[a]Transfer factors for PFAAs in maize kernels after spiking the soil with 0.25 mg and 1.00 mg of the individual substances/kg soil. Comparison of means (*t* test), $p \leq 0.05$; mean value ($n = 4$). Letters (a, b) indicate significant differences between transfer factors after spiking with two different concentrations. *The relationship of the transfer factors of PFAAs after spiking with 1.00 mg and transfer factors after spiking with 0.25 mg are represented (transfer ratio); LOQ = limit of quantification (1 μg/kg).

trend toward increasing transfer ratios (TR = PFAA $TF_{1.00mg}$/PFAA $TF_{0.25mg}$) (Table 2).

Soil-to-Plant Transfer Factors for PFAAs in Maize Kernels. With a spiking concentration of 0.25 mg/kg soil, the transfer factors for kernels ($TF_{kernels}$) were between 0.366 (PFPeA) and 0.008 (PFBS; Table 3). With a spiking concentration of 1.00 mg/kg soil, the transfer factors were between 0.380 (PFPeA) and 0.005 (PFBS). There were no significant differences between transfer factors of PFAAs in maize kernels after spiking at different concentration levels. It was not possible to calculate transfer factors for longer-chain PFCAs and PFSAs since the concentrations in the kernels were below the LOQ of 1 μg/kg DW (Table 3).

Soil-to-Plant Transfer Factors in Maize Straw Compared to Other Carryover Experiments. With calculation from the concentrations of PFOA and PFOS in soil and plants published by Stahl et al.,[19] a spiking level of 0.25 mg of the individual substances/kg soil results in transfer factors for PFOA and PFOS maize straw of $TF_{straw} > 0.27$ (PFOA) and > 0.13 (PFOS) and in maize kernels, $TF_{kernels} = 0.008$ (PFOA). PFOS was not detected in the kernels after spiking the soil with 0.25 mg/kg. At 1.00 mg/kg spiking level, the transfer factors in maize straw (TF_{straw}) for PFOA and PFOS were >0.12 (PFOA) and >0.10 (PFOS) and in kernels, $TF_{kernels}$ was 0.004 (PFOA) and 0.003 (PFOS). TF_{straw} calculated in the present study for PFOA (>0.56) and for PFOS (>0.32) were considerably higher than those reported by Stahl et al.[19] (Table 2). Possible explanations for the differences in PFOA and PFOS in maize straw are differences in maize cultivars and varying cultivation conditions as well as differences in the soil composition.[21] In the present study, just as described by Stahl et al.,[19] only a minimal transfer of PFOA and PFOS into the kernels was observed. PFOS concentrations of the generative organs of the plants were never above the LOQ at either spiking concentration. For PFOA, it was only possible to calculate a transfer factor in the kernels ($TF_{kernels}$) of 0.002 at the 1.00 mg spiking concentration (Table 3) because the amounts of PFOA in the 0.25 mg samples were below the LOQ of 1 μg/kg DW (Figure 2A). From pot experiment results, Lechner and Knapp[18] calculated transfer factors (TF = $[PFAA]_{plant\ (wet\ substance)}$/$[PFAA]_{soil\ (dry\ weight)}$) of PFOA and PFOS in carrots, potatoes, and cucumber grown in soil mixed with PFAAs-contaminated sewage sludge. Levels of contamination in the soil from the sewage sludge reached between 0.28 mg/kg and 0.81 mg/kg soil for PFOA and between 0.01 mg/kg and 0.56 mg/kg soil for PFOS. The highest transfer factors for vegetative plant parts were >0.17 (PFOS) and >0.40 (PFOA). The transfer factors in vegetative plant parts of zucchini plants were TF > 0.76 (PFOA) and > 0.12 (PFOS). Lechner and Knapp[18] calculated transfer factors of TF > 0.03 (PFOA) and TF < 0.01 (PFOS) in generative organs of zucchini plants. When comparing the transfer factors with this study, it must be noted that Lechner and Knapp[18] calculated the transfer factors of PFAA on a fresh weight basis. In a nutrient solution experiment with 14 different PFAAs (C4 to C14), Felizeter et al.[26] showed that the edible-part concentration factors (ECF = log ($[PFAA]_{edible\ part}$/$[PFAA]_{nutrient\ solution}$)) of the shorter-chain PFCAs PFBA, PFPeA, and PFHxA were on average close to 1 in the fruit of zucchini plants and >1 in the fruit of tomato plants after spiking the nutrient solution with PFAA concentrations between 0.01 and 1.00 μg/L. It must be noted, however, that nutrient solution experiments do not reflect field conditions, and the influence of the soil on uptake of PFAAs and its effect on the distribution of PFAAs within the plant are not considered. The subsoil used in the present study was a sandy loam with a low potential cation exchange capacity (CEC_{pot}) of <10 cmol/kg soil and a low organic carbon concentration of C_t < 0.275% (Table S1, Supporting Information). Zhao et al.[21] studied the phytotoxic effect of PFOA and PFOS on Chinese cabbage (*Brassica chinensis*) in different soils and found that the organic matter, followed by the CEC of the soil, has the greatest influence on sorption of PFOA and PFOS. The pH value and the proportion of clay have only minor influence.[21] In addition, climatic influences such as rainfall can alter the distribution of PFAAs in the soil profile. Different chain lengths and functional groups of the PFAAs can result in differences in the degree of leaching along the soil profile so that PFAAs may escape uptake by plant roots.[20] It must also be taken into consideration that, in addition to the soil properties, interactions of PFAAs among one another may occur, in particular when PFAA mixtures are present, and these may influence the sorption in the soil and

DOI: 10.1021/acs.jafc.5b00012
J. Agric. Food Chem. 2015, 63, 3646−3653

finally the uptake via roots and the distribution of PFAAs in maize plants.

Altogether, the results from the present study and the other studies cited here show that PFAAs accumulate to a greater degree in vegetative plant parts and only to a small degree in generative organs. Genotypic and culture-specific differences occur in regard to accumulation in vegetative and generative plant parts. However, the transfer factors for PFOA and PFOS in the generative organs of zucchini are higher than the transfer factors in maize kernels.

Analysis of the results of the present study with different spiking concentrations can be summarized as follows:

- The fingerprints of both spiking levels show that shorter-chain PFAAs predominate both in maize straw as well as in the kernels and are found at the significantly higher concentrations compared to longer-chain molecules.
- A comparison of the spiking concentration levels shows that a 4-fold increase in spiking (1.00 mg of the individual substances/kg soil versus 0.25 mg/kg soil) leads to a 4-fold higher concentration of PFCAs with chain lengths ≥ C6 (PFHxA, PFHpA, PFOA, PFNA, PFDA) and PFSAs with a chain length ≥ C6 (PFHxS, PFOS) in the straw of maize plants.
- In contrast, a 4-fold increase in spiking concentration does not lead to a 4-fold increase of PFBA, PFPeA, or PFBS in the straw, but only to a 2-fold increase.
- For PFOS, however, a 4-fold increase in spiking concentration leads to an 8-fold increase in concentration of the straw.
- Significant differences in concentrations of maize kernels dependent upon spiking concentration could only be shown for PFPeA, PFHxA, and PFBS.
- Regardless of spiking concentration, PFAA concentrations were always significantly lower in the kernels than in the straw.
- Shorter-chain PFAAs (≤C7) have the highest accumulation potentials in above-ground plant parts with transfer factors of >1.00 in straw and >0.01 in kernels.
- Of all the PFAAs tested, PFPeA showed the highest accumulation potential in maize kernels.

The results presented here confirm the results of previous nutrient solution experiments inasmuch as they also show that short-chain PFAAs are particularly mobile under the influence of soil. Shorter-chain PFAAs are preferentially taken up by maize plants from the soil and are stored in above-ground vegetative as well as in generative plant parts. Those molecules consequently exhibit the highest accumulation potentials in maize. Uptake and storage of these substances in above-ground plant parts of maize depend not only on chain length (C4 to C10) but also on the functional group: carboxylate or sulfonate. Significantly lower concentrations of PFCAs and PFSAs are observed with increasing chain length, and as a consequence, short-chain molecules have the highest transfer factors in maize straw and kernels. In addition, PFCAs are always found in higher concentrations than PFSAs in maize. In addition to different rates of uptake, this may be the result of different transport mechanisms for PFCAs and PFSAs from root to kernels, which will be the subject of future studies.

■ ACKNOWLEDGMENTS

Special thanks to our technical staff, Rosa Maria Sobel and Maria Elisabeth Ebel, for their efforts in sample preparation and analysis. We are indebted to Anna Stein for preparation of the graphical abstract. We also wish to thank Barbara Gamb for her assistance in the literature search. We would also like to express our gratitude to Corinna Alles, Helga Tripp, and Lutz Wilming of the Institute of Plant Nutrition at Justus Liebig University Giessen, Germany, for assistance in culturing and harvesting the plants.

Ion leakage was measured with a conductivity meter (DDS-11A, Shanghai, China) according to our previous method.[14] Ion leakage was expressed as relative conductivity. MDA content was measured according to the method of Hodges et al.,[19] and the result was expressed as nanomoles per gram of fresh weight (FW).

GB Content and BADH Activity Measurement. For GB content measure, 10 g of tissue sample was homogenized with 20 mL of methanol−chloroform extraction buffer (60% methanol, 25% chloroform) and then centrifuged at 10000*g* for 20 min at 4 °C. The aqueous phase was purified by an anionic resin (Dowex AG1 OH^-, 200−400 mesh, Dow Chemical Co., Midland, MI, USA). The GB fraction was eluted with 6 mol L^{-1} NH_4OH and then dried under nitrogen at 45 °C. The residue was dissolved with 2 mL of methanol. The GB content was assayed using high-performance liquid chromatography (Agilent 1100, Agilent Corp., Santa Clara, CA, USA) according to the method of Bessieres et al.[20] GB content was expressed as micrograms per gram of FW.

BADH activity was assayed according to the method of Arakawa et al.[21] with some modification. Ten grams of tissue sample was homogenized with 20 mL of 0.2 mmol L^{-1} potassium phosphate buffer (pH 7.4) and centrifuged at 13000*g* for 20 min at 4 °C. The assay mixture consisted of 0.5 mL of crude enzyme extract, 2.9 mL of 0.2 mmol L^{-1} potassium phosphate buffer (pH 7.4), and 0.5 mL of 10 mmol L^{-1} betaine aldehydede. One unit of BADH activity was defined as an increase of 0.01 in absorbance per minute at 340 nm.

Energy Metabolism Enzyme Assays. Crude mitochondria of loquat fruit samples were extracted for enzyme assay. H^+-ATPase and Ca^{2+}-ATPase activities were measured using our previous method.[16] One unit of H^+-ATPase and Ca^{2+}-ATPase activities was defined as the release of 1 μmol of phosphorus per minute under the assay conditions. Succinic dehydrogenase (SDH) activity was measured according to the method of Ackrell et al.[22] One unit of SDH activity was defined as an increase of 0.01 of absorbance at 600 nm per minute. CCO activity was measured according to our previous method.[16] One unit of CCO activity was defined as an increase of 0.1 of absorbance at 510 nm per minute.

ATP, ADP, and AMP Contents and Energy Charge (EC) Measurements. To analyze energy status, 2 g of loquat flesh tissue was ground with 5 mL of 0.6 mol L^{-1} perchloric acid. ATP, ADP, and AMP assays used high-performance liquid chromatography (Agilent 1100) according to the Jin et al.[16] method. ATP, ADP, and AMP contents were expressed as micrograms per gram of FW. EC was calculated using the formula EC = [ATP + 0.5 × ADP]/[ATP + ADP + AMP].

Protein Assay. Protein content of enzyme was measured using the Bradford[23] method. Specific activity of enzymes was expressed as units per milligram of protein.

Statistical Analysis. These experiments were carried out using a completely randomized design. Each treatment in the study was replicated three times. The experiment was carried out for twice and got the similar results. The data were from one experiment and expressed as the mean ± SE (standard error) of three replications. All statistical analyses were performed using SPSS software (version 14.0, SPSS Inc., Chicago, IL, USA). Data were analyzed by one-way analysis of variance. Mean separations were compared by Duncan's multiple-range tests. Differences at $p < 0.05$ were considered as significant.

RESULTS

Effect of LTC Treatment on CI, Ion Leakage, and MDA Content in Loquat Fruit. CI usually develops in loquat fruit during cold storage for a long time. Flesh internal browning was the most obvious symptom of CI in loquat (shown in the Tabove of Contents graphic). The CI index increased gradually after the first week in cold-stored loquat fruit. LTC treatment significantly ($p < 0.05$) inhibited CI increase during storage. As shown in Figure 1, CI index values were 57.3 and 36.2% lower in LTC-treated loquat than in control fruit in the third and fifth weeks, respectively. Ion leakage and MDA content in loquat fruit increased with storage time, which was associated with CI development during cold storage. The increasing tendencies of ion leakage and MDA were significantly ($p < 0.05$) prevented by LTC (Figure 2).

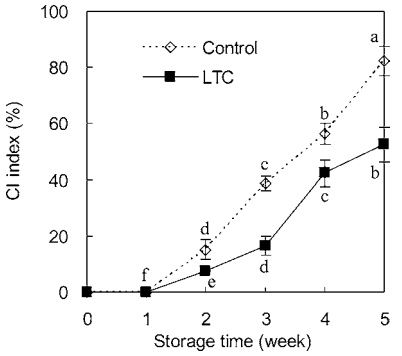

Figure 1. Effect of LTC treatment on CI index of loquat fruit during cold storage. Data are expressed as the mean of triplicate samples ± standard errors. Vertical bars represent the standard errors of the means. Significant differences are shown by different letters.

Effect of LTC Treatment on GB Content and BADH Activity in Loquat Fruit. The content of GB in control fruit decreased steadily during the whole storage time (Figure 3B). LTC treatment increased GB content after the first week in loquat fruit. GB contents were 30.1 and 27.5% higher in LTC-treated fruit than in control fruit in the third and fifth weeks, respectively. BADH activity increased until the third week and decreased slowly afterward in control fruits. LTC treatment significantly ($p < 0.05$) increased the activity of BADH during the whole storage time, which was 69.2% higher than in control loquat fruit at the end of storage.

Effect of LTC Treatment on Energy Metabolism Enzyme Activities in Loquat Fruit. H^+-ATPase and Ca^{2+}-ATPase activities decreased gradually during the whole storage time. LTC treatment significantly ($p < 0.05$) increased the activities of H^+-ATPase and Ca^{2+}-ATPase activities after the first week (Figure 4A,B). SDH activity increased until the second week and then decreased rapidly in control fruit. LTC treatment maintained higher activity of SDH, which was 32.7% higher than that in control loquat fruit at the end of the storage (Figure 4C). CCO activity declined slowly with storage time. LTC treatment could prevent the decrease of CCO activity in loquat fruit (Figure 4D).

Effect of LTC Treatment on Energy Status in Loquat Fruit. ATP content declined gradually with storage time, whereas ADP content increased mildly until the first week and decreased rapidly after the second week (Figure 5). In general, LTC treatment maintained higher contents of ATP and ADP in comparison with the control fruit. AMP content increased gradually in control loquat during the whole storage time. The increasing tendency was significantly ($p < 0.05$) prevented by LTC treatment during the whole storage time except the fourth week. According to the difference in ATP and ADP contents, energy charge in loquat fruit decreased during storage. LTC treatment maintained the high level of energy charge in loquat fruit.

DISCUSSION

LTC is a useful technique to maintain quality and reduce CI in postharvest industry of fruit and vegetables. Increasing evidence has shown that CI symptoms were alleviated in avocado,

zucchini squash, and sweet potatoes by LTC treatment.[24] As to loquat fruit, Cai et al.[5] reported that 'Luoyangqing' loquats conditioned at 5 °C for 6 days had better quality and lower CI symptoms than control fruits. Our previous study found that conditioning at 10 °C for 6 days could be the optimum condition for 'Jiefangzhong' loquat. This different temperature condition for pretreatment is probably due to the different loquat cultivar response to low-temperature stress. The beneficial effects of LTC have been attributed to enhancing antioxidant system, reducing electrolyte leakage, and inducing lipid membrane unsaturation.

Moreover, LTC induced chilling tolerance by regulating the expression of transcripts related to secondary metabolism, hormone biosynthesis, and transcription factors.[25] Our study provided new evidence that LTC alleviated CI in cold-stored loquat fruit associated with accumulation of GB and energy status.

It has been indicated that GB accumulates in some plants responding to environmental stresses, including low temperature, water stress, or drought.[6] Some plants accumulate small molecular substances with cryoprotectant activity against cold stress. Glycine betaine is one of several such osmotic adjustment substances that has a protective function to proteins and enzyme activities and even stabilizes membranes under environmental stresses.[8] Previous evidence has suggested that there is a correlation between GB content and cold tolerance in higher plants. For example, endogenous GB was accumulated by cold acclimation treatment, which induced freezing tolerance in *Arabidopsis*.[7] Similarly, tolerance to low temperatures was also improved in tomato plant GB treatment.[26] In addition, Rajashekar et al.[9] found that exogenous abscisic acid treatment induced cold tolerance and improved freezing survival and regrowth in whole strawberry plants, which triggered endogenous GB accumulation. In our study, GB accumulation was associated with CI development in loquat fruit during cold storage. LTC treatment significantly reduced CI and a maintained higher level of GB content than those in control fruits. These results suggest that the accumulation of GB might contribute to the reduced CI in loquat fruits treated with LTC.

BADH is the key enzyme that plays the important role during GB metabolism. It had been reported that heat treatment resulted in a high expression of BADH gene in transgenic tomato, which was correlated with up-regulated GB accumulation.[27] Yang et al.[28] found that GB accumulation as a result of the introduction of the BADH gene into tobacco enhances the tolerance against high-temperature stress. Chen et al.[29] obtained similar results in maize, which indicated that GB accumulation caused by cold stress was associated with an increase in BADH activity. Our study showed that treatment with LTC maintained higher activity of BADH in loquat fruit. The decline of BADH activity in control fruit after the third week was possibly due to the senescence of loquat fruit, which may account for the low level of GB content. This suggested that the accumulation of GB in LTC-treated loquat fruit could be due to increased activity of BADH, the key enzyme involved in GB biosynthesis. It is worth mentioning that GB plays an important physiological role in stress tolerance involved in osmotic regulation, detoxication of reactive oxygen radicals, and protection of membrane integrity. These results indicated that

LTC induced cold tolerance of loquat due in part to regulating endogenous GB metabolism.

Energy supply in cells plays an important role in controlling fruit ripening, senescence, and physiological disorder after harvest.[11] Many studies have suggested that postharvest CI symptoms of various kinds of fruits, such as pears,[12] litchis,[13] longans,[30] and peaches,[14] mainly resulted from membrane damage related to the energy deficit under cold stress. In the present study, LTC treatment effectively maintained high levels of ATP and energy charge and reduced CI in cold-stored loquat fruit. Moreover, activities of energy metabolism enzymes were significantly higher in loquat fruits treated with LTC than in control fruits. This suggests that these enzymes played positive roles in the process of energy production. Similar results were also found in peach fruit in our previous study.[31] ATP and energy might play important roles in cell membrane protection and fatty acid biosynthesis. Under stress conditions, stress-resistant cultivars could maintain higher energy levels, resulting in a decrease in membrane leakage. Thus, our results indicated that LTC could enhance chilling tolerance in cold-stored loquat fruit by means of enhancing energy accumulation, preventing ion leakage increase, and protecting membrane function.

In conclusion, the results of this work suggest that treatment with LTC decreased CI in loquat fruit contributed to enhancing endogenous GB content and energy status. The GB accumulation plays an important role in enhancing cold tolerance in loquat fruit by LTC treatment, which was attributed to increasing BADH activity. Furthermore, the reduction of CI by LTC treatment may be due to induced enzyme activity related to energy metabolism. However, further studies are needed to evaluate other related enzyme activities and gene expression involved in metabolism of GB or energy.

Gas chromatography−olfactometry (GC−O), often using aroma extract dilution analysis (AEDA) and Osme, coupled with careful quantitative analysis of the odor-active compounds and calculation of odor activity values (OAVs), has enabled significant advances in understanding of important odorants in alcoholic beverages. Aroma recombination and omission experiments are being extensively and successfully used to confirm the key aroma compounds of alcoholic beverages, such as beer,[8] brandy,[2] Chinese rice wine,[9] Chinese liquor,[10] whisky,[11] and wine.[12]

To our knowledge, no studies have reported on the contribution of aroma compounds to the characteristic aroma of chixiang aroma-type liquor. The aims of the present study were (i) to identify important odorants in chixiang aroma-type liquor by GC−O, (ii) to quantify these compounds by different pretreatment methods and various advanced analytic approaches, and (iii) to perform aroma recombination and omission/addition experiments to confirm the key aroma compounds of chixiang aroma-type liquor.

MATERIALS AND METHODS

Liquors. Detailed sample information is listed in Table 1. Only chixiang aroma-type finished liquor (CXFL) and its base distillate (CXBD) were used for GC−O analysis. All liquors (500 mL for each bottle) were stored at 4 °C until analysis.

Chemicals. All chemicals were of analytical reagent grade, with at least 97% purity. Ethyl acetate, ethyl 2-methylpropanoate, ethyl butanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, 3-methylbutyl acetate, ethyl pentanoate, ethyl hexanoate, ethyl heptanoate, ethyl 2-hydroxypropanoate (ethyl lactate), ethyl octanoate, 3-methylbutyl hexanoate, ethyl nonanoate, ethyl decanoate, diethylbutanedioate, 1-propanol, 2-methylpropanol, 1-butanol, 3-methylbutanol, 1-pentanol, 1-hexanol, 1-heptanol, 1-octanol, propanoic acid, 3-methylbutanoic acid, pentanoic acid, hexanoic acid, heptanoic acid, octanoic acid, hexanal, heptanal, octanal, 1,1,3-triethoxypropane, 3-hydroxy-2-butanone, nonanal, 2-nonanone, (*E*)-2-octenal, 2-furancarboxaldehyde (furfural), 2-decanone, (*E*)-2-nonenal, (*E*)-2-decenal, (*E*)-2-undecenal, (*E*,*E*)-2,4-decadienal, styrene, benzeneacetaldehyde, ethyl benzoate, ethyl 2-phenylacetate, 2-phenylethyl acetate, benzyl alcohol, ethyl 3-phenylpropanoate, (*E*)-cinnamaldehyde, 3-(methylthio)-1-propanal (methional), 3-(methylthio)-1-propanol (methionol), 2-phenylethanol, γ-octalactone, γ-nonalactone, 4-methylguaiacol, phenol, 4-ethylguaiacol, 4-ethylphenol, and *O*-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine hydrochloride (PFBHA) were purchased from Sigma−Aldrich Co., Ltd. (Shanghai, China). Acetic acid, 2-methylpropanoic acid, butanoic acid, and naphthalene were supplied by Alfa Aesar (Tianjin, China). Diethyl pimelate, diethyl suberate, and diethyl azelate were provided by ANPEL Scientific Instrument Co., Ltd. (Shanghai, China). Pentyl acetate (internal standard, IS1), 2,2-dimethylpropanoic acid (IS2), ethyl octanoate-d_{15} (IS3), *n*-hexyl-d_{13} alcohol (IS4), ethyl 2-phenylacetate-d_3 (IS5), and *p*-fluorobenzaldehyde (IS6) were purchased from ANPEL Scientific Instrument Co., Ltd. (Shanghai, China). IS1 was used as internal standard for compounds with high concentrations (ethyl acetate, ethyl lactate, 1-propanol, 2-methylpropanol, 3-methylbutanol, and 2-phenylethanol). IS2−IS6 were used as internal standards for fatty acids, esters, alcohols, benzoic compounds, and carbonyl compounds, respectively. The remaining compounds (1,1,3-triethoxypropane, γ-octalactone, and γ-nonalactone) were quantified with IS3. A C_5−C_{30} *n*-alkane mixture (Sigma−Aldrich, Shanghai, China) was used for determination of linear retention indices (RIs). Sodium chloride, sodium bicarbonate, sulfuric acid, anhydrous sodium sulfate, and absolute ethanol were from China National Pharmaceutical Group Corp. (Shanghai, China). Diethyl ether and pentane obtained from ANPEL Scientific Instrument Co., Ltd. (Shanghai, China) were freshly distilled before use.

Sample Preparation. According to literature,[10] a total of 50 mL of liquor sample was diluted to 10% ethanol by volume with Milli-Q water (Millipore, Bedford, MA), boiled for 5 min, and then cooled to room temperature in a 1 L flask, saturated with NaCl. The diluted liquor sample was extracted 3 times with 20 mL of a mixture of pentane/diethyl ether (1:1 by volume). The combined extracts were further separated into acidic/water-soluble fraction (AF) and neutral/basic fraction (NBF). Both fractions were dried with 5 g of anhydrous Na_2SO_4 overnight, concentrated to a final volume of 200 μL under a gentle stream of nitrogen, and then stored at −20 °C until analysis.

Gas Chromatographic−Olfactometric and −Mass Spectrometric Analysis. GC−O and GC−MS analysis were performed on an Agilent 6890 gas chromatograph equipped with an Agilent 5975 mass-selective detector (MSD) and an olfactometer (ODP 2, Gerstel, Germany). Samples were analyzed on both a DB-FFAP column (60 m × 0.25 mm i.d., 0.25 μm film thickness, J&W Scientific) and a DB-5 column (30 m × 0.25 mm i.d., 0.25 μm film thickness, J&W Scientific). The column carrier gas was helium at a constant flow rate of 2 mL/min. Each concentrated fraction (1 μL) was injected into the GC and the sniffing port with a split ratio of 1:1. The injector temperature was set at 250 °C. The oven temperature was held at 50 °C for 2 min, then programmed to 230 °C at a rate of 6 °C/min, and finally

DOI: 10.1021/jf506238f
J. Agric. Food Chem. 2015, 63, 3660−3668

held at 230 °C for 10 min. The temperature of the olfactory port was kept at 280 °C. Mass spectra in the electron ionization mode (EI) were recorded at 70 eV ionization energy. The temperature of the ion source was 230 °C, and the mass range was from 30 to 350 amu. Four trained panelists (two females and two males), three graduate students and one teacher from the Laboratory of Brewing Microbiology and Applied Enzymology at Jiangnan University, were selected for the GC−O study. During a GC run, a panelist placed his/her nose close to and above the top of the sniffing port, recorded the odor of the chromatographic effluent as well as retention time. Analyses were repeated in duplicate by each panelist.

Aroma Extract Dilution Analysis. For AEDA, each concentrated fraction, containing NBF and AF, was diluted stepwise with diethyl ether as the solvent in a series of 1:3, 1:9, 1:27, ..., 1:729 dilution. Each dilution was submitted to GC−O analysis under the same GC conditions described above until no odorant could be detected. The flavor dilution (FD) factor of each compound represented the maximum dilution in which the odorant could be perceived. Identification of each aroma compound was carried out by comparing with their odors, retention index (RI), and mass spectra with those of pure standards.

Quantitative Analysis of Aroma Compounds. *Gas Chromatography with Flame Ionization Detector.* Ethyl acetate, ethyl lactate, 1-propanol, 2-methylpropanol, 3-methylbutanol, and 2-phenylethanol (Table 3) were quantified by gas chromatography with flame ionization detector (GC-FID) according to ref 13. Liquor sample was spiked with IS1 to final concentration 176 mg/L. One microliter of disposed sample was injected into the GC in split mode 37:1. The correction factors calculated in 38% ethanol by volume are showed in Table 3. Nitrogen was used as carrier gas at a constant flow rate of 1 mL/min. The separations were performed on a DB-Wax column (30 m × 0.25 mm i.d. × 0.25 μm film thickness; J&W Scientific). The oven temperature was initially set at 60 °C for 3 min, ramped at 5 °C/min to 150 °C for 5 min, and then increased to 230 °C at 10 °C/min for 5 min. The injector and detector temperatures were set at 250 °C. All analyses were repeated in triplicate.

Liquid−Liquid Microextraction. Fatty acids were quantified by liquid−liquid microextraction (LLME) according to the method of Wang et al.[14] Diluted liquor sample (18 mL) with 6 μL of IS2 solution (3.41 mg/L final concentration) was saturated with NaCl and then extracted for 3 min with 1 mL of redistilled diethyl ether. The GC−MS conditions were set as for GC−O analysis on a DB-FFAP column (60 m × 0.25 mm i.d., 0.25 μm film thickness, J&W Scientific) described above. Selective ion monitoring (SIM) mass spectrometry was used to quantify the odorants. The ion monitored for IS2 was m/z 57. The standard curve for fatty acids was carried out by plotting the response ratio of standard compounds and IS2 against the concentration ratio (Table 3). The limits of detection (LOD) was calculated as the analyte concentration of a standard that produced a signal-to-noise ratio of 3. The recovery of target compounds was estimated according to ref 14.

Headspace Solid-Phase Microextraction−Gas Chromatography−Mass Spectrometry. As the methods reported,[10] each liquor sample was diluted with Milli-Q water (Millipore, Bedford, MA) to a final concentration of 10% ethanol by volume. A total of 8 mL of diluted solution with 10 μL of IS solution (IS3, IS4, and IS5 with concentrations of 87.8, 163, and 207 mg/L in ethanol, respectively) was put into a 20 mL screw-capped vial and then saturated with NaCl. An automatic headspace sampling system (MultiPurposeSample MPS 2 with a SPME adapter, from Gerstel Inc., Mülheim, Ruhr, Germany) with a 50/30 μm divinylbenzene/carboxen/poly(dimethylsiloxane) (DVB/CAR/PDMS) fiber (2 cm, Supelco Inc., Bellefonte, PA) was used to extract volatile odorants. The conditions of HS-SPME remained the same as in ref [10]. The GC−MS conditions were set as for GC−O analysis on a DB-FFAP column (60 m × 0.25 mm i.d., 0.25 μm film thickness, J&W Scientific) described above. The ions monitored for IS3, IS4, and IS5 were m/z 91 and 142, 64 and 78, and 104 and 46, respectively. The LOD and recovery of target compounds were detected by the method described above.

Quantitation of Carbonyl Compounds by Headspace Solid-Phase Microextraction−Gas Chromatography−Mass Spectrometry after Derivatization with O-(2,3,4,5,6-Pentafluorobenzyl)hydroxylamine Hydrochloride. Quantitation of carbonyl compounds after derivatization with PFBHA was performed by GC−MS on a DB-FFAP column (60 m × 0.25 mm i.d., 0.25 μm film thickness, J&W Scientific) modified from literature.[15] The liquor sample was diluted to 10% ethanol by volume. Eight milliliters of dilution was saturated with NaCl and added to a 20 mL standard headspace vial, and then 10 μL of a solution of IS6 (1.0724 mg/L in ethanol) and 120 μL of PFBHA (50 g/L in water) were added. The fiber used was three-phase fiber as described above. The sample was incubated at 65 °C for 10 min and extracted for 45 min at the identical temperature under stirring at a rotation speed of 250*g*, then transferred the fiber to the injector for desorption at 250 °C for 300 s. During the GC run (in splitless mode), a constant flow rate (1 mL/min) of the carrier gas (helium) was maintained. The injector temperature was held at 280 °C. The oven temperature was programed to 50 °C for 2 min and raised to 100 °C at a rate of 6 °C/min for 0.1 min, then to 160 °C at a rate of 2 °C/min for 0.1 min, and finally at 5 °C/min to 230 °C for 10 min. The mass spectrometer was operated in electron ionizationI mode at 70 eV with SIM. The ion monitored for IS6 after derivatization was m/z 319. Monitored ions of carbonyl compounds after derivatization are listed in Table 3. The standard curve and LOD, as well as recovery of carbonyl compounds, were measured by the method mentioned above.

Determination of Odor Thresholds. For the calculation of OAVs, odor thresholds of some aromas were determined in 46% ethanol/water solution by triangle tests based on ref 16.

Aroma Recombination of Chixiang Finished Liquor. Ethanol/water solution (38% ethanol by volume) was used as the matrix for recombination. The aroma compounds with OAVs ≥ 1 (Table 4) of CXFL were spiked into the matrix according to their occurring concentrations (Table 3). The overall aroma profiles of the CXFL liquor and reconstituted models were evaluated by 10 well-trained assessors (five males and five females, 30 years old on average), eight graduate students and two teachers from the Laboratory of Brewing Microbiology and Applied Enzymology at Jiangnan University. All of the assessors were trained for 2 months (45 min/day) to describe and recognize the odor qualities of approximately 30 odorants. Testing samples (20 mL) were presented to assessors in four-digit-coded, covered glasses in a sensory panel room at 20 ± 1 °C. The assessors rated eight aroma attributes to describe the overall aroma: fatty, grassy, sweet, alcoholic, floral, fruity, cheesy, and acidic. The intensity of each aroma attribute was rated on a 6-point scale, where 0 is none, 1 is very weak, 2 is weak, 3 is moderate, 4 is strong, and 5 is very strong. The

[a]MS, compounds were identified by MS spectra; aroma, compounds were identified by comparison to reference standards by GC−O; RI, compounds were identified on FFAP and DB-5 by comparison to reference standards. [b]Fraction(s) in which odorant was detected by GC−O after fractionation. AF, acidic/water-soluble fraction; NBF, neutral and basic fraction. [c]CXFL, chixiang aroma-type finished liquor; CXBD, chixiang aroma-type base distillate.

sensory data were analyzed by one-way analysis of variance (ANOVA) by use of SPSS15.0 (SPSS Inc., Chicago, IL).

Omission/Addition Tests. In triangular tests with forced choice, a recombinant model, in which one odorant or a class of odorants (Table 6) was omitted/added, was evaluated against two complete recombinants. The testing samples were arranged in a random four-digit code, and each test was repeated in triplicate. The assessors were asked to sniff the samples and estimate the differing one. The significance of the differences was evaluated by the method as reported.[17]

RESULTS AND DISCUSSION

Aroma Compounds by Gas Chromatography−Olfactometry in Chixiang Aroma-type Liquor. A total of 64 odorants were perceived by GC−O in chixiang finished liquor and its base distillate. In finished liquor (CXFL), 56 odorants could be detected by AEDA. Among them, octanal and nonanal obtained the highest FD factor (FD ≥729), which gave intense fatty and soapy aromas, respectively. A total of 61 aroma compounds were identified in base distillate (CXBD). 3-Methylbutyl acetate, acetic acid, and 2-phenylethanol (FD ≥ 243) had the highest FD factor, which elicited intense banana, vinegar, and rose- or honey-like aromas, respectively. As shown in Table 2, (*E*)-2-octenal, (*E*)-2-nonenal, (*E*)-2-decenal, (*E*)-2-undecenal, and (*E*,*E*)-2,4-decadienal were first detected in CXFL and CXBD liquors, which exhibited intense fatty aromas. Unsaturated aldehydes usually gave off-flavor in beer,[18,19] and they have been proposed as main note of the roasted mini-pig pork meat aroma.[20] Methionol was detected in both liquors (FD ≥ 1 in CXFL and CXBD), which was previously regarded as one of the characteristic aromas of chixiang aroma-type liquor.[5,7] Diethyl pimelate, diethyl suberate, and diethyl azelate were not detected by GC−O in either liquor.

Concentration of Aroma Compounds in Chixiang Aroma-type Liquor. To gain a deeper insight into the aroma of chixiang aroma-type liquor, a total of 59 compounds, 56 odorants detected by AEDA and three dibasic acid diethyl esters (diethyl pimelate, diethyl suberate, and diethyl azelate), were quantified in CXFL liquor (Table 3). As exhibited in Table 3, ethyl lactate had the highest concentration (585 mg/L), followed by ethyl acetate (385 mg/L) and 3-methylbutanol (354 mg/L). In addition, the data in Table 4 demonstrate that the highest concentrations of (*E*)-2-octenal, (*E*)-2-nonenal, (*E*)-2-decenal, (*E*)-2-undecenal, and (*E*,*E*)-2,4-decadienal were found in CXFL liquor among 10 aroma-type Chinese liquors. (*E*)-2-Octenal was the most abundant unsaturated aldehyde in CXFL liquor with concentration exceeding 400 μg/L, followed by (*E*)-2-decenal (375 μg/L) and (*E*)-2-nonenal (156 μg/L). The total concentration of five unsaturated aldehydes in CXFL liquor was the highest, up to 1040 μg/L, notably higher than any other aroma-type liquors. Besides, CXBD and DJ liquor had higher concentrations of 100−200 μg/L whereas total concentrations of these five unsaturated aldehydes in SSFL, SFL, LFL, CFL, LBGXFL, RSLFL, FXFL, and TXFL liquors were less than 100 μg/L, far lower than that in CXFL liquor (Table 4). Diethyl pimelate, diethyl suberate, and diethyl azelate were included in the quantification experiments because they were frequently described as important aroma compounds in the literature.[7] The concentrations of diethyl pimelate, diethyl suberate, and diethyl azelate were 687, 228, and 2310 μg/L, respectively.

Odor Activity Values. The thresholds were determined in 46% hydroalcoholic solution (by volume). As indicated in Table 5, odor thresholds of 24 aroma compounds were determined, and the odor thresholds in liquor ranged from 7.12 (methional) to 1 280 000 μg/L (diethyl azelate). So contribution to the liquor would depend not only on the concentration of an odorant but also its odor threshold.

To evaluate the contribution of quantified odorants to the overall aroma of the liquor, odor activity values (ratio of concentration to its odor threshold) were calculated for each aroma compound listed in Table 5. A total of 34 odorants were calculated with OAVs ≥1. These odorants should be important contributors to the characteristic aroma of CXFL liquor. The highest OAV in finished liquor was ethyl 2-methylpropanoate (OAV = 336), followed by ethyl octanoate (OAV = 157) and hexanal (OAV = 69). (*E*)-2-Decenal, (*E*)-2-octenal, (*E*,*E*)-2,4-decadienal, and (*E*)-2-nonenal, which give "fatty" flavor,[2,21] were detected with OAVs 31, 28, 5, and 3, respectively. The CXFL liquor was much higher than any other liquors in the OAVs of (*E*)-2-decenal, (*E*)-2-octenal, (*E*,*E*)-2,4-decadienal, and (*E*)-2-nonenal (Table 4). Noticeably, (*E*)-2-nonenal was detected with OAV > 1 only in the CXFL liquor. Two odorants, 2-phenylethanol (rose- or honey-like-aroma) and methionol (cooked potato), might contribute to the overall aroma according to their OAVs (>1). However, diethyl pimelate, diethyl suberate, and diethyl azelate were calculated with OAVs ≤ 1; therefore, they could not contribute to the overall aroma.

Aroma Recombination and Omission/Addition Experiments. To confirm that the aroma compounds were indeed the important odorants of chixiang aroma-type liquor, aroma recombination and omission/addition experiments were undertaken, based on the quantitative results of finished liquor. For this purpose, an aroma recombinate was prepared in a 38% hydroalcoholic solution (by volume), by addition of 34

odorants with OAVs ≥ 1 listed in Table 5. Odor attributes of the recombinate and original liquor were evaluated by a sensory panel consisting of 10 trained assessors. As shown in Figure 1, the aroma of the recombinate showed good similarity for fatty, grassy, alcoholic, floral, fruity, cheesy, and acidic aromas, whereas sweet aroma was slightly lower in the reconstituted

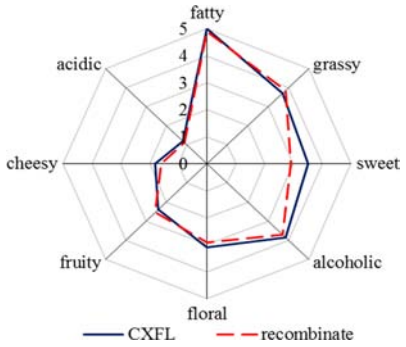

Figure 1. Aroma profile of chixiang aroma-type finished liquor (CXFL) and the complete aroma recombinate.

model. The overall aroma similarities of the reconstitution model with the original liquor were judged to be 4.3 out of 5.0 points. Consequently, this result indicated the success in mimicking the typical aroma of the investigated liquor.

To take deeper consideration of the aroma contribution of certain compounds, a total of 20 aroma omission models (Table 6) missing either a single component or a group of components were investigated by omission experiments. Each of the omission models was evaluated compared with the complete recombinate by a triangle test. The results of the descriptive study for 20 reconstitution samples are shown in Table 6.

[a]Number of correct judgments from 10 assessors evaluating the aroma difference by triangle test. [b]Significance: *, significant ($\alpha \leq 0.05$); **, highly significant ($\alpha \leq 0.01$); ***, very highly significant ($\alpha \leq 0.001$).

The data (Table 6) suggested that all assessors were able to detect the omission of (*E*)-2-octenal, (*E*)-2-nonenal, (*E*)-2-decenal, (*E,E*)-2,4-decadienal, octanal, and nonanal with a very high significance ($\alpha \leq 0.001$). This result indicated the fairly important role of these fatty-smelling compounds for the overall chixiang aroma. Among them, model 1-1 (Table 6) without (*E*)-2-nonenal (fatty) was also evaluated with very high significance ($\alpha \leq 0.001$) in aroma compared to the complete recombinate, thereby pinpointing the crucial role of (*E*)-2-nonenal for the typical aroma of chixiang aroma-type liquor. (*E*)-2-Nonenal has already been detected in alcoholic beverages, such as beer,[22] whisky,[21] brandy,[2] and wine.[23] Researchers have indicated that (*E*)-2-nonenal was formed by lipid oxidation.[18,24] Pork meat contains abundant lipids,[20] which could lead to generation of (*E*)-2-nonenal during storage. When (*E*)-2-octenal was omitted from the complete recombinate, a high significance ($\alpha \leq 0.01$) was obtained. However, no significant difference was observed when (*E*)-2-decenal, (*E,E*)-2,4-decadienal, octanal, and nonanal were respectively omitted from the complete recombinate. Consequently, the fatty note present in the profile of overall aroma could be strongly linked to (*E*)-2-nonenal.

A model mixture without compounds 2-phenylethanol (rose- or honey-like), ethyl 3-phenylpropanoate (floral), and ethyl benzoate (floral) resulted in highly significant difference ($\alpha \leq 0.01$) in aromas. Furthermore, when only 2-phenylethanol (Table 6, model 2-1) was missing, the assessors could detect a highly significant difference ($\alpha \leq 0.01$), whereas the omission of only ethyl 3-phenylpropanoate (Table 6 model 2-2) or only ethyl benzoate (Table 6 model 2-3) could not be detected significantly. These results indicated that 2-phenylethanol could be responsible for the typical floral note of chixiang aroma-type liquor. 2-Phenylethanol has already been detected in Chinese liquor,[25,26] Chinese rice wine,[27] whisky,[21] and brandy.[2] Researchers have demonstrated that L-phenylalanine was the key precursor for formation of 2-phenylethanol through the Ehrlich pathway in alcoholic fermentation by yeast.[28,29]

A model mixture lacking both hexanal and heptanal (Table 6, model 3) was evaluated as significantly different ($\alpha \leq 0.05$) compared to the entire model mixture. A mixture lacking only heptanal (Table 6, model 3-2) was not detected as different from the complete recombinate, while a mixture lacking only hexanal (Table 6, model 3-1) was judged with significance ($\alpha \leq 0.05$). However, in model 4 lacking in all esters, the sensory panel was not able to detect a significant difference between the samples; thereby the fruity note present in the aroma profile of the entire model mixture (Figure 1) could not be correlated to certain aroma components. Fatty acids mostly demonstrated a vinegar or cheesy note; omission of this group of compounds was also determined with no significant difference by the assessors (Table 6, model 6). The same results also occurred with alcohols, γ-nonalactone, and 3-hydroxy-2-butanone, as exhibited in Table 6, models 5, 7, and 8, respectively. Additionally, methionol had been suggested as a characteristic aroma compound in chixiang aroma-type liquor.[5] Our study (Table 6, model 9) showed that this compound did not contribute significantly to the flavor of chixiang aroma-type liquor.

In addition, the complete recombinate was spiked with diethyl pimelate, diethyl suberate, and diethyl azelate and then compared with the complete recombinate. The addition of these compounds was correctly detected by only 4 of 20 assessors in triangle tests. As a consequence, no significant difference was determined for the addition of three dibasic acid diethyl esters, which agrees with the fact that the dibasic acid diethyl esters had not been detected by GC−O.

DOI: 10.1021/jf506238f
J. Agric. Food Chem. 2015, 63, 3660−3668

In conclusion, the aroma-active compounds in chixiang aroma-type liquors were successfully identified by GC−O analysis, and 34 odorants were further detected as important odorants according to quantitative study and OAVs. The aroma profile of chixiang aroma-type finished liquor could be successfully reconstituted by mixing 34 aroma compounds in concentrations measured in this study. Omission experiments further confirmed (*E*)-2-nonenal as the key odorant and revealed the significance of (*E*)-2-octenal and 2-phenylethanol for the overall aroma of chixiang aroma-type finished liquor. Methionol, diethyl pimelate, diethyl suberate, and diethyl azelate had no effects on aroma based on omission/addition experiments. Further research is needed to investigate whether nonvolatile compositions had effects on aroma, which may be of great importance in understanding "sweet" flavors in finished liquor.

SPAD-502 readings in estimating leaf N. The latter might be the consequence of surface-based Chl often compared to mass-based N,[11,15] although the effect of leaf mass per area (LMA) on this relationship has been clearly demonstrated for ligneous species in general[16] or specifically for grapevine.[17] It should be mentioned here that grapevine was also used as a model plant to analyze the potential of optical leaf clips to nondestructively assess leaf Chl content,[18,19] independently of its relation to nitrogen.

Two major problems with the use of the SPAD-502 (N-tester) or equivalent leaf clips are their nonlinearity,[19] especially at optimal and supraoptimal N contents, and the influence of the variable LMA.[20] This sensor nonlinearity is independent of the additional nonlinearity due to the physiological saturation of leaf response to N.[21,22] Recently, in addition to single-parameter Chl leaf clips, both multiparameter leaf clips and multiparameter proximal sensors have become available.[21−23] Therefore, a bi- or multiparametric approach to estimating N can be attempted. Cartelat et al.[24] proposed the use of the nitrogen balance index (NBI), which is the ratio of Chl to epidermal flavonol (Flav) leaf content, for nitrogen nutrition of wheat in the context of precision agriculture. Ten years later, the advent of the new Dualex leaf clip and the proximal sensor Multiplex from FORCE-A has allowed for an easier assessment of this new nitrogen index and has permitted its extension to other crops, including both monocots[21,22,25,26] and dicots.[27,28] Nevertheless, there is a need for a proper quantitative calibration of this index to implement its use in crop diagnostics. Leaf Chl and flavonol contents on a surface basis are both dependent on leaf age and light experienced during growth.[29,30] They both increase with age and light during the first part of the season. During the second part, Chl tends to decrease while Flav remains constantly high.[29] The NBI index (Chl/Flav) is much less sensitive to phenology, and it reflects the N availability better than either of the two indicators used individually.[16,21,22,24,25,31,32]

Most important experiments on N fertilization were performed under controlled conditions in potted plants.[33−35] We wanted to test the NBI approach in vineyards under real viticultural practices for which this optical diagnostic approach was originally designed. There are no published calibrations for N measurements by these new devices, namely, the Dualex and the Multiplex. As the Dualex responds linearly to both Chl and Flav leaf contents,[19] the NBI index can potentially be quantitatively related to leaf N content. Therefore, the objectives of this paper are (1) to provide a calibration of the Dualex response to leaf N content, (2) to verify the robustness of the N estimation by NBI in grapevine as a diagnostic method, and (3) to propose a protocol for leaf sampling for optical diagnostics of N content in grapevine.

MATERIALS AND METHODS

Experimental Design and Sensors. Experiments were performed over a period of 5 years, parallel to the development of the new Dualex leaf clips. Therefore, both the SPAD-502 (Konica-Minolta, Tokyo, Japan) and the Dualex 4 Scientific (FORCE-A, Orsay, France) were used for the Chl measurements. SPAD-502 units were transformed into leaf Chl content on a surface basis (μg cm^{-2}) using the consensus formula from Cerovic et al.[19] The Dualex 4 Scientific Chl was used as given by the device because it was calibrated in μg cm^{-2} units.[19] Epidermal Flav values were measured by the Dualex leaf-clip version Dualex 3.3 (FORCE-A) and the version Dualex 4 Scientific. Absorbance in the UV at 375 nm due to flavonol presence in the epidermis was used as given by the device without transformation.

For the data set Leaves 2007, leaves were sampled at the Fort Chabrol vineyard in Epernay, Champagne, France (03°57′ E, 49°02′ N) in May 2007 just before flowering (BBCH 57).[36] No. 5 leaves counted from the tip of the shoots were chosen from Pinot noir vines. The first leaf having a central vein longer than 3 cm was considered as leaf no. 1. Six light-exposed and six shaded leaves were measured with the SPAD-502 from the abaxial leaf side once on the left-hand side (position 1) and once on the right-hand side (position 2) from the main vein (cf. Figure S2, Supporting Information). Total Chl for each spot was calculated from the SPAD-502 measurements using the consensus equation from Cerovic et al.[19] Flavonols were measured by the Dualex 3.3 on the same leaf spots as for Chl, but from both the adaxial and abaxial leaf sides. The mean Chl value from the two spots was calculated for each leaf. The mean Flav value was calculated for the two spots from the sum of the abaxial and adaxial sides. The NBI[24,37] was calculated from these mean Chl and Flav data for each leaf. A 1 cm^2 disk sampled from the spot in position 1 was used for Chl extraction and a 1 cm^2 disk sampled from the spot in position 2 for nitrogen content analysis.

For the Leaves 2009 data set, leaves were sampled on May 28 and 29, 2009, just before flowering (BBCH 57) at the Plumecoq experimental vineyard near Epernay, France (03°58′ E, 49°01′ N) belonging to the Champagne committee. A total of 59 no. 5 leaves counted from the shoot tip were sampled from Pinot noir (29 leaves) and Chardonnay (30 leaves) planted in 1996 and trained to a "Chablis" system, with three canes. Leaf Chl was measured with both the SPAD-502 and the Dualex 4 Scientific on the adaxial leaf side on the two spots, as for the Leaves 2007 data set (cf. Figure S1, Supporting Information). Flavonols were measured by both the Dualex 3.3 and the first version of the Dualex 4 Scientific on the same leaf spots on both leaf sides. The mean Chl value for the two spots was calculated for each leaf, both for Dualex 4 Scientific and for SPAD-502 measurements. The mean Flav value was calculated for the two spots from the sum of the abaxial and adaxial side measurements with the Dualex 3.3. The SPAD-502 measurements were transformed using the consensus equation from Cerovic et al.[19] The NBI index was calculated from the Chl and Flav data for each leaf. A 0.58 cm^2 disk sampled from the spot in position 1 was used for Chl extraction and a 0.58 cm^2 disk sampled from the spot in position 2 for nitrogen content analysis.

For the Plot 2009 data set, 60 leaves were sampled from each of the 27 commercial plots scattered around Epernay in Champagne. In total, 1620 leaves were measured. Plots from 0.3 to 1 ha, having different soils and cultural practices, planted with Pinot noir, Meunier, and Chardonnay of different ages were chosen. No. 5 leaves were sampled from three rows per plot from May 18 to May 27, 2009, just before flowering (BBCH 55−57). Two spots per leaf, as in the Leaves 2007 data set, were measured by the SPAD-502 for Chl and the Dualex 3.3 for Flav. The total Chl for each spot was calculated from the SPAD-502 measurements using the consensus equation from Cerovic et al.[19] The Chl, Flav, and NBI indices were calculated for each leaf as described in the Leaves 2009 data set. Two 0.58 cm^2 disks were sampled per leaf (both spots) for nitrogen content analysis (see below). The averages of the three optical indices, Chl, Flav, and NBI, and the N content were calculated for each plot from the 60-leaf data.

The Subplots 2012 data set was obtained at Chateau Gazin near Bordeaux, France (0°11′ E, 44°55′ N) on July 27, 2012, at the bunch closure stage (BBCH 79). The plot was planted with Merlot noir on SO4 in 1977 and trained as a double Guyot, with 1.25 m intrarow and 1.4 m interrow spacing. A total of 10 subplots were selected on the basis of a map of the NBI produced by a Multiplex-mounted system (FORCE-A) a few days before (cf. Figure S2, Supporting Information). Three leaves from three consecutive vines were measured by the most recent version of the Dualex 4 Scientific for both Chl and Flav. These nine-leaf batches were repeated three times on each of the 10 subplots. Thanks to the relative heterogeneity inside each of the chosen subplots (cf. Figure S1, Supporting Information), the nine-leaf batches could be used individually, producing a final data

DOI: 10.1021/acs.jafc.5b00304
J. Agric. Food Chem. 2015, 63, 3669−3680

set of 31 samples (3 × 10) + 1, because in the last subplot an extra batch of nine leaves was measured. Although only mature leaves on primary shoots were sampled, as in the three other data sets, there were two major differences: the exact node position on the shoot was not assessed, and only one spot on the leaf was measured; care was taken to only sample leaves from the same height of the canopy at which the Multiplex measurements were made, above the second wire. The details of the mounted Multiplex mapping of a vineyard are described in detail elsewhere (Diago et al., manuscript in preparation). They were not relevant for this study, where NBI maps were only used to choose the sampling sites that will allow a sufficiently large span of variable situations.

Chlorophyll Extraction. Leaf disks were collected immediately after the optical measurements. They were frozen in liquid nitrogen and stored at −80 °C until further processing. Disks were powdered in liquid nitrogen and extracted three times at room temperature with methanol (3 × 1.5 mL) containing calcium carbonate.[19] The three supernatants obtained by centrifugation (10000*g*, 5 min) were grouped, topped to 5 mL, and centrifuged again at 4100*g* for 5 min. The extinction coefficients for Chl in pure methanol of Porra et al.[38] were used to calculate the Chl concentration in the extracts.

Leaf Nitrogen Content. In the Leaf 2007 and Leaf 2009 data sets, individual leaf disks were freeze-dried, and after fine grinding, a 2−3 mg aliquot of the powder was analyzed by the Dumas method using isotope ratio mass spectrometry coupled with elemental analysis (EA−IRMS) using the analytical platform Metabolism-Metabolome of Labex Saclay Plant Science (France). This method measures the total N content, including nitrate. For the Plots 2009 data set, 120 disks were pooled together per plot and the aliquots were analyzed as described above. In the Subplots 2012 data set, nine whole leaves were pooled together per subplot sample after the optical measurements. Leaves were dried at 65 °C until a constant weight was obtained and then ground. Total leaf nitrogen content was determined in 50 mg aliquots for each subplot by the Kjeldahl method in a commercial laboratory (Laboratoire LCA, Bordeaux, France).

Statistical Analysis and Plotting. Data were treated, transformed, statistically analyzed, fitted, and plotted using a combination of software: Excel 2003 (Microsoft, Redmond, WA), Statistica 6 (StatSoft, Tulsa, OK), and Igor Pro 6.02 (WaveMetrics, Portland, OR). The accuracies of the fitted models and of the prediction of leaf N content from Chl and Flav contents and the NBI index were assessed by the coefficient of determination (R^2) and the root mean square error (RMSE):

$$\mathrm{RMSE} = [1/n \sum_{i=1}^{n} (\hat{y}_i - y_i)^2]^{1/2} \quad (1)$$

where $\hat{y}_i$ is the model-predicted value and y_i the measured value. "Major axis" regressions were used in all of the presented graphs, considering that the error is present in both plotted variables.[39]

Other descriptors listed in Tables 1 and 2 for the classification test are defined as usual,[40] using the true positive (TP), false positive (FP), false negative (FN), and true negative (TN) values present in the contingency table (Table 1) that compares the diagnostic test to the gold standard (here the wet chemistry N analysis):

$$\text{sensitivity} = \mathrm{TP}/(\mathrm{TP} + \mathrm{FN}) \quad (2)$$

$$\text{specificity} = \mathrm{TN}/(\mathrm{TN} + \mathrm{FP}) \quad (3)$$

$$\text{Youden index} = \text{sensitivity} + \text{specificity} - 1 \quad (4)$$

$$\text{accuracy index} = (\mathrm{TP} + \mathrm{TN})/(\mathrm{TP} + \mathrm{TN} + \mathrm{FP} + \mathrm{FN}) \quad (5)$$

The number of leaves needed to establish reliable sampling guidelines was calculated according to Dagnelie:[41]

$$\text{sample size} = k(\mathrm{CV})^2/\partial^2 \quad (6)$$

where CV is the coefficient of variation of the sample and ∂ the relative difference among plots that we want to detect. The parameter k is approximately 21 and 40 for acceptable errors of 10% and 5%, respectively.

Table 1. Example of a Contingency Table for the Calculation of the Youden Index[a]

	leaf nitrogen content		
	nitrogen + (N+)	nitrogen − (N−)	
optical index + (I+)	TP	FP	sum of I+
optical index − (I−)	FN	TN	sum of I−
	sum of N+	sum of N−	sample size (n)
	sensitivity	specificity	Youden index

	leaf nitrogen content		
	N+	N−	
I+	15	1	16
I−	1	10	11
	16	11	27
	0.94	0.91	0.85

[a]Data are for the chlorophyll index of the Plots 2009 data set (Figure 3): true positive (TP), false positive (FP), false negative (FN), and true negative (TN). For index definitions and calculation formulas, see the Materials and Methods.

Table 2. Statistics for the Calibration Models and Classification Test Indices for the Optical Indices[a]

optical index		Leaves 2007	Leaves 2009	Plots 2009	Subplots 2012

	accuracy index	0.83	0.48	0.96	0.87

[a]Samples were made of individual leaves for Leaves 2007 and Leaves 2009. Samples were averages of 60 leaves for Plots 2009 and averages of 9 leaves for Subplots 2012. RMSE is expressed in N units. All R^2 values were highly significant ($p < 0.001$). The t test was applied to verify the significance of the differences among the Youden indices of optical indices, both among data sets and among optical indices. The p values for the differences are indicated using asterisks: *, $p < 0.05$; ***, $p < 0.001$.

RESULTS AND DISCUSSION

Calibration of Optical Indices against Leaf N. Although the Dualex can be used on any crop or plant species, we decided to present here the specific case of grapevine, which is a crop and a ligneous species. We calibrated the Dualex against leaf nitrogen content as the "gold standard" by using natural variability of the nitrogen supply to grapevine due to soil heterogeneity, as opposed to controlled fertilization experi-

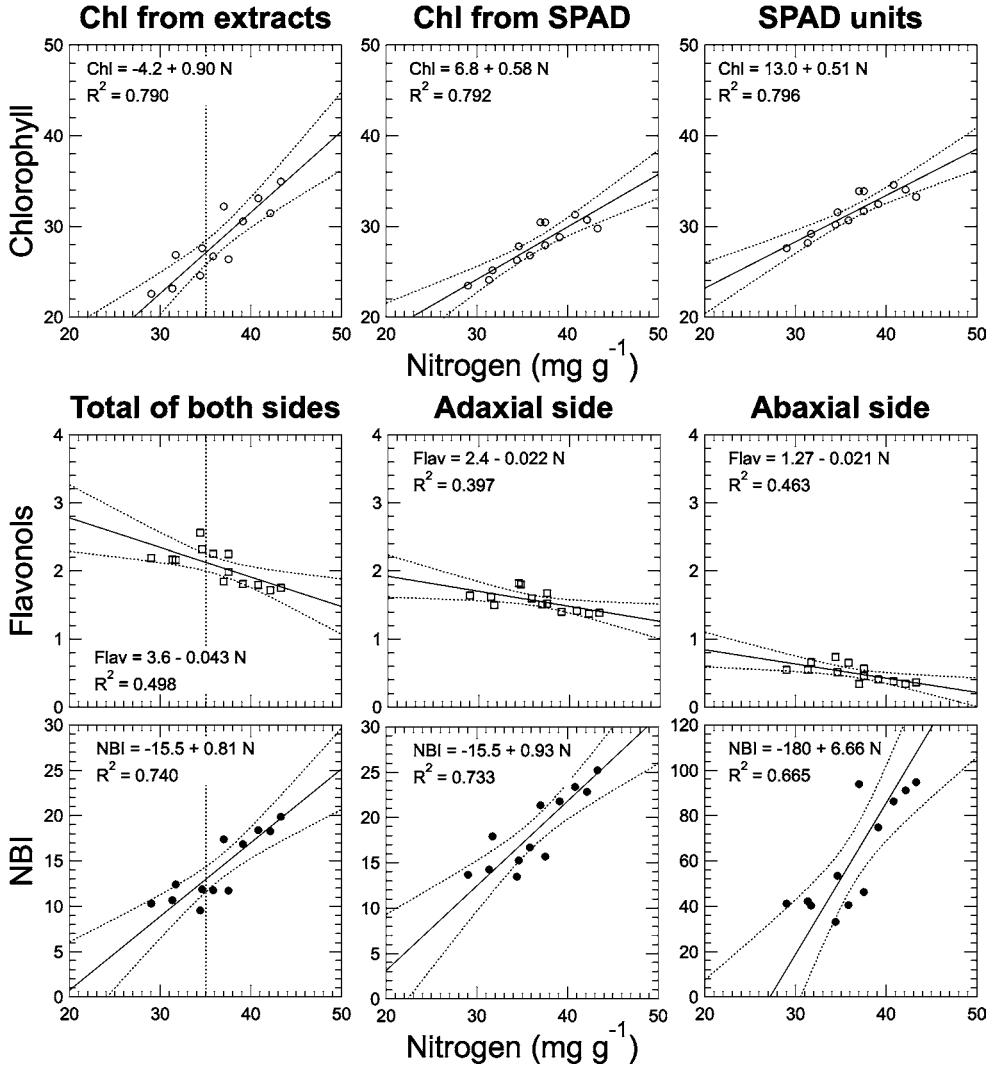

Figure 1. Dependence of optical indices on individual leaf nitrogen content for the Leaves 2007 data set. Each datum represents an individual leaf. The three top graphs are for Chl: total Chl content measured from extracts (left), Chl measured with the SPAD-502 (right), and Chl calculated from the SPAD-502 measurements using the consensus equation from Cerovic et al.[19] (center). Three Flav indices are presented in the middle row of the figure: Flav measured from the abaxial side of the leaf (right), Flav measured from the adaxial side of the leaf (center), and the sum of Flav of the two sides (left). All three NBI indices, total (left), adaxial (center), and abaxial (right), were calculated using the same transformed SPAD-502 measurements (center Chl graph). Regression models are indicated on the graphs by a full line, with dotted lines representing the 95% confidence interval bands. The vertical dotted line indicates the threshold limit used for the classification test presented in Table 2.

ments that usually yield a smaller number of data points and ambiguous results on ligneous perennials.[15] The responses of Chl, Flav, and NBI to N content in individual leaves are presented in Figures 1 and 2, and responses at the level of leaf populations, whole plots or subplots, are presented in Figures 3 and 4, respectively. All figures were plotted with the same N range for an easy visual comparison, although the different data sets did not have the same N average, span, or range. This is especially the case for Subplots 2012 (Figure 4) that was sampled two months later (end of July) than the other three data sets (end of May) (Figures 1−3). Linear regression models were sufficient and were the best in all cases. Determination coefficients (R^2) are indicated in the graphs and in Table 2. Table 2 also includes the corresponding RMSE. Using both criteria and for all three optical indices, Plots 2009 gave the best results with the smallest RMSE for the estimation of N content of 2.3, 2.0, and 1.7 mg g^{-1} for Flav, Chl, and NBI, respectively (Table 2). This is a consequence of the larger number of leaves averaged in the Plots 2009 data set. Data for the three cultivars were analyzed together. This showed the universality of the calibration, at least for these three cultivars. In all four data sets, Chl was better related to N than was Flav, with RMSE for Chl almost 2 times smaller for individual leaves. They were 2.2 vs 4.1 mg of N g^{-1} DW and 4.5 vs 7.6 mg of N g^{-1} DW, for Chl vs Flav, respectively (Table 2). The difference was much smaller in the case of plots and subplots where populations of leaves are sampled and averaged together, 2.0 vs 2.3 mg of N g^{-1} DW and 2.6 vs 3.0 mg of N g^{-1} DW, for Chl vs Flav (Table 2). Moreover, NBI was the best estimator of N content in all situations except for Leaves 2007, in which light-exposed and shaded leaves were mixed. There was a substantial decrease of NBI RMSE to 1.7 and 1.8 for plots and subplots and an increase in R^2 to 0.907 and 0.844 for Plots 2009 and Subplots 2012. Therefore, NBI, which is the ratio of Chl to Flav, improves the estimation of N even though it combines two estimators of inferior quality.

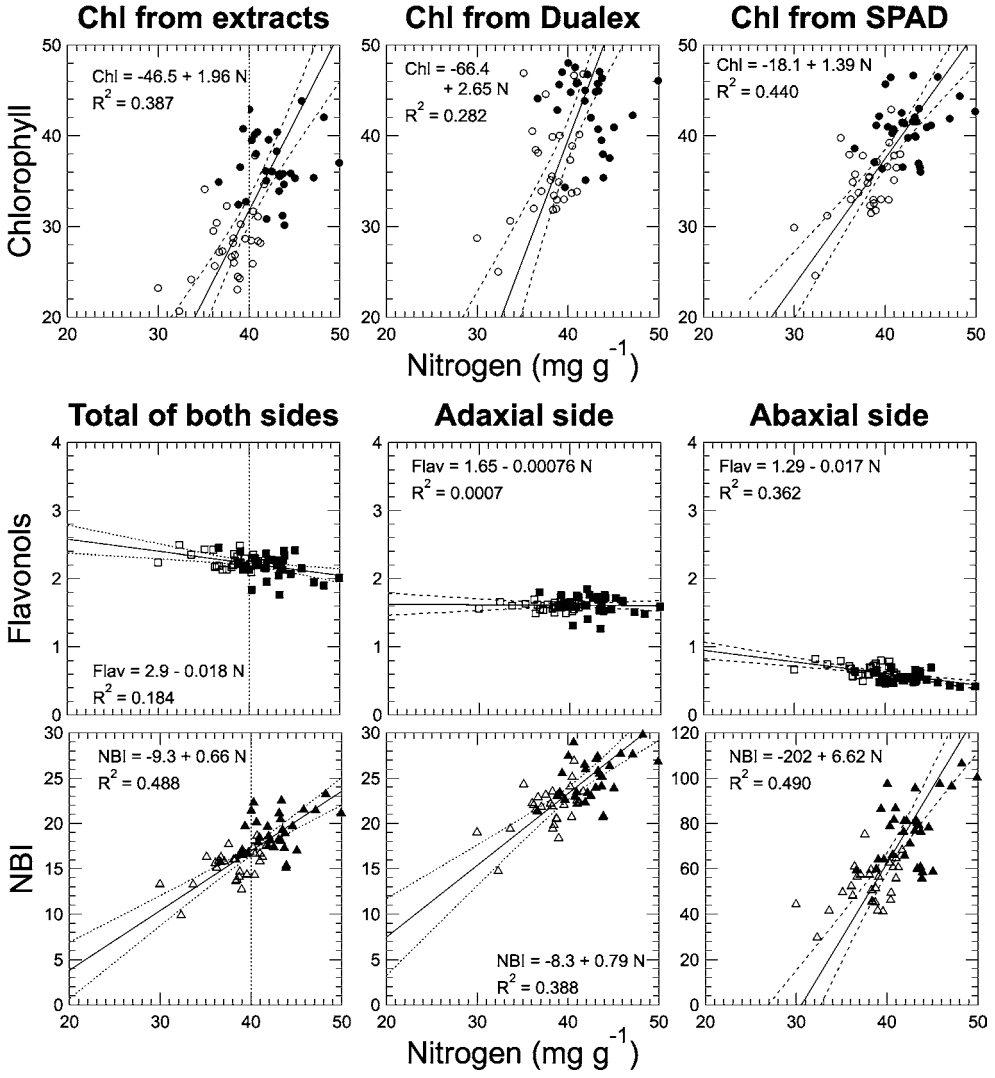

Figure 2. Dependence of optical indices on individual leaf nitrogen content for the Leaves 2009 data set. Each datum represents an individual leaf. Open symbols were used for Chardonnay and closed symbols for Pinot noir. The three top graphs are for Chl: total Chl content measured from extracts (left), Chl measured with the Dualex (center), and Chl calculated from the SPAD-502 measurements using the consensus equation from Cerovic et al.[19] (right). Three Flav indices are presented in the middle row of the figure: Flav measured from the abaxial side of the leaf (right), Flav measured from the adaxial side of the leaf (center), and the sum of Flav of the two sides (left). All three NBI indices, total (left), adaxial (center), and abaxial (right), were calculated using the same transformed SPAD-502 measurements (right Chl graph). Regression models are indicated on the graphs by a full line, with dotted lines representing the 95% confidence interval bands. The vertical dotted line indicates the threshold limit used for the classification test presented in Table 2.

The calibration at the population level, 60 leaves at the plot level (Figure 3) and 9 leaves at the subplot level (Figure 4), which is the agronomical pertinent situation, decreased the variability compared to individual leaf calibration (Figures 1 and 2). Plots 2009 and Subplots 2012 were two very different data sets. The former was obtained for Champagne on Pinot noir at flowering and the latter for Bordeaux on Merlot noir at bunch closure. The two month difference was the major factor governing the differences seen between the two.[16] Flavonol content in Subplots 2012 was greater because flavonols were accumulated with time and light exposure. Leaf N content was smaller because it was diluted with time and LMA increase.[6,42] This had a cumulated consequence on the NBI that also decreased. The data obtained here for Pinot noir (Figure 3) and Merlot noir (Figure 4) correspond to those obtained by Romero et al.[6] on Tempranillo. In both cases, the average N content decreased from 36 mg g^{-1} at the end of May to 28 mg g^{-1} at the end of July. Contrary to our expectations, a precisely controlled situation in which local Dualex sampling on leaf disks was compared to a chemically tested leaf N on the very same disk (Figures 1 and 2) did not produce better calibrations than the mixed-leaf N analysis (Figures 3 and 4). Pooled leaves from a single height without even counting the nodes (Figure 4) produced better results than single leaves (Figures 1 and 2).

Nitrogen Balance Index. The NBI correlates better with N content on a mass basis because it takes into account not only the surface-based variability in N investment in the photosynthetic machinery but also the variation in LMA. This advantageous relationship could be obtained by comparing surface-based Chl with surface-based N after its transformation with the LMA (surface-based N = mass-based N × LMA), but unfortunately, the estimation of LMA is destructive. In ligneous species light controls N investment in leaves to adjust photosynthesis to its light environment (photosynthetically

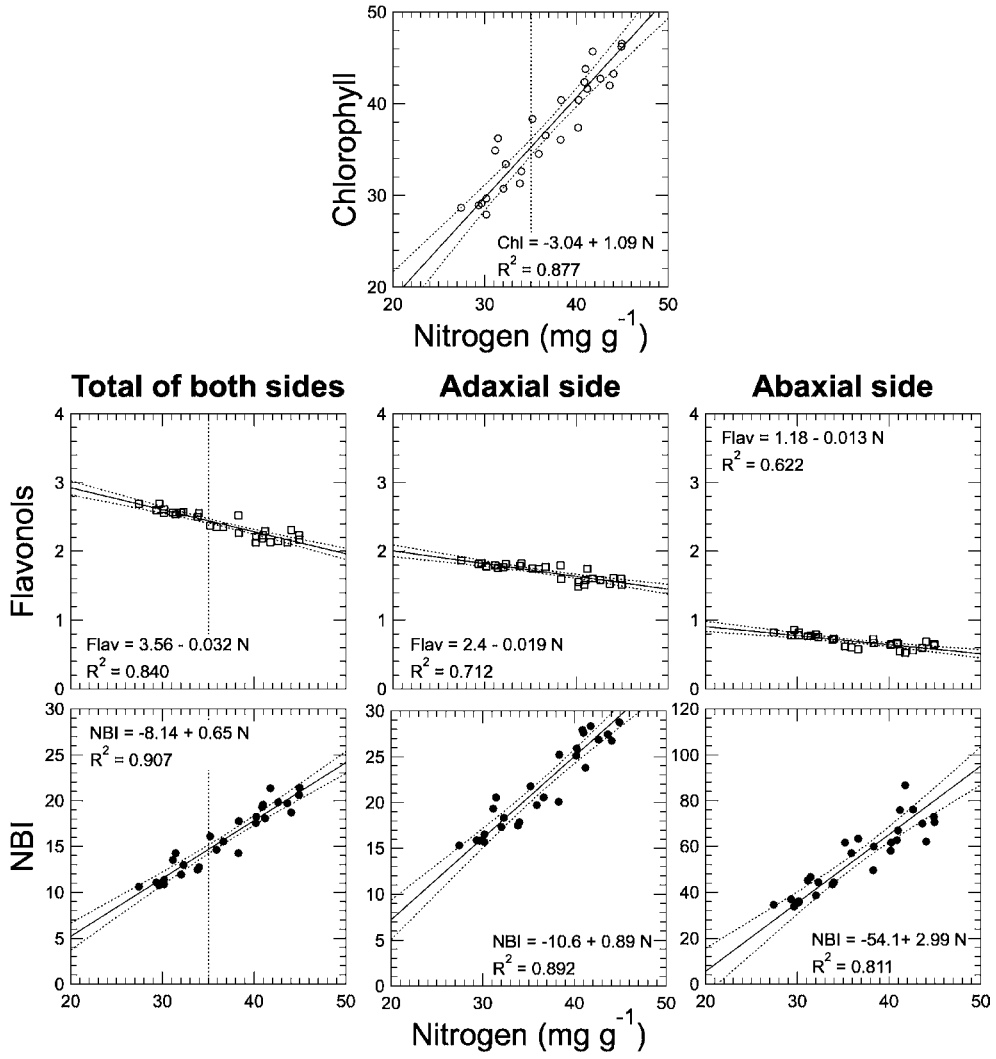

Figure 3. Dependence of optical indices on the mean nitrogen content for the Plots 2009 data set. Each datum represents a single plot characterized by the average of 60 leaves. The top graph is for Chl calculated from the SPAD-502 measurements using the consensus equation from Cerovic et al.[19] Three Flav indices are presented in the middle row of the figure: Flav measured from the abaxial side of the leaf (right), Flav measured from the adaxial side of the leaf (center), and the sum of Flav of the two sides (left). All three NBI indices, total (left), adaxial (center), and abaxial (right), were calculated using the same transformed SPAD-502 measurements (top Chl graph). Regression models are indicated on the graphs by a full line, with dotted lines representing the 95% confidence interval bands. The vertical dotted line indicates the threshold limit used for the classification test presented in Table 2.

active radiation (PAR) irradiance) by increasing LMA (mostly leaf thickness) without changing mass-based N.[43] This has been shown for grapevine,[34] for beech,[44] and for tropical trees.[45] This is why surface-based leaf Chl content obtained with leaf clips might not always correlate to leaf N. Surface-based Chl will reflect leaf N only when comparisons are made among leaves that developed under different N supplies but under the same light regime. Using Flav as a proxy for LMA[16,30] can compensate for different leaf light exposures. Therefore, the introduction of the NBI index will alleviate the frequent problem of surface-based Chl measurements compared to mass-based N (see, for example, the paper by Porro et al.[11]).

The abaxial Flav level was always lower than the adaxial level (Figures 1−4). Later in the season (Figure 4), both leaf sides had larger Flav contents, but the increase was more marked on the abaxial side. The single-sided Flav defines the single-sided NBI because Chl remains the same independent of the side from which it is measured (illustrated in Figure 4). Indeed, Chl in Figure 4 shows that there were no significant differences when it was measured from the adaxial or abaxial side, confirming that a single measurement is sufficient for leaf clips based on transmittance. In all four cases (Figures 1−4), the total NBI calculated using the sum of Flav of both leaf sides was better correlated to N (higher R^2) than single-sided NBI. In addition, it can be seen that sometimes single-sided NBI (adaxial NBI in Figures 1 and 3, abaxial NBI in Figure 2) gives estimations as good as the total NBI. Still, the absolute values of the total NBI are more stable. Single-sided measurements are important for the future use of noncontact fluorescence sensors such as the Multiplex that have a different response depending on the side or measurement[10] (Diago et al., manuscript in preparation), but this is outside the scope of the present paper.

Classification Test. For arable crops that have a quadratic response of yield to N supply, with saturation often above a threshold, the Cate−Nelson classification[46] can be used to separate the responding from the nonresponding regions in the yield-to-N supply curves. Here we have a linear relationship between optical indices and leaf N, so the Cate−Nelson

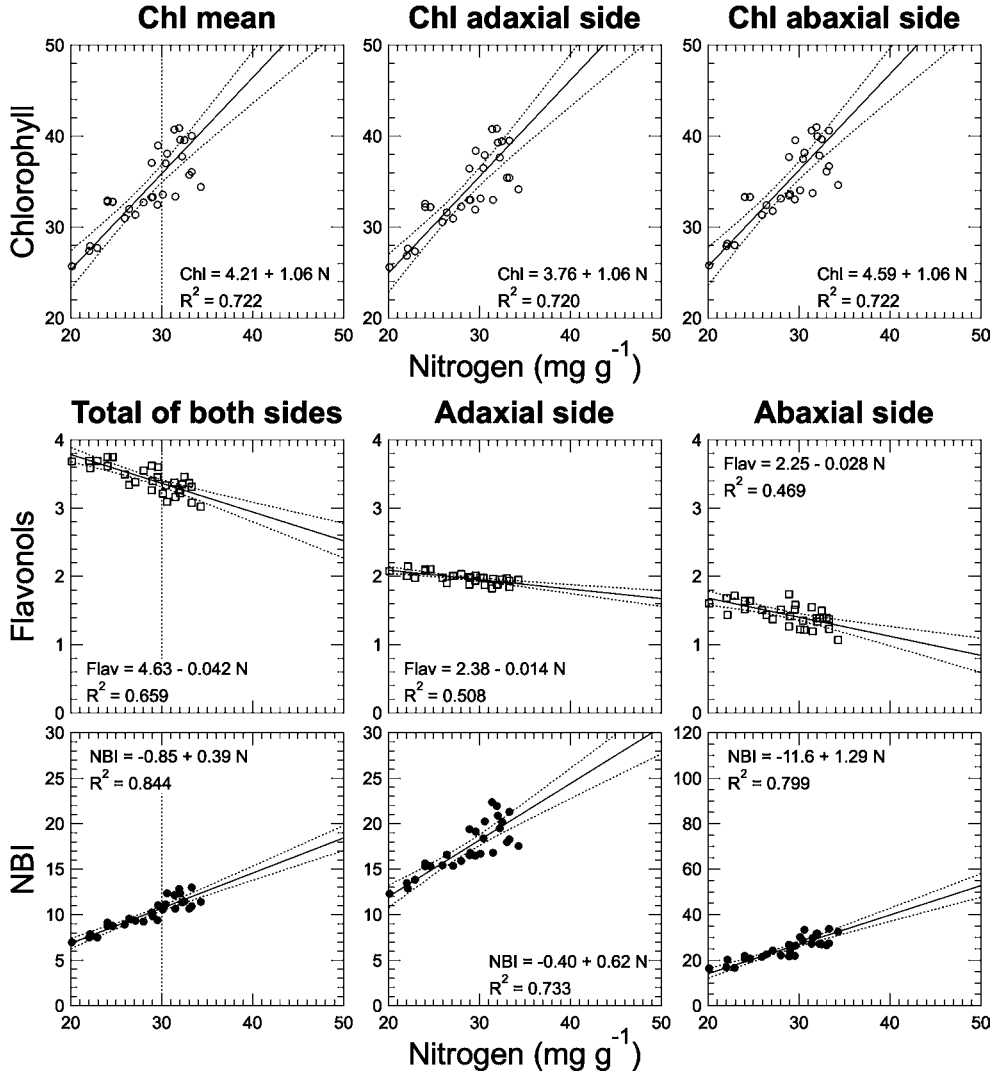

Figure 4. Dependence of optical indices on the mean nitrogen content of leaves for the Subplots 2012 data set. Each datum represents a subplot characterized by the average of nine leaves present on three adjacent vines. The three top graphs are for Chl measured with the Dualex 4 from the abaxial side of the leaf (right) and from the adaxial side of the leaf (center) and the mean Dualex Chl of the two leaf sides. Three Flav indices are presented in the middle row of the figure: Flav measured from the abaxial side of the leaf (right), Flav measured from the adaxial side of the leaf (center), and the sum of Flav of the two sides (left). The three NBI indices, total (left), adaxial (center), and abaxial (right), were calculated using the mean Dualex Chl and the adaxial and the abaxial Chl, respectively. Regression models are indicated on the graphs by a full line, with dotted lines representing the 95% confidence interval bands. The vertical dotted line indicates the threshold limit used for the classification test presented in Table 2.

statistical procedure was not well adapted. However, for practical purposes optical indices are usually used to diagnose deficiency and classify plots to those needing fertilization or not, thanks to their relationship to leaf N. This is why the presented continuous values (Figures 1−4) can also be analyzed on the basis of a cutoff value for sufficient leaf N. An evaluation of the test for this binary classification can be done by calculating the Youden index (Youden's J statistics, informedness)[40] (Table 1). This index is a commonly used measure for overall diagnostic effectiveness of a method. It is especially useful because it combines sensitivity and specificity, which are both prevalence-independent statistics. Leaf N content is considered here as the gold standard for N sufficiency. Generally, levels of N in leaf blades below 20 mg g^{-1} between flowering and véraison indicate deficiency[47] (see Table S1, Supporting Information). For the four different data sets, we had to apply different threshold values to have an acceptable prevalence (proportion of positive values) for the contingency table analysis. The threshold values (cutoffs) were chosen to have a prevalence of around 50%. In addition, they corresponded to the real situation generally recorded in the field (cf. Table S1). The individual leaf data sets (Figures 1 and 2) and the plot data set (Figure 3) for Champagne cultivars were obviously on the high N side; therefore, 35 and 40 mg g^{-1} thresholds were tested (Table 2). For the Leaves 2009 data set, we used a higher threshold (40 mg g^{-1}) because for the 35 mg g^{-1} threshold the prevalence was too large to be acceptable (0.89).[40] According to Youden,[40] the sample size was sufficient for comparisons except for the Leaves 2007 data set, which only had 12 leaves. No significant differences among indices (NBI vs Chl vs Flav) or among data sets (type of data sets) were found, apart from the Leaves 2009 data set, for which the Youden index for Flav was much lower than that for Chl and NBI (Table 2). In plant disease research, as in medicine, one would

J. Agric. Food Chem. 2015, 63, 3669−3680

favor tests that minimize false negatives, that is, tests that maximize sensitivity. On the contrary, farmers' adversity toward loss of yield would prefer an indicator that minimizes false positives, that is, which maximizes specificity. They prefer to fertilize even if it is not needed, rather than to lose some yield. In viticulture at the lower threshold (N-deficient vines), a viticulturist would behave like any other farmer, but at the higher threshold (N overfertilization), he should behave like a physician: he would favor an indicator that avoids false negatives because overly vigorous vines are more prone to diseases and produce grapes of lower technological quality.[4]

The Leaf 2009 data set, which had the largest dispersion of experimental points, is characteristic of the advantage of NBI over the use of Chl and Flav indices alone. Using a poor Flav index that has low sensitivity and specificity (Youden's $J = 0$) to divide a modest Chl index that has a modest sensitivity and specificity (Youden's $J = 0.46$) produced an NBI index that has a fair sensitivity (0.79) and a high specificity (0.88). The Youden index for NBI increased to 0.67, and accuracy reached 0.83. This is an outstanding achievement for an index that has an RMSE of 3.7 mg g^{-1}, which is 2 times larger than the plot (1.7) and subplot (1.8) RMSEs (Table 2). We can conclude that both the Youden index and the accuracy of the leaf-clip method are very good for N nutrition estimation in grapevine. There were two major reasons for this success. First, Dualex had a more linear response than SPAD-502 thanks to the choice of a less absorbed sensing wavelength.[19,48] However, the use of the consensus equation[19,48] for the transformation of SPAD-502 units also helped to obtain quantitative relationships. Second, grapevine is a crop usually fertilized with parsimony; therefore, leaves rarely attain the very high levels of N and Chl found in overfertilized grain crops.[49] Even then, it is expected that epidermal leaf Flav will continue to respond to increased N when Chl stops responding.[10,21,22]

Choice of the Representative Leaf and Growth Stage. Reliable estimation of N content will be dependent on several factors: the most representative leaf, the number of leaves to represent the management unit, the best plant, and the leaf phenological stage.[3,8] In a preliminary experiment, we measured all leaves of all primary shoots of a Merlot noir vine on three dates in July 2014. The within-plant coefficients of variation for Chl, Flav, and NBI were 25%, 12%, and 31%, respectively. Therefore, to discriminate a 10% difference in Chl content with an acceptable error of 10%, a minimum of 131 leaves would be needed to reliably sample a plot (250 leaves for an error of 5%)[41] (see the Materials and Methods). Fortunately, the variation among the leaves at the same node number is much smaller than that, ranging from 6.6% to 14%. By fixing the node position, the needed number of sampled leaves decreases to a minimum of 9 and a maximum of 45 for an acceptable error of 10% (41−78 leaves for an error of 5%). The intraleaf variability can be even smaller. Its coefficient of variation was often 4%, 6%, and 8.5% for Chl, Flav, and NBI, respectively. Therefore, with a measurement on a single well-defined position on a leaf, one could concentrate the sampling effort to different vines because it is advantageous to sample leaves from different plants in a sufficient number to obtain a smaller variance in N estimation.[8]

The leaf opposite the first cluster on node no. 4 counted from the base of the shoot is often used for N analysis.[11] At flowering this leaf corresponds to a just-matured leaf, but at later phenological stages it is not the best choice because it becomes very old. Therefore, attempts were made to replace it by the next leaf just above it, i.e., the leaf opposite the second cluster, or even the leaf four nodes above it.[5,50] It is obvious that a metabolically active younger leaf would be a better choice.[51] If 4−5 nodes are counted above the clusters, as preconized in Italy[50] for later growth stages, it would have forced us to select a leaf on node nos. 8−9 from the base. For a 13−14-leaf shoot, it will actually correspond to leaf no. 5 from the tip. Often used in phytopathology research,[52] leaf no. 5 from the tip is representative of the leaf that has just attained maturity. From an expanding carbon sink leaf, it becomes a carbon source leaf; therefore, it is more sensitive to deficiencies. The universally accepted node and the leaf position for N sampling that we recommend here is around the ninth node from the shoot base for a 14-node fully developed shoot. This leaf will be in the upper half of the vertical shoot positioning (VSP) trained vines, above the second wire in a three-wire trellis system, or just below the second wire in a two-wire trellis system. This would also be the best position for the noncontact on-the-go sensing with optical sensors such as the Multiplex[32] or the Crop Circle.[12]

In addition to postharvest autumnal fertilization, flowering is the best phenological stage for in-season fertilization[34] because at this stage it is still possible to correct for N deficiency by in-season amendments if needed. Véraison, the stage at which most diagnoses are often performed (Table S1, Supporting Information), is too late for efficient in-season amendment.[51] It can only be useful as information for viticultural practice decisions concerning next year's crop, such as the severity of pruning and potential interrow cropping. Therefore, performing leaf N diagnosis somewhere between flowering and bunch closure (BBCH 65−75) would be recommended.

Leaf Nitrogen Norms. For various plant species and independently of the growth stage, N contents in mature leaf tissue of less than 25, between 25 and 45, and above 60 (mg of N g^{-1} DW) are usually considered as deficient, sufficient, and excessive, respectively.[3] In grapevine, excess N can be even more damaging than deficiency because vines would be more subject to diseases and insect infestations.[53] Overfertilization usually produces grapes of lower quality.[4] Overfertilized plants are also prone to flowering abortion and a lack of fruit set.[3,54] Therefore, for grapevine these N thresholds were defined for individual countries or even wine-growing regions[55,56] (cf. Table S1, Supporting Information). For example, for Washington, the critical range proposed is 25−35 mg of N g^{-1} DW at bloom and 22.5−32.5 mg of N g^{-1} DW at véraison.[57] For Bordeaux, leaf N contents at véraison of 22.0, 26.2, and 34.1 mg of N g^{-1} DW were considered limited, mean, and excessive by Hilbert et al.[35] (cf. Table S1).

Calibrations performed in the present work allow us to propose the corresponding values of Chl and NBI for the consensus thresholds drawn from the literature at flowering and bunch closure (Table 3). On the basis of the literature survey, we have chosen 30 and 40 mg of N g^{-1} DW for the lower and upper thresholds at flowering and 22 and 32 mg of N g^{-1} DW at bunch closure. The corresponding Chl values are 30 and 40 μg cm^{-2} for flowering and 29 and 37 μg cm^{-2} for bunch closure. The corresponding NBI values are 11 and 18 for flowering and 8 and 11 for bunch closure.

When proposing the use of absolute thresholds, it is important to estimate the associated uncertainty. Several factors should be taken into account: leaf position (10% error), phenological phase at time of diagnosis (5%), inherent precision (or lack of precision) of the optical diagnostic

J. Agric. Food Chem. 2015, 63, 3669−3680

Table 3. Tentative Grapevine Leaf Content Norm Thresholds for Nitrogen (mg g^{-1}), Dualex Chlorophyll (μg cm^{-2}), and Dualex NBI Index at the Flowering and Bunch Closure Growth Stages

	deficient	sufficient (optimal)	excessive (overfertilized)
		Flowering	
nitrogen	<30	30−40	>40
chlorophyll	<30	30−40	>40
NBI index	<11	11−18	>18
		Bunch Closure	
nitrogen	<22	22−32	>32
chlorophyll	<29	29−37	>37
NBI index	<8	8−11	>11

method (10%), and the precision of the gold standard (5%). The differences in estimation of N content by the reference methods can be substantial because they do not analyze the same type of N. The Dumas combustion method includes all types of N (NH_4, NO_3, and protein and heterocyclic N). The N_2 produced is determined by mass spectroscopy or by thermal conductivity detection with reproducibility not better than 5%. The Kjeldahl digestion method, until now the industry standard, yields lower results than the Dumas method because it neglects heterocyclic N. It can be performed with or without NO_3 and NO_2 recovery, which changes the results among laboratories.[8] Therefore, if we want to use an absolute threshold calibrated against the gold standard, the overall uncertainty of optical estimation including all factors will not be smaller than 16%. The latter value was calculated as the square root of the sum of squares of individual errors assuming that individual errors were independent and uncorrelated. This is larger than the year-to-year variability of ±10% found by Failla et al.,[56] corresponding to an average of 20 mg of N g^{-1} DW ± 2 mg g^{-1}. The regional variability due to soil and climate and the year-to-year variability are what we are looking for, so they were not included in this calculation. In summary, with the best protocol, a plot can be declared N-deficient with certainty if it has an average Chl content lower than 25 μg cm^{-2} at flowering. It can be considered overfertilized if it has a Chl above 47 μg cm^{-2}.

Proposed Protocol. All of the above work incites us to propose a stringent sampling protocol comprising double-sided Dualex measurements on 40 light-exposed primary leaves positioned at the same canopy height, just above the first trellis wire in a two-wire trellis system, which corresponds to the middle of the canopy (i.e., node no. 9). The optimal procedure would be to divide the plot to be diagnosed into three equal parts and to walk through the two interrows that separate these parts. One should then sample (measure with the Dualex) one leaf from the three shoots of a vine, repeating this on five vines from each side of the interrow, left and right, and for the two interrows. This would yield measurements from 60 leaves all together (1 leaf × 3 shoots × 5 vines × 2 row sides × 2 interrows). A single measurement per leaf at the intervein position (Figure S1, Supporting Information) is sufficient. The representative average for the plot for Chl and for NBI (Chl divided by the sum of Flav of the two leaf sides) can be compared to the threshold criteria presented in Table 3. Alternatively, for smaller plots or for visually homogeneous plots, the sampling can be decreased to 36 leaves (1 leaf × 3 shoots × 3 vines × 2 row sides × 2 interrows). Thanks to the knowledge of leaf N dilution during the season,[5,6] a lookup table could also be constructed to correct for seasonal effects when diagnostics cannot be made at the optimal postflowering growth stage (the BBCH 65−75 window). To sum up, we propose to sample 36−60 leaves at flowering at a fixed node position, preferably node no. 9, or at the same height for VSP.

Limitations of Optical Nitrogen Estimation. Water availability influences nitrogen uptake[58] and therefore would influence leaf N content. One should make a distinction between the effect of water availability on nutrient analysis[59] and genuine leaf N content physiological dependence on rainfall.[58] In the first case, a water deficit simply precludes the use of petiole nitrate tests, and leaf N is also affected. In the second case, water availability, rainfall, or irrigation during canopy development interacts with nitrogen availability to optimize simultaneously both nitrogen and water use efficiency by adjusting the total leaf area, N per leaf area, and LMA. This represents the potential limit for the use of absolute values of NBI because Flav is also influenced by light and water stress.[60] As an alternative approach to NBI, Flav can be used to verify that sampled leaves belong to the same sun-exposed category that has the same LMA. In that case, Chl alone could be used as a proxy for N content even when expressed in surface-based units. Then the Chl index would perform sufficiently well and can be used as an absolute value. Knowing that only thoroughly trained and experienced technicians should be responsible for collecting plant tissue samples[8] and that very often this is not the case, this type of objective postacquisition filtering of optically acquired data could be very useful.

Other leaf-clip chlorophyll meters such as the SPAD-502 can also be used for N estimation.[11−15] They would best be used after an adequate transformation into leaf Chl content (cf. the Material and Methods). Still, the SPAD-502 leaf clip has an effective access length of only 1.3 cm because it was originally designed for rice leaves. This is why in the present study we performed the measurement with the SPAD-502 on the disks once they had been cut from the leaf. This can be a real problem for rapid in-field measurements if one wants to avoid leaf edges. To scarify one leaf among the two thousand leaves present on a vine by cutting it might not seem prohibitive, but it will greatly slow the diagnostic speed. The Dualex that was designed for grapevine leaves has an access length of 8 cm to attain the middle of even a 16 cm wide leaf.

The "nitrogen sufficiency index" approach[1] is another potential way to alleviate most of the problems of the use of absolute threshold values for the indices because it is related to a standard condition for the same index. It could mitigate the above-mentioned concerns about both the absolute NBI values and the environmental and phenological influences on N estimation, such as the variable growth rate and leaf age at the time of measurement. Unfortunately, the nitrogen sufficiency index cannot be applied to a ligneous species such as grapevine on a year-to-year basis due to a lack of overfertilized reference and to the latency in N deficiency expression. However, a new approach to explore within the framework of site-specific crop management could be to use a virtual-reference concept,[61] i.e., just the comparison of subplots or homogeneous zones to the one having the largest NBI value. Indeed, for spatial heterogeneity analysis and zoning, both Chl and NBI measurements are valuable, especially with tractor-mounted sensors such as the Multiplex.

Conclusion and Prospects. Technology-based optical sensing is the equivalent of visual estimation. Still, it is more objective and can be automated and georeferenced. It is well

adapted for site-specific crop management in replacement of plant tissue testing. In this paper we presented quantitative optically measured norms for grapevine N nutrition based on extensive studies of Chl and Flav using a new optical leaf clip. The knowledge of the growth stage and the sampling of leaves at a defined node are crucial for a reliable estimation of grapevine N status. The presented grapevine optically measured leaf N sufficiency level thresholds should be refined for different phenological stages, from flowering to véraison, by accumulation of data on different sites. The universality of Chl and NBI indices should be verified for different cultivars. Their robustness against year-to-year variability should also be verified by multiyear surveys on the same sites. Finally, for practical applications of these optical approaches in precision viticulture, indices obtained by mounted optical proximal sensors such as the Multiplex need to be calibrated and validated against the Dualex indices presented in this paper. Grapevine is just an example of the use of optical sensors for the applications of leaf Chl and NBI for crop N management. In viticulture, it is important to estimate vine nitrogen availability for three reasons. First, N affects yield, as in other crops. Second, it influences the grape fermentation potential.[35] Third, it defines the must quality via phenolic and technological grape maturity. The type of analysis presented in this paper can and should be repeated on other crops. Indeed, some data are already available for muskmelon.[28]

Funding

This work was supported by FORCE-A (Orsay) in a joint project with the Centre National de la Recherche Scientifique and Université Paris-Sud (Grant UPS N8780). In addition, the research leading to these results has recently received funding from the European Community's Seventh Framework Program (FP7/2007-2013) under Grant Agreement FP7-311775, Project Innovine.

Notes

The authors declare the following competing financial interest(s): Z.G.C. declares a double link to the FORCE-A company: as one of the co-authors of the Dualex patent that the company exploits and as a part-time consultant to the company. Other authors declare no competing financial interests.

■ ACKNOWLEDGMENTS

We thank the following institutions for giving us access to their vineyards: Moët & Chandon Champagne, the trade association Comité Champagne, and Chateau Gazin. We thank Dr. Gwendal Latouche for his useful advice on the manuscript and Dr. Zorana Ratkovic for proofreading the manuscript. Finally, we thank the anonymous reviewers for comments that helped improve the clarity of the paper.

■ ABBREVIATIONS USED

N, nitrogen; NBI, nitrogen balance index; Chl, chlorophyll; LMA, leaf mass per area; Flav, flavonol; RMSE, root mean squared error; UV, ultraviolet; DW, dry weight

Figure 1. Examples of fungicides structure.

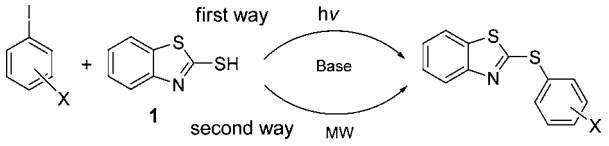

Figure 2. Methodologies employed for the arylation of 2-mercaptobenzotiazole.

DMSO (Carlo Erba) was also distilled under nitrogen and stored in molecular sieve 4 Å (Aldrich). Potato glucose agar (PGA) and Triadimefon were commercially available and used as received. Distilled water was sterilized before their use.

Photostimulated Reactions of Dihalobenzenes with Benzothiazole-2-thiolate Ions in DMSO. The following procedure is representative of these reactions. 2-Mercaptobenzothiazole (1.1 mmol) and *t*-BuOK (1.1 mmol) were added to 8 mL of degassed DMSO. Then, after 10 min when no more solid was present, benzothiazole-2-thiolate ions were ready for use (characterized by a yellow solution). Substrate (1.0 mmol) was added to the solution and the reaction mixture irradiated for 180 min. The reaction was then quenched by adding an excess of water. The solution was then extracted with dichloromethane and water (25 mL). The organic extract was analyzed by GC-MS, and the products were isolated by column chromatography.

A similar procedure was carried out for reactions with substrate excess, adding 1.0 mmol of 2-mercaptobenzothiazole and *t*-BuOK and 5.0 mmol of substrate. These reaction mixtures were irradiated for 30 min.

Microwave Assisted Reactions of Dihalobenzenes with Benzothiazole-2-thiolate Ions in Microwave Oven. 2-Mercaptobenzothiazole (0.5 mmol) and KOH (0.5 mmol) was added to 2 mL of water. Then, after 2 min when no more solid was present, the benzothiazole-2-thiolate ions were ready for use (characterized by a yellow solution). Substrate (0.6 mmol) was added to the solution and the reaction mixture irradiated for 2−7 min. The solid was extracted with dichloromethane. The organic extract was analyzed by GC-MS.

Data for 2-(Phenylthio)benzothiazole (2). The product was isolated as yellow oil after column chromatography using dichloromethane:petroleum ether (70:30). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.27−7.57 (m, 5H), 7.62−7.82 (m, 3H), 7.90 (dd, J = 12.55 Hz, J = 8.17 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) ppm: 121.1, 121.5, 122.2, 124.7, 124.9, 126.5, 130.3, 130.8, 135.7, 135.9, 153.3. HRMS $[MH]^+$ exact mass calculated for $C_{13}H_{10}S_2N$, 244.0249; found, 244.0317.

Data for 1,4-Bis(2-Mercaptobenzothiazol)benzene (3). The nucleophile excess was extracted from the reaction mixture by washing with water. The product was isolated as a white solid after filtrating and washing the precipitate with ethyl acetate; mp: 197.5−199.3 °C. ^{1}H NMR (400 MHz, DMSO-d_6) δ: 7.39 (td, J = 8.14 Hz, J = 1.15 Hz, 2H), 7.49 (td, J = 8.22 Hz, J = 1.27 Hz, 2H), 7.89 (ddd, J = 8.17 Hz; J = 1.00 Hz, J = 0.54 Hz, 2H), 7.92 (s, 4H), 8.00 (ddd, J = 8.05 Hz, J = 1.17 Hz, J = 0.55 Hz, 2H). ^{13}C NMR (100 MHz, DMSO-d_6) ppm: 121.7, 121.9, 125.0, 126.6, 132.1, 135.1, 135.5, 153.2. HRMS $[MH]^+$ exact mass calculated for $C_{20}H_{13}S_4N_2$, 408.9962; found, 408.9986.

Data for 2-(4-Bromophenylthio)benzothiazole[23] (4). The product was isolated as white solid after column chromatography using dichloromethane:petroleum ether (70:30); mp 55.6−56.8 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.29 (ddd, J = 7.97 Hz, J = 7.37 Hz, J = 1.21 Hz, 1H), 7.42 (ddd, J = 8.13 Hz, J = 7.28 Hz, J = 1.25 Hz, 1H), 7.56−7.64 (m, J = 3.00 Hz; J = 1.14 Hz, J = 0.52 Hz, 4H), 7.69 (ddd, J = 8.28 Hz, J = 0.53 Hz, 1H), 7.89 (dd, J = 8.28 Hz, J = 0.53 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) ppm: 120.9, 122.1, 124.6, 125.2, 126.3, 129.1, 133.1, 135.6, 136.5, 139.1, 153.81, 168.0. HRMS $[MH]^+$ exact mass calculated for $C_{13}H_9S_2NBr$, 321.9354; found, 321.9356.

Data for 2-(4-Iodophenylthio)benzothiazole (5). The product was isolated as yellow oil after column chromatography using dichloromethane:petroleum ether (70:30). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.28−7.32 (m, 1H), 7.40−7.45 (m. 3H), 7.56−7.78 (m, 2H), 7.80 (d, J = 8.12 Hz, 1H) 7.89 (dd, J = 8.12 Hz, J = 3.03 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) ppm: 121.2, 122.5, 124.9, 126,7, 130.2, 130.3, 130.6, 135.7, 136.0, 136.9, 139.4, 154.1. HRMS $[MH]^+$ exact mass calculated for $C_{13}H_9S_2NI$, 369.9221; found, 369.9239.

Data for 2-(2-Chlorophenylthio)benzothiazole (6). The product was isolated as brown solid after column chromatography using dichloromethane:petroleum ether (70:30). ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.28−7.34 (td, 1H, J = 1.17 Hz, J = 8.69 Hz), 7.34−7.39 (dd, 1 H, overlapping, J = 1.23 Hz, J = 8.38 Hz), 7.39−7.46 (tt, 2H, overlapping, J = 1.23 Hz, J = 8.01 Hz), 7.66−7.72 (dt, 1H, J = 1.48 Hz, J = 7.54 Hz), 7.73−7.78 (dt, 1H, J = 8.26 Hz), 7.78−7.82 (dt, 1H, J = 1.97 Hz), 7.89−7.95 (dt, 1H, J=8.14 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) (ppm): 120.93, 122.27, 124.63, 126.26, 128.65, 129.73, 131.71, 131.87, 134.19, 135.87, 136.92, 153.87, 166.97. HRMS $[MH]^+$ exact mass calculated for $C_{13}H_8S_2NCl$, 277.9865; found, 277.9860.

Data for 2-(3-Chlorophenylthio)benzothiazole[24] (7). The product was isolated as colorless oil after column chromatography using dichloromethane:petroleum ether (70:30). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.28−7.34 (J = 1.17 Hz, J = 8.69 Hz, td, 1H), 7.37−7.44 (t, 1H, overlapping, J = 7.77 Hz), 7.37−7.44 (dd, 1H, overlapping, J = 1.23 Hz, J = 8.38 Hz), 7.44−7.50 (tt, 1H, overlapping, J = 1.23 Hz, J = 8.01 Hz), 7.58−7.64 (dt, 1H, J = 1.48 Hz, J = 7.54 Hz), 7.68−7.72 (d, 1H, J = 8.26 Hz), 7.72−7.74 (t, 1H, J = 1.97 Hz), 7.83−8.03 (d, 1H, J = 8.14 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) ppm: 120.9, 122.3, 124.7, 126.3, 130.4, 130.9, 131.9, 132.9, 134.5, 135.4, 135.7, 153.7. HRMS $[MH]^+$ exact mass calculated for $C_{13}H_9S_2NCl$, 277.9865; found, 277.9860.

Data for 2-(4-Fluorophenilthio)benzothiazole (8). The product was isolated as brownish solid after column chromatography using dichloromethane:petroleum ether (70:30); mp 54.3−55.5 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.11−7.21 (m, 2H), 7.22−7.31 (m, 1H), 7.40 (ddd, J = 8.65 Hz, J = 7.30 Hz, J = 1.20 Hz, 1H), 7.65 (d, J = 8.17 Hz, 1H), 7.68−7.73 (m, 2H), 7.86 (d, J = 8.17 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) ppm: 117.5, 117.7, 121.1, 122.3, 124.7, 126.8, 135.9, 138.1, 138.2, 154.2, 163.3, 165.8, 169.8. HRMS $[MH]^+$ exact mass calculated for $C_{13}H_9S_2NF$, 262.0155; found, 262.0169.

Bioassays of Fungicidal Activities. Five bunches of botrytized grape clusters (*Vitis vinifera* cv. Chardonnay) were randomly hand-harvested in a vineyard in the district Barrancas, Maipú, province Mendoza (Argentina) in 2010. Solutions of compounds **2**−**8** were prepared with ethanol and were sterilized by filtration with 0.2 μm GHP HPLC filter membrane. Those solutions were each incorporated into polystyrene Petri dishes which contained potato glucose agar (PGA) and the required amount of water to reach the desired concentration of each compound. Fungal growth in the presence of each compound was evaluated at four concentrations (12.5, 25, 50, and 100 μg mL^{-1}) in PGA. Then the culture media were allowed to solidify. The final concentration of ethanol was 1.2% of the final volume of media for all treatments and control. For this instance, ethanol, water, PGA, and HPLC filters, membranes, and syringes were previously sterilized by autoclave for 15 min at 120 °C. For each analysis, three replicates were performed. Radial growth was measured after incubation at 28 °C for 8 days in the dark. For all assays, the fungi were cultured on PGA/water (positive control) and PGA/water/

ethanol (ethanol control). More details are included in the Supporting Information.

RESULTS AND DISCUSSION

Synthesis under Light Irradiation. The photostimulated reaction of benzothiazole-2-thiolate anion with iodobenzene afforded 60% yields of monosubstitution product (**2**) within 180 min (Table 1, entry 1, photostimulated reactions). Photostimulated reaction between 2 mmol of 2-mercaptobenzothiazole and 1 mmol of *p*-diiodobenzene afforded mainly 65% yields of disubstitution product (**3**) within 180 min (Table 1, entry 2).

To decrease the formation of disubstitution product and to produce monosubstitution product with retention of halide, reactions were performed with different benzenedihalides using a relation substrate:nucleophile (1:1). However, the best yields were obtained using a relation substrate:nucleophile (5:1). Thus, benzothiazole-2-thiolate ions reacted with *p*-bromoiodobenzene at a relation substrate:nucleophile (1:1) and (5:1), affording 37% and 98% yields of monosubstitution product with retention of bromine (**4**), respectively (Table 1, entry 3). This reaction did not occur in the dark and was inhibited by *p*-dinitrobenzene (*p*-DNB), a well-known inhibitor of $S_{RN}1$ reactions.[17] These reactions and more details about the optimization for *p*-bromoiodobenzene with **1** are included in the Supporting Information.

Reaction of benzothiazole-2-thiolate anion with *p*-diiodobenzene in a relation (1:1) afforded disubstitution product within 60 min, but by reducing the concentration of benzothiazole-2-thiolate anion and reaction time (30 min), 25% yields of monosubstitution product with retention of iodine (**5**) was obtained. The reaction performed in a relation substrate:nucleophile (5:1) afforded 93% yields of **5** within 30 min (Table 1, entry 4).

Photostimulated reaction of *o*-chloroiodobenzene afforded 44% and 98% yields of monosubstitution product with retention of chloride (**6**) within 30 min (Table 1, entry 5) at a relation substrate:nucleophile (1:1) and (5:1), respectively.

Furthermore, benzothiazole-2-thiolate ions reacted with *m*-chloroiodobenzene and *p*-fluoroiodobenzene, rendering 58% (**7**) and 63% (**8**) yields, respectively, under irradiation during 180 min with a relation substrate:nucleophile (1:1) (Table 1, entries 6 and 7). It has been observed that *o*-chloroiodobenzene was less reactive than *m*-chloroiodobenzene, probably due to hindering.

By contrast, *p*-dibromobenzene, *p*-chlorobromobenzene, or *m*-clorobromobenzene did not react with benzothiazole-2-thiolate ions under these reaction conditions (Table 1, entries 8−10). It is clear that those substrates with reduction potential greater than −1.60 V[25] are able to initiate the reaction while those with lower potential such as *p*-dibromobenzene, *m*-chlorobromobenzene, and *p*-chlorobromobenzene remain unreacted (see reduction potential in the Supporting Information).

Synthesis under Microwave Radiation. As an alternative to reaction initiation and in search of an environmentally benign process, microwave irradiation was employed.[26] Microwave irradiation in polar solvents allows rapid heating to high temperatures enabling short reaction times and often improved yields.[27] The solvent polarity affects the rate of a reaction carried out in a microwave oven because polar molecules absorb microwave causes heating of the substance through frictional effects. It would follow that the rates at which a solvent absorbs microwave radiation depends on its loss factor. The larger the loss factor the greater the coupling with microwaves. Thus, solvents such as water, methanol, DMF,

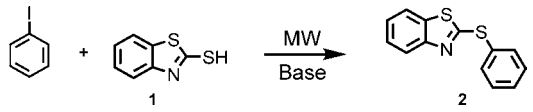
DMSO, etc., are all heated rapidly when irradiated with microwaves.[28]

Arylation of commercial fungicides were also studied in a previous report, allowing the formation of new compounds with potential fungicide activity under microwave irradiation.[29] The synthesis of polyfluorinated 2-benzylthiobenzothiazole derivatives under microwave radiation has been also reported.[30] Recently, Peñéñory et al. reported that microwave irradiation promotes a quick aromatic nucleophilic substitution by a thermally induced electron transfer process to form new C−C bonds by the coupling of aryl radicals and enolate nucleophiles.[31]

The reaction of 0.5 mmol of the benzothiazole-2-thiolate anion with 0.6 mmol of iodobenzene in DMSO was made at low and high temperatures (60, 90, 120 °C), short times (5−60 min), and different microwave radiation modes, but the outcome was nucleophile decomposition in all conditions assessed, which did not allow achievement of the desired product (Table 2, entries 1 and 2).

Table 2. Optimization of 2[a] under Microwave Irradiation



entry	conditions (time, min)[c]	product yields[b] (substrate recovered)
1	DMSO, 60 °C (5−60)[d]	decomposition
2	DMSO, 60−120 °C (5−60)	decomposition
3	DMF, 120 °C (20)[e,f]	**2**, − (97)
4	DMF, 120 °C (20)[g]	**2**, 5 (94)
5	DMF, 120 °C (20)[h]	**2**, 30 (65)
6	DMF, 120 °C (20)[i,j]	**2**, 70 (24)
7	H_2O/polyethylenglycol, 150 °C	**2**, − (95)
8	H_2O, 90 °C (20)[d,e,g,h,i,k]	**2**, − (96)
9	H_2O, 120 °C (20)[a,k]	**2**, 78 (20)
10	H_2O, 120 °C (10)[a,k]	**2**, 78 (20)
11	H_2O, 120 °C (7)[a,k]	**2**, 75 (16)

[a]Base and **1** concentrations were 25 × 10^{-2} M. [b]Yields of isolated products. [c]Dynamic mode and 150 W power was applied. [d]Pulsed mode. [e]With K_2CO_3 as base. [f]With *t*-BuOK as base. [g]With 1 equiv of KOH as base. [h]With 2 equiv of KOH. [i]With 3 equiv of KOH. [j]200 W power was applied. [k]With tetra-*n*-butylammonium bromide (TBABr).

Reaction of 2-mercaptobenzothiazole with iodobenzene in DMF at 120 °C using both K_2CO_3 and *t*-BuOK as base did not occur (Table 2, entry 3). Nevertheless, using KOH as base, the coupling reaction was observed (Table 2, entry 4). Moreover, reaction yields were increased using excess of KOH, proving 30 and 70% yields of (**2**) (Table 2, entries 5 and 6). Thus, this reaction was also carried out using a power of 200 W, and similar results were observed. Under N_2, no changes were observed.

To find an environmental friendly procedure, the reaction was performed in *t*-butanol, isopropyl alcohol, polyethylene glycol, or acetonitrile, which did not allow achieving the desired product. The reaction was also carried out using a solvent mixture which did not allow achievement of the desired product (Table 2, entry 7).

When the reaction was made using water as solvent at 90 °C with different bases and other conditions, no product was detected (Table 2, entry 8), while at 120 °C, the coupling reaction product was observed (Table 2, entries 9−11). Reactions were efficient using solvents with loss factor between 0.1 and 0.2. The best product yields were obtained using water as solvent at 120 °C under microwave irradiation for 7 min. So, subsequent reactions were performed using this last condition.

Thus, the reaction of **1** with *p*-bromoiodobenzene, *p*-diiodobenzene, *o*-chloroiodobenzene, *m*-chloroiodobenzene, and *p*-fluoriodobenzene, rendered 88% (**4**), 72% (**5**), 70% (**6**), 81% (**7**), and 18% (**8**) yields, respectively (Table 1, entries 3−7). Similar to photoestimulation, *p*-dibromobenzene, *p*-chlorobromobenzene, and *m*-clorobromobenzene did not react with **1** under these reaction conditions (Table 1, entries 8−10).

No disubstitution product was obtained from 2 mmol of benzothiazole-2-thiolate anion and 1 mmol of *p*-diiodobenzene using microwave irradiation because the nucleophile got decomposed (Table 1, entry 2). It is very important to notice that this reaction was efficient under photostimulation.

The use of microwave decreased reaction times considerably in comparison to photostimulation. The synthetic procedure reported here is simple and reproducible, and the products are obtained in high yields using water as solvent. It is worthy of mention that this novel process shows environmental and economic advantages over previously reported protocols.

Bioassays of Fungicidal Activity against *Botrytis cinerea*. *B. cinerea* is responsible for the gray mold disease on more than 200 host plants. This necrotrophic ascomycete displays the capacity to kill host cells through the production of toxins, reactive oxygen species, and the induction of a plant-produced oxidative burst.[32] It is well-known that Triadimefon inhibits *B. cinerea*'s growth as well. Triadimefon is widely used to control other fungal diseases. For this reason, it was used as assay control.[33]

Toxicity Test of Solvents on B. cinerea. Solvents used to dissolve tested compounds needed to be nontoxic against *B. cinerea*. Results showed that a solution of ethanol 1.2% final in potato glucose agar (PGA) culture media did not exhibit significant suppression on fungus growth (Figure 3, control with ethanol).

B. cinerea Growth Inhibition Assay. In vitro fungal growth inhibition assay modified from Huang et al. was performed.[33] Fungal growth in the presence of compounds **2**−**8** was evaluated at four concentrations (12.5, 25, 50, and 100 μg mL^{-1}) in PGA.[33] Results in Figure 3 show that all compounds assayed exhibited strong antifungal activity against *B. cinerea* at four concentrations.

Each treatment was performed in triplicate, and the effective concentration 50 (IC_{50}), defined as the concentration required to inhibit 50% of the fungal growth, was used to describe the inhibitory activity of the compounds. IC_{50} of the target compounds along with the standard drug for comparison are summarized in Table 1.

By analyzing the graphs at 12.5 μg mL^{-1}, it can be seen that compounds **2**, **3**, **4**, **6**, and **7** inhibit fungal growth better than Triadimefon. Apparently, the presence of a halogen, either Br, I, or F, in the aromatic ring does not cause large effects in terms of activity against *B. cinerea*. This can be seen if compounds **4**, **5**, and **8** are compared at 25 μg mL^{-1}.

Compounds **2**, **6**, and **7** are those that caused greater inhibition in fungus growth at different concentrations than Triadimefon (IC_{50} values: 0.75, 0.69, 0.65 vs 1.05 μg mL^{-1}). Furthermore, it is easy to see that compounds **6** and **7** showed three times more inhibition than Triadimefon at 25 μg mL^{-1}, presenting the highest antifungal activity.

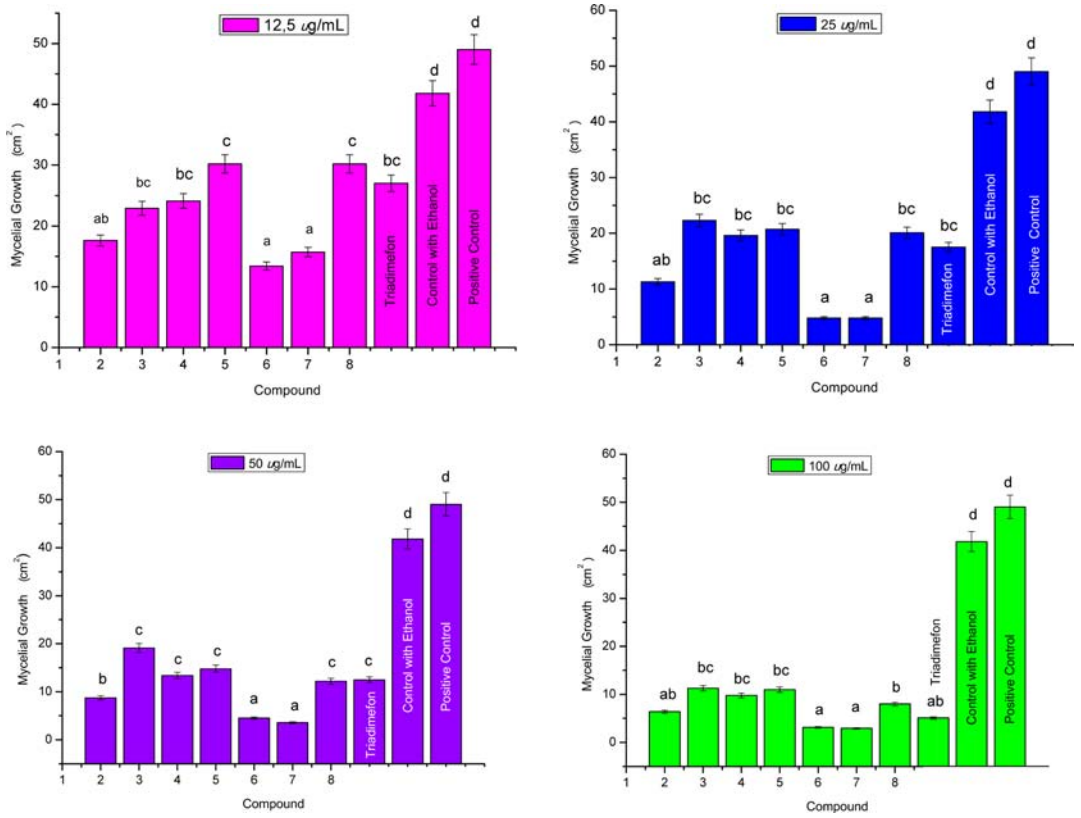

Figure 3. *Botrytis cinerea* growth inhibition assay of aryl-2-thiobenzothiazoles family at different concentrations. Radial growth areas were calculated using the formula for the area of a circle ($A = \pi r^2$) (cm^2). Different letters indicate significant differences ($p \leq 0.05$).

In conclusion, two alternative routes for the arylation of 2-mercaptobenzothiazole have been evaluated. The first pathway involved a photostimulated nucleophilic substitution, while the second consisted in a microwave assisted reaction. Both methodologies were shown to be complementary. Reactivity of the family of dihalobenzene explained by their reduction potentials was reported.

The synthetic procedures reported here are one-pot, reliable, simple, and highly reproducible processes. These are also energy efficient as they involves very short reaction times and in high reaction yields. The methodology using water and microwave irradiation is economical and eco-friendly. Moreover, thermal initiated $S_{RN}1$ reactions of dihalobenzene using controlled microwave heating to promote the reaction were reported.

All compounds assayed have an excellent growth inhibition for *B. cinerea* in the conditions employed. Furthermore, compounds **2**, **6**, and **7** inhibit fungal growth better than Triadimefon. Thus, these compounds could be used as alternative to Triadimefon for fungi control in plants. Further toxicity, persistence, and structure−activity relationship studies for those compounds are underway.

DOI: 10.1021/acs.jafc.5b00150
J. Agric. Food Chem. 2015, 63, 3681−3686

In our pilot study, we first find that AIO can exert neuroprotection by blocking oligomer Aβ42- or NMDA-induced neurotoxicity and OA-induced tau protein hyperphosphorylation through inhibiting the expression of kinase p-ERK1/2. Meanwhile, it may reflect the potential activation of the Aβ-decomposing system, and this is also beneficial to synaptic plasticity. Consequently, AIO, which is abundant in mulberry and other fruits, is a suitable and promising candidate for the development of general food type neuroprotection on AD.

MATERIALS AND METHODS

Plant Material and Reagents. Dried mulberries (*Morus alba* L.) were purchased from Wuhan Qiangkang Pharmaceutical Co. Ltd. (Wuhan, China).

We also used the following in our procedures: poly-D-Lysine (Sigma), *N*-methyl-D- aspartate (Sigma), Neurobasal (Gibco), B27 (Invitrogen), Aβ42 peptide (American peptide), rabbit polyclonal anti-p-tau(Ser396) (1:500; Invitrogen), p-CDK5(1:500; Santa Cruz), P-GSK3α/β(1:500; Santa Cruz) rabbit polyclonal anti-p-tau(Ser235) (1:500; Santa Cruz), mouse monoclonal anti-AT270 (1:500; Santa Cruz), mouse monoclonal anti-tau5 (1:500; Millipore Biotechnology), rabbit polyclonal anti-ERK, JNK, p-ERK1/2, p-JNK1/2 (1:500; Cell Signaling), 6E10(1:1000; Signet), MTT(Sigma-Aldrich Chemical Co). Amaxa Rat Neuron Nucleofector Kit (Lonza), CellTiter-Glo Luminescent Cell Viability Assay (Promega), Microplate reader (IMark, Bio-Rad), AmaxaNucleofector (Lonza), GloMax Luminometer (Promega), ChemiDoc XRS ECL system (Bio-Rad).

Extraction and Purification of AIO from Mulberry. Dried mulberries (15.0 kg) were extracted three times using 5× volumes of 70% ethanol for 2 h at reflux. The filtrate was concentrated to dryness under vacuum at 50 °C to afford 70% ethanol extract. The 70% ethanol extract was suspended in 10 L of distilled water and successively partitioned three times with the same volume of hexane, $CHCl_3$, EtOAc, and *n*-butanol, which yielded hexane (123.0 g), $CHCl_3$ (148.0 g), EtOAc (78.0 g), *n*-BuOH (246.0 g) and water-soluble extracts, respectively, after organic solvent was removed under vacuum at 50 °C.

The chloroform-soluble fraction (148.0 g) was further purified by silica gel chromatography and eluted with a $CHCl_3$/MeOH gradient elution (the ratios of $CHCl_3$/MeOH were from 100:0 to 0:100). The $CHCl_3$/MeOH (20:1) elution (4.1 g) was subjected to a silica gel column, followed by a Sephadex LH-20 column and a semipreparative HPLC column (Cosmosil 5C18-MS- II, 10 ID × 250 mm), resulting in a yield of 27.0 mg for AIO.

Primary Culture of Rat Hippocampus Neurons. Primary hippocampus neurons were prepared from Sprague-Dawley rats at 18 embryonic days according to a previously established method with few modifications.[17] Briefly, hippocampus from fetal rat brains (free of meninges, olfactory bulbs, and striata) were pooled, chopped in Ca^{2+}- and Mg^{2+}-free HBSS, and incubated with 0.025% trypsin for 10 min at 37 °C. The enzymatic digestion was terminated by mixing the suspension with an equal volume of DMEM supplemented with 10% FBS. The cells were passed through 70 μm cell strainers (BD Falcon, Bedford, MA) and collected by brief centrifugation. The hippocampus neuron cells are resuspended in neurobasal medium with 2% B27, 0.5 mM glutamine, 25 μM glutamate, 50 units/mL penicillin, and 50 μg/mL streptomycin or transfected by GFP plasmid DNA using electroperation method. The dissociated cells were plated on 96 well plates or 6 well plates (precoated with 10 μg/mL poly-D-lysine) in seeding medium consisting of neurobasal medium supplemented with 2% B27. The cultures were maintained at 37 °C in a humidified incubator with 5% CO_2. One day following plating, the seeding medium was removed and replaced with maintenance medium (seeding medium without glutamate) and refreshed twice a week. Neurons are the principal surviving cell type under these serum-free culture conditions.

Oligomer Aβ_{42} Preparation. Briefly, Aβ_{42} peptide was dissolved in cold hexafluoro-2-propanol (HFIP) to a final concentration of 1 mM. The peptide was aliquoted and dried under vacuum. The aliquoted peptides were stored at −80 °C until use. For use in cell experiments, the peptide was dissolved in DMSO to a final concentration of 5 mM and then diluted to 100 μM in Ham's/F12 media.

Cell Viability Assay. Neuron cells(DIV14) in culture medium were pretreated by 10 μM AIO for 1 h before incubated by 10 μM oligomer Aβ_{42} for another 24 h or pretreated by 100 μM NMDA for 24 h then the AIO was used. After 24 h of treatment, 0.5 mg/mL MTT was subsequently added to each well. After 4 h of additional incubation, 100 μL of DMSO was added to dissolve the crystals. The absorption values at 570 nm were determined with a microplate reader. Experiments were performed in triplicate for each sample.

ATP Assay. ATP luminescence were detected followed the manufactured information with modification to evaluate the cells viability after Aβ_{42} or NMDA treatment. Neuron cells in culture medium were pretreated by 10 μM AIO for 1 h before treatment with 10 μM oligomer Aβ_{42} for another 24 h, or cells were pretreated by 100 μM NMDA for 24 h, and then the AIO was used. The plates and its contents were equilibrated at room temperature for approximately 30 min after 24 h of treatment. Cell titer reagent (100 μL) was added to each well in a 96-well plate, and the plate was shaken gently for 2 min to induce cell lysis. The plate was allowed to incubate at room temperature for 10 min to stabilize the luminescent signal, and then the luminescence was recorded.

OA and AIO Treatment. To investigate the effects of OA-induced neurotoxicity, the cultured neurons (DIV14) were preincubated with different concentrations of AIO (0, 0.1, 0.3, 1, 3, 10 μM) for 1 h, and then the neurons were treated with10 nM of OA for 24 h at 37 °C.

Western Blot Analysis. Neuron cells treated by AIO and OA or treated by AIO and oligomer Aβ42 were washed in cold PBS and then were lysed in a RIPA buffer that contained a mixture of protease inhibitors. Fifteen micrograms of total protein from each sample were run on a 12% SDS-PAGE gel and transferred to a nitrocellulose membrane. The membranes were incubated with appropriately diluted primary antibodies, followed by horseradish peroxidase-conjugated secondary antibodies against the corresponding species. Labeling was detected using the ECL system (Amersham Biosciences). Reported values are representative of three independent experiments.

Electroperation Transfection. The hippocampus neuron cells were counted, and the required number of cells was centrifuged (4×10^6 cells per sample) at 800 rpm for 5 min at room temperature. The supernatant was removed completely, and the cell pellet was resuspended carefully in 100 μL of room-temperature nucleofector solution per sample with 4 μg GFP plasmid DNA. The cell/DNA suspension was transferred into a certified cuvette (sample must cover the bottom of the cuvette without air bubbles). The cuvette with cell/DNA suspension was inserted into the Nucleofector Cuvette Holder, and the appropriate Nucleofector program was selected to finish the transfection.

Immunofluorescence and Confocal Microscopy. The transfected cells pretreated by 10 μM AIO 1 h before 10 μM oligomer Aβ42 treatment were washed with Dulbecco's phosphate buffered saline (DPBS, pH 7.4), fixed with 4% paraformaldehyde in 0.1 M phosphate buffer (pH 7.4) for 10 min, and then imaged with a confocal laser-scanning microscope (LSM510, Zeiss) using the 63× oil-immersion objective. The selected areas are zoomed according to requirement. Spine density was expressed as the number of spines per 10 μm of dendritic length.

Statistical Analysis. Data are expressed as the mean ± SD. Analyses were performed using Prism 5 software with a two-way ANOVA to identify significant effects. Differences were considered significant at $p < 0.05$, $n = 3$.

RESULTS

Structure Identification of AIO. AIO was obtained as a white powder. The ESI-MS showed the $[M - H]^-$ ion at m/z

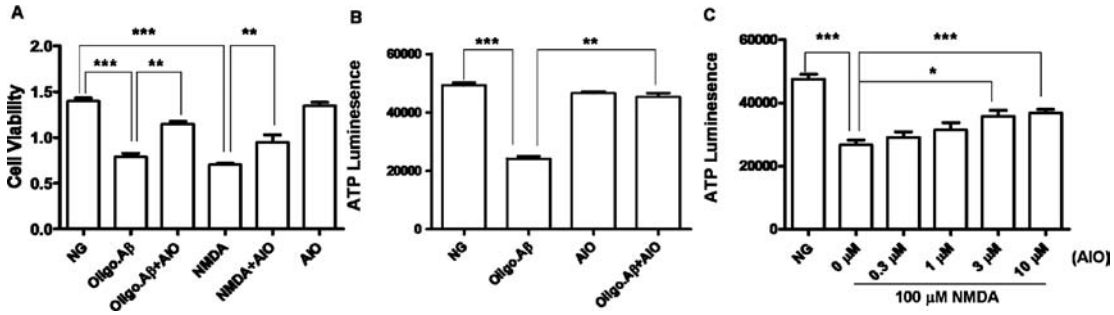

Figure 2. Neuroprotection of AIO on cultured neuron cells treated by oligomer Aβ42 or NMDA. (A) Neuron cells (DIV14) were pretreated with or without 10 μM AIO for 1 h before 10 μM oligomer Aβ42 treatment; or neurons were pretreated by 100 μM NMDA before treatment with or without 10 μM AIO; or neurons were treated by only AIO, then the cells were cultured for another 24 h to detect cell viability using MTT method. (B) Neuron cells (DIV14) were pretreated by 10 μM AIO for 1 h before 10 μM oligomer Aβ42 treatment, then the cells were cultured for another 24 h to detect the ATP level. (C) Neuron cells (DIV14) were pretreated by 100 μM NMDA for 1 h before different does of AIO treatment, and then the cells were cultured for another 24 h to detect the ATP level. * $P < 0.05$, **$P < 0.01$, ***$p < 0.001$, $n = 3$.

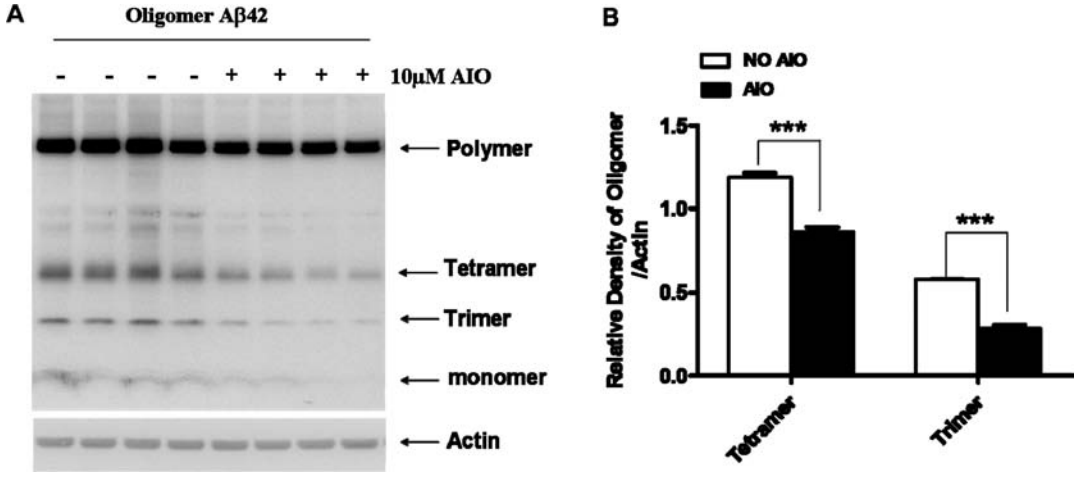

Figure 3. Effect of AIO on Aβ-decomposition system in cultured neurons. After pretreatment without or with 10 μM AIO for 1 h, rat hippocampus neurons (DIV 14) were treated by 10 μM oligomer Aβ42 for 24 h. After being washed with cold PBS, Aβ oligomers in the whole cell lysates were detected by Western blot analysis (12% sodium dodecyl sulfate polyacrylamine gel; a mouse anti-Aβ monoclonal antibody 6E10) and actin was used as a loading control in the same membrane. ***$p < 0.001$, $n = 4$.

323, and its molecular formula was drawn as $C_{20}H_{20}O_4$ from its ^{1}H and ^{13}C NMR. In the ^{1}H NMR (400 MHz, acetone-d_6), an ABX spin-coupling system was ascribed to the three protons of the benzene ring, with signals at 7.43 (H, d, J = 8.4 Hz), 6.99 (H, d, J = 2.4 Hz), and 6.81 ppm (H, dd, J = 8.4, 2.4 Hz), respectively. The proton signals at 5.13 (H, tq, J = 6.5, 1.4 Hz), 3.47 (2H, d, J = 6.4 Hz), 1.67 (3H, s), and 1.64 ppm (3H, d, J = 1.2 Hz) were ascribed to a prenyl group in the molecule. The signal at 3.83 ppm (3H, s) was ascribed to a methoxy group. In the ^{13}C NMR, there were 20 carbons, including a benzofuran, a prenyl, and a benzene ring. Compared to the reported data,[18] it was identified as artoindonesianin O (AIO), the chemical structure of which was given in Figure 1.

AIO Can Exert Neuroprotection after Oligomer Aβ42 or before NMDA Treatment on Hippocampus Neuron Cells. Previous study has demonstrated that oligomer Aβ42 is toxic to a neuron and that NMDA can induce excitotoxicity. In this study, we first investigated the cell viability using the MTT method. The result clearly showed that AIO can significantly enhance the cell viability after oligomer Aβ42 or before NMDA treatment; however, AIO alone has no impact on cell viability even at the concentration of 10 μM (Figure 2A). At the same time, we also detected the ATP level of neurons. We found that the ATP level of neuron was remarkably reduced after 10 μM oligomer Aβ42 treatment compared with negative control. To our surprise, the ATP level of neuron in AIO pretreatment group was enhanced compared with the 10 μM oligomer Aβ42 treatment group (Figure 2B). Excitotoxicity is a key mechanism of cell death following acute neuronal injury that involves deregulation of intracellular calcium. To model excitotoxicity, we used the agonist NMDA to activate NMDA receptors in primary neuron cells.[19] The cells at DIV 14 were pretreated with 100 μM NMDA for 1 h, except for the control group, followed by returning to conditioned media without or with different concentrations of AIO. The ATP level was detected after 24 h treatment. The result clearly showed that NMDA can reduce the cell ATP level, but in the 3 μM and 10 μM AIO groups, there is a remarkable reverse in the reduction (Figure 2C).

AIO May Reflect the Potential Activation of Aβ-Decomposing System. Because AIO could protect the neurons treated by oligomer Aβ42, we wanted to know whether AIO could partly activate the intracellular Aβ-decomposing system to exert its neouroprotection. Interestingly, AIO could significantly decrease cellular Aβ42 tetramer and trimer compared with no AIO treatment group (Figure 3A,B).

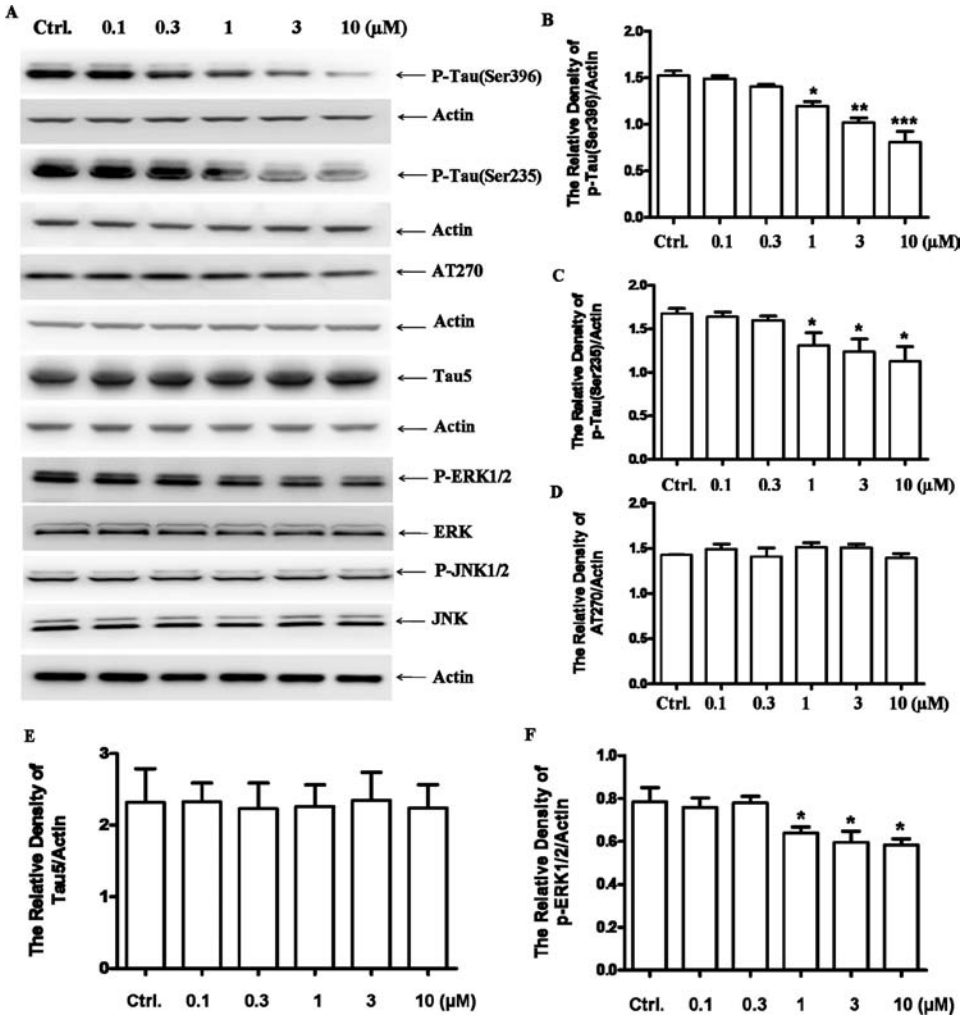

Figure 4. Expressions of okadamic acid (OA)-induced hyperphosphorylated tau-related proteins on neuron cells treated by AIO. Rat hippocampus neurons (DIV 14) were pretreated by various concentrations of AIO (0−10 μM) for 1 h, and then the cells were continuously treated by 25 nM OA for 24 h. Western blot analysis was used to detect the expressions of hyperphosphorylated tau, total tau, and its kinase (panel A). The optical density of the each band was as 1 arbitrary densitometry unit, normalized to actin for the same membrane (panels B−F). * $P < 0.05$, ** $P < 0.01$, *** $p < 0.001$ vs Control.

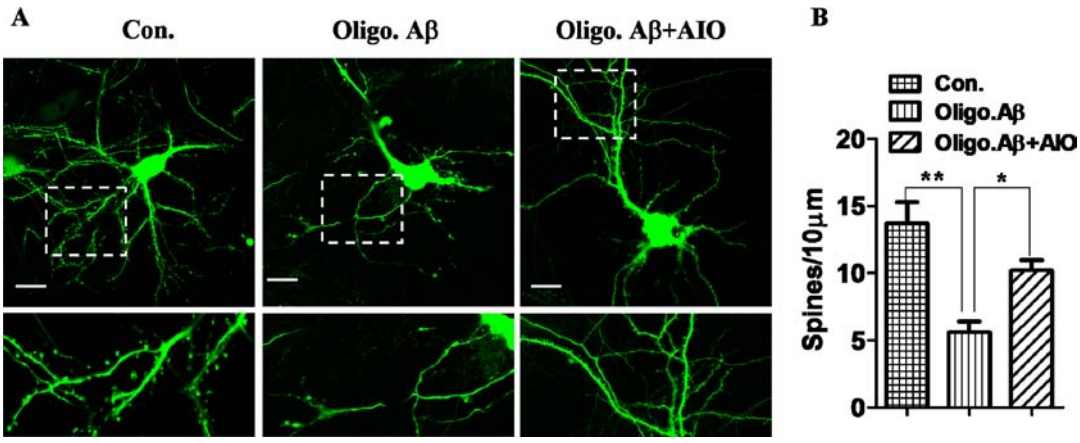

Figure 5. Morphological change on cultured neuron cells transfected by GFP after oligomer Aβ42 and AIO treatment. Neuron cells were transfected by GFP plasmid DNA on the cultured day, and then images of the cells were taken using a confocal microscope (63×) after 21 days of culture (panel A), in which cells were pretreated by 10 μM AIO for 1 h before 10 μM oligomer Aβ42 treatment. Graphical result of dendritic spines on cultured neuron cells (panel B). * $P < 0.05$, ** $P < 0.01$ vs control. Scale bar represents 10 μM.

AIO Attenuates OA-Induced Tau Hyperphosphorylation and Protects the Neuron from Neurotoxicity. On the basis of the above result, we wondered whether or not AIO could impact the tau hyperphosphorylation on cultured neuron

DOI: 10.1021/acs.jafc.5b00396
J. Agric. Food Chem. 2015, 63, 3687−3693

cells. OA was used to induce tau hyperphosphorylation.[20,21] Interestingly, we found that AIO could significantly reduce the expressions of tau hyperphosphorylation at Ser396 and Ser235 from dosage 1 to 10 μM. But it was almost no action about AT270 at Thr181 site (Figure 4A–D).

AIO Has No Obvious Effect on Total Tau (Tau5) Level. Because of the reduction of tau hyperphosphorylation at Ser396 and Ser235, we further investigated the expression of total tau using the same samples. As we expected, total tau did not change (Figure 4A). The quantity result of total tau was shown in Figure 4E.

AIO Inhibits the Expression of Hyper-Phosphorylated Tau Kinase on Neuron Cells. Tau hyperphosphorylation is mediated by several kinases, many of which show large overlap in their ability to phosphorylate tau at the same epitopes in AD.[22] It has been reported that the inhibition of PP2A by OA induced a dramatic increase in the phosphorylation/activation of ERK1/2, and thus, OA could promote the activity of ERK1/2 to phosphorylate the tau in vitro at many abnormal hyperphosphorylatation sites and cause neurotoxicity.[23] Our result showed that the expression of p-ERK1/2 was reduced after AIO treatment in a dose over 1 μM. At the same time, the total ERK did not change. Another kinase, p-JNK1/2, did not change (Figure 4A, 4F). Other related kinases, including p-CDK5 and p-GSK3α/β, remained unchanged (data not shown).

AIO Elevates the Number of Dendritic Spines on Neurons Treated with Oligomer Aβ42. Dendritic spines are related with synaptic plasticity and memory loss in AD. On the basis of the above result, we were curious to know that whether AIO can exert its neuroprotection to improve the synaptic plasticity. Our methods helped to find a compelling result. The numbers of dendritic spines were significantly reduced in the oligomer Aβ42-treated group compared with the control group. Moreover, in the combined AIO oligomer and Aβ42 treatment, the dendritic spines numbers were remarkably increased as expected (Figure 5A,B).

DISCUSSION

The past decade has witnessed an intense interest in herbal medicines, in which phytochemical constituents can have long-term health-promoting or medicinal qualities. Phytochemicals present in vegetables and fruits are believed to reduce the risk of several major diseases, including cardiovascular diseases, cancers, as well as Alzheimer's disease. Identification and characterization of new medicinal plants to cure neurodegenerative diseases has been a major and increasing scientific interest in recent years. In this pilot study, we first evaluated the neuroprotective activity of AIO extracted from mulberry in rat primary hippocampus neurons.

As we know, the formation of amyloid plaques is one of the major pathologies of AD. Aβ is produced by endoproteolysis of the parental amyloid precursor protein (APP), which is achieved by the sequential cleavage of APP by groups of enzymes or enzyme complexes termed β- and γ-secretases. Recent studies suggest that the buildup of oligomer Aβ may be an early event in the pathogenesis of AD.[24] Also it is the trigger to kill the cells in the AD brain. In this study, the ATP level and MTT method were used to evaluate the cells viability after oligomer Aβ42 treatment. Interestingly, we found that AIO could exert neuroprotection against oligomer Aβ42-induced neurotoxicity partly through the activation of the Aβ decomposition system, resulting in the reduction of cellular oligomerization. Excitotoxicity is a distinct mode of neuronal death that is attributed to increased presynaptic glutamate release. Disturbance of extracellular glutamate levels acting on NMDA receptors (NMDAR) results in enhanced calcium influx and death of the cells. Overactivation of NMDAR is a major cause of cell death following acute neuronal injury and is also implicated in neurodegenerative diseases, such as Parkinson, Huntington, and Alzheimer's disease.[17] As we expected, AIO can reverse the neuronal cell death induced by NMDA. All of those data clearly show for the first time that AIO has neuroprotection on hippocampus neuron cells.

Tau-based strategies have received little attention until recently despite that the presence of extensive tau pathology is central to Alzheimer's disease. The discovery of mutations within the tau gene that causes front-temporal dementia demonstrated that tau dysfunction, in the absence of amyloid pathology, was sufficient to cause neuronal loss and clinical dementia. Abnormal levels and hyperphosphorylation of tau protein have been reported to be the underlying cause of a group of neurodegenerative disorders collectively known as "tauopathies". The detrimental consequence is the loss of affinity between this protein and the microtubules, increased production of fibrillary aggregates, and the accumulation of insoluble intracellular neurofibrillary tangles in AD.[25] OA can induce microtubule-associated protein tau hyperphosphorylation leading to the pathological process of analogical AD.[23,26] OA selectively inhibits the serine/threonine phosphatases 2A thereby induces hyperphosphorylation of tau. Hyperphosphoryltion of tau is triggered by multiple mechanisms involving MAP kinases via ERK1/2, Jun N-terminal kinase and other cellular stress and so on. The consequence of tau hyperphosphorylation is neurotoxicity. Thus, the inhibitory effect on tau hyperphosphorylation may reduce the damage of axonal transport and thereby benefit cognitive function. In this study, we wonder whether AIO can impact the tau hyperphosphorylation induced by OA on neurons. Interestingly, we find that AIO significantly reduces the expression of hyperphosphorylation of tau at Ser396 and Ser235, which had been reported to have higher disease incidences in AD brain, but it remains unchanged at about AT270 at the Thr 181 site. Is the reduction of tau hyperphosphorylation at Ser396 and Ser235 followed by the reduction of total tau (tau5)? With this question, the level of total tau is evaluated using the same sample. As we expected, the total tau was not remarkably changed in this process. These studies provide evidence that targeting p-tau may represent an effective treatment strategy.

It is well-known that phosphorylation of tau at certain sites was involved in AD pathogenesis. Some kinases, including cyclin-dependent kinase 5, GSK3α/β, casein kinase 1, protein kinase A, and MAPKs, have been implicated in tau phosphorylation.[27] In this study, we want to know whether the decrease in hyperphosphorylated tau was due in part to an inhibition of tau kinases. The results showed that p-ERK1/2 was involved in the reduction of hyperphosphorylated tau after AIO treatment despite no change in the level of total ERK, but p-JNK1/2, p-CDK5, and p-GSK3α/β keep the basal level. AIO may possibly compete with OA to recover the activity of PP2A and reduce the ERK phosphorylation, but a detailed mechanism still needs to be clarified.

It is known that both Aβ and phosphorylation tau are correlated with synaptic and cognitive deficits.[28] Aβ toxicity is mediated not only by the fibrillar form of the protein but also by the soluble oligomers. The dendritic spines have been

DOI: 10.1021/acs.jafc.5b00396
J. Agric. Food Chem. 2015, 63, 3687–3693

assigned critical roles in the form of synaptic plasticity and memory. Dendritic spine defects are found in a number of cognitive disorders, including AD. Therefore, we hypothesized that the AIO is critical to synaptic function. In this study, we examined the relationship between AIO and synaptic defects induced by oligomer Aβ42. The result surprised us. In comparison, AIO treatment enhances the density of dendritic spines on neurons induced by oligomer Aβ42. Therefore, AIO may be possibly involved in the synaptic plasticity and may prevent memory loss.

Taken together, our results strongly suggest that AIO, a dietary phenolic compound from mulberry, is a potential nutritional candidate for protection against neurodegeneration through the reduction of tau hyperphosphorylation and improvements in the synaptic plasticity. More studies are still needed to elucidate the initial mechanisms that trigger the neuroprotection in order to design appropriate therapeutic interventions to block the progression of AD.

suppression, and inhibition of α-glucosidase and tyrosinase.[18,21−29] Furthermore, it has been reported that regular consumption of coffee is associated with a lower risk of type 2 diabetes mellitus,[30] and 5-CQA in coffee may contribute to the beneficial effects of coffee on type 2 diabetes mellitus.[31] However, the inhibitory effects of CQA derivatives from kudingcha on α-glucosidase have never been reported before. As tea polyphenolic compounds strongly interact with proteins,[32] CQA derivatives from kudingcha may exhibit potential interactions with α-glucosidase. This should inevitably result in the change of enzyme molecular configuration and lead to the loss of catalytic activity, thereby reducing carbohydrate digestibility and protection against diabetes and obesity. Recently, we have reported the potent antioxidant activity of kudingcha polyphenols and isolated CQA derivatives from the leaves of *I. kudingcha* C.J. Tseng.[22,33−35] In this study, therefore, the inhibitory effects against α-glucosidase of six kinds of CQA derivatives (3-CQA, 4-CQA, 5-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA) present in kudingcha made from the leaves of *I. kudingcha* C.J. Tseng were investigated. Furthermore, the potential mechanisms of interactions between α-glucosidase and CQA derivatives were characterized by fluorescence spectroscopy and circular dichroism (CD) spectroscopy.

MATERIALS AND METHODS

Materials and Reagents. Kudingcha made from the leaves of *I. kudingcha* C.J. Tseng was obtained from Hainan Yexian Bio-Science Technology Co., Ltd. (Hainan, China), and the sample was ground by using a domestic blender, stored in sealed polyethylene bags, and kept in a refrigerator at −20 °C until use. α-Glucosidase from *Saccharomyces cerevisiae* (dialysis 48 h before use), 5-CQA, and 4-nitrophenyl α-D-glucopyranoside (≥99%) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Standards of 3-CQA, 4-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA (>95%) were prepared from kudingcha according to our reported methods.[22,34,35] The solvents used for chromatographic purpose were of high-performance liquid chromatography (HPLC) grade, and all other reagents were of analytical reagent grade.

Determination of Total Polyphenols Content and CQA Derivatives. The total polyphenols content was determined by using the Folin−Ciocalteu method according to the reported procedure.[22] The contents of CQA derivatives were measured by HPLC with an Agilent HPLC series 1100 (Agilent, Santa Clara, CA, USA) equipped with a model G1379A degasser, a model G1311A quatpump, a model G1316A column oven, a model G1315B diode array detector (DAD), and Chemstation software. The separation was completed on a TSK gel ODS-80TsQA column (4.6 × 250 mm, 5 μm, Tosoh Corp., Tokyo, Japan) with a gradient mobile phase consisting of ultrapure water (A), methanol (B), and 1.0% formic acid (C, v/v) at a flow rate of 0.5 mL/min. Elution was performed with a linear gradient as follows: 0−45 min, A from 60 to 35%, B from 20 to 45%, C 20%. The temperature of column oven was set at 40 °C, the injection volume was 20 μL, and CQA derivatives were detected at 326 nm with a DAD. The chromatographic peaks were identified by comparing the retention times and UV spectra of standards of CQA derivatives.

Preparation of CQA Derivatives. The preparation of CQA derivatives was performed according to the reported methods[22,33−35] with some modifications. Briefly, the kudingcha powder was extracted with water (10 for the ratio of extraction solvent to material, v/w) for 30 min at 95 °C. After extraction, the extract was centrifuged at 5000*g* for 10 min, and the resulting insoluble residue was treated twice as described above. The combined supernatants were concentrated by a rotary evaporator (Tokyo Rikakikai Co., Ltd., Tokyo, Japan) and lyophilized (Labconco, Kansas, MO, USA) to afford the crude extract. The crude extract was dissolved in deionized water and applied to a column (5 × 30 cm) of HP-20 macroporous resin. Then, the column was washed with 3 times bed volume of distilled water and eluted with 70% ethanol solution, respectively. The collected fractions (10 mL/tube) were analyzed by HPLC as described above, and the fractions containing CQA derivatives were combined, concentrated, and freeze-dried, affording kudingcha polyphenols. The CQA derivatives (3-CQA, 4-CQA, 5-CQA; 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA) were further isolated from the kudingcha polyphenols by HPLC with a semipreparative HPLC column of YMC-Pack ODS-A (20 × 250 mm, 5 μm, YMC Co., Ltd., Kyoto, Japan) according to our reported methods.[22,34,35] The desired fractions containing 3-CQA, 4-CQA, 5-CQA; 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA were combined, concentrated, and lyophilized, respectively. The structures of CQA derivatives were confirmed by electrospray ionization−mass spectrometry (ESI-MS), HPLC, and nuclear magnetic resonance (NMR) spectrometry.

Enzyme Inhibitory Activities Assay. The inhibitory activity against α-glucosidase was measured according to the reported method[26] with some modifications. Briefly, the reaction mixture contained 8 μL of test sample with different concentrations, 30 μL of 2.5 mM 4-nitrophenyl α-D-glucopyranoside as substrate, 20 μL of enzyme solution (0.2 U/mL), and 102 μL of 0.1 M phosphate buffer saline (pH 6.9). The reaction mixture was incubated at 37 °C for 15 min. The reaction was then terminated by the addition of 80 μL of 0.2 M Na_2CO_3 solution. The increase in absorbance at 405 nm due to enzymatic hydrolysis of 4-nitrophenyl α-D-glucopyranoside was monitored with a microplate reader (BioTek Instruments, Inc., Winooski, VT, USA). All samples were analyzed in triplicate. The inhibition percentage was calculated using the formula

$$\text{inhibition rate } (\%) = [((A_{c+} - A_{c-}) - (A_s - A_b)) / (A_{c+} - A_{c-})] \times 100$$

where A_{c+}, A_{c-}, A_s, and A_b are defined as the absorbances of 100% enzyme activity (only the solvent with the enzyme), 0% enzyme activity (only the solvent without enzyme), the test sample (with the enzyme), and a blank (only the sample), respectively. The effective concentration that could inhibit 50% of α-glucosidase activity is defined as IC_{50}.

Assay of Inhibitory Pattern of CQA Derivatives on α-Glucosidase Activity. The effects of CQA derivatives on α-glucosidase activity were investigated with increasing concentrations of enzyme substrate (4-nitrophenyl α-D-glucopyranoside, from 3.0 × 10^{-4} to 1.5 × 10^{-3} M) in the presence or absence of CQA derivatives. Then, the inhibition type was determined by Lineweaver−Burk plot analysis according to Michaelis−Menten kinetics.

Fluorescence Measurement. *General Procedure.* A quantitative analysis of the potential interaction between CQA derivative and α-glucosidase was performed by fluorometric titration as follows: 3.0 mL of solution containing appropriate concentration of α-glucosidase was titrated by the addition of different concentration of 5-CQA, 3,4-diCQA, 3,5-diCQA, or 4,5-diCQA solution. All samples were incubated at fixed temperature (293 or 310 K) for 0.5 h. Then, the fluorescence spectra were recorded with an F-7000 fluorescence spectrophotometer (Hitachi High-Technologies Corp., Tokyo, Japan) by using a 1.0 cm quartz cell and at an excitation wavelength of 280 nm, and the emission spectra were recorded from 300 to 450 nm. Spectral resolution for both excitation and emission was 5 nm. The three-dimensional (3D) fluorescence spectra of enzyme in the absence and presence of CQA derivatives were obtained by recording the excitation and the emission spectra in the range of 200−600 nm with an interval of 5 nm, respectively.

Analysis of Fluorescence Quenching Constant and Thermodynamic Parameters. The fluorescence quenching data were analyzed via the modified Stern−Volmer equation:[36]

$$\lg[(F_0 - F)/F] = \lg K_a + n \lg[Q]$$

Here, F_0 and F are the fluorescence intensities of the enzyme in the absence and presence of quencher, [Q] is the quencher concentration, K_a is the binding constant, and n is the number of the binding sites per

DOI: 10.1021/acs.jafc.5b00420
J. Agric. Food Chem. 2015, 63, 3694−3703

enzyme. The values of n and K_a can be calculated by the slope and intercept with the plots of $\lg(F_0 - F)/F$ against $\lg[Q]$.[37]

Considering that the enthalpy change (ΔH) does not vary significantly over the temperature range, it can be considered as a constant. ΔH and entropy change (ΔS) can be calculated using the van't Hoff equation

$$\ln K = -\frac{\Delta H}{RT} + \frac{\Delta S}{R}$$

$$\ln(K_2/K_1) = (1/T_1 - 1/T_2)\Delta H/R$$

$$\Delta G = \Delta H - T\Delta S$$

where R is the gas constant, T is the experimental temperature, K is the binding constant at the corresponding T, and ΔG is the free energy. Then ΔH, ΔS, and ΔG of interaction can be calculated from the equations above.

CD Measurement. The CD spectra of α-glucosidase and its complexes with CQA derivatives were recorded with the use of a Jasco-810 spectrophotometer (JASCO Corp., Tokyo, Japan) at room temperature. The spectra were measured in the far-UV region (190–250 nm) with a path length of 1.0 mm, a scan speed of 50 nm/min, and a response time of 4 s. In addition, three scans were accumulated for each spectrum. All working solutions were prepared with 20 mM phosphate buffer (pH 6.9). The enzyme concentration was set at 0.2 mg/mL (3×10^{-6} M), and the complexes were prepared by mixing the enzyme with CQA derivative (5-CQA or 3,5-diCQA) at molar ratios of 1:0.5, 1:1, and 1:2 (enzyme to CQA derivative). The resulting CD data were analyzed by curve-fitting program software CDPro using CONTIN, SELCON, and CDSSTR methods, as described by Sreerama and Woody,[38] to obtain the secondary structural contents of α-glucosidase.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD) of triplicates. The IC_{50} value was calculated from linear regression analysis. Any significant difference was determined by one-way analysis of variance (ANOVA) followed by t test for multiple comparisons at $P < 0.05$ level (SPSS Statistics 20.0, IBM, Armonk, NY, USA).

RESULTS

Inhibitory Activity of Kudingcha Polyphenols against α-Glucosidase. The effect of kudingcha polyphenols, partially purified polyphenols from the crude extract of *I. kudingcha* C.J. Tseng by chromatography of HP-20 macroporous resin, on α-glucosidase from *S. cerevisiae* was investigated. As shown in Figure 2A, the kudingcha polyphenols exhibited strong inhibitory activity against α-glucosidase. The IC_{50} value was determined to be 0.42 mg/mL. To further explore the inhibition type of kudingcha polyphenols against α-glucosidase, the kinetic reaction of α-glucosidase was investigated with different concentrations of enzyme. As shown in Figure 2B, it was found that the line obtained from the kinetic reaction plot passed through the origin point (0, 0) of the coordinate, indicating that the inhibition type of kudingcha polyphenols on α-glucosidase was reversible inhibition. As for irreversible inhibition, the inhibitor binds with enzyme covalently and forms a stable complex, making the enzyme inactivated. The enzyme will exhibit its activity only when a certain amount of enzyme is added to the reaction system. Therefore, the plot of enzyme concentration versus reaction velocity does not pass through the origin of the coordinate, whereas for reversible inhibition, which is characterized by the existence of equilibrium between enzyme and inhibitor, the plot may pass through the origin.[39,40] It is obvious that kudingcha polyphenols are reversible inhibitors of α-glucosidase.

As shown in Figure 3A, the kudingcha polyphenols contained 3-CQA (3.2 ± 0.15%), 4-CQA (2.1 ± 0.09%), 5-CQA (8.4 ± 0.13%), 3,4-diCQA (11.8 ± 0.25%), 3,5-diCQA (23.2 ± 1.61%), and 4,5-diCQA (25.6 ± 1.52%). Because the kudingcha polyphenols showed potent α-glucosidase inhibitory activity as mentioned above, CQA derivatives, the main polyphenols in *I. kudingcha* C.J. Tseng, were isolated by semipreparative HPLC from kudingcha polyphenols (78.4% for total polyphenol content determined by the Folin–Ciocalteu method). The purified CQA derivatives, with purity >95% (Figure 3B), were confirmed to be 3-CQA, 4-CQA, 5-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA by HPLC, ESI-MS, and ^{1}H NMR through comparison with the reported data.[22,34,35,41−43]

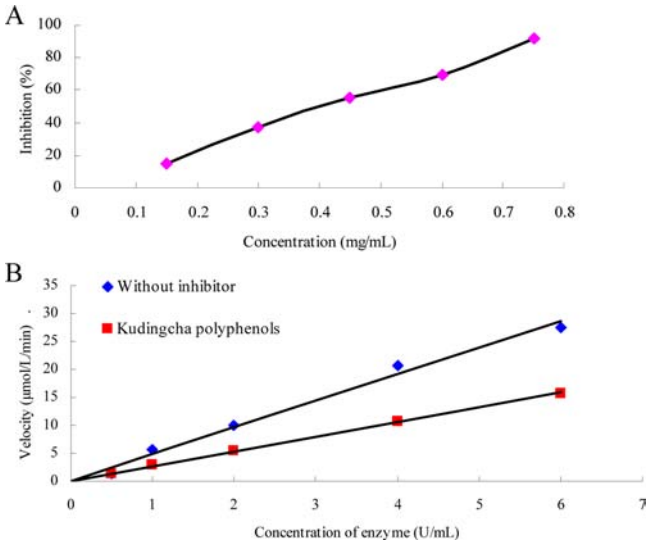

Figure 2. Inhibitory effect (A) and inhibition type (B) of kudingcha polyphenols on α-glucosidase.

Inhibitory Activities of CQA Derivatives against α-Glucosidase. The resulting CQA derivatives from *I. kudingcha* C.J. Tseng were further examined for their inhibition on α-glucosidase by evaluating their IC_{50} values. The results revealed that all of the CQA derivatives had inhibitory activity against α-glucosidase in a dose-dependent manner (Figure 4A). At a concentration of 1.0 mg/mL, α-glucosidase was almost inhibited (98%) by CQA derivatives. The IC_{50} values for 3-CQA, 4-CQA, 5-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA were determined to be 0.39, 0.34, 0.30, 0.27, 0.27, and 0.16 mg/mL, respectively. Notably, diCQA derivatives with double caffeoyl moieties exhibited higher inhibition activities than CQA derivatives with a single caffeoyl moiety, indicating that the addition of caffeoyl moiety significantly increased the inhibitory ability.

To characterize the inhibition pattern of α-glucosidase by CQA derivatives, the enzyme reactions were examined with increasing concentrations of substrate without or with a fixed concentration of inhibitor. As an example, Figure 4B shows the Lineweaver–Burk double-reciprocal plots of α-glucosidase kinetics with 4,5-diCQA as the inhibitor. It is obvious that the V_{max} for α-glucosidase decreased while the K_m (0.68 mM) remained unchanged in the presence of 4,5-diCQA, and the other CQA derivatives showed similar trends. Thus, the inhibition of α-glucosidase by CQA derivatives was non-competitive, in which the inhibitor and the substrate should bind simultaneously with the enzyme.

Fluorescence Spectra. Fluorescence spectroscopy and CD spectroscopy were used to explore the interactions between α-glucosidase and CQA derivatives. As the inhibitory activity of

DOI: 10.1021/acs.jafc.5b00420
J. Agric. Food Chem. 2015, 63, 3694−3703

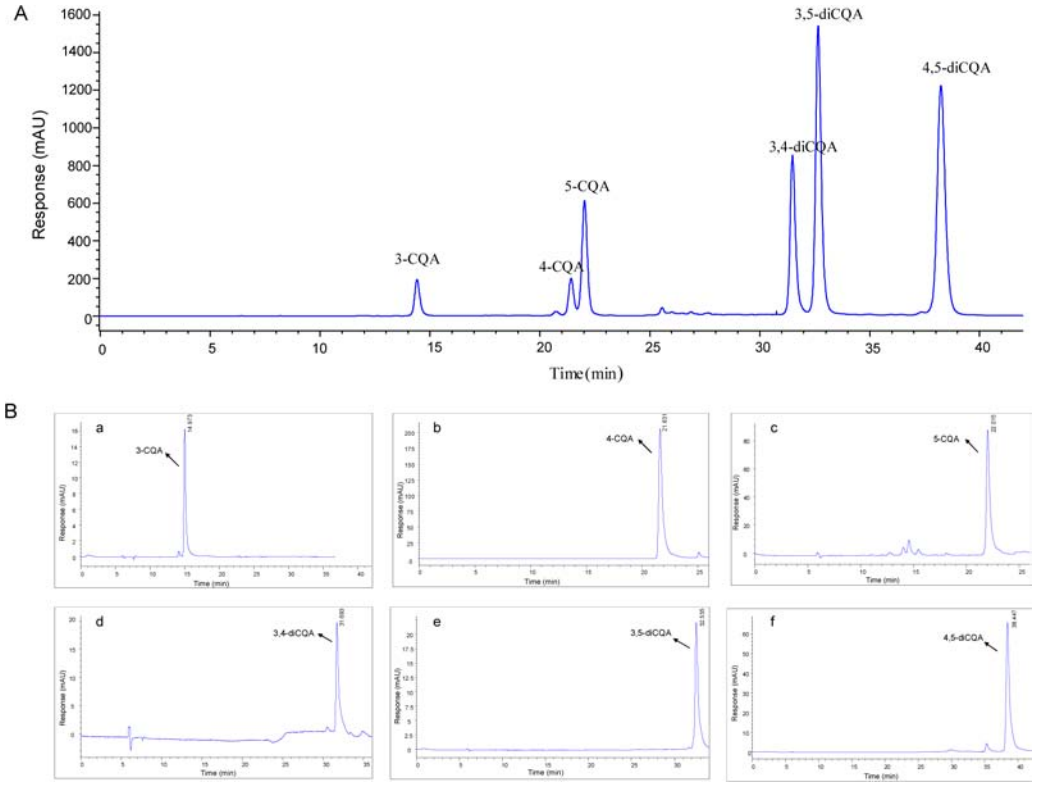

Figure 3. HPLC chromatograms of the extract (A) and six purified caffeoylquinic acids (B) from *Ilex kudingcha* C.J. Tseng.

diCQA derivatives was higher than that of CQA derivatives with a single caffeoyl moiety, 5-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA were used for further studies of interaction mechanisms.

Fluorescence spectroscopy is used to measure the interaction between a biomacromolecule and a small molecule ligand.[44] In a protein molecule, Trp has the most powerful activity to emit fluorescence and the intrinsic fluorescent intensity may change depending on the impact of the interaction between the protein and another molecule.[36] It contains 18 Trp residues in α-glucosidase (obtained from the Brookhaven Protein Data Bank, PDB ID: 1 VAD). Therefore, it is possible to use quenching of the intrinsic Trp fluorescence in enzyme to study the interactions between CQA derivatives and α-glucosidase.

Under our measurement condition (i.e., from 300 to 450 nm), all fluorescence emissions from CQA derivatives, buffer, and other reagents were so weak that their impact could be ignored. As shown in Figure 5, the fluorescence intensities of α-glucosidase decreased gradually with the addition of CQA derivatives at 37 °C, and the maximal absorption peak (near 332 nm) was red-shifted; thus, the CQA derivatives interacted with the enzyme (data at 20 °C not shown). As a result, the maximum emission wavelength was shifted from 332 to 360 nm for the addition of 5-CQA, from 332 to 352 nm for 3,4-diCQA, from 331 to 356 nm for 3,5-diCQA, and from 332 to 356 nm for 4,5-diCQA, respectively. These changes suggested that the interactions between the CQA derivatives and α-glucosidase led to a polarity variation for Trp residues in the enzyme and made the microenvironment change from hydrophilic to hydrophobic, thus resulting in greater exposure of Trp residues and unfolding of protein structure.[45,46]

The 3D fluorescence spectra have been used to investigate the characteristic conformational change of protein in recent years.[47] The 3D fluorescence contour maps of α-glucosidase and the mixtures with four CQA derivatives in different concentrations (0.01 and 0.025 mg/mL) are shown in Figure 6. The 3D spectra showed two distinct peaks in enzyme marked 1 ($\lambda_{ex}/\lambda_{em}$: 280 nm/330 nm) and 2 ($\lambda_{ex}/\lambda_{em}$: 230 nm/330 nm). Peak 1 corresponded to the characteristics of Trp and Tyr residues, and peak 2 provided spectral properties of the polypeptide backbone, which occur mainly due to the presence of the $\pi-\pi^*$ and $n-\pi^*$ transitions, respectively.[48,49] The two peaks were quenched by the addition of CQA derivative in a dose-dependent manner. The corresponding parameters (Table 1) indicated that the fluorescence intensity decreased with the addition of CQA derivatives, following a red shift of 10 nm in each of peaks 1 and 2. It was also found that the quenching effect showed a sequence as diCQA > 5-CQA, which was in accordance with the results of fluorescence experiments. These effects might be due to hydrophobic interactions between the aromatic ring and the hydrophobic moieties present, therefore inducing conformational changes in the α-glucosidase molecule.[14]

Fluorescence Binding Constant and Binding Site. To obtain the binding constant (K_a) and the number of binding site per enzyme (n) between CQA derivative and α-glucosidase, the fluorescence quenching data were analyzed according to the modified Stern–Volmer equation by using the Scatchard plots (Figure 5). The results are summarized as shown in Table 2. The results demonstrated that K_a was in the order diCQA > 5-CQA, indicating that introduction of the second caffeoyl moiety into CQA to form diCQA enhanced the binding affinity to the enzyme. As compared with tea polyphenol–protein interactions with K_a from 1.0×10^4 to 1.0×10^5 M^{-1},[50−52] the K_a values (10^6–10^8 M^{-1}) for interactions of CQA derivatives and α-glucosidase were quite high, indicating comparatively strong ligand–protein interactions.

Thermodynamic Parameters and Binding Mode. The interactions between phenolic compounds and biomolecules may involve electrostatic interactions, van der Waals interactions, hydrophobic forces, hydrogen bonds, and so on. According to ΔH and ΔS data, the model of interaction between quencher and a protein molecule can be concluded.[53] More specifically, if $\Delta H > 0$ and $\Delta S > 0$, the main force would be hydrophobic force; if $\Delta H < 0$ and $\Delta S > 0$, it would be electrostatic force; if $\Delta H < 0$ and $\Delta S < 0$, it would be hydrogen bonding. According to the van't Hoff equation, the thermodynamic parameters were calculated and the results are presented in Table 2. Notably, the ΔH and ΔS values were both positive, indicating that hydrophobic forces played a major role in the bindings between CQA derivative and α-glucosidase. Furthermore, the negative value of ΔG suggested that the binding reaction was spontaneous.

CD Spectra. CD spectroscopy was conducted to evaluate the influence of 5-CQA and 3,5-diCQA on the secondary structure of α-glucosidase in the far-UV CD range (from 250 to 190 nm). As shown in Figure 7, the CD spectra of α-glucosidase were characterized mainly by two negative bands at 208 and 222 nm, which are caused by a negative Cotton effect characteristic of helical structure.[54,55] The CD spectra were analyzed by using the CDPro software package to afford the contents of four secondary structures: α-helix, β-sheet, turns, and unordered in the absence and presence of 5-CQA or 3,5-diCQA. As shown in Table 3, the secondary structure proportions for free α-glucosidase were α-helical, 21.8%; β-

sheet, 18%; turn, 17.2%; and unordered, 25.7%. With the addition of 5-CQA or 3,5-diCQA to enzyme, the α-helix contents decreased to 15.9 and 16.4%, whereas the β-sheet contents increased to 27.5 and 31% and the unordered structure contents increased to 30.7 and 32.1%, respectively. In addition, it was found that the difference was not significant for the effects of 5-CQA and 3,5-diCQA on secondary structure contents of α-glucosidase. The decrease in α-helical contents

and increase in contents of unordered structure suggested that the binding of CQA derivatives to α-glucosidase induced the unfolding of protein structure, which is consistent with the results obtained from fluorescence assay.

DISCUSSION

Natural α-glucosidase inhibitors from plant sources offer an attractive strategy to control postprandial hyperglycemia. To our knowledge, this is the first report on α-glucosidase inhibitory effects and mechanisms of CQA derivatives from *I. kudingcha* C.J. Tseng, although it has been used in China for the treatment of diabetes and coronary heart diseases in traditional natural medicine for a long time.[18]

In our previous works, we investigated the potent antioxidant activity of kudingcha polyphenols and purified and characterized the CQA derivatives present in *I. kudingcha* C.J. Tseng.[22,34,35] As many plant polyphenols with relatively high antioxidant activity exhibit inhibitory effects on digestive enzymes,[26,56] we examined the inhibitory activities of CQA derivatives from *I. kudingcha* C.J. Tseng against α-glucosidase from *S. cerevisiae* and further determined the potential interaction mechanisms in the present study. As a result, the inhibitory activities of CQA derivatives were in the order 4,5-diCQA > 3,5-diCQA ≈ 3,4-diCQA > 5-CQA > 4-CQA > 3-CQA by comparison of their IC_{50} values. The inhibitory activity of diCQA was higher than that of CQA derivative with a single caffeoyl moiety, indicating that the inhibitory activity of CQA derivative increases with increasing number of caffeoyl moieties. In addition, the inhibitory activity was affected by the substitution position of the caffeoyl moiety on quinic acid. The substitution at the 5-position exhibited relatively higher inhibitory activity than that at the 4-position, but it was relatively higher than that at the 3-position ($p < 0.05$). As for the three diCQA derivatives, 3,4-diCQA showed equal inhibitory activity to 3,5-diCQA ($p > 0.05$), but it was weaker than 4,5-diCQA ($p < 0.05$). The differences in the α-glucosidase inhibitory activities of CQA derivatives may be due to their differences in structures, particularly the distribution of caffeoyl group and its position in the quinic acid aromatic ring.[26] Such results are in agreement with the conclusions of previous structure−activity relationship investigations by other researchers.[16,23,57−59] For example, the α-glucosidase inhibitory activities of 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA, separated from flower buds of *Tussilago farfara* L., were higher than that of 5-CQA.[57] For porcine pancreas α-amylase isozyme I, diCQA derivative exhibited higher inhibitory activity than mono-CQA derivatives and feruloylquinic acids.[58] Five CQA derivatives (5-CQA, 3,4-diCQA, 3,5-diCQA, methyl 3,4-di-*O*-caffeoylquinate (3,4-diCQM), and 3,5-diCQM) were isolated from *Lonicera fulvotomentosa* Hsu et S. C. Cheng, and their interactions with bovine serum albumin (BSA) were determined; their binding constants with BSA ranked in the following order: 3,4-diCQM > 3,5-diCQM ≈ 3,4-diCQA > 3,5-diCQA > 5-CQA (IUPAC numbering system: 4,5-diCQM > 3,5-diCQM ≈ 4,5-diCQA > 3,5-diCQA > 5-CQA).[59] It has also been reported that diCQA derivatives with double caffeoyl moieties had higher antioxidant capacity as compared to CQA derivative with a single caffeoyl moiety, indicating the addition of caffeoyl moiety significantly increased the antioxidative ability.[23] Furthermore, the inhibitory types of 3-CQA, 4-CQA, 5-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA from *I. kudingcha* C.J. Tseng for α-glucosidase were found to be noncompetitive in the present study. This is the first report on the inhibitory kinetics of the enzyme of six CQA derivatives from kudingcha, although the α-glucosidase inhibitory activities of several CQA derivatives from other herbs were investigated before.

Some polyphenols have a strong ability to interact with digestive enzymes on the basis of interactions between polyphenols and the protein, which reduce food digestibility.[60,61] Thus, we explored the interactions between the CQA derivative and α-glucosidase by fluorescence spectroscopy and

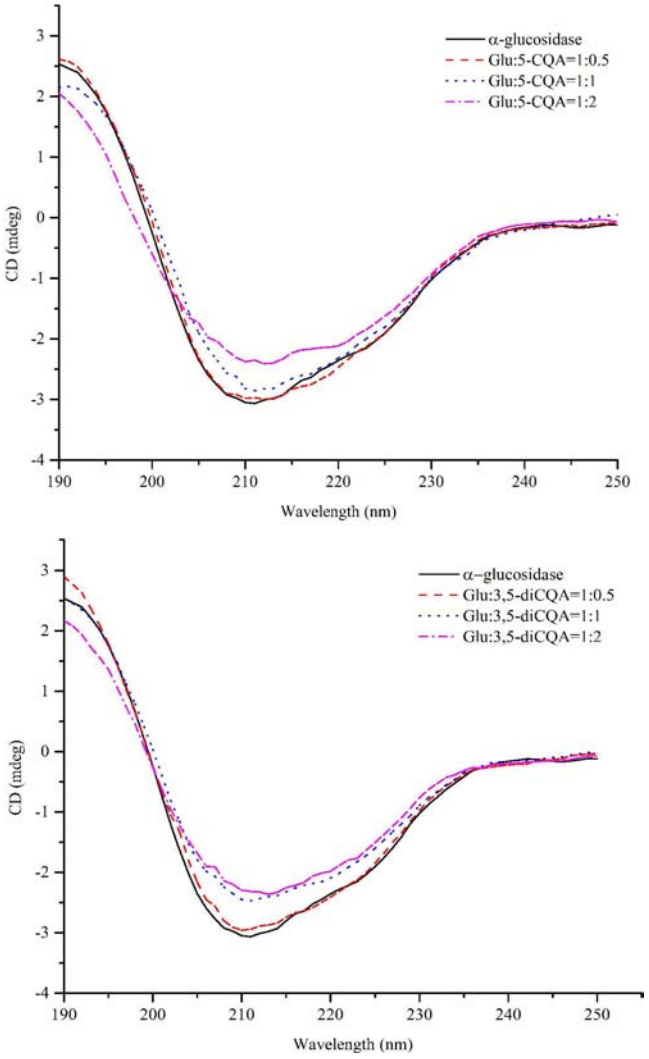

Figure 7. Circular dichroism spectra of free α-glucosidase and enzyme−caffeoylquinic acid complexes: free enzyme and enzyme−caffeoylquinic acid complexes in phosphate buffer solution with a protein concentration of 3×10^{-6} M and caffeoylquinic acid concentrations of 0, 1.5×10^{-6}, 3.0×10^{-6}, and 6×10^{-6} M.

Table 3. Secondary Structure Contents of α-Glucosidase and Its Complexes with 5-CQA and 3,5-diCQA by Circular Dichroism Spectroscopy at Room Temperature

secondary structural content	α-helix (%)	β-sheet (%)	turn (%)	unordered (%)
native α-glucosidase	21.8	18.0	17.2	25.7
glucosidase/5-CQA = 1:0.5	20.7	25.0	20.4	29.6
glucosidase/5-CQA = 1:1	18.5	31.4	22.6	33.1
glucosidase/5-CQA = 1:2	15.9	27.5	20.5	30.7
glucosidase/3,5-diCQA = 1:0.5	21.1	21.6	18.8	27.6
glucosidase/3,5-diCQA = 1:1	18.5	25.4	18.8	28.0
glucosidase/3,5-diCQA = 1:2	16.4	31.0	21.6	32.1

CD spectroscopy for the first time. As for fluorescence spectra, the decrease of fluorescence intensities and a red shift of maximal absorption peak were observed, indicating a conformational change in α-glucosidase. From the fluorescence analysis, the CQA derivative−α-glucosidase binding was achieved by hydrophobic interactions of the interior hydrophobic groups of enzyme and then might be stabilized by hydrogen bonding between polar groups (−OH, −SH, and −NH groups) of the enzyme with the −OH groups of CQA derivative. It has been reported that the integy moment of hydrophobicity descriptors (vsurf_ID4 and vsurf_ID7) in 5-CQA derivatives contributed to the inhibitory activity of α-glucosidase from *Bacillus stearothermophilus* or *S. cerevisiae*. The requirement of the hydrophilic properties on the van der Waals surface of the molecules by properly aligned polar and aromatic/hydrophobic regions for all highly active and less active compounds was confirmed by pharmacophore analysis.[28,62] The binding abilities of CQA derivatives were found to be quite high with a binding constant from 10^6 to 10^8 M^{-1}, and the order was diCQA derivative > CQA derivative with a single caffeoyl moiety, which is in accordance with the results of enzyme inhibition. Interactions between small molecules and enzymes may alter the conformation of the enzyme.[63,64] In our present study, the changes in secondary structures of α-glucosidase with the addition of 5-CQA or 3,5-diCQA were demonstrated by using CD spectroscopy. Thus, CQA derivatives may have a binding effect on α-glucosidase, changing the polarity and molecule conformation of enzyme, resulting in partial loss of the enzyme activity. These structural changes of α-glucosidase finally caused the inhibition of enzyme activity.

In conclusion, six kinds of CQA derivatives, 3-CQA, 4-CQA, 5-CQA, 3,4-diCQA, 3,5-diCQA, and 4,5-diCQA, separated from *I. kudingcha* C.J. Tseng were demonstrated to be effective noncompetitive α-glucosidase inhibitors. The diCQA derivatives exhibited relatively higher inhibition activity than CQA derivatives with a single caffeoyl moiety. Furthermore, the fluorescence spectra suggested that the interaction was spontaneous, and hydrophobic force might be primarily responsible for the interaction. The CD spectra revealed that the change in protein conformation occurred due to the binding of the α-glucosidase molecule to 5-CQA or 3,5-diCQA. All of the present results suggested that the CQA derivatives from *I. kudingcha* C.J. Tseng could be physiologically useful for suppressing postprandial hyperglycemia and therefore may be developed as functional foods for the prevention or treatment of diabetes and obesity.

[a]Data were recorded in $CDCl_3$ (500 MHz). [b]J values of coupling were determined by a homodecoupling experiment.

min, 55 °C annealing for 1 min, 72 °C extension for 2 min, and a final extension at 72 °C for 10 min. The amplified products were purified with a Gel/PCR DNA Fragment Extraction Kit (Geneaid, Taiwan) according to the guidance of the manufacturer and cloned into pGMEMT-Easy vectors (Promega Corporation, Madison, WI) for DNA sequencing. A BLASTN search was used to search for sequences of the closest match in the GenBank database.

C. gloeosporioides was purchased from the Plant Health Clinic, Department of Plant Pathology, Faculty of Agriculture, Kasetsart University, Kamphaeng Saen Campus, Nakhon Pathom, Thailand.

Fermentation. *T. harzianum* F031 from a slant culture was subcultured on PDA for 7 days. The 5 mm discs of growing colonies were cut from the margin of each plate and inoculated into an Erlenmeyer flask containing 250 mL of potato dextrose broth (PDB). After a 27-day incubation at room temperature, the stationary cultures were filtered through filter paper (Whatman No. 1) to obtain the culture filtrate.

Extraction and Purification. The combined culture filtrate (20 L) was exhaustively extracted with EtOAc (3× 1 L). The organic layers were combined, dried over Na_2SO_4, and evaporated under reduced pressure to yield the EtOAc extract (6.10 g). This material was fractionated by the solid-phase extraction (SPE), eluted with EtOAc–hexane and MeOH–EtOAc gradients (5% increasing polarity with 20 mL each). From the basic TLC profiles, four fractions (F1–F4) were obtained.

Fraction F1 (2.32 g, eluted with 5–30% EtOAc–hexane) was separated by CC (SiO_2), eluted with 20% EtOAc–hexane to provide 14 subfractions (S1–S14). Subfraction S3 (24.3 mg) was further purified by CC (SiO_2), eluted with 15% EtOAc–hexane to give compound **1** (12.7 mg) as a colorless amorphous solid. Subfraction S7 (38.4 mg) was separated by CC (SiO_2), eluted with 10% EtOAc–CH_2Cl_2. The product was further purified by CC (SiO_2), eluted with 10% EtOAc–hexane to afford compound **3** (4.2 mg) as a white solid. Subfraction S8 (119.2 mg) was separated by CC (SiO_2), eluted with 5% acetone–CH_2Cl_2 to obtain eight portions (C1–C8). Portion C4 (12.7 mg) was further purified by CC (SiO_2), eluted with 20% acetone–hexane to yield compound **4** (3.0 mg) as a white solid. Subfraction S10 (541.4 mg) was separated by CC (Sephadex LH 20), eluted with 50% MeOH–CH_2Cl_2 to afford four subfractions (D1–D4). Purification of subfraction D2 (326.1 mg) by two consecutive CC (SiO_2; first CC, 10% EtOAc–hexane; second CC, 40% EtOAc–hexane) resulted in compound **2** (8.3 mg), a colorless amorphous solid.

Trichoharzianol (**1**): colorless amorphous solid; $[\alpha]_D^{25}$ +121.5 (*c* 0.13, MeOH); IR ν_{max}, 3489, 1700, 1242, 1218 cm^{-1}; ^1H NMR (500 MHz, $CDCl_3$) and ^{13}C NMR (125 MHz, $CDCl_3$), see Table 1 and the Supporting Information; HRESIMS (*m*/*z*), 365.2686 $[M + H]^+$ (calcd for $C_{22}H_{38}O_4$, 365.2692).

Antifungal Activity Evaluation. The agar dilution method[20] was used to evaluate antifungal activity of the crude extract. The sample was prepared as a stock solution at 10 mg/mL in dimethyl sulfoxide (DMSO). PDA (9.8 mL) was sterilized, and the sample (200 μL) was added at 48 °C to obtain a final concentration of 200 μg/mL and then poured into a 9 cm diameter Petri dish. The dish was left at room temperature overnight. The disc (5 mm diameter), which was removed from the margin of a 3-day-old colony of *C. gloeosporioides*, was placed at the center of the PDA plate and inoculated at room temperature for 3 days. The diameter (in millimeters) of the mycelium growth was recorded and calculated as a percentage of growth inhibition = $(Y - X)/Y \times 100$, where Y is the growth diameter in the untreated control and X is the growth diameter in the treatment. The results of this quadruplicate experiment were reported as the antifungal activity.

The microdilution method, with 96 well microliter plates, was used to evaluate antifungal activity of the fractions and pure compounds.[31] The samples were prepared as 2-fold dilutions and added (50 μL) to each well, which contained the spore suspension (50 μL) and RPMI-1640 medium (100 μL), to give a final concentration of 1024–8 μg/mL for the fractions and 256–0.125 μg/mL for the pure compounds, again performed in quadruplicate. After the mixtures were incubated for 48 h at room temperature, 0.18% resazurin (10 μL) was added to each well and incubated continuously for 3–4 h. Amphotericin B (10 μg/mL, 50 μL) and 1% DMSO (50 μL) were used as a positive control and control, respectively. A positive result was indicated by a

J. Agric. Food Chem. 2015, 63, 3704–3708

color change from blue to pink. The lowest concentration at which the color did not change was taken to be the minimum inhibitory concentration (MIC).

RESULTS AND DISCUSSION

Extraction and Purification. The crude EtOAc extract (6.10 g) of broth culture was fractionated by SEP to provide four combined fractions (F1−F4) based on their TLC characteristics. Subfractions (S1−S14) were obtained from fraction F1 by CC (SiO_2). Subfractions S3, S10, S7, and S8 were further purified to afford compounds **1**, **2**, **3**, and **4**, respectively.

Structural Elucidations. Trichoharzianol (**1**) was shown to possess a molecular formula $C_{22}H_{37}O_4$ as determined by HR-TOF-MS, exhibiting a $[M + H]^+$ peak at m/z 365.2686 (calcd for $C_{22}H_{38}O_4$, 365.2692). Its IR spectrum displayed the absorption bands for hydroxyl (3489 cm^{-1}) and carbonyl (1700 cm^{-1}) groups. The ^1H NMR spectroscopic data (Table 1) displayed characteristics resembling those of eujavanical A.[32,33] However, the two methine protons (H-5 and H-6) were shifted downfield to δ_H 3.71 and 4.26, because they are connected to oxygen atoms of the acetonide group at C_5−C_6. The *gem*-dimethyl groups of acetonide appeared at δ 1.48 and 1.35. The significant downfield shifts of C-5 and C-6 (δ_C 79.7 and 73.6) supported the presence of an acetonide group at C_5−C_6.

The substituents were designated to be a 3-hydroxypropionyl group at C-1, a 1-methylpropyl group at C-2, two methyl groups at C-1 and C-8, and an acetonide group at C-5 and C-6. The assignments of the ^1H and ^{13}C NMR spectra were based on the correlation spectroscopy (COSY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC) data (see Table 1). The attachments of side chains on the decalin moiety were established by the analysis of the HMBC data. The location of the 3-hydroxylpropyl group at C-1 was suggested by the correlations of 1-CH_3 (δ_H 1.21) to C-9. H-2 (δ 1.94) showed correlations to C-2′ and 1′-CH_3, confirming the attachment of a 1-methylpropyl group at C-2. The correlations of a methyl (δ_H 1.21) to C-8a and C-2, together with another methyl (δ_H 0.64) to C-8a, C-8, and C-7, indicated the connections of two methyls at C-1 and C-8, respectively. Furthermore, the correlations between H-5 (δ_H 3.72) and H-6 (δ_H 4.26) to C4′ indicated the presence of an acetonide group at C-5−C-6.

The relative configuration of compound **1** was determined by the nuclear Overhauser effect spectrometry (NOESY) correlations as shown in Figure 2. The above data confirmed that compound **1** was an acetonide derivative eujavanicol A,[33] and the structure of trichoharzianol (**1**) was established as shown in Figure 1.

Eujavanicol A (**2**) was reported previously from *Eupenicillium javanicum*,[33] whereas 5-hydroxy-3-hydroxymethyl-2-methyl-7-methoxychromone (**3**) and 4,6-dihydroxy-5-methylphthalide (**4**) were found in the lichen *Graphis scripta*[34] and *Talaromyces flavus*,[35] respectively. Their structures were identified with spectroscopic data (UV, IR, NMR, and MS) and compared to those reported in the literature.

Antifungal Activity. The crude extract of *T. harzianum* F031 showed the antifungal activity against *C. gloeosporioides* with 76.6% inhibition by an agar dilution assay at a concentration of 0.2 mg/mL. After further fractionation and purification, the fractions and all the pure compounds were evaluated for their antifungal activity and their MIC values were determined by microdilution. Fraction A showed the highest antifungal activity against *C. gloeosporioides* with a MIC of 512 μg/mL, while fractions B−D exhibited MIC values of >1024 μg/mL. Trichoharzianol (**1**) showed the highest antifungal activity against *C. gloeosporioides* with MIC of 128 μg/mL (Table 2), followed by 5-hydroxy-3-hydroxymethyl-2-methyl-7-methoxychromone (**3**) (MIC of 256 μg/mL). It should be noted here that eujavanicol A (**2**) and 4,6-dihydroxy-5-methylphthalide (**4**) showed antifungal activity of >256 μg/mL.

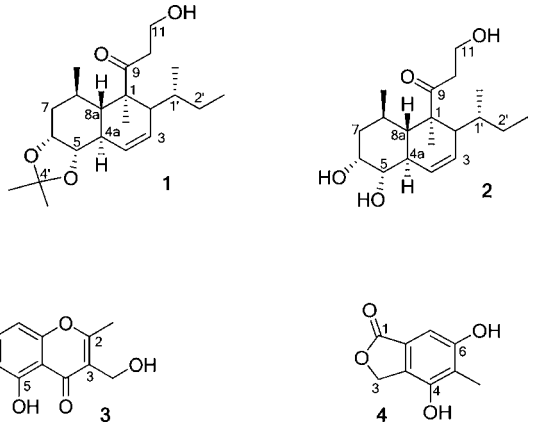

Figure 1. Structure of trichoharzianol (**1**), eujavanicol A (**2**), 5-hydroxy-3-hydroxymethyl-2-methyl-7-methoxychromone (**3**), and 4,6-dihydroxy-5-methylphthalide (**4**).

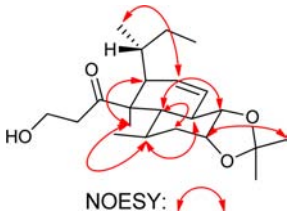

Figure 2. Selective NOESY correlation of trichoharzianol (**1**).

Table 2. Antifungal Activity against *C. gloeosporioides* of Compounds 1−4

compound	MIC (μg/mL)
trichoharzianol (**1**)	128
eujavanical A (**2**)	>256
5-hydroxy-3-hydroxymethyl-2-methyl-7-methoxychromone (**3**)	256
4,6-dihydroxy-5-methylphthalide (**4**)	>256

Trichoharzianol (**1**) is found to be a new and major component from *T. harzianum* F031 strain and shows the highest antifungal activity against *C. gloeosporioides*. In addition, eujavanicol A (**2**), 5-hydroxy-3-hydroxymethyl-2-methyl-7-methoxychromone (**3**), and 4,6-dihydroxy-5-methylphthalide (**4**) are reported from this strain for the first time.

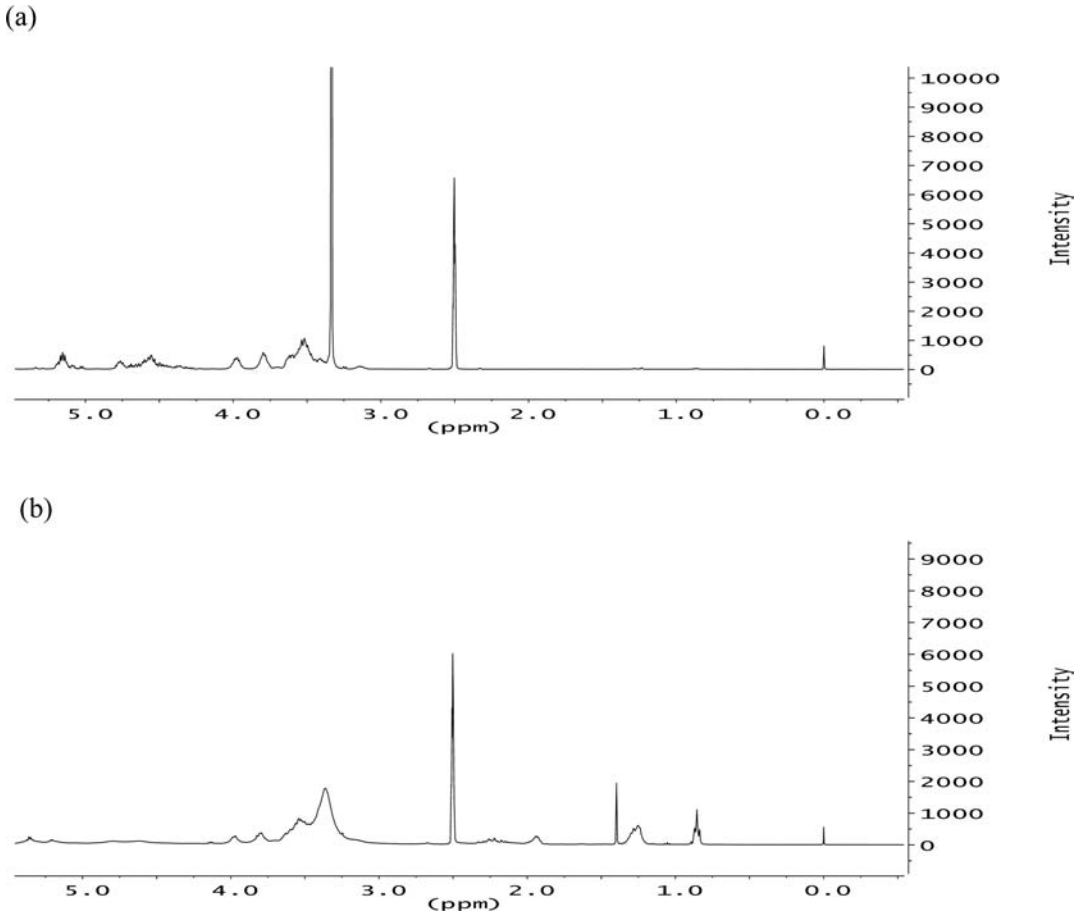

Figure 1. Proton NMR spectra of (a) unmodified inulin (Inutec H25P) and (b) OSA−inulin.

solutions to prevent solidification in the dropping funnel. Throughout the reaction, the pH was maintained at pH 8.3−8.5 through addition of aqueous sodium hydroxide (1, 3, or 10%, w/w). The reaction was continued until no further pH change was observed; typically, this was about 6 h. The reaction mixture was then brought to pH 6.0 by addition of 5% aqueous hydrochloric acid. The solid product was recovered by freeze-drying and washed by Soxhlet extraction with cyclohexane for 6 h prior to drying in a vacuum oven.

Characterization. *NMR Spectroscopy.* H^1 NMR spectra of ASA−inulins were recorded using a 500 MHz NMR Spectrometer at 25 °C. Each sample (5 mg) was added to 0.7 g of DMSO-d_6 then added into a 5 mm thin wall NMR tube and dissolved at 25 °C. The spectra were recorded using the Pulse Program ZG30 together with Mnova 7.0 software, with a 30° pulse and a delay of 1 s.

Fourier-Transform Infrared Spectroscopy. ASA−inulin samples were dried in an oven at 70 °C overnight. Sample (1 mg) was milled with 100 mg of dried KBr using an agate mortar and pestle for several minutes to obtain a fine powder. A thin pellet was produced using a 15 ton manual press and a P/N 03000 13 mm pellet die (maximum load 10.0 tons) from Specac Limited. The FTIR spectra were recorded in the range 4000−400 cm^{-1} using a PerkinElmer FTIR spectrometer RX 1, taking 16 scans at a resolution of 4 cm^{-1}. Spectral analysis and display were performed using the interactive PerkinElmer Read-IR3 software, version 3.0.

Critical Aggregation Concentration. *Dye Solubilization.* The CAC was determined using the dye solubilization technique as described previously.[7] Stock solutions of 1% ASA−inulins were prepared and diluted to give solutions of various concentrations. A 10 mg aliquot of the dye was added to 10 mL of inulin solution, and the samples were left agitating at 40 °C overnight. The solution was then filtered to remove insoluble dye particles using a Millex-GP 0.22 μm filter (Millipore Ireland Ltd.) into disposable UV grade 10 mm path length cuvettes (CXA-110-0053 from Fisher Scientific Ltd.). The absorbance of the solution was determined at a wavelength of 510 nm using a Lambda 25 UV/vis Spectrometer (PerkinElmer). The CAC was obtained from the point at which the absorbance first increased.

Dynamic Light Scattering. Dynamic light scattering measurements were recorded using the Zetasizer Nano ZS (Malvern Instruments Ltd., Malvern, UK) equipped with a 5 mW He−Ne laser (λ_0 = 632.8 nm) and a digital correlator at a 175° angle relative to the incident beam. The temperature was controlled at 25 ± 1 °C. Samples were prepared by serial dilution with filtered distilled water from a stock of 2.0 g/dL to create five sample concentrations in the range of 0.004−1 g/dL. Samples were filtered using a Millex-GP 0.22 μm filter (Millipore Ireland Ltd.). Solutions were placed in disposable plastic cells with a cross-sectional area of 1 cm^2. Fifteen runs were performed for each sample, and the collection time was 180 s. Zetasizer Software (version 6.20, ©2002−2010 Malvern Instruments Ltd.) was used for data analysis. The CAC was determined from the change in the slope of the plot of the intensity of scattered light as a function of concentration. The hydrodynamic diameter of the aggregates formed above the CAC was obtained from the Stokes−Einstein relationship using the instrument software.

Surface Tension. The surface tension of ASA−inulin solutions at varying concentrations was determined using a Tensiometer K8 with a 4 cm circumference Du Nouy ring (RI 01 from Krüss GmbH). All measurements were repeated three times, and the average taken. The temperature was kept constant at 25 ± 1 °C during all the measurements. The CAC was determined from the change in slope of the plot of equilibrium surface tension as a function of ASA−inulin concentration.

Emulsification Properties. Oil-in-water emulsions (15 %, w/w) were prepared by mixing 1.5 g of oil and 8 g of a 2.5% aqueous solution of alkenyl succinylated inulin and 0.5 g of water to make

DOI: 10.1021/acs.jafc.5b00333
J. Agric. Food Chem. 2015, 63, 3709−3715

2.35%. ASA−inulin emulsion samples contained in a 20 mL glass tube were homogenized using an IKA T25 Digital ultra-Turrax homogenizer at 24 000 rpm for 3 min. Emulsions were also prepared using Tween 20 for comparison. The droplet size of the emulsions was measured by laser diffraction immediately after preparation and after storing at room temperature for a period of up to 21 days using the Mastersizer-2000 (Malvern Instruments, UK). Two or three drops of the sample were introduced into the dispersion unit containing distilled water. The dispersion unit pump speed was 2000 rpm, and the obscuration was between 10 and 30%. The refractive index of the dispersing medium and the dispersed particles were 1.33 and 1.45, respectively. Measurements were carried out in duplicate and the average value reported.

RESULTS AND DISCUSSION

Characterization. Figure 1a,b shows the ^{1}H NMR spectra of the native and OSA−inulin samples, respectively. The prominent peaks at 2.5 and 3.35 ppm are from the solvent, i.e., DMSO and HDO, respectively, and the peaks from 3.4 to 5.3 ppm are from the inulin itself (Figure 1a).[7] ^{1}H NMR signals at 0.85, 1.26, and 1.94 ppm[10−12] correspond to the methyl and methylene groups of the octenylsuccinic anhydride (Figure 1b). The amount of alkenyl chains incorporated into the modified samples was calculated from the ratio of the area of the peak at 0.85 ppm to the area of the peaks from 3.4−5.3 ppm, and the results are shown in Table 1.

Table 1. Degree of Substitution of the Modified Inulins

sample	% substitution/mol
OSA	29.6
DSA	28.7
DDSA	22.7
TDSA	26.2
HDSA	39.8
ODSA	12.9

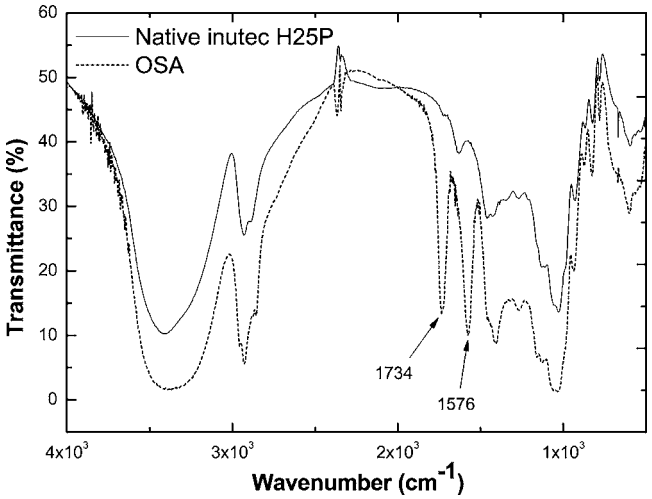

Figure 2. FTIR spectra of unmodified inulin (Inutec H25P) and OSA−inulin.

FTIR spectra of the native and OSA−inulin samples are presented in Figure 2. The peaks for the native inulin at 3398, 2930, and 1028 cm^{-1} indicate O−H stretching, CH_2 stretching, and C−O−C bending, respectively.[7,13] The spectrum of OSA−inulin shows two new peaks at 1576 and 1734 cm^{-1} caused by the formation of the ester linkage. Similar findings were found for the other modified samples (data not shown). The peaks

Table 2. Critical Aggregation Concentrations of the Modified Inulin Samples Using Various Techniques

	CAC %		
sample	dynamic light scattering (intensity)	dye solubilisation	surface tension
OSA	0.08 ± 0.005	0.07 ± 0.01	0.07 ± 0.01
DSA	0.06 ± 0.005	0.04 ± 0.01	0.05 ± 0.01
DDSA	0.04 ± 0.01	0.02 ± 0.005	0.04 ± 0.01
TDSA	0.02 ± 0.005	0.009 ± 0.001	0.015 ± 0.005
HDSA	0.015 ± 0.005	0.007 ± 0.001	0.015 ± 0.005
ODSA	0.012 ± 0.005	0.0045 ± 0.0005	0.005 ± 0.001

are assigned to asymmetric COO− and ester carbonyl stretching, respectively.[13] In studies on starch modification, it has previously been reported that the CH_2 stretching band at 2930 cm^{-1} increased after modification because of the contribution from the carbon chain associated with the alkenyl succinic group.[14] However, the CH_2 stretching band at 2930 cm^{-1} for our modified inulins was not comparably enhanced, in agreement with the findings of Kokubun et al.[7]

Critical Aggregation Concentration. The absorbance values obtained for ASA−inulins in the presence of Sudan IV

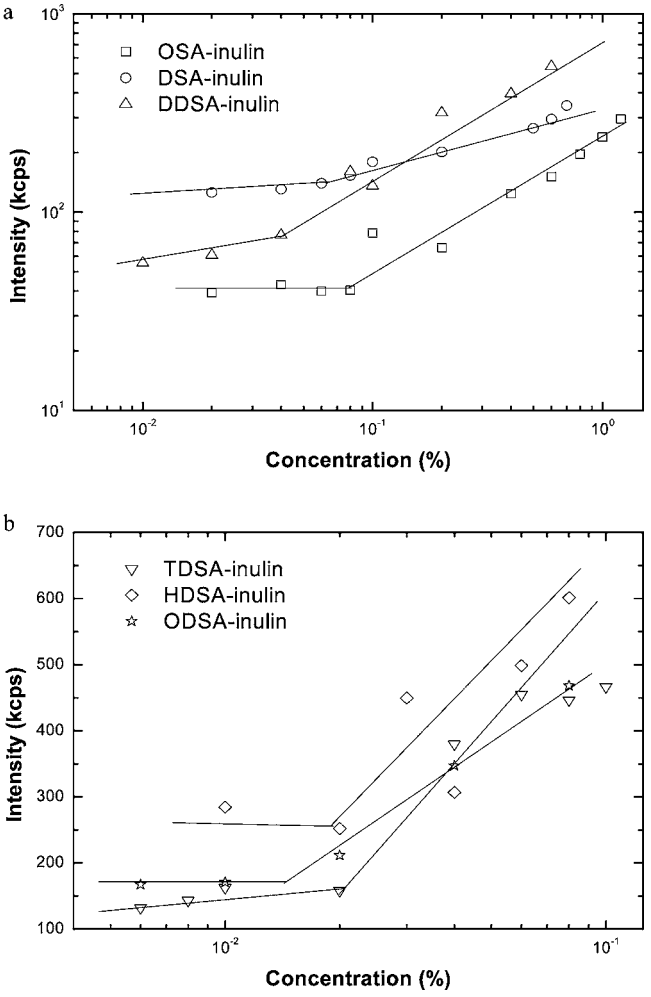

Figure 4. (a) Scattering intensity as a function of concentration for OSA-, DSA-, and DDSA-modified inulins. (b) Scattering intensity as a function of concentrations for TDSA-, HDSA-, ODSA-modified inulins.

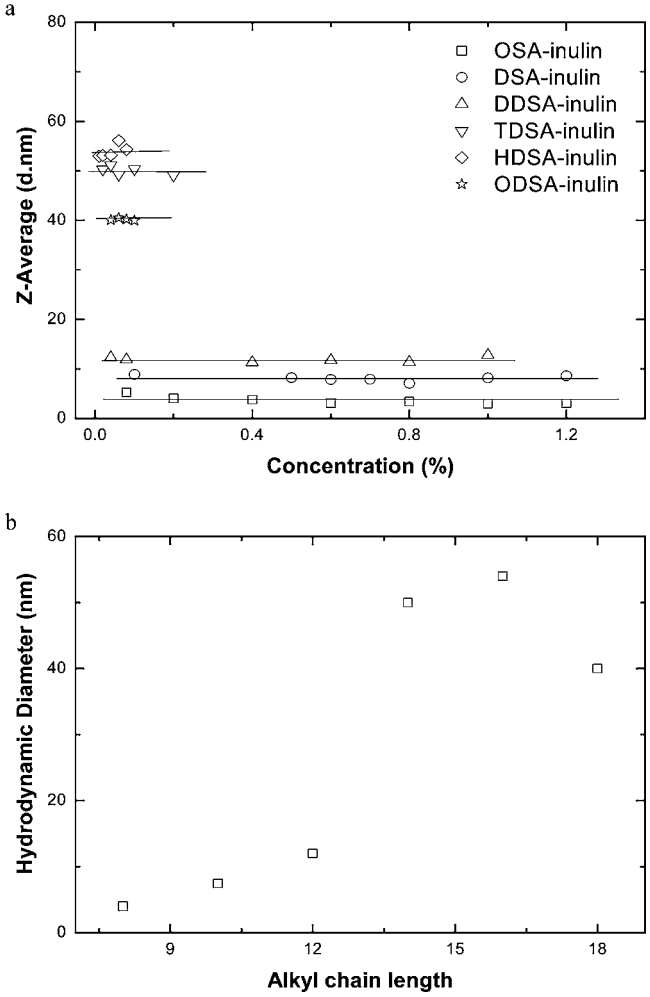

Figure 5. (a) Z-average hydrodynamic diameter as a function of concentration for modified inulins with different alkenyl chain lengths. (b) Z-average hydrodynamic diameter as a function of alkenyl chain length for ASA−inulins.

are given in Figure 3a,b. It is noted that the values increase significantly above a critical concentration which is attributed to the formation of micellar−like aggregates and the dissolution of the dye in their hydrophobic core.[7] The CAC values for all ASA−inulins are summarized in Table 2. It is generally seen that the CAC decreases as the alkenyl chain length increases as expected and also as noted by Kokubun et al.[7] and van Kempen et al.[5] for hydrophobically modified inulins. The actual CAC values for the OSA−inulins are lower than those reported by Kokubun et al.,[7] and this is attributed mainly to the fact that the present samples have a significantly higher degree of alkenylation. The values, however, are higher than those reported by van Kempen et al.[5] This is probably due to the fact that in our study modification was carried out using alkenyl succinic anhydride which leads to the incorporation of a free carboxylate group present in the surfactant headgroup giving an anionic charge. This was not the case for the samples produced by van Kempen et al., which were nonionic.[5] It is well-known that ionic surfactants have a higher critical micelle concentration (CMC) compared to nonionic surfactants because of the fact that for ionic surfactants electrostatic repulsions between the surfactant head groups in the micelle oppose the micellization process.

The scattering intensity of solutions of ASA−inulin samples are plotted as a function of concentration in Figure 4a,b. The sharp increase in the scattering intensity above a certain concentration is attributed to the CAC and the formation of aggregates. The CAC values are given in Table 2 and are of the same order of magnitude as the values obtained by dye solubilization.

The Z-average hydrodynamic diameters of ASA−inulin samples are given as a function of concentration in Figure 5a and are plotted as a function of alkenyl chain length in Figure 5b. It is noted that in general the size of the aggregates increases with the alkenyl chain length as might be expected. The value for ODSA−inulin is a little lower than might be expected from the trend shown, and this is probably due to the fact that it has a significantly lower degree of modification than the other samples. Kokubun et al.[7] reported higher values of 13 and 30 nm compared to values of 4 and 12 nm in this study for OSA- and DDSA-modified inulin samples, respectively. The main reason for the difference is the fact that the DP of the inulin used in the present study was 2−8, whereas in the study of Kokubun et al.,[7] the inulin had a DP of >10. van Kempen et al.[5] also used inulin with a DP of 2−8 and reported values of between 4.3 to 13.4 nm for C8−C18 modified inulins,

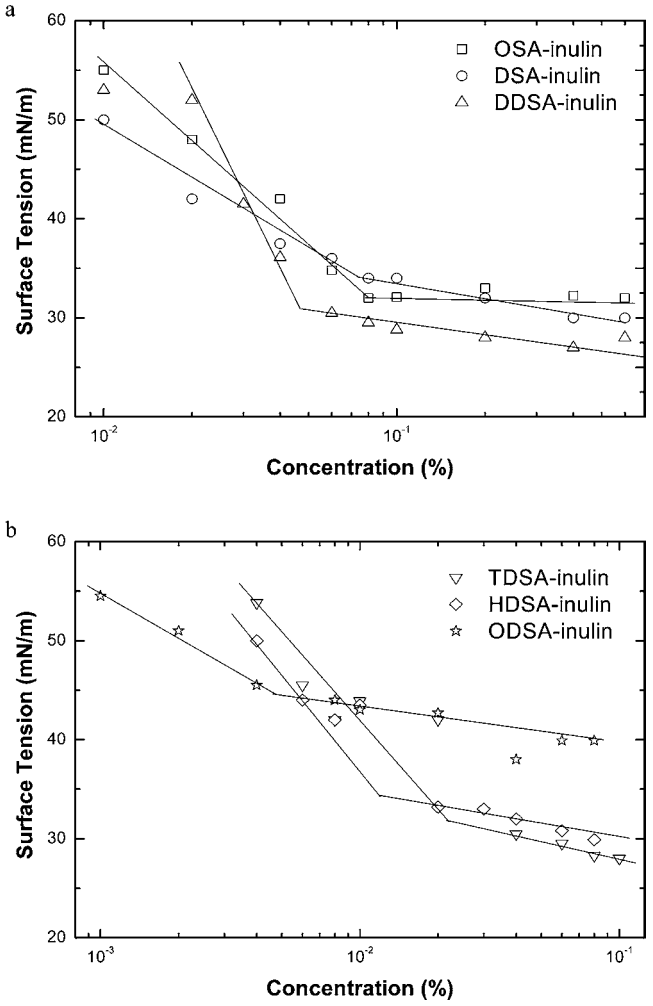

Figure 6. (a) Surface tension of OSA−, DSA−, and DDSA−inulin samples as a function of concentration. (b) Surface tension of TDSA−, HDSA−, and ODSA−inulin samples as a function of concentration.

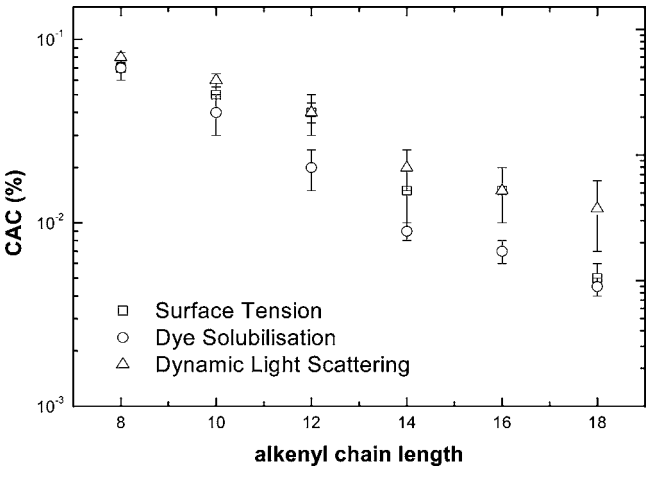

Figure 7. Critical aggregation concentrations of ASA−inulins as a function of alkenyl chain length.

consistent with the values reported here using inulin of a similar DP.

The surface tensions of ASA−inulins at the air−water interface are shown as a function of concentration in Figure 6a,b. The CAC value for each of the samples was obtained from the inflection in the curve, and the results are reported in Table 2. The values are in reasonable agreement with the values obtained using dye solubilization and dynamic light scattering methods. The surface tension was found to be between 31 and 34 mNm at the CAC for all of the samples, apart from ODSA−inulin which had a much higher value (43 mNm). This discrepancy may be due to its lower degree of modification. Kokubun et al.[7] reported values of ∼35−40 mNm for OSA−inulin and DDSA−inulin, and van Kempen et al.[5] reported

values of ∼34−40 mNm for inulin samples modified with C8−C16 alkyl chains.

The CAC values for ASA−inulins obtained using the different techniques are plotted as a function of the alkyl chain length in Figure 7, which clearly shows the decrease in CAC with increasing alkyl chain length. The free energy decrease for the transfer of a $-CH_2-$ unit from the bulk phase to the micelle (ΔG_{mic}) can be calculated by eq 1, derived by Rosen[15,16] and represented as

$$\log \mathrm{CMC} = (\Delta G_{mic}/2.303RT)m + K_{mic} \quad (1)$$

where m is the number of carbons in the alkyl chain and K_{mic} is a constant for the same hydrophilic group. The calculated ΔG_{mic} per CH_2 is −0.79 kJ/mol at 25 °C. Zhang and Marchant[16] reported a ΔG_{mic} value for the *N*-alkylmaltoamide series of −1.86 kJ/mol at 25 °C. Using the same procedure, van Kempen et al.[5] obtained a value of −3.1 kJ/mol.

The surface excess, Γ, is related to surface tension by the Gibbs equation, which for a 1:1 ionic surfactant is given by eq 2,[5] represented as

$$\Gamma = -\left(\frac{1}{2RT}\right)\left(\frac{d\gamma}{d(\ln C)}\right) \quad (2)$$

Surface excess values were determined from the slope of the lines for the plot of γ−ln C just below the CAC,[5,17] and the results are shown in Table 3. The values obtained for the surface excess were used to calculate the surface area occupied by each molecule, A, using the equation

$$A = \frac{1}{\Gamma N_A} \quad (3)$$

where N_A is Avogadro's number.

The area occupied per molecule was found to vary between 0.66 and 1.06 nm^2 for the inulins modified using C8−C16 alkenyl chains and is of an order similar to the values reported by van Kempen et al.[5] of 0.46 to 0.91 nm^2 and by Stevens et al.,[4] who reported an area per molecule of 0.9 nm^2 for a hydrophobically modified inulin sample. The high value obtained for ODSA−inulin (1.78 nm^2) may be a consequence of is low solubility, which is likely to result in molecular aggregation. The values for A are larger than those reported for simple sugar-based surfactants with only one or two sugar residues. For example, Soultani et al.[18] reported values of 0.05−0.2 nm^2 for hydrophobically modified fructose and sucrose surfactants, whereas Garofalakis et al.[19] reported values of 0.29−0.68 nm^2 for surfactants based on xylose, galactose, sucrose, and lactose. For the modified inulins, the area occupied will ultimately depend on the number and position of the hydrophobic groups attached to the backbone. If there are several hydrophobic groups randomly distributed along the backbone, then the carbohydrate moieties would be expected to lie flat at the interface and occupy a much larger surface area than inulin molecules with the hydrophobic groups attached at one end.

Emulsion Stability. The droplet size distributions for the emulsions prepared using the various modified inulin samples and Tween 20 were determined shortly after preparation and after 21 days and are presented in Figure 8a,b, respectively. The

DOI: 10.1021/acs.jafc.5b00333
J. Agric. Food Chem. 2015, 63, 3709−3715

corresponding $d_{3,2}$ and $d_{4,3}$ values are given in Figure 9a,b. It was found that the modified inulin samples with alkylene chain lengths C10−C18 produced emulsions with slightly smaller droplet sizes than did C8 inulin and Tween 20. There was little change observed in the droplet size on storing for 21 days. This is consistent with the study by Kokubun et al.,[8] which showed that DDSA−inulin yielded emulsions with a droplet size smaller than OSA−inulins (both with DS 12 mol %).

The work described in this paper has demonstrated that inulin can be successfully modified in aqueous solution by alkylene succinic anhydrides with alkenyl chain lengths varying from C8−C18, and the derivatives have been shown to form micellarlike aggregates in solution. The CAC values have been found to decrease with increasing alkenyl chain length, whereas the hydrodynamic size of the aggregates has been shown to increase with increasing alkenyl chain length. It has also been shown that inulins are able to produce stable oil-in-water emulsions with a droplet size similar to those formed with Tween 20. The dye solubilization experiments have demonstrated that ASA−inulins are able to form micellarlike aggregates and dissolve hydrophobic compounds within their hydrophobic core. This coupled to the fact that they can stabilize oil-in-water emulsions makes them suitable candidates for the encapsulation and delivery of water-insoluble active compounds, with potential application in food, cosmetic, personal care, and pharmaceutical formulations.

and 7.5−9.5% Na_2O), sodium periodate, and sulfuric acid (98%). Sodium borohydride, cetyltrimethylammonium bromide (CTAB), trimethoxy(octyl)silane (OTMS; 96%), glycerin, glycidyloxypropyltrimethoxysilane (GPTMS 99.7%), *p*-nitrophenol (pNP), *p*-nitrophenyl butyrate (pNPB), acetone, propylene carbonate, methyltetrahydrofuran (Me-THF), *tert*-butanol (*t*-BuOH), palmitic acid, ascorbyl palmitate, and TritonX-100 (laboratory grade) were purchased from Sigma−Aldrich (St. Louis, MO, USA). Lactulose was purchased from Carbosynth (Berkshire, United Kingdom). Lipases from *Pseudomonas stutzeri* (PsL) and *Alcaligenes* sp. (AsL), under the trade names Lipase TL and Lipase QL respectively, were kindly donated by Meito-Sangyio Ltd. (Fuchu, Japan). All other reagents and solvents were of the highest available purity and used as purchased.

Synthesis and Characterization of Supports. *Silica Synthesis.* Synthesis and functionalization of silica was carried out according to a previous work.[18] A typical reaction of synthesis is described below: a mixture with the following molar proportion of reagents: SiO_2:Na_2O:CTAB:EtAc:H_2O = 1:0.3:0.24:7.2:193 was heated at 80 °C for 48 h under quiescent conditions. Then the solid was calcined at 540 °C (heating rate: 1.5 °C min^{-1}) for 3 h and derivatized according to the requirements of the chemical surface.

Octyl Silica Derivatization (OS). One g of silica was activated under vacuum then was mixed with 30 mL of 10% OTMS in toluene solution and gently stirred under reflux for 6 h. After filtration, the solid was washed with acetone and abundant water (conditioning the silica surface for the enzyme) and finally dried at room temperature.[13]

Octyl-glyoxyl Silica Derivatization (OGS). The octyl and glyoxyl cobonded silica (OGS) particles were prepared in a similar way than OS, using a 10% GPTMS-OTMS mixture in a 1:1 proportion. After washing and filtration, the derivatized silica was oxidized by contacting the support with 0.1 M $NaIO_4$ solution for 2 h at 25 °C. Details of the grafting reaction can be found in Bernal et al.[13,19]

Biocatalyst Preparation. *As*L and *Ps*L were immobilized in the supports according to their chemical surface. For OS, the support was prepared at pH 7 to favor its hydrophobic interaction with the lipase, while for OGS preparation, the enzyme was first contacted with the support at pH 7 to favor hydrophobic interaction but, after that, the pH of the suspension was increased to 10 with the aim of favoring covalent bond formation between the glyoxyl groups of the activated silica and the lysine residues of the enzymes. Immobilization was carried out offering 160 and 200 IU of *Ps*L and *As*L per gram of support, respectively. More details about the immobilization process can be found in previous works.[13,18]

Assay of lipase activity was performed by measuring the increase in absorbance at 348 nm produced by the released *p*-nitrophenol in the hydrolysis of 0.4 mM *p*-nitrophenyl butyrate (*p*NPB) in 25 mM sodium phosphate buffer at pH 7.0 and 25 °C. One international unit of lipase activity (IU) was defined as the amount of enzyme that hydrolyzes 1 μmol of *p*NPB per minute under the conditions described above. Expressed activity was determined in IU per gram of biocatalyst.

Stability of Biocatalysts. Stability of the biocatalysts and the soluble lipases was evaluated under two nonreactive conditions: in 25 mM sodium phosphate buffer at pH 7.0 and 60 °C, and in 100% acetone, *t*-BuOH, Me−THF, and propylene carbonate at 40 °C without the addition of surfactant or activity stabilizers in both cases. Aliquots were withdrawn periodically under stirring in order to have a homogeneous biocatalyst suspension. The residual activity of the enzymes was measured as described previously, and half-life (period of time at which the enzyme have lost one-half of its initial activity) was determined.

Lactulose Palmitate Synthesis. Lactulose palmitate was synthesized at a 10 mL scale by esterification of lactulose (5 mM) with palmitic acid (2.5 mM) using different organic solvents: acetone, *t*-BuOH, propylene carbonate, and Me−THF at 40 °C. The reaction mixture contained 15 mg/mL of biocatalyst. Substrates and products of reactions were determined by HPLC using a C-18 column (Waters Symmetry C18, 5 μm 4.6 mm × 150 mm) and a UV−vis spectrophotometer detector (JASCO model AS-2089). Separation was achieved by eluting with acetonitrile:water mixtures as mobile phase at a flow rate of 1 mL/min with the following gradient program: 60:40 (v/v) for 6 min and then 95:5 (v/v) for 18 min. Detection was performed in a UV detector at 270 nm and the monoester of lactulose palmitate was analyzed by HPLC-MS (model 2020, Shimadzu, Kyoto, Japan) with photodiode detector (SPD M 20A) and mass analyzer (MS 2020) with electrospray ionization (ESI) system.

The monoester yield was calculated according to eq 1:

$$Y(\%) = \frac{[\text{monoester}] \times V_{\text{reactor}} \times MW_{\text{lactulose}}}{Wi_{\text{lactulose}}} \times 100 \quad (1)$$

where [monoester] is the lactulose palmitate monoester molar concentration, V_{reactor} is the reactor volume, $MW_{\text{lactulose}}$ is the molecular weight of lactulose, and $Wi_{\text{lactulose}}$ is the initial mass of lactulose in the reaction mixture.

Specific productivity (SP) was calculated according to eq 2:

$$SP = \frac{[\text{monoester}] \times MW_{\text{monoester}} \times V}{t \times W_{\text{biocatalyst}}} \quad (2)$$

where [monoester] is the lactulose palmitate monoester molar concentration, $MW_{\text{monoester}}$ is the molecular weight of the monoester, V is the reactor volume, t is the time of reaction, and $W_{\text{biocatalyst}}$ is the mass of biocatalyst in the reaction mixture.

Purification of lactulose monoester was carried out by scaling-up the HPLC procedure in a preparative column of Silica C-18 (particle size, 40−75 μm; and pore size, 70 Å). Reaction mixture was dissolved in acetone and injected into the column. Mobile phase consisted of acetonitrile and water mixtures at different ratios (60:40 for monoester and 95:5 for other products and residual palmitic acid). The flow rate was kept at 2.0 mL/min, and the injection volume was 0.5 mL. Fractions were analyzed by HPLC according to the methodology described above. Collected peak fractions were evaporated to dryness under reduced pressure at 55 °C.

Experimental Design. With the aim of evaluating the effect of reaction conditions in the lactulose palmitate monoester yield and specific productivity, an experimental design was carried out. For the 2^3 factorial design, temperature and substrates molar ratio were selected as variables: each of them were tested at 5 levels (high, centered, low, and two axials) coded −1.41, −1, 0, +1, and +1.41. The uncoded and coded values for each level of these variables are given in Table 1. The experimental setting (11 duplicate runs) was generated by Design-Expert 6.0.8 software. The reaction media were analyzed after 48 h by HPLC, as described above, analyzing the monoester yield (eq 1).

Table 1. Factors and Their Levels Selected for the 2^3 Full Factorial Design

variable	levels				
	−1.41	−1.00	0.00	1.00	1.41
	Acetone				
temperature (°C)	26.5	30.0	38.5	47.0	50.5
lactulose:palmitic acid molar ratio	0.60	1.00	2.00	3.00	3.41
	Propylene Carbonate				
temperature (°C)	54.1	50.0	40.0	30.0	26.0
lactulose:palmitic acid molar ratio	0.60	1.00	2.00	3.00	3.41

Response surface analysis was carried out from these experiments, and ANOVA analysis, the model adjustment for the final equations, and their graphic representation were done with the Design-Expert 6.0.8 software.

Error obtained between experimental and modeled data (E_y) was calculated according to eq 3:

$$E_y = \frac{\text{experimental yield}}{\text{predicted yield}} \times 100 \quad (3)$$

[a]EA: specific activity per unit mass of biocatalyst. $t_{1/2}$: half-life for every solvent at 40 °C. [b]*Enzyme activity of soluble enzyme expressed in IU per gram of commercial powder.

All experiments were done in triplicate and the standard deviation (σ_x) was calculated according to

$$\sigma_x = \pm\sqrt{0.5 \sum (x_i - x^2)} \quad (4)$$

where x_i is the individual value for every measure and x is the average value in the experiment.

Biocatalyst Reuse. Effect of time and biocatalyst:palmitic acid mass ratio was evaluated with the aim of optimizing the batch reaction of synthesis. At the selected conditions after the experimental design, reaction was carried out during 48 h with 100 IU/g palmitic acid or during 24 h with 200 IU/g palmitic acid. In both cases, the yield of monoester and specific productivity were evaluated (eqs 3 and 4).

Operating performance in successive batches was evaluated with the obtained biocatalysts under the optimum reaction conditions established by the experimental design. At the end of each batch, one aliquot was taken and analyzed by HPLC as previously described in order to determine the monoester yield and specific productivity. Between cycles, the reacted medium was filtered out and the retained biocatalyst washed with acetone and dried at 25 °C to remove residual substrate, products, and solvent prior to using it in the subsequent batch.

RESULTS AND DISCUSSION

Biocatalysts Characteristics. Synthesis of lactulose palmitate was performed with lipases from *Pseudomonas stutzeri* and *Alcaligenes* sp. because they exhibited good esterase activity when immobilized in octyl silica and glyoxyl-octyl silica.[13] Their expressed activities in aqueous media are shown in Table 2, indicating that the orientation into the support influenced the expressed activity and immobilization yield, which was reported in a previous work.[13] Considering that esterification reactions are conveniently conducted in organic solvents, expressed activity and stability at 40 °C was evaluated in acetone, *t*-BuOH, Me−THF, and propylene carbonate. Despite the fact that the activity of lipases in soluble form cannot be measured in organic solvent (the proteins precipitate), it can be seen that immobilization in octyl and octyl-glyoxyl silica favored the expressed activity of both enzymes (in comparison with expressed activity of the biocatalyst in aqueous medium) except when the activity was measured in Me−THF (Table 2). This behavior can be explained by the physicochemical characteristics of acetone, propylene carbonate, and *t*-BuOH, which could favor the opening of the lipase lid and preclude the essential water layer around the active site of the enzyme from being stripped off.[20] Thermal stability of biocatalysts in pure organic solvent (with water content corresponding to the equilibrium moisture) at 40 °C was increased by immobilization in most of cases, it being higher for the heterofunctional support OGS (Table 2). This trend is due to the extra stiffening caused by the covalent attachment of the lysine residues of the enzyme surface to the glyoxyl groups of the support.[13] The highest thermal stability was obtained in the presence of *t*-BuOH. This is due to its high viscosity that can decrease the conformational mobility of the protein, stabilizing its tridimensional structure.[17]

Palmitate Lactulose Synthesis. Sugar ester synthesis was carried out in the presence of pure solvent with the aim of favoring esterification over hydrolysis. Propylene carbonate, acetone, *t*-BuOH, and Me−THF were selected because polar solvents favor the solubility of lactulose, one of the main problems of synthesis of sugar fatty acid esters.[21] After 48 h of reaction, all biocatalysts catalyze the conversion of palmitic acid to palmitate ester (Figure 1); however, only the conversion to monoester was quantified because this molecule has better hydrophilic−lipophilic balance than di- and triester (synthesis yield of di- and triester under evaluated conditions was less than 2%). Monoester identification was reported in a previous work.[13] Immobilized lipases in OS exhibited a higher yield toward monoester synthesis in comparison with OGS-biocatalysts, probably because the lid of lipase in OS support is more open than in OGS silica, which promotes the catalysis.

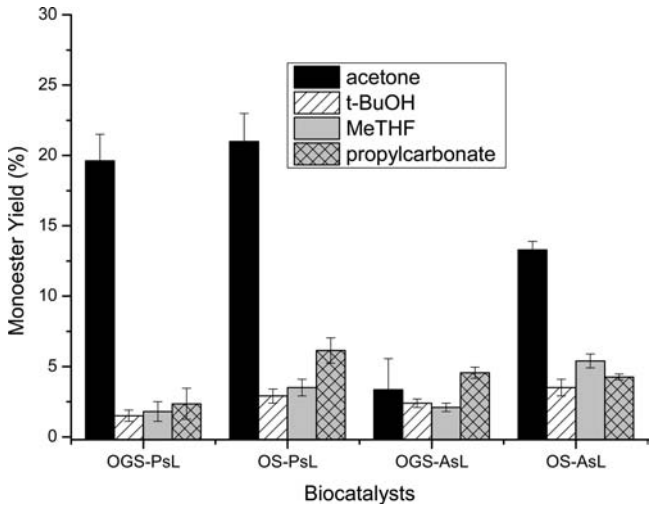

Figure 1. Monoester yield on lactulose palmitate synthesis with *Pseudomonas stutzeri* (*Ps*L) and *Alcaligens* sp. (*As*L) lipases immobilized in porous octyl-silica (OS) and octyl-glyoxyl-silica (OGS) at 40 °C after 48 h with lactulose:palmitic acid molar ratio of 1:2 in the presence of acetone (black), *t*-BuOH (hatched white), Me−THF (gray), and propylene carbonate (cross-hatched gray). Experiments were carried out by triplicate.

being the best solvent in all cases, probably because the balance between high polarity and low viscosity (Table 1) favors the persistence of the essential water layer around the active site of the lipase, the solubility of lactulose and the diffusion of substrates and products into and out of the biocatalyst. In propylene carbonate, the monoester yield was the second highest obtained, possibly because its viscosity is seven times higher than acetone, which reduces the diffusion rates of substrates and products. On the other hand, the reaction of palmitic acid to lactulose palmitate monoester is so slow when *t*-BuOH and Me−THF are used, probably because these solvents have high dielectric constants, similar to water (Table S1, Supporting Information), which favors hydrolysis[22,23] while slowing down esterification (Figure 1).

Effect of Reactions Conditions on Lactulose Palmitate Monoester Yield. Considering the results of monoester yield (Figure 1), the experimental design was done only with acetone and propylene carbonate according to the variables specified in Table 1.

[a] T, temperature (°C); r, lactulose:palmitic acid molar ratio; E, experimental data; M, value predicted by model.

The evaluation of interactions between temperature and substrates molar ratio indicates that lipase from *P. stuzeri* exhibited a similar dependence on these variables, independently from the support used for its immobilization, when the esterification reaction is carried out in acetone. Values of monoester yield obtained are presented in Table 3. The adjustment of data with ANOVA analysis, using the Design-Expert 6.0.8 software, shows that they can be properly modeled by a third-order polynomial in the case of monoester yield (R^2: 0.9945 and 0.9968 for OGS-*Ps*L and OS-*Ps*L, respectively) Some terms were eliminated from the model because its statistical interaction could be irrelevant according to the p-value (T^2r and r^2T), allowing obtaining of the polynomial equations that model the reaction behavior (eqs 5−6):

OGS-*Ps*L in acetone

$$Y(\%) = 425.9T + 64.7r + 0.9T^2 - 45.3r^2 + 0.2Tr - 7.5 \times 10^{-3}T^3 + 8.2r^3 \quad (5)$$

OS-*Ps*L in acetone

$$Y(\%) = 515.6T + 103.7r + 1.3T^2 - 63.6r^2 + 0.2Tr - 0.01T^3 + 11.1r^3 \quad (6)$$

where Y is the monoester yield, r is the lactulose:palmitic acid molar ratio, and T is the temperature.

Data optimization using response surface methodology allowed obtaining of the conditions that maximized monoester yield, as presented in Figure 2 for all biocatalysts.[24,25] The graphical analysis indicates that yield is positively affected by temperature and molar ratio. These models predict that the highest values of monoester yield are obtained for both *Ps*L biocatalysts when the reaction is carried out at 47 °C and lactulose:palmitic acid molar ratio of 1:3, with predicted values of 39.7% and 49.4% for OGS-*Ps*L and OS-*Ps*L, respectively.

Biocatalysts obtained with lipases from *Alcaligenes* sp. exhibited a similar trend for yield, independently of the immobilization support, but those from *P. stutzeri* showed a different behavior when the reaction was carried out in acetone (Figure 2). In the latter case, the monoester yield was adjusted to a second-order polynomial (R^2: 0.9044 and 0.9447 for OGS-*As*L and OS-*Ps*L, respectively). Experimental and predicted data are shown in Table 3. The model equations obtained by ANOVA analysis for the behavior of biocatalyst of lipase from *Alcaligenes* sp. are presented below (eqs 7−8).

OGS-*As*L in acetone

$$Y(\%) = 28.5 - 1.1T - 8.3r + 0.04T^2 + 2.9r^2 - 0.18Tr \quad (7)$$

OS-*Ps*L in acetone

$$Y(\%) = -30.8 + 2.6T - 26.4r - 0.04T^2 + 3.2r^2 + 0.5Tr \quad (8)$$

where Y is the monoester yield, r is the lactulose:palmitic acid molar ratio, and T is the temperature.

In the case of OS-*As*L, the best reaction conditions were similar to those found with OGS-*Ps*L and OS-*Ps*L: 47 °C and molar ratio of substrate 1:3, although a lower value of yield was obtained (Y = 29.5%). In the case of OGS-*As*L, best reaction conditions were 47 °C and a molar ratio of substrate 1:1, at which 20.4% yield was obtained. Differences obtained among biocatalyst can be attributed to the fact that the lipase from *Alcaligenes* sp. is less sensitive to changes in its 3D structure caused by the immobilization by adsorption into hydrophobic surface because this lipase, different from the one from *P. stutzeri*, has only one lid.[26,27] The values are consistent with the response surface for every biocatalyst (Figure 2), showing that the maximum values are unique in both cases.

When propylene carbonate was used as solvent, the monoester yield trend obtained with both biocatalysts could be properly modeled by a second-order polynomial (eqs 10−12) that according to ANOVA analysis represent a good statistical adjustment between predicted and experimental values, as shown in Table 4.

OGS-*Ps*L in propylene carbonate

$$Y(\%) = -13.20 + 0.54T + 3.77r - 4.88 \times 10^{-3}T^2 - 0.38r^2 - 0.06Tr \quad R^2 = 0.938 \quad (9)$$

OS-*Ps*L in propylene carbonate

$$Y(\%) = -10.37 + 0.59T + 2.44r - 6.39 \times 10^{-3}T^2 - 0.51r^2 - 4.11 \times 10^{-4}Tr \quad R^2 = 0.867 \quad (10)$$

where Y is the monoester yield, r is the lactulose:palmitic acid molar ratio, and T is the temperature.

Figure 3 shows the response surfaces for the yield of all biocatalysts during palmitate lactulose synthesis using propylene carbonate. In this case, a different response surface was obtained for each biocatalyst, indicating that the high viscosity of propylene carbonate (Table S1, Supporting Information) produced a more significant effect on the catalytic behavior of the immobilized lipases due to the extra stiffness in the 3D structure when they were immobilized into OGS support. This is reflected by the fact that the type of solvent and the reaction conditions (temperature and substrates molar ratio) at which the highest yield was obtained are different for each biocatalyst (Table 5); however, they were similar when lipases were immobilized in OS, which does not occur when acetone is used as reaction medium, showing the strong effect of the high viscosity of propylene carbonate in *P. stutzeri* lipase activity reducing the yield obtained with this enzyme more strongly than with the enzyme from *Alcaligenes* sp. In the same way, the yield was the lowest when the reaction was catalyzed by OGS-PsL and lower in propylene carbonate than in acetone, also showing the marked effect of viscosity on the performance of this lipase (Table 5).

Considering the results obtained at optimum conditions (Table 5), the effect of reaction time and biocatalyst to substrate mass ratio were evaluated. When the reaction time was decreased to one-half (down to 24 h), and the biocatalyst dose was doubled (up to 200 IU per gram of palmitic acid),

DOI: 10.1021/jf505222x
J. Agric. Food Chem. 2015, 63, 3716−3724

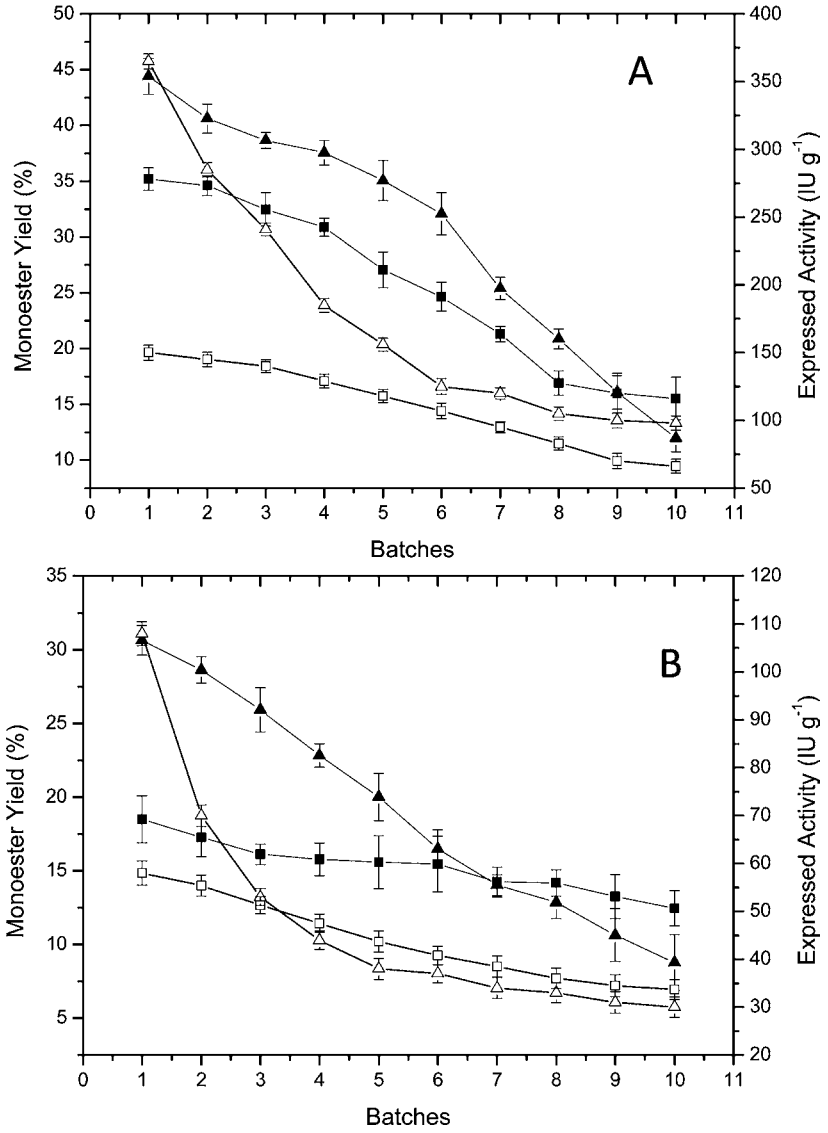

Figure 4. Monoester yield (filled symbols) and hydrolytic expressed activity (empty symbols) during reaction with lipase from *Pseudomonas stutzeri* (A) and from *Alcaligenes* sp. (B) immobilized in octyl-silica (OS) (triangles) and in octyl-glyoxyl-silica (OGS) (squares) in successive batch operation (24 h of operation in each batch) in the synthesis of lactulose palmitate monoester under optimal conditions. Experiments were carried out in triplicate.

similar monoester yields and specific productivities were obtained than those achieved in the experimental design, showing that the performance of the biocatalyst is determined by the enzyme dose and the reaction time, as expected. Differences in the values of yield and productivity between both conditions were lower than 5% (data not shown).

Operating Performance in Successive Batches. Considering the lactulose palmitate monoester yields obtained with all biocatalyst in acetone and propylene carbonate, the biocatalyst reuse was tested in successive 24 h batch operation, using acetone as reaction medium at the optimum reactions conditions (Table 5) with 200 IU per gram of palmitic acid. Yield and cumulative productivity of palmitate monoester synthesis obtained are presented in Figures 4 and 5. After 10 successive batches, monoester yields obtained with all lipase biocatalysts from *P. stutzeri* progressively decreased with each batch. (Figure 4A); however, in the last evaluated batch, the relative hydrolytic activity of OGS-*Ps*L biocatalyst remained higher than the one of OS-*Ps*L in the same batch (44.1% and 26.9% with respect to the initial batch, Figure 4A). On the other hand, lipase from *Alcaligenes* sp. exhibited a different behavior, showing similar values for monoester yield after each batch when immobilized in OGS support (Figure 4B), probably because in this case the additional stiffness provided by covalent bonding to the support precluded its inactivation; the opposite happened when this lipase was immobilized only by adsorption in OS support (67.4% and 28.6% respect to initial, OGS-*As*L and OS-*As*L, respectively, Figure 4B). This behavior was the expected for the lipases immobilized in two steps: adsorption by the hydrophobic pocket and then covalent bond formation with the lysine residues near to the active pocket.[13]

Evaluation of specific productivity in successive batches showed a similar trend regardless of the lipase (Figures 5). In this case, the biocatalysts obtained with octyl silica had a better behavior batch after batch, generating a higher increase in the cumulative productivity in comparison with the biocatalyst obtained with glyoxyl-octyl silica. This behavior can be explained considering the initial hydrolytic activity because

DOI: 10.1021/jf505222x
J. Agric. Food Chem. 2015, 63, 3716−3724

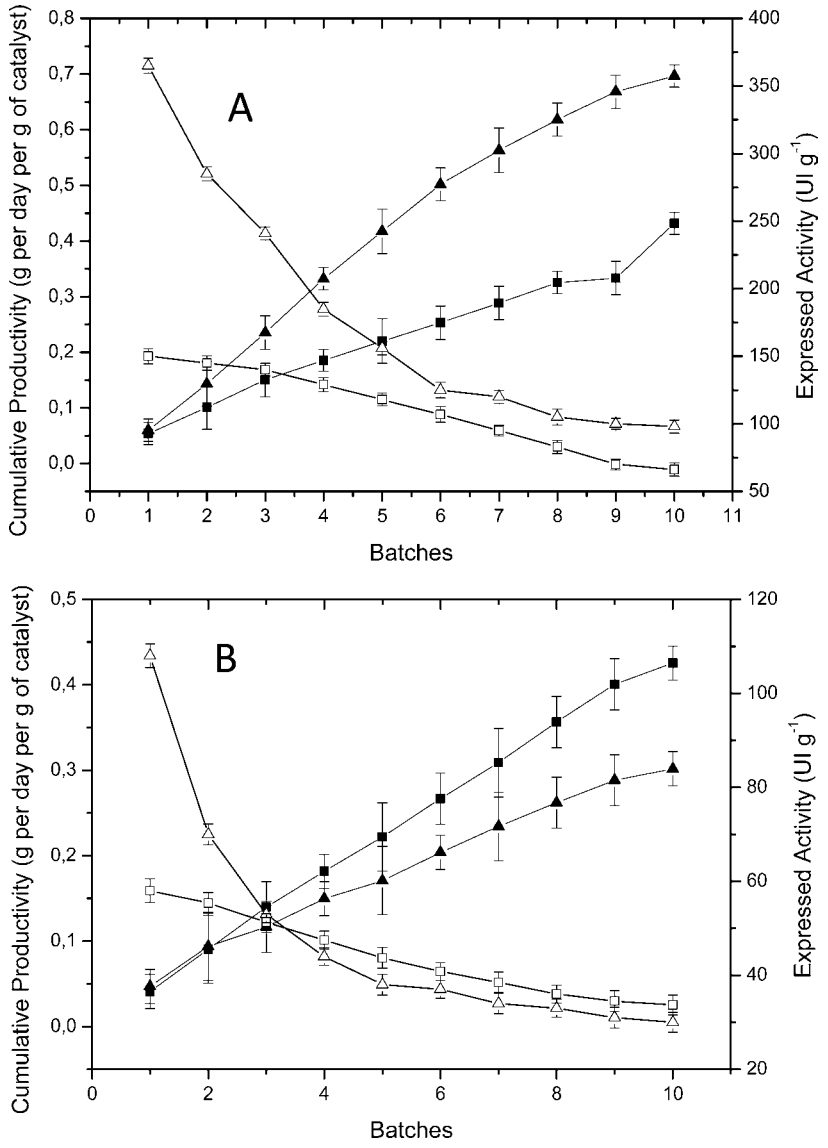

Figure 5. Cumulative productivity (filled symbols) and hydrolytic expressed activity (empty symbols) during reaction with lipase from *Pseudomonas stutzeri* (A) and from *Alcaligenes* sp. (B) immobilized in octyl-silica (OS) (triangles) and in octyl-glyoxyl-silica (OGS) (squares) in successive batch operation (24 h of operation in each batch) in the synthesis of lactulose palmitate monoester under optimal conditions. Experiments were carried out in triplicate.

biocatalysts immobilized by adsorption expressed a higher activity (OS-*Ps*L and OS-*As*L), making the increase in productivity faster than in the case of OGS-*As*L and OGS-*Ps*L (Figures 5). However, it was expected that the cumulative productivity of OGS-*As*L biocatalyst will be higher than OS-*As*L after many batches because in this case the operational stability was significantly higher that the OS-*As*L (Figure 5B).

Lipases from *Alcaligenes* sp. and *P. stutzeri* immobilized in silica with different functional groups were used for the synthesis of lactulose palmitate monoester with very good yields and specific productivities. Solvents, temperature, and substrates molar ratio influenced the biocatalyst performance, best results being obtained with both lipases when acetone was used as solvent.

Enzymatic immobilization influenced also the monoester yields and productivities obtained with each biocatalyst, showing that covalent immobilization into glyoxyl-octyl silica could produce a fairly active and robust biocatalyst able to be reused several times.

AF from *Streptomyces chartreusis* GS901 demonstrated slight reacting with this substrate.[2,18] In contrast, AbfD3 from *Thermobacillus xylanilyticus*, also a member of GH 51, was found to be extremely active on arabinoxylan.[19] Accordingly, it is difficult to find regularity in the substrate specificity of AFs. Consequently, the definition of substrate specificity of certain AFs needs amount of experimental attempts; however, this is cost- and labor-intensive.

Structure understanding and theoretical computation are popular assisting means in the research of various enzymes, including analysis of substrate specificity, rational design of stable protein, and mutation prediction on proteins.[20,21] For example, the programs like PREDIKIN and CaSPredictor were especially written for the prediction of substrate specificity in protein serine/threonine kinases, cytochrome P450, and caspases, achieving medium to good performances.[22−24] In the absence of computational tools, substantial and reliable crystal structures of substrate−enzyme complex were utilized with no hesitation for substrate-specificity analysis with the assist of the automated protocols like SOLVE, ARP/wARP, and REFMAC.[25] In the situation no experimental resulted structure is feasible; the closely related structure can be relied on for molecular modeling of the enzyme under study. And substrate specificity can also be analyzed according to the information obtained from ligand docking through software like Autodock.

We found some AF genes from different strains including *Celf_3321*, "AF domain-containing protein" from *Cellulomonas fimi* ATCC 484, by gene mining on the NCBI Web site (http://www.ncbi.nlm.nih.gov/). In this paper, we described the cloning and expression of this gene in *Escherichia coli* (*E. coli*), termed as *abfCelf*. The expressed enzyme AbfCelf displayed a relatively higher AF activity among the mined AFs. Then, AbfCelf was characterized, and the catalytic activities toward different substrates were determined after purification due to that the substrate specificity of GH 51 AFs was different. In case of no ready-made professional computational tools and crystal structure are available for AbfCelf, structure and mechanism based methods were applied to analyze substrate specificity to the greatest extent. The structure of AbfCelf was built by automated protein structure homology modeling from the Swiss Model server (http://swissmodel.expasy.org/). Substrates bind with the structure of AbfCelf by using Autodock 4.2, and supplementary analysis was conducted by using the discovery studio 4.0. The experimental results were compared with docking values, which helped to analyze substrate specificity of AbfCelf.

MATERIALS AND METHODS

Chemicals and Reagents. Substrates 4-nitrophenyl-α-L-arabinofuranoside (PNP-Abf), PNP-α-D-xylopyranoside, PNP-β-D-xylopyranoside, L-(+)-arabinose, and xylan (from beechwood) were purchased from Sigma-Aldrich Co., Ltd. (St. Louis, MO, U.S.A.). Sugar beet linear 1,5-α-arabinan, sugar beet red debranched arabinan, wheat flour arabinoxylan (medium viscosity), larch arabinogalactan, arabinan (sugar beet), arabinobiose, arabinotriose, and arabinotetraose were obtained from Megazyme International Ireland Co., Ltd. (Wicklow, Ireland). Gum arabic power and soluble starch were from Shanghai Hushi Co., Ltd. (Shanghai, China). Genomic DNA extraction kits, plasmid extraction kits, gel extraction kits, and Ni−Sepharose resin were purchased from Tiangen Biotech Co., Ltd. (Beijing, China). All other molecular cloning reagents were from Takara Biotechnology Co., Ltd. (Dalian, China). Other chemicals used in this study were of analytical grade or higher.

Strain, Media, and Plasmids. The strain used in this study, *C. fimi* ATCC 484, was obtained from own preservation, which was subcultured from a stock culture (50% glycerol) made from the original isolate. *E. coli* DH5α, *E. coli* BL21 (DE3), and the plasmid pET28a (+) were used for cloning and expression. Transformants were grown in Luria−Bertani (LB) medium (1% peptone, 1% NaCl, and 0.5% yeast extract) with 100 μg/mL kanamycin.

Sequence Analysis. Multiple nucleotide sequence alignment of gene *abfCelf* was performed with the DNAMAN program. The molecular weight and pI were predicted by using the Compute pI/Mw tool on the ExPASy Bioformatics Resources Portal (http://web.expasy.org/compute_pi/).

Cloning, Expression, and AbfCelf Purification. The coding sequence of *abfCelf* was amplified by polymerase chain reaction (PCR) with the following forward and reverse primers: forward primer for *abfCelf*, 5′-TTTGGATCCCCTCAGCGCGCCACCGT-3′; reverse primer for *abfCelf*, 5′-TTTGAATTCGCGGGTCAGGGTCGCCG-3′. The products of PCR reaction were cloned in the plasmid pET28a (+) containing both C- and N-terminal His_6-tags for purification of AbfCelf.

The recombinant plasmid was transformed into *E. coli* BL21 (DE3) and grown on solid LB medium. The transformation of *E. coli* strains was performed as described previously.[26]

The target protein was purified by using Ni−Sepharose through eluting with imidazole in a linear gradient from 10 to 500 mM. The active fractions were identified by 12.5% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS−PAGE). Then, imidazole was ultrafiltered by using a 15 mL 10 kDa Millipore's Amicon Ultra-15 centrifugal filter device (Millipore, MA, U.S.A.). The concentrated active fractions were stored in 100 mM phosphate buffer (pH 7.0) containing 10% glycerol in several aliquots at −20 °C. One aliquot was used for enzyme activity verification as described in the following section.

AF Assay and Protein Measurement. The reaction system for AF activity determination consisted of 30 μL of PNP-Abf (7 mM) in 205 μL of sodium acetate buffer. An amount of 15 μL of diluted enzyme sample (10−50 dilution volume by 100 mM phosphate buffer according to the enzyme protein concentration) was incubated at 40 °C for 15 min, then the reaction was stopped by adding 850 μL of 1 M Na_2CO_3. Finally, absorbance at 405 nm was read by using a UV-1200 spectrophotometer (MAPADA, Shanghai, China). One unit of AF activity was defined as the amount of enzyme that liberates 1 μmol of 4-nitrophenol (PNP) per min in the reaction mixture under these assay conditions. The protein content was determined using Bradford reagent with bovine serum albumin (BSA) as standard. Standard curves of PNP and BSA are shown in Figure S1 in the Supporting Information. The molecular mass of the enzyme AbfCelf was determined by SDS−PAGE on a 12.5% polyacrylamide gel. Proteins were visualized by staining with the Coomassie brilliant blue R 250. All assays were performed in triplicate batches, and the results are presented as means ± standard deviation (SD).

Enzymatic Properties. The optimum pH was determined by detecting the enzyme activities in sodium acetate buffer (pH 4.0−6.0), sodium phosphate buffer (pH 6.0−8.0), and Tris−HCl buffer (pH 8.0−9.0) at 40 °C for 15 min. The optimum temperature was determined by measuring the enzyme activities of reactions incubated at temperatures ranging from 5 to 70 °C in 100 mM sodium acetate buffers (pH 6.0) for 15 min. To estimate pH stability, the enzyme was incubated in buffers ranging from pH 4.0 to 8.0 at 40 °C for various periods. And for temperature stability, the enzyme was incubated in 100 mM sodium acetate buffers (pH 6.0) at temperatures ranging from 40 to 60 °C for various phases. Then, the residual enzyme activity was measured under optimum condition.

The kinetic parameters, apparent K_m, and V_{max} values were determined through the Lineweaver−Burk plot method under optimum condition by using PNP-Abf at concentrations ranging from 0.02 to 2 mM for 5 min of reaction.[27]

Substrate Specificity. Substrate specificity was estimated with different synthetic PNP-glycosides, oligosaccharides, and polysacchar-

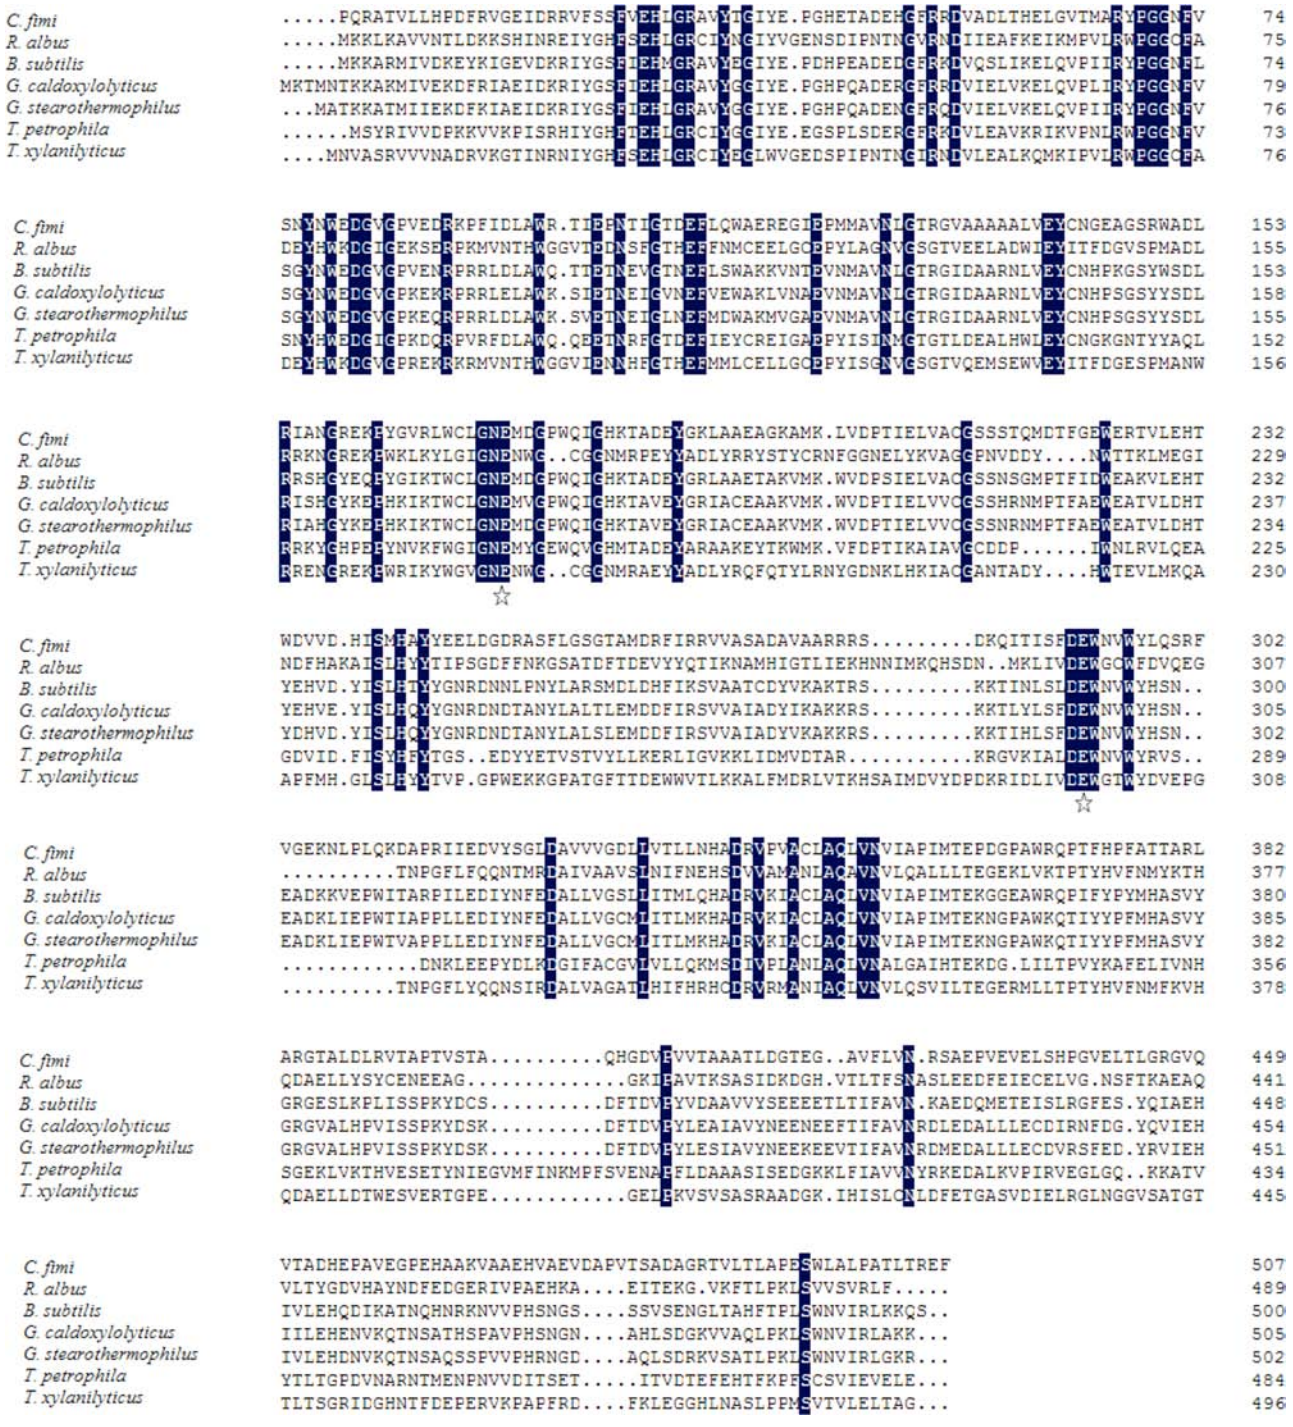

Figure 1. Multiple sequence alignment of AbfCelf with some GH 51 AFs. AbfCelf was compared with AFs from *R. albus* 8 (AEE64774), *B. subtilis* 168T$^+$ (CAA99595), *G. caldoxylolyticus* TK4 (ABI34800), *G. stearothermophilus* T-6 (AAD45520.2), *T. petrophila* RKU-1(ABQ46651), and *T. xylanilyticus* T3 (CAA76421). The catalytic residues are marked with asterisks. Residues that are identical in all sequences are shaded in blue.

ides. PNP-α-D-xylopyranoside and PNP-β-D-xylopyranoside were used as substrates with the method similar to AF assay.

For nonchromogenic substrates, the hydrolysis products were determined by high-performance anion-exchange chromatography (HPAEC) under the following conditions: system, Agilent 1100 series system (Agilent, CA, U.S.A.); column, Waters Sugar-pak1 column (300 mm × 6.5 mm; Waters, MA, U.S.A.); mobile phase, double-distilled deionized and degassed water; flow rate, 0.5 mL/min; column temperature, 80 °C. The eluted compounds were detected by refractive index. One unit of enzyme activity was defined as 1 μmol of L-arabinose produced per min. The nonchromogenic substrates included α-1,5-linked oligosaccharides, xylan from beechwood, linear 1,5-α-arabinan, wheat flour arabinoxylan, larch arabinogalactan, arabinan (sugar beet), gum arabic power, and starch soluble solutions. The substrate level was always 2% w/v.

Homology Modeling. The structure of AbfCelf was built by homology modeling from Swiss Model server with the crystal structure of AbfA from *Geobacillus stearothermophilus* T-6 (1QW9, http://www.rcsb.org/pdb/explore/explore.do?structureId=1QW9) as template. The structure, especially loops, was optimized for energy minimization by Modeler 9.12. Ramachandran plot (RC plot) analysis was used to validate the structure of AbfCelf by using PROCHECK.[28]

DOI: 10.1021/jf5059683
J. Agric. Food Chem. 2015, 63, 3725−3733

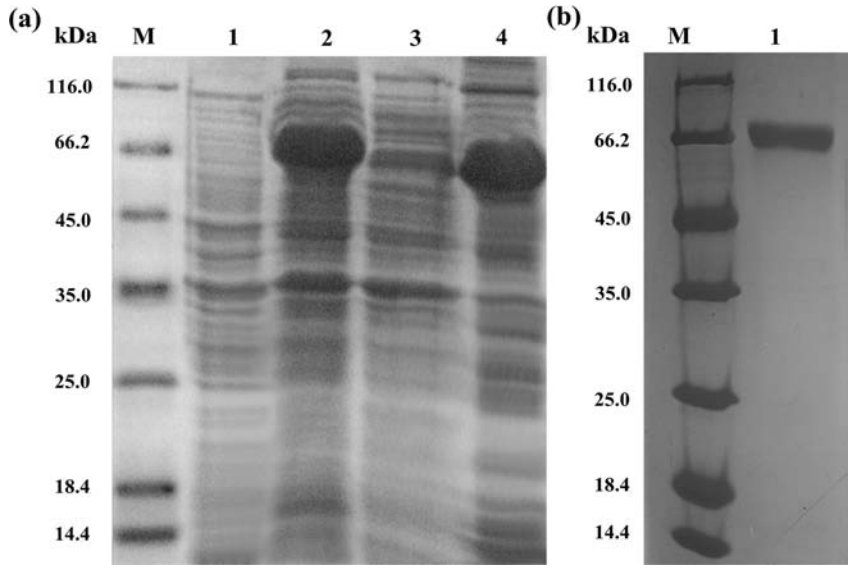

Figure 2. Expression and purification of AbfCelf. (a) Analysis of the protein expression (lanes: M, molecular marker; 1, crude cell lysate after cold osmotic shock of wild BL21; 2, crude cell lysate after cold osmotic shock; 3, soluble fraction of the crude cell lysate after cold osmotic shock; 4, insoluble fraction of the crude cell lysate after cold osmotic shock); (b) recombinant AbfCelf purified by Ni−Sepharose column.

Docking. Autodock 4.2 was selected as the docking tool to predict protein binding partners based on initial-stage flexible-body docking algorithm, according to the User's Guide.[29] The structure of AbfCelf was used as macromolecular receptor in the docking simulation. The structure of ligands was generated with Chemdraw software and the energy-minimized with ChemBio3D Ultra 11. The ligands were sugar molecules, including arabinobiose, arabinotriose, arabinotetraose, α-L-arabinofuranose, α-D-xylopyranose, β-D-xylopyranose, PNP-α-L-arabinofuranose, PNP-α-D-xylopyranose, and PNP-β-D-xylopyranose.

The amino acids of AbfCelf molecule which may form hydrogen bonds with ligands were selected as the flexible amino acid, and the grid box was selected as a certain radius, 40 Å, with the center coordinates of x, 68.676; y, 43.846; z, 75.444. The ligands were docked into AbfCelf with these parameters by using Autodock 4.2 with MGLTools. Binding energy (ΔG, kcal/mol) of Autodock, about ligand−receptor combination, was used as the final criterion to identify the best docking mode.

RESULTS

Sequence Analysis of *abfCelf*. The gene *abfCelf* (NC_015514) had an open reading frame of 1521 bp encoding a protein of 507 amino acids. The protein has a calculated molecular mass of 55.6 kDa and a calculated isoelectric point of 4.87.

AbfCelf was classified as a member of the GH 51 based on its protein sequence, which was also included in CAZy database (Carbohydrate Active enZYmes database, http://www.cazy.org). Moreover, the amino acid sequence of AbfCelf displayed 20.3%, 45.2%, 44.6%, 45.2%, 29.7%, and 22.7% identity with the sequences of AFs from *Ruminococcus albus* 8, *Bacillus subtilis* 168T$^+$, *G. caldoxylolyticus* TK4, *G. stearothermophilus* T-6, *Thermotoga petrophila* RKU-1, and *T. xylanilyticus* T3, respectively (Figure1). The sequence variation may be associated with loop regions and give rise to the diverse substrate-specificity characteristic.

The catalytic domain of AbfCelf comprised two key active sites, both Glu, which were conserved in all members of GH 51 family. On the basis of the results of sequence and structure alignment between AbfCelf and 1QW9, Glu^{173} is the acid/base, and Glu^{292} is the nucleophile.

Cloning, Expression, and AbfCelf Purification. The gene *abfCelf* was cloned and expressed in pET28a (+). Parts of the recombinant AbfCelf overexpressed in *E. coli* BL21 (DE3) were soluble and active (Figure 2a). The enzyme purified by Ni−Sepharose column is shown in Figure 2b, which indicated that the molecular weight of native protein after purification was about 66 kDa. The final preparation of purified AbfCelf was 0.19 mg/mL, and the specific activity measured under optimum condition was 19.4 U/mg.

Enzymatic Properties. The optimum reaction temperature of purified AbfCelf was at 40 °C (Figure 3a). AbfCelf could maintain most of the initial activity after incubation at 40 °C for 20 h while losing most activity mostly when incubated at 60 °C for 30 min (Figure 3b). AbfCelf reached the highest activity at pH 6.0, 40 °C in 100 mM sodium acetate buffer and achieved about 57.9% and 72.1% of the maximal activity at pH 5.0 and pH 7.0, respectively (Figure 3c). AbfCelf was stable at pH 6.0 compared with no activity remaining after 4 h of incubation at pH 4.0 (Figure 3d).

Kinetic parameters were measured at 40 °C, pH 6.0 for 5 min by the Lineweaver−Burk plot, which is shown in Figure S2 in the Supporting Information. The K_m, V_{max}, and k_{cat} toward PNP-Abf are 1.5 mM, 112.4 U/mg, and 123.6 s^{-1}, respectively. The K_m's of AbfD3 from *T. xylanilyticus*, ABF2 from *P. purpurogenum*, and AbfATK4 from *G. caldoxylolyticus* are 0.7 mM, 98.6 μM, and 0.17 mM, respectively.[16,18,19] The V_{max}'s of AF from *B. pumilus* PS213 and AbfD3 are 52.9 and 456 U/mg, respectively.[19,30] Compared with these reported GH 51 AFs, AbfCelf had an average kinetic value, indicating the affinity of AbfCelf toward PNP-Abf was in a medium level.

Substrate Specificity. The substrate specificity of the enzyme was tested by using several oligosaccharides, polysaccharides, heteropolysaccharide, and PNP-glycosides. Sugar beet arabinan, linear 1,5-α-arabinan, and wheat flour arabinoxylan were degraded by AbfCelf when the reaction time was prolonged to 2 h. In contrast, beechwood xylan, soluble starch, gum arabic, and larch arabinogalactan were resistant to the action of AbfCelf even though the enzyme was added in excess. Table 1 displays the specific activity of AbfCelf on different

DOI: 10.1021/jf5059683
J. Agric. Food Chem. 2015, 63, 3725−3733

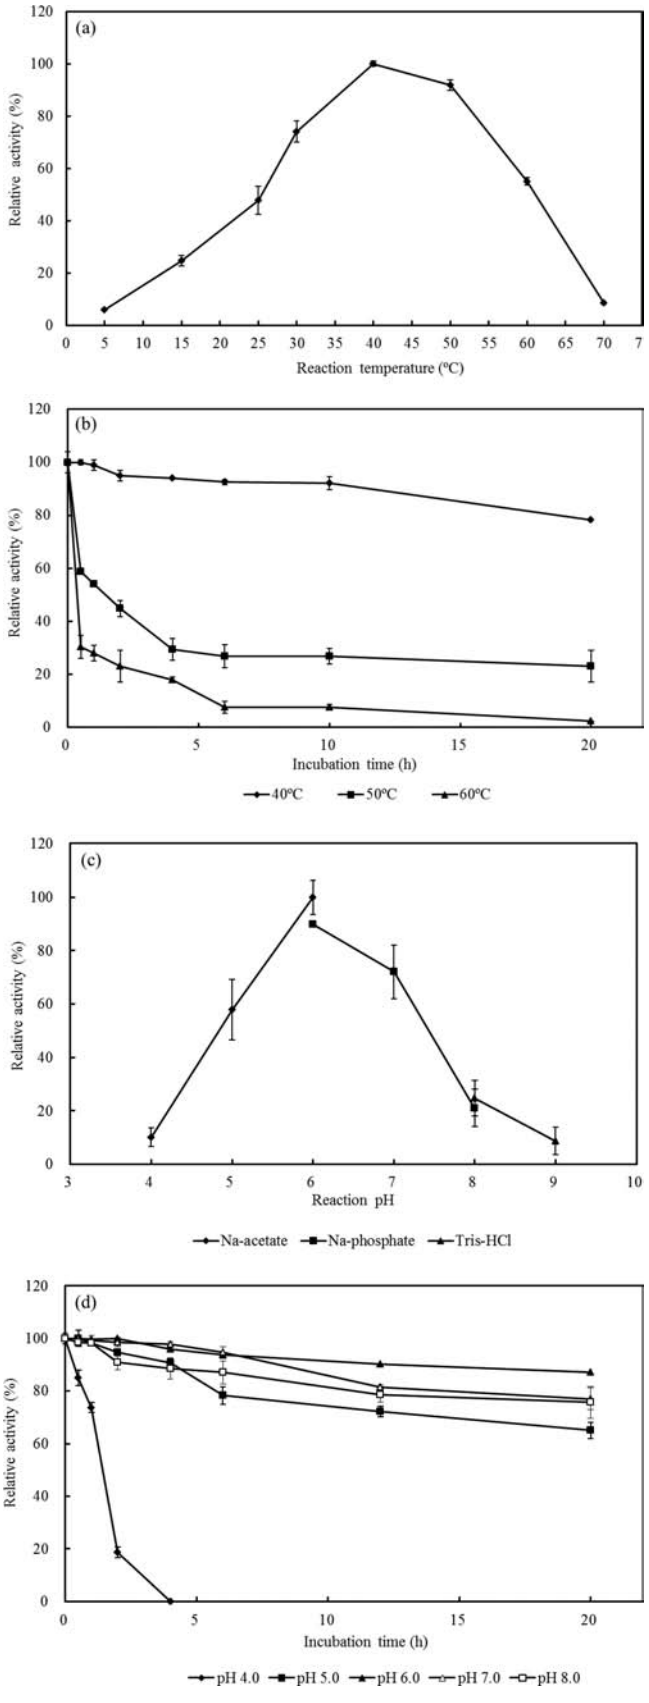

Figure 3. Biochemical properties of AbfCelf on pH and temperature. (a) Effect of temperature on enzyme activity. Reactions were conducted for 15 min in 100 mM, pH 6.0, sodium acetate buffer. (b) Effect of temperature on enzyme stability. The enzyme was incubated at temperatures ranging from 40 to 60 °C in 100 mM, pH 6.0, sodium acetate buffer for a period of time. (c) Effect of pH on enzyme activity. Activity was measured at 40 °C for 15 min at the indicated pH values in 100 mM of each buffer. (d) Effect of pH on enzyme stability. The enzyme was incubated at 40 °C in pH 4.0−8.0 100 mM buffers for a period of time. After that, residual activity was assayed at optimum temperature and pH. In all panels, the highest activity was taken as 100%. Reaction substrate was 0.84 mM PNP-Abf.

oligosaccharides and PNP-glycosides. AbfCelf was able to hydrolyze PNP-Abf and arabino-oligosaccharides, whereas no activity was detected toward PNP-α-D-xylopyranoside and PNP-β-D-xylopyranoside.

Homology Modeling. The structure of AbfCelf was built using the Swiss Model server with the chain B of 1QW9 as template. The sequence identity between template and target was 48.6%, and the QMEAN *Z*-score of the structure was −1.893, which was an evaluation parameter in homology modeling.[31,32] RC plot analysis showed that out of 502 residues, 84.4% were in most favored region, 14.4% in additionally allowed region, and 0.9% in generously allowed region. Only 0.3% of residues were in disallowed regions, indicating that the conformation was reliable.

As shown in Figure 4a, AbfCelf was organized into two domains: a characteristic $(\beta/\alpha)_8$ barrel (residues 19−382) and a 12-stranded β-sandwich with a jelly roll topology (residues 1−18 and 383−502). In Figure 4b, the coloring approximates the actual electrostatic potential. The catalytic area was hydrophobic, where binding clefts and protein surfaces conferred the extensive range of specificities.

Docking. After building the reliable structure of AbfCelf, substrate analysis can be carried out with the aid of the docking method. For the reason for lacking reliable tools (software), docking an enzyme with its macrosubstrate precisely is almost impossible today. Thus, this study examined only small oligosaccharides and PNP-glycosides in silico.

ΔG obtained from Autodock was used as a rapid evaluation of binding free energy.[29] Namely, the binding affinity between ligand and receptor can be expressed in terms of ΔG, which is given in Table 1. The negative number of ΔG means the positive binding affinity between the ligand and receptor. The more negative ΔG is, the larger is the binding constant.[33] In contrast, when ΔG was a positive number (e.g., arabinotetraose), the ligand could not combine into the receptor, and thus the docking cannot be finished. As Table 1 shows, the ΔG of arabinotetraose was the only one positive number in the total tested substrates. The ΔG's of other substrates and all products were negative numbers, among which arabinotriose, arabinobiose, and β-D-xylopyranose achieved the most negative numbers.

DISCUSSION

The strain *C. fimi* was sequenced in 2013, and the gene *Celf_3321* was marked as "AF domain-containing protein".[34] This work confirmed the gene segment encoding a GH 51 AF. Moreover, the AF from *C. fimi* was not reported before. Therefore, it is possible that this enzyme would be a novel AF with prospect activity that was worthy to be studied.

GH 51 AFs including AbfCelf can remove both α-1,2- and α-1,3-arabinofuranosyl moieties from arabinan and arabinoxylans. AbfCelf was also active on α-1,5-linked oligosaccharides, which is a characteristic of GH 43 AFs.[13] The substrate specificity of

PNP-α-D-xylopyranose		-6.17	α-D-xylopyranose		-7.13	< 0.01
PNP-α-L-arabinofuranose		-6.79	α-L-arabinofuranose		-6.3	19.4

AbfCelf is partly different from some previously well-characterized GH 51 AFs such as AbfATK4 from *G. caldoxylolyticus* TK4.[16]

The substrates of AFs include natural polymeric polysaccharides and chromogenic PNP-glycosides. The formers are sugar beet arabinan, debranched arabinan, linear 1,5-α-arabinan, arabinogalactan, gum arabic, arabinoxylan (wheat/rye), xylan (larchwood/beechwood/oat spelt), CMC, mannan, glucomannan, and Avicel, etc. Many relative enzymes are necessary for the complete degradation of these natural substrates. On the other hand, different synthetic substrates were diffusely used also, such as PNP-α/β-L-arabinofuranoside, PNP-α/β-L-arabinopyranoside, PNP-α/β-D-xylopyranoside, PNP-α-D-galactopyranoside, PNP-α/β-D-glucopyranoside, PNP-β-D-fucopyranoside, PNP-α-L-rhamnopyranoside, PNP-β-D-glucosaminide, PNP-α-D-mannoside/mannopyranoside, PNP-α/β-D-galactoside, and so on. These PNP-glycosides can be degraded by a single enzyme, and therefore, they are used to detect the activity of such enzyme. Consequently, the substrates cover 30 kinds of various PNP-glycosides and polysaccharides for AFs, and the large number of substrates leads to large amount of experimental determination in the analysis of substrate specificity. Thus, structure understanding and theoretical computation were utilized to analyze the substrate specificity of GH 51 AFs in this paper.

Among many enzymatic reactions, product release or substrate binding is the rate-limiting step.[35] The more negative ΔG of substrate implied stronger substrate binding affinity in the active center, while the more negative ΔG of product signified the product released more difficultly. PNP-β-D-xylopyranose and PNP-α-D-xylopyranose bound into AbfCelf with ΔG below −6 kcal/mol, while that value of the product was below −7 kcal/mol (Table 1). Apparently, AbfCelf had a higher binding affinity with the product than these substrates, which meant product would occupy the active site and hinder the next binding of a new substrate molecule. In reality, the enzyme activity of AbfCelf on these pyranosidic synthetic substrates also cannot be detected. In these reactions, product release is the rate-limiting step.

AbfCelf displayed specific activity as only 0.05 U/mg toward arabinotetraose, the biggest substrate among the six tested ones, while obtained a positive ΔG of this substrate. In this case, substrate binding is the rate-limiting step, due to the difficulty for the substrate to enter the binding crevice of AbfCelf during docking.

Moreover, PNP-α-L-arabinofuranoside bound with AbfCelf easily and product α-L-arabinofuranoside released rapidly according to the ΔG in Table 1. The real AbfCelf activity on PNP-α-L-arabinofuranoside was coincident with this prediction. Additionally, AbfCelf exhibited a higher activity with arabinobiose than arabinotriose, which was in accord with the difference of ΔG between the substrate and product of docking experiment. Thus, ΔG, and the difference of ΔG between the substrate and product, could describe enzymatic reactions and suggest the reaction possibility.

The structure of AbfCelf is shown in Figure 4. Its $(\beta/\alpha)_8$ barrel, which exists commonly in various GH families, participated in substrate binding and catalysis. The circularly permuted form of the catalytic $(\beta/\alpha)_8$ barrel varied in location, size, and shape. There is correlation of specificity differences with sequence variation in the $\beta \rightarrow \alpha$ segments of the characteristic $(\beta/\alpha)_8$ barrel.[36] The β-sandwich of AbfCelf was previously functioned as a domain for binding the carbohydrate molecules, but lost such function during evolution.[25] The two catalytic residues (Glu173 and Glu292) were situated at C-terminal extensions of β-strands 4 and 7 in the $(\beta/\alpha)_8$ fold, which did superimpose perfectly with different GH 51 AFs. Other residues at $\beta \rightarrow \alpha$ 4, such as Gln171, Asn172, Trp178, Glu181, and Tyr189, that might contain specificity-denoting characteristics, participated in the interaction with sugar ligands.[37]

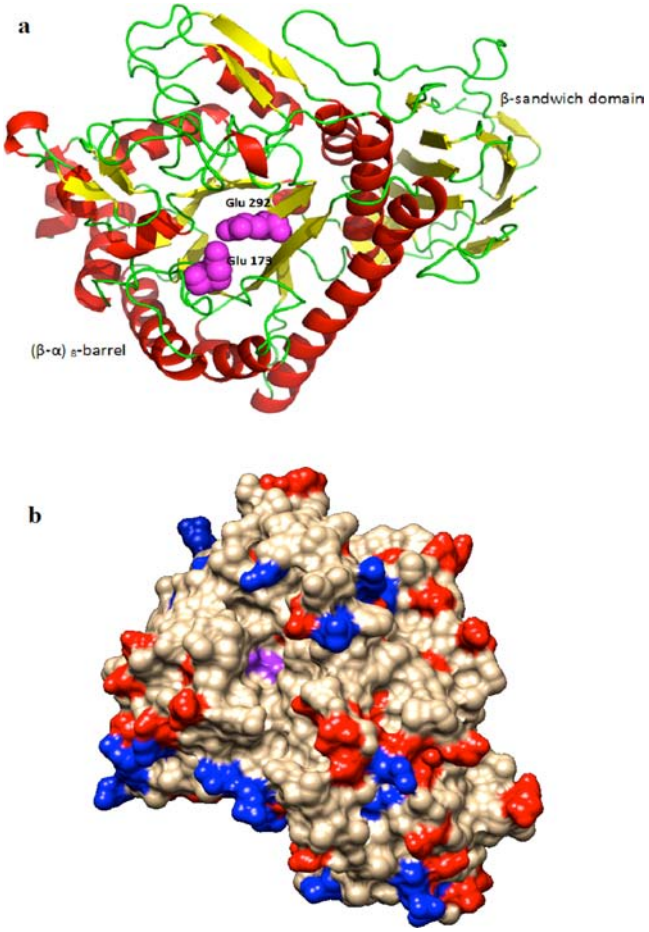

Figure 4. Structure of AbfCelf. (a) The structure of AbfCelf created by Swiss Model. The α-helices and β-sheets are shown in red and yellow, respectively. Loops and other secondary structures are shown in green. The catalytic residues, Glu[173] and Glu[292], are shown in purple balls. (b) The solvent-accessible surface of AbfCelf. Positive and negative residues are shown in blue and red, respectively. The catalytic area is shown in purple.

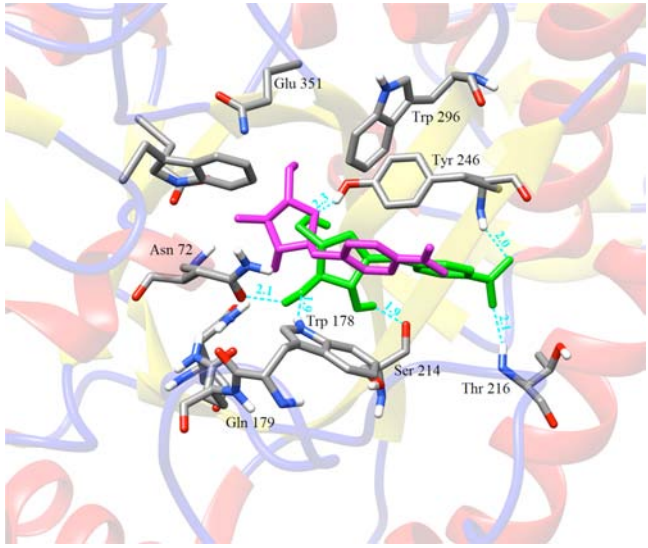

Figure 5. Interaction between ligands and key residues in the active site of AbfCelf. Overlapping of AbfCelf and the homologous structure (1QW9-B chain) in (wall-eyed) stereo. Residues are shown in stick model. PNP-Abf of AbfCelf by docking is in green, while that of template is magenta. Potential hydrogen bonds are shown as dotted blue lines; their length in angstroms is indicated. The α-helices and β-sheets are shown in red and yellow, respectively. Loops and other secondary structures are shown in blue.

The interaction between substrate and binding pocket of AbfCelf is shown in Figure 5. Some key residues were responsible for catalysis and substrate binding interactions like Glu27, Arg67, Asn172, Glu173, His242, Tyr244, Glu292, and Gln351, whose location and function are conserved in GH 51 AFs.[37] The result was in good agreement with sequence alignment in Figure 1.

AbfA crystal 1QW9 was used to test the rationality of docking method in simulating the interaction between enzyme and substrate. The conformation of the ligand with the lowest ΔG was overlapped with that of the 1QW9, which showed the main part of the substrate PNP-Abf in crystal and docking conjugate were partly coincided (Figure 5). Figure 5 also showed the hydrogen-bond network at the active site of AbfCelf. In the structure of covalent glycosyl-enzyme intermediate of AbfA, the arabinofuranose moiety was bound by a large number of hydrogen bonds, at least seven possible hydrogen bonds, which was also shown by Hövel et al.[25] In the AbfCelf complex, the whole PNP-Abf can form six hydrogen bonds and therefore was less tightly bonded than AbfA complex. Interestingly, AbfA hydrolyzed substrate with higher catalytic affinity according to its k_{cat}/K_m of 134 s^{-1} mM^{-1}, compared with that of AbfCelf, 82.4 s^{-1} mM^{-1}. The sequence identity between template and AbfCelf made difficulty in completely overlapping of the crystal and docking conjugate. In addition, the differences in side chains might also lead to the environmental diversity between crystallization and docking. AbfCelf shared less hydrogen bonds based on the docking experiment, and such results matched the lower catalytic efficiency and affinity determined experimentally, indicating the conformation of ligand docking into the binding site of AFs can be simulated in a general credibility.

Finally, the protein−ligand ΔG could manage to find putative ligands in silico and analyze the substrate specificity to some extent. Because L-arabinose residues are linked to form α-1,5-L-arabinan to which L-arabinofuranose units are attached, the lower protein−ligand ΔG of α-1,5-linked oligosaccharides exhibits potential hydrolytic activity against sugar beet arabinan, debranched arabinan, and linear arabinan.[38] Additionally, L-arabinosyl residues constitute side chains on the β-(1→4)-linked xylose backbones in xylans and arabinoxylans.[39] Accordingly, the ΔG of xylopyranoside gave a clue that PNP-xylopyranoside, xylan, and substituted xylan could be the putative ligands for AbfCelf so that some bifunctional AFs are discovered. This mainly depends on the credibility of the method.

In this study, AbfCelf was characterized and showed potent activity, 19.4 U/mg. Substrates were docked into the binding site to obtain the ΔG, indicating the reaction possibility. Then these prediction results were compared with experimental detected enzyme activity, which gave a clue of feasibility for substrate-specificity analysis in silico. After the present work, there is every possibility for us to screen virtually to select diverse bifunctional AFs with high active catalytic performance, thereby expanding the utilization and application in food industries. Also, before the characterization of an enzyme, the present approach to find putative substrates can save huge amounts of experimental labor, time, and cost. We hope to

develop better catalysts in this way for efficient production of L-arabinose and pectin in the future, and AFs will have greater prospects to provide desirable food production properties.

dried by distillation over CaH_2. Thin-layer chromatography (TLC) was performed on silica gel GF254 plates. Column chromatography was performed on silica gel (200−300 mesh). ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra were recorded on a Bruker AVANCE AV400 (400 and 100 MHz). All NMR chemical shifts were referenced to residual solvent peaks or to tetramethylsilane (TMS) as an internal standard. All coupling constants J were quoted in hertz. High-resolution mass spectra (HRMS) were obtained on an IonSpec QFT mass spectrometer with electrospray ionization (ESI). Optical rotations were recorded on a PerkinElmer 341 polarimeter. Melting points were measured on an X4 apparatus.

Herbicidal Activities. The initial herbicidal activities of compounds **1**−**4** and TA against dicotyledon weeds, including *Brassica campestris* and *Amaranthus retroflexus*, and monocotyledon weeds, including *Echinochloa crus-galli* and *Digitaria sanguinalis*, were evaluated according to a previously reported procedure.[21−23]

All title compounds were screened at a adosage of 1500 g ha^{-1}. Then, compounds TA, **1a**, **2a**, and **2f** with higher herbicidal activities were further assayed at lower dosages of 750, 375, and 187.5 g ha^{-1}. Dichlobenil was selected as a positive control. All treatments were carried out in triplicate (Tables 4 and 5).

Treatment. The emulsions of tested compounds were prepared by dissolving them in 100 μL of *N*,*N*-dimethylformamide (DMF) with the addition of a little Tween 20 and diluting with proper water to the desired concentrations. Then, these emulsions were sprayed using a microsprayer. As negative control experiments, the mixture of the same amount of water, DMF, and Tween 20 with no compounds was also tested. Herbicidal activities of dichlobenil at the same concentrations as tested compounds were carried out as positive control experiments.

Pre-emergence. Sandy clay (100 g) in a plastic box (11 × 7.5 × 6 cm) was wetted with water. A total of 15 sprouting seeds of the weed under test were planted in fine earth (0.6 cm depth) in the glasshouse and sprayed with the test compound solution.

Post-emergence. Seedlings (one leaf and one stem) of the weed were sprayed with the tested compounds at the same rate as used for the pre-emergence test.

Data Collection. For both methods, the fresh weights of three parallel plants were determined 20 days later, and the percentage inhibition relative to the controls was calculated by eq 1

$$\text{inhibition}\ (\%) = (w_c - w_t)/w_c \times 100\% \quad (1)$$

where w_c is the wet weight of the negative control and w_t is the wet weight of the tested group.

Crop Selectivity. Compounds TA, **1a**, **2a**, and **2f** were selected for crop selectivity evaluation. Conventional wheat, corn, cotton, and peanut were respectively planted in plots (diameter = 12 cm) containing test soil and grown in a greenhouse at 20−25 °C. After the plants had reached the four-leaf stage, the spraying treatment was conducted at different dosages by diluting the formulations of tested compounds with water. The visual injury and growth state of the individual plant were observed at regular intervals. The fresh weights were determined 30 days later, and the percentage inhibition relative to the controls was calculated. Dichlobenil was selected as a positive control (Table 6).

Protoporphyrinogen Oxidase (PPO) and Acetohydroxyacid Synthase (AHAS) Inhibition Activity. The recombinant tobacco PPO enzyme (mtPPO) was expressed according to the established protocol.[24−27] Oxadiazon, fluazolate, and sulfentrazone were selected as positive controls. The product of the enzymatic reaction has a maximum excitation wavelength at 410 nm and a maximum emission wavelength at 630 nm. PPO activity was assayed by measuring the formation of protoporphyrin IX at room temperature using a fluorescence detector with the excitation and emission wavelengths set at 410 and 631 nm, respectively. The concentration of protoporphyrinogen IX was determined according to the absorption of protoporphyrin IX, and the concentration of protoporphyrin IX was calculated from the calibration graph. In each assay, the stock dimethyl sulfoxide (DMSO) solution (1% total volume) of inhibitor was added to the reaction system. The final inhibitor concentration ranged from 0.005 to 500 μM. The enzymatic reaction rate was measured in a reagent buffer of 100 mM potassium phosphate (pH 7.5), 5 mM dithiothreitol (DTT), 1 mM ethylenediaminetetraacetic acid (EDTA), Tween 80 (0.03%, v/v), 200 mM imidazole, 5 μM flavin adenine dinucleotide (FAD), and approximately 0−40 μg of protein. The IC_{50} value was determined by measuring PPO activity over a range of inhibitor concentrations at a fixed substrate concentration. IC_{50} values were calculated by fitting v versus $[I]$ data to a single binding site model described by eq 2

$$y = \min + \frac{\max - \min}{1 + 10^{x - \log IC_{50}}} \quad (2)$$

where y is the percentage of maximal rate, with max and min being the y values at which the curve levels off, x is the logarithm of the inhibitor

concentration, and IC_{50} is the concentration of the inhibitor that caused 50% of the total inhibition. Because the inhibitors belong to the class of competitive inhibitors, the calculated K_i value can be obtained by applying the following relationship among K_i, K_m, and IC_{50} at any saturating substrate concentration (S) by the following eq 3.

$$K_i = \frac{IC_{50}}{S/K_m + 1} \quad (3)$$

The expression vector pQE-GMwt, containing the wild-type *Escherichia coli* AHAS II gene, was provided by professor D. M. Chipman (Ben-Gurion University). The wild-type *E. coli* AHAS II was expressed from the plasmid pQE-GMwt. A single colony of the *E. coli* strain XL1-Blue, transformed with the plasmid pQE-GMwt, was inoculated in 20 mL of Luria−Bertani (LB) medium containing 100 μg mL^{-1} ampicillin. The culture was incubated overnight at 37 °C. The overnight medium was transferred into 500 mL of LB medium in a 2 L round-bottomed flask. Then, the culture was induced with 0.5 mM isopropyl-β-D-thiogalactoside (IPTG) when A_{600} reached 0.7−0.8. Cells were grown for an additional 3 h at 37 °C and harvested by centrifugation at 6000 rpm for 10 min. The cell pellet was suspended in 10 mL of solution (10 mM imidazole, 0.5 M KCl, 50 mM Tris−HCl at pH 8.0, and 20 μM FAD) for every gram. The solution was cooled in an ice bath and subjected to disruption in a SONICS VCX500 model ultrasonic processor with a 1.3 cm flat-tip probe for 60 cycles (1 s each with 9 s pauses). The disrupted cells were centrifuged at 27000*g* for 1 h at 4 °C to remove cellular debris. The purification of 6× His tag AHAS II was carried out to near homogeneity in a single step by nickel−nitrilotriacetic acid (Ni−NTA) affinity chromatography as described in QIAexpressionist (Qiagen).[28] The enzyme was stored in aliquots at −80 °C. One aliquot was analyzed by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE), with protein concentrations determined by the method of Bradford.[29−32] The inhibitory activity of the title compounds against AHAS enzyme

in vitro was measured according to Westerfeld[33−35] and Singh[36,37] methods. Chlorimuron ethyl and bispyribac sodium were selected as a positive control. The reaction mixture contained a 50 mM potassium phosphate buffer (pH 7.5), 10 mM $MgCl_2$, 1 mM thiamine diphosphate (ThDP), 10 μM FAD, 100 mM pyruvate, and the enzyme in the absence or presence of various concentrations of inhibitors. The mixture was preincubated at room temperature for 5 min before initiation of the reaction. Then, the reaction was started by the addition of AHAS enzyme and allowed to incubate at 37 °C for 1 h, before being stopped by the addition of 3 M H_2SO_4 ($^1/_{10}$ final volume). Acetolactate was converted to acetoin by incubation at 60 °C for 15 min. Acetoin was then quantified by measuring the absorbance at 525 nm after incubation at 60 °C for 15 min with 0.5% creatine and 5% (w/v) α-naphthol. The apparent inhibition constant (K_i) values were determined by fitting the data to eq 4. The K_i values represented the concentration of the inhibitor at 50% inhibition.

$$\nu_i = \nu_\infty + (\nu_0 - \nu_\infty)/(1 + [I]/K_i) \quad (4)$$

In eq 4, ν_i and ν_0 represented the rates in the presence or absence of inhibitor, respectively, and $[I]$ was the concentration of the inhibitor. If the initial analysis indicated that the residual activity (ν_∞) at a saturating inhibitor concentration was not significantly greater

than zero, the data were reanalyzed with $\nu_\infty = 0$. K_i^{app} was calculated by nonlinear least squares and the simplex method for error minimization.[38−41] The K_i values were summarized in Table 7.

Antifungal Activity. Compounds **1**−**4** and TA were evaluated for their antifungal activities against *Candida albicans* [American Type Culture Collection (ATCC) 76615], *Candida utiliz*, *Saccharomyces cerevisia*, and *Aspergillus flavus* according to the National Committee for Clinical Laboratory Standards (NCCLS).[42] Fluconazole was selected as the control. A spore suspension in sterile distilled water was prepared from a 1-day-old culture of the fungi growing on Sabouraud agar (SA) media. The final spore concentration was 1−5 × 10^3 spore mL^{-1}. From the stock solutions of the tested compounds and reference antifungal fluconazole, dilutions in sterile RPMI 1640 medium (Neuronbc Laboraton Technology Co., Ltd., Beijing, China) were made resulting in 11 wanted concentrations (0.25−256 μg mL^{-1}) of each tested compound. These dilutions were inoculated and incubated at 35 °C for 24 h. The growth was monitored visually and spectrophotometrically. The lowest concentration (highest dilution) required to arrest the growth of fungi was regarded as the minimum inhibitory concentration (MIC). All of the antifungal activities were tested 3 times. The MICs were summarized in Table 8.

Data Collection. The tested compounds and reference drugs were prepared in Mueller−Hinton broth by 2-fold serial dilution to obtain the required concentrations of 512, 256, 128, 64, 32, 16, 8, 4, 2, 1, and 0.5 μg/mL. The data were collected only if three of the MIC values were consistent or three of the MICs were ranged in two neighboring concentrations (two MICs were consistent, and this concentration was collected).

RESULTS AND DISCUSSION

Chemistry. The total chemical synthesis of a series of thaxtomin analogues differs in R^1 and R^2 on indole, and R^3, R^4, and R^5 on the diketopiperazine ring are also synthesized. The detailed ^{1}H NMR (Table 2), ^{13}C NMR, optical rotation, and high-resolution mass spectra as well as melting point data (Table 3) of all title compounds are reported, and NMR and high-resolution mass spectrometry (HRMS) spectra are presented (see the Supporting Information).

The synthetic route of title compounds are given in Scheme 1. Compounds **8**[43] and **9**[20] were prepared according to the reported synthetic routes. Compounds **5** and **6** could be obtained in 90% yields by the deprotection of precursors **8** and **9** in solution of dichloromethane/trifluoroacetic acid (4:1, v/v) at room temperature for 30 min. The tryptophan methyl ester **7** was commercially available. The condensation of compounds **5**, **6**, and **7** with *N*-Boc-amino acid respectively in the presence of propylphosphonic acid anhydride (T3P), following by the deprotection of Boc moiety in dichloromethane/trifluoroacetic acid (4:1, v/v), afforded the key intermediates. The cyclization step[44] of the key intermediates with morpholine as a base in dichloromethane at room temperature for 48 h produced the target compounds **1a**−**1e**, **2a**−**2f**, **3a**, and **3b** in yields of 50−90%. The further methylation of compounds **1c**−**1e** and **3a** with MeI and Ag_2O afforded compounds **4a**−**4d** in yields of 80−90%.

Herbicidal Activities. The pre-emergence and post-emergence herbicidal activities in Table 4 manifest that substituents at R^1 and R^5 significantly affect the activities of title thaxtomin analogues, while the methylations of R^2, R^3, and R^4 show a weak influence on the herbicidal efficiency. It is observed that this series of compounds generally exhibits more effective pre-emergence herbicidal activities than post-emergence herbicidal activities. Compounds TA, **1a**, **2a**, and **2f** with the benzyl group and *m*-hydroxybenzyl groups at R^5 show significant pre-emergence herbicidal activity against dicotyledon

[a]MICs were determined by the microbroth dilution method for microdilution plates. [b]*C. albicans*, *Candida albicans* (ATCC 76615); *C. utiliz*, *Candida utiliz*; *S. cerevisia*, *Saccharomyces cerevisia*; and *A. flavus*, *Aspergillus flavus*.

weeds *B. campestris* (≥85.0%) and *A. retroflexus* (≥95.0%). However, when the group at R^5 is exchanged by other substituents, such as *p*-hydroxybenzyl, phenylethyl, or alkyl groups or hydrogen (compounds **1b**–**1e** and **2b**–**2e**), the herbicidal properties disappear (percent inhibitions ≤15.0% to all weeds). Then, to investigate the influence of the nitro moiety at R^1, compounds **3a** and **3b** as controls were tested. The results manifest that the herbicidal activities disappear with the removal of the nitro group. Noticeably, compound **3a** exhibits rather decreased activities (≤10.0%) in comparison to its precursor **1a** with nitro on indole. Then, further methylations of ineffective compounds **1c**–**1e** and **3a** at R^2, R^3, and R^4 to afford compounds **4a**–**4d** lead no significant enhancements of their weed control competence. Besides, benzyl and *m*-hydroxybenzyl at R^5 of these thaxtomin analogues are more favorable for herbicidal activities than other substituents. Nitro at R^1 is essential for herbicidal efficacy, and the N-methylation of R^2, R^3, and R^4 is not helpful for herbicidal activity.

Compounds TA, **1a**, **2a**, and **2f** with effective activities were selected for further herbicidal testing at lower dosages (Table 5). The results indicate that compound **1a** shows moderate activity at 750 g ha^{-1} dosage to weeds but low activity at a lower dosage in most instances. Compounds TA, **2a**, and **2f** exhibit generally better weed control ability against dicotyledons (*B. campestris*, *A. retroflexus*, and *Abutilon theophrasti*) than monocotyledons, which are comparable or even better than positive control dichlobenil even at low dosage of 187.5 g ha^{-1}. Especially, TA and compound **2f** show excellent pre-emergence herbicidal activity against *B. campestris* and *A. retroflexus* with an inhibitory percent up to 86.2% at a dosage of 187.5 g ha^{-1}, which are superior to dichlobenil. Meanwhile, compound **2a** also exerts effective inhibition to monocotyledons *E. crus-galli*, *Setaria glauca*, and *Setaria viridis*. These results enable these compounds to be of much potential for further investigations as new herbicides.

Crop Selectivity. On the basis of the herbicidal activities mentioned above, compounds TA, **1a**, **2a**, and **2f** were selected for crop selectivity evaluation. As depicted in Table 6, four compounds display different crop selectivity to tested crops. Wheat and cotton exhibit absolute tolerance to compounds **1a** and **2a** with benzyl at R^5 by post-emergence application even at the dosage of 750 g ha^{-1}. Meanwhile, compound **2f** with *m*-hydroxybenzyl is safe for cotton at a dosage of 375 g ha^{-1}. Then, TA with *C*-hydroxyl diketopiperazine ring exerts no injury to corn at a high dosage of 750 g ha^{-1}, while wheat and cotton are also absolutely tolerant to TA at the dosage of 375 g ha^{-1}. However, peanut is susceptible to all four tested compounds. These results indicate that the substituents, especially the benzyl moiety at R^5 and the hydroxyl group on diketopiperazine, affect crop selectivity properties of thaxtomin analogues. The tested compounds may have the potential as herbicides in wheat, corn, and cotton fields.

PPO and AHAS Inhibition Activity. It was observed that the injury symptoms of thaxtomins in most instances were similar to known CBI dichlobenil. Meanwhile, the tested compounds also caused substantial wilting on all species following

DOI: 10.1021/jf506153t
J. Agric. Food Chem. 2015, 63, 3734–3741

post-emergence applications, which was similar to PPO or AHAS inhibitors. Thus, the PPO and AHAS inhibition experiments of compounds TA, **1a**, **2a**, and **2f** were carried out. Results shown in Table 7 indicate that TA, **1a**, **2a**, and **2f** all exhibit moderate PPO inhibitory activity but no AHAS inhibition. These results might be a reasonable explanation for why thaxtomins cause substantial wilting on weeds beside CBI mode of action and indicate that thaxtomins might act as multi-target herbicides.

Antifungal Activities. It is revealed that thaxtomins could inhibit the synthesis of cellulose, which is a major component of the fungal cell wall. This situation inspired us to evaluate the antifungal activity of title thaxtomin analogues. The MIC values in Table 8 manifested that the nitro group at R^1 is favorable for antifungal activities, and the introduction of the methyl moiety on indole and diketopiperazine at R^2, R^3, and R^4 has no significant influence on their bioactivities. Compounds **1**, **2**, and TA with nitro group R^1 give relatively better activities in contrast to compounds **3a** and **3b**. Especially the natural compound TC (**2a**) exhibits the most broad and effective antifungal efficacy among the tested compounds, with MICs of 64 μg mL^{-1} to all strains. Additionally, compounds **1b−1d** show moderate inhibition to *C. albicans* (MIC = 32−64 μg mL^{-1}); meanwhile, compounds **1a** and **2c−2d** could inhibit the growth of *A. flavus* at a concentration of 64 μg mL^{-1}. Subsequently, the N-methylations of R^2, R^3, and R^4 in compounds **1c−1e** and **3a** to synthesize compounds **4a−4d** do not result in improved antifungal activities. In summary, compound **2a** displays the broadest and most effective activities among the tested thaxtomin analogues and might be a potential lead compound for further development of novel antifungal agents.

In conclusion, a series of thaxtomin analogues were synthesized and evaluated for herbicidal property, PPO and AHAS inhibition, crop selectivity and antifungal activity. The greenhouse experiments indicate that nitro at R^1 and benzyl or *m*-hydroxybenzyl fragments at R^5 significantly affect herbicidal activities of thaxtomin analogues; meanwhile, N-methylations at R^2, R^3, and R^4 lead to a slight influence on the efficacy. Especially compounds TA, TC (**2a**), **1a**, and **2f** exhibit effective activities, which are comparable or even superior to positive control dichlobenil at a dosage of 187.5 g ha^{-1}. Moreover, the selected compounds show moderate PPO inhibition and satisfactory crop selectivity results. The above results indicate that the selected compounds TA, TC, **1a**, and **2f** might be potential lead compounds for future development of novel herbicides. Additionally, antifungal bioassays show that some compounds, especially TC, display effective inhibition to the tested fungi. Eventually, an attractive biological performance of thaxtomins mentioned above could prove to be of prime importance in future endeavors at understanding the mode of action of thaxtomins and developing new herbicides based on this natural resource backbone.

Therefore, the relationship between metabolites and quality remains to be explored. On the other hand, liquid chromatography−mass spectrometry (LC−MS) coupled with a multivariate statistical analysis of the metabolome (LC−MS-based metabolic profiling technique) has been used in the medical and microorganism/plant physiology fields as a comprehensive, sensitive, and nontargeted (nonbiased) approach.[19] This LC−MS-based metabolic profiling technique can elucidate the relationship between the previously undescribed metabolites in the green beans and the coffee quality.

Recently, we reported on the relationship between the metabolites and maturity levels[20] determined using the LC−MS-based metabolic profiling technique. In the present study, we have investigated the direct relationship between the metabolite properties and the resultant beverage quality (flavor score) and identified the metabolite markers (key compounds) responsible for the resultant beverage quality. The key compounds identified in this study can be utilized as objective criteria for selecting green beans and as indicators for improving beverage quality during technical processes such as roasting, brewing, and storing.

2. MATERIALS AND METHODS

2.1. Chemicals. LC−MS-grade acetonitrile, water, and formic acid were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). High-performance-liquid-chromatography- (HPLC-) grade methanol, ethanol, and hexane and 6N HCl were purchased from Nacalai Tesque (Kyoto, Japan). 3-Methylbutanoic acid for food additives was purchased from Sigma-Aldrich (St. Louis, MO). Deuterated dimethyl sulfoxide (DMSO-d_6) was purchased from Eurisotop (Saint-Aubin, France).

2.2. Green and Roasted Coffee Beans. Forty varieties of green arabica coffee beans were obtained commercially, of which 36 were from Guatemala and 4 were uncharacterized. Each variety of green coffee beans (100 g) was roasted using a laboratory-scale roaster (Suntory laboratory and Suncafe laboratory, Kanagawa, Japan). The roasting degree was adjusted to a luminosity (L) value of 22−23 for all samples.

2.3. Sensory Evaluation. The sensory evaluation experiments were performed for metabolic profiling to identify the markers, for validating the applicability of the markers, and for determining the influence of the thermal degradation product of the markers on the resultant beverage quality (cup quality). All evaluations were conducted by an experienced Licensed Q grader, certified by the Coffee Quality Institute (CQI).

2.3.1. Metabolic Profiling. The sensory evaluation was performed basically in accordance with the Specialty Coffee Association of America (SCAA) cupping protocol.[21] For this study, 36 varieties of coffee beans from Guatemala were utilized. To avoid fatigue of the tongue, a maximum of six samples were compared at a time. A standard session consisted of six sets, with six samples per set (6 sets × 6 samples/set = 36 samples) and two cups from each sample. In addition, one control was used that was assigned 83 points (the mean score for all of the samples), which helped the grader in fixing the scale and scoring more accurately. The standard session was performed twice in a randomized order as blind analyses. The final cupping scores of each sample were given by summing the individual scores in the fragrance/aroma, flavor, aftertaste, acidity, body, balance, sweetness, uniformity, cleanliness, overall, and defects categories. The final scores were analyzed by multivariate statistical analysis.

2.3.2. Validation of the Applicability. The four uncharacterized coffee samples were evaluated (two cups from each sample) in accordance with the SCAA cupping protocol.

2.3.3. Influence of the Thermal Degradation Product of the Markers on the Cup Quality. Two varieties of coffee beans from Guatemala, one of good quality and the other of excellent quality, were studied. The ground powder (30 g) of each variety of roasted beans was extracted with hot water (300 mL, 97 °C). The coffee brew resulting from the coffee beans that were of good quality was used as the basic brew for studying the influence of 0.1 μ/L of flavor compound additives, whereas the brew prepared from the coffee beans of excellent quality was used for calibration reference. The panel assessed and scaled these brews with an SCAA cupping score. Only the aftertaste grades are provided in this article. The intensity values are assigned as line-scale values from 6 to 10 points in quarter point increments.

2.4. Metabolite Extraction and LC−MS Analysis for Metabolic Profiling. The green beans (10 g) frozen in liquid nitrogen were crushed with a small metal device by shaking using a Multibeads Shocker (Biomedical Science, Nagasaki, Japan) at 1100 rpm for 7 min, twice. The crushed powder (50 mg) was extracted with 1.5 mL of 70% methanol/H_2O for 1 h at 80 °C. After centrifugation at 10000 rpm for 10 min at 10 °C, the supernatants were diluted four times with 20% acetonitrile and filtered using a Ultrafree-MC filter units (0.22 μm, Polyvinylidene Fluoride (PVDF), Millipore, Billerica, MA) for use in the LC−MS analysis.

The LC−MS measurement of coffee metabolites was performed as described in our previous study,[20] on a Luna-C18 column (250 × 1.0 mm, 5-μm particle size, Phenomenex, Torrance, CA) using a LC−MS−ion trap (IT)−time-of-flight (TOF) instrument (Shimadzu, Kyoto, Japan).

2.5. Data Processing, Multivariate Statistical Analysis, and Correlation Plots. The data processing (peak picking and alignment) and normalization by the sum of total ion counts of each sample for the ion signals in positive mode were performed as described in our previous report.[20] The ion signals were subsequently filtered according to two criteria: (1) at least one group of a total of 36 categorical groups (36 varieties, n = 3) should exhibit <25% missing values and (2) relative standard deviation (RSD) values are <75%. As a result, 2649 valid peaks were obtained.

Multivariate statistical analysis was performed using the SIMCA P$^+$ version 13.0 software program (Umetrics, Umeå, Sweden). An orthogonal projection to latent structure (OPLS) regression model[22] was created to develop the sensory predictive model for the SCAA cupping score. Correlation plots between the cupping score and the extracted normalized signal intensity of the two markers were drawn.

2.6. LC−High-Resolution MS (LC−HR-MS) Analysis for the Isolation and the Structural Determination of the Markers. LC−HR-MS analyses of the coffee extracts and purified fractions were performed using a Q-Exactive hybrid quadrupole-orbitrap mass spectrometer (Thermo Fisher, San Jose, CA) with an electrospray ionization (ESI) source connected to a 10AV HPLC system (Shimadzu, Kyoto, Japan) on a KINETEX C18 column (250 mm × 2.1 mm, 1.7 μm, Phenomenex, Torrance, CA). For the LC analysis, the mobile phases A and B consisted of 0.1% formic acid/H_2O and 0.1% formic acid/acetonitrile, respectively. A flow rate of 0.2 mL/min; a gradient elution program of 5% B (0−2 min), 5−55% B (2−7.5 min), 55−100% B (7.5−17 min), 100% B (17−23 min), 100−5% B (23−24 min), and 5% B (24−32 min); and a column oven temperature of 40 °C were used. For the MS analysis, spray voltages of 3.5 kV (positive) and −3.5 kV (negative), a capillary temperature of 250 °C, a resolution power of 70000 for the full-scan MS event and MS/MS event, an m/z scan range of 80−1200, and a collision energy for MS/MS analysis of 15−45% (normalized) were used

2.7. Acid Hydrolysis of the Markers. To determine the configurations of the sugar moieties, the purified compounds (200 μg) were hydrolyzed by 6 N HCl (200 μL) at 100 °C for 60 min and analyzed using an HPLC−refractive index (RI) system on a Shodex SUGAR SP0810 column (8.0 mm × 300 mm, 7 μm, Showa Denko, Tokyo, Japan). For the LC analysis, isocratic elution of H_2O with a flow rate of 0.6 mL/min for 30 min was used. The column oven temperature was 80 °C. Identifications were carried out by comparing the chromatographic retention times of authentic sugars (D-glucose, D-fructose, D-galactose, and D-mannose), which were hydrolyzed and analyzed under the same conditions.

DOI: 10.1021/jf5054047
J. Agric. Food Chem. 2015, 63, 3742−3751

2.8. NMR Spectroscopy. For the structural determination of the markers, ^{1}H nuclear magnetic resonance (NMR) spectroscopy, ^{13}C NMR spectroscopy, total correlation spectroscopy (TOCSY), double quantum filter correlation spectroscopy (DQF-COSY), ^{1}H{^{13}C} heteronuclear single-quantum coherence (HSQC) spectroscopy, ^{1}H-{^{13}C} heteronuclear multiple bond correlation (HMBC) spectroscopy, nuclear Overhauser enhancement spectroscopy (NOESY), and rotational nuclear Overhauser effect spectroscopy (ROESY) spectra were obtained using a DMX-750 spectrometer (Bruker BioSpin, Rheinstetten, Germany) at 750 MHz. DMSO-d_6 was used as the solvent, and the chemical shifts were referenced to the solvent signal (δ 2.50 for ^{1}H and δ 39.43 for ^{13}C).

2.9. Quantitative Analysis of the Markers. The quantitative analyses of the markers in four green bean varieties were performed using LC−HR-MS. The purified compounds (markers) with concentrations of 0, 0.1, and 1 mg/L were used for standard calibration. Three replicates of the standards and of each sample were analyzed. The signal intensities at m/z 471.1714 (±10 ppm) were monitored in the negative mode.

2.10. Pyrolysis and Gas Chromatography (GC)−MS Analysis. Pyrolysis of the purified compounds was carried out using the Double-Shot PY-2020D pyrolyzer (Frontier Laboratories Ltd., Fukushima, Japan) at a temperature of 230 °C for 10 min. The thermally decomposed compounds were then separated directly using a 7890A GC system (Agilent Technologies, Santa Clara, CA) on a J&W DB-WAX etr fused silica capillary column (60 m × 0.32 mm i.d., df = 0.25 μm, Agilent Technologies) coupled with electron ionization (EI; 70 eV)−quadrupole (Q)-MS system using a 5075C inert XL MSD mass spectrometer (Agilent Technologies). The GC−MS analysis was conducted with a carrier gas (He) flow rate of 4.1 mL/min (at 40 °C), a transfer-line temperature of 250 °C, an ion-source temperature of 230 °C, a split ratio of 10:1, and an MS scan range of 33−450. The temperature program used was 40 °C for 2 min, raised to 250 °C by a 4 °C/min ramp, and finally kept at 250 °C for 5 min. The identifications were carried out by comparing the chromatographic retention times and mass spectral data of the target compounds with those of reference samples analyzed under the same conditions and by comparing the spectra with those obtained from the National Institute of Standards and Technology (NIST) library.

2.11. Extraction and Purification of the Markers for Structural Determination. Green coffee beans (*Coffea arabica*) (1.6 kg; Guatemala, Pacamara) frozen in liquid nitrogen were crushed using a Multibeads Shocker and defatted with 5 L of hexane. After being dried, the defatted powder was extracted with 8 L of 70% methanol/water for 2 h at 80 °C and filtered. The remaining powder was further extracted with 4 L of 70% methanol/water for 20 h at 4 °C and filtered. The combined filtrate was concentrated and loaded onto six types of columns, which are described below and in Figure S1 (Supporting Information), and the column eluents were analyzed by LC−HR-MS to detect the target compounds. **(1) HP-20 column** (1 L, Mitsubishi Chemical Co., Tokyo, Japan): The target compounds were eluted with water and 10% ethanol/water, and the eluents were separately concentrated to yield 250.8 and 11.4 g of powder, respectively. **(2) COSMOSIL C_{18}-OPN column** (1.2 L, 140 μm, Nacalai Tesque, Kyoto, Japan): The powder (250.8 g) from the water eluent of HP-20 was purified, and the target compounds were eluted with 0.1% formic acid/water and 0.1% formic acid/10% ethanol/water to yield 94.1 g of powder. **(3) COSMOSIL 75C18PREP column** (500 mL, 75 μm, Nacalai Tesque, Kyoto, Japan): The powder (11.4 g) obtained from the 10% ethanol/water eluent on HP-20 and the powder (94.1 g) obtained from the eluent on COSMOSIL C_{18}-OPN were combined and loaded. Fractions 2−9 (containing the target compounds) were concentrated to yield 20.2 g of powder. **(4) Develosil C30-UG-5 column** (20 × 250 mm, 5 μm, Nomura Chemical Co. Ltd., Aichi, Japan): The powder (20.2 g) was further purified. The fractionation was performed 17 times. Fractions 7−10 (containing compound **1**) and fractions 11−15 (containing compound **2**) were separately concentrated to yield 2.28 g (fraction 1A) and 2.00 g (fraction 1B), respectively, of powder. **(5) Shodex Asahipak NH2-P90 20F column** (20 × 300 mm, 5 μm, Showa Denko, Tokyo, Japan): Fraction 1A and fraction 2B were separately purified. Fraction 1A was purified by fractionating twice, and fractions 26−29 (containing compound **1**) were concentrated to yield 42.4 mg of powder (fraction 2A). Fraction 1B was purified by fractionating four times, and fractions 22−25 (containing compound **2**) were concentrated to yield 42.4 mg of powder (fraction 2B). **(6) Develosil C30-UG-5 column** (4.6 mm × 150 mm, 5 μm): Fractions 2A and 2B were separately purified. Fractions 8 and 9 (containing compound **1**) from fraction 2A and fraction 9 (containing compound **2**) from fraction 2B were separately concentrated to yield 2.3 and 6.0 mg, respectively, of a white powder.

3. RESULTS AND DISCUSSION

3.1. Metabolic Profiling. *3.1.1. Prediction of the Coffee Flavor Quality and Study of the Coffee-Flavor-Predicting Metabolite Markers.* The aim of this study is to identify the chemical compounds present in green coffee beans, which are the key compounds for the resultant beverage quality (cup quality). For this purpose, we purchased 36 varieties of green coffee beans from Guatemala that had different coffee qualities and roasted part of them under uniform conditions. Subsequently, an experienced Licensed Q grader evaluated their cup qualities and assigned SCAA cupping scores (Table 1) using the standardized SCAA protocol,[21] to ensure an accurate evaluation of the cup quality.

Table 1. Thirty-Six Coffee Green Beans from Guatemala Evaluated by the SCAA Cupping Score

SCAA cupping score (points)	
89	89.0
88	
87	
86	
85	
84	84.0, 84.0, 84.25
83	83.0, 83.0, 83.25, 83.25
82	82.0, 82.0, 82.0, 82.0, 82.0, 82.25, 82.25, 82.5, 82.75
81	81.0, 81.25, 81.25, 81.5, 81.5, 81.75, 81.75
80	80.0, 80.0, 80.75, 80.75, 80.75
79	79.0, 79.5, 79.5
78	78.25, 78.5
77	77.5
76	76.5

The rest of the green beans were subjected to LC−MS measurements using LC−MS−IT−TOF. The LC−MS spectra obtained were processed for peak picking and alignment, which resulted in a total of 2649 valid peaks.

We then applied a supervised multivariate statistical technique commonly used in metabolomics studies to isolate the most characteristic metabolite markers in our experiments. Using the SIMCA-P^{+} software program, a flavor (SCAA cupping score) prediction model was created, based on the OPLS regression analysis.[22] Although only 5.6% of the variation correlated with the first latent variable, the regression model appeared to be a good predictor of the scores, as indicated by the values of the correlation coefficient (R^2 = 0.957), the cross-

DOI: 10.1021/jf5054047
J. Agric. Food Chem. 2015, 63, 3742−3751

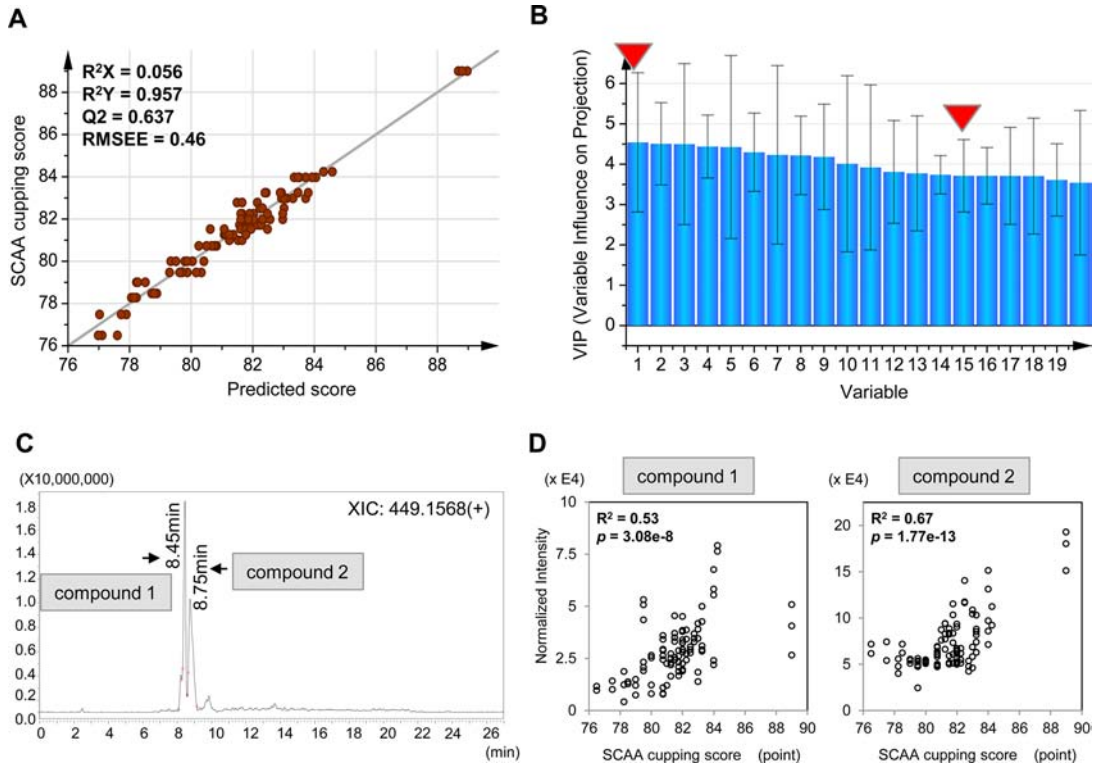

Figure 1. Two markers that strongly correlated with the SCAA cupping score studied by nontargeted metabolic analysis. (A) The OPLS model. The SCAA cupping score was predicted by the metabolomic information. (B) The VIP plot. The top 20 variables are shown. The red arrowhead indicated the two ion signals (markers) with m/z 449.1568(+). (C) The XIC for m/z 449.1568(+) derived from LC−MS−IT−TOF analysis of the coffee green extract (the green beans with SCAA score of 84 points). Two markers with the same m/z value (449.1568) were separately observed at RT 8.45 min (compound **1**) and RT 8.75 min (compound **2**). (D) The correlation plots between the SCAA score and the ion intensities of compound **1** (left) and compound **2** (right).

validated correlation coefficient (Q^2 = 0.637), and the root-mean-square error of estimation (RMSEE = 0.46) (Figure 1A).[23] This finding indicated that the metabolite data in the green beans could predict the SCAA cupping score (or cup quality) after the roasting and brewing processes.

The interpreted OPLS regression model was given by the variable influence on projection (VIP) parameter. We obtained a list of the metabolite ion signals ranked according to their VIP values (Figure 1B). As the higher-ranked metabolite signals are thought to substantially contribute to the regression, the top ranked m/z value of 449.1568 [retention time (RT) of 8.75 min] was considered to be most strongly correlated with the SCAA cupping score. Interestingly, in the VIP list, the signal for the 15th (m/z value of 449.1568) candidate was found to have the same m/z value as the top candidate, but a slightly different LC retention time (8.45 min). Indeed, the extracted chromatograms (XICs) displayed distinct peaks on top of each other (Figure 1C, RT 8.45 min, compound **1**; RT 8.75 min, compound **2**), suggesting that the two signals (markers) had different origins. Furthermore, the correlations between the SCAA scores and the ion intensities of these two markers were shown to be rather strong (for compound **1**, R^2 = 0.53, whereas for compound **2**, R^2 = 0.67) (Figure 1D). Overall, the data obtained indicated that an increasing amount of these two markers could either additively or independently contribute to the enhancement of the SCAA cupping score, raising the possibility that these were the potent precursors of coffee beverage flavor compounds.

3.2. Structural Determination and Quantification of the Markers. *3.2.1. Extraction and Purification.* Next, we purified and determined the chemical structures of the markers, to study their effectiveness in enhancing coffee flavor. The coffee green beans (1.6 kg) were extracted and subjected to several types of chromatography (Figure S1, Supporting Information). As an index of the ion at m/z 449.157 (±10 ppm) using LC−HR-MS, compounds **1** and **2** were successfully purified, resulting in 2.3 and 6.0 mg, respectively, of product.

3.2.2. Structural Determination. By LC−HR-MS, the molecular formulas of both compounds **1** and **2** were determined to be $C_{17}H_{30}O_{12}$ (compound **1**, m/z 449.1630 $[M + Na]^+$, error of −1.1 ppm; compound **2**, m/z 449.1631 $[M + Na]^+$, error of −0.9 ppm).

The LC−HR-MS/MS analyses revealed that both compounds **1** and **2** consisted of aglycone ($C_5H_{10}O_2$) and two hexose moieties with molecular masses of 426 (compounds **1** and **2**, precursor ion at m/z 471.171 $[M + HCO_2H - H]^-$ ($C_{18}H_{31}O_{14}$), fragment ions at m/z 425.167 $[M - H]^-$ ($C_{17}H_{29}O_{12}$), m/z 323.098 $[M -$ aglycone ($C_5H_{10}O_2$) $- H]^-$ ($C_{12}H_{19}O_{10}$), and m/z 161.044 $[M -$ aglycone $-$ (hexose $- H_2O) - H]^- = [$hexose $- H_2O - H]^-$ ($C_6H_9O_5$)).

Moreover, acid hydrolysis of compounds **1** and **2** indicated the presence of glucose in compound **1** and glucose and fructose in compound **2**, which were determined by comparison with pure sugars. The full assignments of the ^1H and ^{13}C NMR data of compounds **1** and **2**, established by one- and two-dimensional NMR spectra are reported in Tables 2 and 3, respectively.

3.2.2.1. Compound 1. The ^1H and ^{13}C NMR signals of compound **1** indicated a partial structure of 3-methylbutanoyl. In the ^1H NMR spectrum, two anomeric proton signals at δ

[a] 6-*O*-(*β*-D-Glucopyranosyl)-1-*O*-octanoyl-*β*-D-glucopyranose measured in CD_3OD.[24] [b] OV, overlapping signals.

5.36 and δ 4.17 were observed. Further, the ^{1}H and ^{13}C NMR data considered along with the results of acid hydrolysis suggested that the two hexose moieties could be assigned to glucose exhibiting a *β*-configuration, based on the values of coupling constants for inner glucose ($J_{1',2'}$ = 8.2 Hz) and terminal glucose ($J_{1'',2''}$ = 7.8 Hz). The ^{1}H and ^{13}C NMR data of the complete sugar moiety of compound **1** were consistent with those of 6′-*O*-(*β*-D-glucopyranosyl)-1′-*O*-acyl-*β*-D-glucopyranose.[24]

Comparison with literature values indicated 1 → 6 linkages of two glucose moieties,[25] and the anomeric proton H-1′ showed a downfield shift indicating an ester linkage of 3MA to the hydroxyl group at the C-1′ position in the inner glucose. Furthermore, the $^{1}H\{^{13}C\}$-HMBC analysis also showed a cross-peak between H-1′ of the inner glucose (δ 5.36) and the carbonyl carbon of the 3-methylbutanoyl moiety (δ 171.16) and between H-1″ of the terminal glucose (δ 4.17) and C-6′ of the inner glucose (δ 67.77). Therefore, compound **1** was deduced to be 6′-*O*-(*β*-D-glucopyranosyl)-1′-*O*-[3-methylbutanoyl]-*β*-D-glucopyranose (Figure 2).

3.2.2.2. Compound 2. Comparison of the ^{1}H and ^{13}C NMR results with the reported data in the literature suggested that

[a] 3-methylbutanoyl-6-O-α-D-glucopyranosyl-β-D-fructofuranoside measured in DMSO-d_6.[26]

compound **2** was a known compound.[26] Briefly, the ^{1}H and ^{13}C NMR data of compound **2** and compound **1** were consistent in terms of the acyl moiety, suggesting the presence of 3-methylbutanoyl. Further, the NMR signals from compound **2** suggested the presence of acyl-6-O-sucrose and glucose moieties,[27,28] in addition to providing indications of an ester linkage at position of 6′ of the glucose moiety. Compound **2** was concluded to be 3-methylbutanoyl-6-O-α-D-glucopyranosyl-β-D-fructofuranoside (Figure 2), and the data obtained were in good agreement with the data reported in the literature (see Tables 2).[26]

The two markers that strongly correlated with the SCAA cupping score were isolated from the green beans and determined to be 3-methylbutanoyl disaccharides (3MDs), 6′-O-(β-D-glucopyranosyl)-1′-O-[3-methylbutanoyl]-β-D-glucopyranose (compound **1**) and 3-methylbutanoyl-6-O-α-D-

DOI: 10.1021/jf5054047

glucopyranosyl-β-D-fructofuranoside (compound **2**). Although compound **2** is a known compound in coffee green beans,[26] to the best of our knowledge, the presence of compound **1** has not been reported so far. These markers were considered to be the isomers of the sugar-bound flavor precursors.

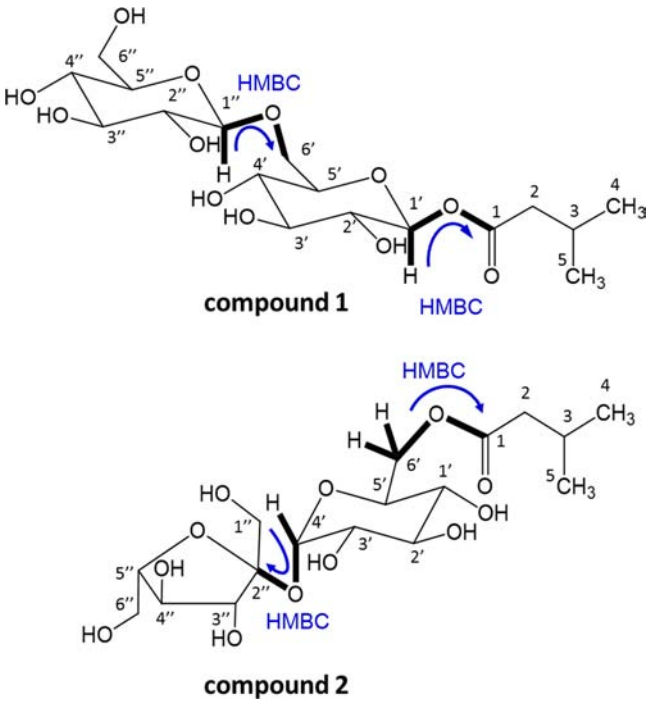

Figure 2. Structures of two markers, compound **1** (upper) and compound **2** (lower). $^{1}H\{^{13}C\}$-HMBCs are shown with thick lines.

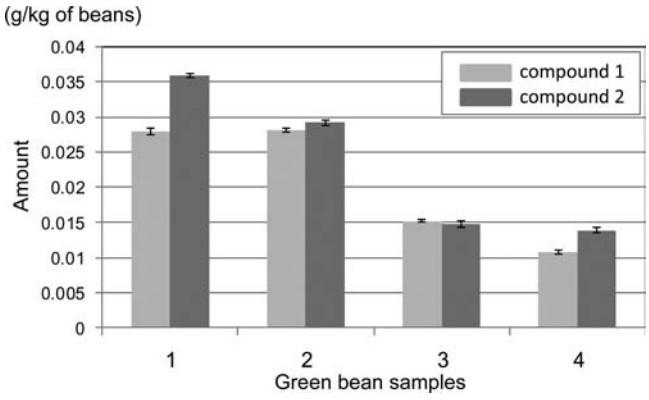

Figure 3. Quantitative analyses of compounds **1** and **2** in four green bean samples by LC–HR-MS.

3.2.3. Quantification. Quantitative analyses revealed that the amounts of 3MDs in four green beans were only 0.01–0.035 g/kg of beans (for both compounds **1** and **2**) (Figure 3). These amounts were only about 1/1000–1/5000 that of chlorogenic acid,[29] which is the major constituent in the coffee green beans. Despite the very small quantity, these were significant flavor-discrimination markers and could be the potent precursors for coffee beverage's flavor compounds that enhance the cup quality. The SCAA cupping score (cup quality) of four samples will be discussed in section 3.4.

3.3. Influence of 3MDs on the Cup Quality. Coffee flavors and aromas are developed during the roasting process.[30] However, the chemical changes in the metabolites during roasting are highly complicated and remain uncharacterized. On the other hand, in food chemistry, pyrolysis coupled with GC–MS has been utilized to study thermal degradation products to mimic processes such as roasting and heating.[31,32] We employed this technique to identify the thermal products of 3MDs and then studied the effects of the thermal products on the cup quality (SCAA cupping score) by model experiments.

3.3.1. Identification of Flavor/Aroma Compounds by Thermal Reaction of 3MDs. First, the thermal degradation products of 3MDs were studied. The two 3MDs were subjected to pyrolysis under the model conditions of roasting (230 °C, 10 min), and the products were detected by GC–MS. Thermal reaction of compound **1** produced compounds mainly consisting of 3-methylbutanoic acid (3MA) (RT 28.9 min), in addition to minor amounts of furfural (RT 22.0 min) and 5-hydroxymethylfurfural (5-HMF, RT 50.2 min), which were identified based on a NIST library search (Figure 4A). Furthermore, the structure of 3MA, which was the main product, was confirmed by comparing the chromatographic retention time and the mass spectral data obtained in the experiments with those corresponding to the standard compound. Interestingly, the pyrolysis of compound **2** produced mostly the same compounds as pyrolysis of compound **1** (Figure 4A). Thermal reactions of both markers mainly resulted in 3MA by hydrolysis (Figure 4B), along with the minor caramelized products furfural and 5-HMF. The caramelized products have been previously reported to be formed from sugars,[33,34] which are one of the main ingredients of green beans.[35] On the other hand, 3MA is a characteristic moiety of 3MDs. Therefore, in this article, we focus on 3MA and discuss its effect on coffee flavor.

3.3.2. Study of the Influence of 3MA on Cup Quality. The effect of the addition of 3MA to the basic coffee brew on the cup quality was investigated next. An experienced Licensed Q grader evaluated the base coffee brew with and without the 3MA additive, and the calibration reference brew (excellent quality), and then assigned aftertaste score, which is one of the axes described in the SCAA protocol. Aftertaste is a significant factor for coffee flavors and represents the impression (length and quality) of coffee flavors that remains after swallowing. Figure 5 shows that the aftertaste intensities increased with the addition of 3MA (0.1 μ/L). Therefore, it was concluded that the addition of 3MA improved the cup quality. The scorings for other attributes, such as acidity, body, and sweetness, need to be interpreted further.

These findings indicate that the two 3MDs are the precursors of 3MA, which significantly enhances the quality of coffee flavors. The two precursors could additively enhance the cup quality. In the literature, some other 3-methylbutanoyl sugar conjugates, such as 3-methylbutanoyl-1-*O*-β-D-glucopyranosyl-β-D-apiofuranoside[26] and 3′-*O*-β-D-glucopyranosyl-2′-*O*-3-methylbutanoyl-2β-(2-desoxy-atracty-ligenin)-β-D-glucopyranoside,[36,37] have been isolated from coffee green beans. These compounds would additively enhance the cup quality. The contribution ratio of these compounds toward the cup quality will be examined further.

3.4. Validation of the Applicability of 3MDs for Predicting the Cupping Score. To verify the applicability of the 3MDs as potent markers, we analyzed another sample set (validation sample set). As described in section 3.2.3, four varieties of uncharacterized coffee green beans, which were procured from different coffee-producing countries, contained

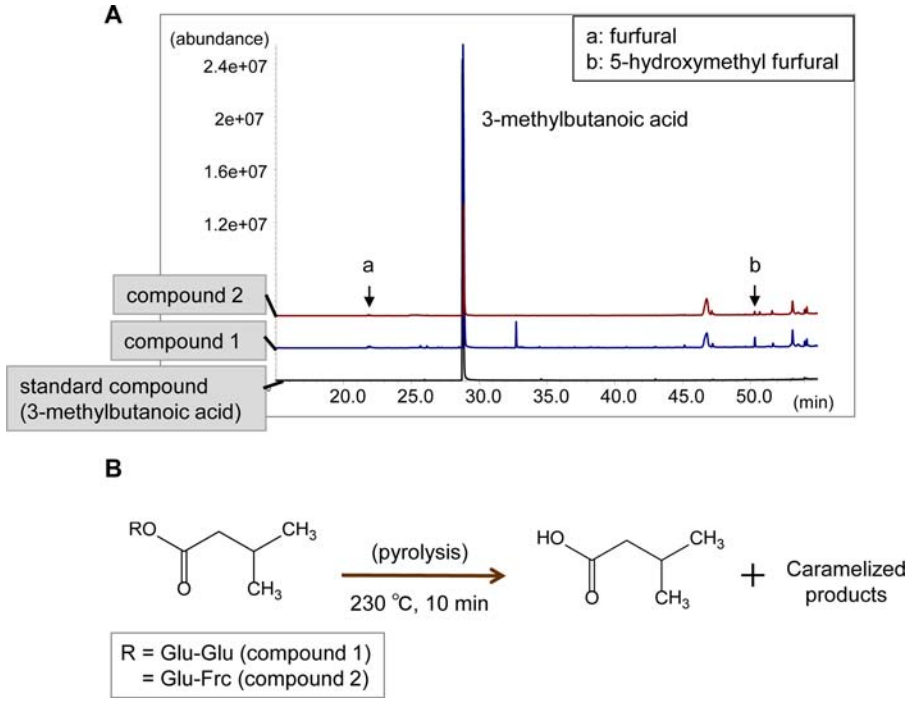

Figure 4. Pyrolysis-GC−MS analyses. (A) Total ion chromatograms of compounds **1** and **2** and the standard compound (3MA). (B) Thermal degradation of compounds **1** and **2** to produce 3MA and caramelized compounds.

Figure 5. Sensory evaluation (aftertaste score) of three coffee brew: the calibration reference brew, the base brew, and the base brew with 3MA additive (0.1 μL/L).

compounds **1** and **2** with different amounts (Figure 3). After we roasted these green beans under uniform conditions, an experienced Licensed Q grader evaluated the cup quality and assigned SCAA scores (Table 4). The results combined Figure 3 with Table 4 indicated that increasing amounts of 3MDs were associated with increasing SCAA cupping scores. Therefore, it was verified that the 3MDs were flavor-discrimination markers in the validation sample set. To highlight the applicability and importance of these markers for practical use, a number of sample sets, including a wide variety of coffee samples obtained from different production areas and countries (different cultivation condition), from different cultivars, and with different processing methods (washed or natural process method to produce green beans from cherries) will need to be examine further.

Table 4. SCAA Cupping Scores for the Validation Coffee Samples

coffee sample	SCAA cupping score
1	85.5
2	85
3	81
4	80

In summary, we focused on the metabolites in green beans to predict and contribute to the resultant beverage quality. We prepared samples from 36 varieties of coffee green beans that had distinct differences in quality (different SCAA cupping scores) and conducted nontargeted LC−MS-based metabolic profiling. It was validated that the LC−MS data of metabolites could predict the beverage quality through the roasting and brewing processes. Further, we successfully explored and identified two isomers of 3MDs, one of which is a novel structure that has not been reported in the literature so far, to the best of our knowledge. Although the 3MDs are present in very small quantities in the green coffee beans, they were found to be significant flavor-discrimination markers and were potent precursors for the flavor/aroma compounds in coffee beverages that enhance the cup quality. Other 3-methylbutanoyl sugar conjugates from coffee green beans have also been reported in the literature and could additively enhance the cup quality along with the 3MDs. The 3MDs could be used as universal criteria to evaluate and predict beverage quality from green beans in the presence or absence of other compounds.

They were allowed access to water and standard rat chow ad libitum for 7 days to acclimatize and fasted overnight prior to the experiments.

Evaluation of Bioavailability of Collagen. The bioavailability of collagen was indirectly evaluated by the bioavailability of Hyp in collagen, which was determined using a pharmacokinetic method after oral administration to rats. Briefly, 30 rats were randomly divided into five groups of 6 each: group I (collagen, 4000 mg/kg bw, i.g.), group II (Hyp, 400 mg/kg bw, i.g.), group III (Hyp, 400 mg/kg bw, i.v.), group IV (NS, i.g.), and group V (NS, i.v.). Group I had the same Hyp dose as groups II and III because the Hyp content of the collagen was 10% (w/w).[13] Groups IV and V were given isometric NS as a control. Before and after treating with sample, ~0.5 mL of blood sample was drawn from orbit into heparinized tubes at different times for each rat. The plasma was obtained by centrifugation at 3000 g for 15 min.

The pharmacokinetic parameters of the area under the concentration−time curve (AUC), half-life ($t_{1/2}$), mean residence time (MRT), peak plasma concentration (C_{max}), and time to peak concentration (T_{max}) were calculated by the software BAPP 2.0 (Center for Drug Metabolism and Pharmacokinetics, China Pharmaceutical University, Nanjing, China). The relative (F_r) and absolute (F_s) bioavailability were calculated by the following equations,[15]

$$F_r = [AUC]_{col} D_{col} / [AUC]_{i.g.} D_{i.g.} \times 100\%$$

$$F_s = [AUC]_{col} D_{col} / [AUC]_{i.v.} D_{i.v.} \times 100\%$$

where $[AUC]_{col}$, $[AUC]_{i.g.}$, and $[AUC]_{i.v.}$ were the area under the concentration−time curve for Hyp in collagen, Hyp (i.g.), and Hyp (i.v.) from zero to infinity; D_{col}, $D_{i.g.}$, and $D_{i.v.}$ were the dose of Hyp in collagen, Hyp (i.g.) and Hyp (i.v.).

Separation of Collagen Peptides from Plasma. Another 20 rats were randomly divided into two groups of 10 each. One group was orally administered collagen at a dose of 4000 mg/kg bw. After 2 h, blood was drawn from the abdominal aorta under anesthesia and centrifuged to separate the plasma. The other group was given isometric NS as a control.

The plasma was filtered with Millipore's Amicon Ultra-15 centrifugal filter devices with the nominal molecular weight cut-offs of 3000 Da. The filtrate was loaded on a Sephadex G10 column (1.5 × 75 cm) and eluted with distilled water at 0.5 mL/min. The resulting fractions were then subjected to an Agilent ZORBAX Eclipse XDB-C18 column (9.4 × 250 mm, 5 μm) and eluted by acetonitrile (2% in 0−5 min, 2−10% in 5−10 min, 10−70% in 10−20 min) with 0.1% TFA at 2.5 mL/min. The absorbance at 220 nm was monitored.

Identification of Collagen Peptides. The collagen peptide was identified using Waters ACQUITY UPLC coupled to SYNAPT Q-TOF-MS with electrospray ionization. The sample was dissolved in distilled water, and 5 μL was then injected into a BEH130 C18 column (2.1 × 150 mm, 1.7 μm) and eluted with a linear gradient of acetonitrile (0−20% in 20 min) at 0.2 mL/min. The mass spectrometer was operated in the positive ion mode with a capillary voltage of 3.5 kV, ion source temperature of 100 °C, desolvation temperature of 300 °C, desolvation gas flow of 10 L/min, cone voltage of 45 V, cone gas flow of 1 L/min, and scanning range of 50−1000 *m*/*z*. The amino acid sequence was analyzed using BioLynx software.

Other Analytical Methods. The Hyp concentration in plasma was determined by the colorimetric method recommended by ISO.[16] Briefly, the plasma was hydrolyzed at 105 °C for 16 h with isometric 6 M H_2SO_4. After filtering and diluting, 2 mL of the plasma hydrolysates was mixed with 1 mL of Chloramine T, and the oxidation was allowed to proceed for 20 min at room temperature. Chromophore was then developed by the addition of 1 mL of Ehrlich's reagent and incubation for 20 min at 60 °C. The absorbance of the complex was measured at 558 nm.

The total amino acid profile of the plasma filtrate was analyzed using an amino acid analyzer after hydrolyzing under vacuum with 6 M HCl at 110 °C for 24 h in the presence of 1% phenol (v/v). The free amino acid profile was measured by the analyzer after deproteinizing by sulfosalicylic acid. The peptide-bound amino acid was calculated by subtracting the free amino acid from the total amino acid.[17]

Statistical Analysis. The data were presented as mean value ± standard deviation. Statistical analyses were performed using one-way analysis of variance. Multiple comparisons of means were done by the LSD test. A P value of <0.05 was considered significant. All computations were made with SPSS 15.0.

RESULTS AND DISCUSSION

Oral Bioavailability of Collagen. The plasma concentration−time curve for Hyp after oral administration of collagen is shown in Figure 1, and the derived pharmacokinetic parameters are presented in Table 1. A negligible amount of Hyp in plasma was observed before the ingestion of collagen. After ingestion, the Hyp increased significantly and reached a maximum (40.4 ± 5.46 μg/mL) at 2 h, which indicated that the collagen was digestible and absorbable in vivo. The peak was followed by a slow decrease, and only 14.7% of Hyp in plasma was retained at 24 h, which was calculated as the ratio of the Hyp concentration at 24 h to the peak concentration at 2 h. This was in agreement with Oesser's report that more than 85% radioactivity in plasma disappeared after oral administration of ^{14}C labeled collagen hydrolysate for 24 h.[9] Moreover, the $t_{1/2}$ (6.91 ± 1.09 h) and MRT (10.8 ± 1.73 h) of Hyp in collagen were significantly higher than the oral administration of Hyp (1.18 ± 0.22 h and 3.45 ± 0.13 h, respectively) because Hyp

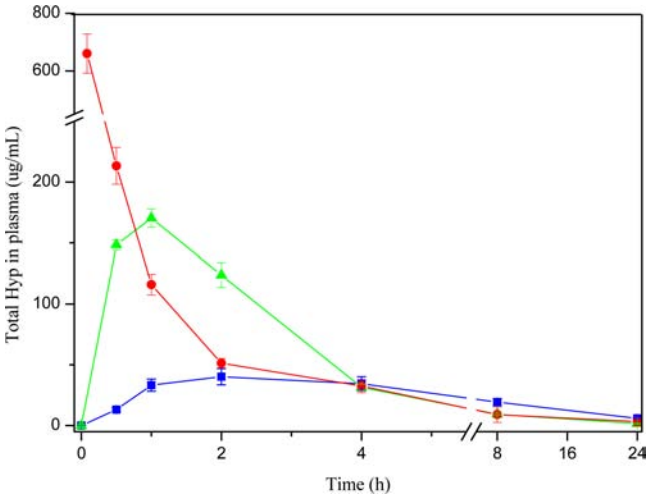

Figure 1. Plasma concentration−time curves for total Hyp in plasma after ingestion of collagen (blue, 4000 mg/kg bw, i.g.), Hyp (green, 400 mg/kg bw, i.g.), and Hyp (red, 400 mg/kg bw, i.v.).

Table 1. Pharmacokinetic Parameters of Hyp in Rat Plasma (n = 6) after Ingestion of Collagen (i.g.), Hyp (i.g.), and Hyp (i.v.)

	Hyp in collagen (i.g.)[a]	Hyp (i.g.)	Hyp (i.v.)
AUC (h·μg/mL)	436 ± 54.2 c	753 ± 16.1 b	877 ± 42.8 a
$t_{1/2}$ (h)	6.91 ± 1.09 a	1.18 ± 0.22 b	0.35 ± 0.04 c

could be absorbed directly from the intestine, whereas there was the need for collagen to be digested into small peptides or free amino acids first.

The F_r and F_s of collagen were 57.8% and 49.6%, respectively, which were lower than 73−92% of animal protein (beef, casein, egg, milk, whey protein) and similar to 45−78% of cereal protein (wheat, corn, rice, oats).[18,19] These indicated the considerable digestibility and absorbability of collagen, although it was a high-molecular-weight scleroprotein with special structure and amino acid profile.[10,11]

Effect of Ingesting Collagen on the Amino Acid Profile of Plasma. The amino acid profiles of plasma filtrate before and after oral administration of collagen for 2 h are given in Table 2. All the free and peptide-bound amino acids in plasma significantly increased after ingestion of collagen, which indicated that the digested collagen could be absorbed in the forms of both free amino acid and peptide. When we compared the increased amount of peptide-bound amino acid with that of total amino acid, it was found that more than 63.4% of the amino acid residues in collagen were absorbed in the form of a peptide. The Glu absorbed in peptide form had the highest proportion (more than 97.5%), and there was a relatively high proportion of Asp, Phe, His, and Arg, whereas Hyp, Pro, Tyr and Hyl were very low.

Table 2. Amino Acid Profile of Plasma before and after Administration of Collagen for 2 h

	free amino acid (μg/mL)[a]		peptide-bound amino acid (μg/mL)

total	141	302	152	431

[a]Mean value ± standard deviation from three separate determinations.

Referring to the amino acid profile of collagen,[13] it was observed that there was a good linear correlation between the increased amount of an amino acid in plasma and its content in collagen (R^2 = 0.9225) (Figure 2), which showed that the absorbed amount of an amino acid from the intestine depended on its content in collagen. Furthermore, Hyp was the closest to the regression curve among all the amino acids, which indicated that it was reasonable to indirectly evaluate the bioavailability of collagen by determining the bioavailability of Hyp in collagen.

Separation of Collagen Peptides. The plasma filtrate was first fractionated into three fractions (F_1, F_2, F_3) by a Sephadex G10 column (Figure 3a), in which molecules are separated by their size. All the fractions significantly increased after ingestion, which indicated the digested collagen could be absorbed within a wide range of molecular weights. These fractions were then separated by the Eclipse XDB C18 column, which was based on their hydrophobic or hydrophilic property (Figure 3b). Compared with the control, a number of new peaks emerged that were deemed the peptides or free amino acids derived from oral collagen. They were eluted in a lower range of acetonitrile concentrations, suggesting their low hydrophobicity.

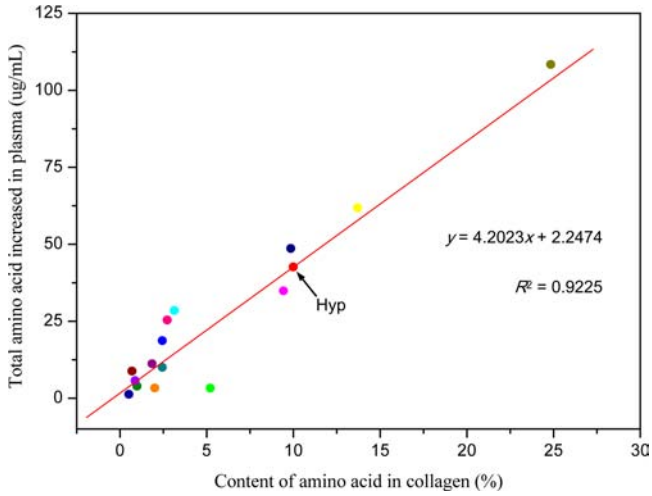

Figure 2. Correlation curve of the increased amount of amino acid in plasma (μg/mL) after ingestion of collagen against its content in collagen (%).

Identification of collagen peptides. The digested collagen in plasma was further identified by UPLC−ESI-MS with a BEH130 C18 column. The F_1 was high-molecular-weight peptides (>500 Da), and the F_3 was free amino acids. The observation was not in agreement with Iwai's report that no collagen peptide larger than Pro-Hyp-Gly could be found in plasma.[7]

From the F_2, 16 kinds of small peptides were identified: Ala-Asn, Ala-Hyp-Gly, Asp-Glu, Glu-Asn, Glu-Asp, Glu-Met, Gly-Pro-Hyp, Leu-Hyp, Leu-Met, Phe-Gly-Asn, Pro-Gly-Leu, Pro-Leu, Ser-Gly-Met, Ser-Hyp, Ser-Pro-Gly, Tyr-Met (Figure 4). These were quite different from previous reports,[1,7,8] which could be due to the differences of the collagen source, experimental animal, and detection method. It is known that oligopeptides are frequently degraded in a short time by peptidase in blood. For example, the half-lives of Ala-Tyr, Gly-Tyr, Ala-Gln, Gly-Gln, *N*-acetyl-Ser-Asp-Lys-Pro, and Pyr-His-Pro-NH_2 in blood were less than 10 min.[20,21] However, combined with the high percentage of collagen peptides in plasma (63.4%) 2 h after oral ingestion, it indicated that these collagen peptides might have a high resistance to digestion by the enzymes in plasma and the gastrointestinal tract.

It has been demonstrated that Pro-Hyp and Pro-Hyp-Gly had chemotactic activity to the human fibroblast, peripheral blood neutrophils, and monocytes.[22] This showed that collagen peptides acted as a biological messenger and triggered the synthesis of new collagen fibers and reorganization of the extracellular matrix by stimulating fibroblast cells. Pro-Hyp and Hyp-Gly had a stimulatory activity on the proliferation, migration, and hyaluronic acid synthesis of the skin fibroblast,[8,23,24] which indicated that collagen peptides modulated the cells and extracellular matrix in the skin. Asp-

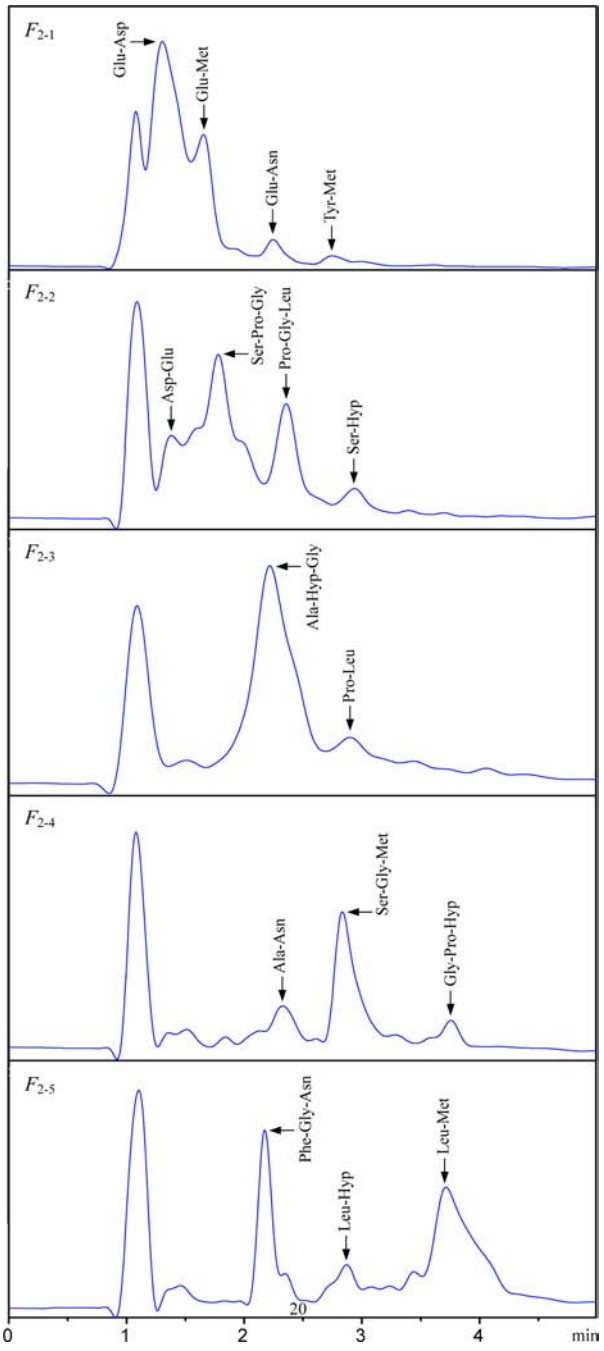

Figure 4. Chromatographic profiles of plasma filtrate fraction (F_2) with a BEH130 C18 column.

Gly-Glu-Ala could stimulate osteoblast-related gene expression of bone marrow cells.[25] Furthermore, Ala-Hyp and Gly-Pro-Val were potential inhibitors of angiotensin-converting enzyme, and Gly-Pro-Hyp was suggested to be involved in platelet aggregation,[26,27] suggesting their beneficial effects on hypertension and thrombosis. However, only a small part of the collagen peptides and their physiological effects are currently known about. It is necessary to obtain more detailed information on the physiological effects and molecular mechanisms of the collagen peptides in further investigation.

In conclusion, the bioavailability and bioavailable forms of collagen after oral administration to rat were investigated in this study. The bioavailability of collagen was lower than animal protein, but was comparable to cereal protein. Most of the digested collagen was absorbed in the form of a peptide rather than a free amino acid, and the absorbed amount of an amino acid depended on its content in collagen. Moreover, some collagen peptides in the plasma were purified and identified, but further studies are needed to investigate their physiological effects and molecular mechanisms.

a variety of techniques. The morphologies of the native forms of gums were compared with their DDSA derivatives using SEM analysis. DGK and its DDSA derivatives were characterized using attenuated total reflectance−Fourier transform infrared spectroscopy (ATR-FTIR), ^{1}H NMR, thermogravimetric analysis (TGA), differential scanning calorimetry (DSC) analysis, and rheological studies. The critical aggregation concentration (CAC) was determined by means of dye solubilization and surface tension. We tested the antibacterial properties of DDSA-DGK using Gram-positive and -negative bacteria and believe this to be the first instance of such experimentation.

MATERIALS AND METHODS

Materials. The GK sample was procured from Girijan Co-operative Corp. (GCC), Hyderabad, India. (2-Dodecen-1-yl)succinic anhydride (DDSA), sodium nitrate, sodium iodide, hydrochloric acid, cyclohexane, and absolute ethanol were obtained from Sigma-Aldrich Co. Ltd. (St. Louis, MO, USA). Sudan IV (dye content 80%) was obtained from Eastman Kodak Co. (Rochester, NY, USA). Deionized water was used for all analyses.

Preparation of DGK. The GK was powdered in a high-speed mechanical blender and later sieved using a bin (mesh size = 250 μm), so as to obtain fine and uniform samples. One gram portions of GK powder were accurately weighed and dispensed into clean glass beakers containing 1 L of deionized water. The gum solutions were placed on magnetic stirrers at room temperature and gently stirred overnight, after which they were allowed to stand at room temperature for 12 h to separate out any undissolved matter. The resulting gum solutions were subsequently centrifuged to obtain clear solutions. Three volumes of each of the gum solutions was deacetylated by mixing with 1 volume of 1 M NaOH. After incubation for 6 h at room temperature (with gentle agitation on a magnetic stirrer), 1 volume of 1 M HCl was added to neutralize the solution to a final pH of 7.0. The resulting DGK solution was dialyzed (dialysis tubing DTV 12000.09.000; M_w range = 12−14 kDa, Medicell International Ltd., London, UK) extensively against deionized water to remove residual salts. The centrifuged DGK solution was dialyzed against deionized water. After dialysis, the gum solution was centrifuged to remove any residual precipitates, and the clear solutions so obtained were freeze-dried and stored until further use. Deacetylation was monitored by FTIR analysis.[4]

Determination of Molecular Mass Distributions of DGK. The molecular mass distributions of DGK were determined using the technique of gel permeation chromatography (GPC) linked to multiangle laser light scattering (MALLS). Sodium nitrate (0.1 M) containing 0.005% sodium azide (biocide) was utilized as the eluent, and the solution was filtered using a GSWP 0.45 μm nylon filter (Millipore) and degassed by means of a vacuum degasser (CS 615; Cambridge Scientific Instruments, UK) before use. The samples of DGK (0.2 wt %) were prepared in 0.1 M $NaNO_3$ solution and left overnight on a roller to achieve complete dissolution. The GPC system consisted of a Suprema 3000 column with these specifications: dimensions, 300 mm × 8 mm; bead size, 10 μm; and pore size, 100 Å. The column was protected by a guard column (Polymer Standards Service GmbH, Mainz, Germany). The flow rate was set to 0.5 mL/min using a Waters Corp. HPLC pump in conjunction with a Rheodyne 7125 model injection system (loop volume = 200 μL). A Dawn DSP Laser Photometer and OPTILAB DSP Interferometric Refractometer (Wyatt Technology Corp., Santa Barbara, CA, USA) were used as detectors. The DGK samples were filtered through 0.45 μm nylon syringe filters before being injected into the HPLC column. All measurements were performed in triplicate. Molecular mass distributions and rms radius moments of the DGK were determined using the designated Astra software for Windows (4.90.08, QELSS 2. XX). Data were fitted using a first-order polynomial and the Zimm model. The refractive index increment (dn/dc) value for DGK was determined to be 0.140 mL/g.[20]

Synthesis of DDSA Derivative of DGK. DGK (15 g, lyophilized dry powder) was suspended in deionized water (100 mL) with gentle agitation and placed on a roller overnight (12 h). The pH of the solution was adjusted to 8.5 by adding 5% NaOH. A weighed quantity of DDSA (5 g) dissolved in absolute ethanol (30 mL) was slowly added to the gum solution. All reactions were performed in 500 mL, three-necked round-bottom flasks placed in a water bath to maintain a temperature of 25 °C. A propeller mixer (Heidolph type: STI) with a PTFE centrifugal stirrer shaft (6 mm diameter, 400 mm length) was used for continuous mixing of the solutions. The pH of the reaction mixtures was adjusted using 5% NaOH and a peristaltic pump. The reaction was continued for 7−8 h until the pH became stable at 8.5. The resultant product was neutralized with 5% HCl to pH 6.0 before being freeze-dried, yielding a white powder. The final product was purified by Soxhlet extraction for 6 h using cyclohexane as solvent. Finally, the DDSA-DGK was dried in an oven overnight at 70 °C.

SEM Analysis. The composition and morphology of the native GK, DGK, and DDSA-DGK were studied using a scanning electron microscope with a beam current of 12−40 nA and an acceleration voltage of 0.02−30 kV. The complete detection system is composed of an In-lens energy and angle selective backscatter detector (EsB), four-quadrant solid-state backscattered detector (AsB), and conventional secondary electron detector (Everhardt-Thornley) (Carl Zeiss, Ultra/Plus, Munich, Germany). Specimens were permanently mounted onto stubs using slow-drying Araldite or silver dag. The stubs with the specimens were then sputter-coated with a thin layer of gold to make the specimens conductive under high-vacuum conditions. The processed specimens were then subjected to SEM analysis.

ATR-FTIR Spectrometry. ATR-FTIR (Nicolet IZ10, Thermo Scientific, USA) was used to characterize the functional groups of GK, DGK, and DDSA-DGK. The spectrometer was equipped with a multireflection, variable angle, and horizontal ATR accessory.

Determination of the Degree of Substitution (DS). The DS of DDSA-DGK was determined by titration and ^{1}H NMR methods. The titration procedure adopted for the determination of the DS for DDSA-DGK was as reported for gum arabic and starch.[13,19] In brief, 1 g of DDSA-DGK was accurately weighed into a 50 mL beaker, after which 20 mL of deionized water was added. The resulting solution was magnetically stirred until complete dissolution was achieved. Subsequently, 0.05 M NaOH was added slowly until the solution pH reached 9.0. The resulting solution was then titrated against 0.05 M HCl. A control reaction was also performed with unmodified DGK. All of the experiments were carried out in triplicate, and average values were noted. The DS was determined using the equation

$$\mathrm{DS} = \frac{M_{\mathrm{DDSA}} MV}{(W - M_{\mathrm{DDSA}})MV} \times 100\% \quad (1)$$

where V is the volume of the titer, M is the molarity of the HCl solution, M_{DDSA} is the molecular weight of the DDSA (266 g/mol), and W is the weight of the DDSA-DGK sample.

^{1}H NMR Spectroscopy. The samples (DGK and DDSA-DGK, 5 mg each) were dissolved in D_2O or DMSO-d_6 and placed in NMR tubes. The ^{1}H NMR spectra were measured using a 500 MHz spectrometer (Bruker DRX-500, Rheinstetten, Germany) at 70 °C. The DS was determined by comparing the intensity (I) of the peak at δ 0.89 due to the $-CH_3$ group from the terminal end of the alkenyl chains with that of anomeric protons of the (1→4)-α-D-GalA-(1→2)-α-L-Rhap units of DGK from the ^{1}H NMR spectra by using the following equation:

$$\mathrm{DS} = \frac{[1/3 \times I_{(\mathrm{DDSA,methyl\ group})}]}{[I_{(1\rightarrow4)\text{-}\alpha\text{-D-GalA}-(1\rightarrow2)\text{-}\alpha\text{-L-Rhap,anomeric protons plus reducing end})}]} \times 100\% \quad (2)$$

The present study was compared to the determination of DS using ^{1}H NMR of DDSA and OSA derivatives of various polysaccharides such as inulin,[15] konjac glucomannan,[16] hyaluronic acid,[21,22] and starch.[13,23,24]

DSC. DSC experiments on DGK and DDSA-DGK were carried out using a Pyris Diamond S6 DSC (PerkinElmer, Boston, MA, USA).

DOI: 10.1021/jf505783e
J. Agric. Food Chem. 2015, 63, 3757−3765

The sample was heated from 30 to 400 °C with temperature increments of 10 °C in a nitrogen atmosphere, at a flow rate of 20 mL/min. Each sample (5 mg) was crimped in an aluminum DSC pan.

TG Analysis. The thermal stability and composition of the DGK and its DDSA derivative were determined using a Mettler Toledo apparatus (TGA/SDTA851, Columbus, OH, USA). The experimental atmosphere was nitrogen at a flow rate of 20 mL/min. The sample was heated from 30 to 800 °C.

Critical Aggregation Concentration (CAC). The CAC was determined using dye solubilization and surface tension techniques.

Dye Solubilization. CAC was determined by the dye solubilization technique using Sudan IV. A total of 10 mg of dye was added to 10 mL of the DGK and DDSA-DGK, at various concentrations in deionized water. The samples were mixed overnight at room temperature and filtered through Mille-GP 0.22 μm filters (Millipore Ireland Ltd.) into disposable, UV-grade, 10 mm path length cuvettes (CXA-110-0053, Fisher Scientific Ltd., Loughborough, UK). The absorbances of the solutions were measured at 510 nm using a Lambda 25 UV−vis spectrometer (PerkinElmer). All of the measurements were carried out in triplicate. The CAC was determined from the increase in absorbance. A blank solution of DGK was used as the control.

Surface Tension Measurements. The Du Noüy ring method was used to determine the surface tension of solutions of DGK and the DDSA-DGK derivative at different concentrations using a Kruss K8 surface tensiometer (Krüss GmbH, Hamburg, Germany). Measurements were carried out in triplicate, and the values were reported as means ± SD. The CAC was determined from the inflection in the plot of the surface tension versus concentration.

Rheological Study. Rheological measurements of both aqueous DGK and DDSA-DGK were performed using a rheometer (Physica MCR 51, Anton Paar GmbH, Graz, Austria). The solutions were characterized for their steady shear viscosity function, $\eta(r)$, using a unidirectional steady-shear flow, with shear rate ranging from 1 to 700 s^{-1} at 25 °C.

Antibacterial Activity Tests. *Bacterial Strains and Culture Media.* The bacterial strains of Gram-negative *Escherichia coli* (CCM 3954) and *Pseudomonas aeruginosa* (CCM 3955) and Gram-positive *Staphylococcus aureus* (CCM 3953) used in this study were obtained from the Czech Collection of Microorganisms, Masaryk University Brno, Czech Republic. Bacterial suspensions were always prepared fresh by growing a single colony overnight at 37 °C in a nutrient broth. All agar plates were freshly prepared before antibacterial testing. A sterilized cotton swab was dipped into the culture suspension, and the cells were spread homogeneously over the agar plates. These plates were immediately used for antibacterial activity tests.

Determining the Zone of Inhibition (ZOI). We determined the antibacterial activity of the DDSA derivative of DGK. The DDSA-DGK solutions (1, 2, 3, 4, and 10% each of DDSA-DGK) were pipetted onto sterilized membrane filters and placed on inoculated agar plates. In addition, 6 mm diameter circles of filter paper were also placed directly onto the inoculated agar plates. Similarly, samples of DGK solution (10%) without DDSA were used as controls. The samples and inoculated agar plates were then incubated for 24 h at 37 °C. The ZOI was determined as being the total diameter (mm) of DDSA-DGK filter paper sample plus the halo-zone where bacterial growth was inhibited. All measurements were performed in triplicate for the DDSA-DGK solutions, and average values were reported.

Statistical Analysis. All of the tests were performed in triplicate. Analysis of variance (ANOVA) was performed, and all experimental values were reported as means ± SD (n = 3). A Duncan test was conducted to examine significant differences among experimental mean values ($P < 0.05$).

RESULTS AND DISCUSSION

Molecular Mass Distribution of DGK. The estimated molar mass distributions (weight-average, M_w; number-average, M_n and z-average, M_z) and average mean square radius moments (R_n, R_w, and R_z, all in nm) of DGK are presented in Table 1. The data were obtained using GPC/MALLS and fitted with first-order polynomials using the Zimm method. The elution profiles of DGK juxtaposed against their corresponding molecular weight distributions (derived using GPC in conjunction with light scattering and refractive index detectors) are also shown in Figure 1. For DGK, the weight-average molecular weight was ascertained to be 1.827×10^6. The weight-average molecular mass of DGK was found to be higher compared to other tree gums reported in the literature.[20,25]

Table 1. Estimated Molar Mass Distributions and Average Mean Square Radius Moments of DGK Using GPC/MALLS and Data Fitting by First-Order Polynomials: Zimm Method[a]

M_n (g/mol)[b]	M_w (g/mol)[c]	M_z (g/mol)[d]	R_n (nm)[e]	R_w (nm)[f]	R_z (nm)[g]
1.537×10^6	1.827×10^6	2.062×10^6	87.0	91.8	95.3

[e]R_n, number−average mean square radius. [f]R_w, weight-average mean square radius. [g]R_z, z-average mean square radius.

Preparation and Characterization of DDSA Derivative of DGK. *Esterification of DGK.* The scheme for esterification of DGK with DDSA is presented in Figure 2. The major parameters that affected the formation of DDSA derivatives of the DGK were the concentration ratio of DDSA and DGK, pH, concentration of NaOH solution, reaction time, and temperature.[13−15] In the present study, the DDSA-DGK ratio was maintained at 3:1; the pH of the reaction mixture was kept between 8 and 9 using 3% NaOH; and the temperature was held between 25 and 30 °C for 8 h.

Confirmation of Esterification by ATR-FTIR. ATR-FTIR spectra of GK, DGK, and the DDSA-DGK are presented in Figure 3. Spectra of GK and DGK displayed peaks at 3300 cm^{-1} (relating to the OH group) and also peaks in the fingerprint region (corresponding to −C−O−C− stretching vibrations of various sugar moieties present in the gums) at 1159, 1082, and 1014 cm^{-1}, respectively. The band at 2923 cm^{-1} represents the characteristic vibration due to C−H stretching. The DDSA-DGK spectrum indicates that the peaks at 1726 cm^{-1} represent the −COOR group. The latter group is absent in the spectra of DGK and is the result of ester bond formation between the −COOH groups of DDSA and the −OH groups of the DGK in the derivatization process (Figure 3c). Compared with DGK spectra, the new absorption bands at 1726 and 1572 cm^{-1} appear after DDSA esterification of DGK corresponding to the C═O stretching vibration of an ester group and the asymmetric stretching vibration of a carbonyl group, respectively (Figure 3c). Furthermore, the predominant band at 2923 cm^{-1} representing aliphatic C−H stretching vibrations suggested the formation of DDSA-DGK (Figure 3c). The prominent peak observed in the DDSA derivative of DGK was a reflection of the high degree of substitution. Similar types of results were reported in the literature when corn starch,[13] inulin,[15] and gum arabic[19] were derivatized with DDSA to form DDSA derivatives of these polysaccharides.

SEM Analysis of GK, DGK, and DDSA-DGK. SEM images relating to the surface morphology of GK, DGK, and the DDSA-DGK derivative are shown in Figure 4. Irregular particles were observed on the surface of GK (Figure 4A),

DOI: 10.1021/jf505783e
J. Agric. Food Chem. 2015, 63, 3757−3765

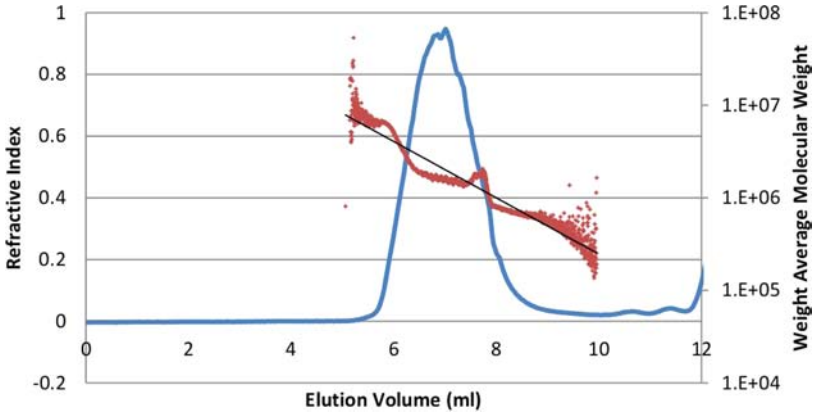

Figure 1. Refractive index and weight-average molecular mass GPC elution profiles of DGK.

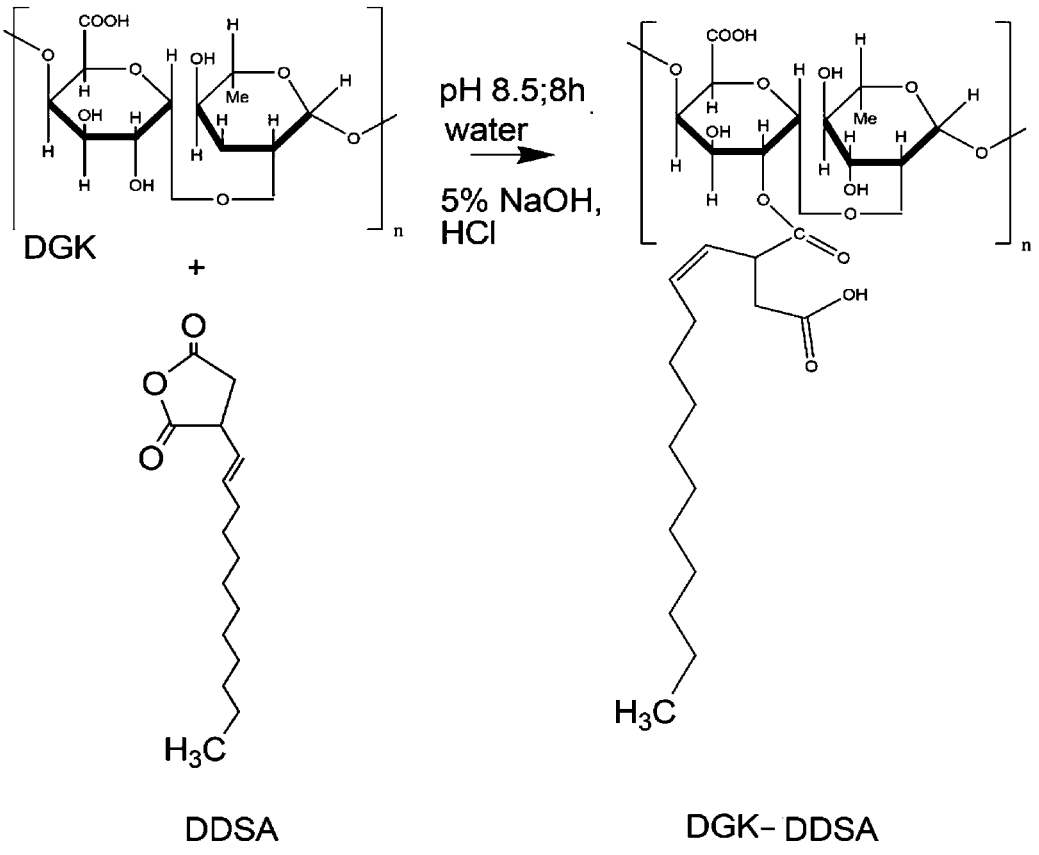

Figure 2. Schematic representation of reaction between DDSA and DGK and formation of the DDSA-DGK derivative.

and flake-like structures were displayed for DGK due to deacetylation of GK (Figure 4B). Significant changes, namely, highly porous structures and cavities, were observed after DDSA derivatization of DGK (Figure 4C). SEM analysis showed that the DDSA treatment caused some changes in the structure of the DGK. The SEM images of DDSA-DGK (Figure 4C) exhibited slightly rough surfaces with greater porosity, and many holes were observed, probably due to the DDSA treatment occurring on the surface of the DGK. This indicated that the esterification reaction had taken place. Similar types of morphological analysis have been reported for octenylsuccinic anhydride modified early "Indica" rice starch.[26]

Determination of the DS Using Titration and ^{1}H NMR Spectroscopy Methods. The DS of DDSA-DGK was determined to be 10.29% by means of titration using eq 1. ^{1}H NMR spectra of DGK and DDSA-DGK are presented in Figure 5. The DS can be calculated from the intensity of DDSA groups' signals as a ratio of the DGK anomeric protons, which are used as an internal reference. The proton signals at δ 3.2–3.7 were very broad and complex. They were attributed to protons of various sugar moieties present in the DGK.[4,27] Compared to the DGK, the DDSA-DGK derivative had several additional signals (Figure 5). It was seen that the peak at δ 0.89 in the ^{1}H NMR spectrum corresponded to the methyl protons of the DDSA group.[13,15] The peaks from δ 1.28 to 2.62 were due to the methylene and methenyl groups of the DDSA.[13,15] There was a multiplex at δ 5.54 and a shoulder with multiple peaks around at δ 5.4. These peaks were ascribed to protons of the double bond in the DDSA group. Signals from δ 4.5 to 5.2 observed in DGK were assigned to the anomeric proton.[27]

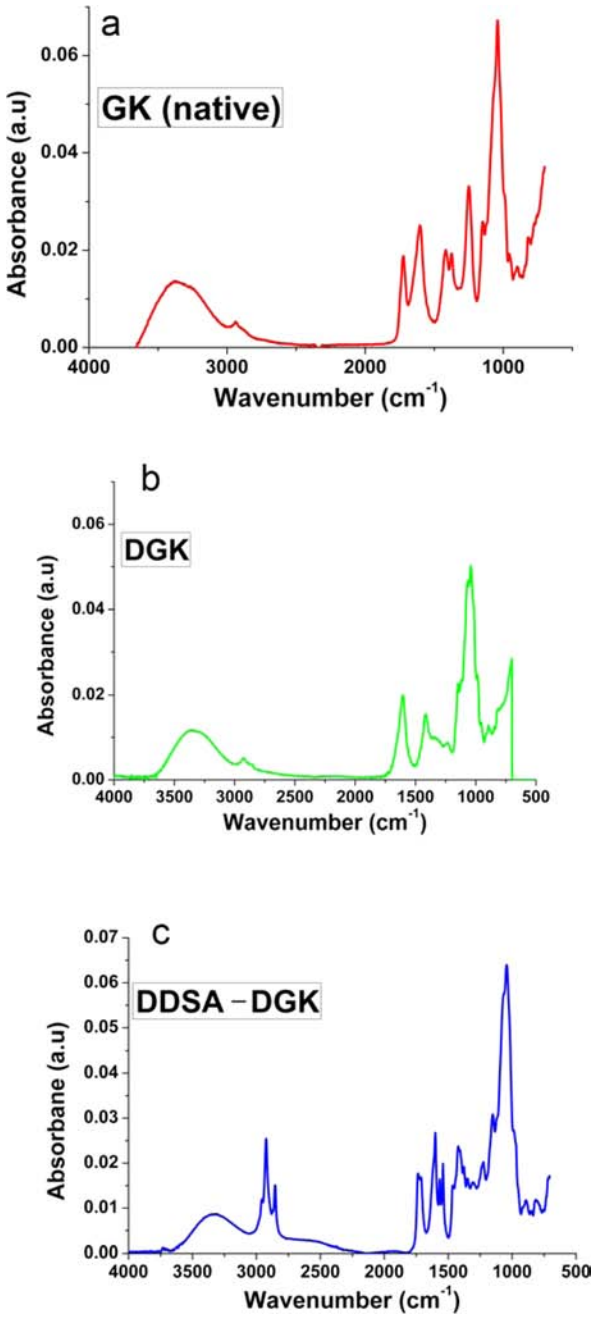

Figure 3. ATR-FTIR spectra of (a) GK, (b) DGK, and (c) DDSA-DGK.

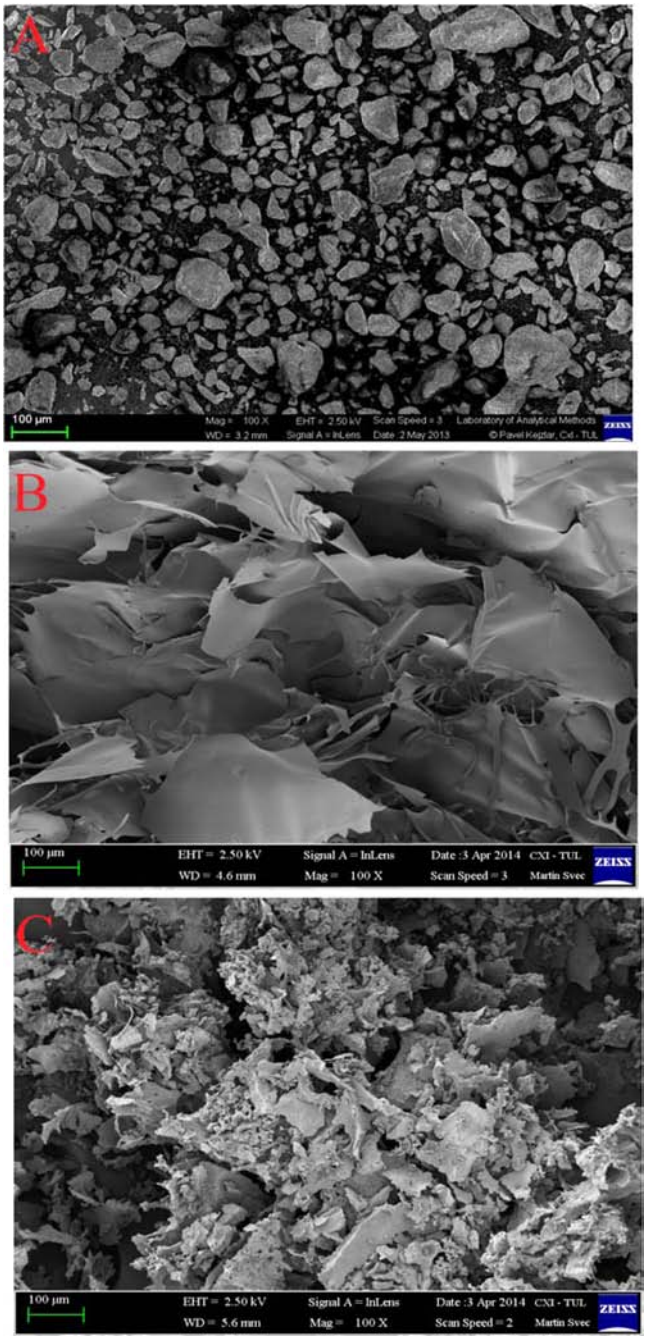

Figure 4. SEM micrographs of the surfaces of (A) GK, (B) DGK, and (C) DDSA-DGK, indicating the morphological changes during esterification.

After DDSA modification, the additional signals appeared in the δ 0.89−3.00 region of the DDSA-DGK spectrum. ^{1}H NMR spectroscopy was utilized for the determination of the DS of the OSA/DDSA anhydrides to many polysaccharides such as inulin,[15] konjac glucomannan,[16] hyaluronic acid,[21,22] and starch,[13,23,24] and the present study is in agreement with these reported methods in the literature.

It was not possible to determine which hydroxyl moieties the DDSA had reacted with or how evenly distributed the modification had been along the polymer chain. According to earlier studies on starches, both primary and secondary hydroxyl groups of the glucose repeating unit had been observed to react with the OSA/DDSA. This was also the case for other starches, hyaluronic acid, and most other polysaccharides, as reported in the literature.[21−24] In the DGK molecule, there are three hydroxyl groups available for chemical modification. They are located at the C-2, C-3, and C-6 positions. Hydroxyl groups at C-2 and C-6 are more active than those at C-3 because of their steric attributes. The extent of alkenyl chain incorporation (DS) was calculated from the ratio of the peak areas at δ 0.89 to the corresponding area from δ 3 to 5.5, due to the contribution of DGK, which we established had a DS of 10.25%. In the present investigation, the values of the DS for DDSA-DGK obtained by titration and ^{1}H NMR methods were 10.29 and 10.25%, respectively. Therefore, the figures obtained from the DS calculation by using both methods complement each other very well. These results are

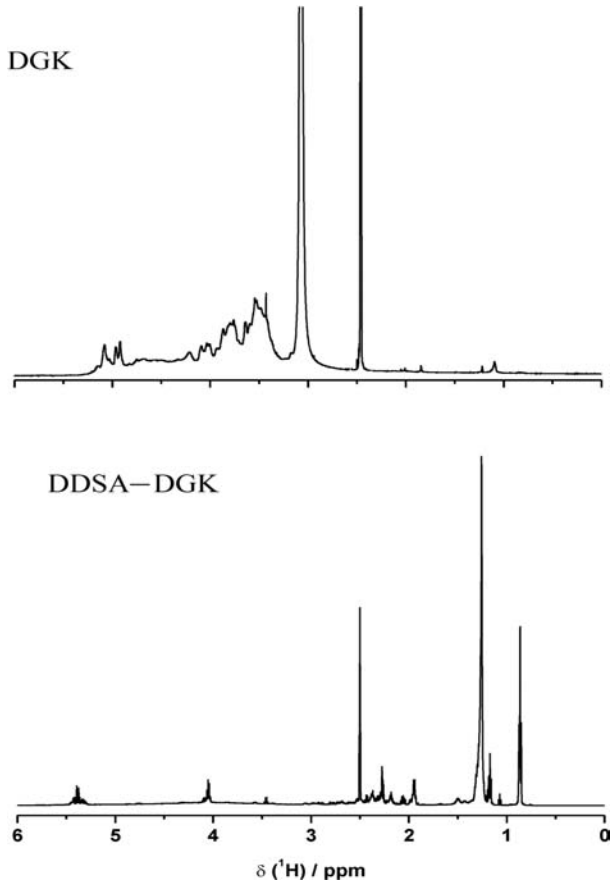

Figure 5. ^{1}H NMR spectra recorded for DGK and DDSA-DGK.

in agreement with those obtained for DDSA derivatives of starch,[13] inulin,[15] and gum arabic[19] previously reported in the literature.

TGA. The TGA and derivative thermogravimetric analysis (DTG) plots of DGK and the DDSA-DGK derivative are presented in Figure 6. TGA was performed in an inert nitrogen atmosphere. From the TGA curves, it is evident that the DDSA-DGK derivative decomposed in two major weight-loss steps as compared to DGK, which decomposed in a single step. The first stage of decomposition occurred in DDSA-DGK at 219 °C. This is attributed to breakage of ester bonds between DDSA and the gum at the aforementioned temperature and the

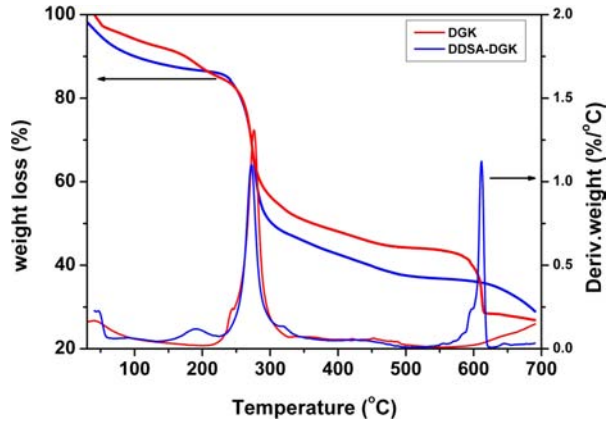

Figure 6. TGA and DGT curves as a function of temperature for DGK and DDSA-DGK.

release of alkyl chains from the DDSA. The second major degradation step shown by the DDSA derivative of DGK occurred at a peak decomposition temperature of 275 °C, this representing the bulk of the weight loss. This substantial weight reduction was due to breakages of main-chain linkages of DGK at this temperature. A similar behavior was reported for TGA of carboxymethyl starch/quaternary ammonium salt complexes, where two-step weight losses caused by the release of alkyl moieties associated with surfactant and the starch matrix were observed.[28] Thus, TGA indicates clearly that pristine DGK is more stable than its corresponding DDSA derivative. However, the DDSA derivatized samples exhibited lower weight loss until approximately 200 °C, owing possibly to the reduced water absorption of the modified samples. DGK in contrast showed a higher weight loss until 200 °C. However, the overall rate of decomposition of DDSA-DGK was faster compared to DGK and gave a low char yield of 20%. The comparative yield for pristine DGK was twice this value.

DSC. Figure 7 shows DSC thermal curves for both DGK and its derivative, DDSA-DGK. The DSC profiles reflect the

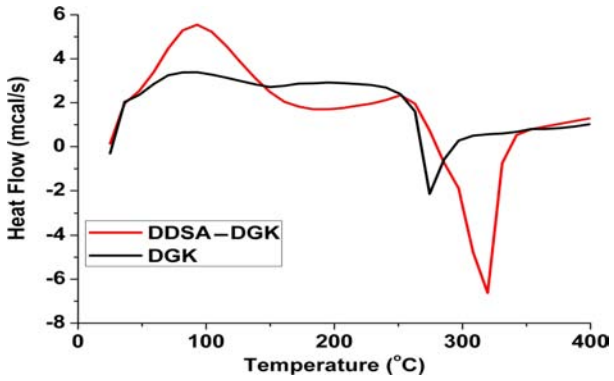

Figure 7. DSC thermograms of DGK and DDSA-DGK.

occurrence of exothermic and endothermic changes with increasing temperature. Thermograms for the DDSA-DGK indicate a broad endothermic transition over the range of 60–140 °C with a melting peak at around 93 °C. This can be attributed to the increased thermoplastic nature of DDSA modified DGK brought about by plasticizing alkenyl groups, probably through internal plasticization. The results suggest that the DDSA-DGK derivative has better thermoplasticity compared to pristine DGK. The decreased enthalpy value of the first transition (Figure 7) also suggests greater interaction between DGK and DDSA. DGK does show a very mild transition in this range, if viewed individually. The improved thermoplastic nature effected by alkyl group modified surfactants and the adoption of simple methodologies have been reported earlier.[28] Both samples exhibited exothermic peaks at higher temperatures, at 276 °C for DGK and at 319 °C for DDSA-DGK. These results suggest that modification by DDSA had improved the thermal stability. The enthalpy changes associated with the first and second transitions were 63 and −116 J/g for DDSA-DGK. In comparison, the DGK gave corresponding figures of 415 and −203 J/g. Furthermore, the results obtained indicate that hydrophobic groups of the DDSA reagent had weakened hydrogen bond formation in the DDSA-DGK derivative. This in turn enhanced structural flexibility, altered the gelatinization temperature, and brought about a

DOI: 10.1021/jf505783e
J. Agric. Food Chem. 2015, 63, 3757–3765

reduction in enthalpy, as had also been reported for OSA derivatives of starch.[29]

CAC. *Dye Solubilization.* Absorbance versus concentration plots for DGK and DDSA-DGK along with Sudan IV dye are presented in Figure 8. The absorbance of DGK does not

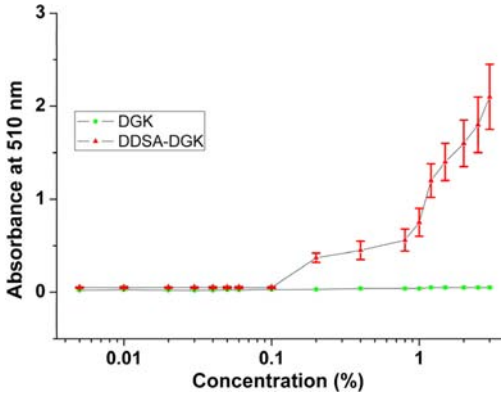

Figure 8. Concentration dependence of the UV−vis absorbances of DGK and DDSA-DGK in the presence of Sudan IV dye.

change over the concentration range studied, confirming that there is no interaction between DGK and the dye. For the DDSA-DGK sample, the absorbance values increase significantly above a certain concentration, indicating the formation of aggregates (Figure 8). The CAC was determined to be 0.1% for DDSA-DGK, the results obtained being in agreement with CAC values reported for DDSA derivatives of inulin[15] and gum arabic.[19]

Surface Tension Measurements. The surface tensions of DDSA-DGK solutions are plotted as a function of concentration in Figure 9. The surface tension of the DGK derivative

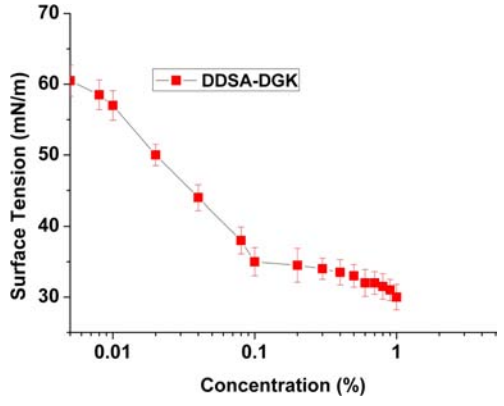

Figure 9. Surface tension of DDSA-DGK as a function of concentration.

was found to decrease with increasing concentration, but there was a distinct inflection in the curve, corresponding to the CAC. This was attributable to the formation of micelle-type aggregates brought about by hydrophobic association of the molecules through the alkyl chains, occurring at a concentration of 0.1%. This value is in good agreement with the result obtained from the dye solubilization experiment (Figure 8). The surface tension was found to be ∼30−35 mN/m at the CAC. The experimental values obtained concur with the CAC values reported in the literature for DDSA derivatives of inulin[15] and gum arabic.[19]

Rheological Properties. The flow behavior of DGK and DDSA-DGK at different concentrations (1, 2, and 3% w/w) was monitored, and the apparent viscosities were plotted as a function of shear rate. It was observed that for both DGK and DDSA-DGK in deionized water, the apparent viscosity increased with rising concentrations of both formulations (Figure 10). The apparent viscosity of the DDSA-DGK

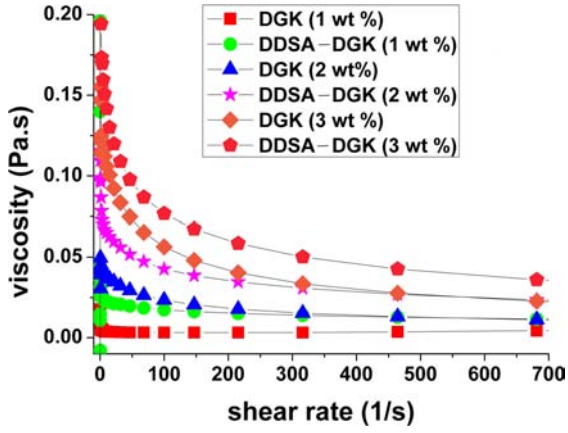

Figure 10. Plots of viscosity as a function of shear rate for DGK and DDSA-DGK of different concentrations (1, 2, and 3%).

derivative was significantly higher than that of DGK alone at the same concentration. This indicated that DDSA derivatization had indeed occurred and had resulted in a higher molecular weight. The higher viscosity values reported for OSA derivatives of starch[30,31] are in agreement with the results of our present study. It was also noted that the viscosities of both DGK and DDSA-DGK decreased sharply with increasing shear rate for all concentrations, eventually reaching a constant value at higher shear rates. The behavior was ascribed to the formation of aggregates through hydrogen bonding and polymer entanglement, producing a highly ordered arrangement of stiff molecules. This ultimately resulted in high viscosity at low shear rates, as reported in the literature for gum kondagogu.[32]

Antibacterial Properties. We tested the antibacterial activity of the DDSA-DGK against Gram-negative *E. coli* and *P. aeruginosa* and Gram-positive *S. aureus* bacteria. The results show that the control sample without DDSA does not display any antibacterial activity. Figure 11 and Table 2 summarize the results ZOI were determined.

The ZOI for Gram-negative *E. coli* and *P. aeruginosa* and Gram-positive *S. aureus* were 8.2 ± 0.8, 8.0 ± 0.8, and 8.2 ± 0.7 mm, respectively, for 1 wt % concentration of DDSA-DGK. The ZOI for DDSA-DGK against *E. coli*, *P. aeruginosa*, and *S. aureus* were seen to increase when the concentration of DDSA-DGK rose from 1 to 10 wt % in all three cases. Furthermore, the antibacterial ZOI for DDSA-DGK against Gram-negative *E. coli* and *P. aeruginosa* and Gram-positive *S. aureus* were observed to be almost equal for all three tested microorganisms of different bacterial strains (Table 2).

These results were in good agreement with earlier reported investigations about antibacterial properties of gum tragacanth/PVA nanofibers, Ag/montmorillonite/chitosan bionanocomposites, and PVA/carboxymethyl-chitosan/Ag-nanowires.[33−35] The present study suggests that antibacterial properties of DDSA-DGK are enhanced with increasing concentration. The improved antimicrobial action of DDSA-DGK may be related

to the balance of hydrophilicity/hydrophobicity and the increased surface roughness of DGK after derivatization with DDSA, the latter helping to increase contact between the surfaces of the material and the bacteria. The current work is in agreement with the antibacterial action of poly(propylene)-modified Cu and Ag nanocomposites and polyethylene/triclosan/chlorohexidene composites[36,37] However, the antibacterial properties of DDSA are less well-known compared to those of Ag nanoparticles.[38] The biocidal attributes and toxicity of Ag nanoparicles have also been studied in detail recently.[39,40] With regard to nontoxicity, the present undertaking emphasizes that natural gum derivatized DDSA materials can be developed as the leading antibacterial agent, which could replace the toxic Ag and Cu of CuO-based polymeric materials in their role as antimicrobial agents. Given that gums are widely used in food and pharmaceutical applications as stabilizing and emulsifying agents,[2] the development of DDSA derivatized gums has potentially two major benefits, namely, as stabilizers and antibacterial agents in food and nonfood applications.

processing conditions and could oxidatively modify side chains and polypeptide backbone of protein, resulting in its conformational changes.[26] Meanwhile, MDA can react with amino groups of proteins, producing strong intermolecular cross-links of the Schiff base type.[27] In our previous study,[25] the novel cold-set MP gel could be formed on the premise of the swelling of MP under 0.6 M NaCl and the non-disulfide covalent bond induced by MDA. The gelation mechanism of salted MP mainly involving simultaneous protein oxidation and internal cross-linking via MDA was also proposed.[25] On the basis of our previous findings, we thus postulated that incubation with MDA in MP-based emulsion systems may result in the formation of a new type of cold-set emulsion gel stabilized by MP. This speculation would provide foundational information for further exploring the potential impact of MDA in real meat emulsions during manufacturing and storage.

The objective of this study was to test the hypothesis that MDA affects the gelation of MP-stabilized emulsion under different ionic strength conditions. The consequential changes in emulsion gel in terms of the amount/fraction of protein entrapped/non-entrapped as well as mechanical properties (gel elasticity, strength, water-holding capacity), microstructure, and oxidative stability were all investigated to elucidate the structure-modifying effect of MDA.

MATERIALS AND METHODS

Materials. Longissimus muscle from three pork carcasses (48 h post-mortem) was purchased from a local commercial abattoir (Zhongshan, China); the pigs were slaughtered at about 6 months of age following standard industrial procedures. Fat was trimmed away, and muscle was cut into cubes, minced, vacuum packaged (ca. 100 g), and frozen at −80 °C until use (within 3 days). Commercially available Jinlongyu soybean oil (pure) produced by Yihai Kerry Food Co. (Shanghai, China) was purchased from a local supermarket. MDA solution was prepared by acid treatment of 1,1,3,3-tetramethoxypropane obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO, USA). Nile Blue A and Nile Red were obtained from Sigma-Aldrich Chemical Co. All other chemicals were of analytical reagent grade.

Extraction of MP. Three batches of MP were prepared from different bags of raw muscle thawed at 4 °C according to the method of Park et al.[24] with slight modifications. The pH of MP suspension at 0.1 M NaCl in the last wash was adjusted to 6.25 before centrifugation. The pellet was finally suspended in 20 mM sodium phosphate buffer (pH 6.0) containing NaCl at different levels (0, 0.2, 0.4, and 0.6 M), and the protein concentration was determined according to the Biuret method using BSA as standard.

Emulsion Preparation. Oil-in-water (O/W) emulsions were prepared by dispersing 20 wt % soybean oil in 20 mM phosphate buffer (pH 6.0) containing 3% (w/v) MP at different NaCl levels (0, 0.2, 0.4, and 0.6 M). Coarse emulsions were prepared using a high-speed blender operating at 11000 rpm for 3 min (Ultra-Turrax, IKA-Labortechnik, Staufen, Germany). The coarse emulsions were further homogenized using a two-stage single-piston homogenizer (APV-1000, Albertslund, Denmark) at 30 MPa. Sodium azide (0.02 wt %) was then added to the emulsions to prevent microbial growth. Emulsions were placed in lightly sealed screw-cap vials or 2 mL centrifuge tubes and stored in a dark oven at 25 °C for 30 days.

Evaluation of Emulsions. *Particle Size Distribution.* The mean particle size and size distribution of emulsions were measured by a Mastersizer 2000 (Malvern Instruments Co. Ltd., Worcestershire, UK) at 25 °C. The refractive indices of soybean oil and phosphate buffer were taken as 1.456 and 1.330, respectively. The absorption index was 0.001. The particle sizes measured are reported as the volume-weighted mean diameter $d_{4,3}$ ($d_{4,3} = \sum n_i d_i^4 / \sum n_i d_i^3$), where n_i is the number of particles with diameter d_i.

Rheological Characterization. The rheological properties of the emulsions stabilized by MP at different ionic levels were characterized using a HAAKE MARS III Rheometer (Thermo Electron GmbH, Karlsruhe, Germany) with a parallel plate (diameter = 35 mm), at 25 °C. The gap between two plates was set to 1.0 mm. For determination of steady shear viscosities, shear rate was ramped from 1 to 200 s^{-1}. Shear stress, shear rate, and steady shear (apparent) viscosity (η) were recorded by a RheoWin 4 Data Manager. Dynamic viscoelastic properties were characterized using small-amplitude oscillatory frequency sweep mode. The frequency was oscillated from 0.1 to 100 rad/s, and all measurements were performed within the identified linear viscoelastic region and made at 0.5% strain. The elastic modulus (G'), loss modulus (G''), and loss tangent (tan δ) were recorded.

Preparation of MDA-Modified MP Emulsion Gels. MDA stock solution was freshly prepared by hydrolyzing 1,1,3,3-tetramethoxypropane according to the method described by Wu et al.[28] with minor modifications.[25] The concentration of MDA was determined by spectrophotometric measurements of the dilution 10^{-5} at 267 nm (ε = 31500).

MP emulsion in the presence of 0.6 M NaCl was mixed with MDA at different concentrations (0, 0.5, 2.5, 5, 10, 25, and 50 mM, final). The resulting mixtures were immediately transferred into tightly sealed glass vials (2.5 cm i.d., 5 cm height) and 2 mL centrifuge tubes and incubated at 25 °C in the dark for 24 h. After incubation, a series of treated samples with different states were obtained. To further investigate the influence of ionic strength, MP emulsions at different NaCl levels (0, 0.2, 0.4, and 0.6 M) were mixed with 10 mM MDA. The incubation condition used was the same as mentioned above. MP emulsion in the presence of 0.6 M NaCl treated without MDA was selected as control.

Evaluation of Gel Characteristics. *Low-Amplitude Dynamic Oscillatory Measurements.* Small-deformation rheological measurements using parallel plates (diameter = 35 mm, 1 mm gap) were investigated in a HAAKE MARS III Rheometer (Thermo Electron GmbH). Frequency sweep analysis between 0.1 and 100 rad/s (at 25 °C and 0.5% strain) was applied to investigate the viscoelastic properties.

Gel Strength. The gel strength of emulsion gels was measured using a cylinder measuring probe (P 0.5SS) attached to a TA.TX2 texture analyzer (Stable Micro System, Surrey, UK) at a constant probe speed of 1.0 mm/min at room temperature (25 ± 1 °C). Gel strength is defined as the initial force required to disrupt the gels. All samples were prepared in triplicate.

Water-Holding Capacity (WHC). WHC values of the emulsion gels were determined according to the method of Wu et al.,[12] with slight modifications. Briefly, gels (3 g) were centrifuged at 8000*g* for 30 min at 4 °C. WHC (%) was expressed as the final weight as a percentage of the weight before centrifugation.

Amount of Protein Entrapped. The amount of proteins entrapped was evaluated according to the method of Chanyongvorakul et al.[29] with modifications. After incubation, the emulsion gels in 2 mL centrifuge tubes were centrifuged (10000*g*, 30 min, 25 °C) and used to determine the amount of proteins entrapped. The protein concentration of separated aqueous layer, filtered through a 0.45 μm filter (Millipore Corp.), was determined according to the Bradford assay, using BSA as standard. The percent of entrapped proteins was calculated as (1 − protein concentration in separated aqueous layer/initial protein concentration in the aqueous phase) × 100.

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS-PAGE) Analysis. SDS-PAGE was performed on entrapped and non-entrapped proteins of the emulsion gels according to the method described Flores et al.,[30] under either nonreducing or reducing conditions. Both aqueous and creamed layers after centrifuging (10000*g*, 30 min, 4 °C) were collected and mixed with certain volumes of sample buffer (with and without 5% β-mercaptoethanol (β-ME)) to obtain a theoretical concentration of 1 mg mL^{-1} protein. Samples were vortexed and incubated at room temperature overnight. The ones with β-ME were boiled for 5 min before centrifugation (10000*g*, 10 min). Then, 24 μL of samples was loaded onto the polyacrylamide gel made of 12% running gel and 5% stacking gel and subjected to electrophoresis at a constant current of

J. Agric. Food Chem. 2015, 63, 3766−3777

25 mA per gel using a Mini-PROTEAN 3 Cell apparatus (Bio-Rad Laboratories, Hercules, CA, USA).

Confocal Laser Scanning Microscopy (CLSM). The microstructure of the MDA-modified emulsion gels was determined in a confocal laser scanning microscope (Zeiss, LSM 710, Germany), using Nile Red and Nile Blue A as fluorescence dyes for the protein and oil phases, respectively.[8] Each freshly prepared MDA-treated emulsion sample (1 mL) was stained with about 40 μL of fluorescence dye mixtures of Nile Blue A (0.1%, w/v) and Nile Red (0.1%, w/v) in 1,2-propanediol. The emulsion gels containing the dyes were directly formed in concave confocal microscope slides (Sail; Sailing Medical-Lab Industries Co. Ltd., Suzhou, China), covered with glycerol-coated coverslips (further sealed with tin foil), according to the same conditions mentioned above. Finally, the CLSM images were examined with a 100 magnification lens and an argon/krypton laser having an excitation line of 514 nm and a helium−neon laser (HeNe) with excitation at 633 nm for Nile Blue A and at 488 nm for Nile Red, respectively. Factually, most of the protein-coated oil droplets would be predominantly yellow in appearance of the overlay image (green + red = yellow).

Lipid Hydroperoxide Measurement. Lipid hydroperoxide was measured according to the method described by Tong et al.[31] with some modifications. Emulsions/emulsion gels were diluted in 4 volumes (w/v) of distilled water before homogenization (11000 rpm, 1 min). Aliquots (0.2 mL) of the dilution ere mixed with 1.5 mL of isooctane/2-propanol (3:1, v/v) and vortexed (10 s, three times). After centrifugation at 3400*g* for 2 min, the organic solvent phase (200 μL) was added to 2.8 mL of methanol/1-butanol (2:1, v/v), followed by 15 μL of 3.94 M ammonium thiocyanate and 15 μ L of ferrous iron solution (prepared by mixing 0.132 M $BaCl_2$ and 0.144 M $FeSO_4$). Twenty minutes later, the absorbance was measured at 510 nm using a UV−vis spectrophotometer (Genesys 10, Thermo Scientific, USA). Distilled water was used instead of diluted emulsion as a reagent blank. Hydroperoxide concentrations were determined using a standard curve made from hydrogen peroxide.

Statistical Analysis. Three batches of MP were prepared on different days, each used for independent trials (i.e., replicate preparation of MP, emulsion, and emulsion gel), and all of the experiments were repeated with three different batches of MP. Statistical calculation was investigated using the statistical package SPSS 11.5 (SPSS Inc., Chicago, IL, USA) for one-way ANOVA. The Student−Newman−Keuls test was used for comparison of mean values among determinations using a level of significance of 5%. Data were expressed as means ± standard deviations (SD) of triplicate determinations unless specifically mentioned.

RESULTS AND DISCUSSION

Emulsion Characteristics. *Particle Size Distribution and Physical Stability.* The particle size distributions and changes in the mean droplet diameter ($d_{4,3}$) for MP-stabilized emulsions at different NaCl levels were used to assess emulsifying ability and physical stability, as shown in Figure 1. The fresh emulsion stabilized by MP without addition of NaCl had an almost bimodal distribution with relatively small $d_{4,3}$ (Figure 1). The increase of NaCl concentration increased $d_{4,3}$ and caused a gradual shift of the size distribution peak to the right, indicating a decreased emulsifying capacity.[20] It has been reported that MP began to expand transversely when exposed to about 0.4−0.5 M NaCl and swell profusely at about 0.6 M NaCl due to enhanced electrostatic repulsion by Cl-binding to actomyosin.[25,32] Thus, the swollen MP in the presence of NaCl, on the one hand, decreased the protein adsorption rate on the droplets' surface due to increased steric hindrance; on the other hand, it increased protein−protein interactions,[18,25] resulting in the formation of a thicker layer surrounding the droplet (Figure 1A, inset) and, thus, the larger $d_{4,3}$ (Figure 1).

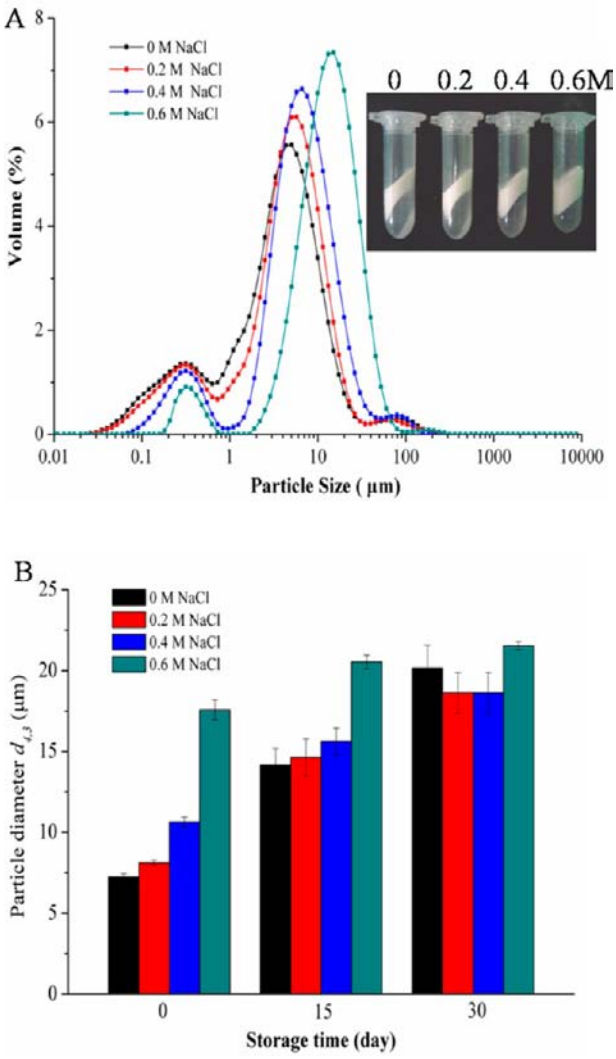

Figure 1. (A) Particle size distributions of fresh emulsions stabilized by MP at different NaCl levels (0−0.6 M). (Inset) Visual observation of fresh emulsions after centrifugation (10000*g*, 30 min). (B) Changes in mean particle diameter $d_{4,3}$ of emulsions during storage for 30 days.

To evaluate the physical stability of emulsions, the changes in the $d_{4,3}$ of emulsions were followed during storage (Figure 1B). As shown in Figure 1B, for the emulsion without NaCl, a marked increase in $d_{4,3}$ was observed with increasing storage time, reaching 20.16 μm at day 30, almost twice larger than that at day 0. Meanwhile, the emulsion exhibited an obvious phase separation (data not shown) after 30 days. These results indicated that MP-stabilized emulsion without NaCl was less stable after 30 days due to the coalescence of oil droplets, which were consistent with our previous study.[20] Compared to the emulsion without NaCl, the stability of emulsions in the presence of NaCl was obviously improved (Figure 1B). Specifically, when 0.6 M NaCl was added, the $d_{4,3}$ showed only a slight increase during the storage (Figure 1B) and no visible phase separation was found (data not shown), suggesting the enhanced stability of emulsions. As has been previously reported, more soluble MP with swollen appearance was available at high NaCl concentrations.[18,32] Therefore, the more hydrated absorbed protein layer with higher thickness around the droplets could be formed (Figure 1A, inset) due to enhanced protein−protein interactions, thus slowing the

J. Agric. Food Chem. 2015, 63, 3766−3777

coalescence of oil droplets and improving the emulsion stability (Figure 1B).[1,10]

Rheological Characterization. The rheological properties, including flow and dynamic viscoelastic properties of emulsions stabilized by MP at different NaCl levels, were characterized, as shown in Figure 2, panels A and B, respectively. All of the

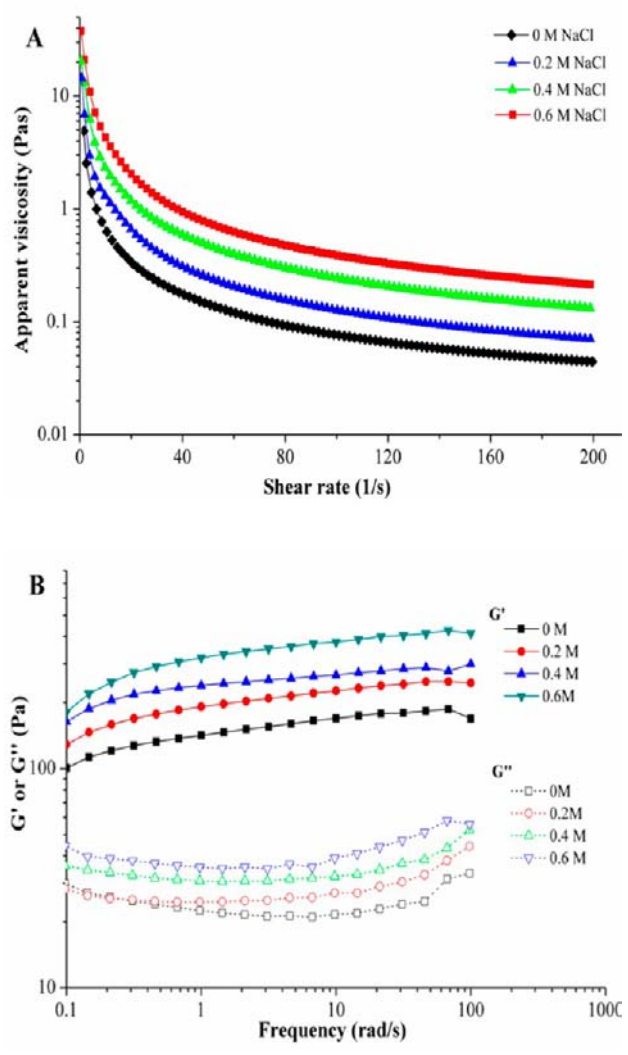

Figure 2. Variation of apparent viscosity (η) with shear rate (A) and of storage modulus (G')/loss modulus (G'') with frequency (B) for MP-stabilized emulsions at different NaCl levels (0−0.6 M).

emulsions exhibited shear-thinning behaviors at the tested shear rates in the range of 0.1−100 s^{-1}, with apparent viscosity (η) progressively decreasing upon increasing shear rate (Figure 2A). This phenomenon is supposed to be associated with the flocculation of fat droplets, as has been well addressed in previous studies.[10,33] Noticeably, at any test shear rate, η progressively increased with increasing NaCl from 0 to 0.6 M (Figure 2A). As has been aforementioned, the swelling of MP with increasing NaCl concentrations could enhance protein−protein interactions,[32] opposing the free flow of the emulsion in a shear field, thus increasing its apparent viscosity (Figure 2A). The increased system viscosity in turn retarded the migration of oil droplets and thus enhanced the emulsion stability (Figure 1B).

As to emulsion viscoelastic properties, in all cases, the storage modulus (G') was higher than the loss modulus (G'') in the test linear viscoelastic range (Figure 2B), suggesting the potential to form elastic gel or gel-like structure. The G' progressively increased with increasing oscillatory frequency (Figure 2B), as has also been observed in some other gel-like emulsions.[10,33] Furthermore, as expected, at any oscillatory frequency, the G' of emulsions stabilized by MP continuously and significantly increased with increasing NaCl concentration from 0 to 0.6 M (Figure 2B), indicating a gradual increase in the stiffness of emulsions. These results completely reproduced the general trends observed in the data from emulsion stability and steady viscosity (Figures 1B and 2A), further suggesting enhanced interdroplet interactions in the presence of 0.6 M NaCl, which contributed to an improvement in the emulsion stability.

Evaluation of MDA-Modified MP Emulsion Gels. *Visual Observation.* Figure 3 shows the images of MDA-modified MP emulsion either at various MDA concentrations (Figure 3A) or at different NaCl levels (Figure 3B). After incubation, vials containing samples were kept upside down for 10 min and photographed. As shown in Figure 3A, in the presence of 0.6 M NaCl, with the increasing addition of MDA, a transition from sol to gel was observed, and emulsion gel samples were obtained when the MDA concentration was >2.5 mM. Nevertheless, an "oil leak" phenomenon was also observed when samples were treated with MDA >25 mM (Figure 3A, bottom). These results indicated that MDA played a critical role in emulsion gel formation. Additionally, the necessity of NaCl in emulsion gel formation was further confirmed, as shown in Figure 3B. After being upside down for 10 min, the emulsion gel sample with 0.2 M NaCl collapsed (Figure 3B), indicating a weak gel structure. Thus, these results indicated that both MDA and NaCl played an important role in controlling gel formation and quality.

Low-Amplitude Dynamic Oscillatory Measurements. For better understanding of the influence of MDA and NaCl on the viscoelastic properties of emulsion gels, variations of G' and tan δ with frequency were recorded, using small strain measurement, as shown in Figure 4. For MDA-modified MP emulsion with 0.6 M NaCl, as can be seen from Figure 4A, G' in magnitude in the test linear viscoelastic range first continuously increased with increasing MDA concentration from 0 to 10 mM. At certain frequency (1 rad/s), G' of the sample treated with 10 mM MDA reached 1986 Pa, representing an evident increase in G' approximately 6.0 times compared to that of control, which indicated the elastic property of the sample was markedly enhanced and corresponded well to the formation of gel structure as shown in Figure 3A. This might be due to the development of protein−protein cross-links under MDA-induced oxidative stress,[25,27] resulting in an entanglement network between adsorbed and nonadsorbed proteins.[10] Nevertheless, further addition of MDA (25−50 mM) sharply decreased the G', suggesting a weakened gel structure, which might be related to the oil leakage (Figure 3A).[13] As has been extensively stated in the literature,[6,34] incorporated oil could functionalize as active filler, leading to a gel network with an enhanced rigidity, and thus the reduced oil incorporated would decrease the gel elasticity (25−50 mM MDA). In addition, the loss factor, tan δ, indicative of whether elastic or viscous properties were predominant, was further measured, as shown in Figure 4C. In all cases, it can be clearly seen that tan δ was almost independent of the frequency throughout the tested

J. Agric. Food Chem. 2015, 63, 3766−3777

range and the tan δ values were <1 (Figure 4C), indicating all of the samples exhibited a predominant elastic behavior with frequency independency.[10] Furthermore, with increasing MDA concentrations from 0 to 10 mM, an evident decrease in the tan δ values was observed, suggesting enhanced elastic properties. However, when MDA concentration was >10 mM, the tan δ values increased. These results were in good agreement with previous analysis (Figures 3A and 4A).

As to the influence of NaCl, changes in G' and tan δ with frequency were also recorded, as presented in Figure 4, panels B and D, respectively. With increasing NaCl concentrations from 0 to 0.6 M, a dramatic increase in G' (Figure 4B) and an overall decrease in tan δ values (Figure 4D) were observed, respectively, indicating improved elastic properties of the emulsion gel. These results were again in line with visual observation (Figure 3B). As mentioned above, emulsions with thicker interfacial layer were obtained in the presence of 0.6 M NaCl (Figure 1A, inset) due to the profuse swelling of MP.[25,32] The thicker protein layer surrounding the oil droplets would increase the interdroplet interactions via several bridges, including ionic interaction and the stronger covalent bonds upon the presence of MDA,[27,35] which thus could promote the formation of emulsion gels with high elasticity (Figures 3B and 4). Nevertheless, in the absence of NaCl, protein fails to swell and disperses unevenly due to its low solubility.[25,32] Thus, the lack of effective molecular interaction between absorbed/nonabsorbed MP and MDA caused protein-coated oil droplet clusters, rather than a network,[25] thus resulting in the failure of gel formation and the low elasticity (Figures 3B and 4).

Gel Strength and WHC. To further evaluate the properties of formed emulsion gels, the gel strength and WHC were further measured and compared, as shown in panels A and B of Figure 5. In the presence of 0.6 M NaCl, the formed emulsion gel could be obtained when MDA concentration reached 2.5 mM (see Figure 3A). As can be seen from Figure 5A, with increasing MDA concentrations, emulsion gel strength remarkably increased, reaching a maximum of 1.09 N at 10 mM. This should be mainly attributed to the enhanced protein−protein interactions due to the swelling of MP and thus the increased inter- and intramolecular interaction within protein absorbed or unabsorbed under MDA-induced oxidative stress.[10,25,27,32] These analyses were in good agreement with the G' and tan δ data of emulsion gels (Figure 4A,C), which was related to the gel strength.[19] Nevertheless, with further addition of MDA (25−50 mM), a drastic decrease in gel strength was observed (Figure 5A), implying a collapse of gel structure. This might be mainly due to the occurrence of separated oil phase (Figure 3A, bottom) and was again in good agreement with gel elasticity (Figure 4A,C). In addition, the influence NaCl concentration on gel the strength in the presence of 10 mM MDA was also investigated as shown in Figure 5A. As expected, gel strength increased along with increasing NaCl levels (Figure 5A), which was largely due to the swollen appearance of MP promoting gel formation, and is in well consistent with results from G' (Figure 4B).

Furthermore, the gel WHC, which could reflect the spatial structure of the emulsion gel, showed a very similar trend as compared to gel strength, as shown in Figure 5B. This was also in good agreement with G' and tan δ data (Figure 4). As has been reported, the gel strength or stiffness played a prominent role in the water-holding property of gels;[8,12] thus, the progressive increase/decrease in WHC can be attributed to

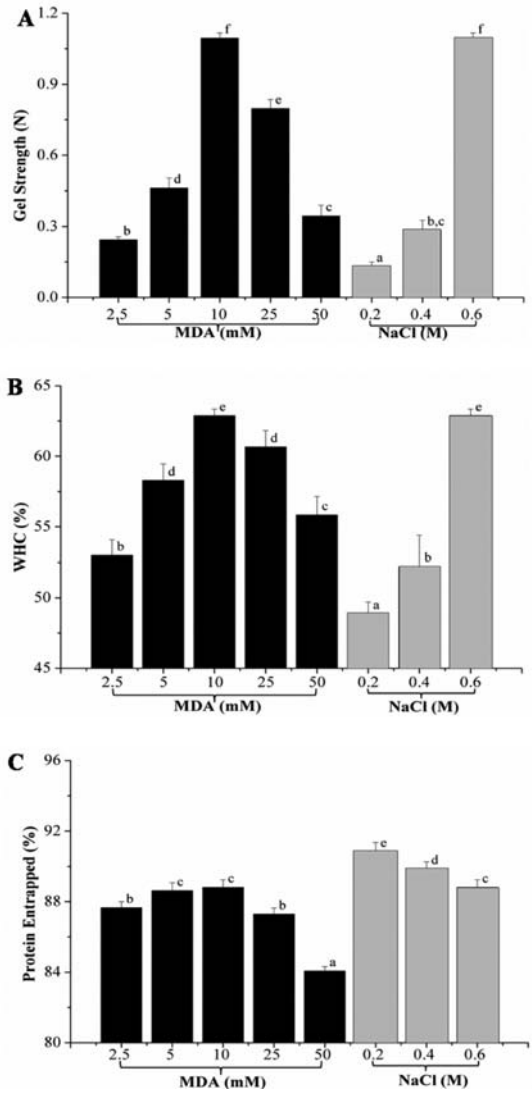

Figure 5. Gel strength (A) and WHC (B) of MDA-modified emulsion gels and protein entrapped (C) in MDA-modified emulsion gels at various MDA concentrations (black columns) or at different NaCl levels (gray columns). Columns with different letters are significantly different ($p < 0.05$).

compact/loose structure and strengthened/weakened gel structure with MDA/NaCl at different levels.

Amount of Protein Entrapped. The MDA-induced gelation of MP emulsions is closely associated with the ionic and covalent interactions between adsorbed and/or unadsorbed proteins, as mentioned above. Once the emulsion gel network is formed, the content of the proteins entrapped, including those adsorbed to the surface of oil droplets and some of the unabsorbed, can be approximately determined using centrifugation of the emulsions or emulsion gels.[9,29] Figure 5C shows the influence of MDA and NaCl on the amount of protein entrapped within the emulsion gel matrix. We could clearly see that in the presence of 0.6 M NaCl, the amount of entrapped proteins slightly but progressively increased as the MDA concentration increased from 2.5 to 10 mM, indicating more proteins participating in the gel network formation. This should be mainly due to the enhanced protein−protein interactions under MDA-induced oxidative stress, which reinforced the gel structure (Figures 4A,C and 5A,B), thus increasing the amount

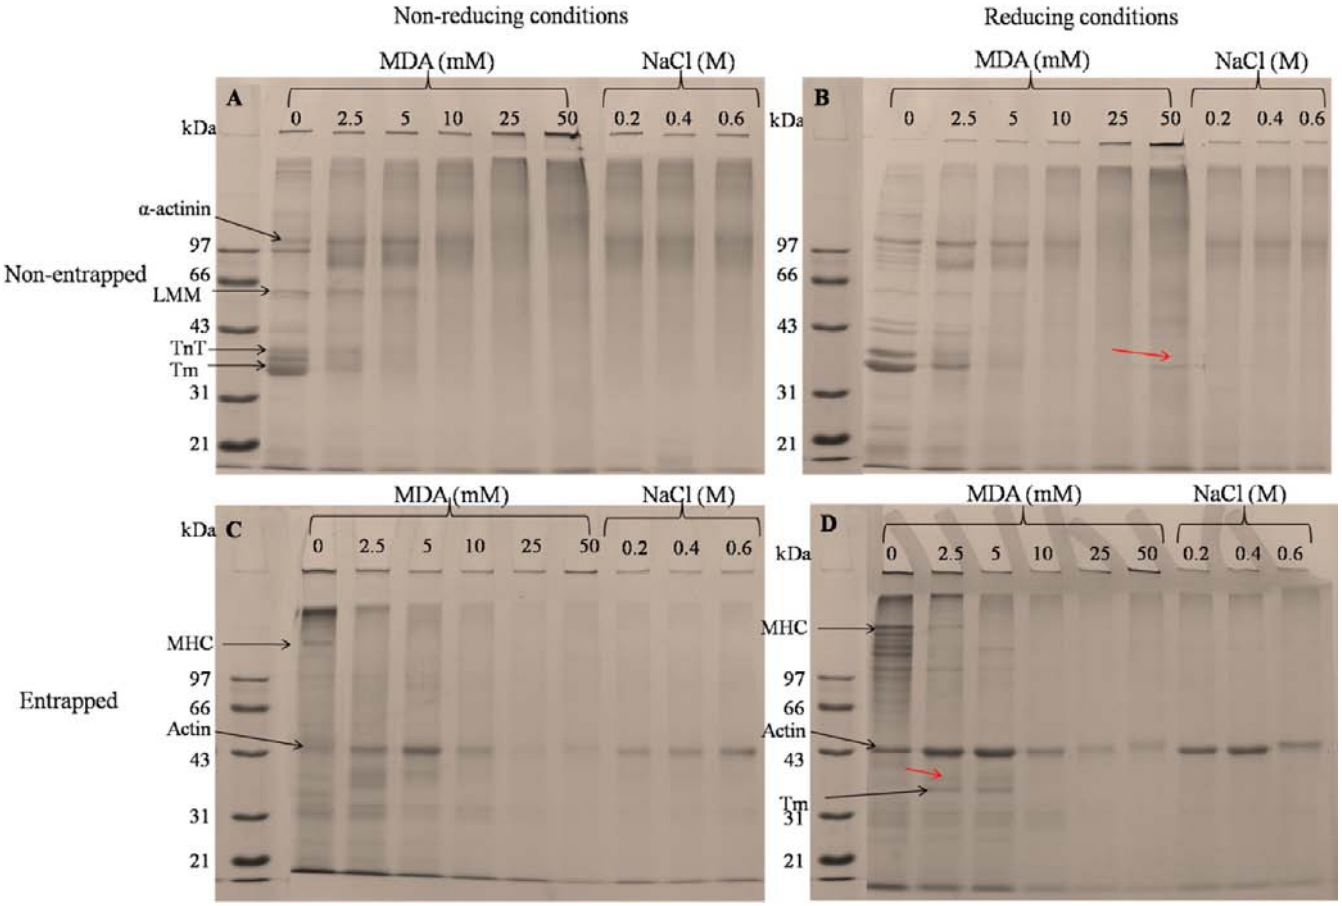

Figure 6. Representative SDS-PAGE patterns of the non-entrapped (A, B) and entrapped (C, D) protein in MDA-induced MP emulsion gels in the absence (nonreducing, A andC) or presence (reducing, B and D) of 5% β-ME. LMM, light meromyosin; MHC, myosin heavy chain; TnT, troponin T; Tm, tropomyosin.

of protein entrapped. Nevertheless, further addition in MDA (25−50 mM) caused a significant ($p < 0.05$) decrease in the amount of protein entrapped. As aforementioned, emulsion gel with separated oil phase and decreased gel elasticity and strength were observed when the MDA concentration added was >25 mM (Figures 3A, 4A, and 5A). Therefore, we could speculate that excessive covalent bonds might be formed when the addition of MDA exceeded 25 mM,[25] which could break protein−protein bonds or drag protein away from interface. Accordingly, the separated oil drops would lead to the protein separated from the gel matrix, no longer staying in the upper layer after centrifugation due to enhanced density and, thus, resulting in the decreased amount of protein entrapped (Figure 5C).

As to the influence of NaCl levels, the amount of protein entrapped decreased with increasing NaCl levels (Figure 5C), which seems to be inconsistent with the visual observation of emulsions after centrifugation (Figure 1A, inset). However, in fact, the amount of interfacial protein of emulsions (Figure 1A, inset) also decreased with increasing NaCl concentrations (data not shown). This could be explained by the fact that MP swells profusely at around 0.6 M NaCl, which decreased the protein adsorption rate on the droplet surface, thus decreasing the amount of interfacial protein of emulsions (data not shown). Furthermore, it is worth noting that, in the presence of 0.6 M NaCl, the amount of protein entrapped within the gel matrix (Figure 5C) was higher than that of interfacial protein of the corresponding emulsion (data not shown), suggesting that the unadsorbed proteins in the aqueous phase of the emulsion was involved in gel matrix formation.[34,36]

SDS-PAGE. Protein patterns of non-entrapped and entrapped proteins in the MDA-induced emulsion gels were examined by performing SDS-PAGE in either nonreducing or reducing conditions, as shown in Figure 6. Additionally, the control emulsion stabilized by MP in the presence of 0.6 M NaCl without MDA was also recorded for better comparison. As can be seen from Figure 6A, for non-entrapped proteins, in the absence of β-ME, basically four MP components—α-actinin, light meromyosin (LMM), troponin T (TnT), and tropomyosin (Tm)—were observed in the control sample (0 mM), within which TnT and Tm were predominant. Previous studies have already indicated that TnT and Tm were uncoagulable and did not contribute to muscle protein gel network formation.[12,37] With increasing concentration of MDA, the band intensities of four MP components progressively decreased or vanished (Figure 6A). Concomitantly, the band intensity of high molecular weight polymers (HMWP), which accumulated on the top part of the stacking gel or barely entered, increased accordingly (Figure 6A). However, in the presence of β-ME, most of these HMWP, but not reduced/lost bands, could be recovered, especially within the MDA range from 0 to 10 mM (Figure 6B). These results implied that HMWP formed were partially through disulfide bonds, rather than mainly non-disulfide covalent bonds as observed in other cases,[25,27] indicating that non-entrapped proteins were less influenced by MDA-induced oxidative modification, similar to

J. Agric. Food Chem. 2015, 63, 3766−3777

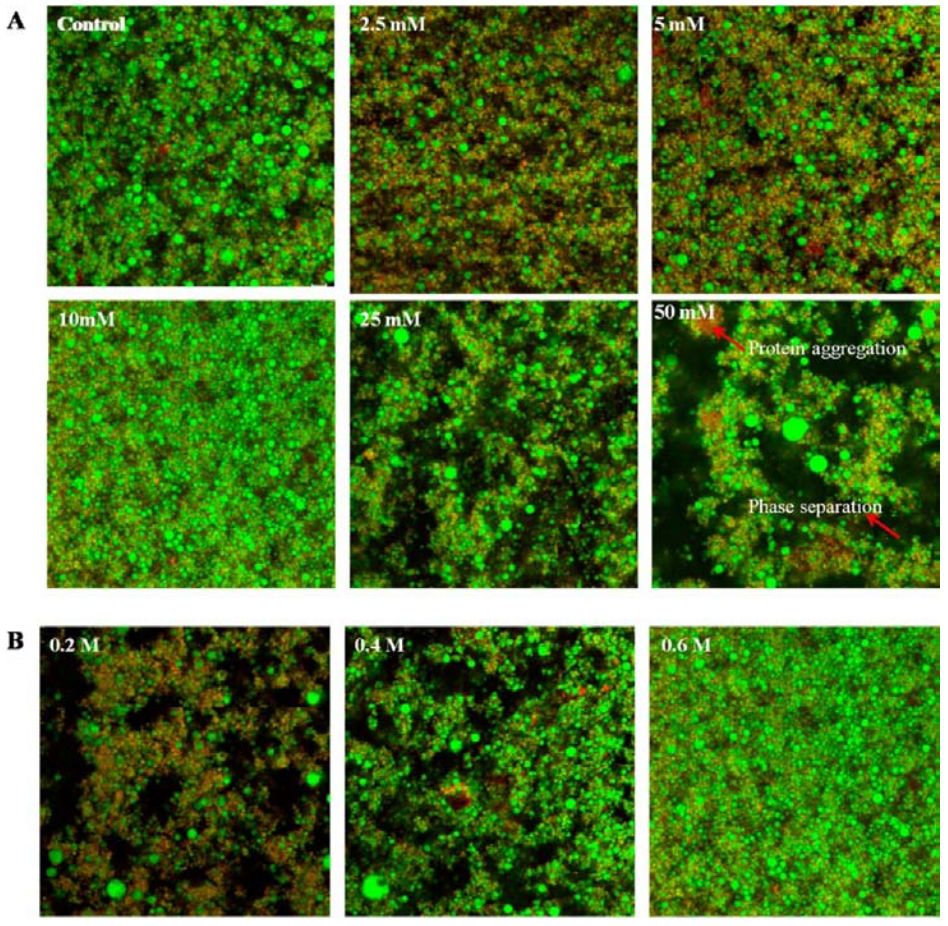

Figure 7. Typical CLSM images of MDA-induced MP emulsion gels at various MDA concentrations (A) or at different NaCl levels (B). All of the images were obtained with the dyes Nile Red (protein) and Nile Blue (oil phase), excited at 488 and 633 nm, respectively.

the previous study.[38] Moreover, when the concentration of MDA reached 50 mM, diffuse bands with molecular weight similar to that of Tm occurred again (Figure 6B), which might be related to the collapse of gel structure (Figure 4A,C).

For entrapped proteins, in the absence of β-ME, essentially myosin heavy chain (MHC) and actin were observed in the control sample (0 mM), and no clear bands corresponding to TnT or Tm, which have been discovered in the non-entrapped (Figure 6A), were obtained (Figure 6C). Nevertheless, MHC in all of the gel samples vanished, and all bands were lost with excessive addition of MDA (>25 mM), besides actin remaining faint (Figure 6C). However, no HMWP were detected with increasing MDA concentration (25−50 mM). This should be due to the over-cross-linking of proteins, leading to the formation of very high molecular weight polymers, which could not penetrate into the gel.[25,39] In the presence of β-ME, MHC in all gel samples could not be recovered (Figure 6D), suggesting that most cross-linking originated from myosin was not through disulfide bonds and the covalent bond in gel was too strong to break, which are similar to the previous reports that MDA can react with amino groups of proteins, producing strong intermolecular cross-links of the Schiff base type.[25−27] In addition, these results also indicated that oxidative modifications concerned more specifically the proteins adsorbed or entrapped, in agreement with a previous paper.[38] Interestingly, TnT and Tm, which have just been observed in the non-entrapped, although progressively reduced or lost with increasing addition of MDA, actually were obtained in the entrapped protein upon incubation with MDA (Figure 6C). These results, together with that obtained from changes in the non-entrapped, implied that within the MDA range of 2.5−10 mM, the reduced/lost protein composition (TnT and Tm) in non-entrapped might participate in the gel network formation under MDA-induced oxidative stress, thus turning into the entrapped proteins. Herein, the progressive entrapment of proteins with strong covalent bonds would provide structure reinforcement, which resulted in a gel matrix capable of sustaining higher stresses and therefore the higher gel strength (Figure 4). These analyses are also in good agreement with the increased amount of protein entrapped as previously stated (Figure 5).

As for the influence of NaCl level, increase in NaCl level did not change the protein pattern of either the non-entrapped or the entrapped (Figure 6), but slightly decreased the stability of actin (Figure 6D), as has been previously reported.[25,40]

Microstructure. The gel strength and WHC of the formed emulsion gels are, to a large degree, related to their gel microstructure. Therefore, the microstructure of the MDA-induced MP emulsion gels, formed at various MDA concentrations (2.5−50 mM) or at different NaCl levels (0.2, 0.4, and 0.6 M), was further characterized using CLSM, as displayed in Figure 7, panels A and B, respectively. In addition, the control emulsion in the presence of 0.6 M NaCl without MDA was also recorded and compared. As shown in Figure 7A, for the control emulsion, most of the oil droplets with similar sizes were evenly dispersed in the emulsion, indicating a

DOI: 10.1021/jf505916f
J. Agric. Food Chem. 2015, 63, 3766−3777

relatively stable state, which was in agreement with the $d_{4,3}$ data of emulsion (Figure 1B). In the presence of 0.6 M NaCl, when the concentration of MDA increased from 2.5 to 10 mM, the dispersed oil droplets coated with protein gradually got close, and the adjacent droplets even became tightly packed when the addition of MDA reached 10 mM. This might be attributed to enhanced protein−protein covalent binding among absorbed or nonabsorbed (Figure 6), forming a compact and homogeneous gel network with oil droplets perfectly adherent to the gel matrix (Figure 7A). These analyses were well consistent with the gel strength and WHC (Figure 5) and were also in good agreement with the data from low-amplitude dynamic oscillatory measurements (Figure 4), for it has been well accepted that the samples that have more compact and homogeneous microstructure possess the higher elastic modulus and lower tan δ.[10,19] Nevertheless, further increase in MDA concentration (25−50 mM) greatly changed the gel morphology, and a gel microstructure with obvious phase separation, accumulated protein aggregation, and oil droplets with larger size were observed. These results indicated the collapse of the gel microstructure, which was well consistent with the "oil leak" phenomenon observed (Figure 3A) as well as the sharp decrease in gel elasticity/strength and WHC (Figures 4 and 5).

As for the influence of NaCl, a more homogeneous gel microstructure was observed with increasing NaCl concentration (Figure 7B). It has been confirmed that the network of emulsion gels was closely related to the state of oil droplets in the original emulsions.[9] Thus, at low NaCl level (i.e., 0.2 M), the relative low emulsion apparent viscosity and small steric hindrance (Figures 1 and 2) easily led to the flocculation of oil droplets. Meanwhile, the protein absorbed or unabsorbed failed to swell profusely,[32,41] which resulted in the insufficient interaction between MP and MDA,[25] thus leading to the resultant discontinuously poor gel microstructure (Figure 7B). However, when the addition of NaCl increased, more stable oil droplets coated with MP were obtained, in a more swollen state, forming a more interactive gel network (Figure 7B).

Oxidative Stability of Emulsion Gels. With the fact of improved emulsion gel structure within a certain MDA range (2.5−10 mM) taken into consideration, the oxidative stability of MDA-modified MP emulsions was further studied, as shown in Figure 8. Lipid hydroperoxides, generally accepted as the first oxidation products, is the most used analysis for determining the initial oxidation rate.[42,43] Compared to the control emulsion, it is interesting to note that hydroperoxides of MDA-modified MP emulsion first decreased along with MDA from 0 to 10 mM, reaching a minimum at the 10 mM MDA level, before increasing sharply to a maximum at 50 mM (Figure 8A). These results indicated that MDA-induced gelation of MP emulsion obtained higher oxidative stability, depending on the MDA concentration. As aforementioned, the emulsion gels with enhanced gel quality (elasticity, strength, WHC) and better microstructure were obtained within MDA ranging from 2.5 to 10 mM (Figures 4, 5, and 7). Thus, the reinforced gel network between absorbed and unabsorbed protein might work as a physical barrier, separating the lipid substrates from the pro-oxidants present in the aqueous phase or retarding the oxygen diffusion within the systems, which thus could well protect the oil droplets (Figure 8A). A similar protective effect of gelation on emulsion oxidative stability has also been reported.[34] Nevertheless, the collapsed gel microstructure due to the formation of excessive covalent bonds led

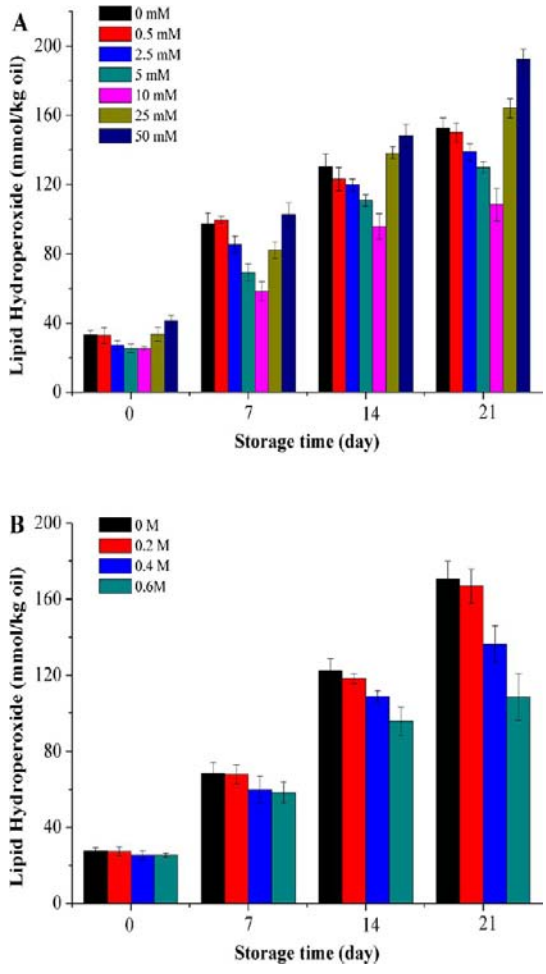

Figure 8. Changes in lipid hydroperoxides of emulsions gels stabilized by MP either at various MDA concentrations (A) or at different NaCl levels (B) during storage at 25 °C for 21 days.

to the "oil leak" (Figures 3 and 6), favoring the direct contact of oil with oxidizer, which thus decreased the oxidative stability of the system (25−50 mM MDA) (Figure 8A). As for the influence of NaCl, similarly, a lower amount of hydroperoxides at higher levels of NaCl was obtained (Figure 8B), which could also be largely attributed to the protective effect of improved gel properties (Figures 3−5). Additionally, the higher interfacial area of emulsions/emulsion gels at lower NaCl level (Figure1) might also promote interactions between lipids and pro-oxidants in the aqueous phase and thus the lower oxidative stability (Figure 8B).[34,44]

General Discussion. On the basis of the analyses above, we can conclude that addition of MDA could lead to the formation of emulsion gel stabilized by MP in the presence of NaCl. Meanwhile, the gel properties as well as the gel oxidative stability were enhanced at certain concentration ranges of MDA (Figures 4, 5, and 8). To clarify a reasonable understanding of either improved or deteriorated gel quality, a schematic illustration of the formation process of the MDA-induced MP emulsion gels is proposed and shown in Figure 9. In the absence of NaCl, MP fails to swell,[32] and thus emulsions with smaller size were obtained due to relatively quick absorption of protein to the oil droplet surface (Figure 1A). Nevertheless, the small steric hindrance of the protein at interface as well as the unevenly dispersed protein in aqueous phase due to its low

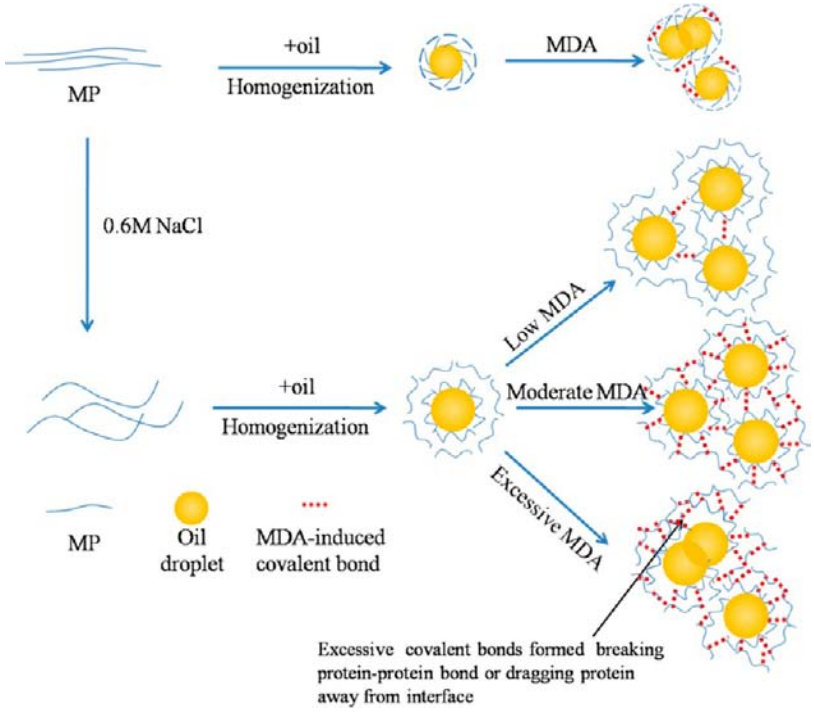

Figure 9. Schematic illustration of formation process of the MDA-induced emulsion gels stabilized by salted MP.

solubility made the droplet free to flow and easier to flocculate (Figures 1B and 2),[32] which further limited the interaction between MP (absorbed or unabsorbed) and MDA, leading to coagulation, rather than gelation of emulsion (Figure 3B). However, in the presence of 0.6 M NaCl, MP swells profusely,[18,32,45] and the swollen MP-stabilized emulsions with larger size possessed a thicker absorbed protein layer due to enhanced protein−protein interaction (Figure 1A),[18,25] which thus increased the physical stability of emulsions (Figure 1B). Upon incubation with MDA, the stretching structure of MP at 0.6 M NaCl first facilitates the interactions among absorbed and/or unabsorbed proteins,[38] forming strong covalent bonds (Figure 6), which thus promoted the gel formation (Figure 3A). Specifically, within MDA concentrations ranging from 2.5 to 10 mM, enhanced protein−protein cross-links were observed with more amounts of protein, even the unabsorbed protein fractions (i.e., Tm), being progressively entrapped (Figures 5C and 6), contributing to a more homogeneous and compact gel structure with higher gel elasticity, strength, and WHC (Figures 4, 5, and 7). Interestingly, with oil droplets perfectly adherent to the homogeneous gel matrix (Figure 7), the enhanced oxidative stability of gelled emulsion was also obtained (Figure 8). Nevertheless, further increase in MDA concentration (above 25 mM) led to the formation of excessive covalent bonds (Figure 6), breaking the protein−protein bonds or triggering the separation of the protein−oil interface, which thus resulted in the resultant "oil leak" as well as the collapse of gel structure (Figures 3−5 and 7). Accordingly, the gel oxidative stability was also remarkably decreased (Figure 8).

In conclusion, this work demonstrated an interesting discovery of the formation of cold-set, MDA-induced emulsion gels stabilized by salted MP, and the possible mechanism involved was also proposed. The gel was formed on the premise of the swelling of MP under certain ionic strengths and the non-disulfide covalent bonds formed via MDA. Within certain MDA ranges (2.5−10 mM), the oil droplets were perfectly adherent to the gel matrix due to the moderate amount of covalent bonds formed between absorbed and unabsorbed proteins, endowing the emulsion gel with a better quality. Meanwhile, the reinforced gel network was also responsible for enhanced oxidative stability of emulsion gels. Considering the real meat manufacturing or storage process, the link between MDA-induced protein oxidation and MP-stabilized emulsion gel is far from straightforward. However, the results presented in this paper could provide a new aspect for better understanding the effect of oxidation in meat protein/oil composite systems.

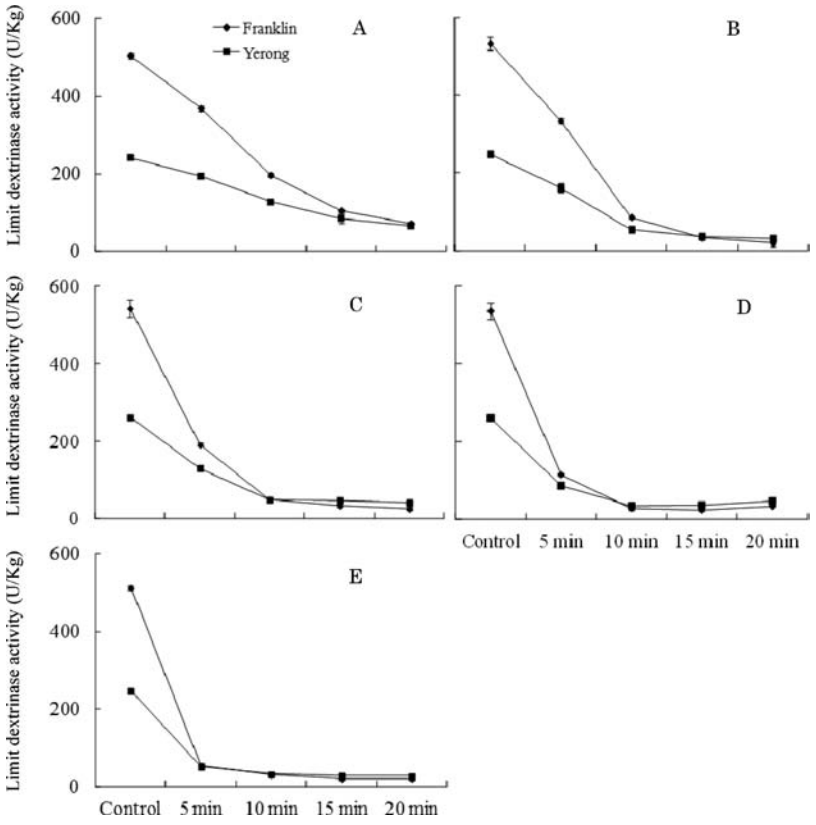

Figure 1. Limit dextrinase activity variation after thermo treatment at different temperatures for 0−20 min. A, B, C, D, and E: Limit dextrinase activity variation after thermo treatment at 54.5, 55.5, 56.5, 57.5, and 58.5 °C, respectively. Control: without thermo treatment.

the current study, a genetic diversity analysis was conducted for the identification of genotypes with high LD thermostability. Moreover, QTLs analysis of LD thermostability was carried out to identify relevant novel genes or genetic factors.

MATERIALS AND METHODS

Plant Materials and Sample Preparation. Fifty-one cultivated barley, 40 Tibetan wild barley genotypes, and a DH population consisted of 177 lines from a cross between Yerong and Franklin was used in this study.[32] Franklin is an Australian two-rowed malting barley cultivar, and Yerong is an Australian six-rowed feed barley variety. Seeds of Tibetan wild barley, collected from the Qinghai-Tibet Plateau of China, were kindly provided by Professor Dongfa Sun of Huazhong Agricultural University, China.

All materials were grown in the field of the experimental farm, Zhejiang University, Huajiachi campus, Hangzhou, China, in 2008−2009 and 2009−2010 winter barley growing seasons, except that the DH population was only cultivated in 2009−2010 growing season. Each genotype or DH line was sown in a 2 m row with 0.25 m between rows, with three replications. Field management, including fertilization, weed, and disease control, was the same as applied locally. At maturity, the plants were harvested and stored in a cool room at 4 °C. Grains were mixed and used for micromalting and LD activity assay after milled to pass through a 0.5 mm screen.

Grain samples (200 g) were micromalted in a Phoenix System Micromalting Apparatus (Adelaide, Australia) in the order of steeping, germination and kilning according to the method described by Dai et al. (2007),[33] with some modification in the steeping stage. Briefly, there were the following stages: 5 h steep and 8 h air-rest at 17 °C, 8 h steep and 12 h air-rest at 16 °C, 4 h steep, 5 h air-rest and 2 h steep at 15 °C followed by 96 h germination at 16 °C. Malting of all the genotypes and DH lines were milled to pass through a 0.5 mm screen for analysis.

Thermo Treatment and LD Activity Assay. LD activity was determined using the Limit-Dextrinase assay kit (Megazyme, Ireland). According to McCleary (1992)[34] and the Megazyme manual, LD was extracted from 0.25 g sample with 4.0 mL extracting solution, 0.1 mM sodium malate buffer (pH 5.5) containing 25 mM dithiothreitol, for 5 h at 40 °C. Thermo treatment in the current study referred to the method described by Evans et al. (2003)[14] and was conducted using a Memmert WNE450 water bath (Memmert, Germany). Specifically, 0.5 mL of supernatant was added to a plastic tube after centrifuging at 1000*g* and incubated in a water bath for thermo treatment. Thermo treatment was terminated with an ice−water bath for 10 min. LD activity of thermo-treated and nonthermo-treated (control) supernatants was determined using Limit-Dextrizyme tablets at 40 °C. One unit of LD activity is the amount of enzyme required to release one μmol of glucose reducing-sugar equivalents per min from pullulan under the defined assay conditions.

QTL Analysis. A genetic linkage map of the Yerong/Franklin DH population was composed of 496 DArT and 28 microsatellite markers.[32] QTLs were analyzed using MapQTL5.0 software package,[35] as described by Dai et al. (2011).[36] Briefly, QTLs were analyzed by interval mapping (IM) and approximate multiple QTLs model (MQM) of MapQTL5.0. Logarithm of the odds (LOD) threshold values (set as 3.0) applied to declare the presence of QTLs were

DOI: 10.1021/acs.jafc.5b00190
J. Agric. Food Chem. 2015, 63, 3778−3783

estimated by performing the genome wide permutation tests with at least 1000 permutations of the original data set for the trait. The percentage of variance explained by each QTL (R^2) was obtained using restricted MQM mapping implemented with MapQTL5.0.

Statistical Analysis. Each measurement was carried out with at least three replications. Statistical analysis was carried out using SPSS v16.0 for windows (SPSS Inc., Chicago, U.S.A.).

RESULTS

Effect of Thermo Treatment on LD Activity. In order to determine the optimal time and temperature for LD activities of the parental lines Franklin and Yerong, time- and temperature-dependent experiments were conducted. The LD activities of Franklin and Yerong after thermo treatments for 0−20 min at a set of temperature gradients are shown in Figure 1A−E, respectively. Under the control condition (without thermo treatment), LD activity of Franklin (521.9 U kg^{-1}) was significantly higher than that of Yerong (250.9 U kg^{-1}). LD activity of Franklin and Yerong declined by 26.9% and 19.8%, 37.3% and 34.9%, 64.8% and 50.1%, 78.6% and 66.8%, 89.2% and 79.0%, after 5 min thermo treatments at 54.5, 55.5, 56.5, 57.5, and 58.5 °C, respectively (Figure 1). The LD activity decreased sharply during the first 5 min of the thermo treatment, and thereafter, the rate of decline became much slower. Hence, the optimum treatment time at 5 min was chosen for comparing the difference in LD thermostability (expressed as a ratio of the remaining LD activities after 5 min thermo treatment to those in the control) between Franklin and Yerong.

LD thermostability of Franklin and Yerong responded differently to increasing temperatures (Figure 2). The LD thermostability of Franklin and Yerong were 68.5% and 71.8%, 73.1% and 80.2%, 59.2% and 64.3%, 62.7% and 65.1%, 47.9% and 58.5%, 35.2% and 49.9%, 33.4% and 43.0%, 21.4% and 33.2%, 19.4% and 30.5%, 10.8% and 21.0%, 7.9% and 17.2% after 5 min thermo treatments at 54, 54.5, 55, 55.5, 56, 56.5, 57, 57.5, 58, 58.5, 59 °C, respectively. According to the method of Arora et al. (1992),[37] we estimated the LT_{50} (lethal temperature of 50%), which is defined as the temperature at which 50% of LD activity lost after thermo treatment. In the current study, LT_{50} of Franklin and Yerong were 54.4 and 56.4 °C, respectively (Figure 2). In order to obtain a relative higher dose of thermo treatment, we chose 56.5 °C as the optimum temperature for thermo treatment in the current study rather than 55.5 °C, which was close to LT_{50} and similar to the results of Evans et al. (2003)[14] and Yang et al. (2009).[2]

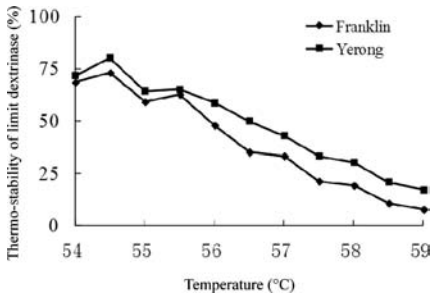

Figure 2. Thermostability variation of limit dextrinase after 5 min thermo treatment at different temperatures from 54 to 59 °C.

Difference in LD Thermostability in Cultivated and Wild Barley. In 2009, LD activity for the 40 wild barley (WB) genotypes ranged from 352.3 U kg^{-1} to 562.8 U kg^{-1}, with a mean of 448.0 U kg^{-1}, whereas LD activity for the 51 cultivated barley (CB) genotypes ranged from 366.2 U kg^{-1} to 787.6 U kg^{-1}, with a mean of 539.6 U kg^{-1} (Table 1). Thermostable LD activity of WB ranged from 229.7 U kg^{-1} to 457.4 U kg^{-1}, with a mean of 327.5 U kg^{-1}, and CB ranged from 177.4 U kg^{-1} to 488.8 U kg^{-1}, with a mean of 318.3 U kg^{-1}. Obviously, WB had lower average value of LD activity than CB. As for the mean of thermostable LD activity, both cultivated and wild barley were basically the same. The LD thermostability of WB ranged from 59.9% to 91.3%, with a mean of 73.3%, and CB ranged from 27.1% to 85.4%, with a mean of 59.8%. It is clear that WB had much larger LD thermostability value than CB. In addition, the coefficient of variation (CV) for LD, thermostable LD, and LD thermostability were slightly smaller in WB than those in CB (Table 1).

In 2010, the LD activity of WB and CB ranged from 285.6 U kg^{-1} to 604.8 U kg^{-1} and from 315.6 U kg^{-1} to 741.6 U kg^{-1}, with means of 405.4 U kg^{-1} and 514.8 U kg^{-1}, respectively. (Table 1). Thermostable LD activity of WB and CB ranged from 181.1 U kg^{-1} to 486.0 U kg^{-1} and from 172.8 U kg^{-1} to 555.6 U kg^{-1}, with means of 275.9 U kg^{-1} and 319.8 U kg^{-1}, respectively. However, for LD thermostability, WB and CB ranged from 50.5% to 80.4% and from 41.5% to 75.3%, with means of 67.8% and 61.3%, respectively. All the parameters in 2010 are very consistent to those in 2009, for instance, the maximum and mean LD thermostability of WB were higher than those of CB. Meanwhile, the CV values of WB were smaller uniformly.

Identification of QTL Associated with Thermostable LD. In view of the significant differences in LD activity and

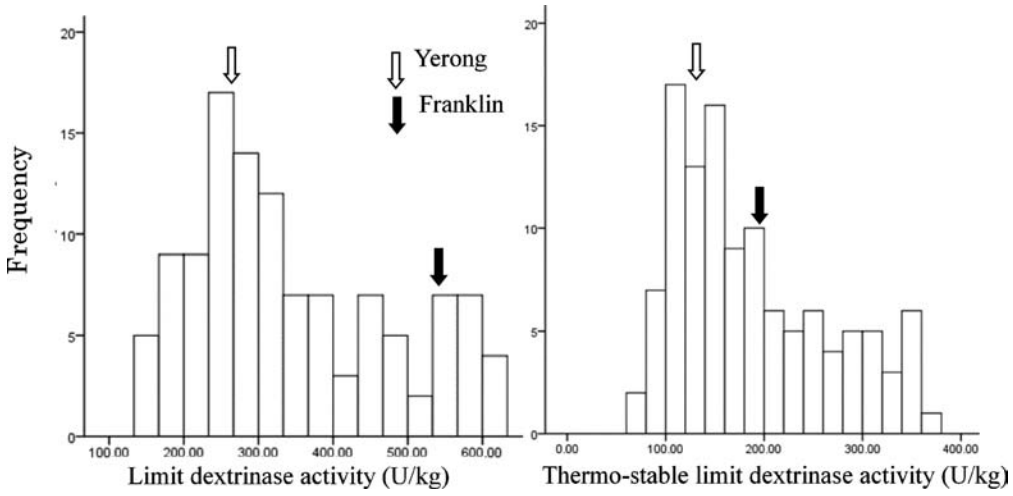

Figure 3. Frequency distribution for limit dextrinase and thermostable limit dextrinase activity in a DH population of Yerong/Franklin.

thermostability between Franklin and Yerong found in our preliminary study, we further conducted the QTL analysis using a DH population consisted of 177 lines from a cross between Yerong and Franklin (Li et al., 2008) in order to identify novel QTLs associated with LD activity and thermostability. Normal distributions of LD and thermostable LD activity exhibited no significant skewness and kurtosis (Figure 3). Transgression beyond the parental values was also observed. Moreover, some favorable combinations, such as high LD activity under both control conditions and thermo treatments, were found in this DH population.

A major QTL controlling LD activity in malt was identified on chromosome 7H under both control (*qLD2*) and thermo treatment (*qTS-LD3*) at the position of 58.7 cM on the genetic map with the nearest marker being bPb-2866 (Table 2). This QTL was able to explain 19.6% of the phenotypic variation of LD activity under thermo treatments, in comparison to 31.0% of the phenotypic variation of LD activity under control condition. Both of these QTLs are contributed by Franklin. In addition, a minor QTL (*qLD1*) controlling LD activity was identified at the position of 58.2 cM on chromosome 4H, with the nearest marker being bPb-0365. This QTL was not detected for LD activity under thermo treatment. Instead, two other minor QTLs were found, one on chromosome 1H (*qTS-LD1*) contributed by Franklin at 102.0 cM and the closest marker of HVHVA1, and another on chromosome 2H (*qTS-LD2*) contributed by Yerong at 83.7 cM and the nearest marker of bPb-5440 (Table 2). No significant QTL was identified for LD thermostability.

Table 2. Quantitative Trait Locus (QTLs) for Limit Dextrinase in the DH Population of Yerong/Franklin Grown in 2009−2010

treatment	QTL	chr.	nearest marker	position (cM)	LOD	R^2 (%)
control	*qLD1*	4H	bPb-0365	58.2	3.71	9.2
	qLD2	7H	bPb-2866	58.7	10.73	31.0
thermo treatment	*qTS-LD1*	1H	HVHVA1	102.0	4.03	9.9
	qTS-LD2	2H	bPb-5440	83.7	3.66	8.9
	qTS-LD3	7H	bPb-2866	58.7	7.49	19.6

DISCUSSION

In this study, we first investigated LD activity and thermostability of parental lines Franklin and Yerong under different temperature and time treatments in order to determine the optimal time and temperature for further research. It was found that both cultivars showed a rapid reduction of LD activity during the first 5 min of thermo treatment, and then leveled off over the course of another 15 min (Figure 1). Hence, we chose 5 min as the optimal time for thermo treatment. However, the time duration is shorter than those used in previous studies.[2,38,39] On the other hand, the optimal temperature was determined according to LT_{50}. Based on the influence of different temperature on LD activity, we chose 56.5 °C as the optimal temperature for thermo treatment. The results are basically consistent with some previous reports.[2,14] Under these thermo treatment conditions, we found Tibetan wild barley demonstrated much greater genotypic variation in LD thermostability than cultivated barley (Table 1), indicating that the wild barley is indeed an elite germplasm for barley breeders in developing cultivars with high LD thermostability.

The wide genetic diversity of LD and thermostable LD activity in the DH population (Figure 3) has enabled us to identify novel QTLs. The Yerong/Franklin DH population has already been used successfully for QTL analysis of waterlogging tolerance[32] and phytase activity.[36] A major QTL associated with LD and thermostable LD activity in malt was identified on chromosome 7H with the nearest marker bPb-2866 and a position of 58.2 cM on genetic map. The QTL is close to the LD gene with a position of 46 cM on chromosome 7H reported by Li et al. (1999).[13] Although there is no available sequence for bPb-2866, the sequence of a marker named bPb-8049 with available sequence has been found (http://www.diversityarrays.com/), which is close to bPb-2866 (2.36 cM) on the genetic map of Yerong/Franklin DH population.[18] We further mapped the sequences of LD gene (AF022725) and bPb-8049 to a synthetic assembly of the barley genome based on the WGS contigs assembly of cv. Morex, Barke and Bowman,[27] in an attempt to identify their physical locations. Interestingly, LD gene and bPb-8049 were mapped to contigs of barke_contig_281373 and barke_contig_275219, respectively. Their physical distance was 1.0 Mega base in the synthetic assembly of the barley genome. Thus, it may be suggested that the major QTL we identified on 7H is the LD gene in barley.

J. Agric. Food Chem. 2015, 63, 3778−3783

Two minor QTLs associated with thermostable LD activity were found to be located on the position of 83.7 cM on chromosome 2H (*qTS-LD2*) contributed by Yerong and 102.0 cM on chromosome 1H (*qTS-LD1*) contributed by Franklin, indicating that it should be exist a gene related to thermostable LD activity in Franklin other than the major QTL of LD activity in 7H. Recently, Huang et al. (2014)[17] identified two DArT markers related to LDI content, bPb-8347 on the 73.4 cM of chromosome 6H and bPb-8399 on the 25.7 cM of chromosome 2H. We compared the position of *qTS-LD1*, *qTS-LD2* and that of bPb-8347, bPb-8399. Although *qTS-LD2* and bPb-8399 are located on the same chromosome, their chromosome positions differ largely according to the consensus maps.[40] It was reported that the synergistic function of LD and *beta*-amylase caused increase of maltose in the mash liquor, and adding LD to mashes resulted in a substantial increase in levels of fermentable sugars.[41] *qTS-LD1* identified in this study coincides with a QTL determining malt-extract, which is located at the position of 91.9−106.5 cM on chromosome 1H.[42] Diastatic power is another important malt quality trait and is also a measure of combined activity of four starch-degrading enzymes, including α-amylase, *beta*-amylase, LD and α-glucosidase.[43] *qTS-LD2* identified in this study is close to a QTL determining diastatic power.[42]

Recent study has shown that only increases in LD activity may increase the production of fermentable sugar.[43] It might be because of the different amino acid substitution, considering the case of *beta*-amylase.[44] One of a possible mechanism is a single amino acid substitution, which improves the persistence of beta-amylase during mashing to result in slightly higher fermentable sugar production during mashing. The other type of mechanism is protein refold after a period of heating. Hence, there is a long way to go and much to be done to figure out the mechanism of LD thermostability. In short, the current study identified the novel QTLs associated with LD thermostability and again proved the wide diversity of Tibetan wild barley in LD thermostability. Moreover, the detected QTLs should be useful for a better understanding of the genetic control of LD activity and thermostability in malt.

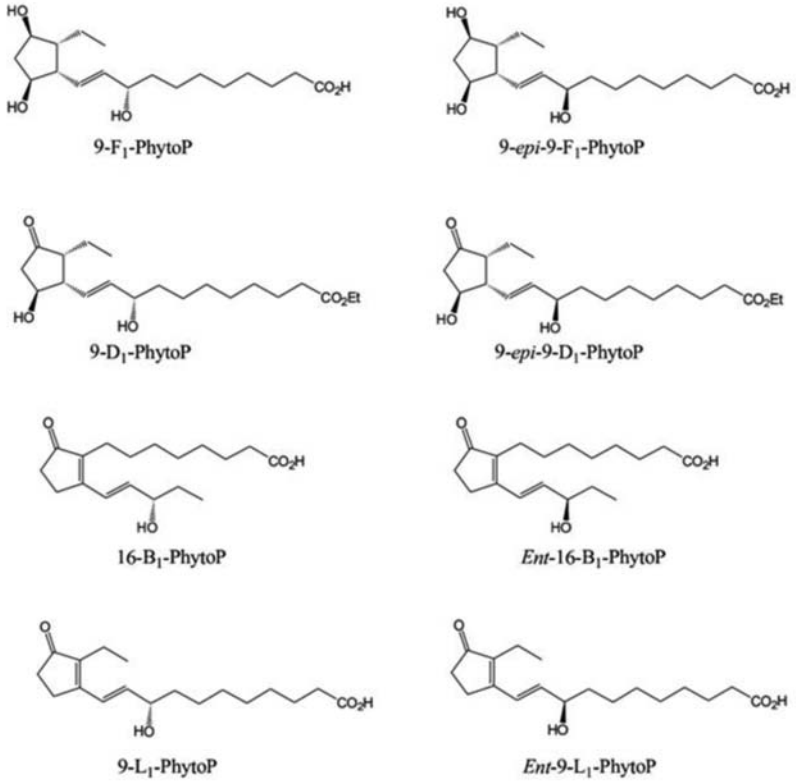

Figure 1. Chemical structures of 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, 9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, 16-B_1-PhytoP, *ent*-16-B_1-PhytoP, 9-L_1-PhytoP, and *ent*-9-L_1-PhytoP.

Parchmann and Mueller[19] showed that α-linolenic acid (ALA, C18:3, ω-3), which is the main polyunsaturated fatty acid (PUFA) present in higher plants, is used for the synthesis of the C18-isoprostanes (IsoPs) in plants termed phytoprostanes (PhytoPs).[20−22] PhytoPs are classified according to a nomenclature system that conforms with the prostaglandins (PG) convention.[22−24] In this paper we will use the Taber/Roberts nomenclature (IUPAC), which is different from the one described by Mueller, so care must be taken by the reader to acknowledge the structure associated with the name.[23]

PhytoPs are not only excellent biomarkers of oxidative degradation of plant-derived foodstuffs but also biologically active molecules because they are components of an oxidant-injury-sensing, archaic signaling system that induces several plant defense mechanisms.[24,25] The levels of PhytoPs in plants increase under a variety of conditions, especially when free radical generation is enhanced.[26] Despite little being known of the biological effects of PhytoPs, they have been identified in urine and are found esterified to lipids in plasma in healthy men consuming vegetable oil.[27] Nevertheless, there is some evidence that they play a role in regulation of the immune function,[28] and according to Durand et al.[29] PhytoPs may contribute to the benefical effects of the Mediterranean diet, because they display potent anti-inflammatory and apoptosis-inducing activities similar to those of other prostanoids.

For these reasons, the aim of the experiment described was to increase our understanding of the PhytoPs profile present in Cornicabra extra virgin olive oil, as plant biomarker of oxidative stress in the olive tree. Moreover, special attention was paid to analyzing for the first time if the pit hardening phenological period is really a noncritical period to water deficit for olive fruit, because some individual PhytoP content in the extra virgin olive oil extracted could be affected and, subsequently, the oxidative stress of the tree.

MATERIALS AND METHODS

Plant Material, Experimental Conditions, and Treatments. The experiment was carried out in 2012 at the El Chaparrillo experimental farm, located in Ciudad Real (Spain) (39°00′ N, 3°56′ W; altitude 640 m). The plant material consisted of olive trees (*O. europaea* L. cv Cornicabra) planted in 1998 and spaced 7 m × 4.76 m (300 trees ha^{-1}). The first crop yield (>5 kg per tree) was obtained in 2003.

The soil is an alkaline (pH 8.1) and shallow Petrocalcic Palexeralfs with a clay loam texture, low electrical conductivity (0.2 dS m^{-1}), organic matter (1.05%), nitrogen (0.12%), and potassium (17×10^{-4} mol kg^{-1}) levels, and high cationic exchange capacity (0.186 mol kg^{-1}) level. A discontinuous petrocalcic horizon is located between 0.75 and 0.85 m. The soil volumetric water content for the first 0.3 m depth is 22.8% at field capacity (soil matric potential −0.03 MPa) and 12.1% at permanent wilting point (soil matric potential −1.5 MPa), and from 0.3 to 0.75 m it was 43.0 and 21.1%, respectively.

Irrigation was carried out daily and during the night using a drip irrigation system with four emitters (each delivering 8 L h^{-1}) per tree and irrigation water with an electrical conductivity of 2.9 dS cm^{-1}. Crop irrigation requirements (ETc) were estimated according to daily crop reference evapotranspiration (ETo), calculated using the Penman−Monteith equation,[30] and a crop factor based on the time of the year[31] and taking into consideration canopy size.[32]

Plants were irrigated from mid-May (day of the year, DOY, 134) to the end of September (DOY 273). Control plants (T0 treatment) were irrigated at 100% ETc of the previous week. When midday stem water potential (Ψ_{stem}) values of that week were below −1.2 MPa before pit hardening (phase I of fruit growth) or −1.4 MPa during and after pit hardening (phases II and III of fruit growth, respectively), irrigation amounts were increased 10% in order to ensure no irrigation-related stress.[33]

DOI: 10.1021/acs.jafc.5b00805
J. Agric. Food Chem. 2015, 63, 3784−3792

In addition to T0, two regulated deficit irrigation treatments (T1 and T2) were applied, which were calculated to avoid water deficit during phase I and III of fruit growth, maintaining Ψ_{stem} values around the threshold values indicated for T0 plants, and save irrigation water during the noncritical phenological period of pit hardening (phase II) developing different situations of water deficit (threshold Ψ_{stem} values of −2.00 and −3.00 MPa in T1 and T2 plants, respectively). The irrigation protocol in T1 and T2 plants was based on that proposed by Moriana et al.[33] Irrigation requirements were determined weekly on the basis of the Ψ_{stem} measurements, and irrigation was begun when measured Ψ_{stem} values were lower than the threshold values suggested. The first irrigation event was always 1 mm in both treatments. After each requirement determination the increase or decrease in the irrigation rate was related to the differences between the Ψ_{stem} measured and the threshold suggested as follows:

- When deviations were <10%, the variation in the irrigation was 0.25 mm day^{-1}.
- When deviations were between 10 and 20%, the variation in the irrigation was 0.5 mm day^{-1}.
- When deviations were between 20 and 30%, the variation in the irrigation was 1 mm day^{-1}.
- When deviations were >30%, the variation in the irrigation was 2 mm day^{-1}.

Irrigation was stopped if this approach indicated a negative application.

During the irrigation season (DOY 134−273), ETc was 202 mm and cumulative amounts of applied water in T0, T1, and T2 treatments, measured by means of flow meters integrated in the irrigation system, were 407, 196, and 141 mm, respectively. The orchard was managed under no-tillage conditions; weeds were controlled with postemergence herbicides. Pest control practices were those usually used by local growers.

Climate and Plant Water Status. Meteorological data, namely, air temperature, solar radiation, air relative humidity, rainfall, and wind speed 2 m above the soil surface, were collected in a nearby automatic weather station. Mean daily air vapor pressure deficit (VPD_m) was calculated according to the method of Allen et al.[30] Daily ETo was estimated using the Penman−Monteith equation.[30]

From DOY 173 to 276, midday (12 h solar time) stem water potential (Ψ_{stem}) was measured on the middle third of the trees, in fully developed leaves near the main trunk from two trees of each replicate, enclosing leaves in small black plastic bags covered with aluminum foil for at least 1 h before measurements in the pressure chamber (model 3005, Soil Moisture Equipment Co., Santa Barbara, CA, USA).

Oil Extraction. Olive fruits were harvested at mid-December (DOY 345). Extra virgin olive oil was extracted using an Abencor system, and the obtained oil was separated by decanting. Samples for analysis were filtered and stored at −18 °C in darkness using amber glass bottles without headspace until analysis.

Chemicals and Reagents. PhytoPs (Figure 1), including 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, *ent*-16-F_{1t}-PhytoP, *ent*-16-*epi*-16-F_{1t}-PhytoP, 9-D_{1t}-PhytoP, 9-*epi*-9-D_{1t}-PhytoP, *ent*-16-B_1-PhytoP, 16-B_1-PhytoP, *ent*-9-L_1-PhytoP, and 9-L_1-PhytoP, were synthesized according to our published procedures.[34−36] As internal standard, 8-iso-$PGF_{2\alpha}$d4 was used (Cayman Chemicals, Ann Arbor, MI, USA). Hexane was purchased from Panreac (Castellar del Vallés, Barcelona, Spain), bis(2-hydroxyethyl)amino-tris(hydroxymethyl)methane (Bis-Tris) was from Sigma-Aldrich (St. Louis, MO, USA) and LC-MS grade solvents, methanol and acetonitrile, were purchased from J. T. Baker (Phillipsburg, NJ, USA). The SPE cartridges used was Strata cartridge (Strata X-AW, 100 mg/3 mL), which was acquired from Phenomenex (Torrance, CA, USA).

Phytoprostanes Extraction. PhytoPs were extracted by using a dilution followed by a solid-phase extraction (SPE), as described previously.[21,37] Briefly, 1 mL of extra virgin olive oil samples was diluted in 10 mL of *n*-hexane, and this solution was rediluted in 2 mL of methanol, stirred, and then rediluted in 2 mL of Bis-Tris buffer (0.02 M, HCl, pH 7). Immediately after, the emulsion of each sample (oil + hexane + Bis-Tris buffer) was subjected to SPE using a Strata X-AW cartridge (100 mg/3 mL), which was, prior to the oil sample loading, conditioned and equilibrated with 2 mL of hexane, 2 mL of methanol, and 2 mL of Milli-Q water. Later, to remove undesired compounds, the cartridge was washed with a series of solvents in the following sequence: 2 mL of hexane, 2 mL of Milli-Q water, 2 mL of a solution of methanol/Milli-Q water (1:3), and 2 mL of acetonitrile. Retained compounds were eluted with 1 mL of methanol, which was evaporated by using a SpeedVac concentrator (Savant SPD121P, Thermo Scientific, Waltham, MA, USA). The residue of each sample was redissolved in 200 μL of a mixture of A/B solvents (90:10, v/v), employing a mixture of Milli-Q water/0.01% acetic acid as solvent A and a solution of methanol/0.01% acetic acid as solvent B. Reconstituted samples were sonicated for 10 min and passed through a 0.45 μm filter (Millipore, Beford, MA, USA) before 20 μL of each was analyzed by UHPLC-QqQ-MS/MS (Agilent Technologies, Waldbronn, Germany).

UHPLC-QqQ-MS/MS Analyses. Ten PhytoPs were analyzed by reversed phase using UHPLC coupled with a 6460 triple-quadrupole MS/MS (Agilent Technologies), as reported by Collado-González et al.[37] Briefly, chromatographic separation was carried out on a BEH C18 column (2.1 × 50 mm, 1.7 μm) (Waters, Milford, MA, USA), the temperature of which was 6 °C (both left and right sides of the column). The solvents used as mobile phase were water/acetic acid (99.99:0.01, v/v) (A) and methanol/acetic acid (99.99:0.01, v/v) (B). The MS analysis was applied in the multiple reaction monitoring (MRM negative) ESI mode. The injection volume was 20 μL, and elution was performed at a flow rate of 0.2 mL/min. The linear gradient started with 60% B at 0 min, rose to 62% B at 2 min and 62.5% B at 4 min to reach 65% B at 8 min and at 8.01 min returned to the initial conditions. In this way, the acquisition time was 8.01 min for each sample, with a postrun of 2 min for the column equilibration. ESI conditions and ion optics were as previously described.[37] Data acquisition and processing were performed using the MassHunter software version B.04.00 from Agilent Technologies. The eight detected PhytoPs were quantified using authentic standards: 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, 9-D_{1t}-PhytoP, 9-*epi*-9-D_{1t}-PhytoP, *ent*-16-B_1-PhytoP, 16-B_1-PhytoP, and *ent*-9-L_1-PhytoP, 9-L_1-PhytoP.

Statistical Design and Analysis. The design of the experiments was completely randomized with four replications, each replication consisting of five adjacent tree rows, each with nine trees. Measurements were taken on the inner trees of the central row of each replicate, which were very similar in appearance (leaf area, trunk cross-sectional area, height, ground shaded area, etc.), whereas the other trees served as border trees. Data were analyzed using SPSS software.[38] Analysis of variance was performed, and mean values were compared by a $Tukey_{0.05}$ test. Values for each replicate were averaged before the mean and standard error of each treatment were calculated. To check the regression model hypothesis (linearity, homoscedasticity, normality, and independency) Kolmogorov−Smirnov was used with the Liliefors correction and the Shapiro−Wilk tests for normality and the Levene test for homoscedasticity on the typified residuals. To do the Levene test, data were divided into two groups according to the median of the abscissa data.

RESULTS

Plant Water Status. During the irrigation season (DOY 134−273), average daily maximum and minimum air temperatures were 31.4 and 13.2 °C, respectively, with a mean relative humidity of 37%. VPD_m ranged from 0.09 to 3.50 kPa, and accumulated ETo was 849 mm (Figure 2). Rainfall achieved 96 mm, taking place in 10 daily episodes mainly during September (Figure 2).

Ψ_{stem} values for T0 plants were high and nearly constant, reaching mean values of −1.48 MPa during the measurement periods (−1.40 MPa during phase I and −1.50 during phases II and III) (Figure 3). During phases I and III of fruit growth Ψ_{stem} values for the three treatment plants were very similar and

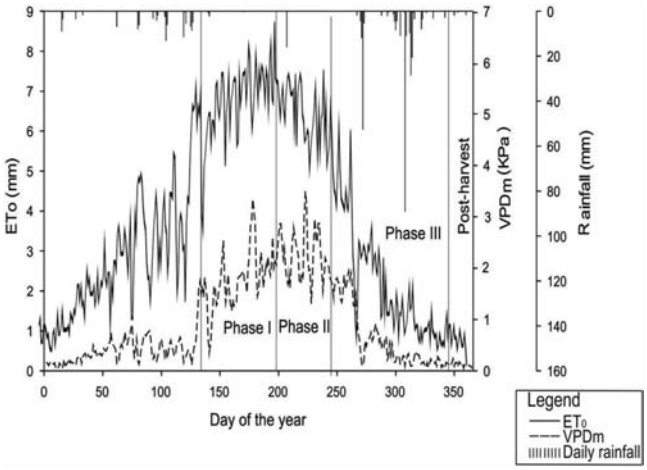

Figure 2. Daily crop reference evapotranspiration (ETo, solid line), mean daily air vapor pressure deficit (VPD_m, short-dash line), and daily rainfall (vertical bars) during year 2012.

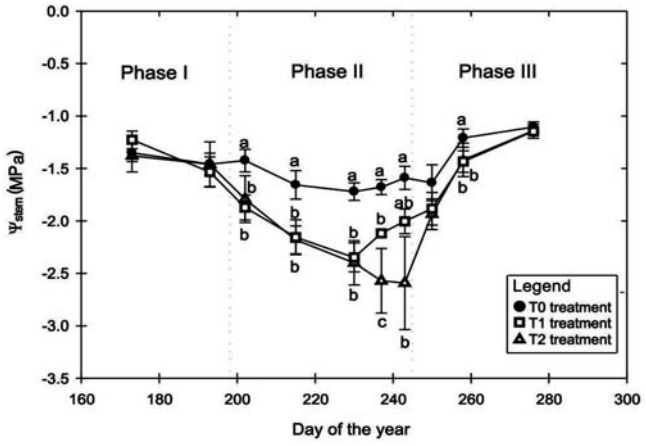

Figure 3. Midday stem water potential (Ψ_{stem}) in T0 (soild symbols), T1 (open squares), and T2 (open triangles) plants during the measurement period. Bars on data points are ±SE of the mean (not shown when smaller than symbols). Different letters on data points at each time indicate significant differences according to the Tukey test ($P \leq 0.05$). Each point is the mean of six values.

slightly increased during phase III of fruit growth (Figure 3). Ψ_{stem} values for T1 and T2 treatments significantly decreased during phase II at a similar rate of around 0.023 MPa day^{-1}, reaching minimum values of −2.35 and −2.59 MPa on DOY 230 and 243, respectively. However, differences between T1 and T2 plants in Ψ_{stem} values during this phenological period were significant only on DOY 237 (Figure 3).

Effect of Water Deficit on PhytoP Content. The PhytoPs profile of the extra virgin olive oil is shown in Figure 4 and Table 1, which indicates the presence of 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, 9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, 16-B_1-PhytoP, *ent*-16-B_1-PhytoP, 9-L_1-PhytoP, and *ent*-9-L_1-PhytoP. It is important to emphasize that two series of PhytoPs, the 16-B_1-PhytoP and the 9-L_1-PhytoP, were not separated, using achiral chromatographic conditions. Each pair of enantiomers was quantified together (sum of both for each pair of enantiomers). PhytoPs were identified on the basis of their mass spectra considering their pseudomolecular ion (*m*/*z* 327.2, 325.2, and 307.2), their most characteristic fragmentations, and their

Table 1. Multiple Reaction Monitoring (MRM) Transitions and Retention Time for Quantification of PhytoPs Using UHPLC-QqQ-MS/MS

phytoprostane	retention time (min)	precursor ion (*m*/*z*)	product ion (*m*/*z*)
9-F_{1t}-PhytoP	1.879	327.2	171.2
9-*epi*-9-F_{1t}-PhytoP	2.086	327.2	171.2
9-*epi*-9-D_{1t}-PhytoP	2.087	325.2	307.2
9-D_{1t}-PhytoP	2.380	325.2	307.2
16-B_1-PhytoP + *ent*-16-B_1-PhytoP	3.070	307.2	235.2
9-L_1-PhytoP + *ent*-9-L_1-PhytoP	3.294	307.2	185.2

elution order according to their retention times as described in Table 1.

The quantification of total PhytoPs in extra virgin olive oil oscillated from 9.18 to 19.31 ng/mL, the dominant PhytoP class being the F_{1t}-PhytoP and the D_1-PhytoPs class the minor components (Table 2). The total PhytoPs content in the extra virgin olive oil increased as a result of water deficit effect, although the differences between T1 and T2 contents were not significant (Table 2). However, the behavior observed in each PhytoP was not similar. In this sense, 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, and a racemic mixture of 16-B_1-PhytoP + *ent*-16-B_1-PhytoP showed a response to water deficit similar to that observed considering the total PhytoPs content, whereas the other PhytoPs (9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, and a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP) showed similar levels in T0 and T1 olive oil, which were significantly lower than those observed in T2 oil (Table 2).

The observations of total PhytoPs and all individual PhytoPs in extra virgin olive oil from the three irrigation treatments showed significant first-order and second-order polynomic correlations with minimum Ψ_{stem} values in phase II of fruit growth, except when 9-F_{1t}-PhytoP was considered in the first-order correlation and a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP in the second-order polynomic correlation (Tables 3 and 4). Moreover, most equations in Tables 3 and 4 predict a negative PhytoP value under high Ψ_{stem} values.

In general, correlations for the second-order polynomic equations of minimum Ψ_{stem} versus PhytoPs were tighter than those of first-order equations, except when 9-D_{1t}-PhytoP or a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP was considered (Tables 3 and 4). In this respect, in the case of a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP versus Ψ_{stem} because the coefficient of determination of the second-order polynomic equation was not significant, and in the case of 9-D_{1t}-PhytoP because both equations showed similar coefficients of determination (Tables 3 and 4).

It is important to indicate that the PhytoPs that increased their contents in T1 and T2 extra virgin olive oil (9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, and a racemic mixture of 16-B_1-PhytoP + *ent*-16-B_1-PhytoP) (Table 2) showed a second-order polynomic relationsship with respect to minimum Ψ_{stem} values characterized by two different phases (Figure 5). Above minimum Ψ_{stem} values of around −2.5 MPa, PhytoP values increased

DOI: 10.1021/acs.jafc.5b00805
J. Agric. Food Chem. 2015, 63, 3784−3792

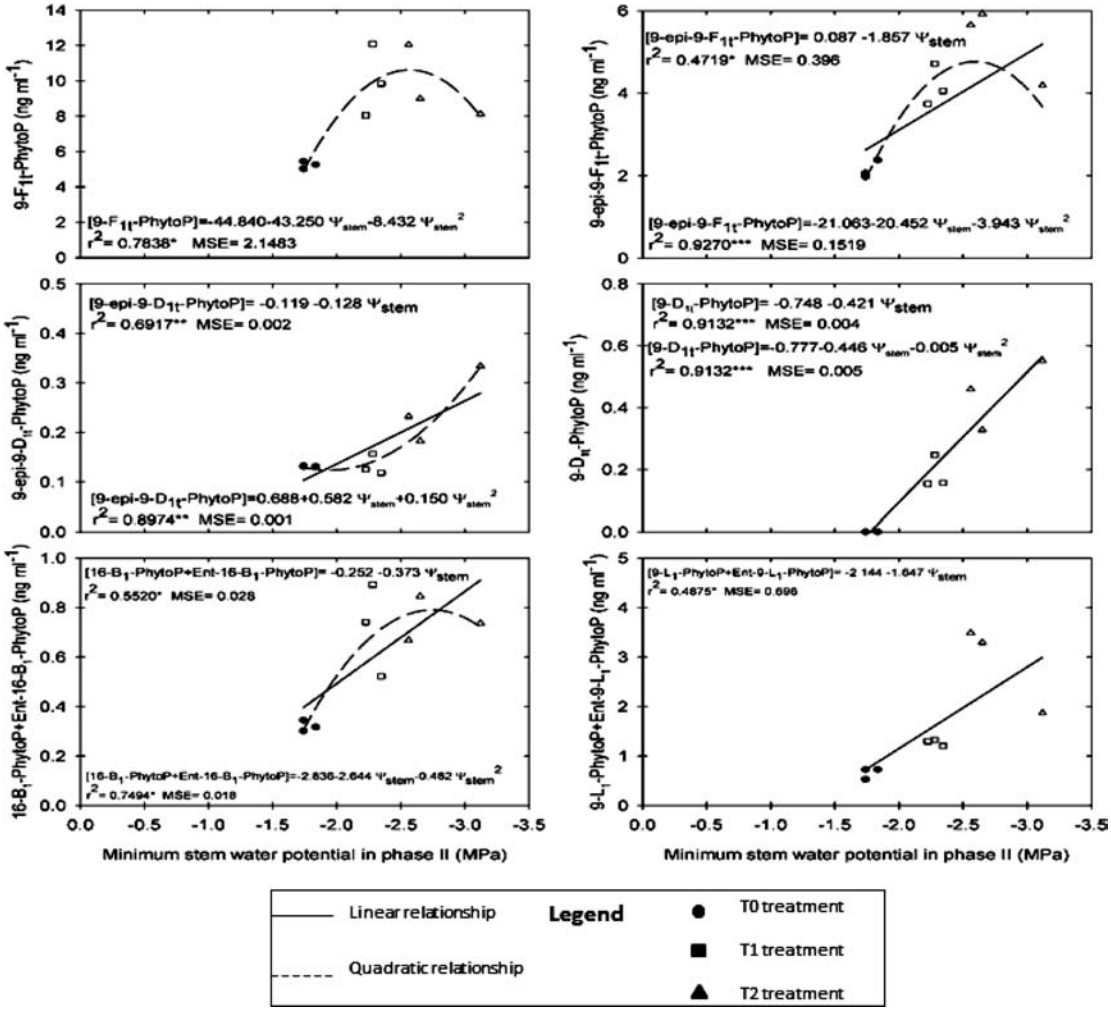

Figure 5. Relationship between PhytoPs content and minimum Ψ_{stem} values in T0 (solid circles), T1 (open squares), and T2 (open triangles) plants during phase II of fruit growth. Each value is the mean of three measurements.

sharply as minimum Ψ_{stem} decreased, and when minimum Ψ_{stem} values were below this threshold value, the relationship changed and any further reduction in minimum Ψ_{stem} was associated with a decrease in PhytoP contents. In contrast, the PhytoPs showed contents in T1 olive oil lower than in T2 (9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, and a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP) and linear regression may be sufficient for modeling the relationship between Ψ_{stem} and PhytoP in the water stress range studied (minimum Ψ_{stem} values in phase II from −3.12 to −1.73 MPa) (Figure 5).

DISCUSSION

The fact that Ψ_{stem} values for T0 plants during phases I, II, and III of fruit growth were slightly below the threshold Ψ_{stem} values (Figure 3) could be because irrigation amounts were not properly managed when Ψ_{stem} values were below the threshold values. Nevertheless, Ψ_{stem} mean values in each fruit growth phase were quite high and nearly constant,[39−41] suggesting that T0 plants were not under irrigation-related stress during the experimental period.[33]

Despite Ψ_{stem} values for T1 and T2 plants during phase II decreased at a similar and slow rate,[42] minimum Ψ_{stem} values indicated that both treatment plants achieved substantial water deficit levels, but were more important in T2 plants at the end of this phenological period (Figure 3).[43,44]

In a previous paper, Collado-González et al.[37] showed in a branded extra virgin olive oil a different PhytoP profile from that shown in Table 2, because they identified 9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, 16-B_1-PhytoP + *ent*-16-B_1-PhytoP, and *ent*-16-*epi*-16-F_{1t}-PhytoP + *ent*-16-F_{1t}-PhytoP. In other words, they additionally detected *ent*-16-*epi*-16-F_{1t}-PhytoP + *ent*-16-F_{1t}-PhytoP, even though did not detect 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, and 9-L_1-PhytoP + *ent*-9-L_1-PhytoP (Table 2). However, the level of total PhytoPs (14.64 ng/mL) in that branded extra virgin olive was within the range found under our experimental conditions in Cornicabra extra virgin olive oil (9.18−19.31 ng/mL). Taking into consideration that both olive oils were extra virgin and that analyses were performed with the same method, using synthetic standards, it is clear that these differences in composition can be ascribed to the decisive effect of cultivar, oil extraction technology, and/or storage conditions prone to autoxidation.[27]

To the best of our knowledge, no previous information exists on the effect of the water deficit on the PhytoPs content. In this sense, the increase in PhytoPs by water deficit effect during pit hardening (phase II of fruit growth) (Table 2) showed that this phenological period can be noncritical considering fruit yield,[18] but is clearly critical for PhytoPs content in olive oil. In this sense, Gómez del Campo and García[45] showed that virgin olive oils from deficit irrigated stress from the end of fruit drop to the

DOI: 10.1021/acs.jafc.5b00805
J. Agric. Food Chem. 2015, 63, 3784−3792

end of July exhibited significantly higher oxidative stability, which coincided with significantly higher contents in phenol derivatives, although deficit irrigation strategies in summer did not determine significant changes in the parameters legally established for evaluating the level of commercial quality of the virgin oils. Moreover, this increase in PhytoPs content could be related to the fact that under drought stress the frail balance between reactive oxygen species (ROS) and scavenging that defines the normal steady-state level of intracellular ROS suffers an upward shift enhancing ROS production due to stomatal closure and the concomitant limitation on CO_2 fixation.[46] A consequence of this enhanced ROS formation in plants is the formation of an array of lipid peroxidation products, including structural congeners of jasmonates, the PhytoPs.[24]

Because all PhytoPs are induced by oxidative stress (OS) from common precursors, the G_1-PhytoPs,[24,47] the fact that the behavior observed in each PhytoP in response to water deficit was not similar (Table 2) indicated that those which increased their contents in the T1 extra virgin olive oil might require a lower OS level to be induced from the precursor and could be used as early markers of water deficit in extra virgin olive oil.

From an nutritional point of view, the increase in total PhytoPs in T1 and T2 olive oil, nearly 2-fold with respect to control (T0) olive oil (Table 2), could be considered a potential beneficial aspect of the extra virgin olive oils from trees cultivated under water deficit conditions during pit hardening, because even though there is no detailed knowledge of the biological effects of PhytoPs, there is some evidence of their beneficial effects on human health, such as regulation of immune function[28,48] and anti-inflammatory and apoptosis-inducing activities.[29]

The fact that the relationships between 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP or a racemic mixture of 16-B_1-PhytoP + *ent*-16-B_1-PhytoP and minimum Ψ_{stem} values in phase II were tighter using second-order polynomic equations, whereas the relations for 9-*epi*-9-D_{1t}-PhytoP or 9-D_{1t}-PhytoP using linear or quadratic equations showed similar levels of significance for their coefficients of determination and the relationship for a racemic mixture of 9-L_1-PhytyoP + *ent*-9-L_1-PhytyoP was defined only by a linear equation (Figure 5), could indicate different development levels of the same behavior. In this sense, Horner[49] indicated that the relationship between plant water status and secondary metabolite contents is defined by a quadratic relationship. Also, some authors showed that the relationship between plant water status and some metabolite contents is not defined by a linear correlation when a wide range of plant water status is considered.[50,51] Then, the first-order relationship between plant water deficit and PhytoPs content (Figure 5) could correspond to the first phase of the quadratic relationship proposed by Horner,[49] indicating that a more severe water deficit could be necessary to induce a decrease in the 9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, or a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP content.

The fact that most equations in Tables 3 and 4 showed a negative intercept could contraindicate the use these equations under high Ψ_{stem} values because negative PhytoPs values could be predicted, which does not make sense from a metabolic or physiological point of view. Nevertheless, PhytoPs values could be predicted using these equations when Ψ_{stem} values were within the range of values used to determine these equations (minimum Ψ_{stem} values in phase II from −3.12 to −1.73 MPa). Therefore, using these Ψ_{stem} boundary values negative PhytoPs values are not predicted.

Overall, the results showed for the first time that pit hardening (phase II of olive fruit growth), a phenological period noncritical for fruit yield, is clearly critical for extra virgin olive oil composition because water deficit enhances the PhytoPs content, with the concomitant potential beneficial aspects on human health because they are bioavailable in humans according to previous results.[48] Also, qualitative and quantitative differences in PhytoPs content with respect to those reported by other authors indicate a decisive effect of cultivar, oil extraction technology, and/or storage conditions prone to autoxidation. The content of each individual PhytoP in the olive oil from T0, T1, and T2 treatments could define different phases of the same behavior. In this sense, when minimun Ψ_{stem} values in phase II were above −2.5 MPa, 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, and a racemic mixture of 16-B_1-PhytoP + *ent*-16-B_1-PhytoP values increased sharply as Ψ_{stem} decreased, and when Ψ_{stem} values were below this threshold value, the relationship changed and any further reduction in Ψ_{stem} was associated with a decrease in PhytoPs contents. In contrast, when minimun Ψ_{stem} values in phase II decreased from −1.73 to −3.12 MPa, the 9-*epi*-9-D_{1t}-PhytoP, 9-D_{1t}-PhytoP, and a racemic mixture of 9-L_1-PhytoP + *ent*-9-L_1-PhytoP increased, indicating that a more severe water deficit could be necessary to induce a decrease in their contents. Therefore, from a physiological and agronomical point of view, 9-F_{1t}-PhytoP, 9-*epi*-9-F_{1t}-PhytoP, and a racemic mixture of 16-B_1-PhytoP + *ent*-16-B_1-PhytoP could be considered as early candidate biomarkers of water stress in olive tree.

improve nutritional and agronomic properties (e.g., resistance to abiotic or biotic stresses in the seed) while maintaining breadmaking characteristics and low allergen levels.

MATERIALS AND METHODS

Plant Materials. Introgression lines (chromosome additions or substitutions) for chromosome 7$\mathbf{H}^{ch}$ from *H. chilense* in bread wheat (*Triticum aestivum* cv. Chinese Spring (CS), $2n = 6x = 42$) used in this work were kindly provided by Steve Reader (John Innes Centre, Norwich, UK) and are summarized in Table 1. Seeds were germinated in Petri dishes on wet filter papers in darkness for 5 days at 4 °C followed by 24 h of incubation at 25 °C. All plants were grown in a greenhouse at 26 °C during the day and 22 °C at night with a photoperiod of long days (16 h of daylight–8 h of darkness).

Protein Extraction. Embryos were removed from mature grains using clean scalpels. Seven mature wheat grains from each line, which were pooled and harvested from five plants, were used for protein extraction. Endosperms were manually milled into a fine powder using a mortar and pestle. Total endosperm proteins were extracted from an equivalent pool of flour per line in a proportion of 600 μL of lysis buffer (7 M urea, 2 M thiourea, 4% 3-[(3-cholamidopropyl)-dimethylammonio]-1-propanesulfonate (CHAPS; Sigma-Aldrich, Madrid, Spain), 1% dithiothreitol (DTT; Sigma-Aldrich), and 1% protease inhibitor cocktail set VI (Calbiochem, Madrid, Spain) per each 20 mg of flour. About 20–30 mg of pooled flour per wheat line was used for independent protein extraction.

To this end, samples were homogenized in lysis buffer and sonicated using an ultrasonic homogenizer (Sonopuls HD2070, Bandelin Electronic, Berlin, Germany) three times during 20 s, leaving the samples for 1 min on ice between sonication intervals and then incubated for 30 min in an orbital rotator at 4 °C. Subsequently, the samples were clarified to remove insolubilized debris by centrifugation at 13000 rpm for 20 min, and the supernatant was recovered and used for analysis. Protein concentrations were determined with the Bradford assay (Sigma-Aldrich) using BSA as standard and according to the manufacturer's instructions for microplate procedure.

Two-Dimensional Gel Electrophoresis (2-DE) and Image Analysis. Three replicates per line were used for 2-DE analysis. For the first dimension, proteins were isoelectrofocused in IPG strips of 7 cm, 3–10 nonlinear pH gradient (Bio-Rad, Madrid, Spain). Immobilized pH gradient (IPG) strips were rehydrated in a total volume of 125 μL containing 100 μg of protein and rehydratation buffer (7 M urea, 2 M thiourea, 4% CHAPS, 20 mM DTT, 0.5% Triton X-100, 0.5 Bio-Lyte ampholytes pH 3–10 (Bio-Rad, Madrid, Spain)). Three strips per line sample were isoelectrofocused simultaneously in a Protean IEF Cell (Bio-Rad), using the following parameters: (1) linear voltage increment; (2) active rehydration at 50 V for 12 h; (3) 250 V for 15 min; (4) rapid ramp to 4000 V h; (5) slow ramp of voltage to 10000 V h; and (6) a final hold step at 500 V. After isoelectrofocusing, the IPG strips were equilibrated for 10 min in 2.5 mL of equilibration buffer I (50 mM Tris-HCl, pH 8.8, 6 M urea, 2% sodium dodecyl sulfate (SDS), 30% glycerol, and 2% (w/v) DTT), followed by 10 min in 2.5 mL of equilibration buffer II (50 mM Tris-HCl, pH 8.8, 6 M urea, 2% SDS, 30% glycerol, and 2.5% (w/v) iodoacetamide (Sigma-Aldrich)). The second dimension separation was performed on 12% SDS–polyacrylamide gels using Mini-PROTEAN 3 Dodeca Cell (Bio-Rad) that allowed running 12 gels under identical conditions. After electrophoresis, gels were rinsed briefly in mQ water and stained with Coomassie Brilliant Blue G-250 (Merck-Millipore, Madrid, Spain).[22] Gels were incubated for 20 h in Coomassie Blue G-250 working solution (8% ammonium sulfate, 2% phosphoric acid, 1% Coomassie Blue G-250, 20% methanol). Then, gels were washed for 1–3 min with 0.1 M Tris–phosphate, pH 6.5, briefly rinsed (<1 min) with 25% methanol, and finally washed overnight with 20% ammonium sulfate. Stained gels were rinsed in water and scanned in a GS800 calibrated densitometer (Bio-Rad). Gel images were analyzed with PDQuest version 7.2 software (Bio-Rad Discovery Series). All gels were analyzed all at once for analysis interlines. Spots were matched simultaneously among all gels from all analyzed lines, which allowed us to compare the same spot/protein among different lines.

Intensity levels of the spots were normalized by expressing the intensity of each protein spot in a 2-DE gel as a proportion of the total protein intensity detected for the entire gel. Spots detected by the software were matched among all gels. All data were manually reviewed for any discrepancies, and only reproducible spots were maintained in the final analysis. The normalized volume of each spot was calculated for each gel and used to calculate the differences in protein expression between lines. Both qualitative and quantitative changes were determined. For quantitative changes a minimum fold-change of 2 was set. For each of the comparisons analyzed, spot intensities were statistically analyzed among three replicate gels using a Student t test, and only significant data ($p < 0.05$) were considered as quantitative changes. Spots identified as qualitative (presence/absence) or quantitative (changes in intensity) changes were selected for identification by MALDI-TOF/TOF mass spectrometry. A heatmap was generated to compile and display the differential expression of the peptides using MeV-multiexperiment viewer software (http://www.tm4.org/mev.html).

Protein Identification by MALDI-TOF/TOF Mass Spectrometry. Spots were automatically excised in a ProPic station (Genomic Solutions, Bath, UK) and digested with modified porcine trypsin (sequencing grade; Promega, Madrid, Spain), by using a ProGest digestion station (Genomic Solutions). Gel pieces were distained twice for 30 min at 37 °C with 200 mM ammonium bicarbonate in 40% acetonitrile (ACN) and subsequently subjected to three consecutive dehydration/rehydration cycles with pure ACN and 25 mM ammonium bicarbonate in 50% ACN, respectively. Finally, gel pieces were dehydrated for 5 min with pure ACN and dried over 4 h at room temperature. Then, 20 μL of trypsin (12.5 ng/μL in 25 mM ammonium bicarbonate) was added to dried gel pieces and digestion proceeded at 37 °C for 12 h. Peptides were extracted from gel plugs by adding 1 μL of 10% (v/v) trichloroacetic acid (TCA) and incubating for 15 min. Then, they were desalted and concentrated by using μC-18 ZipTip columns (Millipore, Madrid, Spain) in a ProMS station (Genomic Solutions) and directly loaded onto the MALDI plate using α-cyanohydroxycinnamic acid as the matrix. Mass analysis of peptides of each sample was performed with a 4800 MALDI-TOF/TOF Analyzer (Applied Biosystems, Madrid, Spain) in automatic mode with the following settings: for the MS data, m/z range from 800 to 4000 with an accelerating voltage of 20 kV and delayed extraction, peak density of maximum 50 peaks per 200 Da, minimal S/N ratio of 10, and maximum peak at 65. Spectra were internally calibrated with peptides from trypsin autolysis ($M + H^+ = 842.509$, $M + H^+ = 2211.104$). For the MS/MS data, fragment selection criteria were a

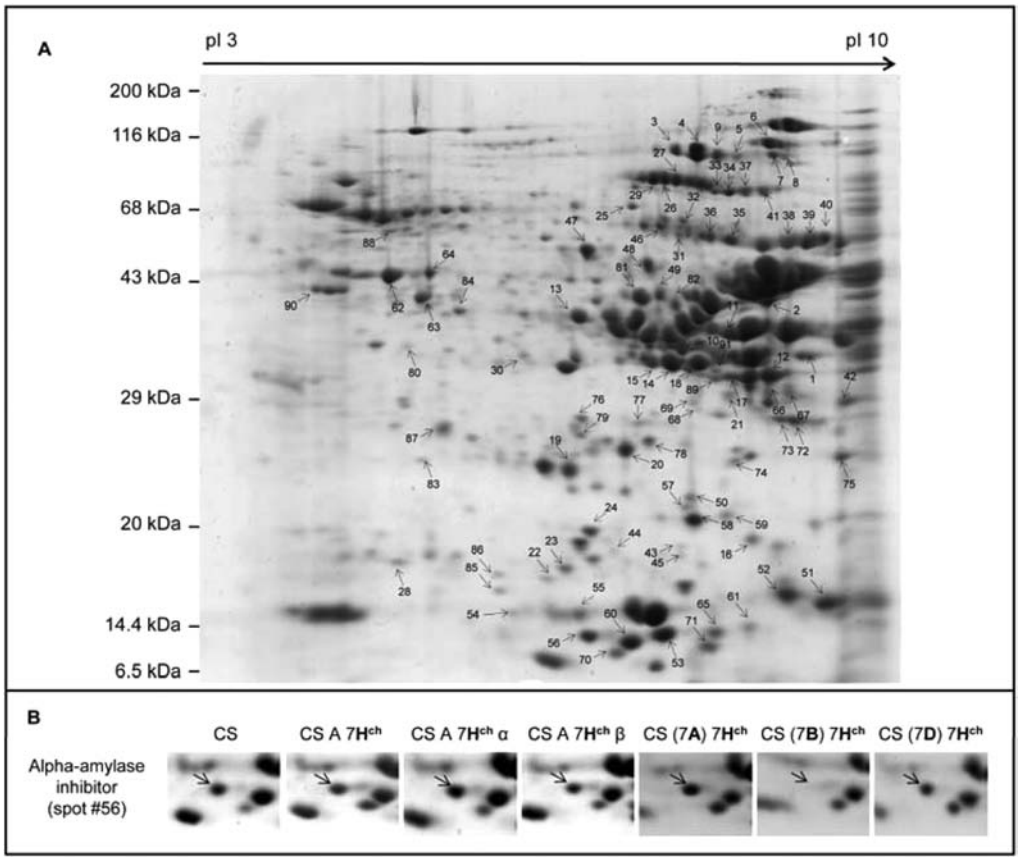

Figure 1. (A) Proteome map of wheat grains displaying all of the proteins that were found to be differentially expressed among wheat lines. (B) Example of a qualitative change among lines.

minimum S/N ratio of 5, a maximum number of peaks set at 65, and peak density of maximum 50 peaks per 200 Da. For each precursor selected for MS/MS analysis, fragment mass values in the range from 60 to 10 Da below precursor mass were used for peptide identification. Protein identification was assigned by peptide mass fingerprinting and confirmed by MS/MS analysis of at least three peptides in each sample. The Mascot 1.9 search engine (Matrixscience, London, UK) was used for protein identification running on GPS software (Applied Biosystems) against the Uniprot Viridiplantae database updated January 2013 (1,351,179 sequences; 457,681,928 residues). The search setting allowed one missed cleavage with the selected trypsin enzyme, a MS/MS fragment tolerance of 0.2 Da, and a precursor mass tolerance of 100 ppm. The 2D-PAGE analysis was carried out in the Servicio de Proteómica (SCAI, member of ProteoRed network, Universidad de Córdoba, Spain).

RESULTS

Identification of Differentially Expressed Proteins in *H. chilense* Chromosome 7 Addition and Substitution Lines in Bread Wheat. A 2-DE-PAGE comparative proteomics analysis was carried out to assess the effect of the addition of *H. chilense* chromosome pair 7$\mathbf{H}^{ch}$ or its 7$\mathbf{H}^{ch}\alpha$ or 7$\mathbf{H}^{ch}\beta$ chromosome arms and the selective substitutions of wheat chromosomes 7**A**, 7**B**, or 7**D** by chromosome 7$\mathbf{H}^{ch}$ from *H. chilense* on the proteome of wheat endosperm. Protein extracts of three biological replicates for each introgression line were run in separate gels and stained with Coomassie Brilliant Blue G-250. The gels were scanned and then analyzed to compare the proteomic profile of the seed endosperm of the different chromosome 7$\mathbf{H}^{ch}$ introgression lines. An example of the 2-DE gels is shown in Figure 1A.

A total of 319 spots were matched across all 2-DE gels and used for comparative analysis among wheat lines (data not shown). The differential protein expression levels were obtained by the comparisons between (1) each chromosome 7$\mathbf{H}^{ch}$ addition or substitution lines versus CS; (2) the addition of the whole chromosome 7$\mathbf{H}^{ch}$ versus the addition of only the 7$\mathbf{H}^{ch}\alpha$ or the 7$\mathbf{H}^{ch}\beta$ addition lines; and (3) among the different (7**A**)7$\mathbf{H}^{ch}$, (7**B**)7$\mathbf{H}^{ch}$, and (7**D**)7$\mathbf{H}^{ch}$ substitution lines ($p < 0.05$ and a minimum fold change of 2). Thus, a total of 91 spots were differentially expressed; 89 of them showed quantitative differences in expression between lines (Figure 1A; Table 2), and spots 90 and 91 uniquely presented qualitative differences, meaning that these peptides were present only in some of the lines but not in others (Figure 1B; Table 3; Supporting Information Supplementary Table 2). Only three spots showed both quantitative and qualitative differences (spots 56, 65, and 75; Table 3). The analysis of the differentially expressed spots was carried out by MALDI-TOF/TOF mass spectrometry and led to the identification of 91 proteins (Supplementary Tables 1 and 2). These proteins have been classified in 13 groups on the basis of their annotation: low molecular weight (LMW) glutenins, high molecular weight (HMW) glutenins, (α-, β-, γ-, and ω-) gliadins, avenin-like proteins, globulins, triticins, puroindolines, α-amylase/protease inhibitors, serpins, xylanase inhibitors, pathogenesis-related proteins (PRs), allergens and putative allergens, and other proteins (Figure 2).

Fifty-six percent of the differentially expressed spots belonged to the storage proteins category, which included the glutenins, gliadins, avenin-like proteins, globulins, and triticins. The most numerous changes were recorded in the globulin

family, followed by the α-amylase/protease inhibitors, the (putative) allergens, and the HMW glutenins. The puroindolines and the LMW glutenins were the least affected proteins because only two spots corresponded to each of these categories (Figure 2).

Qualitative Changes in Protein Expression in *H. chilense* Chromosome 7 Addition and Substitution Lines in Bread Wheat. Only five spots appeared or disappeared when the 2-DE gels of the different chromosome 7**H**^{ch} substitution and addition lines were compared (Table 3). Chymotrypsin inhibitor WCI (spot 65), serpins 2 and 4 (spot 90), and avenin-like b6 (spot 91) were expressed only when chromosomes 7**D** was present, and the presence of chromosome 7**H**^{ch} does not compensate for its absence. In the case of spots 56 and 75, which corresponded to an α-amylase/trypsin inhibitor and Barperm1, respectively, their expression seemed to be related to the presence of chromosome 7**B**.

Quantitative Changes in the Wheat Endosperm Protein Expression Due to the Presence of the *H. chilense* Chromosome 7H^{ch}. The identification of the peptides by mass spectrometry allowed the classification of the 89 spots in 13 groups (Figures 2 and 3). A heatmap was generated with the aim of visualizing the differences in the peptide expression between all of the wheat lines analyzed. Rows and columns represented the spots from the gels and the comparisons between lines, respectively (Figure 3). The addition of chromosome 7 of *H. chilense* increased the quantity of most of the proteins, especially globulins, xylanase inhibitors, and several allergens, whereas the addition of only the 7**H**$^{ch}\alpha$ or 7**H**$^{ch}\beta$ arm introduced fewer changes in the proteome as expected (Figure 3; Table 2). As well as for the addition of the complete chromosome, the repression of protein abundance was rare or absent in the ditelosomic addition lines (Figure 3; Table 2). Hence, the disomic and ditelosomic additions and the (7**A**)7**H**^{ch} substitution led to an increase in protein abundance compared to CS, whereas, in contrast, (7**B**)7**H**^{ch} or (7**D**)7**H**^{ch} chromosome substitutions led to a similar number of proteins with increased or reduced expression (Figure 3; Table 2).

Among the 89 spots, 50 belong to the storage protein category including prolamins (glutenins, gliadins), avenin-like proteins, globulins, and triticins. The prolamin fraction scarcely changed between addition or substitution lines compared to CS; indeed, the ditelosomic addition of the 7**H**$^{ch}\alpha$ chromosome arm did not show any significant differences with CS in any of the prolamins. The most important changes in avenin-like proteins were detected when chromosome 7**A** was substituted by 7**H**^{ch}, whereas the (7**B**)7**H**^{ch} chromosome substitution did not alter their expression (Figure 3). In addition, it is worth remarking that the proteins with the highest number of differentially expressed spots were the globulins (28 spots; Figure 3; Supplementary Table 1). The 7**H**^{ch} addition or substitution lines displayed increased globulin content, especially remarkable in the addition lines. Only four spots identified as triticins were differentially expressed among lines. The (7**A**)7**H**^{ch} substitution presented the highest expression of triticins compared to CS, the addition lines and the other (7**B**)7**H**^{ch} or (7**D**)7**H**^{ch} chromosome substitutions (Figure 3; Supplementary Table 1).

Puroindolines, which are biochemical markers of grain softness,[23] were repressed only when chromosome 7**D** was substituted by 7**H**^{ch}, which suggests that the addition of neither chromosome 7**H**^{ch} itself nor the (7**A**)7**H**^{ch} or the (7**B**)7**H**^{ch}

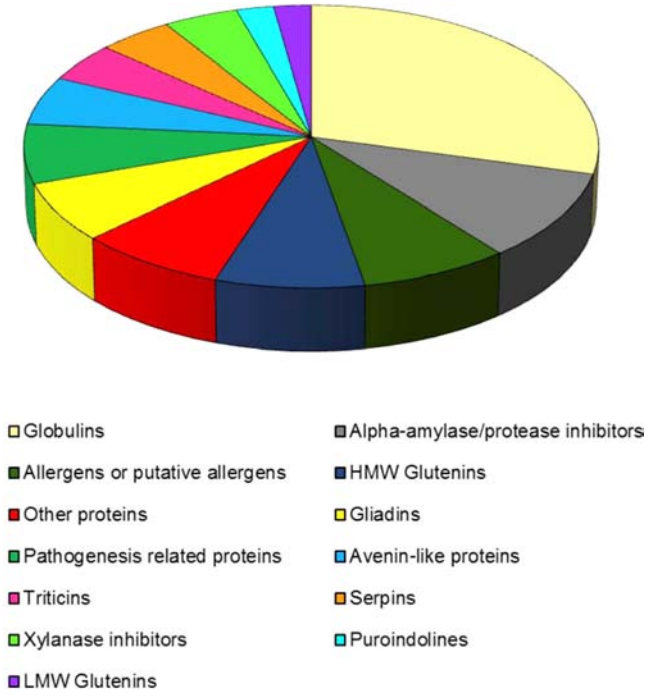

Figure 2. Classification of the proteins that displayed quantitative expression differences between wheat lines by 2-DE-PAGE analysis.

chromosome substitutions affected the abundance of these proteins (Figure 3).

Seventeen spots were classified as protease inhibitors, including α-amylase inhibitors, serpins, and xylanase inhibitors. The addition of chromosome 7H^{ch} induced the accumulation of six α-amylase/protease inhibitors, whereas only three of these types of proteins were enhanced in the ditelosomic addition of 7H^{ch}β and two of them in the 7H^{ch}α ditelosomic addition and the (7A)7H^{ch} chromosome substitution lines. Xylanase inhibitor expression increased in both chromosome 7H^{ch} addition and substitution lines. The (7D)7H^{ch} substitution line did not show any differences in serpin expression (Figure 3; Supplementary Table 1).

Pathogenesis-related proteins (PRs) showed higher expression in chromosome 7H^{ch} addition and in the (7A)7H^{ch} substitution lines. On the contrary, the addition of chromosome arm 7H^{ch}β and the 7B(7H^{ch}) or 7D(7H^{ch}) chromosome substitutions did not affect the quantity of these proteins (Figure 3; Supplementary Table 1).

Related to wheat allergens, the (7D)7H^{ch} substitution line expressed the lowest amount of allergens compared to the other substitution and addition lines for chromosome 7H^{ch} (Figure 3; Supplementary Table 1).

DISCUSSION

Breeding for improving nutrient content in crops is considered a sustainable and cost-effective strategy to address malnutrition in developing countries because it targets staple foods that are daily consumed.[24] Varieties of crops with naturally high content in nutrients can be used in crossbreeding with high-yielding commercial varieties and provide seeds with both desirable features: high yield and increased nutritional value. An example of this strategy could be the introgression of chromosome 7 from the wild barley *H. chilense* into wheat, which leads to an increment in the seed carotenoid concentration.[19]

Apart from the improvement of the nutritional composition, other aspects of flour quality must be considered to obtain wheat lines with commercial potential. Introgression lines from related wild species could produce in wheat unintended proteomic alterations associated with changes in the genome; therefore, the analysis of the proteome of these lines constitutes a helpful tool to decipher the protein composition and the viability of these lines for flour production and, specifically, breadmaking properties.

Although the addition of chromosome 7 from *H. chilense* into wheat is known to increase the seed carotenoid content,[19] none of the proteins identified in this study were related to carotenoid metabolism. This was most likely due to the fact that carotenoid-related proteins are low-abundance or membrane proteins. Consequently, they are rarely detected in 2D gels because large quantities of abundant soluble proteins obscure their detection.[25] Instead, changes in the expression of storage proteins were observed, including prolamins, avenin-like proteins, globulins and triticins, puroindolines, α-amylase/protease inhibitors, serpins, xylanase inhibitors, PRs, allergens, and other proteins (Figure 2).

In wheat, prolamins constitute the major components of the gluten protein fraction, which forms a viscoelastic network and is largely responsible for the ability to process wheat grains.[26] Prolamins comprise 80% of the endosperm protein and consist of the monomeric gliadins (α-, γ-, and ω-) and the polymeric glutenins, including HMW and LMW glutenins.[27] In bread wheat, glutenins and γ- and ω-gliadin genes are located on chromosomes of the homeologous group 1, whereas α- and β-gliadins are located on the short arm of the homeologous group 6.[28] Hence, the low number of changes identified in the prolamin fraction may be explained by the fact that the wheat chromosomes substituted in this study were 7A, 7B, and 7D (Figure 3; Supplementary Table 1) and suggests that the

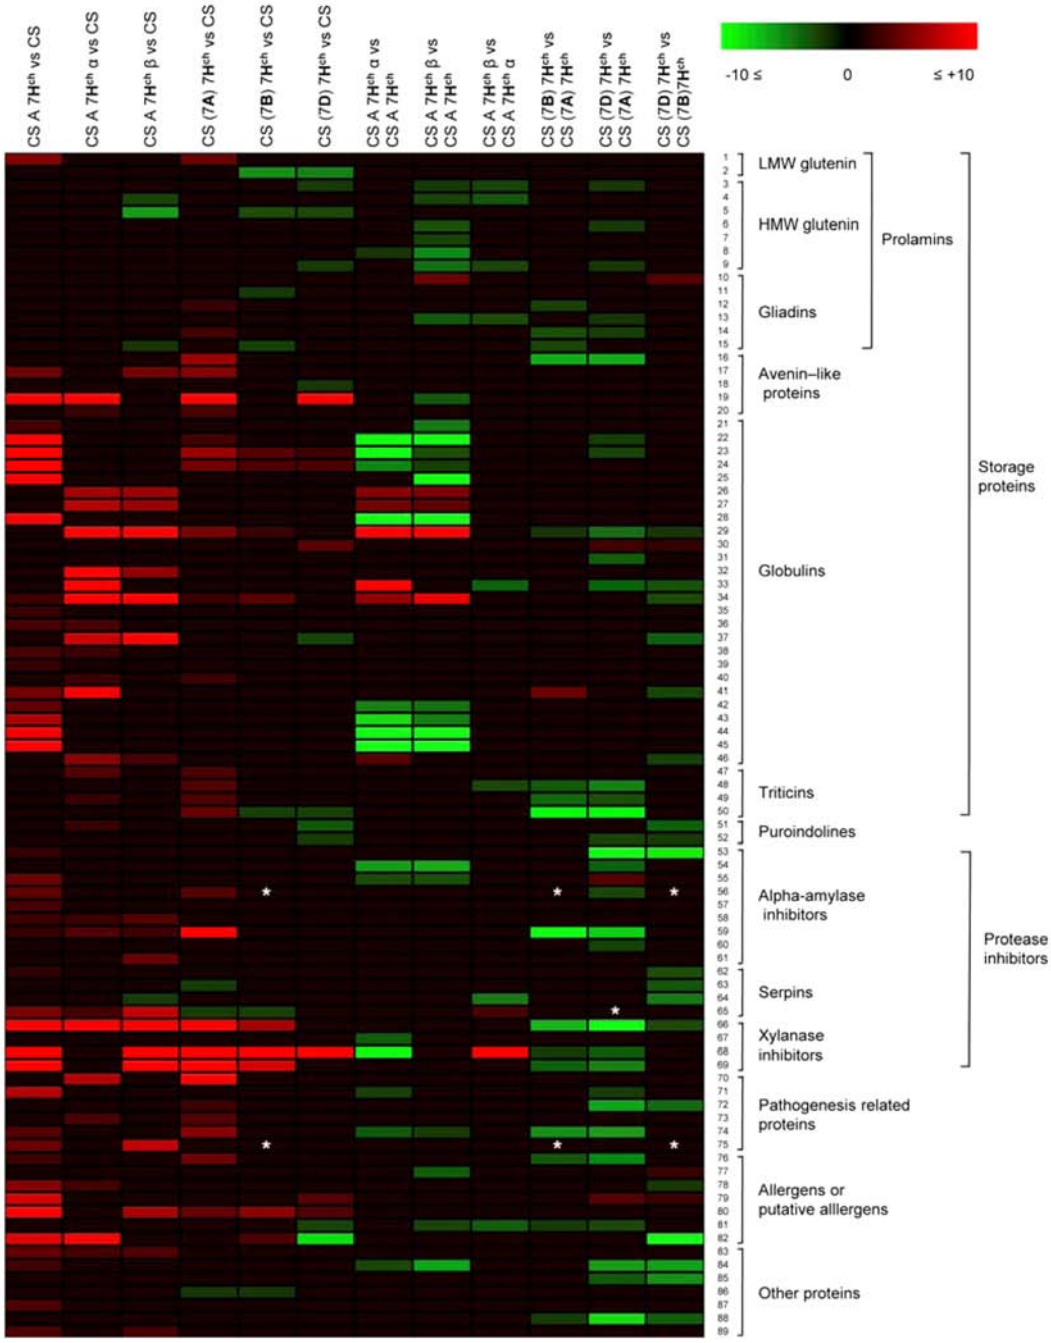

Figure 3. Heatmap depicting the quantitative comparison of the expression of the proteins across several wheat lines. Rows represent the spots from the gels, and the columns are the comparisons between wheat lines. Red, black, and green colors indicate up-regulated, unchanged, and down-regulated peptides, respectively. The asterisks indicate qualitative changes that are described in detail in Table 3 and Supplementary Table 2.

regulation of the synthesis of these proteins is scarcely controlled by genes/proteins located on chromosome 7 (Figure 3; Supplementary Table 1).

Avenin-like proteins are minor storage proteins that are rich in cysteine residues.[29,30] Overexpression of avenin-like b proteins improves dough mixing properties by their incorporation into glutenin polymers.[31] The most important changes in these proteins occurred in the (7**A**)7**H**^{ch} substitution line, which presented higher amounts of four avenin-like proteins. The substitution of 7**B** chromosome did not alter their expression at all, which could indicate that the avenin-like proteins were not located on this chromosome or that they are not regulated by chromosome 7**B** either (Figure 3).

Although globulins represent a small proportion of flour proteins (around 3%), most changes identified in this study were detected in the globulin fraction (Figure 3; Supplementary Table 1), which could be due to the presence of post-translational modifications of the same protein or the identification of monomers,[32,33] which could be the case of the charge trains composed by the spots 26−27 and 38−40 (Figure 1; Supplementary Table 1). As expected the addition of the whole chromosome 7**H**^{ch} was the line in which most of the globulins detected showed higher expression compared to CS

DOI: 10.1021/jf5055672
J. Agric. Food Chem. 2015, 63, 3793−3802

(Figure 3; Supplementary Table 1). Globulins have been demonstrated to be potential food allergens; for this reason the use of wheat lines with an increased content of these proteins (e.g addition lines) is not advisible when wheat is intended for human consumption.[14,34]

Triticin, a minor storage protein of wheat endosperm, is considered to be nutritionally rich due to the presence of lysine-rich decapeptide repeats.[13] Because lysine is the first nutritionally limiting essential amino acid in most cereals, several attempts have been carried out to obtain high-lysine mutants in cereals such as maize; however, in wheat these mutants could not be isolated yet, possibly because of its polyploidy.[13] In the present study, four spots identified as triticins were differentially expressed among lines. Triticins are heterotetramers;[13] therefore, the spots with different mobilities in the 2D gels might be s consequence of the identification of the different monomers. The (7**A**)7**H**^{ch} substitution line presented the highest quantity of triticins compared to CS and to the addition and to the other substitution lines, suggesting that chromosome 7**A** could have a role in the regulation of triticin expression (Figure 3; Supplementary Table 1).

Wheat cultivars with harder grains are best suited for breads, and those that have soft grain are best for cookies, cakes, and pastries.[11] The first biochemical marker of grain softness is fribialin, a mixture of two polypeptides, puroindolines a and b.[23] The hard texture of durum wheat grains is due to s lack of puroindolines and has been associated with the absence of genome **D**. Puroindoline genes are located on the short arm of chromosome 5**D** (*Hardness* locus, *Ha*),[35] but other genetic regions have been associated with kernel hardness, for example, in the long arm of 7**A** chromosome.[11,36] However, in our study, we identified a reduced expression of puroindolines only when chromosome 7**D** was substituted, but the substitution of neither chromosome 7**A** nor 7**B** by chromosome 7**H**^{ch} affected the abundance of these proteins (Figure 2; Supplementary Table 1). Therefore, chromosome 7**D** might be also implicated in puroindoline presence in grain. From the data we have obtained in the current work the concrete causes of the importance of chromosome 7**D** cannot be inferred, but the simplest plausible explanation could be that a transcription factor that regulates the puroindoline expression is encoded in this chromosome and its absence could be the cause for the differences detected. Other likely causes could be that chromosome 7**D** encodes a protein that stabilizes puroindolines. In any case, the reduced expression of puroindolines in substitution 7**H**^{ch} (7**D**) could be potentially used to get varieties with increased grain hardness.

Wheat grain accumulates a wide variety of α-amylase and other protease inhibitors, which have protective roles against insect proteases and abiotic stresses and also act as storage proteins. Interestingly, these proteins have a higher percentage of glutamine and proline and a more balanced amino acid composition than major gluten proteins,[12] which might be exploited for human nutrition. The drawback of these proteins is the fact that they cause IgE-mediated occupational and food allergies.[37−39] Therefore, the increment of these proteins might have a negative impact in bakers' safety and flour processing. The addition of chromosome 7**H**^{ch} induced the accumulation of six α-amylase/protease inhibitors, and two of them were also enhanced in the (7**A**)7**H**^{ch} substitution line (Figure 3; Supplementary Table 1). Although genes encoding for α-amylase inhibitors have been located in 7**B** or 7**D**,[12] the substitution of these chromosomes does not change the expression of most of these proteins, probably due to the complementation with the *H. chilense* chromosome. Interestingly, the absence of spot 56 (α-amylase/trypsin inhibitor CM2) in (7**B**)7**H**^{ch} chromosome substitution line (Figure 1; Supplementary Table 2) would confirm a role of chromosome 7**B** in the expression of this particular protein.

The wheat serine protease inhibitors (serpins) are suicide substrate inhibitors of chymotrypsin and cathepsin A that may function to protect the prolamins from the digestive proteinases of insects.[40,41] The serpins are synthesized by the Srp-A1, Srp-B1, and Srp-D1 genes located in the chromosomes 5**AL**, 5**BL**, and 5**DL** (McIntosh et al., 2013).[42] Spot 90 corresponding to a serpin protein was absent in (7**D**) 7**H**^{ch} lines, which could indicate that it might be encoded or regulated by molecular elements located on the 7**D** chromosome (Table 3).

Xylanases can improve loaf volume and crumb texture by solubilizing wheat cell wall polysaccharides and improving gluten performance. Hence, they are one of the most established baking enzymes, and commercial xylanase preparations are available for the breadmaking industry.[43] However, wheat flour naturally contains xylanase inhibitors that might limit the usefulness of those preparations. Therefore, lines with lower content in xylanase inhibitors could be interesting for breeding. Both addition and substitution lines for chromosome 7**H**^{ch} displayed an increase in xylanase inhibitors, whereas the 7**H**$^{ch}\alpha$ addition and the (7**D**)7**H**^{ch} substitution lines were less affected (Figure 3; Supplementary Table 1). Nevertheless, xylanase inhibitors also play a role in the plant's defense mechanism against pathogens.[44] Therefore, and in contrast to that for the breadmaking industry, lines with higher contents in xylanase inhibitors may be interesting for wheat breeding because they could be used to increase plant resistance to biotic stresses.

The PRs are induced specifically in response to infections by pathogens or by adverse environmental factors.[45] Although increased accumulation of PRs might be considered an advantage for plant defense, their accumulation in food products might have negative consequences in human health, because they may also be plant food allergens.[46,47] PRs showed higher expression in additions and in the (7**A**)7**H**^{ch} substitution lines, whereas, on the contrary, 7**H**^{ch} β arm addition and (7**B**)7**H**^{ch} or (7**D**)7**H**^{ch} substitutions did not affect their expression (Figure 3; Supplementary Table 1). Barperm1 (spot 75) belongs to the PRs family of thaumatin-like proteins, which is known to be differentially expressed in *T. aestivum* developing grains at different stages[48] and involved in seed development in barley.[49]

The abundance of allergens in wheat seeds is involved in hypersensivity reactions that cause food allergies.[14] In the present proteomic analysis of the introgression lines the allegens 1-Cys peroxiredoxin PER1 (spot 79) and glyceraldehyde-3-phosphate dehydrogenase (spot 82),[14,39] were 8-fold more abundant in the 7**H**^{ch} addition than in CS. The (7**D**)7**H**^{ch} substitution line presented minor amounts of glyceraldehyde-3-phosphate dehydrogenase compared to the other lines, which may indicate that this line is a good candidate to reduce the allergenic properties of wheat flour (Figure 3; Supplementary Table 1). Because the number of allergens with known sequences continuously increases, new families of storage and structural proteins and metabolic enzymes are added to the already firmly established protein families that contain allergens (Breiteneder and Radauer, 2004).[50] Therefore, the assessment

DOI: 10.1021/jf5055672
J. Agric. Food Chem. 2015, 63, 3793−3802

of the allergenic properties of the lines is a complex study that would require further analyses.

In summary, the current work showed how the addition or substitution of one particular exogenous chromosome such as chromosome 7$\mathbf{H}^{ch}$ from *H. chilense* can affect the seed endosperm proteomic profile in wheat. The addition of the 7$\mathbf{H}^{ch}\alpha$ arm in wheat was the most promising line for breeding purposes because it did not alter the content of most glutenins and gliadins, and it might therefore maintain, or even improve, dough properties for breadmaking. We also showed that the triticin content was increased in this line compared to CS, and consequently a higher content in lysine (the first nutritionally limiting essential amino acid in most cereals) may be present in seeds. Moreover, the 7$\mathbf{H}^{ch}\alpha$ addition line presented higher quantities of puroindolines, which might improve the plants' resistance to pathogens, and the lower xylanase inhibitor expression may provide more suitable flour for the bakery industry. Finally, it did not present a major increase in the abundance of allergens. Thus, the 7$\mathbf{H}^{ch}\alpha$ addition line seems to be the best option among all other chromosome 7$\mathbf{H}^{ch}$ introgressions to be used in breeding programs to increase the carotenoid content in wheat and not cause negative effects, but positive ones, in the wheat endosperm proteomic profile. On the other hand, the (7**A**)7$\mathbf{H}^{ch}$ substitution displayed enhanced avenin-like b and triticin expression, which may improve dough properties and the nutritional value of flour. Interestingly, (7**D**)7$\mathbf{H}^{ch}$, which showed a reduction in puroindoline proteins, could increase kernel hardness, which may be interesting for the bakery industry. As expected, the addition of the whole chromosome 7$\mathbf{H}^{ch}$ did not display a desirable proteomic profile, at least for human consumption, because there were no important changes that may improve flour quality for breadmaking, but the variation in globulins, α-amylase inhibitors, and other putative allergens could confer negative allergenic features to the wheat flour. The data obtained in this work could provide some indications on how changes in the wheat genome composition by breeding strategies, such as the introgression of related chromosome or chromosome segments, can affect the proteomic profile. This work illustrates the importance of the proteomic characterization of new breeding lines because it provides additional functional information and reveals changes that genomic analysis may not reflect, for example, changes in the expression of proteins that are not codified on the introgressed chromosomes.

During the review process of our paper, waltheriones E−L were reported from the roots of *Waltheria indica* in *Journal of Natural Products* **2014**, *77*, 2304−2311.

The use of the same name to describe two different compounds will bring some confusion to the scientific community. Therefore, we want to change the name of our new compound to 5′-methoxywaltherione A as follows: All instances of "waltherione E" in text, figures, and tables, should be changed to 5′-methoxywaltherione A. In addition, p 71, right-hand column, lines 3 and 4, should read "Thus, compound **1** was identified as 5′-methoxywaltherione A (Figure 2)." On p 72, paragraph 4, line 7, "waltherione A and E" should be "waltherione A and 5′-methoxywaltherione A".

livestock and poultry and reducing the exposure of humans to resistant bacteria. A challenging objective is to develop candidates that could be incorporated into natural, safe formulations to reduce both susceptible and resistant pathogens in animal feeds, food-animal environments, and human foods.

With this aim in mind, a critical assessment by Wright,[14] and additional publications mentioned below, describe the potential impact natural products could have on antibiotic drug discovery. There is general agreement that antibiotic discovery is in crisis and that the discovery of new natural-product-based antibiotics that can also combat the problems of resistance is needed urgently. To help stimulate the research needed to achieve these objectives, this review strives to integrate the widely scattered information on the origin, distribution in the food chain, and proposed approaches to inactivate resistant pathogens and the mechanisms of antimicrobial and resistant effects. Work so far, described here, provides a scientific basis, resource, and rationale for future progress designed to mitigate the adverse potential of resistant pathogens in animal feed, human food, and infectious diseases. Although the present review is largely limited to resistant pathogens, related aspects about susceptible organisms will be mentioned for comparison. The availability of novel and safe antibiotics provides more options for the treatment of livestock, poultry, animal feed, and human food and reduces the exposure of humans to resistant bacteria.

OCCURRENCE OF ANTIBIOTIC-RESISTANT BACTERIA IN THE FOOD CHAIN

Antibiotic-resistant bacteria are prevalent in different environments and can therefore be introduced into the food chain at different points. Here we will briefly describe the prevalence of antibiotic-resistant bacteria in the food chain.

Humans and Livestock. When the impact of resistant bacteria on the food chain is considered, an important area for investigation is people coming into contact with livestock and farms who are at risk of infection by antibiotic-resistant bacteria that are present in that environment. For example, a study in Thailand[15] found that, among 544 healthy adult food factory workers, 75% were positive for a particular resistant bacterium of interest, extended-spectrum β-lactamase (ESBL)-producing *E. coli*. The value for 30 healthy animal farm workers was 77.3%. Among the farm animals, the value was 76.7% in pigs and 40% in poultry broilers. The ESBL-producing *E. coli* was more prevalent in fresh meat samples than in fresh vegetables, in fresh than in cooked foods, and in water samples collected from animal farms than in those from canals and fish and shrimp ponds.

A study has also been conducted on the short-term exposure to resistant bacteria of 30 veterinary students on 40 pork farms, in which nasal swabs of the students and pigs were taken before and after the farm visits.[16] The findings of the study include that (a) methicillin-resistant *Staphylococcus aureus* (MRSA) was present in 30% of the pork farms and 22% of the students; (b) all students found to be MRSA-positive were initially negative; and (c) because the duration of MRSA exposure was brief, it most likely represents contamination of the nasal passages rather than biological colonization.[16]

A Japanese study on the prevalence of resistant pathogens from retail meats and food-animal feces found that (a) resistance to *Campylobacter coli* was higher than to *Campylobacter jejuni*; (b) MRSA was isolated from 3% of the meat samples (9 of 300); (c) vancomycin-resistant Enterococci (VRE) were not detected in any of the samples; (d) *S. aureus* isolates showed the highest resistance to ampicillin and tetracycline; and (e) three *C. jejuni* isolates from a hospital patient with diarrhea and two chicken samples that exhibited resistance to ciprofloxacin had identical pulsed-field gel electrophoresis patterns, suggesting that the resistant pathogen could have originated from the chicken meat.[17] This study shows that the prevalence of MRSA and VRE was low in food-producing animals and domestic meats in Japan. It also provides a good example of how and why antimicrobial-resistant pathogens should be monitored regularly to improve the management of the antimicrobial drug resistance associated with their transfer from food-producing animals to humans.

Related studies indicate that (a) resistant *E. coli* can contaminate meat products during slaughter and enter the food chain regardless of whether or not cattle are administered the antimicrobial growth promoter (AGP) chlortetracycline plus sulfmethazine, with most isolates from meat and environmental samples having similar genetic profiles to hides or digesta;[18,19] (b) a probable relationship exists between swine and human salmonellosis across the food chain;[20] and (c) banning the use of growth-promoting antibiotics seemed to result in decreases in the prevalence of some resistant bacteria in food animals.[21]

The method by which antibiotics are administered to humans or animals could potentially affect the levels of resistant bacteria. For example, a study by Zhang et al.[22] found that oral administration of the medicinal antibiotics ampicillin and tetracycline to mice resulted in increased levels (amplification and development) of antibiotic resistance (AR) in the gut microbiota. The effect may be minimized by intraperitoneal (ip) injection of the antibiotics.

Other Animals. A survey by Gorski et al.[23] of cold-blooded vertebrates (frogs, lizards, newts, salamanders, snakes, and toads) and associated surface waters in a produce-growing region of California to determine the diversity of *Salmonella* found that 66 isolates of 460 samples from amphibians and 119 water samples showed resistance, with 27 isolates resistant to more than one antibiotic and 6 isolates to three classes. The authors suggest that these species may serve as reservoirs of antibiotic resistance, determinants in the environment, and sources of contamination of leafy greens associated with produce recalls. Related studies found that fecal samples of birds and mammals may function as host reservoirs and potential vectors for the spread of resistant *E. coli* bacteria[24] and that the feces of stray dogs and coyotes are also a potential reservoir of resistant *E. coli* and *Salmonella* strains.[25] There is, therefore, a need for good agricultural practices to mitigate microbial risks from animal fecal deposits, especially in produce production areas.

Fresh Fruits and Vegetables. A review of the literature suggests that reducing microbial contamination of irrigation water and soil may help prevent and control produce contamination to produce (such as leafy greens and tomatoes).[26] A study by Oliveira et al.[27] on the transfer of *E. coli* O157:H7 from soil fertilized with contaminated compost or irrigated with contaminated water to the edible part (leaves) of lettuce indicates that microbial contamination takes place from both sources and persists for several months.[28] Holvoet et al.[29] reported a moderate prevalence of antimicrobial resistance in *E. coli* isolates from lettuce, irrigation water, and soil.

A survey of 29 commercial herbal supplements showed that tetracycline-resistant bacteria in onion powders and ground

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

garlic samples and that ginger, goldenseal, mustard, and rosemary contained low levels of resistant bacteria.[30] Related studies report that (a) raw tomatoes are a potential exposure risk for resistant *Enterococcus* spp.;[31] (b) Brazilian ready-to-eat (RTE) salad vegetables contained resistant *Salmonella enterica* isolates;[32] (c) factors other than streptomycin exposure seem to be responsible for resistant bacteria in apple orchards;[33] and (d) the use of fungicides such as fludioxonil for gray mold control in blackberries and strawberries may be a risk for the development of resistant strains in European and North American fields.[34]

Meat and Meat Products. Once livestock has been slaughtered to process into meat and meat products, the problem of antibiotic resistance remains. An Austrian study on the prevalence and genetic characteristics ESBL-producing bacteria, MRSA, and VRE reported the presence of 24 ESBL isolates in 20 of the 100 minced meat samples from a butcher's shop.[35] A Chinese study found that 210 samples collected from a large-scale swine farm contain MDR bacteria that could be transmitted to humans.[36] The large diversity of ESBL-producing *E. coli* may indicate a growing dissemination of ESBL genes in this microorganism from bovine and porcine origins.

A comprehensive review of the literature on the worldwide presence of livestock-associated MRSA indicates that (a) the slaughter process plays a decisive role in MRSA transmission from farm to fork; (b) heat treatment such as flaming and scalding during the slaughter process can significantly reduce the MRSA burden on carcasses; and (c) recontamination with MRSA might occur as a result of fecal contamination at evisceration or by human handling during meat processing.[37] These steps can be improved to minimize the transmission of MRSA from pig to pork.

Poultry Products. Poultry can also be a reservoir for resistant bacteria that can be transmitted to humans. There have therefore been studies conducted on the prevalence and characterization of resistant bacteria in poultry. For example, to assess whether the food chain might contribute to the epidemiology and the transmission of cephalosporin-resistant *E. coli*, Abgottspon et al.[38] used antibiotic susceptibility testing to characterize resistant bacteria isolated from domestic and imported poultry meat. They found that 21 of the 24 isolates were multidrug resistant and that multilocus sequence and phylogenetic group typing indicated a high heterogeneity among different isolates of the same sample.

A German study[39] found that *E. coli* from human stool samples was more resistant than chicken isolates, suggesting that a comparison of ESBL and the multilocus sequence type of the human and poultry isolates are not correlated and that chicken meat is not a major contributor to the colonization of ESBL-carrying Enterobacteriaceae in humans.

The results of a Canadian study[40] on the resistance of 193 *Salmonella* Enteritidis, Hadar, and Typhimurium serovars isolated from broiler production facilities indicated that >43% of the isolates were resistant to multiple antibiotics and that the resistant serovars were genetically diverse, suggesting that the presence of these strains is highly relevant to food safety and public health. A Romanian study found that 23% of 144 chicken carcasses contained MDR *E. coli* and *Salmonella* strains.[41] A Greek study on *E. coli* found in meat from retail stores showed that isolates from chicken had higher levels of resistance to ciprofloxacin (62.5%) than those in lamb/goat isolates,[42] which in turn were higher than those in beef isolates (27.9%).[43] Related studies on the prevalence of resistant pathogens in retail raw poultry in China are described by Yang et al.,[44] in Italy by Giacomelli et al.,[45] in Nigeria by Raufu et al.,[46] in the United Kingdom by McNeece et al.,[47] and in Vietnam by Ta et al.[48]

It is noteworthy that Sapkota et al.[49,50] observed lower levels of resistant bacteria in poultry farms in the United States that transitioned to organic practices without the use of antibiotics. A review of the literature by Smith-Spangler et al.[51] indicates that the risk of isolating bacteria resistant to three or more antibiotics was higher in conventional than in organic chicken or pork (risk difference 33%). By contrast, the study by Mollenkopf et al.[52] on resistant *E. coli* pathogens in organic (antibiotic-free) fresh retail chicken breast does not seem to support this conclusion, suggesting further studies are needed.

Because the consumption of poultry meat is reported to be a major source for foodborne diseases, Adzitey et al.[53] examined the prevalence of resistant *Campylobacter*, *Salmonella*, and *Listeria* isolated from ducks. The mean prevalence for *Campylobacter* is 53% in ducks, 31.6% in duck meat, and 94.4% in the duck-rearing and -processing environment; the lower values recorded for *Salmonella* suggest that ducks were more frequently contaminated with *Campylobacter* than with the other bacteria.

Collectively, the cited studies show that raw and processed poultry products are a major source of resistant pathogens.

Other Food Products. Other studies have been carried out on specific food groups or a range of food groups for comparison. For example, to help define the problem of antibiotic resistance in *E. coli*, the most common Gram-negative pathogen in humans, across a range of food types, Rasheed et al.[54] used the Kirby−Bauer method to determine the antibiotic sensitivity patterns of different foods collected randomly in India. The highest level of resistant bacteria (in %) was found in raw chicken (23.3), followed by vegetable salad (20), raw meat (13.3), raw egg surface (10), and unpasteurized milk (6.7), with an overall incidence of drug-resistant *E. coli* of 14.7. The authors suggest that, because pathogen cycling through food is common, it might pose a potential health risk to the consumer.

The results of a related study from Bangladesh suggested that RTE frozen food contaminated with susceptible and resistant bacteria could be a potential vehicle for transmitting foodborne disease.[55] An evaluation in Poland of the resistant profile of *Staphylococcus* spp. isolated from 858 RTE foods (cheeses, cured meats, sausages, smoked fish, salads) found that 54.9% of the isolates were resistant to at least one class of antibiotics, and, of these, 35.4% of the strains were multidrug resistant, suggesting that RTE food is an important route for the transmission of resistant bacteria.[56]

Fish and shellfish are reported to contain resistant pathogens.[57−60] Duran and Marshall[61] found that 13 commercial brands of RTE shrimp contained high levels of multiple resistant bacteria. The authors suggest that thawing of shrimp products before serving may result in consumer exposure to resistant bacteria and that the worldwide trade of shrimp products may help disseminate resistant pathogens.

Although the incidence of resistant bacteria has been found to be higher in retail meat (69.8%) than in dairy (62.5%) products,[62] many studies that have included dairy products have reported the presence of resistant organisms in retail cheeses, salads, ham, and raw meat,[63] in cow's milk and dairy products,[64] in goat's and sheep's milk,[65] and in Gouda cheese manufactured from raw milk.[66] The cited authors emphasize

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

the need to use improved hygienic conditions to reduce the prevalence of resistant bacteria in dairy products.

The resistance of egg shell *Salmonella* isolates, especially *Salmonella* Typhimurium, to antimicrobial drugs was shown to be serotype dependent and was greater than observed with *E. coli* isolates, suggesting the need to reduce resistant pathogens in shell eggs and shell egg processing water.[67]

In another study that involved a range of food types, Duffy et al.[68] compared the survival of susceptible and resistant strains of *E. coli* in various food matrices. Orange juice and yogurt were inoculated with antibiotic-sensitive (AS) and laboratory-created antibiotic-resistant mutants (MAR) of *E. coli* O157:H7 or *E. coli* O26, and their growth/survival was monitored at 37 °C or in storage at 4 °C. The strains were also inoculated into minced beef and their *D* values (time in minutes for a 1 log reduction of the bacteria) examined at 55 °C, with and without a prior heat shock at 48 °C. The results show that (a) the growth kinetics in the laboratory were similar for both susceptible and resistant bacteria and (b) *E. coli* O157 MAR died out significantly more quickly in orange juice and yogurt and was more heat-sensitive than the other verocytotoxigenic (VTEC) strains. The authors discuss the possible reasons for the observed difference in survival between resistant and VTEC organisms.

METHODS FOR TESTING BACTERIAL RESISTANCE

Many of the studies cited above required methods for the rapid identification of resistant bacteria. Although not discussed in detail here, the development of assays used to detect atypical and multidrug resistance, especially in ESBL and carbapenemase-expressing Enterobacteriaceae, is of worldwide importance. Reviews by Frickmann et al.[69] and Zboromyrska et al.[70] discuss the advantages of rapid assays based on MALDI-TOF mass spectrometry in combination with PCR/electrospray ionization mass spectrometry or minisequencing. A simple, inexpensive, and easy-to-perform assay to screen antimicrobial compounds from natural products or synthetic chemical libraries for their potential to work in tandem with antibiotics against multiple drug-resistant bacteria is based on measuring zones of inhibition in Petri plates.[71]

COMBATTING ANTIBIOTIC RESISTANCE WITH ALTERNATIVES TO TRADITIONAL MEDICAL ANTIBIOTICS

Because the occurrence of resistant pathogens is still a problem, and yet the rate of development of new antibiotics has declined, Allen et al.[72] suggest the need to discover alternatives to antibiotics used in both animal agriculture and human medicine. Suggested alternatives include modulating the gut microbial community, either through feed additives or fecal transplantation, phage therapy, phage lysins, bacteriocins, endolysins isolated from bacteria, and predatory bacteria as well as the alteration of the rumen population and fermentation with the aid of saponin plant glycosides and new natural antimicrobial compounds.[73,74]

Intervention (mitigation) strategies to reduce the prevalence of pathogens in sanitation facilities and in food animals have been described by Callaway et al.,[75] White et al.,[76] Clardy et al.,[77] Wang et al.,[78] Walsh and Fanning,[79] Fischbach and Walsh,[80] Doyle and Erickson,[81] Doyle et al.,[82] Hur et al.,[83] Oliveira et al.,[84] Capita and Alonso-Calleja,[85] Rutkowski and Brzezinski,[86] Allen et al.,[72] Brown et al.,[74] Gyawali and Ibrahim,[87] Jassim and Limoges,[88] and Linden et al.[89] Because bacteria can, in principle, evolve resistance to any antimicrobial, it is important to use antibiotics and alternatives judiciously[72] and to determine whether proposed new antimicrobials develop resistance in bacteria.

Many types of food and other natural products have been used for medicinal purposes for centuries; indeed, most drug-based antibiotics have been based on or derived from natural products. With the increase in antibiotic resistance, the interest in using the natural products themselves as antibiotics has increased. As an example of such a study, in 2004, we reported on the ability of five selected natural products to inhibit three resistant pathogens.[12] After demonstrating the lack of effectiveness of standard antibiotics against the acquired antibiotic resistance of *B. cereus* (NCTC10989), *E. coli* (NCTC1186), and *S aureus*, we showed that the following natural substances inhibited these three resistant pathogens: cinnamon oil, oregano oil, thyme oil, carvacrol (a major component of oregano and thyme oils), (*S*)-perillaldehyde, 3,4-dihydroxybenzoic (*β*-resorcylic acid), and dopamine (3,4-dihydroxyphenylethylamine).[12]

Exposure of the three pathogens to a dilution series of the test compounds showed that oregano oil was the most active substance. The oils and pure compounds exhibited exceptional activity against *B. cereus* vegetative cells, with oregano oil being active at nanogram per milliliter levels. In contrast, activities against *B. cereus* spores were low. Activities of the test compounds were in the following approximate order: oregano oil > thyme oil > > carvacrol (the main constituent of oregano oil) > cinnamon oil > perillaldehyde > dopamine > *β*-resorcylic acid. The order of susceptibilities of the three pathogens to inactivation was *B. cereus* > *S. aureus* > *E. coli*. The cited results show that all test substances were active, and some were highly active, against the resistant organisms.

In a related study, we found that the above-mentioned substances had bactericidal activity against a resistant non-pathogenic *Micrococcus luteus* strain.[90] Unlike the many standard antibiotics evaluated, all of the compounds were active against this organism. This organism can be used as a model to test the efficacy of potential antimicrobials against resistant bacteria. Other investigators reported that the combination of five molecules (*trans*-cinnamaldehyde, *β*-resorcylic acid, carvacrol, thymol, and eugenol) was more effective than individual compounds in overcoming resistant *Salmonella enterica* to one or more antibiotics, suggesting that the natural compounds could potentially be used as feed supplements to reduce antibiotic resistance in food animals.[91] The papers by Gibbons et al.[92] and Oluwatuyi et al.[93] and the above-cited study seem to have been some of the first reports on the inhibition of resistant pathogens by natural compounds and plant extracts. A discussion of the use of such essential oils is continued in the section below on essential oils and their constituents.

PURE NATURAL COMPOUNDS ISOLATED FOR USE AS ANTIBIOTICS

I will now briefly describe in alphabetical order the resistant effects of pure compounds isolated from natural sources and plant extracts. In some cases, the studies on the plant extracts and their pure compounds are linked, so they are dealt with together.

Baicalein. Baicalein is an active constituent isolated from the root of *Scutellaria baicalensis*. It is a flavonoid that has been used as a Japanese herbal supplement and has been shown to

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

significantly reverse ciprofloxacin resistance of MRSA.[94] It may also be an SOS response inhibitor of *S. aureus* (see section below on the SOS response as an antibiotic target).[95]

Chlorogenic Acid. The phenolic compound chlorogenic acid is commonly found in many plant materials, including coffee beans, grapes, and tea. The isolated compound was shown to have antibacterial and antibiofilm activities against clinical isolates of *Stenotrophomonas maltophilia*, including a resistant strain.[96] It could therefore be developed as a safe antibiotic alternative or for use in combination.

Other Phenolic Compounds. An evaluation of the structure−activity relationship (SAR) of pure phenolic compounds isolated from several mushroom species using molecular docking studies showed that (a) 2,4-dihydroxybenzoic and protocatechuic acids inhibited MRSA more than methicillin-susceptible *S. aureus*; (b) MRSA was inhibited by 2,4-dihydroxybenzoic, vanillic, and syringic acids at MICs of 0.5 mg/mL and by *p*-coumaric acid at an MIC of 1 mg/mL; and (c) these compounds at the same concentrations did not inhibit methicillin-susceptible *S. aureus*, suggesting that the presence of COOH, two OH groups in the para and ortho positions, and an OCH_3 group in the meta position of the benzene ring seems to govern anti-MRSA activity.[97,98] We previously reported on a similar SAR study of these and related phenolic compounds against four susceptible pathogens.[99]

An evaluation of anti-*Campylobacter* activities by an MIC assay using microdilution coupled with ATP measurement showed that (a) the natural phenolic compounds of plant origin produced significant, but variable, activities against both resistant and susceptible *Campylobacter*; (b) carnosic and rosmarinic acids showed the highest activity in pure forms and in enriched plant extracts; and (c) inactivation of the efflux pump genes in *Campylobacter* mutants significantly increased antimicrobial activity, suggesting that the drug efflux systems contribute to the resistance to the phenolic compounds.[100]

Phenolic compounds have also been tested for their efficacy in treating fungal infections. A quantitative structure−activity relationship (QSAR) of 11 natural phenolic compounds against four fluoconazole-resistant *Candida albicans* species may make it possible to predict the anti-*Candida* activity of new phenolic compounds in the search for antifungal candidates.[101]

***cis*-Cinnamic Acid.** Although both *cis* and *trans* isomers of cinnamic acid can be found in plants, the *trans* form is the more common. The transformation of *trans*-cinnamic acid to the *cis* isomer and isolation of *cis*-cinnamic acid allowed its antibacterial activity to be measured alone and in combination against resistant *Mycobacterium tuberculosis*.[102] Although both isomers were active against the resistant strain, the *cis* isomer showed greater activity, suggesting its potential value to treat tuberculosis.

Ellagitannins and Gallotannin. Ellagitannins, esters of hydrolyzable tannins, hexahydrodiphenoic acids, and monosaccharides, occur in fruits (blackberry, raspberry, strawberry, and pomegranate), nuts (almonds, walnuts), and seeds. A review by Lipińska et al.[103] on bioactive ellagitannins includes a section on reported inhibition of MRSA by ellagitannins from black raspberry.[104] A gallotannin (1,2,3-tri-*O*-galloyl-β-D-glucopyranose) isolated from the *Terminalia chebula* fruit exhibited efflux-pump inhibitory activity against multidrug-resistant uropathogenic *E. coli*.[105] Tannins from fruits and nuts merit further study for their potential to inhibit resistant bacteria.

Enterocin. The enterocins are bacteriocins that can be isolated from *Enterococcus faecium*. A test of the efficacy of the antimicrobial enterocin AS-48 alone and in combination with biocides such as benzalkonium chloride against three susceptible and three resistant *S. aureus* strains showed that (a) inactivation was greater in combination than with individual antimicrobials; (b) inactivation continued during storage; and (c) higher concentrations of antimicrobials were needed to inhibit the formation of biofilms.[106] Because bacteriocins and related peptide antibiotics are active against susceptible pathogens,[74,107] it would be interesting to determine whether or not they also inhibit resistant organisms.

Human Milk Protein−Lipid Complex (HAMLET). Human α-lactalbumin made lethal to tumor cells (HAMLET) is a protein−lipid complex isolated from human milk that has both tumoricidal and bactericidal activities. Sublethal concentrations of HAMLET potentiated the antimicrobial effect of common antibiotics (penicillins, macrolides, and aminoglycosides) against pneumococci.[108] A combination of HAMLET and antibiotics completely eliminated biofilms and colonization in mice of both susceptible and resistant strains of *Acinetobacter baumanii* and *Moraxella catarrhal*, suggesting the presence of a conserved HAMLET-activated pathway that circumvents antibiotic resistance in bacteria.

Pentacyclic Triterpenoids. Three triterpenoids isolated from the bark of the tree *Callicarpa farinosa* inactivated MRSA and methicillin-sensitive *S. aureus* with MIC values ranging from 2 to 512 μg/mL.[109] A genome-wide transcription analysis revealed that the antibiotic effects involved multiple novel cellular targets governing cell division resulting in destabilization of the bacterial cell membrane, suppression of protein synthesis, and inhibition of cell growth that led to cell death. This novel approach to inactivation of resistant bacteria merits further exploration.

Tomatidine. Hydrolytic removal of the tetrasaccharide side chain from the tomato glycoalkaloid α-tomatine results in the formation of the aglycone tomatidine.[110] Although inactive alone, tomatidine specifically enhances the inhibition of MRSA by aminoglycoside antibiotics by blocking the expression of several genes in the resistant bacteria,[111] suggesting that tomatidine is an aminoglycoside potentiator that acts as an antivirulence agent targeting both susceptible and resistant *S. aureus*. It would be of interest to find out whether the aglycones tomatidenol and solanidine derived from the tomato glycoalkaloid dehydrotomatine and potato glycoalkaloids α-chaconine and α-solanine, respectively,[112] would also enhance inhibition of MRSA.

PLANT EXTRACTS AS ANTIMICROBIALS

Essential Oils and Oil Compounds. We published a series of studies on the inactivation in vitro and in food of individual and multiple foodborne pathogens by plant essential oils and some of their bioactive compounds.[9,10,113−121] The following observations indicate that plant essential oils and some of their bioactive compounds are also strong inhibitors of resistant bacteria, reviewed by Yap et al.[7]

An evaluation of the bioactivity of oregano oil, carvacrol, and thymol against methicillin-susceptible and -resistant *Staphylococci* by Nostro et al.[122] showed that all three substances inhibited both types of pathogens to the same extent, with MIC values for carvacrol of 0.015−0.03%. The essential oil from the Korean *Thymus* plant and its components carvacrol and thymol inhibited both susceptible and resistant strains of *Streptococcus*

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

pneumoniae, *S. aureus*, *Salmonella* Enteritidis, and *Salmonella* Typhimurium with MIC values ranging from 0.125 to 8 mg/mL.[123] Carvacrol and thymol were highly effective in reducing the resistance of microbes, including *Salmonella* and *E. coli*, to several antibiotics; some combinations of the plant and medical antibiotics acted synergistically, suggesting that natural antibiotics can decrease the MIC of a diverse group of drug-resistant bacteria.[124] Subinhibitory concentrations of five natural antimicrobials including carvacrol individually and synergistically increased the susceptibility of resistant *Salmonella* Typhimurium to five medical antibiotics, suggesting the potential value of the natural compounds as feed supplements to reduce the resistance of *Salmonella* in food animals.[91] Carvacrol and cinnamaldehyde rapidly inactivated susceptible and resistant *Campylobacter jejuni* strains, suggesting that the same mechanism probably governs the inactivation of both types of pathogens.[125] These two compounds also inhibited resistant *Campylobacter* on chicken breast[126] and resistant *S. enterica* on celery and oysters,[127] suggesting that these plant antimicrobials have the potential to be used to decontaminate resistant pathogens on seafood, salads, and oysters. Carvacrol, cinnamaldehyde, and eugenol decreased a five-strain mixture of nalidixic acid-resistant *Salmonella* on shell eggs from log 8.0 log CFU/mL to undetectable levels, suggesting that the natural antimicrobials could be used as a wash treatment to reduce *Salmonella* Enteritidis on shell eggs.[128] Our studies also indicate that the antimicrobial efficacy of carvacrol is similar to that of oregano oil with a ~80% carvacrol content, suggesting that the minor components do not seem to contribute to the bioactivity.[9,129]

Tea tree oil (*Melaleuca alternifolia*) was shown to be effective as an adjunctive therapy in treating osteomyelitis and infected chronic wounds in human case studies and small clinical trials.[130] Other studies showed that tea tree oil did not induce bacterial resistance to antimicrobial agents, including carvacrol,[131] and that *Thymus maroccanus* essential oil and its major components carvacrol and thymol modified the susceptibility of resistant bacteria to antibiotics by a membrane-associated mechanism, thereby conferring antibiotic resistance to bacteria.[132] A follow-up study found that the oil can restore antibiotic activities of resistant Gram-negative bacteria by blocking the antibiotic efflux through inhibition of the functional assembly of the efflux pump component.[133]

Extracts of the Brazilian medicinal plant *Lippia origanoides*, containing about 20 compounds including carvacrol and thymol, potentiated the action of neomycin and amikacin against MRSA in vitro, suggesting that the plant could be a source of secondary metabolites for use in antibiotic chemotherapy of MRSA-caused infections.[134] In addition, a Korean study found that essential oils from two *Thymus magnus* plants and their bioactive constituents, carvacrol and thymol, restored the activity of several *Salmonella* and *S. aureus* bacteria to the quinolone antibiotic norfloxacin.[123]

As already mentioned, combinations of extracts or natural products, whether with other natural products or conventional antibiotics, can have a synergistic effect. For example, carvacrol in combination with methyl gallate isolated from *Galla rhois* exhibited enhanced activity against eight nalidixic acid-resistant pathogenic bacteria compared with the activities observed with the individual compounds.[135] These results indicate that carvacrol and methyl gallate alone or in combination have potential use against nalidixic acid-resistant bacteria. It was also reported that carvacrol, cinnamaldehyde, cinnamic acid, and eugenol in combination with antibiotics acted synergistically against 39 pathogenic microorganisms,[136] and cinnamon bark, lavender, and peppermint essential oils evaluated against *E. coli* reduced the resistance to several antibiotics, suggesting the possibility of their use to reverse β-lactam antibiotic resistance and potentially resulting in a reduced use of antibiotics.[137]

Carvacrol and thymol have also been tested against fungal pathogens and were shown to synergistically enhance the efficacy of the antifungal drug fluoconazole against resistant pathogenic *C. albicans* isolates by chemosensitizing the fungal cells to the drug and decreasing its efflux, suggesting their value in therapy for candidiasis.[138]

Essential oil components have also been tested for their use in animal feeds. For example, an in vitro study demonstrated the efficacy of essential oil compounds (carvacrol, thymol, linalool, nerolidol, cinnamaldehyde, eugenol, piperine, and capsaicin) to inhibit susceptible and resistant *Brachyspira intermedia*, the cause of intestinal spirochetosis in hens. Consumption of feed supplemented with coated *trans*-cinnamaldehyde cured the hens of the disease.[139]

Garlic Extracts. An evaluation of an ethanol garlic extract against 15 MDR and 5 non-MDR clinical isolates of *Mycobacterium tuberculosis* showed that the extract inhibited both types of isolates, with MIC values ranging from 1 to 3 mg/mL.[140] The authors suggest that garlic extracts have the potential to prevent/treat MDR tuberculosis.

In another study, an evaluation of the inhibitory activity of a garlic (*Allium sativum*) extract against MDR strains of *Streptococcus mutans* isolated from human carious teeth using disc sensitivity and broth dilution methods showed that (a) of 105 carious teeth tested, 92 (87.6%) isolates of *S. mutans* were recovered; (b) 28 (30.4%) were resistant to four or more antibiotics; and (c) all MDR and non-MDR isolates were susceptible to the garlic extract with MICs ranging from 4 to 32 μg/mL. These results suggest that mouthwashes or toothpaste containing the garlic extract have the potential to prevent human dental caries and possibly also infectious diseases originating from tooth decay.[141]

Organic Herbal Products. An evaluation of resistance in six pathogens from herbal products grown organically and conventionally (garlic, ginger, goldenseal, mustard, onions) revealed the prevalence of low resistance, suggesting that organic farming could contribute to reduced resistance in foodborne bacteria.[30]

It is not immediately apparent why organic food might contain low levels of resistant bacteria. One possible explanation is that, to protect themselves against phytopathogens in the absence of pesticides, organic plants produce greater amounts of bioactive secondary metabolites than do conventionally grown plants.

Honey and Propolis. The commercial honey preparation MEDIHONEY has been approved by the FDA as an antimicrobial to help heal traumatic wounds. MEDIHONEY was shown to inhibit the resistant Gram-negative bacterium *A. baumanii* and also MRSA in vitro with MIC values of 8.5 and 3.5%, respectively,[142] whereas "supermarket honey" induced bacterial and fungal growth. Related studies found that MEDIHONEY in combination with the antibiotic rifamycin acted synergistically against MRSA and clinical isolates of *S. aureus*, suggesting that the combination may be an effective therapy for chronic wound infections.[142,143] The bee product propolis, a resinous mixture, has also been reported to have antimicrobial properties. Indeed, ethanol extracts of the bee

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

products propolis and honey acted synergistically against resistant *S. aureus* and *E. coli*, as well as against the fungus *C. albicans*, suggesting the need to isolate the active antimicrobial ingredients from propolis and honey.[144] Three possible antimicrobial ingredients have been identified in honey, hydrogen peroxide, methylglyoxal, and the peptide defensin-1, and the low pH of honey may contribute to its activity.[145]

Mushroom Extracts. Purified phenolic compounds derived from mushrooms have been tested for their antibacterial activity against resistant strains. In addition, whole extracts have been used against clinical bacterial strains. For example, an ethyl acetate extract of the culture filtrate and fruiting bodies of the mushroom *Xylaria* showed significant antimicrobial activity against clinical MDR *S. aureus* and *Pseudomonas aeruginosa* strains, with MIC values (in μg/mL) of 225−625 and 120−625, respectively, suggesting that *Xylaria* mushrooms are a potential source of new antimicrobial compounds.[146]

Pepper Extracts. An investigation into edible pepper (*Piper nigrum*) and, in addition, the tropical vine *Telfairia occidentalis* plant extracts showed they were active against 29 pathogenic microorganisms in the absence and presence of the efflux pump inhibitor (EPI) phenylalanine-arginine-β-naphthylamide (PAβN), suggesting that these extracts may help control bacterial infection including MDR phenotypes.[147] Nanoliposomes containing the pepper compound piperine and the antibiotic gentamycin were effective against MRSA, with MIC values of 100 and 32 μg/mL, respectively.[148]

Pomegranate Extracts. Methanolic extracts of the pomegranate (*Punica granatum*) fruit pericarp acted synergistically with the antibiotic ciprofloxacin against resistant strains of *E. coli*, *Klebsiella pneumoniae*, and *P. aeruginosa*, suggesting that the observed synergy against ESBL- and MBL-producing Gram-negative bacteria may help provide an inexpensive alternative therapy against resistant pathogens.[149]

Red Cabbage Extracts. Methanol extracts of red cabbage exhibited antimicrobial activity against MDR bacteria that were resistant to 15 antibiotics as well as against human fungal pathogens.[150] The antimicrobial effects are probably due to the high anthocyanin content. Safe cabbage extracts merit evaluation for efficacy against in vivo infections.

Teas Extracts, Tea Catechins, and Theaflavins. We previously reported that commercial teas and their bioactive constituents, catechin and theaflavin, strongly inhibited susceptible *Bacillus cereus* bacteria and that the antimicrobial activity of a large number of teas correlated with their composition as determined by HPLC.[151] The antimicrobial efficacies of the teas correlated with their flavonoid contents determined by HPLC.[152] Table 2 illustrates the exceptional activity of freshly prepared teas and tea compounds against this pathogen at nanogram levels, suggesting that the mentioned pure black and green tea flavonoids might merit further study for their potential to inhibit resistant pathogens.

Other investigators reported that tea compounds also inhibited resistant bacteria. For example, aqueous extracts of Japanese green tea (*Camellia sinensis*) and the epigallocatechin gallate (ECGC) component inhibited oxacillin β-lactam resistance in MRSA. The tea polyphenolic compounds reduced the MIC values several hundred-fold.[153] These results indicate that teas and their bioactive compounds can inhibit both susceptible and resistant pathogens. Long-term storage of teas seems to degrade some of their bioactive compounds.[154] Yerba mate tea, an infusion made from the leaves of the tree *Ilex paraguariensis*, is a widely consumed nonalcoholic beverage in South America.[155] Burris et al.[156] found that low concentrations of the tea inhibited MSRA in culture and in beef.

Table 2. Bactericidal Activity of Tea Flavonoids Compared to Medicinal Antibiotics against *Bacillus cereus*, Where BA_{50} Equals Percent Concentration That Killed 50% of the Bacteria (Lower Number = Greater Activity[151])

compound	BA_{50} (nmol/well)	relative activities to least active compound, (−)-GC
(−)-gallocatechin-3-gallate	0.43	2307
theaflavin-3,3′-digallate	0.54	1837
(−)-epigallocatechin-3-gallate	0.68	1459
theaflavin-3′-gallate	1.8	551
rifampicin	2.1	472
vancomycin HCl	2.3	431
theaflavin-3-gallate	2.8	354
(−)-catechin-3-gallate	5.5	180
tetracycline HCl	12	83
clindamycin	19	52
(−)-epicatechin-3-gallate	22	45
gentamycin sulfate	75	13
chloramphenicol	180	5.5
theaflavin	283	3.5
(−)-epigallocatechin	800	1.2
(−)-gallocatechin (GC)	992	1.0

OTHER METHODS OF TREATING RESISTANT BACTERIA

It is worth mentioning here some of the other more biological and physical methods for combatting bacterial resistance, techniques that could perhaps be used in combination with some of the strategies described above.

Bacteriophages. Immersion of live oysters contaminated with the virulent multiple-antibiotic-resistant *Vibrio parahemolyticus* bacteria in a bacteriophage-containing bath induced a significant reduction in the growth of the pathogens, suggesting the potential use of the phage to avoid infection from aquaculture to consumption.[157] As noted above, carvacrol and thymol inactivated resistant *S. enterica* on contaminated oysters.[127] Will adding these antimicrobials to oyster-containing water tanks reduce microbial contamination?

Chlorine Disinfection. A chlorine dose of 100 mg/L effectively achieved complete removal of susceptible and resistant pathogens in various sites of two anaerobic swine wastewater systems, one anaerobic and the other aerobic.[158] The authors also report that ammonia present in the system can compete with chlorine to form monochloramine and that aeration helps remove ammonia, thus improving the efficacy of chlorine in overcoming antibiotic pollution. A related study[159] found that inactivation of both susceptible and resistant *Salmonella* Typhimurium in chlorinated water displayed nonlinear kinetics with a concave downward curve (R^2 = 0.964) that fit the power law model, with a shape parameter of 1.37. In addition, the *D* value for a single log reduction from an initial concentration of 5.36 log CFU/mL did not differ among the four resistant groups evaluated and ranged from 3.8 to 4.3 min,[159] suggesting that the resistance phenotype does not impart cross-protection to chlorine inactivation in chilled water.

Thermal Inactivation. An evaluation of the effect of temperature (55−70 °C) on 10 MDR and 10 non-multidrug-

DOI: 10.1021/acs.jafc.5b00778

Table 3. Summary of Antiresistant Formulations Described in the Text

pure compound	resistant pathogens inhibited
baicalein	*S. aureus, L. monocytogenes*
aminocoumarins	*S. aureus*
anchovy peptide	*B. cereus, E. coli, Salmonella* Typhi, *S. aureus*
capsaicin	*B. intermedia*
carnosic acid	*Campylobacter* strains, *E. faecalis, S. aureus*
catechins and theaflavins, tea	*L. monocytogenes, S. aureus*
carvacrol	*B. cereus, E. coli, S. aureus, C. albicans*
chlorogenic acid	*Campylobacter* strains, *S. aureus*
cinnamaldehyde	*B. cereus, B. intermedia, E. coli, S. aureus*
citral	*E. coli*
cinnamic acid	*M. tuberculosis*
curcumin	enhanced resistance response in *Salmonella*
dopamine	*B. cereus, E. coli, S. aureus*
ferulic acid	*Campylobacter* strains
gallic acid	*Campylobacter* strains
iberin	*P. aeruginosa*
ellagitannins	*S. aureus*
enterocin	*S. aureus*
gallotannin	*E. coli*
eugenol	*B. cereus, E. coli, S. aureus*
indolecarbinol	Gram-negative bacteria
linalool	*B. intermedia*
methyl gallate	multiple resistant bacteria
milk protein, human	*A. baumanii, Moraxella catarrhalis*
nerolidol	*B. cereus, B. intermedia, E. coli, S. aureus*
piperine	*B. intermedia, S. aureus*
perillaldehyde	*B. cereus, E. coli, S. aureus*
plumbagin	*E. coli*
rosmarinic acid	*Campylobacter* strains
β-resorcylic acid	*B. cereus, E. coli, S. aureus*
sinapinic acid	*Campylobacter* strains
shiknin	*E. coli*
syringic acid	*Campylobacter* strains
tannic acid	*E. coli*
thymol	*B. cereus, B. intermedia, E. coli, S. aureus, C. albicans*
tomatidine	*S. aureus*
triterpenoids	*S. aureus*
vanillic acid	*Campylobacter* strains
plant extracts	
cabbage	multiple MDR bacteria
garlic	*M. tuberculosis*
horseradish	*P. aeruginosa*
mushrooms	*Campylobacter, S. aureus, P. aeruginosa*
Lippia origanoides medicinal plant	*E. coli*
pepper	multiple resistant phenotypes
pomegranate	*E. coli, K. pneumoniae, P. aeruginosa*
Yerba mate tea	*S. aureus*
others	
bacterial quorum sensing	*Salmonella* strains
bacterial SOS response	*E. coli*
bacteriophage	*V. parahemolyticus*
chlorine	multiple pathogens
essential oils	*Campylobacter, E. coli, S. aureus, S. pneumoniae*
heat	*E. coli, Salmonella*
honey, propolis	*A. baumanii, E. coli, S. aureus*
hydrostatic pressure	*E. coli, Salmonella*
pulsed electric fields	*Salmonella*
UV light	*E. coli, Listeria*

resistant (NMDR) *Salmonella* strains isolated from cattle or cattle environments found that NMDR serotypes had a slightly higher heat resistance than MDR serotypes.[160] *Salmonella* Agona and *Salmonella* Anatum serotypes had the highest resistance. The *Salmonella* Agona serotype survived in ground beef patties cooked to an internal temperature of 71 °C. The authors conclude that drug resistance does not seem to affect the heat resistance of *Salmonella* and that serotype or strain is an important consideration in risk assessment of the pathogen's survival at cooking temperatures.

A related study evaluated the inactivation of rifampicin-resistant *E. coli* O157:H7 in pan-broiled or roasted beef at different temperatures.[161] The highest reduction of 5.5 log CFU/g was obtained in samples cooked in the kitchen oven set at 260 °C. The authors suggest that the observed results could facilitate the use of cooking methods to enhance the safety of beef products.

Pulsed Electric Fields (PEF). Repeated rounds of PEF treatment and outgrowth of survivors of *Salmonella enterica* serovar Typhimurium SL1344 resulted in a culture that showed higher resistance to PEF.[162] Additional studies showed that (a) the membranes of the resistant organisms were less susceptible to permeabilization (disruption) than those of the parental strain and (b) resistance to PEF was accompanied by higher tolerance to acidic pH, hydrogen peroxide, and ethanol, but not to heat. The authors suggest the need to study the mechanism of PEF resistance.

UV Disinfection. A Chinese study found that the exposure of resistant bacteria in reclaimed wastewater to UV light resulted in a 4 log CFU reduction of total heterotrophic bacteria. After a standing incubation for 22 h, however, the resistant bacteria mostly reactivated.[163] Related observations indicate that (a) exposure of *E. coli* in wastewater to solar and UV light in the presence of the photocatalyst TiO_2 for 30−60 min inactivated the organisms and that an antibiotic resistant test (Kirby−Bauer) on surviving colonies showed that the photocatalytic process affected the resistance of the strains to the target antibiotics differently;[164] and (b) acid-stressed resistant strains of *Listeria monocytogenes* were more resistant to disinfection in distilled water and a 9% sodium chloride solution by UV light than were unstressed and heat-resistant and heat-shocked strains.[165]

Hydrostatic Pressure. High-pressure processing of green onions inoculated with resistant *Salmonella* and *E. coli* O157:H7 to an average of 5−6 log CFU/g reduced the bacteria by 0.6−5 log CFU/g, depending on the pressure level and sample wetness state.[166] Because the pressure treatment had a minimal adverse effect on most sensory properties and color, it seems that hydrostatic pressure offers an approach to reduce the risk of consumption of contaminated onions. The application of pressure to inactivate resistant pathogens merits further study.[167]

Table 3 summarizes this section, showing the antimicrobial formulations and the respective resistant pathogens inhibited.

Bacterial Resistance Mechanisms. In their review on bacterial multidrug efflux pumps that govern the resistance of bacterial pathogens, Sun et al.[168] note that MDR refers to the capability of bacterial pathogens to withstand lethal doses of

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

drugs that are capable of eradicating nonresistant strains and that among the four general mechanisms that cause resistance (target alteration, drug inactivation, decreased permeability, and increased efflux), drug extrusion serves as an important mechanism of MDR. An understanding of the mechanism of extrusion is therefore of importance for the development of antiresistant interventions.[169,170] We will now briefly summarize some of the reported mechanisms that may govern resistant activities of several natural antimicrobials.

A study of the resistance mechanisms of phenolic compounds [(−)-epigallocatechin gallate and carnosic, chlorogenic, ferulic, gallic, rosmarinic, sinapinic, syringic, and vanillic acids] in resistant *Campylobacter* strains in the absence and presence of EPIs showed that (a) inactivation of the *cmeB* efflux gene rendered the bacteria more susceptible to the phenolic compounds; (b) mutations of the *cmeF* efflux and *cmeR* transcriptional repressor genes produced a moderate effect on the MICs; and (c) efflux pump inhibitors significantly reduced the MICs of the antimicrobials, suggesting that the antiresistant compounds can be developed for use in live poultry or processed meat to reduce transmission of the pathogens to humans.[171]

Three pure plant compounds (plumbagin from *Plumbago indica*, nordihydroguaretic acid from creosote bush, and shikonin from *Lithspermum erythrorhizon*) were able to inhibit substrate efflux from resistant pathogenic *E. coli* cells that is mediated by the multidrug efflux pump AcrB, suggesting that the gene docking used to predict the bioactivity could be used to preselect compounds with potential EPI activity.[172,173]

A study with indole-3-carbinol, a natural compound found in the edible plant family Cruciferae, found that the antimicrobial activity against Gram-negative bacteria was influenced more by the barrier action of the outer cell membrane lipopolysaccharide than by the action of efflux pumps. It was also found that the compound acted synergistically with ampicillin against drug-resistant isolates, possibly by the facilitated entry of the carbinol after the partial disruption of the cell wall by the antibiotic.[174]

The activity of the natural compound carnosic acid on the uptake/efflux of ethidium bromide is correlated with its ability to change the membrane potential gradient in *S. aureus* and *E. faecalis*, suggesting that the acid can function as an efflux pump modulator that can be used in combination therapies against resistant Enterococci and *S. aureus*.[175]

A study of the ability of the essential oil of *Thymus riartarum* to block efflux pump systems of six resistant Gram-negative bacteria showed that (a) the antimicrobial activity of the oil was significantly enhanced by the efflux pump inhibitor PAβN and (b) the oils also enhanced the susceptibility of resistant isolates to the antibiotic chloramphenicol, suggesting that it could be a candidate for a new drug that can restore the antimicrobial activity of antibiotics by chemosensitive and membranotropic effects.[176]

Collectively, the cited studies indicate that natural, food-compatible compounds have the potential to help overcome the resistance of antibiotics, an approach that merits further investigation.

STRATEGIES FOR COMBATTING BACTERIAL RESISTANCE

Conventional antibacterial actions can generally be divided into four mechanisms, three of which involve the inhibition or regulation of enzymes involved in cell wall biosynthesis, nucleic acid metabolism and repair, or protein synthesis, and the fourth involves the disruption of membrane structure. To combat resistance there are, however, some more unusual modes of action that could hinder the evolution of resistance, involving the disruption of bacterial quorum sensing or the bacterial SOS response.

Bacterial Quorum Sensing (QS) Inhibition. Instead of killing the bacteria, interruption of bacterial communication by QS, where individual cells release small signal molecules such *N*-acylhomoserine lactone (AHL), might also benefit microbial food safety.[177] To demonstrate this possibility, the cited authors determined the inhibition of QS in the opportunistic pathogen *Pseudomonas aeruginosa* by the horseradish (*Armoracia rusticana*) compound iberin. Real-time PCR (RT-PCR) and DNA microarray studies showed that iberin blocked the expression of the QS-regulated genes LasIR and RhIIR and downgraded QS-controlled rhamnolipid production in wild-type cultures of the bacterium, suggesting the need for an epidemiological study of the relationship between the ingestion of food known to contain QS inhibitors (such as cabbage, garlic, and horseradish) and the incidence/severity of bacterial infections.

In a related study, *trans*-cinnamaldehyde and tannic and salicylic acids strongly inhibited AHL synthase in *E. coli*,[178] suggesting that the inhibition of the enzyme by natural products may facilitate the discovery of novel anti-infectives based on anti-QS mechanisms. The results of another study demonstrated that cinnamon bark or lavender essential oils, acting as apparent QS inhibitors, individually and in combination with the antibiotic piperacillin, reduced bioluminescence expression in resistant *E. coli*, suggesting that the oils have the potential to reverse resistance to piperacillin in the bacteria via two mechanisms, alteration of the outer membrane permeability and inhibition of bacterial QS as a novel approach to reverse resistance.[179,180] A review by Koh et al.[181] discusses the use of autoinducers such as AHL to regulate the formation and release of virulence factors, biofilm formation, antibiotic production, the potential of numerous plant-derived products to inhibit QS, and the need to explore the synergistic effects of anti-QS antagonists and antibiotics and concludes that anti-QS is as important as antibacterial activity as it is not likely to cause resistance because it does not pose selection pressure.

Bacterial SOS Response Inhibition. Exposure of bacteria to stress (heat, pH, UV light, disinfectants, antimicrobials) may induce a so-called SOS response that facilitates their survival and that may result in the induction of genetic diversity, formation of reactive oxygen species (ROS), formation of biofilms, and stress-resistant subpopulations.[182,183]

The biphasic kinetics of heat and antimicrobial destruction of bacteria in a ground beef matrix described by Juneja et al.[184,185] support the possible significance of the SOS response in microbial foods safety. Other studies have also provided support for the importance of the SOS response. For example, aminocoumarins strongly inhibited fluoroquinolone-induced RecA genes and the SOS response (resistance development) in *S. aureus*, suggesting that the combination could be useful in anti-infective therapy.[186−188] In addition, baicalein, a flavone present in *Scutellariae baicalensis radix* (described above),[189] was found to be a potent inhibitor of the expression rifamycin-resistant genes and ROS and ATP levels in *S. aureus*, suggesting that it may be used to prevent mutations induced by antibiotics.[95] By contrast, the food ingredient curcumin

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

enhanced the ciprofloxacin-induced SOS response in *Salmonella* Typhimurium and *Salmonella* Typhi, thus significantly enhancing *Salmonella* pathogenesis.[190] Whether the SOS response can induce/prevent resistance in different antimicrobials merits further study.

More Conventional Mechanisms of Action. The section on mechanisms of resistance discussed some of the methods by which the compounds overcome the main mechanism of drug extrusion. Here, some of the experimental approaches designed to define the mechanisms that might govern the antimicrobial effects of some of the compounds and extracts described above are briefly mentioned. Most of the methods and mechanisms focused on here involve effects on the bacterial membrane.

Bacterial Membrane Disruption. Exposure of *B. cereus* to carvacrol results in the depletion of the intracellular ATP pool, a change in membrane potential, and an increase in the permeability of the cytoplasmic membrane for protons and potassium ions.[191] The loss of the ion gradient impairs essential metabolic processes in the cell and consequently leads to cell death. We have used the technique of autofluorescence spectra to determine the effect of carvacrol on another pathogen, *E. coli*.[129] The autofluorescence spectra and data showed significant changes at much lower concentrations of carvacrol (0.01 mM) than changes in membrane potential or release of ATP (ATP flux) after disruption of the bacterial cell membrane (1−2 mM), suggesting that autofluorescence detects physiological responses to carvacrol more efficiently than do changes in membrane potential or release of ATP.

We have also used molecular dynamics simulations to study the interactions of green tea catechins and black tea theaflavins with the lipid bilayer of artificial biological membranes.[192−194] The results showed that both catechins and theaflavins have a strong affinity for the lipid bilayer of the cell membranes via hydrogen bonding to the surface, with some able to penetrate underneath the surface. In addition, the molecular structure of the tea compounds influenced their configuration when binding to the bilayer surface, as well as their ability to form hydrogen bonds with the lipid headgroups. These studies help to define structure−function relationships and provide a better understanding of the antimicrobial mechanisms of the tea compounds at the molecular−cellular levels. Computer simulation methods can also be used to predict the antimicrobial and anticarcinogenic properties of natural bioactive compounds.[195−197]

Another study used a Langmuir trough equipped with a computer-controlled microbalance to measure the effect of carvacrol and four other natural antimicrobials on monolayers of model membranes composed of bacterial phospholipids.[198] Surface pressure−area (π−A) and surface potential−area ($\Delta\psi$−A) isotherms were measured to monitor changes in the thermodynamic and physical properties of the lipid monolayers. Carvacrol modified the three lipid monolayer structures by integrating into the monolayer, forming aggregates of antimicrobial−lipid complexes, reducing the packing effectiveness of the lipids, increasing the membrane fluidity, and altering the total dipole moment in the monolayer membrane model.

It has been reported that exposure of *B. cereus* to subinhibitory, nonlethal concentrations of carvacrol resulted in increased resistance of the bacteria to inhibition that was accompanied by a lowering of membrane fluidity associated with changes in their fatty acid and headgroup composition.[199] Similar changes in membrane fatty acid profiles observed by Di Pasqua et al.[200] and by Luz Ida et al.[201] suggest that the mechanism of the antimicrobial effect is associated with an alteration in membrane lipid profiles and damage to the cell envelope.

Some constituents of essential oils including carvacrol were analyzed for their mechanism of action against a range of pathogens using a novel whole-cell biosensor assay. The results suggest that the antimicrobial mechanism of action of carvacrol and related compounds involves damage to cell membranes and disruption to cellular metabolism and energy production.[202] Another set of studies examined the combination of carvacrol and low doses of γ-radiation against *B. cereus*. Various techniques were used to monitor the effects, and it was demonstrated that the combination synergistically inhibited *B. cereus* via disruption of cell membranes, with the combination being more effective than either treatment alone, suggesting that the treatment could be effective in contaminated food.[203,204]

Many other studies have indicated the involvement of membrane disruption in the mechanism of action of some natural products. For example, cinnamaldehyde at MIC induces cell death of *E. coli* and *S. aureus* that results from the lysis of the cell membrane;[205] the antimicrobial activity of a peptide from anchovy (*Engraulis japonicus*) seems to be associated with the disruption of membranes of *B. cereus*, *E. coli*, *Salmonella* Typhi, and *S. aureus*;[206] and an increase in resistance in *E. coli* strains stimulated by *Thymus maroccanus* essential oil was associated with changes in the composition of the microbial membrane, suggesting an adaptation or stimulation of the native resistance to the components of the natural oil.[132] The tea polyphenol (−)-epicatechin gallate (ECG) disrupts the secretion of virulent coagulase and α-toxin by *Staphylococcus aureus*,[207] suggesting action via disruption of the cytoplasmic membrane. Components of pomegranate rind were analyzed to investigate their antibacterial mode of action. The results indicate that the phenolic pomegranate compounds act by impairing the membrane structure of *L. monocytogenes*, suggesting their potential as food preservatives and in the reduction of listeriosis.[208] Bacterial membrane disruptive proteins have been widely reported as promising targets for potential antibacterial therapy, and a greater understanding of the composition and function of the complexes they form could aid antibiotic development.[132,209,210]

DNA Interactions and Other Mechanisms. Many modes of action are not at all well-defined or compounds may have multiple modes of action. For example, in a study on the effects of carvacrol and thymol on bacteria and fungi, it was reported that they induced their antimicrobial activity via a mechanism that involves the production of formaldehyde and its reaction products.[211]

Carvacrol and thymol have also been shown to bind to DNA via H-bonding of the OH group to the guanine N7, cytosine N3, and backbone phosphate group, with binding constants of $K = 1.55 \times 10^3$/M and 2.43×10^3/M, respectively, suggesting that the mechanism of formation of the DNA complexes can serve as a model for drug−DNA interactions.[212] The antibacterial activity of the wine compound resveratrol seems to result from the induction of cellular stress and not from direct membrane perturbation.[213]

The mechanism of action of essential oil components has been shown to be complex, possibly involving different mechanisms depending on the conditions. Indeed, cell death in *E. coli* caused by citral and carvacrol has been reported to be

DOI: 10.1021/acs.jafc.5b00778
J. Agric. Food Chem. 2015, 63, 3805−3822

associated with oxidative DNA damage, suggesting their possible value as alternative antimicrobials.[214]

Free fatty acids have antibacterial properties, and although their main target of action is the cell membrane, their mode of action is diverse, and they are less likely to induce resistance than conventional antibiotics, suggesting their potential for commercial use.[215]

The cited results provide insights into the mechanisms of the molecular interactions between naturally occurring antimicrobial compounds and, in most cases, the phospholipids of the bacterial cell membrane that govern activities. As described, the mechanisms can be complex, however, and are still not yet fully elucidated. Moroever, similar mechanisms might govern membrane disruption of susceptible and resistant pathogens by natural antimicrobials. A better understanding of the mechanisms that govern the antimicrobial activities of natural compounds will help in the design of approaches to inhibit resistant bacteria in different environments. It is largely not known whether the use of many of the natural antimicrobials will result in the development of resistance associated with standard antibiotics.

OUTLOOK AND AREAS FOR FUTURE RESEARCH

Antibiotic resistance often arises from the administration of subtherapeutic levels of antibiotics in animal feeds. Resistant microorganisms may be present in the animal waste, contaminating ground, surface, and irrigation waters and often contaminating fruits, vegetables, and other edible plant tissues. They suffuse throughout the food chain and can enter the human intestinal tract after the produce or the undercooked meat, poultry, and other food products are consumed. There is, therefore, a need to develop new alternatives to standard antibiotics, preferably based on safe, food-compatible plant compounds and extracts that can be effective against both susceptible and resistant bacteria. It is hoped that the present overview of multidisciplinary aspects of antibiotic resistance and its prevention will help meet this need. Largely unanswered questions are whether or not different classes of natural antimicrobials that have been found to be effective against susceptible pathogens will exhibit similar efficacy against resistant bacteria and fungi and whether antimicrobial activities in vitro will be duplicated in vivo after consumption by food-producing animals and by humans.

There are many areas in which further studies could help to address some specific aspects of antiresistance. For example, from a mechanistic point of view, it would be useful to devise strategies to bypass the bacterial membrane barrier comprising influx and efflux mechanisms to restore the activity of antibiotics against resistant bacteria,[216] and determine the relative potencies of structurally different efflux pump inhibitors in resistant pathogens.[175,217]

With regard to the whole food chain, it would be useful to investigate the efficacy of natural antimicrobials as a replacement for antibiotics in animal feed, where antibiotic resistance can arise. As indicated above, there may be differences in the prevalence of resistance between organic and conventional produce. It would be interesting to compare the prevalence of resistant bacteria in various conventional and organic foodstuffs.

The efficacy of many of these compounds is not known in vivo, and safety is paramount. Thus, the bioavailability, metabolism, and safety of antimicrobial compounds in animals and humans remains to be investigated further, and as does whether or not the resistant activities observed in vitro can be duplicated in vivo, especially in humans.

Another area concerning efficacy and safety that would be of interest for investigation is whether resistant formulations can also inhibit endotoxemias associated with human pathogens[218,219] and determining whether or not resistant pathogens release toxins to the same extent as susceptible pathogens.[220]

As discussed in this paper, many of the natural antimicrobials have additive and synergistic effects in combination with medicinal antibiotics, and these synergisitic effects merit further study in vivo. The same applies for their use as food additives. For example, it would be interesting to determine whether or not combinations of resistant food ingredients that act synergistically will be safer and will affect less the color, flavor, and taste of food than the individual compounds.[221] When considering their application as food additives, previous studies have investigated the use of certain natural products to reduce concurrently both resistant pathogens and carcinogenic heterocyclic amines in cooked meat.[119,222,223] Such investigations merit further study. It would be interesting to know if the consumption of compounds elicits a lower risk of infection and cancer in humans.

Some natural products that are inhibitors of bacterial resistance also have other beneficial properties. For example, carvacrol has analgesic, antiarthritic, antiallergic, anticarcinogenic, antidiabetic, cardioprotective, gastroprotective, hepatoprotective, and neuroprotective properties as well.[11] It would therefore be of interest to investigate any additional medicinal properties of the other food-compatible compounds and extracts described here. We are challenged to help solve these problems associated with microbial food safety and human health.

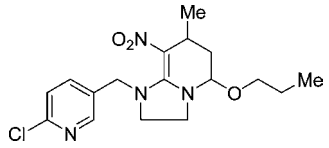

Figure 1. Molecular structure of IPP (1-((6-chloropydidin-3-yl)-methyl)-7-methyl-8-nitro-5-propoxy-1,2,3,5,6,7-hexahydroimidazo-[1,2-α-]-pyridine).

(BMM) in flasks, and 150 μL of an IPP stock solution (20 g L^{-1}) was added as the sole carbon source to give a final concentration of 30 mg L^{-1}. The method of enrichment, isolation, and identification of IPP-degrading bacteria and the composition of BMM media were followed in previous reports.[14−17]

The obtained enrichment suspension was streaked on the nutrient agar plates. All of the plates were incubated at 30 °C for 72 h. The morphologically distinct isolates were selected and preserved on a nutrient agar slant at 4 °C.The larger colonies were selected and streaked on the plate for further purification and study. A comparative 16S rRNA gene sequence analysis of IPP-degrading bacteria was performed according to the previous report,[14] and the amplified PCR product was sequenced by Sangon Biotechnology (Shanghai, China).

Biodegradation Assays. To illustrate the biodegradation pathway of IPP in an aquatic system, 250 mL glass flasks were used in all of the degradation studies and 150 μL of the IPP stock solution (20 g L^{-1}) was added to 100 mL of BMM solution to give a final concentration of 30 mg L^{-1}. Three replicates were conducted for all tests. After being cultured for 72 h, cells of *Sphingobacterium* sp. P1-3 were harvested by centrifugation (21 000*g*, 4 °C, 10 min) and washed twice with a 0.85% (w/w) sodium chloride solution.

The biodegradation experiments by IPP-degrading bacteria were carried out in a 250 mL flask on an environmental orbital shaker at 150 rpm. The factors of the pH value (from 6.0, 7.0, and 8.0) and IPP concentration (10, 30, and 50 mg L^{-1}) were studied upon IPP biodegradation. The cultivation and biodegradation experiments were carried out at 30 °C in the dark. At different time intervals (5, 10, 15, 20, 25, and 30 days), the incubation medium was harvested to determine its concentration and monitor its metabolites. The controlled IPP experiment was followed using the same procedures as mentioned above, except that the cells of *Sphingobacterium* sp. P1-3 were not added to BMM solution.

Extraction and Pretreatment. The cultivation was collected by centrifugation (21 000*g*, 4 °C, 10 min). The supernatant was extracted with dichloromethane three times.[14,18] The recovery of IPP ranged from 91.22 to 107.29%, and the relative standard deviation (RSD) was less than 7.58%. The results showed that the extraction method is feasible and satisfactory for the analysis of IPP residues. The dichloromethane extracts were combined and concentrated through a vacuum rotary evaporator at 40 °C until they were almost dry, and then the extracts were dissolved in 1 mL of methanol.

Analytical Procedures. Bacterial growth was analyzed by recording the increase in OD_{600} with a UV−vis spectrophotometer (Gold Spectrumlab 53, Lingguang, China).

IPP was determined with high-performance liquid chromatography (HPLC, Agilent 1260, Agilent Company, USA). The operation

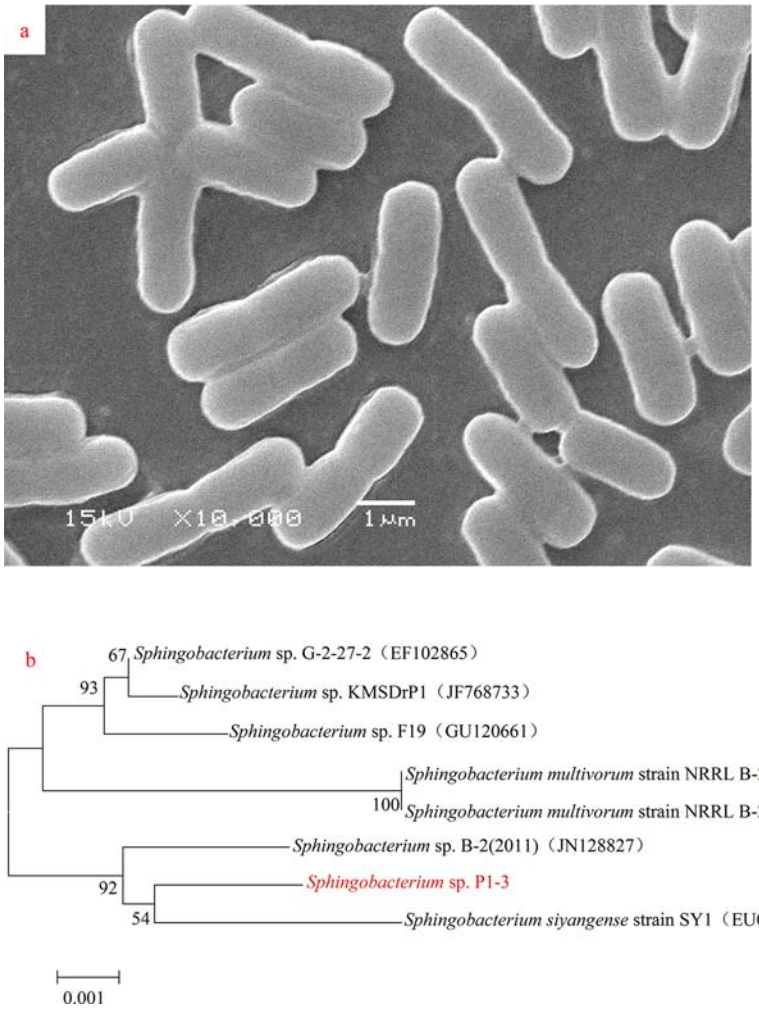

Figure 2. (a) Electron micrograph and (b) phylogenetic tree of strain P1-3 based on the 16S rRNA gene homology.

J. Agric. Food Chem. 2015, 63, 3823−3829

conditions were as follows: 354 nm, Agilent C_{18} column (3.5 μm, 4.6 × 250 mm^2), and 30 °C. The mobile phase was acetonitrile and pure water (50:50 v/v), and the flow rate was 1.0 mL min^{-1}.

IPP biodegradation intermediates were monitored and analyzed with HPLC (Agilent 1260, 268 nm, C_{18} column (3.5 μm, 4.6 × 250 mm^2)) at 30 °C. Acetonitrile with 0.1% (v/v) acetic acid (HPLC grade) and a mixture of 0.1% (v/v) acetic acid in water (HPLC grade) was used in a linear gradient program (minutes/% acetonitrile: 0/15, 7/15, 20/35, 40/100, 45/100, 50/15, 60/15). The flow rate was 1.0 mL min^{-1}.

LC-MS/MS analysis was conducted using a Dionex U3000 HPLC system coupled with a Bruker maXis 4G ion trap mass spectrometer with an electrospray ionization source (ESI). The separate conditions were in accordance with those used for HPLC analysis. The ion source temperature was controlled at 250 °C, and the capillary voltage was −4.5 kV. The analysis mode of ionization was electrospray ionization (ESI, positive). The operation conditions were as follows: collision energy, 10.0 eV; ISCID energy and ion energy, 5.0 eV; dry gas, 6 L min^{-1}; dry temperature, 180 °C; gas pressure, 1.5 bar. The continuous full scanning from m/z 50 to 500 Da was performed in positive ion mode.

IPP Degradation Kinetics and Calculation. IPP degradation by strain P1-3 followed a first-order exponential decay model. The rate constant from the first-order model was used to determine the DT50 (half-life value). DT50 was calculated by

$$-\ln \frac{c}{c_0} = kt \text{ or } \ln c = -kt + \ln c_0 \quad (1)$$

where C_0 is the initial concentration of IPP (mg L^{-1}), C is the real-time concentration of herbicide at a certain time, t is the incubation time (days), and k is the degradation rate constant of the herbicide (day^{-1}). DT50 and DT90 were calculated as $\ln 2/k$ and $\ln 10/k$, respectively.

RESULTS AND DISCUSSION

Isolation and Identification of IPP-Degrading Bacterium. There were 18 morphologically distinct isolates on the nutrient agar plate, and they could use IPP as the sole carbon and energy source. Isolate P1-3 had higher IPP-degrading activity among these isolates and was chosen for further study.

The physiological and biochemical characteristics are as follows: G$^-$, short rod (0.5−0.6 μm × 0.9−1.9 μm, Figure 2a), aerobic. Oxidase and catalase are positive, and strain P1-3 can utilize fructose, glucose, lactose, malt sugar, mannose, melibiose, starch, raffinose, and cellulose as the energy and carbon source. The colony of strain P1-3 was smooth, wet, and orange after 24 h of incubation.

The 16S rRNA gene sequences were compared by using BLAST similarity searches, and the closely related sequences were obtained from GenBank (Figure 2b). On the basis of the sequence identification of the 16S rRNA gene with GenBank, the highest similarity values of strain P1-3 were closely related to strain *Sphingobacterium* sp. G-2-27-2 (99% identity), *Sphingobacterium* sp. KMSDrP1 (99% identity), *Sphingobacterium multivorum* strain NRRL B-23206 (99% identity), *Sphingobacterium* sp. B-12 (99% identity), and *Sphingobacterium* sp. F19 (99% identity). Morphological and biochemical analysis in combination with phylogenetic analysis based on a partial 16S rRNA gene sequence indicated that strain P1-3 was a member of the genus *Sphingobacterium*. On the basis of these results, strain P1-3 was designated as *Sphingobacterium* sp. P1-3 (GenBank accession numbers KP657689).

Genus *Sphingobacterium* was originally proposed by Yabuuchi et al.;[19] it usually includes *Sphingobacterium multivorum, S. spiritivorum*, and *S. mizutae*. There are limited data showing that *Sphingobacterium* sp. was employed for biodegradation and bioremediation. Janbandhu and Fulekar reported that *Sphingobacterium* sp. had an effective phenanthrene-degrading ability.[20] *Sphingobacterium* sp. JCR5 was isolated from activated sludge; it could degrade 17α-ethynylestradiol, and the degradation rate reached 87%.[21] The results reported by Fang et al. showed that *Sphingobacterium* sp. strain D6 could utilize dichlorodiphenyltrichloroethane (DDT), dichlorodiphenyldichloroethane (DDD), and dichlorodiphenyldichloroethylene (DDE) (DDTs) as its sole carbon and energy source.[22] Strain D6 was also used for the remediation of DDT congeners and cadmium in soil. The degradation half-lives of DDTs in soils treated by strain D6 decreased by 8.1% to 68.0%, and strain D6 and *S. alfredii* could successfully control DDTs and Cd in contaminated soil.[23] In this study, the isolated bacterium capable of IPP degradation was unexpectedly affiliated with the family *Sphingobacterium*. This is the first report using *Sphingobacterium* sp. to biodegrade novel insecticide Paichongding, and there are limited data for IPP degradation by microorganisms.

Effect of Initial pH on IPP Biodegradation. The effect of initial pH on IPP degradation by *Sphingobacterium* sp. P1-3 was investigated in this study. The results of kinetic degradation data of IPP at a concentration of 30 mg L^{-1} in BBM at pH 6.0, 7.0, and 8.0 are shown in Figure 3a and Table 1. Throughout the whole experiment, the hydrolysis percentages of IPP were

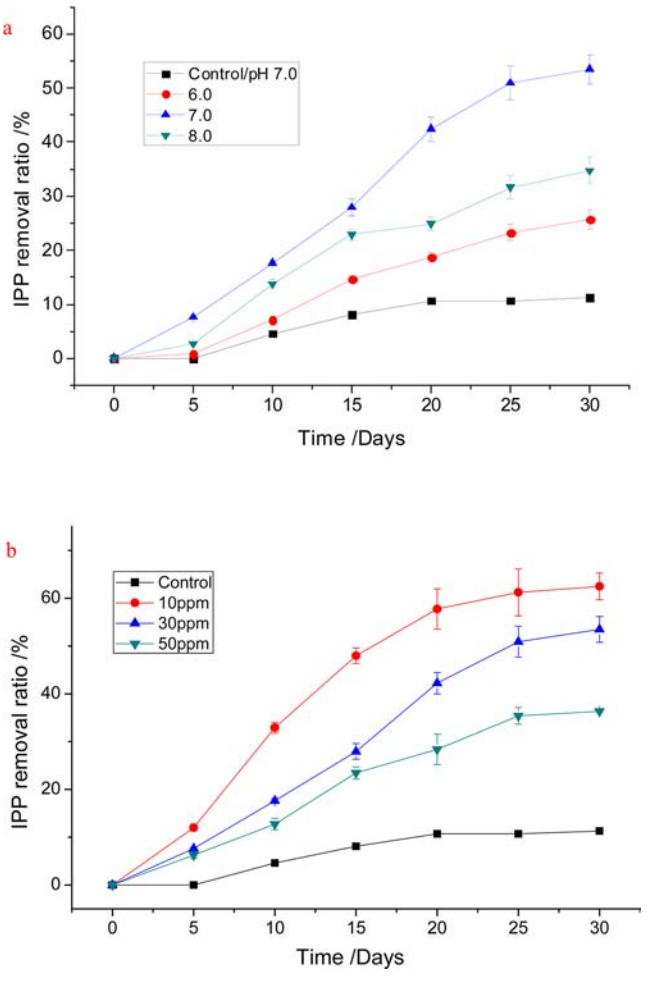

Figure 3. Effects of (a) pH and (b) the initial substrate concentration on IPP biodegradation by *Sphingobacterium* sp. P1-3.

Table 1. Kinetic Data of IPP Degradation by Strain P1-3 at Different pH Values and Concentrations

IPP (mg L^{-1})	pH	kinetic equations	k (day^{-1})	DT50	DT90	R^2
		Effect of pH				
30	6.0	$\ln c = 0.0110t + 3.40$	0.0110	63	209	0.9781
30	7.0	$\ln c = 0.0259t + 3.40$	0.0259	27	89	0.9892
30	8.0	$\ln c = 0.0147t + 3.40$	0.0147	47	157	0.9762
		Effect of Concentration				
10	7.0	$\ln c = 0.0372t + 2.30$	0.0372	19	62	0.9520
30	7.0	$\ln c = 0.0259t + 3.40$	0.0259	27	89	0.9892
50	7.0	$\ln c = 0.0162t + 3.91$	0.0162	43	142	0.9804
		Control				
30	7.0	$\ln c = 0.0046t + 3.40$	0.0046	151	501	0.9348

less than 6%. After incubation for 20 days, the degradation ratio of IPP reached 18.65% at pH 6.0, 42.41% at pH 7.0, and 24.88% at of pH 8.0. The biodegradation rate increases with increasing pH and reaches its maximum at pH 7.0. With further increases in pH, the biodegradation rate decreased and DT50 increased. The results showed that the neutral condition is favorable for IPP biodegradation by strain P1-3, whereas higher or lower pH inhibits degradation. The values of k and DT50 were found to be 0.0259 d^{-1} and 27 d, respectively, whereas DT50 of IPP in the control test was 151 d, which showed that strain P1-3 had a higher IPP degrading activity at pH 7.0 and the IPP degradation rate was highest when the pH value was 7.0. From Figure 3a, it also indicated that IPP could be hydrolyzed in the control test, which was in accordance with the previous report.[5] Compared to the biodegradation process, the hydrolysis ratio was relatively low.

Effect of IPP Concentration on Biodegradation. Figure 3b shows the result of the IPP removal ratio at pH 7.0 and 30 °C at different initial concentrations of 10, 30, and 50 mg L^{-1}. The biodegradation kinetic equations are shown in Table 1. The results show that both the biodegradation rate and the value of k decrease with increasing IPP concentration. The values of k and DT50 were 0.0372 d^{-1}, 19 d and 0.0162 d^{-1}, 43 d when the IPP concentration was 10 and 50 mg L^{-1}, respectively. When the IPP concentration increased, the first-order rate coefficient (k) decreased gradually, indicating that higher initial concentrations of IPP constrain the biodegradation rate, and the degradation rate and DT50 also declined, suggesting substrate inhibition (toxicity to microorganisms or enzymes). Compared to the results of the control experiments, it showed that the removal of IPP was due to bacterial activity and not abiotic degradation. The values of k and DT50 were 0.0046 d^{-1} and 151 d, respectively, in the control experiments.

Identification of Metabolites. The major degradation intermediates of IPP by strain P1-3 in aqueous solution were analyzed and identified by high-performance chromatography time-of-flight mass spectrometry, LC-MS and LC-MS/MS. In this study, five degradation metabolites were observed and analyzed. For each intermediate, its structure and formula were assumed on the basis of information derived from the retention time, elemental formula, its fragmentation pattern from MS^2 spectra, and a comparison with mass spectral data of the metabolite standard.

Novel insecticide IPP had a retention time of 16.87 min, and its mass spectrum showed that ion fragments of IPP were at m/z 367.1551 ($C_{17}H_{23}ClN_4O_3$) $[M + H]^+$, m/z 369.1543, and the ion fragment of m/z 367.1551, including daughter ions of 306.4454 (100), 308.4442 (21), and 137.1082 (50), which were accordance with the structure of standard IPP (Figure 4a).[1,2,5]

During the IPP degradation process by strain P1-3, five metabolites (M1−M5) were monitored and detected by HPLC with retention times of 1.1 min (M1), 32.8 min (M2), 21.2 min (M3), 35.0 min (M4), and 48.6 min (M5), which was accompanied by a decrease in IPP concentration. Among these five metabolites, M1 and M2 appeared first and their concentration increased, followed by the appearance of M3−M5. The content of M3−M5 also decreased gently after 20 days. These results showed that strain P1-3 could not only biodegrade novel insecticide IPP but also could degrade its metabolites (M1, M2, M3, M4, and M5).

According to the LC-MS/MS and MS^2 spectra of the metabolites, the metabolites of M1 and M4 were identified as 1-((6-chloropydidin-3-yl)methyl)-7-methyl-8-nitro- 5-hydroxy-1,2,3,5,6,7-hexahydroimidazo[1,2-α-]-pyridine (Figure 4b) and 1-((6-chloropydidin-3-yl)methyl)-7-methyl-8-amino-1,2,3,5,6,7-hexahydroimidazo [1,2-α-]-pyridine (Figure 4e). The protonated molecular ion clearly showed that there was an even number of nitrogen atoms of M4 and a mass unit loss of 46. This indicated that the oxygen atoms were lost from M1 to form amino product M4. M1 and M4 were also found via IPP degradation in soils as reported by Fu et al.[1,2]

Metabolite M2 was not the daughter of ion of IPP, and the loss of the 26 mass unit was likely a result of the hydroxylation of the nitro on IPP (Figure 4c). M2 had main two daughter ions (281.2967 and 326.3623). Hence, M2 was identified as 1-((6-chloropydidin-3-yl)methyl)-7-methyl-8- hydroxy-5-propoxy-1,2,3,5,6,7-hexahydroimidazo-[1,2-α-]-pyridine.

M3 was determined to be the denitration derivative of M1 based on the elemental formula fit, with the loss of a mass unit of 47 corresponding to $-NO_2$ and H. The M3 ions with m/z was 276.0900 and 278.0796 and matched elemental formula $C_{14}H_{14}ClN_3O$ (Figure 4d); thus M3 was identified as 1-((6-chloropydidin-3-yl) methyl)-7-methyl-5-carbonyl-1,2,3,5,6,7-hexahydroimidazo-[1,2-α-]-pyridine.

Intermediate M5, with m/z 142.1591 (Figure 4f), matched formula $C_7H_{15}N_3$ and was tentatively determined to be generated from M4. An analysis of the daughter ions generated from M5 showed that M5 was 8-amino-1,2,3,5,6,7-hexahydroimidazo-[1,2-α-]-pyridine.

IPP Biodegradation Pathway. On the basis of the five identified metabolites, a biodegradation pathway of IPP by *Sphingobacterium* sp. P1-3 in an aqueous system was proposed (Figure 5). The microbial transformation of IPP revealed four biodegradation patterns of the chloropydidine ring and tetrahydropyridine ring on the IPP parent compound: (i) elimination of propyl, methyl, or nitro; (ii) conversion of nitro to amino; (iii) conversion of nitro group to a hydroxyl; and (iv) cleavage of methyl.

Initially, the propyl group of IPP was de-esterified and hydrolyzed to form M1. Meanwhile, another biocatalyzed reaction was that IPP was hydrolated to generate M2 through the reduction of the nitro group on IPP. The nitro group of M1 was eliminated through the cleavage of the C−N bond, and the hydroxyl was oxidized at the tetrahydropyridine to produce

J. Agric. Food Chem. 2015, 63, 3823−3829

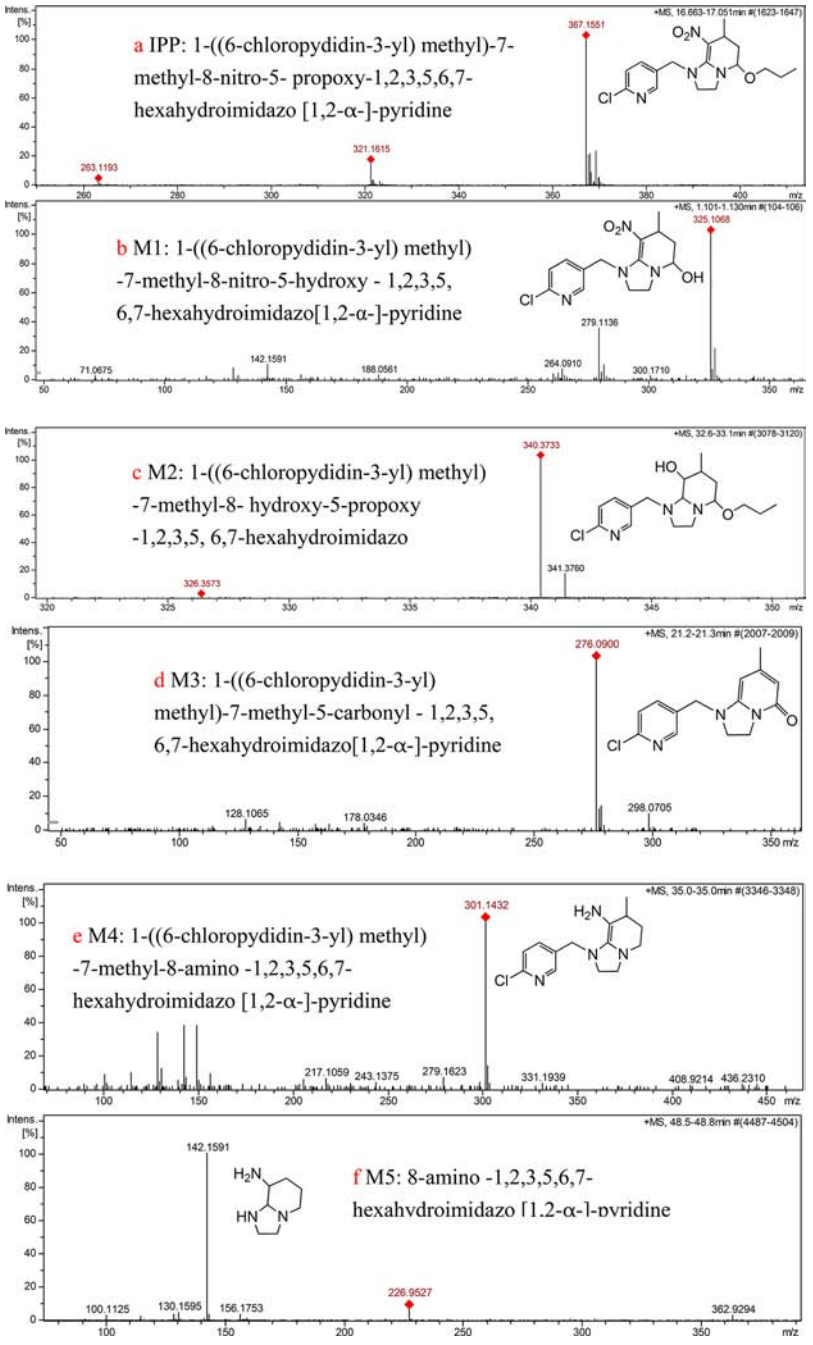

Figure 4. Mass spectra of metabolites formed during the degradation of IPP by *Sphingobacterium* sp. P1-3.

C═O and form carbonyl derivative M3. The nitro group of M1 could also be aminated to form amino product M4. Subsequently, the C−C bond between 1-(6-chloropydidin-3-yl)methyl and 7-methyl-8-amino-1,2,3,5,6,7-hexahydroimidazo-[1,2-α-]-pyridine of M4 was cleaved to form M5. M2, M3, and M5 should be used as carbon source by other microorganism and biodegradated in the environment.

As the proposed pathway described above, the results in this study and observations suggest that the proposed pathway is a major route for IPP degradation by *Sphingobacterium* sp. P1-3 in aquatic systems, which is significantly different from the previously reported pathway in soils and in aqueous systems.[1,2,5] Six metabolites were monitored and identified during the degradation of IPP in soils.[1,2] Zhao et al. reported IPP photodegradation pathway in aqueous solution. In the present study, two metabolites, M1 and M4, were in agreement with those previously studied in soils,[1,2] and M2, M3, and M5 were first monitored and identified in aqueous solution. It was also the first report on IPP biodegradation by a microorganism. The proposed IPP-degrading pathway by *Sphingobacterium* sp. P1-3 provides more information on biodegradation.[1,2]

In this study, *Sphingobacterium* sp. P1-3 with a higher IPP-degrading activity was successfully isolated from soil. The degradation rate by *Sphingobacterium* sp. P1-3 could reach 57.65% within 20 days in an aquatic system. The results indicated that IPP could ultimately be transformed to M5 through continuous biocatalyzed reactions, e.g., de-esterification, elimination of propyl and nitro, amination, hydroxylation, and demethyl reactions. The physicochemical properties of *Sphingobacterium* sp. P1-3 and the investigation of the IPP

with mineral matter in soil, could promote physical protection and therewith a high long-term stability.[16]

In this study, we performed four different composting experiments in order to verify the formation of oxygen-containing functional groups (carboxylic acids and phenols) at the biochar surface through composting. Additionally, we investigated original Terra Preta biochar particles and ancient charcoal pit biochars (CPB) to assess the results of the composting experiments.

2. MATERIAL AND METHODS

2.1. Biochar for Compost Experiments. In total, three different biochars were used in this experiment (Tables 1 and 3). First biochar was made from green cuttings, produced in a Pyreg reactor at ~800 °C (Dörth, Germany, www.pyreg.de). Second biochar was prepared from wood chips (a mixture of forestry residues) by CarbonTerra (Augsburg, Germany, www.carbon-terra.eu) at ~550 °C. A detailed description of the Pyreg and CarbonTerra production technologies are published in Wiedner et al.[5] Third biochar was produced from beech wood in a traditional charcoal pit at ~450 °C in Lower Austria (47°52′20.5″N 15°41′48.5″E).

Table 1. Composition of Composts I, II, II, and IV

	Application rate [Mg]			
Ingredients	Compost I	Compost II	Compost III	Compost IV
Green cutting biochar*	0.7			
Wood chips biochar*		0.7		
Beech biochar*			0.57	0.54
Straw*	1.1	1.1		
Draff*	5.3	5.3		
Horse manure*	1.1	1.1

Total mass of initial compost mixture	18.8	18.8	3	3.9
Turning times	7	7	14	8

*Application rates are based on dry matter.

2.2. Compost Experiments. Four different compost experiments were performed at industrial scale, outdoors and under practical field conditions with full exposure to weather conditions at professional composting facilities. The biochars were mixed into the fresh organic material prior to composting. Detailed information about the compost mixtures is given in Table 1. Biochar particles of all four composts were picked manually and cleaned for further analyses (see Section 2.3.3).

Composts I and II (Table 1) were produced within the ClimaCarbo Project (01LY1110B) near Gartow (Wendland region, Northern Germany) supported by the German Federal Ministry for Education and Science (BMBF). Composts III and IV were produced by "Sonnenerde" in Riedlingsdorf, Austria (47°20′33.5″N 16°08′28.0″E). The experiment aimed to evaluate the effects of ordinary composting occurring under aerobic conditions (Compost III) in comparison to possible effects of anaerobic lactic acid fermentation with effective microorganisms (EM; Compost IV).

Preparations with EM are composed of lactic acid producing bacteria, yeasts, phototropic bacteria, actinomycetes, and fungi. The following two products were used from Multikraft GmbH (Wels, Austria, www.multikraft.com): 0.5 L eMB-Starter and 5 L eMB-Aktiv were sprayed per m^3 related to the organic feedstock material for fermentation at the beginning of the experiment. Compost III was turned 6 times during the first 4 weeks in order to ensure enough oxygen supply. Compost IV was not turned within the first 4 weeks to maintain an anaerobic process. After 4 weeks, both piles were turned once a week for the remaining time (8 weeks) to promote better homogenization and stabilization. After the first 4 weeks, Compost IV was treated with both EM solutions again by applying 1 L m^{-3} and 5 L m^{-3} of eMB-Starter and eMB-aktiv, respectively.

Table 3. Chemical Characterization of Fresh and Ancient Biochars

	Black carbon [g C_{bc} kg^{-1} TOC]	pH [CaCl2]	EC [µS cm^{-1}]	Ash [g kg^{-1}]	Total N [g kg^{-1}]

[a]Data adopted from Wiedner et al.[5] [b]Data adopted from Glaser et al.[25] [c]Ancient biochars used for black carbon analysis were not the same used for SEM-EDS and FTIM but taken from same soil horizon.

2.3. Historical Charcoals. *2.3.1. Terra Preta Biochars (Brazil).* The Terra Preta biochars were collected from a Terra Preta near Manaus with an average age of about 2000 years.[17] Mean annual temperature (MAT) was 26 ± 3 °C and mean annual precipitation (MAP) was 2500 mm with a dry season between August and November. More details on the collected biochar are given in Table 2.

2.3.2. Historical Charcoal Pit Biochars (Northern Italy). Charcoal pit biochars were collected from 3 charcoal pits located in Val di Pejo (2050 to 2171 m a.s.l.), a lateral valley of Val di Sole, Trentino, in the

southern Alpine belt of northern Italy. The charcoal pit biochars have an average ^{14}C age of 500 years. The climate of the valley ranges from temperate to alpine (above the tree line). MAT ranges from 8.2 °C (valley floor 800 m a.s.l.) to around 0 °C at 2400 m a.s.l. and MAP varies from about 800 to 1300 mm.[14] More detailed information about the Pejo Valley is published by Favilli et al.[18]

2.3.3. Preparation of Biochars for Analysis. Fresh biochars were dried to constant weight at 40 °C and stored at room temperature in plastic bags. Composted and ancient Terra Preta and charcoal pit biochars were cleaned carefully to remove adhesions. Ancient biochars were separately given in conventional bottles with snap-on caps and filled up with deionized water. The bottles were placed in an ultrasonic bath for 30 s. Subsequently, cleaned biochars were removed from water and dried to constant weight at 40 °C and stored in snap-on bottles. Investigated biochars had a particle size of averagely 0.6 × 0.6 mm^2.

2.3.4. Paleobotanical Analysis of Ancient Biochars. Biochars from Terra Preta were analyzed taxonomically (see Table 2) using a stereo lens (Nikon SMZ1500, magnifications ×7.5 to 112.5) and an episcopic microscope (Nikon ME600, ×100, ×200, and ×500). Wood anatomical features were observed on freshly broken surfaces on cross, tangential, and radial sections, according to Wheeler et al.[19] With the coding of the observable features, the InsideWood database was used.[20]

Charcoal pit biochars were analyzed microscopically as conifers with a stereomicroscope (magnification 6.4−40 × , Wild M3Z Leica, Germany).[21] The charcoal fragments from the coniferous trees were divided further at the genus level using a reflected-light microscope (objective 5× , 10×, and 20×, Olympus BX 51, Japan). The observations were compared with a histological wood-anatomical atlas, using an identification key.[22] The species identified are *Larix decidua* L. and *Picea abies* L. Analyzed charcoal pit biochars in this study are from *Larix decidua* L.

2.4. Characterization of Biochars. *2.4.1. pH, Electrical Conductivity and Ash.* Fresh biochar pH and electrical conductivity (EC) were measured using suspensions with 0.01 mol/L $CaCl_2$ and distilled H_2O (1:5). After shaking the suspensions for 1 h on a low speed shaker and sedimentation of solids for another hour at room temperature, EC and pH were determined in the supernatant.

For ash determination, samples were dried for 4 h at 105 °C in a drying oven and weighted after cooling. The dry combustion was

DOI: 10.1021/acs.jafc.5b00846
J. Agric. Food Chem. 2015, 63, 3830−3837

performed in a muffle furnace at 550 °C for 8 h and after cooling in a desiccator, samples were weighted again.

2.4.2. Black Carbon. Black carbon content and composition was determined using the benzene polycarboxylic acids (BPCAs) method of Glaser et al.[23] with the modification of Brodowski et al.[24] Separation and quantification of individual BPCAs was carried out with GC/FID using an HP5 column (30 m × 0.25 mm × 0.25 μm). The sum of individual BPCAs was taken as the black carbon content after multiplication with 2.27 (conversion factor for charcoal as suggested by Glaser et al.[23]).

2.4.3. Total N, Surface and Bulk O/C Ratios of Fresh and Ancient Biochars. Surface O/C ratio of fresh, composted, and ancient biochars were measured with scanning electron microscopy (SEM), a Jeol JSM 6300 SEM, which, for energy-dispersive X-ray spectroscopy (EDS), was coupled with a Bruker X-Flash 5010 detector having an energy resolution of 123 eV. The Quantax 200 Software was applied to evaluate the EDS data to characterize spatial distribution of oxygen on biochars surface differing in age and treatment. Samples were fixed on an object slide with conductive silver (Demetron L200) and coated with gold using a Bal-Tec SCD 050 sputter-coater in a low vacuum atmosphere.

Total N and C analysis was carried out with a "vario EL" analyzer by Elementar GmbH (Hanau, Germany) at the Institute of Chemistry of the Martin-Luther-University in Halle (Germany). The total O content was measured by using a EURO EA Elemental Analyzer (EuroVector, Hekatech, Germany) at the Soil Biogeochemistry Department of the Martin-Luther-University in Halle (Germany).

2.4.4. Fourier Transformation Infrared Microscopy (FTIM). In order to verify organically bound oxygen, FTIM was used as a suitable tool to visualize and quantify aromatic, carboxylic and phenolic functional groups at the biochar surface. In this study, a Nicolet Continuum FTIM coupled with a Nicolet iS50 FT-IR spectrometer (Thermo Fisher Scientific Inc., Waltham, U.S.A.) was used.

All samples were analyzed in the reflectance FTIM imaging mode while collecting all FTIM spectra in the mid-infrared range from 1585 to 1600 cm^{-1} (aromatics), 1700−1725 cm^{-1} (carboxylic acids), and 1190−1210 cm^{-1} (phenols) using 4 cm^{-1} spectral resolution and 64 scans for each single point collection. A XT-KBr beamsplitter was used during the analysis, autogain was enabled, and aperture was set to 100%. FTIM surface map areas comprised 16 × 16 spectra using a 10 μm step size resulting in a square map image of 150 × 150 μm^2. The data were preprocessed using the OMNIC Atlus software version 9.1.24 (Thermo Fisher Scientific Inc., Waltham, U.S.A.) by performing a conversion from reflectance to absorbance at first and, second, by undertaking an automatic baseline correction.

2.5. Statistics. The statistical software package SPSS Statistics 17.0[25] and R[26] for Windows was used for statistics. Kolmogorov−Smirnov test was used for testing data on normal distribution. Statistical differences among means were tested using ANOVA or a nonparametric Kruskal−Wallis test for the FTIM-mapping data, followed by a nonparametric multiple comparison test based on Holm−Bonferroni corrections. Tukey HSD post hoc test was applied for normal distributed data to compare means. The nonparametric Mann−Whitney U test was applied when normal distribution could not be achieved by logarithmic transformation. Significance levels were defined as highly significant ($p \leq 0.01$), significant ($0.01 < p < 0.05$), and not significant ($p > 0.05$). For statistical analysis of surface oxidation (O/C ratio), a minimum of 5 EDS spectra were measured on each biochar on three independent biochars per category.

3. RESULTS

3.1. General Characterization of Biochars. Chemical properties of fresh biochars such as pH, EC, ash, and total N are given in Table 3. Due to the small quantity of ancient biochars, general characterization could not be made.

The pH value ($CaCl_2$) of fresh biochar is between 8.1 and 8.6. EC show high variability with values ranging from 200 (beech biochar) to 1000 (green cutting biochar) μS cm^{-1}. Ash content of green cutting and beech biochar is more or less equal (126 and 117 g kg^{-1}, respectively) in contrast to wood chips biochar with an ash content of 235 g kg^{-1}. Total N content ranged between 3.1 (beech biochar) and 9.6 (green cutting biochar).

Black carbon contents (Table 3) were measured on fresh and ancient biochars. It should be noted that the black content of ancient biochars were not analyzed on the same biochars used for SEM-EDS and FTIM analysis. For fresh biochars, black carbon contents show high variations, ranging between 409.9 (green cutting biochar) and 725.7 (beech biochar) g C_{bc} kg^{-1} TOC. Black carbon content of charcoal pit biochars ranges between 382.2 and 403.2 g C_{bc} kg^{-1} TOC, whereas Terra Preta biochars show black carbon contents between 447.6 and 534.5 g C_{bc} kg^{-1} TOC (Table 3).

A more detailed description and discussion about green cutting and wood chips biochar is published in Wiedner et al.[5] Glaser et al.[28]

3.2. Surface and Bulk O/C Ratios of Fresh and Ancient Biochars. Images of Figure 1 show points of EDS analysis, elemental mapping, and an exemplarily EDS spectrum of analyzed points for fresh, composted, and ancient charcoals. Surface O/C ratios of fresh biochars increased significantly ($p < 0.05$) on average from 0.13 to 0.40 after composting (Figure 2).

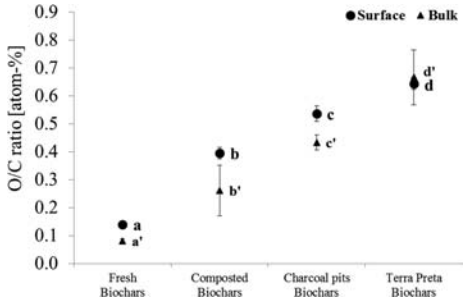

Figure 2. Mean surface (SEM-EDS) and bulk O/C ratios of fresh, composted, and historical biochars (charcoal pit and Terra Preta). Letters indicate significant differences (Tukey HSD test; $p < 0.05$; Error bars show SE).

In contrast, ancient biochars showed mean surface O/C ratios of 0.54 for charcoal pit and 0.64 for Terra Preta, being significantly higher compared to fresh and composted biochars (Figure 2).

The trend of bulk O/C ratios was similar as for surface O/C ratio. Lower bulk O/C ratios (Figure 2) could be observed for fresh, composted, and charcoal pit biochars of 0.08, 0.26, 0.43, and 0.67, respectively, indicating a higher aromaticity in the interior of the biochar particles. Terra Preta biochar particles showed similar surface and bulk O/C ratios of 0.64 and 0.67, respectively, indicating a high oxidation degree even in the interior of the biochar particle (Figure 2).

3.3. Surface Functional Groups. Energy-dispersive X-ray spectroscopy analysis displayed also the presence of Al, Si, and Fe on composted and ancient biochars (Figure 1). Organically bound oxygen is visualized by FTIM mapping (Figure 3) showing the relative distribution of phenols and carboxylic acids on the surface of Terra Preta, charcoal pit, and beech biochar prior and after composting (Compost III and IV). The images show that the ancient Terra Preta and charcoal pit biochars are dominated by carboxylic groups, whereas the proportion of carboxylic and phenolic groups on composted biochars are

DOI: 10.1021/acs.jafc.5b00846
J. Agric. Food Chem. 2015, 63, 3830−3837

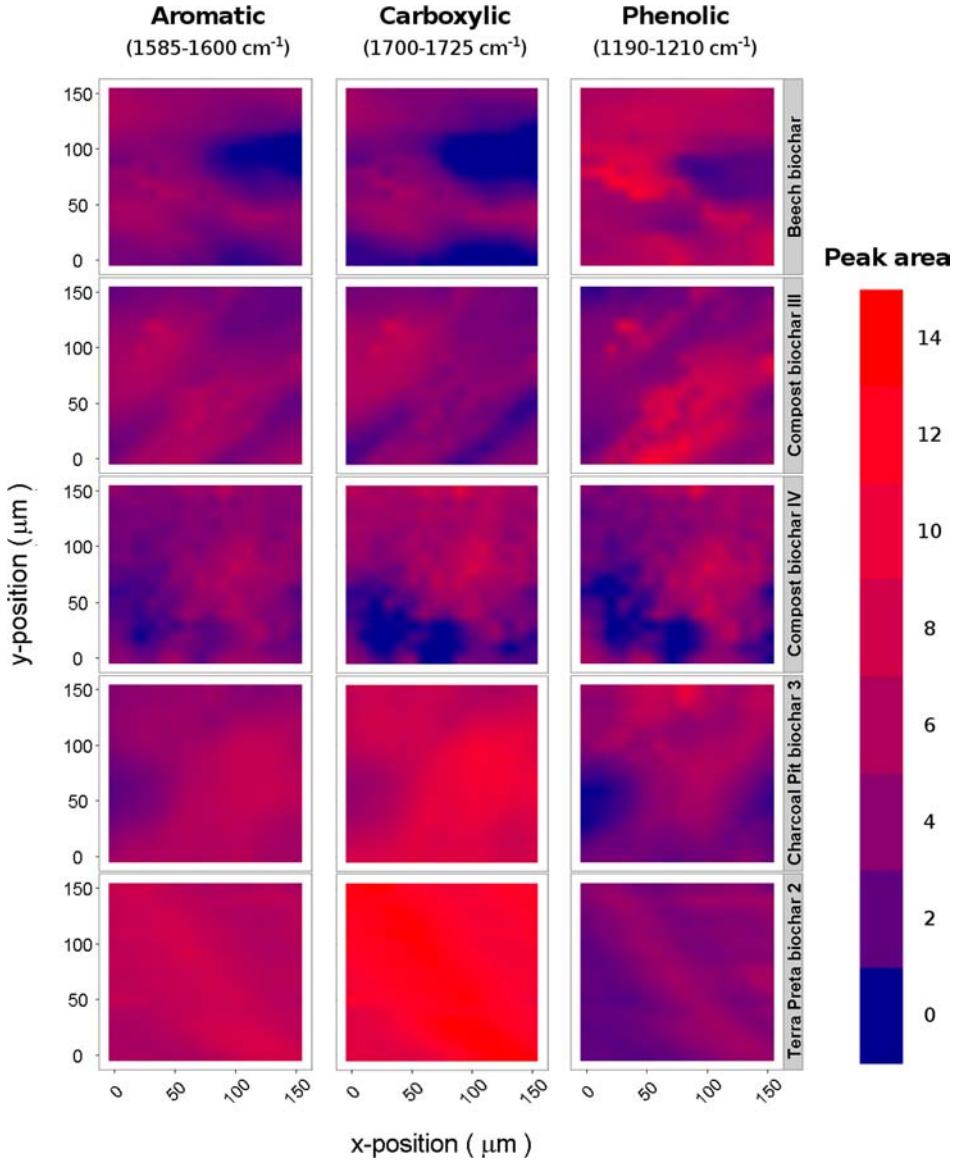

Figure 3. Fourier Transformation Infrared spectroscopy mapping of carboxyl and phenol groups on fresh (beech), composted (Compost III and IV)), charcoal pit biochar3, and Terra Preta biochar2.

equal. Fresh beech biochar is dominated by phenolic groups (Figure 3).

Data in Table 4 and Figure 4 show that the relative contribution of carboxylic acids on fresh biochars increased with increasing production temperature in the following order 20 ± 1% (beech biochar, ~450 °C) < 29 ± 1% (wood chips biochar, ~550 °C) < 41 ± 1% (green cutting biochar, ~800 °C). In contrast, the percentage of phenolic groups are highest at low production temperature (52 ± 1%, beech biochar, ~450 °C) decreasing to 33 ± 1% for wood chips biochar (~550 °C) and 22 ± 1% for green cutting biochar (~800 °C).

After composting, the percentage of carboxylic acids increased significantly ($p < 0.05$) for biochars produced at ~450 °C (beech) and ~550 °C (wood chips) whereas phenolic groups decreased significantly (Table 4). A reversed effect could be shown for composted green cutting biochar (produced at ~800 °C). The percentage of carboxylic acids significantly decreased and phenols significantly increased ($p < 0.05$) from 41 ± 1% to 20 ± 1% and 22 ± 1% to 45 ± 1%, respectively (see Table 4). The comparison of compost experiments III (aerobic) and IV (anaerobic) show that percentage of carboxylic acids increased significantly when composted with EM, whereas phenols significantly decreased (Table 4).

The carboxylic to aromatic ratios of ancient biochars (Table 4) were on average 1.7 and a lower phenolic to aromatic ratio of 0.7 (charcoal pit biochars) and 0.4 (Terra Preta biochars). In contrast, fresh and composted biochars exhibited an average carboxylic to aromatic ratio of 0.9, whereas the phenolic to aromatic ratio was higher (1.1 and 1.0 for fresh and composted biochar, respectively).

4. DISCUSSION

4.1. Properties of Ancient Biochar Particles. The question remains open whether the high surface oxidation of the ancient Terra Preta and charcoal pit biochars is the product of abiotic oxidation leading to the oxidation of exposed C rings with a high density of π-electrons and free radicals or biotic oxidation.[29] In the latter case, microorganisms incorporate O into the biochar structure.[30] Under natural conditions,

[1,2,3]Biochars used for the composts with the same foodnote. [a]Statistical evaluation was performed with the Mann−Whitney U-test; $p < 0.05$. [b]Statistical evaluation was performed with a Kruskal−Wallis test followed by a multiple comparison; $p < 0.05$.

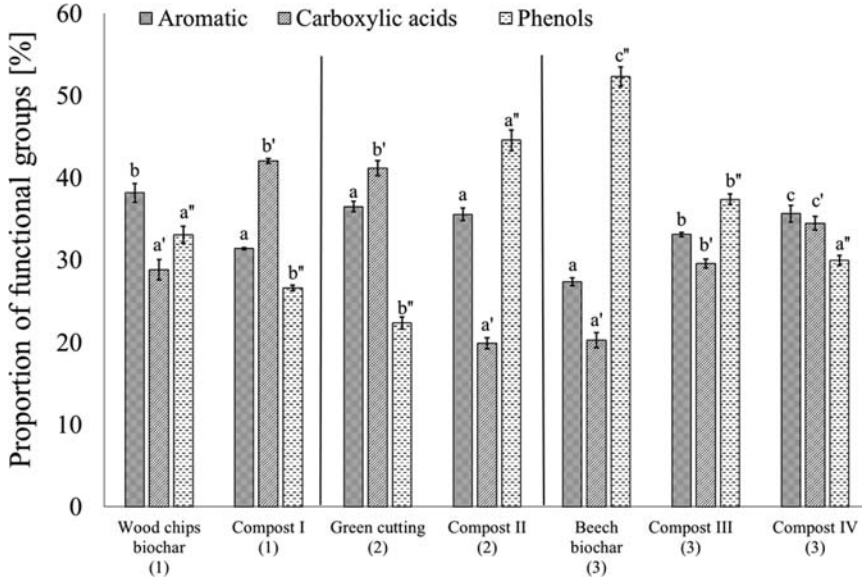

Figure 4. Proportion of functional groups (aromatic, carboxylic, and phenolic) on biochar before and after composting. Letters indicate significant differences (Mann-Withney U-test and Kruskal−Wallis test; $p < 0.05$; Error bars show SE; numbers in brackets indicate same biochar).

formation of O containing functional groups on biochar particles is a matter of time and strongly depends on soil environmental conditions such as moisture, temperature, soil C content or microbial community. For instance, Joseph et al.[27] used XPS to determine fresh and aged biochars after two years exposure in a Ferrosol in subtropical Australia. The authors observed an increase of surface O/C ratio from 0.2 (fresh biochar) to 0.75 (aged biochar). In comparison, Mao et al.[30] investigated biochar particles from a Terra Preta soil in Amazonia (>800 years old) and a Mollisol in Iowa in the U.S. (generated by presettlement fires) using two-dimensional NMR heteronuclear correlation spectroscopy. Terra Preta biochars investigated by Mao et al.[27] had an O/C ratio of ∼0.4, which is in comparison to the O/C ratios of Terra Preta biochars (∼0.64, see Figure 2) in this study rather low. Surface O/C ratios of the Iowa Mollisol biochar particles were only ∼0.2 which is negligible higher than the O/C ratios of fresh biochars determined in this study (Figure 2). The abundance of carboxyl groups on ancient biochar particles as shown by FTIM (Figure 3) was also detected by Mao et al.[30] NMR spectroscopy strongly indicate that carboxyl groups are directly bonded to the aromatic rings of biochar.[30] Joseph et al.[27] however, suggest that the increase of O containing functional groups on biochar surface is a combination of biochar oxidation and/or the absorption of natural organic matter (NOM) or microbial exudates. Liang et al.[31] compared ancient Terra Preta biochar particles from different soil depths applying scanning transmission X-ray microscopy (STXM)-near-edge X-ray absorption fine structure (NEXAFS) spectroscopy. Biochar particles from the A horizon were coated with NOM comparable to humic acids extracts and biofilm substances. In deeper soil horizons, biochar particles had only low proportions of NOM on its surface. Instead, the ratio of oxidized C to aromatic C increased from 2.9 to 3.1 with increasing soil depth showing an increased oxidation with aging.[31]

J. Agric. Food Chem. 2015, 63, 3830−3837

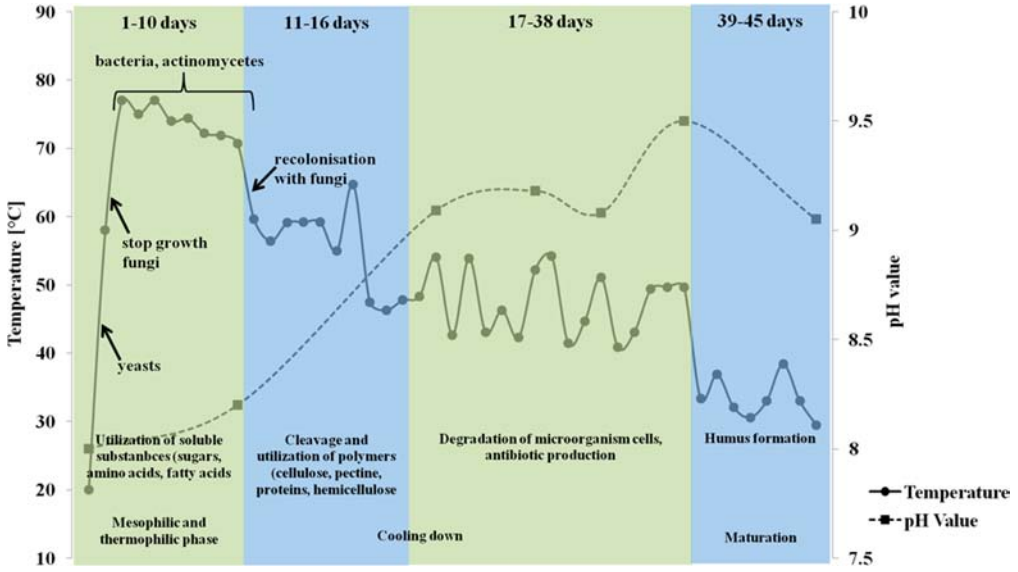

Figure 5. Temperature and pH during the composting process within 45 days of Compost I, complete with supporting information about the chemical and biological process during composting.

4.2. Composting As Driving Force for a Rapid and High Biochar Surface Modification? The compost experiments in this study showed that composting seems to be a suitable method to increase oxygen containing functional groups on biochar surface (Figure 4). However, the high proportion of oxygen as measured on ancient Terra Preta and charcoal pit biochars could not be achieved through composting, neither with ordinary composting (Compost I, II, and III) nor with anaerobic lactic acid fermentation with EM (Compost IV). The formation of carboxylic groups on beech biochar seem to be promoted when comparing compost experiment III and IV, which is not the case for phenols (Figure 4).

It is not clear whether O containing functional groups originated through biochar surface oxidation (abiotic or biotic) during composting or from the adsorption of NOM or microbial residues derived from compost. It is highly probable that the increase of O containing functionality during cocomposting of biochar is due to a complex interaction of both oxidation and adsorption.

O containing functional groups are derived from abiotic and biotic oxidation on biochar surface, resulting from highly complex interactions of temperature and pH, which in turn affect microbial activity and community (Figure 5). For instance, basic soil environments can accelerate self-humification of biochar as studied by Cohen-Ofri et al.[32] in archeological environments. In our biochar compost mixture, the typical acidification phase during the mesophilic phase does not occur (Figure 5). The initial pH value of 8 (first day) increased to 9.5 and slightly decreased to 9.1 on day 45. It is highly probable that biochar acts as buffer and prevents the acidification phase. This potential shift in pH value through biochar addition and the impact on microorganisms and in particular on biochar surface oxidation require further investigation. The incorporation of O into the biochar structure through microbial oxidation is still hard to document. Besides O incorporation, further effects such as cation exchange capacity, charge, or acidity are hard to distinguish from effects due to adsorption/desorption of nonbiochar components, such as microbial exudates or NOM.[29] Prost et al.[33] composted biochar with farmyard manure and observed a significant increase of biochar's potential CEC, but a declined surface area of biochar. The authors suggest that the interception and sorption of compost-derived organic materials clogged micropores, leading to a decreased surface area but adsorbed organic materials increased potential CEC of biochar.[33]

Although it could not be clarified in this study which mechanisms/interactions are responsible for the increase of carboxyl groups on biochar surface by an average of 12% (Compost I, III and IV), however, composting accelerates the development of carboxyl groups which have an important function to retain nutrients on biochar surface.[34] Under natural conditions, the development of carboxyl groups to a significant amount needs years (or even decades), as showed by a study of Singh et al.[35] The authors incubated biochar into four contrasting soils for up to 2 years, which did not lead to a significant increase of carboxyl groups on its surfaces as investigated with NEXAFS and X-ray photoelectron spectroscopy (XPS). In contrast, Hua et al.[8] cocomposted bamboo biochar (produced at 600 °C) and observed an increase of carboxylic groups by 2.4-fold after 42 days of composting, which is inherent with the results of our compost experiments (except Compost II, Table 4). The compost experiments from Hua et al.[8] also showed an increase of penolic groups by 1.5-fold, which is in contrast to our results where the proportion of phenolic groups decreased in extreme cases from 52% initially (beech biochar) to 30% (Compost IV) after composting (Table 4). Except biochar from the Compost II experiment doubled the percentage of phenolic groups (Table 4).

In conclusion, high surface oxidation of ancient biochar particles in Terra Preta is the key factor of increased CEC. The results indicate that composting seem to be a suitable method to accelerate the formation of organically bonded oxygen containing functional groups on the surface of fresh biochars. However, further research is necessary that examines the extent of biotic and abiotic processes during biochar oxidation and how to bring biochar surface properties into a state similar to ancient biochars within a short period of time under practical conditions.

J. Agric. Food Chem. 2015, 63, 3830−3837

volatile compounds analyzed in foods per se could undergo significant differences when the food is consumed and could lead to differences in the final aromatic perception. In fact, considerable physicochemical changes which affect the release of volatile compounds from emulsions occur in the mouth while eating. This is the reason the sensations of odor (the so-called nasal route) and aroma (retronasal route) could be perceived differently, even though the same olfactory sense is involved.[10,11] In fact, salivation, mouth size, shear forces from tongue compression, breathing, pH, and temperature are factors able to change the food matrix structure and sensory properties.[12] Among the physiological parameters, saliva has been described in the literature as the most important. Its first effect is to dilute the oil-in-water emulsion when this latter is tasted. Then, the activity of salivary proteins (mucins, albumin, and proteins rich in proline) and enzymes (amylase, lipase, and lysozymes) are responsible for the emulsion destabilization.[13,14] In addition, it was reported that phenolic compounds, in olive oil-in-water emulsions stabilized by β-lactoglobulin, affect the droplet size, improving the dispersion degree.[15] These changes in the structure of the emulsion could also have an effect on the final perception of the products.[16] Several studies have been aimed at understanding the aroma release of volatile compounds in vegetable oil model solutions and emulsions.[6,17−22] Only two published research papers reported the release of only one volatile compound after the interaction between whey proteins and saliva by *in vivo* analysis. The first one studied the release of ethyl butanoate in gel, while the latter reported on 2-nonanone in aqueous solution.[23,24] Another study reported the aroma release of emulsions obtained by soybean oil and β-lactoglobulin under simulated mouth conditions.[25] Moreover, the majority of *in vitro* studies employed artificial saliva.[20−23] This could be a limit because the effect of numerous enzymes and proteins present in human saliva were not considered.[4,12,26] So far, only one published study has investigated the interaction of phenolic compounds from olive oil with different food proteins, including β-lactoglobulin.[27] From a food technology point of view, the polyphenol−protein interaction is interesting as a possible means to reduce bitterness, whereas the effects of such an interaction on the release of flavor compounds has still to be investigated. Up to now, no study has reported on the aroma release of VOO after the interaction with whey proteins and human saliva. The effect of these interactions could be important in understanding oral mechanisms of the emulsion in relation to sensory perception. This piece of information will also be useful to deepen consumer attraction toward foods or dishes made by pairing olive oil with dairy products. Therefore, it could be the basis of further studies in sensory science about consumer preferences.

The present work aims to study the aroma release of volatile compounds in an oil-in-water model dispersion by adding refined olive oil spiked with VOO biophenols to a whey protein solution (1/5 v/v). In particular, this research aims to verify the changes in headspace release of target volatile compounds due to the interactions between virgin olive oil biophenol extract and whey proteins, in the presence of human saliva, simulating mouth conditions.

MATERIALS AND METHODS

Samples, Standards, and Reagents. Refined olive oil and extra virgin olive oil (EVOO) from the Coratina cultivar were supplied by the IOBM (Industria Olearia Biagio Mataluni, Montesarchio, Benevento, Italy). EVOO from the Ravece cultivar was provided by APOOAT Soc. Coop a.r.l. (Avellino, Italy) in 250 mL green glass bottles. EVOO samples were stored under suitable conditions, avoiding light exposure and high temperatures in order to prevent oxidation, and were used within 8 months from their production (November 2013). For the analysis of volatile compounds, ethyl isobutyrate (99%), ethyl butyrate (99%), ethyl 2-methylbutyrate (99%), hexyl acetate (99%), *cis*-3-hexenyl acetate (98%), *trans*-2-pentenal (95%), *trans*-2-hexenal (98%), 1-hexanol (99%), *cis*-3-hexen-1-ol (99%), linalool (97%), and 1-penten-3-one (97%) were supplied by Sigma-Aldrich (St. Louis, USA). For the analysis, the reagents hexane (95%), methanol (99.9%), glacial acetic acid, trifluoroacetic acid, acetonitrile, diethyl ether, and distilled water were supplied by Romil (Cambridge, England). Potassium iodide and sodium carbonate were provided by AppliChem (Darmstadt, Germany). Ammonium acetate, Folin−Ciocalteu solution, and sodium hydroxide were purchased from Sigma-Aldrich (Steinheim, Germany). Sodium hydroxide, phenolphthalein, and starch were provided by Titolchimica spa (Rovigo, Italy). Sodium thiosulfate was supplied by Fluka (Buchs, Switzerland), and chloroform was supplied by LabScan (Dublin, Ireland).

Sample Preparation. To study the effect of interactions between whey protein isolate and olive oil, added or absent, with biophenols from extra virgin olive oil on the aroma release, the experimental plan reported in the Supporting Information was applied. Six model systems were set up in order to obtain known initial concentrations of aroma compounds in olive oil added with phenolic compound extract and whey protein isolate. In order to verify our results, obtained by using model systems, a blank virgin olive oil was also analyzed. Human saliva was added to the model systems, and samples were subsequently analyzed by using a dynamic headspace simulating mouth conditions by a retronasal aroma simulator (RAS) device. In the systems without saliva, distilled water was added to obtain the same headspace volume in all of the samples, with the same pH of saliva.

Preparation of the Refined Olive Oil Sample with Added Virgin Olive Oil Biophenols (ROOP). The phenolic extract was obtained from extra virgin olive oil *cv.* Coratina, typically known for its high content of phenolic compounds. An aliquot of the oil sample (200 g) was dissolved in hexane (200 mL) and vigorously shaken for 10 s. A subsequent extraction was carried out using a water/methanol mixture (40/60 v/v) in a separatory funnel. This step was repeated three times by using a total of 420 mL of solvent. Subsequently, the obtained hydro-alcoholic extract was washed with hexane to remove any oil contamination and was centrifuged for 10 min at 3500 rpm (ALC International srl, PK-120, Milan, Italy). The organic phase was removed from the sample, and the hydro-alcoholic phase was collected in the flask and evaporated under vacuum in a rotary evaporator at 40 °C (Heidolph, VV 2000). The phenolic compounds were suspended using 40 mL of methanol. An aliquot of the extract was used for the HPLC and Folin−Ciocalteau analyses. A 2 mL amount of polyphenol extract was adjusted to volume using refined olive oil in a 100 mL volumetric flask, and the oil mixture was treated in an ultrasonic bath for 15 min. Then, methanol was evaporated in a vacuum evaporator (Heidolph VV 200) at 38 °C for 15 min.[28] The polyphenol extract was added to the refined oil all at once and stored in a refrigerated environment. Before the analyses were carried out, the solution was brought to room temperature. The amount of phenolic compounds (328 mg kg^{-1}) added to the refined olive oil was chosen on the basis of the average levels reported in the literature for extra virgin olive oil, equivalent to about 260 mg kg^{-1} of total phenolic compounds.[29] This level is between 220 and 340 mg kg^{-1}: i.e., it corresponds to the slightly bitter taste of VOO.[30]

Preparation of the Refined Olive Oil Sample (ROO). In the control sample the phenolic extract was not added; 2 mL of methanol was adjusted to volume using refined olive oil in a 100 mL volumetric flask. Then, the oil phase was submitted to the same protocol previously described for phenolic compound addition.

Preparation of the Oil Aroma Solution. The most abundant and significant volatile compounds of virgin olive oils were considered in our study for preparing the solutions of aroma compounds,

[a] n = number of calibration points. r^2 = linear regression coefficient. [b] The odor descriptors were indicated as reported in the literature. [c] Molecular weight. [d] Number of carbon atoms. [e] The logarithms of octanol/water, octanol/air, and air/water partition coefficients (log P) and vapor pressures of the volatile compounds were calculated using EPI Suite v.4.1 software, U.S. Environmental Protection Agency and Syracuse Research Corp. [f] Bold numbers indicate quantifier ions.

according to the literature.[31] They included five esters, three aldehydes, two alcohols, one ketone and one terpene compound (Table 1). Volatile compounds were dissolved in 10 mL of refined olive oil and homogeneously mixed. The aroma solution was obtained by diluting 4 mL of each volatile compound in oil to 100 mL of refined oil. The aroma solution was added to the oil sample 1 h before the analysis, in order to allow its stabilization. The final concentration for each volatile compound in an oil sample is reported in Table 1. The concentrations were chosen to stay within the range typically found in extra virgin olive oil.[5,31]

Preparation of the Whey Protein Solution (WP). We considered the amount of whey proteins and the pH of the relative solution (11% and 5.8−6.6, respectively) to simulate a real food product commonly used in many food preparations: i.e., ricotta cheese (obtained from whey by adding sodium chloride and thermally treated to separate the upper phase). Whey protein isolate (95%) was supplied by ACEF s.p.a. (Fiorenzuola d'Arda, PC, Italy). Therefore, a water solution at 11% (WP) was prepared in an ammonium acetate buffer solution. The buffer solution was added to 27.5 g of whey protein isolate. The 0.4% ammonium acetate buffer solution (Sigma-Aldrich, Germany) was acidified to pH 6 by using acetic acid solution (Romil, U.K.) by using a few drops in 250 mL of the buffer solution. Whey protein isolate was characterized by 96.7% proteins, 2% ashes, 0.3% fat (dry weight), and 4.7% humidity.

Human Saliva Sampling. Mixed whole saliva (about 150 mL) was separately collected from 14 nonsmoking subjects (8 males and 6 females, 23−48 years of age) from the Department of Agriculture, University of Naples Federico II.[32] Saliva was separated into aliquots of 2 mL and frozen at −20 °C. Before being used, the samples were held in a thermal bath at 37 °C and shaken in order to dissolve any suspension.

Free Acidity, Peroxide Value, and Specific Ultraviolet Absorbances. Refined olive oil (ROO) and EVOO (from Ravece cultivar) were analyzed to determine their acidity levels, peroxide value, and K_{232}, K_{270} and ΔK values according to UE Reg. 2568/91. Acidity was expressed as oleic acid percentage (%), while the peroxide value (PV) was expressed as mequiv of O_2 per kg of oil. For the analysis of spectrophotometric indices a UV−visible Shimadzu UV-1601 spectrophotometer (Shimadzu, Kyoto, Japan) was used. All of the analyses were performed in triplicate.

Extraction and Analysis of Phenolic Compounds. The phenolic compounds were analyzed in both ROO and EVOO Ravece samples. The extraction of phenolic compounds was performed according to Vásquez-Roncero,[33] but slightly modified, in order to minimize the volume of solvent used. A 10 g portion of he sample was dissolved in 10 mL of hexane and vigorously shaken for 10 s. Then, the sample was extracted via a separating funnel by using three 7 mL portions of a water/methanol mixture (40/60 v/v). The obtained hydro-alcoholic extract was washed with hexane to remove any oil contamination and centrifuged (ALC International Ltd., mod. PK 120, Milan, Italy) for 10 min at 3500 rpm. The organic phase was removed from the extract. Thereafter, the lower phase was collected in a flask and evaporated under vacuum in a rotary evaporator (Heidolph, VV 2000) at 40 °C. The obtained residue was dissolved in 2 mL of methanol to obtain the final phenolic extract, and an aliquot of this solution was used for the analysis of phenolic compounds. All of the extractions were performed in duplicate. The quantification of total phenolic compounds was carried out by using the Folin−Ciocalteau colorimetric method according to Gutfinger.[34] The samples were diluted 1/50, and the solvent was completely removed by using a constant nitrogen flow. Distilled water (200 μL) was added to the polyphenol extract, and 800 μL of 7.5% sodium carbonate (Na_2CO_3)

[a]Acidity is expressed as oleic acid equivalent. Peroxide value is expressed as mequiv of O_2 per kg of oil. Values are the average of three replicates (n = 3).

and 1 mL of Folin−Ciocalteau (2 N) previously diluted by using distilled water (1/10) were finally added to the solution. The samples were left for 30 min in the dark at room temperature.[35] Absorbance was measured at 765 nm wavelength by using a UV-1601 spectrophotometer (Shimadzu, Kyoto, Japan). The blank samples consisted of 200 μL of distilled water and all of the other reagents previously described. The total phenolic content was determined by using a calibration curve constructed with caffeic acid and expressed as mg of caffeic acid per kg of oil. The analyses were performed in triplicate for each extraction.

Release of Aroma Compounds in Model Mouth System. The measurement of aroma compound headspace release was performed under dynamic conditions using an experimental RAS, as previously reported in the literature.[6,17,36,37] A 10 μL portion of aroma solution was added to 1.66 mL of the oil sample, and the solution was left to react for 50 min. Subsequently, 8.33 mL of buffer or whey protein solution was added to the system and gently mixed by using a magnetic stirrer (200 rpm) for 10 min. After 1 h, 10 mL of oil-in-water emulsion to which 10 μL of internal standard was previously added (500 mg L^{-1} isobutyl acetate, 99.8% purity, Fluka, Buchs, Switzerland) was transferred into a cylindrical glass jar (100 mL) of the model mouth system. Then, human saliva or distilled water (2 mL), at the same pH of saliva, was added to the system, which was kept in a water bath (Analitica De Mori, Milano, Italy) at 37 °C. The SPME fiber was inserted through the Teflon septum in the RAS and exposed to the sample headspace. Nitrogen flow (20 mL s^{-1}) was passed through the sample for 4 min. During this time, the volatile compounds were trapped on the fiber. The exposure time was chosen according to data previously reported by other authors.[6,38] In addition, this exposure time could represent a realistic application to study the retronasal aroma perception of a food during the simulation of its consumption, as longer times would represent an unrealistic situation.

Dynamic Headspace−Solid Phase Microextraction (SPME) and GC/MS Analysis. The SPME device (Supelco Co., Bellefonte, PA, USA) was equipped with a 50/30 μm thickness divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS) fiber coated with a 2 cm length stationary phase. Volatile compounds were analyzed by GC coupled with a mass spectrometer using a GC/MS Shimadzu Model QP5050A instrument (Kyoto, Japan) equipped with a Supelcowax-10 capillary column (60 m × 0.32 mm i.d., with 0.5 μm thickness) (Supelco Co., Bellefonte, PA, USA). The temperature was set at 40 °C for 4 min followed by an increase of 3.5 °C min^{-1} up to 240 °C and was held at that temperature for 3 min. The injector was kept at 230 °C. Helium was used as the carrier gas (1.4 mL min^{-1}). Volatile compound thermal desorption was carried out by exposing the SPME fiber in the injector for 10 min. The compound identification was performed by comparing retention times and mass spectra obtained by analyzing pure reference compounds under the same conditions. Moreover, the identification was confirmed by comparing mass spectra with those of the NIST database. Mass spectra were recorded at 70 eV. The source temperature was 200 °C, and the interface temperature was 250 °C. Before it was used, the fiber was conditioned at 270 °C for 1 h for the analysis. A blank test was performed before each analysis to prevent the release of undesirable compounds. All of the analyses were performed in triplicate.

Quantitative Analysis. The quantitative analysis of olive oil volatile compounds was carried out by using selected ion monitoring (SIM). The selected ions for each volatile compound are given in Table 1. The peak areas of each compound were normalized with respect to the area of the internal standard peak and interpolated on the calibration curve. A calibration curve for each molecule was constructed by preparing a solution containing known amounts of analyte in the oil and the internal standard. The oil was diluted in order to obtain one to seven solutions with decreasing values of the concentration of analytes, and each of these solutions was analyzed by SPME-GC/MS in selected ion monitoring, by applying the same conditions previously reported. The concentration range considered for the calibration curve of each molecule (Table 1) was within the values typically found in virgin olive oil.[5,31] The peak areas were calculated by using a Lab solutions acquisition system (GCMS solutions version 1.20; Shimadzu, Kyoto, Japan). The linear regression coefficient (r^2) for the studied volatile compounds was satisfactory, resulting in a value higher than 0.9983 (Table 1).

Statistical Analysis of Data. Significant differences among the different model systems were determined for each compound by one-way ANOVA statistical analysis. Tukey's test was used to discriminate among the means of the variables. Differences with $p < 0.05$ were considered significant. In order to better understand the influence of saliva, biophenols, and WP presence in the food model system, as well as their interactions, on the volatile compound concentration, a multifactor analysis of variance (ANOVA) with second-order interactions was carried out. The data elaboration was carried out using XLStat (version 2009.3.02), an add-in software package for Microsoft Excel (Addinsoft Corp., Paris, France).

RESULTS AND DISCUSSION

Table 2 reports the free acidity, peroxide value, ultraviolet indices (K_{232}, K_{270}, ΔK), and total phenolic compounds in refined and extra virgin olive oils. Free acidity, peroxide value, K_{232}, K_{270}, and ΔK of all olive oil samples were within the legal limits of the category they belong to: i.e., extra virgin olive oil (EC 2568/91). VOO total phenolic compounds, quantified by the Folin−Ciocalteau colorimetric method, were 431 ± 93 mg kg^{-1}. With regard to the refined olive oil, the phenolic compounds were about 44 ± 7 mg kg^{-1}, while in the refined olive oil with an extract of VOO biophenols added their level was 328 ± 59 mg kg^{-1}.

Effect of WP Addition on VOO Aroma Release in the Presence of Biophenols. To verify the effect of the interaction between WP and VOO on aroma release, several model systems were added to VOO phenolic compounds, to reach a final concentration of 328 mg kg^{-1}. The aroma compounds were set up and were kept to interact with WP. In these systems, VOO aroma compounds are partitioned between the two liquid phases (water and oil) and liquid and gas phase (air). In addition, by its emulsion destabilization effect,[13,14] saliva could further affect the volatile compound partition. This complex balance could lead to a different aroma release in comparison to the initial level of volatile compounds in olive oil. In order to better detect these differences in headspace aroma release, a comparison was carried out by

analyzing the levels of added volatile compounds by using only refined olive oil (ROO): i.e., without interaction of WP and saliva (it is possible to refer to it as orthonasal odor). In the systems without whey proteins (WP) a buffer solution (B) was added to obtain the same headspace volume in all of the samples. The extent of simulated retronasal release of ethyl esters (Figure 1) was similar among the three molecules belonging to this chemical class (ethyl isobutyrate, ethyl butyrate, and ethyl 2-methylbutyrate). Saliva seems to cause a significant decrease in the release of the three esters analyzed without whey protein interaction (ROOP+B). This result could be explained by the binding effects of human saliva, as demonstrated by other researchers, who attributed it to both the chemical binding or hydrolysis and/or physical trapping of volatile compounds mainly caused by mucin.[17,32,36,39] In addition, in the whey protein system (ROOP+WP) a significant and considerable decrease in the release of the ethyl esters was obtained, and this result is in accordance with the literature,[9] but in the systems in which WP interacted with saliva, the decrease was lower. This behavior could be explained by a possible interaction between human salivary constituents and whey proteins, with the result that their action on these volatile compounds could be limited. In fact, it was shown that mucins form aggregates with β-lactoglobulin in aqueous and in oil-in-water emulsions.[40,41] These kinds of interactions, which occur *in vivo* during the consumption of dairy products, might be responsible for the sensory astringency.[42] In fact, in agreement with the well-accepted astringency model of wine polyphenols,[43] this sensation is due to the loss of lubrication of saliva when mucin and lactoglobulin interact to form an aggregate, which precipitates and leads to a dryness and roughness perception in the mouth. Therefore, as reported for red wine in the case of mucin and polyphenols,[36] in addition to sensory astringency, mucin and whey protein interaction affect the extent of ester release. A similar behavior was observed for acetates (hexyl acetate and *cis*-3-hexenyl acetate). In the case of this class of compounds, the level of aroma release was lower in the presence of saliva in the buffer system (ROOP+B) with respect to that of distilled water (no saliva), while in the systems with WP and saliva the lower decrease of aroma compounds was observed only for *cis*-3-hexenyl acetate (Figure 1). The result obtained for hexenyl acetate was in line with that for other acetates, whereas, in this case, statistical significance was not reached. In fact, it was demonstrated that, within one chemical class, the affinity for β-lactoglobulin increases with hydrophobic chain length or overall hydrophobicity (expressed

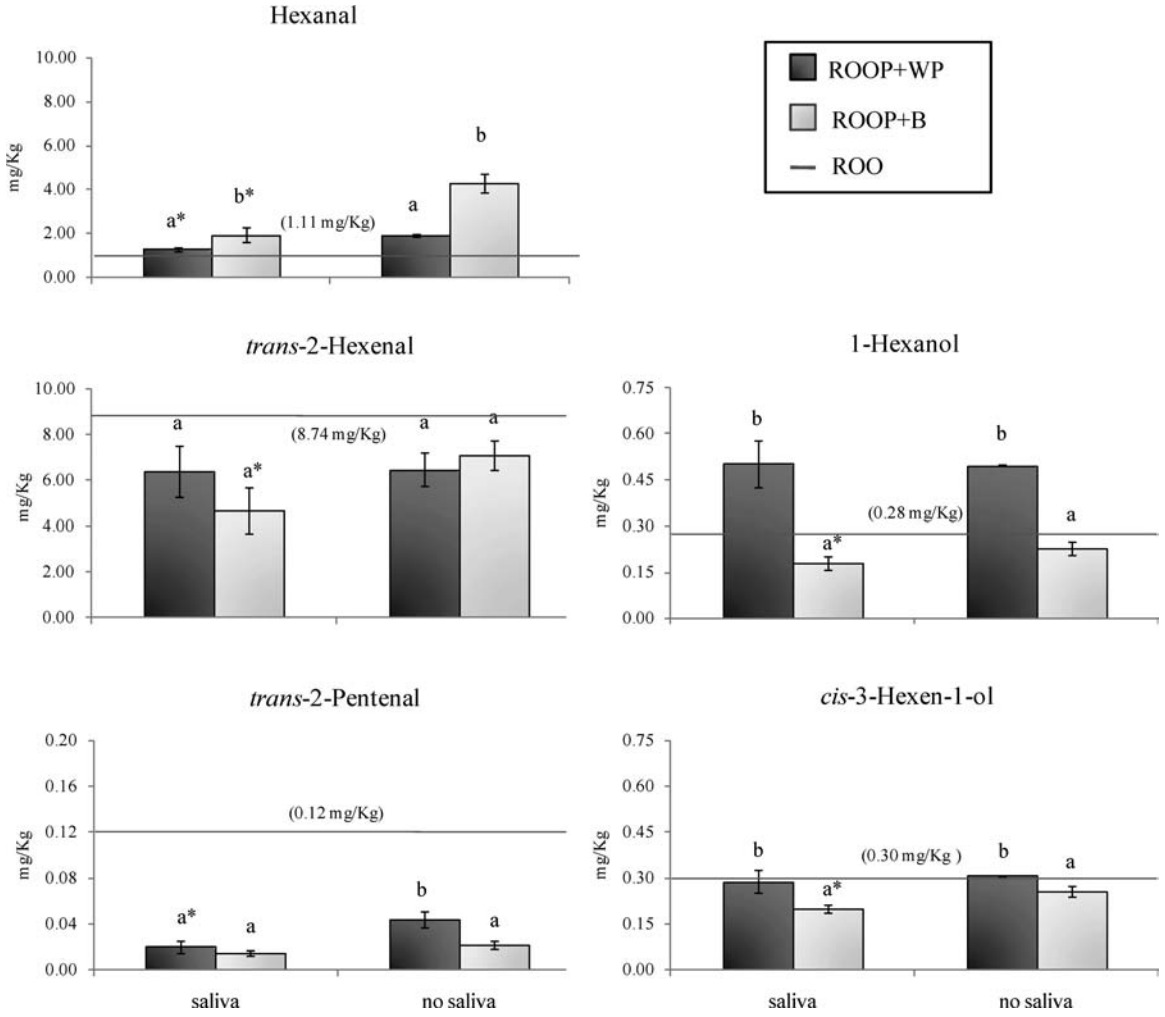

Figure 2. Headspace concentration of aldehydes and C_6-alcohols in the refined olive oil model system with the addition of VOO phenolic compounds (ROOP) in the presence (WP) and absence (B) of whey protein and saliva. Lines indicate the level of volatile headspace release in refined olive oil (ROO) without interaction with WP and saliva. Different letters indicate significant differences ($p < 0.05$) between WP and blank samples. Asterisks indicate significant differences between saliva/no saliva runs.

as log $P_{o/w}$ values).[9] Hexenyl acetate, which has a log $P_{o/w}$ value of 2.83, showed a higher affinity to whey proteins than the other volatile compounds. Therefore, this compound gave a lower release than *cis*-3-hexenyl acetate (log $P_{o/w}$ 2.61), which had lower affinity and higher headspace release.

In all of the systems in which saliva or whey proteins were added, a lower release of ethyl esters was obtained under simulated retronasal conditions with respect to the orthonasal simulation assay, only for refined olive oil (ROO without addition of saliva and whey proteins). In contrast, in the system without saliva and whey proteins, a higher release of ethyl esters was measured. This could indicate not only that aroma release is influenced by the phase separation but also that the increased viscosity of the emulsion could play an important role in the aroma release.

The behavior obtained for aldehydes (hexanal, *trans*-2-pentenal, *trans*-2-hexenal) was quite different (Figure 2). The addition of saliva clearly resulted in a decrease of hexanal headspace concentration with respect to distilled water. When WP was added to the systems, a significantly lower headspace concentration was observed, which indicates a possible further binding of hexanal by whey proteins. However, the behavior was different in comparison to those discussed for esters: i.e., when WP interacted with saliva there was not a significant increase with respect to whey protein or saliva alone, where a further decrease in headspace concentration was observed. Probably, this occurs because most of the aliphatic aldehydes are also linked to proteins by covalent irreversible bonds, as reported for β-lactoglobulin[8,9] and mucin,[7,39] to form Schiff bases. In contrast, in the case of esters and acetates, the interactions between protein and aroma compounds are reversible, involving only hydrophobic binding sites. In the first case, when the bonds to proteins are covalent, i.e. irreversible, a cumulative effect of the individual reaction occurs. Otherwise, in the latter case reversible hydrophobic or hydrogen bonds occur, resulting in an antagonistic and not a cumulative effect. Hexanal headspace concentration decreased in the presence of human saliva and WP, in accordance with Weel et al.,[44] who reported an *in vivo* study. A dissimilar phenomenon was observed in the case of *trans*-2-hexenal and *trans*-2-pentenal. The first showed a lower headspace concentration only in the buffer system with saliva, while the latter had a lower concentration in the presence of whey proteins. As discussed for acetates, this difference could be due to different hydrophobicities (expressed as log $P_{o/w}$ values) of aldehydes.[9] In fact, hexanal, which has a log P value of 1.8,

showed a lower release than *trans*-2-pentenal (log $P_{o/w}$ = 1.9), while *trans*-2-hexenal, characterized by an intermediate log $P_{o/w}$ value (1.58), showed an intermediate release. It is important to note that, among the aldehydes, only hexanal showed a higher retronasal release with respect to the orthonasal simulation assay of only refined olive oil (ROO without addition of saliva and WP). This behavior was also previously reported for fresh sunflower oil-in-water emulsions analyzed by a mouth model system and related to hexanal generation by lipid oxidation reactions.[17]

The two studied alcohols (1-hexenol and *cis*-3-hexen-1-ol) showed similar behavior: when WP was not added to the system, saliva caused a decrease in headspace release (Figure 2). When WP was present, no significant difference was observed in aroma release between the system with distilled water and those with human saliva. As discussed for ethyl esters, this phenomenon occurs because of the interaction between mucin and whey proteins which limits their action on alcohols. Therefore, this finally results in a higher release of these compounds. The retronasal release of 1-hexanol in the system with whey proteins was dramatically higher with respect to the orthonasal simulation assay of only refined olive oil (ROO) and significantly higher with respect to the buffer system. This so-called *salting-out* effect, accompanied by a decrease of about the same magnitude in hexanal headspace concentration, was reported by other authors[44] and was attributed to an enzymatic conversion of these two compounds. In Figure 3 the headspace release of 1-penten-3-one and linanool was shown. The retronasal concentration of 1-penten-3-one was significantly higher when distilled water was used instead of human saliva, but only in the buffer system solution. In fact, no statistical difference was observed between the buffer solution and saliva in the system with whey proteins. This result suggests that the presence of whey proteins has a strong effect over the headspace release of some aroma compounds, resulting in a retention effect similar to that caused by human saliva. Whey proteins seem to have stronger binding effects on retronasal concentration than 1-penten-3-one, due to possible chemical binding, as reported for 2-nonanone, a similar hydrophobic volatile compound.[45] In contrast, in the system with saliva, this phenomenon was not observed, probably because the binding sites of the volatile compound interacting with proteins are not available for further reaction with other proteins such as mucin. In fact, when whey proteins are added to such a system,

covalent and irreversible interactions occur, as was also reported for aldehydes.[7,9]

In the case of linalool, its headspace concentration in simulated retronasal aroma was always lower than that of the orthonasal simulation assay of ROO. Particularly, in both the buffer and whey protein systems, saliva caused a significantly lower concentration of linalool with respect to distilled water. In systems without saliva, a higher release of linalool was measured in the headspace in comparison to that for the buffer system when WP was added. In other words, also in this case the salting-out effect was observed when whey proteins were added to the system with distilled water. This behavior was previously reported in the literature to be particularly affected at low pH values for other terpene compounds, such as limonene and myrcene.[46] These compounds have highly hydrophobic properties (log $P_{o/w}$ = 4.38 and 4.17, respectively, EPI Suite v.4.1 software, U.S. Environmental Protection Agency and Syracuse Research Corp.) close to those of linalool (log $P_{o/w}$ =

3.38). This difference was not detected when human saliva was used, and this result was explained by the interaction between salivary components and whey proteins, as previously discussed.

In order to better understand the influence of saliva and whey proteins, as well as the interactions among these factors on the retronasal aroma release in olive oil, a multifactorial ANOVA analysis was carried out. Table 3 shows the *F* ratio, *p* value, and direction of the effect of the factors on the average relative recoveries of the aroma compounds. The *F* ratio represents the quotient between the variability due to the effect considered and the residual variance. The higher the *F* ratio value, the more marked the effect of that factor with reference to a variable at $p < 0.05$. The sign of the effect shows the direction of the influence. Whey proteins seem to have a negative effect on the aroma release in the case of ethyl esters, hexanal, and 1-penten-3-one, responsible for fruit, green, and pungent odors, respectively (Table 1). In contrast, they showed a positive effect on *trans*-2-pentenal (green), 1-hexanol (fruit), and linalool (floral). Saliva showed a negative effect on all volatile compound concentrations, except for 1-hexanol. The interaction between the two factors took place for the majority of the volatile compounds, except for both acetates and alcohols. The results herein described suggest that whey proteins affect the aroma release of VOO but their interaction with saliva has an antagonistic effect on ester, acetate, and alcohol release while being synergistic for aldehydes and ketones. This different effect may imply a higher perception of fruity notes of VOO and a lower perception of green notes when VOO and dairy products are paired, if confirmed by further sensory studies.

Effect of Whey Protein Addition on EVOO Aroma Release. In the present section of our study a real sample of extra virgin olive oil was tested. In order to compare this system (EVOO cv. Ravece) and the model systems (refined olive oil added with selected aroma compounds), a quantification of volatile compounds was performed. EVOO (Figure 4) generally showed a slightly different behavior in comparison to the "simulated VOO" (Figures 1−3). Ethyl esters and linalool were not found in the EVOO headspace, mainly being present at a trace level. At low levels, ethyl esters contribute to the olive oil flavor,[31] while at higher levels they are associated with the fusty defect of virgin olive oil.[47] Linalool, as well as all terpene compounds, could depend on their variety.[48] Generally, headspace releases of volatile compounds were similar among their chemical classes: e.g., the releases of aldehydes and ketones were lowered by the presence of WP, with no effects or slight effects of saliva addition. For acetate compounds, no

Lines indicate the level of volatile headspace release in refined olive oil (ROO) without interaction with WP and saliva. Different letters indicate significant differences ($p < 0.05$) between ROOP and blank samples (ROO). Asterisks indicate significant differences between saliva/no saliva runs.

dramatic differences were observed. Alcohols had a slight tendency to higher headspace release when WP was added, and also in this case saliva showed no statistical differences. Therefore, it is possible to state that WP affects the VOO aroma release more than our model systems simulating VOO, while human saliva, in contrast, showed an opposite trend. In contrast to the model systems, the release of volatile compounds seems to be more in accordance with the chemical class they belong to. These differences are probably due to the chemical complexity of virgin olive oil in terms of both volatile and nonvolatile compounds. This complexity leads to a higher competition in the interaction among volatile compounds, human saliva, and WP which can affect their partition and release. In addition, the nature of the phenolic compounds and their physicochemical properties affect the dispersion properties and the oxidative stability of olive oil O/W emulsified systems.[49] Further studies to deepen the possible specific effect of individual phenolic compounds on aroma release are needed.

Effect of EVOO Biophenol Addition on Aroma Release in the Presence of Whey Proteins. In the previous section an oil-in-water emulsion was studied, by considering a pairing between VOO and WP. It is known that VOO is naturally rich in phenolic compounds, which are important for human health. They are probably also involved in the *in vivo* aroma release during consumption of this food paired with other food products. For this reason, the specific effect of VOO biophenol presence was studied by comparing a system with refined olive oil and refined olive oil added with olive oil biophenols. All of the model systems were made to interact with whey proteins. As shown in Figure 5, no statistical difference was obtained for ethyl esters between the system with phenolic compounds and the blank (absence of phenolics). Biophenols did not influence the release of either ethyl esters or acetate compounds in the presence of saliva. However, in the system with distilled water a significantly higher level of acetate compounds was found in ROOP in comparison to that for ROO. This phenomenon is probably due to a weak salting-out effect, as occurs for wine polyphenols.[50] In contrast, in the presence of saliva this level decreases due to the possible action of the carboxylesterases, which would be able to hydrolyze these aroma compounds.[32] In all of the systems, however, a lower release of volatile compounds was measured in simulated retronasal assays with respect to the orthonasal simulation assays of ROO.

More interesting results were obtained for aldehydes (Figure 6). In these systems higher release of 1-hexanol was measured in simulated retronasal assays with respect to the orthonasal simulation assay of only ROO. For hexanal, this occurs only for model systems with phenolic compound addition. A significant

effect of addition of both saliva and biophenols was observed. In particular, saliva seems to decrease the headspace release of aldehydes, while the presence of phenolic compounds seems to enhance their headspace release. For *trans*-2-hexenal, the concentration was always significantly higher when biophenols were added, but for this compound no difference was observed between distilled water and saliva, in the system with biophenols. This result strongly suggests that biophenols had a salting-out effect, for a possible interaction between phenolic compounds and WP. In fact, in these model systems the addition of WP is always responsible for both irreversible covalent and hydrophobic bonds with these volatile compounds,[8] as previously discussed. When VOO biophenols were added to the systems, they weakly interacted with whey proteins,[27] with the result that the binding sites may be much less available for hydrophobic interactions with aldehydes. In the model system with saliva addition the release was lower than that for distilled water due to the mucin interaction.[6,39]

A similar result was obtained for alcohols, which resulted in significantly higher headspace concentration in the system with phenolic compounds with no saliva addition. No difference was obtained between water and human saliva for 1-hexanol, while a significant but weak increase was observed for *cis*-3-hexen-1-ol (Figure 6). As previously discussed, this behavior could be due to a WP−mucin interaction, which leads to significantly higher concentration of alcohols because it limits their action in trapping alcohols, the hydrophobic binding sites no longer being available. Thus, for this class of compounds the presence of saliva seems to be of little or no effect, while the interaction with biophenols was significant, however. The behavior observed for 1-penten-3-one was similar to that reported for aldehydes and 1-hexanol, i.e. higher headspace release when biophenols were present, even more than the orthonasal simulation assay of only refined olive oil (ROO without the addition of saliva and whey proteins) (Figure 7). No significant difference was obtained between distilled water and the saliva system, due to the high variability obtained in this latter case. In general, the binding capacity of proteins increases from alcohols to ketones and to aldehydes.[8] For this reason the salting-out effect of VOO biophenols, inversely correlated to the binding capacity of whey proteins, was higher for aldehyde than for ketones and alcohols. Linalool headspace concentration was affected by the presence of phenolic compounds only with distilled water (Figure 7). This result could be due to a possible

linalool trapping during the interaction between biophenols and salivary constituents. In any case, its decrease was not due to mucin.[39] In order to better understand the influence of saliva and olive oil biophenols, as well as the interactions among these factors on the retronasal aroma release in olive oil, a multifactorial ANOVA analysis was carried out. Table 4 shows the *F* ratio, *p* value, and direction of the effect of the factors on the average relative recoveries of the aroma compounds. The VOO biophenols seem to have a strong positive effect on the aroma release in the case of both acetates and alcohols, hexanal, *trans*-2-pentenal, linalool, and 1-penten-3-one being responsible for fruit, green, floral, and pungent odors (Table 1). Saliva showed a negative effect on hexanal, *trans*-2-pentenal, linalool, and 1-penten-3-one concentrations; these compounds are responsible for green, floral, and pungent odors (Table 1). The interaction between the two factors took place only for hexanal, *trans*-2-pentenal, and linalool. Therefore, our results suggest that VOO biophenols could enhance the extent of VOO aroma release of volatiles related to green, floral, and pungent notes, while saliva negatively affects this release.

In conclusion, our results indicate that whey proteins negatively affected aroma release, whereas the interaction between proteins and human saliva led to a lower effect, particularly for some volatile compounds, such as acetates and alcohols. The presence of VOO biophenols positively affected the extent of aroma release, probably in competition with the binding of volatile compounds by whey proteins, for the polyphenol−protein interaction phenomenon. Therefore, it is suggested that, in the presence of a higher level of biophenols, VOO would probably have a higher retronasal release of green notes. Our results could be useful for the formulation of new functional foods to modulate flavor release and consumer acceptability, as well as in the design of new food products by using milk industry byproducts and olive mill biophenols. In fact, as these products considered to be waste and polluting substances, their use in functional foods could at least partially solve the problem of their disposal and could enhance the nutritional value of foods: for example, in the case of whey protein added to beverages as dietary supplements.

Depending on the amount and availability of phosphatides, only parts of oilseed gums have the potential to be processed as lecithins. Common lecithin sources include cottonseed, corn, sunflower seed, and rapeseed. Due to the mass production of soybean oil, soybean gum obtained as a byproduct of the oil-refining process is the primary source of commercial lecithin. Recently, the demand for sunflower lecithin has grown because this lecithin is considered the product of a non genetically modified organism.[1,20−22] Moreover, the rheological and emulsifying properties of sunflower lecithin indicate that it is a desirable alternative to soybean lecithin.[20−22] However, little or no information is available regarding the composition of PC molecular species derived from sunflower lecithin. A previous study only focused on the fatty acid composition of lecithin, which was considered to be largely equivalent to that of the oil source.[1] Thus, analyzing PC species in conjunction with triacylglycerol (TAG) composition in crude lecithins may provide a more complete description of the deposition of fatty acids in plant lecithins.

In our previous study, TAG molecular species were successfully determined through HPLC-ELSD analysis by their retention times and theoretical carbon numbers (TCNs).[23] The retention times were found to correspond with their TCNs, which were calculated on the basis of the total carbon number, unsaturation degree, and types of unsaturated fatty acid. Nevertheless, these attempts to establish a correlation between the HPLC elution sequence of the PC molecular species and TCN with regard to the physical conformation of acyl chains remained inconclusive.

In this study, an RP-HPLC-ELSD method intended for the determination of the PC molecular species was introduced. L-α-PC from soybean origin was used to evaluate the chromatographic characteristics. Furthermore, the correlation between the TCNs of PC molecular species and their respective HPLC retention times was investigated. We revealed that, as for TAG, profiling could be achieved by comparison with TAG standards with reference to retention times to make a regression curve; by calculation of the TCN of respective peaks with reference to the regression analysis, PC peak profiling in the HPLC-ELSD chromatogram could be achieved by the regression curve that was made from the TCNs of known peaks with reference to retention times.

MATERIALS AND METHODS

Chemicals. L-α-PC (≥99%), L-α-PE (≥98%), five molecular species of PC, including LLPC, 1,2-dipalmitoyl-*sn*-glycero-3-phosphocholine (PPPC), 1,2-dioleoyl-*sn*-glycero-3-phosphocholine (OOPC), 1-oleoyl-2-palmitoyl-*sn*-glycero-3-phosphocholine (OPPC), and 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), and 2,5-dihydroxybenzoic acid (2,5-DHB) were obtained from Sigma-Aldrich (St. Louis, MO, USA). All chromatographic-grade reagents used in HPLC and other analytical-grade solvents, as well as thin-layer chromatography (TLC) plates silica gel 60 (No. 5553), were obtained from Merck (Darmstadt, Germany). Silica gel (SiliaFlash G60, 70−230 mesh (60−200 μm), average pore size 25 Å) for column chromatography was obtained from SiliCycle (Quebec, Canada). Silica solid-phase extraction cartridges were obtained from J. T. Baker (Phillipsburg, NJ, USA).

Materials. The crude soybean lecithin was obtained as industrial soybean oil degummed residue from the Taiwan Sugar Corporation (Kaohsiung, Taiwan). Sunflower liquid lecithin was bought from Now Foods Company (Bloomingdale, IL, USA). The acetone-soluble fractions of crude soybean lecithin and sunflower liquid lecithin accounted for 43.6% and 61.7%, respectively.

PC Analysis by RP-HPLC-ELSD. The purity of commercially available L-α-PC was examined by TLC. Briefly, a silica gel 60 TLC plate and a mobile phase consisting of chloroform/methanol/acetic acid/water (75/40/8/3, v/v/v/v) were used for the separation of phospholipids. L-α-PC standard solution was prepared by dissolving 5 mg of L-α-PC in 1 mL of methanol, and then 10 μL of sample was applied by a microsyringe to the TLC plate prior to developing. The spot was visualized using iodine vapor and exposed in an oven set at 60 °C for 5 min. For HPLC analysis, a 20 μL aliquot of the PC sample was analyzed using an HPLC system (P1000, Thermo Fisher Scientific, Barrington, IL, USA) equipped with an ELSD (Alltech 2000, Deerfield, IL, USA) and a C30 analytical column (Develosil C30-UG-5, 4.6 × 250 mm, 5 μm; Nomura Chemical Co., Anada-cho Seto, Japan). The mobile phase was composed of acetonitrile, methanol, and triethylamine in a 40/58/2 ratio (v/v/v) at a flow rate of 1 mL/min. For the ELSD, the temperature of the drift tube was 80 °C and the air flow rate was 1.8 L/min. Each run lasted 40 min and required another 10 min to reach equilibrium. In addition, to quantitate the individual PC species, five species of pure PC molecules, namely LLPC, PPPC, OOPC, OPPC, and POPC, were analyzed at concentrations of 0.25, 0.5, 1, 2, and 5 g/L to prepare calibration curves.

Identification of PC Molecular Species by MALDI-TOF-MS. To identify the fatty acyl chains at the *sn*-1 and *sn*-2 positions, each PC molecular species eluted from HPLC was collected manually by using a flow splitter according to retention time and then analyzed by MALDI-TOF-MS. Aliquots of the PC samples were directly mixed (1/1, v/v) with the 2,5-DHB matrix solution (1 mL of 20 mg/mL 2,5-DHB in 70% acetonitrile with 0.1% trifluoroacetic acid). A 1 μL portion of the PC sample solution was used for MALDI-TOF-MS analysis. The sample/matrix solution was deposited onto the sample plate and vacuum-dried before being transferred into the ion source of a MALDI-TOF-MS (Autoflex III, Bruker Daltonics, Bremen, Germany). The sample spot was irradiated with a neodymium-doped yttrium aluminum garnet (Nd:YAG) laser (emitting at 355 nm; pulse duration, 3 ns; 100 Hz) for desorption and ionization. The extraction voltage was set to 2.5 kV, and gated matrix suppression was applied to prevent detector saturation. Positive ion mass spectra in the range m/z 400−1000 were acquired in reflectron mode under delayed extraction. In total, 300 laser shots were averaged for each sample analysis to obtain representative mass spectra, and three mass spectra were recorded from each sample.

Isolation of PC from Lecithins. The crude lecithins from soybean and sunflower seeds were fractionated by acetone prior to silica gel column chromatography. Briefly, 10 g of the crude lecithin was suspended with acetone (1/5, w/v), and then the insoluble fraction was separated from the solvent. This step was performed two or three times until the supernatant was colorless. The acetone-insoluble fraction was resuspended with 95% ethanol (1/4, w/v). The alcohol fraction was concentrated to approximately 20 mL under vacuum and then mixed with 10 g of Celite to obtain the preadsorbed sample for further silica gel chromatography. After the solvent was removed using a rotary evaporator, the dry powder was transferred to the top of the silica gel column (containing 40 g of silica gel, 2.2 cm i.d. × 28 cm) that had been previously equilibrated with ethyl acetate. Chromatography was performed by eluting the column with 180 mL of ethyl acetate to remove neutral lipids and impurities, and then eluting with 180 mL of ethanol, followed by 300 mL of methanol. The eluate was collected in 30 mL fractions and was monitored by TLC according to retention value (R_f). L-α-PE and L-α-PC standard solutions were used in TLC analysis as references. The fractions dominated by PC were combined, and the solvent was removed under reduced pressure for further analyses of PC content and molecular species.

The PC content of the sample was measured using a normal phase HPLC system equipped with a ConstraMetric 3200 solvent delivery pump and a SpectroMonitor 3200 UV−visible detector (Thermo Fisher Scientific, Barrington, IL, USA). Analysis was performed according to the American Oil Chemists' Society (AOCS) official method Ja 7b-91. The analytical column was a 250 × 4.6 mm i.d. 5 μm Reprosil 70 Si column (Dr. Maisch GmbH, Ammerbuch, Germany).

J. Agric. Food Chem. 2015, 63, 3851−3858

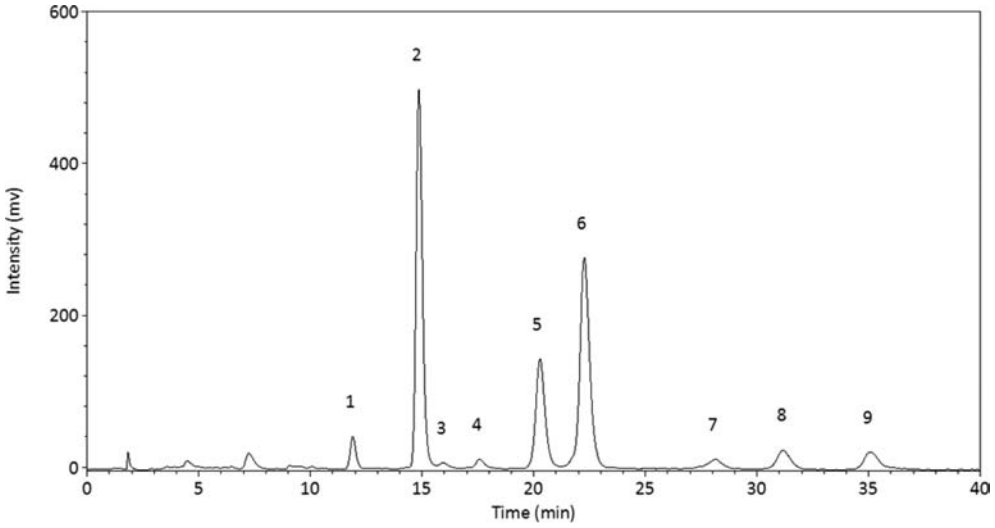

Figure 1. Chromatogram of L-α-PC by RP-HPLC-ELSD. Separation was performed using isocratic conditions: acetonitrile/methanol/triethylamine (40/58/2, v/v/v) at a flow rate of 1 mL/min on a C30 column (250 × 4.6 mm, 5 μm). Numbers were assigned to major identified peaks by MALDI-TOF-MS: (1) LLnPC; (2) LLPC; (3) OLnPC; (4) PLnPC; (5) OLPC; (6) PLPC; (7) SLPC; (8) PPPC; (9) SOPC.

The HPLC mobile phase was composed of *n*-hexane, isopropyl alcohol, and 0.2 M acetate buffer (pH 4.2) in a ratio of 8/8/1 (v/v/v) at a flow rate of 2 mL/min. The detection wavelength was set at 206 nm. The retention time of L-α-PC was used as a reference to determine the PC peak in lecithin profiles. The PC content was calculated from a linear calibrated curve derived from the corresponding peak areas of a serial dilution of authentic L-α-PC standard.

TAG Species Analysis by RP-HPLC-ELSD. The acetone-soluble fractions of crude lecithins were combined, and the solvent was removed under vacuum to obtain the oil. The TAG species of oils were analyzed on the basis of a previous study with some modifications.[23] Briefly, oil samples were dissolved in a small amount of *n*-hexane and pretreated using a silica solid-phase extraction cartridge to remove the potent polar constituents prior to HPLC analysis. The HPLC mobile phase was composed of acetonitrile (solvent A) and isopropyl alcohol (solvent B); the gradient elution started with 85% A, decreased to 30% over 55 min, was held at 30% for 10 min, and finally increased to 85% A over the next 5 min. The flow rate of the mobile phase was 1.2 mL/min. ELSD settings were 70 °C for the drift tube and a 2.0 L/min air flow rate. The peaks were determined by calculating the TCN and referencing the results with our previous study.[23] The percentage of TAG species was calculated using eq 1:

$$\%\ \text{of TAG} = \frac{A(\text{peak area of individual TAG species})}{\sum A(\text{total peak areas of TAG})} \times 100 \quad (1)$$

Data Analysis. The HPLC chromatograms were recorded and analyzed using SISC Chromatography Data Station v3.0 (SISC Inc., Taipei, Taiwan), and the results were calculated using Windows Excel 2010. The peak picking software used with MALDI-TOF-MS was FlexAnalysis 3.3 (Bruker Daltonics).

RESULTS AND DISCUSSION

PC Molecular Species Analysis by RP-HPLC-ELSD. L-α-PC was used as the reference to evaluate the separation of various species. L-α-PC was examined by TLC and presented as a single spot (R_f 0.41) on the silica-TLC plate, indicating that it was an assemblage of PC molecular species. Brouwers et al. reported that the separation was performed by connecting two C18 columns in series; the retention of PC molecular species decreased as the amount of triethylamine in the mobile phase increased, and the optimized solvent system varied with the different PC molecular species patterns of biological samples from animal origin.[11] We considered that triethylamine acted as an ion-pair reagent to reduce extensive peak tailing, because amines are known to prevent interactions between the stationary phase and the phospholipid headgroup moiety. Moreover, because of the repulsion between the positively charged choline of PC and triethylamine, the chromatographic time could be reduced by the addition of triethylamine. We obtained results similar to those of Brouwers et al.;[11] the content of triethylamine in the mobile phase affected the efficiency of separation greatly. Figure 1 revealed that nine molecular species of PC in L-α-PC were separated successfully through an isocratic mobile phase that was composed of acetonitrile/methanol/triethylamine (40/58/2, v/v/v); moreover, only one C30 column was used in the HPLC system, which could reduce excessive back pressure in the HPLC system.

Identification of PC Molecular Species by MALDI-TOF-MS. To identify the PC species corresponding with the individual peaks in the HPLC chromatogram, L-α-PC was analyzed using MALDI-TOF-MS in positive-ion mode. The identification of fatty acyl chains and the regiodistribution of individual PC species in these chains was achieved by verifying the fragment ions from the spectra. Parts A–E of Figure 2 shows the fragmentation patterns of the PC molecules associated with peak nos. 1, 2, 4, 6, and 7 in Figure 1. The mass signal at m/z 520.3 in Figure 2A refers to the molecular ion $[M + H]^+$ of lysophosphatidylcholine (LPC) esterified with linoleic acid. Furthermore, m/z 780.5 was identified as the molecular ion $[M + H]^+$ of linoleoyl-linolenoyl-glycerophosphocholine, whereas m/z 802.5 corresponded to the molecular ion of $[M + Na]^+$. Previous studies have reported that all PC molecular species normally occur in LPCs and fatty acids.[24] In addition, the *sn*-2 position of phospholipids contains unsaturated fatty acid, and the saturated fatty acids are most abundant at the *sn*-1 position.[25] Fuchs et al. reported that the resulting LPCs from diacyl-PCs possess a saturated fatty acid residue at the *sn*-1 position.[26] Therefore, the PC molecular species of peak no. 1 was identified as 1-linoleoyl-2-linolenoyl-*sn*-glycero-3-phosphocholine (LLnPC). Similar results can be observed in

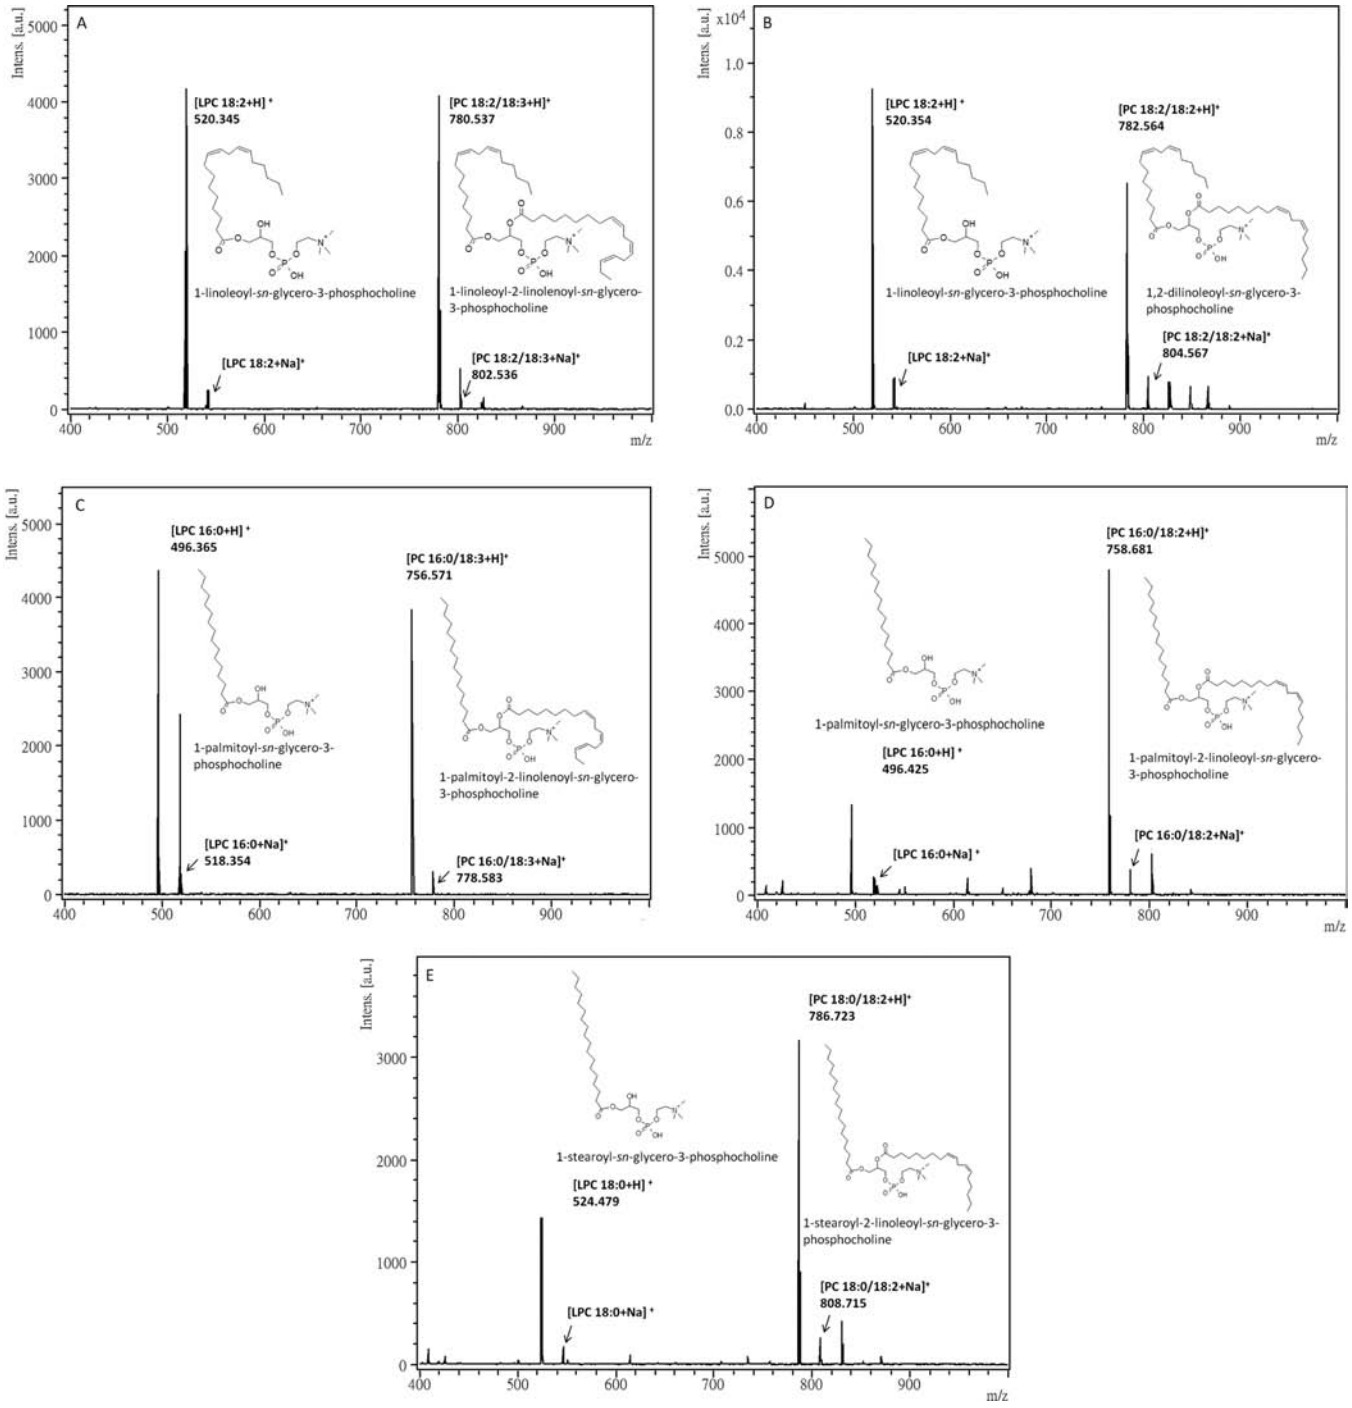

Figure 2. Ions obtained by MALDI-TOF-MS in positive-ion mode from m/z 400 to 1000 and corresponding structures of product nos. 1 (A), 2 (B), 4 (C), 6 (D), and 7 (E) in the L-α-PC profile. C16:0 refers to palmitic acid, C18:0 refers to stearic acid, C18:1 refers to oleic acid, C18:2 refers to linoleic acid, and C18:3 refers to linolenic acid.

Figure 2B–E. As far as L-α-PC was concerned, the major species were LLPC, 1-oleoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (OLPC), and 1-palmitoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (PLPC), with LLPC being the predominant species, whereas minor components included LLnPC, 1-oleoyl-2-linolenoyl-*sn*-glycero-3-phosphocholine (OLnPC), 1-palmitoyl-2-linolenoyl-*sn*-glycero-3-phosphocholine (PLnPC), 1-stearoyl-2-linoleoyl-*sn*-glycero-3-phosphocholine (SLPC), PPPC, and 1-stearoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (SOPC). The PC composition was in good agreement with that in previous studies.[14,15]

PC Profiling: Relation between Retention Time and TCN. The TCN of PC (TCN_{PC}) was calculated according to the TCN of TAG (TCN_{TAG}) with some modification. The equivalent carbon numbers (ECNs), TCNs, and retention times of L-α-PC and soy TAG molecular species are shown in Table 1. According to El-Hamdy and Perkins, TAGs with the same ECN act as critical pairs, which means that these TAGs behaved similarly in response to RP chromatography in spite of the difference in chain lengths, number of double bonds, geometrical configuration, and their ability to be further

[a] ECN_{TAG}, TCN_{TAG}, ECN_{PC}, and TCN_{PC} were calculated based on the basis of eqs 2, 3, 4. and 5, respectively.

separated in sequence with TCN.[27] The ECN of TAG (ECN_{TAG}) and TCN_{TAG} were calculated using eqs 2 and 3:

$$ECN_{TAG} = CN - 2n \quad (2)$$

$$TCN_{TAG} = ECN_{TAG} - \sum_{1}^{3} Ui \quad (3)$$

where CN is the total carbon number of the fatty acid residue per TAG molecule and n is the number of double bonds in the fatty acid residue per TAG molecule. The Ui value of unsaturated fatty acid was calculated from experimental data for known TAG species according to Elhamdy and Perkins.[27] In brief, a plot of retention times versus carbon numbers of several saturated TAG standards was used as a calibration curve. For any saturated TAG, the TCN value is equal to the actual carbon number of fatty acid residues while the Ui of unsaturated fatty acid was calculated from experimental data for the known fatty acyl chains of TAGs. For example, the triolein peak has ECN and TCN (which is calculated from the calibration curve) values of 48 and 46.125, respectively; then, $\sum_1^3 Ui = 48 - 46.125 = 1.875$. Consequently, the Ui factor for oleoyl is 0.625. The other Ui factors were obtained in the same way and are as follows: 0.75 for linoleyl, 0.83 for linolenyl groups, and 0.0 for saturated acyl groups.

As regards PC, only two fatty acids were taken into consideration to calculate their TCN_{PC} values. The ECN of PC (ECN_{PC}) and TCN_{PC} were calculated on the basis of eqs 4 and 5, respectively:

$$ECN_{PC} = CN - 2n \quad (4)$$

$$TCN_{PC} = ECN_{PC} - (U_1 + U_2) \quad (5)$$

where CN is the total carbon number of the fatty acid residue per PC molecule and n is the number of double bonds in the fatty acid residue per PC molecule. U_1 and U_2 are factors adapted from TAG for fatty acyl chains at the *sn*-1 and *sn*-2 positions, respectively.

As shown in Table 1, as the value of TCN increased, the relative retention time increased correspondingly. In addition, the TCNs and retention times of nine PC molecular species in the L-α-PC profile (Figure 1) were selected to construct a curve. The parameters appeared to fit a linear regression model, and the regression curve between the retention time and TCN_{PC} values of PC species showed good linearity (Figure S1A, Supporting Information). For the retention time and TCN_{TAG}, the linearity of the regression curve was also examined (Figure S1B, Supporting Information). The results suggested that, similar to the case for TAG species, L-α-PC could be separated into molecular species by a highly efficient C30 column, and the elution order paralleled TCN correspondingly. Therefore, we considered that linear regression curves from the TCN and retention time of individual molecular species can be used for the determination of molecular species in both PC and TAG.

Brouwers et al. suggested that a mathematical relationship exists between the retention time and ECN of each PE molecule, which was defined as $ECN = CN - 1.505n$ (where CN is the total carbon number of fatty acid residues per PE molecule and n is the number of double bonds in the fatty acid residue); this relationship has been used to assist in the identification of unknown PE species when mass spectrometry is not available.[12] The retention time of the PC molecule increases proportionally to the ECN coefficient ($ECN = CN - 2n$), which is a discriminating factor that can provide valuable information for PC separation.[15,28] Choi et al. developed a retention time index for PC profiling, which showed that the fatty acid chain length and the degree of unsaturation were linked, achieving linear curves between the relative retention time and mass over charge (m/z) of PC.[29] However, the relation between TCN and retention time of phospholipids has remained unclear to date. For those PC species with the same ECN_{PC} values, such as LLPC, OLnPC, and PLnPC, their TCN_{PC} values showed slight differences, enabling further discrimination (Table 1). Elhamdy and Perkins concluded the separate mechanism of TAGs was likely that the affinity between the stationary phase and fatty acids becomes stronger when the methylene groups in the chain increase or double bonds decrease, causing molecules to travel more slowly in a column, resulting in longer retention times.[27] Moreover, the TCN_{PC} and retention time of PC species were easily regressed as a linear curve ($R^2 > 0.98$) (Figure S1A, Supporting Information). Since TCN_{TG} has been widely used to predict

DOI: 10.1021/acs.jafc.5b01022
J. Agric. Food Chem. 2015, 63, 3851−3858

the unknown TG species in previous studies,[27,30] using the plot of the TCN_{PC} and retention time of known PC species to predict the fatty acid components of unknown PC peaks should be a promising alternative to specify the PC molecular species in HPLC-ELSD analysis. In addition, on the basis of the relation of TCN to retention time, we considered not only for TAG and PC species determination but also the molecular species of other phospholipids could be determined. Furthermore, we observed a disadvantage that the *sn* positional isomers, i.e., molecular species such as OPPC and POPC, have identical retention times and cannot be separated under the current HPLC separation conditions. The same situation also occurred in TAG analysis if their TCN_{TAG} values were near or identical. For instance, the TAG molecular species identified as POL represented a mixture of POL, PLO, and OPL. The detailed positional assignment of individual fatty acid residues is much more difficult or even impossible for TAG.

Quantitation of Individual PC Molecular Species. To prepare quantitative curves with this RP-HPLC-ELSD system, five pure PC species, including OOPC, POPC, OPPC, PPPC, and LLPC, were analyzed individually to determine their respective relationships between concentration and peak area. Regression analyses of these linear plots revealed that the correlations between ELSD responses to all analytes were almost identical (Figure S2, Supporting Information). The list of relative response ratio of their interception values showed that the relative response factor values were highly similar to one another (Figure S2, Supporting Information). Therefore, the contents of corresponding HPLC fractions could be determined on the basis of peak area percentage. The percentage of individual PC species was calculated by using eq 6.

$$\%\ \text{of PC species} = \frac{A(\text{peak area of individual PC species})}{\sum A(\text{total peak areas of PC species})} \times 100 \quad (6)$$

Determination of PC Contents in Lecithins and PC Profiling. The contents of PC in crude lecithins were determined according to AOCS method Ja 7b-91 to be 12.3 ± 2.6% (w/w) for crude soybean lecithin and 19.4 ± 1.5% (w/w) for sunflower liquid lecithin. The PC content in lecithin was quantitated by normal-phase HPLC-UV on the basis of the absorbance of the PC at 206 nm being proportional to the number of double bonds in PC from the same origin. Therefore, quantitation by normal-phase HPLC-UV is not appropriate when the PC molecular species of lecithin samples contain diverse fatty acyl chains.

PC profiles of isolated soybean PC and sunflower PC were analyzed by HPLC-ELSD (Figure S3A,B, Supporting Information). The compositions of isolated PC from soybean and sunflower lecithins are given in Table 2. Like the species L-α-PC, the isolated soybean PC was composed of nine PC species. The most abundant PC species was LLPC, accounting for 40.6%. The total amount of PC species with two polyunsaturated fatty acyl chains at the *sn*-1 and *sn*-2 positions, such as LLPC and LLnPC, were 44.4%. The major PC species in the sunflower PC profile were very similar to those in the soybean PC profile. The LLPC level was quite high (64.3%) in sunflower PC, but LLnPC, OLnPC, and PLnPC peaks were absent. Regarding of the fatty acid composition of lecithins, Nieuwenhuyzen and Tomas reported that soy lecithin contains 55% linoleic acid, 17% oleic acid, 16% palmitic acid, 7% linolenic acid, and 4% stearic acid and sunflower lecithin contains 63% linoleic acid, 18% oleic acid, 11% palmitic acid, and 4% stearic acid but no linolenic acid.[1] Our results were comparable with these data, and no linolenic acid was observed in isolated sunflower PC. In other words, sunflower PC lacks the linolenic acid-related PC molecular species, which significantly differentiates it from soybean PC.

Table 2. Distribution of the PC Molecular Species from Soybean Lecithin and Sunflower Lecithin

	area (%)[a]	
PC species	PC soybean	PC sunflower
LLnPC	3.77 ± 0.25	0.00 ± 0.00
LLPC	40.64 ± 0.28	64.25 ± 0.75
OLnPC	0.97 ± 0.01	0.00 ± 0.00
PLnPC	1.28 ± 0.01	0.00 ± 0.00

PPPC	3.63 ± 0.01	2.32 ± 0.16
SOPC	5.29 ± 0.02	0.36 ± 0.19

[a]Data are mean ± SD of triplicate determinations. The contents of PC molecular species were determined according to eq 6.

Soybean oil and sunflower oil from their respective acetone-soluble fractions were analyzed by HPLC-ELSD (Figure S3C,D, Supporting Information). The TAG species were assigned by calculating the TCN_{TAG} value and comparing the results with TAG profiles of known TAG components.[23] The TAG compositions of soybean oil and sunflower oil samples are given in Table 3. The TAG species in soybean oil and sunflower oil were primarily trilinolein (LLL), dilinoleoyl oleoyl glycerol (OLL), and linoleoyl palmitoyl glycerol (PLL), accounting for 63.3% and 85.0%, respectively. Both soybean oil and sunflower oil contained minor amounts of dioleoyl linoleoyl (OLO), palmitoyl linoleoyl oleoyl glycerol (PLO), dipalmitoyl linoleoyl glycerol (PLP), OOO, dioleoyl palmitoyl glycerol (POO), dipalmitoyl oleoyl glycerol (POP), dioleoyl

J. Agric. Food Chem. 2015, 63, 3851−3858

stearoyl glycerol (SOO), and stearoyl oleoyl palmitoyl glycerol (SOP). Similarly, there were several TAGs containing linolenic acid in the soybean oil profile in comparison with the sunflower oil profile, such as dilinoleoyl linolenoyl glycerol (LLnL), oleoyl linolenoyl linoleoyl glycerol (OLnL), and palmitoyl linolenoyl linoleoyl glycerol (PLnL). The main TAGs in soybean oil and sunflower oil were consistent with those found in previous research.[31]

PCs are biologically active lipids and are the principal constituents of biological membranes. To date, publications regarding the characterization of PC molecular species in the food industry are still limited. Chen et al. screened the PC compositions of phospholipase-A_2-catalyzed enzymatic reaction products by LC ESI-tandem MS.[18] Hence, RP-HPLC-ELSD could be used to monitor the fatty acid composition of structured PCs during enzymatic interesterification. Recently, sunflower lecithin has been regarded as a promising replacement for soybean lecithin due to concerns about genetically modified products. As shown in Table 2, the major PC species of soybean lecithin and sunflower lecithin are quite similar. Moreover, sunflower lecithin was rich in the bioactive LLPC and may have the potential to replace soybean lecithin to produce LLPC from a non genetically modified source. Additionally, on the basis of the significant differences in minor PC species such as LLnPC, OLnPC, and PLnPC, determining the content of these PC molecular species was sufficient to differentiate soybean and sunflower lecithins. These various PC species could be viewed as prospective indicators to discriminate plant lecithins.

In conclusion, a method for PC molecular species profiling by RP-HPLC-ELSD was introduced. The PC molecular species were identified by positive-ion MALDI-TOF-MS. The relationship between the TCNs and retention times of standard PC species was developed alongside the RP-HPLC-ELSD analysis. The quantitation of PC molecular species was achieved on the basis of area normalization. This method can be used to characterize PC molecular species from crude lecithins, which would provide further information regarding the properties and functions of lecithins.

[b]Compound is described as (+) present, (−) not detected, (*) the evidence for its presence is inconclusive, and (li) low ionization. [c]$[2M-H]^-$. [d]$[M+Na]^+$. [e]Tentatively identified.

and oil), this study was carried out with a view to characterize their phenol constituents on the basis of HRMS and UV−vis spectroscopic data never collectively presented before. Moreover, simultaneous screening of all of the matrices from the same biological material provided us a basic insight into olive fruit phenols transfer, transformation, and the partition qualitative trail, rarely discussed in the literature to date. Nevertheless, this study also describes some of the new phenol constituents found in the extracts examined.

MATERIALS AND METHODS

Reagents and Standards. All solvents (acetic acid and methanol) were of HPLC grade and purchased from Sigma-Aldrich Co. (Darmstadt, Germany), as were vanillin and vanillic, caffeic, and *p*-coumaric acid standards. Others, hydroxytyrosol, tyrosol, oleuropein, luteolin, luteolin-7-*O*-glucoside, luteolin-4′-*O*-glucoside, apigenin, apigenin-7-*O*-glucoside, verbascoside, quercitrin, and rutin, were obtained from Extrasynthese (Genay, France), while pinoresinol was from ArboNova (Turku, Finland). Standard stock solutions were prepared by dissolving standards in pure methanol, which were rotary evaporated (35 °C) and in turn re-dissolved in a mixture of HPLC eluents (A:B = 90:10 (v/v)).

Sampling and Sample Preparation. Olive fruits of Istrska belica *cv.*, the most widely spread olive variety in Slovenia, were harvested in Gradno (Goriška Brda, Slovenia) at the end of maturation period, which was found to be optimal in terms of the oil content and sensorial characteristics, stored overnight and processed to olive oil the next day using a laboratory-scale Abencor olive mill (Seville, Spain). The fruits were ground to a paste using a hammer mill, and water (100 mL/kg of fruit) was added to improve the rheology. Then the paste was malaxed (30 min/(25 °C)) and centrifuged in order to obtain the three final products: oil and two types of waste (pomace and wastewater). All process-derived matrices were sampled at the end of processing, with the exception of paste, which was collected immediately after fruits crushing. The samples were prepared as previously described,[7,10,11] with destoned fruits, stones, paste, and pomace being frozen with liquid nitrogen, freeze-dried, homogenized, and stored at −25 °C until analysis, while the wastewater was primarily acidified (HCl, pH = 2.0) and defatted with *n*-hexane prior to freeze-drying and storage at −25 °C. The olive oil sample was stored in the dark at room temperature until extraction.

Extraction of Phenols from Destoned Fruits, Stones, Paste, Pomace, and Wastewater. Phenols were extracted according to a previously published ultrasound-assisted solid liquid extraction (USLE) method,[11] with which a freeze-dried sample (1.5 g) was sonicated (3 × 20 min) with 25 mL of methanol. The homogenates of

[a]ESI^- = negative ion mode. [b]$[2M-H]^-$. [c]Abbreviations: decarboxymethyl elenolic acid linked to hydroxytyrosol (3,4-DHPEA-EDA) or tyrosol (*p*-HPEA-EDA).

each extraction step were centrifuged (9000 rpm, 5 min) and combined supernatants diluted with pure methanol to 100 mL.

Extraction of Phenols from Olive Oil. Extraction was carried out using the ultrasound-assisted liquid liquid extraction (US-LLE) method previously described,[10] with 10 g of oil being dissolved in *n*-hexane (10 mL) and sonicated (3 × 10 min) with methanol (5 mL). The homogenates of each extraction step were centrifuged (9000 rpm, 2 min), combined, and defatted with a freeze-based fat precipitation

DOI: 10.1021/jf506345q
J. Agric. Food Chem. 2015, 63, 3859−3872

(20 min, −80 °C). Afterward, the remaining extract was reconstituted to 25 mL with pure methanol.

UPLC-DAD-ESI-QTOF-HRMS Analysis. Prior to analysis, the aliquots of extracts were rotary concentrated (10 times), the dry residue re-dissolved in a mixture of HPLC eluents (A(95:5 water−acetic acid (v/v)):B(methanol) = 90:10 (v/v)) and filtered through 0.22 μm/13 mm poly(vinylidene fluoride) (PVDF) filters from Carl Roth GmbH + Co. (Düren, Germany).

Phenols were characterized using a Waters UPLC system equipped with DAD and HRMS-QTOF Synapt MS with electrospray ionization (ESI) system from Waters Corp. (Milford, MA, USA). Separation was achieved on a Kinetex PFP column (2.6 μm, 100 mm × 4.6 mm) attached to a PFP security guard (2.1 mm × 4.6 mm), both from Phenomenex (Sydney, Australia) at a flow rate of 1 mL/min, using 10 μL of injection volume and a solvent system composed of water−acetic acid (95:5, v/v) (A) and methanol (B). The gradient elution for fruits, stones, paste, pomace, and wastewater analysis involved a nine-step program: 0−7 min, 1% B isocratic; 7−10 min, linear gradient from 1 to 25% B; 10−35 min, linear gradient from 25 to 36.2% B; 35−35.5 min, linear gradient from 36.2 to 36.5% B; 35.5−52 min, linear gradient from 36.5 to 43.7% B; 52−53 min, linear gradient from 43.7 to 45% B; 53−66 min, linear gradient from 45 to 50% B; 66−72 min, linear gradient from 50 to 100% B; 72−76 min, 100% B isocratic; 76−79 min, linear gradient from 100 to 1% B; and 79−88 min, 1% B isocratic. For the oil a 20-step solvent run was used as follows: 0−7 min, 1% B isocratic; 7−10 min, linear gradient from 1 to 25% B; 10−20 min, linear gradient from 25 to 29.4% B; 20−20.1 min, linear gradient from 29.4 to 29.9% B; 20.1−21.1 min, linear gradient from 29.9 to 40% B; 21.1−21.5, 40% B isocratic; 21.5−22.5 min, linear gradient from 40 to 30% B; 22.5−23 min, linear gradient from 30 to 28% B; 23−25 min, 28% B isocratic; 25−26 min, linear gradient from 28 to 30% B; 26−26.5 min, linear gradient from 30 to 31.8% B; 26.5−27 min, linear gradient from 31.8 to 32.8% B; 27−27.5 min, linear gradient from 32.8 to 40% B; 27.5−28 min, linear gradient from 40 to 41% B; 28−28.5 min, linear gradient from 41 to 33% B; 28.5−34 min, linear gradient from 33 to 36% B; 34−35 min, linear gradient from 36 to 36.8% B; 35−35.5 min, linear gradient from 36.8 to 40% B; 35.5−36 min, linear gradient from 40 to 36% B; 36−66 min, linear gradient from 36 to 50% B; 66−72 min, linear gradient from 50 to 100% B; 72−76 min, 100% B isocratic; 76−79 min, linear gradient from 100 to 1% B; and 79−88 min, 1% B isocratic.

The separated compounds were first monitored using DAD (280, 320, and 365 nm) and then MS scans were performed in both positive (PIM) and negative (NIM) ion modes, in the range m/z 50−3000 Da, in the following conditions: capillary voltage, 3 kV; sampling cone, 40 V; extraction cone, 3 V; source temperature, 100 °C; desolvation temperature, 350 °C; cone gas flow (N_2), 50 L/h; desolvation gas flow (N_2), 800 L/h. The MS was calibrated using sodium formate, and leucine encephalin was used as the lock mass. In these conditions the instrument is expected to provide experimental data with accuracy within ±3 ppm. All data were processed using MassLynx software 4.1 (Waters Corp.).

RESULTS AND DISCUSSION

UV−Vis and HRMS Spectroscopic Study of Olive Phenol Extracts. Two screening strategies were used in the phenol profiling study of extracts from the olive oil processing trial. The extracts were first screened for the range of phenols previously reported in *O. europaea* L. matrices and their identification confirmed, based on accurate mass and fragmentation profile comparison with literature data. In addition, the UV−vis spectra from DAD were generated, allowing classification and (if possible) structure/spectra relationship assessment. When the reference compounds were available, the phenols were also compared with standards in terms of R_t, UV−vis, and MS spectral characteristics. Using the strategy detailed earlier, 67 phenols of known identity were found in six olive matrices (Table 1), but the discussion focuses only on those best illustrating the innovative nature of the study (e.g., found for the first time, challenged to analytically characterize and/or detect). The second screening strategy was used for the new constituents and was based on the generation of UV−vis and MS spectra from DAD and TIC chromatograms scanned in both NIM and PIM ion modes, at soft and strong ionizations, obtaining major ESI^- and ESI^+ signals (Table 2).

Table 1 summarizes the MS and UV−vis spectral data of known phenolic compounds identified in extracts of destoned fruits, stones, and olive oil process-derived matrices (paste, pomace, wastewater, and oil). It also provides information about their elution time, molecular formula, theoretical and experimental m/z of deprotonated molecular ions in NIM mode, and calculated errors between them. Moreover, such data organization also allows one to infer the difference between the detectors' ability to assign the presence of individual phenolic compounds and/or to follow their origin, evolution, and disappearance during each operational step. Because data on UV−vis absorption maxima can sometimes vary due to matrix interference (which could lead to possible misinterpretation), the characteristic UV−vis spectral shapes of known and new phenol constituents were also presented in Table 3, along with their MS fragmentation profiles and chemical structures (if possible). The UPLC-DAD chromatograms of all matrices are presented in the Supporting Information (Figures S1−S6).

Simple Phenols. Among the simple phenols, it was possible to confirm the presence of hydroxytyrosol and tyrosol and their glucosides, in addition to hydroxytyrosol acetate eluting as last. All of them were equally well detected by both detectors, with the exception of tyrosol, which failed to ionize as already reported before,[1] but was easily confirmed with the use of the standard. While DAD alone did not permit unequivocal identification of hydroxytyrosol acetate in paste, pomace, and wastewater due to coelution problems, both detectors unambiguously confirmed the identity of two hydroxytyrosol glucosides. Their presence has rarely been reported in olive matrices, which could be a result of analytical issues[28] and/or their microlevels.[29] However, the EIC at m/z 315.1080 displayed the presence of two peaks (R_t 3.2 and 3.3 min) with the same fragmentation profile typical for this glucoside (m/z 153, 123). There are three possible isomers differing in the glycosidation position,[1] but only UV−vis spectra characterization allowed us to distinguish between them. The first eluting isomer had λ_{max} of the B-band at 276, suggesting that glycosidation occurred at 3′ or 4′ OH positions on the ring (Table 3), while the second isomer had its B-band shifted to a higher λ_{max} (~279 nm), indicating an attached glucose moiety in the OH group, outside the phenolic ring, which allowed us to tentatively identify it as hydroxytyrosol-1-β-glucoside.

Benzoic Acids. Two derivatives of benzoic acids were identified, namely, vanillin and vanillic acid, commonly found in olive matrices. However, only the former was well-detected by both detectors, while MS alone failed to confirm the identity of vanillic acid. Its MS ions were suppressed under the analytical conditions applied, increasing error outside the tolerable range of 10 ppm. However, the presence of both was unambiguously confirmed by the use of authentic standards. It is worth noting that vanillic acid was absent in the fruit, but nevertheless appeared in all of the process-derived matrices, unlike vanillin, whose presence was confirmed in the stone, from where it was apparently transferred to the oil.

DOI: 10.1021/jf506345q
J. Agric. Food Chem. 2015, 63, 3859−3872

Cinnamic Acids. Four known cinnamic acids were found in extracts, of which three were esters (verbascoside and its two β-hydroxylated derivatives) and one appeared in the form of a free acid, namely, *p*-coumaric acid. Their presence and/or absence was easily confirmed by both DAD and MS, with the exception of *p*-coumaric acid in destoned fruit, whose UV−vis spectra verification was hindered by coelution problems. However, none of the verbascosides were transferred to the oil but were instead all lost with the wastes. Moreover, the unexpected rise of two β-OH-verbascoside diastereoisomers was observed using DAD after crushing and malaxation, which could point to technologically induced formation and/or release. Indeed, their abundance has already been reported once in Italian solid olive mill waste.[15]

Lignans. One of the most interesting and analytically challenging groups was the class of lignans. Two derivatives were identified in extracts, however only in oil, while in other matrices it was not possible to detect them, despite several attempts. Similar difficulties were also described by López et al.[30] However, in our study, the low ionization of pinoresinol restricted accurate mass-based identification, confirmed instead by the UV−vis spectra and R_t match with the standard. In contrast, the same conditions were adequate for MS identity confirmation of acetoxypinoresinol, determined with an uncertainty of 4.3 ppm. However, it should be emphasized that the high background signal of the nearest eluting compounds (oleuropein and ligstroside aglycones) almost mis-assigned their presence, as DAD alone, due to great UV−vis spectra similarity with simple phenols (e.g., hydroxytyrosol; Table 3).

Flavonoids. MS and DAD had comparable efficiency in terms of the analysis of flavonoids, where seven out of 13 phenols found could be identified using standards, while others were tentatively assigned as follows.

Six peaks were detected when scanning TIC traces at m/z 447.0927 characteristic for luteolin glucosides, which eluted at R_t 4.6, 15.9, 24.1, 26.3, 36.6, and 41.7 min. The accurate mass of the first eluting peak was far above the tolerable level (>15 ppm), and the absence of the fragment at m/z 285 excluded the presence of luteolin glucoside. The identity of the second peak (R_t 15.9 min) was tentatively assigned as luteolin diglucoside, due to its relative short R_t, high mass accuracy (<6 ppm), and characteristic MS ions at m/z 609, 447, and 285. Its UV−vis spectra displayed two absorption maxima at 268 and 338 nm, which is identical to that of luteolin-4′-*O*-glucoside. According to the literature,[31] there are three glycosidation sites possible for luteolin diglucoside—at the 3′,4′-*O*, 3′,7-*O*, and 4′,7-*O* positions. The λ_{max} at 338 nm pointed to 4′-*O* substitution, while at 268 nm to additional 7-*O* glucosidation. The same rationale could also be established from its MS spectra, where the low intensity of aglycone ion at m/z 285 pointed to a loss of glucose from the 7-*O* rather than from the 3′-*O* position.[32] Overall, this indicated the presence of luteolin-4′,7-*O*-diglucoside, which to the best of the authors' knowledge has never been found in olives before, but instead once in the leaves.[24] The later eluting peaks were easily identified, based on the coelution of standards such as luteolin-7-*O*-glucoside (R_t 24.1 min), quercitrin (R_t 26.3 min), and luteolin-4′-*O*-glucoside (R_t 36.6 min), whereas the identity of the last peak was tentatively assigned as luteolin-3′-*O*-glucoside. In the structure of luteolin glucoside, the sugar residue may be either *C*-linked (at the 6 and 8 positions, corresponding to orientin and homoorientin) or *O*-linked at the 5, 3′, 4′, and 7 positions (Table 3). This compound had long R_t (41.7 min), which immediately excluded the presence of orientin, homoorientin, and 5-*O* glucoside, similarly as 4′-*O* and 7-*O*, due to standards availability. This left us only with the existence of luteolin-3′-*O*-glucoside, once indeed proved to elute after 4′-*O*-glucoside under reverse-phase liquid chromatography (RP-LC) conditions.[33] Its presence has already been confirmed once in the leaf,[34] sharing identical UV−vis maxima (λ_{max} 268, 340), which along with the abundance of m/z 285 in its MS spectrum strongly supports our decisive proof. Again, both detectors had an indispensable role in assigning identity with a higher degree of confidence.

Scanning for m/z 593.1506 corresponding to luteolin rutinoside revealed the presence of three peaks (R_t 24.3, 25.5, and 26.6 min), sharing identical fragment ions and relative abundance (m/z 593, 477, and 285). To date, only two isomers have been confirmed in *O. europaea* L. matrices, namely, luteolin 7-*O*-rutinoside and luteolin 4′-*O*-rutinoside, with the former having higher λ_{max} and a shorter R_t.[1,12] In our study, all three isomers eluted after luteolin-7-*O*-glucoside and prior to luteolin-4′-*O*-glucoside, suggesting that the nature of the sugar had no influence on elution order in RP-LC. Moreover, the first two isomers presented similar UV−vis spectra, with λ_{max} around 243 nm, indicating that glycosidation probably occurred away from the chromophore, whereas UV−vis spectra verification of a third isomer was not feasible due to the trace amounts present. These data suggest that these isomers could be either 7-*O*, 5-*O*, 6-*C*, or 8-*C* linked (Table 3); however, only the use of other analysis (e.g., NMR) could provide further structural assignment, and hence the peaks were only tentatively assigned as luteolin rutinoside isomers.

Apart from apigenin-7-*O*-glucoside (R_t 30.3 min), another peak with the same accurate mass, i.e., m/z 431.0978, was detected in fruit, paste, and pomace extracts. This compound, eluting at 35.1 min, showed no affinity for liquid matrices, and its trace levels were beyond DAD detection.

Secoiridoids. The combined use of DAD and ESI-QTOF-HRMS analysis permitted a facile identification of common secoiridoids such as oleuropein, ligstroside, demethyloleuropein, 3,4-DHPEA-EDA, *p*-HPEA-EDA, comselogoside, and caffeoyl-6′-secologanoside. Moreover, it also allowed the detection of others structurally correlated to oleuropein and/or other secoiridoidic derivatives, but the discussion focuses only on those detected in several isomeric forms and hence more challenging to characterize.

Oleoside. The EIC at m/z 389.1084 obtained by ESI-QTOF-MS displayed four peaks (R_t 2.7, 3.0, 3.5, and 8.9 min) with almost the same fragmentation profile characteristic for oleoside. The UV−vis spectra of the first two peaks exhibited two absorption maxima, which is not typical for oleoside and suggests that oleoside is only in their structures. However, their identities were not further investigated due to the trace concentrations present. In contrast, the third and fourth peaks (R_t 3.5 and 8.9 min) had one characteristic λ_{max} at 236 nm (Table 3), though the UV−vis of the former showed some deviation owing to coelution with hydroxytyrosol. This peak was tentatively identified as oleoside, based on high mass accuracy (<6 ppm) and a typical fragmentation profile (m/z 345, 227, 209, and 183), while the second was tentatively identified as secologanoside, owing to the absence of the fragment at m/z 227 and a strong signal at m/z 345 characteristic for this phenol.[19] In contrast, both isomers also displayed the ion species at m/z 779 corresponding to a

DOI: 10.1021/jf506345q
J. Agric. Food Chem. 2015, 63, 3859−3872

presence of dimers, which have sometimes overdominated molecular ions.

Elenolic Acid Glucosides. Five peaks (R_t 7.5, 8.6, 9.2 10.2, and 11.9 min) in EIC at m/z 403.1240 were detected in fruits with the same fragmentation pattern (m/z 371, 223, and 179) typical for elenolic acid glucoside, also described in the literature as 11-methyl oleoside.[13] The fragment at m/z 371 corresponds to a neutral loss of the methyl group, while the fragment at m/z 223 to the elimination of hexose, giving rise to m/z 179 by the neutral loss of CO_2. The presence of dimers was also detected at m/z 807.2559. However, of these peaks only four (nos. 10, 12, 14, and II) had the UV−vis spectra with one absorption maximum, which varied depending on the matrix and isomer investigated (λ_{max} 236−245 nm), but always retained the typical bell-shaped curve (Table 3), while the first eluting peak displayed two and presented a major signal at m/z 891. This could infer that 11-methyl oleoside is in its structure, but further assignment of identity was not feasible (presented elsewhere; Table 2; unknown no. 9). This compound was absent in olive stones but in addition displayed another isomer eluting at R_t 7.8 min. However, several isomers of elenolic acid glucosides have already been found in different olive tissues and olive oil process-derived matrices such as fruits, leaves, and wastes,[1,12,13,22,24,27] but their trail has never been followed during processing before. As evident from our results, only one, i.e., an isomer 2, was thoroughly sustained throughout all of the operational steps, while the others showed no or lower resistance; indeed the majority already diminished after crushing.

Oleuropein. The EIC at m/z 539.1765 in olive extracts showed the presence of three peaks eluting at R_t 22.9, 27.0, and 28.6 min. The first two peaks displayed the fragments at m/z 377, 307, 275, 223, 149, and 139, and presented similar UV−vis spectra characteristics (λ_{max} ∼244 and 280 nm; Table 3). The first eluting peak was identified as oleuropein using an authentic standard, and the second as oleuroside, known to elute afterward under RP-LC conditions.[13] Interestingly, the third peak (R_t 28.6 min) also displayed the predominant ion at m/z 539.1765, but only in the extract of destoned fruit, while in the stone the predominant ion was at m/z 789.2466. No fragment characteristic for oleuropein aglycone (m/z 377) was observed in its MS spectrum, which along with distinct UV−vis (λ_{max} 250, 280sh nm) excluded the presence of a third isomer (presented elsewhere; Table 2; unknown no. 50). However, as evident from our results, neither of the two recognized isomers was transferred to the oil, though representing a major phenolic fraction in fruit. On one hand this points to their relatively low lipophilic character, while on the other it indicates their fast and easy transformation during processing.

Oleuropein Diglucoside. Several peaks were detected in fruit at m/z 701.2293; however, only four (R_t 18.5, 19.5 19.8, and 20.8 min) exhibited the MS profile characteristic for oleuropein diglucoside (m/z 701, 539, 377, 307, 275, and 223). As previously demonstrated by Fu et al.,[22] there are five possible isomers of this diglucoside, but the absence of the fragment at m/z 341 suggested that none of them had the *O*-dihexosyl structure. As before, all eluted between demethyoleuropein and oleuropein, but no UV−vis spectra were provided for further data comparison. Once again, none of them were partitioned to the oily phase during processing, but two nevertheless appeared in the wastes.

Oleuropein Aglycone. Three major peaks with the same accurate mass (m/z 377.1236) and yielding fragments (m/z 345, 327, 307, 275, 149, and 139) were detected in extracts previously identified as oleuropein aglycone isomers in various tautomeric forms.[17] The peak of the first eluting isomer was broad (R_t 21.5−22.8 min) and also contained signals of residual oleuropein (m/z 539) and its diglucoside (m/z 701), while in the second peak (R_t 37.5 min) the presence of dimers (m/z 755) could also be observed. All three isomers appeared in all of the olive matrices, but the initial trace amounts in fruits prevented DAD detection. One significant fact is that crushing implied their rise to a level easily quantifiable using DAD in all process-derived matrices, where indeed they represented a major phenolic fraction. However, in spite of their minor absorption maxima deviations (λ_{max} 244−258 and 276−281; Table 2), they all kept the same spectral shape (Table 3) and could fit to any of the structures proposed by Fu et al.,[17] (Table 3, I−XII). Nonetheless, TIC traces in the oily phase also revealed the presence of other peaks with the same MS and similar UV−vis spectral characteristics; two of them were abundant and coeluted with ligstroside aglycones (peak nos. 48 and 49), whereas the identity of others could not be confirmed due to the ultratrace concentrations present.

Ligstroside Aglycone. Though analogous behavior was expected for ligstroside aglycones, these phenols displayed a distinct transfer/partition trail as compared to oleuropein aglycones. None of the detectors could assign their presence in fruits, while in their process-derived matrices, only one, an isomer 2, and yet only in the oil, was above the detection limit of DAD. Such tiny amounts suggest its fast and easy degradation, probably to *p*-HPEA-EDA, whose appearance in olive oil should be marked at the end of processing. However, the identity of all was unambiguously confirmed based on their high mass accuracy (≤6.1 ppm) and a fragmentation profile fitting well with a previous report,[19] but further distinction between them was not feasible and could hence fit any of the structures illustrated in Table 3 (I−XII).

3,4-DHPEA-EDA. The presence of two 3,4-DHPEA-EDA isomers (R_t 16.0 and 19.9 min) was confirmed based on accurate mass (m/z 319.1182) and characteristic fragment ions at m/z 301, 195, 183, 165, and 139, though a major signal in their MS spectra corresponded to a dimer (m/z 639.2442). In the literature several terms can be found for this compound, known as a dialdehydic form of decarboxymethyl elenolic acid linked to hydroxytyrosol (abbreviated as 3,4-DHPE-EDA),[3] though some others refer to it as 3,4-DHPEA-DEDA,[1] decarboxymethyl oleuropein aglycone[18] or deacetoxy oleuropein aglycon.[19] However, none of the two isomers were detected in olive fruits, whereas both of them appeared in their solid derived matrices, and one (isomer 2) also in the liquid ones, where it indeed represented one of the main phenol constituents. This points to its amphiphilic character, while their abundant evolution after brief crushing to a fast and efficient interconversion of fruit native phenols, probably of oleuropein and/or ligstroside, according to the mechanism previously proposed by Servili et al.[3]

Nüzhenide. Four isomers of nüzhenide were identified in olive stones based on mass accuracy and fragmentation profile (m/z 523, 453, 421, 299, and 223) matching with previous reports.[1,16] However, only three (isomers 2, 3, and 4) were present at levels quantifiable using DAD, of which two further diminished after crushing. In fact only one, namely, nüzhenide isomer 2, was maintained throughout all of the operational steps but showed no affinity for the oil matrix. However, in addition to nüzhenide isomers, the presence of their esters,

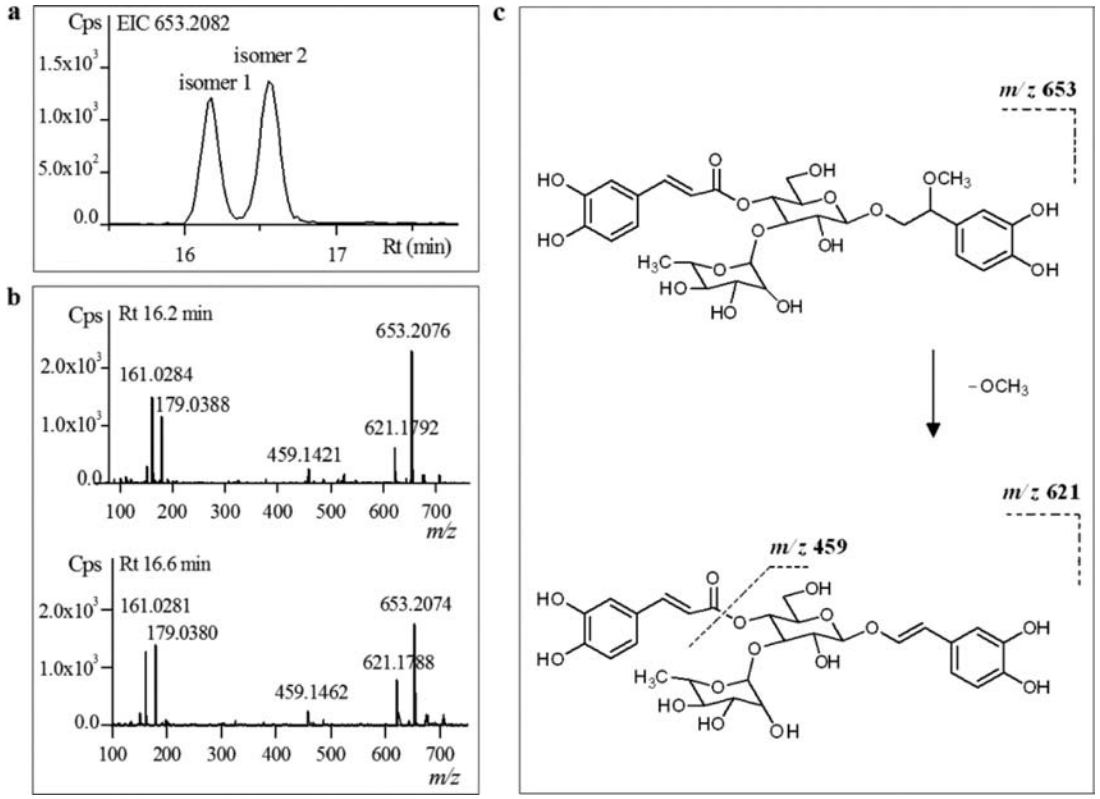

Figure 1. EIC of m/z 653.2082 (a), HRMS spectra (b), and fragmentation scheme (c) proposed for β-methyl-OH-verbascoside diastereoisomers.

namely, nüzhenide 11-methyl oleoside and nüzhenide bis(11-methyl oleoside), could also be confirmed in stones but not in other fruit compartments. While the former eluted as four peaks according to a previous report,[16] the second eluted as three at R_t 51.5, 52.0, and 58.7 min. Again, none of them were transferred to the oily phase, though some remained occluded in wastes.

Unknown Phenol Constituents. Apart from known phenols, the presence of other constituents could also be detected in olive extracts; however, only those for which spectroscopic evidence indicated a potent phenolic structure or which shared strong UV−vis or MS spectral similarities with already known phenols were included in Table 2. Three of them remained with an undefined MW (unknowns nos. 4, 9, and 50), while for four others new molecular formulas were assigned, of which three were also tentatively identified. Detailed MS and UV−vis spectra characterization is presented later for these, which could shed new light on the secondary metabolism of *O. europaea* L. plants.

Unknown A. The peak eluting at R_t 3.7 min was present in all olive matrices, presenting the same UV−vis spectra as a well-known secoiridoid, i.e., comselogoside (Table 3). Its MS spectrum in NIM mode showed the fragments at m/z 409, 389, 355, 241, 209, and 191, while in fruit extract the presence of an additional ion signal was detected at m/z 421. The latter was in fact the predominant ion, as already observed by Cardoso et al.,[12] in fruit and pomace extracts, however, due to its total absence in the other matrices, the MW of this compound was rather marked as undefined. This decision was further supported by the lack of sufficient evidence for its molecular ion in PIM. However, it is possible that the precursor ion signal was weak or absent due to fast dissociation, but the presence of two common fragments at m/z 389 and 241 and a similar elution order indicated that this compound is at least similar to that previously reported.[12] Unfortunately, no UV−vis spectrum characteristics were provided in the earlier study, and hence no further comparison was possible. Further research is undoubtedly needed to assign its identity, which is also interesting due to its widespread presence and apparent technological resistance.

Unknowns 408 MW. Two peaks (R_t 4.0 and 5.5 min) with the same exact mass (m/z 407.1553) and molecular formula $C_{17}H_{28}O_{11}$ generated by ESI-QTOF were detected in extracts, sharing similar UV−vis spectra (Table 3) but a different MS fragmentation profile (Table 2). The first eluting compound was more polar, had its B-band shifted to a lower λ_{max} (312 nm) and presented a similar MS spectrum, as previously reported.[1,12] The second eluting peak was less polar and had a slightly higher λ_{max} of the B-band at 314 nm but displayed many fewer MS fragment ions at lower intensities. Interestingly, both precursor ions corresponded to the same elemental formula ($C_{17}H_{28}O_{11}$) determined with high mass accuracy ($\leq$3.7 ppm), which could indicate the same chemical composition but probably a different structure. There are indeed several models possible for secoiridoid derivatives, differing in terms of the structure of elenolic ring; open or closed, aldehydic or nonaldehydic forms,[9] but beside the molecular formula proposed, no further structural assignment could be established. However, both of them again shared a strong UV−vis similarity with comselogoside, which along with the presence of diagnostic fragments of secoiridoids (m/z 389, 377, 375, and 345) allowed us to classify them among the secoiridoids.

Unknowns 654 MW. Two new diastereoisomers (R_t 16.2 and 16.6 min) of verbascoside derivatives were discovered in olive extracts that to the best of the authors' knowledge have

[a] m/z thr = calculated monoisotopic mass $[M-H]^-$; m/z exp = detected mass; formula = molecular formula; Δm = calculated mass deviation, $[(m/z \text{ exp} - m/z \text{ thr})/m/z \text{ thr}] \times 10^6$ (ppm).

never been reported before. Their tentative identification was performed by calculating the possible molecular formula from experimental m/z and MS fragment data interpretation, yielding $C_{30}H_{38}O_{16}$ with a high mass accuracy (<5 ppm) for all matrices. Parts a and b of Figure 1 present the EIC at m/z 653.2082 and their corresponding HRMS spectra, showing an identical fragmentation profile (m/z 621, 459, 179, and 161) typical for verbascoside derivatives.[14] The ion at m/z 621 is formed by the loss of a methyl group and the formation of a double bond between α- and β- carbons, which subsequently form the fragment at m/z 459 due to loss of the caffeoyl group. The common ions at m/z 179 and 161 correspond to caffeic acid and its dehydrated ion. The structure and fragmentation pattern proposed for these two diastereoisomers is further presented in Figure 1c. As the latter is almost identical to an already known β-ethyl-OH verbascoside diastereoisomer previously found in pomace,[14] we analogously referred to the newly discovered compounds as β-methyl-OH-verbascoside isomers. Their structural correlation with verbascoside and β-OH-verbascoside is further apparent from UV−vis spectra comparison (Table 3) and supports their classification among cinnamic acids. What is of interest to add is their significant rise observed after fruits crushing, which kept increasing also during malaxation.

Unknowns 716 MW. This compound has already been detected before in stones, but not identified, though structurally correlated to nüzhenide having more than 30 mass units.[16] As before, it eluted as two peaks (R_t 17.1 and 20.9 min) and presented the same fragmentation profile (m/z 715, 553, 483, 451, and 329), suggesting the presence of isomers. HRMS analysis of both peaks provided the exact masses of 715.2449, corresponding to $C_{32}H_{44}O_{18}$, determined with less than 5 ppm uncertainty. Their product ion spectra showed a series of ions typical for nüzhenide, with m/z values increased by 30.0105 mass units (Figure 2a), which is probably due to a methoxy group attached to the tyrosol glucose moiety of nüzhenide. The

DOI: 10.1021/jf506345q
J. Agric. Food Chem. 2015, 63, 3859−3872

structure proposed for this compound is, along with the fragmentation scheme, presented in Figure 2c, where the ion at m/z 553 is formed by a neutral loss of glucose, while the ion at m/z 329 is formed by the consecutive loss of methoxytyrosol glucose. The common ions at m/z 483 and 451 originate from m/z 553, as previously demonstrated for nüzhenide.[16] Nevertheless, its UV−vis spectrum shares a strong similarity with nüzhenide (Table 3), which reasonably suggests the presence of methoxynüzhenide isomers. This decisive proof is further supported by the high mass accuracy of all of the characteristic fragment ions shown in Table 4. While their unique presence in the stone could point to a distinct biosynthetic metabolism of this fruit compartment, the traces present in process-derived matrices are probably a result of their transfer from the stone.

Unknown 1102 MW. Another compound found in stones, but never characterized using HRMS analysis, eluted at R_t 43.2 min. This compound is exactly 386.1213 mass units heavier than methoxynüzhenide and shares the same fragmentation pattern (m/z 715, 553, 329; Figure 2b) and similar UV−vis spectrum characteristics (λ_{max} 255 and 276; Table 3). Silva et al.,[16] already assigned its presence in the stone and surmised its structure as 11-methyl oleoside, linked to compound 716 MW. We in addition provide its molecular formula, namely, $C_{49}H_{66}O_{28}$, determined with a high mass accuracy of 5.0 ppm, its structure, and its proposed fragmentation scheme (Figure 2c). The accurate masses of detected fragment ions, their molecular formulas, and the calculated errors between them are also provided in Table 4, indicating that 11-methyl oleoside is indeed likely to be attached to methoxynüzhenide (716 MW). Collectively this information allowed us to tentatively identify the compound as methoxynüzhenide 11-methyl oleoside, with a high degree of confidence. Again, its presence was restricted solely to the stone, from where it was apparently transferred to the paste, pomace, and wastewater, however only in traces detectable by MS.

Olive Fruit Phenols Trail during Olive Oil Processing. The peel and pulp together (destoned fruits) represented a major phenolic fraction of the fruit's native constituents, while the stone represented only a minor fraction, being almost unique in the absence of flavonoids and the presence of nüzheonide-type phenols. While the appearance of these phenols in olive oil process-derived matrices, once released after crushing, is probably a result of their transfer from any of the fruit compartments, the presence of new phenolic compounds reasonably suggests their technologically induced formation and/or release. This is the case of vanillic acid, apigenin, 3,4-DHPEA-EDA, *p*-HPEA-EDA, and ligstroside aglycone found in the paste after crushing. Likewise, the unique presence of pinoresinol and acetoxypinoresinol in olive oil after malaxation, analogously as acetal of 3,4-DHPEA-EDA and unknown isomers of 484 MW in wastewater, could point to their artificial nature. Moreover, the DAD-detected rise observed in certain phenolic derivatives after crushing and/or malaxation could also highlight their transformative origin, probably from the fruit's native phenol constituents, whose disappearance was observed during processing. However, in qualitative terms, the behavior of olive fruit phenols followed a simple partitioning model, where the majority of them showed low or no affinity for the oil matrix, as with few minor exceptions only their aglycones were partitioned to the oil, while the fruit glycosides that yet reached the final products remained occluded in the wastes.

This study has made progress toward improved phenol profile characterization of olives and their olive oil process-derived matrices, as well as toward better understanding of phenols behavior during olive oil processing. In total, 80 different phenols were detected in six olive matrices and fully characterized based on HRMS and UV−vis spectroscopic data, which is far more extensive than previously reported for such matrices. Four new molecular formulas were proposed, and three new tentative identities were assigned to *β*-methyl-OH-verbascoside, methoxynüzhenide, and methoxynüzhenide 11-methly oleoside. However, only 66 were equally well-detected by both detectors; while DAD alone allowed the detection of sixty-nine phenols, ESI-QTOF-HRMS confirmed the presence of 77, due to trace detection outside the limits of DAD. MS was also more selective than DAD and provided elemental composition of known and new phenol constituents with a high mass accuracy below 10 ppm. Conversely, DAD allowed the identification of phenols which failed to ionize or whose ions were hindered by the matrix signal suppression effect. Moreover, it also provided valuable and complementary UV−vis spectra information that sometimes helped to distinguish between the phenols' isomeric forms and allowed one to specify the glycosidation site. Overall, this work demonstrated the power of a combined UPLC-DAD-ESI-QTOF-HRMS screening approach in phenol profile characterization of complex olive matrices.

selectively inhibit the most active α-glucosidases, Ct-MGAM and Ct-SI, causing slower digestion of the α-amylase degradation products of starch.[10] The inhibition of α-glucosidic activity of specific individual subunits of MGAM and SI can be considered as a key approach for controlling glucose release, because the α-glucosidase catalytic activities are responsible for producing virtually all of the free glucose available for intestinal absorption.

A variety of chemical compounds have been shown to have an inhibitory effect on mammalian intestinal α-glucosidases. These compounds are derived either from chemical synthesis[11,12] or from natural sources such as fruits[13,14] or plants.[15−17] Naturally occurring plant phenolic compounds are one group of chemical metabolites reported to have an inhibitory effect on the α-glucosidases. For instance, caffeic and chlorogenic acids are typical hydroxycinnamic acids found in high concentration in potatoes[18] and coffee beans.[19,20] Chlorogenic acids are esters of caffeic acids and quinic acids.[21] They were identified as the main α-glucosidase inhibitors found in the leaf extract of *Nerium indicum*, causing reduced postprandial rise in blood glucose after ingestion of 2 g of maltose or sucrose/kg body weight in rats administered either the leaf extract or pure chlorogenic acid (25 mg/kg body weight).[22] A single serving of coffee can have 70−350 mg of chlorogenic acid, and a regular coffee drinker can take up to 1 g of chlorogenic acids per day.[23] Caffeic acid was shown to be one of the most potent rat intestinal α-glucosidase inhibitors among different cinnamic acid derivatives.[24] The oxidized form of gallic acid caused nearly 40% inhibition of rat brush border sucrase and maltase activities.[25,26] (−)-Epigallocatechin gallate (EGCG), the main catechin found in green tea,[27] was also observed to be a potent inhibitor of maltase activity in rat brush border membrane vesicles,[28] rat intestinal acetone powder,[29] and recombinant human intestinal maltase.[30] It has been also shown that tea catechins, especially EGCG, may have potential for treating type 2 diabetes.[31,32] Subjects who consumed more than 6 cups of green tea daily were at less risk for type 2 diabetes compared to subjects who drank less than a cup per week.[33]

Overall, this information suggests that natural phenolic compounds present as normal dietary components may exert selective and differential inhibition of the individual subunits of MGAM and SI for the potential modulation of digestion of starchy and other glycemic carbohydrate-rich foods. Although there are multiple publications describing inhibition of α-glucosidases by phenolic compounds, the possibility of subunit selectivity for modulating glucose release has not been studied. In the present study, we analyzed the inhibitory properties and potential for the selective inhibition of the individual Ct and Nt subunits of MGAM and SI using five phenolic and polyphenolic compounds [chlorogenic acid, caffeic acid, gallic acid, (+)-catechin, EGCG] commonly found in Western diets and for which α-glucosidase inhibition has been previously described.

MATERIALS AND METHODS

Materials. All reagents including phenolic standards of chlorogenic acid [3-(3,4-dihydroxycinnamoyl)quinic acid], caffeic acid, gallic acid, (+)-catechin, and (−)- epigallocatechin gallate were purchased from Sigma-Aldrich (St. Louis, MO, USA).

Enzyme Preparation. Cloning, expression, and purification of recombinant mouse Ct-MGAM (glucoamylase subunit; spliceform N20), recombinant mouse Ct-SI (sucrase subunit),[4] recombinant human Nt-MGAM (maltase subunit),[34] and human recombinant Nt-SI[35] (isomaltase subunit) were reported previously. Mouse Ct-MGAM and Ct-SI were generated by recombinant expression in a baculovirus-Sf9 insect cell system.[4] Human Nt-MGAM and Nt-SI were expressed in *Drosophila* S2 cells.[34,35] Nickel-Sepharose resin was used to isolate the secreted proteins from the cell media that were further purified using anion exchange chromatography.

Determination of Protein Concentration. Protein concentration of solutions was determined with the Bio-Rad Protein Assay kit (Hercules, CA, USA), using 10 μL of the protein solution and 200 μL of Bradford dye reagent, and allowed to sit for at least 5 min. Absorbance was read at 595 nm using a Synergy HT microplate reader (BioTek, Winooski, VT, USA). Standards of bovine serum albumin were used in the concentration range of 31.25−500 μg/mL.

Enzyme and Inhibition Assays. Glucose release was measured according to the tris glucose oxidase (TGO) method[36] modified for microplate wells. Maltose solution (10 μL) at final concentrations ranging from 2.1 to 16.7 mM (approximately 1−8 times the K_m for maltose of Ct subunits and 0.3−3 times the K_m for maltose of Nt subunits) was mixed with 10 μL of the enzyme solution containing 0.2 mU of activity for Ct-MGAM, Ct-SI, and Nt-MGAM and 0.1 mU of activity for Nt-SI. One unit (U) of enzyme activity was defined as the activity that cleaves 1 μmol of maltose per minute. The mixtures were incubated for 1 h at 37 °C, and then TGO (180 μL) was added and incubated for an additional 45 min.[36] Absorbance was read at 450 nm in the microplate reader.

For inhibition assays, 10 μL of the phenolic inhibitor solutions was added to the above reaction mixtures to attain final concentrations ranging from 0 to 666.7 μM for the gallic acid, caffeic acid, and (+)-catechin, whereas chlorogenic acid and EGCG were used at final concentrations of 0−83.3 μM for C terminals of both MGAM and SI or 0−666.7 μM for N terminals of MGAM and SI. Analyses were conducted in triplicate. To correct for the scavenger effect of phenolics on the oxidative intermediates generated during the glucose oxidase−peroxidase reaction, which can lead to possible misleading readings of optical density (OD),[37] curves of glucose concentration versus OD in the presence of different concentrations of each individual phenolic compound were constructed and used to adjust the OD obtained during the assay of inhibition of the phenolics on the α-glucosidase enzymes. At the selected concentrations, phenolics caused <20% inhibition of the glucose oxidase−peroxidase developing reaction.

Determination of Inhibition Constant and Inhibition Mechanism. The inhibition mechanism and the respective inhibition constant (K_i) of each enzyme subunit−phenolic combination were determined by the best fit of nonlinear regression analysis with the Levenberg−Marquardt algorithm (Sigma Plot; Systat Software Inc., San Jose, CA, USA) and the standard mathematic equations describing the inhibition mechanisms for competitive, uncompetitive, noncompetitive homogeneous, and noncompetitive heterogeneous inhibition.[38] The mathematical fit with the best parameters of quality (highest r^2, lowest p, lowest residuals; $p \leq 0.05$ for the statistical significance) for each enzyme−inhibitor combination was chosen as the most probable inhibition mechanism in each case. For the calculations of kinetic parameters we chose nonlinear regression methods instead of linear transformations and linear regression, to avoid the additional error introduced by the latter procedures.[39,40]

Determination of IC_{50} Values. The concentration of each polyphenolic compound needed to cause 50% inhibition of the activity of the individual enzyme subunits was defined as the IC_{50} value. It was calculated by linear interpolation of the semilog plot of (log [I]) versus the relative activity (v/V_{max} = 0.5) at 16.67 mM maltose concentration (Minitab 14; State College, PA, USA).

RESULTS

Kinetics and Mechanism of Inhibition of the Recombinant Ct-MGAM, Nt-MGAM, Ct-SI, and Nt-SI. The inhibition capacity, the inhibition mechanism, and corresponding inhibition constants were determined for each

phenolic compound against each recombinant α-glucosidase subunit.

Chlorogenic Acid. Chlorogenic acid had higher inhibition binding affinities and correspondingly lower inhibition constants for Ct-MGAM (3 μM) and Ct-SI (1.8 and 28 μM) compared to caffeic acid, gallic acid, and (+)-catechin (Table 1). The binding affinities of chlorogenic acid were approximately 56 and 15 times greater for Ct-SI and Ct-MGAM than for Nt-SI and Nt-MGAM, respectively. Chlorogenic acid showed noncompetitive homogeneous inhibition for Ct-MGAM and Nt-MGAM, whereas Ct-SI and Nt-SI were inhibited in a noncompetitive heterogeneous way.

(−)-Epigallocatechin Gallate. Ct-MGAM was also the most strongly inhibited subunit by EGCG, with K_{i1} and K_{i2} values of 1.7 and 6.5 μM, respectively (Table 1). Figure 1 illustrates the change in the relative activities (v/V_{max}) of Ct-MGAM, Nt-MGAM, Ct-SI, and Nt-SI with the different concentrations (0−666.7 μM) of EGCG in the presence of different maltose concentrations (2.1, 4.2, 8.3, and 16.7 mM). The difference in the sensitivity to inhibition by EGCG observed between the Ct subunits and Nt subunits is notable, the former showing a K_i 2 orders of magnitude smaller than the latter. Thus, EGCG was a comparatively potent inhibitor for Ct-MGAM and Ct-SI (Figure 1a,b). EGCG inhibited Ct-MGAM, Nt-MGAM, and Nt-SI by a noncompetitive heterogeneous inhibition mechanism and caused noncompetitive homogeneous inhibition on Ct-SI.

(+)-Catechin. (+)-Catechin showed similar inhibition potency toward all four subunits (Figure 2). Affinities or inhibition constants of (+)-catechin for Ct-MGAM, Nt-MGAM, and Ct-SI were in the range of 20.4−97.2 μM (Table 1). The value of 33.7 μM (Table 1) for the K_i on Nt-SI indicated a higher inhibitory effect on this subunit compared to the other phenols. (+)-Catechin showed noncompetitive heterogeneous inhibition on Ct-MGAM, Nt-MGAM, and Ct-SI, whereas it showed noncompetitive homogeneous inhibition on Nt-SI.

Caffeic Acid. Caffeic acid had higher binding affinities (lower inhibition constant) for Ct-MGAM and Ct-SI than for the two N-terminal enzyme subunits tested. The inhibition constants, K_{i1} and K_{i2}, for Ct-MGAM were 56.5 and 191.8 μM, whereas they were 58.2 and 323 μM for Ct-SI (Table 1). Caffeic acid showed noncompetitive heterogeneous inhibition for Ct-MGAM, Nt-MGAM, and Ct-SI, whereas it inhibited Nt-SI in a noncompetitive homogeneous manner.

Gallic Acid. As with caffeic acid, Ct-MGAM and Ct-SI were the most sensitive to inhibition by gallic acid, with values for Ct-MGAM of 24.9 and 50 μM for K_{i1} and K_{i2} and 31.3 and 142.8 μM for Ct-SI K_{i1} and K_{i2}, respectively (Table 1). Gallic acid was inhibited by a noncompetitive heterogeneous mechanism for all four subunits.

Overall, inhibition by EGCG and chlorogenic acid showed a marked preference toward the C terminals of MGAM and SI than for N-terminals, but they displayed notable differences in their selectivity to the two enzymes. The greatest inhibition of Ct-MGAM was caused by EGCG and Ct-SI by chlorogenic acid. With the notable exception of (+)-catechin, which showed comparably higher inhibition of Nt-SI, there was a general trend toward higher binding affinities for Ct subunits over Nt.

IC_{50} Values of Inhibitors. IC_{50} values were also determined for the different phenolic compounds on the four individual α-glucosidase subunits. These values result from the overall inhibition effects of the different binding mechanisms that each compound may display and, therefore, are not necessarily expected to be of same ranking as the inhibition constants. In this context IC_{50} represents the required concentration to inhibit 50% of the enzymatic activity and is conducted at a single substrate concentration. The general trends observed

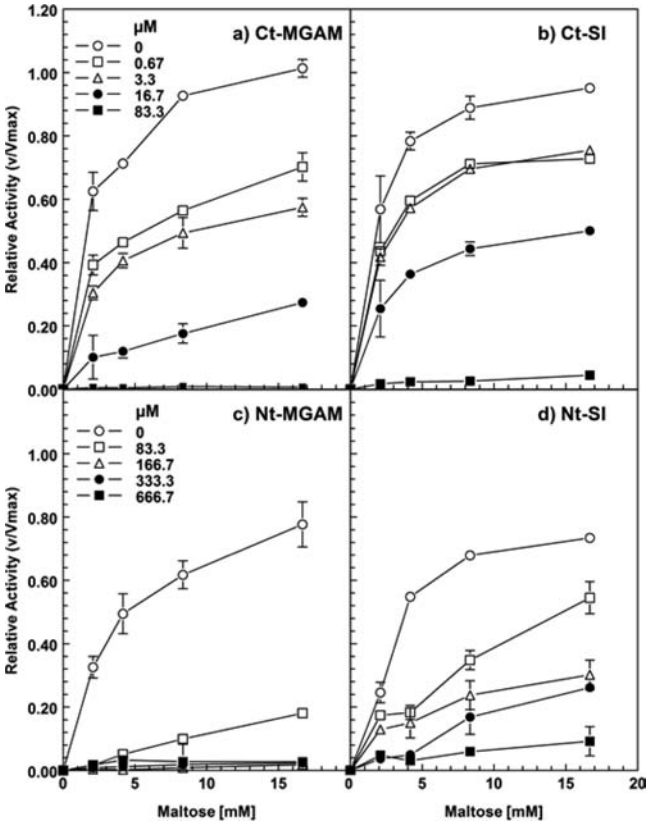

Figure 1. Relative activity (v/V_{max}) of (a) Ct-MGAM, (b) Ct-SI, (c) Nt-MGAM, and (d) Nt-SI at different maltose concentrations (2.1, 4.2, 8.3, and 16.7 mM) in the presence of EGCG at 0, 0.67, 3.3, 16.7, and 83.3 μM for Ct-MGAM and Ct-SI (panels a and b) and at 0, 83.3, 166.7, 333.3m and 666.7 μM for Nt-MGAM and Nt-SI (panels c and d).

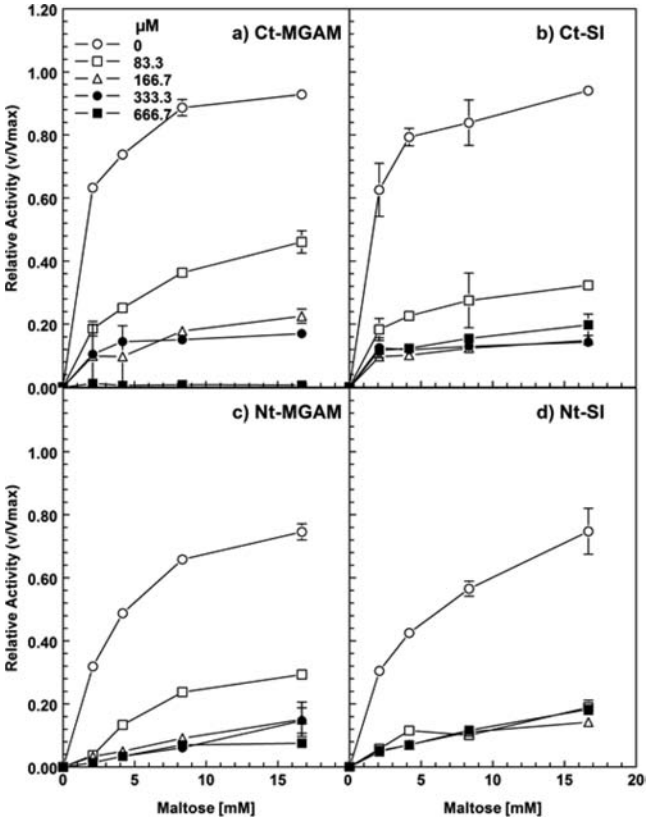

Figure 2. Relative activity (v/V_{max}) of (a) Ct-MGAM, (b) Ct-SI, (c) Nt-MGAM, and (d) Nt-SI at different maltose concentrations (2.1, 4.2, 8.3, and 16.7 mM) in the presence of (+)-catechin at 0, 83.3, 166.7, 333.3, and 666.7 μM.

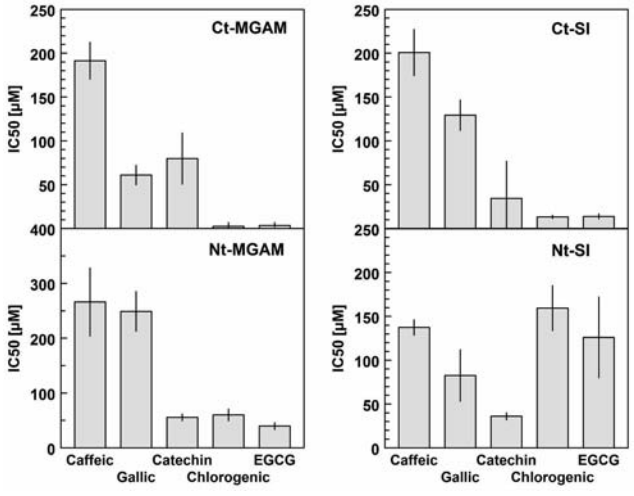

Figure 3. IC_{50} values (μM) of caffeic acid, gallic acid, (+)-catechin, chlorogenic acid, and EGCG for the inhibition of Ct-MGAM, Nt-MGAM, Ct-SI, and Nt-SI. Vertical lines represent the calculated 95% CI for the experimental data.

before for the inhibition constants held up. Among the compounds tested, chlorogenic acid and EGCG required the lowest concentration range (2.3−13.8 μM) to inhibit 50% of the activity of Ct-MGAM and Ct-SI, whereas a higher concentration range (39.6−159.4 μM) was required for Nt-MGAM and Nt-SI (Figure 3). (+)-Catechin showed 50% inhibition of Ct-SI and Nt-SI at comparably lower concentrations of 34.3 and 36 μM, respectively (Figure 3). Caffeic acid showed IC_{50} values in the range of 137.4−266 μM (Figure 3) for all of the α-glucosidase subunits; however, it did inhibit selectively Ct-MGAM and Nt-SI and with lower concentrations than required for the other two subunits (Figure 3). Gallic acid also showed stronger inhibition (lower IC_{50} values) on Ct-MGAM and Nt-SI than on the other two subunits.

DISCUSSION

Phenolic acids and polyphenols have been reported to inhibit the activities of the intestinal α-glucosidases, MGAM and SI.[24−30] The use of phenolic compounds as modulators of the rate of glucose release from starchy foods has been proposed for the treatment of metabolic diseases such as diabetes.[41] Although there are known strong inhibitors of α-glucosidases, such as acarbose,[41] they substantially reduce digestion of starch to glucose, resulting in dumping of starch and starch products into the large intestine to cause bloating and discomfort. The purpose of this study was to explore the selective inhibition by selected phenolic and polyphenolic compounds on individual MGAM and SI subunits. We propose partial inhibition of the highly active Ct-subunits or isomaltase for highly branched substrates could produce a slow, but still complete, digestion in the small intestine of the main glycemic carbohydrates, starch and sucrose. Additionally, slowly digested starch may trigger the ileal brake and gut−brain axis mechanisms that respectively control the stomach-emptying rate and influence hypothalamic

J. Agric. Food Chem. 2015, 63, 3873−3879

regulation of appetite, with potential impact on obesity and associated diseases.[9,42,43]

Our findings reveal that the four subunits of the intestinal α-glucosidases, SI and MGAM, can be selectively and differentially inhibited by certain plant-derived phenolics. This introduces the potential to induce different rates or profiles of digestion for starches, starch products, and sucrose. For instance, selective inhibition of the most active starch degrading subunit, Ct-MGAM (or glucoamylase), was achieved with EGCG and chlorogenic acid. This implies that the reducing activity of this enzyme could slow the rate of starch digestion and reduce particularly the glycemic spike, as was proposed in a recent paper by our group.[44] Chlorogenic acid had the highest binding affinity (K_{i1}) for Ct-SI (sucrase). This suggests the possibility of slowing the rate of digestion of sucrose-rich foods. Third, (+)-catechin showed higher inhibition for Nt-SI, the only subunit with endogenous α-1,6 branch hydrolyzing activity. The combination of (+)-catechin with a highly branched starch or starch products, such as a highly branched maltodextrin,[45] could obtain a slow glucose release effect. The results imply that the low inhibitory effect of phenolics on the slower acting Nt-MGAM and SI subunits may allow for the slow digestion of starch in diets containing such phenolics, but avoiding the inhibition of all four subunits caused by stronger inhibitors such as acarbose, which, although effectively reducing glycemic carbohydrate digestion, causes the delivery of large quantities of carbohydrates into the colon.

The tested phenolics were shown to affect the ability of the substrate to bind the active site of all enzyme subunits (K_{i1}); in some cases, phenolics may also bind an already formed enzyme−substrate complex, although this is with lesser affinity (K_{i2}). It has been reported that the catalytic pockets of Ct-MGAM, Nt-MGAM, and Nt-SI are surrounded by several aromatic amino acids, which may comprise the substrate binding motifs of these enzymes.[4] Therefore, it may be speculated that phenolic compounds could interact with or bind to these aromatic motifs in proximity to the active site, impairing the binding of the substrate with a correct orientation. The substantially higher values for K_{i1} of phenolics than those found for other competitive inhibitors[10] make unlikely the possibility for the existence of a typical competitive binding component in the interaction and therefore discards the possibility of the existence of classic mixed-type inhibition. Thus, the model of typical noncompetitive inhibition was the one that most closely described the effects of phenolics. Therefore, phenolic and polyphenolic inhibitors bind to at least a second additional site. Mathematical fittings of the experimental data indicated that only 5 (Nt-SI/caffeic acid; Nt-SI/(+)-catechin; Ct-MGAM/chlorogenic acid; Nt-MGAM/chlorogenic acid; and Ct-SI/EGCG) of the 20 different inhibitor-subunit combinations studied showed the same values for K_{i1} and K_{i2}. In these cases, therefore, the binding affinity of phenolic compounds to the free enzyme and enzyme−substrate complex was essentially the same, implying that there was a single binding site for phenolics, and the binding of substrate did not interfere with the binding of phenolics at their binding site. This also implies the occurrence of conformational changes in the enzyme after binding of these phenolics, with an effect on their substrate binding capability or catalytic mechanism.[38]

Another study, using rat intestinal powder, showed that chlorogenic acid has a noncompetitive inhibition behavior on maltase and sucrose activities, which agreed with our results.[22] However, the IC_{50} values of chlorogenic acid for maltase and sucrase were 2.99 and 2.18 mM, which are substantially higher than our calculated IC_{50} values (Figure 3).[22] This difference could be explained by binding multiple protein components present in the crude preparations of rat mucosal proteins. In another study, EGCG was shown as a competitive inhibitor and its IC_{50} was estimated as 20 μM for human intestinal maltase.[30] Also, results of an earlier study showed that caffeic acid had a very low inhibitory effect with IC_{50} values of 0.74 and 0.49 mM for maltase and sucrase, respectively.[24] In our study, caffeic and gallic acids were not nearly as strong inhibitors as chlorogenic acid and EGCG.

The stability of phenolic compounds must be considered for such a selective inhibition concept to be pursued in a practical sense. In one study, chlorogenic acid and caffeic acid were found to be stable after incubation with human gastric juice, duodenal fluid, and ileostomy effluent.[21] Another study showed that most (97.9−99.2%) of orally administered chlorogenic acid (700 μmol/kg) and a small amount of caffeic acid (0.8−2.1%) were found in the rat small intestine.[46] Record and Lane[47] tested the stability of gallic acid, caffeine, and EGCG in green tea at acidic pH and at a slightly alkaline pH. Caffeine concentration did not change under the exposure of either acidic (pH 2.0) or slightly alkaline pH (pH 7.5) conditions. Also, the concentration of gallic acid was only slightly reduced at pH of 2.0 and at pH 7.5. On the other hand, although EGCG concentration slightly declined at pH 2.0, its concentration was lower with incubation for 1 h at pH 7.5, decreasing from 1880 to 21 μmol/L in 1 g of green tea/50 mL of water. Several studies also reported that although acidic pH similar to that of the stomach slightly affected the concentration of catechins in green and black tea, the slightly alkaline pH (pH >7.4) caused a significant decrease in their concentration.[48−51] Those studies used alkaline pH (pH >7.4); however, it may not reflect the actual pH of the lumen of the entire small intestine because the pH measured in humans subjects was 6.4−6.6 in the duodenum or proximal small intestine and increased to 7.3−7.5 in the distal small intestine.[52,53] This difference could be important as the glycemic spike seen in the response profile arises from rapid proximal digestion of glycemic carbohydrates, and at this lower pH the catechins could be found with good qualities and high inhibition potential.

Of note, oxidative reactions in the gut lumen may lead to the formation of complex dimers including theasinesins.[54] The ability of these larger phenolic forms to interact with enzymes at the brush border is unknown.

In conclusion, the finding of selective inhibition by plant-derived phenolic compounds of the individual mucosal α-glucosidases implies that the digestion rate of starch, starch products, and sucrose can be differentially affected and modulated by these dietary components. The potential to control glycemic response profiles or sucrose hydrolysis rate using this selective inhibition concept with phenolic compounds warrants further study with an in vivo model.

Further research focused on the regulation of the antioxidant-related gene by curcumin supplementation in experiment 2 was carried out to elucidate the possible mechanism by which supplemental curcumin protected the meat from oxidation under heat stress conditions.

MATERIALS AND METHODS

Ethics Statement. This experimental protocol was approved by the Ethical Committee and conducted under the supervision of the Institutional Animal Care and Use Committee of Nanjing Agricultural University, Nanjing, China.

Reagents and Chemicals. 2,2-Dipheny-l-picrylhydrazyl (DPPH), 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS), and curcumin were purchased from Sigma Chemical Co., Ltd. All other chemicals used in the present study were obtained from Shanghai Chemical Agents Co., China, and were of analytical grade.

Animals and Diets. Two experiments were done to investigate the beneficial effects of curcumin on the meat quality and redox system of breast muscle in broilers.

In experiment 1, 320 1-day-old male broiler chicks (Arbor Acres, *Gallus gallus domesticus*) were obtained from a commercial hatchery (Hefei, Anhui, People's Republic of China) and randomly allotted to four treatments, in which there were eight replicates and 10 birds per replicate. All of the birds were placed in wire cages in a three-level battery and kept in an environmentally controlled room maintained at 34−36 °C until the birds reached 14 days of age and then gradually decreased to 26 ± 1 °C by 21 days of age, after which it was maintained at room temperature (24−26 °C) until the end of the experiment. The birds in the control group (C1) were fed a basal diet (Supporting Information, Table S1), and the other three groups (C2, C3, and C4) were offered the experimental diets based on the basal diet with an additional 50, 100, or 200 mg/kg curcumin, respectively. Feed and water were provided ad libitum to all the birds throughout the 42 day experiment period. At the end of the experiment, one bird per replicate was randomly selected and killed for the left breast muscle samples. One part of the left breast muscle was stored at 4 °C for meat quality measurement (pH, color, drop loss, and cooking loss), and the remainder was stored at −80 °C for biochemical assays.

In experiment 2, a total of 400 Arbor Acres broiler chickens were raised at a recommended environmental temperature from 1 to 20 days of age at the Qing Long Mountain Animal Center, Nanjing, China. At 21 days of age, broilers with similar body weight (BW) were randomly allocated into five treatment groups with eight replicate pens of 10 birds per pen, T1, T2, T3, T4, and T5. Birds in the T1 and T2 groups received the basal diet (Table S1), whereas birds in the T3, T4, and T5 groups received the basal diet containing 50, 100, or 200 mg/kg curcumin, respectively. Birds from the T1 group were housed at 24 °C for 24 h/day, whereas birds from the T2, T3, T4, and T5 groups were housed at 34 °C for 8 h/day (9:00 a.m.−5:00 p.m.) followed by 22 °C for 16 h/day. All of the broiler chickens had free access to water and feed and enjoyed a 12 h light−dark cycle of light regimen during the whole experiment. After 21 days of heat exposure, birds from each replicate were slaughtered and breast muscle examples were collected for homogenate preparation and real-time PCR analysis.

Meat Quality Measurement. The breast muscle pH was measured at 45 min (pH_{45}) and 24 h (pH_{24}) post-mortem using a pH meter (PH-STAR, Mattuas, Germany), as described by Zhen.[24] Three measurements were taken from each sample.

The color of the breast muscle was measured with a colorimeter (Minolta CR-10, Konica Minolta Sensing, Japan), based on the CIE $L^*a^*b^*$ system in which the L^*, a^*, and b^* values were determined as indicators of lightness, redness, and yellowness, respectively.[25] The average of the three measurements was recorded as color coordinate values of the sample.

For estimation of drip loss, breast muscle samples, size of 3 cm (length) × 2 cm (width) × 1 cm (thickness), were stored at 4 °C for 24 h post-mortem. The breast sample was placed in netting and suspended in a vacuumed bag for 24 and 48 h at 4 °C, respectively.[26] The drip loss of the breast muscle was calculated using the equation

$$\text{drip loss (\%)} = \frac{W_{\text{before}} - W_{\text{after}}}{W_{\text{before}}} \times 100$$

where W_{before} is the initial weight of breast muscle sample and W_{after} is the weight of breast muscle sample after 24 or 48 h of hanging.

About 15 g of each breast muscle sample was weighed, held in plastic bags, and immersed in a water bath at 80 °C until the internal temperature reached 75 °C. Then, the bags were cooled to approximately 25 °C, carefully wiped, and reweighed.[27] The cooking loss were calculated by applying the equation

$$\text{cooking loss (\%)} = \frac{W_{\text{before}} - W_{\text{after}}}{W_{\text{before}}} \times 100$$

where W_{before} is the initial weight of breast muscle sample and W_{after} is the weight of breast muscle sample after heating.

Preparation of Breast Muscle Homogenates. The minced breast muscle was homogenized in ice-cold 0.86% sodium chloride buffer (w/v, 1:9) and centrifuged at 3500*g* for 10 min at 4 °C. The supernatant was stored at −80 °C for further analysis. The protein concentrations of the 10% breast muscle homogenates were determined by using the bicinchoninic acid assay.[28]

Measurement of Antioxidant Potential. DPPH, $ABTS^+$, and superoxide radical (O_2^-) radical scavenging activities were estimated according to the methods described in our previous study.[12] Hydroxyl radical (OH^-) radical scavenging assay was determined according to the method by Noda.[29] The percentage inhibition of OH^- generation was calculated using the formula

$$OH^- \text{ radical scavenging effect (\%)} = \frac{A_{\text{control}} - A_{\text{sample}}}{A_{\text{control}}} \times 100$$

where A_{control} is the absorbance of the control reaction and A_{sample} is the absorbance of the test samples.

Determination of Protein Carbonyls (PC) and 8-Hydroxy-2′-deoxyguanosine (8-OHdG). The PC levels in the breast muscle were determined using 2,4-dinitrophenylhydrazine as described by Reiter.[30] The PC content was expressed as nanomoles per milligram of protein. The level of 8-OHdG in the breast muscle was determined by using an ELISA kit (Beijing North Institute of Biotechnology, Beijing, China) with a monoclonal antibody specific for broiler species. The procedure followed the manufacturer's protocols. The 8-OHdG content was calculated by a standard curve generated using 0.05−2 ng/mL 8-OHdG and corrected for the protein concentrations in each breast muscle homogenate sample. The final results were expressed in nanograms per milligram of protein.

Determination of Reactive Oxygen Species. Intracellular ROS production in breast muscle was measured by using 2,7-dichlorofluorescein diacetate as fluorescence probe, as previously described.[11] The fluorescence was measured at the excitation wavelength of 488 nm and an emission wavelength of 525 nm through a fluorescence spectrometer. The result was expressed as a percentage of the control group, which was taken as 100%.

Determination of Total Thiol Contents. The concentration of total thiol groups (T-SH) was determined according to the method of Tabassum.[31] The T-SH content was expressed as micromolers per milligram of protein.

Determination of Antioxidant Enzyme Activity. The activities of total SOD (T-SOD), glutathione peroxidase (GPx), glutathione *S*-transferase (GST), and catalase (CAT) and the contents of malondialdehyde (MDA) and reduced glutathione (GSH) were determined spectrophotometrically with the commercial kits purchased from Nanjing Jiancheng Insititute of Bioengineering (Nanjing, Jiangsu, People's Republic of China).[32] The results of T-SOD, Mn-SOD, GPx, GST, and CAT activities were expressed as units (U) per milligram of protein. The GSH content was expressed as micrograms per gram of protein, and MDA content was expressed as nanomoles per milligram of protein.

Real-Time Polymerase Chain Reaction (PCR) Analysis. Total RNA from the breast muscle was isolated using Trizol reagent (TaKaRa, Dalian, China). The RNA was quantified with a

spectrophotometer (NanoDrop 2000c, Thermo Scientific, USA) and tested by agarose gel electrophoresis. Reverse transcription was performed immediately following the RNA isolation using the Perfect Real Time SYBR PrimeScriP kit (TaKaRa). Then the cDNA samples were amplified with the SYBR Premix Ex *Taq*II Tli RNaseH Plus kit (TaKaRa). Primer sequences are listed in Table S2. The relative amount of each target gene mRNA was calculated using the $2^{-\Delta\Delta Ct}$ method. The expression level of each target gene mRNA was normalized to the mRNA level of β-actin. In the present study, the results of gene expression were expressed as the fold changes between the treated and control groups.

Statistical Analysis. All data (experiments 1 and 2) were analyzed by using one-way analysis of variation (ANOVA) by SPSS 17.0. To evaluate the difference among groups, multiple comparisons were conducted using the Duncan test. Linear and quadratic contrasts were used to determine the effects for different dose levels (0, 50, 100, or 200 mg/kg) of supplemental curcumin in experiment 1. The significance level for difference was $p < 0.05$.

RESULTS AND DISCUSSION

Meat Quality and Antioxidant Status (Experiment 1). The effects of dietary curcumin on meat quality in breast muscle are presented in Table 1. Diet administered with curcumin had no difference on either the pH_{45} or pH_{24} of breast muscle in broilers. For meat color, the a^* value in breast muscle showed a linear and quadratic increase ($p < 0.05$) following the dietary curcumin supplementation ($p < 0.05$), but the L^* and b^* values showed no significant difference among the treatment groups. The water-holding capacity in the breast muscle of broilers was expressed by the drip loss at 24 and 48 h. The drip loss at 48 h of breast muscle was significantly influenced ($p < 0.05$) by dietary supplementation with curcumin and displayed a quadratic dose response. However, there was no significant effect on drip loss at 24 h and cooking loss of the breast muscle following the curcumin treatment.

Table 1 also shows the effects of dietary curcumin supplementation on the levels of antioxidant enzymes in breast muscle of broilers. The CAT activities of the breast muscle in curcumin-supplemented groups showed a quadratic dose response ($p < 0.05$). However, the breast muscle GPx, T-SOD, and GST activities of broilers fed the curcumin diet were not different ($p > 0.05$) from those of the broilers fed the basal diet. Minimal research has been conducted regarding the effect of various levels of curcumin on meat quality and oxidative status of breast muscle in broilers. Poultry meat contains a high concentration of polyunsaturated fatty acids, which makes it sensitive to free radical attack and oxidative deterioration.[33] The oxidant reaction initiated by free radicals destroyed the normal structure of the muscle and accumulated deleterious by-products, eventually influencing the meat quality.[34] On the other hand, the oxidation of myoglobin, which was mainly responsible for the meat color post-mortem, could lead to the discoloration of meat.[35] In the present study, curcumin, similar to fat-soluble antioxidant vitamin E, significantly improved the antioxidant capacity of the breast muscle. Similar beneficial effects of curcumin on enzyme activities were found in the literature.[10,34] It was suggested that curcumin improved the meat quality, especially the meat color, primarily due to its

ability to increase the antioxidant enzymatic activities in breast muscle.

Free Radical Scavenging Activity (Experiment 1). The DPPH radical is a stable nitrogen radical with yellow color and can be dissolved only in organic media.[36] The ABTS radical is a metastable radical with blue color and can be solubilized in both aqueous and organic media.[37] Both of them have been widely used to measure the antioxidant activity of biological materials and characterized by excellent reproducibility and stability under certain assay conditions.[38] O_2^- is one of the most representative free radicals, and its negative effects can be magnified because it produces other kinds of cell-damaging free radicals and oxidizing agents.[39] OH^- is well-known to be the most reactive of all the reduced forms of dioxygen and harmful to several cellular components such as DNA, lipid, and nucleus.[29] The antioxidant capacities of the breast muscle in broilers measured as DPPH, ABTS, O_2^-, and OH^- radical scavenging capacities are shown in Table 2. A linear and quadratic increase ($p < 0.05$) in the ABTS radical scavenging activities of breast meat was found with increasing dietary curcumin supplementation. The ABTS radical scavenging activities of breast meat in 50 and 100 mg/kg curcumin groups were significantly higher ($p < 0.05$) than that of the control group, whereas no difference was observed between the control group and the 200 mg/kg curcumin group. However, there was no significant variation ($p < 0.05$) in the percentage inhibition of DPPH, O_2^-, and OH^- radicals in the breast meat from the curcumin supplemental groups as compared to the control group. The high efficiency of antioxidants in the free radical scavenging assays could be attributed to either its direct capacity to neutralize stable free radicals or an indirect role as a hydrogen donor.[40] Our results suggested that curcumin, as a potential antioxidant, improved the antioxidant properties of breast muscle in broiler, possibly by the enhanced hydrogen-donating ability and free radical scavenging capacity.

Biomarkers of Oxidant Stress-Induced by Heat Treatment (Experiment 2). Studies on heat stress showed that its adverse effects are closely associated with the excessive ROS production.[23,41] A high level of free radicals caused oxidant stress and triggered oxidation of some critical cellular biomolecules, including lipid, protein, and DNA. In the present study, Figure 1 shows the increased ($p < 0.05$) intracellular ROS (Figure 1A), MDA (Figure 1B), PC (Figure 1C), and 8-OHdG (Figure 1D) levels in chickens reared under chronic heat treatment, suggesting the severe oxidant damage in breast muscle. When compared to the heat-stressed group, intracellular ROS levels in curcumin-administered groups (50, 100, or 200 mg/kg) were significantly decreased ($p < 0.05$) with the minimum level at 50 mg/kg. Compared with the heat-stressed group, administration with 100 mg/kg curcumin significantly decreased ($p < 0.05$) the breast muscle MDA and PC levels by 16.54 and 8.24%, respectively. In addition, curcumin supplementation (50, 100, or 200 mg/kg) significantly decreased the level of breast muscle 8-OHdG, which was a quantitative indicator for DNA damage occurring during oxidant stress.[42]

Curcumin had a strong capability of quenching free radicals, such as superoxide radicals and hydrogen peroxide.[12] Studies reported that Cr(VI) induced an increase in ROS level and severe oxidant damage, which were remarkably blocked by curcumin administration.[14] Besides, as a chain-breaking antioxidant, curcumin was proven to stop the reaction of chain propagation of lipid peroxidation through intercepting radical oxidation initiators.[14] A similar result was obtained from the recent work of Waseem et al., which suggested that the protective effects of curcumin against oxidant damage were partly attributed to its excellent free radical scavenging activity.[43]

Effect of Curcumin on Antioxidant Defense System Damaged by Heat Stress (Experiment 2). To evaluate whether dietary curcumin administration attenuated the oxidant damage induced by chronic heat treatment, we determined the capacity of the antioxidant defense system, consisting of the nonenzymatic and enzymatic antioxidant. Results showed that there existed significantly decreasing ($p < 0.05$) T-SH and GSH concentrations in breast muscle after

exposure to heat treatment (Table 3). The T-SH level of chicken supplemented with 50 or 100 mg/kg curcumin was significantly increased by 13.35 and 9.65%, respectively, as compared with the heat-stressed group. The reduction of breast muscle GSH concentrations was attenuated to a significant extent upon curcumin supplementation (50, 100, or 200 mg/kg), but not dose-dependently ($p < 0.05$). Moreover, the weakened antioxidant defense system in breast muscle was also evidenced by the remarkable reductions ($p < 0.05$) of GPx, GST, CAT, and T-SOD activities following the exposure to heat treatment (Table 3). Dietary treatment with curcumin significantly attenuated ($p < 0.05$) heat stress-induced decrease of GPx activity; notably the greatest activities were found at 100 mg/kg curcumin. Chickens supplied with 50 or 100 mg/kg curcumin had 25.13 and 16.67% higher ($p < 0.05$) GST activities than those of the heat-stressed group, respectively. A similar observation ($p < 0.05$) was made regarding the breast muscle CAT and T-SOD activities.

The change of intracellular redox status is relevant to the ability of curcumin to cope with oxidative stress during heat exposure. To restore the balance of redox system caused by oxidant stress, cells facilitated the antioxidant defense system through enhancing activities of enzymatic antioxidants (CAT, T-SOD, and GSH-related enzymes) and elevating concentrations of nonenzymatic antioxidants (total thiols and GSH).[44] The present study showed that GPx, GST, CAT, and T-SOD activities were significantly increased in the breast muscle with the curcumin administration compared with the heat-stressed group. In cells, SOD served as the first line of defense against deleterious effects of ROS via catalyzing the dismutation of endogenous superoxide radicals to H_2O_2, which is further removed by CAT and GPx.[45] GST, a major group of GSH-related enzymes, was responsible for the detoxification of endogenous compounds to reduce the cytotoxicity of ROS.[46] Furthermore, T-SH and GSH levels were significantly increased in curcumin-supplemented groups. Generally, T-SH consists of nonprotein and protein-bound thiols, whereas GSH represents about 90% of the intracellular nonprotein thiols. Consistent with our results, numerous studies have confirmed that the depletion of GSH resulting from oxidant challenge was partially or even fully recovered with curcumin treatment.[11,18] These above results indicated that curcumin had prominent antioxidant activity not only through its enhancement of antioxidant enzyme activities but also through its effect on the redox status of intracellular thiols, especially GSH.

Gene Expression (Experiment 2). In the present study, birds reared in chronic heat stress showed typical characteristics of heat stress, including the overexpression of heat shock protein 70 (HSP70) and heat shock protein 90 (HSP90) mRNA in the breast muscle. As shown in Figure 2, curcumin

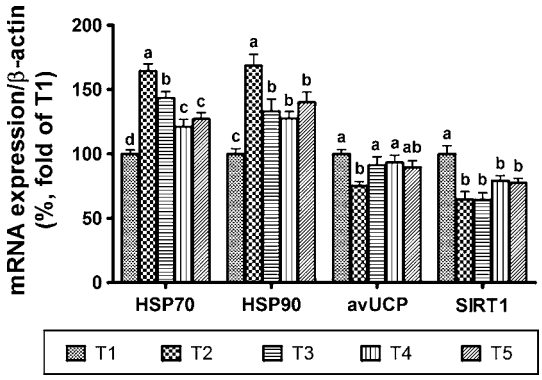

Figure 2. Effect of curcumin and heat treatment on gene expression in breast muscle (experiment 2). Results are expressed as the mean ± SEM. Bars labeled with different letters are significantly different ($p < 0.05$). T1 group, basal diet + normal temperature; T2 group, basal diet + heat treatment; T3, 50 mg/kg curcumin + heat treatment; T4, 100 mg/kg curcumin + heat treatment; T5, 200 mg/kg curcumin + heat treatment.

supplementation (50, 100, or 200 mg/kg) resulted in significant decreases in HSP70 and HSP90 expression levels. HSP70 and HSP90 are stress-defense proteins characterized by overexpression in response to many adverse environmental or physiological stimuli, including heat stress. Similar to our results, Hao et al. found a quick increase of HSP70 mRNA expression when chickens were exposed to heat stress for 2 h.[47] Parallel to the results of Sahin et al., our results have ascertained the protective role of curcumin by suppressing HSP expression in heat-stressed birds.[10] Furthermore, the mRNA expression of avUCP, an important regulator of mitochondrial ROS production,[48] was obviously depressed on exposure to chronic heat treatment while being markedly stimulated by curcumin supplementation (50, 100, or 200 mg/kg). The above data were consistent with the result of ROS level in breast muscle, indicating the inhibitory effect of curcumin on ROS production under heat stress. Moreover, we found that chronic heat treatment also significantly down-regulated sirtuin 1 (SIRT1) mRNA levels. SIRT1, an NAD^+-dependent protein deacetylase, plays an important role in the regulation of cellular oxidative stress burden.[49] Studies reported that the SIRT1 activation significantly decreases ROS levels, either directly or indirectly by deacetylation of the forkhead box class O 3 transcription factor and induction of manganese superoxide dismutase.[50] Recently, Yang et al. identified that SIRT1 activation by curcumin efficiently attenuated oxidant damage in the isolated heart.[15] In the present study, we found that the muscle mRNA expression of SIRT1 in heat-stressed groups, although not

DOI: 10.1021/jf505889b
J. Agric. Food Chem. 2015, 63, 3880−3886

significant, tended to increase in response to dietary curcumin treatment (100 or 200 mg/kg).

In conclusion, this study demonstrated that curcumin could be a potential feed additive that increased the oxidant stability of muscle and the meat quality in broiler chickens. Dietary curcumin supplementation could improve the meat color and increase water-holding capacity, free radical scavenging activity, and antioxidant enzymatic activity. The inclusion of 50 or 100 mg/kg curcumin was more effective in improving the meat quality and antioxidant system of breast muscle in broilers. The various levels of dietary curcumin had a positive effect on the redox status of breast muscle in broilers reared under chronic heat stress. Therefore, these results demonstrated that curcumin could serve as a potential promising antioxidant in poultry production that improved the redox status of breast muscle, in both normal and heat-stressed conditions, and benefit the resulting meat quality.

[a]Abbreviations: FM, fishmeal diet; LP, lupin meal diet; 0, 2, 4, 6, 10, levels of soya saponin inclusion in diets (g/kg). [b]Fishmeal 122/11, LTQ fishmeal, produced by Welcon AS, Norway. [c]Supplied by Holterman AS, Norway. [d]Wheat gluten 159/10, Amytex 100, produced by Syral, Belgium. [e]A 95% concentrate, supplied by Organic Technologies, United States. [f]Fish oil O5/10, NorSalmOil, produced by Norsildmel, Norway. [g]Supplemented to meet requirements.

such as lectins, protease inhibitors, oligosaccharides, phytate, alkaloids, and cyanogenic glycosides.[40,41] Despite the presence of these ANFs, lupin meals are considered highly digestible and good protein sources for salmonids.[42,43]

The purpose of this study was to investigate whether soya saponins alone may affect performance and induce enteritis in Atlantic salmon in the absence of other legume components in the diet, and to disclose the dietary threshold level. The recent introduction of a more purified soya saponin product (95% purity) allows for more conclusive data regarding this line of query. To assess threshold levels when other legume components are present, saponins were also supplemented to a legume-meal-containing diet. To this end, a dose–response design was employed using two basal diets without and with the presence of lupin meal, a diet ingredient that has previously been suggested to potentiate the effect of soya saponins.[16]

MATERIALS AND METHODS

Animal Husbandry. The experiment was conducted in compliance with laws regulating the experimentation with live animals in Norway as overseen by the Norwegian Animal Research Authority (FDU). The feeding trial was performed at Nofima's Aquaculture Research Station at Sunndalsøra, Norway. For each diet, duplicate, mixed-gender groups of 22 Atlantic salmon postsmolts of the Sunndalsøra strain with an initial mean body weight of 442 g (33 g SEM) were randomly distributed into 20 1 m^3 fiberglass tanks containing 250 L seawater replaced at a rate of 20 L/min. The temperature during the feeding trial decreased from 12 to 9 °C due to seasonal variation and affected all tanks equally. Oxygen saturation was above 85% throughout the experiment, whereas salinity varied between 32 and 33 g/L. Fish were fed continuously by automatic disk feeders. The economy and available facilities did not allow quantification of feed waste, but qualitative observations of appetite and waste accumulation in the tanks were made throughout the experiment. As the role of saponins in development of enteritis was the main goal of the study, this was considered an acceptable condition for the purpose of our study. A regimen of 24 h lighting was employed during the experimental period.

Diets. Diet formulations and their chemical compositions are shown in Table 1. Two basal diets were formulated, differing regarding protein sources. One was made with fishmeal supplying about 95% of the protein (FM). In the other, lupin meal and wheat gluten supplied about 25% and 35% of the protein, respectively, with fishmeal the remaining source (LP). Batches of each basal diet were subsequently supplemented with 0, 2, 4, 6, and 10 g/kg purified soya saponins (certified to be 95% pure, obtained from Organic Technologies, Coshocton, OH), replacing wheat starch. Accordingly, the diets were termed FM-0 and LP-0, FM-2 and LP-2, FM-4 and LP-4, FM-6 and LP-6, and FM-10 and LP-10. The basal diets were formulated to be isoenergetic (24 MJ GE/kg; GE = gross energy), and all diets were supplemented to fulfill the fishes' requirements for lysine, methionine, vitamins, and minerals. Fish oil and wheat meal were added as lipid and carbohydrate sources, respectively, to balance the nutrient composition of the diets. The fish were fed the experimental diets for 10 weeks.

Sampling. At the termination of the experiment, 10 randomly selected fish from each tank were sampled. All fish were fully anesthetized with tricaine methanesulfonate (MS222, Argent Chemical Laboratories) and subsequently euthanized by cervical dislocation prior to tissue sampling. Only fish with digesta throughout the intestinal tract were sampled to ensure intestinal exposure to the diets. Body weights and lengths were recorded for all fish. From five anesthetized fish per tank, blood was collected in heparinized vacutainers for plasma preparation. The abdominal cavities of all 10 euthanized fish per tank were opened, and the intestine was removed and cleared of any mesenteric and adipose tissue. Content from the proximal and distal halves of the proximal intestine (PI1 and PI2, respectively), the midintestine (MI), and the proximal and distal halves of the DI (DI1 and DI2, respectively) was collected into separate, preweighed tubes, frozen in liquid N_2, and then stored at −80 °C until further preparation and analyses could be conducted. The empty stomach, intestinal segments (PI, MI, and DI), liver, spleen, head kidney, and gall bladder were weighed. DI tissue samples for the histological evaluation were taken from six of the ten sampled fish per

DOI: 10.1021/jf506242t
J. Agric. Food Chem. 2015, 63, 3887–3902

tank, placed in 4% phosphate-buffered formaldehyde solution for 24 h, and subsequently stored in 70% ethanol until further processing. For mRNA extraction, DI samples from three of the six fish sampled for histology were placed in RNAlater (Ambion, Carlsbad, CA) at 4 °C for 24 h and subsequently stored at −20 °C. DI samples from the same three fish were taken for Western blots. These were frozen in liquid N_2 and then stored at −80 °C. For brush border membrane enzyme activity assessment, PI, MI, and the remaining DI tissues from all 10 fish per tank were frozen in liquid N_2 and stored at −80 °C.

Diet and Digesta Analyses. Feed and feces samples (from DI2) were analyzed for dry matter (EU 71/393), Kjeldahl nitrogen (N) (EU 93/28), lipid (HCl hydrolysis and diethyl ether extraction (EU 98/64)), and starch (AOAC enzymatic method 996.11). Gross energy was measured by bomb calorimetry (Parr 1271 bomb calorimeter, Parr, Moline, IL). Amino acid (except tryptophan) analysis of all samples was performed with a Biochrom 30 amino acid analyzer (Biochrom Ltd., Cambridge, U.K.) after hydrolysis, according to EC Commission Directive 98/64/EC. Tryptophan was analyzed on a Dionex Summit HPLC system, with a Shimadzu RF-535 fluorescence detector. Fatty acid composition of the feeds was determined by use of GC (gas chromatography) as previously described.[44] Yttrium oxide concentration in feed and feces was determined by inductively coupled plasma mass spectroscopy (ICPMS) as previously described by Refstie et al.[45]

Plasma Cholesterol, Total Bile Acids, and Other Metabolites. Analyses of plasma levels of cholesterol, total bile acids (conjugated and nonconjugated bile acids), total protein, glucose, triglycerides, free fatty acids, sodium, and phosphorus were performed by the Central Laboratory of the NMBU School of Veterinary Medicine (Oslo, Norway) according to standard protocols (Advia 1800, Siemens Healthcare Diagnostics, Erlangen, Germany).

Trypsin Activity and Total Bile Acids in the Digesta. Trypsin activity was determined colorimetrically as described by Kakade et al.[46] using the substrate benzoylarginine *p*-nitroanilide (Sigma no. B-4875, Sigma Chemical Co., St. Louis, MO) and a curve derived from standardized bovine trypsin solution. Total bile acid concentrations were determined using the Enzabile test kit (catalog no. 550101, BioStat Diagnostic Systems, Cheshire, U.K.) and a curve derived from standardized taurocholic acid solution.

Brush Border Membrane Enzyme Activity. The activity of the brush border membrane enzyme leucine aminopeptidase (LAP) was measured in PI and DI tissue homogenates diluted in ice cold Tris–mannitol buffer (1:20, w/v) containing 4-(2-aminoethyl)-benzenesulfonyl fluoride hydrochloride (Pefabloc SC, Pentapharm Ltd., Basel, Switzerland) as a serine proteinase inhibitor. The activity was determined colorimetrically using the substrate L-leucine β-naphthylamide hydrochloride as described by Krogdahl et al.[9] LAP specific activity was calculated following tissue protein concentration analysis using the BioRad protein assay (BioRad Laboratories, Munich, Germany).

Histology. Fixed DI tissue samples were processed according to standard histological techniques and stained with hematoxylin and eosin (H&E). Examination was conducted blindly with a light microscope using a continuous scoring scale from 0 to 10 as described elsewhere.[47] The following histological characteristics were evaluated: length and fusion of mucosal folds, cellular infiltration and width of the lamina propria and submucosa, enterocyte vacuolization, nucleus position within the enterocytes, and the relative number of goblet cells.

Immunohistochemistry. Detection of proliferating cell nuclear antigen (Pcna) in fixed sections of DI tissue was performed by immunohistochemistry. Sections were deparaffinized using xylene and subsequently rehydrated. Nonspecific antibody binding was reduced by incubating the sections for 20 min with 5% bovine serum albumin in Tris-buffered saline (BSA/TBS) containing normal horse serum diluted 1:50. This was followed by overnight incubation at 4 °C with the primary antibody (mouse monoclonal anti-Pcna, M0879, Dako Norge, Oslo, Norway) diluted 1:200 in 1% BSA/TBS. After being rinsed in PBS, sections were incubated with biotinylated horse antimouse secondary antibody at 1:200 in 1% BSA/TBS for 30 min. A Vectastain ABC-PO (mouse IgG) kit was used to visualize immunoreactivity. Sections were counterstained with Mayer's hematoxylin. Staining was evaluated by measuring the Pcna staining height as described elsewhere.[11]

Western Blot. Quantification of Pcna and fatty acid binding protein 2 (Fabp2) levels was performed in DI tissue samples from three fish from the control groups (FM-0 and LP-0) and from the 10 g/kg saponin groups (FM-10 and LP-10). Samples of 40 μg of protein were prepared, separated by SDS–PAGE, and blotted onto nitrocellulose membranes as previously described.[48] Membranes were incubated overnight at 4 °C with primary antibodies for the two target proteins: mouse monoclonal anti-Pcna (1:2000) and goat polyclonal anti-Fabp2 (1:4000, NB100-59746, Novus Biologicals, Littleton, CO). Primary antibodies for candidate reference proteins included rabbit polyclonal anti-glyceraldehyde-3-phosphate dehydrogenase (Gapdh; 1:250, PA1-987, Thermo Scientific, Waltham, MA) and rabbit polyclonal anti-actin (1:500, A5060, Sigma-Aldrich, St. Louis, MO). All antibodies were previously validated for use in Atlantic salmon.[48,49] After subsequent incubations with alkaline phosphatase-conjugated secondary antibodies, target and reference proteins were visualized with fluorescence by the ECF Western blotting reagent pack (GE Healthcare) and Typhoon 9200 imager system (Amersham Biosciences). ImageQuant software (Amersham Biosciences) was applied to quantify the band intensities. Both Gapdh and actin expression levels showed significant variation between diet groups and were therefore not suitable as reference proteins in the present study. Instead, total membrane protein content was visualized using a MemCode protein stain kit (Thermo Scientific) and used as a qualitative loading control.

Quantitative Real Time PCR (qPCR). RNA purification and quality control, DNase treatment, cDNA synthesis, and qPCR assays were performed as described by Kortner et al.[50] A selection of previously proposed marker genes for gut health and metabolism was profiled in DI tissue samples. Primer details are shown in the Supporting Information (Table SI 1). *gapdh*, *rnapolII* (RNA polymerase II), and *hprt1* (hypoxanthine phosphoribosyltransferase 1) were evaluated for use as reference genes as described by Kortner et al.[53] The geometric average expression of *gapdh* and *rnapolII* was used as the normalization factor. Mean normalized expression of the target genes was calculated from raw Cq values by relative quantification.[51]

Calculations. The specific growth rate (SGR) was calculated using the tank means for initial body weight (IBW) and final body weight (FBW) and calculated as follows:

$$\mathrm{SGR} = [(\ln \mathrm{FBW} - \ln \mathrm{IBW})/\text{number of days}] \times 100$$

The organosomatic index (OSI) was calculated as follows:

$$\mathrm{OSI}\ (\%) = [\text{organ weight (g)}/\text{body weight (g)}] \times 100$$

The apparent digestibility (AD) was estimated indirectly using Y_2O_3 and calculated as follows:

$$\mathrm{AD} = 100 - 100(M_{\mathrm{feed}}/M_{\mathrm{feces}})(N_{\mathrm{feed}}/N_{\mathrm{feces}})$$

where M_{feed} and M_{feces} are the concentrations (%) of marker (Y_2O_3) in the feed and feces and N_{feed} and N_{feces} are the concentrations (%) of a nutrient in the feed and feces.

The Pcna-positive proliferative compartment length (PCL) was corrected for body length (PCL_{BL}):

$$\mathrm{PCL_{BL}}\ (\mu\mathrm{m/m}) = [\mathrm{PCL}\ (\mu\mathrm{m})/\text{body length (cm)}] \times 100$$

Statistical Analysis. Data waere tested for normality and variance homogeneity using the Shapiro–Wilk *W* goodness of fit test and the Bartlett test, respectively. When necessary, data were transformed to achieve normal distribution (indicated by a superscript "†" in Table 10). Effects of the inclusion of levels of soya saponins were evaluated using regression analysis (GLM). The results were fit to polynomial models of first, second, and third degrees. The model considered to fit the results best on the basis of visual examination and the observed r^2 is reported. Comparison of basal diet effects was performed employing two-way analysis of variance (ANOVA) with the basal diet and saponin level as class variables. When interaction effects were

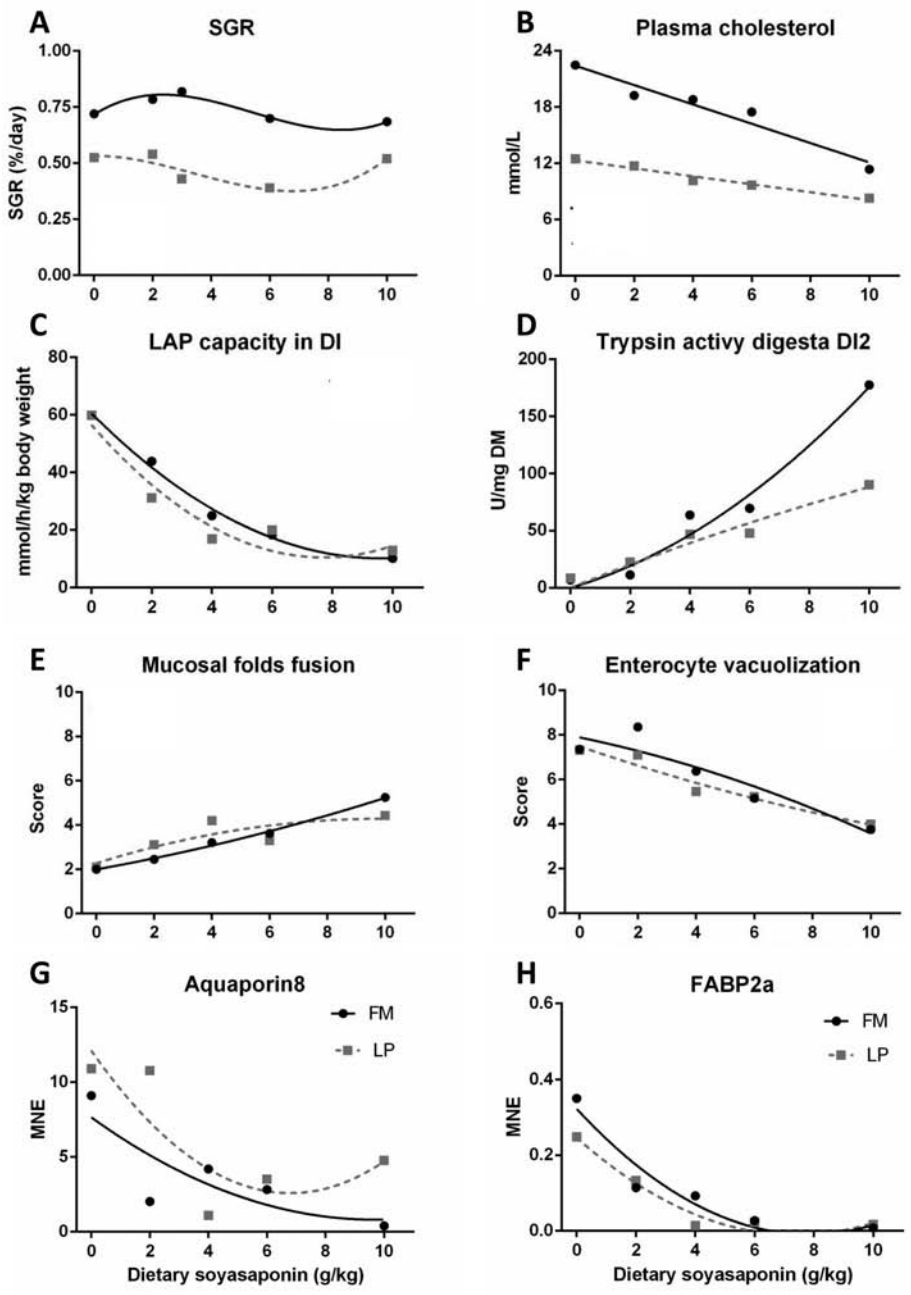

Figure 1. Illustration of relationships between level of dietary saponin supplementation (g/kg) and (A) specific growth rate (SGR; % per day), (B) plasma cholesterol level (mmol/L), (C) total capacity of leucine aminopeptidase (LAP) activity in the distal intestine (DI; mmol/h/kg of body weight), (D) trypsin activity of chyme from the DI (U/mg dry matter [DM]), (E) mucosal fold fusion in the distal intestine, (F) enterocyte vacuolization in the DI (score), (G) mean normalized expression (MNE) of *aqp8* in DI tissue, and (H) MNE of *fabp2a1* in DI tissue. The curves illustrate the regression that fits the results best for fish fed the fishmeal diet (FM; solid lines) and the diet with lupin meal (LP; dashed lines) according to the regressions shown in Tables 2, 4, and 7.

significant, one-way ANOVA and teh posthoc Tukey–Kramer HSD test were performed to aid in the interpretation of interactions.

Since histology and some qPCR data did not fulfill the requirement of normal distribution, the analysis was performed using the Wilcoxon/Kruskal–Wallis test followed by teh posthoc Steel–Dwass method to compare the means. Statistical analysis was performed using JMP statistical software (version 10, SAS Institute, United States), and graphs were made using GraphPad Prism, version 6.0 (GraphPad Software Inc., 2013). The level of significance for all analyses was set at $P < 0.05$. Results showing P values between 0.05 and 0.10 are discussed as results showing clear trends.

RESULTS

The presentation of the results is organized as follows: The response variables are grouped in subsections on the basis of their relationship regarding localization, function, and method of analysis. Within each subsection, the evaluation by regression analyses of saponin supplementation within the two basal diets is given first, followed by a comparison of the two basal diets based on the results of the two-way ANOVA. To allow interpretation of significant interaction effects, means and statistics resulting from a one-way ANOVA are also provided in the respective tables.

Feed Acceptance and Growth Performance. During the course of the feeding trial, differences in feed acceptance of the basal diets regardless of saponin supplementation were observed visually. More feed waste was observed in the tanks of fish fed the LP diets compared to the FM diets, and this was reflected in differences in specific growth rates (Figure 1A). The regression analysis (Table 2) showed a significant cubic (third-degree) relationship between growth and soya saponin level for fish fed the FM basal diet, indicating a stimulating effect at the lower inclusion levels. Growth was similar in fish fed the FM-0 and FM-10 diets. The results did not indicate any negative effect of saponin inclusion within the investigated range of saponin inclusion. For LP-fed fish, the relationship between growth and saponin level was less clear and not significant, and no indication of a stimulating effect at low levels was observed. For fish fed the LP-0 diet, SGR was 0.53, which was 34% less than for fish fed the FM-0 diet with an SGR of 0.72 ($P < 0.0001$).

Apparent Nutrient Digestibilities (See Tables 2 and 3 and Supporting Information Tables SI 2−5). Regression analyses revealed a significant inverse relationship between the dietary saponin level and AD of crude protein and lipid, which followed a second-degree relationship; i.e., the effect became more pronounced at higher levels. The same picture was seen for amino acid ADs. For about half of the amino acids, the results fit a first-degree relationship best, while for the remainder a second-degree relationship was best. However, for crude protein and all amino acids, the effect depended on the basal diet and was clearly significant only for fish fed the FM diet. The LP diet showed significantly and substantially higher ADs for crude protein and all amino acids at all saponin supplementation levels compared to the respective FM diets. For the FM-0 and LP-0 diets the difference in AD of protein was 6%. The apparent digestibility of taurine also decreased with increasing saponin level, but again the effect was only seen in fish fed the FM basal diet. Significantly lower values were observed for fish fed the LP basal diet than those fed the FM diet. For crude lipid AD, an increasing saponin level generally decreased digestibility, but a clear effect was seen only for fish fed the FM diets. ADs of the individual fatty acids showed the same picture. In fish fed the LP diets, negative effects of saponins were observed for C16:0, with a similar trend for C18:0. Fish fed the LP diet generally showed the highest values for crude lipid and fatty acid ADs. ANOVA showed a significant interaction between basal diet and saponin level. For the FM-0 and LP-0 diets, the difference was 1%, whereas for FM-10 and LP-10 diets, the difference was 5%. No significant effect was observed for the AD of starch, either for saponin level or for basal diet. On the basis of the observed ADs of protein, lipid, and starch for diets FM-0 and LP-0, digestible energy values for the basal diets were estimated to be 20.7 and 21.8 MJ/kg, respectively. The values 23.6, 30.5, and 17.3 kJ/g were used, respectively, for the GE of protein (N × 6.25), lipid, and starch.

[a]Abbreviations: FM, fishmeal diet; LP, lupin meal diet; LAP capacity, leucine aminopeptidase capacity in PI or DI; LAP activity, leucine aminopeptidase activity in PI or DI; PI, proximal intestine; DI, distal intestine; TBA digesta, total bile acid in the intestinal content in PI1, PI2, MI, DI1, or DI2; PI1, proximal section of proximal intestine; PI2, distal section of proximal intestine; MI, midintestine; DI1, proximal section of distal intestine; DI2, distal section of distal intestine; trypsin digesta, trypsin activity in the intestinal content in PI1, PI2, MI, DI1, or DI2; X, soya saponin level.

lower OSI of the stomach and MI and a higher OSI of the PI than fish fed the FM basal diet. For the DI, on the other hand, the basal diets did not affect the OSI differently, but for both, a clear negative effect of increasing soya saponin level was observed and the relationship fit a first-degree function best. The liver OSI decreased significantly for the FM fish with increasing soya saponin level, also fitting a first-degree function best. For the LP-fed fish, the relationship was not significant. The two-way ANOVA model did not show significant effects. The saponin level affected the gall bladder OSI significantly in fish fed the FM basal diet only, following a decreasing, second-degree relationship best, with a diminishing effect with increasing level. According to the results of the two-way ANOVA, there was no clear difference between the two basal diets in gall bladder OSI. Neither the spleen nor head kidney indices showed a significant relationship to soya saponin level or basal diet.

Plasma Values (see Table 4, Figure 1B, and Supporting Information Table SI 7). Increasing levels of soya saponins reduced plasma cholesterol following a first-order relationship. The magnitude of the effect, however, depended significantly on the basal diet. Fish fed the LP diet generally showed cholesterol levels 50% lower than those of fish fed the FM diet. Likewise and possibly related to the lower plasma values in general, the effect of saponin dose was less pronounced in fish fed the LP diet than fish fed the FM diet. Fish fed the FM-10 diet showed a reduction in plasma cholesterol of about 50% compared to those fed FM-0. For the LP fish the reduction was 23%. Plasma total bile acid concentrations showed a trend similar to that of the cholesterol results, but with somewhat greater variation. The effect depended on the basal diet. For fish fed the LP-0 diet, the total bile acid concentration was 35% lower than that for fish fed the FM-0 diet. The difference between fish fed the FM-0 and FM-10 diets was about 65%, whereas the decrease was 61% in fish fed the respective LP diets. The other plasma variables showed no significant effects either of soya saponin level or of basal diet.

Brush Border Membrane Leucine Aminopeptidase Activity (See Tables 4 and 5 and Figure 1C). Activities are presented as total capacity (mM/kg body weight) and specific activity (mM/mg of protein). In the PI, increasing levels of soya saponin inclusion significantly increased the total LAP capacity. The regression showed a significant first-order relationship for fish fed the LP diets, with the same trend for the FM-fed fish. In DI, the relationship was opposite and significant for both basal diets, fitting a second-degree relationship best with diminishing reductions with increasing saponin level. The specific activity was also affected by the saponin level, but only in the DI, fitting a first-order function best. Basal diet effects were also only observed on specific activity in the DI, whereas LAP capacity was not affected in any of the intestinal segments.

Total Bile Acid Concentration and Trypsin Activity in Intestinal Content (See Tables 4 and 6 and Figure 1D). Results reveal that increasing saponin levels decreased the chyme total bile acid concentration significantly in PI2, MI, and DI1 significantly for fish fed the FM diet, while a similar trend

[a]Abbreviations: FM, fishmeal diet; LP, lupin meal diet; 0, 2, 4, 6, 10, levels of soya saponin inclusion in diets (g/kg); BW, body weight. Mean values with different online letters a, b, c, d, and e within a column are significantly different ($P < 0.05$).

was observed for the LP-fed fish. In PI2, the difference between the two basal diets was significant (significant interaction), with a more pronounced effect for fish fed the FM diet. For trypsin activity, significant effects of saponin level were observed only for the two most distal segments, DI1 and DI2, in which increasing dietary soya saponin levels increased the activity of trypsin markedly. The magnitude of the effect depended on the basal diet, with a greater effect for fish fed the FM diet. In DI1 the relationship followed a first-degree function, whereas in DI2 the effect seemed to accelerate with increasing saponin level; i.e., it fit a second-degree function better.

Morphology of the Distal Intestine (See Tables 7−9 and Figures 1E,F and 2A−C). The soya saponin level affected all the characteristics assessed and showed alterations typical for mucosal inflammation. The severity increased with increasing level of soya saponin inclusion. The effects seemed independent of the basal diet composition. The results showed decreased height and increased fusion of the mucosal folds, increased width and cellular (leucocyte) infiltration of the lamina propria and submucosa, reduced numbers of supranuclear absorptive vacuoles in enterocytes, displaced nuclei toward the apexes of the cells, and increased frequency of goblet cells in the mucosa. For all these characteristics, regression followed a second-degree relationship best, with increasing effect with increasing saponin level.

Immunohistochemical Examination of the Distal Intestine (See Table 9 and Figure 2D−F). Results of the Pcna staining indicate that increases in saponin levels significantly increased the height of the staining in the mucosal folds, regardless of the basal diet. The regression analyses showed that a second-degree function fit the results best. The height of Pcna staining did not differ for the two basal diets.

Western Blot (See Figure 3). Pcna protein levels in the DI were increased 2-fold by the 10 g/kg saponin dose, but the effect was only observed for fish fed the FM diet. In contrast, Fabp2a protein levels were significantly reduced and again only for fish fed the FM diet.

Gene Expression (See Tables 7, 10, and 11 and Figure 1G,H). Among the immune-related transcripts, interleukin 17a (*il-17a*), interferon γ (*ifnγ*), and myeloid differentiation factor 88 (*myd88*) were significantly increased with increasing saponin levels, and interleukin1β (*il-1β*) and matrix metalloproteinase 13 (*mmp13*) displayed a similar trend. For *il-17a*, the effect was apparent only in fish fed the FM diet as indicated by the significant interaction. The posthoc test based on the results of the one-way ANOVA showed that the effect became pronounced only at the highest saponin inclusion level, i.e., for fish fed FM-10. The FM-10 group also showed the numerically highest values for the other above-mentioned transcripts. Increasing saponin levels down-regulated the expression of *aqp8ab* (Figure 1G), *fabp2a1* (Figure 1H), and interferon γ-inducible lysosomal thiol reductase (*gilt*). For *aqp8ab* this effect seemed to depend on the basal diet with somewhat different dose–response curves for the two. Comparison of the two basal diets showed that fish fed the LP diets presented higher expression of *ifnγ* and mucin 2 (*muc2*) than fish fed the FM diets. For the other expression variables, no significant differences were observed.

DISCUSSION

The data reveal that 2–4 g/kg soya saponins in diets from a 95% purified source elicited signs of inflammation in the DI of Atlantic salmon without the presence of other legume components. Supplementation with 2 g/kg modified some functional characteristics, while a level between 2 and 4 g/kg appeared to be needed to induce signs of inflammatory changes. However, inclusion levels as low as 8% SBM have previously caused inflammation with concomitant digestive dysfunction,[9] which translates to a saponin level of ca. 0.4–0.6 g/kg in the diet. This is 70–80% lower than the lowest supplementation of 2 g/kg diet in the current study. Additionally, for several of the observed variables, such as enterocyte vacuolization, mucosal fold fusion, and Fabp2a, the dose–response effect did not clearly differ between the saponin-supplemented FM and LP diets, despite the apparent difference in feed intake and therefore saponin exposure. Thus, the saponin supplementation was more potent in the LP than the FM basal diet, most likely due to interactions with other lupin components. Therefore, the current study substantiates previous suggestions that the induction of inflammation by soya saponins is potentiated by other ANFs, antigens, or other components in SBM and other legumes such as peas and lupins.[16,19,20]

Effects of Basal Diet Composition. The observed, although not quantified, differences in feed intake, which are most likely the major cause of the differences in growth observed between fish fed the two basal diets along with the implicit underlying differences in digestive and metabolic

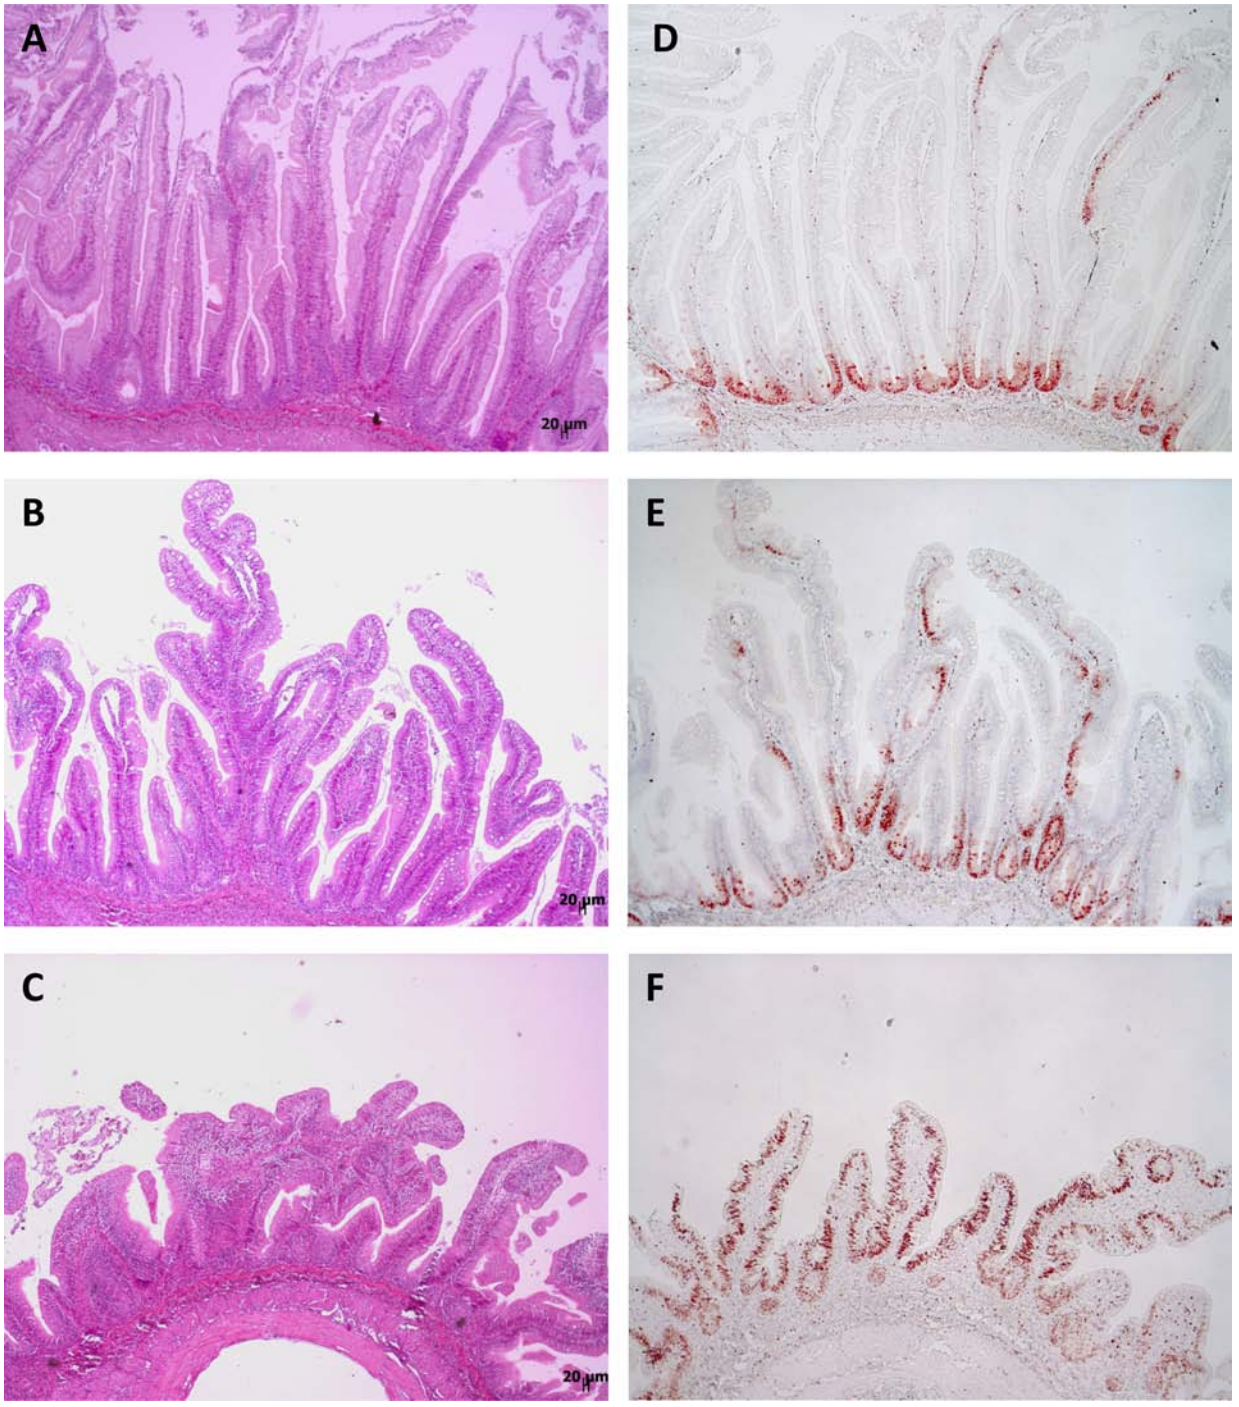

Figure 2. (A–C) Representative histomorphological images from hematoxylin and eosin-stained sections of the distal intestine of Atlantic salmon depicting the dose-dependent increase in the severity of the inflammatory changes with increasing soya saponin supplementation in fish fed the FM-0 (A), FM-6 (B), and FM-10 (C) diets. (D–F) Representative images of the localization and distribution of immunohistochemically labeled proliferating cell nuclear antigen (Pcna) protein in the epithelial cells of the distal intestine of Atlantic salmon depicting the dose-dependent increase in the relative number of proliferating cells with increasing soya saponin supplementation considered low for the FM-0 diet (D), moderately elevated for the FM-6 diet (E), and highly elevated for the FM-10 diet (F). FM = fishmeal diet, and 0, 6, and 10 indicate the levels of soya saponin inclusion in the diets (g/kg).

aspects, makes integration of results from the two groups challenging. The macronutrient digestibilities were generally higher for the LP than the FM diet. The estimates of digestible energy of the basal diets based on the ADs resulted in values of 20.7 and 21.8 MJ/kg for FM-0 and LP-0, respectively. Fish fed the LP-0 diet grew 32% less than those fed the FM-0 diet. Assuming their energy needs to be 17–19 MJ GE/kg of growth,[56] feed consumption is estimated at 230–250 g for the LP diet and 360–400 g for the FM diet. Thus, the LP-fed fish ate ca. 36% less. Lupins contain bitter alkaloids, which may be the cause of the low feed intake in the LP fed fish.[57,58] The lupin alkaloids, however, seem not to affect fish health importantly,[57−60] as supported by the present study.

J. Agric. Food Chem. 2015, 63, 3887−3902

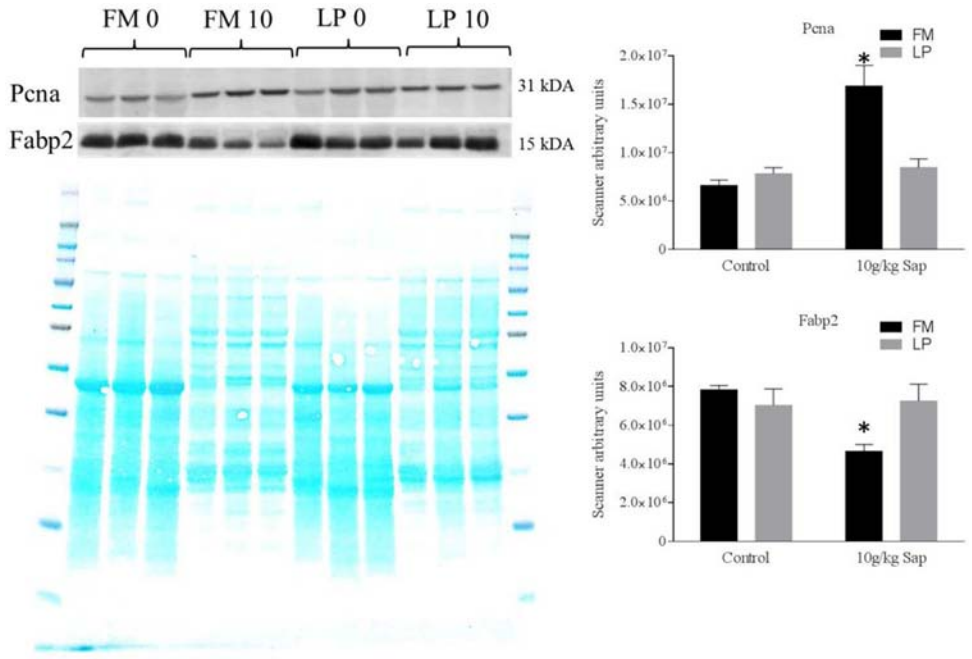

Figure 3. Western blot analysis of proliferating cell nuclear antigen (Pcna) and fatty acid binding protein 2 (Fabp2) proteins in the distal intestinal tissue of fish fed the four diets FM-0, FM-10, PM-0, and PM-10. Immunoblots are shown for $n = 3$ individual fish per diet group. The corresponding total protein stain is shown in blue below each individual blot. Relative staining intensity values in the columns of the graphs are means of the $n = 3$ fish per diet, with their standard errors represented by vertical bars. Asterisks denote saponin diet groups that are significantly different from their respective control diet groups.

The higher nutrient ADs for the LP-fed fish may at least partly be explained by the apparent difference in feed intake, which have been reported to decrease with increasing feed intake.[61,62] However, reported effects of feed intake are in general rather small. The 6% difference in protein AD in the present study was therefore remarkably high, and can only be explained by a higher protein digestibility of the plant meals in the LP diet, i.e., lupin and wheat gluten, compared to the fishmeal in the FM diet. Experience has indicated that protein digestibility may vary greatly among fishmeals, most likely due to differences in the quality of the raw materials, ash content, and processing conditions such as heat treatment.[63]

The lower relative weights of the stomach, MI, DI, and liver in the LP-fed fish were most likely also due to lower feed intake.[64] However, the higher PI weight, the section of the digestive tract that is responsible for the majority of nutrient absorption,[65] may be a result of (1) a higher concentration of digestible nutrients that can stimulate tissue growth and/or (2) a compensatory response to challenges to the digestive processes linked to fibers and possibly other ANFs in lupins. Fiber-rich diets have been shown to induce growth of intestinal tissues in Atlantic salmon[66] and cod,[67] possibly due to a need for a larger absorptive surface area when the volume of the chyme increases due to swelling of the fiber. Growth stimulation by fermentation products produced from the fibers in the digestive tract is another possible mechanism.[68,69] In any case, the effects on PI weight were clearly greater than any diminishing effect of reduced feed intake could be expected to be.

Plasma cholesterol and bile salt levels also differed markedly between the fish fed the two basal diets, with lower values in the LP-fed fish, which can again be explained by lower feed intake and lower diet cholesterol levels in this diet. However, this is also a commonly observed response to plant feed ingredients and foods, with their contents of fibers, phytosterols, phytoestrogens, and saponins all affecting cholesterol and bile salt absorption (reviewed by Krogdahl et al.[18]). In fish, low cholesterol and bile acid absorption and metabolism have been suggested to be a cause of the frequently observed reductions in lipid digestibility of plant ingredients, in particular standard SBM.[70] In the present experiment, however, lipid ADs did not significantly differ between the LP- and the FM-fed fish, although apparent lower feed intake in the LP-fed fish may have masked any negative effects.

Effects of Saponins. Under the condition that the difference in growth was due to a difference in feed intake, saponin exposure would have been lower in the LP fish. On the basis of feed intake estimates (see above), exposures of supplemented saponins were 0, 1.1, 1.7, 2.4, and 5.1 g/kg initial body weight for the fish fed the LP-0 to LP-10 diets and 0, 1.8, 3.8, 4.7, and 7.5 g/kg initial body weight for the FM-0 to FM-10 diets. For the LP diets the estimates are most likely lower than the actual values as the natural saponin contents of the lupins were not taken into account. However, the low levels reported in lupin seeds[36,37] can be considered negligible in this context, adding less than 0.1 g/kg to the LP diet, i.e., less than 5% of the supplementation level of the LP-2 diet. Since current tools used for saponin analysis lack accuracy,[39] saponin analysis was not performed.

On the basis of the above considerations, it might be argued that saponin effects should be evaluated on the basis of exposure, e.g., expressed per unit of fish weight, rather than level in the diet. Similarly, estimates of acceptable dose should also be based on exposure per unit of fish weight. However, the apparent difference in feed intake most likely interacted several ways with saponin effects, making a discussion based on saponin intake very difficult and its value questionable. The discussion on the effects of saponin exposure below is therefore

[a]Abbreviations: FM, fishmeal diet; LP, lupin meal diet; 0, 2, 4, 6, 10, levels of soya saponin inclusion in diets (g/kg); *tcrγ*, T-cell receptor γ; *myd88*, myeloid differentiation factor 88; *mmp13*, matrix metallopeptidase 13; *fxr*; farnesoid x receptor. Data were analyzed using the Wilcoxon/Kruskal–Wallis test followed by the posthoc Steel–Dwass method.

mainly based on the responses seen for the FM-fed fish. Comments regarding effects in the fish fed the LP diet are reserved for response variables of particular importance. Absence of saponin effects in LP fish, as compared to FM fish, is not discussed when they were most likely a result of low saponin exposure.

Low levels of saponin exposure stimulated growth in the FM group, an effect which may have been due to increasing feed intake, or some metabolic or physiological effects. As for other toxins and stressors generally considered detrimental for health at higher doses, the apparently beneficial effects observed at low levels of saponin exposure can be considered a hormetic response. This may also be related to the immune-stimulating effects of saponin's adjuvant characteristics.[28−30,38] The apparent absence of such positive effects in LP-fed fish may be explained by antagonistic, possibly potentiating effects of other lupin components. The apparent lack of a significant effect of soya saponin exposure on growth for either basal diet group is in line with indications from other studies investigating similar saponin preparations in fish feed.[16,19]

The observed negative effects of higher saponin exposure on nutrient digestibilities are in agreement with the results of the work of Chikwati et al.[19] investigating the effect of adding 2 g/kg soya saponin to diets with different plant ingredients. However, in this earlier work, the saponin effects depended on the plant ingredient included in the diet and were significant for a diet containing pea protein concentrate, but not for the other diets with sunflower, horse beans, and rapeseed meal as alternative ingredients. The suggested explanation was differences in saponin level between the plant ingredients, as peas contain more saponins than the others, or other potentiating components in the pea meal.[19]

The mechanisms behind effects of saponin exposure on nutrient ADs may be related to reductions in cholesterol and bile salt levels in intestinal content and subsequently in plasma. Saponin binding to 3-β-hydroxysteroids such as cholesterol forms insoluble, nonabsorbable complexes and increases their excretion,[22,25,71] which alters the normal metabolic pathways of cholesterol and total bile acid production.[50] Thus, the current data support previous investigations suggesting that saponins are at least partially responsible for the drop in plasma cholesterol levels in several animal species fed plant meal diets.[23,25−27,50] Moreover, bile salts have the ability to stabilize pancreatic proteolytic enzymes (reviewed by Krogdahl et al.[18]). Accordingly, a reduction in chyme bile salt concentration may cause reduced protein digestibility, as observed at the highest level of saponin supplementation in the present study. The marked reduction in LAP activity in the DI may also have played a role in the saponin effect on protein and amino acid ADs.

The present study clearly demonstrated that soya saponins alone, supplemented at levels of 2−4 g/kg of diet and above, caused a dose-dependent increase in the severity of inflammatory changes in the DI tissue as described for SBMIE in salmonids,[6,8,9,13,19] strongly suggesting the involvement of saponins as a causatory agent. At the lowest saponin inclusion level, the effects were small, but trends were clearly observed for increased width and cellular infiltration in lamina propria and submucosa. The reductions in DI somatic index and digestive enzyme activities as well as marked reductions in gene expression for various functional proteins (see below) are signs of dysfunction caused by the inflammation and may be directly linked to the shortening of the mucosal folds, which has been suggested to be related to the increase in cell turnover with concomitant increases in proliferation, migration, and apoptosis observed in Atlantic salmon fed SBM.[11,13,72] These phenomena were apparent in the present study as well, as supported by data regarding mucosal fold height and Pcna protein expression in the DI tissue.

At the gene expression level in the DI, alterations observed at the higher saponin inclusion levels in the present study correspond well with the more convincingly up- or down-regulated genes reported for salmon with SBMIE.[52,54] Among these were genes related to recruitment and/or differentiation of inflammatory cells, i.e., *il-17a*, *ifnγ*, and *il-1β* in the FM-10 group and remodeling of the extracellular matrix as suggested by induction of *mmp13*. The cytokine *il-17a* has been suggested as a sensitive molecular marker for SBMIE[52] and may be a candidate marker for exposure to high levels of soya saponins as well, since transcript levels displayed a >30-fold induction in the FM-10 group. Other immune-related genes previously reported to be differentially regulated during SBMIE, but often less convincingly than those mentioned above,[10,52,54] were not significantly or dose-dependently affected in the current study. These include *par2a*, *par2b*, *tcrγ*, *cd4α*, *cd8β*, *gilt*, *mhcI*, *myd88*, *fxr*, and *muc2*. This may further support the theory that other SBM components may work synergistically with saponins to illicit a full inflammatory response.

Among functional transcript markers, *fabp2a1* for fatty acid binding protein and *aqp8ab* for one of the aquaporins were found to be strongly and dose-dependently down-regulated by soya saponin inclusion in both basal diets. A corresponding reduction in Fabp2 protein level was observed for the FM-10 group. These responses in Fabp2 protein and mRNA levels have also been observed during SBMIE[49,73] and inflammation caused by the combination of pea protein concentrate and 2 g/kg soya saponins.[20] Reduced Fabp2 levels could explain the decreased lipid ADs typically observed in fish fed SBM.[49] The transcriptional expression of *aqp8ab* also displayed marked suppression with increasing soya saponin levels for both basal

diets. This response has previously been observed in salmon with DI inflammation[20,73] and in mammals with intestinal inflammation.[74,75] In these latter studies, down-regulation of *aqp8* was concomitant with decreases in the absorption of water, suggesting a possible role of aquaporins in the pathogenesis of diarrhea accompanying intestinal inflammatory disease.

The observation of progressively increasing trypsin activity of the intestinal content supports earlier findings in salmonids,[9,55] as well as in other animals and humans,[76,77] and suggests that this variable is a good marker candidate for inflammation in the DI. In mammals, such increases in chyme trypsin activity of the distal compartments of the intestine have been shown to activate PAR-2, which mediates pro-inflammatory effects in the colon of mammals.[78,79] It may also be partly explained by decreased ability of the more immature or damaged epithelial cells to reabsorb pancreatic enzymes.[66,72]

In the present study, a novel hemagglutinin was purified from the seeds of Northeast China black beans, and its biological properties and antitumor and immumoregulatory effects were characterized.

MATERIALS AND METHODS

Materials and Reagents. Northeast China black beans, a cultivar of *Phaseolus vulgaris,* were purchased from a local vender and authenticated by Professor Shiuying Hu, Honorary Professor of Chinese Medicine, The Chinese University of Hong Kong. Affi-Gel Blue gel, Mono Q 5/50 GL, Superdex 75 10/300 GL columns, and purifier were bought from GE Healthcare, UK. Human hepatocellular carcinoma HepG2 cell line, osteocarcinoma MG-63 cell line, and normal embryonic liver cell WRL 68 cell line were purchased from the American Type Culture Collection. All primary and secondary antibodies were purchased from Cell Signaling Technology (Danvers, MA). TRIZOL and the reverse transcriptase PCR kit were acquired from Invitrogen (Waltham, MA). Power SYBR Green PCR Master Mix was purchased from Applied Biosystems (Warrington, Cheshire, UK). FITC fluorescent dye was purchased from Thermo Scientific (Waltham, MA).

Purification of Hemagglutinin. Dried beans (60 g) were soaked in water overnight and then ground into a slurry. After centrifugation at 14000 rpm for 30 min at 4 °C and filtration through filter paper, the supernatant was adjusted with 2 M Tris−HCl buffer (pH 7.6) until the concentration of the buffer reached 20 mM, and it was then loaded on an Affi-Gel Blue gel column which was equilibrated with 20 mM Tris−HCl buffer (pH 7.6). Unadsorbed fraction and adsorbed fraction were, respectively, eluted with the starting buffer and 1 M NaCl in Tris−HCl buffer (20 mM, pH 7.6). Afterward, the bound fraction was dialyzed against water, lyophilized, dissolved in 20 mM NH_4HCO_3 buffer (pH 9.6), and chromatographed on a Mono Q column equilibrated with the same buffer. The bound fraction was eluted with three successive linear gradients of NaCl (0−0.2, 0.2−0.5, and 0.5−1 M, respectively, collected in 5, 20, and 5 mL of buffer) in the same buffer using fast protein liquid chromatography (FPLC). The active fraction was collected and processed as described in previous steps before loading on a Superdex 75 HR10/300 column attached to the FPLC system. The system was run with 0.1 M NaCl in 20 mM Tris−HCl buffer. Purified hemagglutinin from Northeast China black beans (NCBBH) was dialyzed and lyophilized before storage.

Characterization of NCBBH. To determine the molecular weight of NCBBH, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE, 15% acrylamide gel) was performed in accordance with the procedure previously reported.[17] Besides, a standard curve was constructed by running three marker proteins on the same FPLC-gel filtration system to help further determine the molecular weight.

Amino acid sequence was analyzed by Edman degradation followed by HPLC system analysis or the protein was cleaved into small peptides and analyzed by mass spectrometry.

Hemagglutinating activity assay was conducted by incubating a serially 2-fold diluted hemagglutinin (50 μL) with 50 μL of rabbit blood (2% in phosphate-buffered saline) in microtiter U-plates. Agglutination status of the red blood cells was recorded when the blank had fully precipitated. The hemagglutination unit (HU) was defined as the reciprocal of the highest dilution of the sample which exhibited hemagglutination, and the number of hemaglutination units per milligram of protein was recorded as specific activity.[18]

The stability of hemagglutinin at different temperatures and pH values was determined by the following methods. Purified hemagglutinin was dissolved in phosphate-buffered saline (PBS) and incubated at different temperatures for 30 min. After the mixture was fully cooled to room temperature, the remaining hemagglutinating activity of the mixture was assayed. pH stability was tested by employing the following steps: NCBBH was first dissolved in water and then adjusted with NaOH and HCl to different pH values (0−14). After incubation at room temperature for 30 min, the mixture was neutralized to pH 7. Hemagglutinating activity was then determined.

Ethylenediaminetetraacetic acid (EDTA) at a final concentration of 10 mM was added to NCBBH dissolved in PBS. The mixture was incubated at 4 °C for 5 h with shaking to make sure the hemagglutinin had been fully demetalized. The residual hemagglutinating activity was determined after EDTA had been removed. If the activity decreased or was completely lost, one of the following cations (KCl, AgCl, $CuSO_4$, $MgSO_4$, $MnSO_4$, $CaCl_2$, $ZnSO_4$, $FeSO_4$, and $FeCl_3$ at a final concentration of 40 mM) was added, and after incubation for 3 h, hemagglutinating activity was assayed again to see whether it had been restored.

The inhibition of hemagglutinating activity by carbohydrates was determined. NCBBH was dissolved in PBS buffer which contained different concentrations of sugar (the highest concentration at 100 mM) and serially 2-fold diluted with the same buffer in microtiter U-plates. Wells with only PBS or PBS-containing sugars were taken as the control. The mixture was subsequently mixed with an equal volume of rabbit blood (2%). The changes of HU in the presence and absence of different sugars were recorded.

Labeling NCBBH with FITC. FITC labeled NCBBH was prepared by following the procedure provided by the manufacturer. Briefly, purified NCBBH was dissolved in 50 mM borate buffer at a concentration of 2 mg/mL. FITC dye (Thermo Scientific, Waltham, MA) dissolved in DMF at 10 mg/mL was slowly added to NCBBH solution with its final concentration 15-fold molar higher than that of NCBBH. The mixture was incubated in the dark at room temperature for 1 h. The excess FITC was removed by dialysis in ddH_2O overnight at 4 °C. The FITC-labeled NCBBH was lyophilized and stored at −20 °C.

Anticancer Activity of NCBBH. *Cell Viability Assay.* Osteosarcoma MG-63 cells, hepatoma HepG2 cells, and human embryonic liver WRL 68 cells were cultured in Dulbecco's modified Eagle's medium (DMEM) with 10% fetal bovine serum (FBS) and 1% penicillin/streptomycin (PS) at 37 °C. Cell viability after treatment with NCBBH was evaluated by the 3-(4,5-dimethylthiazol-2-yl)-2, 5-diphenyltetrazolium bromide (MTT) assay. Briefly, cells (5000 cells/100 μL/well) were seeded in a 96-well microtiter plate. Medium was discarded after 24 h, and cells were treated with 2-fold serially diluted NCBBH with a concentration varying from 15 to 0 μM for 24 or 48 h. MTT solution (25 μL 5 mg/mL) was added to each well after removal of the old medium and the solution incubated for another 4 h. Dimethyl sulfoxide (150 μL) was then added to each well to dissolve the crystal formazan. The absorbance at 570 nm was measured by using a BIO-RAD microplate reader.

Cells (5×10^3) were seeded on a 6-well culture plate for 24 h, followed by the treatment of different concentrations of NCBBH for 6 days. Medium was changed every 2 days. After being rinsed with PBS, cells were fixed in 4% formaldehyde and subsequently stained with crystal violet (0.4 g/L). The images were captured by using the Nikon Live Cell imaging System Ti-E. The number of cells was counted by using Image-Pro Plus 6.0. Cell density was compared between the wells treated with and without NCBBH.

Binding of NCBBH on Cells. 1×10^5 cells were seeded on 6-well culture plates overnight, followed by treatment of 20 μg/mL of FTIC-labeled NCBBH for 24 h. The cells were harvested and washed twice with PBS. The FITC signal was then measured by a flow cytometer.

Confocal Imaging Microscopy. 3×10^4 cells were seeded on the cover glass in 24-well culture plates overnight. Cells were then cultured with 0.2 mg/mL of FITC-labeled NCBBH for 3 or 24 h. After fixation in 4% formaldehyde for 15 min and washing three times with PBS, cells were then stained by 1 μM Hoechst 33342 for 20 min. The cover glass with cells were taken out from the culture plates and mounted in 50% glycerol on glass slide. The image was taken on the Olympus FV1000-ZCD laser scanning confocal system with a 60× oil immersion objective lens (Tokyo, Japan) and analyzed by Olympus Fluoview Version 2.0.

Assay of Changes in Nuclear Morphology of MG-63 Cells. MG-63 cells were incubated in the presence of 4.52 μM NCBBH for 24 h and stained with 1 μM Hoechst 33342 for 20 min after removal of the medium and rinsing with PBS. Nuclear morphology was observed under a Nikon Live Cell Imaging System Ti-E.

DOI: 10.1021/acs.jafc.5b00106
J. Agric. Food Chem. 2015, 63, 3903−3914

Flow Cytometry Assay for Apoptosis. Apoptosis-inducing activity of NCBBH was examined by using the Annexin-V (BD Pharmingen, San Jose, CA) and propidium iodide PI (Sigma-Aldrich, St. Louis, MO) staining methods. Briefly, MG-63 cells were treated with different concentrations of NCBBH for 48 h. Trypsinized cells were centrifuged (1500 rpm, 5 min), washed with PBS, and stained with 0.5 mg/mL Annexin V and PI (final concentration 5 μg/mL) in binding buffer (0.01 M HEPES, pH 7.4, containing 140 mM NaCl and 25 mM $CaCl_2$) in darkness at room temperature for 15 min. Cells were then applied to a flow cytometer (after filtration).

Assay of Mitochondrial Membrane Depolarization. The mitochondrial membrane potential of MG-63 cells was measured by JC-1 staining as previously reported, based on the principle that in healthy cells, JC-1 dye accumulates in the mitochondria and emits red fluorescence while JC-1 exists as a monomer in cytosol and emits green fluorescence when the mitochondrial membrane is depolarized.[19] After treatment with NCBBH (1.25, 0.625, and 0 μM) for 24 h, MG-63 cells were collected and stained with 2.5 μg/mL JC-19 dye for 15 min in darkness before analysis using a flow cytometer.

Western Blotting. After treatment of NCBBH for different durations, the MG-63 cells were lysed in ice-cold RIPA lysis buffer. The whole cell extracts were then added to the loading buffer and boiled for 5 min before loading on SDS-PAGE. After electrophoresis, the proteins on the gel were then transferred onto polyvinylidene fluoride membranes and blocked in 5% milk for 40 min. The membranes were subsequently incubated with the first antibody overnight at 4 °C and the second antibody for 2 h at room temperature. The bands were finally visualized by using ECL detection kits.

Effect of *N*-Acetylgalactosamine (GalNAc) on the Antiproliferative Activity of NCBBH. To determine whether GalNAc could partially inhibit the antiproliferation effect of NCBBH, MG-63 cells and HepG2 cells were cultured with different concentration of NCBBH in the presence and absence of GalNAc for 48 h. The highest concentration of GalNAc was 5 mM which is close to the plasma sugar level of human body. The toxicity of GalNAc itself on the cancer cells was also determined by culturing cells in the medium containing different concentrations of GalNAc for 48h.

Detection of Immunomodulatory Effect of NCBBH on Splenocytes. *Real-Time PCR.* The spleen was collected immediately after the mouse (C57BL/6J) was sacrificed and pressed gently through a sterile stainless steel sieve in PBS. The cell suspension was collected and centrifuged at 1500 rpm for 3 min, followed by the addition of lysis buffer (155 mM NH_4Cl, 12 mM $NaHCO_3$, 100 mM EDTA, pH 7.2) to lyse the blood cells. The splenocytes were collected by centrifugation at 1500 rpm and washed twice with PBS before culturing with different concentrations of NCBBH in DMEM for 4 h. The total RNA of splenocytes was extracted with TRIZOL and reverse-transcribed into cDNA with oligo-Dt primers using a Revert first strand cDNA synthesis kit. Real-time PCR was performed using SYBR Green. The target genes include IFN-γ, IL-2, IL-6-, IL-1β, TNF-α, and glyceraldehyde-3-phosphate dehydrogenase known as GAPDH as the standard (shown in Table 1).

Detection of Cytokine Secretion by Western Blotting. The splenocytes were prepared as described above and evenly separated into six cell culture dishes which contained different concentrations of NCBBH in the same final volume of FBS free DMEM. The cells were cultured for 24 h before the conditional medium was collected. The same volume of the conditional medium was taken for Western blotting by following the procedures described above.

Statistics. Results were taken from three independent experiments ($n = 3$), and data were expressed as means ± standard deviation (SD). Scatter diagram and histograms were drawn using GraphPad Prim 5 (Graphpad Software, La Jolla, CA). For PCR experiments, one-way ANOVA followed by a Bonferronni posthoc test was used for the comparisons between multiple groups. A P value <0.05 was considered as statistically significant, $p < 0.05$ (*), $p < 0.01$ (**), $p < 0.001$(***) versus respective control groups. All statistical analyses were performed using software GraphPad Prim 5.

RESULTS

Purification. The crude extract of NCBBH was first loaded on Affi-Gel Blue gel and eluted with 1 M NaCl. The bound fraction which contained hemagglutinating activity was then resolved on Mono Q 5/50 GL by employing an FPLC system. Hemagglutinating activity was confined to fraction M2, as shown in Figure 1A. This fraction was collected and subsequently subjected to size-exclusion chromatography on an FPLC-Superdex 75 column. A single sharp peak S1 was acquired as shown in Figure 1B.

Molecular Weight and N-Terminal Sequence. Purified NCBBH was loaded on SDS-PAGE, and a single band with a molecular weight around 36 kDa was observed (Figure 1C). A standard curve in Figure 1D was generated with three protein markers.

$$\log(\text{molecular weight}) = -0.099X + 2.779$$

$$R^2 = 0.974$$

$$\text{NCBBH elution volume} = 9.25\ \text{mL}$$

X in the equation indicates the elution volume of peaks in the FPLC-gel filtration system. According to the above formula, the molecular weight of NCBBH was estimated to be around 73 kDa. Combining the information from SDS-PAGE and gel filtration, it could be deduced that NCBBH was a dimer. Table 2 summarized the yields and hemagglutinating activities at each step of purification.

The N-terminal of NCBBH was found to be blocked. After the analysis of small peptides in the protein by mass spectrometry and comparison with those in green plant database, they were not found to be the same as with other proteins. Peptides of this hemagglutinin most closely resembled the hemagglutinin precursor peptide of *Phaseolus vulgaris*. Table 3 summarized the data of the three proteins that manifested the most pronounced similarities with NCBBH.

Chemical and Biological Characteristics. Parts A and B of Figure 2 displayed the thermal and pH stability of NCBBH. The hemagglutinating activity of NCBBH remained stable at temperatures from 20 to 60 °C and from pH 2 to 11. The activity decreased by half when temperature was raised to 70 °C or when pH was lowered to 1 and vanished completely at the

after Mono Q	270.4	4000	1082	15.6	52.1
after Superdex 75	110.6	4560	504	17.8	24.1

extreme pH values of 0 and 13 and at high temperatures above 80 °C.

The addition of EDTA could demolish the hemagglutinating activity of NCBBH, which may be attributed to demetalization. After the removal of EDTA, metal ions, KCl, AgCl, $CuSO_4$, $MgSO_4$, $MnSO_4$, $CaCl_2$, $ZnSO_4$, $FeSO_4$, and $FeCl_3$ were supplied in the NCBBH solution, and the activity was found to be reinstated in the presence of divalent cations (Cu^{2+}, Mg^{2+}, Mn^{2+}, Ca^{2+}, Zn^{2+}, and Fe^{2+}ions) and a trivalent cation (Fe^{3+}), which indicated that the hemagglutinating activity of NCBBH is ion-dependent.

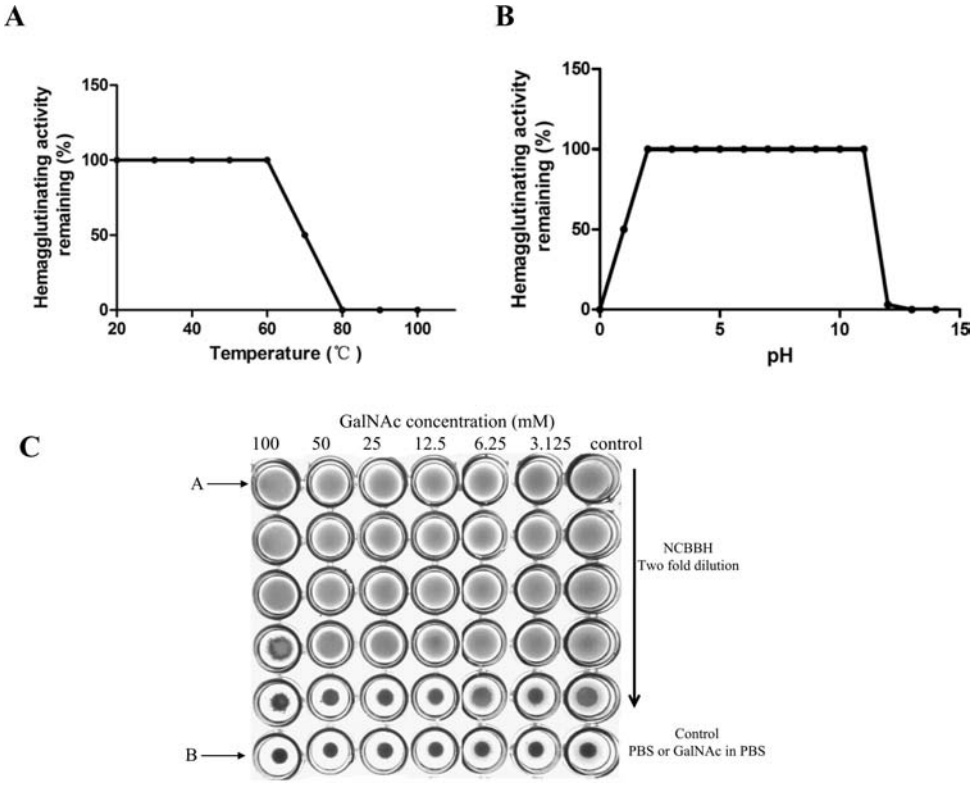

Figure 2. Influence of temperature, pH, and GalNAc on hemagglutinating activity of NCBBH. (A) NCBBH was stable at temperatures from 20 to 60 °C. (B) NCBBH was stable from pH 2 to 11. (C) GalNAc inhibited the hemaggluinating activity of NCBBH. NCBBH in PBS was taken as the control and it had 16 HU. When the cells were agglutinated by hemagglutinin, they appeared in a meshlike pattern and evenly spreaded on the button of microtiter U-plates (as shown with arrow A), while the unagglutinated cells precipitated in the lowest location of U-plants (as shown with arrow B).

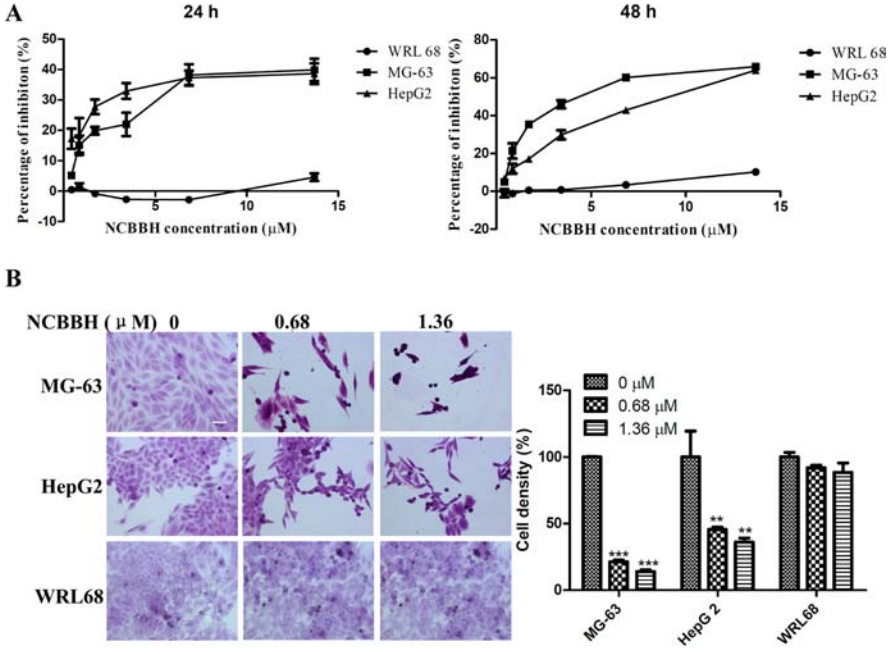

Figure 3. Antiproliferative activity by NCBBH on osteocarcinoma MG-63 cells and hepatoma HepG2 in vitro. (A) NCBBH induced an antiproliferative effect on MG 63 and HepG2 cells in a dose- and time-dependent manner with an IC_{50} of 4.5 and 9 μM at 48 h, but there was no antiproliferative activity on embryonic liver cell WRL68 cells. Results represent in mean ± SD (n = 3). (B) Low dosages of NCBBH suppressed the growth of MG-63 cells and HepG2 cells in a prolonged cell culture condition. Cells were cultured in the medium containing 0.68 and 1.36 μM NCBBH for 6 days. The density of cells was compared with that of control (no NCBBH treatment). $P < 0.05$ was taken as statistically significant; $p < 0.05$ (*), $p < 0.01$ (**), $p < 0.001$(***) versus, respectively, control groups.

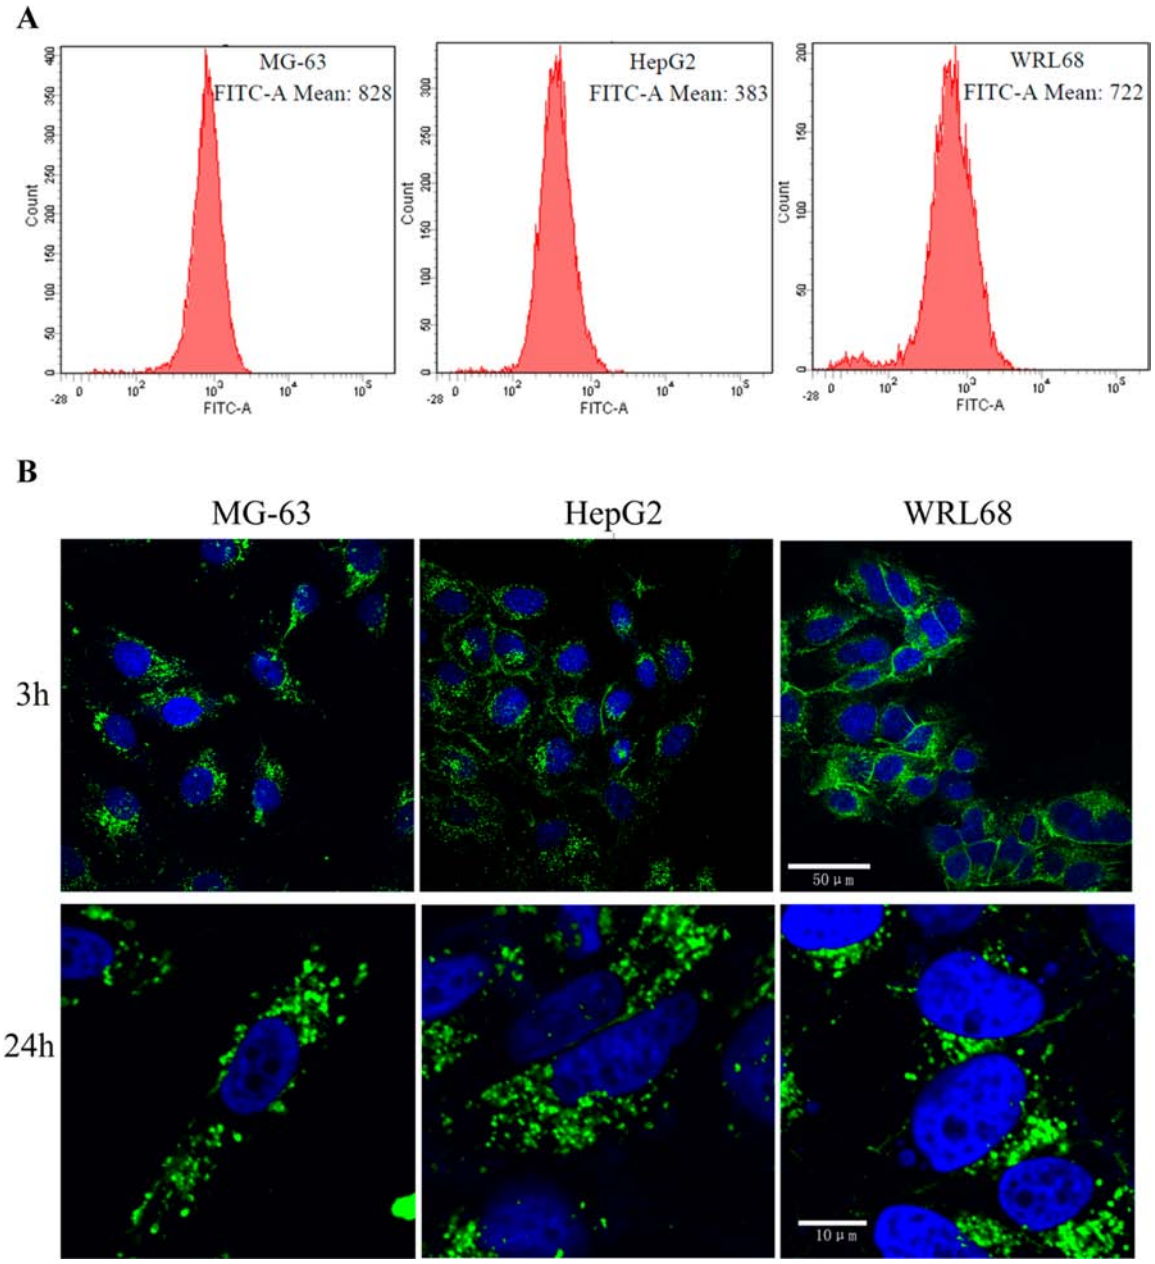

Figure 4. NCBBH detection on cells. (A) After the treatment of FITC-labeled NCBBH, the intake or binding of NCBBH on cells was monitored by use of a flow cytometer. (B) Confocal imaging of NCBBH localization in the cells. NCBBH tagged with FITC and nucleuses stained by Hoechst 33342 were, respectively, present in green and blue.

Among the 13 sugars tested in this experiment, only *N*-acetylgalactosamine (GalNAc) could partially suppress the hemagglutinating activity of NCBBH. In the presence of 100 mM GalNAc, the hemagglutin activity decreased from 16 to 8 HU, and the inhibitory effect faded with the decrease of the concentration of GalNAc as shown in Figure 2C. The remaining sugars tested had no effect on the hemagglutinating activity of NCBBH, and they comprised D-galactose, L-fucose, L-arabinose, D-fructose, D-mannose, D-manitol, D-xylose, D-glucose, maltose, α-lactose, raffinose, and L-rhamnose.

NCBBH Demonstrated Toxicity toward Tumor Cells. The antitumor activity of NCBBH was investigated by the MTT assay. As shown in Figure 3A, NCBBH inhibited the proliferation of MG-63 and HepG2 cells in a dose- and time-dependent manner. The IC_{50} values for MG-63 and HepG2 cells after treatment with NCBBH for 48 h were, respectively ,around 4.5 and 9 μM. After the same treatment, normal embryonic liver cells (WRL 68) were only slightly affected at both 24 and 48 h time points. Consistent with the results of the MTT assay, the density of MG-63 and HepG2 cells cultured in the medium containing 0.68 or 1.36 μM NCBBH was much lower than that of control, while no statistic difference of cell density was observed in WRL 68 cells treated in the presence and absence of NCBBH after 6 days as shown in Figure 3B.

Detection of NCBBH on Cells. After the same treatment with FITC-labeled NCBBH for 24 h, the signal of FITC detected by the flow cytometer on MG-63, WRL 68, and HepG2 cells varied from each other, among which the FITC signal on MG-63 cells was the highest, followed by WRL68 and HepG2 as shown in Figure 4A. NCBBH was observed both on

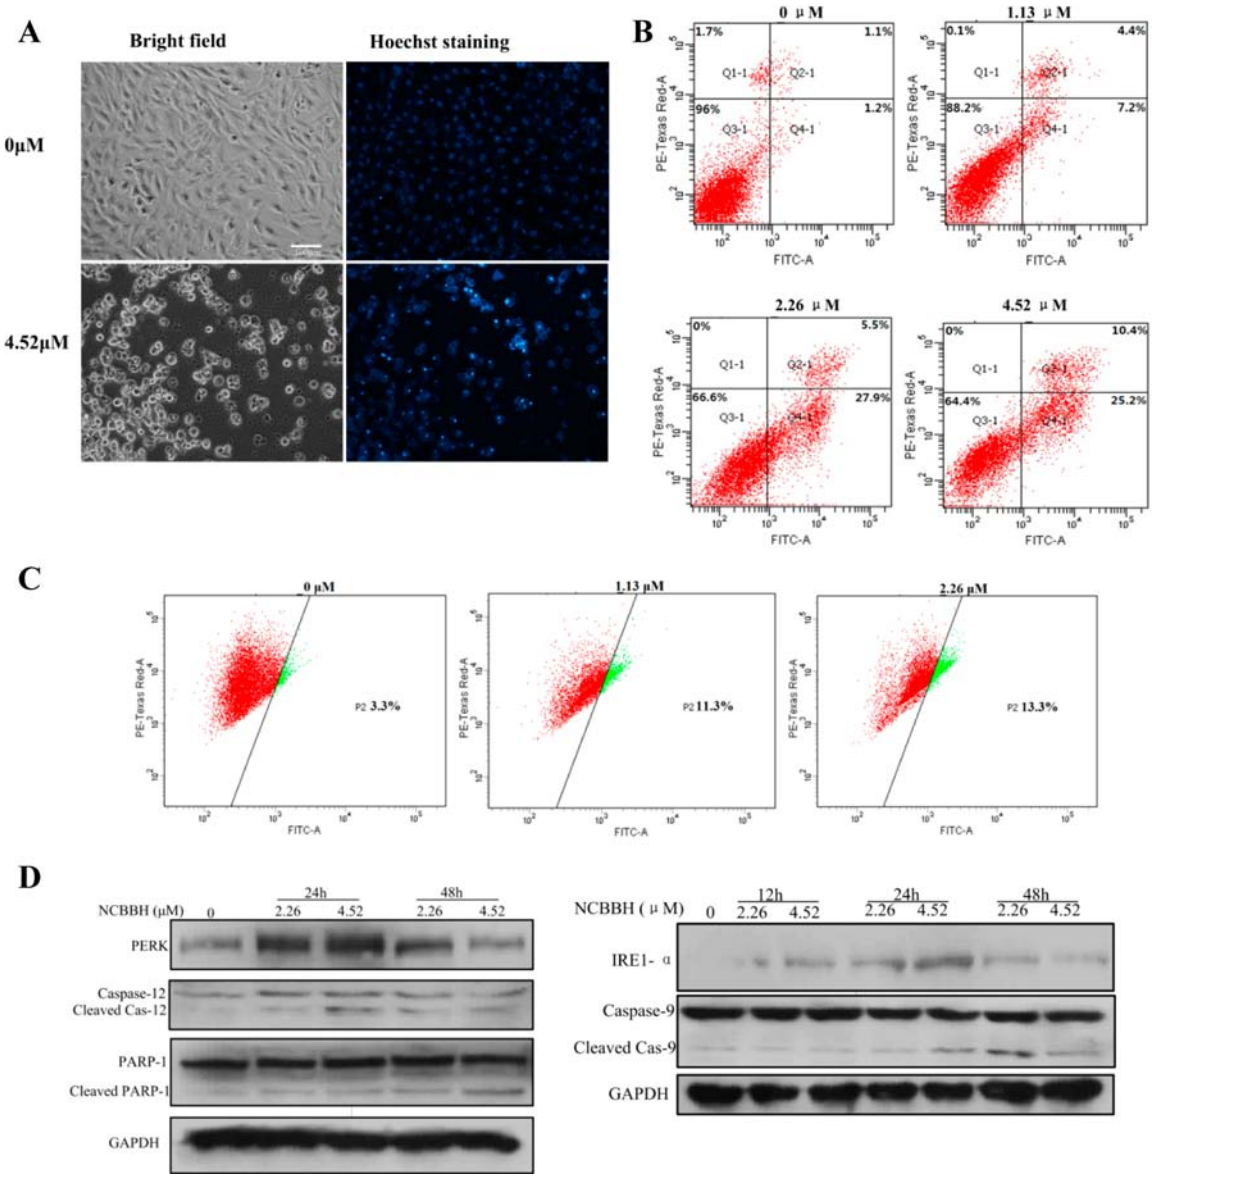

Figure 5. NCBBH-induced apoptosis in MG 63 cells. (A) NCBBH produced nuclear morphological changes in MG-63 cells. After the treatment with 4.52 μM NCBBH for 24 h, cells were stained with 1 μg/mL of Hoechst 33342 for 15 min. Nuclear morphological changes of MG-63 cells were observed with a Nikon Live Cell Imaging System Ti-E. (B) Cell apoptosis analysis by Annexin V-GFP/PI double staining. MG-63 cells were first treated with 0, 1.13, 2.26, and 4.52 μM NCBBH for 48 h. Cells were then harvested and washed with PBS, followed by staining with Annexin V-GFP/PI for 15 min. Apoptosis was then monitored by the flow cytometer. (C) Mitochondrial membrane potential detection by JC-1 staining. MG63 cells were cultured with 0, 1.13, and 2.26 μM NCBBH for 24 h. The mitochondrial membrane potential was then analyzed by a flow cytometer. (D) Treatment of MG 63 cells with NCBBH had initiated the activation of caspase-12 and caspase-9, cleavage of PARP, and up-regulation of IRE1-α and PERK.

the membrane and inside of the cells as early as 3 h. At 24 h, the majority of NCBBH was found in the cytoplasm of cells and discrepancy of NCBBH distribution was found in different cells that NCBBH tended to be evenly distributed in the cytoplasm of MG-63 cells and HepG2 cells, while NCBBH was found in part of the cytoplasm of WRL68 cells as shown in Figure 4B.

Apoptosis-Inducing Effect of NCBBH on MG-63 Cells. MG-63 underwent cellular and nuclear morphological changes after the treatment with NCBBH. Cell shrinkage and chromatin condensation were observed, characterized by bright staining as shown in Figure 5A, which may correspond to the features of apoptosis.

This apoptosis-inducing effect was then confirmed by flow cytometry. As shown in Figure 5B, with the increase of NCBBH dosage, the percentage of MG-63 cells undergoing apoptosis rose. At the concentration of 2.26 μM, apoptosis was detected in around 33% of the cells. In the group treated with 4.52 μM NCBBH, there were more cells found in the late apoptotic stage when compared with that in the group exposed to a lower dosage of NCBBH though the percentage of cells in the early apoptotic stage might be smaller. The loss of mitochondrial membrane potential after NCBBH treatment was also detected as shown in Figure 5C. The percentages of cells that were detected with mitochondrial depolarization in control, 0.165 μM, and 1.13 μM treatment groups were, respectively, 3.3%, 11.3%, and 13.3%.

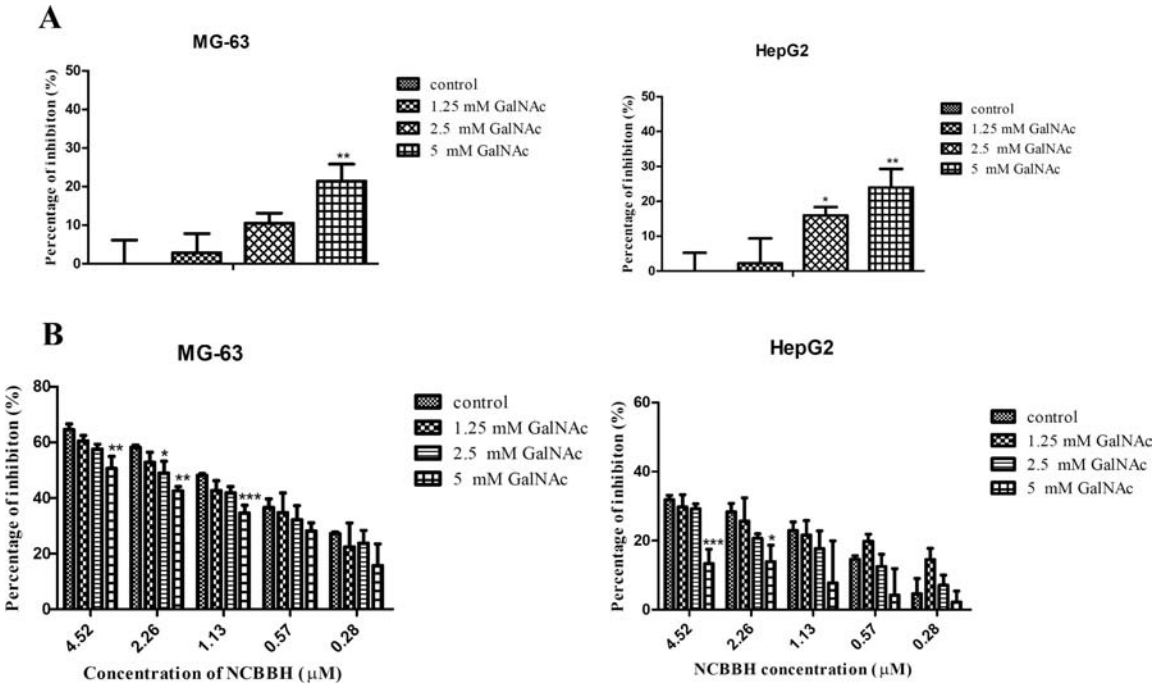

Figure 6. Effect of GalNAc on the anticancer efficiency of NCBBH. (A) GalNAc showed toxicity on tumor cells. Cancer cells were cultured with different concentrations of GalNAc for 48 h. Cells cultured without GalNAc were taken as the control. (B) The presence of GalNAc suppressed the antiproliferative effect of NCBBH. Cancer cells were cultured with different concentrations of NCBBH in the presence or absence of GalNAc for 48 h. To eliminate the antiproliferative effect of GalNAc on cancer cells, cells cultured in the presence of both GalNAc and NCBBH were compared with the cells cultured only in GalNAc to calculate the percentage of inhibition. The statistic analysis compared the inhibition rate of NCBBH (at a specific concentration) in the presence of different concentrations of GalNAc, taking the group cultured in the same concentration of NCBBH but without GalNAc as the control using one way ANOVAL. $P < 0.05$ was taken as statistically significant.

Western blotting assay with results presented in Figure 5D indicated that NCBBH treatment triggered the activation of mitochondrial pathway caspase-9 and apoptotic pathway related to endoplasmic reticulum stress (ERS), like PERK and IRE1-α, etc. The cleavage of PARP was also observed.

GalNAc Partially Inhibited the Antiproliferative Activity of NCBBH. GalNAc itself demonstrated toxicity on the cancer cells and with the increase of GalNAc concentration; there was a trend of a higher toxicity toward the cancer cells as shown in Figure 6A. However, the toxicity of GalNAc on MG-63 and HepG2 cells was only statistically significant at the concentrations of 5 and 2.5−5 mM, respectively. In order to eliminate the interference of GalNAc toxicity, cells cultured in the presence of both GalNAc and NCBBH were compared with the cells cultured at the same concentration of GalNAc to calculate the percentage of inhibition. The final statistical comparisons were made among the groups that were cultured in the same concentration of NCBBH but in different concentrations of GalNAc. From Figure 6B, an obvious trend was observed that with the increase of the concentration of NCBBH, the percentage of inhibition rates increased in both cell lines in the presence or absence of GalNAc and also confirmed that MG-63 cells was more sensitive to the treatment of NCBBH than HepG2 cells. When comparing groups cultured at the same concentrations of NCBBH but different concentrations of GalNAc, there was a trend showing that with the increase of the concentration of GalNAc, the antiproliferative activity of NCBBH decreased, but not all the groups were significantly different from the control which was cultured in the same concentration of NCBBH but without GalNAc.

Cytokine-Inducing Effect of NCBBH. NCBBH exerted an immunomodulatory function. The mRNA expression of IL-2, IFN-γ, and TNF-α were found to be more than 300-, 60-, and 10-fold higher after treatment with 1.37 μM NCBBH when compared with the control, and this augmenting effect was dose-dependent. The upregulation of IL-6 and IL-1β mRNA expression was not as striking as that of IL-2, IFN-γ, and TNF-α, but the differences between the NCBBH-treated groups and control were statistically significant as shown in Figure 7A. The secretion of some of the cytokines under the stimulation of NCBBH was detected by Western blotting as shown in Figure 7B. The secretion of IL-1β and IL-2 increased with the concentration of NCBBH. However, at a concentration of 1.37 μM, NCBBH exhibited an inhibitory effect on the secretion of IL-1β and TNF-α.

DISCUSSION

In the present study, a novel hemagglutinin with a molecular weight of 73 kDa was purified from Northeast China black beans and the similarities, and differences between this newly isolated hemagglutinin and previously reported lectin or hemmagglutinin are also discussed.

This hemagglutinin was found to be ion-dependent, which is in concordance with previous reports. The hemagglutinating activity of concanavalin A (Con A), the first lectin with its crystal structure elucidated, was also abolished after demetalization.[20] It had been pointed out that metal ions could affect the stability of its conformational structure and substrate binding capacity. Kaushik et al. conducted a more detailed investigation about the effect of metal ions on Con A by explicit solvent molecular dynamic simulations and pointed out that metal ions

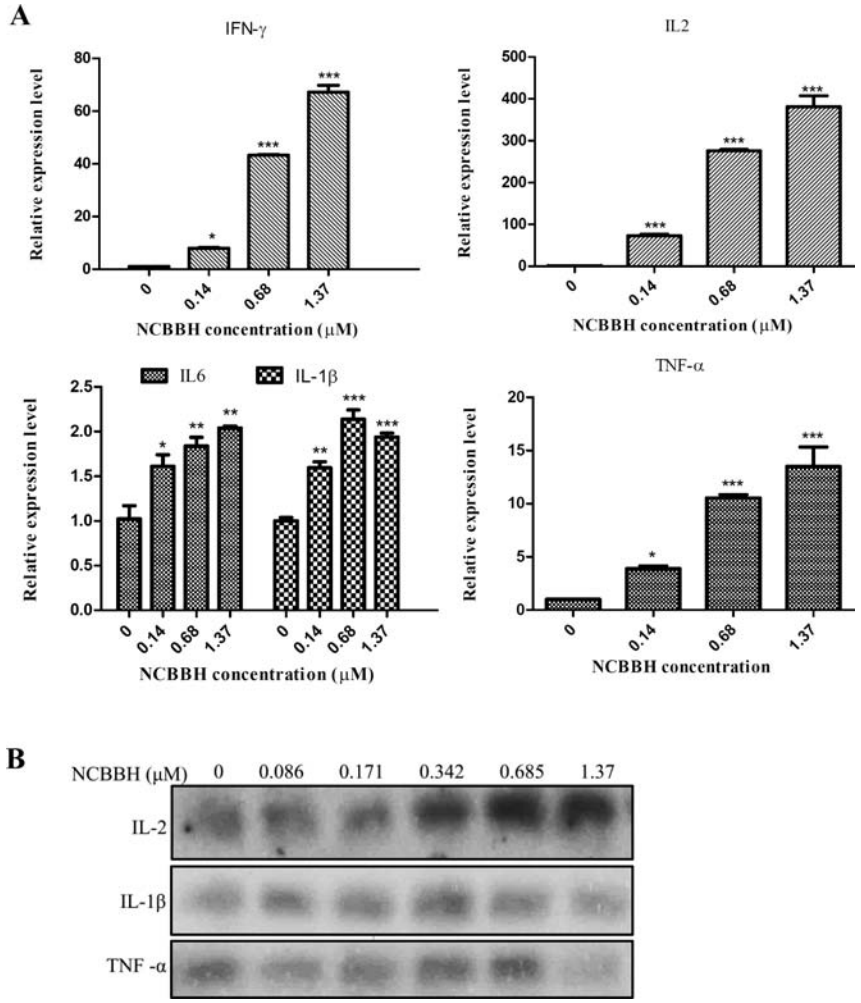

Figure 7. Modulation of the expression and secretion of cytokines by NCBBH. (A) NCBBH regulated the mRNA expression of cytokines. All of the treatment groups were compared with the control using one way ANOVAL. $P < 0.05$ was taken as statistic significant. (B) Splenocytes was cultured in FBS free medium with different concentrations of NCBBH for 24h. The same volume of supernatant from different groups was taken for Western blotting. The number of cells and final volume of medium were kept the same for all groups to make up the vacancy of standards.

in Con A were originally coordinated by residues that carried negative charges; when metal ions were absent, the structure of the ion binding loop would undergo conformational deformation due to strong electrostatic repulsion, leading to the drifting of substrate sugars and abolition of hemagglutinating activity.[21] These studies provide us references on the explanations of the metal ion-dependence phenomenon of some plant lectins.

A comparison was made among lectins or hemagglutinins isolated from different black beans in the aspects of their thermal stability, molecular weight, and antitumor activity, etc., as shown in Table 4.[22,23] The most distinct difference between NCBBH and other black bean lectins is the carbohydrate specificity. Hemagglutinating activity of lectins isolated from Korean large black soybeans, Chinese small glossy black soybean, and Chinese little black soybeans could all be inhibited by galactose, arabinose, raffinose, and melibiose and only differed in lactose while none of these sugars inhibited the activity of NCBBH. Among the 13 sugars tested in the present study, GalNAc could partially inhibit the hemagglutinating activity of NCBBH at a very high concentration. It indicates that NCBBH is different from previously purified lectins of black beans and possesses complex carbohydrate specificity. One of the most interesting issues about lectin or hemagglutinin is whether their biological functions are dependent on their interactions with carbohydrates on the membrane of cells. According to the research of Wong et.al, both Con A and knife bean lectin manifested specify for glucose, but only the antiproliferative activity of Con A could be inhibited by glucose while the anti-HIV activity of both Con A and knife bean lectin could not be abolished by glucose.[24] The importance of lectin/hemagglutinin-carbohydrate interactions is still inexplicit or is case-specific. As we have illustrated previously, except for the specific carbohydrate binding property, structural specificity and other unique features may amplify the biological function.[25] The BH1(of Bcl-2 family)-like domain in gal-3 may contribute to its antiapoptotic function in cancer cells, and except for the B chain (a lectin chain), the A chain (an enzyme chain) in mistletoe lectin-II promoted its anticancer effect by inhibiting protein synthesis.[25]

In the present study, GalNAc partially inhibited the hemagglutinating activity of NCBBH, which indicates that this hemagglutinin may recognize several types of carbohydrate and initiate different biological reactions by binding to them. To determine whether GalNAc could also partially inhibit the antiproliferation effect of NCBBH, we cultured MG-63 cells and HepG2 cells with different concentrations of NCBBH in the presence and absence of GalNAc and made comparisons of their inhibition rates. The results revealed that, consistent with the hemagglutinating assay, GalNAc could also partially inhibit the antiproliferative activity of NCBBH on MG-63 and HepG2 cells, which indicated that this GalNAc binding sites on NCBBH may take a role in its antiproliferative function on these two cell lines.

When compared with lectins or hemagglutinin isolated from different cultivars of the same species, *Phaseolus vulgaris*, like "brown kidney bean", "French bean number 35", Hokkaido red bean, and another French bean, NCBBH differs from them in many aspects. Regarding antitumor activity, the IC_{50} of lectin from "brown kidney bean" and "French bean number 35" on HepG2 cells were, respectively, 32.85 and 100 μM, and lectins isolated from Hokkaido red bean and another French bean exhibited a very weak inhibitory effect on HepG2 cells, with IC_{50} too high to be determined.[10,12,26,27] Therefore, comparatively speaking, NCBBH demonstrated a potent antiproliferative effect on this tumor cell line.

It is interesting to find that NCBBH exhibited selective toxicity toward MG-63, HepG2, and WRL68 cells. This selective activity was thought to be caused by the difference of binding affinities of NCBBH on cells. In order to confirm it, NCBBH was labeled by FITC and allowed to bind cells in culture medium for 24 h. The signal of FITC in the cells was then measured by a flow cytometer. The results showed that MG-63 showed the highest FITC signal, followed by WRL68 and HepG2, which was not completely in consistent with the rank of NCBBH toxicity toward these three cell lines. This may help explain why MG-63 cells were more sensitive to the treatment of NCBBH than HepG2 cell, but it cannot explain why NCBBH was more toxic to HepG2 cells than to WRL68 cells. The difference of distribution of NCBBH in the cells were then monitored and compared. At 3 h, NCBBH was found both on the membrane and cytoplasm of HepG2 cells and WRL68 cells, while in MG-63 cells, NCBBH was mainly found in the cytoplasm, which may indicate that MG-63 was more efficient in the transportation of NCBBH from membrane to the cytoplasm. At 24 h, NCBBH was mainly found in the cytoplasm of cells in all cell lines. As observed in Figure 4B, NCBBH tended to be evenly and wide distributed in the cytoplasm of HepG2 and MG-63 cells. However, in WRL68 cells, NCBBH seemed to cluster in an area around the nucleus. The discrepancy may be caused by the divergence of glycoprotein expression on the organelle in different cell lines. However, further study was in need to elucidate the mechanisms of the selectivity of NCBBH toxicity on these three cell lines.

This novel hemagglutinin demonstrated antiproliferative and apoptosis inducing affects on MG-63 cells. In normal cells, phosphatidylserine (PS) is usually kept on the inner cell membrane. When cells undergo apoptosis, PS will be exposed on the surface to facilitate the recognition of apoptotic bodies by phagocytic cells; hence PS externalization is taken as a general marker of cell apoptosis.[28−30] Annexin V-PI staining suggested that treatment with NCBBH triggered PS externalization. DNA condensation and fragmentation which is another characteristic of cell apoptosis was observed using Hoechst 33342 staining. Mitochondria have been demonstrated to play a key role in cell apoptosis through control of mitochondrial membrane potential ($\Delta\Psi$m) and permeability. The mitochondrial permeability transition pore (PTP) is regulated by both pH and $\Delta\Psi$m. When $\Delta\Psi$m decreases, PTP opening increases and results in the swelling of mitochondrial matrix as well as the leakage of pro-apoptotic proteins.[30] The addition of NCBBH brought about dissipation of $\Delta\Psi$ and triggered the apoptosis of osteosarcoma cells. Besides, NCBBH could also trigger cell apoptosis by initiating endoplasmic reticulum stress (ERS) and unfolded protein response (UPR). This was evidenced by Western blot which disclosed enhanced expression of caspase-12, IRE1-α, and PERK.

Eradicating cancer through immune modulation has been proposed and explored with heightened efforts recently. Cytokines which are molecular messengers to evoke the immune system are demonstrated to directly stimulate immunocytes at the tumor site and facilitate the recognition of tumor cells by cytotoxic effector cells.[31] Animal studies have already demonstrated the effectiveness of cytokine-based approaches in cancer treatment. Two cytokines, IL-2 and IFN-α, have been approved by the FDA (Food and Drug Administration) as anticancer agents, while several other cytokines are undergoing clinical trials. Treatment with high-dose IL-2 can induce significant regression of metastatic melanoma and renal cell cancer in selective patients.[32] In our study, the IL-2 mRNA expression level was enhanced more than 300-fold after treatment with 1.37 μM NCBBH for 4 h when compared with the control, which together with the

DOI: 10.1021/acs.jafc.5b00106
J. Agric. Food Chem. 2015, 63, 3903−3914

apoptosis-triggering effect revealed the great potential of NCBBH as an anticancer agent.

In addition, the high pH and thermal stability of NCBBH make it possible to combine this protein with slow-release and point-insert biomaterials to make the treatment more specific. The application of proteins to the treatment of osteosarcoma has rarely been reported; the present report represents the first time that a lectin has been employed in the treatment of osteosarcoma, and the results are promising. We also found that this hemagglutinin exhibited different levels of toxicity on MG-63, HepG2, and WRL 68 cells. The difference may be attributed to the divergence of sugar or glycoprotein expression of cells, but it still needs further study. Such research may help reveal the functions of certain glycoprotein in cells and contributes to a more specific design of anticancer drugs.

the interaction of an amino group on a protein with a carbonyl group on a polysaccharide, leading to the formation of an N-substituted glycosylamine and then to an aldimine (Schiff base), which undergoes a rearrangement that results in an Amadori rearrangement product.[21] After these initial stages, a series of complex chemical reactions occurs, which eventually leads to degradation of the Amadori products and the formation of a wide variety of reaction products.[22] Some of these products have color and aroma characteristics that are undesirable for food quality. Therefore, it is often important to prevent the later stages of the Maillard reaction from occurring when using it to stabilize proteins.

As mentioned earlier, one of the main limitations to using resveratrol as a nutraceutical ingredient is its low oral bioavailability. Nanoparticles can often be designed to increase the bioavailability of the compounds encapsulated within them. The small size of the particles confers colloidal delivery systems with unique physicochemical characteristics that may enhance the bioavailability of lipophilic nutraceuticals.[23] This increase in bioavailability may occur for a number of different reasons: enhanced solubility in intestinal fluids; improved protection against chemical or metabolic transformations within the gastrointestinal tract; prolonged residence time due to mucoadhesion of the particles to the intestinal wall; or increased absorption by epithelium cells.[24] Studies have shown that the hydrolysis of Maillard conjugates by the digestive enzymes found in the gastrointestinal tract is lower than the hydrolysis of native proteins.[18,25] This could result in differences in the bioaccessibility of compounds encapsulated in conjugated or non-conjugated protein-based delivery systems.

The aim of the current study was to determine the effect of encapsulation on the physicochemical stability and bioaccessibility of resveratrol. Resveratrol was encapsulated using two different approaches: (i) within biopolymer complexes or (ii) within biopolymer nanoparticles. The biopolymer complexes were formed by binding the resveratrol to either caseinate or caseinate−dextran. The biopolymer nanoparticles were formed by coating a zein core with either a caseinate or a caseinate−dextran shell. The caseinate−dextran complexes were formed by heating the protein and carbohydrate together under appropriate conditions to induce the Maillard reaction. The physicochemical stability and bioaccessibility of the encapsulated resveratrol were determined to establish the potential efficacy of these two delivery systems. The results of this study will facilitate the rational design of effective encapsulation technologies that can enhance both the stability and effectiveness of hydrophobic nutraceuticals.

MATERIALS AND METHODS

Materials. Resveratrol standard (purity ≥ 99%) was purchased from Extrasynthese (Lyon, France). Sodium dodecylsufate (SDS), *o*-phthalaldehyde (OPA, ≥99%), leucine, and 2-mercaptoethanol were purchased from Merck (Madrid, Spain). Dextran (40 kDa), pepsin, pancreatin, and bile extract were purchased from Sigma-Aldrich Co. (Madrid, Spain). Ethanol 96% was purchased from OPPAC (Navarra, Spain). Sodium tetraborate analytical grade was purchased from Probus (Barcelona, Spain). Soy lecithin was purchased from Guinama (Valencia, Spain). Ammonium carbonate analytical grade was purchased from Alfa Aesar (Ward Hill, MA, USA). All other chemicals, reagents, and solvents were purchased from Panreac (Barcelona, Spain) and were of analytical grade unless otherwise stated. Resveratrol (99%) from grape skin extract was purchased from Changsha Organic Herb Inc. (Changsha, China). Food grade zein was purchased from Kobayashi Perfumery Co. (Tokyo, Japan). Sodium caseinate was kindly provided by VicorQuimia (Barcelona, Spain).

Maillard Conjugate Formation. Sodium caseinate (2% w/v) and dextran (3.5% w/v) were solubilized overnight at 5 °C in double-distilled water. The completely solubilized and hydrated samples were subsequently spray-dried (Mini Spray Drier B-191, Büchi, Flawil, Switzerland) using an inlet temperature of 180 °C, a feed rate of 7.5 mL/min, a compressed air pressure of 600 kPa, and an air flow rate of 35 m^3/h. Maillard conjugation reactions were performed by incubating the spray-dried mixture at 60 °C and 76% relative humidity for up to 48 h.[17,26] The relative humidity was maintained using a desiccator containing a saturated potassium bromide solution. After conjugation, the samples were allowed to cool to room temperature, ground using a mortar and pestle, and then stored in a desiccator prior to use.

Maillard Conjugate Characterization. *Conjugation Efficiency.* The conjugation efficiency was determined by measuring reduction in free amino groups using the OPA assay. OPA reagent was prepared freshly prior to use according to the method of Pan et al.[26] In short, 40 mg of OPA (dissolved in 1.0 mL of 95% ethanol v/v), 25 mL of 0.100 M sodium tetraborate buffer (pH 9.5), 2.5 mL of 20% SDS solution (w/v), and 0.10 mL of 2-mercaptoethanol were mixed together and brought to a final volume of 50 mL. After solubilization of the conjugates (5 mg mL^{-1}), 0.10 mL of the dispersion was mixed with 2.70 mL of OPA reagent and incubated for 1 min at room temperature. The absorbance at 340 nm was then measured immediately using a UV−vis spectrophotometer (Thermo Scientific Multiskan GO spectrophotometer, ThermoFisher Scientific, Vartaa, Finland). Calibration curves were constructed using L-leucine (0.2−5 mM) as a standard compound containing an amino group.[17,26] The conjugation efficiency was defined as follows:

$$\text{conjugation efficiency (\%)} = \left(1 - \frac{\text{amine groups after conjugation (M)}}{\text{amine groups before conjugation (M)}}\right) \times 100 \quad (1)$$

Stabilizing Effect of the Conjugation. The stabilizing effect of conjugation on casein was assessed by measuring the reduction in turbidity of conjugated samples around the isoelectric point of the protein (pH 4.6). Samples were dissolved in double-distilled water at concentrations of 5 mg mL^{-1} and subsequently acidified to pH 4.6 with HCl. Nephelometric turbidity units (NTU) of the samples were measured in a turbidimeter (Turbiquant 3000 IR, Merck, Darmstadt, Germany).

Browning. To assess browning caused by the Maillard reaction, the absorbance of conjugates was measured at 420 nm. Conjugates were dissolved in double-distilled water (5 mg mL^{-1}) and then diluted 5 times. The absorbance at 420 nm was measured using the UV−vis spectrophotometer with 1 cm polystyrene cuvettes.

Resveratrol Solubility. The solubility of resveratrol in the solvent was assessed by quantifying the amount of resveratrol dispersed in the antisolvent phase [1% (w/v) sodium caseinate solution, pH 7] after 120 h of storage at room temperature.[27] Different amounts of grape skin extract (25−1500 μg mL^{-1}) were dispersed in the antisolvent phase following the procedure described under Fabrication of Resveratrol-Loaded Core−Shell Nanoparticles without zein. After this storage period, samples were centrifuged for 10 min at 1000 rpm using an eppendorf centrifuge (Centrifuge 5415R, Eppendorf, Hamburg, Germany). An aliquot of supernatant was collected, diluted in DMSO, and measured as described under Resveratrol Quantification. The diluted antisolvent phase without grape skin extract was used as a blank.

Fabrication of Resveratrol-Loaded Core−Shell Nanoparticles. Zein (3% w/v) was dissolved in 85% (v/v) ethanol by stirring for 45 min followed by filtration using a filter paper. The filtered zein solution was subsequently added to the antisolvent at a 1:5 ratio under continuous stirring (440 rpm) at room temperature. The antisolvent phase consisted of aqueous sodium caseinate or Maillard conjugate solutions (pH 7.0, final protein concentration of 1% w/v). After addition, the particle suspensions were stirred for an additional 2 min.

DOI: 10.1021/acs.jafc.5b00777
J. Agric. Food Chem. 2015, 63, 3915−3923

Ethanol was removed from the mixtures using a vacuum oven (Binder, Binder GmbH, Tuttligen, Germany) at 30 °C for 1.5 h. For the nanoparticles loaded with resveratrol, 0.15% (w/v) of grape skin extract was dissolved in the solvent phase prior to particle formation. The final particle suspensions contained 0.5% (w/v) zein and 0.025% (w/v) resveratrol.

Fabrication of Resveratrol-Loaded Biopolymer Complexes. Resveratrol-loaded biopolymer complexes were prepared by mixing resveratrol (0.15% (w/v) of grape skin extract in 85% (v/v) ethanol) with an aqueous solution containing sodium caseinate or Maillard conjugates (Resveratrol Solubility). The final particle suspensions contained 1% (w/v) sodium caseinate and 0.025% (w/v) resveratrol.

Resveratrol Quantification. The resveratrol level contained in the nanoparticles was measured using a UV−visible spectrophotometer (Thermo Scientific Multiskan GO spectrophotometer) at a wavelength of 307 nm. Pure resveratrol was dissolved in dimethyl sulfoxide (DMSO) at 100 μg/mL and then diluted to create a calibration curve with concentrations ranging from 0.2 to 6.0 μg/mL.

Characterization of Nanoparticles. *Particle Size and ζ-Potential.* Mean particle diameter, polydispersity index, and particle size distribution based on number were obtained using a dynamic light scattering instrument (Zetasizer 3000, Malvern Instruments, Malvern, UK). The ζ-potential was determined by particle electrophoresis using the same instrument. Samples were diluted 20 times to avoid multiple scattering effects and equilibrated at 25 °C prior to analysis.

Retention Efficiency (RE). The capacity of the delivery systems to retain resveratrol was determined using the following equation:

$$\mathrm{RE}\,(\%) = \left(1 - \frac{C_F}{C_T}\right) \times 100 \tag{2}$$

Here, C_T is the resveratrol contained in the suspension and C_F is the amount of free resveratrol. The free resveratrol was determined as the amount of resveratrol that was collected in the filtrate receiver after being centrifuged at 4020*g* for 30 min using a benchtop centrifuge (Sigma 3K30, Sigma GmbH, Osterode am Harz, Germany). The sample was placed in a centrifugal filter (Amicon Ultracel-10 kDa 2 mL Millipore, Cork, Ireland).[28] The recovery yield of resveratrol after passing through the filter (92%) was taken into account to correct the actual amount of resveratrol in the filtrate. The resveratrol contained in the nanoparticles and the filtrate was assessed by diluting the suspension in DMSO[29] prior to quantification as described under Resveratrol Quantification. The suspensions without resveratrol were used as blank samples.

UV Light Stability. The stability of *trans*-resveratrol to light-induced isomerization was assessed using a UV light lamp and cabinet. An aliquot of 5 mL of each sample was poured into a Petri dish (60 mm diameter) and exposed to UV light at 365 nm for 1 h.[7] The remaining *trans*-resveratrol was measured as described under Resveratrol Quantification after the sample was diluted in DMSO. The suspensions without resveratrol were used as blanks.

In Vitro Digestion Model. A dynamic in vitro gastrointestinal model was used to study the influence of the biopolymer particle composition on resveratrol bioaccessibility. The gastrointestinal model was based on the work by Minekus et al.[30] with modifications. The mouth phase was not included in this work because most liquids do not require an oral phase, mainly due to the very short residence times in the oral cavity.[30]

Gastric Phase. The suspension (10 mL) was mixed with simulated gastric fluid (SGF, 10 mL) that had a composition shown in Table 1. The resulting mixture was readjusted to pH 3.0 using NaOH or HCl solution and then shaken continuously at 150 rpm and 37 °C in an incubator (Incubator Mini Shaker, VWR, Radnor, PA, USA) for 2 h to mimic the temperature and motility of the stomach. The samples were then transferred to the intestinal phase. An aliquot of the gastric phase was diluted 10 times in the simulated gastric buffer, and the particle size and ζ-potential were analyzed as described under Particle Size and ζ-Potential.

Intestinal Phase. The "chyme" sample collected from the gastric phase (15 mL) was mixed with simulated intestinal fluids (SIF, 15 mL) with a composition shown in Table 1. The resulting mixture was then readjusted to pH 7.0 using NaOH or HCl solution and then shaken continuously at 150 rpm and 37 °C in an incubator (Incubator Mini Shaker, VWR) for 2 h to mimic the temperature and movement of the intestine. The samples were then transferred to centrifugal tubes to determine the bioaccessibility of resveratrol. An aliquot of the intestinal phase was diluted 5 times in the simulated intestinal buffer, and the particle size and ζ-potential were analyzed as described under Particle Size and ζ-Potential.

Table 1. Final Concentrations of Constituents before Addition to the Sample of the Simulated Gastric and Intestinal Fluids

	simulated gastric fluid	simulated intestinal fluid
constituent	pH 3	pH 7
	mmol L^{-1}	
KCl	5.52	5.44
KH_2PO_4	0.72	0.64
$NaHCO_3$	20.00	68.00
NaCl	37.76	30.72
$MgCl_2(H_2O)_6$	0.08	0.26
$(NH_4)_2CO_3$	0.40

HCl	22.48	6.72
$CaCl_2(H_2O)_2$	0.07	0.30
lecithin[a]	0.17	
	U mL^{-1}	
pepsin[b]	2000.00	
pancreatin[c]		100.00
	mg mL^{-1}	
bile extract		6.25

[a]Based on the average molecular weight of lecithin (787 g mol^{-1}). [b]Made up in SGF. [c]Made up in SIF and based on the protolithic activity.

Bioaccessibility Determination. The bioaccessibility of resveratrol was evaluated after the samples had passed through the simulated small intestine phase of the gastrointestinal model. Aliquots of 10 mL of the samples were centrifuged (10000*g* for 40 min at 10 °C) using a benchtop centrifuge (Sigma 3K30, Sigma GmbH). After centrifugation, the samples separated into a sediment phase at the bottom and a clear micelle phase at the top. Aliquots (5 mL) were collected from the supernatant ("micelle phase") and filtered using a syringe filter (17 mm, 0.45 μm, PVDF, ThermoFisher Scientific, Rockwood, TN, USA). After filtration, the samples were diluted in DMSO and the resveratrol was measured as described under Resveratrol Quantification. The bioaccessibility (BA) was determined using the equation

$$\mathrm{BA}\,(\%) = \frac{C_M}{C_I} \times 100 \tag{3}$$

where C_M is the resveratrol concentration in the micelle phase and C_I is the initial concentration of resveratrol in the suspension.[27] The suspensions without resveratrol were used as blanks.

Data Analysis. All experiments were performed in triplicate, and the results are given as mean values ± standard deviation. Differences among the treatments were determined using an analysis of variance (ANOVA) and a post hoc Tukey test with a confidence level of 95%. The analyses were made using SPSS software (IBM Corp., Armonk NY, USA).

RESULTS AND DISCUSSION

Conjugation Characterization. Initially, we carried out a series of experiments to assess the time dependence of the formation of protein−carbohydrate conjugates through the

DOI: 10.1021/acs.jafc.5b00777
J. Agric. Food Chem. 2015, 63, 3915−3923

Maillard reaction (Figure 1). The conjugation efficiency of the reaction of sodium caseinate with dextran was analyzed using

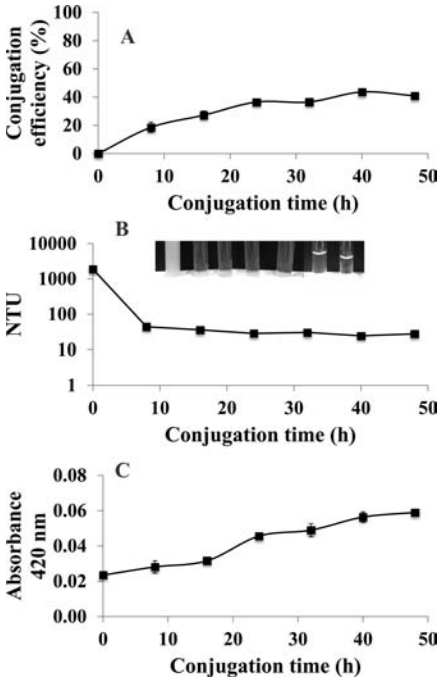

Figure 1. (A) Conjugation efficiency, (B) turbidity at pH 4.6, and (C) absorbance at 420 nm of the conjugates of sodium caseinate to dextran 40 kDa. (Inset) Appearance of the solutions (5 mg mL^{-1}) at pH 4.6: from left to right, 0, 8, 16, 24, 32, 40, and 48 h of conjugation. The conjugation was induced at 60 °C with 76% relative humidity for 48 h. The sampling was at intervals of 8 h. The ratio of dextran to sodium caseinate was 1.75 to 1.0 (w/w).

the OPA test, which quantifies the amount of unreacted amino groups remaining on the protein after conjugation (Figure 1A). The effect of conjugation on the aggregation stability of the sodium caseinate was assessed by measuring the turbidity of the conjugate solutions at the isoelectric point of the protein, that is, pH 4.6 (Figure 1B). The formation of brown colors in the samples as a result of the later stages of the Maillard reaction was determined by measuring the solution absorbance at 420 nm (Figure 1C).

The conjugation efficiency increased with increasing incubation time during the first 24 h and then reached a relatively constant level. The average number of amino groups per caseinate molecule available to react with reducing sugars of the polysaccharides has been reported to be 13.6.[17,26] This suggests that the number of dextran molecules attached per caseinate molecule were about 5.0 after 24 h of incubation (37% efficiency) and about 5.5 after 48 h of incubation (41% efficiency). The reduction in the conjugation rate with incubation time can be attributed to two effects: (i) a reduction in the number of amino groups available to react or (ii) steric hindrance caused by already attached dextran molecules.[17] The turbidity of the samples at pH 4.6 is related to the formation of protein aggregates near the isoelectric point of sodium caseinate. The absence of a net charge on the protein molecules reduces the electrostatic repulsion, which leads to the formation of protein aggregates.[31] Solutions containing aggregated caseinate appeared turbid because the protein aggregates were of a size that scattered light strongly (Figure 1B, inset).[32] The observed reduction in turbidity of the caseinate solutions after conjugation with dextran (Figure 1B), suggested that the carbohydrate chains inhibited protein aggregation near the isoelectric point. This stabilization can be attributed to an increase in the steric repulsion between the molecules after conjugation. The turbidity decreased sharply from 0 to 8 h of incubation, which indicated that this was sufficient time to form stable protein−carbohydrate conjugates. Finally, the presence of a brown color in the solutions due to the formation of secondary Maillard reaction products was determined by measuring changes in their absorbance at 420 nm.[22,33] This type of brown color is usually undesirable from a food quality perspective and should therefore be minimized. In addition, the appearance of color is the result of the degradation of the Amadori product,[22] which in advances stages of the Maillard reaction can lead to dissociation of the protein−carbohydrate conjugate. Therefore, it is important to keep the browning as low as possible. The absorbance of the samples continued to increase throughout the incubation period (Figure 1C), and therefore it is advantageous to use as short a conjugation time as possible.

Overall, our results suggest that a 24 h incubation period was an optimum compromise between increasing conjugation efficiency and decreasing browning reactions. Although there is a sharp increase in absorbance between 16 and 24 h, it is not until 24 that the conjugation efficiency and turbidity reached plateau values, with no changes observed between 24 and 36 h. We therefore used this time to fabricate the conjugates for the rest of the experiments described in this study.

Resveratrol Solubility. One of the factors that determine the efficacy of a delivery system is the maximum amount of the functional ingredient that can be incorporated into it. The amount of resveratrol that could be incorporated into aqueous solutions was therefore determined. Increasing amounts of grape skin extract were dispersed in a 1% (w/v) sodium caseinate solution (Figure 2). The dispersions were prepared

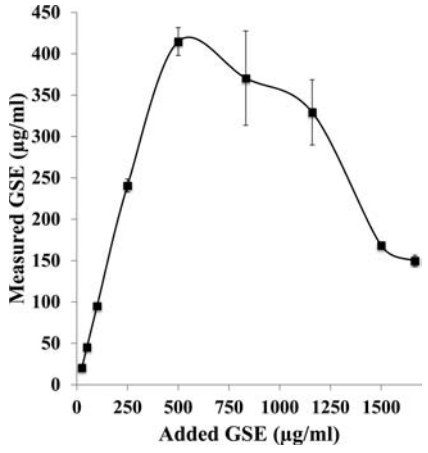

Figure 2. Dependence of the added and the dissolved grape skin extract in a 1% (w/v) of sodium caseinate solution. The dissolved resveratrol measurements were made at 307 nm after the samples had been centrifuged to remove any crystals.

using the same procedure as used to produce the nanoparticles by antisolvent precipitation (see Fabrication of Resveratrol-Loaded Core−Shell Nanoparticles), and then the mixtures were stored for 120 h at room temperature to allow the crystallization of any undissolved resveratrol.[34] The mixtures were then centrifuged, which caused the resveratrol crystals to

DOI: 10.1021/acs.jafc.5b00777
J. Agric. Food Chem. 2015, 63, 3915−3923

form a sediment at the bottom of the tubes, leaving a supernatant containing the dissolved resveratrol. The amount of dissolved resveratrol was then measured using a spectrophotometer. Adding up to 250 μg mL^{-1} of grape skin extract to the aqueous solution resulted in complete solubility of the resveratrol, indicated by the similarity of the added and measured resveratrol amounts. In this region the solution was either saturated or supersaturated with resveratrol. When 500 μg mL^{-1} of grape skin extract was added, the amount of measured resveratrol was only about 83% of the added resveratrol, which indicates that part of the resveratrol crystallized and precipitated. With a further increase in the amount of grape skin extract added, the measured resveratrol concentration actually decreased and the variability of the data became larger. This effect can be attributed to the fact that some of the supersaturated resveratrol crystallized, so that the amount of resveratrol remaining dissolved in the aqueous solution was equal to the equilibrium solubility.

The relatively high supersaturation of resveratrol in the aqueous solutions can be attributed to the presence of the sodium caseinate. It is known that proteins can act as nucleation and crystallization inhibitors by forming complexes with hydrophobic bioactive compounds, thus decreasing the nucleation rate.[34] In particular, resveratrol and sodium caseinate are known to form complexes through hydrophobic interactions and hydrogen bonding.[10] At 500 μg mL^{-1} of added grape skin extract, the amount of protein in the aqueous solution was insufficient to bind all of the resveratrol, leading to the formation of nuclei and crystals during the storage period.[34,35] From Figure 2 it can be deduced that the nucleation rate at grape skin extract concentrations >500 μg mL^{-1} was faster than the ability of the proteins to bind resveratrol, leading to sudden precipitation and lower amounts of resveratrol in the supernatant.

If a hydrophobic crystalline bioactive compound is going to be incorporated into an aqueous-based system, then it is important to ensure that it is present at a level below the loading capacity of the delivery system. Under these conditions, the saturation concentration will not be exceeded, and so bioactive precipitation during production, storage, or utilization will be avoided. For this reason, the grape skin extract concentration used in the remainder of this study was 250 μg mL^{-1}, that is, below the saturation level (Figure 2). Another important consideration when working with bioactive compounds is to reach the minimum concentration to promote a health benefit. In this case 250 μg mL^{-1} of grape skin extract in the colloidal dispersions represents 50 times the concentration typically found in wine (5 mg/L[36]).

Retention Efficiency. In this study, the retention efficiency means the amount of resveratrol associated within the biopolymer nanoparticles or complexes. The retention efficiency is important because it determines the fraction of the bioactive compound within a delivery system that is protected from degradation by external conditions, such as heat, light, or oxygen. The delivery systems could be classified into two groups according to their measured retention efficiencies (Figure 3), with the biopolymer nanoparticles (RE ≈ 83%) having a significantly higher retention efficiency (p < 0.05) than the biopolymer complexes (RE ≈ 68%). The retention efficiency of the biopolymer nanoparticles measured in this work was similar to that obtained in our previous study in which resveratrol was also encapsulated in zein nanoparticles formed by antisolvent precipitation.[8] All of the biopolymer

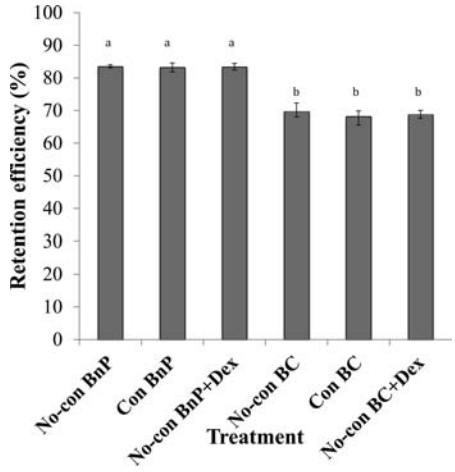

Figure 3. Retention efficiency of resveratrol in biopolymer nanoparticles (BnP) and biopolymer complexes (BC) loaded with grape skin extract prepared with conjugated (Con) and non-conjugated (No-con) sodium caseinate in the antisolvent [1.0% (w/v)]. The ratio of dextran to sodium caseinate was 1.75 to 1.0 (w/w). Zein and grape skin extract concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively. Different letters (a, b) are significantly different for each treatment separately (p < 0.05).

nanoparticles formed in the current study had an inner core of zein surrounded by an outer layer of caseinate molecules. However, in some cases the caseinate molecules were covalently attached to dextran molecules through the Maillard reaction.

The retention efficiency was similar for protein nanoparticles, protein nanoparticles coated by Maillard conjugates, and a physical mixture of dextran and protein nanoparticles (p > 0.05). These results suggest that it was the protein core (zein and caseinate) that was primarily responsible for encapsulating the resveratrol, rather than the carbohydrate shell. Presumably, the nonpolar resveratrol molecules were trapped within the hydrophobic core formed by zein and caseinate. The retention efficiency of the biopolymer complexes was about 15% lower than that of biopolymer nanoparticles (Figure 3). For these systems, the retention efficiencies were similar for caseinate alone, caseinate conjugated to dextran, and a physical mixture of dextran and caseinate (p > 0.05), which suggested that it was the caseinate that was primarily responsible for resveratrol binding. Hydrophobic forces are known to play an important role in the binding of polyphenols to proteins.[10] This would account for the fact that dextran did not play an important role in determining the binding of the resveratrol to the caseinate molecules. In addition, the fact that the retention efficiency was higher for the biopolymer nanoparticles than for the biopolymer complexes may have been because zein has a higher hydrophobicity than caseinate.

UV Light Stability. UV light triggers the isomerization of *trans*-resveratrol to *cis*-resveratrol,[7] which results in a loss of biological activity.[37,38] The stability of the various delivery systems against isomerization was assessed by exposing them to UV light (365 nm) for 60 min in Petri dishes. Resveratrol dissolved in DMSO at the same concentration was used as a control. There was a significant difference (p < 0.05) in the amount of *trans*-resveratrol remaining among the different samples after exposure (Figure 4). Both the biopolymer nanoparticles and complexes were able to protect the resveratrol against isomerization, with the nanoparticles being

DOI: 10.1021/acs.jafc.5b00777
J. Agric. Food Chem. 2015, 63, 3915−3923

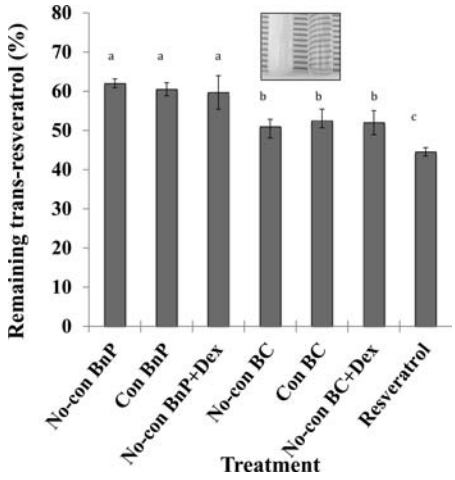

Figure 4. UV light stability of *trans*-resveratrol encapsulated in biopolymer nanoparticles (BnP) and biopolymer complexes (BC) loaded with grape skin extract prepared with conjugated (Con) and non-conjugated (No-con) sodium caseinate in the antisolvent [1.0% (w/v)]. The ratio of dextran to sodium caseinate was 1.75 to 1.0 (w/w). Zein and grape skin extract concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively. (Inset) Left to right, appearance of one treatment containing zein and one without it. Different letters (a–c) are significantly different for each treatment separately ($p < 0.05$).

more effective. Conjugation of the caseinate with dextran, or the addition of free dextran, did not have a significant ($p > 0.05$) effect on the protection of resveratrol in either type of delivery system. The protection of resveratrol against exposure to light may have occurred through a number of different mechanisms. Proteins absorb UV light due to the presence of aromatic groups and double bonds,[39] which would reduce the intensity of light waves reaching the resveratrol. The suspensions of biopolymer nanoparticles contained 50% (w/w) more protein than the suspensions of biopolymer complexes, which may account for their better ability to inhibit isomerization. On the other hand, the higher protection of the nanoparticle systems might be because they scattered light more effectively and, thereby, allowed less light to reach the resveratrol.[32] This effect is seen in the inset of Figure 4, which compares the appearance of suspensions of biopolymer nanoparticles (turbid) and biopolymer complexes (clear). Finally, the retention efficiency of the systems (Figure 3) is closely related to the protection of resveratrol, the systems with higher retention efficiency being more protective. The treatments with lower retention efficiency have a higher amount of free resveratrol dispersed in the aqueous solution, which results in less protection from exposure to UV light.

In Vitro Digestion Model. The biopolymer nanoparticles and complexes were passed through the simulated gastrointestinal tract to assess resveratrol bioaccessibility. Changes in the size and charge of the biopolymer nanoparticles were measured throughout the simulated gastrointestinal tract, and the bioaccessibility of resveratrol for both types of biopolymer delivery systems was measured at the end.

Initial Biopolymer Nanoparticles. The non-conjugated biopolymer nanoparticles had similar diameters in the absence (238 nm) and presence (237 nm) of nonadsorbed dextran, which suggested that this carbohydrate did not directly influence their particle size (Figure 5A). In addition, the ζ-potential of the non-conjugated biopolymer nanoparticles was

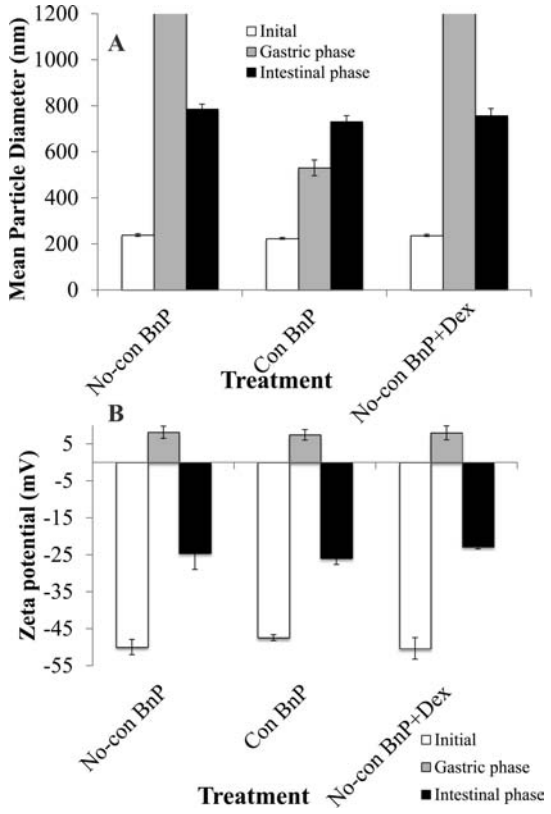

Figure 5. Effect of the in vitro digestion phase on the mean diameter (A) and ζ-potential (B) of grape skin extract loaded biopolymer nanoparticles (BnP) prepared with conjugated (Con) and non-conjugated (No-con) sodium caseinate in the antisolvent [1.0% (w/v)]. The ratio of dextran to sodium caseinate was 1.75 to 1.0 (w/w). Zein and grape skin extract concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively.

similar in the absence (−50 mV) and presence (−50 mV) of nonadsorbed dextran (Figure 5B), which suggested that this carbohydrate did not appreciably modify interfacial properties. The conjugation of the caseinate with dextran did have an effect on particle size and charge, with the mean diameter falling to 224 nm and the ζ-potential falling to −47 mV. Particle size distribution measurements of the suspensions indicated that they had monomodal and narrow distributions (Figure 6). The slight reduction in particle size upon Maillard conjugation suggests that there is a change in the packing of the caseinate molecules at the nanoparticle interfaces due to the presence of the carbohydrate chains.[17] The slight reduction in the ζ-potential can be explained by a reduction of the number of ionizable amino groups on the protein after conjugation with dextran. In addition, the presence of the dextran may have increased the thickness of the hydration layer around the protein nanoparticles where the charge is measured, thereby leading to a decrease in surface potential.[18] Figure 7 shows that there were no flocs or aggregates in the initial conjugated or non-conjugated nanoparticle suspensions.

Gastric Phase. Samples were exposed directly to the gastric phase because liquids typically spend only a very short time in the oral cavity before swallowing.[30] The mean diameter of the non-conjugated nanoparticle suspensions increased greatly ($d > 1000$ nm) after exposure to the simulated gastric phase (Figure 5A). Conversely, the increase in particle size of the conjugated nanoparticle suspensions was much less ($d \approx 530$ nm). The ζ-

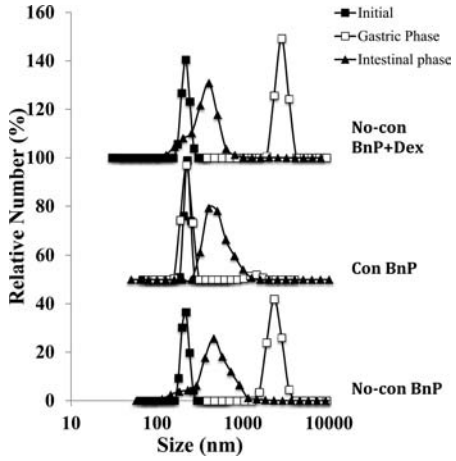

Figure 6. Effect of the in vitro digestion phase on the particle size distribution based on the number of grape skin extract loaded biopolymer nanoparticles (BnP) prepared with conjugated (Con) and non-conjugated (No-con) sodium caseinate in the antisolvent [1.0% (w/v)]. The ratio of dextran to sodium caseinate was 1.75 to 1.0. Zein and GSE concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively. The distributions shown are representative ones for each treatment.

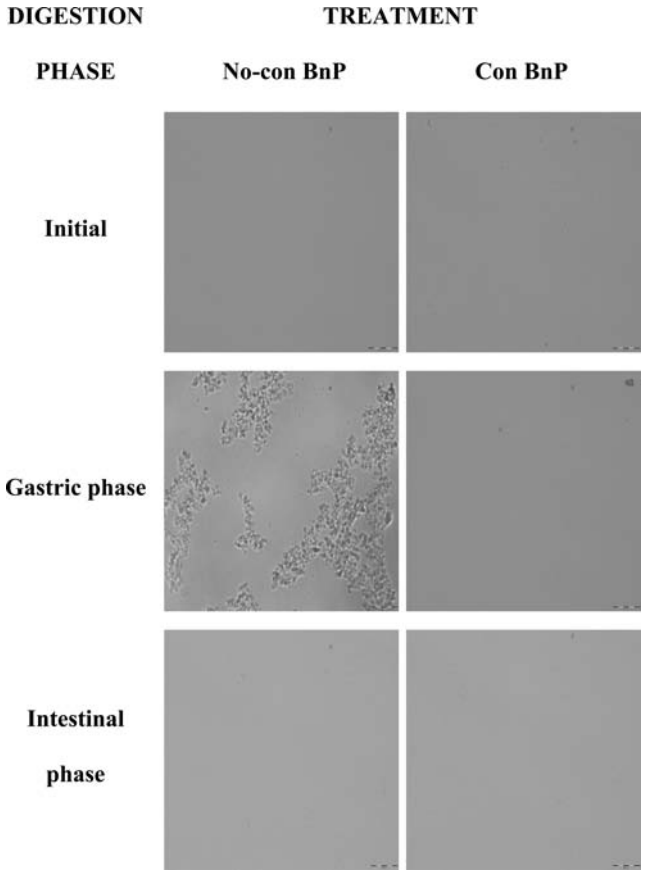

Figure 7. Microscopic images (40×) of grape skin extract loaded biopolymer nanoparticles (BnP) prepared with conjugated (Con) and non-conjugated (No-con) sodium caseinate in the antisolvent [1.0% (w/v)] after each phase of the in vitro digestion. The ratio of dextran to sodium caseinate was 1.75 to 1.0 (w/w). Zein and grape skin extract concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively. Scale bar = 20 μm.

potential of the particles in the gastric "chyme" was slightly positive (Figure 5B), which can be attributed to the fact that both caseinate and zein were below their isoelectric point. The particle size distribution measurements show extensive aggregation of the non-conjugated nanoparticles, but only moderate aggregation of the conjugated ones after exposure to gastric fluids (Figure 6). The destabilization of protein-based colloidal delivery systems under simulated gastric conditions may occur for a number of reasons, including loss of charge due to pH changes, electrostatic screening due to an increased ionic strength, and proteolysis by pepsin.[18] Further information about the relative importance of pepsin on the stability of the nanoparticle systems was obtained by omitting pepsin from the gastric fluids. The particle diameter did not increase for the conjugated nanoparticles and increased by only about 50 nm for the non-conjugated ones (data not shown), suggesting that the hydrolysis of the proteins by pepsin was an important destabilizing factor during this phase.

The observed increase in particle size can be attributed to aggregation of the protein nanoparticles (Figure 7). The lower reactivity of digestive enzymes toward the conjugated nanoparticles can be attributed to the steric hindrance exerted by the dextran molecules attached to their exteriors.[40] Another possible explanation is the reduction of the proteolysis of certain amino acids due to glycation.[25]

Intestinal Phase. After the gastric phase, the resulting "chyme" was mixed with simulated intestinal fluids (SIF) and then incubated for 2 h. After exposure to simulated intestinal conditions, all of the nanoparticle systems had fairly similar size distributions and mean diameters ($d \approx 750$ nm) (Figures 5A and 6). Furthermore, the ζ-potential of all the samples became highly negative (Figure 5B), which can be attributed to the fact that the pH was above the isoelectric point of the proteins and due to the presence of anionic bile salts in the SIF. The fact that all of the samples had relatively similar particle sizes and charges suggests that they all contained fairly similar types of particle after digestion.[41] Presumably, these particles consisted of mixed micelles and liposome kinds of structures formed by bile salts and/or aggregated peptides remaining after digestion of the proteins by proteases. To confirm if the bile salts or the pancreatin were responsible for the changes in size and distribution, a digestion made with only pancreatin or bile extract was performed for the conjugated biopolymer nanoparticles (data not shown). The results indicated that the digestion with only bile salts resulted in the same size and distributions as the ones shown in Figures 5A and 6.

Bioaccessibility. Finally, the bioaccessibility of resveratrol encapsulated within the biopolymer nanoparticles or bound to the biopolymer complexes was determined by measuring the amount of resveratrol in the micelle phase after the intestinal step of the in vitro digestion model. It is assumed that only resveratrol incorporated within the mixed micelles is available for absorption within the small intestine, that is, is bioaccessible.[23] Figure 8 shows the percentage of resveratrol present in the micelle phase after the small intestine stage. In the absence of lipids, the mixed micelle phase will primarily be composed of micelles and liposomes formed by bile salts and phospholipids in the gastrointestinal fluids, as well as any undigested soluble proteins and peptides. Thus, the resveratrol measured in the mixed micelle phase could be present within micelles or liposomes[42,43] or bound to proteins or peptides.[10] It can be seen that there was a significant difference ($p < 0.05$) in the resveratrol contained in the mixed micelle phase between

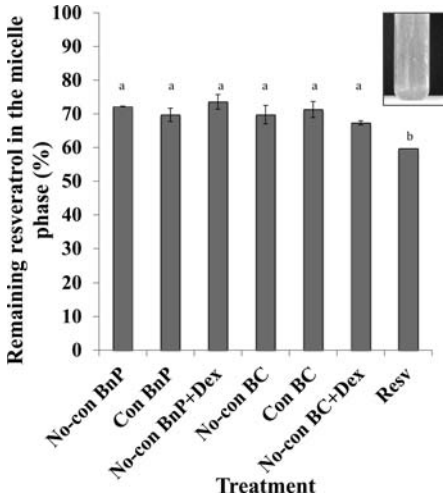

Figure 8. In vitro bioaccesability of resveratrol in biopolymer nanoparticles (BnP) and biopolymer complexes (BC) loaded with grape skin extract prepared with conjugated (Con) and non-conjugated (No-con) sodium caseinate in the antisolvent [1.0% (w/v)]. The ratio of dextran to sodium caseinate was 1.75 to 1.0 (w/w). Zein and grape skin extract concentrations in the particle suspensions were 0.5 and 0.025% (w/v), respectively. (Inset) Appearance of grape skin extract dispersed in water at 0.025% (w/v). Different letters (a, b) are significantly different for each treatment separately ($p < 0.05$).

the different delivery systems and the resveratrol dispersed in water at the same concentration. When resveratrol was directly added to water, it immediately formed crystals that could be seen by the naked eye (Figure 8, inset). Conversely, the resveratrol encapsulated within the biopolymer nanoparticles or complexes did not form any visible crystals. The crystallization and precipitation of resveratrol could explain the lower bioaccessibility of the free bioactive component compared to the encapsulated ones.[27] Nevertheless, the bioaccessibility of resveratrol was still >50%, and it has been demonstrated by fluorescence quenching studies that polyphenols can bind to the enzymes present in the gastric and intestinal fluids, increasing their solubility in the micelle phase.[44] The encapsulation of grape skin extract in the nanoparticles did not affect the bioaccessibility of resveratrol when compared to the ones bound to sodium caseinate. Neither the conjugation nor the presence of dextran had a significant effect ($p > 0.05$). Previous studies have shown that other types of caseinate-based and zein-based delivery systems are also able to retain hydrophobic nutraceuticals under simulated gastrointestinal conditions.[17,28,45,46] The fact that the resveratrol is retained within the colloidal particles in the gastrointestinal tract presumably accounts for the fact that it did not crystallize and was available to be solubilized within mixed micelles or to bind to peptides or proteins after digestion. The fact that all of the biopolymer nanoparticle samples had similar characteristics after the small intestine phase (Figures 5 and 6) can account for the lack of differences in the bioaccessibility among the different delivery systems. It is known from in vivo studies that resveratrol undergoes extensive metabolism within the gastrointestinal tract and liver, mainly due to glucorination and sulfonation, and that only traces reach the circulatory system in an active form.[1] One can speculate that these delivery systems may slow or prevent extensive metabolism and increase the bioactivity of resveratrol after consumption. Further research is clearly needed to test this hypothesis.

Both biopolymer nanoparticles (consisting of a zein core and a caseinate or caseinate−dextran shell) and biopolymer complexes (consisting of caseinate or caseinate−dextran) protected resveratrol against isomerization and increased its bioaccessibility, but the biopolymer particles were more effective. In conclusion, both delivery systems have the potential for application in functional food and beverage products. The biopolymer complexes are easier to form and can be incorporated into transparent products, whereas the biopolymer nanoparticles are more difficult to form and can be used only in turbid or opaque products, but are more effective.

the plant's defense systems to protect it from insect attack, and many are known to have antimicrobial and antifungal properties.[22,23] Among the beneficial health properties attributed to saponins are hypocholesterolemic, anti-inflammatory, immunostimulant, antiobesity, and antiparasitic; all are proven on animal models.[23−27] Cell-based assays have also proven cytotoxic and antimicrobial effects.[28−30]

It has been suggested that the saponin content in agave species is affected by the ripening stage. The sapogenin structure and content are also affected by the agave species. Blunden et al.[19] evaluated 34 agave species and identified 12 sapogenins, with hecogenin and gentrogenin the most commonly found. In addition, hecogenin has been widely studied because of its use as a raw material to produce cortical hormones[31] and has been reported in dried leaves from 22 agave species.[19,28,32−34] Furthermore, Pinos-Rodriguez et al.[35,36] concluded in two studies with *A. salmiana*, that the total saponin content was lower in ripe plants compared with immature ones.

All these studies have been performed in agave leaves or rhizomes. To the best of our knowledge, there is no study performed to characterize the saponin content in aguamiel. Thus, the aim of this research was to identify and quantitate saponins in aguamiel from *A. americana* and *A. salmiana* at two ripening stages. It is important to evaluate the effect of species and maturity to standardize the sap and characterize the saponin content for further functional activity correlations. This would be a starting point for the development of functional foods derived from agave sap.

MATERIALS AND METHODS

Chemical Reagents. HPLC grade water, ethanol, and acetonitrile were obtained from BDH (Poole, UK). The reactive grade *n*-butanol solvent used for extraction was obtained from Desarrollo de Especialidades Químicas (Monterrey, Mexico). Hecogenin standard was purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA), and protodioscin, from Sigma-Aldrich (St. Louis, MO).

Biological Material. Aguamiel samples were donated by AGMEL S.A de C.V. and collected at General Cepeda County, in Coahuila, Mexico (25° 22N, 101° 28W) at an altitude of 1410 m above sea level. The plant was identified by Dr. Marcela González Álvarez from the Universidad Autónoma de Nuevo León (UANL) in Mexico. A voucher specimen was deposited in the herbarium of the UANL under the numbers 025618 for *A. americana* and 025619 for *A. salmiana*. Eight-year-old plants from *A. americana* and *A. salmiana* were used in two ripeness stages: immature plants prior to entering into the reproductive stage and mature plants at the onset of reproductive stage. When the agave enters the reproductive stage, its shoot apex is thinned, displaying black, shiny spines.[11] Agaves were prepared following the traditional process to collect the aguamiel.[14] Aguamiel was collected during the month of May 2013. Samples were immediately placed on dry ice, transported to the laboratory, and stored at −20 °C until analysis. A pool of eight agaves per ripeness stage and species were used, for a total of 32 agaves. Dry matter (DM) was determined by gravimetric means (AOAC 425.45).[37] Sample (2 g) was mixed with 0.5 g of dry silicon dioxide (DEQ, Monterrey, Mexico) and dried at 60 °C for 24 h. Weight was recorded before and after drying to obtain the percentage of DM.

Saponin Extraction and Sapogenin Release. To obtain the saponin crude extract, 50 mL of aguamiel was added to 50 mL of *n*-butanol, and the mixture was shaken for 20 min at 250 rpm and 37 °C. Samples were then centrifuged for 5 min (3000 rpm and 4 °C). The organic phase was collected and dried under vacuum at 40 °C for 2 h. This extract was used to evaluate the saponin content.

To release the sapogenin, all the crude saponin extract was hydrolyzed by adding 5 mL of 2 N HCl and left for 60 min in a water bath at 100 °C. After hydrolysis, samples were neutralized (pH 7.0 ± 0.1) with 2 N NaOH. The neutralized samples were brought to a volume of 25 mL with distilled water, and this solution was added to 25 mL of *n*-butanol. The mixture was sonicated for 1 min and then centrifuged for 5 min (3000 rpm and 4 °C). The organic phase rich in sapogenins was collected and dried under vacuum (2 h at 40 °C). This extract was used to evaluate the sapogenin content.

Prior to analysis, all the samples were resuspended in 2 mL of methanol/water (1:1) HPLC grade and filtered through a syringe filter, pore size 0.45 μm, made of hydrophilic polypropylene (Pall Life Science, Ann Arbor, MI). All extractions were performed in triplicate.

Saponin and Sapogenin Analysis. Saponins and sapogenins were analyzed using a model 1100 high performance liquid chromatography coupled to electrospray ionization mass spectrometer equipped with a model G1969A time-of-flight (HPLC/ESI-MS/TOF) detector (Agilent Technologies, Santa Clara, CA). Conditions were adapted from a methodology to analyze steroidal saponins from Taiwanese yam with some modifications detailed below.[38]

Separation was performed at 25 °C. The column used was a 150 mm × 4.6 mm i.d., 5 μm, Zorbax Eclipse XDB-C18 with a 12.5 mm × 4.6 mm i.d. guard column of the same material (Agilent Technologies, Santa Clara, CA). The sample (20 μL) was eluted at 0.8 mL/min flow rate with a gradient consisting of solvent A, HPLC-grade water containing 0.1% formic acid; and solvent B, HPLC-grade acetonitrile containing 0.1% formic acid. The gradient used was as follows: 0→8 min isocratic at 28% B; 8→28 min, increased to 55% B; 28→31 min, increased to 100% B; 31→40 min, isocratic at 100% B. Mass spectra were collected using an electrospray source in positive mode (ESI^+) under the following conditions: m/z 300−1500 range; nitrogen gas at 350 °C and 9.0 L/min flow rate; 45 psig nebulizer pressure; 4000 V capillary voltage; fragment voltage 145 V; and skimmer at 40 V. Sapogenin identifications were based on the accurate mass previously reported for agave except for hecogenin, which was also confirmed with a commercial standard. For the identification of the glycosylated forms, ionization tests were performed to fragment the molecular ion and obtain the corresponding fragmentation pattern, which was compared with that previously reported for agave saponins. Extracted ion chromatograms were analyzed considering the saponins and sapogenin accurate mass (±0.05 units) using Analyst QS 1.1 software (Applied Biosystems, Carlsbad, CA).

Saponin and Sapogenin Quantitation. Quantitative analysis was performed with a 1200 Series HPLC coupled to an evaporative light scattering detector (HPLC/ELSD) (Agilent Technologies, Santa Clara, CA). Chromatographic conditions were the same as described above. ELSD conditions were adapted from a methodology to analyze steroidal saponins from Taiwanese yam.[38] Detection was accomplished using nitrogen as the drying gas, a pressure of 3.4 bar and tube temperature of 45 °C, gain of 9, and sampling time of 33 ms. All the saponins from the same aglycone were quantitated together. Sapogenin concentrations were obtained as hecogenin

[a]Saponins sharing the same aglycone were quantitated together. [b]PE, protodioscin equivalents μg/g aguamiel dry matter. [c]Data are expressed as mean ± SD of three independent extractions. [d]Mean values in each row with different letter are significantly different ($p < 0.01$).

equivalents (HE) using a standard curve from 10 to 125 ppm. Results were reported in HE μg/g aguamiel (DM). Saponin concentrations were obtained as protodioscin equivalents (PE) using a standard curve from 10 to 500 ppm. Results were reported in PE μg/g aguamiel (DM).

Statistical Analysis. All analyses were performed in triplicate, and results are expressed as mean ± standard deviation. Statistical analyses were conducted by one-way ANOVA, and differences among means were compared with the Tukey test using a level of significance of $p < 0.01$. The software used was GraphPad Prism version 5.0b.

RESULTS AND DISCUSSION

Aguamiel dry matter (DM) content ranged from 11.57 to 13.67%, and it was not affected by the agave species or ripening stage (Table 1). These results are in agreement with previous studies in aguamiel in which a DM of 11.5% was reported.[15]

Analysis and Quantitation of Sapogenins. Four sapogenins (kammogenin **1**, manogenin **2**, gentrogenin **3**, and hecogenin **4**) were released from their saponins by acid hydrolysis (Figures 1 and 2). These were detected across both agave species and ripening stages. These sapogenins have been previously reported in dried agave leaves after an acid hydrolysis treatment.[19,32] Kammogenin and manogenin have also been reported in callus cultures from *A. ameniensis*.[20] Even though kammogenin was the most abundant sapogenin found in aguamiel from both agave species, it has been previously quantitated as an aglycone only in callus cultures. These results also illustrate that the agave species and ripening stage did not affect the sapogenin diversity; however, the sapogenin content was, indeed, affected by both the species and the ripeness stage (Table 1). Aguamiel from immature *A. salmiana* contained more than twice the total amount of sapogenins compared with immature *A. americana* (59.85 ± 14.58 and 15.57 ± 0.80 μg HE/g aguamiel (DM), respectively). In both species, sapogenin content decreased almost half when the plant approached the reproductive stage. Among the four sapogenins identified,

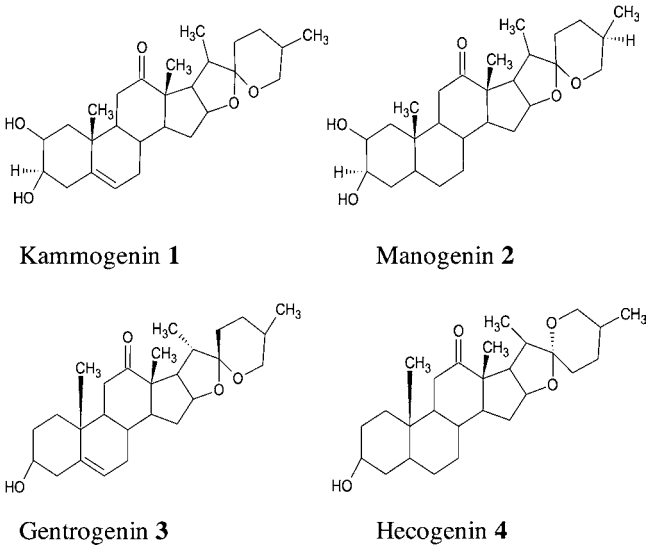

Figure 1. Chemical structures of the sapogenins kammogenin, manogenin, gentrogenin, and hecogenin detected in the hydrolyzed aguamiel extract from mature and immature *A. salmiana* and *A. americana*.

kammogenin was the most abundant, regardless the species and ripening stage. Contrary to what was observed in aguamiel, in callus cultures from *A. amaniensis*, kammogenin content (16 μg/g dry callus) was half the manogenin content (32 μg/g dry callus).[20]

According to a sapogenin screening in 34 agave species,[19] the species with the highest hecogenin content was *Agave franzosini* Nissen, with 0.46% leaf dry weight, in which *A. americana* and *A. salmiana* had 0.4% and 0.12%, respectively. These results differ from ours because *A. salmiana* was a better source of hecogenin as compared with *A. americana*. It is important to mention that in the above analysis, the agave ripeness stage was not standardized, and the plant age was not reported.

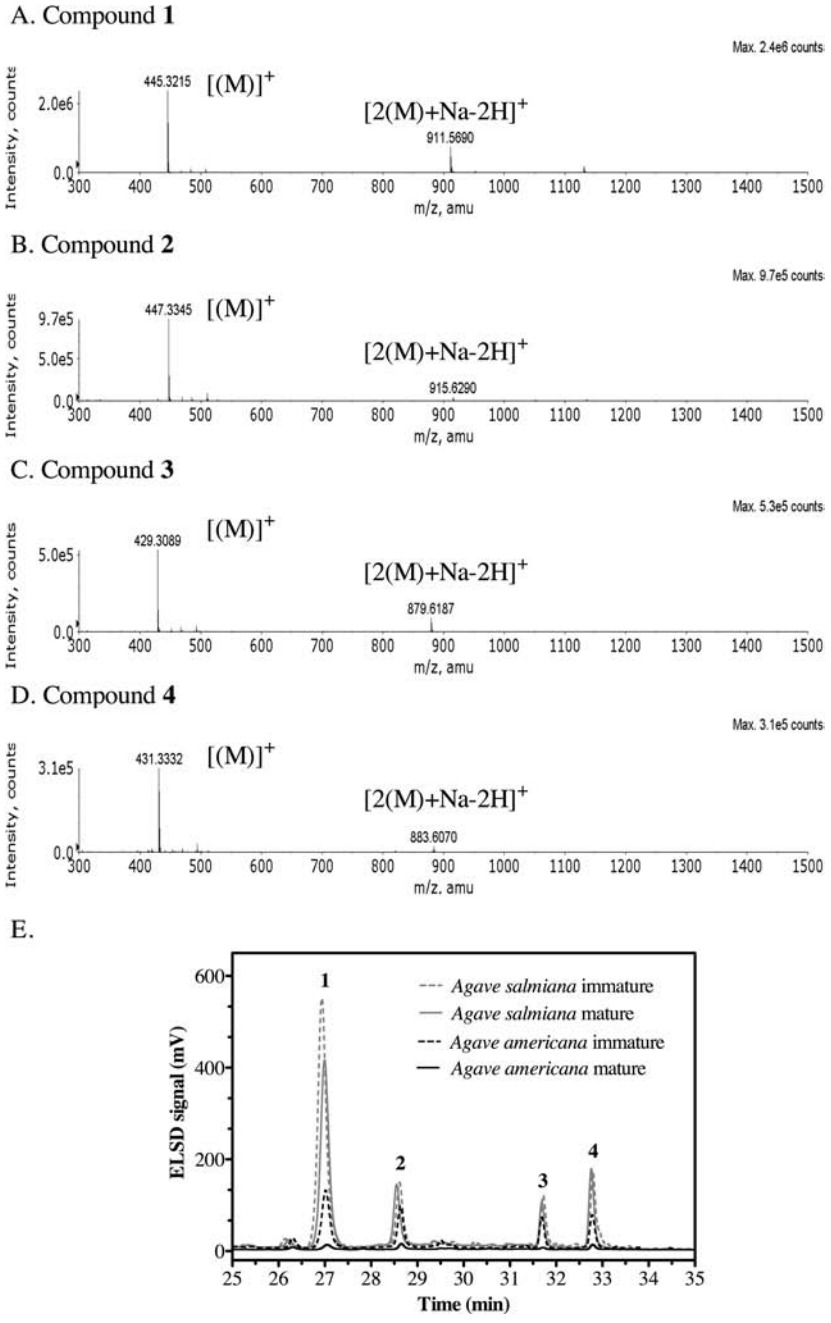

Figure 2. (A–D) Positive-ion mass spectra of kammogenin (**1**), manogenin (**2**), gentrogenin (**3**), and hecogenin (**4**) detected in the hydrolyzed aguamiel extract and (E) HPLC/ELSD chromatograms of the hydrolyzed aguamiel from *A. salmiana* an *A. americana* at two ripening stages.

Analysis and Quantitation of Saponins. Saponins from *A. americana* and *A. salmiana* were exhaustively extracted. A total of eight saponins derived from kammogenin (compounds **5** and **6**), manogenin (compounds **7** and **8**), gentrogenin (compounds **9** and **10**), and hecogenin (compounds **11** and **12**) were detected in aguamiel from both ripening stages of aguamiel (Figure 3A). Except for compounds **5**, **7**, and **10**, all the detected saponins had been previously reported.

Compound **5** mass spectra exhibited characteristic ions at m/z 1247.56 ($[M + Na]^+$), m/z 1115.51 ($[M - 1$ pentose + $Na]^+$), m/z 607.31 ($[M - 3$ hexose $- 1$ pentose$]^+$), and m/z 447.31 ($[M - 4$ hexose $- 1$ pentose$]^+$) (Figure 3B). Compound **6** exhibited the presence of ions at m/z 1217.56 ($[M + Na]^+$), m/z 1085.51 ($[M - 1$ pentose + $Na]^+$), m/z 607.31 ($[M - 2$ hexose $- 2$ pentose$]^+$), and m/z 447.31 ($[M - 3$ hexose -2 pentose$]^+$). This saponin has been recently isolated from the flowers and leaves of *Agave offoyana* and identified as magueyoside A.[39,40]

Compound **7** showed characteristic ion mass spectra at m/z 1249.54 ($[M + Na]^+$), m/z 1117.50 ($[M - 1$ pentose + $Na]^+$), m/z 609.36 ($[M - 3$ hexose -1 pentose$]^+$), and m/z 447.31 ($[M - 4$ hexose $- 1$ pentose$]^+$). Compound **8** exhibited the presence of ions at m/z 1219.56 ($[M + Na]^+$), m/z 1087.56 ($[M - 1$ pentose + $Na]^+$), m/z 609.36 ($[M - 2$ hexose -2 pentose$]^+$), and m/z 445.31 ($[M - 3$ hexose $- 2$ pentose$]^+$) and has also been found in the flowers from *A. offoyana* and was identified as magueyoside D.[40]

DOI: 10.1021/acs.jafc.5b00883
J. Agric. Food Chem. 2015, 63, 3924–3930

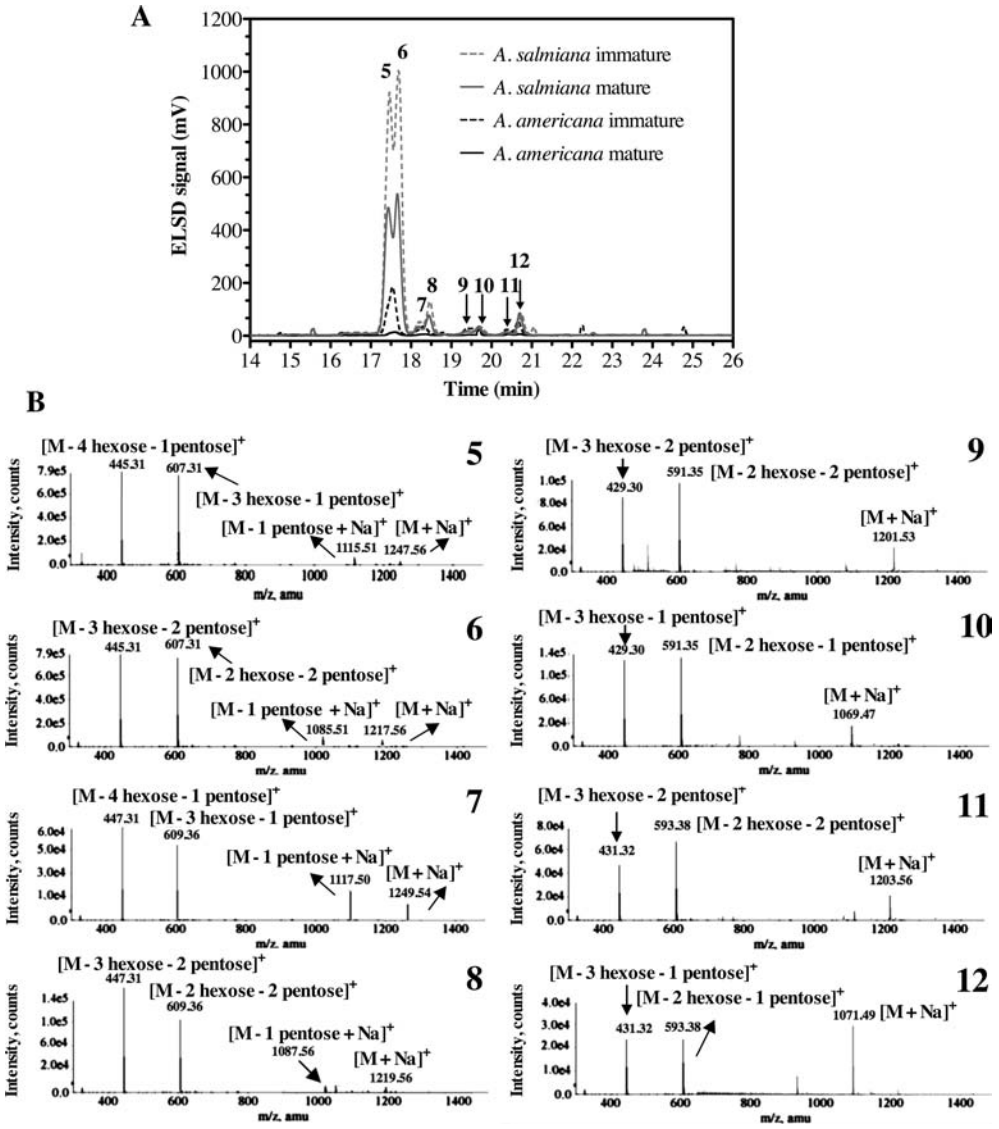

Figure 3. Positive ion mass spectra from compounds **1**−**8** and HPLC/ELSD chromatograms obtained from aguamiel from *A. salmiana* and *A. americana* at two ripening stages.

Compound **9** exhibited the presence of ions at *m*/*z* 1201.53 ([M + Na]$^+$), *m*/*z* 591.35 ([M − 2 hexose − 2 pentose]$^+$), and *m*/*z* 429.30 ([M − 3 hexose − 2 pentose]$^+$) as magueyoside H previously reported in *A. offoyana* leaves.[39] Compound **10** presented characteristic ion mass spectra with *m*/*z* 1069.47 ([M + Na]$^+$), *m*/*z* 591.35 ([M − 2 hexose − 1 pentose]$^+$), and *m*/*z* 429.30 ([M − 3 hexose − 1 pentose]$^+$), and therefore, it was tentatively similar to magueyoside H without a pentose.

Finally, both hecogenin glycosides have been identified in different agave species. Compound **11** presented ion mass at *m*/*z* 1203.56 ([M + Na]$^+$), *m*/*z* 593.38 ([M − 2 hexose − 2 pentose]$^+$), and *m*/*z* 431.32 ([M − 3 hexose − 2 pentose]$^+$) characteristic of those reported for cantalasaponin 4 in flowers from *A. offoyana* and in dried rhizomes from *A. cantalana*.[40,41] Compound **12** showed the presence of ions at *m*/*z* 1071.49 ([M+ Na]$^+$), *m*/*z* 593.38 ([M − 2 hexose −1 pentose]$^+$), and *m*/*z* 431.32 ([M − 3 hexose −1 pentose]$^+$) similar to those reported for a saponin identified in *A. americana* leaves,[42] *Agave cantala* rhizomes,[41] *Agave sisalana* leaves,[30] and *A. offoyana*.[40] This compound has been reported under different names: agavoside C′, agavesaponin C′, agaveside C′, and cantalasaponin 2.[41,42]

Among the aguamiel saponins that have been previously detected, many have shown beneficial properties. Compounds **6**, **8**, and **9** identified as magueyosides A, D, and H, respectively, showed greater phytotoxicity compared with the commercial herbicide Logran.[39,40] In addition, compound **8** extracted from *A. sisalana*, proved to be cytotoxic to human cell lines for gioblastoma, lung cancer, and breast cancer cell lines.[30]

The saponin content was affected by the plant ripening stage and species. When the plant evolved from immature vegetative to the reproductive stage, the saponin content significantly decreased in both species. This reduction was more pronounced in *A. americana* (66%) compared to *A. salmiana* (32%). These results concur with two previous studies with *A. salmiana* leaves in which total saponin content decreased significantly upon plant ripening.[35,36]

The correlation of the physiological phase and saponin content has been demonstrated in different plants.[43] In agreement with our results, the highest diosgenin concentration in the annual plant *Trigonella foenum-graecum* was observed in

DOI: 10.1021/acs.jafc.5b00883
J. Agric. Food Chem. 2015, 63, 3924−3930

young plants and decreased upon plant maturity.[44] In addition, in *Phytolacca dodecandra* berries, researchers found that young racemes contained the highest saponin concentration that decreased in the mature ones without changing the saponin proportion.[45]

It has also been suggested that saponin content and distribution may vary depending on the protection needed.[21] Decrease upon maturity may be explained by the fact that these compounds contribute to the plant's defense systems, because many saponins are known to be antimicrobial or antifungal, and to protect from insect attack.[22,23] A high saponin content in immature agave could serve as a protector to keep predators controlled, ensure full plant development, and guarantee the entrance to the reproductive stage. However, when the plant enters the reproductive stage, its pollination success is strongly correlated to nectar-feeding bats, birds, and insects.[46] This could explain the decrease in the saponin content to decrease pollinators deterrence and guarantee pollination.

Taking in total the presented information, the results of this investigation prove for the first time the presence of saponins in the edible sap or "aguamiel", which decreased with plant ripening. Moreover, *A. salmiana* yielded a greater amount of saponins compared with *A. americana*. Kammogenin saponins were the most abundant, regardless of the agave species and ripening stage. Aguamiel and its byproducts should be considered an edible source of saponins for further studies because these important phytochemicals have potential positive health implications.

ASE) to microwave-assisted[28] and ultrasound-assisted[26,27] organic solvent extraction and supercritical fluid extraction (SFE).[13,16,17] The majority of the methods use organic solvents, such as chloroform, pure alcohols (methanol, ethanol, isopropanol), hexane, dichloromethane, ethyl acetate, and so forth, or mixtures thereof. A combination of chloroform and methanol has been reported in the literature as the best option to recover total lipids from microalgae. These mixtures extract both neutral lipids by chloroform and polar lipids by methanol.[10,11,26] A chloroform/methanol mixture, for example, is used in the method of Folch et al.[29] for the extraction of total lipids from microalgae. This method, originally optimized for the isolation and purification of total lipids from animal tissues, uses 2:1 chloroform/methanol for lipid extraction and water to remove nonlipid substances from the extract.[29,30] Recently, 3:2 hexane/isopropanol has been suggested as an alternative to the chloroform/methanol system.[10,14,18] The mixture works in a similar fashion to the chloroform/methanol system with a higher selectivity toward neutral lipids compared to that of chloroform/methanol.[14,18]

However, these traditional extraction methods have some disadvantages, including the use of hazardous and flammable liquid organic solvents, costly high-purity solvents, and the presence of potentially toxic emissions during extraction. The extraction processes (e.g., Soxhlet) are often slow and time-consuming. Furthermore, an energy-intensive evaporation step is required for solvent removal. Additionally, these organic solvents can cause adverse health and environmental effects. To minimize these drawbacks, alternative, greener extraction techniques have been investigated[5,16] and have led to the development of other extraction methods that are considered to be more sustainable, such as PFE and SFE.

Despite the fact that PFE requires temperatures between 50 and 200 °C and pressures of 10−15 MPa, the associated increased lipid solubility, improved cell wall penetration by solvent, relatively low solvent use compared to other methods, and reduced emission of volatile organic compounds (VOC) due to the required pressure all add up to make this technique somewhat greener than the more traditional methods. Further advantages include its ability to be automated and a lack of light and oxygen within the process, which is beneficial when working with bioactive molecules.[4,5,31]

The vast majority of SFE applications use supercritical CO_2 ($scCO_2$) as the primary solvent. The low critical temperature (31.1 °C) and moderate critical pressure (7.4 MPa) make it particularly useful for extractions of thermolabile compounds.[5,14,16] Numerous literature examples of $scCO_2$ extractions on different natural sources have been reported.[7,8,17,32−34] A common practice in SFE, which has to be mentioned in relation to the physicochemical properties of supercritical fluids, is the use of modifiers (cosolvents). These cosolvents (e.g., methanol and ethanol) are added to the primary fluid to enhance extraction efficiency. For example, the addition of 1−10% methanol or ethanol to $scCO_2$ expands its extraction range to include more polar lipids. The addition of these modifiers is often required to assist $scCO_2$ in the extraction of highly polar compounds.[16] One disadvantage of $scCO_2$ extraction, however, is its high capital cost (CAPEX) due to its pressure-driven nature.

It has also been reported in the literature that differences in lipid extraction arise due to the method and solvent used.[15,35] Furthermore, the extraction efficiency of a particular solvent (system) cannot generally be extrapolated to microalgae species, as indicated in the study by Ryckebosch et al.[10] The main factor that determines recovery from different microalgae species seems to be the permeability of the cell wall.

The purpose of the present study was therefore to compare traditional (Soxhlet, Folch) and modern (PFE, $scCO_2$) extraction techniques for the extraction of lipids from *Nannochloropsis oculata*. Thus, the main focus was on the differences in the fatty acid profiles of the glyco- and phospholipids. The Soxhlet extraction method was included due to its simplicity in operation, relative safety, and potential for scaling up to an industrial plant level. Chloroform/methanol (2:1) was evaluated, as it is used as the extraction solvent in the Folch method, and hexane was selected as it is currently most commonly applied for both commercial extraction of food lipids and extraction of omega-3 LC-PUFA containing triglycerides from heterotrophic microalgae.[10] Ethanol was evaluated due to its low cost, its volatility and strong affinity for membrane-associated lipid complexes because of its ability to form hydrogen bonds.[14] On the basis of UPLC-MS data, the nature of glyco- and phospholipids present in the different extracts has been identified. Therefore, this study aims at providing new insights to the existing literature by giving a comprehensive view of the influence of the extraction method used on the lipid profile of the polar lipids at the molecular level.

MATERIALS AND METHODS

The microalgae species *Nannochloropsis oculata* was used in this study to perform the different extractions. Lyophilized algae were kindly provided by Proviron Industries NV (Hemiksem, Belgium; lot: CCAP 849/1). The algae were first concentrated in a microfiltration unit and subsequently centrifuged, resulting in approximately 9.44 L with a dry weight of ∼12.3%. They were then subjected to a freeze-drying process without delay by pouring concentrated microalgae mixtures onto 600 mL trays (∼1 cm thickness). The freeze-drying process was repeated once to completely dry the algae. Finally, the freeze-dried algae were vacuum packed. The analysis of Proviron Industries NV performed using the procedure described by Ryckebosch et al.[1] specified a total lipid fraction of *Nannochloropsis oculata* amounting to ∼31% with the following breakdown of the different lipid classes: 34% neutral lipids, 24% glycolipids, and 42% phospholipids. This data, obtained by the procedure of Ryckebosch et al.[1] (i.e., extraction with 1:1 chloroform/methanol), will be considered as the reference.

GC-grade chloroform, methanol, ethanol, and hexane were purchased from VWR International (Leuven, Belgium). All weight determinations were carried out on a calibrated analytical balance.

Extraction Conditions. All extractions were performed in triplicate using 7.5 g of freeze-dried *Nannochloropsis oculata* after homogenizing them with a mortar and pestle. For the Folch extraction, however, only 1 g of freeze-dried *Nannochloropsis oculata* was used. For the PFE and Soxhlet extraction, three solvents were selected: hexane, ethanol, and 2:1 chloroform/methanol. Conventional Folch extraction was performed with 2:1 chloroform/methanol, and the SFE extractions were performed with $scCO_2$ or $scCO_2$ plus 30% ethanol as a cosolvent.

More detailed description of the different extraction procedures is given below. After each replicate extraction experiment, with the exception of the Folch extraction, the extract was split into two fractions, and these fractions were accurately weighed. Both fractions were dried under nitrogen atmosphere until visibly dry and stored in a vacuum oven at 23 °C overnight.

Soxhlet Extraction. For Soxhlet extraction, the freeze-dried algae were placed in a 22 × 80 mm extraction thimble (Whatman, VWR, Leuven) and extracted with 80 mL of solvent (hexane, ethanol, 2:1 chloroform/methanol) for 6 h in a 30 mL Soxhlet apparatus.

Pressurized Fluid Extraction. Lipids were extracted from the lyophilized and homogenized algae using an automated Dionex

DOI: 10.1021/acs.jafc.5b00241
J. Agric. Food Chem. 2015, 63, 3931−3941

ASE200 Accelerated Solvent Extraction (ASE) system. The algae (60%) were mixed with Celite 545 (40%) (0.02−1 mm, Merck, VWR, Leuven) prior to being loaded into Dionex standard 33 mL stainless steel extraction thimbles. After a small amount of Celite was added to the extraction cell, the sample mix (12.5 g) was loaded. Sea sand (Merck, PA, USA; VWR, Leuven, Belgium) was finally used to fill any extra space in the cell. Extractions were performed with hexane, ethanol, and 2:1 chloroform/methanol as the extraction solvent. The same conditions were used for all of the solvents: 1500 psi (103 bar) and 125 °C with a 5 min static extraction (after 5 min preheating) and 4 static cycles. Upon completion of the extraction, the thimble was flushed with solvent (50%) and purged with nitrogen for 120 s. The solvent was collected in 60 mL vials with Teflon septa.

Conventional Folch Extraction. One gram of freeze-dried algae was weighed and put into glass vessels. One volume of chloroform, 1 volume of methanol, and 1 volume of chloroform were added in sequence to the algae sample. The mixture was shaken manually after each solvent addition. After addition of the three solvents, the mixture was shaken for 15−20 min at room temperature at high speed. Subsequently, phosphate buffered saline (PBS, pH 7−7.5, 0.8 volume) was added to obtain a final concentration of 1:20 (sample weight/solution volume; g/mL). This PBS was added to increase the ionic strength of the upper phase to improve phase separation.[29] The mixture was then centrifuged at 1000*g* for 1 min to allow the organic and aqueous layers to separate. After the organic layer was removed and collected, the aqueous layer was extracted twice more by adding only 2 volumes of chloroform followed by manual shaking and centrifugation to induce phase separation. The chloroform phases were collected in a tared glass vial. The extract was dried under nitrogen atmosphere until visibly dry and put in a vacuum oven at 23 °C overnight.

Supercritical Extraction. An ISCO SFX 220 Supercritical Fluid Extractor equipped with an ISCO Model 260 D Syringe pump, ISCO Restrictor Temperature Controller and an ISCO SFX 200 Controller (BRS) was used. Supercritical extraction with either CO_2 or CO_2/30% ethanol (cosolvent) was conducted at a pressure of 400 bar and a temperature of 40 °C with a 240 min dynamic extraction. The flow rate of $scCO_2$ and $scCO_2$/30% ethanol was set to 3 and 2.1 mL/min, respectively. The microalgae powder was placed in a high-pressure extraction cell. Carbon dioxide was liquefied by a cooler and pressurized to the preferred pressure using a high-pressure pump. Pressurized CO_2 was then pumped into the heated extraction cell during the SFE process. The extract was collected in a glass tube by venting $scCO_2$. The temperature of the restrictor (2 mL/min TCR 0.75) was set at 90 °C.

Analysis of Total Lipid Content in the Lipid Part of the Extract. With the exception of the Folch extraction, two fractions were obtained from each replicate extraction. One of these fractions was stored at −20 °C under nitrogen. Because it is known that some solvents (mixtures) may not only extract lipids but also nonlipid polar compounds, such as carbohydrates and proteins, the other half was treated with 10 mL 2:1 chloroform/methanol to separate the nonlipid and lipid fractions in the extract.[11,15] The redissolved extract was shaken for 2 min and then centrifuged for 5 min at 3000*g*. The supernatant was removed, and the residue was washed twice more with the chloroform/methanol mixture. The lipid fractions of the three washing steps were collected, dried under nitrogen atmosphere until visibly dry, and finally stored in a vacuum oven overnight. The residue was accurately weighed to determine the total lipid content. After weighing, the extract was resuspended in 10 mL 2:1 chloroform/methanol and divided into different fractions: one was used for analysis of the phosphorus content and the other for fractionation of the lipid classes. After being dried and weighed, the fraction for fractionation and the additional sample were stored at −20 °C under nitrogen to prevent lipid oxidation.

Separation of Lipid Classes. To determine the influence of the different extraction methods and conditions on the lipid class composition, the lipid class content of the extracts was determined using silica solid-phase extraction (SPE) performed according to the procedure described by Ryckebosch et al.[1]

Briefly, a 500 mg/6 mL Grace Pure SPE Silica column (Grace, Lokeren, Belgium) was first conditioned by elution with 10 mL of chloroform. Approximately 10−20 mg of lipids dissolved in 500 μL chloroform was brought onto the silica column. Elution with 10 mL of chloroform yielded the neutral lipids (NL), and 10 mL of acetone was used for elution of the glycolipids (GL). Finally, the phospholipids (PL) were eluted with 10 mL of methanol. The yield of each class was determined gravimetrically in triplicate.

Characterization of the Lipid Extracts and Fractions. The phosphorus concentration was determined in the total lipid extract after washing in 2:1 chloroform/methanol by means of inductively coupled plasma emission spectrometry following DIN EN 14107.

A known quantity of each fraction (NL, GL, and PL) was dissolved in 90:10 isopropanol/acetonitrile with 0.1% formic acid. Analysis was based on ultra performance liquid chromatography (UPLC)−mass spectrometry (MS). A Waters Acquity UPLC system (Waters, Milford, MA, USA) was used, equipped with an Acquity UPLC BEH300 C_{18} column (150 × 2.1 mm; 1.7 μm). The column temperature was maintained at 35 °C. Optimum separation was obtained with a binary mobile phase constituted of 50:50 acetonitrile/water (eluent A) and 90:10 isopropanol/acetonitrile (eluent B) with both solvent mixtures buffered with 0.1% formic acid. The gradient elution program was 0−1 min from 100% A to 45% A, 1−25 min from 45% A to 30% A, 25−26 min from 30% A to 0% A, 26−30 min with 100% B, 30−31 min from 0% A to 100% A, and 31−40 min with 100% A (returned to initial conditions and equilibration of the column). The flow rate of the mobile phase was 0.2 mL/min. Different injection volumes were used to be in the linear range for quantification.

The UPLC system was coupled to a Waters Single Quadrupole mass spectrometer (Waters, Milford, MA, USA), which was operated in the positive electrospray ionization mode (ESI+) in full scan acquisition. The parameters of the mass spectrometer were as follows: electrospray source block and desolvation temperatures of 150 and 300 °C, capillary voltage of 4.5 kV and cone voltage of 85 V.

Positive identification of the compounds was based on chromatographic retention times, molecular weights, and their characteristic m/z ions generated by in-source fragmentation. An overview of the retention times and m/z ions of the different compounds is given in the Supporting Information (Table S1). The ion chromatogram of each m/z ratio, corresponding to a particular compound, was derived from the total ion chromatogram using the MassLynx Mass Spectrometry Software (Waters). The area of the resulting single peak was then integrated.

Finally, quantitative determination of the phospholipids was made using an analytical standard. Thus, a phospholipid mixture for HPLC from Glycine max (soybean) in chloroform, containing phosphatidylcholine (PC), lyso-phosphatidylcholine, phospatidylethanolamine (PE), and phosphatidylinositol (PI), was purchased from Sigma-Aldrich (Bornem, Belgium). The phospholipid standard was dried under nitrogen to remove chloroform and reconstituted with 90:10 isopropanol/acetonitrile with 0.1% formic acid (eluent B). Five dilutions were made in duplicate to obtain the following PC concentrations: 25, 50, 100, 150, and 200 μg/mL. These calibration solutions were injected into the UPLC-MS system using the instrumental conditions described above. The calibration curve was made by plotting the total peak area of PC components in function of the total PC concentration reported on the certificate of analysis of the analytical standard. Linear calibration curves were constructed with a squared regression coefficient R^2 of 0.99. The limit of detection (LOD) and limit of quantification (LOQ) of the applied method were calculated considering the peak-to-peak signal-to-noise ratio in the chromatogram of the standard solution with the lowest concentration of PC (25 μg/mL). Because various PCs bearing different fatty acids were present in the analytical standard, the signal-to-noise ratio of the lowest chromatographic peak was determined (worst case scenario). The LOD and LOQ were defined as the concentration that would give a signal-to-noise ratio of 3 and 10, respectively. Extrapolating from the signal-to-noise ratio observed for the lowest peak, LOD and LOQ were calculated to be 4 and 13 μg/mL, respectively.

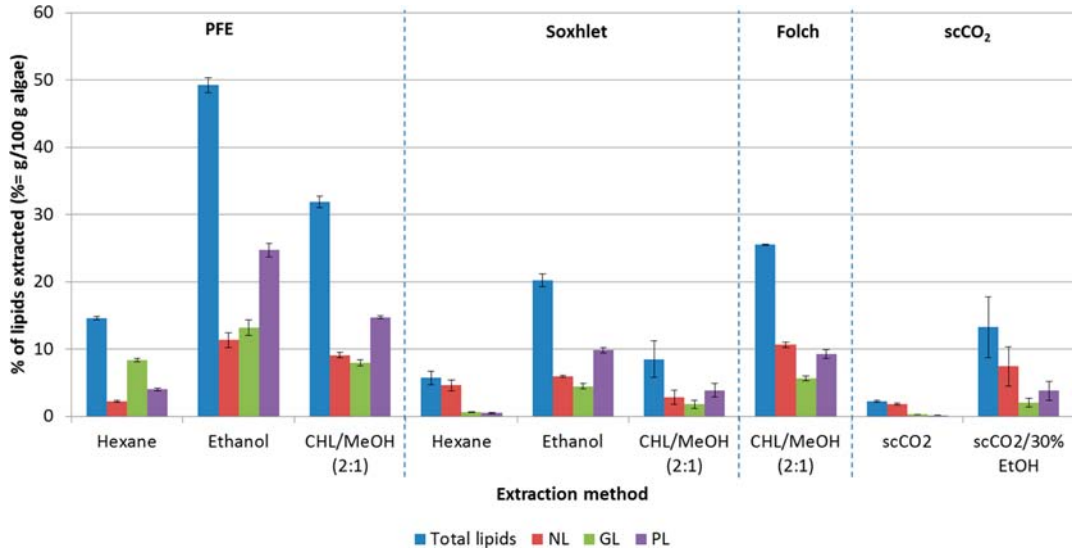

Figure 1. Total amount of lipids and lipid class composition obtained by the different extraction methods from *Nannochloropsis oculata* (mean ± SD; n = 3; CHL: chloroform; MeOH: methanol; EtOH: ethanol).

Calculations and Statistical Analysis. The presence of PC was assessed using the phosphorus content of the different lipid fractions. The phosphorus content was converted to a PC concentration expressed as g PC/100 g algae using the molecular weight of phosphorus (30.97 g/mol) and of oleoyl-palmitoyl-phosphatidylcholine (PC 16:0/18:1) (760 g/mol). PC 16:0/18:1 was used for this purpose because Wang et al. observed that C16:0 and C18:1 are the major fatty acids in PC in *Nannochloropsis* lipids.[15] The total lipid fraction, as well as the NL, GL, and PL fractions, were calculated on a weight basis as g/100 g algae, and the results are expressed as a percentage.

The chromatographic peak area of each compound belonging to a certain class was determined and related to the amount injected. This enabled the various extraction methods to be directly compared on the basis of their effects on each single component. An assessment of the total amount of the different lipid classes present was made by the sum of all chromatographic peak areas in the UPLC chromatogram belonging to the lipid class under consideration. The total peak area per mass algae extracted was then calculated by taking into account the relative contribution of that particular lipid class to the total lipid fraction. Finally, the peak area ratio of one specific compound relative to the total peak area of the lipid class under consideration yields the relative lipid composition (area in %). The PC concentration (μg/mL) was converted to w/w % (mass PC/mass algae) using the sample volume and the weight of the PL fraction. All results are an average of three replicate measurements. Each replicate measurement was obtained from an independent extraction and fractionation. In addition, standard deviations were calculated and are indicated by error bars.

RESULTS AND DISCUSSION

Total Lipid Fraction and Lipid Class Composition. The total lipid fractions were obtained after the washing step with 2:1 chloroform/methanol. Data on the influence of this washing step on the total lipid fraction are shown in the Supporting Information (Figure S1). In general, the total lipid fractions originating from extractions with more polar solvents (e.g., ethanol) were the most affected by the washing step with 2:1 chloroform/methanol, resulting in a larger mass loss compared to nonpolar extractions. The polar extractions are indeed more prone to the coextraction of nonlipid, more polar matrix materials (e.g., proteins and carbohydrates).

The final total lipid fractions after washing with 2:1 chloroform/methanol extracted by the different methods from *Nannochloropsis oculata* are shown in Figure 1. Chloroform/methanol (2:1) as the extraction solvent with PFE, Soxhlet, or Folch extraction resulted in comparable total lipid fractions in the range of 26−32%. These total lipid fractions correspond well with the reference value of 31% obtained by Ryckebosch et al.[1] via extraction with 1:1 chloroform/methanol. The 2:1 chloroform/methanol is the most frequently used solvent mixture for lipid extraction from any living tissue and is applied in methods such as Folch and Bligh and Dyer.[1,14,29,30] This mixture is able to extract both nonpolar lipids by chloroform and polar lipids by methanol. For this reason, mixtures of chloroform/methanol tend to be more efficient for the extraction of total lipids.[26]

The highest total lipid fraction is extracted from *Nannochloropsis oculata* using PFE extraction with ethanol (49%). It can be assumed that, even though a washing step has been performed, coextracted (polar) matrix components, such as phytochemicals, are still present in the extract as observed by Mulbry et al.[36]

On the basis of the total lipid fraction results, it can be concluded that the polarity of the extraction solvent clearly influences the crude lipid yield using both classical extraction methods (Soxhlet, Folch) and modern techniques (PFE, SFE). Nonpolar solvents can only extract very nonpolar lipids, whereas more polar solvents (mixtures) extract lipids of a broader polarity range, resulting in a higher lipid yield.

With either PFE or Soxhlet extractions, the following order of total lipid fraction was observed: ethanol > 2:1 chloroform/methanol > hexane. The addition of 30% ethanol as cosolvent to pure $scCO_2$ increased the total lipid yield relative to the extraction with pure $scCO_2$. Extractions that use only $scCO_2$ usually give good recoveries of nonpolar lipids. Polar lipids, however, have low solubility in $scCO_2$ and are thus not extracted. Adding ethanol expands the extraction range of $scCO_2$ to include the more polar lipids, resulting in a higher extraction yield.

These observations are in accordance with literature data on the influence of solvent polarity on the extraction of lipids from microalgae[10,11,20,34,36,37] For example, McNichol et al. observed

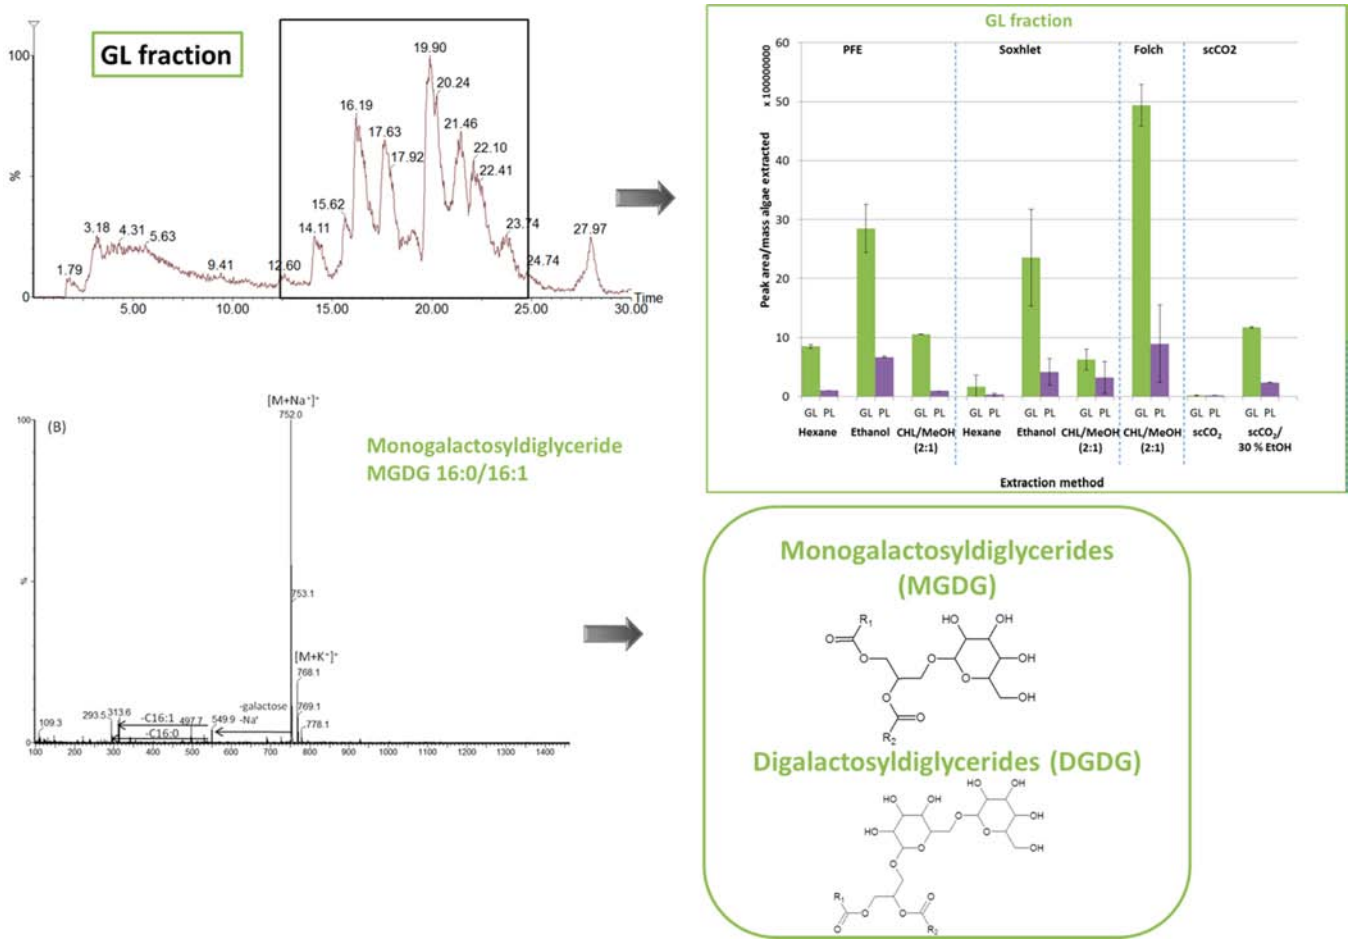

Figure 2. Total ion current (TIC) chromatogram of the GL fraction for PFE extraction with 2:1 chloroform/methanol. In the separate graph, the total chromatographic peak area is shown (mean ± SD; n = 3; CHL: chloroform; MeOH: methanol; EtOH: ethanol). The chemical structure of the compounds identified in the GL fractions is shown. The ESI+ mass spectrum of a compound is given as an example.

that hexane extracted ∼3% of lipids from *Nannochloropsis granulate*, whereas ethanol and 2:1 chloroform/methanol extracted >25% of lipids on a dry weight basis.[20] In a study by Balasubramanian et al., the use of hexane alone gave only 16% lipid yield whereas the addition of a polar solvent improved the yield.[37] Furthermore, no significant difference in the lipid extraction efficiency was observed between the different extraction methodologies (sonication, PFE, homogenization, Soxhlet) all using 2:1 chloroform/methanol as the extraction solvent.

To gain insight into the lipid class composition, we fractionated the different extracts into three portions using SPE to determine the percentages of NL, GL, and PL (Figure 1).[1] The lipid class composition of the 2:1 chloroform/methanol extracts obtained by Soxhlet, PFE, or Folch is in accordance with the specifications on *Nannochloropsis oculata* applying the reference method (1:1 chloroform/methanol). The distribution of the lipids among the different classes is as follows: phospholipids > neutral lipids > glycolipids. Phospholipids are predominantly present in these extracts in the range of 40−45% of total lipids.

Low polarity solvents are best for the extraction of neutral lipids, including waxes and pigments, which are characterized by a very low polarity. In contrast, lipids from the chloroplast and membrane, which contain GL and PL, respectively, are more effectively extracted by more polar organic solvents, such as ethanol or methanol.[10,37,38] The affinity of polar lipids (GL and PL) for more polar solvents (mixtures) is also observed in the present study. The PL fraction in the ethanol extracts is the most abundant, whereas the yield of PL using hexane is almost negligible due to the apolar character of the solvent. For SFE, the same trend is observed. Using pure $scCO_2$, the lipid fraction consists mainly of NL, which demonstrates the selectivity of $scCO_2$ toward nonpolar molecules.[16,39] Its nonpolar nature makes pure $scCO_2$ incapable of interacting with either polar lipids or neutral lipids that form complexes with polar lipids.[14] Through the addition of ethanol, the affinity toward GL and PL is enhanced, although the NL fraction is still predominant.

The findings in this study are consistent with literature data. In the study by Ryckebosch et al. comparing the extraction efficiency of 3:2 hexane/isopropanol and hexane for the extraction of lipids from different microalgae species, the NL content was higher in the hexane extract and lower in the 1:1 chloroform/methanol and 3:2 hexane/isopropanol extracts for each microalga.[10] Hence, the amount of polar lipids (GL and PL) was lowest in the hexane extract. Ryckebosch et al. also compared dichloromethane/ethanol with nonhalogenated solvent systems for the extraction of lipids from *Nannochloropsis gaditana*.[11] Dichloromethane/ethanol extracted the three lipid classes with essentially the same efficiency, whereas all nonhalogenated solvent mixtures more easily extracted NL than the polar lipids (GL and PL). Of the nonhalogenated

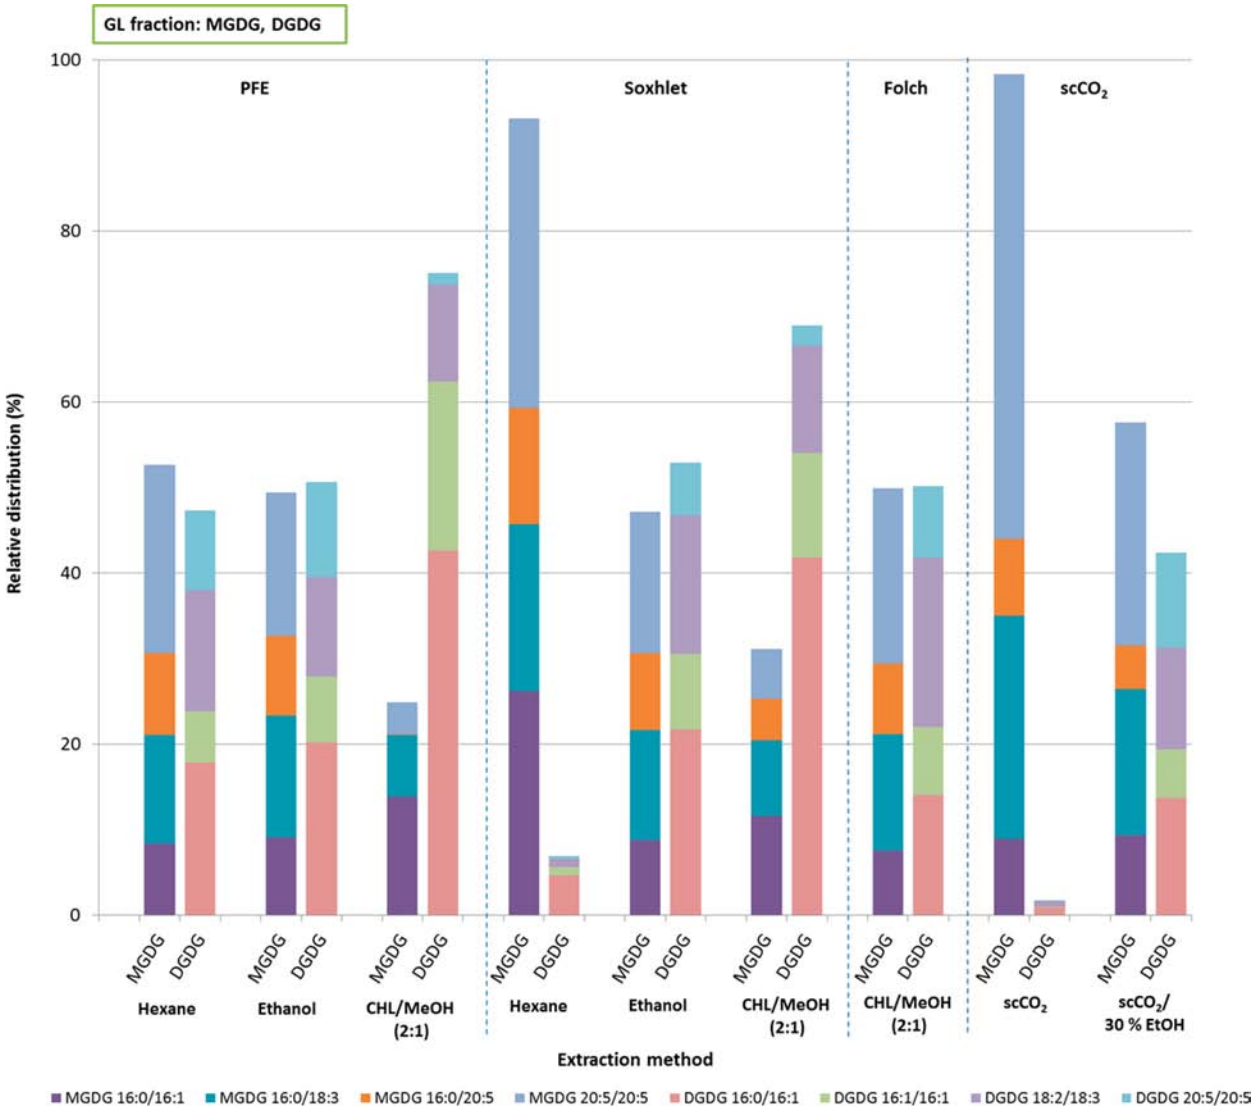

Figure 3. Relative distribution (% of total peak area) of the different MGDGs and DGDGs in the GL fraction. The results are the average of three replicate measurements (mean ± SD; CHL: chloroform; MeOH: methanol; EtOH: ethanol).

solvents, the highest recovery of NL was obtained with 3:2 hexane/isopropanol and ethyl acetate/hexane. Also for the GL, 3:2 hexane/isopropanol proved to be the most efficient solvent, whereas for PL, ethanol was best.[11] Similar results have also been observed by Balasubramanian et al.[37] and Mendes[34] and co-workers in which the latter uses solvent polarities to explain these observations.

The phosphorus content of the lipid extracts gives insight into the presence of phospholipids. According to the literature, PC was reported to be the major component of phospholipids in many microalgae, though its content might vary due to species-specificity or culture conditions.[8,11]

The phosphorus content of the different crude lipid extracts (Supporting Information, Figure S2) is in accordance with the lipid class composition. The extraction of PL is favored by a more polar extraction solvent. Indeed, the highest phosphorus content is observed for ethanol, followed by 2:1 chloroform/methanol, and then hexane. Furthermore, as pure $scCO_2$ is not polar enough to extract the phospholipids, none were detected above the LOQ in the $scCO_2$ extract. The increase in polarity by the addition of 30% ethanol, however, resulted in enhancement of the phosphorus concentration comparable to the content in the lipid extract of PFE with hexane.

Compound Identification in the Polar Lipid Fractions GL and PL. *GL Fractions.* An overview of the total chromatographic peak area integrated for the GLs in the different extracts is given in Figure 2. This data also indicates that by increasing the polarity of the solvent, more glycolipids are being extracted as indicated by the higher total chromatographic peak area. For all of the extraction methods used, the majority of the GLs (i.e., highest total peak area/mass algae extracted) is detected in the corresponding fractions. Analysis of the different PL fractions, however, revealed that quite a persistent proportion of GL is also present in these fractions (Figure 2). Thus, all extraction methodologies lead to higher yields of GL than the analysis of the GL fractions indicate. Similarities in chemical structure, and consequently polarity, between GL and PL lead to the observed incomplete separation, especially when using SPE.

Glycolipids and more specifically monoglycodiglycerides and diglycodiglycerides were detected as sodium adducts in the GL and PL fractions (Figure 2). Because galactolipids are the predominant lipids in photosynthetic membranes, they could

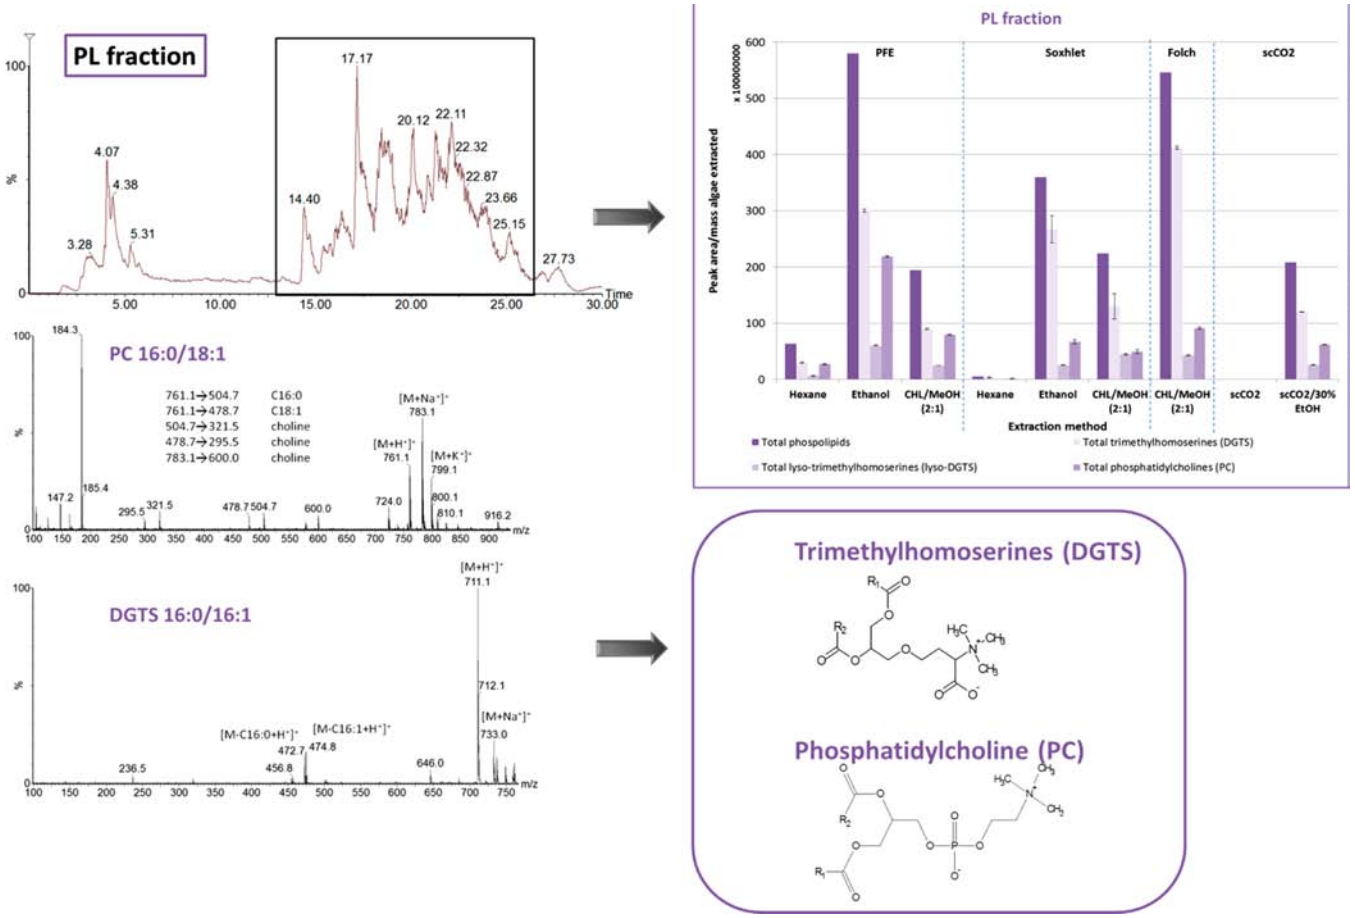

Figure 4. Total ion current (TIC) chromatogram of the PL fraction for PFE extraction with 2:1 chloroform/methanol. In the separate graph, the total chromatographic peak area is shown (mean ± SD; $n = 3$; CHL: chloroform; MeOH: methanol; EtOH: ethanol). The chemical structure of the compounds identified in the PL fractions is shown. The ESI+ mass spectrum of a compound is given as an example.

be assumed to be monogalactosyldiglycerides (MGDG) and digalactosyldiglycerides (DGDG). The structures of MGDG and DGDG are given in Figure 2. In these natural compounds, the galactopyranose moiety is linked to the glycerol backbone, bearing two long fatty acid chains.

As can be seen in Figure 3, the methodology used has a significant effect on the extraction yield of the galactolipids, shifting more toward MGDG or DGDG. SFE with pure $scCO_2$ and the Soxhlet extraction with hexane predominantly yield MGDGs with 98% and 92% of the total peak area, respectively, belonging to MGDG. The additional galactose moiety makes DGDG sufficiently polar to prevent its extraction with a nonpolar solvent. In contrast, the PFE extraction with hexane does extract DGDGs (53% MGDG and 47% DGDG), which can be explained by the higher extraction temperature and pressure. The extraction yield of DGDG is enhanced by increasing the solvent polarity with DGDG contributing >60% for the PFE or Soxhlet extraction with 2:1 chloroform/methanol.

Linked to MGDG and DGDG are different types of fatty acid (Figure 3). All of the galactolipids identified contain at least one site of unsaturation with a strong presence of C20:5. Among the saturated fatty acids, palmitic acid (C16:0) is the most abundant. PUFAs such as C20:5 are prone to oxidation,[30] and the incidence of C20:5 in the GL fractions indicates that the extraction methods used are able to preserve it intact. This occurrence of C20:5 is in accordance with literature data, where it is stated that PUFAs of microalgae are predominantly linked to polar lipids, especially glycolipids (MGDG, DGDG, and sulphoquinovosyldiacylglycerol (SQDG)).[4,10,11]

Also within every class, the abundance of one (or more) MGDG or DGDG compound(s) with a particular fatty acid is favored depending on the extraction method and solvent used (Figure 3). For example, DGDG 16:0/16:1 is the principle DGDG extracted with 2:1 chloroform/methanol as the solvent using either Soxhlet or PFE. The SFE-$scCO_2$ extraction, on the other hand, preferentially extracts MGDG 20:5/20:5. These observations again demonstrate that a more polar solvent mixture extracts more polar lipids (i.e., more sugars and shorter fatty acid chains), whereas the use of a less polar solvent yields less polar lipids (i.e., single sugars and longer fatty acid chains).

Wang et al. characterized the lipid profile of *Nannochloropsis oculata* extracted with ethanol (80 °C, 30 min) followed by separation of the lipid and nonlipid fractions using the Folch's procedure.[15] DGDG was the major GL class, accounting for 28.4% of all quantified polar lipids. The contribution of MGDG amounted to 2.1%. Hence, Wang et al. obtained an excess of DGDG in the ethanol extract, whereas MGDG and DGDG were more equally distributed in the ethanol extracts (PFE/Soxhlet) in the present study. According to Wang et al., the major fatty acids bound were C16:0 (52.3%), C14:0 (14.0%), and C18:1 (10.8%) in MGDG and C16:0 (51%) and C16:1 (19.1%) in DGDG.[15] In this study, however, different types of fatty acids are linked to MGDG and DGDG. Whereas C16:0

and C16:1 are common in both studies, the present study reveals the predominance of particular PUFAs, including C18:2, C18:3, and C20:5. This difference in fatty acid profile of the galactolipids can be explained by the cultivation, harvest (sedimentation, chemical flocculation, etc.), and storage (freeze, dry, freeze-dry, wet, etc.) conditions of the microalgae used. The extent of the production of biomass, lipids, carotenoids, and carbohydrates as well as the exact composition of the final products (e.g., fatty acid pattern of lipids) can vary considerably depending on the prevailing conditions in the cultivation medium.[5,6] In addition, differences in the fatty acid profile[15,35] of the extracts also arise due to the extraction methodology used (i.e., traditional vs PFE must also be taken into account), which can result in a different fatty acid profile.

PL Fractions. A typical chromatogram of a PL fraction is shown in Figure 4. In the PL fractions, two different classes of polar lipids were detected: trimethylhomoserines (DGTS; 1,2-diacylglyceryl-*O*-(*N*,*N*,*N*-trimethyl)-homoserine) and phoshatidylcholines (PC). The chemical structure of both classes is given in Figure 4. DGTS belongs to the betaine lipids, a recently discovered group of complex lipids primarily found in the plant kingdom.[40] Ether-linked glycerolipids containing a betaine moiety occur naturally in algae, bryophytes, fungi, and in some primitive protozoa and photosynthetic bacteria. These lipids contain a polar group linked by an ether bond in the *sn*-3 position of the glycerol moiety with the fatty acids esterified in the *sn*-1 and *sn*-2 positions (Figure 4). A positively charged trimethylammonium group and a negatively charged carboxyl group give them zwitterionic character at neutral pH. At least three types of betaine lipids have been described with differing permethylated hydroxyamino acids linked to diacylglycerols through an ether bond: DGTS, 1,2-diacylglyceryl-3-O-2′-(hydroxymethyl)-(*N*,*N*,*N*-trimethyl)-*β*-alanine and 1,2-diacylglyceryl-3-*O*-carboxy-(hydroxymethyl)choline. Of these, the first is by far the most common in nature.[40,41] There is evidence in the literature that supports betaine lipids (as well as glycolipids) being used to replace part of the membrane phospholipids in cases of phosphorus starvation as observed in the photosynthetic bacterium *Rhodobacter sphaeroides*[42] and plant *Arabidopsis thaliana*.[43]

DGTS can also be present in the lysated form due to the loss of a fatty acid residue, referred to as lyso-DGTS. The total peak area of polar lipids observed in the PL fractions of the different algae extracts is given in Figure 4 with a distinction between PC, DGTS, and lyso-DGTS. DGTS and PC are the major contribution to the total peak area of polar lipids. The highest total peak area was found for the PFE extraction with ethanol, followed by the conventional Folch extraction, with the highest affinity for DGTS. As for the GL fractions, a trend of increasing total peak area with increasing solvent polarity is observed, both for the traditional solvent systems and $scCO_2$.

[a]Results are the average of three replicate measurements (mean ± SD). [b]LOQ of PC analysis: 13 μg/mL. [c]Calculated using the relative peak area of each PC compound and the total PC concentration.

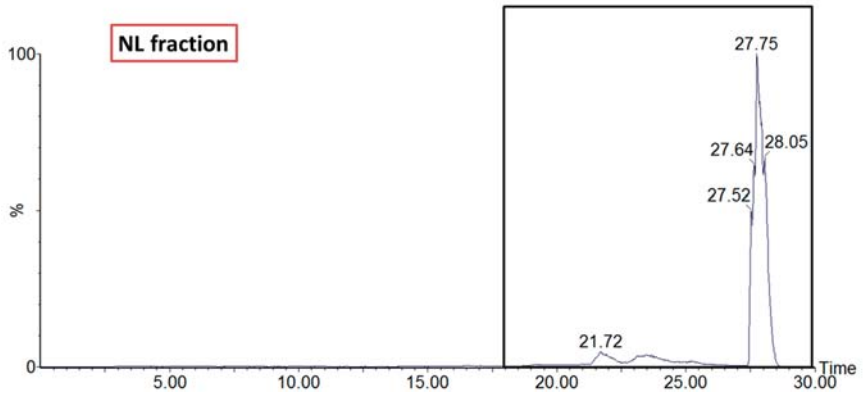

Figure 6. The total ion current (TIC) chromatogram of the NL fraction for PFE extraction with 2:1 chloroform/methanol.

Figure 5 shows the fatty acid profile of the DGTS, comprising large fractions of C20:5, C16:0, and C16:1. On the basis of these results, we can state that the various extraction methods under consideration are able to produce DGTS mixtures with slightly different compositions of fatty acids. However, in general, the methodology of extraction seems to affect the composition less than in the case of the galactolipids. This observation can possibly be explained by the amphiphilic structure of PC and DGTS, which both bear a positively charged group (quaternary ammonium), thus increasing their affinity for polar solvents, such as ethanol. On the other hand, sufficient solubility is maintained in more nonpolar solvents, such as chloroform/methanol mixtures, due to the presence of the two acyclic moieties. Hence, a very similar lipid distribution is generated among the different extraction methods. One exception is the extraction of DGTS 16:0/16:1 which is particularly favored by Soxhlet extraction with hexane.

In addition, two lysated forms of DGTS were identified in the different extracts (i.e., lyso-DGTS 16:0 and lyso-DGTS 20:5 with C16:0 and C20:5, respectively as the remaining fatty acids) (Figure 5). The majority of the extraction methods favor the extraction of lyso-DGTS 20:5. The trend is inverted, however, for Soxhlet extraction with hexane and $scCO_2$ extraction. The nonpolar character of the solvent used in the latter favors the extraction of lyso-DGTS bearing short chain fatty acids.

Because of the availability of a PC analytical standard, quantitative assessment of the PCs in the different extracts was carried out (Table 1). The highest PC concentration was observed in the PL fraction of the PFE extract with ethanol. No PCs were measured above LOQ (LOQ: 14 μg/mL) in the pure $scCO_2$ extract. The addition of 30% ethanol to $scCO_2$, however, results in increased extraction of PC at 0.33% (w/w).

A total concentration of PC in the range of only 1.5−10% (w/w) in the PL fractions, which corresponds to 0.1−2.5% in the algae, raises questions about the nature of other compounds present and their contribution to the total concentration of PLs. The presence of homoserines (DGTS, lyso-DGTS) can be stipulated with certainty, though due to the lack of an analytical standard their quantification was not possible. The presence of other PL classes (i.e., phosphatidylinositols and phosphatidylethanolamines) was investigated. However, these compounds were not detected in a quantifiable amount.

The chromatogram of the different PL fractions, indicating the considerable presence of polar compounds, combined with the low solubility of the PL samples even in a large volume of 90:10 isopropanol/acetonitrile with 0.1% formic acid, clearly suggests the presence of very polar compounds, possibly salts.

J. Agric. Food Chem. 2015, 63, 3931−3941

C16:0, C16:1, C20:5, and C18:3 are the dominant fatty acids linked to PCs in the different extracts (Table 1). The PL fractions of all PFE extractions and the $scCO_2$/30% ethanol extraction show a rather similar PC pattern dominated by PCs 16:0/16:1, 16:0/18:1, and 16:0/18:3. In contrast, the PL fraction originating from the conventional Folch extraction is rich in PC 16:0/20:5, PC 16:1/16:1, and PC 16:1/20:5. From the Soxhlet extract PC 16:0/16:1, PC 16:1/16:1, PC 16:1/20:5, and PC 18:1/16:1 are the most abundant, independent of the solvent used. Hence, in analogy to DGTS, it can be concluded that the different methodologies seem to be able to extract PCs with slightly different fatty acid profiles. Compared to the GL fractions, however, the fatty acid pattern seems to be less affected by the extraction methodology applied. Therefore, it can be stated that the different methods are able to extract PCs with similar fatty acid distribution.

Purity Control of NL Fractions. The UPLC-MS method applied here was specifically developed to assess the presence of GLs and PLs, which were the main focus of this study. Hence, TAGs could not be detected and identified. The NL fractions, however, were also analyzed using this method to establish the purity of these fractions. As expected, no polar lipids (GL and PL) were detected in the different NL fractions. The chromatogram of the NL fraction originating from the PFE extraction with 2:1 chloroform/methanol is given as an example in Figure 6, which clearly shows the absence of peaks belonging to GLs and PLs. Hence, the SPE fractionation of lipid classes results in complete separation of the neutral lipids from the more polar ones.

The peaks present in the chromatograms of the NL fractions can be attributed to pigments (i.e., oxygenated carotenoids, commonly known as xanthophylls). Because the presence of carotenoids in the different algae extracts are not the focus of the present study, no further attention has been paid to the detailed analysis of the carotenoids present.

Cultivation, harvesting, and storage conditions significantly influence the lipid and fatty acid profiles of microalgae species. This study clearly indicates that the extraction methodology also affects the composition of the lipid profile of *Nannochloropsis oculata*, affecting both the efficiency and selectivity of extraction. Nonpolar solvents show the highest affinity for neutral lipids, and the extraction of polar lipids is favored by increasing solvent polarity.

Special emphasis has been given to the identification of the polar lipids present in the GL and PL fractions. Within these lipid classes, the extraction methodology used affects the molecular composition of the extract, in both structure and fatty acid composition. This effect was more pronounced in the GL fractions. Thus, the extraction of lipids from microalgae is not only a matter of "how many", but also of "which ones", according to the different methodologies and solvents used.

J. Agric. Food Chem. 2015, 63, 3931−3941

Arachidin-1 and arachidin-3 have been shown to modulate both cannabinoid receptors CB1 and CB2 in vitro. Molecular modeling studies with these compounds showed that the lipophilic side chain (3-methyl-1-butenyl group) in the structure of these stilbenoids was necessary for the high affinity attained to cannabinoid receptor CB2,[12] a therapeutic target in the treatment of neurodegenerative disorders such as Alzheimer's disease.[13] In addition, arachidin-3 and arachidin-1 are metabolized to fewer glucuronidated products than their nonprenylated analogues, resveratrol and piceatannol. This suggests that the lipophilic side chain might hinder the glucuronidation process and thereby enhance the bioavailability of arachidin-1 and arachidin-3 when compared to piceatannol or resveratrol.[12]

Despite the diverse bioactivities of peanut prenylated stilbenoids demonstrated in in vitro studies, in vivo studies have not been conducted due to their limited availability.[9,11,14,15] Furthermore, the biosynthetic pathways of these compounds have not been elucidated, which restricts potential metabolic engineering strategies for their bioproduction. To address these limitations, peanut hairy roots cultures have been developed as viable production platforms for stilbenoids.[16,17] Upon treatment with selected elicitors, the peanut hairy root cultures produce the same phytoalexins described in fungal-challenged peanut seeds. For instance, after 24 h of treatment with sodium acetate (NaOAc), peanut hairy roots secrete resveratrol, arachidin-1, and arachidin-3 into the culture medium.[16]

Different elicitors have been also used to induce the biosynthesis of stilbenoids in hairy roots of other species. For example, hydrogen peroxide (H_2O_2), a molecule in plants that mediates responses to stresses[18,19] and methyl jasmonate (MeJA), a key compound involved in defense-related signal transduction pathways in plants,[20] have been used as elicitors to induce the biosynthesis of resveratrol, piceatannol, and viniferins in hairy roots of *Vitis rotundifolia*.[21,22]

Previous studies have investigated the interaction between stilbenoids and cyclodextrins (CDs). The latter are torus-shaped oligosaccharides derived from starch that can form inclusion compounds with nonpolar molecules that fit into their hydrophobic cavity. For instance, resveratrol and CD were shown to form 1:1 inclusion complexes.[23] Interestingly, treatments with CD or CD plus MeJA were first used as an approach to increase the production of resveratrol in *Vitis vinifera* cell suspensions[24−26] and proved to be effective in enhancing the production of taxanes in cell suspension cultures of *Taxus* spp.[27] and inducing silymarin accumulation in *Silybum marianum* cell suspensions.[28]

In the current study, NaOAc, H_2O_2, MeJA, CD, and MeJA in combination with CD were tested as elicitors of stilbenoids in peanut hairy root cultures. The levels of stilbenoids in the culture medium were determined along a time course from 0 to 96 h. In addition, the effect of selected elicitor treatments on the expression of resveratrol synthase, the first committed metabolic step in stilbenoid biosynthesis, was investigated. Our results show that peanut hairy root cultures can be developed as controlled and sustainable high-level production systems for arachidin-1 and arachidin-3, two major peanut stilbenoids exhibiting a diversity of biological activities.

MATERIALS AND METHODS

Hairy Root Line and Growth Conditions. All experiments were conducted with hairy root cultures of peanut (*A. hypogaea*) cv. Hull line 3 established previously by the Medina-Bolivar laboratory.[16] Ten root tips (2−3 cm long) were inoculated into 250 mL flasks containing 50 mLof modified MS medium (MSV)[16] with 3% sucrose. The flask cultures were incubated on an orbital shaker (Innova 44R, New Brunswick Scientific) at 90 rpm and 28 °C and maintained under continuous darkness.

Elicitor Treatments. Nine-day-old hairy root cultures were treated under five different conditions to study stilbenoid production: 10.2 mM sodium acetate (NaOAc), 10 mM hydrogen peroxide (H_2O_2), 100 μM methyl jasmonate (MeJA), 9 g/L (6.87 mM) methyl-β-cyclodextrin (CD; Cavasol W7M), and 100 μM MeJA combined with 9 g/L CD. The concentration of NaOAc was established before,[16,17] whereas the concentration of MeJA was determined on the basis of previous studies with hairy root cultures of muscadine grape.[22] Preliminary studies with peanut hairy roots treated with different concentrations of H_2O_2 (Supporting Information, Figure S3) and MeJA combined with different concentrations CD (Figure S4) were used to determine the concentrations of H_2O_2 and CD used in the current study. Before elicitor treatment, the spent medium was removed and replaced with 50 mL of fresh MSV medium containing 3% sucrose and different elicitors. For the control group, the culture medium was replaced with MSV medium with 3% sucrose and 50 μL of absolute ethanol (EtOH; solvent of MeJA) (Sigma).

A 96 h time course per elicitor treatment was conducted including the following time points: 0, 0.5, 1, 3, 6, 9, 12, 15, 18, 21, 24, 30, 36, 40, 48, 72, and 96 h for the NaOAc-treated hairy roots; 0, 1, 2, 3, 6, 12, 18, 24, 48, 72, and 96 h for the H_2O_2-treated hairy roots; 0, 1, 3, 6, 12, 24, 48, 72, and 96 h for the MeJA-treated hairy roots; 0, 3, 9, 15, 24, 48, 72, and 96 h for the CD-treated hairy roots; and 0, 0.5, 1, 3, 6, 9, 12, 15, 18, 21, 24, 30, 36, 48, 60, 72, 84, and 96 h for the MeJA and CD co-treated hairy roots. All treatments were performed at 28 °C under continuous darkness with three biological replicates per time point per treatment.

Extraction and Analyses of Stilbenoids from the Culture Medium. Stilbenoids were extracted from the medium of NaOAc-, H_2O_2-, and MeJA-treated hairy roots as described before.[16] For the CD-treated and MeJA and CD-co-treated hairy roots, each medium sample (40 mL) was extracted twice with 50 mL of EtOAc in a separatory funnel. The organic phases were combined and evaporated to dryness under vacuum at 40 °C in a rotary evaporator (Büchi, rotavapor R-200). The extract was redissolved in 1.5 mL of MeOH and dried to completeness under a nitrogen stream using a Reacti-Vap III apparatus (Pierce). Extracts were redissolved in 1 mL of MeOH, filtered through a 0.2 μm nylon filter, and analyzed by reverse phase HPLC as detailed below.

HPLC analyses were performed in a Dionex Summit system equipped with a photodiode array detector. The separation was performed on a SunFire C_{18}, 5 μm, 4.6 × 250 mm column (Waters) at 40 °C with a flow rate at 1.0 mL/min. The mobile phase consisted of 2% formic acid in water (A) and MeOH (B). The column was initially equilibrated with 100% A for 1 min. Then a linear gradient was performed from 60% A and 40% B to 65% A and 35% B (1− 20 min), followed by a linear gradient from 65% A and 35% B to 100% B isocratic elution in 5 min (20−25 min). Reference compounds included commercially available *trans*-resveratrol (Biophysica) and *trans*-piceatannol (Axxora). *trans*-Arachidin-1 and *trans*-arachidin-3 standards were purified from elicited peanut seeds as described.[16] Dilutions of the standards were made in MeOH to obtain calibration curves for quantitative analysis. Calibration curves were established using absorbance at 320 nm for resveratrol and piceatannol and at 340 nm for arachidin-1 and arachidin-3.

Resveratrol Feeding Experiment. The spent media of 9-day-old hairy root cultures were removed and replaced with 50 mL of fresh MSV medium containing 3% sucrose. Resveratrol was fed into the hairy root culture at a concentration of 60 μM. A second experimental group included 60 μM resveratrol with 9 g/L CD. All cultures were maintained at 28 °C and 90 rpm under continuous darkness. A 1 mL aliquot was collected from each treatment at the following time points: 0, 0.5, 1, 3, 6, 12, and 24 h. Each aliquot was mixed thoroughly with 1 mL of EtOAc, and then the EtOAc phase was collected, dried under a

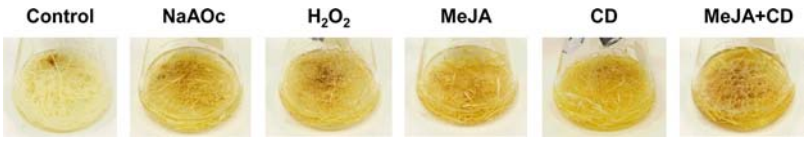

Figure 2. Phenotype of peanut cv. Hull hairy root line 3 after 48 h of treatment with different elicitors: sodium acetate (NaOAc, 10.2 mM); hydrogen peroxide (H_2O_2, 10 mM); methyl jasmonate (MeJA, 100 μM); methyl-β-cyclodextrin (CD, 9 g/L); and 100 μM MeJA with 9 g/L CD (MeJA+CD). Control represents nonelicited culture.

nitrogen stream, and dissolved in 500 μL of MeOH for HPLC analysis as described above. Three biological replicates were included per treatment.

RNA Extraction and Quantitative Real-Time PCR. Nine-day-old hairy root cultures were treated with 100 μM MeJA, 100 μM MeJA with additional 9 g/L CD, and 9 g/L CD alone to study the effect among these treatments on the expression of a previously described peanut resveratrol synthase gene, *JC1* (GenBank accession no. EU418492).[29] A 48 h time course per treatment was conducted including the following time points: 0, 0.5, 3, 9, 15, 24, and 48 h. Three biological replicates were performed at each time point per treatment.

Total RNA was isolated from 15 mg of lyophilized peanut hairy roots using TRIzol reagent (Life Technologies), according to the manufacturer's instructions. RNA concentration was estimated from absorbance readings at 260 nm, and the purity of the total RNA was estimated from the ratio of absorbance readings at 260 and 280 nm using a NanoDrop 800 spectrophotometer (Thermo Scientific). One microgram of total RNA was reversed transcribed in a 20 μL reaction mixture containing oligo (dt) primers using the iScript Select cDNA Synthesis Kit (Bio-Rad) following the manufacturer's instructions. The reaction mixture was incubated at 42 °C for 90 min, followed by an incubation at 85 °C for 5 min, after which the samples were cooled on ice or kept at −20 °C for later use. Quantitative real-time PCR (qPCR) reactions were carried out using iQ SYBR Green Supermix (Bio-Rad). The PCR reaction mixtures comprised 2× qPCR mix (5 μL), forward primer (0.4 μL, final concentration 0.8 μM), reverse primer (0.4 μL, final concentration 0.8 μM), water (0.2 μL), and 18 ng of cDNA template (4 μL) in a final volume of 10 μL. For target gene *JC1*, forward primer 5′-TATGTATTTAACAGAAGAAATAC-3′ and reverse primer 5′-AGTTGCAGCCTCTTTTCCAACT-3′ were used as specific primers as described previously.[29] Three reference genes, *ACT7* (encoding actin 7), *EFα1* (encoding elongation factor α1) and *TBP2* (encoding TATA box binding protein), were selected previously[30] and used to normalize the expression of resveratrol synthase in peanut hairy roots. All of the reactions were prepared using an automated pipetting system (epMotion 5075; Eppendorf) on Hard-Shell Thin-Wall 384-Well Skirted PCR plates (Bio-Rad). Technical replicates were run in triplicate, and the amplification program was followed as described previously.[30]

Statistical Analysis. Each treatment included three biological replicates. Two-way ANOVA with multiple-comparisons tests was conducted for the data in Figures 5 and 6 and analyzed with GraphPad Prism 6, version 6.02. Tukey's Studentized range (HSD) tests were done for the data in Tables S1−S6 of the Supporting Information and analyzed with SAS (Statistical Analysis Systems) statistics program version 9.2.

RESULTS AND DISCUSSION

Response of Peanut Hairy Root Cultures to Different Elicitors. A previously established hairy root culture of peanut cv. Hull line 3 was selected for elicitation studies on the basis of its vigorous growth in liquid MSV medium.[16] Accordingly, the best growth stage for producing the maximum level of arachidin-1 and arachidin-3 in the culture medium after 24 h of treatment with 10.2 mM NaOAc was 9-day-old hairy root cultures.[16] In preliminary studies, cultures at day 9 (mid-exponential growth stage as determined before[16]) showed the most reproducible levels of the different stilbenoids analyzed, independent of the elicitor used, when compared to 6-, 12-, and 15-day-old cultures. Therefore, we used 9-day-old cultures to compare the effects of the five treatments, namely, NaOAc, H_2O_2, MeJA, CD, and MeJA with CD, on production of stilbenoids along a time course from 0 to 96 h. In contrast to the white root tissue observed in nontreated control cultures, the peanut hairy root tissue showed a dark yellow color 48 h after elicitor treatment, the cultures treated with CD or co-treated with MeJA and CD being the ones with the darkest color (Figure 2). Because the hairy roots of peanut secrete most of stilbenoids into culture medium,[16] a slight yellow color that is the characteristic color of stilbenoids found in peanut root mucilage[8] was also observed in the medium of hairy root culture treated with NaOAc, H_2O_2, and MeJA alone. Strikingly, the medium of the cultures treated with CD or MeJA with CD turned a strong and bright yellow color (Figure S1), suggesting higher levels of arachidin-1, arachidin-3, and other stilbenoids in these cultures.

Effect of Different Elicitor Treatments on the Yield of Stilbenoids. The stilbenoids resveratrol, arachidin-1, and arachidin-3 have been described in fungal-challenged seeds[11,31] and elicited hairy roots of peanut.[16,17] Indeed, these stilbenoids accumulated in the culture medium of peanut hairy roots lines from different cultivars (i.e., Andru II and Hull) upon treatment with NaOAc as elicitor.[16,17] Interestingly, the prenylated stilbenoids arachidin-1 and arachidin-3 were not described in elicitor-treated peanut callus. Nonetheless, the nonprenylated analogue of arachidin-1, that is, piceatannol, was reported in these callus cultures upon elicitor treatment.[32−34]

Although resveratrol, arachidin-1, and arachidin-3 were described in peanut hairy root cultures upon 24 h of treatment with NaOAc,[16] detailed studies comparing distinct elicitor treatments over different periods have not been reported. Therefore, in this study a 96 h time course of accumulation of stilbenoids in the hairy root culture medium was conducted for each of the five elicitor treatments (NaOAc, H_2O_2, MeJA, CD, and MeJA with CD). In addition to the three stilbenoids described before (resveratrol, arachidin-1, and arachidin-3), piceatannol was also included in the study because it was previously described in callus cultures of peanut.[32−34] To study the potential molar contribution of the nonprenylated stilbenoids (resveratrol and piceatannol) to the formation of their prenylated analogues (arachidin-3 and arachidin-1), the yield of stilbenoids in culture medium was expressed as nanomoles and normalized per gram dry weight of hairy root tissue (nmol/g DW; Tables S1−S5). The levels of stilbenoids in the MeJA and CD co-treatment group are also reported in milligrams per liter of medium (Table S6). It is worth mentioning that in preliminary studies only trace levels of these stilbenoids were detected in the root tissue upon elicitor treatment; therefore, we report here the levels of stilbenoids in the culture medium.

The accumulation of resveratrol and arachidin-3 in the medium started at 3−6 h post elicitor treatment, whereas

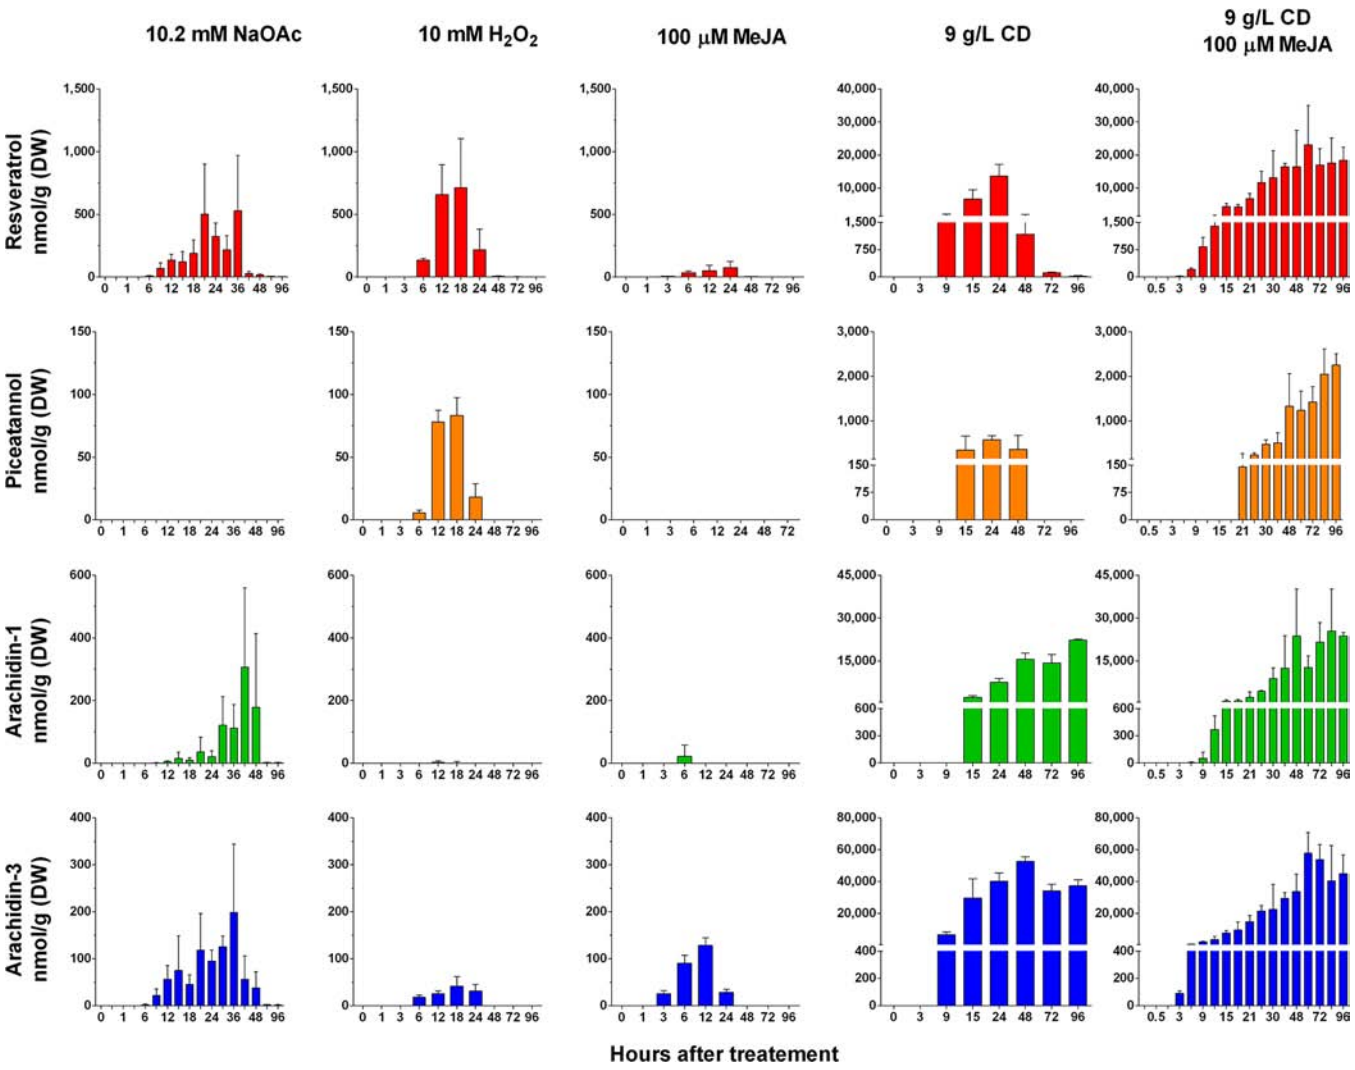

Figure 3. Time course of stilbenoid yield in the medium of peanut hairy roots culture after treatment with different elicitors. Values are the average of three replicates, and error bars represent standard deviation. Statistical analyses are shown in Tables S1−S5. DW, hairy root dry weight.

arachidin-1 was detected 3 h later. Among the five treatments, MeJA combined with CD led to the highest levels of resveratrol in the culture medium (Figure 3). No significant differences were observed in the levels of resveratrol between 24 and 96 h (Table S5), suggesting that resveratrol levels reached a plateau with an average yield of 16716 nmol/g DW. These levels corresponded to an average yield of 40.29 mg/L (24− 96 h time points, Table S6). Most interestingly, the levels of resveratrol remained at these high levels until the end of the time course (96 h). On the other hand, when the cultures were treated with NaOAc, H_2O_2, MeJA, or CD, the levels of resveratrol declined significantly toward the end of the time course (Figure 3 and Tables S1−S4). Remarkably, the yield of resveratrol in the elicited peanut hairy roots was much higher than that obtained from abiotic or biotic stimulated peanut callus[32−34] and sliced and fungi-challenged peanut kernels.[9,14,35] However, the highest yield of resveratrol (~17 μmol/g DW) in peanut hairy root cultures upon co-treatment with 9 g/L (6.87 mM) CD and 100 μM MeJA was still 94 times lower than the 1600 μmol/g DW concentration of resveratrol found in grape cell suspension cultures co-treated with 50 mM dimethyl-β-cyclodextrin (DIMEB) and 100 μM MeJA for >160 h.[25] This increased yield of resveratrol could be due to a higher concentration or different type of methylated cyclodextrin used in the grape study. In preliminary studies with peanut hairy root cultures, 15 mM was the highest concentration of CD used in combination with 100 μM MeJA (Figure S4). Higher concentrations of CD could be tested in peanut hairy root cultures to determine their effect on resveratrol production. Moreover, besides resveratrol, the stilbenoids piceatannol, arachidin-1, and arachidin-3 are also produced by peanut hairy roots, and these compounds may use resveratrol as a biosynthetic precursor. Additionally, the difference in the yield of resveratrol between the grape cell suspension and peanut hairy root cultures could be attributed to the distinct genetic and production capability of each of these systems.

Piceatannol was detected only in the hairy root cultures treated with H_2O_2, CD or MeJA with CD (Figure 3). Similarly to resveratrol, piceatannol levels remained high toward the end of the time course only in the cultures co-treated with MeJA and CD. Statistical analyses showed that the levels of this stilbenoid reached a maximum between 72 and 96 h with an average yield of 1909.92 nmol/g DW (Table S5). In the case of the CD-treated group, the highest yield was 582.13 at 24 h, which was significantly different from the 15 and 48 h elicitor treatments (Table S4), whereas, in the H_2O_2-treated group,

DOI: 10.1021/jf5050266
J. Agric. Food Chem. 2015, 63, 3942−3950

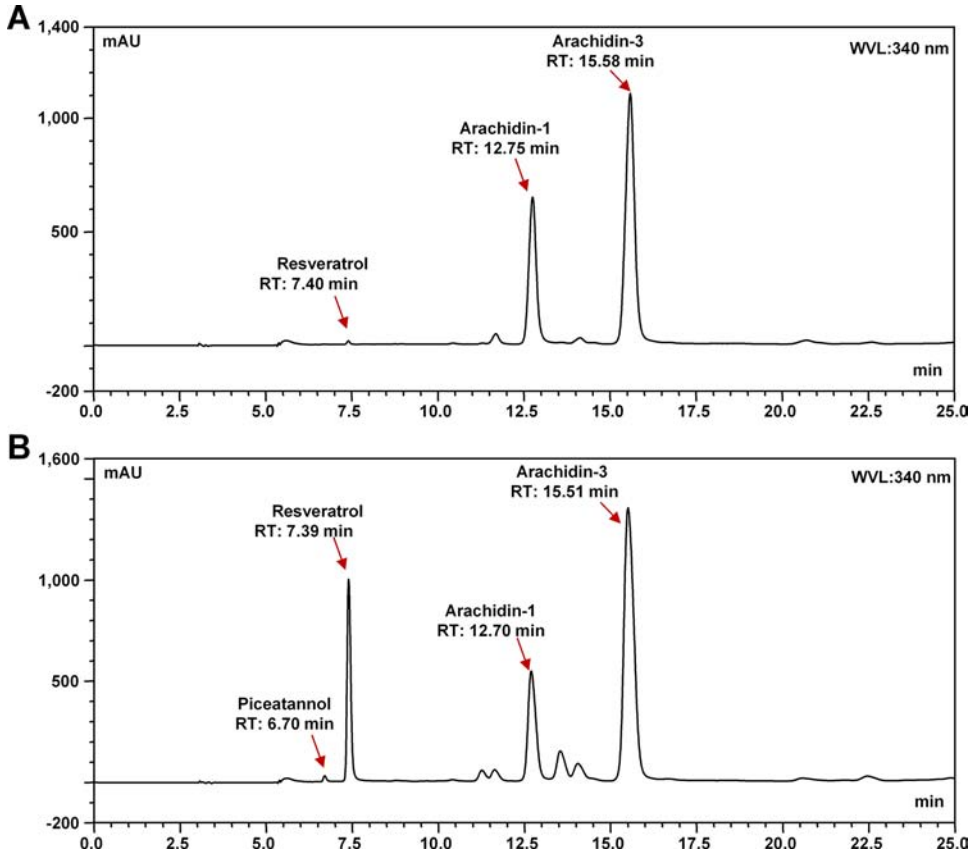

Figure 4. HPLC chromatogram (UV 340 nm) of ethyl acetate extract from the medium of peanut hairy root culture: (A) cultures were treated for 48 h treatment with 9 g/L methyl-β-cyclodextrin (CD); (B) cultures were co-treated for 48 with 100 μM methyl jasmonate and 9 g/L CD.

piceatannol yields reached their maximum at an average of 80.65 nmol/g DW (Table S2). Altogether, yields of piceatannol in the MeJA with CD-co-treated group were ~3-fold higher than in the CD-treated cultures and ~24-fold higher than in the H_2O_2-treated cultures. In the CD-treated and MeJA and CD-co-treated groups, piceatannol started to accumulate later than resveratrol. Similarly, piceatannol was also detected later than resveratrol in peanut callus exposed to fungi and chemicals elicitors,[34] suggesting that piceatannol was synthesized from resveratrol, which contains one fewer hydroxyl group. Meanwhile, in the H_2O_2-treated hairy root cultures, the accumulation of piceatannol was quite similar to the accumulation pattern of resveratrol. To date, the enzyme involved in piceatannol synthesis in peanut has not been described, although the biosynthesis of resveratrol has been elucidated in plants.[3] Interestingly, a cytochrome P450 enzyme capable of converting resveratrol to piceatannol has been identified in a human cancer cell line.[36]

The highest concentrations of arachidin-1 were obtained in the CD-treated and MeJA and CD-co-treated cultures. Under either treatment, the levels of arachidin-1 remained high until the end of the time course (96 h; Figure 3). In the CD-treated cultures, the 96 h treatment showed the highest yield of arachidin-1 (22316.80 nmol/g DW), and this time point was significantly higher than all other time points in the time course (Table S4), whereas in the MeJA and CD-co-treated cultures, the concentration of arachidin-1 reached a plateau at 30 h. The average yield of arachidin-1 from 30 to 96 h was 18396.70 nmol/g DW (Table S4). This yield was equivalent to 56 mg/L (30−96 h time points, Table S6). Arachidin-1 levels declined significantly after 48 h in the NaOAc-treated cultures. In these cultures, arachidin-1 levels were highest between 30 and 48 h with an average yield of 179.73 nmol/g DW. Very low amounts of arachidin-1 were detected at a few time points of the MeJA- or H_2O_2-treated cultures (Tables S2 and S3). Overall, the levels of arachidin-1 in the CD-treated and MeJA with CD-co-treated cultures were ~124- and ~102-fold higher than that in the NaOAc-treated cultures, respectively.

Similarly to arachidin-1, the highest yields of arachidin-3 were obtained in the cultures treated with CD or co-treated with MeJA with CD (Figure 3). In the CD-treated cultures, the highest levels of arachidin-3 were found from 24 to 48 h of treatment with an average yield of 46423.27 nmol/g DW (Table S4), whereas in the MeJA and CD-co-treated cultures, the levels of arachidin-3 reached a plateau after 48 h, because no significant differences in arachidin-3 yields among the different time points between 48 and 96 h were observed (Table S5). During this time period of 48−96 h the average yield of arachidin-3 was 46160.99 nmol/g DW. This yield represented ~148 mg/L of arachidin-3 (48−96 h time points, Table S6). In the NaOAc-treated cultures the levels arachidin-1 declined significantly after 48 h, whereas in the H_2O_2- and MeJA-treated cultures a significant decrease was observed after 24 h. The average maximum yield in the NaOAc-treated cultures was 122.78 nmol/g DW, which represented time points of 15 and 21−36 h. Overall, the yield in either the CD- or MeJA with CD-treated cultures was ~377-fold higher than that in the NaOAc-treated cultures.

As far as we know, arachidin-1 and arachidin-3 have been described only in peanut. Nonetheless, other prenylated

DOI: 10.1021/jf5050266
J. Agric. Food Chem. 2015, 63, 3942−3950

stilbenoids have been reported in a small number of plant species.[37−39] The maximum yields of these compounds in aerated and sliced peanut seeds have been 1586.53 nmol/g DW (495.7 μg/g DW) and 8158.11 nmol/g DW (2414.8 μg/g DW) peanut kernel for arachidin-1 and arachidin-3, respectively.[9] Herein we show that the hairy root cultures of peanut can be designed to produce much higher levels of arachidin-1 and arachidin-3. The accumulation of arachidin-1 was found 3 h later than that of resveratrol and arachidin-3 in any of the different treatments, much earlier than that of piceatannol, the nonprenylated analogue of arachidin-1. Whereas the highest yields of arachidin-1 and arachidin-3 were similar between the CD and MeJA with CD treatments, the levels of resveratrol and piceatannol were always higher under the MeJA with CD co-treatment. These differences could be appreciated by comparing the HPLC chromatograms of extracts from CD-treated versus MeJA and CD-co-treated groups (Figure 4). Therefore, the latter elicitation co-treatment is a preferred strategy to produce higher levels of diverse types of stilbenoids in peanut hairy root cultures.

The location and formation of phytoalexins induced by infection with soil fungal strains in peanut kernels were studied previously. Resveratrol could be found in deeper layers of the kernel slices, which were close to healthier tissue, whereas arachidin-1, arachidin-3, and other stilbenoids were detected near the infected area, suggesting that resveratrol might be the precursor of other stilbenoids in peanut.[40] In the MeJA and CD-co-treated group, the molar ratio of resveratrol to its prenylated analogue arachidin-3 was between 0.4 and 0.5, whereas that of piceatannol to its prenylated analogue arachidin-1 was only between 0.08 and 0.09. Meanwhile, piceatannol was not detected in the medium of the cultures upon treatment with NaOAc or MeJA alone, whereas arachidin-1 was found in these cultures. These results suggest that the main stilbenoids responding to the elicitor treatments are resveratrol, arachidin-3, and arachidin-1 in peanut hairy root cultures.

Effect of Methyl-β-cyclodextrin on the Levels of Resveratrol in the Medium of Peanut Hairy Root Cultures. The degradation of the stilbene-type phytoalexins resveratrol and pterostilbene have been reported during the interaction of grapevines with *Botrytis cinerea*,[41,42] whereas the catabolism of stilbenoids in non-pathogen-challenged plant tissues has not been studied. After treatment with NaOAc, H_2O_2, or MeJA alone, resveratrol and other stilbenoids accumulated in the medium of hairy root cultures of peanut and reached their maximum levels between 12 and 36 h. Thereafter, their concentrations decreased to barely detectable levels after 72 h of treatment (Figure 3). A similar decrease in resveratrol and piceatannol levels was reported when peanut callus was challenged with a fungal spore suspension as biotic elicitor[33] and UV irradiation as abiotic stress,[35] suggesting that peanut might have the ability to degrade these stilbene-type phytoalexins inside the root tissue or secrete specific enzymes to metabolize them after a temporal exposure to stress. However, the levels of resveratrol, piceatannol, arachidin-1, and arachidin-3 in the hairy root cultures co-treated with MeJA and CD remained high even up to 96 h. Interestingly, the levels of arachidin-1 and arachidin-3 also remained high in the medium over time in CD-treated peanut hairy root cultures, whereas resveratrol and piceatannol levels were not sustained over time. In grape cell suspension cultures co-treated with MeJA and CD, resveratrol levels were maintained at high levels in the medium up to 120 h, and this level was much higher than that of cultures treated with MeJA alone. In the latter cultures, no significant amounts of resveratrol were detected in the spent medium after 24 h.[25] These results could be due to CD's capability of forming inclusion complexes with stilbene compounds such as resveratrol,[23,43] piceatannol,[44] and pinosylvin,[45] which might protect stilbenoids from uptake or degradation by the host as suggested before.[23,24]

To study the effect of CD on the levels of resveratrol in the culture medium of peanut hairy roots, resveratrol alone or together with CD (9 g/L) was added to the peanut hairy root culture, and the concentration of resveratrol in the medium was determined at different time points. The 60 μM concentration of resveratrol used in this experiment represented the average level of this stilbenoid found in the culture medium upon co-treatment with MeJA and CD. In the control group containing resveratrol alone, the concentration of this stilbenoid declined dramatically to 27.04 ± 0.83 μM after 0.5 h and to 1.74 ± 1.29 μM after 1 h. These represented reductions of about 47 and 97% of the initial resveratrol concentration, respectively. Resveratrol was not detected after 3 h of incubation (Figure 5).

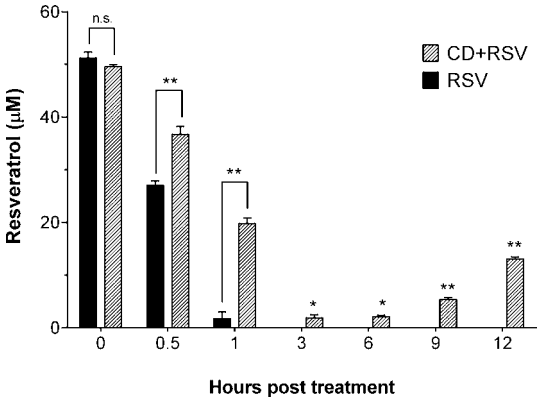

Figure 5. Effect of methyl-β-cyclodextrin (CD) on the levels of resveratrol (RSV) in the medium of hairy root cultures of peanut. Nine-day-old peanut hairy roots were co-inoculated with 60 μM RSV, and the concentration of RSV that remained in the medium was determined by HPLC. RSV, resveratrol alone; CD+RSV, RSV plus 9 g/L CD. Values are the average of three replicates, and error bars represent standard deviation. (*) $p < 0.05$; (**) $p < 0.001$; (n.s.) not significant by two-way ANOVA with Sidak's and Bonferroni's multiple-comparisons test.

Notably, resveratrol was stable in fresh culture medium and in culture medium from elicited cultures after 48 h of treatment with MeJA, in which no stilbenoid was detected (Figure S2). This suggests that peanut hairy roots do not secrete any enzymes that might metabolize resveratrol into the medium. However, resveratrol could have been converted into other metabolites by cell wall bound enzymes. Indeed, a cell wall bound peroxidase has been shown to dimerize resveratrol in grapevine cell suspension cultures.[46]

In the resveratrol and CD coculture group, the concentrations of resveratrol in the medium after 1 and 3 h of incubation were 19.78 ± 1.04 and 1.88 ± 0.61 μM, respectively. The rate at which the levels of resveratrol were reduced in the medium was statistically significantly lower than in control group (Figure 5). CD−stilbenoid inclusion complexes could promote an active biosynthesis and extracellular accumulation of stilbenoids by diminishing the usual feedback inhibition and/

DOI: 10.1021/jf5050266
J. Agric. Food Chem. 2015, 63, 3942−3950

or toxicity expected when a secondary metabolite is present at high levels in the cytoplasm, such as resveratrol in cell suspensions of *Vitis vinifera*[26] and taxol in cell suspensions of *Taxus baccata*.[47] Moreover, after 9 h of treatment with CD and resveratrol, the concentration of resveratrol rose to 5.35 ± 0.39 μM. Interestingly, arachidin-3 was also detected in medium (Table S4), confirming that CD also induces the biosynthesis of stilbenoids in peanut hairy root cultures as shown in Figure 3. Similarly, resveratrol biosynthesis was induced when grapevine cell suspension cultures were treated with CD alone, indicating that CD acts as elicitor.[23,24] Our results show that CD can stabilize resveratrol levels in the medium of peanut hairy root cultures, leading to several hundred-fold increases in the levels of these compounds in culture medium upon co-treatment with MeJA and CD.

Expression of Resveratrol Synthase Gene (*RS*) in Peanut Hairy Roots after Elicitor Treatment. MeJA and CD were reported to have a synergistic effect on the expression of the stilbene pathway in grape cell suspension cultures.[25] To this end, we studied the effect of CD and MeJA on the expression of resveratrol synthase (*RS*), a key gene involved in stilbenoid biosynthesis. In our previous study, a resveratrol synthase gene from peanut was cloned and functionally characterized in planta via transient expression in *Nicotiana benthamiana*. Therefore, the expression of this gene was studied by quantitative PCR in hairy roots of peanut treated with MeJA, CD, or MeJA combined with CD (Figures 6 and S5).

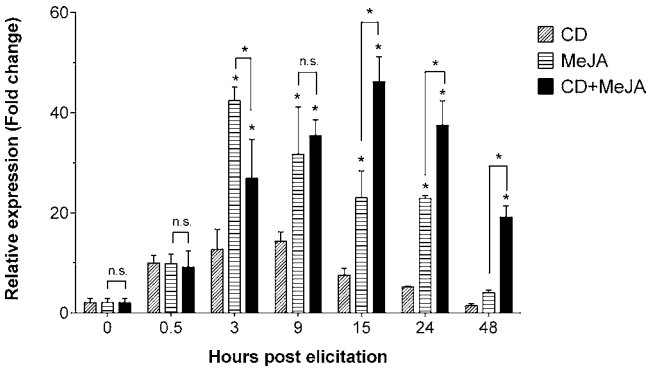

Figure 6. Relative expression of resveratrol synthase gene (*RS*) in peanut hairy roots after treatment with different elicitors. Nine-day-old peanut hairy roots were treated with 100 μM methyl jasmonate (MeJA), 100 μM methyl jasmonate with 9 g/L methyl-β-cyclodextrin (CD+MeJA), and 9 g/L methyl-β-cyclodextrin alone (CD). Relative expression of *RS* was normalized using *ACT7*, *EFα1*, and *TBP2* as reference genes. Values are the average of three replicates, and error bars represent standard deviation. Statistical analysis was performed by two-way ANOVA with Tukey's and Bonferroni's multiple-comparisons test. The asterisks above bars represent significant difference when compared to CD treatment group (*, $p < 0.001$; n.s., not significant), and the asterisks above the connecting line represent significant difference between MeJA and CD+MeJA groups (*, $p < 0.001$; n.s., not significant).

In the CD group, *RS* expression showed a peak at 9 h post treatment followed by a slight decrease during the next 6 h (Figure S5). When compared to the other two treatments, CD alone showed the lowest induction. After 3 h of treatment with MeJA alone, *RS* expression increased rapidly to (42.4 ± 2.7)-fold higher than the minimum *RS* expression value in the time course. This level of expression was significantly higher than the CD or CD with MeJA groups (Figure 6). Then the *RS* expression dropped quickly to (23.0 ± 5.4)-fold change at 15 h post treatment and finally to (4.0 ± 0.5)-fold change at 48 h post treatment, which was close to the *RS* expression at 0 h time point (Figures 6 and S5). This early induction of *RS* expression was also observed in peanut hairy roots treated with the elicitor NaOAc.[48]

In the hairy root cultures co-treated with CD and MeJA, the expression level of the *RS* increased gently to the highest point at 15 h post treatment with (46.2 ± 5.0)-fold change. Then it was followed by a slow decline, after it reached the peak. *RS* expression was maintained at (19.2 ± 1.2)-fold increase at 48 h post treatment, which was significantly higher that that of the CD or MeJA groups. These observations correlated to the highest levels of resveratrol observed in the cultures co-treated with MeJA and CD relative to cultures treated with CD alone (Figure 3). The relative expression level of resveratrol synthase (stilbene synthase) and central phenylpropanoid genes, phenylalanine ammonia-lyase, cinnamate 4-hydroxylase, and 4-coumarate CoA ligase, were also quantified through a time course in grapevine cell suspension culture incubated with MeJA, CD, or the combined treatment with MeJA and CD.[25] Compared to treatments with MeJA or CD alone, a sustainable expression of resveratrol synthase and phenylpropanoid-related genes was also observed in the MeJA and CD co-treated group. These results suggest that in grapevine cell suspension culture and peanut hairy root culture, MeJA and CD have a synergistic effect on stilbene biosynthesis pathway gene expression, which could be correlated with the increased yield of stilbenoids in the medium. Interestingly, a recent study has shown than CD is also capable of encapsulating MeJA to form MeJA−CD complexes with a 1:1 ratio in stoichiometry.[49] Further studies are necessary to evaluate a potential role of CD on the stability of MeJA in peanut hairy root cultures.

In conclusion, although prenylated stilbenoids isolated from treated peanut kernels show a diverse bioactivities in vitro, their production using these biological systems is limited. To address this issue, hairy root cultures of peanut co-treated with MeJA and CD have been developed as a controlled and sustainable system for the high-level production of the prenylated stilbenoids arachidin-1 and arachidin-3. Furthermore, peanut hairy root cultures also provide a viable platform to identify regulatory genes and key enzymatic steps in stilbenoid biosynthesis beyond resveratrol formation. For instance, these genes encode for enzymes involved in prenylation and hydroxylation reactions, which introduce the various functional groups that contribute to the structural and functional diversity of stilbenoids in peanut.

reduction amount in cellulose and total hemicelluloses are observed at veraison and proceed throughout the subsequent phases.[18] In the pectic fraction, the total amount and neutral and acid sugars temporally increase form before veraison to veraison, decreasing rapidly in post veraison.[18,19] Conversely, the neutral sugar content of the hemicellulosic fraction decreases from before veraison to veraison. During veraison, the neutral sugar composition of each fraction changes little.[18] This result discloses a pattern of temporal modifications in grape berry softening from before veraison to veraison.[18]

Water is one of the most valued resources on the planet, and understanding the impact of water deficit on grape development is vital. Mechanisms to cope with drought such as stomata control or extensive root systems developed by the grapevine have been recognized.[20] It is well documented that water stress affects the variation of sugar and phenolic contents.[21−23] Although to a lower extent than shoot organs, berry growth is sensitive to water deficits, being arrested[24] mainly at the mesocarp level, so that the seed and skin mass account more significantly for berry weight,[25,26] leading to an irreversible reduction in berry size[27,28] often with thicker exocarps.

Under water deficit conditions occurring either before or postveraison, the anthocyanin content in the grape skin increases in a cultivar-dependent pattern.[29,30] In ripening Cabernet Sauvignon grapes, water deficit leads to an increase in sugar accumulation only if imposed before veraison,[29] while in the red cultivar Shiraz, water deficit applied at postveraison leads to a reduction in sugar concentration and an increase in phenolic compounds content, except for anthocyanins.[31] Despite that, moderate water stress may increase the extractability of the anthocyanins into wine;[32] therefore establishing a balanced water regime is vital to attaining a quality wine.

Functional genomic resources for *V. vinifera* have proliferated rapidly in the recent years after genome sequencing,[33,34] and such information has paved the way for large-scale studies of gene expression profiling during berry development. CW metabolism related genes were over-represented in gene clusters with significant differential expression in several development stages.[35−40]

In grapes, differences in CW composition[4] and transcriptome[41] were described between red wine varieties, advising investigating the behavior of different genetic backgrounds to understand physiological events and agronomic performances.

The goal of this research was to investigate the effect of nonirrigation versus irrigation practices on grape quality parameters, with emphasis on the berry skin CW in two Portuguese grape varieties, Touriga Nacional (TN) and Trincadeira (TR). Our hypothesis was to verify if the changes in berry composition due to water shortage were related with remodeling of skin CW. For that purpose, berry yield, chemical characteristics, and mechanical properties as well as skin CW composition and expression of key candidate genes associated with berry development and ripening were examined at two developmental moments, veraison and full maturation.

MATERIALS AND METHODS

Experimental Vineyard and Plant Material. The study was conducted in 2012, on a vineyard located at the Centro Experimental de Pegões, Portugal (38° 39′ 1″ N; 8° 38′ 42″ W). The climate in the vineyard is Mediterranean with Atlantic influence, summers with hot days and fresh nights, and mild winters (Figures S1 and S2). The soil is derived from podzols, with a sandy surface layer (0.6−1.0 m) and clay at 1 m depth. Mixed clones of Touriga Nacional and Trincadeira were established in 2002, both varieties grafted on 1103 Paulsen rootstock. The plants spaced 2.5 m between rows and 1 m within rows were trained on vertical trellis and uniformly pruned on a bilateral Royat Cordon, ca. 12 buds per vine. Two irrigation regimes were considered: rain fed, nonirrigation (NI), and full irrigation in which water was supplied according to the evapotranspiration (100% ETc; FI, control). ETc was estimated from the reference evapotranspiration (ET_0), obtained in an automatic weather station located within the experimental vineyard as described in Lopes et al.[42] Irrigation water was applied with drip emitters (4.0 L h^{-1} for FI) two per vine, positioned 30 cm from the vine trunk, and began on June 29. Relative soil humidity in the soil profile was measured with a Diviner 2000 capacitance probe (Sentek Environmental Technologies, Stepney, Australia) in vertical tubes at increments of 0.1 m from the soil surface to a depth of 1.0 m[43] and assessed at plant level by predawn leaf water potential on the preselected plants as described by Scholander et al.[44] Three plants in each treatment and plot were preselected for analysis in a total of six plants per water regime and variety. At veraison (50% colored berries) on July 27 for TR and August 10 for TN and full maturation, the berries were pooled per water regime and variety and development stages (Figure S2). Berries were kept frozen from arrival from the field until further analyses.

Grape Berry Composition. Three samples of 100 berries were used for berry composition analysis per treatment and variety. After detaching the pedicels and acquiring the sample fresh weight, must volume, pH, total soluble solids (TSS in °Brix) and total acidity, skin anthocyanin content and total phenol index were assessed.

The must pH was measured with a calibrated pH meter at room temperature. TSS were quantified using an Atago Brix pocket refractometer. Total acidity was measured via titration with sodium hydroxide and expressed in g dm^{-3} of tartaric acid. Color density is given as the sum of absorbances in a 1 cm pathway at 420, 520, and 620 nm.[45] For extracted anthocyanin content, the skins were treated by the method of Carbonneau and Champagnol.[46] The skins were suspended in 96% ethanol buffered with tartaric acid solution (pH 3.6), and after 24 h of maceration at 37 °C the solution was centrifuged at 5000*g* for 10 min for (1) the calculation of extracted anthocyanin concentration as quantified by the method of Ribereau-Gayon and Stonestreet[47] with the absorbances obtained at 520 nm converted from a standard curve prepared with malvidin 3-glucoside and (2) estimation of total phenol by absorbance in a 1 cm pathway at 280 nm.[48]

Texture Analyses. Two compression tests were employed to address texture attributes. Skin firmness was measured using a penetration test carried out on the detached skin of 50 mature berries trapped between two perforated acrylic plates. Measurements were made using a TA-XT Texture Analyser equipped with a HDP/90 platform and a cylinder flat probe of 2 mm Ø (ref.:P/2), using a 5 kg load cell.[49] Tests were performed at 1 mm s^{-1}, and berry skin breaking force is expressed in Newtons (N). Berry texture analysis was carried out in 50 uniform mature berries. Measurements were made using a TA-XT Texture Analyser (Stable Micro Systems Ltd., UK) equipped with a HDP/90 platform and compression platens of 75 mm Ø, using a 5 kg load cell. The force to deform 10% of the berry equatorial diameter was expressed in Newtons (N).[50]

Cell Wall Analysis. *Cell Wall Extraction.* Ten grams of fresh skins were lyophilized and homogenized in liquid nitrogen and the CW extracted according to the method described by Talmadge et al.[51] as per Fernandes et al.[52]

Cellulose and Lignin Quantification. Cellulose was quantified by the Updegraff[53] method, using the hydrolytic conditions described by Saeman et al.[54] and quantifying the released glucose by the anthrone method.[55] Klason lignin was determined using the method described by Hatfield et al.[56] The results are expressed as microgram per milligram of CW.

Cell Wall Fractionation and Monosaccharide Quantification. The fractionation of berry skin CW at maturation followed the method of Selvendran and O'Neill[57] with minor modifications as in Fernandes et al.[52] Total sugars and uronic acids were determined using the

[a]Lower case letter indicates significant differences between treatments, capital letter indicates significant differences between stages and asterisk indicates significant differences between varieties, at $p < 0.01$ significance.

phenol–sulfuric acid assay and the m-hydroxybiphenyl assay,[58] respectively. Glucose and galacturonic acid were the corresponding standards. Neutral sugars were quantified by Gas Chromatography (GC) according to Albersheim et al.[59] with minor adaptations[52] using a Supelco SP-2330 30 m × 0.25 mm × 0.20 μm Capillary Column in a Varian 450-GC fitted with flame-ionization detector. The temperature program consisted of 210 °C (6 min hold) increased to 230 at 20 °C/min (25 min hold). Helium (2 mL min^{-1}) was used as the carrier gas. Pure rhamnose, fucose, arabinose, xylose, mannose, galactose, and glucose were used as monosaccharide standards and inositol as an internal standard. For data acquisition, the Galaxie Chromatography Software (Agilent, USA) was used.

Quantification of Gene Expression. *RNA Extraction and cDNA Synthesis.* Total RNA was extracted from *V. vinifera* berries using the Spectrum Plant Total RNA Kit (Sigma-Aldrich) with some modifications. Samples were ground in liquid nitrogen, and 400 mg of the material was split into two eppendorf tubes, and 900 μL lysis buffer was added per tube.[60] After centrifugation (10 min), the combined supernatants were filtered using the necessary number of filtration columns. A total of 750 μL of binding solution was added to each filtrate and passed through a single binding column. The RNA was then eluted using Milli-Q water. RNA samples were further treated with RNase-free DNase I (Qiagen) according to the manufacturer protocol, and quantification was carried out in a Synergy HT Multiplate Reader, with Gene5 software, using a Take3Multi-Volume Plate (Bio-Tek Instruments Inc. Winooski, USA). For reverse transcription, the RevertAid reverse transcriptase priming with oligo-d(T) kit was used (Thermo Scientific) according to the manufacturer's recommendations.

Quantification of Gene Expression by Quantitative PCR (RT-qPCR). For each *V. vinifera* cDNA sequence retrieved from public databases (Genoscope 12X (http://www.genoscope.cns.fr/spip/)), a set of specific primers (Table S1) was designed and used to amplify grapevine skin cDNA resulting from the transcription of 2 μg of total RNA, using conventional PCR. When amplification confirmed the expression, the transcripts were quantified by real-time PCR (qPCR), performed in 20 μL reaction volumes composed of cDNA derived from 2 μg of RNA, 0.5 μM gene-specific primers (Table S1), and SsoFast EvaGreen Supermixes (Bio-Rad, Hercules, CA) using an iQ5 Real-Time Thermal Cycler (BioRad, Hercules, CA). Reaction conditions for cycling were 95 °C for 3 min followed by 40 cycles at 95 °C for 10 s, 61 °C for 25 s, and 72 °C for 30 s. Melting curves were generated in each case to confirm the amplification of single products and absence of primer dimerization. Each analysis was performed in triplicate reactions, each in three biologic replicates (n = 9, in which each replicate is the average of three technical measurements). The corresponding quantification cycles (Cq) obtained by the iQ5 optical system software (Bio-Rad, Hercules, CA) were exported to a MS Excel spreadsheet (Microsoft Inc.) for quantification. Cq values of each gene of interest were normalized with respect to actin (Act) and translation initiation factor eIF-3 subunit 4 (TIF) Cqs.[61] Relative gene expression values in NI conditions are presented in heat maps, performed using the MeV software,[62] as log2 fold-change values in relation to control conditions (FI).

Statistical and Principal Component Analysis. All data are presented as mean values ± standard deviation (SD) of at least three biological replicates in each assay. The results were statistically evaluated by variance analysis (ANOVA) and post hoc Bonferroni test with a $p < 0.01$ significance level to compare the meaning of each effect with the SigmaPlot (Systat Software Inc.) statistical package. The Pearson correlation coefficient was calculated to disclose correlations between texture and skin composition values.

Data from 50 individual attributes measured at maturation were standardized, and a pair-wised correlation matrix was calculated and subjected to eigenvalue decomposition to identify orthogonal components of the original matrix and generate a Principal Component Analysis (PCA) biplot, using the NTsys-PC version 2.20e software package.[63] The weight of each character in sample separation was determined by calculating eigenvectors using the mean values of each treatment.

RESULTS

Composition of Grape Berries. A first indication of the effect of stress imposition (rain fed, Non Irrigation (NI) compared with Full Irrigation (FI), control; Figure S1) on the *V. vinifera* berries was gained through the measurement of berry composition. NI treatment decreased berry weight and must volume in all cases and increased TSS at maturity in both varieties, as shown in Table 1, although it was more pronounced in TN at veraison and in TR at maturation. At veraison under a water deficit, total acidity was significantly different between varieties. However, TR was delayed comparing to TN in either sugar increase or acid decrease (Table 1). Furthermore, we observed that in TN, water shortage (TN-NI) induced anthocyanin accumulation, while in TR, higher anthocyanin content was observed at maturity in the absence of water shortage (Figure 1A). The total phenol index followed the same pattern except for a slight increase at veraison in TR-NI (Figure 1B). The color is one of the most important characteristics for a wine. At maturation the water shortage induces a more intense color in the berry skin, which was more intense in TN berries (Figure 1C).

Cellulose and Lignin Content. The cellulose content of TN berry skins was not affected by the water regime, whether in veraison or in maturation. However, in TR, a statistically significant decrease was observed in NI between veraison and maturation and, at maturation, between control and NI (Figure 2A). Following the same pattern, lignin decreased in TR-NI at maturation (Figure 2B).

Berry Texture. Alterations in berry firmness can be addressed by measuring changes in compression, while skin break force is

given by the force rendered in penetration tests. In TN-NI, a higher force for berry deformation was necessary, while skin break force and energy were higher in TR-NI, decreasing from veraison to the maturation as expected (Table 2, see also Table S2). The Young modulus (E_{sk}) that represents the material resistance to axial deformation had the same trend as skin break force, revealing a decrease in the springiness of TR-NI berry skins (Table 2). Our results suggest that these specific properties may be influenced by the amount of phenolic compounds (Table S2).

The Pearson correlation between the berry texture attributes and CW composition showed significant negative correlations between skin break force and skin break energy with anthocyanin and total phenol contents. Noticeably, cellulose content was found to be positively correlated to the force needed to break the skin while lignin correlated to the energy applied to achieve rupture.

Sugar Composition in CW Fractions. Since major differences in cellulose and lignin between irrigation practices and varieties were observed at the maturation stage, only this stage was considered for berry skin CW fractionation. CDTA extracts polysaccharides that are less bound to the CW. The more tightly bound CW polysaccharides are extracted by increasing KOH molarity. The majority of polysaccharides were extracted in the alkaline fractions, particularly the 6 M KOH, with the exception of TR-FI. Considering the responses of the varieties to the irrigation regimes, in TN-NI, weakly bound polysaccharides were shown to be more extractable than under full water availability. In TR-NI, more polysaccharides were extracted in the 6 M KOH fraction, suggesting a more tight binding to the CW (Figure 3). The majority of uronic acids (reflecting the pectin content) was extracted in the CDTA and 0.1 M KOH fractions, with higher amounts in the latter (Figure 4A,B). No differences were observed between treatments or varieties. The analysis of the CW fractions by GC showed that the most abundant neutral monosaccharide present in all fractions was arabinose, followed by glucose, xylose, and galactose. The arabinose-, xylose-, and glucose-containing polysaccharides were in all cases higher in TR in all alkaline treatments, although in the 0.1 M KOH fraction, TR-NI samples showed decreased arabinose-containing polysaccharides when compared to the control (Figure 4B), which were shifted to the strong alkaline fraction (Figure 4C). For TN-NI, the 6 M KOH fraction showed a small but significant increase of arabinose-containing polysaccharides. The majority of xylose-containing polysaccharides were putatively tightly bonded to the CW since they only could be extracted by strong alkaline conditions. Conversely to TN, TR-NI was richer in xylose-containing polysaccharides (Figure 4C).

Changes in the Expression of Selected Key Genes Involved in Modification of the Berry CW. One way to access the effect of a stress on a given metabolic event is to understand the transcription of related genes. Figure 5 shows that water depletion gave rise to different gene expression patterns, some activated at veraison and others at maturation. As compared to TR, TN had more responsive genes, most of them down-regulated after water deficit in the two varieties. The expression of XTH genes was severely down-regulated at veraison on both varieties, with the exception of *VvXTH14* in TN. Conversely, at maturation, members of this family were not affected by the water shortage. At veraison, both PGs investigated were up-regulated in TN while *VvPG1* in TR showed a 3-fold down-regulation when compared to the control. In maturation, the majority of PGs were repressed, including *VvPG6*, which had a 7 fold repression compared to the control (Figure 5). The majority of EXPA gene expression had a similar down-regulation at veraison. EXPA genes were more repressed at maturation (Figure 5). The expression of PME genes unraveled a higher number of members showing down-regulation under water scarcity in both TN and TR. As in the case of EXPA, these genes were more repressed at maturation. Interestingly, under water shortage, PMEI gene expression was shown to be generally not affected at veraison. At maturation in TN, two

genes were down-regulated (*VvPMEI3* and *VvPMEI4*), but the same *VvPMEI3* in TR was up-regulated with a fold change of 6 (Figure 5).

Data Integration. To obtain a global representation of all data collected at maturation, samples were graphically plotted in a reduced number of axis after multivariate analysis (Principal Component Analysis; PCA). Principal components 1 and 2 (PC1 and PC2) in combination explain 58.8% of the total variation and could separate the samples according to the variety and water regime to which they were submitted. Replicates were generally closely clustered, demonstrating the accuracy of the analyses performed and the true biological basis of the measured dissimilarities. The results shown in Figure 6 reveal that PC1 clearly differentiates between varieties while PC2 separates the samples according to the treatments. According to the resultant eigenvectors calculated using the average values of the triplicates (Table S3), the variables that contributed more to PC1 separation were the higher amounts of arabinose- and galactose-containing polysaccharides extracted in the 0.1 M KOH fraction and xylose-containing polysaccharides collected in both alkaline solutions, and the lower relative transcription of *VvPMEI1*, *VvPMEI2*, *VvXTH31*, and *VvXTH15* in the TR variety. PC2 separation was mainly explained by lower amounts of glucose-containing polymers extracted by 0.1 M KOH solutions, by mannose- and fucose-containing polysaccharides present in the 6 M KOH solution

under the FI regime, and by the lower relative expression of two polygalacturonase genes, *VvPG2* and *VvPG4*, in the control.

DISCUSSION

Water deficit during *Vitis vinifera* L. growth, like other abiotic stresses, is known to decrease growth and yield,[64−66] impacting berry physical and chemical composition[67] and, ultimately, influencing the sensorial quality of the final product.[68] In this work, we assessed the influence of nonirrigation in comparison with water full conditions in berry characteristics, CW composition, and gene expression of two widespread Portuguese winegrape varieties, Touriga Nacional and Trincadeira, growing under Mediterranean conditions with Atlantic influence, to which some grapevines varieties are better adapted than others.[69] The clear effects exerted by water deficit on berry characteristics (Table 1) confirm previous results showing that water deficiency results in an increase in anthocyanin concentration,[70] and in total phenols (Figure 1).[29] It is unsure whether the increase in total polyphenol content is purely due to the fluctuations in anthocyanin content or by the increase of other phenolic compounds including flavanols and proanthocyanidins.[29] Moreover, the variety-specific amount of anthocyanin observed is also in agreement with previous studies.[71] The global CW results allowed an evident separation of both varieties and the imposed water regimes, as illustrated by the PCA plots (Figure 6). The separation in the two first components is mainly explained by the amount of monosaccharides extracted in distinct fractions, which suggest different polysaccharide linkages, and by CW-related gene expression (Table S3).

Among the effects on CW, the alterations mostly associated with changes in composition and architecture are the berry texture characteristics. Texture analysis is a rapid and low-cost analytical technique that can be applied in viticulture and enology as a routine tool for monitoring grape quality.[72] In our research, texture measurements were conducted with the objective of comparing the changes in mechanical properties of the berry and berry skin between the two cultivars under the water regimes imposed during grape development. Therefore, and since the assays were conducted with frozen/thawed grapes, the measurements do not describe fresh berries values

but clearly indicate that under our conditions the higher skin break force measured in TR-NI berries (Table 2) seems to be variety dependent, since TN break force was not affected by the water regime. Conversely, in TN-NI compression tests, higher forces were needed to attain the same berry deformation (Table 2). The increase in berry skin break force in TR-NI was also observed in stressed Mondeuse, Becuét, and Fumin grapes obtained during on-vine drying.[73,74] Recent observations by Zsófi et al.[67] in Kékfrankos grapes growing under greenhouse conditions suggest that skin break force increases significantly as a result of water deficit. Conversely, berry firmness measured as berry deformation by the compression test was decreased in TN-NI. As a whole, the skin break force and skin break energy correlated negatively with the amounts of berry secondary metabolites but positively with cellulose and lignin contents, respectively (Table S2). This suggests that the lower cellulose and lignin content verified after water deficiency contributes, although in different dimensions, to the alteration in the skin mechanical properties. The responses obtained so far corroborate the dependence on the variety and the environmental conditions.[75,76] However, and taking advantage of the aftermost results with fresh berries from an experimental water regime similar but not equivalent to the one reported here, for full clarification, the presented results might be confirmed with fresh berries from the cultivars and under the experimental setup as applied in the present study.

Aiming at gaining a further insight on the basis of water deficit on polysaccharide differences, general CW composition was investigated in all samples. In this work, TR-NI showed reduced amounts in cellulose and lignin at maturation (Figure 2), which was accompanied by a marked reduction in berry size (Table 1). In the Muscat Gordo Blanco variety, Nunan et al.[6] found that cellulose remained unaltered during ripening, putting forward the assumption that the decrease in TR may be a genotype-specific response to water availability. Conversely, the increased break force may be caused by CW polysaccharides besides cellulose since this polymer serves as a scaffold for the binding of other CW components.[77] The shift of arabinose-containing polysaccharides from the 0.1 M KOH to 6 M fraction in TR-NI (Figure 4) may indicate that

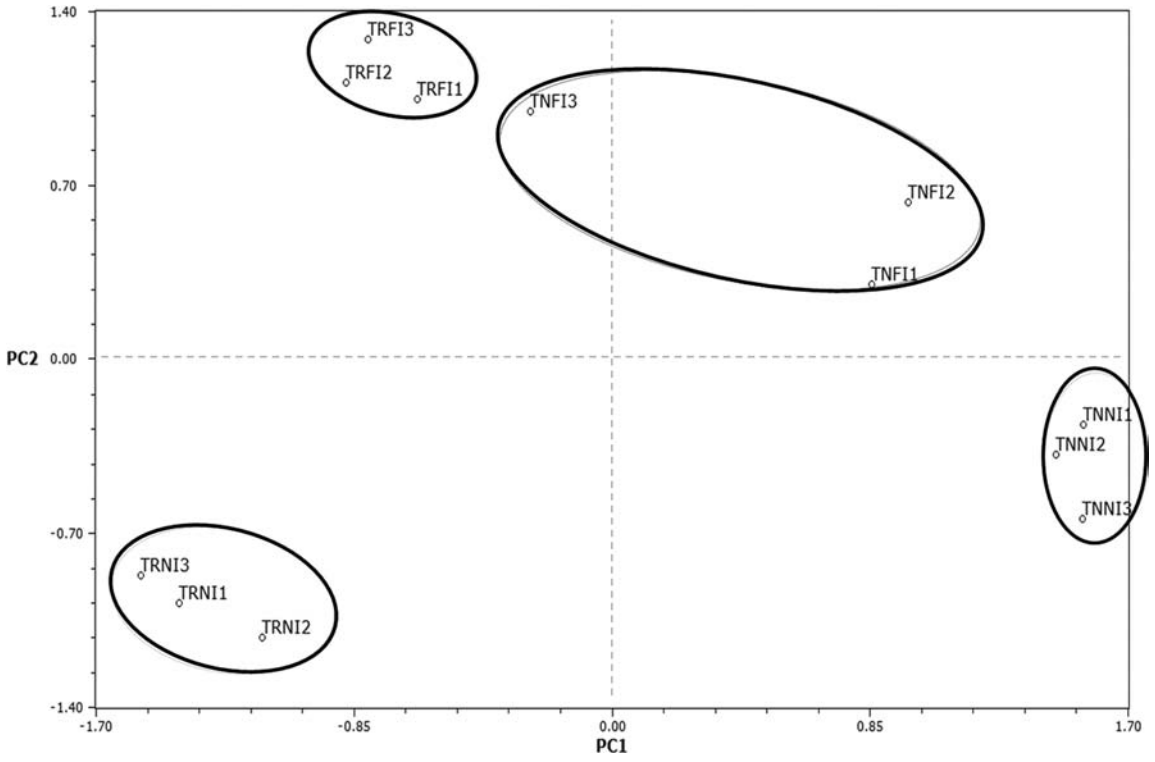

Figure 6. Principal component analysis (PCA) from 50 individual attributes measured at maturation. PC1 and PC2 explain, respectively, 35.3% and 25.6% of the total variation.

rhamnogalacturonan-I (RGI) arabinosyl residues became more tightly bound into CW with water shortage. The presence of RGI decorated with arabinose rich side chains in water deficient conditions can work as CW plasticizers.[78] Under water shortage, arabinose and also galactose rich polymers are known to retain relatively longer mobility than other CW polymers filling the cavities created upon physical rearrangement of the CW.[79] The unusually high arabinan content (approximately 38 mol %) observed in the resurrection plant *Myrothamnus flabellifolius*[80] further suggests an arabinose role for plants coping with water scarcity. Changes in pectin, break energy, and Young modulus (E_{sk}) showed similar patterns to break force, again with a variety dependent behavior, skins becoming less elastic in the absence of water. From the correlation of E_{sk} values with total phenols content (Table S2), it can be inferred that the stiffening of the CW may contribute to the extractability of the phenolic compounds, as observed by Rolle et al.[81] As referred to by other authors, Torchio et al.[82] and Zsófi et al.,[67] an increase in elasticity was observed from veraison to ripening.

Gene expression of key candidate genes was considered to be differential when above a log2 ± 2-fold change relative to the control and showed that all gene families investigated possess members that respond to water shortage (Figure 5). This complementary approach provided evidence that, although with a general pattern of down-regulation, responsive individual genes within each family were different depending on the stages. Exceptions were *VvPG1* and *VvPG2* at veraison in TN and *VvPMEI3* at maturation in TR that are up-regulated, both indicating changes in the pectic network of the CWs, which suggests different patterns of expression depending on the development stage, in accordance with Deluc et al.[36] findings. According to PCA, concerning gene expression, the observed differences between varieties are putatively associated with differences in the inhibition of pectin methylesterification and in the expression of members of the xyloglucan endotransglycosylase/hydrolase (XTH) family. Pectins are embedded within the cellulose/hemicellulose network, forming a hydrophilic gel that imposes mechanical features to the wall such as regulation of the hydration status or defining the porosity and stiffness of the wall.[83] PME activity can alter the degree and pattern of methyl esterification[84] and, therefore, change the biophysical properties of the CW. Under water scarcity, the PME expression decreased, as also observed for some members of Sangiovese grapes.[85] The maintenance in the degree of methyl esterification of pectins, as observed by Zoccatelli et al.[85] in Sangiovese grapes, may lead in our case to the preservation of the CW structure, especially in TR, which is further supported by the penetration tests. At the biochemical level, the activity of PMEs is also regulated by PMEIs. Grimplet et al.[37] reported modifications in the expression of a PMEI member, with downregulation at maturation, which is in agreement with the patter observed in this work in TN. Conversely, in TR its expression is upregulated, which contributes to the variety separation observed in the PCA analysis (Figure 6) This PME activity my change the pectin methyesterification degree. Changes in the degree of pectin methylation seem to be genotype-specific in *Vitis*, decreasing as ripening progresses in some cultivars like Cabernet Sauvignon, Merlot, and Monastrell, while it hardly changes in Syrah.[4] This observation is in accordance with the differences found between TN and TR. A total of 15−25% of the hemicelluloses present in dicot primary CW are constituted by xyloglucans.[12] The xyloglucan frame can be modified by XTHs, which can potentially have two distinct catalytic activities, namely transglycosylase (XET) or hydrolase (XEH).[86−88] These activities have been associated with the fruit softening that occurs during phase III of berry development and largely modulate CW loosening.[6] In the present study, the lowest *VvXTH* expression was observed at veraison, mainly in TR in result of water shortage. The low activity suggested by the down-regulation of XTH genes may lead to maintenance of the CW structure under water shortage. On the other hand, Deluc et al.[36] observed that XTH gene expression declined significantly along berry development.

The effect of distinct water regimes in gene expression was mainly due to the transcript abundance of polygalacturonases (PGs), which are CW-localized enzymes that cleave stretches of unesterified GalA residues and weaken the middle lamella.[89] PG activity is known to accompany fruit ripening.[90] The up-regulation of PG at veraison and subsequent down-regulation at maturation is in agreement with Grimplet et al.[37] under water deficit. In the pectin fraction of the grape mesocarp, both polysaccharide amounts and the neutral and acidic sugars of the water-soluble fraction temporally increase from before veraison to veraison stages, decreasing rapidly thereafter.[18,91] The maintenance of the pectin level in response to water shortage, especially in the 6 M KOH fraction, may be partially explained by the low transcription levels of PMEs and PGs strengthening the CW and increasing the force necessary to break the skin. In the mesocarp, pectin and xyloglucan solubilization seems to occur at later stages of ripening while depolymerization events occur at earlier stages (reviewed by Goulao et al.[92]).

Expansins (EXPA) play also an important role in the CW loosening phenomenon via nonenzymatic mechanisms.[93] Under water shortage, most expansin genes decreased expression during berry development, as observed by Grimplet et al.[37] Studies in postharvest Corvina withering berries, which can be considered as a water stress condition,[35] demonstrated the alteration in expression of several expansin genes, namely the downregulation of *VvEXPA1*, *VvEXPA14*, and *VvEXPA19* during withering. Some authors propose that expansins are associated with pectin turnover, probably by regulating the contact between pectins and pectin-degrading enzymes.[84] Brummell et al.[94] suggest the relation between different networks: the disassembly of the hemicellulosic network by expansin may be necessary for modifications in the pectins promoting physical accessibility of pectin substrates to PGs enzymes. From our results, it is possible to forward the hypothesis that water depletion has an indirect impact on pectins through the process proposed by Brummell et al.[94]

In summary, the overall results suggest differences in pectin metabolism between varieties in response to distinct water availability during growth under field conditions and support its involvement in distinct responses to environmental conditions. Water shortage affects grape berries by stiffening the CW, probably through alteration in PGs expression and pectin structure, in a way that significantly depends on the variety. Contrasting softening behaviors during ripening differs sufficiently between genotypes to allow discrimination regarding technological differences that can influence oenological practices.

J. Agric. Food Chem. 2015, 63, 3951−3961

used it as control because it underwent the same transformation steps as the PGIP plants. Neither PGIP nor NS plants show any significant difference in morphology and growth from the untransformed plants[11] (*T. aestivum* cv. Bobwhite).

Infection Experiments. Wheat seeds were surface-sterilized with sodium hypochlorite (0.5% v/v) for 20 min and then rinsed thoroughly in sterile water. Plants were grown in single pots at 18−23 °C, with a 14 h light/10 h dark photoperiod (300 μE m^{-2} s^{-1}).

At least 12 plants of each genotype (PGIP and NS plants) were subjected to five different infection experiments (corresponding to five biological replicates, hereafter named Fg-I−Fg-V) with *F. graminearum* using a point inoculation method. A 20 μL conidial suspension (5×10^4 conidia mL^{-1}) supplemented with 0.1% Tween-20 was pipetted directly through the glumes of two opposite central spikelets of a primary spike of flowering wheat plants (Zadoks stage 68). Infected spikes were covered with plastic bags for 2 days to maintain high humidity. Disease symptoms were assessed by counting the number of visually diseased spikelets over the following 18 days and by relating the diseased spikelets to the total number of spikelets of the respective head. These data were expressed as a percentage of symptomatic spikelets.

All seeds from the primary infected spikes of PGIP and NS plants and those from secondary mock-infected culms from each experiment were collected, and each group was pooled to obtain whole-grain flour corresponding to the four groups taken into consideration: PGIP seeds infected (PGIP-I) and not infected (PGIP-NI) and NS seeds infected (NS-I) and not infected (NS-NI).

Parameters Related to Yield, Fungal Biomass, DON Content, and Total Starch. Thousand kernel weight (TKW) was used as a yield indicator, along with kernel yield per spike (KYPS) and the number of kernels per spike (NKPS).

All mature kernels of each PGIP and NS plant obtained from each experiment were pooled to make whole wheat flour and used in the subsequent analyses.

Quantification of fungal biomass was performed by qPCR assay for the *Tri6* gene with the primers Tri6_10F and Tri6_4R.[12,13] Briefly, total DNA from whole flour was extracted with DNeasy plant mini kit (Qiagen) according to the manufacturer's instructions. qPCR experiments were performed using the iCycler (Bio-Rad Laboratories) and the master mix iQSYBR Green Supermix (Bio-Rad Laboratories) containing the fluorogenic SYBER Green I DNA binding dye. The actin wheat gene (accession no. AB181991) was used as housekeeping gene for the quantification of plant DNA, extracted from flour. The specificity of the primers was verified by nucleotide sequence of the amplicon.

DON was determined by immune-affinity cleanup and reverse phase HPLC. Briefly, 0.2 g aliquots of finely ground sample was extracted by shaking with 5 mL of 5% (w/v) solution of polyethylene glycol 8000/water for 30 min in the dark. Extracts were filtered by using Whatman no. 1 (Whatman International Ltd., Maidstone, UK) paper filters. A further filtration step was performed with glass fiber filters (VICAM, Watertown, MA, USA). For each sample, 250 μL of the filtrate was eluted in a DONtest (VICAM) immune-affinity column according to the manufacturer's instructions. DON was then eluted with 1.5 mL of HPLC grade methanol (Sigma-Aldrich, Milan, Italy) and collected in a 2 mL microcentrifuge tube. The solvent was evaporated under a gentle nitrogen stream at 40 °C in the dark; the dry residue was then recovered with 500 μL of mobile phase and transferred to an autosampler vial. The HPLC analysis was performed using a SpectraSystem (Thermo Separation Product, Riviera Beach, FL, USA) equipped with a reverse-phase column (Discovery C_{18} 4.6 mm i.d., 150 mm, 5 μm; Supelco, Bellefonte, PA, USA). Samples and standards were injected (100 μL) in duplicate, and the isocratic elution was performed at 30 °C. An acetonitrile/water (10:90) mixture pumped at 0.8 mL/min was used as mobile phase. DON was detected using a SpectraSystem UV6000 diode array detector (Thermo Separation Product) set at 218 nm. In those conditions, DON eluted at 6.1 ± 0.1 min. The area peak integration and data analyses were performed using the ChromQuestTM 3.0 software package (Thermo-Quest Inc., San Jose, CA, USA). The content of DON, expressed as micrograms per gram, was calculated by performing multiple six-point calibrations in the range of 0.016−1.024 ng/mL ($R^2 \geq 0.996$) using a commercial standard (Sigma-Aldrich) preliminarily diluted in HPLC grade acetonitrile. To check the accuracy of the method, recovery experiments were performed by analyzing spiked control flour ($n = 5$; from 0.1 to 2.5 μg DON/kg) as described above. Mean recovery of 91.1% was obtained. According to the 32645 Norma of the German institute for standardization,[14] the limit of detection (LOD) was estimated to be 0.017 μg DON/g.

Total starch content was determined using a Total Starch Amyloglucosidase/α-Amylase Assay Kit (Megazyme International Ireland Ltd., Bray, Ireland).

Gluten Proteins Analysis. Electrophoretic patterns of gliadins and glutenin subunits were analyzed by performing three technical replicates for each of the five biological replicates of the four groups: PGIP-I, PGIP-NI, NS-I, NS-NI.

Gliadins were extracted from whole-grain flour by keeping samples for 2 h at room temperature with a buffer containing 10% (v/v) dimethylformamide in a 1:10 (mg:μL) ratio. After centrifugation at 13000 rpm for 10 min, aliquots (5.5 μL) of the supernatants were loaded on acid PAGE (aluminum lactate buffer, pH 3.2), as reported in Khan et al.,[15] with minor modifications.

With regard to glutenin subunits, they were extracted from the pellets remaining after the previous gliadin extraction, by using 80 mM Tris-HCl, pH 8.5, 50%, 1-propanol, and 1% DTT, in a ratio of 1:5 (mg:μL), for 30 min at 65 °C. After a centrifuge step as above-described, the supernatants were alkylated with 1.4% (v/v) 4-vinylpirydine for 30 min at 65 °C. The proteins were successively precipitated overnight in 1 mL of cold acetone and centrifuged as above. The dried protein pellets were dissolved in a buffer containing 70 mM Tris-HCl, pH 6.8, 2% SDS, 10% glycerol, 0.02% pyronine Y, and 1% DTT, with the same volume used for extraction, centrifuged as above, and aliquots (5 μL) of the supernatant were separated by SDS-PAGE. The main gel was *T* (acrylamide concentration) 12, *C* (cross-linking concentration) 1.28, and the stacking gel was *T* 3.67, *C* 2.68. An SE 600 apparatus (Hoefer) was used. Run was performed at 30 mA per gel at 10 °C. The electrophoresis was stopped 45 min after the tracking dye reached the bottom of the gel. All of the gels were stained with Coomassie BBR 250 (Sigma). Densitometric analyses of total gliadins and of HMW-GS and of B-type LMW-GS were performed with the image software 1D (Kodak).

Total gluten proteins, replicated three times for each sample, were extracted from whole grain flour with 80 mM Tris-HCl, pH 8.5, in 50% 1-propanol and 1% DTT, in 1:20 (mg:μL) ratio for 30 min at 65 °C. After centrifugation at 13000 rpm for 10 min, supernatants were recovered, and with 1.4% 4-vinylpyridine was added for 30 min at 65 °C. The proteins were precipitated and dissolved as described above. Three aliquots of each extracted sample (5.0, 5.5, and 6 μL) were loaded to verify the appropriate loading amount, thus avoiding possible saturation problems. Separation was performed by SDS-PAGE as described above. Three independent SDS-PAGE experiments were run for each biological replicate. Densitometric analyses of HMW-GS (subunits A), LMW-GS (subunits B), and gliadins and gliadin-like LMW-GS (subunits C) were performed with image software Labimage (Kapelan Bio-Imaging, Germany). Outliers falling beside the range of linearity were excluded from the densitometric analysis. The ratios A/B and A/B + C were calculated, as well as the comparison among the sums A + B + C in the different samples.

Metabolic Proteins Analysis. Metabolic seed proteins were extracted according to the method of Hurkman et al.[16] Briefly, flour (150 mg) was suspended in 600 μL of cold KCl buffer (50 mM Tris-HCl, 100 mM KCl, 5 mM EDTA, pH 7.8). The suspension was incubated on ice for 5 min with intermittent mixing and centrifuged (14500*g*, 15 min, 4 °C). The KCl-soluble fraction was collected, and 5 volumes (v/v) of cold 0.1 M ammonium acetate in methanol were added. Following incubation overnight at −20 °C, the methanol-insoluble fraction was pelleted by centrifugation as above. The pellet (containing metabolic proteins) was rinsed with cold acetone, dried, and stored at −20 °C until further use. The 2-D quant Kit Assay (GE Healthcare) was used to have an accurate estimation of protein

DOI: 10.1021/jf506003t
J. Agric. Food Chem. 2015, 63, 3962−3969

amounts. The quality of extracted proteins was checked by SDS-PAGE and classical Coomassie staining,[17] as reported in Laino.[18]

DIGE was initially performed by the classical three-dye scheme, according to the procedure reported in Di Carli et al.,[19] and then we confirmed these data by applying a two-dye scheme, which leads to less noise in the protein analyses, which results in more reproducible results than the three-dye system.[20] In this latter case, metabolic proteins were dissolved in 500 μL of lysis buffer (8 M urea, 10 mM Tris-HCl, 5 mM magnesium acetate, pH 8.8), and the impurities were removed using a 2-D Clean-Up kit (GE Healthcare) following the manufacturer's procedures. Samples were eventually solubilized again in lysis buffer to a final protein concentration between 5.5 and 7.0 mg/mL. Samples were labeled using the fluorescent cyanine dyes developed for DIGE (GE Healthcare) following the manufacturer's recommended protocols. Fifty micrograms of protein was labeled with 400 pmol of amine reactive cyanine dyes, freshly dissolved in anhydrous dimethylformamide. The labeling reaction was incubated on ice in the dark for 30 min, and the reaction was terminated by the addition of 10 nmol of lysine. Equal volumes of 2× sample buffer (7 M urea, 2 M thiourea, 4% CHAPS, 20 mg/mL DTT, and 2% Pharmalytes IPG 3−10NL) were added to each of the labeled protein samples, and the two samples were mixed. Rehydration buffer (7 M urea, 2 M thiourea, 4% CHAPS, 2 mg/mL DTT, and 1% Pharmalytes IPG 3−10 NL) was added to make up the volume to 450 μL prior to IEF.

Nonlinear IPG strips (24 cm long), pH 3−10 (GE Healthcare), were rehydrated with CyDye-labeled samples for 12 h at 20 °C (room temperature). IEF was performed in a IPGphor II apparatus (GE Healthcare) for a total of 92 kVh (200 V for 8 h, 300 V for 3 h, 3500 V 30 min in gradient, 3500 V 3.5 h in gradient, 8000 V 2.30 h in gradient, 8000 V 8 h) at 20 °C. Prior to SDS-PAGE, the strips were equilibrated first for 15 min in 100 mM Tris, pH 6.8, 30% glycerol, 8 M urea, 1% SDS, 1% DTT, and 0.2 mg/mL bromophenol blue and then for a further 10 min in 100 mM Tris, pH 6.8, 30% glycerol, 8 M urea, 1% SDS, 2.5% IAA, and 0.2 mg/mL bromophenol blue on a rocking table. The strips were loaded onto 24 cm 15% polyacrylamide gel, pH 8.8, with about 1 cm of stacker gel (5% polyacrylamide, pH 6.8). The strips were overlaid with 1% agarose in SDS running buffer containing 5 mg of bromophenol blue. The gels were run in an Ettan Twelve apparatus (GE Healthcare) at 5 W/gel for 15 min and then at 20 W/gel at 15 °C. A running buffer of 25 mM Tris, pH 8.3, 192 mM glycine, and 0.1% SDS was used.

Labeled proteins were visualized using a Typhoon 9410 imager (GE Healthcare). The Cy3 images were scanned using a 532 nm laser and a 580 nm band-pass (BP) 30 emission filter. Cy5 images were scanned using a 633 nm laser and a 670 nm BP30 emission filter. All gels were scanned at 100 μm resolution. The PMT was set to ensure a maximum pixel intensity between 50000 and 80000 pixels.

The experimental design was performed to have an appropriate biological variation analysis (BVA) with a total of 20 maps in which both the samples (labeled with Cy3) and the pool or internal standard (a mixture of equal amounts of metabolic protein extracts from each sample) labeled with Cy5 were represented.

Gel analyses were performed using the software DeCyder BVA V5.0 (GE Healthcare). Data were normalized within the software using a ratiometric approach, and a $\log_{10}$ transformation was used on the standardized abundance to stabilize variance. The estimated number of spots for each codetection was set to 2500. Student's t test (p) was calculated, along with the q value, the latter via a point-and-click tool provided by Storey and Tibshirani.[21] Principal component analysis (PCA) of the $\log_{10}$ standard abundance of the spots matched on the 80% of the maps was performed using soft independent modeling of class analogy (SIMCA-P, Umetrics).

The spots of interest were selected according to the following criteria: t test (p) <0.01, fold change >1.2, and spot appearance on at least 80% of the total maps.

The gel spots were excided manually from two preparative silver-stained gels and identified by LC-ESI-ORBITRAP. In-gel reduction and alkylation were carried out using DTT and iodoacetamide, respectively.

Digestion with trypsin was performed according to the method of Coulthurst et al.[22] For LC-MS/MS experiments an Eksigent NanoLC-1D Plus (Eksigent Technologies, Dublin, CA, USA) an HPLC system coupled to an LTQ Orbitrap mass spectrometer (ThermoFisher, Waltham, MA, USA) was used. Separation of peptides was performed by reverse-phase chromatography employing a flow rate of 300 nL/min and an LC Packings (Dionex, Sunnyvale, CA, USA) PepMap 100 column (C_{18}, 75 μm i.d. × 150 mm, 3 μm particle size). Peptides were loaded onto a precolumn (Dionex Acclaim PepMap 100 C18, 5 μm particle size, 100A, 300 μm i.d. × 5 mm) with 0.1% formic acid for 5 min at a flow rate of 10 μL/min.

After elution of peptides from the precolumn onto the analytical column, an elution gradient of 5−50% B in 50 min was employed, where solvent A was 0.1% formic acid in water and solvent B was 0.1% formic acid in acetonitrile. The LC eluant was sprayed into the mass spectrometer by means of a New Objective nanospray source. All m/z values of eluting ions were measured in the Orbitrap mass analyzer, set at a resolution of 7500. Peptide ions with charge status of 2+ and 3+ were then isolated and fragmented in the LTQ linear ion trap by collision-induced dissociation, and MS/MS spectra were acquired. Postrun, the data were processed using Bioworks Browser (version 3.3.1 SP1, ThermoFisher). Briefly, all MS/MS data were converted to dta (text) files using the Sequest Batch Search tool (within Bioworks). The data files were converted to a single mgf file using a SSH script in the SSH Secure Shell Client program (version 3.2.9 Build 283, SSH Communications Corp.). These combined files were then submitted to the Mascot search algorithm (Matrix Science, London, UK) and searched against the NCBI-nr database (all entries, *Viridiplantae*, and human database), using a fixed modification of carbamidomethyl and a variable modification of oxidation (M).

RESULTS AND DISCUSSION

FHB Symptoms on Transgenic and Control Plants. Five independent infection tests were performed by using conidia of *F. graminearum*. FHB disease symptoms usually appeared 3 days post infection (dpi), and the spread of the disease was visually examined for 18 dpi. PGIP plants showed a significant reduction of FHB symptoms compared to control NS plants. In particular, at 18 dpi the average reduction of FHB symptoms in the five experiments was about 35% compared to control plants (Figure 1). Data relative to each experiment are reported in the Supporting Information (nr. 1).

One of the above experiments included also the untransformed cv. Bobwhite. At 18 dpi, statistical analysis revealed that the differences observed between NS-I and the untransformed cv. Bobwhite were not significant, whereas they

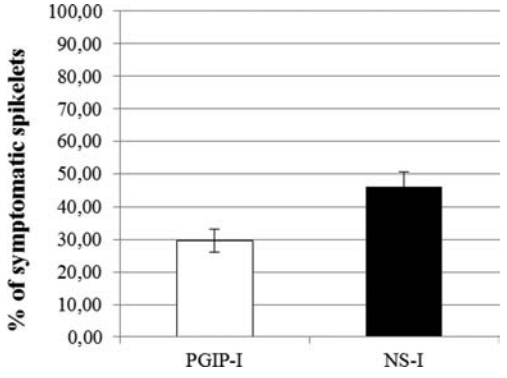

Figure 1. Evaluation of the spread of FHB symptoms in PGIP-I and NS-I plants relative to the five experiments, obtained by combining data collected at 18 dpi. Disease symptoms were evaluated as a percentage of visually diseased spikelets over the total number of spikelets.

DOI: 10.1021/jf506003t
J. Agric. Food Chem. 2015, 63, 3962−3969

were significant between PGIP-I and both NS-I and the untransformed cv. Bobwhite (data not shown).

Parameters Related to Yield. It is noteworthy that seed yield is strongly affected by *F. graminearum* infection. For this reason, we evaluated this aspect by analyzing kernels obtained from PGIP plants and NS plants, both infected and mock-inoculated (not infected). The parameters taken into consideration were the number of kernels per spike (NKPS), the kernel yield per spike (KYPS), and the thousand kernel weight (TKW). PGIP plants and NS plants, both infected and not infected, were not significantly different in regard to NKPS (Figure 2a). KYPS and TKW were significantly different only between infected and not infected NS plants (NS-I vs NS-NI), being higher in NS-NI plants (Figure 2b,c).

These data indicate that constitutive expression of PvPGIP2 in PGIP plants does not have any detrimental effect on parameters related to seed yield; conversely, their higher tolerance to *F. graminearum* infection has a positive effect on grain productivity.

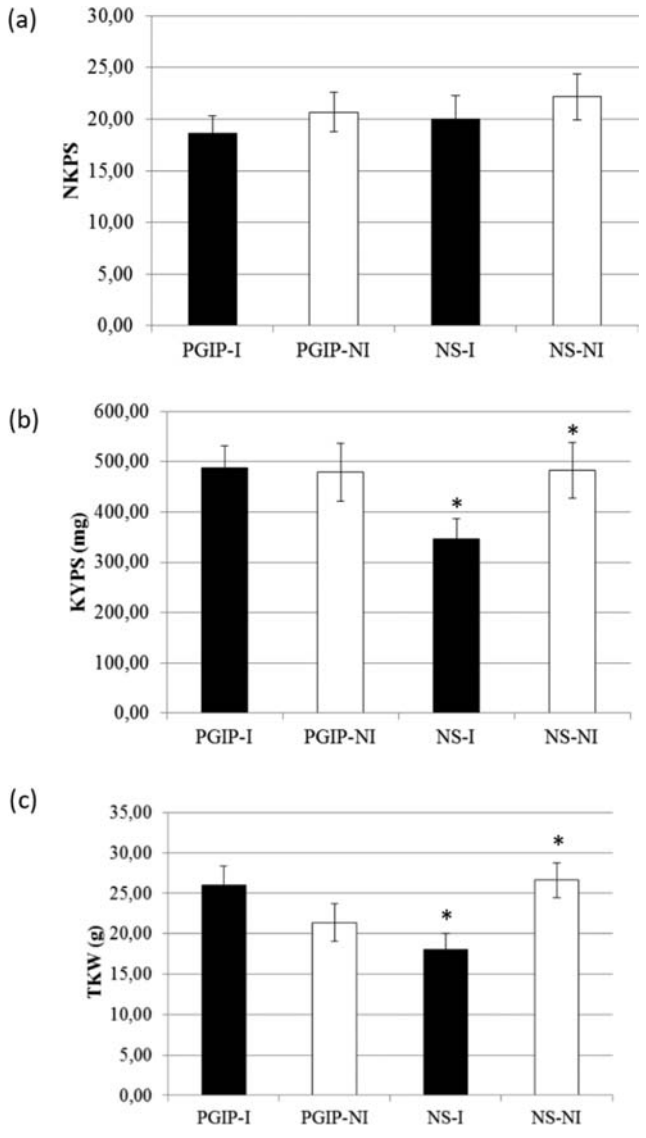

Figure 2. Parameters related to yield (a) NKPS, number of kernels per spike; (b) KYPS, kernel yield per spike (mg); and (c) TKW, thousand kernel weight (g). Data represent means ± standard error of five experiments. (*) In (b) and (c) the difference between NS-I and NS-NI plants is significantly different ($P \leq 0.01$).

Fungal Biomass, DON Content, and Total Starch Content. To verify whether the reduced FHB symptoms of the PGIP plants were associated with a reduced accumulation of fungal biomass in the caryopses of PGIP plants, we performed qPCR analyses with primers specific for the fungal *Tri6* gene,[11] on total DNA extracted from whole-grain flour. Because of limited material, these analyses were performed only on the biological replicates Fg-III and Fg-IV. The results revealed about 4-fold reduced fungal biomass in the flour of infected PGIP-I plants (average value = 0.245 ± 0.007) compared to the flour of infected control NS-I plants (Figure 3a).

The whole-grain flours of experiments Fg-III and Fg-IV were also used to evaluate the content of DON. Similarly to what was observed for the other parameters analyzed, DON accumulation was significantly lower ($p < 0.01$) in the whole-grain flour from PGIP plants as compared to that from NS plants. The results from both experiments showed about 57% reduction of DON content in the flour from infected PGIP-I plants (average = 23 μg/g ± 3.8) compared to the flour from infected control plants (NS-I) (average value = 54 μg/g ± 7.7) (Figure 3b).

Flour from experiments Fg-III and Fg-IV was also used to evaluate the total starch content. These analyses showed a significant difference ($p < 0.05$) between NS-NI and NS-I plants, with the latter sample showing a reduced total starch content. Similarly, a significant difference ($p < 0.05$) was observed between PGIP-I and NS-I plants, with the PGIP-I showing a higher total starch content. No significant difference was observed between NS-NI and PGIP-NI plants or between PGIP-NI and PGIP-I plants (Figure 3c).

Gluten Protein Analysis. Because gluten proteins are the main determinants of dough rheological properties, we verified whether FHB caused an altered pattern of protein accumulation in mature kernels.

Initially we analyzed separated protein fractions to detect better the possible differences in protein accumulation; however, densitometric analyses of gliadin and glutenin patterns did not show any significant difference between the four groups of samples (by comparison of either total amounts or the ratios among protein classes, Supporting Information (nr. 2)). Thus, we decided to analyze also total gluten proteins to avoid possible problems due to the fractionation procedures. In this latter case, only two biological replicates (Fg-III and Fg-IV) were used. Neither of these analyses revealed any significant difference among the four groups of samples by comparing total protein amounts and the ratios among the different protein classes (Supporting Information (nr. 3)).

Metabolic Protein Analysis. A first DIGE experiment was performed according to a three-dye scheme to investigate major protein changes involved during infection with *F. graminearum*. This analysis detected about 2000 protein spots, and any significant differential proteins resulted by considering the false discovery rate (FDR) adjustment of the probability value (data not shown). Thus, a second DIGE experiment based on a two-dye approach was carried out to reduce the higher noise typical of the three-dye approach. The results here reported are those relative to this latter approach.

A total of about 2000 protein spots were detected in this case also (Figure 4). The normalized volumes of the spots present in at least 80% of the total maps were used to perform PCA (Figure 5). The result did not discriminate any clusters among

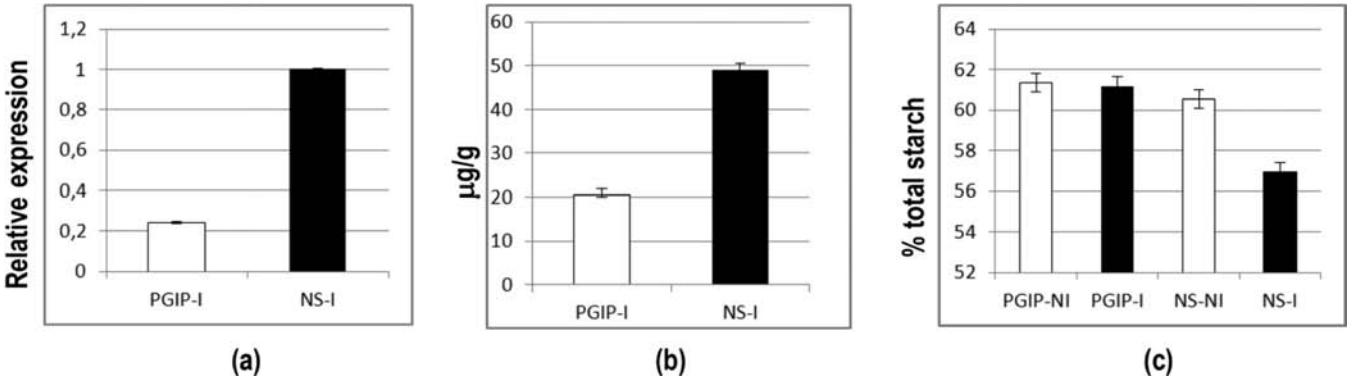

Figure 3. (a) Extent of pathogen contamination as assayed by qPCR; (b) DON content as assayed by RP-HPLC; (c) total starch content as assayed by a total starch amyloglucosidase/α-amylase assay.

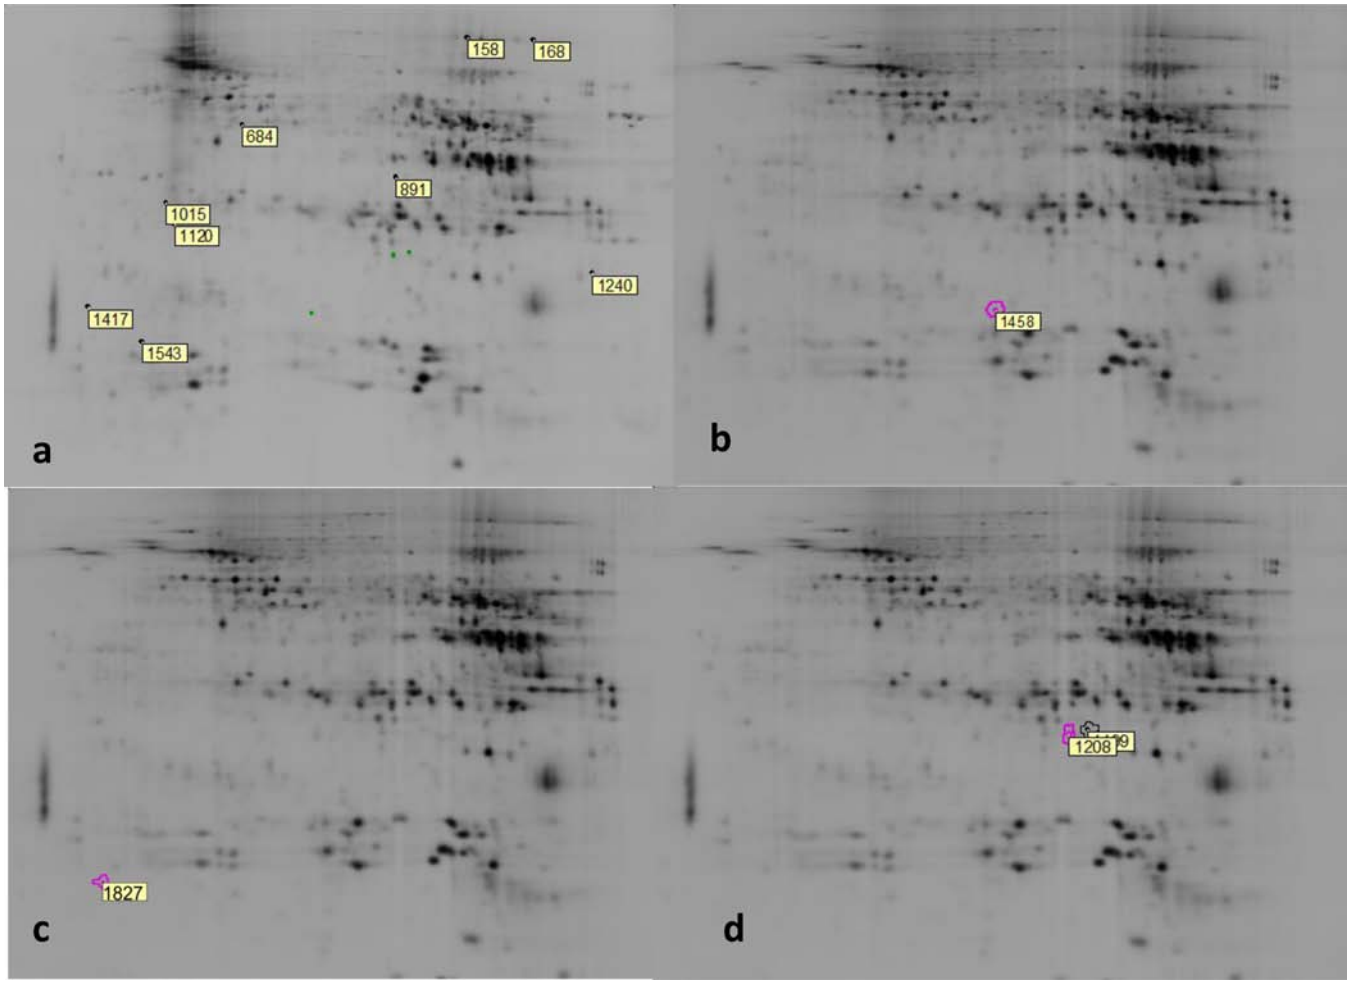

Figure 4. Spots identified as differentially accumulated by comparing NS-NI versus NS-I (a), NS-NI versus PGIP-NI (b), PGIP-NI versus PGIP-I (c), and NS-I versus PGIP-I (d). All of the differential spots represent minor polypeptides, because they are very faint.

the four groups (PGIP-I, PGIP-NI, NS-I, NS-NI), thus showing that they were not clearly differentiated at the protein accumulation level.

The biological variation analysis (BVA) revealed nine spots differentially accumulated in the comparison between NS-NI and NS-I (Figure 4a), one spot in each of the comparisons between NS-NI and PGIP-NI (Figure 4b) and between PGIP-NI and PGIP-I (Figure 4c), and two spots between NS-I and PGIP-I (Figure 4d; Table 1). All of these spots were very faint. The q values calculated for all of the spots were higher than the threshold of confidence (0.05), thus indicating that these spots, considered to be significantly different on the basis of the t test, could be false-positive identifications. However, they were recovered from the gels, digested with trypsin, and submitted to MS-MS analysis, but none of them produced any significant protein identification.

In conclusion, similarly to our previous paper,[9] the present results showed that PGIP-I plants have a significant reduction

NS-I vs PGIP-I	1827	0.0041	1.98	0.8366167

[a]Although the *t* test for these spots is significant, the relative *q* values are higher than the threshold of confidence, indicating possible false identifications.

of FHB symptoms, which was also correlated to a reduced accumulation of fungal biomass in wheat kernels, in comparison to control plants. This reduction had positive consequences on mycotoxin accumulation, because DON content was significantly lower in flour obtained from PGIP-I plants. Moreover, the parameter TKW, indicative of yield, was higher in infected PGIP-I plants, with respect to infected control plants. This difference is probably due to the higher starch content observed in infected PGIP-I plants as compared to NS-I plants. Indeed, the PGIP-I plants did not show any significant difference with the PGIP-NI plants; instead, control plants (NS-I) showed a significant reduction of total starch content. This finding is in agreement with previous studies[23,24] and probably is a consequence of damage to starch granules caused by fungal amylolytic enzymes, although endosperm damage can be quite variable.[25−27]

Interestingly, no significant difference was observed in protein accumulation in PGIP plants, both infected and not infected, in comparison with control plants, with regard to gluten proteins (measured as total gluten proteins and as purified gliadin and glutenin subunits fractions) and metabolic proteins. The latter were analyzed in more detail because this protein fraction is known to contain many allergenic polypeptides, which are usually induced after fungal infection and other stresses.[28]

This result is in agreement with Chetouhi et al.,[29] who made a proteomic survey of the bread wheat susceptible cultivar Recital after *F. graminearum* infection. These authors have taken into consideration three different stages after infection (3 dpi, corresponding to the cell division stage; 7 dpi, corresponding to cell differentiation stage; and 14 dpi, corresponding to grain-filling stage). They measured *F. graminearum* infection by using a RT-PCR approach and evaluated mycotoxin accumulation by measuring the activity of the *FgTrI5* gene (coding for trichodiene synthase, related to mycotoxins biosynthesis). Similarly to what was found in the

DOI: 10.1021/jf506003t
J. Agric. Food Chem. 2015, 63, 3962−3969

present work, they failed to identify any pathogen protein in their proteomic comparison, likely because their amount was not enough to be detected, although the pathogen presence was confirmed by the RT-PCR analysis, and observed that the grain protein pattern was not greatly affected by *F. graminearum* infection, in particular at the latest stage in which they mostly identified a down-regulation of some proteins involved in starch biosynthesis and up-regulation of a protein involved in starch degradation. Similar conclusions were made by Eggert et al.,[30] who, by analyzing the proteome of *Fusarium* infected emmers grown in the field in two different locations, identified only 10 polypeptides differentially accumulated, with a large variation due to the different environments. We made the proteomic comparison on mature dry kernels of a different wheat cultivar, but we also found that the wheat kernel proteome pattern is not severely affected by *F. graminearum* infection.

Taken all together, these results indicate that the expression of PGIP in wheat transgenic plants showing partially bleached spikes after infection with *F. graminearum* decreases the level of infection, as expected, and contributes to prevent yield and starch decreases and to reduce DON accumulation. Moreover, the wheat seed proteome, in both infected and not infected kernels, is not significantly altered by the transgenic PGIP expression.

min^{-1} in octyl/decyl glycerate.[21] In real matrix, Goula et al. found 0.0012 min^{-1} in tomato pulp at 90 °C[22] and Sharma et al. found 0.0048 min^{-1} in watermelon at the same temperature.[23] Colle et al. found a much higher degradation rate constant at 100 °C (0.095 min^{-1}), but in a formulated tomato and oil emulsion.[24] Activation energies found in model systems were 61 kJ mol^{-1} and 77 kJ mol^{-1}.[21] In real matrix, lycopene activation energies were 19.5 and 26.4 kJ mol^{-1} in tomato and watermelon, respectively.[22,23] Colle et al. found an activation energy of 28 kJ mol^{-1} in tomato pulp/olive oil emulsion. These results show that the kinetic parameters of lycopene degradation are also significantly different as a function of the food system, which could be due to the strong influence of the chemical environment and the inclusion of carotenes in complex structures. To overcome this matrix effect, some authors finally proposed to formulate a juicelike system with controlled composition, but which could be complexified progressively to gain greater insight into the effect of the chemical and structural environment and obtain better accuracy in the kinetic parameters. Zepka et al. designed a cashew apple juice model based on a water and ethanol mixture.[25] A more recent study by Hadjal et al.[34] assessed the degradation kinetics of xanthophylls from blood orange in both real and model matrices. They showed that the degradation rates were the lowest in real juice in comparison to the juicelike model. These authors suggested that phytochemical compounds of juice were able to protect xanthophylls, especially at high temperatures.

Kinetic uniresponse models mentioned above are commonly used because they are robust and useful to predict nutrient loss. Kinetic modeling studies of both carotenoid degradation (oxidation and cleavage) and production of neoformed compounds such as isomers are more limited. This approach implies the use of a more sophisticated kinetic model or mathematical tools such as multiresponse modeling.[26−28] However, knowledge of degradation and production rates could be of great interest to predict nutrient loss as well as neoformed compound production. Indeed, products generated during carotenoid degradation may have positive or negative biological activity. In addition, the knowledge of the impact of temperature on kinetic constants may help technologists improve thermal processes such as pasteurization. In addition to the prediction advantages, this approach could provide insight into the degradation reaction scheme. In particular, the use of multiresponse modeling was used to enhance the comprehension of β-carotene degradation in oils[27] or in orange-fleshed sweet potato.[28] The principle of such an approach is to enable the simultaneous study of analytical and literature results so as to be able to draw up possible observable degradation schemes that could be expressed mathematically. The most probable hypothesis can be chosen by discrimination of the best kinetic model: i.e., the model which presents the closest fit to the experimental data.

Consequently, the objectives of this study were to assess the degradation and isomerization kinetics of lycopene and β-carotene from pink grapefruit during heating, both in their natural matrix (juice) and in three different model systems (buffered water/ethanol basis) without or with the addition of ascorbic acid or naringin to simulate major antioxidant phytochemical compounds of pink grapefruit juice.[1] Moreover, multiresponse modeling has been applied to model simultaneous lycopene/β-carotene loss and isomerization during thermal treatment.

MATERIALS AND METHODS

Grapefruit Juice. South American pink grapefruits (*Citrus paradisi* Macf) purchased in a market were cut in half and squeezed using a domestic juicer (Moulinex Masterchef 470, France). The juice was then filtered through a stainless steel sieve (1 mm). The freshly pressed juice was placed in amber glass bottles under nitrogen and stored at −20 °C until analysis or heat treatment.

Preparation of Juicelike Model Systems. Juicelike model systems were formulated with grapefruit juice carotenoid extract to carry out a degradation test in controlled medium. This extract was formulated with three media, acidified aqueous medium (AM) and acidified aqueous medium supplemented with ascorbic acid (AM+AA) or naringin (AM+NAR); these latter supplements are major citrus juice phytochemicals that could have a protective effect.

Preparation of Carotenoid Extract. The first carotenoid extraction step was performed according to Dhuique-Mayer et al. by blending 80 g of grapefruit juice with an ethanol/hexane mixture (4/3, v/v, 0.1% BHT). The hexane fractions were collected, pooled, and evaporated for 15 min at 20 °C (GeneVac EZ-2 compatible, Suffolk, U.K.). The carotenoid extracts obtained were used to formulate the three model systems.[29]

Formulation of Model Systems. The model system was inspired from that of Zepka et al.[25] It first involved solubilization of carotenoid extracts in ethanol. A pH 3 citrate buffer mixture was added at an ethanol/buffer ratio of 25/75 (v/v). This was called the acid medium (AM). The resulting model system was a very homogeneous and stable cloudy liquid, even at high temperature. This mixture was assumed to be a spontaneous microemulsion, which is typically obtained when mixing hydrophobic molecules dissolved in ethanol with water. For AM+AA medium, the ethanolic carotenoid extract was mixed with citrate buffer supplemented with ascorbic acid in the same proportion (25/75, v/v). For AM+NAR medium, naringin was first dissolved in ethanol and mixed with 75% (v/v) citrate buffer. The amount of naringin and ascorbic acid added were calculated to obtain a content equivalent to that reported in the literature for pink grapefruit juice (300 mg L^{-1} for naringin and 400 mg L^{-1} for ascorbic acid).[1]

Heat Treatment. The kinetics of carotene thermal degradation were assessed at four temperatures: i.e. 60, 75, 90, and 95 °C. These temperatures cover the pasteurization treatment range involving low to high temperature (flash) treatments. For each temperature, 2 mL of grapefruit juice or model medium was heated in sealed 10 mL Pyrex tubes. The tubes were immersed in an oil bath with temperature control (Memmert, Legallais, France). A digital temperature probe (EKT 3001, Heidolph, Germany) fitted to a reference tube was used to measure the medium temperature during the thermal experiments. Five sampling points were selected from 5 to 300 min according to the temperature. Three replicates were done for each temperature. The time for juice to reach the set temperature was less than 4 min, and the cooling time was about 1 min in an ice/water bath. The thermal transient could thus be neglected, and the treatment could be considered isothermal. Each tube was stored under nitrogen at −20 °C until analysis.

HPLC Analysis of Carotenoids. *Sample Preparation.* A 2 mL sample of grapefruit juice was extracted with the ethanol/hexane mixture (4/3, v/v). A 20 μL portion of internal standard (apocarotenal) was added in order to estimate carotene losses during the manipulations. The mixture was shaken for 30 s and centrifuged for 7 min at 2400*g*. Four extractions were performed with 2 mL of hexane. The hexane fractions were pooled and then evaporated for 15 min (GeneVac EZ-2 compatible, Suffolk, U.K.). In the case of model systems (AM+AA and AM+NAR), 2 mL was extracted three times with 1 mL of hexane and the pooled hexane fraction was evaporated using the same procedure. All final extracts were solubilized in 500 μL of MTBE/methanol/dichloromethane (40/10/50, v/v/v) before HPLC injection.

HPLC Analysis. Carotenoids were analyzed by reverse-phase HPLC using an Agilent1100 system (Massy, France) according to Dhuique-Mayer et al.[14] The carotenoids were separated using a C30 column (250 mm × 4.6 mm, 5 μm YMC) (Europ GmbH, Germany), and the

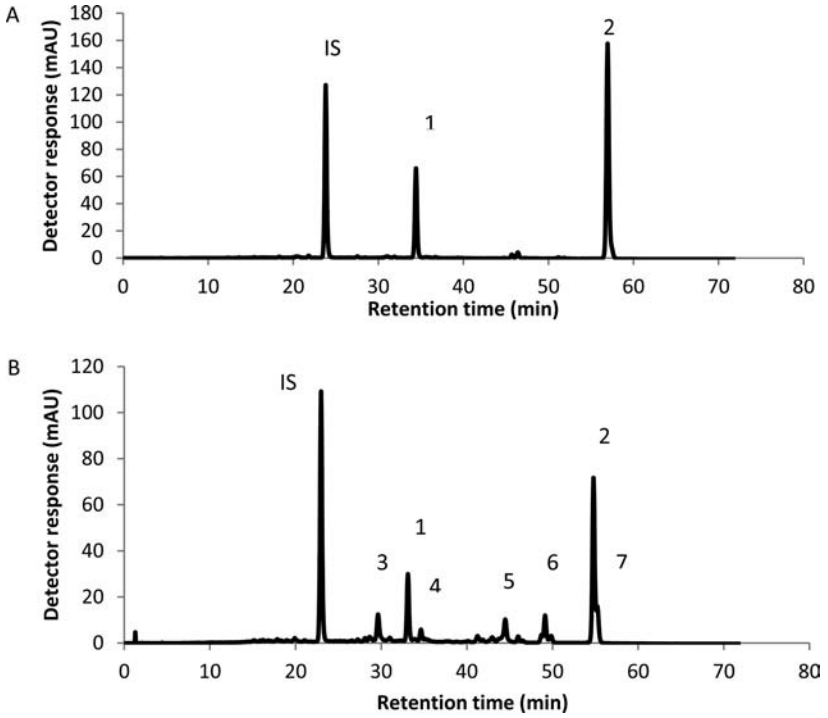

Figure 1. HPLC chromatogram: (A) fresh pink grapefruit juice, peaks 1 (β-carotene) and 2 (lycopene); (B) grapefruit juice heated for 5 h at 95 °C, peaks 3 and 4 (β-carotene isomers) and peaks 5−7 (lycopene isomers).

mobile phase was H_2O as eluent A, methanol as eluent B, and methyl *tert*-butyl ether as eluent C. The flow rate was set at 1 mL min^{-1}, the column was cooled to 15 °C, and the injection volume was 20 μL. A solvent gradient was programmed as follows: initial conditions, 40% A/60% B; 0−7 min, 20% A/80% B; 7−10 min, 4% A/81% B/15% C; 10−60 min, 4% A/11% B/85% C; 60−71 min, 100% B; 71−72 min, return to the initial conditions for rebalancing. β-Carotene and lycopene and their isomers were detected at 450 and 470 nm, respectively, using an Agilent photodiode array detector. Obvious carotenes were quantified on the basis of their calibration curve at the same wavelengths.

Determination of Ascorbic Acid in Real Juice and a Model System. Ascorbic acid was determined by HPLC according to Dhuique-Mayer et al.[29] Grapefruit juice or model juice (2 mL) was homogenized with 4 mL of a 4.5% metaphosphoric acid solution. Extractions were carried out in triplicate. After centrifugation, the supernatant was filtered through a 0.45 μm membrane and analyzed by HPLC using an Agilent Model 1100 system equipped with an RP 18e Licrospher 100 (5 μm) column (250 mm × 4.6 mm i.d.) (Merck KgaA, Darmstadt, Germany). The isocratic solvent system was a 0.01% solution of H_2SO_4, the flow rate was 1 mL min^{-1}, and detection was set at 245 nm. Ascorbic acid was quantified by the external standard method.

Determination of Naringin in Real Juice and a Model System. Naringin was determined by HPLC according to Dhuique-Mayer et al.[29] Briefly, 5 mL of juice was homogenized with 10 mL of dimethylformamide and 10 mL of ammonium oxalate (0.05 M). Then the mixture was heated for 10 min at 90 °C. After the mixture was cooled, the volume was completed with distilled water to 50 mL and centrifuged (1000*g*, 3 min) and the supernatant was filtered (0.45 μm). The HPLC analysis was carried out with an Agilent Model 1100 system (Massy, France) using an RP 18e Licrospher 100 (5 μm) column (250 mm × 4.6 mm i.d.) (Merck KgaA, Darmstadt, Germany). The isocratic solvent system was water/acetonitrile/THF/acetic acid (80/16/3/1, v/v/v/v). Quantification was carried out at 280 nm. The flow rate was set at 1 mL min^{-1}. Naringin concentrations were determined using an external calibration method.

Numerical Analysis of Kinetic Data. *Carotene Degradation in Real Juice and Model Media.* Carotene changes over time can be described by eq 1

$$\frac{d[X]}{dt} = -k[X]^{\alpha} \quad (1)$$

where [X] represents the carotene mass concentration (kg m^{-3}), t the time (s), k the reaction rate constant ($kg^{(1-\alpha)}$ $m^{3(\alpha-1)}$ s^{-1}), and α the apparent reaction order.

The rate constants k were assumed to vary with the temperature according to the Arrhenius equation

$$k = k_{ref} \exp\left(\frac{-E_a}{R}\left(\frac{1}{T} - \frac{1}{T_{ref}}\right)\right) \quad (2)$$

where k_{ref} is the rate constant at the reference temperature chosen in the middle of the studied temperature range (80 °C), with E_a, T, and R respectively denoting the activation energy (J mol^{-1}), medium temperature (K), and gas constant (8.314 J mol^{-1} K^{-1}).

The reaction order was determined by incrementing α in eq 1. Kinetic constants and activation energies were identified by nonlinear least-squares regression using the Levenberg−Marquardt least-squares minimization procedure with Matlab software (Mathworks Inc., Natick, MS, USA).

Multiresponse Modeling of the Thermal Degradation of Carotenes in Real Juice and Model Media. Carotenes and their isomers were monitored during heat treatments. Carotenoids were subjected to degradation, which could lead to other molecules that were not monitored by HPLC and were therefore missing species. These missing products were evaluated by mass balance.

Observable reaction schemes were proposed on the basis of experimental observations and literature data. When a reaction scheme was established, it was translated into a system of differential equations and the kinetic parameters were optimized with the Levenberg−Marquardt algorithm using Matlab software (Mathworks Inc., Natick, MS, USA).

Model Discrimination. To discriminate the appropriate kinetic model under monoresponse (reaction order) or multiresponse (most

[a]Abbreviations: AM, citrate buffer/ethanol mixture; AM+AA, citrate buffer/ethanol mixture with added ascorbic acid; AM+NAR: citrate buffer/ethanol mixture with added naringin.

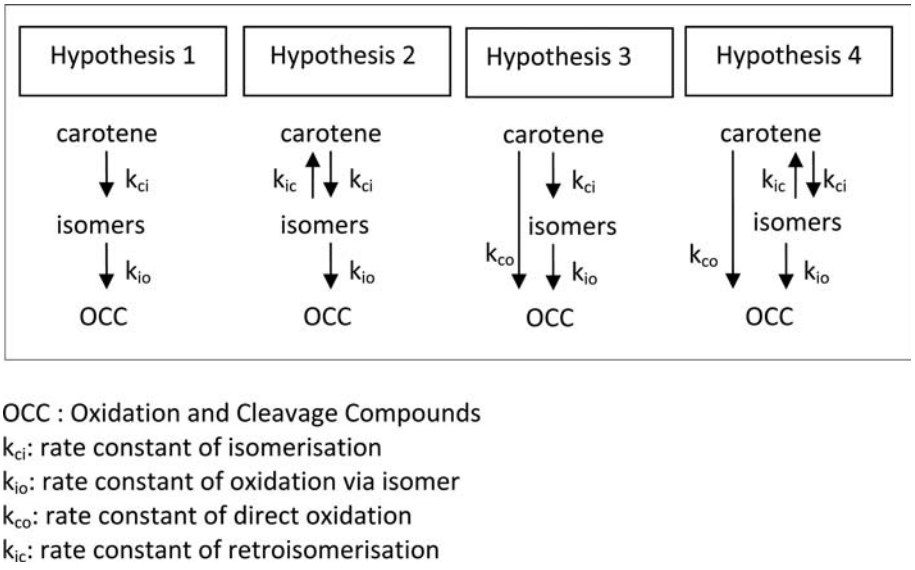

Figure 2. Presumed model of thermal degradation of lycopene and β-carotene (*all-trans*) and of their isomers in model systems.

probable reaction scheme) conditions, the residual sum of squares (RSS) was calculated according to eq 3

$$\mathrm{RSS} = \sum_{i=1}^{n} ([X_i] - [\hat{X}_i])^2 \tag{3}$$

where $[X_i]$ and $[\hat{X}_i]$ are respectively experimental and predicted concentrations of X and n is the number of experimental points. RSS measured the discrepancy between the experimental and simulated data. A small RSS indicated a suitable goodness of fit of the model to the data.

The coefficient of determination R^2 was calculated from the ratio of the explained variance to the total variance (TSS), with the explained variance being TSS minus RSS:

$$R^2 = \frac{\sum_{i=1}^{n} ([X_i] - [\bar{X}])^2 - \mathrm{RSS}}{\sum_{i=1}^{n} ([X_i] - [\bar{X}])^2}$$

where $[\bar{X}]$ is the mean concentration of X, and n is the number of experimental points.

For multiresponse models, RSS was also used to calculate the Akaike information criterion (AIC). AIC is a complementary measure of goodness of fit which was used by van Boekel[30] and which describes the tradeoff between the model accuracy (RSS) and complexity, i.e. the number of parameters (eq 4)

$$\mathrm{AIC} = n \ln\left(\frac{\mathrm{RSS}}{n}\right) + 2(p+1) \tag{4}$$

where n is the data number and p is the number of estimated parameters. AIC is an interesting criterion because it enables comparison of models having a different number of parameters. A small AIC indicates that the model presents a suitable goodness of fit to the experimental data while having a limited number of parameters.

Kinetic Parameter Uncertainty. The parameter uncertainty of the optimized parameters obtained with the Levenberg−Marquardt algorithm was calculated by nonlinear error propagation using Matlab software (Mathworks Inc., Natick, MS, USA).

RESULTS AND DISCUSSION

Identification of Carotenoids from Fresh and Heated Grapefruit Juice. The two major carotenoids found in fresh grapefruit juice (*Citrus paradisi* Macf) were *all-trans-β*-carotene and *all-trans*-lycopene, at 1.25 ± 0.14 and 5.78 ± 0.58 mg L^{-1}, respectively, with the latter representing 80% of both (Figure 1A). The order of magnitude of the ratio lycopene/*β*-carotene found was close to that of the three found by Xu et al. in red grapefruit.[6] In heated grapefruit juice, *β*-carotene and lycopene isomerization was observed (Figure 1B). Thermal treatment led to a significant increase in 13-*cis*-*β*- and 9-*cis*-*β*-carotene. Heating also increased lycopene isomers: i.e., three *cis* isomers were tentatively identified, namely 5-*cis*-, 9-*cis*- and 13-*cis*-lycopene, according to their *cis* peak intensity and maximal absorption wavelength.[18,19,31] For 13-*cis*-lycopene, the *cis* peak intensity, expressed as percent AB/AII, was higher in comparison to that of 9-*cis*-lycopene because the *cis* double bond is closer to the center of the molecule. A hypsochromic shift of 6 nm occurred when the *cis* compound was compared

to the *all-trans* compound, and this trend was similar to that reported in the literature.[24,27,31]

Carotene Degradation Kinetics in Real Juice and Model Media during Thermal Treatment. Kinetic models were drawn up on the basis of the analysis of experimental concentrations over the thermal treatment time for each carotene: i.e., β-carotene and lycopene. By incrementing α, the apparent order of the reaction in eq 1, and the calculation of the corresponding RSS (eq 3), second-order kinetics appeared to best fit the experimental data (minimal RSS). Most previously reported studies uses first-order kinetics to model carotene loss.[12] However, other orders have also been reported, especially in nonaqueous solvents.[32,33] Recently, Colle used a fractional conversion model to represent lycopene degradation in an olive oil/tomato emulsion. Indeed, they found that the carotene degradation pattern was that of an equilibrated reaction (nonzero plateau), which was also observed in real juice in our study.[31] However, a second-order kinetic model was preferred to compare all rate constants (in real juice and ethanol/water mixture).

The resulting rate constants and activation energies are presented in Table 1. All rate constants increased with temperature. The rate constants of β-carotene and lycopene were generally close. In similar matrices and under similar temperature conditions, their degradation rate was 2−10-fold lower than that of hydroxy-carotenoids (xanthophylls).[34] Therefore, carotenes are more stable because of the absence of hydroxyl groups. However, despite this structural similarity,

the rate constants of the two carotenes varied differently as a function of the matrix. For instance, in real juice, the β-carotene rate constants ($(8.83 \pm 1.03) \times 10^{-3}$ to $(5.14 \pm 2.17) \times 10^{-2}$ kg^{-1} m^3 s^{-1}) were 3−80-fold superior to the values obtained for lycopene, in accordance with the findings of Abushita et al., D'Evoli et al., and Chanforan et al. Indeed, they all found a greater stability of lycopene in comparison to β-carotene in a vegetable matrix during heat treatment (tomato). They explained this difference in behavior by the fact that lycopene was more stable when it was bound to protein inside the vegetable matrix. However, when lycopene was not protein-bound, they showed that this pigment was less stable than β-carotene.[18,35,36] This is interesting, because we also noted an inversion of stability when carotenes were not in their initial matrix. Indeed, in all acid media (AM, AM+AA, AM+NAR), the reaction rates of lycopene at 90 and 95 °C were 1.2−3.6-fold higher than those of β-carotene. β-carotene was also less stable out of its original matrix, but to a lesser extent. In comparison to real grapefruit juice, the lycopene rate constant increased from 1- to 14-fold as a function of the temperature in the acid medium (AM), while it increased from 1- to 2-fold for β-carotene.

The activation energy of 45 ± 10 kJ mol^{-1} for β-carotene in grapefruit juice was in accordance with that found by Colle et al. in tomato emulsion (45 kJ mol^{-1}) but lower than that reported by Dhuique-Mayer et al. in orange juice (110 kJ mol^{-1}).[14,24] The activation energy of lycopene was 26 ± 10 kJ mol^{-1} in real juice. Lycopene was thus more sensitive to an increase of temperature than β-carotene, with an activation energy close to that reported for tomato pulp and watermelon juice (19.5 and 26.4 kJ mol^{-1}).[22,23]

Very few studies have compared the activation energies of lycopene and β-carotene in the same vegetal matrix. Demiray et al. found activation energies of 47 and 40 kJ mol^{-1} for lycopene and β-carotene, respectively, in tomato quarters during drying.[37] Colle et al. found activation energies of 28 and 45 kJ mol^{-1} for lycopene and β-carotene, respectively, in tomato emulsion during thermal treatment, which is out of line with the findings of Demiray et al.[24,37] Activation energies should therefore be considered very carefully because they highly depend on the matrix and temperature field studied.[12]

When carotenes were out of their matrix (i.e., in AM), the activation energies did not substantially change for β-carotene but increased from 26 ± 10 to 89 ± 23 kJ mol^{-1} for lycopene. The marked increase in the activation energy of lycopene (70%) showed that this carotene was particularly vulnerable and sensitive to an increase of temperature on isolation from the matrix. Therefore, the juice matrix affected both the rate constants and activation energies and had a protective role for carotenes, and especially lycopene. This was also demonstrated for xanthophylls in a previous study.[34] This protective role could have structural (by covalent or weak bonds or different matter state) or chemical origins. This latter hypothesis was tested by the addition to the acid medium of ascorbic acid (AM +AA) or naringin (AM+NAR), which are major phytochemicals of citrus juice that could have a protective effect. With regard to the rate constants, the addition of ascorbic acid did not significantly change the degradation trends from 75 to 95 °C for β-carotene and lycopene. Indeed, the degradation rate constant of β-carotene was $(6.14 \pm 1.03) \times 10^{-2}$ at 90 °C in AM+AA in comparison to $(6.72 \pm 1.27) \times 10^{-2}$ kg^{-1} m^3 s^{-1} in AM alone. Moreover, for lycopene, the degradation rate constant under the same conditions was $(7.17 \pm 2.52) \times 10^{-2}$ in AM+AA and $(9.23 \pm 2.03) \times 10^{-2}$ kg^{-1} m^3 s^{-1} in AM alone. Conversely, at 60 °C in AM+AA, the degradation rate was 5-fold higher for β-carotene and 17-fold higher for lycopene. This in turn decreased the activation energy from 40 ± 10 to 19 ± 6 kJ mol^{-1} for β-carotene and more slightly from 89 ± 23 to 79 ± 20 kJ mol^{-1} for lycopene. The interaction between ascorbic acid and carotenes has been questioned and is not well documented. Indeed, these molecules that have different polarities are supposed to interact at the interfaces in food matrices. Results reported by Sanchez et al. showed that vitamin C could preserve carotenoid compounds from oxidation in orange juice, but no mechanism was explained.[38] In contrast, Kanner et al. showed that ascorbic acid could have pro-oxidant effects with metal salts toward β-carotene in a linoleate system.[39] In an ethanol/water mixture, ascorbic acid and carotenes may interact as well. This interaction is only visible at 60 °C but no longer at 75 °C and higher temperatures. This may be partially explained by the thermolability of ascorbic acid in acid medium (AM+AA). Indeed, while 60% of ascorbic acid was retained at 300 min and 60 °C, degradation was almost total after 300 min and 95 °C. However, according to the study of Dhuique-Mayer et al., the retention of ascorbic acid after 150 min at 100 °C was 55% in citrus juice.[14] This therefore suggests that there was substantial retention of vitamin C throughout more than the half of the experiment conducted at 95 °C. Another explanation of this weak impact of ascorbic acid at high temperature could be the decrease in the dissolved oxygen concentration, which is known to be involved in ascorbic acid oxidation reactions. The

J. Agric. Food Chem. 2015, 63, 3970−3979

influence of ascorbic acid on the carotenoid degradation rate therefore decreases as the temperature increases. The addition of naringin affected the rate constants, but only at high temperatures. For β-carotene, the rate constants were slightly lower until 75 °C but 2-fold higher at 95 °C. This resulted in a strong 40 ± 10 to 138 ± 15 kJ mol^{-1} increase in activation energy. At moderate temperature (60 °C), the result was in accordance with a previous study that highlighted the protective effect of polyphenols on β-carotene at ambient temperature.[40] However, this protective role was not observed at higher temperature, and the addition of naringin even seemed to increase β-carotene degradation. For lycopene, the rate constants were on average 3-fold higher in AM+NAR. It is noteworthy that naringin, like other flavanone glycoside, is thermostable.[14] Interactions between polyphenols and carotene at different temperatures therefore need to be elucidated.

Rate constants and activation energies were higher in all model systems than in juice, especially for lycopene. The addition of ascorbic acid and naringin did not show a substantial improvement in stability in model systems. Indeed, ascorbic acid had no influence beyond 75 °C, while naringin seemed to increase its degradation from 75 °C. The protective effect of the juice matrix revealed in these experiments thus more have been due to structural protection than to phytochemicals. Indeed, in plant tissues, especially in citrus pulp, carotenoids are localized in chromoplasts within pulp particles. The particle sizes of citrus pulp are from 1 μm to 1 mm in juices.[41] During processing, carotenoids may be released from the matrix and undergo degradation because of the interaction with other fruit constituents (ascorbic acid, flavonoids, etc.). Therefore, the degradation rate is partially controlled by mass transfer from the pulp to the liquid fraction. In the model systems used in this study, carotenoids were homogeneously dispersed in a water/ethanol mixture with particles that were assumed to be very small due to this type of spontaneous microemulsion. Carotenoid degradation was thus less delayed by mass transfer, and surface contact was enhanced because of the emulsion. Despite these differences, the model systems were very convenient, as they enabled composition control and, even though they did not mimic the real juice exactly, the carotenoid reactivity did not differ markedly when comparing rate constants in PJ and AM, especially for β-carotene. The conclusions drawn in model systems concerning the interaction with microconstituents could therefore be transferable to real matrices. In addition to this model system approach, the role of structures surrounding carotenoids in the vegetable matrix, even destructured (juice), should be specified with further works based on microscopic observations, especially for lycopene.

Multiresponse Modeling of Carotene Thermal Degradation in Model Media. β-Carotene and lycopene degradation was limited in real juice (low rate constant), but it was significant in model media. In addition, high amounts of isomers could be measured in such media (dots in Figures 3 and 4). After 100 min and 95 °C, *cis* isomers could proportionally represent 40% and 60% of total β-carotene and lycopene, respectively. The amount of other degradation compounds—which were assumed to be oxidation and cleavage compounds (OCC)—was assessed at each time via mass balance calculations. From these data, we could represent both β-carotene degradation and the formation of neoformed isomers and other degradation compounds according to the different reaction schemes proposed in Figure 2, from the simplest (hypothesis 1) to the most complex (hypothesis 4). The four hypotheses represent different possibilities for carotenoid degradation. Isomer formation before oxidation and cleavage has been documented in many studies about carotenoids.[12] Hypothesis 1 is the simplest two-step reaction. Hypothesis 2 involves a reverse isomerization reaction which was also assumed to occur in previous studies.[27] Hypotheses 3 and 4 are the same as hypotheses 1 and 2, with the addition of direct cleavage from *trans*-carotenoids. Kinetic quantification of this direct reaction may provide evidence of the prevalence of oxidation reactions. Each hypothesis was transformed into an ordinary differential equation system including the different rate constants. As these schemes tend to describe each reaction step, the order for every reaction was assumed to be 1. A multiresponse modeling procedure enabled the identification of individual rate constants and the generation of modeled data (lines in Figures 3 and 4). The best hypothesis of Figure 2 was chosen by calculating the discrepancy between the experimental and simulated data (RSS) and the AIC criterion expressing the best tradeoff between accuracy and complexity. For β-carotene, substantially lower RSS and AIC values were found for hypothesis 4. Therefore, rate constants k_{ci} and k_{co} were the degradation constants of β-carotene in isomers and other oxidative and cleavage compounds (OCC), respectively.

Isomer rate constants were k_{ic} and k_{io} for retroisomerization in the trans form or degradation in OCC, respectively. β-Carotene retroisomerization was also demonstrated in oil medium by Achir et al.[27] All rates were identified at each temperature. The k_{ref} values extracted from eq 2 at a reference temperature of 80 °C are presented in Table 2. AA and NAR increased the k_{ci} isomerization constant from 3- to 7-fold, respectively. The k_{ic} retroisomerization constant only increased by 6.5-fold in the case of AA, while it decreased slightly with NAR. The k_{ci}/k_{ic} isomerization equilibrium constant could thus be calculated: 0.53 for AM, 0.32 for AM+AA, and 7 for AM +NAR. In the case of NAR, the equilibrium constant was thus higher, thus highlighting the importance of isomerization reactions. k_{co} increased by a 4-fold with AA addition. Direct β-carotene oxidation was thus promoted with this molecule. In contrast, k_{co} was very low with NAR, while k_{io} was 3-fold higher ($(2.60 \pm 1.3) \times 10^{-5}$ instead of $(7.67 \pm 1.5) \times 10^{-6}$ s^{-1}). Hence, with the addition of NAR, β-carotene was strongly isomerized and the formed isomers were very sensitive to oxidation and cleavage, giving rise to OCC.

In the case of lycopene, hypothesis 3 was sufficient to represent the experimental data (lowest RSS and AIC). The mechanisms therefore seemed to be different: no retroisomerization was identified with this approach. In this case, k_{ci} was the isomerization constant, k_{co} the direct oxidation constant, and k_{io} the isomer oxidation. With the addition of AA, k_{ci} and k_{io} remained the same. The only difference was the 3-fold increase in k_{co}, which was the direct oxidation rate. This confirmed that AA enhanced direct oxidation. With the addition of NAR, k_{ci} and k_{io} decreased by 27- and 70-fold, while k_{co} increased by 4-fold. With regard to lycopene, direct oxidation of this compound was also enhanced by NAR. Hence, designing a model system associated with multiresponse modeling may be useful to predict neoformation of compounds such as isomers during thermal processes, but it is also a way to quantify the kinetic importance of each reaction path as a function of the formulation and therefore gain insight into the microconsituent reaction mode. Further studies are now needed to better understand the interactions among

carotenoids, polyphenols, and ascorbic acid, which are very important phytochemicals in juice from nutritional and organoleptic standpoints.

of lactations (two to three lactations). Each group was randomly assigned to one of the experimental diets: a control diet (CON), a diet including 300 g/day per head of grape seed (GS group), a diet including 220 g/day per head of linseed (LIN group), and a diet including both 300 g/day per head of grape seed and 220 g/day per head of linseed (MIX group). The ingredients, the chemical composition, and the fatty acid profile of the experimental diets are reported in Table 1. Diets included a common ration composed of commercial concentrate, beet pulp, mixed hay and alfalfa hay, and a mixed meal composed of pea, soybean, corn, grape seed, and linseed. Grape seed and linseed varied according to the different dietary treatments; the quantity of pea, soybean, and corn was calculated in order to make diets isoproteic and to supply the same level of metabolizable energy to each group. The linseed dose of 220 g/day was used to supply 70 g/day of fat per head. Considering that the total phenolic content of grape seed was 333.3 ± 10.1 mg of gallic acid equivalent (GAE)/100 g of dry matter (DM, mean ± S.E.), the grape seed dose of 300 g/day per head was used to provide approximately 1 g/day per head of total grape seed polyphenols. Details of feeding management and feed analysis and the results of feed intake and milk production traits have been previously reported.[16]

Antioxidant E 310 propyl gallate, 4.3 mg/kg. Vitamin supplement: A, 17 971 UI/kg; D3, 3.494 UI/kg; and E, 60 mg/kg. [c]Dehydrated alfalfa hay: NFD, 387 g/kg DM; CP, 196 g/kg DM; and EE, 44 g/kg DM. [d]Mixed hay: NDF, 551 g/kg; DM, CP 116 g/kg; and DM, EE, 11 g/kg DM. [e]NDF, neutral detergent fiber; NFC, nonfiber carbohydrates; ADL, acid detergent lignin; CP, crude protein; EE, ether extract. [f]LA, linoleic acid; LNA, α-linolenic acid; SFA, total unsaturated fatty acids; MUFA, total monounsaturated fatty acids; PUFA, total polyunsaturated fatty acids.

Milk Samples. Individual morning milk samples were collected weekly (7:30 h) in the last 4 weeks of the trial and stored at −20 °C until analysis. The FA composition was determined on individual milk samples. For the analysis of riboflavin, tocopherols, hydroperoxides, and lipid oxidation of volatile compounds, the weekly milk samples were combined for each ewe.

Exposure of Milk to Fluorescent Light. To test the effect of light exposure on the milk oxidative stability, individual milk samples were transferred in a 30 mL capacity flask, previously cleaned with chloroform, stored in a working cooler at 4 °C, and placed under fluorescent light (400−600 nm) from a light source (TL-D 90 de Luxe Pro 18W/965 SLV, Philips, Frankfurt, Germany) with an intensity of 1500 lx and under continuous agitation by a rotator (Stuart rotator SB3, Bibby Sterilin, Stone, U.K.). Control samples were stored in parallel, under the same condition, and wrapped in an aluminum folium to protect the milk from light exposure. Samples were collected at time 0, after 6 and 24 h of light exposure.

Chemicals. Ascorbic acid (99.7%), α-, δ-, and γ-tocopherol (all >96%), citric acid monohydrate, ethylenediaminetetraacetic acid (99%), hexanal (98%), 1-hexanol (99.5%), heptanal (>92%), iron(III) chloride hexahydrate (97%), and riboflavin (>98%) were purchased from Sigma-Aldrich Chemie GmbH (Steinheim, Germany). Reagents such as HCl (37%), trichloroacetic acid (TCA, 99%), $BaCl_2$ (99%), iron(II) sulfate (99.5%), $NaH_2PO_4{\cdot}2H_2O$ (99.5%), $Na_2HPO_4{\cdot}2H_2O$, $CaCl_2{\cdot}2H_2O$ (99%), H_2O_2 (30%), and NaOH (>99%) were obtained from Merck (Darmstadt, Germany). NH_4SCN (99%) was from VWR BHD Prolabo (Leuven, Belgium). Sodium acetate, pentanal (97%), and 4-methyl-2-pentanone (99%) were purchased from Fluka Chemie GmbH (Buchs, Germany). All solvents of HPLC grade (acetonitrile, chloroform, hexane, 2-propanol, and methanol) and heptane (99%) were supplied by Rathburn Chemicals (Walkerburn, Scotland).

Milk Fatty Acid Profile. Milk fat extraction and fatty acid methyl ester (FAME) preparation were performed as described by Nudda et al.[17] A Turbo 3400 CX gas chromatograph (Varian Inc., Palo Alto, CA, USA), equipped with a flame ionization detector (FID) and an automatic injector 8200 (CX Varian Inc., Palo Alto, CA, USA) was used for the determination of FAME. The FAMEs were separated on a capillary column (CP-select CB for FAME; 100 m × 0.32 mm i.d., 0.25 μm film thickness, Varian Inc., Palo Alto, CA, USA) and quantified using pentanoic (C5:0) and nonadecanoic acid (C19:0) methyl esters (Sigma Chemical Co., St. Louis, MO, USA) as internal standards. The programmed temperature was 75 °C for 1 min, increased at 5 °C/min to 148 °C and at 8 °C/min to 165 °C, held for 35 min, increased at 5.5 °C/min to 210 °C, increased at 3 °C/min to 230 °C, and held for 14 min. Helium (1 mL/min flow rate) was used as the carrier gas with a pressure of 37 psi. The split ratio was 1:100. The injector and detector temperatures were held at 225 and 285 °C, respectively. Varian Star 3.4.1 software was used to compute the retention time and area of each individual FAME, identified by comparing their retention times with those of known standards and with published studies as detailed by Nudda et al.[17]

Riboflavin. Milk samples (1 mL) were added to 220 μL of 100% TCA to precipitate protein; after quick agitation they were placed on ice for 10 min and centrifuged (10 000 rpm, 10 min). About 1 mL of supernatant was transferred to a brown-colored vial through a microfilter (cellulose, 0.45 μm) and injected into an HPLC system equipped with a reverse-phase column (Zorbax SB-C8 4.6 mm × 150 mm, 5 μm; Agilent Technologies, USA). Fluorescence detection with excitation and emission at 450 and 530 nm, respectively, was used to measure the riboflavin according to Silva et al.[18] An external riboflavin

standard curve was used for the quantification (5.0, 2.0, 1.0, 0.5, 0.250, 0.1, and 0.05 μg/mL) according to Dalsgaard et al.[19]

Tocopherols. Two milliliters of milk was added to an equal volume of ethanolic ascorbic acid (1%) and 0.3 mL of saturated potassium hydroxide solution and shaken for 10 s. The quantification of tocopherols was performed according to Dalsgaard et al.[19] Briefly, the samples were incubated at 70 °C for 30 min, shaken for 10 s after 15 min from the beginning of the incubation, and then cooled on ice. Then 1 mL of Milli-Q water and 3 mL of heptane were added to the samples, mixed for 1 min, and centrifuged at 1700*g* for 3 min. Thirty microliters of the upper phase was analyzed by HPLC to measure the concentration of α-, δ-, and γ-tocopherols. Chromatographic separation was performed using a Hypersil silica column (4.6 mm × 200 mm, 5 μm; Thermo Fisher Scientific Inc., Waltham, USA) and hexane/2-propanol (98:2) at a flow rate of 1 mL/min as the mobile phase. The elution was monitored by a fluorescence detector using excitation and emission wavelengths of 295 and 330 nm, respectively. An external standard curve was used for quantitative determination.

Lipid Hydroperoxides. Two milliliters of milk was transferred into a 10 mL glass tube and added to 2 mL of methanol and 4 mL of chloroform and shaken for 30 s, and quantification was performed according to Dalsgaard et al.[19] with a few modifications. Briefly, the sample was centrifuged at 3000*g* for 10 min before 1 mL of the chloroformic phase was mixed with 1 mL of iron(II) thiocyanate in a 10 mL glass tube that previously was cleaned with chloroform. Absorbance was measured at 500 nm after 5 min on a UV−vis spectrophotometer (Cary 60, Agilent Technologies, Palo Alto, CA, USA) using chloroform for the blank reading. Quantification was performed using an external standard curve made at concentrations 2, 5, 10, 15, 20, 40, and 60 μmol/L hydrogen peroxide in chloroform/methanol (50:50).

Secondary Lipid Oxidation Products. The volatile compounds (hexanal and heptanal) were identified and quantified by gas chromatography coupled with mass spectrometry headspace analysis, according to Dalsgaard et al.[19] with minor changes including the use of an isotopic internal hexanal standard according to Wold et al.[20] Briefly, 2 mL of milk was transferred to a 10 mL vial, added to deionized (18.2 MΩ) filtered water (0.22 μm) with an isotopic hexanal D12 (50 ng) from Fluka (Steinham, Germany). The samples were sealed with Teflon-coated lids before the headspace was analyzed for volatile compounds using a Carboxen/PDMS SPME fiber with a film thickness of 30 μm from Supelco (Bellefonte, PA, USA), which was incubated at 50 °C for 30 min in the headspace of each sample. Desorption of the sample from the fiber was performed in the inlet of a GC 7890A from Agilent Technologies (Waldbronn, Germany) equipped with an HP5-MS column from Agilent J&W Scientific (Folsom, CA, USA) and coated with a nonmetal 5% phenyl, 95% dimethylpolysiloxane phase with the following dimensions: 0.25 mm i.d., 0.25 μm, 30 m. Helium was used as the carrier gas with a constant flow of 1.2 mL/min. Quantification was performed relatively using an external standard curve with concentrations of 1−500 ng/mL milk of each compound, including isotopic hexanal to avoid in-between sample variation on individual compounds.

Statistical Analysis. A mixed model was used to analyze data for repeated measurements of fatty acids, riboflavin, tocopherols, hydroperoxides, and volatile compounds using the Proc Mixed procedure of SAS (2002, SAS Institute INC., Cary, NC, USA). The model included the diet and time and their interaction as fixed effects plus the random factor of ewes nested within the treatment. The mean values of fatty acids in milk of each animal were used to calculate the ratio between lipid oxidation products after 24 h of light exposure and the milk fatty acid composition; the data were analyzed with one-way ANOVA. Means were separated using the Tukey test ($P < 0.05$).

RESULTS

The BW of the animals was not affected by any of the treatments (CON, GS, LIN, or MIX) and increased with period (+5.9 ± 0.6 kg, mean ± SD). The fatty acid composition of milk was highly affected by the diet (Table 2). All groups receiving the experimental ingredients (GS and LIN alone or in combination (MIX)) showed higher levels of stearic acid (C18:0, SA) and oleic acid (C18:1 *cis*-9, OA) than the CON group ($P < 0.001$). The concentration of linoleic acid (C18:2 *n*-6, LA) increased ($P < 0.001$) in both groups fed grape seed (GS and MIX) compared to the CON and LIN groups. The level of α-linolenic acid (C18:3 *n*-3, LNA) increased ($P < 0.001$) in both groups receiving linseed compared to CON and GS groups, with the LIN group being the highest. The level of rumenic acid (CLA *cis*-9,*trans*-11, RA) was higher in the LIN and MIX groups than in the CON group ($P < 0.001$); the GS group showed a numerically higher concentration of RA than did the CON group, even though the differences did not reach the level statistical significance ($P < 0.10$). The concentration of total UFA increased in all groups receiving the experimental ingredients compared to the CON; the highest value was found in MIX, with GS and LIN being intermediate ($P < 0.001$).

The initial concentrations of riboflavin in milk from the four experimental groups (1.4 ± 0.4, 1.1 ± 0.4, 1.5 ± 0.3, and 1.1 ± 0.4 μg/mL for the CON, GS, LIN, and MIX groups,

DOI: 10.1021/acs.jafc.5b01614
J. Agric. Food Chem. 2015, 63, 3980−3986

respectively) did not show any significant difference ($P > 0.05$, Figure 1A). The level of riboflavin decreased ($P < 0.01$) by

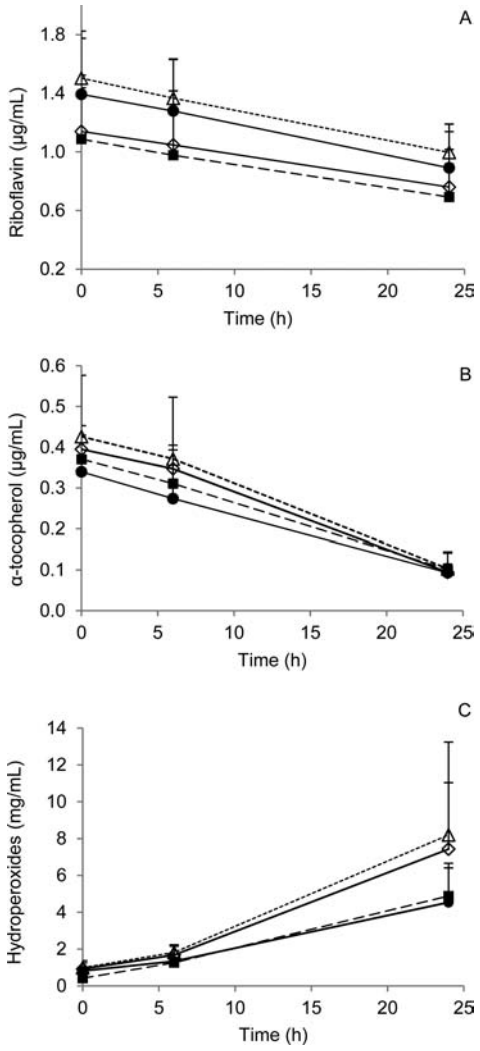

Figure 1. Decrease of riboflavin (A), degradation of α-tocopherol (B), and accumulation of lipid hydroperoxides (C) during illumination with fluorescent light (1500 lx) at 4 °C. Milk from sheep within the feeding groups: control (solid line, ●), grape seed (long-dashed line, ■), linseed (dotted line, △), and a group receiving both grape and linseed (solid line, ◊). Bars indicate standard deviations of the means of six individual animals in each treatment.

8.9% after 6 h of light exposure at 4 °C and by 35% after 24 h in all groups, independently of diets ($P > 0.05$), reaching a final concentration of 0.83 ± 0.1 μg/mL riboflavin. Dark samples of each group (data not shown) did not show any significant reduction of riboflavin after 24 h ($P > 0.05$).

The α-tocopherol was the only tocopherol detected in the milk of the four experimental groups (Figure 1B). No difference was found ($P > 0.05$) in the initial level of α-tocopherol between the groups (0.38 ± 0.09 μg/mL). The milk from all groups showed the same insignificant ($P > 0.05$) decreasing tendency (−14.9%) of α-tocopherol after 6 h. The loss (−74.4%) became significant ($P < 0.01$) after 24 h of light exposure but still without differences between groups ($P > 0.05$), with the α-tocopherol concentration being 0.1 ± 0.03 μg/mL (mean of all groups ± standard deviation).

The accumulation of lipid hydroperoxides in the milk from the four experimental groups during 24 h of fluorescent light exposure at 4 °C is shown in Figure 1C. The level of lipid hydroperoxides after 6 h of light exposition increased significantly ($P < 0.05$) in all experimental groups except for the CON ($P > 0.05$). The concentrations of lipid hydroperoxides after 6 h were 1.49, 1.37, 1.81, and 1.68 mg/mL for CON, GS, LIN, and MIX groups, respectively. After 24 h of light exposure the accumulation of lipid hydroperoxides increased significantly ($P < 0.05$) in both groups receiving linseed supplementation LIN and MIX (8.20 and 7.43 mg/mL, respectively); however, no significant differences ($P > 0.05$) were found in the accumulation of hydroperoxides in the CON and GS groups (4.53 and 4.88 mg/mL, respectively). The level of lipid hydroperoxides after 24 h was numerically greater in the milk of both groups fed linseed (mean, 7.81 mg/mL) compared to that from CON and GS groups (mean, 4.71 mg/mL) even if it did not reach a significant difference ($P > 0.05$). Dark samples of each group (data not shown) and the mean of all groups did not show any significant increase in lipid hydroperoxide accumulation after 24 h ($P > 0.05$).

Figure 2A shows the relationship between the accumulation of lipid hydroperoxides after 24 h of illumination with fluorescent light (1500 lx) at 4 °C and the concentration of UFA (g/100 g of total FAME) in milk samples from sheep of all groups. The level of hydroperoxides increased linearly ($P < 0.01$) with the concentration of total UFA in CON and LIN groups ($R^2 = 0.80$, $P < 0.01$). No correlation was found ($R^2 = 0.08$, $P > 0.05$) between the level of hydroperoxides and the concentration of total UFA in both groups fed grape seed (GS and MIX). Calculating the ratio between the concentration of lipid hydroperoxides in milk after 24 h and the concentration of total UFA (g/100 g of FAME) in the milk (Figure 2B) showed a significantly lower level of lipid hydroperoxides ($P < 0.05$) in GS and MIX (0.13 ± 0.05, mean ± SD) compared to the LIN group (0.26 ± 0.07, mean ± SD). The CON group showed an intermediate level (0.21 ± 0.06, mean ± SD) that is not significant different ($P > 0.05$) from any of the other groups.

As hexanal is accepted to be formed from LA, the ratio hexanal/LA was calculated in the same manner as for the hydroperoxide/UFA ratio (Figure 3A). The hexanal/LA ratio was lower ($P < 0.05$) in GS and MIX (5.26 ± 1.81, mean ± SD) than in the CON group (11.37 ± 1.18, mean ± SD), with LIN being intermediate (6.85 ± 1.47, mean ± SD).

Heptanal was significant higher in the MIX group than in the three others (data not shown). Heptanal has previously been correlated with OA, LA, and RA, and we obtained a good correlation between the concentration of these fatty acids and the accumulation of heptanal in milk samples after 24 h of light exposure ($R^2 = 0.85$, $P < 0.01$). When calculated as the ratio heptanal/(OA + LA + RA) there was no significant difference after 24 h of light exposure between any of the treatments (Figure 3B).

DISCUSSION

The effect of photooxidation on the lipid oxidation of sheep milk was investigated for the first time in the present study. Moreover, the effects of grape seed or linseed alone or in combination included in the sheep diet were studied with respect to the oxidative stability of sheep milk. In the present study the mean concentrations of riboflavin in ewe's milk was 1.3 μg/mL, and it was significantly reduced after 24 h of light exposure, independently of diets. The detected level of

riboflavin in sheep milk in our experiment was similar to those in previous reports (1.58 and 1.77 μg/mL),[21,22] and the bleaching of riboflavin has previously been shown upon illumination in other dairy systems as well.[19,23]

The degree of transfer of α-tocopherol from feed to the milk, in cows, has previously been positively correlated with the levels of LA and LNA in milk.[24,25] In our study the initial level of α-tocopherol seems to be independent of the concentration of LA and LNA; maybe the small differences in the levels of these fatty acids between groups were not enough to affect the transfer of α-tocopherol from feed to milk significantly. The pattern of degradation of α-tocopherol in the present study is in agreement with other studies showing a loss of α-tocopherol in bovine milk after fluorescent light exposure.[26,27] The loss of α-tocopherol did not affect the accumulation of lipid hydroperoxides within 24 h of light exposure; this finding disagrees with previous studies reporting the capacity of α-tocopherol to quench singlet oxygen.[28,29] When α-tocopherol was included in a cow's diet, reaching a concentration of 2.67 μg/mg in the milk, the oxidative stability of milk was improved.[25] This discrepancy could be due to the different concentrations of α-tocopherol in milk; in the present work the levels of α-tocopherol were 7 times lower than in the previously cited study.[25] Our result agrees with other studies where no relationship was found between the loss of α-tocopherol (at a level similar to our finding) and the accumulation of lipid hydroperoxides in cheese under light exposure.[19,30]

The accumulation of lipid hydroperoxides was used as a measurement of the light-induced lipid oxidation in milk. The high amount of UFA in milk samples with linseed made them more susceptible to the lipid oxidation as previously shown.[31] As UFA are logically more susceptible to oxidation,[32] a linear correlation between the concentration of these FAs and the level of lipid hydroperoxides could be hypotized, according to the findings of Havemose et al.,[26] who showed that higher concentrations of LNA were correlated with higher accumulations of lipid hydroperoxides in bovine milk after 24 h of fluorescent light exposure. Hence, the significantly higher level of UFA in the MIX group compared to those in the LIN and GS groups (MIX > LIN = GS > CON) would lead us to expect a higher level of hydroperoxides in the MIX group compared to those in the LIN and GS groups and also a higher level of hydroperoxides in the GS group compared to that in the CON group.

Although no statistical differences were observed among the four groups, it was evident that both groups receiving linseed tended to have higher accumulations of lipid hydroperoxides than the other groups. Biological variation and complex matrices may contribute to uncertainties in the obtained results. However, considering the level of total UFA found in milk, a good correlation was found between the accumulation of lipid hydroperoxides after 24 h of light exposure and the UFA (g/100g total FA) in the milk samples from the CON and LIN groups, whereas no correlation was found in milk from sheep fed grape seed (GS and MIX). The lower level of

DOI: 10.1021/acs.jafc.5b01614
J. Agric. Food Chem. 2015, 63, 3980−3986

hydroperoxides between the LIN and MIX groups indicates an antioxidative capacity of the grape seed that seems to protect UFA in the MIX group against type II photooxidation. This is also supported by a numerically lower level of the ratio hydroperoxides/UFA in the GS group compared to the CON, even though this was not found to be significantly different. The transfer of polyphenols from feed to the milk of ruminants[33−35] and their ability to quench singlet oxygen[36] could potentially explain the protection of the milk from the GS and MIX groups, both with grape seed in their diets. Furthermore, our finding agrees with Jung,[27] showing the protective activity of catechins in the accumulation of lipid hydroperoxides in milk after fluorescent light exposure. It has been proposed that the generation of lipid hydroperoxides in milk with fluorescent light can be a consequence of the reaction between singlet oxygen, resulting from the sensibilization of riboflavin and its reaction with unsaturated lipids,[37] but other photosensitizers may also play an important role in the generation of singlet oxygen.[23]

The secondary oxidation product, hexanal, has been reported to be a typical volatile product derived from LA oxidation.[38,39] It has previously been demonstrated that bovine milk with a high amount of LA was more susceptible to lipid oxidation compared to milk rich in RA, OA, and LNA, respectively.[40] The same authors demonstrated that milk containing a high amount of LA showed the highest production of secondary volatile compounds, compared to other milk models. In the present work, the lower ratio hexanal/LA calculated for milk from the GS group compared to the CON group (and the numerically lower value for MIX compared to that for LIN) supports the hypothesis that polyphenols from grape seed were able to reduce the formation of secondary oxidation product hexanal. This finding agrees with other studies reporting the antioxidant capacity of grape seed polyphenols[41,42] and is corroborated by other findings showing the capacity of catechins to reduce the accumulation of lipid volatile aldehydes in cheese and milk after light illumination.[43,27]

The higher accumulation of heptanal in MIX compared to that of the other groups could be explained with the high levels of OA, LA, and RA found in the milk of this group. In fact the formation of heptanal has been mainly associated with the oxidation of these fatty acids.[44,39,45] The ratio between the accumulation of heptanal after 24 h of illumination and the sum of OA, LA, and RA showed no difference between the experimental groups, supporting these previous finding. This result suggests that the grape seed byproduct may effectively reduce the formation of the secondary oxidation product heptanal, thus to a certain extent offering protection to the PUFA from the linseed. Moreover, the numerically lower value of the ratio heptanal/OA, LA, RA in the GS group compared to that for CON seems to confirm the ability of polyphenols from grape seed to reduce the formation of heptanal.

In conclusion, this study illustrated the differences in the milk's oxidative stability when sheep diets include a source of polyphenols (grape seed) and a source of PUFA (linseed), alone or in combination. The inclusion of linseed in the diet of sheep increased the amount of PUFA in the milk, which is advantageous for health effects, but the high levels of PUFA in milk made it vulnerable to oxidation. The addition of grape seed reduced the extent of oxidation of the total UFA when taking the ratio between lipid hydroperoxides after 24 h of light exposure and the milk fatty acid composition into account.

Gel-1CSH-TP	25	20	18.75		75	0.93	6.45
Gel-2CSH-TP	25	20	18.75		75	0.93	13.13

[a]Abbreviations: Gel, gelatin; Gly, glycerol; TP, tea polyphenol; NS, nanoparticle suspensions; NPs, nanoparticles; CSH, chitosan hydrochloride. Gel (or Gel-TP) and Gel-*x*CSH (or Gel-*x*CSH-TP), films prepared with gelatin + nonactive (or active) nanoparticles at the indicated CSH concentrations (mg/mL).

migration of some free TP to the film surface may be required in order to inhibit the initial oxidation, and perhaps both free TP and encapsulated TP within the film matrix are necessary to guarantee long-term oxidative stability. For TP chitosan nanoparticle incorporated films, it is still not known what differences in antioxidant properties would be presented when different free/nanoencapsulated active agent ratios are applied.

In addition to carrying and protecting bioactive compounds, nanoparticles such as blank chitosan nanoparticles can improve the barrier, thermal, and mechanical properties of films such as those based on hydroxypropyl methylcellulose (HPMC),[15] starch,[16] tara gum,[17] and gelatin.[18] Among them, the addition of chitosan nanoparticles with smaller particle sizes resulted in stronger mechanical properties and better barrier properties, as observed by de Moura et al.[15] in HPMC films. Therefore, the inclusion of antioxidants in chitosan nanoparticles into polymer matrices might bring a twofold advantage: the performance improvement of food packaging/edible film material and the provision of an additional antioxidant function.[19]

In this study, TP was encapsulated in the matrix of CSH and SBE-β-CD nanoparticles and the TP-containing nanoparticles were added into gelatin films. As a natural antioxidant, TP is subject to oxidation. In order to determine if encapsulation improved the antioxidative lifetime of TP and protected it from degradation, gelatin films were also prepared embedded with free TP. The objective of this study was to investigate the antioxidant activities of gelatin films incorporated with free TP and TP-loaded CSH-SBE-β-CD nanoparticle (CSN) suspensions with different encapsulation efficiencies.

MATERIALS AND METHODS

Materials. Gelatin (type B from bovine skin) and glycerol were purchased from China Medicine (Group) Shanghai Chemical Reagent Co. (Shanghai, People's Republic of China). CSH, molecular weight 100 kDa and degree of deacetylation 86%, derived from crab shells was obtained from Golden-Shell Biochemical Co., Ltd. (Hangzhou, People's Republic of China). SBE-β-CD (food grade), molecular weight 2.082 kDa and an average degree of substitution 6, was purchased from Kunshan Chemical Industries Co., Ltd. (Jiangsu, People's Republic of China). TP, polyphenol content ≥98% and catechins ≥90% (determined by manufacturer), was obtained from Qiangsheng Medicine Science Technology Co., Ltd. (Shanghai, People's Republic of China). 2,2-Diphenyl-1-picrylhydrazyl (DPPH) was purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other reagents were analytical grade.

Preparation of CSNs. CSNs were prepared according to a previously reported method,[20] with minor modifications. Briefly, 24 mL of 2, 4, or 8 mg/mL SBE-β-CD in distilled water was added dropwise to 72 mL of 0.5, 1, or 2 mg/mL CSH aqueous solutions, respectively, with vigorous magnetic stirring, leading to the formation of nanoparticles via the ionic gelation mechanism. The CSH/SBE-β-CD mass ratios were controlled at 3/4 (w/w) in all cases. TP-loaded CSNs were prepared by adding an aqueous TP solution to the SBE-β-CD solution to obtain a concentration of 1 mg of TP/mL and stirred for 24 h at room temperature to promote inclusion complex formation. The TP-SBE-β-CD solution was combined with the CSH solution. The nanoparticle suspensions were immediately analyzed or used in film forming. All TP-loaded films contained the same total amount of TP.

Characterization of CSNs. The *z*-average particle size and size distribution of the nanoparticle suspensions were determined by dynamic light scattering (DLS, Zeta-PALS + BI-90Plus, Brookhaven Instrument Co., Holtsville, NY) at a fixed scattering angle of 90° at 25 ± 1 °C. All measurements were run in quadruplicate. The morphology of nanoparticles was examined by a high-performance digital imaging transmission electron microscope (TEM, JEOL 2100, Hitachi High-Technologies Corporation, Tokyo, Japan). The TEM samples were prepared by placing one drop of the suspension on a copper grid, staining with 2% (w/v) phosphotungstic acid, and air drying. Once dried, the sample was imaged by the microscope with an accelerating voltage of 100 kV.

Encapsulation Efficiency of TP-Loaded CSNs. The encapsulation efficiency (EE) of TP in CSNs was determined according to Hu et al.[21] Briefly, TP-loaded nanoparticles were carefully transferred into an AmiconUltra-4 centrifugal filter device (Millipore Co., Billerica, MA) with a 10000 MW cutoff Ultracel membrane. After centrifugation at 4000*g* for 10 min, the concentration of TP in the ultrafiltrate was determined by the Folin−Ciocalteu method. Prior to measurement, the filtrate was diluted fivefold with distilled water. The total content of TP was calculated from the TP concentration in the aqueous medium before CSN formation. The EE of TP was calculated using eq 1:

$$\mathrm{EE}\ (\%) = (((\text{total content of TP}) - (\text{content of TP in ultrafiltrate}))/(\text{total content of TP})) \times 100 \quad (1)$$

Preparation of Films. The gelatin films were prepared by our previously reported method with some modifications.[22] Briefly, 8% (w/v) gelatin solutions were prepared by hydrating gelatin powders in distilled water for 1 h at room temperature and then dissolved by heating at 65 °C with continuous stirring. Glycerol (1.6%) was added as a plasticizer in order to make the films less brittle and easier to handle. The composition of the gelatin films, including films with TP-loaded nanoparticle formulations, are shown in Table 1. The 8% gelatin−1.6% glycerol solutions (25 mL) were diluted with water (75 mL) or nanoparticle suspensions to 2% (w/v) gelatin in all film-forming solutions. A homogeneous solution was achieved after stirring for 1 h. Films were prepared by casting the 2% gelatin solutions (35

DOI: 10.1021/acs.jafc.5b00003
J. Agric. Food Chem. 2015, 63, 3987−3995

mL) in square Petri dishes (10 cm × 10 cm) and drying at 25 °C in an oven to a constant weight (approximately 36 h). The films were peeled off and conditioned at 25 °C and 53% relative humidity (RH) for at least 48 h in a controlled environmental chamber (Shengxing Experimental Equipment Co., Ltd. Shanghai, People's Republic of China) before testing.

Total Phenol Assay. The total phenolic content of films was estimated by the Folin−Ciocalteu method according to Jouki et al.[23] Initially cut conditioned films (2.5 cm × 2.5 cm) were weighed and redissolved in 10 mL of distilled water at 40 °C for 1 min and centrifuged (10000*g*, 10 min) at 20 °C. Supernatant (1 mL) and distilled water (1 mL) were thoroughly mixed with Folin−Ciocalteu reagent (5 mL, 10% v/v). After 6 min, 4 mL of 7.5% (w/v) sodium carbonate was added. The mixture was stirred thoroughly and allowed to stand at room temperature for 60 min prior to recording the absorbance at 765 nm with a spectrophotometer (Shimadzu UV-2450, Japan). The concentration of total phenol was expressed as (mg of gallic acid equivalent)/(g of film sample)according to eq 2

$$\text{total phenolic content} = (C \times V)/M \tag{2}$$

where C is the concentration of gallic acid obtained from the standard curve (mg/mL), V is the volume of the supernatant (mL), and M is the weight of film (g).

Characterization of Films. *Visual Appearance and Light Transmission.* The film-forming solutions and films were evaluated visually for uniform color and the presence of insoluble particles. The ultraviolet and visible light transmittance properties of the films were measured according to the method of Bitencourt et al.[9] Film samples of 10 × 25 mm were placed in the light path of a spectrophotometer (UV-2450, Shimadzu, Tokyo, Japan). Transmittance was recorded from 200 to 800 nm in triplicate.

Microstructure. The cross-section morphology of films was analyzed using a field emission scanning electron microscope (SEM, S-4800, Hitachi, Japan). Films were cryofractured by immersion in liquid nitrogen and conditioned in a desiccator at 25 °C before measurement. Samples were mounted on the specimen holder using double-sided adhesive tapes and then sputter coated with gold under vacuum. The samples were scanned with an accelerating voltage of 1 kV.

An atomic force microscope (AFM, Bruker Dimension Icon, Bruker Co., Germany) was used to observe the surface morphology of films in tapping mode, and 50 μm × 50 μm images under ambient conditions were obtained. All samples were analyzed in triplicate using a Bruker Nanoscope software (version 1.40) to calculate the roughness values. The obtained parameters were R_a, which is the arithmetic average of the absolute values of the surface height deviations (Z) measured from the mean plane, and R_q, which is the root-mean-square average of height deviations taken from the mean image data plane. R_a and R_q were calculated from eqs 3 and 4:

$$R_a = \frac{1}{N}\sum_{j=1}^{N} |Z_j| \tag{3}$$

$$R_q = \sqrt{\frac{\sum Z_i^2}{N}} \tag{4}$$

Determination of Antioxidant Activities in Vitro. The in vitro antioxidant properties of films were performed on the basis of the procedure reported by Wu et al.[10] The supernatant was prepared as stated in Total Phenol Assay and was collected for further analyses, including ferric reducing power and DPPH radical scavenging activity.

Ferric Reducing Power. The determination of reducing power was measured as described by Li et al.[24] with slight modifications. Briefly, 1.0 mL of redissolved film solution was mixed with 2.5 mL of phosphate buffer (0.2 M, pH 6.6) and 2.5 mL potassium ferricyanide (1%, w/v). After incubation at 50 °C for 20 min and rapid cooling, 2.5 mL of trichloroacetic acid (10%, w/v) was added to the mixture followed by centrifugation at 10000*g* for 10 min. The obtained supernatant (2.5 mL) was treated with 2.5 mL of distilled water and 0.5 mL of 0.1% ferric chloride (w/v). The absorbance of the reaction mixture was recorded at 700 nm (Shimadzu UV-2450, Japan) after 10 min of reaction. A higher absorbance indicates higher reducing power.

DPPH Radical Scavenging Activity. The method described by Yi et al.[25] was used to evaluate the DPPH radical scavenging activity, with slight modifications. A 2 mL portion of film supernatant was mixed with 2.5 mL (0.1 mM) of DPPH dissolved in ethanol. The mixture was kept in the dark for 30 min at room temperature followed by centrifugation at 8000*g* for 5 min. The absorbance was measured at 517 nm. The assay was carried out in triplicate. The DPPH radical scavenging activity was calculated as shown in eq 5

$$\text{DPPH scavenging (\%)} = 100 \times (1 - (A_s - A_b)/A_c) \tag{5}$$

where A_s represents the absorbance of sample after film supernatant was added, A_b the absorbance of film supernatant alone, and A_c the absorbance of the control as distilled water was mixed with the DPPH solution instead of the sample.

POV and TBARS of Sunflower Oil in Contact with or without Touching Films. Two methods were used to evaluate the antioxidant properties of films in contact with oil or above the headspace of the oil. The antioxidant properties of the films in contact with the oil was determined by the method of Bao et al.[13] The films were transformed into 4 cm × 4 cm bags by heat sealing, and 1 mL of fresh sunflower oil was added to the bags. The antioxidant properties of the films placed over the headspace of the oil were determined according to Jongjareonrak et al.[4] and Wu et al.[26] A 10 mL portion of fresh sunflower oil was poured into a glass cell (30 mm diameter × 50 mm height) and covered with the film (4 cm × 4 cm) sealed with glue and Parafilm. All samples were stored in a humidity-controlled chamber (53 ± 2% RH) at 28 °C. Samples for peroxide value (POV) and thiobarbituric acid reactive substance (TBARS) analysis were collected at intervals of 1 week over a period of 6 weeks. Samples without film packaging were also assessed as control.

POV Analysis. POV was determined by theAOCS Cd 8-53 Official Method.[27] The amount of oil sample analyzed varied and depended on its oxidation degree. The oil sample was dissolved in 50 mL of an acetic acid/chloroform mixture (3/2 v/v) within a 250 mL Erlenmeyer flask. Then saturated KI solution (0.5 mL) was added and the flask was allowed to stand for 1 min with occasional agitation. After addition of distilled water (50 mL), the mixture was titrated against sodium thiosulfate (0.01 M) with starch as an indicator. A blank titration was treated the same waybut without oil. POV (mequiv of oxygen/kg) was calculated using eq 6:

$$\text{POV} = 1000 \times S \times c/m \tag{6}$$

In this formula, S is the volume of sodium thiosulfate solution (blank corrected) in mL, c is the normality of the sodium thiosulfate solution, and m is the weight of the oil sample in grams.

TBARS Analysis. TBARS were detected using the AOCS Cd 19-90 method.[28] The oil sample (50−200 mg) was solubilized in 10 mL of 1-butanol, mixed with 10 mL of 0.2% TBA in 1-butanol, heated in a 95 °C water bath for 2 h, and rapidly cooled in an ice bath. The absorbance was measured at 532 nm against a corresponding blank (reaction with all the reagents and treatments except for the oil). The standard curve was calculated from the TBARS reaction of a series of aliquots (0.1−1 mL) of 0.2 mM 1,1,3,3-tetraethoxypropane (95%) prepared in 1-butanol. The results were expressed as μmol of malonaldehyde (MDA)/g of oil (n = 3).

Statistical Analysis. Data were presented as mean value ± standard deviation. The data were analyzed by one-way analysis of variance (ANOVA) using the SPSS 19.0 package (IBM, New York). Duncan's multiple range test was used to determine the significant differences of the mean values ($P < 0.05$).

RESULTS AND DISCUSSION

Impact of CSH Concentration on CSNs Size Distribution and Morphology. As observed from TEM in Figure 1a, regular spherical-shaped nanoparticles can be synthesized by ionic cross-linking between the positively charged amine of

DOI: 10.1021/acs.jafc.5b00003
J. Agric. Food Chem. 2015, 63, 3987−3995

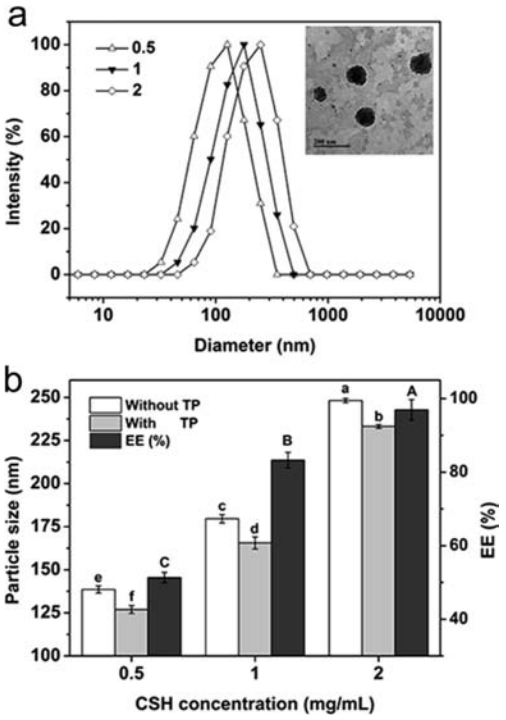

Figure 1. (a) Particle diameter distributions of TP-loaded chitosan nanoparticles prepared with different CSH concentrations (0.5, 1, and 2 mg/mL) and (inset) TEM of TP-CSNs prepared with 1 mg/mL of CSH (CSH/CSH-SBE-β-CD mass ratio is 3/4). The scale bar indicates 200 nm. (b) Particle size as a function of CSH concentration for nanoparticles with or without TP and encapsulation efficiency (EE) of related TP-loaded nanoparticles. Different lower-case or upper-case letters indicate significant differences ($P < 0.05$) for particle size and EE, respectively.

CSH and negatively charged sulfonate groups of SBE-β-CD. EE and release of TP may be related to particle size. Therefore, three particle size ranges were produced (Figure 1a) using three different concentrations of CSH (0.5, 1, and 2 mg/mL) to study the effect of EE and particle size on accessibility of free radicals to TP in gelatin films and/or nanoparticles embedded in gelatin films. Increased concentrations of the cationic and anionic components increase particle size and also entrap more TP, but in solution a larger particle size has been shown to lower TP release.[21] In this study particle size and EE increased as the nanoparticle mass concentration increased (Figure 1b). In a study of protein and peptide loading of nanoparticles, Grenha et al.[29] also reported that larger particles are produced by higher concentrations of chitosan. The mass ratios, salt concentration, and pH also affect particle size but were kept constant in this study.[30]

Incorporation of TP decreased the particle size of TP-CSNs in comparison to the corresponding blank CSNs (Figure 1b), and the smaller particle size may be attributed to a greater cross-linking density between the numerous OH groups of catechins, chitosan, and cyclodextran.[21] Vitamin C was also reported to decrease CSN size by a similar mechanism.[12] As the concentration of particle formers (CSH and SBE-β-CD) increased, the amount of nanoparticles available for encapsulation of TP increased. More TP-SBE-β-CD inclusion complexes were incorporated in the nanoparticles because more TP-SBE-β-CD inclusion complexes were formed as the concentration of SBE-β-CD increased simultaneously.[31]

Free TP Content in the Redissolved Film Solution. The free TP content of films was estimated by measuring the total phenolic content of the supernatant after dissolving the TP-CSN films and removing the CSNs particles by centrifugation. After dissolution in water no visible precipitates were observed and the resulting solutions were similar to the original film-forming solutions showing opacity. Li et al.[32] also reported similar results when sodium caseinate films incorporated with nanoparticles were redissolved. The total phenolic content of blank gelatin films and films with blank CSN nanoparticles were the same, 1.5 mg of gallic acid/g of film (Figure 2a). This value is similar to that reported for silver carp skin gelatin film[10] and may account for some of the antioxidant properties of the gelatin film alone. Total phenol content observed in the blank gelatin film might be attributed to the presence of amino acid residues, such as tyrosine and histidine, since these amino acids are able to reduce the Folin−Ciocalteu reagent.[33] The total phenolic content of the gelatin films increased after adding TP or TP-CSNs. Increasing the CSH concentration resulted in a significant ($P < 0.05$) decrease of the extractable phenols in the supernatant due to loss by entrapment of TP in the nanoparticles, which was related to EEs. The total phenolic content was inversely related to EE, revealing the stability of TP-loaded nanoparticles during the process of film forming.

Distribution of TP and CSNs in Films Analyzed by SEM and AFM. Because the TP and TP-CSNs are fixed in a solid film matrix, the accessibility of oxygen and lipid radicals to TP may depend on the proximity of the TP-CNS to the film surface. The cross-section morphology (by SEM) and surface morphology (by AFM) of gelatin films with nanoparticles with or without TP are shown in parts a and b of Figure 3, respectively. The cross-section of films containing TP appear more compact and smooth in comparison to the blank gelatin film (Figure 3a) and may be due to more hydrogen bonding because of protein−polyphenol interactions.[10] Cross sections of the films showed the disappearance of microvoids (granular appearance) in films containing CSNs or TP-CSNs, indicating that the nanoparticles were well dispersed throughout the film network.

Further support of the interaction between hydrophilic TP and gelatin proteins was suggested by the reduction of surface roughness (R_q and R_a in Figure 3b). Smaller CSNs had surface characteristics similar to that of the control (data not shown); however, larger particles increased the roughness of the surface microstructure from about 3.3 nm in Gel to 6.1 in Gel-2CSH films. Li et al.[32] reported similar results in the surface properties of sodium caseinate films upon adding thymol-loaded zein nanoparticles. The large accumulation of nanoparticles that formed enriched regions on the film surface also is the cause of the more smooth cross-sectional structure at higher CSN concentrations observed by SEM (Figure 3a).

Appearance and Light Transmission. The appearance of packaged food products, including transparency, directly affects consumer acceptability and assessment of quality.[14] The opaqueness of the gelatin solutions increased with increasing concentration of CSNs and corresponding increase in particle size (Figure 4a). However, unlike the case for the solutions, the films were transparent with smooth surfaces. All films had a homogeneous appearance without visible insoluble particles regardless of the CSH concentration, as shown in Figure 4b. Films containing free TP presented a stronger yellowish color due to the brown color of TP itself, which was reduced as the EE increased. The uniform distribution and stability of CSNs in

Abbreviations: Gel, gelatin; TP, tea polyphenol; CSH, chitosan hydrochloride; Gel (or Gel-TP) and Gel-*x*CSH (or Gel-*x*CSH-TP), films prepared with gelatin + nonactive (or active) nanoparticles at the indicated CSH concentrations (mg/mL).

the film-forming solutions and resulting films (Figure 3) suggest that controlled release of TP by entrapment in nanoparticles may occur.[14]

Gelatin-based films have excellent UV barrier properties due to the UV absorption of peptide bonds in the polypeptide chains and aromatic residues of phenylalanine and tyrosine in gelatin.[34] Incorporation of TP into the gelatin films further decreased the values of light transmission in the near-UV range (250−400 nm) in comparison to the gelatin film alone (Figure 4c). TP in gelatin films also slightly decreased the percentage of transmittance in the visible range, below 500 nm, due to the brown coloration of TP. It is of interest to note that the blank CSN-included films showed no significant change in the light barrier properties in comparison to the blank film, and all TP incorporated nanoparticles showed similar light transmission despite the difference in EE or particle size in comparison to the film with free TP. These results may presumably be

In (c) the dashed lines are either Gel alone or Gel-*x*CSH (no TP) and the solid lines are Gel-TP-CSH. Abbreviations: Gel, gelatin; TP, tea polyphenol; CSH, chitosan hydrochloride; Gel and Gel-*x*CSH, film-formation solutions or films prepared with gelatin + nonactive (or active) nanoparticles at the indicated CSH concentrations (mg/mL).

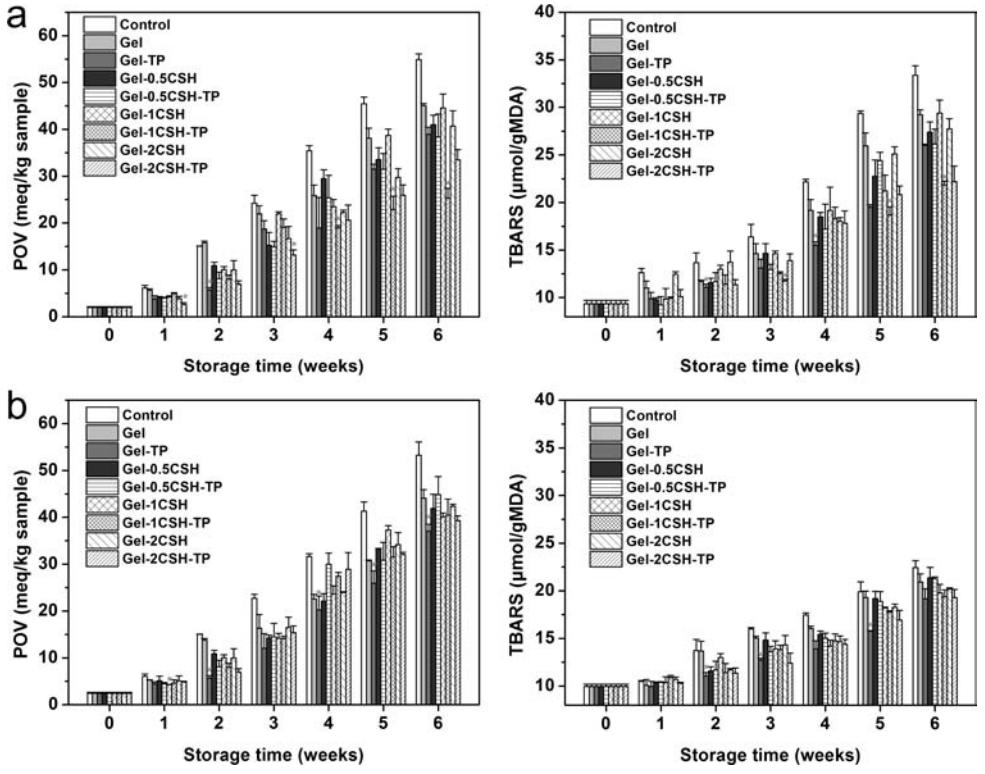

Figure 5. Antioxidant activities of gelatin-based films containing different nanoparticles on (a) oils in bags fabricated by films and (b) oils in cells covered by films. Formations of POV (left) and TBARS (right) were measured separately during storage. Asterisks indicate significant ($P < 0.05$) differences. Abbreviations: control, sunflower oil without film protection; Gel, gelatin; TP, tea polyphenol; CSH, chitosan hydrochloride; Gel (or Gel-TP) and Gel-*x*CSH (or Gel-*x*CSH-TP), films prepared with gelatin + nonactive (or active) nanoparticles at the indicated CSH concentrations (mg/mL).

attributed to the uniform dispersion of CSNs into the gelatin matrix. Films incorporated with TP with a higher UV/visible barrier can better prevent the lipid oxidation of the food product.

In Vitro Antioxidant Activities of Gelatin Films. The ferric reducing power assay is commonly used to study the antioxidant capacity of plant polyphenols.[35] Polyphenols, such as EGCG, are able to contribute a hydrogen atom ($H^{\bullet}$) to oxygen fatty acid radicals ($RO^{\bullet}$) to break the free radical chain reaction. Since the substrate for the ferric reducing power assay was the supernatant of the dissolved film, the assay had a profile (Figure 2b) very similar to that of the total phenolic content (Figure 2a), because the latter assay also used the film supernatant. These two assays verify the increasing antioxidant activity of the films as the EE of the nanoparticles decreased. An increase in the initial amount of free TP within the gelatin matrix led to a higher reducing capacity.

The DPPH radical scavenging activity, also associated with antioxidant activity, is shown in Figure 2c. The DPPH radical scavenging activity did not decrease with increasing EE. The

J. Agric. Food Chem. 2015, 63, 3987−3995

scavenging activity value of the TP-CSN films was reduced significantly ($P < 0.05$) only for CSH concentrations above 0.5 mg/mL and remained constant as the concentration increased. The concentration-independent fluctuation was primarily due to the antioxidant properties of chitosan.[35−37] The radical scavenging capacity of chitosan is believed to be related to the formation of stable radicals from the reaction between free radicals and residual free amino (NH_2) groups. The NH_2 groups could also form ammonium (NH^{3+}) groups by absorbing hydrogen ions from the solution.[35,37] The antioxidant properties of chitosan could also explain the slightly higher antioxidant activity (in the case of reducing power and DPPH) when blank CSN nanoparticles were added.

Antioxidant Activities of Gelatin Films on Sunflower Oil. Sunflower oil is sensitive to oxidation and rancidity because of its high content (~60%) of polyunsaturated linoleic acid. Analyses of POV and TBARS, corresponding to the primary and secondary lipid oxidation products, respectively, were performed to monitor the efficacy of films in inhibiting oil autoxidation.

Antioxidant Activities on Oils within Bags. The antioxidant proprieties of TP in liquid lipid systems such as bulk oil, oil on cellulose carrier, or emulsion have been determined.[38] In this study TP was immobilized in a solid matrix of protein, CSN, or cyclodextrin. As shown in Figure 5a, with increasing storage period the POV and TBARS of oils increased continuously with time regardless of the different packaging films. Lipid oxidation was lower in oils packaged in films in comparison to that in the control oil which was exposed to air. The difference in POV or TBARS inhibition was more pronounced after 3 weeks of storage ($P < 0.05$). This inhibitory effect may be dependent on the presence of antioxidants in the film. The oxygen barrier properties of the films may also play a role in inhibiting the POV and TBARS of oils.[13]

The film with the free homogeneously distributed TP exhibited the least oil oxidation in the first 4 weeks. There was a more conspicuous reduction in the antioxidant effect in comparison to that of 1CSH-TP and 2CSH-TP after 4 weeks, although the accumulated oxidation products (total TBARS) were significantly lower than that of the blank gelatin film ($P < 0.05$). TP in gelatin films is also subject to oxidation. The antioxidant activity of phenolic compounds such as TP is based on the quenching of free radicals of fatty acids; however, the antioxidant loses its activity at the same time.[38] Wu et al.[10] reported that the antioxidant activities of green tea extract in gelatin films decreased during storage due to the oxidation of TP. In this study the oil antioxidant ability of 1CSH-TP and 2CSH-TP remained high throughout the 6 week storage study in addition to 0.5CSH-TP.

No significant differences ($P > 0.05$) in TBARS or POV were observed between the blank gelatin films and those containing CSNs without TP. The protective effect of these films without TP in delaying the rancidity of sunflower oil is likely due to their oxygen barrier properties. The results also suggest that the DPPH scavenging ability of CS did not contribute to reducing fatty acid oxygen free radicals here. Encapsulation of TP in the CSNs greatly enhanced the oxidative protection of oils, especially when the EE of TP-loaded nanoparticles was high: 80% and 100% ($P < 0.05$). These results suggest that TP in contact with the oil is able to react with the reactive oxygen species at the package surface or diffuse from nanoparticles to the films and then into oil. TP-loaded nanoparticles with 50% EE did not show an inhibitory effect significantly higher than that of free TP. This result is not in agreement with the results reported by Imran et al.[14] in the control of food pathogens using nisin nanoliposome embedded films, showing that the POV or TBARS inhibition was not only dependent on the EE but also on the oxidation stability of active agents and other factors. In this study after 6 weeks oil oxidation control was lower for ~80% encapsulated than for ~100% encapsulated TP and free TP. This may be due to an optimum partition of free TP and encapsulated TP. The free TP reacts first to reduce the initial oxidative rancidity and later in the storage period TP released from nanoparticles continue to quench free radicals.

Antioxidant Activities of Gelatin Films Not in Contact with Oils. Containers or cells containing oil with a film over the headspace have been used to evaluate the antioxidant capacity of films[2,39] and also to measure the oxygen barrier properties of films.[26] POV and TBARS increased gradually with increasing storage time for all samples, with the uncovered oil having the highest values (Figure 5b). The film with free TP had the lowest POV and TBARS during all the storage times tested. Oxygen concentration in the headspace is one of the most important factors controlling the rate of lipid oxidation.[2] The homogeneous distribution of TP in the film may more efficiently scavenge singlet oxygen in comparison to the heterogeneous distribution of encapsulated TP.[40]

The incorporation of neither CSNs nor TP-CSN EEs had significant effects ($P > 0.05$) on oxidative rancidity. However, there was a slight decrease in POV and TBARS values (Figure 5b) with increasing CSN concentrations. This result suggests that the oxygen barrier was improved with increasing CSN concentration, possibly due to lower oxygen permeability of the nanoparticles and larger size of the aggregates at the surface (Figure 3b).[41] In addition, the reduction of moisture content (data not shown) would also reduce the film's permeability to oxygen.[2]

In summary, we prepared gelatin films incorporated with different free/encapsulated TP ratios through the fabrication of CSNs with three different EEs. The reduced oxidation of sunflower oil suggests that the incorporation of TP in chitosan nanoparticle form can improve the antioxidant effects of gelatin films. There may be an optimum partition of free and encapsulated TP to control oil oxidation over a long term (6 weeks) without compromising the basic physicochemical attributes of gelatin films. The results found in this study can be used in better designs of active edible film/packaging systems.

from non-milk protein samples. In addition, detailed differences between milk and non-milk proteins were demonstrated by PCA and partial least-squares-discriminant analysis (PLS-DA) using all 15 mole ratios of amino acids. This approach may provide a scientific foundation toward developing an effective nontargeted adulteration detection of foreign protein in milk and maybe other dairy products.

MATERIALS AND METHODS

Materials and Chemicals. Raw milk samples were respectively collected in local dairy farms from Shandong province (192 samples) and Shanghai suburbs (171 samples) during May 2012−May 2013. Between 0.3 and 1 L of milk was collected for each sample. All milking cows were of the Holstein breed. The samples were freeze-dried once transferred to the laboratory, and the dry milk powders were stored in zip-lock bags at −20 °C. Each dried milk powder weighed between 30 and 130 g. The dried milk powders were mixed by shaking the zip-lock bags. Other non-milk protein powders were byproducts from food-processing factories. Whey protein was purchased from Aocheng Trading (Zhuhai, Guangdong, China). Peanut protein was provided by Changshou Food (Qingdao, Shandong, China). Corn 1, corn 2, soy, fish, egg yolk, beef extract, collagen, and cattle bone proteins were provided by Yuantai Biotech (Shanghai, China). Among the non-milk protein powders, six (whey, fish, egg yolk, beef extract, collagen, and cattle bone) were made from animals and the other four (corn 1, corn 2, soy, and peanut) were from plants. The infant formula powder purchased from a local grocery store was used as a reference sample of processed milk product.

Water was purified using a Milli-Q Advantage A10 system (EMD Millipore, Darmstadt, Hesse, Germany). HPLC grade acetonitrile was purchased from Merck KGaA (Darmstadt, Hesse, Germany). The mixed amino acid standard AccQTag Ultra (ATU) eluent A and B and ATU derivatization kit were purchased from Waters Corp. (Milford, MA, USA). Other amino acid standards used in the recovery test were purchased from Sigma-Aldrich (St. Louis, MO, USA). Analytical grade hydrochloric acid was purchased from Linfeng Chemical Reagent (Shanghai, China). Other chemicals or solvents were of the highest commercial grade and used without further purification.

Sample Preparation. Each dried milk powder (30 mg) was hydrolyzed directly with 10 mL of 6 M hydrochloric acid by a Discover SP-D pressurized microwave digestion system (CEM, Matthews, NC, USA). The power was 200 W. The ramp time and the cooling time were 15 and 20 min, respectively. The high prestirring was 15 s, with a temperature of 160 °C and a pressure at 250 psi. After hydrolysis, the samples were mixed for 15 s using a vortexer. Then, 0.4 mL hydrolysates were evaporated using a Buchi R-215 rotary evaporator (Flawil, St. Gallen, Switzerland) and redissolved in 0.5 mL of water. The solution was filtered through a 0.22 μm membrane filter (ANPEL Scientific Instrument, Shanghai, China).

The Waters ATU derivatization kit was used for precolumn sample derivatization. The borate buffer (70 μL), the hydrolysates (10 μL), and the reconstituted reagent (20 μL) were sequentially added to a vial. The solution was mixed using a vortexer for 5 s and allowed to stand for 1 min at room temperature. Then, the solution was immediately transferred into an oven and heated at 55 °C for 10 min. The solution was stored at 4 °C and subjected to UPLC analysis.

UPLC Analysis. The concentrations of 17 amino acids, including histidine, serine, arginine, glycine, aspartic acid, glutamic acid, threonine, alanine, proline, cysteine, lysine, tyrosine, methionine, valine, isoleucine, leucine, and phenylalanine, were quantified. Three amino acids, tryptophan, asparagine, and glutamine, were not quantified. Tryptophan decomposed, and asparagine and glutamine were respectively converted to aspartic and glutamic acids under acidic conditions during hydrolysis. Cysteine, due to its low concentration, was excluded from further data analyses. The hydrolysates were analyzed by using a Waters Acquity H-class UPLC system equipped with a photodiode array (PDA) detector. A Waters ATU C18 column (2.1 mm i.d. × 100 mm, 1.7 μm) was used. The column temperature was 43 °C, and the sample manager temperature was 20 °C. A quaternary solvent system including ATU solvent A (A), 10% (v/v) ATU solvent B (B), water (C), and ATU solvent B (D) was applied. The gradient elution program is listed in Table 1. The flow rate was 0.5 mL/min. The injection volume was 1.0 μL. The PDA detection wavelength was 260 nm. All samples were analyzed in a random order. Triplicate measurements were performed for each hydrolysate, and the mean concentrations were used for further statistical and chemometric analyses. The concentrations of calibration standards were 0.03, 0.05, 0.10, 0.25, 0.50, and 1.00 mmol/L for all amino acids.

Univariate Data Analysis. Univariate analysis classifies milk and non-milk protein powders using a single variable. The chromatographic peak areas were integrated by Empower 3 software (Waters) using a traditional integration algorithm with peak width at 10 and threshold at 300. Manual identification of amino acid peaks was performed after integration. The results were reported as millimoles of each amino acid per gram of dry milk powder. To reduce undesired variances introduced by protein concentration variances between samples, sample moisture, preprocessing, and injection, etc., the relative mole ratios were applied. Mole ratios of individual amino acids to glutamic acid, the most abundant amino acid in milk protein, were calculated for each sample. The sample was classified as a non-milk protein if the relative mole ratio of an amino acid to glutamic acid was outside the 99.7% confidence boundaries of the milk mean value. The boundaries represent the mean ratio ± 3 times the standard deviation.

Chemometric Data Analysis. The relative mole ratio data were processed with multivariate chemometric data analysis methods using a MATLAB R2013b (The MathWorks, Inc., Natick, MA, USA) in-house program. PCA and PLS-DA were performed by the "svd" and "plsregress" (available in statistics toolbox) MATLAB functions, respectively. The data were preprocessed by autoscaling (mean-centering and scaling to unit variance). Typically in PLS-DA, data are divided as training set for building the model and test set for quantitative validation of model. In this study, two-thirds of the samples were divided into a training set (249 samples), and the rest were put into an independent test set (124 samples). The test set included three non-milk samples, which were peanut, corn 2, and beef extract proteins. The milk and non-milk protein samples were coded "1" and "0" in the response variable, respectively.

RESULTS AND DISCUSSION

Method Development. A milk sample was selected randomly for method development. The hydrolysis is an important step that may influence the accuracy and precision when the amino acid concentration is quantified. The ramp time and the container used for hydrolysis were optimized. Three ramp times including 15, 30, and 40 min were compared. There is no significant difference between the hydrolysis effectiveness between 15 and 30 min of reaction, whereas 40 min of hydrolysis resulted in significantly lower amino acid contents, indicating a possible decomposition of amino acids with longer heating. A 15 min ramp time for hydrolysis was

DOI: 10.1021/acs.jafc.5b00702
J. Agric. Food Chem. 2015, 63, 3996−4002

selected for further study. In addition, the 10 and 25 mL hydrolysis vessels in the microwave digestion instrument were compared. There was no significant difference between the analysis results using both vessels, and the 25 mL vessel was employed for subsequent analyses.

The UPLC method was developed on the basis of the procedure recommended by Waters. The method was validated for linearity, repeatability, and stability. The correlation coefficients for all amino acids were >0.98 (Table 2). The limit of detection (LOD) and limit of quantification (LOQ) were determined using a chromatogram of amino acid standard at 12.5 μmol/L by comparing the peak height with the height of the surrounding baseline noise. LOD and LOQ were 0.63 and 2.50 μmol/L for all amino acids, respectively. The linearity ranges were 0.01−1.00 mmol/L for all amino acids. For intra- and interday precision evaluations, all samples were independently sampled and hydrolyzed. The intraday precision was calculated by four samples, and the interday precision was measured over two consecutive days with three samples each day. All intra- and interday variations were <25% other than that of aspartic acid (Table 2). The recovery test was performed at concentration levels of 80, 100, and 120%. The recoveries for all amino acids were >80% except that of histidine and lysine (Table 2).

UPLC Chromatograms. The representative UPLC amino acid chromatograms are plotted in Figure 1. The chromatograms were plotted sequentially toward the top-right corner for better demonstration. 6-Aminoquinoline (AMQ) was a by-product of derivatization. All amino acid peaks were baseline separated and eluted within 9 min. Glutamic acid, proline, and leucine had the highest concentrations among the 16 quantified amino acids in the milk powders. The reported amino acid concentrations were in good agreement with that obtained from previous work using the conventional heating hydrolysis method.[12] The tested non-milk proteins had unique profiles of amino acids. For instance, there was a significantly higher amount of glycine in the collagen. Table 3 lists the relative mole amino acid ratios of the milk and non-milk proteins. Each protein material had a characteristic set of amino acid compositions. For example, beef extract, cattle bone, and collagen had a high concentration of glycine; egg yolk had high ratios of aspartic acid and serine. The amino acid ratios were different for proteins from different biological sources, consistent with previous findings in other food products such as in rice wines and liquors.[13,14] Due to the limited amount of non-milk proteins, these data alone may not be suitable for predicting other proteins outside the scope of this study. However, because these fingerprints exhibited significant dissimilarities from one another, it can be assumed that other

unknown proteins outside this study may also have unique amino acid fingerprints. To establish objective, quantitative, and detailed criteria for differentiation, both univariate and multivariate data modelings were performed.

Univariate Analysis of Milk and Non-milk Proteins. The confidence boundaries are reported in Table 3. The differentiation results by univariate analysis are reported in Table 4. Generally, confidence boundaries calculated from

different amino acid ratios yielded significantly different correct identification rates for non-milk proteins. From the 15 confidence boundaries of amino acid ratios calculated, only the alanine to glutamic acid ratio correctly classifies all 10 non-milk proteins (Table 4). The confidence boundaries calculated by the mole ratio of arginine, glycine, or aspartic acid to glutamic acid yielded 90% correct identifications for non-milk protein samples. On the contrary, mole ratios of tyrosine, methionine, valine, isoleucine, and phenylalanine to glutamic acid yielded poor abilities in distinguishing milk and non-milk proteins (Table 4). In particular, only one non-milk protein was differentiated according to that of tyrosine. To conclude, the confidence bounds calculated from the mole ratios of alanine, arginine, glycine, and aspartic acid to glutamic acid were able to differentiate milk and non-milk proteins with at least 90% correct identification. However, other amino acid ratios, including histidine, serine, threonine, proline, lysine, tyrosine, methionine, valine, isoleucine, leucine, and phenylalanine to glutamic acid, were unable to be used alone as differentiation criteria. The selection of amino acid ratios greatly influenced the classification results in the univariate analysis approach. Therefore, the multivariate techniques PCA and PLS-DA were used in an attempt to better classify samples as milk or non-milk. The multivariate methods use latent variables constructed from combinations of the original variables (amino acid mole ratios) to extract additional information from the data set.

PCA of Milk and Non-milk Proteins. PCA is a mathematical approach that is able to transform the high-dimensional multivariate data into a lower number of dimensions. Figure 2 is the principal component (PC) scores and loading plots for milk and non-milk powders using all amino acid composition ratios. The first and second PCs that explain the top two largest percentages of total variances were plotted. The data points representing milk samples form a defined cluster, and the infant milk powder was inside this cluster (Figure 2A). Contrarily, data points representing non-milk proteins were positioned relatively outside the cluster of milk samples, suggesting that the amino acid compositions of milk samples measured by this method were unique compared to the non-milk proteins. In comparison with the univariate method, PCA could avoid the selection of amino acid ratios and yielded a direct plot for differentiation. The amino acid fingerprints contain much quantitative information on amino acid composition, and PCA conveniently combines and presents all of this information altogether.

Besides the differentiation of milk and non-milk proteins, the relationships between different non-milk proteins can also be studied by PCA to examine whether the sampling of the non-milk proteins was unbiased. All non-milk proteins were located in the lower region of Figure 2A. Although the model was

DOI: 10.1021/acs.jafc.5b00702

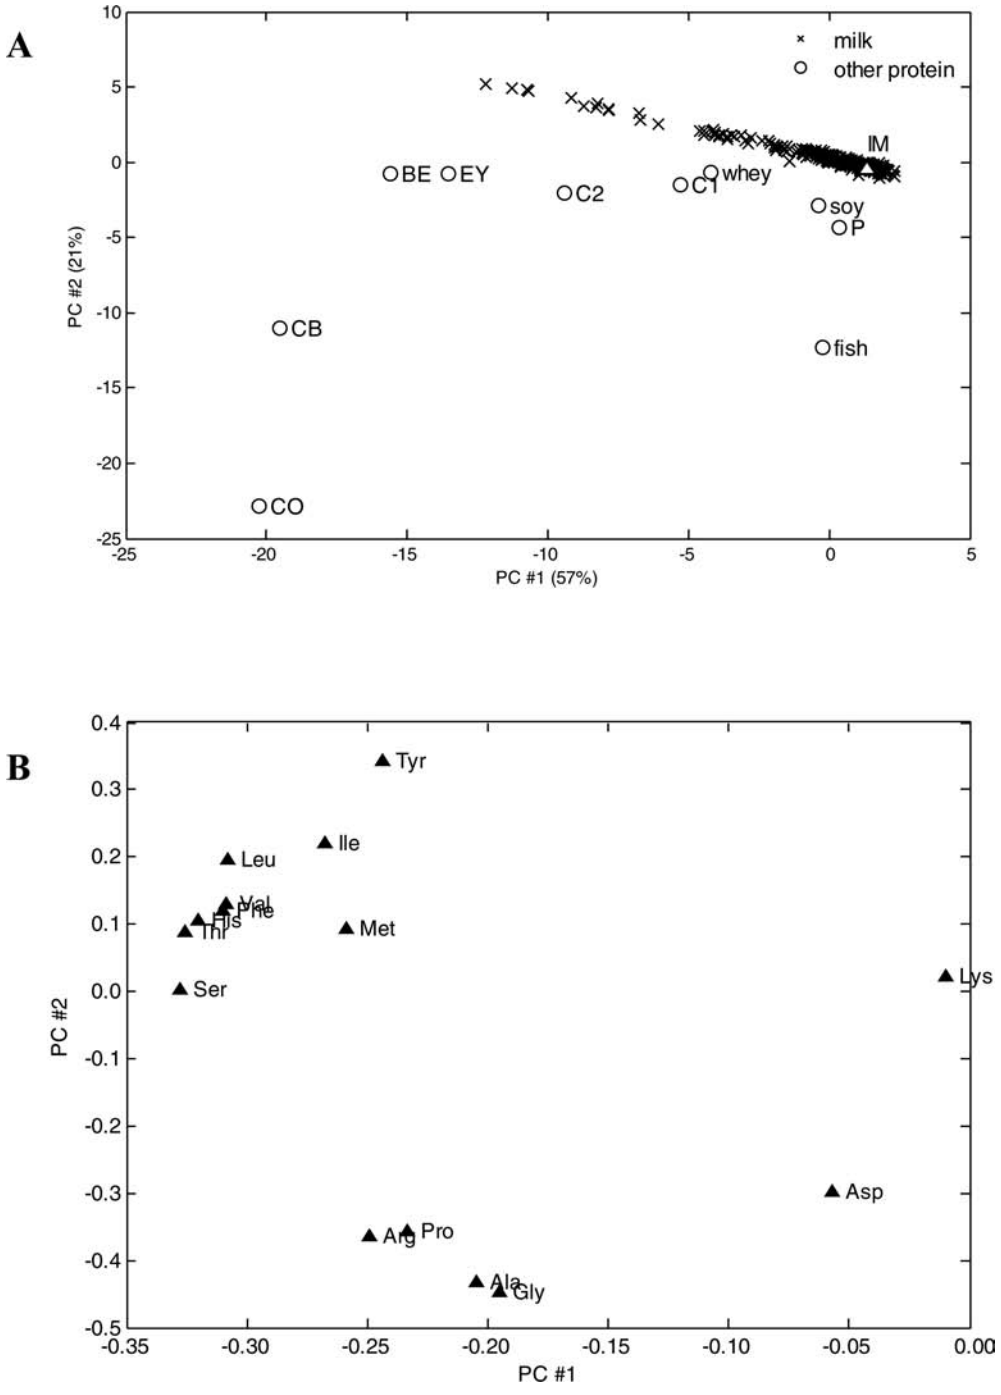

Figure 2. Principal component scores (A, top) and loading (B, bottom) plots for all milk and non-milk proteins. IM, infant milk; C1, corn 1; C2, corn 2; P, peanut; EY, egg yolk; BE, beef extract; CB, cattle bone; CO, collagen.

calculated from only 10 foreign protein samples, these samples spanned a much larger region than 363 milk samples, suggesting a large diversity in the amino acid compositions from different sources of proteins. The diversities in non-milk protein powders indicated that the sampling of the non-milk proteins was unbiased. Among these samples, whey protein was the nearest to milk, probably because whey is a major protein in milk. The plant proteins including corn, soy, and peanut proteins were clustered closely, in comparison with the animal proteins including beef, cattle bone, collagen, and egg yolk, which spanned a wider area. The fish protein was not located in either cluster. The tested animal proteins were generally farther away from the milk samples compared with the plant proteins.

The relative importance of each amino acid ratio for differentiation could be obtained from the loading plot (Figure 2B). According to the loading of the second PC, the mole ratios of tyrosine to glutamic acid were typically high in the milk samples, whereas the ratios of arginine, proline, alanine, glycine, and aspartic acid to glutamic acid were high in the non-milk samples, especially the animal proteins. The conclusion was consistent with the data in Table 4, which reported at least 70% correct prediction by any one of these amino acid ratios. It was also consistent with a previous study that reported aspartic acid,

DOI: 10.1021/acs.jafc.5b00702
J. Agric. Food Chem. 2015, 63, 3996−4002

proline, and alanine were marker amino acids to differentiate non-fat dry milk protein and whey protein.[15] Compared with previous IR spectroscopic studies with multivariate analysis,[6,7,10] spectroscopic methods are superior in analysis time and ease of application. However, the amino acid fingerprints furnish fewer variables and a compact data set, thus obtaining a simple differentiation model. Also, each coefficient in the amino acid fingerprint model can be clearly explained by the amounts of specific amino acid in the sample, in contrast with the IR spectroscopy where significant chemical variances appeared in different milk powders.[10,16] Consequently, the amino acid model might be less influenced by instrumental, environmental, or other sources of variances. In summary, PCA of UPLC amino acid fingerprints is able to demonstrate the differences of all milk and non-milk proteins, as well as to investigate the detailed relationships among non-milk proteins according to the PC scores plot without the selection of any particular amino acid.

PLS-DA of Milk and Non-milk Proteins. PLS-DA is a widely applied modeling technique.[17,18] It was applied to quantitatively evaluate the multivariate differentiation approach. Figure 3 demonstrated the percent of variance explained in the response variable of the training set with respect to PLS-DA models calculated by different numbers of latent variables. In this study, the minimum number of latent variables was determined to be the number required to reach >90% of variances explained in the response variable; meanwhile, the percent variances did not increase greatly with further addition of latent variables. From Figure 3, six latent variables that explained 91.1% of the variance in the response variable were chosen for PLS-DA modeling. All 124 samples in the test set were correctly differentiated as containing milk or non-milk proteins, consistent with the PCA result. Table S1 in the Supporting Information is the number of PLS-DA misclassifications in the test set with respect to different numbers of latent variables. It can be observed that the PLS-DA models built by 5−15 latent variables performed equally in prediction. The predicted and measured responses of the test set by PLS-DA with six latent variables are presented in Figure S1 in the Supporting Information.

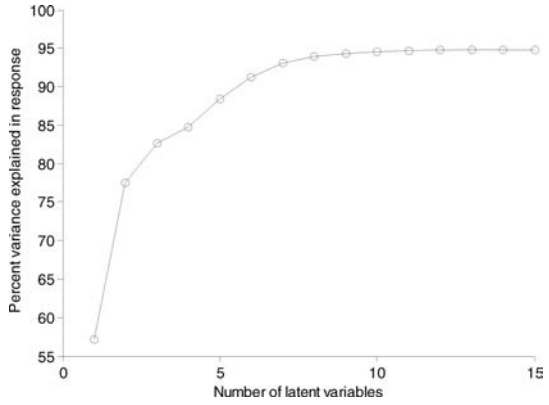

Figure 3. PLS-DA-explained variance plot.

Comparison of the uni- and multivariate approaches shows that the univariate approach offered intuitive confidence ranges. However, different amino acid ratios yielded different differentiation capabilities. Consequently, careful and thorough research about the selection of amino acids in a larger sample set in univariate approaches is necessary before actual application. The multivariate approaches such as PCA and PLS-DA build robust and informative models, although they depend on relatively complicated and specialized data-processing techniques. Both PCA and PLS-DA approaches were able to differentiate all non-milk protein samples from milk protein samples using the amino acid fingerprints. PCA was able to achieve a graphical overview of the relationships between different groups of samples. In PLS-DA, with the additional separation of data into training and test sets, the differentiation could be performed automatically and quantitatively.

In summary, amino acid fingerprinting combined with univariate or multivariate data analyses successfully differentiated milk protein from inexpensive non-milk protein powders. Amino acid fingerprints and chemometric techniques could be potentially developed as a nontargeted foreign protein detection technique for detecting milk adulteration.

Table 1. Main *n*-Alkane and Triterpenoid Components of Cuticular Waxes and Predominant Cutin Monomers Reported in Fruit Species According to Botanical Family

botanical family	fruit type	ripening type	predominant wax components		predominant cutin monomers	refs
Solanaceae						
tomato (*Solanum lycopersicum*)	berry	climacteric	*n*-hentriacontane (C_{31})	triterpenoid alcohols (*α*-, *β*-, and *δ*-amyrin)	C_{16} monomers (10,16-dihydroxy $C_{16:0}$)	69, 71−80, 134
pepper (*Capsicum* sp.)	berry	nonclimacteric	*n*-hentriacontane (C_{31})	triterpenoid alcohols (*α*- and *β*-amyrin)	C_{16} monomers (9(10),16-dihydroxy $C_{16:0}$)	81, 82, 84
eggplant (*Solanum melongena*)	berry	nonclimacteric	*n*-hentriacontane (C_{31})	triterpenoid alcohols (*α*- and *β*-amyrin)	not reported	82
wild tomato (*Solanum* Sect. *Lycopersicon*)	berry	climacteric	*n*-hentriacontane (C_{31}) (in most species studied)	triterpenoid alcohols (*α*-, *β*-, and *δ*-amyrin)	C_{16} monomers (10,16-dihydroxy $C_{16:0}$)	79
Rosaceae						
apple (*Malus* × *domestica*)	pome	climacteric	*n*-nonacosane (C_{29})	triterpenoid acids (ursolic acid)	C_{18} monomers (tetrahydroxy $C_{18:0}$)	60, 85−89
Asian pear (*Pyrus bretchneideri*)	pome	climacteric	*n*-nonacosane (C_{29})	triterpenoid alcohols (*α*-amyrin)	not reported	90
peach (*Prunus persica*)						
melting	drupe	climacteric	*n*-tricosane (C_{23}) *n*-pentacosane (C_{25}) *n*-heptacosane (C_{27})	triterpenoid acids (ursolic acid, oleanolic acid)	C_{18} monomers (*ω*-hydroxy $C_{18:1}$)	92
nonmelting	drupe	climacteric	*n*-pentacosane (C_{25})	triterpenoid acids (ursolic acid)	C_{18} monomers (*ω*-hydroxy $C_{18:1}$)	91, 92
plum (*Prunus domestica*)	drupe	climacteric	*n*-nonacosane (C_{29})	triterpenoid acids (oleanolic acid)	not reported	135
strawberry (*Fragaria* × *ananassa*)	etaerio	nonclimacteric	not reported	not reported	C_{16} monomers (9(10),16-dihydroxy $C_{16:0}$)	62
sweet cherry (*Prunus avium*)	drupe	nonclimacteric	*n*-nonacosane (C_{29})	triterpenoid acids (ursolic acid)	cultivar-dependent (dihydroxy $C_{16:0}$ or dihydroxy $C_{18:x}$ reported mainly)	3, 93, 94
black chokeberry (*Aronia melanocarpa*)	berry	nonclimacteric	not reported	not reported	C_{18} monomers (*ω*-hydroxy-9,10-epoxy $C_{18:1}$ and *ω*-hydroxy-9,10-epoxy $C_{18:0}$)	62
cloudberry (*Rubus chamaemorus*)	syncarp	nonclimacteric	not reported	not reported	C_{16} monomers (74% of 9(10),16-dihydroxy $C_{16:0}$)	62
raspberry (*Rubus idaeus*)	syncarp	climacteric	not reported	not reported	C_{16} monomers (9(10),16-dihydroxy $C_{16:0}$)	62
rosehip (*Rosa rugosa*)	etaerio	nonclimacteric	not reported	not reported	C_{16} monomers (79% of 9(10),16-dihydroxy $C_{16:0}$)	62
rowanberry (*Sorbus aucuparia*)	po*μ*e	nonclimacteric	not reported	not reported	C_{16} monomers (9(10),16-dihydroxy $C_{16:0}$)	62
Rutaceae						
grapefruit (*Citrus* × *paradisi*)	hesperidium	nonclimacteric	detailed composition not reported		C_{16} monomers (*ω*-hydroxy-10-oxo $C_{16:0}$)	61, 64, 96, 98
lemon (*Citrus limon*)	hesperidium	nonclimacteric	*n*-hentriacontane (C_{31}) *n*-nonacosane (C_{29})	not reported	C_{16} monomers (dihydroxy $C_{16:0}$ and *ω*-hydroxy-oxo $C_{16:0}$)	64, 98
mandarin (*Citrus reticulata*)	hesperidium	nonclimacteric	detailed composition not reported		C_{16} monomers (dihydroxy $C_{16:0}$ and *ω*-hydroxy-oxo $C_{16:0}$)	64, 97, 98
orange (*Citrus sinensis*)	hesperidium	nonclimacteric	*n*-hentriacontane (C_{31}) *n*-nonacosane (C_{29})	triterpenoid alcohols (*α*- and *β*-amyrin)	C_{16} monomers (dihydroxy $C_{16:0}$ and *ω*-hydroxy-oxo $C_{16:0}$)	64, 95, 98
Vitaceae						
grape (*Vitis vinifera*)	berry	nonclimacteric	*n*-pentacosane (C_{25}) *n*-heptacosane (C_{27}) *n*-nonacosane (C_{29})	triterpenoid acids (oleanolic acid)	not reported	65, 66, 99−102
Oleaceae						
olive (*Olea europaea*)	drupe	nonclimacteric	*n*-heptacosane (C_{27})	triterpenoid acids (oleanolic acid)	not reported	105

more elastic.[2] Some of these properties are also dependent, at least to some extent, upon the external conditions to which the plant organ is exposed, particularly temperature and humidity.[13−15]

The composition and biosynthesis of cutin[7,16] and cuticular waxes,[9,17−19] cuticle permeability properties,[20−22] and cuticle and cutin biomechanics[2,23,24] have been covered in published reviews and will not be addressed here in detail. However, because the majority of work investigating cuticle biosynthesis and composition has been conducted on vegetative plant tissues and, in contrast, little information is available in relation to the epidermis of fruits, this review adds a further perspective to the current knowledge of the roles of cuticle in plant development. The minimization of water loss has been generally considered the main function of the fruit cuticle, but there is ample experimental evidence that, in addition to water-proofing, it may also play a major role in modulating protection against biotic and abiotic factors, fruit appearance, and textural properties, thus significantly affecting major traits related to postharvest quality.[25] The preservation of all these functions requires structural integrity of the cuticle throughout fruit expansion and development, meaning that a finely tuned mechanism to control cuticular composition and structure must also be a part of the developmental program. Despite their physiological relevance in determining fruit quality attributes and the economic implications of their maintenance throughout the commercial production and distribution chain of fruit, significant questions remain to be answered, including the mechanisms of cuticle biosynthesis and the specific wax and cutin (Table 1) composition of fruit cuticles. This paper reviews currently available information on the specific composition and biochemical changes in cuticles during maturation and ripening of fruits. Such knowledge may help frame putative cuticle impacts when the developmental process of a given fruit is to be investigated.

PATHWAYS AND REGULATION OF CUTICLE BIOSYNTHESIS: A BRIEF OVERVIEW

Fatty acids are precursors for both cutin and wax biosynthesis. These fatty acid precursors are thought to be synthesized de novo in plastids as the result of fatty acid synthase (FAS) activity, which involves, sequentially, the condensation of acetyl CoA with malonyl-acyl carrier protein (ACP), the reduction of 3-ketoacyl-ACP, the dehydration of 3-hydroxyacyl-ACP, and finally the reduction of *trans*-Δ^2-enoyl-ACP.[19,26,27] This fatty acyl primer is further extended by repeated condensations, thus yielding long-chain fatty acids (C_{16} and C_{18}). The precursors for wax production are mainly saturated fatty acids (C_{16} and C_{18}), whereas cutin is a polymer of predominantly $C_{16:0}$ and $C_{18:x}$ hydroxy fatty acids,[6] and hence the partitioning of these long-chain fatty acid precursors into wax or cutin biosynthesis pathways is likely to be a key regulatory point controlling the amount and specific composition of these two types of cuticle lipids.

Whereas de novo fatty acid biosynthesis is ubiquitous, cutin is synthesized exclusively by epidermal cells. Current understanding of the specific pathway that leads to the production of cutin monomers was established essentially 40 years ago by Kolattukudy and co-workers through studies on apple and *Vicia faba* leaves,[6,28] but many remaining knowledge gaps[29,30] still preclude a comprehensive understanding of the biosynthesis and polymerization of cutin monomers including the polymerization site itself, the monomer transport mechanisms, and the enzymes involved in their assembly. Even so, two recent papers have shed some light on these aspects by identifying an acyltransferase responsible for cutin polymerization in fruit cuticles of a range of *Solanum* species.[31,32] The necessary hydroxylation (at both internal and terminal positions) and epoxydation reactions are catalyzed by enzymes showing typical characteristics of the cytochrome P450 (CYP) enzyme family, among which the CYP77A, CYP86A, and CYP94B subfamilies comprise members that catalyze the hydroxylation either at midchain positions or at the terminal methyl group (ω-hydroxylases) on aliphatic fatty acid chains.[33−37] An effective function in cutin biosynthesis has been confirmed for some fatty acid ω-hydroxylases through the physiological and biochemical characterization of the corresponding mutants.[38] Distinctive substrate specificities[39,40] and expression patterns in response to environmental conditions[41] have been revealed, too. Long-chain acyl-CoA synthetases (LACS) are also required for cutin production,[42] indicating that these precursors need to be activated (CoA-bound) prior to the establishment of the cutin network. The ω-hydroxyl groups in the monomers form ester bonds, whereas a variable portion of the midchain hydroxyl groups is involved in ester-type cross-links, thus giving rise to and holding together the final polymeric complex.[7,16] The establishment of these ester linkages is catalyzed by acyltransferases, which transfer the activated cutin monomers to the free hydroxyl groups present in the cutin polymer[28] in a reaction purported to require ATP and a cutin primer, and indeed two glycerol-3-phosphate acyltransferases, GPAT4 and GPAT8, have been proved necessary for cutin assembly.[43] Phenolic esters such as those of ferulic and *p*-coumaric acids also contribute, although to a minor extent, to the establishment of the cutin polymer.[44]

Because genetic and external factors are known to cause changes in the amount and composition of wax, a strict regulation of the underlying biosynthetic pathways is to be expected. The characterization of mutants with deficient or altered wax coatings has contributed to shedding light on wax biosynthesis,[9,45−47] which is likewise restricted to epidermal tissues.[19,48,49] Waxes are often rich in very long-chain fatty acids (VLCFA) esterified to very long-chain alcohols, and hence the elongation of C_{16} and C_{18} fatty acid precursors is required for the synthesis of these wax components. Further extension of C_{16} and C_{18} fatty acids requires ACP elimination by an acyl-ACP thioesterase and activation to fatty acyl-CoA esters, which is catalyzed by long-chain acyl-CoA synthetases.[19,26] Chain elongation is biochemically analogous to de novo synthesis, the four consecutive reactions being catalyzed by ATP-dependent fatty acid elongases (FAE),[18,50−52] which require malonyl-CoA rather than malonyl-ACP as the two-carbon donor. Because elongases catalyze the primary reaction characterizing wax biosynthesis, they have been assigned an essential role in the process and have thus been the object of considerable research effort. The biochemistry and genetics of these elongation systems have been reviewed elsewhere[9,17,19,50,53−55] and will not be considered herein.

In addition to lipids derived from fatty acids, cuticles are also composed of lipids derived from isoprene, which primarily include the triterpenoids present in cuticular waxes. Triterpenoid biosynthesis involves the joining of six isoprene units to yield the hydrocarbon precursor squalene, which is then activated into 2,3-epoxysqualene and then cyclized. The cyclization of 2,3-epoxysqualene represents the first committed step in triterpenoid biosynthesis, which is carried out by oxidosqualene cyclases (OSCs). The diversity of existing OSCs and the large range of possible rearrangements they can catalyze eventually result in a great diversity of triterpenoid structures even though they start from the same substrate.[56]

Wax and cutin secretion to organ surfaces is also a key aspect of cuticle formation, because these lipophilic compounds must be exported from the cytoplasm after biosynthesis, cross the hydrophilic apoplast, and finally be assembled. The delivery to the outer tissues apparently involves lipid transfer proteins (LTP), which are expressed in plant epidermal tissues and secreted to the outside of the cell wall and cuticle.[17,18,57,58] Some members of the ATP-binding cassette (ABC) transporter family have been actually demonstrated to be required for cuticular lipid secretion.[19,59]

THE FRUIT CUTICLE: ARE ALL SPECIES EQUAL?

Many studies on chemical composition of cuticles have been published taking as a model leaves and other plant vegetative tissues. The significant differences observed for over 40 years in cuticle composition of different organs of the same plant, regarding both cutin[60−63] and waxes,[64−66] provide clear evidence that the assumption that fruit cuticle composition can be inferred from that of leaves cannot be sustained.

Taking tomato as a model species, for example, published information on the composition of cuticular waxes and cutin monomers supports the existence of such differences. Noticeable differences in total wax and cutin loads have been observed between fruits and leaves of the 'Micro-Tom' cultivar.[67−69] Total cutin load was reported to amount to 2.5 μg cm^{-2} in leaves[68] and to as high as 586.1 μg cm^{-2} in fruits.[69] Such quantitative differences were found for cuticular waxes as well: total loads of 3.5 and 15 μg cm^{-2} were reported for leaves and fruits, respectively,[67] although total wax amount in fruits of the same cultivar has been recently shown to reach even higher values.[69] More importantly, substantial compositional differences have been also observed between leaves and fruits, in addition to differences in total wax and cutin loads. For waxes, the main compositional differences were found for the percentage of branched alkanes (approximately 22 vs. 8% of total cuticular waxes in leaves and fruit, respectively), whereas the percentages for *n*-alkanes and triterpenoids were similar in both cases,[67,69] and significant amounts of alcohols and fatty acids were found for fruit cuticles.[69] As to cutin monomers, the chief differences in composition between leaves and fruits referred to the amount and type of hydroxy-acids and to the percentage of dicarboxylic acids.[68,69]

Tomato fruit cuticles provide a valuable model for fruit cuticle research, as they are astomatous and comparatively thick, which means that it is possible to isolate considerable amounts of "unperforated" material for biochemical, physical, or structural characterization.[70] Albeit less intensively, cuticles of some other fruit species, mostly corresponding to crops of economic relevance, have also been investigated and revealed significant differences across genotypes in their properties. Because fruit cuticles modulate several traits of economic importance,[25,70] the understanding of the functions and impact of this outer layer on quality, storage potential, and shelf life of produce will require its characterization as a preliminary step.

To highlight interspecific differences in the chemical composition of fruit cuticles, the following subsections review published literature to reveal the variation in the main components of cutin and waxes that exists across different fruit types. With the purpose of revealing possible compositional similarities within fruits of species related taxonomically, this information has been organized according to botanical families. The many unknowns still existing in relation to fruit cuticle composition are highlighted in the summary of available information for each listed fruit species presented in Table 1.

Solanaceae. *Tomato (Solanum lycopersicon).* The cuticle composition of tomato, widely used as a model species for research related to different aspects of fruit development, has been investigated with considerably more intensity in comparison with other fruit species. Cuticular waxes of the 'Micro-Tom' cultivar consist predominantly of very long-chain alkanes and triterpenoids.[67,69,71] The C_{31} alkane *n*-hentriacontane was prevalent in the epicuticular wax film, whereas in the intracuticular wax compartment it was mixed with the pentacyclic triterpenoid alcohols α-, β-, and δ-amyrin. For the 'Ailsa Craig' cultivar, a similar composition of cuticular waxes was reported,[72] 55−60% of the total amount consisting of *n*-alkanes, among which *n*-hentriacontane was also shown as the most abundant, followed by *n*-nocacosane (C_{29}) and *n*-tritriacontane (C_{33}). Amyrins (α, β, and δ) together accounted for about 18% of wax components in this cultivar. When the cutin composition was analyzed, the C_{16} cutin monomer 10,16-dihydroxy $C_{16:0}$ acid was found to account for about 74% of total monomers. The prevalence of *n*-hentriacontane, amyrins, and 10,16-dihydroxy $C_{16:0}$ acid in the composition of tomato cuticles was confirmed in subsequent studies on 'Ailsa Craig',[73−77] 'M82',[76−79] and 'John Baer' and 'Pearson'.[80] However, when cuticles of seven different species of wild tomato were analyzed, substantial diversity in the microscopic morphology of the cuticle and the underlying epidermal cell layer, as well as in the content of cutin and waxes, was found.[79] The cuticular wax content of the wild species surpassed that of

DOI: 10.1021/acs.jafc.5b00013
J. Agric. Food Chem. 2015, 63, 4005−4019

cultivated tomato by up to 7-fold, and variability in the amount of wax esters and triterpenoid isomers was also found. It can be speculated that selection for this species has favored a particular cuticle composition that may be associated with more favorable agronomic characteristics.

Pepper (Capsicum sp.). Kissinger and co-workers[81] examined the cuticles of 10 *Capsicum* sp. cultivars differing in quality attributes such as pungency and fruit size. Globally, the cuticle was found to be particularly rich in C_{16} cutin monomers, the main component in quantitative terms being 9(10),16-dihydroxyhexadecanoic acid, whereas 9,10-epoxy-18-hydroxyoctadecanoic acid was the main representative of the C_{18} monomer type. The major aliphatic constituents of cuticular waxes were *n*-alkanes, in which *n*-hentriacontane was the predominant single compound. Significant amounts of methyl-branched alkanes and of the triterpenoids α- and β-amyrin were also detected. A concurrently published study on 12 bell pepper cultivars also identified *n*-hentriacontane and triterpenoid alcohols as the dominating wax components in these fruit.[82] A later work also disclosed that pepper fruit cuticles contain a cutan-like fraction.[83] More recently, the cuticle lipid composition in a near-isogenic backcross population (BC_2F_2) obtained between an inbred line of *C. annuum* and a wild line of *C. chinense*, which markedly differ in postharvest water loss rates, has been analyzed.[84] Interestingly, the major components of cuticular waxes and cutin were the same as mentioned above,[81] but significant differences in absolute and relative amounts within wax classes and cutin monomers were found between the parents and among the segregating BC_2F_2 population. Such approaches are needed for other fruit species, particularly when quality at harvest and during postharvest is affected by phenomena related with cuticle dynamics, such as water loss or microcracking. This would help identify metabolic signatures associated with particular physiological traits and quality attributes.

Eggplant (Solanum melongena). The surface waxes of eggplant fruit have been also examined in three cultivars.[82] In this study, waxes were extracted in *tert*-butylmethyl ether and chromatographed through a silica gel column, from which two fractions (termed fractions 1 and 2) were eluted using hexane/toluene and methanol, respectively. For all three cultivars, *n*-alkanes (C_{23}−C_{36}) predominated in fraction 1, which represented 77% of all waxes recovered. The dominating compound in this fraction (up to 18%) was *n*-hentriacontane, followed by *n*-tritriacontane. The triterpenoid components were eluted with fraction 2, amyrins and other triterpenols being the main compound detected, similar to the observations for other species within the Solanaceae family. No information was reported on cutin monomers.

Rosaceae. *Apple (Malus × domestica).* The first reports on cuticle composition of apple fruit date back to the 1970s. Three cultivars ('Dougherty', 'Granny Smith', and 'Sturmer') were studied in relation to the composition of their surface waxes,[85] and it was found that *n*-nonacosane and nonacosan-10-ol were prominent in all three cultivars among the constituent hydrocarbons and secondary alcohols, respectively. In contrast, the main primary alcohols differed among cultivars, with *n*-hexacosanol (C_{26}) predominating in 'Sturmer', whereas *n*-tetracosanol (C_{24}) was the most abundant in 'Dougherty' and 'Granny Smith' fruits. Waxes from 'Sturmer' also differed from the other two cultivars studied in regard to the main fatty acids present, showing a comparatively higher content of hexadecanoic and lower content of octadecadienoic acid. Subsequent studies on other cultivars[86,87] confirmed *n*-nonacosane as the main alkane in apple fruit cuticles, but also provided a broader overview of cultivar-specific variability in wax composition of apple cuticles. The analysis of cuticular waxes of 17 cultivars[86] showed triterpenoids as the dominating wax fraction, ursolic acid accounting for 30−72% of total waxes, and furthermore revealed that secondary alcohols were the most cultivar-specific compounds—more so than primary alcohols—contrasting with previous observations.[85] In addition to *n*-nonacosane, surface waxes of 'Red Fuji' apples included important amounts of nonacosan-10-ol and the ketone nonacosan-10-one.[87] Similar results indicative of cultivar-related variability were reported by other researchers as well.[88,89] In the latter case, the secondary alcohol nonacosan-10-ol was found to be the compound explaining the main differences in surface characteristics of 'Jonagold', 'Jonagored', and 'Elstar' fruit.

With respect to cutin monomers, the C_{18}-hydroxylated class of monomers was found to account for 73% of total cutin monomers in 'Golden Delicious',[60] which was much higher than the amounts in leaves and flower parts from this variety, and it was thus hypothesized that the content of C_{18} monomers was related to the rate of expansion of different organs. This finding emphasizes the need to assess compositional differences between particular tissues, as stated above. When the aliphatic components of apple fruit cuticles were characterized using elemental analysis, ^{13}C nuclear magnetic resonance (NMR), and Fourier transform infrared spectroscopy, they were shown to contain lower percentages of the cutan-like fraction than those of pepper fruit and to display slightly different chemical structure, too.[83]

Pear (Pyrus sp.). Despite the economic importance of the world trade of both European and Asian pears, only the latter have been investigated in relation to cuticle composition and uniquely in regard to their waxes. A total of 54 compounds were identified in the cuticular waxes of 'Pingguoli' Asian pear,[90] the main constituents observed being pentacyclic triterpene alcohols (32%), fatty acids (27.8%), and alkanes (25.9%). The composition of each of these three major compound families was dominated by α-amyrin, hexadecanoic acid, and C_{19}−C_{31} *n*-alkanes, respectively. To the best of our knowledge, there is no published information on the cutin composition of pear cuticles, thus also offering ample field for further research.

Peach (Prunus persica). Surprisingly, very limited research has been reported in regard to the cuticle composition of climacteric stone fruits such as peach, apricot, or plum, despite its potential relevance for water loss and decay susceptibility of these fruit species. Peach skin was taken as a model for studying properties of pubescent surfaces concerning water−plant surface interactions,[91] and cuticle composition was analyzed for the content of the main component types. Peach cuticles were found to be composed of 53% cutan, 27% waxes, 23% cutin, and 1% hydroxycinnamic acids, whereas trichomes contained 15% waxes and 19% cutin, filled with 63% polysaccharide material associated with hydroxycinnamic acid derivatives and flavonoids. Nevertheless, the detailed composition of each of these fractions was not described. We have recently analyzed the composition of waxes and cutin monomers in cuticles isolated enzymatically from melting- and non-melting-type peach fruit[92] and identified the $C_{18:1}$ derivative 18-hydroxyoctadecenoic acid as the most abundant cutin monomer (17−20% at harvest, depending on the cultivar), whereas the triterpenes ursolic acid and oleanolic

DOI: 10.1021/acs.jafc.5b00013
J. Agric. Food Chem. 2015, 63, 4005−4019

acid were prominent among the components of cuticular waxes, accounting together for 44−52% at harvest. In contrast to most published studies on fruit cuticles, in which *n*-nonacosane and *n*-hentriacontane were reported to be the main alkane components of cuticular waxes (Table 1), we identified *n*-tricosane (C_{23}), *n*-pentacosane (C_{25}), and *n*-heptacosane (C_{27}) as the predominant alkanes in peach fruit, with substantial cultivar-related differences in the total content of these compounds (10−24% at harvest).

Sweet Cherry (Prunus avium). Considerably more reports than for peach exist for sweet cherry cuticles, although most of them have been mainly concerned with its physical and mechanical properties as related to water permeability and disorders to which these fruit are particularly prone, such as cracking. An early study on ripe 'Bing' cherries[93] revealed ursolic acid and *n*-nonacosane as prominent components of cuticular waxes of fruit. This was confirmed when the composition of both cutin and waxes of four sweet cherry cultivars was studied during on-tree fruit development and maturation.[3] The most abundant constituents of waxes at fruit maturity were the triterpenes ursolic and oleanolic acids, which together accounted for 76% of total wax, followed by the alkanes *n*-nonacosane and *n*-heptacosane and the secondary alcohol nonacosan-10-ol. These data essentially agree with our own observations on 'Celeste' and 'Somerset' cherries, showing ursolic acid (roughly 50% of total waxes) to be the major triterpene, *n*-nonacosane and *n*-heptacosane the most abundant alkanes (7−11%), and *n*-tricosanol (C_{23}) and *n*-triacontanol (C_{30}) the main primary alcohols detected in cuticular wax.[94] Although these studies agree as to the major components of cuticular waxes in all of the cultivars assessed, they show discrepancies for other types of wax constituents. Specifically, cuticular waxes of 'Bing' cherries are rich in hexadecanoic, octadecanoic, octadecenoic, and octadecadienoic acids and contain significant amounts of sitosterol.[93] Because dehydrated fruit skins were used as the source of wax, when these compounds were not found in a later study,[3] it was concluded that their detection might have been an artifact derived from contamination with membrane lipids. However, the analysis of the cuticular waxes of 'Celeste' and 'Somerset' fruit also revealed significant contents of octadecadienoic acid and phytosterols,[94] despite the fact that enzymatically isolated cuticles were used as the source material for wax extraction. Therefore, these discrepancies are likely to reflect actual cultivar-related differences in cuticular wax composition.

Although published reports have shown only minor quantitative differences in wax composition among cherry cultivars, discrepancies have been found as to cutin monomer composition. The cutin fraction of mature 'Kordia' fruit consisted mainly of C_{16} (69.5%) and, to a much lesser extent, C_{18} (19.4%) monomers, the most abundant components being 9(10),16-dihydroxyhexadecanoic and 9,10,18-trihydroxyoctadecanoic acids.[3] However, we have found that the cutin fraction of 'Celeste' and 'Somerset' cherry fruit is composed mainly of C_{18} monomers (65.3 and 57.9%, respectively),[94] which contrasts with previous observations in this species and shows cultivar-related differences in cuticle composition.

Soft Fruit Species. The composition of the cutin fraction of some berries within the Rosaceae family has been investigated.[62] The cutin composition of strawberry (*Fragaria* × *ananassa*), raspberry (*Rubus idaeus*), and rowanberry (*Sorbus aucuparia*) fruit was shown to be dominated by 9(10),16-dihydroxyhexadecanoic acid, although all three species displayed wider variety of cutin monomers in comparison with non-Rosaceae berry fruits that were analyzed in the same work. A similar cutin composition was observed in rosehip (*Rosa rugosa*), black chokeberry (*Aronia melanocarpa*), and cloudberry (*Rubus chamaemorus*) fruits,[62] although additional compounds such as C_{15} monomers and α,ω-dicarboxylic acids with midchain hydroxyl groups were also found. Additionally, strawberry and raspberry cutin proved to be highly resistant to depolymerization, and this observation was suggested to arise from the presence of a particularly high amount of cutan-type compounds. The cutin/cutan ratio is likely to affect significantly the pre- and postharvest evolution of fruit quality attributes, including their value as a dietary fiber, and this topic is thus worthy of more detailed examination. Similarly, no published studies are available for cuticular wax composition of these species, thus offering ample opportunity for further research.

Rutaceae. *Citrus Fruit (Citrus sp.).* In orange, triterpenoids constitute the most abundant wax fraction found in mature fruits, mainly consisting of α-amyrin, β-amyrin, lupeol acetate, and friedelin.[95] Additionally, aldehydes are also major constituents of the cuticular waxes in orange and lemon fruit, together with alkanes, primary alcohols, and fatty acids. The predominant compounds are reportedly *n*-nonacosane and *n*-hentriacontane among the alkanes and *n*-tetracosanal (C_{24}), *n*-hexacosanal (C_{26}), and *n*-octacosanal (C_{28}) among the aldehydes.[64,95] Terpenoids and aldehydes were likewise reported to be the main compound families present in epicuticular waxes of grapefruit, with some differences observed according to the canopy position,[96] which supports the assumption that the environmental conditions cause cuticle modifications and affect fruit development. In contrast, mandarin fruit waxes are dominated by alkanes, followed by esters > ketones > aldehydes > fatty acids > primary alcohols > triterpenes.[97] The detailed compositions of each of these classes of component were not reported, but some differences were also found according to the canopy position of fruit.

We are aware of only two published studies on cutin components of citrus fruit. The fruit cuticles of four different species (orange, lemon, grapefruit, and mandarin) were reported to contain less cutin (59−67%) than those of their leaves (79−82%).[98] The major monomeric constituents detected were dihydroxy C_{16} (30−62%) and 16-hydroxy-oxo C_{16} acids. Similarly, when the cutin monomer composition was analyzed in different tissues of grapefruit, including fruit peel, leaf, juice sac, and inner seed coat, it was found that 16-hydroxy-10-oxo C_{16} acid was a major component in the fruit peel.[61] Substantial tissue-associated variation was observed, as 10,16-dihydroxy C_{16} acid and its positional isomers were the main cutin monomers in leaves, the composition of the juice sac cutin was dominated by dihydroxy C_{16}, hydroxy-oxo C_{16}, hydroxy-epoxy C_{18}, and trihydroxy C_{18} acids, and ω-hydroxy and dicarboxylic C_{16} and $C_{18:1}$, ω-hydroxy-epoxy C_{18} and trihydroxy C_{18} acids were the major components of the inner seed coat cutin.

Vitaceae. *Grape (Vitis vinifera).* Similarly to citrus fruit, aldehydes have also been found to be important constituents in waxes of grapes, where the straight-chain, even-chain length type predominates. Early in 1965, two published works[65,99] reported that the surface waxes of ripe sultana grapes consist largely of the triterpenoid oleanolic acid, with lesser amounts of *n*-alcohols (mainly C_{24}, C_{26}, and C_{28}), *n*-aldehydes (largely C_{28} and C_{30}), esters, free acids (predominantly C_{24}, C_{26}, and C_{28}), and *n*-hydrocarbons (mainly C_{25}, C_{27}, C_{29}, and C_{31}). A

DOI: 10.1021/acs.jafc.5b00013
J. Agric. Food Chem. 2015, 63, 4005−4019

considerable amount (around 30%) of oleanolic acid was also found in cuticle waxes of 'Palomino fino' grapes,[100] although surprisingly *n*-alkanes represented <5% of total mass and, remarkably, no aldehydes were identified. Oleanolic acid was also the dominant component in cuticular waxes of 'Pinot noir' grapes at all stages of fruit development,[101] as well as in eight different cultivars investigated in a recent study,[102] in which triterpenoid contents were found to range from 42% to as much as 80% of total cuticular waxes. Due to their relevance for fermentative processes and their health-promoting properties,[103] major triterpenes (oleanolic acid and β-sitosterol) in grape waxes have been targeted for study and suggested to be a suitable tool to characterize grape varieties.[104] When the cuticular wax of fruit of the European wild vine (*Vitis vinifera* ssp. *sylvestris*) was analyzed, only minor quantitative differences were found in some of the wax fractions in comparison with the cultivated vine (*V. vinifera* ssp. *vinifera*),[66] suggesting their conservation during evolution.

We are not aware of any published studies on the cutin composition of grape berry cuticles, although the evolution of total cutin amounts during fruit maturation has been reported.[101] Taking into account its commercial importance with regard to both fresh consumption of table grapes and winemaking, further studies addressing this topic are desirable.

Oleaceae. *Olive (Olea europaea).* Because the procedure for olive oil extraction may dissolve an important part of the surface waxes, and given its economic importance, a number of published studies have analyzed wax compounds present in the oil. In contrast, little information is available on the intact fruit. When chloroform-soluble waxes of 'Coratina' olives at the green and black maturity stages were extracted, substantial compositional differences were found in each case.[105] Triacylglycerols (17 and 25% in green and black fruit, respectively) and triterpene acids (38 and 26%, respectively) were the predominant families of wax compounds in the fruit. Triterpenols accounted for 14% of total waxes in green fruit, whereas only traces were detected in ripe samples. The major triterpene in both cases was oleanolic acid (70 and 83%, correspondingly). Similar to the observations in grape (see previous subsection), *n*-alkanes were only a small part of the total wax mass (3 and 7% in green and black fruit, respectively), dominated by C_{27} or C_{29}, depending on the maturity stage.

Ebenaceae. *Persimmon (Diospyros kaki).* The total amount of waxes and cutin in fruit cuticles isolated from 27 astringent and nonastringent cultivars of persimmon has been published recently,[12] although the chemical composition of each fraction was not analyzed in detail. The cuticles of these fruit were composed of 22−38% (337−770 μg cm^{-2}) of wax and 33−56% (578−1378 μg cm^{-2}) of cutin. Whereas significant cultivar-related differences in cuticle composition were found, in agreement with other fruit species, these differences were not related to fruit astringency. Additional studies should enable the determination of which are the quality traits, in each fruit species, that are modulated by cuticle subtleties as well as the mechanisms by which this regulation occurs.

Others: Grossulariaceae, Ericaceae, Elaeagnaceae. No published information is available regarding the cuticular wax composition of soft fruit species within these families, and only the composition of cutin monomers has been analyzed and reported. Studies on six non-Rosaceae berry types, namely, sea buckthorn (*Hippophaë rhamnoides*), black currant (*Ribes nigrum*), cranberry (*Vaccinium oxycoccos*), lingonberry (*Vaccinium vitis-idaea*), bilberry (*Vaccinium myrtillus*), and crowberry (*Empetrum nigrum*), have revealed notable differences in total cutin loads (6−47%) across species.[62,106] The predominant cutin monomers were C_{16} and C_{18} ω-hydroxy acids with midchain functionalities, among which epoxy groups were particularly frequent in sea buckthorn and cranberry (71 and 60% over total cutin monomers, respectively). Cuticles of these fruits also contained significant amounts of C_{15} monomers and α,ω-dicarboxylic acids.

Conclusion. This survey shows that fruit cuticles display considerable variability among species and illustrates the inappropriateness of generalizations on fruit cuticle properties. Yet a complete overview of cuticle constituents is available in only a few instances (Table 1). Although *n*-alkanes and triterpenoids are prominent components of cuticular waxes in all of the fruit species for which such information exists, fruit cuticle types seem to emerge according to their main alkane (C_{29} vs C_{31}) and triterpenoid (triterpenoid acids vs triterpenoid alcohols) components. Some grouping is also apparent according to the predominant cutin monomers (C_{16} vs C_{18}). On the basis of the scarce information currently available, these groupings do not seem to show any correspondence with fruit type (berries vs drupes) or with ripening pattern (climacteric vs nonclimacteric). However, this review reveals clear similarities in fruit cuticle composition among phylogenetically close species (Table 1). For example, the investigated species within the Solanaceae family display C_{31} and triterpenoid alcohols as the main *n*-alkane and triterpenoid components of cuticular waxes, respectively, with dihydroxy $C_{16:0}$ as the predominant cutin monomer. In contrast, C_{29} and triterpenoid acids have been reported as the main wax components in most of the species examined within the Rosaceae, with the predominant cutin monomers displaying wider variation. Cutin composition in the cuticles of citrus fruit is reportedly dominated by C_{16} monomers, whereas insufficient information is available to allow generalizations on predominant wax compounds within this botanical family (Table 1).

Recent studies conducted on *Arabidopsis* have identified proteins specifically involved in the elongation of compounds longer than C_{28} and C_{30}, which are moreover expressed differentially in an organ- and tissue-specific manner.[107−111] Although no similar information has been reported for edible fruits, the question arises whether potential differences in the expression of homologous fruit genes or proteins may be related to the dissimilarities in the chain length of the predominant cuticular alkanes across botanical families (Table 1). The potential relationship of these differences with cuticle structure and properties, and hence, with the horticultural attributes of each fruit type, requires intensive research. The implications of cuticle composition and structure for postharvest potential and for the design of handling strategies are huge.[25] In the absence of these studies, any careless generalization is likely to lead to oversimplification and to failure of any postharvest procedure designed on such a weak basis.

CUTICLE BIOSYNTHESIS IN FRUITS

Cuticle Biosynthesis during Fruit Maturation and Ripening. The process of cuticle, cutin, and cuticular wax formation during on-tree fruit development has been studied essentially from the ultrastructural,[101,112] biomechanical/biophysical,[113−116] and biochemical points of view.[3,73,86,87,95,102,117] It has frequently been observed that

J. Agric. Food Chem. 2015, 63, 4005−4019

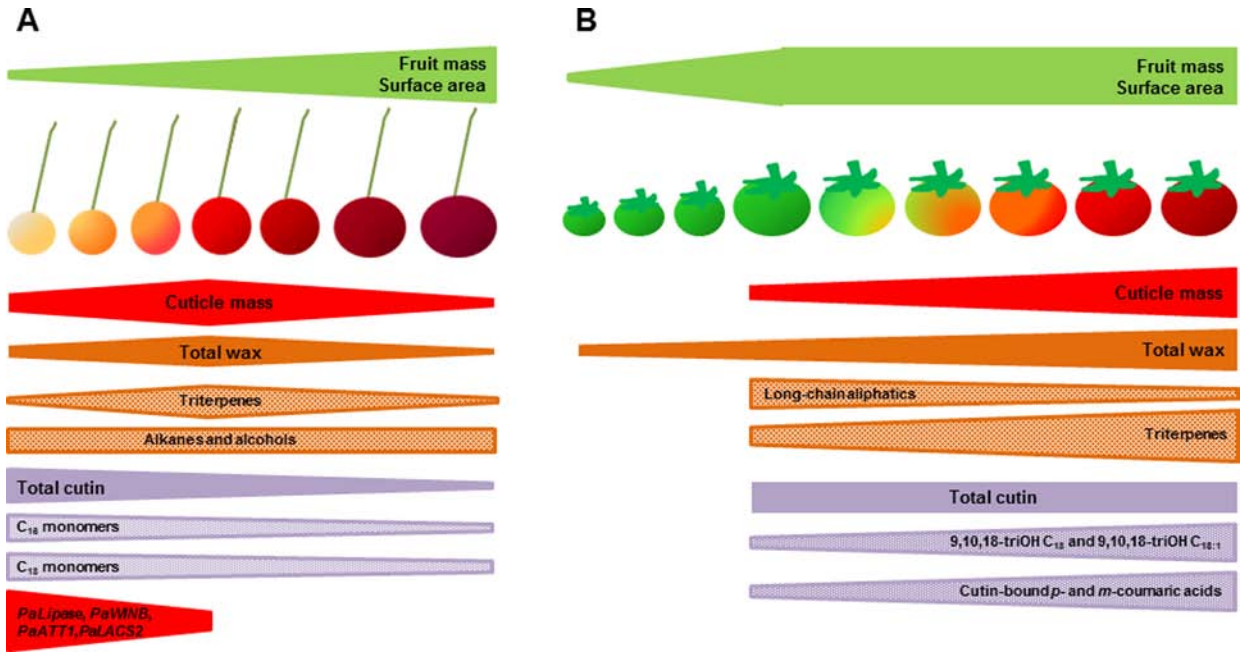

Figure 1. Changes in cuticle deposition and composition during the development of (A) sweet cherry and (B) tomato as an example of a nonclimacteric and a climacteric fruit species, respectively. The figure is intended uniquely as an illustration of the profound dissimilarities reported among different fruit species. The literature survey undertaken in this review indicates that the fate of cuticular compound families during fruit development differs noticeably among fruit species, and therefore these patterns should not be taken as representative of each ripening type. The figure was drawn from data reported in refs 3, 71−73, and 118−120. Changes are expressed per unit of surface area.

cuticle deposition ceases at a given developmental stage, generally corresponding to the transition between growth and ripening, giving rise to decreased amounts of cuticle per unit surface area. This favors increased surface strain as fruit expands, and thus the formation of micro- or macroscopic cracks, the latter having major economic consequences for some commercially important fruit crops. We are not aware of any cause/effect studies relating cuticle composition to the development of this disorder, but some genes are down-regulated concomitantly with arrested cuticle deposition in fruit species particularly prone to this disorder, such as sweet cherry,[118] which may provide the tools to investigate this aspect.

Generalizations on a particular biological event among different species should be treated with caution, as different genetic backgrounds often possess specific mechanisms to cope with environmental stimuli. For this reason, to tackle the compositional evolution of specific cuticular components during fruit development we inspected the available literature on those fruit species for which such information has been published. This survey indicates that any temptation to simplify or generalize the fate of different cuticular compound families during fruit development should be ruled out.

For instance, even the commonly observed trend of early cessation of cuticle deposition is not found in all cases, a notorious exception being tomato (Figure 1). Although long-chain aliphatics were actually found to decrease in developing tomato fruit, the extent of triterpene increases overcompensated for that reduction.[119] A continuous increase in the wax coverage during the developmental course from mature green to red ripe fruits in the 'Micro-Tom' cultivar has also been reported.[71] The total amount of wax and the proportion of alkadienes increased during ripening of 'Ailsa Craig' tomato from the mature green to the red ripe stages, whereas the total amount of cutin monomers per unit of surface area and the relative proportions of the corresponding constituents remained approximately constant during the same period, except for increases in 9,10,18-trihydroxyoctadecanoic and 9,10,18-trihydroxyoctadecenoic acids.[72] This continuous increase in total cuticular waxes during tomato maturation and ripening from as early as the small green stage was subsequently confirmed, with a progressive rise in the absolute content of all wax classes, with the exception of isoalkanes.[63] The amounts of most cutin monomers as well as that of *p*-coumaric and *m*-coumaric acids also increased throughout development. A substantial increase in the phenolic content of the cuticles of 'Ailsa Craig', 'Alicante', and 'Grower's pride' tomatoes was also observed in an earlier work,[120] the major part of the flavonoids detected in ripe fruit being bound to the cutin matrix.

A steady decrease in the proportion of primary alcohols and a progressive increase in esters in cuticular waxes were found during the maturation of grape berries, whereas the content in cutin per surface unit decreased sharply between berry set and véraison.[101] Total triterpenoid contents have also been observed to decline in grapes during fruit ripening.[102] In contrast, a survey on 17 different apple cultivars[86] disclosed increases in the percentage of primary alcohols in the epicuticular waxes as fruit development progressed. More recently, the alkanes *n*-nonacosane and *n*-heptacosane, the alkene *n*-nonacosene, and the secondary alcohol nonacosan-10-ol were observed to increase as fruit reached the mature stage, whereas nonacosan-10-one decreased during the same period.[87] For sweet cherry fruit, it was found that the amount of triterpenes per unit area decreased, with alkanes and alcohols remaining approximately constant throughout fruit development (Figure 1). On the other hand, the amounts of C_{16} and C_{18} cutin monomers per unit area declined, even though divergent trends were shown for different compounds within

Table 2. Tomato Fruit Genotypes Impaired or Altered in Cuticle-Related Genes

genotype	cuticle-related phenotype	refs
alcobaça	altered wax profiles (throughout development) and cuticle lipid compositions (early stages of development); higher relative amounts of C_{18} monomers	73
cutin deficient (*cd1*, *cd2*, *cd3*)	dramatic reduction in cutin content, altered cuticle architecture, increased stiffness of cuticle surface, enhanced water permeability	31, 77, 136
delayed fruit deterioration (*dfd*)	altered cuticle composition and architecture	72
GDSL1-silenced lines[a]	reduced thickness of fruit cuticle, decreased content of cutin monomers, decreased wax load	32
nonripening (*nor*)	altered wax profiles (throughout development) and cuticle lipid compositions (early stages of development); higher relative amounts of C_{18} monomers	73, 137
positional sterile (*ps*)	increased water loss, severe depletion of *n*-alkanes and aldehydes, increased triterpenoids and sterol derivatives, occurrence of alkyl esters not present in the wild-type fruit; similar wax load, unaffected cutin monomer composition	134
ripening inhibitor (*rin*)	altered wax profiles (throughout development) and cuticle lipid compositions (early stages of development); higher relative amounts of C_{18} monomers	73
slcer6 loss-of-function	deficiency in *n*-alkanes and aldehydes longer than C_{30}, increase in intracuticular triterpenoids	67, 71
SlSHN3-silenced lines	reduction in cuticular lipids, lower cutin content, and altered architecture of fruit surface	78
sticky peel (*pe*)[b]	severe reduction in cutin biosynthesis and altered wax deposition	75
sticky peel/light green double mutant (*pe lg*)	glossy soft fruit, severely reduced thickness of fruit cuticle, enhanced water permeability	134, 136
y	reduced thickness of fruit cuticle, lower cutin content, and decreased elasticity	138
16 glossy and 8 dull mutants	altered amount and/or composition of wax and cutin, cuticle thickness, and surface aspect of the fruit	69

[a]GDSL1 is allelic to CD1. [b]PE is allelic to CD2.

each monomer family.[3] The compositional changes in cuticular waxes during fruit development have also been investigated in 'Newhall' orange fruit, and it was found that waxes are secreted continuously during ripening and that decreases in the amount of all major wax fractions were related to the glossy fruit flavedo phenotype of the so-termed 'glossy Newhall' mutant.[95] The mutant fruits have dramatically reduced aldehyde and alkane contents associated with a severe loss of wax crystals. No information was reported on changes in the amount of total cutin or cutin monomers.

This handful of available studies exemplifies how modifications in cuticle composition during fruit maturation and ripening are variable among different fruits. Similar investigations, undertaken on a wide range of additional fruit species, may help identify putative common trends within particular fruit types.

Insights into the Molecular Aspects of Cuticle Biosynthesis in Fruits. Little information exists on the regulation of cuticle formation in fruits at the molecular level. In fact, only a few recent papers have reported the identification of genes related to cuticular wax or cutin biosynthesis in these organs, most of them conducted in tomato as the model species. Cuticle deposition involves a large number of steps and interconnected routes that determine its amount, composition, and correct structural assembly.[7,9,16−19] The identification of the key control points is rendered a difficult task by the multilevel regulation of these pathways, which may involve gene expression, protein modification, and cell environmental changes. A feasible way to tackle this subject is to use mutants altered in fruit cuticle attributes in comparison with the wild-type phenotype. Some of such cuticle mutants exist for tomato (Table 2), and their comprehensive analysis may help detect candidate key genes, proteins, metabolites, and pathways associated with cuticle biosynthesis and functions. The current availability and affordable cost of -omics technologies paves the way for such "systems biology" approaches.

Using this strategy, the gene *LeCER6* (currently referred to as *SlCER6*, owing to the renaming of tomato to *Solanum lycopersicum*), a homologue of *AtCER6*, which codes for a very long-chain fatty acid β-ketoacyl-CoA synthase, has been identified,[67] and a LeCER6 loss-of-function mutant was obtained by reverse genetic techniques. Associated functional characterization showed that waxes of the mutant fruit were deficient in *n*-alkanes and aldehydes longer than C_{30}, whereas hydrocarbons with shorter or branched chains were unaffected. Mutant waxes were also significantly richer in intracuticular terpenoids. Interestingly, these modifications were reflected in cuticle permeability, unquestionably demonstrating a major role of these compounds in the transpiration barrier properties of the cuticle.[67] When the developmental course of maturation and ripening was followed, both in the wild type and in the *LeCER6* mutant, the deficiency was discernible as early as the mature green stage.[71] Comparative transcriptome and metabolome analyses in tomato showed that 17% of 574 peel-associated transcripts were putatively related to cuticle component-generating metabolic pathways.[74] Among these, the expression of *LeCER6* in both fruit exocarp and endocarp was shown to increase progressively during maturation and ripening, supporting the putative association of this gene with cuticular wax formation.

More recently, a homology-based approach has been employed to isolate two oxidosqualene cyclases (OSC) involved in the biosynthesis of triterpene alcohols and expressed exclusively in fruit epidermis, one of which was demonstrated to be a product-specific β-amyrin synthase.[121] When the transcription ratios of these OSCs, designated SlTTS1 and SlTTS2, were compared among three tomato cultivars ('Micro-Tom', 'M82',"and 'Ailsa Craig') differing in their triterpenoid profile, it was found that transcriptional control of these two OSCs accounted only partially for these differences, suggesting the involvement of other factors such as differences in catalytic activity or the presence of additional OSCs.

A few fruit-expressed genes related to cutin deposition have been also identified taking advantage of altered genetic backgrounds (Table 2). The characterization of a tomato mutant designated *cutin deficient 1* (*cd1*), showing only 5−10% cutin content in comparison with the wild-type fruit,[77] revealed

DOI: 10.1021/acs.jafc.5b00013
J. Agric. Food Chem. 2015, 63, 4005−4019

that CD1 is an extracellular acyltransferase with polyester synthesis activity required for cutin accumulation in vivo, demonstrating it to be a cutin synthase directly involved in cutin polymerization.[31] The protein is localized in the cuticle, specifically at the interface with the cell wall, and the expression of its coding gene parallels spatial and temporal patterns of cuticle deposition in the fruit. Similarly, the characterization of the *sticky peel* (*pe*) tomato mutant, which suffers from severe reduction in cutin biosynthesis and alterations in wax deposition, allowed the identification and partial characterization of CD2, a putative transcription factor suggested to act upstream of several metabolic pathways involved in the biosynthesis of a range of surface tissue-associated molecules.[75] A tomato transcription factor (SlSHN3) that regulates fruit cuticle formation and epidermal patterning has also been characterized recently.[78] Silencing the *SlSHN3* gene resulted in remarkable morphological alterations of fruit epidermis and a significant reduction in cuticular lipids. Similarly, a mutation in *SlCYP86A69*, one of the SlSHN3 target genes, led to severe cutin deficiency and altered architecture of the fruit surface. SlCYP86A69 was characterized to possess NADPH-dependent ω-hydroxylation activity, with a preference for oleic acid ($C_{18:1}$) to yield the cutin monomer 18-hydroxyoctadecenoic acid.[78]

In this context, a recent work[69] has shown the potential of a simple phenotypic attribute such as fruit brightness for the identification of cuticle mutants, thus providing an additional tool for the discovery of new genes putatively involved in cuticle biosynthesis. A mutant collection of the 'Micro-Tom' cultivar was screened for altered fruit brightness, which led to the isolation of 16 glossy and 8 dull mutants displaying concomitant differences in cuticle composition, thickness, or structure. Whereas glossy mutants were altered in cutin load and/or composition, dull mutants differed from the wild-type fruit in the characteristics of the epidermis. Surprisingly, no relationship was found between fruit brightness and wax load variations.

Considerably less research effort at the molecular level has been focused on fruits other than tomato. The identification of several candidate genes putatively involved in cuticle formation during development and maturation of 'Regina' sweet cherry fruit revealed that 13 of 18 identified sequences showed expression patterns restricted to fruit exocarp and correlated with cuticle deposition rates.[118] This study recognized some genes that deserve further research as to a major role in cuticle formation, including two transcription factors, one lipase, one LTP, one ABC transporter, two CYP86A hydroxylases, two LACS, and one GPAT. More recently, two of these candidate genes, *PaLACS2* (a putative long-chain acyl-CoA synthetase) and *PaATT1* (a putative cytochrome P450 monooxygenase), were suggested to be major genes involved in cutin biosynthesis on the basis of the effects of their ectopic expression in *Arabidopsis thaliana*.[122]

A similar approach was adopted in apple (cv. 'Prima' and 'Florina') fruit, based on sequence homology studies and transcription profiling.[123] Expression patterns of the selected genes showed that they are active in, and in some cases specific to, fruit skin. The genes identified included some members involved in the FAE complex, wax and cutin modifications, one LTP, one ABC transporter, and one transcription factor. However, these apple and sweet cherry genes were identified on the basis of transcriptomic and homology data uniquely, and an actual involvement in cuticle formation remains to be confirmed. Even so, the proteins encoded by three full-length expressed sequence tag sequences identified in apple cDNA libraries as likely to encode triterpene synthases (*MdOSC1*, *MdOSC2*, and *MdOSC3*) have been actually demonstrated to possess triterpene synthase activity by transient expression in *Nicotiana benthamiana* leaves and by expression in *Pichia methanolica*.[124] Interestingly, MdOCS1 was shown to produce α- and β-amyrin in a 5:1 ratio and, thus, to be the only triterpene synthase identified to date for which α-amyrin accounts for >80% of the total product. This finding implies that MdOCS1 is primarily an α-amyrin synthase, and this is interesting in the light of earlier indications that the main component of the triterpene fraction in apple fruit cuticle is ursolic acid (Table 1), the precursor of which is α-amyrin. The expression levels for these *MdOSC* genes in 'Royal Gala' apple showed preferential expression in the fruit peel and also significantly dissimilar expression levels among tissues, which were reflected in different contents of ursolic and oleanolic acids. The increasing availability of genomic sequences for nonmodel fruit species will provide the basis for shedding light on the current knowledge of cuticle formation in these commodities.

METHODOLOGICAL FOOTPRINT IN CUTICLE COMPOSITION STUDIES

Cuticle components are usually extracted, identified, and quantified following similar methodologies, and therefore major compositional discrepancies found between fruit species are not likely to arise from technical variations across different research groups. This is particularly clear when a given team has found such dissimilarities after using the same methodology for the analysis of cuticles obtained from different fruit species. Even so, it is worth pointing out some methodological aspects that may have some influence on reported results. Indeed, many of the studies reviewed herein were conducted >30 years ago and used different technological solutions.

Waxes are usually extracted by dipping the starting material in an organic solvent such as chloroform, methanol, dichloromethane, hexane, petroleum ether, or toluene, at room temperature or at the boiling point of the solvent, in a single or in a two-step extraction to separate epi- and intracuticular waxes. However, although the sequential extraction with different organic solvents has often been used as an approach to differentiate between epi- and intracuticular waxes, such differential extraction procedures are not selective enough as the resulting extracts are cross-contaminated. For an accurate quantification of the components of both compartments, methods allowing the mechanical removal of epicuticular waxes have been demonstrated to be preferable for this separation, such as those involving the use of adhesives (glycerol, water, nitrocellulose, gum arabic), followed by the stripping off or brushing of the outer film so obtained.[125,126] The starting material, in turn, can involve intact fruit samples, dehydrated fruit skins, or enzymatically isolated cuticles, all of which methodologies have associated weaknesses. For instance, plant cuticles were shown to sorb large amounts of hexadecanoic and octadecanoic acids when incubated in cell slurries obtained through enzymatic digestion of fruits and leaves,[127] thus placing under suspicion the common method of estimating intracuticular wax composition from cuticles isolated enzymatically. Also, the remarkable differences in skin structure found across fruit types (such as those between apple and citrus fruit) may underlie a part of these discrepancies, together with chemical dissimilarities such as pH, which might influence the

DOI: 10.1021/acs.jafc.5b00013
J. Agric. Food Chem. 2015, 63, 4005−4019

extraction of individual compounds. Additional features of fruit skin structure that may prove problematic or account for detected interspecific differences include thickness, flexibility, or the presence of stomata, lenticels, or trichomes.

Gas chromatography (GC) separation of the extracted compounds has been employed since the early 1960s, but the subsequent introduction of capillary columns increased analysis robustness. Compounds in the extracts may be injected directly, with previous chemical derivatization of active functional groups, or with previous hydrolysis of high-molecular-weight esters to release moieties that are then detected. In addition, compound detection by flame ionization (FID) or by mass spectrometry (MS) can result in quantitative and qualitative differences and hence justify some discrepancies.

Effective compound identification can be achieved by the comparison of Kovats retention indices and mass spectral data between the analyses and appropriate standards processed under matching experimental conditions. As standards for cuticle components are not always available commercially, the identification may be impaired or biased with respect to results obtained by other researchers if the group has the possibility to produce them in house. On the other hand, GC-MS identification is not free from drawbacks. For instance, identification is done by comparing the recorded EI-MS spectra with those available in public databases or with those obtained from reference compounds and then interpreting the fragmentation patterns in terms of chemical structure. Yet the spectra of many wax and cutin constituents are not available in MS libraries. In addition, rearrangements and isomerization may occur in unsaturated hydrocarbons, which might lead to the obtained spectra not showing the expected characteristic fragmentation configurations.[128] Even so, chemical techniques such as stereospecific oxidation and trimethylsilylation followed by gas−liquid chromatography coupled to MS have been employed successfully for the determination of double-bond positions of unsaturated fatty acids.[129,130] The use of more sensitive and up-to-date methodologies, such as two-dimensional GC, tandem chromatography arrangements, high-temperature GC (HTGC), HTGC-MS, or infrared and Raman microspectroscopic analysis,[131,132] would provide a valuable complementary tool to add to the current chemical standard analytical methods employed in bulk composition of plant cuticle analyses and hence allow a more accurate comparison between different plant materials, at both the intra- and interspecific levels.

CONCLUDING REMARKS AND FUTURE PROSPECTS

Biological developmental processes in plants are strictly controlled at various levels by cell composition and architecture. Organ- and cell-surrounding structures, such as the cell wall and the cuticle, are now recognized as highly dynamic developmental controllers, at both the signaling and the metabolic levels, as they provide the first communication level in response to conditions imposed on the plant by the surrounding environment. Despite the enormous efforts and advances in understanding cell organization, some cell components have received less attention from the scientific community, even though they are of paramount importance for plant development. Cell walls have been intensively studied and shown to vary in their composition, metabolism, and dynamics among different fruit species and even genotypes of the same species.[133] In contrast, a large number of gaps in knowledge still exist for almost every step of the putative pathways for the biosynthesis of plant cuticle.[7,9,16−19] Differences in cuticle composition between vegetative organs and fruits have been reported, but it is unclear whether exactly the same biosynthetic pathways and regulating mechanisms operate in fruit tissues, and there are many unknowns in regard to cuticle composition of fruits themselves (Table 1).

In this review, we highlight the variability proven to exist across individual fruit species and even across different genotypes of the same species. Such observations raise questions on the precise role of cuticles and on how they act as factors determining organ development and in coping with environmental cues. Answering this challenge will entail further efforts of fundamental research aiming at devising a generalized model of cuticle structure, together with a comprehensive atlas of differences between organisms, organ and cell types, and a track of metabolic regulation, to translate this knowledge into a practical understanding of the resulting biophysical properties. Future perspectives include understanding their impact and a putative premise of manipulating biological features useful to human activity, such as growing rates, respiration and water dynamics, protection against pathogens, or quality preservation of agronomic products.

AUTHOR INFORMATION

*(I.L.) E-mail: lara@quimica.udl.cat. Phone: +34 973 702526.

Funding

B.B. is the recipient of a FI-DGR grant from AGAUR (Generalitat de Catalunya). Financial support through the AGL2010-14801/ALI project, granted by the Ministerio de Ciencia e Innovación (MICINN) of Spain, is gratefully acknowledged.

Notes

The authors declare no competing financial interest.

ABBREVIATIONS USED

ABC, ATP-binding cassette; ACP, acyl carrier protein; CD, cutin deficient; CYP, cytochrome P450; DFD, delayed fruit deterioration; EI, electron ionization; FAE, fatty acid elongase; FAS, fatty acid synthase; FID, flame ionization detector; GC, gas chromatography; GDSL-lipase, Gly-Asp-Ser-Leu esterase/acylhydrolase; GPAT, glycerol-3-phosphate:acyl-CoA acyltransferase; HTGC, high-temperature gas chromatography; LACS, long-chain acyl-CoA synthetase; LTP, lipid transfer protein; MS, mass spectrometry; OSC, oxidosqualene cyclase; VLCFA, very long-chain fatty acids

lees through processing using rotary drum vacuum filtration, specialized lees filtration equipment, or centrifugation—processes that are considered laborious and that can potentially degrade wine quality.[8−10] Quality degradation and loss of wine through bentonite usage has been estimated to cost the global wine industry around U.S.$1 billion per year.[11] Other issues and costs related to bentonite use include tank downtime for bentonite treatment, occupational health risks associated with inhalation of bentonite dust and slip hazards induced by bentonite slurry spills, the disposal of hazardous bentonite waste, and bentonite interference with increasingly common membrane-based winemaking technologies.[12] Consequently, winemakers aim to use the minimum amount of bentonite required for protein stability and would welcome the introduction of alternatives with fewer drawbacks than the current practice.

Since the last extensive review on the topic a decade ago,[8] research efforts have been equally divided into the elucidation of protein haze-forming mechanisms, in particular the effects of different wine components, as well as improving bentonite efficiency and finding alternative stabilization strategies. Significant attention has also been paid to developing methods for protein purification, quantification, and identification, as well as predicting wine haze potential (Figure 2).

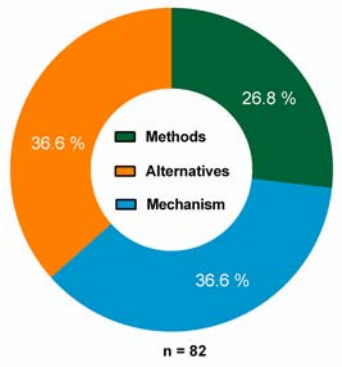

Figure 2. Distribution of peer-reviewed publications on wine protein haze, 2005−2013 (data from Scopus). Methods: papers on the development of methods for purification, quantification, and characterization of proteins, as well as on the prediction of haze potential. Alternatives: papers investigating possible alternatives to bentonite for wine protein stabilization. Mechanism: papers on the elucidation of the mechanism of haze formation in white wines.

This review summarizes recent advances in the knowledge of how protein haze forms in wine, as well as the latest alternatives to bentonite wine protein stabilization. The findings of recent research and the newly proposed mechanisms for haze will be discussed in part I. New alternatives to bentonite will be discussed in part II.

PART I. MECHANISMS OF PROTEIN HAZE FORMATION IN WHITE WINES

Current Model of Haze Formation. The mechanisms associated with haze formation in wines are not well understood and yet commonly cited as a two-stage process. In the first stage, wine proteins unfold in response to stimuli such as elevated storage temperatures. Once unfolded, the proteins aggregate and flocculate to form a visible haze.[13] Recent investigations of the proteins associated with haze formation, as well as the roles of other wine components, have enabled the proposed model to be revised into three separate stages described below. The steps include protein unfolding, protein self-aggregation, and aggregate cross-linking.

Haze-Forming Proteins. The isolation and characterization of proteins from white wines have traditionally been a difficult task due to the presence of grape and yeast proteins as well as their modified versions and degradation products caused by winemaking, which produces a complex protein mixture.[14,15] However, recent advances in techniques for wine protein purification,[16,17] as well as applications of newly developed proteomic techniques,[16,18−25] and the release of the grape genome[26] have significantly improved research capabilities in the identification and quantification of grape and wine proteins.

The most abundant classes of haze-forming proteins that occur in grape (*Vitis vinifera*) juice and white wines are chitinases and thaumatin-like proteins (TLPs).[14,27−29] These proteins are small (<35 kDa) and compact, have globular structures,[30] are positively charged at wine pH, and are tolerant of low pH in juice and wine.[8,31] Other proteins, such as *β*-glucanases, have also been shown to contribute to haze formation,[32,33] although they are much less abundant than chitinases and TLPs in wine and are not extensively studied. A typical electrophoretic profile of grape juice is shown in Figure 3, highlighting that pathogenesis-related (PR) proteins (*β*-1,3-glucanases, chitinases, TLPs, and lipid transfer proteins) are the major protein classes represented. However, haze-forming proteins vary in concentration and composition in ripe grapes and grape juice with cultivar,[34] vintage,[35] disease pressure,[36] and even harvest conditions.[37] The haze-forming proteins have been identified as those that are historically considered to be PR proteins, although they are constitutively expressed during berry ripening and can reach high concentrations regardless of pathogen exposure.[27,38,39] Both chitinases and TLPs have a high number of disulfide bonds that contribute to the highly stable globular structures of these proteins and make them inherently resistant to the enzymatic activity of pathogens.[30,40]

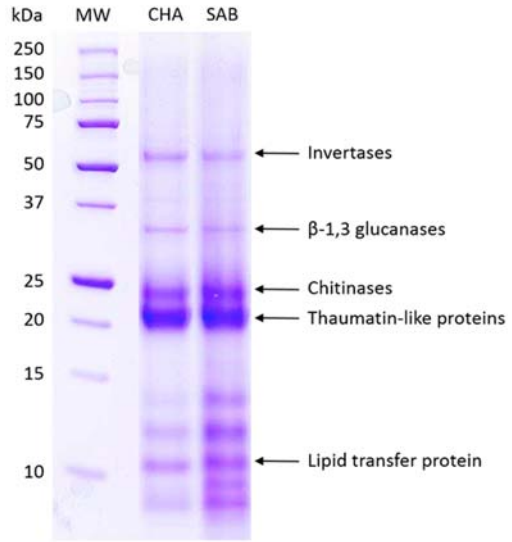

Figure 3. Typical electrophoretic profiles of two unfined grape juices (CHA, Chardonnay; SAB, Sauvignon blanc), with protein band identities assigned by proteomic analysis.[85]

DOI: 10.1021/acs.jafc.5b00047
J. Agric. Food Chem. 2015, 63, 4020−4030

Non-haze-forming proteins are also present in juice and white wine, including yeast mannoproteins,[41,42] grape invertase,[43,44] and grape cell wall glycoproteins and proteoglycans rich in arabinose and galactose (or arabinogalactan-proteins).[45,46] The presence of these non-haze-forming proteins can also affect white wine quality by stabilizing wine against heat-related protein instability,[47−49] influencing foaming properties in sparkling wines,[43,50] and possibly interacting with aroma compounds.[51,52]

The haze-forming tendencies of proteins isolated from white wines have been shown to depend on their aggregation behavior, and developments in the physical techniques used to characterize this behavior have improved the understanding of protein instability.[53−55]

In wines, different classes of haze-forming proteins have different thermal stabilities, as demonstrated by combinatorial peptide ligand libraries (CPLL) analyses[56] and differential scanning calorimetry (DSC).[57] Chitinases are generally less stable than TLPs and can denature within minutes at temperatures >40 °C, compared to weeks for TLPs under the same conditions[57] (Table 1).

Table 1. Predicted Half-Lives of Chitinases and TLPs in Artificial Wine (Based on Falconer et al.[57])

temperature (°C)	predicted half-lives for chitinases	predicted half-lives for TLPs
50	3 min	20 days
45	17 min	11 weeks
40	1.3 h	13 years
35	14 h	180 years
30	4.7 days	>1000 years
25	1.3 months	>1000 years
20	1 year	>1000 years
15	9 years	>1000 years
10	100 years	>1000 years

The temperature at which proteins unfold can also indicate stability, and recent experiments using differential scanning calorimetry (DSC) analyses have demonstrated differences in the melt temperature of chitinases and TLPs. The physical characteristics and aggregation tendencies of these proteins are given in Table 2. Chitinases unfold at a lower temperature than

Table 2. Summary of General Properties of Chitinases and TLPs

property	chitinases	stable TLPs	unstable TLPs
unfolding temperature	55 °C[57]	61−62 °C[57]	56 °C[57]
aggregate characteristics	visible aggregates (≥1 μm)[54]	microaggregates (<150 nm)[53,54]	visible aggregates (≥1 μm)[30,57]
aggregation tendency	self-aggregate[28,54]	cross-linked with other wine components[53,54]	self-aggregate[30]

TLPs, at 55 and 62 °C, respectively,[57] further indicating that they are less stable. As shown in Figure 4, once unfolded, chitinases did not regain their original structure (renature) after cooling, and this irreversible unfolding (denaturation) was shown to lead to protein aggregation and subsequent precipitation of chitinases.[57]

Results from DSC and dynamic light scattering (DLS) experiments have indicated that TLPs generally do not

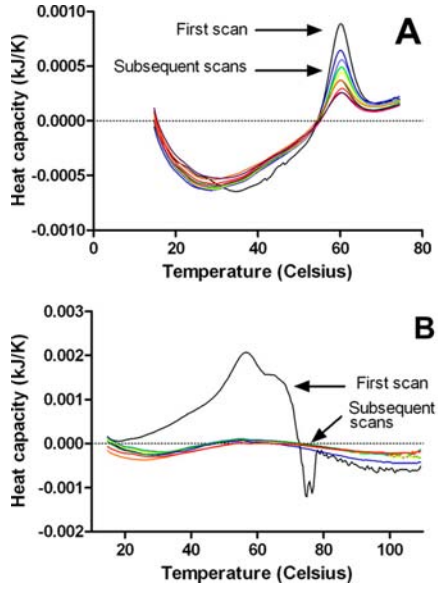

Figure 4. (A) Repeated DSC scans of thaumatin-like protein C from Semillon juice showing a melt temperature of 61 °C and reversibility of thermal unfolding. (B) Repeated DSC scans of chitinase F1 from Sauvignon blanc juice showing a melt temperature of 55 °C, no reversibility of thermal unfolding, and aggregation after unfolding. Reprinted from Falconer et al.[57]

contribute to the formation of visible aggregates,[28,54] although recent studies have indicated the presence of TLPs in wine hazes.[14,32] This apparent conflict of results most likely relates to the particular isoform of TLP that was used in the experiments. Recent studies have shown that some TLP isoforms will reversibly unfold/refold after heating and cooling, whereas other isoforms will irreversibly unfold (denature) and aggregate. Only the TLP isoforms that denature will participate in haze formation.[28,30,53,57,58]

Crystallography has been used to elucidate the 3D structures of three grape TLP isoforms displaying different hazing potentials and unfolding temperatures (Figure 5).[30] That study demonstrated a high degree of structural similarity among different TLP isoforms. However, a TLP isoform (4JRU) with lower unfolding temperature than the other two (56 vs 62 °C) showed the potential to aggregate upon unfolding in the presence of sulfate to form visible haze. The reason for this different hazing potential was attributed to small structural

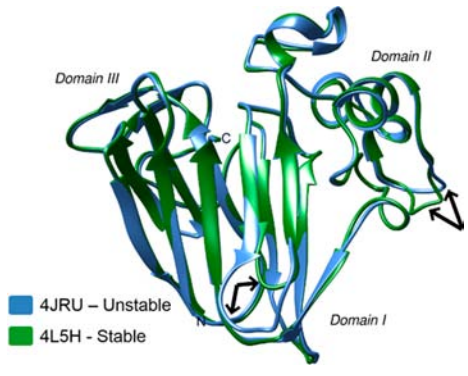

Figure 5. Superposition of the backbone representation of thaumatin-like proteins 4JRU (heat unstable) and 4L5H (heat stable).[30] Arrows indicate differing loops between the two protein isoforms.

DOI: 10.1021/acs.jafc.5b00047
J. Agric. Food Chem. 2015, 63, 4020−4030

differences related to the conformation of a single loop (located in domain 1) and the amino acid composition of its flanking regions, which could explain some of the variation of hazing potential among wines of similar total protein concentrations.

When proteins unfold and aggregate, the protein type can influence the characteristics of the resulting aggregates. TLPs tend to produce metastable microaggregates (<150 nm at normal wine ionic strength) that are invisible to the naked eye, whereas chitinases can rapidly flocculate and produce clearly visible large aggregates (≥1 μm).[13,54] Model studies have indicated that increasing the concentration of protein in solution will increase the amount of haze produced,[59,60] and yet no such correlation has been shown to exist in wine.[28,31] This is most likely due to other components in wine that can facilitate haze or prevent protein aggregation. For example, most TLP isoforms need to interact with other wine components such as salts or polyphenolics to contribute to visible haze.[53,54] Therefore, the size of TLP aggregates is wine-dependent.[13] The chitinases tested to date form aggregates by themselves after unfolding and cooling, assuming that there is sufficient solution ionic strength to suppress electrostatic repulsion.[54,55] This will be discussed in greater detail in the next section.

Other Wine Components That Contribute to Haze Formation. In addition to differing aggregation behaviors of different wine proteins, other components of wine can also contribute to haze formation. These components include polyphenols, sulfate, formerly indicated as the factor X required for protein haze formation,[61] and polysaccharides in particular, as well as characteristics of the wine matrix such as wine pH and organic acids.[28,52−55,58,62] In the two-stage model of haze formation, proteins first unfold and then aggregate to form a haze, and each of these mechanisms has different drivers. The mechanism of protein unfolding is largely influenced by temperature, with higher temperatures leading to more rapid protein unfolding.[13,28,53,54,57,58] However, this does not fully explain the gradual haze formation that can occur during wine storage, indicating that drivers in addition to temperature play a role.

The mechanism of protein aggregation differs for different protein classes,[28] is influenced by a number of factors, and is likely to be affected by other components present in the wine matrix.[54,58] When proteins unfold, they expose hydrophobic binding sites that are generally buried in the core of the proteins, and more hydrophobic proteins tend to cause hazes more easily. This suggests that the aggregation stage of haze formation is likely to be driven by hydrophobic interactions,[63] as recently confirmed by structural studies on TLPs.[30]

Haze-forming proteins also have a net positive charge at wine pH, and this can prevent protein aggregation and haze formation in model systems due to electrostatic repulsion. In white wines the presence of charged ions in solution increases the ionic strength, thus decreasing electrostatic repulsion among protein molecules, so that proteins aggregate upon unfolding and subsequent exposure of hydrophobic protein binding sites.[64] The presence of other charged molecules, particularly sulfates,[61] can also influence protein aggregation, as has been demonstrated with chitinases and, to a lesser extent, TLPs using DLS.[54] In that study model wine containing only chitinases did not form a haze upon heating, whereas increasing sulfate concentration in the matrix led to a dramatic increase in chitinases aggregation. The effect of sulfate on protein aggregation was beyond that which could be attributed to its contribution to ionic strength alone. It was therefore suggested that sulfate not only allows aggregation to occur by suppressing electrostatic repulsion but also allows, if not promotes, hydrophobic interaction-driven aggregation through kosmotropic effects; sulfate anions interact strongly with water, thus weakening hydrogen bonding between water and proteins and promoting salting-out and aggregation.[54]

In combination with ionic strength and temperature considerations, wine pH can prevent some wines from hazing while promoting haze in others.[55,65] Changes to wine pH have been shown to induce minor protein conformational changes that can change the temperature at which wine begins to show turbidity.[66] In that work, Erbaluce wines with lower pH (3.0) did not form a visible haze upon heating to 80 °C, whereas at higher pH (pH 3.30) the wine became hazy when heated to 60 °C.[66] Organic acids have also been attributed a stabilizing effect in wine protein stability.[65] The authors stated that at wine pH organic acids interact electrostatically with the wine proteins and speculated that this interaction would prevent wine compounds of phenolic nature to interact with the wine proteins and thus facilitate haze.[65]

The impact of wine pH on protein stability varies with protein type. Variations in wine pH from 2.5 to 4.0 at room temperature were sufficient to disrupt the native state of chitinases, resulting in the exposure of hydrophobic binding sites that eventually facilitated protein aggregation.[58] Conversely, TLPs and invertases were stable under the same conditions, further demonstrating the comparative instability and haze-forming potential of chitinases compared with stable TLP isoforms.

Polyphenols can also contribute to the aggregation and precipitation of wine proteins, and this can be due to the formation of hydrogen bonds or most likely to hydrophobic interactions.[65,67−69] A wide range of polyphenols have been identified from naturally precipitated proteins in Sauvignon blanc wines that were stored below 30 °C.[70] These include condensed tannins from grapes that are known to readily bind to proteins. Spiking experiments have indicated that polyphenols actively aggregate and precipitate wine proteins at room temperature,[63] most likely due to cross-linking protein aggregates forming larger aggregates that are visible to the naked eye. Cross-linking of proteins with nonprotein molecules includes both covalent and noncovalent interactions. However, because white wines are generally produced under nonoxidative conditions, there are probably few cases of phenolic compounds oxidizing to highly reactive quinones and covalently cross-linking proteins.

Therefore, the growth in size of protein self-aggregates seems also attributable to the cross-linking action of other matrix components. This will be discussed further in the next section. Elevated temperatures can increase polyphenol−protein interactions and aggregation because increased temperatures will increase the number of protein hydrophobic sites that are exposed, as well as the intensity of the hydrophobic interactions.[67] The exposure of hydrophobic sites also differs in magnitude and consequence depending on protein type.[63] Polysaccharides can also influence haze formation, although reports vary between stabilizing proteins against aggregation[41,47,49] to inducing haze formation.[59] This variation may be due to differences in the measured polysaccharide/protein ratio or in the type of protein, such as TLP isoform, used in the analysis.[53] Gazzola et al. showed that wine polysaccharides played a crucial role in haze formation of TLPs, whereas this

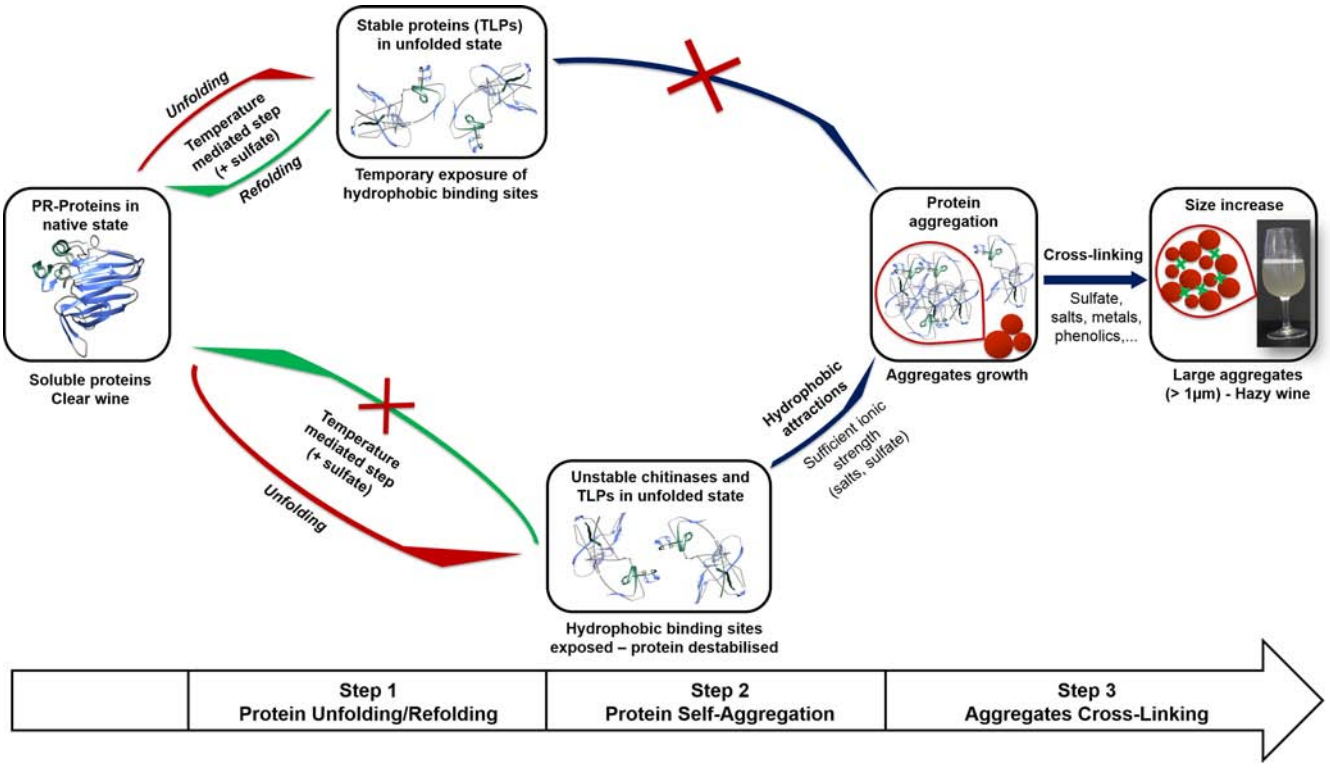

Figure 6. Revised unfolding and aggregation mechanisms of heat-unstable proteins in wine.

was not the case for chitinases. In general, it seemed that the type of protein was always more important than its interaction with polysaccharides.[53]

Another aspect investigated was the theory that denatured proteins (e.g., chitinases) could interact with otherwise soluble proteins (e.g., TLPs) in a coprecipitation mechanism (protein−protein interaction). Although this theory has not been comprehensively disproven in real wines, it has been shown to be insignificant in model wine and one Sauvignon blanc.[28]

Revised Mechanism of Protein Haze Formation. Haze formation is caused by the unfolding and aggregation of grape-derived wine proteins and can lead to precipitation. The current model of wine protein aggregation indicates that protein unfolding and aggregation are separate events, as demonstrated through DLS experiments.[13] Elucidating the mechanisms of haze formation has involved different analytical approaches characterizing naturally forming hazes from wine[28,70] as well as heat-induced haze from real wines.[14,71,72] Heat trials have indicated that proteins can unfold as wine is heated, although the wine becomes hazy only after cooling.[13] The fractionation of heat-unstable wines into their component parts, such as proteins, polysaccharides, and phenolics, and the heat aggregation behavior studied via reconstitution experiments in model or real wines have also improved the knowledge of the haze-forming mechanism.[28,53,54,61,63] Other significant advancements in understanding the mechanisms of wine haze include (i) the finding that sulfate plays an important role in hazing;[54,61] (ii) the explanation of the role of nonproteinaceous wine components, particularly ionic strength,[54,55] pH,[58,66] organic acids,[65] and phenolic compounds;[53,63,70] (iii) the development of an efficient protein purification method;[17] (iv) the release of the grape genome[26] and greater accessibility of proteomic techniques for protein characterization; (v) the discovery that TLPs and chitinases have different unfolding temperatures and unfolding/aggregation behavior;[57] and (vi) the solution of the crystal structure of thaumatin-like proteins.[30] On the basis of these advancements, a new model of haze formation has been proposed (Figure 6).

Immediately following winemaking and clarification, wine proteins are stable and folded in their native state, and the wine is clear. The first stage of haze formation involves the unfolding of these proteins in response to elevated storage temperatures, revealing the hydrophobic binding sites that are generally buried in the core of the proteins.[63] For TLPs this mechanism has recently been elucidated.[30] It appears that unstable TLPs have an exposed loop stabilized by a disulfide bridge that, if destabilized via heat, can expose the neighboring protein region (Figure 7).

In heat-unstable TLPs (e.g., 4JRU) the neighboring region that becomes exposed upon reduction of the disulfide bridge

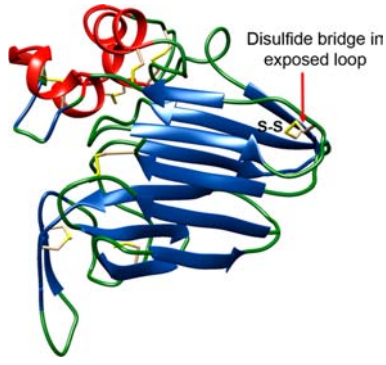

Figure 7. Backbone representation of the heat-unstable thaumatin-like protein 4JRU.[30] Disulfide bonds are yellow. The arrow indicates an exposed disulfide bond that could be susceptible to reduction by heat and sulfites.

DOI: 10.1021/acs.jafc.5b00047
J. Agric. Food Chem. 2015, 63, 4020−4030

located in the exposed loop is hydrophobic; thus, protein aggregation can occur under conditions that favor disulfide bond reduction, such as heating in the presence of sulfites.[30] Conversely, stable TLP does not precipitate due to the hydrophilic nature of exposed regions that prevent protein aggregation and allow refolding upon cooling.[30,57] In the second stage of haze formation unstable proteins begin to self-aggregate via hydrophobic interactions. At this stage wine components able to modify the ionic strength of the solution, such as salts and sulfate, can favor the bindingof the unfolded proteins, further promoting protein aggregation.[63] This is particularly the case with TLPs. In the third and final stage of aggregation the protein aggregates gradually become cross-linked due to the actions of sulfates and polyphenols. Proteins form increasingly larger aggregates until they reach a size that makes them visible to the naked eye ($\geq$1 μm) and eventually precipitate.[13,54,55] The presence of sulfate and salts can also neutralize protein net charges and reduce the natural electrostatic repulsion between similarly charged proteins, whereas polyphenols are more likely to cross-link protein aggregates via hydrophobic interactions. From this mechanism, the role of sulfate as a key wine matrix component for the formation of haze becomes apparent. Sulfate can potentially participate in each of the three stages of haze formation by modifying the melt temperature of proteins in stage 1, by screening the exposed protein charges in stage 2, thus favoring aggregation of unfolded proteins,[28,54] and by mediating the aggregation of small protein aggregates probably through a cross-linking action at stage 3 to modulate the final haze formed.[54]

Following the new insights into haze-forming mechanisms and protein stability, the next stage of research will focus on developing a new test for assessing the haze potential of white wines. The conditions used in the current test, known as the "heat test",[73] may overestimate the risk that a particular wine will haze by denaturing both haze-forming and non-haze-forming proteins. This can overpredict the amount of bentonite needed to stabilize the wine, leading to less cost-effective winemaking practices. Understanding the mechanisms of haze formation and the structures of the proteins involved can also lead to the development of new strategies for haze prevention in white wines.

PART II: BENTONITE ALTERNATIVES

Strategies for Wine Haze Prevention. Considering the mechanisms of wine protein haze formation, there are several possible strategies for preventing wine haze that would either reduce or eliminate the need for bentonite. These include (i) decreasing the ionic strength of the wine; (ii) decreasing the polyphenol concentrations in wine; (iii) stabilizing wine proteins against thermal unfolding; (iv) disrupting hydrophobic protein−protein interactions; (v) degrading wine proteins enzymatically; and (vi) using alternative adsorbents or ultrafiltration to remove proteins.

Strategies 1 and 2 are most likely impractical from a wine sensory quality perspective. Although it is possible to either decrease the ionic strength of wine or remove polyphenols using existing industrial-scale electrodialysis, ion exchange, and fining technologies, these techniques would dramatically change wine sensory attributes. Strategies 3 and 4 are potentially related in practice, as the promotion or addition of specific glycoproteins/proteoglycans/polysaccharides, including specific yeast mannoproteins, could both stabilize wine proteins and interfere with hydrophobic protein−protein interactions.[55] Protein stabilization with polysaccharides such as pectin and carrageenan is well established in other beverages such as milk[74] and beer, and the ability of a yeast mannoprotein to stabilize wine proteins was attributed specifically to the glycan portion of the proteoglycan.[49] However, in both cases, it is unclear at what point protection against haze formation by polysaccharides occurs: do the polysaccharides protect against denaturation or, once proteins are denatured, protect against aggregation? An unexplored alternative to polysaccharides that would implement strategy 4 would be the addition of surfactants to wines to prevent protein−protein interactions. Surfactants such as polysorbates are commonly used in processed foods and beverages to stabilize emulsions. However, their use in wine is not currently permitted, they might not be acceptable to consumers, and they could negatively affect foam properties in sparkling wines.

The most promising strategies for developing bentonite alternatives are strategy 5, the potential to degrade wine proteins with enzymes, and strategy 6, the potential for developing novel fining agents. The use of enzymes and novel fining agents as bentonite alternatives will be discussed in more detail in the following sections.

Protein Degradation Using Enzymes. Degrading haze-forming proteins in wine with enzymes is a particularly appealing alternative to bentonite because it minimizes wine volume loss and aroma stripping. Ideally, effective enzymes would be added to grape juice or ferment without the need for later removal, such as with pectinases and glucanases.[75] The degradation products of grape proteins may also be utilized by yeast as nitrogen sources, potentially reducing the frequent need for nitrogen additions (as diammonium phosphate) and improving wine aroma quality.[76,77] There are two types of enzymatic activity relevant to wine protein degradation: the hydrolysis of peptide bonds by proteases and the reduction of disulfide bonds by protein disulfide reductases. Proteases catalyze peptide bond hydrolysis through nucleophilic attack induced either by an amino acid side chain of the protease, such as for cysteine and serine proteases, or by an activated water molecule, such as for metalloproteases and aspartic proteases.[78] Proteolytic enzymes are routinely used in the beverage industry, for example, papain, a cysteine protease from papaya that is used in beermaking,[79] and are therefore a viable option for use in winemaking. Protein disulfide reductases could, theoretically, destabilize and precipitate haze-forming proteins during winemaking via the enzymatic reduction of disulfide bonds, because the chemical reduction of disulfide bonds has been shown to facilitate the unfolding of these proteins.[63] However, there have been no published examples of protein disulfide reductases being active under wine conditions. For this reason, the search for wine-relevant enzymes to degrade haze-forming proteins has focused on proteases and, at least since the 1950s, researchers have tried to find proteases that destroy haze-forming wine proteins under winemaking conditions.[80] The difficulty in using proteases for specifically degrading haze-forming proteins in wine is associated with the stability of the proteins in wine-like conditions. Chitinases and TLPs are characteristically highly resistant to proteases in their native state due to their rigid peptide backbone structure[72,81,82] and so can tolerate the endogenous proteases that degrade many grape proteins during crushing and pressing.[29] Grape TLPs, as with PR proteins from other plant species, have been found to be

DOI: 10.1021/acs.jafc.5b00047
J. Agric. Food Chem. 2015, 63, 4020−4030

resistant to many different types of proteases and may even inhibit the activity of some proteases.[83,84]

Marangon et al.[85] developed a promising new protease treatment that involves heating grape juice in the presence of a heat-tolerant protease prior to fermentation to produce wine that is free from haze-forming proteins. When juice is heated, the proteins unfold and thus become susceptible to enzymatic activity. The possible drawbacks of exposing grape juice or wine to elevated temperatures are the requirements of high energy inputs and the negative sensory implications,[86−89] even though it has been shown that when applied with care the potential negative sensory changes can be contained, as well as the energy requirements by optimizing the temperature and treatment time.[85] Previous research has focused on the ideal temperature and time of heating required to unfold haze-forming proteins without destroying flavor and aroma compounds.[90]

The method of Marangon et al.[85] involved rapidly heating grape juice to 75 °C for 1 min using flash pasteurization. This technique also required the addition of a protease that is active at the low pH of grape juice and white wines (pH 2.9−3.5) and at 75 °C. Aspergilloglutamic peptidase (AGP), known commercially as Proctase and formerly known as Aspergillopepsin II, was found to be active at 50−75 °C.[85] Adding AGP to clarified grape juice prior to flash pasteurization and fermentation resulted in wines that were heat stable and almost completely free from haze-forming proteins. Chemical and sensory results indicated that there were no significant changes to the main physicochemical parameters or wine preference.[85] This combination treatment of protease addition with flash pasteurization has been shown to be effective at industrial scale,[91] and the use of AGP in wine has recently been approved for Australian winemaking.[92] The cost of this treatment compared favorably to bentonite treatment,[85] making it a potentially cost-effective and commercially viable bentonite alternative.

Other proteases are also currently being investigated that are active at winemaking temperatures and are specific against grape haze-forming proteins. Recent investigations have focused on grape pathogens for specificity against PR grape proteins. Plant PR proteins continuously evolve ways to inhibit pathogen growth, and pathogens continuously evolve ways to counteract the inhibitory effects of PR proteins.[93] Elite grape cultivars have been clonally propagated for centuries; therefore, it is likely that pathogens have evolved proteases to destroy PR proteins encoded by ancient grape genes. The juice of grapes infected with *Botrytis cinerea* was found to have significantly lower concentrations of PR proteins than juice from healthy grapes,[36,94,95] whereas the opposite was true in grapes infected with other pathogens such as powdery mildew.[36] One particular protease from *B. cinerea*, BcAP8, has proven to be effective against grape chitinases during juice fermentation without the need for heating.[96] When BcAP8 was added to juice prior to fermentation, the resulting wines produced significantly less heat-induced protein haze than wines made without BcAP8.

Other potential sources of proteases that are active at wine pH include endogenous winemaking sources such as grapes, yeasts, and bacteria, because protein hydrolysis is known to occur during winemaking.[15,97,98] Endogenous grape (*V. vinifera*) proteases including both cysteine and serine proteases[99] have been found in berries and leaves,[88,100,101] although they are generally not well characterized.[102−106] Grape proteases are active at optima from pH 2 to 2.5 and from 60 to 70 °C,[99,107] and the protease activity is generally short-lived after pressing,[88,100] with few exceptions.[99]

Acid-tolerant yeasts and spoilage microbes have been found to secrete proteases at wine pH, although the secreted protease activity was not sufficient to stabilize wine.[108−114] An extracellular pepsin-like aspartic acid protease of 72 kDa was characterized from a *Saccharomyces cerevisiae* isolate,[115] one of the few isolates that secrete protease activity.[111,115] The secreted yeast protease activity discovered by Younes et al.[115,116] was active at wine pH during grape juice fermentation, although it did not affect grape PR proteins until after fermentation when the wine was incubated at 38 °C for prolonged periods. Nonetheless, the discovery of a secreted protease from a *S. cerevisiae* isolate demonstrates that proteolytic activity can occur prior to autolysis of the cell and the release of a vacuolar acid protease, which is a previously established mechanism of protease activity arising from yeast in wine.[117] The isolate that secretes protease activity is not currently used commercially in winemaking,[115] although it could be used as a tool to develop new industrial wine yeast strains that secrete protease.

Novel Fining Agents. Many novel fining agents and other protein removal techniques with the potential to replace bentonite have been explored in recent years. These include seaweed polysaccharides, chitin, zirconium dioxide, and packed-bed cation exchangers, as well as ultrafiltration techniques. Novel fining agents must meet several criteria to effectively compete with bentonite. They must be cost-effective and nontoxic and must not degrade wine quality.

Negatively charged polysaccharides extracted from seaweeds are a potential class of bentonite alternatives.[118] Carrageenan is a food grade polysaccharide that is extracted from red seaweed and is currently used for protein stabilization in the beer industry.[118] It has been shown to be effective in stabilizing white wines at low addition rates (125−250 mg/L), using only one-third or less of the bentonite concentration required.[119] Carrageenan has been found to produce no deleterious sensory impacts compared to bentonite-treated wines.[120] Although those results are promising, residual amounts of carrageenan in treated wines can potentially induce haze formation,[118,119] and this is likely to restrict commercial viability. Another potential protein-adsorbing polysaccharide is chitin. Chitin is a component of crustacean exoskeletons and, alongside its derivatives, such as chitosan, is widely used in industrial processes, including as a thickening agent for processed foods and in pharmaceuticals.[121] The structure of chitin also makes it selective for binding to chitinases, and in-line systems containing chitin can be effective in removing these particular PR proteins from wine,[122] even if its activity in stabilizing wine has been recently challenged.[123] Chitin could potentially have serious sensory impacts, however, by removing favorable wine components such as positive aroma compounds.[124]

The ultimate objective of novel fining agents and protein-adsorbing materials for the wine industry is to achieve wine stabilization using in-line applications with minimum wine loss and no extra processing steps. Zirconium dioxide (ZrO_2) is a readily available protein-adsorbing material that can be regenerated and thus reused.[125,126] ZrO_2 has shown the potential to remove haze-forming proteins when tested in continuous and batch-wise application both during and post fermentation.[12,127,128] However, despite ZrO_2 showing promise and the ability to be regenerated with a simple washing

DOI: 10.1021/acs.jafc.5b00047
J. Agric. Food Chem. 2015, 63, 4020−4030

procedure,[127] issues with the flow rates and high dosages required limit its commercial viability.

Ultrafiltration can also be effective in removing haze-causing proteins, although the process is not selective and can remove other, desirable, wine components including polysaccharides.[129] This application is not necessarily viable at winery-scale due the expense of equipment. Packed-bed cation-exchangers could improve process efficiency, and their effectiveness in removing wine proteins has been demonstrated,[130] but they have not as yet been adopted for protein removal.

The mechanisms of wine haze formation have been revised from the two-stage model to a three-stage model and now include protein unfolding, protein aggregation, and the cross-linking of aggregates to form a visible haze. Chitinases and TLPs are the most important proteins involved in wine haze formation, and other wine components such as sulfates and polyphenols, as well as wine pH, can influence protein aggregation in the second and third stages. This improved understanding of the mechanisms of haze formation will allow the development of better predictive tools for haze potential and more targeted techniques to prevent hazes forming in bottled white wines. Recent advances in the prevention of haze formation have led to the development of a new bentonite alternative that utilizes a heat-tolerant protease in combination with flash pasteurization. Further investigations into more efficient stabilization strategies, possibly by utilizing proteases that are active at winemaking temperature, will ultimately benefit winemakers worldwide.

Delphinidin	OH	OH	OH
Cyanidin	OH	OH	H
Petunidin	OH	OH	OCH_3
Pelargonidin	H	OH	H
Peonidin	OCH_3	OH	H
Malvidin	OCH_3	OH	OCH_3

Figure 2. Structure of 3,5,7,4′-tetrahydroxylflavilium ion and of the six basic anthocyanins. Reproduced from ref 20.

are more sensitive to oxidation to produce *o*-diquinones, or even *o*-diphenol dimers.[17] Therefore, cyanidin, delphinidin, and petunidin, which contain the *o*-diphenol structure on the B ring, are more sensitive to oxidation. On the contrary, neither malvidin nor peonidin possesses the ortho-positioned hydroxyl groups, which results in their comparatively higher resistance to oxidation.[17] In most plants only O-glycosylation occurs for anthocyanins in which the sugar moiety is typically glucose, but it can be substituted by other sugars such as galactose, rhamnose, arabinose, or xylose.[18] In *Citrus* pigmented varieties, the glucose molecule can be linked to anthocyanidins through the glycosidic bonds at the C3 position to form the 3-*O*-monoglycoside anthocyanins. The junctions can also occur at both C3 and C5 positions to produce 3,5-*O*-diglycoside anthocyanins,[19] which seem to be more stable than their monoglucosidic counterparts. Blood orange [*C. sinensis* (L.) Osbeck] juices contain anthocyanins in differing concentrations depending on the variety, each showing a characteristic seasonal variation of the pigment content.[20] The two major anthocyanins of blood oranges (ca. 90%) have been identified as cyanidin 3-glucoside[19,21−23] and cyanidin 3-(6″-malonylglucoside)[23] in comparable concentrations, these data being confirmed in later studies.[20,24,25] The pioneering work of Maccarone et al.,[19,23] which was carried out by HPLC separation of pigments associated with their spectrophotometric detection, also led to the identification of minor anthocyanin components of blood orange juice [delphinidin 3-glucoside, petunidin 3-glucoside, pelargonidin 3-glucoside, cyanidin 3-(acetyl)glucoside], some of them found as hydroxycinnamic acids derivatives of cyanidin 3-glucoside [cyanidin 3-(feruloyl)glucoside, cyanidin 3- (coumarylferulyl)-glucoside, cyanidin 3-(sinapyl)glucoside, peonidin 3-(coumaryl)glucoside] as well as the diglucosylated forms (3,5) of delphinidin, cyanidin, petunidin, and pelargonidin. Dugo and co-workers[20] identified for the first time peonidin 3-glucoside, cyanidin 3-rutinoside, and the 6″-malonylglucose esters of delphinidin, peonidin, and petunidin as minor additional anthocyanins of blood orange juice by using microhigh-performance liquid chromatography (HPLC)−electrospray ionization mass spectrometry (ESI-MS) (Figure 3). Further investigations revealed the occurrence of cyanidin 3-(6″-dioxalylglucoside), as well as four other anthocyanin-derived pigments, which are formed through a direct reaction between anthocyanins and hydroxycinnamic acids only during prolonged storage of the juice.[25] These novel pyranoanthocyanins (i.e., anthocyanins that contain an additional pyran ring between the C-4 and the hydroxyl group attached to C-5) were identified as the 4-vinylphenol, 4-vinylcatechol, 4-vinylguaiacol, and 4-vinylsyringol adducts of cyanidin 3-glucoside.[25]

BIOSYNTHESIS OF ANTHOCYANINS IN RED ORANGES

Free anthocyanins are synthesized via the flavonoid pathway, which is a ubiquitous and well-described plant secondary metabolite pathway.[16] It has been found that at least two groups of genes are required for anthocyanin biosynthesis: the structural genes encoding the enzymes directly implicated in all of the metabolic reactions and the regulatory genes encoding the transcription factors that control the expression of the

above-mentioned structural genes.[26−28] Most genes encoding the enzymes that biosynthesize the core structure have been cloned and characterized in various species.[1] Previous studies have revealed that the genes acting earlier in the flavonoid pathway are usually encoded by larger gene families, whereas the enzymes directly involved in later steps are encoded by single active genes.[29] This rule, probably resulting from the fact that the earlier acting genes are involved in diverse metabolic functions that require a specific control of gene expression, seems to be applicable to *C. sinensis* anthocyanin biosynthesis. In the *Citrus* genus the early studies on the genes encoding the key enzymes of anthocyanin biosynthesis and their expression analysis occurred more than 10 years ago,[30−32] and new information has since been released.[6,33−35] As shown below, anthocyanins are synthesized by an extremely complex network of all the structural enzymes in the pathway. Therefore, for an efficient production of anthocyanins at the different steps, it is speculated that all of the key enzymes involved in the anthocyanin biosynthesis are associated with each other to form a multienzyme complex.[36] Published evidence indicates the existence of such a complex in some model plants, such as *Arabidopsis thaliana*.[36] Phenylalanine is a direct precursor for the synthesis of anthocyanidins. The conversion of phenylalanine to anthocyanins requires a series of reactions: the first of them is represented by the transformation of phenylalanine to *trans*-cinnamic acid through the elimination of ammonia catalyzed by phenylalanine ammonia-lyase (PAL). PAL has been extensively studied because of its importance in plant stress responses and tissue wounding;[37] protection against UV radiation,[38] low temperature,[6,30] and levels of nitrogen, phosphate, and iron;[38] and pathogenic attack and ethylene response.[39] Two full-length cDNA clones (FPAL1 and FPAL2) were isolated from the flavedo tissue of the Fortune cultivar (*Citrus clementina* Hort. ex Tanaka × *Citrus reticulata* Blanco) library, and the deduced amino acid sequences showed a 75−85% similarity with PAL genes from other plant species.[30] A partial cDNA clone putatively coding for PAL was isolated from the Tarocco fruit juice vesicles [*C. sinensis* (L.) Osbeck] by RT-PCR. The partial nucleotide sequence (DQ088064.1) showed 98.0% identity with the available *C. clementina* sequence.[6] By browsing the *C. sinensis* genome using the BLASTP tool at Phytozome (http://www.phytozome.net/), four sequences matching the translated partial sequence of the Tarocco PAL have been found, and all of them were recognized as PAL (scaffold00201, position 117,512−120,607, *e* value $6.8^{e\text{-}117}$; scaffold00201, position 95,337−97,004, *e* value $2.8^{e\text{-}115}$; scaffold00349, position 92,401−96,606, *e* value $3.1^{e\text{-}111}$; scaffold08490, position 1,157−2,599, *e* value $2.4^{e\text{-}109}$), thus suggesting that the gene is present in four polymorphic forms in the *C. sinensis* genome as also emerged by the in silico analysis of CitEST database performed by Lucheta and co-workers.[40]

In the following steps, 4-hydroxylation of cinnamic acid by cinnamate 4-hydroxylase (C4H) generates *p*-coumaric acid, which is activated by the 4-coumarate:CoA ligase (4CL) to the respective CoA ester. In Valencia sweet orange (*C. sinensis*) two C4H genes were described coding a constitutively expressed C4H2 (AF255014) enzyme that plays an ordinary role in the phenylpropanoid pathway, in contrast to a wound-induced C4H1 (AF255013) isoform.[40,41] In silico studies revealed that the 4-coumarate:CoA ligase (4CL), which converts 4-coumarate (or *p*-coumaric acid) to 4-coumaroyl-CoA, is encoded by a multigene family in the *Citrus* genus.[40]

The first specific enzyme of the anthocyanin biosynthetic pathway is chalcone synthase (CHS) (Figure 4), which condenses three malonyl-CoA molecules and one *p*-coumaroyl-CoA to produce the naringenin chalcone, which is implicated not only in the anthocyanin biosynthesis but also in the creation of other phenolic compounds.[42] As a consequence, different CHS genes may act in different pathways producing distinct secondary metabolites. Two cDNA clones encoding CHS were isolated (CitCHS1, AB009350; and CitCHS2, AB009351) from the Valencia orange (*C. sinensis*) seed library. Southern blot analysis indicated that CitCHS1 (1481 bp long encoding a 389 amino acid protein) is present in a single copy, whereas some sequences related to CitCHS2 (1412 bp long encoding a 391 amino acid protein) are in the *C. sinensis* genome.[31] Furthermore, because hybridization patterns of CitCHS1 and CitCHS2 are different from each other, these cDNA clones have been likely originated from different loci. The expression analysis showed that CitCHS2 mRNA is notably induced by embryogenesis but CitCHS1 mRNA is not, thus indicating that two CHS genes are differentially expressed during citrus somatic embryogenesis and that CitCHS2 may regulate the accumulation of flavonoids in citrus cell cultures.[31]

The naringenin chalcone is isomerized by chalcone isomerase (CHI) to the flavanone naringenin, which is subsequently converted to dihydrokaempferol by flavanone 3′-hydroxylase (F3H). The gene active in the aforementioned stereospecific isomerization of naringenin chalcone into naringenin flavanone (CHI) and the one involved in the following naringen flavanone hydroxylation into dihydrokaempferol (F3H) were later isolated from a *Citrus unshiu* cDNA library, and their expression patterns were analyzed during citrus (Marc.) fruit development in relation to their flavonoid contents. The respective cDNA clones from chalcone isomerase (CHI, CitCHI, AB011794) and flavanone 3′-hydroxylase (F3H, CitF3H, AB011795) are 931 and 1360 bp long, encoding proteins of 222 and 362 amino acid residues, respectively. CitCHI seems to be a single-copy gene, as also confirmed by

browsing the *C. sinensis* genome using the BLASTP tool at Phytozome (http://www.phytozome.net/) (scaffold00024, position 1,113,233−1,115,603, *e* value $2.9^{e\text{-}125}$), whereas a few CitF3H-related sequences are in the *C. unshiu* genome[32] as also found by the in silico analysis of the CitEST database.[40] Messenger RNA levels of the flavonoid biosynthetic genes CitCHI and CitF3H and two previously isolated chalcone synthases (CHS, CitCHS1, and CitCHS2) were analyzed in various tissues during Satsuma mandarin fruit development. Transcript levels for CitCHS1, CitCHS2, CitCHI, and CitF3H are generally high in young tissues that correspond to high accumulation of flavonoids.[32] However, the crucial role of both CitCHS and CitF3H in the development of anthocyanin pigmentation was confirmed by a later study regarding the analysis of the proteomic profile of two orange cultivars with different pigmentation (the blood orange Moro and the blond or common orange Cadenera), at ripening time.[43] Chalcone synthase as well as flavanone hydroxylase were identified as differentially expressed proteins among merely 55 proteins, suggesting that the activation of anthocyanin biosynthetic pathway in blood oranges is one of the major differences distinguishing blood and blond oranges.[43]

The dihydroflavonols, dihydroquercetin and dihydromyricetin, are synthesized from dihydrokaempferol by hydroxylation reactions catalyzed by flavonoid 3′-hydroxylase (F3′H)[44] and flavonoid 3′,5′-hydroxylase, respectively. Dihydroflavonol 4-reductase (DFR) can reduce the dihydroflavonols to their corresponding leucoanthocyanidins. The gene encoding dihydroflavonol 4-reductase was isolated from both a cDNA library (AY519363.1) and genomic DNA (DQ084722.1) (Tarocco and Navel varieties). The data revealed that the cDNA sequences of orange DFR belonging to the red and blond varieties were 100% homologous and contained a 1017 bp open reading frame that encodes a protein of 338 amino acid residues, corresponding to a molecular mass of 38010.76 Da, with a theoretical p*I* of 5.96. Southern blot analysis of genomic DNA indicated that *dfr* is a single-copy gene (as confirmed by browsing the *C. sinensis* genome using the BLASTP tool at Phytozome, http://www.phytozome.net/, scaffold00002, position 3,110,202−3,111,942) in both pigmented and nonpigmented orange varieties. The successful in vitro expression of orange DFR led to an active DFR enzyme that converts dihydroquercetin to leucoanthocyanidin, thus confirming the involvement of the isolated genes in the biosynthesis of anthocyanins.[34] Furthermore, the promoter of the DFR gene was cloned and analyzed.[34] The examination of the sweet orange *dfr* promoter sequence revealed a number of motifs that may be involved in the transcriptional activation of

DOI: 10.1021/acs.jafc.5b01123
J. Agric. Food Chem. 2015, 63, 4031−4041

the DFR genes: a putative unit I, which includes the homologous binding site for the G-box factor, and the downstream MYB homologous binding site were found.[45] Unit I was initially identified in the *chs* promoter and shown to be involved in light induction of the gene expression; it was shown to be necessary and sufficient to impart photoregulation through the phytochromes and the UV-A/blue and UV-B photoreceptors.[46] Two putative GA-myb (gibberellic acid activated myb) homologous binding sites are also located upstream of unit I. Several core elements for Dof3 (one zinc finger), which have been reported to be involved in tissue specificity and light regulation,[47] were observed in the *dfr* promoter. A sequence with homology to the TACpyAT box of the *chs* promoter,[48] which is responsible for organ-specific expression, was also identified immediately upstream of the TATA box. Moreover, three homologous SBF-1 transcription factor binding sites were also detected in the *dfr* promoter.[49] Finally, it was also found that there are no differences in the *dfr* coding and promoter sequences between red and blond oranges. Therefore, as the DFR transcripts are normally detected only in red oranges, its expression should be under extremely strict control of the transcriptional regulators.[34] Anthocyanidin synthase (ANS), an oxoglutarate-dependent Fe^{2+}/Fe^{3+} dioxygenase, converts the colorless leucoanthocyanidins into the colored anthocyanidins, that, once formed, must be immediately modified as they are inherently unstable under physiological conditions (Figure 4). Therefore, the UDP-glucose-flavonoid glucosyl transferase (UFGT) catalyzes the addition of one glucose moiety in the 3-OH positions of anthocyanidins, increasing their hydrophilicity and stability. The sweet orange [(*C. sinensis*) Osbeck, Tarocco] ANS and UFGT genes have been cloned by Lo Piero and co-workers (unpublished data), and their sequences are available at http://www.ncbi.nlm.nih.gov/ (ANS, AY581048; UFGT, AY519364). Both genes are likely in single copy in the *C. sinensis* genome as resulted by the BLASTP search tool at Phytozome (http://www.phytozome.net/) (ANS scaffold00074, position 275,559−279,543; UFGT scaffold00204, position 195,714−197,012). The presence of diglycosylated anthocyanins in blood orange juice[19−23] indicates that other glucosylating enzymes might be involved in anthocyanin modification as occurs in grape,[17] although a homologous gene has not yet been identified in *Citrus*. Acylation is one of the most common modifications of red orange anthocyanins, resulting in greatly increased structural diversity of anthocyanins from the addition of aromatic and/or aliphatic constituents linked to the C6″ positions of the glucosyl groups.[23] Anthocyanins, without the protection of acylation, can be easily and quickly decolorized in neutral or weakly acidic aqueous solutions. The acylation of anthocyanins in plants is catalyzed by the action of anthocyanin acyltransferases (ACT, also known as AAT), which have a really high substrate specificity for both the anthocyanin acceptors and the acyl group donors. In plants, there are mainly two types of ACTs that are classified on the basis of the acyl group donors: the BAHD family using acyl-CoA and the serine carboxypeptidase-like (SCPL) group using acyl-activated sugars.[50] Although in some important *C. sinensis* pigmented varieties the acylated anthocyanins can account for >40% of the total anthocyanin content (cyanidin 3-(6″-malonylglucoside),[23] until now there has been no report about the exact genes required for sweet orange anthocyanin acylation by ACTs.

ANTHOCYANIN TRANSPORTATION INTO THE VACUOLES

Anthocyanins are synthesized by multienzyme complexes that are localized at the cytoplasmic face of the endoplasmic reticulum (ER)[51,52] and then transported to the large vacuole,[53] this localization being necessary to prevent oxidation and for anthocyanins to function as pigments.[54] In some plants, anthocyanins are found in highly pigmented bodies located inside the vacuole; these vacuole-accumulating anthocyanins are also known as anthocyanic vacuolar inclusion (AVI) and contain a dense complex mix of anthocyanins concentrated above the levels that are possible in vacuolar solution.[55] The mechanism of anthocyanin transport to the vacuole has long been debated, with numerous models proposed such as membrane vesicle-mediated or membrane transporter-mediated transport.[56−58] To date, several molecular players involved in the sequestration of anthocyanins have been identified. The importance of glutathione-*S*-transferases (GSTs) for anthocyanin transport has been demonstrated in *Zea mays* (maize) BZ2,[54] petunia AN9,[59] and *Arabidopsis* TT19,[60] where mutations in the encoding genes lead to a reduction in anthocyanin accumulation and pigment mislocalization. A mechanism similar to the detoxification process was then proposed for anthocyanins, according to which they need to be transferred into the vacuoles as glutathione S-conjugates.[54] However, no anthocyanin−glutathione conjugate has been observed in vitro, so it has been suggested that anthocyanins could be transported via the noncovalent binding activity of glutathione *S*-transferase functioning as ligandin.[61,62] Two major transporter families, the multidrug resistance-associated protein (MRP) and the multidrug and toxic compound extrusion transporter (MATE) families, would also be involved in anthocyanin transport in maize[63] and grape.[64] However, the involvement of these different proteins in anthocyanin transport to the vacuole is still unclear. With regard to the anthocyanin transfer into the vacuole in blood oranges, a GST gene homologous to both the AN9 and BZ2 has been isolated from red orange fruit flesh.[35] Having considered gene organization and homology data, it has been suggested that the isolated GST gene is involved in the mechanism of vacuolar import of anthocyanins as confirmed by in vitro expression of orange GST, leading to an enzyme that is active against cyanidin-3-*O*-glucoside.[35] The comparison between colored and uncolored varieties reveals that blood and blond orange GST encoding genes share the same nucleotide sequences, but the GST expression in the nonpigmented orange cultivars (Navel and Ovale) was strongly reduced as compared to that of the pigmented orange (Tarocco). Interestingly, in the crude extracts of pigmented orange fruits, the GST activity is reproducibly detected by providing either 1-chloro-2,4 dinitrobenzene (CDNB) or cyanidin-3-*O*-glucoside as substrates; moreover, cyanidin-3-*O*-glucoside acts as a powerful competitive inhibitor of 1-chloro-2,4-dinitrobenzene conjugation to reduced glutathione (GSH) in the pigmented oranges, confirming that this molecule might easily bind to the active site of the enzyme and functions as a putative substrate.[35] Although the GST involved in anthocyanin conjugation to GSH has been unequivocally identified, it is obvious that the information to precisely understand the working mechanism of the entire complex in vivo is still lacking. As a consequence, more work is needed, and the just released *C. sinensis* genome sequence[65] will likely represent a valued source to recruit

orthologous sequences to provide additional insight into this metabolic pathway.

DEGRADATION OF RED ORANGE ANTHOCYANINS

In contrast to the detailed knowledge available on anthocyanin synthesis, very little is known about pigment stability and catabolism in plants. Transient anthocyanin accumulation and disappearance during plant development or changes in environmental conditions suggest that anthocyanin degradation is controlled and induced when beneficial to the plant.[66] Loss of red pigmentation can occur in young foliage as it matures, in developing flowers, or in response to changes in environmental conditions.[66] Anthocyanin degradation is also observed in Sicilian sweet orange varieties (Tarocco, Moro, and Sanguinello): the pigments accumulated at the late stages of ripening in both the rind and flesh may be degraded, leading to a commercially undesirable partial loss of this color.[67] Enzymatic studies of anthocyanin degradation in postharvest fruits and fruit juices have revealed several enzymes that degrade anthocyanins in these systems and may be candidates for the active in vivo degradation. Three enzyme groups that control degradation rates of anthocyanins in fruit extracts and juices are polyphenol oxidases, peroxidases, and β-glucosidases. Assuming that in planta anthocyanin degradation occurs in the cell vacuoles, the direct oxidation of anthocyanin with peroxidase, which is present in cell vacuoles unlike the oxidizing polyphenol oxidases, is more likely the candidate route for in planta anthocyanin degradation. Nevertheless, the possibility that anthocyanins are transferred out of the vacuoles before degradation exists, and further studies are needed to determine the site of degradation. Therefore, three alternative pathways for enzymatic anthocyanin degradation are presented: (1) direct oxidation of anthocyanin by peroxidase; (2) coupled oxidation, that is, reduction of quinones of phenolic compounds to the original phenolic compounds in parallel to oxidation of anthocyanin to anthocyanin quinine; (3) degradation in two steps, deglycosylation with anthocyanase (β-glucosidase) and then oxidation with polyphenol oxidase or peroxidase. The β-glucosidases may also be involved in the in planta degradation process, because they increase the degradation rate of anthocyanins in fruit extracts of both lychee and eggplant.[66] A specific β-glucosidase was isolated from the fruit juice of Tarocco blood oranges, and the anthocyanin degradation kinetic was followed physiochemically. This enzyme, mainly bound to pectin chains, turns out to be responsible for the degradation of anthocyanins in both the juice and the ripening fruits.[67] The yielded anthocyanidins may be a good substrate for oxidases such as polyphenol oxidase (PPO) in a successive step of the enzymatic degradation process.[66]

Many physical and chemical factors affect the stability of anthocyanins, including temperature, pH, the presence of oxygen, enzymes, the presence of copigments, metal ions, ascorbic acid, sulfur dioxide, sugars, and sugar degradation products. Both low and high temperatures might induce anthocyanin degradation. During cold storage (4 °C for 12 months), the anthocyanic pigments of blood orange juices undergo modifications that lead to the transformation of polycondensation compounds, the color of which changes from brick-red to brown. The process of polymerization is accompanied by the production of chemical indicators of sugar and ascorbic acid degradation (furfural and hydroxymethylfurfural).[68] Reactions between anthocyanic pigments and the aforementioned intermediates of degradation of sugar and ascorbic acid in an acidic environment are the main causes of the formation of these polymers.[69] Moreover, blood orange juice loses its color due to the anthocyanin degradation caused by the standard thermal treatment directed at pectinesterase inactivation, thus negatively influencing the commercial value of blood orange juice.[70] Studies on the thermal degradation of cyanidin 3-(6″-malonyl) glucoside and cyanidin 3-glucoside, which are the two major anthocyanins in blood orange juice,[19,23] as well as of cyanidin-3-glucoside-derived pyranoanthocyanins,[25] indicate that the cyanidin-3-(6′-malonyl)-glucoside is the most stable. Conversely, cyanidin-3-glucoside-derived pyranoanthocyanins show the highest degradation rates, suggesting that acylated anthocyanins could be very promising pigments contributing to the color of different products as stable and intense color molecules.[70] The major intrinsic factors such as ascorbic acid and sugars significantly accelerate the thermal degradation of blood orange anthocyanins, whereas flavonoids have a protective effect on the degradation of anthocyanins; the protective effect of flavonoids plays a more important role in the degradation of anthocyanins compared to the negative effect of ascorbic acid or sugars.[71] The effects of nonthermal preservation technologies including high hydrostatic pressure, pulsed electric field, ultrasound, irradiation, and ozone on the stability of anthocyanins in blood orange juice are reviewed in Tiwari et al.[72]

REGULATION OF ANTHOCYANIN BIOSYNTHESIS IN RED ORANGES

Sweet oranges can be easily divided into two groups based on color, red (or blood) and blond. The red varieties can synthesize and accumulate anthocyanins in both their rind and flesh to express their color, whereas the blond cultivars normally do not produce any anthocyanins in their fruits. The expression profiles of six anthocyanin biosynthetic genes (CHS, CHI, F3H, DFR, ANS, UFGT) were investigated in both blood and blond oranges and revealed that genes involved in the early steps of the anthocyanin biosynthetic pathway, such as CHS, CHI, and F3H, are expressed in juice vesicles of both uncolored and colored oranges. On the contrary, much lower expression levels were observed in the cases of DFR, ANS, and UFGT, the latter being barely detected or even totally unexpressed in blond cultivars (Navel and Ovale).[7,33] Moreover, in the pigmented varieties the anthocyanin content increases during red orange fruit ripening;[7] it is extremely variable among the sweet orange pigmented varieties[7,8] and also may vary due to genetic factors and environmental conditions such as temperature.[5,6,9,73,74]

Genetic Regulation of the Anthocyanin Biosynthesis in Pigmented Orange Fruit. As the secondary metabolites of the flavonoid pathway, anthocyanins are synthesized under the complex regulation of multiple regulatory genes at the transcriptional level. Generally, the spatial and temporal expression of structural genes is under the control of several different families of regulatory genes in plants, such as Myb, Myc (encoding basic helix−loop−helix proteins, bHLH), and WD40-like transcription factors, which also play crucial roles in the regulation of other flavonoid products, such as flavonols and proanthocyanidins.[17] These transcription factors are connected to form a ternary complex (MYB−bHLH−WD40, MBW complex) in a hierarchical network to regulate the expression of the structural genes involved in the flavonoid synthesis, such as CHI, CHS, F3H, and DFR.[17] As mentioned

above, in blood oranges, several anthocyanin biosynthetic genes show increased expression compared with blond oranges.[33−35,73−76] Variation in pigment content or tissue specificity is largely governed by the activity of the R2R3Myb transcription factor in the complex, which has recently been isolated from blood orange and named *Ruby*.[10] The analysis of gene expression revealed that high levels of *Ruby* transcription are in the flesh and rind of blood oranges, whereas no *Ruby* expression is detectable in blond oranges, thus suggesting that a different regulatory mechanism occurs during *Ruby* transcription between blond and blood oranges.[10] The isolation and sequencing of the upstream regulatory regions of *Ruby* from both Moro (blood) and Cadenera (blond) highlighted an insertion of 501 nucleotides in Moro, 254 bp upstream of the initiating ATG in *Ruby*, compared with the otherwise identical *Ruby* promoter from the blond Cadenera orange. This insertion showed sequence similarity to the long terminal repeats (LTRs) of the Copia family of retrotransposons and included a 5 bp direct repeat, typical of LTR retroelement insertion sites.[77] The start of *Ruby* transcription mapped to an A, 551 nucleotides upstream of the initiating ATG of the *Ruby* gene. The insertion generates a TATA box 32 bp upstream of the start of transcription site within the LTR providing the regulatory sequences for initiating expression of the *Ruby* gene, whereas it is not possible to identify a TATA box in the sequence upstream of the *Ruby* gene from blond oranges.[10] The

finding that the *Cs*Myc, gene encoding the bHLH partner in the MWB complex[78] is expressed at detectable levels in both blond and blood oranges supports the hypothesis that the expression of the *Ruby* gene limits anthocyanin biosynthesis in citrus varieties.[10] Recently, a large number of *Citrus* genes belonging to a previously unidentified MYBA gene family were isolated, molecularly characterized, and functionally evaluated.[79] All of these genes were recovered by PCR amplification using primers corresponding to *Vv*MybA1 of grapevine. Transient transgene expression analysis using grapevine somatic embryos revealed that many members of two *Citrus* MYBA subgroups (named b and c) were fully functional and capable of activation anthocyanin biosynthesis in nonanthocyanic explants.[79] Noticeably, the null genes contained single-residue substitution mutations within the R2R3 repeat corresponding to the DNA binding domain. Most of these loss of function substitutions were associated with positively charged amino acids. The isolation of a large number of MYBA genes from *Citrus* suggests the existence of highly homologous regulatory genes involved in the anthocyanin pathway among taxonomically distant genera such as *Citrus* and *Vitis*.[79] Moreover, the identification of many paralogue genes able to turn on the anthocyanin biosynthesis needs to be further investigated to define their role in anthocyanin production likely related with developmental status, tissue specificity, or different color intensity.

Influence of Orange Fruit Ripening Stage and Genotype on Anthocyanin Accumulation. The amount of anthocyanins in blood oranges is strictly correlated with the fruit ripening stage as well as with transcriptional levels of the biosynthetic genes.[7] Figure 5 shows the expression profile of selected anthocyanin biosynthetic genes (CHS, ANS, and UFGT) as well as the total anthocyanin content during the Moro blood orange ripening period. The expression of CHS, ANS, and UFGT increases during the entire period, and the levels of all three transcripts appear to vary correspondingly. Total anthocyanins are undetectable at the beginning, but their levels rise from the third sampling (end of November) onward and show a sharp increase between the VI (late January) and VII samplings (mid-February). Further confirming results have been obtained by microarray analysis performed to study gene expression during blood orange ripening.[76] The custom array was hybridized using samples of the Moro (pigmented) and Cadenera (nonpigmented) cultivars, at three different ripening stages: immature phase, the halfway point of maturation (corresponding to the start of Moro pigmentation), and full ripe time. In Moro, the ripening process, which appears to be closely related to the accumulation of anthocyanins in the fruit flesh, is indeed associated with the induction of genes involved in the anthocyanin pathway.[76]

As shown in Figure 6, the anthocyanin levels might also vary depending on varieties or selections grown under the same environmental conditions ranging from 34 mg/100 g (OTA 9) to 0.25 mg/100g (Tarocco Messina). Generally, a relationship between biosynthetic gene expression and fruit flesh anthocyanin content is evident.[7]

Cold-Temperature Induction of Anthocyanin Content in Blood Orange Fruit. Activation of anthocyanin biosynthesis by cold has received more attention than other inducing environmental factors. In fact, the productivity of most commercially important *Citrus* varieties is severely affected by low temperature due to the induction of several metabolic alterations such as increased electrolyte leakage and decreased photosynthetic capacity and respiration rate.[80] The susceptibility to cold stress varies widely in the *Citrus* genus, ranging from very cold sensitive types, such as *Citrus grandis* (pummelo), to the cold-hardy *Citrus* relative *Poncirus trifoliata*. To complete the picture of the events taking place in cold-exposed *Citrus* fruits also including the pigmented varieties, Lo Piero and co-workers[33,35,74] have shown that postharvest exposure to cold induces an increase of the anthocyanin levels in the blood orange flesh. This enhancement, which may determine an 8-fold increase (from 0.5 to 7.46 mg/100g) depending on storage time, is accomplished by the up-regulation of the genes involved in the anthocyanin biosynthesis (PAL, CHS, DFR, ANS, UFGT, GST). Further transcriptome study based on the construction and analysis of a subtractive cDNA library was performed to address the overall activation of the gene expression in the blood orange [(*C. sinensis*) L. Osbeck, Tarocco Sciara] after exposure to cold stress conditions (4 °C for 77 days). Overall, the enhancement of transcripts involved in the defense mechanisms against oxidative damage, osmoregulating processes, and lipid desaturation as well as many ESTs implicated in both the primary and secondary metabolisms was observed. In particular, the results show that cold stress induces transcriptome modifications undoubtedly oriented toward the enhancement of the flavonoid biosynthesis pathway in blood oranges. They include the activation of genes directly involved in anthocyanin biosynthesis (CHS and ANS) as well as genes intervening in the metabolic pathways supplying it, such as the shikimate pathway, which yields phenylalanine.[9,74] Various functional genes and regulator genes with their target proteins play important roles in regulating low-temperature tolerance. Among low-temperature-induced genes, the dehydration responsive element binding protein (DREB)/C-repeat binding factor (CBF) genes encode key transcription factors implicated in the major transcriptional cascade that responds to cold.[81] Many abiotic-stress-inducible genes are controlled by abscisic acid (ABA), but CBFs are not, thus indicating that both ABA-dependent and ABA-independent regulatory systems are involved in cold stress responsive gene expression.[82] It is worthwhile to mention that in the cited study,[9] homologous cDNAs to CBFs have not been retrieved among the specifically cold-induced genes, suggesting that the blood orange response to cold might involve an ABA-dependent pathway.[9] Interestingly, several transcription factors have been identified for the first time as cold-responsive genes in plants.[9] In particular, a transcription factor belonging to the NAC transcription factor family was found specifically induced in blood oranges, but not in blond oranges, thus proposing it as a candidate gene involved in the signal cascade triggered in response to cold.[73] Recently, a gene encoding a NAC domain transcription factor (TF) was found to be highly up-regulated in blood-fleshed peaches when compared with non-red-fleshed peaches. This NAC transcription factor, designated BLOOD (BL), can activate the transcription of *Pp*MYB10.1, resulting in anthocyanin pigmentation in transgenic tobacco.[83] However, the cold dependency of anthocyanin production in blood oranges might also depend upon the cold induction of the retroelement controlling the *Ruby* gene expression (see Genetic Regulation of the Anthocyanin Biosynthesis in Pigmented Orange Fruit) as elevated levels of these transcripts are observed in Tarocco and Moro blood varieties following the storage of fruit in the cold.[10] Finally, by comparing the blood orange response to cold stress with those of other plant sources, such as grapefruit,[84] it seems to be similar to that of the chilling acclimated species.

Therefore, it is likely that the rise of anthocyanin levels occurring in the oranges subjected to cold stress might contribute to the control of cell osmotic potential, thus coping with the imposed stressful conditions.[9]

Other Anthocyanin Biosynthesis Induction Factors. An assortment of additional intrinsic and environmental factors has been linked to anthocyanin accumulation in several plant species as reviewed by Chalker-Scott[85] and more recently by de Pascual-Teresa and Sanchez-Ballesta.[86] Most research on anthocyanins has focused on their photoinduction by wavelengths in the UV, visible, and far-red regions. Nutrient deficiencies, especially of phosphorus (P) and nitrogen (N), commonly induce the accumulation of anthocyanin in many plant species. Also, exposure to lowered pH, methyl jasmonate, wounding, pathogen infection, and fungal elicitors may trigger a significant increase in the anthocyanin levels.[85,86] Both auxins and/or cytokinins have been shown to induce anthocyanins in cell cultures or whole plant systems, and some authors have linked gibberellins to anthocyanin production.[85] Plant hormones also affect anthocyanin biosynthesis: abscisic acid (ABA) promotes biosynthesis of anthocyanin, and poor coloration of fruit is improved by the application of ABA, which increases the anthocyanin content in both grape skin and cherry skin.[86] Ethylene has been shown to influence the biosynthesis of light-induced anthocyanin formation, improving color development and increasing anthocyanin content in apples.[86] Probably, the above-mentioned factors might have the same enhancing effect upon anthocyanin biosynthesis in pigmented orange but, as far as is known, there is no published experimental evidence confirming their role in activating the anthocyanin biosynthetic pathway. Invaluable personal observations of several researchers report that fruits on the same tree exposed to light in the top of the canopy produce more pigment than those located in a shady position of the canopy interior or that fruit that has fallen from the tree shows increased levels of these pigments. All of these observations leading to the consolidation of the physiological role of anthocyanin as a "defending molecule" in red orange fruit should be experimentally proven and lay the foundation for future work. In this respect, the antifungal activity of salicylic acid (SA) against the devastating pathogen *Penicillium digitatum*, the casual agent of green mold disease of blood oranges, has recently been investigated.[87] The authors showed that SA applications significantly decrease the postharvest decay of fruit as well as positively influence fruit quality parameters such as total soluble solid, titrable acidity, and anthocyanin content. These findings demonstrate that an increase of anthocyanin levels may be closely related to the antifungal activity triggered by SA in blood oranges.[87]

CONCLUSIONS

The importance of anthocyanins is due both to their impact on the organoleptic features of blood oranges, which may influence their technological behavior during juice extraction and processing, and to the beneficial effect on human health correlated with their consumption. The experimental work of several research groups led to greatly improved knowledge of how anthocyanins are synthesized in blood oranges as well as how this biosynthetic pathway is regulated at the transcriptional level by genetic and environmental factors, this being achieved with wide application of new biotechnological approaches such as "omics". However, there are still many aspects that need to be clarified, and it would be worthwhile to focus the next efforts on identifying the genes involved in anthocyanin modification, elucidating the mechanism of vacuole compartmentation of pigments, and defining the role of either phytohormones or biotic and abiotic factors in inducing anthocyanin accumulation.

and southern populations of *Helianthus maximiliani*.[13] For cultivated material, 30 publicly available inbreds were used, 15 each of maintainer (female) and restorer (male) sunflower lines. Although female lines used to produce hybrids differ from the maintainer lines by having male-sterile cytoplasm (CMS), they are considered equivalent in their nuclear genetic material. Furthermore, the use of CMS lines is likely problematic for sampling terpenoids in floral glandular trichomes, because cytoplasmic male sterility in sunflowers often produces significant deformities of florets. Finally, a group of 15 commercial sunflower hybrids was included. Commercial lines included five entries each from three commercial seed companies; the hybrids are not specifically identified to maintain anonymity of companies donating seed. However, the identities of the other 45 entries are available in Table 2. Seed of the identified entries may be obtained either from the USDA National Plant Germplasm System (for all wild entries) or the USDA Sunflower and Plant Biology Research Unit (for inbred lines) in Fargo, ND, USA.

Because pollinators may remove glandular trichomes from blooming sunflowers,[14] florets collected in 2012 were sampled just prior to anthesis. For each entry, five florets were carefully removed from each of three plants. After the corollas were removed from the florets (exposing the glandular trichomes), each group of five florets was stored and allowed to dry under refrigeration until analysis.

Sesquiterpene Lactone Identification and Quantification. To purify sesquiterpene lactones, air-dried wild or cultivated florets (2−6 g) were vortexed in dichloromethane (DCM, 10 mL/g). The solvent was filtered through a cotton plug and evaporated under a stream of nitrogen at 30 °C. Dried residue was dissolved in 1.0 mL of methanol (MeOH), vortexed, and centrifuged at 13000 rpm for 2 min. Distilled water (H_2O) was added to the supernatant to result in a MeOH/H_2O ratio of 25:75. Aliquots (1.0 mL) were injected onto a semipreparative HPLC column (10 × 250 mm Hypersil ODS, 5 μm) and eluted with acetonitrile (ACN)/H_2O (25:75) at 5 mL/min at 40 °C. Peaks were detected by UV at 225 nm. Individual peak fractions were collected and placed in a −80 °C freezer until lyophilized.

Compound identification was performed by means of NMR spectroscopic experiments and data comparison with authentic references. ^{1}H NMR measurements were conducted in a Varian Unity *Inova* spectrometer at 500 MHz. ^{1}H chemical shifts were referenced to residual solvent signals at $\delta_{H/C}$ 7.27 ($CDCl_3$) or 3.35 (CD_3OD), respectively. The following compounds were identified (numbered according to HPLC fractionation in order of decreasing polarity) according to signal identity with data previously reported in references noted:

1, argophyllin B, and **3**, argophyllin A[15]
2, 1,2-anhydrido-4,5-dihydroniveusin A[16]
4, 15-hydroxy-3-dehydrodesoxyfruticin[1]
6, argophyllone B[17]
7, niveusin B, and **8**, niveusin C[18]
9, haageanolide[19]
10, xanthomicrol (5, 4′-dihydroxy-6,7,8-trimethoxyflavone)[20]

An additional compound was identical in most ^{1}H NMR signals with argophyllone B, except for the side-chain signals (H-3′, H-4′, H-5′), which indicated an ester residue at C-8 with tiglic acid instead of angelic acid. This structure appears to be previously undescribed and is described here as *argophyllone B tiglate* (**5**): ^{1}H NMR (500 MHz, $CDCl_3$) δ 6.83 (1H q, H-3′), 6.36 (1H d, J = 1.0 Hz, H-13a), 5.83 (1H dd, J = 1.4 Hz, H-13b), 5.19 (1H t, J = 3.5 Hz, H-8), 4.60 (1H dd, J = 11.5, 3.1 Hz, H-6), 3.88 (1H dd, J = 9.5, 8.7 Hz, H-15a), 3.70 (1H dd, J = 9.5, 5.0 Hz, H-15b), 3.39 (1H dd, J = 9.6, 5.6 Hz, H-1), 3.30 (1H dd, J = 14.5, 9.6 Hz, H-2a), 3.21 (1H m, H-4), 3.06 (1H bs, H-7), 2.75 (1H dd, J = 15.2, 3.4 Hz, H-9a), 2.37 (1H dd, J = 14.4, 9.8 Hz, H-5a), 2.25 (1H dd, H-2b) 1.92 (1H m, H-5b), 1.80 (3H dq, H-4′), 1.79 (3H s, H-5′), 1.40 (3H s, H-14), 1.37 (1 H dd, J = 15.0, 3.2 Hz, H-9b).

Relative quantification of sesquiterpene lactones was accomplished by analyzing three replicate samples from each of the 60 germplasm entries. For each sample, five air-dried florets were vortexed in 0.5 mL of DCM. After 5 min, the samples were vortexed again, and the solvent was pipetted into a microcentrifuge tube and evaporated under a stream of nitrogen at 30 °C. The residue was dissolved by vortexing in 0.2 mL of MeOH. After centrifuging at 13000 rpm for 2 min, the sample was transferred to an autosampler vial for HPLC analysis. Before injection, 0.8 mL of water containing 0.010 mg/mL 2,5-dimethylphenol (2,5-DMP) internal standard was added to the sample vial and mixed using the autosampler. From the 1.0 mL mixed in each sample vial, 0.2 mL was injected onto an analytical column (4.6 × 250 mm Hypersil ODS, 5 μm) and eluted with ACN/H_2O (25:75) at 1 mL/min at 40 °C. Peaks were monitored at 225, 254, and 265 nm. A representative chromatogram showing UV absorbance at 225 nm for a wild *H. annuus* is included as Figure S1 of the Supporting Information.

Insect Assay. An assay with sunflower moth larvae was used to compare larval development upon exposure to mixed and pure extracts of sesquiterpene lactones found in *H. annuus*. Previous tests of biological activity of sesquiterpene lactones and diterpene acids have incorporated a known percentage of tested compounds into artificial diet on a dry mass basis.[4,7] However, because glandular trichomes are found on the outer surface of florets, applying sesquiterpene lactones onto the surface of an artificial diet may more closely resemble how sunflower moth larvae are normally exposed to the contents of glandular trichomes.

Florets from wild (PI 435430) and cultivated (HA 89) entries were collected from sunflower heads protected from pollinators by enclosure in mesh bags. Mixed extracts and pure sesquiterpene lactones were obtained from known numbers of florets as previously described. Each mixed extract or pure compound was dissolved in 600 μL of methanol, after which a 25 μL aliquot was applied to each of 24 wells containing 1.5 mL of a wheat germ-based artificial diet.[21] Treatments included mixed extracts of PI 435430 or HA 89, pure argophyllone B (**6**) or 15-hydroxy-3-dehydrodesoxyfruticin (**4**), and methanol or untreated controls. On the basis of scanning electron micrographs, the surface area of the wells used for the insect assay is approximately 60 times the area over which glands are present on a single *H. annuus* floret tip. Consequently, expressing the amount of sesquiterpene lactone in diet assays as floret-equivalents (60 floret-equivalents = estimated natural exposure) is an area-to-area conversion that incorporates the natural variation in *H. annuus* glandular trichome number.[9] At least 30 min after application of treatments, two newly hatched sunflower moth larvae were placed into each well, and clear adhesive lids were used to contain the larvae. After 7 days, each well was scored for larval mortality; for all larvae still alive at 7 days, mass was also measured.

Data Analysis. Analyses were performed using JMP and SAS software.[22,23] Because relationships between peak area (UV absorption) and concentration (or mass) are not established for any of the compounds, mean peak areas (a relative measure) for sesquiterpene lactones were used for statistical analyses. To assess possible relationships between the seven major sesquiterpene lactones, simple and partial correlations (accounting for glandular trichome density; from ref 9) were calculated. To determine whether significant differences in sesquiterpene lactone composition exist among *H. annuus* germplasm types, quadratic discriminant function analysis was used, which allowed for differing covariance among germplasm types. Variables for inclusion on the discriminant function analysis were chosen by forward stepwise selection ($P < 0.05$ for entry).

To test whether mixed or pure sesquiterpene lactone extracts influenced larval mass at 7 days, a single-factor analysis of variance was used for the seven treatments (five extracts and two controls); infestation date (occurring on two consecutive days) was used as a random blocking effect. Exclusion of outliers (mass more than three deviations above mean of treatment; <2% of observations) produced data with statistically equal variance over treatments, allowing analysis without need for transformation. Differences in larval mass among treatments were assessed using t tests incorporating a Bonferroni correction. The effect of extracts on larval mortality was tested using a Wald Chi-Square test; differences relative to the untreated control were established using 95% confidence limits for the odds ratio (= relative likelihood of mortality).

RESULTS AND DISCUSSION

Correlations among Sesquiterpene Lactones and Number of Glandular Trichomes. Among the 10 peaks identified from *H. annuus* floret samples (Figure 1), seven previously identified sesquiterpene lactones were generally present in amounts sufficient for statistical comparison. Significant correlations among these compounds were common, but in some cases probably incidental, as all seven major peaks were also positively correlated with the estimated density of glandular trichomes. Using partial correlations to account for the effect of glandular trichome number, some strong associations remain; correlations with argophyllone B (**6**) (likely previously identified as 1-methoxy-4,5-dihydroniveusin A),[16] the most prominent peak in wild *H. annuus*, accounted for most of the variation in argophyllin B (**1**), 1,2-anhydrido-4,5-dihydro-niveusin A (**2**), and argophyllin A (**3**) (r = 0.77−0.97; Table 1). The remaining major peaks, 15-hydroxy-3-dehydrodesoxyfruticin (**4**), niveusin B (**7**), and

[a]Correlations with estimated glandular trichome number (from Prasifka, 2014) also provided for comparison. Sesquiterpene lactone pairs below the diagonal show partial correlation coefficients where the effect of correlations with glandular trichome number is removed. Asterisks (*) indicate significant ($P < 0.05$) correlation.

haageanolide (**9**), showed low ($r < 0.30$) or no significant partial correlations with other sesquiterpene lactones. Also detected, but excluded because of their small, inconsistent peaks (at 225, 254, and 265 nm), were niveusin C (**8**) and argophyllone B tiglate (**5**). Xanthomicrol (**10**) (5,4′-dihydroxy-6,7,8-trimethoxyflavone)[20] and another unknown flavonoid were detected in samples but excluded as outside the intended scope of our investigation.

Differences in Sesquiterpene Lactone Composition among *H. annuus* Types. Discriminant function analysis showed that relative amounts of sesquiterpene lactones (Table 2) can be used to distinguish between wild and cultivated *H. annuus* and also between some groups of cultivated sunflower germplasm. The three latent variables used to distinguish among the sample types primarily represent argophyllone B (**6**) (standardized canonical loading = 0.99), niveusin B (**7**) (standardized canonical loading = 1.07), and 15-hydroxy-3-dehydrodesoxyfruticin (**4**) (standardized canonical loading = 0.85). Discrimination among the germplasm types based on the first two canonical variables is shown in Figure 2. Redundancy with argophyllone B (**6**) likely eliminated argophyllin B (**1**), 1,2-anhydrido-4,5-dihydro-niveusin A (**2**), and argophyllin A (**3**) from selection by the discriminant function analysis; a common precursor, possibly costunolide,[24] is one explanation for the strong correlations and is supported by the very similar structures of all four compounds. The final major peak, haageanolide (**9**), may not be useful for discrimination because of its consistency; it was present in all samples and showed relatively little variation across the 60 entries. The reason for the consistency of haageanolide (**9**) is unclear, but may be because it differs from the others in the presence of C-9 (rather than C-8) hydroxylation; whereas the C-8 hydroxylated derivatives of costunolide are subsequently processed by additional specific enzymes (e.g., formation of the side chain esters and P450 modulated oxidations at C-3, C-15) which can be regulated individually, haageanolide is not further processed and may accumulate as a side product of the early stages of sesquiterpene lactone biosynthesis.

On the basis of chemical composition, assignment to a germplasm group was correct for 75% of entries versus a random expectation of 25% over all 60 entries. Most errors in classification were in the maintainer group, for which 11 of 15 entries were incorrectly assigned to one of the other three groups (Table 3). The higher variability in sesquiterpene lactone composition for maintainer lines (used to produce female parents for hybrid sunflowers) could reflect a difference in the diversity of germplasm relative to the restorer group (male parents) or linkage of genes responsible for sesquiterpene lactone production to traits important in the restorer group (e.g., branching or fertility restoration).[25] Although wild *H. annuus* entries were generally distinct from cultivated entries (i.e., with much greater amounts of several compounds), the fact that some maintainer lines were incorrectly assigned to the wild group (and vice versa) indicates that some of the cultivated inbred lines may retain chemical defenses similar to those of wild sunflowers.

Variability in sesquiterpene lactone content has been assessed previously for some *Helianthus* spp. Sesquiterpene lactones extracted from both leaves and florets have been used to characterize intraspecific variation because the contents of capitate glandular trichomes on both tissue types are strongly correlated. Evaluations of leaves and flowers of the wild species, *H. maximiliani*, have shown considerable intraspecific variation, which has been characterized as the presence of distinct chemical races.[13,26,27] On the other hand, within *H. annuus*, an evaluation of sesquiterpene lactones from leaves and florets of 25 accessions of wild sunflowers found few qualitative differences, but significant quantitative variation.[11] Assessment of several ornamental *H. annuus* species showed a similar pattern of low qualitative and high quantitative variation in extracts from leaf tissue.[28] A recent evaluation of sesquiterpene lactones from leaves of one wild and one cultivated (HA 89) *H. annuus* entries showed primarily quantitative differences and was interpreted as evidence that reduced plant defense in sunflower is a trade-off produced by domestication.[10] Our data on sesquiterpene lactone composition from the broader range of 60 *H. annuus* entries both support and expand on previous results; differences between some germplasm types were based on primarily quantitative differences (e.g., wild versus cultivated hybrids; Table 2), whereas others (e.g., restorer group versus wild *H. annuus* or cultivated hybrids) showed strong qualitative differences in the occurrence of various compounds (Table 2; Figure 2).

Effects of Mixed and Pure Extracts on Sunflower Moth Larvae. Bioassays with sunflower moth larvae showed adverse effects from exposure to glandular trichome extracts. Larval mass was reduced at 7 days ($F_{(6;268)} = 10.61$, $P < 0.001$) relative to the untreated and solvent-only controls, although

[a]Values are expressed as mean (± SD) peak area (mAU·min) from HPLC analyses of replicate samples (n = 3). Entries without detectable amounts denoted with dash (–) as value. Commercial hybrids identified by code (i.e., C1-E1 = company 1, entry 1) for anonymity.

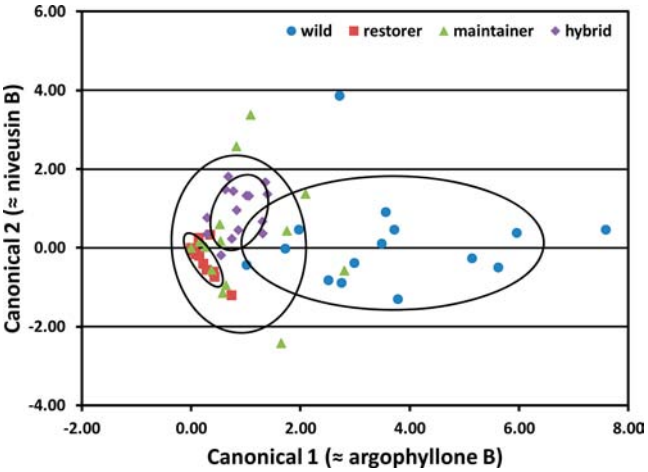

Figure 2. Plot of *H. annuus* entries by variables derived from discriminant function analysis. Canonical variables most closely corresponded to the two sesquiterpene lactones indicated (based upon loading of variables). Ellipses represent 95% confidence limits of means for each of the four groups of entries.

Table 3. Classification of Sunflower Entries to Group Based on Relative Abundance of Sesquiterpene Lactones Using Discriminant Function Analysis (Total of 15 Entries per Group)

actual group	predicted group				% misclassified
	wild	HA	RHA	hybrid	
wild *H. annuus*	12	2	0	1	20.00
maintainers (HA)	2	4	6	3	73.33
restorers (RHA)	0	0	14	1	6.67
commercial hybrids	0	0	0	15	0.00

only for one mixed extract (HA 89) and the higher dose of argophyllone B (**6**). For the treatments with significant effects, larval mass was ≈35% less relative to the solvent-only control (Table 4). Larval mortality was increased relative to the untreated control (Wald $\chi^2_{(6)}$ = 27.40), but only for the mixed extracts HA 89 (estimated odds ratio [OR] = 4.53) and PI 435430 (OR = 6.60), with one-third of larvae dying during the assay. Overall, the statistically similar results with mixed extracts from cultivated and wild entries suggest that cultivated sunflowers retain some significant chemical defenses against sunflower moth larvae. However, as observed for an unrelated insect (western corn rootworm), sunflower resistance to herbivory may manifest through behavioral or developmental changes, including reduced feeding, rather than high mortality.[8] The absence of effects from treatments that included single compounds, except the higher dose of argophyllone B (**6**),

Table 4. Effect of Mixed and Pure Sesquiterpene Lactone Extracts on Survival and Development of Sunflower Moth Larvae[a]

extract	floret-equivalents (dose)	larval mortality[b] (n of 48)	larval mass[c] (mg ± SE)
HA 89 (mixed)	25	14*	8.1 ± 1.1 c
PI 435430 (mixed)	25	18*	10.0 ± 1.2 bc
untreated	n/a	4	15.4 ± 1.0 a
methanol (solvent)	n/a	8	13.4 ± 1.1 ab
argophyllone B	60	5	12.8 ± 1.0 ab
argophyllone B	180	2	9.2 ± 1.0 c
15-hydroxy-3-dehydrodesoxyfruticin	60	4	13.2 ± 1.1 ab

[a]A dose of 60 floret-equivalents is approximately equal to the density of compounds on tips of florets. SE, standard error. [b]Asterisks (*) indicate increased mortality (P < 0.05) relative to untreated control based on 95% Wald confidence limits. [c]Different letters within the column indicate significant differences (P < 0.05) between least-squares estimated means using a Bonferroni adjustment.

suggests that sunflower sesquiterpene lactones are more effective in combinations of several compounds, as has been observed for other secondary metabolites that protect against pests.[29] An alternative, but biologically counterintuitive, explanation is that mixtures of sesquiterpene lactones may be effective only at doses that exceed the natural exposure for insect herbivores of sunflower. However, if the structurally related argophyllone B (**6**), argophyllin B (**1**), 1,2-anhydrido-4,5-dihydro-niveusin A (**2**), and argophyllin A (**3**) have similar effects on herbivores, the effective dose in nature may be similar to the higher tested dose of argophyllone B (**6**).

Results of the bioassays with pure compounds are difficult to compare to previous tests of the effects of sesquiterpene lactones against sunflower moth because of methodological differences; previous tests using sesquiterpene lactones from *Helianthus* spp. mixed a known percentage of compounds into artificial diet rather than applying them only to the surface (which mimics the distribution of glandular trichomes on florets). However, for *H. maximiliani*, significant effects on larval survival, feeding behavior, or development seemed to appear for the primary sesquiterpene lactone, 8β-sarracinoyloxycumambranolide, at concentrations between 1 and 5%.[6,7] Several pure compounds from *H. annuus* (and other species) at 1% delayed larval development and increased mortality for sunflower moth larvae.[4] Whereas previous studies support the role of sesquiterpene lactones as a defense against the sunflower moth, argophyllone B (**6**), one of the most abundant compounds in wild *H. annuus*, was recovered at only approximately 0.15% of floret dry mass; although the proportion of argophyllone B (**6**) recovered was not tested,

J. Agric. Food Chem. 2015, 63, 4042–4049

this observation suggests doses of 1% or more incorporated into artificial diet may exceed normal exposure for floret-feeding insects. Because several of the sesquiterpene lactones showed strong, positive correlations in their relative abundance, additional tests to understand the value of compounds (alone or in combination) would support further efforts to develop cultivated sunflowers with greater levels of sesquiterpene lactones.

Interest in using sesquiterpene lactones for resistance to insect herbivores of cultivated sunflower has persisted over the decades following their identification in wild *Helianthus* spp. An examination of a broad range of wild and cultivated *H. annuus* supports the potential for this host plant defense by finding some overlap between the sesquiterpene lactone composition of wild and cultivated sunflowers. Also, direct evidence for biological activity of argophyllone B (**6**) against sunflower moth larvae agrees with previous research showing antifeedant properties of similar compounds in cultivated sunflowers.[8] Efforts to understand the biological importance of sesquiterpene lactones are confounded; the presence of other compounds in florets with known antiherbivore properties (especially phenolics) likely obscures the effects of terpenoids and limits testing to studies in which sesquiterpene lactones are evaluated by addition to artificial diet.[30,31] However, the successful use of sesquiterpenes for enhanced insect resistance in other crops suggests that continued research is worthwhile.[32] Because sesquiterpene lactones in commercial sunflower hybrids appear qualitatively similar to those in wild sunflowers, future research should be directed to understanding the basis of clear quantitative differences to improve resistance to floret-feeding pests.

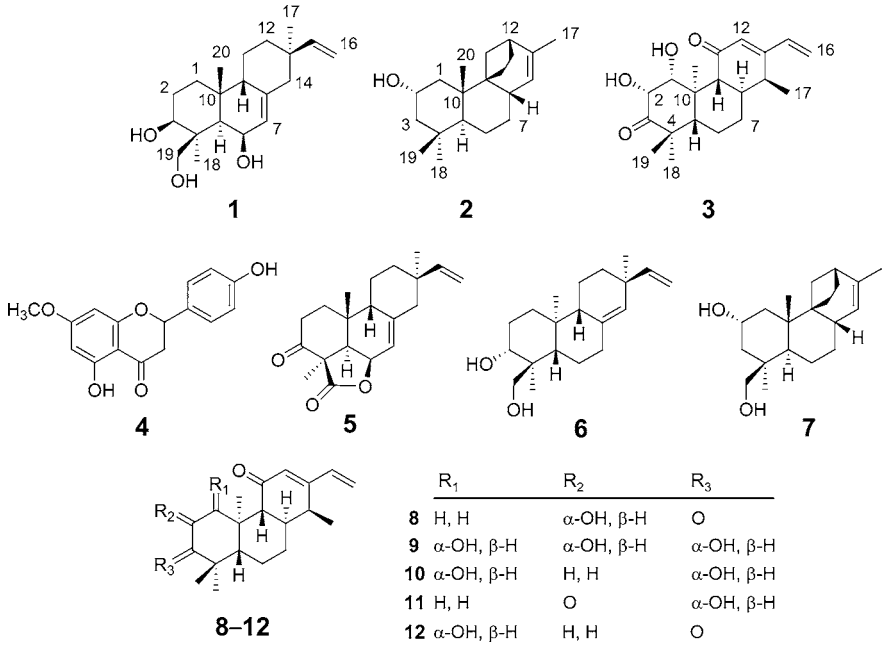

Figure 1. Structures of compounds.

complex mixture of biological origin, it is not suitable for analyzing heat-labile, highly polar, or nonvolatile compounds. In this context, LC/MS can be complementarily used for the analysis of such compounds. In this study, we used both the GC/MS and LC/MS techniques to find novel phytoalexins from UV-irradiated rice leaves, followed by complementary spectroscopic techniques to identify them.

MATERIALS AND METHODS

General Analytical Methods. ^{1}H NMR (400 MHz), ^{13}C NMR (100 MHz), and 2D-NMR spectra were acquired on an AVANCE III FT-NMR spectrometer (Bruker BioSpin, Rheinstetten, Germany) equipped with a 5 mm BBFO probe. The chemical shifts were referenced to TMS (δ_H 0.00; δ_C 0.00) or C_6D_6 (δ_H 7.16; δ_C 128.39) as an internal standard. The IR spectra were acquired using an FT/IR-4100 spectrometer (Jasco, Tokyo, Japan); the samples for IR were prepared as KBr disks. The UV spectra were acquired using a V-550 spectrometer (Jasco); the samples for UV spectroscopy were dissolved in MeOH. The specific rotations were measured using a P-2100 polarimeter equipped with a halogen lamp and a 589 nm filter (Jasco); the samples for polarimetry were dissolved in $CHCl_3$. The electron ionization (EI)-mass spectra (70 eV) were recorded with a JMS-BU25 mass spectrometer (Jeol, Tokyo, Japan) operated in direct inlet mode. GC/MS was performed with a JMS-BU25 mass spectrometer coupled with an HP6890 gas chromatograph (Agilent Technologies, Santa Clara, CA) under the following conditions: column, 30 m × 0.32 mm i.d., 0.25-μm film thickness, J&W Scientific HP-5 (Agilent Technologies); injection port temperature, 280 °C; carrier gas, He; flow rate, 1.0 mL/min; temperature program of column oven, 70 °C for 1 min before heating to 300 °C at 10 °C/min and then maintained at 300 °C for 3 min; ionization mode, EI (70 eV); ion chamber temperature, 200 °C; scan range, m/z 61−627; scan rate, 1 scan/s. LC/MS was performed with a 3200 QTRAP LC/MS/MS system (AB Sciex, Framingham, MA) coupled with a Prominence UFLC system (Shimadzu Co., Kyoto, Japan). The Turbo V ion source was operated in positive ESI mode. Preparative HPLC was carried out with a PU-980 HPLC pump and an MD-910 photodiode array detector (Jasco) under the following conditions; flow rate, 2.0 mL/min; detection, UV 210−350 nm.

Chemicals. Compound **4** was chemically synthesized from naringenin (Sigma-Aldrich, St. Louis, MO) according to the method reported by Aida et al.[27] Compound **5** was purified from rice husks according to the method reported by Kato et al.[28] with some modifications. Compounds **6** and **7** were purified from UV-irradiated rice leaves according to previously described methods with some modifications.[5,6] The standard solution for the quantitation of **8**−**12** was kindly gifted by Dr. Kazunori Okada at the University of Tokyo.

Plant Materials. Rice plants (*Oryza sativa* cv. Koshihikari) were grown in a phytotron at 27 °C under natural light conditions. The leaf blades of the seventh and eighth leaf stages were detached, and the middle regions of those leaf blades were used in the subsequent experiments.

Fungal Materials and Spore Preparation. The rice blast fungus (*Magnaporthe oryzae* strain P-2) had been maintained on a potato dextrose agar (PDA) (Nissui Pharmaceutical, Tokyo, Japan) medium as a stock culture in our laboratory. Spores of the fungus were prepared by the previously described method with some modifications.[29] The mycelia cultured on the oatmeal medium were transplanted to a vegetable-juice medium in a Petri dish and cultured for 2 weeks at 26 °C in the dark. For synchronously produced spores, aerial hyphae were removed by soft scratching with a paint brush in distilled water. The Petri dish was incubated for 48 h at 26 °C under a BLB 20 W near-UV light (Toshiba, Tokyo, Japan) in dry conditions. The produced spores were harvested with distilled water for a time course infection experiment or with a spore germination medium (4 g of glucose, 2 g of yeast extract, 7.4 g of $Na_2HPO_4 \cdot 12H_2O$ and 2 g of citric acid monohydrate dissolved in 1 L of distilled water) for an inhibition assay using a paint brush. The spore suspension was filtered through cheesecloth and stored on ice until use.

J. Agric. Food Chem. 2015, 63, 4050−4059

UV Irradiation of the Rice Leaves. UV irradiation was conducted by the previously described method.[9] UV-irradiated rice leaves were incubated at 26 °C under continuous light condition for 3 days for the screening and isolating of UV-inducible substances, and for 0, 1, 2, 3, 4, and 5 days for the quantitation of **1**−**12** in the UV irradiation time course experiment. The UV-irradiated leaves were stored at −20 °C before use.

Purification of 9β-Pimara-7,15-diene-3β,6β,19-triol, 1, and Stemar-13-en-2α-ol, 2, from UV-Irradiated Rice Leaves. The 400 g of UV-irradiated rice leaves were cut and shaken in 6 L of 80% (v/v) MeOH with a reciprocal shaker for 24 h. The homogenate was filtered to obtain an extract, and the residual leaves were then re-extracted with 4 L of 80% MeOH in the same manner. The combined extract was concentrated in vacuo to remove the MeOH. The resulting aqueous concentrate was extracted with EtOAc, and the organic layer was evaporated to dryness in vacuo. The EtOAc extract was subjected to column chromatography on 50 g of 63-210-μm particle size, silica gel 60N (Kanto Chemical Co., Tokyo, Japan) and eluted with a stepwise gradient of *n*-hexane/EtOAc (95:5, 80:20, 60:40, 20:80, 0:100; 300 mL of each). Each fraction was analyzed by GC/MS to detect the UV-induced substances. Compounds **1** and **2**, exhibiting plausible molecular ions at *m*/*z* 302 and 288, were detected in the fraction eluted with 80:20 and 0:100 *n*-hexane/EtOAc, respectively. Their MS and t_R did not correspond to those of known phytoalexins.

The fraction eluted with 0:100 *n*-hexane/EtOAc was applied to a 20 cm × 20 cm, 1.0 mm thick, silica gel 60 F_{254} preparative TLC plate (Merck Millipore, Billerica, MA) developed with 1:1 benzene/EtOAc. The R_f 0.10−0.40 TLC region, which contained **1**, was scraped off and extracted with EtOAc. The EtOAc extract was evaporated in vacuo to dryness to give a 127 mg of TLC-purified fraction. The fraction was dissolved in MeOH at a concentration of 4% (w/v) and separated by ODS-HPLC under the following conditions: column, 25 cm × 1 cm i.d., 5 μm particle size, COSMOSIL 5C18AR (Nacalai Tesque, Kyoto, Japan); solvent, 70% (v/v) MeOH; injection volume in a run, 200 μL. The peak containing **1** (t_R 30−35 min) was collected and evaporated to dryness in vacuo to afford 2.1 mg of purified **1**. Compound **1** was identified as 9β-pimara-7,15-diene-3β,6β,19-triol by spectroscopic methods. High-resolution electron ionization mass spectrum (HREIMS) (*m*/*z*): (M^+) calcd for $C_{20}H_{32}O_3$, 320.2352; found, 320.2377; ^{1}H NMR (400 MHz, $CDCl_3$, δ): 0.87 (3H, s, H-17), 1.26 (3H, s, H-20), 1.29 (3H, s, H-18), 1.91 (dd, *J* = 12.1, 2.3 Hz, 1H, H-14), 2.08 (d, *J* = 12.1 Hz, 1H, H-14), 3.32 (m, 1H, H-3), 4.03 (d, *J* = 11.6 Hz, 1H, H-19), 4.32 (d, *J* = 11.6 Hz, 1H, H-19), 4.46 (dd, *J* = 5.5, 3.8 Hz, 1H, H-6), 4.90 (dd, *J* = 10.7, 1.2, 1H, H-16), 4.94 (dd, *J* = 17.4, 1.2, 1H, H-16), 5.56 (br d, *J* = 5.5 Hz, 1H, H-7), 5.82 (dd, *J* = 17.4, 10.7 Hz, 1H, H-15); ^{13}C NMR (100 MHz, $CDCl_3$, δ): 21.77 (q, C-17), 21.85 (q, C-18), 24.81 (t, C-11), 26.39 (q, C-20), 27.25 (t, C-2), 35.00 (s, C-10), 35.61 (t, C-1), 37.54 (t, C-12), 39.35 (s, C-13), 44.15 (s, C-4), 47.88 (t, C-14), 48.42 (d, C-5), 53.49 (d, C-9), 62.77 (t, C-19), 65.01 (d, C-6), 80.59 (d, C-3), 109.68 (t, C-16), 121.66 (d, C-7), 141.14 (s, C-8), 149.61 (d, C-15); EIMS (70 eV) *m*/*z*: M^+ 320 (2), 302 (21), 287 (50), 269 (43), 149 (59), 105 (54), 91 (60), 81 (66), 61 (83), 55 (100); IR (KBr) $\tilde{\nu}_{max}$ (cm^{-1}): 3370, 1459, 1377, 1342, 1185, 959, 907; $[\alpha]^{20}_D$ −150 (*c* 0.16, $CHCl_3$).

The fraction eluted with 80:20 *n*-hexane/EtOAc was subjected to preparative TLC and developed with 3:1 benzene/EtOAc. The R_f 0.55−0.82 TLC region, which contained **2**, was scraped off and extracted with EtOAc. The EtOAc extract was evaporated in vacuo to dryness to give a 59 mg of TLC-purified fraction. The fraction was dissolved in MeOH at a concentration of 1% (w/v) and separated by ODS-HPLC under the following conditions: column, COSMOSIL 5C18AR; solvent, 70% (v/v) MeOH; injection volume in a run, 100 μL. A peak containing **2** (t_R 60−65 min) was collected and evaporated to dryness in vacuo to afford 1.3 mg of purified **2**. Compound **2** was identified as stemar-13-en-2α-ol by spectroscopic methods. HREIMS (*m*/*z*): (M^+) calcd for $C_{20}H_{32}O$, 288.2452; found, 288.2446; ^{1}H- and ^{13}C NMR (C_6D_6): see Table 1; EIMS (70 eV) *m*/*z*: M^+ 288 (33), 270 (57), 255 (100), 131 (43), 119 (48), 105 (92), 91 (83), 79 (55), 69 (53), 58 (86); IR (KBr) $\tilde{\nu}_{max}$ (cm^{-1}): 3348, 2954, 1459, 1389, 1317, 1255, 1162, 1039; $[\alpha]^{20}_D$ +60 (*c* 0.1, $CHCl_3$).

Screening of UV-Inducible Substances with LC/MS. The control and UV-irradiated rice leaves were cut, weighed, and shaken in 80% (v/v) MeOH [5 mL/0.1 g fresh weight (FW)] using a reciprocal shaker. The homogenate was filtered through a cotton-plugged Pasteur pipet, and the extract was refiltered through a 13 mm diameter, 0.22-μm pore size, cellulose acetate membrane filter (Lab Lab Company, Tokyo, Japan). A 10 μL volume of the solution was subjected to LC/MS analysis. The liquid chromatographic separation of the analytes was achieved in a 150 mm × 2.1 mm i.d., 3.0-μm particle size, Atlantis T3 column (Waters, Milford, MA) with a binary gradient of 0.1% (v/v) aqueous formic acid (solvent A) and MeOH containing 0.1% (v/v) formic acid (solvent B) at flow rate of 0.2 mL/min and at a temperature of 40 °C. The solvent gradient elution was programmed as follows: initial,

20% B; 0−5 min, isocratic elution by 20% B; 5−35 min, a linear gradient from 20% B to 100% B; 35−40 min, isocratic elution by 100% B. The scan range of MS was set as m/z 100−711 (enhanced MS scan). Every extracted ion chromatogram obtained from the extracts of the control and UV-irradiated leaves were compared using LightSight 2.2 software (AB Sciex) in an attempt to discover novel UV-induced substances. An unknown compound exhibiting an m/z of 333, which was estimated as $[M + H]^+$, was detected at a t_R of 29.7 min in the chromatogram of the UV-treated leaves. Therefore, suspecting a novel phytoalexin candidate, we attempted to purify compound **3**.
