample and formed as a result of C−C bond cleavage during the oxidation of 2-phenyl-d_5-ethanol as had been found previously.[26]

All chromatographic solvents were of HPLC grade; all chemicals were of analytical reagent grade unless otherwise stated; water was obtained from a Milli-Q purification system (Millipore, North Ryde, NSW, Australia). Sulfuric acid (95−97%, synthesis grade) was from Merck (Merck Pty. Ltd., Australia, Kilsyth, VIC, Australia). BondElut EN resins (styrene-divinylbenzene polymer), prepacked in 500 mg cartridges (6 mL total volume), were obtained from Agilent (Agilent Technologies Australia Pty Ltd., Mulgrave, VIC, Australia). All prepared solutions were % v/v with the balance made up with redistilled ethanol and prepared freshly prior to analysis.

Synthesis of 3-(Methyl-d_3-thio)-1-d_2-propanol (d_5-Methionol). Methyl 3-mercapto-propionate (3.94 g, 33 mmol), K_2CO_3 (7.2 g, 52 mmol), and CD_3I (5 g, 35 mmol) in THF (75 mL) were stirred for 7 days at room temperature in a sealed pressure vessel. The mixture was filtered, dried (Na_2SO_4), and filtered again into a fresh round-bottomed flask. The solution was cooled to 0 °C, $LiAlD_4$ (1.25 g, 30 mmol) was added, and the solution was stirred at room temperature overnight. The mixture was quenched with saturated NH_4Cl, and the organic layer was separated, dried (Na_2SO_4), and concentrated in vacuo. The residue was purified by vacuum distillation (85−95 °C; 12 mmHg) to give d_5-methionol (1.78 g, 54%). GC-MS, *m*/*z* (%): 94 (100), 110 (51), 64 (9), 33 (6), 78 (4).

Synthesis of 3-(Methyl-d_3-thio)-propanal (d_3-Methional). d_3-Methional was prepared using a modified version of the method of Sen et al.[27] d_3-Methionol was prepared as described for d_5-methionol above using $LiAlH_4$ in place of $LiAlD_4$. d_3-Methionol (2.6 g, 24 mmol), pyridinium chlorochromate (7.7 g, 36 mmol), and CH_2Cl_2 (125 mL) were stirred for 4 h. The mixture was loaded directly onto silica gel (150 g) and eluted using 30% Et_2O/pentane → 70% Et_2O/pentane to give d_3-methional (0.4 g, 15%). GC-MS, *m*/*z* (%): 51 (100), 46 (41), 79 (30), 64 (30), 50 (24), 107 (20).

Synthesis of 4-Hydroxy-2,5-dimethyl-d_6-3(2*H*)-furanone (d_6-Furaneol). Furaneol (2.0 g, 16 mmol), D_2O (12 mL), and 40 w/v% NaOD/D_2O (8 mL) were stirred for 4 days at 50 °C. The solution was salted (NaCl), acidified to pH 2 using DCl/D_2O, and extracted with anhydrous Et_2O. The combined organic layers were dried (Na_2SO_4) and concentrated in vacuo to give d_6-furaneol (870 mg, 41%). GC-MS, *m*/*z* (%): 134 (100), 46 (62), 60 (32), 88 (26), 78 (4).

Synthesis of d_5-5-Ethyl-4-hydroxy-2-methyl-3(2*H*)-furanone (d_5-Homofuraneol). Homofuraneol was synthesized using the method of Blank et al.[28] Homofuraneol (0.3 g, 2 mmol), D_2O (6 g, 0.3 mol), and 40 wt % NaOD/D_2O (1.0 g, 10 mmol) were stirred for 4 days in a sealed pressure vessel under nitrogen. The solution was acidified to pH 3 using DCl (2.7 M), salted (NaCl), and extracted with anhydrous Et_2O. The combined organic layers were dried (Na_2SO_4) and concentrated in vacuo to give d_5-homofuraneol (160 mg, 54%). GC-MS, *m*/*z* (%): 147 (100), 46 (62), 73 (53), 101 (30), 132 (26).

Synthesis of 3-Hydroxy-4-methyl-5-(methyl-d_3)-2(5*H*)-furanone-5-*d* (d_4-Sotolon). D_2O (5 mL) and 37% w/w DCl/D_2O (0.5 mL) was added to 2-ketobutyric acid (1.25 g, 12 mmol), and the solution was stirred for 1 h. The solution was salted (NaCl), extracted with anhydrous Et_2O, dried (Na_2SO_4), filtered, and then concentrated in vacuo. Additional D_2O (5 mL) and 37% w/w DCl/D_2O (5 mL) was added to the resultant 3,3-d_2-2-ketobutyric acid (0.9 g) in a 50 mL glass high-pressure vessel with a Teflon screw cap seal. The solution was chilled under N_2, and d_4-acetaldehyde (1.0 g, 21 mmol) was added. The vessel was sealed and stirred for 7 days, after which further D_2O (5 mL) was added and the solution was salted (NaCl). The product was extracted using Et_2O and washed with brine (6 × 2 mL), and the organic layer was dried (Na_2SO_4) and concentrated in vacuo to give the product (1.5 g, 92%). GC-MS, *m*/*z* (%): 87 (100), 59 (75), 132 (45), 46 (39), 76 (14), 114 (5).

J. Agric. Food Chem. 2015, 63, 3394−3401

Synthesis of (*E*)-2-Octenal-5,6,7,8-d_9 (d_9-(*E*)-2-Octenal). d_9-(*E*)-2-Octenal was prepared in five steps from d_9-bromobutane as per Heading.[29]

Synthesis of (*E*)-2-Hexenal-3,4,4,5,5,6,6,6-d_8 (d_8-(*E*)-2-Hexenal). d_8-(*E*)-2-Hexenal was prepared from the reduction of d_8-ethyl hexanoate to d_8-hexenol using lithium aluminum hydride and then converted to the aldehyde using the Swern oxidation as described in Grant-Preece et al.[30]

Wine. The wine studied was a Semillon from the Clare Valley region in South Australia, processed entirely in a stainless steel tank with no oak treatment. SO_2 was added postfermentation as well as dimethyl dicarbonate (Velcorin) at 10 μg/L, with the basic composition at bottling of pH 3.16, titratable acidity (as tartaric acid, pH 8.2) 6.1 g/L, volatile acidity 0.56 g/L as acetic acid, free sulfur dioxide 28 mg/L, and total sulfur dioxide 100 mg/L. The wine was bottled with the same closures used by an earlier closure trial[31] and had various flavor compound additions as described in Capone et al.[32] The bottled wines were kept in an inverted position in a near constant temperature storage facility (ca. 15 °C). The closures studied are shown in Table 2.

Table 2. Wine Samples Included in the Study, Bottled in 1999

code	closure	headspace	volume

Syn 2	synthetic extruded	air, 3 mL	750 mL

Gas Chromatography–Mass Spectrometry. GC analysis was performed on an Agilent 7000 Triple Quadrupole GC-MS/MS system, equipped with an Agilent Multimode injector. The column used was a VF-200 ms from J&W Scientific, 30 m × 0.25 mm i.d., with 0.25 μm film thickness. The carrier gas was helium at a constant flow rate of 1.6 mL/min. The extract (2 μL) was injected in splitless mode, with a pressure of 16.95 psi, septum purge flow was 3 mL/min, and splitless time was 1 min. The injector temperature was 180 °C for 1 min and then heated to 260 °C at 250 °C min^{-1}. The oven temperature started at 40 °C, was held for 1 min, then raised to 220 °C at 10 °C/min, and finally heated to 270 °C at 100 °C/min. After each analytical run, backflushing was performed at 270 °C for 7.24 min at a pressure of 25 psi (back inlet pressure 1 psi). The temperature of the transfer line was 240 °C, and nitrogen (1.5 mL/min) was used as the collision gas. The mass spectrometer was operated in electron ionization mode at 70 eV with multiple reaction monitoring (MRM), with the monitored transitions listed in Table 3. Data acquisition and analyses were performed using the MassHunter Workstation software version B.05.01 supplied by the manufacturer (Agilent Technologies Australia Pty Ltd., Mulgrave, VIC, Australia).

Method Development. In order to determine the retention time and the characteristic mass fragments of the compounds, full scan analysis (m/z 50–350) was performed individually on each of the reference compounds as well as on the labeled standards. The aldehydes (10 mL of a 10 mg/L aqueous solution) were separately reacted with *O*-(2,3,4,5,6-pentafluorobenzyl)-hydroxyl-amine hydrochloride (1 mL of a 10 mg/mL aqueous solution) to obtain the oxime derivatives, these were then extracted with a Bond Elut ENV (200 mg) cartridge and eluted with 3 mL of dichloromethane (DCM), and after solvent evaporation to 200 μL the concentrated extract was subjected to GC-MS/MS analysis. The compounds that were quantified in their free forms were individually injected directly as solvent extracts, all in a concentration of 10 mg/L. The full scan experiments showed the precursor ions, and then MS/MS experiments were conducted on the precursor ions to determine their product ions. Once the selection of product ions was established, extracts of wine samples containing additions of the reference compounds and standards (100 μg/L) were injected using a ramp between 0 to 50 eV to determine the optimum collision energies for each of the different transitions (see Table 3).

Sample Preparation for GC-MS/MS Analysis. Isolation of the volatile analytes was performed according to Culleré et al. for quantitation of sotolon, furaneol, and maltol with the following modifications.[19] An ethanolic solution (30 μL) containing the labeled standards in concentrations from 1 to 60 μg/mL, depending on the expected concentration, was added to the wine sample (20 mL) and equilibrated for 15 min. To the spiked wine sample 1 mL of an aqueous solution containing the derivatization agent *O*-(2,3,4,5,6-pentafluorobenzyl)-hydroxylamine hydrochloride at 10 mg/mL was added, and the sample was stirred with a magnetic stir bar for 15 min. Ammonium sulfate (3 g) was then added to the samples prior to loading on the Bond Elut ENV SPE cartridge (500 mg, 6 mL volume) previously conditioned with 5 mL of dichloromethane, 5 mL of methanol, and finally 5 mL of model wine (13% v/v ethanol solution in water saturated with potassium hydrogen tartrate and adjusted to pH 3.3 with aqueous tartaric acid solution). Excess reagent was removed from the cartridge by loading 6 mL of a 0.05 M sulfuric acid solution. Analytes were finally eluted with dichloromethane (6 mL), and the organic layer was concentrated under a nitrogen stream to 200 μL at 40 °C using a turbovap (Turbo Vap LV Evaporator, Zymark). For wine analysis three individual bottles of each wine were analyzed.

RESULTS AND DISCUSSION

Method Development. *Sample Preparation.* For isolation of the different compounds various SPE materials (Bond Elut C18, SDBL, Licholut EN) and wine volumes (2, 5, 10, and 20 mL) were tested (data not shown), with the highest retention of the compounds achieved using a styrene-divinylbenzene polymer cartridge (Bond Elut ENV 500 mg) loaded with 20 mL of wine. The derivatization procedure with PFBHA had been previously investigated thoroughly by Culleré et al.,[19] who showed that the derivatization performed directly on the SPE cartridge was optimal, as derivatizing before the extraction caused interference in the MS spectra with other wine carbonyls that were also derivatized. However, since our method utilizes MS/MS analysis and measures only the specific mass transitions selected, the interference of other wine carbonyls did not constitute a problem. This fact, combined with the observation that derivatization conducted directly in the wine, showed a greater response for the underivatized compounds, allowing us to choose the latter procedure. The issue of a possible incomplete derivatization, and therefore inaccurate quantitation, was addressed by using isotopically labeled analogues of the analytes as internal standards, prior to the derivatization step. After loading the wine sample on the cartridge, the excess derivatizing agent along with other unwanted impurities were removed with 6 mL of a solution of dilute sulfuric acid (0.05 M). The elution of the target compounds was performed with dichloromethane (6 mL), followed by concentration under a stream of nitrogen to a final volume of 200 μL.

Isotopically Labeled Analogues. The synthesis of nine deuterium-labeled analogues including d_5-homofuraneol, d_4-sotolone, d_6-furaneol, d_5-methionol, d_3-methional, d_5-benzaldehyde, 2-phenyl-d_5-acetaldehyde, (*E*)-2-d_9-octenal, and d_8-(*E*)-2-hexenal was carried out in house for accurate quantitation of the compounds of interest.

Isotopically labeled standards were not available for some compounds; therefore, some standards were also used to determine other structurally similar compounds as follows. For the quantitation of 2-methylpropanal and 3-methylbutanal, d_5-benzaldehyde was used as an internal standard. The labeled

standard of sotolon was also used for determination of eugenol and maltol. d_3-Methional was also used to quantitate hexanal. For the determination of 5-methylfurfural the internal standard d_4-furfural was used, and d_9-(*E*)-2-octenal was the standard for (*E*)-2-nonenal and (*E*)-2-heptenal.

GC Parameters. Six GC columns with different polarity (DB-35 ms, Solgel-Wax, DB-FFAP, DB-Wax, DB-5, DB-1701, VF-200 ms) were investigated (data not shown), and the majority of them gave unsatisfactory results for the compound sotolon in terms of peak shape and thus detection limits. The best chromatographic results, especially for sotolon, were

achieved on a VF-200 ms column (30 m × 0. 25 mm i.d., with 0.25 μm film thickness). The injection type selected was liquid mode, and several inlet parameters were assessed, including splitless, split, pulsed splitless, as well as programmable temperature vaporization, with the splitless mode giving the greatest signal-to-noise. The injection in splitless mode was then tested at different temperatures ranging between 160 and 240 °C, and 180 °C was selected as the temperature giving the greatest sensitivity.

MS Parameters. The full scan MS analysis of the individual compounds showed a good signal for the molecular ion of each of the compounds analyzed. MS/MS experiments revealed the characteristic fragmentation of each of the compounds, and the most intense fragment was chosen as a quantifier. The second most intense fragment of each compound was chosen as a qualifier, and the fragmentation of the ions, together with the collision energies selected are shown in Table 3.

As the quantitation of 18 compounds and 10 internal standards requires the recording of 56 mass transitions, the sensitivity could potentially be compromised due to the number of data points that are needed to be collected. To minimize the number of recorded transitions and therefore maximize the sensitivity, the MS/MS experiments were grouped into three time segments over the GC-MS/MS run.

Method Validation. *Linearity.* Linearity was evaluated across a series (15 points) of duplicate standard additions of each of the compounds ranging over a concentration range from 0.01 to 2000 μg/L, depending on the expected concentration of the compound, and validated in red, white, and model wine (13% v/v ethanol solution in water saturated with potassium hydrogen tartrate and adjusted to pH 3.3 with aqueous tartaric acid solution). As shown in Table 4, good linearity was achieved for each of the compounds with coefficient of determination (R^2) values ranging between 0.992 and 0.999.

Repeatability. To assess the precision of the method, seven identical samples were spiked with all of the 18 compounds at two different concentrations (10 and 250 μg/L) in red, white, and model wine, and the relative standard deviation of the calculated concentrations was under 5% in all cases (data not shown).

Recovery. Control samples were spiked with all of the analytes at two different concentrations (10 and 100 μg/L) as well as a nonspiked sample, to determine the concentration in the blank, and the mean recoveries were between 92% and 105% (data not shown).

Limit of Detection. The LOD (S/N = 3) and LOQs (S/N = 10) were determined by calculating the signal-to-noise (S/N) ratio in a spiked nonoxidized wine and a model wine matrix. For some of the derivatized compounds the specific mass transition measured showed hardly any noise, which is a common occurrence for GC-MS/MS analysis. Therefore, the LOD could not be calculated in the conventional way. The limit of quantitation values were determined by measuring seven replicates of unspiked samples and the same number of replicates for samples containing increasing concentrations of the analytes and assessing whether they were significantly different ($P < 0.05$).

For all of the compounds included in the analysis the detection limits (Table 4) were lower than their odor detection threshold and ranged between 0.01 (for derivatized aldehydes) and 10 μg/L (for sotolon).

Analysis of Wines. After validation was complete, the GC-MS/MS method was applied to study a 14 year old white wine (bottled in 1999) under different closures (two natural corks, two synthetic corks, and a screw cap) to determine which of the selected compounds would most be affected by oxidation.

DOI: 10.1021/jf505803u
J. Agric. Food Chem. 2015, 63, 3394−3401

Wines stored under the same closures had been assessed by a trained sensory descriptive analysis panel at a much earlier stage of storage,[31,33,34] with the two wines bottled with synthetic closures being rated much higher in oxidized aroma than the screw cap-sealed wine and the cork-sealed wines being intermediate in scores. This set of samples also included wines stored in glass ampules sealed under nitrogen or air, and the color differences among the samples were clearly visible, indicating the degree of oxidation that occurred. The color of the wine ranged from light yellow in the case of the wines sealed in glass ampules to a dark brown for wines under synthetic corks. In order to account for possible bottle to bottle variations with the same closures, the analysis for each type of closure was carried out on three different bottles.

As expected from the immense differences in color highlighted by visual inspection of the wines, most of the compounds analyzed were found to be present in significantly different ($P < 0.05$) concentrations depending on the closures (Table 5). Among the Strecker aldehydes, the concentration of 2-phenylacetaldehyde, 3-methylbutanal, and methional was significantly higher in the wines sealed with natural corks than in those stored in glass ampules. Notably, the highest concentration of these three compounds was found in the wines stored under the synthetic closures, with 3-methylbutanal reaching concentrations of almost 100 μg/L in Syn 1 compared to around 4 μg/L found in the wines stored in glass ampules under nitrogen. Similarly, for methional and 2-phenylacetaldehyde the wine sealed in glass ampules showed concentrations below 5 μg/L, which increased by a factor of 4 in the wines sealed with synthetic closures (Syn 1 and Syn 2). For each of these flavor compounds (methional, phenylactaldehyde, and 3-methylbutanal) the wines sealed with natural corks had the second highest concentration. The wine sealed under screw cap contained a very low concentration of Strecker aldehydes, which were even lower than in the glass ampule sealed with air, and was very similar to that of the glass ampule sealed under nitrogen. This result is not surprising and is most likely attributed to the differences in volume among the wine vessels: the ratio of the head space to the wine volume was higher for the ampules since the volume of the ampules was 50 mL with 3 mL of headspace, in contrast to that of the wine bottles, where the ratio was much lower since the bottles had a 750 mL volume. Escudero et al. showed that methional is an impact odorant of oxidized wines, giving the wine a cooked vegetable off-flavor.[7] Their study showed that wines spiked with methionol or methionine resulted in an increase in the methional concentration and therefore explains that the possible formation pathway during wine oxidation is the direct peroxidation of methionol or a Strecker degradation of methionine. The same pathway was reported for the formation of 2-phenylacetaldehyde from phenylalanine, which also has a low odor threshold and an aroma described as "honey-like".[35,36]

Four (*E*)-2-alkenals with different chain length were measured, and only (*E*)-2-hexenal and (*E*)-2-nonenal were found in significantly different concentrations among closures, with no significant differences observed in both (*E*)-2-octenal and (*E*)-2-heptenal concentrations. The control ampule sealed under nitrogen contained the highest concentration of (*E*)-2-nonenal compared to all other closure samples, suggesting nonoxygen-induced changes may be contributing to the formation, whereas (*E*)-2-hexenal was about 3−4 times higher in wines sealed with synthetic closures and 1.5 times higher in wines sealed with natural corks compared with that of the control. The (*E*)-2-alkenals have been reported to be important contributors to oxidative off flavor.[5] A positive correlation between the (*E*)-2-octenal content and a "rotten apple" sensory note of oxidized wines was shown by Escudero et al., and (*E*)-2-decenal and (*E*)-2-nonenal were also found to be related to other oxidized wine notes,[4] whereas (*E*)-2-nonenal was associated with a "sawdust" aroma.[14] The concentration of the C_6 compound hexanal was higher only in the wine under synthetic cork Syn 2, whereas in all other samples this compound was not found in significantly different quantities.

The furanones, furaneol and homofuraneol, were found in higher concentration in the control wines (N_2) in comparison to all of the other closures. Homofuraneol was found in very high concentration in the control ampule sealed under nitrogen (212 μg/L) and much lower in all other samples, with the wines sealed with synthetic corks having the lowest concentrations of 20 and 4 μg/L (Syn 1 and Syn 2). The changes for furaneol were less drastic, but again the synthetic corks resulted in significantly lower concentrations than the ampouled controls, suggesting oxidative degradation of these compounds.

The "caramel"-like smelling compound maltol, which is commonly extracted from toasted oakwood used in the aging of wines,[37] was found to be present in approximately one-half the concentration in the wine sealed with the synthetic closure (Syn 2) compared to that of the glass ampules, and the wine sealed in Syn 1 also contained a lower concentration. There was no significant difference observed for all other closures, and the concentration of maltol found was well below its odor detection threshold of 5000 μg/L.[13] Methionol was found in a concentration of almost 500 μg/L in all samples (odor threshold 1000 μg/L[17]), with the only significant difference being with the wine sealed with the synthetic closure 2 (Syn 2), which contained 350 μg/L.

Sotolon has been shown to be a key odorant of aged Sherry wines, Ports, and botrytized wines and has also been reported as a contributor to the oxidative off-flavor of table wines.[5,10,22] In our study this compound was only found in increased concentrations and above its aroma detection threshold in the wines sealed with the synthetic closure 2 (Syn 2).

The compound furfural was present at a high concentration in each of the wines, whereas the structurally similar compound 5-methylfurfural was found at the highest concentration in the wine stored under nitrogen in the glass ampules (N_2) and at the lowest concentration in the wine under synthetic closure (Syn 2).

In previous studies using Maccabeo and Chardonnay wines it was shown that the levels of eugenol increased upon wine oxidation,[38] and gas chromatography-olfactometry (GC-O) investigations showed eugenol as an important odor linked to oxidation.[5] Our results with Semillon are in contrast to these findings, as there were no significant differences in concentration among the wines stored under different closures for this compound even though the wines were clearly and visibly affected by oxidation.

The role of different flavor compounds in contributing to wine aroma was clearly observed through the analysis of 14 year old white wines sealed under different closures and comparison to the reported aroma detection thresholds. The wines had naturally aged and oxidized via varied oxygen ingress over extended bottle storage. In agreement with the literature, 2-phenylacetaldehyde and methional were found in increased concentrations in the wines exposed to high oxygen levels,

DOI: 10.1021/jf505803u
J. Agric. Food Chem. 2015, 63, 3394−3401

which were significantly above their odor thresholds and could therefore add to the oxidative "off-flavor" in Semillon wine.

In conclusion, validation and application of a novel GC-MS/MS method is described that enables the simultaneous quantitation of 18 oxidation-related compounds in wines at mg/L, μg/L, and ng/L levels. The preparation of samples is simple and requires only a small volume of wine. An added advantage is the use of deuterated analogues as internal standards which ensures accuracy of the method. The reliability was established using validation criteria such as linearity, repeatability, and reproducibility. This method, to the best of our knowledge, is the first developed for assessing oxidation-related compounds using GC-MS/MS, and its effectiveness was proven through quantitation of 18 compounds in a white wine closure study. Hence, the GC-MS/MS method will provide new insights when used for future storage and shelf-life studies of wines and related beverages.

Germany). Water for high-performance liquid chromatography (HPLC) and medium-pressure liquid chromatography (MPLC) separation was purified by means of a Milli-Q water advantage A 10 water system (Millipore, Molsheim, France), and bottled water was used for sensory studies (Evian, Danone, Wiesbaden, Germany). Solvents for HPLC were of HPLC grade and for LC-MS were of MS grade (J.T.Baker, purchased through Sigma-Aldrich).

Hop pellets type 90 and spent hop pellets, which were obtained after supercritical carbon dioxide extraction of hops, were delivered from Joh. Barth & Sohn GmbH & Co. KG (Nuremberg, Germany); XanthoFlav 15, XanthoFlav 75, hop tannin extracts (from both aroma and bitter hops), and resin extracts (from both aroma and bitter hops) were obtained from Hopsteiner (Simon H. Steiner GmbH, Mainburg, Germany). A novel *ε*-extract was produced in cooperation with Joh. Barth & Sohn GmbH & Co. KG and NateCO_2 GmbH & Co. KG

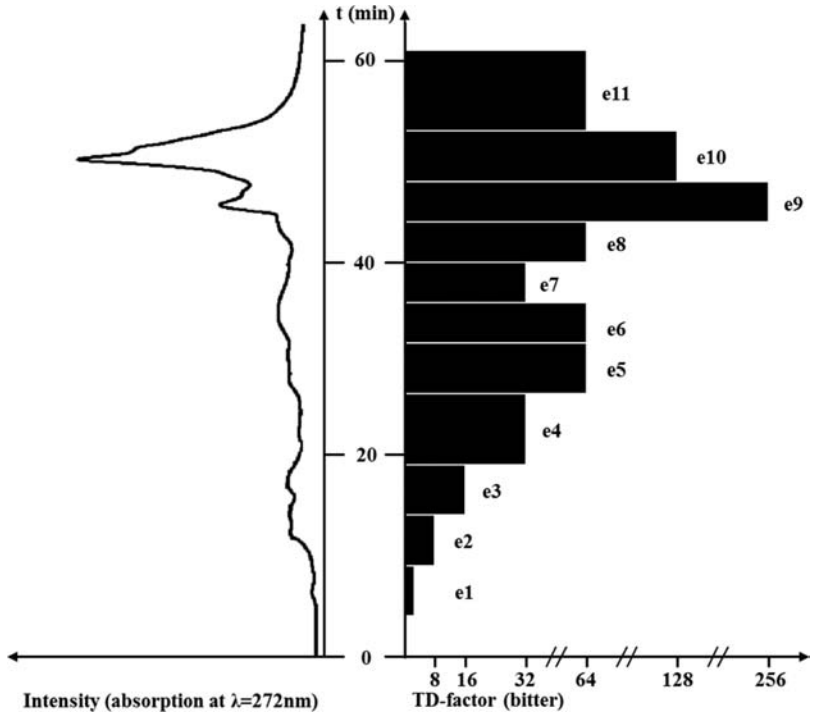

Figure 2. RP-MPLC chromatogram (left) and taste dilution chromatogram (right) of the ε-resin fraction isolated from spent hops.

(Wolnzach, Germany) by means of a supercritical CO_2 extraction using ethanol as a modifier.[27] Reference substances for individual iso-α-acids were purified from an iso-α-acid extract (30%; Hopsteiner), and purified α- and β-acids were isolated from an ethanolic hop extract (Hopsteiner, Simon H. Steiner GmbH, Mainburg, Germany) following the protocol reported recently.[28] Xanthohumol was purified from a commercial xanthohumol extract, and isoxanthohumol was prepared from xanthohumol by alkaline cyclization as reported recently.[28] 8-Prenylnaringenin was prepared from isoxanthohumol by demethylation using scandium trifluoromethanesulfonate.[29] Experimental brewing trails were conducted in the Research Brewery St. Johann St. Johann GmbH & CO. KG (Train-St. Johann, Germany). Unhopped "zero" beer was obtained from the Chair of Brewing and Beverage Technology, Technische Universität München (Freising, Germany).

Preparative Isolation of Soft Resin and δ- and ε-Hard Resin. According to the literature with some modifications,[30] spent hops (100 g) were exhaustively extracted with methanol/diethyl ether (1/5, v/v; 900 mL) for 1 h while stirring. After the addition of hydrochloric acid (300 mL; 0.1 mol/L), the mixture was stirred for additional 10 min and then filtered (320 mm, Macherey-Nagel, Düren, Germany), and the organic layer was extracted with hydrochloric acid (3 × 100 mL; 0.1 mol/L) before the solvent was separated in vacuum. To remove waxes, the residue was solubilized in methanol (400 mL), and, after incubation at −20 °C overnight and filtration (round filter paper, 320 mm, Roth, Karlsruhe, Germany), the solution was applied onto 55 μm, 70A, Strata C18-E Giga Tube cartridges (10 g, 60 mL; Phenomenex, Aschaffenburg, Germany), conditioned with methanol. Chlorophylls were separated by flushing the cartridges with methanol (150 mL), and the effluent was collected and separated from solvent in vacuum. The resin obtained was suspended in hexane and filtered (185 mm, Macherey-Nagel, Düren, Germany). The filtrate was collected and separated from solvent in vacuum to give the soft resin (91.9% yield), whereas the residue was extracted with hexane (50 mL) to give the nonsoluble hard resin (8.1% yield). Following a literature protocol for ε-resin isolation,[31,32] the hard resin was suspended in water at 40 °C during ultrasonification. After filtration (185 mm, Macherey-Nagel, Düren, Germany), the aqueous phase was collected, whereas the residue was again suspended in water (40 °C). After this process was repeated three times, the combined aqueous layer was freeze-dried to obtain the δ-resin (20.2% of total hard resin), whereas lyophilization of the residual material afforded the ε-resin (79.8% of total hard resin).

Fractionation of the ε-Resin by Medium-Pressure Liquid Chromatography (MPLC). Aliquots of the ε-resin (0.5 g) were dissolved in methanol/water (40/60, v/v; 20 mL) and separated on a 460 × 16 mm glass column (Büchi, Flawil, Switzerland) filled with 25−40 μm LiChroprep RP18 material (Merck KGaA, Darmstadt, Germany) using an MPLC system (Büchi Sepacore, Flawil, Switzerland) consisting of two C-605 pumps, a C-620 control unit, a C-660 fraction collector, a 6-way-injection valve, and a C-635 UV detector monitoring the effluent at 272 nm. Data acquisition was performed by means of Sepacore Control Chromatography Software, Version 1.0. Operating with a flow rate of 30.0 mL/min and using 0.1% aqueous formic acid as solvent A and methanol containing 0.1% formic acid as solvent B, chromatography was performed starting with 40% solvent B for 1 min and, then, increasing solvent B to 60% within 6 min, to 70% within 30 min and, finally, to 100% within an additional 20 min, followed by isocratic elution for 20 min. After 86.0 min, solvent B decreased again to 40% and was kept for 10 min prior to the next injection. A total of 11 fractions (e1−e11) were collected, separated from solvent in vacuum, and then used for a taste dilution analysis[33−35] to locate fractions e2 (yield: 3.4%), e3 (yield: 3.0%), e4 (yield: 3.2%), e5 (yield: 3.6), e6 (yield: 3.2%), e7 (yield: 2.6%), e8 (yield: 2.7%), e9 (yield: 18.4%), e10 (yield: 31.3%), and e11 (yield: 22.9%) with the highest bitter impact (Figure 2).

Isolation of Key Bitter Molecules from MPLC Fractions of ε-Resin. MPLC fractions were separated by means of preparative HPLC on a 250 × 21.2 mm, 5 μm, Luna Phenyl-Hexyl column (Phenomenex, Aschaffenburg, Germany) operated with a flow rate of 15 mL/min and using 0.1% aqueous formic acid and acetonitrile containing 0.1% formic acid as solvents. Separation of MPLC fractions e2 to e11 gave subfractions e2-1 to e2-14, e3-1 to e3-13, e4-1 to e4-5, e5-1 to e5-5, e6-1 to e6-11, e7-1 to e7-16, e8-1 to e8-8, e9-1 to e9-9, e10-13 to e10-13, and e11-1 to e11-15, all of which were collected, separated from solvent in vacuum, and subjected to a taste dilution analysis (Figure 3).

Structure Determination of Bitter Compounds in ε-Resin Subfractions. The individual ε-resin subfractions isolated above were directly analyzed by means of LC-TOF-MS and 1D/2D-NMR spectroscopy and, if needed, further purified by means of rechromatography using a semipreparative 250 × 10.0 mm Hypersil RP-18 column (Thermo Hypersil GmbH, Kleinostheim, Germany) using a solvent

gradient of aqueous 0.1% formic acid and methanol containing 0.1% formic acid (flow rate: 4.7 mL/min). Compounds **5**−**7**, **9**−**12**, **14**, **17**−**22**, **25**−**29**, **31**−**34**, **36**, **37**, **40a**, and **42**−**44** were isolated from the subfractions as summarized in Table 1 in a purity of more than 98% and, after the solvent was separated in vacuum and freeze-dried twice, were used for structure determination by means of UV/vis, LC-MS/MS, UPLC-TOF-MS, and 1D/2D NMR, as well as for sensory experiments. Based on the comparison of spectroscopic (UV/vis, LC-TOF-MS, ^{1}H/^{13}C NMR) and chromatographic data with those recorded for references, previously reported compounds were confirmed as xanthohumol (**5**),[24] isoxanthohumol (**6**),[24] desmethylxanthohumol (**7**),[25] 6-prenylnaringenin (**9**),[24] 1″,2″-dihydroxanthohumol C (**12**),[23,36,37] 1″,2″-dihydroxanthohumol K (**14**),[36,37] 5′-prenylxanthohumol (**17**),[24,25] xanthohumol D (**19**),[25] xanthohumol B (**20**),[24,25] xanthohumol C (**21**),[24] xanthohumol H (**22**),[23,36,37] 2″-hydroxyxanthohumol M (**25**),[38] xanthohumol I (**26**),[23,36,37] xanthohumol O (**27**),[39] xanthohumol L (**28**),[39] *cis*-/*trans*-*p*-coumaric acid (**33a**/**b**),[29] *cis*-/*trans*-*p*-coumaric acid methyl ester (**34a**/**b**),[29] quercetin (**36**),[40] quercetin-3-*O*-β-D-glucopyranoside (**37**),[41] 1-*O*-β-D-(2-methylpropanoyl)-phloroglucinol glucopyranoside (co-multifidol glucopyranoside) (**40a**),[43] *trans*-*N*-feruloyltyramine (**42**),[23,36,37] cohumulon (**41a**),[13] *n*-humulon (**41b**),[13] adhumulon (**41c**),[13] colupulon (**44a**),[13] *n*-lupulon (**44b**),[13] and adlupulon (**44c**).[13] The chemical structures of compounds **10**, **11**, **18**, **29**, **31**, and **32** have been determined by means of UV/vis, LC-MS, and 1D/2D NMR experiments and, to the best of our knowledge, have not been earlier reported (Figure 4).

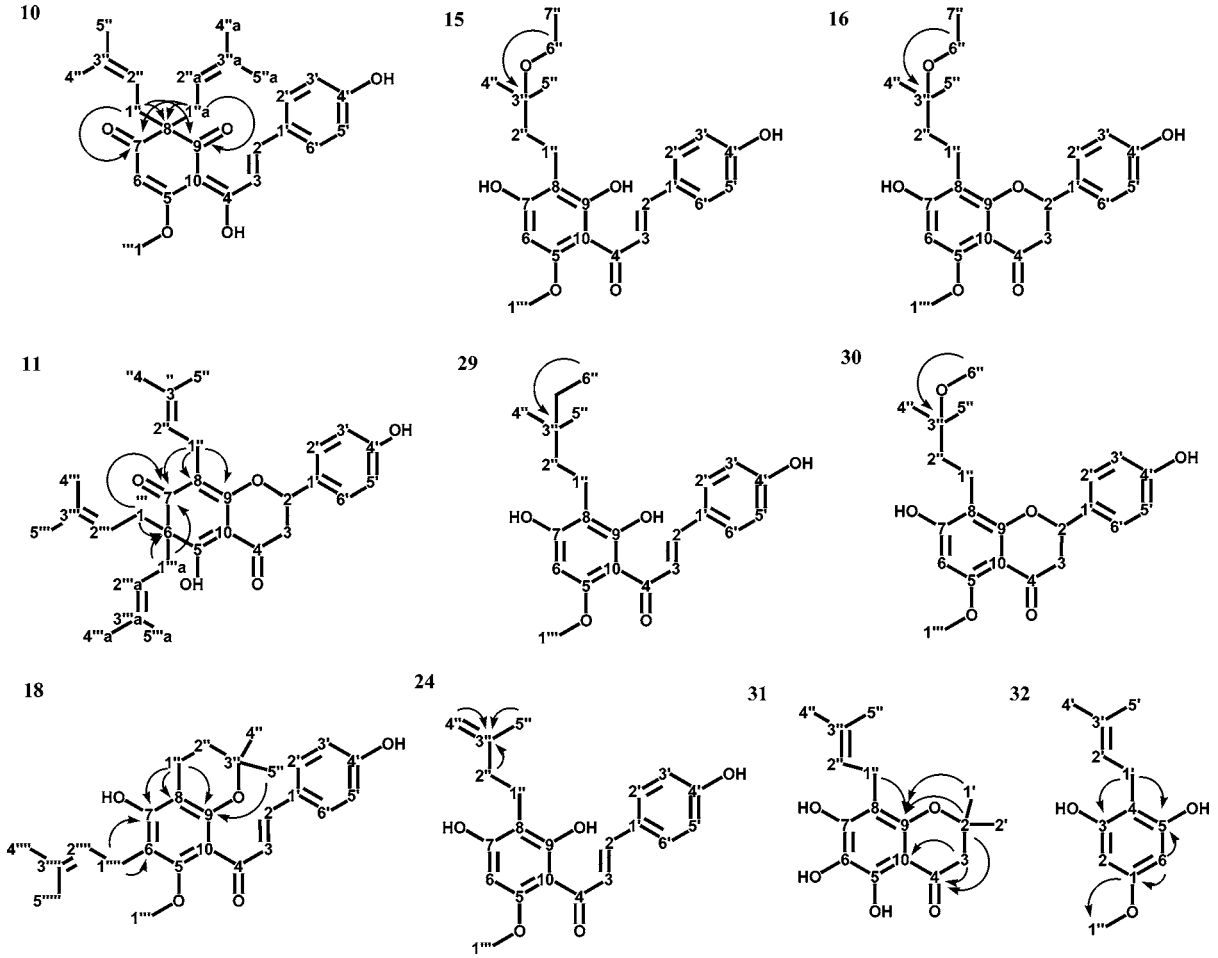

Figure 4. Chemical structures of compounds **10**, **11**, **15**, **17**, **18**, **24**, and **29**−**32** with heteronuclear key correlations (HMBC experiment) highlighted.

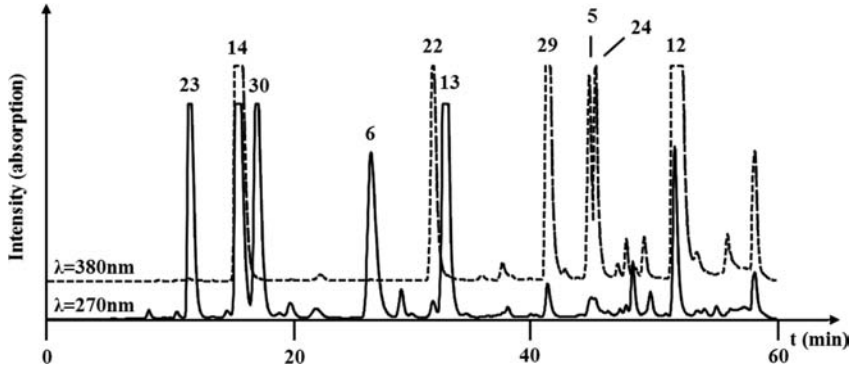

Figure 5. RP-HPLC/UV chromatogram of a methanolic solution of xanthohumol (**5**) after treatment (45 min, rt) with hydrobromic acid solution (33% in acetic acid). Numbering of compounds refer to structures given in Figure 1

Isolation of Compounds from Hop Tannin Extract. Aliquots of the hop tannin extract (200 μL), diluted with water (500 μL), were separated by means of HPLC on a 250 × 21.2 mm, 5 μm, Luna Phenyl-Hexyl column (Phenomenex, Aschaffenburg, Germany) operated with a flow rate of 15 mL/min and using 0.1% aqueous formic acid and acetonitrile containing 0.1% formic acid as solvents. Chromatography was performed by starting with 5% solvent B for 0.5 min, then increasing solvent B to 15% within 0.5 min, and, after keeping at 15% for 34.0 min, solvent B was increased to 25% within additional 7 min, then increased to 100% within 1 min, followed by isocratic elution for 3.0 min. After 46 min, solvent B decreased again to 5% within 1.0 min and was kept for 3.0 min prior to the next injection. The compounds eluting at 24.5 (**37**), 27.0 (**40a**), 30.0 (**38**), and 32.0 min (**39**) were collected and separated from solvent in vacuum and freeze-dried twice. For preparative isolation of additional compounds, the following gradient was used: 5% solvent B for 0.5 min and then increasing solvent B to 15% within 0.5 min. Solvent B was kept for 41.0 min at 15% and, finally, increased to 100% within an additional minute, followed by isocratic elution for 3.0 min. After 46 min, solvent B decreased again to 5% within 1.0 min and was kept for 3.0 min prior to the next injection. Compounds eluting after 31.5 (**40a**), 32.3 (**38**), 33.0 (**40c**), and 33.3 min (**41b**) were collected, separated from solvent under vacuum, and freeze-dried twice. Compounds **37**−**41b** (>98% purity) were analyzed by means of UV/vis, LC-MS/MS, UPLC-TOF-MS, and 1D/2D NMR. Based on the comparison of spectroscopic and chromatographic data with those recorded for references, previously reported compounds were confirmed as

J. Agric. Food Chem. 2015, 63, 3402−3418

quercetin-3-*O*-*β*-D-glucopyranoside (**37**),[41] kaempferol-3-O-*β*-D-glucopyranoside (**38**),[41] kaempferol-3-*O*-*β*-D-(6″-malonyl)glucopyranoside (**39**),[42] 1-*O*-*β*-D-(2-methylpropanoyl)phloroglucinol glucopyranoside (co-multifidol glucopyranoside, **40a**),[43] 1-*O*-*β*-D-(2-methylbutyryl)-phloroglucinol glucopyranoside (ad-multifidolglucopyranoside, **40c**),[43] and phloroisovalerophenon-3,5-di-*C*-*β*-D-glucopyranoside (*n*-multifidol-di-C-glucopyranoside) (**41b**).[43]

Synthetic Preparation of Xanthohumol Derivatives 12−14, 22−24, 29, and 30. An aliquot (50 mg) of xanthohumol (**5**) was solved in a mixture of hydrobromic acid solution (33% in acetic acid; 5 mL) and methanol (5 mL) and stirred for 45 min at room temperature. The reaction mixture was separated by semipreparative HPLC on a 250 × 10.0 mm Hypersil RP-18 column (Thermo Hypersil GmbH, Kleinostheim, Germany) using water (0.1% formic acid) as solvent A and methanol (0.1% formic acid) as solvent B at a flow rate of 4.7 mL/min. Chromatography was performed using the following gradient: 62% solvent B for 4.5 min, then increasing solvent B to 64% within 5.5 min. After 3.0 min solvent B was increased to 70% within 10 s, then to 72% within 5.3 min, to 80% within 0.5 min, kept for 6.0 min and, finally, to 100% within an additional 1.5 min, followed by isocratic elution for 2.5 min. After 29.0 min, solvent B decreased again to 62% within 1 min and was kept for 3.0 min prior to the next injection. Besides xanthohumol (**5**) and isoxanthohumol (**6**), the effluent of the peaks of compounds **12−14**, **22−24**, **29**, and **30** (Figure 5) was collected and, after the solvent was removed in vacuum and freeze-dried twice, the individual compounds (>98% purity) were used for sensory and identification experiments (UV/vis, LC-MS/MS, UPLC-TOF-MS, 1D/2D NMR). Based on the comparison of spectroscopic (UV/vis, LC-TOF-MS, $^{1}H/^{13}C$ NMR) and chromatographic data (retention time) with those recorded for reference substances, compounds reported earlier in the literature were identified as 1″,2″-dihydroxanthohumol C (**12**),[23,36,37] 1″,2″-dihydroisoxanthohumol C (**13**),[45] 1″,2″-dihydroxanthohumol K (**14**),[36,37] xanthohumol H (**22**),[23,36,37] and isoxanthohumol H (**23**).[39] Furthermore, compound **29** was identified as xanthohumol M based on the comparison with the compound isolated above form the *ε*-resin, whereas compounds **24** and **30** have not been previously reported (Figure 4).

*Xanthohumol N, **24** (Figure 4).* UV/vis (ACN/water; 0.1% formic acid): λ_{max} = 368 nm. LC-MS (ESI$^-$): *m/z* (%) 353 (100, [M − H]$^-$), 119 (35), 163 (15), 233 (12), 283 (8). LC-TOF-MS (ESI$^-$): *m/z* 353.1394 ([M − H]$^-$, measured), *m/z* 353.1394 ([M − H]$^-$, calcd for $C_{21}H_{21}O_5^-$). ^{1}H NMR (500 MHz, MeOD; COSY): *δ* (ppm) 1.79 [s, 3H, H−C(5″)], 2.18 [m, 2H, *J* = 8.1, H−C(2″)], 2.69 [m, 2H, *J* = 8.1, H−C(1″)], 3.28 [s, 3H, H−C(6″)], 3.90 [s, 3H, H−C(1‴)], 4.66 [s, 2H H−C(4″)], 6.03 [s, 1H, H−C(6)], 6.83 [m, 2H, *J* = 8.7 Hz, H−C(3′, 5′)], 7.50 [m, 2H, *J* = 8.7 Hz, H−C(2′, 6′)], 7.67 [d, 1H, *J* = 15.5 Hz, H−C(3)], 7.80 [d, 1H, *J* = 15.5 Hz, H−C(2)]. ^{13}C NMR (125 MHz, MeOD; HSQC, HMBC): *δ* (ppm) 22.1 [C(1″)], 22.6 [C(5″)], 37.9 [C(2″)], 56.2 [C(1‴)], 91.6 [C(6)], 106.5 [C(10)], 109.7 [C(8)], 110.1 [C(4″)], 116.9 [C(3′, 5′)], 125.9 [C(3)], 128.5 [C(1′)], 131.2 [C(2′, 6′)], 143.3 [C(2)], 161.0 [C(4′)], 162.5 [C(5)], 163.9 [C(7)], 166.2 [C(9)], 194.1 [C(4)].

*Isoxanthohumol M, **30** (Figure 4).* UV/vis (ACN/water; 0.1% formic acid): λ_{max} = 289 nm. LC-MS (ESI$^-$): *m/z* (%) 385 (8, [M − H]-), 119 (100), 265 (19), 165 (6), 163 (5), 197(4). LC-TOF-MS (ESI$^-$): *m/z* 385.1664 ([M − H]$^-$, measured), *m/z* 353.1657 ([M − H]$^-$, calcd for $C_{22}H_{25}O_6^-$). ^{1}H NMR (400 MHz, MeOD; COSY): *δ* (ppm) 1.13 [s, 6H, H−C(4″, 5″)], 1.60 [m, 2H, H−C(2″)], 2.53 [m, 2H, H−C(1″)], 2.66 [dd, 1H, *J* = 3.0, *J* = 16.9, H−C(3eq)], 3.00 [dd, 1H, *J* = 12.9, *J* = 16.9, H−C(3ax)], 3.06 [s, 3H, H−C(6″)], 3.80 [s, 3H, H−C(1‴)], 5.30 [dd, 1H, *J* = 3.0, *J* = 12.9, H−C(2)], 6.13 [s, 1H, H−C(6)], 6.81 [m, 2H, *J* = 8.7 Hz, H−C(3′, 5′)], 7.33 [m, 2H, *J* = 8.7 Hz, H−C(2′, 6′)]. ^{13}C NMR (100 MHz, MeOD; HSQC, HMBC): *δ* (ppm) 18.1 [C(1″)], 25.6/27.2 [C(4″, 5″)], 38.7 [C(2″)], 46.2 [C(3)], 49.3 [C(6″)], 56.0 [C(1‴)], 76.4 [C(3″)], 80.1 [C(2)], 93.5 [C(6)], 105.9 [C(10)], 110.5 [C(8)], 116.2 [C(3′, 5′)], 129.0 [C(2′, 6′)], 131.4 [C(1′)], 158.9 [C(4′)], 161.9 [C(5)], 163.9 [C(9)], 164.4 [C(7)], 192.9 [C(4)].

Synthetic Preparation of *cis*/*trans*-*p*-Coumaric Acid Ethyl Ester (35a/b). An aliquot (10 mL) of an ethanolic solution of *trans*-*p*-coumaric acid (**33b**; 100 mmol/L) was acidified with 0.1 mL of sulfuric acid. The solution was stirred under reflux for 24 h. Afterward the reaction mixture was subjected to a solid phase extraction using ethanol as an eluent. A HPLC separation with two injections of the crude extract after 0.0 and 3.0 min, using a gradient as follows, was applied to achieve fast separation of the *cis*- and *trans*-isomers: 41% solvent B for 20 min and, then, increasing solvent B to 100% within 0.5 min, followed by an isocratic elution for 1 min. After 21.5 min, solvent B decreased again to 41% within 0.1 min and was kept for 3.0 min prior to the next injection. After removing the solvent in vacuum and freeze-drying twice, compounds **35a** and **35b** were isolated (>98% purity) and were used for sensory experiments as well as UV/vis, TOF-MS, and 1D/2D NMR. Based on the comparison of spectroscopic and chromatographic data with those recorded for references, compounds reported earlier in the literature were identified as *cis*-/*trans*-*p*-coumaric acid ethyl ester (**35a**/**b**).[29]

Synthetic Preparation of Xanthohumol P (15). An aliquot (25 mg) of xanthohumol (**5**) and Amberlyst 15 (1 g) was stirred in ethanol (10 mL) for 4 h at 80 °C. HPLC purification of **15** was achieved using a gradient as follows: 30% solvent B for 2.0 min and, then, increasing solvent B to 80% within 12.5 min and, finally, increasing solvent B to 100% within 1.0 min, followed by isocratic elution for 2.5 min. After 16.0 min, solvent B decreased again to 30% within 1.0 min and was kept for 3.0 min prior to the next injection. The compound eluting after 15.3 min was isolated (>98% purity) and, after the solvent was removed in vacuum and freeze-dried twice, was used for sensory experiments. Structure verification by means of UV−vis, LC-MS/MS, UPLC-TOF-MS, and 1D/2D NMR undoubtedly identified the compound as xanthohumol P, **15** (Figure 4), which has to the best of our knowledge not been described yet in the literature. In addition, compounds **6** and **12−14** were isolated from the reaction mixture.

*Xanthohumol P, **15** (Figure 1).* UV/vis (ACN/water; 0.1% formic acid): λ_{max} = 367 nm. LC-MS (ESI$^-$): *m/z* (%) 399 (57, [M − H]$^-$), 119 (100), 353 (64), 232 (20), 174 (13). LC-TOF-MS (ESI$^-$): *m/z* 399.1802 ([M − H]$^-$, measured), *m/z* 399.1808 ([M − H]$^-$, calcd for $C_{23}H_{27}O_6^-$). ^{1}H NMR (400 MHz, MeOD; COSY): *δ* (ppm) 1.18 [t, 3H, H−C(7″)], 1.23 [s, 6H, H−C(4″, 5″)], 1.65 [m, 2H, *J* = 7.1, *J* = 8.5, H−C(2″)], 2.58 [m, 2H, *J* = 7.1, *J* = 8.5), H−C(1″)], 3.53 [dd, 2H, H−C(6″)], 3.90 [s, 3H, H−C(1‴)], 6.03 [s, 1H, H−C(6)], 6.87 [m, 2H, *J* = 8.7 Hz, H−C(3′, 5′)], 7.50 [m, 2H, *J* = 8.7 Hz, H−C(2′, 6′)], 7.67 [d, 1H, *J* = 15.5 Hz, H−C(3)], 7.80 [d, 1H, *J* = 15.5 Hz, H−C(2)]. ^{13}C NMR (100 MHz, MeOD; HSQC, HMBC): *δ* (ppm) 16.3 [C(7″)], 17.8 [C(1″)], 26.3 [C(4″, 5″)], 39.0 [C(2″)], 56.2 [C(1‴)], 57.5 [C(6″)], 76.4 [C(3″)], 91.7 [C(6)], 106.5 [C(10)], 110.0 [C(8)], 116.9 [C(3′, 5′)], 125.9 [C(3)], 128.5 [C(1′)], 131.3 [C(2′, 6′)], 143.4 [C(2)], 161.1 [C(4′)], 162.4 [C(5)], 163.8[C(9)], 166.2 [C(7)], 194.1 [C(4)].

Alkaline Isomerization of Compounds 9, 12, 15, and 29. An aliquot (10 mg) of the compound **9**, **12**, **15**, and **29**, respectively, was dissolved in 5 mL of methanol and, after adjusting the pH to a value of 14 with potassium hydroxide (0.1 mol/L), stirred for 30 min in a closed glass vial at 60 °C. The reaction mixture was diluted with water and subjected to a solid phase extraction using 55 *μ*m, 70A, Strata C18-E Giga Tube cartridges (200 mg, 3 mL; Phenomenex, Aschaffenburg, Germany) and methanol as an eluent, prior to HPLC separation on a 250 × 21.2 mm, 5 *μ*m, Luna Phenyl-Hexyl column (Phenomenex, Aschaffenburg, Germany). The HPLC system was operated with a flow rate of 15 mL/min, using 0.1% aqueous formic acid and acetonitrile containing 0.1% formic acid as solvents, and using a gradient as follows: 20% solvent B for 2.5 min and then increasing solvent B to 100% within 20.0 min followed by isocratic elution for 2.5 min. After 25.0 min, solvent B decreased again to 20% within 2.0 min and was kept for 3.0 min prior to the next injection. After the solvent was removed in vacuum and freeze-dried twice, compounds **7**, **8**, **13**, **16**, and **30** (>98% purity) were used for sensory experiments and structure determination. Based on the comparison of spectroscopic (UV/vis, LC-TOF-MS, $^{1}H/^{13}C$ NMR) and chromatographic data (retention time) with those recorded for reference substances, the following compounds were identified: desmethylxanthohumol (**7**),[25] 8-prenylnaringenin (**8**),[25] 1″,2″-dihydroisoxanthohumol C (**13**),[45] and isoxanthohumol M (**30**). To the best of our knowledge, isoxanthohumol P, **16** (Figure 4), has not been earlier reported in the literature.

[a]Chemical structures are given in Figure 1. [b]Commercial Pilsner-type beer. [c]Beers I–IV were produced by the Research Brewery St. Johann (Germany) and their International Bitterness Units (IBU) adjusted as follows: beer I (reference) was produced using an Isohop extract (30%) added to the beer to adjust an IBU value of 23. Beers II–IV were produced using the same wort as for beer I just differing in the hop products. For beer II (27 IBU) and beer IV (27 IBU), an ε-extract was added to the wort postboiling and at the beginning of the kettle boiling, respectively. Beer III (51 IBU) was made by adding spent hops, obtained by exhaustive carbon dioxide extraction, to the wort prior to boiling.

[C(6″)], 56.4 [C(1‴)], 75.6 [C(3″)], 79.8 [C(2)], 93.8 [C(6)], 105.3 [C(10)], 109.9 [C(8)], 115.8 [C(3′, 5′)], 128.4 [C(2′, 6′)], 130.6 [C(1′)], 158.2 [C(4′)], 161.2[C(5)], 163.3 [C(9)], 163.2 [C(7)], 192.4 [C(4)].

Quantitation of Bitter Compounds in Hop Extracts and Beer by LC-MS/MS. For quantitation of bitter compounds, aliquots of hop pellets (1.5 g), hop extracts (100 mg), and samples (40 mg) of the advanced hop extracts XanthoFlav 15, XanthoFlav 75, and polyphenol extracts, respectively, were exhaustively extracted for 1 h with methanol (4 × 25 mL) during ultrasonification. After filtration, the extracts were diluted (1:100) with methanol and, after membrane filtration (0.45 μm, Sartorius, Göttingen, Germany), samples (5 μL) were directly injected into a Dionex UltiMate 3000 series UHPLC system consisting of two pumps, a degasser, a column compartment, and an autosampler (Dionex, Idstein, Germany) connected to an API 4000 Q-TRAP mass spectrometer (SCIEX, Darmstadt, Germany) which was equipped with an electrospray ionization (ESI) source and operated in negative ionization mode.

For the analysis of beer samples, the beverage was degassed by ultrasonification and membrane filtered (0.45 μm, Sartorius, Göttingen, Germany), and aliquots (5 μL) were directly injected into the SCIEX LC-MS system. The temperature of the autosampler was set to 5 °C and of the column compartment to 40 °C. The declustering potential (DP), the cell exit potential (CXP), and the collision energy (CE) of the mass spectrometer were optimized for each substance to induce fragmentation of the pseudo molecular ion $[M - H]^-$ to the corresponding target product ions after collision-induced dissociation. Quantitative analysis was performed by means of multiple reaction monitoring (MRM) mode using optimized fragmentation parameters and retention times of the corresponding reference compounds. The ion spray voltage was set to −4500 V, and dwell time for each mass transition was 2.5×10^{-3} s. Nitrogen was used as the collision gas (4×10^{-5} Torr). Using unhopped beer as a blank matrix, 8-point external matrix calibration curves were recorded for the individual analytes **1**–**42** in low (2.5 nmol/L to 200 μmol/L) and high concentrations (0.2 mmol/L to 20 mmol/L) by means of UPLC-MS/MS. Quantitation of the co- and ad-congeners of α-acids (**1**), β-acids (**2**), and *cis*-/*trans*-iso-α-acids (**3**, **4**) was performed by using the calibration curve of the *n*-congeners. Calibration functions were forced through zero, thus leading to correlation coefficients of >0.99 for all the reference compounds in unhopped beer. Concentrations of *cis*-/*trans*-*p*-coumaric acid (**33a**/**b**) were corrected for amounts detected in the nonhopped beer (control). The limit of detection was determined to be 0.3 nmol/L (S/N ratio: 3) for all compounds (**1**–**42**), and the limit of quantification was accordingly estimated to be 0.001 μmol/L (S/N ratio: 10).[46] Data processing and integration was performed by means of Analyst software version 1.5 (AB Sciex Instruments, Darmstadt, Germany). As stationary phase, a 150 × 2.0 mm, 4 μm, Synergi Hydro-RP column (Phenomenex, Aschaffenburg, Germany) was used. The mobile phase consisted of acetonitrile (0.1% formic acid) as solvent A and water (0.1% formic acid) as solvent B. Using a flow rate of 0.6 mL/min, chromatographic separation was achieved (Figure 5) by gradient elution increasing solvent A from 10 to 40% within 15 min and further increased to 60% in 13 min, to 70% in 20 min, and finally to 100% within 2 min. It was maintained at 100% for 1 min, following by readjustment to 10% within 5 min and re-equilibrated for 4 min prior to the next injection.

Sensory Analysis. *General Conditions and Panel Training.* Twelve subjects (7 women and 5 men, ages 23–29 years), who gave

DOI: 10.1021/acs.jafc.5b00239
J. Agric. Food Chem. 2015, 63, 3402–3418

consent to participate in the sensory tests of the present investigation and had no history of known taste disorders, participated for at least two years in weekly training sessions and were recruited from the Chair of Food Chemistry and Molecular Sensory Science (Freising, Germany). To familiarize the subjects with the bitter taste of hop-derived compounds and to get them trained in recognizing bitterness by using the sip-and-spit method,[33] xanthohumol (**5**) and *trans*-isocohumulone (**4a**) were used as references. The sensory experiments were performed at 20−22 °C. To prevent cross-modal interactions with olfactory or visual inputs, the panelists used nose clips and yellow light or whenever necessary red light, respectively, was used.

Pretreatment of Fractions and Pure Compounds. Prior to sensory analysis, the fractions or isolated compounds were suspended in water, and, after removal of the volatiles under high vacuum (<5 hPa), were freeze-dried twice. ^{1}H NMR spectroscopy, GC/MS, and high-performance ion chromatographic analysis of an aliquot revealed that fractions treated by that procedure are essentially free of solvents and buffer compounds used. Formic acid, which is GRAS listed as a flavoring agent for food and feed applications, was used to adjust the pH value of solutions to be sensorially evaluated, because trace amounts of this acid do not influence the sensory profile of the test solution.

Sensory Analysis of Isolated Hop Resins. The individual resin fractions isolated from hops as described above were evaluated in their bitter intensity. To achieve this, each resin sample was taken up in 5% aqueous ethanol adjusted to pH 4.4 with trace amounts of 10% aqueous formic acid. The bitter intensity of these solutions was judged on a scale from 0 (not detectable) to 5 (strongly detectable).

Taste Dilution Analysis (TDA)..[33−35] An aliquot of each fraction isolated from hops was freeze-dried twice and dissolved in water containing 5% ethanol (pH 4.4) in "natural" concentration ratios matching the amounts present in 2.0 g of hops hard resin. After each fraction had been sequentially diluted 1 + 1 with water (pH 4.4), the serial dilutions of each of these fractions were presented to the sensory panel in order of ascending concentration. Using a duo test, panelists were asked to determine the dilution step at which a difference between sample and blank could be detected. This so-called taste dilution (TD) factor[33] determined by the 12 sensory assessors was averaged and did not differ by more than plus/minus one dilution step between the trained individuals.

Bitter Recognition Threshold Concentrations. Bitter taste threshold concentrations of the purified compounds were determined by 12 panelists using a duo test. The geometric mean of the last and the second to last concentrations was calculated and taken as the individual recognition threshold. The threshold value of the sensory group was approximated by averaging the threshold values of the individuals in three independent sessions and did not differ by more than plus/minus one dilution step. Based on the three independent repetitions, the confidence interval (α = 0.05) was calculated for each compound.

Taste Re-Engineering Experiments. To investigate the impact of the hop constituents on the bitter perception of beer, four taste recombinants were produced by spiking unhopped "zero" beer with bitter taste molecules in concentrations as determined in a standard Pilsner-type beer (Table 3) by means of LC-MS/MS. Recombinant A: "zero" beer was spiked with iso-α-acids (**3a−c**, **4a−c**). Recombinant B: recombinant A was spiked with xanthohumol (**5**) and isoxanthohumol (**6**). Recombinant C: recombinant A was spiked with prenylated flavonoids **5−32**. Recombinant D: recombinant A was spiked with compounds **5−42**. Using a linear 5-point scale, the bitterness of these recombinants A−D was then compared with that of a standard Pilsner-type beer (reference).

Sensomics Heatmapping. Data analysis was performed within the programming and visualization environment R (version 2.13.2).[47] The sensomics heatmap was calculated using the heatmap.2 function of R based on the concentration data after scaling the sum of all sensometabolites to an equal value for each beer sample. The dendrograms were constructed by means of an agglomerative linkage algorithm specifying the distance between two clusters as the increase in the error sum of squares after fusing two clusters into a single cluster and seeking for a minimum distance at each clustering step.[48]

Liquid Chromatography/Mass Spectrometry (LC-MS/MS). For compound identification, mass and product ion spectra were acquired on an API 4000 Q-Trap triple quadrupole/linear ion trap mass spectrometer (SCIEX, Darmstadt, Germany). Isolated fractions were dissolved in methanol/water (50/50, v/v) and directly introduced into the mass spectrometer by flow infusion using a syringe pump. Data were acquired in full-scan mode with negative electrospray ionization (−4500 V). Both quadrupoles operated at unit mass resolution. Nitrogen served as curtain gas (30 psi) and as turbo gas (450 °C). Fragmentation of the pseudo molecular ions $[M-H]^-$ into specific product ions was induced by collision with nitrogen (4.5×10^{-5} Torr). Data acquisition and instrumental control were performed with Analyst 1.5 software (SCIEX).

UPLC/Time-of-Flight Mass Spectrometry (UPLC/TOF-MS). Mass spectra of the compounds were measured on a Synapt G2 HDMS mass spectrometer (Waters, Manchester, U.K.) coupled to an Acquity UPLC core system consisting of a binary solvent manager, sample manager, and column oven. The compounds were dissolved in acetonitrile (1 mL), and aliquots (1−5 μL) were injected into the UPLC-TOF-MS system equipped with a 2 × 150 mm, 1.7 μm, BEH C18 column (Waters). Operated with a flow rate of 0.3 mL/min at 40 °C, the following gradient was used for chromatography: starting with a mixture (5/95, v/v) of acetonitrile and aqueous formic acid (0.1%, pH 2.5), the acetonitrile content was increased to 100% within 5 min and held at 100% for 1 min. Measurements were performed using negative ESI and the resolution modus consisting of the following parameters: capillary voltage −3.0 kV, sampling cone 30, extraction cone 4.0, source temperature 150 °C, desolvation temperature 450 °C, cone gas 30 L/h, and desolvation gas 850 L/h. The instrument was calibrated over an m/z range of 100−1200 using a solution of sodium formate (0.5 mM) in a 2-propanol/water mixture (9/1, v/v). All data were lock mass corrected using leucine enkephalin as the reference (m/z 554.2615, $[M-H]^-$). Data processing was performed by using MassLynx 4.1 (Waters) and the tool "elemental composition".

Nuclear Magnetic Resonance Spectroscopy (NMR). 1D/2D-^{1}H and ^{13}C NMR spectra were acquired on a 400 MHz DRX and a 500 MHz Avance III spectrometer (Bruker, Rheinstetten, Germany), respectively. CD_3OD, D_2O, or DMSO-d_6 was used as solvent, and chemical shifts are reported in parts per million relative to the solvent signal. For signal assignment, 2D-NMR experiments (COSY, HMQC, HMBC) were carried out using the pulse sequences taken from the Bruker software library. Data processing was performed by using XWin-NMR software (version 3.5; Bruker, Rheinstetten, Germany) as well as MestReNova 5.1.0-2940 (Mestrelab Research S.L., Santiago de Compostela, Spain).

RESULTS AND DISCUSSION

As the use of the hop's hard resin fraction for beer manufacturing was reported to reveal beers with an intense and pleasant bitter profile,[26] the sensory impact of the hard resin fractions should be evaluated. To achieve this, the hard resin fraction was isolated from hops,[30] chlorophylls and hop waxes were separated by means of solid phase extraction, and the resin was separated to give the water-soluble δ-resin and the nonsoluble ε-resin fraction by extraction with water at 40 °C.[31,32] Aliquots of the δ-resin, ε-resin, hard resin, soft resin, and total hop resin, respectively, were solubilized in 5% ethanolic solution in their "natural" concentration ratio (0.2/0.8/1/9/10; w/w), and the pH was adjusted to 4.4 to match the pH value of a standard beer. The trained sensory panelists, who were asked to rate the bitter intensity on a linear scale from 0 (not detectable) to 5.0 (very intense), judged the bitterness of the soft resin solution with the highest score of 4.25 (±0.25), followed by the ε-resin and the hard resin with 0.51 (±0.08) and 0.5 (±0.25), whereas bitterness was almost not detectable (0.08 ± 0.04) in the solution containing the δ-resin (data not shown). These data confirm the previously reported major bitter contribution of the soft resin

DOI: 10.1021/acs.jafc.5b00239
J. Agric. Food Chem. 2015, 63, 3402−3418

components and indicated the ε-resin to account for the bitterness of the hop's hard resin fraction. The ε-resin was, therefore, further separated to locate and identify the key bitter molecules in that hydrophobic fraction.

Identification of Key Bitter Compounds in the ε-Resin. Fractionation of the ε-resin by means of MPLC on RP18 material revealed 11 fractions (e1−e11), which were dissolved in 5% ethanolic solution in their natural concentration ratio and, then, evaluated in their bitter impact by means of a taste dilution analysis (TDA).[33−35] Fractions e5, e6, and e8−e11 were judged with the highest TD factors of 64 and 256, respectively, followed by fractions e2−e4 judged with TD factors between 6 and 32 (Figure 2). Aimed at locating the key contributors to the bitter taste of fractions e2−e11, each MPLC fraction was separated by means of preparative RP-HPLC and the subfractions were again analyzed by means of TDA to locate most intense bitter tastants (Figure 3).

Comparison of spectroscopic data (UV/vis, LC-MS/MS, $^{1}H/^{13}C$ NMR) of xanthohumol (**5**) in subfractions e8-7, e9-6, and e10-2, isoxanthohumol (**6**) in subfractions e4-2, e5-3, e6-5, and e9-2, desmethylxanthohumol (**7**) in subfraction e7-12, 8-prenyl- (**8**) and 6-prenylnaringenin (**9**) in subfraction e8-5, 5′-prenylxanthohumol (**17**) in subfractions e10-10 and e11-8, xanthohumol D (**19**) in e7-9, xanthohumol B (**20**) in e7-7, and xanthohumol C (**21**) in e10-5 and e11-5 with the literature data[24,25] confirmed the identity of these compounds in the ε-resin (Table 1). In addition, 1″,2″-dihydroxanthohumol C (**12**) was identified in subfractions e10-4 and e11-4, 1″,2″-dihydroxanthohumol K (**14**) in e4-2, e5-3, and e7-3, xanthohumol H (**22**) in e6-7 and e7-4, xanthohumol I (**26**) in e3-4, and 2″-hydroxyxanthohumol M (**25**) in e7-8 (Table 1), the spectroscopic data of which confirmed previously published data.[23,36−38,45] Another polar bitter compound in fraction e2 was identified as co-multifidol glucopyranoside **40a**[43] in subfraction e2-7 (Table 1). Some trace amounts of α-acids (**1a**/**b**/**c**) were identified in e10-8/9 and e11-8/9, and β-acids (**2a**/**b**/**c**) in e11-7, e11-11, and e11-13, thus indicating some residual amounts of soft resin components in the hard resin fraction. Next to these bitter compounds, some astringent molecules were identified as *cis*/*trans*-*p*-coumaric acid (**33a**/**b**)[49] in subfraction e2-4, quercetin (**36**)[40] in e3-5, and quercetin-3-*O*-β-D-glucopyranoside (**37**)[41] in e2-5 (Table 1). The bitter molecules ad-multifidol glucopyranoside (**40c**)[43] and *n*-multifidol-di-*C*-glucopyranoside (**40b**)[44] as well as the astringent molecules *trans*-*N*-feruloyltyramine (**42**),[23,36,37] kaempferol-3-*O*-β-D-glucopyranoside (**38**),[41] and kaempferol-3-*O*-β-D-(6″-malonyl)glucopyranoside (**39**)[42] were isolated from a hop polyphenol extract and were also identified as hard resin constituents (Table 2). For unequivocal structure elucidation by means of NMR spectroscopy, glycosides **37**−**41** were isolated in larger quantities from the hop tannin extract.

In contrast to the above-mentioned taste molecules, compounds **10**, **11**, **18**, **23**, **27**−**29**, **31**, and **32** isolated from the ε-resin have not yet been identified as natural phytochemicals in hops and beer, respectively. Although not yet reported as hop components, xanthohumol O (**27**), xanthohumol L (**28**), and isoxanthohumol H (**23**) were found earlier as metabolites in feces of xanthohumol-fed rats.[39] The chemical structures of the previously not reported hop bitter constituents **10**, **11**, **18**, **29**, **31**, and **32** were determined by means of LC-MS and 1D/2D-NMR experiments.

NMR analysis of compound **29**, isolated from subfractions e8-3 and e9-4, showed similar ^{1}H and ^{13}C shifts as found for xanthohumol H (**22**), thus suggesting a similar chemical structure. However, an additional proton signal for H−C(6″) resonating at 3.28 ppm with an integral of three protons and an additional ^{13}C resonance signal for C(6″) at 50.6 ppm indicated compound **29** as the 3″-methoxy adduct of xanthohumol H (**22**). This was confirmed by the heteronuclear coupling observed between carbon atom C(3″) and the protons of the methyl group H−C(6″) in the HMBC spectrum (Figure 4). To confirm the natural occurrence of **29** and to exclude any artifact formation during workup, hop was extracted with ethanol instead of methanol. LC-MS/MS analysis of this ethanolic extract unequivocally identified xanthohumol M (**29**) in hops.

Compound **18** showed similar ^{1}H and ^{13}C NMR shifts for the naringenin moiety and the cyclic prenylic side chain as found for 1″,2″-dihydroxanthohumol K (**14**) and 1″,2″-dihydroxanthohumol C (**12**), respectively. But in comparison to **12** and **14**, any ^{1}H NMR signal for H−C(6) was lacking, whereas additional signals were observed for a second prenyl side chain as known for 5′-prenylxanthohumol (**17**). The HMBC spectrum indicated a heteronuclear coupling between carbon atom C(6) and the protons at C(1‴) and confirmed the attachment of a prenyl side chain to carbon C(6) (Figure 4). The hypsochromic shift of the UV maximum of xanthohumol (**5**) and 1″,2″-dihydroxanthohumol C (**12**), respectively, from ∼370 to 326 nm was well in line with the intramolecular cyclization of the prenyl side chain attached to carbon C(8) with the hydroxyl group bound to carbon C(9).[50] In consequence, the structure of this previously unknown compound was assigned as 1″,2″-dihydroxanthohumol F, **18** (Figure 4).

The spectroscopic data of compound **10**, showing major differences compared to those reported for other hop constituents in the past, indicated the presence of two prenyl side chains, a *p*-coumaroyl moiety, and a methoxy group in the HSQC spectrum. The HMBC spectrum revealed both prenyl side chains to be attached to carbon C(8) and to show connectivity to two keto functions, thus indicating a cyclohexenedione structure (Figure 4). In contrast to the keto function at C(4) as found in xanthohumol derivatives, carbon C(4) showed a ^{13}C chemical shift as expected for a hydroxylated carbon. However, the proton signal of H−C(2) showed an extraordinarily strong low-field shift as found for xanthohumol due to the *peri*-effect[51] caused by the keto function at C(9). Taking all spectroscopic data into consideration, the target bitter compound was identified as the previously not reported 4′-hydroxytunicatachalcone, **10** (Figure 4), which is the 4′-hydroxy derivative of tunicatachalcone identified earlier.[52]

The ^{1}H and ^{13}C NMR spectrum of compound **11** showed very similar chemical shifts as found for 5′-prenylxanthohumol (**17**) but additional resonance signals indicating the presence of another prenylic side chain and a keto function. Furthermore, an HSQC experiment revealed compound **11** to be a flavonoid showing the characteristic proton resonances at 2.96 and 3.16 ppm for the diastereotopic protons H−C(3). The HMBC spectrum showed a heteronuclear coupling between carbon C(9) and one prenylic side chain, and between carbonyl carbon C(7), resonating at 198.6 ppm, to three prenylic side chains (Figure 4). Taking all spectroscopic data into consideration, the structure of compound **11** was determined to be 5-hydroxy-2-(4-hydroxyphenyl)-6,6,8-triprenyl-6*H*-chroman-4,7-dione, coined isoxantholupon, **11** (Figure 4), which to the best of our knowledge has not previously been reported.

Compared to xanthohumol (**5**), compound **31** was missing the typical ^{1}H shifts of the *p*-coumaric acid moiety. Furthermore, the

DOI: 10.1021/acs.jafc.5b00239
J. Agric. Food Chem. 2015, 63, 3402−3418

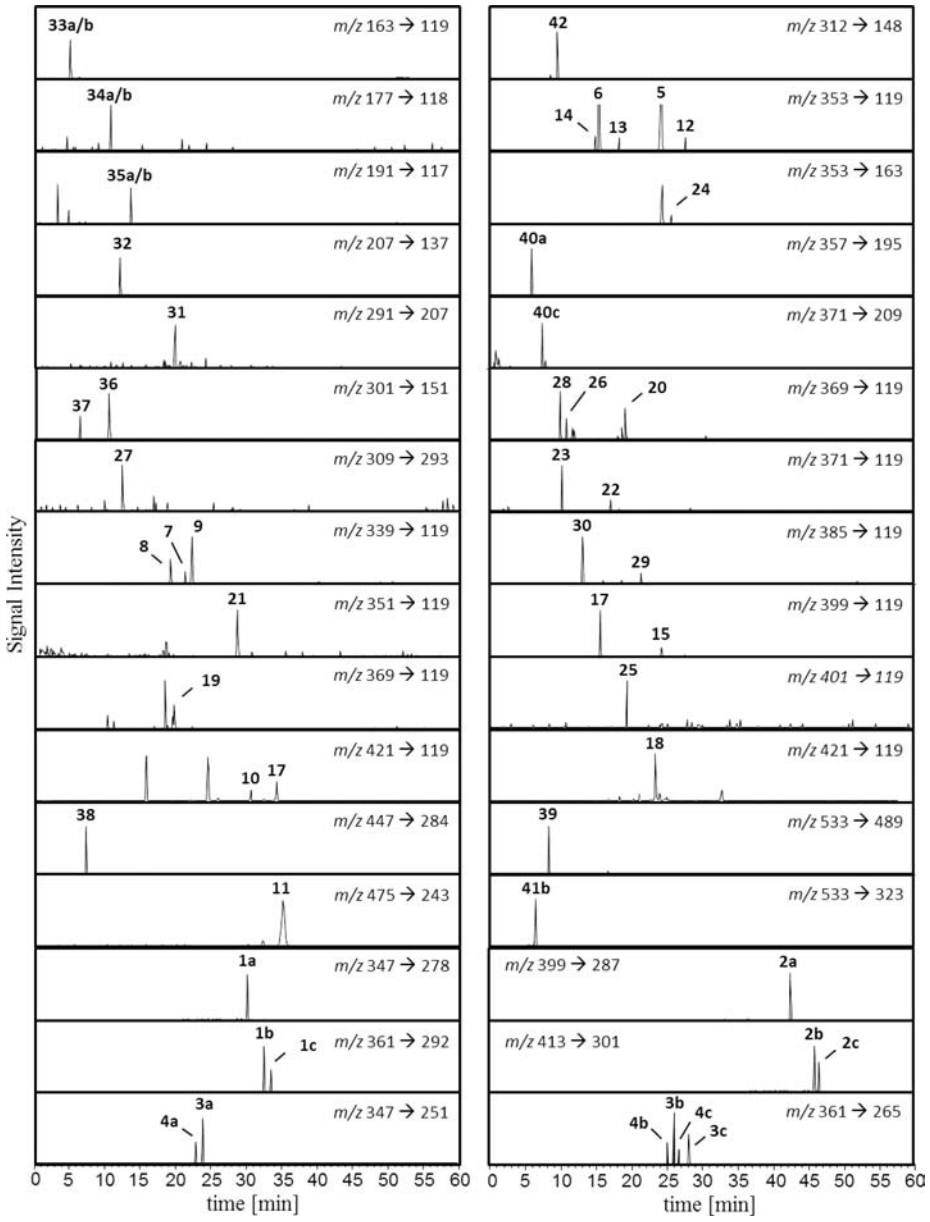

Figure 6. RP-HPLC-MS/MS mass chromatogram of taste compounds in hop extract. Numbering of compounds refers to chemical structures given in Figure 1.

spectra also showed that a substitution had occurred at carbon atom C(6) due to the lacking proton signal at this carbon atom. But interestingly, compound **31** exhibited typical ^{1}H shifts of an intact prenylic side chain as well as signals of two chemically identical methyl groups which showed no ^1J-coupling with any other proton. A long-range coupling of carbon C(9) and the methyl protons H−C (1′, 2′) in the HMBC spectrum revealed the structure of compound **31** to be 2,2-dimethyl-5,6,7-trihydroxy-8-(3-methylbut-2-enyl)chroman-4-one, which is coined 2″,3″-dehydrocyclohumulohydrochinone, **31** (Figure 4), due to its structural similarity with humulohydrochinon.[53] As LC-MS-MS analysis undoubtedly confirmed the presence of this compound in hops and excluded its formation as workup artifact (data not shown), compound **31** is considered a previously not reported hop constituent.

The ^{1}H NMR data of compound **32**, showing a molecular composition of $C_{12}H_{16}O_3$ (TOF-MS), revealed large similarities with those recorded for xanthohumol (**5**), but showed an additional singlet at 5.4 ppm and lacked the typical aromatic proton shifts of the *p*-coumaric acid moiety. Heteronuclear couplings in the HMBC spectrum indicated that a prenylic side chain is attached at carbon C(4) and that a methoxy group is connected to carbon C(1). Taking all spectroscopic data into account, the target compound was identified as the previously not reported 1-methoxy-4-prenylphloroglucinol, **32** (Figure 4). It is proposed in the literature that xanthohumol is biosynthesized from coumaroyl-CoA and three malonyl-CoA to form chalconaringenine, followed by a prenylation reaction to form first desmethylxanthohumol (**7**) and, thereafter, xanthohumol (**5**) by additional methylation.[54] Interestingly, the occurrence of compound **32** in hops provides evidence that the prenylation and methoxylation of the phloroglucin moiety during the biosynthesis of **5** can occur prior to its reaction with *p*-coumaroyl-CoA.

Synthetic Preparation of Xanthohumol Derivatives 12−16, 22−24, 29, and 30. In order to screen the hop fractions for additional xanthohumol derivatives, xanthohumol P

DOI: 10.1021/acs.jafc.5b00239
J. Agric. Food Chem. 2015, 63, 3402−3418

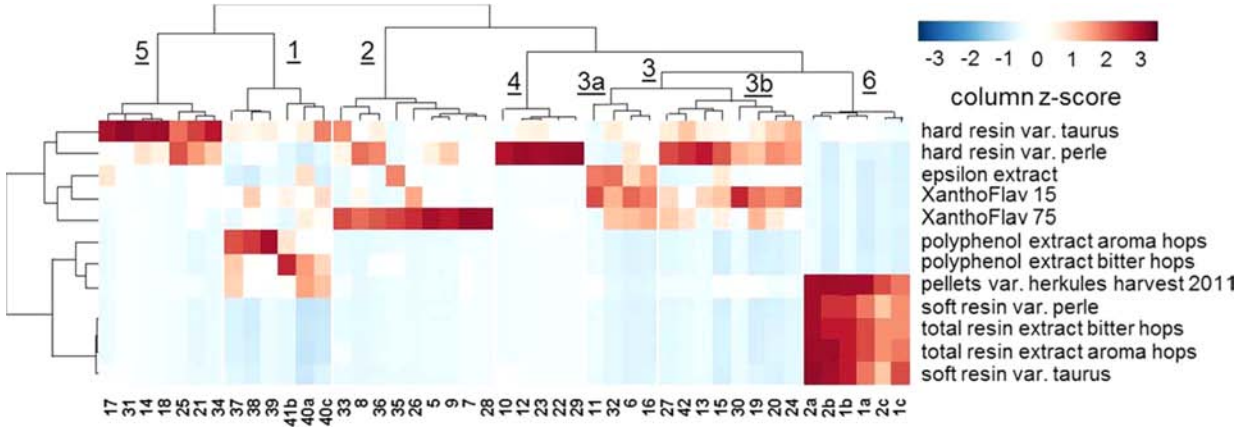

Figure 7. Sensomics heatmapping of concentrations of taste compounds in hop products/extracts taken from Table 3. The dendrogram is based on an agglomerative linkage algorithm.[48] Numbering of compounds refers to structures given in Figure 1

(**15**) was synthesized by heating an ethanolic solution of xanthohumol (**5**) for 4 h at 80 °C in the presence of the acidic cation exchanger Amberlyst 15, while isoxanthohumol P (**16**) and isoxanthohumol M (**30**) were obtained after alkaline isomerization of xanthohumol P (**15**) and xanthohumol M (**29**), respectively. Reaction of xanthohumol (**5**) with hydrobromic acid in methanol/acetic acid revealed, besides compounds **6**, **15**, **16**, **29**, and **30**, additional major transformation products, namely, **12**, **14**, and **22**−**24** (Figure 5). These compounds were identified as 1″,2″-dihydroxanthohumol C (**12**) and K (**14**), and xanthohumol H (**22**) by LC-MS and 1D/2D-NMR experiments as well as by cochromatography with the corresponding reference substance (Figure 4). Isoxanthohumol H (**23**) and 1″,2″-dihydroisoxanthohumol C (**13**) were isolated and identified by comparing the LC-MS and NMR data to those reported in literature.[39,45] Reaction product **24** exhibited similar ^{1}H and ^{13}C shifts as found for the naringenin substructure in xanthohumol (**5**) but with a different proton signal pattern recorded for the prenylic side chain. Instead of two nonaromatic signals integrating for three protons, only one signal at 1.79 ppm with an integral of three protons was observed. In addition, resonance signals integrating for two protons were observed at 2.18 and 4.66 ppm, respectively, suggesting that the double bond in **24** is located between C(3″) and C(4″). The heteronuclear coupling between C(3″) and H−C(4″) observed in the HMBC spectrum (Figure 4) confirmed the structure of **24** as xanthohumol N (Figure 1), which to the best of our knowledge has not yet been reported earlier.

Sensory Evaluation of Purified Hop Components. Prior to sensory analysis, the purity of each compound was confirmed by HPLC-MS as well as ^{1}H NMR spectroscopy to be more than 98%. To determine the human threshold concentrations for the bitter sensation induced by the hop derivatives identified, aqueous solutions of target compounds were evaluated in serial dilutions by means of a duo test (Table 1). The bitter threshold concentrations determined for the α-acids (**1**), β-acids (**2**), xanthohumol (**5**), and isoxanthohumol (**6**) by means of the duo test were comparable to those recorded recently by means of a triangular test,[15−17] thus confirming the suitability of the duo test setup.

Except for the *p*-coumaric acid esters (**34a**/**b**, **35a**/**b**), the human bitter threshold concentrations were relatively low and ranged from 5 to 44 μmol/L (Table 1). Comparably high threshold concentrations (>20 μmol/L) were found for compounds **15**, **16**, **19**, **22**, **23**, **26**, and **30** exhibiting a modified prenylic side chain, while an intramolecular cyclization (**12**, **14**, **20**, **28**) seemed not to influence the bitter threshold levels. More lipophilic molecules like compound **12** that elute later on RP-18 material seem to have a lower human threshold concentration than structurally related earlier eluting substances like compound **14**. Interestingly, the polar *O*-β-D-glycosides of the multifidol congeners **40a** and **40c** feature surprisingly low human threshold concentrations of 5 and 10 μmol/L, respectively (Table 1). As the α/β-acids, iso-α-acids, xanthohumol, and isoxanthohumol activate three bitter taste receptors, namely, hTAS2R1, hTAS2R14, and hTAS2R40 receptor,[21] these data suggest the involvement of another bitter taste receptor responding to the bitter β-glycosides **40a** and **40c**. One candidate receptor would be the hTAS2R16, which has been reported to be activated by β-glycosides like salicin.[55]

Quantitation and Sensomics Heatmapping of Hop-Derived Bitter Compounds in Hop Products and Beer. To gain insight into the occurrence and concentrations of the individual hop-derived bitter compounds in beer, compounds **1**−**42** (Figure 1) were quantitated in hop extracts as well as a Pilsner-type beer by means of HPLC-MS/MS in a single chromatographic run. Operating the mass spectrometer in the multiple reaction monitoring (MRM) mode, a highly selective and sensitive quantitation of the analytes could be accomplished (Figure 6).

As expected, xanthohumol (**5**) was the most predominant compound (>30 mmol/100 g) found in the hard resin (Table 2). With the exception of the very lipophilic isoxantholupon (**11**) and *cis*-/*trans*-*p*-coumaric acid ethyl ester (**35a**/**b**), all other compounds identified above were found in the hard resin as well. 1-Methoxy-4-prenyl-phloroglucinol (**32**) and 2″,3″-dehydrocyclohumulohydrochinon (**31**) were only detectable in the hard resin isolated from the bitter hop variety Taurus (Table 2). As expected, trace amounts of most of the prenylated flavonoid were found in the soft resins too. Only the nonpolar 4′-hydroxytunicatachalcone (**10**) and 5′-prenylxanthohumol (**17**), respectively, were observed in considerable amounts of 1193 and 1320 μmol/100 g in the soft resin of the bitter hop variety Taurus. Analysis of the commercially available pure resin extracts contained high amounts of >700 μmol/100 g of xanthohumol (**5**), whereas all other compounds (**6**−**42**) were present in comparatively low amounts (Table 2).

Quantitative analysis of the XanthoFlav 75% extract revealed, next to xanthohumol (**5**), high concentrations of isoxanthohumol (**6**, 9754 μmol/100 g), desmethylxanthohumol (**7**, 13873

μmol/100 g), xanthohumol L (**28**, 11656 μmol/100 g), and kaempferol-3-*O*-β-D-glycopyranoside (**38**, 45105 μmol/100 g). With the exception of xanthohumol (**1**), the XanthoFlav 15% extract did not differ much in its composition from the xanthohumol enriched extract XanthoFlav 75%. The only significant difference was the presence of much higher amounts (8142 vs 3.87 μmol/100 g) of isoxantholupon (**11**) in the extract XanthoFlav 15%. The ε-extract[27] contained quite the same compounds as the XanthoFlav extracts, however, xanthohumol (**5**) and isoxanthohumol (**6**) were present in comparably low amounts of 8601 and 7671 μmol/100 g, respectively, and the polar compounds **10**, **34**−**39**, **41b**, and **42** were not detectable at all (Table 2).

Commercially available tannin extracts revealed very high amounts of the flavonol glycosides **37**−**39** (813.2−14541 μmol/100 g) and the intensely bitter tasting multifidol glycosides **40a**, **40b**, and **41b** (428.7−4802 μmol/100 g). Interestingly, the extract prepared from an aroma hop variety has higher amounts of the flavononol glycosides **37**−**39** (18.60 vs 11.36 mmol/100 g), whereas the extract made from a bitter hop variety showed higher levels of the multifidol glycosides **40a**, **40b**, and **41b** (2.38 vs 7.08 mmol/100 g). Both extracts contained only minor amounts (<105 μmol/100 g) of xanthohumol (**5**) and its derivatives.

To examine the multivariate distances between the individual sensometabolites throughout the set of different hop products, the concentrations determined for hard resin-derived compounds (**5**−**42**) were scaled, followed by a hierarchical cluster analysis to arrange the taste compounds into six clusters labeled 1−6 as visualized in a sensomics heatmap (Figure 7). Cluster 1 consisted of the glycosides **37**−**41b** present in high concentrations in the tannin extracts and in hop pellets, thus demonstrating the quantitative dominance of glycosides over the xanthohumol derivatives. Cluster 2 comprised xanthohumol (**5**), desmethylxanthohumol (**7**), its isomerization products 8-(**8**) and 6-prenylnaringenin (**9**), xanthohumol I (**26**), *cis*-/*trans*-*p*-coumaric acid ethyl ester (**35a**/**b**), and quercetin (**36**) being the characteristic attribute of the XanthoFlav extract 75%. In comparison, the large cluster 3 consisted of isoxanthohumol (**6**), isoxantholupon (**11**), isoxanthohumol P (**16**), and 1-methoxy-4-prenylphloroglucinol (**32**) separating in subcluster 3a and 1″,2″-dihydroisoxanthohumol C (**13**), xanthohumol P (**15**), xanthohumol D (**19**), xanthohumol B (**20**), xanthohumol N (**24**), xanthohumol O (**27**), isoxanthohumol M (**30**), and *N*-*trans*-feruloyltyramine (**42**) in subcluster 3b. Whereas higher concentrations of compounds in subcluster 3a seem to be characteristic for the ε-extract and the XanthoFlav 75% extract, the extract XanthoFlav 15% and the hard resins showed high concentrations of compounds of subcluster 3b. Interestingly, the hard resin fraction prepared from the hop varieties Taurus and Perle showed significant differences in clusters 4 and 5. Compounds 4′-hydroxytunicatachalcone (**10**), 1″,2″-dihydroxanthohumol C (**14**), xanthohumol H (**22**), isoxanthohumol H (**23**), and xanthohumol M (**29**) are grouped in cluster 4 and are representative for the Perle hard resin, whereas 1″,2″-dihydroxanthohumol K (**14**), 5′-prenylxanthohumol (**17**), xanthohumol C (**21**), 2″-hydroxyxanthohumol M (**25**), 2″,3″-dehydrocyclohumulohydrochinon (**31**), and *cis*-/*trans*-*p*-coumaric acid methyl ester (**34a**/**b**), classified in cluster 5, seem to be typical for the Taurus hard resin. As expected, the α-acids (**1a**/**b**/**c**) and β-acids (**2a**/**b**/**c**) are characteristic for the total resin extract and the soft resin and are therefore grouping together in cluster 6. These data clearly show that the various hop products are distinctive for their content of specific hard resin derived compounds and are a useful resource to adjust levels of desired compounds in final hop-containing products like beer.

The quantitative analysis of a traditional Pilsner beer (Table 3) confirmed that the iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**) are the quantitatively predominant bitter tasting compounds[12−14] with concentrations between 5.0 and 24.5 μmol/L.[56] Due to the isomerization reaction during wort boiling, significant amounts (5.5 μmol/L) of isoxanthohumol (**6**) are present in the beer sample. Next to the iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**) and isoxanthohumol (**6**), the glycosides (**37**−**41b**) are the third largest group with concentrations between 0.9 and 4.0 μmol/L. All other xanthohumol and isoxanthohumol derivates (**5**, **8**−**30**) are present in concentrations below 0.6 μmol/L. With the exception of the iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**), none of the other compounds were detected in beer above their taste threshold concentration (Table 1). In order to investigate whether the subthreshold prenylated flavonoids and glycosides contribute additively to the beer's bitterness, taste re-engineering experiments were performed in the following.

Taste Re-Engineering Experiments. Samples of unhopped "zero" beer were spiked with natural concentrations (Table 3) of the individual purified iso-α-acids **3** and **4** to give recombinant A, the iso-α-acids (**3a**−**c**, **4a**−**c**), xanthohumol (**5**), and isoxanthohumol (**6**) to give recombinant B, the iso-α-acids (**3a**−**c**, **4a**−**c**) and the prenylated flavonoids **5**−**32** to give recombinant C, and the iso-α-acids (**3a**−**c**, **4a**−**c**) plus all the identified compounds **5**−**42** to give recombinant D. Using a linear 5-point scale, the bitterness of these recombinants A−D was then compared with that of a standard Pilsner-type beer as reference (Figure 8). Without any further addition, the bitterness

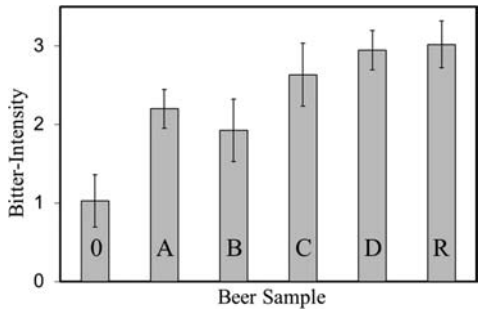

Figure 8. Bitter taste intensity of (R) standard Pilsner-type (reference), (0) unhopped "zero" beer and "zero" beer spiked with (A) iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**), (B) iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**), xanthohumol (**5**), and isoxanthohumol (**6**), (C) iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**) and compounds **5**−**35** and **42**, and (D) iso-α-acids (**3a**/**b**/**c**, **4a**/**b**/**c**) and all hard resin-derived compounds **5**−**42** (Table 1). Confidence interval (α = 5%).

of the "zero" beer was rated with a low score of 1.03 ± 0.33 compared to the reference Pilsner-type beer (3.02 ± 0.29), thus demonstrating that a majority of the beer's bitterness is due to hop-derived components while a marginal portion of remaining bitterness comes from other sources such as, e.g., yeast and malt. Recombinant A containing the iso-α-acids showed an increased intensity of 2.20 ± 0.25 for a scratchy bitterness which was perceived with an instantaneous onset but a short offset. Addition of xanthohumol (**5**) and isoxanthohumol (**6**) to recombinant A induced a marginally decreased bitter intensity of recombinant B (1.93 ± 0.40) which was reported by the panelists to exhibit a more long lasting and less sharp bitter profile when compared to

J. Agric. Food Chem. 2015, 63, 3402−3418

recombinant A. Recombinant C containing iso-α-acids plus compounds **5**−**32** showed a typical beer-like, well-rounded bitterness with a medicinal-herbal-like off-taste, and the bitter intensity increased and was determined to be 2.64 ± 0.25. Sensory evaluation of the total taste recombinant D revealed a bitterness of 2.95 ± 0.26, which did not differ significantly from the bitter intensity of the reference beer (3.02 ± 0.29) and was described as beer-like, long lasting, and well-rounded without any specific off-taste. Taking all these sensory data into account, iso-α-acids (**3a**−**c**, **4a**−**c**) and the identified compounds **5**−**42** were demonstrated for the first time to be truly sufficient for constructing the authentic bitter percept of beer. The knowledge on the structure and concentration of these bitter compounds paves the way for the targeted manufacturing of tailored taste profiles of beer and hop-containing foods and beverages.

Sensory and Quantitative Analysis of Hop-Derived Taste Compounds in Beer Manufactured with ε-Extract and Spent Hops, Respectively. It has been recently reported that the use of hop's hard resin instead of the soft resin fraction for beer production revealed a beer exhibiting an intense and pleasant bitter character.[26] As the above-mentioned ε-extract was found to be enriched in bitter tasting prenylated flavonoids, it was interesting to quantitate the bitter molecules and to sensorially evaluate the bitter taste of a beer manufactured by using this ε-extract as the only hop source. To achieve this, four different beers (beers I−IV) were produced and their International Bitterness Units (IBU) were determined by a trained sensory panel.[57] Beer I was produced as a bitter reference using an Isohop extract (30%) added to the final, fermented beer to adjust an IBU value of 23. Beers II−IV were produced using the same wort as for beer 1 just differing hop products. For manufacturing of beer II (27 IBU) and beer IV (27 IBU), the ε-extract was added to the wort postboiling and at the beginning of the kettle boiling, respectively. Beer III (51 IBU) was made by adding spent hops, which were obtained by exhaustive carbon dioxide extraction, to the wort prior to boiling. Descriptive sensory analysis revealed beer I (23 IBU) and beer IV (27 IBU) as well-rounded with a pleasant and typical Pilsner-type bitter profile. In comparison, beer III produced from spent hops (51 IBU) was described by the trained panelists as strongly bitter with a harsh bitter and irritating character perceived at the back of the tongue, while beer II (27 IBU) was reported to exhibit a medicinal or herbal bitter taste profile.

To gain some more insight into the concentrations of the individual hop-derived bitter compounds in beer, compounds **1**−**42** were quantitated in beers I−IV and a standard Pilsner-type beer by means of HPLC-MS/MS in a single chromatographic run (Table 3). Analysis of beer I revealed about 60 μmol/L iso-α-acids (**3**, **4**) as well as small amounts of 4′-hydroxytunicatachalcone (**10**) and isoxantholupon (**11**). Van Opstaele[58] already described that iso-α-acids extracts also contain some other hop-derived compounds which are accordingly introduced into a beer spiked with an iso-α-acids extract. All other compounds of the hard resin (**5**−**9**, **12**−**42**) were present just in trace amounts or were not detectable. In comparison, beer II contained significant amounts of the nonisomerized xanthohumol derivatives **5**, **12**, **14**, **15**, **17**, **19**−**22**, **24**, and **28**, besides α-acids (**1**) and β-acids (**2**), being well in line with manufacturing the beer by using a xanthohumol derivative enriched extract after wort boiling. Adding the ε-extract at the beginning of the wort boiling procedure (beer IV) resulted in rather low amounts of xanthohumols but significantly increased amounts of isoxanthohumol derivatives, namely, isoxanthohumol (**6**), 6-prenylnaringenin (**9**), 8-prenylnaringenin (**8**), isoxanthohumol H (**23**), and isoxanthohumol M (**30**). Interestingly, high concentrations of isoxanthohumol P (**16**) and *cis*-/*trans*-*p*-coumaric ethyl ester (**35a**/**b**) were found in beer IV, which might be explained by postfermentation reactions with ethanol produced by yeast.

The concentrations of most compounds (**5**−**35**) found in beer III, which was produced with spent hops only, did not significantly differ from those found in beer IV, thus confirming that all target compounds are already present in the spent material and are extracted and/or isomerized during kettle boiling. Interestingly, *trans*-*N*-feruloyltyramine (**42**), quercetin (**36**), and the bitter glycosides **37**−**41b** were also found in beer III in up to 10-fold higher concentrations than in beer IV. With the exception of the multifidol glycosides **40a** and **40c**, these very polar compounds were not present in the ε-extract and are extracted during wort boiling from spent hops. As beer III and beer IV showed quite similar concentrations of prenylated flavonoids (Table 3), but do differ drastically in the content of glycosides **37**−**41**, it is assumed that the overall harsh and unpleasant bitter taste sensation perceived for beer IV is due to the rather high levels of these glycosides.

With the exception of isoxanthohumol (**6**) and 8-prenylnaringenin (**8**), the concentrations of compounds **5**−**42** were much higher in beer IV than in the standard Pilsner-type beer, e.g., beer IV contained 68, 240, and 5500 times higher levels of xanthohumol, isoxanthohumol P, and isoxanthohumol H when compared to the standard Pilsner beer (Table 3). Since prenylated flavonoids have been shown to possess health beneficial effects in vitro[23,45,59,60] but a 60-fold enrichment of xanthumol derivatives is necessary to benefit from the proposed activities,[61] these results impressively demonstrate the possibility to produce beverages strongly enriched with prenylated hop flavonoids.

discourages barrel rejuvenation.[20,24,25] For these reasons, winemakers tend to favor replacement of old barrels.

Previous studies have demonstrated that a thermal gradient occurs within barrel staves during toasting, with temperatures ranging from approximately 175 to 105 °C, at 0−4 and 12−16 mm stave depths, respectively.[26] The middle and outer parts of staves may therefore retain considerable aroma potential since the thermal degradation of oak macromolecules (i.e., lignin, cellulose, and hemicellulose) that results in the formation of oak derived volatile compounds is temperature dependent[8,27] and may therefore occur to a lesser extent, if at all, at the comparatively lower toasting temperatures achieved across a stave. The aim of this study was therefore to investigate whether decommissioned barrels can be reclaimed and utilized as a previously untapped source of quality oak for wine maturation, i.e., to determine the aroma potential of oak battens prepared from the staves of old barrels. During the barrel reclaim process, the inner wine-affected portion of staves is discarded, to lessen the risk of "burnt" characters forming during toasting, as well as the microbial load. However, since spoilage bacteria have previously been found at stave depths of 8 mm,[25] the temperature profiles achieved during toasting were also measured, to evaluate the potential for viable spoilage yeast to remain in reclaimed oak.

MATERIALS AND METHODS

Chemicals. Chemicals were purchased from Sigma-Aldrich. Solvents were of HPLC grade from Merck (Darmstadt, Germany). Reference compounds included *cis*- and *trans*-oak lactone, guaiacol, 4-methylguaiacol, eugenol, vanillin, furfural, and 5-methylfurfural. [$^2H_4$]-(3*S*,4*S* and 3*R*,4*R*)-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid was synthesized in house as previously reported.[28]

Preparation of Reclaimed Oak Battens. Oak battens (48 in total, each approximately 900 × 70 × 6 mm^3) were prepared from randomly selected decommissioned oak barrels (12 French and 12 American) held in stock by Ausvat Pty. Ltd. (Willunga, Australia). Decommissioned barrels (which had been used for ≥5 years) were disassembled, and individual staves (1 from each barrel) were reclaimed to produce oak battens (Supporting Information, Figure 1), i.e., the wine-affected oak was removed and discarded, and the remaining oak split laterally to give two battens (i.e., "inner" and "outer" battens from the middle and outer portions of the stave, respectively), which were then trimmed to remove barrel grooves and planed to expose the fresh grain of the wood. Each batten was then divided lengthways and one-half subjected to far-infrared (FIR) toasting (on each side, sequentially), according to in-house operating procedures employed by Ausvat Pty. Ltd. Temperature profiles were characterized during toasting by positioning thermocouples (HOBO, Onset Computer Corporation, Bourne, MA, USA) on each face of one batten, approximately halfway along the batten (Supporting Information, Figure 1d). A thermocouple was also positioned within the batten itself (via a hole drilled laterally through the side of the batten). Temperature measurements were recorded at 10 s intervals. Two reclaimed American oak battens (both inner battens) were discarded following FIR toasting as they did not meet quality assurance requirements (i.e., due to inconsistent toasting); this reduced the number of samples for this treatment from 12 to 10.

Preparation of Oak Extracts. Oak shavings (approximately 20 g per sample) were prepared from untoasted and toasted battens using a hand-held plane. For the quantitation of oak lactone glycoconjugates, shavings (0.5 g) from untoasted battens were soaked in an aqueous 50% methanol solution (10 mL) with the addition of deuterated (3*S*,4*S* and 3*R*,4*R*)-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid (96 μg/mL in water, 10 μL) as an internal standard. Samples were then sonicated for 60 min, centrifuged (4,300*g* for 5 min), and a portion of the supernatant filtered through a 0.45 μm GHP membrane (Acrodisc, PALL Life Sciences, Cheltenham, Australia) prior to analysis. Preparation of the internal standard has been reported previously.[28] For quantitation of oak volatiles, spectroscopic analysis, and difference testing, shavings (2 g) from toasted battens were soaked in an aqueous 20% ethanol solution (100 mL, saturated with potassium bitartrate, pH adjusted to 3.5 with tartaric acid) for a week at room temperature and in darkness. Samples were then filtered prior to analysis.

Quantitation of Oak Lactone Glycoconjugates by Liquid Chromatography−Tandem Mass Spectrometry (HPLC-MS/MS). Three glycoconjugate precursors to oak lactone, namely, (3*S*,4*S*)-3-methyl-4-*O*-(6′-*O*-galloyl)-β-D-glucopyranosyloctanoic acid, (3*S*,4*S*)-*cis*- and (3*S*,4*R*)-*trans*-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid, and 3-methyl-4-*O*-(6′-*O*-α-L-rhamnosyl)-β-D-glucopyranosyloctanoic acid, hereafter referred to as galloylglucoside, glucoside, and rutinoside, respectively, were quantified in extracts of untoasted reclaimed oak according to the stable isotope dilution assay (SIDA) methods reported previously.[11,28] These publications describe the preparation of deuterated (3*S*,4*S* and 3*R*,4*R*)-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid, method validation, and instrumental operating conditions. Analyses were carried out using an Agilent 1200 HPLC system coupled to an AB Sciex 4000 Q TRAP hybrid tandem mass spectrometer (Agilent, Palo Alto, CA, USA).

Quantitation of Oak Volatiles by Gas Chromatography−Mass Spectrometry (GC-MS). The concentrations of *cis*- and *trans*-oak lactone, guaiacol, 4-methylguaiacol, eugenol, vanillin, furfural, 5-methylfurfural, 4-ethylguaiacol, and 4-ethylphenol in extracts of toasted reclaimed oak were quantified according to SIDA methods reported previously.[5,29−31] These publications describe the preparation of deuterated internal standards (d_4-*cis*- and d_4-*trans*-oak lactone, d_3-guaiacol, d_3-4-methylguaiacol, d_3-vanillin, d_4-furfural, and d_4-4-ethylphenol), method validation, and instrumental operating conditions. Analyses were performed by the Australian Wine Research Institute's (AWRI) Commercial Services Laboratory (Adelaide, Australia) using an Agilent 6890 gas chromatograph coupled to a 5973 mass selective detector (Agilent, Palo Alto, CA, USA) and electron impact ionization.

Sensory Analysis by Difference Testing. Difference tests were performed on a 2011 unwooded Chardonnay, with and without the addition of an oak extract (one French oak extract and one American oak extract, selected at random and spiked at 50 mL/L), using the triangle test method[32] and a panel of 30 judges aged between 18 and 55, with similar numbers of males and females. Wines were presented to the panel using a balanced, randomized presentation order, comprising all possible configurations (i.e., AAB, ABA, BAA, BBA, BAB, and ABB, where A denotes unspiked wine and B denotes spiked wine) an equal number of times. Wines (25 mL) were served at 22−24 °C, in covered ISO tasting glasses (215 mL) with randomly assigned three-digit codes. Panelists smelled the samples and were asked to identify the sample which was different.

Analysis of Toasted Oak by Attenuated Total Reflectance Mid-infrared (ATR-MIR) Spectroscopy. Oak extracts (ca. 0.5 mL) were scanned using a platinum diamond ATR single reflection sampling module cell mounted on a Bruker Alpha instrument (Bruker Optics GmbH, Ettlingen, Germany). Extracts of toasted reclaimed oak (n = 46, as above) and toasted French (n = 12) and American (n = 12) oak chips or powders (sourced from Oak Solutions Group, Tanunda, Australia and Oak Chips Incorporated, Piketon, OH, USA) prepared as for reclaimed oak extracts (as above) were analyzed. MIR spectra were recorded on OPUS software, version 6.5, provided by Bruker Optics. The spectrum of each sample was obtained by taking the average of 64 scans at a resolution of 8 cm^{-1} and acquired between 4000 and 375 cm^{-1}, with a scanner velocity of 7.5 kHz and a background of 64 scans. Background reference spectra were recorded using deionized water. The Unscrambler X software (v. 10.1, CAMO ASA, Norway) was used for principal component analysis (PCA) in order to determine any relevant and interpretable structure in the MIR data associated with the different treatments as well as to detect outlier samples. PCA models were developed using full cross-validation (leave one out).

Statistical Analysis. Chemical data were analyzed by one-way analysis of variance (ANOVA) using GenStat (10th edition, VSN International Limited, Herts, UK). Mean comparisons were performed

DOI: 10.1021/acs.jafc.5b00339
J. Agric. Food Chem. 2015, 63, 3419−3425

by least significant difference (LSD) multiple comparison test at $P < 0.05$.

RESULTS AND DISCUSSION

Inner and outer battens were prepared from randomly selected staves taken from decommissioned French and American oak barrels. The history of each barrel, e.g., cooperage conditions, barrel age, and prior usage, was not known, but compositional variation was expected due to differences in oak origin,[15] species,[14,15] and seasoning conditions,[16] so a range of samples (i.e., staves from 12 French and 12 American oak barrels) was deliberately chosen, to achieve a broad representation of used barrels. Aroma potential was determined by measuring (i) the concentrations of glycoconjugate precursors of oak lactone present in untoasted reclaimed oak; (ii) the concentrations of several oak volatiles present in toasted reclaimed oak; and (iii) the MIR spectra of extracts of new and reclaimed oak. Difference tests were also carried out to establish the sensory impact of reclaimed oak.

Oak Lactone Glycoconjugate Content of Untoasted Reclaimed Oak. Oak lactone is considered one of the most important oak derived volatile compounds and is known to occur in oak wood in both free and glycosidically bound precursor forms,[11,33−35] with three glycoconjugates of 3-methyl-4-hydroxyoctanoic acid (i.e., the ring-opened form of oak lactone) having previously been identified in oak wood: a galloylglucoside, a glucoside, and a rutinoside.[34] Pyrolysis of the galloylglucoside and glucoside at 235 °C for 30 min gave significant amounts of oak lactone;[35] thus, quantitation of glycoconjugates in untoasted oak wood provides a measure of aroma potential.

A recent study investigated the oak lactone glycoconjugate profiles of several French oak woods and found the galloylglucoside to be the predominant precursor.[11] Similar results were observed in the current study (Table 1). The galloylglucoside (quantified as glucoside equivalents) was the most abundant precursor present in reclaimed oak battens, irrespective of the geographical origin of oak. The galloylglucoside content of reclaimed French oak wood ranged from 0.11 to 317 μg/g, while higher levels were observed for reclaimed American oak: 0.18 to 403 μg/g. No significant differences were observed between the galloylglucoside levels of inner and outer battens. Mean glucoside concentrations were less than 25 μg/g for both French and American reclaimed oak, with significantly higher glucoside levels observed in inner vs outer reclaimed American oak battens ($P < 0.05$). Mean rutinoside concentrations (again quantified as glucoside equivalents) were approximately 10 μg/g for reclaimed French oak wood, but considerably higher levels, i.e. 55 to 60 μg/g, were measured in reclaimed American oak wood. That higher precursor levels were observed in reclaimed American oak was not surprising, given that American oak wood typically imparts higher concentrations of oak lactone than French oak wood.[7,14,15,18,26] Several samples of reclaimed oak (i.e., battens from two French oak staves and one American oak stave) gave extremely low levels (<2 μg/g) of each precursor (data not shown), but this could reflect natural variation in oak composition rather than exhaustion of oak flavor since relatively low levels have also been observed in new oak wood.[11] Importantly, the glycoconjugate levels observed in reclaimed oak were comparable to those reported in the literature for new oak wood (Table 1), suggesting reclaimed battens should be capable of releasing commercially significant quantities of oak lactone after toasting.

Table 1. Concentrations of Galloylglucoside, Glucoside, and Rutinoside Precursors of Oak Lactone Present in Extracts of Untoasted New and Reclaimed French and American Oak

FIR Toasting of Reclaimed Oak. Toasting plays an important role in the cooperage process and is largely responsible for the generation of oak volatiles. However, the volatile composition of oak wood is dependent on the temperature and duration of toasting. Chatonnet[27] monitored the evolution of oak volatiles from "light" through to "very heavy" levels of toasting and found thermal degradation of lignin and hemicellulose, and the formation of oak volatiles commenced from "medium" toasting. While the degree of toasting is hard to define and is usually judged empirically by individual coopers,[5] oak flavor research provides examples of "medium toast" conditions, which typically involve heating oak wood for at least 30 min at surface temperatures greater than 160 °C.[26,27,36] In this study, FIR heating was employed to simultaneously straighten and toast reclaimed battens. Battens were toasted on each side (sequentially), during which the temperature profiles on each face of, and within, a reclaimed batten were measured (Figure 1). A temperature differential was observed across the batten, such that the hottest temperatures measured were at the batten surface being toasted, being up to 225 °C by Probe 1 initially, then more than 250 °C by Probe 3. The lowest temperatures measured were at the opposite batten face, i.e., approximately 100 °C by Probe 3 initially, then more than 150 °C by Probe 1. The internal batten temperature (recorded by Probe 2) reached approximately 125 °C, then almost 200 °C, during toasting of each side of the batten. Traditional cooperage involves toasting partially assembled barrels over an open fire. Previous studies have shown that the temperature profile across the depth of a barrel stave, typically 30 mm, decreases rapidly, giving poor generation of volatiles much below the surface, i.e., deeper than 6 mm.[26] In contrast, temperatures capable of thermally degrading oak macromolecules (i.e., lignin and cellulose) and oak lactone glycoconjugates were observed across the batten, which can be explained by the relatively thin depth of the batten (i.e., < 7 mm). Importantly, the temperatures achieved during FIR toasting, i.e., between 150 and 250 °C (Figure 1), would also be sufficient to reduce any microbial load,[37,38] thereby preventing the carryover of yeast and/or bacteria during the barrel reclamation process. The concentrations of 4-ethylphenol and 4-ethylguaiacol were measured in toasted

reclaimed oak, as markers of *Brettanomyces* spoilage.[39] 4-Ethylphenol was not detected in any samples, and only trace levels of 4-ethylguaiacol, i.e., $\leq$ 5.1 μg/g were observed (Supporting Information, Table 1). These results indicate that no carryover of *Brettanomyces*-derived volatile phenols occurred during the preparation of reclaimed oak battens, albeit this may simply reflect the absence of spoilage in the decommissioned barrels that were processed. The removal of wine affected oak (i.e., oak that was in contact with wine) should effectively remove any potential wine spoilage microorganisms since the maximum penetration of microbes into the oak surface appears to be limited by the depth of liquid infiltration to approximately 6 mm.[39] Therefore, the likelihood of battens being a source of contaminating microorganisms is very low.

Volatile Composition of Toasted Reclaimed Oak. To further assess the aroma potential of reclaimed oak, the concentrations of several important oak volatiles were measured in extracts (50% aqueous methanol) of toasted reclaimed oak battens and compared with concentrations reported in the literature for extracts of (new) toasted oak wood (Table 2).

For reclaimed French oak, *cis*- and *trans*-oak lactone levels of up to 33.4 and 73.1 μg/g were observed, respectively. No significant differences were observed between the mean oak lactone concentrations of inner vs outer battens, irrespective of geographical origin. Mean oak lactone levels were comparable or exceeded concentrations reported for new oak wood. Previous studies have shown that the ratio of *cis*- to *trans*-oak lactone isomers present in oak wood differs by region and species.[14,15] While *cis*-oak lactone is usually the predominant isomer, toasted sessile oak (*Quercus petraea*) from central France was found to have a significantly higher proportion of *trans*-oak lactone,[27] and similar results were observed for some reclaimed French oak samples in the current study. Reclaimed American oak contained several-fold higher concentrations of *cis*-oak lactone than *trans*-oak lactone, in agreement with previous findings.[7] Three samples of reclaimed French oak had no detectable oak lactone, including two samples that corresponded to the untoasted battens that gave very low glycoconjugate precursor concentrations (data not shown). Again, this might be indicative of flavor exhaustion, but low levels (i.e., $\leq$ 1 μg/g) of oak lactone have been reported in

DOI: 10.1021/acs.jafc.5b00339
J. Agric. Food Chem. 2015, 63, 3419–3425

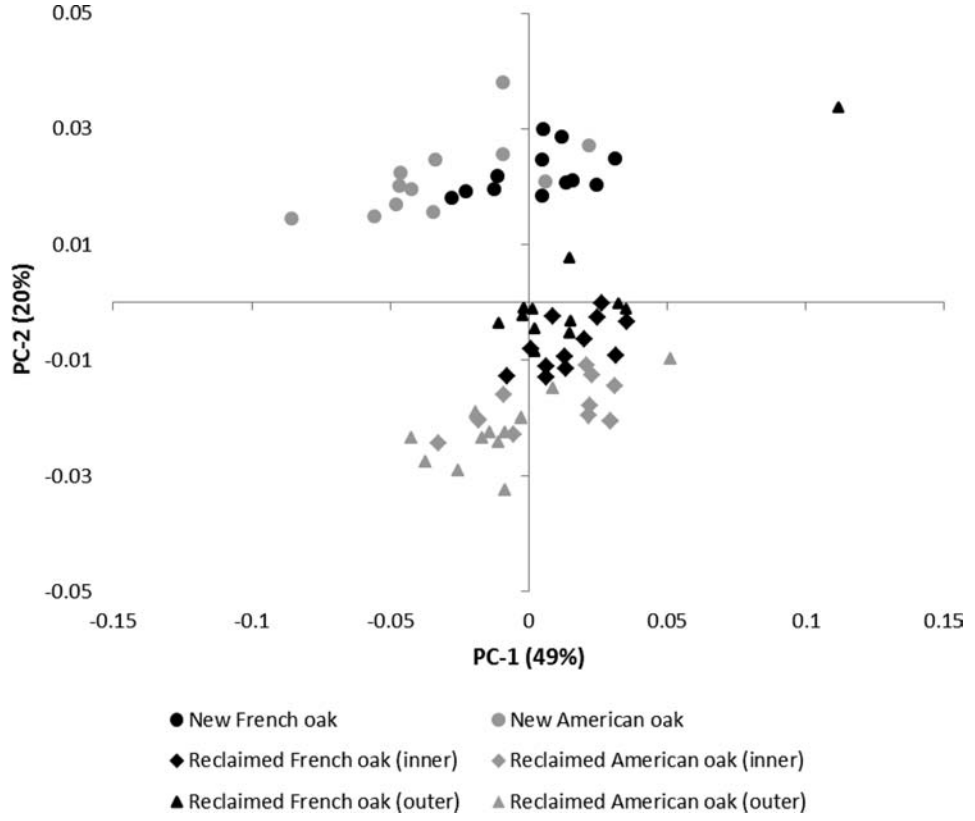

Figure 2. Score plot of the first two PCs derived from the MIR spectra of toasted samples of new and reclaimed French and American oak.

(new) French oak wood,[36] especially pedunculate oak (*Quercus robur*),[15] so this might simply reflect natural variation. Similarly, oak lactone could not be detected in some reclaimed American oak samples. Although American oak usually contains high levels of oak lactone,[17,29] Spillman and colleagues reported low levels of oak lactone in American oak wood samples sourced from Ohio.[16]

Similar guaiacol, 4-methylguaiacol, and eugenol concentrations, up to 12.3, 5.6, and 7.7 μg/g, respectively, were observed in French and American reclaimed oak samples. Vanillin levels ranged from 58 to 115 μg/g in reclaimed French oak, with slightly higher levels, i.e., 70 to 137 μg/g, observed in reclaimed American oak. In general, the concentrations of volatile phenols were comparable to the levels reported for new French and American oak wood[13,17,36] or in the case of eugenol, slightly higher. Again, there were no significant differences observed between the concentrations of these volatiles measured in inner vs outer battens. The influence of toasting temperature on the volatile phenol content of oak has been demonstrated previously, with higher toasting temperatures tending to favor volatile phenol formation.[17] Since oak wood has a low coefficient of thermal conductivity, the size of oak wood is also important, and increased surface area exposure to heat also encourages the formation of volatile phenols,[17] albeit volatiles are subject to volatilization if temperatures are too high.[13,16,17] The toasting temperatures achieved in the current study are comparable to those reported in previous studies involving toasting of oak staves at 200 °C and oak chips at 170 °C.[13,36]

Furfural and 5-methylfurfural were present in reclaimed oak samples at considerably higher concentrations than that for most other oak volatiles. Furfural concentrations ranged from 511 to 1376 μg/g in reclaimed French oak and from 412 to 1134 μg/g in reclaimed American oak. 5-Methylfurfural was less abundant; the levels ranged between 54 and 213 μg/g for reclaimed French oak and 41 and 136 μg/g for reclaimed American oak. These concentrations were again within or above the concentrations reported for new oak wood.

While the oak volatile profiles of reclaimed oak battens further demonstrated their suitability for oak maturation of wine, difference tests were performed to confirm their potential impact on wine aroma. Extracts of either reclaimed French oak or reclaimed American oak (selected at random) were added to a 2011 unwooded Chardonnay at 50 mL/L, i.e., the equivalent of a 1 g/L oak addition and presented as triangle tests to a panel of 30 judges. Seventeen and 20 panelists correctly differentiated wine samples with and without the addition of reclaimed French and American oak extracts, respectively, demonstrating the perceptible aroma impact of reclaimed oak, at the 99% confidence level.

ATR-MIR Analysis of Extracts of New and Reclaimed Toasted Oak. Quantitation of oak lactone precursors and oak volatiles enabled direct but limited comparisons to be made between the aroma potential of new and reclaimed oak wood. ATR-MIR analysis of extracts of new and reclaimed toasted oak was therefore performed as a more holistic approach to compositional analysis. No visual differences were observed in the MIR spectra obtained for extracts of new and reclaimed oak (data not shown), so PCA was performed on spectral data to investigate qualitative differences in oak composition. Figure 2 shows the score plot of the first two principal components (PC), which accounted for 69% of the variation between oak extracts. Two distinct sample clusters were observed: new oak samples were clustered in the upper quadrants, whereas

DOI: 10.1021/acs.jafc.5b00339
J. Agric. Food Chem. 2015, 63, 3419−3425

reclaimed oak samples were clustered in the lower quadrants. This suggests that, despite commercially significant levels of key oak volatiles being observed in reclaimed oak, other compositional differences existed that differentiated new and reclaimed oak wood, by spectral analysis. This could comprise volatile compounds other than those measured and/or nonvolatile oak constituents, such as oak tannins. Interestingly, some differentiation according to geographical origin (i.e., French vs American oak wood) was observed, in agreement with previous research.[40] However, no differentiation of extracts from inner vs outer reclaimed battens was apparent. Instead, extracts derived from inner and outer battens were overlaid, confirming their compositional uniformity.

Despite spectral analysis indicating that some compositional differences exist between new and reclaimed oak, HPLC-MS/MS and GC-MS analyses demonstrated comparable levels of the oak lactone glycoconjugates and oak volatiles that were measured. Difference tests then confirmed the addition of reclaimed oak extracts to wine had a perceptible impact on aroma. Collectively, these results establish the aroma potential of reclaimed oak, and therefore, its suitability as a raw material for oak maturation of wine, particularly given that winemakers can selectively reclaim barrels with a track record of favorable maturation performance. Furthermore, the temperatures achieved during toasting preclude any carryover of spoilage yeast, such as *Brettanomyces*. The reclamation process converts each 225 L barrel into approximately 8 m^2 of reclaimed oak battens, at a cost of AUD$ 150 or between 10 and 20% the price of a new barrique; thus, it is also economically viable.

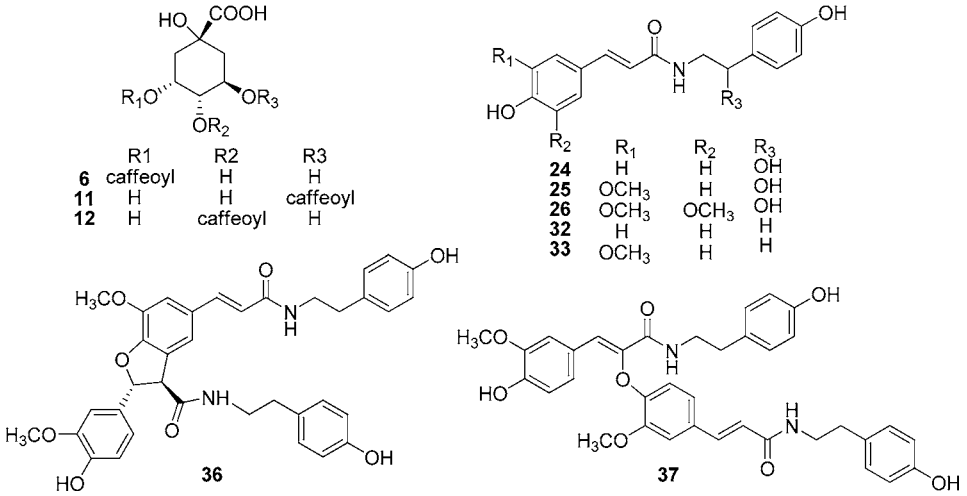

Figure 1. Structures of the 10 reference compounds. The notations for compounds are corresponding to the peak numbers in the HPLC chromatograms as listed in Figures 4 and 5.

A hybrid ion trap time-of-flight mass spectrometer (IT-TOF-MS) integrates the mass spectrometric functions of both ion trap and time-of-flight mass equipment, which could provide accurate structural information for both pseudomolecular ions and tandem fragment ion species. Hence, the analytical platform of the hyphenation of high performance liquid chromatography (HPLC) and IT-TOF-MS has been widely accepted as a powerful tool for targeted and nontargeted analysis of chemical constituents in complicated matrices, for instance, herbal medicine extract, vegetable extract, and food additive extract.[17−21]

In the current study, we aimed to characterize and compare the chemical compositions among the different parts of eggplant, using HPLC coupled with diode array detection (DAD) and IT-TOF-MS. Meanwhile, HPLC-DAD was exploited to simultaneously quantitate seven PAs along with three CAs in the roots of eggplant from different habitats. The results obtained are expected to provide a comprehensive understanding for the different parts of eggplant as well as a reliable tool for the quality control of medicinal materials derived from eggplant.

MATERIALS AND METHODS

Chemicals and Materials. Seven PAs, including *N-trans-p*-coumaroyloctopamine, *N-trans*-feruloyloctopamine, *N-trans*-sinapoyloctopamine, *N-trans-p*-coumaroyltyramine, *N-trans*-feruloyltyramine, grossamide, and cannabisin F, were previously purified and identified from the roots of eggplant in our laboratory, and their structures were established according to extensive spectroscopic and chemical methods.[5,22] Three CAs, namely 3-*O*-caffeoylquinic acid, 4-*O*-caffeoylquinic acid, and 5-*O*-caffeoylquinic acid (Figure 1), were purchased from the National Institutes for Food and Drug Control (Beijing, China). The purity of each compound was determined to be greater than 98% by normalization of the peak areas detected by HPLC-DAD analysis, and confirmed using NMR analysis.

LC-MS grade methanol, acetonitrile, and formic acid were supplied by Merck (Darmstadt, Germany). Ultrapure water was prepared in-house by a Milli-Q Integral water purification system (Millipore, Bedford, MA, USA). All the other reagents were of analytical grade and provided by Beijing Chemical Works (Beijing, China).

Seventeen batches (SM201201−SM201217) of the roots of eggplant were collected from Beijing, Heilongjiang, Guangdong, Henan, Shandong, Hebei, Jiangxi, and Inner Mongolia provinces in China. The stems, leaves, fruit pulps, and peels of SM201217 were also collected and subjected for qualitative analysis. All of the original plants were identified as *S. melongena* by one of the authors (P.-F.T.). The voucher specimens (Nos. SM201201−SM201217) are deposited in Modern Research Center for Traditional Chinese Medicine, Beijing University of Chinese Medicine (Beijing, China).

Sample Preparation. Stock solution was prepared by mixing the 10 reference compounds in methanol to make desired concentrations: 69.45 μg/mL for 3-*O*-caffeoylquinic acid, 1032.40 μg/mL for 5-*O*-caffeoylquinic acid, 125.70 μg/mL for 4-*O*-caffeoylquinic acid, 304.80 μg/mL for *N-trans-p*-coumaroyloctopamine, 812.30 μg/mL for *N-trans*-feruloyloctopamine, 95.80 μg/mL for *N-trans*-sinapoyloctopamine, 376.70 μg/mL for *N-trans-p*-coumaroyltyramine, 589.30 μg/mL for *N-trans*-feruloyltyramine, 52.80 μg/mL for grossamide, and 10.20 μg/mL for cannabisin F, respectively. After that, serial concentration levels of working solutions were obtained by 10-, 16.6-, 25-, 50-, 100-, 166-, 250-, and 500-fold diluting the stock solution with methanol, successively.

Immediately after harvesting, the fresh fruits were separated into pulps and peels (ca. 1−2 mm thick) using a kitchen peeler. The pulps were further cut into small cubes (ca. 1−3 cm). The peels and pulp samples were stored separately at −80 °C under an inert nitrogen atmosphere in ziplock bags. Both of the peels and the chopped pulps were freeze-dried for 48 h. The roots, stems, and leaves were dried in the shade for a couple of days. Afterward, all the dried materials were pulverized and griddled through 50 mesh sieves prior to extraction. The pulverized roots, stems, leaves, peels, and pulps were accurately weighed (approximately 1.0 g for each) and extracted with 25 volumes (w/v) of 50% aqueous methanol by maintaining them in an ultrasonic water bath at room temperature for 1 h, and an aliquot (0.05 mL) of acetic acid was added as an acidic modifier into the solvent to enhance the extraction of peels and pulps. Following extraction, 50% aqueous methanol was added to compensate for the lost weight during the extraction. Each supernatant was filtered through a nylon membrane (0.22 μm, Jinteng Experiment Equipment Co. Ltd., Tianjin, China) and subjected for LC-DAD-IT-TOF-MS analysis.

LC-DAD-IT-TOF-MS Analysis. The liquid chromatographic analysis was conducted on a Shimadzu LC system (Shimadzu, Kyoto, Japan) consisting of two LC-20AD$_{XR}$ solvent delivery units, a SIL-20AC$_{XR}$ autosampler, a CTO-20AC column oven, a SPD-M20A DAD module, a DGU-20A$_{3R}$ degasser, and a CBM-20A controller. A hybrid ion trap time-of-flight mass spectrometer (Shimadzu) equipped with an electrospray ionization (ESI) interface was connected to the LC system via a PEEK tube (0.13 mm i.d.) to perform high-resolution tandem mass spectrometry. Chromatographic separations were carried out on an SB-C$_{18}$ column (250 × 4.6 mm i.d., 5 μm, Agilent Technologies, Palo Alto, CA, USA), and the column oven was maintained at 30 °C. The mobile phase was composed of methanol (A) and 0.1% aqueous formic acid (B), and delivered at a total flow

DOI: 10.1021/acs.jafc.5b00023
J. Agric. Food Chem. 2015, 63, 3426−3436

rate of 1.0 mL/min following a gradient program: 0−10 min, 10−20% A; 10−18 min, 20−30% A; 18−30 min, 30−40% A; 30−40 min, 40−45% A; 40−44 min, 45−41% A; 44−60 min, 41−60% A; 60−65 min, 60−65% A; 65−66 min, 65−95% A; 66−76 min, 95% A. A roughly 20% portion of the effluent was introduced into the ESI interface by splitting the effluent via two PEEK tubes with a length ratio of 1:4. UV absorption over 190−400 nm was recorded by DAD unit, and fixed wavelengths of 280 and 325 nm were used for the simultaneous determination of seven PAs and three CAs, respectively. The injection volume was set at 10 μL. At the end of each run, the initial composition of the mobile phase (10% A) was permitted to re-equilibrate the whole system for 10 min.

In the mass spectrometer domain, an accurate ion axis was calibrated using the sodium trifluoroacetate clusters as a reference. Nitrogen was used as the nebulizing gas and drying gas, whereas ultrahigh purity argon (Ar) was used as the cooling gas and the collision gas for collision-induced dissociation (CID). The mass spectrometric parameters were set as below: ionization polarity, positive; nebulizing gas flow rate, 1.5 L/min; drying gas pressure, 100 MPa; detector voltage, 1.40 kV; curved desolvation line (CDL) voltage, constant level; CDL temperature, 200 °C; block heater temperature, 200 °C; interface voltage, 1.4 kV; and IT vacuum, 1.9×10^{-2} Pa. Positive mass spectra were recorded in the full scan and automatic multiple stage fragmentation scan modes over a range of m/z 100−1000 for all MS^1, MS^2, and MS^3 spectra acquisition. The ion accumulation time was set at 100 ms. The collision energy of CID was set at 50%. Data acquisition and processing were performed with the LCMS solution version 1.1 software package (Shimadzu). The accuracy of the assigned chemical formula was determined using a mass difference tolerance of ± 5 ppm, which was calculated by the deviation between the experimental mass and calculated mass.

Quantitative Method Validation. LC-DAD measurement was used to carry out simultaneous quantitation of 10 analytes, including 3-*O*-caffeoylquinic acid, 5-*O*-caffeoylquinic acid, 4-*O*-caffeoylquinic acid, *N*-*trans*-*p*-coumaroyloctopamine, *N*-*trans*-feruloyloctopamine, *N*-*trans*-sinapoyloctopamine, *N*-*trans*-*p*-coumaroyltyramine, *N*-*trans*-feruloyltyramine, grossamide, and cannabisin F, in SM201201−SM201217, and systematic validation assays were conducted for the developed quantitative method.

Linearity, LLOQ, and LOD. The linearity was assayed using external calibration curves with more than seven concentration levels for each analyte, and each level was conducted in triplicate. Calibration curve generation was performed by plotting the peak area (y) of an analyte against the theoretical concentration (x) over the respective calibration concentration range. The acceptance criterion for each regressive curve was a correlation coefficient (R^2) greater than 0.99. The lower limit of quantitation (LLOQ) and limit of detection (LOD) were termed as the concentration levels at a signal-to-noise ratio (S/N) of about 10 and 3, respectively.

Precision and Repeatability. Intra- and interday variations were chosen to achieve the precision assay for the proposed method. For intraday variability evaluation, 50-fold diluted stock solution (analyte concentrations, μg/mL: 1.39 for 3-*O*-caffeoylquinic acid, 20.65 for 5-*O*-caffeoylquinic acid, 2.51 for 4-*O*-caffeoylquinic acid, 6.10 for *N*-*trans*-*p*-coumaroyloctopamine, 16.25 for *N*-*trans*-feruloyloctopamine, 1.92 *N*-*trans*-sinapoyloctopamine, 7.53 for *N*-*trans*-*p*-coumaroyltyramine, 11.79 for *N*-*trans*-feruloyltyramine, 1.06 for grossamide, and 0.20 for cannabisin F, respectively) was selected and run for six replicates within a single day, while, for interday assay, the same solution was examined in triplicate per day for a consecutive 3 days. The precision was expressed using the relative standard deviation (RSD, %) of the replicate measurements.

For the repeatability assay, one batch of eggplant (SM201217) was selected to prepare extract sample in six replicates, which were subsequently measured using the aforementioned method. Stability assay was achieved by storing the selected sample (SM201217) at room temperature and analyzing at 0, 4, 8, 12, 16, 20, and 24 h, successively. The RSD value was taken as a measure of repeatability and stability.

Recovery Assay. The recovery was implemented to assess the accuracy of the method, and it was carried out by spiking a known amount of mixed standards into pulverized material (SM201217) prior to extraction. The follow-up extractions and HPLC-DAD analysis were then performed in the same manner as mentioned above. Three quantity levels (low, medium, and high) were set, and three replications at each level were conducted. The recoveries and RSDs were calculated using the following formulas: recovery (%) = (amount found − original amount)/amount spiked × 100% and RSD (%) = (SD/mean) × 100%, respectively.

RESULTS AND DISCUSSION

Optimization of Chromatographic Parameters and Extraction Procedure. Chromatographic conditions including analytical column, mobile phase, and elution program were systematically optimized to obtain optimal peak capacity and acceptable resolution for the investigated analytes between their adjacent peaks in the HPLC chromatogram. Several reverse phase (RP) columns were screened, such as Eclipse XDB-C_{18} (250 × 4.6 mm i.d., 5 μm, Agilent, Santa Clara, USA), Shim-pack XR-ODS II (75 × 2.0 mm i.d., 1.8 μm, Shimadzu, Kyoto, Japanese), and Agilent SB-C_{18} column. Finally, an Agilent SB-C_{18} column was chosen due to its superiorities at satisfactory separations for all investigated analytes, acceptable peak shape, and low system back-pressure over the other two columns. The mobile phase was selected between acetonitrile−water and methanol−water, and the latter combination exhibited greater separation potency for all analytes. Aiming to enhance the resolution and to improve the peak shape of the target compounds, formic acid was introduced into water as a mobile phase additive (final concentration, 0.1%, v/v). Fortunately, formic acid could also act as the ionic modifier to advance the overall mass response of the components in eggplant. Afterward, the gradient elution program was carefully optimized to achieve baseline separation for all analytes.

The extraction factors including solvent and extraction duration were optimized. Serial concentrations of aqueous methanol (20, 50, 70, and 100%) were compared with extraction efficiency, and the results suggested that 50% aqueous methanol resulted in the highest overall peak intensity. The extraction duration was compared among 30, 60, and 90 min, and the extraction yield of the investigated analytes did not increase after 60 min. Moreover, ultrasonic-assisted extraction was adopted by taking into account convenience. On the other side, the addition of 0.05 mL of acetic acid into 25 mL of 50% aqueous methanol could significantly enhance the overall response of those investigated compounds in the chromatograms of peels and pulps, which is possibly attributed to the fact that the abundant alkaline compounds like amides, in peels and pulps; thus, the acidified aqueous methanol extracts of the peels and pulps were subjected for LC-DAD-IT-TOF-MS analysis. Collectively, the extraction workflow was described in the Sample Preparation section.

Chemical Profiling of the Different Parts of Eggplant. *UV Absorption Characteristics and Mass Fragmentation Pathways.* Seven PA-type reference compounds, including *N*-*trans*-*p*-coumaroyloctopamine (**24**), *N*-*trans*-feruloyloctopamine (**25**), *N*-*trans*-sinapoyloctopamine (**26**), *N*-*trans*-*p*-coumaroyltyramine (**32**), and *N*-*trans*-feruloyltyramine (**33**), grossamide (**36**), and cannabisin F (**37**), were introduced to propose the mass fragmentation patterns along with UV absorption characteristics of this primary chemical type in eggplant. The UV spectra of the five *trans*-configurational PAs, including *N*-*trans*-*p*-coumaroyloctopamine (**24**), *N*-*trans*-feruloyloctopamine

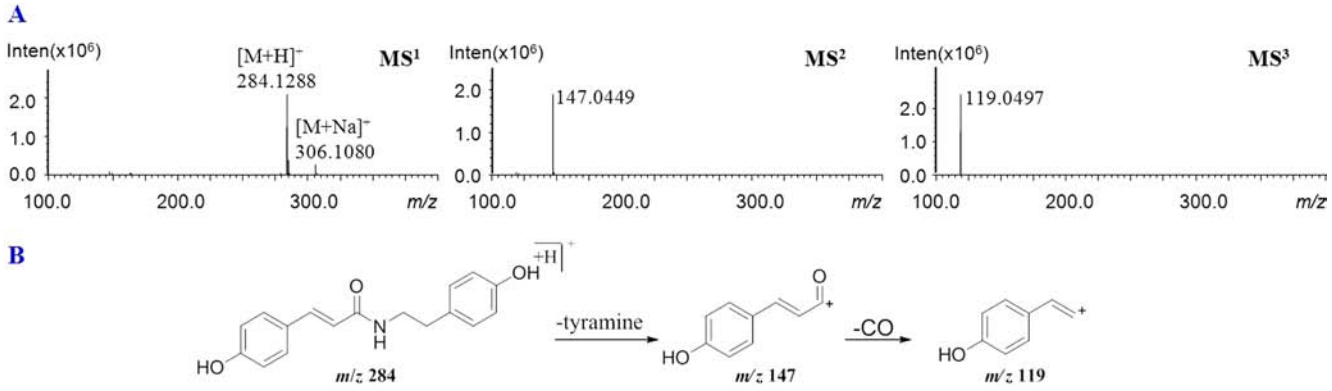

Figure 2. Tandem mass spectra (MS^1, MS^2, and MS^3) under positive ionization mode (A) and proposed schematic of mass fragmentation pathways (B) of *N-trans-p*-coumaroyltyramine (**32**).

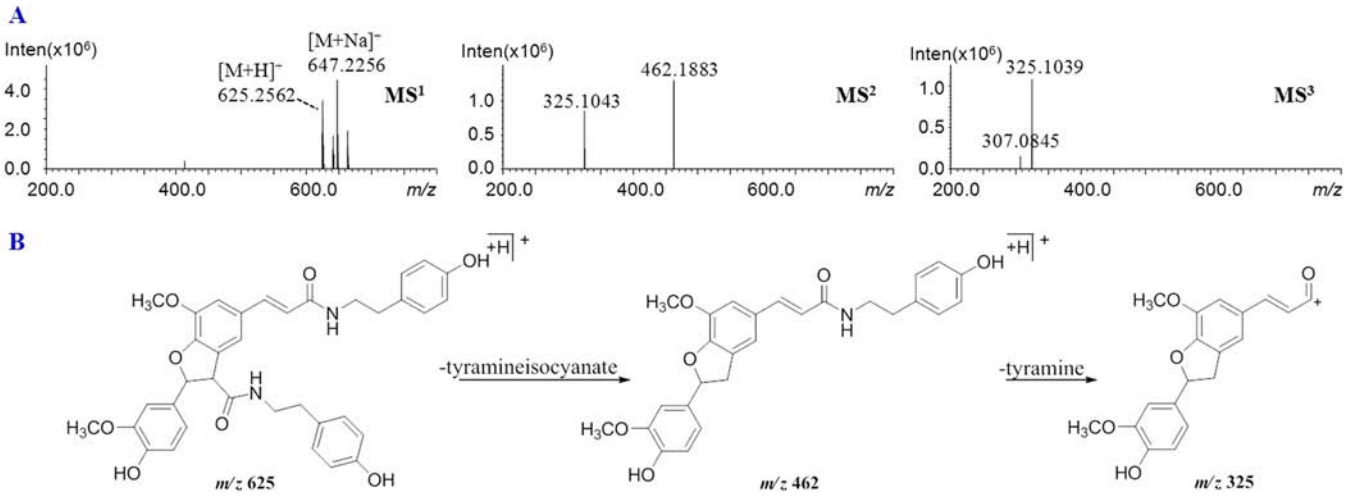

Figure 3. Tandem mass spectra (MS^1, MS^2, and MS^3) under positive ionization mode (A) and proposed schematic of mass fragmentation pathways (B) of grossamide (**36**).

(**25**), *N-trans*-sinapoyloctopamine (**26**), *N-trans-p*-coumaroyltyramine (**32**), and *N-trans*-feruloyltyramine (**33**), showed two common primary absorption peaks at around 290 and 315 nm (Table 1), whereas the typical UV absorption peak of two lignanamides (also known as *bis*-phenylpropanoid amides), grossamide (**36**) and cannabisin F (**37**), was observed at around 318 nm due to their big conjugated systems. These characteristics of the chromophores aided in further detection and identification of PAs in the extract.

The protonated ion and sodium adduct molecular ion of *N-trans-p*-coumaroyltyramine (**32**) were observed at *m/z* 284.1288 ($[M + H]^+$) and 306.1080 ($[M + Na]^+$) (Figure 2A), respectively, corresponding to the molecular formula of $C_{17}H_{17}NO_3$. When the protonated molecular ion was transmitted to a CID cell, the prominent product ions were yielded at *m/z* 147.0449 (element composition: $C_9H_7O_2$) and 119.0497 (element composition: C_8H_7O), indicating the dissociation at the amide group along with a subsequent neutral cleavage of the CO (28 amu) group (Figure 2B). Similarly, the successive neutral losses of the phenylethylamine (octopamine for *N-trans-p*-coumaroyloctopamine (**24**)/*N-trans*-feruloyloctopamine (**25**)/*N-trans*-sinapoyloctopamine (**26**) and tyramine for *N-trans*-feruloyltyramine (**33**), respectively) and CO moiety were detected for all of the compounds **24**−**26**, **32**, and **33** via the dissociation of the amide core (C−N bond) and α-cleavage of the carbonyl group (Table 1). In the case of lignanamides, the sodium adduct ion and protonated molecular ion of grossamide (**36**) were observed at *m/z* 647.2256 ($[M + Na]^+$) and 625.2562 ($[M + H]^+$), respectively, agreeing well with the molecular formula of $C_{36}H_{36}N_2O_8$. In the MS^2 spectrum of the protonated molecular ion, the dominant daughter ion species were detected at *m/z* 462.1883 and 325.1039 (Figure 3A), indicating the successive neutral cleavages of $C_9O_2NH_9$ and C_8ONH_{11} moieties (Figure 3B). Corresponding to the chemical structure of grossamide (**36**), we assumed that the α-cleavage of the carbonyl group at the C−C bond and the subsequent dissociation of the other amide group at the C−N bond gave rise to the generation of the prominent product ions at *m/z* 462.1883 and 325.1039 (Figure 3B). Cannabisin F (**37**) exhibited a similar mass spectral profile with grossamide (**36**) (Table 1). Therefore, the diagnostic fragmentation pathways of lignanamides were speculated as the α-cleavage of the carbonyl group at the C−C bond and the subsequent dissociation of the other amide group (Figure 3B).

On the other hand, the characteristic UV absorption of CAs was featured at approximately 324 nm. The protonated molecular ion of compounds 3-*O*-caffeoylquinic acid (**6**), 5-*O*-caffeoylquinic acid (**11**), and 4-*O*-caffeoylquinic acid (**12**) was observed at *m/z* 355.10, and the characteristic product ion was yielded at *m/z* 163.04 via dissociating the ester group at the C−O bond (Table 1), which could be adopted as a diagnosis for mining and identification of CAs in eggplant.

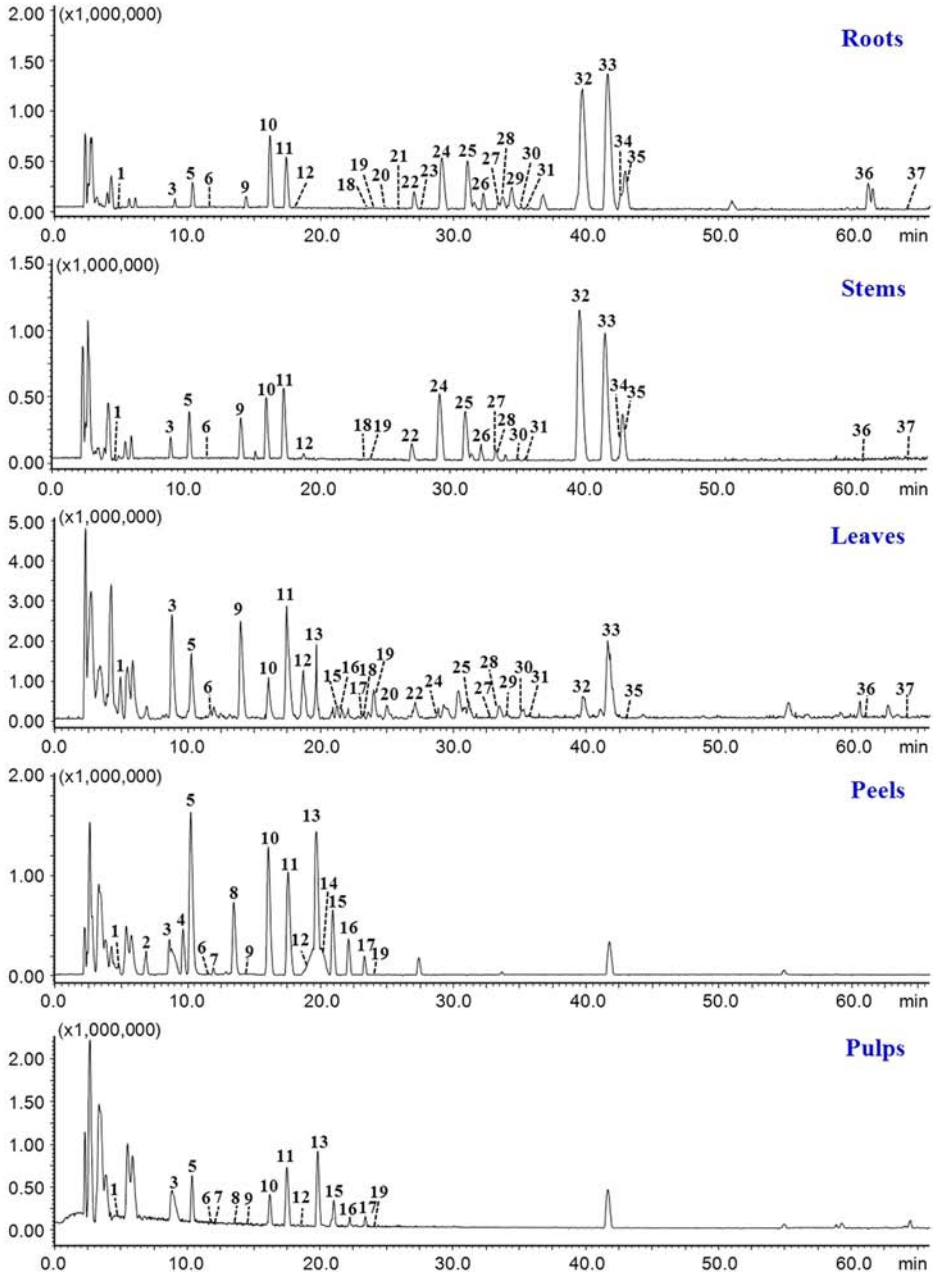

Figure 4. Representative total ion current (TIC) chromatograms of extracts of different parts of eggplant under positive ionization mode. The notation and identification of peaks are included in Table 1.

Characterization of Components in Eggplant. A total of 37 compounds were detected in the different parts of eggplant. The retention times, the wavelengths of maximum absorptions, precursor ions, molecular weights, molecular formulas, prominent fragment ions, plausible identities, and the distribution of each detected compound in different parts are illustrated in Table 1.

Phenylpropanoids and amines could be regarded as the biosynthetic precursors of PAs. PAs in eggplant can be tentatively divided into four types based on the different precursors,[4] including (1) type I, simple conjugates of hydroxycinnamic acid and arylamine, such as tyramine, octopamine, noradrenaline, anthranilate, and dopamine; (2) type II, dimers of type I compounds, also named lignanamides or *bis*-phenylpropanoid amides, which can be recognized as the conjugates of one lignan and two arylamines, such as grossamide (**36**) and cannabisin F (**37**); (3) type III, conjugates of hydroxycinnamic acid and putrescine; (4) type IV, phenylpropanoid polyamine conjugates, for instance, spermidine hydroxycinnamic acid amides.

First, in comparison with the UV spectral profiles, mass spectra, and retention times with the authentic compounds, the seven PAs, including *N-trans-p*-coumaroyloctopamine, *N-trans*-feruloyloctopamine, *N-trans*-sinapoyloctopamine, *N-trans-p*-coumaroyltyramine, *N-trans*-feruloyltyramine, grossamide, and cannabisin F, matched well with compounds **24**, **25**, **26**, **32**, **33**, **36**, and **37**, respectively (Figure 4 and Table 1).

The protonated molecular ions of type I PAs were usually observed as even numbers between m/z 280 and 350, and the predominant product ions were the cation of hydroxycinnamyl moieties. Following careful analysis of the spectral profiles, compounds **18**, **20**, **21**, **23**−**26**, and **28**−**35** were assigned into

DOI: 10.1021/acs.jafc.5b00023
J. Agric. Food Chem. 2015, 63, 3426−3436

this type. The fragment ion at m/z 147.04 (element composition: $C_9O_2H_7$) could be adopted as the diagnosis to search and identify the conjugates of coumaric acid and arylamine, e.g., compounds **24** and **32**. The positive quasi-molecular ion of compound **18** was yielded at m/z 300.1223, indicating a molecular formula of $C_{17}H_{17}NO_4$, and the primary product ion was detected at m/z 147.0456, identical with compound **32**; thus, this compound was assigned as *N-cis-p*-coumaroyloctopamine. Given that the steric hindrance could prevent the conjugation between the carbonyl group and the phenyl plane of the caffeoyl group, a hypsochromic shift might occur for the PAs with the *Z*-configuration of the C=C bond in comparison with *E*-configurational type I PAs; hence, the identity of compound **18** (absorption peak: 275 nm) was confirmed with the assistance of this rule. Interestingly, the precursor and product ions of compound **28** were the same as those of compound **32**, suggesting a pair of isomers for these compounds; consequently, it is reasonable to assume compound **28** as *N-cis-p*-coumaroyltyramine (Table 1). The product ion of m/z 163.0418, which was generated from the quasi-molecular ion (m/z 316.1174 $[M + H]^+$) of compound **20**, was calculated as $C_9O_3H_7$, corresponding to the cation of the caffeoyl group. In combination with the maximal absorption observed at 292 nm, compound **20** was thereby identified as *N-trans*-caffeoyloctopamine. Similarly, compound **29**, which shared an identical product ion (m/z 163.0418) with compound **20**, was correspondingly identified as *N-trans*-caffeoyltyramine. Compounds **21**, **23**, **30**, **31**, and **35** generated a common fragment of $C_{10}O_3H_9$ (calculated from m/z 177.06), indicating that ferulic acid was one of the two precursors for each compound. Integrating the UV chromatograms (maximum absorptions around 290 nm and/or 315 nm), the putative identities of compounds **23**, **31**, and **35** were elucidated in Table 1, whereas the absorption peaks at around 276 nm supported the identities of compounds **21** and **30** as *N-cis*-feruloyloctopamine and *N-cis*-feruloyltyramine (Table 1), respectively. Similar to compound **26**, signals at m/z 207.06 and 175.04 were observed as the prominent product ions for compound **34**, while its positive pseudomolecular ion ($[M + H]^+$) was detected at m/z 344.1477 (Table 1), 60 Da more than that of compound **32** (m/z 284.1228). The element composition of compound **34** was calculated as $C_{19}H_{21}NO_5$, and its maximum absorption peak was detected at 292 nm; therefore, the structure of compound **34** was plausibly assigned as *N-trans*-sinapoyltyramine.

Except for compounds **36** and **37**, no additional type II PAs were found from eggplant in the current study.

Type III PAs were defined as the conjugates of hydroxycinnamic acid and putrescine; hence, their pseudomolecular ions should be observed as odd numbers among m/z 230−270, and the cation of hydroxycinnamyl moieties might usually be yielded as the predominant fragments. Compounds **2**, **4**, **5**, **7**, **8**, and **10** were plausibly assorted to type III PAs. Taking compound **8**, for instance, the positive quasi-molecular ion was observed at m/z 235.1438, and the primary product ions were detected at m/z 218.1179 and 147.0448, corresponding to the neutral losses of a NH_3 molecule (17 u) and a putrescine molecule (88 u), respectively. Referring to the description above, m/z 147.0448 indicated the presence of a coumaryl group, and compound **8** was thereby tentatively identified as *N-trans-p*-coumaroylputrescine. As aforementioned, the product ion at m/z 163.04 could be utilized as the diagnostic product ion for the identification of caffic acid derivatives; therefore, compounds **2** and **5** were tentatively identified as *N-cis*-caffeoylputrescine and *N-trans*-caffeoylputrescine. Because the maximal absorption of compounds **2** and **5** was exhibited at 279 and 292 nm, respectively, the identity of compound **5** was tentatively assigned as *N-trans*-caffeoylputrescine, while *N-cis*-caffeoylputrescine was tentatively assigned to compound **2** (Table 1). Similarly, compounds **4**, **7**, and **10** were tentatively identified as *N-cis-p*-coumaroylputrescine, *N-cis*-feruloylputrescine, and *N-trans*-feruloylputrescine, respectively (Table 1).

The fragmentation patterns of type IV PAs have been previously proposed by Handrick et al.,[23] and the dissociation of the amide group at the C−N bond along with the α-cleavage of the middle amino group of spermidine were demonstrated as the primary features. With the assistance of the descriptions in ref 23, compounds **13** and **15**−**17** were picked out as the conjugates of spermidine and various hydroxycinnamic acids. Taking compound **17** as the representative one to describe the structural characterization process, the positive quasi-molecular ion ($[M + H]^+$) was generated at m/z 470.2283, suggesting a molecular formula as $C_{25}H_{31}N_3O_6$, and the fragment ions were observed at m/z 220.0958 and 163.0413. Identical with compound **5**, the fragment at m/z 163.0413 indicated the occurrence of cafferoyl substitution in compound **17**, and the other product ion of m/z 220.0958 was attributed to the α-cleavage of the middle amino group of spermidine (Table 1). Collectively, compound **17** was tentatively assigned as *N,N′*-dicaffeoylspermidine, which was previously identified from the fruits of eggplant.[11] Correspondingly, compound **15**, which yielded identical fragment ions (m/z 220.0961 and 163.0388) yet a different quasi-molecular ion (m/z 472.2437, 2 u more than that of compound **17**) with compound **17**, was tentatively identified as N^1-caffeoyl-N^8-hydrocaffeoylspermidine (Table 1). Moreover, the putative identities of compounds **13** and **16**, which shared identical product ions (m/z 222.11 and 165.06), were elucidated as N^1,N^8-dihydrocaffeoylspermidine and N^1-hydrocaffeoyl-N^8-caffeoylspermidine (Table 1), respectively.

CAs are widely distributed in the plant kingdom, and compounds **6**, **11**, and **12** were unambiguously identified as 3-*O*-caffeoylquinic acid, 5-*O*-caffeoylquinic acid, and 4-*O*-caffeoylquinic acid, respectively, by comparing with the retention times, mass spectral profiles, and UV spectra with the standards. In addition, compound **19** generated positive pseudomolecular and dominant product ions at m/z 369.1177 and 177.0556, respectively, both of which were 14 u more than those of compound **6**; thus, compound **19** was tentatively identified as feruloylquinic acid (Table 1).

The quasi-molecular ions of compounds **22** and **27** were detected at m/z 193.0500 and 207.0644, respectively, suggesting the molecular formulas as $C_{10}H_8O_4$ and $C_{11}H_{10}O_4$. In comparison with the information archived in refs 6 and 24, compounds **22** and **27** were proposed as isoscopoletin and 6,7-dimethoxycoumarin, respectively, both of which were previously isolated from the roots of eggplant.[6,24] The MS^1 spectrum of compound **14** showed the quasi-molecular ion at m/z 611.1616 ($[M]^+$), suggesting a molecular formula as $C_{27}H_{31}O_{16}$, and 520 nm was observed as the maximal absorption wavelength in the UV spectrum, indicating this compound as an anthocyanin analogue. The primary fragments were observed at m/z 465.1010 and 303.0495 in the MS^2 spectrum, by expelling the rhamose (146 amu) and glucose (162 amu) moieties, successively (Table 1). In comparison with the mass spectral profile documented in ref 25, compound **14**

DOI: 10.1021/acs.jafc.5b00023
J. Agric. Food Chem. 2015, 63, 3426−3436

was plausibly identified as tulipanin. In addition, compounds **1**, **3**, and **9** were characterized as tyrosine, phenylalanine, and tryptophan, respectively (Table 1), by referring to some available databases (HMDB, METLIN, and MassBank).

Compounds **1**−**4**, **7**, **9**, **29**, and **31** were reported in eggplant for the first time. PAs and CAs were observed as the primary components in different parts (Figure 4); thus, these two kinds of ingredients were hypothesized as the prominent efficacy material basis of eggplant. Moreover, a comparison was performed for the chemical profiles among the different parts of eggplant. First, high similarity was observed for the total ion current (TIC) chromatograms of the roots and stems (Figure 4A and B), which may provide chemical evidence for their combinatory use in traditional Chinese medical practices. Significant differences were detected for fruits versus the other parts, suggesting a unique usage. PAs were detected in all parts of eggplant. Type I and II PAs were only found in the roots, stems, and leaves; nonetheless, the fruits, including the peel and pulp parts, were wealthy of putrescine and spermidine derivatives (type III and IV PAs) (Figure 4). Collectively, it is not surprising that the various usages corresponding to the different parts were widely mentioned in the literature.[2]

In terms of fruits, compounds **2**, **4**, and **14** were only detected in the peel parts rather than the pulp parts, and a higher abundance of most PAs was observed in the peel parts rather than the pulp parts, for instance, compounds **5**, **7**, **8**, **10**, **13**, and **15**−**17** (Figure 4). In sight of the bioactivities of PAs and delphinidin-3-rutinoside (**14**) that revealed promising antioxidant potency,[14] we may conclude that the fruit peels of eggplant could exhibit a higher nutritional value than the pulp portion; however, it is a pity that the peels are usually deserted during cooking.

Simultaneous Determination of Seven PAs and Three CAs in the Roots of Eggplant. *Method Validation.* Given the abundant distribution of compounds **6**, **11**, **12**, **24**−**26**, **32**, **33**, **36**, and **37**, these 10 compounds were selected as the indicators to carry out quantitative analysis for the roots of eggplant.

In the linearity assays, calibration curves of all analytes showed good linear regression (R^2 > 0.999) within their respective test concentration ranges. The LODs and LLOQs of all investigated compounds ranged from 0.03 to 0.19 and 0.08 to 0.30 μg/mL, respectively. The overall intra- and interday variations were determined as less than 0.08 and 0.69%, respectively. Results of repeatability assay demonstrated the proposed method to be repeatable with RSDs less than 4.44% (n = 6). RSDs of the 10 analytes were less than 3.96% (n = 6) with 24 h in the stability assay, indicating that the sample solution could stay stable during measurement. Moreover, the recovery assay showed that the developed method showed satisfactory accuracy with recoveries ranging from 96.17 to 105.00%. Above all, the developed method was proved to be precise, accurate, and sensitive for the simultaneous quantitative investigation of the 10 analytes in the roots of eggplant.

Quantitative Analysis of the 10 Compounds in the Roots of Eggplant. The validated method was applied to simultaneously quantitate the 10 analytes in 17 batches of roots of eggplant (SM201201−SM201217). Figure 5 shows the typical HPLC-DAD chromatograms of the mixed standards as well as a representative extract of eggplant roots (SM201217) detected at 325 nm (0−20 min, red trace) and 280 nm (20−66 min, blue trace). The results of the quantitative analysis are summarized in Table 2. As shown in Table 2, the contents of

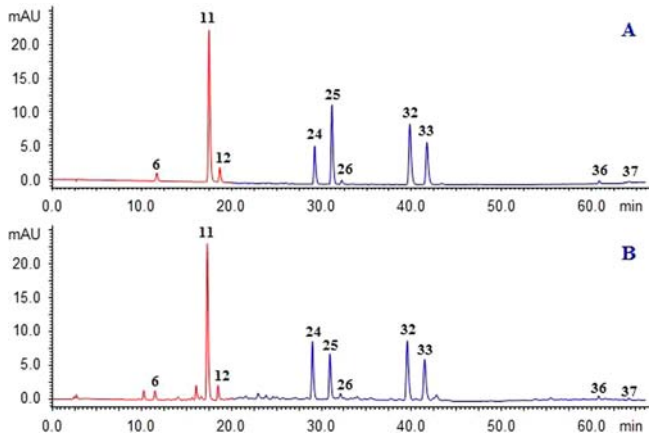

Figure 5. Representative combined HPLC-UV chromatograms (0−20 min: 325 nm, red trace; 20−66 min: 280 nm, blue trace) of mixed standards (A) and the extract of roots of *S. melongena* (B).

the 10 analytes exhibited big variations among different samples, suggesting that it is critical to carry out quality control of this herbal medicine. 5-*O*-Caffeoylquinic acid (**11**), *N*-*trans*-*p*-coumaroyloctopamine (**24**), *N*-*trans*-feruloyloctopamine (**25**), *N*-*trans*-*p*-coumaroyltyramine (**32**), and *N*-*trans*-feruloyltyramine (**33**) were found as the five most abundant compounds in the roots of eggplant, among which the content of 5-*O*-caffeoylquinic acid (**11**) (86.4−1434.8, μg/g) was detected to be higher than the other components in most samples, whereas the two lignanamides (grossamide (**36**), 12.8−161.9 μg/g, and cannabisin F (**37**), 3.0−26.5 μg/g) were determined as the minor components.

The inconsistency of the chemical compositions in different samples was identified by the quantitative analysis, and it might result from diverse factors, such as climate, temperature, soil,[26] cultural practices, and harvest maturity in different provinces.[11] PAs consist of cinnamic acid derivatives and amines, and the shikimate biosynthetic pathway is the key source for their phenylpropenyl groups,[28] which is mediated by several enzymes, such as phenylalanine ammonia lyase (PAL), hydroxycinnamoyl-CoA:shikimate hydroxycinnamoyl transferase (HST), hydroxycinnamoyl-CoA:quinate hydroxycinnamoyl transferase (HQT), shikimate dehydrogenase, and so on. The first committed step in the biosynthesis of most phenylpropanoids by converting phenylalanine derived from the shikimate pathway to *trans*-cinnamic acid and ammonia and HQT was responsible for the formation of chlorogenic acid.[29] As a consequence, the activities and contents of these enzymes, as well as some other enzymes that were involved in the biosynthesis of CAs and anthocyanins, might play key roles for the different chemical profiles of PAs among eggplant from different areas. Eggplant has been reported to be well adapted to high rainfall and high temperatures;[30] thus, humidity and temperature were expected as the determinant factors for the activities of the enzymes aforementioned were active under such conditions. Further research is needed to verify the assumption.

In summary, the mass fragmentation patterns of PAs were proposed with the combination of reference compounds and high resolution tandem mass spectrometry. A total of 37 compounds, including 27 PAs and 10 other compounds, were detected and identified from different parts of eggplant using LC-DAD-IT-TOF-MS, in which 22 compounds were identified from the roots, stems, and leaves and 21 compounds from the

peels and pulps of the fruits. Compounds **1**−**4**, **7**, **9**, **29**, and **31** were reported in eggplant for the first time. PAs and CAs were observed as the primary components in each part of eggplant. Moreover, an LC-DAD-based method was developed and validated for the simultaneous determination of seven PAs along with three CAs in the roots of eggplant, and different wavelengths were applied for PAs and CAs to obtain a satisfactory response. Variations were observed for the contents of the 10 analytes in the roots of eggplant from different habitats. Taken together, the results of this study could provide a new insight for the efficacy material basis of eggplant and also offer a reliable tool for the quality control of the roots of eggplant.

MATERIALS AND METHODS

Materials. Duck (*Anas platyrhynchos*) breasts were purchased from Suguo supermarket in Nanjing, China, and stored at −20 °C until use. Protamex (1.5 AU of N/g) was purchased from Novo Co. (Novozyme Nordisk, Bagsvaerd, Denmark). 1,1-Diphenyl-2-picrylhydrazyl free radical (DPPH•) and L-glutathione reduced (GSH) were obtained from Sigma Chemical Co. (St. Louis, MO). Acetonitrile (ACN) and formic acid were of chromatographic grade, and other chemicals used were of analytical grade.

Preparation of Enzymatic Hydrolysate from Duck Meat. Frozen duck breasts were thawed at 4 °C overnight, and then the skin and connective tissue were removed. The meat was chopped into pieces and mixed with distilled water to give a final protein content of 4% (w/v). The mixture was then homogenized for 1 min at 8000 rpm using a homogenizer (IKA T25 digital ultraturrax, IKA, Germany) with cooling in ice. The pH of the mixture was adjusted to 6.0 with a pH meter (FiveEasy 20, Mettler Toledo, Swiss), and Protamex was added at an enzyme-to-substrate ratio of 0.75/100 (w/w) after a preincubation at 50 °C for 10 min. During the reaction, the pH of the mixture was adjusted to 6.0 every 20 min by addition of 4 mol/L HCl solution. Enzymatic hydrolysis of the meat proteins was performed for 4 h to achieve an optimum level of hydrolysis and was then immediately heated at 100 °C for 10 min to terminate the hydrolysis. The reaction mixture was cooled to room temperature and then centrifuged (Allegra 64R centrifuge, Bechman Coulter, United States) at 10000*g* for 10 min. The supernatant was collected, lyophilized, and stored at 4 °C for further use.

Measurement of DPPH• Scavenging Activity. The DPPH• scavenging activity was evaluated according to the procedure described by Ajila et al.[22] with a slight modification. The sample group was obtained by mixing 0.5 mL of sample (1.0 mg/mL) with 0.5 mL of 0.2 mmol/L DPPH• dissolved in ethanol, the blank group consisted of aliquots of samples mixed 1:1 (v/v) with ethanol, and the control group consisted of aliquots of ethanol mixed 1:1 (v/v) with 0.2 mmol/L DPPH•. The mixtures were shaken and kept in the dark for 30 min at room temperature. Then the absorbance was measured at 517 nm using a multifunctional microplate reader (model Spectral Max M2e, Molecular Devices, United States). The DPPH• scavenging activity was calculated as follows:

$$\text{DPPH radical scavenging activity (\%)} = \left(1 - \frac{A_s - A_b}{A_c - A_b}\right) \times 100$$

where A_s, A_c, and A_b represent the absorbances of the sample, control, and blank groups.

Measurement of Fe^{2+}-Chelating Ability. The Fe^{2+}-chelating ability was measured according to the procedure described by Zhu et al.[23] with a slight modification. Briefly, 0.5 mL of sample (1.0 mg/mL) was mixed with 0.05 mL of $FeCl_2$ (2 mmol/L) and 0.2 mL of ferrozine (5 mmol/L). The mixture was kept at room temperature for 10 min prior to measurement of the absorbance at 562 nm. The chelating activity was calculated as follows:

$$\text{Fe}^{2+}\text{-chelating ability (\%)} = \frac{A_c - A_s}{A_c} \times 100$$

where A_s represents the absorbance of the samples and A_c represents the absorbance of the control in which distilled water replaced the sample solution.

Hydroxyl Radical (•OH) Scavenging Activity. The •OH scavenging activity was assayed according to the procedure described by You et al.[24] Briefly, 1 mL of sample (1.0 mg/mL) was thoroughly mixed with 0.6 mL of 1,10-phenanthroline monohydrate (5 mmol/L), 0.4 mL of phosphate buffer (0.2 mol/L, pH 7.4), 0.6 mL of $FeSO_4$ (50 mmol/L), and 0.6 mL of EDTA (15 mmol/L). Then 0.4 mL of 0.1% H_2O_2 was added. The mixture was incubated at 37 °C for 1 h prior to measurement of the absorbance at 536 nm. The •OH scavenging activity was calculated as follows:

$$\text{hydroxyl radical scavenging activity (\%)} = \frac{A_s - A_d}{A_n - A_d} \times 100$$

where A_s is the absorbance of the samples, A_d is the absorbance of the damaged group without sample solution, and A_n is the absorbance of the nondamaged group without H_2O_2.

Peptide Fractionation by Ultrafiltration. A 2.0 g mass of the lyophilized DMH was dissolved in 350 mL of distilled water and then fractionated by centrifuge tubes fixed with ultrafiltration membranes having molecular weight cutoffs (MWCOs) of 30000 and 10000 (Amicon Ultra-15, Millipore Co., Billerica, MA), consecutively. MWCO-1, MWCO-2, and MWCO-3 represent the fractions with molecular weight distributions of >30000, 30000−10000, and <10000, respectively. Each fraction was collected, lyophilized, and used for determination of DPPH• scavenging activity.

Peptide Separation by Gel Filtration Chromatography. MWCO-3 (1.0 mg/mL) in a 0.5 mL aliquot was subjected to a size exclusion chromatograph (5 × 5 cm) packed with Sephadex G-25 (Amersham Biosciences, Uppsala, Sweden) to fractionate peptides according to their molecular sizes. The column was eluted with distilled water at a flow rate of 0.5 mL/min and monitored at 280 nm. All fractions were collected and lyophilized for the determination of their DPPH• scavenging activity after being redissolved in distilled water. The strongest antioxidant activity fraction was further separated by ion exchange chromatography.

Peptide Separation by Ion Exchange Chromatography. The fraction (1.0 mg/mL) exhibiting the highest antioxidant activity in a 0.5 mL aliquot was loaded onto an anion exchange column (Mono Q 5/50 GL, internal diameter 5 mm, length 50 mm) equilibrated with 20 mmol/L Tris−HCl buffer (pH 8.0) and eluted with a linear salt gradient (0−0.3 mol/L NaCl, over a 15 min period) in the same buffer at a flow rate of 1 mL/min and monitored at 280 nm. Each fraction was pooled and lyophilized for determination of antioxidant activity.

Identification of Antioxidant Peptides by LC−MS/MS. The most effective fraction derived from ion exchange chromatography was first desalted using an OASIS HLB cartridge (Waters Inc., United States). The peptides were then analyzed by nano-LC−MS/MS with a coupled Dionex Ultimate 3000 nano-LC system (Thermo Fisher Scientific Ltd., Fremont, CA) and a linear quadrupole ion trap Orbitrap (LTQ Orbitrap XL) mass spectrometer (Thermo Electron, Bremen, Germany) equipped with a nanoelectrospary ion source. Briefly, 2 μL of sample was injected, in triplicate, onto an Acclaim PepMap 100 column (75 μm × 2 cm, nanoViper C18, 3 μm, 100 Å) (Dionex, Sunnyvale, CA) for nano-LC separation at a flow rate of 300 nL/min. Mobile phases used for LC were (A) 0.1% formic acid in water and (B) 0.08% formic acid in 80% ACN. Gradient elution was carried out according to the following process: 0−8 min, isocratic elution 2% solvent B; 8−12 min, linear gradient 2%−15% solvent B; 12−93 min, linear gradient 15%−45% solvent B; 93−98 min, linear gradient 45%−98% solvent B; 98−121 min, isocratic elution 98% solvent B; 121−122 min, isocratic elution 2% solvent B. The mass spectrometer operated in positive ion mode, with a capillary temperature of 200 °C and a capillary voltage of 2.2 kV, in the mass range from m/z 350 to 1800 in the Orbitrap with a resolution of 60000 at m/z 400, allowing the sequential isolation of the five signal intensity ions for high-energy collisional dissociation (HCD) at a collision energy of 35 V. MS/MS was performed using the dynamic exclusion mode to exclude the previously selected ions during the repeated cycle of 60 s.

The acquired MS/MS data were analyzed using PEAKS de novo sequencing (PEAKS Studio 6.0, BSI, Canada). Basic parameter settings included a precursor mass tolerance of 10 ppm, a product mass tolerance of 0.02 Da, and a "no-enzyme" constraint. Oxidation of Met was used as a variable modification. Only those with a "de novo" peak studio score over 75% (average local confidence, ALC) were considered. The proteome of duck (*Anas*) was downloaded from the Uniprot protein database.

Synthetic Peptides. The peptide sequences derived from duck meat were synthesized by the solid-phase peptide procedure, using the

Fmoc-protected amino acid synthesis method. These peptides were provided by Gen Script (Nanjing) Co., Ltd. Their purity was >95%.

Statistical Analysis. All the tests were repeated in triplicate. Data were evaluated using SAS 8.1 software. Values were expressed as the mean ± standard deviation (SD). The mean values were analyzed using the one-way analysis of variance (ANOVA) test. Duncan's multiple range tests were employed to determine any significant difference between treatments. The significant difference was determined with a 95% confidence interval ($p < 0.05$).

RESULTS AND DISCUSSION

Antioxidant Activity of DMH. The antioxidant properties of peptides result from their free radical scavenging, metal ion chelating, and single oxygen quenching activities.[25] In this study, the antioxidant activities of DMH were evaluated by DPPH• scavenging activity, •OH scavenging activity, and Fe^{2+}-chelating ability (Table 1).

DPPH• is a stable free radical that shows maximum absorbance at 517 nm. When DPPH radicals encounter proton-donating substrates such as antioxidants, the radicals are scavenged and the absorbance is reduced.[26] DMH showed high DPPH• scavenging activity at a concentration of 1.0 mg/mL (82.09%), whereas 1.0 mg/mL GSH exhibited nearly 95% scavenging activity on the DPPH radical (Table 1). This value is somewhat higher than that of many other protein hydrolysates. The chicken breast protein hydrolysate prepared by papain exhibited about 50% DPPH• scavenging activity at a concentration of 1.28 mg/mL.[10] The DPPH• scavenging activities in various hydrolysates (1.0 mg/mL) of round scad muscle were as follows: Alcalase (39.36%), Nnutral (32.33%), trypsin (39.37%), papain (40.21%), and pepsin (32.63%). These values are lower than that found for DMH.[27] Bougatef et al.[28] reported that smooth hound muscle hydrolysates prepared using low molecular weight (LMW) alkaline protease exhibited 76.7% DPPH• scavenging activity at a concentration of 3.0 mg/mL. Thus, we can infer that DMH contained antioxidant peptides that were capable of scavenging radicals.

•OH is the most reactive radical that can induce severe damage to adjacent biomolecules and thereby cause aging, cancer, and other diseases.[29] Therefore, removal of •OH could be one of the most effective defenses against these various diseases. The •OH scavenging activity for GSH (1.0 mg/mL) was about 75%. DMH exhibited a comparable higher •OH scavenging capacity, reaching a scavenging activity of 36.54% at a concentration of 1.0 mg/mL, comparable to that of bullfrog skin protein hydrolysate (34.5%) prepared using papain at a concentration of 1.5 mg/mL,[30] but lower than the pepsin hydrolysate from duck skin byproducts with about 50% •OH scavenging activity at a concentration of 0.55 mg/mL.[19] Thus, we can infer that DMH contained some antioxidant peptides which could convert free radicals to more stable products and terminate the radical chain reactions.

Transition-metal ions such as iron and copper ions are strong agents to catalyze the generation of free radicals via the Fenton reaction.[25] Thus, the chelation of metal ions contributes to antioxidation. As shown in Table 1, the hydrolysate exhibited an effective chelating effect on Fe^{2+} (78.57%).

Purification of Antioxidant Peptides from DMH. DMH was separated into three groups using ultrafiltration membranes (MWCO = 30000 and 10000): MWCO-1 (MW > 30000), MWCO-2 (MW = 10000−30000), and MWCO-3 (MW < 10000). The DPPH• scavenging activities were 29.01 ± 0.60%, 34.42 ± 1.61%, and 83.17 ± 0.73% at 1.0 mg/mL for MWCO-1, MWCO-2, and MWCO-3, respectively (Table 2). The lower molecular weight fraction had higher DPPH• scavenging activity than the higher molecular weight fractions. Therefore, the MWCO-3 fraction was selected for further study.

Table 2. Purification of Antioxidant Peptides from DMH (1.0 mg/mL)

step	DPPH• scavenging activity (%)	purification (fold)	recovery rate (%)
crude	82.09 ± 1.41	1.00	100
ultrafiltration			
>30 kDa	29.01 ± 0.60	0.35	8.21
10−30 kDa	34.42 ± 1.61	0.42	9.53
<10 kDa	83.17 ± 0.73	1.01	69.57
gel filtration chromatography (fraction B)	88.64 ± 1.98	1.08	40.90
ion exchange chromatography (fraction B5)	93.63 ± 0.13	1.14	6.71

The results of the separation of the MWCO-3 fraction by size exclusion chromatography is shown in Figure 1A, where peptides were separated into three fractions (A, B, and C) according to their molecular sizes. The DPPH• scavenging activities of these fractions, after lyophilization and solubilization, are presented in Figure 1B. We found that fractions A, B, and C had radical scavenging activities on DPPH of 40.86 ± 1.10%, 88.64 ± 1.98%, and 33.47 ± 1.18%, respectively, at 1.0 mg/mL, with fraction B showing the highest DPPH• scavenging activity compared to the other fractions.

Fraction B was further separated by anion exchange chromatography into six fractions (B1, B2, B3, B4, B5, and B6) (Figure 2A). Fraction B5 showed the highest DPPH• scavenging activity with a value of 93.63% (Figure 2B). Fraction B5 was further purified and identified by nano-LC−MS/MS for amino acid sequencing.

The DPPH• scavenging activity and stage of purification of the peptides are summarized in Table 2. DMH, MWCO-3, B, and B5 exhibited quite the same DPPH• scavenging activity at a concentration of 1.0 mg/mL; the purification of B5 was 1.14-fold (Table 2). Apart from the antioxidant peptides produced by Protamex, DMH and MWCO-3 may contain antioxidants that are naturally present in meat (e.g., amino acids, carnosine, anserine, conjugated linoleic acid, α-tocopherol, carotenoids, ubiquinone, uric acid, and polyamines)[31] or that are generated by endogenous enzymes during rigor mortis and resolution of rigor mortis.[32] Sacchetti et al.[33] reported that the hydrophilic and lipophilic fractions of poultry meat showed radical scavenging activity. The hydrophilic antioxidants present in

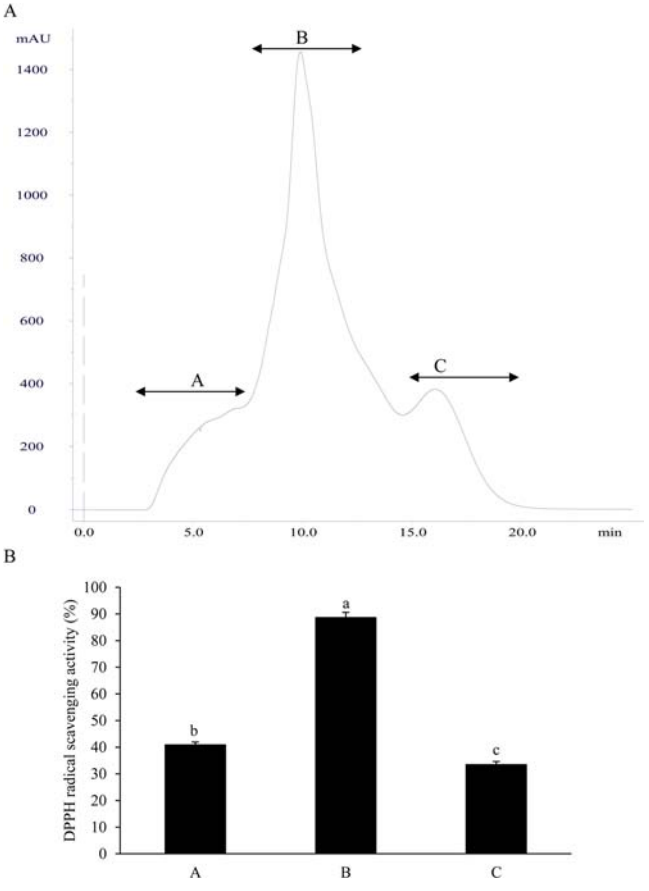

Figure 1. (A) Size exclusion chromatography of antioxidant peptide from duck meat hydrolysate by a Sephadex column packed with Sephadex G-25. Elution was done at 0.5 mL/min with distilled water using a UV detector at 280 nm. (B) DPPH radical scavenging activity of fractions obtained by size exclusion chromatography.

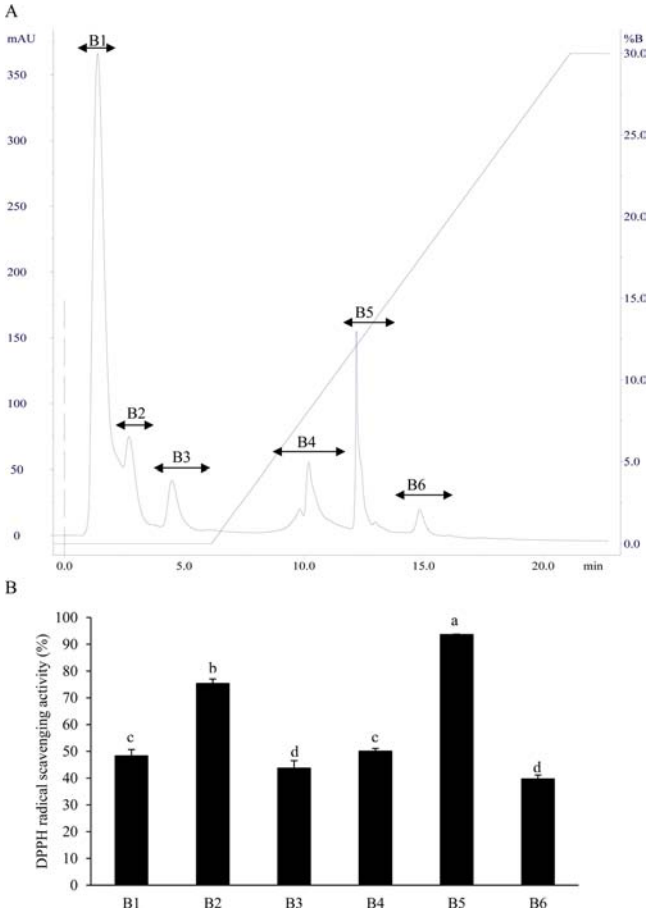

Figure 2. (A) Anion exchange chromatography of active fraction B obtained from a Sephadex G-25 column by Mono Q 5/50 GL. The elution was performed at a 1 mL/min flow rate with a linear NaCl gradient (0−0.3 M) in 20 mM Tris−HCl buffer (pH 8.0) using a UV detector at 280 nm. (B) DPPH radical scavenging activity of fractions obtained by ion exchange chromatography.

meat were thought to be endogenous and could be representative of peptides, uric acid, ascorbate, antioxidant enzymes, and polyamines or exogenous.[33] The lipophilic antioxidants in meat are represented by carotenoids, α-tocopherol, and ubiquinone.[33] These antioxidants may increase the antioxidant activity of DMH and MWCO-3, leading to their DPPH$^{\bullet}$ scavenging activity being close to those of fractions B and B5.

Identification of Antioxidant Peptides by Tandem Mass Spectrometry. For amino acid sequence identification, fraction B5 was further purified and identified by LC−MS/MS. Twenty-nine peptides were found in fraction B5 (data not shown). All the sequences of the peptides identified in this work were searched in BLAST (http://blast.ncbi.nlm.nih.gov/Blast.cgi), among which seven peptides showed 100% homology with the duck (*Anas*) proteome. The MS/MS spectra of these seven peptides are shown in Figure 3. The seven peptides were synthesized to evaluate their DPPH$^{\bullet}$ scavenging activities, $^{\bullet}$OH scavenging activities, and Fe^{2+}-chelating abilities. They had different potencies of antioxidant activities. The highest DPPH$^{\bullet}$ scavenging activity was found to be about 90% at a 1.0 mg/mL concentration of peptides LQAEVEELRAALE, GYDLGEAEFARIM, and IEDPFDQD-DWGAWKK, which was similar to that of GSH. In addition, the LQAEVEELRAALE peptide showed the highest Fe^{2+}-chelating ability, with a value of 87.13%. Peptides NWDDMEK and IEDPFDQDDWGAWKK exhibited the highest $^{\bullet}$OH scavenging activity, with values of 43.34% and 46.51%, at a concentration of 1.0 mg/mL, lower than that of the positive control GSH of about 74.68% (Table 3).

The antioxidant activity of peptides is closely related to their molecular weight, amino acid composition, sequences, and hydrophobicity.[34,35] The identified peptides were in a molecular weight range of 938.38−1851.86 that consisted of 7−15 amino acid residues (Table 3). The results confirmed that typical antioxidant peptides usually contain 2−20 amino acid residues with molecular weights of less of 6000.[4] Other research groups have purified and identified antioxidant peptides which had molecular weights similar to those found in this study, e.g., peptides from tuna backbone protein hydrolysates (1519),[36] venison protein hydrolysates (985, 1121),[7] hoki frame protein hydrolysates (1801),[8] duck skin byproduct hydrolysates (941.43),[19] and yellowfin sole frame protein hydrolysates (1300).[5]

It has been reported that hydrophobic amino acids have significant effects on radical scavenging.[34] For peptides, a high content of hydrophobic amino acids could increase their antioxidant activity.[37] Similar results have also been reported by Ren et al.,[38] who found that hydrophobic peptides contributed more to the antioxidant activities of peptides than the hydrophilic peptides. Zarei et al.[39] identified nine antioxidant peptides with high DPPH$^{\bullet}$ scavenging activities and found that

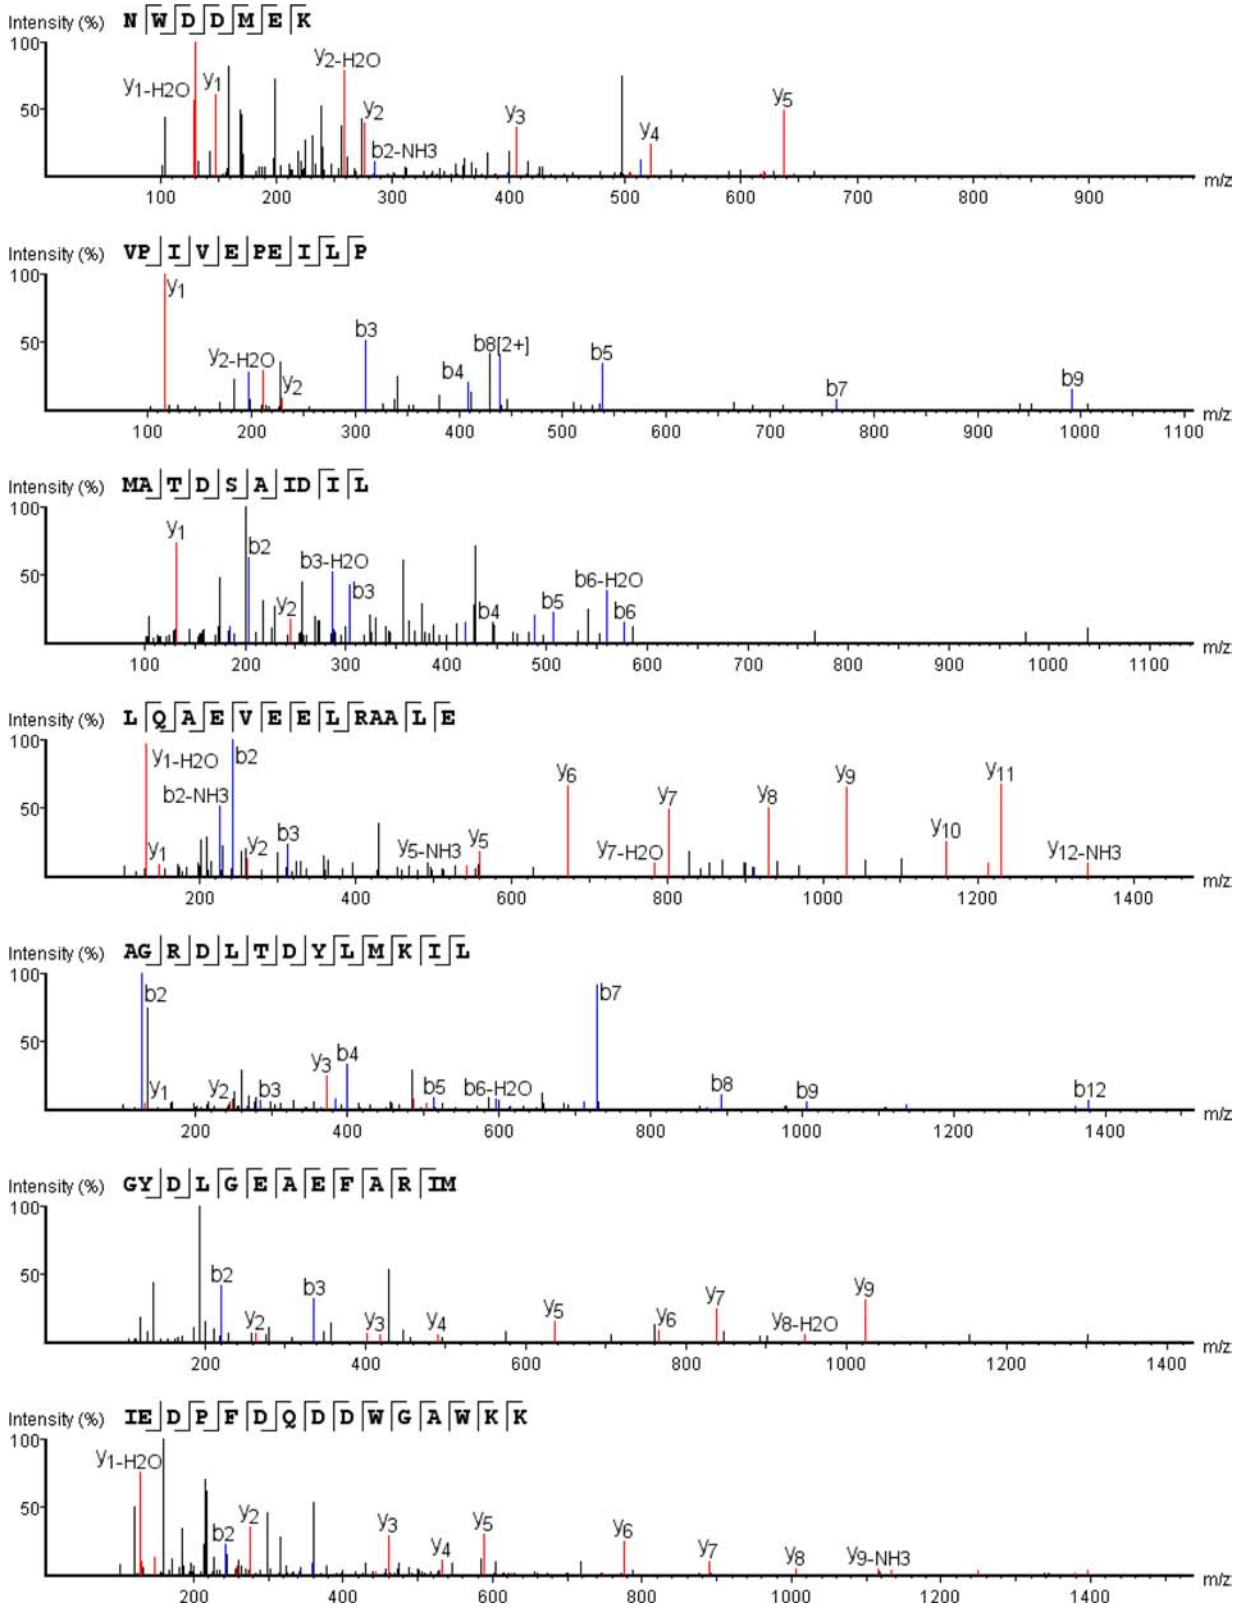

Figure 3. MS/MS spectra of seven peptides identified by a nano-LC system coupled to a linear quadrupole ion trap Orbitrap (LTQ Orbitrap XL) mass spectrometer.

the content of hydrophobic amino acids of each peptide was more than 50%. In the current study, the content of hydrophobic amino acids of NWDDMEK was less than 29%, whereas the percentage of hydrophobic amino acids of other peptides was about 50%. In addition, the existence of leucine (L) and isoleucine (I) at N-termini could increase the accessibility of peptides to the nonpolar phase, allowing full antioxidant capacity.[40] Glycine (G) has been suggested to play a vital role in the antioxidant activity of some peptides.[41−44] In the present study, LQAEVEELRAALE, GYDLGEAEFARIM,

[a]Different letters (a−g) in the same column indicate significant differences ($p < 0.05$).

and IEDPFDQDDWGAWKK were found to have higher DPPH• scavenging activity, presumably due to the L, G, or I at the N-terminal. Furthermore, the amino acid sequence of the peptide might play an important role in the antioxidant activity. The peptide segment EEL contained in the peptide LQAEVEELRAALE with high Fe^{2+}-chelating ability was previously identified as part of the antioxidant peptides EELDNALN and VPSIDDQEELM generated from the hydrolysis of porcine myofibrillar proteins using papain for 24 h. The peptides EELDNALN and VPSIDDQEELM exhibited DPPH• scavenging activity and metal-chelating activity.[11] The segment EEL was also present in the peptidic sequence of the antioxidant peptide YVEEL generated from the hydrolysis of milk proteins.[44] Alanine (A) and leucine (L) might be responsible for the metal-chelating activity of peptides, evidenced by the fact that two peptides isolated from tuna dark muscle hydrolysates with DPPH• scavenging activity and Fe^{2+}-chelating ability contained A and L.[45]

However, the peptide NWDDMEK, with a low content of hydrophobic amino acid residues, had a high hydroxyl radical scavenging activity. Apart from its agreement with the reported antioxidant peptide size, this could be mainly explained by the existence of tryptophan (W) in the peptide sequence. The indolyl-containing amino acid W had the capacity to donate protons to electron-deficient radicals.[25] A study conducted by Tsopmo et al.[46] claimed that W released from human milk upon gastrointestinal digestion may have the potential to act as a powerful radical scavenger.

Antioxidant peptides prepared by enzymes have potential application as antioxidant agents in nutritional supplements and food systems. There are antioxidant applications of commercially available nutraceuticals in some countries, such as LIQUAMEN prepared from molva, which helps in reducing oxidative stress.[47] Khaled et al.[48,49] studied the antioxidant activities of the sardinelle protein hydrolysates (SPHs). In an in vitro test, the SPHs showed high DPPH• scavenging activity and metal-chelating activity. While in an in vivo test, the treatment of rats with SPHs reduced the malondialdehyde (MDA) concentration and increased the activities of antioxidant enzymes (superoxide dismutase, glutathione peroxidase, and catalase) and high-density lipoprotein cholesterol. Egg-yolk protein hydrolysates (0.5 mg/mL) with 83.5% DPPH• scavenging activity and 74.2% •OH scavenging activity effectively inhibited 2-thiobarbituric acid reactive substance (TBARS) formation from ground beef and tuna homogenates.[50] Potato protein hydrolysates with radical scavenging and metal ion chelating ability also inhibited lipid oxidation in muscle foods.[51] In our study, antioxidant peptides such as LQAEVEELRAALE, IEDPFDQDDWGAWKK, AGRALTAYLMKIL, and GYDLGEAEFARIM showed high free radical scavenging activity and metal ion chelating ability (Table 3), with potential use in food systems and nutraceuticals. However, the application of these peptides in foods and animal models should be further studied to confirm the speculation.

The aim of the present study was to investigate the anti-inflammatory properties of the knot extract of *P. sylvestris* and to identify the active constituents and molecular mechanisms behind the immunomodulatory effects. The results reveal that two pine stilbenes, pinosylvin and monomethylpinosylvin, are powerful anti-inflammatory compounds both in vitro and in vivo.

MATERIALS AND METHODS

Chemicals. A knotwood extract of *P. sylvestris* and the purified stilbenes, pinosylvin and monomethylpinosylvin, were prepared at Åbo Akademi University. Knots removed from pine stems were freeze-dried and ground to pass through a 2 mm screen. The ground dry knot material was extracted in an accelerated solvent extractor (ASE) apparatus in two stages: (1) with hexane at 90 °C for 3 × 5 min to remove most of the lipophilic extractives and (2) with ethanol/water (95:5 by vol) at 100 °C for 3 × 5 min. The second extract containing primarily the hydrophilic extractives was evaporated to dryness in a vacuum. This extract was used in the biotests. The extract was analyzed by gas chromatography (GC) and gas chromatography−mass spectrometry (GC-MS) after silylation (1). The extract contained the following identified components, in wt % of dry knot material: monomethylpinosylvin, 12%; resin acids, 12%; oxidized resin acids, 11%; pinosylvin, 5%; nortrachelogenin (NTG), 7%; and matairesinol, 2%.

Pinosylvin and methylpinosylvin were isolated from the hydrophilic knot extract using flash chromatography (Biotage Flash 40i, Biotage AB, Uppsala, Sweden) with silica columns, using a step gradient with cyclohexane/acetone. Further purification was achieved by crystallization. The purity of the pinosylvin determined by GC was 89% and that of methylpinosylvin, 94%.

Resveratrol was bought from Tocris Bioscience (Ellisville, MO, USA), and astringin and isorhapontin were from Polyphenols Laboratoires AS (Sandnes, Norway). Rabbit polyclonal iNOS (sc-650), COX-2 (sc-1745), β-actin (sc-1616-R), and HO-1 (sc-1797) antibodies and HPR-conjugated goat polyclonal anti-rabbit antibody and donkey polyclonal anti-goat antibody were purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA, USA). All other reagents were from Sigma Chemical Co. (St. Louis, MO, USA) unless otherwise stated.

Cell Culture. Murine J774 macrophages (American Type Culture Collection, Rockville, MD, USA) were cultured at 37 °C in 5% CO_2 atmosphere and grown in Dulbecco's modified Eagle's medium (DMEM) with glutamax-I containing 10% heat-inactivated fetal bovine serum, penicillin (100 units/ml), streptomycin (100 μg/mL), and amphotericin B (250 ng/mL) (Invitrogen, Paisley, UK). Cells were seeded on 96-well plates for the XTT-test and on 24-well plates for the measurements of NO, MCP-1, and IL-6 production and HO-1 and iNOS expression. Cell monolayers were grown for 72 h to confluence before the experiments were started, and the compounds of interest were added in fresh culture medium. Any potential cytotoxicity of the tested compounds was determined by measuring cell viability using the Cell Proliferation Kit II (Roche Diagnostics, Mannheim, Germany).

Preparation of the Stable HEK293pGL4.32NFκB Cell Line. To investigate drug effects on the activation of transcription factor NF-κB and on NF-κB-mediated transcription, the HEK-293 cells (ATCC, Manassas, VA, USA) were stably transfected with a luciferase reporter construct, pGL4.32[*luc2P*/NF-κB-RE/Hygro]. The plasmid was purchased from Promega Corp. (Madison, WI, USA) and contained five copies of an NF-κB response element that drives transcription of the luciferase reporter gene.

Nitrite Assays. NO production was determined by measuring the accumulation of nitrite, a stable metabolite of NO in aqueous milieu, by the Griess reaction.[13]

Western Blot Analysis. At the indicated time points, cells were rapidly washed with ice-cold phosphate-buffered saline (PBS) and solubilized in cold lysis buffer containing 10 mM Tris-HCl, pH 7.4, 5 mM EDTA, 50 mM NaCl, 1% Triton-X-100, 0.5 mM phenylmethanesulfonyl fluoride, 1 mM sodium orthovanadate, 20 μg/mL leupeptin, 50 μg/mL aprotinin, 5 mM sodium fluoride, 2 mM sodium pyrophosphate, and 10 μM *n*-octyl-β-D-glucopyranoside. After incubation for 15 min on ice, the lysates were centrifuged (12000*g*, 4 °C for 10 min), and the supernatants were collected and stored in SDS sample buffer at −20 °C. An aliquot of the supernatant was used to determine the protein concentration according to the Coomassie blue method.[14]

Protein samples (20 μg of lysates) were analyzed according to the standard Western blotting protocol as described previously.[15] The membrane was incubated with the primary antibody in the blocking solution overnight at 4 °C and with the secondary antibody in the blocking solution for 1 h at room temperature. Bound antibody was detected using SuperSignal West Pico or Dura chemiluminescent substrate (Pierce, Rockford, IL, USA) and Image Quant LAS 4000 mini imaging system (GE Healthcare Bio-Sciences AB, Uppsala Sweden). The quantitation of the chemiluminescent signal was carried out with Imaging Quant TL software (GE Healthcare).

RNA Extraction and Quantitative RT-PCR. Total RNA was extracted with the GenElute Mammalian Total RNA Miniprep Kit (Sigma-Aldrich). Reverse transcription of RNA to cDNA and PCR reactions were carried out as previously described.[16] Primers and probes (Table 1) for iNOS, heme oxygenase-1 (HO-1), and glyceraldehyde-3-phosphate dehydrogenase (GAPDH, used as a housekeeping gene) were designed with Primer Express Software (Applied Biosystems, Foster City, CA, USA) and supplied by Metabion (Martinsried, Germany).

Luciferase Activity. Firefly luciferase activity was measured using the luciferase assay reagent (Promega), and the results were normalized to the total cellular protein. The protein content was measured using the Coomassie blue method.

ELISA. IL-6 and MCP-1 concentrations in the culture medium were measured by enzyme-linked immunosorbent assay (ELISA) using reagents from R&D Systems Europe Ltd. (Abingdon, UK).

Carrageenan-Induced Paw Edema in the Mouse. The anti-inflammatory effects were studied by measuring carrageenan-induced paw edema in male C57BL/6 mice (Harlan Laboratories BV, Venray, The Netherlands). The study was carried out in accordance with the legislation for the protection of animals used for scientific purposes (Directive 2010/63/EU) and approved by the National Animal Experiment Board (license ESLH-2009-07700/Ym-23). Animals were housed under conditions of optimum light, temperature, and humidity (12:12 h light−dark cycle, 22 ± 1 °C, 50−60%) with food and water provided ad libitum. Male mice were divided into six groups: control group, L-NIL group (50 mg/kg), pinosylvin group (100 mg/kg), monomethylpinosylvin group (100 mg/kg), resveratrol group (100 mg/kg), and dexamethasone group (2 mg/kg). Doses were selected on the basis of our preliminary experiments and data found in the literature.[17,18] Mice were dosed by intraperitoneal injection with 150 μL of normal saline or the tested compound at 2 h before carrageenan was applied. The mice were anesthesized by intraperitoneal injection of 0.5 mg/kg of medetomidine (Domitor 1 mg/mL, Orion Oyj, Espoo, Finland) and 75 mg/kg of ketamine (Ketalar 10 mg/mL, Pfizer Oy Animal Health, Helsinki, Finland), and thereafter the mice received a 30 μL intradermal injection into one hind paw of normal saline containing λ-carrageenan 1.5% (w/v). The contralateral paw received 30 μL of saline, and it was used as a control. Edema was measured 6 h after carrageenan injection by using a plethysmometer (Ugo Basile, Comerio, Italy). Carrageenan-induced edema is expressed as the difference in the volume change between the carrageenan-treated paw and the control paw.

Statistics. Results are expressed as the mean ± standard error of mean (SEM). Statistical significance of the results was calculated by one-way ANOVA with Dunnett's post test (dose curves) or Bonferroni's post test (multiple comparisons) by using GraphPad InStat 3 for Windows XP (Graph-Pad Software, San Diego, CA, USA). Differences were considered significant at * = $p < 0.05$, ** = $p < 0.01$, and *** = $p < 0.001$. EC_{50} values were calculated with GraphPadPrism 6 for Windows (Graph-Pad Software).

RESULTS

Effects of *P. sylvestris* Knotwood Extract, Pinosylvin, and Monomethylpinosylvin on iNOS Protein Expression and NO Production. Neither NO production nor iNOS expression was detectable in resting J774 macrophages. When the cells were activated through the Toll-like receptor 4 (TLR4) pathway by exposure to bacterial lipopolysaccharide (LPS, 10 ng/mL), both iNOS expression and NO production were significantly enhanced. The *P. sylvestris* knotwood extract inhibited iNOS protein expression and NO production in a dose-dependent manner (Figure 2), and about 50% inhibition was achieved at a concentration of 3 μg/mL.

P. sylvestris knotwood extract is rich in stilbenes particularly pinosylvin [5% (w/w)] and monomethylpinosylvin [12% (w/w)], and we continued by investigating the effects of these compounds on iNOS expression and NO production. Both pinosylvin and monomethylpinosylvin inhibited iNOS ex-

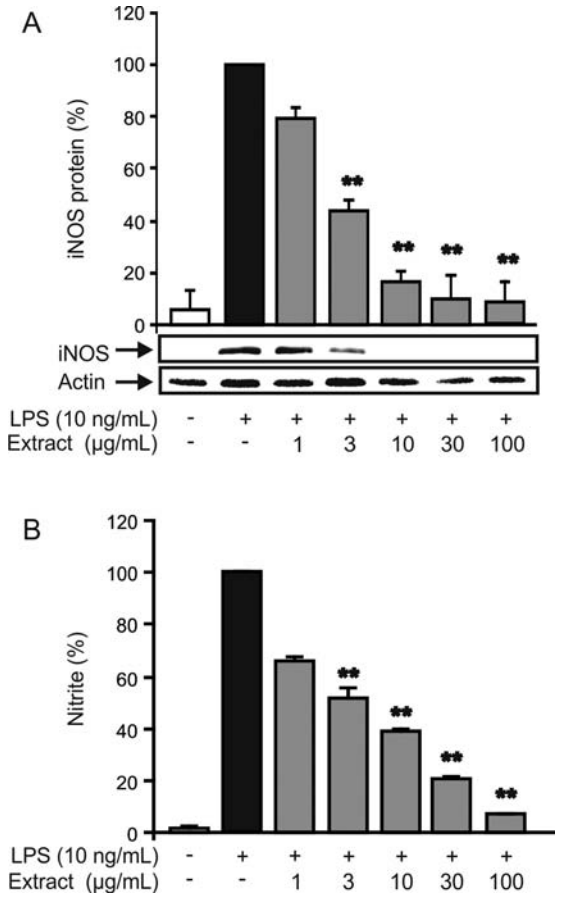

Figure 2. Effects of the *Pinus sylvestris* knot extract on LPS-induced (A) iNOS protein expression and (B) NO production in J774 macrophages as measured after a 24 h incubation. iNOS expression was measured by Western blot, and NO production was determined by measuring its metabolite nitrite in the culture medium by the Griess reaction. Values are expressed as the mean ± SEM, $n = 4$; (**) $p < 0.01$ as compared to cells incubated with LPS only.

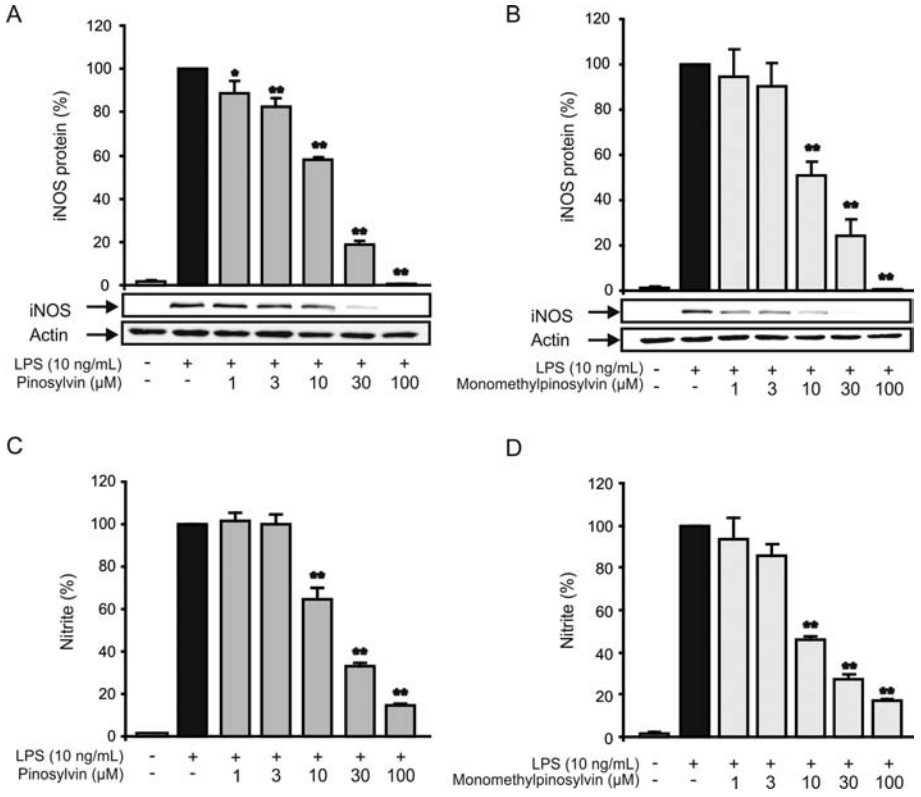

Figure 3. Effects of pinosylvin (A, C) and monomethylpinosylvin (B, D) on LPS-induced (A, B) iNOS protein expression and (C, D) NO production in J774 macrophages as measured after 24 h of incubation. iNOS expression was measured by Western blot, and NO production was determined by measuring its metabolite, nitrite, in the culture medium by the Griess reaction. Values are expressed as mean ± SEM, $n = 4$; (*) $p < 0.05$ and (**) $p < 0.01$ as compared to cells incubated with LPS only.

pression and NO production in a dose-dependent manner (Figure 3). Pinosylvin decreased iNOS expression with an EC_{50} value of 15 μM and monomethylpinosylvin with an EC_{50} value of 12 μM, whereas the EC_{50} values for inhibition of NO production were 13 μM for pinosylvin and 8 μM for monomethylpinosylvin. The effect was comparable to that of a well-known anti-inflammatory drug, dexamethasone, which decreased NO production by about 65% at a concentration of 10 μM.

After demonstrating that the stilbene components of the extract decreased iNOS expression and NO production, we also tested the effects of three other naturally occurring stilbene derivatives on iNOS protein expression and NO production: resveratrol as a positive control (this compound has been extensively evaluated in recent years) and astringin and isorhapontin, which have also been identified in extracts from Nordic conifers.[19] Resveratrol inhibited iNOS expression (EC_{50} = 18 μM) and NO production (EC_{50} = 6 μM) in activated macrophages in a dose-dependent manner (Figure 4), but the two other stilbenes (astringin and isorhapontin) were ineffective.

Effects of *P. sylvestris* Knotwood Extract, Pinosylvin, and Monomethylpinosylvin on iNOS mRNA Levels. In subsequent studies, we used quantitative RT-PCR to investigate the effects of *P. sylvestris* extract, pinosylvin, monomethylpinosylvin, and resveratrol (which was used as a control compound) on iNOS mRNA expression. J774 cells were incubated with the studied compounds for 2 h before LPS was added to activate the cells, and then mRNA levels were measured after a 6 h incubation with LPS. This time point was chosen according to the time curve of iNOS mRNA, where the maximal iNOS mRNA levels were detected at 6 h after the addition of LPS. *P. sylvestris* extract (100 μg/mL) and all tested stilbenes (100 μM) significantly lowered mRNA levels by 51−79% as seen in Figure 5.

Effects of *P. sylvestris* Knotwood Extract, Pinosylvin, and Monomethylpinosylvin on NF-κB-Mediated Transcription. To study in more detail their mechanisms of action, we investigated the effects of *P. sylvestris* extract, pinosylvin, and monomethylpinosylvin on NF-κB-mediated transcription because NF-κB is an important transcription factor for the iNOS gene. We used human embryonic kidney 293 cells that had been genetically modified to express luciferase (LUC) gene under the control of an NF-κB response element containing five NF-κB binding sites. *P. sylvestris* extract, pinosylvin, monomethylpinosylvin, and resveratrol (which was used as a control compound) significantly inhibited NF-κB-mediated transcription (measured as luciferase activity) (Figure 6). MG-132, a known NF-κB inhibitor, was also included in the experiments, and it reduced LUC-activity by >90%.

Effects of *P. sylvestris* Knotwood Extract, Pinosylvin, and Monomethylpinosylvin on Heme Oxygenase-1 Expression. HO-1 is a factor known to regulate NF-κB activation in macrophages.[20,21] Interestingly, the knotwood extract and the two purified stilbenes, pinosylvin and monomethylpinosylvin, as well as resveratrol all enhanced the HO-1 mRNA and protein levels in macrophages exposed to LPS (Figure 7). The HO-1 inducer hemin was used as a control compound.

Effects of *P. sylvestris* Knotwood Extract, Pinosylvin, and Monomethylpinosylvin on MCP-1 and IL-6 Production. We investigated whether *P. sylvestris* extract and the

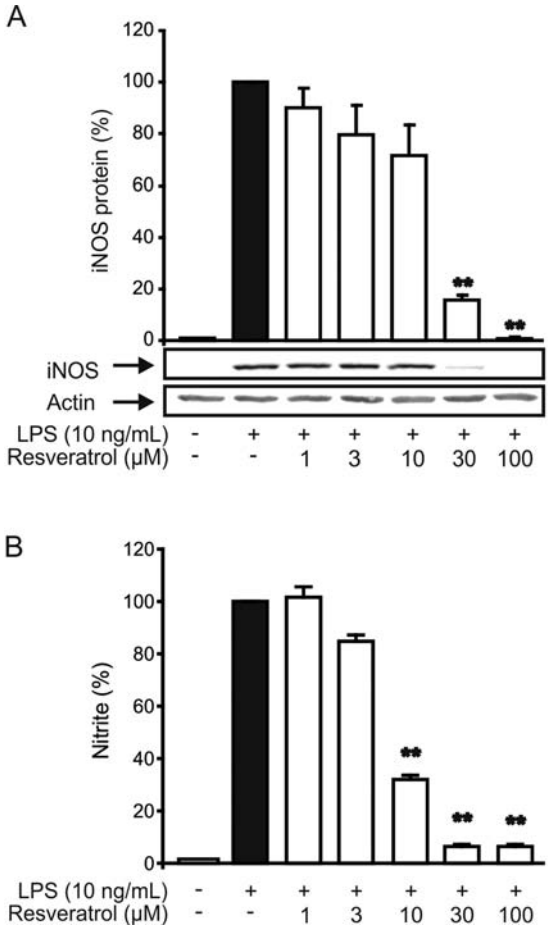

Figure 4. Effects of resveratrol on LPS-induced (A) iNOS protein expression and (B) NO production in J774 macrophages as measured after 24 h of incubation. iNOS expression was measured by Western blot, and NO production was assayed by measuring its metabolite, nitrite, in the culture medium by the Griess reaction. Values are expressed as mean ± SEM, $n = 4$; (**) $p < 0.01$ as compared to cells incubated with LPS only.

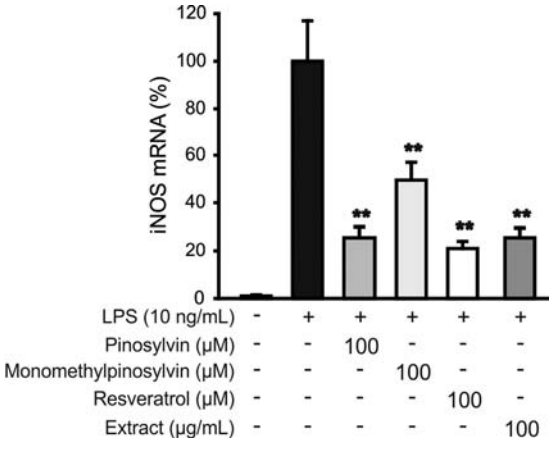

Figure 5. Effects of pinosylvin, monomethylpinosylvin, resveratrol, and the *P. sylvestris* knot extract on iNOS mRNA expression. J774 macrophages were stimulated with LPS in the presence or in the absence of the compounds and the extract for 6 h, and iNOS mRNA expression was measured by quantitative RT-PCR. The results were normalized against GAPDH mRNA and are expressed as mean ± SEM, $n = 4$; (**)$p < 0.01$ as compared to cells incubated with LPS only.

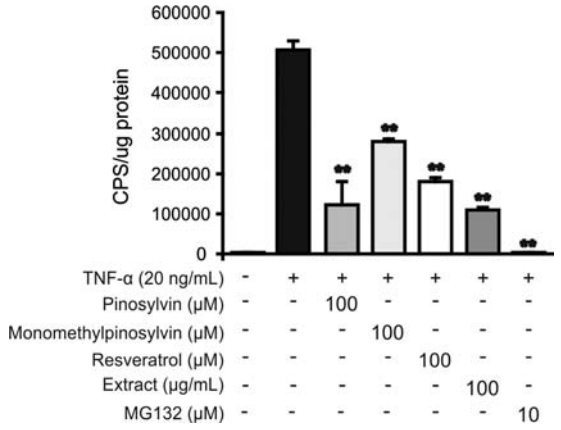

Figure 6. Effects of pinosylvin, monomethylpinosylvin, resveratrol, and the *P. sylvestris* knot extract on NF-κB-dependent transcription in HEK-293 cells transfected with luciferase reporter construct. HEK-pNF-κB(*luc2P*)hygro cells were stimulated with TNFα and treated with the extract or the compounds of interest or with the known NF-κB inhibitor MG132 for 5 h, and luciferase activity was measured. Results are expressed as mean ± SEM, $n = 4$; (**) $p < 0.01$ as compared to cells incubated with TNFα only.

stilbenes isolated from the extract would exert effects on other important inflammatory mediators by determining if they could modify the productions of the chemokine MCP-1 (Figure 8) and the pro-inflammatory cytokine IL-6 (Figure 9) in activated J774 macrophages. The extract of *P. sylvestris* reduced MCP-1 production in a dose-dependent manner with an EC_{50} value of 11 μg/mL. Furthermore, also pinosylvin (EC_{50} = 35 μM), monomethylpinosylvin (EC_{50} = 35 μM), and resveratrol (EC_{50} = 19 μM) reduced MCP-1 production. *P. sylvestris* extract (EC_{50} = 26 μg/mL) and monomethylpinosylvin (EC_{50} = 25 μM) had a moderate dose-dependent inhibitory effect also on IL-6 production. Similarly, resveratrol reduced IL-6 production with an EC_{50} value of 21 μM. Pinosylvin evoked about 30% inhibition on IL-6 production at a concentration of 30 μM. We also tested the effects of *P. sylvestris* extract, pinosylvin, and monomethylpinosylvin on COX-2 levels in activated macrophages, but none of the compounds had any inhibitory effect on the expression levels of COX-2 protein.

Effects of Pinosylvin and Monomethylpinosylvin on Carrageenan-Induced Paw Edema in the Mouse. Because both pinosylvin and monomethylpinosylvin displayed anti-inflammatory effects in the in vitro studies, we decided to test if they could also exhibit in vivo anti-inflammatory properties by using a carrageenan-induced paw inflammation model in the mouse. Intraperitoneal administration of known anti-inflammatory compounds, that is, the iNOS inhibitor L-NIL (50 mg/kg) and the glucocorticoid dexamethasone (2 mg/kg), reduced carrageenan-induced paw edema by >80%. Interestingly, also pinosylvin (100 mg/kg) and monomethylpinosylvin (100 mg/kg) decreased carrageenan-induced inflammation by almost 80%, whereas the inhibitory effect of resveratrol (100 mg/kg; used as a control compound) was only 50% (Figure 10).

DISCUSSION

The present study investigated the anti-inflammatory properties of knotwood extract of *P. sylvestris* and two of its stilbene constituents, pinosylvin and monomethylpinosylvin. We found that the knotwood extract of *P. sylvestris* inhibited LPS-induced NO production in activated macrophages in a dose-dependent

J. Agric. Food Chem. 2015, 63, 3445−3453

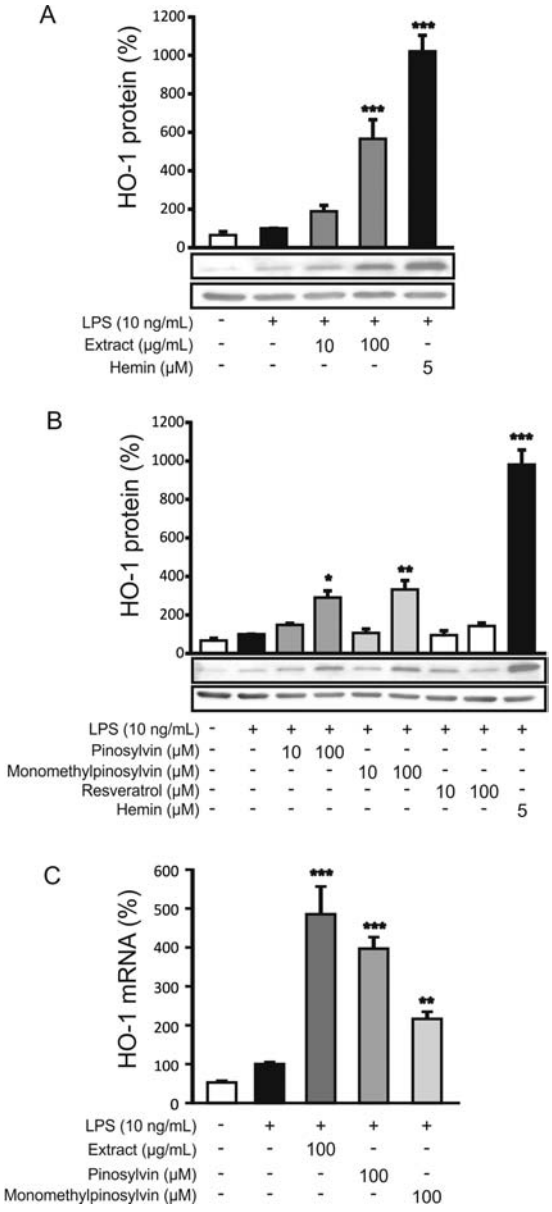

Figure 7. Effects of pinosylvin, monomethylpinosylvin, resveratrol, and the *P. sylvestris* knot extract on HO-1 protein expression (A, B) and mRNA expression (C). J774 macrophages were stimulated with LPS in the presence or in the absence of the compounds or the extract for 6 h, and HO-1 protein expression was measured by Western Blot or for 4 h and HO-1 mRNA expression was measured by quantitative RT-PCR. The results were normalized against GAPDH mRNA. The values are expressed as mean ± SEM, $n = 4$; (**) $p < 0.01$ as compared to cells incubated with LPS only.

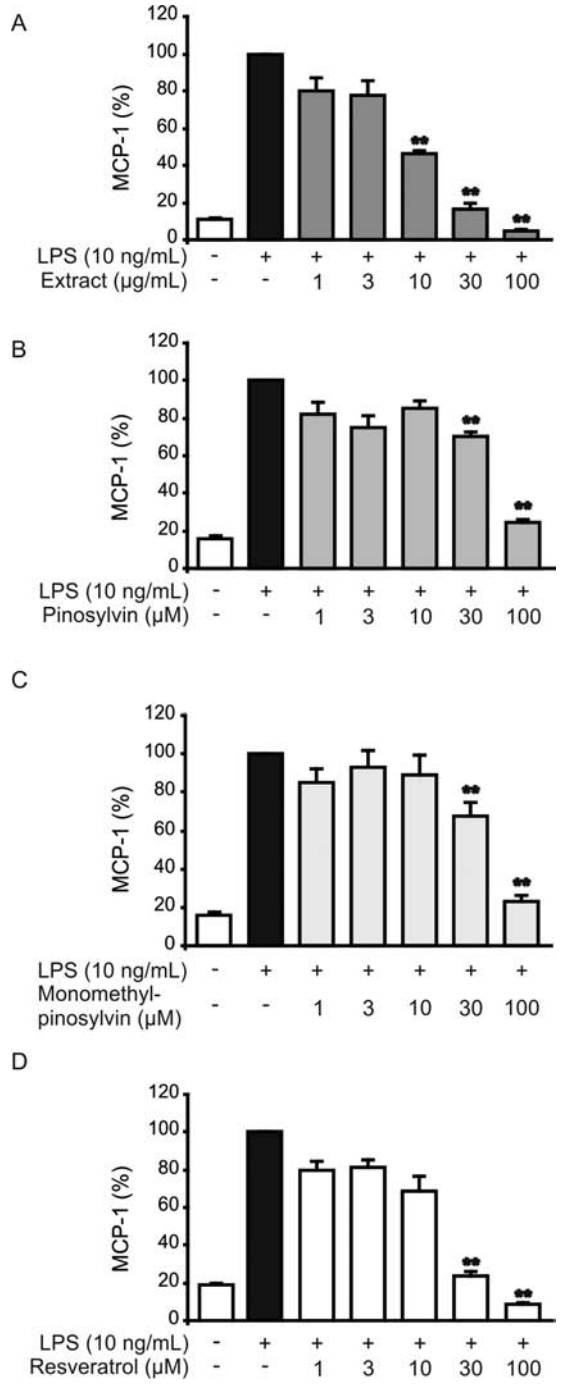

Figure 8. Effects of the *P. sylvestris* knot extract (A), pinosylvin (B), monomethylpinosylvin (C), and resveratrol (D) on MCP-1 production. J774 macrophages were stimulated with LPS for 24 h and thereafter the incubations were terminated and MCP-1 production was determined by ELISA. Results are expressed as mean ± SEM, $n = 4$; (**) $p < 0.01$ as compared to cells incubated with LPS only.

manner. This was attributable to the inhibitory effect on iNOS expression in response to inflammatory stimuli as both the iNOS protein and the mRNA levels were decreased. In addition, a clear reduction was observed in the expression of inflammatory genes IL-6 and MCP-1. Importantly, the anti-inflammatory effects of pinosylvin and monomethylpinosylvin were also found in vivo in a standard carrageenan-induced inflammatory paw edema model.

The immunomodulatory effects of *P. sylvestris* knot have not been reported earlier. It has been shown previously that the extract of *P. sylvestris* leaf buds could reduce NO production and iNOS mRNA expression in LPS and IFN-γ-stimulated murine macrophages but exerted no effects on COX-2 expression or PGE_2 production.[22] Karonen et al. have also reported that pine bark extracts possess anti-inflammatory properties,[23] but in these previous studies, the active constituents were not identified.

The knotwood extract was found to contain 5% (w/w) of pinosylvin and 12% of monomethylpinosylvin. The effects of these two stilbene derivatives on NO production and iNOS

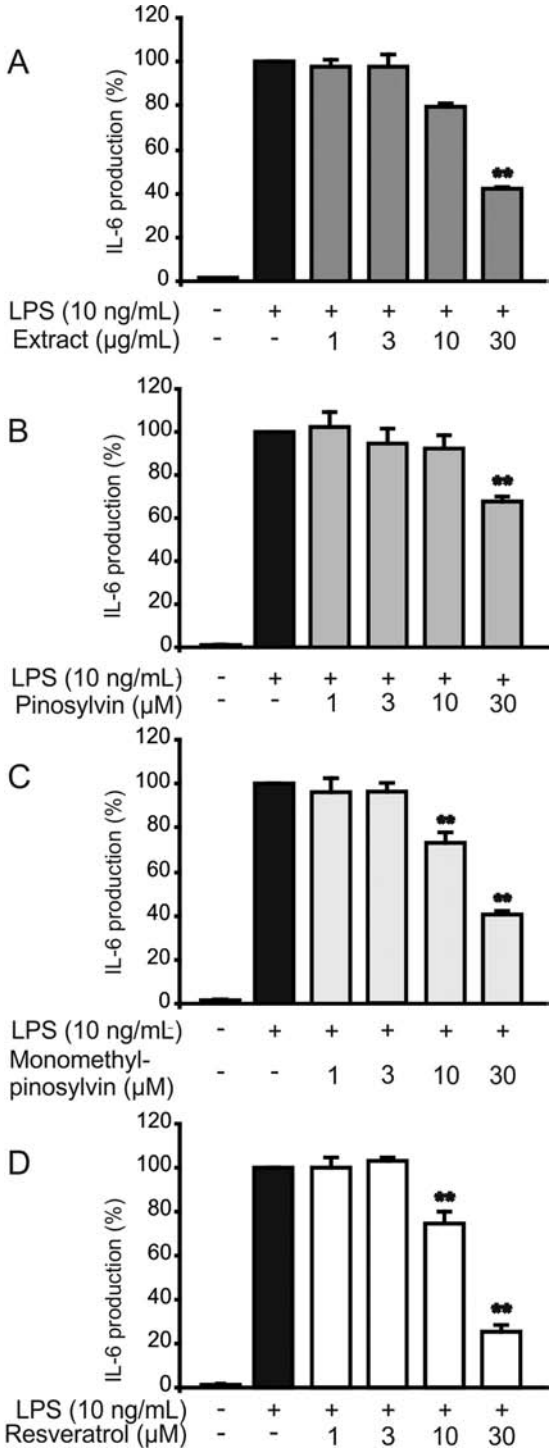

Figure 9. Effects of the *P. sylvestris* knot extract (A), pinosylvin (B), monomethylpinosylvin (C), and resveratrol (D) on IL-6 production. J774 macrophages were stimulated with LPS for 24 h, and thereafter the incubations were terminated and IL-6 production was determined by ELISA. Results are expressed as mean ± SEM, $n = 4$; (**) $p < 0.01$ as compared to cells incubated with LPS only.

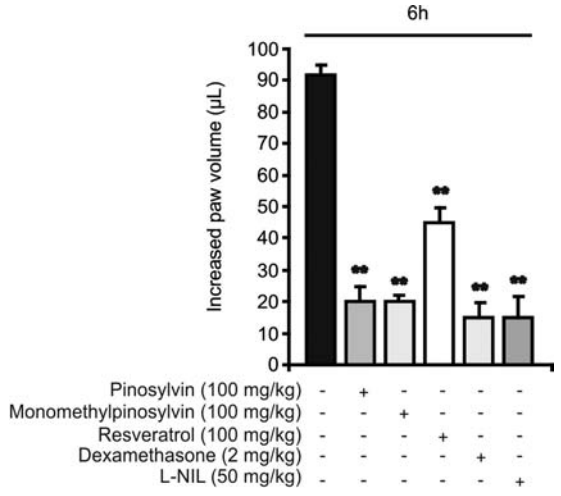

Figure 10. Effects of pinosylvin, monomethylpinosylvin, and resveratrol on carrageenan-induced paw inflammation in the mouse. Pinosylvin, monomethylpinosylvin, resveratrol, and control compounds L-NIL and dexamethasone were administered ip 2 h prior to carrageenan (1.5%) being injected into the paw. The contralateral paw was injected with the solvent and served as the control. Paw edema was measured before and 6 h after the carrageenan injection. Edema is expressed as the differences in the volume change between the carrageenan treated paw and the control paw. Results are expressed as mean ± SEM, $n = 6$; (**) $p < 0.01$.

expression were qualitatively similar to the effects of the extract, and thus it is likely that they account for the anti-inflammatory effects observed with the extract. Therefore, we continued the experiments with pinosylvin and monomethylpinosylvin, but we also included a well-known stilbene, resveratrol, as a control compound. In addition, two other stilbenes present in trees, astringin and isorhapontin, were also investigated.

Previously it has been shown that resveratrol could inhibit LPS-induced NO production in macrophages,[24−28] a result confirmed also in the present study. Furthermore, this effect was found to be shared by pinosylvin and monomethylpinosylvin. The present pinosylvin result is in line with the previous report from Park et al.[29] Some other natural substances from the stilbenoid group, namely, *cis*-mulberroside A, rhapontigenin, and piceatannol, have also been demonstrated to be able to decrease iNOS expression.[24,25,30] There are a few published studies on the structure−activity relationship of stilbenes on LPS-induced NO production which suggest that the structural balance between functional oxygen groups on the benzene rings is important for the biological activity.[24] In the previous study, the presence of a glucoside moiety was also found to reduce anti-inflammatory activity.[25] Here, the ineffectiveness of astringin and isorhapontin as compared to the other tested stilbenes may be explained by the fact that they are glycosylated forms and are perhaps poorly transported into the cell. It was decided to include astringin and isorhapontin in the present study because these compounds have also been reported to be present in Nordic conifers in addition to pinosylvin and monomethylpinosylvin.[19] There were no major differences between the potencies of pinosylvin, monomethylpinosylvin, and resveratrol on NO production or iNOS expression.

No previous data on the anti-inflammatory effects of monomethylpinosylvin have been reported, and there are only a few earlier reports on the corresponding properties of pinosylvin. Pinosylvin inhibited LPS-induced expression of pro-inflammatory cytokines IL-8 and TNF-α in THP-1 cells via the NF-κB signaling pathway.[31] Another study revealed that pinosylvin could reduce prostaglandin E_2 production in activated RAW 264.7 cells.[32]

DOI: 10.1021/jf504606m
J. Agric. Food Chem. 2015, 63, 3445−3453

The present study extends the previous data by showing that the extract of *P. sylvestris* and also pinosylvin and monomethylpinosylvin were able to inhibit the iNOS-NO pathway in activated macrophages. The compounds suppressed also iNOS mRNA levels, which proves that a transcriptional mechanism is behind the inhibitory effect on iNOS expression. NF-κB is one of the key transcription factors regulating iNOS transcription. In the present study, we found that NF-κB-mediated transcription was inhibited by the extract of *P. sylvestris* and its two stilbene constituents, pinosylvin and monomethylpinosylvin, which may, at least partly, explain their inhibitory effects on iNOS and other NF-κB-dependent genes.

HO-1 has been shown to play a role in cellular and tissue defense against oxidative stress, possessing potent anti-inflammatory and cytoprotective properties.[33] In the present study, we found that the knot extract and its active stilbenes increased HO-1 expression in activated macrophages. This may represent a putative mechanism for their anti-inflammatory action and explain how they were able to decrease the NF-κB activity and reduce inflammatory gene expression. Some other compounds of natural origin have been reported to affect HO-1.[33] There is also one study reporting that resveratrol could induce HO-1 in human aortic smooth muscle cells, which supports our original findings on the protective effects of pinosylvin and monomethylpinosylvin through HO-1 expression.[34]

Additionally, it was important to determine whether our findings in vitro could be translated into an anti-inflammatory effect in vivo. We chose to test the effects of pinosylvin and monomethylpinosylvin in carrageenan-induced paw inflammation, which is a widely used experimental model of acute inflammation in preclinical pharmacological studies. The carrageenan-induced inflammatory response in the paw has been reported to be mediated partly by increased NO production because it is sensitive to the anti-inflammatory properties of iNOS inhibitors.[35,36] In the current study, the iNOS inhibitor, L-NIL, also reduced significantly carrageenan-induced acute inflammation. The inhibitory responses of pinosylvin and monomethylpinosylvin were comparable to that of L-NIL and another control compound, dexamethasone, which is a very efficacious anti-inflammatory drug that also inhibits iNOS expression.[37] In the present study, resveratrol was observed to inhibit carrageenan-induced paw edema, although this effect was not detected in the previous study of Gentilli et al.[38] The difference in the dosing of resveratrol in these studies may explain the different results. Gentilli and co-workers injected resveratrol shortly before the carrageenan challenge, whereas we administered the drug 2 h before carrageenan. However, it is noteworthy that pinosylvin and monomethylpinosylvin were more potent than resveratrol in combatting carrageenan-induced paw inflammation. As far as we are aware, there is only one previous study in which pinosylvin has been tested in an inflammatory model in vivo, in adjuvant arthritis in the rat.[18] The results support our present findings that pinosylvin possesses a significant anti-inflammatory action also in vivo.

In conclusion, the most interesting novel finding in this study was that pinosylvin and monomethylpinosylvin were found to have anti-inflammatory properties in vivo, possibly via a mechanism involving the stimulation of HO-1 levels leading to inhibition of NF-κB activity and ultimately to the suppression of inflammatory gene expression. These findings extend our understanding of the potential beneficial properties of naturally occurring stilbenes and may provide new insights in the development of novel anti-inflammatory treatments. In addition, the immunomodulatory potential of pinosylvin and its derivatives as well as their detailed mechanisms of action should be evaluated in further studies.

c-EPS from their cell wall.[22] However, there have been few studies focusing on the anticancer activity and chemical characterization of c-EPS produced by LAB.[23] Recently, the *Lactobacillus helveticus* MB2-1 strain, which produces abundant EPS, was isolated in our laboratory from traditional Sayram ropy fermented milk (SRFM) in the southern Xinjiang region of China.[2] In vitro antioxidant activity assays demonstrated that the c-EPS and three r-EPS fractions (r-LHEPS-1, r-LHEPS-2, and r-LHEPS-3) had strong scavenging activities against four free radicals.[24,25] In addition, we found that all of the r-EPS fractions, especially r-LHEPS-2, exerted high inhibitory activity in vitro against BGC-823 human gastric cancer cells. Furthermore, we elucidated the fine structure of purified r-LHEPS-2, which showed a →4,6-D-Man*p*-(1 → 6)-D-Man*p*-(1 → 4)-D-Gal*p*-(1→ backbone with a single T-D-Glc*p*-(1 → 4)-D-Man*p*-(1 → 6)-D-Glc*p*-(1→ side-branch on the O-6 of the → 4,6-D-Man*p*-(1→ residue.[26]

In the present work, the c-EPS from *L. helveticus* MB2-1 was prepared and characterized by gas chromatography (GC), gas chromatography−mass spectrometry (GC−MS), nuclear magnetic resonance (NMR), atomic force microscopy (AFM), and scanning electron microscopy (SEM). Furthermore, the in vitro anticancer activity of c-EPS against human HepG-2 liver cancer, BGC-823 gastric cancer, and HT-29 colon cancer cells was evaluated.

MATERIALS AND METHODS

Microorganism and Reagents. The *L. helveticus* MB2-1 strain was isolated from SRFM. This strain was grown in liquid medium (1000 mL) containing 80 g of whey and 5 g of yeast extract and adjusted to pH 6.7 with 2.0 M NaOH. HepG-2, BGC-823, and HT-29 cancer cells and human colonic epithelial HCoEpiC cells were obtained from the Cell Bank of the Shanghai Institute of Cell Biology (Shanghai, China). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-2*H*-tetrazolium bromide (MTT) were purchased from Gibco/Invitrogen (Gibco BRL, Grand Island, NY). Dimethyl sulfoxide (DMSO), methyl iodide (CH_3I), 5-fluorouracil (5-FU), penicillin, streptomycin, rhamnose, arabinose, mannose, fucose, glucose, galactose, xylose, and inositol were obtained from Sigma Chemical Co. (St. Louis, MO). DEAE-cellulose 52 and Sephadex G-100 were purchased from Whatman Co. (Maidstone, Kent, UK), and T-series dextrans were purchased Pharmacia Co. Ltd. (Uppsala, Sweden). All other reagents were of analytical grade.

Observation of *L. helveticus* MB2-1 Capsules. The presence of capsules on the cell surface of *L. helveticus* MB2-1 was confirmed by observation by transmission electron microscopy (TEM) using an H-7650 TEM (Hitachi High Technologies Corporation, Tokyo, Japan) operating at 80 kV. The sample was prepared by mounting the cells onto a copper grid, immersing the samples in 2% phosphotungstic acid (pH 7.0) and drying at room temperature.

Isolation and Purification of c-EPS. The c-EPS was isolated and purified according to our previous method, with minor modifications.[23] After growth at 40 °C for 24 h, the cultures were centrifuged at 12 000*g* and 4 °C for 15 min. The viscous cell precipitates were washed twice with 0.85% NaCl and then centrifuged as above. The centrifuged precipitates were resuspended in 1 M NaCl and treated with a JY92-IIN cell sonicator (Ningbo Scientz Biotechnology Co., Ltd., Ningbo, China) at 40 W and 4 °C for 3 min. After centrifugation to eliminate insoluble material, the supernatants were combined and then concentrated using a Laborota 4000 efficient rotary evaporator (Heidolph Instruments GmbH & Co, Schwabach, Germany). The final concentrated supernatant was mixed with three volumes of ice-cold ethanol and stirred vigorously. After standing overnight at 4 °C, the precipitate was collected by centrifugation and dialyzed using a dialysis bag (8000−14 000-Da molecular weight (MW) cutoff) in distilled water for 48 h at 4 °C before being lyophilized using a Heto Power Dry LL3000 freeze-dryer (Thermo Electron Co., Bath, UK). The freeze-dried crude c-EPS was fractionated with a DEAE-cellulose column (2.6 × 30 cm) and was eluted stepwise with distilled water and 0.1, 0.3, and 0.5 M NaCl solutions at a flow rate of 60 mL/h. The fractions were assayed for carbohydrate content by the phenol−sulfuric acid method.[27] The peak fractions containing c-EPS were pooled, dialyzed, and lyophilized. Further purification of c-EPS was performed using a Sephadex G-100 column (2.6 × 100 cm), which was eluted with distilled water at a flow rate of 12 mL/h. The fraction containing purified c-EPS was collected, dialyzed, and lyophilized.

Purity and Molecular Weight Estimation of c-EPS. The purity and MW of the c-EPS were determined by high-performance size-exclusion chromatography (HPSEC) with an Agilent 1200 series system (Palo Alto, CA) equipped with a TSK gel G4000 PW XL column (300 × 7.8 mm, Tosoh Corp., Tokyo, Japan) and an evaporative light-scattering detector (ELSD).[25] Twenty microliters of purified c-EPS (1 mg/mL) was injected and was eluted with distilled water at 50 °C at a flow rate of 0.7 mL/min. The linear regression was calibrated using the T-series dextran standards (T-500, T-200, T-100, T-50, and T-10).

Basic Component Analysis of c-EPS. The total sugar content was measured by the phenol−sulfuric acid method mentioned above.[27] Protein, uronic acid, and sulfate group quantities were determined according to our previous method.[25]

Analysis of Monosaccharide Composition. Five milligrams of purified c-EPS was hydrolyzed with 2 mL of 2 M trifluoroacetic acid (TFA) at 120 °C for 2 h.[5] The hydrolysates were then subjected to aldononitrile acetate precolumn derivatization for GC determination of the monosaccharide composition. GC was performed on an Agilent 6890N GC (Palo Alto, CA) equipped with a flame ionization detector (FID) and a HP-5 capillary column (30 m × 0.32 mm i.d., 0.25 mm, J&W Scientific Inc., Folsom, CA). N_2 was used as the carrier gas at a flow rate of 1 mL/min, and the temperatures of the injector and detector were set to 250 °C and 280 °C, respectively. The following chromatographic conditions were used: the initial column temperature was held at 100 °C for 5 min, increased at a rate of 5 °C/min to 150 °C, held at 150 °C for 5 min, and then subsequently increased at 5 °C/min to 240 °C, where it was held at 240 °C for 2 min. Arabinose, mannose, rhamnose, fucose, glucose, galactose, and xylose standards were prepared for comparison, and inositol was used as an internal standard.

Ultraviolet−Visible (UV−vis) and Fourier-Transform Infrared (FT-IR) Spectroscopy. UV−vis spectroscopy analyses were conducted with a U-4100 spectrophotometer (Hitachi Ltd., Japan). The c-EPS solution was prepared by suspending the sample in distilled water at a concentration of 1.0 mg/mL for UV−vis measurement over a wavelength range of 190−700 nm. FT-IR was recorded from a sample in a KBr pellet on a FT-IR spectrophotometer (Nicolet Nexus470, Thermo Nicolet Co., WI), and the spectrum from 400 to 4000 cm^{-1} was recorded.[25]

Methylation Analysis and Mass Spectrometry. Five milligrams of purified c-EPS was completely methylated using methyl iodide and solid sodium hydroxide in dimethyl sulfoxide, as described in our previous report.[23] Briefly, the permethylated c-EPS was hydrolyzed with 2 M TFA at 120 °C for 2 h. Next, the partially methylated monosaccharides were reduced with $NaBH_4$ for 2 h at room temperature and acetylated with pyridine−acetic anhydride (1:1, v/v) at 100 °C for 1 h. The resulting methylated alditol acetate derivatives were analyzed by GC−MS. GC−MS analysis was performed on an Agilent 5975MSD-6890 GC−MS (Agilent Technologies, Santa Clara, CA) equipped with a HP-5 capillary column and using He as the carrier gas. The initial oven temperature was 100 °C, which was then increased by 6 °C/min to 250 °C, where it was held for 5 min.

Nuclear Magnetic Resonance Spectroscopy Analysis. The NMR spectrum of the c-EPS solution was recorded with D_2O as the solvent using a Bruker AVANCE AV-500 spectrometer (Bruker Group, Fällanden, Switzerland) operating at 500 MHz.[28] The residual solvent signal was used as an internal standard. Both one-dimensional (1D) ^1H and ^{13}C NMR experiments were performed, and the

DOI: 10.1021/acs.jafc.5b01086
J. Agric. Food Chem. 2015, 63, 3454−3463

operating temperature was 323 K. The delay (D_1) and acquisition (AQ) times were 4.00 and 2.92 s for the ^{1}H NMR spectra and 1.08 and 2.00 s for ^{13}C NMR, respectively. The chemical shift (δ) values are given in parts per million (ppm), and coupling constants (J) are given in hertz. Two-dimensional (2D) ^{1}H−^{1}H correlated spectroscopy (COSY), ^{1}H−^{13}C heteronuclear single quantum coherence (HSQC), ^{1}H−^{13}C heteronuclear multiple quantum coherence (HMBC), and nuclear Overhauser effect spectroscopy (NOESY) measurements were used to assign signals and to determine the sequence of sugar residues.

Colorimetric Triple Helix Determination with Congo Red. The conformational structure of the purified c-EPS was established by helix−coil transition analysis according to Villares's procedure.[29] Briefly, the purified c-EPS was dissolved at 1 mg/mL in various NaOH solutions (0.05−0.4 M), and these samples were added to a Congo red solution (40 μM). Spectra were recorded at room temperature (25 °C) with a UV−vis spectrophotometer (U-4100, Hitachi Ltd., Japan).

Atomic Force Microscopy. A c-EPS solution (1 mg/mL) was prepared by adding purified c-EPS to distilled H_2O. The aqueous solution was stirred at 50 °C for approximately 1 h in a sealed bottle under N_2 until the c-EPS dissolved completely. After cooling to room temperature, the solution was diluted to a final concentration of 0.01 mg/mL. Approximately 5 μL of the diluted c-EPS solution was dropped onto the surface of a mica sample carrier and allowed to dry at room temperature. Later, the AFM image was collected using a Bruker Dimension Icon AFM (Bruker Biosciences, Billerica, MA) equipped with Bruker ScanAsyst-Air PeakForce tapping-mode AFM tips. The scan resolution and rate were 512 × 512 and 1 Hz, respectively.

Scanning Electron Microscopy. The morphology of the purified c-EPS was observed using an S-3000 scanning electron microscope (Hitachi Science Systems, Ltd., Hitachinaka, Japan) at an accelerating voltage of 30 kV. For SEM analysis, the sample was mounted on a metal stub and sputtered with gold. Micrographs were recorded at 2000× magnification to ensure clear images.

In Vitro Anticancer Activity. The inhibitory effects of purified c-EPS on the HepG-2, BGC-823, and HT-29 cancer cell lines and on human colonic epithelial HCoEpiC cells in vitro were evaluated using the MTT assay on a 96-well plate.[20] Briefly, 100 μL of cancer cells (2 × 10^5 cells/mL) was cultured at 37 °C for 24 h in DMEM supplemented with 10% FBS, penicillin (100 U/mL), and streptomycin (100 mg/L) under 5% CO_2. The cells were then treated with various concentrations of purified c-EPS (0, 50, 100, 200, 400, and 600 μg/mL) and 5-FU (50 μg/mL) for 24, 48, and 72 h. At the end of each treatment, 10 μL of MTT (5 mg/mL) was added, and the cells were incubated for another 4 h. The liquid was then removed, and 100 μL of DMSO was added to the well. After dissolving the formazan crystals that formed, the absorbance was measured in a Synergy-2 microplate reader (BioTek Instruments, Inc., Burlington, VT) at 570 nm. The inhibitory rate was expressed as follows:

$$\text{inhibitory rate (\%)} = [1 - (A_{\text{sample}} - A_{\text{blank}})/(A_{\text{control}} - A_{\text{blank}})] \times 100$$

where A_{control} and A_{blank} are the absorbance values of the system without the addition of c-EPS and without cells, respectively.

Statistical Analysis. The obtained results were analyzed using SPSS version 16.0 (SPSS Inc., Chicago, IL). All data were analyzed by one-way analysis of variance (ANOVA). Significant differences were determined by Tukey's honest significant difference (Turkey's HSD) post hoc test. Half-maximal (50%) inhibitory concentration (IC_{50}) values were calculated by probit regression analysis. Statistical significance was set to $p < 0.05$. In all cases, there were three replicates ($n = 3$).

RESULTS AND DISCUSSION

Visualization of Capsules. When cells of *L. helveticus* MB2-1 were stained using a negative dyeing method and examined with an optical microscope under an oil-immersion lens, the capsules appeared as unstained, colorless halos surrounding the *L. helveticus* MB2-1 cells against a light violet-gray background, while the bacterial cells stained distinctly violet (Figure 1a). Further visualization by TEM of the stained cells revealed a clearly visible cell wall with fibrillose materials on the bacterial surface, confirming the formation of capsules by *L. helveticus* MB2-1 (Figures 1b and 1c).

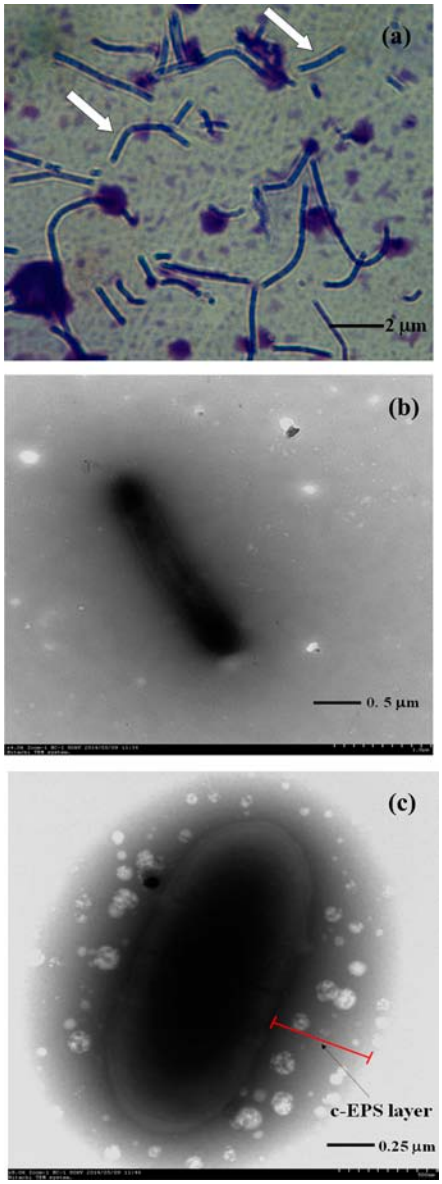

Figure 1. Micrographs showing the capsules of *L. helveticus* MB2-1 cells grown in whey medium. The capsules appear as unstained, colorless halos surrounding the bacterial cells when observed by optical microscopy (a) and as fibrillose materials attached to the bacterial surface when observed by TEM (b and c).

Isolation and Composition Analysis of c-EPS. The crude c-EPS of *L. helveticus* MB2-1 was obtained by ultrasonic extraction; the supernatant fraction was subsequently extracted with cold ethanol and fractionated first on a DEAE-cellulose 52 anion exchange chromatography column (Figure 2a) and then subjected to chromatography on a Sephadex G-100 gel filtration column (Figure 2b) for further purification. The corresponding chromatogram showed only one peak for c-EPS, indicating that the ultrasonically extracted c-EPS may be a

DOI: 10.1021/acs.jafc.5b01086
J. Agric. Food Chem. 2015, 63, 3454−3463

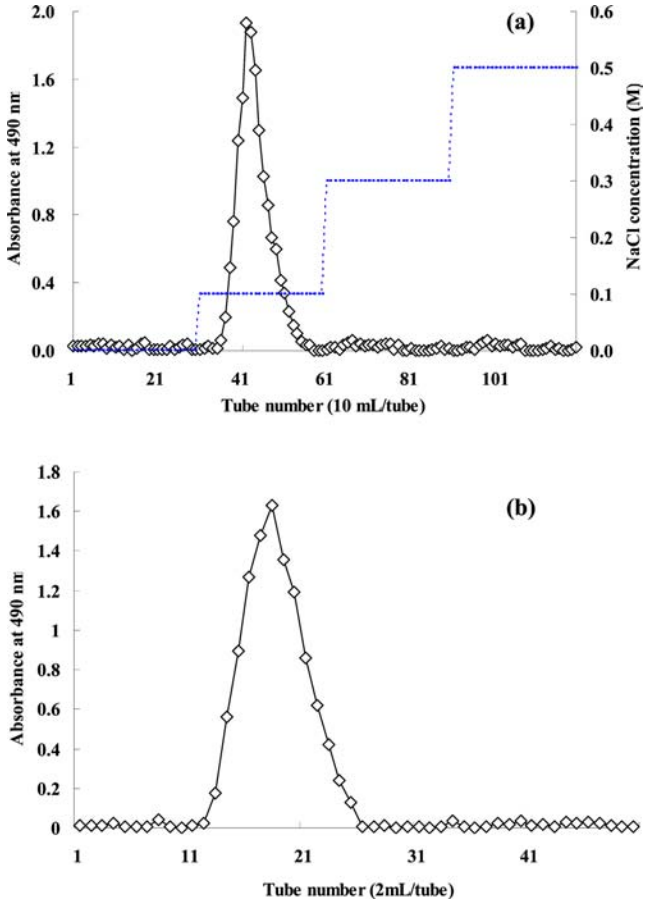

Figure 2. DEAE-cellulose 52 anion exchange chromatogram (a) and Sephadex G-100 gel filtration chromatogram (b) of crude c-EPS.

homogeneous polysaccharide. The recovery rate of c-EPS was 88.75%. Further HPSEC analysis of the purified c-EPS fraction showed a single sharp, symmetrical peak (Figure 3a), confirming that the purified c-EPS was homogeneous. According to the elution curve of the standards, the MW of the purified c-EPS was estimated to be 1.83×10^5 Da, which was less than those of the three r-EPS fractions isolated from *L. helveticus* MB2-1 (approximately 2.00×10^5 Da).[25] This MW was also lower than those of c-EPS from *L. pentosus* LPS26 (2.00×10^6 Da),[30] *L. plantarum* EP56 (8.50×10^5 Da),[31] and *L. rhamnosus* JAAS8 (5.50×10^5 Da).[13] The total carbohydrate content of the c-EPS was 95.45%. The uronic acid and sulfated group contents were 1.48% and 0.89%, respectively (Table 1). The lack of absorption by the purified c-EPS at 280 and 260 nm in the UV−vis spectrum demonstrated the absence of both proteins and nucleic acids in the polysaccharide (Figure 3b). Additionally, the c-EPS showed the same optical rotation, $[\alpha]_D^{20} = -56.8°$ (c 0.5, water), in different low concentrations of ethanol using an analytical AUTOPOL IV automatic polarimeter (RUDOLPH Research, Flanders, NJ) at room temperature.

Determination of the monomer composition was conducted after acid hydrolysis (Figure 3c). Quantitative monosaccharide analysis of the purified c-EPS revealed the presence of glucose, mannose, galactose, rhamnose, and arabinose at a molar ratio of 3.12:1.01:1.00:0.18:0.16 (Table 1). Glucose represented the greatest proportion compared to the other monosaccharides, corroborating previous reports for c-EPS or r-EPS from LAB of food origin, where glucose was often found in equal or greater

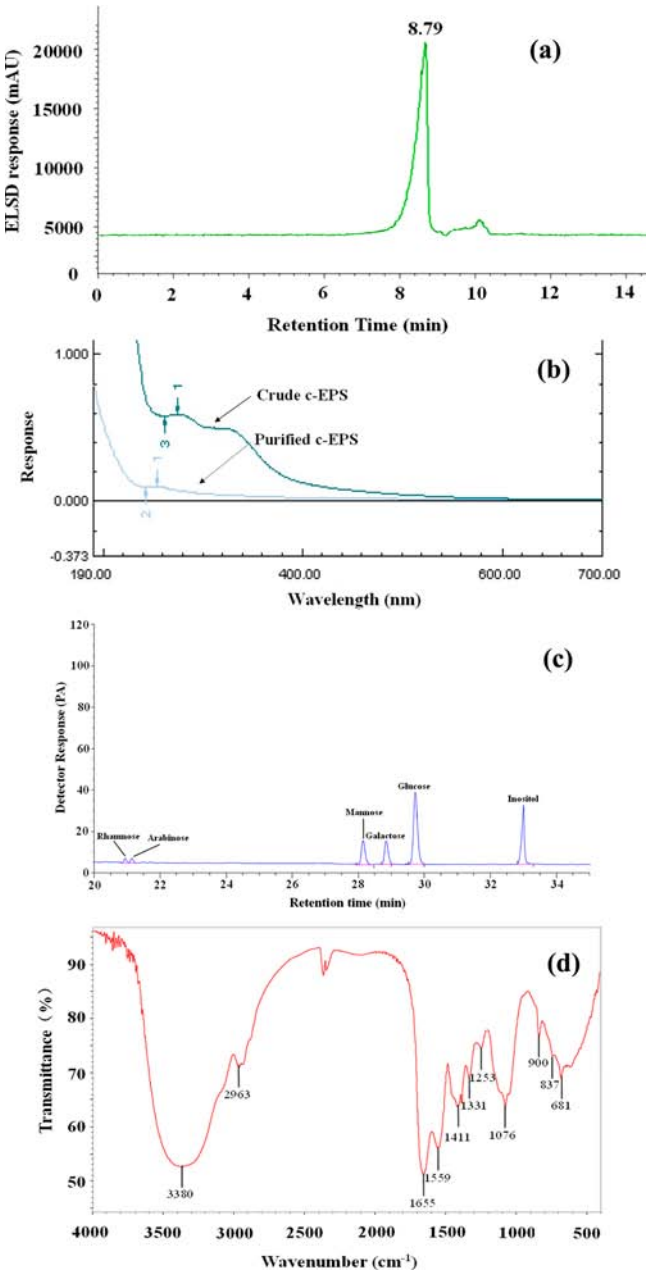

Figure 3. An HPSEC chromatogram of purified c-EPS (a), a UV−vis spectrum of purified c-EPS (b), a GC chromatogram of the monosaccharide composition (c), and a FT-IR spectrum (d) of purified c-EPS.

proportions than other monosaccharides.[14,15] The presence of different sugar moieties suggested that the polysaccharide was a HePS. A similar result was found by Rodríguez-Carvajala et al.,[30] who reported that glucose and rhamnose were the predominant components of c-EPS produced by *L. pentosus* LPS26. Tallon, Bressollier, and Urdaci[31] reported that the c-EPS from *L. plantarum* EP56 was composed mainly of glucose and galactose. Moreover, *N*-acetylglucosamine, *N*-acetylgalactosamine, and phosphoric acid have also commonly been reported as constituents of EPS produced by LAB.[13,14] However, this result was different from that obtained by Svensson, Zhang, Huttunen, and Widmalm,[32] who reported that the c-EPS from *Leuconostoc mesenteroides* ssp. *cremoris* PIA2 was a HoPS containing repeating units of linear galactose

J. Agric. Food Chem. 2015, 63, 3454−3463

Table 1. Monosaccharide Composition and the Carbohydrate, Protein, Uronic Acid, and Sulfate Group Contents of the Crude and Purified c-EPSs

					sugar component (molar ratio)[a]				
sample	carbohydrate (%)	protein (%)	uronic acid (%)	sulfate (%)	Gal	Glc	Man	Rha	Ara
crude c-EPS	84.09	6.49	3.46	1.79	1.00	3.36	1.22	0.12	0.15
purified c-EPS	96.23	–[b]	1.48	0.89	1.00	3.12	1.01	0.18	0.16

[a]Individual components were identified and quantified based on the elution of known standards, and the data are presented as the molar ratio for each sugar. [b]Not detected.

residues. Taken together, these results suggest that the monosaccharide constituents and molar ratios of c-EPS from LAB may be affected by the strain type.

Structural Analysis of Purified c-EPS. To investigate the functional groups of the purified c-EPS, an FT-IR spectrum was recorded over an absorbance range of 4000 to 500 cm^{-1}. As shown in Figure 3d, the spectrum of purified c-EPS displayed an intense, broad band at approximately 3380 cm^{-1}, which was assigned to the hydroxyl stretching vibration. The absorption band at 2963 cm^{-1} was due to the C−H stretching vibration.[33] The band at approximately 1655 cm^{-1} was due to bound water.[34] Peaks at 1559, 1411, and 1331 cm^{-1} were characteristic of carboxyl groups or carboxylates, indicating that c-EPS was an acidic polysaccharide. This result was consistent with its uronic acid content, which was quantified using the carbazole−sulfuric acid method using D-glucuronic acid as a standard.[23] The absorption peaks at 1253 and 1076 cm^{-1} were attributed to the stretching vibrations of the pyranose ring. Moreover, the band at 900 cm^{-1} indicated the β-pyranose form of the glucosyl residue, and the band at 837 cm^{-1} suggested the β-pyranose form of the mannose residue.[5] Finally, a characteristic absorption peak at 681 cm^{-1} indicated the existence of α-configurations in the purified c-EPS.[20]

The fully methylated c-EPS was hydrolyzed with TFA, converted into alditol acetates, and analyzed via GC−MS (Table 2). The analysis revealed the presence of five components. The c-EPS showed three major peaks of 2,4,6-Me_3Glc*p*, 2,3,4-Me_3Man*p*, and 2,3,6-Me_3Gal*p*, which originated from (1 → 3)-linked glucopyranose, (1 → 6)-linked mannopyranose, and (1 → 4)-linked galactopyranose residues, respectively. Trace amounts of 2,3,4,6-Me_4Rha*p* and 2,3,6-Me_3Ara*p* were also detected, indicating the presence of D-Rha*p*-(1 →)-linked rhamnopyranose and (1 → 4)-linked arabinopyranose residues, respectively. The molar ratio of the (1 → 3)-linked glucopyranose, (1 → 6)-linked mannopyranose, (1 → 4)-linked galactopyranose, (1 →)-linked rhamnopyranose and (1 → 4)-linked arabinopyranose residues was 3.29:1.21:1.00:0.12:0.09. No branched structures were found in c-EPS, suggesting that c-EPS may be a linear glucomannogalactan. The trace amounts of Rha*p*-(1 →) and (1 → 4)-Ara*p* linkages are also most likely randomly located within the c-EPS chains.

Table 2. Methylation Analysis of Purified c-EPS from *L. helveticus* MB2-1

retention time (min)	methylated sugar	primary mass fragments (*m*/*z*)	molar ratio	deduced linkage
14.024	2,3,6-Me_3Ara*p*	43.1, 45, 71, 87, 101.1, 117, 128.9, 161.1	0.09	(1→4)-D-Ara*p*
14.835	2,3,4,6-Me_4Rha*p*	43.1, 45, 72, 89, 101.1, 115, 131, 161.1	0.12	T-D-Rha*p*-(1→
15.457	2,4,6-Me_3Glc*p*	43.1, 71.1, 101.1, 128.9, 161.1, 205.1, 244.9, 280.9, 341	3.29	(1→3)-D-Glc*p*
15.813	2,3,4-Me_3Man*p*	43.1, 65, 85, 117, 139, 159.1,201.1, 231, 261.1, 281.9	1.21	(1→6)-D-Man*p*
18.052	2,3,6-Me_3Gal*p*	43.1, 71, 101.1, 125, 145.1, 173.1, 205.1, 245.2, 281.1	1.00	(1→4)-D-Gal*p*

The signals in the ^1H and ^{13}C NMR spectra of the purified c-EPS were assigned based on the component and methylation analyses and on values reported in the literature.[20,23,26,32] As shown in Figure 4a, three clear chemical shift signals from anomeric protons were found at δ 4.80, 4.50, and 4.37 ppm in the ^1H NMR spectrum. The signals at δ 3.40−4.20 represent the signal peak of the remaining proton, which is formed of multiple overlapping signal peaks. The signal at δ 4.71 was from the hydrogen of D_2O. This spectrum indicated that the purified c-EPS contained three residues (named **A**, **B**, and **C**). Based on their chemical shifts (δ) and the values of the coupling constant (J) for the anomeric signals in the ^1H NMR spectrum, residue **A** was determined to have an α-configuration (the $J_{1,2}$ values were 3−4 Hz), while residues **B** and **C** had β-configurations (the $J_{1,2}$ values were 7−8 Hz). The molar ratio of **A**, **B**, and **C** was approximately 1.03:1.00:3.15 when estimated using the ratio of the peak areas from the integration of the H-1 signals for residues **A**, **B**, and **C**. Based on the results of the aforementioned methylation analysis, the signal at δ 4.80 ppm corresponded to 2,3,6-Me_3Gal*p*, and the signals at 4.50 and 4.37 ppm corresponded to 2,3,4-Me_3Man*p* and 2,4,6-Me_3Glc*p*, respectively. The ^{13}C NMR spectrum (Figure 4b) showed that the C-1 signals of the three residues were detectable at δ 105.96, 105.83, and 102.28 ppm, respectively. The ^{13}C NMR chemical shifts in the anomeric carbon region also suggested three types of linkages for the galactose, glucose, and mannose residues.

Complete assignments for the ^1H and ^{13}C chemical shifts of c-EPS are shown in Supporting Information and were completed using 2D $^1H-^1H$ COSY, $^1H-^{13}C$ HSQC, $^1H-^{13}C$ HMBC, and NOESY experiments based on methylation analysis and data from the literature.[3,4,26,35] The single-bond correlations between the protons and the corresponding carbons obtained from the HSQC spectrum (Figure S1, Supporting Information) of c-EPS in D_2O enabled all of the ^{13}C NMR signals to be assigned. The signal at δ105.96 ppm (**C**) was attributed to the C-1 of →3)-β-D-Glc*p*-(1 → , δ105.83 ppm (**B**) to the C-1 of →6)-β-D-Man*p*-(1 → , and δ102.28 ppm (**A**) to the C-1 of →4)-α-D-Gal*p*-(1 →. These signals cross-correlate to the proton signals at δ4.37, 4.50, and 4.80, respectively. The results from the COSY spectrum (Figure S2, Supporting Information), based on stepwise magnetization transfers from the anomeric protons, aided in the assignment of the chemical shifts of other protons. The linkage of the residues was obtained from the HMBC spectrum (data not shown). The sequence of the glycosyl residues of c-EPS was also confirmed

DOI: 10.1021/acs.jafc.5b01086
J. Agric. Food Chem. 2015, 63, 3454−3463

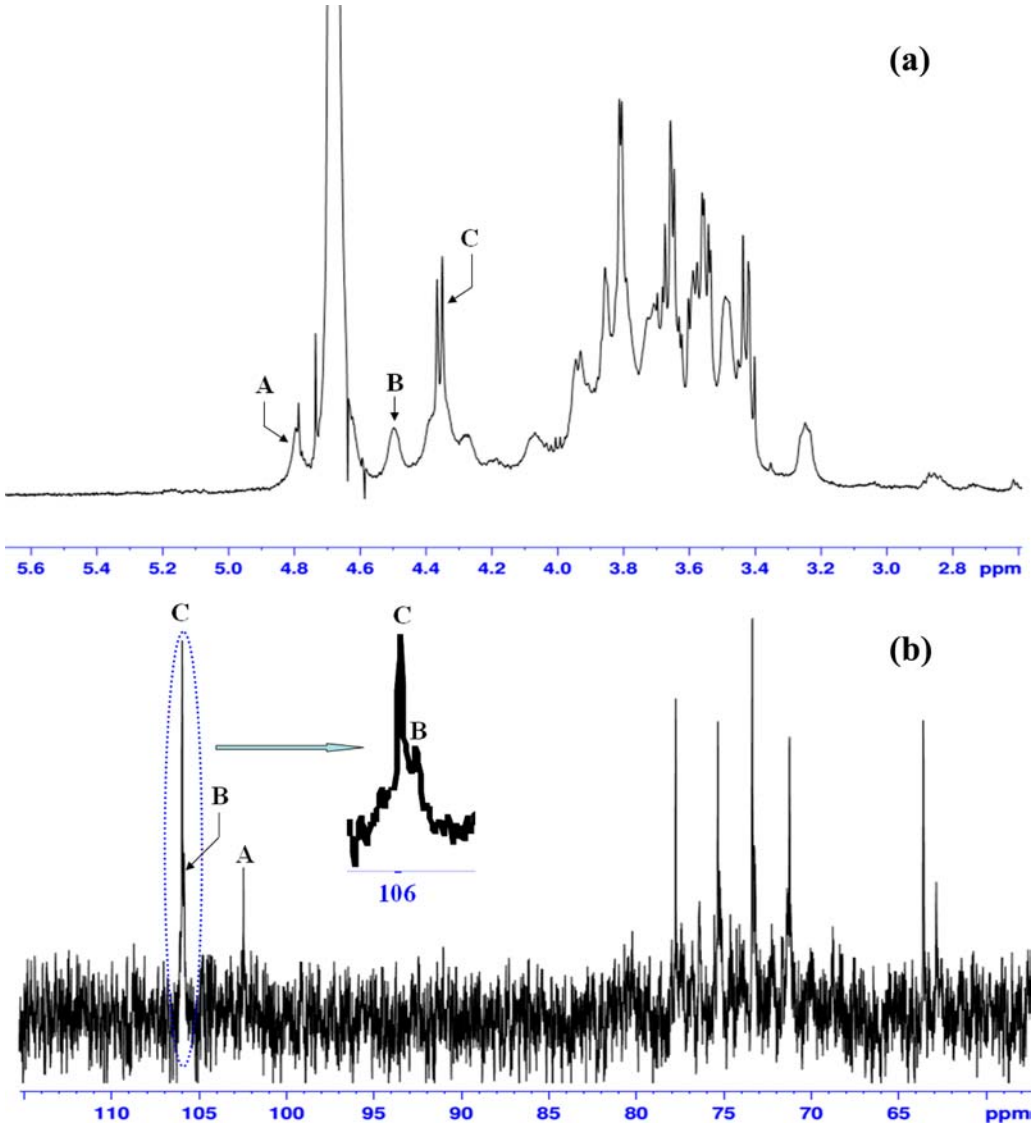

Figure 4. 500-MHz 1D ^{1}H (a) and ^{13}C (b) NMR spectra of purified c-EPS from *L. helveticus* MB2-1. Anomeric protons and carbon atoms are labeled with **A**, **B**, and **C** according to their decreased and increased chemical shifts, respectively.

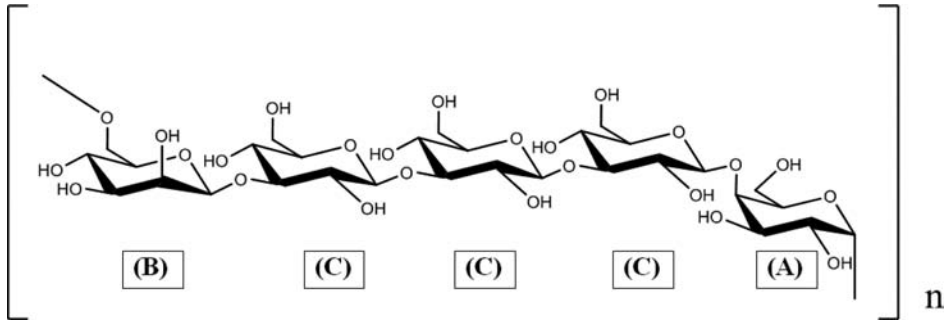

Figure 5. Proposed structure of purified c-EPS from *L. helveticus* MB2-1.

by the NOESY experiment. Inspection of the NOESY spectrum (Figure S3, Supporting Information) showed that the **A** H-1 to **B** H-6, **B** H-1 to **C** H-6, **C** H-1 to **C** H-3, and **C** H-1 to **A** H-4 were in agreement with the **A**-(1 → 6)-**B**, **B**-(1 → 3)-**C**, **C**-(1 → 3)-**C**, and **C**-(1 → 4)-**A** linkages, respectively. These results suggest that c-EPS is a linear glucomannogalactan containing repeating units of →6)-*β*-D-Man*p*-(1 → 3)-*β*-D-Glc*p*-(1 → 3)-*β*-D-Glc*p*-(1 → 3)-*β*-D-Glc*p*-(1 → 4)-*α*-D-Gal*p*-(1 →. In summary, the predicted repeating unit of c-EPS was determined (Figure 5), and the value of "*n*" for the number of repeating structural units in c-EPS was approximately 231.

Conformational and Morphological Characterization. Polysaccharides are considered to exist in an ordered three-dimensional structure, generally a triple-stranded helical

DOI: 10.1021/acs.jafc.5b01086
J. Agric. Food Chem. 2015, 63, 3454−3463

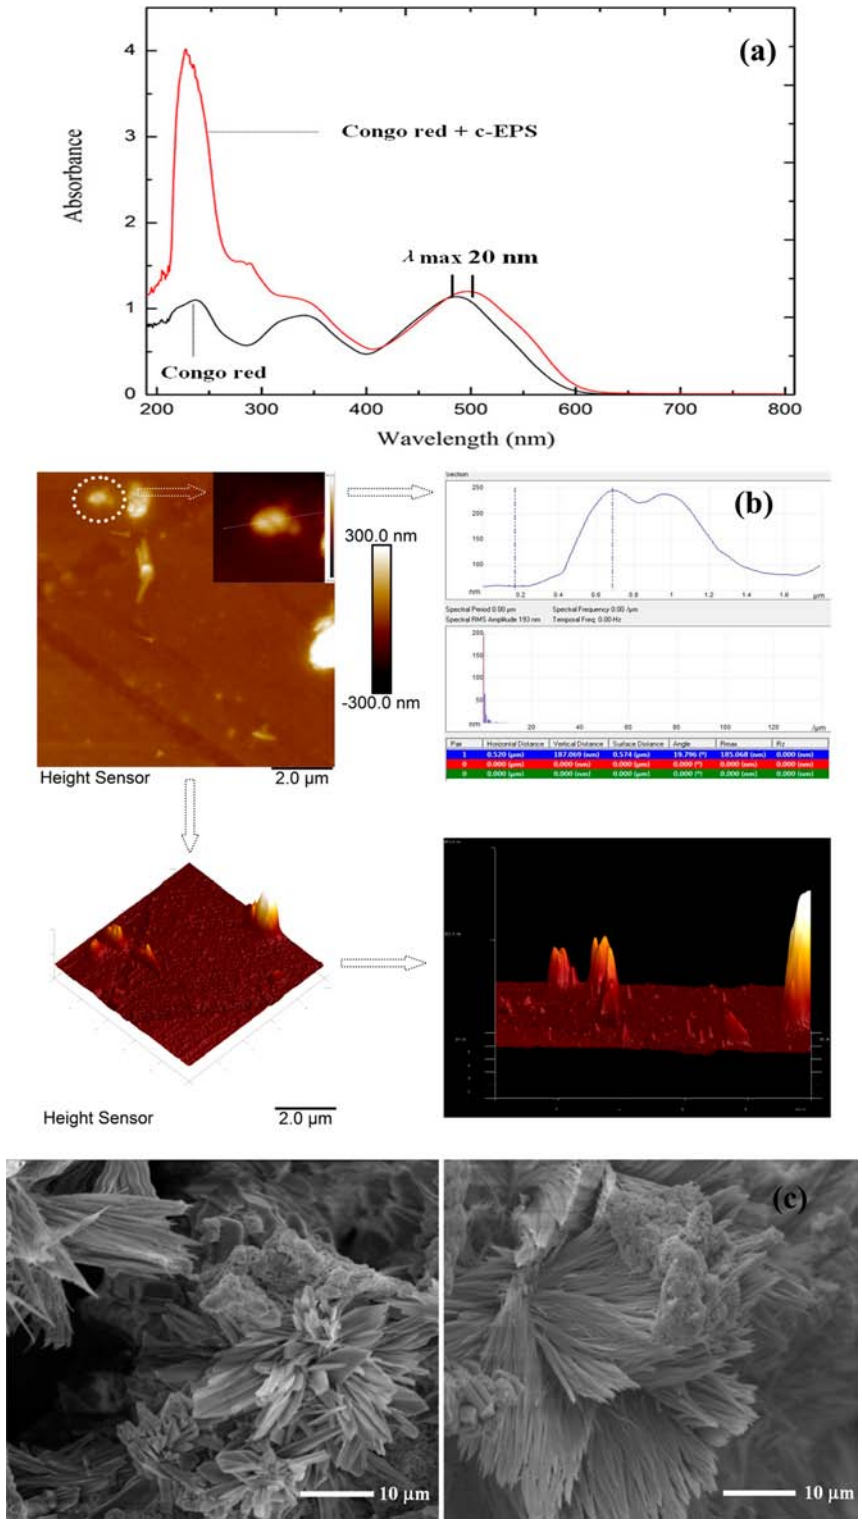

Figure 6. Absorption spectra of Congo red (control) and of Congo red with purified c-EPS (a), AFM (b), and SEM (c) images of purified c-EPS.

conformation, and they form a complex with Congo red in dilute NaOH solutions (less than 1 M). The complexation of polysaccharides with Congo red is denoted by a bathochromic shift in the visible absorption maxima (λ_{max}) of the Congo red spectrum. Hence, a polysaccharide displaying a triple-stranded helical conformation exhibits a shift in the UV absorption spectrum, whereas no shift should be observed for other conformations. Purified c-EPS from *L. helveticus* MB2-1 was complexed with Congo red at different NaOH concentrations. Laminarin and dextran were used as triple-stranded helical and random-coil controls (data not shown), respectively, and Congo red in NaOH was evaluated as the negative control. The absorption spectra of Congo red in NaOH and the c-EPS complexes with Congo red are shown in Figure 6a. The c-EPS solution exhibited a significant bathochromic shift of approximately 20 nm in the λ_{max} between 0.05 and 0.4 M

DOI: 10.1021/acs.jafc.5b01086
J. Agric. Food Chem. 2015, 63, 3454−3463

NaOH. These results suggested that purified c-EPS formed a complex with Congo red, which could be ascribed to its arrangement in a triple-stranded helical conformation.

Recently, EPS has been extensively studied by AFM, which is a powerful tool to observe the conformation of individual macromolecules and the molecular structure and dynamics of EPS.[36−38] Topographical AFM images of c-EPS are shown in Figure 6b. The c-EPS deposited from a 10 μg/mL aqueous solution exhibited rounded-to-spherical lumps with different sizes, and the formation of chains was also visible. However, the tight packing of the molecules suggested that they had a strong affinity for water molecules and had pseudoplastic behavior. Our findings for c-EPS showed rounded lumps with a maximum lump height of 250 nm. SEM is also a very powerful tool to study the three-dimensional and surface morphology of biomacromolecules, and it aids in understanding their common physical properties.[39] Micrographs of the microstructure and surface morphology of purified c-EPS are shown in Figure 6c. The c-EPS predominantly appeared as regular, feather-like structural units. This result differed from the work of Yadav, Prappulla, Jha, and Poonia,[40] who reported that EPS from *L. fermentum* CFR 2195 exhibited flake-like structural units and was highly compact. The different shape and structure, or surface topography, of the polysaccharides was most likely caused by differences in the physicochemical properties of the EPS and by differences in sample extraction, purification, or preparation.[41]

In Vitro Anticancer Activity of Purified c-EPS. The inhibitory effects of purified c-EPS from *L. helveticus* MB2-1 on three cancer cell lines and on human colonic epithelial HCoEpiC cells were measured using an MTT assay after the cells were treated with increasing concentrations (0, 50, 100, 200, 400, and 600 μg/mL) of c-EPS or with the positive control (5-FU, 50 μg/mL) for 24, 48, and 72 h. As shown in Figure 7a and 7b, the inhibitory effects of purified c-EPS on HepG-2 and BGC-823 cells significantly increased with increasing concentration and treatment time ($p < 0.05$). At the lowest concentration (50 μg/mL) and with an incubation period of 24 h, the inhibition rates of c-EPS against HepG-2 and BGC-823 cells were 9.03 ± 0.81% and 8.85 ± 0.78%, respectively. At the highest tested concentration (600 μg/mL), the inhibitory effects of c-EPS increased to 40.98 ± 0.62% and 38.75 ± 0.74% for HepG-2 and BGC-823, respectively. However, the inhibitory effects of c-EPS on HepG-2 and BGC-823 cells were all lower than that of the positive control (5-FU) at the same time points and concentrations. The inhibitory effect of c-EPS on HT-29 cells was also demonstrated to be dose- and time-dependent (Figure 7c). The inhibition rate against the HT-29 cells was significantly higher than against the other two cell lines at all c-EPS concentrations; for HT29 cells, the highest inhibition rates of c-EPS were comparable to those of 5-FU (80.05 ± 3.04%) after 72 h. Moreover, the strong inhibition of the HT-29 cells by c-EPS was evidenced by its IC_{50} value (250 μg/mL), which was much lower than those for the HepG-2 (1,520 μg/mL) and BGC-823 (2,878 μg/mL) cells. The anticancer activity of c-EPS against the HT-29 cells was also higher than that observed when the cells were treated with two r-EPSs that were isolated from the culture supernatant of *L. plantarum* 70810 at the same concentration and time.[20] These results indicated that c-EPS from *L. helveticus* MB2-1 has moderate anticancer activities against HepG-2 and BGC-823 cells and significant inhibitory effects on HT-29 cells. However, the level of c-EPS-mediated cytotoxicity in human colonic

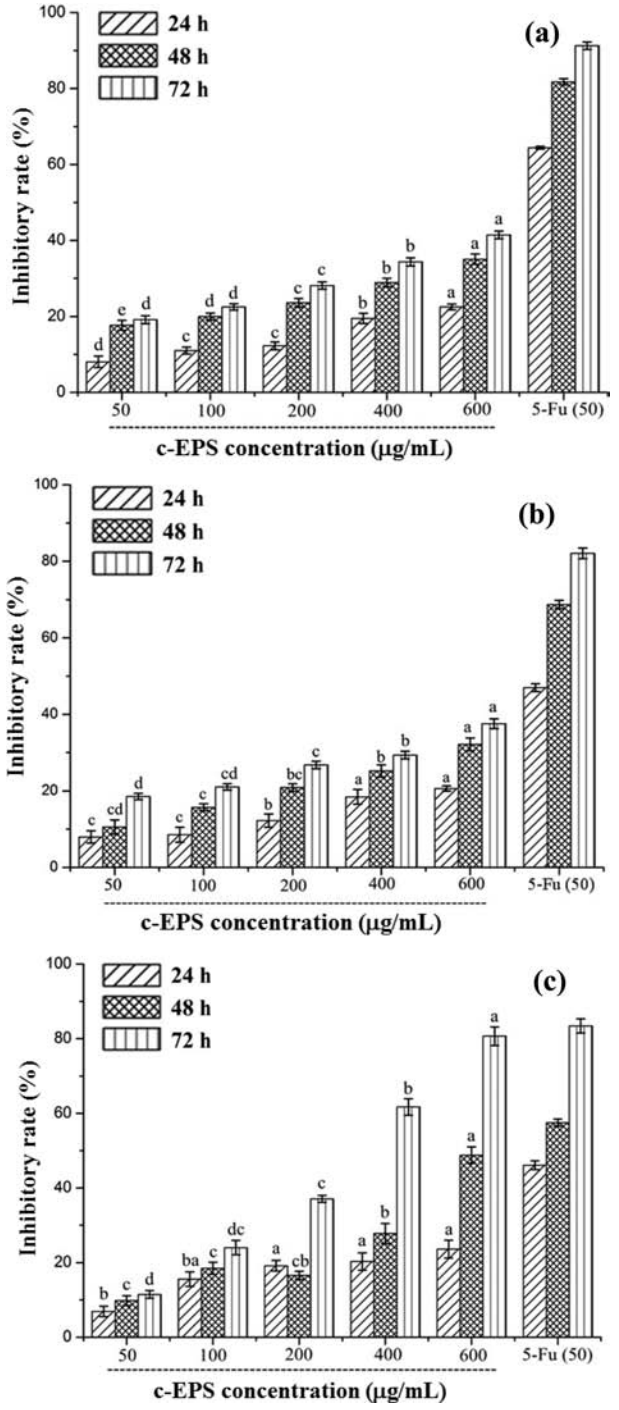

Figure 7. Anticancer effects of purified c-EPS on HepG-2 (a), BGC-823 (b), and HT-29 (c) cells. All values are expressed as the mean ± the standard deviation (SD) of three replicates. Different alphabets (a−d) in superscript donate significant difference ($p < 0.05$) and are determined by Turkey's HSD using SPSS (version 16.0).

epithelial HCoEpiC cells was not dramatic. Even at the highest dose (600 μg/mL), the level of cytotoxicity induced by a 72-h incubation of normal colonic cells with c-EPS was only 3.50 ± 0.89% (data not shown). Therefore, c-EPS possessed high anticolon cancer activity in vitro, but it was not cytotoxic to normal colon cells.

The anticancer activity of polysaccharides is related to their chemical composition, MW, chain conformation, and even charge characteristics.[16,25] Together with our previous study,

DOI: 10.1021/acs.jafc.5b01086
J. Agric. Food Chem. 2015, 63, 3454−3463

although the MW of c-EPS was similar to that of r-LHEPS-2 from *L. helveticus* MB2-1 and to those of r-EPS1 and r-EPS2 from *L. plantarum* 70810, the chemical composition and structure of c-EPS were significantly different from those of the other EPSs obtained. The c-EPS exhibited a triple-stranded helical conformation that is known to be beneficial for the anticancer activity of polysaccharides.[20,25,26] Other physicochemical properties of polysaccharides, such as the presence of uronic acid, sulfate groups, glucose, and β-type glycosidic linkages, are also conducive to increasing their anticancer activity.[14,42,43] NMR analysis revealed that r-LHEPS-2, r-EPS1, and r-EPS2 consisted predominantly of α-mannose residues and contained a minor portion of glucose and galactose residues in the β-configuration, whereas c-EPS contained mainly β-glucose residues with a minor portion of mannose and galactose residues in the α-configuration in its repeating units.[20,26] Such structural variability may profoundly affect the biological activities of EPS molecules. Therefore, certain structural properties of the purified c-EPS, such as a triple-stranded helical conformation, the presence of glucose as the major monosaccharide component, and β-type glycosidic linkages, may contribute to its multiple anticancer activities.

Currently, research on LAB c-EPS is garnering increased attention. Herein, purified c-EPS from *L. helveticus* MB2-1 was prepared and characterized. This novel c-EPS was a linear glucomannogalactan with an estimated MW of 1.83×10^5 Da. Further study revealed that the c-EPS contained repeating units of →6)-β-D-Man*p*-(1 → 3)-β-D-Glc*p*-(1 → 3)-β-D-Glc*p*-(1 → 3)-β-D-Glc*p*-(1 → 4)-α-D-Gal*p*-(1→ and trace amounts of (1 →)-Rha*p* and (1 → 4)-Ara*p* residues. Additionally, the c-EPS displayed a triple-stranded helical conformation. Morphological characterization by AFM and SEM showed that the c-EPS formed aggregates of regular feather-like units, where rounded lumps with a maximum height of 250 nm were observed. This morphology indicated good structural stability that may be utilized for film production and for the generation of edible nanostructures for the encapsulation of drug and food additives. In vitro anticancer analysis demonstrated that the c-EPS had significant anticancer activity against HepG-2, BGC-823, and especially HT-29 cancer cells. Therefore, these results suggest that the c-EPS produced by *L. helveticus* MB2-1 may be suitable for use in foods and in natural anticancer drugs.

Corporation, Jiangmen, China. The material was identified by Professor R. M. Yu, College of Pharmacy, Jinan University, Guangzhou, Guangdong, China.

Experimental Reagents and Materials. Sephadex G-25 and DEAE cellulose-52 were obtained from Whatman, Ltd. Sephacryl S-300 HR was obtained from Amersham Biosciences. XAD-7 macroporous adsorption resin, dimethyl sulfoxide (DMSO), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), penicillin G, and streptomycin were obtained from Sigma Chemical Co. (St. Louis, MO). Ascorbic acid (vitamin C, Vc), chlorosulfonic acid (CSA), pyridine (Pyr), hydrogen peroxide (H_2O_2), potassium ferricyanide [$K_3Fe(CN)_6$], and ferrous sulfate ($FeSO_4$) were obtained from Guangzhou Chemical Reagent Company, China. Human lung adenocarcinoma cell line A549 was obtained from Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences. RPMI-1640 medium and fetal bovine serum (FBS) were purchased from Hyclone (Logan, UT). All reagents were of analytical grade.

Extraction, Isolation, and Purification of Compound 1. The dried powder of cultured *C. militaris* (500 g) was extracted in 0.5 L of distilled water using a domestic blender for 5 min. The mixture was added to a solution of simulated gastric juice (9.5 L, pH 1.5), which was used to mimic the conditions of the stomach according to the method by Golovchenko et al.,[11] with some modifications. Simulated gastric juice contained HCl (1.34 g/L), NaCl (2.16 g/L), KH_2PO_4 (0.63 g/L), $CaCl_2$ (0.12 g/L), KCl (0.39 g/L), and pepsin (0.53 g/L). Extraction was conducted for 4 h at 37 °C. After the filtered extract was centrifuged at 5000*g* for 15 min, the supernatant was concentrated with a rotary evaporator at 60 °C under vacuum. The mixture was obtained by ethanol precipitation at the final concentration of 80% (v/v) of ethanol at 4 °C overnight and then centrifuged at 5000*g* for 15 min to precipitate proteins and high-molecular-weight polysaccharides.[12] The supernatant (CMPA) was collected and lyophilized.

CMPA was fractionated on XAD-7 macroporous adsorption resin column (2.6 × 95 cm) and eluted with distilled water at a flow rate of 2 mL/min.[13] The elute (20 mL) was collected and then determined by the phenol−sulfuric acid method. Fractions 10−30 corresponding to the major peak were combined, concentrated, dialyzed (molecular weight cut-off of 500 Da), and lyophilized to obtain CMPA90.

CMPA90 was dissolved in distilled water, filtered through a filter (0.45 μm), purified on a DEAE cellulose-52 anion-exchange column (2.6 × 40 cm), and eluted with distilled water and a linear gradient from 0 to 1.0 M NaCl at a flow rate of 0.5 mL/min. The eluate (5 mL/tube) was collected automatically, and carbohydrates were assayed by the phenol−sulfuric acid method. A sharp peak was collected, dialyzed, and further purified by a Sephadex G-25 column (1.6 × 70 cm), eluting with distilled water. The flow rate was maintained at 0.3 mL/min. Consequently, a polysaccharide was obtained and coded CMPA90-1 (**1**), with $[\alpha]_D^{20} = -95.5°$ (*c* 1.0, H_2O).

Analytical Methods. The content of total sugar and uronic acid was determined by the phenol−sulfuric acid colorimetric method and the carbazole−sulfuric acid method, respectively.[14,15] Optical rotation was assayed by a Jasco P-1020 polarimeter. The sulfur content was determined by Wang's method.[9] The calibration curve was prepared with sodium sulfate as the standard. The degree of substitution (DS) was calculated on the basis of the following equation:

$$DS = \frac{1.62S\%}{32 - 1.02S\%}$$

Determination of Homogeneity and Molecular Weight. Gel permeation chromatography (GPC) was used to determine the homogeneity and molecular weights of samples. Standard dextrans (blue dextran, T-200, T-70, T-40, T-10, T-7, and T-4) and glucose were passed through a Sephacryl S-300 HR column (1.6 × 70 cm), and elution volumes were plotted against the logarithms of their respective molecular weights. Elution volumes of samples were then plotted in the same graph, and molecular weights of the polysaccharides were measured.[16]

Monosaccharide Composition Analysis. Compound **1** (5 mg) was dissolved in 2 mL of 2 M trifluoroacetic acid (TFA) in a sealed tube and hydrolyzed at 110 °C for 6 h. The excess acid was evaporated with a rotary evaporator after the hydrolysis was completed. The monosaccharide contents were measured by high-performance anion-exchange chromatography coupled with pulsed amperometric detection (HPAEC−PAD). The hydrolysate (1 mg/mL) was used for the ionic chromatography analysis by HPAEC−PAD on the Dionex ICS-2500 system, followed by the elution with a mixture of water and NaOH (200 mM) in the volume ratio of 92:8.[17]

Partial Hydrolysis. Compound **1** (30 mg) was partially hydrolyzed with 0.05 M TFA at 100 °C for 6 h. The hydrolysate was dialyzed in a dialysis bag (molecular weight cut-off of 500 Da) against distilled water for 48 h. The fraction out of the dialysis bag was collected. The excess TFA in the fraction was removed by co-distillation with MeOH, and the fraction was evaporated with a rotary evaporator, named fraction 1. The fraction in the dialysis bag was evaporated to dryness and then hydrolyzed with 0.5 M TFA. The hydrolysate was dialyzed, and the fraction out of the dialysis bag (namely, fraction 2) and the fraction in the dialysis bag (namely, fraction 3) were concentrated. Fractions 1, 2, and 3 were hydrolyzed with 2 M TFA and determined with HAPEC−PAD.[16]

Periodate Oxidation−Smith Degradation. Compound **1** (15 mg) was dissolved in 5 mL of distilled water, and 25 mL of $NaIO_4$ (15 mM) was added. The solution was kept in the dark at 4 °C. Aliquots (0.1 mL) were taken out at 6 h intervals, diluted to 5 mL with distilled water, and measured in a spectrophotometer at 223 nm, until the value became stable. The consumption of HIO_4 was analyzed by a spectrophotometric method, and the production of formic acid was determined by titration with NaOH (0.060 M). The residue was collected and reduced with $NaBH_4$ (30 mg) overnight.[16] After neutralization and dialysis, the retentate was lyophilized and hydrolyzed with TFA (2 M) at 100 °C for 6 h. The products were acetylated and then determined by gas chromatography (GC).[18]

Methylation Analysis. To analyze the glycosyl linkages, compound **1** (20 mg) was methylated 6 times according to the method described in the literature.[19] Disappearance of the OH band (3200−3700 cm^{-1}) in the infrared (IR) spectrum indicated the implementation of complete methylation. The methylated products were hydrolyzed, reduced, and acetylated to produce alditol acetates, which were analyzed by gas chromatography−mass spectrometry (GC−MS).[20] Peaks of methylated products were identified by their mass spectra. The relative molar ratios of products were estimated from the peak areas and corresponding response factors in GC.

Nuclear Magnetic Resonance (NMR) Spectroscopy. Compound **1** (60 mg) was dried in a vacuum over P_2O_5 for 6 h and then deuterium-exchanged by lyophilization with D_2O 3 times to completely replace H with D. After that, the sample was dissolved in D_2O at room temperature for 3 h before NMR analysis. One-dimensional (1D) and two-dimensional (2D) NMR spectra were obtained on an AMX 500 MHz FT NMR spectrometer (Bruker, Germany).

Sulfated Modification of Compound 1. CSA (6 mL) was added dropwise into anhydrous pyridine (12 mL) filled in a three-necked flask, under continuous stirring and cooling in an ice water bath.[9] All chemical reactions were completed in 40 min, and the sulfating reagent was obtained. Compound **1** (500 mg) was suspended in 20 mL of anhydrous formamide at room temperature, and then the mixture was stirred for 30 min. After the sulfating reagent was added, the mixture was kept stirred for 2 h at 70 °C. The product was neutralized with 2.0 M NaOH solution at room temperature, then concentrated, and precipitated with 95% ethanol (3 times volume). The sediment was then redissolved in water and intensively dialyzed against tap water (24 h) and then distilled water (48 h) to remove pyridine, salt, and potential degradation products.[6] Consequently, a sulfated polysaccharide, namely, CMPA90-M1 (**2**) was collected after lyophilization and saved in a dryness box.

FTIR Analysis. The IR spectra of compounds **1** and **2** were determined using a FTIR spectrometer (PerkinElmer, Waltham, MA). The dried powder of each sample was ground with KBr powder and then pressed into 1 mm pellets for FTIR measurement in a frequency range of 4000−500 cm^{-1}.

Ultrastructures of Compounds 1 and 2. SEM images of compounds **1** and **2** were obtained by environmental scanning electron

DOI: 10.1021/jf505915t
J. Agric. Food Chem. 2015, 63, 3464−3471

microscopy (ESEM, Philips XL-30, Netherlands). The dried powder of each sample was directly placed on separate specimen holders by double-sided adhesive tape and then sputtered with gold powder using a sputter coater.[21] Finally, the samples were observed with 2000- and 10 000-fold magnification at 5.0 kV under a high vacuum condition.

The ultrastructures of compounds **1** and **2** were also observed using AFM (BioScope Catylyst NanoScope V, Bruker, Billerica, MA). Each sample was dissolved in doubly distilled water (1 μg/mL) and stirred by a magnetic stirrer apparatus for 4 h. After that, the solution (5 μL) was dropped onto a freshly cleaved mica substrate and allowed to air-dry at room temperature. The AFM was determined in the contact mode.[22] A tube-type piezoelectric scanner (4 × 4 μm) and a Si_3N_4 probe (Olympus, Japan) were employed, and images were obtained simultaneously with 256 × 256 pixels at a scanning rate of 1.0 Hz per line.

Measurement of DPPH Radical-Scavenging Activity. The free-radical-scavenging capacity was measured using the DPPH test according to the method of Braca et al.[23] Briefly, each compound **1** and **2** solution (10 μL) at varying concentrations (0, 25, 50, 100, 200, 400, 800, and 1600 μg/mL) was added to DPPH ethanol solution (190 μL, 0.2 mM). For the positive control, the sample was substituted by Vc. The solution was kept at room temperature for 30 min, and the absorbance was measured at 517 nm. The percentage of DPPH radical-scavenging capability was calculated according to the following equation:

$$\text{scavenging ability } (\%) = [(A_0 - A_1)/A_0] \times 100\%$$

where A_0 was the absorbance in the absence of the sample and A_1 was the absorbance in the presence of the sample.

Measurement of Hydroxyl Radical-Scavenging Activity. The hydroxyl radical-scavenging activity was examined using the method described previously.[17] Vc was used as the positive control. All values were determined in the replicates. The percentage of hydroxyl radical-scavenging activity was calculated from the following equation:

$$\text{scavenging ability } (\%) = [(A_2 - A_1)/(A_0 - A_1)] \times 100\%$$

where A_0 was the absorbance of the blank control (without H_2O_2), A_1 was the absorbance in the absence of the sample, and A_2 was the absorbance in the presence of the sample.

Measurement of Reducing Power. The reducing power was tested referring to the ferric-reducing antioxidant power (FRAP) assay.[24] Samples (0−1600 μg/mL, 2.5 mL) were mixed with 2.5 mL of 0.2 M phosphate buffer (pH 6.6) and 5 mL of 1% (w/v) potassium ferricyanide $[K_3Fe(CN)_6]$. After incubation at 50 °C for 20 min, the reaction mixture was mixed with 2.5 mL of 10% (w/v) trichloroacetic acid. The mixture was then centrifuged at 5000*g* for 10 min. A total of 2.5 mL of the supernatant was mixed with the same volume of distilled water and 0.5 mL of 0.1% (w/v) ferric chloride. The absorbance of the resulting solution was measured at 700 nm after 10 min. Vc was used as the positive control.

Measurement of Ferrous-Ion-Chelating Activity. The ferrous-ion-chelating activity was estimated using the formation of the ferrous iron−ferrozine complex.[25] Samples at different concentrations (0−1600 μg/mL) were mixed with deionized water (3.7 mL), and then reacted with 0.1 mL of 2.0 mM $FeSO_4$ and 0.2 mL of 5.0 mM ferrozine. After the reaction for 10 min, the absorption was measured at 562 nm. For the positive control, the sample was substituted with ethylenediaminetetraacetic acid (EDTA). The chelating activity on ferrous ions was calculated as the following equation:

$$\text{chelating ability } (\%) = [(A_0 - A_1)/A_0] \times 100\%$$

where A_0 was the absorbance of the control (deionized water, instead of the sample) and A_1 was the absorbance of the sample mixed with reaction solution.

Cell Culture and Cytotoxicity Assay. A549 cells were cultured in RPMI-1640 medium containing 10% FBS, 100 units/mL penicillin G, and 100 μg/mL streptomycin in a cell incubator with 5% CO_2 at 37 °C. Experiments were performed when cell growth was approximately 80% confluent. Three independent experiments were performed. The cytotoxicity of compound **1** against the A549 cell line was determined using the MTT assay.[26] Briefly, A549 cells in logarithmic phase were seeded in 96-well culture dishes at a density of 3000 cells/well. After 24 h, the cells were treated with compounds **1** and **2** (final concentrations of 5.6, 16.7, 50, 150, and 450 μg/mL). Cisplatin was used as the positive control. After treatment of 48 h, 20 μL of MTT (5 mg/mL) was added to each well and the cells were incubated for another 4 h at 37 °C. After the media were removed, 200 μL of DMSO was added to each well to dissolve the cellular crystalline deposits and the absorbance was determined spectrophotometrically at 570 nm. The inhibition rate (I%) was calculated according to the formula below.

$$\text{inhibition rate } (I\%) = \frac{A_{570\text{ nm,control}} - A_{570\text{ nm,sample}}}{A_{570\text{ nm,control}} - A_{570\text{ nm,blank}}} \times 100\%$$

Statistical Analysis. Data were analyzed using statistical analysis software SPSS 11.5 and expressed as the mean value ± standard deviation (SD) for three independent experiments. Statistical significance was defined as $p < 0.05$ by analysis of variance (ANOVA), followed by Dunnett's tests.

RESULTS AND DISCUSSION

Isolation, Purification, and Chemical Composition of Compound 1. Crude polysaccharide (20.18 g) was obtained from the cultured fruiting bodies of *C. militaris*. The subsequent purification led to a single and symmetrical sharp peak of compound **1** by analysis of gel-filtration chromatography on a Sephacryl S-300 HR column with the phenol−sulfuric acid assay. The resulting compound **1** also showed the same optical rotation in varying low-content aqueous ethanol. The uronic acid content of compound **1** was below the detection limit. The average molecular weight of compound **1** was determined as 9.3 kDa by the GPC method on a Sephacryl S-300 HR column. The total sugar content of compound **1** was 98.4% (w/w), and the result of the *m*-hydroxybiphenyl colorimetric test was negative.

Structural Characterization of Compound 1. Compound **1** was acidically hydrolyzed, and three monosaccharides, arabinose, mannose, and galactose, were identified in the hydrolysate of compound **1** by HAPEC−PAD analysis, with relative ratios of 1.00:2.89:2.03, respectively. The partial acid hydrolysis of compound **1** afforded three fractions (1, 2, and 3), which were subsequently analyzed by HAPEC−PAD (Table 1).

Table 1. Results of HAPEC−PAD Analysis for the Degradation Products of Compound 1

	molar ratios		
	arabinose	mannose	galactose
CMPA90-1	1.00	2.89	2.03
fraction 1	nd[a]	1.00	nd
fraction 2	2.33	1.00	nd
fraction 3	nd	nd	1.00
Smith degradation	1.00	nd	3.15

[a]nd = not detected.

The component of fraction 3 (the precipitate in the sack) indicated that galactose might be the structural backbone of compound **1**. The results of fractions 1 and 2 suggested that compound **1** had the branched structure consisting of arabinose and mannose, with mannose as the terminal unit.

The results of periodate oxidized−Smith degradations were analyzed by GC and shown in Table 1. No mannose was found in the resulting oxidation products; thus, the linkage manner of mannose could be (1 →), (1 → 2), (1 → 6), (1 → 2,6),

DOI: 10.1021/jf505915t
J. Agric. Food Chem. 2015, 63, 3464−3471

(1 → 4), and (1 → 4,6), which might lead to oxidization of mannose into glycerol and erythritol. The presence of arabinose and galactose revealed that at least partial residues of arabinose and galactose were linked by the manners of (1 → 3), (1 → 2,3), (1 → 2,4), (1 → 3,4), or (1 → 2,3,4), which are stable under the condition of the oxidation.[27] The results of methylation analysis (Table 2) showed the presence of five

Table 2. GC−MS Results of Methylated Products of Compound 1

methylation product	retention time (min)	molar ratio	mass fragments (m/z)	linkage type
2,5-Me_2-Ara	15.22	1.00	87, 101, 117, 129, 189	1 → 3

2,3,4,6-Me_4-Man	17.06	3.22	71, 87, 101, 117, 129, 161, 205	T →
3,4,6-Me_3-Man	17.84	0.89	71, 87, 101, 129, 161, 189	1 → 2
2,4-Me_2-Gal	18.94	6.19	43, 87, 117, 129, 189	1 → 3,6

components, namely, 2,5-Me_2-Ara, 2,3-Me_2-Ara, 2,3,4,6-Me_4-Man, 3,4,6-Me_3-Man, and 2,4-Me_2-Gal, with a molar ratio of 1.00:1.08:3.22:0.89:6.19, respectively. On the basis of the standard data in the Complex Carbohydrate Research Center (CCRC) spectral database for partially methylated alditol acetates (PMAAs), the linkage manners of arabinose were deduced as (1 → 3) and (1 → 5), while those of mannose were (1 →) and (1 → 2) and the those of galactose were (1 → 3,6). This finding was consistent with the linkage of terminal and branched residues. Moreover, the molar ratios also showed a good correlation with the monosaccharide composition analysis of compound **1** described above.

As shown in Figure 1, the characteristic absorption peaks of the polysaccharide are shown in the IR spectrum of compound

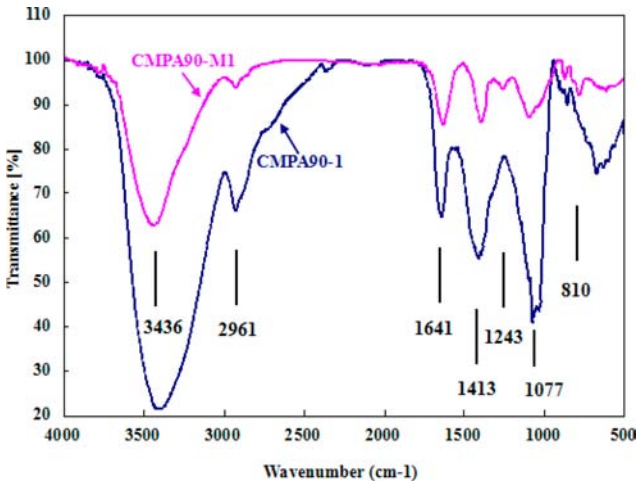

Figure 1. FTIR spectra of compounds **1** and **2**.

1 at 3436, 2961, 1641, 1413, and 1077 cm^{-1}. The absence of the absorbance band near 1243 and 810 cm^{-1} indicated the lack of sulfate ester in compound **1**. The absorption peaks at 866 and 896 cm^{-1} confirmed the co-existence of α- and β-glycosidic bonds. No band around 1740 cm^{-1} was observed, confirming that compound **1** did not contain uronic acid.[17,28]

NMR Spectroscopy Analysis. The planar structure of compound **1** was established by analysis of its 1D and 2D NMR spectra, together with comparison to the reported NMR data.[29−32] Five pairs of ^1H and ^{13}C signals of anomeric CH attributed to five different types of glycosidic bonds were assigned at δ 5.04/105.89, 5.12/104.15, 5.07/100.60, 5.10/99.33, and 4.98/98.08 ppm based on their chemical shifts and the corresponding heteronuclear single-quantum coherence (HSQC) correlations (Figure 2A). These five types of glycosidic bonds indicated the existence of five structural residues in compound **1**, i.e., residues A−E. According to ^1H and ^{13}C NMR spectra of standard arabinose (data not shown)[30] as well as the HSQC correlations, residue A was determined as an arabinose residue and the remaining signals of residue A were assigned as δ 81.53/δ 4.01(CH-2), 78.35/4.05 (CH-3), 86.86/4.12 (CH-4), and 68.40/3.85 (CH_2-5). Similarly, the NMR signals of the other residues were assigned (Table 3).

Five residues were connected together by the analysis of the heteronuclear multiple-bond correlation (HMBC) spectrum (Figure 2B) of compound **1**. In the HMBC spectrum, the following correlations were observed: E H-6 (δ 3.75) and B C-1 (δ 104.15), D H-2 (δ 4.10) and C C-1 (δ 100.60), B H-3 (δ 3.74) and C C-1 (δ 100.60), A H-1 (δ 5.04) and A C-4 (δ 86.86), A H-1 (δ 5.04) and A C-2 (δ 81.53), C H-1 (δ 5.07) and B C-3 (δ 81.11), C H-1 (δ 5.07) and D C-2 (δ 75.50), E H-1 (δ 4.98) and E C-2 (δ 70.62), B H-1 (δ 5.12) and E C-6 (δ 67.20), and A H-1 (δ 5.04) and E C-6 (δ 67.20). The cross-peaks at δ 3.75/104.15 and 5.12/67.20 were observed in HMBC. Because the signal at δ 3.75 corresponded to H-6 in residue E, the signal at δ 104.15 corresponded to C-1 in residue B, the signal at δ 5.12 corresponded to H-1 in residue B, and the signal at δ 67.20 corresponded to C-6 in residue E, it could be concluded that the residues E and B were connected to each other as E-(6 → 1)-B. Moreover, the cross-peaks at δ 5.07/75.50 and 4.10/100.60 were assigned to the inter-residue C H-1, D C-2 and the inter-residue D H-2, C C-1, respectively, indicating that the residues C and D were connected to each other as C-(1 → 2)-D. Similarly, the following sequences were established: E-(6 → 1)-A and C-(1 → 3)-B. Therefore, the structure of compound **1** was established, with a backbone composed of (1 → 3)-linked α-D-galactose and three branches, all of which substitute at O-6 of α-D-galactose, consisting of (1 → 2)-linked α-L-mannose, (1 → 5)-linked α-L-arabinose, and (1 → 3)-linked β-L-arabinose, with α-L-mannose as the terminal unit (Figure 3).

Structure Analysis of Compound 2. Compound **2** was prepared from compound **1** by the CSA−Pyr method.[6] The GPC analysis of compound **2** showed a single and symmetric sharp peak, and the average molecular weight of compound **2** was determined as 8.9 kDa. The specific rotation of compound **2** was determined as $[\alpha]_D^{20} = -35.7°$ (c 1.0, H_2O). The sulfur content was 3.9% (w/w), and the DS value was 0.23 in compound **2**. In comparison to compound **1**, two characteristic absorption bands attributed to sulfate groups occurred in the FTIR spectrum of compound **2**, one at 1243 cm^{-1}, corresponding to an asymmetrical S═O stretching vibration, and the other at 810 cm^{-1}, corresponding to a symmetrical C−O−S vibration associated with a C−O−SO_3 group, which indicated that the sulfate groups were successfully introduced into compound **2**.[33]

Ultrastructures of Compounds 1 and 2. Chemical modification could change the spatial structure of polysaccharides and, thus, affect the structure−activity relationship.[34] SEM of compounds **1** and **2** at magnifications of 2000 and 10 000 showed that compound **1** had a rough surface with a sheet-like

appearance composed of many small lumpish particles and irregular pores, while compound **2** appeared to be a smooth surface with pore openings, which consisted mainly of randomly distributed individual spherical particles, with diameters of approximately 2 μm (panels A and B of Figure 4). The different surface topography of the polysaccharides was probably due to

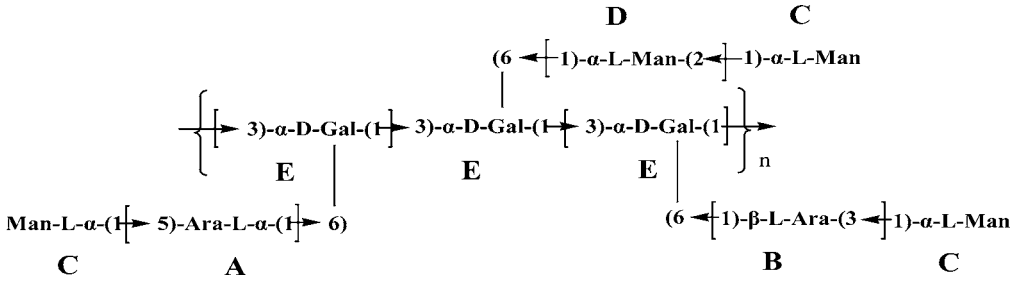

Figure 3. Predicted structure of compound **1**.

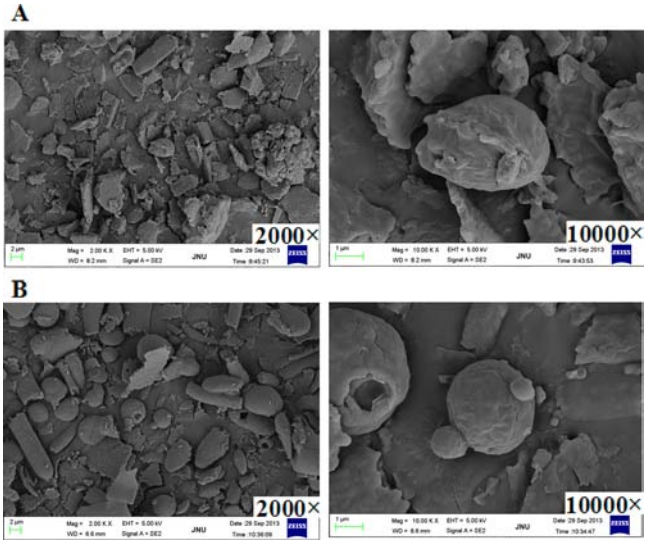

Figure 4. SEM images of compounds (A) **1** and (B) **2**.

the sulfated modification and changes of physicochemical properties; therefore, SEM could be set as a characteristic to qualitatively identify sulfated polysaccharides.

AFM has been applied as a valuable metrological tool to characterize surface topology on the nanometer scale of particles, macromolecules absorbed to surfaces, biopolymers, and the linear and circular triple helix structures of polysaccharides.[34]

Herein, AFM images showed that compound **1** aggregated to form homogeneous, smooth, and elastic dome-shaped particles (diameter ranged from 150 to 300 nm, and height was approximately 15 nm), while compound **2** particles aggregated to form a coral-like structure, with dimensions ranging from 500 to 1000 nm in length, from 100 to 300 nm in width, and from 2 to 3 nm in height (panels A and B of Figure 5). The size of polysaccharide chains of both compounds **1** and **2** was over 1.0 nm, which was larger than the usual size (approximately 0.1−1.0 nm).[34] Aggregation of polysaccharides occurs from their side branches entangling each other, and the substitution of the hydroxyl group of polysaccharides by the sulfate group can cause twisting and converting of the sugar ring conformation, which leads to a decrease of the size of the resulting sulfated polysaccharides.

Scavenging Activity of Compounds 1 and 2 against DPPH Radicals. As a stable free-radical compound with maximum absorbance at 517 nm, DPPH has been widely used to determine the free-radical-scavenging capacity of various antioxidative samples.[35] As shown in Figure 6A, compounds **1** and **2** and Vc scavenged DPPH radicals to different degrees in the given concentration range. IC_{50} values of compound **2** and Vc were 285.33 and 104.17 μg/mL, respectively.

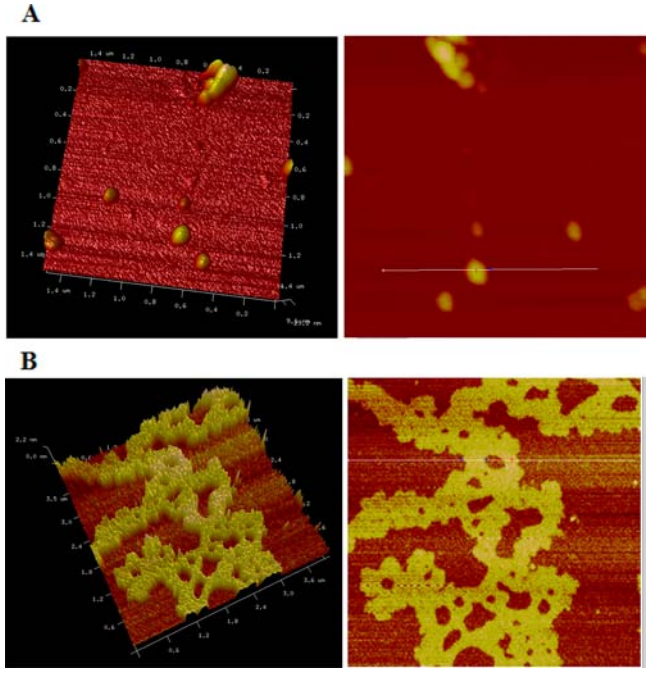

Figure 5. AFM images of compounds (A) **1** and (B) **2**.

Scavenging Activity of Compounds 1 and 2 against Hydroxyl Radicals. The hydroxyl radical generated by the Fenton reaction in this system was scavenged by samples with antioxidant activity. The scavenging activity of compounds **1** and **2** and Vc against hydroxyl radicals is shown in Figure 6B. IC_{50} values of compound 2 and Vc were 405.62 and 136.54 μg/mL, respectively.

Reducing Power of CMPA90-1 and CMPA90-M1. Figure 6C depicted the increase in the reducing power of compounds **1** and **2** and Vc at the gradient concentrations. Higher absorbance of the reaction mixture indicated a stronger reducing power of samples. The reducing abilities of compounds **1** and **2** and Vc at 400 μg/mL were 0.49, 0.82, and 1.21, respectively.

Ferrous-Ion-Chelating Effect of Compounds 1 and 2. The chelating abilities of compounds **1** and **2** and EDTA on Fe^{2+} are shown in Figure 6D. In the range of concentrations from 25 to 1600 μg/mL, they were found to possess a more potent chelating effect on Fe^{2+} in a concentration-dependent manner. EC_{50} values of compound 2 and EDTA were 385.68 and 107.14 μg/mL, respectively.

Cytotoxicity of Compounds 1 and 2 against A549 Cells. The cytotoxicity induced by compounds **1** and **2** was investigated in human cancer cell line A549 using the MTT assay. As shown in Figure 7, compounds **1** and **2** exhibited the capability of antiproliferation in A549 cells, with the IC_{50} values

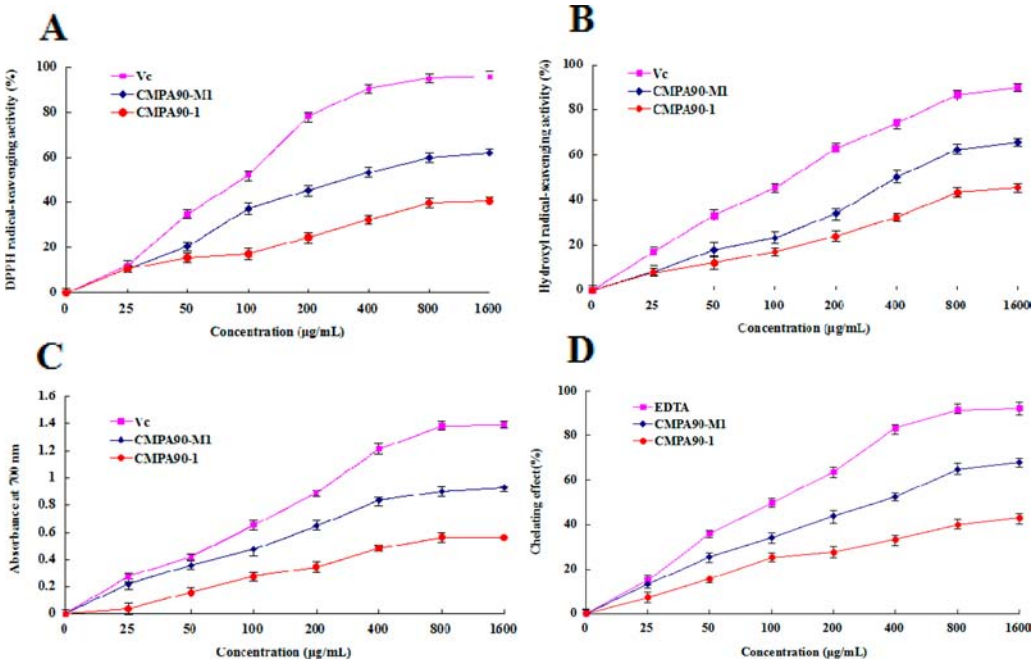

Figure 6. Antioxidant activities of compounds **1** and **2**: (A) DPPH radical-scavenging activity, (B) hydroxyl radical-scavenging activity, (C) reducing power, and (D) ferrous-ion-chelating effect. Values are the mean ± SD of three separate experiments.

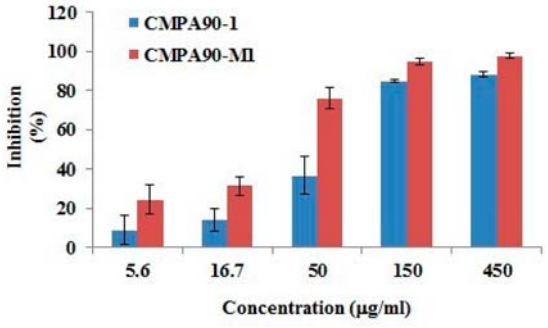

Figure 7. Inhibitory effects of compounds **1** and **2** on human tumor cell growth. A549 cells were treated by compounds **1** and **2** at different concentrations for 48 h in 96 well plates. The absorbance of the culture was measured at 570 nm. Data are presented as the mean ± SD of three separated experiments.

of 39.08 and 17.33 μg/mL, respectively. Cisplatin exhibited the capability of antiproliferation against A549 cells, with the IC_{50} value of 0.70 μg/mL.

In conclusion, a novel polysaccharide (**1**) was isolated from the cultured fruiting bodies of *C. militaris* containing predominantly D-galactose, L-mannose, and L-arabinose. The results showed that the structural characteristics of compound **1** are different from those of the polysaccharides previously found from *Cordyceps* sp. in monosaccharide ratios, molecular weights, etc.[1,2,4,36,37] Sulfation of compound **1** by the CSA−Pyr method led to its sulfate derivative (**2**). SEM and AFM exhibited that the ultrastructure of compound **2** differed greatly from that of compound **1**, which could result in an improvement of antioxidant and cytotoxic activities. Relative to compound **1**, compound **2** showed more noticeable free-radical-scavenging activity, ferrous-ion-chelating ability, and reducing power and stronger antiproliferative effect on A549 cells. The results of this study indicate that some specific substitutions occurring on original groups of polysaccharides might alter or improve their physicochemical and biological properties. This research may provide new insights into the development and application of polysaccharides from *C. militaris*.

radical-scavenging activities.[14−17] After intake, Rg5 is metabolized by intestinal bacteria and transformed to Rh3, which is taken up by the body.[16] Some evidence shows that Rh3 has anti-inflammatory effects in a chronic dermatitis model[16] and neuroprotective effects in a scopolamine-induced memory deficit model,[18] but its effect on neuroinflammation has not been well explored. Therefore, we examined the anti-inflammatory effect of Rh3 in LPS-induced microglia and investigated its underlying molecular mechanism.

MATERIALS AND METHODS

Isolation of Ginsenoside Rh3. Heated red ginseng extract was prepared as previously described,[18,19] and its main constituent ginsenoside Rg5 was isolated following a previously described procedure.[19,20] Briefly, ginsenoside Rg5 (0.2 g) was incubated with human fecal suspension (approximately 1 g) in anaerobic medium (0.5 L) according to a previously described method.[21] The reaction mixture was extracted with *n*-BuOH (1 L) twice and evaporated (dried extract, 0.15 g). The *n*-BuOH extract was subjected to silica gel column chromatography (2 × 15 cm), eluted with a stepwise gradient of $CHCl_3$ and methanol, and then underwent further chromatography on silica gel columns, employing the same eluent systems, to yield ginsenoside Rh3 (43 mg) (Figure 1). The extracted ginsenoside Rh3 was identified by comparison to an authentic standard by nuclear magnetic resonance spectrometry (Bruker AMX 400, 400 MHz) and fast atom bombardment mass spectrometry (FAB-MS). Ginsenoside Rh3 (purity, >95%), colorless powder (MeOH); melting point (mp), 161−162 °C; FAB-MS (*m*/*z*), 605 $(M + H)^+$.

Reagents. All reagents used for cell culture were obtained from Gibco BRL (Grand Island, NY). LPS (*Escherichia coli* serotype 055:B5), 5-aminoimidazole-4-carboxamide-1-β-D-ribofuranoside (AICAR), and nicotinamide were purchased from Sigma Chemical Co. (St Louis, MO). Antibodies against phospho-/total forms of mitogen-activated protein kinases (MAPKs) and Akt were purchased from Cell Signaling Technology (Beverley, MA). Antibodies against hemeoxygenase-1 (HO-1) and phospho-forms of janus kinase 1 (JAK1) and STAT1 were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Phosphatidylinositol 3-kinase (PI3K)/Akt- and JAK/STAT-specific inhibitors (LY294002, Ruxolitinib) were obtained from Calbiochem (La Jolla, CA) and MedChem Express (Princeton, NJ), respectively. Griess reagent for NO measurement, all of the reagents for reverse transcription polymerase chain reaction (RT-PCR), and oligonucleotides for electrophoretic mobility shift assay (EMSA) were purchased from Promega (Madison, WI).

Microglial Cell Cultures. Immortalized murine BV2 microglial cells[22] were grown and maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% heat-inactivated fetal bovine serum, streptomycin (10 μg/mL), and penicillin (10 units/mL) at 37 °C. Primary microglial cells were cultured from the cerebral cortices of 1−2-day-old Sprague−Dawley rat pups as described previously.[23] The purity of microglial cultures was greater than 95%, which was confirmed by western blot and immunocytochemistry analyses using an antibody specific to ionized calcium-binding adapter protein-1 (data not shown). The use of rat for primary culture was approved by the Institutional Animal Care and Use Committee in the Medical School of Ewha Womans University (ESM13-0242).

Measurement of Cytokine and Nitrite Levels. BV2 cells (1×10^5 cells per well in a 24 well plate) or primary microglia (2.5×10^5 cells per well in a 48 well plate) were pretreated with Rh3 or AICAR for 1 h and stimulated with LPS (0.1 μg/mL for BV2 cells and 10 ng/mL for primary microglia). The supernatants of the cultured microglia were collected 24 h after LPS stimulation, and the concentrations of tumor necrosis factor (TNF)-α and interleukin (IL)-6 were measured by enzyme-linked immunosorbent assay (ELISA) as previously described.[24] Accumulated nitrite was measured in the cell supernatant by Griess reagent.

RT-PCR. BV2 cells (7.5×10^5 cells on a 6 cm dish) or rat primary microglia (7×10^6 cells on a 6 cm dish) were treated with LPS in the presence of Rh3, and total RNA was extracted with TRI reagent (Sigma). For RT-PCR, total RNA (1 μg) was reverse-transcribed in a reaction mixture containing 1 unit of RNase inhibitor, 500 ng of random primers, 3 mM $MgCl_2$, 0.5 mM dNTP, 1× RT buffer, and 10 units of reverse transcriptase (Promega). The synthesized cDNA was used as a template for PCR using GoTaq polymerase (Promega), and the primers are shown in Table 1. GAPDH was used as an internal control for normalizing target gene expression.

EMSA. Nuclear extracts from treated microglia were prepared as described previously.[24] Double-stranded DNA oligonucleotides containing the NF-κB or antioxidant response element consensus sequences (Promega) were end-labeled by [γ-^{32}P] ATP. Nuclear proteins (5 μg) were incubated with ^{32}P-labeled probe on ice for 30 min and resolved on a 5% acrylamide gel as previously described.[24]

Intracellular Reactive Oxygen Species (ROS) Measurement. Intracellular accumulation of ROS was measured with H_2DCF-DA (Sigma) by modifying previously reported methods.[25] In brief, BV2 microglial cells were stimulated with LPS for 16 h and stained with 20 μM H_2DCF-DA in Hank's balanced salt solution buffer for 1 h at 37 °C. 2′,7′-Dichlorofluorescein (DCF) fluorescence intensity was measured at 485 nm excitation and 535 nm emission on a fluorescence plate reader (Molecular Devices, Sunnyvale, CA). For image analysis of ROS production, BV2 cells were placed on coverslips and treated with Rh3 1 h prior to LPS treatment. Cells were stained with H_2DCF-

J. Agric. Food Chem. 2015, 63, 3472−3480

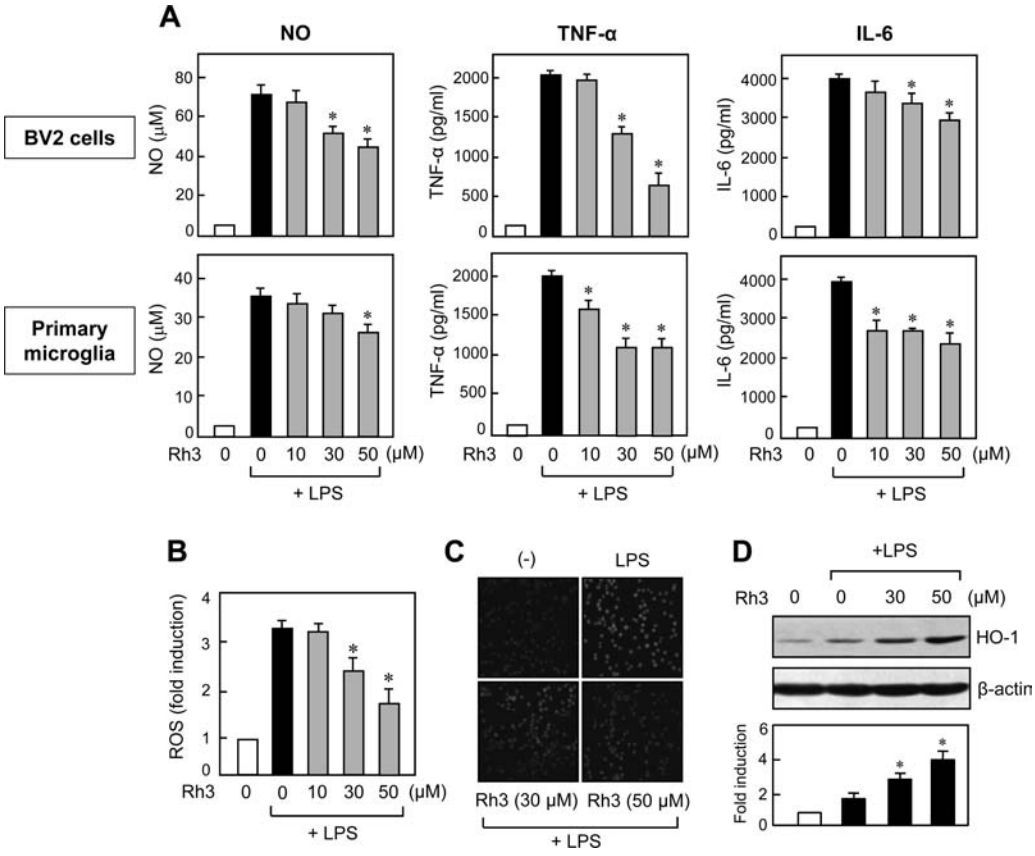

Figure 2. Rh3 inhibits NO, TNF-α, IL-6, and ROS production and enhances HO-1 expression in LPS-stimulated microglia. (A) BV2 cells or rat primary microglia were pretreated with Rh3 1 h prior to LPS (100 ng/mL) and incubated for 16 h. The supernatants were obtained, and the amounts of nitrite, TNF-α, and IL-6 were measured. (B) BV2 cells treated with the above conditions were stained with 20 μM H_2DCF-DA, and DCF fluorescence intensity was measured. (C) Confocal image analysis of intracellular ROS production. (D) Levels of HO-1 protein expression in BV2 cells were determined by western blot analysis. The data are expressed as the mean ± SEM for three independent experiments. (*) $p < 0.05$ versus cells treated with LPS alone.

DA for 1 h, mounted onto a microscope slide, and analyzed using confocal laser scanning microscopy.

Western Blot Analysis. Cell extracts were prepared as described previously.[24] Proteins were separated by 12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and transferred to nitrocellulose membrane (Amersharm, Piscataway, NJ). The membranes were blocked with 5% skim milk in 10 mM Tris−HCl containing 150 mM NaCl and 0.5% Tween 20 (TBST) and then incubated with primary antibodies (1:1000) recognizing the phospho- or total forms of extracellular signal-regulated kinase (ERK), p38 MAPK, c-Jun N-terminal kinase (JNK), or Akt. Primary antibodies recognizing JAK1, STAT1, or HO-1 were also used. β-Actin was used as the loading control for normalizing protein expression. After thoroughly washing with TBST, horseradish peroxidase-conjugated secondary antibodies (1:1000 dilution in TBST; New England Biolabs, Beverly, MA) were applied and blots were developed using an enhanced chemiluminescence detection kit (Thermo Fisher Scientific, Waltham, MA).

Knockdown of AMPK by Small Interfering RNA (siRNA). BV2 cells (0.5×10^5 cells per well in a 12 well plate) were transiently transfected with 100 pM AMPK siRNA using Ambion siPORT NeoFX transfection reagent following the protocols of the manufacturer (Ambion). A scrambled control siRNA was used as a negative control. The siRNA sequences were as follows: AMPK-α1 siRNA (5′-GCAGAAGUUUGUAGAGCAA-3′) and control siRNA (5′-AAUCGCAUAGCGUAUGCCGUU-3′). The cells were harvested 48 h after siRNA transfection, and the expression levels of AMPK protein were measured by western blotting.

Statistical Analysis. Unless otherwise stated, all experiments were performed with triplicate samples and repeated at least 3 times. Data are presented as the mean ± standard error of the mean (SEM), and statistical comparisons between groups were performed using one-way analysis of variance followed by Newman−Keuls multiple comparison test. p values less than 0.05 were deemed to indicate statistical significance.

RESULTS

Rh3 Inhibits LPS-Induced Production of NO, TNF-α, and IL-6 in BV2 Cells and Primary Cultured Microglia. BV2 cells were treated with Rh3 for 1 h before stimulation with LPS, and the effects of Rh3 on the LPS-induced production of NO and cytokines were examined. As shown in Figure 2A, Rh3 significantly inhibited NO, TNF-α, and IL-6 production in LPS-stimulated BV2 cells. The anti-inflammatory effects of Rh3 were also observed in rat primary microglia (Figure 2A). Rh3 did not have any cytotoxicity in the concentrations used in this study in both the BV2 and primary microglial cells at least for 48 h (data not shown).

Rh3 Suppresses LPS-Induced ROS Production and Upregulates HO-1 Expression. Previous studies indicate that ROS play a crucial role in oxidative and inflammatory responses.[1,4] To determine the effect of Rh3 on ROS production in LPS-stimulated BV2 cells, we measured intracellular ROS scavenging activities of Rh3 using the DCF-DA method. As shown in Figure 2B, Rh3 had an inhibitory effect on LPS-induced ROS production in BV2 cells. Confocal microscopic analysis also showed the inhibition of LPS-induced

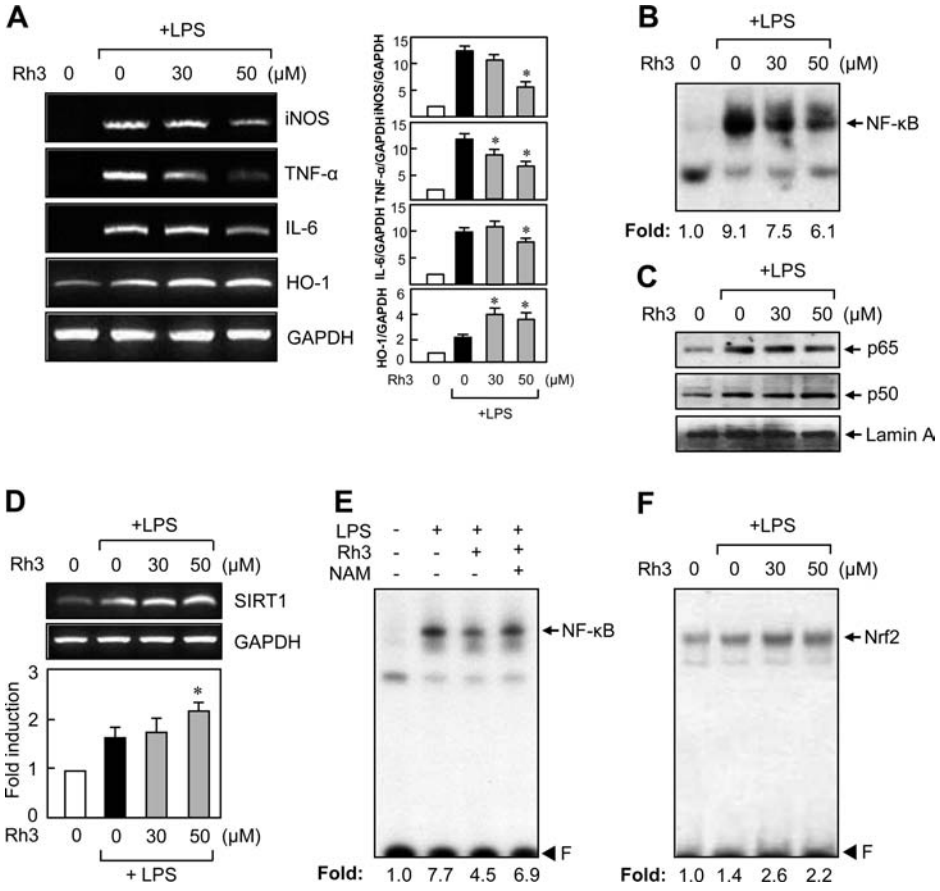

Figure 3. Rh3 suppresses LPS-induced mRNA expression of iNOS, TNF-α, and IL-6 and increases HO-1 expression by modulating NF-κB and Nrf2 activity. (A) To examine mRNA expression of iNOS, TNF-α, IL-6, and HO-1, BV2 cells were pretreated with Rh3 1 h before incubation with LPS (100 ng/mL) for 6 h. The mRNA levels of iNOS, TNF-α, IL-6, and HO-1 were determined by RT-PCR. The results are representative of three independent experiments (left panel). Quantitative analysis of mRNA expression was performed by densitometric analysis. GAPDH was used as an internal control. The data are expressed as the mean ± SEM for three independent experiments (right panel). (*) $p < 0.05$ versus cells treated with LPS alone. (B) EMSA for NF-κB DNA-binding activity. Nuclear extracts were prepared from BV2 cells after treatment with LPS (100 ng/mL) for 3 h in the presence or absence of Rh3, and gel shift assay was performed using NF-κB oligonucleotide probe. "F" indicates free probe. (C) Amount p65 or p50 protein was determined in the same nuclear extracts used in the EMSA, by western blot. Lamin A was used as the loading control for nuclear protein. (D) Effect of Rh3 on SIRT1 mRNA expression in BV2 cells stimulated with LPS for 3 h. The results are representative of three independent experiments. Quantitative analysis of mRNA levels of SIRT1 was performed by densitometric analysis. The data are expressed as the mean ± SEM for three independent experiments. (*) $p < 0.05$ versus cells treated with LPS alone. (E) Effect of nicotinamide (NAM) on NF-κB DNA-binding activity. Nuclear extracts were prepared from BV2 cells after treatment with LPS (100 ng/mL) for 3 h in the presence or absence of Rh3 (50 μM) or Rh3 (50 μM) + nicotinamide (50 μM), and EMSA was performed. (F) EMSA for Nrf2 DNA-binding activity.

ROS production by Rh3, which is consistent with DCF-DA data (Figure 2C). In addition, Rh3 significantly increased LPS-induced expression of HO-1 (Figure 2D), which is an important molecule involved in cellular defense against oxidative stress.[26,27]

Rh3 Inhibits LPS-Induced mRNA Expression of iNOS and Pro-inflammatory Cytokines and Increases HO-1 Expression by Modulating the NF-κB/Nrf2 Axis and Sirtuin 1 (SIRT1) Expression. Next, we examined the effect of Rh3 on the transcription of iNOS, TNF-α, IL-6, and HO-1 genes in LPS-stimulated BV2 cells. Rh3 significantly inhibited the mRNA expression of iNOS, TNF-α, and IL-6 and increased HO-1 mRNA expression (Figure 3A). A similar pattern of transcriptional regulation by Rh3 was observed in primary microglia (data not shown). These results suggest that Rh3 regulates the expression of iNOS, TNF-α, IL-6, and HO-1 at the mRNA level. To analyze the molecular mechanism underlying the anti-inflammatory effect of Rh3, we examined the effect of Rh3 on NF-κB, a key transcription factor modulating pro-inflammatory gene expression. Rh3 inhibited LPS-induced NF-κB DNA-binding activity (Figure 3B). However, it did not affect the nuclear translocation of p65 or p50 subunit protein (Figure 3C). Because SIRT1 is known to inhibit NF-κB signaling via deacetylation of the p65 subunit, we investigated whether Rh3 affects SIRT1 expression. RT-PCR analysis showed that Rh3 increased SIRT1 expression (Figure 3D). Next, to see whether the upregulation of SIRT1 led to NF-κB inhibition in Rh3-treated BV2 cells, we examined the effects of SIRT1 inhibitor, nicotinamide, on NF-κB activity. EMSA data showed that nicotinamide reversed the Rh3-mediated inhibition of NF-κB in LPS-stimulated BV2 cells (Figure 3E). The data suggest that SIRT1 is at least partly involved in Rh3-mediated inhibition of NF-κB signaling. Moreover, Rh3 increased Nrf2 binding to antioxidant response element, which is important for HO-1 gene expression (Figure 3F).

Rh3 Enhances AMPK Phosphorylation and Inhibits Phosphorylation of Akt and JAK1/STAT1 in LPS-

DOI: 10.1021/jf506110y
J. Agric. Food Chem. 2015, 63, 3472−3480

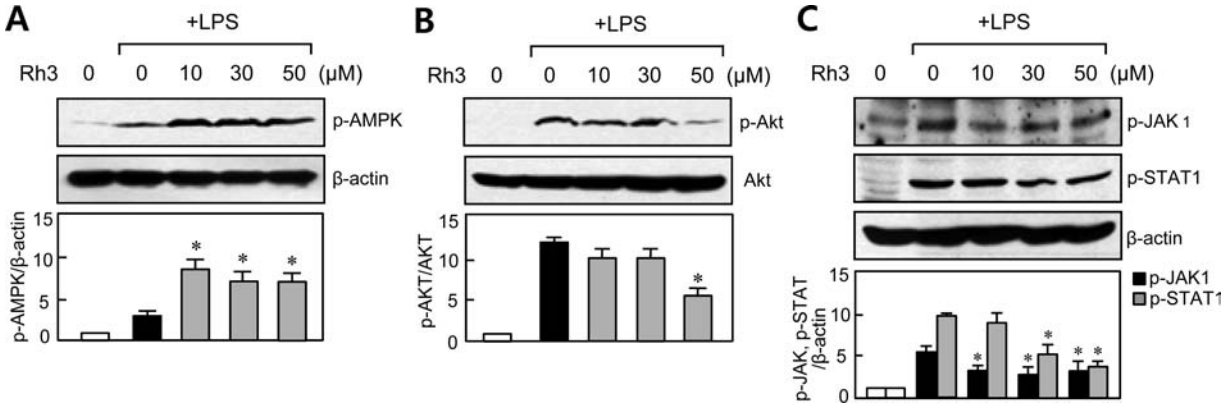

Figure 4. Rh3 enhances AMPK phosphorylation and inhibits the phosphorylation of Akt and JAK1/STAT1 in LPS-stimulated BV2 cells. Cell extracts were prepared from BV2 cells treated with LPS for 1 h in the absence or presence of Rh3 and were subjected to immunoblot analysis. The data show the effect of Rh3 on phosphorylation of (A) AMPK, (B) Akt, and (C) JAK1/STAT1. The results are representative of three independent experiments. p-Akt was normalized by total Akt, and p-AMPK, p-JAK1, and p-STAT1 were normalized by β-actin. Quantification data are shown in the bottom panel. The data are expressed as the mean ± SEM for three independent experiments. (*) $p < 0.05$ versus cells treated with LPS alone.

Stimulated BV2 Cells. To investigate the signaling pathways involved in the anti-inflammatory effect of Rh3, we examined the effect of Rh3 on the phosphorylation of AMPK, which is an important anti-inflammatory signaling molecule.[6−8] We found that Rh3 enhanced LPS-induced AMPK phosphorylation (Figure 4A). Next, we examined the effect of Rh3 on LPS-induced phosphorylation of three types of MAPKs, Akt (a downstream substrate of PI3K), JAK1, and STAT1, which are upstream signaling molecules that regulate gene expression of pro-inflammatory cytokines.[28−31] Rh3 had an inhibitory effect on Akt, JAK1, and STAT1 phosphorylation (panels B and C of Figure 4), but it did not affect the phosphorylation of MAPKs in LPS-induced BV2 cells (see Supplementary Figure 1 of the Supporting Information). To further investigate the role of PI3K/Akt and JAK1/STAT1 in Rh3-mediated anti-inflammation, we treated BV2 cells with PI3K/Akt or JAK/STAT pathway-specific inhibitors (LY294002, Ruxolitinib) before stimulation with LPS. We found that both inhibitors significantly inhibited the production of TNF-α, IL-6, NO, and ROS induced by LPS (see Supplementary Figure 2 of the Supporting Information). These results suggest that AMPK, PI3K/Akt, and JAK1/STAT1 signaling pathways are largely involved in the anti-inflammatory effect of Rh3 in LPS-stimulated BV2 cells.

AMPK Is an Upstream Signal of PI3K/Akt and JAK1/STAT1 and Mediates the Anti-inflammatory Effect of Rh3 in LPS-Stimulated BV2 Cells. To investigate a possible involvement of AMPK in Rh3-mediated anti-inflammation, BV2 cells were treated with AICAR, an AMPK activator. AICAR decreased LPS-induced phosphorylation of Akt and JAK1/STAT1 (Figure 5), suggesting that AMPK is an upstream signal of PI3K/Akt and JAK1/STAT1. In addition, AICAR, like Rh3, inhibited NO, TNF-α, IL-6, and ROS production, suppressed NF-κB DNA-binding activity, and upregulated SIRT1 (a negative regulator of NF-κB) expression (panels A−C of Figure 6). Furthermore, AICAR upregulated HO-1 expression by enhancing Nrf2 DNA-binding activity (panels D and E of Figure 6). These results suggest that Rh3 exerts anti-inflammatory/antioxidant effects in microglia by modulating AMPK. To confirm this possibility, we examined whether knockdown of AMPK by siRNA reversed the anti-inflammatory effect of Rh3. As shown in Figure 7, in comparison to the control siRNA group, AMPK siRNA

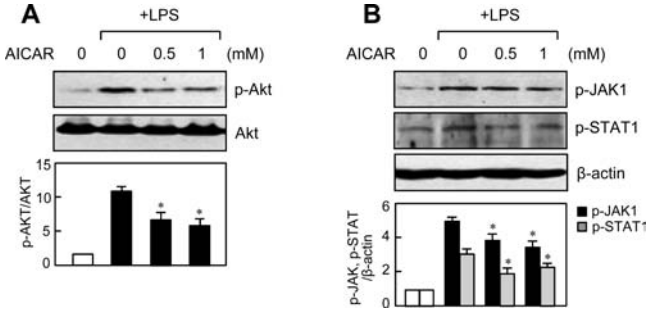

Figure 5. AICAR, an AMPK activator, has an inhibitory effect on LPS-induced phosphorylation of Akt, JAK1, and STAT1. (A) Cell extracts were prepared from BV2 cells treated with LPS for 1 h in the presence of AICAR and were subjected to immunoblot analysis using antibodies against phospho- or total forms of Akt. The total form of Akt was used as an internal control. (B) Effect of AICAR on the phosphorylation of JAK1 and STAT1. The results are representative of three independent experiments. Quantification data are shown in the bottom panel. The data are expressed as the mean ± SEM for three independent experiments. (*) $p < 0.05$ versus cells treated with LPS alone.

attenuated Rh3- and AICAR-mediated inhibition of TNF-α, IL-6, NO, and ROS production. We observed that AMPK siRNA also augmented LPS-induced inflammatory responses (Figure 7B). However, the percent increase of inflammatory responses induced by AMPK knockdown compared to control siRNA was much higher in the LPS + Rh3- or LPS + AICAR-treated group than the LPS-only group. These results collectively suggest that AMPK is at least partly involved in the anti-inflammatory effect of Rh3 in LPS-stimulated microglia.

■ DISCUSSION

In the present study, we demonstrated that Rh3 has an anti-inflammatory effect in activated microglia. Rh3 significantly inhibited the production of NO, TNF-α, and IL-6 in LPS-stimulated BV2 cells and rat primary microglia. In addition, Rh3 decreased levels of intracellular ROS, which is associated with upregulated antioxidant enzyme HO-1 expression. RT-PCR analysis showed that Rh3 regulated iNOS, TNF-α, IL-6, and HO-1 at a transcriptional level. Further mechanistic studies revealed that the inhibition of NF-κB and enhancement of Nrf2

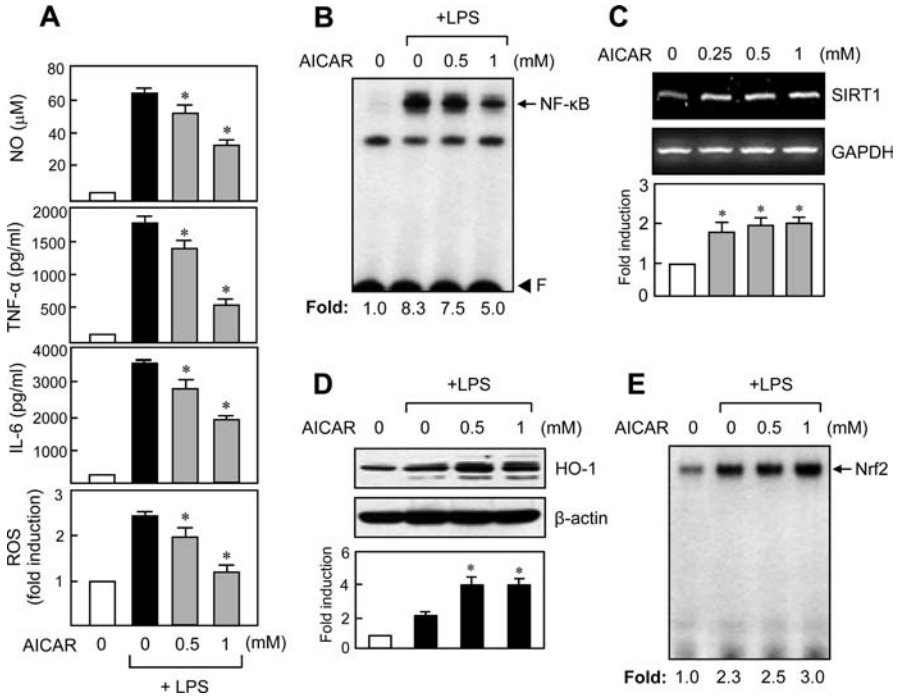

Figure 6. AICAR suppresses LPS-induced NO, TNF-α, IL-6, and ROS production and induces HO-1 expression by modulating NF-κB and Nrf2 DNA-binding activities. (A) BV2 cells were pretreated with AICAR 1 h prior to incubation with LPS (100 ng/mL) for 16 h, and the amounts of NO, TNF-α, and IL-6 released into the media and level of intracellular ROS were measured. The data are expressed as the mean ± SEM for three independent experiments. (*) $p < 0.05$ versus cells treated with LPS alone. (B) EMSA for NF-κB DNA-binding activity. Nuclear extracts were prepared from BV2 cells after treatment with LPS for 3 h in the presence of AICAR, after which EMSA was performed. The results are representative of three independent experiments. (C) Effect of AICAR on SIRT-1 mRNA expression was determined by RT-PCR analysis. (D) Levels of HO-1 protein were determined by western blot analysis. Quantification of three independent experiments is shown in the bottom panel. (E) EMSA for Nrf2 DNA-binding activity. The results are representative of three independent experiments.

pathways are involved in the anti-inflammatory effect of Rh3. We showed that upregulation of SIRT1 is responsible for NF-κB inhibition. Of interest, Rh3 inhibited the phosphorylation of PI3K/Akt and JAK1/STAT1 and upregulated AMPK. Finally, we found that AMPK modulated downstream signaling molecules, such as PI3K/Akt, JAK1/STAT1, and the NF-κB/Nrf2 axis, suggesting that AMPK plays a pivotal role in the anti-inflammatory mechanism of Rh3.

A number of studies indicate that the activity of AMPK can regulate the inflammatory responses induced by NF-κB.[6−8] AMPK does not directly target NF-κB but rather mediates the inhibition of NF-κB by modulating SIRT1, PGC-1α, p53, and FoxO.[6] For example, SIRT1 inhibits NF-κB signaling via deacetylation of the p65 subunit.[32,33] To confirm whether Rh3 acts through the AMPK-SIRT1-NF-κB signaling pathway, we compared the effects of Rh3 and AICAR, a chemical activator of AMPK. Indeed, we found that AICAR treatment increased SIRT1 expression and decreased NF-κB activity and expression of downstream pro-inflammatory genes, similar to Rh3 treatment. These findings suggest that the AMPK-SIRT1-NF-κB signaling pathways are at least partly involved in the anti-inflammatory mechanism of Rh3 in LPS-stimulated microglia.

In the present study, we also found the association of AMPK with other inflammatory signaling molecules, such as PI3K/Akt and JAK1/STAT1. AICAR inhibited the phosphorylation of Akt and JAK1/STAT1 in LPS-stimulated microglia, suggesting that AMPK is an upstream regulator of PI3K/Akt and JAK1/STAT1 signaling pathways. Consistent with this finding, several papers report that AMPK activation can inhibit JAK−STAT signaling. AMPK inhibits IL-6-stimulated STAT3 phosphorylation and pro-inflammatory gene expression in hepatocyte cell lines.[34] AMPK-mediated induction of an orphan nuclear receptor protein, small heterodimer partner, was suggested as one possible mechanism of STAT3 inhibition.[35] In addition, AMPK blocks IFN-γ-induced STAT1 expression in rat primary astrocytes and microglia.[11] As to the effect of AMPK on PI3K/Akt signaling, a recent study reports that AMPK activation blocks LPS/IFN-γ-induced phosphorylation of Akt and, thus, inhibits inflammation in mouse mesangial cells.[36] Therefore, our results suggest that AMPK activation by Rh3 may contribute to its anti-inflammatory effect via inhibition of PI3K/Akt and JAK1/STAT1 signaling pathways in LPS-stimulated microglia.

Besides its anti-inflammatory effect, Rh3 also showed an antioxidant effect in LPS-stimulated BV2 cells by decreasing ROS production and inducing HO-1 expression via the Nrf2/antioxidant response element (ARE) pathway. Previous studies demonstrate an AMPK-dependent inhibition of ROS synthesis in human umbilical vein endothelial cells (HUVECs), LPS-stimulated macrophages, and vascular smooth muscle cells.[37−39] Silencing of AMPK increases nicotinamide adenine dinucleotide phosphate (NADPH) oxidase expression and decreases antioxidant enzymes in HUVECs.[39,40] These studies suggest that AMPK activation limits excessive ROS synthesis by NADPH oxidase. Furthermore, some studies indicate that AMPK stimulates antioxidant Nrf2 signaling. Liu et al.[41] reports that AMPK induces HO-1 expression via the Nrf2 signaling pathway in endothelial cells. In addition, the crosstalk between Nrf2 and AMPK signaling pathways has been shown to be important for the anti-inflammatory effect of berberine in LPS-

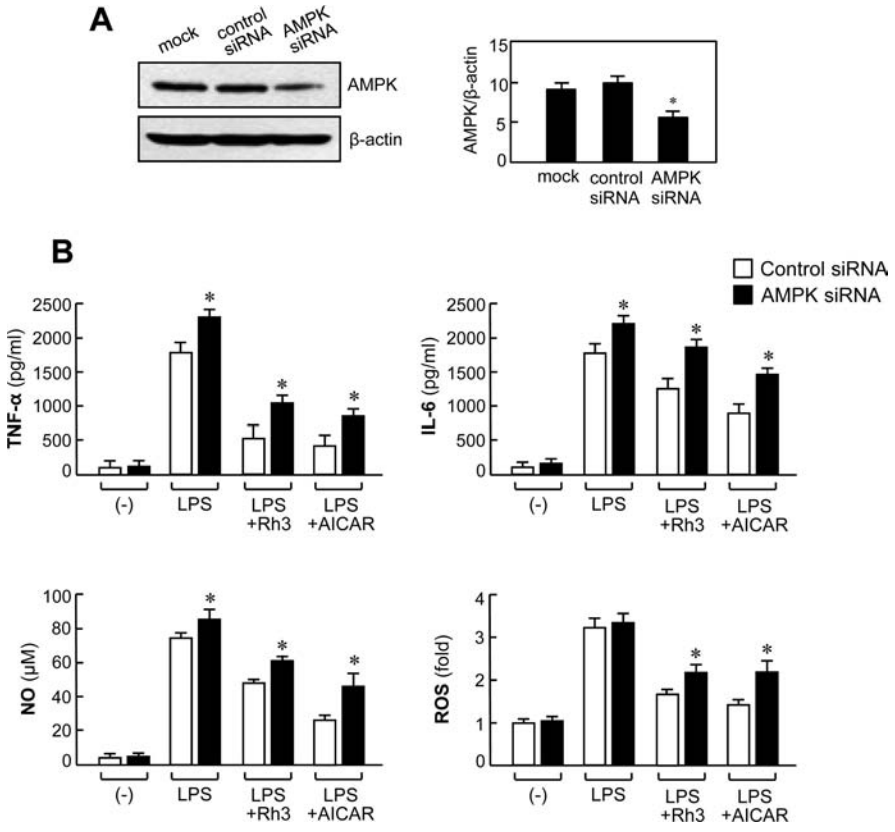

Figure 7. Knockdown of AMPK attenuates the anti-inflammatory effects of Rh3. (A) AMPK protein reduction by siRNAs was confirmed by western blotting. The data are representative of three independent experiments. Quantification data are shown in the right panel. (*) $p < 0.05$ versus the control siRNA-treated group. (B) Effects of AMPK siRNA on TNF-α, IL-6, NO, and ROS production in LPS-stimulated BV2 cells. Cells transfected with AMPK siRNA were treated with LPS (100 ng/mL) in the presence or absence of Rh3 (50 μM) or AICAR (1 mM) for 16 h, and the amounts of NO, TNF-α, and IL-6 released into the media and level of intracellular ROS were measured. Values are expressed as the mean ± SEM for three replicates using different cell cultures. (*) $p < 0.05$ versus the control siRNA-treated group.

stimulated macrophages and endotoxin-shocked mice.[42] Therefore, the results of the present study suggest that AMPK activation is largely involved in Rh3-mediated ROS inhibition and Nrf2/HO-1 upregulation, contributing to anti-inflammatory/antioxidant effects in LPS-stimulated microglia.

In summary, this study is the first to demonstrate the anti-inflammatory effect of Rh3 in LPS-stimulated microglia and its underlying molecular mechanisms. We showed that Rh3 inhibited microglial activation, at least partly, by modulating AMPK and its downstream signaling molecules, such as PI3K/Akt, JAK1/STAT1, and NF-κB/Nrf2. These findings suggest that Rh3 may offer therapeutic potential for the treatment of various neuroinflammatory disorders that are accompanied by microglial activation.

protection for active food components in the core from thermal, light, and other storage condition constraints.[16,18]

In this study, PVA and β-CD were chosen as the base material and RA as a core bioactive. The nanofiber encapsulation based on PVA has been extensively reported as a protecting coat for food materials.[16,18,24] The aim of this study was to use the electrospinning technique in order to develop a PVA/RA/β-CD nanofiber functional matrix that provides support of thermal stability and long shelf life of RA. The RA was incorporated separately into the PVA nanofibers for assessing the relation between the inclusion complex and the variation of the retained core. Furthermore, the RA in the nanofibers demonstrated the effect and influence on the morphology of the fibers and also determined release kinetics as a function of fiber material composition under room storage conditions.

MATERIALS AND METHODS

Materials. Poly(vinyl alcohol) (PVA) (Mw: 85 000−124 000, 99+ % hydrolyzed), retinyl acetate (RA), β-cyclodextrin (β-CD), and tetrabutyl ammonium hexafluorophosphate were purchased from Sigma-Aldrich (Castle-Hill, NSW 1765, Australia). Ethanol (100% proof) and acetonitrile (99.8%) were obtained from Chem-Supply (Gillman, SA 5013, Australia). All of the reagents used were of analytical grade and used as received. Milli-Q water was used throughout the experiments.

Preparation of the Solutions. The powdered PVA was dissolved in Milli-Q water at 75 °C using a magnetic stirrer (1 krpm) for 2 h to make up a 12% (w/v) solution.[12] In the same method, 10% (w/v) PVA solution was prepared containing a different concentration of retinyl acetate and β-CD inclusion complex. To this solution, 30% (w/w, with respect to polymer PVA) of β-CD was added at 75 °C with constant stirring for 10 min. Subsequently, the solution was cooled to 25 °C with stirring and 10% (w/w, respective to PVA) of retinyl acetate powder was added to make the PVA/retinyl acetate/β-CD solution. The solutions were stirred for a further 1 h at 25 °C prior to electrospinning.

Homogeneous and clear solutions were obtained for PVA and PVA/β-CD compositions. In contrast, these solutions turned turbid by addition of retinyl acetate. Finally, the prepared solution of PVA and composition with retinyl acetate and β-CD were electrospun separately at room temperature. The composition and rheological properties of the solutions are summarized in Table 1.

Electrospinning. The prepared solutions were placed in a 5 mL syringe connected with a stainless steel needle having an inner diameter of 0.5 mm. The solution in the syringe was pumped at 200 μL/h horizontally (model: KDS Legato 111, KD Scientific, Holliston, MA, USA), and the solutions were electrospun with an applied voltage of 18 kV using a homemade high voltage power supply. Then, the nanofibers were deposited on a grounded stationary metal collector covered with aluminum foil at 20 cm from the syringe nozzle to the tip. The electrospinning experiments were carried out at room temperature in an enclosed Plexiglas box.

Measurements and Characterization. Ionic conductivities of the polymer solutions were measured using a conductivity meter (METTLER TOLED: S230, Zurich, Switzerland) that was calibrated with 1413 μS/cm standard conductivity solution at room temperature. The viscosity of the solutions was measured with an AR2000 Advanced Rheometer (4 cm, 2° cone, TA Instruments, Delaware, USA) at 23 °C with a shear rate from 1 up to 1000 s^{-1}. The morphology and the fiber diameter of the electrospun nanofibers were analyzed by a field-emission scanning electron microscope (FE-SEM, Zeiss Supra 40 VP, Oberkochen, Germany). The nanofiber samples were coated with 15 nm of Au (EMITECH K975X) prior to SEM imaging. The average fiber diameter (AFD) for the samples was calculated by analysis of 100 fibers from the SEM images. The X-ray diffraction (XRD) patterns of powder PVA, β-CD, RA, and nanofiber membranes were obtained with a Bruker D8 Advance XRD with Cu Kα radiation at a scanning rate of 1°/min over a 2θ range of 5−40°. Thermal properties of the samples were investigated by using a differential scanning calorimeter (DSC) and a thermogravimetric analyzer (TGA) (DSC-TGA-2960 SDT V3.0F, TA Instruments Inc., Delaware, USA). For DSC analyses, the sealed 5 mg samples were initially equilibrated at 10 °C and then heated to 300 °C at a rate of 10 °C/min using nitrogen as a purge gas. TGA measurements were performed for electrospun nanofibers after 1 day of storage. The TGA data for 10 mg samples were recorded from room temperature to 600 °C at a heating rate of 10 °C/min, under a nitrogen atmosphere. X-ray photoelectron spectroscopy (XPS) (Kratos Axis Nova Analytical Ltd., Manchester, U.K.) was used to determine the surface chemistry of the nanofiber membranes. A monochromated Al Kα X-ray source was used at a power of 150 W. Elements were identified from survey spectra (0−1200 eV) with a detector pass energy of 160 eV. The atomic concentrations of the detected elements were calculated using integral peak intensities and the sensitivity factors supplied by the manufacturer.

Electrochemical Measurements. Electrochemical experiments were performed with a CH Instruments Model CH610 Electrochemical Analyzer. The electrochemical cell consisted of a three-electrode system: a glassy carbon (GC) working electrode (BASi MF-2012), a platinum wire (BASi MW-4130) auxiliary electrode, and a $Ag/AgNO_3$ reference electrode filled with 100 mM TBAP−acetonitrile (BASi MF-2062). The working electrode was cleaned with a polishing cloth (Buehler, Lake Bluff, IL, 60044, USA) impregnated with a 0.05 μm alumina slurry until a mirror-like surface was obtained. The polished electrodes were sonicated in acetonitrile to remove any alumina.

Sample Preparation. The nanofibers of PVA/RA and PVA/RA/β-CD-IC were measured frequently to determine the remaining retinyl acetate against the storage time. These nanofiber membranes were stored at room temperature in the laboratory for a certain period of time prior to analyses. Sample solutions of each type of nanofiber were prepared by soaking 40 mg of nanofibers in ethanol with sonication for 30 min at 25 °C to release the retinyl acetate into the solution.

The release rates of retinyl acetate from the nanofibers were monitored by square-wave voltammetry (SWV) using 0.1 M tetrabutyl ammonium hexafluorophosphate ($TBAPF_6$) in acetonitrile at 25 °C. The SWV conditions were as follows: step potential, 4 mV; amplitude, 25 mV; frequency, 15 Hz. The amount of retinyl acetate present in the nanofibers was monitored using a scanning potential range from 0 to 0.9 V. To perform the kinetic analysis, the signal obtained from each voltammogram was baseline subtracted and the value of the peak current (I_p) with the corresponding storage day was used for the subsequent analyses. The exact concentration of the released retinyl acetate was obtained using a calibration graph of retinyl acetate standard. The released amount was determined according to the

decrease of peak current with respect to storage time. The release (%) is expressed by the equation

$$\text{Release (\%)} = 100 \times \frac{I_p(\text{Day } k) - I_p(\text{Day } k + t)}{I_p(\text{Day } k)}$$

where I_p(Day k) is the peak current for an earlier storage time compared to the peak current I_p(Day $k + t$) with longer storage time.

Statistical Analysis. All data were expressed as mean ± standard deviation. Statistical significance by analysis of variation (ANOVA) was used to determine the difference among samples' viscosity, conductivity, and AFD, $P < 0.05$.

RESULTS AND DISCUSSION

Measurements and Crystalline Structure. The PVA solutions containing retinyl acetate and retinyl acetate/β-CD-IC were electrospun from the aqueous solution mixture. The conductivity and shear viscosity of the PVA and PVA/β-CD with and without retinyl acetate solutions are shown in Table 1. The addition of 10% (w/w) RA to the PVA and PVA/β-CD solutions significantly affects the viscosity and the conductivity of the solutions, as shown in Table 1. The viscosity of PVA/β-CD has a higher value compared to the PVA. In the same manner, the viscosity of PVA/RA has the highest value compared to all the rest of the samples. In general, the conductivities of all the sample solutions are significantly different in the presence of RA ($P < 0.05$) and the mean fiber diameters also are significantly different as the compositions of the polymer solutions vary, as shown in Table 1. The results showed that the addition of RA did not change the morphology of the PVA and PVA/β-CD nanofibers; instead, the diameters of the nanofibers decreased slightly (Figure 1). Similar findings were observed in the range between 200 and 360 nm in other studies when PVA and PVA/β-CD were used for encapsulation of food flavors.[13,18] For comparison, both the PVA and PVA/β-CD nanofibers were produced in the same concentration solutions as fibers which have RA.

In the electrospinning, uniform nanofibers were obtained and no huge variation was encountered along the electrospun fibers in the whole sample. The representative SEM images and the fiber diameter distribution along with the average fiber diameter of PVA, PVA/β-CD-IC, PVA/RA, and PVA/RA/β-CD-IC nanofibers are depicted in Figure 1. The SEM images of electrospun nanofibers were obtained from homogeneous solutions of 12% (w/v) PVA in Milli-Q water and 30% (w/w) β-CD and 10% (w/w) RA with respect to PVA. Uniform nanofibers were obtained from all the solutions of the mixture. In the case of PVA/RA/β-CD-IC, nanofibers were mostly uniform and had smaller diameters. The fibers were also obtained without any aggregates of retinyl acetate on their surfaces, implying that RA was uniformly incorporated within the fibers. The result showed that incorporation of RA in the electrospun PVA and PVA/β-CD fibers had little effect upon the morphology. The average fiber diameter with the RA had smaller diameters compared to controls (Table 1 and Figure 1).

The X-ray diffraction pattern measurements were carried out in order to elucidate the form of crystalline aggregates in the nanofibers and the crystalline nature of the pure powder PVA samples. The nanofibers with samples of PVA, RA, and β-CD

DOI: 10.1021/acs.jafc.5b00103
J. Agric. Food Chem. 2015, 63, 3481−3488

were subjected to X-ray powder diffractometry at RT. The XRD patterns obtained are depicted in Figure 2. The β-CD has

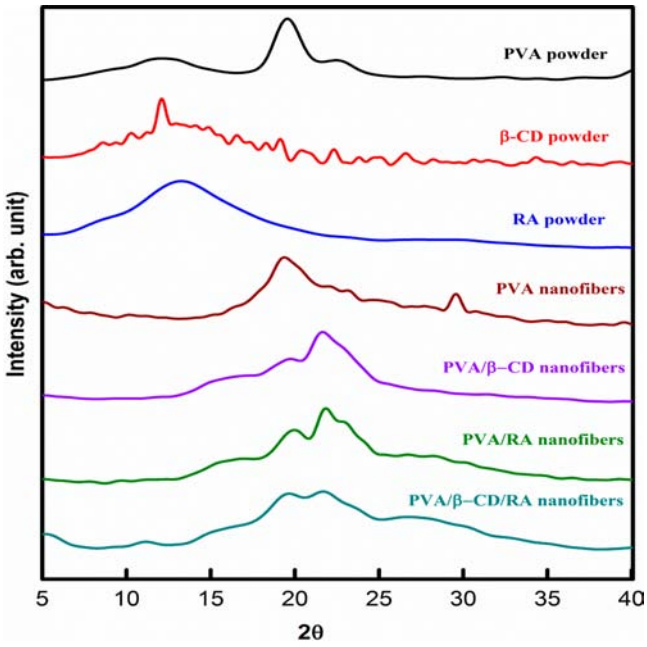

Figure 2. XRD spectra of received samples and electrospun nanofibers.

guest molecules which are localized separately from each other that affect the formation of crystals.[25] A wide spectral peak of the RA centered at 2θ = 13° suggests a semicrystalline structure. The diffractogram peak at 2θ = 19.5° for PVA powder and PVA nanofibers largely reveals their similarity. The PVA nanofibers preserve the semicrystalline nature of the powder after electrospinning except for a small additional peak at 2θ = 29.5°. These observed XRD diffraction peak results agree well with the literature. The reflection peak for electrospun PVA/β-CD and PVA/RA was detected at 2θ = 21.5° and shifted to the lower shoulder peak, which indicates the slight change in crystallinity. In addition, the PVA/RA/β-CD fibers had broad peaks at 2θ = 19.5° and 2θ = 21.5°, which is evidence of the existence of the introduced RA and β-CD in the PVA nanofiber matrix. In these spectra, the existence of RA is not apparent in the nanofibers of PVA/RA/β-CD and this implies that the RA incorporates in the form of RA/β-CD-ICs in the PVA nanofiber matrix. The existence of RA in the nanofibers of PVA/RA and PVA/RA/β-CD-IC affected the crystallization behavior of the nanofibers. This may need further study as to the reasons why RA has a greater tendency to alter the crystal structure of the final products. The absence of the peak for RA in the PVA/RA/β-CD nanofibers confirmed that the RA dispersed homogeneously in the PVA matrix and is deprived of the formation of crystal aggregates.

Thermal Analyses. The thermal stability was determined by thermogravimetric analysis in a temperature range of 25 °C up to 600 °C, as shown in Figure 3 for the TGA and DTGA curves. Thermogravimetric analysis revealed the thermal effects of PVA nanofibers with the presence of β-CD and RA at different concentrations. Figure 3a shows TGA curves of the PVA powder and the PVA nanofibers, with and without the composite β-CD and RA. All the samples exhibited three main weight loss steps. The first weight loss from 5 to 10%, which covers the temperature range of about 25−230 °C, corresponds to weakly physisorbed water (indicated in the inset of Figure 3a), while the loss in the range 230−400 °C is due to the decomposition of the PVA side chains with the decomposition of the main chain occurring at about 400−600 °C. A great deal of weight loss is observed in the range of the second stage of thermal decomposition, as shown in Figure 3, of the TGA and first order differential of the thermograms (DTGA). The powdered PVA shows a small weight loss in the first stage as compared with the nanofibers of PVA. For the electrospun nanofibers with β-CD, better thermal stability is observed than for the other samples (Figure 3b). This is evidence that β-CD improves the thermal stability of the encapsulate.[18,26]

The retinyl acetate weight loss was exhibited in four different stages. The first weight loss up to 100 °C corresponds to the evaporation of the adsorbed moisture. The second stage has 15% weight loss in the range 200−300 °C. The next 15% weight loss was observed in the range 300−430 °C. Moreover, the predominant and further weight loss was exhibited in the fourth stage in the range 430−600 °C. It is noticed that greater than 80% of the loss is observed after 300 °C. According to the

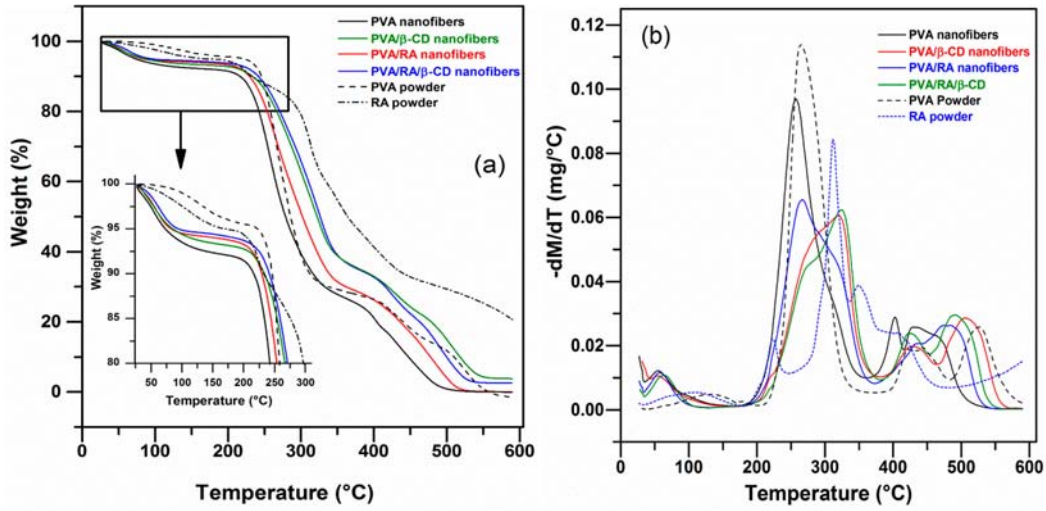

Figure 3. (a) TGA thermograms for the PVA and RA powders and the electrospun fibers and (b) first order derivatives of the TGA thermograms for powdered PVA and RA and the electrospun fibers.

DOI: 10.1021/acs.jafc.5b00103
J. Agric. Food Chem. 2015, 63, 3481−3488

TGA finding (Figure 3a), the RA in PVA/β-CD nanofibers has more thermal stability than the RA incorporated into PVA nanofibers. These results are consistent with results in other studies,[13,26] which include reports on how incorporating cyclodextrin inclusion improved the stability of the capsulate.

Differential scanning calorimetry (DSC) is used to identify if the guest molecules are incorporated inside the CD cavities.[25,27] The semicrystalline polymer of PVA has both the removal of its moisture and melting temperature (T_m), as depicted in Figure 4. Due to the introduction of RA, the

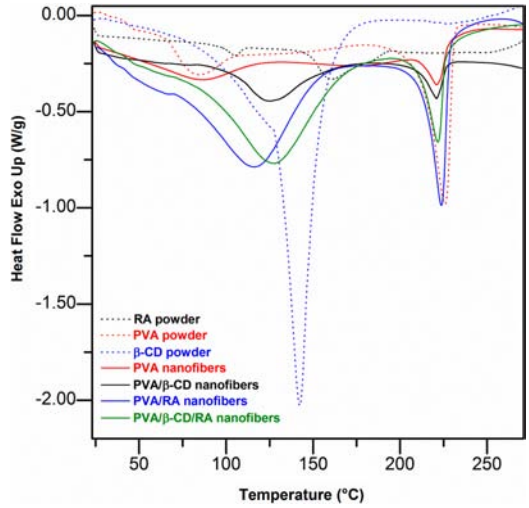

Figure 4. DSC thermograms of powders and electrospun nanofibers.

thermal behavior of PVA is expected to affect the composition interaction. Figure 4 shows the DSC curves of the powdered PVA and the electrospun nanofibers. The moisture content of the RA powder was removed at 105 °C, and the melting point at 160.6 °C was observed. The sharp melting point peak of β-CD appeared at 142.5 °C. The powder of PVA had moisture removed at 84 °C, whereas it occurred at 87 °C for the electrospun PVA nanofibers. The melting temperature of PVA powder and electrospun PVA nanofibers appeared at 221 and 225.5 °C, respectively. This result agrees with the literature value.[28] However, the melting point of PVA nanofibers increased by 4.5 °C, which may be due to the processing of the fibers. Generally, the melting point of the nanofibers is exhibited at the same temperature around 221 °C. The melting points of RA and β-CD powder were not observed in the nanofibers. This absence of the melting point suggested that RA incorporated inside the cavity and β-CD distributed through the nanofiber matrix for formation of inclusion complexation.

Several studies have elucidated the β-CD unique molecule delivery nature that can be used for vitamin A encapsulation to increase the thermal stability and control release.[29,30] For instance, the retinyl acetate without encapsulation starts to lose its stability earlier than 150 °C.[31] However, the stability of encapsulated retinyl acetate is improved in the range 230−300 °C without the presence of high chemical deterioration.[32,33]

XPS Characterization. X-ray photoelectron spectroscopy (XPS) was used to investigate chemical changes at the surface of the electrospun nanofibers and identify the atomic concentrations of the PVA, PVA/β-CD, PVA/RA, and PVA/RA/β-CD nanofibers. Accordingly, XPS survey spectra of the nanofibers were used to identify the surface elements present in ~10 nm of the outer surface of the samples. XPS wide energy surveys of PVA and PVA/β-CD nanofibers show different atomic concentrations of oxygen and carbon, namely, 65.6%/33.8% and 48.2%/49.0%, respectively (Table 2 and Figure 5).

Table 2. Surface Atomic Composition Measured by XPS

	total atomic composition (%)			
material	C	O	N	Na
PVA	65.6	33.9		0.5
PVA/β-CD	48.2	49.0	1.7	1.1
PVA/RA	42.7	54.6	0.8	2.0
PVA/RA/β-CD	41.7	56.2	2.0	0.2

The atomic composition identified of PVA nanofibers contains exclusively carbon, oxygen, and sodium. The electrospun PVA/β-CD nanofibers were analyzed to study the difference of compositions in detail (Figure 5b). In addition, the surface chemistry study by XPS investigated the variation of the surface composition with the presence of β-CD and retinyl acetate (Table 2). The XPS spectra of the PVA/RA and PVA/RA/β-CD nanofiber composites show four distinct peaks, corresponding to Na, N, C, and O, as shown in Figure 5c and d. Particularly, in the nanofibers of PVA/RA and PVA/RA/β-CD, increased concentrations of oxygen and slight variations of nitrogen were observed due to the introduction of retinyl acetate into the nanofibers (Figure 5c and d). The potential of using β-CD was assessed by observing its tendency to preserve oxygen against some common oxidation of the retinyl acetate. The electrospun nanofibers of PVA were used as a control for comparing the variation due to the introduction of functional groups from the RA and β-CD inclusion complex.

The result displayed a high oxygen atomic concentration, which is in agreement with the previous finding that the β-CD inclusion complex has a critical role to reduce loss of oxygen mainly in the form of oxidation that reduces the shelf life of the samples.[34,35] These results confirmed the formation of an inclusion complex and its preserving capacity to prolong the shelf life of the products.

Monitoring Release of Retinyl Acetate. The quantity and release kinetics of RA in electrospun nanofibers of PVA/RA and PVA/β-CD/RA were determined using the square-wave voltammogram peak current response against storage time under room storage conditions. The peak signal response of the retinyl acetate corresponds to the concentration of RA found in the nanofibers using the calibration graph of standard retinyl acetate (inset of Figure 7). The subsequent controlled release kinetics from the nanofibers.

A known amount of electrospun PVA/RA and PVA/β-CD/RA nanofibers was soaked in ethanol and sonicated to release the retinyl acetate. Subsequently, 600 μL of this solution was added into 0.1 M $TBAPF_6$ in acetonitrile solution in a 10 mL electrochemical cell. The SWV signal response revealed the amount of entrapped RA in the nanofibers according to the storage time, as shown in Figure 6. As can be seen from Figures 6 and 7, the concentration of RA in the nanofibers PVA/RA/β-CD and PVA/RA decreased with respect to increased storage time. Furthermore, the release rate was faster in both the PVA/RA/β-CD and PVA/RA nanofibers during the first 3 weeks as compared to the remaining times. Generally, the peak current signal suggested that the release rate of PVA/RA/β-CD-IC was slower than PVA/RA within the same storage conditions. This slower release rate for the PVA/RA/β-CD-IC nanofibers can be

Experimental conditions: supporting electrolyte acetonitrile with 0.1 M $TBAPF_6$ with a glassy carbon electrode; scan from 0.0 to 0.9 V using an amplitude of 25 mV, step of 4 mV, and frequency of 15 Hz.

attributed to the effective host−guest complex formation between the retinyl acetate and the β-CD.

Since it is known that RA is highly unstable and sensitive to oxidation and light when it is stored without a coating matrix, studies carried out with RA shelf life tests aided in the formation of free-radicals, confirming that it has a short storage time due to subsequent loss of activity.[36,37] In contrast, RA encapsulated into 2-hydroxypropyl-β-CDs was stable for 3

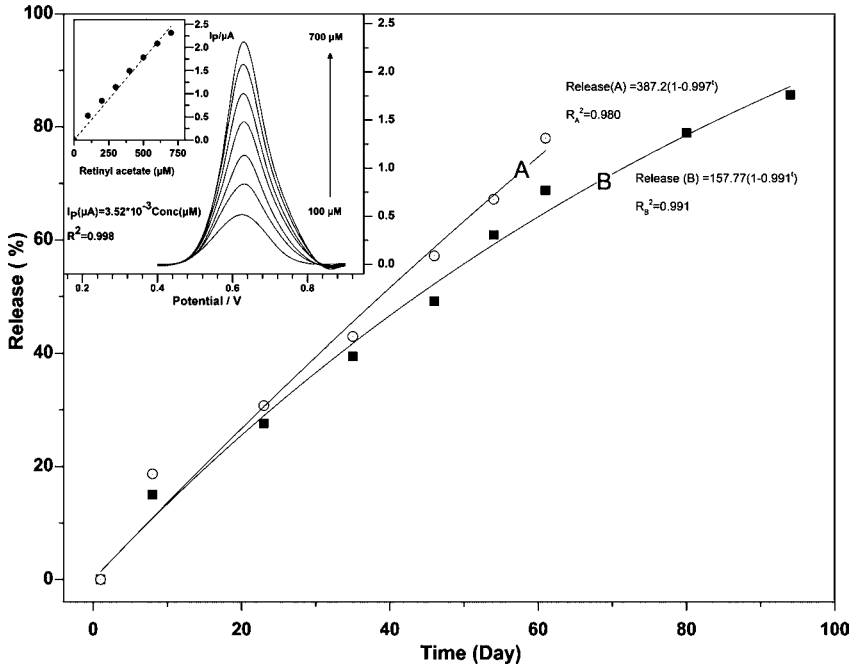

Figure 7. Releasing kinetics monitored by square-wave voltammograms of retinyl acetate in the nanofibers of (A) PVA/RA and (B) PVA/RA/β-CD. Inset: the calibration graph of retinyl acetate and graph equation used to calculate the corresponding concentration signal of retinyl acetate in the electrochemical cell released from nanofibers of PVA/RA and PVA/β-CD/RA. Experimental conditions same as those for Figure 6.

months of storage at room temperature.[38] In addition, RA encapsulated through nanoencapsulation into a polymer poly(ethylene glycol)−4-methoxycinnamoylphthaloylchitosan (PCPLC) increased its stability by 99% from free RA.[5] Similarly, the electrochemical detection results in Figure 7 showed these encapsulations protected RA to extend the shelf life.

These results demonstrate that electrospinning can be used as a method to fabricate nanofibrous structures for encapsulating bioactive retinyl acetate to prolong shelf life and thermal stability. This was achieved by encapsulating retinyl acetate inside the cavity of β-CD within the fibers to improve stabilities over longer time periods. Thus, electrospun nanofibers could be suitable for encapsulating food materials effectively and efficiently for prolonged shelf life and higher temperature stability and may be applicable in other areas such as the pharmaceutical and cosmetics industries, for edible food packaging, encapsulating antioxidants, food colors, flavors, and drugs.

is able to produce by SSF of different agro-industrial byproducts more than 19 types of enzymes (cellulase, pectinase, protease, etc.) and several added-value bioactive products (citric acid, alcohols, etc.).[18] Most of the phenolic compounds occur primarily in conjugated form with one or more sugar residues linked to hydroxyl groups. Association with organic acids, amines, and lipids is also common.[19] These bounded forms of phenolics reduce their ability to function as good antioxidants because the resonance stabilization of free radicals is highly dependent on the availability of free hydroxyl groups on the phenolic rings.[1] The free phenolics can be released from the conjugated form via enzymatic hydrolysis with carbohydrate metabolizing enzymes (such as β-glucosidase) produced by fungi during SSF of lignocellulosic wastes, improving the health functionality of these phytochemicals in this way.[19] Enhancement of phenolic content and antioxidant potential using SSF was reported in cranberry[1] and apple pomaces,[19] pomegranate,[20] and pineapple[21] wastes and different cereals.[22] To our knowledge, there is no data available in the literature about the use of *Sambucus* berry pomaces as support in SSF processes for the production of value-added compounds. The hydrolytic enzyme complex excreted by *Aspergillus niger* in the SSF system, comprising mainly cellulase, pectinase, and protease, can also increase the lipid yields, hydrolyzing the polysaccharides from the seed cell walls and releasing the extra oil from its bounded forms, such as lipoproteins and lipopolysaccharides, which are otherwise nonextractable.[23] Therefore, the objective of the present work was to evaluate the influence of SSF by *A. niger* on phenolic contents and antioxidant activity in *Sambucus nigra* L. and *Sambucus ebulus* L. berry pomaces. Furthermore, the effect of fermentation time on the total fats and major lipid classes (neutral and polar) in bioprocessed substrates was also investigated. This solid-state bioprocessing approach can enhance the functional value of this berry byproduct.

MATERIALS AND METHODS

Chemicals. Folin−Ciocalteu's phenol reagent, gallic acid, sodium carbonate, acetic acid, acetonitrile, methanol, chlorogenic acid, rutin, cyanidin chloride, DPPH (1,1-diphenyl-2 picrylhydrazyl), the lipid standards, and other chemicals (used for the total fat extraction, fractionation, and preparation of fatty acid methyl esters (FAMEs)) were purchased from Sigma-Aldrich (Steinheim, Germany). The thin layer chromatography (TLC) plates (silica gel 60 F254, 20 × 20 cm) were purchased from Merck (Darmstadt, Germany). The FAMEs standard (37 component FAME Mix, SUPELCO) was obtained from Supelco (Bellefonte, PA, U.S.A.).

Raw Material. The freshly pressed berry pomaces were obtained in our laboratory from the fully ripened berries of wild *Sambucus nigra* L. (black or European elderberry) and *Sambucus ebulus* L. (dwarf elder, elderberry, or danewort) collected in September−October of 2013 in the northwest of Transylvania (Romania).

Culture Medium and Fermentation Conditions. The berry press residues of two *Sambucus* species were used as natural substrates for the SSF. The berry pomaces were homogenized with a high-power homogenizer (MICCRA D-9, Germany) and stored at −20 °C prior to use. The substrates were autoclaved for 30 min at 121 °C. The moisture content in the berry pomaces was 60% w/w. The fungal strain of *Aspergillus niger* (ATCC-6275; LGC Standards GmbH, Wesel Germany) was selected as a suitable fungus for solid-state fermentation due to its potential for higher enzyme production. *A. niger* was propagated according to the procedure developed by Oberoi et al.[23] The fungus was maintained on potato dextrose agar (PDA) plates at 4 °C. The culture of *A. niger* was grown on PDA Petri dish and incubated at 30 °C. The fungal spores were collected from the sporulation medium plates, inoculated into sterile distilled water, and stored in the freezer.

Solid-State Fermentation. Fifty grams of solid substrates (pH 5) in 500 mL Erlenmeyer flasks were thoroughly mixed and autoclaved at 121 °C for 30 min. The substrates were inoculated with spore suspension (2×10^7 spores/g of solid). After mixing, the flasks with inoculated substrates were incubated at 30 °C for 6 days. To carry out the chemical characterization, samples were withdrawn at the beginning and every 24 h and stored at −20 °C. The experiment was performed in triplicate. Because the lipid accumulation process in solid−state fermented medium is favored due to the low content of nitrogen or phosphorus sources and an excess of carbon source,[23] in this study, the solid substrates were not supplemented with any extra nutrient solution.

Extraction of Phenolic Compounds. Extraction was performed according to the method described by Veberic et al.[7] with some minor modifications. The samples of berry pomaces (1 g) were extracted with 20 mL of extraction mixture (hydrochloric acid/methanol/water in the ratio of 1:80:19) in an ultrasonic bath for 30 min at 40 °C. The mixtures were centrifuged at 4000*g* for 10 min, and the supernatants were filtered under vacuum through the glass frit. The filtrates were evaporated to dryness under vacuum. The resulting dried extracts were dissolved in methanol and then used for phenolic content and antioxidant activity measurements.

Determination of Total Phenolic Content. The content of total polyphenols (TP) was determined by the Folin−Ciocalteu method[24] using a Synergy HT Multi-Detection Microplate Reader with 96-well plates (BioTek Instruments, Inc., Winooski, VT, U.S.A.). A combination solution consisting of 25 μL sample extract, 125 μL of Folin−Ciocalteu reagent (0.2 N), and 100 μL of sodium carbonate (Na_2CO_3) solution (7.5% w/v) was homogenized and incubated at room temperature (25 °C) in the dark for 2 h. The absorbance was measured at 760 nm against a methanol blank. Gallic acid (0.01−1 mg/mL) was used as a standard, and the content of TP in the extract was expressed as gallic acid equivalents (GAE) in mg/g dry weight (DW) of pomace.

Phenolic Compound Analysis by High-Performance Liquid Chromatography-Diode Array Detection-Electrospray Ionization Mass Spectrometry (HPLC-DAD-ESI MS). An Agilent 1200 HPLC equipped with DAD detector, coupled with MS detector single quadrupole Agilent 6110 was used to confirm and quantify each individual phenolic compound. Separations were carried out using an Eclipse column, XDB C18 (4.6 × 150 mm, particle size 5 μm) (Agilent Technologies, U.S.A.) at 25 °C. All samples were analyzed in triplicate on the basis of the method described by Pop et al.[25] using as mobile phase 0.1% acetic acid/acetonitrile (99:1) in distilled water (v/v) (A) and 0.1% acetic acid in acetonitrile (v/v) (B) and the following gradient: 5% B (0−2 min), 5−40% B (2−18 min), 40−90% B (18−20 min), 90% B (20−24 min), 90−5% B (24−25 min), 5% B (25−30 min). The flow rate was 0.5 mL/min in all separations. For MS fragmentation, the ESI(+) module was applied, with a capillary voltage of 3000 V, at 350 °C and nitrogen flow of 8 L/min. Scan range was 100−1000 *m*/*z*. The eluent was monitored by DAD, and the

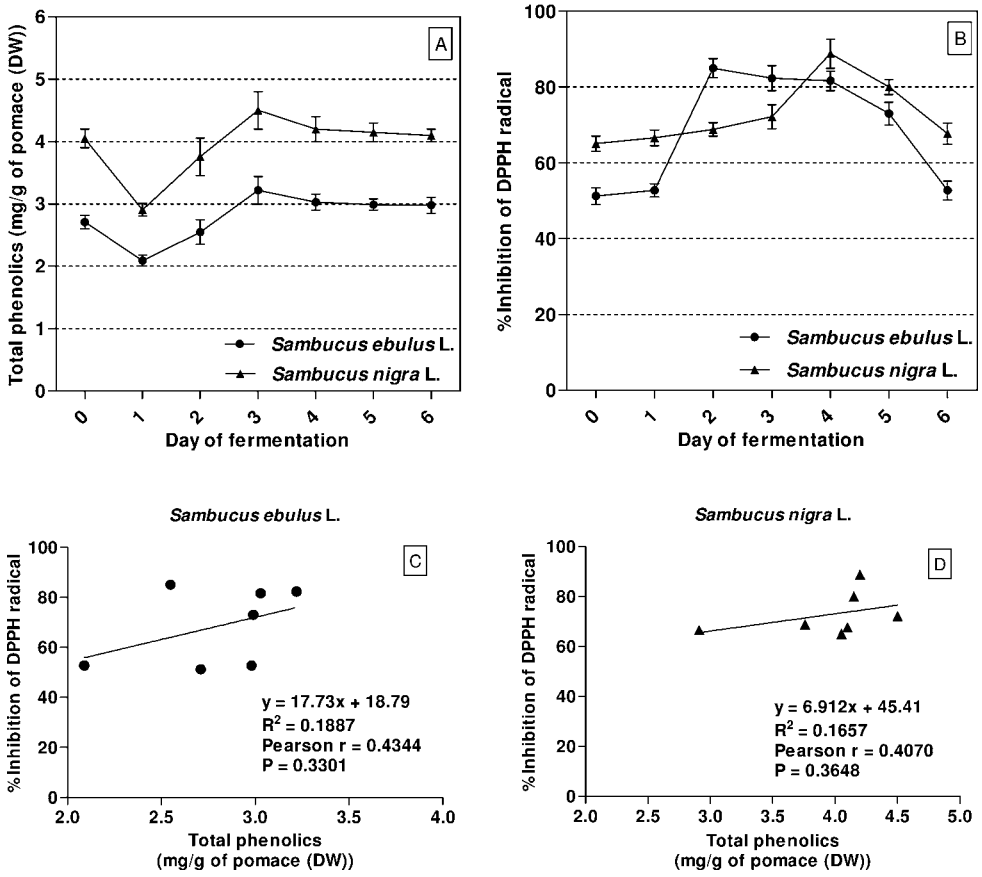

Figure 1. Total phenolic content (A), free radical scavenging activity of phenolics (B) and relationship between radical scavenging capacity (DPPH assay) and total phenolic content (C and D) of extracts from solid state fermented *S. ebulus* L. and *S. nigra* L. pomaces. Values are mean ± SD of three samples, analyzed individually in triplicate ($n = 3 \times 3$).

absorbance spectra (200−600 nm) were collected continuously during the course of each run. The flavonols were detected at 340 nm and the anthocyanins at 520 nm.[25] Data analysis was carried out by Agilent ChemStation Software (Rev B.04.02 SP1, Palo Alto, California, U.S.A.). The identification of the phenolics was made according to UV−visible spectra, retention time, cochromatography with authentic standards (when available), and mass spectra. The identified anthocyanins were quantified using cyanidin chloride as external standard and calculated as equivalents of cyanidin (mg cyanidin/100g dry weight (DW) of the substrate) (r^2 = 0.9935). Using the same quantification procedure, the chlorogenic acid was expressed in mg chlorogenic acid/100g DW of the substrate (r^2 = 0.9937) and quercetins were calculated as equivalents of rutin (mg rutin/100g DW of the substrate) (r^2 = 0.9981).[25]

Determination of the Antioxidant Activity with the DPPH Free Radical Scavenging Method. A method described by Mărghitaş et al.[26] with adaptation on the microplate reader was used to detect the 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical scavenging activity of the examined extracts. Methanol extract (40 μL) was mixed with 200 μL of DPPH solution (0.02 mg/mL) and left to stand 15 min at room temperature and then the absorbance was measured at 517 nm. The percentage inhibition was calculated using the equation:

$$\text{Inhibition (\%)} = [1 - (\text{test sample absorbance/blank sample absorbance})] \times 100$$

Lipid Extraction. Total lipids (TLs) of berry pomaces were extracted from 5 g of samples, using a methanol/chloroform extraction method.[27]

Isolation of Neutral (TAGs, MAGs, 1, 2- and 1, 3-DAGs, FFAs, and SEs) and Polar lipid (PL) Fractions from TLs. Using a previously described method,[16,28,29] the TL extracts were fractionated by TLC into seven fractions. The separated bands (PLs, MAGs, 1, 2- and 1, 3-DAGs and FFAs) were scraped off, and extracted in a solvent mixture of chloroform/methanol (2:1, v/v). The TAG and SE bands were also scraped off and extracted with chloroform. After filtration and solvent evaporation, the dry residues were subjected to transesterification and gas chromatographic (GC) analysis. Trinonadecanoylglycerol (70 μg for TAGs) and nonadecanoic acid (10−50 μg for PLs, MAGs, DAGs, SEs and 200 μg for FFAs) were added as internal standards before the transesterification process.

Analysis of Fatty Acids and Calculation of Lipid Fractions Content in TLs. The isolated lipid fractions were transesterified into FAMEs using the acid-catalyzed method.[16] The FAMEs were analyzed with a gas chromatograph (GC) coupled to a mass spectrometer (MS): PerkinElmer Clarus 600 T GC-MS (PerkinElmer, Inc., Shelton, CT, U.S.A.)[27] on a Supelcowax 10 (60 m × 0.25 mm i.d., 0.25 μm film thickness; Supelco Inc., Bellefonte, PA, U.S.A.) capillary column. The temperature program was set as follows: initial temperature, 140 °C, then to 220 °C at 7 °C/min, and held at 220 °C for 23 min. The injector was set at 210 °C, with a 1:24 split ratio, and 0.5 μL was injected. The column flow rate (He) was 0.8 mL/

The values represent the means of three samples, analyzed individually in triplicate ($n = 3 \times 3$). Totals with different superscript letters ($^{a\text{-}f}$) (within a column for the different *Sambucus* pomaces) were significantly different (repeated measures ANOVA "Tukey's Multiple Comparison Test", $p < 0.05$).

min. The EI (positive ion electron impact) mass spectra were recorded at 70 eV and a trap current of 100 μA with a source temperature of 150 °C. The mass scans were performed within the range of m/z: 22−395 (0.14 scans/s with an intermediate time of 0.02 s between the scans). The FAMEs were identified by comparing the retention times with those of known standards (37 components FAME Mix, Supelco no. 47885-U) and the resulting mass spectra to those in our database (NIST MS Search 2.0). Fatty acids were quantified by comparison to peak areas of the methyl nonadecanoate without application of any correction factor. The fatty acid compositions of lipid fractions were expressed as molar percentages of the fatty acids. The neutral (TAGs, MAGs, 1,2- and 1,3-DAGs, FFAs, and SEs) and polar lipid contents in TLs were calculated using an average molecular weight of fatty acids of the fraction in question and were expressed as weight percentages (wt %) in oils.

Statistical Analysis. All values were expressed as the mean ± standard deviation (SD) of three independent experiments with samples in triplicate. Correlations between the antioxidant activity and total phenolic content were examined using Pearson's correlation. Statistical differences among samples were estimated using Student's t test and ANOVA (repeated measures ANOVA; Tukey's Multiple Comparison Test; GraphPad Prism Version 5.0, Graph Pad Software Inc., San Diego, CA). A probability value of $p < 0.05$ was considered to be statistically significant.

RESULTS AND DISCUSSION

Total Phenolics. During the first 3 days of growth, both *Sambucus* species showed a similar trend, the total phenolics content decreased in the first 24 h and increased until the maximum yield (Day 3) (Figure 1A). Similar results were previously obtained by Correia et al.[21] in the production of phenolics by the solid-state bioconversion of pineapple waste using the *Rhizopus oligosporus*. The rapid fall of the observed measurable phenolics during the early stages of fermentation suggests that the most phenolics were present in bound form and only a small amount was in free soluble- form. However, it should be noted that under the given fermentation conditions the phenolics increased only with 18.82% for *S. ebulus* L. and 11.11% for *S. nigra* L. from initial values of 2.71 mg/g DW and 4.05 mg/g DW for unfermented pomaces to 3.22 mg/g DW and 4.50 mg/g DW for fermented pomaces. Vattem et al.[1] and Ajila et al.[19] reported that polyphenol content increases when the β-glucosidase activity increases, showing that this carbohydrate-cleaving enzyme plays an important role in the bioconversion or liberation of free phenolics from different pomaces during solid-state growth of *Phanerochaete chrysosporium*, *Lentinus edodes* , and *Rhizopus oligosporus*. According to previous studies,[1,21] the low nitrogen content of a media could act as a barrier for free phenolic compounds production. It can be concluded that to improve the TP production, the SSF should be carried out with the solid substrate supplemented with organic or inorganic nitrogen sources. Further investigation is needed. The measurable free phenolics for both berry wastes showed a slight decrease after 3 days of fermentation, probably due to the depletion of the nutrients and to the stress induced on the fungus. As response, it enabled the lignifying and tannin forming peroxidase enzymes in the fungus, causing the polymerization and lignification of the free phenolics and as an consequence, the intensity of the reaction of the molecules with Folin-Ciocalteu reagent decreased.[1] The ranges for obtained phenolic contents are in accordance with literature data,[4] indicating that significant amount of these biomolecules could be extracted from *Sambucus* berry pomaces, compared to whole berry or juice. Ozgen et al.[30] reported in their study on 14 purple- black American elderberry accessions (*Sambucus canadensis* L.) TP content values between 3.30 and 3.90 mg/g fresh weight, whereas Bermúdez-Soto and Tomás-

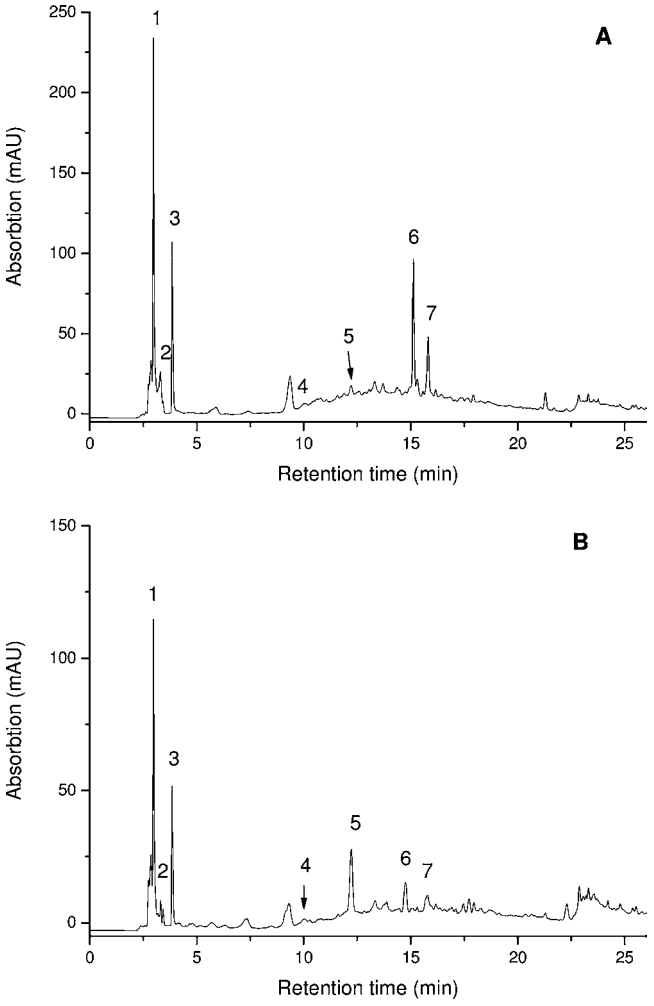

Figure 2. HPLC chromatograms (detected wavelength at 280 nm) of *A. niger* fermented (A) *S. nigra* L. (fourth day of SSF) and (B) *S. ebulus* L. (second day of SSF) berry pomaces: (1) cyanidin 3-sambubioside-5-glucoside; (2) cyanidin 3-sambubioside; (3) cyanidin 3,5-diglucoside; (4) cyanidin 3-glucoside; (5) 5-caffeoylquinic acid; (6) quercetin 3-rutinoside; (7) quercetin 3-glucoside.

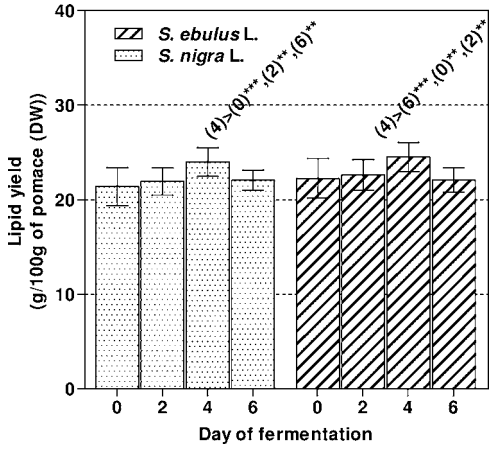

Figure 3. Time course of lipid production by strain *Aspergillus niger* from the *S. ebulus* L. and *S. nigra* L. berry press residues during solid-state fermentation. Results are given as mean ± SD (n = 3); ** p < 0.01, *** p < 0.001 (repeated measures ANOVA "Tukey's Multiple Comparison Test").

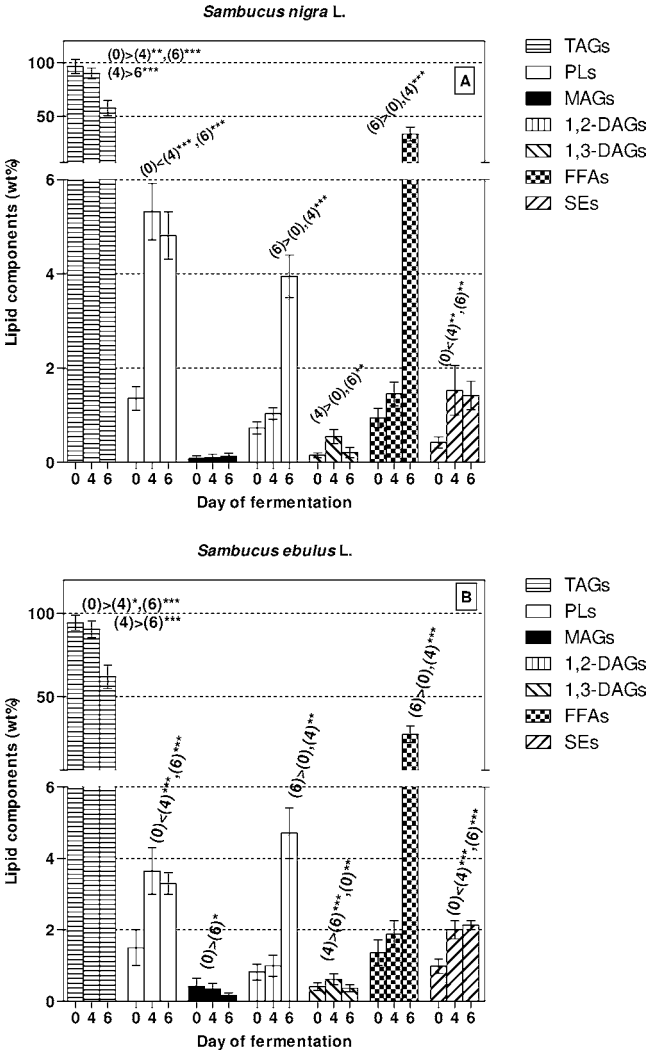

Figure 4. Lipid components in oils from the *S. nigra* L. (A) and *S. ebulus* L. (B) berry press residues during solid-state fermentation. Values are mean ± SD of three samples, analyzed individually in triplicate (n = 3 × 3); * p < 0.05, ** p < 0.01, *** p < 0.001 (repeated measures ANOVA "Tukey's Multiple Comparison Test"). TAGs − triacylglycerols, PL − polar lipids, MAG − monoacylglycerols, DAG − diacylglycerols, FFAs − free fatty acids, SEs − sterol esters.

Barberán[3] determined 30.50 mg/mL of elderberry juice concentrate. The TP amounts for aqueous and methanol extracts of *Sambucus ebulus* L. fruits reported by Ebrahimzadeh et al.[14] were 41.59 and 27.37 mg GAE/g of extract powder, respectively. In their study on anthocyanin and other polyphenolic profiles of different genotypes of *S. canadensis* and *S. nigra* L., Lee and Finn[31] reported TP contents between 277 and 582 mg GAE/100 g berries, depending on the growing seasons and cultivators. It should be mentioned that the phenolic compounds from the *Sambucus* berries coexist with different toxic and allergenic lectins. However, Jimenez et al.[9] showed that the negative effects of these lectins can be eliminated by a short-time heat treatment of berry-derived products, without any significant reduction in the content of the antioxidant compounds.

HPLC-DAD-MS Analysis of Phenolic Compounds. The contents of major phenolics in the berry press residues of two species of *Sambucus* were determined during fermentation (Table 1). The characteristic HPLC chromatograms are shown

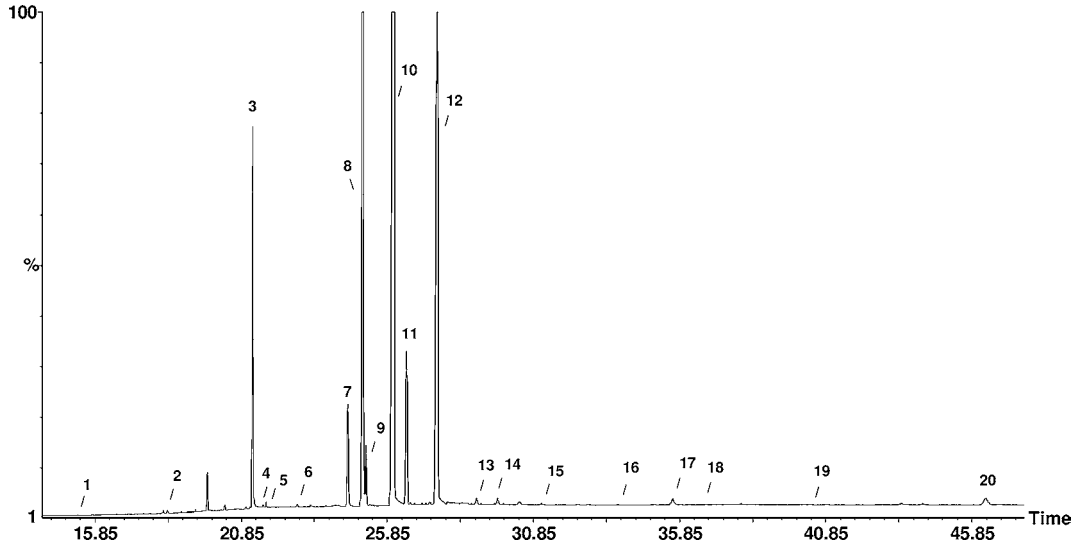

Figure 5. GC-MS chromatogram of FAMEs in the TLs of the *S. ebulus* L. berry pomaces after SSF with *A. niger* (the fourth day) analyzed with a Supelcowax 10 capillary column. Peak identification: (1) lauric (12:0); (2) myristic (14:0); (3) palmitic (16:0); (4) *cis*-7 hexadecenoic (16:1n-9); (5) palmitoleic (16:1n-7); (6) margaric (17:0); (7) stearic (18:0); (8) oleic (18:1n-9); (9) vaccenic (18:1n-7); (10) linoleic (18:2n-6); (11) nonadecanoic (19:0, internal standard); (12) α-linolenic (18:3n-3); (13) arachidic (20:0); (14) 11-eicosenoic (20:1n-9); (15) 11,14-eicosadienoic (20:2n-6); (16) eicosatrienoic (20:3n-3); (17) behenic (22:0); (18) erucic (22:1n-9); (19) tricosanoic (23:0); (20) lignoceric (24:0) acids.

in Figure 2. Both species contained seven dominant polyphenolics; four anthocyanins (cyanidin 3-sambubioside-5-glucoside, cyanidin 3-sambubioside, cyanidin 3,5-diglucoside and cyanidin 3-glucoside), cinnamic acid (chlorogenic acid) and two quercetins (rutin and isoquercitrin). The fruits of *Sambucus* contain an appreciable amount of cyanidin as a diglucoside (sambubioside), which is not common in most berries.[12] The proportion of the individual phenolics differed between species (Table 1). Cyanidin 3-sambubioside-5-glucoside was the major phenolic compound in both residues of the *Sambucus* species. The next predominant polyphenolics in *S. nigra* L. were rutin, isoquercitrin and cyanidin 3, 5-diglucoside, whereas in *S. ebulus* L. the second major phenolic compound was chlorogenic acid (Table 1 and Figure 2). The air-dried elderberries examined by Bridle and Garcia-Viguera[32] also had cyanidin 3-sambubioside-5-glucoside as the major anthocyanin. Our findings concerning the identity and number of quercetins in *S. nigra* L. press- residues match the literature data.[8] Quercetin-based glycosides were the major flavonol glycosides in both processed *Sambucus* residues. The identified flavonols were mostly rutinosides: from 61% (nonfermented) to 71% (the third day of fermentation) of total flavonol glycosides of *S. nigra* L. residues and from 56% (nonfermented) to 58% (the first day of fermentation) of total flavonol glycosides of *S. ebulus* L. residues, while the remainders were conjugated to glucose (Table 1). In most cases berry juice or air-dried, freeze-dried or frozen fruits were analyzed.[3,13,31] To our knowledge this is the first study investigating the variation of the amounts of phenolic compounds in wild-grown *S. nigra* L. and *S. ebulus* L. berry pomaces in correlation to fermentation days in solid-state system by *A. niger*. As shown in Table 1, at the beginning stage of fermentation (0—first day), the levels of all phenolic compounds decreased significantly ($p < 0.05$) (except cyanidin 3, 5-diglucoside from *S. ebulus* L. extract). After 24h, the contents of phenolics increased slightly during the course of SSF by day 3, after which the concentrations of individual polyphenols in both *Sambucus* berry residues decreased significantly ($p < 0.05$). In *S. ebulus* L. pomace extracts the level of cyanidin 3-sambubioside-5-glucoside increased significantly ($p < 0.05$) with 2.46% by day 3 from initial value before gradually decreasing for the remaining period of fermentation. The magnitude of this major anthocyanin change was higher for the *S. nigra* L. pomace, increased with 4.32% in the third before sharply decreasing in the sixth day (Table 1). The increase of the individual phenolic amounts during the first days of fermentation may be explained by the enzymatic release of bound phenolic compounds from the pomaces by means of lignin-degrading peroxidases and carbohydrate-cleaving enzymes expressed by the fungus during the initial stages of growth, to allow penetration of the tissues and the use of available nutrients from residues.[19] The decline of individual phenolic concentrations during the later course of growth could be due to polymerization of the released phenolic compounds. Qin et al.,[33] in their study on polyphenol and purine alkaloid contents during solid-state fermentation of pu-erh tea leaves, reported that most of the flavone glycosides were degraded after bioconversion with *Aspergillus* fungi.

Antioxidant Activity. The ability of phenolic compounds to inhibit DPPH (2,2′-diphenyl-1-picrylhydrazyl) free radical in methanol extracts of two *Sambucus* berry press residues during the course of solid-state bioprocessing was measured, and the results are shown in Figure 1B. In the methanolic extracts of *S. nigra* L. berry press residue the radical inhibition capacity increased by 36.50% by day 4 compared with the initial value (%I = 65) before sharply decreasing for the remaining period of the fungal growth. The increase in the radical inhibition activity was higher for the *S. ebulus* L. pomace, which increased with 66% in the second day versus initial value (%I = 51.20) before gradually decreasing by day 4 (Figure 1B). The literature shows that the antioxidant activity of *Sambucus* berries is mainly connected with the presence of flavonols and anthocyanins.[9,13,15] Moreover, Mandrone et al.[15] have determined a strong correlation between the antioxidant activity of *S. nigra* L. fruits and their cyanidin-3-sambubioside-5-glucoside composition. Phenolic compounds in fruits and their processing wastes have been ascribed important roles. Nontheless, there is

[a]The values represent the means of three samples, analyzed individually in triplicate ($n = 3 \times 3$). TLs − total lipids, TAGs − triacylglycerols, PLs − polar lipids, MAGs − monoacylglycerols, DAGs − diacylglycerols, FFAs − free fatty acids, SEs − sterol esters; SFAs − saturated fatty acids, MUFAs − monounsaturated fatty acids, PUFAs − polyunsaturated fatty acids, VLCSFAs − very long chain saturated fatty acids; tr. − trace. Different superscript letters (^{a,b}) in the same row mean significant differences between TLs of the two fermentation days. $^{*}p < 0.05$. $^{**}p < 0.01$. $^{***}p < 0.001$ (paired *t*-test). C12:0, lauric; C14:0, myristic; C16:0, palmitic; C16:1n-9, *cis*-7 hexadecenoic; C16:1n-7, palmitoleic; C17:0, margaric; C18:0, stearic; C18:1n-9, oleic; C18:1n-7,vaccenic; C18:2n-6, linoleic; C18:3n-3, α-linolenic; C20:0, arachidic; C20:1n-9, 11-eicosenoic; C20:2n-6, 11,14-eicosadienoic; C20:3n-3, eicosatrienoic; C22:0, behenic; C22:1n-9, erucic; C23:0, tricosanoic; C24:0, lignoceric acids.

confusing data about the correlation between antioxidant activity and TP contents. Several authors have reported that a high linear correlation exists between antioxidant potential and TP contents in berries and different pomaces.[12,19] However, on the other hand, some scientific reports also claim that there is a bad correlation between these two parameters,[12,34] which could be explained by the fact that different types of phenolic compounds may contribute differently to total antioxidant capacity of the analyzed plant matrix. The relationships between the free radical scavenging activity (DPPH assay) and total phenolic content of methanolic extracts from SSF *S. ebulus* L. and *S. nigra* L. berry press residues are shown in Figure 1C,D. In both bioprocessed pomaces the radical inhibition capacity of the extracts showed no significant correlations with the total phenolic content (R^2 = 0.1887, p = 0.3301 for *S. ebulus* L. and R^2 = 0.1657, p = 0.3648 for *S. nigra* L., respectively). Our results are in agreement with some earlier reports[1,21] which present weak correlations between these two parameters among different bioprocessed fruit byproducts. Due to the fact that these observations are common in studies that explore the ability of different fungi to produce enhanced levels of phenolic antioxidants, it can be concluded that the SSF process had an effect on the correlation between total phenolic content and the antioxidant potential of the fermented fruit byproducts. The possible explanation for this phenomenon could be that in certain stages of growth of fungi, the amount of the measurable phenolics decreases because of the polymerization of the free phenolics, caused by the stress induced on the fungus. Vattem et al.[1] and Di Majo et al.[34] claim that the inhibition of the free radicals tends to increase along with the order of polymerization.

Lipid Accumulation in SSF of the *S. ebulus* L. and *S. nigra* L. Berry Press Residues by *A. niger*. The lipid recovery for both the *Sambucus* berry press residues showed a similar trend (Figure 3). After a significant increase ($p < 0.05$) until day 4, there was a slight but statistically significant decrease ($p < 0.05$) in the TL content for the remaining days of fermentation. The extracted lipids increased with 12% for *S. nigra* L., and 10.50% for *S. ebulus* L. compared with initial values of 21.41g/100 g DW and 22.20 g/100 g DW of unfermented pomaces to the maximum amounts of 24 g/100 g DW and 24.53 g/100 g DW of fermented pomaces. The literature shows that the enzyme consortia (cellulase, pectinase, protease, etc.) secretion of the strains has a considerable impact on lipid yield, and a strong correlation between these two parameters was found. The enzyme productivity by *A. niger* is a function of culture conditions (temperature, pH, culture medium conditions), amount of available carbon source (glucose, cellulose, hemicellulose, pectin, etc.), and C/N ratio.[23,35] Previous research conducted on hydrolytic enzyme production by *A. niger* in SSF of different agro-residues have shown maximum cellulase and protease activities after 72 or 96 h,[23,36] when the enzyme secretion had almost stabilized or decreased. These observations are consistent with our results regarding the dynamics of the oil yields from Figure 3, with the maximum lipid amounts in day 4. At the early fermentation stage, fungi consume the readily available sugars (particularly glucose) and secrete hydrolytic enzymes; when the level of sugar monomer is too low, the strains start to use these enzymes to produce available sugars, resulting in a decrease of enzyme activity and lipid yield.[23] Oberoi et al.[23] used different crude enzyme extracts to improve the oil recovery from mustard seeds and reported that about 7% more oil was recovered when seeds were pretreated with enzyme consortium obtained from the individual culture of *A. niger*.

Neutral (TAGs, MAGs, 1,2- and 1,3-DAGs, FFAs, and SEs) and Polar Lipid (PL) Contents of Oils from the Solid-State Fermented Pomaces. Profiles of the different lipid classes in the oils of the SSF *S. ebulus* L. and *S. nigra* L. berry press residues are presented in Figure 4. The results showed that the major lipid fraction from SSF products (days 4 and 6) was TAG, constituting about 90−94% of the fermented berry-waste oils obtained in the early stages of fungal growth (within 4 days) and about 57−62% of the oils in the sixth day of fermentation. It should be noted that the proportions of FFAs increased significantly ($p < 0.05$) after the fourth day, from average values of 1.50% (*S. nigra* L.) and 1.90% (*S. ebulus* L.) to averages of 32% (*S. nigra* L.) and 27.50% (*S. ebulus* L.) of the total extracted lipids in the sixth day of SSF. The quality of the vegetable fat extracted from pomaces depends not only on the fatty acid composition but also on its lipid profile.[16] Due to the presence of lipase in the culture medium, TAGs are hydrolyzed to FFAs and DAGs or MAGs. A high amount of FFAs indicates a low quality of the oil. Accumulation of this lipid fraction in fats leads to an unacceptable flavor, which can be prevented by inactivation of the enzymes involved in the lipid degradation.[23] Among microorganisms, fungi are extensively recognized as the best lipase sources and are widely used in the food industry. It was reported that the lipase activity is induced by the presence of lipids in the medium.[37] The same authors had observed that in SSF system the lipase production by *Aspergillus niger* was partially associated with the fungal growth, the synthesis of this enzyme starting after the second day of fermentation. It is interesting to note that along fermentation processes, statistically significant ($p < 0.05$) increases (3-fold for *S. nigra* L. and around 2-fold for *S. ebulus* L.) in proportions of SEs were observed (Figure 5). These positive changes can be attributed to the ability of the *Aspergillus* strains to synthesize SEs. According to the study of Tőke et al.,[38] the filamentous fungi (especially *Aspergillus* spp.), in addition to their lipase production capacity, could produce significant amounts of sterol esterases under SSF conditions, enzymes able to efficiently catalyze the synthesis of sterol esters from phytosterols and free fatty acids. The free phytosterols and their esterified forms are known to reduce the cholesterol level in blood.[39] However, the sterol esters are generally preferred in the food and nutraceutical industry because of their better fat-solubility and compatibility.[38] Finally, analysis of the various lipid fractions demonstrated that the percentages of PLs also tends to increase (around 4-fold for *S. nigra* L. and more than 2-fold for *S. ebulus* L.) during fermentation processes (Figure 1 (A)). This observation is consistent with experimental data provided by Oliveira et al.[40] showing that in oleaginous microorganisms, during lipid turnover phase (which starts when the culture media is depleted of the carbon source), neutral lipid fraction (mainly composed of TAGs) are preferentially degraded, while significant amounts of membranar polar lipids are synthesized.

TLs Fatty Acid Compositions and Their Lipid Classes Obtained through Solid-State Fermented Products. The GC-MS analysis (results presented inTables 2 and 3) showed that the major fatty acid compositions of TLs from the solid-state fermented pomaces (day 4) were linoleic acid (C18:2n-6, 45.19% in *S. ebulus* L. and 38.25% in *S. nigra* L.), α-linolenic acid (C18:3n-3, 23.34% in *S. ebulus* L. and 35.59% in *S. nigra* L.), oleic acid (C18:1n-9, 23.30% in *S. ebulus* L. and 16.92% in

S. nigra L.) and palmitic acid (C16:0, 6.02% in *S. ebulus* L. and 6.88% in *S. nigra* L.) (Figure 5). The fermentation resulted in a slight increase of the linoleic (C18:2n-6) and oleic (C18:1n-9) acids levels (43.11% and 20.22% in *S. ebulus* L. and 37.16% and 14.28% in *S. nigra* L. unfermented pomaces, respectively). These results are in line with earlier findings showing that strains of *Aspergillus* produce lipids with significant amounts of oleic and linoleic acids.[41,42] As shown in Tables 2 and 3, statistically significant differences ($p < 0.05$) were found between the proportions of fatty acid classes of investigated TLs, extracted from *Sambucus* wastes before and after fermentation. Substantial decreases in the contents of saturated fatty acids (SFAs) were observed for both fermented residues (from 11.47% to 7.56% in *S. ebulus* L., and from 11.40% to 8.33% in *S. nigra* L., respectively). The differences were also statistically significant ($p < 0.05$) for the content of mono- (MUFAs) and polyunsaturated fatty acids (PUFAs), the average proportions in fermented substrates being slightly higher than those in the unfermented raw materials (Tables 2 and 3). The elevated levels of PUFAs from TLs of fermented berry press residues (68.53% in *S. ebulus* L. and 73.90% in *S. nigra* L.) determined in the present study are comparable to those of PUFA-rich vegetable oils, such as grape seed, sunflower, linseed, blackcurrant seed, safflower, and hemp seed oils.[43] The results also showed that the TLs of both bioprocessed wastes are characterized by high levels of PUFAs/SFAs (8.87−9.07) and low levels of n-6/n-3-PUFAs (1.08−1.94) ratios. Due to their high linoleic and α-linolenic acid contents, the unsaturated fats are more susceptible to the oxidation process.[16] The values of n-6/n-3 ratios reported in this study are close to the optimal range for human health (2/1−4/1), suggested by the nutritional scientists.[44] The profiles of fatty acids in TAGs were practically identical to the profiles of the TLs, with the same dominating fatty acids in both solid-state fermented pomaces (Tables 2 and 3). The fatty acid composition of all minor lipid classes was somehow affected by the fermentation period. The PL fractions of SSF berry wastes were poorer in palmitic (C16:0), oleic (C18:1n-9), and linoleic (C18:2n-6) acids and much richer in stearic (C18:0) and α-linolenic acids (C18:3n-3) compared with the unfermented pomaces (Tables 2 and 3). This enrichment process of PLs with n-3 PUFAs could be attributed to phospholipases produced by *Aspergillus* strains. In addition to the crucial role in the metabolism and biosynthesis of PLs, these enzymes are able to produce particular PLs or create novel molecular species of PLs with added-value characteristics (such as PLs esterified with n-3 fatty acids).[45] From the health point of view, the n-3 PUFAs have been shown to reduce the risk of coronary diseases and may be useful in the prevention and treatment of hypertension.[46] Moreover, in humans, α-linolenic acid can be converted to other biologically active PUFAs (eicosapentaenoic and docosahexaenoic acids) by a series of desaturation and elongation reactions.[47] All minor neutral lipid (NL) fractions (SEs, FFAs, MAGs, 1, 2- and 1, 3- DAGs) were highly unsaturated (Tables 1 and 2). In general, the fermentation process decreased SFAs, while unsaturated fatty acids (MUFAs + PUFAs) increased. Due to their nonionic molecular structures (with both hydrophilic and hydrophobic parts) MAGs and DAGs show excellent emulsifying properties, being successfully used in the food, cosmetic and pharmaceutical industries.[48] Moreover, DAGs play a significant role in the prevention of body fat accumulation and diseases associated with obesity. For this reason, they are considered as functional ingredients.[49] The SEs exhibited significantly higher SFA levels (38.13% in *S. nigra* L. and 46.93% in *S. ebulus* L.) than the other four NL fractions in fermented samples, because of the dominance of palmitic acid (C16:0) in their structures. Furthermore, it was observed that by the SSF process, the SE fractions were enriched in n-3 and n-6 essential fatty acids. The levels of n-3 PUFAs increased with 48% (in *S. nigra* L.) and 77% (in *S. ebulus* L.), while the amounts of n-6 PUFAs increased with 40% (in *S. nigra* L.) and 95% (in *S. ebulus* L.), respectively. A comprehensive study of 91 patients tested the benefit of omega-3 plant sterol esters (n-3-PSE) on lipid profile and other cardiovascular disease risk factors in subjects with mixed hyperlipidemia.[50] The study showed that n-3-PSE treatment decreased the serum triglyceride concentrations significantly (by 19%) without adversely affecting the plasma low-density lipoprotein cholesterol levels in mixed hyperlipidemic patients, after a 12 week intervention period.

This global characterization may potentially provide the basis for a sustainable integrated process of *Sambucus* berry pomaces exploitation as potential, inexpensive, and easily available sources of bioactive phytochemicals for the pharmaceutical and food industries.

were expressed in δ (ppm) referring to the solvent residual peaks at δ_H 2.05, δ_C 29.8 for acetone-d_6, and coupling constants in Hertz. Silica gel (200−300 mesh) for column chromatography was purchased from the Qingdao Marine Chemical Company (Qingdao, China). Preparative high-speed counter-current chromatography (HSCCC) was performed on a TBE-300B instrument (Tauto Biotech, Shanghai, China) equipped with three preparative coils, a polytetrafluoroethylene tube (2.6 mm in diameter and total volume of 280 mL), and a 20 mL sample loop. The separation was carried out at 25 °C using a two-phase solvent system at flow rate of 3.0 mL/min, revolution speed of 900 rpm, and detection wavelength at 280 nm. Semipreparative high-performance liquid chromatography (HPLC) separation was carried out on a Lumtech instrument (Lumiere Tech. Ltd., Beijing, China) equipped with a K-501 pump (flow rate: 3 mL/min) and a K-2501 UV detector (detection was set at 280 nm) using a Luna-C18 column (250 mm × 10 mm i.d., 5 μm, Phenomenex Inc., Torrance, California). A BioTek PowerWave HT microplate spectrophotometer (BioTek Instruments Inc., Winooski, Vermont) was employed to measure the light absorption value.

Fungal Material. The pathogenic fungus *U. virens* UV-2 was kindly provided by Prof. Zhiyi Chen (Institute of Plant Protection, Jiangsu Academy of Agricultural Sciences, China). This fungus was isolated from the smut balls grown on the rice panicles collected in a paddy field of Jiangsu Province of China in the fall of 2008. A voucher specimen has been deposited in Prof. Chen's laboratory.

Fermentation, Extraction, and Isolation. The fungus *U. virens* UV-2 was grown on PDA (potato 200 g/L, dextrose 20 g/L, and agar 20 g/L) medium in Petri dishes at 28 °C for 8 days. Then, three agar plugs (0.5 cm × 0.5 cm) containing mycelia were added into a 1000 mL Erlenmeyer flask containing 300 mL of potato dextrose broth (potato 200 g/L, and dextrose 20 g/L) under aseptic condition and incubated at 28 °C in the dark for 7 days on a rotary shaker (150 rpm). This liquid culture was subsequently used to inoculate the solid rice medium, which was composed of rice and deionized water in a ratio of 1.0:1.1 (w/w) and autoclaved at 120 °C for 30 min before use. The fermentation was carried out in 50 1000 mL Erlenmeyer flasks each containing 100 g of rice and 110 mL of water, and incubated at 28 °C for about 2 months before harvest.

The moldy rice was collected and extracted with EtOAc at room temperature for 24 h (five times). The EtOAc extract was concentrated under vacuum at 38 °C on a rotatory evaporator to give a brownish residue (200 g). The crude extract was chromatographed over silica gel eluting with CH_2Cl_2:MeOH (9:1, v/v) to give four fractions (Fr. A−D). Fraction B (20 g) was repeatedly separated by preparative HSCCC using a two-phase solvent of petroleum ether−EtOAc−methanol−water (containing 0.01% oxalic acid) (5.0:5.0:6.5:4.5, v/v/v/v) to yield seven subfractions (Fr. B-1−B-7).

Fractions B-1−B-3, and B-5−B-7 were each purified by semi-preparative HPLC using MeOH-H_2O (0.01% oxalic acid) (80:20, v/v) as mobile phase to yield ustilaginoidin A, **8**, (1.3 mg, t_R 21.0 min) from Fr. B-1; ustilaginoidin G, **12**, (4.2 mg, t_R 10.0 min) from Fr. B-2; ustilaginoidin F, **11** (7.2 mg, t_R 13.0 min), ustilaginoidin P, **6** (0.8 mg, t_R 24.6 min), and ustilaginoidin L, **2** (5.5 mg, t_R 28.6 min) from Fr. B-3; ustilaginoidin E, **10**, (20.1 mg, t_R 23.0 min) from Fr. B-5; isochaetochromin B_2, **13** (3.5 mg, t_R 20.0 min), and ustilaginoidin M, **3** (27.9 mg, t_R 23.9 min), from Fr. B-6; and ustilaginoidin D, **9**, (46 mg, t_R 20.0 min) from Fr. B-7. Similarly, ustilaginoidin E_1, **7** (2.8 mg, t_R 18.0 min), ustilaginoidin O, **5** (7.2 mg, t_R 21.5 min), ustilaginoidin N, **4** (26.3 mg, t_R 23.0 min), and ustilaginoidin K, **1**, (1.6 mg, t_R 27.0 min) were isolated from Fr. B-4 by HPLC eluting with MeOH−H_2O (0.01% oxalic acid) (75:25, v/v).

Ustilaginoidin K, 1. Red amorphous powder; [α]20 D −46.7 (*c* 0.03, DMSO); UV (DMSO) λ_{max} (log ε) 281 (5.29), 295 (5.34), 329 (4.45), 424 (4.56) nm; CD (DMSO) 266 ($\Delta\varepsilon$ +62.13), 294.5 ($\Delta\varepsilon$ −72.43), 354 ($\Delta\varepsilon$ +8.26), 441 ($\Delta\varepsilon$ +1.16) nm; IR ν_{max} 3373, 2925, 2854, 1645, 1611, 1468, 1418, 1365, 1207, 1185, 1140, 1090, 839 cm^{-1}; ^1H NMR (CD_3COCD_3, 600 MHz) and ^{13}C NMR (CD_3COCD_3, 150 MHz) data, see Tables 1 and 2; HRESIMS *m/z* 541.11288 $[M-H]^-$ (calcd for $C_{30}H_{21}O_{10}$, 541.11402).

Ustilaginoidin E$_1$, **7**. Yellow amorphous powder; [α]20 D −51.7 (*c* 0.03, DMSO); UV (DMSO) λ_{max} (log ε): 263 (4.73), 297 (5.06), 331 (4.58), 420 (4.53); CD (DMSO) 265.5 (Δε +52.42), 293.5 (Δε −52.65), 341 (Δε +3.82), 420.5 (Δε +0.78) nm; IR ν_{max} 3734, 3382, 2923, 1682, 1633, 1547, 1454, 1384, 1341, 1206, 1143, 1028, 996, 843, 802 cm^{-1}; ^1H NMR (CD_3COCD_3, 600 MHz) and ^{13}C NMR (CD_3COCD_3, 150 MHz) data, see Tables 1 and 2; HRESIMS *m*/*z* 531.12883 $[M-H]^-$ (calcd for $C_{29}H_{23}O_{10}$, 531.12967).

Antibacterial Assay. The antibacterial activities of the isolated compounds were evaluated against the plant/human pathogenic bacteria *Bacillus subtilis* ATCC 11562, *Staphylococcus hemolyticus* ATCC 29970, *Ralstonia solanacearum* ATCC11696, *Xanthomonas vesicatoria* ATCC 11633, *Agrobacterium tumefaciens* ATCC 11158, and *Pseudomonas lachrymans* ATCC 11921. Streptomycin sulfate was used as the positive control. The minimum inhibitory concentrations (MICs) and median inhibitory concentrations (IC_{50} values) of the tested substances were determined in sterile 96-well plates by the modified broth dilution-colorimetric assay.[30,31]

Cytotoxic Assay. Cytotoxicity was tested against five human carcinoma cell lines, including colon cancer cells (HCT-116), liver hepatocellular carcinoma cells (HepG2), gastric cancer cells (BGC-823),

DOI: 10.1021/acs.jafc.5b00694
J. Agric. Food Chem. 2015, 63, 3501−3508

nonsmall-cell lung carcinoma cells (NCI-H1650), and ovarian cancer cells (A2780), using the microculture tetrazolium (MTT) assay as described previously.[32] Taxol was used as the positive control, which showed inhibition on these cell lines with IC_{50} values of 3.0×10^{-2}, 1.2×10^{-2}, 4.1×10^{-3}, 3.6×10^{-2}, and 6.1×10^{-3} μM, respectively.

Inhibitory Activity Assay on the Radicle Elongation of Rice Seeds. The isolated compounds were evaluated for their inhibitory activities on the radicle elongation of rice (*Oryza sativa*) seeds. The seeds of two rice varieties (Lijiang, and Zhonghua 11), by courtesy of Prof. Zejian Guo (Department of Plant Pathology, China Agricultural University), were used.

The bioassay was performed using the method described by Aliferis and Jabaji[33] with some modifications. Five three-day-germinated rice seeds of each rice variety were sown directly onto the well containing 200 μL of working solution in a 24-well plate. The pure compounds were evaluated at 50, 100, 200, and 400 μg/mL dissolved in sterile distilled water containing a final concentration of 2.5% DMSO. The 2.5% DMSO in distilled water was used as the negative control and glyphosate (*N*-(phosphonomethyl)glycine) at 50, 100, 200, and 400 μg/mL as the positive control. Three replicates were used for each treatment. Plates were incubated in a moist chamber at 25 °C in the dark. The length of each root was measured after treatment for 48 h. The inhibition of radicle elongation was calculated as follows: Inhibition (%) = $[(Lc - Lt)/Lc] \times 100$, where Lc is the root length of the control group, and Lt is that of the treated.

All the experiments were repeated three times, and the results were expressed by their mean values and the standard deviations (SD). The data were submitted to analysis of variance to detect significant differences by PROC ANOVA of SAS (version 8.2). The term significant has been used to denote the differences for which $p \leq 0.05$.

RESULTS AND DISCUSSION

Column chromatography of the fungal extract, followed by HSCCC and HPLC purification, has led to the isolation of 13 ustilaginoidins, **1**–**13** (Figure 1).

Ustilaginoidin K, **1**, was isolated as a red amorphous powder. It showed a prominent pseudomolecular peak at m/z 541.11288 $[M\text{-}H]^-$ in the negative mode of HRESIMS, indicating its molecular formula as $C_{30}H_{22}O_{10}$. The UV spectrum showed maximal absorptions at 281, 295, 329, and 424 nm, which was similar to those of ustilaginoidin A, **8**,[4,6] suggesting the presence of a similar chromophore in **1**. The IR spectrum indicated the presence of hydroxyl group (3373 cm^{-1}), conjugated carbonyl group (1645 cm^{-1}), and aromatic double bond (1611 cm^{-1}). The ^{13}C NMR spectrum of **1** exhibited a total of 15 carbon signals including one carbonyl (δ_C 184.0), 12 sp^2-hybridized carbons, of which two methine carbons (δ_C 100.8, 99.3), five oxygenated quaternary carbons, and five nonoxygenated quaternary carbons were assigned, and two methyl groups (δ_C 18.6, 8.9). The ^1H NMR spectrum showed the presence of two aromatic protons (δ_H 6.50 and 6.34, each s) and two olefinic methyl groups (δ_H 2.23 and 2.02, each s). Taking into consideration of the molecular formula, **1** should have a symmetric structure. Comparison of the NMR data (Tables 1 and 2) with those of ustilaginoidin A, **8**,[6] which was also a symmetric dimer of naphtho-γ-pyrone, revealed their great similarities. However, the signal for the olefinic proton of the γ-pyrone ring in **8** was missing, whereas an additional olefinic methyl group (δ_H 2.02, s; δ_C 8.9) was present in **1**, which suggests that a methyl group was substituted at C-3/C-3′ of the γ-pyrone ring. This was corroborated by analysis of the HMBC spectrum (Figure 2), as correlations were seen from 2/2′-CH_3 (δ_H 2.23, s) to C-2/2′ (δ_C 166.2) and C-3/3′ (δ_C 113.3) and from 3/3′-CH_3 (δ_H 2.02) to C-2/2′, C-3/3′, and C-4/4′ (δ_C 184.0). Thus, compound **1** was established as 3,3′-dimethyl derivative of ustilaginoidin A.

Ustilaginoidin L, **2**, was isolated as an orange amorphous powder. It showed similar UV and IR absorptions to those of **1**,

J. Agric. Food Chem. 2015, 63, 3501−3508

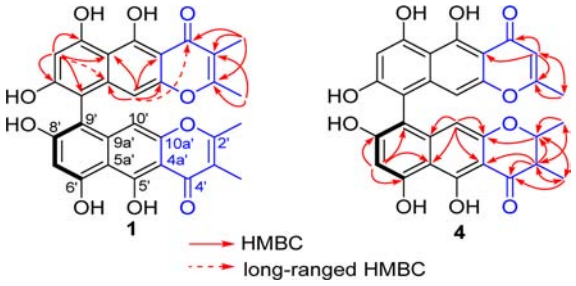

Figure 2. Selected HMBC (H → C) correlations of **1** and **4**.

indicating that **2** was a congener of **1**. The molecular formula of **2** was determined as $C_{29}H_{20}O_{10}$ by HRESIMS, containing one less CH_2 unit than that of **1**. In the ^{1}H NMR spectrum, four aromatic protons assignable to H-7 (δ_H 6.52, s), H-7′ (δ_H 6.50, s), H-10 (δ_H 6.38, s), and H-10′ (δ_H 6.33, s) were observed, suggesting the asymmetric nature of **2**. In addition, one olefinic proton resonated at δ_H 6.12 (s) and three olefinic methyl groups at δ_H 2.28, 2.26, and 2.03 (each s) were seen. Taking into consideration of the aforementioned data and the chemical shifts of the olefinic methine (δ_H 6.12, s; δ_C 106.6, CH) suggested that the methyl group at C-3 of **1** was replaced by that of a proton in **2**. This was confirmed by analysis of the HMBC spectrum, in which the correlations from 2-CH_3 (δ_H 2.26, s) to C-2 (δ_C 170.9, C) and the methine carbon (δ_C 106.6, C-3) were found. Thus, ustilaginoidin L, **2**, was a demethylated derivative of ustilaginoidin K, **1**.

The molecular formula of ustilaginoidin M, **3**, was established as $C_{30}H_{24}O_{10}$, bearing 2H more than that of **1**. The NMR data of **3** (Tables 1 and 2) comprised two sets of signals, each assignable to one naphtho-γ-pyrone moiety. Among them, one set of the signals was almost superimposable on that of ustilaginoidin K, **1**, while the other one was different from that of **1** in the γ-pyrone part, in which signals ascribed to a nonconjugated carbonyl group (δ_C 201.7, C), two methine groups (δ_H 3.95 (dq)/δ_C 78.8; δ_H 2.74 (dq)/δ_C 46.7), and two methyl groups (δ_H 1.33 (d)/δ_C 19.6; δ_H 1.24 (d)/δ_C 9.7) were discerned, indicating the presence of a 2,3-dimethyl-2,3-dihydro-γ-pyrone ring in **3**. The large coupling constant (11.0 Hz) between the two methine protons (H-2′ and H-3′) suggested the *trans* orientation of the 2′-CH_3 and 3′-CH_3 in the dihydro-γ-pyrone ring.[6] Thus, compound **3** was a dihydro derivative of ustilaginoidin K, **1**, as depicted in Figure 1. From a structural point of view, **3** was composed of one-half of ustilaginoidin K, **1**, and one-half of ustilaginoidin D, **9**.[6]

Ustilaginoidin N, **4**, was isolated as a congener of compound **3**. The molecular formula of **4** was $C_{29}H_{22}O_{10}$ as determined by HR-ESI−MS, which contained a CH_2 less than that of **3**. Inspection of the NMR data (Tables 1 and 2) suggested that both compounds were similar, except that the signal for one olefinic methyl group in **3** was replaced by that of an olefinic proton (δ_H 6.10, s) in **4**. The chemical shift of this proton together with its attached carbon (δ_C 106.6) as revealed by HSQC experiment, which indicated that the C-3 methyl group in **3** was replaced by a hydrogen atom in **4**. This conclusion was secured by the observed HMBC correlations from H-3 (δ_H 6.10, s) to C-2 (δ_C 170.9, C), 2- CH_3 (δ_C 20.6, CH_3), C-4 (δ_C 184.7, C), and C-4a (δ_C 102.8, C) (Figure 2). Therefore, ustilaginoidin N, **4**, was determined as the 3-desmethyl derivative of ustilaginoidin M, **3**.

Ustilaginoidin O, **5**, was isolated as an orange amorphous powder whose molecular formula was determined as $C_{29}H_{22}O_{10}$ by analysis of the pseudomolecular ion peak at m/z 529.11209 $[M-H]^-$ in the HRESIMS spectrum. The UV, IR, and NMR data of **5** were similar to those of ustilaginoidin G, **12**,[6] indicating it to be an ustilaginoidin-type compound. However, their NMR data differed in the γ-pyrone part. In the ^{1}H NMR spectrum of **5**, signals were observed for two olefinic methyl groups (δ_H 2.28, 1.99, each s), while those for the olefinic proton, as reported in ustilaginoidin G, **12**, were missing. This indicated that the olefinic proton (H-3′) of the γ-pyrone ring in ustilaginoidin G, **12**, was replaced by a 3′-methyl group in that of **5**. Therefore, compound **5** was elucidated as 3′-methylustilaginoidin G.

Ustilaginoidin P, **6**, was isolated as a minor compound, which had a same molecular formula as that of ustilaginoidin N, **4**. The NMR data of **6** resembled those of **4**, and both showed signals for a 2,3-dimethyl-2,3-dihydropyran-4-one and a 2-methyl-pyran-4-one moiety (Tables 1 and 2). However, the NMR data for the 2,3-dimethyl-2,3-dihydropyran-4-one ring in both compounds were notably different. H-2′ (δ_H 4.53, dq) of **6** significantly shifted to downfield compared to that of **4** (δ_H 4.06, dq), while large chemical shift differences between both compounds were observed at C-2′ (−2.6 ppm), C-3′ (−1.8 ppm), 2′-CH_3(−3.2 ppm), and C-4′ (+1.9 ppm). Thus, the stereochemistry of C-2′ in **6** should be different from that of **4**, that is to say, H-2′ and H-3′ were *cis*-configured in **6**, which was consistent with the observed small coupling constant (3.0 Hz)[6] between both protons. Therefore, ustilaginoidin P, **6**, was determined to be a 2′-epimer of ustilaginoidin N, **4**.

The new compound, ustilaginoidin E_1, **7**, was isolated as an isomer of ustilaginoidin E, **10**.[6] Both compounds showed nearly identical UV, IR, and MS spectra and similar NMR data. The differences were ascribed to the 2,3-dihydro-pyran-4-one ring, in which the vicinal methyl groups were *cis* oriented ($J_{H\text{-}2',\ H\text{-}3'}$= 3.2 Hz) in **7**, not like those of the *trans* isomer ($J_{H\text{-}2',\ H\text{-}3'}$ = 10.4 Hz) in ustilaginoidin E, **10**.[6] Furthermore, the NMR data of **7** were almost superimposable on those of **6** regarding the 2,3-dimethyl-2,3-dihydro-γ-pyrone ring located in the lower half of the molecule. Thus, ustilaginoidin E_1, **7**, was an epimer of ustilaginoidin E and also a dihydro derivative of ustilaginoidin P, **6**.

The absolute configuration of the 9/9′ axis of the new ustilaginoidins, **1**−**7**, was determined as *R* by comparing the CD spectra with the literature,[8] as these compounds all exhibited strong negative first (294 nm) and positive second (266 nm) Cotton effects. However, the absolute configuration of the chiral centers of the 2,3-dihydro-pyran-4-one ring in compounds **3**−**7** remains to be determined. This would require X-ray crystallographic analysis; however, no suitable crystals were obtained after several attempts to crystallize these metabolites in different solvent systems, which was not so surprising as until now, only the X-ray analysis of the 6-*O*-*p*-bromobenzoate of the 5,5′,6′,8,8′-pentamethyl ether of chaetochromin A has been reported.[8]

The known compounds were identified by comparison of the specific optical rotation, CD, NMR, and HRESIMS data with those reported in literature and included ustilaginoidin A, **8**,[4,6] ustilaginoidin D, **9**,[6] ustilaginoidin E, **10**,[6] ustilaginoidin F, **11**,[6] ustilaginoidin G, **12**,[6] and isochaetochromin B_2, **13**.[14]

Interestingly, all the isolated bis-naphtho-γ-prones from the cultured *U. virens* in the present study have a *R* configuration of the 9,9′-axis, and they only differed in the γ-pyrone ring, which was either a pyran-4-one or a 2,3-dihydropyran-4-one ring substituted with one or two methyl groups. In addition to

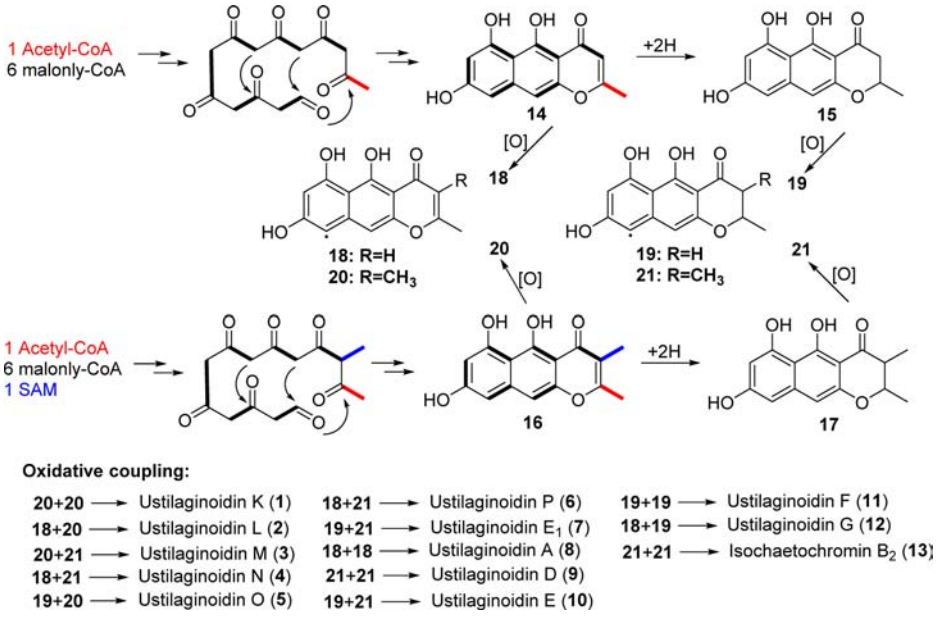

Figure 3. A plausible biosynthetic route for compounds **1**−**13**.

these structural types, some other analogues, such as ustilaginoidins B, C, H, I, and J, containing one or two hydroxymethyl groups at C-2 of the γ-pyrone rings, were reported from the extracts of rice false smut balls,[4−6] indicating a further oxidative reaction occurred in natural environment.

A hypothetical biosynthetic pathway for the isolated bis-naphtho-γ-pyrones was proposed (Figure 3). These metabolites should be dimers of heptaketides, by analogized with that of chaetochromin A,[34] a diastereomer of ustilaginoidin D. The condensation of one acetyl-CoA and six malonyl-CoA units, followed by cyclization, could form the heptaketide norrubrofusarin, **14**,[35] which could further undergo reduction to give its dihydro derivative, **15**. Similarly, the condensation of one acetyl-CoA, six malonyl-CoA, and one methyl unit donated by *S*-adenosylmethionine (SAM) would yield the other heptaketide, **16**, which could be further reduced to form its dihydro derivative, **17**. These heptaketide derivatives could be oxidized to give its corresponding radical intermediates, **18**, **19**, **20**, and **21**. The oxidative coupling of these monomeric naphtho-γ-pyrone radicals would yield the dimeric compounds (Figure 3), for instance, the coupling of **18** and **20** would yield ustilaginoidin L, **2**. In literature, the oxidative coupling between monomeric phenolic precursors was proposed to form the spirobisnaphthalenes.[36,37]

Some ustilaginoidins are mycotoxins. Ustilaginoidin A was reported to have teratogenic effects on mouse embryo limb bud and midbrain cells with IC_{50} values of 2.53 and 1.24 μM, respectively,[22] while ustilaginoidins A, D, E, and G were significantly cytotoxic to KB cells with IC_{50} values (μM) of 0.58, 0.42, 0.43, and 1.94, respectively.[23] Thus, in the current study, all the isolated ustilaginoidins were tested for their cytotoxicities against five human carcinoma cell lines including HCT-116, HepG2, BGC-823, NCI-H1650, and A2780. Only ustilaginoidins K, **1**, and L, **2**, showed inhibitory effects against the A2780 cells with IC_{50} values of 4.18 and 7.26 μM, respectively, whereas the other compounds were inactive with IC_{50} > 10 μM. It is worth mentioning that these compounds were 2−3-order less active than the positive control (taxol).

Meanwhile, the isolated compounds were screened for their inhibitory activities on seed radicle elongation of two rice varieties (Lijiang, and Zhonghua 11) (Table 3). Ustilaginoidins O, **5**, E, **10**, and F, **11**, and isochaetochromin B_2, **13**, showed inhibition at different test concentrations, though not as effective as that of positive control (glyphosate). Among them, ustilaginoidin F, **11**, showed the strongest activity against the tested rice seeds. In general, Lijiang variety was more susceptible to the compounds than Zhonghua 11.

The antibacterial effects of the isolated compounds were tested against six pathogenic bacteria including *A. tumefaciens*, *B. subtilis*, *P. lachrymans*, *R. solanacearum*, *S. hemolyticus*, and *X. vesicatorya* (Table 4). Among them, ustilaginoidins E, **10**, and G, **12**, showed inhibition against all the tested bacteria, while ustilaginoidins N, **4**, and D, **9**, displayed inhibitory activity against only four bacteria including *A. tumefaciens*, *B. subtilis*, *S. hemolyticus*, and *X. vesicatoria*. However, the other compounds were inactive at the highest test concentration of 64 μg/mL. Both ustilaginoidin D and isochaetochromin B_2 were previously reported to have inhibitory effects against *Mycobacterium phlei* with the same MIC value of 50.0 μg/mL.[16] Three related bis-naphtho-γ-pyrones, namely, isochaetomium A_2, chaetochromins A and B, possessing an a*S* axial chirality, showed antibacterial effects against *Escherichia coli*, *S. aureus*, and *B. subtilis*.[12]

In conclusion, 13 bis-naphtho-γ-pyrones, including the new ustilaginoidins K−P, **1**−**6**, and E_1, **7**, and the known ustilaginoidins A, **8**, D, **9**, E, **10**, F, **11**, and G, **12**, and isochaetochromin B_2, **13**, were isolated from the extract of rice false smut pathogen *U. virens*. Previous chemical investigation related to this pathogen was focused on chemical constituents of the smut balls grown on the infected rice panicles.[4−6] In the current study, chemical investigation of this fungus grown on solid rice medium was reported for the first time. This led to not only the identification of known ustilaginoidins that previously obtained from rice false smut balls, but also the discovery of new congeners. It is interesting that no hydroxymethyl derivatives were obtained in the current study; on the contrary, these metabolites were reported from the smut balls

[a]The other isolated compounds did not show inhibitory activity at 128 μg/mL. [b]Positive control. [c]nd: not detected.

collected in paddy field.[4−6] The cytotoxic and antibacterial activities of the isolated compounds were evaluated. Ustilaginoidins K, **1**, and L, **2**, were cytotoxic to A2780 cells, while ustilaginoidins N, **4**, D, **9**, E, **10**, and G, **12**, displayed inhibitory activities on the tested pathogenic bacteria. In addition, the in vitro phytotoxic activity of the bis-naphto-γ-pyrones on the inhibition of the rice radicle elongation was first reported. Ustilaginoidins O, **5**, E, **10**, and F, **11**, and isochaetochromin B_2, **13**, displayed moderate inhibition against the radicle elongation of rice seeds. Thus, *U. virens* was an intriguing producer of interesting bioactive ustilaginoidins. Further characterization of the physiological and ecological roles of the ustilaginoidins such as the role in the disease cycle of *U. virens* should be studied in detail.[38]

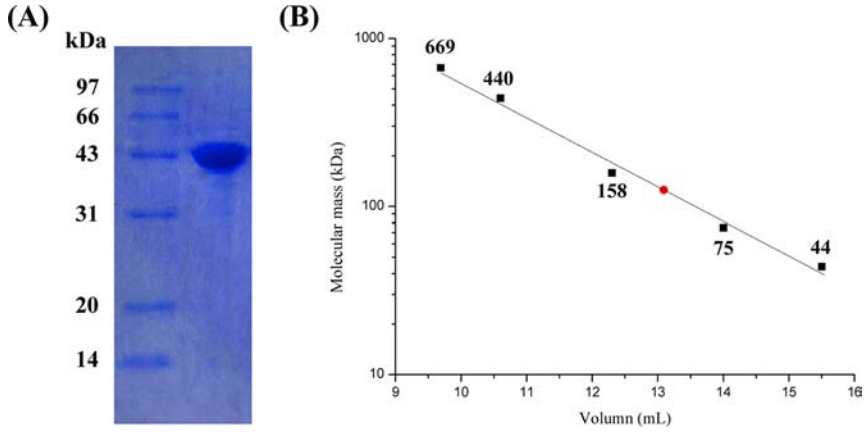

Figure 1. SDS−PAGE and gel filtration analysis of the purified recombinant enzyme. (A) SDS−PAGE of the protein stained with Coomassie Blue. Lane 1, molecular mass marker proteins; lane 2, the purified recombinant protein by metal-affinity chromatography. (B) Determination of the molecular mass of native protein. The column was calibrated with thyroglobulin (669 kDa), ferritin (440 kDa), aldolase (158 kDa), conalbumin (75 kDa), and ovalbumin (44 kDa) as reference proteins, and the native enzyme was eluted at a retention volume corresponding to 125 kDa (labeled by the red circle).

however, the values of most IFTases (DFA III forming) are less than 2000 units/mg.

In this work, a novel IFTase was characterized from *Arthrobacter* sp. 161MFSha2.1. The structure of depolymerized products from inulin was identified as DFA III by nuclear magnetic resonance (NMR) analysis. The enzymatic properties were studied in detail and were compared to those of other IFTases. The enzyme displays the highest thermostability and the second highest specific activity among the already characterized IFTases (DFA III forming), suggesting that it has great potential for industrial DFA III production.

MATERIALS AND METHODS

Chemicals and Reagents. The sugar standards, including DFA III, 1-ketose (GF_2), and nystose (GF_3), were from Wako Pure Chemical Industries (Osaka, Japan). Inulin was purchased from BENEO-Orafti NV (Tienen, Belgium). Chelating Sepharose Fast Flow, the resin for affinity chromatography, was obtained from Amersham Biosciences (Arlington Heights, IL). All other chemicals used in this study were at least of analytical grade, obtained from Sigma (St. Louis, MO) and Sinopharm Chemical Reagent (Shanghai, China).

Plasmids, Microorganisms, and Culture Conditions. The plasmid pET-22b(+) and *E. coli* BL21(DE3) were used as a vector and host to express the target gene, respectively. The *E. coli* strain was cultured in the Luria−Bertani (LB) medium. The LB medium used was composed of 5 g/L yeast extract, 10 g/L trypone, and 5 g/L NaCl (pH 7.5).

Gene Cloning and Expression. The nucleotide and protein sequence information were obtained from the National Center for Biotechnology Information (NCBI), with accession numbers NZ_KB895786 and WP_018778058, respectively. The full length of the encoding gene was designed to contain an in-frame 6× histidine-tag sequence before the stop codon and *Nde*I and *Xho*I restriction sites at the 5′ and 3′ termini. The designed DNA sequence was synthesized by Shanhai Generay Biotech Co., Ltd. (Shanghai, China) and was subcloned into the pET-22b(+) vector with the same restriction sites.

The recombinant plasmid was then transformed into *E. coli* BL21(DE3) for expression. A single colony of transformant was inoculated in LB medium plus ampicillin (100 μg/mL). When the cells were grown to an optimal density (600 nm) of 0.6 at 37 °C, protein expression was initiated by the addition of isopropyl-β-D-1-thiogalactopyranoside (IPTG) to a final concentration of 1 mM and the extracellular expression was performed at 28 °C for 72 h.

Purification of Recombinant IFTase. All purification steps were conducted at 4 °C. The culture broth was centrifuged at 10000*g* for 20 min to remove cell pellets. The supernatant containing 6× histidine-tagged recombinant proteins was directly loaded on Chelating Sepharose Fast Flow resin for metal-affinity chromatography using an ÄKTA purifier (GE Healthcare, Sweden). The purification was performed according to the protocol of the manufacturer (pET His Tag System, Novagen).

The protein concentration was calculated using the Bradford method, and the molecular mass was assessed by both sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and gel filtration. For SDS−PAGE, 12 and 5% (w/v) acrylamide were used for the separating and stacking gels, respectively, and Coomassie Brilliant Blue R250 was used for protein staining. For gel filtration, the native purified protein was loaded on a Superdex 200 10/300 GL gel filtration column (GE Healthcare, Sweden) and was eluted with 150 mM NaCl in 50 mM phosphate buffer (pH 6.5) at a flow rate of 0.5 mL min^{-1}.

Identification of the Reaction Product from Inulin. The reaction products from inulin by the recombinant enzyme were separated by high-performance liquid chromatography (HPLC, Agilent 1260 system, Santa Clara, CA) equipped with a refractive index detector and a preparative column, Carbomix H-NP5 (5 μm, 10 mm inner diameter × 300 mm, Sepax Technologies, Inc., Newark, DE). The column was eluted at 80 °C with a flow rate of 0.8 mL/min. The main product was collected and freeze-dried in the 4.5 L FreeZone freeze-dry system (Labconco Corp., Kansas City, MO).

The freeze-dried sample (30 mg) was dissolved in 0.45 mL of D_2O and analyzed by NMR using a Bruker Avance III 400 MHz Digital NMR spectrometer (Bruker, Karlsruhe, Germany). The NMR was operated at 400 MHz for ^{1}H NMR, ^{13}C NMR, and two-dimensional (2D) NMR spectra, including 2D ^{1}H shift correlated spectroscopy (^{1}H−^{1}H COSY), ^{1}H-detected heteronuclear single-quantum coherence (^{1}H−^{13}C HSQC), and ^{1}H-detected heteronuclear multiple-bond correlation (^{1}H−^{13}C HMBC). The sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS) was used as a standard to reference the chemical shifts.

Enzyme Assay. The enzyme activity was determined by measuring the amount of produced DFA III from inulin. The reaction mixture was composed of 1 mL of solution containing phosphate buffer (pH 6.5), substrate inulin (10 g/L), and purified enzyme (6 nM). The reaction was conducted at 55 °C for 5 min and was stopped by boiling for 10 min. The generated DFA III was determined by HPLC [system, Agilent 1260; column, Asahipak NH2P-50-4E system, 4.6 mm inner diameter × 250 mm; column temperature, 25 °C; mobile phase, 65% (v/v) of acetonitrile; elution rate, 1 mL/min; and detector, refractive index detector]. One unit of enzyme activity was defined as the

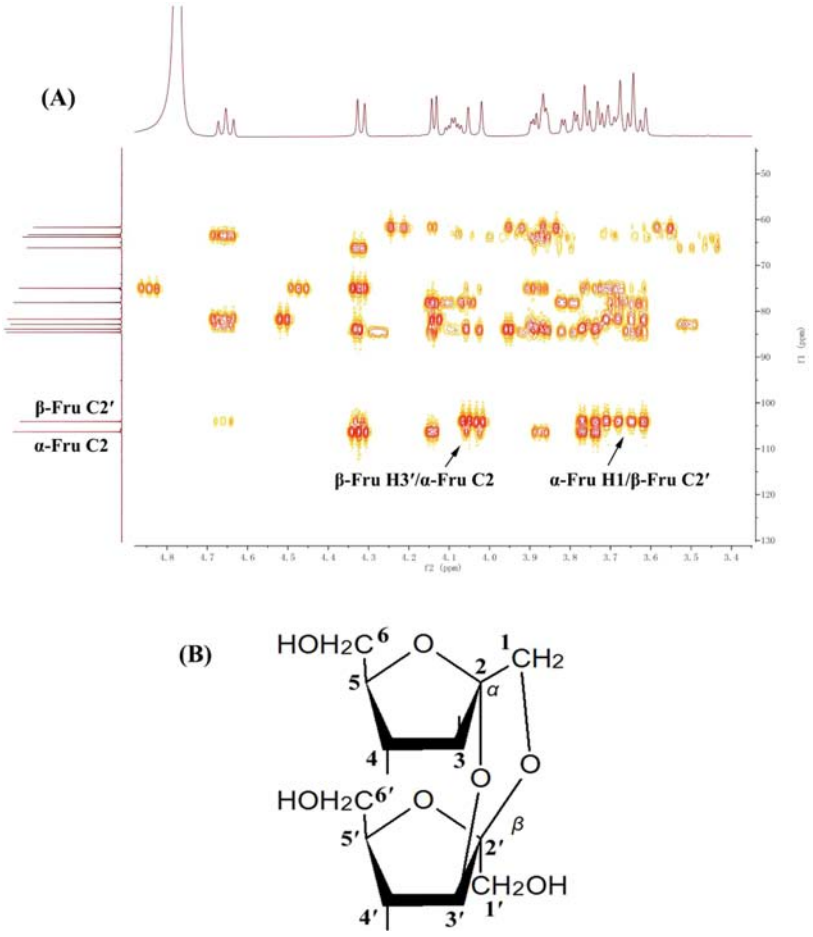

Figure 2. Identification of the structure of the main product produced from inulin by the recombinant enzyme. (A) $^{1}H-^{13}C$ HMBC spectrum of the purified main product. Connectivities of α-D-fructofuranose (2, 3′) β-D-fructofuranose and β-D-fructofuranose (2′, 1) α-D-fructofuranose were deduced by the correlation between α-D-Fru-C-2 and β-D-Fru-H-3′ and that between β-D-Fru-C-2′ and α-D-Fru-H-1, respectively. (B) Chemical structure of the main product.

amount of enzyme catalyzing the formation of 1 μmol of DFA III per minute at pH 6.5 and 55 °C.

Effect of the pH and Temperature. The optimum pH and temperature for recombinant IFTase (DFA III forming) were determined by assaying the enzyme activity in 50 mM different buffers (acetate buffer, pH 4.0−5.5; phosphate buffer, pH 6.0−7.0; and Tris−HCl buffer, pH 7.5−8.0) at 55 °C or at different temperatures (30−80 °C) in 50 mM phosphate buffer (pH 6.5). The thermostability was determined by calculating the residual activity of the enzyme, which was pre-incubated at 55, 60, 70, and 80 °C for 4 h. The initial activity without pre-incubation was taken as a control.

Conversion of Inulin to DFA III by Recombinant IFTase. Production of DFA III from inulin was studied in 100 mL of reaction volume using 80 nM recombinant enzyme at pH 6.5 and 55 °C. Different initial inulin concentrations were tested, including 50, 100, and 200 g/L.

J. Agric. Food Chem. 2015, 63, 3509−3515

RESULTS

Heterologous Expression and Protein Purification. The IFTase-encoding gene from *Arthrobacter* sp. 161MFSha2.1 is heterologously expressed in *E. coli* with a C-terminal 6× histidine tag. After expression by IPTG induction, extracellular inulin depolymerization activity is significantly detected, indicating that the recombinant enzyme is successfully secreted to the culture media. The culture supernatant is collected and loaded into a nickel-affinity column for enzyme purification. The recombinant enzyme is purified to homogeneity, showing a single band of 43 kDa in SDS−PAGE (Figure 1A). The molecular weight of the native enzyme determined by gel filtration is calculated to be 125 kDa (Figure 1B). These data indicate that the recombinant enzyme is a homotrimeric protein.

NMR Analysis of the Reaction Product. The ^{13}C and ^{1}H NMR spectra are shown in panels A and B of Figure S1 of the Supporting Information, respectively. The chemical shifts obtained from the spectra (shown in Table 1) are compared to the results of the DFA III standard. The ^{13}C NMR spectrum (see Figure S1A of the Supporting Information) shows 12 carbons containing two sugar carbons (106.3 and 104.1 ppm) with large downfield shifts and four methylene oxylated carbons (66.36, 63.81, 63.33, and 61.69 ppm) with upfield shifts, indicating the existence of two hexoses. The two hexose moieties are assigned as α-D-fructofuranose and β-D-fructofuranose by $^{1}H-^{1}H$ COSY (see Figure S3A of the Supporting Information) and $^{1}H-^{13}C$ HSQC (see Figure S3B of the Supporting Information). As shown in Figure 2, the C2 of α-D-fructofuranose (δ_C, 106.30 ppm) and the C2′ of β-D-fructofuranose (δ_C, 106.30 ppm) have HMBC correlation with the H3′ of β-D-fructofuranose (δ_H, 106.30 ppm) and the H1 of α-D-fructofuranose (δ_H, 106.30 ppm), respectively, indicating the α-D-fructofuranose (2, 3′) β-D-fructofuranose and α-D-fructofuranose (2′, 1) β-D-fructofuranose connectivities, respectively. Therefore, the produced compound is determined as α-D-fructofuranose-β-D-fructofuranose 2′,1:2,3′-dianhydride (DFA III).

Effect of the pH and Temperature on the Recombinant Enzyme. The purified recombinant IFTase (DFA III forming) from *Arthrobacter* sp. 161MFSha2.1 shows relatively high activity under acidic conditions and exhibits optimum activity at pH 6.5 in 50 mM phosphate buffer (Figure 3). Its relative activity is more than 80% of the maximal activity under the pH range of 5.0−6.5 and decreases sharply when pH is shifted to the alkaline side.

The optimal temperature of the recombinant enzyme is determined to be 55 °C (Figure 4A). The relative activity is kept at more than 95% of the maximal activity at the temperatures between 50 and 60 °C but decreases obviously at other temperatures. Although the relative activity is sensitive to the temperature (Figure 4A), the enzyme displays remarkably thermal stability (Figure 4B). When incubated at 55, 60, 70, and 80 °C for 4 h, the enzyme still retains 91, 86, 77, and 51% initial activity.

Reaction Product Analysis. The recombinant enzyme shows specific activity at 2391 units/mg at optimum reaction conditions (pH 6.5 and 55 °C). When the substrate inulin is depolymerized completely by using excess recombinant enzyme, the reaction mixtures analyzed by HPLC contain DFA III as the main product and some minor products composed of sucrose (GF), GF_2, and GF_3. In addition, the catalytic activities toward different types of fructosyl oligosaccharides, such as GF_2 and GF_3, are tested. The recombinant enzyme cannot act on GF_2 but hydrolyzed GF_3 to DFA III and GF, suggesting that the smallest substrate is GF_3.

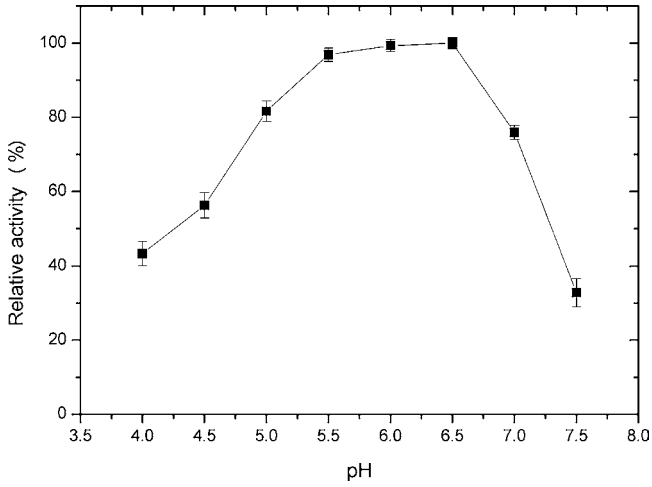

Figure 3. Effect of the pH on the recombinant enzyme activity. The enzyme was mixed with various buffers (50 mM): acetate buffer (pH 4.0−5.5), phosphate buffer (pH 6.0−7.0), and Tris−HCl buffer (pH 7.5−8.0). The maximal enzyme activity was set as a reference value of 100%, and relative activity was expressed as a percentage of the maximal activity. Each point represents the mean (n = 3) ± standard deviation.

Conversion of Inulin to DFA III by Recombinant IFTase. Under the optimum pH and temperature, biological production of DFA III is studied using 80 nM recombinant enzyme and various concentrations of substrate inulin. The conversion of inulin to DFA III reaches 88, 81, and 58% after reaction for 20 min, when the initial inulin concentration is set as 50, 100, and 200 g/L, respectively (Figure 5).

DISCUSSION

Thus far, there are two types of IFTases that have been identified, which depolymerize inulin to DFA III and DFA I (α-D-fructofuranose-β-D-fructofuranose 2′,1:2,1′-dianhydride), respectively.[16,34] Both types of IFTases have been mostly characterized from *Arthrobacter* species strains.[16] The genomic sequence of *Arthrobacter* sp. 161MFSha2.1 has recently been released in the GenBank database (accession number NZ_ARGU01000000). In the genome, there is an annotated gene encoding a hypothetical protein (accession number WP_018778058) proposed as fructotransferase. The protein displays relatively high homology with both IFTase (DFA III forming) and IFTase (DFA I forming). In this work, the protein was heterologously expressed in *E. coli*, and the recombinant protein was purified and characterized. The purified recombinant enzyme displayed depolymerization activity toward inulin. The reaction product from inulin was purified and determined as DFA III by NMR analysis. Thus, the enzyme was identified as IFTase (DFA III forming).

On the basis of the results of SDS−PAGE and gel filtration, the recombinant enzyme was suggested as a homotrimer. It was the same as the result of the crystal structure of *Bacillus* sp. IFTase (DFA III forming).[14] Also, the IFTase (DFA III forming) from *Arthrobacter* sp. A-6 was a trimeric enzyme.[21] However, other characterized IFTases were suggested as monomers or dimers. For examples, the IFTases from *A.*

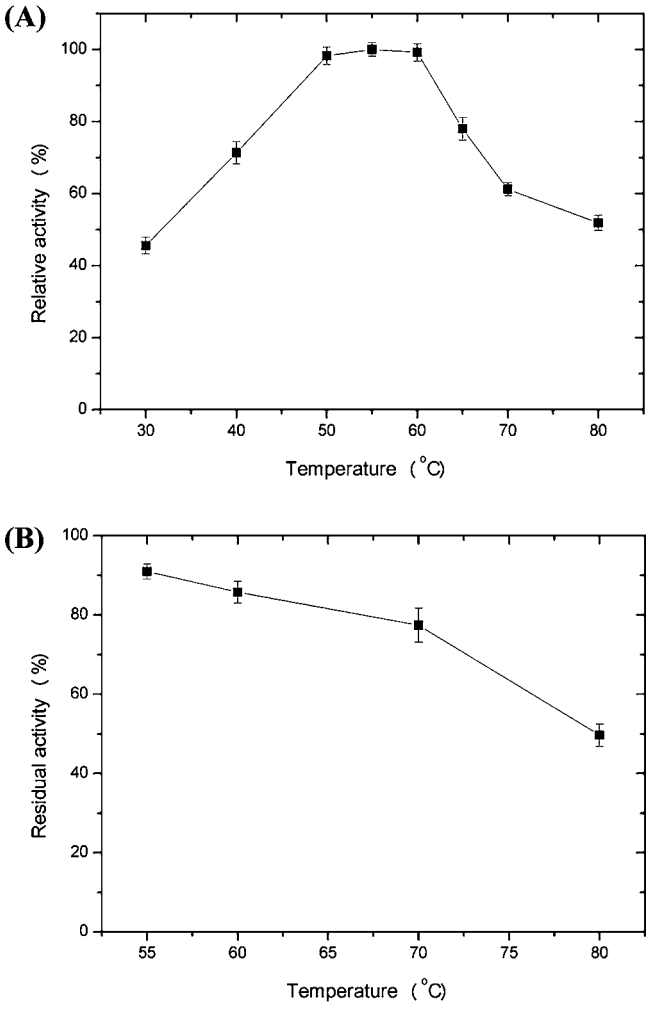

Figure 4. Effect of the temperature on the activity and stability of the recombinant enzyme. (A) Effect of the temperature on the enzyme activity. The maximal enzyme activity was set as a reference value of 100%, and relative activity was expressed as a percentage of the maximal activity. (B) Effect of the temperature on the enzyme stability. The effect on stability was studied by incubating the enzyme for 4 h at different temperatures, and the activity of the unincubated enzyme was taken as 100%. Each point represents the mean (n = 3) ± standard deviation.

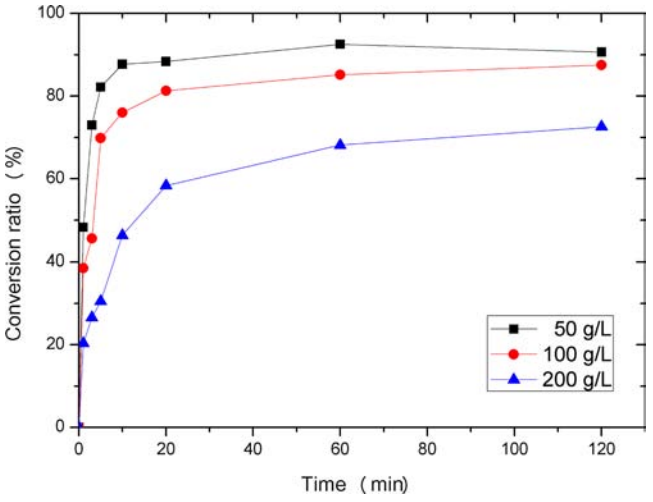

Figure 5. Production of DFA III from inulin by the recombinant enzyme. Three initial concentrations of inulin, 50, 100, and 200 g/L, were used for DFA III production.

aurescens SK 8.001,[27] *A. ureafaciens* D13-3,[25] *Flavobacterium* sp. LC-413,[28] and *A. globiformis* C11-1 were monomers,[17] and the IFTases from *Leifsonia* sp. T88-4,[31] *Arthrobacter* sp. L68-1,[24] *A. pascens* T13-2,[23] *Arthrobacter* sp. H65-7,[20] and *A. ilicis* OKU17B[19] were dimers.

The recombinant enzyme displayed maximal activity at pH 6.5 and 55 °C. The optimum pH and temperature were not much different from those of other reported IFTases (DFA III forming).[16] However, the IFTase (DFA III forming) from *Arthrobacter* sp. 161MFSha2.1 exhibited very high specific activity and significant thermostability when compared to others (Table 2). The specific activity reached 2391 units/mg, which was only less than that of IFTase (DFA III forming) from *Flavobacterium* sp. LC-413 (5728 units/mg).[28] Interestingly, the IFTases (DFA III forming) from non-*Arthrobacter* strains have relatively high specific activities (>1000 units/mg), except the IFTase from *Leifsonia* sp. T88-4 (644 units/mg).[16] By comparison, the IFTases from *Arthrobacter* strains show specific activities below 1000 units/mg, except the IFTases from *Arthrobacter* sp. A-6 (1,195 units/mg)[21] and the herein-reported *Arthrobacter* sp. 161MFSha2.1 (2391 units/mg).

On the contrary, the non-*Arthrobacter* IFTases (DFA III forming) with high specific activity usually display low thermostability (Table 2). For examples, the IFTases (DFA III forming) from *Nonomuraea* sp. ID06A0189[16] and *Leifsonia* sp. T88-4[31] were completely inactivated after incubation at 80 °C for 20 min and at 70 °C for 30 min, respectively; the IFTase from *Bacillus* sp. snu-7 was rapidly inactivated at 70 °C with half-life of only 6.6 min;[30] and the IFTase from *Flavobacterium* sp. LC-413 retained less than half of the initial activity when incubated above 75 °C for 30 min.[28] In comparison, some *Arthrobacter* IFTases exhibited higher thermostability. The IFTases (DFA III forming) from *A. aurescens* SK 8.001[27] and *Arthrobacter* sp. L68-1[24] were stable up to 70 and 80 °C, respectively, after 30 min of incubation, and the IFTase from *Arthrobacter* sp. A-6 retained more than half of the initial activity after 300 min of incubation at 70 °C.[21] Herein, a novel thermostable IFTase (DFA III forming) was reported having the highest thermostability, which was stable up to 80 °C for 4 h of incubation. Therefore, IFTase (DFA III forming) from *Arthrobacter* sp. 161MFSha2.1 has great potential for industrial application for DFA III production, because of both high specific activity and significant thermostability.

The smallest substrate was determined to be GF_3. IFTases (DFA III forming) from *A. aurescens* SK 8.001[26,27] and *Bacillus* sp. snu-7[29] displayed the smallest substrate as GF_3 and fructofuranosyl nystose (GF_4), respectively (Table 2). In this study, the recombinant enzyme degraded inulin to DFA III as a major product and small amounts of GF, GF_2, and GF_3. The result was the same as that of *A. ureafaciens* D13-3.[25] In comparison, the IFTases (DFA III forming) from *Arthrobacter* sp. L68-1,[24] *A. pascens* T13-2,[23] *Arthrobacter* sp. A-6,[21] and *Leifsonia* sp. T88-4[31] produced GF_3 and GF_4 as minor products. The IFTase from *A. aurescens* SK 8.001 produced small amounts of GF_2, GF_3, and GF_4.[26] The native crude IFTase from *Nonomuraea* sp. ID06A0189 could produce a very small amount of D-fructose,[33] while D-fructose was not produced from inulin by the purified recombinant enzyme.[32] The authors suggested that the *Nonomuraea* sp. ID06A0189 might also secrete other inulin-degrading enzymes to produce D-fructose.[32]

Table 2. Comparison of Biochemical Properties of Various Microbial IFTases (DFA III Forming)

microbial source	strain	native or recombinant	specific activity (units/mg)	thermostability[a]	minor reaction products from inulin	smallest substrate	reference
Arthrobacter strains	*Arthrobacter* sp. 161MFSha2.1	recombinant	2391	80 °C; 240 min	GF, GF_2, and GF_3	GF_3	this study
	A. aurescens SK 8.001	recombinant	NR[b]	70 °C; 60 min	GF_2, GF_3, and GF_4	GF_3	26
	A. aurescens SK 8.001	native	381	70 °C; 60 min	NR	GF_3	27
	A. ureafaciens D13-3	native	290	70 °C; 30 min	GF, GF_2, and GF_3	NR	25
	Arthrobacter sp. L68-1	native	NR	80 °C; 60 min	GF_3 and GF_4	NR	24
	A. pascens T13-2	native	NR	75 °C; 20 min	GF_3 and GF_4	NR	23
	Arthrobacter sp. A-6	native	1195	70 °C; >300 min 80 °C; <60 min	GF_3 and GF_4	NR	21
	Arthrobacter sp. H65-7	native	NR	70 °C; 20 min	NR	NR	20
	A. ilicis OKU17B	native	853	70 °C; 30 min	NR	NR	19
	A. globiformis C11-1	recombinant	227	NR	NR	NR	18
	A. globiformis C11-1	native	294	75 °C; 20 min	NR	NR	17
	A. ureafaciens	native	162.4	50 °C; 30 min	NR	NR	15
non-*Arthrobacter* strains	*Nonomuraea* sp. ID06A0189	recombinant	1991	70 °C; 20 min	NR	NR	32
	Nonomuraea sp. ID06A0189	native[c]	NR	70 °C; 20 min[c]	D-fructose, GF_2, GF_3, and GF_4[c]	NR	33
	Leifsonia sp. T88-4	native	644	60 °C; 30 min	GF_3 and GF_4	NR	31
	Bacillus sp. snu-7	recombinant	1276	60 °C; 103 min	NR	NR	30
	Bacillus sp. snu-7	native	48.5	60 °C; 10 min	GF_2 and GF_3	GF_4	29
	Flavobacterium sp. LC-413	native	5728	75 °C; 30 min	GF_2	NR	28

[a]The values showed that the enzyme could remain more than half of the initial activity after incubation at a specified temperature for a specified time. [b]NR = not reported. [c]The biochemical properties were characterized using crude enzyme.

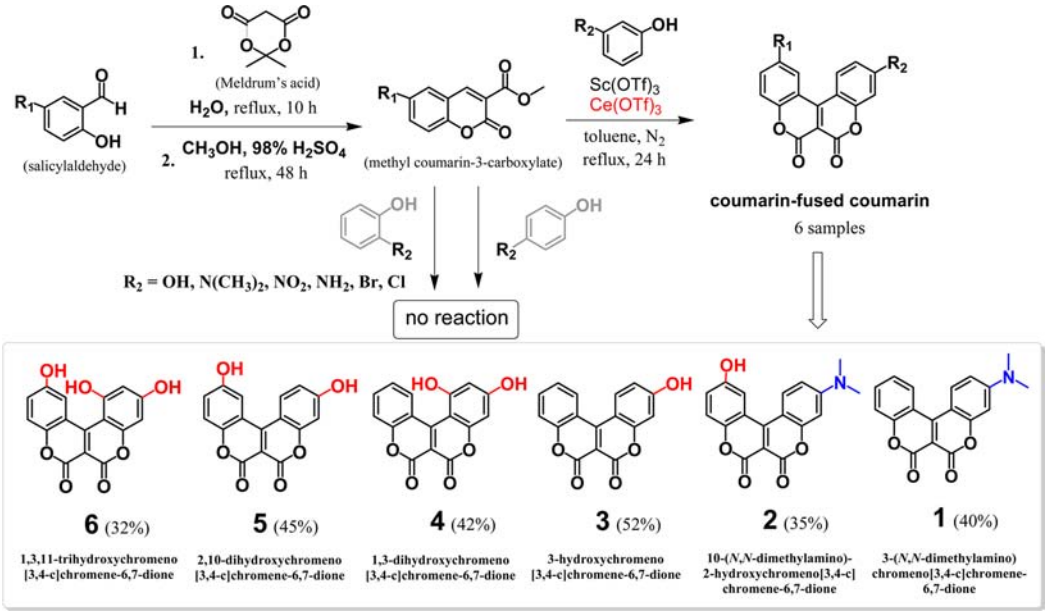
Scheme 1. Synthesis and Structures of Coumarin-Fused Coumarins Employed in This Work



mmol) was refluxed in water (20 mL) under stirring for 10 h. Then, the mixture was cooled by ice water, and the precipitate was filtered and washed with ice water to obtain white or green product. The yields were higher than 93%.

Esterification of Coumarin-3-carboxylic Acids. To 20 mL of methanolic solution of coumarin-3-carboxylic acid (10 mmol), H_2SO_4 (98%, 0.6 mL) was added dropwisely under stirring. The above mixture was refluxed for 48 h and cooled to room temperature. After the solvent was evaporated under vacuum, the residue was purified by silica chromatography with ethyl acetate and petroleum ether (1:3, v/v) being eluent to afford a white product, yield >90%.

Oxidative Annulation for the Formation of Chromeno[3,4-*c*]chromene-6,7-diones. $Ce(OTf)_3$ (0.05 g), $Sc(OTf)_3$ (0.05 g), methyl coumarin-3-carboxylate (4 mmol), and phenol (2 mmol) were mixed in 10 mL of toluene and heated at 110 °C for 24 h under a protective atmosphere of N_2. Then, the mixture was cooled to room temperature by ice water, and the precipitate was purified by silica chromatography with methanol and dichloromethane being eluent to afford the product, yield 32%∼ 52%.

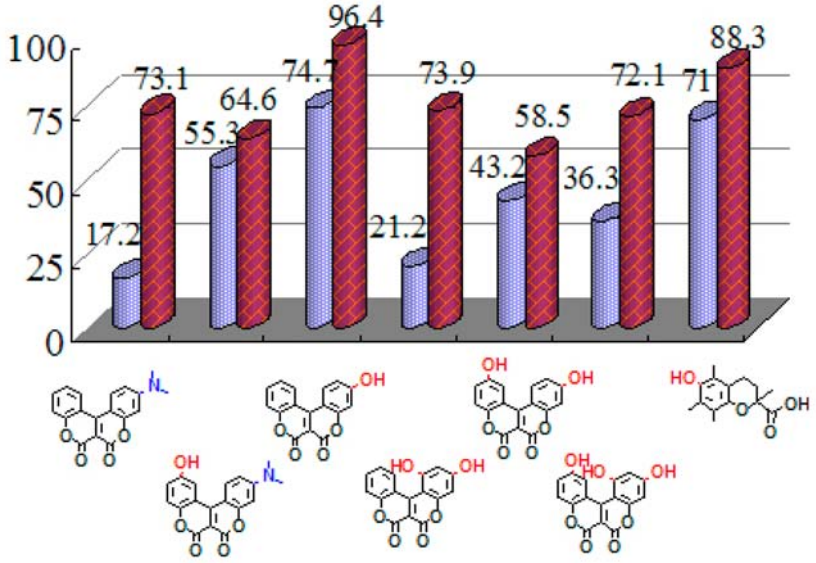
Scheme 2. TBARS Percentages (Data on the Column) in the Presence of 0.10 mM Coumarin-Fused Coumarins When the Oxidation of DNA (2.0 mg/mL) Is Caused by 5.0 mM Cu^{2+} and 3.0 mM GSH for 90 min (Right Column for Every Compound) or 4.0 mM H_2O_2 and 2.0 mM TCHQ for 30 min (Left Column for Every Compound)



3.0 mM), which were dissolved in phosphate-buffered solution (PBS_1: 6.1 mM Na_2HPO_4, 3.9 mM NaH_2PO_4, pH = 7.0). The coumarin-fused coumarin was dissolved in dimethyl sulfoxide (DMSO) as the stock solution and added to the aforementioned solution. The final concentration of tested compound was 0.10 mM, and the volume of DMSO was less than 0.5% in the total volume of the solution. The mixture of DNA, Cu^{2+}, GSH, and coumarin-fused coumarin was delivered into test tubes in a total volume of 2.0 mL. The control experiment contained the same volume of DMSO without the tested compounds dissolved. The test tubes were incubated at 37 °C for initiating the DNA oxidation, and three of them were taken out at 90 min and cooled immediately. PBS_1 solution of EDTA (1.0 mL, 30.0 mM) was added to chelate Cu^{2+}, followed by adding 1.0 mL of thiobarbituric acid (TBA) solution (1.00 g of TBA and 0.40 g of NaOH dissolved in 100 mL of PBS_1) and 1.0 mL of 3.0% aqueous solution of trichloroacetic acid. The test tubes were heated in boiling water for 30 min and cooled to room temperature by ice water; subsequently, 1.5 mL of *n*-butanol was added and shaken vigorously to extract thiobarbituric acid reactive substance (TBARS) for measuring the absorbance at 535 nm.

$^{\bullet}OH$-induced oxidation of DNA was performed in a mixture of DNA (2.0 mg/mL), tetrachlorohydroquinone (TCHQ, 4.0 mM, dissolved in DMSO as the stock solution), and H_2O_2 (2.0 mM), which were dissolved in phosphate-buffered solution (PBS_2: 8.1 mM Na_2HPO_4, 1.9 mM NaH_2PO_4, 10.0 μM EDTA, pH = 7.4). The coumarin-fused coumarin was dissolved in DMSO as the stock solution and added to the aforementioned solution with a final concentration being 0.10 mM, while the volume of DMSO was less than 0.5% in the total volume of the solution. The solution of DNA, TCHQ, H_2O_2, and coumarin-fused coumarin was delivered into test tubes in a total volume of 2.0 mL. The control experimental system contained the same volume of DMSO without the tested compounds dissolved. The test tubes were incubated at 37 °C for initiating the oxidation of DNA, and three of them were taken out at 30 min and cooled immediately. Then, 1.0 mL of TBA solution (1.00 g of TBA and 0.40 g of NaOH dissolved in 100 mL of PBS_2) and 1.0 mL of 3.0% aqueous solution of trichloroacetic acid were added and heated in boiling water for 30 min. After the test tubes were cooled to room temperature by ice water, 1.5 mL of *n*-butanol was added and shaken vigorously to extract TBARS for measuring the absorbance at 535 nm. In the aforementioned two tests, the absorbances in the control experiment and in the presence of coumarin-fused coumarins were assigned as A_0 and A_{detect}, respectively. The effects of coumarin-fused coumarins on the oxidation of DNA were expressed by $A_{detect}/A_0 \times 100$, called TBARS percentage.

AAPH-Induced Oxidation of DNA Test. AAPH-induced oxidation of DNA was performed in a mixture of DNA (2.0 mg/mL, dissolved in PBS_2) and AAPH (40.0 mM, dissolved in PBS_2). The solution of DNA, AAPH, and a certain concentration of coumarin-fused coumarin (dissolved in DMSO as the stock solution) was delivered into test tubes in a total volume of 2.0 mL. The control experimental system contained the same volume of DMSO (0.5% of the total volume) without the tested compounds dissolved. The test tubes were incubated at 37 °C for initiating the oxidation of DNA, and three of them were taken out at every 2 h and cooled by ice water. Then, 1.0 mL of TBA solution (1.00 g of TBA and 0.40 g of NaOH dissolved in 100 mL of PBS_2) and 1.0 mL of 3.0% aqueous solution of trichloroacetic acid were added and heated in boiling water for 15 min. After the test tubes were cooled to room temperature, 1.5 mL of *n*-butanol was added and shaken vigorously to extract TBARS for measuring the absorbance at 535 nm. The absorbance of TBARS was plotted versus the reaction period.

Scavenging $ABTS^{+\bullet}$, DPPH, and Galvinoxyl Radicals. A 2.0 mL aqueous solution containing 4.0 mM ABTS salt and 1.41 mM $K_2S_2O_8$ was kept for 20 h to form $ABTS^{+\bullet}$ and then diluted by 100 mL of ethanol. The absorbance of $ABTS^{+\bullet}$ was around 1.00 at 734 nm ($\varepsilon_{ABTS^{+\bullet}} = 1.6 \times 10^4\ M^{-1}\ cm^{-1}$). DPPH and galvinoxyl radicals were dissolved in ethanol, respectively. The absorbances of DPPH and galvinoxyl radicals were around 1.00 at 517 nm ($\varepsilon_{DPPH} = 4.09 \times 10^3\ M^{-1}cm^{-1}$) and 428 nm ($\varepsilon_{galvinoxyl} = 1.4 \times 10^5\ M^{-1}cm^{-1}$), respectively. A certain concentration of DMSO solution of coumarin-fused coumarin

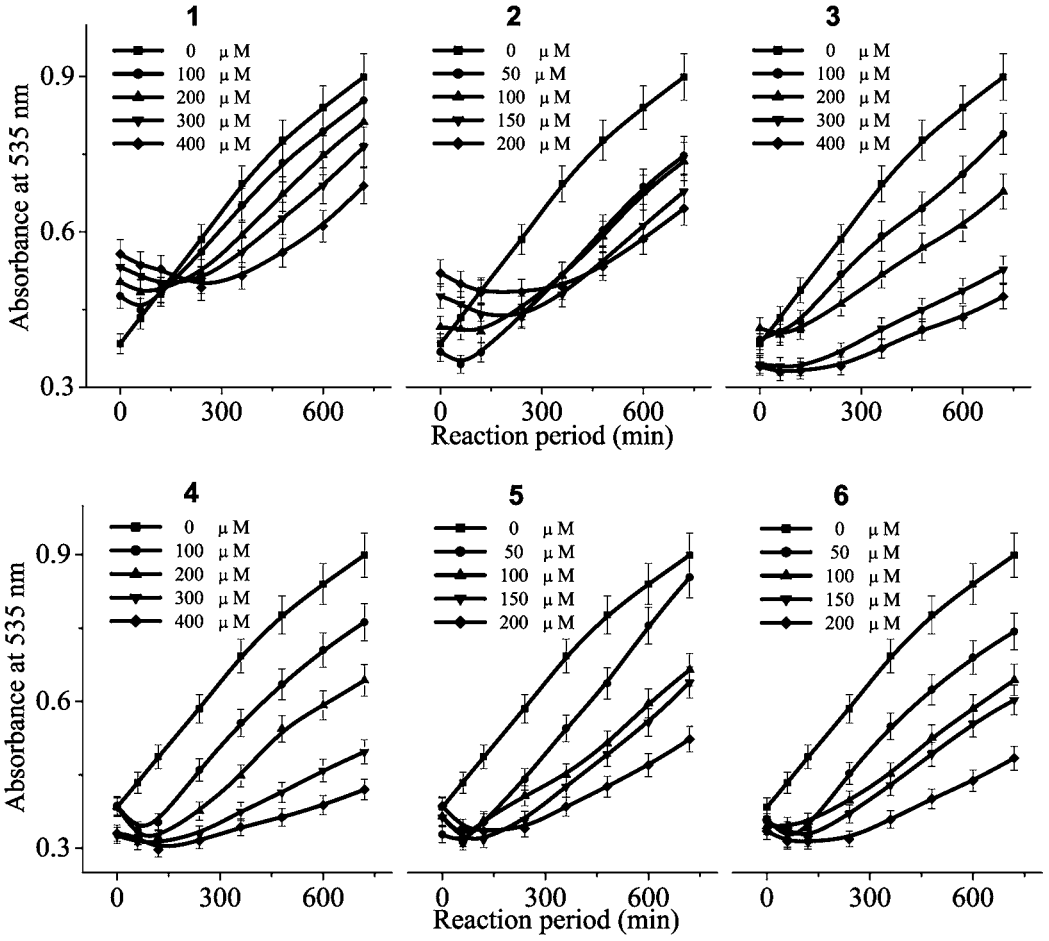

Figure 1. Variation of the absorbance of TBARS in the mixture of 2.0 mg/mL DNA, 40 mM AAPH, and various concentrations of coumarin-fused coumarins at 37 °C.

(0.1 mL) were added to 1.9 mL of $ABTS^{+\bullet}$, DPPH, and galvinoxyl radicals solution, respectively. The decreases of the absorbance of these radicals were recorded at 25 °C at a certain time interval.

Statistical Analysis. All the data were the average values from at least three independent measurements with the experimental error within 10%. The equations were analyzed by one-way ANOVA in Origin 6.0 professional software, and $p < 0.001$ indicated a significance difference.

RESULTS AND DISCUSSION

Synthesis of Coumarin-Fused Coumarins. Many efforts are contributed to develop synthetic protocols for constructing coumarin-fused heterocycles. The C═C in the lactone of coumarin possesses high reactivity for driving nucleophilic addition, leading to the formation of the fused heterocyclic[15] or spirocyclic coumarins.[16] For example, the C═C in the lactone can be shared with the C−C in cycloheptanone, forming a tricyclic fused coumarin as NO inhibitor.[17] In the synthetic operation, some novel techniques such as ultrasound vibration[18] and solvent-free heating[19] are widely used, but the formation of the lactone for coumarin-fused coumarin scaffold still depends upon appropriate catalysts. For example, the usage of cationic ruthenium complex catalyzes Diels−Alder reaction of enediynes can produce coumarin-fused polycycles.[20] The Cu(II) and Pb(II) are able to drive the cyclization of lactone,[21] and $Sc(OTf)_3$ can lead to the formation of chromeno[3,4-*c*]chromene- 6,7-dione, called coumarin-fused coumarin (see Scheme 1) in the yield of 33% with nitrobenzene being oxidant.[7] In this work, we follow our previously reported method[22] to apply $Ce(OTf)_3$ as the oxidant (instead of nitrobenzene) for catalyzing the annulation of methyl coumarin-3-carboxylate and *m*-substituted phenol. The mild oxidizability of $Ce(OTf)_3$ cannot oxidize the phenolic hydroxyl groups when resorcinol and phloroglucinol act as reactants in the synthesis of **3** ∼ **6**, and $Ce(OTf)_3$ can be conveniently removed in the purification of products via silica chromatography. The methyl 6-hydroxy-coumarin-3-carboxylate (a single coumarin scaffold) is prepared following a reported method,[23] and toluene is applied for the annulation between the single

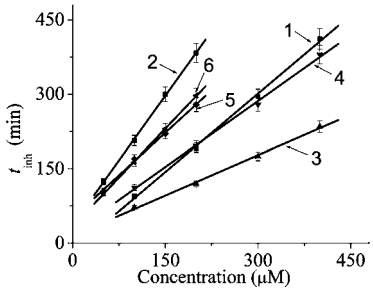

Figure 2. Linear relationships between concentrations of coumarin-fused coumarins and inhibition period (t_{inh}) in protecting DNA against AAPH-induced oxidation.

Table 1. Equations of t_{inh} ~ [Coumarin-Fused Coumarin] and *n* of Coumarin-Fused Coumarin in Protecting DNA against AAPH-Induced Oxidation[a]

compd	t_{inh} (min) = (n/R_i) [coumarin-fused coumarin (μM)] + constant[b]	n
1	t_{inh} = 1.05 (±0.05) [**1**] + 14.73 (±0.74)	3.53(±0.18)
2	t_{inh} = 1.74 (±0.09) [**2**] + 36.35 (±1.82)	5.85(±0.29)
3	t_{inh} = 0.54 (±0.03) [**3**] + 14.45 (±0.72)	1.81(±0.09)
4	t_{inh} = 0.89 (±0.04) [**4**] + 20.40(±1.02)	2.99(±0.15)
5	t_{inh} = 1.14 (±0.06) [**5**] + 50.73 (±2.54)	3.83(±0.19)
6	t_{inh} = 1.31 (±0.07) [**6**] + 33.52 (±1.68)	4.40(±0.22)

[a] $R_i = R_g = 1.4 \times 10^{-6}$ [AAPH] s^{-1} = 3.36 μM·min^{-1} when 40 mM AAPH was employed, thus, n = coefficient ×3.36 μM·min^{-1}. [b]The constant was generated from the linear regression analysis.

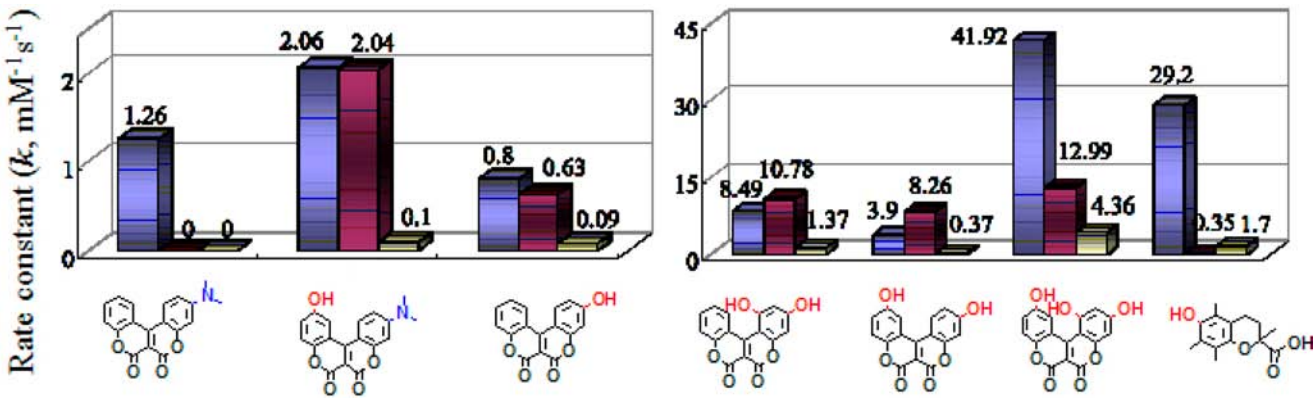
coumarin scaffold and *m*-substituted phenol because of the temperature controlled around 140 °C. We have attempted to enlarge the scale of suitable phenols for the annulation. As shown in Scheme 1, *ortho*- and *para*-substituted phenols are applied to carry out the reaction, and −OH, $-N(CH_3)_2$, and $-NH_2$ represent the electron-donating group (EDG), while $-NO_2$, −Br, and −Cl stand for the electron-withdrawing group (EWG). The annulation for forming coumarin-fused coumarin scaffold is not successful when the EDG or EWG (as R_2) locates at *ortho*- or *para*-position in the phenol because the first step in the formation of coumarin-fused coumarin is a transesterification between the methyl group in coumarin-3-carboxylate and the hydroxyl group in *meta*-substituted phenol, and then, the carbon atom at *para*-position in the phenol performs a C−C coupling reaction with the carbon atom in the lactone of coumarin. An EDG as $\mathbf{R_2}$ in the phenol is beneficial for the C−C coupling reaction, and other functional groups cannot take place in the same reaction. So, the limitation of the present synthetic protocol results in that only EDG at *meta*-position of phenol can successfully produce the coumarin-fused coumarin scaffold, and thus, we just explore the interaction of −OH (at the same or different benzene ring) and $-N(CH_3)_2$ (as a typical EDG) on the antioxidant effectiveness and do not mention coumarin-fused coumarins with other functional groups contained.

Inhibiting Cu^{2+}/GSH and •OH-Induced Oxidations of DNA. The glutathione radical (GS•) can be produced by the reaction of glutathione (GSH) and Cu^{2+},[24] while •OH can be produced by the reaction of H_2O_2 and tetrachlorohydroquinone (TCHQ).[25] DNA is susceptible to be oxidized by GS• and •OH, and the inhibitory effects on Cu^{2+}/GSH and •OH-induced oxidations of DNA are important index for an antioxidant. The oxidative products from the DNA oxidation can be readily detected after reacting with thiobarbituric acid (TBA).[26] Thus, a low percentage of thiobarbituric acid reactive substance (TBARS) (comparing with that in the control experiment as 100%) indicates that the antioxidant possesses high ability to inhibit the DNA oxidation. Scheme 2 outlines the TBARS percentage in the presence of 0.10 mM coumarin-fused coumarin added to the experimental systems of Cu^{2+}/GSH and •OH-induced oxidations of DNA with Trolox being the reference, which exhibits weak activities in inhibiting •OH- and Cu^{2+}/GSH-induced oxidation of DNA (TBARS% = 71.0 and 88.3, respectively).

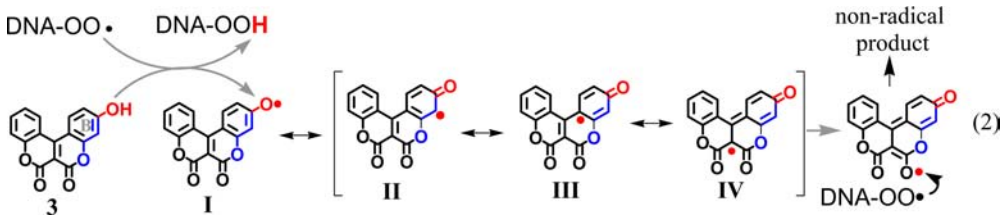
The TBARS percentages of coumarin-fused coumarins in inhibiting •OH-induced oxidation of DNA are lower than those in inhibiting Cu^{2+}/GSH-induced oxidation of DNA. Hence, coumarin-fused coumarins possess higher abilities to inhibit •OH-induced oxidation of DNA than to inhibit Cu^{2+}/GSH-induced DNA oxidation. An antioxidant may inhibit Cu^{2+}/GSH-induced oxidation of DNA by chelating copper ions.[27] A single hydroxyl group such as Trolox (TBARS % = 88.3) and **3** (TBARS % = 96.4) cannot exhibit high activity for chelating Cu^{2+}, and antioxidant effectiveness is low in this case. With the amount of phenolic hydroxyl groups increasing, the TBARS % decreases from 73.9 of **4** to 58.5 of **5**. The comparison of TBARS % of **4** (73.9) with **6** (72.1) leads to an interesting conclusion that the hydroxyl group at benzene ring **A** seems not very active in inhibiting Cu^{2+}/GSH-induced DNA oxidation. But the lowest TBARS % of **5** (58.5) demonstrates that double hydroxyl groups locating at benzene rings **A** and **B**, respectively, exhibit the highest ability in this case. Taking **1** and **2** into consideration, it can be found that the TBARS % of **1** (73.1), similar to that of **4** (73.9), indicates that -$N(CH_3)_2$ (an EDG) at benzene ring **B** is equivalent to double hydroxyl groups for inhibiting Cu^{2+}/GSH-induced DNA oxidation. In addition, as in **2** (TBARS % = 64.6), -$N(CH_3)_2$ (at benzene ring **B**) and a hydroxyl group (at benzene ring **A**) are beneficial for chelating copper ion, and the decrease of the amount of copper ion cannot generate much more GS· for oxidizing DNA.

Scheme 2 also reveals that coumarin-fused coumarins are more active in inhibiting DNA oxidation caused by •OH than

Scheme 3. Rate Constant (*k*, Data on the Column) for Coumarin-Fused Coumarins and Trolox in Scavenging $ABTS^{+\bullet}$ (Left Column for Every Compound), DPPH (Middle Column for Every Compound) and Galvinoxyl Radical (Right Column for Every Compound)



DOI: 10.1021/acs.jafc.5b00399
J. Agric. Food Chem. 2015, 63, 3516−3523



by Cu^{2+}/GSH. As we have pointed out in our previous work, the skeleton of a fused heterocycle is beneficial for the electrophilic addition by •OH.[9] Thus, the double latones in coumarin-fused coumarin may also be able to accommodate •OH, and thus, it may play antioxidative role in •OH-induced oxidation of DNA. Moreover, it can be found that more hydroxyl groups attaching to the benzene ring **B** increase the antioxidant effect of **4** (TBARS % = 21.2), and hydroxyl group at benzene ring **A** is not active because TBARS % of **6** (36.3, another hydroxyl group attaching to benzene ring **A** comparing with **4**) is higher than that of **4** (21.2). But all the efforts from phenolic hydroxyl groups on inhibiting •OH-induced oxidation of DNA cannot reach the level of the contribution from -$N(CH_3)_2$ at benzene ring **B** because **1** has the lowest TBARS % (17.2) among these compounds. On the other hand, TBARS % of **2** increases to 55.3, demonstrating again that the hydroxyl group attaching to benzene ring **A** may not be a positive factor in inhibiting •OH-induced oxidation of DNA.

Inhibiting AAPH-Induced Oxidation of DNA. The aforementioned experimental systems for evaluating antioxidant effectiveness are based on qualitative comparison. We have estimated a method for quantitatively expressing antioxidant effectiveness by using the experimental system of AAPH-induced oxidation of DNA.[9] As shown in Figure 1, an increase of the absorbance means that much more TBARS is generated for the longer reaction time than in the control experiment. But TBARS cannot be formed for a period when a coumarin-fused coumarin is added to the reaction system. Then, TBARS is produced as in the control experiment. The *inhibition period* (t_{inh}) is measured from the beginning of the reaction to the cross point of tangents for the inhibiting and the increasing period in TBARS absorbance line. Then, relationships between t_{inh} and concentrations of coumarin-fused coumarins are outlined in Figure 2 and expressed by the equation of $t_{inh} \sim$ [coumarin-fused coumarin] (see Table 1). Based on equations of $t_{inh} \sim$ [coumarin-fused coumarin], numbers of radical trapped by a coumarin-fused coumarins can be calculated by chemically kinetic method.

In view of chemical kinetics, the t_{inh} correlates proportionally with the concentration of an antioxidant as shown as eq 1.[28]

$$t_{inh} = (n/R_i)[\text{antioxidant}] \quad (1)$$

R_i refers to the initiation rate of the radical-induced reaction, and n is the *stoichiometric factor*. Both AAPH and the sodium salt of DNA are water-soluble compounds, and radicals generated from AAPH can attack DNA at water phase. R_i is thereby assumed to be equal to the radical generation rate (R_g, $R_g = (1.4 \pm 0.2) \times 10^{-6}$ [AAPH] s^{-1}[28]). The coefficient in the equation of $t_{inh} \sim$ [coumarin-fused coumarin] (see Table 1) is equivalent to (n/R_i) in eq 1. Hence, when R_i is equal to $R_g = 1.4 \times 10^{-6} \times 40$ mM·s^{-1} = 3.36 μM·min^{-1}, the n is the product of the coefficient in the equation (see Table 1) and R_i. The obtained n values of coumarin-fused coumarins are involved in Table 1 as well.

The usage of Trolox in AAPH-induced oxidation of DNA does not generate t_{inh}, and the n of Trolox cannot be obtained. As shown in Table 1, the n of **3** is 1.81, meaning that **3** can trap ~**2** radicals in protecting DNA against AAPH-induced oxidation. This can be understood by eq 2, in which DNA-OO• refers to the radical deriving from the DNA oxidation. DNA-OO· can abstract a hydrogen atom from hydroxyl group in **3**, producing a phenoxyl radical (**I**). The phenoxyl radical (**I**) accommodates the single electron via a series of resonance structures, **II**, **III**, and **IV**, and then to form another phenoxyl radical at C═O for quenching another DNA-OO•. So, two radicals trapped by **3** can be regarded as the contribution from the hydroxyl group and the adjacent lactone motif.

Moreover, the n values of **4**, **5**, and **6** are 2.99, 3.83, and 4.40, respectively, implying that **4**, **5**, and **6** (with 2, 2, and 3 hydroxyl groups, respectively) can trap ~3, ~4, and 4−5 radicals, respectively. The numbers of trapped radicals increase with the amount of hydroxyl group. But the n of **1** (3.53) is higher than that of **3** (1.81), indicating that -$N(CH_3)_2$ can improve the radical-scavenging property of the lactone motifs in the absence of hydroxyl group. So, the ring of lactone in the fused coumarin is an efficient radical-receptor in the presence of electron-donating group.[9] The n value of **2** is further increased to 5.85 by the hydroxyl group at benzene ring **A**, demonstrating that -$N(CH_3)_2$ in combination with hydroxyl group at different benzene rings can improve the ability to inhibit AAPH- induced oxidation of DNA.

Rate Constants in Scavenging Radicals. The radical-scavenging test reveals the direct interaction of an antioxidant with radicals, in which $ABTS^{+\bullet}$, DPPH, and galvinoxyl radicals are usually applied to evaluate the ability of the antioxidant to donate its hydrogen atom to *N*- and *O*-centered radicals, respectively. The expression on the radical-scavenging ability usually focuses on the amount of radicals trapped by the antioxidant.[29] We have developed a chemically kinetic method for measuring the rate constant (k) of the antioxidant quenching radicals.[30] Briefly, the concentrations of radicals decreases rapidly when coumarin-fused coumarins are mixed with radicals (see Supporting Information). The decay of the concentrations of radicals can be quantitatively expressed by eq 3, in which t represents the reaction time.

$$[\text{radical}] = Ae^{-(t/a)} + Be^{-(t/b)} + C \quad (3)$$

The differential operation is performed on eq 3 to obtain the reaction rate (r), −d[radical]/dt, as shown in eq 4.

$$-\text{d}[\text{radical}]/\text{d}t = r = (A/a)e^{-(t/a)} + (B/b)e^{-(t/b)} \quad (4)$$

If the reaction time is assigned to 0 (the beginning of the reaction), the reaction rate at $t = 0$ (r_0) can be calculated by eq 4. Meanwhile, [radical] and [antioxidant] at $t = 0$ are concentrations of radical and antioxidant at the beginning of the reaction. So, the rate constant (k) can be calculated by eq 5 (see Supporting Information).

DOI: 10.1021/acs.jafc.5b00399
J. Agric. Food Chem. 2015, 63, 3516−3523

$$r_0 = k[\text{radical}][\text{antioxidant}] \quad (5)$$

The rate constants (k) of coumarin-fused coumarins together with Trolox are outlined in Scheme 3. It can be found that k of **3** (only one hydroxyl group contained) in reducing $ABTS^{+\bullet}$ (0.80 $mM^{-1}\cdot s^{-1}$) is only 0.80 $mM^{-1}\cdot s^{-1}$, while those of **4** (two hydroxyl groups contained) and **6** (three hydroxyl groups contained) are 8.49 $mM^{-1}\cdot s^{-1}$ and 41.92 $mM^{-1}\cdot s^{-1}$, respectively. So, the ability of coumarin-fused coumarin to trap radical is related to the amount of hydroxyl group. The high k values of **3**, **4**, and **6** in trapping DPPH (0.63, 10.78, and 12.99 $mM^{-1}\cdot s^{-1}$, respectively) and galvinoxyl radical (0.09, 1.37, and 4.36 $mM^{-1}\cdot s^{-1}$, respectively) indicate that coumarin-fused coumarin prefers to donating the hydrogen atom in −OH to *N*- and *O*-centered radicals. In particular, three hydroxyl groups in **6** increase the radical-scavenging property even higher than that of Trolox. But k values of **4** (in trapping three radicals) are higher than those of **5**, implying that two hydroxyl groups locate at the different benzene rings are not beneficial for scavenging radicals. Moreover, **1** (without hydroxyl group contained) can reduce $ABTS^{+\bullet}$, indicating that $-N(CH_3)_2$ makes the scaffold of coumarin-fused coumarin a radical-scavenger.

In conclusion, $-N(CH_3)_2$ and the hydroxyl group play synergistically antioxidative role for coumarin-fused coumarin even though they do not locate at the same benzene ring. In particular, $-N(CH_3)_2$-involved coumarin-fused coumarin shows the highest activity in inhibiting $^{\bullet}OH$-induced oxidation of DNA even in the absence of a hydroxyl group. Therefore, $-N(CH_3)_2$ is an assisting group for the antioxidant effectiveness in the coumarin-fused heterocycles.

been rarely used to study SS-mediated interactions of soy protein.

In this study, the protein forms rearranged by heating were identified by diagonal SDS-PAGE and MALDI-TOF/TOF MS. The SH contents of different subunits/polypeptides of soy protein were determined using thiol-specific fluorescent monobromobimane (mBBr) labeling combined with SDS-PAGE. The transformation of cysteine side chains between SH and SS was identified to discuss disulfide-mediated interaction of soy protein.

MATERIALS AND METHODS

Materials. Acrylamide, *N*,*N*′-methylenebis(acrylamide), sodium dodecyl sulfate (SDS), monobromobimane (mBBr), 4,4′-dithiodipyridine (DPS), *N*-ethylmaleimide (NEM), iodoacetamide (IAM), and dithiothreitol (DTT) were purchased from Sigma-Aldrich Trading Co., Ltd. (Shanghai, China). All other chemicals were of analytical reagent grade.

Soy Protein Preparation. Soybean Nannong 88-31 (moisture content, 9%) was used. Dehulled and milled soybean flour was treated with *n*-hexane five times to remove oil and was then dried at room temperature. The defatted soybean flour was treated with hexane/ethanol (1:2, v/v) at 4 °C for 1 h. The slurry was vacuum filtered, and the filter cake was treated with 95% (v/v) ethanol at 4 °C for 1 h to remove soluble sugars.[25] After drying at room temperature, the meal was dispersed in distilled water (1:10, w/v), and the pH was adjusted to pH 7.0 using 2 mol/L NaOH. After stirring for 1 h at 20 °C, the suspension was centrifuged at 15800*g* for 30 min at 4 °C. The supernatant was adjusted to pH 4.5 with 2 mol/L HCl and centrifuged at 4000*g* for 30 min at 4 °C. The precipitate was washed twice with distilled water and was resuspended in 5-fold (w/w) of the same and neutralized to pH 7.0 using 2 mol/L NaOH. After centrifuging at 15000*g* for 30 min at 4 °C to remove a small amount of insoluble substances, the supernatant was freeze-dried and then stored at 4 °C until use. Protein content in the prepared soy protein powder was 90% (w/w) as determined by using the micro-Kjeldahl method.

Heat Treatment of Soy Protein. Soy protein powder was suspended in 0.01 mol/L sodium phosphate buffer (pH 7.0). After centrifuging at 25000*g* for 30 min at 4 °C (Himac CR21GII, Hitachi, Tokyo, Japan) to remove a small amount of insoluble particles, the suspension (30 g/L) was obtained. The elongated screw-capped test tubes were filled with the soy protein solutions to prevent water evaporation. After heating in a water bath at 80 or 90 °C for different time lengths, the soy protein solutions were immediately cooled in an ice−water bath.

Sulfhydryl Content Determination by Colorimetric Method. The total free sulfhydryl content (SH_T) was determined according to the method of Ruan et al.[4] Soy protein solutions were diluted with the SDS buffer (pH 7.0) to make the final SDS concentration of 2% (w/v), and protein concentration was 3 g/L. The excess SH detecting reagent 4,4′-dithiodipyridine (DPS) (0.16 mmol/L) was added before the addition of SDS. The samples were vortexed and detected immediately at 324 nm against a buffer blank in a UV−vis spectrophotometer (UV-2450, Shimadzu, Kyoto, Japan) until the absorbance reached the maximum value (A_{324}). In the parallel reagent blank ($A_{324\,r}$), protein solution was replaced with 0.01 mol/L buffer (pH 7.0), mixed with DPS, and incubated for the same time. In the parallel protein blank ($A_{324\,p}$), DPS was replaced with water. SH_T was obtained as μmol SH/g soy protein. The calculation was

$$SH_T = (A_{324} - A_{324r} - A_{324p})/(\varepsilon \times L \times C) \times 10^6$$

where ε is the molar absorption coefficient ($M^{-1}\ cm^{-1}$), L is the light path (1 cm), and C is the protein concentration (g/L).

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed on a vertical slab unit (Bio-Rad, purchased from Nanjing, China). A 12% resolving gel overlaid with a 3% stacking gel was used. Each sample was adjusted to the same concentration (Lowry method) and mixed with nonreducing 2× sample dissolving buffer (4% SDS, 20% glycerol, 0.125 mol/L Tris-HCl buffer (pH 6.8), 0.02% bromophenol blue). The samples were heated at 100 °C for 3 min and loaded onto SDS-PAGE gels. After running, the gel was fixed in methanol/water/acetic acid (5:5:1, v/v/v) overnight and stained for 2 h using 0.05% (w/v) Coomassie brilliant blue (CBB) R250. After staining, the gels were destained using a 10% (v/v) acetic acid solution until a clear background was obatined. The gels were scanned using a computing densitometer (Molecular Imager Chemi Doc XRS+, Bio-Rad, purchased from Nanjing, China). The CBB stained intensities of the protein bands were integrated using Image Lab software (Bio-Rad, purchased from Nanjing, China). The content of each band in soy proteins (*C*, g/g soy protein) was determined by comparing the individual band intensities with the total intensity of all bands in a lane. Molecular weights (MW) of the gel bands were estimated by molecular weight markers (Prestained Precision Plus, Bio-Rad, purchased from Nanjing, China), and the regression method is cubic spline.

mBBr Labeling Combined with SDS-PAGE. Soy protein was mixed with SDS buffer to make the final SDS concentration of 2%. The fluorescent labeling reagent monobromobimane (mBBr) was added immediately to label SH of soy protein in the dark.[26] After reaction finishing, the mixture was exposed to light to destroy unreacted mBBr because of susceptibility to photodegradation.[27] The mBBr-labeled protein was subjected to SDS-PAGE. After running, the gel was fixed in methanol/acetic acid/water (5:5:1, v/v/v) overnight with at least three solution changes. The fluorescence of bands was visualized with UV light excitation on a computing densitometer (Molecular Imager Chemi Doc XRS+, Bio-Rad, purchased from Nanjing, China). The same gel was stained with CBB R250 and scanned.

The fluorescence intensities were integrated by Image Lab software (Bio-Rad, USA). The allocation of free SH on the components of soy protein (SH^a, μmol SH/g soy protein) and the free SH content of the components (SH^c, μmol SH/g component) can be obtained as

$$SH^a = \frac{FI_i}{FI_T} \times SH_T \quad (1)$$

$$SH^c = \frac{SH^a}{C} \quad (2)$$

where FI_i is fluorescence intensities of individual band, FI_T is total fluorescence intensities of all bands in a lane, SH_T (μmol SH/g soy protein) is total free SH content of soy protein determined by colorimetric method, and *C* is content (by mass) of the component in soy proteins (g/g soy protein).

Diagonal SDS-PAGE. The mBBr-labeled protein dissolved in the nonreducing sample buffer was subjected to the first-dimensional electrophoresis. After running, the lane of interest was excised from the gel, immersed in distilled water (containing 50 mmol/L DTT) for 10 min at room temperature, and then boiled for 5 min to reduce SS. The reduced lane was placed on the top of another gel and overlaid with 0.5% low-melting agarose (Bio-Rad, purchased from Nanjing, China). Then the second-dimensional electrophoresis was conducted. The fluorescent spots were visualized with UV light excitation. Then the same gel was stained with CBB R250 and scanned. If the bands had SS in the first-dimensional electrophoresis lane, they would resolve into spots below the oblique diagonal line of the second-dimensional electrophoresis gel. If SS was not present in the bands of the first-dimensional electrophoresis lane, the spots in the second-dimensional electrophoresis gel would lie on an oblique diagonal line. The fluorescence intensities and CBB-stained intensities of the spots were integrated by Quantity One software (Bio-Rad, USA). The allocation of free SH on the spots (SH^a_{spot}, μmol SH/g soy protein) and the free SH content of the spots (SH^c_{spot}, μmol SH/g spot) can be obtained as

$$SH^a_{spot} = \frac{FI_{spot}}{FI_{T\,spot}} \times SH^a \quad (3)$$

$$SH^c_{spot} = \frac{SH^a_{spot}}{C_{spot}} \quad (4)$$

DOI: 10.1021/jf504519z

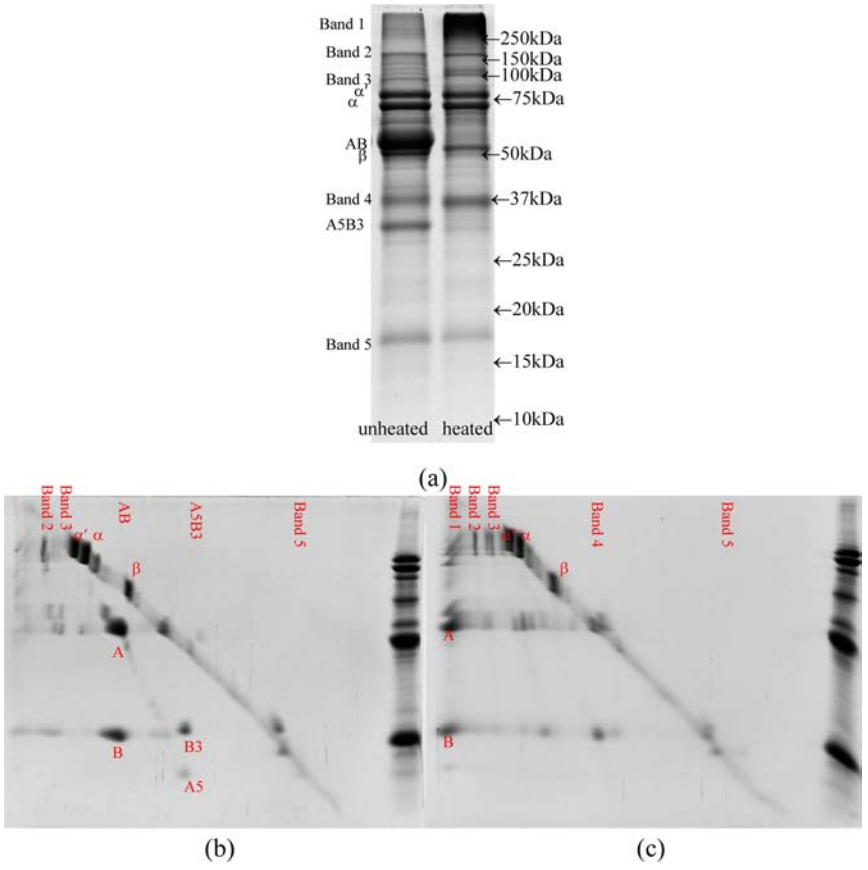

Figure 1. (a) Nonreducing SDS-PAGE pattern of unheated soy protein and heated soy protein (90 °C, 1800 s); diagonal SDS-PAGE pattern of unheated soy protein (b) and heated soy protein (90 °C, 1800 s) (c).

where FI_{spot} is the fluorescence intensity of the spot resolved from the original band, $FI_{T\ spot}$ is total fluorescence intensities of all spots resolved from the original band, SH^a (μmol SH/g soy protein) is the free SH allocation on the original band, and C_{spot} is the content (by mass) of the spot in soy protein (g/g soy protein).

In-Gel Tryptic Digests and Matrix-Assisted Laser Desorption/Ionization−Time-of-Flight/Time-of-Flight Mass Spectrometry (MALDI-TOF/TOF-MS). The SH of soy protein was blocked with NEM in the presence of 2% SDS. The NEM-modified soy protein was subjected to noreducing SDS-PAGE. After running, gel was stained with zinc negative staining. The zinc staining method was used to avoid protein fixation by organic solvent and interference of the dye.[28] Gels were first equilibrated in deionized water for 5 min, stained with 200 mmol/L imidazole, 0.1% SDS for 15 min, washed with deionized water for 1 min, and then developed with 0.1 mol/L $Zn(Ac)_2$ until sufficient contrast was obtained.

Gel pieces were excised from the gel and destained with 1% citric acid twice for 20 min by vortexing. The gel pieces were washed with three times for 10 min in deionized water and dehydrated in a vacuum centrifuge. The gel pieces were incubated with 10 mmol/L DTT at 56 °C for 45 min and subsequently with 60 mmo/L IAM at room temperature for 30 min to ensure complete reduction and carbamidomethylation of cysteine residues.[29] After deionized water washing and dehydration in a vacuum centrifuge, gel pieces were rehydrated on ice for 30 min with 20 μL of 10 μg/mL trypsin (Promega, V5111) in 25 mmol/L NH_4HCO_3 at pH 8.0. After the addition of 20 μL 25 mmol/L NH_4HCO_3, the samples were incubated for 20 h at 37 °C. The trypsin digests was collected, and the gel pieces were extracted with 50 μL of 0.1% trifluoroacetic acid in 60% acetonitrile by sonication for 15 min at room temperature. The extracts were combined with the trypsin digests and dried in a vacuum centrifuge. Peptides were redissolved in 3 μL of 0.1% trifluoroacetic acid.

The alternative SS reduction protocol without carbamidomethylation was also conducted:[20] The gel pieces were excised, destained, washed, and dehydrated. Protein digestion was carried out following the addition of trypsin. The resulting peptides were collected and dried. The SS were reduced by dissolving the dried peptides in 3 mmol/L DTT for 45 min at 56 °C. The peptides were dried again under vacuum and redissolved in 0.1% trifluoroacetic acid.

In the final step before MALDI-TOF/TOF analysis, 0.7 μL of peptide and 0.7 μL of 4-hydroxy-α-cyanocinnamic acid (used as a matrix) were loaded on a MALDI target and air-dried. The mass spectra were obtained with an ultrafleXtreme MALDI-TOF/TOF MS (Bruker Daltonics, Germany, purchased from Shanghai, China). All mass spectra were analyzed by flexAnalysis and Biotools software provided by Bruker Daltonics Corp (Germany).

Data Interpretation Using Database. The experimentally determined mass-to-charge ratio (m/z) values were used to search theoretically generated peptide masses from known protein sequences. Protein identification was performed by searching the National Center for Biotechnology Information (NCBI) nonredundant database using the Mascot search engine (www.matrixscience.com), which uses a probability-based scoring system. For database searches, the parameters were used as follows: average mass, 300 ppm peptide mass tolerance; 1.0 Da MS/MS mass tolerance; peptide charges of +1; trypsin as digesting enzyme with two missed cleavages allowed; carbamidomethylation of cysteine; oxidation of methionine; and NEM of cysteine as allowable variable modifications. Taxonomy was limited to green plants for both MALDI-TOF-MS and MS/MS ion searches.

Statistical Analysis. Three separate soy samples were used, and each sample was run in triplicate. Data were subjected to an analysis of variance (ANOVA) with SAS 9.1 package (SAS 2005). Significant differences among variables were determined by LSD all-pairwise multiple comparisons ($p < 0.05$). Data were expressed as the mean ± SD ($n = 3$).

RESULTS AND DISCUSSION

Newly Formed SS-Linked Products of Soy Protein by Heating. The unheated soy protein dissolved into several

DOI: 10.1021/jf504519z
J. Agric. Food Chem. 2015, 63, 3524−3533

bands in nonreducing SDS-PAGE (Figure 1a): subunits of β-conglycinin (α', α, β), AB (glycinin subunit), A5B3 (SS-linked portion of A4A5B3, one type of glycinin subunit), and some other bands.[30]

Diagonal SDS-PAGE was used to determine the SS-linked bands (Figure 1b). Table 1 shows the results of unheated soy protein. α', α, and β were positioned on the diagonal line, indicating that they had no SS; AB resolved into A and B, and A5B3 resolved into A5 and B3 below the diagonal line, indicating the presence of interchain SS between A and B; band 2 resolved into α' and α below the diagonal line and should be an SS-linked dimer of α' and/or α; band 3 resolved into A and B below the diagonal line and should be an SS-linked dimer of AB;[3,7] band 4 should be A4;[1] and band 5 was positioned on the diagonal line.

The bands of unheated soy protein in nonreducing SDS-PAGE were subjected to in-gel digestion, and the tryptic peptides were analyzed by MALDI-TOF/TOF MS. The proteins identified from the bands are shown in Table 1. The bands of α', α, and β were matched to the corresponding subunits of β-conglycinin. All five species of glycinin subunit (G1−G5) were detected in the AB band. The A5B3 band was matched to G4. G4 was detected in the AB band, indicating the presence of another SS-linked form (A4B3) in G4, except for A5B3. A4B3 might be formed in the soy protein extraction process. α' and α were detected in band 2, in agreement with the result of diagonal SDS-PAGE. Band 2 could be a homodimer of α'/α or a heterodimer of α' and α. The dimer could be formed in the cotyledon cell of soybean or generated during the soy protein extraction process.[30,31] Three species of glycinin subunits (G1, G4, and G5) were detected in band 3, which could form homo/hetero dimers. Band 4 was matched to A4. Band 5 was matched to Kunitz trypsin inhibitor (KTI).

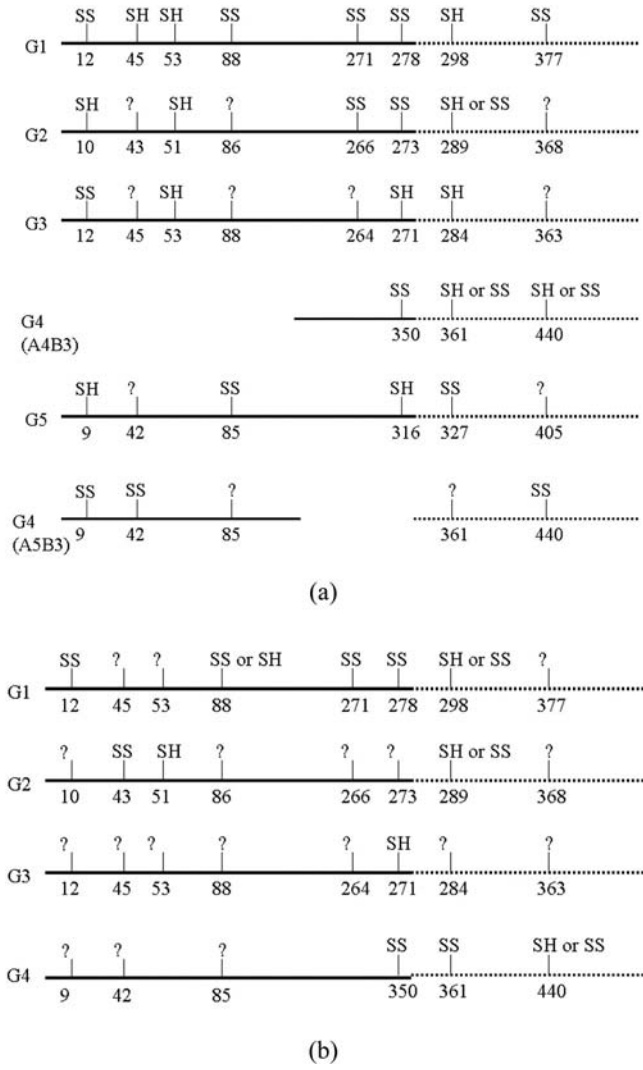

Figure 2. (a) Cysteine status (SH or SS) of glycinin subunit; (b) cysteine status (SH or SS) of polymer: solid line, acidic polypeptides (A); dotted line, basic polypeptides (B).

After heat treatment (90 °C, 1800 s), the glycinin subunits (AB and A5B3) disappeared completely, accompanied by the formation of band 1 on the top of the resolving gel and band 4 (Figure 1a). The newly formed SS-linked bands were also examined by diagonal SDS-PAGE (Figure 1c), and the result is shown in Table 2. Band 1 was a polymer composed of A, B, and small amounts of α' and α, which interacted with each other via intermolecular SS.[18] Band 4 resolved into two spots: the one on the diagonal line was A; the other below the diagonal line was B. This revealed that band 4 contained two components: monomer of A and SS-linked dimer of B (A&BB).

The proteins identified from the bands of heated soy protein (90 °C, 1800 s) in nonreducing SDS-PAGE are shown in Table 2. Five species of glycinin subunits (G1−G5) were detected in the polymer, indicating the complex heterogeneity of the polymer. Although G4/G5 has higher thermal stability than G2/G3/G1,[32,33] little effect has been seen for the formation of polymer. α' and α were not detected in the polymer, which might be because of their lower content in the polymer. Five species of glycinin subunits (G1−G5) were detected in the A&BB.

DOI: 10.1021/jf504519z
J. Agric. Food Chem. 2015, 63, 3524−3533

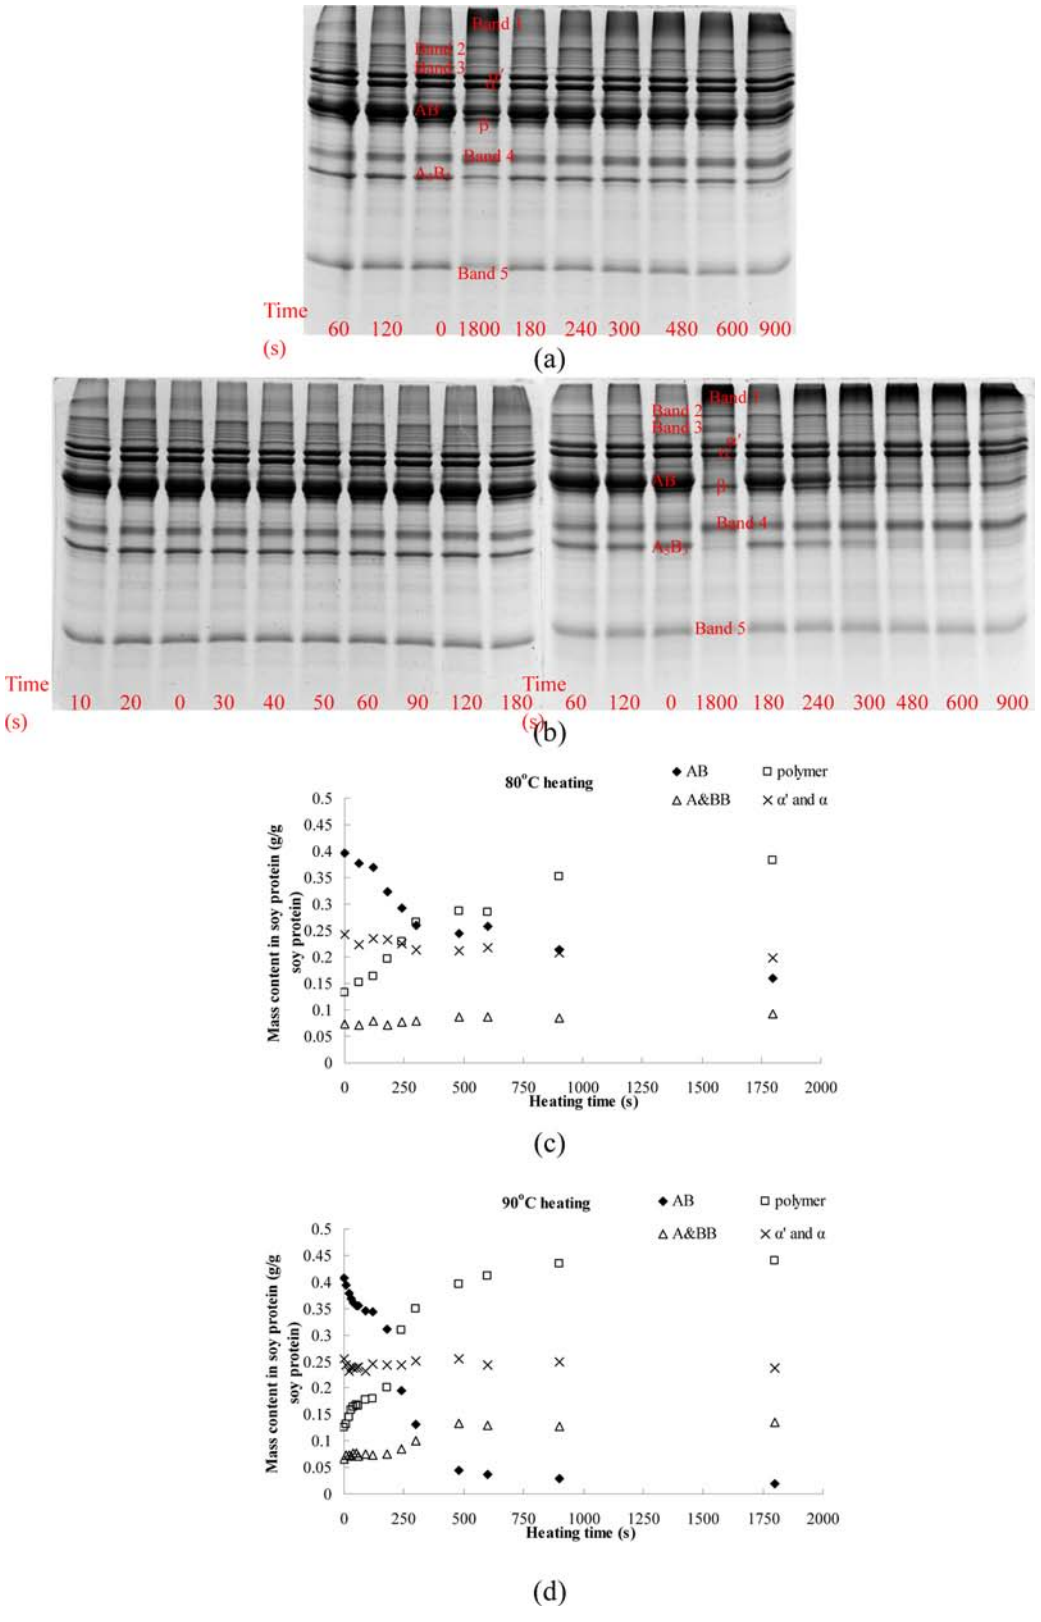

Figure 3. Nonreducing SDS-PAGE pattern of soy protein heated at 80 °C (a) and 90 °C (b) for different time lengths (0−1800 s); effect of heating temperature and time on relative mass content of AB, polymer, monomer of A and dimer of B (A&BB), and α' and α in soy protein (c, 80 °C; d, 90 °C).

The composition of band 2 (α' and α) was unchanged, indicating that the dimer of α' and/or α was stable by heating. The α', α, G1, and G2 were detected in band 3, and this oligomer might be a byproduct in the process of polymer formation.

In general, most of the glycinin was associated by intermolecular SS for forming polymer, and a small amount of glycinin was dissociated to form the A&BB by heating. Many researchers have found that heat-treated soy protein exhibited

bands with large molecular weight containing intermolecular SS, suggesting the presence of intermolecular SS due to the SH oxidation and/or SH−SS exchange reactions.[7,14−16]

Analysis of the Conversion of Cysteine Status between SH and SS. The glycinin subunit was associated so as to form polymer due to SH oxidation or SH−SS exchange reaction, leading to the conversion of cysteine side chain between SH and SS consequentially. The cysteine status (SH or SS) was examined by mass spectrometry analysis. The bands in nonreducing SDS-PAGE were subjected to in-gel tryptic digestion. The cysteine side chains in SH form were NEM-modified, causing a 125 Da mass increase of tryptic peptides. The SS were reduced and IAM-modified, causing a 57 Da mass increase of tryptic peptides. (Detailed information is shown in the Supporting Information).

The cysteine status of β-conglycinin of unheated soy protein was first examined. The α' and α subunits of β-conglycinin theoretically have only Cys7 (SH).[1] The peak at m/z 2798.5280 in the peptide map of the α' band represented the peptides containing NEM-modified Cys7, indicating the Cys7 (SH) of α'. The peak at m/z 2730.2954 in the peptide map of the dimer of α' or α represented the peptides containing IAM-modified Cys7 of α'. This indicated that the Cys7 (SH) of α' was oxidized to form an intersubunit SS of dimer of α' or α. Unluckily, the peptides containing Cys6 of α were not found in tryptic digests of α or dimer.

For the dimer of glycinin subunit of unheated soy protein, the cysteine status identified was (1) G5, A3, Cys9 (SH and SS), Cys85 (SS), Cys316 (SH); B4, Cys327 (SH and SS), Cys405 (SH); (2) G1, A1a, Cys12 (SS), Cys45 (SH), Cys88 (SH); B1b, Cys298 (SH); (3) G4, Cys440 (SH and SS). For G5, the presence of Cys9 (SH) and Cys327 (SH) indicated that the theoretical intrachain SS in A3 (Cys9−Cys42) or theoretical interchain SS between A3 and B4 (Cys85−Cys327) was likely to be broken by SH−SS exchange and then form an intersubunit SS. For G1, theoretical intrachain SS in A1a (Cys12−Cys45) and theoretical interchain SS between A1a and B1b (Cys88−Cys298) could be broken by SH−SS exchange to form intersubunit SS.

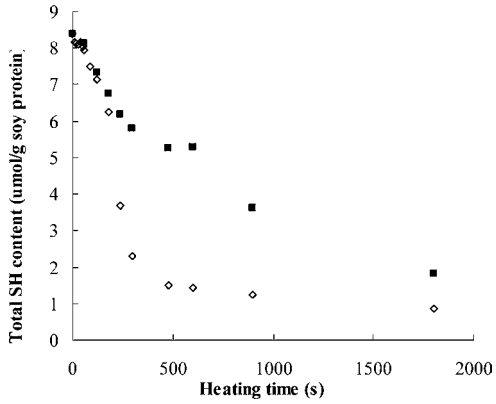

Figure 4. Effect of heating temperature and time on total free sulfhydryl content (SH_T) of soy proteins: (■) 80 °C; (◇) 90 °C.

The cysteine status identified from the AB band of unheated soy protein is shown in Figure 2a. For G1, the theoretical interchain SS between A1a and B1b should be Cys88−Cys298, but Cys298 (SH), Cys88 (SS), and Cys377 (SS) were identified. Because the glycinin subunit (AB) remained intact, Cys377 might have replaced Cys298 to form the Cys88−Cys377, resulting in Cys298 (SH). Cys271 (SS) and Cys278 (SS) suggested the presence of intrachain SS in A1a (Cys271−Cys278). Cys12 (SS) and Cys45 (SH) indicated that theoretical intrachain SS (Cys12−Cys45) in A1a might be broken. The theoretical SH in A1a (Cys53) was detected from tryptic peptides. For G2, the Cys289 (SH and SS) in B1a was identified, whereas Cys289 theoretically should be involved in interchain SS between A2 and B1a. Similarly, Cys284 of G3 theoretically involved in interchain SS between A1b and B2 was identified as SH. Interestingly, G4 was found in the AB band, indicating that A4 and B3 were linked by SS. The Cys350 (SS) in A4, Cys361 (SH and SS) in B3, and Cys440 (SH and SS) in B3 indicated that Cys350−Cys361 or Cys350−Cys440 could be the interchain SS between A4 and B3. For G5, Cys85 (SS) and Cys327 (SS) indicated the presence of interchain SS (Cys85−Cys327) between A3 and B4, and Cys316 (SH) in A3 was identified. Cys440 (SS) was identified from the peptide map of A5B3 band, indicating that Cys440 might be involved in the interchain SS between A5 and B3.

Figure 2b shows the cysteine status identified from polymer. Cys12 (SS), Cys271 (SS), Cys88 (SH and SS), and Cys298 (SH and SS) of G1 were identified in polymer. Cys298 of G1 was SH before heating. The presence of Cys298 (SS) in polymer, identified from the peptide containing IAM-modified Cys298 at $[M + H]^+$ 1724.90, indicated that the Cys298 (SH) was involved in SH−SS exchange or SH oxidation for forming intermolecular SS of polymer. The Cys88 of G1 was involved in Cys88−Cys377 between A1a and B1b before heating. The emergence of Cys88 (SH) in polymer, identified from the peptide containing NEM-modified Cys88 at $[M + H]^+$ 2751.2972, indicated that Cys88−Cys377 was most likely to be broken by SH−SS exchange for forming intermolecular SS. In addition, the possibility could not

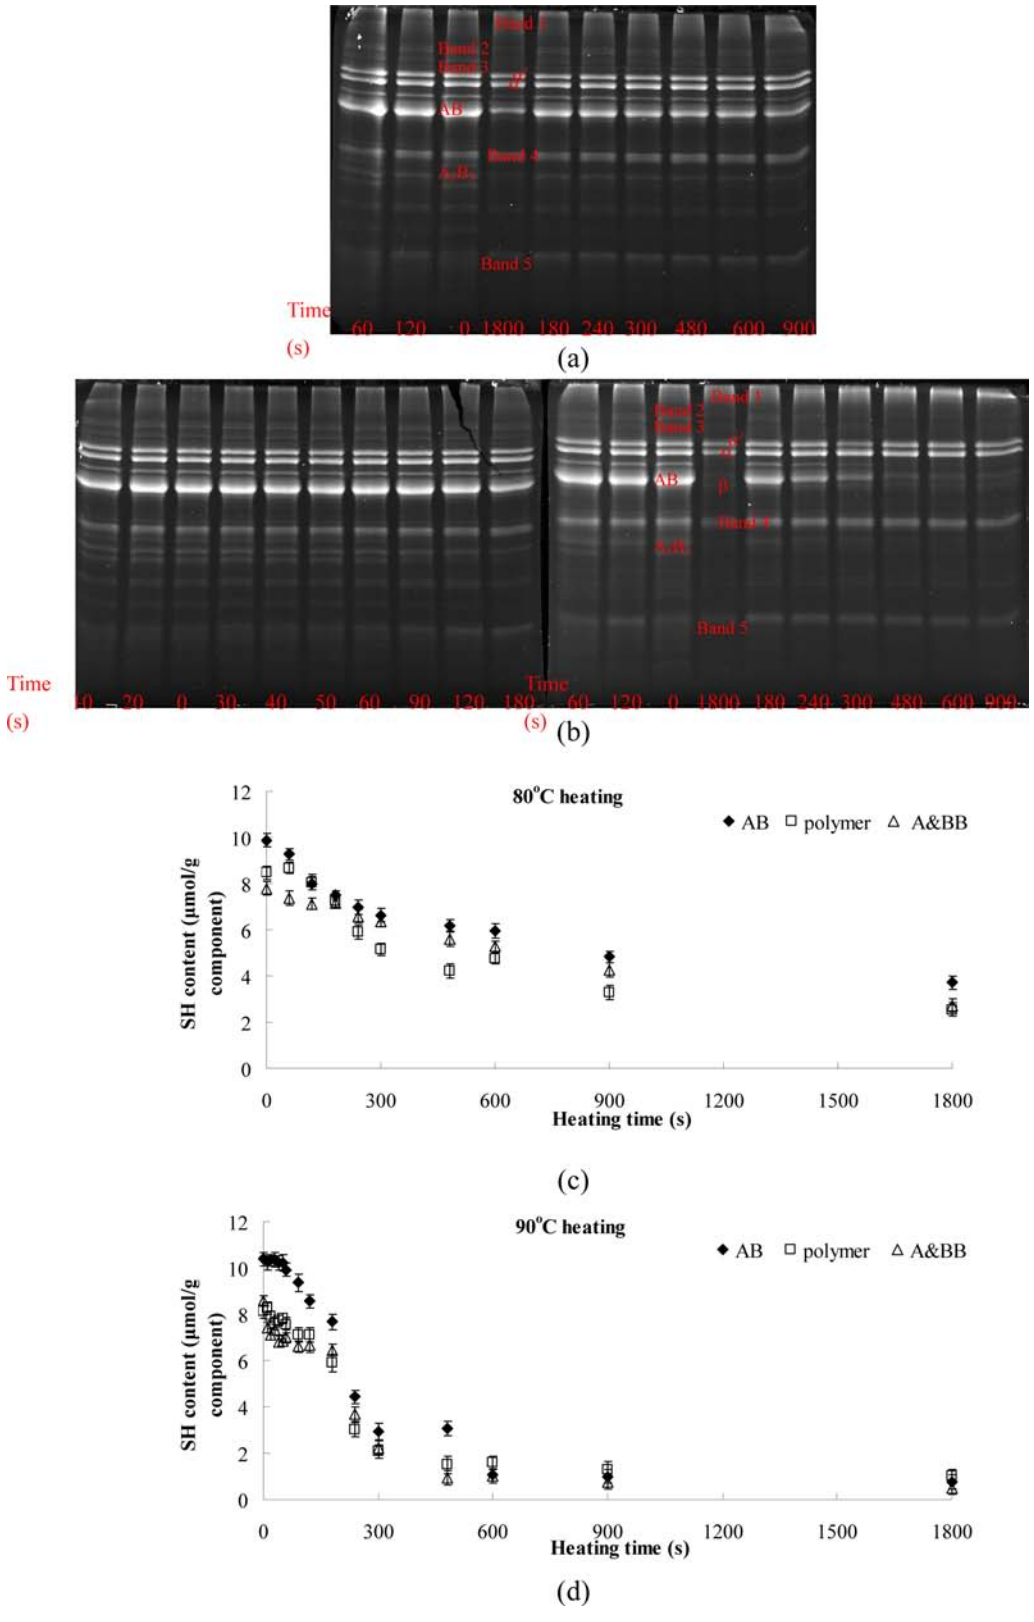

Figure 5. Fluorescence pattern of nonreducing SDS-PAGE of mBBr-labeled soy protein heated at 80 °C (a) and 90 °C (b) for different time lengths (0−1800 s); effect of heating time and temperature on SH contents of glycinin subunits (◆), polymer (□), and monomer of A and dimer of B (A&BB) (△) (c, 80 °C; d, 90 °C).

be eliminated that Cys12 and Cys271 in A1a were included in intermolecular SS of the polymer.

Cys289 (SH and SS) in B1a of G2 was identified in the polymer. The intensities of peptides containing NEM-modified Cys289 at $[M + H]^+$ 2062.0936 and 1662.9355 were higher than that of peptides containing IAM-modified Cys289 at $[M + H]^+$ 1764.9568 for G2 before heating. However, in the polymer the intensity of peptides containing NEM-modified Cys289 at

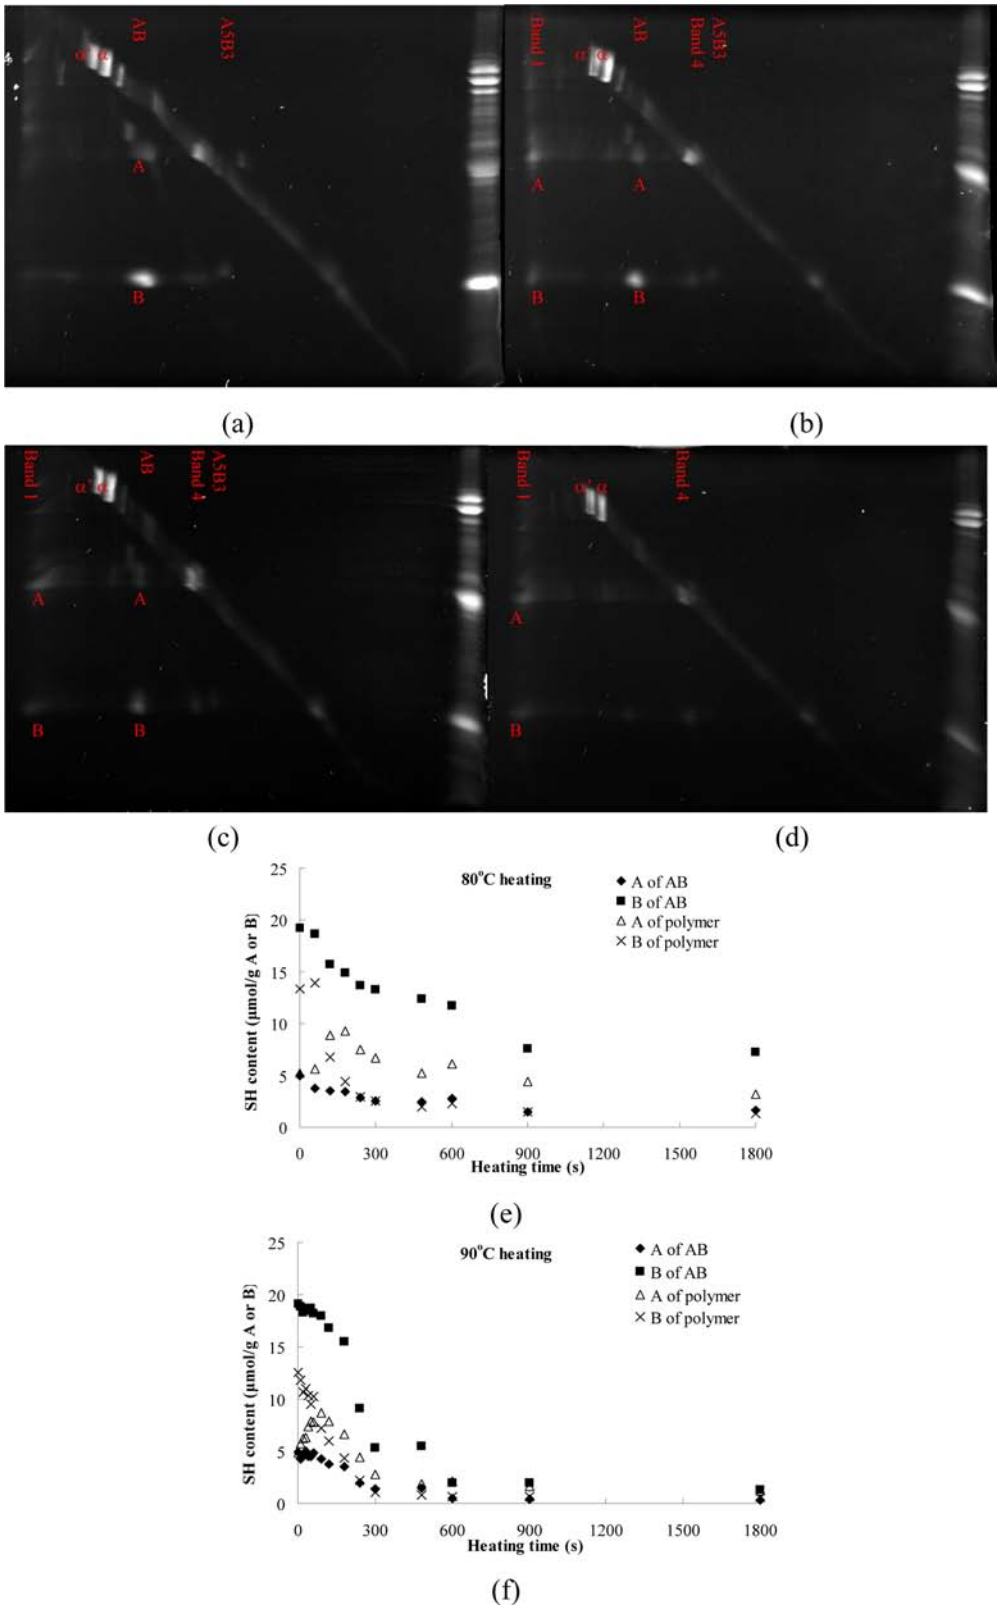

Figure 6. Fluorescence patterns of diagonal SDS-PAGE of soy protein (a, unheated; b, 80 °C, 1800 s; c, 90 °C, 300 s; d, 90 °C, 1800 s) (parts of the patterns are shown here); effect of heating time and temperature on the SH contents of acidic (A) polypeptide and basic (B) polypeptide in glycinin subunit (A, ◆; B, ■) and polymer (A, △; B, ×) (e, 80 °C; f, 90 °C).

$[M + H]^+$ 1792.9779 and 2062.0936 was adjacent to the intensity of peptides containing IAM-modified Cys289 at $[M + H]^+$ 1724.8674 and 1764.9508, suggesting that the Cys289 (SH) participated in SH−SS exchange or SH oxidation to form intermolecular SS of polymer. Cys440 of G4 was involved in Cys85−Cys440 and Cys350−Cys440 before heating. Cys440 (SH and SS) was identified in the polymer, suggesting that Cys440 (SH) was released by breaking the SS due to SH−SS exchange.

J. Agric. Food Chem. 2015, 63, 3524−3533

The cysteine status identified from the peptides map of A&BB contained (1) G1 (A1a, Cys12 (SS); B1b, Cys298 (SH)); (2) G2 (B1a, Cys289 (SH); A2, Cys273 (SH)); (3) G3 (A1b, Cys264 (SS)); (4) G4 (B3, Cys440 (SS)); and (5) G5 (B4, Cys405 (SH)). Cys440 (SS) in B3 of G4 suggested that Cys440 was one of the cysteine-forming SS between two monomers of B. Cys298 (SH) of G1, Cys289 (SH) of G2, and Cys405 (SH) of G5 might imply that the other cysteine of B, Cys377 of G1, Cys368 of G2, and Cys327 of G5, would be involved in SS between two monomers of B.

The cysteines identified from the peptides map of the oligomer (α', α, G1, and G2) of heated soy protein included (1) G1 (B1b, Cys298 (SH); A1a, Cys88 (SS)) and (2) G2 (B1a, Cys289 (SH and SS); A2, Cys266 (SH and SS), Cys273 (SS)). Cys88 (SS) of G1, Cys289 (SS) of G2, Cys266 (SS) of G2, and Cys273 (SS) of G2 were involved in the intermolecular SS of oligomer. (Cys86−Cys289) or (Cys266-Cys273) of G2 could be broken due to SH−SS exchange for forming intersubunit SS, resulting in Cys289 (SH) and Cys266 (SH).

In general, according to the cysteine status analysis, it was found that the interchain SS between A1a and B1b of G1 (Cys88−Cys298) was replaced by Cys88−Cys377, which might occur during the protein extraction process. Cys298 of G1, Cys289 of G2, and Cys440 of G4 were prone to participating in SH−SS exchange or SH oxidation for forming intermolecular SS of the polymer.

Evidence for SH Oxidation and SH−SS Exchange Reaction Supplied by SH Content Change of Subunit/Polypeptide. Soy protein heated at 80 and 90 °C for different times was subjected to nonreducing SDS-PAGE (Figure 3a,b). As shown, the glycinin subunits (AB and A5B3) progressively disappeared with heating time (0−1800 s).[7] The polymer and A&BB were gradually formed with heating time. The phenomena were further enhanced at higher temperature. The relative mass content of bands in soy proteins (C, g/g soy protein) was determined by comparing the individual band intensities with the total intensity of all bands in a lane (Figure 3c,d). The relative mass content of glycinin subunits decreased from 40 to 15% after heating at 80 °C for 1800 s, whereas at 90 °C glycinin subunits almost disappeared. More polymer was formed than A&BB. The relative contents of polymer and A&BB were approximately 45 and 13%, respectively, after heating at 90 °C for 30 min.

The total free SH content of soy protein (SH_T) was first determined and is shown in Figure 4. The SH_T of unheated soy protein was 8.4 μmol SH/g protein, which was in the wide range (0.2−14.8 μmol SH/g protein) reported in previous studies. The SH_T was decreased with heating time, which was promoted by increasing temperatures. This was in accordance with previous researches.[7,8,12] The decrease of SH_T indicated that the SH oxidation may be responsible for forming intermolecular SS of polymer. SH oxidation by molecular oxygen in aqueous solutions is suggested to be a common route for SS formation.[34] Sulfenic acids (RSOH) are formed by the oxidation of SH with dissolved molecular oxygen. Sulfenic acids exhibit potent electrophilic reactivity. Thiols can react with sulfenic acids to form SS.[35−38] SH−SS exchange is another way to break or form SS. The SH−SS exchange is a bimolecular nucleophilic substitution reaction (SN_2) in which the attacking nucleophile is the thiolate. The driving force of the reaction is the relatively low activation energy required for SH to break SS.[34,35]

Panels a and b of Figure 5 show the fluorescence pattern of nonreducing SDS-PAGE of mBBr-labeled soy protein. The SH contents of three major components (glycinin subunit, polymer, and A&BB) were calculated according to eqs 1 and 2, and the effects of heating time and temperature on the SH content are shown in Figure 5c,d. The SH content of all three major components was decreased obviously with heating time. An important feature was that the SH content of heat-generated products, polymer and A&BB, was lower than that of the principal-sourced proteins, glycinin subunit at heating phase. This confirmed that part of the intermolecular SS of polymer was formed by SH oxidation.

The fluorescence pattern of diagonal SDS-PAGE of mBBr-labeled soy protein (Figure 6a−d) and the corresponding CBB-stained patterns were also obtained (all heating samples were conducted but not all patterns are shown here). Panels e and f of Figure 6 show the SH content of A and B in glycinin subunit and polymer calculated according to eqs 3 and 4. The SH content of B (20 μmol/g B) was about 4 times higher than that of A (5 μmol/g A) in glycinin subunit before heating. The heat-induced decrease of SH content of B in glycinin subunit was more severe than that of A. The SH content of B in polymer was also decreased by heating, and much lower than the SH content of B in glycinin subunit, indicating the oxidation of SH of B. An important feature was that the SH content of A in polymer, which was lower than the SH content of B in polymer before heating, increased and exceeded the SH content of B after a short heating time and then remained higher than the SH content of B for prolonged heating. In addition, the SH content of A in polymer was always higher than the SH content of A in glycinin subunits. These results indicated that the SH was transferred from B to A when glycinin subunits were associated with form polymer, which was most likely due to the SH−SS exchange reaction between SH of B and SS of A.

As above, the SH of B in glycinin subunit was subjected to not only SH oxidation but also SH−SS exchange reaction for forming intermolecular SS of polymer. SH−SS exchange reaction was confirmed between SH of B and SS of A for the first time. The SH of B was suggested to be reactive for forming intermolecular SS of polymer, supporting the inference of Yamauchi et al.[39,40]

In this study, the disulfide-mediated interactions of soy protein during heat treatment were studied by nonreducing SDS-PAGE, diagonal SDS-PAGE, thiol-specific fluorescence labeling, and mass spectrometry analysis. The polymer was the major product composed of A, B, and small amounts of α' and α, which interacted with each other via intermolecular SS. The SH of B in the glycinin subunit was subjected to not only SH oxidation but also SH−SS exchange reaction for forming intermolecular SS of polymer. The SH of B (Cys298 of G1, Cys289 of G2, Cys440 of G4) identified by mass spectrometry was suggested to be reactive.

combined form polyelectrolyte complexes by molecular entanglements, ionic forces, hydrogen bonding, or hydrophobic forces.[17] The assembly of the protein-loaded CS/CRG magnetic nanoparticles was mediated by polyelectrolyte complexation under mild conditions, thus avoiding harmful organic solvents or high shear forces and retaining protein activity during immobilization.

Currently, because of high costs and complex methodology, enzyme immobilization has not yet been widely employed in industrial applications and is instead conducted either for the purpose of basic research or for use in technical processes.[9] Therefore, there is a need for the development of simple and green methods to facilitate the use of enzyme immobilization in industry. In the present work, we describe a simple, green, and novel method for the immobilization of pullulanase by adsorption. Chitosan was utilized as a flocculating agent to prepare pullulanase/chitosan complexes, which were then electrostatically coupled with Fe_3O_4/carrageenan nanoparticles. To prevent the adsorbed enzymes from leaking during repeated uses, which would restrict their application in enzyme immobilization, we further coated the immobilized enzymes with carrageenan by electrostatic interaction, expecting the interaction of chitosan, enzymes, and carrageenan to enhance the stability of the biocatalysts. Such structure was supposed to provide the advantage of high residual activity, besides the merit of enzyme recovery. To achieve these aims, the Fe_3O_4–κ-carrageenan nanoparticles were first prepared in situ under mild conditions without any surfactants. Pullulanase/chitosan mixtures were brought to complexing conditions by the slow addition of NaOH, and the effects of pH and protein/chitosan ratio on turbidity were investigated. The hybrid magnetic nanoparticles were then mixed with the pullulanase/chitosan complexes to obtain the immobilized enzymes and further coated with carrageenan. The effects of support/enzyme ratio on enzyme activity and protein loading were studied. Finally, the properties of the immobilized enzyme, such as kinetic behavior, pH and temperature profiles, thermal and operational stability, were also investigated.

MATERIALS AND METHODS

Materials. Pullulanase from *Klebsiella pneumoniae* and pullulan were purchased from Sigma-Aldrich. κ-Carrageenan (CRG, commercial grade) and chitosan (degree of deactylation = 90%) were obtained from Aladdin Industrial Co., Ltd. Ferric chloride hexahydrate ($FeCl_3 \cdot 6H_2O$), ferrous sulfate heptahydrate ($FeSO_4 \cdot 7H_2O$), and sodium hydroxide (NaOH) were obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). All other chemicals were analytic-grade and available from commercial sources.

Preparation of Hybrid Magnetic (Fe_3O_4–κ-Carrageenan) Nanoparticles. In situ synthesis of magnetic Fe_3O_4–κ-carrageenan nanoparticles was carried out as reported previously with minor modification.[12] In brief, 0.5 g of κ-carrageenan was dissolved in 100 mL of deoxygenated water, stirred until dissolved completely at 60 °C, and cooled to 40 °C. After cooling, 2 mL of $FeCl_3$ solution (0.2 M), freshly prepared in deoxygenated water, and 65 mg of $FeSO_4$ were immediately added to 20 mL of κ-carrageenan solution. To account for the possible oxidation of Fe^{2+}, ferrous ion was added in slight excess of the magnetite stoicheometric molar ratio (Fe^{3+}/Fe^{2+} = 2:1). After stirring the mixture for 15 min, 2.2 mL of 1 M sodium hydroxide was added, giving a final pH of over 10. The mixture immediately turned black, indicating that the Fe_3O_4–κ-carrageenan composite was successfully prepared.

Preparation of Pullulanase/Chitosan Complex Solutions. Chitosan powder was dispersed in 0.1% acetic acid solution (v/v) under magnetic stirring for 4 h at room temperature to prepare a 0.1% chitosan solution (w/v). Pullulanase was diluted with sodium acetate buffer (10 mM) to a final concentration of 1 mg/mL. Each solution was adjusted to a pH of 2.8. Turbidity titration of pullulanase/chitosan mixture was conducted by first mixing the two solutions at different ratios, ranging from 10:1 to 1:1, then slowly adjusting the pH to 8.0 with 0.1 M NaOH. Homogenous pullulanase (1 mg/mL) and chitosan solutions (0.1%, w/v) were used as blanks.[18]

Measurement of Turbidity. A UV–vis spectrophotometer (Shimadzu, Japan) with a 0.5 cm cuvette was used to measure turbidity at 600 nm. By the addition of gradated NaOH solutions (1, 0.5, 0.1 M), turbidimetric titration was carried out in increments of ∼0.1 pH unit up to a final pH of 8.0 under gentle stirring. Titrations were carried out at 25.0 ± 1.0 °C, and the pH (±0.01 pH unit) was monitored with a Mettler Toledo Delta 320 pH meter.[19]

Enzyme Immobilization. Fe_3O_4–κ-carrageenan nanoparticles were incubated with the pullulanase/chitosan complex solutions (pH 4.8) at 40 °C for 4 h under gentle stirring. After immobilization, successive washings with the buffer (pH 4.8) were conducted to remove the excess enzyme until no more activity was detected in the washing fractions. Then, the immobilized enzyme was further incubated with 0.1% (w/v) carrageenan solution (pH 4.8) at 40 °C for 1 h under gentle stirring and washed with the buffer several times.

The immobilized activity was calculated by taking the difference between the applied and the recovered activities. The amount of the immobilized protein was determined by subtracting the amount of protein remaining in the supernatant and washing solutions after 4 h of stirring from the amount of protein added to immobilization, according to the Bradford protein assay method reported previously.[20] The activity retention (AR) and enzyme loading efficiency were calculated according to the following equations:

$$\text{activity retention} = \frac{A_{\text{im}}}{A_0} \times 100 \quad (1)$$

where A_0 is the specific activity of free pullulanase and A_{im} is the specific activity of the immobilized enzyme.

$$\text{enzyme loading efficiency} = \frac{C_0V_0 - C_iV_i}{C_0V_0} \times 100\% \quad (2)$$

where C_0 and V_0 are the protein concentration and the volume of the free pullulanase solution added to immobilization, respectively, and C_i and V_i are the protein concentration and the volume of the supernatant solution after immobilization, respectively.

Characterization. A Zetasizer Nano ZS (Malvern Instruments, Malvern, UK) with a He/Ne laser of 633 nm wavelength was used to determine size distribution of freshly prepared nanoparticles; each sample was diluted to the appropriate concentration with ultrapure water, then placed in the electrophoretic cell at 20 °C. A high-performance digital imaging transmission electron microscopy (TEM) machine (JEM-2100 (HR), JEOL Ltd., Tokyo, Japan) was used to determine the particle size and morphology of the magnetic nanoparticles. Image-Pro Plus 6.0 (Media Cybernetics, Inc., Bethesda, Maryland, USA) was used to analyze the TEM micrographs to obtain the size distribution of nanoparticles. An average result of nanoparticle size was obtained by analyzing TEM images of 20 (total counts of particles: 200). Fourier transform-infrared (FT-IR) spectra were recorded using a Thermo Nicolet iS10 FT-IR Spectrometer (Thermo Electron Corp., Madison, WI, USA). X-ray diffraction (XRD) measurements were carried out with a BRUKER AXS GMBH D8 (Karlsruhe, Baden-Wuerttemberg, Germany) instrument; a continuous scan mode was used to collect 2θ data from 10 to 80°, at a constant rate of 4°/min. A vibrating-sample magnetometer (VSM, Lakeshore-7304, Westerville, Ohio, USA) was used to obtain magnetization curves at room temperature. Thermogravimetric analysis (TGA) was carried out with a Mettler Toledo SDTA 851e (Zürich, Canton of Zürich, Switzerland) instrument at a heating rate of 10 °C/min from 30 to 700 °C.

Activity Assay of Pullulanase. The activities of free and immobilized pullulanase were determined by the 3,5-dinitrosalicylic acid (DNS) method using pullulan as substrate.[2] In brief, 2 g of

DOI: 10.1021/jf505981t
J. Agric. Food Chem. 2015, 63, 3534–3542

pullulan was added into 100 mL of sodium acetate buffer (0.04 M, pH 4.4) to obtain a homogeneous pullulan solution (2%, w/v). Then 0.1 mL of free (50 μg/mL) or immobilized pullulanase (0.5 mg.d.s.mL^{-1}) solution was incubated with 1 mL of pullulan solution at a water bath of 50 °C for 30 min. The reaction was stopped by adding 1.5 mL of 3, 5-dinitrosalicylic acid (DNS). After incubation, the reaction mixtures were kept in boiling water for 10 min and then immediately cooled to room temperature. The reducing sugars were determined at an absorbance of 540 nm by the ultraviolet−visible (UV−vis) spectrophotometer. One unit of pullulanase activity was defined as the amount of enzyme that produced 1 μmol of reducing sugars (as maltotriose equivalents) in 1 min at 50 °C.

Kinetic Parameters of Free and Immobilized Enzyme. The kinetic properties of free and immobilized pullulanase were determined by using different substrate concentrations of 1−10 mg/mL. The kinetic constants K_m and V_m were calculated according to the Lineweaver−Burk plots.[21]

pH Stability. Stabilities of free and immobilized enzyme against pH were evaluated in light of the catalytic activity of enzyme by incubating enzyme at a pH range of 2.5−6.4 for 30 min at 50 °C, and their residual activities were determined.

Reusable Stability. The operational stability was assessed by incubating immobilized enzyme with pullulan (2%, w/v) in a water bath of 50 °C for 30 min, after which the activity was assayed immediately. After each reaction period, the immobilized pullulanase were removed from the reaction medium and washed with sodium acetate buffer (40 mM, pH 4.4). Then, the fresh pullulan solution was added again to start the reaction. The activity of the first run was defined as 100%.

Thermal Stability. The thermostabilities of free and immobilized pullulanases were tested in light of the optimum temperature and thermal inactivation courses. For the optimum temperature, enzymes were incubated in sodium acetate buffer (pH 4.4, 10 mM) in a water bath (20−65 °C) for 30 min, and their residually activities were determined. For the thermal inactivation courses, enzymes were incubated at 60 °C in 40 mM sodium acetate buffer (pH 4.4) for 6 h, and samples were withdrawn after incubation for 10, 20, 30, 60, 180, and 300 min, then immediately assayed for residual activity.

Statistical Analysis. The data expressed in various studies were plotted using Origin-8.5. Experiments were triplicated. Data represent the mean of three independent assays carried out in duplicate, and the results are presented as mean ± SD. Significant differences were determined statistically using one-way analysis of variance (ANOVA) posthoc Tukey test. Statistical significance was established at $p < 0.05$.

RESULTS AND DISCUSSION

Pullulanase/Chitosan Complexing Behavior as a Function of pH and Mixing Ratio. Chitosan is a well-known biopolymer commonly used in the formation of protein−polysaccharide complexes. Complex coacervates have many applications in the biotechnology, pharmaceutical, and food industries.[22] Amino groups in chitosan chains intensively interact with the carboxyl groups of enzymes largely by electrostatically driven forces, which in turn leads to the formation of a complex.[23] By controlling the conditions, this protein−polysaccharide complex could form nanoscale particles in soluble form in aqueous solution. For this reason, we first prepared pullulanase/chitosan complexes, then incubated them with magnetic nano−κ-carrageenan particles to prepare the nanoscale immobilized enzyme, and further coated them with carrageenan, expecting the interaction of biopolymers and enzymes to further prevent the adsorbed enzymes from leaking.

The complexing behavior of pullulanase/chitosan was affected by pH changes. The increase in absorbance at 600 nm upon addition of NaOH to the pullulanase/chitosan mixtures was indicative of the formation of colloidal dispersions via the self-assembly of the oppositely charged polyelectrolytes pullulanase and chitosan. Figure 1 shows the turbidity curves for the pullulanase/chitosan system. Below pH_c (the pH at

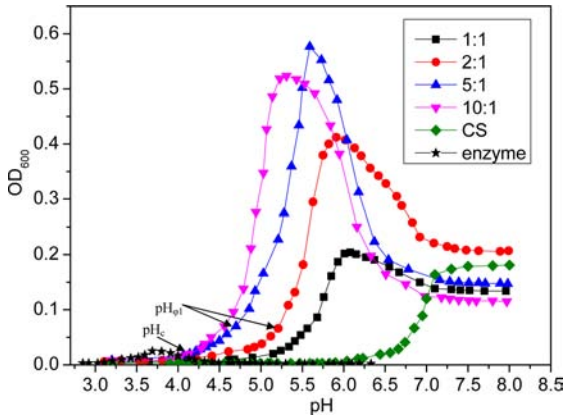

Figure 1. Turbidity curves for the pullulanase/chitosan system (C_p = 1 mg/mL) as a function of pullulanase/chitosan mixing ratio. Enzyme and chitosan (CS) solution at their corresponding concentrations were used as controls. The values of pH_c and $pH_{\varphi 1}$ were determined graphically as the intersection point of two tangents to the curve: pH_c corresponds to the pH value at which soluble complexes form, and $pH_{\varphi 1}$ corresponds to the pH value at which insoluble complexes form. Results are the mean of triplicates.

which soluble complexes form because of the local negative charges carried by proteins), the turbidity remained at the baseline because the electrostatic repulsive forces prohibited the formation of complexes. An abrupt increase in turbidity was observed with further addition of NaOH (at $pH_{\varphi 1}$), indicating the formation of insoluble complex particles. Before complexation with proteins, the chitosan solution was transparent until the pH increased to the pK_a of its amine (pH 6.3), where a protonated effect was observed. Therefore, the turbidity curve (Figure 1) for chitosan showed an abrupt increase at pK_a, followed by a maximum at around pH 7.0, and then reached the plateaus of turbidity, corresponding to the insolubility of chitosan.

Meanwhile, the pullulanase/chitosan interaction also can be affected by the mixing ratio. The decrease in pullulanase/chitosan ratio resulted in less negative charges being carried by proteins and more positive charges being carried by chitosan; as the consequence, $pH_{\varphi 1}$ shifted to higher pH values to achieve the charge neutralization.[24] At pullulanase/chitosan ratio = 2:1, the formation of soluble complex was distributed in a wide pH range from 4.0 (pH_c) to 5.27 ($pH_{\varphi 1}$). Ratios such as 5:1 and 10:1 had narrower pH ranges for soluble complex formation, whereas the 1:1 ratio yielded weak pullulanase−chitosan interactions that occurred near the deprotonation point of chitosan (pH 6.3). Therefore, the most flexible pH range for pullulanase−chitosan complex formation is seen using a mixing ratio of 2:1. From the view of charge neutralization (obtained at $pH_{\varphi 1}$), the negative charge of pullulanase (−12.5 mV, pH 4.8) was insufficient to neutralize the positive charge of chitosan solution (45.2 mV, pH 4.8) at the concentration of 0.1% (w/v), and the zeta potential of the complex was about 15.6 mV (pH 4.8), indicating the possibility that all the proteins were adsorbed in the chain of chitosan. Moreover, increased pH values led to the formation of insoluble complexes (pH 5.27), and there was almost no activity in the supernatant after centrifugation. These observations mean that the pullulanase was completely absorbed by chitosan at pH 5.27, indicating the

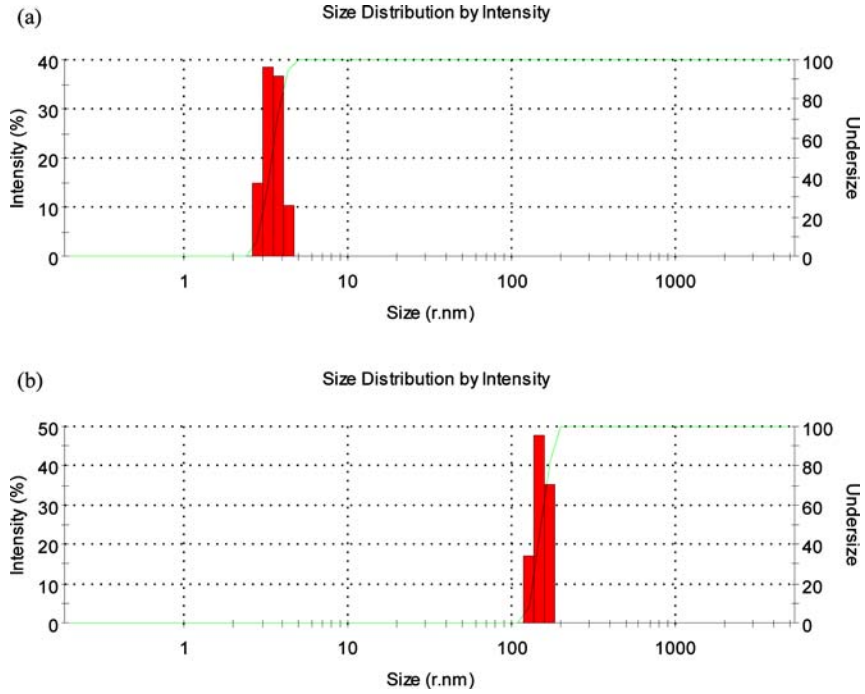

Figure 2. (a) Particle size distribution of the pullulanase/chitosan complex and (b) immobilized pullulanase.

high content of protein adsorbed by chitosan at pH 4.8 before phase separation.

In our research, the pullulanase/chitosan complexes formed at the ratio of 2:1 (pH 4.9) possessed an average diameter of 3.5 nm (Figure 2a), and after incubation of the complex with Fe_3O_4–κ-carrageenan nanoparticles, the immobilized enzyme showed an average diameter of 152 nm (Figure 2b). This indicated that the pullulanase/chitosan complexes take advantage of forming immobilized enzyme on the nanoscale because the diameter of immobilized enzyme was not in nanoscale when chitosan and pullulanase were added separately. Schematics for the fabrication process and the structure of the hybrid magnetic nanoparticles with immobilized pullulanase are shown in Figure 3.

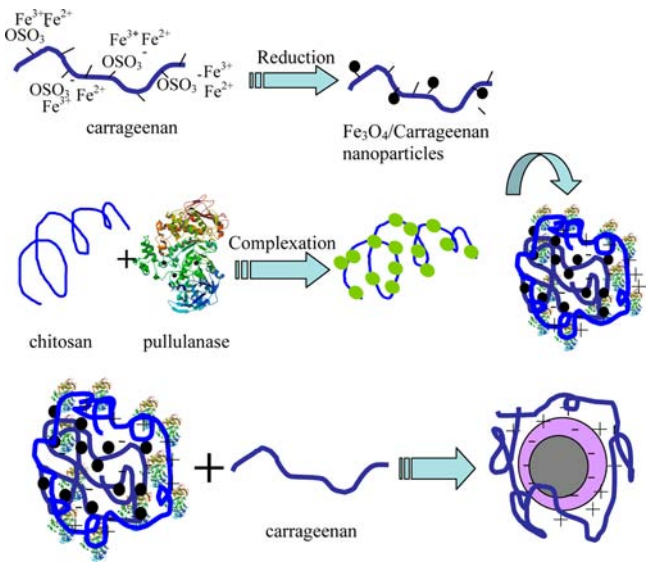

Figure 3. Schematic diagram of experimental design.

Characterization of Immobilized Enzymes. *Magnetic Properties.* At the first stage, the in situ synthesis of magnetic carrageenan nanoparticles involves the chelation of ferric (and ferrous) ions with the sulfate and hydroxyl groups of carrageenan at low pH, promoting the physical cross-linking of the carrageenan chains and formation of microgel; upon increasing pH, self-capped iron oxide nanoparticles are formed involving biopolymer molecules, with a number of the sulfate groups released. However, some sulfate groups still remain chelated to the nanoparticle surfaces, resulting in the high colloidal stability of this system.[12] This high colloidal stability results in a weak magnetic response of the nanoparticles to an external magnetic field. After the addition of the pullulanase/chitosan complex, the charge of the sulfate groups was neutralized, and the problem of weak magnetic response was solved. As shown in Figure 4, within the external magnetic field, immobilized enzymes aggregated completely in 15 s, whereas Fe_3O_4–κ-carrageenan nanoparticles moved slowly and finally aggregated completely in 8 min.

The hysteresis loops of Fe_3O_4–κ-carrageenan nanoparticles and immobilized enzymes were also calculated by a vibrating-sample magnetometer. As can be seen from Figure 4, both magnetic nanoparticles and immobilized enzymes exhibited superparamagnetic behavior. The saturation magnetization (M_s) of the immobilized enzymes was higher (42.6 emu/g) than that of the Fe_3O_4–κ-carrageenan nanoparticles (37.8 emu/g), whereas pure Fe_3O_4 was 98.1 emu/g. The excellent response to an applied magnetic field suggests that the immobilized enzymes meet the requirements for reuse in the food industries.

Morphology and Particle Size Distribution. Figure 5 shows a typical TEM image of immobilized enzymes. As can be seen from the picture, the average diameter of the immobilized enzymes was 156 nm, which is consistent with the result obtained on the zetasizer (Figure 2b). These results indicate that mixing of pullulanase/chitosan complex and magnetic carrageenan nanoparticles showed feasibility in the preparation

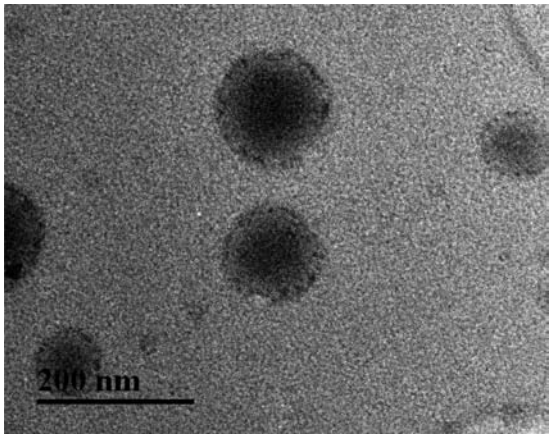

Figure 5. TEM micrographs of the immobilized pullulanase.

of nanoscale immobilized enzymes. The uniform and flexible environment of the pullulanase/chitosan complexes and magnetic carrageenan nanoparticles facilitated the homogeneous distribution of the enzymes.

FT-IR Analysis. FT-IR spectra of chitosan, carrageenan, immobilized enzymes, and Fe_3O_4 are shown in Figure 6. As can be seen from the figure, chitosan showed the typical peaks of amide I at 1651 cm^{-1}, amide II at 1597 cm^{-1}, and glycosidic bonds at 1080 cm^{-1}.[25] As for κ-carrageenan, the characteristic peaks at 1262, 847, 1068, and 928 cm^{-1} corresponded to the sulfate groups, galactose-4-sulfate, glycosidic linkage, and 3,6-anhydrogalactose, respectively.[26] The FT-IR spectrum of the immobilized enzymes exhibited the characteristic peaks of carrageenan at 1224, 1065, 929, and 845 cm^{-1} and the characteristic amide peak of chitosan, which converted into a single band at 1636 cm^{-1}. This verified the presence of carrageenan and chitosan in the biocatalyst. In the spectrum of the immobilized enzyme, the characteristic peak around 580 cm^{-1} was attributed to vibrations of the Fe–O bond of Fe_3O_4. Moreover, upon complexation of chitosan, carrageenan, and pullulanase, a new absorption band at 1530 cm^{-1}, assigned to NH_3^+ groups, was observed, which was absent in the spectra of

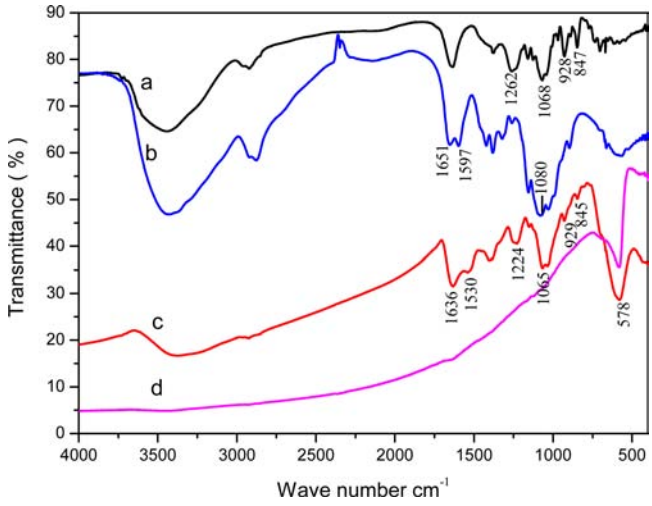

Figure 6. FT-IR spectra of chitosan (a, black trace), carrageenan (b, blue trace), immobilized pullulanase (c, red trace), and Fe_3O_4 (d, pink trace).

both chitosan and carrageenan. The spectra confirmed the successful formation of an immobilized enzyme.

XRD Patterns. XRD analysis of Fe_3O_4 and immobilized enzymes is shown in Figure 7. According to Joint Committee

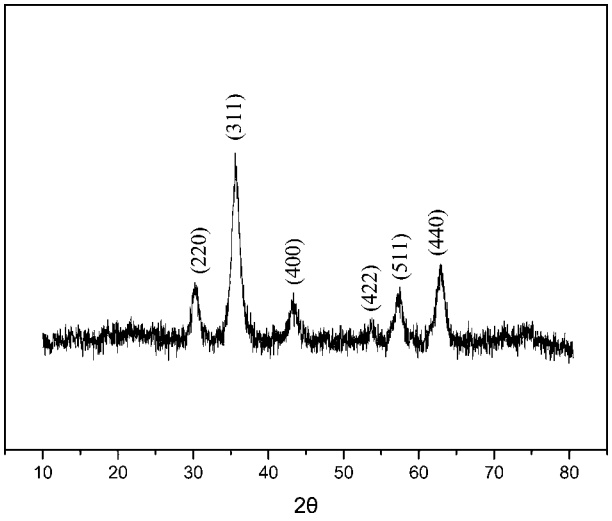

Figure 7. Wide-angle XRD patterns of immobilized pullulanase.

on Powder Diffraction Standards, JCPDS, entry 19-629, the powder XRD of immobilized enzymes matches the typical diffraction patterns observed for magnetite, which can be assigned to the six characteristic peaks at 2θ = 30.1, 35.4, 43.1, 53.2, 56.9, and 62.5°, corresponding to (220), (311), (400), (422), (511), and (440), respectively. Especially, the presence of the characteristic peak at 35.4° represents the formation of the spinel structure of Fe_3O_4, indicating that the immobilized enzyme still maintains its natural crystalline structure of Fe_3O_4 with no phase change.

Thermal Degradation. The thermal properties of pure Fe_3O_4, Fe_3O_4–κ-carrageenan nanoparticles, and immobilized enzymes studied by TGA are shown in Figure 8. Fe_3O_4 was thermally stable, and there was no weight loss in the interval of 200–800 °C (Figure 8a). For the Fe_3O_4–κ-carrageenan nanoparticles and immobilized enzymes, the derivative of

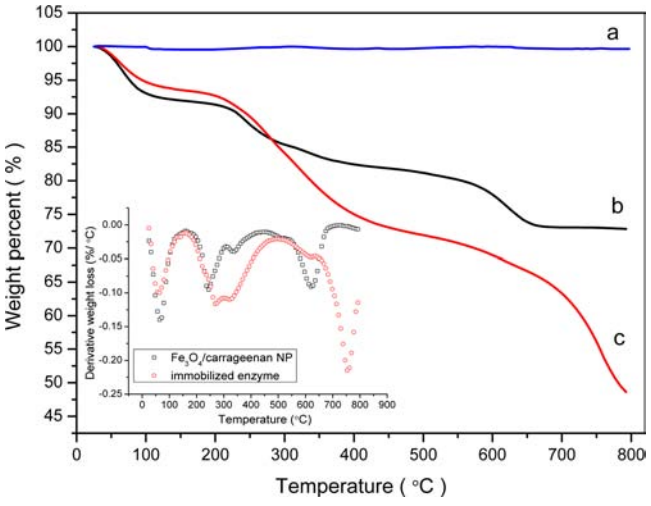

Figure 8. Thermogravimetric analysis of Fe_3O_4 (a, blue trace), Fe_3O_4–carrageenan nanoparticles (b, black trace), and immobilized pullulanase (c, red trace). The inset shows the derivative weight loss curves for Fe_3O_4–carrageenan nanoparticles and immobilized pullulanase.

weight-loss curves clearly indicated the inflection point of thermal decomposition, which was observed around 100, 240, 330, 620, and 750 °C (inset Figure 8). The weight loss below 200 °C was attributed to the loss of residual water.[27] The polysaccharide units of chitosan and carrageenan began to decompose at 200 °C.[28] In the interval of 200–800 °C, the degradation of carrageenan caused a weight loss of 18.41% estimated from the TGA curve of Fe_3O_4–κ-carrageenan nanoparticles (Figure 8b). At least three thermal events were observed: (i) From 200 to 300 °C, the degradation of carrageenan is associated with sulfur dioxide leaving and carbohydrate backbone fragmentation with weight loss of 5.80%. (ii) When the temperature increased to 450 °C, the degradation of carrageenan is related to polysaccharide decomposition with weight loss of 3.65%. (iii) The residual carrageenan or the intermediate compounds degradation caused a 8.96% weight loss that is continued until approximately 800 °C. Although in the interval of 200–800 °C, the degradation of chitosan, pullulanase and carrageenan (further coated) caused a 43.86% weight loss estimated from the TGA curves of Fe_3O_4–κ-carrageenan nanoparticles (Figure 8b) and immobilized enzymes (Figure 8c). At least three thermal degradations were also observed: an 8.28% weight loss from 200 to 300 °C, an 11.10% weight loss from 300 to 450 °C, and a 24.48% weight loss from 450 to 800 °C. Moreover, a new inflection point in the derivative weight-loss curve of immobilized enzymes was observed (inset Figure 8), which may be due to the complexation of chitosan, carrageenan, and pullulanase.

Reusability of Immobilized Pullulanase. Reusability of the immobilized enzyme is very important from the viewpoint of practical applications, and an improved stability makes the immobilized enzyme more advantageous than its free counterpart. However, as for absorption method, the leakage of enzymes from support in practice should be considered. To compare the stability of the immobilized pullulanase prepared as discussed in this paper with that of immobilized enzyme prepared by simply mixing magnetic carrageenan nanoparticles with pullulanase, we determined the reusability of the different immobilized enzymes. The activity of the immobilized pullulanase was assayed in 10 batches, and the same assay conditions were used for all batches. Activity of the first run was defined as 100%. In run 1, the immobilized enzyme was prepared as discussed in this paper. In run 2, the immobilized enzyme was prepared by simply mixing magnetic carrageenan nanoparticles with pullulanase. In run 3, the latter immobilized enzyme was further coated with carrageenan. As illustrated in Figure 9, the immobilized enzyme prepared in this paper (run

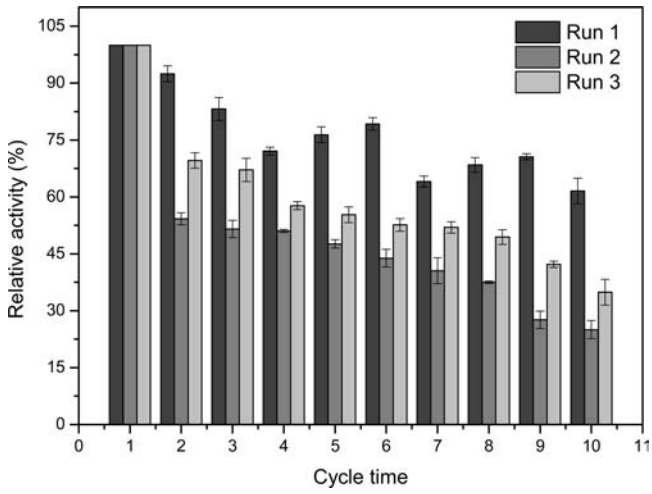

Figure 9. Reusability of the immobilized pullulanase. Experiments were triplicated, and the results are presented as mean ± SD.

1) showed the best reusability, retaining more than 76 and 61% of its original activity after 5 and 10 consecutive reuses, respectively. Pullulanase immobilized by simply mixing with magnetic carrageenan nanoparticles (run 2) exhibited a loss in activity of approximately 53 and 75% after 5 and 10 batch reactions, respectively. The immobilized enzyme prepared in run 3 also experienced a large loss in activity after 5 and 10 batch reactions (residual activity ≈ 52 and 34% of the initial value, respectively). Moreover, these enzymes undergo a fast decline in catalytic activity (residual activity ≈ 54 and 69% of the initial value) after the first use. In contrast, the immobilized enzyme prepared in this paper maintained its activity well (92% of the initial activity) after the first use. Obviously, the leakage of enzymes was remarkably abated.

Enzyme Immobilization and Loading Capacity. Activity retention, amount of protein immobilized, and loading efficiency after immobilization for different amounts of enzyme were summarized in Table 1. The amount of protein

Table 1. Activity Parameters of the Free and Immobilized Pullulanase[a]

applied activity (U.g.d.s.$^{-1}$)[b]	amount of protein immobilized (mg/g)	protein loading efficiency (%)	specific activity (u/mg)	activity retention (%)
37910	40.3 ± 2.4	70.7 ± 4.4	182.5 ± 3.9	51.2 ± 1.5
63183	51.2 ± 1.2	54.9 ± 3.8	222.1 ± 2.6	62.3 ± 2.5

J. Agric. Food Chem. 2015, 63, 3534–3542

immobilized increased when the loading efficiency decreased because saturation of the support was being achieved. The maximum quantity of pullulanase immobilized on 1 g of magnetic nanoparticles was 102 mg. Similarly, the activity retention increased from 51.19 to 95.58%, which implies that the activity of the enzyme was preserved well by this mild method; however, activity retention decreased with further increase of the bound protein. These results suggest that when a small amount of protein is immobilized on the support, its activity is totally expressed; however, when more proteins are attached, the enzyme molecules either become aggregated, forming a multilayer of enzyme molecules at the particle surface and blocking the active site, or the presence of neighboring enzyme molecules reduces the accessibility of substrate to the active sites,[29] resulting in decreased activity retention.

Effect of Immobilization on the pH Profile of Pullulanase. The effect of pH on the activity of free and immobilized pullulanase was estimated in the range of pH 2.5−6.4 (Figure 10a). The maximum pullulanase activity was

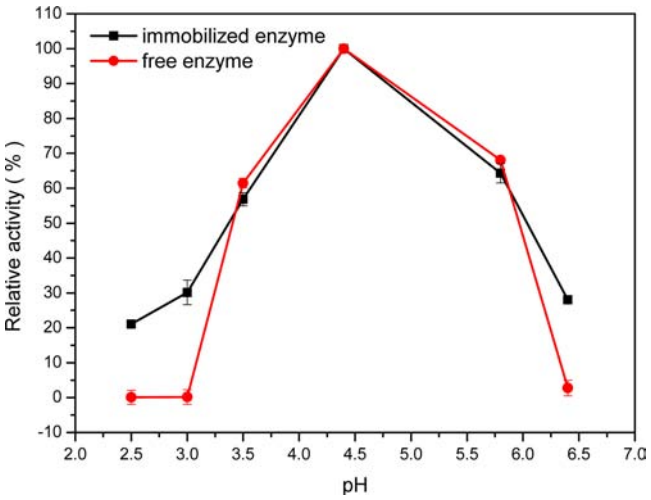

Figure 10. Effect of pH on pullulanase activity. Experiments were triplicated, and the results are presented as mean ± SD.

defined as 100%. It was observed that the activity of both free and immobilized pullulanase was greatly affected by pH, and the maximum activity was observed at pH 4.4 for both free and immobilized pullulanase. Compared with free pullulanase, the immobilized enzyme exhibited a better pH resistance at pH ≤ 3.0 and pH > 6. For example, at pH ≤ 3.0, there was a significant difference ($p < 0.01$) in enzyme activity: for the free enzyme, there almost no activity was detected, whereas for the immobilized enzyme, the relative activity was 21.05 and 30.14% at pH 2.5 and 3.0, respectively. Mechanisms of the decreased pullulanase activity might be attributed to the changed protein folding and binding modes (electrostatic or via hydrogen bonds).[7]

Catalytic Property (Activity and Kinetic Parameters) of Immobilized Pullulanase. Catalytic kinetics of the free and immobilized enzymes were further investigated. The Lineweaver−Burk plot for pullulan reduction (1−10 mg/mL) with free and immobilized pullulanase is shown in Figure 11. The apparent Michaelis constant, K_m, and the maximum reaction rates, V_m, of pullulanase calculated from the equations of these plots were summarized in Table 2. K_m relates to the affinity of substrate molecule and enzyme that depends upon

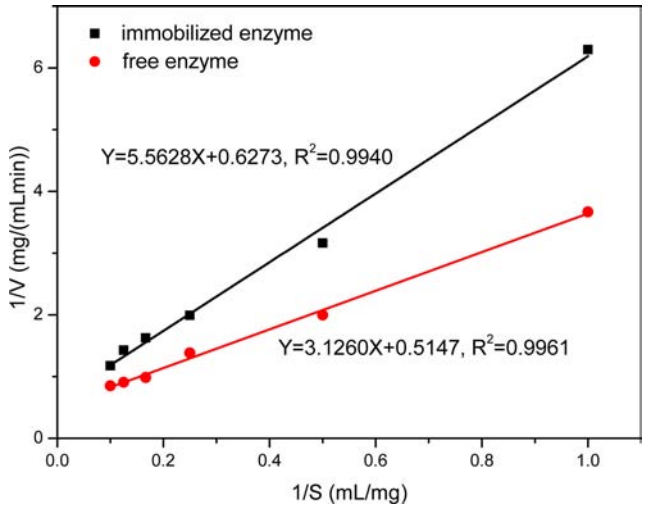

Figure 11. Lineweaver−Burk plots for the pullulan reduction with free and immobilized pullulanase (pH 4.4 at 50 °C). Results are the mean of triplicates.

Table 2. Kinetic Parameters of Free and Immobilized Pullulanase

enzyme type	K_m (mg/mL)	V_m (mg/(mL min))	enzymatic catalytic efficiency (V_m/ K_m)
free enzyme	6.073	1.942	0.319
immobilized enzyme	8.867	1.594	0.179

both partitioning and diffusional effects; V_m reflects the scale of mass transportation.[30] The K_m value of the immobilized enzyme (8.867 mg/mL) was higher than that of the free enzyme (6.073 mg/mL), and the V_m value of the immobilized enzyme (1.594 mg/(mL min)) was lower than that of the free enzyme (1.942 mg/(mL min)). The above results imply that the immobilized enzyme has an apparent lower affinity between enzyme and substrate, suggesting that it was more difficult for the substrate to diffuse and access the enzyme and that a higher concentration of substrate is needed when utilizing the immobilized enzyme. The lower affinity may be due to the negative effect of immobilization in terms of increased steric hindrance of the active site or substrate diffusion resistance.[31] Moreover, the lower affinity of the immobilized enzyme may be caused by the loss of enzyme flexibility necessary for substrate binding.[32] Therefore, a decrease in V_m of immobilized pullulanase was observed.

Thermal Stability of the Immobilized Pullulanase. The activity of free and immobilized pullulanase was assayed at temperatures in the range of 20−65 °C (pH 4.4). The maximum pullulanase activity was defined as 100%. As shown in Figure 12A, immobilization had no effect on the optimum temperature (50 °C) of pullulanase. A dramatic decrease in enzyme activity was observed in both systems when temperature went above 60 °C; however, the immobilized pullulanase showed higher activity than the free enzyme ($p < 0.01$). For example, at 65 °C, the relative activity of immobilized pullulanase was 66.7%, whereas that of free enzyme was only 25.5%. This result indicated that the immobilized enzyme possesses a better tolerance to heat.

The effect of temperature on the activity of free and immobilized enzyme at 60 °C versus the reaction time was also investigated. The initial activity was defined as 100%. As shown

DOI: 10.1021/jf505981t
J. Agric. Food Chem. 2015, 63, 3534−3542

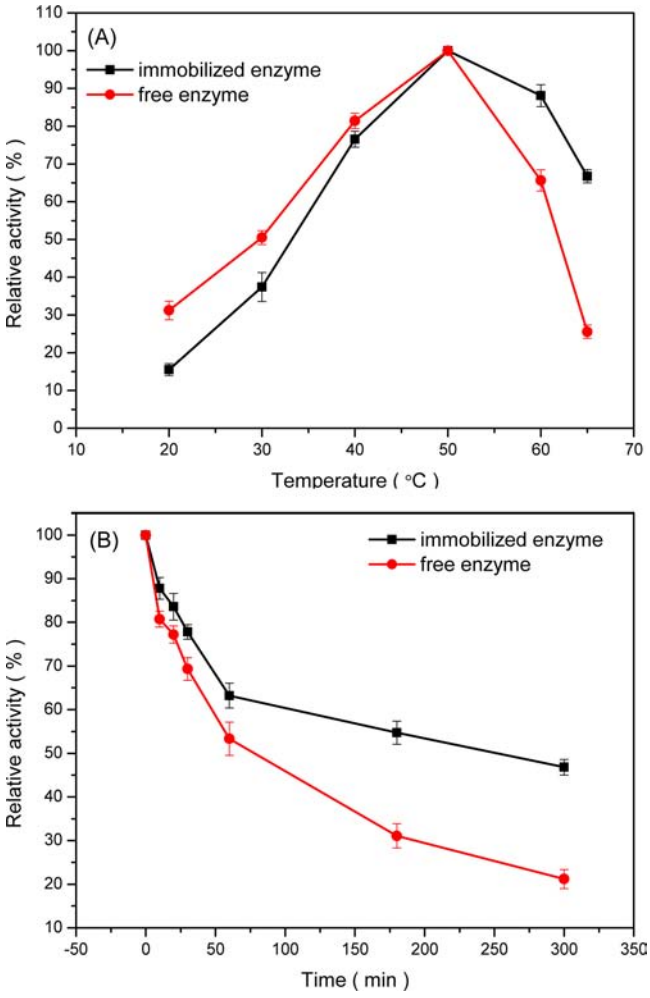

Figure 12. (A) Effect of temperature on activity of free and immobilized enzyme. (B) Thermal inactivation courses of free and immobilized enzyme (60 °C, pH 4.4). Experiments were triplicated, and the results are presented as mean ± SD.

in Figure 12B, the immobilized enzyme presented a higher thermal stability compared to the free enzyme. The rate of inactivation of the free enzyme was markedly higher than that of the immobilized enzyme. After 5 h, the immobilized enzyme retained more than 45% of its initial activity, whereas the free enzyme retained only 21% of its initial activity. This implies that immobilization had a positive effect on the thermal stability of pullulanase and was able to protect the active conformation of the enzyme from damage.[33] With this stabilizing effect, immobilized pullulanase exhibits an advantage in continuous applications in food industry.

the adsorption properties of anthocyanins; however, the purity of anthocyanins has not yet been significantly improved. This lack of improvement is most likely because the matrix of the most commercial adsorbent is hydrophobic (e.g., polystyrene), and the adsorption mechanism is mainly based on the hydrophobic interaction between adsorbents and anthocyanins. The hydrophobic affinity is non-specific, especially in aqueous solution.

There are multiple phenolic hydroxyl or hydrophilic sugar moieties in the structure of anthocyanins, which leads to the increasing hydrophilicity of anthocyanins. Therefore, hydrophilic adsorbents with amide, hydroxy, or other polar functional groups, such as polyamide or dextran, were selected for the preparation of anthocyanins with high purity, which were expected to have better adsorption selectivity toward anthocyanin.[25,26] However, in practical applications, these adsorbents did not exhibit good adsorption performance, because the extraction and separation of natural products based on the adsorption method usually occurs in aqueous solution, in which water molecules significantly destroy the polar affinity between adsorbents and adsorbates.[27−29] Hence, in aqueous solution, a rigid hydrophobic structure remains necessary, which is consistent with the results concerning the adsorption performance of peptide molecules in aqueous solution. In this consideration, the copolymerization of a monomer containing polar functional groups with styrene or divinylbenzene (DVB) becomes the most advantageous method. Commercial macroporous resins AB-8 and ADS-17 are examples of copolymerization of methacrylate and DVB. Nevertheless, to maintain skeleton stability, a sufficient cross-linking degree is indispensable for resin synthesis, which indicates that the content ratio of the polar monomer and hydrophobic monomer can only be modulated in a much smaller range, which definitely limits the application of these resins. In addition, the large difference in polarity between the two monomers means that the monomers do not readily copolymerize with each other to produce a uniform cross-linked network in free-radical polymerization. Therefore, some of the functional groups derived from the polar monomers were not uniformly distributed on the pore surface of the adsorbent, which indicates why the adsorption selectivity of the weak polar commercial adsorbent was improved at the expense of a decrease in adsorption capacity.[28]

To solve this problem, in the present study, we selected ethylene glycol dimethyl acrylate (EGDMA) as the monomer providing functional groups. EGDMA not only regulates the polarity of the adsorbent but also acts as cross-linking agent to copolymerize with DVB because it contains two polymerizable double bonds. Therefore, the necessary network structure of the adsorbent was maintained, whereas the concentration of the weak polar monomer can be adjusted across a larger scale. In this paper, a series of poly(EGDMA-*co*-DVB) with different EGDMA contents was synthesized. The resins with the best adsorption performance were screened out through static adsorption and desorption experiments. On this basis, the parameters of the dynamic adsorption and desorption experiments were optimized to achieve anthocyanins with high purity of 96%. The high-performance liquid chromatography (HPLC) fingerprint of the products is consistent with USP35-NF30. The established method of separation and purification of anthocyanins from bilberry will hopefully be applied in industrial production.

MATERIALS AND METHODS

Materials. EGDMA [analytical-reagent (AR) grade] and DVB (purity of 80%) were obtained from the Chemical Plant of Nankai University (Tianjin, China). 2,2′-Azobis(isobutyronitrile) (AIBN), toluene, 200 gasoline, poly(vinyl alcohol) (PVA), ethanol, hydrochloric acid, and sodium chloride were purchased from Tianjin Chemical Co. (Tianjin, China) and were all AR grade.

Bilberry fruits (frozen) was purchased from Sweden. Bilberry dry extract CRS was purchased from European Directorate for the Quality of Medicines & HealthCare (EDQM). The percentage content of cyanidin 3-*O*-glucoside chloride in bilberry dry extract CRS is 3.44 wt %.

HPLC-grade anhydrous formic acid, acetonitrile, and methanol were purchased from Concord Technology (Tianjin, China). All of the solutions prepared for HPLC were filtered through 0.45 μm nylon membranes before use.

Pretreatment of Commercial Adsorbents. The macroporous adsorbent Amberlite XAD-7 was purchased from Rohm and Hass (Philadelphia, PA). The macroporous adsorbents XAD-4, AB-8, and ADS-17 were purchased from Nankai Hecheng S&T (Tianjin, China). Before the adsorption experiments, the adsorbents were soaked in ethanol and then thoroughly washed with deionized water.

Synthesis of Adsorbents with Functional Groups. The beads were prepared using a suspension polymerization method. An organic solution composed of DVB, EGDMA, porogenic agent (toluene/200 gasoline = 70:30, w/w), and the initiator AIBN (0.5%, w/w) were mixed with the aqueous solution composed of poly(vinyl alcohol) (PVA, 1%, w/w) and sodium chloride (5%, w/w) in a 1000 mL three-necked round-bottomed flask equipped with a mechanical stirrer, reflux condenser, and thermometer. The round-bottomed flask was heated using a programmed heater. The mixture was stirred to yield a suspension of oil beads with a suitable size in the aqueous solution (100−120 rpm), heated at 65 °C for 4 h, and maintained at 85 °C for 6 h. The copolymer beads were filtered out, washed with a large amount of hot water followed by ethanol, then packed in a Soxhlet extractor, and eluted with petroleum ether.

The proportion between EGDMA and DVB was changed in the synthesis process to obtain polymeric adsorbents with different hydrophobic affinities. The adsorbents were named DE-5, DE-10, DE-20, DE-30, DE-40, corresponding to 5, 10, 20, 30, and 40% EGDMA contents in weight, respectively. The synthesis process is shown in Figure 1.

Determination of Pore Structure Parameters of Adsorbents. The pore structure parameters of the adsorbents were measured using an automatic surface area and pore size analyzer (Autosorb-1 MP,

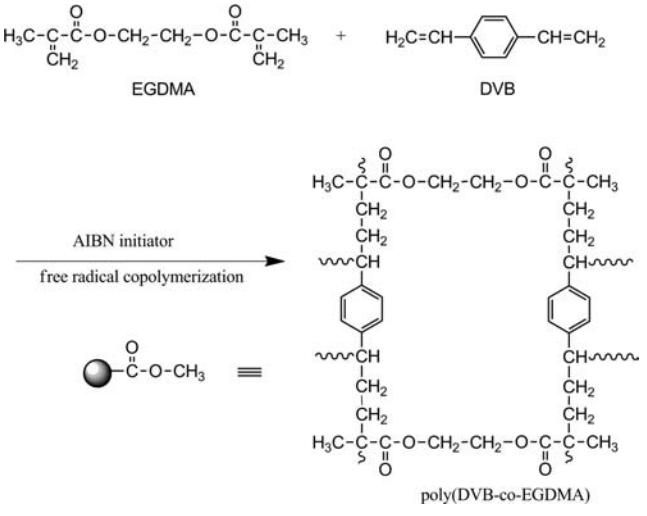

Figure 1. Synthesis process of poly(DVB-*co*-EGDMA) adsorbent, namely, DE resin.

J. Agric. Food Chem. 2015, 63, 3543−3550

Quantachrome Instruments, Boynton Beach, FL) based on the Brunauer–Emmett–Teller (BET) nitrogen adsorption method.

Determination of the Moisture Content Imbedded in the Adsorbents. The hydrated adsorbents disposed of deionized water were weighed accurately and then dried in an oven at 105 °C until a constant weight was attained. The following equation was used to calculate the moisture content (α, %) imbedded in the adsorbent:

$$\alpha = \frac{W_{wet} - W_{dry}}{W_{wet}} \times 100\% \quad (1)$$

where W_{wet} and W_{dry} are the weights (g) of the hydrated and dry adsorbents, respectively.

Characterization of Adsorbents. Infrared spectra of DE adsorbent were obtained from a Nicolet Magna 560 Fourier transform infrared (FTIR) spectrometer with a pellet of potassium bromide and adsorbent in the range of 500–4000 cm^{-1}. The inner surface morphology of the copolymer particles was investigated using a scanning electron microscope (SEM, Hitachi 3500N). The appearance of adsorbent beads was observed by an optical microscope (Olympus BX5).

HPLC Analysis of Anthocyanins. The HPLC analysis method of anthocyanins was based on USP35-NF30 with some adjustments. First, 0.1250 g of bilberry dry extract CRS was dissolved in the mixed solvent (hydrochloric acid/methanol = 2:98, v/v) and diluted to 25.0 mL. The reference solution was obtained by diluting 5.0 mL of the above solution to 20.0 mL with 10% phosphoric acid. The concentration of prepared reference solution is 1.25 mg/mL.

The analysis was performed on an Agilent 1200 series HPLC system with a 1200 diode array detector and 1200 quaternary pump with a degasser. A reversed-phase column (250 × 4.6 mm inner diameter) packed with Venusil ASB C_{18} (5 μm) was used for chromatographic analysis. The mobile phase was composed of mobile phase A (anhydrous formic acid/H_2O = 8.5:91.5, v/v) and mobile phase B (anhydrous formic acid/acetonitrile/methanol/H_2O = 8.5:22.5:22.5:41.5, v/v/v/v) and was used by the gradient program shown in Table 1. The flow rate was 1.0 mL/min. The detection wavelength was 535 nm. The entire column system was at a constant 30 °C using an Agilent 1200 thermostated column compartment.

Table 1. Gradient Program of HPLC Analysis of Anthocyanins

time (min)	mobile phase A (%)	mobile phase B (%)	elution
0–20	82 → 78	18 → 22	linear
20–35	78 → 72	22 → 28	linear
35–50	72 → 35	28 → 65	linear
50–51	35 → 0	65 → 100	linear
51–55	0	100	isocratic
55–56	0 → 82	100 → 18	linear
56–70	82	18	isocratic

The peaks corresponding to the anthocyanins and anthocyanidins were identified by the chromatogram supplied with bilberry extract CRS and USP35-NF30. The retention times and elution orders of the peaks are shown in Table 2. The chromatogram of bilberry extract CRS was used as a standard to calculate the concentration of anthocyanins in the tested solution, expressed as cyanidin 3-*O*-glucoside chloride, using the following expression:

$$c = \frac{Ac_r wV_r}{A_r V} \quad (2)$$

where c is the concentration (mg/mL) of anthocyanins (peaks 1–8, 10–15, and 17) in the chromatogram obtained with the test solution, c_r is the concentration (mg/mL) of reference solution, A is the sum of the areas of the peaks corresponding to the anthocyanins (peaks 1–8, 10–15, and 17) in the chromatogram obtained with the test solution, A_r is the area of the peak corresponding to cyanidin 3-*O*-glucoside chloride (peak 5) in the chromatogram obtained with reference solution, V and V_r are injection volumes (μL) of test solution and reference solution, respectively, and w is the percentage content of cyanidin 3-*O*-glucoside chloride in bilberry extract CRS.

Table 2. Anthocyanins/Anthocyanidins and Corresponding Retention Time in the HPLC Chromatogram

peak number	anthocyanins/anthocyanidins	retention time (min)
1	delphinidin 3-*O*-galactoside chloride	10.7
2	delphinidin 3-*O*-glucoside chloride	12.6
3	cyanidin 3-*O*-galactoside chloride	14.8
4	delphinidin 3-*O*-arabinoside chloride	15.9
5	cyanidin 3-*O*-glucoside chloride	18.0

13	malvidin 3-*O*-galactoside chloride	33.7
14	peonidin 3-*O*-arabinoside chloride	36.4
15	malvidin 3-*O*-glucoside chloride	38.3
16	cyanidin chloride	41.2
17	malvidin 3-*O*-arabinoside chloride	42.3
18	petunidin chloride	45.8
19	peonidin chloride	50.1
20	malvidin chloride	51.4

Preparation of Bilberry Crude Extraction Solution. According to the literature,[20,30,31] as the molecular forms of anthocyanins change with the pH value in aqueous solution, their stability also changes. The experimental results suggest that the stability of anthocyanins is optimal when the pH is 2.0; thus, the aqueous solution environment was maintained at pH 2.0 during the entire experimental process. The preparation of bilberry crude extraction was as follows: first, 500 g of bilberry frozen fruit was crushed into pulp in a cooking machine. Then, the pulp was transferred into a round-bottom flask with acidified 60% ethanol aqueous solution (adjust pH 2.0 with hydrochloric acid). The solid–liquid (fruit/extraction media, m/v) ratio was 1:3, and extraction was carried at 50 °C for 1 h twice. Collected supernatants were concentrated by rotary evaporation at 50 °C under vacuum for 1 h. The crude extraction solution was filtered using talcum powder to remove slime before use. The concentration of the solution obtained was 3.5 mg/mL, determined by the HPLC method.

Static Adsorption and Desorption Tests. The static adsorption tests were performed as follows: 1.0 g of hydrated test adsorbents was placed into a 100 mL flask with a lid, and 20 mL of the crude extract solution was added. The flask was then shaken (100 rpm) at a constant temperature of 25 °C until the adsorption equilibrium was reached. The concentrations of the anthocyanins in the solution before and after the adsorption were analyzed by HPLC. The following equation was used to quantify the equilibrium adsorption capacity (Q_e, mg/g of dry resin) of the adsorbent:

$$Q_e = \frac{(C_0 - C_e)V}{W_{wet}(1 - \alpha)} \quad (3)$$

where C_0 and C_e are the initial and equilibrium concentrations of anthocyanins in the solutions, respectively (mg/mL), V is the volume of the solution (mL), W_{wet} is the weight of the hydrated adsorbent (g), and α is the moisture content of the adsorbent (%).

After adsorption, the beads were washed with deionized water and then desorbed with 60% ethanol aqueous solution. The desorption ratio (D_d, %) was calculated using the following equation:

$$D_d = \frac{C_d V_d}{(C_0 - C_e)V} \times 100\% \quad (4)$$

DOI: 10.1021/jf506107m
J. Agric. Food Chem. 2015, 63, 3543–3550

Table 3. Structure Parameters of Adsorbents

adsorbent	DVB content (wt %)	structure	functional group	specific surface area(m^2/g)	moisture content (%)
XAD-4	100	poly(DVB)	none	780	61.8
AB-8	95	poly(MA-*co*-DVB)	ester group	750	67.5
ADS-17	60	poly(MA-*co*-DVB)	ester group	625	69.6
XAD-7	0	poly(EGDMA)	ester group	450	51.2
DE-5	95	poly(EGDMA-*co*-DVB)	ester group	854	67.0
DE-10	90		ester group	850	68.7
DE-20	80		ester group	842	70.1
DE-30	70		ester group	837	71.9
DE-40	60		ester group	828	73.4

where C_d is the concentration of anthocyanins in the desorption solution determined by HPLC (mg/L), V_d is the volume of the desorption solution (mL), and C_0, C_e, and V are the same as the parameters in eq 3.

To calculate the purity of the extract, the solid content was measured using the following method: the desorption solution measured accurately by HPLC was placed into a weighing bottle of constant weight, which was then placed in an oven to dry to constant weight at 105 °C to completely remove the solvent. The purity of the extract was calculated using the following equation:

$$\text{purity} = \frac{C_d V_d}{W - W_0} \times 100\% \quad (5)$$

where W is the total weight of the weighing bottle and residue solid after drying (g), W_0 is the weight of the weighing bottle (g), and C_d and V_d are the same as the parameters in eq 4.

Dynamic Adsorption and Elution Tests. Dynamic adsorption tests were performed as follows: the hydrated test adsorbent was packed into a glass column (Ø = 15 mm), and the bed volume (BV) was 30 mL. The solution prepared as described flowed through the adsorbent column.

The elution tests were performed as follows: after the adsorption equilibrium was reached, the adsorbate-laden column was first washed with deionized water and then eluted by desorption agents (pH 2.0).

The concentration of anthocyanins in the effluent solution was monitored by HPLC analysis, and the desorption ratio and purity of desorption solution were calculated using eqs 4 and 5.

Acquirement of Products and Repeated Tests. After the optimized process of dynamic adsorption and desorption tests was confirmed, experiments based on the selected adsorbent were performed 4 times under the optimized conditions.

RESULTS AND DISCUSSION

Characterization of Selected Commercial Adsorbents and Synthesized DE Adsorbents. The structural parameters of the commercial adsorbents and synthesized adsorbents were characterized, and the results are presented in Table 3. We know that a higher specific surface area of the adsorbent provides more sites for the adsorbate, thus improving the adsorption capacity. As demonstrated in Table 3, for the selected commercial adsorbents, with the increase of the polar moiety content, the DVB content decreased. The moisture content data reveals that the hydrophilicity of these adsorbents increased (except XAD-7), whereas the corresponding specific surface area declined remarkably, indicating the damage of the high cross-linking structure of the adsorbent. In contrast, the synthesized adsorbents with similar DVB content exhibited completely different trends; their specific surface area gradually decreased, but all remained at a relatively high level. From Table 3, it can be observed that, for the adsorbents AB-8 and DE-5 or ADS-17 and DE-40, whose DVB contents were almost equivalent, the specific surface area of the latter was greatly increased in comparison to that of the former. This finding suggested that EGDMA plays a supporting role for the adsorbent matrix instead of lowering the specific surface area because of the introduction of a weak polar monomer. In addition, we also noticed that the parameter of the adsorbent XAD-7 was unique. Although XAD-7 was composed entirely by the polymer of EGDMA and should have exhibited a high cross-linking degree, its specific surface area was reduced greatly because the chain of EGDMA is more flexible than that of DVB because of the existence of benzene. The weaker skeleton rigidity could cause a collapse of the pore structure of the adsorbents, thus reducing the specific surface area of the resin. It is inferred that the content of EGDMA should be controlled in a certain range. In addition, the moisture content of the DE adsorbent increased with increasing the EGDMA content, indicating the increasing hydrophilicity of this series of adsorbents.

The structure of adsorbents with different EGDMA contents was characterized by FTIR spectroscopy. The strong stretching vibration band at 1732 cm^{-1}observed in Figure 2 indicates that

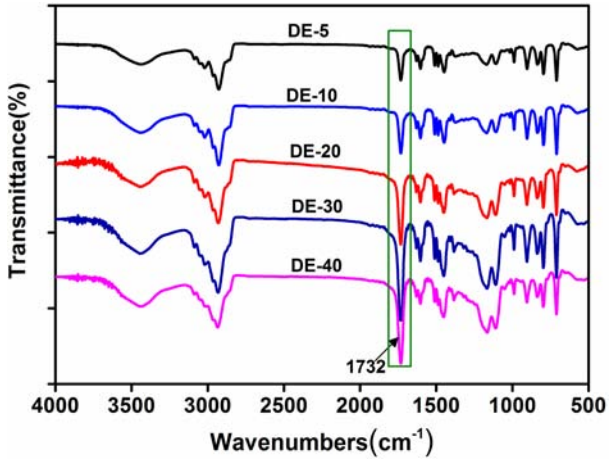

Figure 2. Infrared (IR) spectra of DE adsorbents with various EGDMA contents.

ester groups were successfully introduced into the DE adsorbents. The intensity of ester groups increased with increasing the EGDMA content, which indicates that adsorbents with different EGDMA contents were synthesized.

The optical microscope and SEM results of DE-20 are shown in Figure 3. The exterior of the beads had an intact spherical appearance, whereas the interior consisted of a distinct porous structure, which also indirectly demonstrated that the necessary high cross-linking structure of DE adsorbent was successfully sustained.

Results of Static Equilibrium Adsorption Experiments. Several representative commercial adsorbents were selected, and the static equilibrium adsorption and desorption experiment was conducted. The results are presented in Figure 4. The

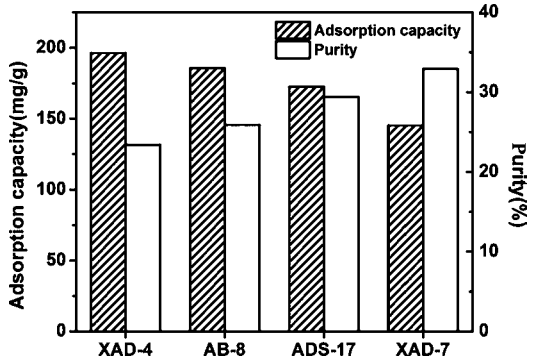

Figure 4. Adsorption capacity of four commercial resins (XAD-4, AB-8, ADS-17, and XAD-7) and purity of anthocyanins obtained through static adsorption experiments on these resins.

purity of the anthocyanins in the desorption solution increased significantly with increasing hydrophilicity of the selected adsorbents, indicating better adsorption selectivity. However, the adsorption capacity declined notably because of the decreasing specific surface area. Therefore, regulating the hydrophilicity of the resin on the premise of maintaining a high specific surface area is of great importance.

As demonstrated in Table 4, for DE resins, the adsorption capacity results agreed with those of the specific surface area, both showing slight declines with increasing polarity. Because of the introduction of EGDMA, the synthesized adsorbents exhibited better adsorption selectivity compared to commercial adsorbents, which was demonstrated by the purity of the anthocyanins in the eluent. The purity increased gradually and then decreased with increasing the EGDMA content because the interaction between the adsorbents and adsorbate also plays an important role in the adsorption selectivity in addition to the specific surface area. In addition, the synergistic dipolar and hydrophobic interactions can be used to explain this phenomenon very well. When the content of EGDMA exceeded 20%, the hydrophobic interaction decreased significantly caused by the decline of the percentage of DVB. There was not a sufficient driving force for the adsorbent to overcome the obstacles of the water molecules to bring the adsorbate molecule closer to the adsorbent matrix; the synergistic effect weakened, and thus, the adsorption ability decreased. Therefore, it is suggested that the synergistic dipolar and hydrophobic interaction between DE-20 and anthocyanins comes to an optimum point. All of these results confirmed that our strategy to regulate the adsorption selectivity of adsorbents by introducing EGDMA was successful. Consideration must be given to both the adsorption capacity and purity. The DE-20 adsorbent possessed the best selectivity, and its adsorption capacity and desorption ratio were acceptable. Hence, further experiments were performed using the DE-20 adsorbent.

Table 4. Results of Static Adsorption and Desorption of DE Resins

		eluent	
adsorbent	Q_e (mg/g)	purity (%)	desorption ratio (%)
DE-5	213.2	32.2	96.7
DE-10	210.9	34.5	95.4

Effect of the Adsorption Rate on the Adsorption Property of DE-20 Adsorbent. To further investigate the adsorption property of the DE-20 adsorbent toward anthocyanins, adsorption curves were measured under different adsorption rates, and the results are presented in Figure 5.

If the solution flows through the column too fast, parts of the anthocyanins rapidly rush out of the column before interacting with the adsorbent, resulting in a decrease of the adsorption capacity. Reducing the rate of adsorption is beneficial for the adsorbate to thoroughly contact the adsorbents; however, when the flow rate is too low, the production period will be extended and the efficiency is reduced. In Figure 5, anthocyanins leaked early at 80 mL at a flow rate of 3 BV/h. When the flow rate was reduced to 2 BV/h, the leak point moved to 120 mL. In comparison to the leakage point corresponding to the adsorption rate of 1 BV/h, there was no obvious difference between the two adsorption curves. Considering both the experiment period and adsorption capacity, we select the flow rate of 2 BV/h, and the corresponding volume of the adsorption solution is 120 mL (4 BV).

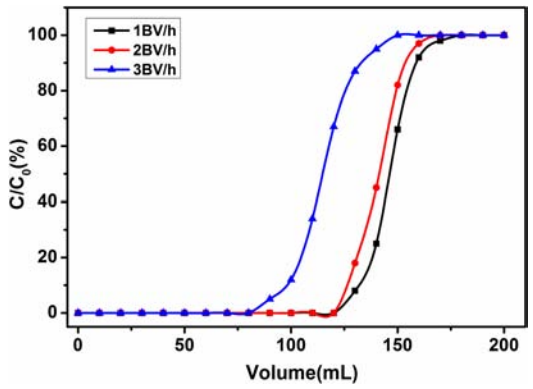

Figure 5. Dynamic leakage curves of anthocyanins on adsorbent DE-20 at different adsorption rates of 1, 2, and 3 BV/h.

Results of Gradient Dynamic Elution on DE-20 Adsorbent. The dynamic desorption experiments were conducted as described. After reaching the adsorption equilibrium, the adsorbent column was washed with deionized water and then desorbed by gradient elution with 10, 20, 30, and 60 vol % ethanol aqueous solutions in sequence; the results are presented in Figure 6.

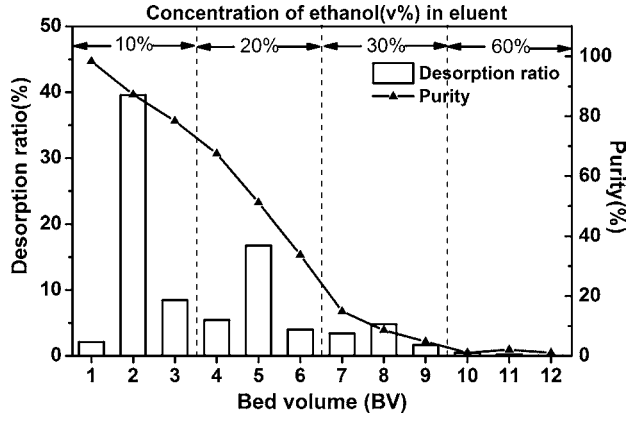

Figure 6. Purity and desorption ratio of anthocyanins obtained from gradient elution by ethanol aqueous solution at different concentrations of 10, 20, 30, and 60 vol % in sequence, as a function of the BV. The experiment was conducted on DE-20 resin, and consumption of ethanol aqueous solution of each concentration is 3 BV.

During the gradient elution process, the anthocyanins and other components laden on the adsorbent gradually migrated down according to their affinity to the adsorbents and elution. Figure 6 shows that approximately 40% of the anthocyanins can be desorbed when eluted by 10% ethanol solution in the second BV, which indicated that the affinity between anthocyanins and adsorbents was relatively weak, such that a low concentration of ethanol solution could break the bonding interaction. The purity of the anthocyanins in the desorption solution declined greatly with increasing the desorption volume, from 96% for the highest drops to less than 10%. Therefore, we concluded that a low concentration of ethanol solution was more suitable for obtaining anthocyanins at high purity. Considering the relatively low desorption ratio of 10% ethanol, we decided to perform the dynamic experiments in isocratic mode using ethanol aqueous solution of higher concentration as the desorption solvent.

Results of Isocratic Elution on DE-20 Adsorbent. Increasing the ethanol concentration in the eluent is one solution to effectively solve the trailing phenomenon observed in Figure 6. Therefore, we selected 20, 30, and 40% ethanol aqueous solution as the desorption solvent, and its suitable consumption is 3 BV. Figure 7 shows the results of isocratic elution with different desorption solvents on DE-20 adsorbent.

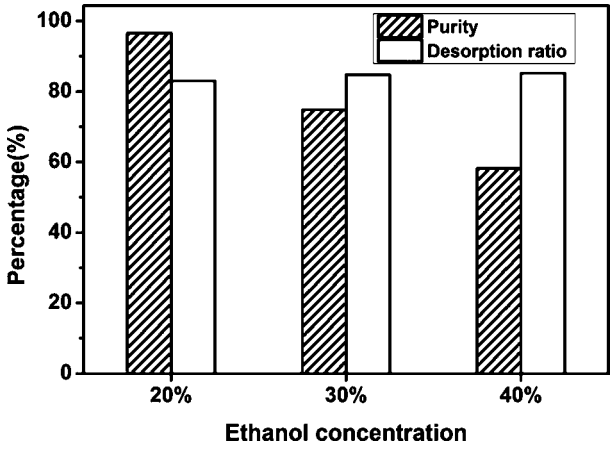

Figure 7. Purity and desorption ratio of anthocyanins eluted by ethanol aqueous solution of different concentrations (20, 30, and 40 vol %) in isocratic elution mode on DE-20 resin.

The desorption ratio and purity of the anthocyanins obtained are the most important factors in dynamic desorption experiments. According to Figure 7, we found that the desorption ratio was obviously improved to above 80% after increasing the concentration of ethanol in desorption solvent. A total of 83.2, 84.7, and 85.2% of the total anthocyanins can be obtained by eluting with 20, 30, and 40% ethanol solution, corresponding to purities of 96, 74, and 57%, respectively. It can be observed that the desorption ratio improved slightly under different elution conditions; however, the purity decreased remarkably with increasing the ethanol concentration in the desorption agents. These results can be explained by the different affinities of different components in bilberry toward adsorbents. The affinity between anthocyanin and the adsorbent was relatively weaker because anthocyanin is more hydrophilic, whereas the hydrophobic interaction between other impurities and adsorbents was much more intensive. In addition, the latter interaction was easier to break down using a higher ethanol concentration; thus, more impurities flowed out along with anthocyanins simultaneously, leading to the lower purity of anthocyanins.

In summary, the 20% ethanol aqueous solution (3 BV, pH 2.0) was selected as the most suitable desorption solvent, and the anthocyanin product was recycled at a high desorption ratio of 83% and high purity of 96%.

Results of Enrichment and Purification of Anthocyanins from Bilberry Based on DE-20 Resin. Briefly, the optimization of the purification process of anthocyanin on DE-20 adsorbent can be summarized as follows:

First, the hydrated adsorbent DE-20 is packed into a glass column (Ø = 15 mm), and the BV is 30 mL. Then, the crude extraction solution of anthocyanins (3.5 mg/mL) flows through the adsorbent DE-20 column at a flow rate of 2 BV/h. The adsorption capacity is 120 mL (4 BV). The adsorbate-laden column is then washed with 3 BV deionized water (pH 2.0),

DOI: 10.1021/jf506107m
J. Agric. Food Chem. 2015, 63, 3543−3550

followed by the elution of 20% ethanol aqueous solution (pH 2.0), at a flow rate of 2 BV/h. Finally, anthocyanins are successfully obtained at a high purity of 96% and high desorption rate of 83%.

Figure 8 shows a HPLC chromatogram of the highly pure anthocyanins and crude extraction solution of bilberry. The

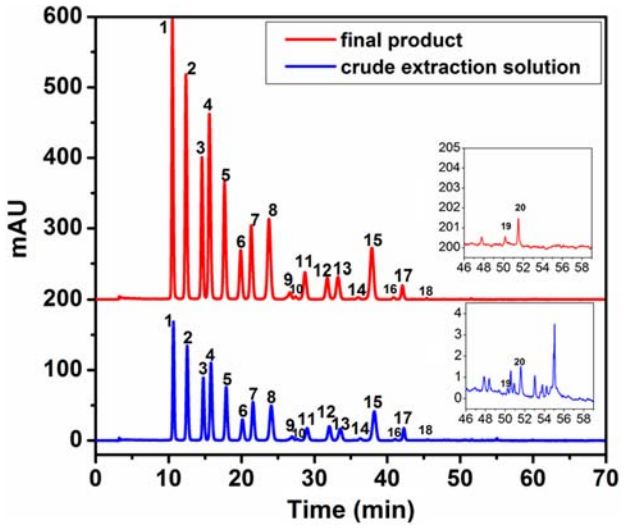

Figure 8. HPLC chromatograms for anthocyanins/anthocyanidins obtained from the final product (red line) and crude extraction solution (blue line), which are consistent with the HPLC chromatogram of USP35-NF30 (powdered bilberry extract). Peaks are numbered according to Table 2. Inset figures are magnified chromatograms for anthocyanidins numbered 19 and 20.

peaks of both of the chromatograms are consistent with USP35-NF30 (powdered bilberry extract), indicating that, in the entire process of extraction and purification, the composition of anthocyanins remains the same as in the fruit, except that the purity is improved remarkably and the amount of contained anthocyanidins is lower, which is also consistent with USP35-NF30.

Results of Repeatability of Anthocyanins on the Adsorbent DE-20. The results of repeatability of anthocyanins on the adsorbent DE-20 are listed in Table 5. Different

Table 5. Results of Purification and Repeatability of DE-20

test number	desorption ratio (%)	purity (%)
1	83.2	96.2
2	84.0	95.9
3	82.4	96.8
4	82.7	98.1
average	83.1	96.7
standard deviation (SD)	0.61	0.84

batches all exhibited good purification effects on the anthocyanins, which indicates that the method based on the synthesized macroporous adsorbent DE-20 was entirely practical for the purification of anthocyanins in bilberry.

Through a simple extraction and separation process, the content of anthocyanins increased from the original 0.5% in bilberry frozen fruits to high purity of 96% in the final product, which illustrates the effectiveness and practicality of the separation and purification method based on macroporous resin DE-20. For the first time, anthocyanins with high purity are achieved via separation technology based on macroporous polymeric adsorbents, which represents both a novel breakthrough and a method involving simple operation, low cost, and high efficiency, which is suitable for industrial-scale production. The product of anthocyanins with high purity is beneficial for further research concerning their medicinal and pharmacological applications.

(TAG), increased.[19] Therefore, many mutants are impacted in the structure of subcellular organelles, e.g., ER, protein bodies, and amyloplasts, delimited by lipoprotein membranes. Surprisingly, no research was conducted on the relationships between endosperm lipids and maize vitreousness, especially by using normal maize inbred lines.

It is also important to consider endosperm programmed cell death (PCD). PCD starts at the center of the grain in the floury area to finally affect the entire endosperm.[20] Moreover, 10 days after pollination, endosperm faces hypoxia stress (DAP)[21] and desiccation at the end of development.[22] To delineate the biochemical basis of endosperm vitreousness, it is therefore more judicious to consider separately the floury and vitreous regions than the whole endosperm as was outlined for proteins.[23]

In this context, we report here the lipid composition of the vitreous and floury mature endosperms of dent and flint maize inbred lines. The results highlight a close relationship among starch lipids, amylose, and vitreousness. The differences observed in the composition and content of nonstarch lipids of vitreous and floury endosperm might be related to differences in their respective metabolic specificities and stress responses occurring along the PCD of developing endosperm.

MATERIALS AND METHODS

Plant Material, Vitreousness, and Milling Properties. Thirteen maize inbred lines were grown in the Limagrain station in Mons (France). Maize kernels from self-pollinated homozygote plants were collected in the middle third of the ear. For lipid analyses, grains were frozen in liquid nitrogen and stored at −80 °C. For vitreous area determination, 10 grains were cut vertically along the germ center. Sections were scanned, and pictures were analyzed with ImageJ software to determine total endosperm and vitreous areas. Vitreous endosperm mass percentage was measured after hand-dissection of 3 series of 4 grains. For semolina yield determination, a lab degerminator (Satake, Satake Europe LTD) was used in order to remove germ and bran, and to separate the vitreous from the other part of the grain. Vitreous areas and vitreous endosperm weight have a close ranking and are strongly correlated with the milling properties, i.e., semolina yield (Table S1, Supporting Information) $R = 0.79$ ($p < 0.01$) and $R = 0.82$ ($p < 0.001$), respectively. Principal component analysis of these texture parameters highlighted different groups of vitreousness that correspond to flint (L1 to L4) and dent (L05 to L13) phenotypes. In these inbred lines, L11 is a markedly different dent variety with a very low vitreousness (Figure S1 and Table S1, Supporting Information). The genetic diversity of the 13 inbred lines was characterized by the Nei-Li genetic distance matrix calculated with 3000 SNPs distributed on 10 chromosomes (Table S2, Supporting Information).

The floury and vitreous fractions were isolated using hand dissection after the removal of peripheral layers and the aleurone. The fractions were lyophilized and ground under liquid nitrogen. The protein content of isolated dried endosperm was determined by the Kjeldahl nitrogen determination method using a 5.7 factor for protein content.

Vitreous/floury statistical analyses were performed using Student's paired *t*-test. Error bars are standard deviations and represent differences between vitreous/floury fractions, as far as differences between maize inbred lines.

Starch and Amylose Content. Starch was quantified according to a modification of the Megazyme Total starch assay procedure. Briefly, 50 mg of flour was washed in 5 mL of 80% ethanol at 80 °C for 5 min. Starch was subsequently dispersed in 2 mL of DMSO for 10 min at 100 °C. Samples were hydrolyzed 6 min at 100 °C with 3 mL of a 50 mM, pH 7 thermostable α-amylase solution (100U/mL) in MOPS (3-(*N*-morpholino)propanesulfonic acid), before adding 4 mL of 200 mM ammonium acetate at pH 4.5 and 100 μL of amyloglucosidase (3300U/mL). The hydrolysis was conducted during 30 min at 50 °C. We added water up to 50 mL, and a diluted aliquot (10 X, 66 μL) was placed in the 96-well plate with 200 μL of GOPOD buffer and incubated for 20 min at 50 °C. Absorbance was read at 510 nm, and the subsequent glucose contents were determined using a standard curve. Glucose content was further converted to starch contents.

Amylose was quantified according to a modification of the Megazyme amylose/amylopectin assay procedure. Briefly, zeins were extracted from 25 mg of flour with 70% ethanol for 1 h. Starch was subsequently dispersed in 1 mL of DMSO for 15 min at 100 °C, and then we added 2 mL of 95% ethanol and 4 mL of absolute ethanol. After starch precipitation, the supernatant was removed. Starch was dispersed in 2 mL of DMSO for 15 min at 100 °C, then 0.6 M sodium acetate at pH 6.4 was added up to 25 mL. An aliquot was used for starch quantification, and another one was used for amylose quantification, after amylopectin and dextrin precipitation with concanavalin-A. Aliquots were hydrolyzed with α-amylase and amyloglucosidase in 100 mM sodium acetate at pH 4.5, then 40 μL was placed in 96-well plate with 200 μL of GOPOD buffer and incubated for 20 min at 50 °C. The amylose content was determined from the absorbance ratio at 510 nm.

Total Starch and Nonstarch Lipid Contents. Endosperm flour lipids were extracted by adding 1 mL of 2-propanol in 20 mg of flour. After 1 h at room temperature and centrifugation (3000*g*, 5 min), the pellet was extracted twice with 1 mL of chloroform/methanol 2:1 (v/v) for 1 h. The three supernatants containing nonstarch lipids were pooled and dried under nitrogen flux. Nonstarch lipids were methyl-esterified with 1 mL of 14% BF3 in methanol at 70 °C for 1 h in the presence of heptadecanoic acid (Sigma-Aldrich, France) as internal standard.

To quantify starch lipids, the residual defatted flour was dried and incubated in 5 mL of 2% sulfuric acid in methanol at 50 °C for 12 h in the presence of heptadecanoic acid as internal standard.[24] The resulting fatty acid methyl esters (starch and nonstarch) were analyzed by coupling gas chromatography with flame ionization detection (GC-FID Clarus680, PerkinElmer, France) using a DB225 (Agilent technologies, France) capillary column (30m × 0.32 mm, 0.25 μm) and a temperature gradient from 50 to 220 °C.

Starch and Nonstarch Lipid Composition. To determine the composition of nonstarch lipids, 1 g of endosperm flour (about 20 dissected grains) was extracted in 10 mL of 2-propanol for 1 h and centrifuged (3000*g*, 5 min). The pellet was extracted three times in chloroform−methanol (2/1) for 1 h. The supernatants were pooled and dried on a rotary evaporator. To remove nonlipid material, lipids were solubilized in 8 mL of chloroform−methanol (2/1), to which 2 mL of 0.9% NaCl in water were added.[25] The lower organic phase was collected and dried under nitrogen flux. Then, lipids were solubilized in 1 mL of chloroform containing 1% acetic acid and loaded on a silica (100 mg) cartridge (SupelClean LC-Si, Supelco, USA). Neutral lipids, galactolipids, and phospholipids were eluted with 1% chloroform-acetic acid, acetone, and methanol, respectively. Lipids were dried under nitrogen flux and solubilized in chloroform before UPLC analysis. An aliquot was taken for quantification by GC-FID as described above.

To analyze the starch lipid composition, 100 mg of thoroughly delipidated flour was dispersed in 1 mL of water during 5 min at 100 °C in water. Then, 4 mL of 1-propanol was added and mixed for 5 min at 100 °C. After centrifugation (3000*g*, 5 min), the pellet was washed with 80% 1-propanol in water. After centrifugation, the supernatants were pooled and dried under nitrogen flux, and the lipids were purified by phase partitioning in chloroform−methanol−0.9% NaCl as described above. Dried lipids were solubilized in 0.4 mL of chloroform before UPLC analysis. Lipids were analyzed on Dionex Ultimate 3000 UPLC equipped with an Uptisphere Strategy 2.2 μm 100 Å column (4.6 × 150 mm) and an evaporative light-scattering detector (Sedex80, Sedere, France). Lipids were eluted using a gradient from solvent A, chloroform, to solvent B, methanol−ammoniac 30%−chloroform 460:35:5 (v/v). The gradient started from 100% A to 20% B in 3 min, and then increased to 100% B in 9 min. After a plateau at 100% B for 3 min, the column was equilibrated in 100% A for 3 min. The analysis was carried out at 30 °C with a flow rate of 1.5 mL/min. Lipid content

DOI: 10.1021/acs.jafc.5b00293
J. Agric. Food Chem. 2015, 63, 3551−3558

was calculated in regard to a calibration curve obtained with lipid standards. Phosphatidylethanolamine (PE), phosphatidylcholine (PC), and phosphatidylinositol (PI) were from soybean (Avanti Polar Lipids Inc., USA). Bovine brain phosphatidylserine (PS), egg yolk phosphatidic acid (PA), 1-palmitoyl-lysophosphatidylcholine (C16 lysoPC), and linoleic acid were from Sigma-Aldrich Chimie (Lyon, France). 1-Heptanoyl-lysophosphatidylethanolamine (C17 lysoPE) was provided by Avanti Polar Lipids (Alabaster, Alabama, USA). Galactolipids, i.e., digalactosyldiacylglycerol (DGDG), and monogalactosyldiacylglycerol (MGDG) standards were purified from wheat flour as previously described.[26] Standard TAG were purified from the corresponding commercial sunflower oil on SiOH cartridges using stepwise elution with hexane−diethyl ether 99:1 and 95:5 (v/v).

RESULTS

Sequential Extraction Procedure Enabling Quantification and Characterization of Starch and Nonstarch Lipids of Maize Endosperm. The selected sample of 13 maize inbred lines displays a wide range of vitreousness and protein content (from 8.8 to 12.3% DW). The starch content varies from 71.2 to 74.5% DW (Table S1, Supporting Information). In maize endosperm, a part of the lipids are embedded in starch granules and are mainly composed by FFA and lysophospholipids.[27] They are not extractible using cold solvents, being only released after starch hydrolysis or by using hot water−alcohol solvents. Therefore, we developed a sequential extraction procedure where lipids are first thoroughly extracted with solvents at room temperature, i.e., nonstarch lipids, while the residual unextracted lipids, i.e., starch lipids, were extracted with hot water−1-propanol or released by acid methanolysis as fatty acid methyl esters (FAME). Compared to nonstarch lipids, starch lipids are characterized by a higher proportion of palmitic acid (about 40% vs about 18%). Conversely, nonstarch lipids contained a higher proportion of unsaturated fatty acids, namely, linoleic (18:2 n-6), linolenic (18:3 n-3) and oleic acids (18:1 n-9), than starch lipids (Figure 1a). These fatty acid compositions are in agreement with previous data obtained for purified maize starch and isolated maize endosperm.[28] Finally, when delipidated maize endosperms were extracted with hot aqueous 1-propanol, lipid analysis by normal-phase UPLC showed that these lipids are mainly composed of FFA and lysophospholipids, lysoPE, and especially lysoPC (Figure 1b and Figure S2a, Supporting Information) that specifies starch lipids.[27]

Starch lipid contents vary from 0.27 to 0.35% of endosperm DW (Table S3, Supporting Information). Therefore, about a third of endosperm lipids occur inside the starch granules. Related to starch contents, these values correspond to 0.37 and 0.49% of starch DW, respectively. These amounts are close to the value found for purified starch from a commercial maize hybrid, i.e., about 0.5%.[28] In contrast, nonstarch lipid contents vary from 0.47% to 0.83% of endosperm DW. In all inbred lines, nonstarch lipids are mainly composed of neutral lipids (79 to 95% of nonstarch lipids) (Table S3, Supporting Information) as previously observed in hybrids as well as in amylo- and waxy maize.[28] TAG and FFA compose the neutral lipids where only very small quantities of monoacyl (MAG)- and diacylglycerol (DAG) can be detected (Figure S2b, Supporting Information, and Figure 3b). This contrasts with the results obtained by Tan and Morrison[28] who found very low TAG levels, high amounts of FFA, and measurable levels of DAG and MAG. In regard to the results reported by Tan and Morisson,[28] the higher proportion of TAG vs FFA observed herein is probably due to our primary extraction with 2-propanol, which is known to inhibit lipases.[25] Finally, membrane lipids, i.e., galactolipids and phospholipids, were minor compounds and represented from 1 to 7.6% and from 2.5 to 13.6% of nonstarch lipids, respectively (Table S3, Supporting Information). Therefore, our sequential extraction procedure is a simple way to accurately determine the starch and nonstarch lipid contents and composition. It does not need extraction of starch, avoiding contamination by residual nonstarch lipids present inevitably on the surface of granules[28,29]

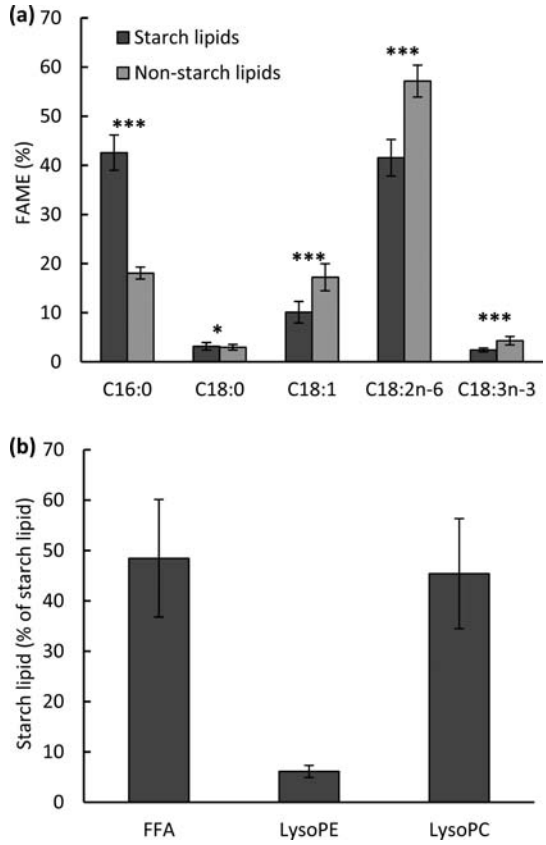

Figure 1. (a) Fatty acid composition of starch lipids and nonstarch lipids expressed as percentage of total FAME. Values are the average of two independent biological replicates for the 13 lines (error bar, SD; $n = 26$) (asterisks indicate significant difference; Student's t test; $^{*}P < 0.05$; $^{***}P < 0.001$). (b) Starch lipid composition of total endosperm expressed as percent of total starch lipids. FFA, free fatty acid; LysoPE, lysophosphatidylethanolamine; LysoPC, lysophosphatidylcholine. Mean values for the 13 lines (error bar, SD; $n = 13$).

FFA to Lysophospholipid Ratio of Starch Lipids Is a Marker of Vitreous and Floury Endosperm. In order to explore whether any relationship between biochemical composition and vitreousness can be assessed, the vitreous and floury regions were isolated by hand dissection. As previously shown in opaque and inbred maize lines,[23,30] protein contents were higher in the vitreous area, whereas higher starch contents were observed in the floury one (Table S4, Supporting Information). Similarly, slight but significant higher amylose levels were systematically evidenced in the starch of the vitreous endosperm when compared with the starch of the floury area (Table S4, Supporting Information). This result is in accordance with the higher amylose contents measured in maize hybrids and a QPM population with increased vitreousness.[31,32] Accordingly, starch lipids and

J. Agric. Food Chem. 2015, 63, 3551−3558

nonstarch lipids of vitreous and floury endosperm were quantified as FAME. When lipid contents are related to endosperm dry weight, the starch lipid content is not significantly different between the floury and vitreous regions. However, when lipid contents are related to starch dry weight content, a clear and significant trend for higher lipid content in the starch granules of the vitreous fraction than in the starch granules of the floury one is evidenced (Figure 2a).

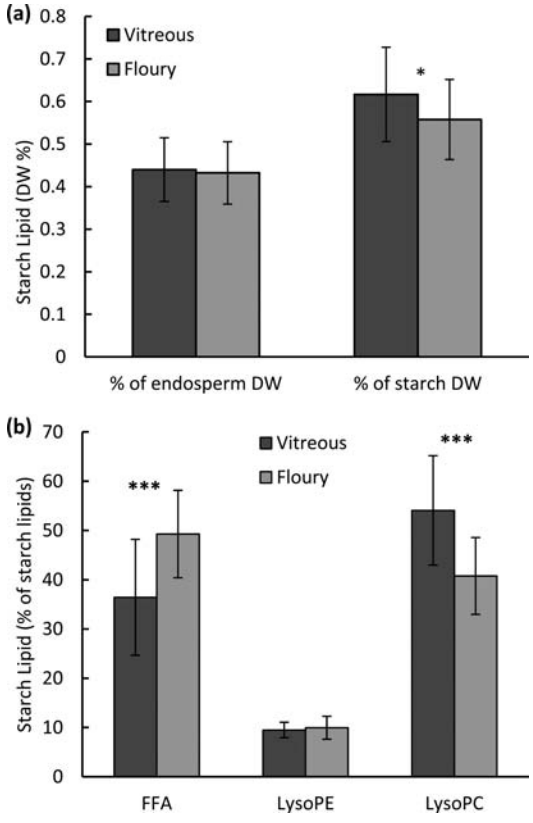

Figure 2. (a) Starch lipid content in vitreous and floury endosperm from the 13 lines expressed on endosperm and starch dry weight and expressed in dry weight percent. Values are averages of the 13 lines (error bar, SD; n = 13) (asterisks indicate significant difference; Student's t test; *P < 0.05). (b) Lipid content in vitreous and floury starch from the 13 lines expressed as percent of total starch lipid. FFA, free fatty acid; LysoPE, lysophosphatidylethanolamine; LysoPC, lysophosphatidylcholine. Values are averages of the 13 lines (error bar, SD; n = 13). (Asterisks indicate significant difference; Student's t test; **P < 0.01; ***P < 0.001.)

Interestingly, this increase of lipid contents comes with a major shift in the FFA to lysophosphopholipid ratio due to an increase of the lysoPC content, the major starch phospholipid (Figure 2b and Figure S2a, Supporting Information).

Partitioning of Storage and Membrane Lipids in Vitreous and Floury Endosperm. The highest nonstarch lipid contents are observed in the floury endosperm for each inbred line. Indeed, the mean nonstarch lipid amounts of the floury endosperms are almost twice those observed in the case of the vitreous endosperm, i.e., 1 and 0.6% endosperm DW, respectively (Figure 3a). This difference is mainly due to neutral lipids, the main lipid fraction of maize endosperm (Table S3 and Figure S2b, Supporting Information). Indeed, the amounts of membrane (polar) lipids are quite low in all inbred lines, and no significant differences are observed

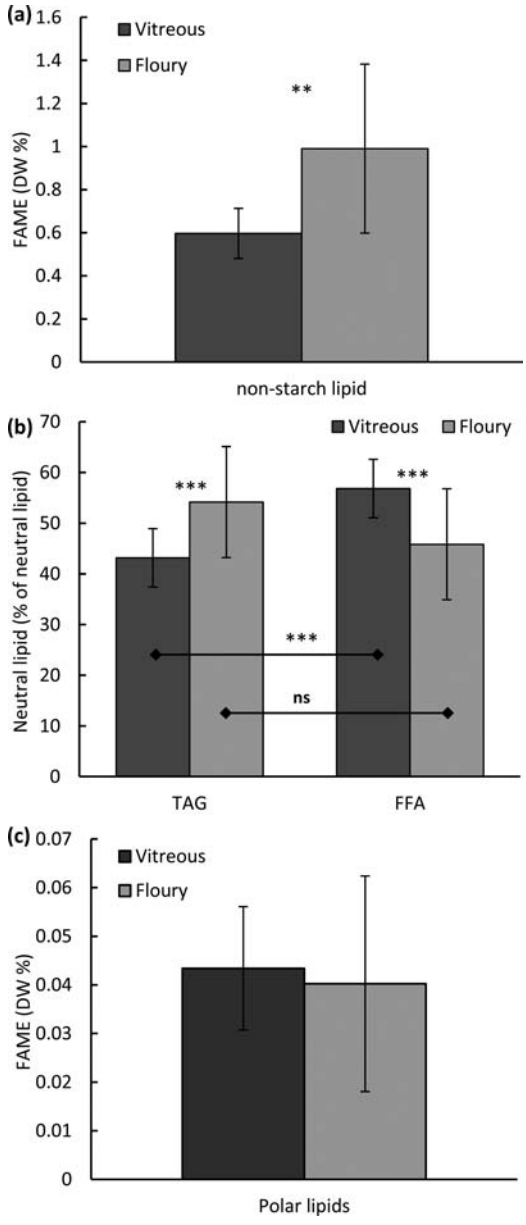

Figure 3. (a) Nonstarch lipid content in vitreous and floury endosperm from the 13 lines, expressed in dry weight percent of endosperm. Mean values for 13 lines (error bar, SD; n = 13) (asterisks indicate significant difference; Student's t test; **P < 0.01). (b) Vitreous and floury endosperm neutral lipid composition expressed as percent of total neutral lipids. TAG, triacylglycerol; FFA, free fatty acid. Values are averages of the 13 lines (error bar, SD; n = 13) (asterisks indicate significant difference; Student's t test; ***P < 0.001; ns, nonsignificant). (c) Polar lipid contents in vitreous and floury endosperm from the 13 lines expressed in dry weight percent of endosperm. Mean values for the 13 lines (error bar, SD; n = 13).

between the polar lipid contents of the vitreous and floury endosperms (Figure 3c). While the vitreous endosperm is significantly richer in FFA than in TAG, there is no significant difference between the FFA and TAG contents of floury endosperm (Figure 3b). Therefore, in regard to the vitreous endosperm, the higher amounts of neutral lipids in the floury endosperm are mainly due to TAG (Figure 3b).

Remarkably, the partition of nonstarch polar lipids between the vitreous and floury areas follows a different pattern. While the levels of total membrane lipids are not significantly different

DOI: 10.1021/acs.jafc.5b00293
J. Agric. Food Chem. 2015, 63, 3551−3558

between vitreous and floury endosperm (Figure 3c), their compositions, i.e., galactolipid to phospholipid ratio, differ significantly. Indeed, galactolipids represent 30% of membrane lipids in the floury region, whereas they represent 20% in the vitreous region (Figure 4a). Similarly, vitreous endosperm contains more phospholipids than the floury one, with 80% of phospholipids in vitreous endosperm and 70% in floury endosperm. These tendencies are observed in most lines except for L05 and L06 where the proportions of galactolipids and phospholipids in their floury and vitreous regions were similar (data not shown). We do not observe significant differences in the galactolipid composition of the vitreous and floury endosperm (Figure 4b). MGDG and DGDG are the major galactolipids, and in most maize lines, except for L02 and L13 (data not shown), we observe the same MGDG/DGDG ratio in the vitreous and floury endosperm (Figure 4b). Similarly, we do not observe significant differences in PE, PA, and lysoPC proportions between the floury and vitreous regions (Figure 4c). Conversely, a higher proportion of PC is observed in the vitreous endosperm, where it represents about 59% of phospholipids versus 54% in the floury part. This difference is partially balanced by a significant increase of PI level in floury areas, i.e., 12.6% of phospholipids vs 10.6% in vitreous endosperm.

Lipids of Vitreous Endosperm Display a Higher Level of PUFA than the Floury Endosperm. The fatty acid composition of vitreous and floury endosperm lipids display systematic differences. Acyl lipids of vitreous endosperm contained higher proportions of polyunsaturated fatty acid (PUFA) and lower levels of saturated and monounsaturated fatty acids (Figure 5). The proportions of linoleic acid and linolenic acid are significantly higher in the vitreous region. Nonstarch lipids consist of about 64% of PUFA in the vitreous region, whereas they represent at most 58% in the floury endosperm. In regard to the vitreous endosperm, the decrease of PUFA proportion in the floury endosperm is balanced by an increase of saturated and monounsaturated fatty acids, namely, palmitic, stearic, and oleic acids. We observed the same shift in fatty acid saturation level in both storage and membrane lipid classes. This shift was observed in starch lipid too, although it is less pronounced (data not shown). Therefore, a higher PUFA content in the lipid of the vitreous region than in the floury one is systematically observed in both starch and nonstarch lipids.

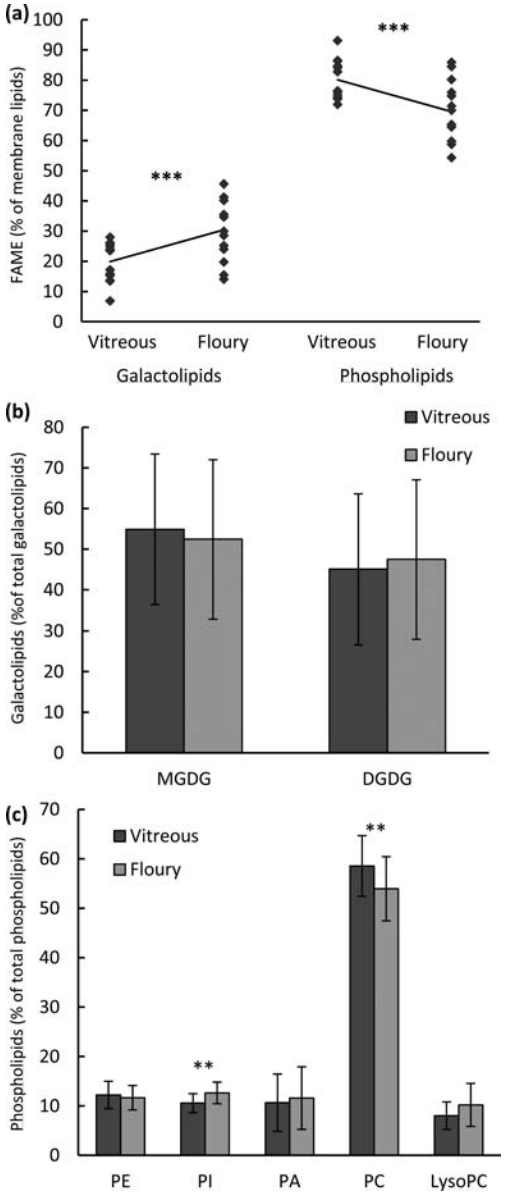

Figure 4. (a) Galactolipid and phospholipid levels in vitreous and floury endosperm of the 13 individual inbred lines (markers). The black line shows average lipid evolution. Lipids were quantified as FAME and expressed as percent of total polar lipids. Values are the average of two independent biological replicates (asterisks indicate significant difference; Student's *t* test; ***$P < 0.001$). (b) Vitreous and floury endosperm galactolipid composition expressed as a percent of total galactolipids. MGDG, monogalactosyldiacylglycerol; DGDG, digalactosydiacylglycerol. Values are the average of three independent biological replicates for the 13 lines (error bar, SD; $n = 39$). (c) Vitreous and floury endosperm phospholipid composition expressed as percent of total phospholipids. PE, phosphatidylethanolamine; PI, phosphatidylinositol; PA, phosphatidic acid; PC, phosphatidylcholine; LysoPC, lysophosphatidylcholine. Values are the average of three independent biological replicates for the 13 lines (error bar: SD; $n = 39$) (asterisks indicate significant difference; Student's *t* test; **$P < 0.01$).

DISCUSSION

Although lipids are minor compounds of the cereal endosperm, they play a major role in the assembly of the starch−protein matrix of mature kernels and therefore in grain texture (hardness). In this context, numerous research works were conducted on the lipids of wheat endosperms.[33] Surprisingly, only few research works were devoted to maize endosperm lipids and especially, no work had been realized on the relationships between endosperm lipids and vitreousness of maize seeds.

Endosperm lipids can be classified in starch and nonstarch lipids. Starch lipids are embedded in the starch granules and are extracted only with hot alcohol−water solvents or after starch hydrolysis.[27] They account for about 30% of total lipids and are characterized by a high palmitic acid content in regard to nonstarch lipids in agreement with previous results.[28] These starch lipids are almost exclusively composed of monoacyl-lipids, i.e., FFA and lysophospholipids, mainly lysoPC. In this inbred line population, no correlation could be found between these lipids and maize vitreousness or milling properties (semolina yield). Indeed, any significant correlation could be also observed between these physical properties and protein and starch contents as well. However, by considering separately the floury and vitreous regions obtained by hand dissection,

DOI: 10.1021/acs.jafc.5b00293
J. Agric. Food Chem. 2015, 63, 3551−3558

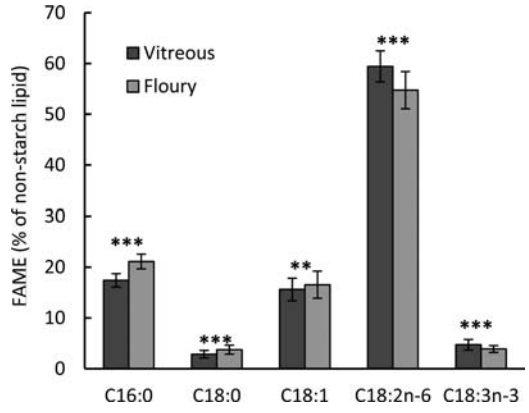

Figure 5. Fatty acid composition of nonstarch lipids quantified as FAME and expressed as percent of total fatty acid. Values are the average of two independent biological replicates for the 13 lines (error bar, SD; $n = 26$) (asterisks indicate significant difference; Student's t test; $^{**}P < 0.01$; $^{***}P < 0.001$).

significant differences were found. Starch lipid content was higher in the starch of vitreous endosperm than in the starch of floury endosperm. Similarly, the amylose content of starch is systemically higher in the vitreous than in the floury endosperm. This is in agreement with previous works reporting a relationship between the amylose and starch lipid contents when considering different groups, i.e., low-amylose (waxy), normal-amylose, and high-amylose maize starches. Indeed, higher amylose content is associated with higher starch lipid content.[34,35] Furthermore, our work shows that the higher lipid content of starches from vitreous endosperm than that of the starches of floury endosperm was mainly due to a shift in the FFA to lysoPC ratio. On the contrary, both FFA and lysophospholipid contents increased when comparing normal and high-amylose maize mutants emphasizing the difference between normal maize and mutants.[34,35] Starch lipids can form complexes with amylose in native starch granules[36,37] and impact amylose chain assemblies, starch crystallinity, and obviously play a role in the architecture of starch granules.[38] These changes of starch lipid content and composition may be compared with changes of the crystallinity and morphology of starch granules with an increase of endosperm vitreousness in QPM.[4,39] This also has to be compared with differences observed for the surface structure of starch granules isolated from the vitreous and floury endosperm regions of maize hybrids and the QPM population.[31] Therefore, the biosynthesis of starch lipids and its regulation can also be regarded as one of the significant molecular and cellular mechanisms determining maize endosperm vitreousness. Actually, the origin and the biological function of the monoacyl lipids entrapped in the starch granules are still unknown. Regarding lysoPC, it is the form used to import lipids from the ER into plastids for the synthesis of some plastid lipids.[40] Although it is not known if this way is operative in amyloplasts, it is interesting to note that the highest lysoPC level is observed in the vitreous endosperm where the synthesis of storage proteins, i.e., zeins, which occurs in the ER, is particularly more intense than in the floury region. Indeed, it is also in the vitreous endosperm where the highest level of PC, the precursor of lysoPC, is observed. Beside a role of these lipids in the synthesis of amyloplast membrane lipids as in plastids,[41−43] starch lipids could regulate the activity of enzymes involved in amylose and amylopectin synthesis. In this regard, it was shown that phospholipids could inhibit starch branching enzymes.[44]

Actually, differences in the biosynthesis of nonstarch lipids also exist between floury and vitreous endosperms. Indeed, nonstarch lipids are mainly composed by TAG and FFA for all inbred lines, and a higher accumulation of these lipids is observed in the floury than in the vitreous region of the maize endosperm. Concerning membrane lipids, galactolipids, and phospholipids, it was surprising to observe such low contents in all maize lines. Indeed, in wheat endosperm, with similar protein and starch content, the membrane lipid content[29,45]is more than 10 times the content found in maize endosperm (this work and ref 28). This low membrane lipid content in all inbred lines of our maize population seems to confirm and generalize the significant degradation of endosperm membrane lipids observed during endosperm development of a maize hybrid.[46] This specificity of endosperm maize development could be related to autophagy. Actually, autophagy and especially macroautophagy is a ubiquitous cellular mechanism that is involved in the degradation of damaged organelles and their membrane components.[47] Autophagy is operative in plants.[48,49] It is worthy to note that in maize endosperm the lipidation of an autophagy protein, i.e., Atg8, a marker of the formation of functional autophagosomes, starts almost at the same time[50] as membrane lipid degradation.[46] Furthermore, it is interesting to note that the decrease of TAG contents and the increase of FFA contents from mid to the end of endosperm development[46] occurs also at the onset of the expression of Atg8. Indeed, in animals as in plants, autophagy could be involved in TAG degradation.[51,52]

Whatever the origin and extent of the degradation of membrane lipids, it is worthwhile noting that there is a tendency toward higher galactolipid contents in the floury endosperm than in the vitreous one. This is in agreement with our observation that the floury endosperm has higher starch content than the vitreous one. Actually, galactolipids are specific compounds of the amyloplast membranes.[18] However, the higher phospholipid contents in the vitreous endosperm can be related to its higher protein content. Indeed, protein bodies, where protein accumulates, emerge from the ER, and their membrane lipids are composed by phospholipids. Finally, the lipid composition of the floury and vitreous endosperm could reflect some specificity in the regulation of their metabolism, which is essentially directed toward carbon and nitrogen storage.

In this regard, it is worthy to note that phospholipids of the floury endosperm display significantly higher PI level. Shank et al.[19] reported an increase of PI content in the Fl2 mutant that was also paralleled with an augmentation of TAG content. These relationships are not surprising since phospholipid and TAG biosynthetic pathways share common steps.[43] Shank et al.[19] showed that, in the Fl2 mutant, these lipid changes were related to UPR. UPR is a ubiquitous mechanism that controls the ER production of correctly folded protein and ER homeostasis.[53] Therefore, the PI and TAG increase observed in the floury endosperm in regard to the vitreous endosperm could suggest differences in the UPR responses between these endosperm regions. The lower proportion of PC in the floury endosperm also supports this. Indeed, studies on *C. elegans* report that PC decrease leads to UPR and is associated with an increase in saturated fatty acid.[54] Moreover, we observed that the lower proportion of PUFA, i.e., both linoleic and linolenic acids, in the floury endosperm than in the vitreous one is

DOI: 10.1021/acs.jafc.5b00293
J. Agric. Food Chem. 2015, 63, 3551−3558

systematically observed and is balanced by a significant increase of the proportion of both saturated and monounsaturated fatty acids. These differences could be related to differences of Δ12-desaturase activity. Actually, fatty acid saturation level and desaturase activity are good markers of cell stress in plants.[55,56] Therefore, the nonstarch lipid contents and compositions of the floury vs those of the vitreous endosperm can be linked to the stress occurring during endosperm development. Indeed, PCD starts early in the central region, which almost will correspond to the floury endosperm of the mature grain.[20,57] However, as outlined above for the membrane lipid and lysophospholipid partition, it could not be excluded that these differences in the fatty acid unsaturation level are also due to the metabolic specificities of the different endosperm regions. Indeed, the Δ12-desaturase activity seems centered in the endoplasmic reticulum of maize endosperm,[45] a compartment highly solicited for zein synthesis in the vitreous endosperm.

At this stage of the investigation, the role of nonstarch lipids of endosperm vitreousness cannot be clearly determined. It is, however, important to emphasize that lipids, especially membrane lipids, have to be considered in terms of surface potential in contrast with starch and proteins that have to be regarded in terms of volume occupancy. Actually, in dry mature wheat endosperm membrane lipids are mainly localized at the interface between the starch granule and the protein matrix,[58] and correlations have been found between the extractability of membrane lipids and wheat hardness.[59]

Although lipids are minor components of maize endosperm, this first analytical approach reveals that these compounds could be good markers of endosperm development. Indeed, the significant changes impacting the content and composition of lipids in relation to endosperm vitreousness are related to differences in the metabolism of cells that will lead to the vitreous and floury regions of the endosperm. The most important feature of this study is the probable important role of starch lipids, especially lysoPC, in determining with amylose the starch architecture and finally the starch−protein interactions.

with some dietary polyphenols impaired the digestibility of many proteins, e.g., β-lactoglobulin. Using green tea catechins, Tantoush et al.[28] contrarily reported that the complexation could distinctly improve the pepsin digestibility of some food allergens. Venkatachalam and Sathe[29] reported that the presence of some phenolic compounds, including catechin and ellagic acid, did not adversely affect the in vitro pepsin hydrolysis of phaseolin (a 7S globulin from kidney bean). With in vivo experiments, Carbonaro et al.[31] also indicated that the binding of polyphenols produced an insignificant influence on the protein digestibility of proteins from several legumes. All these observations suggest that the influence of complexation with phenolic compounds on the protein digestibility is dependent on the type and nature of the tested proteins and even phenolic compounds. For legume storage proteins, the structural characteristics seem to play a vital role in their digestibility,[25,31] which might be highly affected by some pretreatments, including heating. From this viewpoint, it would be a very interesting subject to characterize the influence of complexation with curcumin on the in vitro digestibility of soy proteins.

The main objective of this study was systematically to investigate the complexation between nanoparticles of unheated and preheated (75−95 °C) SPI and curcumin. The correspondingly formed nanocomplexes were characterized in terms of surface characteristics, particle size, and microstructure, as well as the encapsulation efficiency of curcumin. Furthermore, the influence of the nanocomplexation on the storage stability and/or bioaccessibility of curcumin, as well as the in vitro digestibility of SPI, was also characterized using a gastrointestinal in vitro model. Our findings indicate that the nanocomplexation between SPI and curcumin not only provides a promising strategy to improve the stability and bioaccessibility of curcumin, but also can be applied to improve the nutritional value of soy proteins.

MATERIALS AND METHODS

Materials. Curcumin (~98% purity, from *Curcuma longa*) was purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Defatted soy flour with low protein denaturation was obtained from Shandong Yuwang Industrial and Commercial Co. Ltd. (Yucheng, Shandong Province, China). All other chemicals were of analytical grade. SPI was prepared according to the conventional process as follows. In brief, the flour was dispersed in deionized water at a weight-to-volume ratio of 1:15, and the pH of the resultant slurry was adjusted to 8.0 using 2 M NaOH. The slurry was stirred for 2 h (if necessary, the pH was adjusted to 8.0 during the stirring) and then centrifuged at 8000*g* for 20 min to remove the insoluble material. The resulting supernatant was adjusted to pH 4.5 with 2 M HCl, and the isoelectric-precipitated curd was collected by centrifugation at 5000*g* for 20 min. The obtained precipitate was redispersed in deionized water at a weight-to-volume ratio of 1:5, and the pH of the dispersion was adjusted to 7.0 with 2 M NaOH. The final dispersion was lyophilized to produce the SPI. The protein content of this SPI was approximately 91.5% (wet basis), as determined using a Dumas combustion method (Elemental Analyzer rapid N cube, Germany), with a nitrogen conversion factor of 6.25.

Complexation of Curcumin with SPI. The SPI stock solution (5%, w/v) at pH 7.0 was prepared by dispersing the freeze-dried SPI sample in water under the stirring conditions for at least for 2 h. The heated SPI solutions were obtained by heating the same volume of the SPI stock solution in a water bath at 75, 85, and 95 °C for 15 min, and then immediately cooling to room temperature in an ice bath. Stock curcumin solution of 4.5 mg/mL concentration ([cur]) was prepared in ethyl alcohol absolute (if necessary, the preparation was centrifuged to remove the insoluble material). For the characterization of SPI−curcumin complexes, an amount of curcumin stock solution was added dropwise at a volume ratio of 1:50 to 5% (w/v) unheated or heated SPI solutions under magnetically stirred conditions. The final [cur] in the mixtures was about 88 μg/mL. The mixtures were further kept for 8 h on a magnetic stirrer at room temperature. Last, the insoluble curcumin was removed by centrifugation at 8000*g* for 20 min. The resultant supernatants were subject to the particle property characterization or freeze-dried to produce the SPI−curcumin complex powders.

To investigate the influence of variation in [cur] on the encapsulation efficiency (EE) and load amount (LA) of curcumin, increasing amount of the curcumin stock solution was added to a specific volume of 5% (w/v) unheated SPI solution. If necessary, a certain volume of ethanol was added to make sure that, in the final mixtures, the final ethanol and protein concentrations in the mixtures were constant at 30% (v/v) and 3.5% (w/v), respectively.

Determination of the Surface Hydrophobicity (H_0) and ζ-Potential of Proteins in Solutions. The H_0 of proteins in unheated and heated SPIs, before and after complexation with curcumin, was determined using a fluorescence probe, 1-anilinonaphthalene-8-sulfonate (ANS^-).[32] In brief, stock solutions of 8×10^{-3} M ANS^- and 1.5% (w/v) SPIs were prepared in 0.01 M phosphate buffer (pH 7.0). A 20 μL volume of ANS^- stock solution was added to 4 mL of the buffer containing increasing amounts (0−50 μL) of 1.5% (w/v) SPI solution. The relative fluorescence intensity (FI) was measured at 25 °C, with excitation and emission wavelengths of 390 and 470 nm, respectively. For each protein, the initial slope of the FI versus protein concentration plot was calculated by linear regression analysis and used as an index of H_0.

The ζ-potential of proteins in the unheated and heated SPI solutions at pH 7.0 was measured using a Zetasizer Nano ZS (Malvern Instruments Ltd., Malvern, Worcestershire, U.K.) in combination with a multipurpose autotitrator (model MPT-2, Malvern Instruments). Freshly prepared protein solutions were diluted to 0.1% (w/v) with the same applied buffer and filtered through a 0.45 μm HA Millipore membrane prior to analysis.

Differential Scanning Calorimetry (DSC). The thermal transition of unheated and heated SPIs was examined using a TA Q100-DSC thermal analyzer (TA Instruments, New Castle, DE) according to the process described in our previous work.[33] All the unheated and heated SPI samples with or without complexation with curcumin for the DSC examination were prepared by freeze-drying the corresponding solutions (5%, w/v). Approximately 2.0 mg of the freeze-dried samples was weighed into aluminum liquid pans (Dupont), and 10 μL of 0.05 M phosphate buffer (pH 7.0) was added. The pans were hermetically sealed and heated from 20 to 110 °C at a rate of 5 °C/min. A sealed empty pan was used as a reference. The denaturation temperature (T_d) and enthalpy change of the endotherm (ΔH) of the β-conglycinin and glycinin components in the samples were computed from the thermograms by Universal Analysis 2000, version 4.1D (TA Instruments-Waters LLC). All experiments were conducted in triplicate. The sealed pans containing protein samples and buffers were equilibrated at 25 °C for 12 h.

Particle Size Distribution and *z*-Average Diameter (D_z) Measurement. The particle size distribution of particles in unheated and heated SPI solutions, before and after the complexation with curcumin, was evaluated using the dynamic light scattering (DLS) technique. Each SPI solution was diluted to a protein concentration of about 0.1% (w/v) with 0.05 M phosphate buffer (pH 7.0) and filtered with a 0.22 μm filter. DLS analysis was performed at a fixed angle of 173° using a Zetasizer Nano-ZS instrument (Malvern Instruments) equipped with a 4 mW He−Ne laser (633 nm wavelength) at 25 °C. The D_z of the particles was calculated on the basis of the Stokes−Einstein equation, assuming protein particles to be spherical. Each determination was performed in duplicate, and the means were used for statistical analyses.

Atomic Force Microscopy (AFM). AFM images were acquired in tappng mode using a Dimension 3000 microscope (Digital Instruments-Veeco, Santa Barbara, CA) equipped with a "G" scanning head (maximum scan size 10 μm) and driven by a Nanoscope II Ia

DOI: 10.1021/acs.jafc.5b00448
J. Agric. Food Chem. 2015, 63, 3559−3569

controller. Various unheated and heated SPI solutions (5%, w/v), with and without complexation with curcumin, were diluted by 5000-fold with deionized water. A droplet (2 μL) of each diluted sample was immediately spread on a freshly cleaved mica disk in air for 30 min at ambient temperature. For imaging under ambient conditions, single-beam uncoated silicon cantilevers (type OMCL-AC, Olympus, and RTESP, Veeco) were used. The drive frequency was set at 300 kHz, and the scan rate was 1.2 Hz. Images were processed by Digital Nanoscope software (version 5.3 or 3, Digital Instruments). For each preparation condition, at least two samples were used for duplication. Approximately 10 images were obtained for each preparation.

Determination of the EE and LA of Curcumin. The EE (%) of curcumin in the SPI−curcumin complexes was estimated as the percentage of curcumin encapsulated in the proteins by the following equation:

$$\text{EE}\ (\%) = \left[1 - \frac{\text{amount of free curcumin (mg)}}{\text{total amount of added curcumin (mg)}}\right] \times 100 \quad (1,)$$

where the amount of free curcumin is determined from the precipitate obtained by centrifugation (see the section "Complexation of Curcumin with SPI"). The precipitate was extracted in 5 mL of ethanol with mild stirring for 5 min under magnetically stirred conditions and then centrifuged at 9000*g* for 15 min at 20 °C to remove the protein aggregates. The supernatant was subjected to spectrophotometric analysis at 426 nm with a UV754N UV−vis spectrophotometer, and the curcumin concentration was determined using an established standard curve of curcumin (with $R^2 > 0.999$).

The LA of curcumin was calculated by dividing the amount of encapsulated curcumin by the total protein amount in the system.

Stability Measurement. The storage stability of free curcumin in water and curcumin in the SPI−curcumin complexes in water (pH 7.0) was evaluated by monitoring the decrease in the kinetics of absorbance at 426 nm at 25 and 95 °C. The SPI−curcumin complex solutions (1%, w/v) were prepared by dispersing the freeze-dried samples in water under stirred conditions for more than 2 h. The free curcumin solution was prepared by dispersing 1.2 mL of the stock curcumin solution (4.5 mg/mL in ethanol) into 40 mL of water under the same conditions as for the SPI−curcumin complex solution. Then all the samples were centrifuged at 8000*g* for 20 min, and the supernatants were subjected to the storage stability experiment. The initial absorbance for all the cases was set as 100%. Each experiment was performed in duplicate, and the means were used for the statistical analyses.

Sequential in Vitro Gastric and Intestinal Digestion. An in vitro model that simulated sequential gastric and intestinal digestion was applied to evaluate the influence of digestion on the bioaccessibility of curcumin (free or encapsulated in the nanocomplexes with SPI) and/or in vitro protein digestibility of unheated and heated (at 95 °C) SPI according to the process described in our previous work[34] with a few modifications. In brief, 10 mL of SPI solutions, or solutions containing SPI−curcumin nanocomplexes at a protein concentration of 5.0% (w/v), was well mixed with 40 mL of 0.1 M HCl (pH 1.5) and preincubated in a shaker (at 37 °C) at a rate of 95 rpm for around 10 min. If necessary, the pH of the mixtures was adjusted to 1.5 with 1.0 M HCl. The curcumin content in the nanocomplexes was about 871.5−892 μg of curcumin/g of protein. Then 10 mg of pepsin powder was added and well mixed to start the simulated gastric digestion (0−60 min). After 60 min, the pH of the resultant pepsin digests was immediately adjusted to 7.0 with 4 M NaOH, and 250 mg of bile extract powder was added and well dispersed in the shaker for 10 min. Last, 20 mg of pancreatin powder was added to start the intestinal digestion (60−180 min). For free curcumin (control), the curcumin dispersion was prepared by mixing 500 μL of curcumin ethanol solution (4.5 g/L) with 25 mL of deionized water and then subjected to the same digestion process as above. At the end of the whole digestion, 1 mL of digest dispersions was collected and centrifuged at 10000*g* for 30 min at 10 °C. The amount of curcumin in the resultant supernatants and the whole digests was extracted and determined (see the next section).

Curcumin Extraction and Determination. Aliquots (200 μL) of the final digests (obtained after 180 min of digestion) or their supernatants (after centrifugation) were extracted two times with 2 mL of ethyl acetate for 5 min under vortexing conditions and then centrifuged at 5000*g* for 5 min. The absorbance of the pooled ethyl acetate extracts was determined at 420 nm with a UV−vis spectrophotometer, and the curcumin concentration in the extracts was calculated using an established standard curve of curcumin in ethyl acetate (with a coefficient factor of >0.999).

Characterization of the Digests of SPIs and Their Nanocomplexes with Curcumin. The hydrolysis of proteins in unheated and heated SPIs and or their nancomplexes with curcumin was characterized using sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) and release of trichloroacetic acid (TCA)-soluble nitrogen. For SDS−PAGE experiments, aliquots (50 μL) of the digest samples at specific time periods of digestion (0−180 min) were taken and immediately mixed with 300 μL of sample buffer (2-fold), namely, 60 mM Tris−HCl buffer (pH 8.0) containing 2.0% (w/v) SDS, 25% (v/v) glycerol, 0.1% bromophenol blue, and 5% (v/v) β-mercaptoethanol. The electrophoresis was performed on a discontinuous buffered system using 12% separating gel and 4% stacking gel with some modification. The gel was stained with 0.1% Coomassie brilliant blue (R250) in a solution containing 45% methanol and 10% acetic acid for 40 min and further destained in a methanol/ehanol/water = 1/1/8 solution for 24 h.

To characterize the TCA-soluble nitrogen release, aliquots (1 mL) of the digests were taken after specific periods of digestion and immediately mixed with 2 mL of 20% TCA solution to precipitate the proteins with large molecular weights. The mixtures were placed for 10 min and then centrifuged at 5000*g* for 5 min. The nitrogen content of the resultant supernatants was determined by the micro-Kjeldahl method. The percentage of TCA-soluble nitrogen released during the digestion was estimated from the following equation:

$$\text{release of TCA-soluble nitrogen}\ (\%) = 100 - \frac{\text{amount of TCA-soluble nitrogen}}{\text{total amount of nitrogen}} \times 100 \quad (2)$$

The particle size distribution profiles of different digests were characterized using the DLS technique according to the same process as above. All the digests were diluted with the same background solvent to a concentration of about 0.05% (w/v) prior to the determination.

Statistical analysis. An analysis of variance (ANOVA) of the data was performed, and a least significant difference (LSD) with a confidence interval of 95% was used to compare the means.

RESULTS AND DISCUSSION

Formation and Characterization of SPI−Curcumin Nanocomplexes. Curcumin binds to hydrophobic clusters of proteins, mainly through hydrophobic interactions.[7,12,15,17,19,20,35] Heating can result in structural unfolding and denaturation of proteins, thus increasing their surface hydrophobicity (H_0). The improvement of the H_0 would be favorable for the binding of curcumin to the proteins. In the present work, the potential of both unheated and heated (at 75, 85, and 95 °C for 15 min) SPIs to form complexes with curcumin was investigated. As expected, increasing the temperature from 75 to 95 °C resulted in a progressive increase in protein denaturation of the β-conglycinin and/or glycinin components in the SPIs, as well as H_0; e.g., the H_0 considerably increased from 2248 to 5173 (Tables S1 and S2, Supporting Information). The observations about the influence of heating on the protein denaturation of SPI are in accordance with those of our previous findings.[33] In contrast, the ζ-

DOI: 10.1021/acs.jafc.5b00448
J. Agric. Food Chem. 2015, 63, 3559−3569

potential (−13.4 to −13.9 mV) of SPI at pH 7.0 was almost unchanged by the heating (Table S2). Figure 1 A shows the

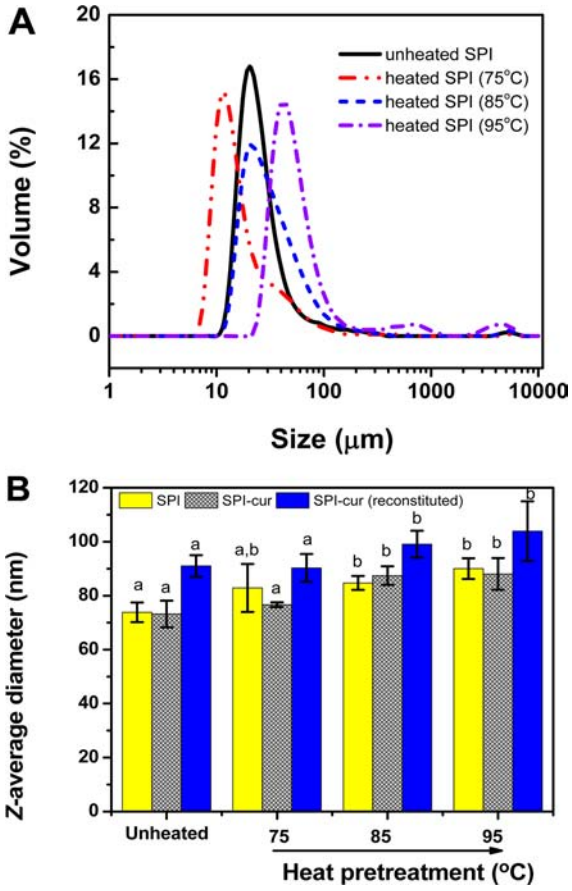

Figure 1. (A) Typical size distribution profiles of particles for unheated and heated SPI solutions. (B) *z*-average diameter of particles in unheated and heated (at 75, 85, and 95 °C for 15 min) SPI solutions or dispersions before and after nanocomplexation with curcumin. Different characters (a, b) on top of the columns represent a significant difference at $p < 0.05$ between the different treatments.

typical size distribution profiles of particles in unheated and heated SPI dispersions, and the *z*-average diameter (D_z) data are summarized in Figure 1B. Most of the particles in these unheated and heated SPI dispersions were present in the nanoparticle form, with D_z progressively but insignificantly increasing from 74 to 90 nm with the temperature of heating (Figure 1B). The progressive increase in D_z was closely associated with the heating-induced denaturation and subsequent aggregation. The D_z of the particles in unheated and heated SPIs is consistent with that of our previous findings.[24] This can be further confirmed by the AFM observations (Figure 2 A–D), where most of the particles in these SPIs were present in dissociated nanoparticles with heights of several nanometers.

After unheated or heated SPI (5%, w/v) was mixed with the curcumin stock solution (4.5 mg/mL, in 100% ethanol) at a volume ratio of 50:1, all the resultant dispersions were transparent and yellow in appearance (Figure 3 A), indicating formation of curcumin–SPI complexes at the nanoscale. Under the conditions, the EE of curcumin for all the preparations was within the range of 96.8–99.1%, and there was no significant difference in EE between the different preparations (Table S1, Supporting Information). The EE is comparable to that (>96%) of curcumin encapsulated in β-lactoglobulin nanoparticles produced by desolvation,[12] but considerably higher than that of curcumin encapsulated in casein nanocapsules by spray-drying (about 83.1%[19]) and in zein-based colloidal particles synthesized by an antisolvent precipitation (71–87%[14]). The differences in EE might be related to the differences in incorporated curcumin amount between these previous works and the present case. When all the SPI–curcumin nanocomplex preparations were freeze-dried and reconstituted, the transparency and yellow color of the resultant reconstituted dispersions were the same as those of the original counterparts (Figure 3), indicating good dispersion and curcumin stability of these formed nanocomplexes. As expected, the curcumin LAs of different dried samples were similar and within the range of 1.743–1.784 μg/mg of SPI (Table S1). The LA is much lower than that (19 μg/mg of casein) in the supernatant of curcumin encapsulated in casein nancapsules,[19] but close to 2 times greater than that (0.892 μg/mg of SPI) encapsulated in the same protein by spray-drying.[14] If the dried SPI–curcumin nanocomplex preparation in the present work is prepared at a protein concentration (*c*) of 1.0% (w/v), the solubility of curcumin in water will reach 17.43–17.84 mg/L, which is more than 1600-fold higher than that (approximately 11 μg/L) for free curcumin in water.[18]

To further unravel the potential of SPI to bind curcumin, we evaluated the complexation of unheated SPI with increasing amount of incorporated curcumin (in ethanol). When the fraction of curcumin-containing ethanol was above 0.3 (relative to the total volume of mixed dispersions), the dispersions exhibited a sol–gel state. Thus, the complexation of SPI with curcumin was performed at a final *c* value and ethanol volume fraction of 3.5% (w/v) and 0.3, respectively, with increasing [cur] from 0.0315 to 1.35 mg/mL of dispersion. From Figure 4, we can interestingly see that, as the [cur] increased, the EE progressively decreased from 98% to 78%, almost in an exponentially decaying way, while the LA of curcumin linearly increased from about 0.9 to 31 μg/mg of SPI. Similar changes in EE and LA with the increase in [cur] in the water–ethanol phase have been observed for the zein–curcumin composite colloidal particles.[14] At the highest [cur] (1.35 mg/mL) in the present work, the solubility of curcumin in water was enhanced by more than 98000-fold, as compared with the 11 μg/L free curcumin in water.[18] The solubility improvement was slightly lower than that (131000-fold) observed for a synthesized diblock copolymer micelle,[6] but considerably higher than those observed for hydrophobically modified starch and HP-γ-cyclodextrin (1670- and 4700-fold, respectively)[36,37] and camel β-casein (at least 2500-fold).[15] The [cur] of soluble curcumin in the supernatant of the 3.5% SPI dispersion at [cur] = 1.35 mg/mL was determined to be about 1.085 mg/mL, which was several-fold higher than the 136.7 μg/mL for the supernatant obtained by centrifuging the reconstituted spray-dried curcumin in casein nanocapsules (at 7.2 mg/mL casein[19]).

The influence of complexation with curcumin on DSC and surface characteristics, as well as the particle size of unheated and heated SPIs, was also investigated. The thermal denaturation of β-conglycinin and glycinin components in these SPIs was nearly unaffected by the complexation, but the complexation resulted in a considerable reduction in H_0, with the decreasing extent depending on the extent of heating (Tables S1 and S2, Supporting Information). The highest

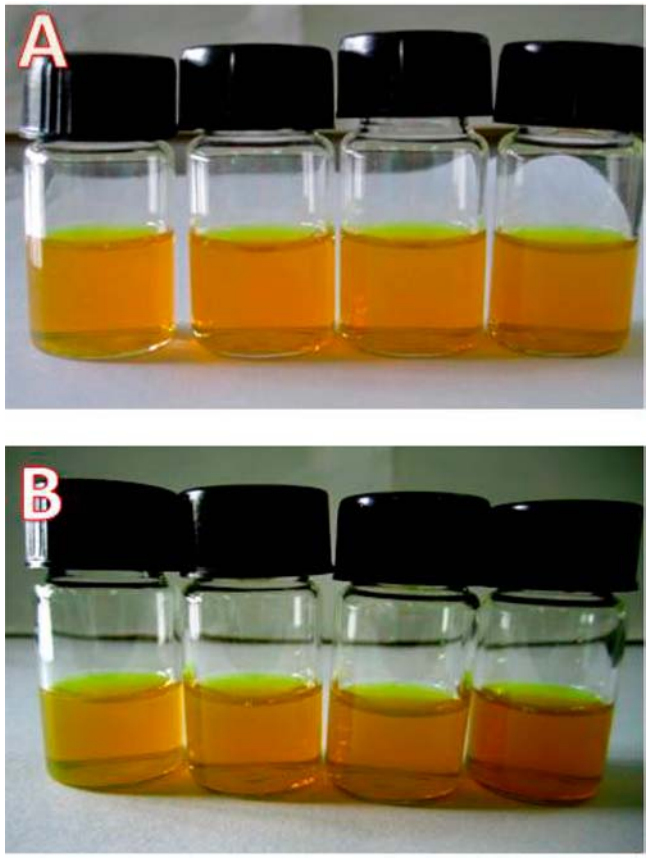

Figure 3. Visual observations of the original (A) and reconstituted (B) SPI–curcumin nanocomplexes in water. Unheated or heated SPI (5%, w/v) was mixed with the curcumin stock solution (4.5 mg/mL, in 100% ethanol) at a volume ratio of 50:1. The samples from left to right represent untreated SPI (control) and SPI preheated at 75, 85, and 95 °C, respectively.

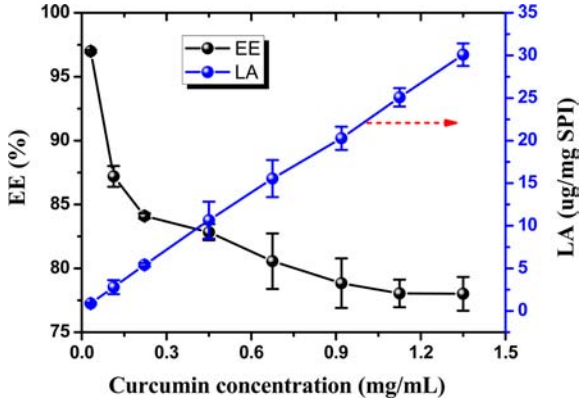

Figure 4. Influence of the curcumin concentration (in the mixed dispersions) on the encapsulation efficiency (EE) and load amount (LA) of curcumin in unheated SPI–curcumin nanocomplexes. The final c value and curcumin-containing ethanol volume fraction were kept constant at 3.5% (w/v) and 0.3, respectively. Each data point is the mean and standard deviation of triplicate measurements performed on separate samples.

reduction in H_0 was observed for the SPI heated at 85 °C among all the test preparations. Furthermore, the complexation also resulted in a slight but insignificant decline in the magnitude of ζ-potential in all the cases (Table S2). Curcumin molecules have two phenolic OH groups with pK_a values of 8.38 and 9.88 in aqueous solution, and are usually in the neutral form at around pH 7.0.[6] Thus, the decreased H_0 might be largely due to the masking of hydrophobic clusters of the proteins by binding with curcumin. Since the hydrophobic clusters are usually evenly distributed over the whole protein molecules, the complexation with curcumin will also mask some charged groups, thus causing the reduction in ζ-potential. The gradual decrease in the ζ-potential of the particles upon increasing the [cur] has also been observed for the complexation of zein colloidal particles with curcumin, though the complexation was performed at acidic pH values (3.5–4.1).[14] When these SPI–curcumin nanocomplexes were freeze-dried and reconstituted, the H_0 considerably increased (relative to that before the freeze-drying), but the magnitude of ζ-potential remarkably declined (Table S2), indicating that the additional freeze-drying markedly changed the surface properties of the SPI–curcumin nanocomplexes.

For any test SPI solution, the complexation with curcumin did not significantly change the size of particles in the aqueous solutions (Figure S1, Supporting Information), as could be further confirmed by the AFM observations of the particles (Figure 2). However, when the solutions containing SPI–curcumin complexes were freeze-dried and reconstituted, the particle size significantly increased relative to that before the freeze-drying (Figure S1), suggesting that the noticeable changes in surface characteristics of proteins after the freeze-drying led to protein aggregation or formation of larger particles. On the other hand, the complexation with curcumin did not affect the secondary structure of the proteins in unheated and heated SPIs, as evidenced by no discernible changes in the Fourier transform infrared (FTIR) spectra (Figure S2, Supporting Information). Previous works also indicated that no distinct conformational changes (at secondary and tertiary levels) occur for many proteins, e.g., β-lactoglobulin and BSA, upon complexation with curcumin or its derivatives.[12,17,20]

Storage Stability. Curcumin in aqueous solution is readily susceptible to hydrolysis or degradation, even at physiological pH.[8,9] Wang et al.[9] indicated that curcumin at neutral and basic pH values degraded by about 90%, within 30 min of storage at room temperature. This can be further confirmed in our experiment that free curcumin degraded by about 70% after storage of 30 min at 25 °C (Figure 5 A). If the storage was further elongated to 4 h, more than 80% of curcumin was degraded. In contrast, almost 90% of curcumin in the nanocomplexes with SPIs remained stable after storage for up to 4 h (Figure 5 A), indicating remarkable improvement of the degradation stability of curcumin. There was no noticeable difference in the degradation kinetics of curcumin between the nanocomplexes with unheated and heated (at 95 °C) SPIs (Figure 5 A). Tapal and Tiku[16] similarly reported that more than 80% of curcumin in the SPI–curcumin complexes was stable upon storage for up to 12 h in water or even in simulated gastric fluid and simulated intestinal fluid. A similar improvement of storage stability has also been observed for curcumin in complexes with serum albumins[8,9,38] and milk proteins including α_{s1}-casein and β-lactoglobulin.[11,12]

As expected, the degradation of curcumin, free or protein-bound, was greatly accelerated by increasing the temperature of storage to 95 °C (Figure 5 B). In this instance, the curcumin in all preparations (free or protein-bound) dramatically decreased within 30 min, and the rate of degradation gradually slowed upon further storage. However, at any specific time of storage,

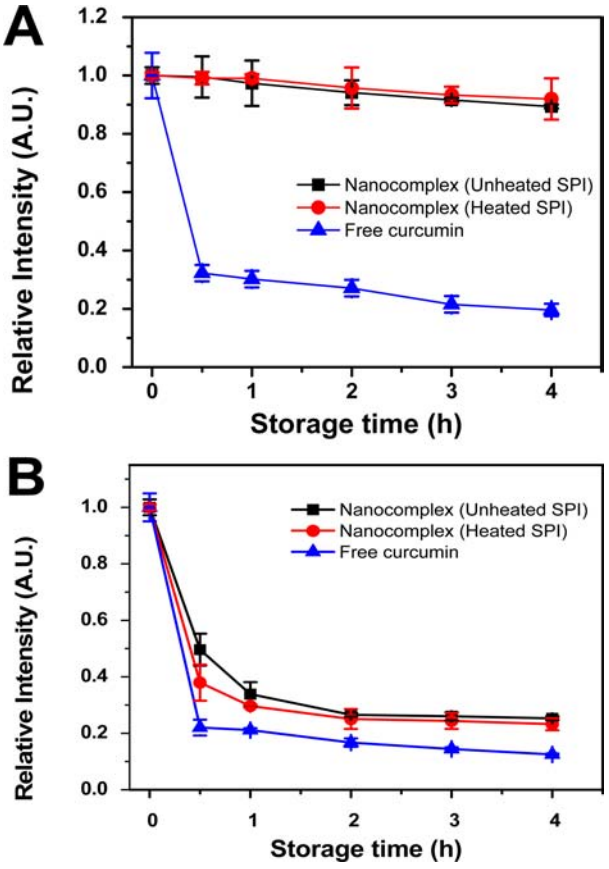

Figure 5. Degradation kinetics of free curcumin and curcumin in the nanocomplexes with unheated and heated (95 °C) SPIs in water at pH 7.0 upon storage for up to 4 h at 25 °C (A) and 95 °C (B). Data are presented as the means and standard deviations of triplicate measurements.

the amount of remaining curcumin was significantly higher for the SPI−curcumin nanocomplexes than for free curcumin (Figure 5 B). For example, approximately 25% of curcumin remained in the SPI−curcumin nanocomplexes after storage of 4 h at 95 °C, while it was about 12% for free curcumin. The observations indicated that the nanocomplexation of curcumin with SPI greatly improved the heat stability of curcumin.

Simulated Gastric and Intestinal Digestion. *Bioaccessibility and Stability of Curcumin.* During the digestion, the nanocomplexes of curcumin with SPI may undergo dramatic changes in environmental conditions (pH and ionic strength), action of proteases on the proteins, and even changes due to the presence of different active surfactants. After sequential processes of in vitro gastric (60 min) and intestinal (120 min) digestion, in the absence or presence of proteases, the bioaccessible amount of curcumin transferred to the aqueous phase of the digests for free curcumin and its nanocomplexes with SPI is shown in Figure 6 A. It should be noted that the bioaccessibility of curcumin might be dependent on its stability throughout the digestion process. If curcumin encapsulated in the nanocomplexes is susceptible to the digestion process, the stability of curcumin would be the prominent parameter affecting its bioaccessibility. Due to this consideration, we also evaluated the stability (against degradation) of curcumin upon digestion, as displayed in Figure 6 B.

Interestingly, it can be observed that the presence of proteases during digestion greatly improved the stability of curcumin, but the improvement was closely dependent on the present state of curcumin, free or bound (Figure 6 B). For free curcumin, about 88% of curcumin degraded after the digestion of 180 min without addition of proteases, whereas in the bound form case, it was only 30%. This observation is consistent with the observation of storage stability at ambient temperature (Figure 5 A), indicating strong stabilization of complexation with SPI toward degradation for curcumin. The presence of proteases considerably increased the amount of free curcumin that survived the whole digestion from 12% to 80%; for the curcumin in the nanocomplexes, there was no significant loss throughout the digestion in the presence of enzymes. The improvement of curcumin stability by the presence of enzymes during digestion might be largely attributed to the curcumin−

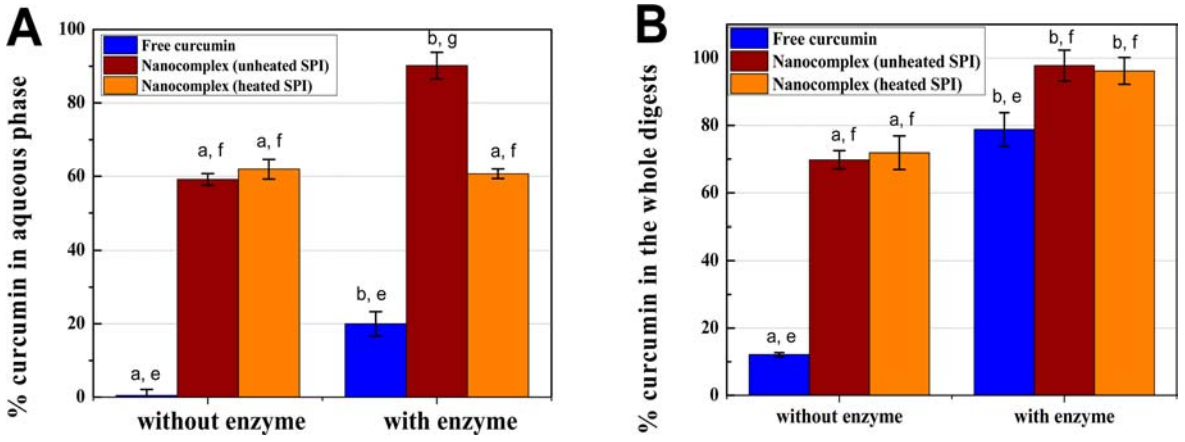

Figure 6. (A) Percentage of curcumin remaining in the aqueous phase for free curcumin and curcumin nanocomplexes with unheated and heated (at 95 °C) SPI after the whole simulated digestion of 180 min in the absence or presence of proteases. (B) Percentage of curcumin in the whole digests of free curcumin and curcumin nanocomplexes with unheated and heated SPI after the digestion of 180 min in the absence or presence of proteases. Data are presented as triplicate measurements on separate samples. Error bars represent standard deviations. Different letters (a, b) on top of the columns represent a significant difference at $p < 0.05$ among curcumin in free and complexed form due to the absence or presence of proteases. Different letters (e−g) on top of the columns represent a significant difference among the same set of samples without or with enzyme due to the different forms of curcumin (free or nanocomplexes with unheated or heated SPI).

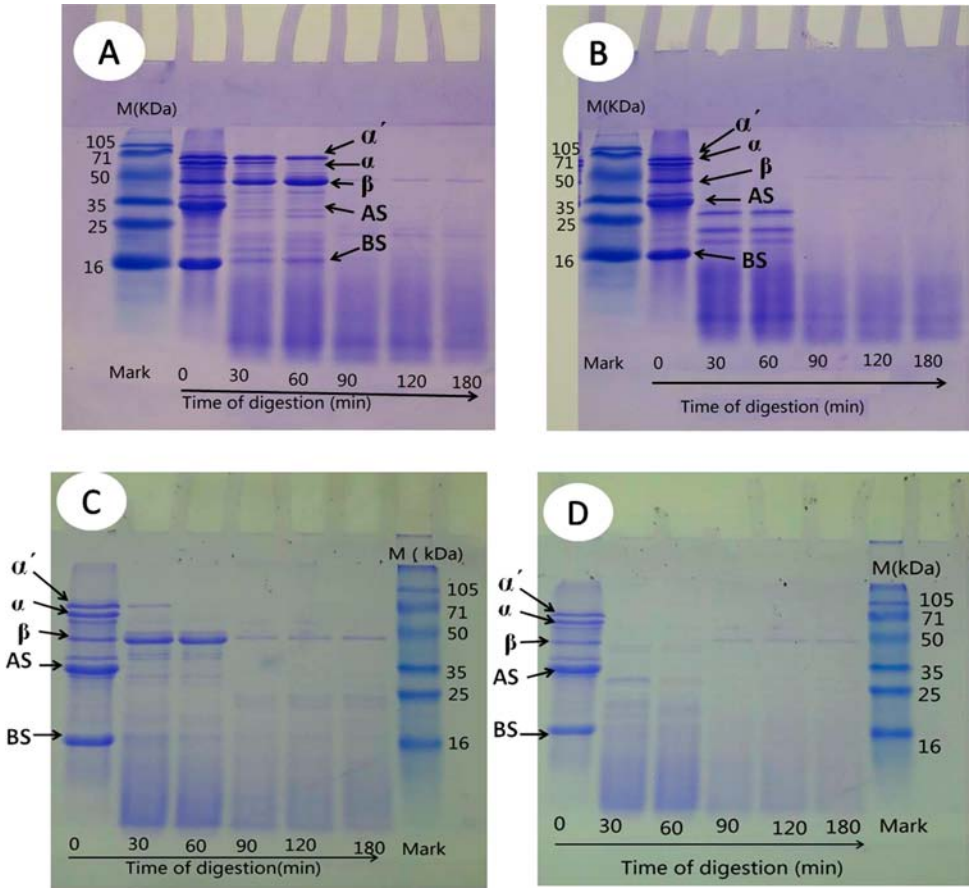

Figure 7. Changes in SDS−PAGE patterns of unheated (A, C) and heated (B, D) SP, during the digestion in SGF (0−60 min) and SIF (60−180 min) as a function of the digestion time. (A, B) Controls (without complexation with curcumin). (C, D) Nanocomplexes with curcumin. The symbols α', α, and β within the figure represent the major α'-, α-, and β-subunits of β-conglycinin, while AS and BS represent the acidic and basic subunits (or polypeptides) of glycinin, respectively.

protein interaction or complexation, since the enzymes are proteins themselves.

On the other hand, the bioaccessible amount of curcumin also highly depended on the present state of curcumin, as well as the presence or absence of enzymes (Figure 6 A). Without the enzymes during the digestion, only less than 1% of curcumin was transferred to the aqueous phase for free curcumin, indicating extremely low bioaccessibility. In contrast, the bioaccessibility of curcumin in the nanocomplexes with unheated and heated SPI reached approximately 60% (Figure 6 A). If the degradation of curcumin during the digestion is considered, the ideal bioaccessibility of curcumin in the nanocomplexes with SPI, in this case, may reach about 85%. In the presence of enzymes during the digestion, the bioaccessibility of free curcumin reached about 20% (Figure 6 A). Relative to the amount of undegraded curcumin, the ideal bioaccessibility for free curcumin would be around 25%. The presence of enzymes also significantly improved the bioaccessibility of curcumin in the nanocomplex with unheated SPI (from 60% to 90%), but did not significantly affect that with heated SPI (Figure 6 A). The difference in the improvement between the unheated and heated SPI might be due to the differences in their protein hydrolysis and protein aggregation.

Protein in Vitro Digestibility. The bioaccessibility of curcumin in the nanocomplexes with proteins may be associated with protease hydrolysis of the proteins during digestion. Furthermore, the complexation with curcumin also produces an influence on the digestibility of the proteins. During the simulated gastric fluid (SGF) and simulated intestinal fluid (SIF) digestion, the protease-induced hydrolysis of proteins in unheated or heated SPI, with or without complexation with curcumin, was characterized using SDS−PAGE and TCA-soluble nitrogen analyses, as displayed in Figures 7 and 8. As expected, the digestion resulted in a progressive hydrolysis of protein polypeptides in SPI, with dramatic changes observed in the SGF digestion, as evidenced by SDS−PAGE and the TCA method (Figures 7 and 8). By comparison between the unheated and heated SPI (without complexation with curcumin), it can be generally observed that (1) all the protein components in SPI were more susceptible to the gastric protease (pepsin) hydrolysis relative to the SIF hydrolysis and (2) the polypeptides of glycinin were much more easily digested by the protease hydrolysis than those from β-conglycinin (Figures 7 A,B and 8). The protease hydrolysis and TCA-soluble nitrogen release of unheated SPI during digestion are similar to those observed in our previous work.[34] Furthermore, the heat pretreatment could increase the susceptibility of β-conglycinin polypeptides to the pepsin hydrolysis, but it to a certain extent impaired the TCA-soluble nitrogen release during the SIF digestion (Figures 7 A,B and 8). The observations confirm the previous viewpoint that the protease susceptibility and/or in vitro digestibility of β-conglycinin or other vicilins is affected by the heat-induced protein denaturation (positive), as well as subsequent protein

aggregation (negative).[25,26,29] The improvement of the susceptibility to pepsin hydrolysis by the heating could thus be largely attributed to the thermal denaturation of the protein, as similarly observed for phaseolin (a 7S globulin from kidney bean[25,29]). However, the influence of heating on the digestibility of these proteins is also dependent on the nature of their conformations and whether other components are present (e.g., in the protein isolate or flour form). For example, Deshphande and Damodaran[25] also pointed out that the vicilin from green peas with a flexible conformation underwent an undesirable change in conformation upon heating, and as a consequence, the heated vicilin exhibited more resistance to proteolysis than the native one. In fact, the undesirable change in conformation in this case can also be explained as the occurrence of a high extent of heat-induced protein aggregation. The importance of structural characteristics to the digestibility of legume proteins has also been confirmed using in vivo experiments with growing rats.[26]

On the other hand, in both unheated and heated SPI cases, the proteins in the nanocomplexes with curcumin were much more susceptible to the protease hydrolysis, especially during the gastric digestion (Figure 7). For example, the α'-subunit of β-conglycinin in the unheated SPI remained almost intact after 60 min of the SGF digestion, while that in its nanocomplex counterpart had been completely degraded even after 30 min of digestion. The improvement of protein hydrolysis by the nanocomplexation can be further confirmed by the TCA-soluble nitrogen release observations (Figure 8), wherein it can be observed that the release of TCA-soluble nitrogen during the SGF digestion was significantly higher in the nanocomplex case than in the controls. There was no significant difference in the TCA-soluble nitrogen release between the nanocomplexes with unheated and heated SPI (Figure 8). Since curcumin is a phenolic compound, the observations thus indicated that the nanocomplexation with curcumin greatly improved the protein digestibility of SPI, irrespective of heat pretreatment. A similar

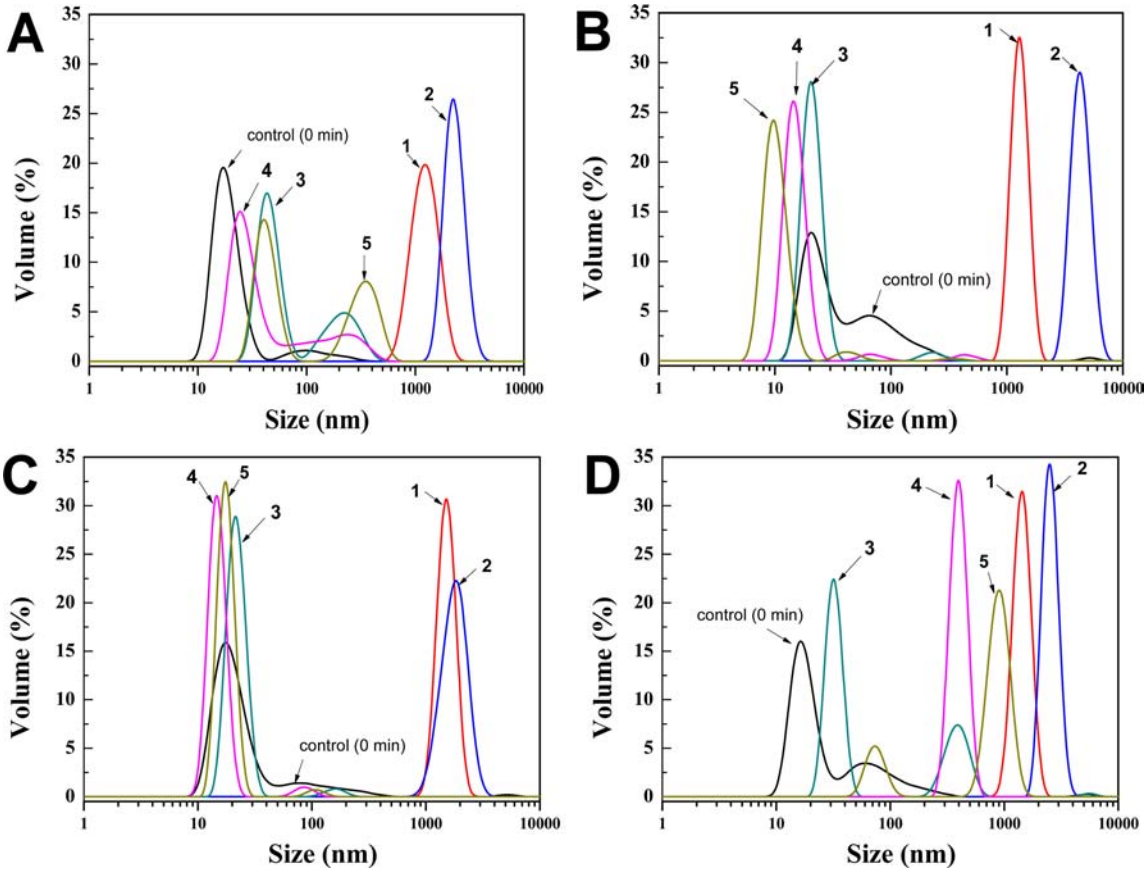

Figure 9. Typical particle size distribution profiles of unheated (A, C) and heated (B, D) SPI without (A, B) and with (C, D) complexation with curcumin as a function of the digestion time (0−180 min). The numbers 1−5 within the figures correspond to the digestion times of 30, 60, 90, 120, and 180 min, respectively. The digestion consisted of sequential SGF (0−60 min) and SIF (60−180 min) processes.

improvement of pepsin digestibility has been reported for some major food allergens when they interact with green tea catechins.[28] Tagliazucchi et al.[27] even observed that the complexation with some phenolic compounds distinctly improved the pepsin activity during simulated gastric digestion. However, some contrasting observations that the complexation with phenolic compounds may also produce an adverse or insignificant influence on the digestibility of many proteins, e.g., β-lactoglobulin[30] and legume proteins,[29,31] are available. Thus, the influence of complexation with phenolic compounds on the digestibility of proteins is a complex process related to the nature of both the phenolic compounds and proteins.

Hydrolysis-Induced Aggregation. The protease hydrolysis of proteins during digestion may lead to exposure of their hydrophobic clusters to the aqueous phase or release of hydrophobic peptides, thus resulting in protein aggregation.[39] Figure 9 shows changes in the particle size distribution profiles of unheated and heated SPI and its nancomplexes with curcumin upon increasing digestion time (0−180 min) in sequential in vitro SGF and SIF digestion. As expected, unheated SPI consisted of approximately two protein fractions with sizes centered at 17 (major) and 100 (minor) nm (Figure 9 A). The heat pretreatment led to a remarkable reduction of the 17 nm protein fraction and, concomitantly, a distinct increase of the fraction with a large size (∼100 nm) (Figure 9 A,B), indicating the occurrence of heat-induced aggregation of proteins. When both unheated and heated SPIs were subjected to the SGF digestion, it was observed that a new particle distribution peak occurred at a much larger size (>1000 nm) at the expense of all the initially present protein fractions (centered at 17 and 100 nm) (Figure 9 A,B). The observations clearly indicated that the pepsin hydrolysis resulted in aggregation of all the proteins. By comparison, we can approximately see that the extent of pepsin-induced aggregation was higher in the heated SPI case than in the unheated counterpart, and it also increased with increasing digestion time (0−60 min).

When the pepsin-treated digests of both unheated and heated SPI were further subjected to the SIF digestion for more than 30 min (and accordingly, the pH also changed from 1.2 to 6.8), the size of the formed aggregates (at 60 min) considerably decreased to much lower values (Figure 9 A,B), indicating disruption of the initially formed aggregates. However, the changing pattern of particle sizes was dependent on the type of proteins (unheated or heated) and the time of SIF digestion. In the unheated SPI case, minimal particle sizes (larger than that of the control) were observed at 120 min of digestion, while, in the heated case, the digestion with increasing time up to 180 min resulted in a progressive decrease in particle size (Figure 9 A,B). The observations suggest that although the heat pretreatment greatly increased the pepsin-induced aggregation of proteins, it facilitated the SIF digestion.

The particle size distribution of unheated and heated SPI was nearly unchanged by the nanocomplexation with curcumin, but the changing pattern of the particle size distributions upon protease hydrolysis, especially during the SIF digestion, was remarkably affected (Figure 9). In the unheated SPI case, the nanocomplexation with curcumin greatly favored the formation of smaller sizes of particles during the SIF digestion, as compared with the control (Figure 9 A,C). In this case, the particle sizes of the final digests seemed to be slightly dependent on the digestion time. In contrast, the situation is different in the heated SPI case, and in the latter case, it can be observed that increasing the digestion time during the SIF digestion resulted in a progressive increase in particle size (Figure 9 C,D). The observations indicated that, upon the sequential SGF and SIF digestion, the nanocomplexation of unheated SPI with curcumin greatly lessened the extent of protein aggregation occurring during the digestion, while the situation for the heated SPI was the reverse. Thus, the remarkably lower bioaccessibility of curcumin in the nanocomplex with heated SPI (relative to that with unheated SPI, Figure 6 A) could be largely attributed to the occurrence of protease-induced protein aggregation, especially in the SIF digestion.

In summary, we reported that SPI can easily form nanocomplexes with curcumin, thus remarkably improving its solubility (in the aqueous phase), stability, and even bioaccessibility. The complexation with curcumin did not distinctly change the size and morphology of the nanoparticles in SPI solutions, though the surface hydrophobicity of the proteins considerably decreased upon binding. Under the investigated conditions, the amount of loaded curcumin at a given c (e.g., 3.5%, w/v) was mainly dependent on the initial [cur] in the dispersion. Although the heated SPI exhibited a higher capacity to bind curcumin than unheated SPI, the bioaccessibility was significantly lower. The lower bioaccessibility of curcumin in the nanocomplexes with heated SPI relative to that with unheated SPI was largely attributed to the protein aggregation occurring during the SIF digestion. The present work reveals that SPI is an excellent nanovechicle for the delivery of water-insoluble bioactive ingredients, and the nanocomplexation exhibits a great potential to be applied in functional food formulations. However, the denatured or aggregated state of the proteins in SPI might produce a significant influence on the bioavailability of encapsulated bioactive ingredients. Further work is necessary to verify the effectiveness of curcumin in the nanocomplexes of SPI using in vivo digestion models.

assessment of uptake of silver particles. To avoid sample preparation artifacts, the silver coating is only treated with a drop of water and the particles in the eluted fraction are analyzed.

MATERIALS AND METHODS

Sample Preparation. Silver "pearls" meant for decoration of pastry were obtained from a local supermarket. The pearls were stored in a plastic vial. The ingredient list on the label clearly indicated that the product contains silver. Visual inspection suggested that the pearls have an interior that mainly consists of sugar and that they are covered with a smooth silver coating. TEM analysis was performed on the coating only and not on the entire pearl, while ICP-MS and SP-ICP-MS analyses were performed on the entire pearl.

As a positive control, the representative test material NM-300K (new number JRCNM03002a),[9] obtained from the nanomaterial repository of the European Commissions' Joint Research Centre, Institute for Health and Consumer Protection (JRC, Ispra, Italy), was analyzed by TEM, ICP-MS, and SP-ICP-MS using similar experimental conditions. NM-300K is distributed as a dispersion of silver nanoparticles in a glass vial, sealed under argon atmosphere with a nominal silver content of 10% w/w. Specific material characteristics are summarized in the JRC Scientific Report on NM-300K.[10]

For TEM analysis, silver pearls were treated with double-distilled water to separate the silver coating from the inner part. Each pearl was brought in contact with a 25 μL droplet of distilled water, placed on parafilm. The pearl was held with a pair of tweezers, which allowed moving the pearl in the water droplet. This resulted in a quick detachment of the silver coating that appeared to float onto the water droplet. Part of this coating was collected on an EM grid. A pointed piece of filter paper was used to dry the grid from beneath, which avoided removal of the silver particles of the grid. NM-300K samples were prepared by the grid-on-drop method.[11] For SP-ICP-MS analysis, each sugar pearl (±180 mg) was dissolved in 2 mL of Milli-Q water and 0.5 mL of the suspension was diluted in 50 mL of Milli-Q water. The latter suspension was 50 and 100 times further diluted for analysis (total dilution factors of 5000 and 10000, respectively). The NM-300K dispersion was diluted 2×10^{10} times for analysis. To determine the total silver concentration of the pearls by ICP-MS, one pearl (±180 mg) per sample was mineralized by microwave digestion (MarsXpress, CEM Corporation, NC, USA) in the presence of 8 mL of a mixture of HNO_3 (spA grade, ROMIL Ltd., Cambridge, UK) and bidistilled water (1:1, v/v). Digested samples were appropriately diluted with bidistilled water before ICP-MS analysis.

Each sample was prepared and analyzed on the same day because of the reported reactivity of silver nanoparticles which can compromise their stability.[12] All TEM experiments were done in duplicate to ensure repeatability of the results. The ICP-MS measurements to determine the total silver concentration were performed three times.

Because the X-rays generated in a TEM specimen can travel over a long distance and can cause fluorescence of other X-rays from for instance the EM-grid, two types of grids were used for the EDX analyses. Part of the silver pearls and NM-300K samples were collected on homemade 400 mesh pioloform- and carbon-coated copper EM-grids, which were pretreated (charged) with Alcian blue for 10 min to increase attachment of particles on the grid. To exclude that the copper signal in the EDX spectra originated from the particles, additional samples of the silver pearls and NM-300K were prepared on 400 Mesh holey polymer-coated nickel grids. Because Alcian blue contains copper as well, the nickel grids were not pretreated.

TEM Imaging and Analysis Conditions. Bright-field TEM images and diffraction patterns were recorded using a Tecnai Spirit microscope (FEI, Eindhoven, The Netherlands) operating at 120 kV. Digital micrographs were recorded using a bottom-mounted 4 × 4 K Eagle CCD-camera (FEI) at a magnification of 49000×, resulting in a pixel size of 0.2 nm, and were converted to .tif format using the TIA software (FEI, Eindhoven, The Netherlands). A systematic micrograph selection procedure was used and allowed unbiased random image collection as described by De Temmerman et al.[13]

Diffraction patterns of both the silver pearls and NM-300K were recorded and compared. The camera length was obtained by recording a diffraction pattern of 30 nm gold nanoparticles under the same experimental conditions.

Chemical analysis was performed using a Titan 80−300 "cubed" microscope (FEI, Eindhoven, The Netherlands) with a probe corrector operating at 200 kV. This microscope allowed obtaining analytical information with a high enough resolution to determine the elemental composition of each individual nanoparticle. The specimens were not plasma cleaned before analysis. The specimens were imaged in TEM and HAADF-STEM mode at magnifications ranging from 16000× to 320000×. In STEM mode, the probe current ranged between 100 and 500 pA. EDX elemental maps were acquired in STEM mode using a Super-X detector (FEI) which consisted of four windowless silicon drift detectors integrated into the objective lens. Each EDX map was acquired during 10−15 min. By selecting a specific region on an EDX map, an EDX spectrum was obtained in which the signal originated solely from this region.

Image Processing Conditions for Qualitative and Quantitative TEM Analysis. On the basis of visual inspection of the bright-field TEM images, the homogeneity and stability of the material under the applied conditions were examined. Furthermore, a qualitative description and a quantitative analysis of the material were performed on all samples. The quantitative analysis was performed on the basis of numerical parameters, which describe characteristic particle features (such as size, shape, surface properties, etc.).

Threshold-based detection of the nanomaterials was applied using iTEM software (Olympus, Münster, Germany) as described by De Temmerman et al.[13] and Verleysen et al.[14] This approach included optimizing the contrast and brightness of the image, applying a 10 × 10 smoothing filter, enclosing the particles in a region of interest (ROI), and setting the threshold to separate particles from the background based on their gray values. Particles consisting of less than 250 pixels, particles on the border of the ROI, and structures with an aberrant morphology, judged to be artifacts based on visual inspection, were omitted from analysis. There were 23 characteristic parameters measured for each particle.[13,14] The data collected for each characteristic parameter was represented as a number-based distribution using Sigmaplot software (Systat, Cosinus Computing, Drunen, The Netherlands).

Iterative curve fitting was applied on the distributions by maximum likelihood estimation using Fityk 0.9.8 software.[15,16] The parameters of the fitted function (height, center, width, etc.) can be used to describe the distribution, and the errors on these parameters were determined as described by Wojdyr[15] and Wolberg.[16]

TEM and HAADF-STEM micrographs, EDX spectra and elemental maps, and qualitative and quantitative analysis results were stored in a dedicated iTEM database, together with the specimen references and with the imaging conditions.

Validation of the Quantitative TEM Measurements. The measurement uncertainties associated with the quantitative TEM measurement of particle properties were estimated using a top-down approach based on measurements on NM-300K. The repeatability (within 1 day variability) and intermediate precision (day-to-day variability) for measurements on NM-300K were estimated as described by De Temmerman et al.[17] Three different vials were analyzed on 3 days within 1 week. On each day, three TEM specimens were prepared from one vial. From each TEM specimen, micrographs of seven regions on the grid were recorded and analyzed. The calibration of the microscope magnification using the cross-grating method was performed following ASTM-E766 guidelines.[18] The microscope was calibrated with the automatic HM magnification (Mi, SA) calibration procedure (FEI). The total intralaboratory uncertainty combined the repeatability, intermediate precision, and calibration uncertainties, and was calculated based on the mean of the measured medians of each of the 23 selected parameters.

ICP-MS Analysis Conditions. Total silver determination in the pearls was performed using a VG PQ-ExCell ICP-MS apparatus (Thermofisher Scientific, Winsford, UK). Silver was measured at the ^{107}Ag isotope. The sample batch was accompanied by three replicates of the certified reference material DOLT-4, in which the mass fraction of silver was certified (0.93 ± 0.07 mg/kg).

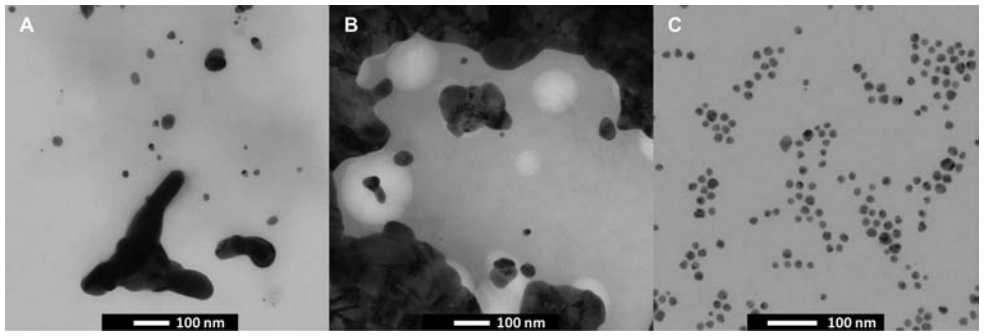

Figure 1. Representative TEM micrographs of nanoscale particles from (A,B) the coating of a pearl after treatment with distilled water, and from (C) the control sample NM-300K on a Cu grid. (A) and (B) are the result of independent experiments.

SP-ICP-MS Analysis Conditions. SP-ICP-MS analysis was performed using an Agilent 8800 ICP-MS apparatus (Agilent Technologies) equipped with a MicroMist nebulizer. The sample flow rate to the nebulizer was 0.5 mL/min. Data acquisition was performed using the MassHunter software in time-resolved analysis (TRA) mode. An acquisition time of 60 s per measurement and a dwell time of 3 ms were selected. Data were transferred to a CSV (comma-separated values) file, which was processed in Microsoft Excel for calculation of particle sizes and particle size distribution, particle number concentration, and particle mass concentration. Signals were treated as background if they were lower than 2500 counts per second. The corresponding size detection limit for silver was 13 nm, determined as the "mean +2.528 SD" of the Ag signal intensities (in cps) registered in 20 blank Milli-Q samples. This corresponded to a probability of 1% of false positive signals. The corresponding signal intensity was recalculated to particle size by taking into account the flow rate and nebulization efficiency during the analysis. NIST-8013 (gold nanoparticles) was used as particle calibration standard and diluted in Milli-Q water to a concentration of 50 ng/L. The calibration for silver was performed with a silver standard for ICP (Fluka Analytical) diluted to 1 and 2.5 μg/l.

RESULTS

Qualitative TEM Analysis. Visual inspection of TEM micrographs indicates that all TEM specimens prepared using Alcian blue treated Cu grids contain particles which are distributed over the complete grid surface, suggesting that the charge of the nanomaterial is compatible with the charge of the grid (Figure 1A–C). When using the Ni grids which were not treated with Alcian blue, only a small amount of particles remained attached to the grid surface and the particles tended to lie close to the border of the holes in the polymer film.

A simple treatment with water releases nanoscale particles from the coating of the pearls (Figure 1A,B). The micrographs show single as well as aggregated/agglomerated particles. In addition, large chunks of material were found abundantly on the EM-grids (Figure 1B). Most particles were round, suggesting a spherical 3D structure, although sometimes particles with a rectangular or triangular shape were detected as well. The aggregates and agglomerates tended to have a complex morphology. Diffraction contrast was observed in the particles. Even the single particles could consist of multiple crystallites. Sugar was found in all samples, on every part of the EM-grid, and caused intensity fluctuations in the background of the TEM images (Figure 1A,B). Identical results were obtained by duplicating the experiment.

The general appearance and the observed morphologies of the particles eluted from the silver pearls resembled the appearance and morphology of the representative test material NM-300K (Figure 1C). For NM-300K, a large amount of particles was found, evenly distributed over the complete grid surface (Figure 1C). Mainly single particles were found, although a few agglomerates were detected as well. The general morphology of the particles was round, suggesting a spherical 3D structure. Particles with a rectangular or triangular shape were sometimes detected as well. The agglomerates tended to be more or less equi-axed.

Electron Diffraction Analysis. All examined diffraction patterns of the particles eluted from the silver pearls show an excellent agreement with the diffraction pattern of silver (NM-300K) (Figure 2). However, the signal in the diffraction

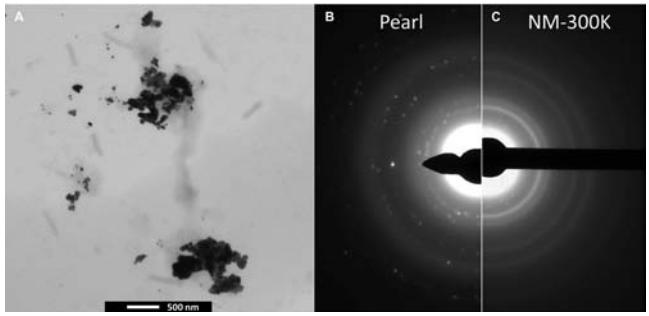

Figure 2. (A) TEM micrograph of nanoscale particles released from the coating of a pearl after treatment with distilled water, (B) corresponding diffraction pattern and agreement with (C) the electron diffraction pattern of NM-300K.

pattern cannot be attributed to nanoscale particles only. It cannot be excluded that a large part of the intensity in the diffraction pattern originated from larger (bulk) particles. If a small region which contained only nanoparticles was selected, the intensity in the corresponding diffraction pattern was too low to be observed.

Chemical Analyses by HAADF-STEM and EDX. The silver particles were easily detected on the HAADF-STEM images because their atomic number is relatively high compared to the background (Figure 3). The corresponding EDX elemental maps of silver clearly showed that the silver distribution coincided with the position of the particles on the HAADF-STEM images (Figure 3). To examine the presence of other chemical elements, EDX spectra of the particles were generated from the elemental maps and analyzed. Small amounts of oxygen and carbon, probably originating from the supporting film and from contamination, were always detected together with the particles. Comparison of copper and nickel grids excluded that the copper and nickel signals in the EDX spectra originated from the sample. In the specimens supported on a carbon and pioloform

Quantitative TEM Analysis of the Physical Particle Properties. The particles were semiautomatically detected and measured on the BF-TEM images based on their mass thickness contrast. Because very similar size and shape distributions were obtained by duplicating the experiment, the distributions obtained from individual analyses (shown in Supporting Information, files 1 and 2 for the particles eluted from the pearls and NM-300K, respectively) were combined into single data sets (Figure 4).

The Feret min (i.e., the minimum distance of parallel tangents at opposing particle borders) distributions of the particles eluted from the pearls and of NM-300K lie almost entirely below

DOI: 10.1021/acs.jafc.5b00578
J. Agric. Food Chem. 2015, 63, 3570−3578

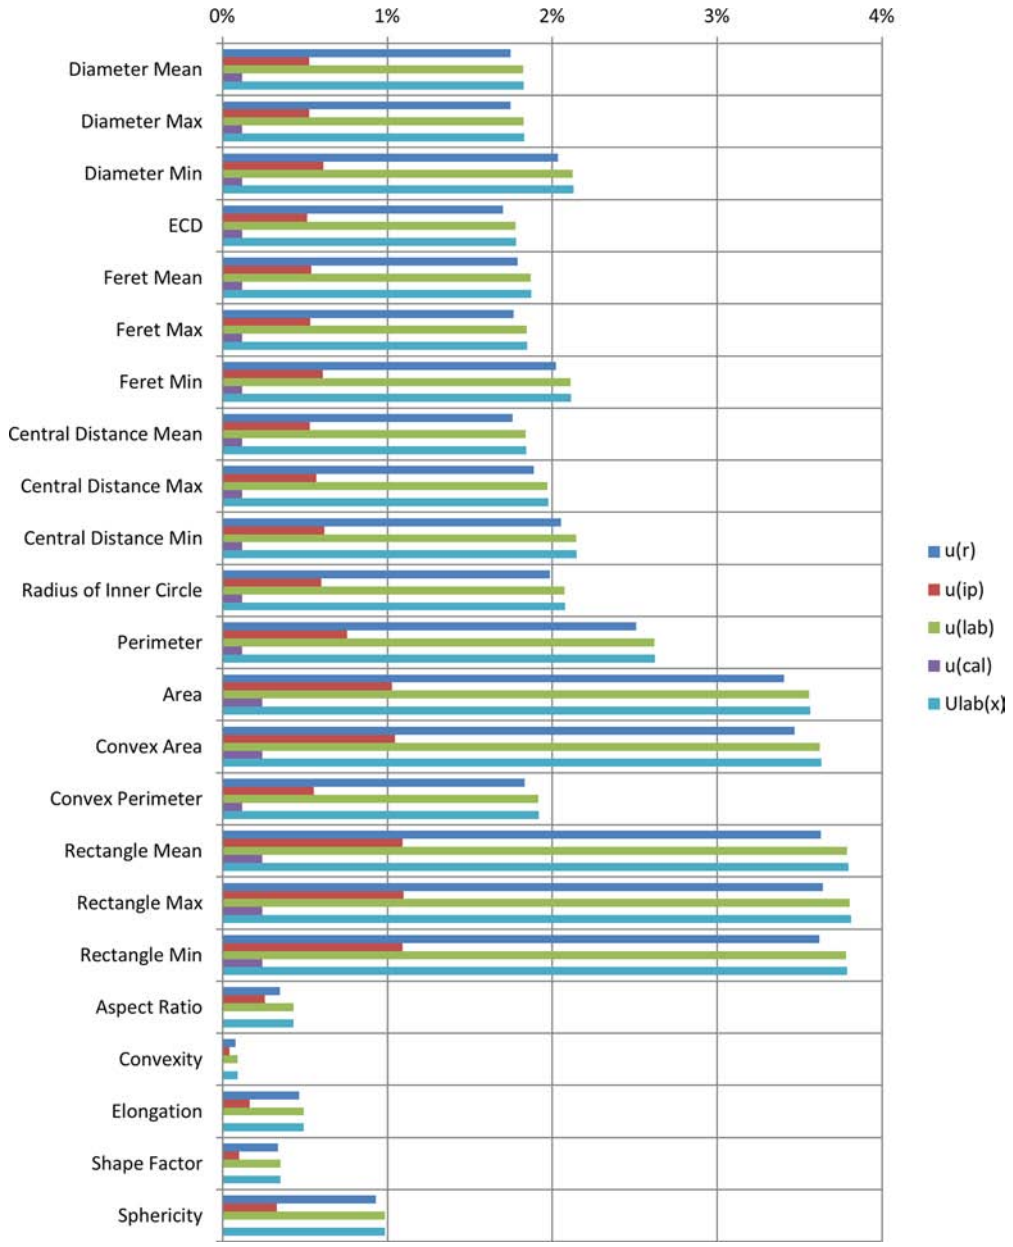

Figure 5. Relative standard and combined uncertainties (in %) for 23 parameters of NM-300K.

100 nm (Figure 4). A Feret min value smaller than 100 nm was measured for 94.70% and 99.94% of the particles eluted from the pearls and from NM-300K, respectively. The amount of particles with a Feret min value smaller than 10 nm was 14.57% and 1.60%, respectively.

As opposed to NM-300K, the particles eluted from the pearls have a log-normal Feret min distribution with tailing on the right-hand side. This tailing can be attributed to the occurrence of aggregates, agglomerates, and larger chunks of material. A log-normal function was fitted through the distributions. The center, width, and asymmetry of the fitted log-normal function are given together with the standard errors in Figure 4. The center represents the mode. The width is defined as two times the half-width at half-maximum (HWHM) at the left side of the mode. The log-normal function was selected because it is the most suitable physical model to describe the distribution which gives a high goodness-of-fit value. The agreement between the binned data and the fitted function is given by the R^2 value. The high amount of agreement between the log-normal functions fitted to the individual size distributions shown in Supporting Information files 1 and 2 justifies the combination of the data into single data sets.

The particles eluted from the pearls have a broader sphericity distribution than the particles of NM-300K, meaning that a larger fraction of the measured particles did not have spherical shape. The sphericity was larger than 0.67 for 40.73% and 89.47% and smaller than 0.33 for 18.87% and 0.42% of the particles eluted from the pearls and of NM-300K, respectively. In agreement with the classification of Krumbein and Sloss,[19] particles eluted from the pearls have a medium sphericity and particles of NM-300K have a high sphericity. Both log-normal sphericity distributions showed tailing on the left-hand side, which can be attributed to the occurrence of triangular and rectangular particles and aggregates and agglomerates. Tailing was significantly larger for the distribution of the particles eluted from the pearls due to the presence of larger chunks of material in this sample. A log-normal

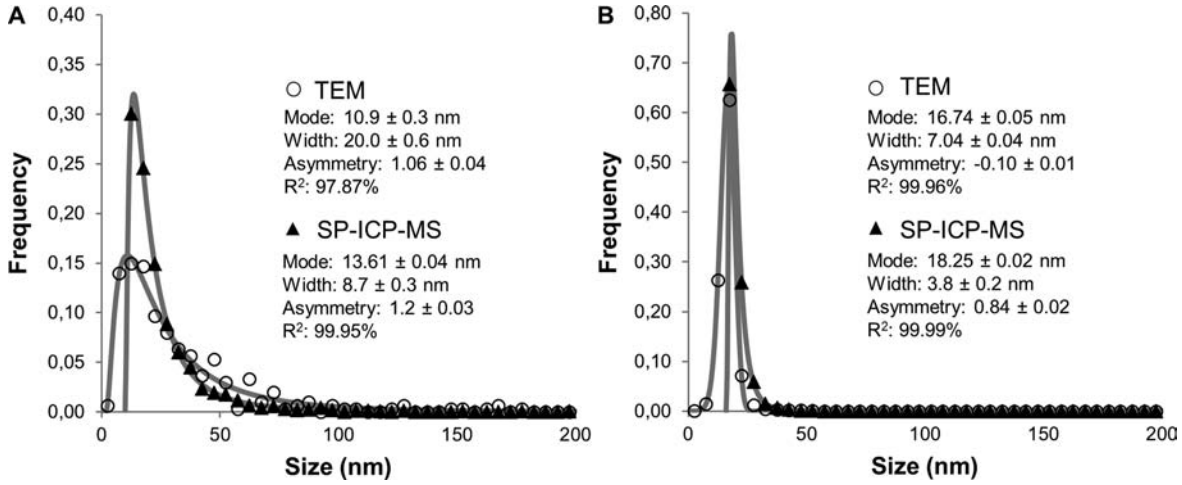

Figure 6. Comparison of TEM particle size measurement (Feret min) and SP-ICP-MS particle size measurement (volume equivalent spherical diameter) for (A) the particles eluted from the pearls and (B) NM-300K.

function was fitted through the data sets. The R^2 value, center, width, and asymmetry of the fitted log-normal function and associated standard errors are given in Figure 4. The R^2 value is relatively low for the sphericity distribution of the pearls due to the high amount of scatter of the data.

Combined Measurement Uncertainty. Table 1 and Figure 5 summarize the results of the determination of measurement uncertainties on NM-300K. Because no certified values are available for NM-300K, the trueness and trueness uncertainty could not be assessed. The mean median size, corresponding standard deviation, intralaboratory precision, calibration uncertainty, and combined laboratory uncertainties were determined.

The repeatability (u(r)) is the largest contribution to the combined uncertainty for all parameters. The intermediate precision (u(ip)) uncertainty and the calibration uncertainty contribute only for a small amount to the uncertainty budget. The total uncertainty budget is always smaller than 4%. For the 1D size parameters (e.g., diameter or Feret), the uncertainty budget is often lower than 2%.

ICP-MS Analysis. The mean silver concentration measured in the certified reference material DOLT-4, 1.02 ± 0.12 mg/kg (mean ± expanded uncertainty, k = 2), does not differ significantly from the certified value (0.93 ± 0.07 mg/kg). The mean total silver concentration in the pearls was 8.4 mg/kg, but the variation among pearls was elevated (RSD = 38%).

SP-ICP-MS Analysis. Figure 6 shows the number-based size distributions obtained by TEM (Feret min) and SP-ICP-MS (volume equivalent spherical diameter) for the particles eluted from the pearls and NM-300K. Because the detection limit of SP-ICP-MS for Ag is about 13 nm, only a part of the distributions was measured. Figure 6 shows that for both the particles eluted from the pearls and NM-300K, only one binned data point was obtained on the left side of the mode. Although the error on the estimation of the left side of the distribution is large, modes similar to those obtained by TEM were found by fitting a log-normal function through the distributions.

The calculated particle number concentration is 4.4 ± 0.5 × 10^9 particles/g of pearl. Note that particles smaller than 13 nm were not considered in this calculation. The mass concentration of the detected particles is 1.8 ± 0.6 μg/g of pearl. This corresponds to approximately 20% of the mean total silver concentration of the pearls.

DISCUSSION

Several TEM-based methods to analyze particle size, morphology, crystal structure, and chemical composition have been applied to formally prove that a fraction of silver nanoparticles is released from the coating of silver pearls, meant for decoration of pastry, after a simple treatment with distilled water. Generally, an extensive sample preparation method adapted for a specific nanomaterial−matrix combination is required to identify nanomaterials in a food matrix.[20] In this case, the simple treatment with distilled water is sufficient to identify the nanoparticles in the matrix by conventional TEM. Because the difference in atomic number of the particles and the matrix is large, the particles could be readily detected in the TEM and HAADF-STEM images, even without complete separation from the matrix.

TEM imaging allows visualizing the similarities in size and shape between the particles eluted from the silver pearls and the nanoparticles of the representative test materials NM-300K[10] (Figure 1). Because of the presence of both aggregated/agglomerated particles and larger chunks of (bulk) material extracted from the silver coating of the pearls, tailing of the number-based size distribution occurrs (Figure 4). Consequently, a modal Feret min diameter of 10.9 ± 0.3 nm, which is smaller than the median Feret min diameter of 23.3 nm, is obtained.

The abundant subpopulation of nanoparticles on a number-basis (Figure 4) highlights the importance of using counting techniques such as TEM, which can produce number-based distributions. The measurement of a mass-based distribution would make this fraction of nanoparticles seem insignificant compared to the fraction of larger particles. Scattering- and volume-based ensemble methods, such as dynamic light scattering (DLS) and centrifugal particle sizing, which are historically applied to estimate particle size distributions of food additives, tend to underestimate such subpopulation of small particles in polydisperse samples[21] and may even consider them as a background signal.

Although similar interplanar distances are found for the particles eluted from the pearls and NM-300K (Figure 2), the electron diffraction experiments do not irrefutably demonstrate that the fraction of nanoparticles consists of silver because the intensity in the diffraction patterns mainly originates from larger particles in the field of view. Instead of recording high resolution

DOI: 10.1021/acs.jafc.5b00578
J. Agric. Food Chem. 2015, 63, 3570−3578

TEM images and determining the interplanar distances from the corresponding fast Fourier transforms (FFTs), the composition of the particles is studied by analytical TEM. The coincidence between the positions of the nanoparticles detected on the HAADF-STEM images and on the EDX elemental silver maps, and the fact that no silver signal is found outside the detected particles, indicates that the spatial resolution of the EDX measurement is high enough to measure the composition of the individual nanoparticles. Comparison of samples deposited on copper and nickel grids excludes that the copper and nickel signals in the EDX spectra originates from the sample. It is assumed that the Si signal measured in all EDX spectra originates from the original samples or from storing the samples in glass vials.

Once identified, the number-based size and shape distributions of the particles could be determined by combining conventional BF-TEM imaging with image analysis. This method is validated for silver nanoparticles by estimating the measurement uncertainties of the quantitative TEM analysis of the representative test material NM-300K using a top-down approach. The obtained values of the different measurement uncertainties are in line with the results of earlier estimations of TEM measurement uncertainties.[17] By correlation analysis, the 23 measured parameters can be grouped into three classes representing size, shape, and surface properties (data not shown). The uncertainties of the measurements of the parameters within each class are similar (Figure 5), and the relative uncertainties of the 2D size parameters are twice as large as the 1D size parameters, as expected from propagation of error analysis. Consequently, each parameter within one class can be selected as a representative parameter to characterize the nanomaterial. The estimated expanded intralaboratory uncertainty of 1D size parameters is in the order of 2%, which allows precise determination of the Feret Min, relevant in the scope of EC regulations.[22,23]

Because 94.70% of the eluted particles have a Feret min diameter smaller than 100 nm, the eluted fraction classifies as a nanomaterial according to the EC regulations for novel food[22] and the EC Recommendation on the definition of a nanomaterial.[23] In future experiments, the nanofraction of particles in the original E174 food additive will be examined.

The guidance documents on the testing of manufactured nanomaterials[24] and on the risk assessment of the application of nanoscience and nanotechnologies in the food and feed chain[25] require that the size parameter of a nanomaterial is measured by at least two independent methods (one being electron microscopy) because the results obtained from different measurement techniques may differ because of the physical principles applied in the measurement method. Therefore, the TEM size measurements are independently confirmed using SP-ICP-MS. Because of its limit of quantification for Ag of about 13 nm, this method fails to detect a substantial fraction (about 26%) of the particles eluted from the pearls, which are detected by TEM. In this case, fitting a log-normal function to the incomplete distribution results in a mode (13.6 nm) similar to that obtained by TEM (10.9 nm). However, because the smallest particles are not detected by SP-ICP-MS, the uncertainty on the estimation of the left side of the distribution is large. Even so, SP-ICP-MS can be applied as a method to screen for the presence of a fraction of nanosized particles and allows determination of the particle number concentration ($4.4 \pm 0.5 \times 10^9$ particles/g of pearl) and the mass concentration of the detected particles (1.8 ± 0.6 μg/g of pearl). By combining these results with the ICP-MS results, the mass concentration of the detected particles is estimated to be about 20% of the mean total silver concentration of the pearls.

It is expected that the silver nanoparticles in the silver pearls do not increase or improve the function (metallic silver coloring) of the food additive and serve no technological function in the finished product. Dried NM-300K has a dark-blue color, and colloidal silver nanoparticles are typically yellow to gray depending on their size, concentration, and agglomeration state,[26,27] which would make intentional addition of a nanofraction to the coating of the silver particles ineffective. Therefore, the nanofraction can be considered as an unwanted contaminant fraction that counteracts the function of the food additive.

Even so, because of concerns about possible health effects of increased usage and exposure to silver nanoparticles,[4] this case study remains relevant. The oral uptake of silver nanoparticles in the food additive E174 is a factor that should be considered in future studies that examine possible health effects caused by exposure to nanosilver.

The presented approach to identify silver nanomaterials can be applied to analyze the size, shape, crystal structure, and chemical composition of the particles in the re-evaluation of food additives as foreseen in article 32 of Regulation (EC) no. 1333/2008.[7] This regulation requires that all food additives added to food for a technological purpose permitted in the EU before 20 January 2009 should be subjected to a new risk assessment by the European Food Safety Authority (EFSA) by 2020.

It remains debatable whether the silver food additive examined in this example should be labeled as nanomaterial. Because the food additive is intentionally produced and because it is composed of discrete functional parts, most of which have one or more dimensions of the order of 100 nm, it qualifies as an "engineered nanomaterial" according to EU Regulation 1169/2011 on the Provision of Food Information to Consumers.[28] This regulation specifies that besides information such as nutrition values, allergens, or country of origin, all ingredients present in the form of engineered nanomaterials shall be clearly indicated in the list of ingredients. The names of such ingredients shall be followed by the word "nano" in brackets. This mandatory labeling entered into force on 13 December 2014. However, because no significant change in production method, in starting materials used, or in particle size can be demonstrated for this already authorized food additive, one could consider that it is not a new additive, and thus at present it would not be subject to labeling requirements.

peptide fraction and to the differences due to the countless brewing styles, preclude a reliable quantitative assessment of glutenlike harmful epitopes in beer and hence the possibility to establish beer (at least some types) as safe or hazardous for celiacs. The presence of immunoactive components, even in beer presumed to be gluten-free,[11] supports the precautionary exclusion of barley malt beers from the consumption by celiacs.

Wheat beer (also Weissbier or Weizen Beer) is a traditional beer produced with mixed barley malt and wheat adjunct (*Triticum aestivum*). According to the style, wheat can be malted (e.g., German Weissbier) or unmalted (e.g., Belgian Witbier). German regulations specify a share of at least 50% wheat malt for brewing Weissbier. Because of an average protein content higher than all-barley-malt beers (BMB) and to the sequence specificity of toxic epitopes from wheat prolamins, beer brewed with a large wheat grist bill is expected to be largely unsuitable for a strict gluten-free diet. However, ELISA determinations are heavily biased because of the commonly used gliadin standards, resulting in aberrant values (up to 47 000 ppm, i.e., ∼4.7 g/L) that are clearly inconsistent with the total protein content of wheat beer, which does not normally exceed the 2.5−2.8 g/L.[17] A gliadin-equivalent content of 250−400 ppm for wheat beer[13,18] appears to be a rather realistic range, as also determined by antibody-independent MS-based methods.[17]

Despite its relatively high commercial importance and an increasing trend of consumers' appreciation,[19] no attempt to elucidate the proteome of wheat beer has been reported so far. In this work, we explored the proteome of three commercial wheat beer samples (Weissbier style), hereafter referred to as WB#1, WB#2, and WB#3, by 2DE-MS. We primarily aimed to understand if homologous barley- and wheat-derived proteins survive the process of selection that determines the protein/peptide content of beer, or, on the contrary, that barley and wheat generate dissimilar protein patterns, with a focus on the set of potentially immunogenic proteins. The proteome and the peptidome of a representative Weissbier sample (WB#1) were investigated in detail using LC-MS/MS approaches. The gluten-equivalent content of WBs was determined using the G12 competitive ELISA method. Furthermore, we compared the IgA-immunoreactivity of WB proteins to that of a BMB sample by Western blot analysis, using sera from celiacs as the source of specific antigliadin antibodies.

MATERIALS AND METHODS

Samples and Chemicals. Three commercial trademarks of Weissbier (indicated as WB#1, WB#2, and WB#3; collectively as WBs) and an Italian BMB sample (double malt label) were purchased in a local supermarket. A commercial gluten-free beer, brewed with millet malt, was used as the control for the G12-based determinations. Relying on the producers' technical information, WBs were brewed according to the German style, using 50−60% of malted wheat as a grist adjunct. Chemicals were purchased from Sigma (St. Louis, MI, USA). HPLC-MS-grade solvents were from Carlo Erba (Milan, Italy). Total protein content of beers was measured in triplicate by the modified micro-Lowry protein assay (Sigma-Aldrich).

Extraction of the Protein/Peptide Fraction. The extraction protocol was optimized in order to limit the noncovalent interchain aggregation mediated by hydrophobic interactions. It consisted of the following steps: 20% TCA-insoluble proteins derived from 20 mL of degassed beer samples were redissolved in denaturing/reducing buffer (6 M guanidine, 50 mM Tris, 10 mM dithiothreitol, DTT, pH 8.0) and incubated for 30 min at 55 °C. Proteins were Cys-alkylated with iodoacetamide and then desalted with G-25 Econo-Pak 10 DG column (Biorad, Milan, Italy; exclusion limit = 6 kDa), eluting with 1% acetic acid. Proteins were quantified using the Bradford assay and lyophilized. For the shotgun proteomic analysis, the protein fractions (>6 kDa) were digested with proteomic-grade modified trypsin (Sigma) at a 1:100 (w/w) enzyme−substrate ratio in 50 mM ammonium bicarbonate, pH 8.0, overnight at 37 °C.

Peptides (<6 kDa) were isolated from an aliquot of beer using a G-25 Econo-Pak 10 DG column, eluting with 1% acetic acid, and then concentrated and purified from polar compounds using C18 Sep-pak cartridges (Waters, Mildord, MA, USA), eluting with 70% acetonitrile/0.1% TFA. Peptides were finally lyophilized.

1D and 2D Gel Electrophoresis. Beer proteins (15 μg) were separated by 1D SDS-PAGE using hand-cast 15% polyacrylamide gels mounted on a Mini-Protean Tetracell system (Biorad). For 2DE separations, freeze-dried protein extracts (400 μg) were dissolved in 340 μL of 8 M urea, 2% w/v CHAPS, 2% v/v IPG buffer, pH 3−10 (Amersham Biosciences/GE Healthcare, Uppsala, Sweden), containing traces of Bromophenol Blue and 20 mM DTT. Isoelectric focusing (IEF) was carried out on passively rehydrated IPG 18 cm 3−10 strips using a IPGphorII electrophoresis system (all from Amersham Biosciences). Proteins were focused up to a total of 32 000 V hrs, stepwise increasing the voltage up to 8000 V at 20 °C. Prior to the second dimension, the IPG strips were equilibrated for 15 min in equilibration buffer (50 mM Tris/HCl pH 8.8, 6 M urea, 30% v/v glycerol, 2% w/v SDS, traces of Bromophenol Blue, 10 mg/mL DTT), followed by 15 min in the same equilibration buffer containing 25 mg/mL iodoacetamide instead of DTT. The second dimension was run on 15% acrylamide gels using an Ettan DALTsix vertical system (Amersham Biosciences) using 15 mA/gel for 30 min and then 30 mA/gel. 1D- and 2DE-separated proteins were detected by Coomassie Brilliant Blue G-250 staining.

For peptide mass fingerprinting (PMF)-based identification, manually excised protein bands (1DE) or spots (2DE) were in-gel digested using 12.5 ng/mL proteomic-sequencing-grade trypsin (Sigma) as previously described.[5]

Size-Exclusion Chromatography. Size-exclusion liquid chromatography (SEC) separation of wheat beer proteins/peptides (100 μL of degassed beer) was carried out using a 152 A Gilson chromatograph (Gilson Inc., Middleton, WI, USA) equipped with a Superdex 75 HR 10/30 column (Amersham Biosciences), eluting with 50 mM sodium phosphate containing 150 mM NaCl, pH 7.2. The SEC separation was monitored by UV at 220 and 280 nm.

Reversed-Phase High-Performance Liquid Chromatography. HPLC separations of beer peptides were carried out using an Agilent 1100 HP Series (Agilent Technologies, Palo Alto, CA, USA) modular system equipped with a multiwave UV−vis detector. The stationary phase was a C18 reversed-phase (RP) column (250 cm × 2.1 mm i.d., Vydac, Hesperia, CA, USA). Separations were carried out at constant flow rate of 0.2 mL/min, applying a 5−60% solvent B (0.1% TFA in acetonitrile) linear gradient over 5−65 min. Solvent A was 0.1% TFA in Milli-Q water.

MALDI-TOF MS. MALDI-TOF MS analyses were carried out using a Voyager DE-Pro instrument (Perseptive Biosystem, Framingham, MA, USA) as previously described.[5] α-Cyano-4-hydroxycinnamic acid (10 mg/mL in 50% acetonitrile/0.1% TFA) was used as MALDI matrix. Spectra were elaborated with the Data Explorer software, version 4.0, supplied with the instrument. PMF was carried out using the MS-Fit tool of Protein Prospector (http://prospector.ucsf.edu).

HPLC-ESI-Q-TOF MS and MS/MS. Tryptic peptides (30 μg) arising from the entire pools of beer proteins and the peptide components (15 μg) were analyzed by HPLC-ESI-MS/MS analysis, using an Infinity 1290 UHPLC (Agilent Technologies, Santa Clara, CA, USA), equipped with a LUNA 5 μm C18(2) column (150 cm × 2 mm i.d., 100 Å, Phenomenex, Torrance, CA, USA) and coupled to a Q-Exactive Hybrid Quadrupole-Orbitrap mass spectrometer (Thermo Scientific, San Jose, CA, USA) that operated in the data-dependent acquisition mode (ddMS).[2] Source parameters: spray voltage, 3.2 kV; capillary temperature, 210 °C; S-lens RF level, 80; auxiliary gas temperature, 210 °C; sheath gas flow rate, 25; auxiliary gas flow rate, 12.

DOI: 10.1021/acs.jafc.5b00631
J. Agric. Food Chem. 2015, 63, 3579−3586

Full MS scans were acquired over the range m/z 350−1800, with a mass resolution of 70 000. The target value (AGC) was 3×10^6, and the maximum allowed accumulation time (IT) was 200 ms. For the ddMS^2 analyses, a top ten method was used: The ten most intense peaks (charge states 2, 3 and 4) were selected for sequencing and fragmented with a normalized energy of 20, 30, and 40%. AGC was 2×10^5. The ion-selection threshold was 20%, and the IT was 100 ms.

For the HPLC peptide separations, the elution gradient was 5% B isocratic for 5 min followed by 25 min to B 15%, 15 min to B 50% and 5 min to B 100%, maintained for 15 min. Eluents were (A) 0.1% FA in water and (B) 0.1% FA in ACN. The flow rate was 0.2 mL/min.

The raw spectra files were transformed into mgf files with the Mascot Distiller Software (version 2.5.1, Matrix Science Ltd., London, UK) and used to search the NCBI and Uniprot databases through Mascot, version 2.3 (Matrix Science, http://www.matrixscience.com) and the Batch-Tag Web (Protein Prospector) search engines. The searching parameters were the following: taxonomic restriction, none; for further confirmation searches were restricted to *Triticum*, *Hordeum* and *Saccharomyces* spp.; type of search, MS/MS ion search; enzyme, trypsin; max missed cleavages, 1; fixed modifications, carboamidomethylation (Cys); variable modifications, pyro-Glu formation (N-terminal Gln), Met-oxidation, deamidation (Gln); mass values, monoisotopic; precursor charge range, +2, +3, +4; parent ion tolerance, 10 ppm; fragment ion tolerance, 50 ppm. The peptide fraction was analyzed with the Batch-Tag Web engine using the same search parameters, except that no enzyme was selected during the search and "no fixed modification" was set for any of the amino acids. Output entries were separately validated by manual inspection of raw MS/MS spectra. Identifications were validated by manual inspection of the MS/MS spectra. Peptide identifications were considered successful when the measured molecular weight (MW) corresponded to the expected value, a sequence of at least three consecutive b- or y-fragment ions occurred in the spectrum, and the score corresponding to the identity was higher that 15 ($p < 0.05$). Outputs were homology filtered.

Western Immunoblotting with ECL Detection. Western blotting was carried out by transferring hordeum and wheat (positive controls), maize (negative control), and beer proteins separated by SDS-PAGE onto a 0.45 μm nitrocellulose membrane (Biorad). The membrane was blocked with 5% BSA. Pooled serum of four celiac subjects (age range = 5−36 years old, average = 24 years old), diluted 1:500 in T-TBS, was used as the source of primary IgA antigliadin antibodies. Secondary antibody was HPR-conjugated monoclonal antihuman IgA (Sigma) diluted 1:10,000 in T-TBS. Blots were developed with the ECL-plus kit (Amersham).

G12 Assay. Gluten content of beer samples was determined using the G12 assay kit, according to manufacturer's instructions (Biomedal SL, Sevilla, Spain). A standard curve was built with gliadin at various dilutions (0−120 ng/mL). To minimize possible protein−polyphenols interactions, beer samples were previously warmed for 40 min at 50 °C. Afterward, beer aliquots were diluted (1:50−1:200) in the dilution buffer (room temperature) and assayed in triplicate. Statistical analyses were carried out with the Excel 2010 software (Microsoft Co., WA, USA).

RESULTS AND DISCUSSION

Electrophoresis-Based Proteomic Analysis of Weissbier. The total protein content of Weissbier samples was 2.7−2.9 g/L (mean of three determinations), roughly 2-fold higher than BMB (1.4 g/L), as measured with the modified micro-Lowry assay. However, discrepancies can be found about the protein content of beer depending on the method of analysis.[1] After 20% TCA precipitation, polypeptides >6 kDa, here referred to as the protein fraction, were grossly separated from the low-molecular-weight (low-MW) peptides by SEC using G-25 Econo-Pak 10 DG columns.[9] Proteins from WB and BMB samples were analyzed with 1D SDS-PAGE, as shown in Figure 1. The main bands of WBs migrated with an apparent MW

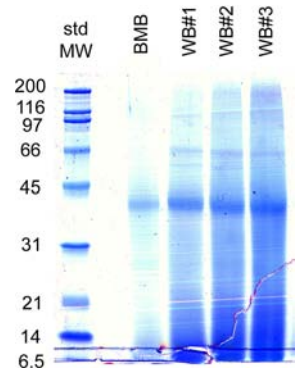

Figure 1. SDS-PAGE separation of proteins from Weissbier samples (WB#1, WB#2, and WB#3) compared to an all-barley-malt beer (BMB) sample. The band at ∼43 kDa and the quite broad band at low molecular weight are Z-type serpins and ns-LTP, respectively.

corresponding to that of BMB Z4 serpin and ns-LTPs. Indeed, the bands at ∼43 and ∼9.5 kDa were identified as barley Z4-serpin (UniProt Knowledge Base, UniProt: P06293) and ns-LTP1 (UniProt: P07597) by MALDI-TOF MS-based PMF after excision and in-gel trypsinolysis.

The cereal serpins (serine protease inhibitors) are Z-type cereal inhibitors that have been classified into five subfamilies, sharing 70−75% homology. Members within a subfamily share more than 89% sequence identity. Barley serpins are catalogued into three subfamilies, namely BSZ4, BSZ7, and BSZx, the latter having been never detected at the protein level.[20] Hexaploid *T. aestivum* wheat encodes a higher number of serpin proteoforms than the diploid barley. Actually, five different Z-type serpins, grouped into two subfamilies according to structural and functional homology with the barley serpins, have been cloned and sequenced in wheat.[21] Low-intensity peptides specific to wheat Z2A (UniProt: Q9ST57) and Z2B (UniProt: P93692) were detected among the tryptic digests of the band at ∼43 kDa, demonstrating that minor amounts of wheat serpins comigrated with the barley cognates (not shown). Similarly, minor signals of wheat ns-LTP1 co-occurred in the spectra with those of the barley homologue counterpart. These findings indicated that the brewing processes enrich specific homologous protein subsets of wheat and barley. PMF analysis demonstrated that a faint protein band of WBs at MW ≈ 65 kDa contained peptide ions specific to the Z-type serpins. In agreement with previous data, these bands have to be attributed to aggregates resulting from heat-induced covalent cross-linking of proteins.[22]

Although no appreciable difference was observed among the three WBs, a protein smear at MW = 28−40 kDa distinguished WBs from BMB. These diffuse bands were attributed to traces of gliadins and, at least in part, to enzymes of the yeast glycolytic pathway (e.g., triosophosphate isomerase). In fact, WBs supposedly contained significant amounts of haze-active yeast proteins because they are generally unfiltered and undergo an in-bottle refermentation following the addition of a viable yeast population (Hefeweizen beer style).

Z-serpins and ns-LTPs appeared as dominant diffuse zones in the 2DE gel of a representative Weissbier sample (WB#1, Figure 2). Substantially identical maps were observed for the other WB samples (not shown) and the BMB control, in-line with an early attempt to elucidate the protein profile of Weissbier.[23] The protein spots of Z-type serpins and ns-LTPs were identified by PMF, whereas minor protein spots were

DOI: 10.1021/acs.jafc.5b00631
J. Agric. Food Chem. 2015, 63, 3579−3586

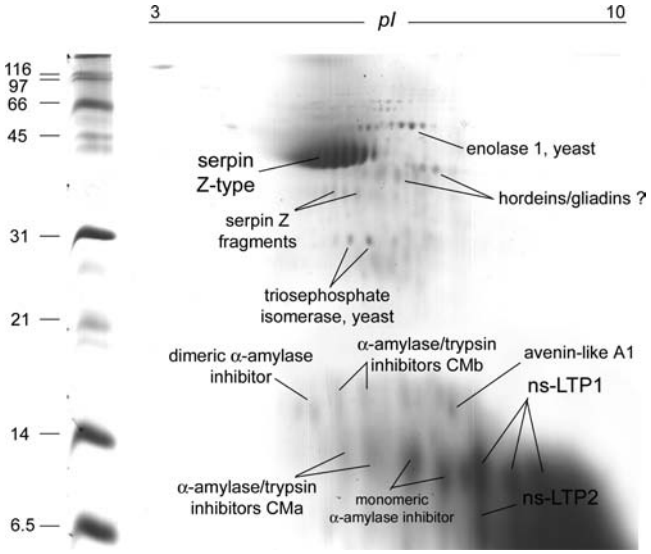

Figure 2. 2D electrophoresis (2DE) map of a representative Weissbier sample (WB#1). Major protein spots have been identified by PMF and on the basis of the MW/p*I* coordinates (also compare with ref 23).

tentatively assigned also relying on the MW/p*I* coordinates and by comparison with previous literature data.[24,25] Apparently, the respective broad spots only contained the barley Z-serpins and ns-LTPs. However, the probable comigrating wheat homologue proteins were not detected due to the lower relative abundance and to a certain degree of dispersion over numerous isoforms, which are additionally affected by variable nonenzymatic glycation.[26,27] Notably, a series of protein spots, previously described as α-amylase/trypsin inhibitors and aveninlike protein A1, was detected at MW = 13−17 kDa. Only protein traces possibly ascribable to hordeins/gliadins occurred at MW = 35−40 kDa and p*I* 7−7.5,[2] whereas fragments of barley Z4-serpin and proteoforms of yeast triosephosphate isomerase populated the MW range = 28−40 kDa.

Shotgun Proteomic Analysis of Weissbier. 2DE maps provided a general picture of the beer protein systems, evidencing the pattern of the main components and preserving the information about the protein integrity.[28] Nevertheless, beer is a complex biochemical system constituted by a heterogeneous protein fraction and polypeptides with peculiar properties (e.g., very high p*I*) that are in part severely glycated, hydrolyzed, or aggregated.[22]

The Weissbier proteome is expectedly even more complex than the BMB one because of the occurrence of hexaploid wheat as an additional source of gene-expression products. In cases like this, gel-free shotgun proteomics (bottom-up strategy) expands the analytical dynamic range, contributing to comprehensive protein inventories that include those less-abundant components hardly detectable by different strategies.[3,4,6,8,9] Thus, to deeply explore the proteome of Weissbier, the 2DE-based investigation was complemented with peptide-centric LC-ESI MS/MS-based shotgun proteomic analysis of a representative sample (WB#1). Overall, we identified 58 gene products with high confidence ($p < 0.05$), among which 41 (71%) were from *H. vulgare* and *T. aestivum*. The homology-filtered protein hits are listed in Table 1. The emPAI value, assigned by the Mascot search engine on the basis of the spectral count in a label-free fashion,[29] provided a rough estimate of the relative protein abundance.

Z-type serpins were by far the most represented proteins of WBs similar to those of the BMB.[9] Z4 and Z7 serpins were from barley, five serpin proteoforms from wheat. By summing the relevant emPAI values, Z-serpins were estimated to occur at an expression degree comparable to one between those of barley and wheat.

The search engine assigned three "unique" peptide matches to the barley ZX serpin, whose expression at the protein level has not been confirmed. These tryptic peptides actually were degenerate sequences that occur identical in both the Z4 and Z7 serpins. Therefore, ZX serpin was not computed within the list of the entries during the process of homology filtering. Similarly, several protein hits in Table 1 are indicative of a series of possible homologous gene products.

Barley and wheat ns-LTPs, especially the ns-LTP1 types, ranked as the second-most abundant protein family of Weissbier. Despite the important proportion of malted wheat used for brewing, the barley ns-LTPs appeared much more abundant than those of wheat, according to the electrophoretic and emPAI data, probably because of several differences of the primary structures (barley and wheat ns-LTP1 and ns-LTP2 share 74 and 65% identity, respectively) that might affect the stability of the ns-LTPs to proteases.[30] Anyhow, the proteins from both the sources are known to exhibit a relatively high resistance to proteases as well as to heat treatments.

As a general trend, similar to BMB, the process of protein selection during Weissbier production enriches a few classes of endosperm proteins generally categorized among the seed pathogenesis-related proteins, which are able to survive even the harshest brewing injuries.[31] Because of their functional role in the grain, pathogenesis-related proteins and protease inhibitors are also highly resistant to human physiological gastrointestinal digestion, and for this reason they could reach the gut in an immunologically active form and behave as type-I allergens in IgE-mediated food allergies.[32] To this purpose, α-amylases/trypsin inhibitors occurring as several isoforms in Weissbier are pest-resistance effectors besides being physiologically deputed to balance the accumulation and release of starch during the seed's transition from dormancy to germination. α-Amylases/trypsin inhibitors and thioredoxin are well established wheat IgE allergens, for instance in baker's asthma. Recently, it has been proposed that α-amylases/trypsin inhibitors are stronger elicitors of the innate immune response and could be involved in several inflammatory disorders of the gastrointestinal tract, including the recently emerged nonceliac gluten sensitivity.[33]

Probably because of an effect of suppression exerted by yeast proteins, hordeins appeared to be missing in Weissbier, whereas in BMB they have been detected, albeit at low amounts. Minor levels of gluten proteins, including wheat α/β- and γ-gliadins as well as high- and low-MW glutenin subunits, were clearly identified instead, demonstrating that Weissbier do contain prolamins that are potentially harmful for celiacs.

The relatively high number of gene products arising from *S. cerevisiae* (17 proteins, 29%) is consistent with the lack of the filtering step during brewing. Importantly, the great majority of the proteins identified are structurally and/or functionally related to components already described in BMB, thus actually validating the outcome of the analysis.

Peptidome Analysis of Weissbier. The analysis by SEC demonstrated that 75−80% of the protein fraction of WBs consisted of medium-/small-sized soluble polypeptides released from the barley and wheat malt, similar to results from BMB

(Figure 3). The peptide fraction (MW < 6 kDa) from the WB samples showed indistinct RP-HPLC patterns containing a

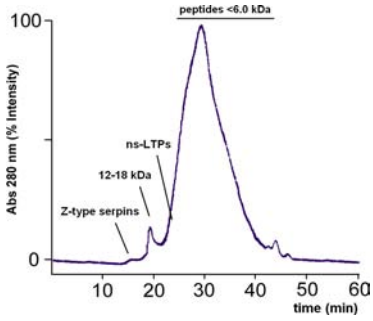

Figure 3. Size-exclusion chromatography of polypeptides from a representative Weissbier sample (WB#1). Fractions were collected and analyzed by SDS-PAGE or by MALDI-TOF MS.

multitude of unresolved, low-abundance peaks and a few dominant peaks, attributed to free aromatic amino acids (e.g., tryptophan), detected at λ = 280 nm, and possibly to polyphenols (not shown).[5] The low-MW peptide fraction of beer is extremely complex because of a series of concomitant factors, including the extreme heterogeneity of the parent proteins, which is further increased in Weissbier, the variable degree of heat-induced nonenzymatic glycation (Maillard reaction), and the unpredictable nature or lack of specificity of the proteolytic cleavage. The peptides from WB#1, representative of Weissbier samples, were analyzed by RP-HPLC-ESI-Q-Orbitrap MS/MS analysis coupled to the database search. Relying on the high resolution of the MS (and MS/MS) measurements and the power of the search engine, we identified 167 peptides deriving from 44 different proteins (Table S1). Many of the peptides were from metabolic proteins of *Saccharomyces* spp., confirming that yeast contributes to the proteome and peptidome of WBs much more than it does to the peptidome of BMB. A significant number of peptides (37) arose from α/β- and γ-gliadins and several other from low- and high-MW glutenin subunits. Therefore, the overall immunogenic potential of Weissbier is clearly incompatible with a gluten-free diet.

Some of the peptides could be encrypted in multiple protein entries because of the occurrence of repeated motifs within specific subfamilies of gluten proteins. In line with the parsimony principle, only protein entries representative of the subfamilies have been selected for cataloguing. The N-terminal region of α-gliadin that also is known to be resistant to proteolysis in sourdough[34] was particularly well-represented. Interestingly, no peptides from ω-gliadins were detected, mirroring the lack of fragments from the homologue C-hordeins in BMB.[6,9] In contrast, significant amounts of C-hordein-derived peptides have been recently described in a home-brewed beer.[35] Immunogenic-proteases-resistant toxic 33-mer 56−88 of α2-gliadin[36] was not detected, whereas N-terminal fragment 56−63 LQLQPFPQ of the same protein was clearly retrieved. (In Table S1 the sequence is indicated as 76−83, because the numbering includes the 1−20 signal peptide.) This result indicates that the 33-mer α2-gliadin peptide is at least partly hydrolyzed during brewing.

Pentapeptide QQPFP, common to other celiacogenic cereals and included in the 34−54 peptide of gliadins, is the main antigen of the R5 antibody used for assaying gluten in foods. QPFPQ, encrypted in the 56−63 α-gliadin fragment, is an additional epitope recognized by the R5,[37] whereas the extended sequence contains the QXQPFP consensus sequence for antigliadin IgA and IgG binding.[38−40] α-Gliadin fragment 33−54 (53−74 with the signal peptide) is part of toxic peptide 31−55, described as one of the main elicitors of the innate response in the immunopathogenesis of celiac disease.[41] Epitope DQ2.5-glut-L1[42] is partly contained in the low-MW glutenin-derived peptides.

Several other peptides of Weissbier harbored the restricted motifs associated with the induction of the celiac disease (e.g., PQQP).[43,44] However, many additional extended multivalent harmful epitopes,[36] distinctly sequenced in BMB,[9] were missing in Weissbier. We argue that this apparent incongruence is due in part to the intrinsic system complexity and to the pitfalls of the peptidomic pipeline. Specifically, the relatively high abundance of yeast-derived peptides in WBs overwhelmed the gluten-derived peptides, which additionally suffer from intrinsic low ionization efficiency. The effect of suppression exerted by yeast-derived peptides is confirmed by the relatively scarce presence of fragments of Z-type serpin and ns-LTPs, which in contrast are largely represented in BMB.[9] Also, it can not be ruled out that many gluten epitopes in Weissbier including the 33-mer are still encrypted within large-sized polypeptide fragments, so escaping MS/MS sequencing. To this purpose, it has to be underlined that several hundreds of peptide ions detected by MS remained unidentified. This demonstrates that the peptidomic picture emerging from the Weissbier system most likely is still the tip of an iceberg because the repertoire of peptide components is far from complete.

G12 Competitive ELISA and Western Blotting of Weissbier. G12 competitive ELISA determinations supported the relatively high abundance of gluten epitopes in WBs. The reliability of the ELISA methods based on the Mendez R5 and Skerritt antibodies for quantifying hordeins in beer has been questioned.[17] Moreover, it should be noted that the relationship between ELISA measurements of gluten and gluten toxicity is not clinically validated.[45] In an attempt to overcome these shortcomings, an assay has been introduced that is based on the G12 antibody raised against hexapeptide epitope QPQLPY of the α-gliadin 33-mer.[46] G12 antibody exhibits affinity to related toxic sequences from hydrolyzed prolamins of barley and rye and some cultivars of oats.[47] Because the standard curve is built using variable concentrations of gliadins, the assay of substrates containing mixed glutenlike epitopes also derived from different cereal species such as barley, as in the case of Weissbier, could result in an overestimation of the results. However, specifically targeting epitopes reactive against T-cell of celiac patients, the G12 ELISA determinations appear to correlate with the actual immune reactivity of gluten-containing foods.[11,48]

The gluten content of Weissbier samples assayed with the competitive G12 ELISA was 374, 372, and 382 ppm (mean of three determinations with different beer batches; standard deviations < 5%) for WB#1, WB#2, and WB#3, respectively, which is almost 10-fold higher than that of the BMB sample (41 ppm). Gluten-free beer, used as the control, contained 2.8 ppm gliadin equivalents.

Western blotting using a pool of sera from celiac patients as the source of antigliadin IgA antibodies confirmed the higher level of immunoreactive polypeptides in WB samples (Figure 4). Although the BMB sample only exhibited a responsive band because of a D-hordein,[9] WBs showed complex patterns of

DOI: 10.1021/acs.jafc.5b00631
J. Agric. Food Chem. 2015, 63, 3579−3586

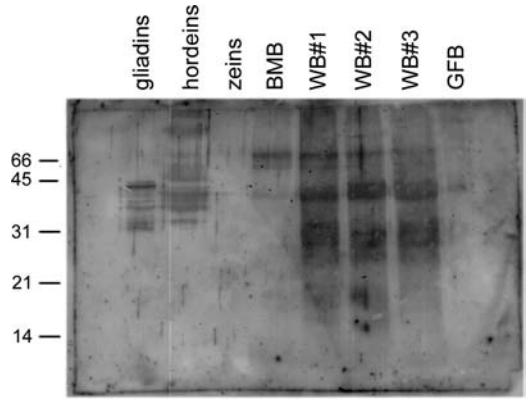

Figure 4. Western immunoblotting of Weissbier samples (WBs) compared to all-barley-malt (BMB) and gluten-free beers. SDS-PAGE-separated proteins were immunostained with pooled sera of celiac patients ($n = 4$) as the source of antigliadin IgA. Wheat (gliadins) and barley (hordeins) prolamins were used as the positive controls, whereas maize prolamins (zeins) were the negative control.

reactive components with the MW values expected for α/β-gliadins (34−38 kDa) in addition to responsive high-MW glutenin subunits, which are D-hordein homologues. WBs also showed a smear at MW < 30 kDa indicative of possible immunoreactive large-sized gluten fragments. Consistent with the G12 evaluation, the Western blotting analysis demonstrated a potential immunotoxicity of WBs significantly higher than that of BMB. The much higher gluten level of WBs compared to that of the lager/Pilsner BMB also supports previous ELISA and Western blotting assessments carried out with first-generation antigluten antibodies.[49]

CONCLUSIONS

The proteome of Weissbier, here explored for the first time, has shown a protein pattern in which the wheat-derived gene products mirror the homologue barley-derived proteins already catalogued in BMB. The correspondence between barley- and wheat-derived proteins was not trivially predictable, taking into account that biochemical events occurring during wheat malting are largely underinvestigated compared to the barley counterpart[50] and that wheat proteins significantly affect the properties of wheat beers.[51] Because of the contribution of hexaploid wheat, the brewing grist of Weissbier and, consequently, its proteome are substantially different from those of BMB. Proteolysis during malting and other brewing steps releases an even more heterogeneous peptide assortment that has been partly characterized in this study. Comprehensive profiling of the protein/peptide repertory is partly hampered by the abundance of interfering yeast-derived gene products that are present in relatively large amounts as a consequence of the brewing process (Hefeweizen beer). However, it emerged clearly that Weissbier contains a large number of protease-resistant and heat-stable proteins that are potential elicitors of IgE-mediated immunoreactions and sensitization events not related to celiac disease. The content of gluten epitopes in Weissbier, encrypted in either intact proteins or soluble hydrolyzed peptides, is much higher than that of lager/Pilsner BMB. The data presented herein demonstrate that although the compatibility of some lager BMB brands could be arguable[13] Weissbier is definitely incompatible with the celiacs' gluten-free diet.

[a]Frequency was 500 MHz for ^{1}H NMR and 150 MHz for ^{13}C NMR in pyridine-d_5 for **13** and CD_3OD for **14**. [b]ND, not detected. [c]The chemical shifts of H-7 and H-8 overlapped.

fractions (G1−G9) were grouped according to the TLC profile. Fraction G3 (H_2O/MeOH, 6:4, v/v, 248.4 mg) was subjected to a semipreparative ODS-HPLC, using a linear gradient system of 5% MeCN (pH 2.65 by TFA, eluent A) and 60% MeCN (pH 2.65 by TFA, eluent B), from 100% A to 17% B for 30 min and increased to 100% B for 45 min, to yield fraction G3a (t_R 22.8 min, 5.2 mg), **2** (t_R 28.2 min, 9.1 mg), a mixture of **2** and **3** (t_R 28.8 min, 13.6 mg), a mixture of **4** and **5** (t_R 30.0 min, 10.1 mg), and **6** (t_R 33.5 min, 7.6 mg). Compound **1** (t_R 31.5 min, 2.4 mg) was isolated from fraction G3a (5.2 mg) by semipreparative ODS-HPLC, using a linear gradient system of 2% MeCN (pH 2.65 by TFA, eluent C) and 40% MeCN (pH 2.65 by TFA, eluent D), from 100% C to 17% D for 30 min.

Fraction G8 (H_2O/MeOH, 2:8, v/v, 1216.2 mg) was suspended in distilled water (100 mL) and partitioned with $CHCl_3$ (3 L, three times) to obtain G8-C ($CHCl_3$ layer, 779.4 mg). Fraction G8-C (779.4 mg) was subjected to semipreparative ODS-HPLC, using a linear gradient system of 30% MeOH (eluent E) and 70% MeOH (eluent F), from 100% E to 100% F for 30 min, to yield **7** (t_R 17.2 min, 4.0 mg), **8** (t_R 19.7 min, 7.6 mg), **9** (t_R 21.0 min, 75.0 mg), **10** (t_R 23.0 min, 67.5 mg), G8-C7 (t_R 24.7 min, 16.7 mg), G8-C8 (t_R 27.1 min, 20.2 mg), and G8-C9 (t_R 29.4 min, 32.1 mg). Through further purification by semipreparative ODS-HPLC, using a linear gradient system of 20% MeCN (pH 2.65 by TFA, eluent G) and 40% MeCN (eluent H), from 100% G to 100% H for 30 min and held at 100% H for 60 min, **11** (t_R 24.2 min, 1.1 mg), **12** (t_R 27.7 min, 3.0 mg), and **13** (t_R 29.5 min, 1.0 mg) from G8-C7 (16.7 mg), **14** (t_R 19.4 min, 1.1 mg) and **15** (t_R 26.8 min, 1.6 mg) from G8-C8 (20.2 mg), and **16** (t_R 31.4 min, 1.6 mg) from G8-C9 (32.1 mg) were isolated, respectively.

*Compound **9** (White Amorphous Powder).* $[\alpha]_D^{25}$ −0.03 (c 0.025, $CHCl_3$); UV $CHCl_3$ λ_{max} (nm) (log ε) 336 (3.82); ^{1}H NMR spectrum (500 MHz, pyridine-d_5, TMS) δ 8.48 (1H, d, J = 7.8 Hz, H-5), 7.42 (1H, t, J = 7.8 Hz, H-6), 7.71 (1H, t, J = 7.8 Hz, H-7), 7.83 (1H, d, J = 7.8 Hz, H-8), 4.02 (2H, t, J = 8.0 Hz, H-1′), 1.89 (2H, m, H-2′), 2.96 (2H, t, J = 7.0 Hz, H-3′); ^{13}C NMR (125 MHz, pyridine-d_5, TMS) δ 160.6 (C-2), 161.3 (C-4), 121.8 (C-4a), 127.0 (C-5), 126.6 (C-6), 134.6 (C-7), 127.9 (C-8), 150.8 (C-8a), 47.1 (C-1′), 19.8 (C-2′), 32.9 (C-3′); HRESI−MS (positive) m/z 187.0881 $[M + H]^+$ (calculated for $C_{11}H_{11}N_2O$, m/z 187.0871, +1.0 mDa).

HPLC−ESI−MS/MS Analysis of 9, 13, and 14 in Chestnut Honey. The chestnut honey (20 g) was homogenized using a homogenizer (BM-2 Nissei biomixer) with MeOH (40 mL). After extraction for 24 h at room temperature, the mixture was filtered under vacuum through No. 2 filter paper (Whatman). The residue was extracted with EtOH (40 mL) for 24 h at 4 °C and then filtered under vacuum through No. 2 filter paper (Whatman). The MeOH and EtOH solutions were combined and concentrated under vacuum at 38 °C. The extracts were suspended in distilled water (60 mL) and partitioned with *n*-hexane (60 mL, three times) and EtOAc (60 mL, three times), successively. The EtOAc fraction was evaporated under vacuum at 38 °C. The EtOAc fraction (60 mg) was suspended in distilled water (50 mL) and partitioned with $CHCl_3$ (50 mL, three times). After evaporation under vacuum at 38 °C, the $CHCl_3$ fraction (11.5 mg) was dissolved in MeOH (4.6 mL). The fraction was analyzed using a high-performance liquid chromatography−electrospray ionization tandem mass spectrometer (HPLC−ESI−MS) (Shimadzu, Kyoto, Japan). Compounds **9**, **13**, and **14** were separated under the following HPLC conditions: column, MG III (C18, 3 μm, 3.0 × 100 mm^2) (Shiseido, Tokyo, Japan); flow rate, 0.2 mL/min (LC10AD, Shimadzu). The sample was eluted using a gradient system of 100% H_2O (containing 1% formic acid, eluent I) to 100% MeCN (containing 1% formic acid, eluent J), starting with 100% I, increasing

J. Agric. Food Chem. 2015, 63, 3587−3592

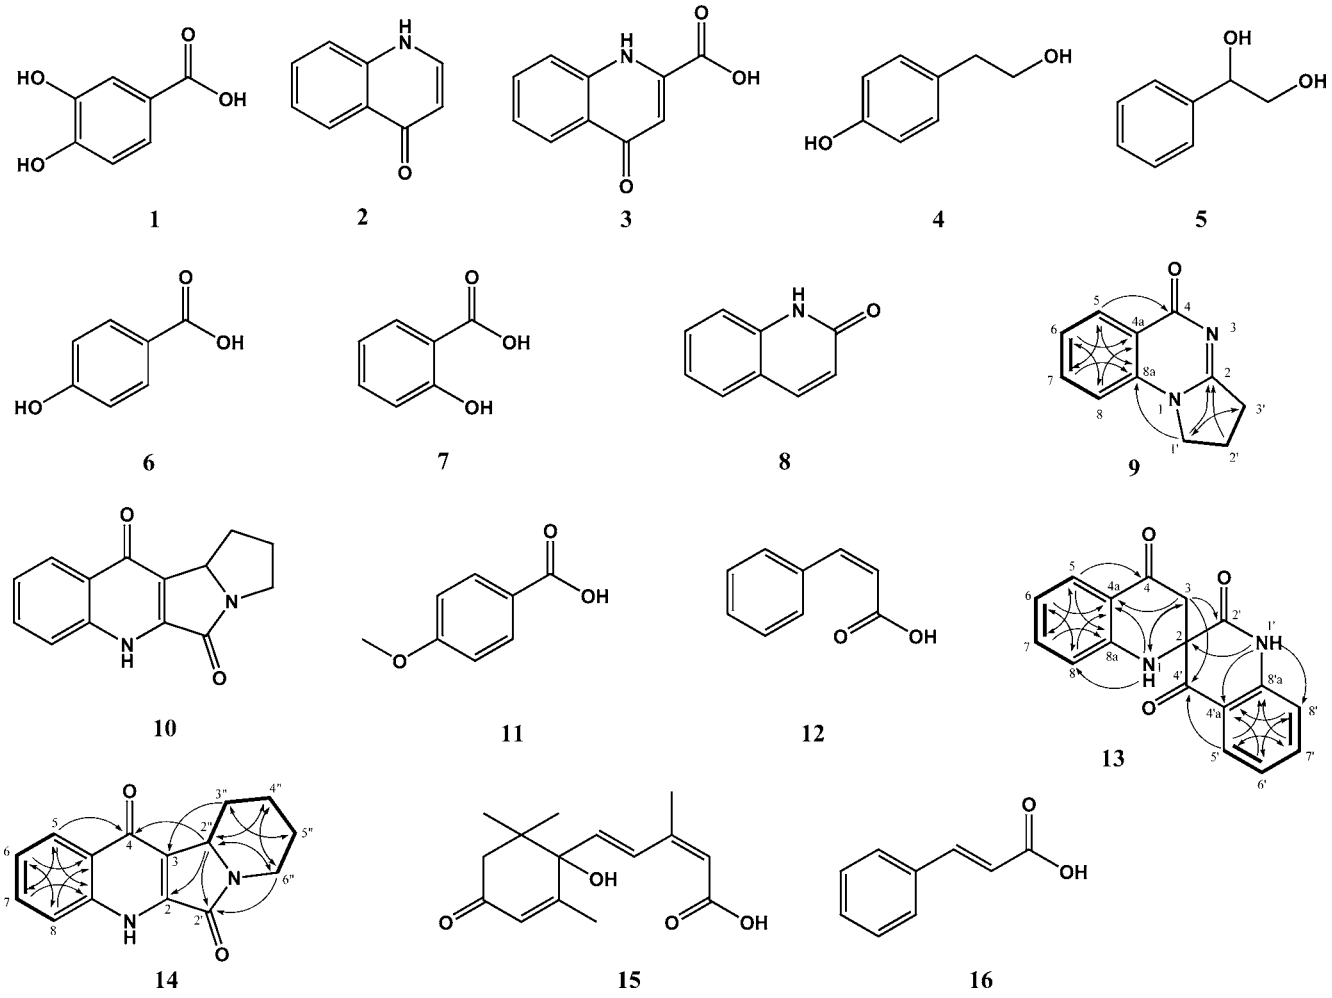

Figure 1. Structures of the isolated compounds from chestnut honey and the important $^{1}H-^{1}H$ correlation spectroscopy (COSY, bold lines) and heteronuclear multiple bond correlation (HMBC, arrows) correlations for **9**, **13**, and **14**.

to 20% J for 10 min, increasing to 50% J for 20 min, increasing to 100% J for 22 min, and holding at 100% J for 25 min. The mass spectrometer (positive ion mode) was set up for multiple reaction monitoring (MRM) to monitor m/z 187.0 → 92.1 for **9**, m/z 293.2 → 247.2 for **13**, and m/z 255.4 → 89.1 for **14** with the a dwell time of 0.1 s per transition. The optimal MS conditions for **9**, **13**, and **14** were employed; ESI source voltage 3.5 kV, detector voltage 45 V, heat block temperature 400 °C, and desolvation line temperature 250 °C. Nebulizing gas and drying gas flows were 3.0 L/min and 15.0 L/min, respectively. Argon was used as the collision gas at a pressure of 230 kPa. The optimized collision energies for **9**, **13**, and **14** were −36 eV, −26 eV, and −50 eV, respectively.

The content of **9**, **13**, and **14** in chestnut honey was analyzed quantitatively by HPLC−ESI−MS/MS analysis at the analytical scale. Sample and standard solutions were prepared just prior to analysis. The calibration curves (n = 6) were constructed using **9**, **13**, and **14** (0.1−50 ng) that were isolated from chestnut honey in this study. Accuracy and reproducibility were evaluated using the standard spike method. External standards of **9**, **13**, and **14** were added to aliquots of chestnut honey at three concentrations (n = 3) to determine their precision. The contents of **9**, **13**, and **14** in chestnut honey were determined in triplicate experiments.

RESULTS AND DISCUSSION

Thirteen known compounds isolated from chestnut honey were additionally identified as protocatechuic acid (**1**), 4(1*H*)-quinolinone (**2**), kynurenic acid (**3**), 4-(2-hydroxyethyl)phenol (**4**), 1-phenyl-1,2-ethanediol (**5**), *p*-hydroxybenzoic acid (**6**), salicylic acid (**7**), 2(1*H*)-quinolinone (**8**), 3-pyrrolidinyl kynurenic acid (**10**), 4-methoxybenzoic acid (**11**), *cis*-cinnamic acid (**12**), *trans*-abscisic acid (**15**), and *trans*-cinnamic acid (**16**) (Figure 2) based on NMR and MS spectroscopic data (Figure 1). All of these compounds have been found in chestnut honey or other honeys.[1,11−17]

The molecular formula of **9** was $C_{11}H_{10}N_2O$ (MW, 186), as established by a pseudomolecular ion peak in the HRESI−MS (positive). The ^{1}H NMR spectrum exhibited four sp^2 carbon proton signals of *ortho*-substituted benzene ring at δ 8.48 (1H, d, J = 7.8 Hz, H-5), 7.42 (1H, t, J = 7.8 Hz, H-6), 7.71 (1H, t, J = 7.8 Hz, H-7), and 7.83 (1H, d, J = 7.8 Hz, H-8). A propane moiety was also assigned by coupling patterns of three sp^3 methylene carbon protons at δ 4.02 (2H, t, J = 8.0 Hz, H-1′), 1.89 (2H, m, H-2′), and 2.96 (2H, t, J = 7.0 Hz, H-3′) in the ^{1}H NMR spectrum and their proton−proton correlations (bold lines) in the $^{1}H-^{1}H$ correlation spectroscopy (COSY) spectrum (Figure 1). This result was also supported by the ^{13}C NMR spectrum, which contained 11 carbon signals including eight sp^2 carbons with four quaternary carbons at δ 175.9−121.8 and three sp^3 carbons at δ 47.1 (C-1′), 32.9 (C-2′), and 19.8 (C-3′). Considering the molecular formula of **9**, the chemical shifts of four sp^2 quaternary carbons indicated that three of them were nitrogen-bearing carbons at δ 160.6 (C-2) and 150.8 (C-8a) with evidence of a carbonyl carbon at δ 161.3

DOI: 10.1021/acs.jafc.5b01027
J. Agric. Food Chem. 2015, 63, 3587−3592

(C-4). From the HRESI−MS and 1D NMR spectra, **9** was suggested to be quinazolinone connected with a propane moiety. The ^{1}H and ^{13}C NMR spectra of **9** were similar to those of 2,3-dihydropyrrolo[1,2-b]quinazolin-5(1*H*)-one, which has been synthesized as reported previously.[18] Complete NMR assignment and connectivity of **9** were further determined by ^{1}H−^{1}H COSY, heteronuclear single quantum correlation (HSQC), and heteronuclear multiple bond correlation (HMBC) experiments. Quinazolinone and propane moieties were also confirmed from the spectra. In particular, correlations (arrows) from H-1′ to C-8a and C-2 and from H-2′ to C-2 observed in the HMBC spectrum indicated that the propane moiety was connected with the 1 and 2 positions of the quinazolinone (Figure 1). Consequently, the structure of **9** was unambiguously determined to be 2,3-dihydropyrrolo[1,2-a]quinazolin-5(1*H*)-one (Figure 1). This compound has been synthesized, as reported previously.[19,20] However, this compound was identified for the first time in nature.

The molecular weight of **13** was determined to be 292 by the pseudomolecular ion peaks detected at *m*/*z* 293.1 $[M + H]^+$ and 315.1 $[M + Na]^+$ in the ESI−MS (positive) spectrum. The molecular formula ($C_{17}H_{12}N_2O_3$) was established by a pseudomolecular ion peak in the HRESI−MS (positive). The ^{1}H NMR spectrum of **13** showed the presence of eight proton signals occurring from two *ortho*-substituted benzene rings at δ 8.15−6.75. In addition, one methylene proton signal at δ 3.76 (1H, d, *J* = 13.5 Hz, H-3a) and 3.59 (1H, d, *J* = 13.5 Hz, H-3b) and two nitrogen-bearing proton signals at δ 8.52 (1H, s, H-1) and 12.26 (1H, s, H-1′) were observed. Considering the molecular formula and the chemical shifts of 17 carbon signals observed in the ^{13}C NMR spectrum of **13**, two *ortho*-substituted benzene ring moieties were assigned from 12 carbons at δ 149.6−114.7. Three carbonyl carbons at δ 189.5 (C-4), 169.8 (C-2′), and 191.3 (C-3′), one quaternary sp^3 carbon at δ 68.0 (C-2), and one sp^3 methylene carbon at δ 40.9 (C-3) were also observed, and four of them were nitrogen-bearing carbons at δ 169.8 (C-2′), 149.6 (C-8a), 141.0 (C-8′a), and δ 68.0 (C-2). From the MS and 1D-NMR data, the skeleton structures of **13** were suggested to be dihydroquinolinone and quinolinedione. In particular, the presence of one quaternary sp^3 carbon at δ 68.0 (C-2) indicated that **13** was a spiro compound consisting of dihydroquinolinone and quinolinedione. The complete NMR assignment and connectivity of **13** were further determined by the ^{1}H−^{1}H COSY, HSQC, and HMBC. The important correlations observed in ^{1}H−^{1}H COSY (bold lines) and the HMBC (arrows) spectra are shown in Figure 1, and the two partial structures of **13** were determined to be 2,3-dihydroquinolin-4(1*H*)-one and quinoline-2,4(1*H*,3*H*)-dione (Figure 1). In particular, correlations between H-1/C-8 and C-4a and H-3/C-4a were observed in the HMBC spectrum. Therefore, the planar structure of **13** was determined to be 3-dihydro-spiro[2(1*H*),3′(1′*H*)-diquinoline]-3′,4,4′-trione (spirodiquinolinone) (Figure 1), which is a new compound. However, structural determination for the absolute stereochemistry of **13** was impossible in the nuclear Overhauser effect spectroscopy experiment. Therefore, unambiguous determination of the absolute stereochemistry for **13** isolated in this study should be studied further with X-ray crystallography.

The molecular weight of **14** was determined to be 254 by the pseudomolecular ion peaks detected at *m*/*z* 255.1 $[M + H]^+$ and 277.1 $[M + Na]^+$ in the ESI−MS (positive) spectrum. The molecular formula ($C_{15}H_{14}N_2O_2$) was established by a pseudomolecular ion peak in the HRESI−MS (positive). The ^{1}H- and ^{13}C NMR spectra of **14** except for one methylene group were closely related to those of 3-(2′-pyrrolidinyl)-kynurenic acid isolated from chestnut reported previously[12] and in this study. That is, the ^{1}H NMR spectrum of **14** showed the presence of four *ortho*-substituted benzene ring proton signals at δ 8.32−7.46. In addition, one methine proton signal δ 4.46 (1H, dd, *J* = 11.8, 3.8 Hz, H-2″) and four methylene proton signals at δ 4.37−1.09 were observed. The ^{1}H NMR spectrum of **14** was supported by the ^{13}C NMR spectrum, which showed the presence of 15 carbon signals including 10 sp^2 carbons with six quaternary carbons at δ 176.3−120.5 and five sp^3 carbons at δ 58.9−24.2. Considering the molecular formula of **14**, the chemical shifts of six sp^2 quaternary carbons indicated that three of them were nitrogen-bearing carbons at δ 162.6 (C-2′), 143.0 (C-2), and 141.9 (C-8a) with two carbonyl carbons at δ 176.3 (C-4) and 162.6 (C-2′). The MS and 1D-NMR data suggested that the skeleton of **14** was kynurenic acid. In addition, a piperidine moiety was assigned as the partial structure from the split patterns of five sp^3 protons at δ 4.46−1.09 in the ^{1}H NMR spectrum and the correlations (bold lines) of H-2″/H-3″, H-3″/H-4″, H-4″/H-5″, and H-5″/H-6″ detected in the ^{1}H−^{1}H COSY spectrum (Figure 1). Therefore, the MS and 1D NMR data suggested that **14** was a pyrrolidinylkynurenic acid. The complete NMR assignment and connectivity of **14** were further determined by the HSQC and HMBC experiments. On the basis of the proton−carbon correlations (arrows) observed in the HMBC spectrum (Figure 1), **14** was determined to be 3-(2′-piperidine)-kynurenic acid (Figure 1), which is a new compound.

Qualitative and Quantitative Analyses of 9, 13, and 14 in Chestnut Honey. Several studies have already reported the presence of quinolinone alkaloids **2**, **3**, **8**, **10** in honey,[1,9−12] and these compounds were also confirmed in this study. We additionally isolated and identified three quinolinone derivatives **9**, **13**, and **14** from chestnut honey in this study. Compound **9** and its similar derivatives have been synthesized, as reported previously.[19] However, this is the first study where **9** was identified in nature. Furthermore, of the quinolone alkaloids isolated in the present study, **13** and **14** were determined to be new compounds. Thus, a further investigation on the occurrence and content of three compounds **9**, **13**, and **14** in chestnut honey was required. The three compounds **9**, **13**, and **14** were analyzed qualitatively and quantitatively by HPLC−ESI−MS. We used HPLC system and selective MRM detection of tandem MS using the isolated compounds as external standards to confirm the occurrence of three compounds in chestnut honey. The $CHCl_3$ fraction obtained after solvent fractionation of the chestnut honey MeOH and EtOH extracts was analyzed by MRM via HPLC−ESI systems. The three peaks of **9**, **14**, and **13** were detected at t_R 11.4, 17.0, and 14.3 min, respectively, on the MRM chromatogram of chestnut honey (Figure 2A−C). These data were in agreement with the retention times of authentic compounds (**9**, **14**, and **13**) purified from chestnut honey in the present study (Figure 2D). These results indicate that the occurrence of **9**, **13**, and **14** in chestnut honey was unambiguously revalidated.

The external calibration curve of each compound at a concentration range of 0.1−50 ng produced a good linear correlation (R^2 > 0.99). Therefore, the optical dilution of chestnut honey in MeOH was 1:920. The precision of **9** (3.5%), **14** (5.6%), and **13** (4.1%) ranged from 3.5−5.6%. The recovery percentage was calculated by comparing the slope of

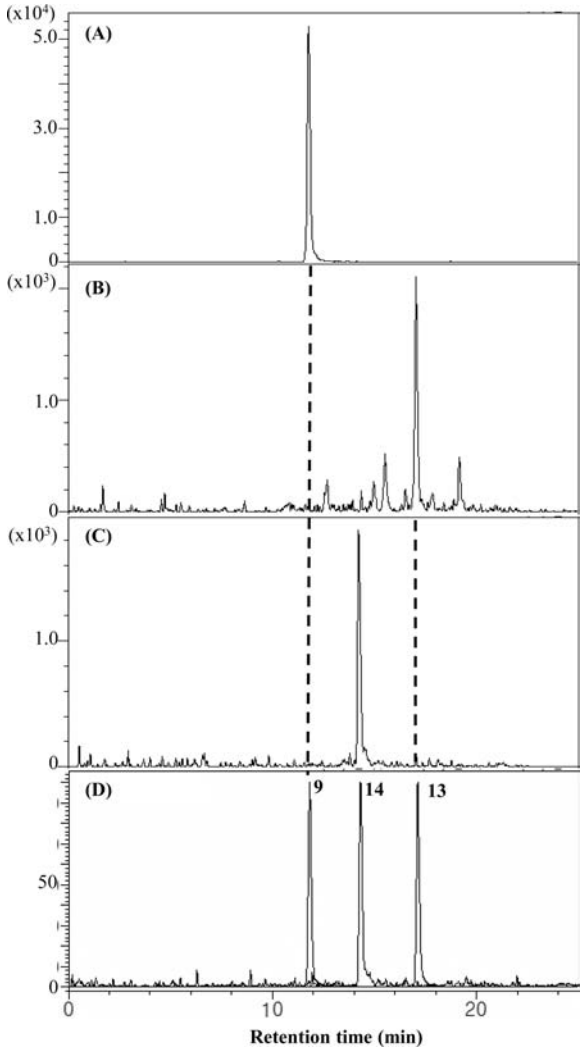

Figure 2. Multiple reaction monitoring (MRM) chromatograms of: (A) **9**, (B) **13**, and (C) **14** in chestnut honey and (D) standards.

the standard addition and the calibration curve for each compound. As a result of this analysis, the recovery of **9** (102.2 ± 3.9%), **13** (101.0 ± 3.44%), and **14** (98.8 ± 2.1%) ranged from 98.8−102.2%. Three compounds **9**, **13**, and **14** in chestnut honey were quantitatively analyzed by HPLC system and selective MRM detection of tandem MS. In the present study, the contents (μg/100 g) of **9**, **13**, and **14** in chestnut honey were 630.5 ± 62.5, 10.8 ± 0.7, and 734.8 ± 28.5, respectively. Compounds **9**, **13**, and **14** were present in very small amounts in chestnut honey when compared to quinolinone alkaloids **2** (2.3−211.5 mg/100 g) and **3** (8.1−64.4 mg/100 g), as reported previously.[11]

Quinoline alkaloids are widely distributed in nature and possess antimalarial, antimicrobial, anti-inflammatory, and analgesic activities.[21−23] In addition, kynurenic acid derivatives, which included **3**, **10**, and **14** identified in this study, are endogenous nonselective antagonists of α-7-nicotinic acetylcholine and *N*-methyl-D-aspartate receptors.[24] Furthermore, quinazolinone derivatives including **9** have anti-inflammatory and analgesic activities.[18] Therefore, quinolinone alkaloids including the two new compounds **13** and **14** identified in this study may be biologically active substances. These molecular-level investigations may offer very useful information for establishing the chemical profiles of honeys.

hemagglutinating activity,[16] are both found in the seed meal after extraction of the valuable oil, constraining the development of castor as an alternative to petroleum for energy and as a raw material for a wide variety of industrial and consumer products.[17] The immunochemistry of ricin has been extensively studied, particularly to optimize therapeutic immunotoxins containing ricin A chain[18] and to define potentially protective and therapeutic antibodies.[19] Exploitation of ricin antibodies and the amplification afforded by the polymerase chain reaction (PCR) has contributed new tools for food defense.[20,21] In an earlier study, we used BLI to study the interaction of ricin and RCA-1 with antibodies.[22] In this report, we describe BLI and ELISA experiments to quantitate milk matrix effects and mitigate their impact on the analysis of a carbohydrate-binding protein, such as ricin.

MATERIALS AND METHODS

Chemicals, Biological Reagents, and Milk Samples. Analytical-reagent-grade chemicals and reverse-osmosis water filtered to 0.055 μS/cm were used in these studies. Ricin was obtained from Vector Laboratories (Burlingame, CA). Asialofetuin was obtained from Sigma (St. Louis, MO). The principal buffers and milk samples used in ELISAs and BLI were phosphate-buffered saline (PBS), PBS−0.05% (v/v) Tween-20 (PBST), and PBST with 10 mg/mL bovine serum albumin (BSA), and 0.01% (w/v) thimerosal (BPT).[4,22] For binding in the BLI system, both PBS and kinetics buffer (KB, PBST with 1 mg/mL BSA) were used at pH 7.4. Biotinylated mAbs were detected with horseradish peroxidase (HRP)−streptavidin (SA) conjugate (Invitrogen, Eugene, OR) at 0.3−1 μg/mL. Nonfat dry milk (NFDM), pasteurized and fortified with vitamins A and D (Safeway, Oakland, CA), was reconstituted (9.6 g/100 mL) and used immediately. Fresh milk labeled as fat-free (0% fat), reduced fat (2.1% fat), or whole (3.3% fat) milk was used before its sell-by date (Clover Stornetta Farms, Petaluma, CA). Milk samples and samples dialyzed against PBS were stored up to 1 week at 4 °C with the addition of 0.02% (w/v) NaN_3. Dialyses were conducted in SpectraPor 2 cellulose tubing, 10 mm flat width (Spectrum Laboratories, Rancho Dominguez, CA), and sealed with plastic clips or knots.

BLI. BLI studies were conducted using a model QK Octet biosensor and amine-reactive (AR) or SA sensor tips (ForteBio, Menlo Park, CA) to determine association and dissociation rate constants (k_a and k_d) and k_d/k_a, the equilibrium dissociation constant, K_D.[22] Binding rate constants were determined in three replicate experiments using five analyte concentrations in KB (2-fold dilutions from 10 μg/mL), unless otherwise noted. Regeneration of sensor tips following binding used a series of three 10 s immersions in 10 mM glycine−HCl at pH 1.7, alternating with PBS. The criterion for acceptable BLI data was fit of the sensorgrams to a 1:1 binding model, with $R^2 \geq 0.9$, and data are expressed as the mean ± standard deviation.

Analysis of Ricin Binding to ASF. ASF was immobilized on AR sensor tips at 20 μg/mL. Milk samples were diluted to 0.5% (v/v) and spiked with ricin at 1 μg/mL. Association steps were 600 or 1200 s, after which dissociation occurred in the same milk/buffer mixture. Replication was as follows: undialyzed (control) fresh milk, $n = 5$; dialyzed fresh milk, $n = 6$; and NFDM samples, $n = 3$.

BLI Sandwich Format. mAb 1797 was immobilized on AR sensor tips at 20 μg/mL. For the association step, sensor tips were dipped into wells containing ricin in buffer with or without reconstituted NFDM (2%, v/v). After ricin binding, sensors were moved immediately to wells containing b-mAb 1443, the same reagent used for detection in ELISA. Rate constants were normalized as a percent of values for the control buffer matrix ($n = 25$).

BLI Analysis Using Milk as a "Sink". Biotinylated mAb 1797 was immobilized on SA sensor tips at 10 μg/mL. After association under standard conditions (10 μg/mL ricin in KB), sensor tips were moved to wells containing buffer or reconstituted NFDM (10−100%, v/v) for the dissociation step.

MAbs and ELISA. The monoclonal antibodies that bind ricin were described previously.[3,23] MAbs were isolated from hybridoma culture supernatants by hydrophobic charge-induction chromatography on MEP-Hypercel (Pall Life Sciences, Port Washington, NY)[24] and affinity chromatography on Protein G-agarose (Pierce, Rockford, IL) in accordance with the protocols of the manufacturers. Purified mAbs were stored at 0.5−1 mg/mL in the presence of NaN_3 and a mixture of serine, cysteine, and acid protease inhibitors (Sigma). Biotinylated mAbs (b-mAbs) were prepared using *N*-hydroxysuccinimide (NHS)−biotin ester (Pierce) with an initial ester/antibody molar ratio of 10. ELISA was performed as described previously,[4] and data were fit to a logistic equation ($y = a_0 + a_1/(1 + (x/a_2)^{a_3})$) using SlideWrite, version 7.01 (Advanced Graphics, Rancho Santa Fe, CA). Coefficient a_2 is the analyte concentration at half-maximal binding (EC_{50}). Briefly summarized, analytical samples and immunoreagents (ricin, mAb dilutions, biotinylated mAbs, and diluted HRP−SA conjugate) were prepared and applied to ELISA wells with 30 min incubations. Spiked milk samples were incubated for 10 min before application to ELISA wells. Ricin-containing analyte and the first wash from ELISA are collected by a pipet and inactivated using sodium hypochlorite solution. After the analyte binding step and subsequent wash, biotinylated mAb (b-mAb 1443 at 100 ng/mL, unless noted otherwise) was added (100 μL/well) and incubated for 30 min. After an additional wash step, ELISAs were developed with HRP−SA and K-Blue tetramethylbenzidine substrate (Neogen, Lexington, KY). The reaction was stopped by the addition of 100 μL of 0.3 M HCl, and $A_{450\ nm} - A_{650\ nm}$ was determined using a M2 microplate reader (Molecular Devices, Sunnyvale, CA). Two or three well replicates were averaged for each ELISA data point, and experiments were conducted in triplicate, unless otherwise noted.

ELISA on Asialofetuin-Coated Microwells. Ricin (0, 1.25, 2.5, 5, 10, 20, 40, 80, and 100 ng/mL or a subset of these standards as shown on graphs) and b-mAb 1443 (100 ng/mL) were added sequentially, with intervening wash steps.

Effect of Milk in ELISA on ASF- and mAb 1797-Coated Microwells. Ricin (10 ng/mL) was prepared in neat and diluted 0% fat fresh milk in PBST + BSA. The ELISA was then conducted and developed under standard conditions with b-mAb 1443, HRP−SA, and substrate.

ELISA with Ricin-Spiked Milk or Milk Sequentially Applied. For the "spiked" condition, ricin (10 ng/mL) was added to buffer or to milk at various dilutions with a 10 min pre-incubation before application to wells and incubation for 30 min. In the "sequential" condition, ricin in buffer was applied to the wells. After incubation (30 min) and washing, the dilutions of milk were added to the wells for a further incubation of 30 min. For both conditions, plates were washed and b-mAb 1443 (100 ng/mL) was applied to detect bound ricin. Assays were developed with HRP−SA and substrate. To determine the time course for changes in ASF-bound ricin during the incubation with 1% milk in the "sequential" condition, 100 μL of milk was added to the ELISA wells containing ASF-bound ricin but removed at various times from 1 to 30 min and replaced with the standard ELISA buffer, BPT.

Sugar Effect on Ricin Binding to mAb 1797. Ricin was used as the analyte (20 ng/mL in control buffer or 0.133 M galactose or lactose). ELISA used mAb 1797-coated ELISA wells and b-mAb 1642 or b-mAb 1443 (100 ng/mL; $n = 2$, for each condition) as the detection antibody. Experiments were also conducted in kinetics buffer to mimic conditions used for BLI experiments. The dose−response effect of galactose was determined using 0, 14.7, 44.3, and 133 mM galactose.

Multiple Sample Comparisons. For multiple sample comparison of binding data under differing conditions, one-way analysis of variance (ANOVA) was used with Tukey's *post hoc* honestly significant difference (HSD) procedure to determine which means were significantly different (Statgraphics Centurion, version 15, Statpoint Technologies, Warranton, VA). A p value of <0.05 was considered significant.

Safety Information. Ricin is highly toxic and is regulated as a Select Agent (7 CFR Part 331 and 9 CFR Part 121). Special handling and inventory control are required.

RESULTS AND DISCUSSION

Immunosorbent Analysis of Ricin Binding to ASF. The binding of ricin to ASF was studied in sandwich ELISA, with ASF-coated wells and b-mAb 1443 as the detection antibody, as shown in Figure 1. In control experiments, ricin bound with

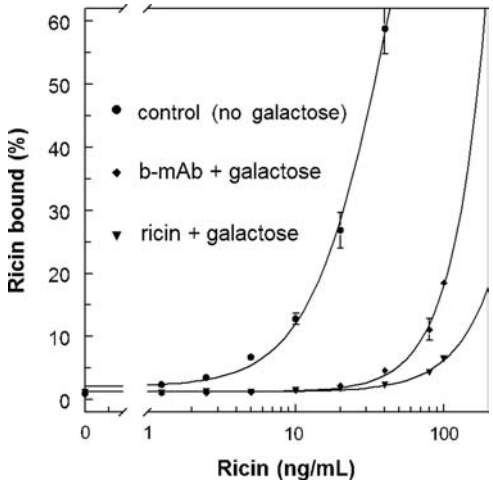

Figure 1. ELISA on ASF-coated microwells: (●) control, both ricin analyte and b-mAb 1443 applied in BPT; (◆) ricin applied as in the control and b-mAb 1443 applied in BPT containing 100 mM galactose; and (▼) ricin applied to wells in BPT containing 100 mM galactose and b-mAb applied as in the control.

EC_{50} = 30 ng/mL. When ricin was applied to the microwells as in the control but b-mAb 1443 was applied in buffer containing 100 mM galactose, binding was greatly reduced, with EC_{50} approximately 200 ng/mL. The presence of 100 mM galactose in the ricin sample solution reduced the binding more dramatically, to less than 5% of the control level (EC_{50} > 1000 ng/mL). This pattern of binding was expected from the known lectin activity of ricin,[25] and the reversibility of ricin binding reflects that ASF is only a moderate-affinity ricin receptor.[13]

Effect of Milk on Binding of Ricin to mAbs and ASF in ELISA. The effect of milk on the binding of ricin to mAbs and ASF was studied by ELISA using mAb- and ASF-coated microwells. The results of one set of assays are illustrated in Figure 2 and show that nonfat milk inhibits 50% of ricin binding at about 0.3% (v/v) for ASF. Comparable inhibition of binding to mAb 1797 occurred at a milk concentration of 55% (v/v). The effect of milk on ricin binding to ASF was further explored to determine whether the reduction of ricin binding to ASF by milk required that milk be present during initial ricin binding, the "spiked" milk condition. This condition was compared to a "sequential" ELISA in which milk was added to assay wells after the ricin-binding and wash steps were completed. The results are illustrated in Figure 3. The results show that milk does not have to be present during the binding step to have an inhibitory effect. The inset graph shows the time course for removal of previously ASF-bound ricin in the presence of milk. The process is nearly complete within 30 min, under the 1% milk condition. The effect of milk on ricin binding to ASF is consistent with the demonstration that milk could abrogate the effect of ricin on Vero cells.[6] Cellular and *in vivo* ribosome-inactivating activity begins with binding of ricin to cellular receptors.[26] We next conducted preliminary experiments that showed dialysis relieved the effect of milk

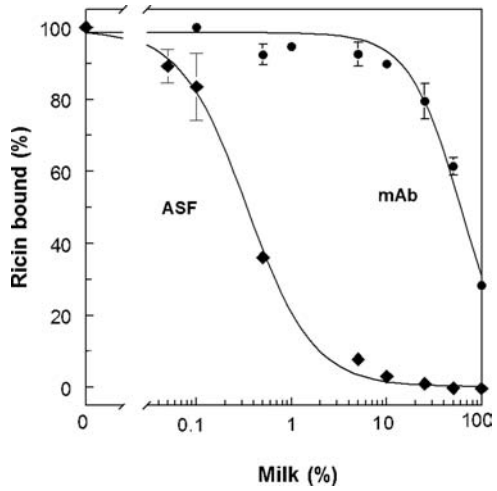

Figure 2. Effect of milk on ricin binding to ELISA wells coated with ASF or mAb 1797.

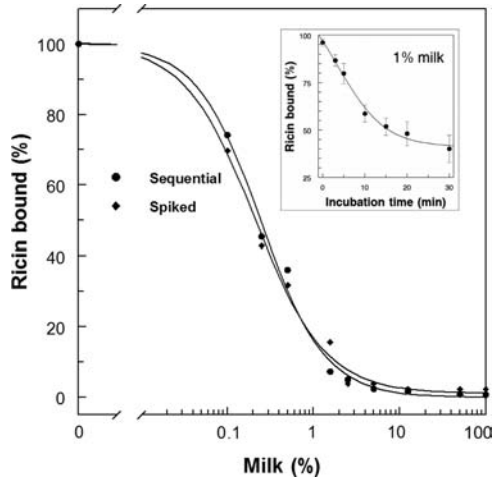

Figure 3. ELISAs using microplate wells coated with ASF conducted under two conditions: (◆) ricin (10 ng/mL) spiked into buffer or diluted milk applied to wells with 30 min of incubation and (●) ricin in buffer applied to the wells, incubated, and washed, followed sequentially by incubation with dilutions of milk. (Inset) Time course for removal of ASF-bound ricin during the incubation with 1% milk in the "sequential" condition.

on binding to ASF (data not shown). It seemed a reasonable hypothesis that sugars found in milk could account for this observation. Bovine milk contains approximately 48 g/L (0.14 M) lactose, β-D-galactopyranosyl-(1 → 4)-D-glucose,[27] the principal milk sugar, and we next tested the hypothesis.

Effect of Sugars on Ricin Capture by mAb 1797 in ELISA. Figure 4 shows the effect of sugars on the detection of ricin in ELISA using mAb 1797 for capture. When present in the analyte "capture" incubation step, galactose and lactose inhibited binding, producing about 20 and 40% inhibition, respectively, at 0.133 M. Means for galactose and lactose were significantly different from controls ($p < 0.05$, paired t test). Similar results were obtained when ELISAs used kinetics buffer (1 mg/mL), instead of PBST + BSA (10 mg/mL BSA), to mimic matrix conditions used in BLI studies described below. The inset graph shows a representative data set from three experiments determining the dose dependence of the galactose effect. Experiments were also performed with other capture/b-

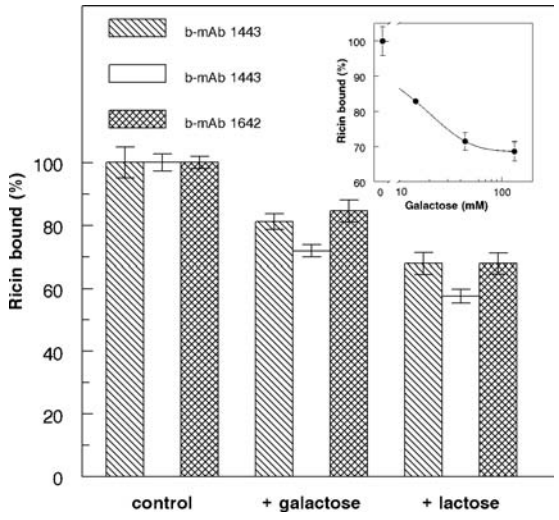

Figure 4. Effect of sugars on binding of 20 ng/mL ricin to mAb 1797, with b-mAb 1642 or b-mAb 1443. The cross-hatched bars illustrate results with ricin in KB, and the open bars illustrate results with ricin in BPT. (Inset) Galactose concentration dependence for ELISA in kinetics buffer with b-mAb 1443.

mAb detection sandwich ELISAs, but no significant sugar effects were observed (data not shown), suggesting that the inhibition observed with mAb 1797/b-mAb 1443 was epitope-dependent.

Studies Using BLI. To identify which steps in ricin binding to ASF and mAbs are affected by components of milk, we next determined rate constants for binding.

Ricin Binding to ASF. For these experiments, ASF was immobilized on AR sensor tips as ligand. The ricin analyte (1 μg/mL) was present in buffer or various types of milk (0.5%, v/v, in kinetics buffer), with or without prior dialysis versus PBS. The upper panel of Figure 5 shows the k_a values determined for ricin binding in four milk samples, undialyzed and dialyzed, and the lower panel of Figure 5 shows the dissociation constants. Multiple-sample comparison of the four control and four dialyzed milk samples indicated no significant differences among the means of either group of samples. For NFDM, the control sample k_a was significantly higher than the dialyzed ($p = 0.012$), but the difference was not significant for the other three samples. The values of k_d for all dialyzed fresh milk samples were lower than corresponding values for controls, but the difference was not significant for NFDM. Dialysis thus resulted in stronger binding of ricin in the fresh milk samples.

Ricin Binding to mAb 1797 in a BLI Sandwich Configuration. We wished to analyze ricin binding in BLI by mimicking ELISA conditions using the Octet biosensor. The first two layers of the "sandwich" were applied in turn as follows. Capture mAb 1797 was immobilized on AR sensors, and then sensors were moved to wells containing ricin in buffer with or without reconstituted NFDM (2%, v/v). After ricin binding, sensors were moved immediately to wells containing b-mAb 1443, for the upper layer of the sandwich, as for ELISA, although no secondary conjugate was used or needed in the BLI experiment that relied on the optical properties of the biolayer to provide a signal. The results are shown in Figure 6. Overall, the results indicate that ricin binds well to mAb 1797 in the presence or absence of milk, whether dialyzed against PBS or not. This is consistent with results that we reported[4] on the effectiveness of mAb 1797 as a capture antibody for ELISA

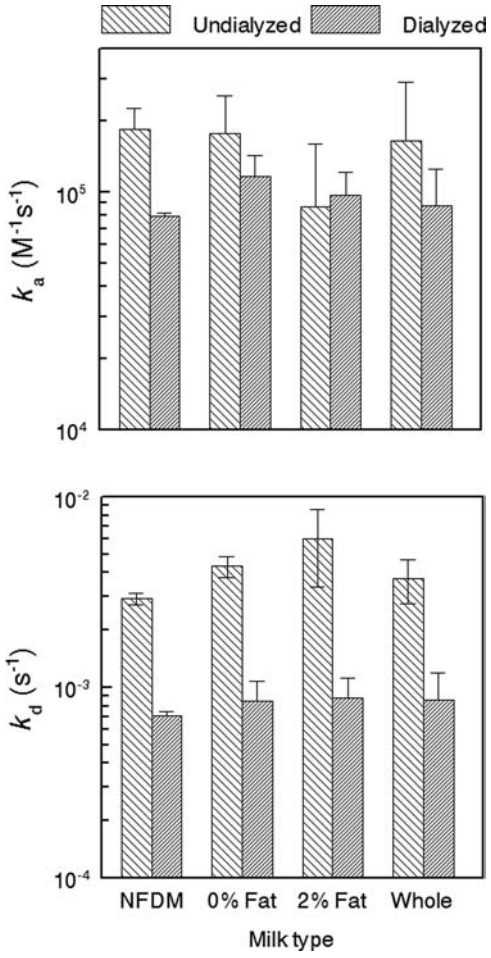

Figure 5. BLI analysis of ricin binding to ASF immobilized on AR sensor tips: (top panel) association constants, k_a, and (bottom panel) dissociation rate constants, k_d.

of ricin in food matrices. As in the ELISA, b-mAb 1443 is incubated in buffer, without milk, and is able to provide the upper layer of the sandwich on this platform. Once ricin is tightly bound to mAb 1797, it is available to bind b-mAb 1443. Ricin is thought to have three galactose-binding sites[28−30] and can therefore interact with ASF with much higher avidity than indicated by the relatively low association constants of individual sites. The higher affinity binding of mAb 1797 compared to ASF, even with lower probability of multiple site binding, overcomes the milk effect on dissociation of ricin from the antibody binding site.

Effect of Milk on Dissociation of Ricin from mAb 1797. The ELISA results above (Figure 3) indicated that milk inhibits the binding of ricin even in the "sequential" procedure. The effect of milk on dissociation of the ricin−mAb complex was studied using biotinylated mAb 1797 immobilized on SA sensors. To achieve greater accuracy near the limit of instrument sensitivity, this experiment included varying percentages of reconstituted NFDM in kinetics buffer during the dissociation step. These conditions were expected to minimize re-association of ricin with immobilized mAb, a procedure referred to as a sink method.[31]

Figure 7 shows the effect of analysis of ricin binding to mAb 1797 (b-mAb 1797 immobilized on SA sensor tips) in the absence or presence of milk. The association constant, k_a, was not affected significantly by the presence of milk, but the

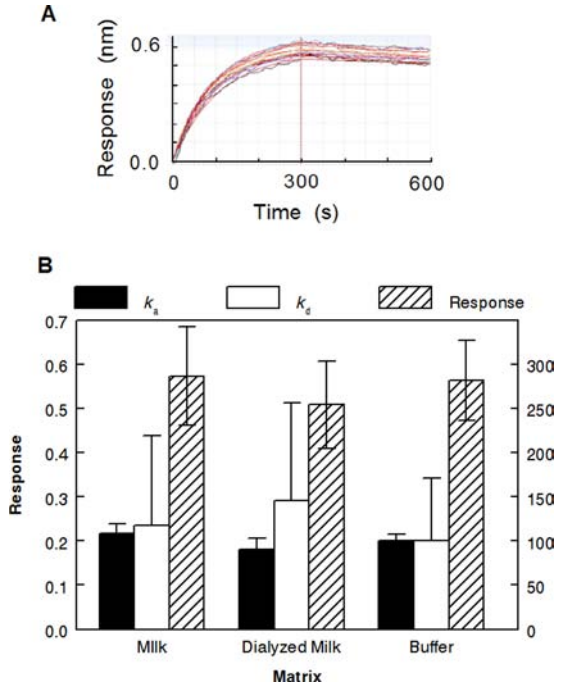

Figure 6. BLI analysis using a mAb sandwich: (A) typical sensorgrams from one set of experiments (ricin in dialyzed milk) and (B) response (biolayer thickness) and association and dissociation rates shown for three conditions.

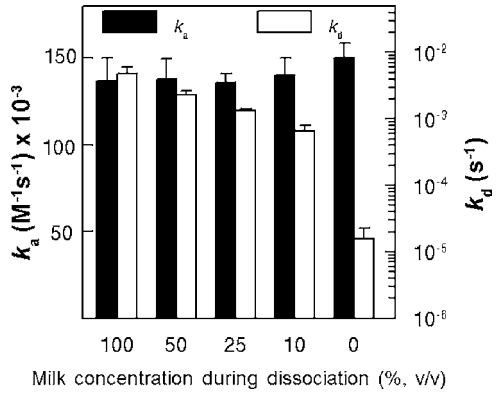

Figure 7. BLI analysis of ricin binding to b-mAb 1797 on SA sensor tips, with dissociation conducted under various conditions.

dissociation rate increased in the presence of milk. The multi-sample comparison test showed that the 50 and 100% milk samples were significantly different from the 0% control at the 95% confidence level, and the 25% sample was significantly different only at the 90% confidence level (Tukey's HSD test).

In this study, we demonstrated that the effect of milk on ricin binding to an antibody and a model receptor could be observed using BLI and ELISA, with complementary results. We also tested the use of a binding molecule as a "sink" to prevent the rebinding of analyte to a very high affinity ligand, mAb 1797. In this case, the sink was milk, a food. The "sink concept" in the context of well-based binding measurements refers to the use of a high-affinity ligand in solution that prevents rebinding of dissociated analyte to the sensing ligand.[31,32] The system can therefore emulate microfluidic-based systems that remove dissociating ligand from the sensor vicinity by flow. Because the antibody binding is fit well using a 1:1 binding model, this concept seemed relevant to the analysis of binding by mAb 1797. Even so, the contribution of divalent binding may also be significant, and increased dissociation in the presence of milk could result from abrogation of divalent binding. In either event, estimation of the dissociation rate constant was facilitated by the presence of a binder during dissociation. Although sensing techniques, such as BLI and surface plasmon resonance, use sophisticated, bulky instrumentation to measure optical properties of a surface that are influenced by the binding reactions in the "biolayer", miniaturized implementations of both sensor platforms have appeared in the marketplace. The practical use of these platforms in the field, in addition to the laboratory, will likely be realized in the near future, providing well-characterized, portable systems for detecting analytes that impact the safety and authenticity of the food supply. The results demonstrated that the effects of milk on the binding of ricin to carbohydrate receptors, as modeled by ASF, are mediated principally by dialyzable factors and that the use of high-affinity mAbs in ELISA mitigates the milk matrix effect on ricin analysis.

stress in the target organs, is one of the mechanisms by which Cd induces its toxicity.[18] Several investigations have reported that Cd induces oxidative stress and causes oxidative damage by interrupting the antioxidant defense systems.[20,21] Moreover, the antioxidant defense system consists of enzymes such as superoxide dismutase (SOD), glutathione peroxidase (GPx), and catalase (CAT)[20] that have vital roles in maintaining cellular homeostasis by eliminating ROS.[22] Chronic exposure to Cd results in an imbalance between oxidants and antioxidants of the cell tissues, revealing oxidative damage in the liver and kidney.[23]

However, less attention has been paid to assessing the bioavailability and toxicity of Cd in human cells using a complete chain (soil−rice−human) transfer of Cd.

The bioaccessibility, bioavailability, and toxicity of Cd from rice can be determined by in vitro methods. The development of an in vitro Cd bioavailability model technique that revives gastric and small intestinal digestion in humans, coupled with intestinal epithelial cells (Caco-2), presents an advanced physiological measure for assessing Cd bioavailability issues.[24] Caco-2 cells under suitable and controlled conditions can differentiate into polarized enterocyte-like monolayers. After differentiation, they develop microvilli and in several ways work similarly to small intestinal epithelial cells.[25] Evaluations by different laboratories showed that the expressions of transporters by Caco-2 cells monolayers and the small intestine were similar.[26] This in vitro model is currently considered as the best approach, in terms of cost and time, to investigate the bioavailability of different food components as a prelude to in vivo study.[27] In the present study, this model was used in combination with a HL-7702 cell model to assess the bioaccessibility, bioavailability, and toxicity of Cd from contaminated polished rice grain.

Few studies have investigated the bioaccessibility and bioavailability of heavy metals in vegetables.[16,24,28] To the best of our knowledge, this is the first study reporting the transfer of Cd from two soils of different texture to rice and subsequent effects on bioaccessibility, bioavailability, and toxicity in humans.

The objectives of this study were to (i) assess the impact of different textured soils on Cd accumulation in polished rice; (ii) examine the relationship of Cd in polished rice with Cd bioavailability in soil using a Caco-2 cell model; and (iii) confirm the maximum limit of Cd that does not cause toxicity in human liver cells using in vitro digestion coupled with Caco-2/HL-7702 cell models.

MATERIALS AND METHODS

Chemicals and Reagents. $Cd(NO_3)_2$ was purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Porcine pepsin, pancreatin, bile salts, and 3[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Dulbecco's modified Eagle medium (DMEM with glucose 4.5 g L^{-1}), trypsin−EDTA, phosphate-buffered saline (PBS), and fetal bovine serum (FBS) were purchased from Gibco Life Technologies (Grand Island, NY, USA). All enzyme testing kits were purchased from Nanjing KeyGen Biotech. Co., Ltd. (Nanjing, China). All reagents were prepared with deionized water (= 0.1 μS cm^{-1}) using a Milli-Q system (Millipore, Billerica, MA, USA).

Glass House Experiment, Sampling, and Analysis. *Soil Collection, Analysis, and Cd Spiking.* Two typical Chinese representative soils were used for investigation in this study. Samples of yellow (Periudic Argosols) soil and calcareous (Calcaric Regosols) soil were collected from the surface layer (0−20 cm) in Huzhou (119°14′−120° 29′ E; 30°22′−31°11′ N) and Ya'an counties (102°37′−103°12′ E, 29°23′−30°37′ N), respectively. The soils were air-dried and ground to pass through a 2 mm sieve. Both types of soil were analyzed for relevant physicochemical properties (Table 1).

Table 1. Selected Physical and Chemical Properties of the Soils

	yellow soil	calcareous soil
OM (g kg^{-1})	11.6 ± 0.72	21.8 ± 0.09
CEC (cmol kg^{-1})	12.05 ± 0.61	26.00 ± 1.34
pH	4.92 ± 0.06	8.11 ± 0.43
total N (g kg^{-1})	1.14 ± 0.07	1.46 ± 0.05
total P (g kg^{-1})	1.72 ± 0.08	1.00 ± 0.03
total K (g kg^{-1})	7.27 ± 0.19	9.53 ± 1.05
total Cd (mg kg^{-1})	0.47 ± 0.02	0.96 ± 0.03
total Zn (mg kg^{-1})	12.92 ± 0.85	33.9 ± 0.48
Fe(II) (mg kg^{-1})	25.4 ± 1.33	36.7 ± 2.18

Both soils were spiked with Cd as $Cd(NO_3)_2$ dissolved in an aqueous solution at loading rates of 2, 6, and 9 mg Cd kg^{-1} soil along with background value (CK). Distilled water was added to maintain soil moisture at 70% of its water-holding capacity. All of the Cd-spiked soil samples were aged for 1 year prior to usage for pot experiments and Cd analysis.

Glasshouse Experiment. A glasshouse experiment was conducted by growing rice (*Oryza sativa* L. var. Zhongzheyou 1) in pots during June−October 2012 at Zhejiang University, Hangzhou, China. Thirty-day-old seedlings were transplanted to plastic pots (20 cm diameter and 20 cm height). Each pot contained 5 kg of soil. All tests were conducted in triplicate under a completely randomized design. Fertilizers were applied (per pot) at rates of 180.5 mg of N (70% applied as the basal dose and 30% as the topdressing at the panicle initiation stage), 65.7 mg of P_2O_5, and 92 mg of K_2O.

Rice Sample Preparation. Plants were harvested at maturity and oven-dried at 65 °C for 45 h. Rice samples were manually threshed to separate rice grains. The biomass was determined by measuring the dry weight of grains. Brown rice was obtained by removing the husk using a laboratory dehusker (JLGJ4.5, Taizhou Cereal and Oil Instrument Co. Ltd., Zhejiang, China), which was then developed to polished rice using a laboratory polishing machine (JNMJ3, Taizhou Cereal and Oil Instrument Co. Ltd.). The polished rice sample was ground using a ball mill (Retsch, MM-301, Germany) and passed through a 60-mesh sieve and then kept at −20 °C prior to Cd analysis. Subsamples of the rice were cooked for 15−20 min with 1:2 rice/deionized water (w/v). The cooked rice sample was homogenized in a polytron homogenizer, and the homogenate was frozen and lyophilized before testing via the in vitro digestion/Caco-2/HL-7702 cell model.

Chemical Analysis. *Total Cd in Soil and Rice Grain.* A 0.20 g soil sample was digested with $HNO_3/HClO_4/HF$ (5:1:1). Similarly, 0.2 g of each rice sample was digested with HNO_3/H_2O_2 (4:1). The digested solution was transferred to a 25 mL volumetric flask, and the volume was made up with deionized water and filtered. Concentration of Cd in the filtrate was determined using inductively coupled plasma-mass spectrometry (ICP-MS, Agilent 7500a, Agilent Technologies, Santa Clara, CA, USA).

Cadmium Bioavailability and Toxicity Assays. *In Vitro Digestion of Rice Sample.* The method of Wei et al.[29] was used for in vitro digestion of rice samples. Briefly, 15 mL of mixed solution of 140 mM NaCl and 5 mM KCl was added to 5 g of cooked rice powder, and the pH was adjusted to 2.0 with 6 M HCl. For gastric digestion, 0.5 mL of pepsin (0.2 g of pepsin in 5 mL of 0.1 M HCl) was added, and the sample was incubated at 37 °C in a shaking water bath for 2 h. Before gastrointestinal digestion, the pH of the digester was raised to 5.0 with 1 M $NaHCO_3$ solution, 2.5 mL of pancreatin−bile solution (0.45 g of bile salts and 0.075 g of pancreatin in 37.5 mL

DOI: 10.1021/jf505557g
J. Agric. Food Chem. 2015, 63, 3599−3608

of 0.1 M $NaHCO_3$) was added, and the mixture was again incubated in a shaking water bath for 2 h at 37 °C. The sample was cooled in an ice bath for 10 min, and then the pH was adjusted to 7.2 with 0.5 M NaOH. The intestinal digester was heated for 4 min at 100 °C in a water bath to inhibit protease. The gastrointestinal digester was then cooled on ice and centrifuged at 3500*g* for 1 h at 4 °C. Then supernatant was transferred and pooled. Prior to the addition of rice soluble fraction to the cells, glucose (5 mM) and HEPES (50 mM) were added to the soluble fraction to make it similar to the culture media.

Cell Culture. The Caco-2 cells and HL-7702 cells were obtained from the Institute of Biochemistry and Cell Biology (SIBS, CAS, Shanghai, China) and used in assays at passage 20−41. Both cells were normally cultured in 25 cm^2 flasks (Corning Inc., Corning, NY, USA) and maintained in high glucose (4.5 g L^{-1}) DMEM, supplemented with 20% (v/v) heat-inactivated fetal bovine serum, 1% (v/v) nonessential amino acids, 4 mM L-glutamine, and 1% (v/v) and antibiotics (complete medium). The cells were incubated in a cell culture incubator (Heraeus, BB15, Germany) at 37 °C, 5% CO_2 in a humidified atmosphere, and the medium was changed every 48 h. Monolayers were subcultured with 7 and 4 day passage frequencies for Caco-2 cells and HL-7702 cells, respectively, by treatment with 0.25% trypsin−EDTA solution. For the Caco-2 cell model, 5×10^4 cells cm^{-2} in 1.5 mL of complete DMEM was seeded in permeable polycarbonate filters (24 mm diameter, 0.4 μm pore size, Costar Corp.), and 2.5 mL of complete DMEM was added in the basal compartment. For Cd toxicity assays HL-7702 cells were seeded in 6-well culture plates (Costar Corp.) at a density of approximately 5×10^3 cells/well. The medium was changed every 2 days, and the Caco-2 and HL-7702 cell cultures were maintained for 21 and 10 days to reach the stationary growth phase and to allow for maximal functional differentiation. Subsequently, the integrity of the Caco-2 cell monolayer was checked by measuring transepithelial electrical resistance (TEER) using a Millicell-ERS meter (Millipore Corp.) according to the manufacturer's protocols. Only those filters that had TEER values >250 Ωcm^2 at the beginning and the end of the experiment were included. The monolayer used in this study exhibited adequate TEER values of 520−610 Ωcm^2.

Cadmium Uptake Experiment in Caco-2 Cell. Before the Caco-2 uptake experiment, the growth medium was removed from each transwell and the Caco-2 cell layer was washed twice with phosphate-buffered saline (PBS) at a temperature of 37 °C and pH 7 to remove any unattached cells. Then 2.5 mL of standard transport solution (130 mM NaCl, 10 mM KCl, 1 mM MgSO4, 5 mM glucose, and 50 mM HEPES, pH 7.4) was added into the basolateral compartment, and the apical compartment was filled with 1.5 mL of rice soluble fraction. Cell cultures were incubated for 2 h at 37 °C, 5% CO_2, and 95% relative humidity.[29] After 2 h of incubation, basolateral compartments were collected to determine the Cd transport across the monolayer, and part of it was used to check the toxicity in the HL-7702 cells. In the apical chamber cell monolayer was washed with PBS to remove nonspecifically bound mineral and residual medium. The cells were lysed by the addition of 1 mL of deionized water in the well and then harvested.

The concentrations of Cd in cell retention (Cd fraction in the Caco-2 cell monolayer), the transport solution (Cd collected from basolateral compartment), and the gastrointestinal digestion solution (soluble added) from cooked rice sample were determined using the ICP-MS. Bioaccessibility of Cd was analyzed according to the method of Oomen et al.,[30] as follows:

$$\text{bioaccessibility \%} = \frac{\text{Cd mobilized from rice sample during digestion } (\mu g)}{\text{Cd present in rice sample before digestion } (\mu g)} \times 100\%$$

Cadmium Toxicity Assays in HL-7702 Cells. To assess the toxicity of Cd, HL-7702 cells cultured in 6-well plates were exposed to the transport solution from Cd uptake experiment for 3 h at 37 °C, 5% CO_2, and 95% relative humidity.[31] Hereafter, the cells were washed two times with PBS to remove extracellular bound Cd. The cell monolayer was lysed by the addition of 1 mL of 0.25% trypsin−EDTA in the well and then harvested. Cytological and biochemical assays were carried out on the cell lysate and culture medium for determination of markers of cell damage and TEM.

Cytotoxicity Assay. *MTT Assay.* Cytotoxicity induced by Cd was assessed by MTT assay. Exponentially growing HL-7702 cells were trypsinized and plated at 5×10^4 cells per well in 96-well plates overnight to allow attachment. Cell cultures were treated with different transport solutions from Cd uptake experiment for 3 h at 37 °C. Control groups consist of cells in media, which are processed identically and incubated simultaneously as treated groups. Following exposure, cells were incubated with MTT at 5 mg mL^{-1} for 4 h at 37 °C. Then the medium was replaced with 100 μL of DMSO agitated for 10 min at room temperature. Absorbance was measured at 570 nm using a microplate spectrophotometer system (Bio-Rad-680, Bio-Rad, Hercules, CA, USA). Cell viability was expressed as a percentage of the control group. Cell MTT response (percent of control) was calculated by using the following equation:

$$\%\ \text{of control} = \frac{\text{absorbance}_{\text{treatment}}}{\text{absorbance}_{\text{control}}} \times 100\%$$

LDH Release. Cadmium cytotoxicity in HL-7702 cells was also assessed by LDH release into the culture medium after 3 h of exposure to Cd containing transport solution. The LDH release into the culture medium was determined with a commercially available kit (Jiancheng Biochemical Co., Ltd., Nanjing, China). The change in absorbance was recorded at 440 nm using a microplate spectrophotometer system (Bio-Rad-680). LDH release (percent of control) was calculated from the equation

$$\%\ \text{of control} = \frac{(\text{U LDH/mg of cell protein})_{\text{treatment}}}{(\text{U LDH/mg cell protein})_{\text{control}}} \times 100\%$$

Enzyme Assays. The HL-7702 cell antioxidant (SOD, GPx) and oxidant (H_2O_2) enzyme and lipid peroxidation (MDA) activities were measured using respective cellular activity assay kits (Jiancheng Biochemical Co., Ltd.). SOD and GPx activities were expressed in terms of international units per mg cell protein. MDA and H_2O_2 enzyme activities were expressed as nanomoles per milligram of cell protein and millimoles per milligram of cell protein, respectively. The HL-7702 cell protein was determined using a semimicro adaptation of the Bio-Rad DC protein assay kit (Bio-Rad Laboratories) according to the manufacturer's instructions.

Transmission Electron Microscopy. To morphologically observe the alterations in Cd-contaminated HL-7702 cells, an ultrastructural analysis was performed following the procedure of Charqui et al.[32] Following Cd treatment, HL-7702 cells were harvested and fixed overnight in 4% (v/v) glutaraldehyde 0.1 M PBS and post fixed in 1% (v/v) osmium tetroxide for 1 h. Samples were then dehydrated by treating with a graded series of ethanol followed by acetone. Then samples were rinsed and impregnated with Spurr's resin overnight. The ultrathin sections were prepared and mounted on copper grids for viewing in a transmission electron microscope (JEOL TEM-1230EX) at an accelerating voltage of 60.0 kV.

Quality Control of Cadmium Analysis. Standard reference material (soil GSBZ 50013-88 and rice flour NCSZC 73008), approved by General Administration of Quality Supervision, Inspection and Quarantine of the People's Republic of China (AQSIQ), were used to check the accuracy of Cd analysis. The analytical results showed that the recoveries for SRMs were nearly 98 and 102.3%, respectively, and the precision and bias of the analysis were generally <5% for Cd.

Statistical Analysis. Data were analyzed using SPSS software version 18.0 (SPSS Inc., Chicago, IL, USA). Analysis of variance (ANOVA) was applied, with the least significant difference (LSD) test as a post hoc test, to compare the various means of different treatments in each series of experiments. Means were considered to be significantly different if the P value was smaller than 0.05 ($P < 0.05$).

RESULTS

Physicochemical Properties of Soils. Soils used in this study varied widely in their physicochemical characteristics (Table 1), which could influence the accumulation of Cd in rice grain. Total Cd and Zn concentrations (background value) in the YS were 0.47 and 12.92 mg kg^{-1}, whereas for CS, 0.96 and 33.9 mg kg^{-1}, respectively. Soil pH ranged from 4.92 for the yellow to 8.11 for the calcareous, namely, strongly acidic to mildly alkaline. The total organic matter was 11.6 g kg^{-1} in yellow and 22.6 g kg^{-1} in calcareous soil. The cation-exchange capacity (CEC) ranged from 12.05 cmol kg^{-1} for the yellow to 26.0 cmol kg^{-1} for the calcareous soil. Fe(II) in soil (background value) ranged from 25.4 to 36.7 mg kg^{-1} in yellow and calcareous soils, respectively.

Yield of Rice Grain. As compared to the control (nonspiked soils), rice grain yield appeared to increase at a low level of Cd (<2 mg kg^{-1}) in both soils, but the differences in grain yield were not statistically significant. The grain yield in YS decreased significantly at Cd loadings of 6 and 9 mg kg^{-1}, whereas in CS yield did not differ at all with Cd loading rates. Dry weights (DWs) of rice grain in relation to external Cd loading rates are summarized in Table 2.

Table 2. Effect of Cd Loading on Dry Weight (Grams per Pot) of Rice Grown in the Two Soils

Cd loading (mg kg^{-1})	YS[a]	CS[a]
CK	30.31 ± 0.76a	47.68 ± 1.97a
2	30.90 ± 0.58a	46.48 ± 2.32a
6	25.37 ± 0.73b	48.28 ± 1.22a
9	18.44 ± 1.68c	45.93 ± 2.70a

[a]YS refer to yellow soil and CS to calcareous soil. The results are expressed as the mean ± SD with three replications. Values within a column followed by a different letter are significantly different at $P < 0.05$.

Cd Concentration in Polished Rice Grain. The concentration of Cd in polished rice grain was significantly affected by soil type and increased with increasing external Cd loading (Figure 1). Cd concentration in rice was in the order straw > husk > polished rice and ranged from 0.98 to 86.11 mg kg^{-1}, from 0.26 to 22.48 mg kg^{-1}, and from 0.18 to 14.22 mg kg^{-1}, respectively. Cadmium accumulation in different rice parts was found to be significantly different due to the difference in Cd phytoavailability between the two soil types.

Bioaccessibility of Cd in Polished Rice Grain. The amount of Cd solubilized after in vitro digestion is an indicator of bioavailability. Increasing Cd loading rate had a significant effect on Cd bioaccessibility (Figure 2). Cadmium bioaccessibility in YS and CS rice ranged from 18.45 to 30.41% and from 6.89 to 11.43%, respectively. A significant increase was found in Cd bioaccessibility of polished rice from both soils at the higher loading rates (6 and 9 mg kg^{-1}) as compared to the control. These results suggest that most of the cadmium in CS rice at lower treatment levels remains nonbioaccessible and will not cause adverse health effects to local residents. However, in YS rice a considerable amount of cadmium was released during the in vitro digestion process.

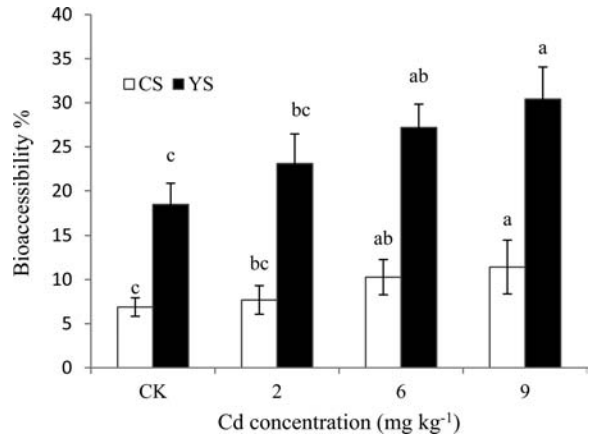

Figure 2. Effect of different Cd loading rates on bioaccessible fractions of Cd expressed as a percentage of the total concentrations in the polished rice grain. YS refers to yellow soil and CS to calcareous soil. The results are expressed as the mean ± SD with three replications. Different letters indicate significant differences at $P < 0.05$ as calculated by the least significant difference (LSD) test.

Cd Bioavailability of Polished Rice. Cd concentration in the bioaccessible fraction added to Caco-2 cells (soluble added), in cell monolayer (retention), basal medium (transport), and percentages of uptake are shown in Table 3. The

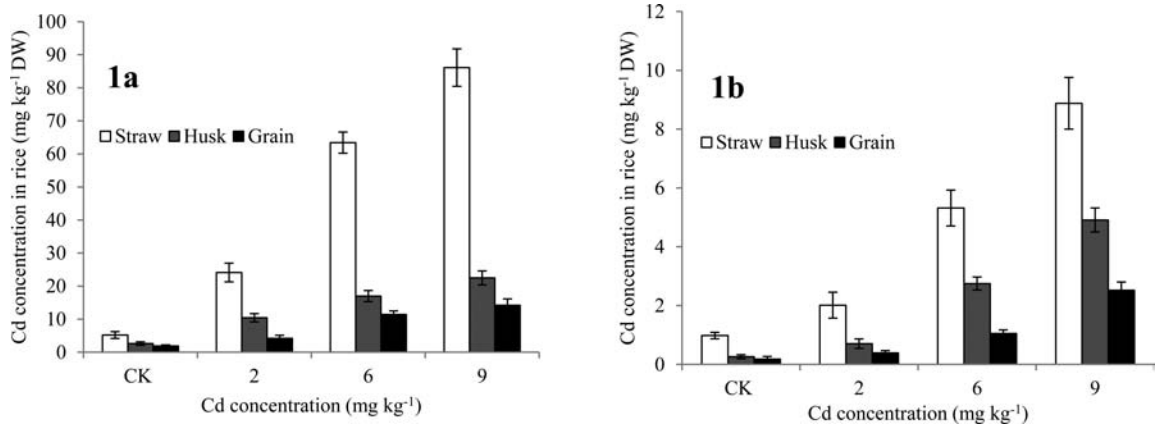

Figure 1. Cadmium concentration (mg kg^{-1} DW) in polished rice grain grown under different Cd loading rates in YS (a) and CS (b). The results are expressed as the mean ± SD. Different letters indicate significant differences at $P < 0.05$ as calculated by the least significant difference (LSD) test, $n = 3$. YS refers to yellow soil and CS to calcareous soil.

[a]Results are expressed as the mean ± SD, $n = 3$. Values for each soil within a column followed by a different letter are significantly different at $P < 0.05$, as calculated by the least significant difference (LSD) test. Retention % or transport % is the percentage of Cd retention or transport in the total amount added (soluble added) Cellular uptake is calculated as [(retention + transport)/total Cd amount added to cell culture (soluble added)] × 100.

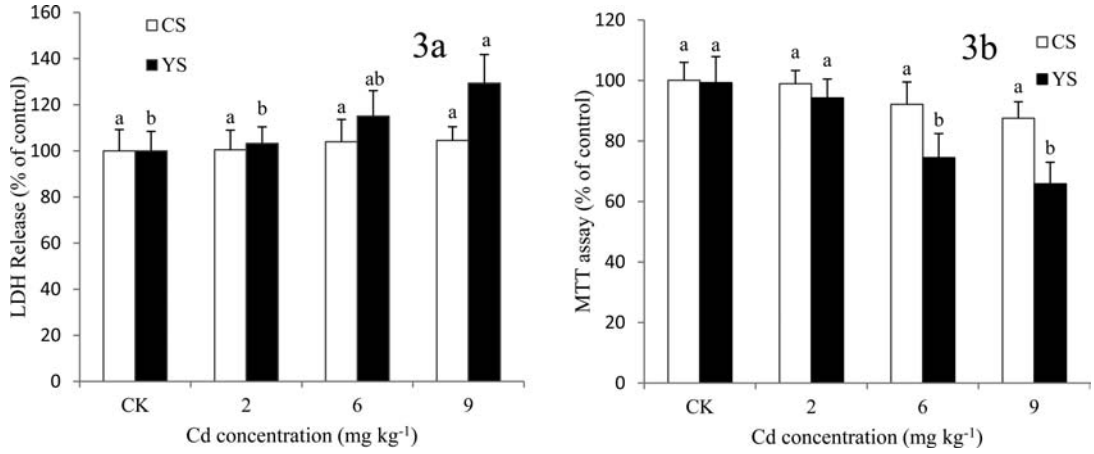

Figure 3. Effect of Cd loadings on LDH release (a) and MTT viability assay (b) in HL-7702 cells. Results are expressed as the mean ± SD. Different letters indicate significant differences at $P < 0.05$ as calculated by the least significant difference (LSD) test, $n = 3$.

[a]YS refers to yellow soil and CS to calcareous soil. Results are expressed as the mean ± SD, $n = 3$. Values within a row followed by a different letters are significantly different at $P < 0.05$, as calculated by the least significant difference (LSD) test.

results indicate that there were differences between the polished rice grains grown on two different soil types.

In the cell monolayer (retention), Cd concentration significantly varied from 0.25 to 6.61 μg and from 0.01 to 0.14 μg in YS and CS rice, respectively. Cadmium concentration in transport solution was increased, from 0.10 to 2.71 μg and from 0.00 to 0.02 μg, respectively, for YS and CS. Increasing Cd concentrations in the soluble fraction affected the percentages of Cd retention, transport, and uptake in YS rice, whereas for CS rice the percentages did not differ significantly from the control. Expressing retention, transport, and uptake of Cd calculated as percentage of the amount initially added revealed that in YS and CS rice, Cd retention (2.88−6.11 and 1.61−1.94%), transport (1.15−2.51 and 0.16−

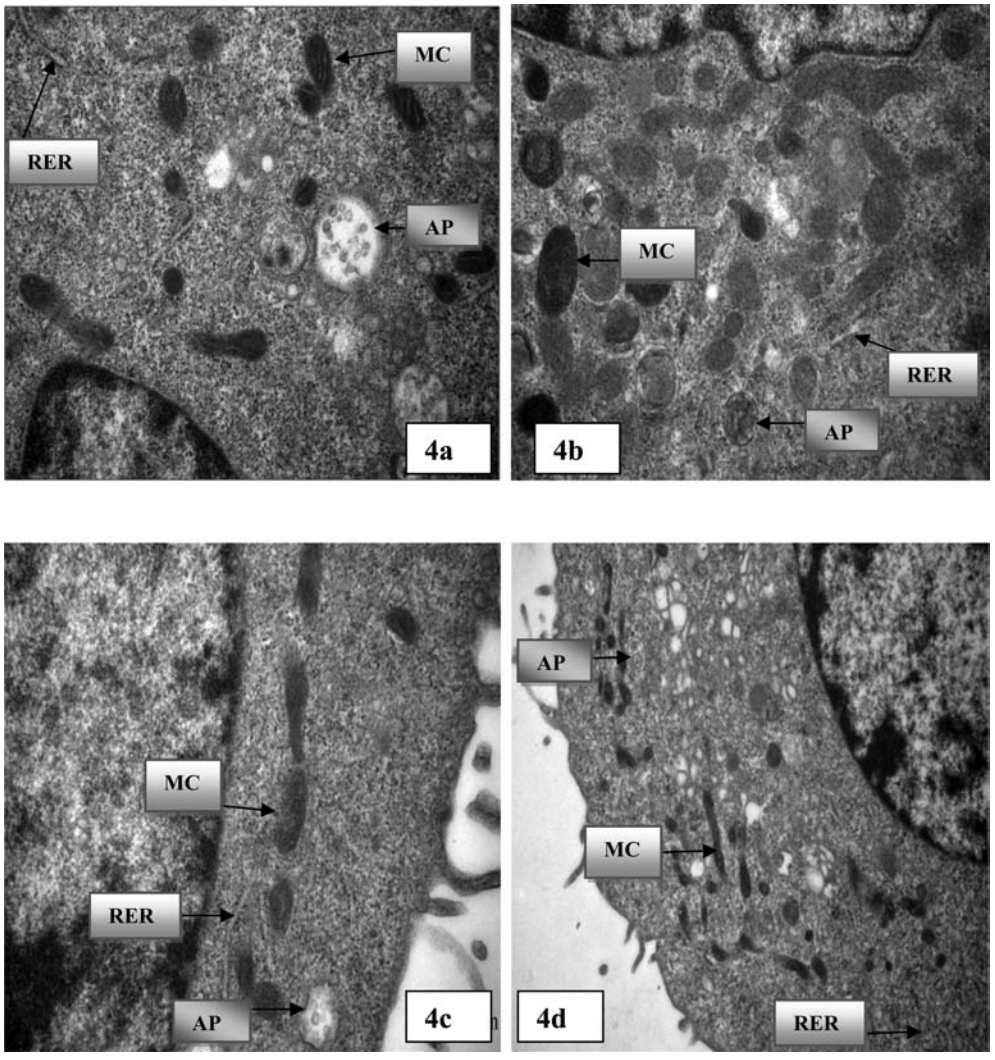

Figure 4. Electron microscopic graphs of HL-7702 cells: (a, b) TEM microscopic graphs of HL-7702 cells of YS at the control (CK) and Cd 9 mg kg^{-1} levels, respectively; (c, d) TEM microscopic graphs of HL-7702 cells of CS at the control (CK) and Cd 9 mg kg^{-1} levels, respectively. MC, mitochondria; RER, rough endoplasmic reticulum; AP, autophagy. YS refers to yellow soil and CS to calcareous soil.

0.31%), and uptake (4.04−8.62 and 1.77−2.25%) varied largely due to contrasting properties of the two soils.

Effect of Cadmium on Cytotoxicity Assays (LDH Release and MTT Viability Assay). To first establish the optimal experimental conditions for characterizing the effects of Cd on the human liver, HL-7702 cell membrane stability and viability were measured using LDH release and MTT assay as a function of increasing Cd concentrations in the transport solution. Statistical analysis of cytotoxic activities showed that Cd from CS rice did not have a significant effect on LDH release and MTT assay, but YS rice grown at Cd level >2 mg kg^{-1} significantly affected both LDH release and MTT assay. It was found that increasing Cd levels increased the LDH release in HL-7702 cells (Figure 3a) in CS and YS rice by 4 and 30%, respectively. The MTT assay to monitor the effects of different Cd concentrations transported from Caco-2 cells revealed that Cd from YS and CS rice suppressed cell stability by 12.47 and 34.14%, respectively (Figure 3b). A comparison of the two cytotoxicity assays showed that the LDH leakage assay was less sensitive than the MTT assay. However, both cytotoxicity assays showed initial cytotoxicity at the 6 mg kg^{-1} Cd level in YS rice (Figure 3).

Effect of Cadmium on Lipid Peroxidation and Enzymes (Oxidant + Antioxidant) Activities in HL-7702 Cells. The results for lipid peroxidation (MDA), oxidant (H_2O_2), and antioxidant (SOD, GPx) enzyme activities in normal human liver cells (HL-7702) due to Cd transported from Caco- 2 cells are shown in Table 4.

It was found that lipid peroxidation (MDA) in YS and CS rice was increased by 11.3 and 4%, respectively, from its respective control. As can be observed in the case of oxidant enzyme (H_2O_2), the YS and CS rice had a significant increase in H_2O_2 activity (by 19 and 2.66%, respectively, as compared to the control). The results showed that SOD activities in the YS and CS rice had decreases of 35 and 11%, whereas for GPx the decreases were about 30 and 13%, respectively, as compared to the control. In YS rice all toxicity assays showed a statistically significant effect at a Cd loading rate of 6 mg kg^{-1}. There was, however, no significant effect on lipid peroxidation and both enzyme activities on CS rice, indicating that a small amount of Cd transported from Caco-2 cells does not result in toxicity in HL-7702 cells.

Effect of Cd Stress on Ultrastructural Changes in HL-7702 Cells. Indeed, low doses (<1.55 μg) of Cd did not induce

DOI: 10.1021/jf505557g
J. Agric. Food Chem. 2015, 63, 3599−3608

apoptosis and toxicity in vitro in HL-7702 cells, as revealed by cytotoxicity assays and enzyme assays. A deeper understanding of Cd hepatotoxicity requires the identification of its intracellular localization and targets.

The TEM microscopic graphs of HL-7702 cells under CK and 9 mg kg^{-1} Cd stress from YS and CS rice are shown in Figure 4. As revealed by TEM microscopic graphs, the untreated (CK) HL-7702 cells exhibited large nuclei, surrounded by cytoplasm with healthy-looking mitochondria containing visible cristae, visible RER with attached granules, and autophagosome in their natural shape (Figure 4a,c). In YS rice treated cells (at the Cd rate of of 9 mg kg^{-1}) we found that Cd treatment promotes autophagy and swelling in mitochondria and rough endoplasmic reticulum. Cristae were not visible in mitochondria (Figure 4b). In CS rice TEM microscopic graphs of HL-7702 cells at the 9 mg kg^{-1} Cd level (Figure 4d) did not show any clear ultrastructural change in comparison to the control.

DISCUSSION

Significant amounts of Cd have been added and will continue to be added to the soils globally due to anthropogenic activities. Cadmium, a very toxic element, is of primary concern in soil and food contamination, particularly in rice cropping systems[33] as rice is the major crop that supplies food to a large portion of world population.[34] Therefore, rice grown on a Cd-contaminated soil has been an issue of human health concern. The present work is an attempt to improve our understanding about the health risk posed to humans from Cd accumulation in rice.

In the present study, it was observed that the yield of rice was not significantly decreased by Cd loading in CS, whereas in YS the rice yield was significantly decreased at the external Cd loading rates of 6 and 9 mg kg^{-1}. The observed effect of Cd on rice yield can be attributed to the adverse effects of Cd on physiological and biochemical functions in plants. Different mechanisms can explain this stimulatory effect of Cd on rice yield; for instance, metal ions may simulate the enzyme(s) activation in cytokinin metabolism, which enhances plant growth,[35] and a lower level of metal exposure may cause alterations in cytokinins and plant hormones that control the growth and development of plants.[36] Kaminek[36] found that cytokinins may delay senescence by maintaining photosynthetic activity and producing chlorophyll in plant leaves. However, previous studies also revealed that Cd could suppress plant growth by interfering with metabolic processes, inhibition of the proton pump, reduction of root elongation, and damage to photosynthetic machinery.[37,38] These results are in agreement with Rafiq et al.,[9] who observed that Cd at 8 mg kg^{-1} decreased polished rice grain yield by 11.7−168.5%, depending on soil type.

Cadmium loading at different rates significantly affected its accumulation in polished rice grains. Phytoavailability of Cd is related to soil properties, aging, and rate of Cd applied. Physicochemical characteristics of soil affected phytoavailability of Cd.[39] For example, changes in pH affect the sorption of Cd by soils and thereby its concentration in soil solution.[40] Rafiq et al.[9,39] stated that the Cd content of rice grain was highly dependent upon the soil pH, being highest at pH 4.85. An increase in soil pH decreases Cd concentration in soil solution or reduces it phytoavailability.[41] Other factors including exposure time, soil texture, and organic matter contents in soil also influence phytoavailability of Cd in soil.[9,39]

The bioaccessibility of Cd in polished rice grain was evaluated by simulated gastrointestinal digestion followed by a measurement of soluble Cd in the digester and thus covered only the first phase of the overall Cd absorption process. The soluble fraction obtained from the gastrointestinal digestion was used to carry out retention and transport experiments in Caco-2 cell models, and the transport solution was used to carry out the Cd toxicity experiment in the HL-7702 cell model. Both of these models offer a more physiological tool for determining Cd bioavailability and toxicity in food matrices, particularly when combined with a simulated digestion step. Cd bioaccessibility ranged from 6.89 to 30.41% for the rice investigated. These values are in the range reported by previous studies.[24,28,42,43] Our results are in agreement with Intawongse and Dean,[28] who observed a higher bioaccessibility for Cd and reported that it can be found in the gastric phase or the small intestinal phase depending on Cd concentration in a vegetable and the vegetable species. The metal bioaccessibility of food is controlled by many factors, such as microfibers of crystalline cellulase and phytates, phytochelatins, nutritional characteristics, and microbial processes.[44−46] The bioavailability of Cd (total uptake) from polished rice ranged from 1.77 to 8.62%, which is concordance with the previous reports.[24,42] The results indicated that soil type and Cd concentration in the soluble fraction had a significant effect on Cd bioavailability by Caco-2 cells. A possible explanation for the concentration-dependent Cd bioavailability in our study might be its chemical and physical properties related to essential metals such as iron (Fe) or zinc (Zn), which aid Cd transport and uptake in the cells by "ionic and molecular mimicry".[47] Whenever there is a deficiency of these essential elements, Cd absorption and toxicity are enhanced. Reeves and Chaney[48] reported that the association between subsistence rice population and food chain Cd disease may be linked to Fe and Zn deficiency commonly found in these rice-based diet consuming populations. The soils used in this study also supported this possibility as concentrations of Zn and Fe are lower in YS than in CS, which ultimately enhanced the bioavailability of Cd from rice grown in YS. Our findings suggest further investigations to assess the turnover pool of Cd in Caco-2 cells with marginal concentrations of iron and zinc. Regardless of soil type, our results indicated that rice from both soils had higher Cd retention percentages than transport. This finding is also in accordance with Zalups and Ahmed,[49] who reported that intestinal absorption of Cd is characterized by a rapid rate of metal accumulation within the intestinal mucosa and a low rate of diffusive transport into the circulatory system.

The main objective of the present study was to assess the toxicity of Cd in rice from YS and CS. The cytotoxicity assays revealed different profiles. In YS rice the MTT assay was more sensitive, which showed initial cytotoxicity at the Cd rate of 6 mg kg^{-1}, whereas the LDH leakage assay revealed Cd toxicity at a higher external loading rate (9 mg kg^{-1}). However, CS rice did not show any significant difference at all Cd levels for both cytotoxicity assays. The possible explanation can be that relatively low Cd concentrations (<1.55 μg) might enhance cell proliferation in a dose-dependent manner,[50] whereas at higher concentrations (>1.55 μg) Cd could induce apoptosis in many tissues, organs, and cells.[51,52] This finding is well in line with the result of Fotakis and Timbrell,[31] who compared the four in vitro cytotoxicity assays and found that only the MTT assay showed initial toxicity in HTC cells after 3 h of exposure to different Cd concentrations. This differential sensitivity can be

DOI: 10.1021/jf505557g
J. Agric. Food Chem. 2015, 63, 3599−3608

explained by the different nature of each assay. The LDH leakage assay is based on the release of the enzyme into the culture medium after cell membrane damage, whereas the MTT assay is mainly based on the enzymatic conversion of MTT in mitochondria.[31] It is thought that inhibition of the mitochondrial respiration induces active oxygen related cell death. Reactive oxygen species generated within the mitochondria can also damage mitochondrial components,[53] and therefore a cytotoxicity assay based on mitochondrial respiratory activity would give early signs of toxicity following exposure to a mitochondrial toxicant.

Cadmium-induced cytotoxicity is known to be intimately related to the generation of oxidative stress, so we have examined the lipid peroxidation (MDA), oxidant (H_2O_2), and antioxidant (SOD, GPx) effects of Cd in HL-7702 cells. The results clearly indicated that Cd at high concentrations (>1.55 μg) induced oxidative (MDA, H_2O_2) stress by inhibiting antioxidant (SOD, GPx) enzyme activities in human liver cells (HL-7702). These results are in agreement with Cuypers et al.,[54] who reported that Cd can induce oxidative stress via the inhibition of antioxidants. The production of oxidants as well as the protection against them is intrinsic to every living cell.

MDA, a well-known indicator of lipid peroxidation and oxidative stress, has been reported to increase in the liver and kidney upon exposure to Cd.[19] A statistically significant increase in MDA activity in YS rice due to Cd stress indicated oxidative stress in HL-7702 cells. These results are well in line with the previous findings.[51,55] The Cd-induced lipid peroxidation mechanism is multidirectional and may involve a decrease in the level of glutathione and the total pool of sulfhydryl groups and changes in the activities of antioxidant enzymes. Because Cd causes lipid peroxidation in numerous tissues both in vivo and in vitro,[56] it has been suggested that Cd may be able to initiate oxidative stress by producing hydroxyl radicals[57] and hydrogen peroxide.[53] Moreover, it has been shown that several oxidants and antioxidant defense systems protect cells from Cd-induced toxicity.[16]

To minimize oxidative damage, organisms have developed antioxidative mechanisms triggered by an increased ROS production. Oxidants such as ROS are balanced against this antioxidative defense system that consists of enzymes and metabolites in all subcellular compartments.[58] SOD and GPx are important antioxidant enzymes that protect against oxidative stress via elimination of ROS. Physiologically, SOD converts O_2 to H_2O_2 and thus protects against superoxide-induced damage.[59] GPx, in particular, is highly dependent on glutathione concentration. According to our findings, the major toxic effects of increasing doses of Cd involve decreased antioxidant enzyme levels. In our previous study we observed that Cd at 10 mg L^{-1} decreased the SOD and GPx activities in HL-7702 cells by 58 and 80.3%, respectively, which showed that Cd from salt solution had more toxic effects on HL-7702 cells than Cd transported from the rice soluble fraction.[51] These results agreed with previous studies.[55,60] According to Arroyo et al.,[61] Cd decreases the activity of antioxidant enzymes such as SOD, CAT, glutathione reductase (GR), and GPx. Moreover, Cd may increase the amount of free Cu and Fe ions that can promote oxidative stress via the Fenton reaction.[61] By these ways, Cd induces a pro-oxidative state in biological systems, resulting in the overproduction of ROS such as superoxide anion (O_2), hydroxyl radical (OH), and hydrogen peroxide (H_2O_2).

This study concludes that soil characteristics greatly influenced the bioavailability of Cd to rice and ultimately to Caco-2 cells. By selecting the proper soil type for rice cultivation, we may be able to avoid the dietary toxicity of Cd. This study also raises the possibility of a simple soil remediation method such as phytoextraction by using the coculture of Cd hyperaccumulator plants and rice, especially in acidic soils, to prevent further Cd disease. The results demonstrated that Cd is able to initiate oxidative stress and cell damage in human liver cell lines (HL-7702) when its transported concentration exceeds 1.55 μg. An effort was made to estimate the Cd bioavailability and toxicity in human (Caco-2, HL-7702 cells) from rice grown on Cd-contaminated soils, but further research to investigate the biochemistry and mechanism involved in the bioavailability and toxicity of Cd from rice would help resolve remaining questions and establish proper therapeutic approaches for acute and chronic intoxication of Cd.

MATERIALS AND METHODS

Reagents and Materials. Solid standard of OTA was purchased from Sigma-Aldrich (Milan, Italy). The stock solution (1 mg/mL) was prepared by weighing 1 mg of the toxin that was dissolved in 1 mL of toluene/acetic acid (99:1, v/v). To assess the exact concentration of the OTA stock solution, an aliquot was evaporated to dryness, redissolved in methanol at concentration of about 10 μg/mL, and spectrophotometrically tested (ε = 6330 cm^2/mmol, at λ = 332 nm). Standard solutions of OTA for HPLC calibration or spiking purposes were prepared by dissolving adequate amounts of the stock solution, previously evaporated to dryness under nitrogen stream, in the HPLC mobile phase. Acetonitrile, methanol, water (HPLC grade), and glacial acetic acid were purchased from Mallinckrodt Baker (Milan, Italy).

Sodium chloride (ACS grade), polyethylene glycol (PEG 8000), and sodium hydrogen carbonate ($NaHCO_3$, ACS grade) were purchased from Sigma-Aldrich. OchraTest immunoaffinity columns were purchased from Vicam (Watertown, MA). Filter paper and GF/A glass microfiber filters were obtained from Whatman (Maidstone, U.K.).

Commercial Samples. Commercially available PFS, food coloring agents, and leavening agents containing tartrates, all derived from *V. vinifera*, were purchase from retail stores in Bari province (Italy) or via the Internet for a total of 41 samples. The dose forms of PFS were tablet (seven samples), powder (three samples), solution (two samples), ampule (two samples), comfit (one sample), syrup (one sample), or capsule (eight samples). Food coloring agents were as powder (six samples) or liquid (seven samples), whereas the leavening agents containing tartrates (four) were as powder.

Samples from Distilleries. Eight additional samples were collected in two processing industries (distilleries) located in Puglia region (South Italy) that use wine lees (distillery 1), grape pomaces (distillery 2), and wine as starting materials for the production of ethyl alcohol, tartrates, dried grape seeds, and dried grape skins. In particular, grape pomaces or lees are mixed with wine or water and distilled to obtain ethyl alcohol. Dealcoholated pomaces or lees are washed with warm water to obtain a liquid borlanda. Washed pomaces are dried and separated into grape skins and grape seeds. Borlanda is used to precipitate and collect tartrates. Exhausted borlanda and exhausted lees are mixed and submitted to digestion in a purification plant constituted of an anaerobic fermenter to produce biogas followed by an aerobic fermenter containing activated sludge. Samples of 0.5−1 kg of starting materials (lees, grape pomaces) and final materials (dried grape seed, dried grape skins, tartrates, and mud) were collected and sent to our laboratory. These samples were collected in the same day, and they were considered sufficiently representative of the lot of pomaces or lees because they were homogenized during maceration or sedimentation processes in the winery.

All solid samples were ground before OTA extraction, powders were directly extracted, and liquid samples were used as such, whereas PFS available as capsules were opened to recover their content that was weighed and analyzed for OTA. Solid samples containing high humidity (grape pomaces and wine lees collected from distilleries) were dried before grinding. The list of the 49 samples analyzed for OTA is reported in Tables 1−3.

Determination of OTA. Each sample was analyzed as reported previously.[12] In particular, solid and liquid samples (5 g) were extracted with 30 mL of acetonitrile/water (60:40, v/v) by shaking for 60 min. Some liquid samples containing high levels of sugars showed two liquid layers after the addition of the extraction solvent. New aliquots of these samples were extracted with acetonitrile/methanol/water (90:90:80, v/v/v). The addition of methanol to the extraction solvent mixture prevents the formation of two liquid layers. After centrifugation (4000 rpm, 5 min) and filtration through a Whatman No. 4 filter paper, 6 mL of filtrate was diluted with 44 mL of water solution containing PEG (1%) and $NaHCO_3$ (5%), mixed, and filtered through Whatman GF/A glass microfiber. A 10 mL volume of diluted extract (equivalent to 0.2 g of solid sample or 0.17 g of liquid sample) was passed through an OchraTest immunoaffinity column at a flow rate of about 1 drop/s. The column was washed with 10 mL of water solution containing NaCl (2.5%) and $NaHCO_3$ (0.5%), followed by 10 mL of distilled water at a flow rate of 1−2 drops/s. The eluates were discarded, and OTA was recovered in a vial by passing 2 × 1 mL of methanol through the column. The purified extract was dried under nitrogen stream at about 50 °C and reconstituted with 500 μL of the HPLC mobile phase. One-hundred microliters, corresponding to 0.04 g of solid sample or 0.034 g of liquid sample, was injected into the HPLC apparatus by a full loop injection system. The HPLC determination and confirmation of OTA were performed according to the AOAC Official Method 2001.01.[16] The HPLC apparatus was an 1100 series equipped with a G1312A binary pump, a G1313A autosampler, a G1316A column thermostat set at 25 °C, a G1321A spectrofluorometric detector set at 333 nm (λ_{ex}) and 460 nm (λ_{em}), and a Chemstation G2170AA Windows 2000 operating system (Agilent, Waldbronn, Germany). The column used was a 150 mm × 3 mm i.d., 4 μm, Synergi Hydro-RP (Phenomenex, Torrance, CA, USA) with a 3 mm, 0.45 μm pore size guard filter (Rheodyne, Cotati, CA, USA). The mobile phase was an isocratic mixture of acetonitrile/water/acetic acid (99:99:2, v/v/v) eluted at a flow rate of 1.0 mL/min.

The identity and concentration of OTA in the purified extracts of two food supplements (#23 and #24) containing low levels of OTA were confirmed by LC−MS/MS by using the apparatus and analytical conditions reported elsewhere.[17]

Recovery Experiments. The performances of the analytical method were checked on blank samples of PFS based on red grape

seeds (#1), food coloring agent based on grape powder (#32), and leavening agent containing tartrates obtained from grape (#39) spiked in triplicate with OTA at 5 and 20 μg/kg. Spiked samples were left overnight to allow for solvent evaporation.

RESULTS AND DISCUSSION

Method Performance. Analysis of spiked blank samples demonstrated that the method generated accurate and precise results. Recovery and repeatability results were in the range of 87−102% and 2−4%, respectively (Table 4), and the chromatograms of blank and spiked samples did not show matrix interfering peaks at retention time of OTA (Figure 2). Values of limit of detection (LOD) and limit of quantitation (LOQ), calculated as signal-to-noise ratios of 3:1 and 6:1, were 0.50 μg/kg and 1.16 μg/kg, respectively. Figure 2 shows the chromatograms of a PFS blank sample (#10) and two PFS samples naturally contaminated with OTA at 20.23 μg/kg (#9) and 5.19 μg/kg (#11). The identity and levels of OTA were confirmed in the purified extracts of two samples of PFS (#23 and #24) that were analyzed by LC−MS/MS.

Table 4. Recovery and Repeatability Results for OTA Determination in Spiked Samples. Results Are Mean of Three Replicates

sample	spiking level (μg/kg)	mean recovery (%)	SD[a]	RSD_r[b] (%)
PFS based on red grape seeds (#1)	5	88	2.9	3
	20	87	3.2	4
food coloring based on grape powder (#32)	5	102	1.7	2
	20	103	4.1	4
leavening agent containing tartrates derived from *V. vinifera* (#39)	5	99	3.8	4
	20	97	2.1	2

[a]SD, standard deviation. [b]RSD_r, within laboratory relative standard deviation.

Occurrence of OTA in Commercial Samples. Eighteen out of twenty-four PFS samples (75%) were found contaminated with OTA at levels ranging from <1.16−20.23 μg/kg (Table 1). For each sample of PFS, we have reported the dose form, daily consumption, composition, percentage of derivatives of *V. vinifera*, OTA level, and its calculated probable daily intake (PDI). Assuming that most of the OTA measured in positive PFS samples originated from *V. vinifera* used as ingredient, the calculated OTA level in this ingredient was in the range of <1.16−809.20 μg/kg. These levels of OTA are not surprising since levels up to 849.1 μg/kg of OTA were reported for samples of grape pomaces collected in South Italy.[12] The percentages of *V. vinifera*, mainly extracts of grape pomaces, in the PFS considered in this study were quite variable in the range of 0.5−52.3%, but no correlation was found between these percentages and OTA levels (R^2 = 0.01). This suggests that either OTA contamination of *V. vinifera* was variable or other ingredients used for PFS formulation could have contributed to OTA contamination. The calculated values of PDI of OTA for consumers of PFS analyzed in this study are reported in Table 1 and ranged from <0.007−0.54 ng/kg bw, which correspond to <0.04−3.2% of TDI (17.14 ng/kg bw) for this mycotoxin.

The occurrence of OTA in other kind of PFS was previously investigated by several authors.[18−20] In particular, six out of 62 PFS (10%) were found positive for OTA at levels <0.3−6 μg/kg with a calculated PDI of 0.15 ng/kg bw for the sample containing the highest OTA level (6 μg/kg).[18] OTA was also reported in 18 out of 50 samples (36%) of green coffee bean extracts-based PFS at levels in the range of <1−136.9 μg/kg.[19] Thirty-two samples (63%) of brewer's yeast food supplements were found contaminated with 0.03−1.53 μg/kg OTA.[20] OTA was also found, at different range levels, in dried fruits and botanicals such as medicinal plants (43% positive, up to 2340 μg/kg OTA), ginseng (40% positive, 0.4−1.8 μg/kg OTA), ginger (100% positive, 1.8−2.9 μg/kg OTA), red pepper (31%

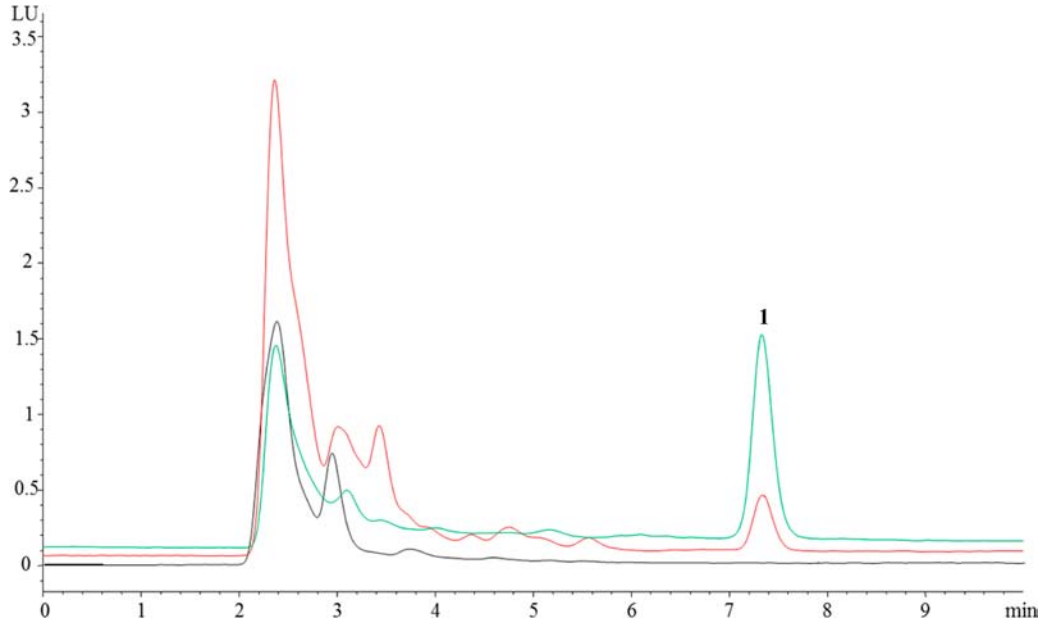

Figure 2. Chromatograms of a blank sample #10 (black) and samples #9 (green) and #11 (red) naturally contaminated with OTA (**1**) at 20.23 μg/kg and 5.19 μg/kg, respectively.

J. Agric. Food Chem. 2015, 63, 3609−3614

positive, 10.6−66.2 μg/kg OTA), and liquorice (45% positive, 0.3−217 μg/kg OTA).[21]

The consumption of PFS across different countries is not homogeneous, and their production, marketing, and control are regulated by every national legislation, although anyone can freely purchase products marketed on World Wide Web sites.[2] People living in the United States and northern Europe are the major consumers of PFS, mainly by people who are in good health and not by people who really need them.[22,23] Several research groups collected data on the habits of adult populations from different areas of the USA and EU to characterize the consumptions of PFS, but no clear information is yet available about average consumption in various age groups.[2,23−25] One of the problems that still prevents the creation of a reliable database is the extreme variability of the ingredients in the PFS available on the market. Some types of PFS may contain toxic compounds, which are constituents of plants used as ingredient of these types of PFS.[26] The results of our study indicate that OTA is widespread in PFS derived from *V. vinifera*; therefore, it should be considered as an additional safety issue for PFS.

Grape pomaces and wine lees are also used to manufacture either food coloring agents or tartrates. Anthocyanins (E 163), a food additive belonging to the functional class food coloring agents, can be produced from grape skin extracts.[27] Anthocyanins (E 163) refers to the food additives that are not sufficiently characterized and may contain both the glycosides (anthocyanins) and the aglycones (anthocyanidins).[27] Tartrates can be manufactured from grape pomaces or wine lees.[28] The results on the contamination of OTA in commercial samples of 13 food coloring agents and four leavening agents containing tartrates are reported in Table 2. Within the 13 food coloring agents, nine samples (69%) were contaminated with OTA at levels between <1.16−32.00 μg/kg, whereas none of the four samples of leavening agents containing tartrates were contaminated by OTA. As far as we know, this is the first report on the occurrence of OTA in food coloring agents manufactured from *V. vinifera*.

Occurrence of OTA in Samples from Distilleries. The results of the samples collected in the two distilleries that used grape pomaces or wine lees to produce tartrates, ethyl alcohol, grape skins, grape seeds, and biogas are reported in Table 3. All samples were contaminated, and the levels of OTA in tartrates were 2−4% of the level of OTA measured in the starting materials (wine lees or grape pomaces). The levels of OTA in samples of grape skins (72.20 μg/kg) and grape seeds (23.86 μg/kg) were comparable to that of the starting grape pomaces (46.50 μg/kg). These results confirm the stability of OTA during processing of grape pomaces to produce grape skins, ethyl alcohol, and grape seeds. Moreover, the levels of OTA measured in grape skins and grape seeds account for the total amount of OTA originally present in starting grape pomaces. This suggests that the toxin does not pass into ethyl alcohol during distillation of pomaces as previously reported on a laboratory scale.[12]

As shown in Table 3, a low level of OTA (3.87 μg/kg) was measured in the mud sample collected from the purification plant in spite of the high levels of OTA present in the starting wine lees (240.93 μg/kg). A possible explanation of this result could be a OTA degradation made by some of microorganisms used for anaerobic and aerobic digestion. In this case, the materials present in the purification plant could be a good source of OTA degrading microorganisms. Further investigations are necessary to support this hypothesis.

Maximum permitted levels of OTA are in force in Europe for some products derived from *V. vinifera* such as wine and grape juice (2 μg/kg) and raisins and sultanas (10 μg/kg).[28] The results reported herein demonstrate the high incidence and, for some samples, the high level of OTA in PFS and food coloring agents derived from *V. vinifera*, which require maximum permitted levels of OTA to be established also for these products.

substances is plant material such as garlic, broccoli, green tea, soybeans, tomatoes, carrots, Brussels sprouts, kale, cabbages, onions, cauliflower, red beets, cranberries, cocoa, blackberries, blueberries, red grapes, prunes, and citrus fruits. With a huge market for functional foods comprising antioxidative attributes, there is renewed interest in the search for new diverse sources of antioxidants that can be safely used. Dairy products have also been reported to possess antioxidant properties (Table 2) and among various dairy supplements, probiotics have been recently known as potential sources of antioxidants.

PROBIOTICS

Probiotics are defined as "live microorganisms which when administered in adequate amounts, confer health benefits to the host".[8] Probiotics have established their efficacy as dietary factors that can regulate gastrointestinal functions, thereby imparting health benefits to consumers. Alleviation of lactose intolerance, prevention of different forms of diarrhea and urogenital infections, cholesterol reduction, reduction of atopic diseases, and modulation of the immune system are some of the functions attributed to probiotics.[9,10] Other benefits include prevention of cancer, particularly colon carcinoma and food allergy.[11,12] The competitive exclusion of pathogens and the reduction in number as well as metabolic activities of harmful organisms by probiotics have been demonstrated in vitro.[13] Lactobacilli are the major source of probiotics and are usually explained as Gram-positive bacteria, devoid of cytochromes and preferring anaerobic conditions, but are aero tolerant, fastidious, and strictly fermentative and produce lactic acid as the main product.[14] Various species and strains of lactobacilli, namely, *Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus rhamnosus*, and *Lactobacillus helveticus* are considered as successful probiotics, and different variants have been available on the market for human consumption. *Bifidobacterium*, even though not grouped with lactic acid bacteria, is another genus with probiotic functions. *Bifidobacterium lactis* (*Bifidobacterium animalis* ssp. *lactis*) is a very commonly used probiotic, although it is not a normal inhabitant of the human gastrointestinal tract. *Bifidobacterium longum* ssp. *longum* (and ssp. *infantis*) and *Bifidobacterium breve* are mainly used in supplements.[15] Although various strains of lactobacilli and bifidobacteria have been known for various health beneficial effects, their role as antioxidants has been understudied.

Table 2. Antioxidant Values of Dairy and Dairy Products (Modified from Carlsen et al., 2010)[100]

sr. no.	product	antioxidant content[a] (mmol/100 mg)
1	buttermilk, special, 1.5% fat	0.04
2	buttermilk, skimmed	0.05
3	cheese, Gorgonzola dolce	0.54
4	cream, 22% fat	0.06
5	goat's milk	0.04
6	milk, 2%	0.04
7	ice cream, chocolate, regular fat	0.76
8	ice cream, regular fat, natural vanilla	0.05
9	ice cream with strawberry	0.21
10	milk, skimmed fermented with blueberries	0.42
11	sour cream	0.15
12	yogurt, original	0.06
13	yogurt, mixed wild berries	0.25
14	yogurt, strawberries	0.08
15	yogurt, frozen, fat-free, vanilla	0.06
16	yogurt, 99% fat-free, strawberry	0.11

[a]Values were estimated using the ferric reducing ability of plasma (FRAP) method.

APPLICATION OF PROBIOTICS IN FOOD

During the past 20 years, consumers' perception of functional foods including probiotics has changed. The presence of probiotics in commercial food products has been very well accepted and has been known for a number of health benefits. In this direction, industries worldwide are concentrating on applications of probiotics in food products as well as constructing a new era of "probiotic health" foods. Foods are considered better delivery vehicles for probiotic organisms than others due to the role played by the food matrix in maintaining the viability of organisms during the transition through the gastrointestinal tract. Dairy foods are considered natural carriers for lactobacilli and bifidobacteria due to their ability to utilize lactose and produce lactic acid.

Table 3. Description of Commonly Used Methods for Screening of in Vitro Antioxidant Potential of Natural Compounds

assay	principle	observation	refs
DPPH	antioxidants are able to reduce the free, stable, and purple-colored 2,2-diphenyl-1-picrylhydrazyl radical to the yellow-colored diphenylpicrylhydrazine	yellow color substance by spectrometry or visible	18, 19
ABTS	2,2′-azinobis(ethylbenzothiazoline 6-sulfonate) is oxidized by oxidants to its radical cation, $ABTS^{\bullet-}$, which is intensely colored, and antioxidant capacity is measured as the ability of test compounds to decolorize the ABTS radical directly	decoloration by spectrometry or visible observations	21, 22
hydroxyl radical scavenging activity	hydroxyl radical is indirectly confirmed by the hydroxylation of *p*-hydroxybenzoic acid in the presence of iron	spectrophotometric determination	23
FRAP	characterized by the ability of antioxidant to reduce ferric 2,4,6-tripyridyl-*s*-triazine complex $[Fe^{3+}-(TPTZ)_2]^{3+}$ to $[Fe^{2+}-(TPTZ)_2]^{2+}$ depending on the available reducing species followed by the alteration of color from yellow to blue in acidic condition (pH 3.6)	analyzed through spectrophotometer	24−26
ORAC	principle is based on decreasing intensity of fluorescent molecule such as *β*-phycoerythrin or fluorescein of the target along with time under reproducible and constant flux of peroxy radicals	analyzed by fluorometer	34−36

METHODS FOR ANTIOXIDANT ACTIVITY SCREENING OF PROBIOTICS

Various methodologies have been adopted to determine the antioxidative potential for natural compounds; however, it is important to use consistent and rapid methods. Each antioxidative activity assay has a specific target within the well-defined matrix. Each method has its own merits and demerits. In the absence of a universal method that can give unambiguous results, the best way is to use multiple methods instead of one. Some of the procedures involve the use of synthetic antioxidants or free radicals; few are specific for lipid peroxidation and require animal and plant cells, some have a broader scope, some require minimum preparation and information, and few methods produce speedy results.[16] The antioxidative activity of food products including probiotic products has been studied by using different in vitro and in vivo methods.

In Vitro Antioxidative Methods. The in vitro assays are based on determination of scavenging capacity against ROS such as superoxide anion scavenging assay, hydrogen peroxide scavenging assay, and scavenging activity against stable nonbiological radicals. Several assays have been used to assess the total antioxidant content in foods such as the 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) equivalent antioxidant capacity (TEAC) assay, the ferric-reducing antioxidant power assay (FRAP), and the oxygen radical absorbance capacity assay (ORAC) assay. However, it has been found that the most common and reliable methods are the 2,2-diphenyl-1-picrylhydrazyl (DPPH) and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) methods; these methods are simple, rapid, sensitive, and reproducible and have been modified and improved as per research requirements.[17] A brief description of some antioxidant potential screening methods used for probiotics is presented here and summarized in Table 3.

DPPH Assay. This widely used discoloration method was first described by Blois (1958).[18] This assay is based on the premise that a hydrogen donor is an antioxidant. The antioxidants are able to reduce the free, stable, and purple-colored DPPH radical to the yellow-colored diphenylpicrylhydrazine, which is monitored by using a colorimeter. DPPH is usually used as a reagent to evaluate the free radical scavenging activity of antioxidants.[19]

ABTS Assay. The ABTS radical scavenging method was developed[20] and was then modified by others.[21] In this assay, ABTS is oxidized by oxidants to its radical cation, $ABTS^{\bullet+}$, which is intensely colored, and the antioxidant capacity is measured as the ability of test compounds to decolorize the ABTS radical directly. $ABTS^{\bullet+}$ radicals are more reactive than DPPH, whereas generation of its radical cation forms the basis of one of the spectrophotometric methods that have been applied for measuring the antioxidant property of pure substances, aqueous mixtures, and beverages.[22]

Hydroxyl Radical Scavenging Activity Assay. The hydroxyl radical ($^{\bullet}OH$) is the neutral form of the hydroxide ion (OH^-). This radical is known as the most reactive species and is known for lipid peroxidation and DNA damage.[23] In this assay, the hydroxyl radical is indirectly confirmed by the hydroxylation of *p*-hydroxybenzoic acid. However, iron plays a central role in the hydroxyl radical formation via the Fenton reaction.

FRAP Assay. The FRAP assay is characterized by the ability of an antioxidant to reduce ferric 2,4,6-tripyridyl-*s*-triazine complex $[Fe^{3+}-(TPTZ)_2]^{3+}$ to $[Fe^{2+}-(TPTZ)_2]^{2+}$ depending on the available reducing species followed by the alteration of color from yellow to blue in acidic condition (pH 3.6) and is analyzed through a spectrophotometer.[24−26] This method was employed to measure reducing power in plasma, but the assay subsequently has also been adapted and used for the assay of antioxidants in different foods or beverages,[27−32] teas, and fruits. A drawback of this method is that the antioxidant capacity of certain compounds which can react with ferrous ion (Fe^{2+}) and SH group-containing antioxidants cannot be measured.[33]

ORAC Assay. The ORAC assay uses the area-under-curve technique and combines the inhibition time and inhibition degree of free radical action by an antioxidant into a single quantity. On the other hand, similar methods use either inhibition time at a fixed inhibition degree or the inhibition degree at fixed time as the basis for quantifying the outputs.[34−36] ORAC evaluates antioxidant inhibition of peroxy radical-induced oxidations and thus reflects the classical radical chain-breaking antioxidant activity by hydrogen atom transfer (HAT).[37] The peroxy radicals are generated through thermal decomposition of 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH) in aqueous buffer. The principle of this method is based on decreasing the intensity of fluorescent molecules such as *β*-phycoerythrin or fluorescein of the target along with time under reproducible and constant flux of peroxy radicals.

ANTIOXIDATIVE POTENTIAL OF PROBIOTIC MICROORGANISMS AND FOODS

Each characteristic of probiotic organisms is first established using in vitro methods and subsequently in vivo experiments

DOI: 10.1021/jf506326t

conducted in suitable animal models. On confirmation of the suitability of the organism, it is incorporated in suitable food products, and further studies are conducted using probiotic foods to establish its efficacy, survival under storage conditions, etc.[8] In vitro antioxidative studies have been conducted on different probiotic organisms (mainly lactobacilli and bifidobacteria), and food products containing probiotic organisms have also been studied. The following section reviews these studies, and a summary is presented in Table 4.

■ *LACTOBACILLUS* SP.

Lactobacillus rhamnosus. Different antioxidative capacities of *Lactobacillus* species to modify the bacterial profile and prevent the oxidative stress in the Fe-overloaded mice colon were studied.[38] The generation of hydrogen peroxide and hydroxyl radical as well as growth of Fe-dependent bacteria is encouraged by iron (Fe). Findings of this study showed that survival time of *L. rhamnosus* GG strain was significantly longer in the presence of H_2O_2 and hydroxyl radical as compared to non-antioxidative strains, *L. paracasei* Fn032 and *L. plantarum* Fn001, respectively. In addition, *L. paracasei* Fn032 and *L. plantarum* Fn001 were specific for free radical scavenging activities of their intracellular free extracts (ICFE). Scavenging activities increased to various extents when bacterial strains were exposed to gastric and pancreatic juice. However, Achuthan et al.[39] also reported the resistance of a total of 39 *Lactobacillus* cultures to ROS. Most of the isolates showed moderate to strong resistance toward 0.4 mM H_2O_2. The majority of cultures demonstrated high resistance to hydroxyl radicals, and isolate *L. plantarum* 21 (Lp21) was most resistant with log count reduction of 0.20-fold only. Of 39 isolates, *Lactobacillus* spp. S3 showed highest total antioxidative activity of 77.85 followed by 56.1 of isolate *L. plantarum* 55 (Lp55) in terms of percent inhibition of linolenic acid oxidation. Moreover, isolate *L. plantarum* 9 (Lp9) up-regulated the expression of superoxide dismutase (SOD) gene 2 in HT-29 cell at concentrations of 0.1 mM (1.997-fold) and 1.0 mM H_2O_2 (2.058-fold). In addition to this, cultures Lp9, *L. plantarum* 91 (Lp91), and Lp55 showed significant up-regulation in the expression of GPX-I gene to levels of 5.451-, 8.706-, and 10.083-fold, respectively, when HT-29 cells were challenged with 0.1 mM H_2O_2. On the other hand, CAT gene expression was also significantly regulated by all of the isolates used in this study in the presence of 0.1 mM H_2O_2.

Grompone et al.[40] developed a new, fast, predictive, and convenient in vitro method for the screening of antioxidative potential of new probiotic strains using the nematode *Caenorhabditis elegans* as host (model organism). In this study, a total of 78 strains of lactic acid bacteria (LAB) (*Lactobacillus* and *Bifidobacterium*) were examined. This collection is composed by 62 *Lactobacillus* strains belonging to *L. acidophilus*, *L. bulgaricus*, *L. casei*, *L. paracasei*, *L. plantarum*, and *L. rhamnosus* species, 9 *Streptococcus thermophilus* isolates, and 6 *Bifidobacterium* strains belonging to the *B. animalis*, *B. breve*, and *B. longum* species. The LAB stains used in this study were fed to *C. elegans*, and the survival rate of *C. elegans* was examined upon exposure to H_2O_2-induced stress by comparison with the protective effect exerted by *Escherichia coli* OP50. As a result of this screening, a *Lb. rhamnosus* strain (CNCM I-3690) demonstrated a high antioxidant capacity.

Kapila et al.[41] examined the antioxidative activity of ICFE of 13 strains of *Lactobacillus* sp. by using microsome–thiobarbituric acid (MS-TBA) and linoleic acid peroxidation methods. Maximum antioxidant capacity in terms of percent inhibition of oxidation was expressed in *L. casei* ssp. *casei* 19 (76.82%) followed by *L. acidophilus* 14 (62.21%), *Lactobacillus* sp. L13 (59.25%), *L. casei* ssp. *casei* 63 (53.30%), *L. helveticus* 6 (52.70%), and *L. delbrueckii* ssp. *bulgaricus* 4 (52.64%), whereas the remaining strains showed <50% activity. In addition to this, strain *L. casei* ssp. *casei* 19 showed 72.04% linoleic acid peroxidation followed by *L. acidophilus* 14 (51.74%), *Lactobacillus* sp. L13 (51.38%), and the remaining strains exhibited <50% activity.

Similarly, other authors[42] reported the antioxidative potential of ICFE of 19 strains of lactic acid bacteria (16 lactobacilli, 2 streptococci, 2 lactococci) of 570 strains using MS-TBA. However, the highest inhibitory activity of oxidation was observed in *Lactobacillus* sp. SBT-2028 (91%) followed by *L. casei* ssp. *pseudoplantarum* SBT-0624 (77%). The antioxidative potential of ICFE of 19 strains of LAB including *L. acidophilus* B, E, N1, 4356, LA-1, and Farr; *L. bulgaricus* 12, 278, 448, 449, Lb, 1006, and 11 842; *S, thermophilus* 821, MC, 573, 3641, and 19 987; and *B. longum* B6 and 15 708 was studied by using inhibition of ascorbate autoxidation, ferrous and copper ion chelating assays, hydroxyl and hydrogen peroxide radical scavenging activity, reducing power assay, SOD activity, and SOD induction assay.[43] All strains exhibited the inhibition of ascorbate autoxidation in the range of 7–12%. The strain *L. acidophilus* E showed the highest (33.1 mM) and *S. thermophilus* 3641 the lowest (0.5 mM) hydroxyl radical scavenging capacities, equivalent to that of uric acid. Furthermore, the reducing activity of *B. longum* B6 was found to be higher, equivalent to 225.3 μM cysteine and 50-fold higher than that of *S. thermophilus* 19 987, which had the reducing activity equivalent to 4.3 μM cysteine, whereas strains of *L. acidophilus* B, E, N1, and 4356 also showed the lowest reducing activity. Among the 19 strains of lactic acid bacteria tested, *L. bulgaricus* strains demonstrated higher metal ion Fe^{2+} chelating ability (ranging from 5.6 to 52.9 ppm) than *L. acidophilus*. On the other hand, *S. thermophilus* strains showed a very wide range of Fe^{2+} chelating ability ranging from 0.5 to 72.7 ppm. *S. thermophilus* 821 and 19 987 demonstrated the highest and lowest Fe^{2+} chelating abilities, respectively, whereas *B. longum* B6 and 15708 had high chelating activities for Fe^{2+} at 40.7 and 26.6 ppm, respectively.

Moreover, for copper ion chelation, *L. acidophilus* and *S. thermophilus* strains showed a wide range of chelation abilities ranging from 0 to 34.8 ppm and from 2.4 to 51.0 ppm, respectively. Six *L. bulgaricus* strains tested had high Cu^{2+} chelating abilities ranging from 13.2 to 48.3 ppm. Both *B. longum* B6 and 15 708 had not only high Fe^{2+} chelating ability but also high Cu^{2+} chelating ability (18.5 and 63 ppm, respectively). All of the strains were unable to inhibit the SOD activity, whereas SOD activity also was not induced when growth medium was supplemented with metal ions Mn^{2+}, Fe^{2+}, Cu^{2+}, or Zn^{2+}.

Saide and Gilliland[44] demonstrated antioxidative activity by evaluating the oxygen radical absorbance capacity of whole cells and ICFE of selected strains of lactobacilli species, which was expressed as Trolox equivalents per 10^9 cells. Cell-free extract of *L. delbrueckii* ssp. *lactis* RM5-4, *L. acidophilus* NCFM, *L. delbrueckii* ssp. *bulgaricus* 18, 10442, and Y-23 and *L. casei* 9018 exhibited higher oxygen radical absorbance capacity (total antioxidative capacity) than that of the intact cells.

Ou et al.[45] reported the comparative antioxidative potential of intact cells and ICFE of *B. longum* and *L. delbrueckii* ssp.

DOI: 10.1021/jf506326t
J. Agric. Food Chem. 2015, 63, 3615–3626

bulgaricus. In this direction, intact cells of both strains showed 71.3% and 70.4% and ICFE of both strains showed 72.6% and 75.1% DPPH radical scavenging activity respectively. On the other hand, both strains were capable to protect liposome lipid from oxidation and the inhibition rate ranged from 25−31% while no significant difference in lipid peroxidation by intact cells and ICFE of both strains was reported. There was significant reduction in malondialdehyde production in intestine 407 cells.

***Lactobacillus fermentum* ME-3.** The *L. fermentum* ME-3 strain has been comprehensively studied at University of Turku, Finland. It is a unique strain of *Lactobacillus* species, having at the same time antimicrobial and physiologically effective antioxidative properties and expressing health-promoting characteristics.[45] Research on *L. fermentum* ME-3 has established that the particular strain has double functional properties: antimicrobial activity against intestinal pathogens and high total antioxidative activity (TAA) and total antioxidative status (TAS) of intact cells and lysates. *L. fermentum* ME-3 is characterized by a complete glutathione system: synthesis, uptake, and redox turnover. The functional efficacy of the antimicrobial and antioxidative property has been proved by the eradication of *Salmonella* and the reduction of liver and spleen granulomas in *S. typhimurium*-infected mice treated with the combination of ofloxacin and *L. fermentum* ME-3.[46,47] It also revealed the antioxidative potential of probiotic *L. fermentum* ME-3 in soft cheese spreads containing different fatty acids. Moreover, *L. fermentum* E-3 and E-18 contained remarkable levels of glutathione and expressed Mn-SOD, which is of vital importance for the prevention of lipid peroxidation and secretion of hydrogen peroxide.[48] Few researchers[49] have worked on *L. fermentum* FTL2311 and *L. fermentum* FTL10BR strains isolated from miang, traditional fermented tea leaves, which liberate certain substances that possess antioxidative activity expressed in terms of TEAC and equivalent concentration (EC) values for free radical scavenging and reducing mechanisms, respectively. The culture supernatant of *L. fermentum* FTL2311 revealed TEAC and EC values of 22.54 ± 0.12 and 20.63 ± 0.17 μM/mg respectively, whereas that of *L. fermentum* FTL10BR yielded TEAC and EC values of 24.09 ± 0.12 and 21.26 ± 0.17 μM/mg, respectively. These two strains isolated from miang present high potential as promising health-promoting probiotics.[50] On the other hand, *L. fermentum* demonstrated higher free radical scavenging activities of against hydroxyl, superoxide, and DPPH radicals. Scavenging activities at populations of 10^6 and 10^9 CFU/mL for hydroxyl radical, superoxide radical, and DPPH were 7.35, 12.86, and 64.26% and 91.84, 80.56, and 87.89%, respectively.[51]

***Lactobacillus acidophilus*.** The antioxidative potential of intestinal lactic acid bacteria *L. acidophilus* ATCC 4356 was reported.[52] In this study, both intact cells and ICFE showed 28.1 and 45.3% inhibition of linoleic acid peroxidation, whereas 43.2 and 20.8% inhibition of DPPH radical scavenging activity, respectively. The cytotoxicity of 4-nitroquinoline-*N*-oxide (4NQO) to intestine 407 cells was reduced by intact cells up to 49%, whereas no inhibition was observed for ICFE. Findings of this study suggest that ICFE showed better antioxidative activity than intact cells.

***Lactobacillus plantarum*.** Studies by others[53] exhibited the antioxidative attributes of the intact cells of *L. plantarum* AS1 isolated from the South Indian fermented food *kallappam*. Strain AS1 showed 50.96% inhibition of linoleic acid peroxidation, whereas DPPH radical scavenging activity was found to be 29.15%. This study concluded that a significant antioxidant effect might be a reason for the reduction of cancerous tumors and related symptoms in rats (also discussed for in vivo studies).

The antioxidative property of *L. rhamnosus* in combination with *B. longum* containing fruit juice permeates such as lemon juice and mango and guava pulps was studied.[54] The superoxide anion radical scavenging capacity of *L. rhamnosus* GG was higher than those of several other bacteria such as *L. rhamnosus* Lc 705, *L. acidophilus* LA, *L. paracasei* YEC, *Bifidobacterium* sp. BB12, and *E. coli*.[55]

***Lactobacillus casei*.** Both intact cells and ICFE of *L. casei* KCTC 3260 demonstrated high antioxidative activity and inhibited lipid peroxidation by 46.2 and 72.9%, respectively. The culture had higher levels of chelating activity for both Fe^{2+} and Cu^{2+} ions at 10.6 and 21.8 ppm, respectively, which suggested that the antioxidative capacity of *L. casei* KCTC 3260 may be caused by chelating metal ions instead of SOD activation.[56] Moreover, Yoon and Byun[57] found that *L. casei* HY 2782 contained the highest level of glutathione sulfhydryl (GSH) among different probiotic strains tested. GSH levels in *L. casei* HY 2782 reached maximum values after 24 h of cultivation but decreased for 72 h. The effect of culture media on GSH activity was also studied, and it was found that GSH levels were significantly higher during cultivation in de Man Rogosa and Sharpe (MRS) broth than in tryptone phytone yeast extract broth or bromcresol purple dextrose broth. Significant positive correlation between antioxidative activity and cellular GSH contents was observed.

***Lactobacillus gasseri*.** Kim et al.[58] investigated the protective effect of the selected *L. gasseri* NLRI 312 against oxidative damage to cellular membrane lipid and DNA in the Jurkat cell line. *L. gasseri* NLRI 312 had a protective effect on the Jurkat cell lines in terms of oxidative damage, although supplementation had no effect on malondialdehyde (MDA) production. There was a 50% reduction in DNA damage after probiotic treatment of cell lines. Many peptides are identified in fermented milk, which contributes to the antioxidant potential of products. A κ-casein-derived peptide with DPPH radical scavenging activity has been found in milk fermented with *L. delbrueckii* ssp. *bulgaricus*.[59]

***Lactobacillus helveticus*.** *L. helveticus* CD6 producing a folic acid derivative 5-methyltetrahydrofolate (5-MeTHF) was studied for antioxidative activity. The ICFE of *L. helveticus* CD6 demonstrated antioxidative activity with the inhibition rate of ascorbate autoxidation in the array of 27.5%, which showed highest metal ion chelation ability for Fe^{2+} (0.26 ± 0.06 ppm) as compared to Cu^{2+}. The DPPH and hydroxyl radical scavenging activities of intact cells found to be 24.7 and 20.8%, respectively, proved its antioxidative potential. Moreover, it demonstrated 14.89% inhibition of epinephrine autoxidation, 20.9 ± 1.8 μg of cysteine equivalent reducing activity, and 20.8% hydroxyl radical scavenging effect. This study also reported the detection of SOD by using 10% nondenaturing polyacrylamide gel electrophoresis. It was observed that SOD activity was absent in the ICFE of *L. helveticus* CD6.[60]

Two strains each of lactobacilli (*L. rhamnosus* GD 11 and *L. plantarum* LA3) and bifidobacteria (*B. breve* A28 and *B. breve* A10) were studied for exopolysaccharide (EPS) production, antioxidative characteristics, and their role in gingival fibroblast. Among four cultures, *B. breve* A28 showed high EPS production at 122 mg/L. It also showed 72% DPPH free radical scavenging

DOI: 10.1021/jf506326t
J. Agric. Food Chem. 2015, 63, 3615−3626

activity and 88% iron ion chelation activity. The strain also showed 71% inhibition of lipid peroxidation.[61]

***Bifidobacterium* sp.** Several studies have been conducted on the antioxidative activity of *Bifidobacerium* sp. Lin and Chang[52] investigated the antioxidative potential of the intestinal lactic acid bacteria *B. longum* ATCC 15708. Both intact cells and ICFE, respectively, showed 32 and 48% inhibition of linoleic acid peroxidation and 52 and 42% DPPH radical scavenging activity. The cytotoxicity of 4NQO to intestine 407 cells was reduced by intact cells up to 89%, whereas no inhibition was observed for intracellular extract. Furthermore, intact cells and ICFE showed 16.2 and 34.3% inhibition rates of plasma lipid peroxidation for 10^9 cells of *B. longum* ATCC 15708. Another study[62] reported that *Bifidobacterium* was involved in the transformation of lignan glucosides. In this view, only 10 *Bifidobacterium* cultures partially hydrolyzed secoisolariciresinol diglucoside (SDG), giving both secoisolariciresinol (SECO) and the monoglucoside with yields <25% of 28 strains. *B. pseudocatenulatum* WC 01 gave highest SDG conversion to SECO, which exhibited 75% yield in cellobiose-based medium after 48 h. The antioxidative activity of *B. animalis* 01 culture supernatant, intact cells, and ICFE exhibited an inhibitory effect on linoleic acid peroxidation. The inhibitory effect was 30.48, 41.12, and 71.02% for culture supernatant, intact cells, and ICFE, respectively. Culture supernatant of *B. animalis* 01 demonstrated the highest DPPH scavenging effect (73.11%), which was significantly ($P < 0.05$) higher than that of MRS broth, whereas the relatively lowest DPPH free radical scavenging effect was found in intact cells among the tested groups. In addition, culture supernatant showed 78.32% hydroxyl radical and 86.39% superoxide anion radical scavenging activities, which were also significantly higher than that of MRS broth, whereas intact cells exhibit a weak scavenging effect.[63] Work by others[64] reported the in vitro antioxidative properties of 34 strains of *Bifidobacterium*, *Lactobacillus*, and *Lactococcus* against ascorbic and linolenic acid oxidation (TAA_{AA} and TAA_{LA}), TEAC, intracellular glutathione (TGSH), and SOD. Of these cultures *B. animalis* subsp. *lactis* DSMZ 23032, *L. acidophilus* DSMZ 23033, and *L. brevis* DSMZ23034 exhibited among the highest TAA_{AA}, TAA_{LA}, TEAC, and TGSH values.

Probiotic Products with Antioxidant Activity. Fermented milk was prepared from cow's, goat's, and camel's milk supplemented with probiotic bacteria *Pediococcus pentosus* and studied for antioxidative property and fatty acid profile.[65] The finding showed that probiotic fermented milk obtained from goat's milk has the highest DPPH radical scavenging activity (98%) followed by product from camel's milk (86%) and cow's milk (79%). Moreover, it has also been reported that different protein peptides present in fermented milk are responsible for increased radical scavenging activity.[66]

Recently the antioxidative potential of two synbiotic dairy products, namely, synbiotic lassi with honey and whey-based synbiotic drink with inulin and orange juice containing *L. helveticus* MTCC 5463 as probiotic strain, was evaluated.[67] Both products showed antioxidative activity in terms of hydroxyl radical scavenging activity, radical scavenging activity, and antiradical scavenging activity. The storage of products at 4 ± 1 °C had an adverse effect on these activities as for whey-based drink, the activity reduced for all parameters. The synbiotic yogurt samples containing *L. plantarum* and *L. fermentum* expressed radical scavenging in the form of DPPH radical inhibition of 85 and 82%, respectively, at day 1, and the values increased as the storage time increased.[68] In this study, fructooligosaccharide was used as prebiotic for preparation of synbiotic yogurt. To measure the antioxidant activity of probiotic strain *L. plantarum* NBIMCC 2415, which was used as starter culture for production of dried fermented products,[69] four methods for cell disintegration of strain *L. plantarum* NBIMCC 2415 were investigated such as temperature, alkaline, enzymatic, and ultrasound. An alkaline cell lysis method was found to be appropriate, and with this method *L. plantarum* NBIMCC 2415 showed high antioxidant activity (5.57 μmol TE/log N). The study concluded that meat starter culture *L. plantarum* NBIMCC 2415 was not only involved in fermentation process but also preserved the color, formed the flavor, and increased the meat products' shelf life as well. Antioxidative activity in soy milk fermented with LAB and bifidobacteria simultaneously was reported to be significantly higher than that fermented with either of the cultures individually. Unfermented soy milk showed hydrogen peroxide-scavenging effect. Freeze-dried product had significantly lesser reduction in the antioxidative activity of soy milk than spray-dried. The antioxidative activity of fermented soy milk reduced after drying.[70]

Some researchers worked on the effect of prebiotics (inulin, lactulose, and raffinose) on multiplication of some probiotic strains of *Lactobacillus* and *Bifidobacterium*, used in a pollen and honey medium for obtaining a bee bread-like product. The prebiotics were tested and compared to pollen and honey medium for the viability and total antioxidative activity. In this view, medium B2 supplemented with ground pollen and honey (inoculated with studied probiotic strain) showed ∼45% DPPH radical scavenging activity after 7 days of incubation.[71]

IN VIVO STUDIES IN ANIMAL MODEL

The effect of oral administration of live *B. breve* strain Yakult (BBY) on skin barrier perturbation caused by UV and ROS was studied in hairless mice.[72] Strain BBY prevented the UV-induced increase in transepidermal water loss (TEWL). It also significantly suppressed the hydrogen peroxide level, oxidation of proteins and lipids, and xanthine oxidase activity, induced by UV in the skin.

Wang et al.[51] reported that *L. fermentum* could keep pigs growing healthily by increasing SOD and GPX activities and decreasing MDA levels in serum. Similarly, increased activity of hepatic CAT was also observed with decreased MDA levels. The effect of supplemented diets on the generation of intestinal nitric oxide (NO_x) and antioxidant activities with two strains of *L. delbrueckii* subsp. *bulgaricus* B3 and A13, which produced highest (211 mg/L) and lowest (27 g/L) amounts of exopolysaccharide, was studied.[73] The result showed that the small intestinal glutathione (GSH) and thiobarbituric acid-reactive substances (TBARS) were increased by administration of the probiotic organisms, but amino acid levels did not change in either control or experimental groups. NO_x also increased in both samples. An excessive amount of NO_x may contribute to lipid peroxidation because of increased ROS and reactive nitrogen species. The antioxidative capacity of the small intestine was ameliorated by administration of two strains of *L. delbrueckii* subsp. *bulgaricus* B3 and A13. Probiotic Dahi was prepared by coculturing selected strains of *L. acidophilus* and *B. bifidum* and Dahi culture in standardized buffalo milk and evaluated for its antioxidative effects on rats.[74] The activities of SOD and CAT were determined in red blood cells (RBC) at monthly intervals and in liver and colorectal tissue at

DOI: 10.1021/jf506326t
J. Agric. Food Chem. 2015, 63, 3615−3626

the conclusion of the experiment. The SOD activity in RBC increased with probiotic Dahi but not with Indian Dahi. In addition, the CAT activity in RBC increased with probiotic Dahi as well as normal Dahi and the former was more efficacious. In the liver, the SOD activity was stimulated by probiotic Dahi, whereas in colorectal tissue, both normal and probiotic Dahi effectively stimulated SOD activity. Milk fermented with *L. acidophilus* and *B. bifidum* when fed to rats enhanced the activity of SOD and decreased TBARS accumulation in liver and colorectal tissues.

Probiotic Dahi containing *L. acidophilus* LaVK2 (La-Dahi) and *B. bifidum* BbVK3 (LaBb-Dahi) alleviated age-inflicted accumulation of oxidation products, antioxidant enzymes, and improved expression of biomarkers of aging in mice.[75] In this direction, La-Dahi or LaBb-Dahi increased CAT and GPX activities in RBCs and hepatic tissue and led to a significant decline in TBARS in plasma, kidney, and hepatic tissues and protein carbonyls in the plasma of mice. Probiotic Dahi also reversed the age-related decline in expression of biomarkers of aging, peroxisome proliferators activated receptor-α, senescence marker protein-30 (SMP-30), and Klotho in hepatic and kidney tissue. The findings of this study suggested that probiotic Dahi containing selected strains of LAB can be used as potential nutraceutical intervention to combat oxidative stress and molecular alterations associated with aging. On the other hand, in vivo antioxidant activities of selenium/zinc-enriched probiotics preparation were studied using indigenous dogs (30 day trial).[76] In this study, two probiotic strains, particularly *L. acidophilus* and *Candida utilis*, highly tolerant to high concentrations of inorganic selenium (Se), zinc (Zn), and bile salts and low pH conditions were used. The results of this study indicated that the SOD ($P < 0.01$) and TAOC ($P < 0.05$) activity in the group supplemented with Se/Zn-enriched probiotics were higher as compared to the control group. In addition, there were no significant variations in the increased activity of GPX in both control and experimental groups. The MDA activity of the experimental group was lower than that of the control after 15 days of trial. However, at 30 days of trial, the activities of GPX, SOD, and TAOC in the experimental group were superior to those in the control group, with all of them showing very significant differences ($P < 0.01$). The MDA level of the experimental group was significantly decreased in comparison with the control group ($P < 0.01$).

Furthermore, Dahi containing probiotic *L. acidophilus* NCDC14 and *L. casei* NCDC19 significantly suppressed STZ-induced oxidative damage in pancreatic tissues by inhibiting the lipid peroxidation and formation of nitric oxide and preserving the antioxidant pool such as glutathione content and activities of SOD, CAT, and GPX.[77] The same authors also reported that *L. acidophilus* and *L. casei* with Dahi increased the ability of Dahi to suppress STZ-induced diabetes in rats by inhibiting depletion of insulin as well as preserving diabetic dyslipidemia and inhibiting lipid peroxidation and nitrite formation.

The cholesterol-lowering and antioxidative potential of *L. casei* ssp. *casei* was studied,[41] and it was reported that the cholesterol levels were lower in the plasma of groups fed fermented milk by 2−11 and by 15−25% in groups fed lyophilized culture as compared to the group fed skim milk. The levels of TBARS were lower in the LDL fraction of plasma in rats fed fermented milk or culture than the control group fed skim milk.

The comparative effects of probiotic curd (*Acidophilus casei* Dahi) prepared using *L. acidophilus* and *L. casei* and normal curd (DRC-1, prepared using *Lactococcus lactis* spp. biovar. *diacetylactis*) on lipid peroxidation level (TBARS level) of 1,2-dimethylhydrazine-treated rats were studied.[78] The TBARS levels were estimated in tissues obtained from the liver and colon. The *A. casei* Dahi inhibited the lipid peroxidation in comparison to normal curd by reducing the TBARS level in both the liver and colon.

The in vivo antioxidative properties of *L. plantarum* AS1 isolated from South Indian fermented food *kallappam* were reported.[79] In this study, male albino rats were used and an increased level of lipid peroxide (LPO) products and increased activities of antioxidant enzymes (SOD, CAT, and glutathione *S*-transferase) and marker enzymes (alkaline phosphatase and acid phosphatase) in the colon and plasma of cancer-bearing animals have been observed. Strain AS1 showed its anticancer effect through its potent antioxidative attributes.

The antioxidative activities of three lactobacilli, *L. rhamnosus* GG, *L. paracasei* Fn032, and *L. plantarum* Fn001, in the colon of Fe-overloaded mice were evaluated.[80] In this study, decreased mucosal total antioxidative capacity and oxidative enzyme activity were observed in Fe-overloaded mice. *L. rhamnosus* GG significantly inhibited the increase of colonic mucosal free radicals and MDA content. Moreover, strain *L. paracasei* Fn032 inhibited only MDA, whereas *L. plantarum* Fn001 showed no significant antioxidative potential in vivo.

Sengul et al.[81] demonstrated the antioxidative activity of two exopolysaccharide producing probiotic strains, *L. delbrueckii* subsp. *bulgaricus* (first group: high-EPS producing) B3 and A13 (second group: low-EPS producing) on gut oxidative damage in a rat model of experimental colitis. It was reported that the activities of antioxidative enzymes such as SOD, CAT, and GPX were higher in both probiotic-treated groups compared to that of the colitis model group. Furthermore, lipid peroxidation was also significantly enhanced in both probiotics groups. In this direction, oxidative damage was associated with a high level of MDA activity and reduced activity of antioxidative enzymes in the colitis model group significantly. Activities of antioxidative enzymes and MDA contents in serum and liver of aging mice were evaluated[63] using culture supernatant, intact cells, and cell-free extract of *B. animalis* 01. Monoamine oxidase (MAO) activity and lipofuscin level in brains of aging mice were also characterized. Results showed that *B. animalis* 01 culture supernatant, intact cells, ICFE, and ascorbic acid significantly ($P < 0.05$) enhanced the activities of antioxidant enzymes (SOD, CAT, and GPX) and the TAOC level in mice sera. In addition, findings suggest that the culture supernatant was more effective than MRS broth in enhancing activities of antioxidant enzymes and reducing MDA content in mice sera while lipofuscin level and MAO activity in mouse brains also reduced. This study indicated that *B. animalis* 01 has the potential to be developed into a dietary antioxidant supplements.

Amaretti et al.[64] studied the in vivo antioxidative potential of strains *B. animalis* subsp. *lactis* DSMZ 23032, *L. acidophilus* DSMZ 23033, and *L. brevis* DSMZ 23034 within lactobacilli and bifidobacteria groups (total of 34 strains). Potential antioxidative probiotic formulations of the same stains were prepared and administered to rats at doses of 10^7, 10^8, and 10^9 CFU/day for 18 days. The probiotic strains colonized the colon of the rats during the trial and promoted intestinal saccharolytic metabolism. In this direction, selected probiotic strains

DOI: 10.1021/jf506326t
J. Agric. Food Chem. 2015, 63, 3615−3626

neutralized the oxidative stress induced in animal model. Although in basal condition, probiotic treatment did not modify the tested markers of oxidative stress. On the other hand, the increase of reactive oxygen metabolites (ROM) concentration and decrease in TAA and GSH levels were found in non-probiotic-supplemented doxorubicin (DOXO) administered rats, whereas no alteration was detected in animals supplemented with two higher probiotic concentrations as compared to that of not supplemented, not stressed rats.

Administration of *Lactobacillius* GG helped in increasing the efficacy of treatment of cholesterol-induced peroxidation damage in plasma lipoproteins as well as in liver.[82] *Lactobacillus* GG ameliorated alcohol-induced liver protein carbonyl deposition in rats.[83] The same study reported that alcohol and *L. rhamnosus* GG (LGG) fed rats had significantly less severe alcoholic steatohepatitis (ASH).

A rat intestinal isolate, *E. coli* CFR 16, having probiotic potential, was used to study the role of probiotics in 1,2-dimethylhydrazine (DMH)-induced oxidative damage in the colon of a rodent model. The results revealed that there was a reduction in the activity of antioxidant enzymes (SOD, CAT, and GPX), and there was increased lipid peroxidation in liver and intestinal tissues in animals treated with DMH only. Not only did the DMH-treated animals show reduced lipid peroxidation activity but also the activity of antioxidant enzymes was maintained at normal level. The colonic histological sections also showed significant protection.[84]

Selenium-enriched probiotics were used to study the effect on various health parameters such as growth, immune function, and selenoprotein gene expression along with antioxidant status in crossbred weanling piglets kept under high natural summer temperatures. The results indicated a high growth in the probiotic-treated group along with an increase in activity of blood GPX and expression of tissue thioredoxin reductase 1 mRNA.[85]

The effect of diet supplemented with *L. plantarum* along with bursin (a peptide isolated from bursa of Fabriciuos) immunization was studied for immune characteristics, antioxidant status, and intestinal microflora in broilers. The probiotic supplementation increased the antioxidant capacity by increasing activity of enzymes such as CAT in liver and GPX in serum and liver and decreased MDA content in serum.[86]

As mentioned earlier, in vivo antioxidative potential of *L. rhamnosus* strain CNCM I-3690 was also evaluated through transcriptomics study, which was correlated with an increase in signaling of the insulin-like pathway mediated by the DAF-16 transcriptional factor.[40]

IN VIVO STUDIES ON HUMAN VOLUNTEERS/CLINICAL STUDIES WITH HUMAN

To verify the antioxidative properties of probiotic organism *L. fermentum* ME-3, different clinical study designs (including double-blind, placebo-controlled, crossover studies) and different subjects (healthy volunteers, allergic patients, and those recovering from a stroke) have been conducted using capsules or foodstuffs.[46] Clinical studies have been carried out on volunteers with clinical symptoms because it was difficult to assess the impact of probiotics without clinical symptoms and thus related to its effect on host health. In this context, the functional efficiency of *L. fermentum* ME-3 was examined in the human gastrointestinal tract (GIT) of healthy volunteers by measuring the influence of two different formulations, that is, *L. fermentum* ME-3 fermented goat's milk and *L. fermentum* ME-3 capsules, on intestinal flora and oxidative stress markers of blood and urine after 3 weeks of consumption.[87] In this study, human body oxidative stress status was evaluated by measuring the total antioxidative activity (TAA), total antioxidative status (TAS), and ratio of glutathione oxidized (ox) and glutathione reduced (red) in blood serum. In the goat's milk-treated group, TAA and TAS were found to be 6 and 9%, respectively, as compared to control, but 4 and 2.5%, respectively, in probiotic capsule group as compared to placebo. Furthermore, the glutathione red-ox ratio was found to significantly decrease in both the study group and the control in the goat's milk trial. However, no significant decrease was demonstrated in the probiotic capsule treated group. On the other hand, fermented milk containing the *L. fermentum* ME-3 strain also exhibited the antioxidative (enhanced TAA) and antiatherogenic effects in healthy human volunteers.[50]

MECHANISMS OF PROBIOTICS AS ANTIOXIDANTS

Antioxidant supplements or foods containing antioxidants would greatly help in reducing oxidative damage, free radical scavenging rate, and reducing activity of SOD and GPX in the human body. Probiotics from the LAB family can be potential candidates for the production of functional foods or natural antioxidant supplements.[58,88] It has been reported that some probiotics result in increased activity of antioxidative enzymes or modulation of circulatory oxidative stress, which protects cells against carcinogen-induced damage. These enzymes include glutathione *S*-transferase, glutathione, glutathione reductase, GPX, SOD, and CAT.[53] Some authors hypothesize that probiotics exert their defensive effects against oxidative stress by re-establishment of the gut flora.[83,89] Most LAB have scavenging systems for oxygen free radicals. Some lactobacilli possess antioxidant activity and are able to decrease the risk of accumulation of ROS during ingestion of food.[42] Metabolic activities of probiotic bacteria may have shown the antioxidative effect through the scavenging of oxidant compounds or the prevention of their generation into the intestine.[90] Production of bioactive peptides has been considered an effective mode of antioxidative activity in foods containing probiotic bacteria. Peptides obtained from hydrolyzed food proteins have been shown to possess antioxidative activities, which can impart protection against the peroxidation of lipids or fatty acids.[91] It has been observed that the peptic digest of casein liberates small peptides with radical scavenging activity.[92] The antioxidant ability was considered due to the presence of histidine and some hydrophobic amino acids in high concentrations. Increased antioxidant activity of milk during fermentation with commonly used dairy starter cultures, including *Leuconostoc mesenteroides* ssp. *cremoris* strain, *L. jensenii*, and *L. acidophilus* has been observed.[93]

The intestinal *Lactobacillus* species are particularly foci for development of novel foods by food industry due to the increasing interest of consumer in healthy diet.[94] During the past decade, oxidative stress and antioxidative potency have been revealed as the key points in molecular regulation of cellular stress responses.[95] In the case of *Lactobacillus* spp., it has been concluded that their antimicrobial effect is also expressed via ROS such as hydrogen peroxide, superoxide anions (O_2^-), and hydroxyl radicals ($^-{}^\bullet OH$), which may have a selective influence on the intestinal microbiota, whereas a similar mechanism has been described for oral streptococci.[96] Some lactobacilli possess antioxidative activity and are able to decrease the risk of accumulation of ROS during the ingestion

DOI: 10.1021/jf506326t
J. Agric. Food Chem. 2015, 63, 3615−3626

of food.[41,97] *L. rhamnosus* strain GG was reported to have potent antioxidative activity by down-modulating the ROS production and phagocytic capacity of neutrophils.[98]

In conclusion, the antioxidative property of probiotics has been the subject of many studies in recent times, and a few patents have been granted recently in this area[102] on the use of *Bifidobacterium lactis* BS 05, *Lactobacillus acidophilus* LA 06, and *Lactobacillus brevis* LBR01. Strong evidence for the antioxidative activity of *Lactobacillus plantarum*, *L. helveticus*, *L. acidophilus*, *L. fermentum*, *L. casei*, *Lactobacillus* GG, and a few bifidobacteria and foods containing these organisms is put forward by the studies conducted. However, it should be noted that the antioxidative property is strain specific. Methods used in the study of such activity are modifications of those used for the determination of the antioxidative property of plant-based foods. It is necessary to harmonize methods for dairy-based foods as these foods are considered as the most suitable carriers of probiotics. The mechanisms of antioxidative action that have not been properly understood and elucidated could be the focus of probiotic research in years to come.

and environmental safety of *Bt* rice. Results from this study will provide important information concerning the environmental safety of genetically modified (GM) strains of rice.

MATERIALS AND METHODS

Chemicals. Human chorionic gonadotropin (hCG) and methanesulfonate (MS-222) were purchased from Sigma Chemical Company (St. Louis, MO, USA). Commercial frog feed was obtained from Cargill Feed Co., LTD (Nanjing, People's Republic of China). Liver and kidney function detection kits and *Bt*-Cry1Ab/1Ac protein detection kits were purchased from JianCheng Bioengineering Institute (Nanjing, People's Republic of China) and EnviroLogix Inc., (Portland, OR, USA), respectively.

Test Materials. The HH1 transgenic rice line expressing the fusion gene Cry1Ab/1Ac exhibits resistance to stem borers, such as *Chilo suppressalis*, *Scirpophaga incertulas*, and *Cnaphalocrocis medinalis*.[4] The insecticidal activity of HH1 seeds were previously confirmed at the seedling stage.[26] The parental nontransformed control line (MH63) is an elite *Indica* restorer line for cytoplasmic male sterility commonly grown in China. These lines were simultaneously planted in two adjacent plots at a scientific research base at Jiangxi Academy of Agricultural Sciences (Nanchang, Jiangxi Province, People's Republic of China). Transgenic rice had not been previously planted in these plots. Crops were managed in accordance with regulations of the Agricultural Genetically Modified Organism (GMO) Safety Management of China. Rice was harvested at the end of October 2013, and grains were collected and stored at −20 °C until use. The conventional nutrient components of each rice line were analyzed by the Beijing Research Institute for Nutritional Resources, People's Republic of China.

Animals. Mature female and male *X. laevis* were maintained separately in glass tanks containing dechlorinated water at 21 ± 2 °C on a 12 h light/12 h dark cycle and were fed chopped pork liver once per week. One pair of parent frogs was chosen and injected with 100 IU hCG to induce breeding. After eggs were laid, the mating pair was removed from the breeding tank. Fertilized eggs were incubated at 22 ± 2 °C on a 12 h light/12 h dark cycle. Tadpoles were started on a daily diet of green algae and *D. magna* on day 5 after fertilization and switched to commercial frog feed when they completed metamorphosis. Approximately 2 months after metamorphosis, froglets with uniform body weight (∼4.30 g) and body length (∼32.0 mm) were used for experimentation. Frogs were treated in accordance with the NIH Guide for the Care and Use of Laboratory Animals.

Diet Formulation. Synthetic frog diets were produced based on the nutrient composition of a commercial frog feed. Two test diets contained 30% rice flour, whereas the control diet was formulated using cornstarch and soybean meal without rice. The detailed diet compositions are shown in Table 1.

Experimental Design. A total of 96 froglets were equally divided into three experimental groups of 32 according to body weight, and their sexes were not considered. Each group was randomly divided into four glass jars (20 × 34 × 24 cm) to give four replicates. Froglets were fed daily (∼3% weight/body weight). Fresh dechlorinated water was replenished every 2 days and monitored daily to stay at 20−22 °C. A 12 h light/12 h dark cycle was maintained throughout the course of the experiment. Animals were observed twice daily, and body weight and length (from the tip of the snout to the tip of cloaca) were measured every 15 days for 90 days. Animals were fasted overnight before being sacrificed.

Gross Necropsy and Histopathology. At the end of the experiment, the frogs were anesthetized by immersion in 1% MS-222. Before dissection, body weight and length were measured, and the gender was determined on the basis of gross gonadal morphology. A complete necropsy was then performed, and the following organs were excised and weighed: heart, liver, spleen, lung, kidneys, body fat, ovaries or testes, and intestines. Paired organs (lungs, kidneys, ovaries and testes) were weighed as a total of left and right. Additionally, the tissues (stomach, intestines (divided into duodenum, ileum, and rectum), liver, spleen, and gonad) of one male and one female from each glass jar were fixed for a minimum of 24 h in 4% phosphate-buffered formaldehyde before histological processing. Tissue samples were embedded in paraffin, and ∼4 to 6 μm thick sections were cut and stained with hematoxylin and eosin for light microscopy.

Table 1. Composition of Nutritionally Balanced Test and Control Diets for *X. laevis* Froglets

	amt of ingredient (%)		
ingredient	HH1	MH63	control
transgenic rice	30.0	0.00	0.00
nontransgenic rice	0.00	30.0	0.00
pregelatinized starch	8.00	8.00	8.00
corn	0.00	0.00	17.0
soybean meal	6.00	6.00	21.0
soybean oil	3.00	3.00	3.50
fish meal	52.0	52.0	38.0
wheat bran	0.00	0.00	5.00
meat and bone meal	0.00	0.00	6.00
rock flour	0.00	0.00	0.50
additive[a]	1.00	1.00	1.00
total	100	100	100

[a]Contents in mg/kg of diet: iron, 70; copper, 11; manganese, 70; zinc, 65; iodine, 0.49; selenium, 0.3; vitamin A, 8000 (IU); vitamin D, 2400 (IU); vitamin E, 20 (IU); vitamin K, 0.5 (IU); vitamin B1, 2; vitamin B2, 8; vitamin B6, 3.5; vitamin B12, 0.01; calcium pantothenate, 20; niacin, 35; folic acid, 0.75; biotin, 0.26.

Determination of Liver and Kidney Function. The liver and spleen from the remaining six froglets in each glass jar (a total of 24 samples per treatment) were used to determine the following parameters: alkaline phosphatase (AKP) activity, albumin (ALB), alanine aminotransferase (ALT) activity, aspartate aminotransferase (AST) activity, urea (BUN), cholinesterase (CHE) activity, total protein (TP), creatinine (CR), glutamic acid (GLU), total cholesterol (TC), and triglycerides (TG). All parameters were detected using kits provided by the JianCheng Bioengineering Institute. All of the detection kits used in this study use a corresponding standard substance to show assay validity prior to analysis. Moreover, these kits are used strictly according to the recommendations and protocols set by the manufacture.

Determination of Cry1Ab/1Ac Content. The Cry1Ab/1Ac protein content in rice grains, frog diets, frog tissues (stomach and intestine), and frog feces (∼0.20 g each) were determined using a *Bt*-Cry1Ab/1Ac protein kit with a detection limit of 0.1 ng/g total protein. Solid feces were collected immediately after the renewal of rearing water at the later stage of the present study. Before analysis, animal tissues were washed in phosphate-buffered saline/Tween-20 to remove *Bt* toxins from the outer surface, lyophilized, and then homogenized in 1 mL phosphate-buffered saline/Tween-20 using a micropestle and mortar on ice. After centrifugation and appropriate dilution of the supernatants, an ELISA was performed following the manufacturer's protocol. Optical density values were read using a microplate spectrophotometer (PowerWave XS2, BioTek, Winooski, VT, USA). A standard curve derived from purified Cry1Ab/1Ac samples was used to calculate Cry1Ab/1Ac levels.

Statistical Analyses. All data are presented as mean ± standard deviation (SD) unless indicated otherwise. Statistically significant differences in conventional nutrient compositions between HH1 and MH63 rice grains were analyzed by Student's *t* test. Body weights and lengths were analyzed using repeated measures analysis of variance (ANOVA), whereas a one-way ANOVA, followed by least significant difference (LSD) multiple comparison tests, was used to analyze differences in organ weight, as well as liver and kidney function among the three treatment groups. Differences were considered significant at $p < 0.05$.

Table 2. Nutrient Composition of Rice Grains and Diets for *X. laevis* Froglets

component	rice grain (n = 3)			diet (n = 1)		
	amt of component[a] in HH1[b]	amt of component[a] in MH63[b]	p value[c]	amt of component[a] in HH1	amt of component[a] in MH63	amt of component[a] in control
crude protein (%)	6.63 ± 0.24	6.85 ± 0.12	0.22	38.1	38.2	42.2
crude fat (%)	2.83 ± 0.58	2.90 ± 0.00	0.18	8.40	8.80	8.10
crude fiber (%)	6.97 ± 0.06	6.65 ± 0.50	0.17	3.30	3.20	3.00
crude ash (%)	11.8 ± 0.26	11.9 ± 0.06	0.89	11.2	11.4	10.7
calcium (g/kg)	0.66 ± 0.16	0.61 ± 0.13	0.71	3.50	3.50	2.40
phosphorus (%)	0.36 ± 0.01	0.37 ± 0.01	0.25	1.81	1.84	1.73

[a]Units for the amount of component are given in column 1. [b]Data are presented as mean ± SD. [c]Student's t test, $p < 0.05$.

RESULTS

Nutrient Composition of Rice Grains and Froglet Diets. Levels of conventional nutrients (crude protein, crude fat, crude fiber, crude ash, calcium, and phosphorus) were very similar in HH1 and MH63 rice grains (Table 2), and no statistical differences were observed between the two ($p > 0.05$). Moreover, the measured values of these same nutrients in the HH1 diet were comparable to those in the MH63 and control diets (Table 2).

General Health. Animal wellbeing was observed twice daily, and body weight and length were measured every 15 days for 90 days. No adverse effects on animal behavior were observed during the experiment. The mean body weights and body lengths of animals from each treatment are shown in Tables 3 and 4, respectively. Statistically significant differences were observed among the seven repeated measures within each treatment group from day 0 to day 90 ($p < 0.01$ for body weight and body length), but not among the three treatments ($p = 0.81$ for body weight, $p = 0.98$ for body length). Additionally, the only significant difference in organ weight among the three dietary groups was the relative weight of fat body, which was significantly higher in the HH1 group in comparison to control ($p < 0.05$, Table 5).

Table 3. Mean Body Weight over Time in *X. laevis* Froglets Fed Test versus Control Diets (n = 32)

time (days)	body weight (g)[a]		
	HH1	MH63	control
0	4.35 ± 0.01	4.36 ± 0.06	4.32 ± 0.04
15	6.02 ± 0.23	6.13 ± 0.30	5.85 ± 0.21
30	8.85 ± 0.25	9.33 ± 0.57	8.97 ± 0.27
45	12.0 ± 0.40	12.3 ± 1.01	12.2 ± 0.38
60	16.7 ± 0.39	17.2 ± 1.46	16.8 ± 0.56
75	21.2 ± 0.34	22.2 ± 2.11	22.5 ± 1.12
90	27.7 ± 2.17	27.4 ± 2.40	27.9 ± 1.67

[a]Data are presented as group mean values ± SD. Repeated measures ANOVA, $p < 0.05$.

Table 4. Mean Body Length over Time in *X. laevis* Froglets Fed Test versus Control Diets (n = 32)

time (days)	body length (mm)[a]		
	HH1	MH63	control
0	31.6 ± 0.44	31.7 ± 0.42	31.8 ± 0.19
15	34.8 ± 0.60	34.7 ± 0.48	33.9 ± 0.39
30	39.2 ± 0.27	39.5 ± 0.68	39.5 ± 0.51
45	43.2 ± 0.39	43.3 ± 0.98	43.7 ± 0.54
60	47.8 ± 0.42	48.3 ± 0.50	48.5 ± 0.53
75	52.5 ± 0.78	52.0 ± 1.74	52.2 ± 1.38
90	60.2 ± 1.55	59.3 ± 2.33	59.7 ± 1.64

[a]Data are presented as group mean values ± SD. Repeated measures ANOVA, $p < 0.05$.

Liver Function, Kidney Function, and Fat Metabolism. Parameters for liver and kidney function, as well as fat metabolism, are given in Table 6. There were no statistically significant differences among the three groups ($p > 0.05$).

Cry1Ab/1Ac Protein Content in Diets and Frogs' Digestive Tracts. Cry1Ab/1Ac was present in HH1 rice grain at an average concentration of 752 ± 78.0 ng/g and was not detectable (ND) in the nontransformed control strain MH63 (Table 7). The measured Cry1Ab/1Ac contents in the HH1, MH63, and control diets (221 ± 21.2 ng/g, ND, and ND, respectively; Table 7) were close to the predicted values (226, 0, and 0 ng/g, respectively). To investigate the degradation of Cry1Ab/1Ac protein in the frog digestive tract, intestinal contents and feces were collected, and the Cry1Ab/1Ac protein content was determined by ELISA. Cry1Ab/1Ac protein was detected in the intestinal contents (249 ± 16.9 ng/g) and in feces (160 ± 34.7 ng/g) of froglets fed on the HH1 diet but not in those fed on the MH63 or control diet (Table 7).

Gross Necropsy and Histopathology. Histological examinations of stomach, intestine (ileum), liver, kidneys, spleen, testes, and ovaries are shown in Figure 1. None of the three sections of intestines showed apparent pathological abnormalities; only representative images of ileum are shown in Figure 1. Overall, there were no gross pathological findings during the necropsies, and no group-related histopathological abnormalities were observed.

DISCUSSION

An integral part of the safety evaluation of GM plants is testing for substantial equivalence to the unmodified parent strain, which provides a starting point for the overall assessment.[27] In the present study, we analyzed the differences in nutrient composition between HH1 and MH63 before evaluating the effects of the GM rice strain on development of froglets. No significant differences in composition, including crude protein, crude fat, and crude ash levels, were found between the two rice lines or between diets containing them (Table 2). Schrøder et al. found significant differences in some nutritional composition indices between brown rice material from transgenic Cry1Ab and its corresponding parental line, but all differences were within the normal reference intervals.[7] Indeed, most studies have shown that transgenic *Bt* rice lines have nutrient compositions similar to those of their parental lines,[6,8,28] which is consistent with our results.

Table 7. Cry1Ab/1Ac Protein Content in Rice Grain, Diet, and Digestive Tract of *X. laevis* Froglets Fed Test versus Control Diets (ng/g)[a]

	HH1	MH63	control
rice grain ($n = 6$)	752 ± 78.0	ND	NA
diet ($n = 6$)	221 ± 21.2	ND	ND
intestinal tract ($n = 24$)	249 ± 16.9	ND	ND
feces ($n = 6$)	160 ± 34.7	ND	ND

[a]ND, not detectable; NA, not applicable.

The consequences and potential risks associated with expressed insecticidal proteins are of particular concern in any safety assessment.[29] Numerous experimental studies have consistently indicated that the health and performance of animals fed GM crop lines and isogenic non-GM crop lines are comparable.[30] The food and feed safety of *Bt* rice has been tested in many animals, including rats,[6−9] broilers,[10] pigs,[11] and carp,[12] and all of the above studies showed that the safety of the GM line and that of the parental line were comparable. For example, TT51 rice, the same *Bt* rice line as in the present study, showed no significant differences on reproduction performance of rats in comparison with MH63 and control.[9] Moreover, Xu et al. found that Cry1Ab/Ac fusion protein produced in *Escherichia coli* has no adverse effects in mice by gavage at a high dose level of 5 g/kg body weight.[31] Our results using *X. laevis* froglets were consistent, as there were no significant differences among the three dietary groups with respect to general health, including animal behavior, body weight (Table 3), and body length (Table 4). In addition, we assessed organ weight and relative organ weight, which are important indicators reflecting organ development. A change in organ weight can signal adverse effects from the external environment, including food.[32] Our findings show that the diet containing HH1 rice resulted in no significant differences in absolute or relative organ weights in comparison with the MH63 and control diets, except for an increase in the relative weight of fat bodies in the HH1 group in comparison to the control group (Table 5). Furthermore, pathology exams revealed no obvious lesions in any group (Figure 1), and

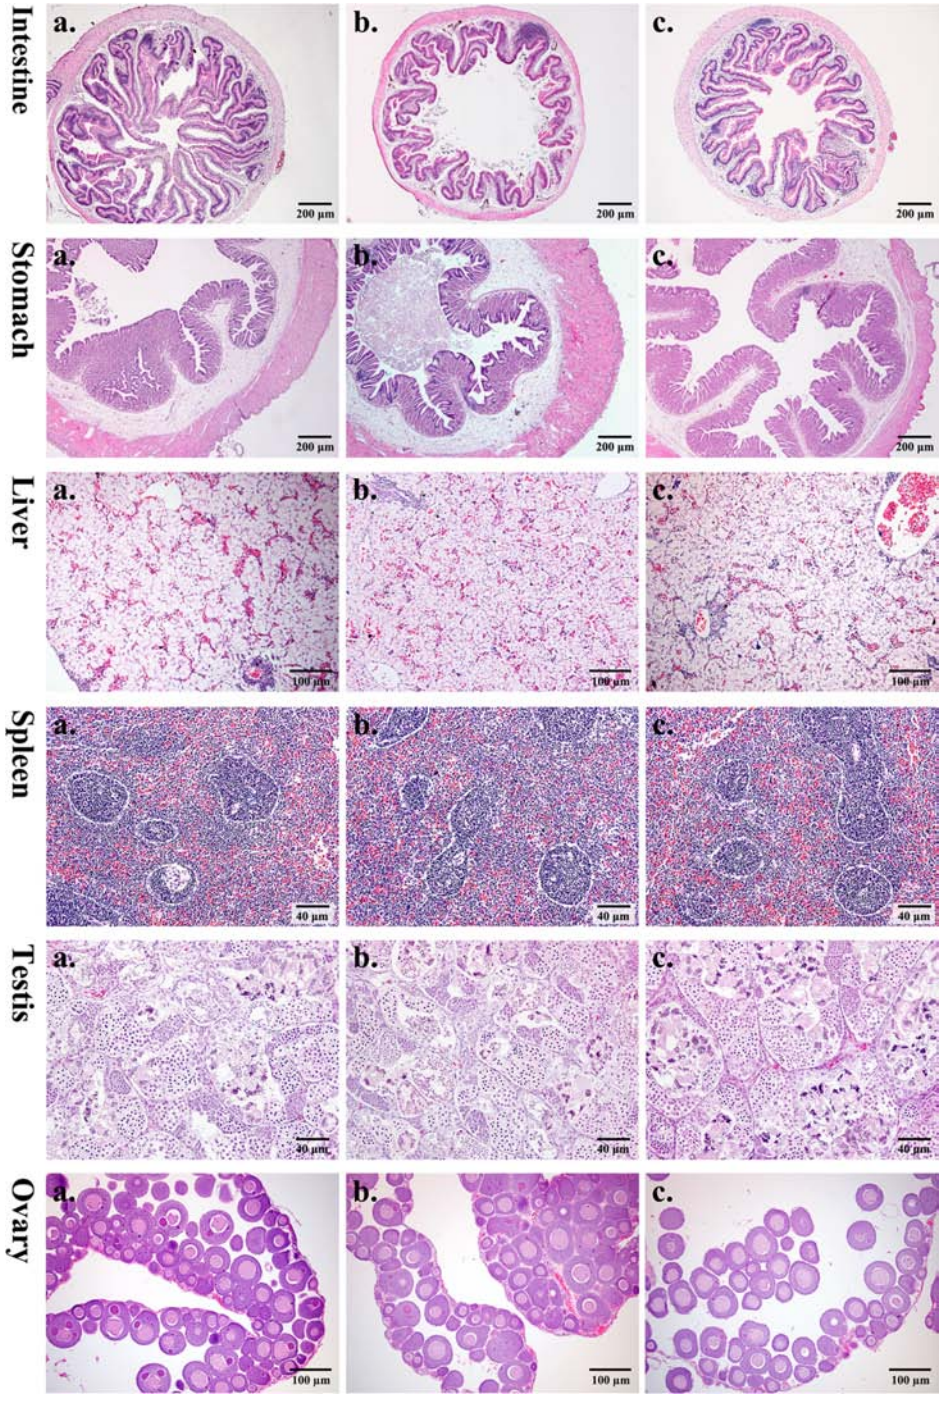

Figure 1. Histopathological staining of tissues from *X. laevis* froglets after consuming the HH1 test diet (a), MH63 test diet (b), or control diet (c) for 90 days. For intestine, only representative images of the ileum are shown.

liver function, kidney function, and fat metabolism (Table 6) were not significantly different among the groups. Taken together, these results indicate that Cry1Ab/Ac protein had no significant adverse effect on organ development.

The planting of GM crops brings huge economic and environmental benefits to humans; however, it also raises questions and concerns regarding their safety. Some people fear that foreign proteins will enter the food chain and eventually enter the human body, where they may cause potential harm to humans. They also fear that foreign proteins may be present in the feces of animals fed GM crops, where they may affect the environment. Whereas some researchers found that transgenic DNAs and proteins could not be detected in the gastrointestinal contents or feces of animals fed diets containing GM crops,[11,33,34] others were able to detect foreign transgenic proteins in the gastrointestinal contents and/or feces of pigs,[35] bovines,[36,37] deer,[38] and insects[39] that were fed transgenic crops or diets containing transgenic crops. The amount of transgenic protein ingested by livestock depends on the concentration of the protein in the feed, the amount of feed intake, and the species.[29] From previous studies we can conclude that *Bt* proteins can survive passage through an animal's gastrointestinal tract but are not transferred to the visceral organs or their products.[33,36] In the current study, Cry1Ab/1Ac

J. Agric. Food Chem. 2015, 63, 3627−3633

protein was detected in the intestinal contents and feces of froglets in the HH1 group (Table 7), indicating that they were exposed to Bt proteins by consuming a diet containing the Cry1Ab/1Ac protein. However, the microstructure of the digestive tract (Figure 1) and the froglets' overall development were not adversely affected. Our results, combined with those of others, demonstrate that expressed foreign *Bt* proteins do not produce harmful effects in the digestive tract or elsewhere after ingestion by animals.[29]

Consumption of *Bt* rice fed arthropods is the main route through which frogs are exposed to the rice-produced Cry proteins. Zhang et al. found that the Cry2Aa protein content in most of the arthropods collected from the Cry2Aa rice field were much lower than 200 ng/g dry weight.[22] Studies of *Bt* soybean and *Bt* maize showed that the plant-produced Cry proteins are diluted when moving through the foodweb.[39,40] Additionally, Wang et al. did not detect Cry1Ab/1Ac protein in the stomach and intestine of frogs collected from HH1 rice field.[26] In the present study, the Cry1Ab/1Ac protein concentration in the HH1 diet was 221 ± 21.2 ng/g (Table 7), which was much higher than the likely exposure under field conditions.

In this 90 day study, *X. laevis* froglets were exposed to *Bt* proteins by consuming a diet containing HH1 rice that carries the gene encoding Cry1Ab/1Ac. Froglet development was not adversely affected in comparison with froglets fed a diet containing the parental rice (MH63) or no rice. Combining this laboratory study with our previous field experiment,[26] we conclude that the planting of transgenic Cry1Ab/1Ac rice will not adversely affect the development of frogs.

field.[32] Recently, a magnetic molecularly imprinted polymer using bare Fe_3O_4 as supporting matrix was applied to extraction of sulfonylurea herbicides.[33] However, the bare Fe_3O_4 magnetic nanoparticles is easy to agglomerate. If a protective layer is coated on the surface of bare Fe_3O_4 magnetic nanoparticles, the stability of Fe_3O_4 magnetic nanoparticles would have been largely improved. To address the question, we developed a new type of core−shell magnetic MIPs with SiO_2-coated Fe_3O_4 magnetic particles as supporting matrix and bensulfuron-methyl as the template molecule. The core−shell magnetic molecularly imprinted polymers have been synthesized as the sorbent materials of SPE and successfully applied to assessing sulfonylurea herbicide residues in food and environmental media. The objective of the study was to provide an efficient, selective, and accurate method for analyzing sulfonylurea herbicide at trace abundance in multiple media.

MATERIALS AND METHODS

Materials and Chemicals. The pesticides BSM (methy α-(4,6-dimethoxypryrimidin-2-yl-carbamoyl sulfamoyl)-*O*-toluate, 96.1%), triasulfuron (TS, *N*-(6-methoxy-4-methyl-1,3,5-triazin-2-yl-aminocarbonyl)-2-(2-chloroethoxy)-benzenesulfonamide, 95%), prosulfuron (PS, *N*-((3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl) amino)carbonyl)-2-(3,3,3-trifluoropropyl)benzone sulfonamide, 95%), pyrazosulfuron-ethyl (PSE, ethyl-5-(4,6-dimethoxypyrimidin-2-yl-carbamoylsulfamoyl)-1-methylpyrazole-4-ca, 98%), and propazine (PPZ, 6-chloro-*n*,*n*′-bis-(1-methylethyl)-1,3,5-triazine-2,4-diamine, 97%) were obtained from Syngenta Nantong Crop Protection Co., Ltd. Fe_3O_4 (200 nm), trimethylolpropane trimethacrylate (TRIM) were purchased from Aladdin Co., Ltd. 3-Methacryloyloxypropyltrimethoxysilane (MPS) was purchased from Shanghai Jiachen Chemical Co., Ltd. HPLC grade acetonitrile was from ROE scientific INC. All other chemicals were of analytical grade provided by Nanjing Chemical Reagent Co., Ltd. Azodiisobutyronitrile (AIBN) was recrystallized by methanol. *N*,*N*-Dimethylformamide (DMF) was dried over 3 Å molecular sieves.

Instruments and Analytical Methods. The interaction between BSM and functional monomer MAA was studied by UV-2600 spectrophotometer (Shimadzu, Japan) at 190−280 nm. A series of solutions were prepared in acetonitrile in which the molar ratio of BSM and MAA was set at 0:1, 1:0, 1:1, 1:2, 1:4, 1:8, 1:10, 1:20, 1:30, 1:40, 1:50, and 1:60. The background UV absorbance of only BSM or MAA was taken out by the absorbance of solvent acetonitrile, and the background UV absorbance of other solutions was taken out by the absorbance of corresponding MAA. A TENSOR-27 FT-IR spectrometer (Bruker, Germany) with a 2 cm^{-1} resolution and a spectral range of 400−4000 cm^{-1} was employed to examine the FT-IR spectra of nanopaticle samples by a pressed tablet (sample: KBr = 1:100, w/w). The size and morphology of nanoparticle samples were analyzed using an S-4800 field emission scanning electron microscope (SEM, Hitachi High-Technologies Corporation, Japan) and a Tecnai 12 transmission electron microscope (TEM, Philips, Holland). Phase identification was done using X-ray polycrystal diffraction (XRD, Bruker-AXS Corporation, Germany) patterns, using a D8 Advance X-ray diffractometer with Cu $K_{\alpha 1}$ irradiation at $\gamma = 0.15418$ nm. The magnetic properties were studied using an EV7 vibrating sample magnetometer (VSM, ADE, US) operating at room temperature. All chromatographic measurements were performed using a HPLC system (Waters 2489, Waters Technologies Co. Ltd.), equipped with a 515 pump and a UV−vis detector. A C_{18} column (250 mm × 4.6 mm i.d., 5 μm) was used, with the mobile phase of acetonitrile−water (acidified with glacial acetic acid to pH 3.0) (60:40, v/v), detection at 235 nm, and a flow rate of 0.3 mL min^{-1}. The injection volume was 20 μL.

Preparation of Magnetic and Microsphere MIPs. Prior to use, the bare Fe_3O_4 magnetic nanoparticles were modified with negatively charged citrate groups.[34] Fe_3O_4 magnetic nanoparticles (2 g) were mixed in 150 mL (20 mM) of trisodium citrate and sonicated for 0.5 h, followed by magnetic stirring at 30 °C for 24 h. The obtained citric acid-modified Fe_3O_4 magnetic nanoparticles were washed several times with double-distilled water and acetone, isolated with a magnet, and dried under vacuum overnight.

The citric acid-modified Fe_3O_4 magnetic core was well protected by a silica film by Stöber method with a slight modification.[35] Fe_3O_4 magnetic nanoparticles (1 g) were mixed with 100 mL of 2-propanol and 20 mL of double-distilled water and sonicated for 30 min. Four milliliters of tetraethylorthosilicate (TEOS) and 2.5 mL of ammonium hydroxide were added to the mixture drop by drop. The mixture was stirred under a nitrogen atmosphere at room temperature for 20 h. The resultant product (Fe_3O_4@SiO_2) was separated with a magnet and rinsed with ethanol and double-distilled water several times, and dried under vacuum.

The Fe_3O_4@SiO_2 particles were allowed to react with MPS to introduce double bonds for polymerization. Briefly, 300 mg of Fe_3O_4@SiO_2 was added in 90 mL of toluene, sonicated for 10 min, and stirred vigorously. The mixing solution of 5 mL of MPS and 10 mL of toluene was then dropped into the resulting solution for 30 min. The stirring continued under a nitrogen atmosphere at 110 °C for 24 h. The product (vinyl-modified Fe_3O_4@SiO_2) was collected by a magnet, rinsed with methanol several times thoroughly, and dried under vacuum.

The synthesis procedure for bensulfuron-methyl (BSM)-imprinted microspheres with a molar ratio of BSM/methacrylic acid (MAA)/TRIM = 1:4:10 is described as follows. Prior to polymerization, the prearranged solution of bensulfuron-methyl (0.625 mM) and functional monomer (MAA, 2.5 mM) in 30 mL of anhydrous DMF was placed in a refrigerator and kept for 12 h to form the template−monomer complex. Vinyl-modified Fe_3O_4@SiO_2 (0.1 g), TRIM (6.25 mM), AIBN (50 mg), and 30 mL of DMF were mixed by ultrasonication for 15 min. The mixture and template−monomer complex were added into the flask and purged with high purity nitrogen for 10 min. To obtain a high cross-linking density, prepolymerization was undertaken at 50 °C for 6 h and then stirred at 60 °C for 24 h. After polymerization, the polymers (MIP1) were separated and washed with methanol/acetic acid (9:1, v/v) several times in a Soxhlet extraction apparatus until no template molecule (BSM) was detected by HPLC. The polymers were washed with double-distilled water several times until neutral and dried under vacuum. In parallel, nonimprinted microspheres (NIP1) were prepared in a similar way with no addition of template BSM. Meanwhile, in MIP2 (or NIP2) and MIP3 (or NIP3) preparation, vinyl-modified Fe_3O_4@SiO_2 was substituted by citric acid-modified Fe_3O_4 and Fe_3O_4@SiO_2, successively (Supporting Information, Table S1).

Molecular Simulation. Interactions between template BSM and functional monomer MAA were simulated using the Hyperchem 7.5 software package (Hypercube, Inc., USA). The structures of BSM, MAA, and their complexes were drawn using Chembiodraw Ultra 12.0 software. The three-dimensional structure of BSM and MAA were optimized. The minimum energies of the structures were analyzed iteratively until the convergence value was less than 0.01 kcal mol^{-1} and calculated through semiempirical quantum methods (PM3). The dimers of BSM and MAA were optimized, and the binding energies of BSM and MAA were calculated at the same level. The binding energy (ΔE) was defined as

$$\Delta E = E_{complex} - (E_{template} + E_{monomer})$$

Measurement of Adsorption Isotherm and Kinetic Adsorption Curve. Static equilibrium adsorption experiments were conducted: 10 mg of MIP1 or NIP1 was added into the centrifuge tubes containing 5 mL of methanol/water (3/7, v/v) solution with BSM concentration varying from 0.02 to 0.40 mM and shaken for 24 h at room temperature. The supernatant and polymer were separated by a permanent magnet. The BSM concentration in the supernatant was measured by HPLC.

MIP1 or NIP1 (10 mg) was mixed with 5 mL of methanol/water (3/7, v/v) solution with BSM at 0.2 mM and shaken at regular time intervals. The supernatant and polymer were separated by a permanent magnet. Concentrations of BSM in the supernatant were determined by HPLC. According to the BSM concentration before and after adsorption, the equilibrium amount of substrate bound to the polymer (Q, mg g^{-1}) was calculated by following eq 1:

DOI: 10.1021/jf506239b
J. Agric. Food Chem. 2015, 63, 3634−3645

$$Q = \frac{MV(C_0 - C_1)}{m} \quad (1)$$

where C_0 and C_1 represent the initial solution and final solution concentration (mM) of BSM, respectively; V is the solution volume (mL); m (mg) is the weight of the polymer particles; and M (g mol^{-1}) is the molar mass of the template. All average results from three independent tests were used for the following discussion.

In order to further study the binding properties of magnetic MIP1, experimental data were fitted to the Langmuir isotherms (eq 2), Freundlich isotherms (eq 3), and Langmuir−Freundlich isotherms (eq 4).

$$\frac{C_e}{Q_e} = \frac{C_e}{Q_m} + \frac{1}{Q_m K_L} \quad (2)$$

$$\log Q_e = (1/n)\log C_e + \log K_F \quad (3)$$

$$B = \frac{N_t a F^m}{1 + aF^m} \quad (4)$$

where Q_e (mg g^{-1}) and C_e (mg L^{-1}) are the amount adsorbed on magnetic MIP1 and concentration of BSM in the solution at equilibrium, respectively; Q_m (mg g^{-1}) is the theoretical maximum adsorption capacity; K_L (L mg^{-1}) is the Langmuir constant related to the affinity of adsorption sites; K_F (L mg^{-1}) and n are determined from a linear plot of log Q_e versus log C_e, demonstrating adsorption capacity and intensity, respectively; N_t is the total number of binding sites; a is related to the binding affinity (K_0) via $K_0 = a^{1/m}$, and m is the heterogeneity index that varies from 0 to 1 (m = 1 means the media is homogeneous).

Selectivity Experiment. To evaluate the specific recognition ability of MIP1 for BSM, 10 mg of MIP1 (or NIP1) was added into 10 mL centrifuge tubes containing 5 mL of methanol and water (3/7, v/v) solution with 0.2 mM of BSM, TS, PS, PSE, or PPZ. Meanwhile, 10 mg of MIP1 (or NIP1) was added into the mixed solution of these five pesticides with initial concentrations of 0.2 mM. Each mixture with MIP1 (or NIP1) was shaken at room temperature for 24 h. The supernatant was separated with a permanent magnet. Concentrations of BSM, TS, PS, PSE, and PPZ were determined by HPLC. The interrelated absorbed coefficient was evaluated by the following equation:

$$\text{Static distribution coefficient } K_d = \frac{C_p}{C_s} \quad (5)$$

where C_p is the concentration on the absorbed medium, and C_s is the final free concentration of the solution. The selectivity coefficient of MIP1 to BSM with respect to the competitor species can be obtained according to eq 6.

$$\text{Selectivity coefficient } k = \frac{K_d(SU_s)}{K_d(PPZ)} \quad (6)$$

where K_d (SU_s) stands for static distribution coefficient of the template or the structural analogues; and K_d (PPZ) is the static distribution coefficient of pesticide PPZ.

The value of the relative selectivity coefficient k' defined in eq 7 indicates the enhanced extent of adsorption affinity and selectivity of MIP1 to the template BSM.

$$k' = \frac{k_{MIP}}{k_{NIP}} \quad (7)$$

where k_{MIP} and k_{NIP} are the selectivity coefficients of MIP1 and NIP1, respectively.

Separation Enrichment of Sulfonylurea Herbicides. MIP1 was used directly as sorbents for sulfonylurea herbicides. Water samples (20 mL) and 100 mg of magnetic MIP1 particles were mixed in a centrifuge tube. After being shaken at room temperature for 3 h, MIP1 was removed by a permanent magnet, first washed with water, and then washed with 4 mL of methanol. The eluent solution was collected and filtered through a 0.45 μm filter before HPLC analysis.

MIP1 was used as sorbents to prepare the SPE cartridge. MIP1 particles (100 mg) were packed in an empty 3 mL solid phase extraction (SPE) cartridge. The SPE cartridge was capped with PTFE frits at the top and bottom, respectively. The MIP-SPE cartridge was washed with 10 mL of methanol−acetic acid (9:1, v/v) to remove residue and preconditioned with 5 mL of methanol and 5 mL of ultrapure water. Standard solution or sample solution was loaded onto the preconditioned MIP-SPE cartridge at a rate of 0.5 mL min^{-1}. After sample loading, the MIP-SPE cartridge was washed with 2 mL of methanol/water (3/7, v/v). The elution step was performed using 2 mL of methanol. The eluate was collected and filtered through a 0.45 μm filter before HPLC analysis. For comparison, C_{18} SPE (Supelco, 3 mL, 500 mg) was used with a similar protocol to that of the MIP-SPE columns.

Determination of Environmental Samples. Rice water (paddy soil water), soil, and rice grain were collected for analysis. Water sample was directly added into the centrifuge tube containing magnetic MIP or loaded onto the preconditioned MIP-SPE column. The soil was collected from a rice field, and the plant debris was removed from the soil. The soil was dried under natural conditions and passed through a 2 mm sieve. The soil sample was extracted ultrasonically with 20 mL of acetone−water (3:1, v/v) for 30 min and centrifuged. The extraction procedure was performed in triplicate. The supernatant was concentrated to remove acetone at 40 °C by a rotary evaporator. The residual water was loaded onto the preconditioned MIP-SPE column. The rice was ground. The rice grains were rinded in a grinder (FW177, Taisite Instrument Co. Ltd., China) and passed through a 0.38 mm sieve. The rice grain was soaked and ultrasonicated with dichloromethane three times, each time with 20 mL for 30 min. The extracting solution was centrifuged, and the supernatant was combined and concentrated by a rotary evaporator at 40 °C. The residue was redissolved in 1 mL of methanol and then diluted with 20 mL of water. The diluting solution was loaded onto the preconditioned MIP-SPE column. The MIP-SPE column was washed. The eluent was collected and analyzed using the methods indicated above. Each sample was repeated in triplicate.

To evaluate accuracy of the method, the spiked recoveries of samples were investigated. Test samples of soils (10.0 g) and ground rice grains (10.0 g) were prepared using an appropriate volume of standard mixture solution (each pesticide 1.0 mg·L^{-1}) to obtain the final concentrations of 0.1, 0.25, and 0.5 mg kg^{-1}, respectively. The spiked samples were incubated and left to stand for about an hour. The water samples were spiked with each herbicide at the concentrations of 0.05, 0.25, and 0.5 mg L^{-1}. Extraction, purification, and concentration were performed in the same way indicated above.

Statistic Analysis. All of the experiments were performed at least three repetitive independent treatments. The values were expressed as the means ± standard deviation. ANOVA was conducted using the mixed model procedure in SPSS statistics 20. The significance of the differences among the means was calculated by Turkey's test. Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Preparation of Imprinted Magnetic Microspheres. The schematic representation of MIP preparation is illustrated in Figure 1. The synthetic approach included the following procedures: (1) obtaining the shell−core structure of vinyl-modified Fe_3O_4@SiO_2; (2) self-assembly of the template and functional monomers; (3) polymerization in the presence of cross-linker, initiator and porogen; and (4) achieving recognition cavities in the polymer matrix by eluting template BSM.

To obtain highly stable and well-dispersed magnetic nanoparticles, silica was selected to encapsulate Fe_3O_4. Silica has a small dimension with extremely high surface-to-volume ratio.[25] It can screen the magnetic dipolar attraction between the magnetic Fe_3O_4 molecules in liquid media. Also, most of the template molecules are situated at the surface or are in the proximity of surface. Furthermore, since the silanol group stands on the Fe_3O_4 surface coated by silica, the modified Fe_3O_4 could increase

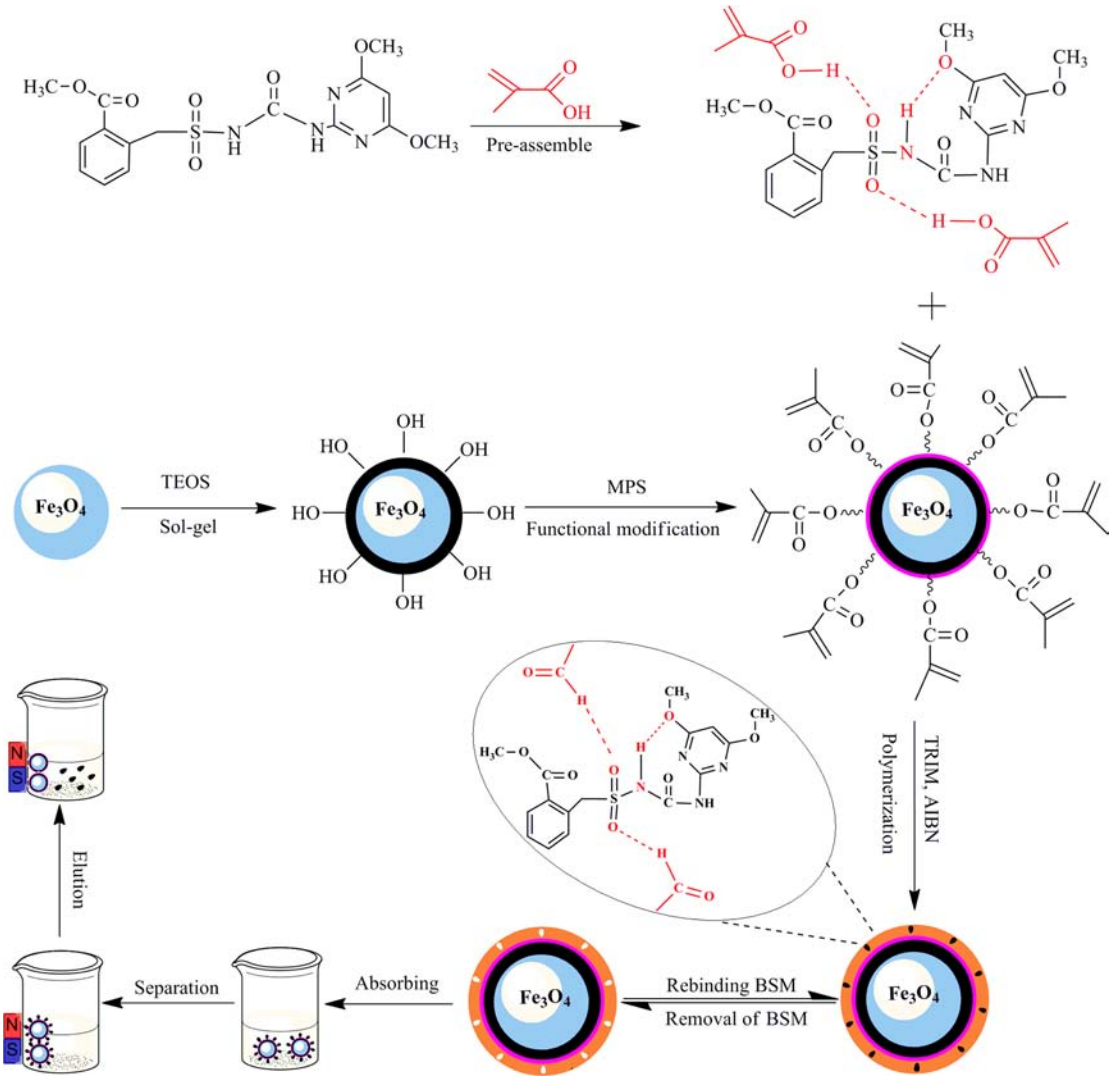

Figure 1. Schematic representation of the possible process of BSM imprinted polymers.

biocompatibility and bioconjugation with various groups. The silanol group on the Fe_3O_4@SiO_2 surface further reacted with MPS to introduce vinyl groups, which subsequently reacted with the functional monomer MAA. The copolymerization of terminal C═C double bonds of MPS with MAA can directly produce the network structures and form MIP nanospheres.

To investigate the modification of Fe_3O_4, a series of molecularly imprinted and nonimprinted polymers were prepared (Supporting Information, Table S1). All BSM-imprinted polymers (MIP) had much greater adsorption capacity for the template than the corresponding referenced polymers (NIP) (Supporting Information, Table S1). Among the three MIPs, MIP1 showed the greatest binding capacity for BSM, about twice as much as MIP2 and MIP3, suggesting that more recognition sites existed in MIP1 than in MIP2 and MIP3. MIP3 showed the lowest binding capacity for BSM among three MIPs. MIP1 was therefore selected for further investigation.

Interaction between BSM and MAA in Solution. In order to acquire the high adsorption capacity of MIP, interactions between the functional monomer and template were investigated. Since hydrogen-bonding can provide precise molecular recognition depending on both distance and direction between the monomer and template, it is commonly used for assembling the noncovalent MIP.[36] When BSM concentration is kept constant and the ratio of BSM/MAA increased from 1:0 to 1:60 (BSM/MAA), the maximum absorption wavelengths of BSM presented obviously red shifts, and the maximum absorbance intensity of BSM also largely decreased with the increasing molar ratio of MAA (Figure 2). The result indicated that hydrogen bonding existed between BSM and MAA, and affected the $\pi-\pi^*$ absorption band of BSM.

To confirm the hydrogen bonding between BSM and MAA, we employed a molecular simulation technique that is widely adopted to study molecular interactions between the template and functional monomer at the molecular level.[15,37−39] Simulated results showed that the binding energies (ΔE) of BSM with MAA were −11.14 and −17.03 kcal mol^{-1}, respectively, when BSM interacted with MAA at mole ratios of 1:1 and 1:2, indicating that the binding energy was lowest with −17.03 kcal mol^{-1} and that the complex with a mole ratio of 1:2 was most stable. Stable hydrogen bonding interactions between BSM and MAA were observed involving two intermolecular hydrogen bonds (at each O in the $-SO_2$-group) and an intramolecular hydrogen bond at O27 and H38 (Supporting Information, Figure S1). Although molecular simulation showed the theoretic binding sites and ratio between BSM and MAA, the

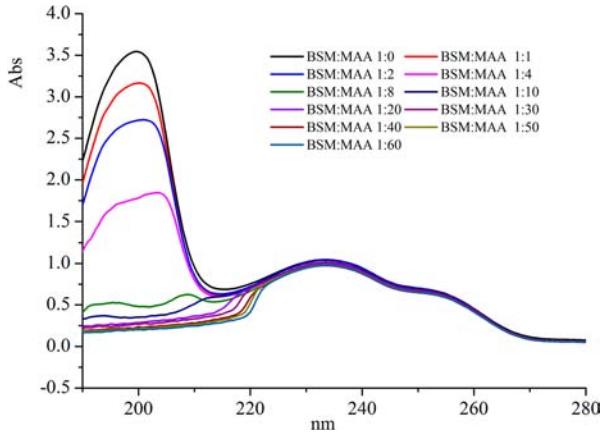

Figure 2. UV spectra of BSM with different molar ratios of MAA in acetonitrile. Concentration of BSM, 0.05 mmol L^{-1}; concentration of MAA for lines 1−11, 0, 0.05, 0.1, 0.2, 0.4, 0.5, 1, 1.5, 2, 2.5, and 3 mmol L^{-1} respectively. Corresponding pure MAA solutions as blank.

experimental approach affected the choice of the most appropriate ratio between them. Since the association between the monomer and template is governed by an equilibrium in the noncovalent approach, the functional monomers normally have to be added in excess relative to the number of moles of the template to favor the formation of the template−monomer complex. Therefore, the working molar ratio of the template to functional monomer was typically set with 1:4.[40]

Characterization of Core−Shell Magnetic Molecularly Imprinted Polymers. The TEM images showed that the size of Fe_3O_4 magnetic particles was around 200 nm with an irregular shape (Figure 3A). The diameter of the uniform spherical Fe_3O_4@SiO_2 with silica coating was extended to about 620 nm, corresponding to a 420 nm thickness of SiO_2 layers coated on the Fe_3O_4 particles (Figure 3B). The silica shell of Fe_3O_4@SiO_2 enhanced the biocompatibility and stability of Fe_3O_4 magnetic particles and prevented oxidation and aggregation of Fe_3O_4 magnetic particles. However, Fe_3O_4@SiO_2 provided the sites to react with MPS, which could offer vinyl end groups favorable for further grafting.[41] Furthermore, the uniform core−shell MIP was successfully constructed, and the MIP1 had a polymer layer with about 20 nm thickness (Figure 3C), revealing that the binding sites almost existed at the surface of Fe_3O_4@SiO_2-MIP. The MIP1 spheres appear more irregular, presumably due to the presence of the imprint. In contrast, NIP1 spheres appear smoother, showing more uniform appearance (Figure 3E). However, the MIP1 had a three-dimensional structure and appeared more porous and looser in comparison with that of NIP1. The result demonstrated the fixing of template BSM and functional monomer MAA on the Fe_3O_4@SiO_2 surface in the presence of the cross-linker, porogen, and initiator in the polymerization system (Figure 3D). This core−shell structure of MIP1 should be effective in mass transport for rebinding and releasing the template.

In FT-IR spectra, the peak at 580.54 cm^{-1} was attributed to the stretching vibrations of Fe−O (Figure 4A). In comparison with the infrared data of Fe_3O_4, the peaks at 804.41, 948.85, and 1089.67 cm^{-1} correspond to the stretching vibrations of Si−O, Si−O−H, and Si−O−Si, respectively (Figure 4B−D), pointing to the formation of silica coating on the surface of Fe_3O_4. The vibration at 1696.29 cm^{-1} in vinyl-modified Fe_3O_4@SiO_2 was the peak of carbonylic groups, indicating the successful modification using MPS on the Fe_3O_4@SiO_2 surface (Figure 4B). Meanwhile, the strong peaks of the C═O group at 1736.01 cm^{-1} and C−H

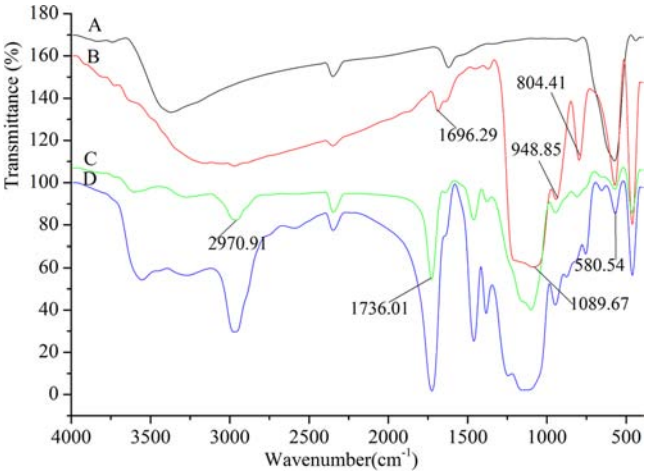

Figure 4. FT-IR spectra of Fe_3O_4 (A), vinyl-modified Fe_3O_4@SiO_2 (B), MIP1 (C), and NIP1 (D).

group of methyl at 2970.91 cm^{-1} (Figure 4C and D) indicated the successful grafting of a polymer layer on the vinyl-modified Fe_3O_4@SiO_2. In addition, MIP1 had the same characteristic peaks with NIP1, showing the complete removal of the template from MIP1.

XRD is a powerful tool for crystal structure characterization. The XRD patterns for the magnetic particles with and without coating were displayed in Supporting Information, Figure S2. These samples with specific diffraction peaks were highly crystalline materials, and the four particles contain Fe_3O_4 with a spinel structure.[42] The peak positions of the four samples remained unchanged, indicating that the step-by-step procedure of coating and polymerization made no crystalline structure change of Fe_3O_4. The intensities of the characteristic peaks in MIP1 slightly decreased owing to the encapsulation by the polymer layer.

VSM was applied to the characterization of the magnetic properties of the synthesized particles. The remnant magnetization (M_r) and coercivity (H_c) can be determined from the VSM data (Figure 5). The values of M_r and H_c were 5.44 emu g^{-1}

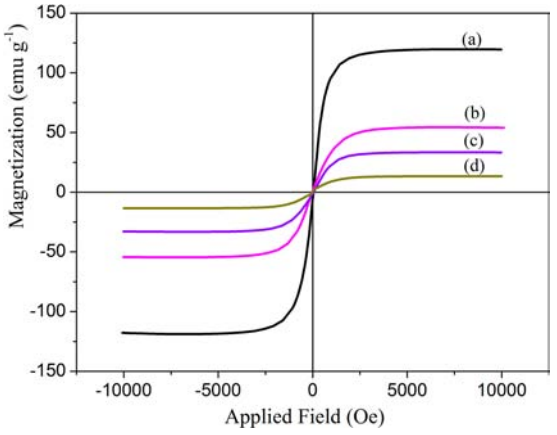

Figure 5. Magnetization curves at 298 K of Fe_3O_4 (a), Fe_3O_4@SiO_2 (b), vinyl-modified Fe_3O_4@SiO_2 (c), and MIP1 (d).

and 34.25 Oe for Fe_3O_4, 1.17 emu g^{-1} and 27.68 Oe for Fe_3O_4@SiO_2, 1.10 emu g^{-1} and 41.77 Oe for vinyl-modified Fe_3O_4@SiO_2 and 0.57 emu g^{-1} and 12.92 Oe for MIP1, respectively. The very weak hysteresis indicated that four samples had good superparamagnetism at room temperature. We were sure that all of the nanoparticle samples with good superparamagnetism can be redispersed rapidly as soon as the external magnetic field was removed. Furthermore, the saturation magnetization of Fe_3O_4@SiO_2 (54.3 emu g^{-1}) and vinyl-modified Fe_3O_4@SiO_2 (33.4 emu g^{-1}) were lower than that of Fe_3O_4 (119.5 emu g^{-1}) (Figure 5) because the small particle surface was inactive and the magnetic layer was not collinear with the magnetic field.[43] The saturation magnetization of MIP1 with an additional polymer layer was significantly decreased to 13.4 emu g^{-1}. However, the MIP1 remained strongly magnetic and could be isolated using an external magnet in a few seconds.

Adsorption Isotherms. The adsorption isotherm experiments were conducted with different initial concentrations of BSM ranging from 0.02 to 0.4 mM. The adsorbability of MIP1 continuously increased with the increment of BSM ranging from 0.02 to 0.35 mM and reached equilibrium at 0.35 mM (Figure 6A). The adsorption capacity of MIP1 (37.32 mg g^{-1}) was about 2.02-fold over that of NIP1 (18.45 mg g^{-1}) at 0.4 mM of BSM. The result confirmed that the arrangement of MAA in MIP1 was inherently different from that of NIP1.

The corresponding parameters fitting Langmuir, Freundlich, and Langmuir−Freundlich isotherm models to the experimental data were obtained (Figure 6B−D). The values of Q_m and K_L were 43.48 mg g^{-1} and 0.0083 L mg^{-1}, respectively; the values of n and K_F were 1.247 and 1.0007 L mg^{-1}, respectively; and the values of N_t and m were 98.67 mg g^{-1} and 1, respectively. K_0 is equal to a (3.517M^{-1}). Although the Freundlich model has been shown to be generally applicable to most noncovalently imprinted polymers,[28,44] it did not fit the experimental data well. The Langmuir isothermal equation with an R^2 value of 0.9267 seemed more desirable to describe the adsorption of BSM on magnetic MIP1 than the Freundlich isothermal equation (R^2 = 0.7532) and the Langmuir−Freundlich equation (R^2 = 0.7527). However, the isotherms (MIP1) showed 3 distinct regions: region 1, a low slope linear relationship at low concentration demonstrating weak adsorption; region 2, a higher slope linear relationship at intermediate concentrations; and region 3, a low slope linear relationship at high concentration, suggesting that sites were nearly saturated (Figure 6A).

Adsorption Kinetics. The adsorption kinetics of magnetic MIP1 was investigated at 0.2 mM BSM. An overall 5-fold increase was observed in adsorption capacity with magnetic MIP1 versus NIP1 (Figure 7). For MIP1 there was a fast rising adsorption during the first 60 min before the adsorption equilibrium was reached. In the first 60 min, the magnetic MIP1 attained up to 86% of equilibrium absorption amounts of BSM. These results indicated that most of the template was sorbed to the imprinted sites at a fast rate, suggesting that the binding sites of the magnetic MIP1 were on or near the surface. In contrast, the magnetic NIP1 showed a low affinity but similar equilibration time to that of MIP1 as there was a clear increase in amount sorbed from time 0 to 60 min.

Magnetic MIP Binding Specificity. In order to investigate the selectivity of magnetic MIP1 microspheres for sulfonylurea herbicides, binding experiments were conducted by choosing triasulfuron (TS), prosulfuron (PS), and pyrazosulfuron-ethyl (PSE) as the structural analogues of BSM template and propazine (PPZ) as a representative of different classes of compounds of dissimilar structure. NIP1 was used for comparison. The binding amounts of BSM for magnetic MIP1 were higher than those of the other three sulfonylurea herbicides and PPZ,

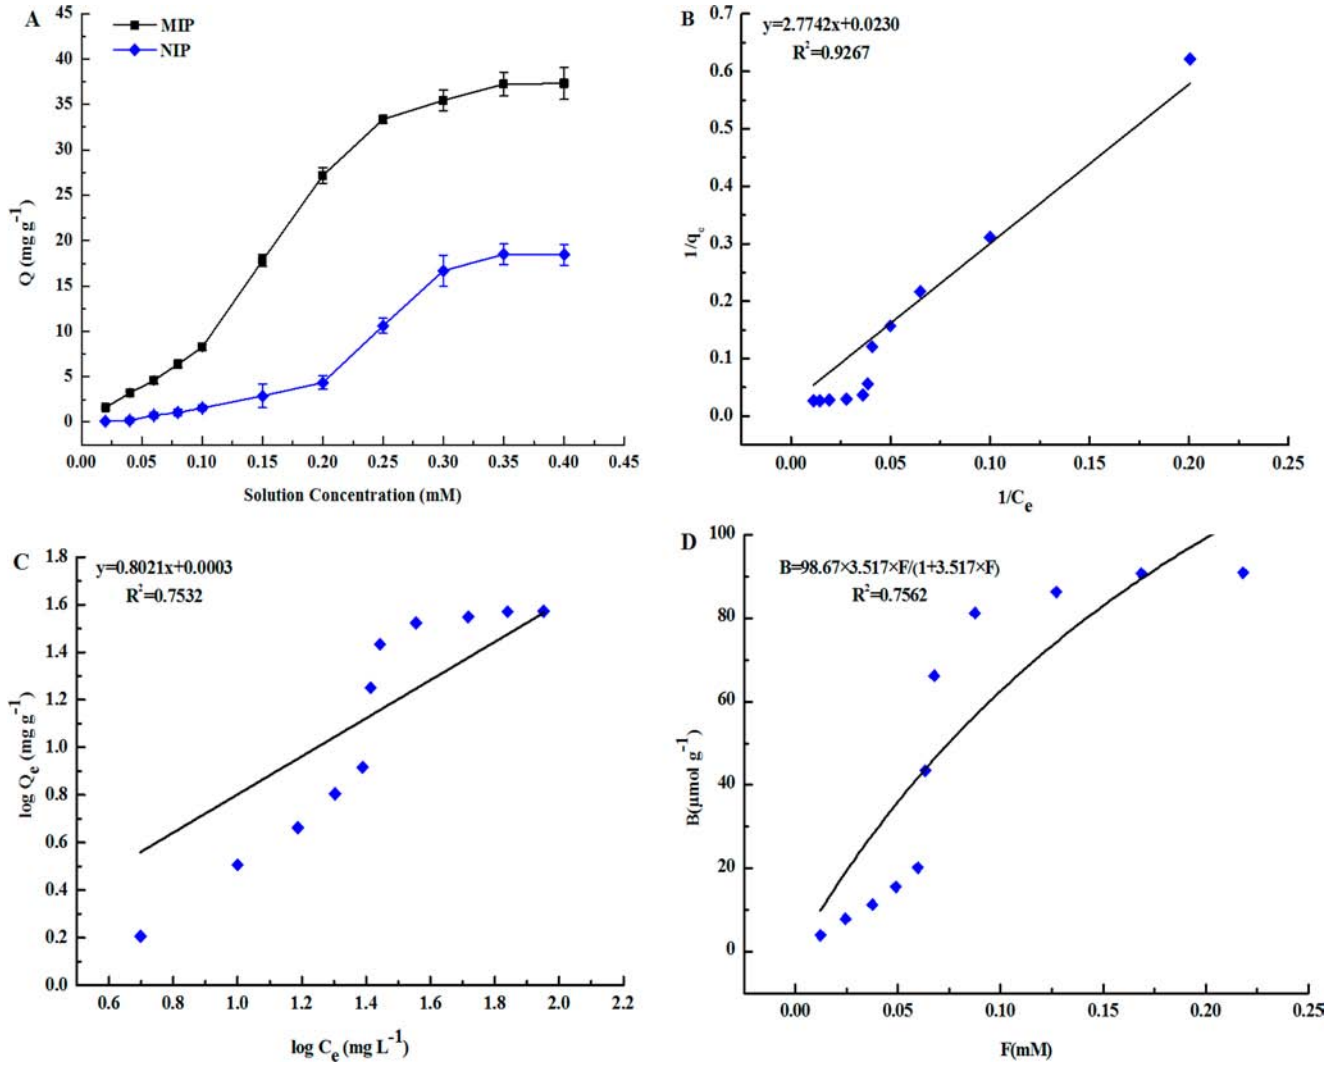

Figure 6. Adsorption isotherms (A) of BSM on MIP1 and NIP1, Langmuir plot (B), Freundlich plot (C), and Langmuir–Freundlich plot (D) to estimate the binding nature of MIP1. Experimental conditions: 0.02–0.4 mmol L^{-1} BSM with 10.0 mg of the polymers for 24 h, and the binding medium was 5 mL of methanol–water (30:70, v/v). The measurements were repeated three times.

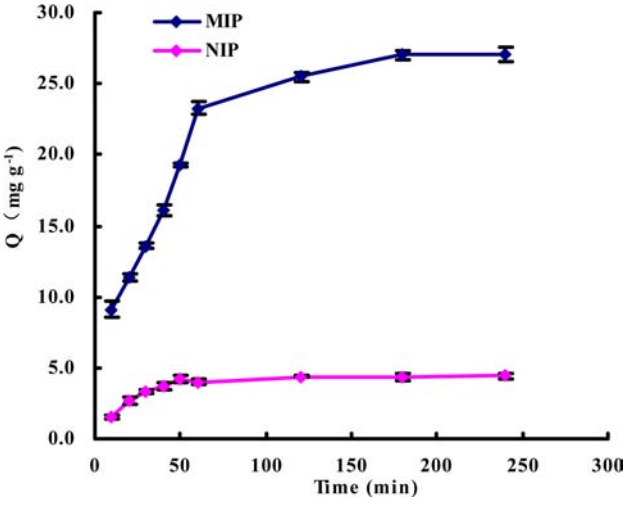

Figure 7. Adsorption kinetic curves of BSM on MIP1 and NIP1. Experimental conditions: 0.2 mmol L^{-1} BSM in the binding medium of 5 mL of methanol–water (3:7, v/v) with 10 mg of MIP1 or NIP1 for a certain time period. The measurements were repeated three times.

suggesting that the template molecule BSM had a relatively higher affinity for the imprinted polymer than others (Figure 8). It was possible that the specific sites existing in magnetic MIP1 were complementary in shape, size, and spatial distribution to template BSM. The template fitted the cavities well in the imprinted polymer.[45] Moreover, the absorption amounts of magnetic MIP1 toward the five pesticides were lower in the mixture (Figure 8B) than in individual solutions (Figure 8A). The phenomenon demonstrated that the binding sites were fixed in magnetic MIP1 and that the five compounds competed with each other in the mixed solution, leading to the reduced adsorption on magnetic MIP1. There were interactions of hydrogen bonding between the hydroxyl group in MAA and sulfonyl group in BSM (Supporting Information, Figure S1). Three analogous pesticides (TS, PS, and PSE) also have the group ($-SO_2-$) that is the same in BSM (Supporting Information, Figure S3). Therefore, the binding capacities of the analogues were much higher than that of PPZ, indicating that magnetic MIP1 also possessed high selectivity to the structural analogues of BSM. This was supported by the fact that the relative binding affinity was a function of compound structure (Supporting Information, Figure S1). PSE is most similar to BSM in molecular dimensions and

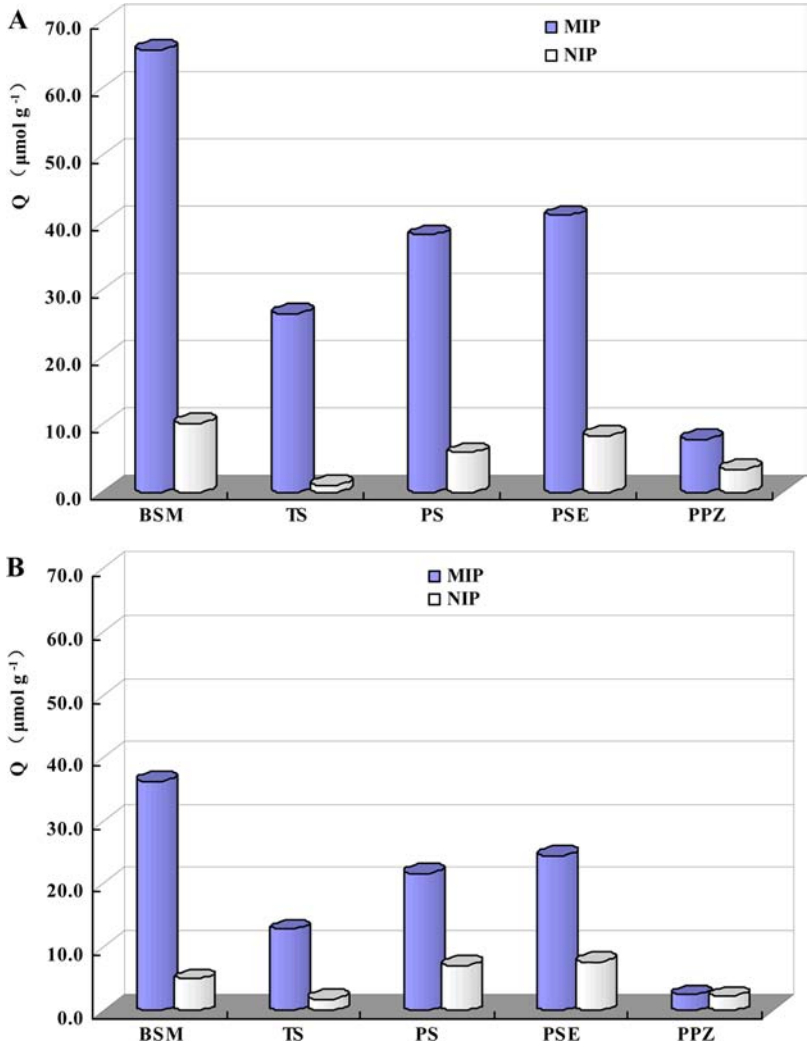

Figure 8. Adsorption selectivity of BSM onto MIP1 and NIP1 in single solution (A) and mixed solution (B). Ten milligrams of the polymers was suspended in 5 mL of methanol−water (3:7, v/v), in which the concentration of BSM, TS, PS, PSE, and PPZ was 0.2 mmol L^{-1} (A). Ten milligram polymers were suspended into 5 mL of mixed solution containing a mixture of BSM, TS, PS, PSE, and PPZ with a concentration of 0.2 mmol L^{-1} for each compound (B). The measurements were repeated three times. BSM, bensulfuron-methyl; TS, triasulfuron; PS, prosulfuron; PSE, pyrazosulfuron-ethyl; PPZ, propazine.

Table 1. Specific Recognition Properties of Magnetic MIP1 and NIP1

	MIP1			NIP1			
analytes	C_s (mM)	K_d	k	C_s (mM)	K_d	k	k'
BSM	0.127	0.573	22.038	0.190	0.053	2.208	9.981
TS	0.174	0.148	5.692	0.196	0.019	0.792	7.187
PS	0.157	0.278	10.692	0.186	0.077	3.208	3.333
PSE	0.151	0.327	12.577	0.185	0.083	3.458	3.637
PPZ	0.195	0.026	1	0.195	0.024	1	1

functional groups, and it had the highest binding affinity among the competing herbicides tested. The binding of PSE on magnetic MIP1 was greater than those of TS and PS. Compared with BSM, the mismatch of the structure and size with specific cavities might hinder TS entering the imprinted cavities and lead to the lowest binding capacity of TS among the four analogues. Since the three F atoms in PS bind to hydroxyl hydrogen in MAA, the binding affinity of magnetic MIP1 to PS was larger than that of TS. In addition, PPZ, with the least structural similarity to BSM, showed the lowest binding capacity (3 μmol g^{-1}) (Figure 8B). In contrast, there was no obvious difference of the NIP1 binding capacity for five herbicides, which likely depended on the same mechanism of nonspecific absorption.

To further assess the molecular recognition property for MIP1, the static distribution coefficient (K_d), selectivity coefficient (k), and relative selectivity coefficient (k') were calculated based on the data in Figure 8B by eqs 5−7. The k values of magnetic MIP1 showed a significant increase compared to the values of NIP1 due to the imprinting effect (Table 1). The k' for PPZ was much lower than that for TS, PS, and PSE, indicating that the magnetic MIP1 had a high binding affinity for these

Methodological Validation and Application to Real Samples. The magnetic MIP-SPE cartridges were applied for purifying and concentrating the selected sulfonylurea herbicides in real samples. The washing step for the MIP-SPE is the key parameter for the method of sample pretreatment.[46] To obtain maximum selectivity and recovery of sulfonylurea herbicides in the washing step, water containing different percentages of methanol was tested. Two milliliters of methanol/water (45/55 or 35/65, v/v) led to lower recoveries among all ratios of methanol and water (Supporting Information, Figure S4). The recovery of BSM showed no significant difference at 30:70, 25:75, and 15:85 ($MeOH/H_2O$). For the recovery of PS, the use of 30:70 ($MeOH/H_2O$) showed no significant difference compared to 25:75, as well as 25:75 compared to 15:85. The recoveries of TS and PSE using 30:70 ($MeOH/H_2O$) were lower than 25:75 and 15:85 but were also reached or greater than 80%. As more interference in paddy soil and grain occurred, an appropriately high ratio of methanol in washing solution could provide high elution strength. Thus, 2 mL of methanol/water (30/70) was chosen as the washing solution in the experiment in order to eliminate the impurities and keep the recoveries of the four sulfonylurea herbicides. Under the optimized conditions of magnetic MIP-SPE coupled with HPLC, a good linearity was achieved for standards in the range of 0.04−0.8 μM for BSM, TS, PS, and PSE with correlation coefficients of 0.9996, 0.9954, 0.9936, and 0.9941, respectively (Supporting Information, Table S2). Their LODs were in the range of 6.4−9.5 nM.

The created methodology was applied to the rice water, paddy soil, and grain samples. Initial analyses confirmed that the three samples were free of sulfonylurea herbicides. The detecting signals of four sulfonylurea herbicides with MIP-SPE procedure (Supporting Information, Figure S5-Ac, Bc, and Cc) were stronger than that without the MIP-SPE procedure (Supporting Information, Figure S5-Ab, Bb, and Cb) in the water, soil, and grain samples. The analysis of blank samples showed that most of the interference substances were washed during the methanol/water (3/7, v/v) cleaning up process (Supporting Information, Figure S5-Aa, Ba, and Ca). Although there were some impurities after the soil sample was treated by magnetic MIP-SPE, they had the least impact on the quantitative determination of sulfonylurea herbicides (Supporting Information, Figure S5B).

The accuracy of the method was evaluated by the recovery test conducted with spiked samples. The relative recoveries of BSM, PS, and PSE with magnetic MIP-SPE as columns for the spiked rice water, soil, and grain were 78.14−102.00%, 80.77−95.78%, and 73.21−91.50%, respectively, and the relative standard deviations (RSDs) were 0.22−8.74%, 0.81−4.55%, and 1.61−7.08%, respectively (Tables 2 and 3). The recoveries of four herbicides for rice water using magnetic MIP as sorbents were slightly lower than those with the MIP-SPE column. The recoveries of TS in the three spiked samples were 50.81−100.80%, with RSDs ranging from 0.93% to 7.54% (Tables 2 and 3). The C_{18} column only had the nonspecific adsorption, resulting in much lower recoveries of sulfonylurea herbicides in the spiked samples. The results demonstrated that the magnetic MIP-SPE coupled with HPLC was an efficient and effective methodology for selective extraction and sensitive assessment of multiple sulfonylurea herbicides at a very low concentration.

Reusing MIPs. To verify the recyclability of MIP-SPE, regeneration (adsorption/desorption) cycles were conducted with four sulfonylurea herbicides. After MIP-SPE columns were used to analyzed samples in food or environmental media, the columns could be regenerated by washing with 5 mL of acetic acid, 5 mL of methanol, and 5 mL of water. The result showed that MIP-SPE columns could be used for six cycles at least, and the average recovery had only a loss of less than 5.5%, indicating that the selectivity of the MIP-SPE was specific and stable for four sulfonylurea herbicides in food and environmental media.

may vary dependent upon soil properties, affecting the free concentration of plant-available PFAAs in soil solution.[21,27] Since sorption to soil particles cannot occur in nutrient solution experiments and consequently the well-established leaching of PFAAs in soil must necessarily remain unconsidered, it is possible that the exposure time-dependent uptake of PFAAs by the root surface may be overestimated. In addition, differing sorption characteristics of PFAAs on soil particles depending upon varying chain lengths and functional groups may have an impact on the uptake of PFAAs and consequently on the PFAA distribution pattern.[27] This may, in turn, have an effect upon the resulting accumulation potential of PFAAs in above-ground plant parts. In addition, the time period of exposition to PFAAs, particularly in regard to reproductive parts of plants, is shortened in nutrient solution experiments. To the best of our knowledge, there have not been any systematic studies of the accumulation of different PFAAs in fully mature maize plants. A pot experiment, in which the soil was spiked with PFAAs, was therefore designed to determine whether the soil plays an important role in the uptake of PFAAs by maize. The uptake of a mixture of 10 PFAAs from soil by maize plants was determined for two different concentration levels (0.25 mg/kg and 1.00 mg/kg soil) under controlled conditions in a pot experiment. The mixture of seven perfluoroalkyl carboxylic acids (C4 to C10) and three perfluoroalkyl sulfonic acids (C4, C6, and C8) was selected in order to study the effect of various chemical properties of PFAAs on the uptake and distribution of these molecules in maize. Those properties included different functional groups and chain lengths. A mixture of PFAAs was chosen to mimic real conditions since PFAAs occur in the environment, especially in hot-spot regions, in heterogeneous mixtures, not in the form of isolated single substances. Based on the PFAA concentrations applied in the soil and those measured in maize, the soil-to-plant transfer factors were calculated for each substance in the straw and kernels of maize. The PFAA concentration levels chosen for this study reflect those levels found in the soil of "hot-spot regions" in Germany, including regions in Hesse, North Rhine Westphalia, and Baden-Württemberg.[28−31]

MATERIALS AND METHODS

Chemicals. All standards—perfluoro-*n*-butanoic acid (PFBA), perfluoro-*n*-pentanoic acid (PFPeA), perfluoro-*n*-hexanoic acid (PFHxA), perfluoro-*n*-heptanoic acid (PFHpA), perfluoro-*n*-octanoic acid (PFOA), perfluoro-*n*-nonanoic acid (PFNA), perfluoro-*n*-decanoic acid (PFDA), potassium perfluoro-1-butanesulfonate (PFBS), sodium-perfluoro-1-hexanesulfonate (PFHxS), and sodium-perfluoro-1-octanesulfonate (PFOS) (chemical purity each ≥98%)—as well as mass-labeled internal standards—perfluoro-*n*-[1,2,3,4-$^{13}C_4$]-butanoic acid, perfluoro-*n*-[1,2-$^{13}C_2$]hexanoic acid, perfluoro-*n*-[1,2,3,4-$^{13}C_4$]octanoic acid, perfluoro-*n*-[1,2,3,4,5-$^{13}C_5$]nonanoic acid, perfluoro-*n*-[1,2-$^{13}C_2$]decanoic acid, and sodium perfluoro-1-[1,2,3,4-$^{13}C_4$]octanesulfonate (chemical purity each ≥98%, isotopic purity ≥99%) by Wellington Laboratories (Guelph, Canada)—were obtained from Campro Scientific (Berlin, Germany). Acetonitrile, methanol, and water with a purity of ≥99.97% as well as ammonium acetate were obtained from Biosolve BV (Valkenswaard, Netherlands). QuEChERS-Mix[32] used for cleanup during sample preparation containing $C_6H_5Na_3O_7 \cdot 2H_2O$ (15%) with a purity of ≥9.5%, $MgSO_4$ (62%) with a purity of ≥97.0%, and $C_6H_6Na_2O_7 \cdot 1.5\ H_2O$ (8%) with a purity of ≥99.0% were from Sigma-Aldrich Chemie GmbH (Steinheim, Germany), and NaCl (15%) with a purity of ≥99.5% was obtained from Merck (Darmstadt, Germany). Formic acid with a purity of ≥96.0% from Sigma-Aldrich (Steinheim, Germany) was used in water for conditioning and washing solid phase extraction (SPE) cartridges. Ammonium hydroxide, A.C.S. reagent for eluting PFAAs from cartridges, was obtained from Sigma-Aldrich. Unless otherwise noted, all chemicals and solvents were from Merck, Darmstadt, Germany and from Sigma-Aldrich, Taufkirchen, Germany of the quality, "purum" or "suprapur".[25]

Spiking Solution. The soil for cultivation of maize was spiked by first creating a 1 L stock solution with 10 different PFAAs at a concentration of 200 mg/L of each individual substance. The stock solution was made up of seven perfluoroalkyl carboxylic acids (PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA) as well as three perfluoroalkyl sulfonic acids (PFBS, PFHxS, PFOS). To improve the solubility of the substances, 220 mL of PFAA-free absolute ethanol (purity 100%) was added to the stock solution, and the PFASs were then dissolved individually beginning with the longer-chain followed by the shorter-chain molecules. PFAA-free ethanol was also added to all of the treatments in order to ensure the same physiological conditions for cultivation of all plants.[25]

Study Design. Maize (*Zea mays* L. cv. Amadeo, Kleinwanzlebener Saatzucht, German plant breeding company) was chosen for the pot experiment. This maize hybrid is suitable for use as grain maize and silage as well as a substrate for biogas plants and has been established as an experimental plant for plant physiology studies by the Institute of Plant Nutrition (Justus Liebig University Giessen, Germany). Each maize plant was cultivated in 12 kg of nutrient-poor subsoil in 12 L Ahr pots. The soil used in the experiment did not contain any PFAAs above the limit of quantification (LOQ) of 1 μg/kg soil and had the following properties: pH 7.2 (in 0.01 M $CaCl_2$), 18% clay, 34% silt, 48% sand (Supporting Information, Table S1). The soil was air-dried at room temperature for 5 days before use, sieved to a particle size <10 mm, and then weighed into the cultivation pots. To ensure an adequate supply of nutrients for the maize plants, 24 g of ground PFAA-free mineral fertilizer (<LOQ of 1 μg/kg) were mixed by hand into the soil (12 kg) in each pot; providing 2.88 g of nitrogen, 1.26 g of phosphorus, 3.36 g of potassium, 0.28 g of magnesium, and 1.44 g of sulfur per pot. After 8 weeks, 5 g of mineral fertilizer was again added to each pot (0.60 g of nitrogen, 0.26 g of phosphorus, 0.70 g of potassium, 0.06 g of magnesium, 0.30 g of sulfur). Additionally, micronutrients were supplied in optimum. The plants were divided into three different treatments. Allocation into the three groups was made 24 days after sowing of maize kernels. In two of the treatments, the soil was spiked with an aqueous solution of PFAA mixture at target concentrations of 0.25 mg and 1.00 mg of the individual substance per kg of soil. The spiking solution consisted of seven PFCAs and three PFSAs (see also Spiking Solution above). A third treatment served as the control. This treatment was not spiked in order to document cross-contamination of PFAAs throughout the entire experiment and sample preparation (blank-value determination). Throughout the experimental period, the moisture level of the soil in all three treatments was maintained at 60% of its maximal water-holding capacity in order to provide the plants with an adequate water supply and to maintain identical levels of moisture in all of the pots. Only deionized, PFAA-free water was used. Four replications per treatment were cultivated to maturity, and after 128 days straw and kernels were harvested. The samples were dried to a steady state in a drying cabinet at 39 °C and ground to a particle size <1.0 mm in a cross beater (hammer) mill (Retsch, Haan, Germany). To avoid cross-contamination during grinding, the mill was rinsed with 20 mL of ethanol (100%) after each use. Homogenized samples of 0.2 g of straw dry weight (DW) and 0.5 g of kernels DW were used in sample preparation for PFAA analysis.

Analytical Method for Plant Material. Samples of 0.2 g (straw) or 0.5 g (kernels) of dried and homogenized plant material (see also Study Design) were spiked with 50 μL of internal standard solution consisting of $^{13}C_4$-perfluorobutanoic acid, $^{13}C_2$-perfluorohexanoic acid, $^{13}C_4$-perfluorooctanoic acid, $^{13}C_5$-perfluorononanoic acid, $^{13}C_2$-perfluorodecanoic acid, and $^{13}C_4$-perfluorooctanesulfonate with a concentration of 100 μg/L and suspended in 2 mL of acetonitrile and 2 mL of water in a centrifuge tube (VWR, Darmstadt, Germany) and were vigorously shaken for 30 s by hand. The tube was then tightly closed and shaken on a mechanical shaker (Heidolph,

DOI: 10.1021/acs.jafc.5b00012
J. Agric. Food Chem. 2015, 63, 3646−3653

Schwabach, Germany) for 30 min. After the addition of 1.5 g of QuEChERS-Mix (see also Chemicals) developed by Anastassiades et al.[32] for the determination of pesticide residues in agricultural products, the sample was again shaken for 30 s by hand and centrifuged for 5 min at 1800*g*. Addition of the salt mixture to the sample resulted in a well-defined phase separation. The organic supernatant was mixed with 2 mL of water before enrichment of PFAAs by solid-phase extraction. Oasis WAX cartridges (60 mg of sorbent, 3 mL cartridge—Waters, Eschborn, Germany) that had been conditioned first with 2 mL of 0.1% formic acid in water (v/v) and then with 2 mL of methanol served as the solid phase. Finally, the organic supernatant mixed with water was applied. The cartridge was then washed first with 2 mL of 2% formic acid in water and then with 2 mL of methanol. Elution of the target components was performed with 2 mL of 0.1% ammonia in methanol (v/v). The extracts were evaporated to dryness at 39 °C under nitrogen gas (biostep, sample concentrator, Jahnsdorf, Germany) and reconstituted with 0.25 mL of methanol/water-mixture (50:50 v/v) by means of a vortex mixer (VWR, Darmstadt, Germany). The sample was then strained through a polyester filter (pore size 0.45 μm, Macherey and Nagel, Düren, Germany) attached to a 2 mL disposable syringe and then transferred to a sample vial. A matrix-free sample (blank value) was prepared and analyzed exactly as were the samples in order to determine any potential background contamination. Analysis was performed using HPLC-tandem mass spectrometry with negative ionization. Data were collected on an Alliance 2695 separation module coupled to a Quattro-Micro tandem-mass spectrometer (Waters, Eschborn, Germany). Separation was performed on a binary gradient of methanol and ammonium acetate solution (2 mM) using a Luna C18 HPLC column, 150 mm × 3 mm, 3 μm particle size (Phenomenex, Aschaffenburg, Germany). Chromatographic separation was performed on a gradient (0.3 mL/min) beginning with 55% solution A (10 mM ammonium acetate in methanol) and 45% solution B (10 mM ammonium acetate in water). The proportion of A increased to 95% in the first 4 min and then further increased from 95% to 98% from 6.5 to 6.6 min and was maintained at 98% from 6.6 min until 10 min. Initial conditions were repeated beginning at the 11th minute. The injected volume was 20 μL.

Statistical Analysis. Data were processed using the IBM SPSS Statistics package (version 20). Significant differences between concentrations of PFAAs in straw and kernels with homogeneous variance were evaluated by single-factor variance analysis (ANOVA) and the Tukey-HSD test. In cases of inhomogeneous variances, the data were first subjected to logarithmic transformation ($\log_{10}(x)$) in order to obtain homogeneous variances. The transformed data were then evaluated by single factor variance analysis and the Tukey-HSD test. The results of the comparison of means were then applied to the original data.

When comparing just two random samples with homogeneous variances, the *t* test was used, and in cases of inhomogeneous variances the Welch test was applied. Variance homogeneity was assessed with the Levene test and was shown to be $p > 0.05$. Soil-to-plant transfer factors (TF) of PFAAs were calculated for straw (eq 1) and kernels (eq 2) as follows:

$$\mathrm{TF}_{\mathrm{straw}} = \frac{\text{PFAA concentration in straw (mg/kg dry weight)}}{\text{PFAA concentration in soil (mg/kg dry weight)}} \quad (1)$$

$$\mathrm{TF}_{\mathrm{kernels}} = \frac{\text{PFAA concentration in kernels (mg/kg dry weight)}}{\text{PFAA concentration in soil (mg/kg dry weight)}} \quad (2)$$

Validation of Methods for Testing Plant Samples. Calibration solutions were prepared with substance concentrations between 0 and 100 μg/L (0, 20, 50, 100 μg/L). Samples that were found to contain higher concentrations than the highest calibration standard were diluted until the concentrations were within the calibration range. Quality assurance was carried out on two samples of our standard quality control plant materials (carrots, wheat) using 10 replicates of each material. As part of the validation of the PFAAs in-house method, quality assurance was carried out on two samples of our standard quality control plant materials (carrots, wheat) using 10 replicates of each sample (Hessian State Laboratory 2011). The concentrations of each of the compounds analyzed in each plant species were below the LOQ of 1 μg/kg. The samples were spiked with 10 μg/kg of each compound to be measured. The absolute recovery rate (mean) ranged between 85% for PFBS (carrots) and 112% for PFHxA (wheat). Coefficient of variation values between 1% (PFOA) and 9% (PFPeA, carrots) were determined (Stahl et al.).[20]

RESULTS AND DISCUSSION

PFAA Concentration of Maize Straw after Soil Spiking with Two Different PFAA Concentrations. *Spiking Concentration 0.25 mg/kg Soil per Individual Substance.* At this spiking level, PFBA exhibited the highest concentration (15 911 μg/kg DW) in maize straw. Concentrations of all PFCAs in the straw decreased significantly with increasing chain length (Figure 1A). Of all the PFSAs tested, PFBS was found at the highest concentration in the straw (962 μg/kg DW). With increasing chain length, PFSA concentrations significantly decreased in maize straw (Figure 1B).

Spiking Concentration 1.00 mg/kg Soil per Individual Substance. Similar to the lower spiking level, at a spiking level of 1.00 mg/kg soil, PFBA was found at the significantly highest level with a mean of 35 233 μg/kg DW in straw (Figure 1C). PFBS was found at a concentration of 1843 μg/kg DW (Figure 1D). Decreasing concentrations of both PFCAs and PFSAs in straw were detected as chain lengths of the PFAAs increased.

Comparison of Both Spiking Levels (0.25 mg and 1.00 mg/kg Soil). All 10 of the PFAAs tested were detected in the maize straw, both in the 0.25 mg and in the 1.00 mg spiked treatment. The PFAA concentrations of straw of the 1.00 mg treatment were always significantly higher than in the 0.25 mg-treated plants (Supporting Information, Figure S1). The concentration ratios of PFAAs (= PFAA $\text{concentration}_{1.00\ \mathrm{mg}}$/PFAA $\text{concentration}_{0.25\ \mathrm{mg}}$) increased with increasing chain length for both PFCAs and PFSAs in straw (Table 1).

PFAA Concentrations of Maize Straw Compared to Results from Other Carryover Experiments. Yoo et al.[33] applied PFAA-contaminated sewage sludge to agricultural soils and obtained results in grass that are comparable to ours. They found higher accumulation potentials for PFHxA, the shortest-chain substance they tested, than for longer-chain PFCAs (C7 to C14). In a nutrient solution experiment, Krippner et al.[25] showed a significantly higher uptake of shorter-chain PFAAs by the roots and a significantly higher translocation in young maize plants than of longer-chain PFAAs.[25] Felizeter et al.[17] also observed increased mobility and translocation of shorter-chain PFAAs within lettuce. The shorter-chain PFAAs accumulated in larger amounts in the above-ground parts of the plants. This finding was confirmed in a study on the basis of foliage-root-concentration factors (FRCF = $[\mathrm{PFAA}]_{\mathrm{foliage}}/[\mathrm{PFAA}]_{\mathrm{root}}$) > 1 for PFBA and PFPeA.[17] In a latter nutrient solution experiment, Felizeter et al.[26] reconfirmed their previous results from lettuce in tomato, cabbage, and zucchini plants. Those distinctly higher concentrations of shorter-chain PFAAs than longer chain molecules in the above-ground parts of plants can consequently be explained in terms of a lower sorption of shorter-chain PFAAs by soil particles[21,27] and thus a greater availability to the plants as well as to a higher mobility and translocation rate within the plants.[17,25,26]

PFAA Concentrations of Maize Kernels after Spiking the Soil with Two Different PFAA Concentrations.

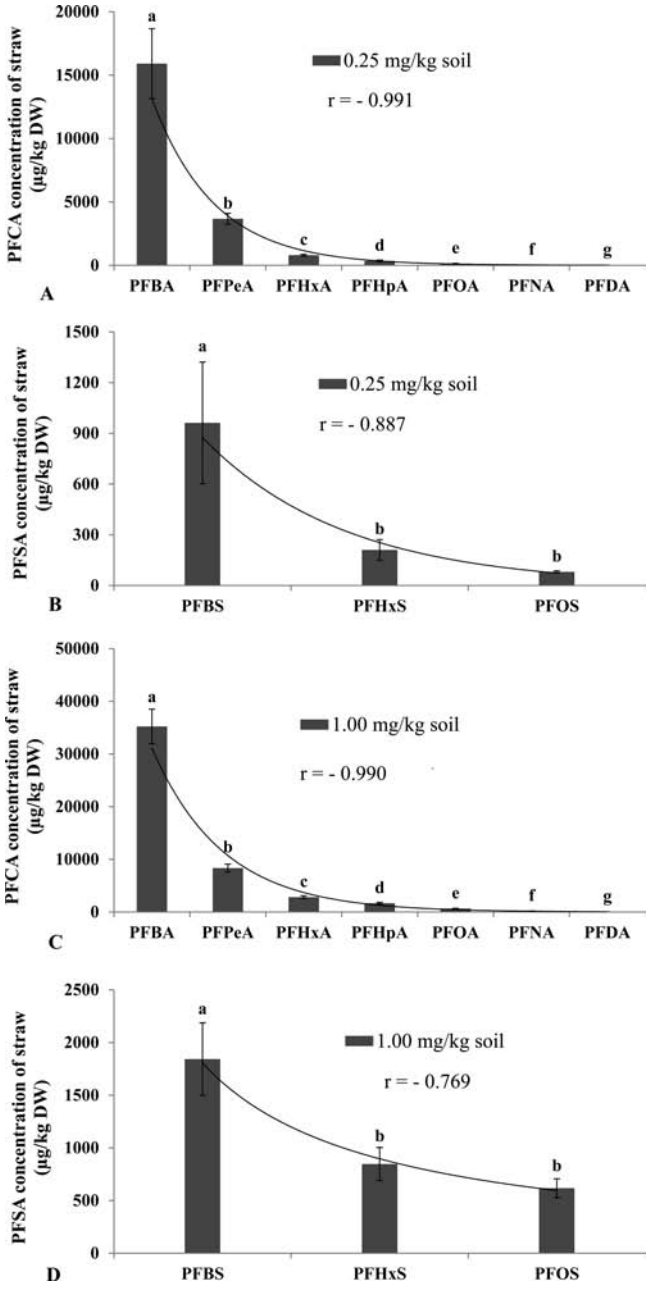

Figure 1. PFCA and PFSA concentrations of maize straw. PFCA (A) and PFSA (B) concentrations of maize straw after spiking the soil with 0.25 mg of the individual substances/kg soil; PFCA (C) and PFSA. (D) Concentrations of maize straw after spiking the soil with 1.00 mg of the individual substance/kg of soil. Paired comparison (Tukey-HSD), $p \leq 0.05$; mean value ($n = 4$) with standard error bars. Letters (a–g) indicate significant differences depending upon chain length; trend line (exponential), r = Spearman rank correlation coefficient; DW = dry weight.

Spiking Concentration 0.25 mg/kg Soil per Individual Substance. Of all PFAAs tested, the shorter-chain PFCAs PFBA, PFPeA, and PFHxA were found at the highest concentrations in maize kernels. The significantly highest concentrations in kernels were measured for PFPeA at 91.4 µg/kg, PFBA at 33.1 µg/kg, and PFHxA at 30.7 µg/kg DW. The concentrations of longer-chain PFCSs (≥C8) in the kernels were below the LOQ of 1 µg/kg DW (Figure 2A). Of all the

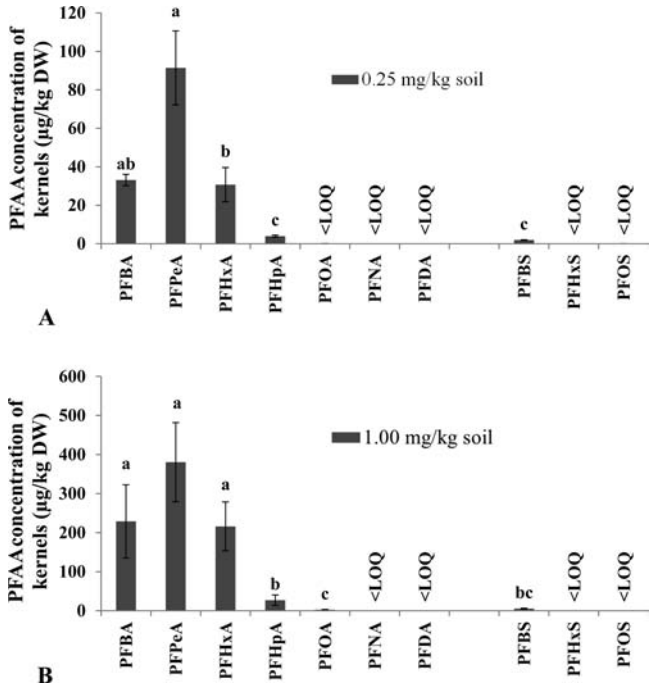

Figure 2. PFCA and PFSA concentrations of maize kernels. PFCA and PFSA concentrations of maize kernels after spiking the soil with (A) 0.25 mg and (B) 1.00 mg of the individual substances per kg of soil. Paired comparison (Tukey-HSD), $p \leq 0.05$; mean ($n = 4$) with standard error bars. Letters (a–c) indicate significant differences among PFAAs; DW = dry weight; LOQ = limit of quantification (1 µg/kg DW).

PFSAs, only PFBS was detected above the LOQ of 1 µg/kg DW in maize kernels, at a concentration of 1.93 µg/kg. At the soil-spiking level of 0.25 mg/kg, the concentrations of PFAAs detected in maize kernels were always lower than those found in the straw (Supporting Information, Table S2).

Spiking Concentration 1.00 mg/kg Soil per Individual Substance. A 4-fold higher spiking concentration resulted in significantly higher concentrations of maize kernels of 228 µg/kg, 380 µg/kg, and 216 µg/kg DW for PFCAs PFBA, PFPeA, and PFHxA compared to 27.1 µg/kg, 2.45 µg/kg and 5.44 µg/kg DW for PFHpA, PFOA, and PFBS.

PFNA and PFDA concentrations were below the LOQ of 1 µg/kg DW. As in the 0.25 mg/kg soil spiked treatment, the only PFSA that was detected in maize kernels above the LOQ

Table 1. PFAA Concentration Ratios of Both Spiking Concentrations (0.25 mg and 1.00 mg/kg soil)[a]

concentration ratio	PFBA	PFPeA	PFHxA	PFHpA	PFOA	PFNA	PFDA	PFBS	PFHxS	PFOS
straw	2.21	2.27	3.53	4.75	4.62	5.48	4.56	1.92	4.03	7.64
kernels	6.91*	4.16	7.03	6.85*				2.82		

[a]Concentration ratio = PFAA concentration$_{1.00mg}$/PFAA concentration$_{0.25mg}$; comparison of means (t test or Welch test). *No significant differences between spiking levels (0.25 mg and 1.00 mg/kg).

J. Agric. Food Chem. 2015, 63, 3646–3653

(1 μg/kg DW) was PFBS at a concentration of 5.44 μg/kg (Figure 2B). The concentrations of PFAAs in kernels at a spiking concentration of 1.00 mg/kg soil were always significantly lower than the PFAAs concentrations measured in the straw of maize (Supporting Information, Table S2).

Comparison of the Two Spiking Levels (0.25 and 1.00 mg/kg Soil). The spiking of 1.00 mg/kg soil resulted in 4-fold higher PFAA concentrations of maize kernels than concentrations of kernels of maize plants treated with 0.25 mg/kg soil. The concentration of PFHxA was 7-fold higher after spiking with 1.00 mg/kg soil than after spiking with 0.25 mg/kg soil (Table 1). A spiking concentration of 1.00 mg/kg did not result in significantly higher concentrations of PFBA or PFHpA of maize kernels than in 0.25 mg treated maize plants (Supporting Information, Figure S2). With a spiking concentration of 1.00 mg/kg soil, just as with 0.25 mg/kg soil, PFBS was the only PFSA detected above the LOQ of 1 μg/kg DW (Figure 2B). The concentration of PFBS of the kernels after spiking with 1.00 mg/kg soil was 5.44 μg/kg DW and therefore 2.5-fold higher than after spiking with 0.25 mg/kg soil (1.93 μg/kg DW; Table 1). The graphical depiction of individually measured values from every single experimental replication (n = 4 maize plants—evaluation of every individual plant) per spiking concentration shows that in individual maize plants comparable fingerprints of PFCAs existed in their kernels. PFPeA was found at the highest concentrations in maize kernels both after spiking with a concentration of 0.25 mg of the individual substances/kg soil (Figure 3A) and 1.00 mg/kg soil (Figure 3B). At a spiking concentration of 0.25 mg, a significantly lower concentration of PFHxA was found than that of PFPeA and PFBA in the kernels (Figure 3A). At a spiking level of 1.00 mg, no significant differences were found between PFBA, PFPeA, and PFHxA. However, at the lower spiking level, PFPeA tended to result in higher concentrations than PFBA and PFHxA in the kernels (Figure 3B). These data suggest that PFPeA was more translocated into the kernels than the other PFCAs tested (Figure 3B). Due to the small sample size (n = 4), it is presently not possible to confirm the greater mobility of PFPeA over other PFCAs in maize kernels statistically.

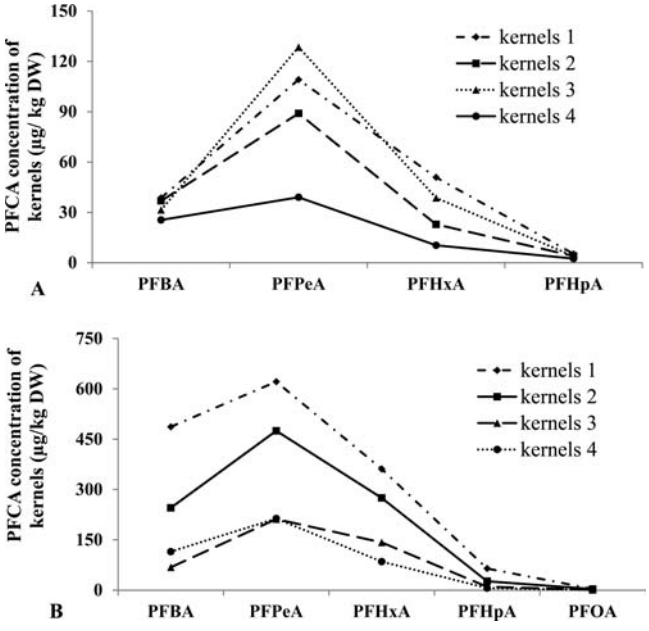

Figure 3. PFCA concentrations of maize kernels for each experimental repetition. PFCA concentrations of maize kernels after spiking the soil with (A) 0.25 mg and (B) 1.00 mg of the individual substances/kg soil in kernels from every maize plant (individual values). DW = dry weight.

PFAA Concentrations of Maize Kernels Compared to Results from Other Carryover Experiments. Only few systematic studies have been carried out on the translocation of PFAAs from soil to generative organs of plants.[18−20] These studies were all limited to the two key compounds, PFOA and PFOS. Stahl et al.[19,20] presented results comparable to those of the present report in a study of the uptake of PFOA and PFOS by the generative organs of various cultivated plants. Those studies showed that PFOA and PFOS concentrations were significantly lower in the kernels than in the vegetative organs of wheat, rye, barley, canola, and maize. Stahl et al.[19] also demonstrated a concentration-dependent carryover of PFOA and PFOS from soil to plants: The higher the soil concentrations of PFOA and PFOS, the higher the plant concentrations. In addition, PFOS concentrations were found to be always lower than PFOA concentrations in plants. Lechner and Knapp[18] also determined in zucchini plants that the concentrations of PFOA and PFOS were substantially lower for generative than for vegetative organs. Studying 14 different PFAAs (C4 to C14), Felizeter et al.[26] performed a study in which nutrient solution was spiked with PFAA concentrations between 0.001 and 1.00 μg/L. The authors showed that the edible-part-concentration factors (ECF = $\log([\mathrm{PFAA}]_{\text{edible part}}/[\mathrm{PFAA}]_{\text{nutrient solution}})$) were highest for short-chain PFAAs in generative plant parts of zucchini and tomato plants and as the chain length of PFCAs and PFSAs increased the ECF decreased. This present study, which represents the first systematic analysis of short-chain PFAAs under natural conditions in soil, demonstrates that shorter-chain PFAAs are also taken up by plants from the soil and are transferred to both vegetative and generative organs. This has, until now, only been shown for PFOA and PFOS.[18−20]

Accumulation potential of PFAAs in Maize Straw and Kernels after Spiking with Two Different PFAA Concentrations. *Soil-to-Plant Transfer Factors for PFAAs in Maize Straw.* Spiking with a concentration of 0.25 mg of the individual substances/kg of soil resulted in a transfer factor (TF_{straw}) of 63.6 for PFBA in the straw, 14.7 for PFPeA, 3.19 for PFHxA, 1.41 for PFHpA, and 3.85 for PFBS. In contrast, the transfer factors for PFOA, PFNA, PFDA, PFHxS, and PFOS were all <1.00. The PFAA transfer from soil to straw decreased with increasing chain length. Spiking with a concentration of 1.00 mg of the individual substances/kg of soil also showed that transfer factors of PFAAs to the straw were lower for molecules with longer chain lengths than for shorter-chained PFAAs (Table 2).

Comparison of the Two Spiking Levels (0.25 and 1.00 mg/kg Soil). Comparison of the two different spiking concentrations of 0.25 mg of the individual substances/kg soil and 1.00 mg of the individual substances/kg soil showed that a 4-fold increase in PFAA concentration in the soil significantly reduced the transfer factor of PFBA in the straw to 35.2 and of PFPeA to 8.33. For PFOS, the 4-fold increase in soil concentration resulted in a significant doubling of the transfer factor from 0.32 to 0.62. For PFHxA, PFHpA, PFOA, PFNA, PFDA, PFBS, and PFHxS, increasing soil concentration to 1.00 mg did not result in a significant change of the soil-to-plant transfer factors. However, increasing the chain length of the PFAAs did show a
