Purification of 1α,2α-Dihydroxy-*ent*-12,15-cassadiene-3,11-dione, 3, from UV-Irradiated Rice Leaves. The LC/MS/MS analysis conditions were defined for a rapid monitoring of **3** during the purification procedure. The liquid chromatographic separation of the analytes was conducted using a 50 mm × 2.0 mm i.d., 3.0 μm particle size, TSKgel ODS-100V column (Tosoh, Tokyo, Japan) with a binary gradient of 0.1% (v/v) aqueous formic acid (solvent A) and MeOH containing 0.1% (v/v) formic acid (solvent B) at a flow rate of 0.2 mL/min and at a temperature of 40 °C. The solvent gradient elution was programmed as follows: initial, 20% B; 0−10 min, a linear gradient from 20% B to 100% B; 10−12 min, isocratic elution by 100% B. The scan range of MS was set as m/z 80−338 (enhanced MS scan). Compound **3** was detected at a t_R of 9.4 min under these conditions.

EtOAc extract was prepared from 400 g of UV-irradiated rice leaves in the same manner as the purification of **1** and **2**. The EtOAc extract was subjected to column chromatography on 60 g of silica gel and eluted with a stepwise gradient of *n*-hexane/EtOAc (95:5, 80:20, 60:40, 40:60, 20:80, 0:100; 300 mL of each). Each fraction was analyzed by LC/MS/MS under the previously described conditions to detect compound **3**. Compound **3** was detected in the fraction eluted with 20:80 *n*-hexane/EtOAc. The fraction was subjected to preparative TLC and developed with 10:1 chloroform/MeOH. The R_f 0.41−0.76 TLC region, which contained **3**, was scraped off and extracted with EtOAc. The EtOAc extract was evaporated in vacuo to dryness to give a 65 mg of TLC-purified fraction. The fraction was subjected to reversed-phase column chromatography using 6 g of 200−300 mesh, Chromatorex ODS (Fuji Silysia Chemical Ltd., Kasugai, Japan) and eluted with a stepwise gradient of MeOH/H_2O (20, 50, 80, 100% MeOH; 96 mL of each). Each fraction was also analyzed by LC/MS/MS in the same manner as the previous purification step. The fraction containing **3**, which was eluted with 80% MeOH, was then evaporated in vacuo to dryness to give a 26 mg of reversed-phase-chromatography-purified fraction. The fraction was dissolved in MeOH at a concentration of 2% (w/v) and separated by ODS-HPLC under the following conditions: column, 25 cm × 1 cm i.d., 5 μm particle size, Luna 5 μm C18(2) (Phenomenex, Torrance, CA); solvent, 60% (v/v) MeOH; injection volume in a run, 100 μL. A peak containing **3** (t_R 70−74 min) was collected and evaporated to dryness in vacuo to afford 1.9 mg of purified **3**. Compound **3** was identified as 1α,2α-dihydroxy-*ent*-12,15-cassadiene-3,11-dione by spectroscopic methods, as described in the Results and Discussion section. **3**. HREIMS (m/z): (M^+) calcd for $C_{20}H_{28}O_4$, 332.1988; found, 332.1955; ^{1}H- and ^{13}C NMR ($CDCl_3$): see Table 2; EIMS (70 eV) m/z: M^+ 332 (2), 315 (10), 279 (4), 229 (5), 203 (6), 167 (11), 149 (85), 83 (42), 57 (100); UV (MeOH) λ_{max} (log ε): 269 (4.0); IR (KBr) $\tilde{\nu}_{max}$ (cm^{-1}): 3453, 2963, 2857, 1726, 1634; $[\alpha]^{20}_D$ −147 (c 0.17, $CHCl_3$). During the purification of **3**, we also purified 2.6 mg of **8** from the 60:40 *n*-hexane/EtOAc-eluted silica gel column chromatography fraction, followed by reversed-phase chromatography and ODS-HPLC. The ^{1}H- and ^{13}C NMR data of **8** coincided with those previously reported.[7]

Assay of the Antifungal Activity against the Rice Blast Fungus. For the fungal colony growth inhibition assay, each test compound was dissolved in an unsolidified PDA medium containing 1% (v/v) dimethyl sulfoxide at a concentration of 75 or 300 μM. The PDA medium was poured into a 9 cm Petri dish and solidified at room temperature. A PDA medium containing 1% (v/v) dimethyl sulfoxide was used as a control. Four 25 mm^2 pieces of the blast fungus, which had been cultured on a PDA medium, were transplanted to the PDA medium. The inoculated PDA medium was incubated at 26 °C in the dark. After 0, 1, 2, 3, 4, and 5 days of incubation, the distance between the front of the planted pieces and the front of the mycelium colony was measured using a ruler.

For the spore germination and germ tube growth inhibition assay, the concentration of spore suspension was adjusted to 6 × 10^4 spores/mL with a prechilled spore germination medium. The samples were dissolved in distilled water containing 0.2% (v/v) dimethyl sulfoxide and 0.1% (v/v) Tween 80. The 12.5 μL of spore suspension and the 12.5 μL of sample solution were mixed on a concavity slide and then incubated for 16 h at 26 °C in a highly humidified box in the dark. The germination rate and germ tube length of the *M. oryzae* spores were measured under a microscope. The inhibitory activity against spore germination and germ tube elongation was determined according to the previously reported method.[9]

Quantitative LC/MS/MS Analysis of 9β-Pimara-7,15-diene-3β,6β,19-triol, 1, Stemar-13-en-2α-ol, 2, 1α,2α-

J. Agric. Food Chem. 2015, 63, 4050−4059

Dihydroxy-*ent*-12,15-cassadiene-3,11-dione, 3, and Other Phytoalexins, 4−12. The liquid chromatographic separation of the analytes was achieved in an Atlantis T3 column with a binary gradient of 0.1% (v/v) aqueous formic acid (solvent A) and MeCN containing 0.1% (v/v) formic acid (solvent B) at a flow rate of 0.2 mL/min and at a temperature of 40 °C. The solvent gradient elution was programmed as follows: initial, 40% B; 0−3 min, isocratic elution by 40% B; 3−23 min, a linear gradient from 40% B to 100% B; 23−28 min, isocratic elution by 100% B. The selective reaction monitoring (SRM) transitions and the parameters of the mass spectrometer were optimized for detecting **1**−**12** using Analyst 1.5.1 software (AB Sciex). Calibration curves were obtained from the SRM peak areas of the standards for **1**−**12** in a concentration range of 1−1000 ng/mL. The concentrations of the analytes were calculated from their individual SRM peak area based on the calibration curves.

Quantitation of 9*β*-Pimara-7,15-diene-3*β*,6*β*,19-triol, 1, Stemar-13-en-2*α*-ol, 2, 1*α*,2*α*-Dihydroxy-*ent*-12,15-cassadiene-3,11-dione, 3, and Other Phytoalexins, 4−12, from UV-Irradiated and *M. oryzae*-Inoculated Rice Leaves. UV-irradiated rice leaves (ca. 3 leaves) were cut, weighed and shaken in 80% (v/v) MeOH (5 mL/0.1 g FW) using a reciprocal shaker. The extract was filtered through a cotton-plugged Pasteur pipet and was refiltered through a membrane filter.

The spore suspension of *M. oryzae* was diluted with water to a concentration of 2×10^5 spores/mL and 25 μL of the spore suspension was then applied to press-injured spots with a diameter of 1 mm on the rice leaves. The leaves were maintained in a highly humidified box and incubated for 1, 2, 3, 4, and 5 days at 26 °C under light irradiation. The leaf tissues around the injured spots were excised with a 4 mm i.d., cork borer. Approximately 45 pieces of the excised leaf tissues (ca. 100 mg) were collected and shaken in 5 mL of 80% MeOH using a reciprocal shaker. The homogenate was filtered through a cotton-plugged Pasteur pipet and a membrane filter.

A 5 μL volume of the sample solution was subjected to the aforementioned LC/MS/MS analysis to quantitate **1**−**12**.

RESULTS AND DISCUSSION

Purification and Structural Elucidation of 9*β*-Pimara-7,15-diene-3*β*,6*β*,19-triol, 1, Stemar-13-en-2*α*-ol, 2, and 1*α*,2*α*-Dihydroxy-*ent*-12,15-cassadiene-3,11-dione, 3, from UV-Irradiated Rice Leaves. We detected UV-induced compounds **1** and **2** in the silica gel column chromatography-purified fractions of UV-irradiated rice leaves by GC/MS analysis. Compounds **1** and **2** were detected at t_R 19.2 and 18.2 min and their mass spectra showed plausible molecular ions at m/z 302 and 288, respectively. These t_R and mass spectra did not correspond to those of known phytoalexins or to their biosynthetic precursors when compared to the t_R and mass spectra of authentic samples. Compounds **1** and **2** were not detected in healthy rice leaves that had not been UV-irradiated. Therefore, we isolated **1** and **2** to determine their structures. Compounds **1** (2.1 mg, a white solid) and **2** (1.3 mg, a colorless oil) were successfully purified from the 400 g of UV-irradiated rice leaves by chromatographic methods.

Although we estimated m/z 302 as the molecular ion of **1** in the GC/MS analysis, m/z 320 was detected as a more reasonable molecular ion in the MS analysis using the direct inlet mode, suggesting that m/z 302 should be $[M-H_2O]^+$. The HREIMS analysis of **1** suggested a molecular formula of $C_{20}H_{32}O_3$ and five degrees of unsaturation. The NMR spectra of **1** suggested that it contains two oxygenated methines and one oxygenated methylene. The acetylation of **1** using acetic anhydride gave a triacetylated compound, indicating that **1** has three hydroxyl groups (data not shown). The 1D- and 2D-NMR spectra indicated that the structure of **1** was 9*β*-pimara-7,15-diene-3*β*,6*β*,19-triol, which had been reported as a $LiAlH_4$-reduction product of **5**.[30] We also synthesized the compound from **5** using the method reported in the literature, and the ^{1}H- and ^{13}C NMR data of the synthetic **1** coincided with those of **1** obtained and purified from the UV-irradiated rice leaves (data not shown). Therefore, UV-induced compound **1** from rice leaves was identified as 9*β*-pimara-7,15-diene-3*β*,6*β*,19-triol.

The HREIMS analysis of **2** suggested a molecular formula $C_{20}H_{32}O$ and five degrees of unsaturation. The number of carbon atoms agreed with the ^{13}C NMR data (Table 1). IR data indicated the presence of a hydroxyl group, whose proton was not observed in the ^{1}H NMR spectrum. ^{13}C NMR and distortionless enhancement by polarization transfer (DEPT) spectra indicated the presence of one olefinic methine (C-14; δ_C 124.64 ppm) and one olefinic quaternary carbon (C-13; δ_C 139.06 ppm), suggesting that **2** has one C−C double bond. Five degrees of unsaturation and the presence of one C−C double bond indicated that **2** has four rings. ^{13}C NMR and DEPT data showed that **2** consists of four methyl, seven methylene, five methine, and four quaternary carbons. These results suggested that **2** should be a monohydroxylated tetracyclic diterpene. The ^{13}C chemical shifts of **2** were very similar to those of **7**, a rice stemarane-type phytoalexin, except that **2** lacks an oxymethylene signal corresponding to the C-19 of **7**.[31] Moreover, four methyl signals were observed in the ^{1}H- and ^{13}C NMR spectra of **2**, whereas three methyl signals were observed in those of **7**. Typical signals of a stemar-13-ene skeleton, such as δ_H 5.05 (H-14), 2.13 (H-12), 1.63 (H-17), 0.89 (H-20), 0.83 (H-18), and 0.79 (H-19), were observed in the ^{1}H NMR spectrum.[31−36] 2D-NMR correlations confirmed the stemar-13-ene skeleton (Figure 2). A methine carbon at δ_C 64.5 ppm (C-2) should be connected to a hydroxyl group. The coupling constants between H-2 and H-1/H-3 as well as nuclear Overhauser enhancement and exchange spectroscopy (NOESY) correlations between H-2 and H-19/H-20 indicated that the 2-hydroxyl group should be equatorial (α-orientation). These results suggested that the structure of **2** should be 19-deoxyoryzalexin S. Although the absolute stereochemistry of **2** was not determined experimentally, given its origin, it likely has the same stemarane skeleton as **7**. We thus concluded that **2** must be stemar-13-en-2*α*-ol.

UV-induced compounds **1** and **2** were successfully found using GC/MS analysis. We subsequently attempted to search for novel phytoalexins using LC/MS analysis. As a result, we discovered compound **3**, which showed an m/z 333 estimated as $[M + H]^+$ and a t_R of 29.7 min in the chromatogram of the UV-treated leaves. Its t_R and mass spectrum did not correspond to those of known phytoalexins or their biosynthetic precursors, as determined by a comparison with authentic samples and theoretical m/z values. Moreover, we estimated that the accumulated amount of **3** was as high as that of **5** based on the peak area, whose induction level was reported to be relatively high among known phytoalexins in UV-irradiated and *M. oryzae*-infected rice leaves.[9] Compound **3** was not detected in healthy rice leaves that had not been UV-irradiated. Therefore, we performed a large-scale isolation of **3** to determine its structure. Compound **3** (1.9 mg, a pale-yellow

oil) was successfully purified from the 400 g of UV-irradiated rice leaves by chromatographic methods. Compound **3** could not be detected by GC/MS, likely because of its high polarity or heat-labile property.

The HREIMS analysis of **3** suggested a molecular formula $C_{20}H_{28}O_4$ and seven degrees of unsaturation. The numbers of carbons and hydrogens agreed with the ^{1}H and ^{13}C NMR data (Table 2). ^{13}C NMR and IR data indicated that two of four oxygens belonged to two carbonyl groups and the two remaining oxygens belonged to two hydroxyl groups. ^{13}C NMR and DEPT data indicated the presence of two olefinic methines, one terminal olefinic methylene and one olefinic quaternary carbon, suggesting that **3** had two C−C double bonds. Seven degrees of unsaturation and the presence of two C−C double bonds and two carbonyl groups indicated that **3** had three rings. Correlated spectroscopy (COSY) and heteronuclear single quantum coherence (HSQC) correlations suggested OH-1/C-1/C-2/OH-2, C-15/C-16 and C-5/C-6/C-7/C-8/C-9/C-14/C-17 connectivities (Figure 2). Heteronuclear multiple bond correlation (HMBC) data (Figure 2), as well as UV (269 nm) and IR (1634 cm^{-1}) absorptions indicated the presence of an $\alpha,\beta,\gamma,\delta$-unsaturated ketone (C-11/C-12/C-13/C-15/C-16). The HMBC data suggested a quaternary carbon (C-4) bearing geminal methyls (C-18 and C-19) at the α-position of a ketone (C-3). The HMBC data were used to connect these fragment structures and the remaining fractions, including a quaternary carbon (C-10) and a methyl group (C-20). The skeleton of the deduced structure coincided with phytocassanes, the rice *ent*-cassadiene-type diterpene phytoalexins.[7,8,37] The ^{13}C chemical shifts of **3** were very similar to those of **12** except for the C-2, which bore a hydroxyl group in **3** but not in **12**. Moreover, NOESY correlations indicated that H-1/H-2/H-5/H-9/H-17/H-19 were located on the same side of the ring and that H-8/H-14/H-20/1-OH were located on the other side. These results suggested that **3** had the same relative configuration as phytocassanes. Although the absolute stereochemistry of **3** was not determined experimentally, given its origin, **3** likely has the same *ent*-cassadiene skeleton as phytocassanes. Therefore, the structure of **3** was determined as 1α,2α-dihydroxy-*ent*-12,15-cassadiene-3,11-dione.

Accumulation of 9β-Pimara-7,15-diene-3β,6β,19-triol, 1, Stemar-13-en-2α-ol, 2, and 1α,2α-Dihydroxy-*ent*-12,15-cassadiene-3,11-dione, 3, in UV-Irradiated and *M. oryzae*-Inoculated Rice Leaves. We subsequently developed a quantitation method for **1**, **2**, and **3**. The leaf extract was subjected to LC/MS/MS analysis, which resulted in the detection of these compounds in the SRM mode by positive ESI. The change in the accumulated levels of **1**−**12** after UV irradiation was analyzed using this method. We observed that brown spots dramatically increased in number and area 24−48 h after UV irradiation, and this change was not observed in the control leaves. Corresponding to this apparent change, the amounts of **1**, **2**, and **3** significantly increased after UV irradiation, reaching a maximum after 48 h and then slightly decreasing after 72−120 h (Figure 3). The leaves that had not been UV-irradiated did not show the presence of these compounds. In the case of *M. oryzae* infection, brown spots

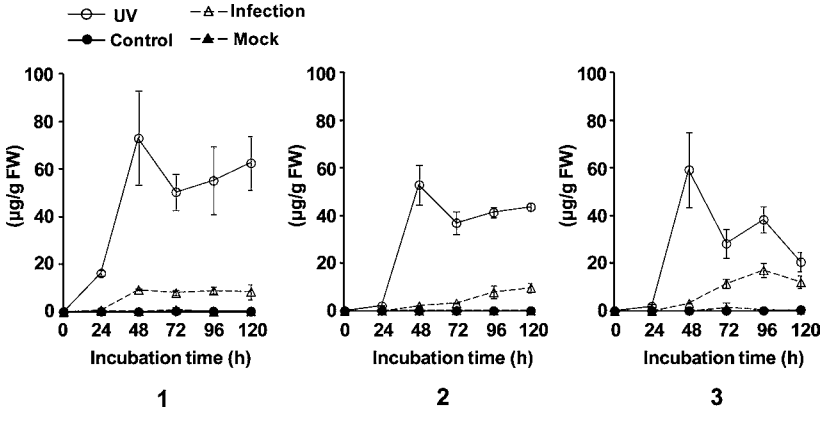

Figure 3. Time-dependent accumulation of 9β-pimara-7,15-diene-3β,6β,19-triol, **1**, stemar-13-en-2α-ol, **2**, and 1α,2α-dihydroxy-*ent*-12,15-cassadiene-3,11-dione, **3**, in UV-irradiated and rice blast fungus-inoculated rice leaves. Values are presented as the mean ± SD (n = 3).

J. Agric. Food Chem. 2015, 63, 4050−4059

emerged at the inoculated site 24 h after inoculation, and their areas gradually spread up to 120 h after inoculation. The brown spots were not observed in the mock-treated leaves. The amounts of **1**, **2**, and **3** also gradually increased up to 96 h after inoculation and were almost stable until 120 h after inoculation (Figure 3). The mock-treated leaves did not accumulate **1**, **2**, and **3**.

The contents of **1**−**12** in the UV-irradiated and *M. oryzae*-inoculated leaves are summarized in Table 3. A flavonoid-type phytoalexin, **4**, accumulated at the highest level in the UV-irradiated and *M. oryzae*-inoculated leaves. The levels of diterpenoid-type compounds in the UV-irradiated leaves were similar. The accumulation levels of **1**, **2**, and **3** in the *M. oryzae*-inoculated leaves were not substantially different from those of known phytoalexins, **6** and **8**−**12**, but were lower than those of **5** and **7**.

Antifungal Activities of 9β-Pimara-7,15-diene-3β,6β,19-triol, 1, Stemar-13-en-2α-ol, 2, and 1α,2α-Dihydroxy-*ent*-12,15-cassadiene-3,11-dione, 3. The antifungal activities of **1**, **2**, **3** and phytoalexins against *M. oryzae* were determined by a spore germination and germ tube growth assay. Initially, we tested the solubility of these compounds in an aqueous liquid medium and observed that **3** and **5** were insoluble at high concentrations. To ensure the effective concentration of insoluble compounds in the test, we attempted to add dimethyl sulfoxide and Tween 80 to the test solution in final concentrations of 0.1% and 0.05%, respectively. The additives did not affect the spore germination rate (95%) or germ tube growth of the control experiment. The spore germination was completely suppressed by the addition of **3** or **4** at a concentration of 300 μM. In the germ tube growth assay, **4**, **5**, **7**, and **3** exerted a dose-dependent inhibitory activity (Figure 4). The IC_{50} values of these compounds were calculated as 37, 74, 122, and 16 μM, respectively. Compounds **1** and **2** inhibited germ tube growth only in high doses, and their IC_{50} values were calculated to be approximately equal to or greater than 300 μM.

Furthermore, we investigated whether **3** inhibited the fungal mycelial colony growth of *M. oryzae* on a solid medium. Compound **3** showed dose-dependent inhibition of fungal colony growth, and the inhibition rate was calculated as 26% at 300 μM after 5 days of incubation (Figure 5). We also examined the inhibitory activity of known phytoalexins, **4**, **5**, and **8**. The inhibition rates of **4** and **8** were calculated as 51% and 22% at 300 μM after 5 days of incubation, respectively. However, **5** only slightly inhibited fungal growth. The inhibitory activities of **4** and **5** were approximately the same as that observed in previous reports.[12,13] Thus, the antifungal

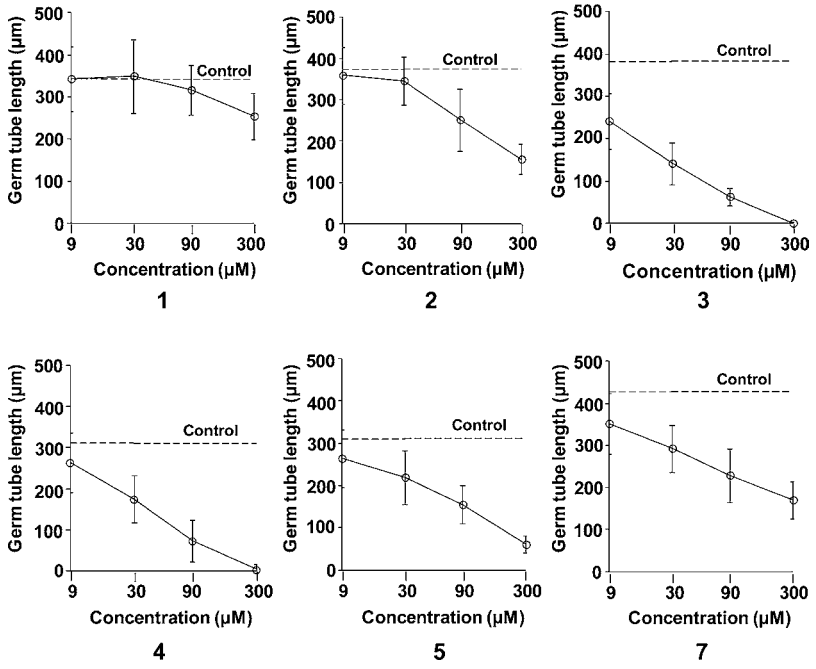

Figure 4. Antifungal activity of 9β-pimara-7,15-diene-3β,6β,19-triol, **1**, stemar-13-en-2α-ol, **2**, and 1α,2α-dihydroxy-*ent*-12,15-cassadiene-3,11-dione, **3**, against the germ tube growth of rice blast fungus. Values are presented as the mean ± SD (n = 100).

DOI: 10.1021/acs.jafc.5b00785
J. Agric. Food Chem. 2015, 63, 4050−4059

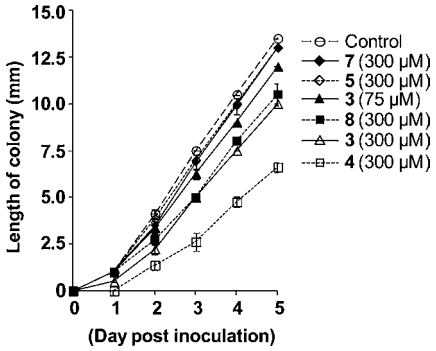

Figure 5. Antifungal activity of 1α,2α-dihydroxy-*ent*-12,15-cassadiene-3,11-dione, **3**, and phytoalexins against the mycelium growth of the rice blast fungus. Data are presented as means ± SD (n = 4) from four independent samples.

activity of **3** on mycelial growth was estimated to be approximately the same as that of **8** and lower than that of **4**.

The formation of compound **1** and **2** were induced by both UV irradiation and *M. oryzae* infection (Figure 3). However, **1** and **2** exhibited only slight antifungal activity on *M. oryzae* (Figure 4). Thus, these are not recognized as rice phytoalexins. Its structure clearly indicated that **1** should be biosynthesized by the oxidation of 9β-pimara-7,15-diene, which is a biosynthetic precursor of **5**. We speculated that **1** may be a biosynthetic intermediate of **5**. The structure of compound **2** suggested that **7** can be produced from **2** by the hydroxylation of the C-19. Kato et al.[20] identified a potential precursor of oryzalexins E and F, *ent*-isopimara-8(14),15-dien-3β-ol, from UV-irradiated rice leaves. They also confirmed that the enzymatic hydroxylation of each precursor was an important activation step for the antifungal activity of oryzalexins E and F.[19] In the case of **7**, C-19 oxidation is likely important for its antifungal activity.

The structure of **3** is regarded as 1-hydroxyphytocassane A, 3-dehydrophytocassane B, or 2-hydroxyphytocassane E. The accumulated level of **3** was approximately the same as that of **8** in the UV-irradiated and *M. oryzae*-inoculated leaves (Figure 3 and Table 3). Compound **8** has been reported to be the most abundant phytocassane in *M. oryzae*-inoculated rice leaves.[8] Thus, **3** is considered a major compound among rice cassane-type diterpenes. Phytocassanes A–D were isolated from *Rhizoctonia solani*-infected rice leaf stems,[7] and phytocassane E was isolated from elicitor-treated rice suspension cells.[8] We speculated that the difference between the materials may be critical to the isolation of **3** in this study. Moreover, compound **3** has a strong inhibitory activity on the spore germination and germ tube elongation of *M. oryzae*, to the same extent as **4** (Figure 4). The antifungal activity of **3** on fungal colony growth was greater than that of **5**, lower than that of **4** but approximately the same as that of **8** (Figure 5). Therefore, **3** is recognized as a phytoalexin with a *ent*-cassane-type diterpene skeleton and should be named phytocassane F.

Our study should contribute to greater understanding of the resistance of rice against *M. oryzae* and strengthen the foundation of phytoalexin biosynthetic pathways. In total, a flavanone **4** and 16 diterpene phytoalexins, including **3**, were identified from rice leaves.[2−11] Obara et al.[29] reported that many monoterpenes and sesquiterpenes were emitted from rice leaves in response to *M. oryzae* infection. Taniguchi et al.[38] also reported a volatile sesquiterpene, β-elemene, with an antifungal effect on *M. oryzae*. In addition to terpenoids, diverse antibacterial and antifungal components, such as oxidized fatty acids,[39] tryptophan-derived metabolites or phenylamides,[40,41] have been discovered in rice leaves. We found that **4** and **5** could be metabolized and detoxified by *M. oryzae*.[12,13,42] On the basis of these findings, we speculate that rice does not depend on only one or a few defensive compounds but rather divides its own resistant capacity among diverse compounds.

■ ACKNOWLEDGMENTS

Compounds **1** and **2** were discovered in our laboratory by Hideki Kato for the first time. Unfortunately, he passed away on May 13, 2010. We would like to express our respect for his pioneering work. We thank Shigeru Tamogami and Randeep Rakwal for critical reading of the manuscript. We thank Kazunori Okada for providing the standard solution of phytocassanes. We thank Hiroshi Kawaide for his helpful advice.

■ ABBREVIATIONS USED

COSY, correlated spectroscopy; DEPT, distortionless enhancement by polarization transfer; EI, electron ionization; FW, fresh weight; HMBC, heteronuclear multiple bond correlation; HSQC, heteronuclear single quantum coherence; HREIMS, high-resolution electron ionization mass spectrometry; NOESY, nuclear Overhauser enhancement and exchange spectroscopy; PDA, potato dextrose agar; SRM, selected reaction monitoring

profile, some leaflets were crushed between fingertips and then orthonasally evaluated by experienced panelists familiar with authentic Sri Lankan cuisine.

Reference Odorants. **1**, **2**, (*R*)-**2**, (*S*)-**2**, **4**−**7**, **10**, **14**−**19**, (*R*)-**19**, **20**, **21**, and **23**−**27** were obtained from Sigma-Aldrich (Taufkirchen, Germany); **3**, **8**, **11**−**13**, (*R*)-**21**, and (*S*)-**26** were synthesized as detailed below.

Miscellaneous Chemicals and Reagents. 6-Methylheptanoic acid was purchased from Alfa Aesar (Karlsruhe, Germany). 7-Methyloctan-1-ol was from C/D/N Isotopes (Pointe-Claire, QC, Canada). Dess−Martin periodinane and (2*S*)-2-methylbutan-1-ol were from Sigma-Aldrich. Dichloromethane, diethyl ether, and pentane were freshly distilled before use. Silica gel 60 (0.040−0.063 mm) was purchased from VWR (Darmstadt, Germany) and purified as follows: After extraction with hydrochloric acid (32%; 3 h), the gel was washed with water until the eluate was acid free, dried at 120 °C until constant weight, and adjusted to 7% water content. Mercurated agarose gel was prepared from Affi-Gel 10 (Bio-Rad, Munich, Germany).[21]

Syntheses. The following reference odorants were synthesized using procedures detailed in the literature: **3**,[22] **11**,[23] **13**,[24] and (*S*)-**21**.[25] (*S*)-**26** was obtained from (2*S*)-2-methylbutan-1-ol by oxidation with Dess−Martin periodinane,[26] as detailed below for the synthesis of 6-methylheptanal.

6-Methylheptan-1-ol. In an argon atmosphere a solution of 6-methylheptanoic acid (288 mg, 2 mmol) in anhydrous diethyl ether (5 mL) was added to a suspension of lithium aluminum hydride (152 mg, 4 mmol) in anhydrous diethyl ether (10 mL) under stirring. The mixture was heated at reflux for 1 h. Under cooling (0 °C) a saturated aqueous ammonium chloride solution (10 mL) was added, followed by hydrochloric acid (2 mol/L; 10 mL). The phases were separated, and the aqueous phase was extracted with diethyl ether (10 mL). The combined organic phases were washed with saturated aqueous sodium hydrogen carbonate solution (5 mL) and dried over anhydrous sodium sulfate. The solvent was removed in vacuo to give 6-methylheptan-1-ol as a colorless oil (226 mg = 87%). RI FFAP, 1510; MS (EI, 70 eV), *m*/*z* (%) 39 (19), 40 (3), 41 (75), 42 (32), 43 (74), 44 (4), 45 (3), 53 (5), 54 (3), 55 (89), 56 (100), 57 (33), 67 (6), 68 (21), 69 (81), 70 (30), 71 (4), 83 (6), 84 (19), 97 (20), 98 (2).

*6-Methylheptanal (**8**).* 6-Methylheptan-1-ol (130 mg, 1 mmol) in dichloromethane (5 mL) was added to Dess−Martin periodinane (530 mg, 1.25 mmol) in dichloromethane (5 mL), and the mixture was stirred for 1 h at ambient temperature. Diethyl ether (80 mL) and a solution of sodium thiosulfate (1 mol/L; 100 mL) in saturated aqueous sodium hydrogen carbonate solution were added, and the mixture was intensely shaken until the initial opacity disappeared. The organic phase was washed with aqueous sodium hydrogen carbonate solution (0.5 mol/L; 100 mL) and dried over anhydrous sodium sulfate. The solvent was removed, and the raw product was purified by column chromatography with silica gel (6 g). After a washing with pentane (50 mL), the target compound was eluted with pentane/diethyl ether (45 mL + 5 mL) and its exact concentration in the eluate (50 mL) was determined by GC-FID using octanal as internal standard. Yield, 74.2 mg = 58%; purity, 90% (GC-FID); MS (EI, 70 eV), *m*/*z* (%) 39 (16), 41 (79), 42 (13), 43 (100), 44 (30), 45 (9), 53 (4), 55 (17), 56 (30), 57 (44), 67 (12), 68 (6), 69 (36), 71 (4), 82 (31), 83 (4), 84 (11), 85 (21), 93 (2), 95 (18), 100 (4), 109 (1), 110 (2); ^{1}H NMR (400 MHz, $CDCl_3$), δ 0.87 (d, 6H, J = 6.6 Hz, $CH(C\underline{H}_3)_2$), 1.15−1.26 (m, 2H, $CH_2C\underline{H}_2CH(CH_3)_2$), 1.28−1.37 (m, 2H, $CH_2C\underline{H}_2CH_2CH_2CHO$), 1.54 (nonet, 1H, J = 6.6 Hz, $CH_2C\underline{H}(CH_3)_2$), 1.61 (quint, 2H, J = 7.4 Hz, $CH_2C\underline{H}_2CH_2CHO$, 2.42 (td, 2H, J = 7.4, 1.9 Hz, $CH_2C\underline{H}_2CHO$), 9.76 (t, 1H, J = 1.9 Hz, $CH_2C\underline{H}O$); ^{13}C NMR (100 MHz, $CDCl_3$), δ 22.3 ($\underline{C}H_2CH_2CHO$), 22.5 ($CH(\underline{C}H_3)_2$), 26.9 ($\underline{C}H_2(CH_2)_2CHO$), 27.8 ($\underline{C}H(CH_3)_2$), 38.6 ($\underline{C}H_2CH(CH_3)_2$), 43.9 ($\underline{C}H_2CHO$), 203.0 (CHO).

*7-Methyloctanal (**12**).* Using the procedure detailed for **8**, **12** was obtained by oxidation of 7-methyloctan-1-ol (144 mg, 1 mmol) and purification by silica gel chromatography. The exact concentration of **12** in the eluate (50 mL) was determined by GC-FID using nonanal as internal standard. Yield, 64.4 mg = 45%; purity, 96% (GC-FID); MS (EI, 70 eV), *m*/*z* (%) 39 (16), 41 (73), 42 (16), 43 (78), 44 (32), 45 (7), 53 (4), 54 (6), 55 (63), 56 (68), 57 (100), 58 (5), 67 (24), 68 (18), 69 (24), 70 (15), 71 (9), 72 (3), 81 (27), 82 (16), 83 (9), 95 (7), 96 (11), 98 (5), 99 (4), 109 (19), 114 (3), 124 (3); ^{1}H NMR (400 MHz, $CDCl_3$), δ 0.87 (d, 6H, J = 6.6 Hz, $CH(C\underline{H}_3)_2$), 1.13−1.34 (m, 6H, $C\underline{H}_2C\underline{H}_2C\underline{H}_2CH(CH_3)_2$), 1.52 (nonet, 1H, J = 6.6 Hz, $CH_2C\underline{H}(CH_3)_2$), 1.58−1.67 (m, 2H, $CH_2C\underline{H}_2CH_2CHO$, 2.41 (td, 2H, J = 7.4, 1.9 Hz, $CH_2C\underline{H}_2CHO$), 9.75 (t, 1H, J = 1.9 Hz, $CH_2C\underline{H}O$); ^{13}C NMR (100 MHz, $CDCl_3$), δ 22.1 ($\underline{C}H_2CH_2CHO$), 22.5 ($CH(\underline{C}H_3)_2$), 27.1 ($\underline{C}H_2(CH_2)_3CHO$), 27.9 ($\underline{C}H(CH_3)_2$), 29.4 ($\underline{C}H_2(CH_2)_2CHO$), 38.7 ($\underline{C}H_2CH(CH_3)_2$), 43.9 ($\underline{C}H_2CHO$), 202.9 (CHO).

Isolation of Curry Leaf Volatiles. Curry leaves (10 g) and anhydrous sodium sulfate (50 g) were cryomilled at the temperature of liquid nitrogen. The obtained homogenate was added to dichloromethane (150 mL) and stirred for 30 min at ambient temperature. After filtration, nonvolatiles were removed by SAFE during 45 min at 40 °C. The distillate was concentrated to a final volume of 1 mL, first using a Vigreux column (50 × 1 cm) and subsequently a Bemelmans microdistillation device.[27] Separate curry leaf volatile isolates were prepared for screening by AEDA, fractionation by silica gel chromatography, and isolation of volatile curry leaf thiols.

Fractionation of Curry Leaf Volatiles. A curry leaf volatiles isolate prepared as detailed above was applied onto a slurry of purified silica gel (8 g) in pentane in a water-cooled (12 °C) glass column (1 cm i.d.). Elution was performed by pentane/diethyl ether mixtures of 100 + 0, 90 + 10, 70 + 30, 50 + 50, and 0 + 100 (v + v; 50 mL each), and the eluate was collected in 15 10 mL portions followed by two 50 mL portions. Each fraction was concentrated to 0.5 mL.

Isolation of Volatile Curry Leaf Thiols. From a curry leaf volatiles isolate prepared as detailed above, the thiols were isolated using a procedure published earlier[28] with some modifications. In detail, the isolate was initially applied onto mercurated agarose gel (1 g) in a glass column (0.5 cm i.d.). After the column had been rinsed with dichloromethane (50 mL), the thiols were eluted with dithiothreitol (10 mmol/L) in dichloromethane (50 mL). The excess of dithiothreitol was removed by SAFE distillation, and the distillate was concentrated to 0.5 mL.

GC-O and GC-FID Analyses. A Trace GC Ultra gas chromatograph (Thermo Scientific, Dreieich, Germany) was equipped with a cold-on-column injector, an FID, and a tailor-made sniffing port. The following fused silica columns were used: (1) DB-FFAP, 30 m × 0.32 mm i.d., 0.25 μm film; (2) DB-5, 30 m × 0.32 mm i.d., 0.25 μm film (both Agilent, Waldbronn, Germany); (3) BGB-176, 30 m × 0.25 mm i.d., 0.25 μm film; (4) BGB-174E, 30 m × 0.25 mm i.d., 0.25 μm film (both BGB Analytik, Rheinfelden, Germany). The carrier gas was helium at 70 kPa (DB-FFAP, DB-5) and 120 kPa (BGB-176, BGB-174E), respectively. The initial oven temperature was 40 °C (2 min). Gradients typically were 6 °C/min for DB-FFAP and DB-5 and 2 °C/min for BGB-176 and BGB-174E. For GC-O analyses, the column effluents were divided 1:1 using a deactivated Y-shaped glass splitter and two deactivated fused silica capillaries (50 cm × 0.25 mm i.d.) connecting the splitter to the FID and the sniffing port, respectively. The sniffing port consisted of a cylindrically shaped aluminum device (105 mm × 24 mm o.d.) with a beveled top and central drill hole (2 mm) housing the capillary. It was mounted on a heated (250 °C) detector base of the GC. During a GC-O run (35 min), the panelist placed her/his nose closely above the top of the device and sniffed the effluent. Whenever an odor was perceived, the retention time and the odor quality were noted in the FID chromatogram printed by a recorder. Linear retention indices (RI) of the odor-active compounds were calculated from their retention times and the retention times of adjacent *n*-alkanes by linear interpolation. GC-O analyses of the concentrated curry leaf volatiles isolate were performed by six trained panelists, and results were combined.

AEDA. The concentrated curry leaf volatiles isolate (1 mL) was stepwise diluted 1:2 with dichloromethane to obtain dilutions of 1:2, 1:4, 1:8, 1:16, etc. Each diluted sample was then analyzed by GC-O using the FFAP column. Odor-active compounds were assigned a flavor dilution (FD) factor, representing the dilution factor of the

[a]Each odorant was identified by comparing its retention indices on two GC capillaries of different polarity (FFAP, DB-5) and its mass spectrum obtained by GC-MS, as well as its odor quality as perceived at the sniffing port during GC-O with data obtained from authentic reference compounds analyzed in parallel. [b]Odor quality as perceived at the sniffing port during GC-O. [c]Retention index; calculated from the retention time of the compound and the retention times of adjacent *n*-alkanes by linear interpolation. [d]Flavor dilution factor;[20] dilution factor of the highest dilution of the concentrated SAFE distillate in which the odorant was detected during GC-O by any of three panelists. [e]Reference reporting the compound for the first time as a curry leaf volatile. The dash (−) indicates compounds that have not been reported in curry leaves before. [f]A clear mass spectrum of the compound could not be obtained in the curry leaf isolates, identification was based on the remaining criteria detailed in footnote *a*. [g]No reference compound was available. The compound was tentatively identified on the basis of MS database[30] spectra and RI data in the literature.[34] Stereochemistry was not assigned.

highest dilution in which the respective odorant was detected by any of three trained panelists (two females, one male).

Gas Chromatography−Mass Spectrometry (GC-MS). Mass spectra were generated in the electron impact (EI) mode at 70 eV and a scan range of *m*/*z* 35−300 using a HP 5890 gas chromatograph (Hewlett-Packard, Heilbronn, Germany) connected to an MAT 95 sector field mass spectrometer (Finnigan, Bremen, Germany). Columns and further GC conditions were equivalent to those used in the GC-O analyses.

Static Headspace Gas Chromatography (SH-GC). Curry leaves (1 g) and anhydrous sodium sulfate (5 g) were cryomilled, and the homogenate was placed into a 20 mL septum-sealed vial. After 5 min at ambient temperature, 5 mL of the headspace was withdrawn using a gastight syringe and injected by means of a Combi PAL autosampler (CTC Analytics, Zwingen, Switzerland) via a cold-on-column injector (helium, 110 kPa) onto a deactivated fused silica precolumn (0.2 m × 0.53 mm i.d.) installed in a Trace GC Ultra gas chromatograph (Thermo). Volatiles were trapped on the precolumn using a cold trap 915 at −150 °C. The precolumn was connected to the main column and an outlet solenoid valve via a three-way connector. During trapping, the solenoid valve was open to maintain a flow of 20 mL/min through the precolumn. After injection had been finished, the solenoid valve was closed, and the trap was heated to 250 °C to transfer the trapped volatiles onto the main column, a DB-5, 30 m × 0.25 mm i.d., 1 μm film (Agilent). The oven start temperature was 0 °C maintained by liquid nitrogen oven cooling. After 2 min, the temperature was raised at 6 °C/min. The end of the main column was connected to a pressure-controlled stream switching system (S+H Analytik, Mönchengladbach, Germany), which transferred the eluate to an FID and a sniffing port and/or a Saturn 2100 mass spectrometer (Varian, Darmstadt, Germany).

Two-Dimensional Heart-Cut Gas Chromatography−Mass Spectrometry (GC-GC-MS). A Combi PAL autosampler (CTC) was mounted on a Trace GC Ultra equipped with a cold-on-column injector (Thermo) and an FFAP capillary, 30 m × 0.32 mm i.d., 0.25 μm film, or a DB-5 capillary, 30 m × 0.25 mm i.d., 1 μm film (Agilent). The column end was connected to a moving column stream switching system (MCSS) (Thermo), conveying the eluate time-programmed through deactivated fused silica capillaries (0.32 mm i.d.) either simultaneously to an FID and a sniffing port or via a heated (250 °C) transfer line to a cold trap localized in the oven of a CP 3800 GC (Varian). The tailor-made trap consisted of a piece of steel tubing housing the capillary and could be cooled by means of liquid nitrogen. Downstream, the capillary was connected to the BGB-176 or BGB-174E column described above. The end of this column was connected to a Saturn 2200 mass spectrometer (Varian) operated in the CI mode with methanol as reagent gas. For the determination of the enantiomeric distribution of **2**, **19**, and **21**, start temperatures were 40 °C (2 min) and gradients were 6 °C/min in the first dimension (FFAP) and 3 °C/min in the second dimension (BGB-176). For the determination of the enantiomeric distribution of **26**, start temperatures were 40 °C (2 min) and 35 °C (2 min) and gradients were 1 and 2 °C/min, in the first (DB-5) and second dimensions (BGB-174E), respectively. A heart-cut (0.5 min) of the eluate of the first column containing the respective target compound was transferred via the MCSS and the transfer line to the precooled trap. Then the trap cooling was turned off, and the second oven was started. The retention times of the target compounds in the first and second dimensions were previously determined using reference compounds.

NMR Spectroscopy. ^{1}H and ^{13}C NMR spectra were recorded at 25 °C using an Avance 400 NMR spectrometer (Bruker, Rheinstetten, Germany) and tetramethylsilane as the internal standard (δ = 0.00

DOI: 10.1021/acs.jafc.5b01174
J. Agric. Food Chem. 2015, 63, 4060−4067

ppm). Correct signal assignment was confirmed by 2D NMR spectroscopy using COSY, HMQC, and HMBC experiments (data not shown).

RESULTS AND DISCUSSION

Screening the Curry Leaf Volatiles for Odorants by AEDA. Freshly picked curry leaflets were cryomilled under addition of anhydrous sodium sulfate. The obtained powder was extracted by dichloromethane. Then, SAFE was applied on the extract to remove any nonvolatile material. The SAFE distillate, when placed on a fragrance test strip and sniffed after evaporation of the solvent, still fully reflected the characteristic aroma of fresh curry leaves. The SAFE distillate was gently concentrated, and the concentrate was submitted to AEDA.

AEDA resulted in 23 odorants in the FD factor range of 1−8192 (Table 1). The highest FD factor (8192) was found for sulfury- and burnt-smelling odorant **21**, clearly resembling the dominating aroma note in the overall sensory profile of the curry leaves. High FD factors were further determined for citrusy-smelling odorant **19** (FD 4096), resinous-smelling odorant **2** (FD 2048), eucalyptus-like-smelling odorant **7** (FD 1024), grassy-smelling odorant **4** (FD 256), and cooked potato-like-smelling odorant **17** (FD 128).

Structural Assignment of Odorants. As a first step, the RIs and odor descriptors of the odorants detected during AEDA were compared to previously published data of roughly 1600 odor-active compounds compiled in an in-house database. In the case of matching data, authentic reference compounds were obtained by purchase or synthesis and analyzed in an appropriate dilution by GC-O in parallel (i.e., same instrument, same day) to the curry leaf volatiles isolate. Because retention time and odor characteristics of the compound in the curry leaf volatiles isolate were in agreement with the retention time and odor characteristics of the reference compound on two GC-O systems of different separation phase polarities (DB-5, FFAP), the structures of 19 of the 23 curry leaf odorants (**1**−**7**, **10**, **11**, **13**−**21**, **23**) could be assigned. Final confirmation of these assignments was made by comparing the mass spectra of the curry leaf odorants and the reference compounds as obtained by GC-MS analysis. To avoid any overlay of mass spectra due to coelution, a particular problem with odor-active trace compounds, the curry leaf volatiles isolate was further fractionated before GC-MS analysis. Using silica gel as stationary phase and pentane/diethyl ether mixtures as eluents, the curry leaf volatiles were separated into 17 fractions according to their polarity. In a separate experiment, the thiols among the curry leaf volatiles were selectively isolated using mercurated agarose gel. Each fraction was then analyzed by GC-O to localize the odorants. Fractions containing any odorant detected during AEDA were subjected to GC-MS analysis (DB-5 and FFAP) in parallel with the reference compounds.

Using this approach, 14 of the 19 previously assigned structures were confirmed by mass spectral data, among them all odorants with high (≥32) FD factors (Figure 1). Sulfury- and burnt-smelling odorant **21**, exhibiting the highest FD factor (8192) in the AEDA, was recovered in the thiol fraction and finally identified as 1-phenylethanethiol. 1-Phenylethanethiol has not yet been reported in curry leaves and has rarely been found in nature before. Its only mention as an odor-active compound refers to Pontianak orange peel oil,[25] where it significantly contributes to the specific odor.[29] In that study, it was observed that 1-phenylethanethiol, when exposed to

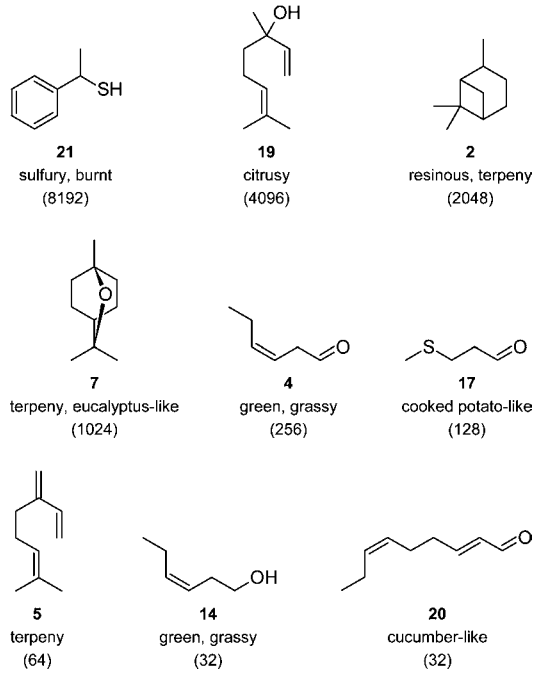

Figure 1. Most potent odorants (FD factor ≥ 32) in the SAFE distillate obtained from fresh curry leaves. FD factors are given in parentheses.

increased temperatures, readily undergoes 1,2-elimination to form H_2S and styrene.[25] This might explain why the compound has escaped discovery in curry leaves so far. The compound might have been destroyed by the high temperatures applied during hydrodistillation or in the hot GC injection port. This finding exemplifies the importance of avoiding elevated temperatures in aroma research, for example, by using mild isolation techniques such as SAFE and by using the cold-on-column injection technique in GC.

Odorants **19**, **2**, and **7**, assigned the second (4096), third (2048), and fourth highest FD factors (1024) in the AEDA, were identified as citrusy-smelling linalool, resinous-smelling *α*-pinene, and eucalyptus-like-smelling 1,8-cineole. All three have been identified in curry leaves before, but their high aroma potency has not been recognized yet. Further odorants with comparatively high FD factors were identified as (3*Z*)-hex-3-enal (green, grassy; FD 256; **4**), 3-(methylsulfanyl)propanal (cooked potato-like; FD 128; **17**), myrcene (terpeny, geranium leaf-like; FD 64; **5**), (3*Z*)-hex-3-en-1-ol (green, grassy; FD 32; **14**), and (2*E*,6*Z*)-nona-2,6-dienal (cucumber-like; FD 32; **20**). Of these, only myrcene has been reported as curry leaf constituent before. Mass spectral confirmation of the structural assignment was furthermore achieved for 2-acetyl-1-pyrroline (roasty, popcorn-like; FD 8; **11**), (2*E*)-oct-2-enal (fatty, nutty; FD 8; **16**), octanal (citrusy, soapy; FD 4; **10**), limonene (terpeny, citrusy; FD 2; **6**), and nonanal (citrusy, soapy; FD 1; **15**). No clear mass spectra were obtained for five trace odorants with low FD factors (**1**, **3**, **13**, **18**, **23**). However, their retention times and odor properties on the two GC-O systems (DB-5, FFAP) were identical to those of butane-2,3-dione (**1**), 3-methylbut-2-ene-1-thiol (**3**), (5*Z*)-octa-1,5-dien-3-one (**13**), 3-isobutyl-2-methoxypyrazin (**18**), and *γ*-heptalactone (**23**).

The retention indices and odor qualities of four odorants (**8**, **9**, **12**, **22**) did not match with any available database entries, but GC-MS analyses of the curry leaf fractions resulted in

J. Agric. Food Chem. 2015, 63, 4060−4067

congruent mass spectra on both separation systems (DB-5, FFAP) for odorants **8**, **12**, and **22**.

An MS database[30] library search applied on the mass spectra of odorants **8** and **12** (Figure 2) returned octanal and nonanal,

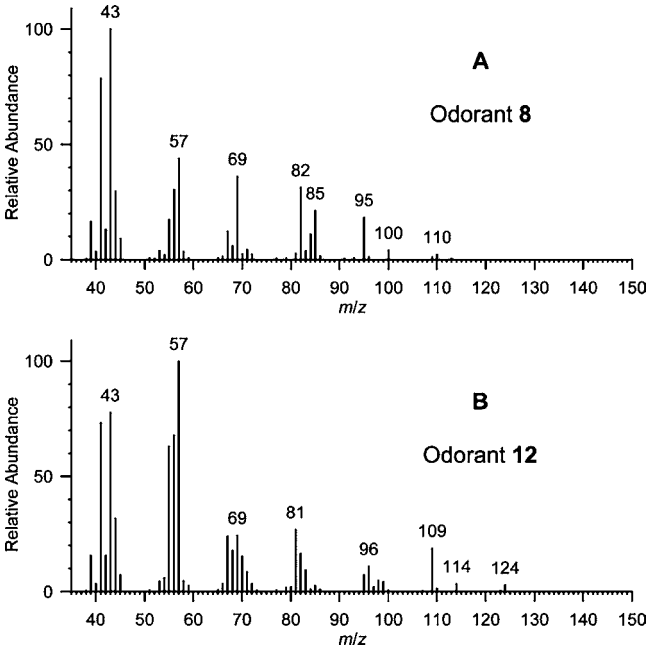

Figure 2. Mass spectra (EI) obtained for the citrusy-, soapy-smelling odorants **8** (A) and **12** (B) isolated from curry leaves.

respectively, with high matching factors. Octanal and nonanal, which had also been detected by AEDA of the curry leaf volatiles (odorants **10** and **15**), however, showed clearly different RIs. On the other hand, the similarities in the mass spectra were obvious. Similar to octanal (MS not shown), odorant **8** showed characteristic fragments of *m/z* 110, corresponding to a loss of water from the molecular ion *m/z* 128, and *m/z* 110, corresponding to a loss of carbon monoxide, thus suggesting the presence of an aldehyde group and a molecular mass of 128 u in analogy to octanal. Accordingly, odorant **12** showed fragments of *m/z* 124 and 114 in analogy to nonanal. Odorants **8** and **12** not only shared similar mass spectra with octanal and nonanal but also appeared in the same fraction after silica gel chromatography and exhibited virtually the same citrusy, soapy odor quality. In summary, the data suggested that odorants **8** and **12** were chain isomers of octanal and nonanal. A branched carbon skeleton would also correspond to the clearly lower RIs of odorants **8** (DB-5, 964; FFAP, 1232) and **12** (DB-5, 1068; FFAP, 1340) in comparison to octanal (DB-5, 1004; FFAP, 1278) and nonanal (DB-5, 1104; FFAP, 1385), respectively. Branched isomers typically show lower RIs than the corresponding straight-chain molecules due to their smaller surface and thus lower ability to interact with the GC stationary phase. Type and position of the branching, however, were difficult to predict. The similarity in the odor qualities at least suggested that the branching was rather distant from the odotope, that is, rather not too close to the aldehyde group.

Following the latter idea, we hypothesized that odorant **8** could be 6-methylheptanal. The compound was synthesized from commercially available 6-methylheptanoic acid by reduction with lithium aluminum hydride and subsequent reoxidation of the obtained alcohol to the aldehyde using Dess–Martin periodinane. Analysis of the synthesized compound by GC-O and GC-MS on the two separation systems (DB-5, FFAP) resulted in the same data as obtained for odorant **8**, which thus was finally identified as 6-methylheptanal. 6-Methylheptanal has not been reported from curry leaves yet, but has been found among the volatiles of other plants in the rue family.[31−33] In particular, it has been found as an aroma-active compound in mandarin peel oils[32] and orange essence oil.[31]

As odorant **12** exhibited RIs (DB-5, 1068; FFAP, 1340) that were approximately 100 units higher than those of 6-methylheptanal (DB-5, 964; FFAP, 1232), it was assumed to be its homologue, 7-methyloctanal. Synthesis of the compound by oxidation of the corresponding alcohol 7-methyloctan-1-ol confirmed this structural assignment, and odorant **12** was finally identified as 7-methyloctanal. This compound has rarely been reported from nature yet, and was also previously unknown as curry leaf constituent.

Clove-like-smelling odorant **22**, after silica gel fractionation, was recovered in the hydrocarbon fraction. Its mass spectrum matched the MS database[30] entry of calamenene, an aromatized sesquiterpene hydrocarbon, and its RI was in agreement with data from the literature.[34] However, no reference compound was available. For that reason, the identification of calamenene remained tentative.

No mass spectrum could be obtained for mushroom-like-smelling odorant **9**. Its odor quality, however, was clearly reminiscent of the odor of the button mushroom impact compound 1-octene-3-one. Taking into account that the RI of odorant **9** (FFAP, 1252) was lower than that of 1-octene-3-one (1293), and the difference was similar to that observed for the methyl-branched aldehydes **8** and **12** and their respective straight-chain isomers, it might be speculated that compound **9** could be a branched isomer of 1-octene-3-one such as 6-methyl-1-hepten-3-one. However, no attempt was made to prove this assumption, and odorant **9**, therefore, remained unidentified.

Screening for Highly Volatile Odorants by SH-GC-O. Very highly volatile odorants with boiling points below that of the extraction solvent are not covered by AEDA, because they are lost during the concentration of the SAFE distillate, so a static headspace GC-O analysis was performed as a complementary screening method. Four additional odorants were detected in the headspace above freshly cut curry leaves and structurally assigned by comparing their GC-O and GC-MS data with those of reference compounds. These odorants were fresh-, green-, and fruity-smelling acetaldehyde (**24**) and the malty-smelling compounds 2-methylpropanal (**25**), 2-methylbutanal (**26**), and 3-methylbutanal (**27**) (Table 2).

Enantiomeric Distribution of Chiral Curry Leaf Odorants. As enantiomers of chiral odorants may exhibit different odor thresholds or even different odor qualities, proper structure assignment of odor-active compounds must include the determination of the enantiomeric ratio. Seven of the total of 26 structurally assigned curry leaf odorants in this study were chiral. Among these were the three compounds with the highest FD factors in the AEDA, namely, 1-phenylethanethiol (**21**), linalool (**19**), and α-pinene (**2**), as well as highly volatile 2-methylbutanal (**26**) detected by SH-GC-O. To determine their enantiomeric ratios, a heart-cut GC-GC-MS system was equipped with a chiral cyclodextrin phase in the second dimension. Baseline separation of the enantiomers was achieved

Table 2. Odorants (RI DB-5 < 1000) in the Headspace above Fresh Curry Leaves

no.	odorant[a]	odor[b]	RI[c] DB-5	first report[d]
24	acetaldehyde	fresh, green, fruity	<500	–
25	2-methylpropanal	malty	550	–
1	butane-2,3-dione	buttery	580	–
26	2-methylbutanal[e]	malty	649	2
27	3-methylbutanal[e]	malty	649	–
4	(3*Z*)-hex-3-enal	green, grassy	800	–
2	α-pinene	resinous, terpeny	931	3
5	myrcene	terpeny, geranium leaf-like	992	4

[a]Each odorant was identified by comparing its retention index on capillary DB-5 and its mass spectrum obtained by GC-MS, as well as its odor quality as perceived at the sniffing port during GC-O, with data obtained from authentic reference compounds analyzed in parallel. [b]Odor quality as perceived at the sniffing port during GC-O. [c]Retention index; calculated from the retention time of the compound and the retention times of adjacent *n*-alkanes by linear interpolation. [d]Reference reporting the compound for the first time as a curry leaf volatile. The dash (−) indicates compounds that have not been reported in curry leaves before. [e]Methylbutanal isomers were not separated on the GC column used.

by using a 2,3-dimethyl-6-*tert*-butyldimethylsilyl-derivatized β-cyclodextrin-based phase for α-pinene (**2**), linalool (**19**), and 1-phenylethanethiol (**21**) and a 2,3-diacetyl-6-*tert*-butyldimethylsilyl-derivatized β-cyclodextrin-based phase for 2-methylbutanal (**26**). The elution order of the enantiomers was determined by analyzing enantiopure samples of the target compounds. Because of their comparatively low FD factors, no efforts were made to determine the enantiomeric ratios of limonene (**6**), calamenene (**22**), and γ-heptalactone (**23**).

Results showed enantiomeric ratios apparently different from racemic mixtures for all four compounds analyzed, but the odor qualities of the respective optical antipodes as perceived during GC-O analysis were virtually the same (Table 3). In α-pinene, the (1*S*,5*S*)-isomer clearly dominated with 93%. The threshold values reported in the literature, however, were in the same range for both enantiomers.[35] In linalool, an enantiomeric ratio of 62/38 was found in favor of the more odor-active[36] (3*R*)-form. The *R*-isomer also predominated in 1-phenylethanethiol. Its percentage in the curry leaves (67% *R*) was close to that recently reported in Pontianak orange peel oil (76% *R*).[25] As Pontianak oranges belong to the genus *Citrus* and thus also to the Rutaceae family, the similarity in the enantiomeric ratio may reflect a common biosynthetic pathway. The odor thresholds of (1*R*)- and (1*S*)-1-phenylethanethiol were reported to be in the same order of magnitude.[25]

In summary, gentle isolation of the volatile fraction from fresh curry leaves followed by systematic and nontargeted screening for odor-active compounds by application of an AEDA and a SH-GC-O analysis resulted in a total number of 27 odorants, among which, on the basis of their high FD factors, sulfury-smelling 1-phenylethanethiol, citrusy-smelling linalool, resinous-smelling α-pinene, eucalyptus-like-smelling 1,8-cineole, and grassy-smelling (3*Z*)-hex-3-enal most likely show a vital contribution to the overall aroma. To confirm this assumption and to unequivocally identify the key aroma compounds of fresh curry leaves, further experiments are currently under way. These will include exact quantitation of the most potent odorants detected in the screening experiments, the sensory evaluation of aroma reconstitution models based on the obtained concentration data as proof of success, and finally omission tests to assess the contribution of the individual odorants to the overall aroma of curry leaves.[37] The omission tests will particularly elucidate whether 1-phenylethanethiol can be considered as the character impact compound of fresh curry leaves. Its exceedingly high FD factor, its characteristic sulfury and burnt odor quality, and the absence of any other potent odorant with a sulfury odor note, however, support this assumption.

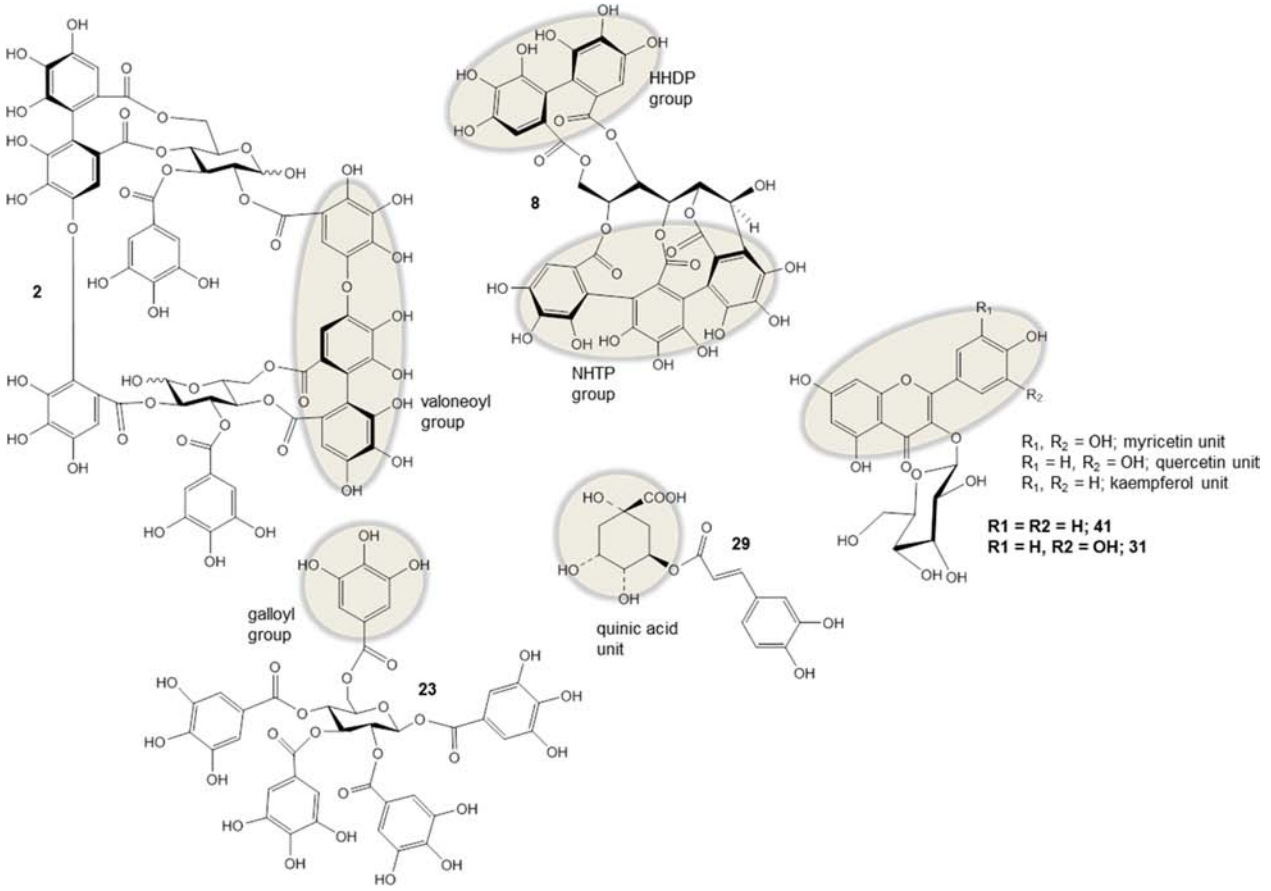

Figure 1. Example structures of the studied polyphenol subclasses. Compound identities: oenothein B (**2**), vescalagin (**8**), pentagalloyl glucose (**23**), 3-*O*-caffeoylquinic acid (**29**), quercetin-3-*O*-glucoside (**31**), and kaempferol-3-*O*-glucoside (**41**) (HHDP, hexahydroxydiphenoyl; NHTP, nonahydroxytriphenoyl).

quantitation impossible. If even more parent ion scans for different polyphenol groups are included, then also the measurement of qualitative group-specific fingerprints becomes impossible due to insufficient numbers of data points per single polyphenols. Therefore, more rapid nonscanning MS/MS methods are needed to enable more efficient quantitation and/or fingerprint detection of polyphenol groups. The speed of MRM technology would be especially suitable for this job as one MRM transition can be measured in 5 ms (vs 200 ms of the parent ion scan). However, to our knowledge, MRM-based LC-MS/MS methods for polyphenol subgroups have not been reported to be used for fingerprinting other than proanthocyanidins from plant extracts.[27]

To screen thousands of plant samples for their bioactive polyphenol content, rapid and specific methods are required. In these cases total concentrations of compounds belonging to different polyphenol subclasses are often of primary interest. If this is done by simultaneously recording the LC-MS/MS traces of many of the major polyphenol groups, overall views of sample-specific polyphenol fingerprints are achieved for every analyzed sample. The present study explored the potential of ultrahigh-performance liquid chromatography combined with a triple-quadrupole mass spectrometer for the rapid fingerprint analysis of different plant polyphenol subclasses from plant crude extracts. Our main interest was in establishing a fast, sensitive, and selective method for the simultaneous analysis of six common plant polyphenol subclasses: (1) ellagitannins, (2) gallic acid derivatives, (3) quinic acid derivatives, (4) quercetin-based flavonol glycosides, (5) kaempferol-based flavonol glycosides, and (6) myricetin-based flavonol glycosides (Figure 1).

MATERIALS AND METHODS

Chemicals and Reagents. Acetonitrile (LC-MS grade) used in the UPLC analyses was from Sigma-Aldrich (Steinheim, Germany). Formic acid was from VWR (Helsinki, Finland). Water was purified with a Millipore Synergy Water Purification System (Merck KGaA, Darmstadt, Germany). Flavonoids and quinic acids were from ExtraSynthese (Genay, France). Catechin was from Sigma (Sigma Chemical Co., St. Louis, MO, USA).

Materials. Pure compounds, simple galloylglucoses, ellagitannins, the less characterized flavonoids, quinic acids, and the gallotannin fractions used were isolated from different plant materials as described in Moilanen and Salminen.[28] The identities and purities of these compounds were established by UPLC-DAD-QqQ-MS and HPLC-ESI-Q-TOF-MS. The simple galloylglucoses and ellagitannins were additionally identified by NMR.[28,29] The compounds used are listed in Table 1. Plant materials used for plant extracts (Table 2) were collected from the Botanical Garden of the University of Turku and nearby forests in Turku, Finland. After collection, samples were freeze-dried and ground into powder. The plant powder was extracted with acetone/water (80:20, v/v) for 2 h, and the extraction was repeated two times. The acetone was evaporated from the extracts, and the extracts were frozen and freeze-dried. Freeze-dried samples were dissolved in 1 mL of water, filtered via 0.20 μm filters, and diluted 5 times with water before UPLC-MS/MS analyses.

UPLC-MS/MS Analysis. Sample analysis was carried out with an Acquity UPLC system (Waters Corp., Milford, MA, USA) coupled with a Xevo TQ triple-quadrupole mass spectrometer (Waters Corp.).

The UPLC system consisted of a sample manager, a binary solvent manager, a column, and a diode array detector. The column used was a 100 mm × 2.1 mm i.d., 1.7 μm, Acquity UPLC BEH Phenyl column (Waters Corp., Wexford, Ireland). The flow rate of the eluent was 0.5 mL min^{-1}. The elution profile used two solvents, acetonitrile (A) and 0.1% aqueous formic acid (B): 0−0.5 min, 0.1% A in B; 0.5−5.0 min, 0.1−30% A in B (linear gradient); 5.0−6.0 min, 30−35% A in B (linear gradient); 6.0−9.5 min, column wash and stabilization. UV and MS data were collected from 0 to 6 min. Negative ionization mode was used for MS analyzes. ESI conditions were as follows: capillary voltage, 2.4 kV; desolvation temperature, 650 °C; source temperature, 150 °C; desolvation and cone gas (N_2), 1000 and 100 L/h, respectively; and collision gas, argon. Catechin (1 μg mL^{-1}) was used to monitor the stability of the ionization efficiency of the mass spectrometer, and a mixture of different flavonoids (4 μg mL^{-1}) was used to monitor variations in retention time and m/z values.

Optimization of Cone Voltages and Collision Energies. When cone voltages and collision energies were optimized for the selected compounds, aqueous solutions of different compounds were directly infused into the ESI source with a syringe pump at a flow rate of 5−40 μL min^{-1}. The concentrations of the aqueous solutions were 40 μg mL^{-1} for pure compounds and 1 mg mL^{-1} for the gallotannin fractions. The ranges of cone voltage and collision energy varied between 10 and 170 V and between 5 and 50 eV, respectively.

Testing the UPLC-MS/MS Method with Plant Extracts and Polyphenol Mixtures. The method was first tested by three polyphenol mixtures made from pure compounds. This was necessary to avoid coelution of interfering substances with known compounds so that UV chromatograms could be directly compared with MRM chromatograms. The first mixture (1) contained compounds **1**, **2**, **6**, **8**, and **29**, the second mixture (2) compounds **30**, **32**, **33**, and **41**, and the third one (3) compounds **23**, **31**, **36**, **42**, **43**, and **49** (see Table 1 for compound identities). Mixture 1 was prepared in formic acid/acetonitrile/water (0.1:5:94.9, v/v/v), and mixtures 2 and 3 were prepared in formic acid/acetonitrile/water (0.1:10:89.9, v/v/v). The dilution range was from 20 μg mL^{-1} to 0.08 ng mL^{-1}. Three replicates of each sample were run. The mixtures were prepared fresh the same day as the analysis. Plant extracts were prepared as described under Materials, and samples of 1 mg mL^{-1} were prepared and diluted with water to the final test concentration of 0.2 mg mL^{-1}. The polyphenol mixtures mentioned above were utilized for quantification purposes in the present work. For estimating total concentrations, the responses of compounds belonging to the same polyphenol subgroup were combined and calibration curves prepared by using these values. For the comparison of group-specific and compound-specific methods with single compounds, calibration curves with corresponding compounds were prepared. The dilution range was from 0.08 ng mL^{-1} to 20 μg mL^{-1}, and only the linear parts of the calibration curves were used for quantification.

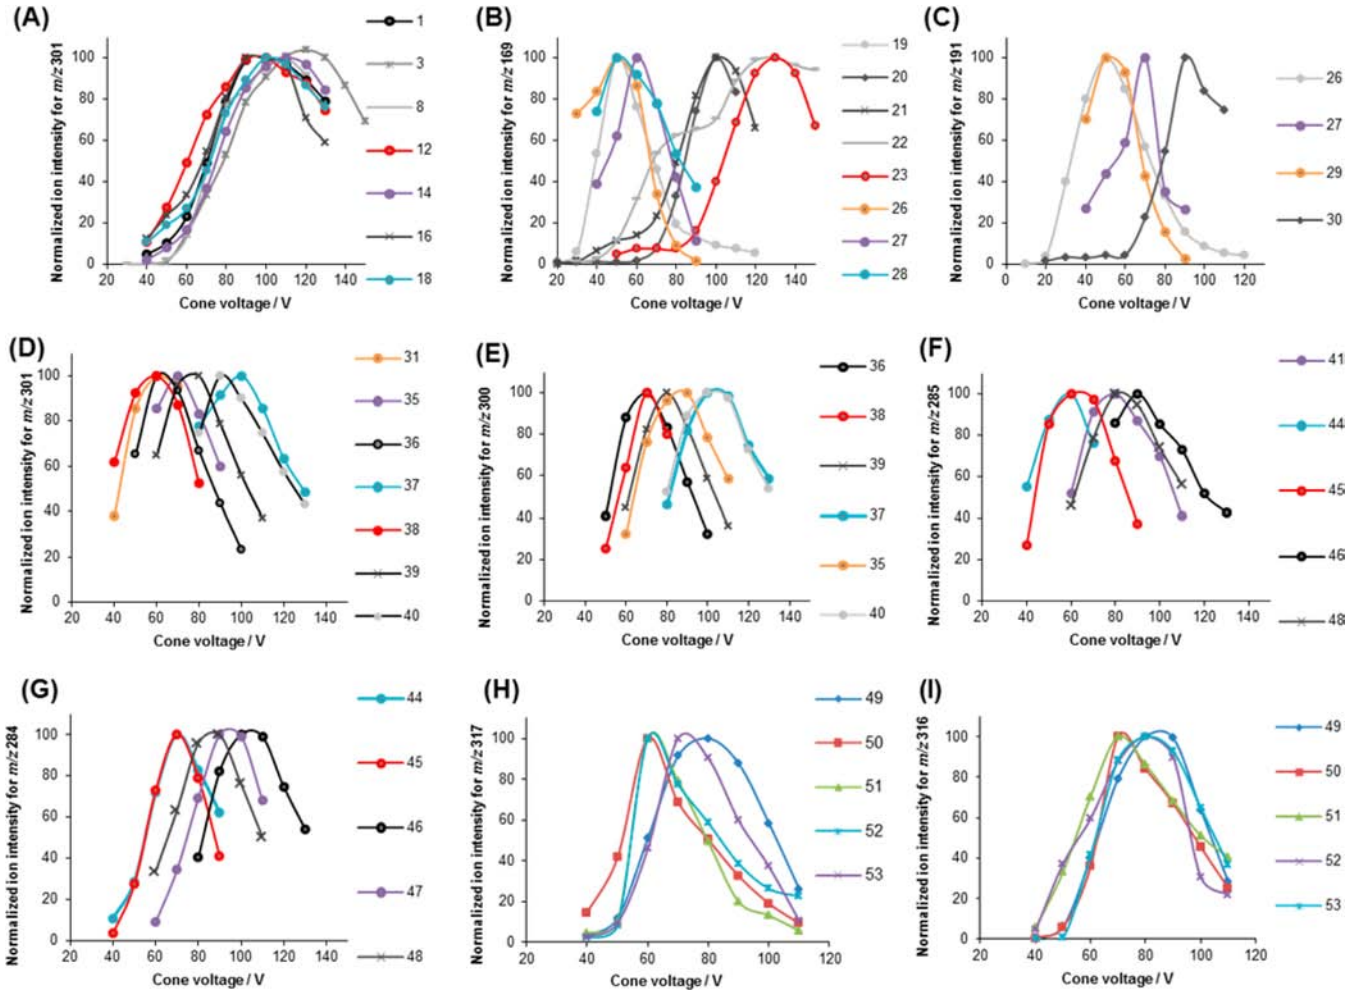

Figure 2. Optimization of cone voltages for the accumulation of precursor ions presenting ellagitannins (A), gallic acid derivatives (B), quinic acid derivatives (C), quercetin-based flavonoids (D, E), kaempferol-based flavonoids (F, G), and myricetin-based flavonoids (H, I). See Table 1 for compound identities.

Method Validation. Three mixtures containing different polyphenols (see Testing the UPLC-MS/MS Method with Plant Extracts and Polyphenol Mixtures) were used for the determination of the limit of detection (LOD), limit of quantitation (LOQ), linearity, repeatability, and sensitivity of the developed method. LOD and LOQ were determined as peak to peak values by the signal to noise process function in MassLynx software. Signal to noise ratios (S/N) were > 3 and >10 for LOD and LOQ, respectively. Dilution series were prepared from stock solutions of 40 μg mL^{-1} and diluted with formic acid/acetonitrile/water (0.1:5:94.9, v/v/v) (mixture 1) or formic acid/acetonitrile/water (0.1:10:89.9, v/v/v) (mixtures 2 and 3). The dilution range was from 0.08 ng mL^{-1} to 20 μg mL^{-1}. Three replicates of each sample were run for LOD, LOQ, and linearity and five replicates for repeatability.

RESULTS AND DISCUSSION

Optimization of the Cone Voltages. Because compounds that belong to the same polyphenol subgroup share similarities in their structural skeletons,[2,30,31] it was hypothesized that it would be possible to develop group-specific MRM methods for different polyphenol subclasses. To optimize MRM methods for ellagitannins, gallic acid derivatives, quinic acid derivatives, quercetin-based flavonol glycosides, kaempferol-based flavonol glycosides, and myricetin-based flavonol glycosides, direct flow injection experiments of the reference compounds (Table 1) were performed in both positive-ion and negative-ion modes. Negative mode was more sensitive than positive mode (data not shown) and, thus, negative-ion mode was selected to be used in the MRM methods. In addition, negative ion mode fragmented compounds less extensively and thus produced clearer fragmentation patterns.

As hypothesized, it was possible to find common precursor ions for fragments of compounds belonging to the same polyphenol subclass. For ellagitannins the selected precursor ion was m/z 301, which is in agreement with the earlier findings where m/z 301 has been reported as the main ellagitannin fragment.[32−36] This ion is formed when the hexahydroxydiphenoyl (HHDP) groups characteristic for ellagitannins fragment from the original structure to produce m/z 301.[37−39] The optimal cone voltage required for maximal accumulation of m/z 301 in the first quadrupole varied between 90 and 130 V (examples in Figure 2A), depending on the structural differences of the studied molecules: for example, the position of the HHDP group, additional galloyl groups attached to HHDP(s) (such as in valoneoyl and sanguisorboyl groups), size of the molecule, and rigidity of the structure. In general, HHDP groups located at the 2,3-position required higher cone voltages than HHDP groups at the 4,6- or 3,6-position for maximal accumulation of m/z 301. Valoneoyl, sanguisorboyl, and nonahydroxytriphenoyl groups either provided further stability to the ellagitannin structure or needed to be

DOI: 10.1021/acs.jafc.5b00595
J. Agric. Food Chem. 2015, 63, 4068−4079

fragmented before m/z 301 could be formed from the larger fragments. This was confirmed for ellagitannins with valoneoyl groups because these structures first yielded the valonic acid dilactone moiety and then ellagic acid when the cone voltage was further increased. Comparison of oligomeric series of ellagitannins with the same monomeric units suggested that the rigidity brought by the bonds between the monomeric units affected the required cone voltage more than the size of the molecule. For example, for the monomer tellimagrandin I and its dimeric and trimeric macrocyclic oligomers, oenothein B and oenothein A, the optimal cone voltages for the accumulation of m/z 301 were 90, 100, and 130 V, respectively. However, for both dimeric and trimeric sanguiin H-6 and lambertianin C the optimal cone voltage was the same, 120 V. In addition, the difference between the two dimers (oenothein B and sanguiin H-6; 100 vs 120 V) could be due to different types of linkages, DOG and GOD,[40] between the monomers. It is thus clear that a single cone voltage is not optimal for all types of ellagitannins and that the use of several cone voltages could produce different types of ellagitannin fingerprints, depending on the ellagitannin composition of the tested plant sample. Similar patterns have been earlier witnessed for other tannin fingerprints as well: large proanthocyanidins required higher cone voltages than their monomers to be witnessed in the crude extracts.[27]

For gallic acid derivatives the selected precursor ion was m/z 169, which is formed when galloyl groups fragment from the original gallic acid derivative.[38,41] Also for gallic acid derivatives, the size of the molecule along with the positions of the galloyl groups affected the required cone voltage for maximal accumulation of m/z 169. The optimal cone voltage varied between 50 and 130 V (examples in Figure 2B). Lowest, 50−70 V, cone voltages were optimal for simple gallic acid derivatives, such as galloyl quinic acids, gallocatechin gallate, and monogalloylglucose. For di-, tri-, tetra-, and pentagalloylglucoses the optimal cone voltages were between 100 and 130 V. Gallotannins have both galloyl groups attached to the core polyol and additional galloyls linked to the core galloyl groups via depside bond(s).[41,42] As a consequence, two cone voltages, 50 and 130 V, were obtained for the maximal accumulation of m/z 169. As previously reported,[31,41] the results indicated that depside bonds between two galloyls are less stable than ester bonds between the core polyol and galloyl groups.

For quinic acid derivatives the cone voltage optimization was straightforward. The tetraol moiety of quinic acid at m/z 191 was selected as the precursor ion.[43] The optimal cone voltage for accumulation of the precursor ion m/z 191 varied between 50 and 90 V (Figure 2C) and mainly depended on how easily the other functional groups of the studied compounds were fragmented from the quinic acid moiety. In some cases, these other functional groups could be detected separately as well. For example, galloylquinic acids can be detected by the galloyl-based MRM method. On the contrary, caffeoylquinic acids did not fragment into clearly detectable levels of caffeic acid, leaving these compounds to be detected by the quinic acid-based MRM method. Both digalloyl- and dicaffeoyl-substituted quinic acids required higher optimal cone voltages than the monogalloyl (50 → 70 V) or monocaffeoyl (50 → 90 V) derivatives (Figure 2C). This information could be used to screen plant samples for highly substituted quinic acid derivatives, because their quinic acid fingerprint is better visible by high than low cone voltages, whereas the opposite is true for monosubstituted quinic acids.

Formation of flavonol aglycone radical ions from flavonols during electrospray ionization mass spectrometry is a well-known phenomenon.[44−48] In the present study, the three flavonoid-based polyphenol groups studied, quercetins, kaempferols, and myricetins, formed two characteristic ions, the aglycone and the aglycone radical ions, in the cone voltage optimizations. These ions were m/z 301 and 300 for quercetin-based flavonoids, m/z 285 and 284 for kaempferol-based flavonoids, and m/z 317 and 316 for myricetin-based flavonoids. The optimal cone voltages for maximal accumulation of those ions varied depending on the structure of the original flavonol glycoside (examples in Figure 2D−I). The cone voltage experiments revealed that for some flavonol glycosides, ions at m/z 316, 284, and 300 derived from the ions at m/z 317, 285, and 301, respectively, by using higher cone voltages, whereas for other flavonol glycosides these ion pairs accumulated with the same cone voltages. Also, the ratio of the two adjacent ions depended on the exact structure of the studied molecule (Figure 3). Being in agreement with previous

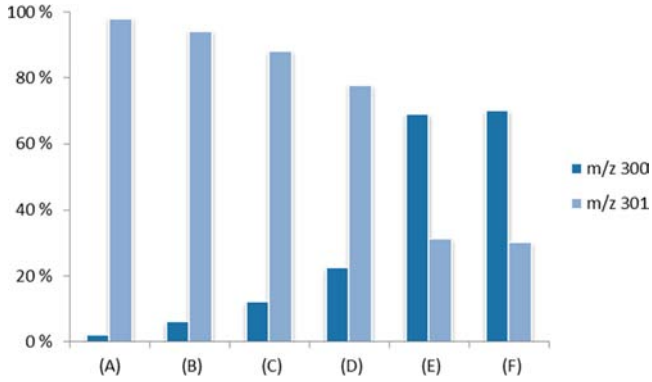

Figure 3. Ratio of quercetin aglycone and aglycone radical ions in (−)-ESI for quercetin aglycone (A), quercetin-4′-*O*-glucoside (B), quercetin-3,4′-*O*-diglucoside (C), quercetin-7-*O*-glucoside (D), quercetin-3-*O*-glucoside (E), and quercetin-3-*O*-galactoside (F).

studies,[44,48,49] the results suggested that 3-*O*-glycosylation favors formation of ions at m/z 300, 284, and 316, whereas 4′- and 7-glycosylations favor formation of ions at m/z 301, 285, and 317. This indicates that the comparison of ratios of different flavonol fingerprints (e.g., m/z 301 vs 300) of a given plant extract may yield information on the types of glycosylation patterns present in the flavonol glycosides (3-*O*-glycosides vs other types) in that plant.

Optimization of Collision Energies. Enhanced selectivity and sensitivity of the method are achieved by collision energies separately optimized for product ions of the specific precursor ions. Such an approach allows the accurate qualitative and quantitative analysis of different polyphenol subgroups directly from plant crude extracts. In contrast to identifying optimal cone voltages, the choice of optimal collision energy was straightforward. For ellagitannins, gallic acid and quinic acid derivatives, and quercetin, kaempferol, and myricetin glycosides, the selected product ions deriving from the selected precursor ions always had the same optimal collision energies. The optimal collision energies are presented in Table 3. Two transitions, one qualifier and one quantifier, were selected for the detection of each group of compounds to avoid detection of false positives. The ratios of the peak areas obtained by the qualitative and quantitative MRM transitions are shown in Table 3. These ratios are constant for true detections and

change as a result of false positives. This was demonstrated with the total peak areas of the 15 plant extracts, the individual compounds of each extract, and the pure compounds presented in Table 3. These ratios should be used to verify that the correct polyphenol groups have been detected by the MRM methods.

Testing the UPLC-MS/MS Method with Plant Extracts and Polyphenol Mixtures. After optimization of MRMs, the new method was rigorously tested with 14 different plant extracts and 3 mixtures of different polyphenols and their dilution series. All samples were analyzed by using the developed group-specific MRM method and compound-specific MRM methods (Table 3). When the mixtures of pure compounds were analyzed, it was noted that the peak areas obtained with the group-specific MRM method depended both on the cone voltage used and on the number of the units in the studied polyphenol structure that yielded the precursor ions (Figure 4). As suggested already for cone voltage optimization, this indicated differences in the collision-induced dissociation of different molecules belonging to the same polyphenol subgroup. Due to this, the intensities of the peaks obtained, for example, for vescalagin (**8**) and agrimoniin (**6**) differed even if both molecules yielded maximum accumulation of m/z 301 when the cone voltage was 110 V (Figure 4B). In contrast, even though the change in applied cone voltage affected absolute peak areas, it did not affect the shape of the concentration versus peak area plots when dilution series were analyzed. This indicates that group-specific fingerprints can be detected even by using nonoptimal cone voltages, and fingerprints can be converted to quantitative data, if suitable standards of each detected polyphenol groups are available. Without proper standards, however, MRM fingerprints should not be converted into quantitative results, because this might result in severe over- or underestimation of the polyphenol groups, depending on the standards used.

Detection with the presented group-specific MRM method was also compared with compound-specific MRM methods (Figure 4) that were separately optimized for every quantified compound. The results indicated that for all but two compounds the compound-specific methods were more sensitive and yielded better responses than the group-specific methods. The two exceptions were tellimagrandin I and pentagalloyl glucose, which were better detected with the galloyl-specific MRM method than with the compound-specific MRM methods. In fact, tellimagrandin I, which contains one HHDP and two galloyl groups, was better detected by the galloyl than the ellagitannin method (**1** in Figure 4B,C). All in all, compound-specific MRM methods cannot be substituted by the developed group-specific methods, but both could be used parallel, depending on the need. For instance, Figure 5 shows how the UPLC-DAD chromatogram at 349 nm was able to reveal nine flavonoids from the crude extract of *Epilobium hirsutum* (characterization confirmed by UV spectra[28]). During the same UPLC run, group-specific MRM methods were able to classify three of these compounds as myricetin derivatives, three as quercetin derivatives, and the remaining three as kaempferol derivatives. Simultaneously acquired full scan MS revealed the molecular weights of these compounds, enabling their further characterization. It was found that all three sets of three flavonol glycosides presumably contained the same three

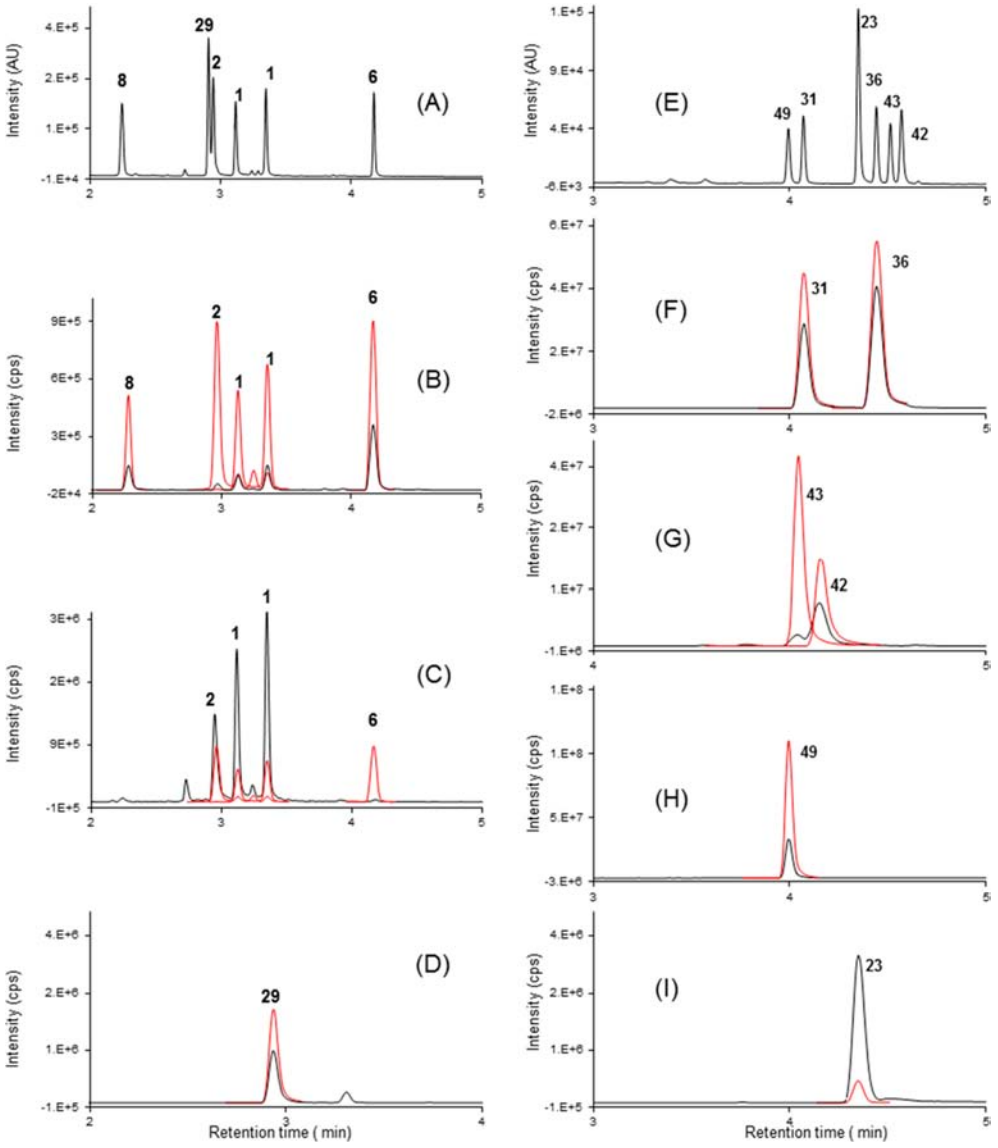

Figure 4. UPLC fingerprints of polyphenol mixtures 1 (A–D) and 3 (E–I) as detected by UV at 280 nm (A, E) and group-specific (black lines) and compound-specific (red lines) MRM methods for ellagitannins (B), gallic acid derivatives (C, I), quinic acid derivatives (D), quercetin-based flavonoids (F), kaempferol-based flavonoids (G), and myricetin-based flavonoids (H). See Table 1 for compound identities.

carbohydrates as building blocks: the first compound in the set of three peaks always gave the mass of 180 Da for the carbohydrate (possibly glucose or galactose), the second compound gave the mass of 132 Da (xylose/lyxose, but more presumably arabinose), and the third compound gave the mass of 146 Da (rhamnose) for the carbohydrate part of the glycoside. This could not have been achieved by full scan only as aglycone fragments are not always unequivocally witnessed. Furthermore, these findings were confirmed by compound-specific MRMs (see examples in Figure 5F–I). This illustrates the logic of how the created group-specific methods should be used to facilitate compound characterization and the measurement of group-specific fingerprints. For every species and polyphenol group analyzed, one should first reveal the percentage of the fingerprint produced by the qualifier MRM transition of that produced by the quantifier MRM transition. If the ratio deviates from values shown in Table 3, then further examination of the sample by UV and full scan MS is needed either to verify the results obtained by the fingerprint method or to reveal the causes for false positives. For instance, some flavonols and flavones share the same mass for their aglycone part (e.g., 286 Da for luteolin and kaempferol), but these two types of flavonoids are easily separated by both UV spectra and MS/MS spectra recorded for the aglycone part. The latter difference in MS/MS spectra explains why flavones produce variable ratios with the qualifier/quantifier transitions from those of flavonols.

In the present work, quantification was established by preparing calibration curves with pure compounds (polyphenol mixtures 1, 2, and 3). The results obtained by group- and compound-specific MRM methods (Table 3) for the 15 plant extracts are presented in Table 4. Results were expressed as milligrams per gram of plant dry weight. The developed group-specific MRM method was able to produce quantitative data comparable to the compound-specific MRM methods for all of the studied polyphenols. However, in some extracts detection of tellimagrandin I (**1**) with the compound- and group-specific methods yielded divergent results (see Table 4). Due to the

coelution of compounds from the same polyphenol subgroup, tellimagrandin I could not be detected separately anymore by the developed group-specific MRM method, but instead a combined signal of several ellagitannins was detected. This resulted in overestimated quantification when compared to the results obtained by the compound-specific methods. This further demonstrated the purpose for which the method was developed: for fingerprint analysis and quantification of total concentrations of different polyphenol subgroups, not for quantification of individual compounds. The results indicated also that in the present work the matrix effect of the plant extracts was not remarkable, and calibration curves produced with pure compounds were sufficient for obtaining quantitative data. This highlights the importance of correct sample concentration: to minimize matrix effect, sample concentration should be preferably adjusted to such a level where no detection rises above the 1×10^6 limit. Also, compounds used for quantification must be carefully selected. In present work, compounds used in the standard mixtures were selected so that they would as well as possible resemble the range of polyphenols in the studied plant extracts. If this is not possible, the quantitation results should be treated as relative ones, not absolute, and expressed as equivalents of the compounds used as standards.

[a]Results are expressed as mg g^{-1} of dry material. See Tables 1 and 2 for compound and plant extract identities, respectively.

One of the most common problems for the developed methods is related to both ellagitannins and quercetin-based flavonoids producing precursor ions with the very same m/z value (m/z 301), and therefore LC-MS/MS methods have been used in previous studies to distinguish their conjugates.[32,33] In the present study, it was noted that even if the ellagitannin and quercetin MRM transitions had different product ions (301 → 200/301 → 145 and 301 → 151/301 → 179 respectively), a small false-positive ellagitannin response (0.1−1%) was obtained from quercetin derivatives when their concentrations were >1 μg mL^{-1}. For qualitative analysis this will not cause any problems because the false-positive response of ellagitannins is easily distinguished directly from the MRM chromatograms: Figure 6C shows a false-positive detection of ellagitannins that is due to high levels of quercetin glycosides (panel B), and panel F shows the true ellagitannin detection that is not disturbed by the 0.1−1% false positive caused by the quercetin glycosides (panel E). As noted above, these findings can be confirmed by comparing peak areas obtained by quantifier versus qualifier MRM transitions as well. All in all, although the new MRM methods significantly aid in the mission of fingerprinting plant extracts for various polyphenol groups, they cannot be used as such without careful inspection of the data produced. Once the findings are confirmed for each studied species, the methods can be used to more routinely screen the differences of polyphenol fingerprints between individual plants of the selected species.

Method Validation. LOD, LOQ, and linearity were determined with the presented method for polyphenols present in the three mixtures containing different polyphenols. For both ellagitannins and gallic acid derivatives LOD and LOQ were 150 and 310 ng mL^{-1}, respectively. For quinic acid derivatives LOD was 20 ng mL^{-1} and LOQ, 80 ng mL^{-1}. The linear range was the same, 15−0.7 μg mL^{-1} for ellagitannins, gallic acid, and quinic acid derivatives. For the quercetin, kaempferol, and myricetin glycosides the linear ranges were 7.5−0.02, 7.5−0.08, and 10−0.3 μg mL^{-1}, respectively. For both quercetin and kaempferol glycosides LOD was 0.3 ng mL^{-1} and LOQ, 1.2 ng mL^{-1}. For myricetin-based flavonol glycosides LOD and LOQ were 40 and 80 ng mL^{-1}, respectively.

As witnessed in a previous section when the method was tested with polyphenol mixtures, these results further indicated that, in general, the developed UPLC-MS/MS method was more sensitive for the quercetin and kaempferol glycosides than for the other studied polyphenol subclasses. Also, the LOD, LOQ, and linear ranges varied slightly within each polyphenol subclass, depending on the exact structure of the studied molecule. The presented values were obtained with molecules for which the present method was most insensitive; that is, with other types of molecules the method would have performed better.

The repeatability of the method was determined using Student's t test at the 95% confidence interval. Five replicates in two different concentrations (20 and 5 μg mL^{-1}) were analyzed, and the results were presented as confidence intervals of the sums of peak areas obtained for ellagitannins, gallic acid and quinic acid derivatives, and quercetin-, kaempferol-, and myricetin-based flavonol glycosides. The relative standard deviation (RSD) for all six samples with five replicates was determined from these results. The RSD for peak areas was 2.4%, which demonstrates the pronounced reliability of the developed UPLC-MS/MS method. The results suggested that the quantitative determination of ellagitannins and quinic acid derivatives was slightly less accurate than for the other polyphenol classes (RSD, 3.1, 2.7, and 1.8−2.4%, respectively). Naturally, more accurate results were obtained when operating at the linear range than above the linear range.

In this study we created novel methods for the analysis of six common classes of plant polyphenols. UPLC enabled rapid chromatography of different kinds of polyphenols, whereas TQ-MS fragmented compounds into group-specific precursor and product ions for detection with MRM methods. With the

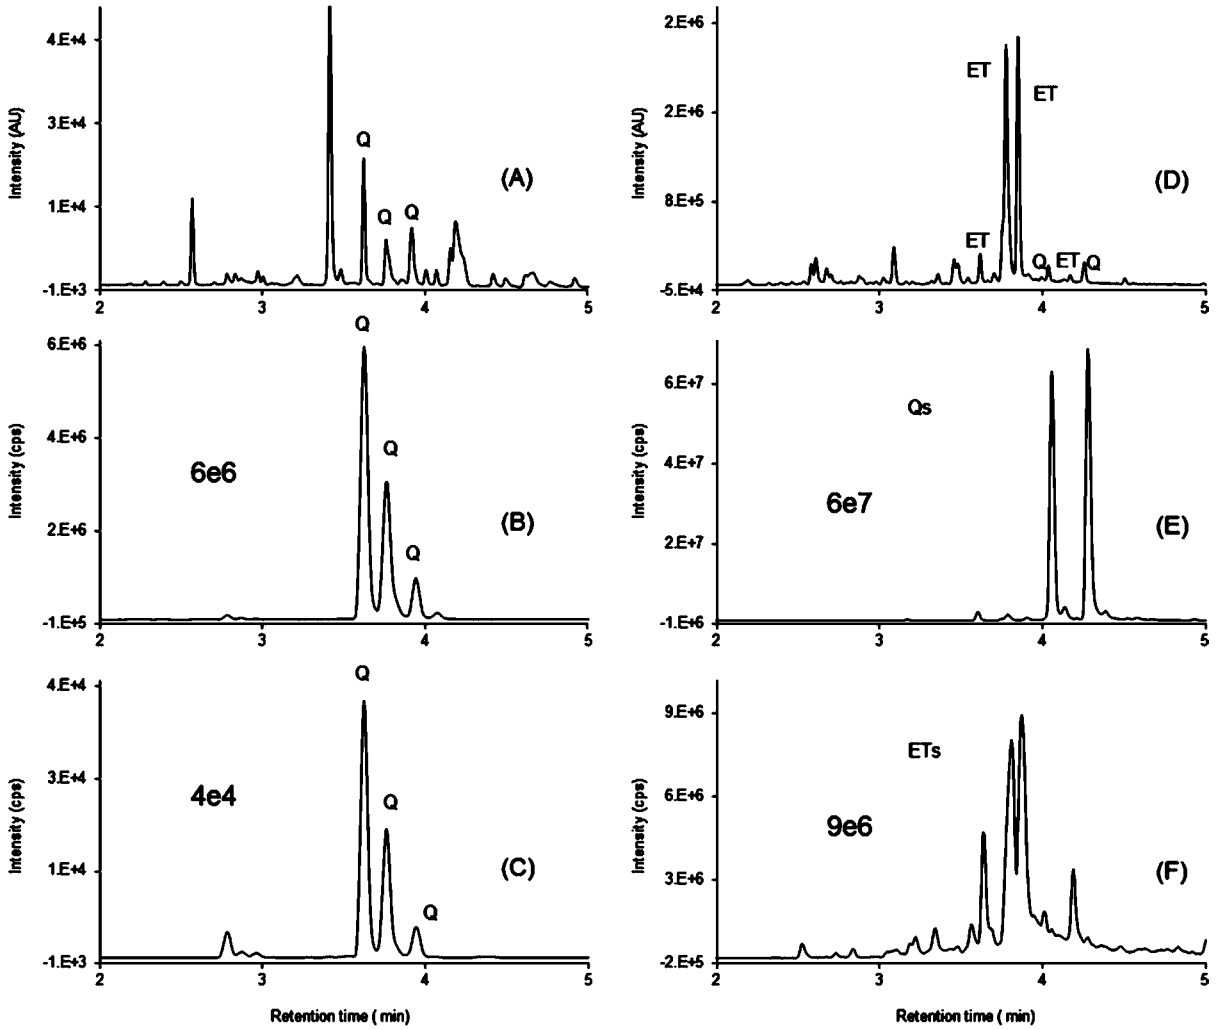

Figure 6. UPLC traces at 280 nm for polyphenol extracts of *Fumaria officinalis* flowers (A) and *Rubus saxatilis* leaves (D). Panels B and E show MRM fingerprints detected for quercetin-based flavonoids, and panels C and F show MRM fingerprints detected for ellagitannins. Quercetins produce <1% false-positive response with the ellagitannin method that can be verified by intensities of the matching fingerprints of panels B and C, because *F. officinalis* does not contain any ellagitannins. The true ellagitannin fingerprint of *R. saxatilis* (F) is not disturbed by the false positive of quercetins, because the ellagitannin detection is more than an order of magnitude higher than the false positive in the background. Q, quercetin-based flavonoid; ET, ellagitannin.

present methods, fingerprints of ellagitannins, gallic acid and quinic acid derivatives, and quercetin, kaempferol, and myricetin glycosides can be simultaneously recorded with UV and full scan mass spectra. The developed method is complementary for the UPLC-MS/MS method reported by Engström et al.[27] for the fingerprint analysis of procyanidin and prodelphinidin oligomers and polymers. By combining these two methods, a broad overview of fingerprints of eight common polyphenol classes can be achieved in relatively short time. The method is able to handle 140 extracts, produced from as little as 1 mg of plant powder, in a day, and it offers a user-friendly, robust, and fast addition to the chemistry tools currently used for the qualitative and quantitative screenings of large numbers of samples for their bioactive polyphenol types and contents. However, it must be remembered that the results of these types of semiautomatic fingerprint methods cannot be used without careful verification of the true presence of the detected polyphenol groups in tested samples. We offered tools for this by the use of quantifier and qualifier MRM transition for each polyphenol group and by using UV and MS spectra to verify the polyphenol groups of the main metabolites.

has permitted researchers to solve a lot of ineresting problems unaddressed using other structural methods alone, has created significant impacts on structural characterization of macromolecules during the past several decades.[22] The combined studies via SAXS, circular dichroism (CD), fluorescence spectroscopy, and dynamic light scattering (DLS) have been conducted to investigate how the conformation and structure of BSA change as a function of the reaction time coexisting with dextran.

MATERIALS AND METHODS

Materials. BSA (fraction V) with a molecular weight of 66 kDa was obtained from Sigma Chemical Co. (St. Louis, MO). Technical-grade dextran (DT10) with an average molecular weight of 10 kDa was provided by Pharmacosmos (Danmark). The other chemicals, such as sodium chloride (NaCl), potassium chloride (KCl), $Na_2HPO_4{\cdot}7H_2O$, and $NaH_2PO_4{\cdot}H_2O$, were of analytical reagent grade and purchased from Sigma Chemical Co. (St. Louis, MO).

Preparation of BSA–Dextran Conjugates. The conjugates were synthesized through Maillard reaction by dry heating based on the method introduced by Kato et al.,[9] with minor modification. The BSA–dextran mixture in a 1:12 molar ratio was solubilized in phosphate buffer solution (PBS, pH 7.0, 0.1 M NaCl), followed by freezing dry. The freeze-dried mixtures were then put into a desiccator containing saturated KCl solution and incubated at 60 °C for different times (8, 19, and 26 h). The samples with BSA alone were also treated in the same way for comparison.

After incubation, the samples were solubilized in deionized water (0.25%, w/v) and then pre-filtered via a 0.45 μm pore membrane filter (Millipore Corp., Bedford, MA). A 20 mL Microsep advance centrifugal device (Pall Corporation, Port Washington, NY) was used for ultrafiltration with the molecular weight cut-off of 100 000. The samples were centrifuged at 1000 revolutions/min for 30 min to $^1/_8$ of the initial volume to maintain. The deionized water was added to complement the original volume. This procedure was repeated in triplicate to remove excess dextran and BSA. Afterward, the retentates (conjugates) were freeze-dried. It has been proven that the native or dry-heated BSA and 10 kDa dextran could penetrate through the cartridges.[4] The control samples containing pure protein or dextran were also treated accordingly.

SDS–PAGE. Electrophoresis analysis was conducted on the basis of the method provided by Jung et al.,[19] with minor modification. A 10% acrylamide separating gel and a 5% stacking gel containing 0.1% SDS were used. Samples were dissolved in phosphate buffer solution (pH 7.4, 10 mM). Afterward, samples were incubated for 3 min at 100 °C. Electrophoresis was conducted at about 10 mA until the dye front arrived at the bottom of the separating gel. The Coomassie Brilliant Blue R solution was used for gel staining to visualize protein. Later, it was discolored with a solution composed of 10% methanol and 10% acetic acid.

Binding Ratio of DT10 to BSA. Colorimetric methods for determing protein and polysaccharide concentrations were used to calculate the binding ratio of DT10 to BSA. The BSA content was assayed using the Bio-Rad Protein Assay Kit II (Bio-Rad Laboratories, Hercules, CA).[23] The dextran content was quantified by the phenol–sulfuric acid method.[24]

SAXS. BSA and BSA–dextran conjugate were dissolved in deionized water with 2 mg/mL BSA. The content of BSA in solustions was adjusted using the Bio-Rad Protein Assay Kit II for SAXS measurements. SAXS experiments were carried out at the BioCAT, 18-ID beamline of the Advanced Photon Source (Argonne National Laboratory) according to the way that we used previously.[25,26] A sample–detector distance of 3.5 m was taken to lay over a combined Q range from 0.006 to 0.37 Å^{-1}. The scattering data were obtained by a single exposure of 1 s, and 15 replicas were measured and averaged.

Fluorescence Spectroscopy. Fluorescence spectra were recorded with a Cary Eclipse fluorescence spectrophotometer (Varian Instruments, Walnut Creek, CA). A conjugate solution was prepared with 0.1 mg/mL BSA in deionized water. The quartz cuvette of a 1 cm path length was used for holding samples. The intrinsic fluorescence was detected at an excitation wavelength of 280 nm, and the emission wavelength ranged from 287 to 500 nm at 25 °C. The slit width of excitation and emission was 5 nm, respectively.

Far-ultraviolet (UV) CD Spectroscopy. CD of BSA and glycoconjugates was investigated by an Aviv model 420SF CD spectrometer (Biomedical, Inc., Lakewood, NJ). The spectral bandwidth was set at 1 nm. The glycoconjugate was solubilized in deionized water with the BSA concentration of 0.1 mg/mL and then added to the quartz cell of 0.1 cm light path length. CD spectra was obtained from 190 to 250 nm at 25 °C. Molar ellipticity (θ) was analyzed to obtain the α-helix content via the CDPro2 software.

DLS. The mean hydrodynamic diameters of protein and conjugates were determined with the methods described in our previous paper.[25] A dynamic-light-scattering-based BIC 90 plus particle size analyzer was used, fitted with a BI-9000AT digital correlator (Brookhaven Instrument Corporation, Holtsville, NY). Measurements were carried out in triplicate at room temperature.

RESULTS AND DISCUSSION

Binding of BSA with DT10. SDS–PAGE patterns of BSA–DT10 conjugates with different Maillard reaction times were used to prove the covalent binding between DT10 and BSA (Figure 1). It was found that the high-molecular-weight

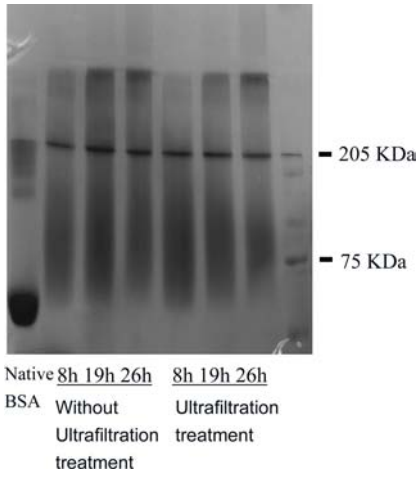

Figure 1. SDS–PAGE pattern of the BSA–DT10 mixture after Maillard reaction.

bands were broad using protein staining. There were bands (~205 kDa) at the head of the separating gel, implying the existence of high-molecular-weight product. Under the conditions of dry heating in this study, oligomers might first arise based on monomeric BSA; subsequently, Maillard reaction proceeded.[19] Therefore, larger oligomeric BSA–DT10 conjugates might exist in the product. In the electropherogram of the reactant (8 h), there was almost no band from the unreacted BSA. We also measured the composition of the conjugates with three reaction times. It was displayed that about 1.68 M DT10 was attached to 1 M BSA. With the reaction time prolonging to 19 and 26 h, about 2.50 and 3.12 M DT10 were bound to 1 M BSA, respectively.

SAXS Profiles. Heating of proteins may lead to conformational changes.[6] The scattering intensity profiles of pure BSA, dextran (DT10), and BSA–DT10 conjugate solutions were presented in Figure 2.

DOI: 10.1021/jf506267r
J. Agric. Food Chem. 2015, 63, 4080–4086

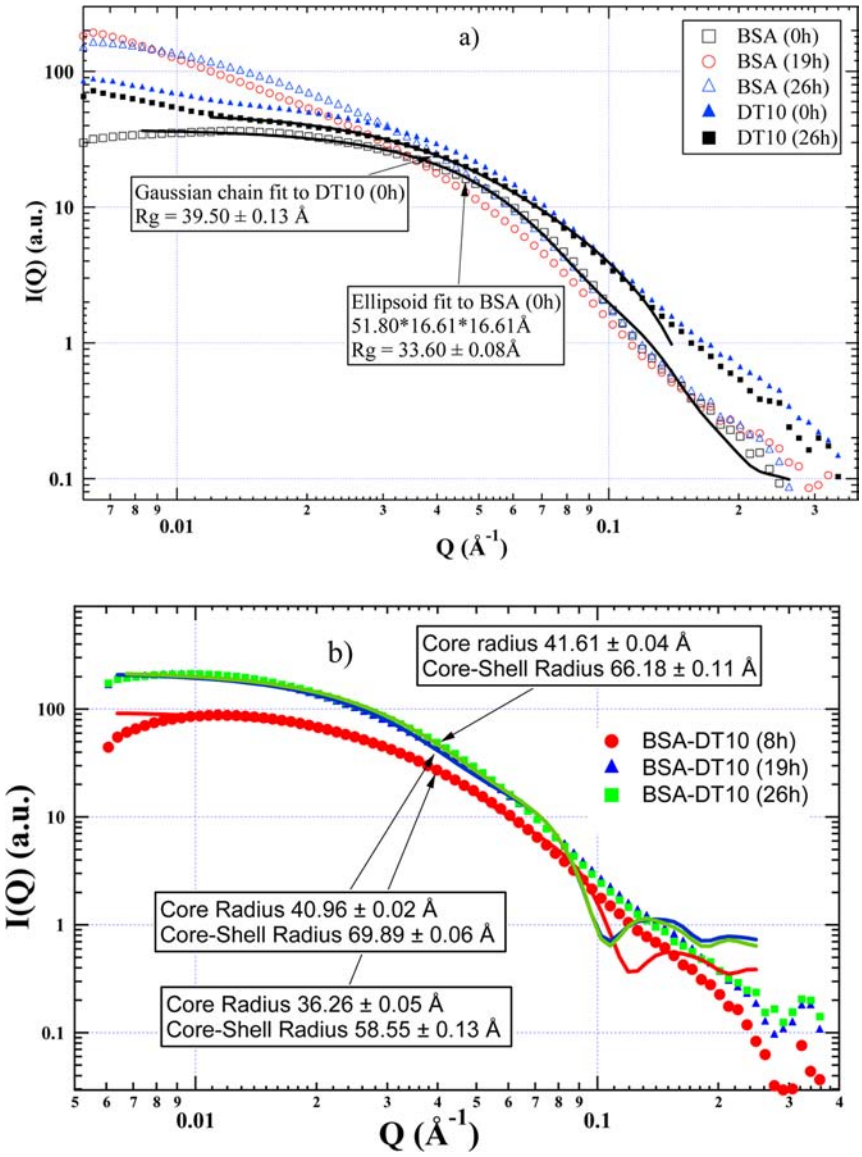

Figure 2. (a) Scattering intensity profiles of BSA and dextran (DT10) during the controlled dry heating period. (b) Spherical shell-fitting plots for scattering intensity profiles of BSA during the dry-heating period in the presence of dextran. Scaling exponents were obtained through the best fit in a log−log plot. The solid line is the fit to a Schultz polydisperse core spherical shell.

For the dry-heated BSA alone, the slopes in the large q range transformed little (Figure 2a). At small q range, the slopes increased sharply with the heating time prolonged. It changed from −0.23 to −1.19 in dilute solutions when the dry heating time prolonged up to 19 h, suggesting that large aggregates formed by interchain correlation of BSA. Such an obvious transformation also suggested that the aggregation of BSA during dry heating might undergo a rod-like shape (slope of −1).[26] However, at a longer heating time (26 h), the slope changed little, revealing that protein did not aggregate further. The 17 disulfide bridges inside BSA make the tertiary structure stable at room temperature, while they do not prevent changes of shape and size as a function of the temperature. Furthermore, a free thiol group (Cys34) is present in the BSA structure, which has been verified to be involved in heat-induced aggregation pathways of BSA. According to the literature, heat-induced aggregation of BSA takes place via two ways in solution. One is the formation of intermolecular disulfide bonds,[27−29] and the other is the formation of intermolecular β-sheet (i.e., β-amyloid).[30] The dry state may prefer β-amyloid because of the lower conformational relaxation freedom; this is also indicated from the CD results.

For BSA dry heated from 8 to 19 h in the presence of dextran (Figure 2b), the slopes also changed when the heating time prolonged in the small q range. It was noted that the slopes did not increase significantly, provided that the heating time prolonged to 26 h. This suggested that the conjugation reaction reached a steady state with the prolonging of the reaction time. The phenomenon was associated with the steric hindrance existing near ε-lysyl amino groups in BSA and branched structure in DT10.[19] Furthermore, the steric effect deriving from the attached dextran might bring an obstacle for further binding.

Guinier Analysis. The quantity radius of gyration (R_g) was commonly used to reflect the volume of solution occupied by the extended micromolecule.[20] Guinier analysis of the scattering curve gave an estimation of R_g. The R_g of particles in solutions was determined using the Guinier relationship.

DOI: 10.1021/jf506267r
J. Agric. Food Chem. 2015, 63, 4080−4086

$$\ln[I(Q)/(Q=0)] = -(QR_g)^2/3 \quad (1)$$

The data range for Guinier analysis was in accordance with $QR_g < 1.57$, which is appropriate to Guinier fitting.[26] Figure 3

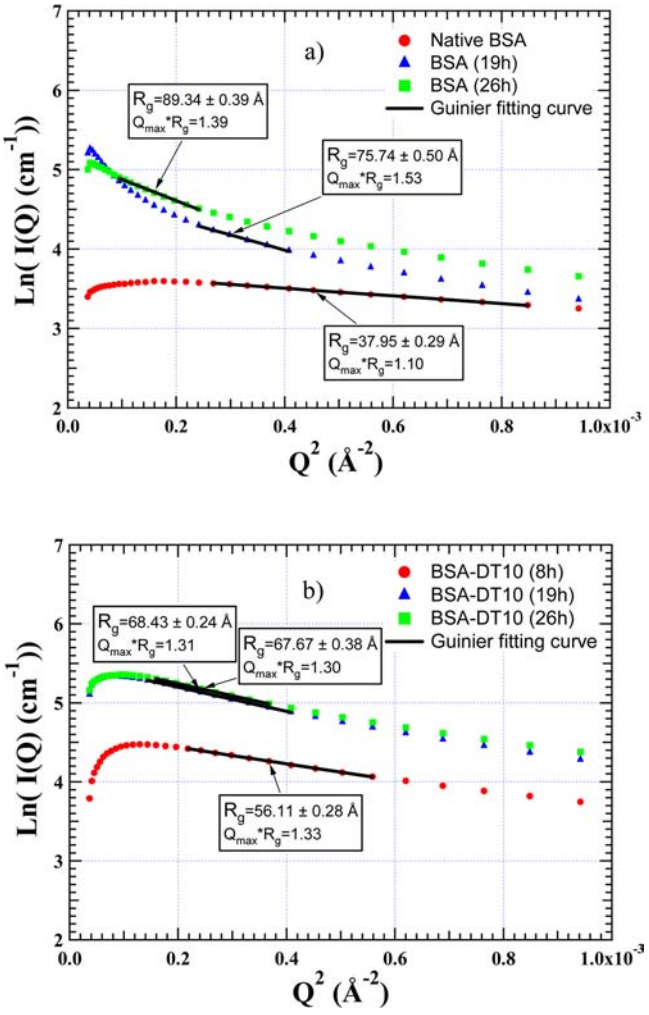

Figure 3. Guinier plots for scattering intensity profiles of BSA during the dry-heating period in the (a) absence and (b) presence of dextran (DT10, 10 kDa). Scaling exponents were obtained through the best fit in a log−log plot.

displayed the fitting line and the influence of heating time on R_g. With the prolonging of the reaction time, $I(Q)$ increased in a small Q range, which might be attributed to the aggregation of protein.[26]

The reaction time and dextran presence dependence of R_g are listed in Table 1. The R_g values of pure BSA increased from 3.8 nm (native) to 5.3 nm (8 h), 7.6 nm (19 h), and 8.9 nm (26 h) as the reaction time increased. However, the R_g values of conjugates just increased from 3.8 nm (native BSA) to 5.6 nm (8 h), 6.8 nm (19 h), and 6.8 nm (26 h). The R_g difference corresponding to the same reaction time may come from the competition between glycosylation and aggregation of BSA. It has already been found that free cysteine plays a notable role on the aggregate growth of BSA in the aqueous system via intermolecular disulfide bridges and S−S exchange.[31] The participation of the unique free cysteine in the aggregation pathway can be affected by the formation of glycosylated albumin. In fact, Maillard reaction of proteins generally involved amino groups (lysine and arginine residues) and thiol groups of the cysteine residue, owing to its powerful nucleophilic property.[32,33] Therefore, the adduction of dextran on the unique sulphydryl group could occur, which might prevent the cysteine residue from taking part in the formation of intermolecular bonds.[30]

The pure dextran was incubated in the same dry-heating condition too. The SAXS results indicated that the structure of DT10 was unchanged (Figure 2a). The dry heating has no significant impact on the conformation of dextran. The gyration radius is slightly changed from 3.6 to 3.8 nm with 26 h of heating.

Spherical Core−Shell Fitting. Conferred from the spherical core−shell fitting (Figure 2b), the core (BSA) has a radius of around 3.6−4.2 nm. When reaching a steady state, the conjugate has a shell with a thickness of around 6.8 nm. BSA conjugates with dextran are slightly smaller in shell thickness (~5.8 nm) for 8 h of dry heating compared to 19 h (~7.0 nm) and 26 h (~6.6 nm). The core radii (BSA) increased slightly with the increase of the dry-heating time. Hence, hydrophilic dextran was bound to the protein surface, followed by enclosing the protein, and the dextran reacted more extensively as the heating time increased. It might also be deduced that the conjugation between DT10 and BSA had no obvious influence on the BSA peptide backbone. In addition, because the steric effect depended upon the polymer chain density of the colloidal particle surface, the shell, owing to the attached dextran with a longer reaction time, agreed with the better stability against heat-induced aggregation of protein.

DLS Measurements. It was also found that the prolonging of the heating time was accompanied by the formation of larger molecules (Figure 4). This tendency could relate to the

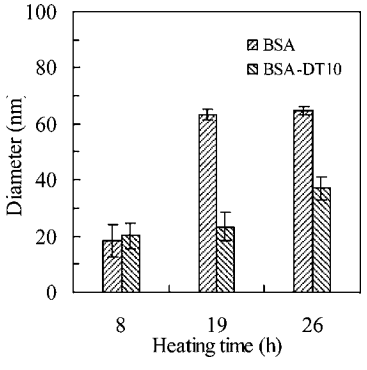

Figure 4. Average diameter of BSA for dry-heated [60 °C and 79% relative humidity (RH)] time periods in the absence and presence of dextran (DT10, 10 kDa).

Table 1. Variation of Radii of Gyration (R_g) during the Dry-Heating Period in the Absence and Presence of Dextran (DT10)

time (h)	0	8	19	26
R_g (Å) of BSA	38.0 ± 0.3	52.8 ± 0.1	75.7 ± 0.5	89.3 ± 0.4
R_g (Å) of BSA−DT10		56.1 ± 0.3	67.7 ± 0.4	68.4 ± 0.2

J. Agric. Food Chem. 2015, 63, 4080−4086

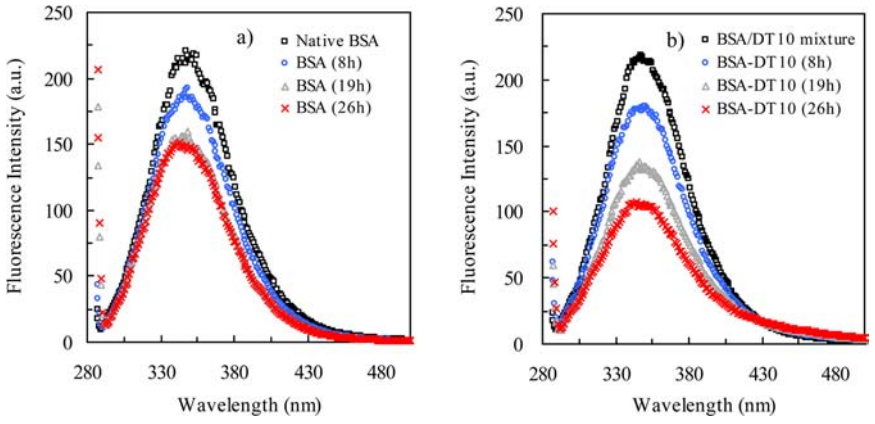

Figure 5. Intrinsic fluorescence spectra excited at 280 nm of BSA for dry-heated (60 °C and 79% RH) time periods in the (a) absence and (b) presence of dextran (DT10, 10 kDa). Fluorescence spectra of BSA samples were measured at 0.1 mg/mL.

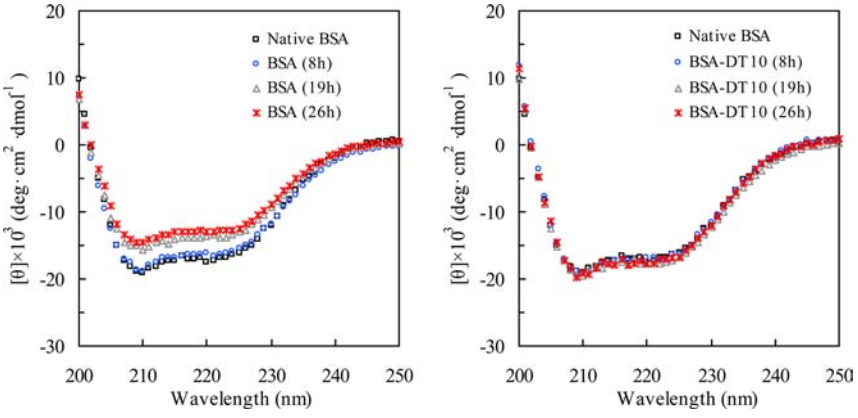

Figure 6. CD spectra of BSA for dry-heated (60 °C and 79% RH) time periods in the (a) absence and (b) presence of dextran (DT10, 10 kDa).

oligomerization of BSA.[19] Thermally induced denaturation and aggregation of BSA have been widely studied. The thiol groups and nonpolar amino acid residues are exposed because of denaturation, which results in the formation of irreversible aggregates via intermolecular disulfide bonds and hydrophobic attraction. This was the reason that the BSA formed aggregates when it was dry-heated alone. Whereas the aggregation and glysolation may occur simultaneously provided that there is dry heating in the presence of dextran, the shell by glycosylation may form a barrier to prevent BSA from aggregation further. This difference is in virtue of the introduction level of hydrophilic dextran to protein. The DLS results are in agreement with the SAXS experiments, in which the aggregation of BSA was concomitant with the reaction time and the extra aggregation was inhibited by the presence of dextran upon the increase of the dry-heating time.

Fluorescence Measurements. There are two tryptophan (Trp) residues possessing intrinsic fluorescence in BSA. Trp212 lies in a hydrophobic pocket of BSA, and Trp134 lies in a hydrophilic region of the molecule surface.[16] Moreover, tryptophan displays an emission maximum near 348 nm in water.[20] The intrinsic fluorescence spectra were used to elucidate the conformation change around the Trp microenvironment.

As shown in Figure 5, the fluorescence emission spectra of native BSA and BSA/DT10 mixture were compared to BSA dry heated alone and glycoconjugate. It was observed that native BSA presented fluorescence emission maxima at 350.92 nm. Once dry heating alone, the alternation of fluorescence intensity of BSA was significant, which came with an obvious shift of the emission maximum to 340.9 (19 h) and 343.9 (26 h), respectively. It is common knowledge that the protein aggregation produces a decrease of the fluorescence intensity, which is accompanied by a blue shift of the maximum emission intensity wavelength. Considering the results, it was implied that the protein underwent conformation change, resulting in the Trp residue exposure to a nonpolarity microenvironment when dry heating alone.

In contrast, there was little change in the emission maximum wavelength of glycoconjugates (λ_{max} = 347.81 nm at 19 and 26 h), suggesting that the conformation around the Trp microenvironment of glycoconjugates resembled with that of native BSA and BSA/DT10 mixture. Whereas in comparison to the controlled BSA by dry heating alone and BSA/DT10 mixture without the heating process, the fluorescence intensity in each glycoconjugate was lowered. Therefore, it could be postulated that the attachment of dextran to BSA took place on the surface of the protein molecule, which corresponded to the core−shell microstructure deduced from SAXS results. It might also be assumed that the binding between BSA and dextran had no significant influence on the conformation of BSA. A previous study of BSA−dextran conjugates with Maillard reaction time reaching 48 and 72 h showed little change in the fluorescence intensity when compared to the native protein.[4] On the contrary, the fluorescence intensity in native BSA alone increased upon dry heating at the same time period.

DOI: 10.1021/jf506267r
J. Agric. Food Chem. 2015, 63, 4080−4086

The reason for the discrepancy may be correlated with the long reaction time. As in our preliminary experiments, it was found that the solubility of the conjugates was very low and floccules formed in the aqueous dispersion when the reaction time reached 36 h or even higher. Jung et al. also characterized the structure of BSA−dextran (69 000 Da) conjugates after controlled dry heating for 7 days by fluorescence spectroscopy and found the similar fluorescence shielding effect by the dextran molecule bound to BSA.[19]

Far-UV CD Measurements. CD spectroscopy was used to investigate the influence of dextran on the characteristics of BSA at the secondary structure level during controlled dry heating. As shown in Figure 6, the helix presented two negative absorption bands at around 209 and 222 nm. Native BSA was reported to have a fraction of about 55% α-helix and 19% β-sheet at pH 7.[34] Herein, the α-helix content of native BSA was about 49% in deionized water, and it almost stayed constant in dry-heating BSA samples containing dextran (Table 2). In view of the minor difference in the CD spectra, the changes in the secondary structure of BSA upon the formation of the glycoconjugate were small. In contrast, the CD spectra changed significantly when the protein alone was dry-heated for 19 and 26 h (Figure 6a), and the α-helix content was found to decrease significantly (Table 2). This suggested that BSA underwent secondary structure changes because of thermal treatment and the presence of dextran might serve to maintain the structural integrity of BSA during dry-heat treatment. This behavior is consistent with the SAXS experimental finding, in which minor loss of secondary structure is accompanied with the prolonged reaction time upon glycosylation with dextran. Spectroscopic analysis by Kim et al. also found that the surface of glycoconjugate was covered with galactomannan and the hydrophobic interior conformation as well as the secondary structure were unchanged obviously.[20] In addition, alteration of the albumin tertiary structure with the glycation process by glucose in the aqueous system had no significant impact on the secondary structure of protein, which was probed after glycation for 7 weeks.[21,35]

Table 2. α-Helix Content of BSA by Dry Heating Alone and in the Presence of Dextran

		BSA			BSA−DT10		
dry-heating time	native BSA	8 h	19 h	26 h	8 h	19 h	26 h
α-helix (%)	48.9	46.5	38.2	34.9	50.8	50.5	49.9

In summary, SAXS, fluorescence, CD, and DLS were employed to investigate the structural change of BSA and BSA−dextran conjugate as a function of dry-heating time. Dextran was found to be able to protect BSA from denaturation and aggregation during dry heating. During incubation in controlled dry heating, BSA endures an obvious change in secondary structure, tertiary structure, and aggregation. Because of the protection from the conjugated dextran layer, the secondary structure of native BSA is well-preserved. The conjugate thickness after reaching a steady state is around 7 nm, with a core of 4 nm. It is necessary to study further to have good knowledge of the relationship between the glycoconjugate structure and functionality.

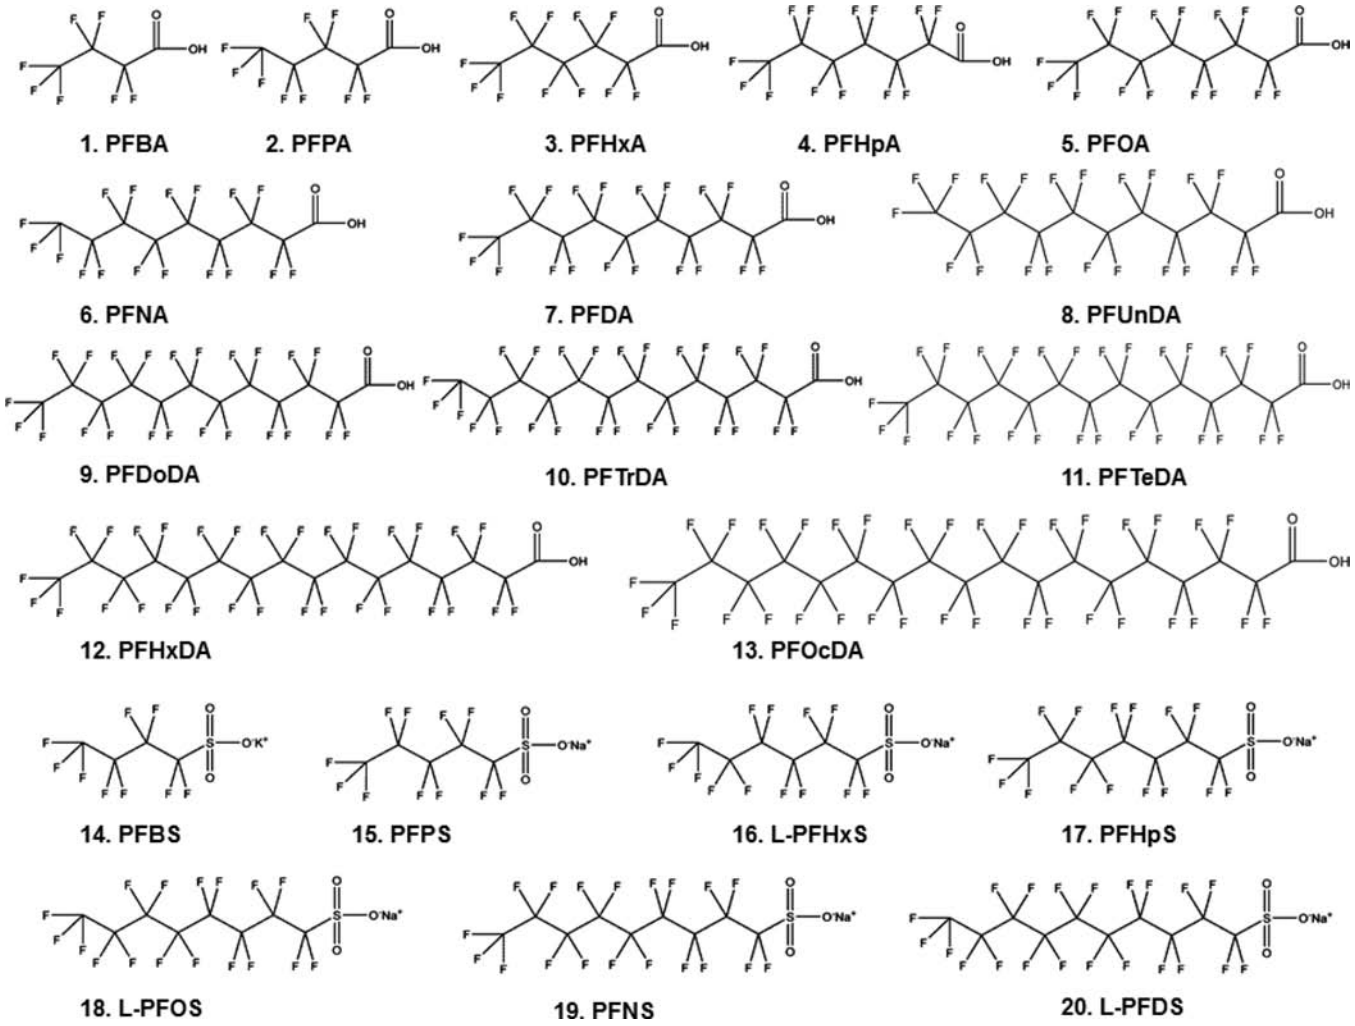

Figure 1. Molecular structures of the 20 PFASs.

Currently, PFASs have been found in cow milk and human milk in many countries including Germany,[22,23] Canada,[24] Italy,[25] China,[26,27] and the U.S.,[28] which is consistent with the persistence and bioaccumulative features of PFASs.[1,3] Furthermore, it was pointed out that the precision and LOD of most previously reported methods for PFASs measurement in the milk matrix varied largely, which might be caused by many factors including the background PFASs from solvents and the apparatus and different extraction efficiencies in milk.[22] With the decline in PFASs levels resulting from worldwide regulations and actions, a more sensitive and reliable method is highly demanded for monitoring PFASs in the complicated but representative milk matrix, which would enable a comprehensive survey and clarification of the exposure routes, particularly in rapidly developing industrialization regions such as China.

Currently available methods for the detection of PFASs in milk are mainly based on HPLC-MS/MS. The corresponding sample extraction methods include an ion-pairing technique,[29] alkaline digestion,[30] and direct methanol extraction.[31] The samples after extraction are normally loaded onto the SPE column for further cleanup.[32,33] However, SPE cleanup is often time-consuming, and not all compounds are retained in the SPE column efficiently, which may lead to low recovery. An alternative universal extraction and cleanup approach, QuEChERS, has been widely applied in pesticide residue screening in various food matrixes since it was first reported,[34] and it may be extended to the analysis of other contaminants such as PFASs in food. In addition, because of the ubiquitous presence of PFASs, the background level of PFASs from the entire analytical procedure has been paid particular attention by replacing the common laboratory apparatus and tubing with those made of glass and stainless steel as well as using an isolation column in the LC system,[8,22,32] which otherwise may lead to an overestimation of the PFASs levels in the measuring subjects and a decrease in the measurement precision. On the basis of the literature mentioned above and our laboratory practice, we are aiming at developing an approach to improve the PFASs measurement accuracy and reliability in milk by integrating the QuEChERS approach with an online trapping LC-MS/MS method and the least-biased quantitation using stable-isotope-labeled internal standards and further applying this method to the simultaneous screening of the common PFASs in dietary milk products.

MATERIALS AND METHODS

Reagents and Materials. The 20 PFASs are perfluoro-*n*-butanoic acid (PFBA), perfluoro-*n*-pentanoic acid (PFPA), perfluoro-*n*-hexanoic acid (PFHxA), perfluoro-*n*-heptanoic acid (PFHpA), perfluoro-*n*-octanoic acid (PFOA), perfluoro-*n*-nonanoic acid (PFNA), perfluoro-*n*-decanoic acid (PFDA), perfluoro-*n*-undecanoic

[a] L to the left of compound names **16**−**20** means the levorotary isomer of the compounds. [b] M to the left of compound names **21**−**29** means monoisotope-labeled compounds, used as internal standards. [c] Qualitative MRM.

acid (PFUnDA), perfluoro-*n*-dodecanoic acid (PFDoDA), perfluoro-*n*-tridecanoic acid (PFTrDA), perfluoro-*n*-tetradecanoic acid (PFTeDA), perfluoro-*n*-hexadecanoic acid (PFHxDA), perfluoro-*n*-octadecanoic acid (PFOcDA), potassium perfluoro-1-butanesulfonate (PFBS), sodium perfluoro-1-pentanesulfonate (PFPS), sodium perfluoro-1-hexanesulfonate (PFHxS), sodium perfluoro-1-heptanesulfonate (PFHpS), sodium perfluoro-1-octanesulfonate (PFOS), sodium perfluoro-1-nonanesulfonate (PFNS), and sodium perfluoro-1-decanesulfonate (PFDS). The nine isotopically labeled internal standards are $^{13}C_4$−PFBA, $^{13}C_2$−PFHxA, $^{13}C_4$−PFOA, $^{13}C_5$−PFNA, $^{13}C_2$−PFDA, $^{13}C_2$−PFUnDA, $^{13}C_2$−PFDoDA, $^{18}O_2$−PFHxS, and $^{13}C_4$−PFOS. The molecular structures of these compounds are shown in Figure 1. All standard compounds were purchased from Wellington Laboratories (Guelph, Canada), with purity greater than 98%.

Methanol and acetonitrile were HPLC grade and were obtained from Merck (Darmstadt, Germany); ammonium acetate (HPLC grade) was from TEDIA (Fairfield, OH); hydrochloric acid (12 mol/L) and analytical grade sodium chloride were from National Chemical Groups (Beijing, China); sorbents such as primary and secondary amine (PSA), C18, and graphitized carbon black were obtained from Bonna-Agela Technologies Ltd. (Tianjin, China); water was purified with a Milli-Q system to yield a resistivity of 18.2 MΩ·cm.

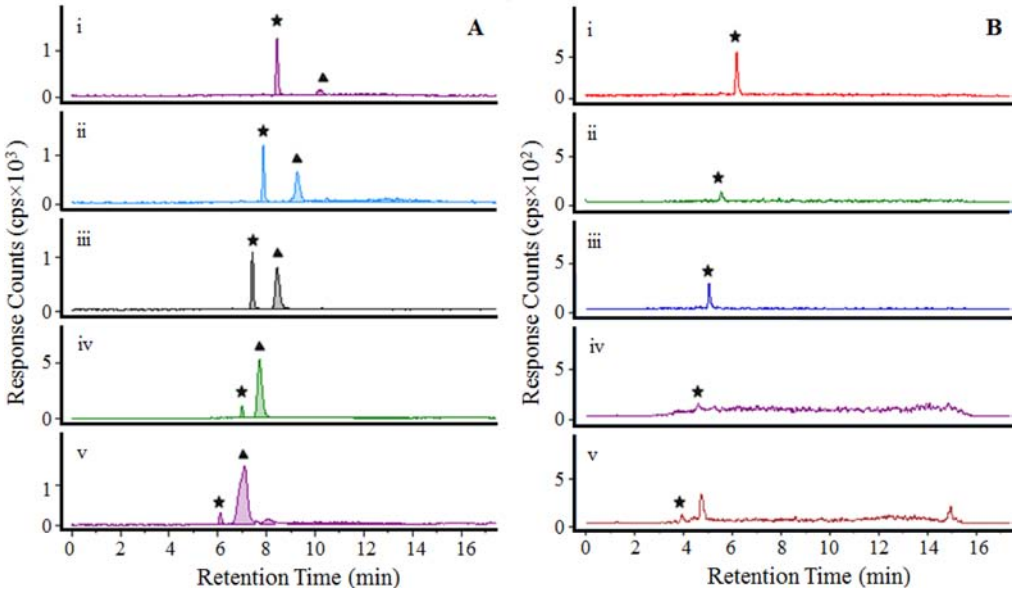

Figure 2. MRM chromatograms demonstrating the separation of target compounds from the background interference. (A) With the trapping column. (B) Without the trapping column. (i) PFOA, (ii) PFHpA, (iii) PFHxA, (iv) PFPA, and (v) PFBA. The spiking level of the analytes was 0.10 μg/L; ★ is the target compound, and ▲ is the interference compound. Note that the retention time for each compound is delayed 2.3 min by the increase in void volume introduced by the trapping column which delayed the gradient profile.

Instrumentations and Experimental Conditions. The separation was conducted using an Infinity UHPLC 1290 system consisting of a binary bump, an autosampler, and a column temperature control compartment (Agilent Technologies, Santa Clara, CA). The precolumn for interference trapping was a 50 mm × 4.6 mm i.d., 5 μm Zorbax Eclipse Plus C18 (Agilent Technologlies, Santa Clara, CA), and the analytical column was an 100 mm × 2.1 mm i.d., 2.7 μm Poroshell 120 Eclipse Plus C18 from the same manufacturer. The effluent from the analytical column was directed to an Agilent 6460 QQQ mass spectrometer fitted with a jetstream electrospray ionization source.

The chromatographic conditions were optimized to achieve high separation efficiency and selectivity. The column was maintained at 30 °C. A binary gradient elution was selected for separation of the 20 PFASs, with solvent A being 5 mmol/L ammonium acetate aqueous solution and solvent B being methanol containing 5 mmol/L ammonium acetate. The gradient profile was the following: %B increased from 10 to 70% within 3 min and then increased to 100% in the next 10 min. The %B was then reduced to 10% in 1 min and maintained at 10% for 6 min until the next analysis. The total LC analysis time was 20 min for each sample, and the flow rate was set at 0.2 mL/min. The injection volume was set at 5 μL.

All of the analytes were detected using triple quadrupole multiple reaction monitoring (MRM) mode under negative ionization; nitrogen was used as a nebulizer gas at 45 psi; the drying gas and flow rate were set at 300 °C and 6 L/min, respectively; those for the sheath gas were set at 260 °C and 11 L/min, respectively; the electrospray voltage (capillary voltage) was 3500 V. Each compound was detected using two MRM transitions: the one with the higher intensity was used for quantitation, and the other was used for qualitative confirmation. The detailed parameters for MRM transitions are listed in Table 1.

Sample Collection. A total of 46 cow milk samples from major brands were collected from 6 sampling sites in China in the provinces of Shandong, Anhui, Liaoning, Fujian, Jiangxi, and Guangdong. Samples were either collected in 50 mL low-density polyethylene (LDPE) (Linc-Bio, Shanghai, China) bottles directly and shipped frozen to the laboratory or left liquid and transported on ice to the laboratory, followed by transferring into 50 mL LDPE bottles upon receipt. The samples were then frozen at −20 °C until they were tested.

Sample Extraction and Cleanup. QuEChERS protocol was applied for PFAS extraction and cleanup. Briefly, a milk sample of 5.0 mL was transferred to a 50 mL LDPE centrifuge tube, and the mixture of internal standard compounds (1.0 ng each) and 5.0 mL of pure water were then added to the tube. After homogenization for 1 min, 10.0 mL of acetonitrile and 30 μL of concentrated hydrochloric acid were added, followed by vortex mixing for 1 min. Two grams of sodium chloride was then added to the tube, followed by 1 min of vortex mixing and sequential centrifugation at 5000 rpm for 10 min. The supernatant solution (acetonitrile layer) was transferred to a clean glass test tube and subjected to drying under nitrogen with a final volume of approximately 4 mL.

The extract from above was transferred to a 15 mL LDPE centrifuge tube containing 60 mg of PSA, 40 mg of C18, and 10 mg of graphitized carbon black. The tube was then vortex mixed for 5 min, followed by centrifugation at 5000 rpm for 10 min. The supernatant solution (approximately 4 mL) was transferred to another clean LDPE centrifuge tube and subjected to drying under nitrogen at 45 °C. The residue was dissolved in methanol to a final volume of 1.0 mL. The solution was then filtered through a 0.22 μm Whatman nylon membrane (GE Healthcare, Buckinghamshire, U.K.) and transferred to a 2 mL glass vial for LC-MS/MS analysis.

Quality Assurance and Quantitation. Because of the wide presence of PFASs in the environment, the experimental apparatus and the LC system such as the mobile phases, the tubing, and the other parts in the LC flow (e.g., seals) may introduce high level of background, which will lower the accuracy for the trace analysis of PFASs. To minimize quantitation bias, possible sources of contamination from both the instrument and sampling procedure were reduced by replacing fluoropolymer materials such as poly-(tetrafluoroethylene) (PTFE) tubing with stainless steel tubing and Teflon centrifuge tubes with LDPE tubes. Calibration solutions containing various amount of standard compounds (ranging from 0.010 to 20.0 μg/L for PFCAs and from 0.050 to 20.0 μg/L for PFSAs) and fixed amounts of isotope -labeled internal standards (1.0 μg/L for each) were prepared in pure methanol. The calibration curve was obtained by plotting the peak area ratios of standards to the corresponding isotope-labeled internal standards versus the amount of added standards. To ensure accurate measurement, quality control standards were measured every 10 injections to monitor the instrumental drift. When the quality control standard was outside

DOI: 10.1021/acs.jafc.5b00068
J. Agric. Food Chem. 2015, 63, 4087−4095

±20% of its theoretical value, a new calibration curve was established for the quantitation of the subsequent samples. The limit of detection (LOD) and limit of quantitation (LOQ) for method were estimated at the lowest spiking concentration at which an S/N could reach 3 and 10, respectively. A solvent blank, solvent standards, and a matrix-spiked standard subjected to the entire sample extraction and cleanup procedure were all analyzed during each set of samples to ensure accurate and precise measurement. When necessary, background subtraction was applied to further avoid the quantitation bias.

RESULTS AND DISCUSSION

Interference Trapping to Improve Detection Sensitivity and Accuracy. As stated above, care has been taken to reduce the interference resulting from the apparatus and tubing. In addition, common HPLC solvents including Milli-Q water and organic solvents often contain trace levels of PFASs, which may inevitably increase the background and result in low sensitivity as well as a quantitation bias for the real samples. To minimize the impact of interference from both mobile phases of the LC system, a precolumn was inserted between the mobile-phase mixer in the LC pump and the autosampler to trap the PFASs from the LC system.

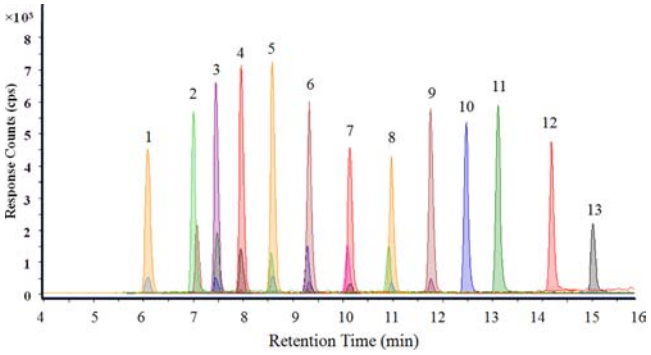

Figure 3. Overlapped MRM chromatograms for the 20 PFASs and 9 internal standard compounds under the optimized LC-MS/MS conditions. The concentration of each analyte was 10.0 μg/L, and the internal standard concentration was 1.0 μg/L. **1**, PFBA/MPFBA; **2**, PFPA/PFBS; **3**, PFHxA/PFPS/MPFHxA; **4**, PFHpA/PFHxS/MPFHxS; **5**, PFOA/PFHpS/MPFOA; **6**, PFNA/PFOS/MPFNA/MPFOS; **7**, PFDA/PFNS/MPFDA; **8**, PFUnDA/PFDS/MPFUnDA; **9**, PFDoDA/MPFUnDA; **10**, PFTrDA; **11**, PFTeDA; **12**, PFHxDA; **13**, PFOcDA.

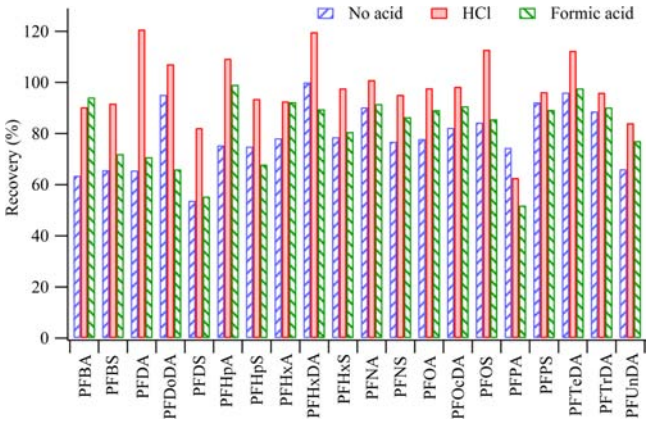

Figure 4. Comparison of the extraction efficiency using three different solvents.

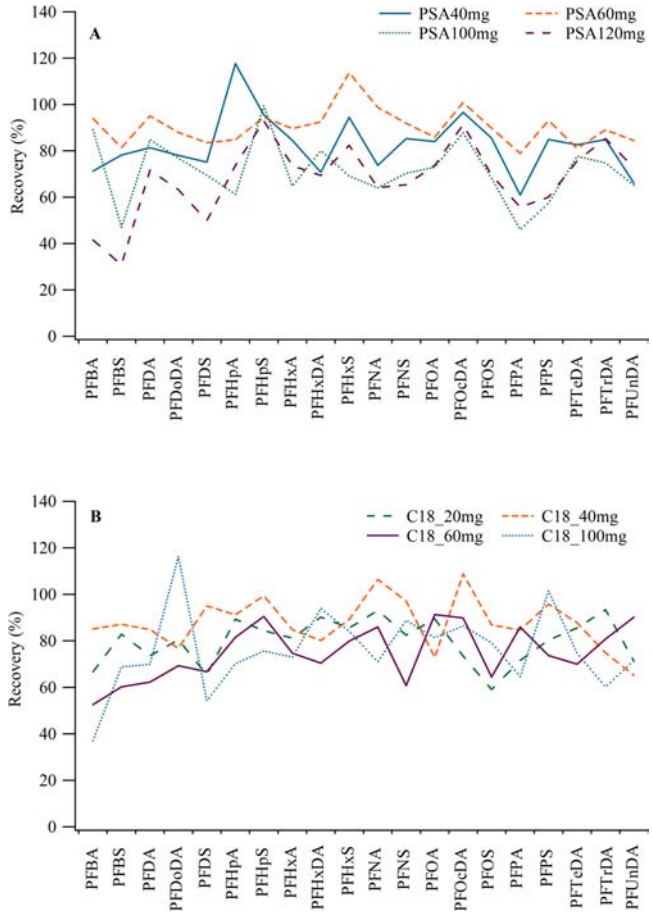

Figure 5. Cleanup efficiency using various amounts of (A) PSA and (B) C18.

With such a setup, during column equilibrium using the starting mobile phase with a low percentage of organic solvent, the interference from LC systems is trapped in the precolumn as a result of the hydrophobic properties of the interference. Upon sample injection, the analytes are transported to the analytical column. During LC gradient elution, with the increasing percentage of organic solvent, the interference trapped in the precolumn is eluted out and further loaded into the analytical column. Becasue the interference trapped in the precolumn is transported to the analytical column later than the analytes loaded through the autosampler, the background interference is delayed from eluting out of the analytical column. Through such a trapping-triggered delay elution, the background interference can be excluded from the elution time window of the analytes.

To efficiently trap the PFASs-related background interference, a high capacity of the precolumn should be selected for trapping. Considering the adsorption capacity, system equilibrium time, and system pressure, the column with a large diameter, large particle size, and shorter length should provide better trapping performance. In practice, it was found that the Zorbax Eclipse Plus-C18 column showed excellent trapping efficiency. As shown in Figure 2A, the majority of interfering species including PFOA, PFHpA, PFHxA, PFPA, and PFBA can be clearly separated from the target analytes by the baseline, and a trace level of the analytes can thus be accurately quantitated with much less bias and a lower background level. In contrast, the signal-to-noise ratio for the above compounds

spiked at the same level is significantly lower in the absence of the precolumn (Figure 2B).

Optimization of HPLC-MS/MS Conditions. To monitor the PFASs with sufficient selectivity and sensitivity, MS scanning was initially acquired to find the precursor ions for all of the compounds. The fragmentor voltage was then optimized to achieve maximum intensity for the precursor ions. Product ion scanning was further applied to find the fragment ions and the corresponding optimized collision energy. It was found that perfluorinated carboxylic acids (PFCAs) are liable to lose the carboxyl group (COO^-) in the collision cell in the presence of nitrogen gas and generate $[M\text{-}H\text{-}44]^-$; perfluorinated sulfonic acids (PFSAs) can easily release the sulfonate group (SO_3^-) and the fluorinated sulfonate group (FSO_3^-) and produce fragments $[M\text{-}H\text{-}80]^-$ and $[M\text{-}H\text{-}99]^-$. The resultant fragments with high intensity and selectivity were selected for MRM detection and are listed in Table 1.

Because PFASs are substances with weak polarity, the C18 column could be selected for the separation of the 20 PFASs. With 5 mmol/L ammonium acetate/H_2O and 5 mmol/L ammonium acetate/MeOH as the binary mobile phases for gradient elution, 20 analytes can be separated with 13 major peaks (Figure 3). Those PFASs with similar carbon numbers cannot be separated completely by retention; nonetheless, the detection of these compounds is highly selective with the selection of the specific MRM transitions, which allow accurate quantitation of these compounds.

Optimization of the QuEChERS Procedure. The QuEChERS method has been widely used in the analysis of pesticide residues since 2003.[34] It involves two major steps: sample extraction and cleanup. Considering that PFASs contain acidic groups, it is expected that strongly acidic extraction solvents may extract more interference;[35] in addition, acetonitrile extraction was reported to have advantages over ion pair and formic acid extraction.[36] Hence, weakly acidic solvents including acidified acetonitrile using formic acid or hydrochloric acid (HCl) and pure acetonitrile were examined here. The recoveries of PFASs using different extraction solvents were then compared. As shown in Figure 4, nonacidified solvent showed the lowest recovery for most PFASs, formic acid/acetonitrile showed better recovery for PFBA compared to HCl/acetonitrile, and similar recoveries could be achieved using formic acid/acetonitrile or HCl/acetonitrile for other PFCAs. However, very low recovery was found for PFSAs using formic acid/acetonitrile compared to HCl/acetonitrile. Eventually, HCl/acetonitrile was selected as the extraction solvent. The amount of HCl in the extraction solvent was then examined, and the highest recoveries for PFASs were observed when 30 μL of HCl was added to 10 mL of acetonitrile. By further increasing the amount of acid, more interference compounds were coextracted, which can coelute with target analytes and affect the accuracy of the target quantitation. Hence, 0.3% HCl in the acetonitrile was selected as the extraction solvent.

During the QuEChERS cleanup step, conventional sorbents such as PSA, C18, and graphitized carbon black are often applied to remove organic/fatty acids, lipids, and pigments, respectively. Because of the large quantity of proteins and lipids in the milk matrix, the above sorbents were selected and the corresponding amount was further optimized. With the low selectivity of PSA for the acidic substances, it is necessary to control the adsorption of the target PFASs.[37] Examining the amount in the range of 40−120 mg, it was found that recoveries for PFASs were highest when using 60 mg of PSA (Figure 5A). As for C18, the recoveries for PFASs were highest when 40 mg of C18 was used (Figure 5B). In comparison, including graphitized carbon black did not clearly improve the recoveries for PFASs, which might be due to the low levels of pigment in milk. Hence, a very small amount of graphitized carbon black was added. In combination, a sorbent mixture containing 60 mg of PSA, 40 mg of C18, and 10 mg of graphitized carbon black was selected for cleanup.

Calibration Linearity and Detection Sensitivity. Initial laboratory practice demonstrated that the matrix effect could lead to low recovery when using an external standard calibration method for quantitation in LC-MS analysis. To better reduce the matrix effect and improve the accuracy of the measurement, here a stable-isotope-labeled internal standard was applied for quantitation. For the 20 PFASs, only 9 isotopic analogs were obtained. Hence, for those compounds without corresponding isotopic analogs, they were assigned an isotope-labeled standard with similar chemical structure, as shown in Table 1. By analyzing a series of calibration solutions containing various amounts of standard compounds and fixed amounts of isotope-labeled internal standards, the calibration curve for each analyte was then established by linearly plotting the peak area ratios of standards to the corresponding isotope-labeled standards versus the amount of added standards. It was found that all PFASs had very wide dynamic linear ranges, with PFCAs in the range of 0.010−20.0 μg/L and PFSAs in the range of 0.050−20.0 μg/L. The correlation coefficients of

[a]Number of samples from the corresponding sampling sites. [b]<0.010 represents the level below LOQ but higher than LOD for PFCAs. [c]<0.050 represents the level below LOQ but higher than LOD for PFSAs. [d]ND indicates under LOD and not detectable. [e]Each compound was reported with a concentration range of the tested samples from the corresponding region, and the average levels among the samples are listed in parentheses.

determination were all higher than 0.997, with most above 0.999.

In contrast to previous reports where the LOD and LOQ of the method are commonly obtained on the basis of the procedural blank and their deviation levels,[22] here seven concentrations of each PFAS (0.0010, 0.0030, 0.0050, 0.010, 0.030, 0.050, and 0.10 μg/L) were used to spike the blank milk matrix, and the levels which produced chromatographic peaks with S/N = 3 and 10 for the quantifier ions were set as the LOD and LOQ of the method, respectively. The LODs for PFCAs and PFSAs were 0.0030 and 0.010 μg/L, respectively, and LOQs for both groups were 0.010 and 0.050 μg/L, respectively. Such LOD and LOQ values are comparable to the currently reported method in milk;[10,22] moreover, they are adequately measurable.

Accuracy and Precision. Because the LOQs for PFSAs are 5- to 10-fold higher than those for PFCAs, the spiking levels for PFSAs were set at 0.050 (LOQ level), 0.50, and 2.0 μg/L and those for PFCAs were set at 0.010 (LOQ level), 0.50, and 1.0 μg/L. At each spiking level, six replicates were used with a blank matrix as the control. As shown in Table 2, the recoveries for PFCAs ranged from 78.5 to 111%, with RSD (n = 6) within 1.20−13.1%, and those for PFSAs were in the range of 72.8−105%, with RSD within 3.53−14.8% (n = 6). Even at a level as low as the LOQ, the recovery and precision for both groups of PFASs have no significant differences compared to those obtained at the higher spiking levels. This indicates that the method is very accurate and repeatable.

Real Sample Analysis. The developed method was applied to the real sample survey. Here, 46 milk samples randomly collected from various manufacturers in 6 provinces of China were analyzed. On the basis of the occurrence frequency, these 20 PFASs can be classified into 4 groups. PFUnDA, PFBS, PFHpS, and PFNS belong to the undetectable group in which the level of PFUnDA was under the detection limit of 0.0030 μg/L across all samples, and those of PFBS, PFHpS, and PFNS were undetectable at an LOD of 0.010 μg/L.

PFPA, PFOA, and PFOS were found to be the intermediate group with the occurrence frequency in approximately 50% of the total tested samples. As shown in Table 3, PFPA was more frequently detected at sites 3, 5, and 6, with the levels ranging from ND to 0.043 μg/L and the highest average of 0.018 μg/L at site 3. PFOA was detected primarily at sites 1, 3, 5, and 6, with the concentration across the whole sample within the range of ND−0.11 μg/L and the highest average of 0.058 μg/L at site 1. PFOS was detected within the range of ND−0.12 μg/L mainly in sites 1, 2, 4, and 5, with the highest average as 0.086 μg/L at site 2.

Furthermore, PFBA, PFNA, PFHxDA, and PFTrDA were classified as the high occurrence frequency group, found in 41 out of 46 (89%) milk samples (Table 3). PFBA was detected in the range from ND to 0.34 μg/L, with the highest average

DOI: 10.1021/acs.jafc.5b00068
J. Agric. Food Chem. 2015, 63, 4087−4095

levels found at site 1; PFNA was detected in the concentration range of ND−0.37 μg/L among the whole samples, and the average ones at sites 1 and 4 were particularly high. For PFHxDA and PFTrDA, the detected levels across the whole samples ranged from ND−0.12 μg/L and ND−0.23 μg/L, respectively, and the highest average levels for both were found at site 1.

The other nine PFASs consisting of PFHxA, PFHpA, PFDA, PFTeDA, PFOcDA, PFPS, PFHxS, PFHpS, and PFDoDA were occasionally detected in some samples, and the levels are relatively low, ranging from ND to 0.092 μg/L, except for PFOcDA, which was detected at a level as high as 0.33 μg/L in one sample at site 2. The average levels for these PFASs ranged from ND to 0.028 μg/L across all six sampling sites. In summary, the total concentration of PFASs in the 46 milk samples ranged from 0.19 to 0.66 μg/L.

A previous report from China has determined 13 PFASs in milk and its related products collected from 3 cities in China, and it was found that PFHpA, PFOA, PFOS, PFNA, PFDA, PFUnDA, and PFTA were positively detected.[26] Among them, the concentrations for PFDA were within <0.015−0.044 μg/kg with a mean value of 0.007 μg/kg, which is comparable to the current study. The maximum detected levels for PFOA, PFOS, PFNA, and PFUnDA in the aforementioned study are higher than those determined in the current study. However, most of the average values in the current study are slightly higher. Also, both the maximum level and the mean level of PFHpA found in the current study are relatively lower. In addition, 19 out of the 20 PFASs except PFNS were in the monitoring list of the 2012 EFSA report[6] in which comparable results were found for 13 PFASs belonging to the undetectable group and the occasionally detected group, with reported levels mostly under the LOQ of the method in milk and related products. For the remaining 6 PFASs, PFOS was reported with levels ranging from 0.005 to 1.2 μg/kg and an occurrence frequency of 3%; PFOA was found in 4 out of 319 samples, with the levels ranging from 0.007 to 3.7 μg/kg; PFNA was found in 3 milk and related products with a concentration range of 0.005−0.02 μg/kg; the levels of PFBA and PFHxDA were under the corresponding detection limits and those of PFTrDA were under the LOQ level.[6] In comparison, the maximum and average levels and the occurrence frequencies of PFPA, PFBA, PFHxDA, and PFTrDA in the present study are significantly higher. Although the maximum levels of PFOS and PFOA in the current study are lower, the occurrence frequency is much higher compared to the EFSA report.[6] It should be noted that the two PFASs with longer carbon chains, PFTrDA and PFHxDA, are particularly high at sites 1 and 2 where PFTrDA and PFHxDA ranged as high as 0.048−0.11 μg/L and <0.010−0.23 μg/L, respectively. Such high levels have not been reported previously. They may be related to the local industrial contamination and require further investigation.

Global industrialization has led to the ubiquitous presence of PFASs in the environment. Although the voluntary stewardship program has been making an effort to eliminate the new production of some PFASs,[3] the impact of PFASs already in the environment will continue be an issue in the food chain because of the persistent and bioaccumulative nature of these compounds. Knowledge and survey data on the level of PFASs through dietary exposure is essential to evaluating the impact of these compounds on human health. Compared to the previously reported methods, QuEChERS combined with the online interference trapping LC-MS/MS method developed here has the advantages of low background interference, high sensitivity, and high selectivity. It is also very rapid and can be applied for screening the trace level of PFASs in milk.

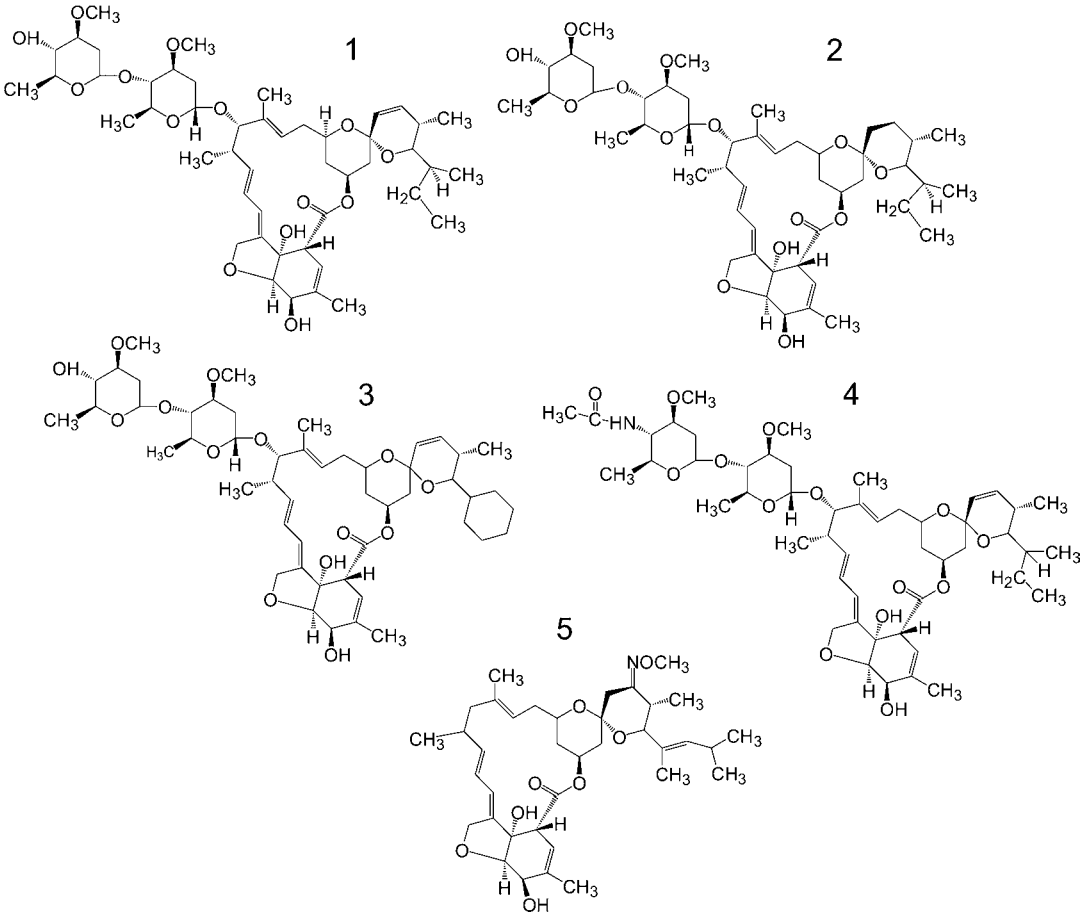

Figure 1. Chemical structures of five avermectins of interest.

matrices.[25−31] Polymeric monolithic materials possess obvious advantages including excellent biocompatibility, high permeability, and fast mass transfer, which are able to effectively extract trace target analytes from complicated food samples even at high flow velocities and under extreme pH conditions. Furthermore, organic polymer-based monoliths can be easily fabricated within the device, without the further packing steps required in the case of packed particulate adsorbents. Additionally, the porous structure and surface chemistry of the polymer are usually tunable and flexible. Therefore, several polymer-based monolithic columns have been shown to be promising tools for sample preparation.[32−35]

To further expand the application of monolithic sorbents, the present study focuses on the development of a robust and reusable polymeric monolithic sorbent capable of fast online SPE of five avermectins from both plant and animal origin food samples. In this work, a poly(butyl methacrylate-*co*-ethylene glycol dimethacrylate) (poly(BMA-*co*-EGDMA)) monolithic column was prepared and used as sorbent for online SPE of avermectins coupled with liquid chromatography tandem mass spectrometry (LC-MS/MS). The factors affecting the online SPE were studied in detail. A new method was established for the fast, automatic, and simultaneous determination of five avermectins in fresh pear, chili seed, bovine muscle, and milk samples.

MATERIALS AND METHODS

Reagents and Solutions. All chemicals and reagents used were at least of analytical grade or better. Purified water was obtained from a Waters Milli-Q system (Milford, MA, USA) and was used throughout all experiments. Butyl methacrylate (BMA) was purchased from Aladdin (Shanghai, China), and ethylene glycol dimethacrylate (EGDMA) was purchased from Alfa Aesar (Ward Hill, MA, USA). 1-Propanol and polyethylene glycol 400 were acquired from Tianjin Guangfu Fine Chemical Research Institute (Tianjin, China). Azobis(isobutyronitrile) (AIBN) was acquired from Tianjin Damao Chemical Reagent Factory (Tianjin, China) and was recrystallized with ethanol before use. HPLC-grade methanol (MeOH) and acetonitrile were provided by Fisher Scientific (Geel, Belgium). Ammonium acetate (NH_4OAc), acetic acid, formic acid, acetone, and isopropyl alcohol were purchased from Dikma (Beijing, China). Ammonium hydroxide (NH_4OH) was acquired from Chemical Reagent Factory (Shijiazhuang, China).

Abamectin (97%), ivermectin (96%), doramectin (96%), eprinomectin (91%), and moxidectin (87%) were purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany). Stock standard solutions of the avermectins were separately prepared at a concentration of 100 μg/mL in MeOH and stored at 4 °C in the dark. Working mixture solutions were freshly prepared from the stock solutions by stepwise dilution with MeOH. All solvents and solutions for LC analysis were filtered through a 0.45 μm Millipore filter.

Sample Preparation. The representative samples of plant origin (fresh pear and chili seed) and animal origin (bovine muscle and milk) were collected from supermarkets and local markets. Preliminary analysis showed that they were free of the analytes of interest. The samples including fresh pear, chili seed, and bovine muscle were first minced with a homogenizer, and the homogeneous samples were stored at −4 °C before use.

Plant origin samples (fresh pear and chili seeds): 2.0 g of pear and chili seed samples were weighed into a 50 mL centrifuge tube. Then, 10.0 mL of MeCN and 2.0 g of NaCl were added, and the samples

[a]The mobile phases for the loading pump: (A) 10 mmol/L NH_4OAc solution, (B) MeCN, and (C) a mixture of MeCN, isopropyl alcohol, and acetone (1:1:1, v/v/v). [b]The mobile phases for the eluting pump: (D) MeCN, (E) 0.1% NH_4OH solution.

were blended with a homogenizer for 1 min. The samples were subsequently centrifuged at 0−4 °C for 5.0 min at 5000 rpm, and the supernatant was filtered through a 0.22 μm filter prior to the online extraction.

Animal origin samples (milk and bovine muscle): First, 2.0 g of previously minced bovine muscle was weighed into a centrifuge tube of 50 mL. After addition of 8.0 mL of MeCN, the sample was blended with a homogenizer for 1 min. Subsequently, the samples were extracted with MeCN twice. For the milk samples, 2.0 g of the sample was weighed into a 50 mL centrifuge tube. Next, 8.0 mL of MeCN, 1.0 g of NaCl, and 2.0 g of $MgSO_4$ were added. After being mixed with a vortex mixer for 2.0 min, the sample was centrifuged at 0−4 °C for 5.0 min at 5000 rpm. Subsequently, the supernatant was collected and the samples were extracted twice with MeCN. Finally, for the milk and bovine muscle samples, the supernatant was collected and diluted to 30.0 mL with MeCN. Three milliliters of each extraction solution was dried under flowing nitrogen gas at 40 °C. The residues were dissolved in 1.0 mL of MeCN and filtered through 0.22 μm filters prior to analysis.

Spiked samples were prepared in the same way with spiking required amounts of avermectins.

Fabrication of Poly(BMA-*co*-EGDMA) Monolithic Extractor. The poly(BMA-*co*-EGDMA) monolithic extractor was fabricated in a stainless steel chromatographic column (10 mm × 2.1 mm i.d.). Briefly, the polymerization mixture consisted of 0.5 mmol of BMA, 1.5 mmol of EGDMA, a mixture of 6.5 mmol of 1-propanol and 1.3 mmol of polyethylene glycol 400, and 4.0 mg of AIBN.[36−38] After sonication for 30 min, the solution was introduced into the column with both ends sealed and placed vertically in a water bath. The polymerization was performed for 2−24 h at 55 °C, and the temperature was 55, 60, or 65 °C; the reaction time was fixed at 4 h. The resulting column was connected to the LC system and washed with MeOH to remove the porogen and monomeric residues. Since the poly(BMA-*co*-EGDMA) monolithic extractor is a typical hydrophobic column, we chose a neutral compound, toluene, as the marker analyte. The retention factor (k) of toluene of each monolithic extractor was calculated to evaluate the corresponding hydrophobicity. The retention factor k was calculated from the equation $k = (t_R - t_0)/t_0$, where t_R and t_0 are the retention times of toluene and the void marker (MeOH), when MeOH/water (80:20, v/v) was used as the mobile phase. The scanning electron microscopy (SEM) images of the monoliths were obtained using an S-4800 scanning electron microscope (Hitachi, Tokyo, Japan).

Online Sample Extraction Based on the Poly(BMA-*co*-EGDMA) Monolithic Extractor. The online cleanup and separation was performed on an Aria TLX-2 system (Thermo Fisher Scientific, Franklin, MA, USA) equipped with a PAL autosampler (CTC Analytics, Zwingen, Switzerland) with a 200 μL sample injection loop, two high-pressure mixing quaternary pumps, one for online SPE (loading pump) and the other for analytical separation and elution (eluting pump), a multiple-column module, and a three-valve switching device unit with a six-port valve controlled by the Aria software, version 1.6.3. Automated SPE was achieved on the synthesized poly(BMA-*co*-EGDMA) monolithic column (10 mm × 2.1 mm i.d.). The online SPE procedure can be divided into four general steps: loading, washing, transfer, and conditioning. The mobile phases used for the loading pump were (A) 10 mmol/L NH_4OAc solution, (B) MeCN, and (C) the mixture of MeCN, isopropyl alsohol, and acetone (1:1:1, v/v/v). All of the parameters used for online cleanup on the poly(BMA-*co*-EGDMA) monolithic extractor and subsequent LC-MS/MS separation are listed in Table 1. In the loading step (step 1 in Table 1), 50 μL of the sample was injected into the poly(BMA-*co*-EGDMA) monolith. Then, during the washing step, the poly(BMA-*co*-EGDMA) monolithic column and the analytical column were not connected. The matrix components were washed out (waste) using solvent B, and the analytes were retained on the poly(BMA-*co*-EGDMA) monolith. For the transfer step (step 3 in Table 1), the poly(BMA-*co*-EGDMA) monolithic extractor was placed online with the LC-MS/MS system by switching the six-port valves, and the analytes were transferred from the poly(BMA-*co*-EGDMA) extractor into the analytical column. The last stage involved washing and conditioning of the poly(BMA-*co*-EGDMA) extractor (steps 4−7 in Table 1), while the analytes were being separated via LC-MS/MS. The poly(BMA-*co*-EGDMA) monolith was sequentially washed with solvents C and B to completely remove any residual contamination and to recondition the extractor for the next effective extraction. After that step, the entire online SPE procedure was completed. During the washing and conditioning steps, the poly(BMA-*co*-EGDMA) monolithic extractor and the analytical column were not connected.

LC-MS/MS Separation. Analytical separation was achieved using a 100 mm × 4.6 mm, 3 μm Hypersil Gold C_{18} column (Thermo Fisher Scientific, Pittsburgh, PA, USA). The mobile phase for separation consisted of (D) MeCN and (E) 0.1% NH_4OH solution. The parameters of LC-MS/MS separation (eluting pump) are shown in Table 1. The detection was performed by a triple-quadrupole Thermo Scientific TSQ Quantum Ultra mass spectrometer (Thermo Fisher Scientific, San Jose, CA, USA) equipped with an atmospheric-pressure chemical ionization probe that was maintained at 350 °C. All analyses were performed in the negative ionization mode. The sheath and auxiliary gases were nitrogen at 30 and 5 arbitrary units, respectively. The system was operated in multiple reaction monitoring (MRM) mode with argon as the collision gas at a pressure of 1.5 mTorr. The ion-transfer tube was maintained at 320 °C. The scan time and width were 0.02 s and m/z 0.01, respectively. The data were processed using the LC Quan software version 2.6. The retention time and mass spectrometer parameters for each analyte are given in Table 2. The total analytical run time for this method, including both SPE and separation, was 15.0 min.

RESULTS AND DISCUSSION

Characterization of the Poly(BMA-*co*-EGDMA) Monolithic Extractor. SPE sorbents based on hydrophobicity (reversed-phase retention) are most commonly used because of their versatility and ability to trap several compounds with weak polarity from a variety of food samples. Therefore, SPE

[a]Quantitative ion.

for avermectins is usually performed on a reversed-phase C_{18} or C_8 column depending on their polarities.[19,23] Thus, in the present experiment, since it is a widely accepted and convenient monomer, BMA was chosen to polymerize with EGDMA to prepare a miniature monolithic extractor with hydrophobicity provided by the butyl groups on the surface of the polymer skeletons. The monolithic extractor was fabricated via thermally initiated polymerization in the cartridge of a stainless steel column (10 mm × 2.1 mm i.d.). With the composition of the polymerization mixture fixed, the effects of the reaction time and reaction temperature on the performance of the extraction were investigated. The retention factor (k) of toluene on each monolith was calculated to evaluate the hydrophobicity of the extractors. The effects of reaction time over the range from 2 to 24 h and of the temperature in the range from 55 to 65 °C on k are shown in Figure 2A. No significant changes were observed when the reaction time exceeded 4 h and the temperature was higher than 55 °C. The procedure is easy, and the preparation conditions, including the reaction time and temperature, are controllable. A fast, robust and reproducible polymerization was established, offering the possibility for the facile fabrication of a hydrophobic monolithic sorbent. Thus, on the basis of these results, the monolithic column prepared at 55 °C for 4 h was chosen for further experiment. In addition, the mechanical stability of these monolithic columns is one of the most practical factors for SPE sorbent, especially for online operation. The relationship between the flow rate and the pressure in the synthesized columns was investigated when MeOH was used as the mobile phase. As shown in Figure 2B, a good linear (r = 0.999) dependence of the column pressure on

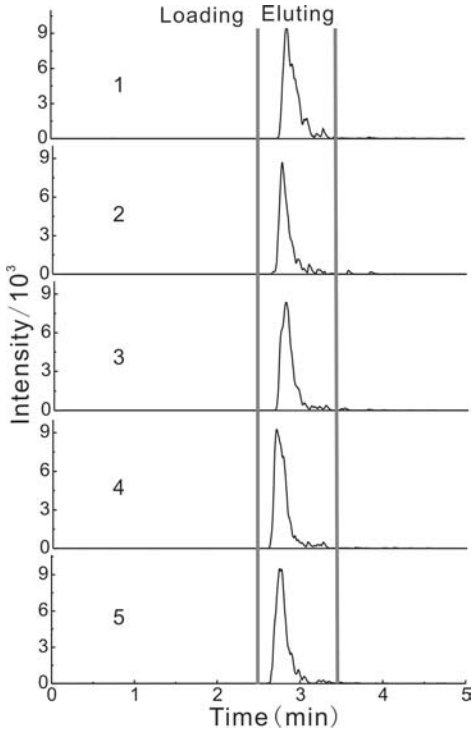

Figure 3. MRM chromatograms of the online SPE of the five avermectins with a 10 mmol/L NH_4OAc solution as loading solution and MeCN as eluting solution.

the flow rate was obtained. The pressure drop was lower than 1.0 bar at a flow rate of 0.5 mL min^{-1}, demonstrating the high permeability of the monolithic materials. The prepared monolith exhibited an adequate mechanical strength of up to 80 bar when it was operated in online mode. A SEM image of a poly(BMA-*co*-EGDMA) monolithic column further demonstrated the distinct continuous porous structure (Supporting Information, Figure S1). These results clearly indicate that the high mechanical strength and permeability allow the monolithic extractor to be available for online SPE, thus shortening the whole analysis time.

Online SPE and LC-MS/MS. The online analysis procedure includes loading, washing, transfer, conditioning, and LC-MS/MS separation. For the loading step, the loading solvent affects the efficiency of preconcentration and matrix elimination. The influence of the loading solvent was tested using 0.1% and 0.5% formic acid and 5 and 10 mmol/L NH_4OAc solution. To

evaluate the loading efficiency, the five extracted avermectins were eluted with MeCN and the chromatograms were compared. The most concentrated, sharp, and symmetric peaks with the maximum peak heights were obtained when 10 mmol/L NH_4OAc was used as the loading solution (Figure 3), providing the most efficient extraction for target compounds. After the loading and washing steps, the extracted analytes were transferred from the poly(BMA-*co*-EGDMA) monolithic extractor into a C_{18} analytical column for LC-MS/MS separation. MeCN and MeOH were each evaluated for use as the eluting solvent. The results showed that both MeCN and MeOH gave an effective eluting for the extracted avermectins. However, the peaks with MeCN as eluting solvent were more symmetrical and less broadened (Figure 3). Therefore, the adsorbed compounds may be quickly transferred into the subsequent LC-MS/MS without diffusion and any loss of the analytes. Considering peak broadening and tailoring in separation caused by the diffusion, MeCN was selected as the eluent.

The LC-MS/MS parameters were optimized to ensure proper resolution and symmetry and adequate separation of the analytes. In this work, to enhance ionization of the avermectins in the MS source, a mixture of MeCN and a 0.1% NH_4OH solution was found to be optimal for LC-MS/MS separation. The starting composition of MeCN for the gradient was investigated in the range 80−10%, and the final composition of MeCN was fixed at 95%. Baseline separation of five avermectins is achieved in all investigated mobile phases. However, different responses of the target compounds are found. Lower composition of MeCN may lead to better chromatographic resolutions and enhanced ionizations (Supporting Information, Figure S2). To reduce the retention time

and improve the sensitivity of the avermectins, the mobile phase consisting of MeCN/0.1% NH_4OH (10:90, v/v) was selected as starting mobile phase.

The proposed approach enabled us to enrich the analytes online from the sample matrix and accomplished the analysis in a very short time of less than 15 min. The online SPE procedure reduced manual handling to a minimum and thus saved both manpower and solvents. In addition, the use of LC-MS/MS ensured both highly sensitive and selective results.

Validation of the Method. A very generic sample extraction method is necessary to extract the compounds from a broad range of complicated matrices. The monolithic materials have been demonstrated to be available for plant[26] or animal origin[27,32,34] samples. In this work, the foodstuffs of both plant and animal origins including pear, chili seed, bovine muscle, and milk were pretreated using the poly(BMA-*co*-EGDMA) monolithic extractor. To evaluate the extraction efficiency and potential interfering compounds originating from the plant and animal origin matrices, blank samples, spiked samples, matrix effect, and recovery experiments were performed using the poly(BMA-*co*-EGDMA)-based SPE method.

Matrix Effect. The matrix effect was investigated by comparing the slopes of calibration curves obtained from a standard mixture of avermectins in solvent and the standards spiked with the samples. The matrix-matched calibration curves were constructed by spiking the avermectin standard solutions at seven concentration levels in the corresponding matrices. The solvent calibration curves were constructed in the same manner but without the addition of the matrix aliquots. For the bovine muscle sample, good linear relationships for five avermectins are achieved over the concentration range 0.5−100.0 ng/mL with a correlation coefficient (r) value higher than 0.995, and the matrix/solvent slope ratio for each avermectin in the bovine muscle sample ranged from 0.93 to 1.07 (Supporting Information, Table S1). The signal enhancement or suppression effect was considered acceptable if the ratio of the slope was in the range 0.8 to 1.2. Slope ratios with values higher than 1.2 or lower than 0.8 indicate a distinct matrix effect. Additionally, the matrix/solvent slope ratios in pear, chili seed, and milk samples were in the range 0.95−1.05, showing no significant matrix effect presented in the analysis of these real samples.

Specificity, Accuracy, and Precision. Figure 4 shows the MRM chromatograms of the blank samples and the corresponding blank samples spiked with 10 μg/kg of the standard avermectins. The results showed that the spiked samples were effectively purified by the poly(BMA-*co*-EGDMA) extractor. Compared with the blank samples, no interference peaks are observed in the chromatograms of any of the spiked samples. The results were further confirmed by the recovery experiments. The recovery of the proposed method was assayed on spiked real samples at three levels of five avermectins in four kinds of matrices, and the precision was described on the basis of the intraday and interday relative standard deviations (RSDs). As shown in Table 3, the recoveries of six replicate extractions ranged from 71.8% to 101.3%. The intraday and interday RSDs were in the range 4.38−8.62% and 5.49−8.94%, respectively (Table 4). These results indicate the suitability and the satisfactory reproduci-

bility of the developed method for the determination of five avermectins in four matrices of both plant and animal origin.

LODs and LOQs. The limit of detection (LOD) was determined as the concentration that produced a peak with a height 3 times the level of the baseline noise, and the limit of quantitation (LOQ) was determined as the sample concentration that produced a peak 10 times greater than the baseline noise. The LODs and the LOQs of the proposed method were 2 μg/kg and 5 μg/kg for each analyte, which showed that the present method is sufficiently sensitive to measure avermectins at the MRLs[6−10] in various matrices.

Reusability and Reproducibility of the Poly(BMA-*co*-EGDMA) Monolithic Extractors. Traditional commercial SPE sorbents, such as C_{18}, C_8, and Al_2O_3 particles, are disposable. The reusability and reproducibility of the poly(BMA-*co*-EGDMA) monolithic sorbent trap were studied. Under the optimized conditions, at least 500 injections of pear sample were performed. Moreover, poly(BMA-*co*-EGDMA) monolithic extractors prepared from various batches were also used. No significant changes were observed in the extraction efficiency. The column-to-column reproducibility was assessed by calculating the RSDs of the extracted amount of abamectin while performing the online SPE. The intrabatch and interbatch RSDs were in the range 4.6−6.3% and 6.7−9.3%, respectively, indicating that the proposed sample preparation method is robust and practical.

Assay of Avermectins in Real Samples. The feasibility of the developed poly(BMA-*co*-EGDMA) monolithic column based on the online SPE method was further demonstrated for the analysis of real samples. Among the assayed samples from a local market, abamectin was detected in one bovine muscle sample with a concentration of 5.9 ± 0.6 μg/kg and ivermectin was detected in two chili seed samples with concentrations of 7.9 ± 0.9 and 8.2 ± 0.9 μg/kg. The present study focused on the development of a robust, simple, and practical method that is capable of quickly and simultaneously extracting and determining five avermectins in samples of both plant and animal origin. Although the poly(BMA-*co*-EGDMA) monolithic extractor gave better or comparable recovery and detection limits compared with other reported adsorbents,[15−21] this method gave more advantages by reducing analysis time and improving reusability of the sorbent. An offline cleaning and preconcentration process using a conventional SPE required several steps and took more than 2 h, while the time for online SPE and analysis of this work was only 15 min. In addition, the cost of the determination was also significantly reduced because the poly(BMA-*co*-EGDMA) monolithic extractor could be reused more than 500 times without any loss of extraction efficiency, even for different varieties of food samples. Since this kind of hydrophobic monolithic extractor could be easily obtained and showed good availability, we believe that the method was able to deal with a wide range of compounds with weak polarity from complicated samples.

sensitive or allergic individuals. Regardless of the retrospective studies on plant lectins, they are still detected by hemadsorption, hemeagglutination, or bacterial agglutination assays.[21,22] These assays are qualitative and serve a common platform for all lectins; hence, they are not efficient in discriminating different lectins. Apart from classical agglutination assays, Con A detection in animal serum, plasma, cell culture supernatants, body fluid, and tissue homogenate is performed using ELISA and immunoelectrophoresis assays. However, these antibody-dependent assays are often costly due to the requirement of live hosts for antibody production. There is also a potential risk of antibody contamination with microorganisms or other immunologically active compounds. Contrary to this, aptamers are easy and rapid to produce with negligible batch-to-batch variability, are significantly cheap, and have higher thermal tolerance. Therefore, the aptamer-based assays are advantageous over antibody-based assays.

In this paper, we have identified an aptamer that selectively targets the Con A and has nanomolar affinity. As the developed aptamer is highly specific to Con A, it can be utilized as a valuable tool for the selective determination of Con A in food and agricultural products.

EXPERIMENTAL PROCEDURES

Materials. Concanavalin A (from jack bean), bovine serum albumin, acrylamide and bis-acrylamide solution (30%, w/v), TEMED, ammonium persulfate, nitrocellulose membrane, *o*-phenylenediamine dihydrochloride, 3,3′-diaminobenzidine, and 30% H_2O_2 were purchased from Sigma-Aldrich, USA. All PCR reagents were procured from New England BioLabs Inc., USA. Streptavidin-coated magnetic bead (Dynabeads M-280 Streptavidin, Invitrogen) was utilized to separate the biotinylated and non-biotinylated strands of PCR-amplified aptamer. *N*-Hydroxysuccinimide (NHS)-activated agarose columns were purchased from Pierce, Thermo Scientific, USA.

Oligonucleotide Synthesis. A oligonucleotide library of 77 nt length, comprising a central randomized region of 41-mer and 18-mer flanking sequences at both ends (5′-ATACCAGCTTATTCAATT-41nt -AGATAGTATGTGCAATCA-3′), was synthesized at 1.3 μmol scale on a Gene Assembler Special (Pharmacia LKB Biotechnology, Uppsala, Sweden) using standard phosphoramidite chemistry. Labeled primers were synthesized at 0.2 μmol scale. Synthesized sequences were deprotected and surface-cleaved using 30% ammonia and desalted on size exclusion columns (NAP-10, GE Healthcare, Sweden). The purity of synthesized oligonucleotides was checked on 15% polyacrylamide gel.

Preparation of Food Samples for Con A Detection. Seeds of jack bean, mung bean, kidney bean, and lentils and the wheat grains were crushed in a mixer grinder. A 10% meal was prepared for each sample by soaking their finely crushed powder in 0.5 M NaCl at 4 °C overnight (14−15 h). Homogenized meals were filtered through cheesecloth, and the homogenates were centrifuged at 10000 rpm for 10 min. Supernatants were collected and labeled separately as jack bean, mung bean, kidney bean, lentils, and wheat extracts.

Protein Preparation and SELEX Screening. NHS-treated agarose resin was used as solid support to carry out SELEX screening. For this, 330 mg of resin in a 5 mL column was charged with 1 g of Con A and incubated at room temperature (~27 °C) for 2 h with end-over-end mixings. The unreacted active ester groups on the resin were quenched with 1 M Tris buffer. The DNA library for SELEX screening was prepared by heat denaturing the library sequences at 95 °C for 10 min following a rapid cooling on ice. For the first round of selection, 10 nmol of prepared DNA library in 500 μL of aptamer binding buffer (20 mM Tris-HCl, pH 7.6, 120 mM NaCl, 5 mM KCl, 1 mM $MgCl_2$, and 1 mM $CaCl_2$) was added to the prepared agarose resin having 5 nmol (determined using BCA protein assay) of immobilized Con A. The column was incubated at room temperature for 2 h with end-over-end mixing. Thereafter, the unbound oligonucleotides were removed by washing with aptamer washing buffer (binding buffer with 0.2% Tween-20). Con A-bound DNA sequences were collected using high salt elutions (1.5 M NaCl in 10 mM Tris, pH 7.2) and PCR amplified with unlabeled forward and biotinylated reverse primers using the following thermal cycling: one hot start of 95 °C for 5 min and 15 thermal cycles of 95 °C for 30 s, 46 °C for 30 s, and 72 °C for 30 s and a final extension of 72 °C for 3 min. The PCR-amplified biotinylated double-stranded oligonucleotide sequences were converted to their respective single strands using the streptavidin magnetic beads. For this, PCR-amplified sequences were first immobilized over streptavidin beads followed by strand separation using alkaline denaturation (0.15 M NaOH). Separated non-biotinylated strands in the supernatant were collected and, after desalting, were utilized for the next round of screening. The mole ratio of immobilized Con A to oligonucleotides during subsequent SELEX screening was varied using a controlled number of Con A-coated agarose beads. Enrichment of Con A binding sequences was monitored by saturation binding assay. Upon adequate enrichment of Con A binding sequences, the entire enriched pool was PCR amplified and ligated to pCR2.1 TOPO TA vector. Transformation was carried out in competent *E. coli* cells (DH5α), and the transformed colonies were selected on the basis of blue-white screening. Positive colonies were picked and cultured overnight in 5 mL of LB broth. Plasmids were isolated from each culture via the mini prep plasmid isolation method, and the presence of insert in the isolated plasmid was checked using specific restriction digestion and PCR amplification. Subsequently, the plasmids were sequenced using Sangers Capillary sequencing, and the base sequences of enriched pool were obtained.

Activation of Microtiter Plates and Polypropylene Microtest Plates (PPμTP) by 1-Fluoro-2-nitro-4-azidobenzene (FNAB). Microtiter plates and polypropylene microtest plates were activated according to published procedures.[23−25] Briefly, the wells of a microtiter plate were loaded with 30 μL of methanolic solution of FNAB (1.82 mg/30 μL) and kept in the dark in a fume hood to evaporate the methanol. Thereafter, the FNAB-coated plates were exposed to UV light (365 nm) for 15 min in a UV Stratalinker (model 2400, Stratagene, USA). The plates were then washed thoroughly with methanol and dried. Wells of polypropylene microtest plate (PPμTP) were activated in the same way except that a lower amount of FNAB (0.125 mg/3 μL methanol per well) was used and the photoirradiation time was reduced to 12 min.

Enrichment Monitoring. Enriched sequences obtained during various rounds of SELEX screening were collected in their respective single-stranded biotinylated forms by making use of specific PCR amplification and strand separation over magnetic streptavidin beads. A fixed amount of these sequences (500 nM) was added to the wells of an activated polypropylene microtest plate (APPμTP) carrying the already immobilized Con A and incubated at room temperature for 2 h. After removal of the unbound sequences, retained DNA sequences in the microtiter plate were detected by probing the wells with streptavidin−HRP conjugate (1:1000 dilution; Sigma-Aldrich) and its substrate dye. Developed color was quantified as described earlier.[25]

In Silico Analysis of the Enriched Sequences. Secondary structure prediction and free energy of secondary structure formation were calculated using the Mfold Web server. Mean free energy ($\bar{E}$) and the standard deviation (SD) for enriched DNA sequences were calculated using a set of 1000 random sequences. The Quikfold Web server (Quikfold/mfold.rit.albany.edu) was used to predict the free energies of random sequences. Folding predictions for structural grouping were performed at default conditions of DNA folding (37 °C, 1 M NaCl, no divalent ions) on the Mfold server. Web-based QGRS Mapper was used to predict G-quadruplex forming abilities of the sequences.

Affinity and Specificity Measurement. Affinity and specificity measurements of the enriched sequences were carried out using the enzyme-linked aptamer assay. For affinity determination, 1.5 μg of Con A was coated to the activated wells of a 96-well microtiter plate by 4 h of incubation at 37 °C. After the unbound surface had been blocked with 2% BSA, the wells were titrated with 500 nM labeled sequences (seq-1−8) and incubated for 2 h at room temperature. After

DOI: 10.1021/acs.jafc.5b00784
J. Agric. Food Chem. 2015, 63, 4104−4111

the stipulated time, the wells were washed with aptamer washing buffer, probed with 100 μL of streptavidin−HRP conjugate (1:1500 dilution), and incubated at room temperature for 1 h. This followed the color development by the addition of 100 μL of substrate dye (*o*-phenylenediamine) to the wells of a microtiter plate and subsequent recording of absorbance at 490 nm. Nonspecific binding of DNA sequences to the microtiter plate was ruled out by performing a control experiment wherein aptamer was added to BSA-coated wells and the binding was measured.

For dissociation constant (K_d) measurement, 1−1000 nM biotinylated seq-1 was titrated against immobilized Con A in the wells of a microtiter plate. Con A-bound sequence was detected using the streptavidin−HRP colorimetric assay. The dissociation constant for aptamer−Con A interaction was determined by fitting the calculated absorbance values and aptamer concentrations to one-site specific binding (nonlinear) in GraphPad Prism (version 5.03 for Windows, GraphPad Software, San Diego, CA, USA), using the equation

$$Y = B_{max} \times X/(K_d + X)$$

For specificity measurements, an equivalent amount (1.5 μg) of Con A, jack bean meal extract, and bovine serum albumin was coated to the FNAB-activated wells of a microtiter plate and probed with 300 nM biotinylated seq-1. Binding was measured by recording absorbance values and were plotted against individual target protein.

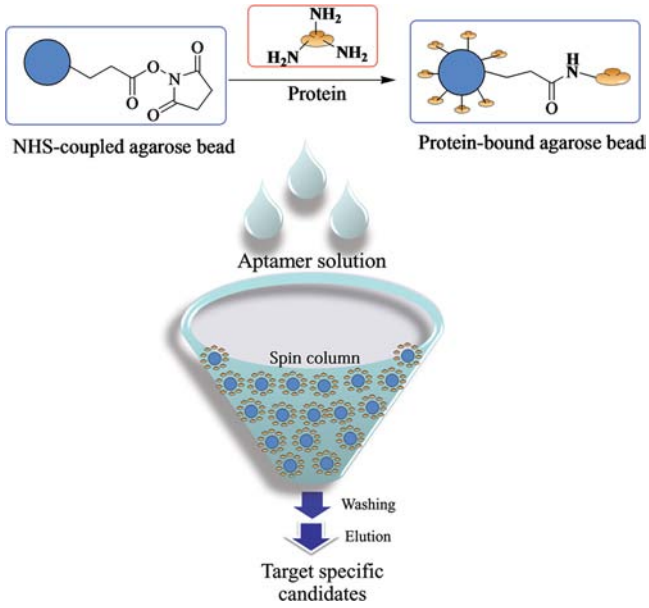
Enzyme-Linked Aptamer Assay and Western Blot. For the enzyme-linked aptamer assay, pure Con A and two different dilutions of jack bean seed extracts were coated to the activated wells of a microtiter plate. After the wells had been blocked with 2% BSA, 300 nM biotinylated seq-1 was added to the wells, and the plate was incubated for 2 h at room temperature. Unbound sequences were removed by washing, and the bound seq-1 was detected by probing the wells with streptavidin−HRP and measuring the signal colorimetrically. In the control, the same set of samples was detected by enzyme-linked immunosorbent assay using Con A antibody.

For Western blot analysis, two different amounts of Con A (1 and 0.5 μg) were electrophoresed on 12% SDS-PAGE gel and blotted to nitrocellulose membrane. Thereafter, the membrane was incubated with 300 nM biotinylated seq-1 for 2 h at room temperature. After the stipulated time, the membrane was washed three times with 1× TBST, probed with HRP-conjugated streptavidin for 1 h at room temperature, and developed using DAB dye. In the control, the same proteins were detected using Con A-specific antibody.

RESULTS AND DISCUSSION

SELEX Enrichment of Con A-Binding DNA Sequences. To find the Con A aptamer, an oligonucleotide library of 77-mer with a central randomized region of 41 was used as the starting pool of oligonucleotides. Seven rounds of positive selections along with two negative screenings were carried out on NHS-activated agarose beads having Con A covalently attached to the bead surface (Scheme 1). The amount of oligonucleotides in the first round of SELEX screening was kept to 10 nmol to ensure a sufficient number of sequences during subsequent round of selections. Blocking the protein-bound surfaces prior to oligonucleotide binding is a common practice to counteract nonspecific enrichment. However, such practices also result in enrichment of "blocking agent-binding sequences". To overcome this, we omitted the BSA blocking and have introduced a negative selection step wherein the starting DNA library is incubated with agarose beads (without immobilized Con A) and the bead bound sequences were removed from the initial pool library. Any chance of enriching nonspecific sequences during the course of selection was additionally minimized by introducing two such negative selections before the fourth and sixth rounds of SELEX. Furthermore, a selection pressure was applied to SELEX

Scheme 1. Schematic Illustration of SELEX Screening over an Agarose Spin Column



enrichment by decreasing the mole ratio of Con A to DNA from 1:1 to 1:10 during the fourth and fifth rounds and then to 1:20 during the sixth to seventh rounds of SELEX. The incubation time was also decreased concomitantly (Table 1).

Table 1. Summary of the SELEX Screenings Carried out on NHS-Activated Agarose Beads

SELEX round	protein (pmol)	aptamer (pmol)	incubation time (min)
1	5000	10000	120
2	500	500	60
3	500	500	60
4	10	100	30
5	10	100	30
6	5	100	15
7	5	100	15

Enrichment of potential aptamers during the SELEX run was monitored through our recently developed photocolorimetric method.[25] As shown in Figure 1, seven rounds of selections on NHS-activated agarose beads carrying the immobilized Con A has resulted in sufficient enrichment of Con A binding sequences. After satisfactory enrichment, the entire enriched pool of the last SELEX round was cloned and sequenced using Sangers' capillary sequencing. Analysis of the sequencing data showed the enrichment of eight different sequences, each having different sequence copy numbers (Table 2). Sequence 1 was found to have the highest copy number of 20, whereas other sequences showed varying sequence copy numbers between 1 and 5. This predominance of seq-1 over the remaining sequences indicated its superior binding propensities for Con A. Thus, SELEX enrichment over agarose spin columns was found to be an excellent approach as it resulted in enrichment of Con A binding DNA sequences in a mere seven to eight rounds of screening without having cumbersome binding and elution procedure.

Furthermore, we did in silico analysis of the enriched sequences to find the most potent Con A-aptamer. To figure out the most probable Con A-aptamer of the eight sequences,

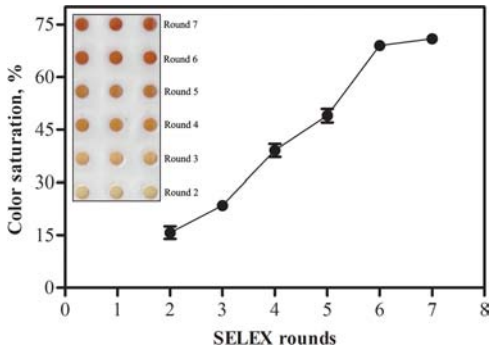

Figure 1. Aptamer enrichment monitoring during SELEX screening. A fixed amount of enriched ssDNA from different SELEX rounds was incubated with Con A followed by photocolorimetric quantification of Con A-bound sequences. A reasonable enrichment was attained by the seventh round of SELEX screening. (Inset) Image of developed color on APPμTP.

we carried out preliminary analyses such as free energy comparisons and structural stability and homology measurements. First, we folded these sequences to their secondary structures and divided them into three different groups based on secondary structure similarities (Figure 2). Group I included two sequences, seq-1 and seq-4, both forming dumbbell-shaped extended hairpin loops; group II had three sequences, seq-6, seq-7, and seq-8, each forming similar bihairpin loops; and group III also carried three sequences, seq-2, seq-3, and seq-5, each forming single hairpin loops. Consequently, the free energy of secondary structure formation was also calculated (Table 3). Free energy comparison was made by measuring the *Z*-score score of individual sequences. *Z*-score was calculated for each sequence using the equation

$$Z = (E_{apt} - \overline{E})/SD$$

where E_{apt} is the predicted affinity or score of individual solutions, $\overline{E}$ is the energy mean of random sequences, and SD is the standard deviation of random sequences. Here, the *Z*-score of a sequence/structure defines its specificity toward the observed or predicted conformation. A higher negative *Z*-score implies a more specific conformation and hence better structure prediction. As calculated in Table 3, seq-1 showed a minimum *Z*-score value of −1.51, demonstrating better structural folding of this sequence over same-length random sequences. Also, the observed free energy of secondary structure formation for seq-1 was found to be significantly lower than that of same-length random sequences, which indeed proves the better structural folding and selective enrichment of seq-1.

We also carried out homology measurements to find base similarities in the enriched sequences. However, no homology or pattern was observed. This shows that the observed homology in secondary structure formation was not due to the sequence similarities, rather an independent behavior. Conversely, few of the enriched sequences showed multiplicity of G stretches in their base sequences and therefore prompted us to analyze their G-quadruplex forming capability. To our surprise, one of the sequences, namely, seq-1, was predicted to have a quadruplex-forming G-rich sequence (GGAAGGCGG-AGGG; G-score = 20, length = 13 base; Table 4). Because quadruplex-forming sequences usually have better binding characteristics for their targets, seq-1 may represent the best ligand to Con A in the panel of selected sequences. Therefore, on the basis of structural analysis, free energy comparisons, and unique structural properties, we put forward seq-1 as the most probable aptamer for Con A.

Nanomolar Affinity of Selected Seq-1 for Purified Con A. To confirm the in silico predictions and subsequently determine the sequence with best binding credentials, we carried out saturation binding assays wherein each sequence was analyzed for its binding with the target Con A. Binding assays were carried out in a 96-well microtiter plate. Wells were coated with Con A and incubated with 500 nM biotinylated sequences (seq-1−8). Binding reaction was carried out for 2 h, after which the target-bound sequences were detected by probing the wells with streptavidin−HRP conjugate and its chromogenic substrate dye. Binding propensities were measured as color absorbance. As depicted in Figure 3A, seq-1 showed highest binding, followed by seq-4 and the remaining sequences, which showed almost equal and comparably lower bindings to Con A. These observations were in agreement with our in silico predictions that showed seq-1 to be the most probable aptamer. As a result, we selected seq-1 as the aptamer of Con A (Con A-aptabody) and subsequently measured the dissociation constant (K_d) and target specificity of the Con A-aptabody. For K_d determination, varying concentrations of aptabody (0−1000 nM) were titrated against a fixed amount of Con A. Binding was measured through color development assay using the streptavidin−HRP. A dissociation constant of 172.7 ± 29.7 nM was calculated by fitting the control subtracted values to one-site specific binding (nonlinear) in GraphPad Prism (Figure 3B).

We then measured the target specificity of aptabody for Con A. Three distinct samples, pure Con A, jack bean seed extract, and bovine serum albumin, were used as potential binding partners. As shown in Figure 4, the aptabody showed considerable binding to pure Con A and jack bean seed extract, but not to BSA. As jack bean is the major source of Con

A, the observed binding to seed extract of jack bean was obvious and also proves the target specificity of the aptabody. The absence of any binding to bovine serum albumin further confirmed the target specificity of identified aptabody. Here, we used the term "aptabody" to emphasize the unique recognition and binding properties of the developed aptamer of Con A, which were akin to those of Con A-antibodies.

In further assays, we checked the utility of this aptabody in Con A detection and method development of Con A quantification in food or agriculture products.

Development of Enzyme-Linked Aptamer Assays for Quantification of Con A in Jack Bean (*Canavalia ensiformis*). As aptamers offer substantial advantages over antibodies in terms of their production cost and time, production chemistry, and structural and functional stability, development of aptamer-based detection assays can provide an efficient and cost-effective substitute for immunoassays. To achieve the same, we utilized the ELISA concept to develop an aptamer-based detection methodology for Con A. For this, we coated the wells of a 96-well microtiter plate with an unknown quantity of pure Con A and jack bean seed extracts. Thereafter, 300 nM biotinylated aptabody was added to these wells and incubated for 2 h. Afterward, target-bound aptabody was detected by probing the wells with streptavidin−HRP and measuring the binding as color absorbance. Subsequently, the amount of Con A in all three samples was quantified from the Con A standards' curve prepared using specific-enzyme-linked aptamer assay (standard curve concentrations were 5−1000 ng/mL).

In the control, the same protein samples were detected using a conventional ELISA procedure employing Con A-antibody as a detection molecule. Furthermore, we determined the amount of Con A in all three samples, namely, an unknown Con A preparation, jack bean seed extract 1, and jack bean seed extract 2, by aptabody- and antibody-based assays. The results show that the values of the developed enzyme-linked aptamer assay are akin to those of the conventional ELISA assay (Figure 5A). As the methodology of the developed assay is similar to that of conventional ELISA, no specific training or instrumentation is required. However, the overall cost of the aptamer-based assay is comparably low and can be operated at ambient conditions.

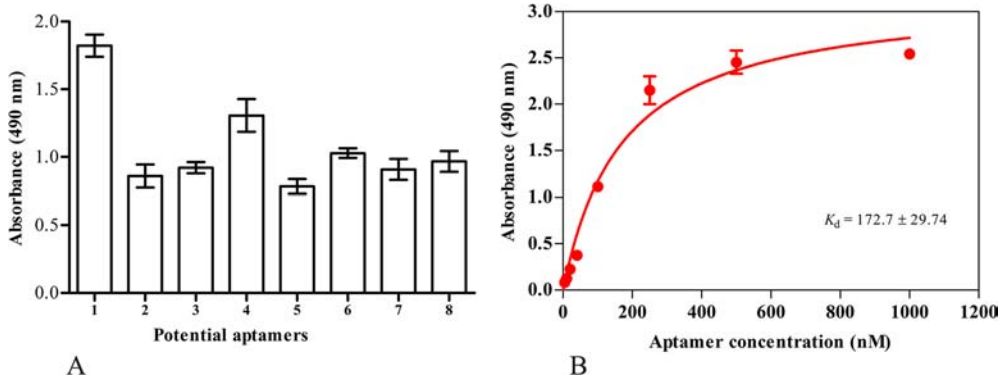

Figure 3. Affinity determination for enriched sequences. (A) Binding of enriched sequences (500 nM each) with immobilized Con A (1.5 μg) was measured by colorimetric saturation binding assays. (B) Equilibrium dissociation constant (K_d) is calculated by titrating 0−1000 nM seq-1 against a fixed amount of Con A (1.5 μg).

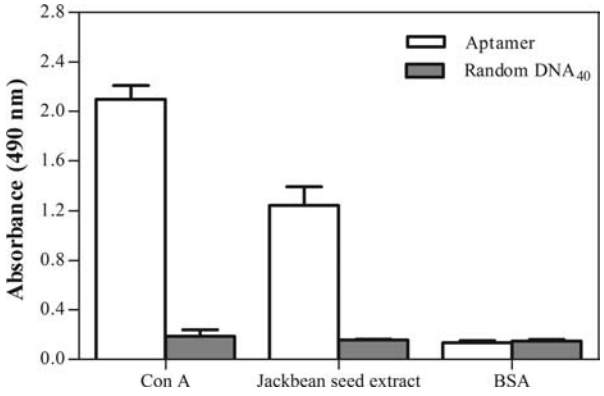

Figure 4. Specificity measurement for seq-1 as analyzed by binding reaction with pure Con A, extract of jack bean seed, and BSA. Target-bound seq-1 was detected colorimetrically.

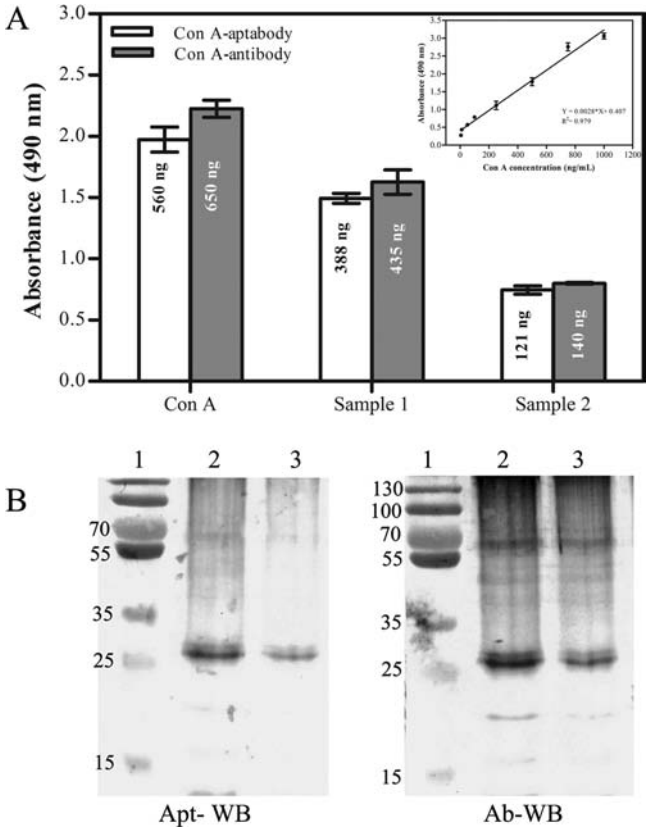

Figure 5. Enzyme-linked aptamer and Western blot assay. (A) Quantitation of Con A in three different samples, pure Con A, jack bean seed extract 1, and seed extract 2, was carried out using Con A-aptabody and -antibody in enzyme-linked aptamer and immunosorbent assays, respectively. The calculated amount of Con A in each sample is written in its corresponding bar. (Inset) Con A standard curve with concentrations of 5−1000 ng/mL. (B) Analysis of different amounts of Con A via aptamer-based Western blot and antibody-based Western blot assays: lane 1, protein marker; lanes 2 and 3, 1.0 and 5.0 μg of Con A, respectively.

Due to the ease in handling and storage and higher tolerance to thermal and environmental denaturation, Con A-aptabody provides a novel substitute for Con A-antibody. The detection range of the aptamer-based enzyme-linked aptamer assay was quantitated by plotting a standard curve for Con A in the working range of 5−1000 ng/mL (inset, Figure 5A). The enzyme-linked aptamer assay was performed in a sandwich format. The assay showed a linear rise in color absorbance in the dynamic range of 10−750 ng/mL Con A with a limit of detection of 13.229 ng/mL and a limit of quantification of 44.097 ng/mL. The precision of the assay is expressed as the coefficient of variation with intra-assay CV <12% (11.96, 5.18, and 2.87% for 5, 100, and 1000 ng/mL, respectively).

In another attempt to validate the utility of Con A-aptabody, we performed an aptamer-based Western blot assay for Con A detection. PAGE-separated dilutions of Con A (1 and 0.5 μg, respectively) were transferred to nitrocellulose membrane, and the membrane was probed with biotinylated Con A-aptabody. The blot was developed by probing with streptavidin−HRP conjugate and HRP substrate−dye. In the control, the same Con A samples were detected by antibody-based Western blot assay. The aptabody depicted an antibody-equivalent concentration-dependent detection of Con A (Figure 5B). This shows that the Con A-aptabody can efficiently be utilized to rival antibody-based affinity assays in Western blot and related applications.

Con A Determination in Food Samples. As lectins are abundantly present in common food products, such as plant seeds, raw legumes, and tubers, and most of them act as allergens, their determination is crucial for human health. Con A is one such lectin that causes toxicity to humans. In our most crucial effort to determine Con A using our developed Con A-aptabody, we analyzed five different food products—kidney bean (*Phaseolus vulgaris*), jack bean (*Canavalia ensiformis*),

DOI: 10.1021/acs.jafc.5b00784
J. Agric. Food Chem. 2015, 63, 4104−4111

wheat (*Triticum* spp.), mung bean (*Vigna radiata*), and lentil (*Lens culinaris*). Con A detection in these samples was carried out using the developed Con A-aptabody as well as the putative Con A-antibody. The results of this combined study are summarized in Figure 6. Seed extract of jack bean plant showed

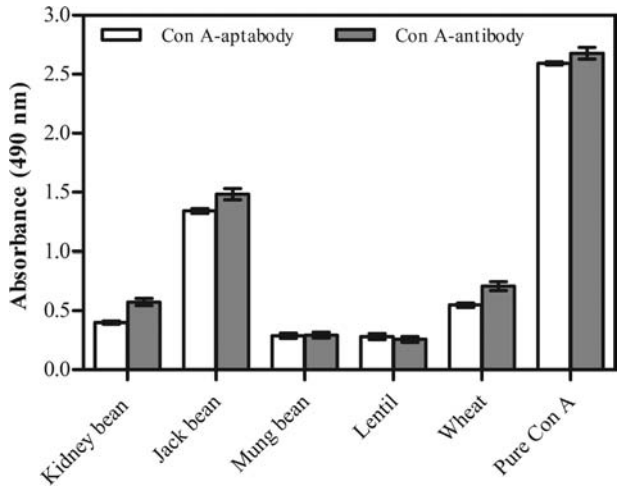

Figure 6. Con A determination in different food samples. Simultaneous analyses of five different samples by Con A-antibody and the aptabody showed similar trends.

the highest Con A, whereas kidney bean and wheat were calculated to contain low amounts of Con A. On the other hand, negligible amounts of Con A were detected in mung bean or lentils. Pure preparation of Con A was included as positive control. The results are in agreement with the literature, which reports jack bean as the major source of Con A.[26] Typical seeds of jack bean contain approximately 20−28 g (per 100 g dry seed mass) of protein, 60 g of carbohydrate, 10 g of ether extracts, and the remaining 10 g includes ash, crude fiber, and moisture contents. The protein contents of remaining food samples (*Phaseolus vulgaris*, *Vigna radiata*, *Lens culinaris*, and *Triticum* spp.) were also in the range of 20−26 g/100 g dry seed mass.[27] This means that irrespective of equivalent total proteins in the extracts of jack bean, mung bean, kidney beans, wheat, and lentils, the developed method and the aptabody are capable of determining the proportional Con A quantity specifically and precisely. At the same time, consecutive analysis of all five samples using putative Con A-antibody showed an almost similar pattern. From the results, it is clear that the developed aptabody of Con A is capable of detecting Con A in common food samples.

Taken together, we can conclude that the developed aptamer of Con A is highly specific, has a high binding affinity, and thus can rival antibodies in Con A detection. Its ability to detect Con A makes it a potentially useful molecule for lectin analysis in common food and agricultural products and research laboratories.

Table 1. Resonance Assignments and Integration Ranges for Egg Liqueurs and Calibration References of ^{1}H NMR Spectra (400 MHz)[a]

resonance assignment with δ in ppm	structural formula	integration ranges (δ in ppm) for egg liqueurs	integration ranges (δ in ppm) for calibration references
caffeine[13]: δ ≈ 7.8 (s, 1, C8H)		7.83 - 7.75	7.77 - 7.69
cholesterol[13] δ ≈ 0.7 (s, 3, C18H$_3$)		0.72 - 0.67	0.72 - 0.67
ethanol[13] δ ≈ 1.1 (t, 3, C2H$_3$)		1.25 - 1.10	1.06 - 0.99
α-D-fructofuranose/ β-D-fructofuranose[14] δ ≈ 4.1 (m, 1, C3H)/ δ ≈ 4.1 (m, 1, C3H), δ ≈ 4.1 (m, 1, C4H)		4.12 - 4.09	4.13 - 4.10
α-D-glucopyranose[15] δ ≈ 5.2 (d, 1, C1H)		5.25 - 5.21	5.26 - 5.22
sucrose[13] δ ≈ 5.4 (d, 1, gluco-pyranosyl-C1H)		+/- 5 Hz from signal middle at about 5.40	

[a]MeOH-d_4/$CDCl_3$ (50:50, v/v) as solvent for caffeine and cholesterol and H_2O/D_2O (90:10, v/v) for ethanol, fructose, glucose, and sucrose.

(99%), glucose (99.5%), KI (99.5%), and sucrose (99.5%) were from Sigma (St. Louis, MO, USA), $CuSO_4 \cdot 5H_2O$ (99.5%), KOH (85%), $KNaC_4H_4O_6 \cdot 4H_2O$ (99%), $Na_2S_2O_3$ (99.5%), $ZnSO_4$ (99.5%), and MeOH-d_4 (99.8 atom % D) were from Carl Roth (Karlsruhe, Germany), MeOH (99.8%) was from Fisher Scientific (Pittsburgh, PA, USA), H_2SO_4 (96%) was from Fluka (Buchs, Switzerland), and isopropyl alcohol was from VWR Scientific Products (New York, NY, USA). A ready kit for enzymatic determination of cholesterol was purchased from r-biopharm (Boehringer Mannheim/r-biopharm, Darmstadt, Germany), and sea sand from Merck (Darmstadt, Germany).

TSP-d_4 solution consisted of 7 mM TSP-d_4 and 2 mM NaN_3 in D_2O, Carrez I solution of 15% $K_4[Fe(CN)_6] \cdot 3H_2O$ in demineralized water, Carrez II solution of 30% $ZnSO_4$ in demineralized water, and $CDCl_3$ solution of 7 mM TMS and 21.5 mM caffeine in $CDCl_3$.

^{1}H NMR Analysis of Egg Liqueurs. *Sample Preparation for Egg Liqueurs.* Fifteen different egg liqueurs were purchased from supermarkets in Germany. For analysis of alcoholic strength and total sugar content, about 2 g of egg liqueur was diluted to 10 mL with demineralized water, and 1000 μL of this dilution was mixed with 50 μL of Carrez I solution, 50 μL of Carrez II solution, and 100 μL of TSP-d_4 solution; subsequently this mixture was centrifuged at 6260*g* for 5 min, and 600 μL of clear supernatant was transferred to 5 mm NMR tubes. For analyzing cholesterol, about 200 mg of egg liqueur was mixed with 500 μL of MeOH-d_4 and 500 μL of $CDCl_3$ solution. After shaking for 30 min, samples were centrifuged at 1565*g* for 5 min, and 600 μL of clear supernatant was transferred to 5 mm NMR tubes.

Sample Preparation for Checking Recovery Rates. The increase in concentration by addition of reference solutions (ethanol/sucrose/egg yolk mixture) was divided by the theoretical increase in concentration in order to yield the percentage of recovery rates.

To check recovery rates of ethanol and total sugar content, five different egg liqueurs were analyzed. For ethanol, 5 g of egg liqueur was diluted to 50 mL with demineralized water, and 5 g of the same egg liqueur was mixed with 0.8 g of pure ethanol and diluted to 50 mL with demineralized water. A 1 mL amount of each dilution was mixed with 50 μL of Carrez I solution, 50 μL of Carrez II solution, and 100 μL of TSP-d_4 solution and centrifuged at 6260*g* for 5 min. For total

DOI: 10.1021/acs.jafc.5b00940
J. Agric. Food Chem. 2015, 63, 4112−4119

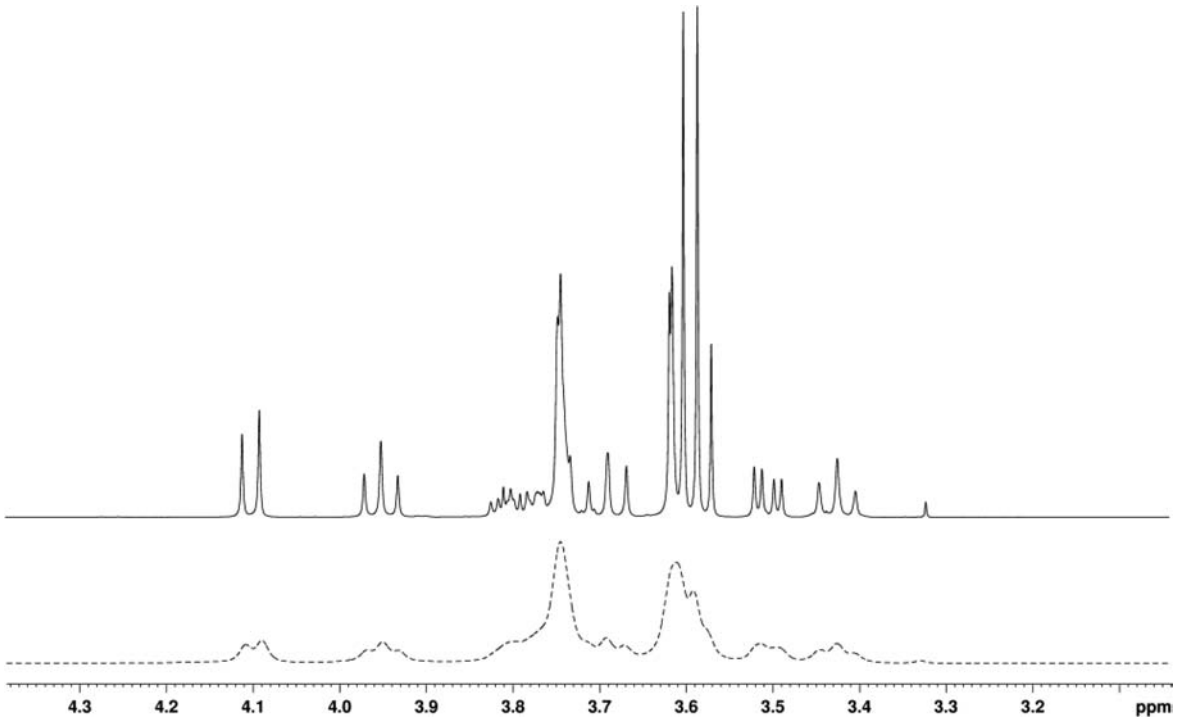

Figure 1. ^{1}H NMR spectrum of an egg liqueur without further preparation (1:2 diluted with demineralized water; dotted line) and after Carrez precipitation (1:5 diluted with demineralized water; constant line) at the spectral range from δ = 3.1 to 4.3 ppm, measured with a 400 MHz spectrometer.

sugar content, 2 g of egg liqueur was diluted to 10 mL with demineralized water. A 1 mL portion of this dilution was mixed with 100 μL of sucrose solution (containing 200 g/L sucrose), and 1 mL was mixed with 100 μL of demineralized water. Subsequently, the samples were mixed with 50 μL of Carrez I solution, 50 μL of Carrez II solution, and 100 μL of TSP-d_4 solution and centrifuged at 6260*g* for 5 min. Each 600 μL of clear supernatant was transferred to 5 mm NMR tubes, and the ethanol or sucrose content was determined by qNMR.

For checking cholesterol recovery rates, five egg liqueurs were prepared by adding different amounts (ranging between 6.6 and 25.9 g) of an egg yolk mixture (containing 335.3 g/L egg yolk and 4.2 g/L cholesterol on the assumption of 12.5 mg/g cholesterol in egg yolk[10]) to 50 g of an egg liqueur with a known content of cholesterol (calculated as the average value of five qNMR results). A 200 mg sample of this was mixed with 500 μL of MeOH-d_4 and 500 μL of $CDCl_3$ solution. After shaking for 30 min, samples were centrifuged at 1565*g* for 5 min, and 600 μL of clear supernatant was transferred to 5 mm NMR tubes.

^{1}H NMR Measurement. Hardware and software equipment for ^{1}H NMR measurement consisted of a Bruker Avance 400 spectrometer with a 5 mM SEI probe with Z-gradient coils, an automatic SampleChanger (SampleXpress), a BCU 05 temperature unit, and TopSpin 3.0 software.

Samples in aqueous solution were measured without rotation at 301.8 ± 0.1 K using 4 dummy scans prior to 16 scans. Acquisition parameters have been set as follows: size of FID = 64k, spectral width = 20.55 ppm, receiver gain = 16, acquisition time = 3.98 s, relaxation delay = 4 s, FID resolution = 0.25 Hz per point. Water suppression was achieved by an experiment using a 90° pulse with a NOESY-presaturation pulse sequence (Bruker 1D noesygppr1d) with irradiation of the water frequency during the recycle and mixing time delays. All spectra were automatically phased and manually baseline corrected.

Samples in MeOH-d_4/$CDCl_3$ solution were measured without rotation at 300 ± 0.1 K using 2 dummy scans prior to 256 scans. Acquisition parameters have been set as follows: size of FID = 64k, spectral width = 25.82 ppm, receiver gain was automatically set by *rga* command, acquisition time = 3.17 s, relaxation delay = 1 s, FID resolution = 0.32 Hz per point. A flip angle of 30° was used within the zg30 experiment. All spectra were manually phased and baseline corrected.

Quantification. Resonance assignments were based on spectral databases[13] and literature,[14,15] and integration ranges are displayed in Table 1. Quantification was performed by external calibration with concentration ranges from 12.5% to 22.5% by volume for ethanol, 100 to 500 g/L for sucrose, 20 to 80 g/L for glucose and fructose, and 1 to 3 g/L for cholesterol. For each calibration graph, linearity was verified by Mandel's fitting test (*F*-values were lower than reported values in *F*-tables with a confidence level of 95%). The limit of detection/limit of quantification values were determined according to DIN 32645[16] (significance level 5%; uncertainty of result 33%) and amounted to 0.80/2.78% by volume for ethanol, 6.79/26.11 g/L for sucrose, 0.56/2.23 g/L for glucose, 1.39/5.33 g/L for fructose, and 0.08/0.28 g/L for cholesterol, respectively.

To consider the influence of the pulse length on signal intensities, the signal areas of ethanol, sucrose, glucose, and fructose were converted into their theoretical values for an equal 90° pulse length of 11 μs. For this, each signal area was multiplied by the factual 90° pulse length (in μs) and divided by 11. To quantify cholesterol, the ratio of the signal area of cholesterol compared to the signal area of caffeine was used for examination of egg liqueurs as well as for calibration references.

Conventional Analytics of Egg Liqueurs. Alcoholic strength was determined pycnometrically after distillation,[3] total sugar content was determined as reducing sugars by a redox titration after reaction with Cu^{2+} as oxidizing agent (Luff–Schorl method),[4] and cholesterol was analyzed enzymatically subsequent to saponification (for saponification: 10 mL of 1 M KOH solution was added to 2 g of egg liqueur and 1 g of sea sand and heated under reflux for 25 min; the supernatant and two amounts each of 6 mL of isopropyl alcohol (used for washing solid residues) were diluted to 25.0 mL with isopropyl alcohol, and in case of turbid solutions, filtration was performed using a folded filter). Enzymatic determination of cholesterol was performed according to the instructions of a ready kit (purchased from Boehringer Mannheim/r-biopharm, Darmstadt, Germany).

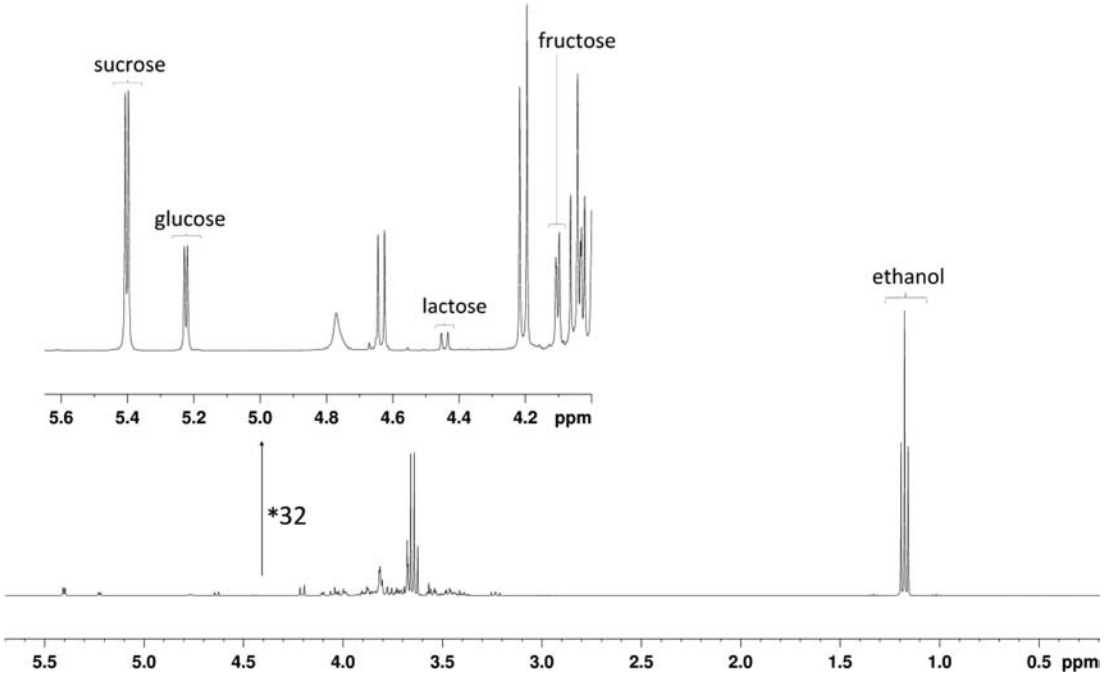

Figure 2. ^{1}H NMR spectrum of an egg liqueur after Carrez precipitation (1:5 diluted with demineralized water) at the spectral range from δ = 0.2 to 5.7 ppm with an enlarged view on the spectral range from δ = 4.1 to 5.6 ppm, measured with a 400 MHz spectrometer.

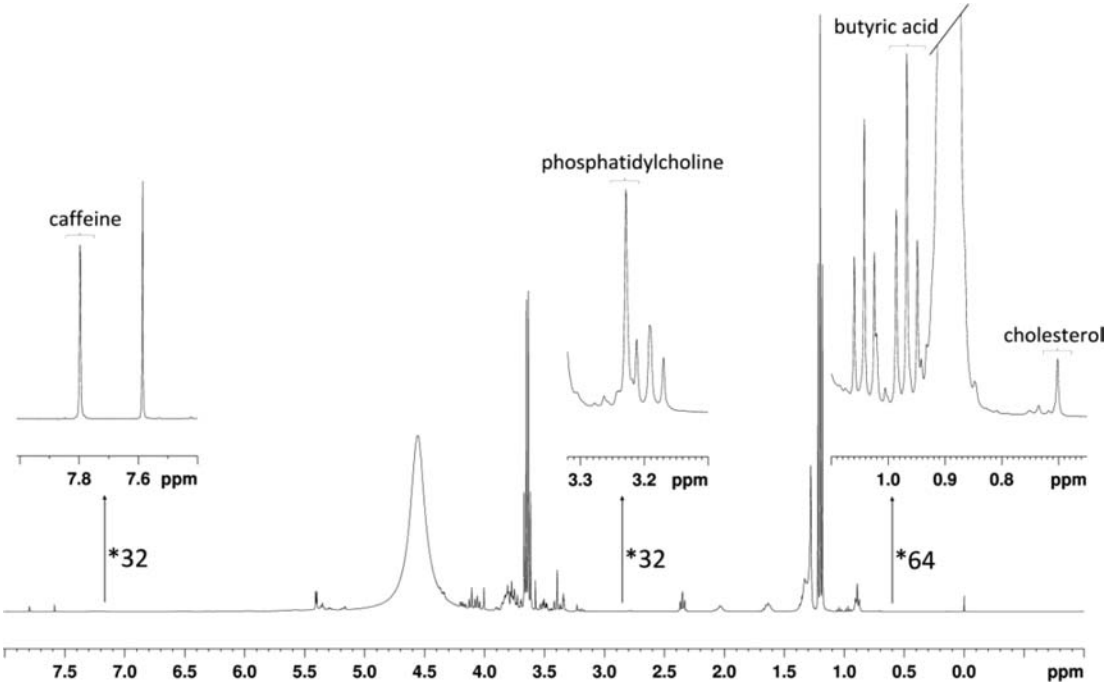

Figure 3. ^{1}H NMR spectrum of an egg liqueur extract (MeOH-d_4/$CDCl_3$ = 50:50 (v/v)) at the spectral range from δ = 0 to 8.0 ppm with an enlarged view of the spectral range from δ = 7.4 to 8.0 ppm, δ = 3.1 to 3.3 ppm, and δ = 0.7 to 1.1 ppm, measured with a 400 MHz spectrometer.

RESULTS AND DISCUSSION

Sample Preparation for ^{1}H NMR Measurement. Foremost, optimized conditions for sample preparation were developed. Considering the high viscosity of egg liqueurs, direct ^{1}H NMR measurements are not applicable. First, it is difficult to accurately fill viscous egg liqueurs into NMR tubes, and second, poor spectral resolution is obtained (Figure 1). By precipitation of proteins the viscosity of liqueurs is reduced, which increases spectral resolution. Figure 1 shows a ^{1}H NMR spectrum of an egg liqueur (1:2 diluted with water) without further preparation steps and of an egg liqueur (1:5 diluted) after Carrez precipitation. ^{1}H NMR spectra of the supernatant, obtained after Carrez precipitation of diluted egg liqueurs, revealed distinct resonance signals of ethanol, sucrose, glucose, and fructose (Figure 2), and the respective signal areas enabled the determination of alcoholic strength (as ethanol) and total sugar content (sum of sucrose, glucose, and fructose).

J. Agric. Food Chem. 2015, 63, 4112−4119

As cholesterol is difficult to dissolve in water, it was not detectable by use of this preparation process. Therefore, MeOH-d_4 and $CDCl_3$ (50:50, v/v) were added to a small amount of liqueur, and this solution was subsequently mixed for the extraction of cholesterol. Although this mixture contained nonpolar solvents and water (originating from liqueurs) at the same time, no layer separation occurred during extraction. Thus, it can be excluded that extraction losses of cholesterol are caused by partially dissolved cholesterol in different solvent phases. The appearance of a homogeneous solution can be attributed to the emulsifying effect of phospholipids from egg yolk. Aside from that, due to the precipitation of proteins by MeOH-d_4, a clear and nonviscous solution was available after centrifugation, and the supernatant was used for qNMR analysis of cholesterol (Figure 3).

Capabilities and Requirements of Quantitative ^{1}H NMR. As quantitative ^{1}H NMR spectroscopy (qNMR) presents a primary method,[17] the concentration of substances can be directly derived from the signal areas without the application of response factors or reference substances.[18] One major advantage of qNMR is the possibility for straightforward sample preparations, since every step of sample pretreatment implies a potential source of error. Furthermore, in contrast to analytical methods that are restricted in applicability by the selectivity of detectors, ^{1}H NMR spectroscopy enables simultaneous detection of all ^{1}H atoms and, thus, implements optimum conditions for multimethod approaches.

To gain benefit from these advantages, general prerequisites need to be fulfilled in order to yield accurate quantification results. In general, appropriate spectrometer configuration and measuring conditions as well as suitable processing parameters must be considered. Furthermore, distinct and well-separated resonance signals as well as sufficiently high concentrations are needed for proper integration, and the relaxation delay between consecutive pulses must be set adequate to ensure complete relaxation of the substances to be quantified.[19] Another effect to be considered is that the NMR signal strength is affected by the 90° pulse length that is inversely proportional to the signal intensity.[20,21]

When sample preparations were applied as previously described, distinct signals for ethanol, sucrose, glucose, fructose, and cholesterol were achieved (Figures 2 and 3) and integration ranges for qNMR were set adequate to eliminate nearby resonance signals from other components. With the exception of fructose and glucose, which were not contained in each egg liqueur, all concentrations were well above the respective limit of quantification. After integration, quantification was performed by external calibration with individual calibration graphs for each substance (ethanol, sucrose, glucose, fructose, and cholesterol). The sample preparation for qNMR of cholesterol included caffeine as an internal standard in the extraction solvents in order to avoid quantification errors caused by evaporation of volatile solvents. Thus, instead of the signal area of cholesterol, its ratio to the signal area of caffeine was used for examination.

To consider the influence of the 90° pulse length on signal intensities, the signal areas for ethanol, sucrose, glucose, and fructose were converted into their respective value for an equal 90° pulse length (11 μs; Materials and Methods). Since all resonance signals were affected by variations of the 90° pulse length, the signal areas of cholesterol and caffeine as internal standard were likewise influenced. Thus, the impact of the pulse length was already eliminated during examination of the cholesterol content, since the cholesterol signal areas were considered as their respective ratio to the signal areas of caffeine as internal standard.

The correctness and precision of qNMR were investigated by recovery rates (n = 5) and replicate measurements (n = 5). Accurate results were achieved for all quantified components (Table 2). Thus, the conditions for quantification were set adequately.

Table 2. Precision and Recovery Rates for qNMR of Ethanol, Total Sugar, and Cholesterol (n = 5)

component	precision	recovery rate
ethanol	0.5%	97.6 ± 2.0%
total sugar	3.2%	96.1 ± 7.6%
cholesterol	2.3%	106.6 ± 8.1%

Comparison of the Results of qNMR with Conventional Analysis. The direct comparison with the results of established conventional analysis is an important step in order to verify applicability and validity of qNMR as a rapid alternative method. Even if no factual concentrations for the egg liqueur samples were available, the methods accordance between established classical methods and qNMR gives a first impression of the suitability of NMR analysis. For comparison with qNMR, the following conventional analytical methods were applied: pycnometry after distillation for alcoholic strength, redox titration for sugar, and enzymatic analysis (after saponification of lipids) for cholesterol. However, the respective results are subject to individual uncertainties of measurement, and thus, they do not reflect real values but rather trusted estimations.

Correlations between data of qNMR and conventional methods were calculated for their comparability. Since correlation coefficients do not accommodate systematic differences, too optimistic results may be delivered, and thus, we additionally used the Bland−Altman plot to factor in eventual biases.[22] It is performed by plotting the differences between two methods against the respective mean value of both methods for each sample. For a better overview, three parallel lines for the mean deviation and mean deviation ± 1.96-fold standard deviation are indicated in the plot. This diagram offers information about systematic deviations between two methods, the variance around the mean deviation, and eventual dependencies between deviations and concentration range.[23] We analyzed overall 15 egg liqueurs by both quantitative ^{1}H NMR analysis and classical analytical techniques. The results are displayed in Table 3.

When qNMR results were plotted against results of customary analysis techniques, high correlations were achieved for alcoholic strength (R = 0.996, p < 0.001), content of total sugar (R = 0.989, p < 0.001), and content of cholesterol (R = 0.995 p < 0.001).

Regarding alcoholic strength, the absolute deviation between the methods averaged 0.2 ± 0.3% by volume and the relative deviation 1.0 ± 1.5% (with an average alcoholic strength of 19.0% by volume, determined by results of pycnometry). Thus, the results showed a tendency for marginally higher values for qNMR analysis. Besides a possible systematic error of qNMR, this may be due to a bias of the classical method (for instance caused by incomplete distillation processes prior to pycnometric analysis). The Bland−Altman plot shows no dependency between the concentration range and the deviation

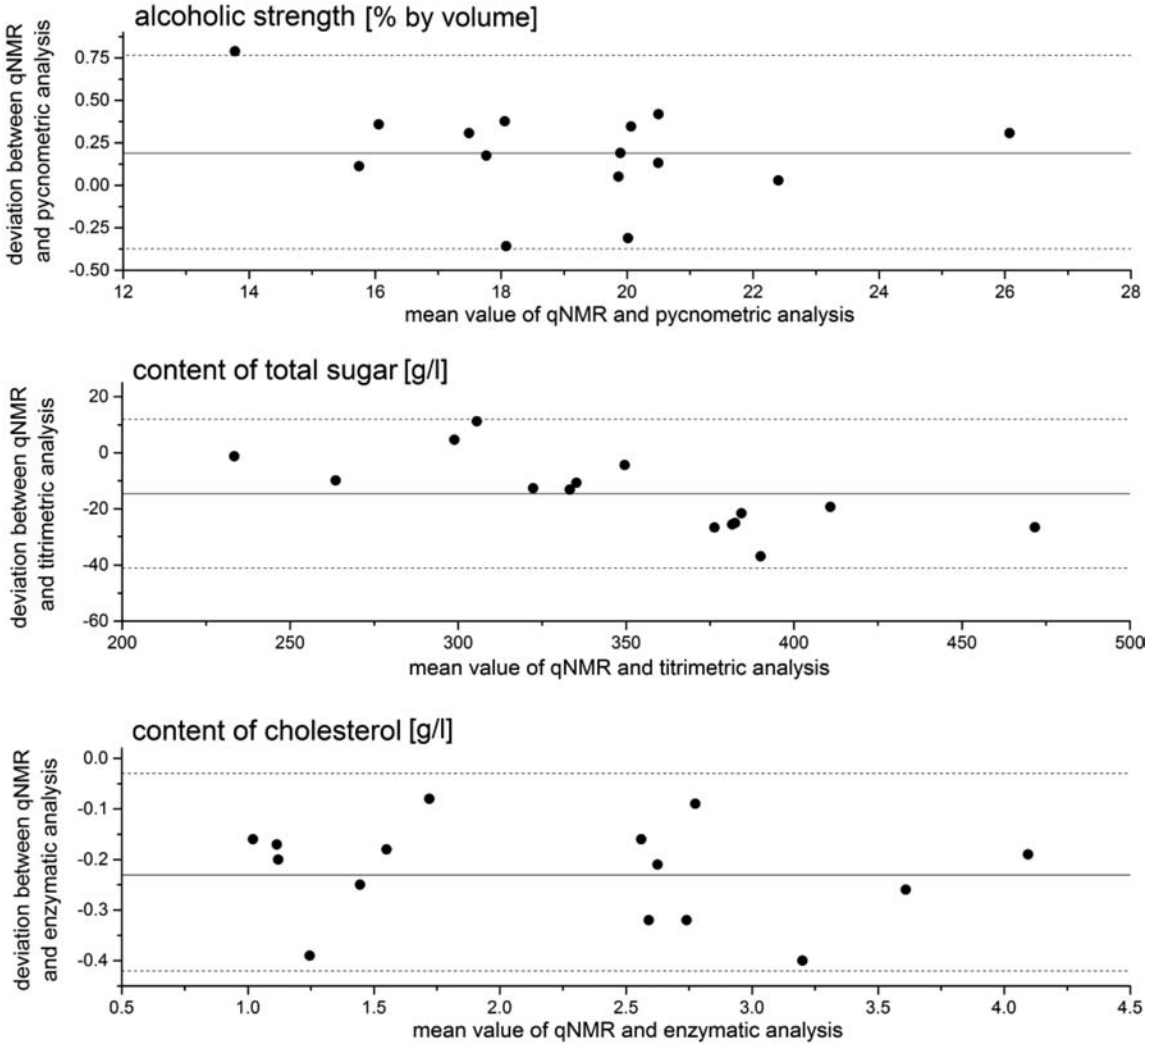

Figure 4. Bland−Altman plot for a comparison of the results of qNMR and classical analysis methods for the quantification of alcoholic strength, total sugar, and cholesterol in 15 different egg liqueurs; the mean deviation between the methods is plotted as a constant line, and the mean deviation ± 1.96-fold standard deviation as a dotted line.

DOI: 10.1021/acs.jafc.5b00940
J. Agric. Food Chem. 2015, 63, 4112−4119

between the methods (Figure 4). The deviations were rather symmetrically distributed between mean deviation ± 1.96-fold standard deviation (0.2 ± 0.6% by volume).

For total sugar, the absolute mean deviation between the methods amounted to −15 ± 13g/L, and the respective relative mean deviation to −4.1 ± 3.7% (with an average sugar content of 357 g/L, determined by results of titrimetry). Thus, the results of qNMR were found to be on average lower than the results of titrimetric analysis. The integral used for qNMR of total sugar derived from the same ^{1}H NMR spectrum that was used for quantification of ethanol. Since qNMR data of ethanol complied well with values of classical techniques for alcoholic strength, it is unlikely that the sample preparation of qNMR is responsible for the deviation between the methods in terms of total sugar content. Besides, lower results of qNMR may be due to the fact that only sucrose, fructose, and glucose were taken into account for examination, while titration involved all reducing sugars. For instance, egg liqueurs occasionally contain cream or condensed milk, and an addition of milk products implies an addition of lactose (on average 3.3 g/100 g cream or 10.2 g/100 g condensed milk[24]), which is analyzed as a reducing sugar during titrimetric analysis but not considered for qNMR. Thus, the average deviation between the methods was higher for egg liqueurs with lactose (−19 g/L; averaged by the results of nine egg liqueurs) than for egg liqueurs without lactose (−8 g/L; averaged by the results of six egg liqueurs). As the legal requirement for total sugar in egg liqueurs refers to invert sugar,[1] which is defined as the sum of sucrose, glucose, and fructose, this rather supports the approach of qNMR. Furthermore, performing classical titrimetry involved elaborate sample preparation as well as imprecise end points of titration, which can cause measurement errors and possibly resulted in deviations from qNMR data. The Bland−Altman plot demonstrates that the deviations between the methods tended to grow with increasing concentration (Figure 4). As titration of sugars was performed by means of a back-titration, high sugar concentrations resulted in small needs of titrant, which in turn means that the measurement error potentially increased with growing content of total sugar. This represents a possible explanation for the dependencies of deviations between the methods and the concentration range of total sugar. By all means, the aim of analyzing the total sugar content is simply to ensure that the minimum of 150 g/L[1] is exceeded. For this purpose qNMR is definitely suitable, especially as the absolute mean deviation between qNMR and classical analysis amounted to only −5 ± 10 g/L for egg liqueurs with sugar contents of less than 350 g/L.

The absolute mean deviation between qNMR and enzymatic analysis of cholesterol amounted to −0.2 ± 0.1 g/L, and the relative mean deviation to −9.7 ± 4.2% (with an average cholesterol content of 2.3 g/L, determined by results of enzymatic analysis), showing on average lower values for qNMR than for enzymatic investigations. As the Bland−Altman plot demonstrates (Figure 4), the deviations between the methods were independent from the measuring range. An overestimation of enzymatic results due to insufficient specificity of cholesterol oxidase[25] is unlikely, since egg liqueurs do not contain vegetable oils and structurally similar sterols are potentially also included in qNMR results. Comparing the sample preparations for both techniques, enzymatic determination is in general more elaborate and consequently more prone to errors than qNMR. However, since no factual data on cholesterol contents were available for the analyzed liqueurs, the reason for the observed deviations cannot be identified with certainty. Similar to the legislative background for total sugar, the purpose of cholesterol quantification is to control the egg yolk content with respect to the given minimum of 140 g/L[1] (1.75 g/L cholesterol, respectively, on the assumption of 12.5 mg/g cholesterol in egg yolk).[10] As a screening method for this, qNMR achieved absolutely appropriate results. In addition, since the deviation between enzymatic determination and qNMR was systematic, correction factors can be applied to adjust qNMR values to respective data of enzymatic analysis by use of the linear correlation between the methods' results ($\text{cholesterol}_{\text{qNMR}}(\text{g/L}) = 0.978\text{cholesterol}_{\text{enzymatic analysis}}(\text{g/L}) - 0.176$ g/L).

Taking the results together, the comparison of qNMR and classical data confirms NMR spectroscopy to be a suitable method to verify the accordance of egg liqueurs with the given legal limits. qNMR can be used as a screening tool, and in case of suspicious results the respective samples undergo additional analysis by reference methods. This enables risk-oriented sample management and high sample throughputs due to rapid determinations by qNMR. For the future, final assessment of the qNMR method should be achieved by analyzing egg liqueurs with a known alcoholic strength and known total sugar and cholesterol contents, for instance by participating in interlaboratory ring tests.

^{1}H NMR Spectrsocopic Fingerprint of the Basic Egg Liqueur Composition. Aside from the opportunity to use qNMR as a powerful innovative and economic analytical tool for simultaneous quantitative analysis of several components, ^{1}H NMR also provides further comprehensive information on egg liqueur composition, since each spectrum provides a fingerprint of all organic components.

For instance, a signal of phosphatidylcholine ($\delta \approx 3.20$ ppm, s, 9, choline-N($C\underline{H}_3$)$_3$; assignment according to the SDBS spectral database[13]) was detected in the ^{1}H NMR spectra after extraction with MeOH-d_4/$CDCl_3$, which is performed during cholesterol analysis (Figure 3). It is often claimed that the natural deviation of cholesterol in egg yolk is very high[5] (for instance due to breed[26] and age of hens[27]), and its validity as an indicator of the content of egg yolk is accordingly low. Thus, simultaneous analysis of phosphatidylcholine as a second marker substance of egg yolk ensures the results for the egg yolk content via cholesterol. As the chemical shift of this signal depends on the concentration level of phosphatidylcholine, integration ranges were adapted at 3 Hz to the left and right sides of the signal top for each spectrum. A comparison of the signal integrals for cholesterol (chol) and phosphatidylcholine (PC) showed a very high correlation with $R = 0.991$ ($p < 0.001$). The ratio of the integrals ($\text{signal area}_{\text{PC}}/\text{signal area}_{\text{chol}}$) averaged a value of 8.94 ± 0.78. Hence, it can serve as a value for the plausibility of the calculated egg yolk content by cholesterol quantification.

Additionally, a significant signal of lactose ($\delta \approx 4.46$ ppm; d, 1, C1$\underline{H}$; assignment according to the Bruker BBIOREFCODE database[28]) in the ^{1}H NMR spectrum after Carrez precipitation (Figure 2) as well as a characteristic signal of butyric acid ($\delta \approx 0.97$ ppm; t, 3, C4$\underline{H}_3$; assignment according to the SDBS spectral database[13]) in the ^{1}H NMR spectrum after extraction with MeOH-d_4/$CDCl_3$ (Figure 3) indicated an addition of milk products that has to be labeled to inform lactose-intolerant consumers.[2] The qualification of lactose or butyric acid by ^{1}H NMR spectroscopy compensates for an additional classical

DOI: 10.1021/acs.jafc.5b00940
J. Agric. Food Chem. 2015, 63, 4112−4119

analysis of lactose (e.g., by enzymatic analysis), to determine if milk products were added despite missing labeling.

Finally, ^{1}H NMR spectra generally indicate striking deviations from the typical composition of egg liqueurs. The example of melamine in milk powder[29] clearly demonstrated that it is of advantage to use analytical methods that also detect unsuspected adulterations. Thus, an increased use of methods such as qNMR (with nonselective detection and wide information) is beneficial for improved consumer protection.

Therefore, the present study has focused on the profile and content of bioactive lipophilic (carotenoids, phytosterols, fatty acids) and hydrophilic compounds (L-ascorbic acid, polyphenols) in chosen cultivated berries of *Hippophaë rhamnoides* subsp. *mongolica*.

MATERIALS AND METHODS

Reagents and Chemicals. Quercetin glycosides (3-*O*-glucoside, 3-*O*-galactoside, 3-*O*-rhamnoside, 3-*O*- rutinoside), kaempferol glycosides (3-*O*-glucoside, 3-*O*- rutinoside), isorhamnetin glycosides (3-*O*-glucoside, 3-*O*-rutinoside), *p*-coumaric acid, (+)-catechin, (−)-epicatechin, and procyanidins B1 and B2 were purchased from Extrasynthese (Lyon Nord, France). Acetic acid, phloroglucinol, methanol, sterol standards, and Sylon BTZ were purchased from Sigma-Aldrich (Steinheim, Germany, and St. Louis, MO, USA). Acetonitrile for UPLC (gradient grade) and ascorbic acid were from Merck (Darmstadt, Germany). UPLC grade water, prepared by using an HLP SMART 1000s system (Hydrolab, Gdańsk, Poland), was additionally filtered through a 0.22 μm membrane filter immediately before use.

Plant Material and Atmospheric Conditions in Harvesting Season. Ripe berries of eight Russian sea buckthorn (*H. rhamnoides* subsp. *mongolica*) cultivars (cv.), 'Aromatnaja', 'Avgustinka', 'Botaniczeskaja', 'Botaniczeskaja Ljubitelskaja', 'Luczistaja', 'Moskwiczanka', 'Podarok Sadu', and 'Porożrachnaja', were collected from the Institute of Horticulture in Skierniewice, Lodz province, Poland (51.59° N, 20.139° E) in September 2011. Manual harvesting fruits were picked, rinsed, and stored at −20 °C until analysis.

According to data from the meteorological station in Lodz, the average temperature in 2011 was 9 °C with total annual precipitation of 483 mm, insolation of 1966 h, and 5.1 octants of average cloudiness.

Lipophilic Compounds Analysis. Determination of Total Carotenoids Content. The content of total carotenoids in fruits was determined according to the spectrophotometric method described in Polish Standard (PN-90/A-75101/12: *Fruits and vegetables preserves. Preparation of samples and physicochemical test methods. Determination of total carotenoids and β-carotene)*.[10] All samples were analyzed in triplicate. Results were expressed in milligrams per 100 g of fresh weight (fw).

Sample Preparation of Phytosterols and Fatty Acids Content Analysis. Whole fruit pulp (±20 g) was quenched with 100 mL of a chloroform and methanol mixture (2:1) with the addition of BHT (0.1%), shaken in a separating funnel for 10 min, and allowed to separate. After phase separation, the extraction mixture was three times shaken in a separatory funnel with the addition of water. The chloroform layer was collected, centrifuged for 10 min at 15000*g* (MPW-380R, MPW Med. Instruments, Warszawa, Poland), and filtered through anhydrous sulfate(VI). The extracts were concentrated on a rotary evaporator (Rotavapor R-215, Büchi, Flawil, Switzerland) to 50% of the original volume.

Phytosterols Content Analysis. Sterol content and composition were determined according to AOCS Ch 6-91.[11] Fifty milligrams of extract (the procedure described above) with 100 g of 5-cholestanol as an internal standard were saponified with 2 mL of 1 mol of KOH in methanol, mixed, and placed for 18 h in the dark. Then 2 mL of distilled water and 5 mL of methyl *tert*-butyl ether (MTBE)/hexane (1:1, v/v) were added to extract the nonsaponifiable phase. The upper layer was transferred to a test tube, and the residue was washed twice by the addition of 3 and 2 mL of a mixture of MTBE/hexane. The solvent collected in the tube was evaporated to dryness under a nitrogen stream. Sterols were silylated with Sylon BTZ reagent for 4 h at 20 °C.

Chromatographic separation was performed on a Hewlett-Packard 6890 equipped with flame ionization detector (FID) and a capillary column DB-35 ms, 30 mm × 0.25 mm × 0.25 μm, in 30 min. The analysis was carried out without a split, and the temperature at the time of separation was programmed. In the initial phase (5 min) the temperature was 100 °C and then increased at 25 °C/min to 250 °C, which was maintained for 1 min and then increased at 3 °C/min to 290 °C. The temperature in the injection system and detector was 300 °C. All samples were analyzed in triplicate. Results were expressed in micrograms of phytosterols per 100 mL of lipid extract.

Determination of Fatty Acid Composition. Methyl esters of fatty acids (FAME) were prepared according to AOCS Method Ce 1k-07.[12] Diluted FAME were separated on a HP 5980 series II (Hewlett-Packard, Palo Alto, CA, USA) equipped with an Innowax capillary column (30 m × 0.20 mm × 0.20 μm) and flame ionization detector (FID). Hydrogen was used as the carrier gas at flow rate of 1.5 mL/min. The column temperature was programmed from 60 to 200 °C at 12 °C/min, and the final temperature was held for 25 min. Detector and injector temperatures were set at 250 °C. Fatty acids were identified by comparison of the retention times with authentic standards, and the results were reported as weight percentages after integration and calculation using ChemStation (Agilent Technologies). All samples were analyzed in triplicate. Results were expressed in percent.

Hydrophilic Compounds Analysis. Analysis of L-Ascorbic Acid Content. L-Ascorbic acid content analysis was based on the method previously described by Oszmiański and Wojdyło.[13] Seedless berries (ca. 5 g) were mixed with 50 mL of 0.1 M phosphoric acid and centrifuged at 14000*g* for 10 min at 4 °C. The estimation of L-ascorbic acid was carried out on the Waters liquid chromatograph with a tunable absorbance detector (Waters 486) and a quaternary pump with a Waters 600 Controller apparatus (Waters Associates). A 20 μL sample was injected into a Chromolith Performance RP-18e column (100 mm × 9 mm × 4.6 mm) (Merck). The elution was carried out using 0.1 M phosphoric acid, and the flow rate was 1 mL/ min. The absorbance was monitored at 254 nm. L-Ascorbic acid was identified by comparison with the standard. The calibration curve was prepared by plotting different concentrations of the standard versus the area measurements in HPLC. All samples were analyzed in triplicate. Results were expressed in milligrams per 100 g of fw of fruits.

Sample Preparation for Polyphenols Content Analysis. Extracts were prepared by mixing of 2 g of berries, 10 mL of HPLC grade methanol (30 mL/100 mL) with ascorbic acid (2 g/100 mL) and acetic acid (1 mL/100 mL), and 10 mL of hexane. Samples were sonicated for 15 min (Sonic 6D Polsonic, Warszawa, Poland), placed for 24 h at 4 °C, sonicated again for 15 min, and centrifuged (MPW-380R, MPW Med. Instruments, Warszawa, Poland) for 10 min (20000*g* at 4 °C). The hexane layer was removed. The methanol layer was purified with Merck Samplicity Filtration System (Merck Millipore, Ireland) and collected in 10 mL PE vials.

Determination of Polyphenols by UPLC Coupled to PDA and FL Detector. Conditions of quantitative polyphenols determination were previously described by Wojdyło et al.[14] Analysis was carried out on a UPLC system Acquity (Waters Corp., Milford, MA, USA) with a binary solvent manager, sample manager, PDA, and fluorescence detector (FL) (model λe). For chromatographic data collection and chromatograms integration Empower 3 software was used. The UPLC analyses were performed on a BEH Shield C18 analytical column (2.1 mm × 50 mm × 1.7 μm). The flow rate was 0.42 mL/min. A partial loop injection mode with a needle overfill was set up, enabling 5 μL injection volumes when a 10 μL injection loop was used. Acetonitrile (100%) was used as a strong wash solvent and acetonitrile in water (10%. v/v) as a weak wash solvent. Two milliliters of fruit extracts was centrifuged for 10 min at 15000*g* at 4 °C. The analytical column was kept at 30 °C by column oven, whereas the samples were kept at 4 °C. The mobile phase was composed of solvent A (4.5% formic acid) and solvent B (acetonitrile). Elution was as follows: 0−5 min, linear gradient from 1 to 25% B; 5.0−6.5 min, linear gradient from 25 to 100%; 6.5−7.5 min, column washing; and reconditioning for 0.5 min. PDA spectra were measured over the wavelength range of 200−600 nm in steps of 2 nm. The runs were monitored at the following wavelengths: flavan-3-ols at 280 nm, hydroxycinnamates at 320 nm, and flavonol glycosides at 360 nm. Retention times (t_R) and spectra were compared with those of pure standards. Calibration curves at concentrations ranging from 0.05 to 5 mg/mL (r^2 = 0.9998) were made from (−)-epicatechin, (+)-catechin,

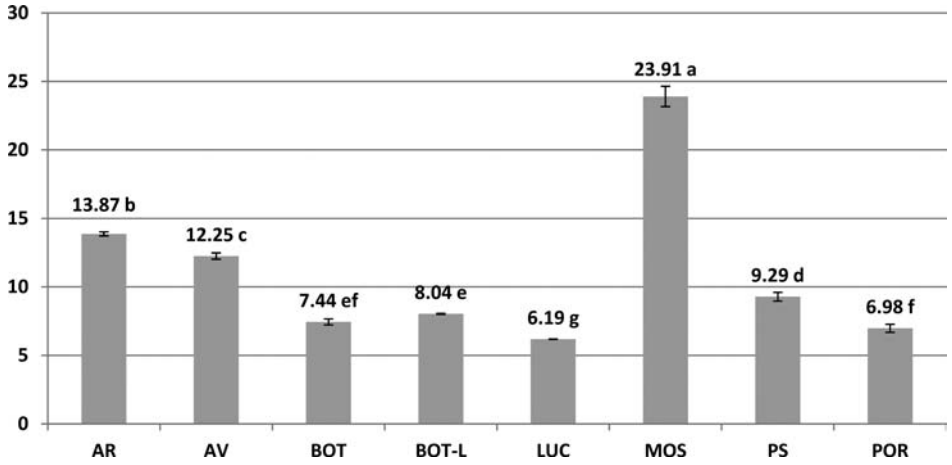

Figure 1. Total carotenoids content (mg/100 g fw) in berries of eight sea buckthorn cultivars.

procyanidin B1, *p*-coumaric acid, quercetin, isorhamnetin, and kaempferol 3-*O*-glucoside as standards.

All samples were analyzed in triplicate. Results were presented as total flavan-3-ols, hydroxycinnamates, and flavonol glycosides content and expressed in milligrams per 100 g of fw of fruits.

Analysis of Proanthocyanidins by Phloroglucinolysis. Polymeric proanthocyanidins content were determined in freeze-dried sea buckthorn berries (Alpha 1-4 LSC; Martin Christ GmbH, Osterode am Harz, Germany) according to a method described by Wojdyło et al.[14] Parameters of freeze-drying process were as follows: 18 h (time), 0.960 mbar (vacuum), 26 °C (shelf temperature). A 0.5 g portion of lyophilized seedless fruits was placed into 2 mL Eppendorf vials and mixed with 0.8 mL of methanolic solution containing phloroglucinol (75 g/L) and ascorbic acid (15 g/L) and then with 0.4 mL of methanol with HCl addition in a dose of 0.3 mol/L. The vials with reaction mixture were closed and incubated for 30 min at 50 °C with all time-vortexing by thermo shaker (TS-100, Biosan, Riga, Latvia). The reaction was stopped by placing the vials in an ice bath; 0.5 mL of the reaction medium was withdrawn and diluted with 0.5 mL of 0.2 mol/L sodium acetate buffer. Next the vials were cooled in ice water and centrifuged immediately at 20000*g* for 10 min at 4 °C. The temperatures in the column oven and sample manager were 15 and 4 °C, respectively. The mobile phase was composed of solvent A (2.5% acetic acid) and solvent B (acetonitrile). Elution was as follows: 0−0.6 min, isocratic 2% B; 0.6−2.17 min, linear gradient from 2 to 3% B; 2.17− 3.22 min, linear gradient from 3 to 10% B; 3.22−5.00 min, linear gradient from 10 to 15% B; 5.00−6.00 min, column washing and reconditioning for 1.50 min. The fluorescence detection was recorded at an excitation wavelength of 278 nm and an emission wavelength of 360 nm. The calibration curves, which were based on peak area, were established using (+)-catechin, (−)-epicatechin, and procyanidin B1 after phloroglucinol reaction as (+)-catechin and (−)-epicatechin-phloroglucinol adduct standards. The results were calculated as milligrams per 100 g of fw of fruits.

Identification of Polyphenols by the Ultraperformance Liquid Chromatography−Mass Spectrometry (UPLC-MS) Method. The method was previously described by Wojdyło et al.[14] Half a gram of freeze-dried powdered fruit (parameters of freeze-drying process described in the previous section) was extracted twice with 15 mL of 80% acetone acidified with 1% acetic acid. The extracts were sonicated for 15 min, centrifuged at 19000*g* for 10 min at 4 °C, and concentrated on a vacuum rotary evaporator to a volume of ca. 3 mL. The samples were applied to the Sep-Pak C18 cartridge (Waters, Milford, MA, USA) containing 1 g of the carrier, washed with distilled water to remove the sugar and organic acid (extract = 0 °Brix), and then collected into a vacuum flask with 15 mL of 80% methanol acidified with 1% HCl. The methanol extract was evaporated to dryness. The dry residue was dissolved in 4 mL of 4.5% formic acid, centrifuged for 5 min at 15000*g*, and then given to the analysis. Identification of sea buckthorn polyphenols was carried out using an ACQUITY Ultra Performance LC system (UPLC) with binary solvent manager (Waters, Milford, MA, USA) and a Micromass Q-Tof Micro mass spectrometer (Waters, Manchester, UK) equipped with an electrospray ionization (ESI) source operating in negative mode. For instrument control data acquisition and processing MassLynxTM software (version 4.1) was used. Separations of individual polyphenols were carried out using a UPLC BEH C18 column (1.7 μm, 2.1 mm × 50 mm; Waters, Milford, MA, USA) at 30 °C. Samples (10 μL) were injected and elution completed in 12 min with a sequence of linear gradients and isocratic flow rates of 0.45 mL/min. The mobile phase was composed of solvent A (0.1 mL/100 mL formic acid, v/v) and solvent B (100 mL/100 mL of acetonitrile). The program began with isocratic elution with 99% A (0−1 min), and then a linear gradient was used for 12 min, lowering A to 0%; from 12.5 to 13.5 min, the gradient returned to the initial composition (99% A) and then was held constant to reequilibrate the column. Analysis was carried out using full scan, data-dependent MS scanning from m/z 100 to 1000. The effluent was led directly to an electrospray source with a source block temperature of 130 °C, desolvation temperature of 350 °C, capillary voltage of 2.5 kV, and cone voltage of 30 V. Nitrogen was used as a desolvation gas at flow rate of 300 L/h.

Statistical Analysis. Statistical analysis (variance test and standard deviation values) was made using Statistica 10.0 (StatSoft, Kraków, Poland). Significant differences ($p \leq 0.05$) between means were evaluated by one-way ANOVA and Duncan's multiple-range test.

RESULTS AND DISCUSSION

Analysis of Lipophilic Bioactive Compounds. Total Carotenoids Content. In raw material total carotenoids (Figure 1), phytosterols, and fatty acids content (Tables 1 and 2) were examined.

The sea buckthorn fruits were characterized by a high concentration of carotenoids, 11.00 mg/100 g fw (mean value). The content of these compounds in berries was significantly correlated with cultivar and ranged from 6.19 to 23.91 mg/100 g fw (in 'Luczistaja' and 'Moskwiczanka', respectively). Similar values in nine cultivars of sea buckthorn were noted by Kruczek et al.[15] (from 8.85 in 'Botaniczeskaja Ljubitelskaja' to 43.06 mg/100 g fw in 'Botaniczeskaja'). It also should be emphasized that the content of these compounds in examined sea buckthorn fruits was comparable to that determined by Müller[16] in tomatoes, young carrots, and red peppers (12.69, 9.46, and 30.37 mg/100 g of edible part, respectively).

Carotenoids are located mainly in the soft parts of the fruit, giving them a characteristic orange-yellow color. In sea buckthorn berries 15−55% of all compounds of this group is β-carotene. In lower concentrations are also α-, γ-, and

J. Agric. Food Chem. 2015, 63, 4120−4129

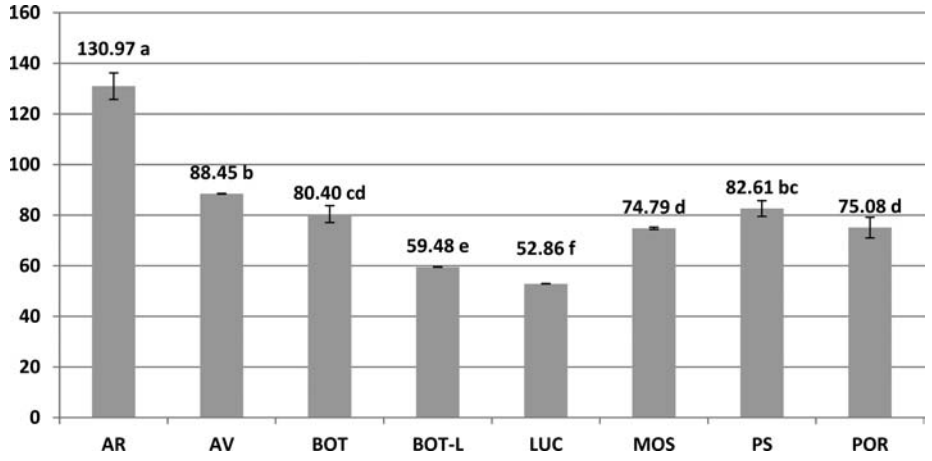

Figure 2. L-Ascorbic acid content (mg/100 g fw) in berries of eight sea buckthorn cultivars.

dihydroxy-β-carotene, lycopene, zeaxanthin, and cantha-xanthin.[17] The content of carotenoids in fruits is subject to extreme diversity. In the same population and species of the genus *Hippophaë* a 10-fold difference in the content of these components can be observed. As Yang's[18] study showed, the concentration of β-carotene ranged between 0.2 and 17 mg/100 g and that of total carotenoids from 1 to 120 mg/100 g fw of sea buckthorn berries.

Phytosterols Content. Bioactive substances of sea buckthorn include phytosterols characterized by a documented beneficial role in the prevention of cardiovascular diseases, mainly hypercholesterolemia[19,20] or cancer.[21] The results of qualitative and quantitative analyses of these compounds are presented in Table 1.

The total content of phytosterols in the lipid fraction from sea buckthorn pulp ranged from 6168.24 ('Moskwiczanka') to 13378.22 μg/100 mL ('Aromatnaja'). The results of GC analysis showed that in the examined extracts there occurred 14 compounds belonging to three subclasses of plant sterols, that is, 4-desmethyl sterols (cholestanol derivatives, including β-sitosterol, stigmasterol, campesterol, Δ^5-avenasterol), 4α-monomethyl sterols (e.g., citrostadienol), and 4,4-dimethyl sterols (e.g., 24-methylenecycloartanol). The predominant compound was β-sitosterol (26.64−42.57% of the total phytosterols in 'Luczistaja' and 'Aromatnaja', respectively). In the high concentration occurred also 24-methylenecycloartanol. This compound was determined in the range from 1454.21 to 4048.89 μg/100 mL in the lipid fraction from 'Moskwiczanka' and 'Avgustinka' berries.

Sea buckthorn can be considered as a valuable source of squalene. Depending on the cultivar, the lipid fraction isolated from berry pulp contained between 885.71 and 2714.37 μg/100 mL ('Luczistaja' and 'Botaniczeskaja'). Moreover, concentrations in a range from 300 to 800 μg of substances, such as erythrodiol > friedelan-3-ol > citrostadienol > or cycloartenol, were noted. In sea buckthorn trace amounts of stigmasterol were also detected. This compound was found only in two cultivars, 'Avgustinka' and 'Moskwiczanka', and its contents were 68.22 and 24.08 mg/100 mL ($p < 0.05$), respectively.

The results of the sterols profile analysis in sea buckthorn were confirmed by studies of other authors, such as Li et al.[22] or Cenkowski et al.[23] According to Bal et al.,[2] the major phytosterols in sea buckthorn oil are β-sitosterol and Δ^5-avenasterol. Other compounds are present in relatively minor quantities. The total quantity of phytosterol is quite high in sea buckthorn and may exceed soybean oil by 4−20 times. β-Sitosterol and β-sitosterol-β-D-glucoside in sea buckthorn oils are important for the antiulcerative activity. The efficacy of the two compounds may differ depending on the cause of ulcer formation.[24]

Fatty Acids Composition. The fatty acid (FA) compositions of sea buckthorn pulp oil are listed in Table 2. In the examined samples 11 fatty acids were identified, including 3 PUFAs, 4 MUFAs, and 4 SFAs. The FA profile was dominated by two compounds: palmitic acid (C16:0), which constituted from 33.66 to 39.65% of the total fatty acids content (in 'Podarok Sadu' and 'Porożrachnaja', respectively), and palmitoleic acid C16:1 n-7 (from 31.41% in 'Podarok Sadu' to 38.51% in 'Luczustaja'). In relatively high concentration occurred also 18-carbon unsaturated acids, that is, linoleic C18:2 n-6 (9.69−14.11% in 'Porożrachnaja' and 'Podarok Sadu', respectively), followed by *cis*-vaccenic C18:1 n-7 (6.66−9.79% in 'Botaniczeskaja Ljubitelskaja' and 'Podarok Sadu') and oleic C18:1 n-9 (4.26−8.02% in 'Luczistaja' and 'Botaniczeskaja'). Other compounds presented in concentrations between ∼0.5% in the case of eicosenoic acid (C20:1 n-9) and ∼1% for stearic acid (C18:0). From these results it can be concluded that MUFAs were the dominant fatty acid classes (46.50−52.63%), followed by SFAs (35.05−41.05%) and PUFAs (10.77−15.61%).

According to Dulf,[25] the dominating fatty acids in sea buckthorn berry pulp/peel oils were palmitic (23−40%), oleic (20−53%), and palmitoleic (11−27%). Small or trace amounts of vaccenic, linoleic, α-linolenic, stearic, myristic, pentadecanoic, *cis*-7-hexadecenoic, margaric, and two long-chain fatty acids, arachidic and eicosenoic acids, were observed in all analyzed oils. As the author showed, in two from six tested cultivars (C1 and C2), the proportions of oleic acid (32.76% for C1 and 53.08% for C2) exceeded that of palmitoleic acid (19.53% for C1 and 11.05% for C2). The fatty acid profile of sea buckthorn was presented also by Khabarovet al.[26] Oil samples from berry pulp and skin (species *H. rhamnoides*) contained the highest concentrations of palmitoleic > palmitic > and oleic acid. Our research showed that the quantified relationships between C16:1 and C16:0 acids noted by these authors occurred only in the oil fraction from 'Avgustinka' and 'Luczistaja' fruits. At the same time, a higher content of linoleic acid in all extracts was found. However, in the presented study fractions from whole berries (with skin and seeds) were examined, which could explain the observed differences. This is

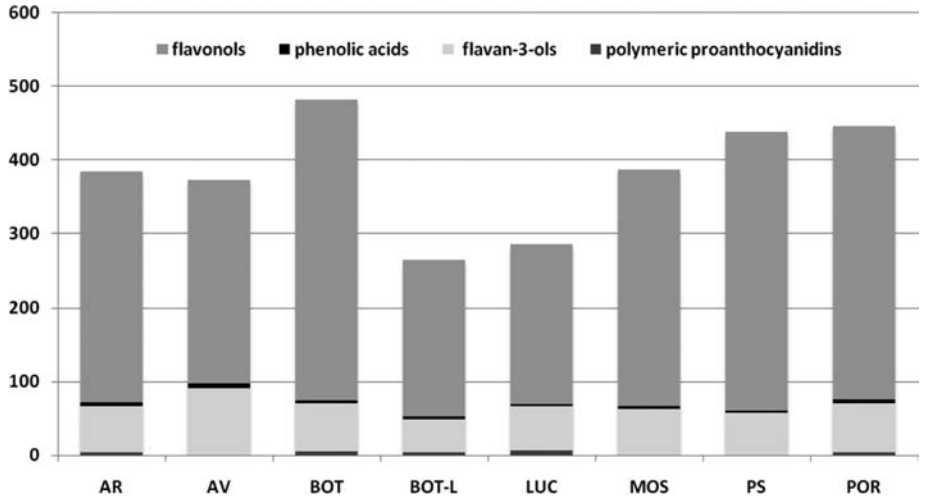

Figure 3. Polyphenols content (mg/100 g fw) and profile of sea buckthorn berries.

confirmed by George and Cenkowski.[27] They proved that three major fatty acids (palmitic, palmitoleic, oleic) accounted for approximately 32.2, 26.5, and 18.7% of the total fatty acids in the sea buckthorn fruit fraction, respectively. High levels of palmitoleic acid are present in only a few plants products, such as sea buckthorn pulp or macadamia nut oils. Because this fatty acid is a major constituent of skin fat, the pulp oil is used for cosmetic and healing purposes.[3]

Analysis of Hydrophilic Bioactive Compounds. L-Ascorbic Acid Content. Except for the lipophilic active compounds, such as carotenoids and phytosterols, sea buckthorn is also rich in hydrophilic substances known for health benefits properties, including L-ascorbic acid (Figure 2).

The mean content of ascorbic acid (AA) in the raw material was 80.58 mg/100 g. Likewise, as in the case of previously described compounds, the cultivar factor determined abundance of sea buckthorn in ascorbic acid ($p < 0.05$). The highest concentration of this compound were characterized in 'Aromatnaja' (130.97 mg/100 g fw) followed by 'Avgustinka' (88.45 mg) > 'Podarok Sadu' (82.61 mg) > 'Botaniczeskaja' (80.40 mg) > 'Moskwiczanka' and 'Porożrachnaja' (74.79 and 75.08 mg; $p > 0.05$) > 'Botaniczeskaja Ljubitelskaja' (59.48 mg) > 'Luczistaja' (52.86 mg). The presented results clearly showed that in terms of ascorbic acid content most of the examined sea buckthorn cultivars were definitely more valuable than many other popular fruit species including strawberries (65 mg/100 g fw), raspberries (29 mg), lemons (74.3 mg), mandarins (37.7 mg), or blackberry (21 mg).[28]

According to Tang,[29] the content of ascorbic acid in sea buckthorn (depending on the species, variety, region) was from 28 to 2500 mg/100 g. Berries of six cultivars examined by Rop et al.[30] contained between 398 and 573 mg AA/100 g fw (in 'Buchlovicky' and 'Ljubitelna', respectively). Kawecki et al.[31] determined the highest content of ascorbic acid in 'Trofimovskaja' (197 mg/100 g) > 'Otrodnaja' (191 mg) > 'Botaniczeskaja' (178 mg) > and 'Podarok Sadu' (161 mg). These values are therefore higher than in our study. However, the authors paid attention not only to varietal but also seasonal variation of ascorbic acid content in *H. rhamnoides* berries, which explains the observed differences.

Polyphenols Content and Profile. Interesting results were obtained indicating the content of polyphenols in sea buckthorn (Figure 3). Berries were characterized by a high concentration of flavonols (from 212.89 to 407.48 mg/100 g fw in 'Botaniczeskaja Ljubitelskaja' and 'Botaniczeskaja', respectively; $p < 0.05$). The structure of these compounds was investigated by qualitative analysis in LC-ESI/MS system performed in negative ionization mode (Table 3; Figure 4).

Table 3. LC-MS Identification of Sea Buckthorn Flavonols

no.	t_R[a] (min)	λ_{max}	$[M - H]^-$ (m/z)	MS-MS (m/z)	compound
1	5.56	352	639	315	isorhamnetin-3,7-diglucoside
2	5.90	354	785	639	isorhamnetin-3-sophoroside-7-rhamnoside
3	6.37	354	755	609	quercetin-glucoside-rhamnoside-7-rhamnoside
4	6.77	354	609	301	quercetin-3-rutinoside
5	7.33	352	609	301, 447	quercetin-3-glucoside-7-rhamnoside
6	7.51	354	771	625	quercetin-3-sophoroside-7-rhamnoside
7	7.59	355	623	315	isorhamnetin-3-rutinoside
8	8.49	348	593	285	kaempferol-3-rutinoside
9	8.78	353	623	315	isorhamnetin-3-rhamnosylglucoside
10	9.03	354	477	315	isorhamnetin-3-glucoside
11	11.28	356	869	723	isorhamnetin-3-acylo-glucoside-glucoside-7-rhamnoside

[a] t_R, retention time.

The examined sea buckthorn cultivars contained 11 flavonols, which were primarily derived of isorhamnetin (6 compounds), quercetin (4 compounds), and kaempferol (1 compound). The strongest signal in the obtained mass spectrum with a value of $[MH]^-$ at m/z 623 and a retention time of 8.78 min came from isorhamnetin-3-rhamnosylglucoside (compound **9**). The source of two successive intensity signals was compound **7** with a molecular weight $[M - H]^-$ at m/z 623 and **10** ($[MH]^-$ at m/z 477). In regard to the fragmentation direction of both compounds, that is, loss of the aglycone molecule with MS-MS (m/z) 315, UV−vis spectrum, and LC-MS standards analysis, as well as the literature data,[32] these compounds were identified as monoglycosides: isorhamnetin-3-rutinoside (compound **7**; t_R 7.59 min) and isorhamnetin-3-glucoside (compound **10**; t_R 9.03 min). Among the quercetin derivatives,

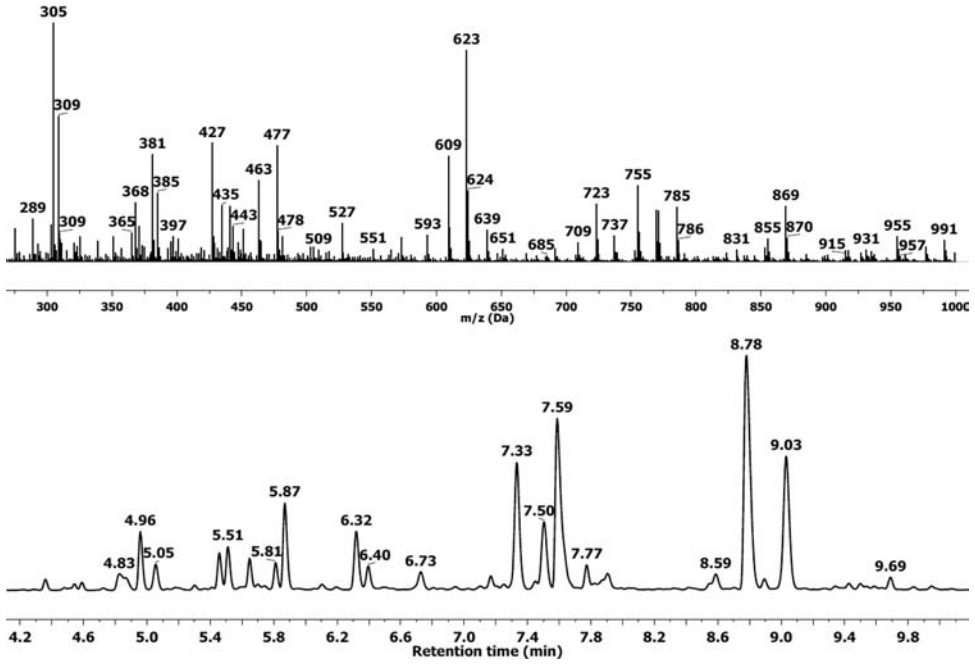

Figure 4. LC-ESI/MS spectrum and the chromatogram (360 nm) of sea buckthorn flavonols (cv. 'Porożrachnaja').

quercetin-3-glucoside-7-rhamnoside was dominant (compound **5**; $[MH]^-$ at m/z 609, t_R 7.33 min). After ion fragmentation, a strong, typical signal was registered from an ion with molecular mass MS-MS (m/z) 301. The signals from fission products of glucose ($[M - H^- 162]^-$ at m/z 447) and rhamnose ($[M - H^- 146]^-$ at m/z 463) were less abundant and characterized by a similar intensity.

According to Yang et al.[33] sea buckthorn berries of subsp. *mongolica* contain 80.6 mg flavonols/100 g fw, which is a significantly higher value than noted in chokeberry (23−40 mg/100 g fw),[34] cranberry (20−40 mg/100 g fw),[35] black currant (17−38 mg/100 g fw),[36] or bilberry (10−16 mg/100 g fw).[37,38] The results of our study also confirm this relationship;, however, in sea buckthorn we noted ca. a 4-fold higher content of flavonols.

The most common flavonols in sea buckthorn fruits are isorhamnetin derivatives with mono-, di-, and triglycoside structures.[33,39] As Pop et al.[40] research showed, in fruits and leaves of *H. rhamnoides* L. subsp. *carpatica* (cv. 'Serpenta', 'Serbanesti 4', 'Victoria', 'Sf. Gheorghe', 'Ovidiu', and 'Tiberiu') 17 and 19 flavonols occurred, respectively. Isorhamnetin-3-neohesperidoside, isorhamnetin-3-glucoside, isorhamnetin-3-rhamnosylglucoside, isorhamnetin-3-sophoroside-7-rhamnoside, and free isorhamnetin were predominant in the case of berries. In *rhamnoides* subspecies, the major compounds indicated by Kallio et al.[39] were isorhamnetin-3-sophoroside-7-rhamnoside > quercetin-3-glucoside > quercetin-3-rutinoside > isorhamnetin-3-rutinoside > isorhamnetin-3-glucoside. Chen et al.[41] isolated from the *n*-butanol fraction of sea buckthorn (subsp. *sinensis*) berries a novel acylated flavonol glycoside, isorhamnetin (3-*O*-[(6-*O*-*E*-sinapoyl)-*β*-D-glucopyranosyl-(1→2)]-*β*-D-glucopyranosyl-7-*O*-*α*-L-rhamnopyranoside), together with two known acylated flavonols glycosides, quercetin (3-*O*-[(6-*O*-*E*-sinapoyl)-*β*-D-glucopyranosyl-(1→2)]-*β*-D-glucopyranosyl-7-*O*-*α*-L-rhamnopyranoside) and kaempferol (3-*O*-[(6-*O*-*E*-sinapoyl)-*β*-D-glucopyranosyl-(1→2)]-*β*-D-glucopyranosyl-7-*O*-*α*-L-rhamnopyranoside). Due to such significant differences of sea buckthorn berries in terms of flavonol glycosides content, these compounds can be used as biomarkers for classification or recognition of sea buckthorn berries belonging to different species and varieties.[40]

Besides flavonols in sea buckthorn berries compounds belonging to three other groups of polyphenols, that is, polymeric proanthocyanidins, mono-, di-, and oligomers of flavan-3-ols, and phenolic acids, were determined. The highest contents of flavan-3-ols (88.04 mg/100 g fw) and phenolic acids (5.81 mg/100 g fw) were characterized by fruits of 'Avgustinka'. 'Luczistaja' was the richest in polymeric proanthocyanidins (5.76 mg/100 g fw), but contained the least value of phenolic acids (3.11 mg/100 g fw). Similarly to the flavonols determination, also flavan-3-ols concentration was the lowest in 'Botaniczeskaja Ljubitelskaja' (44.94 mg/100 g fw).

Compared to Hosseinian et al.[42] total proanthocyanidins content in examined samples was significantly different, especially in the case of polymeric form. In the whole fruit methanol fraction the authors noted 36.56 mg of polymeric proanthocyanidins per 100 g fw basis and 98.95 mg of mono-, di-, and oligomeric compounds. In our study a similar value of simple flavan-3-ols was determined only in 'Avgustinka' berries. This proves, however, that the content of polyphenols in plants is a result of many factors, such as cultivar, harvest year, or geographical origin. This correlation has been previously described in the literature.[43,44]

The proanthocyanidins profile in sea buckthorn is varied. According to Rösch et al.[45] the concentration of reaction products after acid-catalyzed cleavage (determined by HPLC) and calculated composition of sea buckthorn proanthocyanidins showed that major compounds were phloroglucinol adducts with (+)-gallocatechin, followed by (+)-catechin and (−)-epicatechin. The ratio between prodelphinidins (PD) and procyanidins (PC) was 2.1:1. On the basis of ESI-MS analysis, the authors detected compounds with different polymerization degrees, including pentameric, hexameric, heptameric, nonameric, and decameric proanthocyanidins.

With the phenolic acids structure taken into account, the compounds liberated from soluble esters are predominant in sea buckthorn berries (from 53.9 to 66.6%). Free phenolic acids are a minor fraction and constitute only 1.3−2.3%.[46] According to Arimboor et al.,[47] berry pulp contained a total of 1068 mg/kg phenolic acids, of which 58.8% was derived from phenolic glycosides. Free phenolic acids and phenolic acid esters constituted 20.0 and 21.2%, respectively. As the authors showed, gallic acid was identified as the predominant phenolic acid in both free and bound forms (66.0% of total phenolic acids in pulp). Considerable amounts of protocatechuic (136 mg/kg), ferulic (69 mg/kg), salicylic (54 mg/kg), *p*-hydroxybenzoic (40 mg/kg), and *p*-coumaric acid (37 mg/kg) were found to be present in berry pulp. The presence of vanillic (7 mg/kg), cinnamic (12 mg/kg), and caffeic acids (8 mg/kg) was also detected.

Sea buckthorn berries are a valuable source of compounds with beneficial effects for human health. The high concentrations of flavonols, L-ascorbic acid, but mostly lipophilic substances, namely, carotenoids, phytosterols, and fatty acids, determine the uniqueness of its chemical composition in comparison to other fruits. Our research confirms that the content of plant bioactives in the raw material significantly affects the cultivar factor. 'Aromatnaja' was characterized by the highest content of L-ascorbic acid and phytosterols, whereas 'Podarok Sadu' berries were rich in PUFAs. In 'Moskwiczanka' the highest carotenoids and in 'Botaniczeskaja' the highest polyphenol concentrations were noted.

Among the tested active compounds of sea buckthorn, the most diverse was the phytosterols profile, which consisted of 14 compounds, including 4-desmethyl sterols (e.g., β-sitosterol, stigmasterol, campesterol, Δ^5-avenasterol), 4α-monomethyl sterols (e.g., citrostadienol), and 4,4-dimethyl sterols (e.g., 24-methylenecycloartanol).

J. Agric. Food Chem. 2015, 63, 4120−4129

content in rice was about 130 mg/100 g of grain. The content of proanthocyanidins in barley varied between 25 and 250 mg/100 g of grain.[4,10−12] Kamimura and Takahashi[13] demonstrated that procyanidin B-3 from barley can directly promote hair epithelial cell growth *in vitro*, counteract the growth-inhibiting effect caused by TGF-β1 *in vitro*, and stimulate anagen induction *in vivo*.

The analytical technique usually applied to determine the proanthocyanidins in cereal consist of high-performance liquid chromatography (HPLC) coupled to a diode array detector (DAD), fluorimetric detector (FLD), and mass spectrometer detector (MSD)[5,6,14] or matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) analysis.[15] However, in the last few years, the use of infrared (IR) spectroscopy as a non-destructive method has been evaluated.[16−18]

Because of the large use of barley in food production, the aim of this work was to investigate the oligomeric proanthocyanidin content in different barley genotypes (waxy and non-waxy) using high-performance liquid chromatography−fluorescence detection−electrospray ionization−mass spectrometry (HPLC−FLD−ESI−MS). Moreover, Fourier transform near-infrared (FT-NIR) spectroscopy was performed to evaluate the possibility to discriminate between waxy and non-waxy samples and to estimate the proanthocyanidins in barley flours using a fast and non-destructive method.

MATERIALS AND METHODS

Samples. A total of 14 different varieties of barley grown under the same agronomic conditions in the same experimental field at the Department of Food Technology (DISTAAM), University of Molise (Italy) (41° 34′ 00″ N, 14° 40′ 00″ E) were analyzed.

The soil of the site is classified as a fine silty clay loam with 29% silt, 35% clay, 36% sand, 1.7% organic matter, total available P (6.1 mg kg^{-1}), total available K (78.3 mg kg^{-1}), and pH 7.3.

The trials were sown in a three-replication split-plot experimental scheme in October 2013 (sowing density was 300 seeds/m^2). Four of the barley varieties were waxy genotype (Canada, USA2, USA3, and USA7), and the other 10 were non-waxy genotype (Acquarelle, Bombay, Boreale, Margret, Messina, Metis, Naturelle, Otis, Rangoon, and Svenja). Harvest took place in June 2014 at grain full-ripening stage.

Whole grains were milled (particle size of 150−250 μm), and the flours were used for the analysis. The resulting flours reported moisture between 11.4 and 12.0%.

Chemicals. HPLC-grade acetonitrile, water, methanol, and acetone were purchased from Merck KGaA (Darmstadt, Germany). Catechin and procyanidin B2 were from Sigma-Aldrich (St. Louis, MO).

Extraction of Proanthocyanidins in Barley Samples. The protocol of Verardo et al.[11] was used to isolate the proanthocyanidin fraction. Briefly, barley flour (2 g) was extracted in an ultrasonic bath (20 min) with 20 mL of a solution of acetone/water (4:1, v/v). After centrifugation at 1000*g* for 10 min, the supernatant was removed and the extraction was repeated once more. The supernatants were collected, evaporated, and reconstituted in 2 mL of methanol/water (1:1, v/v). The final extracts were filtered through 0.2 μm polytetrafluoroethylene (PTFE) syringe filters and stored at −18 °C until the analyses.

Determination of Proanthocyanidin Compounds by HPLC−FLD−ESI−MS. Normal-phase (NP)-HPLC analysis was performed by an Agilent 1200 Series (Agilent Technologies, Santa Clara, CA), equipped with a binary pump delivery system, a degasser, an autosampler, a FLD, and a MSD.

A Develosil Diol 100 Å column, 5 μm, 250 × 4.6 mm inner diameter (Phenomenex, Torrance, CA), was used. All solvents were HPLC-grade and filtered through a 0.45 μm filter disk. The gradient elution was the same reported by Robbins et al.[19] Fluorescence detection was conducted with an excitation wavelength of 230 nm and an emission wavelength of 321 nm.

The injection volume was 5 μL. All of the analyses were carried out at 35 °C. Calibration curves of (+)-catechin and procyanidin B2 were arranged from 5 to 500 and from 1 to 500 μg/mL, respectively, at six concentration levels for each compound; correction factors suggested by Robbins and co-workers[19] were used for trimer, tetramer, and pentamer compounds.

The HPLC analysis was replicated 3 times for each extract and calibration point (n = 3).

Mass spectrometer analyses were carried out using an electrospray ionization (ESI) interface at the following conditions: drying gas flow (N_2), 9.0 L/min; nebulizer pressure, 50 psi; gas drying temperature, 350 °C; capillary voltage, 3500 V; and fragmentor voltage and scan range, variable. The fragmentor and m/z ranges used for HPLC−ESI/MSD analyses were as follows: 120 V and m/z 50−1000 and 140 V and m/z 1000−2000.

FT-NIR Spectroscopy. A spectrophotometer Vector 22/N (Bruker Optics, Ettlingen, Germany) in diffuse reflectance mode was used to obtain the NIR spectra. The instrument was equipped with a rotating integrating sphere that allows for a wide illumination of the sample and a better reduction of light scattering because of the irregularity of the particle surfaces. NIR spectra were obtained by an average of 32 scans of each sample. Three replicates for each individual sample (about 60 g of barley flours) were collected for a total of 42 spectra. The background was defined by acquiring the spectrum of the quartz support without the sample in the same instrumental conditions (25 °C). The speed of acquisitions was 10 kHz in a range from 800 to 2500 nm.

Statistical Analysis. The Pearson correlation coefficients (p < 0.05) were calculated to define a relation between the proanthocyanidins using Statistica 8.0 software (2007, StatSoft, Tulsa, OK).

Significant differences (at p < 0.05) between means of the proanthocyanidin compounds were explored using analysis of variance (ANOVA) combined with Tukey's post-hoc test using Statistica 8.0 software. Mean-centered data were subjected to principal component analysis (PCA) to find a possible discrimination between the sample as a function of barley genotypes (waxy and non-waxy) using The Unscrambler, version 9.7 (CAMO, Oslo, Norway).

With regard to the NIR spectra, to remove the effects of light scattering, NIR spectra were pretreated with multiplicative scattering correction (MSC). The first part of the spectra, until 1100 nm, was deleted before processing because it contained no useful chemical information but only instrumental noise. Data were also treated by applying the first derivative (Savitsky−Golay) to the absorbance data. Subsequently, the spectral data were subjected to PCA and partial least square (PLS) regression. The first one was applied as an exploratory analysis to define a possible discrimination between the sample as a function of barley genotypes (waxy and non-waxy), while the second one was applied to predict the proanthocyanidin compounds. The PLS models were validated using a full cross-validation and a test set validation technique. For the first validation, the same data set, characterized by an amount of 42 cases (three replicates for 14 samples), was used to calibrate and validate the model: a sample of total entire data set is removed one by one from the construction of the model and used to validate. For the test set validation, the data set was randomly divided into two sub-samples, one to calibrate the system (70% of the entire data set) and the other (30%) to validate it. Test set validation was repeated 5 times for each reference value (proanthocyanidin compounds), and the prediction indices [determination coefficient (R^2) and root mean square error (RMSE)] were averaged, because the PLS convergence is influenced by the data set.

All of the statistical elaborations were carried out using The Unscrambler, version 9.7 (CAMO, Oslo, Norway).

RESULTS AND DISCUSSION

Proanthocyanidin Identification by HPLC−ESI−MS. The method established by Robbins et al.[19] was used to

DOI: 10.1021/acs.jafc.5b01425
J. Agric. Food Chem. 2015, 63, 4130−4137

determine the proanthocyanidin oligomers in barley flours, and the resulted chromatogram is shown in Figure 1.

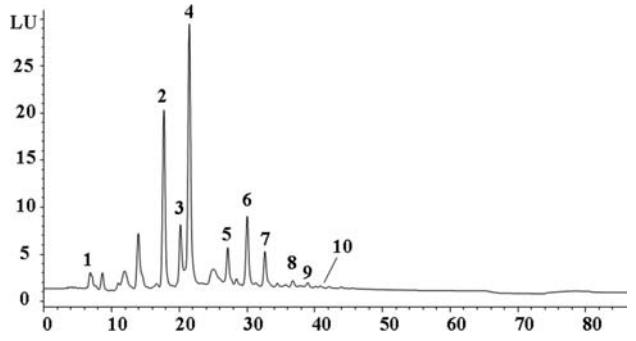

Figure 1. HPLC–FLD chromatogram of oligomeric proanthocyanidins in the barley sample. The number of the peaks are the same as reported in Table 1.

To identify the proanthocyanidins revealed by fluorimetric detection, mass spectrometry was used to confirm the peak identity (Table 1). As reported from several authors,[19,20] the compounds eluted according to their degree of polymerization, first eluting the monomers and then the different oligomers according to their degree of galoylation (for the same degree of polymerization).

Table 1. HPLC–ESI–MS Data of Proanthocyanidins in Barley Samples

	compound	Rt (min)	$[M - H]^-$	fragment (m/z)
1	catechin/epicatechin	7.13	289	245
2	procyanidin dimer	17.61	577	425, 289
3	prodelphinidin dimer I	20.30	593	467, 425, 289
4	prodelphinidin dimer II	21.66	593	467, 425, 289
5	procyanidin trimer	27.30	865	739, 713, 289
6	prodelphinidin trimer I (monogalloylated)	30.00	881	593, 577, 303
7	prodelphinidin trimer II (digalloylated)	32.87	897	771, 729, 593
8	procyanidin tetramer	36.65	1153	865
9	prodelphinidin tetramer (digalloylated)	38.81	1457	728
10	procyanidin pentamer	41.03	1441	

Catechin/epicatechin was the first compound that was identified. It provided a molecular ion at m/z 289; in addition, a fragment ion at m/z 245 ($[M - H - CO_2]^-$) was also shown.

Several oligomeric procyanidins (PCs) and prodelphinidins (PDs) were identified; many of them reported the fragmentation pathways for proanthocyanidins, such as (a) retro-Diels–Alder (RDA) cleavage and subsequent elimination of a water molecule, (b) interflavanic bond cleavage through the quinone–methine (QM) mechanism, and (c) heterocyclic ring fission (HRF).[5]

A procyanidin dimer with molecular ion at m/z 577 and two principal fragments at m/z 425 and 289 (corresponding to RDA and QM, respectively)[21] was detected at 17.6 min.

Two prodelphinidin dimers were also detected at 20 and 20.2 min; they showed a molecular ion at m/z 593 and three fragment ions at m/z 467, 425, and 289 corresponding to HRF, RDA, and QM, respectively.[5]

For procyanidin trimer (molecular ion at m/z 865), fragments at m/z 739, 713, and 289 were obtained as a result of HRF, RDA, and QM, respectively.

Two single peaks eluting at 30 and 30.2 min with m/z 881 and 897 ($[M - H]^-$) were detected. The first peak produced three fragment ions at m/z 593, 577, and 303. This compound was identified as prodelphinidin trimer monogallate; moreover, the presence of fragment ions at m/z 593 (corresponding to GC–C dimer) and m/z 577 (corresponding to C–C dimer) suggested that the peak was the sum of (epi)gallocatechin–(epi)catechin–(epi)catechin and (epi)catechin–(epi)-gallocatechin–(epi)catechin trimers.

The other peak at m/z 897 with fragment ions at m/z 771, 729, and 593 was identified as digalloylated prodelphinidin trimer according to Friedrich and co-workers.[22]

Two proanthocyanidin tetramers were detected. Procyanidin tetramer with molecular ion at m/z 1153 and a fragment ion at m/z 865 ($[M - H - \text{catechin}]^-$) was revealed at 36.7 min.

A prodelphinidin tetramer at 38.8 min was identified because of its molecular ion at m/z 1457; the fragment ion at m/z 728 permits identifying this compound as digalloylated oligomer, according to Lazarus et al.[23]

Finally, the compound at 41.0 min and m/z 1441 was identified as procyanidin pentamer according to Robbins et al.[19] As far as we are concerned, this is the first time that procyanidin pentamer has been detected in barley samples.

Proanthocyanidin Quantification by HPLC–FLD. To quantify the proanthocyanidins in barley samples, catechin and procyanidin B2 calibration curves were used. Moreover, the correction factors suggested by Robbins and co-workers[19] were chosen to calculate trimer, tetramer, and pentamer contents.

Barley samples exhibited ample variability of total proanthocyanidin content, with a range from 293.2 to 652.6 μg/g of flour (Table 2), and waxy and non-waxy genotypes reported statistical differences ($p < 0.05$). In fact, the mean of the total oligomeric content in waxy genotypes was about 1.6 times higher than that in non-waxy samples.

Monomers ranged between 10.9 and 48.3 μg/g of flour in non-waxy barley samples, whereas the content of monomers in waxy barley was significantly higher ($p < 0.05$), ranging from 44.1 to 87.1 μg/g of flour. Generally, these data are in the same order of magnitude of those reported by other authors.[12,24,25]

Dimer compounds were the principal proanthocyanidin constituents of barley samples. Total dimers content ranged between 116.8 and 214.6 μg/g of flour, and these amounts are in agreement with the results reported in the literature.[12,24,25] As seen for monomers, waxy samples showed a higher content of dimers (182.9–214.6 μg/g of flours) compared to non-waxy samples (116.8–173.8 μg/g of flour). Procyanidin dimers represented 35.4–51.2% of the total dimer class, and waxy samples contained a higher content (except for the Bombay sample), with an average of 89.6 μg/g of flour. Barley samples contained from 67.8 to 118.6 μg/g of flour of total prodelphinidin dimers, and waxy samples showed the highest content.

Proanthocyanidin trimers ranged between 149.8 and 317.4 μg/g of flour. Significant differences ($p < 0.05$) between waxy and non-waxy samples were found for procyanidin trimer: waxy samples showed an average of 127.4 μg/g of flour, while non-waxy barley had an average of 61.3 μg/g of flour. Similar amounts were determined by Holtekjølen and co-workers.[12]

According to Holtekjølen and co-workers,[12] monogalloylated prodelphinidin trimers ranged between 53.6 and 105.3 μg/g of flour and represented 55.5−70.0% of total prodelphinidin trimers. Digalloylated prodelphinidin trimers were 31.7−63.7 μg/g of flour. No statistical differences ($p < 0.05$) between waxy and non-waxy samples were noticed for prodelphinidin trimer content.

Tetramers constituted 6.3−10.0% of total proanthocyanidin content, and their amounts varied from 20.8 to 55.2 μg/g of flour. Procyanidin tetramers ranged from 6.7 to 18.9 μg/g of flour, whereas digalloylated prodelphinidin was contained in the range of 14.1−36.3 μg/g of flour; no statistical differences ($p < 0.05$) were shown between waxy and non-waxy samples.

Pentamer oligomers were represented exclusively by one procyanidin that showed a total content from 4.5 to 22.7 μg/g of flour; waxy samples showed a higher content (average 14.3 μg/g of flour) compared to non-waxy samples (average 6.6 μg/g of flour).

The sum of tetramers and pentamers is in the same order of magnitude of the results reported by Hellström and co-workers.[6]

When the data obtained for barley to literature results[4,8] about other cereals are compared, it is evident that sorghum and rice are characterized by a higher content of total proanthocyanidins and a higher degree of polymerization of proanthocyanidins. As reported by several authors,[4,26] sorghum proanthocyanidins were represented by 68% of polymers, followed by oligomers from 4 to 10 monomeric units. A similar composition was reported by Min et al.[8] for rice. Instead, barley showed a low degree of polymerization, from monomers to pentamers, but reported a higher content of dimers and trimers compared to sorghum and rice and a higher content of monomers than rice and equal or higher than sorghum.

This aspect encourages the use of barley in functional food formulation as a cereal source of proanthocyanidins because, as reported by Ou and Gu,[1] proanthocyanidins with a degree of polymerization over 4 (DP > 4) are not absorbable because of their large molecular size and gut barrier.

The Pearson correlation matrix (Table 3) points out that all of the compounds are positively correlated; the correlation between PD trimer II and monomers or PD dimer I is not significant.

The score plot of the PCA performed to discriminate between samples with different barley genotypes is reported in Figure 2. The two first principal components accounted for 83% of total variance. PC1, explaining 66% of total variation, is clearly linked to proanthocyanidin composition. A clear separation between waxy (gray) and non-waxy (black) samples

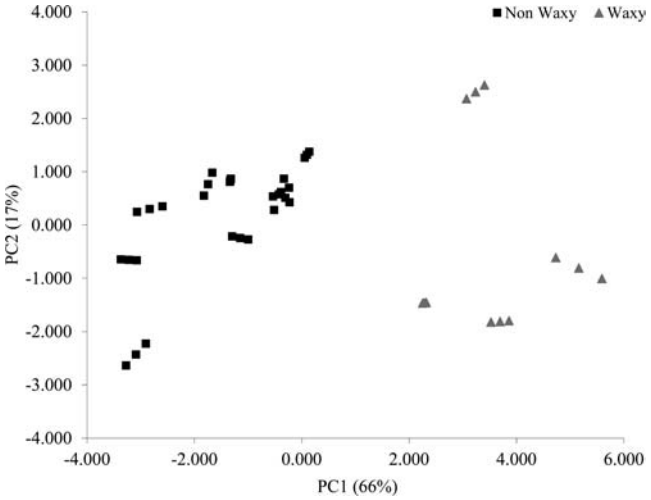

Figure 2. Score plot obtained by the PCA of the proanthocyanidin compounds determined by HPLC−FLD.

was observed. The waxy samples were grouped along the positive values of PC1 (x axis), while the non-waxy samples were grouped on the negative side of the axis.

The X-loadings plot shows how well a variable is taken into account by the model components, and it is used to understand how much each variable contributes to the meaningful variation in the data and to interpret variable relationships. Further, the comparison between score and loadings plot allows for interpretation of the relationships and dependence between variable and samples. In this case, the X-loadings plot (Figure 3) shows that all waxy samples are characterized by higher values of all proanthocyanidin compounds than non-waxy samples. Particularly, the USA3 sample, with respect to the other waxy samples, is characterized by a high content of PD trimer II, PD dimer II, and PD trimer I and by a low content of monomers, PD dimer I, and PC trimer.

NIR Spectroscopy. NIR spectra provided characteristic broad and overlapping peaks between 1100 and 2500 nm. The spectra of all of the samples and an example of first derivate are reported in Figure 4. All of the samples showed the main absorption bands. In particular, the overtones of the C−H bonds of the methylic and methylenic groups between 1170 and 1230 nm, the bands of the O−H bonds because of water and starch at about 1450 and 1940 nm, and the bands of the N−H bonds at about 1500−1570 and 2050−2070 nm were identified. The absorptions of constituents, such as starch, cellulose, and protein, are located at higher wavelengths. The flavonoid constituents can be observed in the regions from

DOI: 10.1021/acs.jafc.5b01425

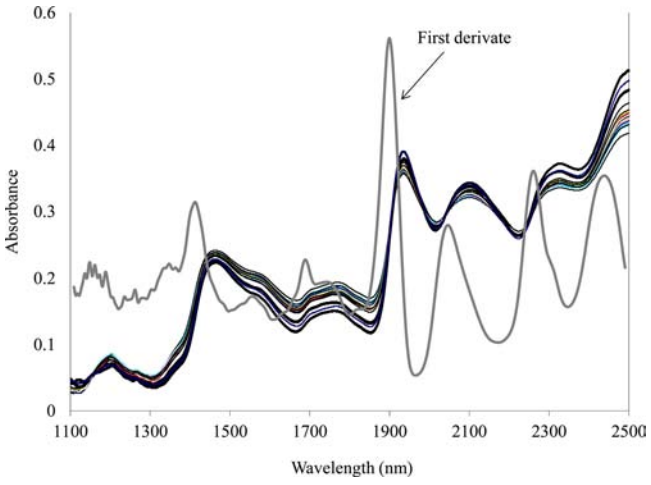

Figure 4. NIR spectra and first derivate.

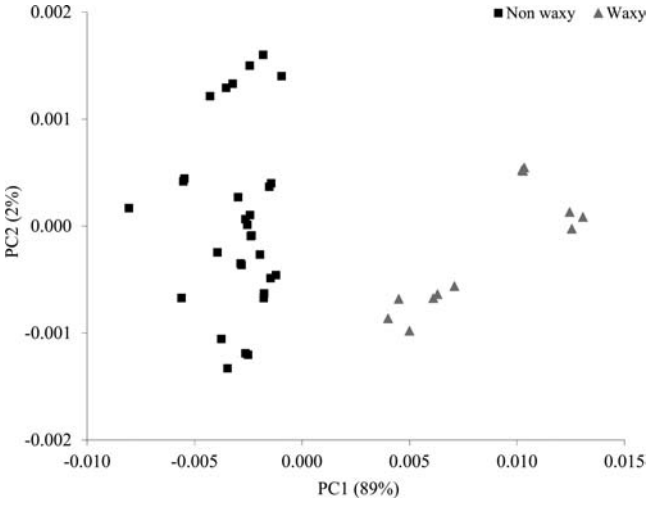

Figure 5. Score plot obtained by the PCA of the proanthocyanidin compounds determined by FT-NIR.

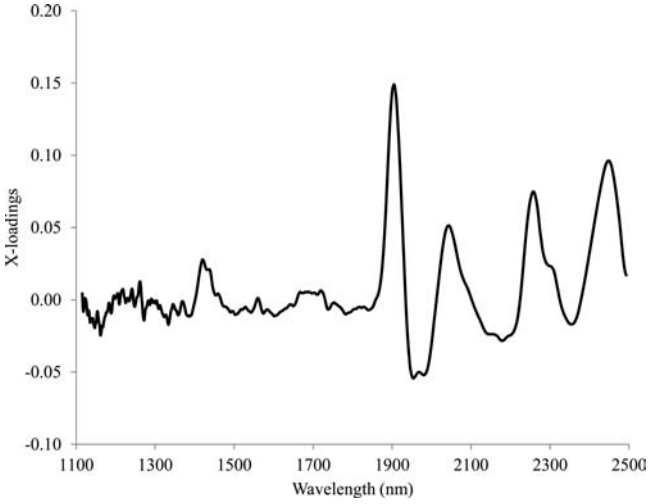

Figure 6. X-loadings for the PCA carried out with NIR spectra (from 1100 to 2500 nm).

1415 to 1512 nm, from 1650 to 1750 nm, and from 1955 to 2035 nm.[16,17,27]

The score plot of the PCA (in the 1100−2500 nm range, with MSC and first derivate treatments), performed to discriminate between waxy and non-waxy samples, is reported in Figure 5. A clear separation between waxy and non-waxy samples was observed along the PC1 (89%). The X-loadings plot (Figure 6) of the first component shows that maximum variance between spectra was identified from 1850 to 2500 nm; as a consequence, the discrimination might be attributed to flavonoid constituents, starch, cellulose, and protein.

The potential of NIR to determine proanthocyanidin oligomers in barley has been evaluated. Table 4 shows the results of PLS regressions in terms of R^2 and RMSE for calibration, full cross-validation, and test set validation. The models were built considering all of the spectrum points (from 1100 to 2500 nm) or the only absorption bands related to phenolic and flavonoid constituents (1415−1512, 1650−1750, and 1955−2035 nm). Generally, in full cross-validation and test set validation, the best results were obtained using the NIR regions associated with phenolic and flavonoid constituents. In full cross-validation, the R^2 values range from 0.94 (PC tetramers) to 0.98 (monomers), while in test set, the R^2 values range from 0.97 (PC trimer) to 0.92 (PD trimer II). However, the difference between the results obtained using all of the spectrum points and bands related to phenolic and flavonoid constituents is very low.

Because of that, the capability of FT-NIR spectroscopy technology as a rapid and non-destructive method to determine the proanthocyanidin oligomers in barley samples could be hypothesized.

In conclusion, the coupling of HPLC with FLD and MSD allows for the determination of proanthocyanidin oligomers in barley samples. Proanthocyanidins include procyanidins and prodelphinidins, and some of them are galloylated. The lower degree of polimerization of barley proanthocyanidins compared to other cereals encourages the use of barley in food formulation. Moreover, waxy barley genotype showed a higher proanthocyanidin content than non-waxy genotype.

In addition, the PLS results obtained by FT-NIR spectroscopy indicate that IR methodology has a good potential to predict proanthocyanidin compounds in barley samples. This aspect represents an advantage and proposes the use of this fast and non-destructive methodology for industry application. To confirm these preliminary results and the performance of NIR

digestive physiology as a functional dietary fiber, which escapes digestion before the colon but can be fermented by the colonic bacteria. Depending on this property, it has been reported from our group that RS3[12] and RSA (resistant starch acetate; one of RS4) can be used as potential carrier materials for oral colon-specific drug delivery.[13−16]

However, the bioadhesion of RS is nonspecific, which may limit the delivery efficacy (including targeting accuracy) and the bioavailability of bioactive peptides and proteins.[17,18] It has been found that the GI mucosa epithelial cells are covered with specific glycan moieties in different sites of the GI tract.[19,20] If RS is coupled by certain ligands that can bind to the surface of predetermined colonic mucosa epithelial cells, the specific bioadhesion of RS carriers could be achieved, with increased residence time and enhanced adsorption of bioactive peptides and proteins in the colon. Lectins are glycoproteins of nonimmune origins that are able to specifically recognize sugar molecules and bind to glycosylated membrane components. Lectin−sugar interactions play crucial roles in many cell recognition and adhesion processes.[21−24] It has been reported that lectin-conjugated particles were of benefit to bioactive ingredients absorption because of the interactions between lectin and cells.[25,26] Considering this, it is worth conjugating suitable lectin to RSA, which has proved to have good colonic targeting and controlled-release properties.[13] Using this method, a colon-specific bioadhesive delivery system might be achieved that will improve the oral bioavailability of bioactive peptides and proteins.

In this regard, the fluorescein-labeled lectins (wheat germ agglutinin, concanavalin-A, peanut agglutinin, *Lens culinaris*, *Dolichos biflorus* agglutinin, *Ulex europaeus* agglutinin I, *Pisum sativum* agglutinin, *Phaseolus vulgaris* agglutinin and *Galanthus nivalis* agglutinin) of different carbohydrate specificities were screened in our lab for binding to human colonic mucosa epithelial cells through three types of human GI mucosa epithelial carcinoma cells, namely, MGC803, Hic, and Caco-2 cell lines, which were derived from human stomach, small intestine, and colon carcinomas, respectively. In addition, the colon-bioadhesion of the screened lectins was confirmed further in vivo in the gastrointestinal epithelial tissues of rats by tissue immunocytochemistry. Our previous research indicated that concanavalin A (Con A), one of the most abundant lectins that could bind to the mannose of glycoprotein on the surface of cells,[27] showed better colon bioadhesion. Thus, this lectin was conjugated to the surface of RSA-film-coated microparticles. The structure of the Con A−RSA complex was investigated using Raman spectra and X-ray diffraction. On the basis of this, the insulin-loaded microparticles coated with this Con A−RSA complex film were prepared, and their colonic targeting and bioadhesion of the decorated microparticles were determined by in vivo optical imaging and tissue section tests. Furthermore, the in vivo hypoglycemic response of this kind of insulin-loaded microparticles was evaluated in streptozotocin (STZ)-induced diabetic rats.

MATERIALS AND METHODS

Materials. RSA was synthesized in our laboratory according to a previously published method.[13] 1,1′-Carbonyldiimidazole (CDI) was purchased from Alfa Aesar. (Shanghai, China). Commercial long-acting insulin glargine injection was supplied by Sanofi-Aventis Deutschland GmbH (Frankfurt am Main, Hessen, Germany). Microcrystalline cellulose was purchased from Anhui Shanhe Medicinal Accessary Material Co., Ltd. (Huainan, Anhui, China). Insulin was purchased from Newprobe Bioscience & Technology Co., Ltd. (Beijing, China). Native corn starch (medicinal grade) used for excipients in the preparation of insulin-loaded microparticles cores was supplied by Defeng Starch Sugar Co., Ltd. (Shunde District, Foshan, Guangdong, China). Con A, molecular weight 102 000, was purchased from Medicago (Quebec, Canada). Fluorescein isothiocyanate (FITC), glycine, and STZ were purchased from Sigma-Aldrich Co. LLC (Santa Clara, CA, USA). Acetone, ethanol, phosphate buffer solution, isoflurance, ether, and glucose were purchased from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China). The remaining chemical reagents were of analytical grade.

Synthesis of Con A-Conjugated RSA. Con A was introduced to the hydroxyl groups of RSA by the CDI activation method.[28] RSA was suspended in acetone, followed by the addition of CDI, and stirred at 30 °C for 8−26 h. The concentration of RSA was 10−35%. The weight ratio between CDI and RSA was 0.08−0.5. After reaction, the mixture was filtered and washed with ethanol to remove unreacted CDI. The product (N-resistant starch acetate imidazolyl carbamate) was dried at 45 °C and sieved. The nitrogen content was determined by a Kjeldahl meter (BÜCHI distillation unit B-324, Buchi, Flawil, Switzerland). Then 1−10 g of N-resistant starch acetate imidazolyl carbamate was suspended in phosphate buffer solution (10 mmol/L; pH 7.4), followed by addition of Con A (the weight ratio between N-resistant starch acetate imidazolyl carbamate and Con A was varied from 0.001 to 0.03) and kept at 37 °C for 8−28 h. After reaction, the products were filtered and washed several times in phosphate buffer solution to remove unreacted Con A and incubated for 1 h in 0.5% glycine (w/v) in phosphate buffer solution to quench activated sites to which Con-A was not bound. The filtrate and washing liquor after reaction were collected, and the leftover of Con A was analyzed using a Coomassie Brilliant Blue kit (G-250, Bio-Rad Corp., Hercules, California, America) at 595 nm by a UV spectrophotometer (Unico, UV-3802, Shanghai, China). The coupled Con A was the difference value of Con A between the amount added and that left without reaction.

Structures of Con A-Conjugated RSA. *Raman Spectrometry.* The Raman spectra were acquired using a micro-Raman spectroscopy system (LabRAM Aramis, Horiba Jobia Yvon Corp., Villeneuve d'Ascq, France) equipped with a 532 nm laser source and grating of 1200 g/mm. Data were collected over a range of 100−4000 cm^{-1} at an interval of 1 cm^{-1} using 2 scans per sample with an exposure time of 5 s.

X-ray Diffraction. Wide-angle X-ray powder diffraction analysis was performed using an X-ray diffractometer (X'Pert Prox, Panalytial, Eindhoven, Netherlands) operating at 40 kV and 40 mA with Cu−K radiation (λ = 0.1542 nm). The diffractograms of samples were acquired at an angular range of 2θ from 4° to 60° with a step size of 0.033° and a counting time of 4 s for each step. The samples were sieved through 0.180 mm and equilibrated at 25 °C for 24 h prior to the analysis.

Preparation of Con A−RSA Film-Coated Microparticles. The preparation of insulin-loaded microparticle cores were obtained via extrusion−spheronization.[13] The N-resistant starch acetate formate imidazole obtained above was dissolved in acetone at a concentration of 5% and used as the initial coating material. The 1% insulin-loaded microparticle cores (500 μm in diameter) were coated by a bottom-spray method in a fluidized bed coater (Mini-XYT, Xinyite Co., Ltd., Shenzhen, Guangdong, China) until a proper film coating thickness was achieved, which was represented by the dry weight gain of the microparticles.[13] The parameters for the film coating process were as followed: inlet temperature, 30−35 °C; product temperature, 23−27 °C; spray rate, 0.7−0.8 mL/min; atomization pressure, 0.125−0.2 MPa; and fluidization pressure at 0.1−0.15 MPa. Then the film-coated microparticles were conjugated with Con A according to the method mentioned above and dried at 26 °C.

In Vivo Colonic Targeting and Bioadhesion of the Con A−RSA Film-Coated Microparticles. *In Vivo Fluorescent Imaging.* Six 5- or 6-week-old SPF grade nude mice (half males and half females, Vital River Laboratory Animal Technology Co., Ltd., Beijing, China)

DOI: 10.1021/acs.jafc.5b00393
J. Agric. Food Chem. 2015, 63, 4138−4147

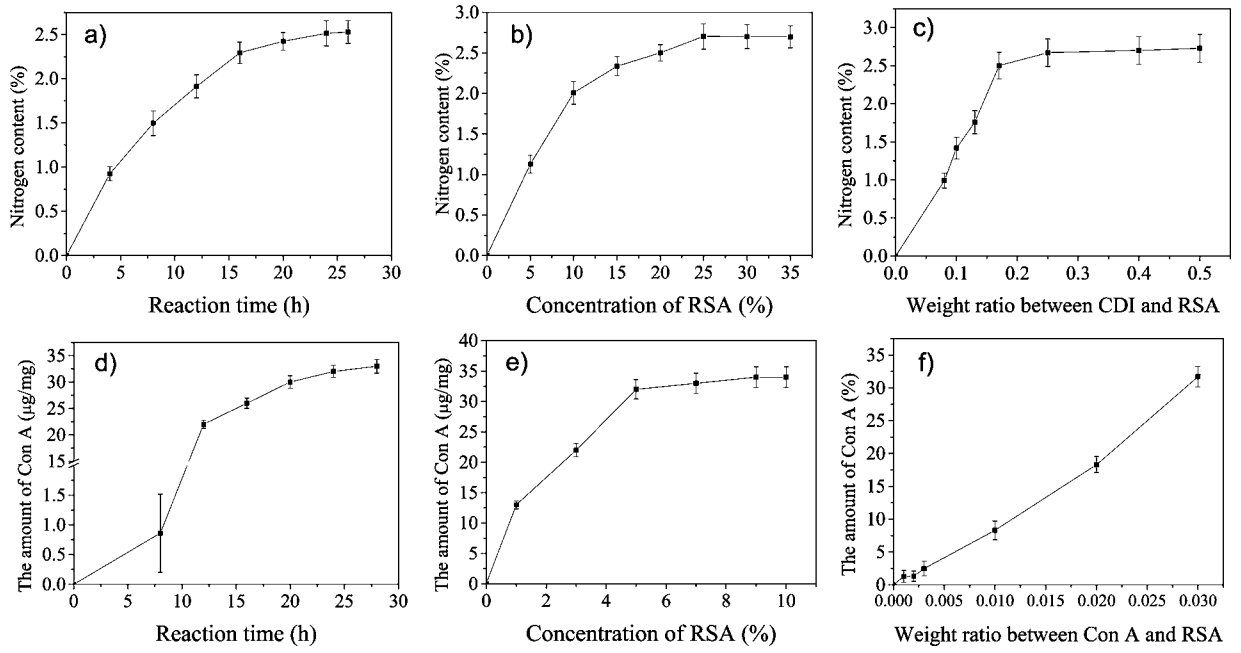

Figure 1. Effects of reaction time (a), concentration of RSA (b), weight ratio between 1,1′-carbonyldiimidazole and RSA (c) on the RSA activation by 1,1′-carbonyldiimidazole method; and the effects of reaction time (d), concentration of RSA (e), and weight ratio between Con A and RSA (f) on the reaction of Con A conjugated to RSA.

weighing approximately 12−14 g were fasted for 24 h before the study. The FITC-loaded microparticles coated with Con A−RSA film were orally administrated to the stomach via polyethylene tubing under light ether anesthesia. The microparticles were dosed at 0.2 mg per gram of body weight. At 2, 8, 14, and 44 min and at 24, 48, and 72 h after oral administration, the fluorescence intensity and transmission of the microparticles in the nude mice were observed by a whole-body small-animal in vivo imaging system (IVIS 200, Xenogen Corp., Alameda, CA, USA) at 445−490 nm of exciting light and 515−575 nm of emitted light with an exposure time of 5 s. The nude mice were anesthetized by isoflurance before being photographed.

Tissue Slices and Fluorescence Distribution. Six 5- or 6-week-old SPF grade KM mice (half males and half females, Vital River Laboratory Animal Technology Co., Ltd., Beijing, China) weighing approximately 18−22 g were fasted for 24 h before the study. The oral administration and dosage of FITC-loaded microparticles coated with Con A−RSA film was described in the previous section In Vivo Fluorescent Imaging". At 2, 4, 12, 24, 48, 72, and 144 h after oral administration, the mice were sacrificed by cervical dislocation, and the tissues of the stomach, small intestine, and colon were obtained. After washing the mucosal surface, the different parts of the mouse GI tract tissues were embedded with Optimum Cutting Temperature Compound and then cut on a cryostat microtome (Shandon cryotoZFE, ThermoFisher Scientific Inc., Waltham, MA USA) into 5 μm sections, and the tissue slices were thaw-mounted onto surface-treated glass slides. The FITC distribution in the different parts of the mouse GI tract and the fluorescence intensity were observed by a fluorescence microscope (BX51TRF, Olympus, Tokyo, Japan) at 445−490 nm of exciting light and 515−575 nm of emitted light.

In Vivo Hypoglycemic Response of Insulin-Loaded Microparticles Coated with Con A−RSA Film. The in vivo hypoglycemic response of the microparticles was evaluated using STZ-induced diabetic male Sprague-Dawley (SD) rats (Guangdong Animal Experimental Centre, Foshan, Guangdong, China).[12] The type II diabetic rats were randomly divided into five groups (n = 5 for each group, and the average plasma glucose concentrations of the different groups differed less than 2 mmol/L). The group that was subcutaneously injected with commercial long-acting insulin glargine injection at 35 IU/kg was the positive control group, and the diabetic group without insulin treatment was the negative control group. The other three groups are experimental groups. Before the tests, all the rats were fasted for 12 h with free access to water.

Effect of Con A Conjunction on the Surface of RSA Film on the Hypoglycemic Response after Single-Dose Oral Administration. The insulin-loaded microparticles coated by RSA film and Con A−RSA film were orally administered to the stomach via polyethylene tubing under light ether anesthesia. Insulin was dosed at different dosages: 60, 80, and 100 IU per kg body weight. After insulin administration, the rats in all the groups were allowed to diet freely. At predetermined time points, the plasma glucose concentrations of the rats were monitored by the glucose oxidase method.

Hypoglycemic Response after Successive Oral Administration. Current clinical use of long-acting insulin injections is generally subcutaneously injected at 19:00−21:00 every day. To coincide with the clinical use, the insulin-loaded microparticles coated with Con A−RSA film were orally administered at 19:00 on each of 5 consecutive days. On the first day, the insulin was dosed at 100 IU/kg; and from the second to the fifth days, the dose was 25, 40, 50 IU/kg, respectively. According to the predetermined time points for monitoring the plasma glucose concentrations of people with diabetes, the plasma glucose concentrations of the rats were monitored immediately before and 2 h after breakfast (8:00), lunch (12:00) and dinner (17:00) every day by the glucose oxidase method.

Oral Glucose Tolerance Test (OGTT). After oral administration for 5 successive days of the insulin-loaded microparticles coated with Con A−RSA film, all the rats from each group were fasted for 12 h with free access to water and orally administered with 20% glucose solution at 5.0 g/kg, and the rats of the negative control group received the same volume of distilled water. After glucose administration, the plasma glucose concentrations of the rats were measured at 30, 60, and 120 min.

Statistical Analysis. All data were subjected to statistical analysis using the SPASS 10.0 statistical package and were presented as mean ± standard deviation (± SD). Differences between groups were estimated by analysis of t test, and $P < 0.01$ was considered to indicate a statistically significant difference between two groups.

RESULTS AND DISCUSSION

Synthesis of Con A-Conjugated RSA. Con A was introduced to the hydroxyl groups of RSA by the conventional

DOI: 10.1021/acs.jafc.5b00393
J. Agric. Food Chem. 2015, 63, 4138−4147

CDI activation method.[28] The RSA with a DS of 1.94 and resistant starch content of ~90% was selected in this study. Its hydroxyl groups were activated by CDI and formed an imidazolyl carbamate complex that may be displaced by binding to the free amino group of Con A. The reaction is an N-nucleophilic substitution and results in a stable *N*-alkylcarbamate linkage of the ligand to the molecules of RSA. To investigate how the activation time, the RSA concentration, and the weight ratio between CDI and RSA will influence the level of activation, different amounts of RSA, activator and time periods were applied (shown in Figure 1). The optimized parameters for activating RSA were as follows: RSA concentration, 25% (w/v); weight ratio between CDI and RSA, 0.25; reaction temperature, 30 °C; and reaction time, 16 h. At these optimized conditions, the nitrogen content of RSA was at the highest value of 2.7%. This CDI-activated RSA was further treated with Con A. It can be seen from Figure 1b–d that the coupled Con A was at 0.86–34 μg/mg. The amount of coupled Con A could be 32 μg/mg when the concentration of RSA was 5% (w/v), the weight ratio between Con A and RSA was 0.03, and the reaction took place at 30 °C for 24 h.

The structural changes of RSA after conjugation with Con A were analyzed using Raman spectrometry and X-ray diffraction. The Raman spectrum of Con A had two bands at 620–640 cm^{-1} that indicated the stretching frequency associated with the C–S bond. The intense band at 1006 cm^{-1} presented in the spectra was the characteristic of the ring breathing of the benzene ring of phenylalanine. From Figure 2, the Raman spectrum of Con A–RSA possessed an absorption peak at 1006 cm^{-1}, indicating that the phenylalanine residue had been conjugated to RSA after reaction. In general, the presence of proteins can be noticed by amide I and amide III bands at about 1300 and 1655 cm^{-1}.[29,30] In the Raman spectrum of Con A, the absorption peaks at 1240 cm^{-1} were attributed to the N–H bending vibration band and the C–N stretching vibration band of amide III. The ν(C═O) stretch vibration band and N–H bending vibration of amide I caused an intense band at 1670 cm^{-1}.[31] The Raman spectrum of Con A-conjugated RSA had two bands at 1240 and 1670 cm^{-1}, which means the material has an O═C–NH group. The results of the Raman spectrum indicated that Con A had been successfully conjugated to RSA.

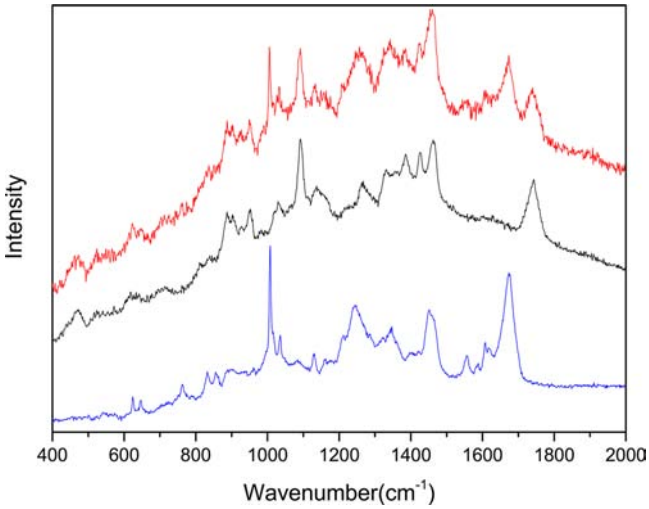

Figure 2. Effect of the conjugation of Con A on the molecular structure of RSA (from bottom to top are the Raman spectrum of Con A, RSA, and the Con A–RSA complex).

The XRD patterns of Con A and RSA coupled with different contents of Con A are shown in Figure 3. It can be seen that

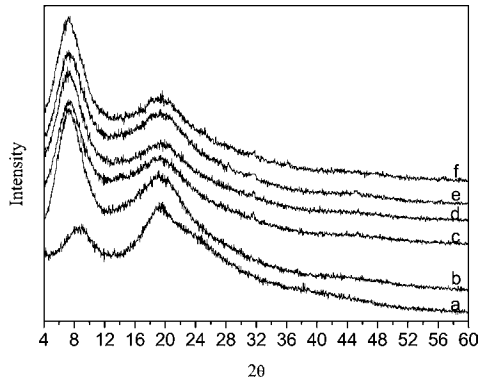

Figure 3. X-ray diffraction pattern of RSA with different contents of Con A (a, Con A; b, RSA; the contents of Con A are 8 (c), 18 (d), 32 (e), and 34 μg/mg (f)).

RSA had two humps on the XRD pattern at 7.2–7.3° and 19.0–19.7° that were related to the V-type starch crystalline structure. Thus, RSA presented a V-type diffraction pattern.[32] Con A had two humps on the XRD pattern at around 9° and 19° that were similar to that of RSA. After Con A was conjugated to RSA, the XRD pattern of Con A-conjugated RSA changed slightly. All the XRD patterns of Con A-conjugated RSA showed two humps on the diffraction pattern, suggesting that Con A-conjugated RSA was amorphous. The amorphous molecular chains of Con A-conjugated RSA could be easy to extend, which makes it possible to pass through mucosa and adhere to the surface of colonic epithelium cells.

Oral Colon-Targeting and Bioadhesive Property of the Con A–RSA Film-Coated Microparticles. *In Vivo Colonic Targeting in Mouse GI Tracts.* The size of Con A–RSA film-coated microparticles was ~500 μm in diameter (data not shown). Using in vivo fluorescent imaging observed by a whole-body small-animal in vivo imaging system, the oral colonic targeting capability of FITC-labeled microparticles coated with Con A–RSA film (the coupled Con A was 32 μg/mg) was studied. The images showing the microparticles distribution in different parts of the GI tract of nude mice at different times after oral administration of Con A–RSA film-coated microparticles are shown in Figure 4. Before administration, no fluorescence was shown in the nude mice (Figure 4a). With increased transit time after oral administration of Con A–RSA film-coated microparticles (from 2 to 44 min), the fluorescence spots moved from the stomach to the small intestine and then to the colon. The fluorescence intensity in the colon gradually increased. At 44 min after oral administration, all the fluorescence spots concentrated in the colon, indicating that the microparticles had been moved mainly to the colon (Figure 4b–e). As the transit time was prolonged further, the fluorescence intensity at the colon was gradually increased, and the fluorescence spots were enlarged, which suggested that FITC was released from the microparticles. When the transit time reached 72 h, the size of the fluorescence spot was smaller, but the intensity was still strong (Figure 4f–h). This indicated that Con A–RSA film-coated microparticles still existed in the colon. These results showed

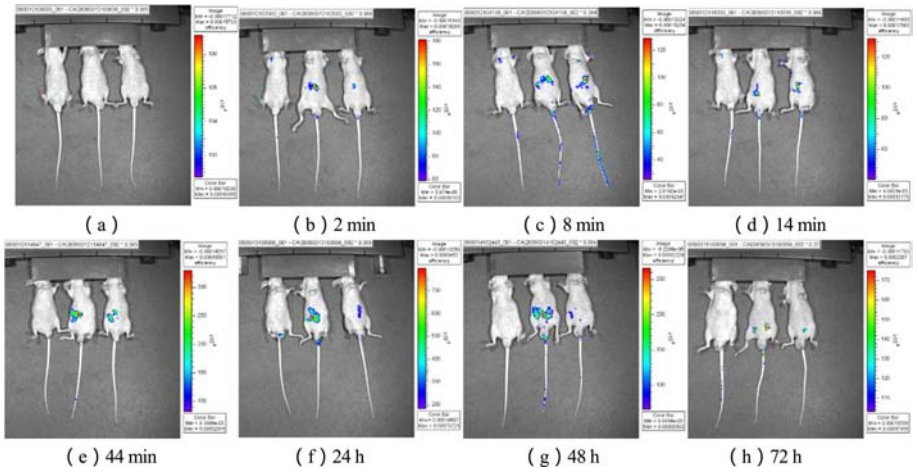

Figure 4. Microparticle transit after administration of fluorescein isothiocyanate loaded microparticles coated with Con A−RSA film in the gastrointestinal tract of nude mice at different time intervals (from left to right are the blank group and two Con A−RSA film-coated microparticle groups).

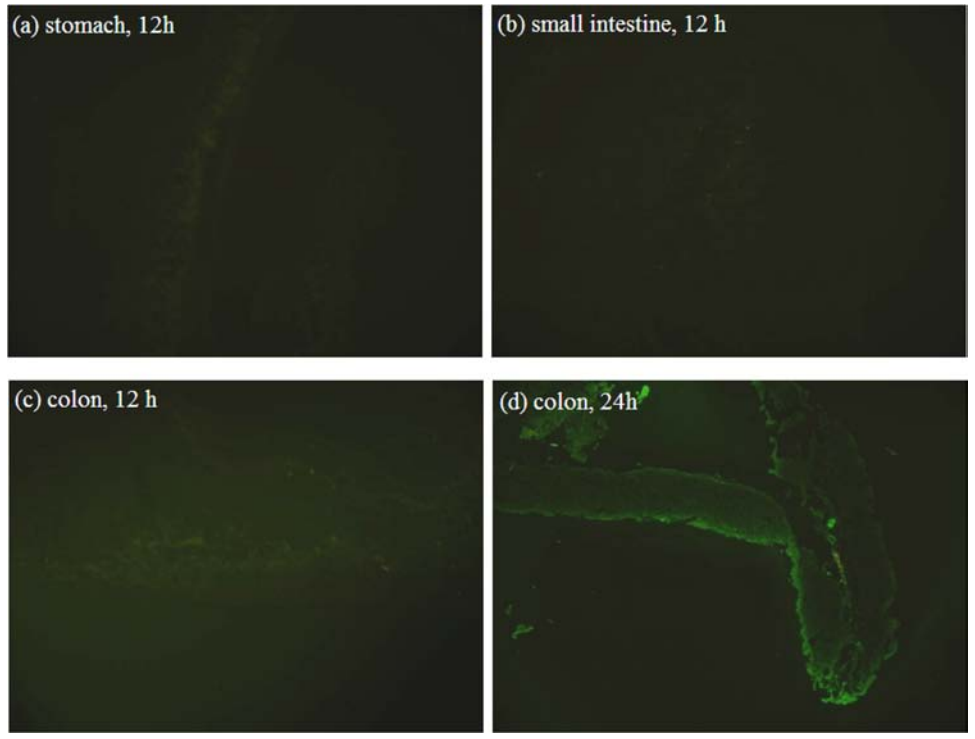

Figure 5. Fluorescence distribution after administration of fluorescein isothiocyanate-loaded microparticles coated with Con A−RSA film in the different regions of the gastrointestinal tract epithelial tissue of mice at different time intervals.

that Con A−RSA film-coated microparticles could not only target bioactive molecules to the colon but also stay in the colon for a longer time and continuously release bioactive molecules (FITC). This indicated good colonic targeting and bioadhesion abilities of Con A−RSA film-coated microparticles.

FITC Distribution in the Mouse GI Tract Epithelial Tissue. At 2 and 4 h after oral administration of Con A−RSA film-coated microparticles, no fluorescence was found in the GI tract epithelial tissue of mice because no FITC was released (the pictures are not shown). At 12 h after oral administration, very slight fluorescence was observed in the stomach and small intestine epithelial tissues (Figure 5a,b), meaning a very small amount of FITC was released in the stomach and small intestine. Meanwhile, minor green fluorescence was shown in the colon epithelial tissue (Figure 5c), suggesting that some of the FITC began to be released from the microparticles. When the administration time was prolonged to 24 h, the fluorescence intensity concentrated in the colon, indicating a large amount of FITC released in the colon (Figure 5d). These results showed that Con A−RSA film-coated microparticles could target and release the bioactive molecules to the colon.

To estimate the bioadhesion of Con A−RSA film-coated microparticles to the colon epithelial tissue, the difference in the FITC distribution in the mouse colon epithelial tissue was analyzed after prolonged administration of Con A−RSA film-coated microparticles and RSA film-coated microparticles, respectively. Figure 6 showed the FITC distribution in the mouse colon epithelial tissue at 24, 48, 72, and 144 h after oral

administration of these two types of microparticles. By comparing the fluorescence intensity between images, the release behaviors of these two types of microparticles were shown to be different. It can be seen from Figure 6 that at the same time, the fluorescence intensity of the colon epithelial tissue slices after administration of Con A−RSA film-coated microparticles was stronger than that of the slices after administration of RSA film-coated microparticles. Moreover, at 24 h, the fluorescence intensity of the colon epithelial tissue slices after administration of RSA film-coated microparticles showed the highest value and then decreased as the time was further prolonged. This indicated that the microparticles could be easily eliminated from the body. When the time reached 144 h, the fluorescence had almost disappeared; however, for the colon epithelial tissue slices after administration of Con A−RSA film-coated microparticles, the fluorescence intensity still increased from 24 to 72 h and reached the highest value at 72 h. At 144 h, the fluorescence intensity was weaker but still

stronger compared with that of slices after administration of RSA film-coated microparticles, indicating that Con A conjugated RSA film-coated microparticles can extend the residence time of the microparticles in the colon. These results showed that Con A conjugation to the surface of the RSA film could increase the microparticle residence time in the colon and enhance the bioactive molecules' (FITC) absorption effectively through bioadhesion to the surface of colonic mucosa cells.

In Vivo Hypoglycemic Response of Insulin-Loaded Microparticles Coated with Con A−RSA Film. *Hypoglycemic Response Improvement after Con A Conjunction on the Surface of RSA Film-Coated Microparticles.* After administration of the commercial long-acting insulin solution subcutaneously, the plasma glucose concentration decreased significantly within 1 h. A strong hypoglycemic response was observed between 4 and 12 h after injection; subsequently, the plasma glucose concentration increased with time and returned to the basal level at 30 h (Table 1). However, glycopenia (an abnormally low plasma glucose level of 3.5 ± 0.6 mmol/L) occurred at 6 h after injection. On the other hand, after RSA film-coated microparticles with different insulin dosages were orally administered, the hypoglycemic response was slowly but steadily maintained for a long time, and no glycopenia was observed between 8 and 36 h (total 28 h) (seen from Table 1). The hypoglycemic response was increased by an increase in the dosage of oral administration. It can be seen that the plasma glucose concentration declined into a lower range (6.3−9.7 mmol/L) at 10 h after oral administration of the low-dose microparticles and stayed within the lower range for 26 h. The medium-dose and the high-dose groups experienced a steady decrease in the plasma glucose concentration and stayed within the lower range for a total of 28 h, which was a little more rapid than that of the low-dose group. These results indicated that the plasma glucose concentration of the diabetic model rats was decreased steadily by using the RSA film-coated microparticles for the delivery of insulin; however, the plasma glucose

[a] $n = 5$ for each group. [b] Compared with those of the diabetic model group ($P < 0.01$). [c] Compared with those of the insulin injected group ($P < 0.01$). [d] Compared with those of the low-dose microparticles group ($P < 0.01$).

concentration increased with time and returned to the basal level from 48 h after administration, suggesting that the RSA film-coated microparticles could be easily eliminated from the body.

The hypoglycemic response with different insulin dosages is shown in Table 2 for after Con A was conjugated to the surface of RSA film-coated microparticles. Comparing the data between Table 2 and Table 1, it is concluded that the time of the hypoglycemic response (when the plasma glucose concentration kept within a low range) was prolonged after the Con A−RSA film-coated microparticles with the same insulin dosage were orally administered. It can be seen that the plasma glucose concentration declined to a low range (5.2−9.2 mmol/L) from 10 to 54 h after administration of the low-dose and medium-dose microparticles and was kept within the lower range for 44 h. The high-dose group also showed the longest time of staying within a lower plasma glucose concentration from 8 to 60 h (for a total of 52 h). There was no glycopenia due to the steady release of insulin from the microparticles. In the treatment of diabetes mellitus, steadily decreasing the plasma glucose concentration is important to the patients.[33] Con A−RSA film-coated microparticles could adhere to the surface of colonic mucosa cells, increase the residence time in the colon, and steadily and sustainably release insulin. Thus, the plasma glucose concentration within the normal range could be maintained for a prolonged time (18−24 h with different insulin dosages), showing improved bioavailability of insulin.

Hypoglycemic Response after Successive Oral Administration. For investigating the continuous bioavailability of insulin delivered through Con A−RSA film-coated microparticles, the insulin-loaded microparticles were orally administered at 19:00 on each of 5 consecutive days. The plasma glucose concentration was assayed at 2 h before and after meals every day. Table 3 shows the blood glucose change by continuous administration of insulin-loaded Con A−RSA film-coated microparticles. After administration of microparticles, the plasma glucose concentration of experimental groups on the first day was at a low range, which was consistent with the results above. The differences among groups existed the following day. For the low-dose microparticles group, the plasma glucose concentration was at the upper level of the normal range on the second day. Then the plasma glucose concentration was out of the normal range, indicating that insulin for the low-dose microparticles group was not enough to decrease the plasma glucose. The plasma glucose concentration of the medium-dose microparticles group was within the normal range until the final day, but in the end, the plasma glucose concentration was higher than the normal level.

J. Agric. Food Chem. 2015, 63, 4138−4147

The plasma glucose concentration of the high-dose microparticles was steady during all the 5 days, which showed a hypoglycemic response similar to that of the group subcutaneously injected with commercial long-acting insulin.

OGTT mimics the physiological conditions of the glucose/insulin system closely and evaluates the insulin sensitivity and the β-cell function.[34,35] After 5 days of continuous administration with insulin-loaded Con A−RSA film-coated microparticles, the OGTTs were conducted; the results of different groups are shown in Figure 7. It can be seen from Figure 7 that

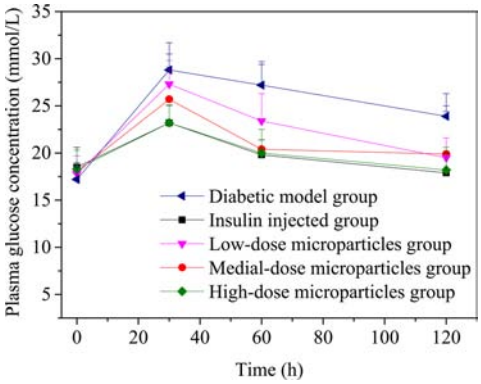

Figure 7. Results of oral glucose tolerance test in different rat groups.

the glucose tolerance of the type II diabetic rats after administration of the microparticles was gradually enhanced, with greater enhancement seen with increased insulin dosage. Compared with the diabetic model group, the high-dose microparticles group had a glucose tolerance similar to that of the insulin-injected group. In conclusion, Con A−RSA film-coated microparticles could adhere to the surface of colonic mucosa cells, prolonging the insulin release time and enhancing the hypoglycemic response. Thus, this study demonstrates the potential of Con A−RSA film-coated microparticles for oral colon-targeted delivery of polypeptide or protein ingredients with enhanced oral bioavailability.

Although the use of lectins as targeting ligands remains problematic because of their cytotoxic effects, which would preclude their use in targeting delivery systems,[36,37] the toxic effects of lectins are varied with different varieties. We did the toxicity tests when we screened the lectins of different carbohydrate specificities for binding to human colonic mucosa epithelial cells. The relative growth rate of Caco-2 cells was high (80%) when Caco-2 cells were exposed to Con A solutions in the microgram range (7.8−50 μg/cell) for 60 h (data not shown). This result indicated that the toxic effects of Con A would not be aggravated because the amounts of Con A conjugated to the microparticle surface were in the microgram range. Furthermore, the approach to overcome this limitation is to produce recombinant lectins with modified properties and to design and synthesize peptides or other organic molecules that mimic the function of the lectins.[38−40] Thus, better biocompatibility may result from the lectin-sugar interactions, which is applicable to the colon-specific bioadhesive delivery system.

J. Agric. Food Chem. 2015, 63, 4138−4147

Flavonoids are abundant constituents of fruits, vegetables, and herbal beverages. Several food-derived flavonoids are associated with effects that prevent human disease, including protection from oxidative stress, inflammation, cardiovascular disease, neurodegeneration, and cancer.[10] Most of the beneficial effects of flavonoids have been demonstrated to involve the modulation of gene expression by activating or interacting with miRNAs. Recently, dietary flavonoids have been reported to regulate miRNA expression in animal and cell culture models. Flavonoids such as epigallocatechin-3-gallate (EGCG), quercetin, proanthocyanins, and citrus flavonoids have been shown to modulate miRNA transcription and, consequently, to control several biological functions in vitro or in vivo.[11,12]

Luteolin (3′,4′,5,7-tetrahydroxyflavone), a member of the flavone subgroup of flavonoids, is found in many vegetables, fruits, and herbs and is especially enriched in celery, parsley, orange, broccoli, cabbage, and green pepper. It exhibits antioxidant, anti-inflammatory, and anticancer activities.[13] Recently, several studies have shown that luteolin potentially exerts neuroprotective effects. Luteolin has been reported to reduce the neurotoxicity induced by neurotoxic agents in cell culture systems.[14,15] In addition to neuroprotection, luteolin has been shown to possess the neuritogenic activities in PC12 cells.[16,17] In animal studies, luteolin has been demonstrated to permeate the BBB to exert antiamnesic effects against amyloid toxicity in mice, protect against cognitive dysfunction induced by chronic cerebral hypoperfusion in rats and improve MPTP-induced Parkinsonism in mice.[18−20] In our previous studies, we have demonstrated that luteolin is a neurotrophic agent that promotes neurite outgrowth and neuronal differentiation via the activation of cell signaling cascades including the PKC-dependent and PKA- or ERK-dependent CREB/miR-132 pathways in PC12 cells.[21,22]

In the present study, we performed miRNA microarray analysis and identified luteolin-responsive miRNAs during neurite outgrowth of PC12 cells. Among the miRNAs up- or down-regulated by luteolin in PC12 cells, we focused on miR-34a, which was robustly and significantly upregulated in response to luteolin. We further elucidated in detailed mechanisms by which luteolin regulated miR-34a expression and examined the effects of miR-34a on the luteolin-mediated neurite outgrowth of PC12 cells.

MATERIALS AND METHODS

Materials. Luteolin, poly-L-lysine, dimethyl sulfoxide (DMSO), pifithrin-α (PFT-α), H-89, RPMI-1640 medium, nonessential amino acids (NEAA), and other chemicals, unless otherwise indicated, were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). The mouse 7S nerve growth factor (NGF) was purchased from Millipore (Billerica, MA, USA). Resveratrol was purchased from Tokyo Chemical Industry (Tokyo, Japan). The inhibitors U0126, SB203580, and LY294002 were purchased from Promega (Madison, WI, USA). SP600125 was purchased from Enzo Life Sciences (Ann Arbor, MI, USA). Bisindolylmaleimide I (BIM) was purchased from Cayman Chemical (Ann Arbor, MI, USA).

Cell Culture. PC12 cells were obtained from Bioresource Collection and Research Center (Hsinchu, Taiwan) and were maintained in RPMI-1640 medium supplemented with 10% heat-inactivated horse serum (HS), 5% fetal bovine serum (FBS) (Invitrogen, Carlsbad, CA, USA), and 1% NEAA in a 5% CO_2 incubator at 37 °C.

RNA Extraction and microRNA Microarray Analysis. Total cellular RNA was extracted from cells using Trizol reagent (Invitrogen) according to the manufacturer's protocol. Fluorescent targets were prepared from 2.5-μg total RNA samples using the miRNA ULSTM Labeling Kit (Kreatech Diagnostics, The Netherlands). The labeled miRNA targets enriched using NanoSep 100 K (Pall Corporation, NY, USA) were hybridized to the Mouse & Rat miRNA OneArray (Phalanx Biotech Group, Hsinchu, Taiwan), which contains triplicate unique miRNA probes from mouse and rat (miRBase Release 15.0). The fluorescence intensities of each spot were analyzed using GenePix 4.1 software (Molecular Devices, Sunnyvale, CA, USA). The normalized spot intensities were transformed to $\log_2$ ratios of gene expression between the control and treatment groups. The spots displaying a $\log_2$ ratio ≥ 0.7 or ≤ -0.7 and a p-value < 0.05 were selected for further analysis.

Analysis of Neurite Outgrowth in PC12 Cells. The quantification of neurite outgrowth in PC12 cells was performed as described previously.[4] Briefly, PC12 cells (2×10^5/ml) were seeded on poly-L-lysine-coated 6-well plates in standard serum-containing medium. After 24 h of incubation, the medium was replaced with low-serum (1% HS and 0.5% FBS) medium and treated with vehicle (0.1% DMSO) or luteolin for the indicated period. The cells were photographed using an inverted microscope (Olympus IX71), and the images were subsequently examined by counting the cells that were positive for neurites. The neurite-bearing cells were counted from ten randomly selected microscopic fields, which contained an average of 100 cells per field. The number of differentiated cells was measured by counting those cells that had at least one neurite with an length equal to the cell body diameter. The data are expressed as percentages of the total cells in the field. Each experiment was conducted in triplicate.

Reverse Transcription Quantitative PCR (RT-Q-PCR) Analysis of Pre-miR-34a and Mature miR-34a. PC12 cells were seeded on poly-L-lysine-coated 60 mm plates in standard serum-containing medium. After 24 h of incubation, the cells were incubated in low-serum medium and exposed to vehicle (0.1% DMSO) or the indicated compounds for the indicated period. Total cellular RNA was prepared using Trizol reagent (Invitrogen) according to the manufacturer's protocol. For the pre-miR-34a measurement, total cellular RNA was reverse-transcribed using a High Capacity cDNA reverse transcription kit (Applied Biosystems, Foster City, CA, USA). Quantitative real-time PCR was then performed using specific primers [pre-miR-34a, 5′-CGGCTGTGAGTAATTCTTTGG-3′ (forward) and 5′-CAACG-TGCAGCACTTCTAGG-3′ (reverse); β-actin, 5′-CCTCTGAAC-CCTAAGGCCAA-3′ (forward); and 5′-AGCCTGGATGGCTA-CGTACA-3′ (reverse)] and Maxima SYBR Green/ROX qPCR Master Mix (Fermentas, Burlington, ON, CA). Amplification was performed using an ABI Prism 7300 Real-Time PCR System. The PCR conditions used were as follows: 94 °C for 4 min followed by 40 cycles at 94 °C for 1 min, 58 °C for 1 min, and 72 °C for 1 min. The $\Delta\Delta C_t$ method was used for the data analysis of pre-miR-34a expression, which was estimated in triplicate samples and was normalized to the β-actin expression levels.

For the determination of mature miR-34a expression, RNA was reverse-transcribed using a TaqMan MicroRNA Reverse Transcription Kit (Applied Biosystems), and this product was subjected to a TaqMan miRNA assay (Applied Biosystems) using primers and probes specific for miR-34a or for the internal control U6 RNA according to the manufacturer's protocol. Amplification was performed using an ABI Prism 7300 Real-Time PCR System. The PCR conditions were as follows: 95 °C for 10 min followed by 40 cycles at 95 °C for 15 s and 60 °C for 1 min. The $\Delta\Delta C_t$ method was used for the data analysis of miR-34a expression, which was estimated in triplicate samples and was normalized to the U6 RNA expression levels.

Transfection of Anti-miR-34a Oligonucleotides. Transfection of anti-miR oligonucleotides was performed as described previously.[22] Briefly, PC12 cells were seeded on poly-L-lysine-coated 6-well plates in standard serum-containing medium for 24 h. The cells were then incubated in serum-free OPTI-MEM and transfected with antisense miR-34a (Ambion Anti-miR miRNA inhibitor) (Applied Biosystems) or a scrambled control miRNA (Ambion Anti-miR negative control #1) (Applied Biosystems) at a final concentration of 150 pmol/mL using the Lipofectamine 2000 reagent (Invitrogen) for 5 h. After

transfection for 24 h, the cells were incubated in low-serum medium and treated with vehicle or luteolin for 72 h.

Western Blot Analysis. PC12 cells were seeded on poly-L-lysine-coated 100 mm dishes in standard serum-containing medium. After 24 h of incubation, the cells were then incubated in low-serum medium and exposed to vehicle or luteolin for the indicated period. Total cellular protein samples were prepared using RIPA buffer (Thermo Fisher Scientific, Inc., Rockford, IL, USA). The proteins were separated via 10% SDS-PAGE and were subsequently transferred to a PVDF membrane (PerkinElmer, Boston, MA, USA). The membranes were incubated in the following specific antibodies: anti-p53 (Santa Cruz Biotechnology, Santa Cruz, CA, USA), antiphospho-p53 (Ser15), anti-SirT1, anti-p38, antiphospho-p38 MAPK (Thr180/Tyr182), anti-JNK, antiphospho-JNK (Cell Signaling Technology, Danvers, MA, USA), anti-p53 (Acetyl K381) (Abcam, Cambridge, MA, USA), and monoclonal anti-β-actin (Sigma-Aldrich). Then, the membranes were incubated in the appropriate HRP-conjugated secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA, USA) for 1 h. The proteins were detected using Amersham ECL Prime Western Blotting Detection Reagent (GE Healthcare, Buckinghamshire, UK), and the signal was visualized on Amersham Hyperfilm ECL (GE Healthcare).

Statistical Analysis. All experiments were repeated at least three times, and the values are expressed as the mean ± SD. Statistic calculations were performed using IBM SPSS Statistics 22.0 software. The results were analyzed using one-way ANOVA with Dunnett's posthoc test, and a p-value < 0.05 was considered statistically significant.

RESULTS

miR-34a: Highly Expressed during Luteolin-Induced Neurite Outgrowth in PC12 Cells. In our previous studies, we have demonstrated that luteolin (20 μM) significantly induced neurite outgrowth and neuronal differentiation in PC12 cells.[21] We first examined the differential expression of miRNAs during the luteolin-induced neuronal differentiation of PC12 cells via a genome-wide screen. To identify the miRNA expression profile of luteolin-mediated neurite outgrowth, the PC12 cells were treated with luteolin (20 μM) for 0, 8, 24, 48, or 72 h, and the miRNA levels were analyzed using Mouse & Rat miRNA OneArray expression profiling microarrays as described in the Materials and Methods section. A total of 16 and 3 miRNAs were robustly and significantly up-regulated ($\log_2$ ratio ≥ 0.7) and down-regulated ($\log_2$ ratio ≤ -0.7), respectively, in the PC12 cells treated with luteolin for 8−72 h compared to the 0 h-treated control cells (Table 1 and Figure S1, Supporting Information). Based on microarray analysis, among the 16 luteolin-induced miRNAs, the induction of miR-34a was the most pronounced, displaying increases of 2.3-, 2.9-, 5.3- and 6.0-fold after treatment of the cells with luteolin for 8, 24, 48, and 72 h, respectively (Figure 1).

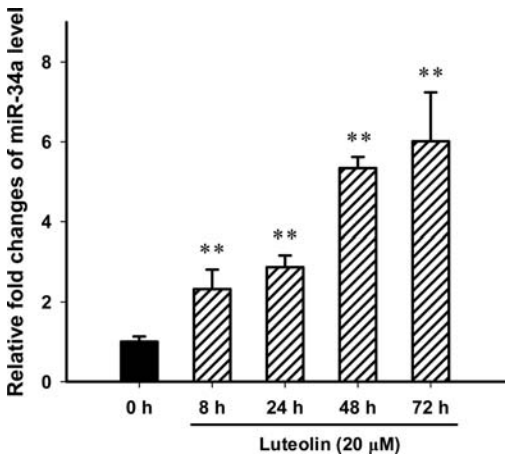

Figure 1. Fold-changes in miR-34a expression in luteolin-treated PC12 cells based on microarray analysis. The fluorescence intensities from the microarray data were analyzed as described in the Materials and Methods section. The fold-change in the expression level of miR-34a was measured and presented as the mean ± SD from the analysis of duplicate arrays. **$p < 0.01$ represents a significant difference compared to the 0 h group.

J. Agric. Food Chem. 2015, 63, 4148−4159

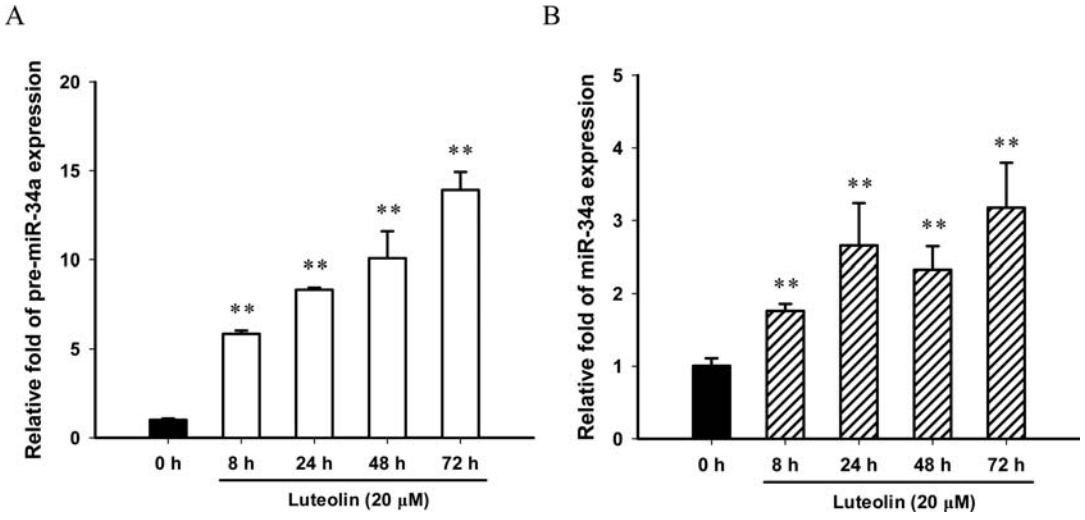

Figure 2. Luteolin induces miR-34a expression in PC12 cells. PC12 cells were treated with vehicle (0.1% DMSO) or luteolin (20 μM) for 8−72 h. Cellular RNA was prepared, and (A) the levels of pre-miR-34a and (B) mature miR-34a were determined via RT-Q-PCR as described in the Materials and Methods section. The data are presented as the means ± SD from three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the 0 h group.

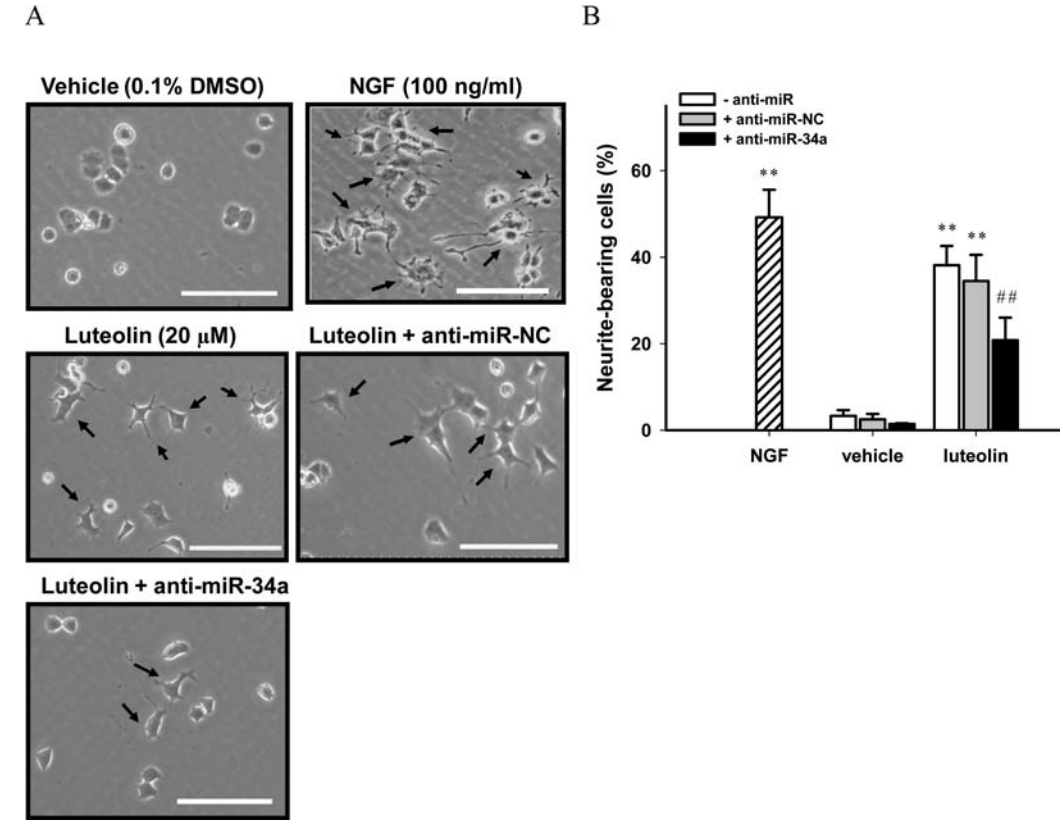

Figure 3. miR-34a is involved in the luteolin-induced neurite outgrowth of PC12 cells. (A) PC12 cells were transfected with antisense oligonucleotides targeting miR-34a (anti-miR-34a) or a scrambled negative control antisense miRNA (anti-miR-NC) for 24 h as described in the Materials and Methods section. After transfection, the PC12 cells were exposed to vehicle (0.1% DMSO) or luteolin (20 μM) for 72 h. The PC12 cells were treated with NGF (100 ng/mL) alone for 72 h as a positive control. Cell morphology was observed and photographed. The arrowheads indicate neurite-bearing cells; scale bar, 100 μm. (B) Neurite-bearing cells analyzed as described in the Materials and Methods section. The data are presented as the means ± SD from three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the vehicle-treated cells. $^{\#\#}p < 0.01$ represents a significant difference compared to the anti-miR-NC-treated cells.

To verify the effect of luteolin on miR-34a expression, PC12 cells were treated with luteolin (20 μM) for the indicated period. The RNA levels of precursor or mature miR-34a were determined via RT-Q-PCR as described in the Materials and Methods section. As shown in Figure 2A, the treatment of the cells with luteolin for 8 or 72 h markedly increased pre-miR-34a expression by 5.9- and 14.0-fold, respectively. Mature miR-34a expression was significantly elevated by 2.7-fold after 24 h-

J. Agric. Food Chem. 2015, 63, 4148−4159

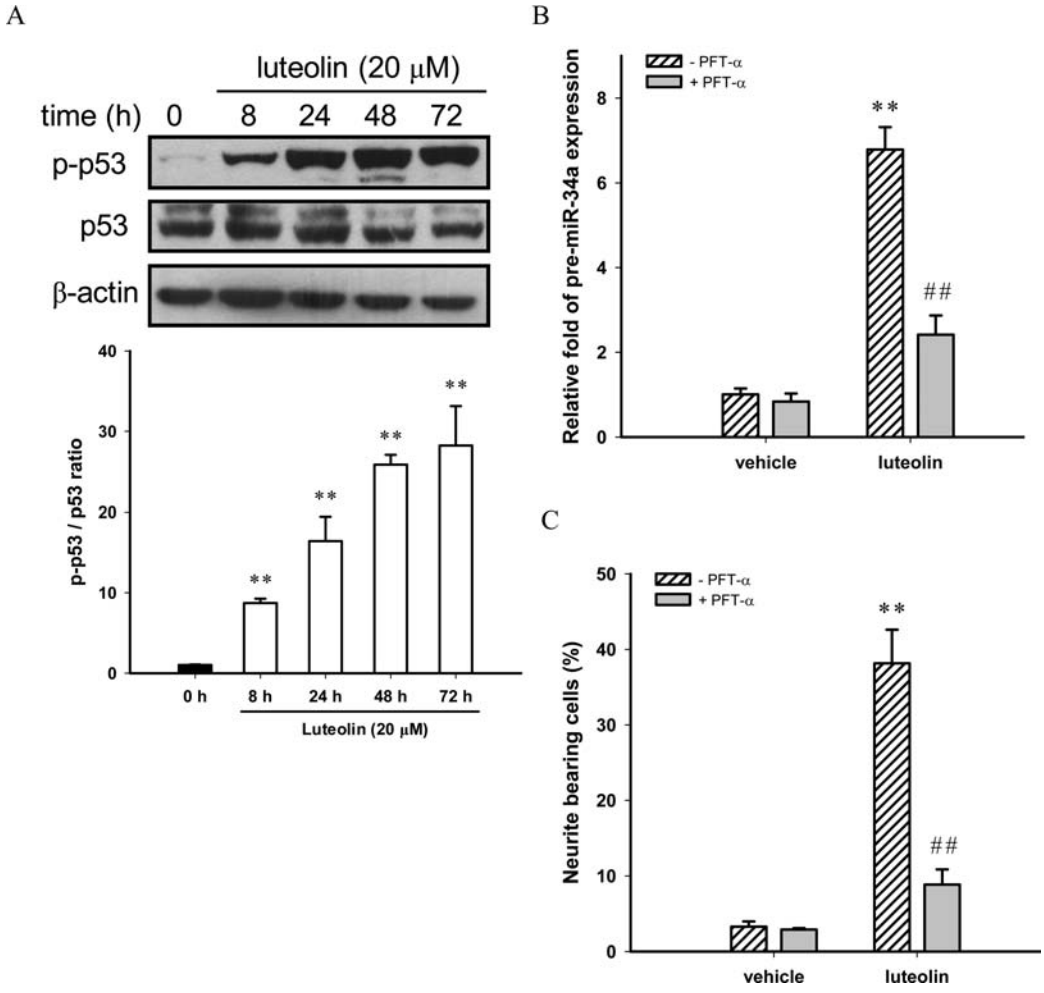

Figure 4. Contribution of p53 phosphorylation to luteolin-induced miR-34a expression and neurite outgrowth. (A) PC12 cells were treated with luteolin (20 μM) for 8−72 h, and the p53 and β-actin protein levels were analyzed via Western blot analysis. The immunoblot experiments were replicated at least three times, and a representative Western blot is shown. The intensity of phospho-p53-Ser15 (p-p53) normalized to that of p53 is presented as the means ± SD of three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the 0 h group. (B) PC12 cells were pretreated with the p53 inhibitor pifithrin-α (PFT-α, 20 μM) for 30 min and then exposed to vehicle (0.1% DMSO) or luteolin (20 μM) for 8 h. The levels of pre-miR-34a were determined via RT-Q-PCR. (C) PC12 cells were pretreated with pifithrin-α (PFT-α, 20 μM) for 30 min and then exposed to vehicle or luteolin (20 μM) for 72 h. Neurite-bearing cells were analyzed as described in the Materials and Methods section. The data are presented as the means ± SD from three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the vehicle-treated cells. $^{\#\#}p < 0.01$ represents a significant difference compared to the PFT-α-untreated cells.

treatment with luteolin (20 μM), and the miR-34a levels remained increased by 3.1-fold after 72 h of luteolin exposure ($p < 0.01$) (Figure 2B). This result indicated that luteolin exposure for 8−72 h highly up-regulates miR-34a expression in PC12 cells.

Effects of miR-34a Expression on the Luteolin-Induced Neurite Outgrowth of PC12 Cells. To investigate the effect of miR-34a expression on the luteolin-induced neurite outgrowth of PC12 cells, we used antisense miR-34a (anti-miR-34a) to knock down the levels of miR-34a. The PC12 cells were transfected with a negative control antisense miRNA (anti-miR-NC) or anti-miR-34a as described in the Materials and Methods section and then treated with vehicle or luteolin (20 μM) for 72 h; we achieved approximately a 92% knockdown of miR-34a in PC12 cells (Figure S2, Supporting Information). The percentage of neurite-bearing cells was further measured. Figure 3A and B shows that luteolin significantly increased the percentage of neurite outgrowth to 38.1 ± 4.5% relative to vehicle (3.3 ± 1.3%) ($p < 0.01$), as expected. The activity was comparable to those of the positive control, nerve growth factor (NGF). However, luteolin-mediated neurite outgrowth was significantly attenuated to 20.8 ± 5.2% in the cells transfected with anti-miR-34a; luteolin-induced neurite outgrowth remained unchanged in the anti-miR-NC-transfected cells (36.5 ± 6.1%). These results revealed that luteolin-induced miR-34a expression is involved in the neurite outgrowth of PC12 cells.

p53 Activation Involved in Luteolin-Mediated miR-34a Up-Regulation and Neurite Outgrowth. It has been reported that the primary miR-34a transcript is induced by p53 activation.[23] Ser15 of the p53 protein is a major target of primary phosphorylation, and its phosphorylation is required for p53 function in the physiological context of p53-responsive promoters.[24] Thus, to investigate whether luteolin-induced miR-34a up-regulation acts via p53 activation in PC12 cells, Western blot analysis was performed as described in the Materials and Methods section. As shown in Figure 4A, the treatment of PC12 cells with luteolin (20 μM) for 8 h markedly

J. Agric. Food Chem. 2015, 63, 4148−4159

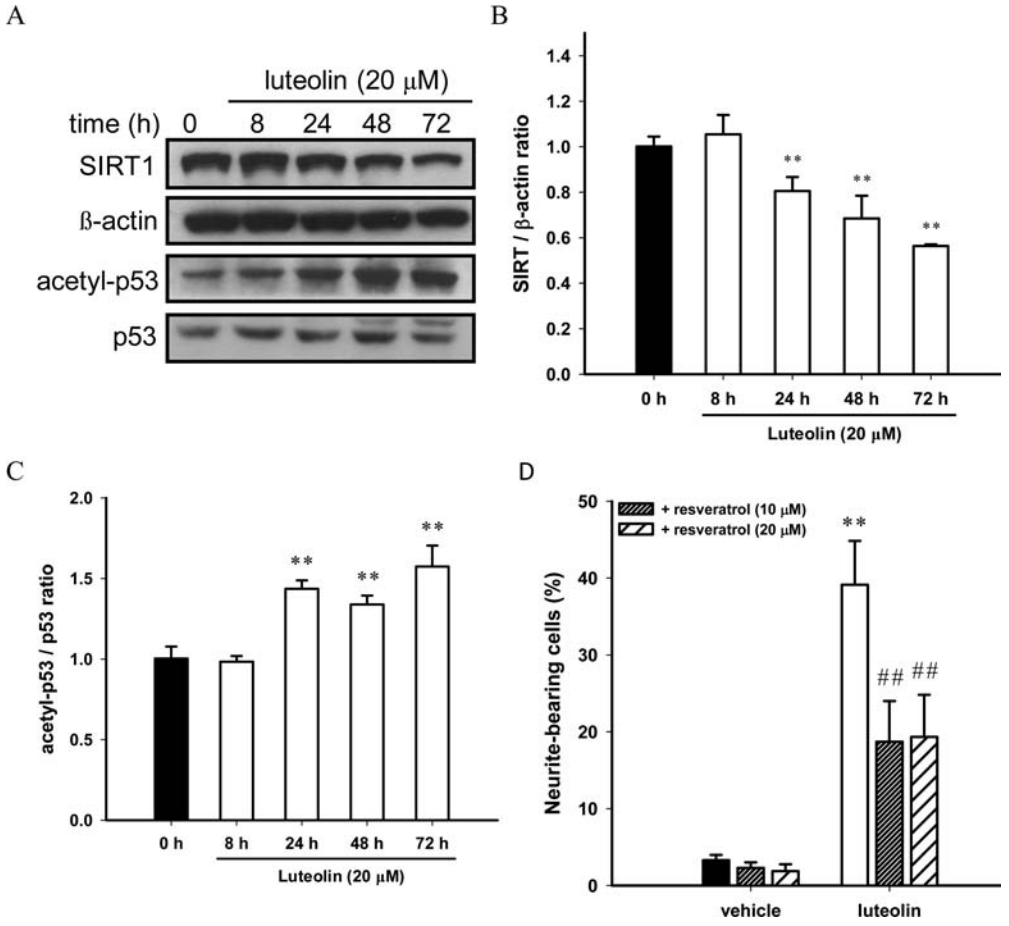

Figure 5. Effect of Luteolin on the Level of SIRT1 Protein. PC12 cells were treated with luteolin (20 μM) for 8−72 h. (A) SIRT1 and acetylated p53-Lys379 (acetyl-p53) proteins were analyzed via Western blot analysis. The immunoblot experiments were replicated at least three times, and a representative Western blot is shown. (B) Intensity of SIRT1 normalized to that of β-actin and (C) intensity of acetylated p53 normalized to that of p53 is presented as the means ± SD of three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the 0 h group. (D) PC12 cells were preincubated in resveratrol (10 or 20 μM) for 30 min and then exposed to vehicle or luteolin (20 μM) for 72 h. Neurite-bearing cells were analyzed as described in the Materials and Methods section. The data represent the means ± SD from three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the vehicle-treated cells. $\#\#p < 0.01$ represents a significant difference compared the resveratrol-untreated cells.

increased the phosphorylation of p53 at Ser15 by 8.7-fold, peaking at 48−72 h, compared to the 0 h treatment ($p < 0.01$).

The direct relationship between p53 phosphorylation and miR-34a up-regulation was further investigated by exposing the PC12 cells to pifithrin-α (PFT-α), a specific inhibitor that was shown to block the transcriptional activity of p53.[25] Luteolin-mediated pre-miR-34a expression was markedly attenuated by the treatment of PC12 cells with 20 μM PFT-α for 8 h (Figure 4B). Furthermore, the treatment of PC12 cells with PFT-α for 72 h significantly reduced the percentage of luteolin-induced neurite outgrowth from 38.1 ± 4.5% to 9.6 ± 1.9% ($p < 0.01$) (Figure 4C). These results suggested that luteolin induces neurite outgrowth via the p53-dependent up-regulation of miR-34a in PC12 cells.

Effect of Luteolin on Sirtuin 1 (SIRT1) Expression in PC12 Cells. It has been reported that overexpressed miR-34a targets the 3′-untranslated region (3′-UTR) of sirtuin 1 (SIRT1) and reduces its protein level, leading to enhanced levels of acetylated p53, elevated p53 binding activity, and promoted neuronal differentiation in embryonic cortical neuron and neuroblastoma cell lines.[26−28] Therefore, we further investigated the effect of luteolin exposure on the SIRT1 protein level in PC12 cells. As shown in Figure 5A and B, the protein level of SIRT1 was significantly reduced by treatment with luteolin (20 μM) for 24−72 h. Furthermore, we examined the effect of luteolin on the level of acetylated p53, a substrate of SIRT1-mediated deacetylation. As shown in Figure 5C, the level of acetylated p53 (K379) protein was significantly elevated by treatment with luteolin (20 μM) for 24−72 h. In addition, luteolin-induced neurite outgrowth was significantly attenuated by exposure to resveratrol, a SIRT1 activator,[29] compared to treatment with luteolin alone in PC12 cells (Figure 5D). These data indicated that the SIRT1 protein level is reduced, leading to increased acetylated p53 levels, during luteolin-mediated neuronal differentiation.

Signaling Pathways Involved in Luteolin-Mediated miR-34a Up-Regulation and Neurite Outgrowth in PC12 Cells. It has been known that the activation of signal transduction pathways, including MAPK, protein kinase C (PKC), protein kinase A (PKA), and PI3/Akt, is involved in the control of neuronal differentiation.[21,30,31] Thus, the possible involvement of these signaling pathways in luteolin-induced pre-miR-34a transcription and neurite outgrowth was investigated using kinase-specific inhibitors of these pathways. As shown in Figure 6A, luteolin-induced miR-34a transcription was markedly abolished by inhibitors of JNK (SP600125) or

J. Agric. Food Chem. 2015, 63, 4148−4159

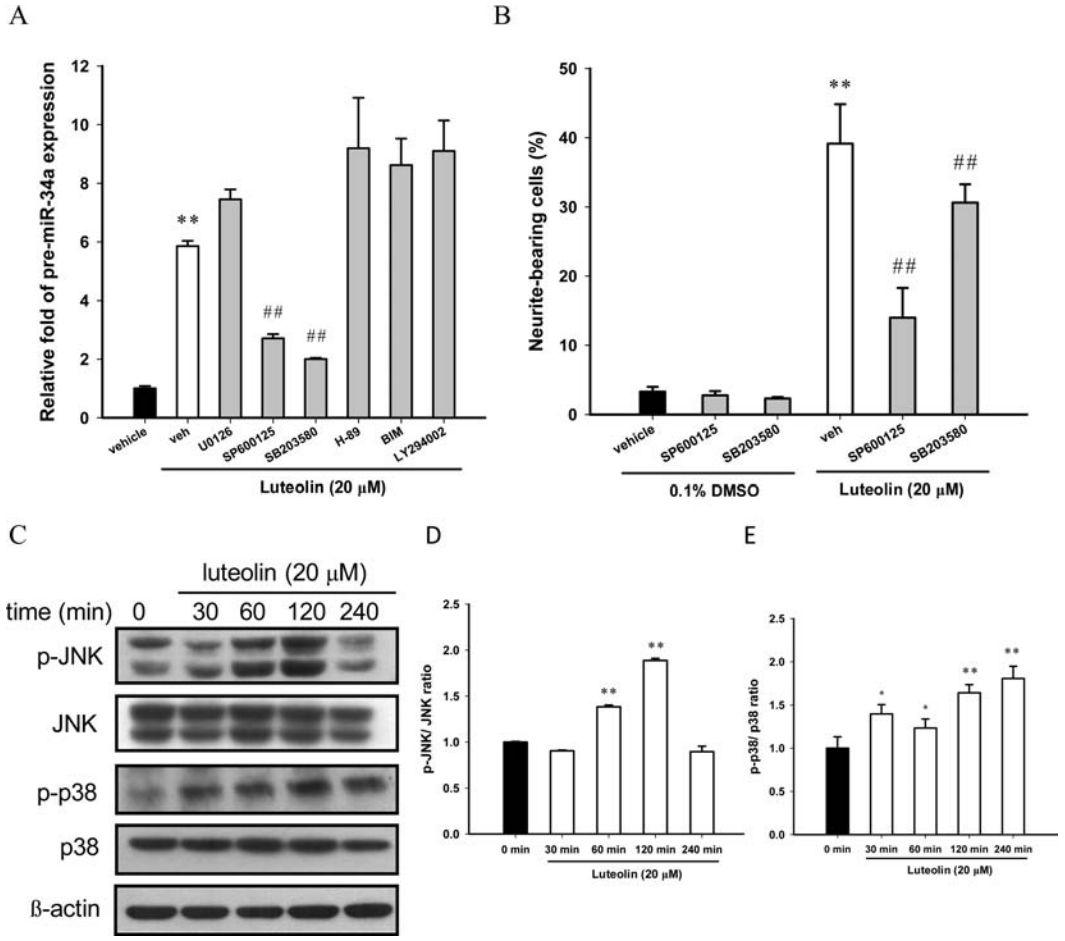

Figure 6. Involvement of JNK and p38 MAPK activation in luteolin-mediated miR-34a expression and neurite outgrowth. (A) PC12 cells were pretreated for 30 min with vehicle or one of the following inhibitors: U0126 (10 μM), SP600125 (10 μM), SB203580 (10 μM), H-89 (10 μM), BIM (2.5 μM), or LY294002 (40 μM). Then, the cells were exposed to luteolin (20 μM) for 8 h. The levels of pre-miR-34a were determined via RT-Q-PCR. $^{**}p < 0.01$ represents a significant difference compared to the vehicle-treated cells. $^{\#\#}p < 0.01$ represents a significant difference compared to the inhibitor-untreated (veh) group. (B) PC12 cells were pretreated for 30 min with vehicle, the inhibitor SP600125 (10 μM) or SB203580 (10 μM), followed by exposure to luteolin (20 μM) for 72 h. Neurite-bearing cells were analyzed, and the data are presented as the means ± SD from three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the vehicle-treated cells. $^{\#\#}p < 0.01$ represents a significant difference compared to the inhibitor-untreated (veh) group. (C) PC12 cells were treated with luteolin (20 μM) for 30, 60, 120, or 240 min. The phospho-JNK (p-JNK), JNK, phospho-p38 (p-p38), p38, and β-actin protein levels were analyzed via Western blot. The immunoblot experiments were replicated at least three times, and a representative Western blot is shown. (D) Intensity of p-JNK normalized to that of JNK and (E) intensity of p-p38 normalized to that of p38, respectively, presented as the means ± SD of three independent experiments. $^{*}p < 0.05$ and $^{**}p < 0.01$ represents a significant difference compared to the 0 min group.

p38 MAPK (SB203580) ($p < 0.01$). However, the inhibitors of MEK1/2 (U0126), PKC (BIM), PKA (H-89), and PI3/Akt (LY294002) did not reduce the level of miR-34a transcription in the luteolin-treated cells. Luteolin-induced neurite outgrowth was also attenuated by pretreatment of PC12 cells with the inhibitor SP600125 or SB203580 (Figure 6B). Next, we attempted to verify the signaling pathways activated by luteolin in PC12 cells. As shown in Figure 6C–E, the phosphorylation of JNK by luteolin (20 μM) treatment peaked at 120 min. Luteolin induced p38 MAPK activation at 30 min and peaked at 240 min after treatment ($p < 0.01$). These results confirmed the critical roles of the activation of the JNK and p38 MAPK pathways in the luteolin-mediated up-regulation of miR-34a and enhancement of neurite outgrowth. Furthermore, we examined whether these kinase-mediated signaling pathways are associated with luteolin-mediated p53 phosphorylation. As shown in Figure 7, the results showed that the inhibition of kinase activity using SP600125 or SB203580 did not block the luteolin-mediated phosphorylation of p53 at Ser15. Our findings demonstrated that luteolin induced miR-34a up-regulation and neurite outgrowth via p53-dependent and p53-independent pathways in PC12 cells.

DISCUSSION

High intake of fruits, vegetables, and beverages rich in polyphenolic phytochemicals may be associated with a decreased risk of several human chronic diseases, including neurodegenerative disorders. Emerging evidence supports that dietary flavonoids exert direct neuroprotective effects by interacting with cell signaling pathways, regulating transcription factors, and modulating gene expression. MicroRNAs are known as post-transcriptional modulators that regulate various biological activities, such as cell growth, differentiation, apoptosis, and metabolism. In the present study, we identified the changes in the miRNA expression profile caused by luteolin treatment in PC12 cells. The major finding of this study was

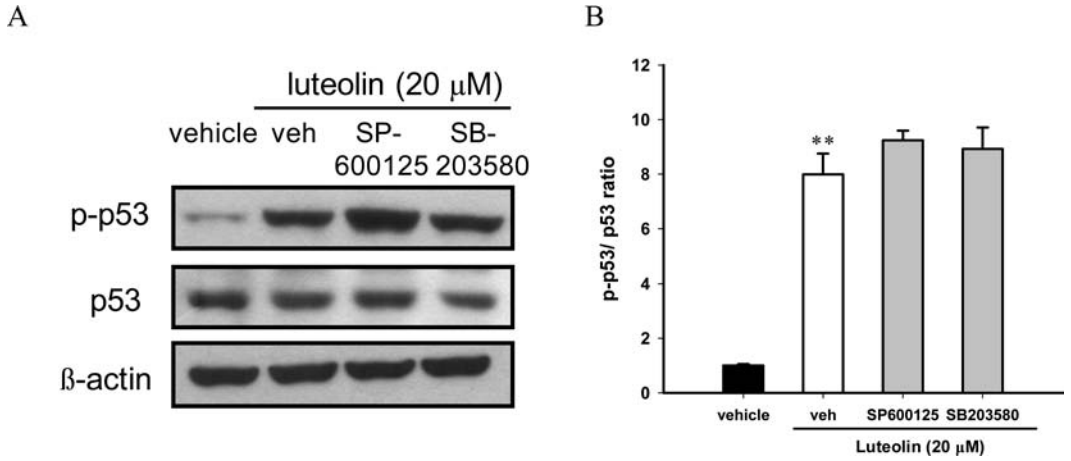

Figure 7. Activation of the JNK and p38 pathways did not affect luteolin-induced p53 phosphorylation. PC12 cells were treated with vehicle, the inhibitor SP600125 or SB203580 for 30 min prior to exposure to luteolin (20 μM) for 8 h. The levels of phospho-p53-Ser[15] (p-p53), p53, and β-actin were analyzed via Western blot. (A) Immunoblot experiments replicated at least three times. A representative Western blot is shown. (B) Intensity of p-p53 normalized to that of p53 presented as the means ± SD of three independent experiments. $^{**}p < 0.01$ represents a significant difference compared to the vehicle-treated group.

that luteolin induced a high level of miR-34a expression by increasing p53 phosphorylation and by activating the JNK and p38 MAPK p53-independent signaling pathways in response to luteolin-mediated neuronal differentiation in PC12 cells. Moreover, our findings revealed that luteolin attenuates the level of SIRT1, a known target gene of miR-34a, and induces an increase in the level of acetylated p53 (Figure 8). Our findings

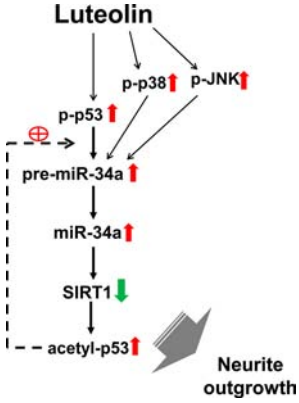

Figure 8. Hypothetical mechanism by which the miR-34a/SIRT1 axis is involved in the luteolin-mediated neurite outgrowth of PC12 cells. Luteolin induces the up-regulation of miR-34a via the activation of JNK-, p38-, and p53-dependent pathways. Thus, miR-34a may serve as a modulator of SIRT1 activity to increase p53 acetylation, potentially stimulating and maintaining neurite outgrowth in PC12 cells.

suggested the existence of a positive feedback loop in which p53 stimulates miR-34a expression, which modulates SIRT1 to increase p53 activity, potentially stimulating and maintaining neurite outgrowth in PC12 cells.

Several studies have demonstrated that luteolin has great potential to provide a neurotrophic or neuroprotective efficacy for prevention or treatment of neurodegenerative disorders. The bioavailability of luteolin is low because of its poorly soluble in water. Zhou et al. reported that oral administration of luteolin (14.3 mg/kg) in rats, it found that the plasma concentration of luteolin gradually increased and the maximal concentration (C_{max}) of luteolin was 1.97 ± 0.15 μg/mL (equivalent to 6.9 ± 0.5 μM).[32] Lin et al. demonstrated that the plasma concentration of luteolin was rapidly distributed and slowly decayed after luteolin administration via the femoral vein at a dose of 10 mg/kg in rats. The maximal concentrations (C_{max}) of luteolin could reach 7.47 ± 3.78 μg/mL (equivalent to 26.1 ± 13.2 μM) at 5 min and continually decreased up until 360 min after luteolin administration. During the oral administration of luteolin at 100 mg/kg in rats, the C_{max} of luteolin was 3.07 ± 0.72 μg/mL (equivalent to 10.7 ± 2.5 μM) and slowly decreased; it still could be detected up to 12 h after oral administration.[33] In the current study, we reported that the neurotrophic action and up-regulation of miR-34a by luteolin at a concentration of 20 μM, which is widely used in cell culture study, although it was higher than what can be reached in vivo. Several studies of flavonoids in foods have been reported to be permeable across the blood-brain barrier and provide good therapeutic efficacy.[34] Flavonoids could reach the peak plasma concentration of approximately 1−5 μM indicating that they are biologically active at low concentration.[35] To improve the bioavailability of luteolin in vivo, novel formulation or delivery systems such as nanoparticle delivery, nanostructured lipid carriers, and microemulsions may enhance its absorption and reach the concentration employed in this study.[36,37]

miR-34a belongs to the miR-34 family and is encoded by a gene located on chromosome 1p36.2. In mice, miR-34a expression is ubiquitous and is detected at the highest levels in the brain and the testes. The function of miR-34a has been shown to regulate genes involved in apoptosis and cell cycle control and to be an important mediator of tumor suppression in cancer.[26] Recently, specific roles of miR-34a in neuronal development and differentiation have been reported. In *Drosophila*, miR-34a up-regulation promotes neuronal survival and reduces neurodegeneration induced by polyglutamine-containing proteins.[38] In a mouse model, miR-34a has been demonstrated to regulate neuronal differentiation, synaptogenesis, and neuronal development.[39] miR-34a was shown to modulate mouse embryonic stem cell, neural stem cell, and neural differentiation.[27,40,41] These findings suggested that miR-34a expression may play a critical role in neuronal function. In the current study, we demonstrated that luteolin (20 μM) markedly increased the transcriptional levels of pre-miR-34a

DOI: 10.1021/acs.jafc.5b01005
J. Agric. Food Chem. 2015, 63, 4148−4159

and mature miR-34a during the neurite outgrowth of PC12 cells and verified the microarray analysis data showing miR-34a up-regulation. The silencing of miR-34a using antisense RNA oligonucleotides significantly attenuated the percentage of cells displaying neurite outgrowth, which was induced by luteolin. Our results indicated that luteolin-induced neurite outgrowth occurs, at least in part, via the up-regulation of miR-34a expression. In this study, we found that pre-miR-34a level changes do not correlate well with mature miR-34a after 24 h treatment of luteolin. It is unclear that luteolin continued to increase pre-miR-34a expression over time; however, in the mature form no further changes were detected by real-time PCR during 24−72 h treatment. Whether luteolin affects pre-miRNA stability, microprocessor activity, or mature miRNA turnover in PC12 cells remains to be further investigated.

The primary miR-34a transcript has been shown to be most strongly induced transcript by the tumor suppressor protein p53 among all identified microRNAs. The promoter of the miR-34a gene contains several p53-responsive elements, which have been shown to can directly bind to p53 to increase the transcriptional activity of miR-34a.[23,42] The p53 protein is known to display antiproliferative properties via the mediation of cell cycle arrest and apoptosis. However, high levels of p53 expression have been detected in areas of the developing brain in the absence of apoptosis. Hudson et al. reported that p53 expression was associated with cell differentiation and protection against apoptosis in neural progenitor cells.[43] Recent studies have demonstrated that p53 is required for axon regeneration, neurite outgrowth, neural precursor cell self-renewal, and neuronal differentiation.[44,45] Di Giovanni et al. reported that the early induction of nuclear p53 was observed in NGF-differentiated PC12 cells and that the transactivation of the actin-binding protein Coronin 1b and GTPase Rab13 was associated with neurite outgrowth.[44] In the current study, we clearly demonstrated that the treatment of PC12 cells with luteolin (20 μM) for 8−72 h markedly enhanced the levels of phosphorylated p53-Ser15, an active nuclear form of the p53 protein, and miR-34a transcriptional activation. The addition of the inhibitor pifithrin-α, which blocks p53 activity, significantly attenuated the luteolin-mediated induction of pre-miR-34a transcription and neurite outgrowth in PC12 cells. Our findings suggested that luteolin stimulates p53 phosphorylation, which, in turn, up-regulates miR-34a, a downstream target of p53, and other p53-responsive genes involved in the neurite outgrowth of PC12 cells. In addition, we found that at the concentration of luteolin (10 and 20 μM) used in the PC12 cell model did not induce apoptosis (data not shown). It has been reported that the phosphorylation of p53 at Ser15 can enhance the interaction of p53 with histone/lysine acetyltransferases (HATs), such as p300 and CBP.[46] Activated p53 coordinates a program of gene transcription that is dependent on the cell type and the growth status of the cells. The phosphorylation of p53 at Ser15 may play a central role in selectively regulating p53-dependent transcription in a cell type-specific manner. In mammary epithelial cells, p53-Ser15 phosphorylation and histone modification have been reported to contribute to ionizing radiation-induced miR-34a transcription.[47] Our current findings revealed that luteolin enhanced the phosphorylation of p53 at Ser15, which contributed to miR-34a expression and potentially played a critical role in the modulation of neuronal differentiation, but not apoptosis, in PC12 cells. The p53 protein may not be the only transcription factor that regulates miR-34a expression. The phosphorylation of p53 induced by luteolin may directly or indirectly control the expression of other transcription factors that may bind to the miR-34a promoter to modulate miR-34a transcription. In addition, luteolin-induced p53 activation may regulate neuronal differentiation-related gene expression to control neuronal function.

MicroRNAs are known to down-regulate the expression of several target genes in vivo and to mediate large-scale changes in the proteome to control cellular processes.[6] Many target genes of miR-34a have been identified and validated in various cellular processes.[26] One primary target of miR-34a is sirtuin 1 (SIRT1), a NAD^+-dependent lysine deacetylase that is involved in important biological functions, including energy metabolism, nutrient availability and neuroprotection.[48] SIRT1 is predominantly expressed in neurons of the adult brain, including the cortex, the hippocampus, the cerebellum, and the hypothalamus.[49] Recently, several substrates of STRT1-mediated deacetylation, such as p53, NF-κB, and PPARγ, were identified and shown to be involved in cell survival, stress responses, and neuronal differentiation.[50] Liu et al. reported that decreased SIRT1 expression was associated with the differentiation and maturation of embryonic cortical neurons and neural progenitor cells.[28] In mouse neural stem cells, miR-34a overexpression enhanced neurite outgrowth via the down-regulation of its target SIRT1, which increased the acetylation of p53 at Lys379 and the DNA-binding activity of p53, thus reinforcing the role of p53 in neural differentiation.[27] In the current study, we found that the level of SIRT1 protein was reduced during luteolin-mediated cell differentiation. However, the exposure of PC12 cells to resveratrol, a SIRT1 activator, markedly blocked luteolin-induced neuronal differentiation. These findings verified that SIRT1 activity may be involved in luteolin-induced neuronal differentiation. Our findings also showed that treatment of PC12 cells with luteolin increased the acetylation of the p53 at Lys379 protein. Several reports have been demonstrated that acetylated p53 may participate in regulating of genes involved in neuroprotection, neuritogenesis and neuronal differentiation.[27,51,52] In this study, our finding suggested that acetylated p53 may be involved in the maintenance and stimulation of p53 activity to further enhance pre-miR-34a and neuronal differentiation-related gene transcription in luteolin-treated PC12 cells.

In this study, we further demonstrated that inhibitors of JNK (SP600125) and p38 MAPK (SB203580) significantly blocked luteolin-induced miR-34a transcription and neurite outgrowth in PC12 cells. These results indicated that these signaling pathways may be involved in the induction of miR-34a transcription by luteolin. However, neither a MEK1/2 inhibitor (U0126), a PKA inhibitor (H-89), a PKC inhibitor (BIM), nor a PI3/Akt inhibitor (LY294002) attenuated luteolin-mediated pre-miR-34a expression. In our previous study, we identified the involvement of the PKA- and ERK-dependent CREB signaling pathways in luteolin-mediated miR-132 expression and neurite outgrowth in PC12 cells.[22] Treatment of PC12 cells with luteolin (20 μM) for 2 h significantly induced miR-132 expression and gradually reduced during 4−8 h exposure. miR-132 has been reported be involved in the regulation of neurite outgrowth, synaptic plasticity and neuroprotection. In this study, the microarray data showed that the induction of miR-132 displayed increases of 1.6-, 1.3-, 0.98-, and 0.96-fold after treatment of the cells with luteolin for 8, 24, 48, and 72 h, respectively (data not shown). These data indicated that miR-132 induced by luteolin may serve as an early response regulator to modulate neurite outgrowth in PC12 cells.

DOI: 10.1021/acs.jafc.5b01005
J. Agric. Food Chem. 2015, 63, 4148−4159

However, miR-34a up-regulation was sustained during 8−72 h treatment of luteolin. The miR-34a overexpression induced by luteolin may play a critical role to consistently augment p53 activation for promotion and maintenance of neurite outgrowth in PC12 cells. These findings revealed that different signaling cascades are involved in various types of luteolin-induced miRNAs expression, which, in turn, modulate different downstream targets affecting neuronal differentiation.

We further demonstrated that luteolin (20 μM) activated the phosphorylation of JNK and p38 in PC12 cells. The JNK and p38 MAPK pathways have been reported to regulate p53 phosphorylation at Ser15 in different cell types.[53,54] However, we found that the inhibition of JNK or p38 MAPK activation did not block luteolin-induced p53 phosphorylation in PC12 cells. No crosstalk was observed between these activated pathways and p53 phosphorylation at Ser15 in luteolin-treated PC12 cells. In this study, we found that pretreatment of cells with SP600125 (JNK inhibitor) or SB203580 (p38 MAPK inhibitor) significantly attenuated luteolin-mediated neurite outgrowth of PC12 cells. This data indicated that involvement of JNK and p38 phosphorylation during luteolin-induced neuronal differentiation. This finding is different from earlier study,[17] which showed that neurite outgrowth induced by high concentration of luteolin (100 μM) was significantly enhanced by treatment with inhibitor SB203580 in PC12 cells cultured in serum free medium. These results suggested that the inhibition of p38 activation may effectively enhance neurite outgrowth. It is plausible that the discrepancy effect of p38 activation on luteolin-mediated neurite outgrowth is due to the different luteolin dosage or experimental conditions. Several studies have been reported that activation of JNK and p38 is required for neuritogenesis and neuronal differentiation.[55,56] Our data supported that phosphorylation of JNK or p38 MAPK was involved in the luteolin-induced neuronal differentiation in PC12 cells. In addition to p53-mediated miR-34a transcription and neurite outgrowth, our findings suggested that JNK- and p38-mediated p53-independent cascades are involved in luteolin-induced miR-34a expression and neurite outgrowth in PC12 cells. Taken together, our findings provide evidence that the activation of p53-dependent and p53-independent miR-34a/SIRT1 pathways plays a critical role in the mechanisms underlying luteolin-induced neuronal differentiation.

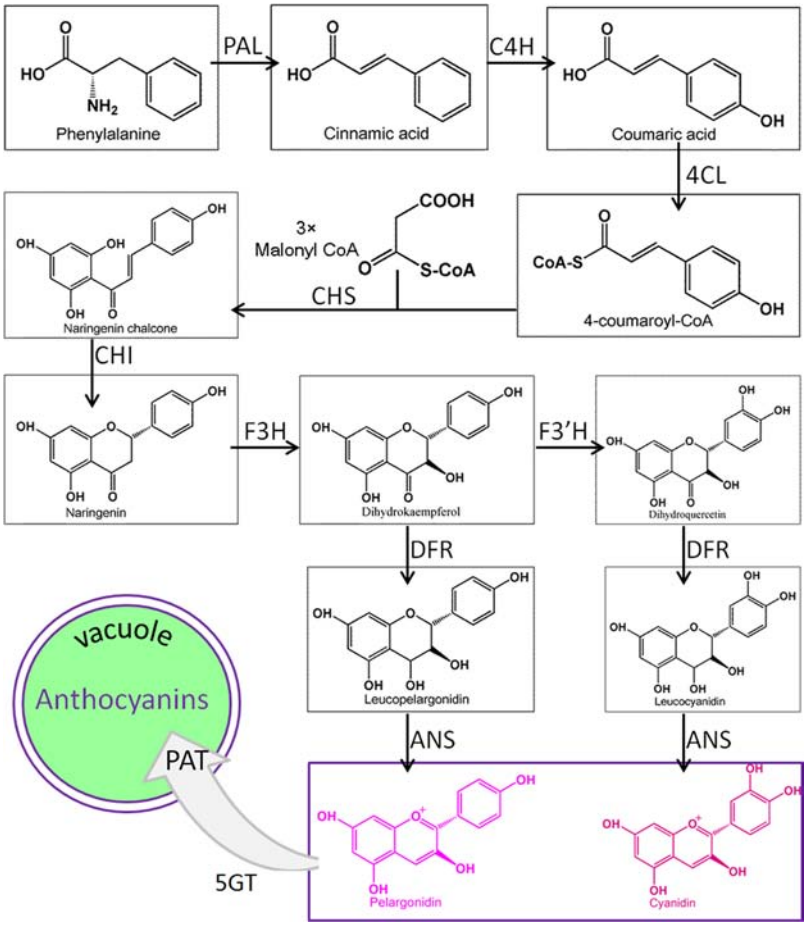

Figure 1. Schematic representation of the biosynthetic pathway of the anthocyanins. The names of the compounds in boxes are indicated. The enzyme names are as follows: PAL, phenylalanine ammonia lyase; C4H, cinnamate 4-hydroxylase; 4CL, 4-coumarateCoA ligase; CHS, chalcone synthase; CHI, chalcone isomerase; F3H, flavanone 3-hydroxylase; F3′H, flavanone 3′-hydroxylase; DFR, dihydroflavonol 4-reductase; ANS, anthocyanidin synthase; 5-GT, flavonoid-5-glucosyltransferase; PAT, putative anthocyanin transporter.

depending on pH, metal cations, copigmentation, and modifications of the backbone.[24]

Anthocyanins, as the metabolites of the flavonoid pathway, are synthesized under the complicated regulation of diverse regulatory genes mainly at the transcriptional level.[22,23,25] The flavonoid downstream pathway (from F3H to 5GT) of anthocyanin biosynthesis is regulated by several different families of regulatory genes, including MYB transcriptional factors, bHLH transcriptional factors, and WD40-like proteins.[26] By analysis of mutants of *Arabidopsis thaliana* with abnormal levels of anthocyanins and protein interaction assays, it has been proved that the transcription of anthocyanin biosynthetic genes is directly regulated by a transcriptional activation MYB-bHLH-WD40 complex (MBW) consisting of R2R3MYB, bHLH, and WD40 proteins.[27−29] Recent studies show that the variation in content of anthocyanins or tissue specificity in plants is governed mainly by the activity of the R2R3MYB transcription factors in the MBW complex.[30−36] However, the bHLH proteins always play essential roles in the synergistic regulation of anthocyanin accumulation.[29,37−39] In addition, heterogenous expression of bHLH genes individually greatly induced visible anthocyanin accumulation in the host plant.[40−42]

As a biennial plant native to northern Europe, kohlrabi (*Brassica oleracea* var. *gongylodes*) belongs to the Brassicaceae family and is grown widely for the round swollen stem at the base of the plant. Extensive studies show that cruciferous vegetables (including kohlrabi) supply human beings with a healthy diet due to the high levels of carotenoids, ascorbic acid, and tocopherols contained in the edible parts.[43,44] In addition to the natural antioxidants mentioned above, most of the antioxidative effects associated with food intake are largely due to the presence of phenolic compounds, including anthocyanins, flavones, flavonols, and so on.[45] In comparison with the green cultivars of kohlrabi, the purple cultivars which display abundant anthocyanin accumulation in the stems and leaves have attracted more attention from consumers due to their brilliant color and high levels of health-promoting ingredients. However, even though purple kohlrabi is consumed worldwide as a nutritious Brassica vegetable, the molecular mechanisms underlying its biosynthesis of anthocyanins in still remain unknown. In this paper, the components of anthocyanin production in a purple kohlrabi cultivar (Kolibri) were characterized with high-performance liquid chromatography−electrospray ionization tandem mass spectrometry (HPLC-ESI-MS/MS). In the following, the transcripts of anthocyanin biosynthetic and regulatory genes have been analyzed by quantitative real-time polymerase chain reaction (qRT-PCR) in different tissues of the purple and green cultivars (Kolibri and Winner). Furthermore, the influence of light on the development and anthocyanin accumulation of kohlrabi sprouts at different stages were analyzed. The consistent increase of the

Structures and major cleavage of cyanidin 3-(caffeoyl)-*p*-coumaroyl (sinapoyl)-diglucoside-5-glucoside in reference to peak 6 are shown in the inset box.

anthocyanin biosynthetic genes with regulatory factors indicate that transcriptional activation of *BoPAP2* and *BoTT8* in a light-independent manner mainly accounts for the upregulation of anthocyanin structural genes and the onset of anthocyanin accumulation in purple kohlrabi. The results above enhanced our understanding about the mechanisms of anthocyanin biosynthesis in purple kohlrabi at both the metabolic and molecular levels.

MATERIALS AND METHODS

Chemicals and Solvents. Anthocyanin (cyanidin 3,5-diglucoside) for external standards was purchased from Phytolab (Germany). High-performance liquid chromatography (HPLC) grade formic acid and methanol (MeOH) were bought from Sigma. All other solvents were provided from Aldrich (St. Louis, MO).

Plant Materials and Culture Conditions. Kohlrabi (*Brassica oleracea* var. *gongylodes* L.) seeds of green cultivar (Winner) and purple cultivar (Kolibri) were obtained from the Chongqing Academy of Agriculture Sciences. The samples used for HPLC-ESI-MS/MS analysis were collected from the cuticles of swollen stems from two cultivars of kohlrabi which were grown in a greenhouse with a 16 h photoperiod at 22 °C. In addition, the mature leaves and the cuticles and fleshes of swollen stems were used for total anthocyanin and qRT-PCR analysis. The light- and darkness-treated samples used for total anthocyanin and qRT-PCR analysis were collected from the sprouts of green and purple cultivars which were generated by the following procedures. Kohlrabi seeds were surface-sterilized with 70% ethanol for 60 s and 2.5% (v/v) bleach solution for 5 min and rinsed six times in sterile water. These seeds were then placed on half-strength sterilized Murashige−Skoog medium (1/2 MS) solidified with 0.8% agar. The two cultivars were germinated in a growth chamber under light/dark (16/8 h) or dark conditions at 26 °C and approximately 60% humidity. Samples were harvested after 3, 6, 9, and 12 days, measured for their length and fresh weight, frozen in liquid nitrogen, and stored at −80 °C until further analysis.

RNA Extraction and qRT-PCR Analysis. The samples of the two kohlrabi cultivars were grounded into powder in liquid nitrogen. Total RNA was isolated from various tissues for three biological repeats using RNAiso reagent according to the manufacturer's instruction (Takara, Dalian, People's Republic of China). RNA samples (1 μg) were reverse transcripted into complementary DNA (cDNA) with an oligo(dT)20 primer and M-MLV reverse transcriptase (Promega, Madison, WI) following the manufacturer's protocol. The synthesized cDNAs were diluted five times in H_2O for qRT-PCR analysis. qRT-PCR was carried out using the CFX96 Real-Time System (C1000 thermal cycler). All reactions were performed using the GoTaq qPCR Master Mix according to the manufacturer's instructions. Reactions were performed in triplicate using 5 μL of Master Mix, 0.25 μM of each primer, 1 μL of diluted cDNA, and DNase-free water to a final volume of 10 μL. The PCR amplification was as follows: 1 cycle of 2 min at 95 °C, 40 cycles of denaturation for 5 s at 95 °C, annealing for 20 s at 60 °C, and elongation for 15 s at 72 °C. Amplification was followed by a melting curve analysis with continual fluorescence data acquisition during the 60−95 °C melt. A melt curve analysis of qPCR samples revealed that there was only one product for each gene primer reaction. The primers used for qPCR analysis of kohlrabi were designed by Primer Premier 5 and given in Supplementary Table 1 (Supporting Information). The PCR products were sequenced to confirm the specific amplifications. The gene expression was normalized to *BoApr* as a reference gene for kohlrabi. Values reported here were calculated from three biological repeats for each sample.

Anthocyanin Extraction and HPLC-ESI-MS/MS Analysis. Anthocyanin extraction of kohlrabi was carried out in the same way as described for radish.[46] The extract was filtered through a 0.2 μm PTFE syringe filter. The samples were then analyzed by an Agilent Technologies 1200 Series HPLC (Agilent Technologies, Palo Alto, CA), equipped with an Agilent 1200 HPLC variable-wavelength detector. The results were analyzed by Agilent 1200 HPLC ChemStation software. The chromatographic separation was performed on a Zorbax Stablebond Analytical SB-C18 column (4.6 mm × 250 mm, 5 μm, Agilent Technologies, Rising Sun, MD). The injection sling was 5 μL. Elution was performed using mobile phase A (aqueous

total					nd	3.02 ± 0.21

[a]The number corresponds to the elution order by HPLC analysis in Figure 1C. [b]RT stands for the retention time. [c]Green indicates the green kohlrabi cultivar (Winner) and purple the purple kohlrabi cultivar (Kolibri). [d]Nd, not detected.

2% formic acid solution) and mobile phase B (methanol). The detection was at 520 nm, and the column oven temperature was set at 40 °C. The flow rate was 0.6 mL/min. The gradient program is described as follows: 0−2 min, 10−20% B; 2−40 min, 20−55% B; 40−41 min, 55−80% B; 41−45 min, 80% B; 45−50 min, 80−10% B; 50−55 min, 10% B. Quantification of the different anthocyanins was based on peak areas and calculated as equivalents of the standard compounds. All contents were expressed as milligrams per gram of dry weight. Low-resolution electrospray mass spectrometry was performed with a solariX ion trap mass spectrometer (Bruker Daltonics, Billerica, MA). The experimental conditions were as follows: ESI interface, nebulizer, 50 psi; dry gas, 15.0 psi; dry temperature, 320 °C; MS/MS, scan from m/z 200 to 1500; ion trap, scan from m/z 200 to 1500; source accumulation, 50 ms; ion accumulation time, 300 ms; flight time to acquisition cell, 1 ms; smart parameter setting (SPS), compound stability, 50%; trap drive level, 60%.

Total Anthocyanin Analysis. Spectrophotometric differential pH methods were used for the total anthocyanin measurement of kohlrabi following the procedure of Yuan et al. with slight modifications.[25] The protocols are described as follows. Frozen samples (100 mg) were crushed into powder in liquid nitrogen and extracted separately with 2 mL of pH 1.0 buffer and 2 mL of pH 4.5 buffer. In addition, pH 1.0 buffer contains 50 mM KCl and 150 mM HCl, while pH 4.5 buffer contains 400 mM sodium acetate and 240 mM HCl. The mixtures were centrifuged at 14000*g* for 15 min at 4 °C. The supernatants were gathered for measurement of absorbance at 510 nm. The amount of total anthocyanin was calculated according to the equation

$$\text{amount (mg g}^{-1}\text{ FW)} = (\text{A1} - \text{A2}) \times 484.8/24.825 \times \text{dilution factor}$$

A1 represents the absorbance of supernatants gathered from pH 1.0 buffer solution at 510 nm, while A2 represents the other absorbance. The value 484.8 represents the molecular mass of cyanidin-3-glucoside chloride, while 24.825 reflects its molar absorptivity at 510 nm. The total anthocyanin of the sample was analyzed in triplicate.

Statistical Analyses. SPSS, version 17.0 (SPSS Inc., Chicago, IL), was used for the data analysis. One-way analysis of variance (ANOVA) followed by pairwise comparisons was performed with posthoc Tukey's honest significant difference (HSD) test, with significance set at $p < 0.05$ and $p < 0.01$.

RESULTS AND DISCUSSION

Phenotypic Characterization of Kolibri and Winner. To study the biosynthesis of pigments in kohlrabi, the purple cultivar Kolibri and green cultivar Winner were chosen to study. Visual inspection of the kohlrabi cultivars showed that Kolibri displays more purple pigments than Winner (Figure 2A and Figure 1S in the Supporting Information). The pigments extracted from purple tissues of Kolibri share the same spectral properties with anthocyanin standards (cyanidin-3,5-diglucoside) and were confirmed as anthocyanins in the following HPLC-ESI-MS/MS analysis (Figure 2C). In comparison with those of Winner, most of the organs of Kolibri contain a high amount of anthocyanins (Figure 2B). During all the developmental stages of vegetative growth, the Kolibri synthesizes and accumulates anthocyanins constantly (Figure 1S in the Supporting Information). Meanwhile, the young sprouts of Winner only show a faint purple color at the very beginning of germination but turn into green immediately as the elongation of hypocotyls. During the initial weeks of growth, all the leaves of Winner turn solid green, while those of Kolibri display dark purple pigments in the veins of leaves and a pale purple color in the mesophyll tissue (Figure 2A and Figure 1S in the Supporting Information). The purple pigments of Kolibri plants, especially in the round stems, become intense during the development. After 2 months of cultivation, Winner possesses green swollen stems, while Kolibri displays dark purple pigments at the skin of the swollen stems. The intense accumulation of anthocyanins in the purple cultivar indicates a high ability to synthesize and accumulate anthocyanins. The total anthocyanin content of the skin of the purple swollen stem is about 0.63 mg/g of fresh weight, while little is detected in the corresponding tissue of Winner. These results show that the drastic differences in anthocyanin accumulation arise from cultivar and genetic specificity.

Identification and Quantitative Analyses of Anthocyanins in Purple Kohlrabi. A total of six major anthocyanins were separated and characterized from the cuticle extracts of the purple swollen stem with the method of HPLC-ESI-MS/MS (Figure 2C). In order to verify the identity of anthocyanins in Kolibri, MS/MS fragmentation patterns (m/z) corresponding to the compounds emerging in HPLC profiles were analyzed according to the information on radical groups reported previously.[21] Consequently, six new kinds of modified cyanidin were identified as the major anthocyanins in the purple cultivar (Table 1). However, it is strange that pelargonidin-based anthocyanins were not detected in the purple kohlrabi. Furthermore, all of the anthocyanin modifications in Kolibri were found to be glycosylated cyanidin at the C5 position of anthocyanidins. Meanwhile, acylation at the C3 position of anthocyanidins seems like a common modification in this study.

The total anthocyanin content was found to be 3.02 mg/g of dry weight for the swollen stem skin of Kolibri with the application of HPLC, while there was no trace amount of anthocyanins detected in the corresponding tissue in Winner (Table 1). The content of anthocyanins in Kolibri is similar to those found in the head tissues of red cabbage reported

Different lowercase letters indicate significance at $P < 0.05$.

before.[25] Moreover, the anthocyanin cyanidin 3-(caffeoyl)-*p*-coumaroyl (sinapoyl)-diglucoside-5-glucoside shows the highest level (2.08 mg/g dry weight) in the stem skin of Kolibri (Table 1).

Transcriptional Analysis of Anthocyanin Biosynthetic and Regulatory Genes in Both Kohlrabi Cultivars. In order to investigate the mechanisms underlying the anthocyanin accumulation in purple kohlrabi, the transcripts of anthocyanin biosynthetic enzymes and regulatory genes were examined in the leaves, skins, and flesh of the two cultivars by qPCR. The expression of anthocyanin biosynthetic genes *BoPAL, BoC4H, BoCHS, BoCHI, RsF3H, BoF3′H, BoDFR, BoANS*, and *Bo5GT* are shown in Figure 3. In comparison with the pigmentless tissues, most of the anthocyanin pathway genes were significantly upregulated in the purple leaves and stem skins of Kolibri. In the leaves, the expression of anthocyanin structural genes from *BoF3H* was drastically increased in purple kohlrabi in comparison with the green cultivar. In the cuticles of swollen stems, the purple kohlrabi displayed increased expression of nearly all anthocyanin pathway genes except for *BoCHI* and *BoC4H*. Consistent with pigment production, the higher folds of expression changes happened in the skins of swollen stems, while the lower folds of expression changes happened in the leaves. Among the upregulated genes, *BoF3H* exhibited the highest fold increase (1000 folds at least) in both the leaves and skins of swollen stems. In the results shown in Figure 2, trace amounts of all the anthocyanin structural genes were detected by qPCR in different organs of Winner with the absence of visible anthocyanin production. These results indicate that a large amount of transcripts of structural genes is a prerequisite for abundant anthocyanin accumulation. Moreover, the constant upregulation of anthocyanin biosynthetic genes in certain colorful organs and/or tissues rich in anthocyanins was also found in red-fleshed apple, purple eggplant, purple tomato, red pear, and pap1-D *Arabidopsis*.[30,32,34−36] Collectively, purple kohlrabi shares similar mechanisms of transcriptional regulation in mediating anthocyanin accumulation with those high anthocyanin content plants mentioned above.

Here, the absence of pelargonidin-based pigments we have referred to in the anthocyanin profile analysis of the purple kohlrabi is worth discussing. First, the fact that the biosynthetic pathway for anthocyanin accumulation is intact should be admitted for the apparent anthocyanin accumulation in certain tissues in Kolibri. In addition, the substrate specificity of the *BoDFR* and *BoANS* is also relatively broad.[47] Then, the question seems to become more confused. However, the higher activity of *BoF3′H* due to the dramatically increased transcripts in purple kohlrabi might provide a reasonable answer to this question (Figure 3). In the anthocyanin biosynthetic pathway shown in Figure 1, most of the dihydrokaempferol has been applied to produce dihydroquercetin with two hydroxyl groups. Consequently, there is no doubt that most of the final products should be cyanindin-based anthocyanins. By the same token, the common glycosylated cyanidin at the C5 position of anthocyanidins in Kolibri might be due to the increased expression of *Bo5GT* in purple stem skins.

To verify whether any of the regulatory genes controlling the transcription of anthocyanin structural genes were upregulated in Kolibri, the transcripts of some vital anthocyanin biosynthesis regulatory orthologous genes of *Arabidopsis*, *BoPAP1*, *BoPAP2*, *BoMYB113*, *BoMYB114*, *BoTT8*, and *BoTTG1*, were examined. In *Arabidopsis*, four R2R3MYB genes (*AtPAP1*, *AtPAP2*, *AtMYB113*, and *AtMYB114*) are known to regulate

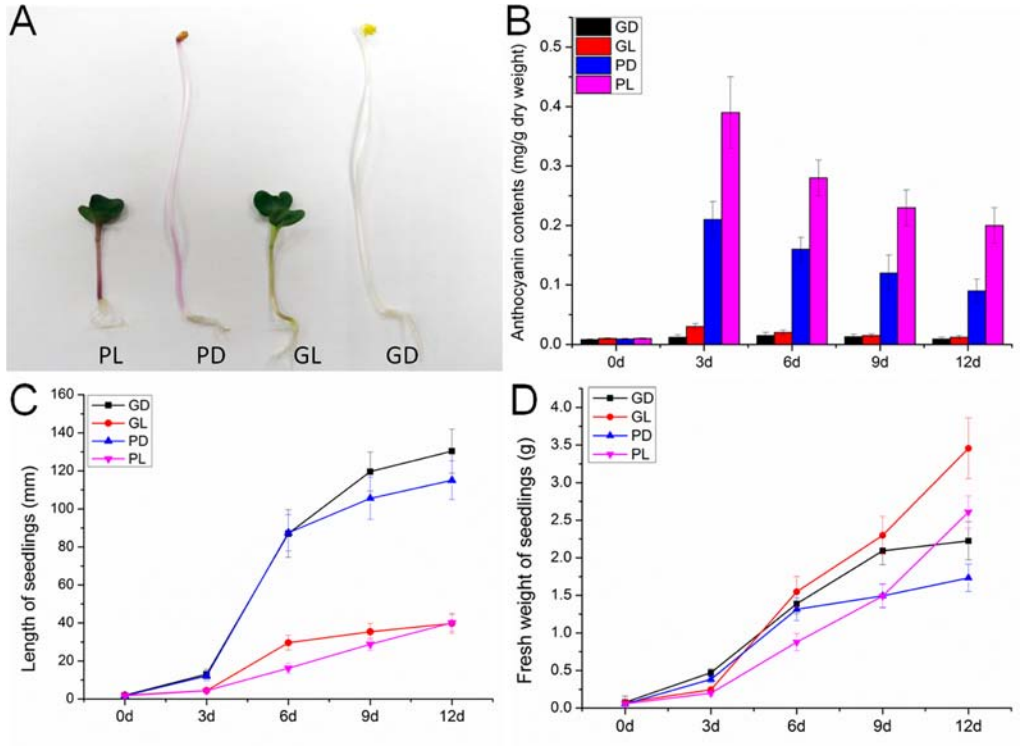

Figure 5. Phenotype of kohlrabi sprouts grown under dark and light conditions. (A) Photographs of kohlrabi sprouts of the two cultivars obtained at 6 days after sowing under dark and light conditions. (B) Anthocyanin contents (mg/g dry weight) during the development of kohlrabi sprouts under dark and light conditions. (C) Average length of sprouts of kohlrabi from 0 to 12 days after sowing (n = 30 per treatment). (D) Average fresh weight of sprouts of kohlrabi from 0 to 12 days after sowing (n = 30 per treatment). Abbreviations: PL, purple cultivar grown in the light; PD, purple cultivar grown in the dark; GL, green cultivar grown in the light; GD, green cultivar grown in the dark. Error bars represent the standard error of the mean (n = 3).

the biosynthesis of anthocyanins directly, while bHLH proteins *AtTT8* and *AtTTG1* play coordinate roles in the formation of a transcriptional regulation complex (MBW).[26] Thence, four MYB genes which shared high similarities with anthocyanin biosynthesis activators of *Arabidopsis* were cloned from the kohlrabi and designated as *BoPAP1*, *BoPAP2*, *BoMYB113*, and *BoMYB114*. Similarly, *BoTT8* and *BoTTG1*, as the orthologous genes of *AtTT8* and *AtTTG1*, respectively, were also cloned. In the results shown in Figure 4, *BoPAP2* and *BoTT8* were the only two regulatory genes greatly upregulated in tissues rich with anthocyanins. In the leaves, the expression levels of *BoPAP2* and *BoTT8* in Kolibri were about 990- and 6.8-fold higher than those in Winner, respectively. In the skins of swollen stems, the expression levels of *BoPAP2* and *BoTT8* in

Different lowercase letters indicate significance at $P < 0.05$.

Kolibri were about 452- and 57.7-fold higher than those in the green cultivar, respectively.

In the process of activating anthocyanin biosynthetic genes, the MYB and bHLH transcription factors make different contributions among plant species. In the anthocyanin biosynthesis regulatory complex of MBW, R2R3MYB transcription factors regulate anthocyanin biosynthesis specifically.[48] However, the functions of bHLH transcription factors and WD proteins are rather pleiotropic.[26] In addition, the increased expression of both MYB and bHLH is necessary for transcriptional activation of anthocyanin biosynthetic genes in petunia, cauliflower, and *Arabidopsis*.[26,31,49] Consequently, the dramatic increase of the pigment production and anthocyanin structural genes in purple kohlrabi should be due to the coordinated transcriptional activation of *BoPAP2* and *BoTT8*.

Light Sheds Evident Influence on the Growth and Anthocyanin Accumulation of Kohlrabi Sprouts. To study the effects of light on the development and pigment production of kohlrabi, sprouts of both cultivars grown under light and dark conditions were used as materials. The length, fresh weight, and total pigment content of sprouts were examined every 3 days until 12 days after sowing (DAS). As the results in Figure 5 show, the treated sprouts of Kolibri and Winner displayed completely different phenotypes in the production of anthocyanins. Kolibri showed apparent anthocyanin accumulation during all stages of development, regardless of light or dark conditions. However, the pigment intensity in sprouts of Kolibri cultured in the light is higher than that cultured in the dark. This phenomenon suggests that the production of pigments is not totally independent of light. In contrast, only a tiny amount of pigment was detected in the sprouts of Winner grown in the light and the production of pigments is totally dependent on light (Figure 5A,B). However, these two kohlrabi cultivars shared similar trends of growth (Figure 5C,D). The length increased with time during the entire process of the experiments. The sprouts cultured in the dark showed a much higher speed of elongation in comparison to those cultured in the light. The lengths of sprouts grown under dark conditions were 2-fold higher than those under light conditions after culturing in the medium for 9 days. In addition, the fresh weight of sprouts cultured for 12 days under dark conditions was not enhanced evidently in comparison with 9 day old sprouts. That is to say, the maximum biomass for kohlrabi sprouts cultured in the dark was reached at around 9 days. These results are concordant with the findings for buckwheat sprouts in a previous report.[50]

Expression Profiles of Anthocyanin Biosynthetic and Regulatory Genes in Sprouts of the Two Kohlrabi Cultivars Grown in Light and Dark Conditions. To investigate the molecular mechanism of anthocyanin accumulation under light and dark conditions, the expression profiles of the anthocyanin pathway and regulatory genes in the four groups of materials gathered at different stages were examined. The expression patterns of *BoPAL*, *BoC4H*, *BoCHS*, *BoCHI*, *BoF3H*, *BoF3′H*, *BoDFR*, *BoANS*, and *Bo5GT* are shown in Figure 6. During the different development stages in the light-treated sprouts of Kolibri, all of the anthocyanin structural genes exhibited the top expression level at 3 DAS. The expression patterns agree well with the amounts of pigment production in the corresponding tissues (Figure 5B). In

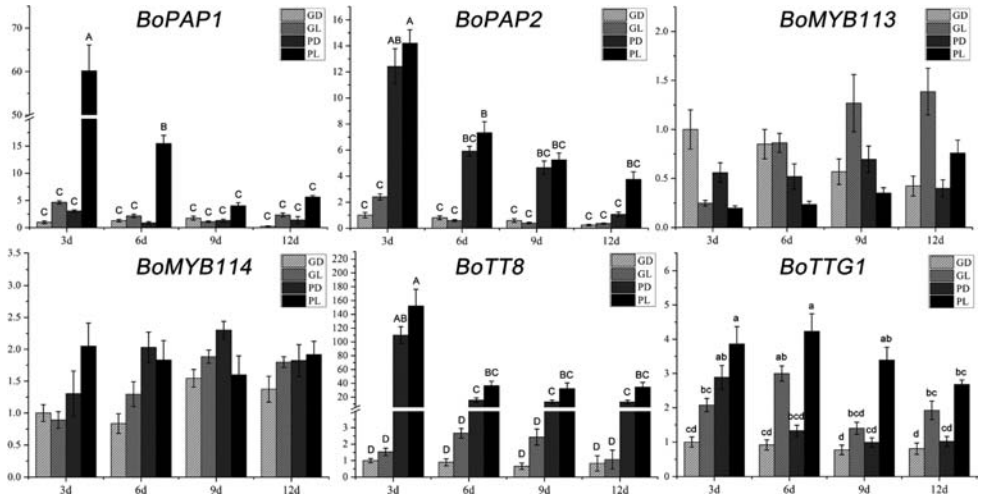

Figure 7. Expression profiles of anthocyanin biosynthesis regulatory genes during the development of kohlrabi sprouts under dark and light conditions. Abbreviations: PL, purple cultivar grown in the light; PD, purple cultivar grown in the dark; GL, green cultivar grown in the light; GD, green cultivar grown in the dark. The longitudinal axis indicates the expression levels of genes relative to the level of *BoApr*. Error bars represent the standard error of the mean (n = 3). The statistical significance of the differences between samples was calculated with ANOVA by paired-group comparisons. Different uppercase letters indicate significance at $P < 0.01$. Different lowercase letters indicate significance at $P < 0.05$.

comparison with the purple sprouts treated in the dark at 3 DAS, the expressions of *BoPAL*, *BoC4H*, *BoCHI*, *BoF3H*, *BoF3′H*, *BoDFR*, *BoANS*, and *Bo5GT* were all slightly raised in the purple sprouts treated in the light. In the same development stage, the expression of *BoCHS* in light-treated purple sprouts was significantly higher (8.2-fold) than that of purple sprouts in the dark. These results suggest that the expression of *BoCHS* in purple kohlrabi sprouts is strictly light dependent. Therefore, it is reasonable that the contents of anthocyanins in light-treated Kolibri sprouts are higher than those in dark-treated sprouts during all developmental stages. In combination with the expression analysis of anthocyanin biosynthetic genes at other developmental stages in purple sprouts, it can be concluded that light enhances the existing production of anthocyanins by strengthening the expression of structural genes, especially *BoCHS*, at the mRNA level. As we have mentioned that a trace amount of anthocyanins was detected in the light-treated sprouts of Winner, it is not astonishing that the transcripts of most anthocyanin pathway genes in the corresponding samples were significantly higher than those in dark-treated sprouts.

Expression profiles of anthocyanin biosynthesis regulatory genes in sprouts of the two kohlrabi cultivars grown under light and dark conditions are shown in Figure 7. In the light-treated sprouts of Kolibri at the stage of 3 DAS, the expression levels of *BoPAP1*, *BoPAP2*, and *BoTT8* were about 11-, 6-, and 101-fold higher than those in the light-treated green cultivar, respectively. It seems that the anthocyanin structural genes are coordinated regulated by *BoPAP1*, *BoPAP2*, and *BoTT8* in sprouts of Kolibri under light. Furthermore, *BoPAP1* was significantly raised at a transcriptional level under light conditions in purple sprouts during all stages of development and was about 23-fold higher than that in the dark-treated sprouts at 3 DAS. However, light did not have a significant influence on the transcription of *BoPAP2* and *BoTT8* in purple sprouts. In conclusion, the anthocyanin accumulation and upregulation of structural genes in the purple kohlrabi sprouts is mainly due to the transcriptional activation of *BoPAP2* and *BoTT8*. In addition, *BoPAP1* is the major regulatory gene responsible for the enhanced production of pigments in light-treated sprouts.

MYB genes associated with the regulation of anthocyanin accumulation are characterized by a conserved DNA-binding domain including two imperfect repeats (R2R3) with a specific motif for the interaction with the bHLH domain of bHLH proteins in the plant kingdom. The four MYB genes cloned from kohlrabi exhibited high sequence similarities with each other. The putative proteins contain conserved R2R3MYB domains and belong to the same subgroup 10 of MYB proteins as described by Allan et al. in anthocyanin production regulation.[48] In purple swollen stems of Kolibri, the upregulation of *BoTT8* and *BoPAP2* probably account for the accumulation of anthocyanins by transcriptional activation of the structural genes. Transcriptional factors of MYB or bHLH have been reported to be responsible for pigment production in many plant species. In certain anthocyanin-accumulating plants (such as red-fleshed apple, purple sweet potato, pap1-D *Arabidopsis*, and maize), the anthocyanin accumulation has been found to be due to an activation of a MYB transcriptional factor.[30,36,51−53] In contrast, white-skinned grapes arise from the mutations in a R2R3MYB protein.[54] In addition, the heterologous expression of bHLH transcriptional factors alter pigment production in the transgenic tomato.[40−42,55] In tissues rich with anthocyanins in Kolibri, both *BoPAP2* and *BoTT8* genes were constitutively upregulated. In the light-treated sprouts of Kolibri, *BoPAP1* was upregulated in large folds. A model illustrating that the transcriptional regulation complex consists of MYB, bHLH, and other proteins (*BoTTG1*) which regulate anthocyanin accumulation coordinatedly is presented in Figure 8. In the model, *BoTT8* and *BoPAP2* promote kohlrabi coloration in a light-independent manner, while the light-induced transcription factor *BoPAP1* (indicated by the dashed cycle) enhanced the existing production of pigments in the light-treated sprouts of Kolibri. In summary, the eye-catching purple kohlrabi not only supplies human beings with a healthy diet due to its high levels of carotenoids, ascorbic acid, and tocopherols contained in the edible parts but also contains large amounts of the natural antioxidants anthocyanins. The elucidations of anthocyanin accumulation at the molecular and metabolic levels in purple kohlrabi provide an important basis

(mainly histamine and tyramine) from different foods and foodstuffs: dry and raw sausages, cheese, fish slurry, Thai fish sauce, Myeolchi-jeot salted and fermented anchovy.[22−27] Some examples of these species are *Staphylococcus xylosus* (sausages), *Brevibacterium linens* (cheese), *Lactobacillus sakei* (fish slurry), and *Virgibacillus* sp. (Thai fish sauce). In contrast to García-Ruíz et al.,[28] who failed to show the ability of wine lactic acid bacteria (LAB) to reduce BA in wine, we have recently found that wine-associated strains of *L. plantarum*, as well as other LAB from sausages (*L. farciminis*) and beer (*P. acidilactici*) are competent to degrade histamine, tyramine, and putrescine in wine.[29]

In this work we show that cells of *K. varians* LTH 1540 are able to degrade putrescine in wine, providing the first report on putrescine degradation in wine by a species of *Micrococcus* genus. We also describe the purification, identification, and biochemical characterization of a novel amine oxidase enzyme responsible for putrescine degradation.

MATERIALS AND METHODS

Chemicals. Commercial standard proteins, reagents, and amines (putrescine, cadaverine, histamine, tyramine, methylamine, propylamine, ethanolamine, triethylamine, spermidine, and spermine) were obtained from Sigma-Aldrich (Steinheim, Germany).

HPLC analytical grade organic solvent methanol was supplied by Panreac. Reagent 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate solution (AQC solution) was purchased from Waters (Milford, MA, USA). Horseradish peroxidase was purchased from Merck (Darmstadt, Germany). Ultrapure water was obtained from a Milli-Q Gradient water system (Millipore, Bedford, MA, USA).

Organism and Culture Conditions. The strain *K. varians* LTH 1540, formerly isolated from artisanal fermented sausage and deposited in Dr. Hammes' culture collection (Universität Hohenheim, Germany), was kindly provided by Professor Dr. Herbert Schmidt. Cells were cultured overnight at 30 °C in nutrient broth medium supplemented with putrescine at 10 mg/L under stirred aerobic conditions.

Assay for Putrescine Degradation by *K. varians* Cells. The ability of *K. varians* cells to degrade putrescine in buffer system, synthetic media, and wine was tested. Putrescine degradation assays in 50 mM sodium phosphate buffer, pH 7.4, were performed using cells from a 6 unit OD_{600} culture, collected by centrifugation, washed twice in that buffer, and resuspended in the same buffer supplemented with 100 or 1000 mg/L of putrescine. Reaction mixtures were incubated at 28 °C with shaking, aliquots were taken at different time periods, and their putrescine content was measured by LC-FLD according to a previously reported method[30] and described below. The ability of *K. varians* cells to degrade putrescine was also tested in modified Dapkevicius' medium.[23] To this end, 100 μL of an overnight culture grown on nutrient broth medium was added to 10 mL of the medium supplemented with 150 mg/L of putrescine (pH 5.5). After static incubation for 48 h at 28 °C, residual putrescine was measured by LC-FLD.

For the analysis of putrescine degradation in wine, cells from 20 mL of nutrient broth medium culture (OD_{600} around 1 unit) were collected by centrifugation, washed twice with 50 mM sodium phosphate buffer, pH 7.4, and finally resuspended in 2 mL of red wine containing 40 mg/L putrescine (pH 3.5). Cell suspension was incubated at 28 °C under shaking conditions for 1 week, and then putrescine concentration was determined by LC-FLD as described below. In addition, viable cell counts on nutrient agar plates at 0 and 7 days were performed to estimate survival of *K. varians* LTH 1540 in wine.

BA from synthetic medium and wine samples were extracted with Oasis MCX 1 cm^3 extraction cartridges (Waters) as described in Peña-Gallego et al.[31] An Agilent 1200SL LC-FLD system equipped with an in-line degasser, autosampler, column heater, and fluorescence detector was employed. Chromatographic separation was carried out on an LC-FLD Luna C18 silica Phenomenex column (250 × 4.6 mm) with a guard precolumn (20 × 4.6 mm) of the same type. A solution of 140 mM sodium acetate and 17 mM triethanolamine (TEA, pH 5.05) was used as mobile phase A, and methanol was used as mobile phase B. A volume of 10 μL of samples was mixed with 25 μL of a solution of 0.2 M sodium borate (pH 8.8) and 5 mM EDTA. The derivatization reaction was performed by adding 15 μL of AQC solution according to the optimized procedure described by Cohen and De Antonis.[32] A volume of 5 μL of the derivatized sample was injected for each analysis. Gradient conditions used for separation were described by Hernández-Orte et al.[30] Column temperature was kept at 65 °C, flow rate was 0.8 mL/min, and total elution time was 70 min. The excitation and emission wavelengths of the fluorescence detector were set at 250 and 395 nm, respectively. Quantification was performed by comparing integrated peak areas of the sample with the control.

Purification and Identification of Putrescine Oxidase (PuO) Enzyme. Resting cells from a 2 L culture grown overnight were harvested by centrifugation at 10000 rpm at 4 °C for 20 min (Beckman coulter Avanti J-E, JA 10 rotor) and washed with 50 mM sodium phosphate buffer, pH 7.4. Cells were then resuspended in 10 mL of the same buffer and disrupted in a Mikro-Dismembrator-S (Sartorius) with 1 g of 106 μm glass beads. Cell suspensions were subjected to 10 cycles of breakage at 3000 rpm for 40 s each, alternating with cooling periods of 5 min on ice. Cell homogenate was centrifuged at 10000 rpm for 15 min at 4 °C, and the supernatant was saved as whole-cell extract.

To isolate the putrescine-oxidizing enzyme, the whole-cell extract was further ultracentrifuged at 47000 rpm for 1 h in an SW55Ti rotor (Beckman L-70 Ultracentrifuge), and the resulting supernatant was subjected to fractionation by ammonium sulfate precipitation.[29] The fraction showing enzyme activity, as revealed by an in-gel assay (see later), was retained. After dialysis against equilibration buffer (50 mM Tris-HCl, pH 8.0, 0.1 M NaCl, 0.1% Tween 20), redissolved proteins were fractionated by anion-exchange chromatography on a Macro-Prep Q (Bio-Rad) column (0.9 × 6 cm) and eluted with a 0.1−0.6 M NaCl gradient as described previously.[29] Fractions containing the highest putrescine-degrading activity, as determined by the liquid PuO activity assay described below, were pooled and used for further purification by preparative gel electrophoresis. First, an 8% polyacrylamide nondenaturing gel electrophoresis was performed as described by Callejón et al.[29] After revealing in-gel PuO activity, the resulting brown bands were cut off, fragmented by passing them through a hole at the bottom of a microcentrifuge tube, and the resulting small gel fragments were resuspended in SDS-PAGE loading solution. The suspension, without boiling, was directly loaded on an 8% polyacrylamide gel containing SDS, and after running, PuO activity was also revealed by the in-gel assay (see later). Protein purity was checked by Coomassie blue staining of a parallel lane loaded with identical sample. The brown band corresponding to PuO enzyme was cut out and sent to the Experimental Research Support Centre (SCSIE, Universitat de València) for protein identification.

Tryptic digest of the protein from the excised gel fragment was analyzed by MALDI-TOF-TOF MS/MS on an Autoflex speed instrument (Bruker). Samples were prepared using 4-cyano-4-hydroxycinnamic acid (CHCA) as matrix on Prespotted Anchorchip targets (Bruker Daltonics). Calibration was performed by an external mode using a peptide calibration standard kit (Bruker Daltonics). Spectra were processed using Flex Analysis 3.3 software (Bruker Daltonics). In MS analysis, peak lists were generated using the signals in the m/z 800−4000 region, with a signal-to-noise threshold >3. The SNAP algorithm included in the software was used to select the monoisotopic peaks from the observed isotopic distributions. After removal of m/z values corresponding to usually observed matrix cluster ions, an internal statistical calibration was applied. The final list of the resulting peaks was used to identify the proteins by peptide mass fingerprint, once keratin and trypsin peptides were removed. For MS/MS analysis, the most significant peptides were analyzed. The Mascot 2.2 program (Matrix Science Ltd., London, UK) was used to search the NCBInr_20100430 database, limiting the search to actinobacterial

DOI: 10.1021/jf5026967
J. Agric. Food Chem. 2015, 63, 4170−4178

proteins. Searches were done with tryptic specificity allowing one or two missed cleavages and a tolerance on the mass measurement of 100 ppm in MS mode and 0.5 Da for MS/MS ions. Carbamidomethylation of Cys was used as a fixed modification and oxidation of Met as variable modification.

Putrescine Oxidase Assays. The amine oxidase activity assay on putrescine in a nondenaturing PAGE was carried out essentially as previously described.[29] Whole-cell extracts or fractions from the different purification steps were mixed with an equal volume of 2× loading buffer (100 mM Tris-HCl, pH 6.8, bromophenol blue 0.04%, and glycerol 10%), loaded on a stacking 4% polyacrylamide gel and resolved on a nondenaturing 8% polyacrylamide gel, using Tris−glycine as electrophoretic buffer (25 mM Tris, 192 mM glycine). These native gels were run at 30 mA for an hour. After electrophoresis, gels were soaked in sodium phosphate buffer (50 mM, pH 7.4) containing 1 mM putrescine and incubated at room temperature with gentle agitation for 15 min. Then, the solution was replaced by the same buffer containing horseradish peroxidase (HRP; 1000 U/L) and diaminobenzidine (DAB, 0.25 mM) as chromogenic substrate. The appearance of a brown band, due to the formation of a colored precipitated product from DAB oxidation, revealed putrescine-oxidizing activity. This brown color takes usually 10 min to appear. Control assays were carried out without putrescine.

As the enzyme PuO maintains activity after SDS treatment, the identity of the band corresponding to the PuO enzyme could be checked in SDS-PAGE. To do that, samples were dissolved in SDS-PAGE loading buffer (50 mM Tris-HCl, pH 6.8, 2% SDS, 1% β-mercaptoethanol, 10% glycerol, and 0.02% bromophenol blue), but not boiled, and then loaded onto standard SDS-8% polyacrylamide gels. Following electrophoresis, gels were washed in 50 mM sodium phosphate buffer, pH 7.4, and PuO activity was revealed by the same procedure described above for native gels.

To assess which fractions of the chromatographic purification process contained PuO activity, the liquid PuO assay described by Federico et al.,[33] but modified and adapted to microplates, was also employed. This kind of assay was likewise used for the biochemical characterization of the enzyme. Briefly, 2 μL from the chromatographic fractions was mixed with 198 μL of a peroxidase-coupled reaction solution containing 2 mM putrescine, 0.5 mM 4-amino-antipyrine (AAP), 5 mM 3,5-dichloro-2-hydroxybenzenesulfonic acid (DCHBS), and 1000 U/L of HRP in 50 mM sodium phosphate buffer, pH 7.4. Relative PuO activity was determined by registering absorption at 515 nm (ε_{515} = 26000 M^{-1} cm^{-1})[33] by a microplate reader, FLUOstar Optima (BMG Labtech), over a time period of 30 min.

Mass Spectrometry Analysis. Putrescine degradation assays by cells or by the partially purified enzyme, to detect Δ^1-pyrroline as PuO reaction product that forms spontaneously from 4-aminobutanal as described by DeSa and Richard,[34] were performed in 50 mM tetraborate buffer, pH 8.0. Cells at DO_{600} of 6 were incubated in the buffer cited containing 1 g/L putrescine for 6 h. After that, sample was centrifuged at 13500 rpm for 10 min, cells were discarded, and supernatant was directly injected into the mass spectrometry equipment for analysis. In the same way, partially purified enzyme was incubated for 1 h and then injected. Samples from the mixtures were taken at time 0 and processed for mass spectrometry examination as controls. Analyses were performed using the Turbo V source in an electrospray positive ion mode at an ionspray voltage of −4500 V on an AB SCIEX TripleTOF 5600 system (Applied Biosystems, Life Technologies, Canada). Curtain gas (CUR) was set at 25 psi, nebulizer gas (gas 1) at 35 psi, drying gas (gas 2) at 35 psi, and temperature at 650 °C, scan TOF MS. Data acquisition was performed using the software Analyst and was qualitatively evaluated using PeakView software (Applied Biosystems, Life Technologies, Canada).

Biochemical Characterization of the Enzyme PuO. Fractions from anion-exchange chromatography containing partially purified enzyme were used for biochemical characterization of *K. varians* PuO. Enzymatic activity was measured by liquid assay in microplates, as described previously.

The relative molecular mass of the catalytic polypeptide was estimated by comparison with molecular weight markers after a SDS-10% PAGE and subsequent in-gel assay to identify the protein with PuO activity. Molecular size determination of the native protein was performed by size exclusion chromatography and also by sucrose gradient ultracentrifugation. Chromatography was developed in a column (0.9 × 60 cm) of Sephacryl S-200 HR (GE Healthcare) equilibrated with 50 mM sodium phosphate buffer, pH 7.4, and operated at room temperature with a flow rate of 15 mL/h. Fractions of 0.5 mL were collected and analyzed for PuO activity by liquid assay. The column was calibrated using as standard molecular mass markers catalase (240 kDa), alcohol dehydrogenase (120 kDa), ovalbumin (47 kDa), and cytochrome *c* (12.5 kDa). For ultracentifugation experiments, linear sucrose gradients (7−18%) in 50 mM sodium phosphate buffer, pH 7.5, were used. Partially purified PuO was layered on the top of an 11 mL gradient and centrifuged in a Beckman SW41Ti rotor at 40000 rpm for 20 h. After centrifugation, tubes were bottom-punctured, and fractions of 0.45 mL were recovered and subjected to PuO activity liquid assay. In a parallel gradient, a mixture of the same molecular mass markers used in size exclusion chromatography was also ultracentrifuged and employed for gradient calibration.

To determine the optimal pH value of the enzyme, the following buffers (and their corresponding pH ranges) were employed at a concentration of 50 mM: acetic acid−sodium acetate buffer (for a pH range of 3.7−5.5), citric acid−Na_2HPO_4 (for pH values between 4.5 and 7.4), NaH_2PO_4−Na_2HPO_4 (pH 6.5−8.0), Tris-HCl (pH 7.2−9.0), and glycine−NaOH (pH 8.0−9.5). All samples were incubated at 28 °C. Immediately after starting the reaction by addition of 0.007 U of enzyme, absorbance at 515 nm was registered each minute for a total time of 10 min, and the initial slope of plots of A_{515} versus time, representing relative PuO activity, was calculated.

Temperature dependence was tested by an end point procedure in which the reaction mixtures were incubated at different temperatures between 4 and 75 °C. Tubes, containing 198 μL of 50 mM sodium phosphate buffer, pH 7.4, plus putrescine, and the components for the peroxidase-coupled reaction, were pre-incubated at the corresponding temperature for 5 min before the start of the reaction by adding 0.007 U of enzyme. Relative PuO activity was determined as absorbance at 515 nm. The maximum absorbance registered was considered as 100% relative activity.

For thermal stability tests, aliquots of enzyme solution were pre-incubated at different temperatures at 28, 30, 45, 55, 65, 75, 85, and 100 °C for 10 min and then were placed at 28 °C for 15 min and assayed by the PuO liquid assay. The activity obtained at 28 °C was considered as 100% relative activity.

To determine substrate specificity, different monoamines (histamine, tyramine, methylamine, propylamine, and ethanolamine), diamines (putrescine and cadaverine), and polyamines (spermine and spermidine) were used at concentrations of 2 and 50 mM, and enzyme activity was tested by liquid assay at 28 °C. In all cases reaction was initiated by the addition of 0.007 U of PuO enzyme. Absorption at 515 nm was regularly measured over 30 min in a microplate reader, and then amine oxidase activity was determined from the initial slope of plots of ΔA_{515} versus time. PuO activity on putrescine was considered as 100% relative activity. Enzyme activity on different amines was confirmed by in-gel activity assay, as previously described.

Kinetic parameters K_m and V_{max} were determined for putrescine and cadaverine by liquid assay, with various amine concentrations from 0.1 to 5 mM. Reactions were initiated by the addition of 0.007 U of PuO enzyme. Rate constants were deduced from the slope and intercept of double-reciprocal plots of initial velocity versus diamine concentration.

Bipyridyl, phenanthroline, *N*-(3-(dimethylamino)propyl)-*N*′-ethyl-carbodiimide (EDC), deprenyl, cyclopropilamine, rasagiline, pargyline, and semicarbazide were assessed as putative inhibitors of *K. varians* PuO. Inhibitor compounds were added to the reaction mixture to final concentrations of 0.1, 0.5, 1.0, and 5.0 mM. Enzyme (0.007 U) was pre-incubated at 28 °C for 5 min in the presence of each inhibitor before initiation of the reaction by adding putrescine. PuO activity measured in the absence of any inhibitor was considered as 100%

DOI: 10.1021/jf5026967
J. Agric. Food Chem. 2015, 63, 4170−4178

relative activity (control). As negative control a reaction mixture containing heat-denatured enzyme was used.

Given the potential use of the enzyme in wine, the effect of ethanol on enzyme activity was tested by adding it to the reaction mixture to a concentration between 0 and 15% (v/v). The PuO liquid assay with 0.007 U of enzyme was employed in these experiments. The volume of buffer solution was adjusted accordingly to maintain the final reaction volume. Enzyme activity in the absence of ethanol was taken as 100% relative activity (control).

To investigate the ability of PuO to degrade putrescine in wine, 10 μL of enzyme solution containing 2.8 mg/mL of partially purified enzyme was mixed with 10 volumes of red wine supplemented with 40 mg/L putrescine (pH adjusted to 3.5). Following incubation at 37 °C for 24 h, putrescine content was quantified by LC-FLD, as described above. Two controls were performed: one containing an identical non-incubated (time zero) reaction mixture and a second sample without enzyme but incubated in the same conditions as the test samples. The percentage of degradation in the test samples was calculated by comparison with those controls.

Statistical Analyses. All data are presented as the mean ± SE. Group means were compared using one-way ANOVA followed by Duncan's multiple-range tests to identify differences among groups when appropriate. Two-group comparisons of control and inhibitor-exposed groups were carried out using a two-tailed Student's *t* test. All analyses were carried out using IBM SPSS Statistics 19 (SPSS Inc., Chicago, IL, USA). Percentage data were normalized by arcsine transformation prior to the analysis.

RESULTS AND DISCUSSION

Ability of *K. varians* Cells To Degrade Putrescine. Previous experiments using different strains of this species isolated from fermented foods provided indications of their potential to degrade BA. We therefore started out by investigating the ability of *K. varians*, a microorganism initially obtained from dry sausages, to eliminate putrescine in different media: a defined buffered solution, Dapkevicius' medium, and wine. In the buffer solution, when the initial concentration was 100 mg/L, all putrescine was degraded by cells in <24 h. Under similar conditions, when the concentration of putrescine was 1000 mg/L, more than half of the amine was eliminated after only 4 h of incubation.

In Dapkevicius' medium, putrescine was completely removed after 48 h when the initial concentration was 150 mg/L. Furthermore, *K. varians* cells were able to degrade up to 30%, from an initial concentration of 40 mg/L in wine, after 7 days of incubation (Figure 1). At this time no viable *K. varians* cells were recovered from wine.

Purification and Identification of Putrescine Oxidase from *K. varians*. Twelve milliliters of cell-free extract with a protein concentration of 10.4 mg/mL (Table 1) was obtained after bead beating of *K. varians* LTH 1540 cells. Putrescine oxidase activity (5.6 U/mL) was recovered in the ammonium sulfate 70% saturation fraction (Table 1). PuO liquid assay of collected fractions from the Macro-Prep Q chromatography showed a single enzyme activity peak at fractions eluted around 300 mM NaCl. Table 1 summarizes the yield and purification of the *K. varians* putrescine oxidase in the first three steps of the procedure described under Materials and Methods. We performed a native gel electrophoresis as an additional purification step, which led us in the end to identify the protein with PuO activity. To do this, the Macro-Prep Q fraction showing the highest activity was loaded on a semipreparative 8% native polyacrylamide gel electrophoresis. PuO activity was revealed as a brown band by the in-gel assay. The native electrophoresis has not been included in the purification table (Table 1) because the in-gel activity assay, employed after this purification step, is neither quantitative nor comparable with the liquid assay used in the previous steps. Nonetheless, native electrophoresis generated the highest degree of purification of our protocol, given that the protein band corresponding to the enzyme accounts for >82% of total protein after this step (based on a densitometry analysis with ImageJ software of the gel after SDS-PAGE, see Figure 2, lane 5). Taking into account the protein amount (estimated also by densitometry) remaining after native-PAGE and supposing, as an upper limit, the absence of activity loss, a 4400-fold purification overall may be roughly estimated by our purification procedure. In any case, native electrophoresis was an essential step for the identification of *K. varians* PuO. When the PuO brown band from the native gel was cut out and subjected to an 8% PAGE in the presence of SDS, a single band was visualized after Coomassie blue staining, which moreover matched exactly with the brown band revealed by in-gel PuO assay on a parallel lane (Figure 2). Subjecting the brown band to a second SDS-10% PAGE, again, only one Coomassie blue stained band appeared and also coincident with a brown band resulting from the PuO in-gel assay (results not shown). Putrescine oxidase activity was recovered following exposure to, and subsequent removal of SDS, indicating that denaturation of the enzyme did not result in an irreversible loss of activity. This property of the enzyme together with the excellent resolution of proteins by SDS-PAGE enabled us to purify and identify the catalytically active polypeptide of the enzyme oxidizing putrescine. Figure 2 shows the protein analysis by SDS-PAGE corresponding to the different steps of PuO purification described under Materials and Methods. The single band with PuO activity, which appears as a homogeneous polypeptide, migrated to a position corresponding to a molecular mass of 43 kDa. Digestion of the excised brown band by trypsin gave eight internal peptides that were resolved

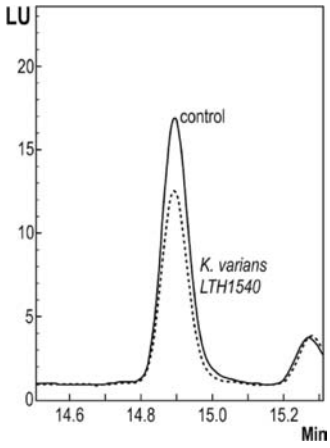

Figure 1. Degradation of putrescine in wine after incubation in the presence of *K. varians* LTH 1540 cells (equivalent to 10 OD_{600} units, approximately 7.6 × 10^{10} CFU/mL) (dotted line). Wine was supplemented with 40 mg/L of putrescine prior to inoculation of cells. Remaining putrescine in wine was quantified by LC-FLD. The graph shows the retention time on the *x*-axis versus fluorescence units (LU) recorded by the detector (*y*-axis). As negative controls, an identical mixture not incubated obtained at time zero (control 1) and wine supplemented with putrescine without the addition of cells incubated equally (control 2) were used. Because both controls gave the same peak area, only control 1 is shown. Only the chromatographic profile region corresponding to the putrescine peak is shown.

Table 1. Purification of *Kocuria varians* LTH 1540 Putrescine Oxidase[a]

step	volume (mL)	protein concentration (mg/mL)	enzyme activity[b] (units/mL)	specific activity (units/mg)	purification (-fold)
crude extract	12	10.4	1.22	0.12	1
$(NH_4)_2SO_4$ precipitation	2.4	7.4	5.60	0.76	6.4
Macro-Prep Q chromatography	1.0	2.8	6.70	2.40	20

[a]The table shows results of typical experiments starting from 2 L of a culture of cells grown overnight. [b]Enzyme activity is expressed in enzyme activity units (U), where 1 unit is defined as that amount of enzyme which oxides 1 μmol of substrate per minute, in the reaction mixture for the microplate PuO liquid assay as described under Materials and Methods.

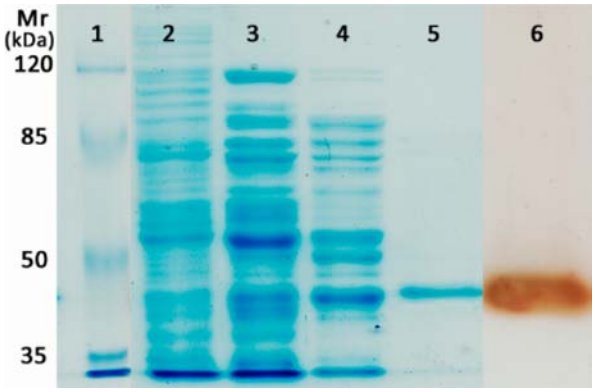

Figure 2. Electrophoretic analysis of proteins at different steps of the PuO purification in SDS-polyacrylamide gels. Lanes: 1, prestained molecular weight markers (Fermentas); 2, crude extract (~42 μg); 3, 70% saturation of ammonium sulfate precipitate (~42 μg); 4, Macro-Prep Q chromatography eluted fraction (34 μg); 5 and 6, proteins of the brown band resulting from native PAGE in which 250 μg of Macro-Prep Q partially purified protein was loaded. Lanes 1−5 were stained with Coomasie blue dye, and lane 6 was cut off and subjected to the in-gel PuO activity assay. Molecular masses of marker proteins are indicated on the left (kDa).

by mass spectrometry. Six of these peptides matched the putrescine oxidase enzyme of *K. rhizophila* (gil184199732) with a score of 321.4, covering 11.5% of protein sequence; 2 peptides matched the putrescine oxidase of *K. rosea* (gil730425) (syn. *M. rubens*) at a score of 229.3, which covers 8.2% of sequence; and 3 peptides were common to the two cited proteins (Supporting Information, Supplementary Figure 1). From this score value the putrescine degrading protein from *K. varians* LTH 1540 was unequivocally identified as a putrescine oxidase, because its score was >81, which is considered to be statistically significant for identification.[35] This protein is an ortholog of putrescine oxidase of *K. rhizophila* and belongs to the EC 1.4.3.10 class.

Supporting identification of the enzyme as PuO by mass spectrometry is the fact that Δ^1-pyrroline was detected by Mass qTOF as the product of putrescine degradation. Δ^1-Pyrroline is the product of the spontaneous condensation of 4-amino-butanal, which is the final product of putrescine oxidation by flavin-dependent PuO enzymes. A peak of m/z 70.06, corresponding to Δ^1-pyrroline, was obtained after incubation of putrescine with cells or partially purified enzyme in tetraborate buffer (Supporting Information, Supplementary Figure 2). The intensity of the Δ^1-pyrroline peak generated by the enzyme was 5-fold higher than that generated by cells.

Properties of the *K. varians* PuO. Partially purified enzyme from anion-exchange chromatography was employed to estimate the molecular mass of native PuO by size exclusion column chromatography and by sucrose density gradient ultracentrifugation. Analysis by size exclusion chromatography on Sephacryl S-200 HR yielded reproducibly an apparent PuO molecular mass of ~150 kDa. However, PuO molecular mass estimated by sucrose gradient centrifugation was around 87 kDa (results not shown). Because gel filtration and sedimentation should give similar values for globular macromolecules, our results strongly suggest that the shape of native *K. varians* PuO is elongated. Consequently, the actual molecular mass of the native enzyme probably lies somewhere between 87 and 150 kDa. Most importantly, these data demonstrate that the native form is notably higher than that of the catalytic single polypeptide obtained by SDS-PAGE (Figure 2), indicating that the *K. varians* native PuO must be a protein oligomer. The *K. varians* native enzyme is likely to be a dimer of identical subunits, given the homology with PuO from the nearby species *K. rosea*, which has been described in its native form as a homodimer with a molecular mass around 88 kDa,[34] similar to our ultracentrifugation results with *K. varians* PuO. To analyze the dependence of PuO enzyme activity on pH, different buffers with overlapping buffering capacities were used. *K. varians* PuO was found to be active over a relatively broad range of pH, which includes values from 5.5 to >9.5 (Figure 3A). No significant activity was detected below pH 5.0.

The optimal temperature for PuO activity was found to be 45 °C, although the enzyme retained activity in a rather wide temperature range, from 4 to 75 °C (Figure 3B). Moreover, temperature stability experiments revealed that *K. varians* PuO is a relatively thermostable enzyme compared to other amine oxidases. As deduced from the heat inactivation experiments (Figure 3C), the enzyme retained >50% of the activity after a pre-incubation treatment at 55 °C. In contrast, it was found that the putrescine oxidase from *K. rosea* suffered rapid inactivation at 50 °C.[20] Temperatures >65 °C completely inactivated the *K. varians* enzyme (Figure 3C).

Our substrate specificity analysis showed that none of the tested monoamines (histamine, tyramine, methylamine, propylamine, and ethanolamine) was oxidized by *K. varians* PuO (data not shown). The diamine putrescine was by far the best substrate for this enzyme, although the diamine cadaverine and, to a much lesser extent, the polyamine spermidine were also oxidized by the enzyme, as can be deduced from the relative activity data obtained from each substrate (Figure 4A). These results are consistent with previous data reported for known PuO enzymes from different species: *K. rosea*,[34,36] *M. luteus*,[16] and *R. erythropolis*.[37] Similarly to these enzymes, *K. varians* PuO apparently requires substrates with a minimum of two amino groups and, moreover, given that spermine cannot act as substrate (not shown) unlike spermidine, a free 4-aminobutyl moiety also seems to be essential for catalysis. Reactivity of *K. varians* PuO toward cadaverine and spermidine was verified by an in-gel assay after native 8% PAGE (Figure 4B), replacing putrescine with one of these other amines to reveal activities. In

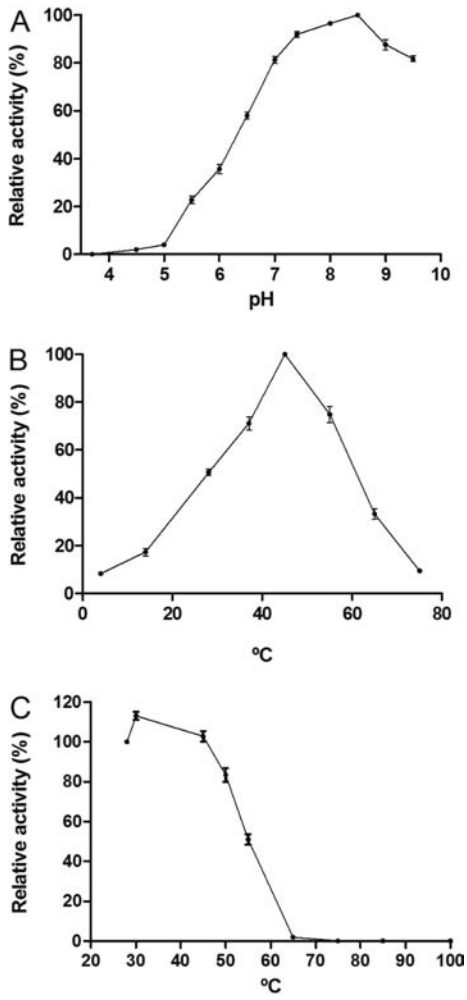

Figure 3. pH effect, temperature dependence, and thermal stability of the *K. varians* PuO. (A) pH effect. Reaction mixtures prepared with 50 mM of different buffers, at the shown pH, were assayed by the liquid procedure as described under Materials and Methods. The activity measures corresponding to the overlapping pH values were employed for normalization, and the resulting data expressed as percentage with respect to the maximum are plotted versus pH. (B) Temperature dependence. Liquid enzymatic reaction solutions were incubated at the indicated temperatures for 5 min. A_{515} was measured with a microplate reader and plotted as relative percentage to the maximum value. (C) Thermal stability. Equal aliquots of the enzyme solution were pre-incubated at the shown temperature for 10 min before being re-equilibrated to 28 °C. Putrescine was added to aliquots and degradation measured by the standard liquid assay. The residual enzymatic activity is represented as percentage relative to the value at 28 °C.

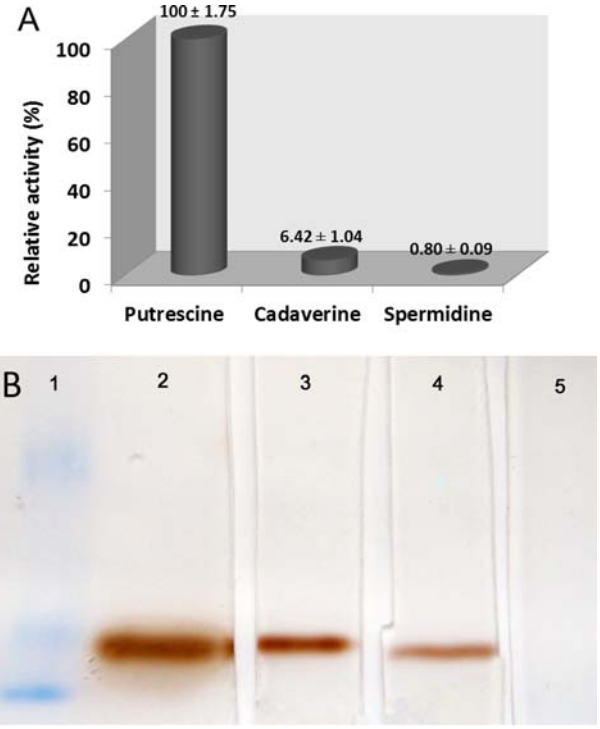

Figure 4. Substrate specificity analysis of partially purified *K. varians* LTH 1540 PuO. (A) Results from the liquid assay. Oxidation progression of the substrates, putrescine, cadaverine, and spermidine (2 mM), was determined as the absorption increase at 515 nm in a microplate reader. The initial slope of A_{515} versus time, expressing activity, was calculated and depicted as a percentage relative to that obtained with putrescine (100%). (B) Enzyme activity determined on a native−8% polyacrylamide gel and revealed by in-gel assay with 2 mM putrescine (lane 2), cadaverine (lane 3), or spermidine (lane 4). Lane 5 is a negative control without amine. Lane 1 was loaded with prestained protein markers (Fermentas) and used as reference during the electrophoresis progression.

all cases, a brown band was observed, but whereas it took only a few minutes to become visible when putrescine was the substrate, it lasted around 30 min with cadaverine and about 2 h with spermidine. No brown band was obtained in the absence of amine. These results evidence different preferences for substrate of *K. varians* LTH 1540 PuO enzyme.

We determined the steady state kinetic parameters for the diamine substrates, putrescine and cadaverine. The double-reciprocal plot of calculated initial velocities versus substrate concentrations was used to deduce K_m and V_{max}. The resulting kinetics parameters were as follows: $K_m = 94 \pm 10$ μM and $V_{max} = 2.30 \pm 0.1$ μmol/min·mg for putrescine; and $K_m = 75 \pm 5$ μM and $V_{max} = 0.15 \pm 0.02$ μmol/min·mg for cadaverine. *K. varians* PuO K_m for putrescine is in the same value range as that described for the homologue *K. rosea* PuO, slightly higher than that reported by DeSa[34] (38 μM), and a little lower than that reported by Okada et al.[36] (240 μM). It is, however, substantially higher than that for *R. erythropolis* (8.2 μM).[37] V_{max} values and results shown in Figure 4 clearly indicate that cadaverine (the five carbon analogue of putrescine) is worse than putrescine as substrate of *K. varians* PuO. However, the K_m value for cadaverine is slightly lower than that for putrescine, which suggests, as proposed for *K. rosea* PuO,[36] that hydrophobic interaction between the enzyme and the amine substrate must increase with methylene chain length.

Percentages of *K. varians* PuO enzymatic activity after the addition of different compounds, which are known inhibitors for amine oxidases from diverse origins, are shown in Table 2. In short, no inhibitor at a concentration of 100 μM showed any significant effect on enzyme activity (not shown). However, at concentration of 0.5 mM, EDC already revealed an important inhibitor effect, and at 1 mM rasagiline and pargyline also showed a decrease in putrescine oxidation. Deprenyl, cyclopropylamine, bipyridyl, phenanthroline, and semicarbazide did not affect PuO activity at the same concentration of 1 mM. When the concentration of inhibitors was 5 mM, PuO activity was diminished by deprenyl, semicarbazide, rasagiline, EDC, and pargyline, as can be seen in Table 2. EDC was described as

[a]Enzyme activity was measured by the 4-APP/DCHBS/HRP liquid assay as described under Materials and Methods. Results are expressed as percent inhibition related to the control in the absence of inhibitor. The negative control of the heat-denatured enzyme showed 100% inhibition. The experiments were done in triplicate. Asterisks indicate a *P* value of (*) <0.05 or (**) <0.01.

a carboxyl group modifying agent that affects the catalytic properties of PuO from *K. rosea*, which resulted in changes in substrate specificity and a ∼95% reduction of its catalytic potential.[38] As Table 2 shows, *K. varians* PuO was also inhibited by EDC, although to a lesser extent (∼70% reduction). It remains to be determined if modification by EDC causes the same alterations of properties in *K. varians* PuO as have already been described in *K. rosea*.

Rasagiline, deprenyl, and pargyline inhibit human monoamine oxidases (MAO)[39] through the formation of adducts with the FAD cofactor, and thus, unsurprisingly, the highest concentrations of these agents also inhibit the flavin-dependent PuO from *K. varians*. In contrast, cyclopropylamine, another MAO inhibitor, acts through alkylation of the active site.[40] Because the catalytic center of human MAOs differs from bacterial PuO as has been demonstrated by Van Hellemond et al.,[37] cyclopropylamine should act in a different way not exercising an inhibitory effect on *K. varians* PuO.

The fact that two metal chelating agents, bipyridyl and phenanthroline, did not affect the enzymatic activity of PuO suggests that no metallic cofactor is involved in catalytic activity, although both compounds significantly inhibit the activity of Cu-dependent amine oxidases.[41] Furthermore, phenanthroline at 1 mM did not affect enzymatic activity of the ortholog PuO enzyme from *K. rosea*.[42]

Semicarbazide is a carbonyl-modifying agent and a representative potent inhibitor of a specific group of amine oxidases, named semicarbazide-sensitive amine oxidases (SSAO). A high sensitivity to inhibition by semicarbazide, around 0.1 at 1 mM, distinguishes SSAOs from other amine oxidases, particularly from MAO.[43] *K. varians* PuO was not affected at all by 0.5 or 1 mM semicarbazide (Table 2) but was inhibited (by 30%) at the higher tested concentration of semicarbazide (at 5 mM), in contrast with *K. rosea* enzyme, which was not inhibited with up to 10 mM.[42]

Although the cofactor requirements of the enzyme have not been specifically analyzed in this work, MALDI-TOF identification and various physical properties including structure and substrate specificity similar to those of phylogenetically close species indicate that it is a flavin-dependent putrescine oxidase. The fact that it is inhibited by deprenyl, rasagiline, pargyline, and EDC, specific inhibitors of flavin-dependent amine oxidase, lends further support to this assumption. Likewise, the detection of Δ^1-pyrroline as product of putrescine degradation by Mass qTOF (Supporting Information, Supplementary Figure 2) confirms this idea.

Putrescine degradation in wine experiments showed that partially purified enzyme was able to degrade only 5% of putrescine after 24 h of incubation. Clearly wine conditions are not optimal for PuO activity; possible limiting factors could be ethanol and the low pH. Probably, ethanol is not the most limiting factor, as the enzyme maintains 82% activity in the presence of 15% ethanol (a higher concentration than normally found in wine). The most limiting factor should be thus the low pH of the wine (3.5 units in this case), a value at which PuO is almost completely devoid of activity (see Figure 3A). Higher reduction of putrescine in wine was achieved (30% approximately) using whole cells. Possibly inside cells, the enzyme may find a more appropriate environment for performing putrescine degradation, even if they are not growing.

Although the preferred methods for controlling BA in food are those involving prevention, it is not always possible to apply this kind of measure. Nowadays, the most widespread method for controlling BA in food is refrigeration. However, some bacteria can grow and produce BA below 5 °C, which demonstrates that refrigeration alone cannot always prevent the increase of BA and, thus, emerging control measures should be considered. New emerging control measures for delaying BA formation include high hydrostatic pressure, irradiation, packaging, microbial modeling, and the use of food additives or preservatives. These methods operate primarily through the inhibition of bacterial growth or the inhibition of the decarboxylase enzyme activity responsible for BA production.[21] In the case of wine, strategies that could be adopted to avoid BA formation are mainly reduction of precursor levels (amino acids) and prevention of growth of spoilage bacteria. Reduction can be achieved by avoiding practices such as long skin maceration, aging on lees, and amino acid addition for enhancing yeast growth during alcoholic fermentation, but these practices are not possible when full-bodied wines are intended. On the other hand, the prevention of bacterial growth is difficult due to the limited action of preservatives (lysozyme and SO_2) approved for enological use.[44]

Some authors have used BA-degrading bacteria to reduce BA content in several fermented products, either as starters for food fermentation or as additives. For instance, Leuschner and Hammes[22] used three different strains of *Brevibacterium linens* to eliminate tyramine and histamine in cheese. These authors also demonstrated the applicability of the strain *K. varians* LTH 1540 to degrade tyramine during sausage ripening.[17] Our results suggest that the use of this bacterium to eliminate putrescine in this process should be evaluated. Likewise, two different strains of *L. sakei* were applied to remove histamine in fish slurry by Dapkevicius et al.[23] Furthermore, Gardini et al.[24] achieved reduced concentrations of tyramine, spermine, and spermidine in dry sausages by inoculating a mixed starter consisting of *L. sakei* G20 and *S. xylosus* S8. Similarly, the inoculation of 10% (w/w) of *Virgibacillus* sp. SK33 in Thai fish sauce fermentation reduced histamine content by 50%.[26] More recently, Mah and Wang attained BA reduction in Myeolchi-jeot, a salted and fermented anchovy (*Engraulis japonicas*), by applying starter cultures of *S. xylosus* during ripening.[27] Finally, it is worth mentioning that multiple lactic acid bacteria strains are able to degrade amines in wine as described by Callejón et al.[29]

Purified enzyme amine oxidases have also been applied to reduce the BA content in food. With this aim, Dapkevicius et al.[23] utilized purified amine oxidase from porcine kidney to reduce histamine in ensiled fish slurry. Similarly, U.S. patent 4725540 describes the use of histaminases from *Lactobacillus* bacteria and from *Candida* yeast cells to eliminate BA from foodstuffs, beverages, and forages.[45] Therefore, cells containing amine oxidase activity or the direct use of the purified enzyme can be used to eliminate BA already generated in food. This strategy would be a potential measure of control when all other prevention practices have been ineffective.[21] In our case, the limited activity of the partially purified enzymatic fraction in wine does not support its use to decrease putrescine content. However, the fact that entire cells are able to degrade 30% of the amine opens the possibility of using them as an alternative to the enzyme. Because it has been shown that cells are unable to grow in wine, the use of high densities of nonproliferating cells is proposed. A similar strategy has been used to perform malolactic fermentation in wines in which very low pH values or high ethanol content prevented bacterial growth.[46]

In this work, we have demonstrated that *K. varians* LTH 1540 degrades diamines, mainly putrescine, in buffer, Dapkevicius' medium, and wine. We have identified the enzyme responsible for diamine degradation in this bacterium as a PuO; it has been biochemically characterized, and a strategy is proposed to degrade putrescine in wine. The applicability of *K. varians* LTH 1540 PuO in the food industry is a new challenge to be considered in the near future.

complex coacervates were expected to dissociate or precipitate. Nevertheless, the secondary aggregates of these biopolymer nanoparticles would possibly occur at a particular pH range such as physiological pH conditions. The stability problem of biopolymer nanoparticles formed by heating protein and polysaccharide electrostatic complexes has not yet been completely solved.

Whey protein isolate (WPI) is widely used as a food ingredient because of not only its high nutritional value but also its excellent functional properties, including emulsifying, foaming, and gelation. WPI consists mainly of several globular proteins, α-lactalbumin (α-la), β-lactoglobulin (β-lg), and bovine serum albumin (BSA). The functional properties of WPI are mainly dominated by β-lg, the major component of WPI. β-Lg is a suitable candidate for the preparation of drug delivery systems for lipophilic compounds because of its ability to bind hydrophobic constituents.[1,4] To the best of our knowledge, WPI and β-lg can form biopolymer nanoparticles with or without ionic polysaccharide through thermal treatment. However, these biopolymer nanoparticles are unstable at a pH range below their p*I* values with and without high salt concentrations, leading to the secondary aggregation. The stability problem of WPI-based nanoparticles under acidic pH conditions and high salt concentrations is greatly challenging.

The Maillard reaction is a complex series of reactions between reducing carbonyl groups of polysaccharide and free amino groups of protein, and it has become more and more popular for the preparation of glycosylated proteins compared with chemical glycosylation reagents. The covalent grafting of glycosyl residues to protein can significantly improve the solubility, thermal stability, and emulsifying properties of proteins.[22−26] Dextran is a neutral polysaccharide with high solubility, low viscosity, and no gelation. It has been widely used in the glycosylation of proteins to avoid the complication due to the formation of electrostatic complexes. Many studies have focused on the optimization process of the Maillard reaction and functional properties of protein−polysaccharide conjugates as well as their applications.[22−30] However, much less work has been reported on the influence of glycosyl residue introduction on the stability of biopolymer nanoparticles against pH and salt, which were formed by heating protein−polysaccharide conjugate and ionic polysaccharide electrostatic complexes.

Chondroitin sulfate (ChS) is a mucopolysaccharide extracted from animal cartilage as an important food grade material. ChS contains weakly acidic carbonyl groups and strongly acidic sulfate groups. Thus, ChS has a higher negative charge density and can form ionic complexes with positively charged substances. In addition, ChS has been investigated as a potential carrier for drug delivery due to its numerous appealing properties, including safety, biocompatibility, and biodegradability.[31,32]

Lutein, a non-provitamin A carotenoid, is widely distributed in fruits and vegetables and is one of the two carotenoids found in the macula and lens of the human eye, which is responsible for central vision and visual acuity. In addition, lutein is a powerful antioxidant, which plays an important role in the prevention of excessive ultraviolet light exposure, stroke, cardiovascular disease, and lung cancer.[33] Unfortunately, lutein is not synthesized in the human body. Therefore, dietary ingestion is the only source for the supplementation of lutein. However, the bioavailability of lutein is limited by its inherent poor water solubility.[33] Recent studies have demonstrated that nanoencapsulation is a promising approach to improve the bioavailability of poorly water-soluble compounds.[34,35]

The objective of the present study was to prepare stable nanoparticles against pH and salt by heating WPI−dextran conjugate/ChS electrostatic complexes and to elucidate the stability mechanism of the biopolymer nanoparticles over a wide pH range and at high salt concentration. The biopolymer nanoparticles were characterized by spectrophotometry, dynamic light scattering, zeta potential, transmission electron microscopy (TEM), atomic force microscopy (AFM), and scanning electron microscopy (SEM). As a nutrient model, lutein was used to evaluate the encapsulation efficacy of the biopolymer nanoparticles for hydrophobic compounds.

MATERIALS AND METHODS

Materials and Reagents. Whey protein isolate (WPI) was purchased from Hilmar Ingredients (Hilmar, CA, USA). WPI contained about 95.6% total solid, 88.7% protein, and 2.7% ash. Dextran with an average molecular weight of 40 kDa was obtained from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Chondroitin sulfate (ChS) was supplied by Shandong Yibao Biologics Co., Ltd. (Yanzhou, China). ChS was composed of 95.4% sodium ChS and 4.6% protein. Lutein (98% pure) was obtained from Zhejiang Medicine Co., Ltd. (Shaoxing, China). Hydrochloric acid, sodium hydroxide, anhydrous ethanol, phenol, sulfuric acid (98%), Coomassie brilliant blue G-250, and *o*-phthaldialdehyde (OPA) were purchased from Sinopharm Chemical Reagent Co., Ltd. All materials were used without further purification. All aqueous solutions were prepared with deionized water.

Preparation of WPI−Dextran Conjugates. WPI−dextran conjugates were prepared under macromolecular crowding conditions according to a method described previously with minor modifications.[23,36] Briefly, the conditions of pH 6.5 and 60 °C were used to maximize the extent of formation of Schiff base, which is the initial product of the Maillard reaction. The mixtures of WPI and dextran were dissolved in 10 mM sodium phosphate buffer solution (PBS) (pH 6.5) containing 0.02% (w/v) sodium azide to prevent bacterial growth. The degree of glycosylation (DG) increased with increasing protein concentration and mass ratio of dextran to WPI. However, protein concentration above 10% (w/w) would lead to the formation of WPI gelation during thermal treatment,[15,29,36] and dextran concentration above 30% could not significantly increase the DG of WPI.[36] In this work, the optimal concentrations of WPI and dextran were 7.5 and 22.5% (w/w), respectively. The solutions were carefully adjusted to pH 6.5 using 0.1 M HCl or 0.1 M NaOH and gently stirred for 6 h at room temperature to dissolve completely the mixtures. The mixed solutions were stored at 4 °C overnight for complete hydration. The following morning, 6 mL aliquots of the solutions were dispensed into 10 mL screw-top, glass vials sealed with Teflon tape to prevent evaporation and then incubated in a water bath at 60 °C for 24, 48, and 72 h (denoted WPI−dextran conjugates 1, 2, and 3, respectively). These reacted solutions were then removed from the water bath and immediately cooled in an ice−water bath. The reacted mixtures were diluted 4-fold with deionized water (pH 6.5, containing 0.02% NaN_3) and centrifuged at 10000*g* for 30 min. There were few white precipitates after centrifugation. The white precipitates were dissolved when resuspended in deionized water and heated at 100 °C for 30 min. After the redissolved solution was assayed by using the Coomassie brilliant blue and phenol−sulfuric acid methods, the white precipitates were identified as dextran self-associates due to its high concentration during thermal treatment.[36] The supernatant solutions were kept at −20 °C until use. WPI and dextran were separately incubated and centrifuged using the same treatment to serve as controls. All experiments were performed in triplicate.

Preparation of Biopolymer Nanoparticles from Mixtures of WPI/Polysaccharide. Biopolymer nanoparticles were prepared according to the method previously described.[12,13,37] Briefly, 1% (w/w) ChS stock solution was prepared by dissolving ChS in deionized

DOI: 10.1021/acs.jafc.5b00794
J. Agric. Food Chem. 2015, 63, 4179−4189

water and stirring for 2 h at room temperature. ChS stock solution was stored at 4 °C overnight for complete hydration. The stability of biopolymer nanoparticles prepared by the mixtures of protein and polysaccharide was investigated by the following experiments. (i) The WPI supernatant (WPI incubated at 60 °C for 48 h) and ChS stock solution were mixed and diluted with deionized water (WPI/ChS). (ii) The WPI and dextran supernatants (WPI and dextran separately incubated at 60 °C for 48 h) were mixed and diluted with deionized water (WPI/dextran). (iii) The WPI and dextran supernatants (WPI and dextran separately incubated at 60 °C for 48 h) and ChS stock solution were mixed and diluted with deionized water (WPI/dextran/ChS). WPI, dextran, and ChS concentrations were adjusted to fixed concentrations at 0.2, 0.55, and 0.008% (w/w), respectively (as discussed below). The concentrations of WPI and dextran in the supernatants were determined by using the Coomassie brilliant blue and phenol−sulfuric acid methods. After stirring for 2 h, the mixed solutions were adjusted to pH 5.2 (near the p*I* of WPI) with 0.1 M HCl and then heated at 85 °C for 15 min. The mixtures were finally cooled for 10 min in an ice−water bath. The nanoparticle suspensions obtained by the above process were kept at 4 °C before analysis.

Preparation of Biopolymer Nanoparticles from WPI−Dextran Conjugate and ChS. The WPI−dextran conjugate (*n*) supernatant and ChS stock solution (denoted WPI−dextran conjugate *n*/ChS, *n* = 1, 2, 3) were mixed and adjusted to the fixed final concentrations as described above. When WPI−dextran conjugate 2 (WPI and dextran mixtures incubated at 60 °C for 48 h) supernatant was adjusted to 0.2% (w/w) WPI, the dextran concentration was 0.55% (w/w). To keep experimental conditions as consistent as possible, the concentrations of WPI and dextran and ChS were fixed. All other procedures were the same as described above.

pH and Salt Stability. The stability of biopolymer nanoparticles against pH and salt was determined using spectrophotometry and dynamic light scattering. The nanoparticle suspensions were divided into two parts: one was adjusted to the desired pH values (1.0 to 8.0) using hydrochloric acid (2.0, 1.0, 0.1, and 0.01 M) or sodium hydroxide solution (0.1 and 0.01 M). The other portion was first added with NaCl stock solution (3 M NaCl) to reach a final concentration of 200 mM NaCl and then adjusted to the desired pH values as described above. In this study, the final NaCl concentration was 200 mM, slightly higher than physiological salt concentration, which was to verify salt stability of biopolymer nanoparticles in physiological concentration.

Lutein Loading. Lutein-loaded WPI−dextran conjugate/ChS nanoparticles were prepared according to the ethanol injection−ultrasonic method.[35] Lutein ethanol solution (0.2%, w/w) was obtained by dissolving lutein in anhydrous ethanol by sonication treatment (SK5210HP, Shanghai Kudos Ultrasonic Instrument Co., Ltd., China) for 1 min. Ten milliliters of lutein ethanol solution was rapidly injected into 100 mL of WPI−dextran conjugate/ChS nanoparticle suspension under agitation. After stirring for 1 h, the ethanol in the coarse suspension was removed by a rotary evaporator under reduced pressure at 40 °C. Then the lutein-loaded suspension was subjected to ultrasonic treatment in an ice bath for 4 min at 400 W with a pulse mode of 1 s of sonication and 1 s of rest using a probe sonicator (JY98-IIIDN, Ningbo Scientz Biotechnology Co., Ltd., China). The final suspension was kept at 4 °C in the dark before analysis.

Lutein was absorbed on the surface and entrapped in the lutein-loaded nanoparticles. To determine the amount and efficiency of lutein loading into the nanoparticles, the amount of lutein un-entrapped on the surface of nanoparticles was measured as follows: 0.5 mL of nanoparticle suspension was added to 2.5 mL of ethyl acetate, violently vortexed for 1 min, and then centrifuged at 1000*g* for 5 min. The resultant upper ethyl acetate layer was collected. The above treatment was repeated twice. The collected extracts were combined and concentrated to dryness under nitrogen conditions and redissolved in 10 mL of ethanol for spectral analysis. Lutein concentration was determined using a spectrophotometer (UV-1600; Mapada Instruments Co., Ltd., Shanghai, China) at 446 nm and calculated by the following equation: $C = 0.0322A - 0.0065$ (R^2 = 0.9992), where C and A were the concentration and absorbance of lutein in anhydrous ethanol, respectively. R^2 was the correlation coefficient of linear regression equation. The lutein loading content (LC, % w/w) and encapsulation efficiency (EE, %) were respectively calculated using the following equations:

$$\text{LC (\%w/w)} = \frac{\text{entrapped amount of lutein}}{\text{amount of WPI}} \times 100$$

$$\text{EE (\%)} = \frac{\text{total lutein} - \text{un-entrapped lutein}}{\text{total lutein}} \times 100$$

LC was defined as the content of lutein in the biopolymer nanoparticles measured by determining the ratio of entrapped amount of lutein to the total amount of WPI. The amount of lutein entrapped inside the biopolymer nanoparticles was calculated as the difference between the total amount of lutein added to the nanoparticle suspensions and that of lutein recovered by extraction. The amount of WPI in the biopolymer nanoparticles was obtained from the initial WPI concentration. EE was defined as the amount of lutein entrapped inside the biopolymer nanoparticles measured by determining the ratio of entrapped amount of lutein to the total amount of lutein.

Turbidity Measurements. Turbidity analysis of the biopolymer nanoparticle suspensions was carried out using an ultraviolet−visible spectrophotometer (UV-1600 spectrophotometer, Mapada Instruments Co., Ltd.) at 633 nm with a glass cuvette (1 cm path length).[37] Deionized water was used as blank for all solutions. All experiments were performed in triplicate.

Dynamic Laser Scattering (DLS) Measurements. The apparent *Z*-average hydrodynamic diameter (D_h) and polydispersity index (PDI) of biopolymer nanoparticles were measured by DLS using a Malvern Zetasizer Nano ZS analyzer (Malvern Instruments Ltd., Malvern, UK) fitted with a 633 nm He−Ne laser beam. Measurements were taken at 25 °C and 173° scattering angle. D_h and PDI were obtained by cumulant analysis (software of Zetasizer Nano ZS, Malvern Instruments Ltd.). The nanoparticle samples were measured directly without filtering or removing dust.

Zeta Potential Measurements. The zeta potential (ζ-potential) of nanoparticles was determined by laser Doppler electrophoresis at 25 °C using a Malvern Zetasizer Nano ZS analyzer (Malvern Instruments Ltd.). ζ-Potential was calculated by the Zetasizer Software (Malvern Instruments Ltd.) according to the Henry equation.[38] The nanoparticle samples were measured directly. Each sample was analyzed in triplicate.

Transmission Electron Microscopy Measurements. A drop of a 1000-fold dilution of the sample suspensions (approximately 7 μL) was deposited onto a carbon-coated copper grid. The samples were then allowed to dry for 72 h at ambient temperature. TEM images of biopolymer nanoparticles were recorded with a commercial TEM (JEM-2100, JEOL Ltd., Japan) operating at an accelerating voltage of 200 kV.

Atomic Force Microscopy Measurements. The nanoparticle suspensions for AFM measurement (Dimension icon, Bruker Co., USA) were diluted 400-fold with deionized water. AFM samples were prepared by dropping an aliquot (1 μL) of the diluted suspensions on a freshly cleaved mica surface and air-drying at room temperature for 72 h. The ScanAsyst mode was carried out using a silicon tip (TESP, Bruker, nom freq 320 kHz, nom spring constant of 42 N/m) with a scan resolution of 512 × 512 pixels in the dimension of 5 μm × 5 μm. Images were generated and processed using NanoScope software (Digital Instruments, version V614r1).

Scanning Electron Microscope Measurements. A drop of a 1000-fold dilution of the sample suspensions (approximately 7 μL) was deposited onto a carbon-coated copper grid. The samples were allowed to dry for 72 h at ambient temperature and then coated with gold palladium using a sputter coater. The morphology of biopolymer nanoparticles was observed at 40000× magnification with a field emission scanning electron microscope (S-4800, Hitachi Science Systems, Ltd., Japan) operating at an accelerating voltage of 5 kV.

Statistical Analysis. All experiments were performed in triplicate. Data were presented as a mean value with its standard deviation. The

means were compared with one-way analysis of variance (ANOVA) followed by Duncan's multiple-range tests, and $p < 0.05$ was regarded as significant. Statistical analyses were conducted using SPSS 17.0 for Windows (SPSS Inc., Chicago, IL, USA).

RESULTS AND DISCUSSION

pH and Salt Stability of WPI/Polysaccharide Nanoparticles. *pH and Salt Effect on Turbidity of WPI/Polysaccharide Suspensions.* The effect of pH on the turbidity of protein/polysaccharide suspensions is shown in Figure 1A. All of the suspensions had a similar trend when the pH changed from pH 1.0 to 8.0. WPI solution (0.2%, w/w) rapidly coagulated, and the white precipitates were found at the bottom of the bottle during thermal treatment near its p*I*, whereas dextran did not form aggregates under the same experimental conditions (data not shown). Similar phenomena have previously been observed by other researchers. Jones and co-authors reported that solutions of β-lg alone at pH 4.0−5.5 became very turbid after heating at 83 °C for 15 min.[12] The reason may be related to the unfolding and self-association of protein through hydrophobic interactions and disulfide bonds, which led to the formation of irreversible particulate aggregates in the absence of interprotein charge repulsion and above its thermal denaturation temperature. Additionally, Jones and co-authors also found that when 0.5% (w/w) β-lg solution was heated at pH 5 in the absence of pectin, large protein aggregates (d > 6000 nm) were formed and remained large (d > 3000 nm) across the entire pH range.[20] The results suggested that the aggregation occurring near the p*I* of the globular protein was pH-irreversible.

Although the WPI/dextran solution did not rapidly form much white precipitates during thermal treatment, the turbidity of WPI/dextran suspensions remained relatively high and constant at high pH values (pH 6.0−8.0) and had a maximum turbidity at pH 5.0. In addition, the turbidity of WPI/dextran suspensions gradually decreased with pH values decreasing from 5.0 to 1.0. In most cases for biopolymer mixtures, WPI and dextran are cosoluble in very dilute solutions. Above WPI's denaturation temperature and near its p*I*, phase separation (aggregation) would take place, resulting in WPI-rich and dextran-rich domains. Due to the very low turbidity resulting from the dextran-rich domain, the turbidity of WPI/dextran suspensions was dominated by WPI self-association, which suggested that WPI was the core component of the nanoparticles. The results also indicated that dextran could only partly suppress the formation of large sediments during thermal treatment. It was possible that dextran could decrease the frequency of encounters between protein molecules and thereby reduce the magnitude and range of protein−protein interaction during thermal treatment. However, due to the lack of electrostatic repulsion and steric hindrance between dextran and WPI molecules, dextran could not completely prevent WPI self-association. Similar results were reported by Chakrabortee and co-authors.[39] They demonstrated that dextran behaved as a molecular shield polysaccharide and used physical interference to reduce protein aggregation caused by desiccation. These studies have shown that the neutral dextran could indeed partly affect the aggregation or gelation process of protein during thermal treatment.

As shown in Figure 1A, the turbidity of WPI/ChS suspensions significantly decreased at pH 5.0. This was due to the fact that ChS molecules could increase the electrostatic and steric forces between particles, but these forces were not sufficient to prevent the particle aggregation at pH 4.0. Similar results were reported in previous studies.[11,40] Pectin stabilized the β-lg/pectin particles against aggregation around the p*I* of β-lg, which was presumably due to an increase in the electrostatic

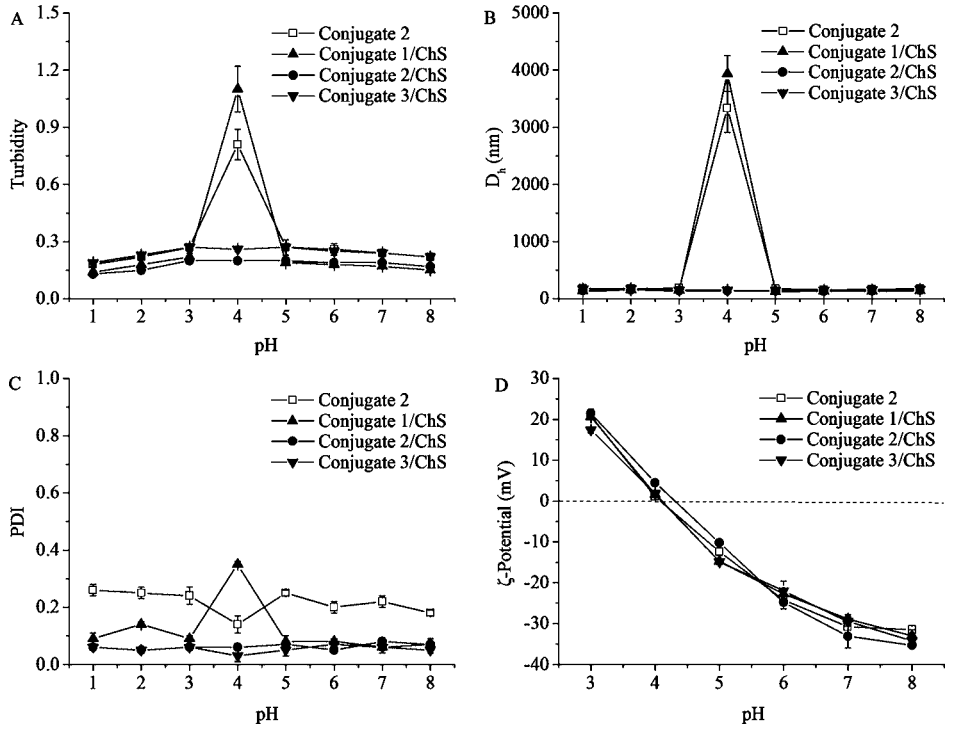

Figure 2. Effect of pH on turbidity (A), hydrodynamic diameter (D_h) (B), polydispersity index (PDI) (C), and ζ-potential (D) of WPI−dextran conjugate 2 (9.7% degree of glycosylation) and WPI−dextran conjugate/ChS suspensions. Suspensions were prepared by heating WPI−dextran conjugate 2 solutions or WPI−dextran conjugate/ChS electrostatic complexes at pH 5.2 and 85 °C for 15 min. Conjugate 1, WPI−dextran conjugate with 5.2% degree of glycosylation; conjugate 2, WPI−dextran conjugate with 9.7% degree of glycosylation; conjugate 3, WPI−dextran conjugate with 12.2% degree of glycosylation.

and steric repulsion between the biopolymer nanoparticles, whereas extensive aggregation was still observed at lower pH values.[11] In addition, the turbidity of WPI/ChS suspensions was relatively low in the pH ranges of 1.0−3.0 and 5.0−8.0, which was possible due to the lack of disulfide bond formation (pH 1.0−3.0) and the increase of repulsive electrostatic interaction (pH 1.0−3.0 and 5.0−8.0) between biopolymer nanoparticles.

The maximum turbidity of WPI/ChS and WPI/dextran/ChS suspensions was obtained at pH 4.0 and 5.0, respectively (Figure 1A). This was attributed to the fact that dextran could also decrease the collision frequency between WPI and ChS molecules as between WPI molecules. Therefore, dextran significantly weakened the suppressing effect of anionic ChS on WPI self-association. Similar results were reported in previous studies, demonstrating that the incompatibility between gelatin and pectin was attributed to the competitive interactions between dextran and the reactive groups of gelatin.[41] Additionally, it is well-known that high salt concentration can destabilize polyelectrolyte complexes due to the electrostatic screening effect. All suspensions in the presence of 200 mM NaCl had higher turbidity over a wider pH range compared with those in the absence of salt (Figure S1A and Figure 1A, respectively).

pH and Salt Effect on Particle Diameter of WPI/Polysaccharide Suspensions. The turbidity of the biopolymer suspensions was further supported by DLS measurements (Figure 1B,C and Figure S1B,C). As observed in Figure 1B, the *Z*-average particle diameter (160−250 nm) of WPI/ChS nanoparticles remained relatively stable in the pH ranges of 1.0−3.0 and 6.0−8.0. Figure 1C shows that the biopolymer nanoparticles had a small polydispersity index (PDI < 0.15) in the same pH ranges. However, the particle diameter significantly ($p < 0.05$) increased from 550 nm at pH 5.0 (PDI = 0.41) to 5600 nm at pH 4.0 (PDI = 0.46) (Figure 1B,C). The change trends of particle diameter of WPI/dextran and WPI/dextran/ChS suspensions were the same as that of WPI/ChS suspensions. In the presence of salt, the large aggregates in all suspensions occurred over a wider pH range compared with those in the absence of salt (Figure S1B and Figure 1B, respectively).

pH Effect on ζ-Potential of WPI and/or Polysaccharide Suspensions. The ζ-potential is directly related to the net charges on the surface of macromolecules and particles in solutions.[42] Figure 1D shows that the ζ-potentials of native WPI changed from negative at high pH values to positive at low pH values, with a zero charge point between pH 4.0 and 5.0. The pH value at the zero charge point was close to the p*I* of native WPI (4.8−5.2) reported in the literature.[14] ChS was negatively charged across the entire pH range of 3.0−8.0. Although dextran has no charges, its solution had a relatively low negative ζ-potential, which was attributed to the increased ionic strength when the solution was adjusted to various pH values by adding hydrochloric acid or sodium hydroxide. These results are in agreement with previous findings, which reported that the ζ-potential of dextran solution (phosphate buffer 0.01 M, pH 7.4) was −9.9 ± 0.5 mV.[43]

The absolute ζ-potential values of WPI/dextran suspensions, formed by heating at pH 5.2, were smaller than those of individual WPI solutions. The results confirmed that the principal component of the nanoparticles was composed of WPI, and dextran could affect the interactions between WPI molecules as discussed above. The ζ-potentials of WPI/ChS suspensions were between those of the individual WPI and ChS

DOI: 10.1021/acs.jafc.5b00794
J. Agric. Food Chem. 2015, 63, 4179−4189

solutions below pH 6.0, suggesting that there was electrostatic attraction between cationic patches on the protein surface and anionic groups on the polysaccharide backbone.[44] Therefore, ChS would influence the net surface charge of the outer periphery of WPI/ChS particles. It was important that the ζ-potentials could provide a good explanation for the turbidity and particle diameter of WPI/polysaccharide suspensions at different pH values. For example, the ζ-potentials of WPI/ChS suspensions went from negative (−36.8 mV) to positive (+15.8 mV) as pH values decreased from 8.0 to 3.0 (Figure 1D). The electrostatic repulsions between nanoparticles decreased with decreasing absolute ζ-potential values. Therefore, the turbidity and particle diameter of WPI/ChS suspensions increased.

Preparation of WPI−Dextran Conjugates. The Maillard reaction is a natural nontoxic process, which produces conjugates from the graft reaction between reducing end carbonyl groups of polysaccharide and free amino groups of protein. WPI−dextran conjugates prepared by the Maillard reaction have been reported in previous studies.[22,23,26,29,36] WPI−dextran conjugates exhibit higher solubility and thermal stability than those of the native WPI around its p*I*. In this study, WPI−dextran conjugates were prepared with the weight ratio of WPI to dextran 1:3 under macromolecular crowding conditions, which were previously reported by other researchers.[23,36] The formation of WPI−dextran conjugates was validated by the *o*-phthalaldehyde (OPA) method and Fourier transform infrared spectra (FT-IR) (Supporting Information, Figures S2 and S3, respectively). Meanwhile, the degree of glycosylation (DG) of the WPI−dextran conjugates was determined by the OPA assay from the loss of free amino groups of WPI.[29,45] The analysis revealed that DGs of WPI−dextran conjugate 1 (incubated for 24 h), conjugate 2 (incubated for 48 h), and conjugate 3 (incubated for 72 h) were 5.2, 9.7, and 12.2%, respectively (Supporting Information, Figure S2).

Stability of WPI−Dextran Conjugate/ChS Nanoparticles against pH and Salt. *Stability of WPI−Dextran Conjugate 1/ChS Nanoparticles against pH and Salt.* The stability of WPI−dextran conjugate/ChS nanoparticles against pH in the absence or presence of salt is shown in Figures 2 and 3, respectively. Compared with WPI/polysaccharide suspensions (Figure 1 and Figure S1), the turbidity and particle diameter of WPI−dextran conjugate or WPI−dextran conjugate/ChS suspensions significantly decreased ($p < 0.05$) at the same pH values in the absence or presence of salt, which illustrated that the dextran conjugated to WPI could significantly decrease the turbidity and particle diameter of the suspension systems. The results also suggested that the dextran conjugated to WPI could be extended to the periphery of the inner core of the nanoparticles and prevent their aggregation. The WPI−dextran conjugate 1/ChS suspensions had a relatively constant turbidity and smaller particle size diameter (about 150 nm, PDI < 0.15) at a low pH range of 1.0−3.0 and a high pH range of 5.0−8.0 (Figure 2A−C) and in the presence of 200 mM NaCl (Figure 3), indicating that the nanoparticles were fairly stable to association or dissociation. However, the turbidity and particle diameter of WPI−dextran conjugate 1/ChS were higher at the pH range of 3.0−5.0 regardless of salt. The results indicated that the steric hindrance provided by the dextran conjugated to WPI with only 5.2% DG could not effectively inhibit the aggregation of biopolymer nanoparticles in this pH range.

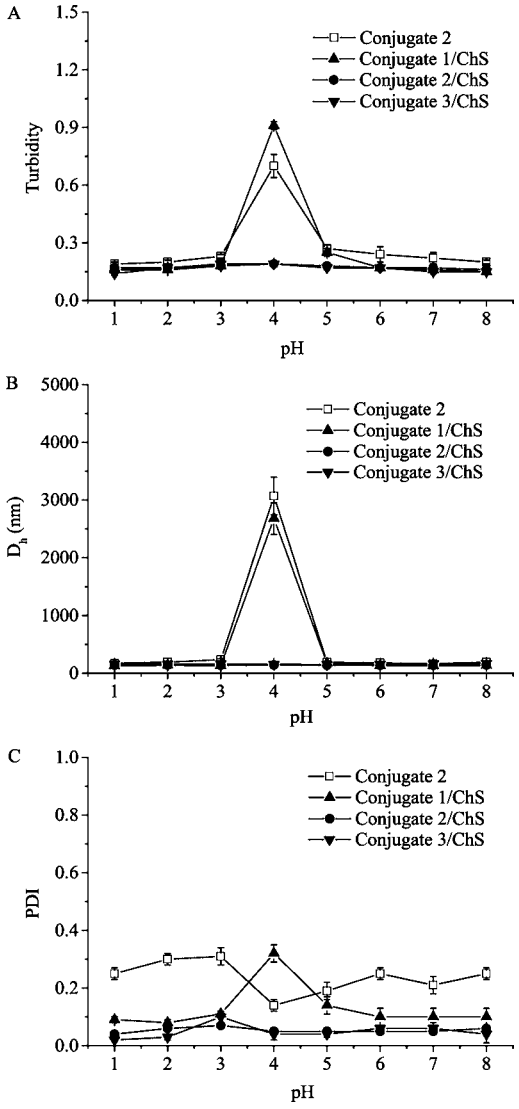

Figure 3. Effect of pH and 200 mM NaCl on turbidity (A), hydrodynamic diameter (D_h) (B), and polydispersity index (PDI) (C) of WPI−dextran conjugate 2 (9.7% degree of glycosylation) and WPI−dextran conjugate/ChS suspensions. Suspensions were prepared by heating WPI−dextran conjugate 2 solutions or WPI−dextran conjugate/ChS electrostatic complexes at pH 5.2 and 85 °C for 15 min. Conjugate 1, WPI−dextran conjugate with 5.2% degree of glycosylation; conjugate 2, WPI−dextran conjugate with 9.7% degree of glycosylation; conjugate 3, WPI−dextran conjugate with 12.2% degree of glycosylation.

Stability of WPI−Dextran Conjugate 2/ChS Nanoparticles against pH and Salt. It has been demonstrated that nanoparticles with 50−200 nm size acquire the best properties for cellular uptake.[46,47] The WPI−dextran conjugate 2/ChS nanoparticles (*Z*-average particle diameter about 150 nm and PDI 0.08) could remain stable in the entire pH range of 1.0−8.0 and in the absence or presence of salt (Figures 2 and 3, respectively), which was ideal for the encapsulation and transportation of nutraceuticals and drugs. Although the WPI/dextran/ChS nanoparticles had a smaller particle diameter (about 170−270 nm and PDI 0.08−0.23) at the pH ranges of 1.0−4.0 and 6.0−8.0, the secondary aggregates of the nanoparticles occurred in the pH range of 4.0−6.0 and in the presence of salt, and largest aggregates (about 6400 nm and

DOI: 10.1021/acs.jafc.5b00794
J. Agric. Food Chem. 2015, 63, 4179−4189

PDI 0.52) appeared at pH 5.0 (Figure 1B). Obviously, dextran conjugated to WPI could significantly improve the stability of WPI−dextran conjugate 2/ChS nanoparticles against pH and salt. However, the turbidity and particle diameter of WPI−dextran conjugate 2 suspensions were fairly similar to those of WPI−dextran conjugate 1/ChS suspensions (Figures 2 and 3, respectively). Only the introduction of dextran, from the WPI−dextran conjugate 2 with 9.7% DG, was not strong enough to stabilize the nanoparticles in the pH range from 3.0 to 5.0. This suggested that the combined action of the dextran conjugated to WPI with 9.7% DG and ChS could stabilize the nanoparticles against pH and salt.

Stability of WPI−Dextran Conjugate 3/ChS Nanoparticles against pH and Salt. There was no significant difference in the turbidity, particle diameter, and PDI between WPI−dextran conjugate 2/ChS and WPI−dextran conjugate 3/ChS suspensions over a wide pH range of 1.0−8.0 and in the absence or presence of salt (Figures 2A−C and 3A−C, respectively). The results illustrated that both dextran covalently conjugated to WPI with 9.7% DG and ChS electrostatically interacted with WPI were the minimum requirements to stabilize the nanoparticles. The WPI−dextran conjugate 2 was more economical than the WPI−dextran conjugate 3 because the latter required more preparation time. Therefore, the WPI−dextran conjugate 2/ChS complexes were used to further determine the characteristics of the stable nanoparticles.

ζ-Potentials of WPI−Dextran Conjugate 2 and WPI−Dextran Conjugate/ChS Suspensions. The ζ-potentials of biopolymer nanoparticle suspensions at different pH values are shown in Figure 2D. The ζ-potential values of all WPI−dextran conjugate or WPI−dextran conjugate/ChS suspensions were slightly lower than those of WPI/dextran or WPI/dextran/ChS suspensions (Figures 2D and 1D, respectively). For example, the ζ-potentials of WPI−dextran conjugate 2, conjugate 1/ChS, conjugate 2/ChS, and conjugate 3/ChS suspensions at pH 8.0 were −31.5, −33.0, −35.3, and −34.2 mV, respectively (Figure 2D), whereas the ζ-potentials of WPI/dextran and WPI/dextran/ChS suspensions at pH 8.0 were −38.1 and −37.7 mV, respectively (Figure 1D). The decrease of absolute ζ-potential values after protein glycosylation was probably related to the highly hydratable dextran lowering the electrophoretic mobility of the WPI−dextran conjugate and WPI−dextran conjugate/ChS suspensions. Similar results have been reported in previous studies.[25,27]

WPI−Dextran Conjugate 2/ChS Nanoparticle Formation Mechanism. As evidenced above, the stability of the nanoparticles was closely related to the degree of glycosylation of WPI. This indicated that the steric repulsions would stabilize the protein nanoparticles against aggregation, which were contributed by both dextran covalently conjugated to WPI and ChS electrostatically interacted with WPI. Therefore, the results suggested that the repulsive steric interactions were the major mechanism for the formation of the stable nanoparticles against pH and salt. It has been demonstrated that the steric hindrance of dextran conjugated to protein almost completely suppressed the protein aggregation during thermal treatment.[22−25,28] Combined with the present findings, it was further confirmed that the appropriate glycosylation of protein molecules was a crucial step to prepare the size-controlled nanoparticles. In addition, the ζ-potentials of WPI−dextran conjugate suspensions were slightly lower than those of WPI or WPI/dextran (Figures 2D and 1D, respectively), which indicated that dextran chains conjugated to WPI extended in the shell of the nanoparticle. Previous studies have also illuminated that steric hindrance was a function of polysaccharide chains on the colloidal particle surface to improve the heat stability of protein, which was supported by ζ-potentials of protein and glycosylated protein.[24,25,27,30]

Although the formation of the nanoparticles prepared by heating protein and ionic polysaccharide complexes undergoes a variety of interactions and processes, the electrostatic attraction and hydrophobic interaction primarily contribute to the initial structure development during gelation. Proteins might only electrostatically couple with a certain amount of ionic polysaccharides during thermal treatment. At the high mass ratio of WPI to ChS, most of the ChS chains could be partly or completely entrapped and fixed in the inner core of the nanoparticles during the process of denaturation and aggregation of WPI. It has been demonstrated that the β-lg/pectin nanoparticles prepared by thermal treatment were primarily composed of β-lg, but some pectin was still present.[12] In addition, Chakrabortee and co-authors have indicated that there was some association between proteins and neutral polysaccharides such as dextran during desiccation.[39]

The turbidity and particle diameter of WPI−dextran conjugate 2/ChS suspensions were stable in the pH range of 1.0−8.0 regardless of salt, but secondary aggregates occurred in the WPI−dextran conjugate 2 suspensions at pH 4.0 in the absence and presence of salt (Figures 2A,B and 3A,B, respectively). The results confirmed that not all ChS chains loosely distributed at the periphery of WPI−dextran conjugate 2/ChS nanoparticles after thermal treatment, but most of the ChS chains were incorporated into the nanoparticles to improve their stability, through the electrostatic interaction between the WPI−dextran conjugate or WPI and ChS molecules during thermal treatment. Although there was a slight difference in the ζ-potentials between WPI−dextran conjugate 2/ChS and WPI−dextran conjugate 2 suspensions in the pH range of 3.0−8.0, the ζ-potentials of the former and latter were from −24.8 to −35.3 mV and from −24.2 to −31.5 mV at the pH range of 6.0−8.0, respectively (Figure 2D), where the electrostatic repulsion between WPI−dextran conjugate and ChS was predominant. This suggested that some of the ChS chains extended in the shell of the nanoparticles. Therefore, the shell of the nanoparticles was composed of both ChS and dextran conjugated to WPI. Multiple interactions finally contributed to the stability of the nanoparticles against pH and salt. As discussed above, ChS, WPI, and WPI−dextran conjugate with an appropriate degree of glycosylation could be assembled into the stable nanoparticles with WPI-dextran conjugate/ChS shell and WPI/ChS core in a wide range of pH values and high salt concentration.

Lutein Loading of WPI−Dextran Conjugate 2/ChS Nanoparticles. There were no significant differences in the turbidity, particle diameter, and ζ-potential between lutein-unloaded and lutein-loaded nanoparticles in the absence or presence of salt (Figures 2, 3 and 4). The results illustrated that lutein loading did not impair the stability of the nanoparticles. The WPI−dextran conjugate 2/ChS suspension with light blue opalescence was obtained as shown in Figure 5A-1 (as inset), and the lutein-loaded nanoparticle suspension was uniformly stable as shown in Figure 5B-1 (as inset). Previous studies showed that the *Z*-average particle diameter of nanoemulsions decreased with sonication treatment.[48] This discrepancy was attributed to the good stability of the conjugate/polysaccharide nanoparticles formed by thermal treatment. On the contrary,

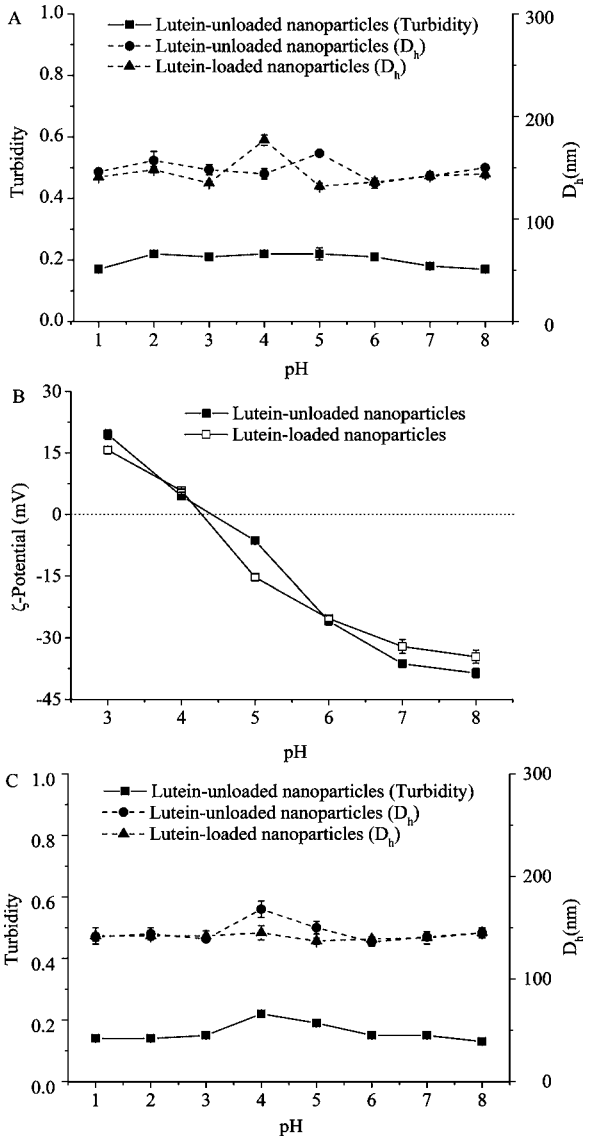

Figure 4. Effect of pH on turbidity and hydrodynamic diameter (D_h) of lutein-unloaded and lutein-loaded nanoparticle suspensions (A), effect of pH on ζ-potential of lutein-unloaded and lutein-loaded nanoparticle suspensions (B), and effect of pH and 200 mM NaCl on turbidity and hydrodynamic diameter (D_h) of lutein-unloaded and lutein-loaded nanoparticle suspensions (C). Suspensions were prepared by heating WPI–dextran conjugate 2 (9.7% DG)/ChS electrostatic complexes at pH 5.2 and 85 °C for 15 min, and then lutein-unloaded and lutein-loaded nanoparticle suspensions were evaporated by a rotary evaporator and subjected to ultrasonic treatment.

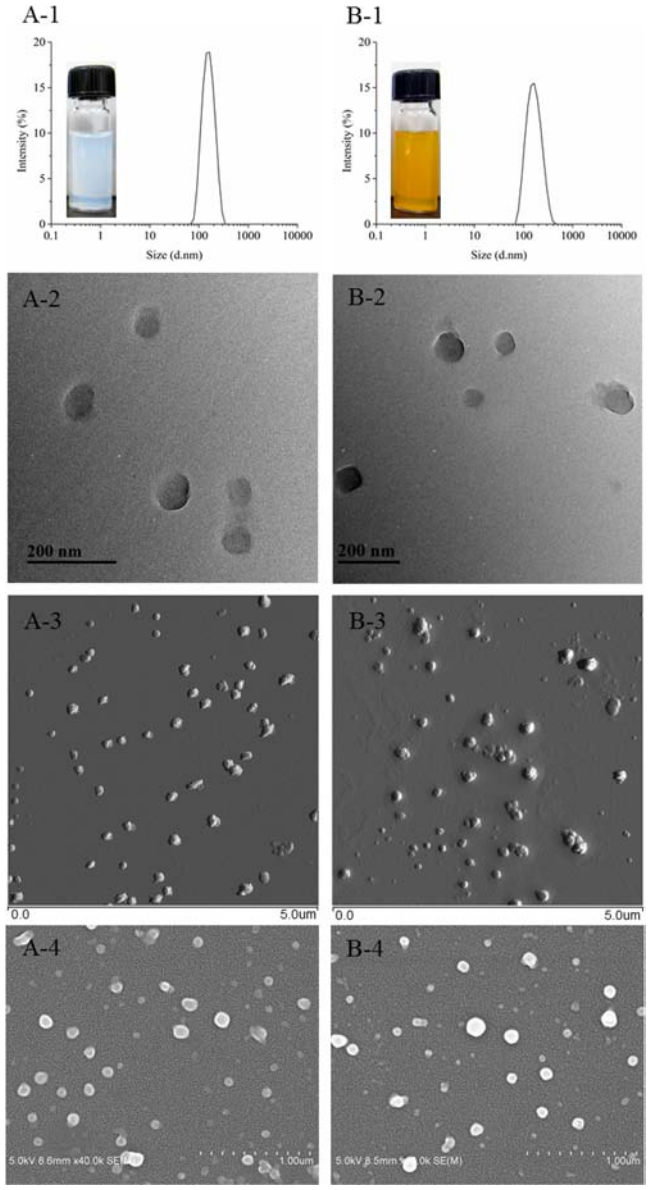

Figure 5. Particle size distribution of lutein-unloaded (A-1) and lutein-loaded (B-1) WPI–dextran conjugate 2 (9.7% DG)/ChS suspensions, TEM images of lutein-unloaded (A-2) and lutein-loaded (B-2) WPI–dextran conjugate 2 (9.7% DG)/ChS nanoparticles, AFM images of lutein-unloaded (A-3) and lutein-loaded (B-3) WPI–dextran conjugate 2 (9.7% DG)/ChS nanoparticles, and SEM images of lutein-unloaded (A-4) and lutein-loaded (B-4) WPI–dextran conjugate 2 (9.7% DG)/ChS nanoparticles. The insets are direct images of lutein-unloaded and lutein-loaded WPI–dextran conjugate 2 (9.7% DG)/ChS suspensions.

the ultrasonic cavitation could promote lutein molecules to migrate into the interior of the nanoparticles. Lutein molecules were trapped in the hydrophobic regions of the nanoparticle core, by hydrophobic interactions. In this study, the nanoparticles could effectively encapsulate lutein with the loading content and encapsulation efficiency of 8.03 and 94.07%, respectively. The ζ-potentials had no significant difference between lutein-unloaded and lutein-loaded nanoparticles (Figure 4B). Apparently, the neutral lutein could not influence the surface charge of the nanoparticles. The *Z*-average particle diameter of lutein-loaded nanoparticles remained almost unchanged over the entire pH range (1.0–8.0) regardless of salt (Figure 4A,C), indicating that lutein-loaded nanoparticles had good stability against pH and salt.

Morphology of WPI–Dextran Conjugate 2/ChS Nanoparticles. *TEM.* The morphology of lutein-unloaded and lutein-loaded nanoparticles was characterized using TEM, AFM, and SEM as shown in Figure 5. TEM images of the nanoparticles revealed a homogeneous size distribution and a spherical shape with smooth surface, as shown in Figure 5A-2,B-2. The particle diameters of lutein-unloaded and lutein-loaded nanoparticles in TEM images were approximately 70 and 90 nm, respectively, much smaller than the hydrodynamic diameter obtained from DLS (about 150 nm) (Figure 5A-1,B-

DOI: 10.1021/acs.jafc.5b00794
J. Agric. Food Chem. 2015, 63, 4179–4189

1). It is well-known that DLS determines the data for the particle swollen in solution, whereas the particle diameters in TEM images are obtained by spreading and drying the nanoparticles on a carbon-coated copper grid.[7,19] Meanwhile, Figure 5B-2 also shows that the lutein-loaded nanoparticles had greater density in the inner core of the nanoparticles compared with the lutein-unloaded nanoparticles because of the higher gray level in the former. Therefore, TEM images further confirmed that the lutein molecules were located in the core of the nanoparticles.

AFM. AFM and SEM are both powerful instruments to observe the three-dimensional morphology of the nanoparticles. AFM images of the nanoparticles are shown in Figure 5A-3,B-3. The images of all nanoparticles appeared to be fairly uniform and spherical in shape, indicating that the encapsulation of lutein did not greatly change the morphology of nanoparticles. Additionally, the dimensions of the lutein-loaded nanoparticles were slightly bigger than those of the unloaded nanoparticles, consistent with the results of TEM. The height of the nanoparticles in the AFM images was much smaller than their diameter, suggesting that the nanoparticles were very soft and collapsed on the mica surface during air-drying.[12,18,27]

SEM. SEM images showed that the nanoparticles had a fairly uniform spherical shape (Figure 5A-4,B-4) as observed by AFM. The diameters in SEM images exhibited a narrow size distribution from 50 to 100 nm, which was in good agreement with the dimensions obtained from TEM images. Our findings are consistent with previous studies.[34,46] The results confirmed the microstructure of the nanoparticles observed by AFM and TEM. It has been demonstrated that large amounts of water or biological fluids were imbibed into the three-dimensional networks of the hydrogel nanoparticles, and drugs could be entrapped into the mesh space between the hydrogel nanoparticle networks.[49] Li and co-authors have illuminated that lysozyme−dextran nanogels had a low-density structure and could contain a large amount of water by the swelling ratio of the nanogels estimated from the ratio of average volumes of DLS to AFM.[27] Therefore, the fact that the sizes observed by TEM, AFM, and SEM were smaller than those obtained by DLS was due to the syneresis of the nanoparticles during air-drying. These results also suggested that there were adequate mesh spaces between the nanoparticle networks, which could provide an opportunity to encapsulate other components within themselves.

Potential Application of WPI−Dextran Conjugate 2/ChS Nanoparticles. There has been great interest in applications of nanoparticles as biomaterials for delivering hydrophobic bioactive compounds such as nutraceuticals and drugs. Moreover, biopolymer nanoparticles can be easily prepared and scaled up during manufacture.[1,2] Several nanoparticles have been launched in the area of cancer treatment. For example, Abraxane (paclitaxel−albumin nanoparticle) with an approximate diameter of 130 nm is the first nanotechnology-based chemotherapeutic approved by the U.S. FDA and has shown significant benefit in treatment of metastatic breast cancer.[1,4] The commercial success of albumin-based nanoparticles has created a great interest in other proteins.[1,4,5] Whey protein has been used to prepare biopolymer-based nanoparticles using the bottom-up approach.[5,8] β-Lg, the major whey protein, is known to be stable at low pH and highly resistant to digestion by gastric proteases. β-Lg has been investigated for drug delivery applications.[1,4] Whey protein nanoparticles were successfully fabricated by pH-cycling treatment and thermal processing.[50] Jones and co-authors discussed the effect of polysaccharide charge on the formation and properties of biopolymer nanoparticles, which were created by heat treatment of β-lg/pectin complexes.[12] Chitosan/β-lg core−shell nanoparticles were prepared with the aim of developing a biocompatible carrier for the oral administration of nutraceuticals.[7]

However, the biopolymer nanoparticles were unstable over a wide pH range (especially the entire physiological pH range) and at high salt concentration. Glycosylation of whey protein with dextran increased protein solubility and thermal stability.[22] Liu and co-authors illustrated that the glycosylation of whey protein with maltodextrins prevented protein aggregation before and after heating, and steric hindrance was concluded to be the primary mechanism responsible for transparent dispersions with protein structures smaller than 12 nm after heating.[24] The results suggested that glycosylation of protein would offer an excellent opportunity to improve the stability of biopolymer nanoparticles. Therefore, the stable biopolymer nanoparticles against pH and salt, having spherical shapes with smooth surface, would be used as a promising delivery system for hydrophobic nutrients or drugs in physiological conditions. Additionally, it has been demonstrated that complexes of proteins and strong polyelectrolytes such as sulfated or phosphate polysaccharides tend to form precipitates or solid-like structures, and there is a narrow range of physicochemical conditions at which electrostatic complexes are formed and stay in solution.[9] Sulfated polysaccharides such as ChS may be suitable for delivering active compounds to target cells.[32] This method would provide an approach to prepare target nanoparticles from protein and sulfated polysaccharide.

and the European Union (EU Directive 110/2001).[28] Preliminary analyses on a number of fresh RJ samples showed that HMF concentrations were over the limit of quantification (LOQ) only in samples stored at room temperature. Hence, the principal aim of this study is to monitor the evolution of the concentration of HMF in fresh RJ stored for months at different temperatures in order to ascertain the potential suitability of HMF as a freshness marker for this foodstuff.

MATERIALS AND METHODS

Chemical and Reagents. The chromatographic solvents used were a 0.05 mol dm^{-3} H_2SO_4 aqueous solution and methanol (HPLC grade, Riedel de Haen, Milan, Italy). Before their use, all solvents were filtered through a 0.45 μm membrane from Millipore (Bedford, MA, USA) to remove any particulates. 5-Hydroxymethyl-2-furaldehyde was purchased from Lancaster (Milan, Italy). Trichloroacetic acid (TCA) was obtained from Sigma-Aldrich (Milan, Italy). All aqueous solutions were prepared using type I ultrapure water (New Human Power II Scholar UV, Human Corporation, Seoul, Korea).

Instrumentation. The HPLC equipment used for the experiments consisted of a Series 200 binary pump, a sampling valve, a 20 μL sample loop, a Series 200 LC column oven, and a Series 200 UV−vis variable wavelength detector, all from PerkinElmer, Milan, Italy. Separation was performed using a 250 mm × 4.6 mm Ascentis C18 column, 5 μm particle size (Supelco, Bellefonte, PA, USA), thermostated at 20 °C and fitted with a guard cartridge packed with the same stationary phase. Data were processed using Turbochrom Workstation Software (PerkinElmer, Milan, Italy).

Experimental Protocol. A freshly harvested RJ sample was obtained from "Organizzazione Produttori Apicoltori Sardi Terrantiga" (San Sperate, Sardinia, Italy). Once harvested, the RJ was homogenized, divided into 12 dark glass bottles (1−12), and kept at −18 °C until the beginning of the experimental protocol. The initial HMF content of RJ was determined within 5 days from delivery.

To study the evolution of the level of HMF in RJ stored under different conditions, the 12 bottles were divided into three groups of four samples. The groups were stored at −18, 4, and 25 ± 2 °C (room temperature), respectively. Each sample was analyzed in triplicate after 30, 90, 180, and 270 days from delivery. Samples stored at −18 and 4 °C were equilibrated at room temperature before analysis. Prior to each analysis, all of the samples were homogenized for 5 min.

Determination of HMF Content in Royal Jelly. The HMF concentration was determined using the same RP-HPLC procedure previously developed and validated for RJ by our research group.[26] Briefly, the analytical steps involved first a pretreatment of the sample with an aqueous solution of trichloroacetic acid followed by a gradient elution RP-HPLC analysis and analyte detection at 280 nm.

RESULTS

Review of the LOD and LOQ Values According to the Experimental Results of the Study. The calculation of the LOD in the method recently proposed by us was accomplished using the ULA1 approach.[29] This choice was supported both by the preliminary experience gained in the validation of HPLC methods devoted to measure HMF concentration in honey samples of different origin[19,21] and by the knowledge that the ULA1 method is optimal for reducing any decision error approach.[25] It is crucial, however, that the concentration of the most diluted standard solution used to evaluate LOD turns out to be close enough to the real LOD value. In this connection, the improved knowledge of the method acquired during this study has allowed us to observe that both the LOD and LOQ values previously measured were overestimated (i.e., the effective concentration of analyte associated with both qualitative and quantitative information was lower than that evaluated during the relevant validation step[26]). On the basis of these findings, we have repeated the evaluation of the LOD and LOQ with a better choice of the HMF standard solutions. Hence, four 4% TCA aqueous solutions containing respectively 4, 6, 8, and 10 μg L^{-1} of HMF have been analyzed in triplicate, now giving LOD and LOQ values of 0.13 and 0.39 mg kg^{-1}, respectively.

Figure 1 gives a comparison of selected portions of chromatograms (retention time between 5.5 and 6.5 min) of the blank solution (line 1), of the RJ sample 9 after 1 month of storage at 25 °C (line 2), and of the same RJ sample spiked with 50 μL of a freshly prepared 4 mg/L HMF aqueous solution (line 3).

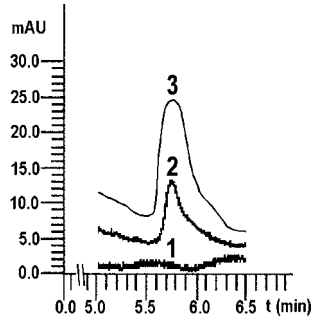

Figure 1. Overlapped chromatographic portions (retention time between 5.0 and 6.5 min) of a blank solution (line 1), sample 9 after 1 month of storage at 25 °C (line 2), and the same sample 9 spiked with 50 μL of a freshly prepared 4 mg/L HMF aqueous solution (line 3).

Monitoring of HMF in RJ on Variation of the Storage Temperature and Storage Time. In our previous study on the assessment and validation of the analytical method to measure the HMF concentration in RJ,[26] we observed proportionality between the amount of HMF measured and the age of RJ samples. In particular, whereas HMF was not quantifiable in any fresh samples, its concentration was higher than 9 mg kg^{-1} in the oldest RJ sample stored at room temperature. In this study, in order to verify the fitness of HMF as a potential marker of freshness of RJ, we carefully monitored the evolution of this analyte in RJ samples stored at different temperatures for the 9 months following their harvest. The RJ samples were always kept in dark glass bottles to prevent any degradation effect promoted by light. The initial concentration of HMF was under the LOD of the method for all samples, as shown in Table 1.

Samples stored at 4 and −18 °C showed only negligible levels of HMF for the entire duration of the study. On the other hand, in samples stored at room temperature we observed an exponential increase of the HMF concentration as a function of storage time. The dependence of the HMF concentration in RJ samples kept at room temperature and the storage time are shown in Figure 2.

DISCUSSION

The choice of a proper freshness marker for functional foods is a very complex problem that requires the careful and simultaneous consideration of a wide number of parameters, related to both the candidate marker and to the analytical method used to determine it. First, the optimal freshness marker should not be traceable in the fresh food product,[7,30] so that the mere presence of the marker is indicative of spoilage. If, on the other hand, the marker is present in the fresh matrix,

slight variations in concentration with respect to the "expected" value for the unaltered matrix might be in principle ascribed not only to a loss of freshness but also to the natural variability of the analyte content. Hence, the only way to effectively apply this strategy is to evaluate the natural variability of the marker. However, such an effort has a high risk of being inconclusive, since the composition of RJ varies with seasonal and regional conditions.[9] In addition, the marker should be monitored in the matrix of interest for a period of time comparable to its expected shelf life.

Furthermore, the choice of the analytical method is critical to the effectiveness of the marker. The ideal analytical method must be simple to use and validated for the considered matrix and its chemical background must be completely known. In addition, the instrumentation required must be commonly available in any routine laboratory. Unfortunately, almost none of the RJ freshness markers proposed until now meet all these key requirements. The current situation is summarized in Table 2.

Most of the freshness markers proposed for RJ are traceable in the freshly harvested matrix. Even furosine, a promising index proposed by Marconi et al.,[7] is quantifiable in fresh samples, even if at low concentrations. Physical parameters—such as viscosity[9] and color[5,9,11]—are unreliable[1,7] and are characterized by an uncertain chemical background. On the other hand, protein-based candidate markers are usually measured with methods that require specific instruments and chemicals[5,8,9,14] and thus are unsuitable for routine applications. Finally, a complete validation protocol for the determination of a marker in a RJ matrix has rarely been provided,[13,15] meaning that the reliability of any conclusions based on the levels of those markers is questionable.

In this work, we suggest the use of HMF as a possible freshness marker for RJ. This molecule was found absent in the freshly harvested matrix in a preliminary study.[26] This is not surprising, HMF being a well-known neoformation intermediate in the Maillard reaction—i.e., in the process responsible for the most important alterations of RJ when it is improperly stored.[5,7,9] Our results clearly demonstrate that, when RJ is stored at low temperatures (equal to or less than 4 °C), even for long periods of time, the Maillard reaction is effectively slowed and the concentration of HMF remains under the LOD of the method. On the other hand, the storage of RJ at 25 °C for 1 month is sufficient to reach an HMF content that overcomes the LOQ, providing quantitative evidence of the alterations suffered by the matrix. These results are in excellent agreement with those reported earlier by Smith,[31,32] who observed no changes in the properties of the RJ stored at 5 °C for 1 year and in samples stored at −20 °C for years, while noting the deterioration of RJ's properties after only 1 month of storage at room temperature. This general behavior was more recently confirmed by results obtained by a number of different research groups.[7,8,13,14,16]

Interestingly, the growth of the HMF concentration in the RJ samples follows an exponential trend, representative of a pseudo-first-order kinetic model. Excellently correlated experimental data (the coefficient of the regression R^2 is 0.9994) substantiate the analogous exponential trend reported by Tosi, Ciappini, Rè, and Lucero[33] in a study on the effects of thermal treatments applied to honey samples on the amount of HMF. In spite of the deep and well-known differences between the chemical and physical properties of honey and royal jelly, it is evident that the heat-induced formation of HMF is active and measurable in both matrices and also that both formation

[a]Definitions: +, the value of the parameter increases with storage time; −, the value of the parameter decreases with storage time; +−, the variation of marker concentration with increasing storage duration is not monotonic. [b]Semiquantitative parameter. [c]Unsuitable for the evaluation of storage periods longer than 1 month at room temperature. [d]Unsuitable for the evaluation of storage periods longer than 7 days at room temperature. [e]Method not widespread in control quality laboratories. [f]Analyte already present in RJ matrix; thus, a study to establish the "normal" concentration range of the analyte is needed before proposing it as a freshness marker. [g]Pure royalactin, needed as a standard, is not commercially available. [h]Study performed only for a short storage period (15 days). [i]Nonlinear behavior (maximum after 3 months of storage at room temperature) of the proposed markers. [j]LOD, LOQ, precision, recovery. [k]Validation protocol absent for this analyte in a RJ matrix. [l]Evaluation of analytes has only been performed on fresh and one-year-old samples.

processes roughly follow the same kinetic model. The value of the pseudo-first-order kinetic constant for HMF formation in RJ stored at room temperature in the period from 30 to 270 days (i.e. in the interval of time where the HMF concentration has been found over the LOQ of the method) is estimated at ca. 570 s^{-1}.

Finally, we remark on the fitness of the analytical method adopted for the purpose of this study. It appears completely validated and uses instrumentation commonly available in unspecialized laboratories. In addition, it has a consistent chemical background, since the generation of HMF by the Maillard reaction in foods containing both reducing sugars and amino acids (or their relevant precursors) has been thoroughly studied elsewhere.[34] Finally, it can be used to monitor RJ along its entire potential shelf life (in Europe: 18 months for refrigerated RJ; 24 months for RJ stored at −17 °C).[1]

In conclusion, the formation of HMF in fresh RJ as a function of storage temperature (from −18 °C to room temperature) and storage time (up to 270 days) was monitored by means of a RP-HPLC method, previously assessed in other work. While all the RJ samples stored at temperatures lower than room temperature did not show any detectable levels of HMF, those kept at 25 °C showed amounts of HMF which become quantifiable starting from the first month of storage. The exponential increase in HMF concentration as a function of the storage time at room temperature is representative of a pseudo-first-order kinetic model—already reported for honey. The results obtained in this study allow us to maintain that HMF can be taken into account as an eligible freshness marker for RJ, since the amount of sugars and proteins in this matrix is evidently adequate to provide an increase of the HMF concentration as a function of the storage time. Further studies may contribute to establish the dependence of the evolution of HMF in RJ as a function of intrinsic parameters (e.g., sugar and amino acidic composition, seasonality, geographic origin, botanical origin of the pollen fed by bees, race of the bees, harvesting time after grafting) and storage parameters (e.g., exposure to light, short exposure of RJ to heat).

In this study, to understand how maltogenic α-amylase affects the retrogradation of AP, we subjected cooked waxy maize starch (WMS), which contained only AP, to different degrees of hydrolysis (DH) by maltogenic α-amylase and examined the structure and retrogradation properties of the resulting hydrolysates. We further related retrogradation properties to the chain length (CL) distributions of debranched starch hydrolysates. Our objective was to study the action of maltogenic α-amylase on AP, relate the structure of the hydrolysates to their retrogradation properties, and determine how much hydrolysis was needed to prevent the retrogradation of AP.

MATERIALS AND METHODS

Materials. WMS (Amioca) from National Starch LLC (Bridgewater, NJ, USA) was used for the study. Maltogenic α-amylase, Novamyl (BSuA, 3.2.122), was provided by Caravan Ingredients (Lenexa, KS, USA). Enzyme activity was assayed by quantifying the reducing sugars released from soluble starch (1.0% (w/v) solution) (St. Louis, MO, USA) according to the Somogyi–Nelson method[21] relative to a maltose standard curve. One enzyme unit is the amount of enzyme that releases 1 μmol of maltose/min at 62 °C and pH 5.0 (100 mM sodium acetate buffer containing 5 mM $CaCl_2$) for Novamyl. Isoamylase (EC 3.2.1.68) was obtained from Hayashibara Biochemical Laboratories, Inc. (Okayama, Japan) and had an enzyme activity of 1.41×10^6 isoamylase activity units (IAU)/g.[22] All chemicals and reagents were of analytical grade.

Enzymatic Starch Hydrolysis. Starch (1.8 g db) was mixed with 90 mL of 100 mM sodium acetate buffer containing 5 mM $CaCl_2$ (pH 5.0), heated at 120 °C for about 40 min in a pressure bottle (Ace Glass Inc., Vineland, NJ, USA), and cooled to the optimum temperature of 62 °C for Novamyl. Enzyme (9 EU/g starch db) was added to the starch slurry to initiate the enzyme reaction. This enzyme concentration was selected on the basis of previous studies.[20,23] Starch was hydrolyzed to ca. 5, 10, 20, 30, 40, and 50% by taking aliquots at different time intervals. Enzyme was denatured in a boiling water bath for 10 min. Starch hydrolysates were cooled to 25 °C and centrifuged at 8000*g* for 10 min. Part of the supernatant was further analyzed for saccharide composition, and the rest of the samples were freeze-dried for further study.

High-Performance Anion-Exchange Chromatography (HPAEC-PAD). Sacchaaride profile analysis of the supernatants from WMS hydrolysates was done using the procedure of Cai and Shi.[22] Eluents were (A) 500 mM NaOH and (B) 150 mM NaOH with 0.5 M sodium acetate. The gradient program was as follows: 85% eluent B for 0–0.4 min, 30% at 20 min, 25% at 30 min, 0% at 35 min, 0% at 40 min, 85% at 41 min, and 85% at 55 min. The separations were carried out at 25 °C with a flow rate of 1 mL/min. The concentration of the injected sample was 20 μg/mL in deionized (DI) water. Percentage DH was expressed as the total amount of saccharides released at any given time on the basis of initial dry weight of starch.

Size Exclusion Chromatography (SEC). After waxy maize starch (2%) was hydrolyzed by Novamyl, the mixture was heated at 95 °C for 30 min, cooled to 25 °C, and diluted with deionized water to a concentration of 10 mg/mL. Two drops of 0.25 M NaOH was added to further solubilize the sample. Samples were filtered with a 1 μm nylon syringe filter, and 100 μL was injected onto SEC columns. SEC separations were achieved using a HPLC (1200, Agilent, Santa Clara, CA, USA) equipped with OHpak SB-806 M HQ and OHpak SB-805 HQ columns in series with a OHpak SB-G guard column (Shodex, Showa Denko America, New York, NY, USA). The mobile phase, 0.1 M sodium nitrate, was pumped at a 0.5 mL/min flow rate and maintained at 55 °C. Elution was monitored using a multiangle light scattering detector (Dawn Heleos II, Wyatt Technology, Santa Barbara, CA, USA). A refractive index detector (1200, Agilent) was used to determine concentration (dn/dc = 0.147). Astra 6 software was used for data analysis.

Differential Scanning Calorimetry (DSC). Each starch hydrolysate and water (40% solid, w/w) were weighed in a DSC pan. The DSC pans were sealed, heated from 10 to 140 °C at 10 °C/min, and analyzed in duplicate using a Pyris-1 DSC (PerkinElmer, Norwalk, CT, USA). An empty pan was used as a reference. The first scan was done on day 0, and the second scan was done on day 7 after storage of the sample at 4 °C. The onset (T_o), peak (T_p), and conclusion (T_c) temperatures and enthalpy (ΔH) were obtained from the DSC endotherm with DSC software (TA Instruments, New Castle, DE, USA).

Debranching of Starch Hydrolysates. Freeze-dried starch samples were dissolved in 0.01 M acetic acid buffer (pH 4.0) with a starch/buffer ratio of 2:1. Starch solutions were cooked at 100 °C to ensure complete dissolution and then cooled to 50 °C. Isoamylase (1% based on dry weight of starch) was added. Debranching was done for 24 h, and the enzyme was denatured by boiling samples at 100 °C for 10 min. The samples were cooled to room temperature before further analysis.

CL Distribution Analysis. Debranched AP samples were further analyzed for CL distribution. Part of the samples was directly injected into HPAEC following debranching, and the remaining samples were freeze-dried for MS distribution analysis. For HPAEC, the sample was prepared at a concentration of 1.5 mg/mL in 150 mM sodium hydroxide. Analysis was performed according to the previously cited procedure.[22]

Statistical Analysis. Each experiment was performed in duplicate. Data were analyzed by analysis of variance (ANOVA) with Tukey's studentized range (HSD) test using SPSS version 20.0 (IBM Corp., Inc., Armonk, NY, USA). Mean values from the duplicated experiments were reported. The least significant differences (LSD) for comparison of means were computed at $p < 0.05$.

RESULTS AND DISCUSSION

Saccharide Composition of Starch Hydrolysates. WMS hydrolysates were analyzed for the saccharides produced and to

determine %DH. Individual sugar percentages (based on initial starch weight) in the reaction mixture are given in Table 1. Saccharides up to degree of polymerization (DP) 6 were formed, and their concentrations continued to increase with increase in hydrolysis time. Maltose was the predominant sugar produced. The rate of formation of maltose was significantly higher than that of other saccharides. The maltose/glucose ratio increased with an increase in %DH, indicating the exoaction of enzyme producing maltose during earlier hydrolysis stages. A change in action pattern of maltogenic amylase from exo to endo with increase in hydrolysis time[18] and increase in temperature[4] was reported in earlier studies, as was the production of sugars up to DP 7−9, which were further hydrolyzed to maltose by this enzyme.[24,25]

Thermal and Retrogradation Properties. Retrogradation properties of starch hydrolysates after 7 days of storage at 4 °C are shown in Table 2. Starch hydrolysates produced no endothermic peak during the initial scan before storage (day 0) because the starch crystallinity was completely destroyed during cooking prior to hydrolysis. After 7 days of storage at 4 °C, WMS showed significant retrogradation. AP retrogradation enthalpy decreased to 0.8 J/g for 20% hydrolyzed starch. As the DH increased, the extent of retrogradation decreased, with no retrogradation observed for starches hydrolyzed to >20% DH. We suggest that the shortened outer chains inhibited formation of double helices and prevented AP recrystallization. Another reason for this result might be the increase in low molecular

[a]Calculated as total amount of saccharides released at any given time based on initial starch weight.

weight dextrins with an increase in DH, which interferes with AP recrystallization. These results are consistent with previous studies conducted on bread crumb.[4,11] The retrogradation tendency of AP depends on its CL distribution,[27−29] with retrogradation rate having a positive correlation with the mole fraction of unit chains of DP 14−24 and a negative correlation with mole fraction of unit chains of DP 6−11.[29,30] Using model compounds, other researchers observed no retrogradation when DP was <10;[31−33] however, in the presence of longer chains, chains as short as DP 6 can cocrystallize.[33]

Molecular Weight (M_w) Distributions of Starch Hydrolysates. To understand the reduced extent of retrogradation of starch hydrolysates, changes in the molecular structure of amylopectin during the enzymic hydrolysis were determined by SEC. Unique M_w distributions of the starch hydrolysates were observed (Figure 1). The proportion of the original AP in waxy maize starch (peak 1 with a peak retention time ca. 25 min) decreased, whereas a fraction with reduced M_w (peak 2 with peak retention time ca. 31 min) and low M_w saccharides (peak

DOI: 10.1021/jf506215s
J. Agric. Food Chem. 2015, 63, 4196−4201

3 with peak retention time ca. 45 min) increased with an increase in DH (Figure 1A). It is interesting to note that no peak or little hydrolyzed product was observed between peaks 2 and 3 (Figure 1A), indicating that few low M_w dextrins were produced during the hydrolysis. This unique M_w distribution suggests mostly exoaction during the early stage of hydrolysis. HPAEC results (Table 1) confirmed that only low M_w saccharides (DP 1−6) were detected and maltose was the predominant product.

Detailed M_w information (Figure 1B and Table 3) revealed that after 10% DH, M_w of the products increased at peak 2 was >10% of the original M_w of AP (peak 1), indicating that there was endoenzymic action on AP. However, few low M_w dextrins (DP 7−20) were detected between the low M_w saccharides (peak 3 with peak retention time ca. 45 min) and reduced AP (peak 2 with peak retention time ca. 31 min).

HPAEC (Table 1) and SEC (Figure 1 and Table 3) results suggest that the maltogenic α-amylase used in this study is unique and able to produce maltose through its exoaction, thus shortening outer CL of AP and reducing the M_w of AP through its endoaction but without producing excess low M_w dextrins. This unique action of the maltogenic α-amylase on amylopectin is schematically presented in Figure 2. The endoaction of the maltogenic α-amylase helps weaken the starch network by hydrolyzing the long polymer chains connecting the clusters, whereas the exoaction of the enzyme shortens the amylopectin side chains, making them too short to crystallize.[4]

CL Distributions of Debranched Waxy Maize Starch Hydrolysates. To further determine the fine structure of residual AP after the hydrolysis by maltogenic amylase, WMS hydrolysates were debranched with isoamylase and their unit chain length distributions were analyzed by HPAEC-PAD (Figure 3). At low DH, little difference was observed compared with the control, but with an increase in DH, the unit chains with DP <10 increased with a corresponding decrease in higher DP unit chains. These results concur with previous findings.[26] Higher relative amounts of CL with DP ≤9 support the complete suppression of retrogradation with a %DH >20 because of a decreased tendency of these short chains to participate in double-helix formation and give rise to crystalline lamellae.[34]

With an increase in hydrolysis, unit chains of DP 17−24 and DP 24 decreased, whereas unit chains of DP ≤9 increased (Table 4). Chains with DP 9−11 and DP 12−16 also increased, but only slightly compared with the control. Relating the retrogradation data with CL distributions, we can conclude that the higher the proportion of unit chains with DP ≤9, the lower the retrogradation rate. A minimum CL of DP 10 is required for the formation of stable double helices.[31,32] The short A chains with a DP of 5−10 cannot participate in stable double-helix formation, and they disrupt the formation of an ordered crystalline structure negatively affecting the perfection of AP crystalline structure.[35] Outer AP chains (mainly A and B1) greatly influence AP's molecular reorganization and aggregation during storage.[20] The net decrease in the proportion of unit chains with DP 14−24 could be another reason for reduced AP retrogradation.[29] The large decrease we observed for outer AP chains is in agreement with previous findings suggesting that the exo-like action of this enzyme[24,36] is similar to that of β-amylase, which removes the external chains from AP.[37] Compared with conventional α-amylase, which cleaves only internal starch chains and results in reduced MS without having much effect on the outer branches of AP, maltogenic α-amylase effectively shortens AP side chains and thus prevents crystalline junction zone formation.[4] High relative amounts of very short AP chains were correlated with reduced AP retrogradation.[8,27,29]

In conclusion, saccharide profile analysis of starch hydrolysates showed the formation of low DP saccharides during the course of hydrolysis with maltose constituting a major fraction in the reaction mixture. Maltogenic α-amylase was able to shorten the outer CL of AP and permanently prevent it from retrogradation after 20% hydrolysis. AP retrograded to one-third after 10% hydrolysis compared with unhydrolyzed AP. We found a positive correlation between the level of unit chains (DP ≤9) and retrogradation inhibition with an increase in % DH. These results illustrate the antistaling effect of this enzyme even at limited starch hydrolysis (20%).

Enzymatic Modification of Starch: Debranching. Starch (15 g wet basis) was added to 400 mL of water (3.75% w/v) and gelatinized in a boiling water bath for 1 h with constant stirring. The temperature of the solution was equilibrated to 45 °C, and the pH was adjusted to 5.0 with 0.5 M HCl. To the starch solution, isoamylase and pullulanase, each at 1.33% (v/w, starch db), were added and then incubated at 50 °C with constant stirring for 48 h. The starch was recovered with a 4-fold volume of pure ethanol, centrifuged at 7000*g* for 10 min, dried at 40 °C for 48 h with a forced air oven (VWR, Cornelius, OR, USA) and milled using a UDY cyclone mill (UDY Corp., Ft. Collins, CO, USA) fitted with a 0.5 mm screen.

***β*-Amylase Treatment.** A portion of the debranched starch was further subjected to *β*-amylase hydrolysis to reduce the degree of polymerization (DP). After debranching for 48 h, the starch slurry pH was adjusted to 6.5 with 0.5 M NaOH and incubated with 0.5% (v/w, starch db) *β*-amylase at 40 °C for 4 h. The enzyme reaction was terminated by boiling for 15 min. The *β*-amylase-treated starch was recovered as previously described.

Characterization of Starch Structure. The molecular size distributions of debranched unacetylated and acetylated starch without or with the *β*-amylase treatment were recovered after complexation with oleic acid and characterized using a high-performance size-exclusion chromatography (HPSEC) system (Waters Corp., Milford, MA, USA). Starch (10 mg) was dissolved in 5 mL of 90% DMSO, boiled for 1 h, and filtered through a 5.0 μm filter prior to injection into the HPSEC system. The HPSEC system consisted of a guard column (OHpak SB-G, 6.0 × 500 mm^2 i.d. × length), two Shodex columns (OHpak KB-804 and KB-802, both 8.0 × 300 mm^2 i.d. × length), a 200 μL injector valve (model 7725i, Rheodyne, Cotati, CA, USA), an inline degasser, a model 515 HPLC pump, and a model 2414 refractive index detector. The mobile phase of 0.1 M sodium nitrate with 0.02% sodium azide was eluted at a flow rate of 0.6 mL/min. The temperature of the column was maintained at 60 °C, and that of the detector, at 40 °C. Dextran standards of molecular weight of 5200, 11 600, 23 800, 48 600, 273 000, and 410 000 g/mol from Waters Corp. (Milford, MA, USA) and 1 050 000 g/mol from Sigma-Aldrich (St. Louis, MO, USA) were used to establish the calibration curve.

The amylopectin chain-length distribution was characterized by high-performance anion-exchange chromatography equipped with pulsed-amperometric detection (HPAEC-PAD) according to the method of Wong and Jane.[27] The chains were divided into DP ranges and classified as follows: A chains (DP 6−12), B1 chains (DP 13−24), B2 chains (DP 25−36), and B3+ chains (DP 37+).[28] The average chain length was calculated as the cumulative sum of the product of DP and the percentage of relative areas for all of the identified peaks.

Complexation of Starch and Oleic Acid. All samples were prepared in replicates. The starch solution (3.75% w/v), debranched or debranched and *β*-amylase-treated, was adjusted to pH 7.0, equilibrated to 80 °C, and mixed with 1 g of oleic acid dissolved in warm 95% ethanol. The mixture was maintained at 80 °C for 30 min and stirred at 400 rpm continuously with a Barnstead supernuova stirring hot plate (model SP131825, Barnstead/Thermolyne, Dubuque, IA, USA) to ensure that there was sufficient interaction between starch and oleic acid, and then the temperature was maintained at 45 °C overnight with continuous stirring. The resulting mixture was centrifuged at 7000*g* for 10 min, from which the precipitate, that is, the insoluble complex, was obtained, whereas the soluble complex was recovered by precipitating the supernatant with a 4-fold volume of pure ethanol. Any uncomplexed oleic acid was removed from both the insoluble and soluble complexes by rinsing with excess 95% ethanol. Complexes were rotated in excess 95% ethanol using a labquake shaker rotisserie (Barnstead/Thermolyne, Dubuque, IA, USA) at room temperature for 2 h, centrifuged at 7000*g* for 10 min, dried at 40 °C for 48 h, milled using a mortar and pestle, sieved through a 250 μm sieve, and stored for further analysis.

Hydrolysis of Complexes and Oleic Acid Analysis. Soluble or insoluble complex (100 mg) was added with 10 mL of 1 M HCl and heated with continuous stirring in a boiling water bath for 1 h. After the complex mixture was cooled, 5 mL hexane was added, and the solution was rotated on the rotary shaker for 1 h. The hexane layer with the extracted oleic acid was recovered, and the extraction was repeated with another 5 mL of hexane for 1 h. To the recovered hexane phase, boron trifluoride methanol was added to convert oleic acid to oleic acid methyl esters. An internal standard of methyl heptadecanoate (~1 mg) was subsequently added to all samples. The oleic acid methyl ester was injected into a gas chromatographer (GC) (GC-2010, Shimadzu, Kyoto, Japan) equipped with a BP 21 capillary column (30 m × 0.25 mm^2 i.d.; SGE Inc., Austin, TX) with a flame ionization detector (FID), and responses were collected with a Shimadzu GCsolution Workstation 2.3 (Kyoto, Japan). The injection port and detector temperatures were set at 220 and 230 °C, respectively. The column oven temperature was equilibrated at 100 °C for 1 min, ramped up at 15 °C/min to 160 °C, again ramped up at 5 °C/min to 200 °C, and maintained at 200 °C for 10 min. The flow rate of the carrier gas (helium) was 30 mL/min. The concentration of oleic acid was determined from a standard curve prepared by using oleic acid methyl ester solution (0.1, 0.2, 0.4, 0.6, 0.8, and 1 mg/mL) containing a methyl heptadecanoate (0.5 mg/mL) internal standard.

Physicochemical Properties. A diffractometer (PW1830 MPD, Philips, Almelo, The Netherlands) was used to determine the powder X-ray diffraction (XRD) pattern of complexes. The generator voltage was set at 45 kV, and the current, at 40 mA. The sample was scanned over the 2θ angular range from 5 to 35° with a step size of 0.02° and a time of 1 s per step.

The thermal stability of all complexes was measured using a differential scanning calorimeter (DSC, Pyris-Diamond, PerkinElmer, Shelton, CT, USA). Approximately 8 mg of complex was weighed into a stainless steel pan, 16 μL of distilled water was added with the aid of a microsyringe, and the pan was hermetically sealed. The sample was equilibrated for 24 h at room temperature before scanning and was scanned from 25 to 180 °C at 10 °C/min, immediately cooled from 180 to 25 °C at 40 °C/min, and rescanned from 25 to 180 °C at 10 °C/min to confirm the formation of the starch−fatty acid complex. The onset temperature (T_o), peak temperature (T_p), conclusion temperature (T_c), and enthalpy (ΔH) of the endotherms were calculated using the Pyris data analysis software.

Statistical Analysis. All experiments were conducted in replicates, and data were analyzed using JMP software (SAS Institute Inc., Cary, NC, USA). The means were compared using Tukey's honestly significant differences (HSD) test.

RESULTS AND DISCUSSION

Degree of Substitution. The low- and high-acetylated starches used for complex formation with oleic acid had DS values of 0.041 and 0.091, respectively (Table 1). Acetylated starches were then debranched with isoamylase and treated with or without *β*-amylase prior to complexation. After

Table 1. Degree of Substitution (DS) of Acetylated Starches and Oleic Acid Complexes[a]

starch	*β*-amylase treatment	type of complex	DS

complexation the soluble and insoluble complexes were recovered and analyzed for their DS of acetylation. Similar to the previous study,[23] the soluble complex fractions had a significantly higher DS than the insoluble ones for the same treatments. When β-amylase was combined with acetylation, an increase in DS was observed for all soluble and insoluble complexes. The lowest DS of acetylated starch to form a soluble complex with stearic acid was 0.063 in our previous study;[23] however, oleic acid formed soluble complexes at a lower DS of 0.045 in the present study. In addition, the difference in DS of acetylation between the soluble and insoluble complexes of oleic acid was significantly smaller than that of stearic acid. These differences in DS suggest that a lower DS of acetylation on starch was sufficient to encourage soluble complex formation with more polar molecules, such as oleic acid, compared to less polar molecules, such as stearic acid.

Complex Recovery and Complexation Yield. Complex recovery was determined by comparing the individual recovered complex weight against the initial material weight. The highest recovery for the insoluble complexes was 0.73 g/g from the unacetylated β-amylase-treated starches (Table 2),

Table 2. Complex Recovery and Percentage of Oleic Acid Content Recovered from All Complexes[a]

[a]Data of at least two measurements with standard deviation. Means in a column not sharing the same letter are significantly different based on Tukey's honestly significant difference test ($p < 0.05$).

which is similar to results from previous studies.[6,15,23] The total recovery when both soluble and insoluble complexes were included was 0.92−0.96 g/g, except for the unacetylated β-amylase-treated starch with a total recovery of 0.85 g/g. These results indicate that the modification of starch prior to complex formation did not change the total recovery but changed the proportions of the soluble and insoluble complexes for most complexes. The recovery of the insoluble complexes decreased with increasing DS of acetylation, whereas the opposite trend was observed for the soluble complexes. Acetylation increased the recovered soluble complexes by 65 and 94% for low- and high-acetylated starches, respectively, compared to that for the unacetylated one.

When an additional β-amylase treatment was incorporated, the recovery of the soluble complexes was decreased or unchanged, whereas that of the insoluble complexes was increased or unchanged. These results imply that the length of starch chains present in the debranched-only starches was more favorable to the formation of soluble complexes. The β-amylase treatment hydrolyzed some starch chains to a length that was too short to form complexes, thus resulting in a decrease in the proportion of recovered soluble complexes. Within the β-amylase-treated starches, the recovery of the soluble complexes was increased by 233−375% for low- and high-acetylated starches, respectively, when compared to that of the unacetylated starch.

The oleic acid content in all starch complexes was determined by GC (Table 2). Acetylated starches resulted in significantly higher amounts of complexed oleic acid per gram of complex in the recovered complexes compared to that for unacetylated starches for most treatments, suggesting that acetylation encouraged the formation of both soluble and insoluble complexes between starch and oleic acid. However, the amounts of complexed oleic acid were significantly lower than those of complexed stearic acid reported in the previous work.[23] This is attributed to the better stability of the complexes formed between starch and stearic acid, a saturated fatty acid, than oleic acid of an unsaturated fatty acid.[8,10,29,30]

For the insoluble complexes, the highest amount of oleic acid per gram of complex was recovered from the low-acetylated starch (37.6−42.9 mg), which also complexed the higher amounts of stearic acid (101.0 and 123.1 mg) in the previous study.[23] This indicates that the presence of a low level of acetylation (DS 0.036−0.045) hindered starch retrogradation and encouraged complexation with oleic acid. However, a high level of acetylation (DS 0.062−0.072) decreased not only the complex recovery but also the complexation yield with oleic acid. This indicates that the further increase in the number of acetyl groups on starch might destabilize the starch helices for complexation. In addition, when β-amylase treatment was combined with a high acetylation of starch, the amount of complexed oleic acid remained unchanged, suggesting that with the β-amylase treatment of high-acetylated starch there were still starch chains with favorable lengths that could participate in complexation with oleic acid.

For the soluble complexes, the highest amount of oleic acid was recovered from high-acetylated-only starch (38.0 mg), which was similar to the highest amount of complexed oleic acid in the insoluble complexes. In contrast, the highest amount of stearic acid was recovered from the high-acetylated and β-amylase-treated starch (61.2 mg).[23] It is hypothesized that the cis double-bond structure of oleic acid might require slightly longer starch chains than stearic acid to form soluble complexes with high-acetylated starch.

Molecular Size Distribution. Except for the high-acetylated-only starch (Figure 1E), all recovered starch in the starch complexes displayed an amylose peak at a retention time of 18.2−18.5 min, which corresponded to DP ∼7000 (Figure 1). The relative proportion of the amylose peak was greater in the insoluble complexes than in the soluble complexes and increased with increasing acetylation level. This increasing trend in the amylose peak was also noted in the previous study with stearic acid,[23] which was attributed to an increased hydrodynamic volume from higher acetyl contents.

The peak DP of soluble complexes shifted to a higher DP for unacetylated and acetylated starches after the β-amylase treatment, indicating that the β-amylolysis of starch hydrolyzed short chains and reduced the chain length of longer chains. For the insoluble complexes, the DP remained unchanged for unacetylated and low-acetylated starch and slightly increased for the high-acetylated starches after the β-amylase treatment.

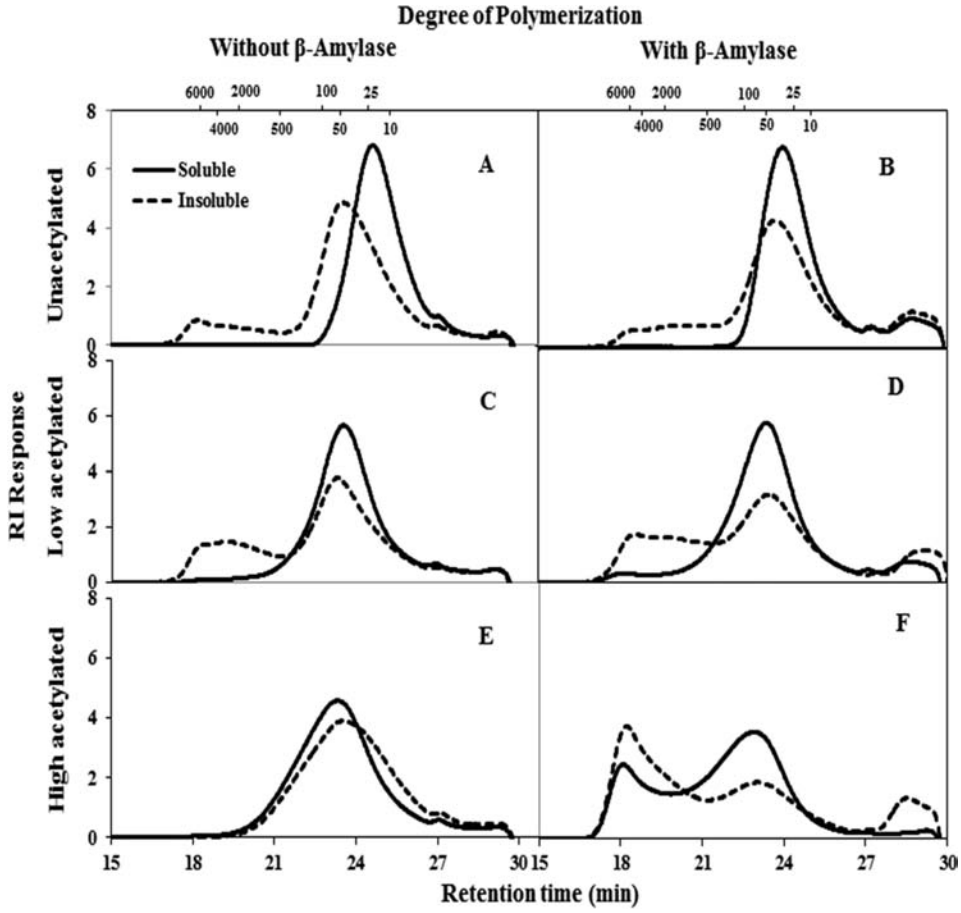

Figure 1. Normalized size-exclusion chromatograms of recovered soluble and insoluble starch complexes from unacetylated and acetylated potato starches after complexing with oleic acid: (A) potato starch, (B) β-amylase-treated potato starch, (C) low-acetylated potato starch, (D) low-acetylated β-amylase-treated potato starch, (E) high-acetylated potato starch, and (F) high-acetylated β-amylase-treated potato starch.

All complexes displayed a main peak at a retention time of between 23 and 24 min, which corresponded to DP 91 and 36, respectively, and were composed of mainly amylopectin long branched chains that were assumed to be involved in complex formation with oleic acid. The retention time of this peak shifted to a shorter time with increasing acetylation, which was similar to that of the amylose peak. The relative proportion of this main peak was greater in the soluble complex than in the insoluble complex for the same treatment. These results are similar to those in the previous stearic acid study, although a smaller amount of oleic acid was complexed in the present study. Although previous studies reported that the carbon atoms adjacent to the double bond in cis-unsaturated fatty acids may be capable of rotating freely to give rise to a relatively linear structure,[10,31] the complexation of starch with stearic acid was still more favored than with oleic acid. Overall, starch fractions with a DP of between 14 and 363 corresponding to retention times of 25 and 21.5 min, respectively, were observed in all starch complexes, indicating that these starch chain lengths were primarily responsible for complex formation with oleic acid. This agrees with Gelders et al.[32] that amylose chains with a DP of up to 400 were effective in forming complexes with glyceryl monostearate (GMS) and docosanoic acid (C22).

The chain-length distributions of starch chains of up to DP 60 of all starch complexes without and with the β-amylase treatment are displayed in Figures 2 and 3, respectively. For the soluble complexes, the additional β-amylase treatment resulted in an increase in the peak DP and the proportion of the higher DP peak, but it did not change the profiles of the insoluble complexes as much. The peak DPs for the soluble complexes of acetylated starches in the present work were slightly higher but not significantly different from those reported in the starch–stearic acid study,[23] although a larger amount of stearic acid versus oleic acid was complexed. Similar to the starch–stearic acid study,[23] the fraction of DP 6-17 was prominent in all starch complexes, but it represented the proportion of starch chains too short to form complexes. The proportion of DP 6-17 decreased with the β-amylase treatment for the soluble complexes but increased slightly for the insoluble complexes. These results indicate that when the amylopectin chains were considered, the favorable chain length for complexing with fatty acid, which was reported[9] to be DP >20, was longer for the soluble complexes than for the insoluble complexes.

Characterization of Starch–Oleic Acid Complexes. X-ray Diffraction Pattern. Most soluble and insoluble complexes of unacetylated starches displayed a mixture of the B-type and V-type X-ray diffraction patterns (Figure 4A,B) with peaks at 2θ = 17.0, 22, and 24° and 2θ = 12.9 and 20°, respectively. The only exception was the soluble complex from the unacetylated-only starch (Figure 4A), which displayed predominantly the A-type pattern with peaks at 2θ = 15.3, 17.2, 18.2, and 23.1° besides minor peaks at 2θ = 10, 11.5, 20, and 26.5° from the V-type pattern. The presence of the A-type polymorph may be ascribed to the high proportion of

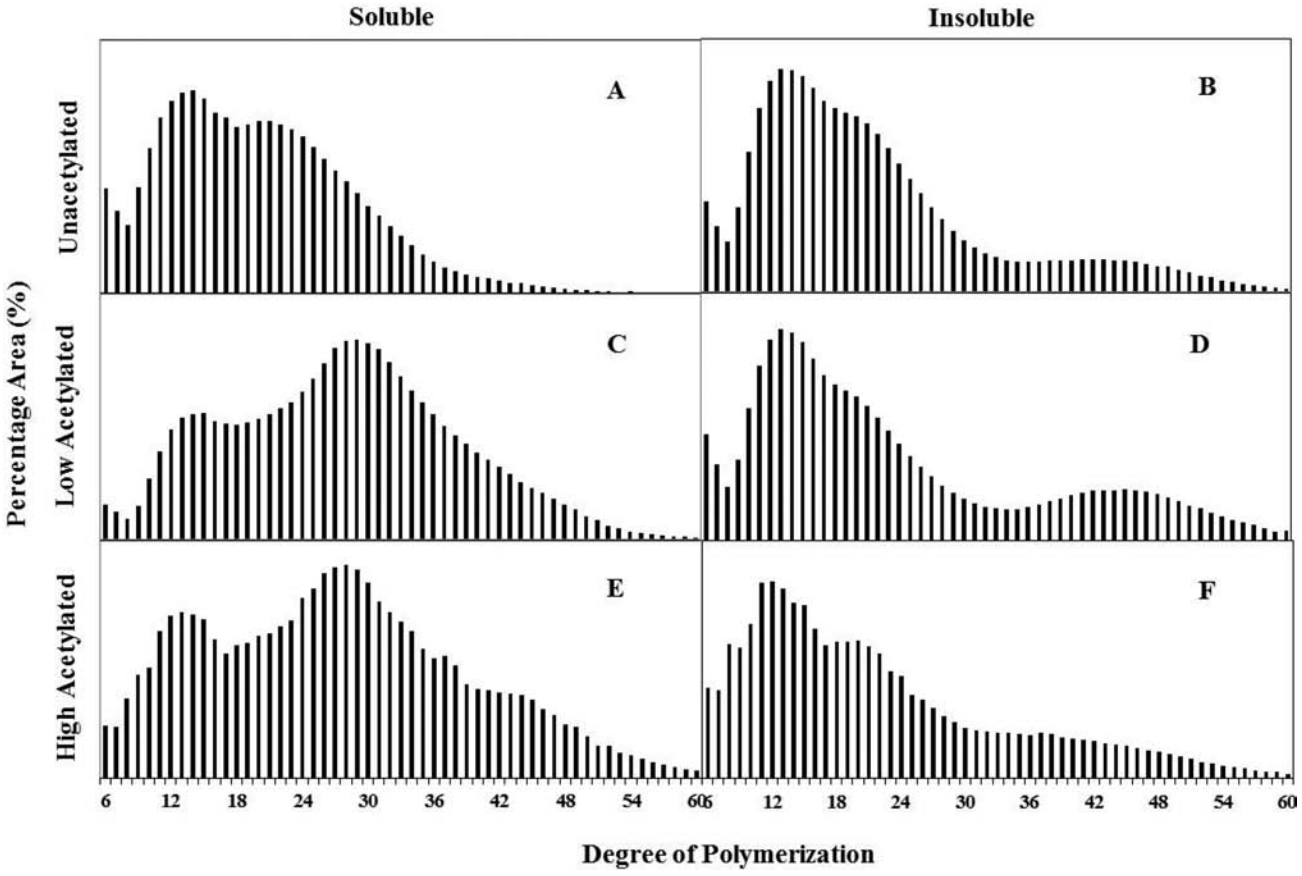

Figure 2. Normalized chain-length distributions of recovered soluble and insoluble starch complexes from unacetylated and acetylated potato starches without the β-amylase treatment after complexing with oleic acid using high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD): (A) potato starch, (B) β-amylase-treated potato starch, (C) low-acetylated potato starch, (D) low-acetylated β-amylase-treated potato starch, (E) high-acetylated potato starch, and (F) high-acetylated β-amylase-treated potato starch.

amylopectin short chains (Figure 2A) that were too short to complex with oleic acid but prone to reassociation to form a very ordered structure.[33] The additional β-amylase treatment on unacetylated starch decreased the intensity of the V-type pattern for the insoluble complexes, implying that the formation of insoluble starch−oleic acid complexes may require longer starch chains than would starch−stearic acid complexes.[23] The soluble complexes of the unacetylated starch changing from the A-type to B-type pattern after β-amylase treatment supports the HPSEC results that shorter chains have been hydrolyzed to result in predominantly longer chains. This is in agreement with previous works in which starches with shorter average chain lengths exhibited the A-type pattern (DP <19.7) and starches with a longer average chain lengths (DP >21.6) exhibited the B-type pattern.[34]

All soluble and insoluble acetylated complexes displayed the V-type pattern with peaks at 2θ = 7.4, 12.9, and 20° (Figure 4C−F). In previous work on starch−stearic acid complexes,[23] the V-type structure was not observed in the soluble complexes from acetylated debranched-only starches, even though a significant quantity of stearic acid was detected by GC. The XRD results imply that soluble starch−oleic acid complexes were formed, but when the GC results (Table 2) were considered, these complexes did not include as much oleic acid as did the soluble complexes of stearic acid from the previous work. The reason for the difference in the XRD patterns observed in the two studies may be due to the fact that stearic acid and oleic acid interacted differently with the acetylated starch helix because of their structural differences. The presence of the double bond in oleic acid may have created a different spatial arrangement which differed from that of stearic acid upon complexation with acetylated starch. However, limited information exists for inclusion complexes from chemically modified starch; therefore, more research is needed to explain the differences between XRD patterns and the complexed amount for acetylated starch complexes with stearic acid and oleic acid.

The acetylation of starch noticeably increased the intensity of the V-type pattern of the starch−oleic acid complex and reduced the starch retrogradation peak at 2θ = 17°. For the insoluble complexes, high-acetylated β-amylase-treated starch displayed the highest peak intensity (Figure 4F), which, however, did not contain the highest amount of complexed oleic acid by GC. This suggests that the intensity of the V-type pattern might not necessarily correlate with the quantity of complexed fatty acids, both soluble and insoluble complexes, such as oleic acid in this study and stearic acid in the previous study, but reflects only the level of organization and arrangement of the type of complex formed. When low-acetylated starches were treated with β-amylase, the peak intensity of the starch−oleic acid complex slightly increased for the soluble complexes but decreased for insoluble complexes (Figure 4C,D). Again, there was no correlation between the X-ray peak intensity and the amount of complexed oleic acid.

Melting Properties by Differential Scanning Calorimetry. All insoluble complexes and some soluble complexes

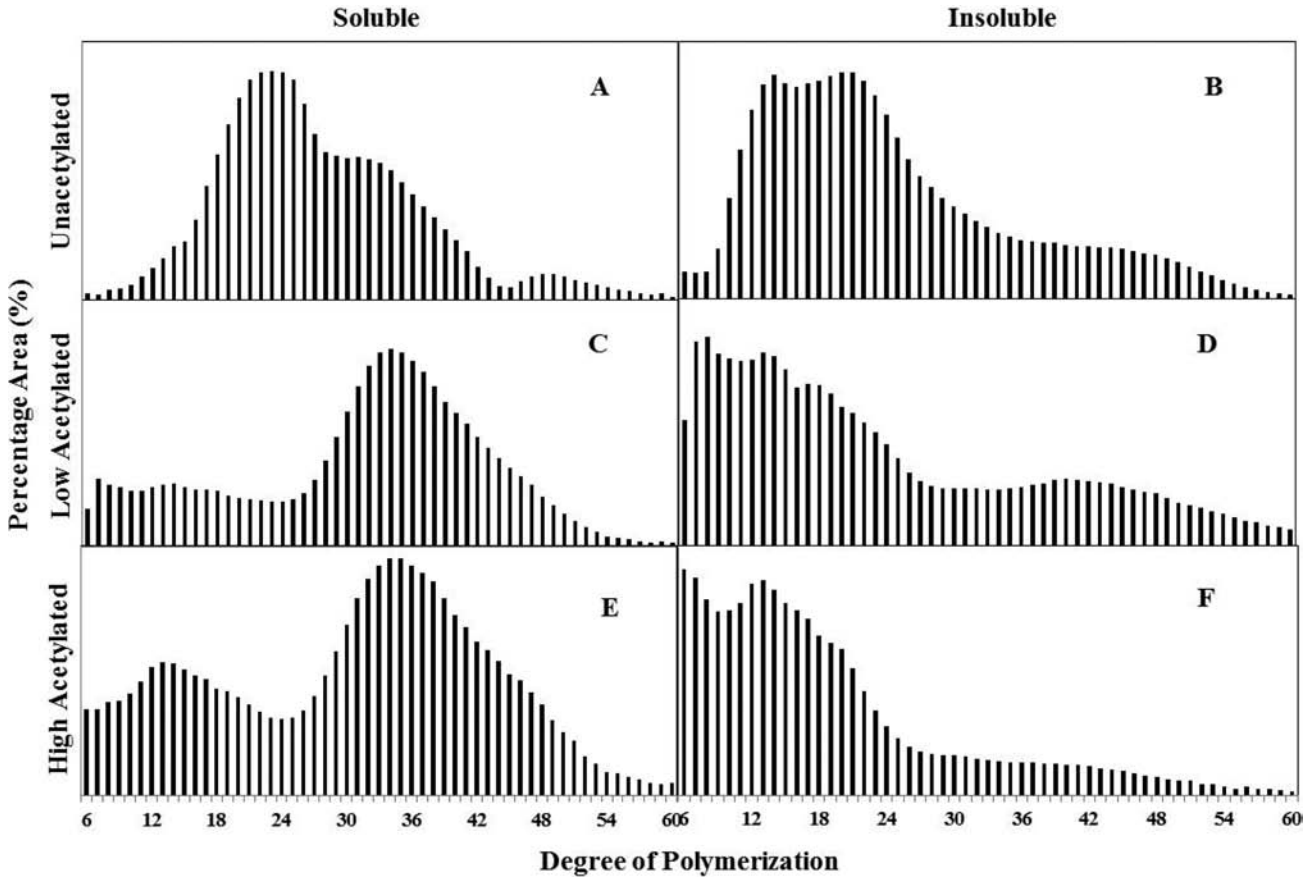

Figure 3. Normalized chain-length distributions of recovered soluble and insoluble starch complexes from unacetylated and acetylated potato starches with the β-amylase treatment after complexing with oleic acid using high-performance anion-exchange chromatography with pulsed amperometric detection (HPAEC-PAD): (A) potato starch, (B) β-amylase-treated potato starch, (C) low-acetylated potato starch, (D) low-acetylated β-amylase-treated potato starch, (E) high-acetylated potato starch, and (F) high-acetylated β-amylase treated potato starch.

displayed melting endotherms, but only the insoluble complexes exhibited the type II complex peak (Table 3). Within the unacetylated starches, the insoluble complexes of the debranched-only starch displayed a single melting endotherm with T_p at 106.7 °C, signifying the presence of the type II starch−fatty acid complex, whereas the soluble complex within the same treatment displayed only a type I complex with T_p at 94.8 °C. The type I complex has been reported to form at a lower temperature of ∼60 °C, leading to the production of randomly oriented helical segments,[35] whereas the type II complex is formed at temperatures of around 90 °C and produces well-defined crystallites.[36] Godet et al.[9,37] showed that longer starch chains can complex more lipids to produce crystals with higher melting temperatures.

When the unacetylated starch received the additional β-amylase treatment, two melting endotherms were observed for the insoluble complexes, including the type I and type II complex[38] with T_p at 94.9 and 102.9 °C, respectively. Lagendijk and Pennings[39] previously reported that amylose with DP 900 may contain between 10 and 12 helices, consisting of 6 glucose units per turn, and each helix can complex at least 1 glycerol monopalmitate. The bimodal distribution of the insoluble starch complexes consisting of both short and long starch chains (Figure 1B) may lead to the production of type I and type II complexs, respectively, which is in agreement with previous works.[37,39] However, although the type II complexes were formed for the unacetylated starch complexes, the amount of complexed oleic acid were still low, presumably because of the increased reassociation of starch chains as evidenced in the XRD results (Figure 4B). The additional β-amylase treatment of unacetylated starches had no significant effect on the T_p and the enthalpy of the soluble complexes, but it decreased that of the insoluble complexes slightly, indicating that the β-amylase treatment resulted in starch chains that formed insoluble complexes with a lower stability and required a lower energy to dissociate.

The introduction of acetyl groups to starch chains significantly decreased the T_o and T_p for all complexes. These findings are in agreement with previous works[22,23,40] in which the acetylation of starch was reported to decrease the complexing ability and dissociation temperature of amylose−lipid complexes, although the complexes referred to in these studies were only the insoluble complexes. In addition, acetylated starch complexes displayed only the type I complex melting peak, supporting the previous study in which the presence of the acetyl groups on starch may hinder the aggregation of the starch−oleic acid complexes.[23] However, there was no clear trend in melting enthalpy in terms of the β-amylase treatment. The enthalpy values also did not correlate with the amounts of complexed oleic acid as measured by GC (Table 2). This suggests that the enthalpy values might not necessarily represent the amount of oleic acid included in the starch complexes but might indicate the energy required to melt the starch−oleic acid complex due to the degree of order or level of organization existing within the complexes.

Although no melting endotherm was observed for the soluble complexes from the low-acetylated without or with the *β*-amylase treatment and the high-acetylated *β*-amylase-treated starch, the presence of the starch−oleic acid complex was supported by the recovered oleic acid from the GC (Table 2) as well as by the presence of the V-type pattern displayed in the XRD results (Figure 4C,D,F). An opposite trend was observed in the soluble complexes of the low-acetylated-only starch from the previous study with stearic acid,[23] in which the presence of the starch−stearic acid complex was not observed in the XRD and DSC analyses, but stearic acid was recovered from the complexes as measured by GC. These results support the

J. Agric. Food Chem. 2015, 63, 4202−4210

hypothesis that acetylated starch complexes may exist in different polymorphic arrangements[21] because the presence of acetyl groups on starch rendered them more soluble and affected their structural characterization by DSC. Nevertheless, there may be other factors causing the absence of the melting endotherm in some of the soluble starch−oleic acid complexes in the present study. Therefore, further investigations such as different chemical modifications or analytical techniques such as FTIR may provide a better understanding of the various types of polymorphs that can be generated during the complexation of acetylated starch and oleic acid and their structural characteristics.

In conclusion, the present study demonstrates that the acetylation of starch alone can enhance the formation of both soluble and insoluble starch−oleic acid complexes compared with its unacetylated counterpart. Overall, high-acetylated-only starch and low-acetylated β-amylase-treated starch resulted in the highest complex formation with oleic acid for the soluble and insoluble complexes, respectively. All acetylated soluble and insoluble complexes displayed the V-type X-ray diffraction pattern regardless of the type of modification. The melting temperatures were reduced by acetylation for all complexes; however, little correlation was found among the melting enthalpy values, X-ray intensity, and amount of either the soluble or insoluble complex. The amount of complexed oleic acid in the present work was consistently lower than the amount of complexed stearic acid in the previous study for all treatments, confirming that the cis configuration in fatty acids is not favored to form stable soluble or insoluble complexes and longer starch chains were preferred for complexation with oleic acid than with stearic acid.

J. Agric. Food Chem. 2015, 63, 4202−4210

the present study, non-network proteins, as with dextran[16,23,24] or PEG,[17−22] were used as "probes". The diffusion coefficients of non-network proteins with different molecular weights in heat-induced soy protein gels, in terms of the effect of the protein concentration and heating time, were investigated. Fick's diffusion law was used to analyze the release kinetics of the non-network proteins. The relationship between the release behavior of non-network proteins and the structure of the heat-induced soy protein gel in response to the protein concentration and heating time are discussed. The quantitative characterization of the diffusion behavior provides insight into the structure and properties of heat-induced soy protein gels.

MATERIALS AND METHODS

Materials. Low-temperature soy meals were kindly provided by Shandong Gushen Industrial & Commercial Co., Ltd. (Dongying, Shandong, People's Republic of China). The flakes had a protein content of 55.0% (N × 6.25, dry base) and a nitrogen solubility index of 87%. Defatted soy flakes were extracted with 85% aqueous alcohol at room temperature for 1 h with a ratio of 1/5 (w/v) flakes to solvent. The slurry was vacuum-filtered, and the filter cake was mixed with 95% (v/v) ethanol at room temperature for 1 h with a ratio of 1/2 (w/v). After it was dried for 2 days at room temperature, the meal was dispersed in distilled water (1/10, w/v) and adjusted to pH 7.0 by adding a small amount of 2 M NaOH. After it was stirred for 1 h at room temperature, the suspension was centrifuged (15800*g*, 30 min, 4 °C) to recover the supernatants. Soy protein was precipitated by adjusting the pH to 4.5 with 2 N HCl and centrifuged at 10000*g* for 30 min at 4 °C. After it was washed with distilled water, the protein precipitate was resuspended in distilled water and solubilized by adjusting the pH to 7.0. The protein dispersions were stirred overnight at 4 °C to enhance protein dissolution. The protein solution was lyophilized and stored at −18 °C. Proximate analysis showed that the dried powder had protein and ash contents of 91.65 ± 0.8% (*N* × 6.25) and 4.26 ± 0.04%, respectively, on a dry basis, and the 7S/11S ratio of native isolate was 0.79 ± 0.02 (determined by reducing-SDS-PAGE).[28] All other reagents were of analytical grade.

Preparation of the Protein Gels. Rehydration of the soy protein powder was performed by thorough magnetic stirring at room temperature with 0.1 M NaCl and 10 mM sodium phosphate buffer (pH 7.0) at the desired concentration (12%, 15%, and 18%, w/v) (soy gels with a protein concentration higher than 12% are easy to handle during the release process). In each case the pH was adjusted to 7.0 with 1 N HCl or 1 N NaOH. Sodium azide was added (0.02% w/v) to each solution to prevent bacterial development. The soy protein suspensions were centrifuged at 40000*g* for 30 min to remove gas and then carefully placed in SEBC bottles (special glass bottles with a tight screw-threaded blue cover and with high temperature, acid, and alkali resistance, Biocolor Co., Ltd., Shanghai, People's Republic of China). Gelation was then conducted by heating the soy protein dispersions in SEBC bottles at 95 °C, after the temperature of the solution reached the target value (95 °C), which occurred after approximately 3 min in a preliminary experiment. The solution was maintained in the water bath for exactly 30 min or for different time periods (30 min, 1 and 2 h). After heating, the bottles were immediately cooled in ice water for 5 min and stored at 4 °C overnight to ensure complete gelation before further use.

Release of Non-Network Proteins from Gels. The gels (approximate 20 g) generated under different conditions were cut into 1.5 mm thick slices with a razor and transferred to 10 mM sodium phosphate buffer (pH 7.0) (10 times excess w/v) in 500 mL SEBC bottles. NaN_3 (0.02% w/v) was added to each solution to inhibit bacteria growth. The SEBC bottles were gently rotated in a water bath at 25 °C. The non-network proteins in the gels were allowed to diffuse out of the gel slices for 56 h, which was sufficiently long to reach equilibrium on the basis of preliminary experiments. During diffusion, 0.5 mL samples were periodically collected and replaced with fresh buffer.

Determination of the Protein Concentration. The protein concentration of the samples (filtered through a cellulose acetate membrane with a pore size of 0.22 μm; Sartorius Co., Ltd., Gottingen, Germany) at different time points was determined using the bicinchoninic acid (BCA) method,[29] with bovine serum albumin as a standard. The BCA reagent was prepared by mixing 50 volumes of reagent A (containing 1% BCA, 2% Na_2CO_3, 0.16% $Na_2C_4H_4O_6$, 0.4% NaOH, 0.95% $NaHCO_3$) with 1 volume of reagent B (4% $CuSO_4$) immediately before use. Then, 100 μL of the sample and 2 mL of BCA reagent were pipetted into a test tube and mixed thoroughly. The mixture was allowed to stand for 30 min at 37 °C and then returned to room temperature, and the absorbance was monitored at 562 nm, using 100 μL of water as a control. All of the measurements were performed in triplicate.

Contents of Released Non-Network Proteins. The content (W_{rp}, g/100 g of total protein) of released proteins was calculated as

$$W_{rp} = \frac{C_{non}V_{buffer}}{1000C_pM_{gel}} \times 100$$

where C_{non}, V_{buffer}, C_p, and M_{gel} are the concentration (mg mL^{-1}) of non-network proteins in the buffer at equilibrium (48 h), the volume (mL) of buffer used, the protein concentration (g/g) in the gel, and the weight (g) of the gel in the buffer, respectively.

Contents of Released Undenatured 11S Proteins and Denatured Proteins. The contents of released proteins (W_{rp}, g/100 g of total protein) were divided into two parts. One part is the content of released undenatured 11S proteins. (The 7S component is completely denatured at 90 °C after 30 min according to Sorgentini et al.,[28] and therefore, the undenatured component in the released protein is native 11S-AB. Ruan et al.[30] found that the disruption of the interpolypeptide disulfide bond between A and B occurred even at 70−80 °C lower than the denaturation temperature (93.21 °C) of 11S. Therefore, the intact AB band in nonreducing SDS-PAGE can be identified as undenatured 11S.) The other part is the content of denatured proteins released from the protein gel. The content of undenatured 11S proteins ($W_{undenatured}$, g/100 g of total protein) released from the gel was calculated from the equation

$$W_{undenatured} = W_{rp}r_{AB} \quad (1)$$

where W_{rp} and r_{AB} are the content of released proteins (W_{rp}, g/100 g of total protein) and the ratio of the content of undenatured 11S proteins to that of released network proteins, obtained by comparing the AB band intensity with the total intensity of all of the bands in the same nonreducing SDS-PAGE lane.

The content of denatured proteins ($W_{denatured}$, g/100 g of total protein) in the released network proteins was calculated as

$$W_{denatured} = W_{rp}(1 - r_{AB}) \quad (2)$$

where $1 - r_{AB}$ represents the ratio of released denatured proteins to the content of released network proteins.

Network Protein Content per 100 g of Gel. The network protein content (W_{net}, g/100 g of gel) was calculated using the equation

$$W_{net} = C_p\left(1 - \frac{W_{rp}}{100}\right) \quad (3)$$

where C_p and W_{rp} are the protein concentration (g/g) in the gel and the content of released proteins (g/100 g of total protein).

High-Performance Size Exclusion Chromatography (SEC-HPLC). The molecular weight distribution of the samples was determined according to the method reported by Wu et al.[31] with some modifications. The samples were filtered through a cellulose acetate membrane with a pore size of 0.22 μm (Sartorius Co., Ltd., Gottingen, Germany). A Hitachi liquid chromatography system equipped with a Shodex protein KW-804 column (Shodex Separation and HPLC Group, Tokyo, Japan) was used. The elution was performed with 50 mM phosphate buffer (pH 7.0, including 0.3 M NaCl) at a flow rate of 1.0 mL/min. Each sample (20 μL) was injected

into the column, and the effluent was monitored at 214 nm. The column was calibrated using standard proteins (Bio-Rad) between 1350 Da and 670 kDa (vitamin B_{12}, 1350 Da; horse myoglobulin, 17 kDa; chicken ovalbumin, 44 kDa; bovine gamma globulin, 158 kDa; thyroglobulin, 670 kDa). All of the samples were measured in triplicate, and an Agilent Chemistry Station was used to analyze the peak area.

Diffusion Coefficients of Non-Network Proteins in Gels and in Water. Non-network proteins with different molecular weights released from soy gel slices were characterized by calculating the apparent diffusion coefficient (D), which was estimated on the basis of the release kinetics curve, fitted using an analytical solution of Fick's second law:[32]

$$\frac{M_t}{M_\infty} = 4\left(\frac{Dt}{\pi\delta^2}\right)^{1/2} \quad (4)$$

where M_t and M_∞ are the amounts of protein released from the gel at time t and the protein in the buffer in the equilibrium state (48 h), respectively, while D and δ are the diffusion coefficient and the gel thickness, respectively. M_t/M_∞ can also be expressed as S_t/S_∞ (given that the volume of the diffusion buffer is almost constant), in which S_t and S_∞ are the SEC-HPLC peak areas at time t and at the time of equilibrium, respectively. Therefore, the diffusion coefficient of non-network proteins can be calculated as

$$D = \frac{k^2\delta^2\pi}{16} \quad (5)$$

where k is the slope of the relative solute release (S_t/S_∞) versus the square root of the time curve.

The diffusion coefficients in water (D_0) were calculated using the Stokes−Einstein equation, for different fractions:

$$D_0 = \frac{kT}{6\pi\eta R_h}$$

where T, k, and η are the kelvin constant (293.5 K), Boltzmann constant (1.38×10^{-23} J K^{-1}) and the viscosity of pure water (1.00×10^{-3} Pa s at 25 °C). The R_h values of peaks 1−3 used for calculations are 5.85 nm (Stokes radius of native 11S globulins),[33] 2.80 nm (ovalbumin, 45 kDa), and 2.01 nm (α-lactalbumin, 14 kDa), respectively.

SDS-PAGE. SDS-PAGE was performed to examine the protein compositions according to the method proposed by Laemmli.[34] Electrophoresis was performed with a continuous and dissociating buffer system: 0.375 M Tris-HC1 (pH 8.8) and 0.1% SDS for the separating gel and 0.025 M Tris-HC1 (pH 8.3), 0.192 M glycine, and 0.1% SDS for the run buffer. A 12.5% resolving gel overlaid with a 3% stacking gel was used. Aliquots of each sample were mixed with 1× sample dissolving buffer (4% SDS, 20% glycerol, 0.125 M Tris-HCl buffer, pH 6.8, 0.01% bromophenol blue) and divided into two parts: one part with 0.02% 2-mercaptoethanol (w/w) heated to 5 min at 100 °C and the other part without 2-mercaptoethanol. These two parts were centrifuged at 15000g for 10 min at room temperature. The two parts were loaded separately into SDS-PAGE gels and subjected to electrophoresis. The gel was then stained with Coomassie brilliant blue R250 and destained with deionized water that was changed two to three times. Finally, the gels were scanned using a computing densitometer (Molecular Imager Chemi Doc XRS+, Bio-Rad, USA). To investigate the protein compositions of the peak area of the SEC-HPLC curve, the eluates of the corresponding area were collected 50 times and then concentrated using an Amicon Ultra 15 mL centrifugal filter (Millipore Corporation, Germany) with a membrane NMWL (nominal molecular weight limit) of 3 kDa. The concentrated eluates were analyzed by SDS-PAGE. The intensities of the protein bands were analyzed using Image Lab software (Bio-Rad, USA). The content

DOI: 10.1021/acs.jafc.5b00132
J. Agric. Food Chem. 2015, 63, 4211−4219

of each component was determined as a percentage of the component in the sample by comparing the individual band intensities with the total intensity of all of the bands in the same lane.

Statistical Analysis. Experiment data were subjected to analysis of variance (ANOVA) using SAS 9.1. A least significant difference (LSD) test with a confidence interval of 95% was used to compare the means. All of the treatments were performed in triplicate. Data are expressed as the mean ± SD (n = 3).

RESULTS AND DISCUSSION

Release of Non-Network Proteins from 15% Soy Protein Gels. *Changes in the Released Non-Network Protein Concentration.* The protein concentrations after diffusion time of 0.5, 1, 2, 4, 6, 9, 12, 23, 27, 32, 40, 48, and 56 h were determined, and the results are displayed in Figure 1a. The concentration of released proteins increased steadily over the first 12 h, but there was essentially no change during the final 8 h. Therefore, the diffusion of non-network proteins reached an equilibrium state at approximately 48 h.

The diffusion of non-network proteins as a function of the diffusion time was fitted to Fick's second law by plotting the relative mass release of non-network proteins (M_t/M_{48}) against the square root of the diffusion time, as shown in Figure 1b. A linear relationship was observed during the first 12 h, indicating that the initial phase of the diffusion of non-network proteins could be described using the Fickian diffusion law.

Molecular Weight Distribution and Protein Composition of the Released Non-Network Proteins. Released proteins from the gel were sampled at different diffusion times, and the size distributions of the proteins were analyzed by SEC-HPLC (Figure 2a). Four peaks were observed, among which the last peak was attributed to solvent absorption. Peaks 1−3 were identified as proteins, with molecular weights of 253.9 ± 22.5, 44.8 ± 5.1, and 9.7 ± 1.6 kDa, respectively, as determined using a standard calibration curve. It is interesting to note that the areas with different protein peaks did not change synchronously during the diffusion period.

The protein compositions of peaks 1−3 on the basis fo SDS-PAGE are shown in Figure 2b. The protein gel per se (lane 2) contained all of the major components of soy proteins, including the 7S α', α, γ, and β subunits as well as the 11S A, B, A_3, and A_5 polypeptides,[35] in addition to a faint band with a size of 15 kDa protein (named 15K protein). Lane 3 shows the composition of the released proteins in the buffer. Only a very small amount of 7S α', α, and β subunits and a moderate amount of B polypeptides were detected, in comparison to the large amount of A and 15K band. Peak 1 (lane 4) contained almost all of the protein species found in the original diffusion sample (lane 3) in addition to a faint 15K band. A nonreducing SDS-PAGE analysis (data not shown) revealed that the A and B polypeptides in the diffused sample and peak 1 actually existed in the form of AB subunits. Peak 2 (lane 5) contained several unidentified proteins with molecular weights of 23 and 20 kDa as well as small amounts of B polypeptides. On the basis of the SDS-PAGE analysis, the 15K and small amount of A_5 polypeptides were eluted in peak 3 (lane 6). The SDS-PAGE analysis indicated that the proteins released from the 15% gel were composed of AB subunits of 11S and other small proteins. Because there was a very low content of 7S subunits in the diffusion buffer, it can be inferred that 7S contributed to the gel network, while a fraction of undenatured 11S and some small proteins were not involved in the formation of the gel network. Utsumi et al.[2,3] also discovered a difference in the contribution of soy protein components to the network structure of gels. Subunits that are weakly involved in the network should be relatively free and released from the gels by ultracentrifugation. Puppo et al.[9] reported that the 11S fractions remained in the native state after heating and would exist as soluble peptides in gel matrix interstices.

Diffusion Coefficients of Non-Network Proteins with Different Molecular Weights. Figure 3 shows the relative peak areas (S_t/S_∞) of peaks 1−3, respectively, as a function of the square root of the diffusion time ($t^{1/2}$). The cumulative release appeared to be proportional to the square root of the diffusion time up to approximately 70% protein release. This finding indicates that the release of peaks 1−3 was all controlled by Fickian diffusion processes in the initial stage (during the first 12 h). The diffusion coefficients (D) were calculated from the slope of the fitted lines according to eq 5. As shown in Table 1, the diffusion coefficients (D) increased from 2.90×10^{-12} to 1.64×10^{-11} m^2 s^{-1} as the protein molecular weight decreased from 253.9 ± 22.5 to 9.7 ± 1.6 kDa. Colsenet et al.[20] studied the diffusion of PEG in whey protein gels with a 75% protein denaturation ratio. They reported that the diffusion coefficient increased from 3.0×10^{-12} to 6.0×10^{-11} m^2 s^{-1} when the molecular weight of PEG decreased from 82.25 to 1.08 kDa. Moreover, the diffusion coefficients of PEG with molecular weights of 4, 12, 20, and 36 kDa were 8.9×10^{-11}, 3.8×10^{-11}, 2.0×10^{-11}, and 1.3×10^{-11} m^2 s^{-1}, respectively, in calcium alginate hydrogels with an alginate concentration of 16.5 g L^{-1}.[36]

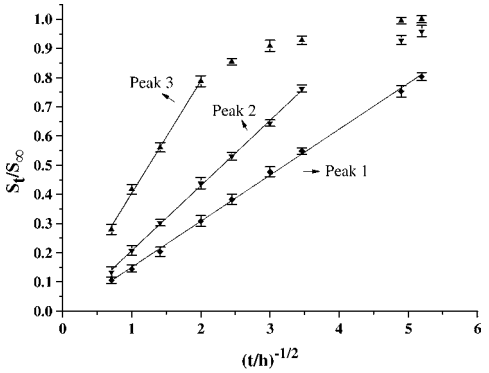

Figure 3. Cumulative release (%) of the proteins corresponding to peaks 1−3 (Figure 2a, SEC profiles) as a function of the square root of the diffusion time.

Table 1 also shows the diffusion coefficients in water (D_0). The results show that the gel matrix decreased the diffusion of non-network proteins by approximately 1 order of magnitude. This finding is in agreement with those reported by Schillemans et al.,[37] who demonstrated that the diffusion coefficients of myoglobin from chemically cross-linked dextran hydrogels decreased from 1.06×10^{-10} m^2 s^{-1} in pure water to $(0.9–1.3) \times 10^{-11}$ m^2 s^{-1} in hydrogels.

Moreover, Table 1 shows the theoretical values of D/D_0 using the predictive expression suggested by Davis[38] on the basis of studies of diffusion in polyacrylamide gels:

$$\frac{D}{D_0} = \exp(-(0.05 + 10^{-6}M)c_p) \quad (5)$$

where M and c_p are the molecular weight of the solute and the polymer gel mass fraction (expressed as a percent). According

	D (m^2 s^{-1})		
protein concentration (% w/v)	peak 1	peak 2	peak 3
12	$(3.43 \pm 0.14) \times 10^{-12}$a	$(6.95 \pm 0.23) \times 10^{-12}$d	$(16.80 \pm 0.46) \times 10^{-12}$f
15	$(2.90 \pm 0.16) \times 10^{-12}$b	$(6.43 \pm 0.17) \times 10^{-12}$d	$(16.43 \pm 0.47) \times 10^{-12}$f
18	$(2.11 \pm 0.12) \times 10^{-12}$c	$(6.01 \pm 0.19) \times 10^{-12}$e	$(16.39 \pm 0.36) \times 10^{-12}$f

to eq 5, D/D_0 depended on the molecular weight of the solute and the polymer concentration of the gel. Although the calculated D/D_0 using Davis' model also increased with a decrease in molecular weight, the predictions of eq 5 are very different from the observed values, suggesting that the diffusion behavior of solutes in soy protein gels was substantially different from that in polyacrylamide gels. In fact, polyacrylamide gels behaved like a screen with homogeneous mesh size: peaks 2 and 3 with molecular weights of less than 44.8 kDa showed a much higher diffusion rate than that of peak 1 with a molecular weight of 253.9 kDa. On the other hand, soy protein gels were more heterogeneous in nature. Therefore, no clear-cut distinction between diffusion coefficients for high- and low-MW proteins was observed.

Effect of Protein Concentration on the Release of Non-Network Proteins. Heat-induced soy gels were made at 95 °C and 30 min using three protein concentrations: 12%, 15%, and 18% (w/v). With an increased protein concentration, more proteins were involved in the formation gel network as shown in Figure 4a. There were 10.61, 13.05, and 15.36 g of network proteins per 100 g of gel for the 12%, 15%, and 18% protein concentrations, respectively. However, the amount of released proteins, which was calculated on the basis of net protein mass rather than the gel mass, also increased. Figure 4a shows released undenatured 11S proteins ($W_{undenatured}$) and denatured proteins ($W_{denatured}$) calculated from eqs 1 and 2. When the protein concentration increased from 12% to 15% and finally to 18%, the corresponding released undenatured 11S proteins were 3.71, 5.17, and 7.18 g, respectively, per 100 g of gel proteins, which can also be explained by the increase in AB subunits (AB + A_3B_3) bands from 32.1 ± 0.4% to 39.7 ± 0.7% and 48.9 ± 0.5% in the released samples from gels with protein concentrations of 12%, 15%, and 18%, respectively, by nonreducing SDS-PAGE (Figure 4b). Concomitantly, the amounts of released denatured proteins were 7.85, 7.86, and 7.49 g, respectively, per 100 g of gel proteins. Thus, the increase in the total released non-network proteins (11.56, 13.03, and 14.67 g/100 g of total protein for protein concentrations of 12%, 15%, and 18%, respectively) was contributed mainly by the increase in the undenatured AB subunits. Several studies have reported that the degree of denaturation decreased with the increase in protein concentration. Zhang et al.[39] and Mills et al.[40] found that the onset temperature and peak temperature (in DSC curves) increased with an increasing content of crude soy protein. Mori et al.[41] also reported that the heat-induced association−dissociation of 11S globulin differs depending on the protein concentration, as evidenced by the finding that 11S-AB subunits did not dissociate into A and B polypeptides at a protein concentration of 5% to the extent they did at a protein concentration of 0.5%. At the same time, other studies have demonstrated the formation of higher molecular weight aggregates[1,40,41] and a decreased gelation temperature[26] when soy proteins are heated at higher concentrations. Thus, it is reasonable to postulate in our studies that, although the degree

DOI: 10.1021/acs.jafc.5b00132
J. Agric. Food Chem. 2015, 63, 4211−4219

of denaturation of 11S decreased, more proteins were involved in the gel network at higher protein concentrations.

The diffusion coefficients of non-network proteins with different molecular weights in the soy gels at different protein concentration are shown in Table 2. It is clear that the diffusion coefficients of the protein fractions with higher molecular weights were substantially more affected by the gel protein concentration. Gireeshkumar[23,24] found that the diffusion coefficients of dextran decreased strongly with the increase in the protein concentration of β-lactoglobulin gels and that the larger molecular size of dextran resulted in a greater decrease in the diffusion coefficient. For smaller molecular tracers (PEG) with MW values of 1 and 8.5 kDa, respectively, Colsenet[18] found that the structural changes of casein gels induced by different protein concentrations had essentially no effect on their diffusion in the gel, and the same effect was observed for the changes in the diffusion coefficients of peak 3.

For globular proteins, R_h is related to the cubic root of the molecular weight:

$$R_h = \sqrt[3]{\frac{3M_w}{4\pi N_a \rho}}$$

where M_w is the molecular weight, N_A is the Avogadro constant, and ρ is the density of a protein. From the Stokes−Einstein equation

$$D = \frac{kT}{6\pi\eta R_h}$$

the following power law dependence can be obtained:

$$D = AM_w^{-\alpha} \quad (6)$$

where A is a pre-exponential factor and α is the characteristic exponent. Equation 6 is often used to describe the self-diffusion of polymer chains in different systems with α ranging from 0.55 for dilute systems[42] to 2 in concentrated systems.[43] The diffusion coefficients determined for different protein fractions were plotted against MW on the double-logarithmic coordinate as shown in Figure 5. The exponent α yielded from the plot increased from 0.58 to 0.69 when the protein concentration increased from 12% to 18%. Favre et al.[36] determined the diffusion rate of PEG with a MW value from 4 to 35 kDa in calcium alginate hydrogels, and they reported that the exponent increased from 0.768 to 1.017 as the alginate concentration increased from 8.7 to 28.5 g mL^{-1}. On the other hand, in the study reported by Colsenet,[19] the diffusion of PEG in whey protein gels was determined by NMR. They found that α shifted from 0.59 to 0.84 as the protein concentration increased from 0.1 to 0.4 g/g. These authors[20] suggested that the diffusion of the probe was affected by the changes in the gel microstructure and that the increase in α occurred in accordance with a decrease in the interparticle distances in the gels. The power law exponent α would theoretically tend toward 1 for nonentangled polymer chains when the network mesh size of the gel decreases and approaches the solute radius.[44] For α equal to 2, eq 6 represents the reptation model first introduced by de Gennes.[42] The reptation model can be used to describe the dynamics of long polymer chain diffusion in a cross-linked gel, and according to this model, when the mesh size of the gel is less than the solute radius, the macromolecular solute would be forced to adopt a wormlike displacement behavior. The exponent determined in the present study was close to the theoretical value of 3/5 for a swollen coil in a good solvent.[42] Therefore, theoretically and practically, the pore size of the soy protein gel network is larger than the radius of non-network proteins. In addition, α gradually shifted toward higher values when the protein concentration or gel network density increased.

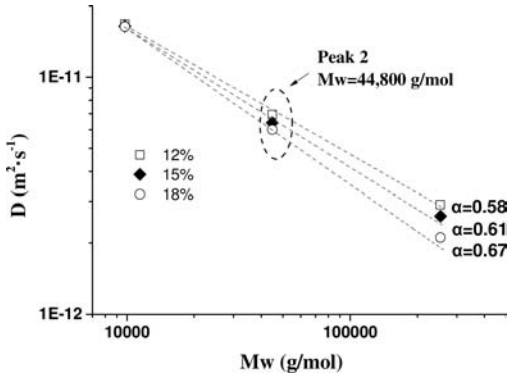

Figure 5. Power law representation of non-network protein diffusion coefficients in gels with different protein concentrations as a function of the non-network protein molecular mass.

Effect of Heating Time on the Release of Non-Network Proteins. The effect of heating time on the gel properties was investigated at 95 °C at a protein concentration of 18% (w/v) for 0.5, 1.0, and 2.0 h. Figure 6a shows that the amounts of undenatured 11S proteins released from the gels were 7.17, 3.92, and 1.54 g/100 g of total protein for heating times of 0.5, 1.0, and 2.0 h, respectively. Furthermore, the corresponding release of denatured proteins was of 7.49, 9.07, and 9.23 g/100 g of total protein, respectively. Moreover, the network protein content (W_{net}, g/100 g of gel) increased from 15.36 to 15.63 and 16.09 g/100 g of gel as the heating time increased.

As shown using nonreducing SDS-PAGE (Figure 6b), the intensity of the AB subunits decreased with an increase in heating time. Prolonging the heating time resulted in small increases in the contents of A polypeptides (17.1 ± 0.3%, 16.7 ± 0.5%, and 19.4 ± 0.6% for 0.5, 1.0, and 2.0 h, respectively; data not shown) and dimers of A polypeptides (2.3 ± 0.2%, 3.1 ± 0.3%, and 3.3 ± 0.2% for 0.5, 1.0, and 2.0 h, respectively; data not shown) but a slight decrease in trimers of A polypeptides from 3.2% to 0.5%. However, a remarkable increase in protein polymers was observed (7.8 ± 0.5% to 30.6 ± 0.7% for heating times from 0.5 to 2.0 h), in which A polypeptides were the main components on the basis of nonreducing/reducing diagonal electrophoresis (data not shown). Therefore, the increase in the amount of released denatured proteins ($W_{denatured}$ in Figure 6a) with an increase in heating time was probably contributed by the increase in polymers that were formed by the disassociated A polypeptides. The increase in network protein content (W_{net} in Figure 6a) can be explained by the increase in the amount of dissociated B polypeptides as a consequence of the preferential interaction between the β subunit of 7S and the B polypeptides of 11S, which has been reported to contribute to the gel network.[2,3] Marleen et al.[45] and Philippe et al.[16] also found that, upon prolonged heating of whey proteins or β-lactoglobulin, more proteins were incorporated into the gel network.

Diffusion coefficients (D) for different MW fractions from gels with different heating times are illustrated in Table 3. A higher molecular weight clearly resulted in greater sensitivity to

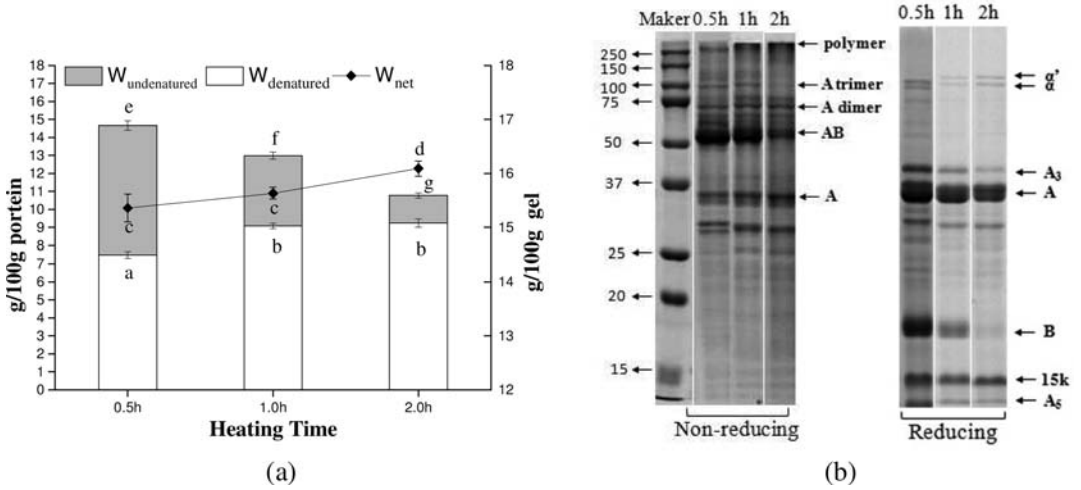

Figure 6. (a) Contents of undenatured 11S proteins ($W_{undenatured}$, g/100 g of total protein) and denatured proteins ($W_{denatured}$, g/100 g of total protein) released from the gels with a 18% protein concentration for heating for 0.5, 1.0, and 2.0 h, and the content of network protein content (W_{net}, g/100 g of gel). The three parameters are plotted as the heating time at a protein concentration of 18%. (b) SDS-PAGE of non-network proteins released from 18% soy gels at different heating times (h).

Table 3. Diffusion Coefficients of Non-Network Proteins in 18% Protein Gels as a Function of Heating Time

	D (m^2 s^{-1})		
heating time (h)	peak 1	peak 2	peak 3
0.5	$(2.11 \pm 0.12) \times 10^{-12}$a	$(6.01 \pm 0.23) \times 10^{-12}$c	$(16.39 \pm 0.46) \times 10^{-12}$e
1.0	$(2.06 \pm 0.14) \times 10^{-12}$a	$(5.75 \pm 0.17) \times 10^{-12}$cd	$(16.36 \pm 0.55) \times 10^{-12}$e
2.0	$(1.71 \pm 0.20) \times 10^{-12}$b	$(5.30 \pm 0.19) \times 10^{-12}$d	$(16.20 \pm 0.26) \times 10^{-12}$e

changes in diffusion with heating time. Good fits for the diffusion coefficients shown in Table 3 with eq 6 could also be obtained, yielding α values of 0.67, 0.69, and 0.75 for heating times of 0.5, 1.0, and 2.0 h, respectively. This finding suggested that a more compact gel network was obtained with a longer heating time. Lucey et al.[46] came to the same conclusion on the basis of a comparison of permeability measurements, demonstrating that the gels made from reconstituted skim milk heated at 80, 85, and 95 °C for 30 min had permeability coefficients lower than those that were heated for 15 min. Marleen et al.[45] also found that prolonged heating caused a decrease in pore size by studying the effect of the duration of heating on the properties of whey protein gels. Jacoba et al.[1] demonstrated that, after the onset of soy protein gelation, an increase in G' was observed upon further heating. They suggested that G' increased because more protein became incorporated into the network, leading to further accumulation of the network structure. Alternately, G' might have increased as a consequence of rearrangements in the network. A type of rearrangement that might occur is fusion of the protein aggregates in the strands, which results in an increase in protein−protein interactions per cross-section and thus in denser and stiffer strands.

In summary, this study demonstrated that the diffusion behavior of non-network proteins can be used to probe the structural characteristics of heat-induced soy protein gels. The major parts of the released non-network proteins were occupied by undenatured AB subunits, monomers, dimers, trimers, and polymers of A polypeptides, as well as the unidentified 15 kDa protein, while the amounts of 7S subunits and B polypeptides were very small among the released proteins. By SEC-HPLC, the released proteins could be classified into three fractions according to their size, with characteristic molecular weights of 253.9, 44.8, and 9.7 kDa. The release behavior of non-network proteins was fitted to Fick's second law. The increase in the gelling concentration resulted in a rise in non-network protein content in the gel, which was mainly contributed by undenatured AB subunits. A prolonged heating time reduced the amount of released non-network proteins and caused the composition to shift to more denatured proteins. In all of the cases, the diffusion coefficients of non-network proteins decreased with an increasing gel network density. An increase in the molecular weight of the protein fractions increased the sensitivity of the non-network protein diffusion coefficients to the structural changes in soy gels induced by different conditions. More proteins appeared to be involved in the gel network at elevated protein gelling concentrations to form a denser matrix, whereas the structural changes in the gels during prolonged heating might have been caused by rearrangements in the network structure and probably to some extent by further incorporation of protein into the network. Due to the elucidation of the relationship between the release behavior and structure of soy protein gels, further investigations are underway to reveal whether diffusion experiments can be affected by rheological properties and different proteins (7S and 11S).

receptors. 5-Hydroxy-*N,N,N*-trimethyltryptamine was found to be a cholinergic agent about 10-fold more powerful than *N,N,N*-trimethyltryptamine.[14] Considering their pharmacological properties, it was hypothesized that both compounds may represent the arrival point of a biosynthetic pathway aimed to provide *Citrus* plants with chemical defense against biotic agents. Our observation that leaves and seeds, more frequently attacked by biotic agents, are the plant parts where the highest levels of those compounds were found further suggests that possibility.[13] It is also well-known that many plants store their defense metabolites as inactive glycosides that can be hydrolyzed by specific glycosidases to release their toxic aglycones as a consequence of plant tissue damages caused by herbivores.[15] To date, the presence of this mechanism in *Citrus* is still unknown. Therefore, we sought to investigate the occurrence of glycosylated derivatives of serotonin and its N-methylated forms (Figure 1). To this aim, among *Citrus*, sweet orange, bitter orange, bergamot, citron, chinotto (*Citrus myrtifolia*), clementine, lemon, mandarin orange, and pomelo were investigated for the presence of glycosylated forms of serotonin and its N-methylated derivatives. Furthermore, for some species, the distribution of the glycosyl derivatives and their aglycones in flavedo, albedo, juice, and seeds was assessed.

MATERIALS AND METHODS

Reagents. Serotonin (5-hydroxytryptamine, **5**), *β*-glucosidase from almonds, and *β*-galactosidase from *Aspergillus oryzae* were purchased from Sigma-Aldrich (Milan, Italy). 5-Hydroxy-*N*-methyltryptamine (**6**), bufotenine (5-hydroxy-*N,N*-dimethyltryptamine, **7**), and bufotenidine (5-hydroxy-*N,N,N*-trymethyltryptamine, **8**) were synthesized and purified as reported.[16−18] Formic acid and 0.1% solution of formic acid in water used for the liquid chromatography−electrospray ionization−mass spectrometry (LC−ESI−MS) analyses were from Sigma-Aldrich. All other chemicals were of analytical reagent grade. Purified water was obtained from a Milli-Q system from Millipore (Milan, Italy).

***Citrus* Plant Materials.** *Leaf Extracts.* *Citrus* leaves of sweet orange, bitter orange, bergamot, citron, chinotto (*C. myrifolia*), clementine, lemon, mandarin, and pomelo were harvested in October and December 2013 from the Research Centre for Citrus Crops and Mediterranean (CRA-ACM), arboretum of Reggio Calabria (Italy). Leaves were washed with distilled water and dried with filter paper. For each species, 25 g of leaves, finely chopped, were homogenized in a blender with 100 mL of 0.1% formic acid in Milli-Q-grade water and then kept under stirring for 30 min. Homogenates were, finally, centrifuged at 18000*g* for 30 min, and the supernatant were stored in 20 mL vials at −20 °C.

Flavedo and Albedo Extracts. The preparations of flavedo and albedo extracts started by washing fruits, followed by manual scraping of the exocarp to remove the essential oils from the glands on the fruit surface, which is made by a continuous layer of epidermal cells with a thick cuticle containing stomata. The colored part just below the epidermis, called flavedo or epicarp, was obtained by manual scraping. Under the flavedo, the white spongy part of the fruit, called albedo, was also collected manually. Both flavedo and albedo were separately homogenized in a mixer with water in a 1:1 (w/w) ratio. The homogenates were kept for 2 h under constant agitation and then centrifuged at 18000*g* for 30 min. The supernatants were frozen at −20 °C until used for the subsequent determinations.

Endocarp Extracts (Juice). The endocarp (the edible part of the fruit constituted of carpels containing the juice cells) deprived of seeds was homogenized in a mixer and then centrifuged at 18000*g* for 30 min. The supernatant was frozen at −20 °C until used for the subsequent determinations.

Seed Extracts. The seeds were initially washed with water, drained, and dried on filter paper. Then, 4 g of seeds were homogenized in a mixer with 20 mL of Milli-Q water. The homogenate was kept under constant agitation for 3 h and then centrifuged at 18000*g* for 30 min. The supernatants were frozen at −20 °C until used for the subsequent determinations.

Extracts from Seeds of Zanthoxylum piperitum. The dried fruits were purchased in a local market. The seeds (1.0 g), freed from pericarps, were homogenized in a blender with 4.0 mL of 0.1% formic acid in Milli-Q water and stirred for 30 min. The homogenate was centrifuged at 18000*g* for 30 min, and the supernatant was stored in 20 mL vials at −20 °C.

Enzymatic Hydrolysis of Glycosyl Derivatives in Plant Tissue Extracts. The pH of the extracts from the different plant tissues was adjusted to 5.0, and then a solution of *β*-glucosidase from almonds or *β*-galactosidase from *A. oryzae* in 0.1 M sodium acetate buffer at pH 5.0 was added. The final enzyme concentration in the extracts was 1 unit/mL. After incubation at 37 °C for various times, the samples were centrifuged and analyzed by high-performance liquid chromatography−electrospray ionization−tandem mass spectrometry (HPLC−ESI−MS/MS).

Determination of Aglycones and Glucosides in Plant Tissue Parts. As the standards of serotonin and its N-methylated derivatives were available, the levels of such compounds in the extracts were determined by comparison of the areas of the respective peaks in the

DOI: 10.1021/acs.jafc.5b01031
J. Agric. Food Chem. 2015, 63, 4220−4227

tandem mass chromatograms to those in the chromatogram of the standard mixture. However, because the standards of the glucosides were not available, an estimate of their levels was indirectly obtained by subjecting the extracts to the action of β-glucosidase and then determining for each analyte the increases (in the case of aglycones) and the decreases (in the case of glucosides) of the peak areas in the tandem mass chromatograms with respect to the corresponding peaks in the extracts without enzyme. By comparison to standards, the production of each aglycone can be calculated from the increase of the respective peak area. The aglycone production, in terms of moles, is equal to the moles of glucoside that, because of hydrolysis, caused the decrease of the corresponding area of the chromatographic peak. This provides a value of the peak area per mole of the glucoside to be known and, consequently, converts into moles the area of the corresponding peak in the chromatogram of the extract without enzyme.

HPLC–ESI–MS/MS Analyses. Analyses were carried out using a 1100 series HPLC equipped with an autosampler coupled online with a LC–MSD SL quadrupole ion trap (Agilent Technologies, Milan, Italy). The liquid chromatography (LC) separation of all serotonin derivatives was carried out using a Discovery-C_8 column (Supelco, Milan, Italy), 250 × 3.0 mm inner diameter, 5 μm, with a 5 mm × 3 mm inner diameter guard column of the same material, eluted isocratically with 0.1% formic acid in water, at a constant flow rate of 0.1 mL/min. The injection volumes were 10–20 μL for each sample. Electrospray ionization (ESI) was performed in positive-ion mode, with nitrogen as the nebulizing and drying gas under the following conditions: nebulizer pressure, 30 psi; drying temperature, 350 °C; and drying gas, 7 L/min. The ion charge control (ICC) was applied with the target set a 30 000 and maximum accumulation time at 20 ms. Multiple reaction monitoring (MRM) was used for the detection of analytes in HPLC–ESI–MS/MS analyses. The retention times and peak areas of the monitored fragment ions were determined by Agilent Chemstation version 4.2 software. The chemical structures and the transitions used for monitoring in MRM mode the serotonin derivatives analyzed in this study by LC–ESI–MS/MS are reported in Figure 1.

RESULTS AND DISCUSSION

Identification and Characterization of the Glycosylated Forms of Serotonin and Its N-Methylated Derivatives. Our recent findings of the occurrence of serotonin (**5**) and all its N-methylated derivatives[12,13] in several *Citrus* genus plants prompted us to investigate the possibility that those compounds might also be stored in glycosyl derivative forms in the plant tissues. To this aim, we first subjected leaf extracts of various *Citrus* plants to HPLC–ESI tandem mass analysis. A representative HPLC–ESI–MS^2 chromatogram of a bergamot leaf extract is shown in Figure 2. The chromatogram was obtained by isolating the ion masses at m/z 339.2, 353.2, 367.2, and 381.2, which coincide with those of the protonated masses of glycosylated serotonin (**1**), *N*-methylserotonin (**2**), *N*,*N*-dimethylserotonin (**3**), and *N*,*N*,*N*-trimethylserotonin (**4**), respectively (Figure 2). In the same chromatographic analysis, the ion masses at m/z 177.1, 191.1, 205.1, and 219.1, which correspond to those of the protonated aglycones, were also monitored (Figure 2). The identity of the putative glycosides was first assessed by their MS^2 fragmentation patterns and, in successive analyses, by MS^3 fragmentation patterns of selected ions occurring in the MS^2 fragmentation patterns. Figures 3–6 report the fragmentation patterns of the four peaks of Figure 2 eluted at the retention times of 27.4, 33.2, 40.4, and 45.6 min, which correspond to the four putative glycosides. In the same chromatogram, serotonin (**5**), *N*-methylserotonin (**6**), *N*,*N*-dimethylserotonin (**7**), and *N*,*N*,*N*-trimethylserotonin (**8**) are seen to elute at retention

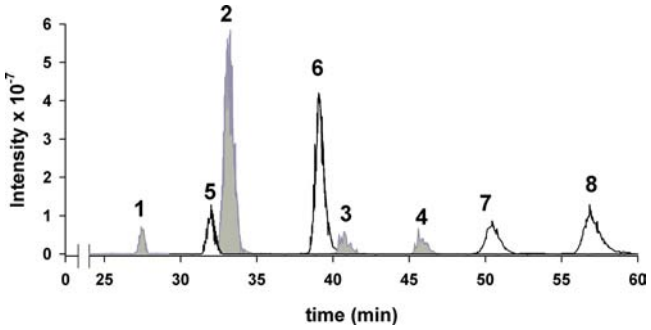

Figure 2. Representative MS^2 extracted ion chromatogram, in MRM mode, of a lemon leaf extract. Peaks in gray correspond to the glucosylated forms, and those in white correspond to the aglycones. The MS^2 transitions followed were 339.2 → 322 for serotonin 5-*O*-glucoside (**1**), 353.2 → 322 for *N*-methylserotonin 5-*O*-glucoside (**2**), 367.2 → 322 for *N*,*N*-dimethylserotonin 5-*O*-glucoside (**3**), 381.2 → 322 for *N*,*N*,*N*-trimethylserotonin 5-*O*-glucoside (**4**), 177.1 → 160 for serotonin (**5**), 191.1 → 160 for *N*-methylserotonin (**6**), 205.1 → 160 for *N*,*N*-dimethylserotonin (**7**), and 219.1 → 160 for *N*,*N*,*N*-trimethylserotonin (**8**). Retention times in minutes were 27.4 (**1**), 32.0 (**5**), 33.2 (**2**), 39.0 (**6**), 40.4 (**3**), 45.6 (**4**), 50.1 (**7**), and 56.8 (**8**).

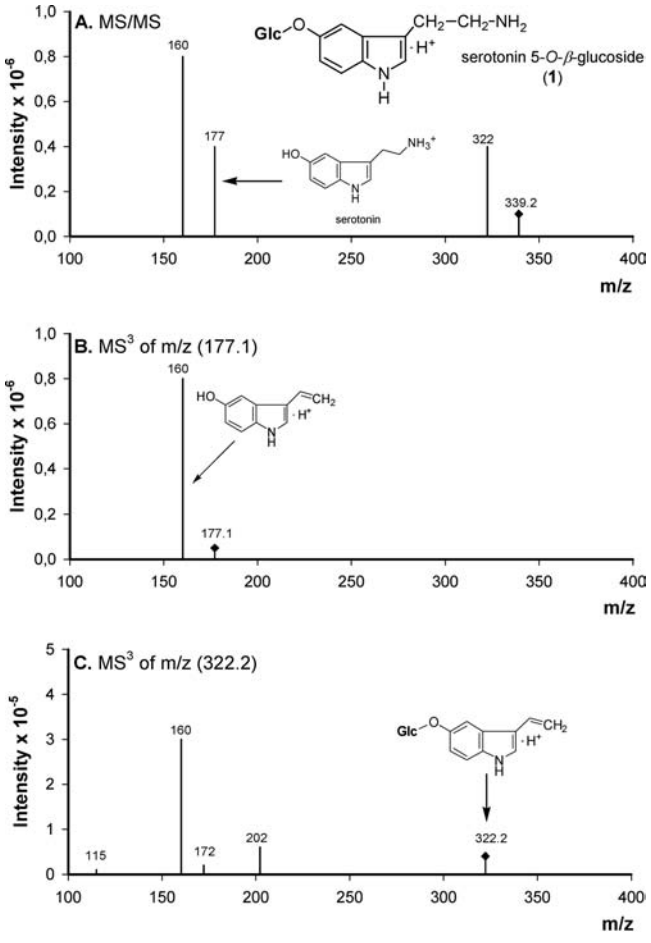

Figure 3. Mass spectra of serotonin 5-*O*-glucoside (**1**): (A) MS^2 fragmentation pattern, (B) MS^3 fragmentation pattern by isolating m/z 177.1, and (C) MS^3 fragmentation pattern by isolating m/z 322.2.

times of 32.0, 39.0, 50.1, and 56.8 min, respectively. The mass spectrometric behaviors of serotonin (**5**), *N*-methylserotonin (**6**), *N*,*N*-dimethylserotonin (**7**), and *N*,*N*,*N*-trimethylserotonin (**8**) were well-characterized by ESI–MS^n.[13,19,20] In particular,

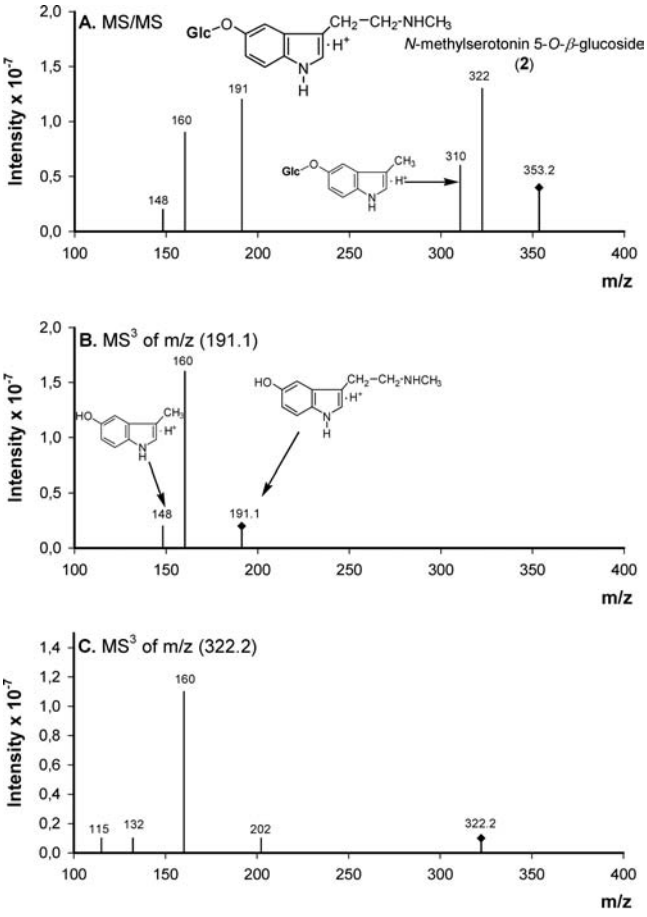

Figure 4. Mass spectra of *N*-methylserotonin 5-*O*-glucoside (**2**): (A) MS^2 fragmentation pattern, (B) MS^3 fragmentation pattern by isolating *m/z* 191.1, and (C) MS^3 fragmentation pattern by isolating *m/z* 322.2.

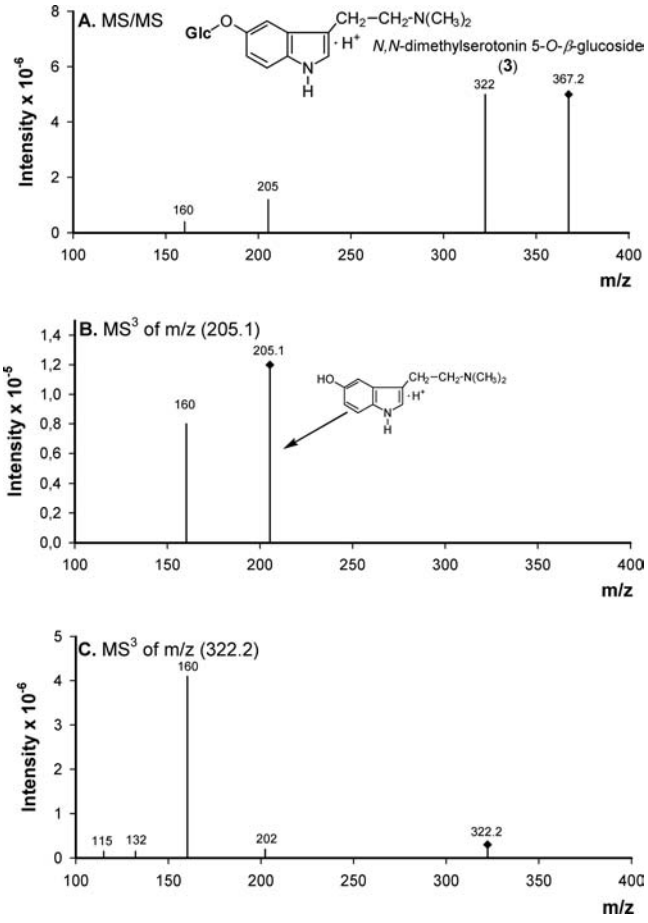

Figure 5. Mass spectra of *N*,*N*-dimethylserotonin 5-*O*-glucoside (**3**): (A) MS^2 fragmentation pattern, (B) MS^3 fragmentation pattern by isolating *m/z* 205.1, and (C) MS^3 fragmentation pattern by isolating *m/z* 322.2.

the MS^2 fragmentation patterns are in each case dominated by the ions at *m/z* 160, corresponding to protonated hydroxyvinylindole, which derives from the neutral loss of NH_3 for serotonin (**5**), CH_3NH_2 for *N*-methylserotonin (**6**), $(CH_3)_2NH$ for *N*,*N*-dimethylserotonin (**7**), and $(CH_3)_3N$ for *N*,*N*,*N*-dimethylserotonin (**8**).

As far as we know, the mass spectrometric features of the four glycosides of serotonin and its N-methylated derivatives have never been reported elsewhere, and therefore, it is of interest to address this issue. The MS^2 fragmentation pattern of all four peaks corresponding to the putative glycosides show an abundant fragment at *m/z* 322, which very likely derives from the neutral loss of NH_3, CH_3NH_2, $(CH_3)_2NH$, and $(CH_3)_3N$ from the ions at *m/z* 339.2, 353.2, 367.2, and 381.2, respectively, as it happens for aglycones. Furthermore, all four peaks in their MS^2 fragmentation pattern show ions at *m/z* corresponding to those of the protonated aglycone (that is *m/z* 177.1, 191.1, 205.1, and 219.1), which derive from the neutral loss of the glycosyl moiety from the parent ions to give the fragments at *m/z* $[M + H^+ - 162]$, specific for the loss of the precursor ion of a hexose residue (Figures 3A−6A).[21] Furthermore, the identical structure of the MS^2 fragments at *m/z* 322 deriving from each of four peaks is demonstrated by the identical MS^3 fragmentation patterns, in which, in all cases, the most abundant MS^3 fragment is that at *m/z* 160, likely corresponding to the protonated hydroxyvinylindole (Figures 3C−6C). Interestingly, when the ions at the *m/z* corresponding to each of the protonated aglycones are isolated from the MS^2 fragmentation pattern of each of the four glycoside peaks and fragmented, the most abundant MS^3 fragment is found at *m/z* 160 (Figures 3B−6B).

Glycosylated *N*-methylserotonin (**2**) deserves a separate discussion because it behaves quite differently from the other homologues, useful for its identification. In fact, the MS^2 fragmentation pattern of the peak at *m/z* 353, besides the expected fragments at *m/z* 322, 191, and 160, shows two unexpected fragments at *m/z* 310 and 148. The former is produced by the neutral loss of 43 Da ($CH_2{=}N{-}CH_3$) from the protonated parent molecule at *m/z* 353, and the latter is produced by the same neutral loss of 43 Da ($CH_2{=}N{-}CH_3$) from the fragment *m/z* 191 (protonated aglycone), as demonstrated by the MS^3 fragmentation pattern obtained by isolating the MS^2 fragment at *m/z* 191 (Figure 3B). On the other hand, the MS^2 fragmentation pattern of authentic *N*-methylserotonin (**6**) shows an identical fragmentation pattern.[13,19] All together, these results give strong evidence of the identity of the aglycone moieties.

An indication of the nature of the glycoside moiety in the compounds under study was obtained by subjecting *Citrus* leaf extracts to enzymatic hydrolysis by β-glucosidase from almonds, an enzyme specific for β-D-glucosides. The time course of the hydrolysis performed on a lemon leaf extract

DOI: 10.1021/acs.jafc.5b01031
J. Agric. Food Chem. 2015, 63, 4220−4227

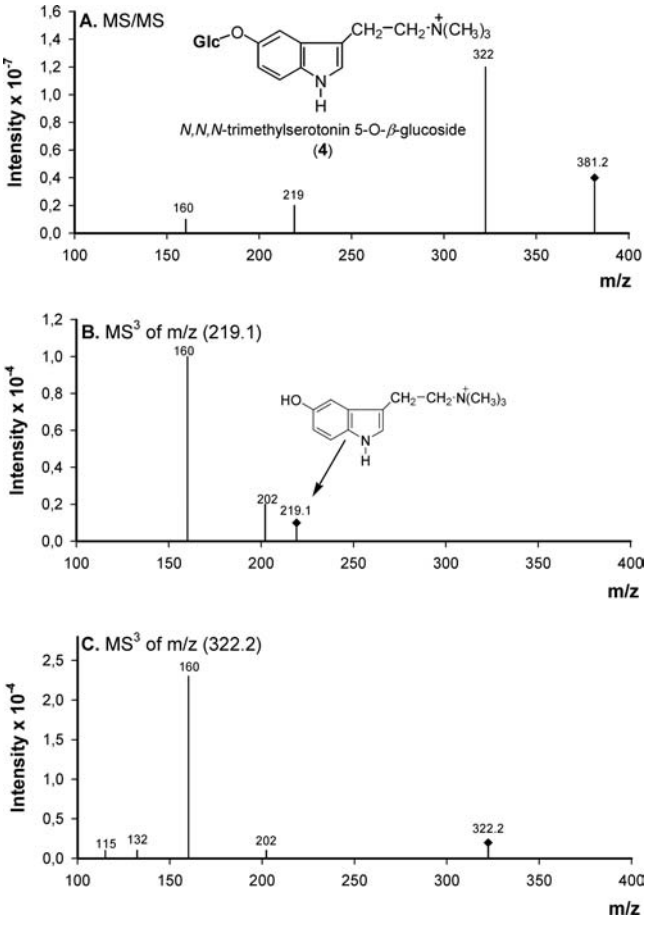

Figure 6. Mass spectra of *N,N,N*-trimethylserotonin 5-*O*-glucoside (**4**): (A) MS^2 fragmentation pattern, (B) MS^3 fragmentation pattern by isolating *m/z* 219.1, and (C) MS^3 fragmentation pattern by isolating *m/z* 322.2.

(Figure 7) clearly indicates the increase with time of the aglycone peaks and the decrease of those of the glycosides, thus showing that those compounds are substrates for the enzyme. Interestingly, the variations appear reduced when the N-methylation degree of the compound increases. As matter of fact, the putative 5-*O*-*β*-glucoside of serotonin (**1**) is the compound most affected by the enzymatic hydrolysis, while the

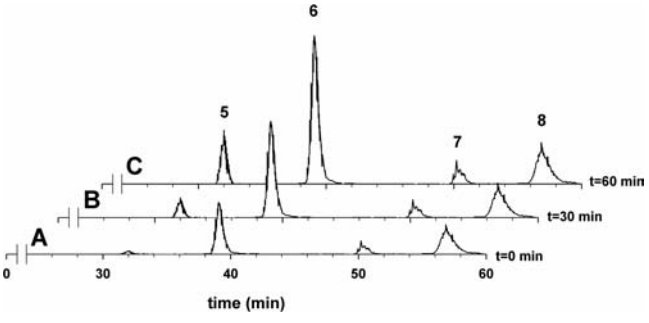

Figure 7. Time course of hydrolysis catalyzed by *β*-glucosidase from almonds of a lemon leaf extract: (A) 0 min, (B) 30 min, and (C) 60 min of incubation. The MS^2 extracted ion chromatograms in MRM mode show the production over time of serotonin (**5**), *N*-methylserotonin (**6**), *N,N*-dimethylserotonin (**7**), and *N,N,N*-trimethylserotonin (**8**). The *m/z* of the parent and extracted ions is the same as in the legend of Figure 3.

putative 5-*O*-*β*-glucoside of *N,N,N*-trimethylserotonin (**4**) appears almost unmodified after the same incubation time (Figure 7). Similar experiments were also conducted by performing the enzymatic hydrolysis with *β*-galactosidase from *A. oryzae*, but in this case, much slighter modifications were observed than those produced when using *β*-glucosidase (data not shown). Taken together, these experiments gave strong indications that the glycosidic moiety of the unknown compounds is represented by D-glucose. Conclusive evidence of the structures of at least two of the four substances under study comes from the comparison to the authentic 5-*O*-*β*-glucosides of *N*-methylserotonin (**2**) and *N,N*-dimethylserotonin (**3**). Actually, these two compounds were discovered in seeds of the plant *Z. piperitum* (Japanese pepper), and their structures were elucidated by nuclear magnetic resonance (NMR) studies.[22] We prepared extracts from seeds of this plant and compared their HPLC–ESI–MS^2 chromatograms to those of extracts from *Citrus* plant leaves. A complete superimposition of the two peaks from *Citrus* plants corresponding to the putative 5-*O*-*β*-glucosides of *N*-methylserotonin (**2**) and *N,N*-dimethylserotonin (**3**) was observed by comparison to those of the authentic substances present in the chromatogram of the *Z. piperitum* seed extracts. Moreover, the corresponding peaks showed identical MS^2 fragmentation patterns (data not shown).

Distribution of the Glucosylated Serotonin Derivatives in *Citrus* Plant Leaves. The distribution of the glucosylated forms of serotonin and its N-methylated derivatives in *Citrus* plant leaves indicates expression levels of the substances quite different among the species (Figure 8). The analysis of the distribution made it possible to divide the various species into three groups. The first group, represented by lemon, pomelo, and bergamot, expresses the highest levels of these compounds. The second group, represented by bitter orange, chinotto, and sweet orange, expresses levels of the four glucosides about one-half of the first group. Finally, the third group, represented by citron, mandarin, and clementine, shows very low expression levels of these metabolites, below 5% of those expressed by the richest species. The analysis of the levels of the four glucosides in the various *Citrus* species, reported relatively to the top species (first group), indicates that *N*-methylserotonin 5-*O*-*β*-glucoside (**2**) is the most expressed glucosylated form, followed by serotonin 5-*O*-*β*-glucoside (**1**), then *N,N*-dimethylserotonin 5-*O*-*β*-glucoside (**3**), and finally, *N,N,N*-trimethylserotonin 5-*O*-*β*-glucoside (**4**), which appears almost unexpressed in the third group (Figure 8).

Distribution of the Aglycones and Glucosylated Serotonin Derivatives in Bergamot and Bitter Orange Fruits. The distributions of glucosylated forms of serotonin derivatives and those of the corresponding aglycones were also estimated in the two *Citrus* plant species, bitter orange and bergamot, in various parts, that is, flavedo, albedo, juice, and seeds. The results showed that the aglycones are expressed at the highest levels in the seeds of both species (Table 1). *N*-Methylserotonin (**6**) and *N,N*-dimethylserotonin (**7**) resulted from being the more represented aglycones, with average values of 14 and 18 mg/kg, in bitter orange and bergamot seeds, respectively. In contrast, the level in seeds of *N,N,N*-trimethylserotonin (**8**) was about 4 mg/kg and even lower than that of serotonin (≤2 mg/kg). As for the glucoside fraction, it was distributed for both species in an almost uniform manner in flavedo (epicarp), albedo (the spongy white part under the epicarp), and fruit juice (Table 1). These results are similar to those found for other *Citrus* secondary metabolites,

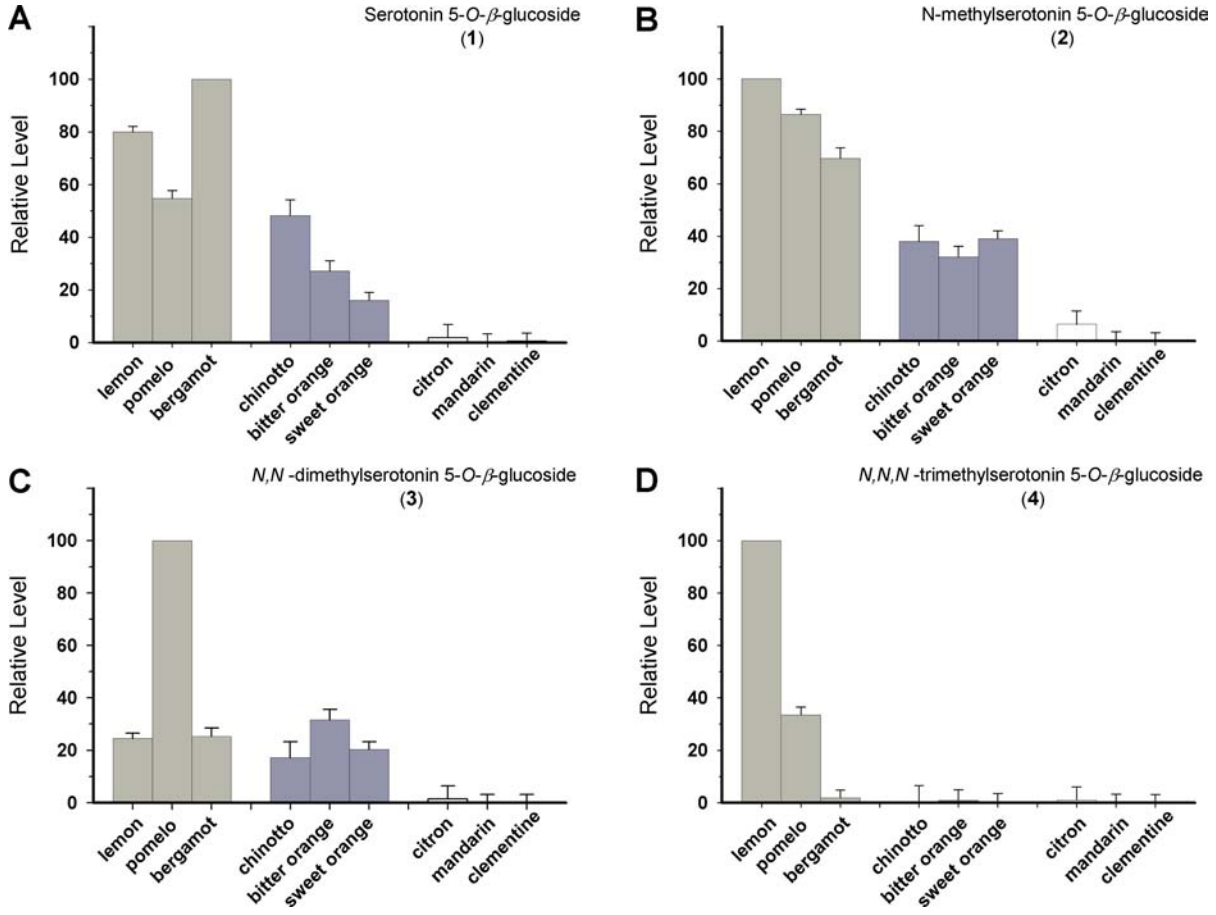

Figure 8. Relative levels in leaves of various *Citrus* species of serotonin 5-*O*-*β*-glucoside and its N-methylated forms: (A) serotonin 5-*O*-*β*-glucoside, (B) *N*-methylserotonin 5-*O*-*β*-glucoside, (C) *N*,*N*-dimethylserotonin 5-*O*-*β*-glucoside, and (D) *N*,*N*,*N*-trimethylserotonin 5-*O*-*β*-glucoside. The graphs are normalized to 100%, representing the level of the top productive species. The level of each compound is the average of three determinations. Bars represent the standard deviations.

Table 1. Percentage Distribution of Aglycones and Glucosylated Serotonin Derivatives in Tissue Parts of Bergamot and Bitter Orange Fruits

Citrus species	tissue	aglycones (%)	glucosides (%)
bergamot	flavedo	21	79
	albedo	30	70
	juice	13	87
	seeds	64	26
bitter orange	flavedo	13	87
	albedo	10	90
	juice	22	78
	seeds	66	34

such as flavanone and limonoids,[23−26] which play a key role in chemical defense and interaction with the environment.

Interrelationship of the Tryptamine Derivatives in *Citrus* Genus. In the genus *Citrus*, tryptamine is the biosynthetic precursor of a broad group of indole metabolites generated from biosynthetic steps of methylation and hydroxylation.[12,13] The results shown here indicate that an additional transformation of indole metabolites can occur through the biosynthetic step of glycosylation. The possible pathways that take into account these three steps, i.e., methylation, hydroxylation, and glycosylation, might involve a sequence of reactions starting with the formation of tryptamine from tryptophan, catalyzed by the enzyme tryptophan decarboxylase (Figure 9). Indeed, the absence of 5-hydroxytryptophan in the *Citrus* plants excludes that 5-hydroxytryptamine (serotonin) can be derived from decarboxylation of this amino acid. Once produced, tryptamine may be N-methylated by the action of the same or different methyltransferase(s) acting in a consecutive manner (Figure 9). Then, each methylated intermediate could be transformed in the corresponding hydroxylated form, or alternatively, tryptamine could be first hydroxylated to serotonin, which is successively N-methylated in a consecutive manner (Figure 9). Finally, in the last step, the transfer of the sugar residue occurs from the donor molecule, likely UDP-glucose, which is the most commonly used nucleotide sugar in plants,[27] to the acceptor molecule (Figure 9). In our case, the acceptor molecules are serotonin and its N-methylated derivatives. Alternatively, serotonin 5-*O*-*β*-glucoside (**1**) could also be N-methylated in a consecutive manner to produce forms at higher methylation degree. Of course, more in depth studies are required to support such hypothetical pathways.

The occurrence of the glucosylated serotonin derivatives in *Citrus* plants suggests a physiological role for these metabolites because it is well-known that glycosylation, by making many compounds less reactive and more water-soluble, represents a way adopted by plants to prevent cell damage and safely store toxic compounds important for their defense. When a plant is attacked, the toxic aglycones are released from the glycosylated compounds by action of glycosidases, which can occur in either

DOI: 10.1021/acs.jafc.5b01031
J. Agric. Food Chem. 2015, 63, 4220−4227

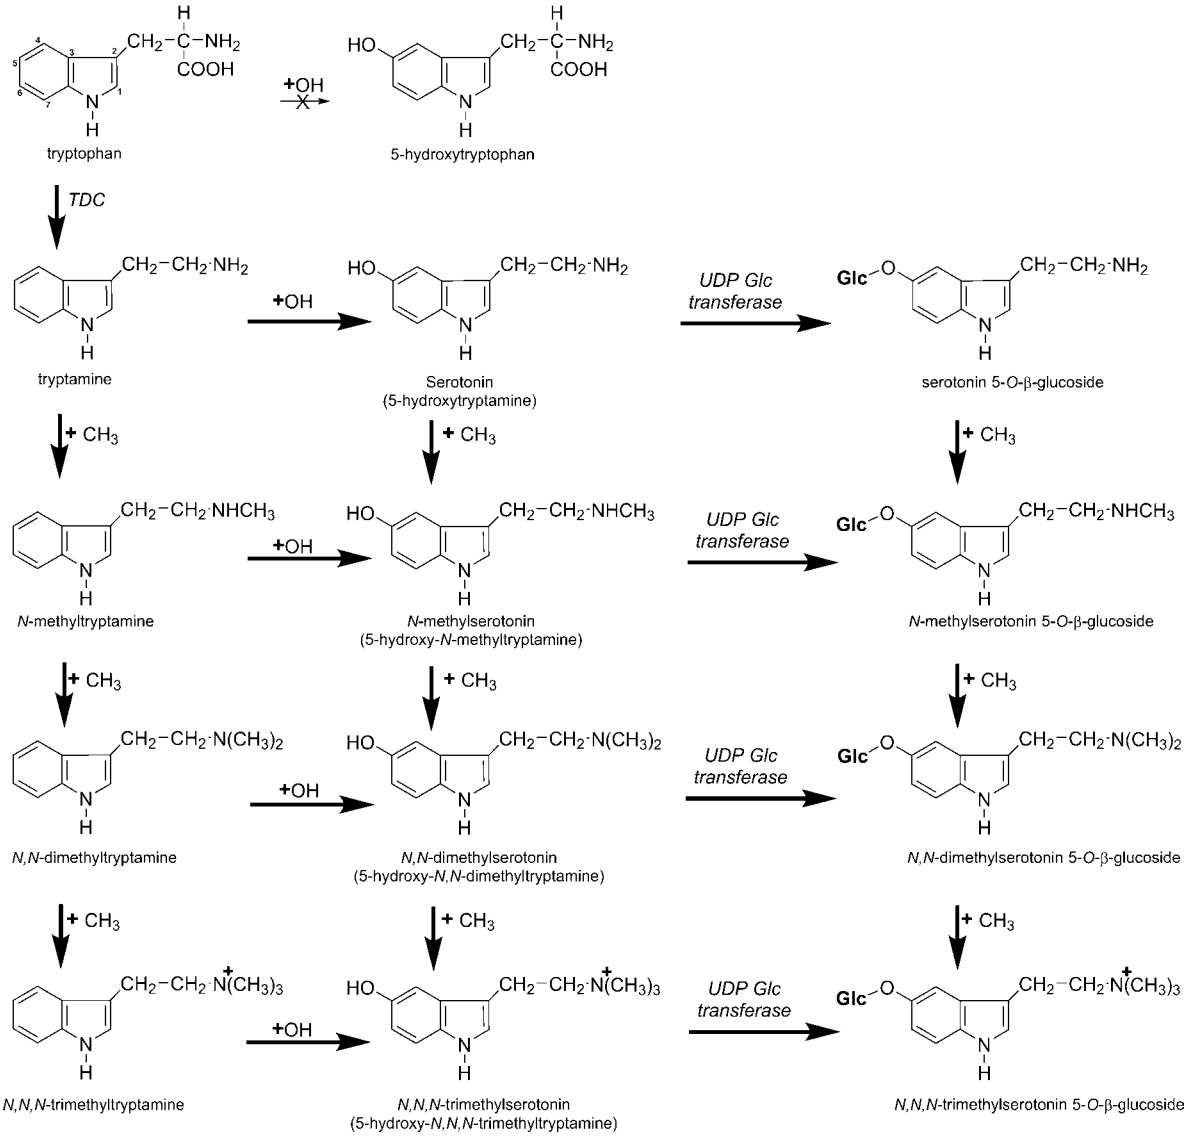

Figure 9. Hypothesized pathways for the biosynthesis of the tryptamine derivatives.

the plant or also aggressor tissues. In some cases, aglycone is also able to influence the behavior and physiology of insects and herbivores.[28,29] The distribution of the aglycone and glycosylated forms of serotonin derivatives found in various parts of the two *Citrus* species examined is consistent with the hypothesized defensive role (Table 1). In fact, in both bergamot and bitter orange, the aglycones are expressed mainly in the seeds, whose protection is crucial for plant diffusion. Conversely, the glycosylated derivatives are predominant in epicarp, albedo, and juice (Table 1). The distribution of glycosylated and aglycone forms of serotonin derivatives resembles that of other *Citrus* metabolites involved in defense and resistance mechanisms,[23−26] such as limonoids and flavanones, which act as powerful natural pesticides[30,31] and antifungal agents.[23,26] In fact, also for these compounds, the active forms are the aglycones, and their highest concentration is found in seeds.[23−25]

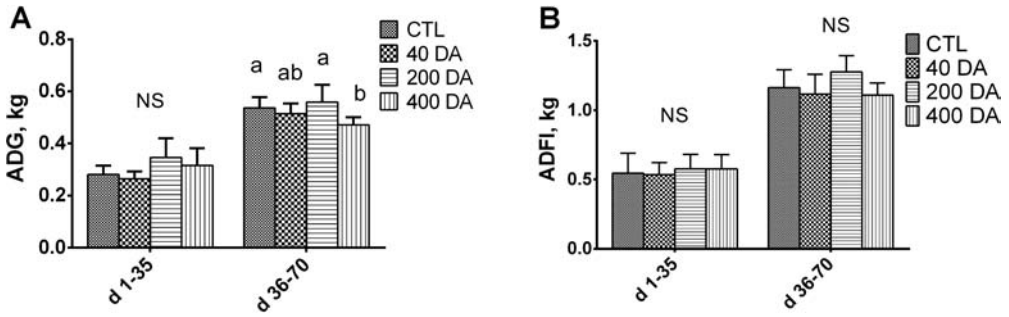

Figure 1. Effects of increasing concentrations of daidzein on performance of pigs in phase 1 (days 1−35) and 2 (days 36−70). (A) Average daily weight gain (ADG) of repeated dose daidzein-treated piglets with an initial average BW of 6.4 kg. (B) Average daily feed intake (ADFI) of repeated dose daidzein-treated piglets. Each bar represents the mean ± SD of six experimental units (pens). CTL, control group fed a basal diet. 40/200/400 DA, 40/200/400 mg/kg daidzein supplemented to CTL. *Significantly different from control at $P < 0.05$. NS, not significant ($P > 0.05$).

units/mL of glucuronidase activity and 775 units/mL of sulfatase activity) were obtained from Sigma-Aldrich Co. (St. Louis, Mo., USA). All other reagents used for residue measurement were of HPLC-grade. Deionized water was used throughout.

Experimental Design and Animal Management. Ninety-six crossbred [(Large White × Landrace) × Duroc] weaned pigs (23 ± 2 days postfarrowing; 48 males and 48 females) were sorted by body weight (BW) and sex and randomly allotted to dietary treatment in a 70 day experiment [phase 1 (days 1−35), 4 treatments; 6 replicates (pens) per treatment; 4 pigs per pen; phase 2 (days 36−70), 4 treatments; 6 replicates (pens) per treatment; 3 pigs per pen]. Average initial BW was 6.4 ± 0.1 kg. Diets were arranged as follows: (1) The NRC (1998) standard commercial feed without any soy source was used as the control group (CTL), (2) CTL + 40 mg/kg of daidzein (the manufacturer's recommended dose in young pigs), (3) CTL + 200 mg/kg of daidzein, and (4) CTL + 400 mg/kg of daidzein. Feed intake and BW measurements were obtained at the beginning of the experiment and weekly thereafter for the duration to determine average daily weight gain (ADG) and average daily feed intake (ADFI).

All pigs were housed in a temperature-controlled room with continuous lighting. Each pen contained a single nipple waterer and a single self-feeder to facilitate ad libitum access to water and feed.

Sample Collection. One pig was randomly selected from each pen to obtain blood samples collected from jugular veins on day 35 and day 70 before weighing (14 h after feeding); 10 mL of blood was collected into EDTA-coated pediatric Microvette tubes (Sarstedt AG and Co., Numbrecht, Germany) for hematological analysis. Another 10 mL of blood from each pig was centrifuged at 3000*g* for 15 min to obtain serum, which was stored at −20 °C until needed for the determination of blood markers and hormonal levels. Then the selected pigs were slaughtered by a lethal injection of sodium pentobarbital to obtain samples of small intestinal segment, mesenteric lymph, muscle, and organs (liver, heart, kidney, and spleen). The middle sections (4 cm) of duodenum, jejunum, and ileum were isolated and kept in 10% formalin for microscopic assessment of mucosal morphology. About 5 cm^3 of a regular shape sample from each organ was kept in the same way for morphological assessment. About 10 g of semitendinosus and liver samples was collected from each pig and kept at −20 °C for residue analysis of isoflavones.

Hormone Levels and Blood Parameters. Serum estradiol (E2), testosterone (T), growth hormone (GH), type-1 insulin-like growth factor (IGF-1), triiodothyronine (T3), and tetraiodothyronine (T4) were assayed using commercially available swine ELISA kits (BioSource International Inc., Camarillo, CA). The minimum detectable levels were 0.8 μg/L for GH, 10 μg/L for IGF-1, 1.8 pmol/L for estradiol, 20 ng/L for testosterone, 3 ng/mL for T3, and 10 ng/mL for T4. Heparinized whole blood was assayed for white blood cell count, red blood cell count, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, hemoglobin concentration, and platelet count on an automated hematology analyzer (Sysmex XT 1800, Roche Diagnostics). Serum was assayed for the total protein, albumin, globulin, total bilirubin, alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, urea nitrogen, and glucose by an automatic biochemical analyzer (Hitachi 7180, Japan). Antioxidant indices, including glutathione peroxidase (GSH-PX), superoxide dismutase (SOD), malondialdehyde (MDA), and total antioxygenic capability (T-AOC), were determined with commercially available reagent kits (Nanjing Jiancheng Bioengineering Institute, China). All measurements were done in duplicate at minimum.

Intestinal Morphology and Organ/Tissue Histopathology. Organ (liver, heart, spleen, and kidney) samples, mesenteric lymph samples, and intestinal segments were embedded in paraffin wax. Cross sections (6 μm thick) of each sample were stained with hematoxylin and eosin. A biological microscope with a built-in digital camera was used (DM BA300, Motic, China). Organ and mesenteric lymph segments were observed at 100× to 400× magnifications to determine the morphological structures. The villus height and crypt depth of the intestinal segments were determined at 40× magnification to measure the lengths of 10 well-oriented intact villi and their associated crypt according to the methods of Touchette et al.[19] The villus height-to-crypt depth ratio (VCR) was calculated.

All sections were reviewed and graded in a blinded manner by a well-experienced vet from the pathology laboratory for histopathological analysis. For intestine, liver, kidney, heart, spleen, and lymphoglandulae mesentericae, qualitative scorings with respective scores and grading standards (see Table S1 in the Supporting Information for details) were used to evaluate the health status of the pigs. The highest score of the pathological change observed would be the score of the section. For example, if in a field a pathological change score of 1 and another score of 2 were observed at the same time, the score of this section is 2. The average value of the scores of all the sections in one group would be the viscera damage indices of the treatment, ranging from 0 to 3.

Distribution of Isoflavones in Body Tissues. Tissues from pigs (liver and semitendinosus muscle) were thawed at room temperature. Tissues (3−5 g depending on the type and amount of sample available) weighed with an electronic analytical balance (Hengping FA2004, Shanghai, China) with an accuracy of 1/10 000 g were diluted with 10 mL of ammonium acetate buffer solution (pH 5.0), homogenized with a Polytron System PET 2100 (Kinematica AG, Lucerne, Switzerland), and combined with 80 μL of hydrolytic enzyme (β-glucuronidase from *Helix pomatia*). The sample mixture solution was incubated at 37 °C for 8 h in a forma orbital shaker (Shanzhi TS-1102C, Shanghai, China). Then 10 mL of acetonitrile (Merck, Germany) and 10 mL of ethyl acetate (Merck, Germany) were added in sequence. After being sufficiently mixed with a vortex shaker (V-5, qilinbeier, Haimen, China), the samples were centrifuged at 10 000*g* for 10 min at 4 °C. All of the supernatant was transferred to clean Erlenmeyer flasks. The remaining isoflavones in the precipitate were extracted two more times with 20 mL of ethyl acetate each time to the same Erlenmeyer flasks. The extracts were concentrated to dry in a rotary evaporator at a negative pressure and then dissolved with 3 mL

of 50% (v/v) methanol in deionized water. The solutions were centrifuged at 10 000*g* for 10 min at 4 °C and subsequently filtered through a 0.22 μm nylon membrane prior for analysis by UPLC/MS with the chromatographic conditions as follows: chromatographic column, thermoelectric C18.24 μm 2.4 × 50 mm (thermo); mobile phase, (A) water, (B) acetonitrile + methanol = 1 + 1; column temperature = 35 °C; sample size = 5 μL, using an electrospray ion source, negative ion mode (ESI−), and multiple reaction monitoring (MRM) mode. The synthetic standards (glycitein, genistein, daidzein, equol) were obtained from Sigma-Aldrich. Three linear calibration curves (low, medium, and high) with a minimum of four concentrations per curve were prepared according to the procedure of Gilani et al.[18] for glycitein, genistein, daidzein, and equol, and only calibration curves with high linearity from all analytes ($R^2 > 0.998$) in the expected calibration range were used.

Statistics. Data were compared between all of the four groups by subjecting them to ANOVA for a randomized complete block design by using the GLM procedure (SAS Inst. Inc., Cary, NC). Statistical differences among treatments were separated by Duncan's multiple range tests. Results were expressed as mean ± standard deviation

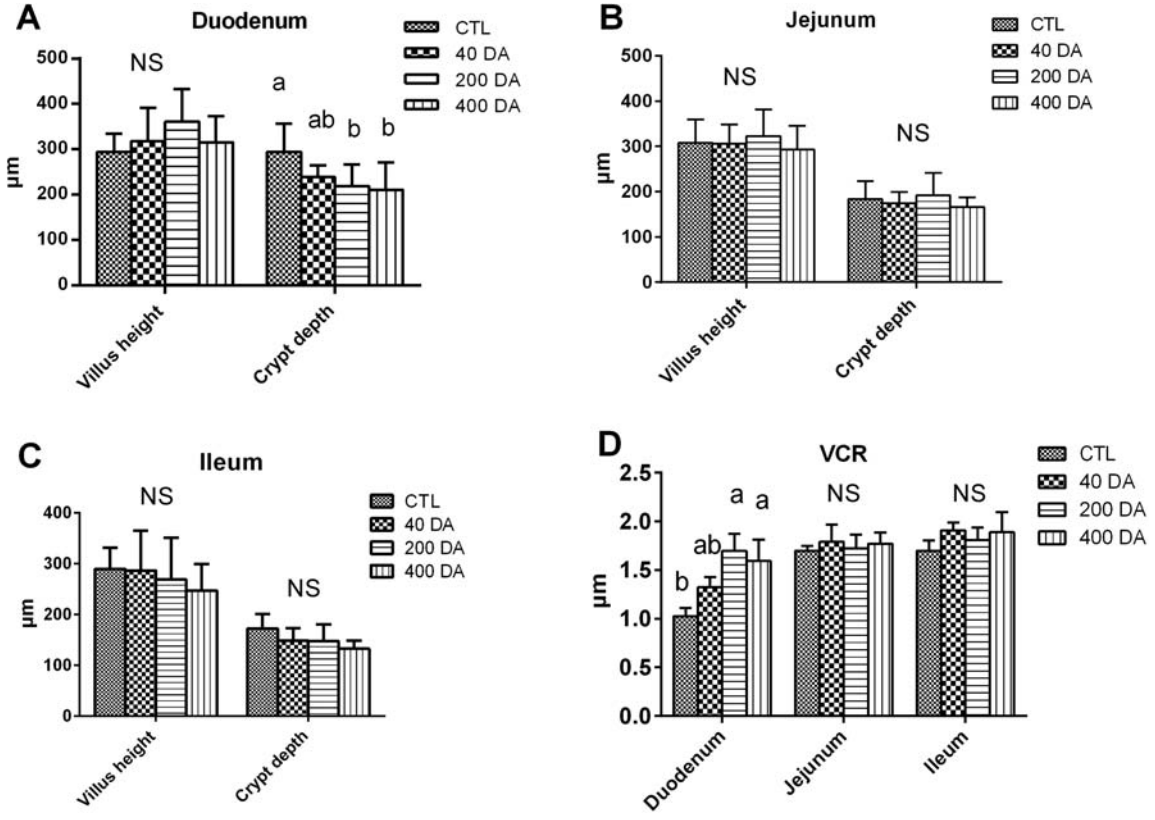

Figure 2. Intestinal morphology of repeated dose daidzein-treated piglets. (A–C) Villus height and crypt depth of duodenum, jejunum, and ileum, respectively on day 35. (D) Villus height-to-crypt depth ratio (VCR) of duodenum, jejunum, and ileum. Each bar represents the mean ± SD of six experimental units (pens) ($n = 6$). CTL, control group fed a basal diet. 40/200/400 DA, 40/200/400 mg/kg daidzein supplemented to CTL. Bars with different letters are significantly ($P < 0.05$) different from each other. NS, not significant ($P > 0.05$).

(SD). Probability values less than 0.05 were used as the criterion for statistical significance. The pen served as the experimental unit in the analyses.

RESULTS

Weight Gain and Feed Intake. In phase 1, there was no significant difference in average daily gain between the four groups. However, pigs fed 200 mg/kg of daidzein tended to have a greater ADG ($P = 0.082$) compared with those in CTL. In phase 2, ADG of pigs was decreased ($P = 0.03$) by 400 mg/kg of daidzein supplementation when compared with CTL. No differences were found in feed consumption (ADFI) throughout the whole experimental period (Figure 1). No gender differences were found in ADG or ADFI.

Hormone Levels and Blood Parameters. There were no effects ($P > 0.05$) of daidzein treatments on the content of triiodothyronine, tetraiodothyronine, IGF-1, GH, or estradiol in the serum of pigs in both phase 1 and phase 2 (Table 1). However, gilts receiving 200 and 400 mg/kg daidzein had a reduced ($P = 0.02$, phase 1; $P = 0.004$, phase 2) serum testosterone level compared with pigs in CTL.

Hematology analysis revealed that HCT, MCV, and MCH in pigs was significantly increased at the dose of 400 mg/kg of daidzein ($P < 0.05$), while other hematological parameters were not changed after 35 days of treatment (Table 2). It is shown that 200 mg/kg of daidzein supplementation also increased HCT ($P < 0.05$) of pigs compared with CTL. Beyond that, no significant differences in other tested hematological parameters were noted after a 35 day treatment. There was no significant differences between all the parameters in phase 2. We also investigated the effects of daidzein on some serum biochemical indices; however, there was no significant differences (data now shown). Gender differences were not found in any of the blood parameters.

Pigs receiving 200 mg/kg daidzein had greater ($P < 0.05$) SOD activity and lower ($P < 0.05$) MDA content in serum

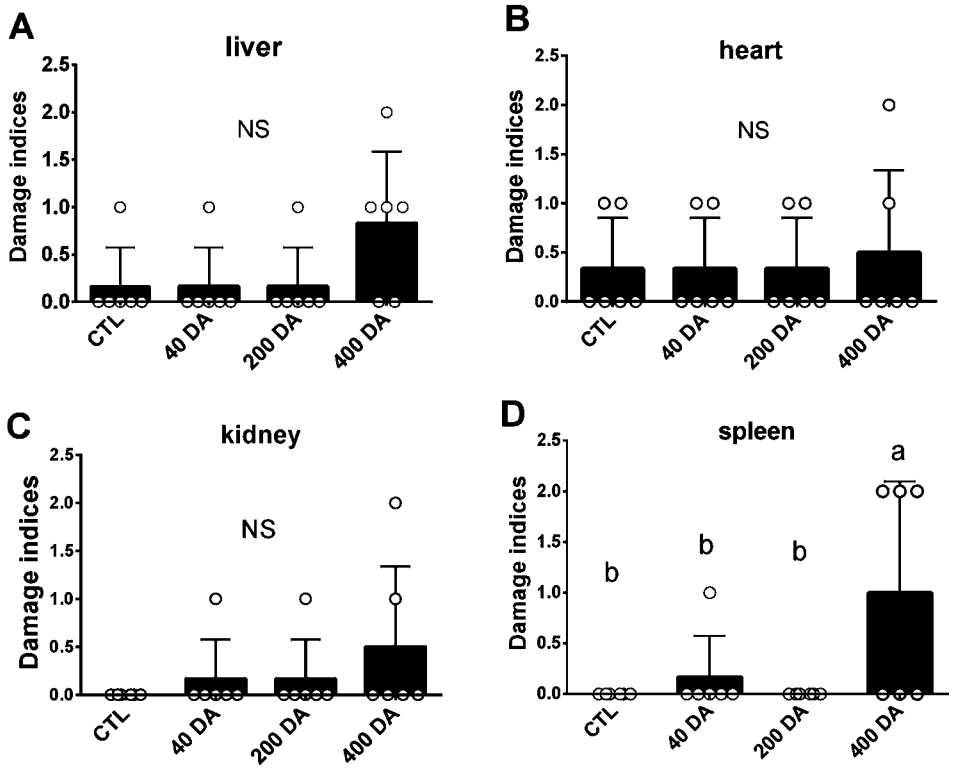

Figure 3. Organ damage indices of repeated dose daidzein-treated pigs on day 70. (A–D) Damage degree of liver, heart, kidney, and spleen of pigs in the four treatments, respectively. The damage indices ranges from 0 to 3 [0, completely healthy; 1, mild injury; 2, moderate injury; 3, severe injury (not shown in the graphs)]. Each dot represents the organ damage score of an individual pig (n = 6). Data are also expressed as mean ± SD. CTL, control group fed a basal diet. 40/200/400 DA, 40/200/400 mg/kg daidzein supplemented to CTL. Bars with different letters are significantly (P < 0.05) different from each other. NS, not significant (P > 0.05).

compared with CTL in phase 1 (Table 3). However, T-AOC and GSH-PX were not affected by treatments. There were no significant differences between treatments on antioxidant activities in phase 2 (data not shown). Besides, there were no gender differences found in the antioxidant indices tested.

Intestinal Morphology and Organ/Tissue Histopathology. Histological evaluation showed no effect of dietary supplementation of daidzein on villus height of the small intestine. However, pigs fed 200 and 400 mg/kg of daidzein had smaller (P < 0.05) crypt depth and greater (P < 0.05) VCR in the duodenum compared with that in CTL on day 35 (Figure 2). However, intestinal morphology was not effected by daidzein in phase 2 (data not shown). No gender differences were observed in villus height, crypt depth, or VCR.

According to the histology score (organ damage index), there were few observable effects of 40 and 200 mg/kg of dietary daidzein supplementation on the morphology of all the organs and tissues examined in both phases 1 and 2. However, 400 mg/kg of daidzein supplementation could cause mild damage (P < 0.05) to the spleens of weanling pigs by day 70 (Figure 3) (this effect was not obvious on day 35; data not shown). Meanwhile, 400 mg/kg of daidzein had a trend to increase (P = 0.08) the histology score of livers at the end of phase 2. Histology score shows no evident gender differences.

Distribution of Isoflavones in Body Tissues. The results (Figure 4) indicate that the amount of daidzein deposited in the liver and muscle of pigs was not affected (P > 0.05) by dietary daidzein supplementation for 35 days. In view of the fact that trace amounts of the soy isoflavones were detected in the diet (data not shown), we also monitored levels of glycitein and genistein in animal tissues. On day 35, the contents of glycitein and genistein in the liver were decreased by ingesting daidzein. Genistein level in the muscle (semitendinosus) was also decreased by 400 mg/kg dietary daidzein supplementation compared with CTL. On the 70th day of this experiment, dietary daidzein supplementation improved the content of daidzein (P < 0.05) in the pigs' livers compared with that in the control group. Similar to the result on the 35th day, the content of glycitein in the liver was decreased by 200 or 400 mg/kg of dietary daidzein supplementation compared with CTL on day 70. In addition, the contents of equol tended to be enhanced in livers (P = 0.09) and muscles (P = 0.1) of pigs by dietary daidzein supplementation in phase 2. It was shown that there were greater distributions of isoflavones in liver than in muscle in both phase 1 and phase 2. Meanwhile, in any of the four groups, the level of daidzein in the liver on day 70 was higher (P < 0.01) than on day 35. No gender differences were found in tissue residues of isoflavones.

■ DISCUSSION

Previous studies show that 20 or 40 mg/kg of dietary daidzein has no effect on the growth of mice,[20] but that 1000 mg/kg significantly decreases the body weight of female rats.[17] This suggests that there is a dose effect in terms of growth, regardless of gender. As mentioned above, the structure and function of daidzein resembles that of steroid estrogens. In many animals, including pigs, low concentration of daidzein binds weakly to estrogen receptors. However, daidzein at higher levels may act as anti-estrogen by antagonizing the binding of potent natural estrogens to its receptors.[21,22] Studies show that estrogen

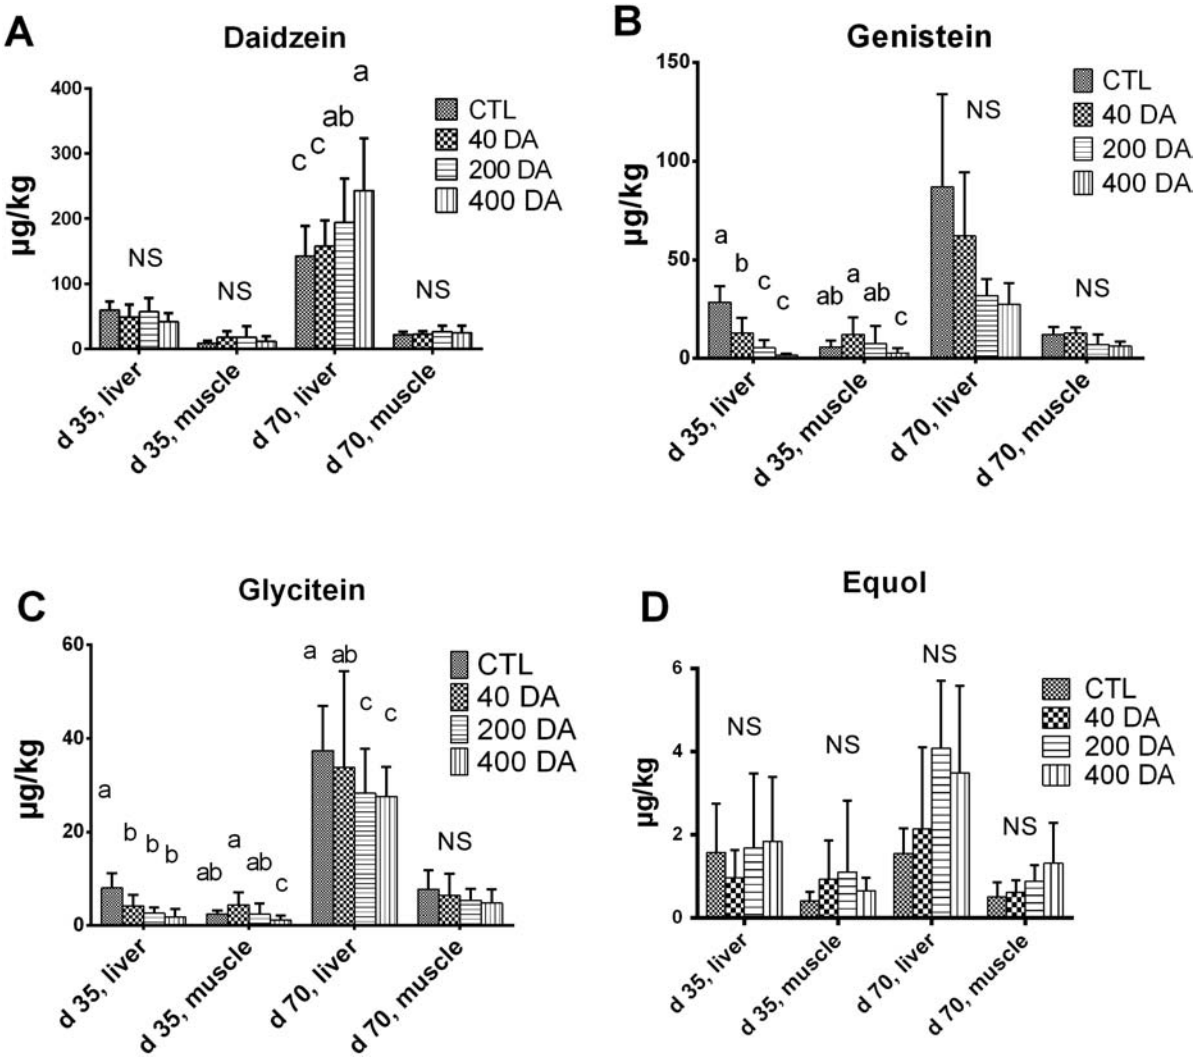

Figure 4. Concentrations of several isoflavones (μg/kg) in livers and muscles (semitendinosus) of repeated dose daidzein-treated pigs on day 35 and day 70. (A–D) Residual amount of daidzein, genistein, glycitein, and equol in tissues, respectively. Each bar represents the mean ± SD of six experimental units (pens) (n = 6). CTL, control group fed a basal diet. 40/200/400 DA, 40/200/400 mg/kg daidzein supplemented to CTL. Bars with different letters are significantly (P < 0.05) different from each other. NS, not significant (P > 0.05).

affects weight gain in human and murines.[23,24] Therefore, we speculate that the mechanism for daidzein's effects on pig growth relates to this feature. Further research is needed to elucidate the growth axis of daidzein/estrogen receptors.

Nevertheless, it is unclear whether other hormones related to growth are linked to daidzein's effects on regulating weight gain. Some studies show that daidzein promotes levels of growth-regulating hormones in breeding poultry (GH and tetraiodothyronine)[25,26] and intact male piglets (IGF-1).[27] Other research indicates the inhibitory effect of daidzein in vitro and in vivo.[14,28] Beyond these debates, our results show that daidzein is not effective enough to alter these hormones related to growth. This suggests that the function of daidzein in regulating growth is not through these hormones. Furthermore, studies show that endogenous estradiol is not affected by daidzein ingestion,[29] which accords with our results.

Other studies indicate that dietary genistein (20 mg/kg/day) decreases testosterone plasma levels of male rats, while the same doses of daidzein have no effect in this regard.[29] However, our results reveal the inhibitory effect of higher concentrations (200 and 400 mg/kg) of daidzein on the serum testosterone content for female pigs. This suggests that gender and dosage may be critical factors for daidzein in terms of regulating testosterone. This effect is also evident in porcine ovaries, suggesting that daidzein may disturb reproductive processes in pigs.[22] An in vitro study showed that daidzein increases StAR and 3β-HSD-1 mRNA levels, thereby increasing testosterone production in cultured mouse leydig cells in the presence of the chorionic gonadotropic hormone.[30] Alexa et al. reported that daidzein alone increases testosterone production in porcine ovarian cells, but that in the presence of follicle-stimulating hormone (FSH), daidzein prevents the FSH-stimulated release of testosterone.[31] In fact, the endocrine system is a complex regulatory system involving various interactions between hormones. Therefore, the mechanisms for the testosterone-reducing effect of daidzein in female piglets and how it plays a role in regulating steroid hormone metabolism in vivo warrant further study.

Numerous studies reveal daidzein's reactivity with active oxygen species. Therefore, it appears to have antioxidant potential via a radical-scavenging mechanism.[4,32] Our results indicate the efficacy of daidzein in piglets (day 35) in an oral

DOI: 10.1021/acs.jafc.5b00677
J. Agric. Food Chem. 2015, 63, 4228–4235

dose of 200 mg/kg, suggesting that the protective effects of daidzein against oxidation are more pronounced in piglets than growing pigs. A decrease in MDA suggests decreased lipid peroxidation, a process which is initiated by free radical reactions.[33] However, in our study, a decrease in MDA may also be associated with an increase in the activity of total SOD. It is not yet clear whether daidzein develops its antioxidant potential via a direct radical-scavenging mechanism or by improving the activity of other antioxidant enzymes such as SOD. Therefore, additional functional analyses are required to reveal how daidzein affects the free-radical-scavenging system.

In this study, we originally evaluated the effect of daidzein on intestinal morphology. Results show an increasing proliferation of duodenal mucosa with 200 mg/kg of daidzein. As previously noted, the same dose of daidzein tended to improve the ADG of pigs. This may be partially due to the increased VCR in the duodenum because the absorption capacity of the small intestine is affected by VCR.[34] Some studies show that increases in SOD lead to a decrease in intestinal crypt depth,[35] which accords with our results. Including soybean meal (5 g/day) in the diets of early weaned pigs has been found to decrease villus height and increase crypt depth, leading to transient hypersensitivity and subsequently poor growth performance.[36] However, there is no evidence to indicate that this effect mainly stems from soy isoflavones.

Previous studies on the effect of daidzein or isoflavones on organ development have mainly focused on reproductive issues. Findings show that daidzein or isoflavones at low concentrations have no significant effect on reproductive organs in hens (50 mg/kg daidzein) and mice (2 mg daidzein + 5 mg genistein/kg body weight/day).[37,38] To our knowledge, our study is the first to evaluate the long-term effects (35 and 70 days) of dietary daidzein at the high level of 400 mg/kg on pig organs. We employed histopathological scoring to identify the effects of dietary daidzein on pig organs. Our results suggest that ingesting high doses of daidzein for 70 days may increase spleen damage in pigs. This may compromise the ADG of pigs. However, the mechanisms involved are not clearly understood, and hence, the biochemical and toxic responses of daidzein deserve further study.

Previous studies on the tissue distribution of isoflavones in animals are limited. Urpi-Sarda et al. found that the major metabolites recovered in ewe tissues (liver and mammary glands) after consumption of red clover silage were equol and daidzein.[39] Gilani et al. studied tissue distribution of isoflavones in pigs following a daily dose of 2.3 g of total isoflavones. They found higher levels of daidzein, equol, genistein, and glycitein in livers compared with the CTL containing no isoflavones. The same effect was found in mammary gland extraparenchymal tissue of pigs for only daidzein and equol.[18] Our literature review found no studies on buildup in tissues when daidzein is added alone.

In our study, it was not surprising that daidzein was the metabolite found in the greatest amounts in pig livers. Unlike the findings of Urpi-Sarda and Gilani, we found that equal levels in both liver and muscle were low. The production of equol differs between species[40] and age stages (in a rat study).[41] These levels were not affected by the amount of daidzein ingested, which was possibly due to the pigs being too young to produce equol themselves.

Another notable finding from our study is that genistein and glycitein displayed an opposite distribution from that of daidzein in pig tissue when the level of dietary daidzein was increased. Reports had shown that the fraction of daidzein absorbed is greater than that of genistein.[42,43] Thus, we can speculate that daidzein acts as a competitive inhibitor against genistein and glycitein when they are deposited in animal tissue. Further studies will elucidate the absorption approach and deposition method of daidzein and other isoflavones, as well as the interaction between them in terms of buildup in animal tissue.

Another concern is that isoflavones may have a cumulative effect,[44] so that the biological effect is evident only after longer durations. Our findings indicate that daidzein may have a cumulative effect over time in terms of buildup in body tissues, as indicated by daidzein levels in pig livers on day 35 and day 70. This suggests a link between daidzein levels in animal products and the duration of ingestion.

In conclusion, this study on the biological activity of daidzein in pigs depends on dosage and the age of the pigs, as well as the duration of treatment. It may be a feasible option to give up to 200 mg/kg of daidzein to weanling pigs without negative consequences. As for the effects on consumer health, our findings reveal that the residual content of daidzein in pork products was not likely to raise safety concerns.

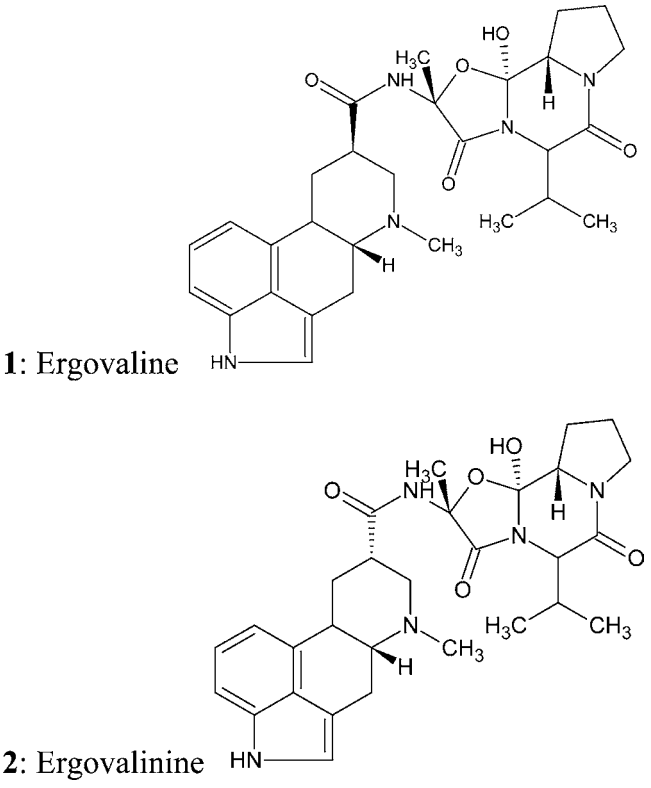

Figure 1. Chemical structures of ergovaline (**1**) and ergovalinine (**2**).

Sigma-Aldrich (St. Louis, MO). Anhydrous magnesium sulfate ($MgSO_4$), 99.5%, was purchased from UCT (Bristol, PA). Ammonium hydroxide, ACS grade, was purchased from VWR BDH Prolabo (West Chester, PA). Ultrapure water (18.2 MΩ cm^{-1}) was purified with a PURELAB Ultra Genetic system (Elga, Marlow, Buckinghamshire, U.K.).

Ergovaline tartrate was prepared by Dr. Forrest Smith, Department of Pharmacal Sciences, Auburn University, Auburn, AL. Chemical characterization and assessment of purity of the crystalline standard was established by nuclear magnetic resonance (NMR) and HPLC/mass spectrometry (HPLC/MS). It was established that the ergovaline tartrate was comprised of ergovaline/tartrate/water in the ratio 2/1/1. The **1** standard was weighed on an analytical balance, diluted in MeOH, dispensed in 10 μg aliquots, evaporated under nitrogen, and stored frozen at −20 °C. The working standard was prepared by dilution of a 10 μg aliquot in MeOH.

Sample Preparation. Tall fescue seed and straw samples were ground in a Cyclotec 1093 sample mill (Foss, Hilleroed, Denmark) to pass through a 0.5 mm screen and stored at −20 °C prior to analysis. Details on the collection of a representative straw or seed sample for forage testing can be found online.[20]

Optimization of Extraction Solvent. The first step of the extraction/partitioning process of the QuEChERS method was evaluated in a tall fescue seed sample with a known high **1** level (1998 μg/kg, n = 3/solvent). The extraction solutions were selected from published procedures that were used to extract mycotoxins via the QuEChERS method or used in the extraction of ergot alkaloids via other techniques and were as follows: extraction solvent 1, 1% acetic acid in MeCN (v/v);[11] extraction solvent 2, MeOH/MeCN (15/85, v/v);[11] extraction solvent 3, MeOH/MeCN (85/15, v/v);[11] extraction solvent 4, MeOH/water (60/40, v/v);[11] extraction solvent 5, MeOH/water (80/20, v/v);[11] extraction solvent 6, 2.1 mM ammonium carbonate/MeCN (16/84, v/v), modification from a method for the quantitation of ergot alkaloids in cereals and foodstuffs;[20] extraction solvent 7, isopropyl alcohol/1% lactic acid (50/50, v/v), method developed to quantitate **1** and peramine in grass tillers;[21] extraction solvent 8, MeCN/0.1% formic acid (57/43, v/v), modification of a method developed for detection of *Fusarium* mycotoxins in cereals;[13] extraction solvent 9, ethyl acetate/MeOH/4.1 mM ammonium carbonate (62.5/25/12.5, v/v), modification of a method for ergot alkaloid extraction from food and feed sources;[22] extraction solvent 10, water/0.5% acetic acid in MeCN (50/50, v/v), modification of a QuEChERS method developed for the analysis of 17 mycotoxins in cereals;[15] extraction solvent 11, ethyl acetate/MeOH/25% ammonium hydroxide solution (75/5/7, v/v), modification of a method developed for analysis of ergot alkaloids in rye and rye products;[23] extraction solvent 12, MeCN/1.0% acetic acid (80/20, v/v); extraction solvent 13, MeCN/1 mM ammonium carbonate (80/20, v/v); extraction solvent 14, MeOH/1% acetic acid (80/20, v/v).

For the initial survey of solvent systems, 1.0 g samples of ground tall fescue seed were placed into 16 × 125 mm glass screw top tubes in triplicate. A 5 mL portion of the solvent mixture was added; the tubes were capped and vortexed for 10 s. The tubes were placed on an end-over-end rotary mixer for 30 min, after which 0.5 g of $MgSO_4$ and NaCl (4/1, w/w)[9] was added. The tubes were capped and vortexed immediately to prevent agglomeration of the salts for 10 s, four times during a 10 min period. The samples were then centrifuged at 913*g* for 10 min. A 1 mL portion of the supernatant was evaporated to dryness at 50 °C under a gentle stream of nitrogen. The samples were reconstituted in 0.5 mL of MeOH and, after vortexing and sonication for 20 s each, transferred to a centrifugal filter tube with a 0.45 μm modified nylon membrane (VWR, Radnor, PA). The tubes were centrifuged at 8161*g* (10000 rpm) for 5 min; the filtrate was then transferred to an amber HPLC vial for analysis.

Final Extraction Procedure. A 5 mL portion of 2.1 mM ammonium carbonate/MeCN (50/50, v/v) extraction solvent was added to 0.5 g of ground plant material, mixed by vortexing for 30 s, and then placed on the rotary mixer for 30 min. Subsequently, 0.4 g of preweighed $MgSO_4$ and 0.1 g of NaCl was added and the tubes were capped and vortexed immediately for 10 s, four times during a 10 min period. Samples were centrifuged at 913*g* for 10 min. A 2.0 mL aliquot of the separated MeCN phase was evaporated to dryness at 50 °C under a gentle stream of nitrogen. The samples were reconstituted in 0.5 mL of MeOH and, after vortexing and sonication for 20 s each, were transferred to a centrifugal filter tube. The tubes were centrifuged at 8161*g* for 5 min, and the filtrate was transferred to an amber HPLC vial for analysis.

HPLC Analysis. A Series 200 HPLC system (PerkinElmer, Waltham, MA) was used throughout the experiment. This system consisted of an autosampler, binary pump, column oven, and fluorescence detector (λ_{ex} 250 nm, λ_{em} 420 nm). Chromatographic data were managed using TotalChrom Workstation Software version 6.3.2 (PerkinElmer). HPLC separations were performed with a 100 mm × 4.6 mm i.d., 2.7 μm Brownlee SPP C18 HPLC column (PerkinElmer), with a 4.6 mm i.d. SecurityGuard ULTRA C18 guard column (Phenomenex (Torrance, CA)) maintained at 35 °C. The mobile phase consisted of 30% MeCN in 200 mg/L ammonium carbonate in purified water (solvent A) and 100% MeCN (solvent B), run at a flow rate of 1.8 mL/min. Initial gradient conditions were 5% B held for 1.0 min, increasing linearly to 65% B over 0.8 min and held for 0.8 min. Finally, there was a linear return to initial conditions over 0.3 min, which was then held for 1.3 min for a total run time of 4.2 min. The injection volume was 10 μL.

Method Validation. Performance characteristics were evaluated using guidelines developed by the Food and Drug Administration for bioanalytical analysis.[24] Validation of the optimized extraction method included linearity, selectivity, recovery, limit of detection (LOD), limit of quantitation (LOQ), precision, accuracy, and stability. Linearity was assessed using matrix-matched calibration curves established using extracts of endophyte-free (E−) tall fescue seed and straw fortified with the working **1** standard at 50, 100, 500, 1000, 2500, and 3500 μg/kg. Selectivity was established using comparison of noninfected seed and straw sample chromatograms with **1**-fortified extracts. Interference (visual examination of the chromatogram for coelution of other peaks) at the retention times of **1** (1.75 min) and ergovalinine (**2**) (3.60 min) was checked.

For recovery investigations, the **1** standard was added to E− tall fescue seed and straw at fortification levels of 100, 1000, and 2500 μg/kg (n = 10/level). To avoid epimerization of **1**, the MeOH in the spiked sample was evaporated under a gentle steam of nitrogen, and then the

DOI: 10.1021/acs.jafc.5b01149
J. Agric. Food Chem. 2015, 63, 4236−4242

tube was capped and frozen at −20 °C until extraction. The LOD and LOQ were estimated by measurement of the peak-to-peak signal-to-noise ratio (S/N) and calculated at $S/N > 3$ and $S/N > 10$, respectively. LOQ values must meet an accuracy of ±20% and a precision of <20% relative standard deviation (RSD).

The accuracy and precision of the method was determined using in-house tall fescue seed and straw reference material. The **1** content of the reference material was established using the Ergosil silica gel solid phase extraction (SPE) method.[5,8] The intraday precision was established using five replicates at four levels of **1**. Interday precision and accuracy were evaluated over three separate days of analysis of five replicates at the four concentration levels. The stability of the sample extracts was investigated by repeat analysis of the samples ($n = 48$) after 24 h at room temperature.

Statistical Analysis. Statistical analyses (averages, standard deviations (SD), relative standard deviations (RSD), *t* tests (two-tailed, two-sample equal variance) and ANOVA) were performed in Excel (Microsoft Office 2010, Redmond WA) or GraphPad Prism (Version 5.01, La Jolla, CA). Results were considered significant when the p value was less than 0.05.

RESULTS

Optimization of Extraction Procedure. The 14 solvent mixtures were significantly different from each other in their ability to extract **1** (Kruskall-Wallis test, $P = 0.001$) (Figure 2).

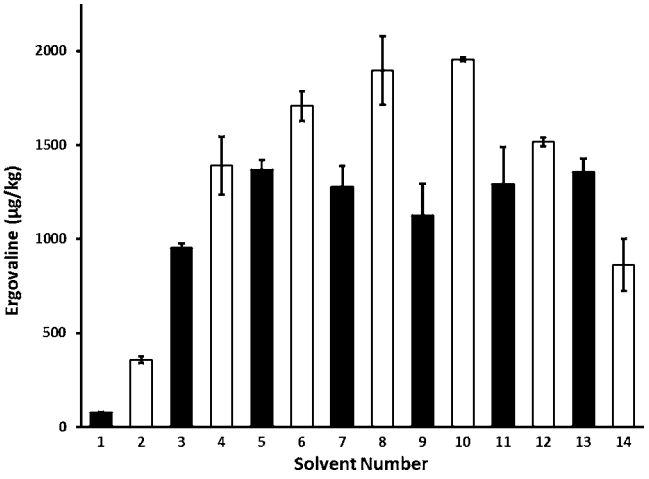

Figure 2. Evaluation of different solvent mixtures for extraction of **1** from endophyte-infected tall fescue seed containing 1998 µg of **1**/kg using the QuEChERS method ($n = 3$/solvent). For solvents tested refer to Materials and Methods.

The maximum amount of extracted **1** was obtained with water/0.5% acetic acid in MeCN (50/50), which extracted 98% of the 1998 µg of **1**/kg in the seed that was being used, with a low standard deviation of 12 µg/kg (RSD 0.6%). The MeCN/0.1% formic acid (57/43) mixture showed a similar ability to extract **1**, extracting 95% of the 1998 µg of **1**/kg in seed, but had a higher standard deviation of 182 µg/kg (RSD 9.6%). While the two solvent combinations were not statistically different from each other ($p = 0.611$), the water/0.5% acetic acid in MeCN (50/50) mixture was chosen for its lower standard deviation, which would ensure greater throughput under the rigorous quality control standards in a diagnostic laboratory setting. Once this was established, different types of aqueous solution, namely 0.5% and 1% acetic acid, 1% formic acid, 2.1 mM ammonium carbonate, and 1 mM ammonium carbonate, were studied in both seed (1998 µg of **1**/kg) and high **1** content straw (850 µg/kg). It was found that the highest and most consistent recoveries were achieved with 2.1 mM ammonium carbonate (Figure 3). This

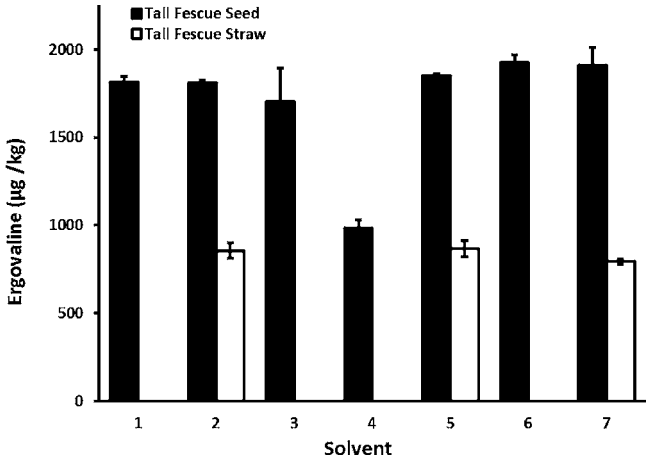

Figure 3. Additions to the aqueous component of the extraction solution evaluated for recovery of **1** from tall fescue seed (1998 µg of **1**/kg) and tall fescue straw (850 µg of **1**/kg) ($n = 3$/sample type/solvent mixture): (1) 1% acetic acid/MeCN (50/50); (2) 2.1 mM ammonium carbonate/MeCN (50/50); (3) 1 mM ammonium carbonate/MeCN (50/50); (4) 1% formic acid/MeCN (50/50); (5) 0.5% acetic acid/MeCN (50/50); (6) water/1% acetic acid in MeCN (50/50); (7) water/MeCN (50/50).

solvent mixture extracted 90.5 ± 1.0% of the **1** in the tall fescue seed (1998 µg/kg) and 100.5 ± 5.3% in the tall fescue straw (850 µg/kg) that were used. The addition of the 2.1 mM ammonium carbonate/MeCN extraction solution added as a mixture or separately as two components to tall fescue seed containing 1998 µg of **1**/kg was investigated; no statistical difference was found between either method ($n = 3$ replicates/method, *t* test $p = 0.656$). Thus, combining the 2.1 mM ammonium carbonate/MeCN (50:50, v/v) as one addition to the sample was chosen.

The optimum mixing time for the sample and extraction solvent was evaluated at 30, 60, 90, and 120 min in both seed and straw samples (Table 1). Thirty minutes was found to be a

Table 1. Comparison of Mixing Times for Solutions of 2.1 mM Ammonium Carbonate/MeCN (50/50, v/v) from Tall Fescue Seed and Straw for Extraction of Ergovaline (1) Using the QuEChERS Method

	amt of ergovaline (**1**), µg/kg[a]			
	30 min	60 min	90 min	120 min
tall fescue seed (1998 µg/kg)	1901(3)	1771(4)	1637(4)	1644(3)
tall fescue straw (776 µg/kg)	712(8)	675(8)	568(11)	620(9)

[a]RSD values are given in parentheses ($n = 5$).

sufficient amount of time for the sample and extraction solvent to mix to maximize the amount of **1** extracted, with low RSD values. Following addition of the 0.4 g of anhydrous $MgSO_4$ and 0.1 g NaCl, immediate vortexing and mixing four times during a 10 min period was required to give the most consistent mixing and to promote homogeneity.

Figure 4 shows representative HPLC-fluorescence chromatograms of the final, optimized QuEChERS procedure for tall fescue seed and straw, in comparison to the Ergosil SPE method currently used in our laboratory.[5]

Method Validation. *Linearity.* A calibration curve was constructed by plotting the peak area of **1** against the nominal concentrations of **1** at 50, 100, 500, 1000, 2500, and 3500 µg/kg. The correlation coefficient (R^2) generated from the calibration

DOI: 10.1021/acs.jafc.5b01149
J. Agric. Food Chem. 2015, 63, 4236−4242

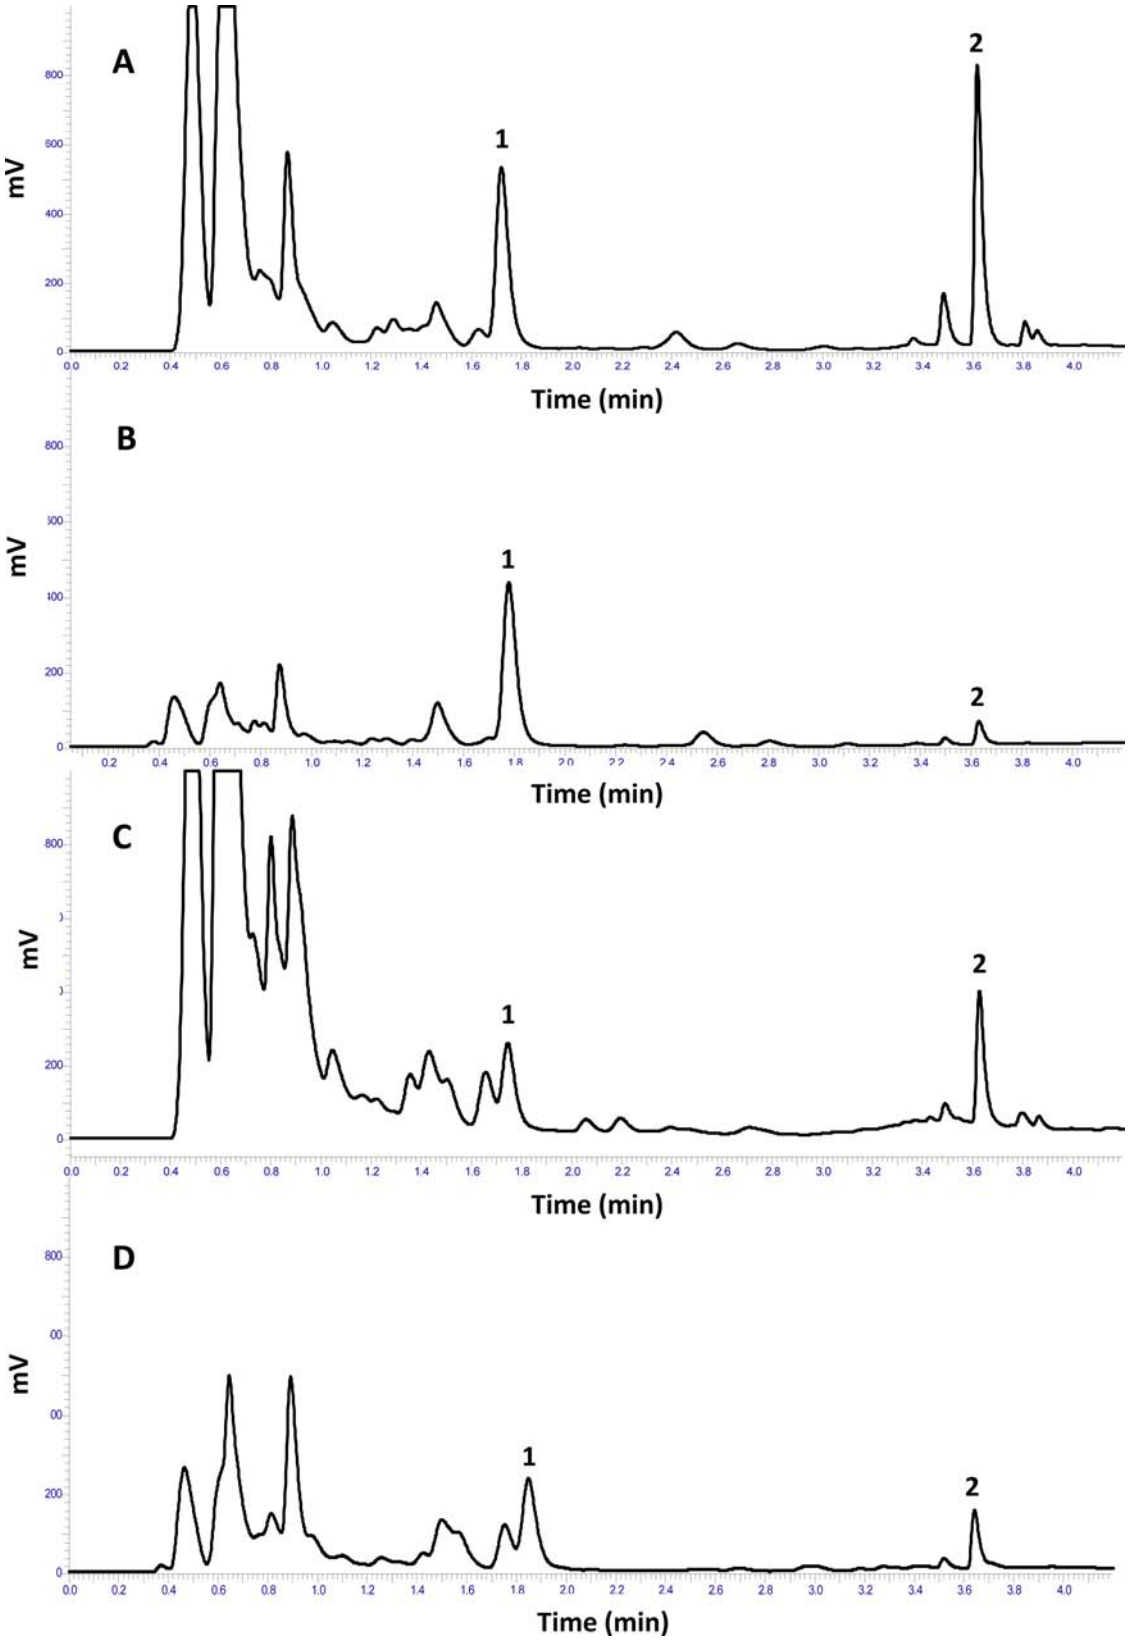

Figure 4. Representative HPLC-fluorescence chromatograms comparing extraction of tall fescue seed and straw between the optimized QuEChERS method and an Ergosil SPE method for **1** and its epimer **2**: (A) QuEChERS extract of tall fescue seed; (B) Ergosil SPE extract of tall fescue seed; (C) QuEChERS extract of tall fescue straw; (D) Ergosil SPE extract of tall fescue straw.

curve was >0.999 in both seed and straw from six replicate standard sets. The linear dynamic range was found to be 100−3500 μg/kg.

Selectivity. Noninfected seed and straw samples were extracted to verify that there were no peaks interfering with the fluorescent detection of **1** or its epimer **2** at

DOI: 10.1021/acs.jafc.5b01149
J. Agric. Food Chem. 2015, 63, 4236−4242

their expected retention times (1.75 and 3.60 min, respectively).

Recovery. **1** was spiked into E− seed and straw samples at three levels: 100, 1000, and 2500 μg/kg (n = 10/level). The mean recoveries varied from 91.3 to 97.2% in tall fescue seed and 89.6−98.1% in tall fescue straw.

LOD and LOQ. The LOD values were determined to be 37 and 30 μg/kg in tall fescue seed and straw, respectively. An LOQ level of 100 μg/kg was established in both seed and straw, with demonstrated accuracies of 98% and 91% and precision of 9% and 6%, respectively.

Precision and Accuracy. Precision and accuracy were determined by the extraction of **1** from tall fescue seed (143−1998 μg of **1**/kg) and straw (181−1061 μg/kg) reference material. The intraday precision, expressed in RSD, ranged from 1.8 to 5.8% in tall fescue seed and 0.5−3.4% in tall fescue straw. The interday precision ranged from 1.9 to 6.4% in seed and 0.7−4.8% in straw. The results from the experiments to establish accuracy ranged from 97.9 to 98.6% in tall fescue seed and 97.3−99.2% in tall fescue straw.

Stability. The extracted samples demonstrated stability comparable with that of the Ergosil SPE method upon repeat analysis after storage at room temperature for 24 h.

Application of the Method to Real Samples. The validated method was applied to 17 tall fescue straw samples which were previously analyzed using the Ergosil SPE method.[5,8] Including the standard reference material, controls, and samples run in duplicate, the run size was 48 individual extractions, which is a typical sample run in our laboratory. There was good agreement between the two different methods. Both methods found that 7 of the samples had less than a quantitative amount of **1** (<100 μg/kg). The results from the remaining 10 samples had a RSD of 10% or better agreement. **1** values for the QuEChERS/Ergosil SPE methods were 119/119, 156/173, 203/224, 237/244, 238/240, 339/318, 499/469, 523/530, 526/518, 535/482, and 632/603 μg/kg, respectively. Comparative statistics showed that application of the two extraction methods to the 17 samples gave results that were not different from each other (t test, p = 0.258) and that the methods were very well correlated (correlation coefficient 0.9978).

DISCUSSION

Endophyte (*Epichloë coenophiala*)-infected tall fescue (*Festuca arundinacea*) is used as forage for livestock in the form of pasture, straw, silage, and pellets. Some endophyte strains produce ergot alkaloids as a protective mechanism against herbivory which cause vasoconstrictive and reproductive abnormalities that present as the diseases known as "summer syndrome" and "fescue foot" in livestock.[2,3] **1** is the ergopeptide alkaloid produced in highest concentration in tall fescue[25] and is a potent vasoconstrictor with the potential to bioaccumulate in vascular tissue;[26,27] as such, it has been used to establish thresholds of toxicity for these diseases in relevant livestock species.[5] When it is used safely with these thresholds in mind, tall fescue can be fed as an important nutritional component in livestock feeding programs. To achieve this, accurate testing of **1** concentration in tall fescue material is vital. While we currently employ a robust SPE method for **1** quantitation,[5,8] we were interested in application of a QuEChERS method to make the assay more efficient and eliminate the use of chlorinated solvents.

Fourteen extraction solvents were examined, and 2.1 mM ammonium carbonate/MeCN (50/50, v/v) was found to have the highest and most consistent recovery (90.5 ± 1.0% and 100.5 ± 5.3% for tall fescue seed and straw, respectively) (Figures 2 and 3). Thirty minutes was found to be an adequate amount of time for mixing and produced the best recovery of **1** from tall fescue seed and straw (Table 1). Total extraction time was improved to 4.4 h, in comparison to 5.9 h using traditional SPE, giving a time savings of 1.5 h.

On validation of the method, performance characteristics were similar to existing extraction procedures using HPLC-fluorescence for detection. The QuEChERS procedure had an LOD of 37/30 μg/kg in tall fescue seed/straw, respectively, a LOQ level of 100 μg/kg in both seed and straw, a linear dynamic range of 100−3500 μg/kg, and recoveries of spiked **1** from 91.3 to 97.2% for seed and 89.6−98.1% for straw. The Ergosil SPE method[5,7] has an LOD value of 31 μg/kg, an LOQ value of 100 μg/kg, a linear dynamic range of 100−2000 μg/kg, and a recovery of 91% and is the method currently in use by the Endophyte Service Laboratory at Oregon State University. Previous extraction methods upon which the Ergosil SPE method was based also showed similar values with an LOD value of 50 μg/kg and a recovery of 85%[28] or 93%.[8] These parameters are in line with the ability to determine clinically relevant concentrations of **1** in feed, on the basis of the established thresholds of toxicity (300−800 μg of **1**/kg, depending on species and climatic conditions).[5] Another method using 2-propanol/lactic acid as an extraction solvent to examine **1** distribution throughout the plant established an LOQ value of 100 μg/kg, a linear dynamic range of 400−10000 μg/kg, and recoveries of 93−105% and had the advantage that small (2−5 mg) sample amounts could be used for quantitation.[21] More recently, an SPE method using sodium-neutralized strong cation exchange columns was developed which accounted for both the native toxicologically active *R* epimer of ergot alkaloids as well as their biologically inactive -inine *S* epimer forms in rye flour and wheat germ oil samples, while minimizing epimer formation during the extraction itself.[29] They achieved LOD values of 0.3−0.8 μg/kg, LOQs of 0.7−2.0 μg/kg, linear dynamic ranges of 8−200 μg/kg, and recoveries of 71−120%.

Advancements in LC-MS have made it increasingly common in diagnostic laboratories. Application of the QuEChERS extraction method to cleanup samples, particularly for those destined for screening of multiple ergot alkaloids via LC-MS/MS, is a logical next step, as this mode of detection will likely allow the limits of detection and quantitation to be lowered. Two methods using electrospray ionization (ESI) (+) for detection of **1** and other ergot alkaloids analyzed by selected reaction monitoring (SRM) laid out a robust framework which also allowed for elucidation of "unusual" ergot alkaloid compounds and metabolites.[30,31] Another LC-MS method, using extraction procedures developed by Spiering et al.,[21] employed SRM for the transition m/z 534−268 and found concentrations of 240−3480 μg of **1**/kg in five populations of tall fescue from Iran.[32] While **1** was not specifically included, LC-MS/MS determination of multiple ergot alkaloids in the following methods had performance characteristics of LOQs of 0.17−2.78 μg/kg (with LODs similar to LOQs), recoveries of 69−105%, concentration ranges of 0.5−200 μg/kg,[33] LODs of 0.04−0.29 μg/kg, LOQs of 0.1−1 μg/kg, and recoveries of 88−110%.[34] Finally, a method using saphenous vein tissue as a matrix gave an LOD value of 1 nM, an LOQ value of 2 nM, a linear dynamic range of 0.1−50 pmol, and a recovery of 86−90% for spiked **1**.[35]

We have observed epimerization of **1** to **2** in SPE-extracted samples at room temperature after approximately 12 h. On this basis, a complete batch of samples, validated reference materials, and controls are either always run immediately after extraction

DOI: 10.1021/acs.jafc.5b01149
J. Agric. Food Chem. 2015, 63, 4236−4242

via HPLC-fluorescence or stored in a freezer, which halts epimerization until samples can be analyzed.[36] For quantitation, only **1** and not **2** is analyzed for total concentration in this method, as the Ergosil silica material in the SPE appears limited in its ability to bind **2**. Further, the thresholds of toxicity for fescue toxicosis in livestock[5] were established using analysis of feed samples for **1** (and not its epimer) via the SPE method; thus, measurement of **1** in feed samples which will be used in livestock feeding programs to avert fescue toxicosis remains relevant. On the other hand, the QuEChERS method had a significant peak for **2** in both seed and straw samples (Figure 4A,C); this technique appears to be able to extract more of this stereoisomer than the SPE method and/or epimerization from the *R* to the *S* isomer configuration is occurring at a greater rate over the course of performing this method. However, quantitation was again performed using only **1**, to compare extractability of **1** alone between the two methods. When the QuEChERS extraction procedure was applied to 17 tall fescue straw samples that had also been quantitated for **1** using the Ergosil SPE method, a correlation coefficient of 0.9978 was obtained on comparison of the two methods. The concentrations tested ranged from 7 that were below the LOQ value (100 μg/kg) to an additional 10 from 119 to 632 μg/kg, giving a good representation of the **1** concentrations that are typically seen in samples submitted to the Endophyte Service Laboratory.

In summary, a method following the QuEChERS extraction procedure was developed for determination of **1** in tall fescue seed and straw material using HPLC-fluorescence for detection. The method has eliminated the need for halogenated/chlorinated solvents, is as fast and efficient as the Ergosil SPE method currently in use in our laboratory, and was validated to perform across a linear range of 100−3500 μg of **1**/kg in tall fescue seed and straw material. These features make it ideal for application in a high-throughput food safety laboratory.

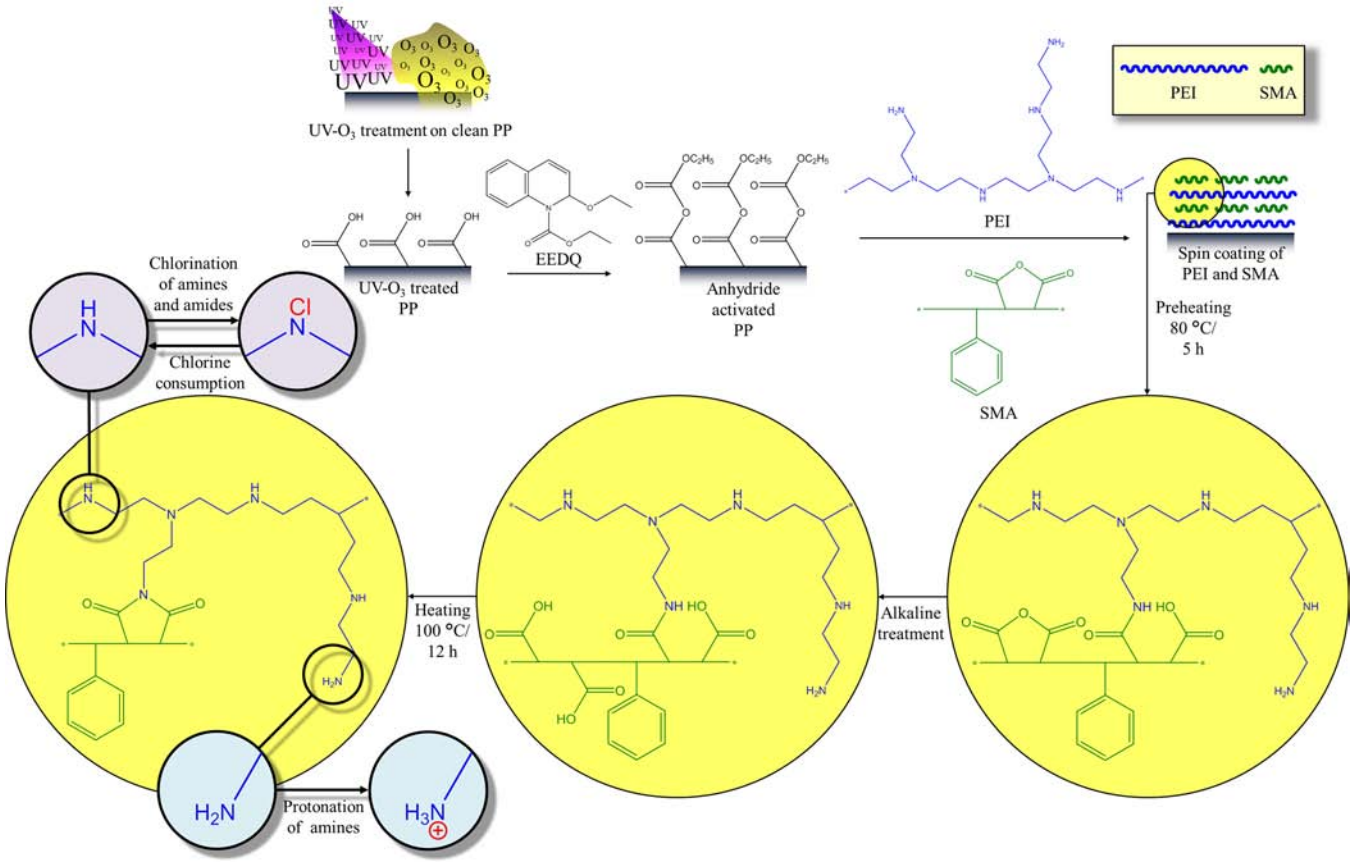

Figure 1. Process for application of the reported antimicrobial coating.

Polymer Products (Ontario, NY, USA). Isopropanol, acetone, methanol, and glycerol were from Fisher Scientific (Pittsburgh, PA, USA). Branched polyethylenimine (PEI, MW 25000), 2-ethoxy-1-ethoxycarbonyl-1,2-dihydroquinoline (EEDQ, MW 247.3), and 4-(2-hydroxyethyl)-1-piperazineethane-sulfonic acid (HEPES) were from Sigma-Aldrich (St. Louis, MO, USA). 2-(*N*-Morpholino)-ethanesulfonic acid sodium salt (MES, MW 217.2) was from GenScript Inc. (Piscataway, NJ, USA). The dye Orange (II) (Cert) (AO7), the sodium hypochlorite solution (5% chlorine), ethylene glycol, and absolute ethanol were from Acros Organics (Fair Lawn, NJ, USA). *N*,*N*-Diethyl-*p*-phenylenediamine DPD total chlorine reagent powder (DPD) was from Hach Co. (Loveland, CO, USA). Tryptic soy broth (TSB), tryptic soy agar (TSA), and neutralizing buffer were from Difco, Becton Dickinson (Sparks, MD, USA).

Antimicrobial Coating Application onto Polypropylene Coupons. *Preparation of PP Coupons.* PP pellets were cleaned by sonication first with isopropanol, then with acetone, and finally with deionized (DI) water (two cycles of 10 min were applied for each solvent). Cleaned PP pellets were left to dry overnight under anhydrous calcium sulfate (RH < 20%) and then hot pressed at 170 °C with a load force of 9000 lb. Coupons of 2 × 2 cm were cut from the obtained films (thickness = 0.5 ± 0.1 mm) and cleaned and dried under the same conditions applied to the PP pellets.

PP Surface Activation. The 2 × 2 cm coupons were UV-ozone-irradiated from one side with a Jelight Co. model 42 UVO Cleaner (Irvine, CA, USA) for 15 min to create carboxylic acid groups on their surfaces[28,29] (this step will be referred as UV-O_3). To create surface anhydride groups (and make the PP surface reactive toward the primary amines of PEI through nucleophilic attack), UV-O_3 coupons were shaken for 2 h at room temperature in a 0.1 mM solution of EEDQ in 50 mM MES buffer (pH 5.5).[30] Before mixing with the MES buffer, the necessary amount of EEDQ was dissolved in a volume of methanol equal to <1% of the final volume of the mix. This step will be referred to as EEDQ. EEDQ-treated coupons were rinsed with 1:100 methanol/DI water solution and dried under an air gun.

Assembly of Antimicrobial Coating. PEI and SMA were dissolved in acetone at a concentration of 60 and 43.2 mg mL^{-1} (respectively) by sonication for 20 min or until completely dissolved. This proportion of PEI and SMA was chosen so that there would be approximately three polymer chains of SMA for every polymer chain of PEI. Alternating volumes of the PEI and SMA solutions were spin-coated onto an anhydride-activated PP coupon (EEDQ-treated) for 1 min at 3000 rpm to produce two bilayers. PEI would covalently bind to the surface of anhydride-activated PP through amide bond formation between the anhydrides and the primary amines of PEI, and the alternating layers of PEI and SMA would cross-link through formation of the same type of bond (Figure 1). After spin-coating, a preheating step was applied to the coupons at 80 °C for 5 h to promote amide bond formation between the PEI and SMA layers.[31] Coupons were then subjected to an alkaline treatment (1 h at room temperature in a 50 mM, pH 10, MES buffer) to promote anhydride ring opening.[32] Coupons were then rinsed with DI water, dried under an air gun, and subjected to a final heating step of 12 h at 100 °C to promote imide ring closing[33] (Figure 1). Coupons were then kept in closed glass Petri dishes until use.

Antimicrobial Coating Surface Characterization. *Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy (ATR-FTIR).* Changes in surface chemistry were analyzed by a diamond crystal ATR-FTIR (penetration depth ∼ 2 μm) after every step in the surface modification process with an IRPrestige 21 spectrometer (Shimadzu Corp., Tokyo, Japan). Coupons from three separately prepared sets were analyzed (three replicates), with at least one randomly chosen coupon from each preparation step. Three spots were analyzed per coupon using Happ−Genzel apodization with a resolution of 4 cm^{-1}, capturing 32 scans per spot. Spectra were obtained with the IR-solution software (Shimadzu Corp.) and interpreted with KnowItAll software (Bio-Rad Laboratories, Phila-

DOI: 10.1021/acs.jafc.5b00445
J. Agric. Food Chem. 2015, 63, 4243−4251

delphia, PA, USA). Average spectra from every step of the antimicrobial coating preparation were selected and combined for comparison after linear baseline correction. After the rechargeability evaluation (explained below), coupons were analyzed with the same criteria.[28,29]

X-ray Photoelectron Spectroscopy (XPS). As a complementary source of coating characterization, a 0.5 × 0.5 cm piece of modified PP cut from a randomly selected coupon at every step of the antimicrobial coating preparation was analyzed using a Physical Electronics Quantum 2000 (Physical Electronics, Chanhassen, MN, USA). A single 100 μm spot was analyzed from every coupon at an angle of 45° relative to the coupons' surface with Al Kα excitation (penetration depth of 2.5−3.0 nm). Survey scans were collected at a pass energy of 187.85 eV, and high-resolution spectra of C 1s, O 1s, and N 1s were collected at a pass energy of 46.95 eV. Atomic percentages and high-resolution spectra were analyzed with Multipak software version 6.1A (Physical Electronics). High-resolution bands of C 1s, O 1s, and N 1s were fitted using the Gaussian−Lorentzian model with 90% Gaussian. Three coupons from every surface modification step were analyzed, each taken from separately prepared sets (three replicates).[29,34]

Atomic Force Microscopy (AFM). Surface topographies were analyzed with a Dimension 3100 atomic force microscope (Digital Instruments, Santa Barbara, CA, USA) under tapping mode with a Si N-type tip (uncoated, f_0 = 200−400 kHz; Applied NanoStructures, Inc., Mountain View, CA, USA). Three measurements were taken from PP and as-prepared modified PP coupons. SPIP software version 6.0.6 (Scanning Probe Image Processor, Image Metrology, Hørsholm, Denmark) was used to calculate mean square roughness (R_q).

Primary Amine Quantification. The Acid Orange 7 (AO7) colorimetric assay[35] was followed to determine the primary amine content of the antimicrobial coating. At least two 1 × 1 cm coupons were taken from each of three separately prepared sets of samples (three replicates, at least two coupons per replicate) for analysis. Coupons were submerged in pH 3, 1 mM, solution (1 mL cm^{-2} of modified surface) of AO7 dye and shaken for 3 h. Then, coupons were rinsed with pH 3 DI water to remove unbound AO7 dye. Following rinsing, coupons were immersed in 5 mL of pH 12 DI water and shaken for 15 min to desorb dye. Absorbances of the solutions containing desorbed dye were read at 455 nm, and the concentrations were determined from a standard curve prepared with different AO7 concentrations in pH 12 DI water.

N-Halamine Quantification. To quantify the *N*-halamine content of the antimicrobial coating, a colorimetric assay published earlier was followed.[28,29,34] Coupons were first chlorinated by exposure to 200 ppm of chlorine (pH 9.7) prepared from sodium hypochlorite solution (5% chlorine), the chlorine content of which was previously confirmed through a standard procedure.[36] During chlorination, coupons were randomly taken at different points in time and rinsed with copious DI water to remove unbound chlorine. To quantify the *N*-halamine content of the chlorinated antimicrobial coatings, rinsed coupons were immersed in 2 mL of DI water, to which 50 μL of the DPD reagent was applied. DPD reagent was prepared by mixing one pack of DPD total chlorine reagent powder with 1 mL of DI water. The solutions containing the coupons were shaken for 5 min for color generation, and absorbances were read at 512 nm. *N*-Halamine content was determined from a standard curve prepared with multiple chlorine concentrations. Chlorination kinetics (and time of chlorine saturation) were determined by fitting data with the exponential association model using GraphPad Prism 5 version 5.04 (GraphPad Software Inc., La Jolla, CA, USA):

$$\mathrm{NH} = \mathrm{NH}_{\mathrm{asympt}}(1 - \mathrm{e}^{-Kt}) \quad (1)$$

NH is the *N*-halamine content in nmol cm^{-2}, $\mathrm{NH}_{\mathrm{asympt}}$ is the asymptotic *N*-halamine content (in nmol cm^{-2}, theoretical amount of *N*-halamines at saturation), K is the exponential rate constant (min^{-1}), and t is the time (min).

Surface pK_a Determination. Surface pK_a of the antimicrobial coating was quantified following a protocol reported in previous works.[37,38] Buffers (pH levels from 2 to 10) were prepared with 10 mM HEPES solutions. For every pH level evaluated, a 5 μL HEPES buffer drop was applied in at least two spots of the surface of a previously cut 1 × 2 cm PP and modified PP coupon. After 15 s, the static contact angle θ_S was measured with a drop shape analyzer DSA100 using its Drop Shape Analysis software version 1.91.0.2 (Krüss, Hamburg, Germany). Coupons from three sets prepared separately were analyzed (three replicates), with at least one coupon per replicate. To calculate surface pK_a, data from each replicate were fitted with the sigmoidal dose−response model through nonlinear regression using the GraphPad software:

$$\theta_S = \theta_{\min} + \frac{\theta_{\max} - \theta_{\min}}{(1 + 10^{(\mathrm{p}K_a - \mathrm{pH})})} \quad (2)$$

θ_S is the static contact angle (in degrees), $\theta_{\max}$ and $\theta_{\min}$ are the maximum and minimum angles obtained from the sigmoidal curve (respectively), and pH is the pH level of the buffer used.

Surface Energy Determination. The Zisman method was applied to calculate the surface energy[39] (surface tension, γ_{GS}, in mN m^{-1}) of the antimicrobial coating. Advancing contact angle (θ_A) was obtained with the same DSA100 Drop Shape Analyzer using liquids of different surface tensions:[40,41] DI water (72.8 mN m^{-1}), glycerol (63 mN m^{-1}), ethylene glycol (47.7 mN m^{-1}), and acetone (25.8 mN m^{-1}). A 5 μL drop of each liquid was applied in at least two spots of the surface of 1 × 2 cm coupons of PP and modified PP. For each liquid and each type of PP, at least one coupon was analyzed from each of three separately prepared sets (three replicates). The cosine of the values of θ_A (in radians) was plotted against the values of surface tension of the corresponding liquid (γ_{GL}) for each treatment (PP and modified PP). After linear regression analysis had been applied to the data with the GraphPad software, γ_{GS} values for PP and modified PP were obtained from the regression curves when $\cos(\theta_A) = 1$.

Antimicrobial Evaluation. The antimicrobial activity of native PP, as-prepared coated PP, and coated PP after exposure to dilute bleach was studied following a protocol published earlier.[28,29] Bacterial suspensions of *L. monocytogenes* Scott A (provided by Dr. Martin Wiedmann, Food Science Department, Cornell University, Ithaca, NY, USA) were prepared by streaking a loopful of stock culture kept at −80 °C in 25% glycerol onto TSA, which was incubated at 37 °C for 24 h. Then, a single colony was inoculated in 9 mL of TSB and incubated overnight for 14 h at the same temperature. A 1% dilution of this overnight broth was prepared with fresh and sterile TSB and incubated for 4 h at 37 °C. The bacterial suspension with approximately 6 log(CFU mL^{-1}) was obtained by preparing a 0.1% dilution of the broth incubated for 4 h in DI water. PP, chlorinated PP, modified PP, chlorinated modified PP, bacterial suspension alone, and bacterial suspension with chlorine added were tested. PP and modified PP 1 × 1 cm coupons were chlorinated for 45 min with a solution having 200 ppm of chlorine following the same procedure explained before. The chlorination time was chosen because (as will be explained later) that is the time required to reach chlorine saturation. A volume of 1 mL of bacterial suspension was put in contact with four 1 × 1 cm coupons of each treatment in individual test tubes and incubated for 2 h with rotation (60 rpm) at 32 °C.[28,29] For the case of bacterial suspension with chlorine added, the amount of chlorine was adjusted to mimic the amount of chlorine given by the four 1 × 1 cm coupons of chlorinated modified PP. After the 2 h of incubation, serial 10% dilutions were prepared from the bacterial suspensions. For the first dilution, neutralizing buffer was used to quench chlorine, and subsequent dilutions were prepared with 0.9% saline water. A volume of 100 μL of each dilution was inoculated onto TSA plates using an automated spiral plater (Autoplater 4000, Spiral Biotech Inc., Norwood, MA, USA) and incubated for 48 h at 37 °C. After incubation, colonies were counted with a plate reader Scan 500 (Interscience, Saint-Nonla-Brèteche, France). To lower the detection limit to 1 log(CFU mL^{-1}), the whole volume of the first dilution after incubation was inoculated manually onto three TSA plates (333 μL per plate). This antimicrobial evaluation was repeated three times using coupons from separately prepared sets (three replicates). For the chlorine rechargeability study (explained below) coupons were

DOI: 10.1021/acs.jafc.5b00445
J. Agric. Food Chem. 2015, 63, 4243−4251

challenged against *L. monocytogenes* at the 10th rechlorination under the same conditions explained for the antimicrobial evaluation.

The inactivation kinetics given by the antimicrobial coatings in cationic and *N*-halamine form was evaluated as follows.[28] Multiple test tubes with 1 mL of bacterial suspension with approximately 6 log(CFU mL^{-1}) containing four 1 × 1 cm coupons of either modified or chlorinated modified PP (chlorinated for 45 min as explained above) were incubated for up to 2 h under the same conditions described above. Test tubes were taken randomly over time and the corresponding dilutions prepared in the same way explained before and inoculated onto TSA plates to be incubated for 48 h at 37 °C. The number of survivors was quantified as in the preliminary evaluation. Data were fitted with the following models[42] using nonlinear regression with the software GraphPad:

$$\log\left(\frac{N}{N_0}\right) = -kt^n \tag{3}$$

$$\log\left(\frac{N}{N_0}\right) = -\frac{at}{(b+t)} - \frac{ct}{(d-t)} \tag{4}$$

Equation 3 corresponds to the Weibull model where $\log(N/N_0)$ is the survival ratio, k is the kinetic constant in min^{-1}, n is the shape factor, and t is the time in minutes. Equation 4 corresponds to a sigmoidal isothermal semilogarithmic model, where a, b (min), c, and d (min) are temperature-dependent coefficients. Two replicates were performed for the inactivation kinetics evaluation, with coupons from two independently prepared sets.

Scanning Electron Microscopy (SEM). To demonstrate that reductions in microbial populations were a result of the antimicrobial nature of the coating and not due to adhesion onto the surface, coupons were evaluated by electron microscopy following antimicrobial activity assays. Coupons were rinsed three times with sterile DI water and then immersed for 45 s in absolute ethanol to fix any attached bacteria.[43] Then, coupons were sputter-coated with gold for 20 s under argon with a Cressington Sputter Coater 108 Auto (Ted Pella, Inc., Redding, CA, USA). Surfaces of the coupons were extensively observed with a scanning electron microscope JCM-6000 NeoScope (JEOL, Japan) at 10 kV, and at least 10 images were taken from coupons of each treatment.

Chlorine Rechargeability. Modified PP coupons were subjected to 10 chlorination cycles to evaluate the ability of the antimicrobial coating to be rechlorinated. Each cycle consisted of 45 min of exposure to 200 ppm of chlorine. *N*-Halamine content was quantified through the DPD assay. Coupons were analyzed through ATR-FTIR as described before to evaluate changes in surface chemistry after the 10 rechlorinations.

Statistical Analysis. In addition to the regression analyses, significant differences between treatments were determined when appropriate through the general linear model followed by Tukey's pairwise comparisons with the software Minitab version 16.1.1 (Minitab Inc., State College, PA, USA), using a confidence interval of 95%. Unless otherwise stated in the corresponding section, three replicates were performed for each evaluation or analysis.

RESULTS AND DISCUSSION

Surface Characterization. An antimicrobial coating has been prepared that exhibits dual antimicrobial functionality by the presence of both cationic and *N*-halamine moieties (Figure 1). ATR-FTIR spectroscopy was performed at each step of the antimicrobial coating preparation to characterize changes in surface chemistry (Figure 2).

Figure 2 contains different regions of the infrared range in which the spectra corresponding to every step of the antimicrobial coating application are displayed: (a) PP, (b) UV−O_3, (c) EEDQ, (d) spin-coating, (e) preheating, (f) alkaline treatment, and (g) heating. The presence of the carbonyl group (C═O) from carboxylic acids can be observed

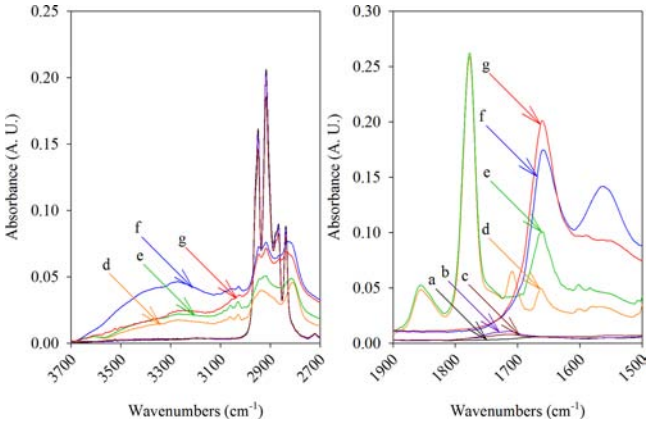

Figure 2. ATR-FTIR spectra showing characteristic bands throughout the antimicrobial coating preparation: PP (a), UV−O_3 (b), EEDQ (c), spin-coating (d), preheating (e), alkaline treatment (f), and heating (g).

in the 1740−1720 cm^{-1} range and confirms activation by the UV-O_3 (creating carboxylic acid groups) and EEDQ (creating anhydride groups) treatments (Figure 2, spectra b and c). After spin-coating, an increase of the carbonyl group of carboxylic acids is observed (1740−1720 cm^{-1} range, attributed to maleic anhydride units in SMA), as well as the formation of a band at ∼1650 cm^{-1} that corresponds to the carbonyl group of amides and imides (Figure 2, spectrum d). This confirms initial covalent cross-linking between the primary amine groups of PEI and the anhydrides from maleic anhydride units of SMA through nucleophilic attack. It can be observed from the increment in absorbance at ∼1650 cm^{-1} and the decrease in the carbonyl group of carboxylic acids (1740−1720 cm^{-1}) that the amide bond formation increases during the preheating step (Figure 2, spectrum e), which again confirms further cross-linking between PEI and SMA. After the alkaline treatment, the bands at ∼1780 and ∼1850 cm^{-1} that correspond to the vibration of C═O from anhydrides disappear (Figure 2, spectra d and e), which confirms the opening of the maleic anhydride rings of SMA, which makes them available for further covalent bond formation with the primary amines of PEI (Figure 1). Finally, after the heating step, the increase in absorbance from the carbonyl group of amides and imides at ∼1650 cm^{-1} (Figure 2, spectrum g) as well as the decrease in the absorbance of the O−H vibration from carboxylic acids in the 3400−3200 cm^{-1} range (Figure 2, spectra g, that confirms further condensation of the free carboxylic acids) and the decrease in absorbance at ∼1550 cm^{-1}, which belongs to the N−H bond in-plane bend of secondary amides (Figure 2, spectrum g), confirm the closing of the ring that results in imide formation through a ring-closing step that releases water (Figure 1).

X-ray photoelectron spectroscopy confirmed the anhydride surface activation of PP after the EEDQ treatment, as noted by the increase in the O—C═O deconvolution band from O 1s (Figure 3). The effect given by the preheating and heating steps was also confirmed from the increase in the amide bond formation exhibited by the increase in the N—C═O deconvolution band from O 1s and N 1s (Figure 3; Table S1 in the Supporting Information). A decrease in the band that encloses both O—C═O and N—C═O in O 1s[44] after the alkaline treatment and an increase in the deconvolution band

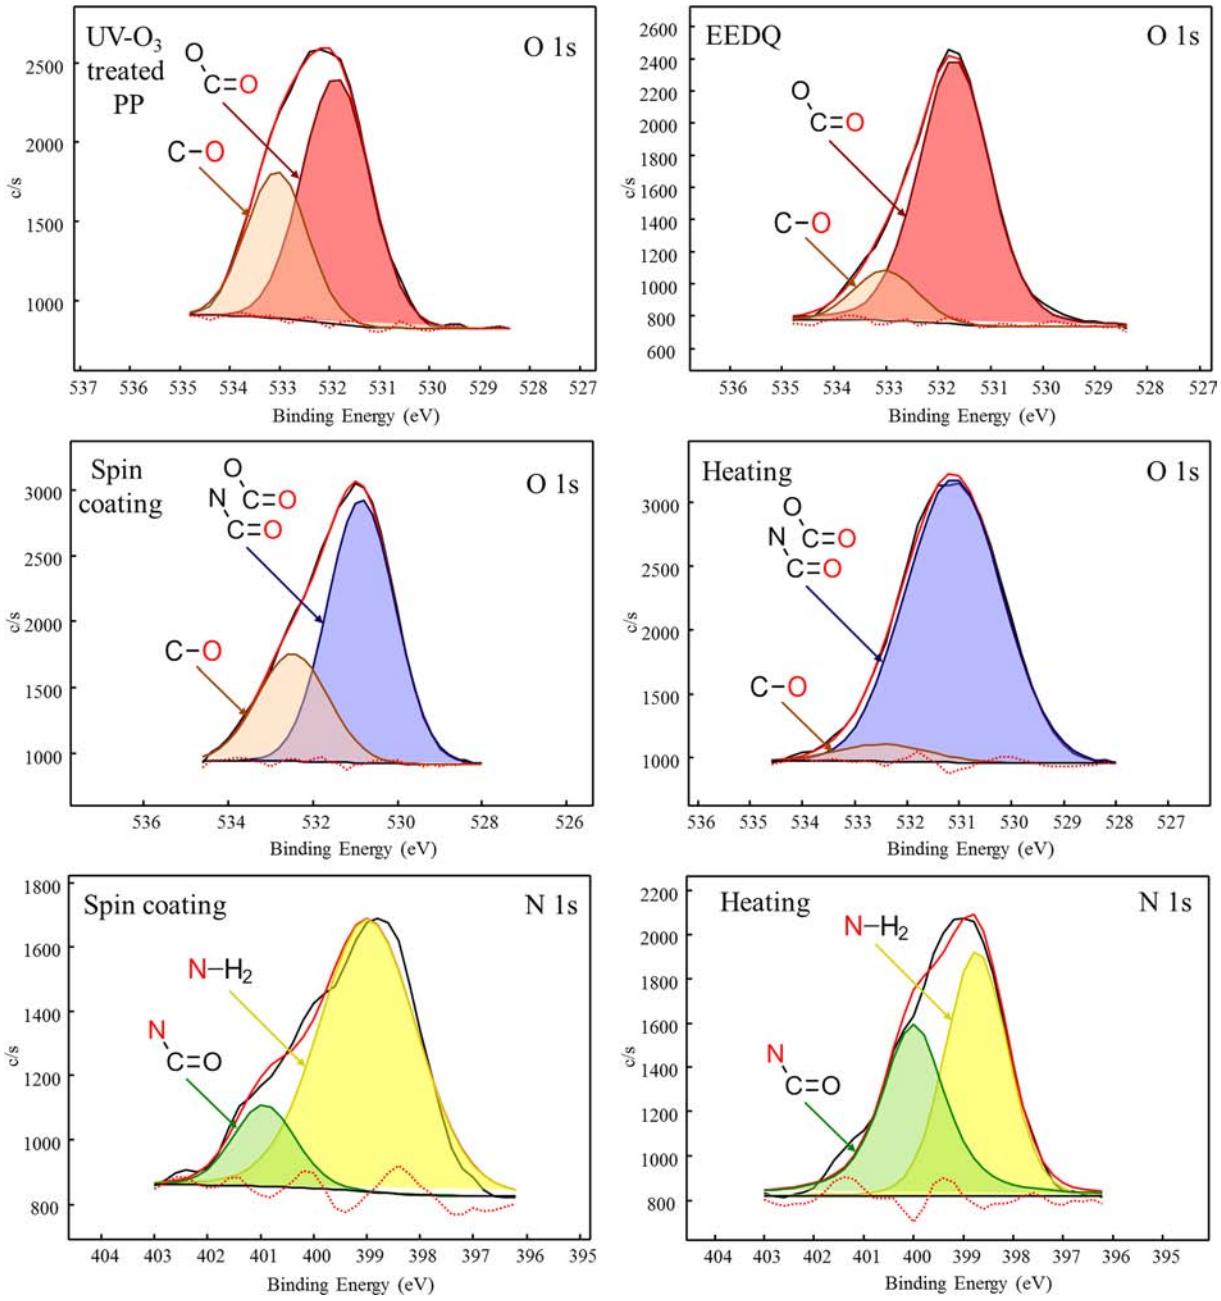

Figure 3. XPS high-resolution bands of O 1s and N 1s.

characteristic of the C—O bond confirms the resulting anhydride ring opening (Supporting Information, Table S1).

AFM images were obtained to characterize changes in surface morphology resulting from application of the antimicrobial coating (Figure 4). A significant ($P < 0.05$), although minor in terms of practical importance, increase in *Rq* was obtained after the application of the antimicrobial coating, going from 8.8 ± 2.6 to 18.3 ± 1.1 nm. A porous surface was observed from modified PP. This effect may be created by the evaporation of the solvent that contains PEI and SMA (acetone) during spin-coating and after heating. The scratches in PP may be originated by the hot pressing of the PP pellets. As can be observed, the antimicrobial coating possesses pores <1 μm in diameter, and electron microscopy confirmed that there was no evidence of bacterial adhesion in them.

Materials were further characterized by quantifying the number of primary amines and *N*-halamine-forming moieties, *N*-halamine chlorination kinetics, and surface pK_a. Application of the antimicrobial coating introduced approximately 500 nmol cm^{-2} of primary amines to the surface of the modified PP. Figure 5A shows the *N*-halamine content of the antimicrobial coating as a function of chlorination time according to eq 1 (NH_{asympt} = 151 ± 22 nmol cm^{-2}, K = 0.03 ± 0.01 min^{-1}, R^2 = 0.88 ± 0.1). As can be observed, the coating reaches chlorine saturation after 45 min, and this chlorination time was used for subsequent antimicrobial activity characterizations. Surface pK_a was determined by plotting static contact angles of dilute buffers on control and modified PP against their corresponding pH values (Figure 5B). Data were fitted with eq 2 (bold line, R^2 = 0.83 ± 0.04) and the data obtained from PP (dashed line represents the average θ_S value of PP in all of the pH range

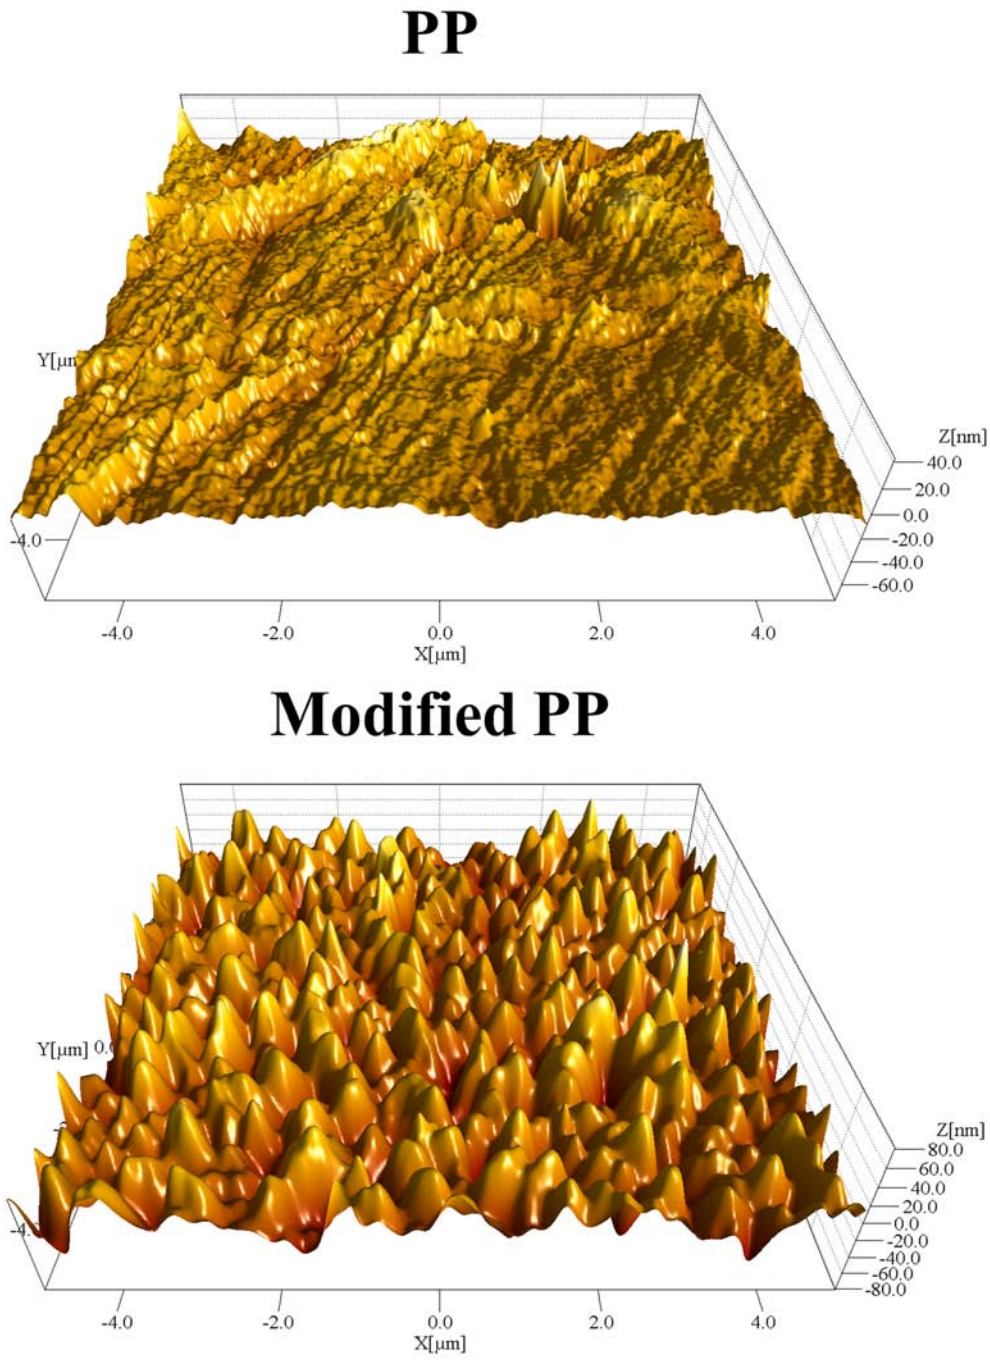

Figure 4. Atomic force micrographs of native and modified PP coupons.

evaluated). The shape of the sigmoidal curve obtained corresponds to that of a cationic surface (character given by the high amount of primary amines), and the obtained pK_a value (4.6 ± 1.4) is comparable to the ones reported in previous works involving similar surface chemistries.[38,45] A similar shift in pK_a values has been seen in previous works concerning attachment of basic (aminated) species on different substrates. The pK_a of the corresponding basic compounds when free in solution is substantially higher than after anchoring onto surfaces, and the reason is believed to be reorientation of the basic compounds toward the substrate, which prevents them from having the same behavior as a pure substance in solution.[46] In previous works in which surface pK_a has been evaluated through contact angle titration, surfaces containing carboxylic acids exhibit a *decrease* in contact angle as pH increases, whereas amine-containing surfaces exhibit an *increase* with increasing pH value. The transition of the sigmoidal curve for both types of ionizable groups can fall within an acidic, neutral, or alkaline pH range, depending on the chemical structure of the acid or amine moiety. In both cases, the surface pK_a values can differ substantially from those of the same chemical entities in solution. This phenomenon (also observed in the present study) can be attributed to a higher difficulty in creating a charged group at the surface

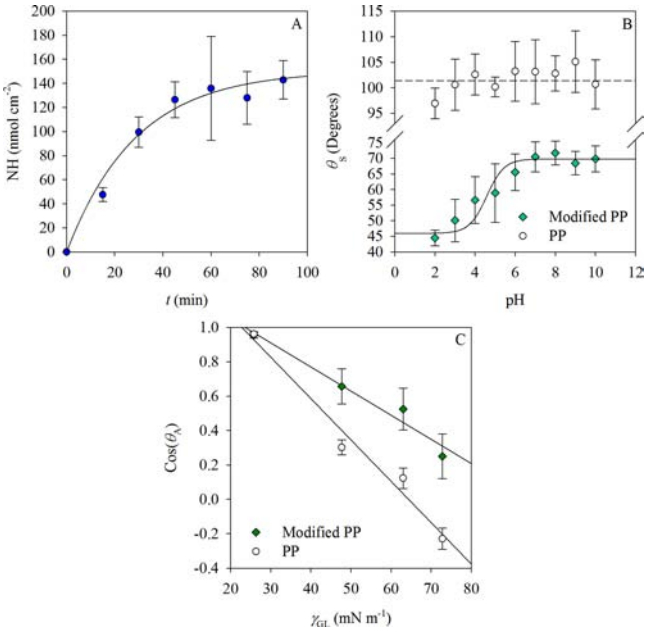

Figure 5. *N*-Halamine formation on the antimicrobial coating (A), contact angle titration curve for pK_a determination (B), and Zisman plot for surface energy determination (C).

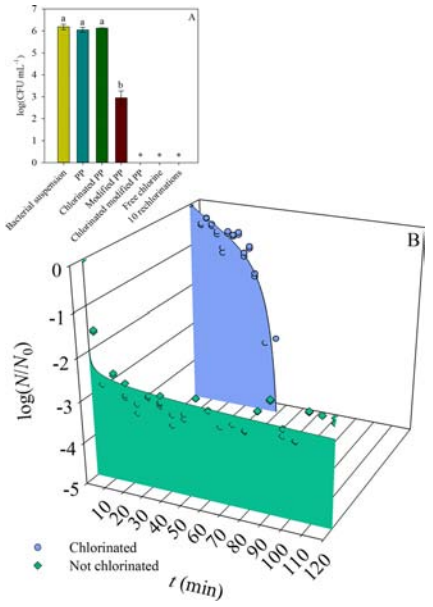

Figure 6. Antimicrobial evaluation (A, results after 2 h of incubation; treatments followed by the same letter are not significantly different, $P > 0.05$) and inactivation kinetics of modified PP and chlorinated modified PP (B; ∗ indicates inactivation below the limit of detection (<1 log(CFU mL^{-1}))).

interface (as compared to in solution), which in turn can be explained by a low local dielectric constant, as well as charge−charge interactions. Additionally, it is believed that as the pH increases, the amine moieties become deprotonated, which in turn decreases the polarity of the surface and increases the contact angle.[47] Even though a higher hydrophilicity was observed on coated PP compared to native PP, there was no significant difference ($P > 0.05$) in surface energy (Figure 5C). Values of γ_{GS} of PP and modified PP were 22.5 ± 0.5 and 23.9 ± 2.3 mN m^{-1}, respectively. Comparable results of surface energy for PP have been reported.[48] The low level of surface energy may have been given by the presence of styrene units in SMA, providing low polarity to the antimicrobial coating. Surfaces with surface energy values <30 mN m^{-1} can be considered as nonfouling.[49] The obtained value of surface energy (γ_{GS}) of modified PP is lower than those of other common food contact surfaces such as stainless steel 304 (39.2 mN m^{-1}), glass (33.8 mN m^{-1}), granite (46.2 mN m^{-1}), and marble (40.2 mN m^{-1}).[27]

Antimicrobial Evaluation. Antimicrobial activity of the cationic, *N*-halamine polymeric coating was characterized against *L. monocytogenes* by exposing coupons of control and modified PP to aqueous bacterial suspensions under rotation. As expected, no antimicrobial effect was observed from either PP or chlorinated PP, and after 2 h of incubation, approximately 3 logarithmic reductions were given by modified PP and >5 logarithmic reductions were given by both chlorinated modified PP and an equivalent concentration of free chlorine (Figure 6A). Because the pH of the bacterial suspension used was 6.0 ± 0.1, which falls in the range of the surface pK_a, the antimicrobial effect can be attributed to the positively charged nature of the surface. In addition, antimicrobial activity was preserved from modified PP coupons that had been subjected to 10 rechlorination cycles, providing also >5 logarithmic reductions. The inactivation kinetics showed a different behavior between modified PP and chlorinated modified PP (Figure 6B). The inactivation kinetics of unchlorinated modified PP exhibited a Weibullian behavior (the cationic form, eq 3, $R^2 = 0.84$), whereas chlorinated modified PP showed a sigmoidal behavior (*N*-halamine form, eq 4, $R^2 = 0.84$). Cationic polymers have been reported to inactivate microorganisms in previous studies, and the possible explanations provided for their action have been an ion exchange process between the positive charges of the polymers and the cell membrane (causing its deterioration), the generation of reactive oxygen species that can provoke oxidative stress and damage genetic information and other biomolecules, and interruption of the electron transport chain, vital for energy generation.[19−21] In previous works, *N*-halamines[11,28] and cationic polymers[50] have exhibited inactivation kinetics similar to the ones observed here. In the cited works, inactivation kinetics given by *N*-halamines exhibits an initially slow biocidal effect, which is followed by a drastic and abrupt reduction in the microbial population. In contrast, according to the cited reference in the case of cationic polymers, the inactivation kinetics shows initially a drastic and fast decrease in the microbial population, which is followed by a plateau or by an abrupt decrease in the speed of inactivation.

Scanning Electron Microscopy (SEM). To confirm that reductions in bacterial populations were due to inactivation by the antimicrobial coating and not a result of adhesion onto its surface due to its cationic nature, electron microscopy was performed on coupons following antimicrobial activity assays (Supporting Information, Figure S1). No visual evidence of attached bacteria was found on native or coated PP. Previous works have shown that PP exhibits a low level of surface attachment of *L. monocytogenes* as compared to other materials' surfaces. In the same mentioned studies, adhesion of *L. monocytogenes* cells on surfaces has not been possible to link with materials properties such as roughness and hydrophobicity,[27] which makes this phenomenon unpredictable on the basis of surface properties. The results obtained confirm that, under the test conditions and at the inoculum level used,

DOI: 10.1021/acs.jafc.5b00445
J. Agric. Food Chem. 2015, 63, 4243−4251

the reduction in microbial load exerted by modified PP and chlorinated modified PP is not caused by cell adhesion on the coupons' surfaces.

Chlorine Rechargeability of the Antimicrobial Coating. Modified PP was exposed to 10 cycles of chlorination to demonstrate the ability of the coating to regenerate *N*-halamines (Supporting Information, Figure S2). Some of the bonds that hold together the layers of PEI and SMA exhibited hydrolysis after the 10 rechlorinations according to the ATR-FTIR spectra. The absorbance increases in the 3400−3200 cm^{-1} range (Supporting Information, Figure S2A) and in the 1740−1720 cm^{-1} range (Supporting Information, Figure S2B), which are characteristic of the C—O and C═O vibrations of carboxylic acids, respectively, and an absorbance reduction at ∼1650 cm^{-1} (Supporting Information, Figure S2B, C═O vibration of amides) confirm the hydrolysis of amide and imide bonds. As can be observed (Supporting Information, Figure S2C), an initial increase in chlorine absorption is exhibited, followed by stabilization. From the SEM images (Supporting Information, Figure S1D), it can be seen that a single chlorination causes a change in the surface pattern. However, as the antimicrobial evaluation confirmed, the biocidal efficacy was retained after 10 rechlorinations (Figure 6A). Similar results have been reported in studies involving rechlorination of polymeric *N*-halamines.[29]

Table 1. Compilation of the Investigated Barley Cultivars

cultivar	origin	characteristics[a]
Argentinian Mutant 6519	Argentina; chemically induced mutant of Quilmes Paine (1993)	drought resistance; salt stress resistance
Mackay	Australia; Cameo × Coru (2001)	drought tolerance;[27] powdery mildew resistance; net blotch susceptibility; spot blotch susceptibility[28]
Palmella Blue (CIho 3609)	Ethiopian landrace	drought tolerance
IPZ 24727	Germany; Maresi × Omega	stress tolerance; ramularia tolerance; nonparasitic leaf spot tolerance; mildew susceptibility
Marnie	Germany; 6429f Havanna × (Prisma × Br 4714a) (2003)	mildew resistance; leaf rust resistance; net blotch resistance[26]
Iron	Germany; Marnie × LP 813.6.98 (2009)	leaf rust resistance
Barke	Germany; Libelle × Alexis (1996)	stress susceptibility; leaf disease resistances; mildew resistance
Steina	Germany; (Sultan × St.434/62) × (Voldagsen × Carlsberg × Volla) (1980)	leaf rust resistance
Streif	Germany; Pasadena × Aspen (2007)	mildew resistance; leaf rust resistance
Emperor	Canada; HB320 × Maresi	net blotch susceptibility; leaf rust moderate susceptibility; powdery mildew resistance
Polygena	Germany; 46401-80 × 45465-78 (1994)	leaf rust resistance

[a]According to descriptions provided by the plant breeders or in the literature.

studies on grain from plants grown under water limitation were performed to compare different hybrids.[9]

Additionally, there are some studies that investigated the cultivar-specific impact of drought stress on metabolites via targeted analyses. For example, Thakur and Rai studied the alterations of levels of amino acids in maize shoots from differently drought-resistant cultivars.[17] Singh et al. specifically analyzed the accumulation of proline in leaves of barley varieties with different adaptions to drought.[18]

The objective of the present study was to apply metabolite profiling to identify metabolites that might serve as markers for barley cultivars differently adapted to drought stress. Therefore, a set comprising both stress resistant/tolerant cultivars and cultivars, for which no drought resistance/tolerance had been described, were field-grown in three consecutive growing seasons under normal weather conditions as control and under induced drought stress using a rain-out shelter. The same barley cultivars were also grown under natural weather conditions in a second field trial at another location. Using metabolite profiling in combination with multivariate and univariate analyses, this setup should enable screening for cultivar-specific responses of barley grain to drought stress.

MATERIALS AND METHODS

Sample Material. Eleven two-row spring barley cultivars were field-grown under natural weather conditions at two control locations in Bavaria, Germany, and under drought stress induced by using a rain-out shelter in the growing seasons 2010−2012; information on the cultivars is provided in Table 1. The first control location (Freising, C1) was situated next to the rain-out shelter, whereas the second control location (Frankendorf, C2) was 30 km distant. GPS coordinates of the field sites were as follows: C1 and rain-out shelter, latitude 48.3924, longitude 11.7569, elevation 448 m above normal null (NN); C2, latitude 48.3667, longitude 12, elevation 455 m above NN. Two biological replicates were taken from field trials with totally randomized field plot design and analyzed in triplicate (laboratory replicate samples). For further information regarding growing periods, soil quality, and weather conditions, see Wenzel et al.[12]

Metabolite Profiling. *Preparation of Standard Solutions.* The following internal standards were used for nonpolar (fractions 1 and 2) and polar (fractions 3 and 4) extracts of barley (see later for fractionation protocol): 0.5 mg/mL heptacosane in hexane (fraction 1); 0.6 mg/mL 5α-cholestan-3β-ol in dichloromethane (fraction 2); 0.8 mg/mL phenyl-β-D-glucopyranoside in distilled water (fraction 3); 0.4 mg/mL *p*-chloro-L-phenylalanine in distilled water (fraction 4). The retention time mixture consisted of 1.5 mL of undecane (2 mg/mL in hexane), 2.5 mL of hexadecane (1.5 mg/mL in hexane), 4 mL of tetracosane (1.5 mg/mL), and 4 mL of triacontane (1.5 mg/mL) dissolved in 15 mg of octatriacontane. Internal standards and retention time mixture standards were purchased from Fluka (Buchs, Switzerland).

Sample Preparation. Barley plants were harvested and samples were prepared as previously described.[12] Barley kernels from each biological replicate were ground with a cyclone mill (Cyclotec 1093, Foss Tecator, Rellingen, Germany) using a 500 μm sieve and immediately freeze-dried for 48 h. Samples were transferred to LDPE bottles (Kautex Textron, Bonn, Germany) and stored at −18 °C until analysis.

Sample Workup. Freeze-dried barley samples were subjected to an extraction and fractionation scheme resulting in four fractions containing nonpolar (fractions 1 and 2) and polar constituents (fractions 3 and 4) as previously described in detail for maize.[19] Flour (200 mg) was weighed into a cartridge, and 100 μL of methanol was added for cell disruption. After 20 min, methanol was removed by application of vacuum (30 mbar, 30 min), and nonpolar and polar compounds were extracted. One hundred microliters of standard solutions 1 and 2 as well as 300 μL of standard solutions 3 and 4 was added to the nonpolar and polar extracts, respectively. The nonpolar extract was transesterified with sodium methoxide and separated by solid phase extraction (SPE) into fractions 1 and 2 containing fatty acid methyl esters (FAME) and hydrocarbons as well as phytosterols, free fatty acids (FFA), and fatty alcohols, respectively. An aliquot of the polar extract was silylated and purified by selective hydrolysis to obtain fraction 3 containing sugar and sugar alcohols. Fraction 4 containing acids, amino acids, and amines was obtained by subjecting a second aliquot of the polar extract to silylation, oximation, and selective hydrolysis. For gas chromatography−mass spectrometry (GC-MS) analysis, 1 μL of fractions 1 and 2 as well as 0.5 μL of fractions 3 and 4, respectively, was injected. In addition, 1 μL of a 1:10 dilution of fraction 1 was injected to quantitate constituents present in high concentrations. The GC-MS conditions were as previously described.[12]

Metabolite Identification. Metabolites were identified by comparison of mass spectra and retention indices with those of reference compounds, with data from the NIST08 mass spectra library, the GOLM metabolome database, and the literature.[20−22]

Quantitation of Free Amino Acids. Quantitation of proteinogenic free amino acids was based on the equation

DOI: 10.1021/acs.jafc.5b01114
J. Agric. Food Chem. 2015, 63, 4252−4261

$$c(\mathrm{A}) = \frac{\mathrm{height(A)} \times c(\mathrm{IS}) \times \mathrm{Rf} \times 100}{\mathrm{height(IS)} \times W} \times 5\ (\mathrm{mg/kg\ flour})$$

where c is the concentration (μg/g), height the average absolute peak height of three repetitions, IS the internal standard, A the analyte, Rf the response factor, W the recovery rate, and 5 the dilution factor. A mixture containing 0.1 mg/mL alanine, glycine, tyrosine, leucine, lysine, glutamine, isoleucine, proline, valine, phenylalanine, and tryptophan, 0.5 mg/mL serine, threonine, and asparagine, 0.3 mg/mL aspartic acid, and glutamic acid in MeOH/H_2O (80:20, v/v) was prepared for validation.

Response Factor. For calculating response factors (Rf), 1 mL of amino acid standard mixture was silylated and analyzed in triplicate. Response factors were calculated by using the equation

$$\mathrm{Rf} = \frac{\mathrm{height(IS)} \times c(\mathrm{A})}{\mathrm{height(A)} \times c(\mathrm{IS})}$$

where Rf is the response factor, height the averaged absolute peak height of three repetitions, IS the internal standard, A the analyte, and c the concentration.

Repeatability. Repeatability was determined by triplicate analysis of one barley sample. Relative standard deviations (RSD) of peak heights normalized to internal standard 4 were calculated for each amino acid.

Recovery. Recovery rates of amino acids were determined by analyzing nine aliquots of a polar extract. The first three aliquots of the extract were spiked with 50 μL of amino acid standard mixture at the beginning of the analytical workup, whereas three further aliquots were spiked at the end of the procedure prior to GC-MS measurement. The last three aliquots were analyzed to calculate peak heights of the amino acids naturally occurring in the unspiked flour. Recovery rates were calculated by using the equation

$$W = \frac{H_{\mathrm{P1}} - H_{\mathrm{P3}}}{H_{\mathrm{P2}} - H_{\mathrm{P3}}} \times 100\%$$

where W is the recovery rate, H_{P1} the average relative peak height from three aliquots of the extract spiked at the beginning of the analytical procedure, H_{P2} the average relative peak height from three aliquots of the extract spiked prior to GC-MS measurement, and H_{P3} the average relative peak height from three unspiked aliquots. Relative peak heights were normalized to the internal standard.

Linearity. Linearity was determined for each amino acid by analyzing different amounts of the amino acids standard mixture (corresponding to 10−2500 mg amino acid/kg barley flour) after silylation in triplicate. Calibration curves were plotted, and the respective regression coefficients were calculated.

Analysis of Protein. Analysis of protein contents was performed by near-infrared transmission spectroscopy (NIT) according to the method of Grausgruber and Vollmann and calculated as percent in grain.[23] Amino acid spectra of free and protein-derived amino acids were analyzed in duplicate according to Commission Regulation (EC) No. 152/2009, III, F and G.[24]

Quality Control. To ensure constant analysis conditions, reference material (commercially available barley kernels) was analyzed in triplicate at the beginning and end of each sample set (2 field replicates × 3 seasons) and regularly together within each batch. Data were considered acceptable when the variation coefficient of representatives of each compound class did not exceed 25%. The representatives were as follows: FAME (C16:0, C18:0, C20:0), hydrocarbons (squalene), free fatty acids (C16:0, C18:0), sterols (campesterol, β-sitosterol, β-sitostanol), monosaccharides (fructose, glucose, galactose), trisaccharides (raffinose), sugar alcohols (xylitol, *myo*-inositol), organic acids (citric acid, malic acid), and amines (γ-aminobutyric acid). Furthermore, data obtained by GC-MS analysis of the reference material were checked for additional peaks to control for potential laboratory contamination.

Data Processing and Statistical Analysis. Freeze-dried flour from each biological replicate was analyzed in triplicate. For analysis, the samples were grouped into randomized batches; each batch consisted of three biological replicates (C1, C2, rain-out shelter) analyzed in triplicate and one quality control. In total, there were 66 batches (11 cultivars × 2 field replicates × 3 seasons).

The GC-MS chromatograms were integrated by means of Xcalibur 2.1 (Thermo Fisher Scientific, Waltham, MA, USA). Standardization of peak heights and retention time matching were performed using Chrom*pare* 1.1.[25] For retention time matching characteristic compounds of the fractions 1−4 (fraction 1, myristic acid methyl ester, palmitic acid methyl ester, stearic acid methyl ester, arachidic acid methyl ester, and internal standard 1; fraction 2, silylated myristic acid, palmitic acid, stearic acid, internal standard 2, and β-sitosterol; fraction 3, silylated fructose, *myo*-inositol, internal standard 3, sucrose, and raffinose; fraction 4, silylated alanine, phosphoric acid, malic acid, internal standard 4, and citric acid) were used. Normalization of peak heights was done by using the internal standards 1−4. On the basis of noise levels of 1 and 2% peak heights relative to the internal standards in fractions 1/2 and 3/4, respectively, peaks below this threshold were discarded.

For multivariate data analysis, principal component analysis (PCA) was performed using XLSTAT version 2013.3.02 (Addinsoft, Paris, France).

Analysis of variance (ANOVA) was undertaken within GenStat 16 (VSN International Ltd., Hemel Hempstead, UK). The following described models were fit for each metabolite from polar fractions 3 and 4 across 11 cultivars, or for each cultivar, to evaluate the effect of growing across 11 cultivars or within each cultivar, respectively:

$$v_{ijkl} = \hat{i} + \hat{a}_i + s_j + n_k + t_l + (sn)_{jk} + (st)_{jl} + (nt)_{kl} + \mathring{a}_{ijkl} \quad \text{(i)}$$

$$v_{ijk} = \hat{i} + \hat{a}_i + s_j + n_k + (sn)_{jk} + \mathring{a}_{ijk} \quad \text{(ii)}$$

v_{ijkl} (or v_{ijk}, respectively) is the response for the ith block of the jth growing conditions/location and the kth season (and the lth cultivar for v_{ijkl}), μ is the overall mean, β_i is the random effect of the ith block, s_j is the effect of the jth growing conditions/location, n_k is the effect of the kth season, t_l is the effect of the lth cultivar, $(sn)_{jk}$ is the effect of the interaction between the jth growing conditions/location and the kth season, $(st)_{jl}$ is the effect of the interaction between the jth growing conditions/location and the lth cultivar, $(nt)_{kl}$ is the effect of the interaction between the kth season and the lth cultivar, and e_{ijkl} (or e_{ijk}, respectively) is the random error. Differences for the effect of growing conditions/location were considered to be statistically significant if the effect was significant by ANOVA, and changes were consistent for (i) each cultivar and season or (ii) for each season.

The effect of growing conditions/location was additionally statistically tested by Tukey's test. The significance level was set to $p < 0.01$ for all statistical comparisons.

RESULTS AND DISCUSSION

To reveal changes in the metabolite profiles reflecting the adaptation of cultivars to drought stress, the set of barley grain previously investigated by Wenzel et al. was further extended.[12] The material comprised two groups of spring barley assigned according to the descriptions provided by the plant breeders or in the literature.[26−28] The first consisted of three cultivars ('Argentinian Mutant 6519', 'Mackay', 'Palmella Blue') from countries with hot and dry summers reported to be drought resistant/tolerant and of one cultivar ('IPZ 24727') from Germany described to be generally stress tolerant. The second consisted of seven cultivars originating from countries with moderate climates being either stress susceptible ('Barke') or without specific reports on drought resistance/tolerance ('Marnie', 'Iron', 'Steina', 'Streif', 'Polygena', 'Emperor') (Table 1). PCA based on agronomic parameters (e.g., yield, grain size, thousand kernel weight) confirmed the different performances of the two groups upon drought stress in the three growing seasons.

DOI: 10.1021/acs.jafc.5b01114
J. Agric. Food Chem. 2015, 63, 4252−4261

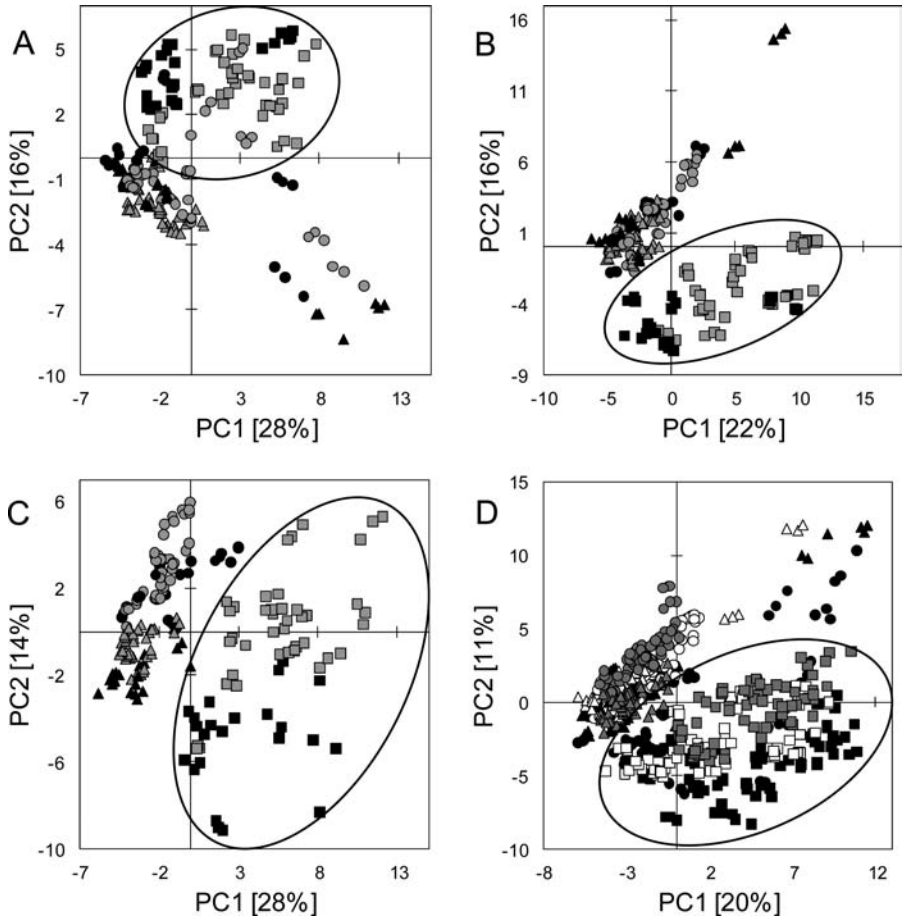

Figure 1. PCA of GC-MS metabolite profiling data of combined polar fractions 3 and 4 from stress resistant/tolerant barley cultivars (A–C, black symbols) and from cultivars reported to be either stress susceptible or without specific reports on drought resistance/tolerance (A–C, gray symbols) grown under drought stress in a rain-out shelter (squares) and under natural weather conditions at control location 1 (circles) and control location 2 (triangles) in (A) 2010, (B) 2011, and (C) 2012 and in (D) 2010 (black symbols), 2011 (white symbols), and 2012 (gray symbols). Circles encompass samples from the drought-stress conditions. Two field replicates were analyzed each in triplicate.

The 11 cultivars were field grown under induced drought stress using a rain-out shelter and under control, that is, natural weather conditions (C1 and C2), in three consecutive seasons. The GC/MS-based metabolite profiling was performed as previously described; the procedure results in four fractions containing FAME and hydrocarbons (fraction 1); FFA, sterols, and fatty alcohols (fraction 2); sugars and sugar alcohols (fraction 3); and amino acids, acids, and amines (fraction 4).[12,19] A total of 214 peaks (90 polar and 124 lipophilic) were detected; 60 polar and 77 lipophilic metabolites were identified by comparison of retention indices and mass spectra to those of reference compounds or from MS libraries.[12]

Changes Due to Drought Stress Irrespective of Cultivars. PCA of the GC-MS metabolite profiling data obtained for fractions 1 and 2 from the extended set of cultivars grown under induced drought stress and control conditions, respectively, confirmed the results from the previous study: Differences in lipophilic metabolites were mainly due to seasonal impact rather than to drought stress.[12]

In contrast, PCA of polar fractions 3 and 4 demonstrated that in each season samples subjected to drought stress were clearly separated from those grown under control conditions (Figure 1). The PCA plots are in agreement with those previously obtained for the smaller set of cultivars.[12] The best separation was observed in 2011 (Figure 1B). Again, the clustering in 2010 turned out to be influenced by a distinct aridity period in that season, and the clustering in 2012 also revealed separations according to growing location under the control conditions (Figure 1A,C). Importantly, the separation due to the factor growing conditions was still observed even when the data from all seasons were combined (Figure 1D).

These multivariate analyses revealed that the polar fractions are the most prominent metabolites contributing to a differentiation of barley grown under control conditions and induced drought, respectively. Therefore, the polar constituents were additionally subjected to univariate statistical analysis on the basis of the mean values of all cultivars. On the basis of the employed cutoff threshold, 49 components were assessed via ANOVA and Tukey's test. There were metabolites for which the responses were either significantly decreased or increased upon drought stress compared to C1 and C2, irrespective of the cultivar. They were the same 16 as those previously reported for the smaller set of cultivars;[12] the 13 identified metabolites including, for example, the monosaccharides fructose and glucose, the trisaccharide raffinose, the sugar alcohol mannitol, several organic acids, the biogenic amine γ-aminobutyric acid (GABA), and the amino acid glutamic acid are listed in Table 2.

They comprise many metabolites commonly reported to be involved in adjustment mechanisms to drought, such as

fructose, glucose, raffinose, mannitol, several organic acids, and the well-known stress marker GABA.[4,5,12,29−34]

The data demonstrate that responses to drought stress commonly known for plants and their vegetative tissues are not readily transferable to grain. For instance, levels of mannitol and glutamic acid decreased due to drought stress in barley grain, but have been described to be increased in vegetative tissues of several plants.[4,30,32] These differences in responses of metabolites to drought stress depending on the investigated tissue are in line with the results reported by Harrigan et al. in grain of maize hybrids grown under different water regimens.[9] Changes in the contents of raffinose, mannitol/sorbitol, and several organic acids observed in grain from drought-stressed maize were in accordance with those found in the present study.

For some of the constituents shown in Table 2, changes in concentrations upon stress have been reported to depend on the adaptation of the plant. For example, Sanchez et al. found species-specific differences for plant tissue of legumes with regard to their quantitative response to drought stress for fructose.[8] Levels of tricarboxylic acid cycle intermediates increased in leaves of a tolerant barley cultivar due to salinity stress, but were unchanged in a sensitive cultivar.[35] Analyzing drought-stressed rice grain, Nam et al. found increasing GABA, fructose, and glucose levels especially in the drought-tolerant genotypes.[10] For barley grain such correlations between the drought stress-induced responses of these metabolites and the degree of adaptation of the different cultivars could not be found.

Cultivar-Dependent Changes Due to Drought Stress. To reveal cultivar-specific changes in the responses of polar metabolites upon drought stress, statistical analysis (ANOVA, $p < 0.01$) of the polar metabolites was subsequently performed not on the basis of the mean values of all cultivars but for each individual cultivar. For 19 constituents the responses were not statistically significantly different; 30 metabolites including those from Table 2 showed significant results for at least one cultivar.

For two of the constituents presented in Table 2, mannitol and succinic acid, significant decreases and increases, respectively, were found for each cultivar. For the remaining metabolites, there were individual cultivars that did not show significant changes. However, despite these cultivar-specific results, the data of the 13 metabolites from Table 2 did not allow a correlation to be established between the number of significant differences and the degree of drought stress adaptation.

On the other hand, the components shown in Table 3 turned out to exhibit statistically significant differences corresponding to groups of cultivars. The stress-susceptible cultivar 'Barke' and the two cultivars 'Marnie' and 'Iron', for which no drought resistance/tolerance had been described, were characterized by significant changes, particularly for the branched-chain amino

acids (BCAAs) valine, leucine, and isoleucine, for alanine and threonine, and for *myo*-inositol. In the reportedly stress resistant/tolerant cultivars ('Mackay', 'Palmella Blue', 'IPZ 24727') these compounds were not significantly changed. This group of cultivars, in turn, showed significant differences for the amino acids glutamine, asparagine, and serine and, in addition, for pyroglutamic acid and putrescine. The drought-resistant cultivar 'Argentinian (Arg.) Mutant 6519' did not show significant differences at all. Among the remaining cultivars ('Steina', 'Streif', 'Emperor', 'Polygena'), for which no

Sums of concentrations of free amino acids alanine, valine, leucine, isoleucine, proline, tryptophan, serine, threonine, aspartic acid, asparagine, glutamine, lysine, tyrosine, and phenylalanine. Dotted bars indicate (A) stress-resistant/tolerant cultivars, and plain bars indicate (B) cultivars reported to be either stress susceptible or without specific reports on drought resistance/tolerance. Two field replicates were analyzed each in triplicate. Gray bars, control location 2; white bars, control location 1; black bars, rain-out shelter.

drought resistance/tolerance had been described, only 'Streif' (alanine) and 'Emperor' (threonine) showed significant differences.

Quantitation of Proteinogenic Free Amino Acids. The data shown in Table 3 indicate that changes in the contents of proteinogenic free amino acids might be of importance as potential markers for the degree of drought stress adaptation in barley cultivars; therefore, these metabolites were quantitated. The mean values of the concentrations of proteinogenic free amino acids across 2010−2012 showed a high dependency on the growing season. Therefore, in a subsequent step only values that were consistently changed across the three consecutive growing seasons were assessed (Figure 2). In total, 44 consistent changes for single cultivars across three consecutive growing seasons were found; thereof, 20 changes were found to be significant. On the basis of the consistent changes, the following rule was observed: For stress-tolerant/resistant cultivars amino acid concentrations decreased, whereas for cultivars for which no drought resistance/tolerance had been described, levels of amino acid concentrations increased due to water deficit, except for the changes in concentrations of aspartic acid in 'Iron' and phenylalanine in 'Polygena'. This phenomenon of increasing concentrations of amino acids was particularly pronounced for BCAAs as well as for their precursor threonine in the stress-susceptible 'Barke' and in 'Marnie' and 'Iron', for which no drought resistance/tolerance had been described. In contrast, Bowne et al. reported BCAAs to be increased in leaves independent from the different tolerance levels of the investigated wheat plants as a response to water deficit treatment.[11] In leaves of drought-stressed *Arabidopsis* plants from one cultivar, levels of leucine and valine were increased, whereas levels of isoleucine were decreased.[7] In shoots of barley seedlings subjected to drought, the expression of a branched-chain amino transaminase (BCAT) was increased.[36] The authors suggested that increased BCAT expression protects cells from toxic BCAAs levels.[36] The fact that comparable changes (either decreased or increased) as observed for the concentrations of BCAAs have also been seen for threonine reflects their close biogenetic relation.

Proline is an amino acid commonly reported to show increasing levels in plants under drought conditions.[37,38] In the present study, either a consistent decrease or a consistent increase could be found for only one drought-tolerant ('Mackay') and one stress-susceptible ('Barke') cultivar, respectively. Proline accumulated upon drought in leaves of resistant and sensitive barley seedlings, even though many fold higher in drought-resistant than in drought-sensitive cultivars.[18] Similarly, Thakur and Rai found 4- or 3.5-fold increases in maize shoots of resistant or susceptible plants, respectively.[17] For salinity-tolerant barley genotypes, both increasing and decreasing levels of proline were observed in leaves of drought-stressed plants, whereas for one drought-tolerant barley genotype only increasing levels were reported.[39] The cited studies focused on the investigation of vegetative plant tissues and therefore cannot be readily extrapolated to the results found in grain.

Figure 3 shows the sums of the concentrations of proteinogenic free amino acids. In accordance with the results found for the individual amino acids, for the stress-susceptible 'Barke' and for 'Marnie' and 'Iron', for which no drought resistance/tolerance had been described, distinct increases of the sums of proteinogenic free amino acids were found for drought-stressed samples in the three consecutive growing seasons. In contrast, for the other cultivars for which no drought resistance/tolerance had been described and for stress tolerant/resistant cultivars, there were no consistent results for the investigated growing seasons.

Changes in the levels of free amino acids as a general response to stress and also specifically to drought have been described for several plants including barley; in most of the studies the concentrations of free amino acids have been shown to increase upon stress.[6,40−43] For leaves and roots/shoots of drought-stressed barley plants both increases and decreases of free amino acids have been reported.[13,44] However, only a few studies focused on the impact of water deficit in light of differences between cultivars regarding their adaptation to drought. Thakur and Rai demonstrated that in shoots of a resistant maize cultivar, concentrations of amino acids were much more increased than in a susceptible maize cultivar subjected to drought.[17] Similarly, in leaf blades of maize hybrids levels of amino acids increased due to drought stress except for one genotype, which was the only fully susceptible genotype.[45] In potato tubers from a drought-sensitive genotype free amino acids valine, leucine, and tyrosine increased, whereas in the drought-tolerant genotype they were decreased due to severe drought stress induced in a glasshouse experiment.[46] In leaves and roots of barley cultivars, it was shown that the more sensitive cultivar 'Clipper' had elevated levels of amino acids due to salinity stress.[35] In contrast, levels of free amino acids from leaves of wheat were all increased, although the

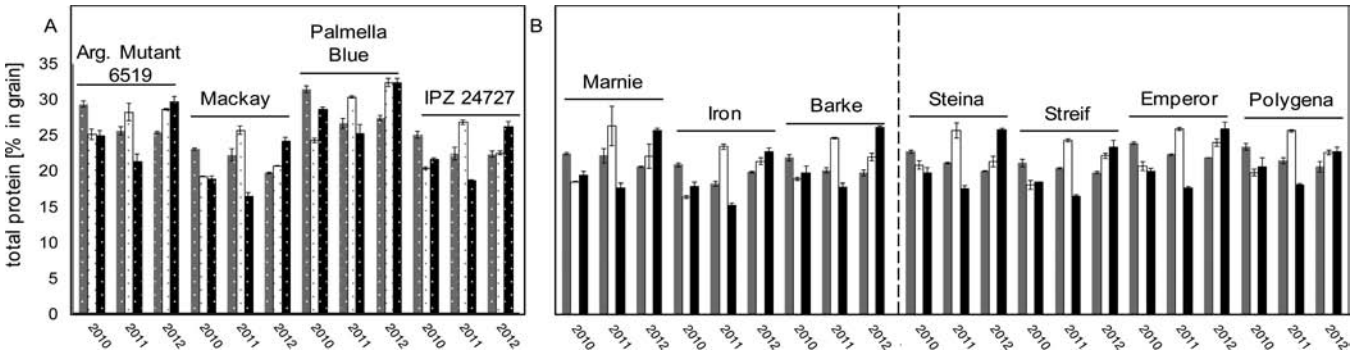

Figure 4. Concentrations of protein in grain (wt %) calculated as means of two field replicates. Dotted bars indicate (A) stress resistant/ tolerant cultivars, and plain bars indicate (B) cultivars reported to be either stress susceptible or without specific reports on drought resistance/tolerance. Gray bars, control location 2; white bars, control location 1; black bars, rain-out shelter.

investigated cultivars differed in their degree of drought tolerance.[11]

In the present study, increasing concentrations of proteinogenic free amino acids were observed only in cultivars for which no drought resistance/tolerance had been described. In contrast, decreasing levels upon drought stress were found only for stress-resistant/tolerant cultivars. However, this correlation was valid only if the results were consistent across all investigated growing seasons. This requirement of a strict restriction to consistent results is in accordance with the concerns expressed by Harrigan et al.;[9] they observed cultivar-specific differences in the changes of the concentrations of free amino acids in grain from maize hybrids, but did not consider them reliable because data were available from only one season.[9]

Another aspect that has to be considered is the dependency on the time interval during which drought treatment was induced. Harrigan et al. investigated grain from maize hybrids exposed to drought during the vegetative or the grain-filling developmental stages.[9] Taking into account the different points of treatment, they found opposite changes (decreases or increases) in the concentrations of some constituents.[9] Similarly, on the basis of targeted analyses of reducing sugar, starch, and protein, time-dependent compositional changes in grain from salinity-stressed rice plants have been observed.[47] The experimental setup employed in the present study does not allow the drought treatment to be assigned to one specific time point. Therefore, an interpretation of the data taking the plants' developmental stage into account is not possible.

Protein and Protein-Derived Amino Acids. Changes in proteinogenic free amino acids upon stress are frequently attributed to protein synthesis/degradation.[6,35] Therefore, it seemed reasonable to investigate not only the changes in the levels of free amino acids but also those of protein and protein-derived amino acids.

In 2011, the protein contents were decreased due to drought stress (rain-out shelter versus C1) in all cultivars, whereas in 2010 and 2012 the protein contents were increased in 64 and 77%, respectively, of the samples. Thus, the protein content is highly dependent on the growing season and less affected by drought (Figure 4).

The spectra of total (free and protein-derived) amino acids were analyzed in combined samples (field replicates 1 and 2) of the drought stress tolerant cultivar 'Mackay' and the stress-susceptible cultivar 'Barke' from 2011. The concentrations of all amino acids decreased due to water deficit, except for cysteine/cystine (sum calculated as cysteine) of cultivar 'Barke' (data not shown).

There are reports of increasing protein contents in kernels of barley plants subjected to drought.[48,49] Except for methionine, levels of total (free and protein-derived) amino acids were reported to be increased in grain of drought-stressed barley plants for each genotype, irrespective of the different adaptations to water deficit.[48] In the present study, the protein content was found to be highly dependent on the growing season. There was no correlation between the levels of protein or protein-derived amino acids, as determined by NIT or by amino acid analyzer, and the levels of free amino acids, as determined by GC-MS metabolite profiling, with regard to their responses to drought stress. This is in agreement with previously reported results that protein in barley grain is unaffected by water deficit.[50] Therefore, consistent changes of proteinogenic, free amino acids in correlation with the degree of drought stress adaptation of different cultivars cannot be attributed to an altered degradation/incorporation into protein.

In conclusion, this study, on the one hand, confirmed that there are metabolites which are significantly changed, either consistently increased or consistently decreased in all cultivars, in barley grain upon drought stress. On the other hand, responses of proteinogenic free amino acids were shown to be suitable for a classification of barley cultivars depending on their adaptation to drought. The well-known environmental variability of the concentrations of free amino acids was also observed under the experimental setup employed in this study; nevertheless, it could be demonstrated that changes which were consistently expressed for three growing seasons correlated with the degree of drought stress adaptation reported for the respective cultivar. Consistent increases of the concentrations of proteinogenic free amino acids were observed only in cultivars for which no drought resistance/tolerance had been found, whereas consistent decreases were seen only in the group of stress-tolerant/resistant cultivars. These cultivar-specific correlations were particularly pronounced for BCAAs; however, in principle they are valid for all amino acids, and the assignment of a cultivar is stronger the higher the number of amino acids exhibiting these consistent increases and decreases in concentrations, respectively.

The application of the described prediction model resulted in a correct assignment of all four stress-tolerant/resistant cultivars ('Arg. Mutant 6519', 'Mackay', 'Palmella Blue', 'IPZ 24727') investigated in the present study. Among the seven cultivars for which no drought resistance/tolerance had been described, five

DOI: 10.1021/acs.jafc.5b01114
J. Agric. Food Chem. 2015, 63, 4252−4261

('Marnie', 'Iron', 'Barke', 'Streif', 'Emperor') were correctly classified. Two cultivars could not be properly assigned because either no consistent change could be observed ('Steina') or the only observed consistent difference was based on a decrease rather than an increase of the amino acid ('Polygena').

Of course, the general validity of the observed consistent changes of the concentrations of free amino acids in grain as a parameter for the prediction of the adaptation of barley cultivars to drought stress needs confirmation in further field trials with additional cultivars. In particular, issues such as the responses of free amino acids depending on the developmental stage of the plant during which drought stress occurred would have to be investigated. Nevertheless, the data emphasize that metabolite profiling can serve as a tool supporting breeders to select cultivars that are able to cope with drought stress. To increase the usefulness of the described approach in breeding or for farmers, it should be investigated whether the potential markers are also confirmed under more time-saving experimental conditions, for example, in the glasshouse. This could pave the way to the use of metabolite profiling as a technique assisting in the screening of drought-tolerant barley cultivars at an early stage of the breeding process.

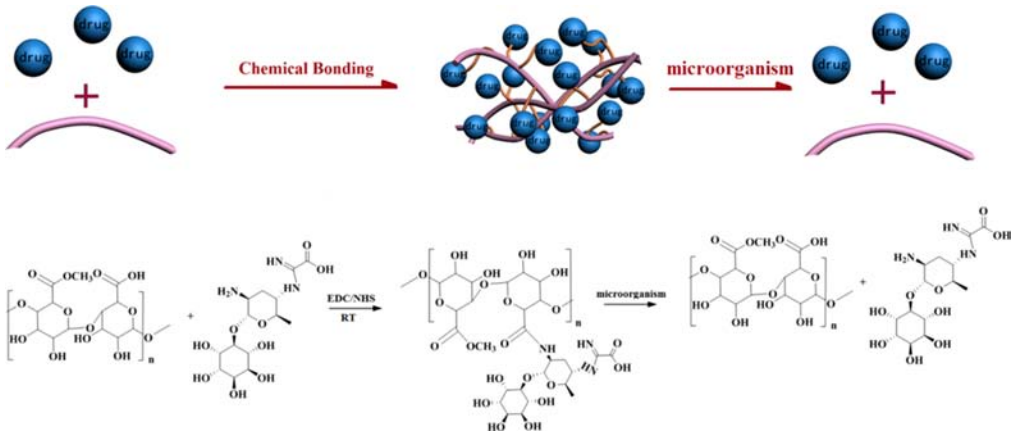

Figure 1. Reaction scheme of kasugamycin with pectin molecule.

(TGA). The stability of the conjugate under conditions of various pH, temperature, and UV irradiation and its release property triggered by Psl were investigated.

MATERIALS AND METHODS

Chemicals, Reagents, and Materials. Pectin (70 kDa, degree of esterification = 25%) was purchased from Quzhou Pectin Co., Ltd. (Zhejiang, China). Kasugamycin was obtained from the reference material service center of the National Institute for the Control of Pharmaceutical and Biological Products (Beijing, China). All other reagents were purchased from J. T. Baker (Phillipsburg, NJ, USA) and were of ACS grade or better. Milli-Q water used in all experiments was obtained in the laboratory using a Milli-Q water purification system (Millipore, Billerica, MA, USA). The 0.1 M phosphate-buffered solutions with pH 5.0, 7.0, and 8.5 were prepared by mixing 0.1 mol L^{-1} NaH_2PO_4 solution with 0.1 mol L^{-1} Na_2HPO_4 solution. The glycine buffers with pH 3.0 and 10.5 were prepared by mixing 0.05 mol L^{-1} glycine, 0.2 mol L^{-1} HCl solution, and 0.2 mol L^{-1} NaOH solution. Luria–Bertani (LB) medium was prepared with 0.5% NaCl, 0.5% yeast extract, and 1.0% peptone, and the pH was adjusted to 7.0 with 5 N NaOH before autoclaved sterilization. M9 minimal medium was prepared by mixing liquid A (0.05%NH_4Cl, 0.3% Na_2HPO_4, 0.15% KH_2PO_4, autoclaved sterilization) and liquid B (0.05% $MgSO_4 \cdot 7H_2O$, 0.0011% $CaCl_2$, 0.4% glucose, filter sterilization). Psl was obtained from the Laboratory of Seed Pathology and Fungicide Pharmacology, China Agricultural University.

Synthesis of Kasugamycin–Pectin. Due to the steric hindrance of the polysaccharide backbone and low reactivity of the carboxyl group, direct conjugation of kasugamycin to pectin is inefficient. Therefore, EDC and NHS were utilized to form the amide bond between the amino group in kasugamycin and the carboxyl group in pectin. The reaction scheme of kasugamycin with pectin molecule is presented in Figure 1. Briefly, pectin (1.0 g), EDC (1.15 g), and NHS (0.69 g) were dissolved in 20 mL of H_2O, stirring at 200 rpm for 30 min. Then kasugamycin (1.5 g) dissolved in 5 mL of H_2O was added dropwise into the reaction mixture under vigorous stirring at 1200 rpm. The whole solution was adjusted to pH 6 with 1 N HCl and kept at 4 °C for 24 h. Finally, the solution was precipitated and washed sufficiently with acetone, and the residue was filtered and then dried at 60 °C in an oven.

Characterization of Kasugamycin–Pectin. The product was sufficiently dialyzed against water using a dialysis membrane (MWCO 10 kDa; Spectrum Laboratories, Laguna Hills, CA, USA) for 3 days (water changed every 12 h), until the kasugamycin could not be detected in the water, and then vacuum-dried at 313 K for characterization.

Fourier Transform Infrared Spectroscopy. FT-IR spectra, recorded on a Jasco FT-IR 5300 spectrophotometer, were used to compare the structures of kasugamycin, pectin, and kasugamycin–pectin. Samples were prepared as KBr pellet and scanned against a blank KBr pellet background at wavenumbers ranging from 4000 to 450 cm^{-1} with a resolution of 4.0 cm^{-1}.

Ultraviolet Spectrophotometer. UV–vis experiments were performed with a UV-2100S spectrophotometer (Shimadzu, Tokyo, Japan) to compare the difference in UV absorption among kasugamycin, pectin, and kasugamycin–pectin.

Thermal Gravimetric Analysis. TGA was carried out with an SDT Q600 (TA Instruments-Waters LLC, New Castle, DE, USA) analyzer from 25 to 600 °C with a heating rate of 10 °C/min.

Determination of Kasugamycin. Kasugamycin was detected by using the HPLC method referenced from Ceshing Sheu with improvement.[31] Briefly, the mobile phase consisted of eluent A, acetonitrile, and eluent B, water with 0.1% H_3PO_4 and 0.1% sodium dodecyl sulfate (SDS) (40:60 v/v). An analytical C_{18} ODS column (250 mm × 4.6 mm, 5 μm; DIKMA, Beijing, China) was equipped with a guard column (4 mm × 3 mm) and pre-equilibrated with the mobile phase for about 40 min before analysis. The injection volume was 20 μL. The detection wavelength was 210 nm (LC-20ATvp, purchased from Shimadzu), and the flow rate was kept at 1.0 mL min^{-1}. Each sample was assayed in six replicates, and all of the assays were carried out at ambient temperature.

Substitution Degree for Kasugamycin–Pectin. The substitution degree for kasugamycin–pectin was defined as the ratio of the number of carboxyl groups coupled with kasugamycin to the number of total carboxyl groups of pectin, which can be determined by using the phenolphthalein method revised from the United States Pharmacopoeia.[32] One gram of pectin was acidized for 10 min by a mixture 5 mL of hydrochloric acid and 100 mL of 60% alcohol. Then it was filtered and washed until the filtrate was chloride free and then was dried. After cooling, the pectin was moistened by alcohol and dissolved in carbon dioxide-free water. Then phenolphthalein TS was added to the pectin solution, which was then titrated with 0.5 N sodium hydroxide. The consumed volume was recorded as the initial titer, V_i. The purified conjugate with same amount of pectin was tested in the same way, and the titer was defined as V_a.

The substitution degree for kasugamycin–pectin was calculated as

$$\text{substitution degree} = \frac{V_i - V_a}{V_i} \times 100\% \quad (1)$$

The mass ratio of kasugamycin in the conjugate was calculated as

$$\text{mass ratio of kasugamycin} = \frac{M_{r,k} \times (V_i - V_a) \times C_{NaOH}}{1 + M_{r,k} \times (V_i - V_a) \times C_{NaOH}} \times 100\% \quad (2)$$

C_{NaOH} is the concentration of sodium hydroxide, and $M_{r,k}$ is the relative molecular mass of kasugamycin.

Stability of Kasugamycin–Pectin. The stability of kasugamycin–pectin was measured as the release rate of kasugamycin from the conjugate under different conditions. Kasugamycin–pectin with a

DOI: 10.1021/jf5055062
J. Agric. Food Chem. 2015, 63, 4263–4268

kasugamycin concentration of 20 mg L^{-1} was dissolved in buffer at different pH values (3.0, 5.0, 7.0, 8.5, 10.5) and at different temperatures (25, 35, 45 °C) to study the hydrolysis property. The effect of UV irradiation (high-pressure mercury lamp; light intensity = 700 $\mu W/cm^2$ detected using ZDZ-1 UV irradiation photometer) on the release of kasugamycin−pectin was also investigated. The technical, a mixture of kasugamycin and pectin with equivalent amounts of kasugamycin and pectin, was set as control. Equal known aliquots of sample were sealed in dialysis tubing (10000 MWCO) and suspended in buffer solutions under different condition. The dialysis tubes were shaken in a shaking water bath and sampled at 2 mL at predetermined intervals. Each sample was evaporated under a stream of nitrogen at 25 °C for concentration, and then the residue was reconstituted to 0.5 mL with the same buffer and vortex-mixed for 1 min. The resulting solution was filtered through a 0.45 μm filter membrane and determined by HPLC to measure the amount of kasugamycin. Each sample was repeated in triplicate.

Kasugamycin Released by Psl from Kasugamycin−Pectin. *Pathogen Culture and Inoculum Preparation.* *Pseudomonas syringae* pv. *lachrymans* was streaked on a nutrient agar plate and cultured for 24 h and then incubated aerobically in 10 mL of CM medium at 28 °C in a water bath shaking at 150 rpm for 6 h to yield exponential-phase cells ($OD_{600\ nm}$ of 0.5), which used in all treatments.

Release of Kasugamycin during the Incubation. Two hundred microliters of Psl bacterial suspension was inoculated in 10 mL of CM liquid medium with kasugamycin−pectin at different concentrations (5, 10, 20 mg L^{-1} of kasugamycin), and kasugamycin with the same concentration was used as control. Psl was grown at 150 rpm for 24 h at 28 °C. Each concentration was sampled at 1.5, 3, 4.5, 6, 7.5, 9, and 24 h after inoculation, and the analysis was conducted in three replicates. In each sample, the medium was washed with buffer by centrifugation three times to separate medium from bacteria. Then each medium sample was evaporated under a stream of nitrogen at 25 °C for concentration, and the residue was reconstituted with the same buffer and vortex-mixed for 1 min, followed by filtration through a 0.45 μm filter membrane and analyzed by HPLC to measure the kasugamycin released in the medium. Each sample was repeated in triplicate.

RESULTS AND DISCUSSION

Structural Characterization of Kasugamycin−Pectin. *Fourier Transform Infrared Spectroscopy.* Figure 2 represents the FT-IR spectra of kasugamycin, pectin, and kasugamycin−pectin. Compared with pectin, the kasugamycin−pectin shows peaks at 1676 and 1536 cm^{-1}, which could be attributed to the newly formed amide bond (CO−NH stretch) (Figure 2B). In addition, another characteristic peak at 1725 cm^{-1} corresponding to the carboxyl group in pectin significantly decreases in the spectrum of kasugamycin−pectin (Figure 2A). These indicate that the $-NH_2$ of kasugamycin has reacted with the −COOH of pectin.

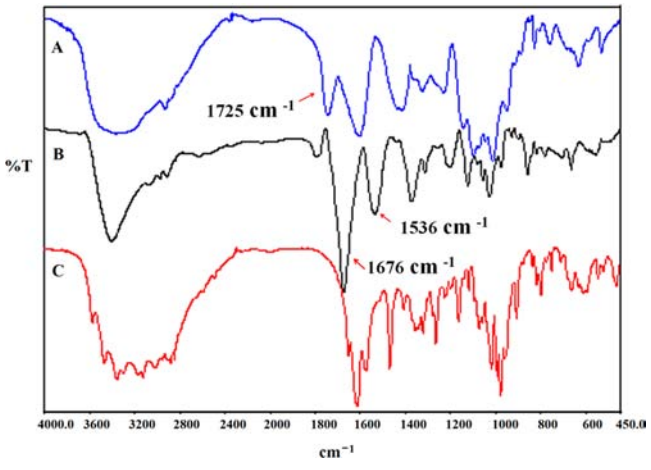

Figure 2. FT-IR spectra of pectin (A), kasugamycin−pectin (B), and kasugamycin (C).

Ultraviolet Spectrophotometer. UV−vis absorption spectra of kasugamycin, pectin, and kasugamycin−pectin from 200 to 450 nm with a magnified spectrum from 240 to 320 nm are analyzed (Figure 3). There are two characteristic peaks at 210 and 280 nm in kasugamycin−pectin, which are attributed to kasugamycin and pectin, respectively. Because the free kasugamycin was removed after dialysis, the absorption spectrum indicated that kasugamycin was assembled with the pectin successfully.

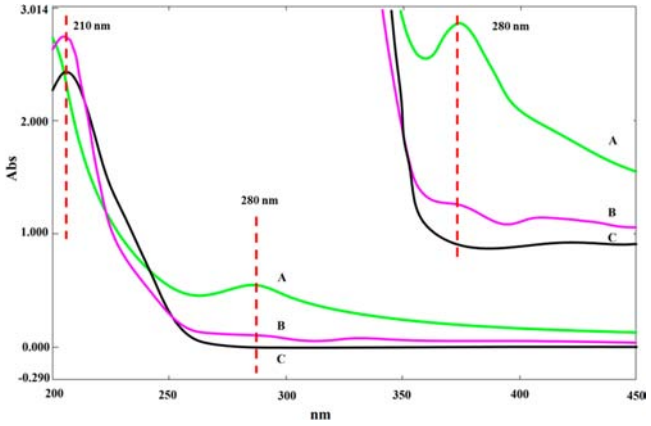

Figure 3. UV−vis spectrogram of pectin (A), kasugamycin−pectin (B), and kasugamycin (C).

Thermal Gravimetric Analysis. Figure 4 illustrates the TGA and DTG curves of kasugamycin, pectin, and kasugamycin−pectin. The results exhibited that about 8.4% weight of pectin and kasugamycin−pectin was lost around 120 °C, because of the water evaporation and decomposition of polymer into smaller molecules. However, the major decomposition of pectin happened around 236 °C, which could be attributed to the splitting of the saccharide rings, and reached about 70% weight loss at 600 °C, whereas kasugamycin−pectin showed this typical weight loss at a lower temperature, 226 °C, and about 85% weight was lost at 600 °C. Kasugamycin decomposed mainly at 197 and 263 °C. The thermal stability of

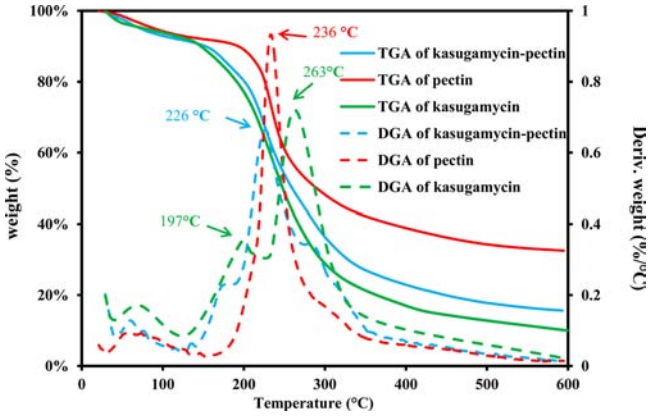

Figure 4. TGA and DTG curves of kasugamycin, pectin, and kasugamycin−pectin.

DOI: 10.1021/jf5055062
J. Agric. Food Chem. 2015, 63, 4263−4268

kasugamycin–pectin is not so strong as that of unmodified pectin because the introduction of the substituent groups decreases the crystallinity of pectin.

Substitution Degree for Kasugamycin–Pectin. According to eqs 1 and 2, the substitution degree of kasugamycin–pectin was 35.7 ± 0.7%. The mass ratio of kasugamycin in the conjugate was 40.5 ± 0.5%. Those results proved that the formation of amide between pectin and kasugamycin was effective. The formation of a new amide bond occurs easily between polymer and ingredient with EDC and NHS.[33,34]

Stability of Kasugamycin–Pectin. To study the hydrolysis property of kasugamycin–pectin, the effects of pH, temperature, and UV irradiation on this conjugate were investigated. The results showed that kasugamycin–pectin was stable at different conditions.

Effect of pH on the Stability of Kasugamycin–Pectin. Figure 5 shows the effects of different pH values (3.0, 5.0, 7.0, 8.5, 10.5) on the stability of kasugamycin–pectin at 25 °C. Technical was unstable in alkaline condition and degraded 22.5, 43.7, and 59.8% at 63 days at pH 7.0, 8.5, and 10.5, respectively. However, kasugamycin–pectin did not release any kasugamycin in the first 3 days and released little kasugamycin at all conditions during the 63 day evaluation. These results suggest that the kasugamycin can be stably kept within kasugamycin–pectin in aqueous conditions.

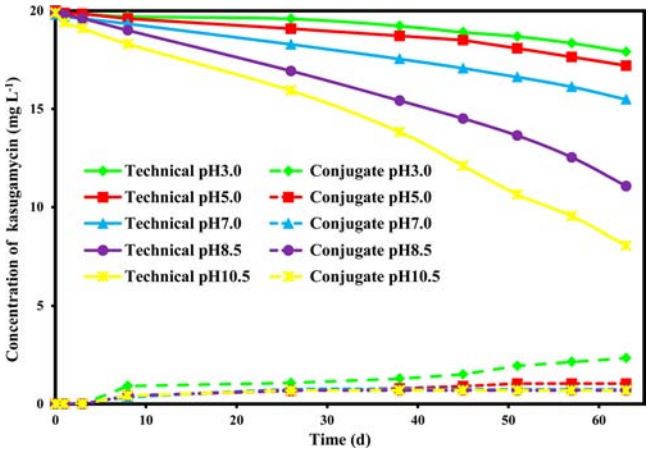

Figure 5. Effect of pH on the stability of kasugamycin–pectin, at 25 °C, without irradiation.

Effect of Temperature on the Stability of Kasugamycin–Pectin. Effects of different temperatures (25, 35, 45 °C) on the stability of kasugamycin–pectin at pH 7.0 are shown in Figure 6. In kasugamycin technical, there are about 11.5, 22.3, and 42.8% of kasugamycin degradation after 30 days at 25, 35, and 45 °C, respectively, but the release percent of the conjugate in all conditions was <9%. These results indicate that the kasugamycin–pectin has good stability against degradation within a wide range of temperatures. This property can be explained by the strong chemical bond between kasugamycin and pectin, and the phenomenon that the release percent of kasugamycin reduces with decreasing temperature indicates that the bond uncoupling can be accelerated by heat.

Effect of UV Irradiation on the Stability of Kasugamycin–Pectin. Kasugamycin–pectin and kasugamycin technical were irradiated under high-pressure mercury lamp (700 μW/cm^2) at pH 7.0 and 25 °C to investigate the effect of UV irradiation on the release of kasugamycin–pectin (Figure 7). The irradiated

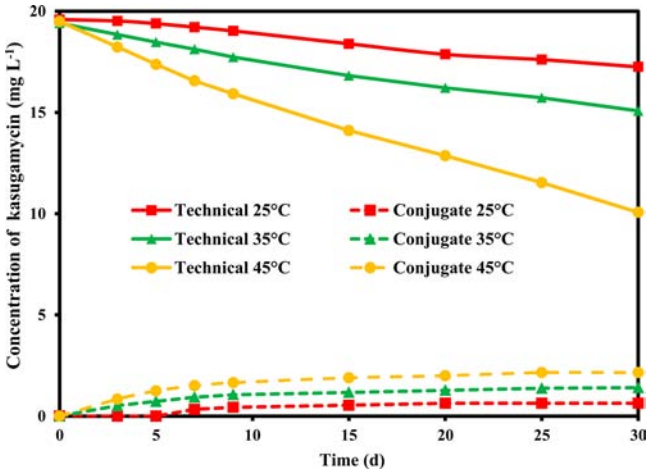

Figure 6. Effect of temperature on the stability of kasugamycin–pectin, at pH 7.0, without irradiation.

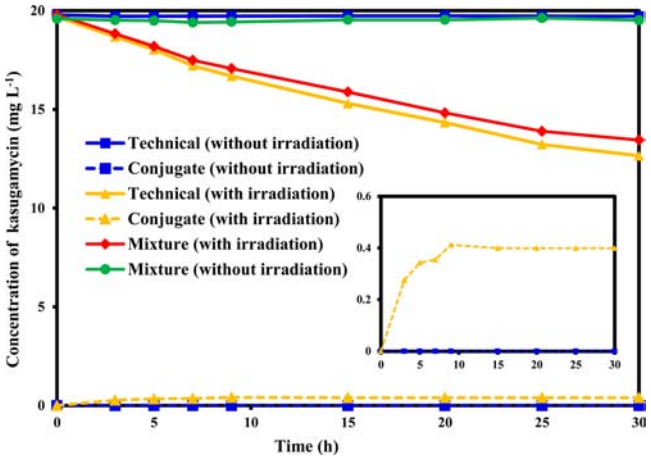

Figure 7. Effect of UV irradiation on the stability of kasugamycin–pectin, at 25 °C, pH 7.0.

kasugamycin technical samples had a 34.3% degradation after 30 h, which was far more than the nonirradiated one (1.95%). Nevertheless, the amount of kasugamycin in kasugamycin–pectin samples showed no significant difference between irradiation and non-irradiation conditions. The results indicate that the kasugamycin–pectin can provide further protection for kasugamycin against sunlight and offer a promising stability of kasugamycin, which guarantees the existence of kasugamycin in the environment for a long time. This fact shows that the concentration of kasugamycin in mixture is a little more than the technical on irradiation condition; therefore, the stability of kasugamycin–pectin relies not only on the chemical bond but also the protection of pectin.

Kasugamycin Released by Psl from Kasugamycin–Pectin. The release rate of kasugamycin from conjugate during the incubation at different concentrations is shown in Figure 8. The concentration of kasugamycin in the kasugamycin–pectin treatment keeps increasing during the incubation. Considering the conjugate exhibits a stable property under different conditions as above, the increased release of kasugamycin is attributed to bacteria. These results indicate that the release of the effective component from the conjugate can be triggered by the release of pathogenic bacteria. The potential underlying mechanism is that the pectin and the amide linkage in

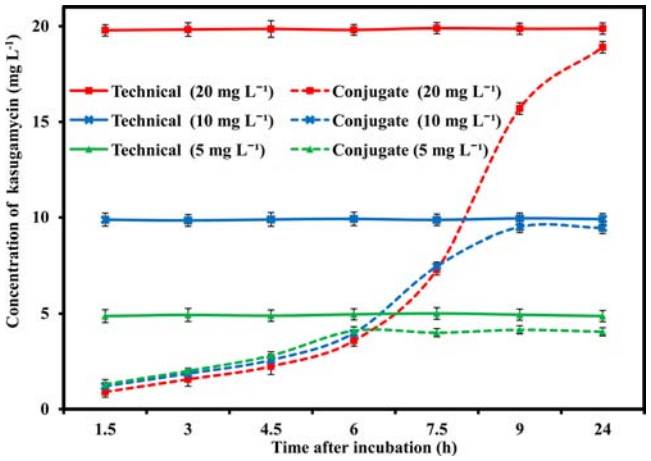

Figure 8. Concentration of kasugamycin in the medium at different times.

kasugamycin−pectin are degraded by enzymes such as pectinase and amidase secreted by Psl, which is a common process of bacterial infection in plant.[27] Noticeably, the release rate of kasugamycin also increased with time; the more enzymes were released during the propagation of bacteria, the more kasugamycin was freed.

In this research, kasugamycin was directly coupled with pectin to form a kasugamycin−pectin conjugate and the conjugate was characterized by FT-IR, UV−vis, and TGA. The results of controlled-release evaluation reveal that the pectin in the conjugate can effectively protect the active agent from degradation, and the conjugate exhibited a sustained release property. The conjugate was degraded by the pathogenic bacteria to release kasugamycin in the process of proliferation. Hence, with high stability and targeted release performance, kasugamycin−pectin can be a promising polymer conjugate in the application of kasugamycin and provide a new method to control plant disease.

18β-glycyrrhetinic acid (**7**)	469.47	425.45	90	40	355.37	90	50

the basis of the literature available, this is the first attempt to determine the extraction efficiency of different samples of TPOMW (several types of drying and degreasing procedures, including the olive stones or not) on their triterpene content. This study is expected to provide researchers information on an efficient extraction method of triterpene compounds from TPOMW for industrial application.

MATERIALS AND METHODS

Materials and Reagents. Oleanolic (**1**) and linoleic (**6**) acid standards were purchased from Fluka (Steinheim, Germany) (Figure 1). Maslinic (**2**) and ursolic (**3**) acids standards were purchased from Sigma-Aldrich (St. Louis, MO, USA). Erythrodiol (**4**) and uvaol (**5**) were purchased from Extrasynthese (Genay, France). 18β-Glycyrrhetinic acid (**7**), also from Extrasynthese, was used as an internal standard. Methanolic-stock standard solutions in the range of 0.05−1.0 μg mL^{-1} were prepared for each analyte and stored at −20 °C. Standard solutions were analyzed by LC−MS daily. HPLC-grade ethyl acetate and methanol were purchased from Sigma-Aldrich (St. Louis, MO, USA). Analytical-grade hexane, from Panreac (Barcelona, Spain), was used for the oil extraction in samples with the Soxhlet method. Deionized water, acetonitrile, and methanol of LC−MS grade, from Waters (Barcelona, Spain), were used for the preparation of chromatographic mobile phases. Formic acid, from Waters (Barcelona, Spain), was used as an additive in the mobile phases to enhance ionization required for MS detection.

Sample Preparation. All samples of TPOMW were obtained from virgin olive-oil extraction using an Abencor laboratory oil mill (MC2 Ingeniería y Sistemas S.L. Sevilla, Spain), which kneaded the olive paste at 28 °C for 30 min. This system provided more homogeneous and representative samples with the control of two key variables, that is, temperature and extraction time, not an easy task in an industrial system.

(A) Fresh sample (FS). Original wet sample from the TPOMW.
(B) Dried sample (DS). The FS was dried in a forced-air oven at 105 °C until constant weight.
(C) Dried-extracted sample (DES). DS was placed in cellulose-extraction thimbles and extracted in a Soxhlet apparatus with 200 mL of hexane for 6−8 h. Then the solvent of the sample without oil was evaporated in a forced-air oven at 60 °C for 6 h. This type of oven has been used given the high stability of the compounds studied.
(D) Dried-sifted sample (DSS). DS was sifted sequentially with a 0.5 mm and a 0.1 mm pore size to separate the olive stones.

Extraction of Triterpene Compounds. The extraction procedure is similar to the method described by Guinda[31] and Romero,[30] with some modifications. That is, 1 g of each sample (FS, DS, DES, or DSS) was mixed, in a 15 mL centrifuge tube, with 10 mL of methanol or ethyl acetate. The mixture was stirred for 1 h and then centrifuged at 4000 rpm for 6 min. Finally, the extract was separated from the solid phase, and the solvent of this extract was removed under reduced pressure. The residue was dissolved in 2 mL of methanol or ethyl acetate and then was filtered through 0.45-μm pore size. This solution was diluted (1:20, v/v) in acetonitrile/water (75:25, v/v) (mobile phase). Finally, this solution was filtered through 0.2-μm pore size, and an aliquot (100 μL in methanol or ethyl acetate) together with 100 μL of a solution of 18β-glycyrrhetinic acid (**7**, 5 mg/L), as an internal standard, was injected into the liquid chromatograph.

UPLC−MS Analyses. The UPLC system consisted of an AcQuity ultra-performance liquid chromatographer equipped with a binary pump system, using an AcQuity UPLC BEH C18 column (100 mm × 2.1 mm, 1.7 μm), all from Waters (Milford, MA, USA). The mobile phase consisted of (A) acetonitrile and (B) water, containing 0.1% formic acid, 75:25 (v/v), and was kept isocratic for 10 min with a flow rate of 0.4 mL/min. During the analysis, the column was kept at 30 °C, and the injection volume was 10 μL.

The UPLC was coupled to a PDA detector AcQuity UPLC and a TQD mass spectrometer (Waters, Milford, MA, USA). The software used was Masslynx 4.1. The wavelength in the PDA detector was set at 205−215 nm. For ionization, an electrospray (ESI) interface was used, operating in the negative mode, and the data were collected in the selected reaction monitoring (MRM). The ionization source parameters were: capillary voltage 3 kV, source temperature 150 °C, and desolvation gas temperature 350 °C with a flow-rate of 650 L/h. Nitrogen (99.99% purity, N2 LC−MS nitrogen generator ZEFIRO 35, Strumenti Scientifici Cinel, Vigonza, Italy) and argon (>99.99% purity, Air−Liquide, Madrid, Spain) were used as cone and collision gases, respectively. The MRM transitions and the individual cone voltage and collision energy for each triterpene compound were evaluated by infusing 5 μg/mL to establish the best instrumental conditions. Two MRM transitions were studied to find the most abundant product ions, selecting the most sensitive transition for quantitation, and a second one for confirmation purposes. For the positive identification of the analytes in the sample, the chromatographic retention time of each analyte should not vary more than 2% compared to the standard, and the relative abundance of the two MRM transitions monitored had to be within 15% of the ratios calculated for the standards (Table 1).

Standards oleanolic, maslinic, ursolic, and linoleic acids, as well as uvaol and erythrodiol, were used to identify peaks. Stock solutions containing 10 μg/mL were prepared by dissolving the standards in methanol and diluted to a series of appropriate concentrations to construct the calibration curve. Triterpene compounds were quantified using a TargetLynx (Waters Inc.) system.

Statistical Analysis of Data. All data are presented as the means ± standard deviation from the independent experiments made in triplicates. The data were evaluated by one-way ANOVA with the Statistix 8 program for Windows, and the differences between means were assessed using the Fisher LSD test. Statistical significance was considered at $p < 0.05$.

RESULTS AND DISCUSSION

UPLC−MS/MS Method Validation. The development of the UPLC−MS/MS method was validated in terms of precision, accuracy, and linearity. The regression curve of the six compounds was drawn using the external-standard method. All of the correlation coefficient ($r > 0.9950$) values indicated appropriate correlations between the concentrations of the investigated compounds and their peak areas, within the test ranges. Assay precision was verified by using six independent tests. The accuracy of the assay method was evaluated in

triplicate using low, middle, and high concentration levels. The limit of detection (LOD) and limit of quantitation (LOQ) were determined by injecting a series of diluted solutions with known concentrations. LOD and LOQ were defined as the signal-to-noise ratio equal to 3 and 10, respectively. These results are shown in Table 2. An internal standard, 18β-glycyrrhetinic acid (7), was added to the fresh TPOMW sample before any handling (extraction procedure, drying, and sifting) to gain information about the recovery of the compounds studied. This recovery was 96.3% for methanol and 99.5% for ethyl acetate.

Comparison of Extraction with Different Solvents. The selection of the most suitable solvent for extracting the analytes of interest from the sample matrix is not only a fundamental step for the development of an extraction method, but also for the solubility of the analytes in the solvent. Methanol, ethanol, ethyl acetate, and diethyl ether are the most frequently solvents used to extract the triterpene acids from plant material.[23,30−33] Ethanol and ethanol/water[29,33] are poor extractors for triterpenes, while better results were achieved with methanol and diethyl ether.

In this study, the solvents methanol and ethyl acetate, for their polarity, were selected for the extraction of the value-added compounds from the TPOMW samples (Table 3). These value-added compounds extracted from TPOMW samples (FS, DS, DES, and DSS) were triterpene acids (oleanolic, maslinic, and ursolic) and diols (erythrodiol and uvaol) (Figure 1). Also, the extract showed a large content in linoleic acid, a fatty acid of the olive oil saponifiable fraction. The extraction results (Table 3) showed that methanol was the most efficient solvent in extracting the value-added compounds from the FS, in agreement with several authors who consider methanol the best solvent,[23,29] probably because the sample contained water. By contrast, ethyl acetate, the best solvent for Romero et al.,[30] proved to be the best extracting solvent with the DSS. With the other samples (DS and DES), the results varied depending on the type of compound analyzed. Thus, ethyl acetate gave the best extraction results with oleanolic and linoleic acids, the less polar compounds, whereas methanol was the best for the more polar products, maslinic acid, and diols (erythrodiol and uvaol). Finally, ursolic acid had the same results of extraction with both solvents.

Effects of the Type of TPOMW Sample Preparation on Their Content of Each Compound. In this study, classic techniques such as drying (DS), drying and olive oil extraction with a Soxhlet (DES), and drying and sifting of the olive stones (DSS) were compared with the FS to analyze the influence of the type of sample on the content of each compound extracted from them.

The average content in oleanolic acid (1) was highly varied for the diverse TPOMW samples (FS, DS, DES, and DSS; Figure 2). The best results of extraction (Table 3) were achieved using the FS with both solvents (2.03 g kg^{-1} in methanol, and 1.81 g kg^{-1} in ethyl acetate) while using the DES with ethyl acetate (1.89 g kg^{-1}). Conversely, with the DS and DSS samples, the extraction of this compound (1) was clearly lower (between 0.82 and 0.55 g kg^{-1}).

Maslinic acid (2) is a more abundant compound in these olive-mill wastes (Figure 2). The average content of this triterpenic acid in the extraction of the diverse TPOMW samples was more regular (between 27.9 and 23.0 g kg^{-1}; Table 3), except for the DS, for which the extraction was considerably lower (15.6 g kg^{-1} in methanol, and 11.7 g kg^{-1} in ethyl acetate).

Table 3. Average Content of Several Value-Added Compounds Isolated from Different Preparations of Two-Phase Olive-Mill-Waste Samples[a]

		solvent extraction	
compound	sample	methanol	ethyl acetate
	FS[b]		
oleanolic acid (g/kg)		2.03 ± 0.25a	1.81 ± 0.43a
maslinic acid (g/kg)		25.5 ± 1.75a	23.7 ± 1.2b
ursolic acid (mg/kg)		287 ± 24a	181 ± 53b
erythrodiol + uvaol (mg/kg)		632 ± 91a	466 ± 61a
linoleic acid (mg/kg)		542 ± 94a	385 ± 31a
	DS[c]		
oleanolic acid (g/kg)		0.74 ± 0.13a	0.82 ± 0.15a
maslinic acid (g/kg)		15.6 ± 1.2 a	11.7 ± 0.8b
ursolic acid (mg/kg)		133 ± 17a	131 ± 14a
erythrodiol + uvaol (mg/kg)		523 ± 122a	400 ± 52a
linoleic acid (mg/kg)		403 ± 16a	449 ± 22a
	DES[d]		
oleanolic acid (g/kg)		1.47 ± 0.27b	1.89 ± 0.15a
maslinic acid (g/kg)		27.9 ± 1.20a	25.2 ± 0.93b
ursolic acid (mg/kg)		169 ± 29a	169 ± 22a
erythrodiol + uvaol (mg/kg)		509 ± 40a	378 ± 28b
linoleic acid (mg/kg)		323 ± 7a	324 ± 8a
	DSS[e]		
oleanolic acid (g/kg)		0.55 ± 0.08b	0.74 ± 0.08a
maslinic acid (g/kg)		23.0 ± 0.64b	25.4 ± 1.5a
ursolic acid (mg/kg)		240 ± 27a	242 ± 39a
erythrodiol + uvaol (mg/kg)		317 ± 28a	348 ± 39a
linoleic acid (mg/kg)		545 ± 63a	626 ± 33a

DOI: 10.1021/jf506171y
J. Agric. Food Chem. 2015, 63, 4269−4275

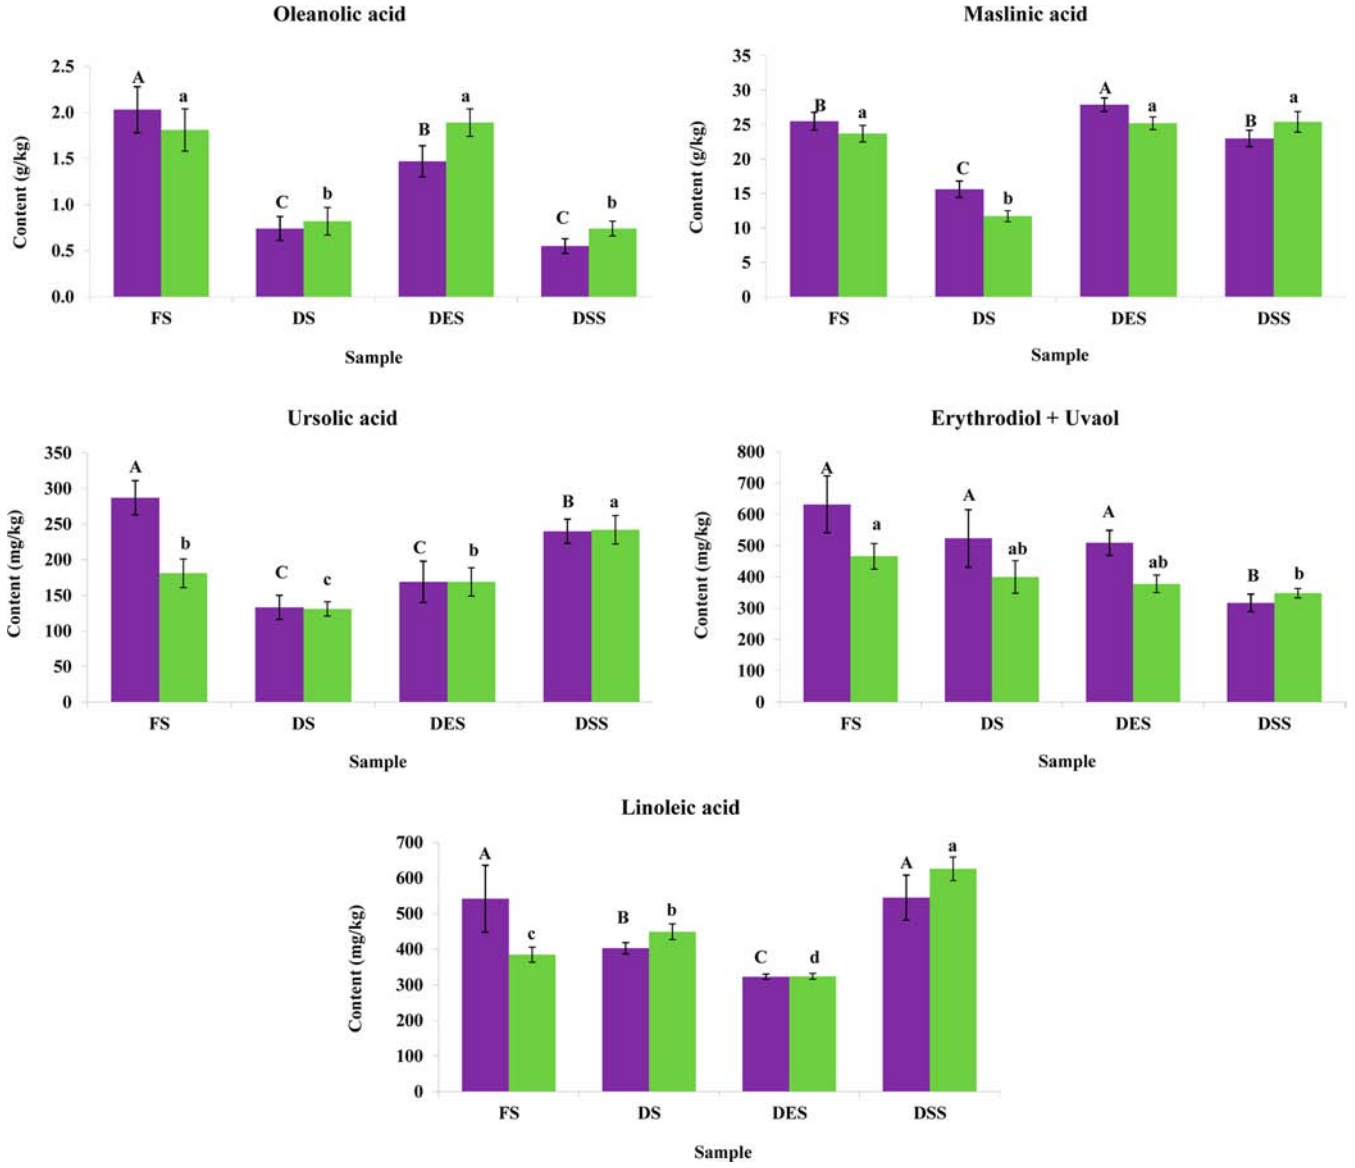

Figure 2. Content of triterpene compounds found using methanol (purple) or ethyl acetate (green) as solvent extraction from the different samples of TPOMW. The results are referenced to the sample weight and expressed as mean ± standard deviation (n = 10). Vertical bars with different capital letters (methanol) or small letters (ethyl acetate) indicate significant differences between the sample preparation process according to the Fisher LSD test at a $P < 0.05$ level of probability.

Ursolic acid (**3**) was the less abundant triterpene acid in these olive-mill wastes (Figure 2). The best extraction result (Table 3) was reached using the FS with methanol (287 mg kg^{-1}), which was clearly higher than with ethyl acetate (181 mg kg^{-1}). In the other TPOMW samples (DS, DES, and DSS), no differences were found between the two solvents, achieving the best extraction results (around 240 mg kg^{-1}) using the DSS.

In summary, the comparison of the average contents of the three triterpene acids (**1**–**3**) of the dried sample (DS) with those of the dried sample extracted in a Soxhlet (DES) suggests that the oil presence in the first sample seems to hinder the extraction of these triterpene acids (Table 3).

The average content of erythrodiol (**4**) and uvaol (**5**) of the diverse TPOMW samples (Figure 2) was higher when the corresponding sample was extracted with methanol (632–509 mg kg^{-1}) than with ethyl acetate (466–378 mg kg^{-1}), except for the DSS sample (Table 3). Therefore, it seems that the elimination of the olive stones from the DS by sifting techniques (DSS) hinders the extraction of the more polar fraction (triterpene diols).

The best results of extraction of linoleic acid (**6**) were achieved from the DSS with both solvents (626 mg kg^{-1} in ethyl acetate, and 545 mg kg^{-1} in methanol) and from the FS with methanol (542 mg kg^{-1}) (Figure 2). In this case, the removal of the olive stones from the DS seemed to help the extraction of the lipid fraction (linoleic acid, **6**) contrary to what happened with the triterpene diols (**4** and **5**).

In conclusion, the analysis of the average content of the different value-added compounds for all the TPOMW samples (FS, DS, DES, and DSS) indicated that for compounds **1**, **3**, **4**, and **5**, the best results were achieved by extraction with methanol from the FS. Furthermore, for compound **2**, the best results were reached also with methanol but from the DES. Finally, for linoleic acid (**6**), the best solvent was ethyl acetate on the DSS.

Study of the Type of TPOMW Sample on the Triterpenic Compound Contents by PCA. When the results of the extraction with methanol of the compounds with higher content (**1**, **2**, **4**, and **5**) on the TPOMW samples (FS, DS, DES, and DSS) were submitted to "principal component analysis" (PCA), we could see that maslinic acid (**2**) explained 98% of the data variance (PC1), whereas oleanolic acid (**1**) and the triterpene diols (**4** and **5**) accounted for only 1% (PC2). The visualization of the four sample types, as well as their distribution into groups according to principal-component scores, is displayed in Figure 3. The groups of

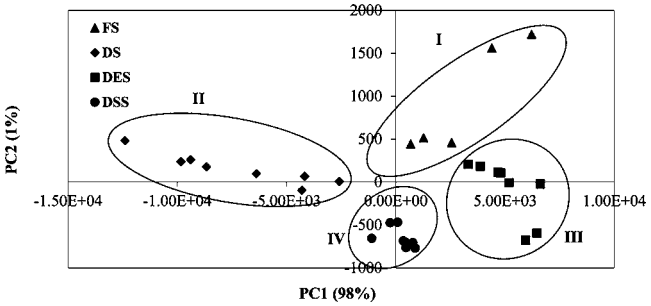

Figure 3. PCA plots for TPOMW samples using the oleanolic acid, maslinic acid, and erythrodiol + uvaol content with their methanol responses. FS (original fresh sample), DS (dried sample), DES (dried-extracted sample), and DSS (dried-sifted sample).

TPOMW samples established were as follows: Group I (FS), very high content of the triterpene compounds analyzed; Group II (DS), high content of erythrodiol + uvaol and low content of maslinic and oleanolic acids; Group III (DES): very high content of maslinic acids and intermediate content of oleanolic acid and erythrodiol + uvaol; and Group IV (DSS), high content of maslinic acid and low content of oleanolic acid and erythrodiol-uvaol.

Loading plot of array is displayed in Figure 4. Maslinic acid presented the highest value for the first principal component

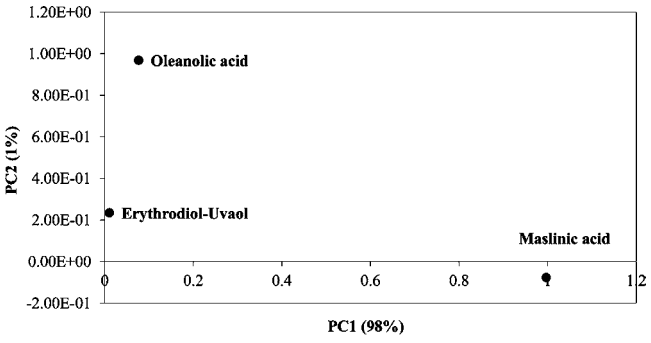

Figure 4. PCA loading plot for TPOMW samples using compounds **1**, **2**, and **3**−**4** content with their methanol responses.

(PC1), and the oleanolic acid had the highest one for PC2, while the triterpene diols (erythrodiol and uvaol) showed lower values for both components (PC1 and PC2).

When the extraction solvent was ethyl acetate and these data were submitted to the PCA (Figure 5), we found that maslinic acid (**2**) explained 99% of the data variance (PC1), while oleanolic acid (**1**) and triterpene diols (**4** and **5**) accounted for only 1% (PC2). Loading plot of array is displayed in Figure 6. Maslinic acid presented the highest value for PC1, and

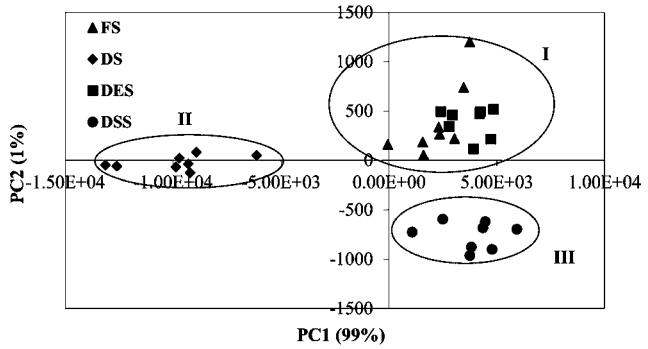

Figure 5. PCA plots for TPOMW samples using oleanolic acid, maslinic acid, and erythrodiol + uvaol content with their ethyl acetate responses. FS (original fresh sample), DS (dried sample), DES (dried-extracted sample) and DSS (dried-sifted sample).

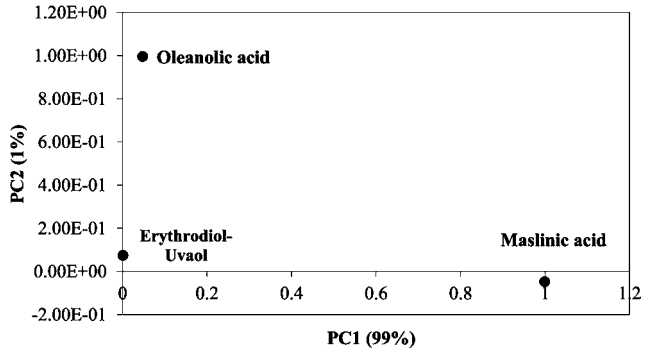

Figure 6. PCA loading plot for TPOMW samples using **1**, **2**, and **3**−**4** content with their ethyl acetate responses.

oleanolic acid had the highest one for PC2, while the triterpene diols (erythrodiol and uvaol) showed lower values for both components (PC1 and PC2). The groups of TPOMW samples established were as follows: Group I (FS and DES), very high content of maslinic and oleanolic acids; Group II (DS), high content of erythrodiol + uvaol and low content of maslinic and oleanolic acids; and Group III (DSS), very high content of maslinic acid and low content of oleanolic acid and erythrodiol + uvaol.

In summary, we describe and validate a UPLC−MS method for separating and quantitating five value-added compounds in several sample-preparation processes of TPOMW. Moreover, these extraction processes offer greater advantage for future applications due to the simplicity and relatively good extraction efficiency. For an industrial DES TPOMW sample, methanol should be used as the solvent for the highest extraction of maslinic acid, and ethyl acetate for oleanolic acid. For the industrial extraction of the highest content of triterpene diols (erythrodiol and uvaol), methanol should be used with a FS TPOMW sample. For the selective extraction of linoleic acid, industry should start from a DSS TPOMW sample and use ethyl acetate as solvent extraction.

In conclusion, the use of these processes for extracting the solid wastes of the olive-oil industry can reduce the environmental impact of these residues, since several bioactive compounds with high value-added can be isolated. These results may contribute to the revaluation of the TPOMW in view of the promising bioactivity properties of the natural triterpene acids.

MATERIALS AND METHODS

Chemicals. Rotundone ((3*S*,5*R*,8*S*)-3,4,5,6,7,8-hexahydro-3,8-dimethyl-5-(prop-1-en-2-yl)-1(2*H*)-azulenone) and $^{2}H_{5}$-rotundone was synthesized as described previously.[2,3] Working solutions of standards were prepared volumetrically in ethanol and stored at 4 °C until required. High-performance liquid chromatography (HPLC)-gradient-grade ethyl acetate, *n*-pentane, methanol, and ethanol were obtained from Rowe Scientific (Doveton, Victoria, Australia). Analytical-reagent-grade potassium L-tartrate monobasic, tartaric acid, and other chemicals were obtained from Sigma-Aldrich (Castile Hill, New South Wales, Australia). Water was purified by the Milli-Q system (Millipore Australia, Bayswater, Victoria, Australia).

Vineyard Site. The study was conducted in a commercial vineyard (The Old Block, Mount Langi Ghiran, 37.31° S, 143.15° E) located in the Grampians wine region of Victoria, Australia. The vineyard is approximately 15.5 km east of the nearest Bureau of Meteorology (BOM) weather station at Ararat Prison (Australian BOM Station 089085), where the long-term mean January temperature is 18.9 °C and annual average rainfall is 587.9 mm, and is classified as a cool-climate production region.[13] The vineyard was planted in 1968 with *Vitis vinifera*, cv. Shiraz on its own roots at 3.0 m between rows and 1.8 m between vines, with rows oriented northeast to southwest. Grapevines are trained to a vertical shooting positioning trellis (VSP). Grapevines are irrigated using drip irrigation when required at a rate of 5.76 L h^{-1} $vine^{-1}$. Weather conditions and irrigation volume for both studied seasons are included in the Supporting Information. No significant pest or disease pressures were observed during the experimental seasons.

Experimental Design and Sampling. The experimental block has been previously divided into three vineyard zones based on plant cell density (PCD), electrical soil conductivity, and slope using the *k*-mean clustering tool. PCD is the ratio of reflected infrared to red light and has been used as a surrogate measure of vine vigor.[11] The values are provided for zone 1 (104, 63.5 mS/m, and 8.3%), zone 2 (174, 45.6 mS/m, and 5.9%), and zone 3 (134, 53.1 mS/m, and 3.4%) for mean PCD, electrical soil conductivity, and slope, respectively (Figure 1A).[11] The three identified zones have different aspects, with zone 1 having a northern aspect, most of zone 2 having a southern aspect, and zone 3 being located along the ridge, having all four aspects (Figure 1B). In the southern hemisphere, a northerly aspect has the highest amount of sunlight exposure. Separating the vineyard into these zones is important to assess the involvement of vine vigor, vineyard soil conductivity, and topography on rotundone accumulation in Shiraz grapes.

Within-Vineyard Variability of Rotundone. Five random field replicates were selected and georeferenced from each of the three vineyard zones (described previously in the study by Scarlett et al.[11]) as the sampling points for bunches (Figure 1A). Each replicate consisted of six vines each distributed in two adjacent rows (three vines in each row). Bunches were sampled from the northwest side of canopies at the time near commercial harvest in two continuous seasons (2011−2012 and 2012−2013) on April 5, 2012 and April 10, 2013, respectively. Commercial harvest was performed between April 11 and 18, 2012 and between April 9 and 16, 2013 with selective hand-harvest first, followed by machine harvest at the later dates. Three bunches of grapes were sampled from each selected grapevine in zip-lock plastic bags, frozen at −20 °C, transferred to the University of Melbourne laboratories in styrofoam boxes on dry ice, and stored at −20 °C before conducting bunch sectorization and laboratory analysis detailed in the within-bunch variability study below. The rotundone concentration in grapes has previously been reported to be stable under normal ambient temperature conditions.[4]

Within-Vine Variability of Rotundone. To assess within-vine variability, shading treatments were applied on three adjacent rows in zone 1 (Figure 1A). This design was chosen to minimize variation between vines because large within-vineyard variation in the berry rotundone concentration was previously reported for this experimental block by Scarlett et al.[11] Within these three rows, four replicates (blocks of six vines each) were separated by six vines as buffers and

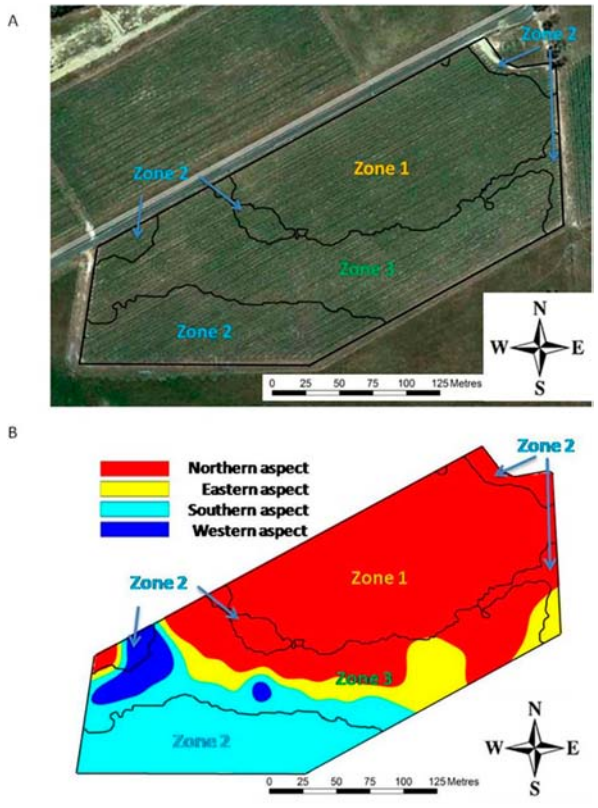

Figure 1. Vineyard zones of the experimental Shiraz block at Mount Langi Ghiran in the Grampians wine region of Victoria, Australia: (A) three vineyard zones previously established by Scarlett et al.[11] and (B) variation in the aspect of the experimental block, generated on the basis of the study by Scarlett et al.[11]

were randomly distributed for each of the following artificial shading treatments for the 2012−2013 growing season: (i) naturally occurring shade [control (Ctrl)], (ii) fruit zone shaded vines from veraison to harvest (FS), and (iii) whole vine shaded from veraison to harvest (WS). Artificial shading was achieved using commercial shade cloth, which is ultraviolet (UV)-stabilized high-density polyethylene (HDPE) shade cloth blocking 56.94% of light and 59.83% of UV (Coolaroo, Gale Pacific, Ltd., Australia).

Within individual vines, grape bunches on two sides of the vineyard row were considered as separated groups because of differing degrees of incident solar exposure. For the FS treatment, the shade cloth was cut into 0.4 m widths and placed on both sides of the fruit zone. For the WS treatment, the whole vine was shaded with the shading cloth (see panels A and B of Figure S1 of the Supporting Information). Sampling was performed at commercial harvest (April 10, 2013). Grape bunches from both sides of the canopy wall were sampled separately. Samples from the northwest-facing side of Ctrl, FS, and WS were labeled as Ctrl-NW, FS-NW, and WS-NW, while samples from the southeast-facing side were labeled as Ctrl-SE, FS-SE, and WS-SE. Three bunches of grapes were sampled from each selected grapevine in zip-lock plastic bags, frozen at −20 °C, transferred to the laboratory in styrofoam boxes on dry ice, and stored at −20 °C before analysis. Total soluble solids (TSS), titratable acidity (TA), and pH of the grape samples were analyzed using a refractometer, an alkaline titration, and a pH meter, following published protocols.[14]

To monitor the fruit zone temperature on both sides of the canopy walls, temperature loggers (Tinytag transit 2, Gemini Data Logger, Ltd., Chichester, U.K.) were placed next to grape bunches on both sides of the canopy for each treatment group, and six temperature loggers were used in total. The loggers were shaded by bunch zone leaves to minimize direct solar exposure. These loggers have an operational range from −40 to 70 °C, with a sensitivity of 0.01 °C.

DOI: 10.1021/acs.jafc.5b00590
J. Agric. Food Chem. 2015, 63, 4276−4283

The temperature was measured every 30 min from veraison (early February) to harvest, and the data recorded were analyzed with Tinytag Explorer software (version 4.7, Gemini Data Logger, Ltd., Chichester, U.K.), following the method described by Winter et al.[15] Fruit zone temperature overtime was calculated as degree hours and reflected the heat accumulated in the fruit zone. Degree hours in different temperature ranges and their percentage to the total degree hours were calculated and associated with the rotundone concentration of grape berries.

Within-Bunch Variability of Rotundone. Grape bunches from the within-vineyard variability study were also used for the within-bunch variability study. All berries from each representative bunch collected were divided into four sectors: top front (TF), top back (TB), bottom front (BF), and bottom back (BB), dependent upon their position in the bunch and bunch orientation in relation to incident solar radiation (Figure 2A). The *X* and *Y* axes in Figure 2A represented the direction of sunlight and vineyard row, respectively. TF and BF sectors were the directly exposed solar side of the bunch, while the TB and BB sectors were shaded. Grape bunches were divided into top and bottom parts with a length ratio of 4:6 to balance the weight of both parts (Figure 2B). Sectorized berry samples were collected in zip-lock plastic bags and stored at −20 °C before conducting laboratory analysis. TSS, TA, pH, total anthocyanins, and total phenolics of bunch samples were analyzed using a refractometer, an alkaline titration, a pH meter, and spectrophotometric measurements at $A_{520\ nm}$ and $A_{280\ nm}$, following published protocols.[14]

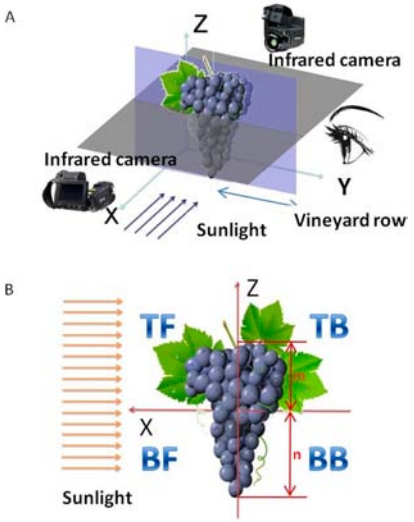

Figure 2. Illustration of grape bunch separation and surface temperature measurement of the within-bunch study: (A) separation of the grape bunch based on the direction of sunlight and vineyard row, with the grape bunch surface temperature being obtained by taking thermal images on both sides of the grape bunch, and (B) separation of the grape bunch into top and bottom parts based on the ratio of the distance between end points of the bunch to separating point (m/n = 4:6).

Infrared thermal images were obtained to assess the variability of berry surface temperatures and distribution within grape bunches from 24 randomly selected vines in the vineyard. The camera had a 0.3 megapixel (640 × 480) microbolometer sensor, sensitive in the temperature range from −40 to 2000 °C, with the thermal sensitivity of 0.04 °C, and a lens with an angular field of view of 25° (T640 model, FLIR System, Inc., Notting Hill, Australia). Thermal images were obtained between 15:30 and 16:00 h (Australian Eastern Daylight Time) on March 26, 2013 from both sides of the row with a distance of approximately 1 m between sampled bunches and the camera (Figure. 3A). Thermal images were processed using the FLIR ResearchIR software (FLIR System, Inc., Notting Hill, Australia). Maximum, minimum, and average surface temperatures of the top and bottom parts of the bunch were analyzed separately, selecting regions of interest manually using the FLIR software.

Preparation of Samples and Solid-Phase Microextraction–Gas Chromatography–Mass Spectrometry (SPME–GC–MS) Analysis of Rotundone. Grape samples were prepared for rotundone analysis based on the protocol described by Siebert et al.[2] Briefly, 100 g of destemmed grapes were sub-sampled before being homogenized using a hand-held blender. Sub-samples were centrifuged to separate the juice and solid parts. The solid parts were mixed with 30 mL of ethanol, 30 mL of water, and 100 μL of d_5-rotundone (516 ng/mL in ethanol) as the internal standard, then shaken for 24 h at 22 °C, and sonicated before adding the juice back. Sub-samples were then centrifuged (10 000 rpm for 20 min at 22 °C) and filtrated (1.6 μm glass fiber) to obtain berry extract filtrate, which was topped up to 200 mL with Milli-Q deionized water before subjected to solid-phase extraction (SPE), performed as reported previously.[2] The SPE residue supernatant collected was dried with nitrogen and reconstituted in 0.5 mL of ethanol and 9 mL of Milli-Q deionized water. The sample was then analyzed and quantified at the Australian Wine Research Institute using a published SPME–GC–MS protocol.[16]

Statistical Analysis. The rotundone concentration, TSS, pH, and TA of the within-vine study samples were analyzed using one-way analysis of variance (ANOVA) at $p < 0.05$ (CoStat, version 6.4, CoHort Software, Monterey, CA). The relationship between the percentage of degree hours under the canopy and the grape rotundone concentration was calculated using MatLab software 2014a (The MathWorks, Inc., Natick, MA). The berry surface temperature, rotundone concentration, TSS, pH, TA, total anthocyanins, and total phenolics of the within-bunch study samples were analyzed using one-way and two-way ANOVA at $p < 0.05$ (CoStat, version 6.4, CoHort Software, Monterey, CA). Data were graphed into a spider plot using MatLab software 2014a (The MathWorks, Inc., Natick, MA).

RESULTS AND DISCUSSION

In this study, we examined the berry rotundone concentration and other grape quality parameters as a function of the berry exposure and berry surface and bunch zone temperature over two growing seasons. Distinct within-vineyard, within-vine, and within-bunch variabilities have been observed in rotundone and other key grape quality attributes in this study. Dissection of the vineyard into distinctly different zones (as per Scarlett et al.[11]), vines into sides based on sunlight orientation, and grape bunches into sectors based on exposure to solar radiation has allowed for the influence of vine vigor, sunlight, and temperature to be considered for berry compositional parameters, including rotundone. Vineyard topography, vine vigor, vine orientation, and bunch orientation together influence grape berry surface/bunch zone temperature and, therefore, can influence grape quality parameters.

Within-Vineyard Variability of Rotundone. The differences in grape quality trait parameters and rotundone concentration between experimental vineyard zones in the 2011–2012 and 2012–2013 growing seasons were examined by two-way ANOVA ($p < 0.01$) (panels A and B of Figure 3). Overall, Shiraz grapes from zone 1 had a significantly lower concentration of rotundone (118.2 ng/kg) compared to zone 2 (196.9 ng/kg) and zone 3 (233.9 ng/kg), while the 2011–2012 growing season had a significantly higher concentration of rotundone overall (346.8 ng/kg) compared to the 2012–2013 growing season (19.2 ng/kg). In the 2011–2012 growing season, the rotundone concentration of Shiraz grapes from zone 2 (373.8 ng/kg) and zone 3 (447.3 ng/kg) was significantly higher compared to zone 1 (219.4 ng/kg) (Figure 3C). However, no statistical significant differences in rotundone were observed among vineyard zones in the 2012–2013 growing season (Figure 3D).

DOI: 10.1021/acs.jafc.5b00590
J. Agric. Food Chem. 2015, 63, 4276–4283

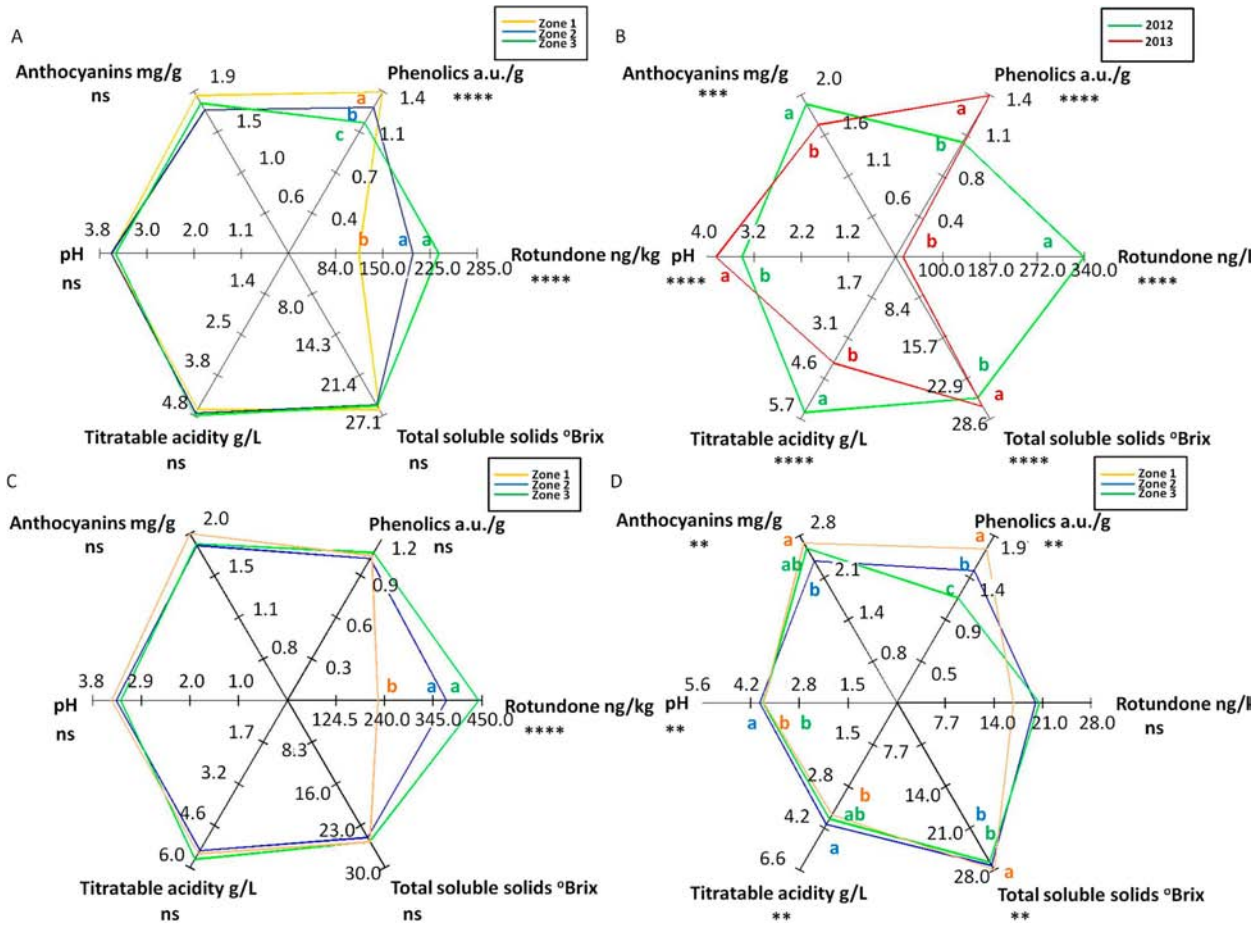

Figure 3. Comparison of the rotundone concentration and quality parameters among vineyard zones in the 2011−2012 and 2012−2013 growing seasons. Two-way ANOVA was conducted considering (A) vineyard zones and (B) growing seasons as two ANOVA independent variables for each quality parameter, while one-way ANOVA was conducted to compare each quality parameter among three zones in individual growing season (C) 2011−2012 and (D) 2012−2013, where ns, *, **, ***, and **** stand for no significant difference, no significant difference but $0.5 \leq p < 0.1$, $p < 0.05$, $p < 0.01$, and $p < 0.001$, respectively. a, b, and c were used to label the differences between experimental groups.

The differences in the grape rotundone concentration between three vineyard zones were associated with variations in vine vigor and, therefore, natural shading. Although vine vigor of the experimental block was measured in 2012, it has been proven to be relatively stable across different growing seasons.[17] The high vigor areas (zones 2 and 3) (Figure 1A, with a PCD index of zone 2 of 174 and zone 3 of 134) had more canopy coverage, mainly a southern, eastern, and western aspect (Figure 1B), and therefore, more natural bunch shading, receiving less direct solar radiation and, as a consequence, a relatively lower bunch zone/surface temperature compared to zone 1 (PCD index of zone 1 of 104), which were associated with the higher grape rotundone concentrations observed in zones 2 and 3, particularly in the 2011−2012 growing season (panels A and C of Figure 3). In the 2012−2013 growing season, where the temperature and solar exposure from veraison to harvest was high, the bunch zone temperature and surface temperatures under shading could still be too high for rotundone accumulation. As a result, no significant differences in the grape rotundone concentration were observed between grape samples from the three vineyard zones (zone 1, 17.0 ng/kg; zone 2, 20.5 ng/kg; and zone 3, 20.0 ng/kg) in the 2012−2013 growing season.

Large differences in the rotundone concentration were observed between the two studied growing seasons (2011−2012 and 2012−2013) (Figure 3B). The variation in the rotundone concentration between the two studied seasons (18-fold) is higher than the differences among vineyard zones (2-fold), the differences between shading treatments (1.7-fold), and the differences among bunch sectors (2-fold). This may be due to the large differences in weather patterns from veraison to harvest between the two studied seasons because rotundone mainly accumulates post-veraison.[16] The 2012−2013 growing season has a higher mean ambient temperature (18.9 °C) and mean solar exposure (18.1 MJ/m^2) from veraison to harvest but a lower total water precipitation (rainfall + irrigation) (208.4 mm) compared to the 2011−2012 growing season (16.7 °C, 16.1 MJ/m^2, and 259.8 mm). Higher temperatures in the 2012−2013 growing season led to higher evaporation and, therefore, more water loss.[18] As a result, higher water deficiency in the 2012−2013 growing season may have decreased vine vigor and natural shading and, therefore, increased the berry surface temperature to influence the grape rotundone concentration. Importantly, the zones and vines that showed high rotundone in the 2011−2012 growing season also show high rotundone in the (lower rotundone overall) 2012−2013 growing season. Thus, the factors contributing to the high or low rotundone accumulation between seasons is constant, despite the overall averages being different in the two seasons studied.

	mean SE	35.4 ± 11.3 B	27.0 ± 1.7 ns	3.83 ± 0.10 ns	4.02 ± 0.23 B	n/a

[a]TSS = total soluble solids. [b]TA = titratable acidity as tartaric acid equivalents. [c]Dh_{25} = percentage of degree hours above 25 °C. [d]Ctrl, control; FS, fruit zone shading; WS, whole vine shading; NW, samples from the northwest side of the canopy; and SE, samples from the southeast side of the canopy. [e]ns = no significant difference ($p < 0.05$). [f]a, b, c, and d represent significant differences ($p < 0.05$) between treatment groups, while A and B represent significant differences ($p < 0.05$) between two sides of the vine. [g]n/a = not applicable.

Differences in grape quality trait parameters were observed among vineyard zones and between study seasons. Overall, significant differences were only observed in the total phenolics among the three zones (Figure 3A). Grapes from the 2012−2013 growing season had significantly higher total phenolics (1.45 au/g), pH (3.89), and TSS (27.0 °Brix) and lower total anthocyanins (1.68 mg/g) and TA (3.91 g/L) compared to the 2011−2012 growing season (1.06 au/g, 3.35, 25.6 °Brix, 1.93 mg/g, and 5.61 g/L) (Figure 3B). The differences in grape quality parameters between vineyard zones were further compared in individual seasons (panels C and D of Figure 3). In the 2011−2012 growing season, no significant differences in grape quality parameters were observed among the three zones (Figure 3C). In the 2012−2013 growing season, zone 1 had significantly higher total anthocyanins, total phenolics, and TSS and lower TA compared to zone 2, while grapes from zone 3 had intermediate levels of most grape quality parameters (Figure 3D).

Within-Vine Variability of Rotundone. A range of grape quality parameters and rotundone concentration were compared between the artificial shading treatments and two sides of the vine canopy (two-way ANOVA; $p < 0.05$) (Table 1). No significant differences were observed between shade treatment groups in the rotundone concentration, while berries from the SE side of the canopy had a significantly higher rotundone concentration compared to those from the NW side. WS treatments had significantly lower TSS (25.8 °Brix) compared to Ctrl (28.1 °Brix) and FS (27.6 °Brix) treatments, while no significant differences were observed between two sides of the canopy in TSS. Ctrl treatments had significantly lower TA (3.74) compared to the FS (3.99) and WS (4.02) treatments, while the NW side (3.81) of the canopy has significantly lower TA compared to the SE side (4.02). No significant differences were observed between artificial shading treatments and two sides of the canopy in pH.

The relationship between rotundone and the fruit zone temperature was explored. The fruit zone temperature over time was calculated as degree hours. Degree hours in different temperature ranges and their percentages to the total degree hours were calculated and associated with the rotundone concentration of grape berries. Percentages of degree hours in different temperature ranges higher than 25 °C (above 35 °C, between 30 and 35 °C, and between 25 and 30 °C) were found to have negative relationships with the grape rotundone concentration (details in the Supporting Information). Therefore, the percentage of degree hours above 25 °C (Dh_{25}) was used to analyze the relationship between the fruit zone temperature and the grape rotundone concentration (Table 1), which was explored in Figure 4. A power curve between the grape rotundone concentration and the percentage of degree hours above 25 °C [$y = 130.6x^{-0.696}$; $R^2 = 0.61$; root-mean-square error (RMSE) = 4.87; and $p = 0.065$] was established. Thus, a higher percentage of degree hours in a temperature range above 25 °C lead to a lower rotundone concentration in the berry.

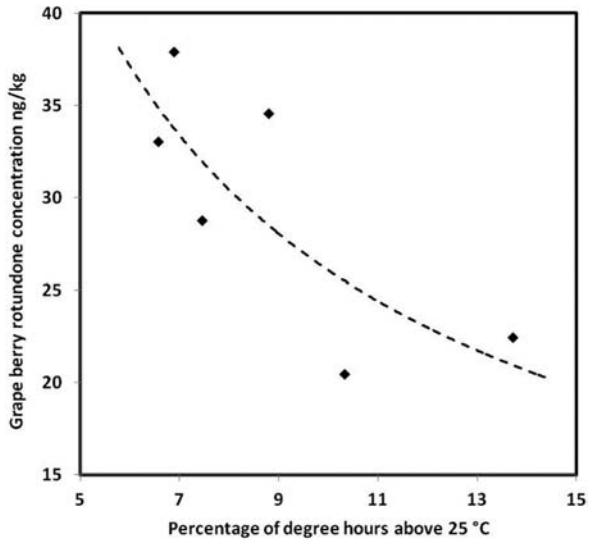

Figure 4. Relationship between the rotundone concentration and the percentage of degree hours above 25 °C in fruit zone from veraison to harvest in the 2012−2013 growing season. The equation for the trend lines is $y = 130.6x^{-0.696}$ ($R^2 = 0.61$; RMSE = 4.87; and $p = 0.065$).

The higher rotundone concentrations of berries located in the shaded side of the rows were associated with lower bunch zone/surface temperature. Because rotundone is found only in the skin of the Shiraz berries[9] and sesquiterpene biosynthesis occurs mainly in the berry skin,[8] this study indicates that the temperature/solar interception of grape berry skins is critical to

J. Agric. Food Chem. 2015, 63, 4276−4283

rotundone accumulation. No significant differences in the concentration of rotundone in grapes were observed among artificial shading treatments (Table 1), likely because of the large variation in the concentration of rotundone among vines. Another possible explanation is that the actual bunch zone solar radiation/temperature is determined not only by the artificial shading but also the natural canopy, which cause more variations in the actual light intensity in the canopy. Therefore, a better way to assess the impacts of shading is to directly study the relationship between the actual bunch zone temperature and the concentration of rotundone in grapes (Figure 4). While the relationship established in Figure 4 ($y = 130.6x^{-0.696}$; $R^2 = 0.61$; and RMSE = 4.87) was not statistically significant ($p = 0.065$), likely because of the small sample size ($n = 6$ shading levels) and large variation in the concentration of rotundone, the data nevertheless suggest the importance of the daytime bunch zone temperature on the concentration of rotundone in berries. Thus, increasing the duration of bunch zone temperatures higher than 25 °C will result in a lower concentration of rotundone in grapes. The impacts of sunlight on grapevine can be separated into direct illumination and indirect solar-radiation-induced temperature increases, which should be investigated separately to test their importance for the accumulation of rotundone in grapes.

Within-Bunch Variability of Rotundone. Grape berry surface temperature data of both the forward and backward sides of the bunch were obtained from thermal images (Figure 2A) taken on March 26, 2013 between 3:30 pm and 4:00 pm, with a mean bunch zone air temperature of 31.4 °C recorded in the vineyard during this period. Grape berry surface temperature data had a wide range, from 30.6 to 42.9 °C with a coefficient of variation (CV) of 8.09% for the maximum surface temperature, from 29.3 to 35.9 °C with CV of 4.57% for the minimum surface temperature, and from 30.05 to 39.05 °C with CV of 6.14% for the average surface temperature (Table 2). As expected, the sun-facing TF and BF sectors of the bunch had significantly higher maximum, minimum, and average surface temperatures than backward-orientated TB and BB sectors (Table 2).

Table 2. Comparison of the Grape Berry Surface Temperature among Four Bunch Sectors in the 2012−2013 Growing Season[a]

within-bunch sectors	grape surface temperature (°C)		
	average	maximum	minimum
TF[b]	34.74 ± 1.84 a[c]	37.11 ± 2.58 a	32.36 ± 1.38 a
TB	32.26 ± 1.44 b	33.27 ± 1.59 b	31.24 ± 1.37 b
BF	34.90 ± 1.88 a	37.13 ± 2.68 a	32.68 ± 1.26 a
BB	32.70 ± 1.64 b	33.79 ± 1.91 b	31.60 ± 1.42 b
overall range	30.05−39.05	30.60−42.90	29.30−35.90
mean (CV[d])	33.65 (6.14%)	35.32 (8.09%)	31.97 (4.57%)

[a]The average surface temperature was calculated by taking the average of maximum and minimum temperatures. [b]TF, top front sector of the bunch; TB, top back sector of the bunch; BF, bottom front sector of the bunch; and BB, bottom back sector of the bunch. [c]a, b, c, and d represent significant differences ($p < 0.05$) between bunch sectors. [d]CV = coefficient of variation.

In both seasons, the TB sector (2011−2012, 493.5 ng/kg; 2012−2013, 25.9 ng/kg) had a significantly higher concentration of rotundone compared to all other sectors ($p < 0.05$) (Table 3). In the 2011−2012 season, the TF sector (339.9 ng/kg) had a significantly higher concentration of rotundone compared to the BF sector (250.2 ng/kg) and the BB sector (303.7 ng/kg) tended to have a higher rotundone concentration compared to the BF sector ($p = 0.091$). No statistically significant differences were observed in the berry rotundone concentration between the TF and BB sectors. In the 2012−2013 growing season, the TF sector (19.2 ng/kg) had a higher concentration of rotundone compared to both BF (15.3 ng/kg) ($p = 0.068$) and BB (16.2 ng/kg) ($p = 0.057$). However, no differences were observed between the BB and BF sectors for berry rotundone concentration. The pattern of rotundone concentration distribution within bunch sectors was consistent across the two seasons.

Three possible reasons may explain the higher concentration of rotundone of berries from the top sectors of bunches (Table 3). First, the variation in the concentration of rotundone might reflect differences in grape surface temperatures because more shading from proximal leaves and/or the canopy and/or bunch architecture with a higher berry number within the top part of bunches could contribute to buffer the temperature of berries from these zones, lowering the surface temperature compared to fully exposed berries. On the contrary, the bottom part of bunches had less buffer capacity to maintain the temperature (in contact with fully exposed berries), which might explain higher temperatures in these sections (Table 2). Furthermore, the lower part of bunches is exposed to radiated transference of heat from the soil. Even though berry transpiration may lower the temperature of all berries, it cannot prevent the temperature increase caused by solar radiation. Therefore, the position of a berry in the bunch is crucial to its temperature, which is associated with its rotundone concentration. Notably, the position of a berry in the bunch might also result in increases in direct precursors to rotundone, such as guaiene, and increased concentrations in rotundone would then reflect the precursor concentrations. A second explanation is that the bottom sector of a bunch typically matures faster than the top sector.[19] The maximum rotundone concentration in grape berries is reached after veraison and slowly decreases afterward in the lead up to harvest.[16] As a result, a more mature bottom sector would have a lower rotundone concentration compared to the later ripening top sectors; i.e., rotundone concentrations would reflect the biochemical differences linked to a variation in maturity. A third possible explanation (the "transport theory") is that a shorter distance from berries to leaves and stems affects rotundone accumulation, because it has been reported that leaves and stems may contain higher concentrations of rotundone than berries and are potentially having a role as a source or storage.[7] This possibility requires an internal transportation mechanism for rotundone in grapevines. In other plant species, namely, *Asarina scandens* (Scrophulariaceae) and *Catalpa speciosa* (northern catalpa), it has been reported that monoterpene glycosides, antirrhinoside, and catalpol can be translocated via phloem transport.[20,21] However, translocation of aroma compounds has been studied in grapevines, with little evidence to show that it is a widespread phenomena. For example, translocation of monoterpene glycosides and their precursors from other parts of the vine into berries is unlikely in Muscat, unless an active transport mechanism exists for a specific compound.[22] In addition, the guaiacol glycosides can translocate between leaves and berries in Cabernet Sauvignon but to a very limited extent.[23] Therefore, there is a possibility that rotundone or a precursor,

[a]Grape berry parameters were not collected in 2011−2012. [b]TSS = total soluble solids. [c]TA = titratable acidity. [d]Bunch sectors are illustrated in Figure 2. [e]a, b, c, and d represent significant differences ($p < 0.05$) between bunch sectors.

to some extent, may be formed elsewhere and is then translocated between berries, leaves, and stems, depending upon the availability of active transportation mechanisms, and this warrants further investigation.

In the 2012−2013 growing season, significant differences in grape quality parameters were observed (Table 3). Berries from the BF sector (26.8 °Brix) had slightly yet significantly lower TSS compared to the BB sector (27.1 °Brix). Berries from the solar exposed side of the bunch (TF and BF) had significantly lower TA and higher pH compared to their corresponding shaded side (TB and BB). In addition, berries from the TB sector had significantly higher total anthocyanins (1.77 mg/g) and total phenolics (1.58 au/g) compared to the bunch TF sector (1.64 mg/g and 1.35 au/g).

The differences in grape quality parameters between studied seasons and among vineyard zones, shading treatment groups, and bunch sectors are associated with berry surface temperature and solar radiation. Higher TSS has been shown with greater sunlight exposure and temperature and may explain the variances between studied seasons (Figure 3B), among vineyard zones (Figure 3D), shading treatments (Table 1), and bunch sectors (Table 3).[24,25] Higher temperatures stimulate respiration and modify organic acid metabolism, leading to decreased malate and citrate concentrations and, therefore, a likely decrease in TA and increase in pH.[26] As a result, berries from the warmer season (2012−2013) (Figure 3B) and the exposed sectors of bunch (Table 3) had higher pH and lower TA, while the unshaded treatment groups and the northwest side of the vine had lower TA (Table 1). A high temperature (>35 °C) has been shown to reduce the grape anthocyanin concentration, which explains the lower total anthocyanin concentration in the berries from the warmer season (2012−2013) (Figure 3B) and the exposed bunch sectors (Table 3).[27] However, moderate solar exposure increases anthocyanin concentration in grape berries, which explains the relatively higher concentration of total anthocyanins in berries from the low vigor zone (zone 1) (Figure 3D).[25,28] A previous study has demonstrated that the concentration of total phenolics increases gradually with increasing solar exposure and becomes relatively stable under higher solar exposure levels.[25] This is consistent with the higher total phenolics observed in the berries from the higher solar intensity season (2012−2013) and lower vigor zone (zone 1) (panels A, B, and D of Figure 3). However, the shaded bunch sectors tend to have higher total phenolics than the exposed sectors (Table 3), which may be due to degradation of certain phenolics under a higher temperature, such as anthocyanins.[27] In addition, grape quality parameters tend to be more sensitive at higher temperatures or solar exposure.[25,27] This could be the reason that differences in grape quality parameters among zones were only observed in the 2012−2013 growing season (panels C and D of Figure 3).

Fruit zone temperature and berry surface temperature are correlated with the concentration of rotundone in Shiraz grapes at this site. Vineyard topography, vine vigor, location of bunches within the vine, and bunch orientation to incident solar radiation also influence rotundone accumulation in Shiraz grapes. These factors affect the shading of grape berries and, therefore, adjust bunch surface and bunch zone temperatures. Sunlight interception and water availability may also influence rotundone production, which requires further investigation. Apart from climatic parameters, physiological parameters, such as the source−sink relationships between leave/stems and bunch in rotundone, may also influence its concentration in grape berries, which warrants further study. This study demonstrates the importance of the vine growing microenvironment and, specifically, the importance of the temperature on the formation of a key sesquiterpene compound responsible for wine aroma.

However, other alternatives can be used to reduce the volume of data that hyperspectral imaging acquires. Characteristic vector analysis has been used to identify the most important wavelengths in the visible region by several authors. Then, these authors could reconstruct the visible spectra of other samples from these important wavelengths. In the visible region, characteristic vector analysis has been applied to the reflectance spectra of wines, brandies, vinegars, liquid honeys, and orange juices.[14−17] The aforesaid reflectance spectra were acquired by means of different spectroscopic tools (i.e., spectrophotometry and spectroradiometry). To check the accuracy of the reconstructed spectra, CIELAB coordinates were calculated from experimental and reconstructed spectra. Then, color differences were also calculated using the coordinates obtained from the experimental spectra as reference coordinates and the coordinates obtained after applying the characteristic vector method as recalculated coordinates.

However, to the best of our knowledge, characteristic vector analysis has not been applied to near-infrared spectra to identify the most important wavelengths and reconstruct the spectra. Nonetheless, characteristic vector analysis is an interesting tool to be applied to near-infrared spectra. By means of this tool, important wavelengths could be found and low-cost multispectral imaging systems could be developed. Thus, it would be possible to measure parameters of interest in food, reducing the total volume of data, using this method in a number of food fields, such as grape and wine industry.

Grape maturity is one of the most fundamental aspects that have influence on the future of wine quality. It is composed of technological and phenolic maturity, especially phenolic maturity of grape skin. Technological maturity is mainly related with the sugar concentration, titratable acidity, and pH. The sugar concentration determines the potential alcohol strength. The titratable acidity and pH help to control the wine quality and color. Phenolic maturity shows the ripening degree for the skins, pulp, and seeds, taking into account the phenolic composition.[18,19]

Nowadays, at wineries, maturity of grapes is usually controlled using classic physical and chemical analyses (e.g., refractometric, volumetric, chromatographic, or spectrophotometric analyses). As preliminary approaches, we have described some methods to screen grape maturity by means of near-infrared hyperspectral imaging.[20−22] These are useful and nondestructive hyperspectral methods. However, as described above, hyperspectral imaging involves high costs and achieves a high volume of data, while multi-spectral imaging reduces these problems considerably.

The main aim of this study is to check the feasibility of using characteristic vector analysis in the near-infrared spectral region. This method may provide the most important wavelengths to reconstruct the whole spectrum from discrete measurement. Furthermore, the spectra obtained using this simplified method are evaluated to screen technological maturity of red grape and total phenolic contents of red grape skin. To our knowledge, this is the first time that characteristic vector analysis has been applied to near-infrared spectra to face the aforementioned goals.

MATERIALS AND METHODS

Samples. *Vitis vinifera* L. cv. Tempranillo is the most often grown red grape cultivar in Spain for producing quality red wines, and *V. vinifera* L. cv. Syrah is a resistant cultivar to warm climatic conditions.[23,24] Tempranillo and Syrah samples were collected at different dates from mid-July to early September in the 2012 vintage. In this way, samples were collected at different stages of physiological maturity and from two vineyards located in the Condado de Huelva Designation of Origin D.O. (Andalusia, Spain) as previously described elsewhere by Nogales-Bueno et al.[21] Briefly, 16 and 17 dates were taken into account for Tempranillo and Syrah, respectively, and three groups of at least 150 berries were collected from several bunches for each date and vineyard. With the aim of achieving representative samples, the berries were collected from both sides (sunlight and shade) of vines located in different rows within the vineyard. Edge rows and the first two vines in a row were avoided. Berries were collected from the top, middle, and bottom of the cluster. A total of 99 samples were collected, 3 × 16 Tempranillo samples and 3 × 17 Syrah samples. From the three samples of each date, one (33%) was randomly allocated into the validation set and the other two (66%) were allocated to the calibration set.

Near-Infrared Hyperspectral Imaging. The hyperspectral imaging device (Infaimon S.L., Barcelona, Spain) comprised a Xenics XEVA-USB InGaAs camera (320 × 256 pixels, Xenics Infrared Solutions, Inc., Leuven, Belgium) and a spectrograph (Specim ImSpector N17E Enhanced, Spectral Imaging, Ltd., Oulu, Finland) covering the spectral range between 900 and 1700 nm (spectral resolution of 3.25 nm). The hyperspectral image of each sample was recorded. The equipment and procedure used for image recording are described in detail elsewhere by Hernández-Hierro et al.[20]

After the calibration and segmentation process, the average spectral profile for each sample was saved. Noisy wavebands at both extremes of the spectral range were removed. Thus, only spectral data in the resulting effective wavelength of 950−1650 nm regions were used in data analysis because of reduced efficiency outside this range in the used device. Finally, the average spectra were transformed into $\log(1/R)$ units, and 99 near-infrared absorbance spectra were obtained, with each of them composed of 215 wavelengths.

Reference Parameters. Reference parameters were total phenolic concentration in grape skins, sugar concentration, titratable acidity, and pH. The total phenolic concentration in grape skins was determined using the Folin−Ciocalteu method,[25] and it was expressed as gallic acid equivalents per gram of grape skin. This method was applied to an aqueous extract obtained from grape skin. Grape skins were separated manually from the whole grapes. Afterward, 1 g of grape skin was macerated in 10 mL of methanol containing 0.1% 12 M HCl. Methanolic phases were centrifuged (3000 rpm for 10 min) and successively pooled; approximately 2 mL of water was added; and the extract was concentrated under vacuum at 30 °C until methanol was removed and finally made up to 10 mL with ultrapure water. Technological maturity parameters were determined using the analytical methods recommended by the International Organisation of Vine and Wine (OIV)[26] as described elsewhere by Nogales-Bueno et al.[21]

Chemometrics Tools: Characteristic Vector Method. A mathematical statement of the characteristic vector analysis[27] might be given as follows:

Hyperspectral imaging spectra (HIS) are near-infrared absorbance spectra obtained from the hyperspectral device. An individual response data ρ_λ (absorbance spectrum between 950 and 1650 nm, at $\Delta\lambda = 3.25$ nm) is available for r (215) levels of the variable λ (wavelength) and can be plotted as a response curve. Therefore, for each sample, the r values of ρ_λ constitute a one-row r-column vector of response data. For n samples, the response vectors can be arrayed to form a data matrix of n rows and r columns.

If the variance−covariance matrix $\mathbf{S}$ from the original $(n \times r)$ data matrix is computed, characteristic vectors (or eigenvectors) are the solutions of the equation

$$\det(\mathbf{S} - \mathbf{LI}) = 0 \quad (1)$$

where $\mathbf{L}$ is the diagonal matrix $(r \times r)$ of the characteristic root and $\mathbf{I}$ is the $(r \times r)$ unit matrix.

It is possible to find a set of p characteristic vectors, $(p < r)$, which, added in the proper amounts, will adequately approximate any of the

DOI: 10.1021/jf505870s
J. Agric. Food Chem. 2015, 63, 4284−4290

original family of response vectors. The result is that the components of the generic vectors (i.e., the absorbance or reflectance spectra) can be expressed as

$$\rho_\lambda = M_1 V_{1\lambda} + M_2 V_{2\lambda} + ... + M_p V_{p\lambda}, \qquad p < r \tag{2}$$

where $V_{i\lambda}$ represents the components of the characteristic ith vector and M_i represents the specific coefficients, called scalar multiples, of each reconstructed vector. The M_i coefficients depend upon the absorbance values at as many wavelengths as characteristic vectors have been needed. These wavelengths are selected to maximize the accuracy of the characteristic vector reconstructed spectra (CVRS).

This analysis must be applied to a large number (n) of experimental curves. The iterative mathematical procedure calculates the characteristic vectors, the M_i coefficients to reconstruct each of these curves, and the percentage of variability among the family of homologous response curves explained for each characteristic vector.

The derivation of the vectors ensures that the first vector accounts for the largest amount of total response variability, the second vector accounts for the second-largest amount of variability, etc.

The inconvenience of this methodology is that it allows us to reconstruct the spectra of samples only from the calibration set (also called model group). If the results are to be applied to spectra of samples other than those used previously, it is necessary to calculate the corresponding M_i coefficients in a different way.

To solve this issue, characteristic vectors are calculated. Then, expressions to calculate the M_i coefficients are obtained. These expressions are functions of the absorbance or reflectance values at as many wavelengths as characteristic vectors have been needed. Therefore, these expressions allow us to calculate the M_i coefficients for the samples from the calibration set as well as for other samples from a different set called validation set. In this way, one of the requirements from the statistical methodology is completed that requires testing of a model with samples different from those used to obtain the model. Therefore, when the characteristic vector method is established, the absorbance or reflectance values at only a few wavelengths are necessary to reconstruct a spectrum.

Finally, to check the accuracy of the CVRS, root-mean-square error (RMSE) is calculated. This error measures the differences between CVRS and HIS for the calibration and validation sets. However, a small RMSE does not provide sufficient guarantee to conclude that the structural information offered by the near-infrared HIS may be kept.

Chemometrics Tools: Modified Partial Least-Squares (MPLS) Method. To check that CVRS keep the main structural information related to molecular bonds after the application of the characteristic vector method, a checking process has been purposed. Using the calibration models described in our previous study,[21] it was checked how, from CVRS, the aforementioned reference parameters were predicted. Then, the differences between the reference parameters predicted from the former data (HIS data) and the reference parameters predicted from the CVRS were checked.

Briefly, in our previous study,[21] it was established what spectral pretreatment was the best for each reference parameter. For red grapes, standard normal variate (SNV), detrend, or spectral derivative pretreatments were used to predict the different reference parameters. These pretreatments were shown to be the most effective tools to remove scattering effects. Then, calibration models were performed using MPLS regression, and the aforementioned reference parameters were predicted.

Consequently, these spectral pretreatments have been applied to the CVRS; quantitative calibrations have been developed by MPLS regression; and external validations have been carried out. Then, RSQ coefficients and SEP errors have been calculated and compared to the statistical parameters obtained from HIS.

To study the feasibility of the characteristic vector method to be used in the near-infrared region, this method has been developed from 3, 6, 9, and 12 characteristic vectors and the aforesaid process has been carried out from the different sets of CVRS.

RESULTS AND DISCUSSION

Reference Parameters. The total phenolic concentration ranged from 2.2 to 14.3 mg g^{-1} of grape skin expressed as gallic acid equivalents. The sugar concentration ranged from 4.1 to 25.4 °Brix. Titratable acidity ranged from 3.1 to 52.9 g L^{-1} expressed as tartaric acid equivalents. Finally, pH ranged from 2.5 to 3.8.

Spectral Samples and Spectral Reconstruction Process. After hyperspectral imaging acquisition, near-infrared HIS were combined into the spectral matrix (99 × 215), this spectral matrix was split into calibration (66 × 215) and validation (33 × 215) matrixes. Then, the characteristic vector method was applied to the calibration matrix, and the first 12 characteristic vectors were calculated. Both, calibration and validation matrixes were reconstructed using the first 3, 6, 9, and 12 characteristic vectors successively. The expressions and used wavelengths to calculate the M_i coefficients are available in the Supporting Information.

Figure 1 shows the first 12 characteristic vectors calculated from the HIS allocated into the calibration set. These vectors

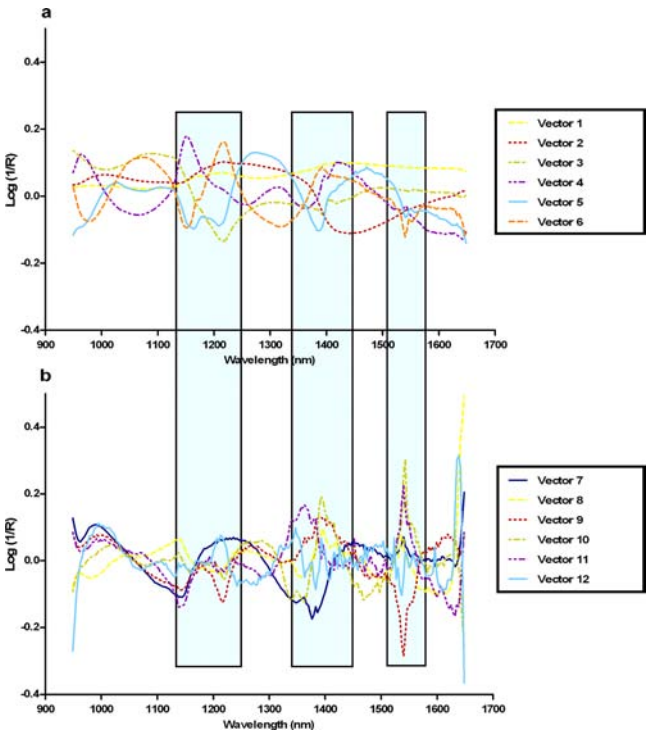

Figure 1. Characteristic vectors calculated from the spectra allocated into the calibration set. The first 6 characteristic vectors are shown in panel a, and the next 6 characteristic vectors are shown in panel b.

form the basis of a vector space, and thus, the HIS allocated into the calibration set belong to this vector space. The first 6 characteristic vectors are shown in Figure 1a, and the next 6 characteristic vectors are shown in Figure 1b. A strong feature of the characteristic vectors was the pattern around 1150, 1350, and 1550 nm wavelengths. The pattern around these wavelengths is mainly related to bands of the −CH and −OH functional groups.[28] Table 1 shows the RMSE values of the reconstruction of the calibration and validation matrixes. As expected, in all cases, the reconstruction of the calibration matrix is better than the reconstruction of the validation matrix. Nevertheless, all of these errors are really low; in fact, if a HIS is

Table 1. RMSE Obtained in the Reconstruction of the Calibration and Validation Matrixes from 3, 6, 9, and 12 Characteristic Vectors

RMSE[a]	3 vectors	6 vectors	9 vectors	12 vectors
calibration set (66 samples)	0.004778	0.001513	0.000819	0.000746
validation set (33 samples)	0.004873	0.001790	0.001149	0.001223

[a]RMSE = root-mean-square error [log(1/R) units].

plotted together with its respective CVRS, there are very few differences between them. However, it is not certain that CVRS keep all of the structural information related to molecular bonds. To check this, calibration models were developed from the different sets of CVRS.

Development of MPLS Calibrations. Table 2 resumes the calibration statistical descriptors for the different equations developed. Equations have been developed for each reference parameter using five different groups of spectra: the group of HIS and four groups of CVRS reconstructed from the first 3, 6, 9, and 12 characteristic vectors. In this table, it can be observed how models developed from CVRS achieve different results depending upon the number of characteristic vectors used to reconstruct them. Groups of CVRS reconstructed from 3 and 6 characteristic vectors show high values of error in the cross-validation process (SECV) and low correlation coefficients (RSQ). In addition, these equations have needed less PLS factors than the rest of spectral groups. This means that the spectral variability of the independent variable (X) related to the dependent variable (Y) is lower in groups of CVRS reconstructed from 3 and 6 vectors than in the rest of the groups of CVRS, and this spectral variability can be explained with a small number of PLS factors. In conclusion, these two reconstructions have not been able to reproduce all of the spectral variability of the HIS related to the dependent variable (Y).

The group of CVRS reconstructed from 9 and 12 characteristic vectors shows better results. In fact, the results obtained from the group reconstructed from 12 characteristic vectors are really close to the results obtained from HIS (Table 2).

For each model developed from the different calibration sets, its robustness was tested using its respective validation set (33 samples), which did not belong to the calibration set, as external validation. Using the characteristic vector analysis described above, these 33 HIS were reconstructed from 3, 6, 9, and 12 characteristic vectors and these matrixes were used in the different validation processes. As result of these external validations, standard errors of prediction (SEP) for each reference variable were obtained; these values were also included in Table 2. Figure 2 shows the SEP expressed as percentages. These errors follow the same pattern described for SECV: high errors for models developed from 3 and 6 characteristic vectors and lower errors for models developed from 9 and 12 vectors. For sugar, concentration errors obtained are not as low as expected; however, the model developed from 12 characteristic vectors predicts this parameter with sufficient precision. Furthermore, for total phenolic concentration and titratable acidity, SEP obtained in the model developed from 12 characteristic vectors is lower than SEP obtained in the model developed from HIS. This is perhaps due to the absence of noise in the CVRS. The characteristic vector method can reproduce the features of a spectrum linked to the chemical or physical properties of the sample. However, this method cannot reproduce the instrumental noise of a HIS, by its random nature. Consequently, in the CVRS, the instrumental noise cannot mask the features linked to the chemical or physical

properties of the sample, and the models developed from the CVRS reconstructed from 12 characteristic vectors can be more accurate than models developed from HIS.

To analyze the significance of differences between errors of prediction for the models developed from HIS and from the group of CVRS reconstructed from 12 characteristic vectors, a Student's *t* test for paired values was carried out. In each case, the level of significance was obtained. When this value was greater than 0.05 (chosen as the minimum level of significance), the null hypothesis was accepted (i.e., there were no differences among the different results). The levels of significance were 0.22 for total phenolic concentration, 0.76 for sugar concentration, 0.18 for titratable acidity, and 0.13 for pH. For all parameters, the level of significance was higher than 0.05. It may be concluded that the models developed from the group of CVRS reconstructed from 12 characteristic vectors provide significantly similar results to models developed from HIS.

Furthermore, the error of prediction (EP) of each sample was calculated to test the robustness of the developed models. For each developed model, differences between individual predicted and experimental reference parameters have been calculated and expressed as percentages. These percentages are plotted in Figure 3, which shows the distributions in error of predictions of samples allocated into the validation set. For all reference parameters, the number of samples with an error of prediction lower than 20% is very similar for the models developed from HIS and from the group of CVRS reconstructed from 12 characteristic vectors. This means that characteristic vector analysis reproduces, with only 6% of the spectral information that the hyperspectral device provides, the results reported in our previous study[21] in a very satisfactory way (RSQ between 0.84 and 0.97 units and SEP between 4 and 14%). In addition, Figure 3 also shows that pH could be predicted with an EP of lower than 20%, even using the model developed from the group of CVRS reconstructed from 3 characteristic vectors (Figure 3d).

In conclusion, simplified methods for the screening of technological maturity of red grape and total phenolic compounds of red grape skin have been described. These methods use characteristic vector analysis to reduce the volume of data that hyperspectral imaging acquires. This data reduction can, from a theoretical point of view, help to develop cheap spectral devices, such as multi-spectral systems.

The characteristic vector method allows us to reconstruct near-infrared spectra from a few characteristic vectors and wavelengths. To achieve good results, the correct number of characteristic vectors must be taken into account. The results reported here indicate that 12 characteristic vectors are sufficient to reconstruct near-infrared spectra and to develop from these spectra useful calibration models. Hence, this study is an important step to reduce the spectral information necessary for food evaluation and the cost of this technology.

to gain a maximum of reliability.[32] The assay was evaluated in terms of the correlation coefficient, slope of the regression line, amplification efficiency, dynamic range, relative repeatability standard deviation, limit of detection (LOD), and limit of quantification (LOQ).

MATERIALS AND METHODS

Spore Lysis. The spores used in the presented work (Table 1) were from our in-house collection and also provided by Dr. B. Schütze, LADR GmbH (Geesthacht, Germany). To obtain the 16S rDNA, spores were diluted in double-distilled water (ddH_2O) to a total volume of 400 μL and about 250 mg of glass beads (Ø = 0.5 mm, Sigma-Aldrich Chemie GmbH, Munich, Germany) were added and subsequently ground twice in a TissueLyser (Qiagen GmbH, Hilden, Germany) for 5 min at 30 Hz. The resulting fragmented spore mixtures were centrifuged for 5 min at 12000*g* to precipitate the glass beads and the spore fragments. The supernatant was used directly as a template for real-time PCR.

Real-Time PCR Design. To design primers, which are suitable for a wide variety of *Alicyclobacillus* spp. strains, the 16S rDNA sequences of various *Alicyclobacillus* spp. were collected from the National Center for Biotechnology Information (NCBI, Bethesda, MD). Suitable primers (Table 2) were designed using the PrimerQuest Tool (Integrated DNA Technologies, Inc., Leuven, Belgium).

The real-time PCR was performed in 96 well PCR plates (Sarstedt Inc. & Co., Nümbrecht, Germany) sealed with sealing tape (Sarstedt Inc. & Co., Nümbrecht, Germany) in a total volume of 20 μL. Each PCR reaction mix consisted of the following components: 1× DreamTaq buffer (10×, Fisher Scientific-Germany GmbH, Schwerte, Germany), 0.8 mM dNTPs (10 mM, Bioline GmbH, Luckenwalde, Germany), 0.25 unit DreamTaq polymerase (0.5 U/μL, Fisher Scientific-Germany GmbH, Schwerte, Germany), 0.2 μM of each primer (16S rDNA Fw and 16S rDNA Rv, Integrated DNA Technologies, Inc., Leuven, Belgium), 0.3125× SYBR Green I nucleic acid gel stain (10000×, Invitrogen GmbH, Karlsruhe, Germany), various concentrated spore lysates, and ddH_2O filled up to 20 μL. The PCR amplification was carried out in an iCycler iQ5 (BioRad Laboratories, Inc., Hercules, CA). The real-time PCR starts with a 5 min denaturation step at 95 °C, followed by 35 cycles of denaturation at 95 °C for 30 s, annealing at 58 °C for 30 s, elongation at 72 °C for 30 s, and detection at 84 °C after 30 s. The last step is a final elongation at 72 °C for 5 min. The fluorescence was excited at 485 nm, with the resulting emission measured at 530 nm, and the threshold cycle was calculated using the Optical System Software (version 2.0, BioRad Laboratories, Inc., Hercules, CA). Real-time PCR reaction curves with C_T values of >32 were defined as no amplification, and C_T values of ≤32 were defined as positive results, together with the expected amplicons. The calibration lines were obtained by plotting C_T values against the formed logarithm of diluted and prepared spore suspensions.

RESULTS AND DISCUSSION

Spore Lysis. For the DNA extraction from *Alicyclobacillus* spp. spores, several spore lysis methods were tested, e.g., (i) chemical lysis using surfactants, acids, and alkali, (ii) temperature treatment using liquid nitrogen, heat, and autoclaving,

DOI: 10.1021/acs.jafc.5b00874
J. Agric. Food Chem. 2015, 63, 4291−4296

(iii) various DNA extraction kits, (iv) mechanical spore treatment using glass beads or sonic waves, and (v) different combinations of the above-mentioned techniques.[28,33−38] The application of a TissueLyser with glass beads (0.5 mm diameter) and the subsequent centrifugation provide a very simple method for a rapid extraction of DNA from spores. Because of the fact that the spore lysis was performed in ddH_2O, the resulting supernatant is directly useable for the real-time PCR assay to quantify *Alicyclobacillus* spp. spores.[22]

Real-Time PCR Design. The 16S rDNA primers used in the presented work were designed regarding *A. acidoterrestris* DSM 2498 (accession number AB059675.1; Figure 1). This sequence was previously aligned with several *A. acidoterrestris* strains (e.g., DSM 3922, DSM 12489, ATCC 49025, NBRC 106291, NBRC 106287, and NBRC 106295) and other *Alicyclobacillus* spp., for example, *A. acidiphilus* (DSM 14558), and *A. herbarius* (DSM 13609). Sequences were obtained from the NCBI and aligned using GENtle (version 1.9.4, University of Cologne, Cologne, Germany). The 16S rDNA primers were designed by PrimerQuest Tool (Integrated DNA Technologies, Inc., Leuven, Belgium) and possess melting temperatures of 61.5 and 62.1 °C (Table 2). After optimization of the PCR assay, 58.0 °C seems to be the optimal annealing temperature, resulting in an amplicon with a length of 143 bp (Figure 1). To avoid detection of primer dimers and PCR artifacts, fluorescence monitoring was performed at 84 °C.[39] From this temperature, the detection of byproducts is suppressed, resulting in an overall increased sensitivity of the PCR assay (Figure 2).[40]

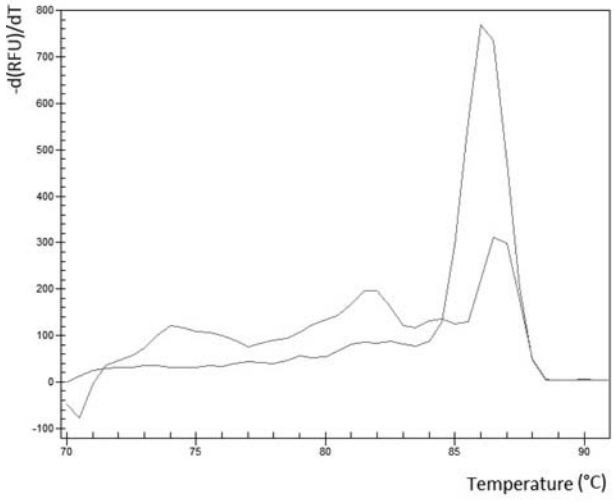

Figure 2. Melting temperature analysis of two different prepared spore concentrations [8.45 and 8.45 × 10^5 colony forming units (cfu)/mL].

The DNA amplification was monitored using the intercalating fluorescence dye SYBR Green I. These real-time PCR assays have various advantages, such as a high dynamic range for quantification and superior reproducibility.[24,41,42] Even though crude spore DNA was used as a template, SYBR Green I enables sensitive and precise quantification results (Figure 3 and Table 3).[43] Moreover, it is also useful for high throughput screening in incoming control of the fruit juice industry because of robustness, practicability, high standardization potential, and running expenses.[32,44]

Real-Time PCR Evaluation. The performance requirements of the ENGL were used to evaluate the real-time PCR for quantification of *Alicyclobacillus* spp. spores in terms of the correlation coefficient, slope of the regression line, amplification efficiency, dynamic range, relative repeatability standard deviation, limit of detection, and limit of quantification.[32,45]

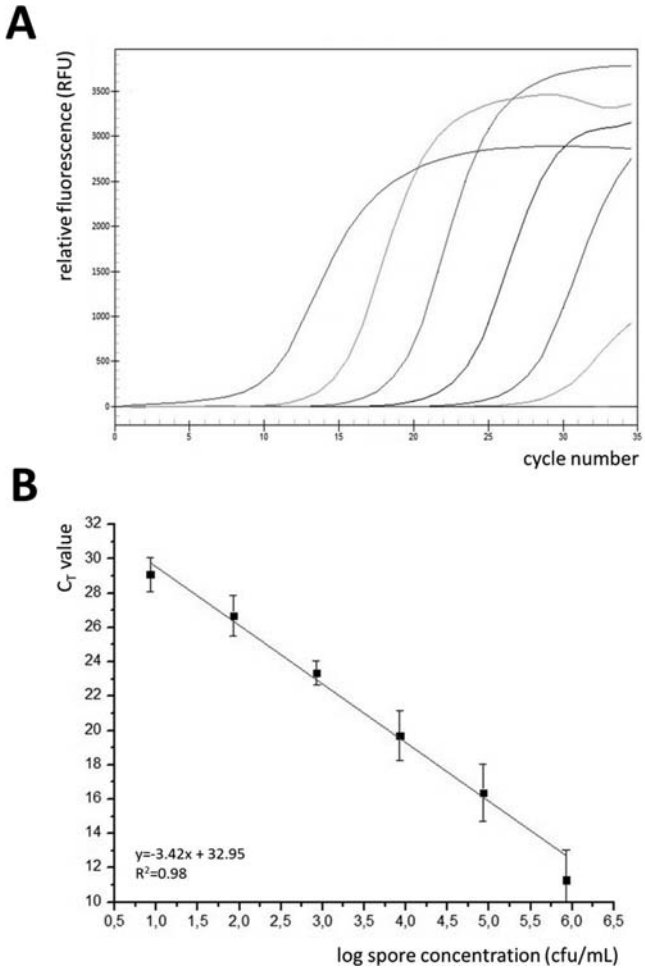

Figure 3. (A) Example of observed reaction curves during real-time PCR validation with different spore concentrations (cfu/mL). Spore concentrations from left to right: 8.45 × 10^5 cfu/mL, 8.45 × 10^4 cfu/mL, 8.45 × 10^3 cfu/mL, 8.45 × 10^2 cfu/mL, 8.45 × 10^1 cfu/mL, and 8.45 cfu/mL. (B) Resulting calibration line during real-time PCR validation with E = 96% (m = −3.42) and R^2 = 0.983. Spore concentrations from left to right: 8.45 cfu/mL, 8.45 × 10^1 cfu/mL, 8.45 ×10^2 cfu/mL, 8.45 × 10^3 cfu/mL, 8.45 × 10^4 cfu/mL, and 8.45 × 10^5 cfu/mL.

Table 3. Evaluation Parameters According to ENGL and Results of the Validation of Developed Real-Time PCR

evaluation parameters	ENGL criteria	results of developed real-time PCR
dynamic range (cfu/mL)		8.45−8.45 × 10^5
slope of the regression line	$-3.1 \geq m \geq -3.6$	−3.42
amplification efficiency (%)	110−90	96
correlation coefficient	≥0.98	0.983
relative repeatability standard deviation (%)	≤25	3.0−15.4
limit of quantification (LOQ) (cfu/mL)		8.45
limit of detection (LOD) (calculated by the regression line) (cfu/mL)		0.28

DOI: 10.1021/acs.jafc.5b00874
J. Agric. Food Chem. 2015, 63, 4291−4296

For the real-time PCR evaluation, spore concentrations from 8.45×10^2 to 8.45×10^6 cfu/mL of a strain mix (1:1, v/v, *A. acidoterrestris* DSM 2498/*A. acidoterrestris* wild type) were used. To increase the dynamic range of spore quantification, the lysed spore suspension of 8.45×10^2 cfu/mL was further diluted in 10-fold serial steps to a theoretical spore concentration of 0.845 cfu/mL. Mentioned dilutions of the applicable DNA templates were possible because of the high copy number of the 16S rDNA.[29−31]

During the extensive validation of the real-time PCR assay, a dynamic range of *Alicyclobacillus* spp. spore concentrations from 8.45 to 8.45×10^5 cfu/mL was established (Figure 3 and Table 3). The evaluation of a higher spore concentration than 8.45×10^5 cfu/mL is not necessary because it can be assumed that these concentration ranges never occur in orange juice samples or could be bypassed by dilution.

A correlation coefficient (R^2) of 0.983 was determined by linear regression analysis (Figure 3B and Table 3), which fulfills the performance requirements of the ENGL (according to ENGL, the correlation coefficient should be ≥0.98). Hence, this evaluation parameter confirms a linear correlation and, therefore, justifies the usage of a linear fit.[32] In addition, the slope of the regression line (m) of −3.42 (Figure 3 and Table 3) fulfills the performance requirements of the ENGL ($-3.1 \geq m \geq -3.6$) and is therefore considered as appropriate. Moreover, the amplification efficiency (E) was calculated by use of the regression line slope ($E = 10^{-1/m} - 1$). For the developed real-time PCR assay, an efficiency of approximately 96% was achieved, which is also within the requirements of ENGL (Figure 3 and Table 3).

The relative repeatability standard deviation (RSD_r) of the assay results indicates the reproducibility of the developed real-time PCR assay and should be ≤25% over the whole dynamic range of the developed method according to ENGL.[23] Moreover, the relative repeatability should be determined by a sufficient number of test results (at least 15), as indicated in ISO 5725-3.[32,46] During the whole assay development, the relative repeatability standard deviation was in the range of 3.0−15.4%. This is in accordance with the ENGL criteria and was obtained by considerably more than 15 approaches per amplification point (Figure 3 and Table 3).

Because of the above-mentioned aspect of unknown target concentrations after aptamer-based spore enrichment, one of the ENGL criteria [limit of detection (LOD) should be less than $^1/_{20}$ of the target concentration] is not determinable. However, according to ENGL, the LOD can also be determined by ensuring that ≥95% of false negative results are detectable. Under the assumption that C_T values of >32 are blank samples, this evaluation parameter could be fulfilled.[15] Therefore, the limit of detection of the present real-time PCR assay is below the dynamic range of quantification. A further equimolar dilution of spores would lead to a concentration of <1 cfu/mL, which is not relevant for the application. However, to indicate a theoretical detection limit, the LOD was calculated using a C_T of 32. Thus, the theoretical detection limit value is 0.28 cfu/mL.

According to ENGL, the limit of quantification (LOQ) should be less than $^1/_{10}$ of the target concentration, which is also not determinable because of the mentioned aspect of unknown target concentrations after spore enrichment. However, this spore concentration can be determined in consideration of the mentioned and defined performance requirements of the ENGL. Moreover, a further LOQ criterion (≤25% RSD_r) is achieved for the estimated spore concentration of 8.45 cfu/mL. Nevertheless, the statistical probability to receive precise results in a lower range of the spore concentration is significantly decreased and leads to C_T values beyond the RSD_r range of >25%.

In addition, the selectivity of the developed real-time PCR was assessed by an end-point PCR experiment and analysis by agarose gel electrophoresis (AGE). Because of the final application in conjunction with an aptamer-based spore enrichment for a rapid and direct proof and quantification of *Alicyclobacillus* spp. spores in orange juice, the selectivity toward several of the fruit juice industry relevant spores is especially important. In this context, 13 spores of various *Alicyclobacillus* spp. DSM strains, 34 *Alicyclobacillus* spp. wild types, 5 *Bacillus cereus*, 1 *Bacillus weihenstepanensis*, 2 *Bacillus thuringiensis*, 1 *Bacillus licheniformis*, 1 *Bacillus subtilis*, 1 *Bacillus coagulans*, 1 *Bacillus polymyxa*, 1 *Bacillus circulans*, 1 *Bacillus sphaericus*, and 2 *Clostridium perfringens* strains were analyzed (Table 1). All 47 *Alicyclobacillus* spp. spore strains yielded the calculated 143 bp amplicon, whereas neither *Bacillus* spp. nor *C. perfringens* spore strains were amplified.

In general, the developed method is suitable for spore quantification subsequent to an affinity enrichment procedure, for instance, from orange juice. Because of the intended spore elution with water after the enrichment process, the determination of spore suspensions in water is required. Moreover, this simple approach enables the variation of spore lysis volumes during the spore elution after the enrichment step. In summary, the aim of the whole technique includes (i) the aptamer-based enrichment step by magnetic spore separation with (ii) consecutive determination of *Alicyclobacillus* spp. spore concentration by real-time PCR.

As described by Hünniger et al., the selected aptamers possess a substantially high affinity to *Alicyclobacillus* spp. spores and a rather low affinity to *Bacillus* spp. or *Clostridium* spp. spores (see Figure S3 of the Supporting Information).[22] In the end, this given selectivity is substantially increased by the presented PCR, which allows for the distinction between *Alicyclobacillus* spp., *Bacillus* spp., and *Clostridium* spp. However, if further non-*Alicyclobacillus* spp. strains will be identified in orange juices in the future, their sequences have to be further characterized to assess the selectivity of the test system developed in this study.[47]

On the whole, the combination of the prior spore-collecting step by immobilized aptamers in combination with the very selective real-time PCR assay developed in this study appears as the scientific basis for the development of a rapid and reliable incoming control in the beverage plant. In an upcoming study, the whole system will be assembled, evaluated, and assessed using real and spiked orange juice samples of different origins.

and size of azoxymethane-induced distal tumors in Fisher 344 male rats as compared with controls.[22] In humans, a combination of supplements curcumin and quercetin regressed adenomas in patients with FAP.[3] DIM synergistically suppressed the proliferation of human colorectal cancer cells when combined with sulforaphane.[23] DIM in combination with genistein resulted in decreased proliferation by working on estrogen and androgen receptors in vitro LNCaP PCa cells.[24] These and others have shown the potential for synergistic activity of multiple phytochemicals to exert greater anticancer effects.

In this study, we aimed to elucidate the anticancer properties of the combined use of capsaicin and DIM with regard to cell growth inhibition and apoptosis in human colon cancer cells. Here we report that treating cells with the combination of capsaicin and DIM results in inhibition of cell proliferation and increased apoptosis through targeting transcriptional activation of p53 and NF-κB and activation of genes downstream of these transcription factors.

MATERIALS AND METHODS

Chemicals and Reagents. Cell culture media, Dulbecco's modified Eagle medium (DMEM), was purchased from Lonza (Walkersville, MD, USA), and Eagle's minimum essential medium (EMEM) was purchased from American Type Culture Collection (Manassas, VA, USA). Antibodies for p21, p27, CDK4, CDK6, Bak, Bid, Bax, Puma, Fas-L, Traf2, and Traf3 were purchased from Cell Signaling (Danvers, MA, USA). Antibodies for p53, TBP, and actin was purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA, USA), and Bcl-2 antibody was purchased from BD Bioscience (San Jose, CA, USA). Capsaicin (catalog no. E2028) was purchased from Sigma-Aldrich (St. Louis, MO, USA), and DIM (catalog no. BML-GR207) was purchased from Enzo Life Science (Farmingdale, NY, USA). Capsaicin and DIM were dissolved in ethanol and dimethyl sulfoxide (DMSO), respectively. All chemicals were purchased from Fisher Scientific, unless otherwise specified.

Cell Culture and Treatment. Human colorectal cancer cell lines, HCT116, SW480, LoVo, Caco-2, and HT-29 were purchased from American Type Culture Collection and grown in DMEM supplemented with 10% fetal bovine serum (FBS), 100 U/mL penicillin, and 100 μg/mL streptomycin. Human normal colon cells, CCD112CoN, were purchased from ATCC and grown in EMEM supplemented with 10% FBS. The cells were maintained at 37 °C under a humidified atmosphere of 5% CO_2. Ethanol and DMSO were used as a vehicle and added into culture media at 0.1% (v/v).

Measurement of Apoptosis. Apoptosis of HCT116 cells was measured according to the manufacturer's instruction of propidium iodide/annexin V-FITC apoptosis detection kit (BD Biosciences) as described previously.[25] Early apoptosis and late apoptosis were quantified by flow cytometry in FACS facility at the University of Maryland. Apoptosis of other human colorectal cancer cells were tested using a Cell Death Detection ELISAPLUS Kit (Roche Diagnostics, Indianapolis, IN, USA) as we described previously.[26]

Measurement of Cell Proliferation. Cell proliferation was assessed by using the 4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (Sigma, St. Louis, MO, USA) method. The optical density was recorded at 490 nm using an enzyme-linked immunosorbent assay plate reader (Bio-Tek Instruments Inc., Winooski, VT, USA). Briefly, cells were plated at the concentration of 1000−2000 cells/well in 96-well tissue culture plates and then treated with capsaicin, DIM, or a combination as described in the figure captions. After 0, 24, and 48 h, MTT was added to each well and the plate was incubated for 3 h at 37 °C; absorbance was measured in an ELISA plate reader (Bio-Tek Instruments).

Transient Transfection and Luciferase Assay. Transient transfection for *NF-κB Luc* and *p53 Luc* plasmid was performed using a Polyjet DNA transfection reagent (SignaGen Laboratories, Ijamsville, MD, USA) according to the manufacturer's instructions. HCT116 cells (2×10^5 cells/well) were plated in 12-well plates in three replicates and incubated overnight. The next day, plasmid mixtures containing 1 μg of *NF-κB Luc* or *p53 Luc* and 0.1 μg of *pRL-null* were transfected into the cells for 24 h. The transfected cells were treated in the compounds for 24 h. The cells were harvested in 1× luciferase lysis buffer. The luciferase activity was measured and normalized to the *pRL-null* luciferase activity using a dual-luciferase assay kit (Promega).

Reverse Transcription (RT) Polymerase Chain Reaction (PCR). Total RNA was isolated from cells using the RNeasy Micro Kit (QIAGEN, Valencia, CA, USA), and cDNA was synthesized using a VERSO cDNA SYN RT KIT (Thermo Scientific). PCR was performed using PCR master mix (Promega) with targeted primers for p21, Bak, and GAPDH. The PCR primers were synthesized from Sigma-Aldrich. Amplification was performed under conditions of 95 °C for 10 min, followed by 35 cycles of 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 45 s. Primer sequences are following: p21, forward 5′-GAGCGATGGAACTTCGACTT-3′ and reverse 5′-CAGGTCCACATGGTCTTCCT-3′; Bak, forward 5′-TCTGGCCCTACACGTCTACC-3′ and reverse 5′-ACAAACTGGCCCAACAGAAC-3′; GAPDH, forward 5′-ACCCAGAAGACTGTGGATGG-3′ and reverse 5′-TTCTAGACGGCAGGTCAGGT-3′. Reaction products were analyzed on 1% agarose gel.

SDS-PAGE and Western Blot. Cells were washed with ice-cold 1× phosphate-buffered saline (PBS) and lysed in radioimmunoprecipitation assay (RIPA) buffer (Boston Bioproduct Inc., Ashland, MA, USA) supplemented with protease and phosphatase inhibitor cocktail (Sigma-Aldrich) and centrifuged at 12000*g* for 10 min at 4 °C. After protein concentration was determined by the bicinchoninic acid (BCA) protein assay (Pierce, Rockford, IL, USA), equal amounts of proteins were subjected to 10 or 12% SDS-PAGE, and the separated protein was transferred onto nitrocellulose membranes (Osmonics, Minnetonka, MN, USA). The membranes were blocked for nonspecific binding with 5% nonfat milk in Tris-buffered saline containing 0.05% Tween 20 (TBS-T) for 1 h at room temperature and then probed with primary antibodies overnight at 4 °C, followed by incubation with horseradish peroxidase (HRP)-conjugated immunoglobulin G (IgG) for 1 h at room temperature. Chemiluminescence was detected with Pierce ECL Western Blotting substrate (Thermo Scientific) and visualized by Chemidoc MP Imaging system (Bio-Rad, Hercules, CA, USA).

Isolation of Cytosol and Nucleus Fraction. Cytosol and nuclear fraction of cells were prepared according to the manufacturer's protocols of a nuclear extraction kit (Active Motif, Carlsbad, CA, USA). Briefly, after HCT116 cells were treated in the compounds for 24 h, the cells were washed twice with ice-cold PBS containing phosphatase inhibitors (Sigma-Aldrich). Cells were harvested with hypotonic buffer containing detergent and incubated at 4 °C for 15 min. The supernatants (cytoplasmic fraction) were collected after centrifugation at 14000*g* for 1 min at 4 °C and stored at −80 °C. For nuclear fractions, cell pellets were resuspended with lysis buffer and incubated at 4 °C for 30 min under shaking. After 30 min, nuclear suspensions was centrifuged at 14000*g* for 10 min at 4 °C, and the supernatants (nuclear fraction) were stored at −80 °C for further analysis

Statistics. Statistical analysis was performed with IBM SPSS, and the data were analyzed by one-way ANOVA with Duncan's multiple-comparison tests. Data are expressed as means ± SD, and differences were considered significant at $P < 0.05$.

RESULTS

Effect of Compounds on Apoptosis and Cell Proliferation. Previously we studied the anticancer activity of capsaicin in human colorectal cancer.[16] To further extend our understanding of the anticancer activity of capsaicin, we screened several phytochemicals including EGCG, ECG, apigenin, genistein, DIM, and resveratrol for potential synergistic activity with capsaicin, based on the expression of a newly identified pro-apoptotic gene, NSAIDs-activated gene 1 (NAG-1). As a result, we found that capsaicin and DIM synergistically induced expression of NAG-1 gene (data not shown). Therefore, in the

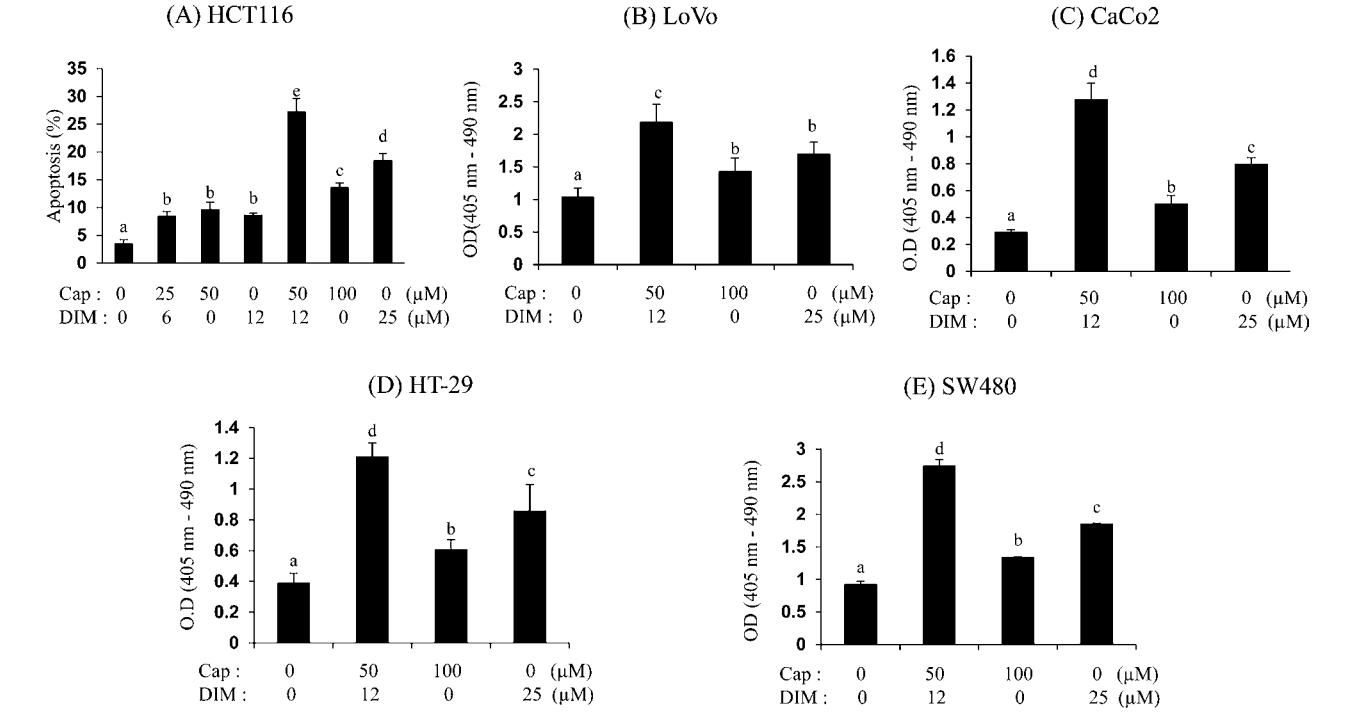

Figure 1. Synergistic effect of capsaicin and DIM on apoptosis of multiple human colorectal cancer cell lines. Apoptosis of different human colorectal cancer cells, HCT116 (A), LoVo (B), CaCo2 (C), HT-29 (D), and SW480 (E), was tested with FACS (HCT-116 cells) and a Cell Death Detection ELISA^{PLUS} Kit (Roche Diagnostics, Indianapolis, IN, USA) according to the manufacturer's instruction. Values are means ± SD, $n = 3$. Different letters indicate significant differences at $P < 0.05$.

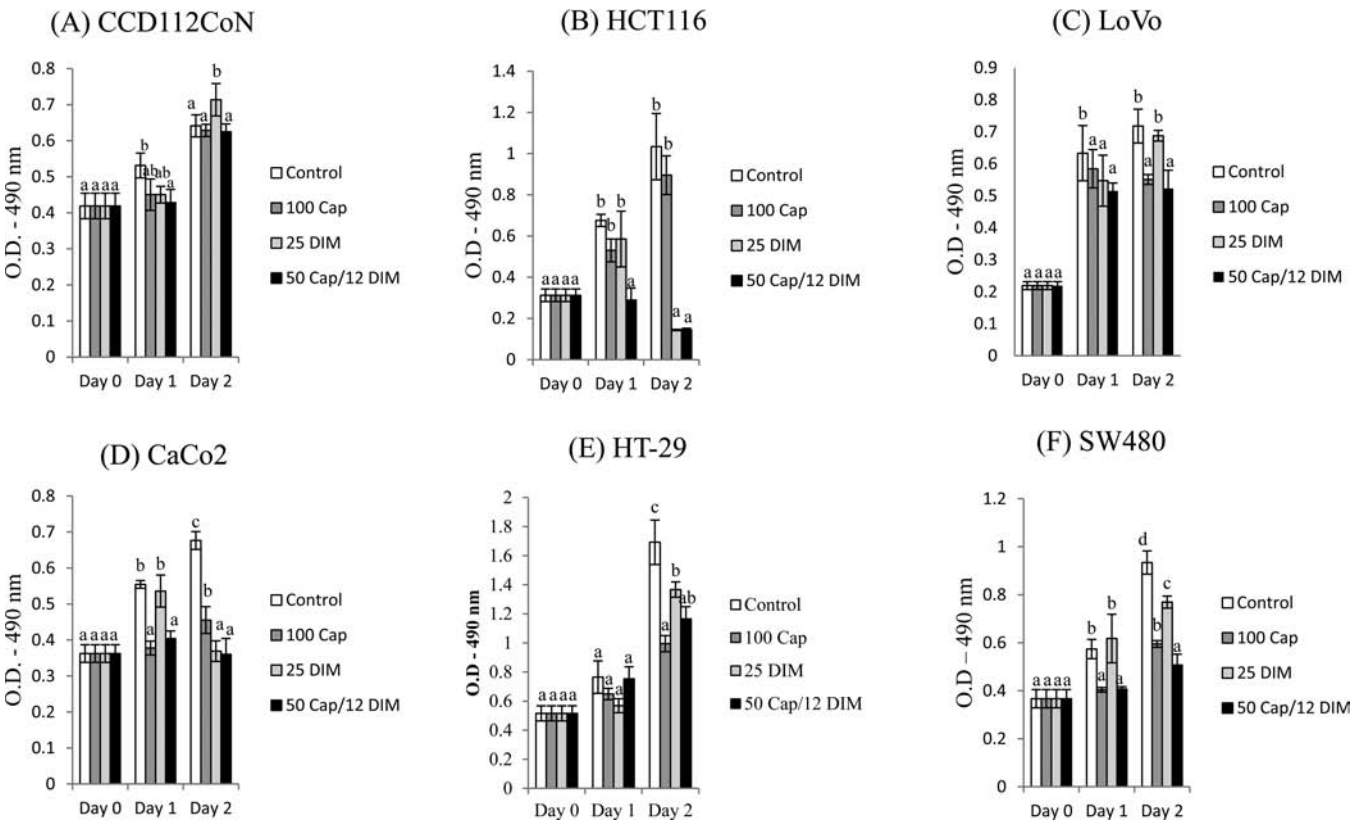

Figure 2. Combination treatment inhibits cell proliferation in multiple human colorectal cancer cell lines, but not normal colon cells. Normal human colon CCD112CoN (A) and human colorectal cancer cell lines HCT116 (B), LoVo (C), CaCo-2 (D), HT-29 (E), and SW480 (F) were plated onto a 96-well plate and grown overnight. The cells were treated with different concentrations of capsaicin (0 or 100 μM), DIM (0 or 25 μM), or a combination (50 μM capsaicin and 12 μM DIM) in media supplemented with 1% FBS for 24 and 48 h at 37 °C under 5% CO_2. Values are means ± SD, $n = 3$. Different letters indicate significant differences at $P < 0.05$.

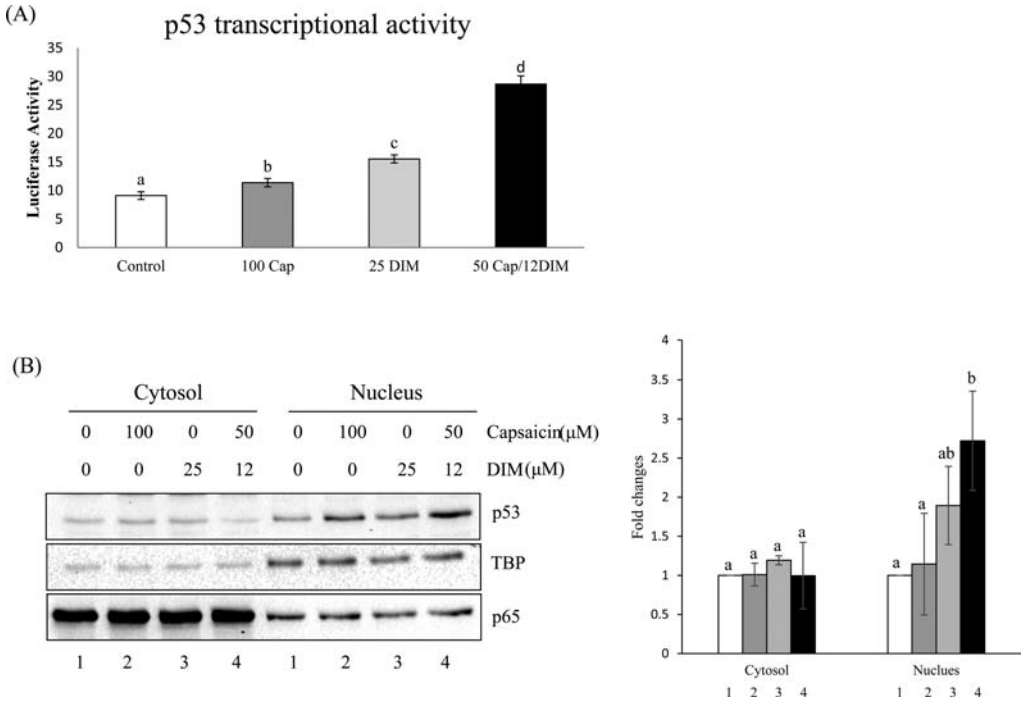

Figure 3. Combination treatment synergistically increases transcriptional activity of p53 and increases expression of p53 in nucleus. (A) HCT116 cells were transfected with plasmid containing 1 μg of p53 luciferase plasmid and 0.1 μg of pRL-null vector for 24 h at 37 °C. The transfected cells were then treated with the vehicle as the control or 100 μM capsaicin and 25 μM DIM individually or in combination for 24 h in serum-free media. The cells were harvested in 1× luciferase lysis buffer, and luciferase activity was measured. Values are means ± SD, $n = 3$. Different letters indicate significant differences at $P < 0.05$. (B) HCT116 cells were treated with 100 μM capsaicin and 25 μM DIM individually or combination for 24 h in serum-free media. Cells were washed with ice-cold PBS and harvested. The cytoplasm was separated from the nucleus and cell lysates were analyzed by Western blot for p53, TATA-binding protein (TBP), and p65. TBP was used as a nuclear loading control. The graph (right panel) indicates statistics of three independent experiments. Different letters indicate significant differences at $P < 0.05$ (1, control; 2, 100 μM capsaicin; 3, 25 μM DIM; 4, 50 μM capsaicin + 12 μM DIM combination).

present study, we hypothesize that capsaicin and DIM possess combinational anticancer activity.

To test this hypothesis, we treated HCT116 cells with different concentrations of the two compounds individually or combined and then measured apoptosis. As shown in Figure 1A, the combination of 50 μM capsaicin and 12 μM DIM resulted in a significant increase in the percentage of apoptotic cells. To assess if the compounds had the same effect in multiple colorectal cancer cell lines, LoVo, CaCo2, HT-29, and SW480 (Figure 1B–E) were all treated individually or in combination with the compounds. Interestingly, the combination of 50 μM capsaicin and 12 μM DIM significantly increased apoptosis in all of the cell lines. Thus, we chose this concentration for further study.

To assess the effect of treatment on normal colon cancer cells, CCD112CoN (Figure 2A) was treated with the compounds individually or in combination and cell proliferation was assessed. Whereas there was a small but significant decrease seen in cell proliferation following cotreatment for 24 h, this was not seen after 48 h of treatment. This is in agreement with others that have shown that capsaicin and DIM are nontoxic to normal cells.[10,27−29] However, when multiple colorectal cancer cell lines were treated with the compounds, significant inhibition of cell proliferation was noted in all cell lines (Figure 2B–F). Although the patterns of response of human colorectal cancer cells to capsaicin and DIM are different according to types of cells, the combination of low-dose capsaicin and DIM showed activity similar to that of high doses of single compounds in terms of suppressing cell proliferation. The synergistic antigrowth activity was also observed in non-colorectal cancer cell lines such as A549 and PC-3 (data not shown), indicating that antiproliferative activity by a combination of two dietary compounds might be common in human cancers.

Combination Treatment Increases Transcriptional Activity of p53 and Increases Expression in the Nucleus. The tumor suppressor gene p53 plays a major role in the regulation of apoptosis, cell cycle arrest, and DNA repair. Dysregulation of p53 leads to evasion of apoptosis and rapid growth of cancer cells;[30] many genes associated with cell cycle, senescence, DNA repair, and apoptosis are transcriptional targets of p53, and they are all essential barriers to tumor initiation and progression. Therefore, targeting p53 and the downstream transcriptional targets in cancer cells offers promising therapeutic interventions for cancer prevention and treatment.[31] For further study, we selected HCT116 cells, which is a p53 wild type, whereas other cell lines (CaCo-2, SW480, and HT-29) have truncated or point mutation of p53. To test if combination treatment targeted the p53 tumor suppressor, we measured the transcriptional activity of p53 in HCT116 cells transfected with the p53 luciferase plasmid. As shown in Figure 3A, treatment with the individual compounds resulted in increased transcriptional activity, but combination treatment was much more significant. To assess the level of p53 proteins in the cells, HCT116 cells were treated with the compounds for 24 h and harvested, and the cytoplasm and nucleus were separated. The fraction was analyzed by Western blotting for p53, and TATA-binding protein (TBP) and p65 were used as nuclear fraction marker and loading control, respectively. As seen in Figure 3B, there was an increase in the level of p53 in the nucleus of the cells

incubated with the combination of both capsaicin and DIM as compared to control and the individual compounds.

Combination Treatment Synergistically Increased Transcriptional Activity of NF-κB. The NF-κB family of transcription factors has been shown to play an important role in regulating apoptosis, in both inducing apoptosis and blocking it. It has also been shown to act on cell cycle regulation through sensitizing or desensitizing a cell to apoptotic signals. The dual roles of NF-κB transcription factors have led to much debate regarding its role in cancer initiation and progression.[32,33] Given that both p53 and NF-κB are transcription factors stimulated with cellular stress, and the compounds already have demonstrated the ability to increase p53 transcriptional activity, we tested if capsaicin and DIM affect the transcriptional activity of NF-κB. HCT116 cells were transfected with plasmid containing 1 μg of NF-κB luciferase plasmid and 0.1 μg of pRL-null vector for 24 h at 37 °C. The transfected cells were then treated with the vehicle as the control or capsaicin and DIM individually or in combination for 24 h. The cells were harvested in 1× luciferase lysis buffer, and luciferase activity was measured (Figure 4). Interestingly, the transcriptional activity of NF-κB significantly increased with combination treatment as compared with the individual compounds.

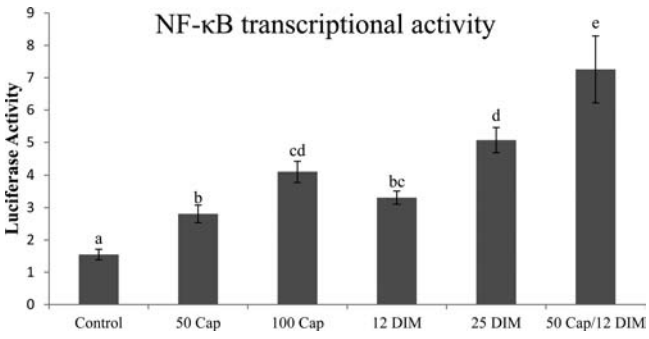

Figure 4. Combination treatment synergistically increases transcriptional activity of NF-κB. HCT116 cells were transfected with plasmid containing 1 μg of NF-κB luciferase plasmid and 0.1 μg of pRL-null vector for 24 h at 37 °C. The transfected cells were then treated with the vehicle as the control or 100 μM capsaicin and 25 μM DIM individually or combination for 24 h in serum-free media. The cells were harvested in 1× luciferase lysis buffer, and luciferase activity was measured. Values are means ± SD, $n = 3$. Different letters indicate significant differences at $P < 0.05$.

Effect of Combination Treatment on Expression of Genes Involved in Apoptosis and Cell Cycle. After observation of the effect of combination treatment on cell proliferation, apoptosis, p53, and NF-κB transcription, it was hypothesized that genes and proteins known to be regulated by p53 and NF-κB could be modulated through combination treatment. Western blot analysis was used to analyze target proteins that are involved in these processes, and RT-PCR was used to confirm mRNA levels of the target genes. As seen in Figure 5A, combination treatment resulted in increased expression of both p21 and 27 with subsequent inhibition of CDK4 and CDK 6. Treatment of HCT-116 cells with the combination of capsaicin and DIM significantly increased or tended to increase expression of multiple pro-apoptotic proteins (Figure 5B). Bak, BID, Bax, Puma, and Fas-L are all pro-apoptotic proteins that have been shown to be downstream of p53.[30,34,35]

Combination treatment resulted in down-regulation of pro-survival protein, Bcl-2 (Figure 5C). Bcl-2 inhibits apoptosis and has been shown to be overexpressed in many types of cancer cells.[36] Reduced Bcl-2 expression promotes apoptotic responses to anticancer drugs, whereas increased expression leads to resistance to chemotherapeutic drugs and radiation therapy and is a target to prevent drug resistance and increased apoptosis. Tumor necrosis factor receptor-associated factors 2 and 3 (Traf2 and Traf3) have also been shown to be oncogenes that regulate the noncanonical signaling of NF-κB. Previous groups have shown that suppression of Traf2 and Traf3 results in decreased proliferation and tumorigenesis.[37] Combination treatment resulted in down-regulation of these two oncogenes (Figure 5C).

Following treatment with capsaicin and DIM, cells were harvested, and RT-PCR was performed to analyze levels of mRNA for p21 and Bak (Figure 5D). Increased levels of p21 and Bak mRNA were identified following treatment with both capsaicin and DIM, although significantly so only in p21.

Modulation of Target Proteins in a p53-Dependent Manner. The p53 tumor suppressor protein performs a critical role in inducing apoptosis. Many of the pro-apoptotic Bcl-2 family members including Puma, Bax, and Bak have been reported to be transcriptional targets of p53.[34] Also, the cell cycle regulating proteins, p27 and p21, are also transcriptional targets of p53.[31] To test if the target genes modulated by combination treatment identified previously were dependent on p53, HCT116 p53 null cells were plated and treated with various concentrations of capsaicin individually (100 μM) and DIM individually (25 μM) as well as in combination (50 μM capsaicin and 12 μM DIM). The cells were harvested and the lysates subjected to analysis by Western blot. Interestingly, p21, p27, and Bak were all up-regulated in a p53-dependent manner (Figure 6).

DISCUSSION

There is growing evidence from in vitro and in vivo studies indicating that combinations of phytochemicals can result in significant activities at concentrations where any single agent is inactive. Here, we propose two mechanisms by which a combination of capsaicin and DIM increases apoptosis and changes expression of cell growth and apoptosis-related genes. First, we observed that the compounds increased transcriptional activity (Figure 3A) as well as p53 nuclear accumulation (Figure 3B). p53 accumulation in the nucleus seems to be associated with its protein stability. Ser15 phosphorylation of p53 suppresses ubiquitination of p53[38] and subsequent 26S proteasome-mediated degradation by reducing the interaction of p53 with E3 ligase and MDM2 and eventually promotes the accumulation and transactivation.[39] Most studies support that p53 degradation occurs exclusively on cytoplasmic proteasome by focusing on nuclear export of p53 via the CRM-1 pathway. However, proteasomes are abundant in both cytosol and nucleus, and many studies support proteosomal degradation of transcription factors in the nucleus. In addition, inhibition of proteasomal degradation using MG-132 leads to localization of p65 and p53 in nucleolus (fibrillar centers) compartments.[40]

Second, in the present study, we observed that combination of capsaicin and DIM synergistically increased the transcriptional activity of NF-κB. The transcription factor NF-κB is recognized as a key mediator of the cellular stress response upon anticancer therapy, and the activation of NF-κB can lead to a pro-death response. It is believed that increased NF-κB mediates apoptosis induced by anticancer agents.[41−44] Thus, further study is

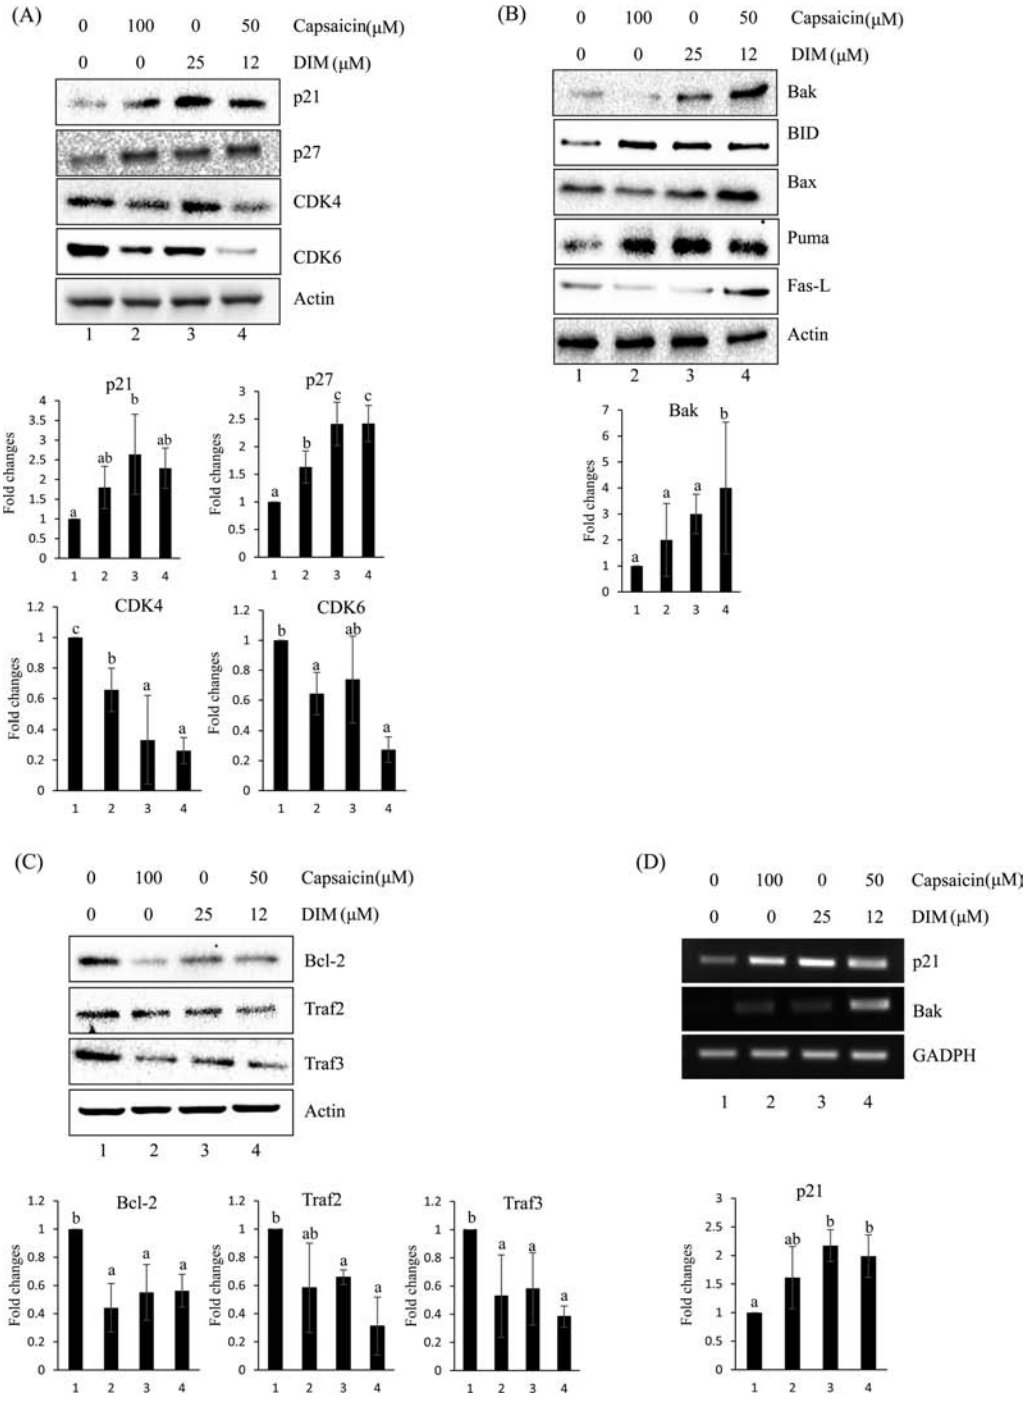

Figure 5. Analysis of protein and mRNA expressions in HCT116 cells treated with capsaicin and DIM. HCT116 cells were treated with different concentrations of capsaicin (0 or 100 μM), DIM (0 or 25 μM), or a combination (50 μM capsaicin and 12 μM DIM) for 24 h in serum-free media. The cells were harvested, and cell lysates were analyzed with Western blot for target proteins. (A) Expression of proteins regulating the cell cycle including p21, p27, CDK4, and CDK6. (B) Proteins with pro-apoptosis functions including Bak, BID, Bax, Puma, and Fas-L were analyzed. (C) Anti-apoptotic proteins including Bcl-2, Traf2, and Traf3 were analyzed. (D) HCT116 cells were treated with capsaicin (100 μM), DIM (25 μM), or a combination (50 μM capsaicin and 12 μM DIM) in serum-free media. Total mRNA was harvested and RT-PCR was performed. The graph indicates statistics of three independent experiments. Different letters indicate significant differences at $P < 0.05$ (1, control; 2, 100 μM capsaicin; 3, 25 μM DIM; 4, 50 μM capsaicin + 12 μM DIM combination).

required to investigate how compounds activate the transcriptional activity of NF-κB.

Although the main control of NF-κB activation is cytoplasmic IκB, recently many studies propose additional mechanisms that are required to activate or prevent activity of NF-κB protein. In fact, NF-κB recruitment is dynamically regulated by multiple signaling inputs, and NF-κB depends entirely on cooperative interactions with partner transcription factors for recruitment to some genes. NF-κB also can be regulated in the nucleus by complex mechanisms that are still obscure. They include post-translational modification and nuclear distribution of p65, which could determine cell fate, pro-apoptotic or anti-apoptotic, and

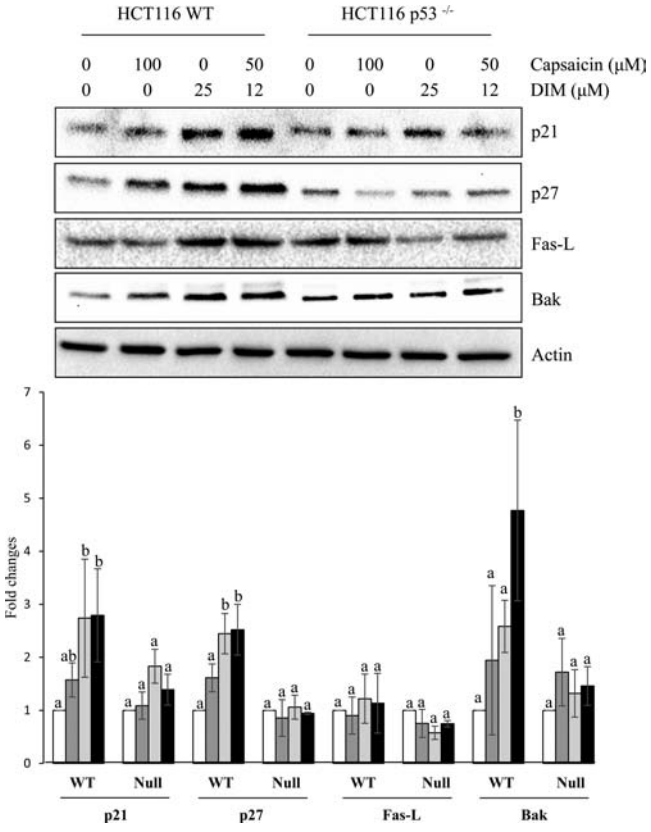

Figure 6. Modulation of target proteins in a p53-dependent manner. HCT116 wild type (WT) and HCT116 p53 null (−/−) cells were treated with capsaicin (100 μM), DIM (25 μM), or a combination (50 μM capsaicin and 12 μM DIM) for 24 h in serum-free media. The cells were harvested, and cell lysates were analyzed with Western blot for target proteins. The graph indicates statistics of three independent experiments. Different letters indicate significant differences at $P < 0.05$.

influence its transcriptional activity. For example, an increased accumulation of p65 in nucleoplasm results in apoptosis, whereas accumulation of p65 in nucleolus is a mechanism of apoptosis activation in response to apoptotic stimuli.[45]

Another interesting point is that p53 and NF-κB have shown an ability to interact with each other and coordinate induction of apoptosis. For example, many pro-apoptotic stimuli such as DNA-damaging agents lead to transcriptional coactivation of p53 and NF-κB. Ryan et al.[46] suggested that p53 directly activates transcriptional activity of NF-κB, which is required for p53-induced apoptosis. Other studies demonstrate that p53-dependent NF-κB activation could contribute to the apoptotic response,[47] and the loss of p53 could abrogate NF-κB-mediated apoptotic response.[48] p65 has been reported to promote apoptosis by actively repressing transcription of anti-apoptotic genes through association of p65 with histone deacetylase-containing complexes acting as co-repressor.[49] Overall, even though we did not study direct interaction between p53 and NF-κB, it is possible that both NF-κB and p53 may be essential for apoptosis induced by combination treatment. Fas ligand (FasL) is believed to be a common target for p53 and NF-κB, and induction of FasL is required for p53- and NF-κB-dependent apoptosis.[50−52] Therefore, FasL is a good target protein for studying p65- and p53-mediated apoptosis. Although we claim that p53 mediates capsaicin and DIM's effect, we do not exclude the possibility that this combination suppressed cell proliferation and induced apoptosis through a p53-independent mechanism because some cell lines such as SW480 and CaCo-2 are p53 mutants, and we showed in these cell lines increased apoptosis and inhibited cell proliferation with combinations (Figures 1 and 2).

In summary, the data presented here show that combination treatment is able to work synergistically to mediate inhibition of cell proliferation and induction of apoptosis. Interestingly, the compounds targeted p53 and NF-κB transcriptional factors and modulated known downstream target proteins. Dietary phytochemicals offer a safe colorectal cancer preventive alternative for targeting multiple pathways.

NASH. Therefore, in the present study, we investigated whether genistein alleviates NASH development in *db/db* mice fed an MCD diet.

MATERIAL AND METHODS

Animals and Diets. At 5 weeks of age, male C57BLKS/J-*db/db* mice were purchased from Japan SLC, Inc. (Hamamatsu, Japan). After a 2 week acclimation period, confirmed high-glucose *db/db* mice were randomly divided into three groups and fed a control MCS diet (no. 518811; Dyets Inc., Bethlehem, PA), an MCD diet (no. 518810), or an MCD diet supplemented with genistein (0.5 g/kg diet; ChromaDex Inc., Irvine, CA) for 6 weeks. A previous study reported that the serum genistein concentration of C57BL/6J mice fed a genistein-supplemented diet (0.6 g/kg diet) for 4 weeks was 3.97 μmol/L,[20] which is similar to that detected in women consuming soy products.[21] Body weight was recorded every week, and blood glucose levels were measured with a glucose meter (Accu-chekGo, Roche, Basel, Switzerland) after 6 h of fasting. All mice were maintained in a temperature-controlled (22 ± 3 °C), humidity-controlled (50 ± 10%) room with a 12 h dark−light cycle. All treatment protocols for this study were approved by the Seoul National University Institutional Animal Care and Use Committee (SNU-100524-5). At the end of the study, the mice fasted for 16 h, blood was collected by cardiac puncture, and tissues were removed, quickly frozen in liquid nitrogen, and stored at −80 °C until analysis.

Serum and Hepatic Biochemical Analyses. Serum was analyzed using commercial colorimetric assay kits (Asan Pharmaceutical Co., Seoul, Korea) for glucose, triglycerides, total cholesterol, and alanine aminotransferase (ALT) according to the manufacturer's protocol. Serum insulin levels were measured using an insulin ELISA kit (Millipore, Billerica, MA). Homeostasis model assessment-insulin resistance (HOMA-IR) was calculated using the following formula: HOMA-IR = [fasting glucose (mmol/L) × fasting insulin (μU/mL)]/22.5.

Hepatic total lipids were extracted according to the method of Folch et al.[22] Triglyceride and cholesterol concentrations were determined using the same commercial kits used in serum samples. Hepatic thiobarbituric acid reactive substances (TBARS) were measured according to the method of Ohkawa et al.[23] The absorbance of the butanol layer was measured at 532 nm using 1,1,3,3-tetraethoxypropane as a standard. The hepatic lipid peroxide level was expressed as malondialdehyde equivalents per milligram of protein. The protein content of the homogenate was measured with a protein assay kit (Bio-Rad, Hercules, CA).

Liver Histology Examination. Formalin-fixed liver tissue was processed into 4-μm-thick paraffin sections and stained with hematoxylin and eosin (H&E) for histological evaluation. Liver fibrosis was assessed with Masson's trichrome staining for collagen fibers. The morphology was observed under an Olympus BX50 microscope with a DP-72 digital camera (Olympus, Japan), and the image was captured using the Image-Pro Plus ver. 4.5 program (Media Cybernetics Inc., USA).

Immunoblotting. Liver tissues were homogenized in 10 volumes (w/v) of ice-cold protein lysis buffer. Thirty micrograms of protein was loaded into the lanes of an SDS-PAGE gel, separated, and blotted onto a PVDF membrane. After being blocked with 5% nonfat milk or bovine serum albumin in TTBS, membranes were probed with specific antibodies diluted in TTBS with 5% nonfat milk or bovine serum albumin as follows: anti-AMP kinase alpha (AMPKα; Cell Signaling, Danvers, MA), anti-p-AMPKα (Cell Signaling), anti-C/EBP homologous protein (CHOP; Santa Cruz Biotechnology, Santa Cruz, CA), anti-KDEL (Enzo Life Sciences, Farmingdale, NY), or anti-70-kDa heat shock cognate protein (HSC70; Santa Cruz Biotechnology). The membranes were then incubated with an IgG-peroxidase-conjugated secondary antibody for chemiluminescent detection. The band intensities were quantified using Quantity One software (Bio-Rad).

Semiquantitative and Quantitative PCR (qPCR) Analyses. The total RNA of the liver tissues was isolated using the RNAiso Plus (Takara Bio Inc., Otsu, Japan), and cDNA was synthesized with SuperscriptII Reverse Transcriptase (Invitrogen, Carlsbad, CA). Hepatic mRNA levels were analyzed by qPCR with a StepOne Real Time PCR System (Applied Biosystems, Carlsbad, CA) using the SYBR Green PCR Master Mix (Applied Biosystems). Mouse ribosomal protein L19 (RPL19) was used as a reference gene, and relative gene expression levels were analyzed using the $2^{-\Delta\Delta}$Ct method. To determine mRNA levels of spliced XBP-1, semi-quantitative PCR was used as previously described.[24] The expression of β-actin was examined as an internal control. The primer sequences are described in Supporting Information Table S1.

Statistical Analysis. All data were analyzed using SPSS software (ver. 21.0, SPSS Inc., Chicago, IL). For all experiments, one-way ANOVA followed by Duncan's multiple range test or the Student *t* test was employed to assess the statistical significance. Data were expressed as the mean ± SEM, and differences were considered to be statistically significant at $P < 0.05$.

RESULTS

Effects of Genistein on Body Weight and Serum Biochemical Parameters in *db/db* Mice Fed an MCD Diet. We observed a gradual body weight decrease in *db/db* mice fed an MCD diet (Supporting Information Figure S1). Blood glucose was also significantly reduced in mice fed an MCD diet within a week. Consistently, the epididymal fat mass weight was significantly lower in *db/db* mice fed an MCD diet than those fed an MCS diet (Table 1). Genistein supplementation significantly increased the relative epididymal fat mass weight. Although MCD feeding significantly reduced the relative liver weight, the effect of genistein on liver weight was not observed.

Table 1. Characteristics of *db/db* Mice Fed an MCS, MCD, or MCD with Genistein Diet[a]

	MCS	MCD	MCD + GEN
final body weight (g)	42.0 ± 1.4[b]	29.1 ± 1.2[a]	29.8 ± 1.1[a]
epididymal fat (g)	2.27 ± 0.10[b]	1.47 ± 0.08[a]	1.69 ± 0.08[a]
relative epididymal fat weight (% of body weight)	5.47 ± 0.21[ab]	5.01 ± 0.10[a]	5.67 ± 0.09[b]
liver weight (g)	3.47 ± 0.26[b]	1.62 ± 0.10[a]	1.69 ± 0.10[a]
relative liver weight (% of body weight)	8.19 ± 0.38[b]	5.55 ± 0.27[a]	5.64 ± 0.19[a]

[a]Results are given as the mean ± SEM ($n = 10$). Means that do not share the same superscript are significantly different by ANOVA ($P < 0.05$).

Table 2. Fasting Serum Biochemical Analyses of *db/db* Mice Fed an MCS, MCD, or MCD with Genistein Diet[a,*]

	MCS	MCD	MCD + GEN
glucose (mg/dL)	765.9 ± 74.7[b]	105.4 ± 7.1[a]	127.0 ± 14.4[a]
insulin (ng/mL)	1.59 ± 0.24[c]	0.92 ± 0.13[b]	0.39 ± 0.09[a]
HOMA-IR	67.86 ± 12.00[a]	5.63 ± 1.04[b]	2.48 ± 0.34[b]*
triglyceride (mg/dL)	122.8 ± 14.0	121.4 ± 12.8	108.4 ± 2.9
total cholesterol (mg/dL)	230.9 ± 21.9[b]	126.7 ± 4.7[a]	128.3 ± 10.7[a]
ALT (IU/L)	180.1 ± 23.6[a]	332.1 ± 43.9[b]	296.8 ± 9.8[b]

[a]Results are given as the mean ± SEM ($n = 7$). Means that do not share the same superscript are significantly different ($P < 0.05$). *MCD vs MCD + GEN by the *t* test ($P < 0.05$).

We observed significantly reduced serum glucose and insulin levels and HOMA-IR in mice fed an MCD diet compared to mice fed an MCS diet (Table 2). Supplementation of genistein

DOI: 10.1021/acs.jafc.5b00398
J. Agric. Food Chem. 2015, 63, 4305−4311

significantly reduced serum insulin levels and HOMA-IR (P = 0.014, t test). MCD feeding significantly reduced serum total cholesterol levels but not serum triglyceride levels. Serum ALT levels were significantly increased in *db*/*db* mice compared to those in mice fed an MCD diet, but there was no significant effect of genistein on serum ALT levels.

Effects of Genistein on Liver Steatosis in *db*/*db* Mice Fed an MCD Diet. The MCD diet significantly increased hepatic triglyceride levels in *db*/*db* mice (Figure 1A). The supplementation of an MCD diet with genistein did not alleviate the accumulation of hepatic triglyceride in *db*/*db* mice. There was no significant difference in hepatic cholesterol levels among the groups. The microscopic examination of H&E staining of liver tissues was consistent with hepatic lipid biochemical characteristics (Figure 1B). We observed the microvascular steatosis in *db*/*db* mice fed an MCS diet. Interestingly, the MCD diet induced macrovascular steatosis and inflammatory foci, which were less observed in *db*/*db* mice fed a genistein-supplemented diet.

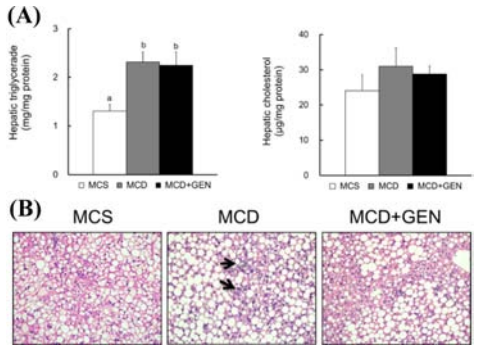

Figure 1. (A) Hepatic triglycerides and cholesterol contents in *db*/*db* mice fed an MCS diet, MCD diet, or MCD with genistein diet. Each bar represents the mean ± SEM (n = 7), and bars that do not share the same letter are significantly different by ANOVA (P < 0.05). (B) Representative H&E staining of liver tissue sections (n = 4). Black arrows indicate inflammatory foci.

Effects of Genistein on Oxidative Stress and ER Stress in *db*/*db* Mice Fed an MCD Diet. The increased generation of ROS by microsomal CYP2E1 enzyme has been proposed as an initiator of oxidative stress associated in MCD-diet-mediated steatohepatitis in mice.[25] To determine the oxidative stress, we measured hepatic malondialdehyde levels and hepatic enzyme levels involved in oxidative stress. Mice on an MCD diet exhibited significantly higher TBARS levels, which were alleviated by genistein supplementation (Figure 2A). Accordingly, the mRNA levels of heme oxygenase (HO-1) were significantly induced in mice fed an MCD diet (Figure 2B). Genistein supplementation significantly reduced the mRNA levels of HO-1.

In addition to oxidative stress, endoplasmic reticulum (ER) stress has been shown to be induced in an MCD-diet-induced NASH model. To determine the effects of genistein on ER stress, we examined the cellular markers of ER stress including glucose-regulated protein 78 (Grp78/BiP) and CHOP proteins

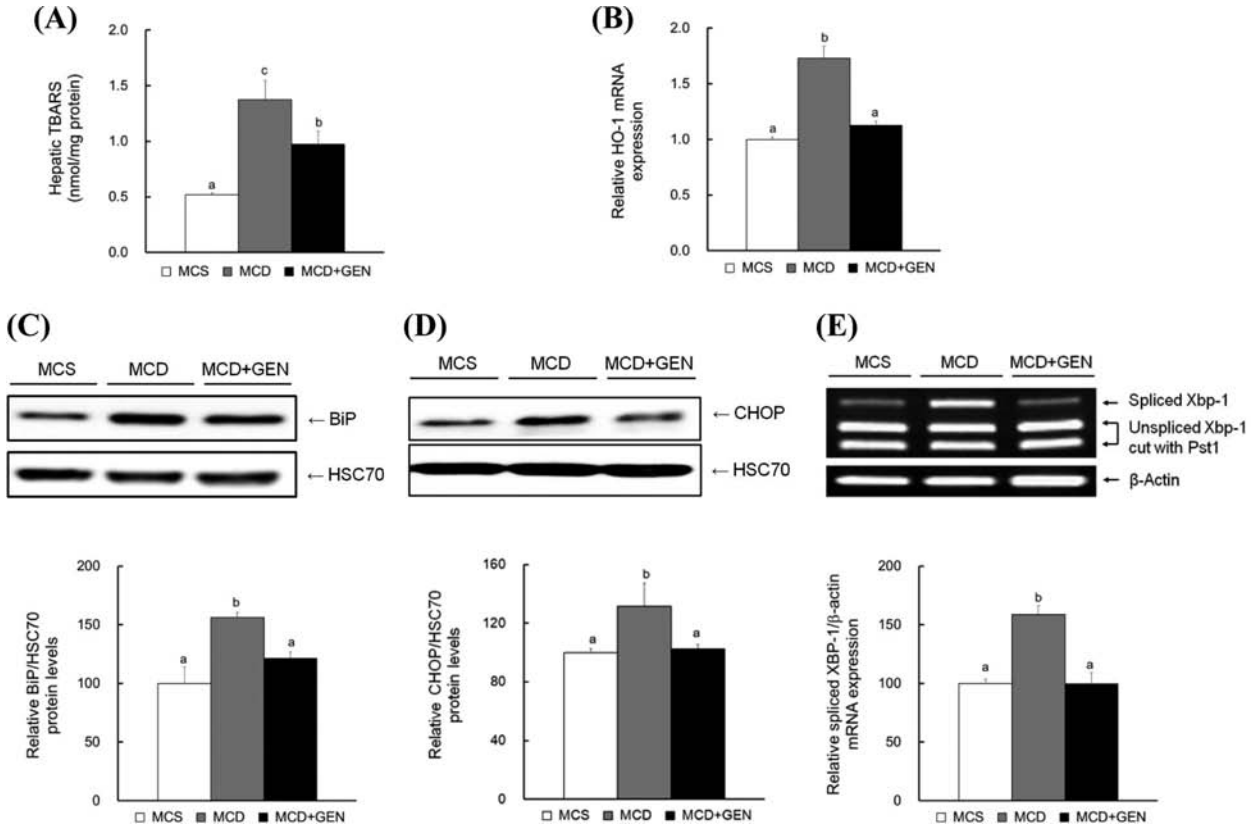

Figure 2. Oxidative stress and ER stress markers in *db*/*db* mice fed an MCS diet, MCD diet, or MCD with genistein diet. (A) Hepatic TBARS levels (n = 5). (B) Relative mRNA expression of HO-1/RPL19 determined by qPCR (n = 3–4). (C) Relative BiP/HSC70 and (D) CHOP/HSC70 protein levels determined by immunoblotting (n = 3). (E) Relative mRNA expression levels of the spliced form of XBP-1/β-actin determined by semiquantitative PCR (n = 3–4). Each bar represents the mean ± SEM, and bars that do not share the same letter are significantly different by ANOVA (P < 0.05).

DOI: 10.1021/acs.jafc.5b00398
J. Agric. Food Chem. 2015, 63, 4305–4311

and the spliced form of XBP-1 mRNA.[26] As shown in Figure 2C,D, protein expression levels of Grp78/BiP and CHOP were significantly increased in *db*/*db* mice fed an MCD diet compared to those in *db*/*db* mice fed an MCS diet. Genistein supplementation significantly alleviated Grp78/BiP and CHOP induced in mice fed an MCD diet. We also observed a significant induction of the spliced form of XBP-1 mRNA in mice fed an MCD diet. The suppressive effect of genistein on the induction of the spliced form of XBP-1 mRNA was significant (Figure 2E).

Effects of Genistein on Hepatic Inflammation in *db*/*db* Mice Fed an MCD Diet. Consistent with increased inflammatory foci, the MCD diet significantly induced the mRNA levels of tumor necrosis factor alpha (TNF-α), monocyte chemoattractant protein 1 (MCP-1), toll-like receptor 4 (TLR4), and interleukin 1 beta (IL-1β) (Figure 3A). These inflammatory gene expressions were significantly alleviated by genistein supplementation.

The hepatic adiponectin resistance has been suggested to be involved in steatohepatitis progression by changing peroxisome proliferator-activated receptor alpha (PPARα) activity and ROS accumulation.[27] Therefore, we determined whether genistein modulates the AMPK pathway in the MCD-mediated steatohepatitis model. Feeding an MCD diet significantly inhibited AMPK activation, which was alleviated by genistein supplementation (Figure 3B). Furthermore, mRNA levels of PPARα, a downstream transcription factor of adiponectin signaling, were significantly reduced in mice fed an MCD diet (Figure 3C). Although genistein supplementation tended to increase PPARα mRNA levels, the difference was not significant. As previously reported,[28] adiponectin resistance was not associated with an altered adiponectin receptor expression in the livers of MCD-diet-fed mice (data not shown).

Effects of Genistein on Liver Fibrosis in *db*/*db* Mice Fed an MCD Diet. To examine the effects of genistein supplementation on liver fibrosis, sections of liver were stained with Masson's trichrome. Mild periportal fibrosis in the absence of apparent hepatocellular ballooning was observed in MCD-diet-fed mice (Figure 4A). Genistein apparently reduced Masson's trichrome-stained fibrils induced by an MCD diet. Parallel to the changes in histological fibrosis, increased hepatic transforming growth factor β (TGF-β), procollagen, type I, alpha 1 type I (COL1A1), and tissue inhibitors of metalloproteinase 1 (TIMP1) mRNA levels in MCD-diet-fed *db*/*db* mice were significantly diminished by genistein treatment (Figure 4B).

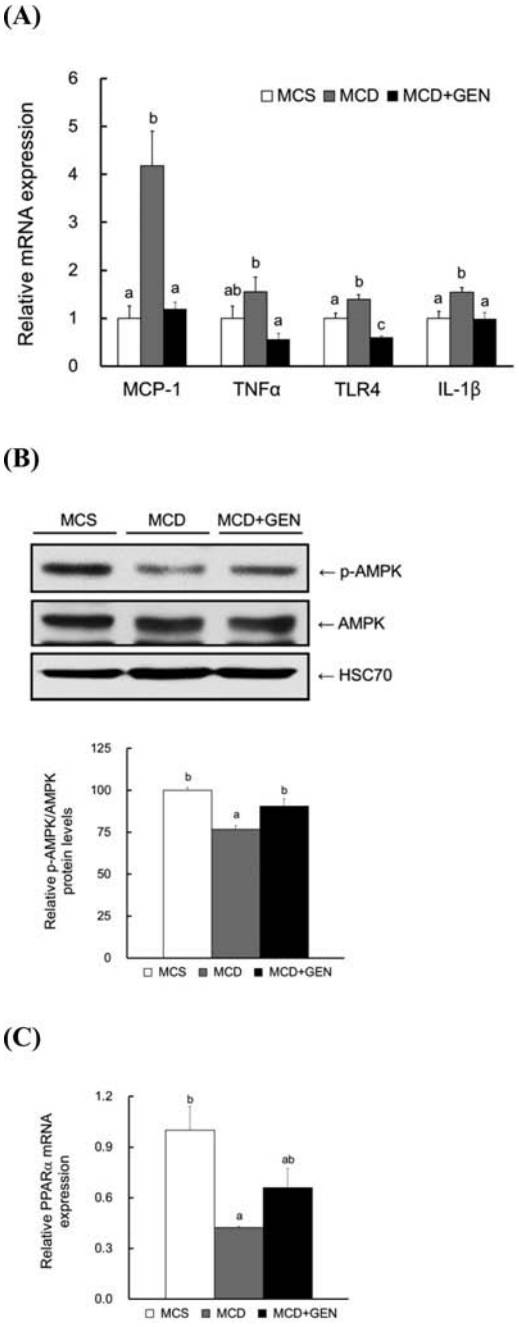

Figure 3. Hepatic inflammatory markers in *db*/*db* mice fed an MCS diet, MCD diet, or MCD with genistein diet. (A) Relative mRNA expression of genes involved in inflammation determined by qPCR and normalized to RPL19 (n = 3–4). (B) Relative p-AMPK/AMPK protein levels determined by immunoblotting (n = 3). (C) Relative mRNA expression of PPARα/RPL19 determined by qPCR (n = 3). Each bar represents the mean ± SEM, and bars that do not share the same letter are significantly different by ANOVA (P < 0.05).

DISCUSSION

We observed that genistein inhibited oxidative stress and ER stress, allowing for the alleviation of liver inflammation and fibrosis in the MCD-diet-mediated NASH model. Although this animal model has its own limitations, including the lack of obesity and peripheral insulin resistance,[29] it is a useful model for clarifying whether genistein could alleviate the progression of steatohepatitis to liver fibrosis, which is not easily induced in dietary NASH models. In addition, the present study allows us to clarify whether genistein could exhibit the anti-inflammatory effect in the NASH model which is not accompanied by obesity.

In the MCD model, the "first hit" is the impaired mitochondrial β-oxidation, and the "second hit" is increased oxidative stress and lipid peroxidation,[30] which induce proinflammatory gene expression, neutrophil chemotaxis, and hepatic stellate cell activation.[31−33] The protective action of genistein may be due to the inhibition of the pathway involved in the second hit because we did not observe a significant decrease in hepatic triglyceride levels by genistein supplementation. Indeed, genistein attenuated the oxidative stress in the liver of mice fed an MCD diet. In support of this view, we observed the antioxidative effect of genistein in the previous study, in which genistein supplementation (0.5 g/kg diet) in a

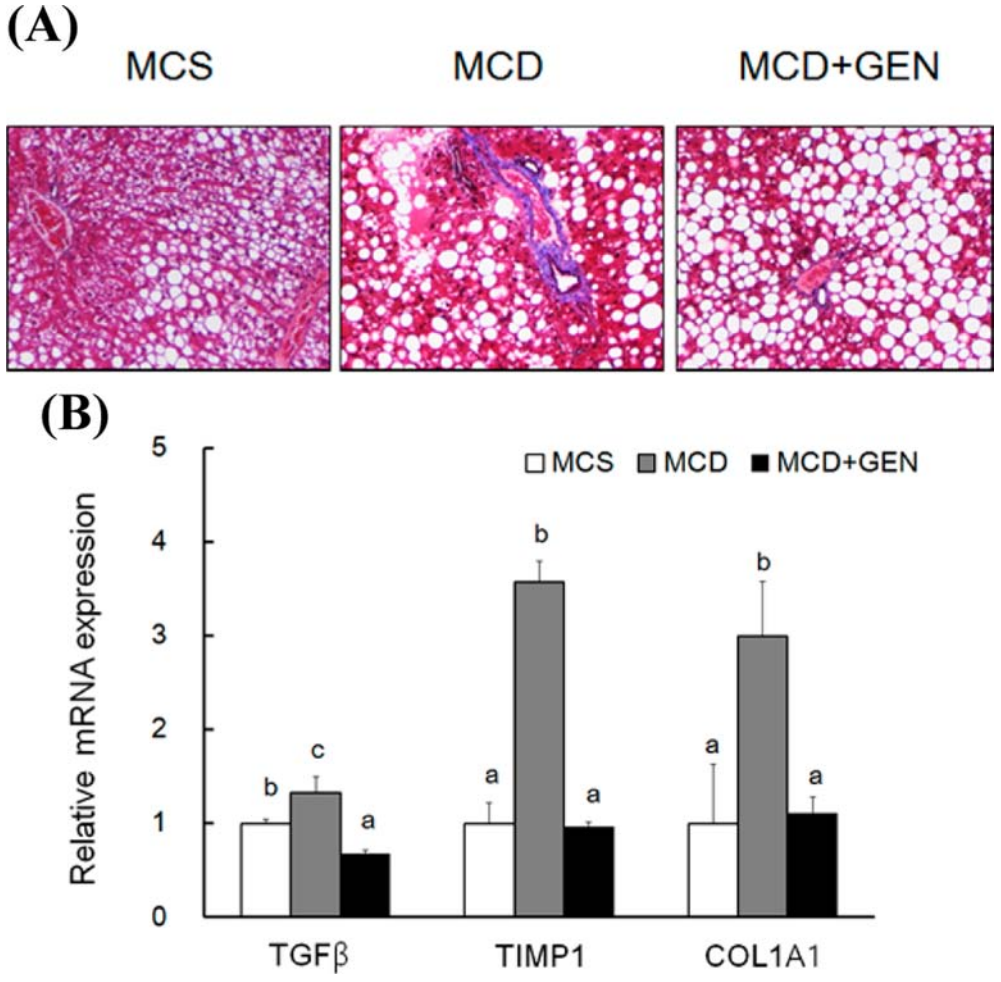

Figure 4. Hepatic fibrosis markers in *db*/*db* mice fed an MCS diet, MCD diet, or MCD with genistein diet. (A) Representative Masson's trichrome staining of liver tissue sections (n = 4). (B) Relative mRNA expression of genes involved in fibrosis determined by qPCR and normalized to RPL19 (n = 3–4). Each bar represents the mean ± SEM, and bars that do not share the same letter are significantly different by ANOVA (P < 0.05).

high-fat diet significantly lowered hepatic lipid peroxidation levels in ApoE knockout mice.[18] Antioxidants including vitamin E and α-lipoic acid have been shown to prevent the development and progression of NASH in mice fed an MCD diet.[34,35] ROS is shown to be involved in TLR4-mediated inflammasome activation in NASH,[36] which has been shown to be involved in hepatocyte pyroptosis, liver inflammation, and fibrosis.[37]

Furthermore, we observed that dietary supplementation of genistein attenuates liver fibrosis via the inhibition of collagen synthesis and the activation of extracellular matrix degradation. Several experimental studies have shown the protective effect of estrogen against liver fibrosis. Estradiol inactivated transcription processes involved in TGF-β1 expression by suppressing ROS generation and the mitogen-activated protein kinase pathways in hepatic stellate cells from rats,[13] suggesting that the estrogenic effect of genistein may be associated with the observed antifibrogenesis. Previous studies reported that genistein had positive effects on liver fibrosis induced by CCl_4 administration in rats[38,39] and by chronic alcohol administration in rats.[40] However, this is the first study to report the antifibrotic effect of genistein in dietary models of NASH.

We also demonstrated that genistein alleviated the impaired adiponectin signaling pathway. Previous studies reported that feeding an MCD diet induces hepatic adiponectin resistance, which fails to activate AMPK or PPARα,[28] and that the administration of a PPARα agonist reduces MCD-induced steatohepatitis in part by limiting lipid peroxidation.[31] Adiponectin has been shown to increase gene expressions of antioxidant enzymes and regulate the recruitment and phenotype polarization of Kupffer cells.[41] The anti-inflammatory effects of adiponectin in macrophages, although still not clearly understood, are likely to involve the inactivation of the TLR4 signaling pathway.[42] Additionally, the enhancement of adiponectin signaling reduced the hepatic expression of TGF-β1, a profibrotic factor involved in hepatic stellate cell activation in mice fed an MCD diet.[43]

Although some studies reported that hepatic steatosis is critical to the pathogenesis of liver injury in MCD-diet-fed mice,[32] we observed that hepatic inflammation and subsequent fibrosis could be regulated independently of hepatic steatosis in the MCD model. These data are in keeping with a previous study in which the treatment of MCD-diet-fed mice with a pan-caspase inhibitor decreased liver inflammation and fibrosis. However, serum ALT levels and hepatic triglyceride levels were comparable between the control and treated mice.[44] Polaprezinc, a zinc-carnosine chelate compound, also significantly alleviated MCD-mediated liver fibrosis without the inhibition of steatosis,[45] suggesting that liver steatosis is not

DOI: 10.1021/acs.jafc.5b00398
J. Agric. Food Chem. 2015, 63, 4305–4311

correlated with liver injury in the MCD model. In another setting, treating MCD-diet-fed mice with diacylglycerol O-acyltransferase 2 antisense oligonucleotide alleviated hepatic steatosis but increased lipid peroxidation, inflammation, and fibrosis.[25] Several biopsies in pediatric-type NASH (type 2 NASH) show prominent zone 3 steatosis and minimal zone 1 steatosis with the confined fibrosis in the portal area, suggesting that steatosis in the portal area may not be required for fibrogenesis.[46] Further studies are needed to investigate the molecular mechanism in the development of portal NASH in the MCD model.

Contradictory to the previous studies using obese animal models, the effects of genistein on either body weight change or serum profiles were not significant in the present study using the NASH model associated with lipodystophy. These minimal effects of genistein on metabolic profiles may be attributed to the overwhelming effect of the MCD diet per se. Previous observations reported that inhibitory effects of genistein on the development of NASH in obese mice are accompanied by a significant decrease in body weight. However, our present results clearly show that genistein could alleviate the development of NASH without reducing the adipose tissue and body weights of the subjects. Indeed, we observed that genistein activated adiponectin signaling in the liver of mice fed an MCD diet, suggesting that improved adiponectin resistance may be involved, at least in part, in alleviation of NASH progression.

When these results are taken together, our study shows that genistein supplementation alleviated liver inflammation and fibrosis in the MCD-diet-induced NASH model. The beneficial effects of genistein on NASH development seem to be mediated by its ability to inhibit oxidative stress and ER stress, to diminish proinflammatory cytokine expression, and to modulate impaired PPARα-mediated signaling even without affecting hepatic TG accumulation at least in the MCD model.

Study objectives were to (1) experimentally show the incorporation of 1-naphthol in the amylose lumen of the soluble nanoparticle and (2) evaluate the incorporation mechanism using MD simulation.

EXPERIMENTAL SECTION

Materials. High-amylose corn starch, AmyloGel, containing 50% amylose (w/w) was provided by Cargill, Inc. (Cedar Rapids, IA). β-Lactoglobulin, linoleic acid (C18:3), and 1-naphthol were purchased from Sigma Chemical Co. (St. Louis, MO).

Table 1. Amount of 1-Naphthol Incorporated into the Nanoparticle[a]

solution concentration (mM)	incorporated concentration (mM/M glucose)
	1-naphthol
1	28.4 ± 1.8
2.5	47.6 ± 9.4
5	79.9 ± 6.3
10	91.8 ± 3.1

[a]Values are the average value and standard error of the mean. Note that the "solution concentration" column in the table indicates the amount of 1-naphthol added in the nanoparticle suspension, whereas the "incorporated concentration" column indicates the actual quantity of 1-naphthol incorporated into the nanoparticles collected in the HPSEC fraction.

Preparation of the Nanoparticle. Dilute nanoparticle suspensions were prepared as described by Zhang et al.,[3] whereby a hot-water-extracted amylose-rich supernatant was mixed with a β-lactoglobulin solution (10 mg/mL) and linoleic acid, maintaining a weight ratio among the three components of 20:2:1. The mixture was then heated for 20 min in a boiling water bath with continuous stirring at 450 rpm, followed by cooling to room temperature for 4 h.

Incorporation of 1-Naphthol into the Nanoparticle. Different amounts of 1-naphthol powder were added to suspensions containing the nanoparticle to obtain concentrations of 1, 2.5, 5, and 10 mM 1-naphthol. The mixtures were then heated to 75 °C for 20 min with continuous stirring at 450 rpm to facilitate the 1-naphthol incorporation and then cooled to room temperature under stirring. The formation of the loaded nanoparticle was monitored using high-pressure size-exclusion chromatography (HPSEC) coupled with multi-angle light scattering (MALS) and refractive index (RI) detectors. The obtained suspension was passed through a 0.45 μm filter and injected (100 μL) into a Sephacryl HR-500 column (GE Healthcare, Piscataway, NJ) with 0.02% sodium azide in purified water as the mobile phase (flow rate of 1.3 mL/min). Light scattering was performed using a Dawn Heleos-II MALS detector equipped with a 658 nm GaAs laser diode and an Optilab rEx RI detector (Wyatt Technology Corporation, Santa Barbara, CA). Data collection and analysis were carried out using ASTRA software (version 5.3.4.10, Wyatt Technology Corporation). Light scattering data were analyzed by the Zimm method using a range of angles between 14.4° and 163.3° and a dn/dc value of 1.46 to obtain average molecular weight (M_w) and the radius of gyration (R_g). Samples were analyzed in triplicate.

For detection of 1-naphthol, samples were injected (500 μL) into the HR-500 SEC column attached to ultraviolet−visible (UV−vis) and RI detectors (Varian models 9040 and 9050, Walnut Creek, CA). Sodium azide (0.02%) in purified water was used as the mobile phase. A wavelength of maximum absorption for 1-naphthol (319 nm) was used to detect the presence of 1-naphthol in the nanoparticle. A nanoparticle solution was used as a control to assess potential interference of β-lactoglobulin at 319 nm. HPSEC fractions were collected to obtain purified nanoparticle with and without 1-naphthol, immediately frozen (−40 °C) by immersion in liquid nitrogen, and freeze-dried.

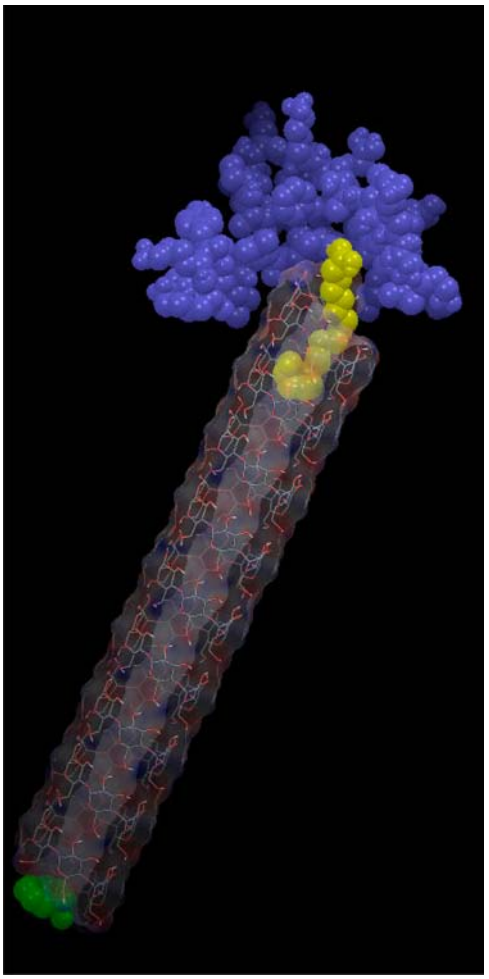

Figure 1. Initial configuration of the participating molecules at the start point of the four-component system, including the 55 glucose segment representing amylose [colored according to its three elements: oxygen (red), carbon (white), and hydrogen (blue)], α-linoleic acid (yellow), β-lactoglobulin-like peptide (blue), and 1-naphthol (green).

Potentiometric Titration. To assess 1-naphthol binding in the luminal space of the amylose molecule, potentiometric titration was used. A digital pH/mV meter (Corning pH/Ion Analyzer 350, Corning, NY) connected to a platinum redox combination electrode with a BNC connector (Corning, catalog number 476516, Big Flats, NY) was used. For the titrations, 5 mL solutions of amylose, amylose−fatty acid complex, nanoparticle, and 1-naphthol-loaded nanoparticle were mixed with 2.5 mL of 0.4 M potassium iodide. Mixtures were stirred at a constant rate, and the temperature was maintained at 25 °C. Potassium iodate (0.05 M) was added gradually to attain change in the voltage between 240 and 290 mV.[8] The volume of potassium iodate solution required to attain the voltage change provided information about the available space in the lumen of the amylose helix for binding of 1-naphthol. A blank containing 5 mL of purified water and 2.5 mL of 0.4 M potassium iodide was used as the control. Tests were conducted in triplicate.

Thermal Analysis. Thermal analysis was carried out on freeze-dried HPSEC-purified nanoparticle and 1-naphthol (5 mM)-loaded nanoparticle using a differential scanning calorimeter (DSC, Q2000, TA Instruments, New Castle, DE). Samples were mixed with water (1:3, w/w), placed in T-zero hermetically sealed pans (TA Instruments), and allowed to equilibrate overnight. The modulation mode of the DSC (MDSC) was used for the assay. A linear heating ramp from 20 to 120 °C at 3 °C/min was used, followed by cooling to

DOI: 10.1021/acs.jafc.5b00037
J. Agric. Food Chem. 2015, 63, 4312−4319

20 °C using the same rate. The modulation amplitude during the heating and cooling cycle was set to ±0.6 °C/min.

Dissociation of the 1-naphthol-loaded nanoparticle was detected by the endothermic peak in the heating cycle, whereas reassociation was detected by the exothermic peak in the cooling cycle. A similar methodology was applied to detect dissociation/reassociation in amylose inclusion complexes.[16] Controls were pure 1-naphthol and the nanoparticle. Tests were conducted in triplicate.

Quantification of the Amount of 1-Naphthol in the Nanoparticle. The amount of 1-naphthol in the HPSEC-isolated loaded nanoparticle was determined by its absorption at 319 nm using a UV−vis spectrophotometer (Beckman DU530, Danvers, MA). Different solution concentrations of 1-naphthol were used, and the amount of 1-naphthol incorporated into the nanoparticle is reported in Table 1. A standard curve for 1-naphthol in a concentration range of 1−5 mg/mL was prepared from a stock solution. Analyses were performed in triplicate.

MD Simulation. *Model Containing Amylose Segment, β-Lactoglobulin Peptide, α-Linoleic Acid, and 1-Naphthol.* An amylose segment of 55 glucose residues was used to form a 6-fold left-handed helix with inner and outer diameters of approximately 54 and 135 nm, and a length of 738 nm, as described by Tusch et al.[17]

A β-lactoglobulin peptide segment was used on the basis of the three-dimensional (3D) structure determined from a NMR analysis performed by Uhrinova et al.[18] This information was loaded into the Protein Data Bank (PDB; 1DV9). On the basis of a previous hypothesis of the role of lysyl residues in the nanoparticle formation,[4] a lysine-rich peptide segment of β-lactoglobulin was generated containing the following amino acid sequence from 67 to 101 (KKIIAEKTKIPAVFKIDALNENKVLVLDTDYKK) using the PRODRG server (http://davapc1.bioch.dundee.ac.uk/prodrg/).[19]

The PDB file for α-linoleic acid was obtained from the Hetero-compound Information Centre in Uppsala, Sweden.[20−23] The PDB file with ideal coordinates for 20 atoms was chosen using the Macromolecular Structure Database containing chemoinformatics (MSDchem database, http://www.ebi.ac.uk/pdbe/). The starting structure of α-linoleic acid was then generated using the same PRODRG server as in the case of the peptide segment above.

The PDB file of 1-naphthol was obtained from the Dictionary of Metabolites and Drug Binding Sites (SuperSite).[24] Similar to α-linoleic acid, the PDB file with ideal coordinates for 19 atoms was selected using the MSDchem database.

Force Field Details. The glucose force field was parametrized according to the method described by Damm et al.[25] and Kony et al.[26] All simulations for the amylose-like molecule were carried out using the glucose force field. The labels and corresponding charges of the atoms are shown in Table S1 and Figure S1 of the Supporting Information. The other three components were compatible with the glucose force field used.

MD Simulation Protocol. The Gromacs 4.6.1 MD package (Scala Life Competence Center, European Research Council) was used for the simulation. MD simulations were performed using the leapfrog motion routine with a 2 fs (1 fs = 10^{-15} s) time step. A total of 500 000 simulation steps (for a total simulation time of 500 ns) was performed to assess the progression of the self-assembly process. The LINCS algorithm was used to constrain all bond lengths with lincs_iter = 1 and lincs_order = 4. Because MD simulation is at the atomic level, our interest was how single molecules interact with each other. At a high temperature, the faster movement of the molecules facilitates their interaction and complexation by surpassing intrinsic energy barriers.[27,28] Therefore, even though the experimental work indicated that the exothermic event related to complex formation was lower, in the simulation, the temperature was set at 100 °C, necessary for initial formation of the complex. This was performed using the modified Berendsen thermostat coupling between the different groups, with a relaxation time of 0.1 ps, and pressure was maintained at 1.0 bar using the Parrinello−Rahman coupling to a pressure bath via an isotropic coordinate scaling, with a relaxation time of 2 ps, as described by Lopez et al.[29] Non-bonded interactions were handled using a neighboring grid cell cutoff scheme. Within a short-range neighbor list cutoff of 0.9 nm, the interactions were evaluated at every time step based on a pair list. A short-range electrostatic cutoff radius of 0.9 nm and a long-range van der Waals cutoff of 1.4 nm were evaluated simultaneously with each pair list update.

Simulations and Analysis. Because of limitation of computational capacity, as a beginning point, the amylose-like chain was pre-complexed with α-linoleic acid, the β-lactoglobulin-like peptide (blue) was located near α-linoleic acid (yellow), and 1-naphthol (green) was placed at the bottom of the amylose-like molecule (Figure 1). Because the whole system had for lysyl groups a net charge of +4, four chloride ions were added to neutralize the charges. The system was embedded in a rectangular box with a 10 × 5 × 5 nm^3 volume and filled with 7648 water molecules. The behavior of the water molecules was described by the TIP4P model.[30]

RESULTS AND DISCUSSION

Characterization of the Nanoparticle. As per previous work,[3,5] the nanoparticle was formed and identified by HPSEC−RI (Figure 2). UV absorbance at 280 nm at the same elution time confirmed the presence of protein in the nanoparticle. An average molar mass of the nanoparticle was 8−10 million Da, and radius of gyration was between 50 and 55

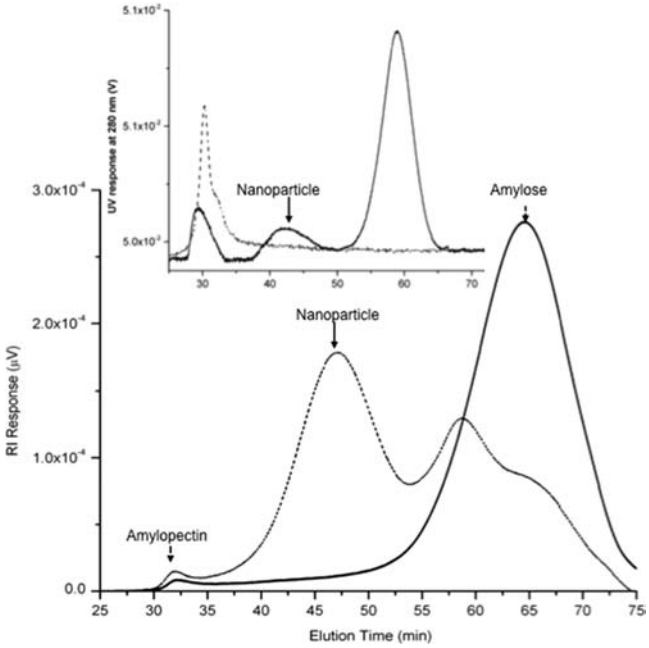

Figure 2. HPSEC−RI profile of the nanoparticle eluting between amylose and amylopectin. The inset illustrates the HPSEC−UV profile showing the presence of protein in the nanoparticle. The broken line trace is the HPSEC−UV profile of the starch supernatant.

Table 2. Changes in the Nanoparticle Structure Because of Mixing with Different Amounts of 1-Naphthol[a]

amount of 1-naphthol (mM)	M_w (Da)	R_z (nm)	M_w/M_n	slope of the conformation plot
control	8.1 × 10^6 (±8)	54.1 (±2)	2.9	0.68 (±6)
1	1.2 × 10^7 (±7)	50.4 (±7)	2.4	0.54 (±17)
2.5	1.6 × 10^7 (±3)	51.1 (±11)	2.1	0.47 (±13)
5	1.9 × 10^7 (±7)	48.6 (±8)	1.6	0.40 (±3)
10	2.7 × 10^7 (±6)	49.4 (±4)	1.5	0.38 (±3)

[a]Values are the average value. Values in parentheses indicate percent experimental error among the MALS detectors.

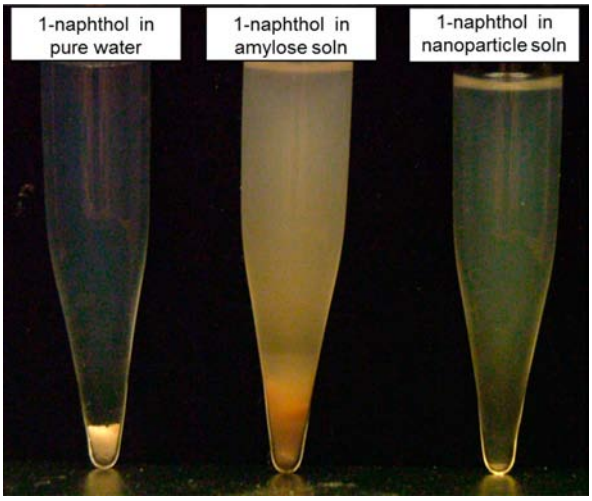

Figure 3. Photograph showing solubility of the 1-naphthol-loaded nanoparticle (right tube) compared to 1-naphthol in pure water (left tube) and incorporated with amylose (middle tube).

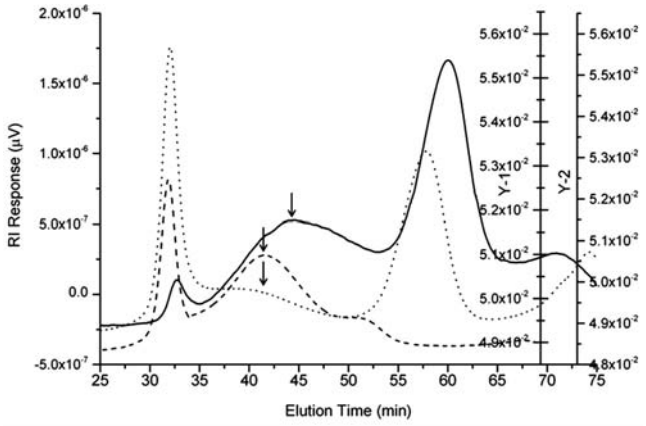

Figure 4. HPSEC profiles (RI and UV tracings) of the nanoparticle loaded with 5 mM 1-naphthol. The presence of the nanoparticle is indicated by the arrows. Solid line, RI response (left *y* axis); broken line, UV response at λ_{319} (Y-1, right axis); and dotted line, UV response at λ_{280} (Y-2, right axis).

nm (Table 2). These results are in general agreement with previous findings by Zhang et al.[4]

Characterization of the 1-Naphthol-Loaded Nanoparticle. 1-Naphthol has limited solubility in water (left tube in Figure 3). The addition of the same amount of 1-naphthol in an amylose-rich solution caused precipitation (center tube in Figure 3). This indicates complexation with amylose, and subsequent precipitation as has been reported by others for 1-naphthol[12] and other small hydrophobic flavor molecules.[31,32] When 1-naphthol was incorporated into the nanoparticle, it remained in solution (right tube in Figure 3).

1-Naphthol inclusion in the nanoparticle is shown in the HPSEC–UV chromatograms in Figure 4, where monitoring at 319 nm, the λ_{max} of 1-naphthol, resulted in a similar peak elution time as the nanoparticle RI and protein (280 nm) tracings. Incorporation of increasing amounts of 1-naphthol into the nanoparticle slightly increased its molecular size (Figure 5), which was quantitatively estimated by MALS analysis (Table 2). While addition of 1-naphthol (10 mM) increased the average molar mass of the nanoparticle from 8.1 $\times$ 10^6 to 2.7 $\times$ 10^7 Da, it did not change the radius of gyration.

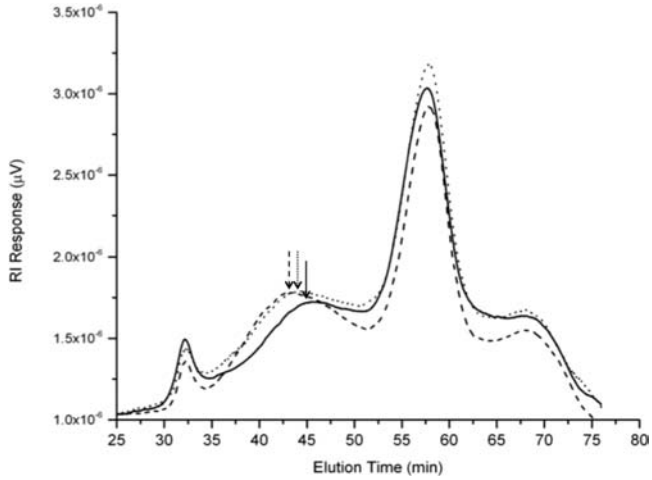

Figure 5. HPSEC–RI profiles of the nanoparticle mixed with different amounts of 1-naphthol. Peaks indicating the presence of the nanoparticles are indicated by the arrows. Solid line, pure nanoparticle; dotted line, nanoparticle mixed with 5 mM 1-naphthol; and broken line, nanoparticle mixed with 10 mM 1-naphthol.

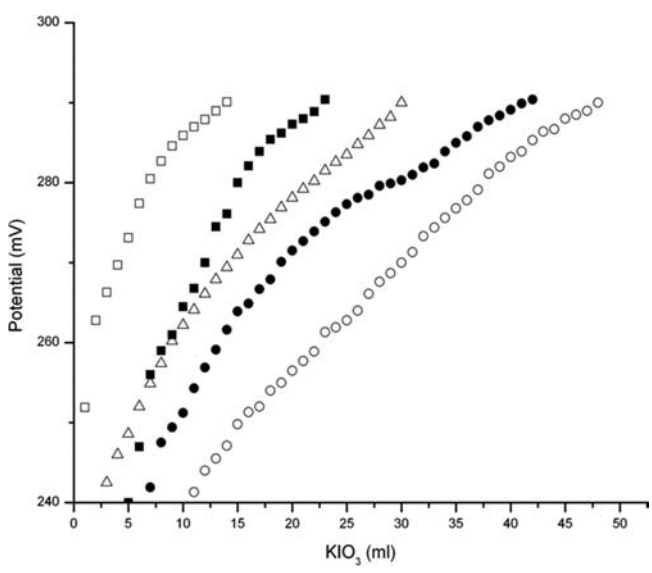

Figure 6. Iodine binding capacity of the 1-naphthol-loaded nanoparticle measured by potentiometric titration [□, blank; ○, amylose; ●, nanoparticle; △, amylose–fatty acid complex; and ■, 1-naphthol-loaded nanoparticle (mixed with 10 mM 1-naphthol)].

This suggested that inclusion of 1-naphthol changed the conformation of the nanoparticle, which was confirmed using a conformation plot (log–log plot of the root-mean-square radius as a function of the molar mass), showing a reduction in slope with increasing 1-naphthol concentration. The slope of the conformation plot is associated with shape of molecules in solution. For instance, a slope of 0.33 indicates a spherical arrangement, while a higher slope value (>0.6) is indicative of rod-like conformations.[33] Accordingly, the shape of the pure nanoparticle was rod-like, while the 1-naphthol-loaded nanoparticle was more spherical, and its spherical shape increased (decreasing slope) with higher concentrations of 1-naphthol (Table 2). Perhaps the explanation for the 3× increase in molar mass is a weak aggregation of a few nanoparticles that retain their individual nature.

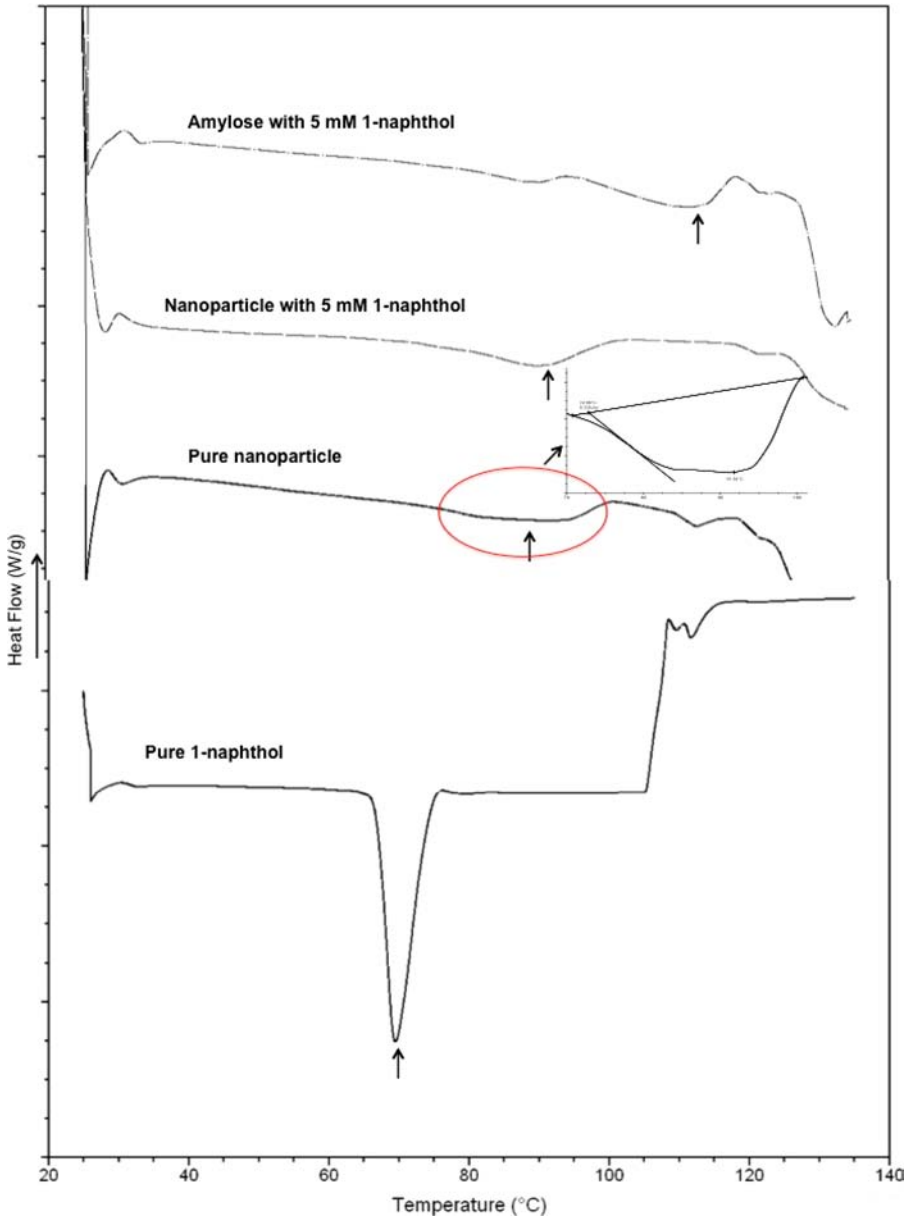

Figure 7. Thermal behaviors during heating of hydrated samples of amylose with 1-naphthol, nanoparticle with 1-naphthol, pure nanoparticle (with inset), and pure 1-naphthol.

Table 3. Melting Temperature and Enthalpy of Hydrated Samples of the Pure Nanoparticle, Pure 1-Naphthol, 1-Naphthol-Loaded Nanoparticle, and 1-Naphthol-Loaded Amylose[a]

	T_p (°C)	enthalpy (ΔH) (J/g)
nanoparticle	95.2 ± 0.9	7.3 ± 1.4
1-naphthol (pure)	69.5 ± 1.2	144.4 ± 5.9
1-naphthol (5 mM)-loaded nanoparticle	91.9 ± 0.2	12.2 ± 1.7
1-naphthol (5 mM)-loaded amylose	102.0 ± 2.9	10.0 ± 0.4

[a]Values are the average value and standard error of the mean.

Table 4. Reassociation Temperature and Enthalpy, after Heating and Cooling, of Hydrated Samples of the Pure Nanoparticle, Pure 1-Naphthol, 1-Naphthol-Loaded Nanoparticle, and 1-Naphthol-Loaded Amylose[a]

	$T_{reassociation}$ (°C)	enthalpy (ΔH) (J/g)
nanoparticle	80.1 ± 1.1	4.9 ± 0.1
1-naphthol (pure)	46.4 ± 2.9	1.2 ± 0.1
1-naphthol (5 mM)-loaded nanoparticle	62.8 ± 1.3	7.4 ± 1.2
1-naphthol (5 mM)-loaded amylose	77.5 ± 3.4	8.9 ± 1.8

[a]Values are the average value and standard error of the mean.

Evidence of 1-Naphthol in the Amylose Lumen of the Nanoparticle. Using the potentiometric titration technique, the nanoparticle was previously shown to have about 50% available space in the lumen of the amylose helix compared to about 15% for the amylose–fatty acid complex.[8] Here, potentiometric titration showed good binding of 1-naphthol in the amylose lumen of the nanoparticle (Figure 6). The amount of bound iodine of the pure nanoparticle was in between that of the uncomplexed amylose and the amylose–fatty acid inclusion complex, while for the 1-naphthol-loaded

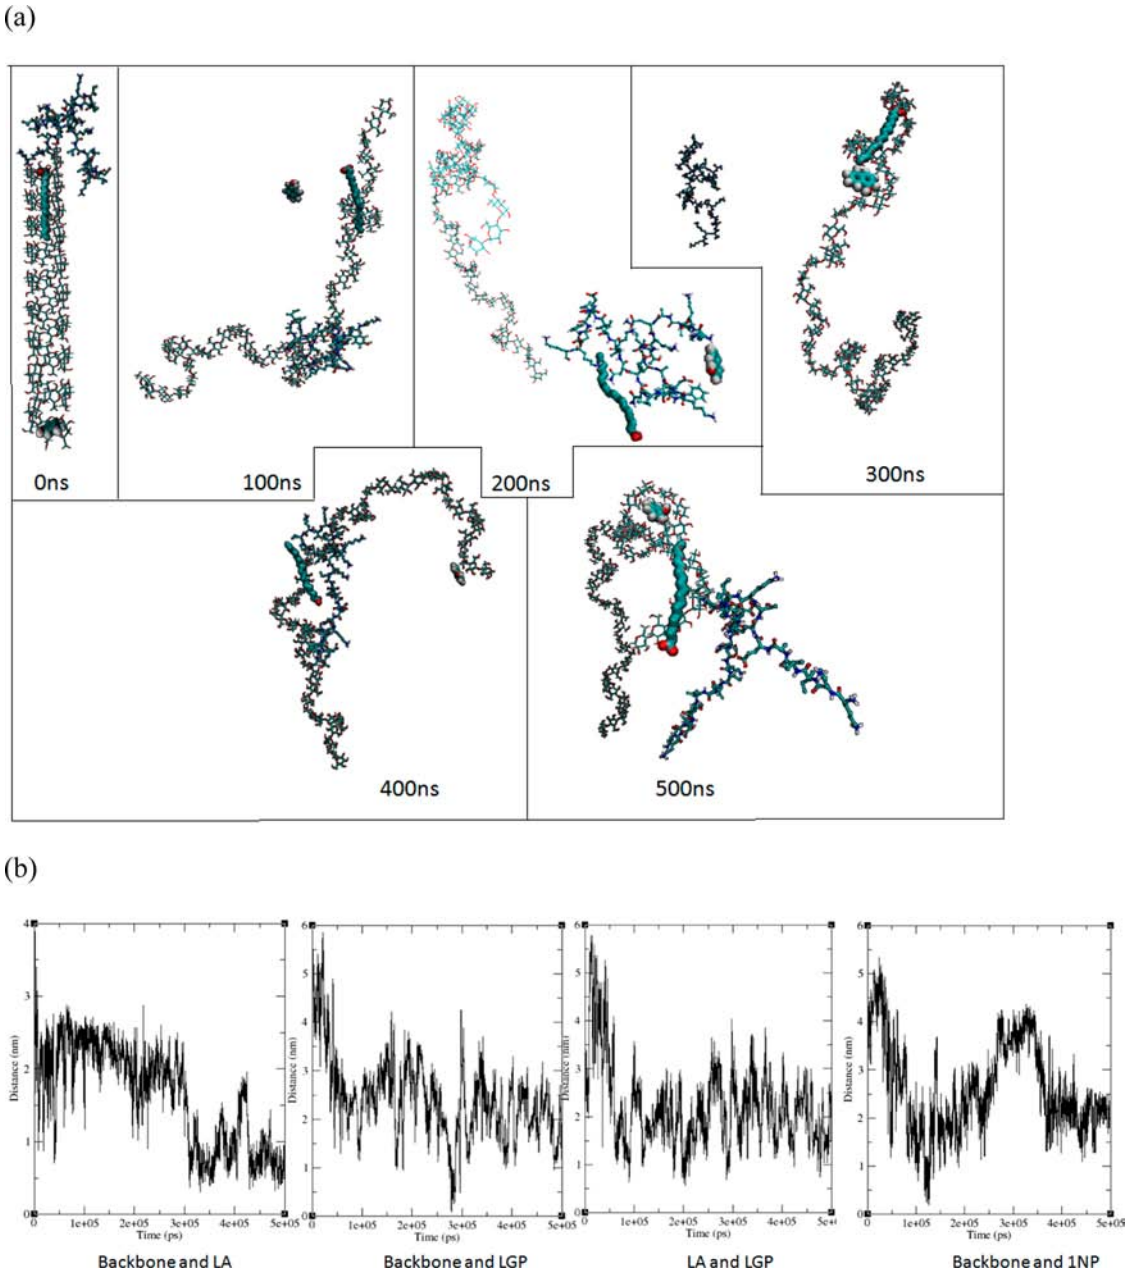

Figure 8. Time-dependent conformational transitions of a mixture of the amylose segment of 55 glucose residues (amylose backbone), β-lactoglobulin peptide (LGP), α-linoleic acid (LA), and 1-naphthol (1NP). (a) Snapshots from the simulations for the four-component system showing structural changes from the initial conformation to a final conformation at 500 ns. (b) Sequence of plots showing the distance between the amylose backbone and LA, amylose backbone and LPG, LA and LPG, and amylose backbone and 1NP.

nanoparticle, there was essentially no bound iodine, indicating that the amylose lumen of the nanoparticle was nearly fully occupied by 1-naphthol.

Thermal Behavior of the 1-Naphthol-Loaded Nanoparticle. Incorporation of 1-naphthol in the nanoparticle and amylose was further noted by thermal analysis, where a change in the melting endotherm was observed compared to hydrated pure 1-naphthol (Figure 7 and Table 3). The melting endotherm of hydrated pure 1-naphthol at 69.5 °C disappeared when the compound was incorporated. The pure nanoparticle melting endotherm occurred at 95.2 °C, while complexing 1-naphthol with the nanoparticle reduced it to 91.9 °C and significantly increased the melting enthalpy from 7.3 to 12.2 J/g (Table 3).

Reassociation after heating and cooling of the 1-naphthol-loaded nanoparticle occurred at a lower temperature (62.8 °C) and with higher enthalpy (6.4 J/g) than the pure nanoparticle (80.1 °C and 4.9 J/g) (Table 4). The large change in enthalpy suggests that additional non-covalent bonds were created during the formation of the 1-naphthol-loaded nanoparticle.

Quantification of 1-Naphthol Incorporation in the Nanoparticle. At the higher concentration of 10 mM 1-naphthol in the formation mixture, 91.8 mM 1-naphthol/mol of anhydroglucosyl unit (AGU) was found in the loaded nanoparticle (Table 1). This compares to previous studies showing the maximum binding capacity of 1-naphthol in the lumen of amylose of about 62−65 mM/mol of AGU.[31,34] Because potentiometric titration showed that only about 50%

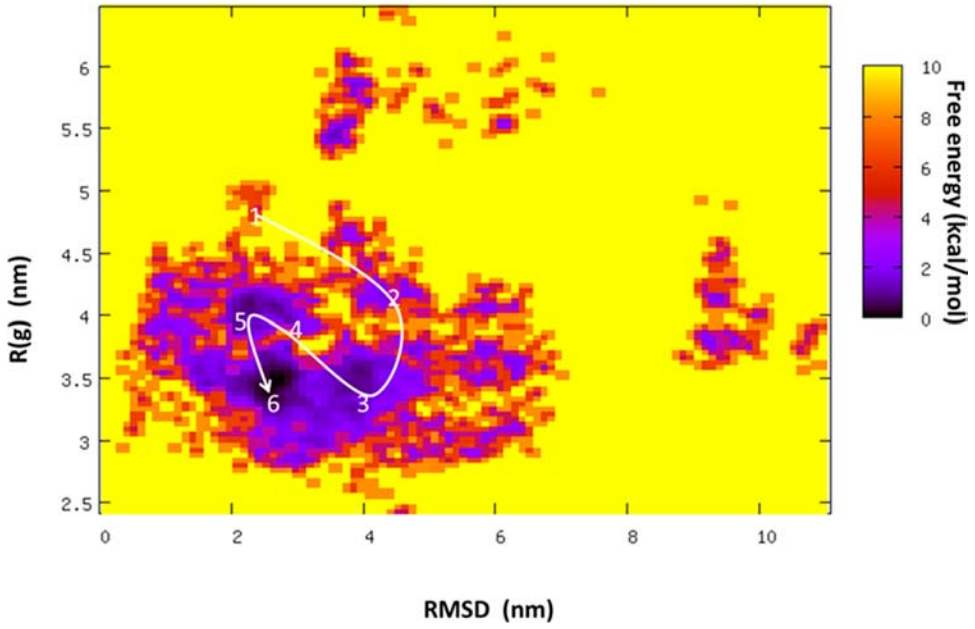

Figure 9. Free energy surface map of the four-component system composed of a mixture of the amylose segment of 55 glucose residues (amylose backbone), β-lactoglobulin peptide, α-linoleic acid, and 1-naphthol. Numbers correspond to snapshots at 100 ns intervals, as shown in Figure 8.

of the amylose inner helices was available for binding of 1-naphthol, the maximum inclusion capacity of the nanoparticle can be predicted to be only about 30 mM 1-naphthol. It is not clear where the remaining 1-naphthol is bound in the nanoparticle.

MD Simulation of the 1-Naphthol-Loaded Nanoparticle. *Structural Dynamics.* Figure 8 shows snapshots of the interaction of the four components in a 500 ns timeline, starting with the initial arrangement, as shown in Figure 1. Rearrangement of components over time shows a final structure with both the fatty acid and the 1-naphthol molecules residing in the lumen of the amylose helix with the 1-naphthol close to the hydrophobic tail of the fatty acid. The β-lactoglobulin peptide is found at the carboxyl head of the fatty acid. The sequence of interactions, as shown in Figure 8a, is as follows. In the first 100 ns, α-linoleic acid is included by the amylose-like segment, whereas the β-lactoglobulin peptide surrounds it and the 1-naphthol molecule is left out of the complex. At 200 ns, α-linoleic acid, β-lactoglobulin peptide, and 1-naphthol are close to each other, but all are separated from the amylose-like segment. At 300 ns, although the β-lactoglobulin peptide is still far from the amylose-like segment, both the α-linoleic acid and 1-naphthol molecules are incorporated into the amylose-like segment again. At 400 ns, α-linoleic acid is included in the middle of the amylose segment and the β-lactoglobulin peptide surrounds it; 1-naphthol remains out of the complex. Lastly, at 500 ns, both α-linoleic acid and 1-naphthol are included in the lumen of the amylose helix and the β-lactoglobulin peptide is associated with the carboxyl head of α-linoleic acid.

To analyze the conformational transitions quantitatively, the mutual distances between the interdomain backbone of the amylose-like segment, α-linoleic acid, β-lactoglobulin peptide, and 1-naphthol were calculated and are illustrated in Figure 8b. The shortest interdomain distance occurs between the amylose backbone and α-linoleic acid at 300 ns, which implies that these two molecules have a key role in stabilizing the system. The other three combinations of components show a rapid although more moderate decrease in interdomain distances, and corresponding distances were higher.

Free Energy Surface Map. Free energy changes from the initial time (0 ns) to the final time (500 ns) were calculated from the simulations and are presented as a free energy surface map tracing at 100 ns intervals during the assembly of the four components (Figure 9). With constituents placed initially as specified in Figure 1, the initial 0 ns state is thermodynamically unfavorable (region 1 in Figure 9), with a free energy of 6.3 kcal/mol. It then changes rapidly to a more stable second state (region 2 in Figure 9), with a free energy of 4.2 kcal/mol. At that moment, the complex separates into two parts, one being the amylose backbone and the other being the three components with an overall free energy decrease to 1.8 kcal/mol (region 3 in Figure 9). At a similar free energy state (1.5 kcal/mol), α-linoleic acid, 1-naphthol, and the amylose-like segment come together, while β-lactoglobulin peptide is set aside (region 4 in Figure 9). Then, a further lowering of free energy occurs as the constituents further assemble into a more compact macrostructure (regions 5 and 6 in Figure 9). Finally, a conformation was obtained with the lowest free energy of 0.05 kcal/mol, where both α-linoleic acid and 1-naphthol reside in the amylose helix and β-lactoglobulin peptide surrounds the amylose-like segment near the carboxyl group of α-linoleic acid. Such a process indicates a spontaneous self-assembling of the four components, which corresponds to the decrease in the estimated free energy and demonstrates that the self-assembling of these components comprises a thermodynamically favorable process.

Here, we have shown, experimentally and theoretically, that a previously identified soluble nanoparticle formed by the three macronutrients starch, protein, and fatty acid self-assembles with a sparingly soluble molecule (1-naphthol). 1-Naphthol occupies space in the amylose lumen and exists in a stable and soluble system. MD simulation of an amylose-like segment, β-lactoglobulin peptide, α-linoleic acid, and 1-naphthol confirmed that these molecules are thermodynamically driven into a four-component nanoparticle. 1-Naphthol was found to be included

DOI: 10.1021/acs.jafc.5b00037
J. Agric. Food Chem. 2015, 63, 4312−4319

in the lumen of the amylose helix and located in proximity to the hydrophobic tail of the fatty acid. The incorporation capacity of sparingly soluble small molecules in this soluble, safe, and soft nanoparticle suggests a number of potential applications, including the carrying and release of hydrophobic nutraceuticals and drugs.

the properties of a protein, such as on stability, solubility, and metabolic energy.[2] Glycosylation of phytase has been shown to affect thermostability,[13,17,18] which would be a concern regarding enzyme activity loss due to heat such as that from feed pelleting. Phytases for commercial use have been isolated mainly from fungi and bacteria,[6,8,11] and selection for an efficacious product is greatly dependent on the source,[1] tolerance to processing factors, digestive resistance, and production costs.[6,8,19] Major feed crops have been genetically modified to increase phytase expression and are at various stages of product development.[20] For example, two separate studies on transgenic phytase barley have both reached an advanced developmental stage complete with field trials; however, only transgenic phytase corn (Event B23-3-1) has received approval status for commercial sale. Integration of such phytases as transgenes in agricultural products in a growing industry would benefit from inclusion of a means to verify transgenic phytase presence in food nutritional and environmental management strategies wherein concerns of phytate mineral availability and environmental issues need to be assessed. Development of a rapid diagnostic test (RDT), which is a qualitative immunoassay (consisting of target specific antibodies) used in point-of-care testing, for transgenic phytase would offer an efficient, convenient, and affordable method of detection.

Aspergillus niger phytase (*phy*A2), which has 10 potential N-glycosylation sites,[2] was cloned and expressed in a methylotrophic yeast, *Pichia pastoris*.[21] This same phytase was cloned into corn, yielding seeds with a maximal phytase activity of 125 FTU/g kernels, 1000-fold above that of the wild type, and with 1000 g of kernels containing up to 67 times the feed industry requirement.[22] Corn is a globally important animal feed crop; in China, corn occupies 30 million hectares of land from which much is used to feed 500 million pigs (approximately 50% of the global herd) and 13 billion chickens, ducks, and poultry.[23] As mentioned above, only transgenic phytase corn has been approved for commercialization; accessibility coupled with the ensuing demand for corn production, all make it an ideal product candidate for this project. Herein, two pairs of highly sensitive and specific monoclonal antibodies (MAbs) raised against *A. niger* recombinant phytase and generated through an extensive screening technique were described whereby each was found to detect a phytase protein of different sizes, possibly due to glycosylation. Using these MAbs, the transgenic corn was found to express lower levels of the larger-sized phytase than the recombinant phytase had expressed in yeast; however, the level of detection was predicated on the condition of the expressed phytase. Together, these findings provide important insight regarding the structural properties of phytase epitopes, suggesting a possible role of carbohydrates within antibody binding sites, and lead to the development of RDT strips coated with MAbs that can detect two differently sized proteins of transgenic phytase.

MATERIALS AND METHODS

Recombinant Phytase, Seeds, and Antibodies. *A. niger* 963 *phytase* (*phy*A2) expressed in *P. pastoris* was isolated by and donated from the Biotechnology Research Institute, Chinese Academy of Agricultural Sciences in Beijing, China. This recombinant protein was freeze-dried, reconstituted in PBS (at 200 μg/mL), and stored at 4 °C until required. This group also donated genetically modified (GM) phytase corn seeds, expressing this same *A. niger* phytase gene *phy*A2. Seeds from various plants [six varieties of GM corn, one variety of a GM soybean, corn (2733) from Pickseed, six corn varieties from West Coast Seeds (WCS; two of F1, two of P, one of DF1, and one unknown), green bean, white bean, and seven generic varieties of corn (purchased from local markets)] were used in characterization studies.

Phytase monoclonal antibodies (MAbs, EH10a, FA7, AF9a, and CC1) raised against a recombinant *A. niger* 963 (*phy*A2) phytase were donated by the Chinese Biotechnology Research Institute in Beijing and prepared in a manner similar to that described in Chen et al.[24]

Epitope Characterization. To characterize the epitopes recognized by the purified phytase MAbs, an ELISA and the additivity index (AI) described by Friguet et al.[25] were used. Briefly, wells of a 96-well plate were coated with 100 μL of 2 μg/mL recombinant phytase and incubated overnight at 4 °C. The following day, the wells were incubated with 100 μL of antibodies, EH10a, FA7, AF9a, CC1, individually or in paired combinations (50 μL each) of equivalent concentrations at 1:1000 overnight at 4 °C. The following day, the wells were incubated with 100 μL of a goat anti-mouse IgG−HRP secondary antibody at 1:1000 for 30 min at 37 °C. The absorbance value for each treatment was recorded at 450 nm. The AI was calculated using the following equation: $\{[2A_{1+2}/(A_1 + A_2)] - 1\} \times 100\%$, where A_1, A_2, and A_{1+2} are the absorbance values for the individual antibodies and the respective combined pairs. If the two antibodies are directed against different epitopes (no competition), A_{1+2} should be equal to the sum of A_1 and A_2 and the AI value should approach 100%. If the two antibodies are directed against the same epitope (competition), A_{1+2} should be equal to the mean value for A_1 and A_2 and AI should be close to 0%. The threshold was determined by AI $\geq$ 40%.

Protein Analysis. Protein and Western blot analyses on the specificity of the MAbs were evaluated by 15% SDS-PAGE using 1 μg of recombinant phytase and 50 mg of ground seeds from GM phytase corn, generic corn, green bean, white bean, Pickseed2733 corn, WCS F1 corn, four varieties of GM corn, and one GM soybean variety. The phytase could be released from the GM phytase corn only by homogenizing the corn seeds in a modified Tris buffer [50 mM Tris-HCl (pH 8.0), 10 mM KCl, 3 mM $MgCl_2$, 1 mM EDTA, 1 mM β-mercaptoethanol, 0.1% BSA, 13% sucrose, and SigmaFAST Protease inhibitor cocktail (Sigma-Aldrich, St. Louis, MO, USA)] at 400 μL per 100 mg tissue, after which the sample was centrifuged at 4500*g* for 10 min. Laemmli loading buffer[26] was then added to the supernatant and incubated at 65 °C for 20 min. The remaining seeds were ground, homogenized in 500 μL of Laemmli buffer, boiled for 10 min, and centrifuged for 2 min at 12000*g*. To improve Western blot detection, 5 μg of recombinant phytase and 100 mg of ground seeds were used. Twenty microliters of each prepared seed supernatant was used for protein and Western blot analysis. The recombinant phytase, 20 μL of water, and 10 mM Tris (the latter two as negative controls) were also boiled in Laemmli buffer as described above. The membrane blot was incubated overnight at 4 °C with a combined mixture of EH10a, FA7, AF9a, and CC1 MAbs (each at 1:400), whereas the SDS-PAGE protein gel was stained with Coomassie Brilliant Blue. The following day the membrane was incubated with horseradish peroxidise conjugated goat anti-mouse immunoglobulin (IgG−HRP at 1:1000) for 90 min at room temperature. Proteins on the blot were developed using the 3,3′-diaminobenzidine tetrahydrochloride (DAB; Sigma-Aldrich) method with 0.1% hydrogen peroxide.

To evaluate the nature of the MAbs directed to epitopes on phytase, an additional Western blot analysis was performed. Purified recombinant phytase protein isolated from yeast and ground seeds of GM phytase corn were both resuspended with PBS to a concentration of 200 μg/mL and stored at 4 °C until required. Every 2 weeks for a period of 10 weeks, 10 μL from each of the recombinant phytase and GM phytase corn was boiled with 10 μL of loading buffer for 5 min and loaded onto a 10% SDS-PAGE. Each transferred membrane blot was incubated overnight at 4 °C with a combined mixture of MAbs as described above. The subsequent steps are as described above, except the concentration of the IgG−HRP secondary antibody was 1:5000 with an incubation time of 30 min.

Construction and Evaluation along Immunolateral Flow Test Strips. The detection phytase antibody (the test line antibody, either FA7 or CC1) and the goat anti-mouse IgG (the control line

DOI: 10.1021/acs.jafc.5b00188
J. Agric. Food Chem. 2015, 63, 4320−4326

antibody) were diluted to a standard concentration of 1.5 mg/mL with 10 mM Tris-HCl (pH 8.0) and applied in a thin line onto a nitrocellulose membrane. The colloidal gold conjugated phytase capture antibody was prepared as described in Chen et al.[24] Briefly, 1.4 mL of 1% $Na_3C_6H_5O_7$ was first added to 100 mL of boiled 0.01% $HAuCl_4$. The colloidal gold solution was then allowed to cool gradually, after which the pH was adjusted to 8.4 with 1% K_2CO_3. The EH10a or AF9a antibodies were added dropwise into 10 mL of the colloidal gold solution and left to stabilize at 4 °C. After 30 min, BSA blocking agent was added, and the solution was placed at 4 °C for another 2 h. The mixture was centrifuged twice, the first time to recover the supernatant and the second to conjugate pellet, which was then suspended in 10 mM borax buffer (with 2% BSA and 0.05% NaN_3, pH 8.0). The conjugated antibody (i.e., EH10a if the detection antibody was FA7 or AF9a if the detection antibody was CC1) was sprayed twice onto a sheet of fiberglass and dried at 37 °C. The phytase lateral flow test strips were assembled as described in Chen et al.[24]

Two grams of each seed variety was ground in 10 mM Tris-HCl. The absorption pad end of a prepared test strip was immersed in seed supernatant. Test strips were also immersed in 200 μg/mL of recombinant phytase, 200 μg/mL of transgenic corn, distilled water, and 10 mM Tris-HCl (the latter two as negative controls). A response was observed within 5 min. The appearance of two bands, one each at the test and control sites, represents a positive test result; a single band at the control site represents a negative test result. The absence of a line at the control site indicates the test is invalid.

To determine the sensitivity of the antibodies to phytase along an immunolateral flow test strip, recombinant phytase was diluted in concentrations from 200 to 0.002 μg/mL by 10 mM Tris-HCl (pH 8.0) and tested using the EH10a−FA7 MAb match pair, whereas the transgenic phytase corn was tested in concentrations from 400 to 0.001 μg/mL using the AF9a−CC1 MAb match pair. The responses of the strips were evaluated as above.

The nature of the MAbs directed to epitopes on phytase was evaluated along an immunolateral flow test strip. Individual test strips consisting of either the EH10a−FA7 or the AF9a−CC1 MAb match pairs were immersed in the reconstituted recombinant or GM corn phytase samples every 2 weeks for a period of 10 weeks. The samples were stored at 4 °C until required. With the "MAX" line on the test strip positioned above the liquid level, a sample was allowed to migrate halfway up the strip, after which the strip was removed. The results were obtained within 30 min, and the strips were evaluated as above.

The stability of test strips was assessed when kept for 1 year at room temperature.

RESULTS AND DISCUSSION

Monoclonal Antibody Characterization. Phytase is considered the most prominent enzyme to hydrolyze phytate and release bound phosphorus in a form available to animals for growth and development. A recombinant *A. niger* phytase (*phy*A2) expressed in *P. pastoris*[21,22] was used to produce MAbs employing a very extensive and novel screening technique.[24] From a total of 976 hybridoma cell strains, 32 positive cell clones using repetitive ELISAs and cross-responsive screening of MAbs against *A. niger* (*phy*A2) phytase were generated (personal communication, Biotechnology Research Institute). Cell lines screened for the strongest positive signal in phytase-challenged cultures were selected, culminating in four MAbs candidates (EH10a, FA7, AF9a, and CC1). AI values were calculated to determine competition for the binding sites between the four MAbs. The following AI values were found for the following antibody pairs: FA7+AF9a (67.7%), FA7+CC1 (91.4%), AF9a+EH10a (57.7%), EH10a+CC1 (69.7%), FA7+EH10a (59.6%), and AF9a+CC1 (≥99%). These results indicate that any pair of these antibodies would result in the targeting of a different phytase epitope.

Evaluation of Monoclonal Antibody Pairs to Phytase Protein. *P. pastoris* is a methylotrophic yeast that, when under the control of a methanol-inducible alcohol oxidase (AOX1) promoter, has been successfully used to produce many proteins with varying degrees of success,[27−29] and these proteins are often glycosylated.[30] Protein analyses of various seed varieties (Figure 1A) were used to assess MAb specificity along with a

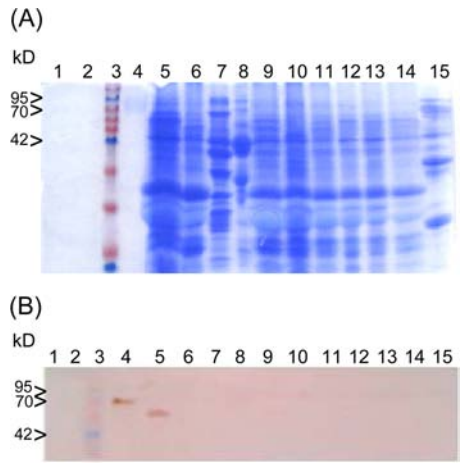

Figure 1. Monoclonal antibodies (MAbs) target phytase. (A) Fifty micrograms of plant seeds was ground in 500 μL of Laemmli buffer of which 20 μL was loaded into each lane. The lanes are as follows: (1) water; (2) 10 mM Tris-HCl, pH 8.0; (3) marker; (4) 1 μg of recombinant phytase; (5) GM phytase corn; (6) corn 1; (7) green bean; (8) white bean; (9) Pickseed2733 corn; (10) WCS F1 corn; (11) GM corn 1; (12) GM corn 2; (13) GM corn 3; (14) GM corn 4; (15) GM soybean. (B) Western blot analyses were conducted on the samples used in (A), except that 5 μg of recombinant phytase and 100 mg of ground plant seeds were used and probed with an equal mixture of MAbs EH10a, FA7, AF9a, and CC1. The protein marker sizes in kilodaltons (kD) are indicated on the left of the blot. GM, genetically modified; WCS, West Coast Seeds. Unless stipulated, GM corn samples are not GM phytase corn. Additional methods are described in the text.

recombinant *A. niger* phytase expressed from yeast and a genetically modified (GM) corn containing this same *A. niger* phytase. The samples were probed with a MAb mixture of EH10a, FA7, AF9a, and CC1 (in equal proportions). The recombinant *A. niger* phytase expressed from yeast shows a band of approximately 75 kDa (Figure 1B, lane 4), whereas the GM *A. niger* phytase corn reveals a band of about 60 kDa (Figure 1B, lane 5). Further, this MAb mixture did not cross-react with the other test seeds as shown from Western blot analysis (Figure 1B, lanes 6−15). The larger-sized protein from the yeast-expressed phytase may be due to the greater degree of glycosylation often observed in proteins expressed from yeast. Differences in glycosylation pattern expressed from different hosts may be attributed to the discrete processes found in their respective cellular environments. For example, *A. fumigates* was found to produce a phytase that can tolerate boiling at 100 °C for 20 min, retaining 90% of its initial activity.[31] Lucca et al.[32] found that when rice containing the *A. fumigates* phytase was boiled for 20 min, the enzyme had retained 50% of the enzyme activity. However, when rice seeds were cooked under the same conditions, only 8% of the phytase activity was retained. Similarly, these differences in thermotolerance may be attributed to the different glycosylation patterns in phytase expressed between diverse hosts. Phytases that have high

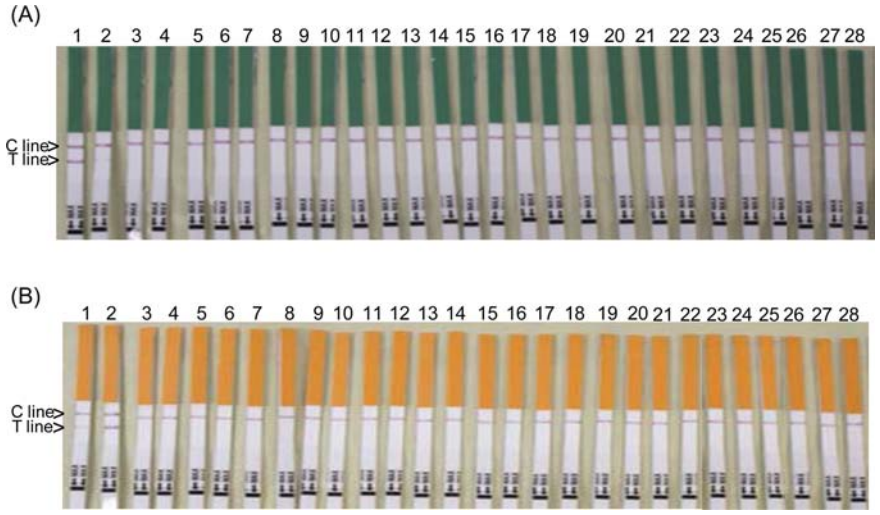

Figure 2. Both match pair EH10a−FA7 and AF9a−CC1antibodies show high specificity to phytase. (A) Phytase specificity analysis was conducted using lateral flow strips containing the EH10a conjugate antibody and the FA7 capture antibody. Strips 1−4 were immersed in a 10 mL solution consisting of (1) 200 μg/mL recombinant phytase, (2) 200 μg/mL transgenic phytase corn, (3) 10 mM Tris-HCl, and (4) distilled water. Strips 5−28 were immersed in the supernatant of 2 g of seeds ground in 10 mL of 10 mM Tris-HCl for 1−5 min. The strips were tested using the following seeds: (5) corn 1; (6) corn 2; (7) corn 3; (8) corn 4; (9) GM corn 1; (10) GM soybean; (11) Pickseed2733 corn; (12) GM corn 2; (13) GM corn 3; (14) GM corn 4; (15) WCS F1 corn 1; (16) WCS F1 corn 2; (17) WCS P corn 1; (18) WCS P corn 2; (19) WCS DF1 corn; (20) green soybean; (21) WCS corn; (22) green bean; (23) white bean; (24) corn 5; (25) corn 6; (26) corn 7; (27) GM corn 5; (28) GM corn 6. For each strip the upper line is the control (C) line containing antibodies to goat anti-mouse IgG and the lower line (if present) is the test (T) line with the FA7 capture antibody. The corn samples used in strips 5−8 and 24−26 were generic (non-GM) varieties. (B) Phytase specificity analysis was conducted using lateral flow strips containing the AF9a conjugate antibody and the CC1 capture antibody. Each strip was prepared and tested with the same samples as described in (A) except the lower T line (if present) contains the CC1 capture antibody.

tolerance to heat are advantageous not only for feed production due to temperatures associated with pelleting but for food processing activities such as cooking and baking.[6] Locations for new sources of thermotolerant as well as the engineer of technologically improved phytases to withstand increased temperatures and GM phytase crops are invaluable to industries that must deal with phytate and the challenges it represents.

Characterization of Phytase Monoclonal Antibody Pairs Using Lateral Strip Assays. The additive index results indicated that the four MAbs target different phytase epitopes; therefore, lateral flow strip comparison assays using all possible MAb pair combinations were conducted and showed that the EH10a−FA7 and AF9a−CC1 MAb pairs exhibited the strongest potential to be used in lateral flow strip products (data not shown). To determine the specificity of the phytase MAb pairs, immunoassays comprising of antibody-coated lateral strips were constructed and tested with different seed varieties of commercial plants. Lateral strips that consisted of the gold-conjugated EH10a antibody and the FA7 membrane capture antibody showed that this antibody pair was able to detect the *A. niger* recombinant (*phy*A2) phytase expressed in *P. pastoris* and, to a lesser extent, the GM (*phy*A2) phytase corn (Figure 2A, lanes 1 and 2). In contrast, strips that consisted of the gold-conjugated AF9a antibody and the CC1 membrane capture antibody showed that this antibody pair was able to detect the GM phytase corn more efficiently that the recombinant phytase (Figure 2B, lanes 1 and 2). Further, phytase could not be detected in any of the test seed varieties using either of the antibody pairs, indicating a high specificity to the *A. niger* recombinant protein that is used in GM phytase crops.

Antibody-coated lateral strips were also used to determine the sensitivity of the phytase MAb pairs. The EH10a−FA7 and AF9a−CC1 antibody pairs were able to efficiently detect the recombinant phytase and GM corn phytase, respectively. Therefore, serial dilutions were prepared with the recombinant phytase for the EH10a−FA7 antibody pair, with the GM phytase for the AF9a−CC1 antibody pair and tested on lateral flow strips. The detection limit to recombinant phytase using the EH10a−FA7 antibody pair was 5 ng/mL (Figure 3A), whereas the detection limit to GM phytase corn using the AF9a−CC1 antibody pair was as low as 2 ng/mL (Figure 3B). The strips were confirmed to be stable when kept at room temperature for 1 year.

Reactive Antibody Binding Sites May Involve Glycosylation. As stated earlier, the EH10a−FA7 antibody pair showed a greater ability to detect the yeast-expressed phytase, whereas the AF9a−CC1 antibody pair showed a greater ability to detect the GM corn phytase. Additionally, different-sized phytase proteins could be detected from these two sources. We wanted to further explore the nature of the epitopes between yeast- and plant-expressed phytases and assess whether glycosylation has a role that determines the responses to their respective antibody match pairs. Using Western blot analysis, phytases expressed from yeast and GM corn were probed with a combined MAb mixture of EH10a, FA7, AF9a, and CC1 and monitored over time. During the first 2 weeks, the 75 kDa band dominated with a lesser abundant 60 kDa band from the yeast-expressed phytase (Figure 4A, top row). By the fourth week, this 75 kDa band was progressively less detectable, whereas the 60 kDa band was progressively more detectable (Figure 4A, top row). In contrast, the 60 kDa band from the GM corn phytase was progressively less detectable over time (Figure 4A, bottom row) and the 75 kDa was not detectable at all (data not shown).

Phytase samples were prepared as above and tested over the same time periods using lateral flow strips consisting of either the EH10a−FA7 or the AF9a−CC1 antibody match pair. As

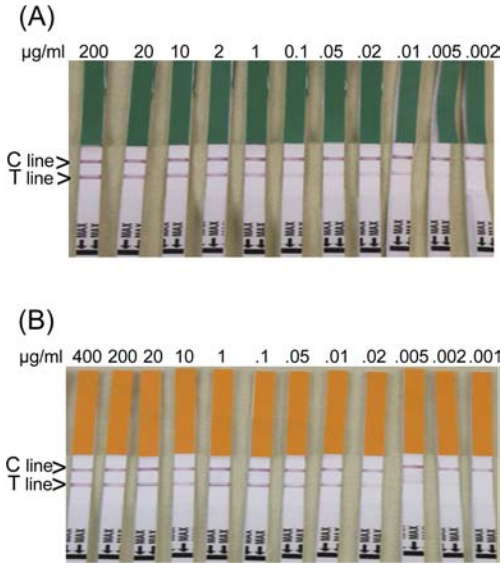

Figure 3. Match pair EH10a–FA7 and AF9a–CC1 antibodies were able to detect low concentrations of phytase. (A) To determine the sensitivity of the EH10a–FA7 antibodies, concentrations from 0.002 to 200 μg/mL of recombinant phytase were applied to lateral flow strips containing the EH10a conjugate antibody and the FA7 capture antibody. (B) To determine the sensitivity of the AF9a–CC1 antibodies, concentrations from 0.001 to 400 μg/mL of the GM phytase corn were applied to lateral flow strips containing the AF9a conjugate antibody and the CC1 capture antibody. The strips were immersed in a 10 mL solution of recombinant phytase (A) and GM phytase corn (B) at the various concentrations indicated above the strips. The arrangement of the control (C) and test (T) lines along the strips is as described in Figure 2.

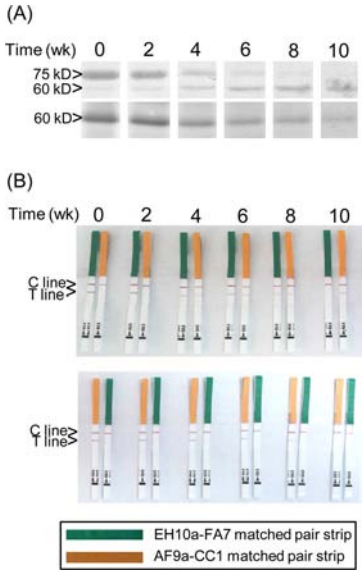

Figure 4. Nature of phytase epitopes affects detection by EH10a–FA7 and AF9a–CC1 match-pair MAbs over time. (A) Ten microliters of (200 μg/mL) purified recombinant phytase (phy2A) expressed from yeast (top row) and (200 μg/mL) phytase expressed from GM corn (bottom row) was prepared and evaluated every 2 weeks over a period of 10 weeks using Western blot analysis. Each blot was probed with a mixture of MAbs EH10a, FA7, AF9a, and CC1. Record dates are indicated above the blot with the protein marker sizes kilodaltons (kD) on the left. (B) Purified recombinant phytase (phy2A) expressed from yeast (top row) and phytase expressed from GM corn (bottom row) were prepared and tested along immunolateral flow strips. Test strips containing the EH10a conjugate antibody and FA7 capture antibody (green colored) and the AF9a conjugate antibody and CC1 capture antibody (brown colored) were immersed in a solution of their respectively prepared phytase, and detection was recorded on the dates indicated above the strips. The arrangement of the control (C) and test (T) lines along the strips are as described in Figure 2.

the yeast-expressed (75 kDa) phytase degrades, it becomes less detectable when using strips with the EH10a–FA7 antibody match pair (Figure 4B, top row, green strips) and becomes more detectable when using strips with the AF9a–CC1 antibody match pair over time (Figure 4B, top row, brown strips). This effect corresponds to the detection of the smaller-sized phytase protein, which is similar to that detected from the transgenic corn (60 kDa) phytase, which, too, becomes less detectable upon degradation using the AF9a and CC1 antibodies (Figure 4B, bottom row, brown strips) and was barely discernible on strips coated with the EH10a–FA7 antibody match pair (Figure 4B, bottom row, green strips). If the larger phytase size is indeed due to glycosylation and a loss of this glycosylation results in a change in antibody recognition, it may be tempting to assume that the epitope binding sites of one or both of the MAbs, EH10a and FA7, consists of a carbohydrate moiety. Guirakhoo et al.[33] demonstrated that a carbohydrate side chain was essential in stabilizing epitopes within the envelope protein of the tick-borne encephalitis (TBE) virus. Although little is known about the structure of phytase antibody binding sites, antibodies have been shown to recognize carbohydrate epitopes.[34] On the basis of our findings, one can assume that the epitope structural organization of the four MAbs is similar, albeit the carbohydrate group required for EH10a and FA7 MAbs and the antibody that prevails is dependent upon glycosylated sites and that glycosylation may be required to maintain site stability. Or one can assume that the epitopes are not similar in structure but lie near enough together so that the carbohydrate group is inhibiting or blocking the binding sites to antibodies that do not recognize glycosylation. Cryptic sites within the TBE virus envelope containing antigenic determinants when exposed allow cross-reactive antibodies to be efficiently recognized, which would not have been accessible in a native virus.[35] Further studies are required such as structural analysis of the antigenic sites of the phytase protein expressed from various sources to verify the contribution of carbohydrates to antibody binding.

The development of transgenic phytase plants and the call for greater awareness of the distribution of GM organisms brings about a need for accurate product verification. Further, the ability to correctly detect glycosylation within transgenic phytase plants may be beneficial when a product with a more thermostable enzyme is required. Methods to assess phytase activity usually involve detection of released inorganic phosphates by adding phytate as a substrate, requiring generation of a calibration curve and complex laboratory equipment.[36−38] In this study, MAbs were generated which are able to bind to different protein epitopes that were both highly sensitive and specific to transgenic phytase, efficiently so as to be differentiated from the yeast-expressed phytase. An RDT, which is an immunochromatographic capillary flow assay consisting of MAbs, one immobilized on the surface of the membrane and the other conjugated to particles near the sample pad, allows for an efficient and sensitive point-of-care testing method that would deliver immediate results, requiring little skill or additional equipment. Here we present the

bound compounds for the assessment of the total phenolic compounds content of spent coffee extracts and to determine the most accurate method for this purpose.

MATERIALS AND METHODS

Chemicals and Reagents. Methanol of HPLC grade, sodium chloride, ethylenediaminetetraacetic acid (EDTA), ascorbic acid, sodium hydroxide, and hydrochloric acid were obtained from Panreac (Barcelona, Spain). Pure reference standards of caffeic acid, ferulic acid, *p*-coumaric acid, 4-hydroxybenzoic acid, sinapic acid, and 5-caffeoylquinic acid were purchased from Sigma-Aldrich (Steinheim, Germany) and of 3,4-, 3,5-, and 4,5-dicaffeoylquinic acids from Phytolab (Vestenbergsgreuth, Germany).

Coffee Brew Preparation. Roasted coffee from Guatemala (*Coffea arabica*, 3.03% water content, $L^* = 24.69 \pm 0.74$, roasted at 219 °C for ca. 15 min) was provided by a local factory. The lightness value (L^*) indicates the coffee roasting degree, and it was analyzed by means of a tristimulus colorimeter (Chromameter-2 CR-200, Minolta, Osaka, Japan) using the D65 illuminant and CIE 1931 standard observer. The instrument was standardized against a white tile before sample measurements. Ground roasted coffee was spread in an l cm

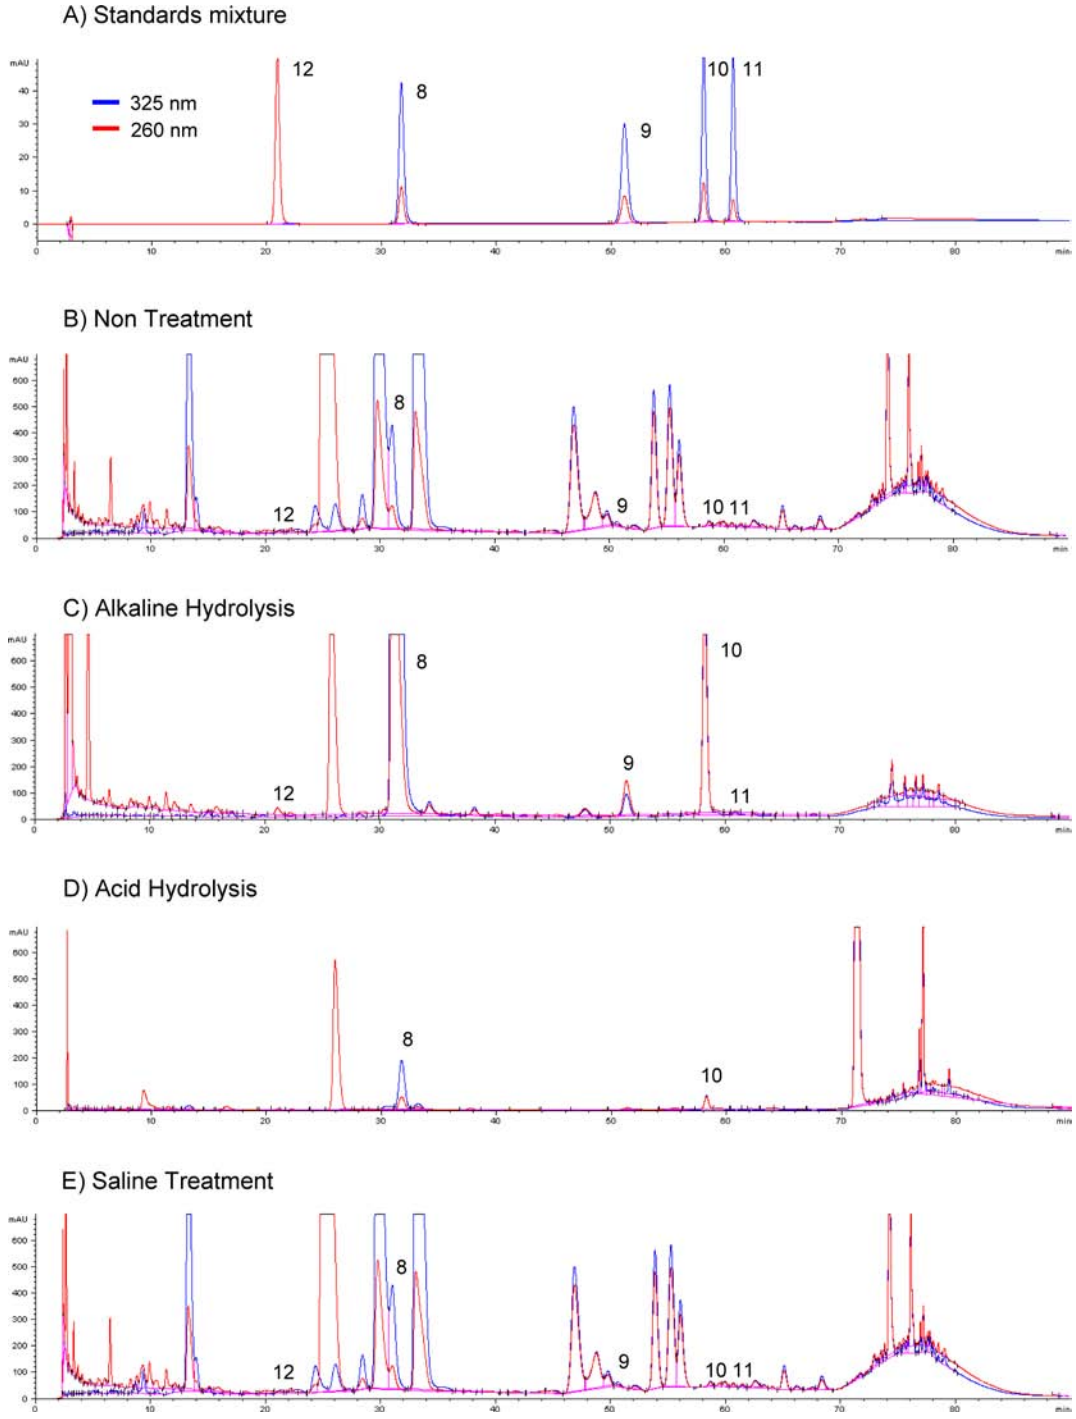

Figure 2. Chromatograms of (A) standards mixture, (B) nontreated coffee brew, (C) alkaline-hydrolyzed coffee brew, (D) acid-hydrolyzed coffee brew, and (E) saline-treated coffee brew. Peaks: (8) caffeic acid; (9) *p*-coumaric acid; (10) ferulic acid; (11) sinapic acid; (12) 4-hydroxybenzoic acid.

Petri plate, and the L^* value was measured in triplicate on the CIELab scale.

Roasted coffee beans were ground to a powder in a Moulinex coffee grinder (model Super Junior "s", Paris, France) for 20 s immediately before sample preparation. Filter coffee brew was prepared from 36 g of ground roasted coffee for a volume of 600 mL, using a filter coffee machine (model Avantis 70 Aroma plus, Ufesa, Spain). Extraction took approximately 6 min at 90 °C. Extraction as the percentage of total solids with respect to ground roasted coffee was 23.3%.

Spent Coffee Extract. Spent coffee extracts were prepared according to the method described by Bravo et al.[6] Briefly, first, spent coffee was defatted with petroleum ether (1:11, w/v) for 3 h at 60 °C in a Soxhlet extraction system (Extraction Unit B-811 Standard BUCHI, Flawil, 127 Switzerland). Then, 24 g of spent coffee was extracted with a volume of 400 mL of water using a filter coffeemaker (model AVANTIS 70 Inox, Ufesa, Spain). Extraction took approximately 6 min at 90 °C. Extraction as the percentage of total solids with respect to ground spent coffee was 11%.

Both coffee brew and spent coffee extract were lyophilized using a Cryodos Telstar (Terrassa, Spain).

Alkaline Hydrolysis. The procedure was performed according to the method of Nardini et al.,[16] with some modifications. A volume of 5

[a]Data are expressed as μmol/g of lyophilized coffee brew or spent coffee extract. All values are shown as means ± SD (n = 3). nd, not detected. In each row, asterisks indicate different significance: (*) $P > 0.05$; (**) $P > 0.01$; (***) $P > 0.001$ from nontreated sample; ns, $P < 0.05$.

mL of spent coffee extract (0.05 g) or coffee brew (0.08 g) was added to a 5 mL of 2 M NaOH solution containing 1% (w/w) ascorbic acid and 10 mM EDTA. The mixture was incubated for 30 min at 30 °C.

Acid Hydrolysis. The hydrolytic method was applied according to that of Alves et al.,[22] with some modifications. An aliquot (20 mL) of coffee brew (0.32 g) or spent coffee extract (0.2 g) was hydrolyzed by adding 20 mL of methanol, 4 mL of concentrated HCl (10.2 M), and 600 μL of antioxidant solution (1% BHT and 1% ascorbic acid). The mixtures were heated under reflux at 75 °C for 150 min. After the hydrolysis, samples were neutralized with 10 M NaOH.

Saline Treatment. Ionically bound phenolic compounds were obtained according to the method described by Delgado-Andrade and Morales.[14] Briefly, NaCl was added to an aliquot (50 mL) of coffee brew (0.8 g) or spent coffee extract (0.5 g) to have a 2 M concentration. Then, samples were maintained at 4 °C overnight.

After each treatment, samples were acidified to pH 3 with concentrated HCl and then were centrifuged, and the supernatant was stored at 4 °C for further analysis.

Chlorogenic Acids Analysis. Extraction of chlorogenic acids was carried out according to the method of Bicchi et al.[28] The compounds were analyzed by HPLC following the method described by Farah et al.[4] with some modifications.[5] HPLC analysis was achieved with an analytical HPLC unit model 1100 (Agilent Technologies, Palo Alto, CA, USA) equipped with a binary pump and an automated sample injector. A reversed-phase Poroshell 120 C-18 (2.7 μm particle size, 250 × 4.6 mm) column was used at 25 °C. Samples were properly diluted, and the sample injection volume was 100 μL. The chromatographic separation was performed using a gradient of methanol (solvent A) and Milli-Q water acidulated with phosphoric acid (pH 3.0, solvent B) at a constant flow of 0.8 mL/min. Elution was initiated at 10% A and maintained for 5 min; the percentage of solvent A was increased to 20% in 10 min and maintained for 10 min, then

DOI: 10.1021/acs.jafc.5b01619
J. Agric. Food Chem. 2015, 63, 4327−4334

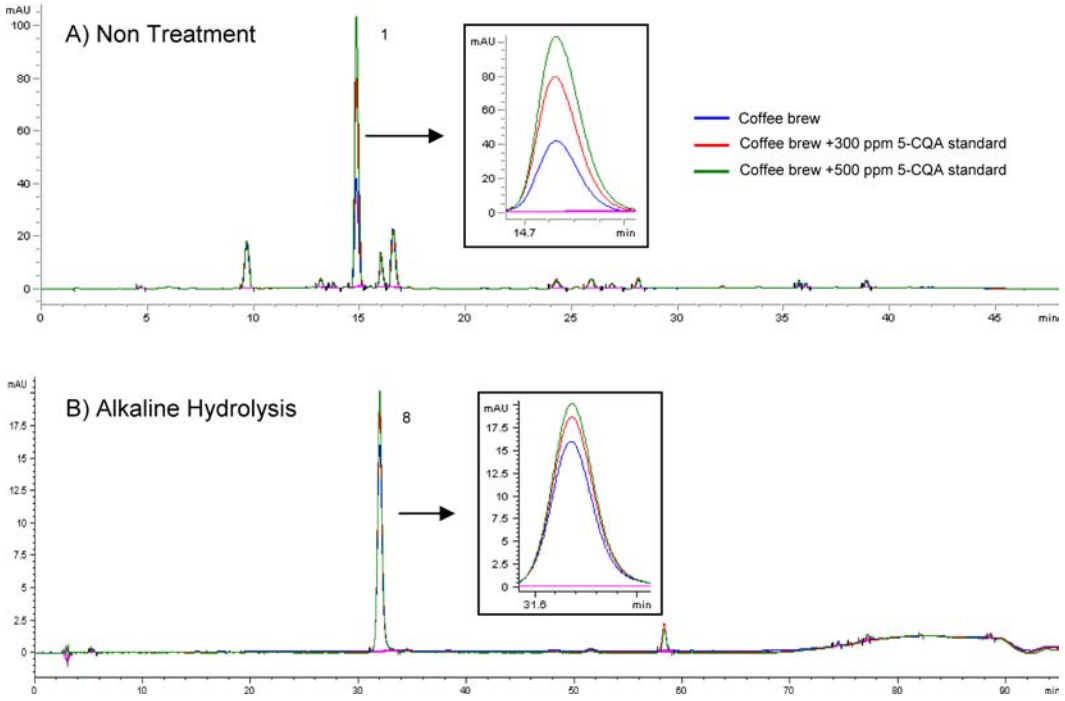

Figure 3. Chromatograms of (A) nontreated coffee brew spiked with 5-CQA standard and (B) alkaline-hydrolyzed coffee brew spiked with 5-CQA standard. Peaks: (1) 5-CQA; (8) caffeic acid.

increased to 50% in 20 min and maintained for 3 min, and finally increased to 80% for 15 min. Detection was accomplished with a diode array detector (DAD), and chromatograms were recorded at 325 nm. Identification of 5-CQA and diCQAs was performed by comparing the retention time and the photodiode array spectra with those of their reference standards compounds. 3-CQA and 4-CQA were identified by the isomerization of 5-CQA standard. Quantitation of 5-caffeoylquinic acid (5-CQA) was made by comparing the peak areas with those of the standards. Quantitation of the other CGAs was performed using the area of 5-CQA standard combined with their respective molar extinction coefficients as reported by Trugo and Macrae[29] and Farah et al.[4]

Other Phenolic Acids. The extraction of hydroxycinnamic acids and benzoic acid derivative was carried out according to the method of Alvarez-Vidaurre et al.[30] The HPLC analysis was performed following the method described by Nardini et al.,[16] with modifications. HPLC analysis was achieved with an analytical HPLC unit model 1200 (Agilent Technologies) equipped with a binary pump and an automated sample injector. The sample injection volume was 50 μL. Chromatographic separation was performed at 25 °C using a reversed-phase Gemini NX (5 μm particle size, 250 × 4.6 mm) column (Phenomenex, Torrence, CA, USA) and a mobile phase consisting methanol (solvent A) and Milli-Q water acidulated with phosphoric acid (pH 2.5, solvent B). The flow rate was 1 mL/min. Elution was initiated at 15% A and maintained for 20 min; the percentage of solvent A was increased to 20% in 10 min, to 45% in 5 min, to 55% in 10 min, then maintained for 10 min, and finally increased to 80% for 15 min. Detection was accomplished with a diode array detector at 325 nm for caffeic acid, ferulic acid, *p*-coumaric acid, and sinapic acid and at 260 nm for 4-hydroxybenzoic acid. Identification of phenolic acids was performed by comparing the retention time and the photodiode array spectra with those of their reference compounds. Calibration curves of standard were used to quantitate. Coefficients of linearity for the calibration curves were typically $R^2 > 0.99$.

Statistical Analysis. Each parameter was analyzed in triplicate. Results are shown as means ± standard deviations. A Student's *t* test was applied to determine differences of phenolic compounds between nontreated samples and each treatment. All statistical analyses were performed using the SPSS v.15.0 software package.

RESULTS AND DISCUSSION

Spent coffee is the byproduct generated after a brewing process and might be considered a valuable source of easily extracted phenolic compounds by the food industry. However, identification and quantitation of the total (free and bound) phenolic compounds should be a previous step before further applications. Therefore, spent coffee extracts were submitted to three treatments (alkaline, acid, and saline). Phenolic compounds were analyzed by HPLC-DAD and compared to those in their respective coffee brew. Figures 1 and 2 showed the chromatograms of phenolic compounds of coffee brews before and after each treatment. Similar chromatograms were obtained for spent coffee extract because samples were properly diluted before injection in HPLC to have areas ranged within calibration curves.

First, free chlorogenic acids (CGAs), the most abundant phenolic compounds in coffee, were identified and quantitated in nontreated samples. Figure 1C shows the CGAs peaks, which were identified as 3-caffeoylquinic acid (peak 3), 4-caffeoylquinic acid (peak 2), 5-caffeoylquinic acid (peak 1), 3,4-dicaffeoylquinic acid (peak 4), 3,5-dicaffeoylquinic acid (peak 5), and 4,5-di caffeoylquinic acid (peak 6), as compared with the standards mixtures (Figure 1A,B). Spent coffee extract showed less content of free CQAs than the coffee brew, whereas the concentration of free diCQAs was 1.8-fold higher in the byproducts (Table 1). Furthermore, the content of other phenolic compounds, such as hydroxycinnamic acids and benzoic acid derivative, was also measured by HPLC, and chromatograms are shown in Figure 2. The results (Table 1) showed low amounts of caffeic acid (peak 8), ferulic acid (peak 9), *p*-coumaric acid (peak 10), and sinapic acid (peak 11), as well as 4-hydroxybenzoic acid (peak 12), in both spent coffee extract and coffee brew (Figure 2B).

Alkaline Hydrolysis. Alkaline hydrolysis or saponification is applied to release compounds bound to polymers by covalent

DOI: 10.1021/acs.jafc.5b01619
J. Agric. Food Chem. 2015, 63, 4327−4334

interactions.[10] Spent coffee extract and coffee brew treated with alkaline solutions showed differences in the chromatographic phenolic acids profile compared with nontreated samples. The chromatogram (Figure 1D) showed the disappearance of the major CGAs, only one large peak (8) being detected. Even though the elution time of peak 8 was quite similar to that of 4-CQA (2), the spectral data confirmed that it was caffeic acid. Some authors have reported that phenolic compounds are susceptible to oxidation at pH 8 and higher, leading to degradation into their corresponding molecules derivatives.[9,31] Quantitation of the caffeic acid was carried out with the second chromatographic method (Figure 2C). It was also observed that ferulic acid, *p*-coumaric acid, sinapic acid, and 4-hydroxybenzoic acid peaks remained after the hydrolysis. Moreover, the numerical data showed a significant increase ($p < 0.01$) in the amounts of hydroxycinnamic acids in samples treated with alkaline conditions in comparison with nontreated spent coffee extract and coffee brew (Table 1). These results agree with previous studies, where high amounts of caffeic and ferulic acids were found in coffee brew or in the HMW melanoidins fraction after the application of alkaline hydrolysis.[16,17]

Chlorogenic acids are an ester formed between a quinic acid molecule and one or more hydroxycinnamic acid molecules. Alkaline medium can break not only the covalent bonds between melanoidins and phenolic compounds but also CGAs' internal bonds. Our findings suggest that the high concentration of caffeic, ferulic, and coumaric acids found in hydrolyzed samples were partially due to the cleavage of the ester linkages in free CGAs. In fact, an additional experiment showed that all 5-CQA from coffee brew and spiked standard (300 and 500 ppm of 5-CQA) has been hydrolyzed into caffeic acid, but only 50% of the expected caffeic acid was quantitated (Figure 3). With this loss taken into account, our results indicate that the amount of caffeic acid obtained after alkaline hydrolysis was approximately 58 and 35% higher than the expected in spent coffee extract and coffee brew, respectively. This fact could be partially explained by the presence of other chemical compounds with caffeic acid in their structure. A complete free phenolics profile of Arabica spent coffee extract and coffee brew (unpublished data) showed that CQLs were 18% of the total CQAs and diCQAs and as well an additional 8% of caffeoylquinic isomers were found. Then, the caffeic acid derived from overall free chlorogenic acids was deducted from the total caffeic acid, which included that obtained after alkaline hydrolysis and the estimated due to losses. Thus, the results suggest that around 47% (spent coffee extract) and 19% (coffee brew) of the caffeic acid found after the alkaline hydrolysis could come from CGAs or caffeic acids attached to other structures. In the case of coffee brew, this percentage of bound phenolic compounds is in the range of 1−29% proposed by Perrone et al.[19] depending on the roasting degree. The amount of bound phenolics in coffee might also be influenced by coffee variety because it has been reported that darker roasted Robusta coffees showed higher losses of chlorogenic acids, but an increase in bound compounds.[19,32]

Similarly, the increment of ferulic and coumaric acids concentration could be explained by the release of hydroxycinnamic acids from feruloylquinic and coumaroylquinic acids present in coffee brew and spent coffee extract. Unlike the caffeic acid, the other hydroxycinnamic acids do not suffer losses by the alkaline treatment. Moreover, the proportion of FQAs and FQLs in the samples was close to 9% of the total content of free CGAs (unpublished data). Thus, the percentage of extra ferulic acid found in hydrolyzed samples was similar, which indicates that a minor amount of this compound was released from melanoidins and other macromolecules. Even though the concentrations of sinapic and 4-hydroxybenzoic acids were lower than those of caffeic, ferulic, and coumaric acids, 2−3-fold significant increases ($p < 0.001$) were found in comparison to the values in the nontreated samples. There is scarce literature about the presence of sinapic acid in coffee. To our knowledge, sinapic acid linked to quinic, caffeoylquinic, and feruloylquinic acids has been reported only in Robusta green coffee.[33] Consequently, part of these chlorogenic acids could remain attached to melanoidins during roasting process. Finally, the increase of 4-hydroxybenzoic acid agrees with Nunes and Coimbra,[18] who found benzoic acid and derivatives as 4-hydroxybenzoic acid attached to the HMW melanoidins fraction of roasted coffee after applying alkaline fusion.

Acid Hydrolysis. Acid hydrolysis is also proposed to release bound compounds. The chemical basis is similar to alkaline hydrolysis, which is the rupture of covalent bonds using in this case a strong acid (HCl). Figure 1E shows a chromatogram of a hydrolyzed coffee brew, where four small peaks are observed. Two peaks were identified as 5-CQA and caffeine (peaks 1 and 7). Peak 8 eluted at the same time as 4-CQA, but it has been identified as caffeic acid by the spectrum data. The last peak (ca. 35 min) was the antioxidant used in the assay. Similarly, antioxidants used were detected in Figure 2 (ca. 71 and 77 min), as well as the caffeine (ca. 26 min). In spent coffee, caffeoylquinic and dicaffeoylquinic acids were completely lost after acid hydrolysis. Also, ferulic, coumaric, sinapic, and 4-hydroxybenzoic acids totally disappeared in both spent coffee extracts and coffee brews after acid treatment. Furthermore, minor changes in caffeic acid concentration were found in comparison to nontreated samples (1.50 μmol/g of spent coffee extract and 2.01 μmol/g of coffee brew). A previous study reported that this technique could be used to release and to quantitate phenolic compounds such as isoflavones from other coffee components.[22] However, our results strongly suggest that phenolic acids, such as CGAs and hydroxycinnamic acids, are very susceptible to acid hydrolysis. This in agreement with the study of Mattila et al.,[23] who found that phenolic compounds are affected by extreme pH conditions but that oxidation processes are more likely to occur in acid pH. Consequently, acid hydrolysis is an inadequate technique to release the main bound coffee phenolic compounds (phenolic acids), but it can be applied to evaluate others such as isoflavones.

Saline Treatment. This method has been used to release phenolic compounds ionically bound to proteins or melanoidins, using 2 M NaCl. Barbeau and Kinsella[24] reported that the chlorogenic acid carboxyl group is predominately ionized at neutral pH. Therefore, the increase of ionic strength tends to neutralize charge interaction between dissociated carboxylic groups of chlorogenic acid and positively charge side chain groups, like the amide carbonyls of the peptide bonds in proteins and melanoidins leading to the release of ionically bound phenolics. The chromatograms of CGAs (Figure 1F) and hydroxycinnamic acids (Figure 2E) after saline treatment show peak profiles similar to those of coffee samples without treatment. However, the results (Table 1) showed that samples treated with 2 M NaCl had higher concentrations of caffeoylquinic acids, with highly significant differences ($p < 0.001$). The amount of diCQAs was also higher ($p < 0.01$) in

DOI: 10.1021/acs.jafc.5b01619
J. Agric. Food Chem. 2015, 63, 4327−4334

comparison to nontreated samples, even though no statistical differences were detected for 3,5-diCQA in spent coffee extracts. The extra amounts of CQAs and diCQAs found after the saline treatment mean those compounds ionically attached to other structures. Thus, it should be highlighted that free and ionically bound CQAs were found in similar amounts in spent coffee extracts, whereas clearly lower amounts of bound CQAs (33.23 μmol/g) were in coffee brew. The addition of a caffeic acid moiety in the case of diCQAs increases the hydroxyl groups that can ionically interact with melanoidins, explaining the higher amount of bound diCQAs in coffee brews in comparison to spent coffee extracts. This is in agreement with previous works, which showed that a second extraction of ground coffee to obtain spent coffee extracts using a filter coffeemaker favors the extraction of bound CQAs, mainly diCQAs, probably due to the turbulences that facilitate contact of grounds and water.[5,34]

With regard to hydroxycinnamic acids, coumaric acid showed the largest increase, with values 3-fold higher than in nontreated samples. Sinapic acid and 4-hydrobenzoic acid raised their concentrations from 1.2- to 1.5-fold. However, caffeic acid and ferulic acid showed slight variations in the final content, with no significant differences ($p > 0.05$). Some authors did not find phenolic acid increases after applying high ionic strength treatment to the coffee brew HMW melanoidins fraction,[18,19] whereas others found caffeoylquinic acids ionically bound to the HMW melanoidins core contributing to the high antioxidant capacity of coffee.[14] Our data strongly suggest that the extra phenolic compounds found after the ionic treatment have been released from the melanoidins core or other medium and low molecular weight melanoidins or Maillard reaction products. In fact, our results support the theory of Bekedam et al.[20] that chlorogenic acids are also incorporated into the melanoidins through nonester linkages.

Total Phenolic Compounds. Free and estimated bound and total phenolic acids of spent coffee extracts are summarized in Table 2. Spent coffee extracts had around 2-fold higher content of total phenolics than those measured directly (without hydrolysis or saline treatment), showing an underestimation of phenolic acids. Phenolic compounds with one or more caffeic acid molecules were approximately 54% linked to macromolecules such as melanoidins, mainly by noncovalent interactions (up to 81% of bound phenolic compounds). The rest of the quantitated phenolic acids were mainly attached to other structures by covalent bonds (62−97% of total bound compounds).

Table 2. Free and Estimated Bound Phenolic Acids Content of Spent Coffee Extract[a]

	free	bound	ionically bound	total
total CQA	116.83	141.41	114.68	258.24
total diCQA	4.08	4.94	0.52	9.02
caffeic acid	2.00	2.42	0.51	4.42
ferulic acid	0.17	6.44	0.02	6.61
p-coumaric acid	0.24	2.36	0.43	2.60
sinapic acid	0.12	0.22	0.03	0.34
4-hydroxybenzoic acid	0.17	0.29	0.09	0.46

[a]Data are expressed as μmol per g of lyophilized spent coffee extract.

In conclusion, spent coffee extract is a rich source of phenolic acids with a high percentage of compounds linked to macromolecules such as melanoidins or other Maillard reaction products, mainly by noncovalent interactions. In contrast, coffee brew had only around 20% of attached phenolics. Moreover, caffeoylquinic acids are the most abundant and represent 70% of the total CGAs. With regard to the treatments, it could be said that two of the three methodologies provide accurate information about spent coffee extract and coffee brew bound phenolic compounds. The alkaline hydrolysis is a suitable method to know total phenolic compounds both free and bound. However, it cannot be used to directly quantitate total parent compounds, due to the susceptibility of coffee component internal linkage and oxidative losses at high pH conditions. On the other hand, saline treatment allowed ionically bound phenolic compounds to be quantitated. Thus, both methods increased the knowledge about the total content of phenolic compounds (free + bound) in spent coffee. All of the reported data must be taken into account for the characterization of this byproduct for use as a potential food ingredient by the food industry. Spent coffee phenolic compounds (free and bound) may add beneficial health properties to food, specifically in the prevention of oxidative stress related diseases, such as cancer and cardiovascular and neurodegenerative diseases.

J. Agric. Food Chem. 2015, 63, 4327−4334

ionic conditions all alter the aggregation process. Thus, there is a need to evaluate the colloidal stability of whey proteins in the context of consumer beverages under conditions that deliver a mixture of proteins and other compounds, in pH ranges that limit negative sensorial attributes, and after an industrially relevant thermal process.

Classical definitions of protein stability refer to maintaining secondary and tertiary structure and/or bioactivity after exposure to heat. In a beverage application, it is colloidal stability of a protein sol after thermal processing, which is commonly evaluated using indicators such as solubility[19] and turbidity.[20] Variations in protein solubility are due to physical and chemical properties of aggregates formed in thermal processing, including size, shape, density, and surface reactivity. Heating exposes free thiols and normally buried hydrophobic regions to initiate aggregation, and the balance of attractive and repulsive forces will determine the extent of aggregation. For example, heat treatment of β-Lg increases reactivity of the free thiol group, promoting aggregation and an increase in particle size[21,22] that potentially leads to decreased solubility and increased turbidity. Aggregation is more likely to occur in solution conditions producing weak electrostatic repulsion (pH close to the pI or high ionic strength)[17] but can potentially occur under strong electrostatic repulsive conditions.[23]

State diagrams have been used to represent the various physical states produced as a result of aggregation.[23−25] Unlike the traditional approach of showing treatment effects by selecting a limited set of conditions, state diagrams can be used to identify critical regions and transitions between sets of variables and can be tailored to specific parameters. Additionally, changes in experimental conditions can be evaluated via shifts in the critical transitions. This general approach has previously been used to evaluate β-Lg aggregation under steady state heating conditions by showing how pH, protein concentration, and salt concentration interrelate in forming a sol, precipitate, homogeneous gel, or microphase-separated gel.[23] Although this approach shows transitions between states, using extensive heating time at temperatures below 100 °C to achieve a steady state of aggregation is not valid for thermally processed beverages. The state diagram approach has also been used to evaluate WPI gelation[24] and changes in turbidity after thermal treatment.[25] In the context of whey protein beverages, this approach can be used to identify changes in colloidal stability such as sol−precipitate transitions or significant changes in turbidity or protein solubility. One of the limitations of this approach is that depending on the attributes that are desired (such as clarity or solubility), a single state diagram may not be the best representation of colloidal stability.

The goal of this investigation was to develop a state diagram approach to determine how whey proteins function in beverages after thermal treatments that mimic industrial ultrahigh-temperature (UHT) conditions. We chose to focus on the pH range in which beverages would typically be produced (pH 3−7). Additionally, instead of representing stability with one state diagram, we chose to depict three: protein solubility, turbidity, and macroscopic colloidal state. The combination of state diagrams provides a more complete view of colloidal stability over experimental conditions. To further explain state diagram trends and to identify key transitions, we developed pH−solubility curves for several protein concentrations. Gel electrophoresis and reverse phase chromatography were used to identify changes in the proportions of soluble β-Lg, α-La, GMP, and BSA after heating to elucidate the selectivity of the proteins toward heat-induced aggregation. The results of this study provide a framework for examining protein stability over a range of industrially relevant conditions and will assist in the formulation of beverages delivering higher levels of protein and potential health benefits.

MATERIALS AND METHODS

Preparation of Protein Solutions. Commercial WPI was provided by Glanbia Nutritionals (Twin Falls, ID, USA). Protein content was 92.13% as determined by Kjeldahl analysis (N × 6.38). The breakdown of whey proteins as determined by the manufacturer was 51.2% β-Lg, 21.3% α-La, 24.3% GMP, 1.6% immunoglobulins, 0.8% BSA, and 0.2% lactoferrin. Mineral composition as determined by inductively coupled plasma atomic emission spectroscopy was 14.44% N, 0.27% P, 0.42% K, 0.56% Ca, 1.05% S, and 0.23% Na. Chemical reagents were of analytical grade and supplied by Sigma-Aldrich (St. Louis, MO, USA). All subsequent calculations factor in purity and are expressed as protein concentration, not concentration of whey powder. All data are from three independent experimental replications unless stated otherwise.

Stock solutions (12% w/w protein) were made by solubilizing WPI in deionized water under magnetic agitation (400 rpm) for 3 h at 22 °C and storing overnight at 5 °C for maximum hydration. Solutions were diluted to the appropriate concentration (w/w protein) with deionized water. Sodium azide was added at a final concentration of 0.02% w/w to inhibit microbial growth. All pH adjustments were made with a combination of acids commonly used in commercial beverages (65:35 v/v phosphoric acid/citric acid) and 1 M sodium hydroxide. The volume added during pH adjustment was accounted for in determining final concentration of each protein solution.

Thermal Treatment. Two different heat treatments were used to mimic UHT thermal processing based on beverage pH: 109 °C for 3 s when pH ≤4.5 (LT) and 141 °C for 6 s when pH >4.5 (HT). A preliminary experiment was performed to determine the time required for solutions to reach the processing temperature in a Neslab EX7 silicon oil bath (Thermo Scientific, Waltham, MA, USA) set at 150 °C. Protein solutions were equilibrated to 20 °C, and 2 mL was placed in capped borosilicate test tubes (16 mm o.d.) before being processed in the 150 °C oil bath. Tubes were manually agitated during processing and remained quiescent in the bath for the respective hold time for total processing times of 29 + 3 and 62 + 6 s for LT and HT, respectively. At the conclusion of the hold time, test tubes were cooled in an ice slurry for 1 min and allowed to equilibrate overnight at 5 °C before analysis.

Nano Differential Scanning Calorimetry (nDSC). Samples of WPI were diluted to either 1.5 or 3.0 mg mL^{-1} with deionized water and adjusted to either pH 3.5 or 6.0 using the aforementioned acid blend. Both samples and reference deionized water were degassed at ∼1100 Torr for 1 h prior to analysis. Sample volumes of 300 μL were placed into a sample well with degassed water in the reference well, both under 3.0 atm of pressure to prevent gas bubble formation during heating. Thermograms were produced using a N-DSC II scanning calorimeter (TA Instruments, previously Calorimetry Sciences Corp., Provo, UT, USA) from 25 to 110 °C at a rate of 1 °C min^{-1}. Analysis of enthalpy and denaturation temperature was performed using NanoAnalyze software. Molar heat capacity was calculated using an average molecular weight of 16 kDa to reflect the main two proteins, β-Lg and α-La. A baseline scan of deionized water was subtracted from protein scans. A polynomial equation was fit to the scan and used to calculate enthalpy of unfolding (ΔH) and peak unfolding temperature (T_d).

Protein Solubility. Protein solubility after thermal treatment was determined using the method described by Morr et al.[26] with several modifications. After thermal processing, 2 mL samples were centrifuged at 17200g for 20 min at 15 °C, and the supernatant was removed and diluted 1:20 with deionized water. A Pierce bicinchoninic acid assay kit (Rockfold, IL, USA) was used to determine the concentration of protein in the supernatant per the manufacturer's instructions. The samples were combined with working reagent (1:8

DOI: 10.1021/acs.jafc.5b00633
J. Agric. Food Chem. 2015, 63, 4335−4344

ratio) in 96-well plates and incubated at 36 °C for 30 min. The absorbance of the plates was read at 562 nm on a Tecan Safire^2 (Männedorf, Switzerland) plate reader. The standard curve was developed using serial dilutions of centrifuged WPI to correct for the small amount of native insoluble protein. Solubility is expressed as the percentage of protein in the supernatant compared to the initial concentration of the solution.

Turbidity. The turbidity of the protein solutions after thermal treatment was determined using a Hach 21000AN Turbidimeter (Hach Co., Loveland, CO, USA). The solutions were analyzed in the 16 mm o.d. tubes in which they were thermally processed. Solutions were diluted by a factor of 5 with deionized water to fall within the range of the instrument, and reported values account for the dilution step. A preliminary test was performed to ensure that dilution did not cause disaggregation of particles (data not shown). The blank value for a test tube containing deionized water was subtracted from all values, which are given as nephelometric turbidity units (NTU).

Colloidal State Diagrams. State diagrams were developed for WPI solubility, turbidity, and macroscopic colloidal state after thermal processing. On the basis of pH, two different thermal treatments were used as described above. For ease of comparison across the entire pH range, these two treatments are shown on the same state diagram. For the macroscopic colloidal state diagram, each possible outcome (sol, precipitate, gel) was assigned a numeric value and averaged for each respective point. Definitions for states are as follows: sol, no visible aggregation; precipitate, visible aggregation; gel, solution does not flow when tilted 90°. All three state diagrams were plotted with triplicate values using the contour map function of Sigma Plot (Systat Software, San Jose, CA, USA).

Electrophoresis. Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) was performed under reducing conditions using a Novex NuPage gel system (Thermo Fisher Scientific, Waltham, MA, USA) per the manufacturer's instructions. After LT or HT heat treatment, solutions were centrifuged as described above; the supernatant was collected and diluted to 2 mg mL^{-1} with deionized water. Samples were mixed with Novex LDS sample buffer and Novex reducing agent and adjusted to a final protein concentration of 0.3 mg mL^{-1} with deionized water. Samples were heated to 70 °C for 10 min. In each gel, 5 μL of Novex Sharp prestained protein standard (Invitrogen Corp.) was used as a molecular weight reference in lane 1, and 3 μg of protein was added per lane to 4−12% mini Bis-Tris gels (Thermo Fisher Scientific). Gels were run with NuPage MES SDS running buffer (Thermo Fisher Scientific), and 500 μL of antioxidant was added to limit oxidation of disulfide bonds. The loaded gel received 200 V until the dye front reached the bottom of the gel. Gels were stained using SafeStain Coomassie stain (Thermo Fisher Scientific) for 1 h and destained with 100 mL of deionized water and 20 mL NaCl (20% w/v) for 3 h. Gel imaging was performed using a Gel Doc XR+ molecular imager (Bio-Rad Laboratories, Hercules, CA, USA), and bands were quantified with ImageLab software. Bands of β-Lg, α-La, and BSA were identified by comparison to known standards. Band intensities were determined and expressed as a percentage of the total band intensity in each respective lane, with unheated WPI used as a control. Data are average intensities of two independent replicates.

Reverse Phase High-Performance Liquid Chromatography (RP-HPLC). The percent loss of soluble GMP, α-La, and β-Lg after heat treatments was determined using RP-HPLC. After the heating, dilution, and centrifugation steps listed above, the supernatant was diluted 1:1 with the starting solvent blend and filtered through 0.1 μm Millipore filters. A gradient of solvent A (acetonitrile/water/TFA, 100:900:1 v/v/v) and solvent B (acetonitrile/water/TFA, 900:100:0.7 v/v/v) was applied using LC-20 AD pumps (Shimadzu Corp., Kyoto, Japan) at 0.8 mL min^{-1}. The ratio started with 74% solvent A and 26% solvent B, with iterative increases in solvent B percentage per the method described by Visser et al.[27] Chromatographic separations were performed using an Alltech Alltime 300 A 5 μm C_{18} column (Grace & Co., Columbia, MD, USA) at 30 °C and 1450 psi. Detection occurred at 220 nm using an SPD-M20-A photo diode array (Shimadzu Corp.). Peak areas were determined using LAB solutions software (Shimadzu Corp.) and were normalized against unheated WPI controls at each protein concentration to determine percent loss after heating. Average elution times were 6.9 and 11.9 min for GMP A and B, 38.1 min for α-La, and 52.3 and 53.6 min for β-Lg variants B and A, respectively.

Statistical Analysis. Statistical analysis of nDSC results was performed using the general linear model procedure in SAS v9.3 (Cary, NC, USA). Statistical significance was indicated at $p < 0.05$. Values for ΔH and T_d are shown plus/minus standard deviation. Differences between mean values were determined using Tukey's HSD comparison test.

RESULTS AND DISCUSSION

Thermal Properties of WPI Using nDSC. Thermal properties of native WPI were studied using nDSC (Figure 1) to determine the influence of pH on denaturation temperature (T_d) and enthalpy of unfolding (ΔH). The two pH values (3.5 and 6.0) were selected as values below and above the p*I* of whey proteins, respectively. Calorimetry cannot differentiate between denaturation and aggregation processes, so solutions were heated at dilute concentrations (1.5 and 3.0 mg mL^{-1}) to minimize the effects of aggregation. Additionally, the two concentrations served as a check to see if concentration affected the thermal properties of the proteins, which would most likely indicate aggregation.

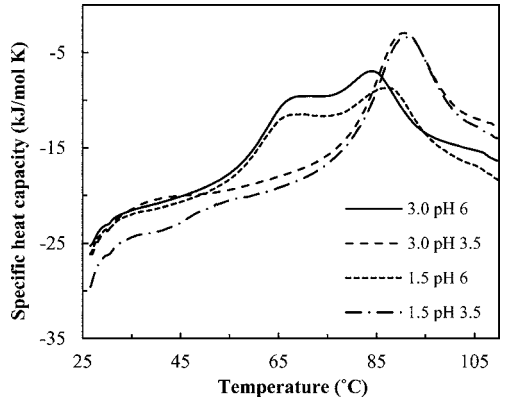

Figure 1. Calorimetric thermograms of WPI (1.5 and 3.0 mg mL^{-1}) at pH 3.5 and 6.0 heated from 25 to 110 °C at a rate of 1 °C min^{-1}.

Table 1. Denaturation Temperature (T_d) and Enthalpy (ΔH) of WPI at 1.5 and 3.0 mg mL^{-1} and pH 3.5 and 6.0[a]

protein (mg mL^{-1})	pH	ΔH (J g^{-1})	T_m (°C)
1.5	3.5	9.1 ± 0.1a	90.4 ± 0.1a
	6.0	11.7 ± 0.1b	87.4 ± 0.5b
3.0	3.5	9.2 ± 0.1a	90.2 ± 0.1a
	6.0	11.5 ± 0.2b	84.1 ± 0.9c

[a]Values listed are means of three replicates ± standard deviation. Lower case letters indicate significant differences in means within the column ($p < 0.05$).

At pH 3.5, WPI had a significantly ($p < 0.05$) greater T_d than at pH 6.0, suggesting greater thermal stability of protein structure. Both concentrations of WPI at pH 3.5 presented one large transition on the thermograph with a peak just above 90 °C. This is higher than reported T_d values of β-Lg (82 °C) and α-La (59 °C),[28] but α-La in particular has an increased T_d in the presence of β-Lg,[29] making it difficult to compare WPI with data from the individual proteins.

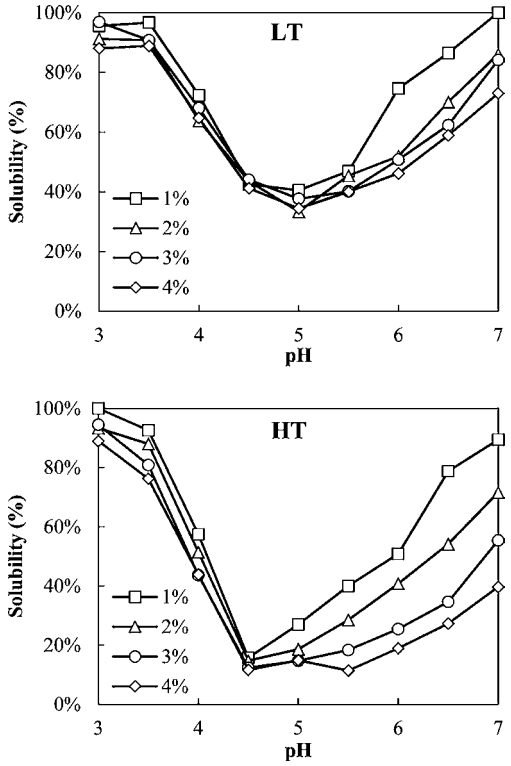

Figure 2. Solubility of WPI (1, 2, 3, and 4% protein w/w) after LT (top) or HT (bottom) heat treatments. Solubility is expressed as the amount of protein in the supernatant after centrifugation as a percentage of the initial protein prior to thermal treatment. Error bars are omitted for ease of viewing and were typically in the range of ±4%.

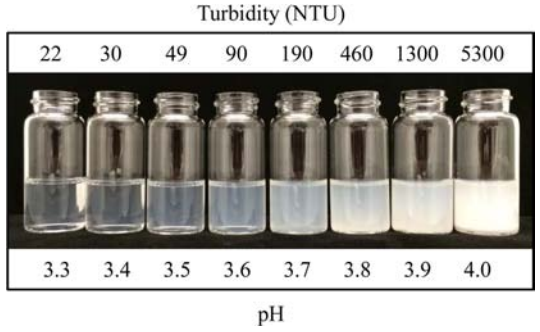

Figure 3. Turbidity of 1% w/w WPI solutions from pH 3.3 to 4.0 after heating to 109 °C for 3 s. The average turbidity (in NTU) of the solutions at each pH is shown above each sample.

At pH 6.0, one distinct peak was present near 85−87 °C, with a shoulder down to ∼65 °C. It has been shown that T_d is dependent on pH for individual whey proteins[28] and generally increases with a decrease in pH from 6.5 to 3.5, as seen in our experimental results. The lower shoulder of the pH 6.0 curve corresponds to the denaturation of α-La, which varies from 64 to 70 °C depending on calcium content.[30] The loss of calcium generally occurs at acidic pH[31] and converts α-La from the holo state to the apo state, with a T_d near 27 °C.[30] This explains the absence of an α-La peak on the pH 3.5 curve.

The enthalpy (ΔH) of unfolding was determined by analyzing the area between the endothermic curves and extrapolated baselines (Table 1). This represents the energy requirement to overcome noncovalent bonds during denaturation.[29] There was no difference in ΔH for each protein at

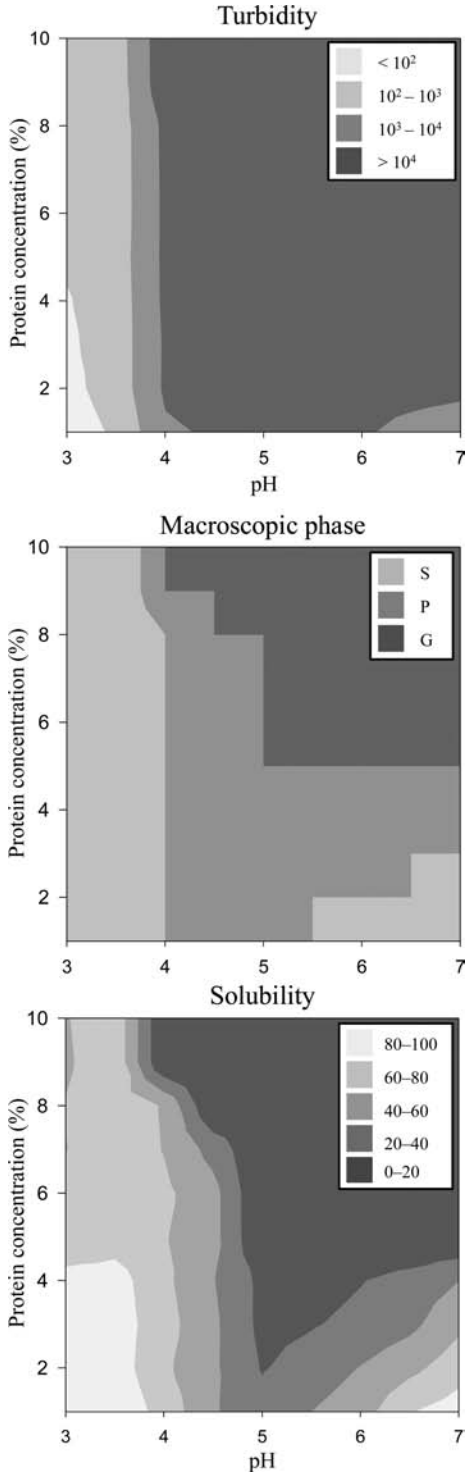

Figure 4. WPI (1−10% w/w, pH 3−7) state diagrams for turbidity (top), macroscopic colloidal state (middle), and solubility (bottom). Turbidity is presented as logarithmic NTU, with each iterative shade depicting a one $\log_{10}$ increase in solution turbidity after thermal treatment. Macroscopic colloidal state definitions are as follows: sol, no visible aggregation; precipitate, visible aggregation; gel, solution does not flow when turned on side. For the solubility diagram, different shaded regions represent 20% differences in solubility.

different concentrations, suggesting the major contribution was endothermic denaturation with minimal exothermic aggregation. Enthalpy at pH 6.0 is greater than at pH 3.5, but this value includes the peaks for both α-La and β-Lg, whereas ΔH for the

J. Agric. Food Chem. 2015, 63, 4335−4344

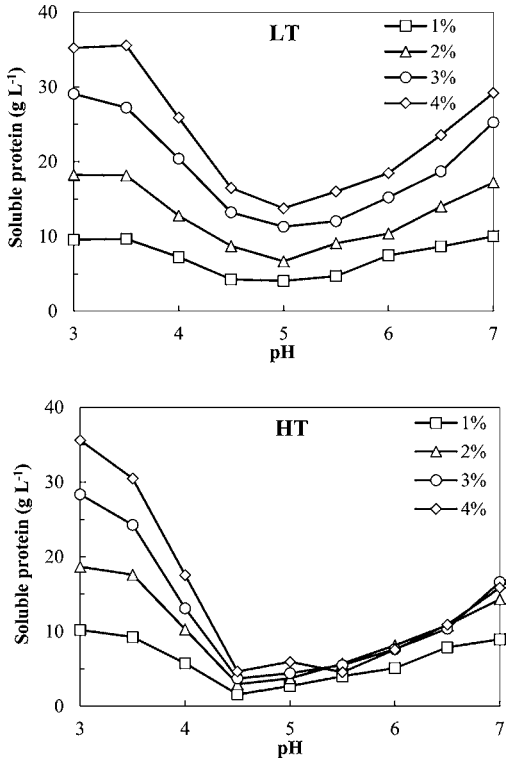

Figure 5. Solubility−pH profiles of 1, 2, 3, and 4% w/w WPI after LT (top) and HT (bottom) treatments. Values are expressed as protein concentration in the supernatant after centrifugation, instead of percent solubility. Error bars are omitted for ease of viewing and were typically in the range of ±4%.

pH 3.5 curves includes only β-Lg. The data generally agree with the literature, although one previous study found no change in enthalpy of WPC at pH 3.0 and 6.0 despite differences in T_d.[32]

Effects of Thermal Processing on Protein Solubility. Calorimetry was used to determine the thermal stability of individual proteins based on unfolding. In contrast, thermal stability in beverages is based on principles of colloidal stability. Protein solubility is often used as a marker for thermal stability of protein dispersions because loss of solubility is associated with decreased protein functionality.[33] Solubility−pH profiles were developed to determine the effects of the LT (109 °C for 3 s) and HT (141 °C for 6 s) processes on WPI solubility over a range of pH and protein concentrations (Figure 2). These thermal treatments mimic UHT thermal processing used to produce shelf-stable protein beverages.

For both thermal treatments, WPI solubility decreased as the pH approached the p*I* for all protein concentrations tested, in agreement with previous studies.[34−36] After the LT process, increased protein concentration from 1 to 4% was associated with decreased solubility at all pH values. Increasing concentration of β-Lg has been linked to the formation of higher molecular weight aggregates,[37,38] which settle at a faster rate during storage or centrifugation. Solubility was not significantly affected by increasing pH from 3.0 to 3.5, suggesting electrostatic repulsion at pH ≤3.5 is strong enough to limit further aggregation under the experimental conditions. Increasing pH from 3.5 to 5.0 decreased solubility for all concentrations. Above pH 5.0, solubility increased as pH increased, suggesting greater electrostatic repulsion. However, only 1% WPI had the same solubility at pH 7.0 that was seen at pH ≤3.5; all other concentrations had lower solubility at pH

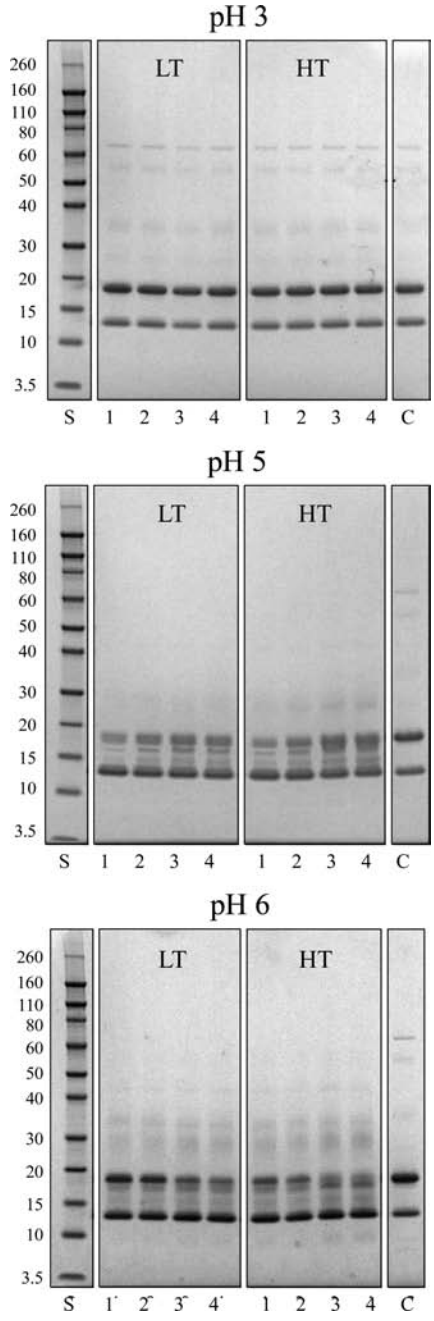

Figure 6. SDS-PAGE patterns of WPI supernatant after LT and HT treatments. The pH is shown at the top of each gel, and lane assignments are as follows: lane 1, molecular weight standards (S); lanes 2−5, initial starting protein concentration 1−4% w/w after LT; lanes 6−9, initial starting protein concentration 1−4% w/w after HT; lane 10, unheated WPI control (C).

7.0 than at pH 3.5. It is important to note that even at pH ≤3.5, solubility is not 100%, possibly due to the formation of insoluble protein aggregates during whey protein ingredient production.[39] These aggregates would be removed during centrifugation and thus not detected during analysis for solubility.

More severe drops in solubility were observed with the HT treatment. At pH 3.0, >80% solubility was retained for all concentrations regardless of thermal treatment, but dropped precipitously upon increasing pH to 4.5. All four concentrations retained only 12−16% solubility at pH 4.5. Above the p*I*,

DOI: 10.1021/acs.jafc.5b00633
J. Agric. Food Chem. 2015, 63, 4335−4344

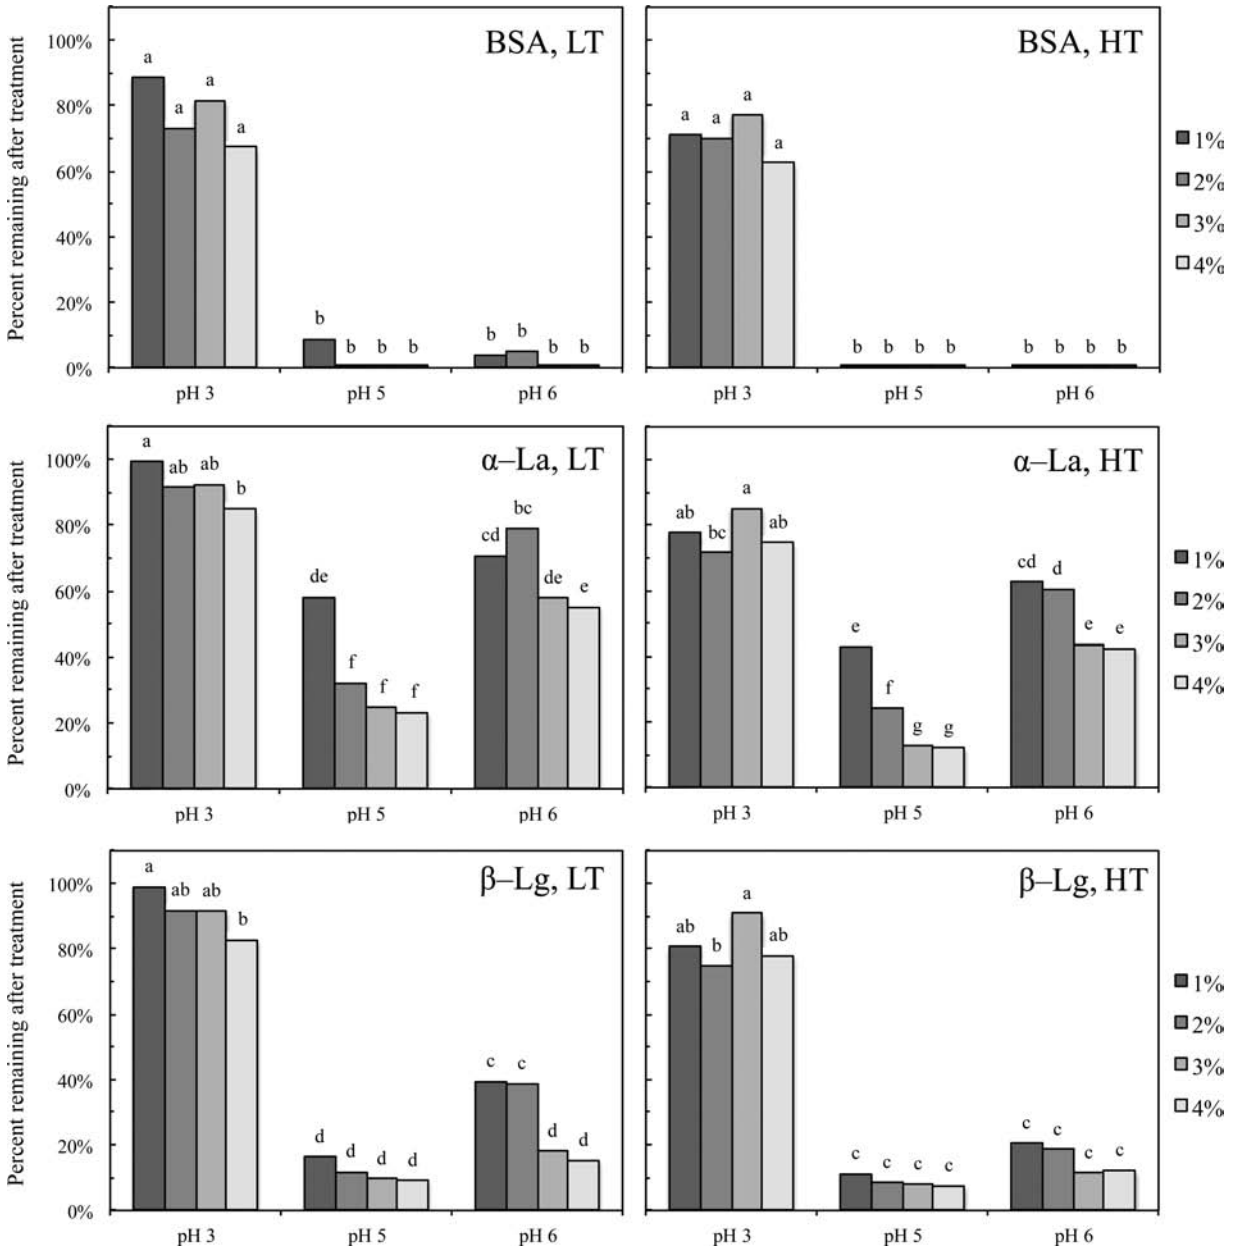

Figure 7. Percent soluble BSA, α-La, and β-Lg remaining after LT and HT compared to unheated controls as determined by band intensity after SDS-PAGE. Percentage (1−4%) indicates initial protein level. Lower case letters indicate significant differences between means within each individual treatment ($p < 0.05$).

increasing WPI concentration from 1 to 4% resulted in drops of solubility at pH 7.0 from 89 to 40%. Our nDSC results cover the temperature range of only the LT process, but it has been reported that β-Lg has a second transition peak just above 125 °C[40] that may be indicative of structural changes favoring aggregation. Increasing pH from 5.5 to 7.0 has been shown to increase onset temperature of WPI aggregation.[41] This would suggest decreased extent of aggregation and a higher degree of soluble protein, which our experimental data show. However, solubility is not as high above the p*I* as it is below. This may be explained by charge differences. Using the number of ionizable residues for calculations as an example, β-Lg has a net charge of approximately +16 at pH 3.6, but at pH 6.6 (∼equal pH units above the p*I*) the net charge is only −7.6.[42] Decreased net charge would favor aggregation and decreased solubility. Moreover, intermolecular disulfide interactions are favored more at pH > p*I* than below.[43] The pK_a of a cysteine thiol is ∼8.0, so thiol reactivity and disulfide bond formation are enhanced between pH 6.4 and 8.0.[37,44] Additionally, β-Lg undergoes a conformational change near pH 7 known as the Tanford transition,[18] associated with a marked increase in thiol reactivity.

Investigations on thermal denaturation and aggregation of whey proteins typically focus on temperatures below 100 °C. As such, very few studies have examined the effects of temperatures in excess of 100 °C, which is the temperature range for UHT processing. Noncovalent interactions may play a much more important role in aggregation at temperatures >90 °C.[45] Our results agree with a previous study showing significant drops in solubility after heating at temperatures ∼140 °C.[46]

J. Agric. Food Chem. 2015, 63, 4335−4344

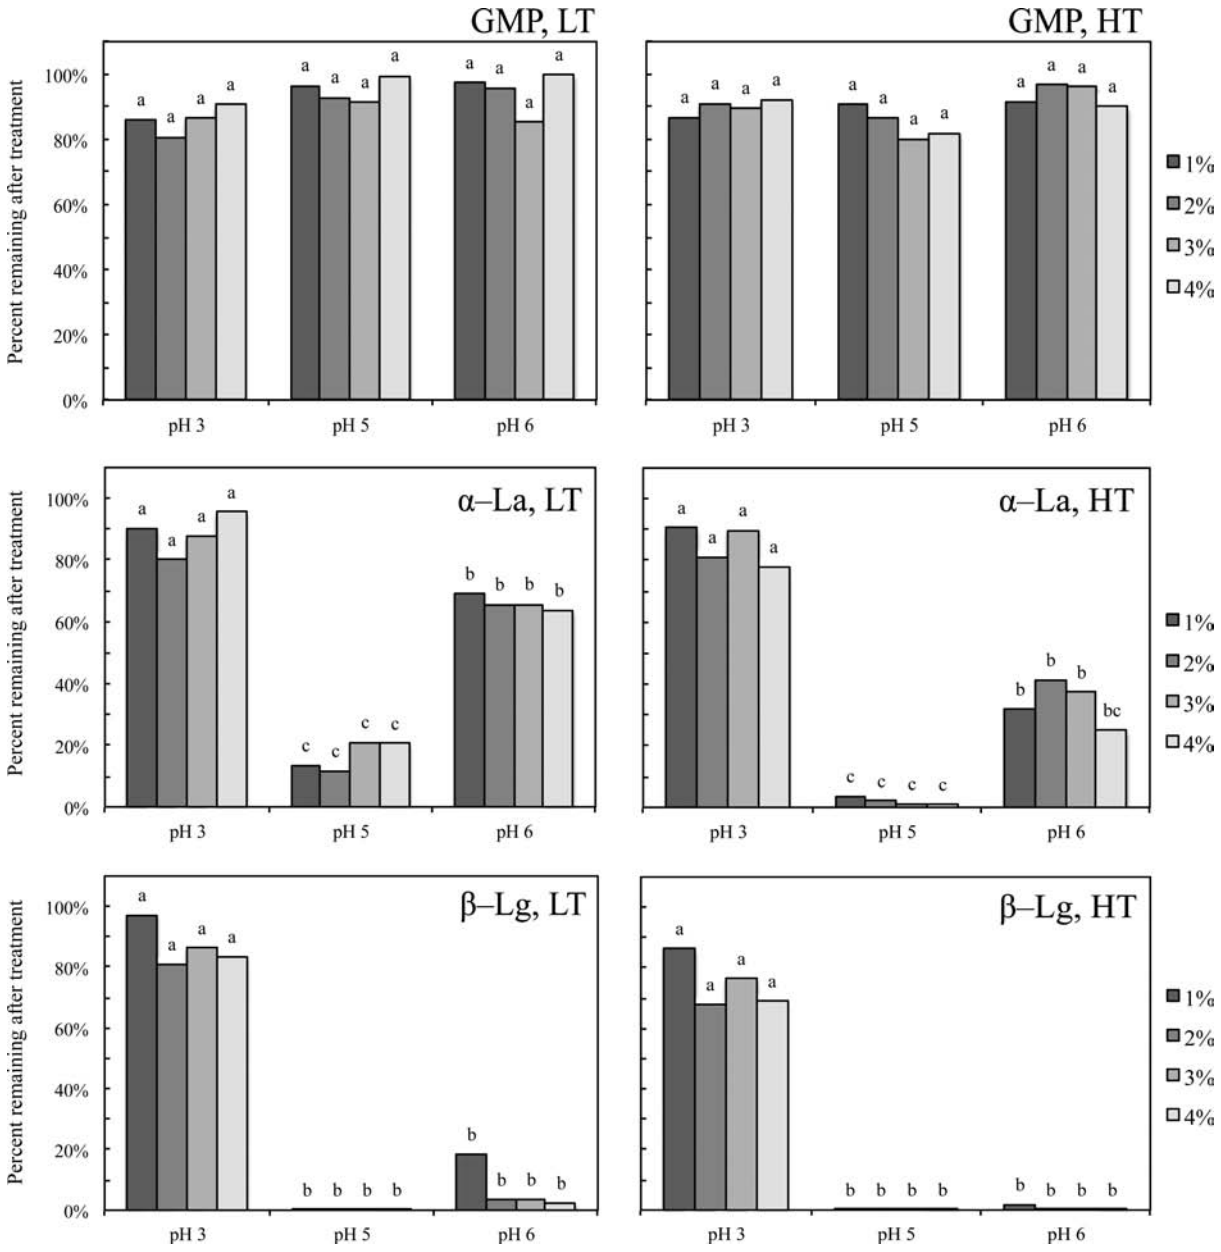

Figure 8. Percent soluble GMP (top), α-La (middle), and β-Lg (bottom) remaining after LT (left) and HT (right) as determined by HPLC. Percentage (1−4%) indicates initial protein level. Lower case letters indicate significant differences between means within each individual treatment ($p < 0.05$).

Effect of pH on Turbidity of Acidic Beverages. In the context of a whey protein beverage, turbidity is affected by many factors that influence aggregation, including protein concentration, thermal process time and temperature, pH, ionic strength, and other ingredients.[47] Turbidity is an important marker of stability in beverage applications due to consumer perception, as clear beverages are rated as more thirst quenching than turbid beverages.[48] Additionally, turbidity reflects size of dispersed particles, which is a predictor of colloidal stability per Stokes' law. We examined the turbidity of 1% WPI solutions over a pH range of 3.3−4.0 to provide a practical example of beverage turbidity (Figure 3). It is within this range that previous literature has reported a transition from clear to opaque beverages at pH 3.5,[25] 3.6,[49] and 3.7.[28] Beverages with turbidity below 50 NTU have been previously described as clear beverages.[49] However, as our state diagrams are represented on a logarithmic scale, we have designated 100 NTU as the cutoff for "clear" beverages. Our results show that at pH ≤3.6, solutions remained clear (90 NTU at pH 3.6) after thermal treatment. Beverages were no longer clear but only slightly turbid as pH increased to pH 3.7 (190 NTU) and 3.8 (460 NTU) and became completely opaque at pH 3.9 and 4.0 (>1300 NTU). This transition in turbidity is due to the formation of larger aggregates during thermal treatment, presumably because of diminished electrostatic repulsion close to the p*I*.

WPI State Diagrams as a Means To Represent Colloidal Stability. State diagrams were used to identify key regions of colloidal stability. We chose to depict three interrelated aspects of stability: turbidity, solubility, and the macroscopic colloidal state. Protein concentration (1−10% w/w) and pH (3−7) were varied over a range to depict conditions

DOI: 10.1021/acs.jafc.5b00633
J. Agric. Food Chem. 2015, 63, 4335−4344

suitable for whey protein beverages. Solution turbidity is expressed as log NTU values (Figure 4). Each iteratively darker region is a logarithmic increase in turbidity starting with clear beverages at <100 NTU. Solutions remained clear after heating, with a critical transition near pH 3.5 for 1% WPI or at pH 3.0 up to 4% WPI. At constant protein concentration, turbidity increased dramatically with increasing pH. Turbidity values began to decrease at pH > p*I*, but not by appreciable values except for low concentrations of WPI above pH 6.0. Thus, beverages in which clarity is desired require a pH below the critical transition, whereas clarity at neutral pH is not feasible under these conditions.

Similar trends are seen in the macroscopic colloidal state diagram (Figure 4). Solutions form stable sols at low pH independent of protein concentration due to the net positive charge on suspended protein particles. Near neutral pH, solutions with low protein concentration still form stable sols, but they are opaque instead of clear. The state diagram indicates a critical protein concentration required for gelation between 4 and 5% WPI for pH values from ∼4.8 to 7.0. Below the p*I*, higher protein levels are required for gelation. It should be noted that one limitation of the qualitative state diagram is the inexact demarcations between states. With only three possible numeric outcomes (sol, precipitate, or gel), the precision of the contour plot is somewhat limited without testing infinitesimally small increments of variables.

The solubility state diagram shows that at low pH (pH <3.5) and conditions of strong electrostatic repulsion, solubility after heating remained >80%, but decreased to 60−80% at protein concentrations >4% (Figure 4). Near the p*I*, solubility dropped below 40% for all protein concentrations. At a constant pH, increasing protein concentration also resulted in decreased solubility. Increasing β-Lg concentration has previously been associated with both the formation of larger aggregates[38] and increased rates and extent of β-Lg aggregation.[50] Even when heated to only 65 °C, higher concentrations of β-Lg shifted the fraction of aggregates toward higher molar mass aggregates.[37] Similar drops in solubility with WPI concentrations up to 10% have been reported.[36] In the context of colloidal stability, larger aggregates are more likely to be separated during centrifugation, resulting in decreased solubility.

Solubility−pH Profiles Based on Protein Concentration. The effects of the LT and HT thermal treatments on solubility are more apparent when expressing solubility as a concentration of protein in the supernatant after centrifugation rather than a percentage of the initial protein (Figure 5). After the LT treatment, the solubility−pH profiles for each protein concentration are similar. Solubility remains high at low pH, drops near the p*I*, and increases near neutral pH while remaining below the low pH levels. Beverages at pH 3 have approximately the same solubility after both LT and HT treatments. However, above pH 3, solubility drops more precipitously after the HT treatment, with higher initial protein concentration resulting in greater drops in solubility. Increased protein concentration has previously been associated with larger aggregate sizes,[38] decreased solubility,[36] and increased rates and extent of aggregation[50] while also affecting the morphological characteristics of protein aggregates.[4]

After the HT treatment, solubility gradually increased above the p*I*, but was lower than solubility levels after the LT treatment. The soluble protein concentration for 1% WPI (10 g L^{-1}) after heating was similar for the LT and HT treatments. For the other tested concentrations, the soluble protein concentration after HT treatment at pH 7 was 14, 17, and 16 g L^{-1} despite initial concentrations of 20, 30, and 40 g L^{-1}, respectively. This suggests that the protein remaining soluble is either a protein with limited participation in aggregation (i.e., GMP) or a combination of aggregating and nonaggregating proteins. We then chose to use complementary separation techniques to determine the aggregation selectivity of the individual proteins.

Electrophoretic Patterns of WPI Supernatant after Thermal Treatment. To determine aggregation selectivity of β-Lg, α-La, and BSA during heating, we used SDS-PAGE analysis. Samples were run under reducing conditions to compare the relative intensities of β-Lg, α-La, and BSA to that of native, unheated WPI. Several concentrations of WPI were compared at pH values above, near, and below the p*I*. Both thermal treatments (LT and HT) were also tested. Equal amounts of protein (not volume) were added to each lane, so changes in band intensity relative to the control indicate the participation of the proteins in forming insoluble aggregates and thus a change in the ratio of the proteins in the electrophoretic gel.

At pH 3.0, neither protein concentration nor heat treatment had a significant impact on the proportion of the major proteins in each lane (Figure 6). In the unheated control, the percentage of total protein in each lane was as follows: β-Lg, ∼54%; α-La, ∼30%; BSA, ∼4%. These values did not significantly change with increased protein content or heat treatment, suggesting limited aggregation and/or similar participation of individual proteins in aggregation across all concentrations. At pH 5.0, α-La comprises a greater percentage of total protein in each lane (43−52%) than the unheated control (30%), indicating that α-La was less involved in forming large aggregates than BSA and β-Lg. This is confirmed by the absence of BSA bands on the gels and the decreased intensity of the β-Lg bands compared to the control. Additionally, both LT and HT treatments at pH 5.0 resulted in a greater proportion of bands between α-La and β-Lg, between 20 and 30 kDa molar mass, and extending above 40 kDa.

The percentages of BSA, α-La, and β-Lg remaining after heating were also calculated (Figure 7). Solubility of BSA at pH 3 varied from ∼90% at 1% protein to ∼70% at 4% protein for the LT process and dropped slightly after the HT process. However, very little BSA remained at pH 5 and 6 for the LT process, with none remaining after the HT process, indicating a high propensity to aggregate. Both α-La and β-Lg generally trended toward lower solubility with increasing concentration, although the trends were not always statistically significant. Solubility was highest at pH 3 and lowest at pH 5 near the p*I*. Solubility at pH 6 was lower than at pH 3, which matches the trends in the pH−solubility profiles. β-Lg solubility was typically lower than that of α-La for all treatments.

Changes in Soluble GMP, α-La, and β-Lg after Heating As Determined by HPLC. Chromatography was used as a complementary method of comparing protein selectivity to heat-induced aggregation. Additionally, the HPLC method provided sensitivity for GMP detection, which SDS-PAGE could not provide. The same experimental variables (pH, initial protein concentration, and heat treatment) were explored (Figure 8). There were no significant losses in GMP solubility under all conditions tested. Heat stability at mildly acidic and near-neutral pH is in agreement with previous studies, but GMP heat stability has previously been shown to decrease at low pH.[51] This difference could be due to the different heat

DOI: 10.1021/acs.jafc.5b00633
J. Agric. Food Chem. 2015, 63, 4335−4344

treatments the authors used, but that remains to be established. At pH 3, there was no significant loss of α-La or β-Lg solubility after LT and HT treatments, which is in agreement with both the solubility state diagram and SDS-PAGE results. At pH 5, α-La and β-Lg solubility drops below 20% after LT, and negligible amounts of both proteins remain soluble after HT. Solubility of both proteins is higher at pH 6, suggesting greater thermal stability corroborated by increased solubility in the state diagrams. The decreased solubility of β-Lg as determined from both SDS-PAGE and HPLC suggests a higher propensity toward aggregation than that of α-La. β-Lg tends to form fewer small aggregates and more large aggregates in the presence of α-La.[52] It is also important to address the disparity between SDS-PAGE and HPLC results. Solubility for the same samples was lower per HPLC, likely due to the filtration step in HPLC that may have removed some of the medium-sized aggregates. Moreover, the small aggregates may have been broken up under reducing conditions for SDS-PAGE, allowing them to be quantified during image analysis.

Conclusions. Protein concentration, pH, and thermal treatment all influence the colloidal stability of whey protein beverages. Judicious selection of these variables is required to formulate stable protein beverages. Because of the complexity of protein beverages, state diagrams can be used to identify critical transition regions under set parameters to predict regions of thermal stability. This approach identified regions of colloidal stability at pH <3.5 (low turbidity and high solubility) and >6.5 (moderately high solubility). Thermal processing at higher temperatures and longer times resulted in a loss of protein solubility, even at pH 3.5. Closer to the p*I*, β-Lg and BSA were more likely to participate in aggregation reactions than α-La. The state diagram approach can also be used to elucidate the effects of alternate ingredients or formulations, gaining an understanding of how critical regions of the state diagrams are altered under different conditions.

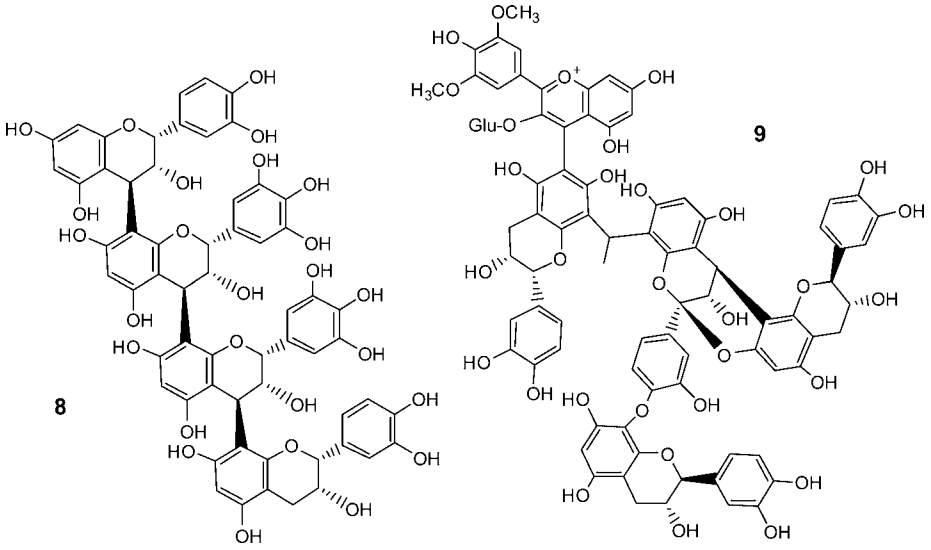

Figure 2. Examples of grape tannin (**8**) and wine tannin (**9**) structures showing B ring ether linkages, A-type linkages, and ethyl linkages.

in water were dominated by hydrogen bonding.[20] The structure of tannins also influences the extent of protein interaction, and larger tannins with more binding sites and flexible structures have been shown to interact more readily than smaller tannins.[18,21−25] Sensory studies have indicated that smaller wine tannins are less astringent than larger wine tannins,[26,27] which may relate to the extent of interaction between wine tannins and salivary proteins. Larger tannins bind proteins with a combination of hydrophobic interaction and hydrogen bonding, whereas flavan-3-ol monomer−protein interactions are driven by hydrogen bonding alone.[28] The strength of monomer interactions with poly(L-proline) (PLP) (**5**) are influenced by the relative hydrophobicity of the monomer, with the more hydrophobic epicatechin gallate (**3**) binding more strongly than the less hydrophobic epigallocatechin gallate (**4**) (Figure 1).[28] Conversely, comparatively hydrophilic grape tannins (**8**) have been shown to bind more strongly to PLP than the more hydrophobic wine tannins (**9**) (Figure 2).[29] The oxidation of grape tannins during crushing and fermentation, which form wine tannins, reduces the proportion of acid-labile interflavan bonds, thus creating a more rigid structure with potentially fewer binding sites than grape tannins due to intramolecular bonding and steric hindrances,[29−31] suggesting that overall tannin structure may be more important in protein interactions than hydrophobicity. Dimers and trimers with extended structures bind more readily to proteins than those with compact structures, where intramolecular interactions within the polyphenol dominate.[23] Proteins that are larger, such as gelatin, or have more extended structures, such as salivary PRPs, also bind more tannin due to the presence of more available binding sites, such as proline residues and amine groups,[11,14,18,24,32,33] compared with more globular proteins such as bovine serum albumin (BSA).[34−36] Binding of tannins and PRPs shows preference for available proline residues that are not obscured by stereochemistry or interfering structural moieties such as carbohydrate side chains of the protein,[37,38] and the residual structures of PRPs such as PPII helices promote tannin interactions due to the conformation of these structures.[39] The mechanism of interaction reportedly involves hydrophobic interactions and hydrogen bonding, although there are differences in the reported literature about which is the driving mechanism of the first stage of interaction.[15,23,29,40] Hydrophobic interactions involve $\pi-\pi$ bonding between the planar surfaces of the phenolic tannin structure and the proline ring of the PLP moiety,[15] whereas hydrogen bonding occurs between the carbonyl groups of the proline and the hydroxyl groups of the tannin.[1,23] Conversely, interactions between tannins and BSA have been found to be nonspecific and are likely to be driven by hydrogen bonding.[34,41]

Solvent composition, particularly ethanol concentration, can influence tannin solubility as well as tannin−protein interactions and astringency.[11,18,24] In the wine matrix, the ethanol concentration generally ranges from 10 to 15%, and this has been shown to influence the wine astringency,[42−44] with the intensity of overall astringency decreasing with increasing ethanol concentrations (from 0 to 15% ethanol).[44] The concentration of ethanol in wine can also alter the astringency subqualities, including "velvety" and "silkiness",[44] potentially by changing the extent of tannin−salivary protein interactions or via direct impact on the oral surfaces.[42,43] More research is also underway to decrease the concentration of ethanol in wine, such as the development of low-alcohol yeast strains,[45] which may also affect wine astringency. Wine tannin size and shape are not directly affected by ethanol concentration,[46] and therefore the changes in astringency with ethanol are more likely to be associated with the physicochemical properties of the different tannins in solvents with different ethanol concentrations.[16] Ethanol can disrupt tannin−cell wall binding of apple pulp at concentrations between 20 and 40%,[22] demonstrating the influence of ethanol on noncovalent tannin−protein binding. Storage of red wine can decrease the astringency of a wine as a result of decreased tannin concentrations as well as structural changes in wine tannins.[6,47] Tannin structures change over time as a result of gradual oxidation and structural rearrangement reactions that occur under the acidic conditions of wine (pH generally 3.0−4.0). Isothermal titration calorimetry (ITC) experiments have indicated that this can reduce the strength of the tannin−protein binding, potentially contributing to the decrease in astringency intensity.[29]

In this study, the binding strengths between PLP and a range of different wine tannins and tannin fractions were measured using ITC across a range of ethanol concentrations (5, 10, 15,

and 40% ethanol) to assess the impact of ethanol on tannin–peptide interactions for tannins with different structures.

MATERIALS AND METHODS

Chemicals. All solvents used were of high-performance liquid chromatography (HPLC) grade, all chemicals were of analytical reagent grade, and water was sourced from a Milli-Q purification system. Ethanol was purchased from Merck Australia (Kilsyth, VIC, Australia). Ammonium formate and poly(L-proline) (**5**, DPn 58, molecular weight 5600 Da) were purchased from Sigma-Aldrich (Castle Hill, NSW, Australia), and formic acid (99% w/w AR grade) was purchased from Chem-Supply.

Tannin Isolation and Composition. Wine tannin was isolated from 3- and 7-year-old Cabernet Sauvignon wines and fractionated as described previously[26] to give six tannin samples: total tannin (TT), aqueous (Aq) tannin, and butanol-soluble (Bu) tannin for each vintage wine. Fractionation of the TT tannins produced greater proportions of Aq tannin than Bu tannin for both wines with Aq/Bu mass ratios of 3.6:1 and 2.9:1 for the younger and older wines, respectively. The molar extinction coefficients (ε) of each tannin sample were determined as described previously[26,29] and used in calculating the concentration of tannin in the stock solutions for ITC analysis. Tannin analysis was performed in a previous study[26] using gel permeation chromatography for molecular size, phloroglucinolysis for percent yield (proportions of acid-labile interflavan bonds), and subunit composition and octanol–water coefficients (Log P). The percent yield of the young wine tannin samples was 30.2 ± 4.2% and for the aged wine tannin samples was 13.2 ± 2.3%, demonstrating the formation of non-acid-labile bonds in tannins as the wine ages. The percentages of epicatechin gallate subunits (**3**) were 3.4 ± 0.5 and 2.0 ± 0.2% for young and aged wines, respectively. There was no significant difference in the percent epigallocatechin between tannin samples of different ages.

Isothermal Titration Calorimetry. An auto-ITC 200 (GE life sciences) was used to measure the change in heat induced by tannin–PLP interactions, and data were analyzed using the MicroCal Origin version 7.0 software package adapted for auto-ITC data analysis. Tannin fractions were prepared for ITC and titrated using the method previously described.[29] Briefly, tannin samples (2 mM) in buffer solution (10 mM ammonium formate) were titrated into a cell containing 0.075, 0.050, or 0.033 mM PLP in the same buffer solution. The titration consisted of 17 × 2 µL injections at 25 °C. The concentration of ethanol was varied in the buffer solution (5, 10, 15, and 40% v/v ethanol), and this concentration was the same in both the titrant and PLP solutions for each experiment. Wine tannins were not soluble without ethanol; hence, 5% ethanol was considered the low-alcohol control sample. Solutions of 5–15% ethanol were at pH 3.5, and the 40% ethanol solution was at pH 4.0 due to the reduced proportion of the buffer solution. The influence of the different pH was considered to have a lesser impact than ethanol concentration on the basis of previous reports.[18,44,48] Experiments were replicated six times, and results were averaged. Thermograms and binding isotherms were used to determine the enthalpy (ΔH), binding constants (K), stoichiometry (N), and entropy ($T\Delta S$) using a single-site binding model. The change in standard Gibbs free energy (ΔG) was calculated using the Gibbs–Helmholz thermodynamic equation: $\Delta G = -RT \ln K$, where R is the ideal gas constant (1.985 cal mol^{-1} K^{-1}) and T is the temperature (298 K). Examples of the thermograms and binding isotherms for the different wine tannins are given in Figure 3.

Statistical Analysis. Differences in thermodynamic parameters between different tannins in each matrix and between the same tannin in different matrices were determined using ANOVAs and Tukey analyses with GraphPad Prism statistics software.

RESULTS AND DISCUSSION

Wine Tannin–Peptide Interactions. Tannins from 3- and 7-year-old Cabernet Sauvignon wines were isolated and fractionated in previous experiments[26] to produce a range of wine tannins with different structural properties: TT, Aq, and Bu tannins. The Bu tannins were consistently smaller with molecular weights of 1865 ± 92 g mol^{-1} compared with 3020 ± 182 g mol^{-1} for the TT and Aq tannins (Table 1).[26] The most notable difference between young and aged wine tannins was the proportion of acid-labile interflavan bonds at around 30 and

Table 1. Characteristics of Wine Tannins Used in This Study including the Molecular Weight (MW), Octanol/Water Partition Coefficient (Log P), and Extinction Coefficient (ε)

tannin sample	MW[a] (g mol^{-1})	Log P[a]	ε (×10^3) (M^{-1} cm^{-1})
TT3	2930	−0.61	44.3
Aq3	3030	−1.31	37.4
Bu3	1800	−0.7	27.1
TT7	2850	−0.55	36.3
Aq7	3270	−1.34	45.6
Bu7	1930	−0.72	29.2

[a]Values are shown as the average of six results ± one standard deviation, and letters indicate values in columns that are significantly different ($p < 0.05$).

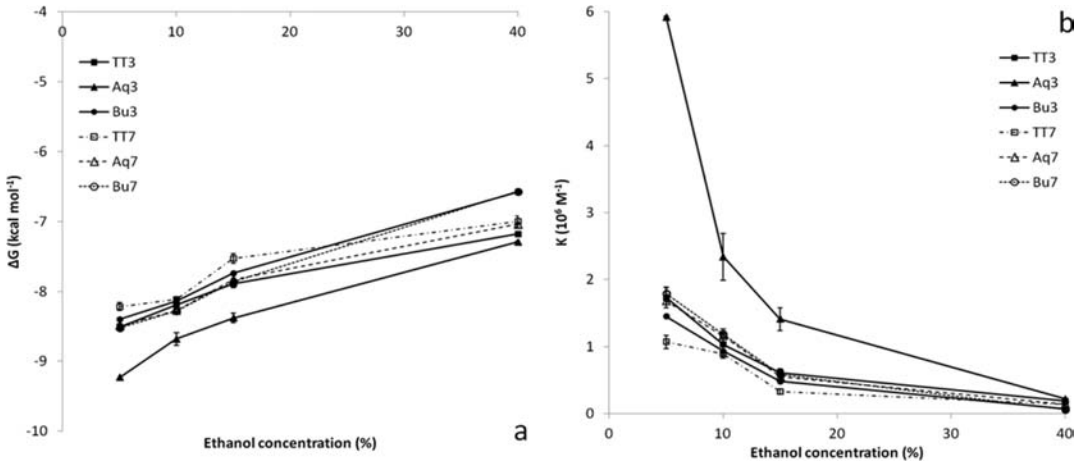

Figure 4. Overall binding strength of wine tannin samples and PLP across the range of ethanol concentrations as measured using (a) changes in Gibbs free energy (ΔG) and (b) binding association constants (K).

13%, respectively.[26] Gradual oxidation and structural rearrangement of tannin subunits over time have been shown to cause this reduction in acid-labile bonds.[30,47,49]

The strength of the interactions between wine tannins and the peptide, PLP (**5**), was measured across a range of ethanol concentrations, from 5 to 40% v/v, using ITC. Comparisons of the strength of tannin−peptide interactions for the different tannin samples were made at 10% ethanol (Table 2). The mechanisms of binding were assessed by comparing the change in enthalpy (ΔH), where a favorable change is indicated by a negative ΔH value and has been associated with hydrogen bonding, and the change in entropy ($T\Delta S$), where a favorable change is indicated by a positive $T\Delta S$ value and has been associated with hydrophobic interactions. Overall binding strength was assessed as a change in Gibbs free energy (ΔG), which is the sum of the changes in enthalpy and in entropy. The negative value of the change in Gibbs free energy indicates a spontaneous process. The binding constants (K) and stoichiometry (N) for each tannin sample were calculated on the basis of a single-site binding model. Greater K values indicated stronger PLP−tannin interactions, and greater N values indicated that more tannin molecules bound to each PLP molecule. For all tannin samples, binding with PLP was spontaneous and exothermic. At 10% ethanol, the changes in enthalpy and in entropy were favorable (Table 2), suggesting that PLP−wine tannin interactions involved both hydrophobic interactions and hydrogen bonding as previously reported.[28,29]

Hydrogen bonding contribution (ΔH) was greater in the young wine tannins when compared with the same type of tannin from the aged wine at 10% ethanol (Table 2), which is consistent with previous studies.[29] The contribution of hydrophobic interactions was greater in the Bu tannins and in the aged wine tannins compared with young wine tannins, as suggested by the greater $T\Delta S$ values. The combination of changes in enthalpy and entropy influenced the overall strength, ΔG, of the tannins. For the younger wine tannins, ΔG was greater for Aq3 and similar for TT3 and Bu3, whereas the ΔG values for the tannins from aged wines were similar for Aq7 and Bu7 and less for TT7. The binding association constant (K) for Aq3 tannin−peptide interactions at 10% ethanol was around double that of the other tannins. This may reflect a three-dimensional conformation of this tannin in this solution that was more favorable for peptide binding. Tannins that have more extended structures have been shown to interact more readily with proteins,[23,34] and Aq3 may have a more extended structure with more available binding sites. The molecular weight of the Aq tannin from the younger wine is slightly lower than that of the Aq tannin from the aged wine; however, changes in the tannin structure that are known to occur with wine aging result in tannins that have potentially more rigid structures with fewer acid-labile bonds.[6,30] Hence, Aq3 is likely to have a greater proportion of available binding sites than Aq7 despite a smaller molecular weight. The stoichiometry (N) of the interaction refers to the number of tannin molecules that bind to each PLP molecule. The number of tannins that can bind with each PLP molecule depends on the number of available binding sites, which relates to the molecular weight of the tannin as well as the structure. The calculated N was inversely proportional to the molecular weight of the tannin sample, indicating that the PLP molecules were

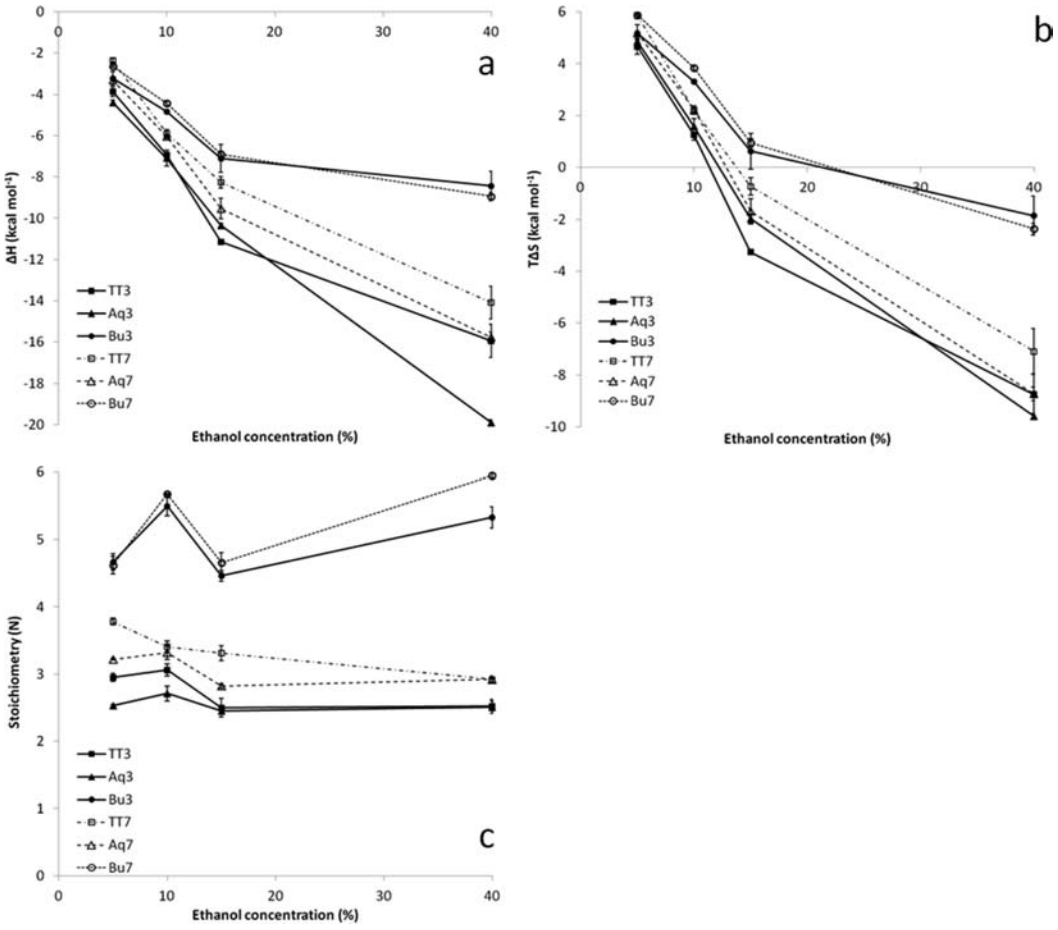

Figure 5. Impact of ethanol concentration on the interaction between wine tannin samples and PLP as measured with (a) change in enthalpy (ΔH), (b) change in entropy ($T\Delta S$), and the (c) the stoichiometry (N) of interaction (number of tannin molecules binding per PLP molecule).

able to bind more smaller tannins and fewer larger tannins (Tables 1 and 2). More aged wine tannins also bound to each PLP molecule compared with the younger wine counterparts, suggesting that these tannins have fewer available binding sites.[29] The structural changes of the tannins in wine over time form a more rigid structure as indicated by a reduction in the number of acid-labile interflavan bonds. Many more Bu tannins were able to bind to each PLP compared with either Aq or TT tannins, further suggesting that these tannins contained fewer available sites for peptide binding. The Aq tannin from the younger wine (Aq3) demonstrated the strongest peptide interactions of the measured tannins in 10% ethanol, and this is likely to relate to its 3D structure.[46]

Tannin−Peptide Interactions at Different Ethanol Concentrations. Tannin astringency reportedly decreases as ethanol concentration in model wines increases from 10 to 15%,[43] and the reason for this may relate to changes in the mechanisms of tannin−salivary protein interactions. In this study, ITC measurements were used to assess the strength of the interactions between wine tannins and PLP across a range of ethanol concentrations, from 5 to 40% v/v, as well as any differences in the changes in enthalpy and in entropy that may suggest differences in binding mechanisms. The binding strengths between the wine tannins and PLP as measured with changes in Gibbs free energy (ΔG) and binding constants (K) indicated that the wine tannin−PLP interactions were weaker at the greater ethanol concentrations (Figure 4). Ethanol has been shown to disrupt tannin−apple cell wall binding at higher concentrations such as 40% ethanol,[22] and the weak interaction between tannin and PLP at this higher ethanol concentration is also demonstrated here. The weaker tannin−peptide interactions at 15% ethanol compared with 10% ethanol may, at least in part, contribute to the previously observed reduction in wine astringency across this ethanol concentration range.[43,44]

The mechanism of binding of the tannin samples with PLP also changed over the wine-like ethanol range, and differences were observed in tannins with different solubilities. For the TT and Aq tannins, the change in entropy ($T\Delta S$) was favorable (positive) at 10% ethanol and unfavorable (negative) at 15% ethanol, whereas the Bu tannins also demonstrated slightly favorable entropy at 15% ethanol. The change in enthalpy (ΔH) was favorable for all tannin samples. A favorable ΔH value is associated with binding due to hydrogen bonding, whereas a favorable $T\Delta S$ value has been associated with hydrophobic interactions and the increased disorder due to the displacement of bulk water.[28] The favorable $T\Delta S$ at 10% ethanol and unfavorable $T\Delta S$ at 15% ethanol suggested that there were differences in the mechanism of tannin−peptide interactions across the wine-like ethanol range. Below 15% ethanol, there is evidence of hydrophobic interactions between tannins and PLP, and for solutions with ethanol concentrations ≥15%, peptide association appears to be driven only by hydrogen bonding. The combination of favorable ΔH (negative) and unfavorable $T\Delta S$ (negative) contributed to

DOI: 10.1021/acs.jafc.5b00758
J. Agric. Food Chem. 2015, 63, 4345−4352

the weaker overall binding (ΔG) in solutions containing 40% ethanol (Figure 4).

The different tannin samples varied in the strengths and mechanisms of peptide binding. The $T\Delta S$ was favorable for the Bu tannins at 15% ethanol, suggesting that the structure of these tannins promoted more hydrophobic interactions than the Aq and TT tannins, which showed unfavorable $T\Delta S$ at the same ethanol concentration. The differences between the changes in enthalpy and in entropy for the different tannin fractions were more pronounced at 40% ethanol compared with 5% ethanol, and this may relate to differences in tannin structure. Smaller tannins, such as Bu tannins, have fewer binding sites for peptide interactions than larger tannins such as TT and Aq, and therefore these interactions are more readily disrupted by higher ethanol concentrations. The number of TT and Aq tannin molecules that interacted with each PLP molecule (N) decreased slightly across the ethanol concentrations (Figure 5), whereas the number of Bu tannins that interacted with PLP ranged from around 4.6 to 5.6, independent of the ethanol concentration. This also may relate to the structure of these tannins and the limited number of available binding sites.

Different papers on the primary mechanism for tannin−protein interactions have indicated either hydrophobically driven interactions or hydrogen bond driven interactions,[15,23,40] and the reason for this discrepancy is likely to relate to the solvent system used as well as the particular tannin structure used in the analysis. Similarly, studies on the impacts of ethanol on sensory analysis have varied from ethanol increasing astringency to decreasing astringency,[43,50] and this again may relate to the structure and relative hydrophobicity of the tannins and the solvents used for analysis. More hydrophilic tannins such as grape skin tannins at higher ethanol concentrations are likely to interact with proteins primarily through hydrogen bonding, whereas more hydrophobic grape seed tannins may be driven by a combination of hydrophobic and hydrophilic interactions.[22,28] Similarly, the astringency of tannins in model wines will depend on the structure and physicochemical properties of the tannins in the study, particularly given the differences in binding strength and mechanisms of interaction for wine tannins over the wine-like ethanol concentration range. This demonstrates the need for reporting the hydrophobicity of the tannins used in structure−function experiments.

Impact of Wine Age on Tannin−Peptide Interactions. Red wine astringency reportedly decreases with wine age,[51] and this may relate to changes in the properties of the tannins, which subsequently affect the tannin binding capacity.[29,47] The tannin samples selected for this trial were isolated from red wines of 3 and 7 years of age, to compare the binding strength of wine tannin after different periods of aging. For Aq and TT tannins, those from the younger wine demonstrated slightly stronger binding (ΔG) across the different ethanol concentrations, even though the molecular weights were similar or smaller than those of the tannins from the aged wine (Table 1; Figure 4). The is in agreement with previous results.[29] During wine aging, wine tannin structures change due to gradual oxidation and structural rearrangement reactions, which can reduce the number of hydroxyl groups available for hydrogen bonding and potentially increase the proportion of hydrophobic binding sites[30,31] Differences in the ΔH and $T\Delta S$ for younger and aged wine tannins suggested differences in the mechanisms of interactions. Peptide interactions with aged wine tannins produced more favorable changes in entropy and smaller changes in enthalpy than with the younger wine tannins (Table 2), suggesting that the structures of these tannins promoted more hydrophobic interactions. The stoichiometry (N) indicated that more aged wine tannin molecules bind to PLP than the same fraction of young wine tannin molecules, suggesting that aged wine tannins may be more compact and have fewer binding sites for peptide interaction than younger wine tannins. The weaker binding of more aged wine tannins may, in part, contribute to the decrease in wine astringency with aging because protein interactions are associated with astringency.[14,52]

In summary, the strength of wine tannin−PLP binding was shown to decrease with increasing ethanol concentration, and the mechanisms of interaction changed between 10 and 15% ethanol. For the larger tannins, peptide interactions consisted of favorable changes in both entropy and enthalpy at 10% ethanol, but at 15% ethanol, interactions involved favorable changes in enthalpy and unfavorable changes in entropy. Peptide interactions with smaller tannins showed slightly favorable changes in entropy at 15% ethanol. This suggests that at lower ethanol concentrations, peptide interactions with wine tannin involve a combination of hydrophobic interactions and hydrogen bonding, whereas only hydrogen bonding occurred in the higher ethanol concentration. Tannins from aged wines also demonstrated more hydrophobic interactions than those from younger wines. These results indicate that the solvent composition and wine tannin structure can influence the mechanisms for tannin−protein interaction, which, in turn, may influence wine astringency. This may contribute to some of the differences observed in wine styles with different astringency qualities. Additionally, this work demonstrates the need for reporting the relative physical chemistry characteristics such as the hydrophobicity of the tannins used in structure−function experiments.

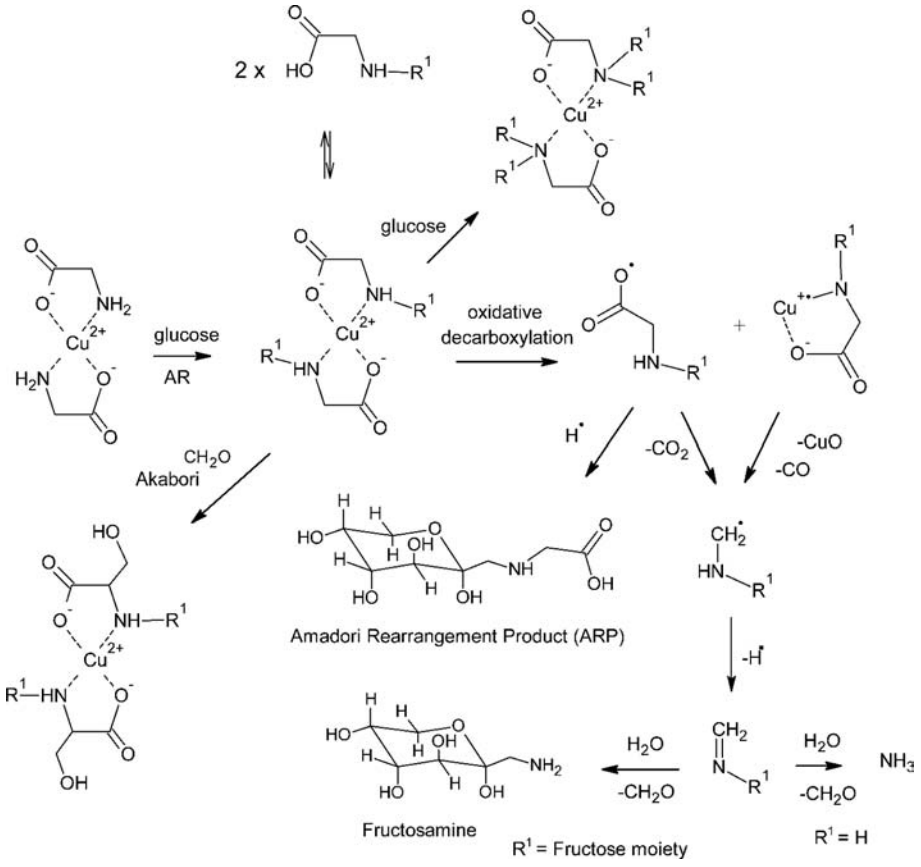

Figure 1. Mechanism of oxidative decarboxylation of free or sugar-conjugated amino acid copper complexes based on ref 8. ARP, Amadori rearrangement product; AR, Amadori rearrangement; and R^1, H or sugar moiety.

flight/mass spectrometry (ESI/qTOF/MS) analysis at m/z 233.9665 $[M + Na]^+$ (calculated for $C_4H_8CuN_2NaO_4$ with an error of 5.4 ppm). Isotope-labeled precursors were prepared similarly.

Sample Preparation. Model systems (10 mg) consisting of glycine/glucose (in a 2:1 relative molar ratio), glycine/glucose/$CuCl_2$ (in a 2:1:1 relative molar ratio), and $(Gly)_2Cu$/glucose (in a 1:1 relative molar ratio) with or without excess paraformaldehyde (20 mg) were dissolved in water (2 mL) and heated on a sand bath in an open vial (5 mL capacity) at 110 °C for 2 h until dry. During the reaction, the water evaporated and the sample was completely dried during the last 20 min of heating. To confirm the formation of some of the observed intermediates, commercial standards, such as glycine Amadori compound and 1-amino-1-deoxy-β-D-glucose, were used in appropriate model systems, as shown in Table 1. The reaction mixtures were subsequently analyzed by ESI/qTOF/MS, and some were analyzed by pyrolysis–gas chromatography/mass spectrometry (Py–GC/MS) for their volatile content. All of the samples were analyzed in duplicates.

Ninhydrin Test. Amino acid loss (glycine) was determined using the "ninhydrin reagent solution" test method by Sigma-Aldrich, Inc., using ninhydrin reagent (2% in DMSO and lithium acetate buffer). Model systems comprising glycine/glucose and $(Gly)_2Cu$/glucose, both containing 0.05 μmol/mL (50 μM) glycine in the final concentration, were dissolved in water (2 mL) and heated at 110 °C for 2 h in a sand bath until completely dry. After heating, the residues were dissolved in water (0.5 L) and 1 mL aliquots were pipetted into test tubes. To each aliquot, ninhydrin (1 mL) reagent was added, and the test tubes were placed in a sand bath at 100 °C for 10 min. After cooling to room temperature, 95% ethanol (5 mL) was added to each test tube. The absorbance was measured at 570 nm using distilled water as a blank on an Evolution 300 ultraviolet–visible (UV–vis) spectrophotometer (Thermo Fisher Scientific, Waltham, MA).

Table 1. Composition of the Model Systems

Model Systems Prepared under Akabori Reaction Conditions
glycine/glucose/paraformaldehyde[a,b] (2:1)
$(Gly)_2Cu$/glucose/paraformaldehyde[b]
Model Systems Prepared under Maillard Reaction Conditions
glycine/glucose[a,c] (2:1)
glycine/glucose/$CuCl_2$[a] (2:1:1)

N-(1-deoxy-D-fructos-1-yl)glycine/$CuCl_2$
1-amino-1-deoxy-β-D-glucose[d]
glucose/1-amino-1-deoxy-β-D-glucose
glucose/1-amino-1-deoxy-β-D-glucose/$CuCl_2$

[a]Model systems that were prepared and analyzed in a 2:1 molar ratio. All other model systems in the table were prepared and analyzed in a 1:1 molar ratio. [b]Paraformaldehyde was added in excess in the Akabori reaction model systems. [c]Analyzed by Py–GC/MS in addition to ESI/qTOF/MS analysis. [d]Analyzed before and after heating at 110 °C for 2 h.

Spectrophotometric Measurements. Absorbance at 420 and 550 nm was used to estimate browning of the model systems heated on a sand bath in an open vial at 110 °C for 2 h until dry. Samples (10 mg) comprising glycine/glucose (in a 2:1 relative molar ratio), glycine/glucose/$CuCl_2$ (in a 2:1:1 relative molar ratio), and $(Gly)_2Cu$/glucose (in a 1:1 relative molar ratio) were dissolved in water (2 mL), and their absorbance was measured before and after heating, as indicated above. In both cases, the samples were diluted in distilled water (0.5 L) and 1 mL of each solution was used for the measurements. Absorbance of the samples were measured on an

[a]All of the ions listed in Figure 2 are included in this table. [b]The calculated error [in parts per million (ppm)] in all of the reported ions ranged between 0.02 and 22 ppm, and the two masses shown represent copper isotopes ^{63}Cu/^{65}Cu. [c]Products formed only in the model system containing CH_2O. [d]na = not analyzed.

Evolution 300 UV−vis spectrophotometer (Thermo Fisher Scientific, Waltham, MA) using distilled water as a blank.

ESI/qTOF/MS Analysis. The dry reaction mixtures were dissolved in liquid chromatography (LC)-grade water to a concentration of 1 mL/mg. The samples were then diluted 10-fold in 10% methanol prior to analysis by ESI/qTOF/MS. The ESI/qTOF/MS system was comprised of a Bruker Maxis Impact quadrupole-time-of-flight mass spectrometer (Bruker Daltonics, Bremen, Germany) operated in positive-ion mode. Samples (1 μL) were injected directly into ESI/qTOF/MS. Instrument calibration was performed using sodium formate clusters. The electrospray interface settings were the following: nebulizer pressure, 0.6 bar; drying gas, 4 L/min; temperature, 180 °C; and capillary voltage, 4500 V. The scan range was from m/z 100 to 1000. The data were analyzed using Bruker Compass DataAnalysis software, version 4.1. Tandem mass spectrometry (MS/MS) was carried out in multiple reaction monitoring (MRM) mode using 20.0 eV collision energy for the ions at m/z 180 and 342.

Thermal Desorption by Py−GC/MS. A Varian CP-3800 gas chromatograph coupled to a Saturn 2000 ion-trap detector interfaced to a CDS Pyroprobe 2000 unit through a valved interface (CDS 1500) was used for the desorption of the volatiles from glycine/glucose and $(Gly)_2Cu$/glucose model systems before and after heating in water (2 mL) at 110 °C for 2 h. For each analysis, approximately 0.5 mg of sample was weighed into a quartz tube, sealed with glass wool, inserted into the pyroprobe, and pyrolyzed for 20 s at 250 °C. The separation was performed using a fused silica DB-5MS column (50 m length × 0.2 mm inner diameter × 33 μm film thickness). The GC method used for the analysis of the volatiles was as follows: GC column flow rate was regulated by an electronic flow controller (EFC) and set at a pressure pulse of 55 psi for the first 3 min, then decreased to 32 psi at the rate of 300 psi/min, and finally, increased to 70 psi at a rate of 1.23 psi/min for the rest of the run. The GC oven temperature was set at −5 °C for the first 5 min using CO_2 as the cryogenic cooling source and then increased to 50 °C at a rate of 50 °C/min. Then, the oven temperature was again increased to 270 °C at a rate of 8 °C/min and kept at 270 °C for 5 min. The samples were detected using an ion-trap mass spectrometer. The MS transfer-line temperature was set at 250 °C; the manifold temperature was set at 50 °C; and the ion-trap temperature was set at 175 °C. The ionization voltage of 70 eV was used, and the electron multiplier voltage (EMV) was set at 1600 V. The generated data were analyzed using the AMDIS 32, version 2.69, computer software, and peak identification will be performed using the National Institute of Standards and Technology (NIST), version 2.0, mass spectral research program.

Structural Identification. Evidence for the proposed structures of non-volatile reaction intermediates was provided through ESI/qTOF/MS analysis of their elemental composition and the use of commercial or synthetic intermediates and isotope-labeling studies. Furthermore, MS/MS spectra of selected product ions were compared to those of commercial standards. The incorporation of copper in the identified complexes was confirmed by the isotopic signature of copper through detection of M + 2 peaks at 30% relative intensity.

RESULTS AND DISCUSSION

The development of color and aromas during the Maillard reaction is highly dependent upon the nature of amino acids and sugars used and the stability of the resultant Amadori products, in addition to other environmental factors that can either promote or hinder the reactivity of Amadori compounds, such as the transition metal ions. Such ions in their free form can accelerate oxidative degradation of sugars and Amadori products and enhance browning. On the other hand, amino acids can serve as potent ligands for metal ions not only to form strong complexes but also to provide stable backbones that can act as molecular scaffolds upon which up to four sugar molecules can be conjugated as Schiff bases or Amadori rearrangement products (see Figure 1). The buildup of such relatively stable intermediates can serve as a vehicle for their slow and steady release over the course of the reaction that in theory can affect the overall reaction profile. There are three possible pathways that allow for the release of the amino acids or their conjugates from the complexes; dissociation of the complex and ligand exchange[10,15] are considered as non-destructive mechanisms of release, and the third is through oxidative decarboxylation,[8] where one of the amino acid moieties in the complex is decomposed and the other is released intact, as shown in Figure 1. Previous experiments with glycine copper complexes[10] have demonstrated the enhanced ability of the amino groups in the complexes to undergo Schiff base formation with small aldehydes and their subsequent

[a]The calculated error (in ppm) in all of the reported ions ranged between 0.5 and 15 ppm. [b]Base peak.

solutions in the presence and absence of paraformaldehyde at 110 °C for 2 h and the dry residues were analyzed by ESI/qTOF/MS, with the major ions observed listed in Table 2. Control reactions conducted between free glycine and glucose indicated that the ions listed in Table 2 were not generated in the absence of the copper complexes. However, in the presence of free $CuCl_2$, the glycine/glucose mixture also generated the same peaks, although to a lesser extent. A logical sequence of reaction steps between $(Gly)_2Cu$ and glucose using the identified ions is shown in Figure 2. This figure also shows all of the corresponding ions generated through Akabori reaction[10] in the presence of formaldehyde. Interestingly, in the presence of glucose, formaldehyde Schiff bases of $(Gly)_2Cu$ complexes were not observed.

Glucose Conjugation with the Glycine Copper Complex. Much like the initial phase of the Maillard reaction, $(Gly)_2Cu$ can react with glucose via one of its amino groups to form Schiff bases or its Amadori rearrangement products. Theoretically, up to four sugar molecules can be conjugated with the complex. Mono- and diconjugated complexes were observed in the $(Gly)_2Cu$/glucose model system at *m/z* 374.0355 and 536.0925, respectively (see Figure 2). In the presence of formaldehyde, the Akabori reaction will transform glycine into a serine moiety;[10] consequently, in a $(Gly)_2Cu$/glucose/paraformaldehyde model system, monoconjugated complexes with either mixed amino acids observed at *m/z* 404.0508 or only serine at *m/z* 434.0611 and diconjugated complexes with mixed amino acids at *m/z* 566.1019 (Table 2 and Figure 2) were also detected. In Figure 2, diconjugated complexes are depicted as one of the two possible isomeric structures. Both mono- and diconjugated complexes can dissociate or undergo ligand exchange to release the sugar-conjugated amino acids at *m/z* 238.0930 (as glycine) or *m/z* 268.1038 (as serine). Furthermore, these complexes also underwent an oxidative decarboxylation reaction similar to the unreacted $(Gly)_2Cu$ complex,[8] as confirmed through observation of a series of ions consistent with the process shown in Figure 1. This process is capable of generating free (*m/z* 238.0930) and a monomeric copper complex of Amadori compound (*m/z* 300.0079) in addition to fructosamine (*m/z* 180.0872) through hydrolysis of the Schiff base observed at *m/z* 192.0856. Furthermore, the formation of a monomeric Amadori copper complex at *m/z* 300.0079 was further confirmed by observing the formation of the same ion in a control experiment, where the synthetic glycine Amadori compound and $CuCl_2$ mixtures were reacted under the same conditions. The detection of the Amadori copper complex at *m/z* 300.0079 represents the first evidence for the *in situ* formation of the complex from glucose and a $(Gly)_2Cu$ complex.

Release of Amadori Products. The conjugated Amadori products could be released from the mono- or dimeric complexes observed at *m/z* 374.0355 and 536.0925, respectively, through either dissociation or their oxidative decarboxylation and formation of the Amadori carboxyl radical, which can combine with a hydrogen radical to form the free Amadori compound. Ions associated with the free glycine Amadori product at *m/z* 238.0930 along with its dehydrated derivatives were observed at *m/z* 220.0816 and 202.0709 in the $(Gly)_2Cu$/glucose mixtures. The Amadori product incorporated six carbon atoms from glucose and two carbon atoms (C-1 and C-2) and one nitrogen atom from glycine. The serine Amadori compound observed at *m/z* 268.1038 was similarly identified in the $(Gly)_2Cu$/glucose/formaldehyde mixture incorporating six carbon atoms from glucose and two carbon and one nitrogen atom from glycine (see Table 2).

Formation of Fructosamine and Deoxy-fructosamine. In the process of oxidative decarboxylation of $(Gly)_2Cu$ complexes shown in Figures 1 and 2, two free radical species can be formed: one is the Amadori carboxyl radical, and the other is the copper-centered radical in the Amadori monocopper complex at *m/z* 300.0079. The former can decarboxylate, and the latter can lose CO and CuO molecules to form the same decarboxylated Amadori free radical, which can immediately lose a hydrogen atom to form the Schiff base

observed at m/z 192.0856 (see Figure 2). In this reaction mixture, an ion at m/z 180.0872 was also observed that was assigned to the fructosamine structure, the hydrolysis product of the above Schiff base through the loss of the Strecker aldehyde. This structure is expected to be formed from oxidative decarboxylation reactions of $(Gly)_2Cu$ complexes.[7,8] The tentative assignment of the fructosamine structure was based on its proposed mechanism of formation shown in Figure 2. In addition, the ion had a consistent elemental composition ($[M + H]^+$ $C_6H_{14}NO_5$) to that of fructosamine and showed incorporation of six carbon atoms from glucose and only one atom (nitrogen) from glycine (Table 2 and Figure 2). The structural information regarding the ion at m/z 180.0872 can also apply to its corresponding Schiff base, glycosylamine, which is typically synthesized by reacting glucose with highly reactive ammonia.[16,17] To further confirm the structure of the

[a]Samples were pyrolyzed (250 °C at 20 s) before and after heating. [b]The absorbance of the unheated model systems was the same as that of the blank. [c]The relative extent of browning is compared to the glycine/glucose model system.

ion observed at m/z 180.0872, the commercially available Schiff base precursor (1-amino-1-deoxy-glucose or glycosylamine) was heated alone or in the presence of glucose and $CuCl_2$ in water at 110 °C for 2 h and the MS/MS spectra of the ions at m/z 180 generated in the model systems were recorded (Table 3). The observed MS/MS fragmentation pattern of m/z 180.0865 in the heated standard matched exactly the ions generated from the ion at 180.0872 in the heated $(Gly)_2Cu$/glucose mixture and was different from the ions in the unheated sample of 1-amino-1-deoxy-glucose, indicating that, during heating in an aqueous solution, the standard Schiff base was rearranged into its observed Amadori form. Fructosamine and the associated ions at m/z 180.0872, 192.0856, and 330.0228 were similarly generated in the formaldehyde-containing model system. The assigned fructosamine structure was further supported by the observation of its glucose adduct observed at m/z 342.1405 and its further dehydration product at m/z 324.1268. The MS/MS fragmentation of m/z 342.1405 in the reaction mixture and that generated from the heated mixtures of glucose in the presence of 1-amino-1-deoxy-glucose was also compared and found to match (Table 4). To our knowledge, fructosamine thus far has not been identified in any Maillard model systems, except in synthetic preparations.[18] An ion related to fructosamine was also identified in the reaction mixture at m/z 164.0924; this ion, similar to fructosamine, consisted of six carbon atoms derived from glucose and one nitrogen and no carbon atoms from glycine and was predicted to originate from fructosamine (m/z 180.0872) through the loss of an oxygen atom (see Figure 3). Such a loss could be envisaged to occur through copper-catalyzed carbon−oxygen bond cleavage with a simultaneous hydride transfer, as suggested by Rao and Rao.[19] A proposed mechanism based on this suggestion is presented in Figure 3. In this proposal, the copper-centered free radical complex that forms as a result of oxidative decarboxylation of $(Gly)_2Cu$ shown in Figure 1 can either scavenge a hydrogen radical formed during oxidative decarboxylation and form copper hydride observed at m/z 138.9689 (pathway A) or combine with the oxygen-centered free radical on fructosamine (see Figure 3) and generate a new copper complex at m/z 316 (not observed, pathway B). In pathway A, fructosamine can undergo copper-catalyzed carbon−oxygen bond cleavage, preferably at the α position to carbonyl, with simultaneous hydride transfer[19] to from deoxy-fructosamine and the amino acid copper hydroxide complex observed at m/z 154.9627. Alternatively, the hypothetical ion at m/z 316 in pathway B can degrade into a 3-deoxy-fructosamine radical and an amino acid carboxyl radical with the loss of CuO. Both radicals can combine with hydrogen radicals formed during the process to generate glycine and the ion observed at m/z 164.0924. Similar to fructosamine, deoxy-fructosamine was also observed to react with glucose and form the ion at m/z 326.1426, shown in Figure 3. These ions at m/z 326.1426 and 342.1405, shown in Figure 2, along with their subsequent dehydration products (see Table 5 and Figure 3) constituted the major ions observed in the reaction mixture. All of the observed ions above had incorporated the expected number of labeled glucose atoms and labeled nitrogen atoms from glycine and, as expected, none of the labeled glycine carbon atoms (see Table 5). The above findings further support the importance of metal-catalyzed oxidative decarboxylation reactions of not only $(Gly)_2Cu$ complexes but also their corresponding sugar conjugates, generating simultaneously Amadori products, Strecker aldehydes, and fructosamine.

Consequences of Sugar Conjugation with Bis-(glycinato)copper(II) Complexes to Browning and Total Volatile Formation. As demonstrated above, glucose tends to form various conjugates with bis(glycinato)Cu(II) complexes, which can eventually undergo oxidative decarboxylation or dissociation to release the amino acid conjugates as Amadori products. It is expected that such complexes can serve as molecular scaffolds upon which different sugar moieties can accumulate and eventually be released over time, generating colors and aromas. This fact can create the opportunity for controlled release of aroma and flavor precursors. To demonstrate the role of amino acid metal complexes in aroma formation, the total volatiles generated from model systems of glycine/glucose and $(Gly)_2Cu$/glucose were analyzed using Py−GC/MS before and after heating in aqueous solutions at 100 °C for 2 h in open vials. Heating in open vials can lead to loss of volatiles but not loss of conjugated aroma precursors. The quantitation of the volatiles was performed through comparison of their total ion abundances after thermal desorption. As expected, the total ion current of both model systems decreased after heating in open vials (see Table 6). The

J. Agric. Food Chem. 2015, 63, 4353−4360

glucose/glycine model system exhibited a ~6-fold decrease in intensity, while the heated $(Gly)_2Cu$/glucose model system showed only a ~1.5-fold decrease relative to the unheated samples. These results indicated that, although heating in an open vial can lead to the loss of volatiles, however, as predicted, the $(Gly)_2Cu$ complex was able to retain the aroma precursors in the reaction medium and generate ~1.6-fold more volatiles upon reheating relative to the glucose/glycine model system. These results were also consistent with the measurement of the total content of ninhydrin-active[20] amino acid moieties (free amino acid, amino acid−metal complex, Amadori, and Amadori−metal complex) in glycine/glucose and $(Gly)_2Cu$/glucose model systems before and after heating (100 °C for 2 h) in aqueous solutions. Table 6 indicates that, at the end of the reaction, the $(Gly)_2Cu$/glucose model system retained almost 94% of its total ninhydrin-active amino acid content, whereas the glucose/glycine model showed only 55.2% retention. These changes in ninhydrin-active moieties indicate that, after 2 h of heating at 100 °C, the mixture containing $(Gly)_2Cu$ was still rich in aroma precursors, such as Amadori and Amadori−metal complexes, relative to the glycine/glucose sample, consistent with ESI/qTOF/MS studies reported above and shown in Figure 2. Furthermore, the role of metal ions in their free forms ($CuCl_2$/glycine) and as amino acid complexes, such as $(Gly)_2Cu$, in generating browning (heating at 100 °C for 2 h) in the presence of glucose was also investigated. Using the measurements from two different wavelengths (λ = 420 and 550 nm), the obtained data have indicated that the presence of free $CuCl_2$ in the glucose/glycine model system did not change the browning of the solution, whereas the $(Gly)_2Cu$ complex reduced the browning of the reaction mixture by 15% relative to the model system lacking a source of metal (see Table 6), indicating the dual role that metals can play as either free ions enhancing browning or part of complexes of amino acids inhibiting the browning.

DOI: 10.1021/jf5047514

and dehulled after harvest. The initial moisture content of brown rice was 12.3 ± 0.5% (w.b.). Brown rice was irradiated using a Gammacell-220 ^{60}Co γ irradiator at the Jiangsu Academy of Agricultural Sciences (JAAS, Jiangsu province, People's Republic of China), with irradiation doses of 0, 0.2, 0.5, 1.0, and 2.0 kGy. The irradiation was conducted at room temperature (23 °C) with a dose rate of 5.0 Gy min^{-1}. After irradiation, brown japonica rice was sealed in polyethylene (PE) bags and stored at a temperature of 15.0 °C for 18 months.

Measurement of Physicochemical Parameters. Physicochemical parameters such as hardness, pasting viscosity, and lipid acidity were measured every 3 months. The hardness of cooked rice was measured using a Texture Analyzer (TA.XT2i, Stable Micro Systems, Godalming, U.K.). The cooked rice was placed in a cylindrical container and was compressed to 75% with a rod-type probe (2.5 cm diameter ×15 cm length) under the prespeed of 0.7 mm/s, a test speed of 0.5 mm/s, and a postspeed of 1.0 mm/s. The hardness was measured from the two-cycle curves using Texture Export for Windows (Stable Micro Systems, Godalming, U.K.). The pasting viscosity of rice flour was determined with a Rapid Visco Analyzer (RVA, Newport Scientific Instrument and Engineer, Warriewater, Australia). Brown rice was milled using a laboratory roller-type grinder (PQX) and then passed through an 80 mesh sieve. Flour samples were packed in polyethylene (PE) bags and stored at 4 °C until testing. The sample (3.5 g of rice flour) was dispersed in distilled water (25.0 mL) and stirred in an RVA container initially at 960 rpm for 10 s and finally at 160 rpm for the remaining test. The temperature profile was started at 50 °C, heating was carried out from 50 to 95 °C at a heating rate of 12 °C/min, the temperature was held for 2 min and 30 s at 95 °C, and cooling was carried out to 50 °C at the same rate. The pasting curves obtained were analyzed using an RVA Starch Master Software Setup Tool (SMST) to obtain the characteristic parameters. For lipid acidity analysis, lipid was extracted using ethanol and titrated with KOH using phenolphthalein as an indicator and then free fatty acid (FFA) content was measured by titration according to the method of Seibel;[33] the thiobarbituric acid (TBA) content assay was determined by the method described by Mariod et al.[34] The colormetry assay of brown rice was conducted in terms of L^* value (lightness) and b^* value (yellowness) using a spectrophotometer (Model CM-5, Konica Minolta, Inc. Japan).

Microstructure of Starch Granules in Brown Rice. The microstructures of kernels were measured at storage times of 0, 12, and 18 months. Brown rice samples were dried in a vacuum oven at 40 °C and cooled in a desiccator. Rice kernels were broken by a sharp blade. The treated samples were stuck on a specimen holder using a silver plate and coated with a thin film of gold (10 nm) in a vacuum evaporator. The obtained specimens were observed with a scanning electron microscope (SEM) (Model 27021-H, England) at a magnification of 1000× with an accelerating voltage of 7.0 kV.

Sensory Analysis. Sensory analysis was conducted after 18 months of storage. Milled rice samples (10 g each) were placed in aluminum cup, put into a rice cooker machine in which water boiled immediately, and then covered and heated for 40 min. Cooked rice then cooled naturally for sensory evaluation. A sensory panel consisting of 15 trained graduate students majoring in food science participated in this study. A hedonic scale (1 = extremely dislike and 9 = extremely like) was applied to determine consumer preference among cooked rice samples. The intensities of individual attributes of cooked rice were rated by the panelists, including appearance, color, odor, taste, and overall acceptability.

Data Analysis. The γ irradiation treatments and all analyses were performed at least three times. Mean values, standard deviation, and analysis of variance (ANOVA) were computed using the SPSS system (version 17.0, SPSS Inc.; Chicago, IL). These data were then compared using LSD tests. Correlation analysis was performed with the pooled data of irradiation dose, storage time, pasting viscosities, hardness, TBA content, FFA content, and rice color. Statistical significance was established at $P < 0.05$.

RESULTS AND DISCUSSION

Pasting Properties. The pasting curves of brown japonica rice flour were measured by RVA changed upon 18 months of storage (Table 1). Most of the pasting properties, including peak, through, breakdown, final, and setback viscosity, decreased ($P < 0.05$) considerably with irradiation dose increase. The peak viscosity (PV) decreased ($P < 0.05$) from 2,189 cP for the unirradiated sample to 1,672 cP for the 2 kGy sample without storage (0 month). PV was mainly related to swelling of starch granules.[14,35] The decrease in PV was mainly caused by reduction of the swelling index in rice starch due to its degradation upon irradiation.[12,36,37] The final viscosity (FV) was also decreased after γ irradiation, which showed that the starch gel became softer after γ irradiation. These results were

consistent with the statement of Gani et al.[15] The lower breakdown viscosity (BD) of irradiated brown japonica rice was detected in comparison with that of nonirradiated brown japonica rice, which showed that starch might be broken in the irradiated rice as the viscosity breaks down, giving a measure of the fragility of the granules. Reports on changes in the viscosity breakdown of brown japonica rice after γ irradiation have been inconsistent.[36,37] Setback (SB) is an indicator of the firmness of cooked rice, a higher value of which indicates a firmer texture. A significantly lower SB value for irradiated brown japonica rice was exhibited in comparison with nonirradiated rice. The decrease in SB caused by γ irradiation was ascribed to the degradation of amylose and long linear amylopectin.[38] The higher pasting temperature (PT) of brown japonica rice meant that more water could be absorbed during the pasting process and the rice samples were more resistant to cooking.[39] It could be concluded that γ irradiation may improve the cooking quality. Also, it could be inferred that the starch gel was softer after an increased irradiation dose and the cooking quality was improved upon increasing doses of irradiation. Many studies have been conducted on the effect of γ irradiation on rice pasting viscosity.[7−9,30,40,41] γ irradiation caused starch polymer degradation, which resulted in a progressive reduction in the molecular weight of amylose and amylopectin and decreased viscosity while the solubility increased with increasing radiation dose.[8] It is commonly known that the chemical changes induced by ionizing radiation could be the result of "direct" or "indirect" action, depending on the radiation conditions.[42] In direct action, a sensitive target such as the DNA of a living organism was damaged directly by an ionizing particle or ray. This mechanism caused lethal effects in the microorganism. In indirect action, changes in the carbohydrate were caused mostly by the free radicals (i.e., radiolytic products) formed on dissociation of the excited molecules upon irradiation: in particular hydroxyl radicals (i.e., oxidizing agent) and hydrogen atoms (i.e., reducing agent) derived from water radiolysis. Ozone, a powerful oxidant, could also be formed from oxygen during irradiation. These free radicals substantially attacked the glycosidic bonding in the carbohydrate, causing depolymerization or degradation. The cleavage of glycosidic bonds subsequently caused the rupture of starch granules and gave rise to a reduction in viscosity; these might be the reason for viscosity changes in the current study. The same phenomena have been observed in wheat,[43] maize,[10,44] and legumes.[45]

Most parameters of pasting viscosity (i. e., peak, through, breakdown, final, and setback viscosity) increased within 12 months of storage, whereas these parameters decreased after 12−15 months of storage. γ irradiation fragmented the starch chain into short linear polymers, which might cause difficulty in the formation of helical structures with fatty acids during storage, and therefore passage of water might not be as restricted as that occurring naturally.[30] Storage could also decrease the rice flour pasting viscosity by increasing the disulfide bonds between protein networks.[46] Storage decreased the PT significantly ($P < 0.05$); this might be attributed to rice aging, which could form disulfide bonds between proteins.[47]

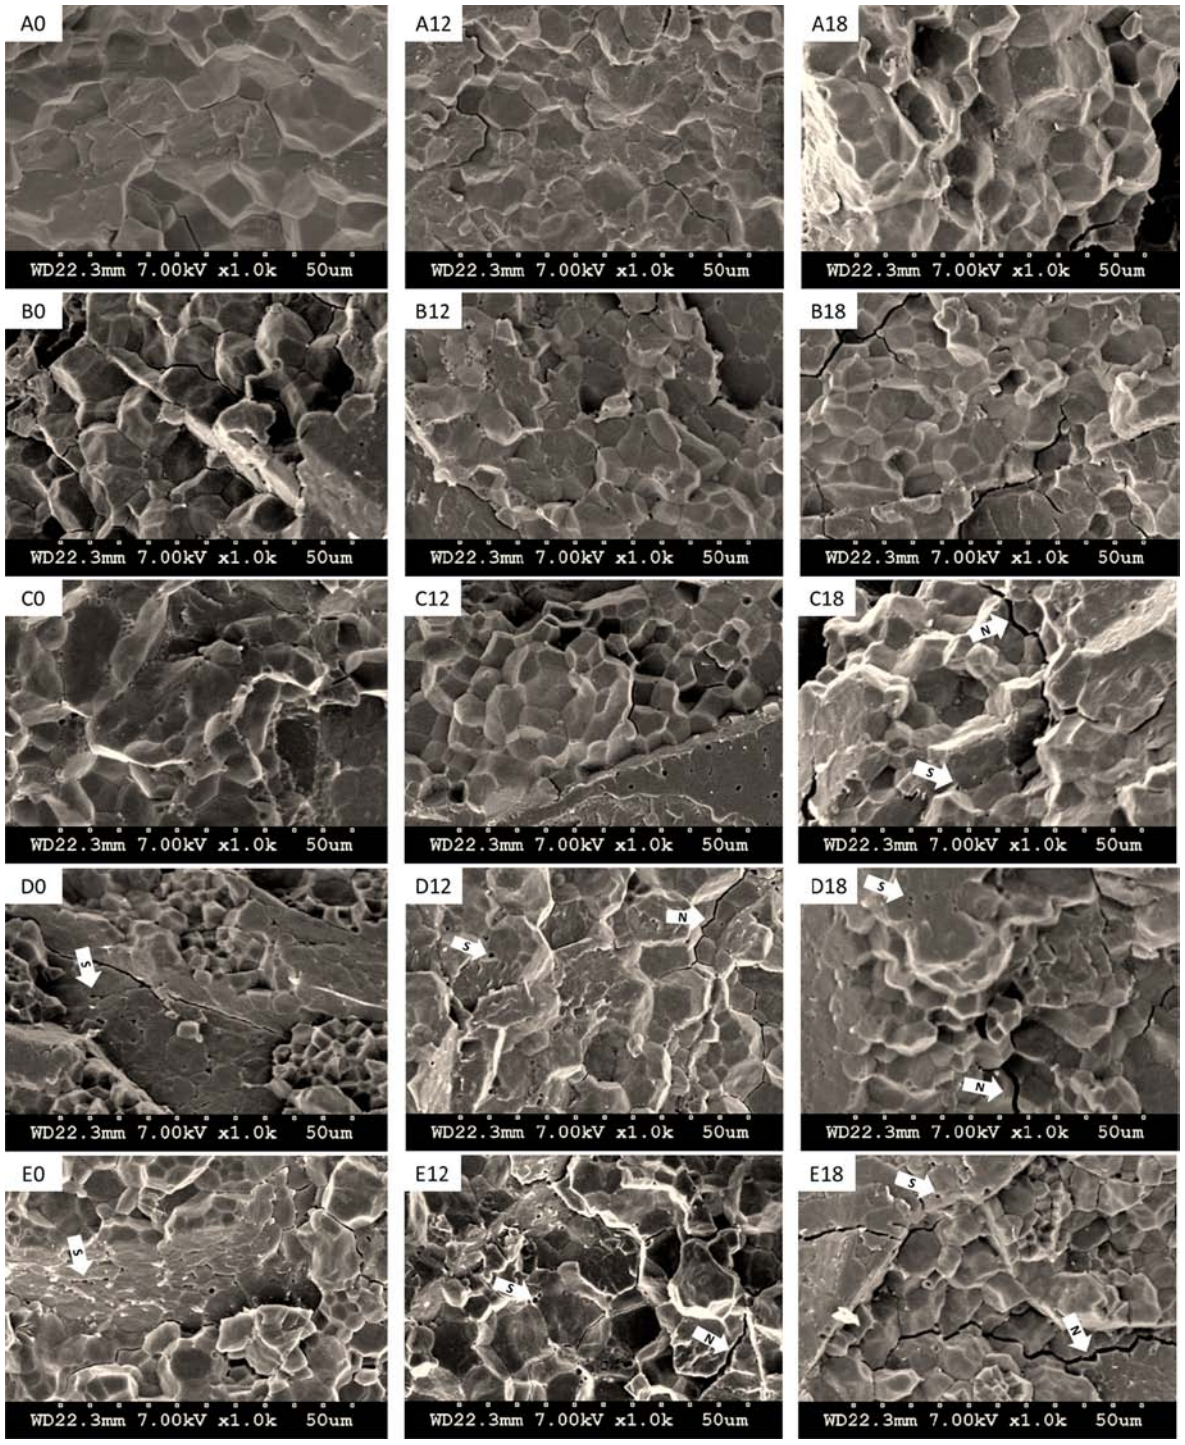

Figure 6. Scanning electron micrographs of exposed endosperm from irradiated brown japonica rice kernels with storage times of 0, 12, and 18 months (×1000 magnification): (A) 0 kGy; (B) 0.2 kGy; (C) 0.5 kGy; (D) 1.0 kGy; (E) 2.0 kGy. Arrows indicate the dark spots (S) and narrow cracks (N) among starch granules (distance between two adjacent scale points 5 μm).

The PT of nonirradiated and low-dose-irradiated brown japonica rice decreased significantly ($P < 0.05$) over 6 months of storage and remained almost constant until the end of storage (18 months). However, the PT of brown japonica rice irradiated at 2.0 kGy decreased throughout the period of storage. Studies that have analyzed pasting viscosities showed that protein had a major influence on flour pasting viscosity.[48] Aging significantly affected the pasting behavior of rice flour.[49] Thus, changes in protein content and disulfide bonds might control the differences in rice pasting viscosity during storage. As the main pasting viscosities of various starches were reduced by γ irradiation,[41,50] RVA measurement could be used as a potential method for analytical identification of irradiated grain.

Hardness of Cooked Rice. Overall, the hardness of irradiated or nonirradiated cooked rice showed an upward trend during storage (Figure 1). The hardness of cooked rice decreased ($P < 0.05$) significantly on treatment with irradiation doses of 0.5 kGy or more. After 18 months of storage, the

[a]Sensory quality is defined as scores ranging from 1 (dislike extremely) to 9 (like extremely); means for each characteristic within a column followed by the same letter are not significantly different at $P > 0.05$ by LSD test.

differences in hardness between nonirradiated rice and low-dose irradiated rice (0.2 and 0.5 kGy) were not significant. Changes in cooked rice hardness might be due to γ-irradiation-induced structural degradation in starch granules,[51] which would enable water to penetrate relatively easily.[30,36,52] When rice starch was heated with steam or excess water, the crystalline structure was disrupted due to the breakage of hydrogen bonds, and molecules of water became linked by hydrogen bonding to the exposed hydroxyl group of amylose and amylopectin. This phenomenon causes an increase in granule swelling and solubility. The hardness of cooked rice in the current study increased in all samples with prolonged storage times. After 18 months of storage, nonirradiated brown rice had the highest increase in hardness (45.64%), whereas there were relatively small increases (35.75%, 39.42%, 37.89%, and 24.55%) for brown rice irradiated at 0.2, 0.5, 1.0, and 2.0 kGy, respectively. Thus, we consider that γ irradiation could improve the cooking quality induced by rice aging during long-term storage.

Lipid Properties. The lipid content of brown japonica rice obtained in this study was approximately 2.1−3.4% and did not change significantly during 18 months of storage. During storage, the surface lipids of brown japonica rice had undergone hydrolysis to form FFAs. These FFAs were particularly susceptible to oxidation and could form intermediate peroxides, followed by the decomposition of intermediate peroxides into various oxidation products. TBA reacted with oxidation products and produced a color pigment.[30] Initially, the TBA content obtained from irradiated brown japonica rice (2.0 kGy) was significantly higher ($P < 0.05$) than other samples (0, 0.2, 0.5, and 1.0 kGy) (Figure 2). During storage, the TBA content of brown japonica rice irradiated at doses of 0.2, 0.5, and 1.0 kGy had no significant difference ($P > 0.05$) from that of nonirradiated brown japonica rice, whereas the TBA increased significantly ($P < 0.05$) with irradiation doses up to 2.0 kGy. This might be due to the medium dose of 2.0 kGy having a marked function on lipids and accelerating lipid oxidation. A sharp increase of TBA content in all samples was observed after 3 months of storage, and this content then decreased significantly ($P < 0.05$) after 6 months of storage. At the end of storage (18 months), the TBA contents did not show significant differences in nonirradiated and irradiated brown japonica rice and were in the range of 0.014−0.018 μmol/g. During long-term storage, the TBA content of brown japonica rice had shown a dynamic change; this might be ascribed to changes in the duration of end products. These results were consistent with the research reported in the literature.[30] The FFA content in brown japonica rice is shown in Figure 3. Initially, the FFA content in nonirradiated brown japonica rice was 10.7 mg of KOH/100 g. After irradiation, the FFA content increased slightly (13.6, 14.1, 12.8, and 11.5 mg of KOH/100 g with doses of 0.2, 0.5, 1.0, and 2.0 kGy, respectively); however, no significant difference ($P > 0.05$) was observed among brown japonica rice samples with different irradiation doses (0.2, 0.5, 1.0, and 2.0 kGy). With 9 months of storage, the FFA contents of all irradiated brown japonica rice samples increased significantly ($P < 0.05$) in comparison with the values after short-term storage (0, 3, and 6 months). During storage from 12 to 18 months, the FFA content of irradiated brown rice remained constant within a range of 22.7−25.0 ($P > 0.05$). However, the FFA content of unirradiated brown rice increased steadily and reached a peak of 29.9 mg of KOH/100 g at 18 months of storage. Changes in lipids due to ionizing radiation could be brought about in two ways: (1) by catalyzing their reaction with molecular oxygen, i.e., autoxidation, or (2) by the action of high-energy radiation (direct or indirect) on lipid molecules.[53,54] In the presence of oxygen, both oxidative and radiolytic effects would occur and could be superimposed. The general mechanism of the radiolysis of lipids was thought to involve primary ionization, followed by migration of the positive charge toward the carboxyl group or double bonds. Cleavage occurred preferentially at the positions near carbonyl groups. As a result, the yield of hydrocarbon was increased. These effects subsequently brought about an increase in TBA content and FFA content.

Rice Color. Values of L^* (brightness) and b^* (yellowness) recorded for brown japonica rice are shown in Figures 4 and 5. After irradiation, in comparison to unirradiated rice (0 kGy), the L^* values of irradiated rice (0.2, 0.5, 1.0, and 2.0 kGy) decreased ($P < 0.05$) whereas the b^* values of irradiated rice (0.2, 0.5, 1.0, and 2.0 kGy) increased ($P < 0.05$). These results are consistent with research reported in the literature.[14,30,40] Brightness and yellowness changes might be explained by the breakdown of glycosidic and peptidic linkages promoted during irradiation. The free radicals, including hydroxyl radical, and hydrogen atoms derived from water radiolysis substantially attacked the glycosidic bonding in carbohydrates, causing depolymerization or degradation and the Maillard reaction. The cleavage of glycosidic bonds subsequently caused the rupture of starch granules and gave rise to browning. With prolonged storage time, the L^* and b^* values of brown rice varied differently. However, the lightness (L^*) values of brown rice irradiated with different doses began to converge and remained constant after 12 months of storage (varying within the range 57.3−58.0, $P > 0.05$). However, the yellowness (b^*) values of brown rice varied differently within 9 months of storage and then remained constant after 9 months. The yellowness values over 18 months were linearly dose dependent as follows: 21.62 for 0 kGy, 21.71 for 0.2 kGy, 22.08 for 0.5 kGy, 22.65 for 1.0 kGy, and 23.10 for 2.0 kGy. The changes in brightness and yellowness of brown rice after long-term storage might be explained by the fact that the cleavage of glycosidic bonds

DOI: 10.1021/jf5047514
J. Agric. Food Chem. 2015, 63, 4361−4369

carried out by free radicals became extremely weak after long-term storage. As the consumer favors rice with a low chroma value (i.e., yellowness) and a high lightness value, low-dose irradiation with short storage time is preferred for commercial storage.

Correlation among Properties of Irradiated Brown Japonica Rice. Pearson's correlation coefficients for the relationship among various functional properties of irradiated brown japonica rice during storage are shown in Table 2. Storage time had a positive correlation with hardness (r = 0.721, P < 0.01) and FFA content (r = 0.805, P < 0.01), whereas it had a negative correlation with SB (r = −0.542, P < 0.01) and PT (r = −0.691, P < 0.01). The irradiation dose had a positive correlation with PT (r = 0.504, P < 0.01), b^* value (r = 0.624, P < 0.01), and TBA content (r = 0.407, P < 0.05) and a negative correlation with L^* value and all pasting parameters except PT (r = 0.504, P < 0.01; these results were in agreement with the findings reported by Liu.[37] PV had a positive correlation with TR (r = 0.972, P < 0.01), BD (r = 0.849, P < 0.01), FV (r = 0.941, P < 0.01), and SB (r = 0.441, P < 0.01). Similar phenomena have been revealed in pasting properties on irradiation.[17,52]

Kernel Morphological Structure. The SEM photographs of starch granules showed an uneven surface with angular and polygonal shapes in all rice samples (Figure 6). After irradiation, dark spots developed among starch granules, especially in irradiated rice (1.0 or 2.0 kGy). These dark spots were probably the small spherical holes with diameters of about 1 μm. As the storage time was prolonged, these dark spots became rather dense and the narrow cracks became wider. However, the mean granule range and the shapes of starches did not vary significantly. The reason different levels of cracks and spots formed in irradiated rice samples and how they formed during storage were not clear and required further investigation. The isolated starches of irradiated rice grains (0.35 kGy) also showed similar morphology with respect to polygonal shape and size of starch granules but with few round starches.[50] However, with high-dose irradiation (maximum dose range from 10 to 50 kGy), microscopic observation of the starches indicated surface cracking of the starch samples with irradiation treatment, and the extent of surface cracking was dose-dependent and increased with increasing irradiation dose in rice,[9] corn,[10] potatoes,[12,14] and beans.[12,16] These changes were due to the cleavage of large starch molecules by free radicals generated from the treatment of γ irradiation;[55] the breakage or cleavage of long chains in amylopectin decreased the apparent amylose content, which might aid humans in digesting rice starch.[9,56,57] However, rice starch granules are the smallest granules known in cereal grains,[58] with sizes ranging from 4 to 8 μm in the current study; the granules were loosely packed and look like clusters. Wu et al.[51] observed the shape of the starch granule deformed by medium-dose γ irradiation (1 kGy) and considered that γ irradiation was capable of degrading starch through the cleavage of large molecules of starch into smaller fragments. However, in the current study, we did not observe any significant changes in starch granule shape except for the appearance of narrow cracks and dark spots among starch granules, even with medium-dose irradiation (1 and 2 kGy; Figure 6).

Panelist Acceptance of Cooked Rice. Sensory evaluation was one of the most important methods for shelf life determination in food products.[59] The results of sensory qualities of cooked rice stored for 18 months were presented in Table 3. Panelists did not report differences (P > 0.05) in appearance, color, odor, taste, and overall acceptability among samples after irradiation with 0, 0.2, and 0.5 kGy at the end of storage (18 months). However, very low scores for odor were obtained after γ irradiation, especially with medium-dose irradiated (1.0 and 2.0 kGy) brown japonica rice (P < 0.01). The disagreeable odor of brown japonica rice irradiated at 1.0 and 2.0 kGy might be ascribed to the increase in lipid degradation products (determined from an increase in TBA content) during 18 months of storage. The unsaturated fatty acids in brown japonica rice are easily oxidized to peroxides and change to carbonyl compounds,[53,54] which caused disagreeable odor and flavor of brown japonica rice stored long-term. Poor scores of appearance, color, and taste from cooked rice were obtained for irradiation doses up to 1.0 kGy (P < 0.05). For overall acceptability, scores given by panelists varied from 4.6 to 6.7. Irradiated rice at 0.5 and 0.2 kGy had significantly high scores ranging from 6.6 to 6.7 in comparison scores with irradiation doses of 1.0 and 2.0 kGy (P < 0.01). The unpleasant odor and color might be the main reason for the low scores. These results meant that, at the end of storage (stored for 18 months), panelists preferred irradiated rice with doses as follows: 0.5 kGy > 0.2 kGy > 0 kGy > 1.0 kGy > 2.0 kGy. Therefore, rice irradiated with relatively low doses was the most acceptable.

In conclusion, physicochemical, structural, and sensory properties of irradiated brown rice during long-term storage were characterized in the current work. A low or medium dose of γ irradiation (from 0.2 kGy to 2.0 kGy) increased the main pasting values and improved the storage performance of brown japonica rice. Irradiation decreased the FFA content of brown rice with long-term storage (from 12 to 18 months). Narrow cracks and dark spots developed among starch granules, especially in irradiated rice, which became wider and more dense with prolonged storage time. Extremely low scores for odor and overall acceptability were obtained from panelists on γ-irradiated brown rice especially with medium doses (1.0 or 2.0 kGy). On the basis of these observations, we considered that a dose of 0.5 kGy or below could be suitable for γ irradiation on brown japonica rice before long-term storage. These results could serve as a basis for developing an efficient method for grain storage.

Next, Gray et al.[16] studied the efficacy of MON and SAL in the presence of sodium bentonite. The authors concluded that sodium bentonite could reduce the efficacy of MON and SAL but only at levels below the recommended dosages.

In vitro or in vivo literature data for other clays or other mycotoxin binders and for other veterinary medicinal products are not available despite the possible risk of binder−drug interactions and consequently the reduced efficacy of the drug. In the case of antibiotics, not only is the lack of efficacy of concern but also the possible increase of antimicrobial resistance due to exposure to subtherapeutic concentrations.[17−19] These concerns were also incorporated in the EFSA recommendations for this class of additives.[20] Besides macrolides, tetracycline antibiotics are frequently used in veterinary medicine, more specifically in feed or drinking water medication in pig and poultry farming. Doxycycline (DOX) is a broad-spectrum bacteriostatic tetracycline of the second generation. It is mainly used in broiler chickens to treat respiratory and systemic infections caused by *Mycoplasmata*, *Ornithobacterium rhinotracheale*, *Avibacterium paragallinarum*, *Pasteurella multocida*, and *Chlamydia* spp.[21−24]

Therefore, the aim of the present study was to evaluate the in vitro adsorption of DOX to four montmorillonite and one sepiolite clay, one leonardite-based binder, and including activated carbon (AC) as positive control. Next, to confirm and validate the in vitro model, an in vivo pharmacokinetic study was performed using oral bolus dosing of DOX and two of the in vitro studied mycotoxin binders in broiler chickens.

MATERIALS AND METHODS

Chemicals, Solutions, and Mycotoxin Binders. Sigma-Aldrich (Bornem, Belgium) supplied DOX hyclate, demethylchlortetracycline (DMCTC, used as internal standard), potassium chloride (KCl), and phosphoric acid (H_3PO_4). Water (H_2O), methanol (MeOH), and acetonitrile (ACN) used for the high-performance liquid chromatography (HPLC) analysis and preparation of stock solutions were of HPLC grade and provided by Fisher Scientific (Wijnegem, Belgium). Stock solutions of 10 mg/mL were made for DOX and DMCTC in, respectively, H_2O and MeOH/H_2O (50:50; v/v). Sodium chloride (NaCl), magnesium chloride ($MgCl_2{\cdot}6H_2O$), and calcium chloride ($CaCl_2{\cdot}2H_2O$) were supplied by VWR (Leuven, Belgium). Potassium dihydrogen phosphate (KH_2PO_4), disodiumhydrogen phosphate (Na_2HPO_4), formic acid (HCOOH), trifluoroacetic acid (TFA), and sodium hydroxide (NaOH) were obtained from Merck (Darmstadt, Germany). Six mycotoxin binders were evaluated and obtained from Sigma-Aldrich, Kemin (Herentals, Belgium) and Poortershaven (Rotterdam, The Netherlands)[7] and were identified as "montmorillonites 1, 2, 3 and 4", "leonardite", and "sepiolite". With regard to the composition of the evaluated binders, X-ray diffraction spectrometry (XRD) analysis of montmorillonite 1 indicated montmorillonite as the most prevalent mineral, but also the presence of mica, quartz, and kaolin was detected, and the mineral fraction was 97.0%. XRD analysis of montmorillonite 2 indicated mixed layered montmorillonite as the most prevalent mineral, but also trace amounts of quartz were detected, and the mineral fraction was 78.6%. XRD analysis of montmorillonite 3 indicated pure montmorillonite as the only mineral; the mineral fraction was 86.8%. Montmorillonite 4 contained montmorillonite, sepiolite, and a trace amount of calcite; the mineral fraction was 92.7%. XRD analysis of the leonardite indicated the presence of humic substance and small amounts of quartz; the mineral fraction was <16%. The sepiolite contained small amounts of a smectite clay; and the mineral fraction was 96%.[7] AC (Norit Carbomix), used as positive control, was obtained from Kela (Hoogstraten, Belgium) and was of pharmaceutical grade and applied in a granulated form. Doxycycline hyclate (Soludox 15%) used for the in vivo study was supplied by Dechravet (Heusden-Zolder, Belgium).

In Vitro Binding Assay. The protocol used for the in vitro binding assay was adapted from Sabater-Vilar et al.[25] The main adaptations were the use of phosphate-buffered saline (PBS) buffers of two different pH values instead of adjusting the pH during the conduct of the experiment. Also, the sample preparation, that is, centrifugation instead of filtering, and chromatographic sample analysis differed. PBS was prepared by adding first 24.0 g of NaCl, 0.3 g of $MgCl_2{\cdot}6H_2O$, 0.6 g of KCl, and 0.4 g of $CaCl_2{\cdot}2H_2O$ to 3 L of HPLC grade water. Next, a buffer system consisting of H_3PO_4 and KH_2PO_4, or KH_2PO_4 and Na_2HPO_4, was added to 1 L of salt solution to obtain a buffer solution of ±9.6 mM.[25] The pH was adjusted with H_3PO_4 or NaOH to obtain buffers of pH 2.5 and 6.5, respectively. Five milliliters of the respective PBS at pH 2.5 or 6.5 was added to a 60 mL flask containing 20 mg of the respective binder or AC. Finally, DOX hyclate was added to a concentration of 100 μg DOX/mL. All samples were prepared and analyzed in triplicate. The ratio DOX/binder of 1:40 (w/w) corresponds with a dose of 20 mg DOX/kg BW and a feed intake of 80 g/kg BW with inclusion of 1% binder.

The flask was shaken on a lateral shaker (IKA, Staufen, Germany) for 4 h at 37 °C and 180 rpm (New Brunswick Scientific, Rotselaar, Belgium). Next, samples were transferred to a 15 mL tube and centrifuged (10 min, 524*g*, 4 °C), and 100 μL of the supernatant was transferred to an Eppendorf cup, supplemented with 50 μL of a 50 μg/mL aqueous solution of DMCTC and diluted with HPLC grade H_2O to a volume of 1 mL. After thorough vortex mixing, 100 μL was transferred into an autosampler vial and diluted with ACN/H_2O 80:20 (v/v) to a final volume of 1 mL for further liquid chromatography−tandem mass spectrometric (LC-MS/MS) analysis. Negative control samples were included at 10 and 100 μg/mL DOX and were submitted to the same treatment as the other samples, but without addition of binder.

In Vivo Oral Bolus Pharmacokinetic Study. Montmorillonites 2 and 3 were selected for further research because montmorillonites are the most frequently used mycotoxin binders and because of the high purity of these two montmorillonites. Furthermore, montmorillonite 2 differs from montmorillonite 3 in terms of cation exchange capacity (CEC; 51.0 vs 111.7 $cmol_c/kg$),[7] type of montmorillonite, that is, mixed layered and normal layered, and mineral fraction. Thirty-two 14-day-old broiler chickens (Ross 308, as hatched) were randomly divided in four groups of eight birds, namely, DOX, DOX+AC, DOX +montmorillonite 2, and DOX+montmorillonite 3. The animals were housed and treated according to European guidelines for animal experiments.[26] Each group was housed in floor pens of 2 m^2 covered with wood shavings and equipped with a heating lamp. The animals had ad libitum access to feed and drinking water. Temperature and relative humidity were controlled between 15 and 25 °C and between 40 and 80% respectively. After 1 week of acclimatization, the animals were weighed and fasted 12 h before the onset of the experiment. According to their group, the birds received an oral intracrop bolus (2 mL) of tap water for the animals of the negative control group (DOX), AC dispersed in 2 mL of tap water for the positive control group (DOX+AC), and montmorillonite 2 or montmorillonite 3 also dispersed in 2 mL of tap water for the other two groups (DOX +montmorillonite 2 and 3, respectively). The montmorillonite and AC dose was equivalent to the expected daily intake when 1% (w/w) is included in the feed. Immediately after this bolus administration, an oral Soludox 15% bolus (1 mL) containing 20 mg DOX/kg BW in tap water was administered, followed by 1 mL of tap water to flush the tube. The ratio DOX/binder was with respect to the in vitro trial, namely, 1:40 (w/w). Next, blood samples were taken at 0 min (just before administration), 15, 30, and 45 min, and 1, 1.5, 2, 3, 4, 6, 8, 12, and 24 h postadministration (pa) of the binder and DOX. Blood samples were collected in heparinized tubes and centrifuged (524*g*, 10 min, 4 °C), and plasma was stored at ≤ −15 °C until analysis. This experiment was approved by the local Ethical Committee of the Faculty of Veterinary Medicine and Bioscience Engineering of Ghent University (Case EC 2014/08).

Quantification of Doxycycline in Buffer (in Vitro) and in Plasma (in Vivo). The sample preparation for the in vitro buffer samples is presented under In Vitro Binding Assay. Sample

DOI: 10.1021/acs.jafc.5b00832
J. Agric. Food Chem. 2015, 63, 4370−4375

preparation for plasma samples was as follows: 100 μL of plasma was supplemented with 15 μL of TFA, 50 μL of a 10 μg/mL aqueous DMCTC solution, and 50 μL of HPLC water. The sample was vortex mixed for 30 s before centrifuging at 10800*g* for 10 min at room temperature. The supernatant was diluted 5-fold in HPLC water before analysis. The HPLC system for all samples consisted of a Waters 2690 pump and an autosampler (Waters, Milford, MA, USA). Chromatographic separation was achieved on a Hypersil Gold column (100 mm × 2.1 mm, particle size = 5 μm) and corresponding guard column (Thermo Scientific, Erembodegem, Belgium). The mobile phases were (A) 0.1% HCOOH in H_2O and (B) 0.1% HCOOH in ACN. The following gradient elution program for the samples derived from the in vitro study was applied: 0−2 min, 98% A, 2% B; 2−5.5 min, 40% A, 60% B; 5.5−12 min, 98% A, 2% B. The flow rate was set at 0.30 mL/min, and 5 μL of sample was injected. For the analysis of plasma samples, the following gradient was applied: 0−0.3 min, 95% A, 5% B; 0.3−3.5 min, 10% A, 90% B; 3.5−8.5 min, 70% A, 30% B; 8.5−15 min, 95% A, 5% B. The flow rate was set at 0.45 mL/min, and a 5 μL aliquot of the sample extract was injected.

The HPLC effluent was interfaced to a Quattro Ultima tandem mass spectrometer (Micromass, Manchester, UK). The capillary and cone voltages were 3.0 kV and 40 V, respectively, the source temperature was set at 120 °C, and the desolvation temperature was set at 250 °C. Cone gas flow and desolvation gas flow were, respectively, 101 and 898 L/h. The positive electrospray ionization (ESI+) mode was applied, and collision energy was optimized to 25 eV for both DOX and DMCTC in plasma samples and to 25 and 20 eV for DOX and DMCTC in the samples from the in vitro study, respectively. The following selected reaction monitoring (SRM) transitions were monitored and used for quantification: m/z 445.0 → 428.2 for DOX and 465.0 → 448.1 for DMCTC.

The method was validated for DOX in plasma as well as samples from the in vitro study according to a validation protocol previously described by De Baere et al.,[27] using matrix-matched calibration curves. All parameters met the requirements and were in compliance with the recommendations and guidelines defined by the European Community[28,29] and with international criteria described in the literature,[30−32] except for carry-over of DOX on the instrument. A small interfering peak of 0.4−1% area relative to the area of the highest calibrator was detected when a solvent sample was injected directly after the highest calibrator; no peaks were detected when solvents were injected after the other calibrators. Because the majority of the samples fell below the concentration range in which carry-over was expected, no overestimation was present. The limit of quantification (LOQ) was 1 μg/mL for PBS at pH 6.5 and 2.5 and 50 ng/mL for plasma. Between-run recoveries ± standard deviation (SD, n = 6) of the quality control samples prepared in PBS at pH 2.5 were 10.9 ± 0.5 and 94.2 ± 2.2 μg/mL for blank samples spiked at 10 and 100 μg/mL, respectively. For pH 6.5 the recoveries were 10.4 ± 0.5 and 101.3 ± 3.9 μg/mL. Within-run recoveries (n = 6) in PBS at pH 2.5 were 10.7 ± 0.2 and 95.3 ± 0.2 μg/mL, whereas in PBS at pH 6.5 the recoveries were 10.1 ± 0.2 and 99.8 ± 1.8 μg/mL. Validation of the analytical method for the plasma samples included blank plasma samples spiked at 250 ng/mL (n = 6) and 2500 ng/mL (n = 6, both within- and between-run); between-run recoveries were 242.2 ± 4.6 and 2518.2 ± 59.8 ng/mL, respectively. For the within-run recovery, values of 243.8 ± 5.6 and 2460.4 ± 68.1 ng/mL were obtained.

Pharmacokinetic Analysis. A noncompartmental analysis of the DOX plasma concentration−time data was performed to determine the pharmacokinetic (PK) characteristics of DOX using WinNonlin 6.3 (Phoenix Pharsight, St. Louis, MO, USA). The following main PK variables were determined for each animal: C_{max}, T_{max}, area under the plasma concentration−time curve from time 0 to infinite and 24 h (AUC_{0-inf} and AUC_{0-24h}), elimination rate constant (k_{el}), elimination half-life ($T_{1/2el}$), volume of distribution relative to the absolute oral bioavailability (Vd/F), and clearance relative to the absolute oral bioavailability (Cl/F). The relative oral bioavailability (relative F) was calculated according to following formula:

$$\text{relative } F = \frac{AUC_{0-\text{inf, DOX + tested binder}}}{AUC_{0-\text{inf, DOX negative control}}} \times 100$$

Statistical Analysis. The free DOX concentrations in the in vitro trial were analyzed using a one-way analysis of variance (ANOVA) and executed using the statistical package SPSS for Windows (IBM, Brussels, Belgium). The PK values for each group in the in vivo study were compared using a one-way ANOVA; p values below 0.05 were considered as statistically significant.

RESULTS

Results of the in vitro binding assay are presented in Figure 1. The concentrations of DOX in the negative control samples at pH 2.5 were 10.6 ± 0.3 and 91.0 ± 1.8 μg/mL for the samples spiked at 10 and 100 μg/mL, respectively. For the samples at pH 6.5 the concentrations of DOX were 11.0 ± 6.8 and 100.3 ± 4.7 μg/mL, respectively. Low free concentrations of DOX after incubation are indicative of high adsorption and are seen in all of the tested binders. No significant differences were observed between the binders and AC; however, all of the tested binders differed significantly (p < 0.001) from the negative control samples.

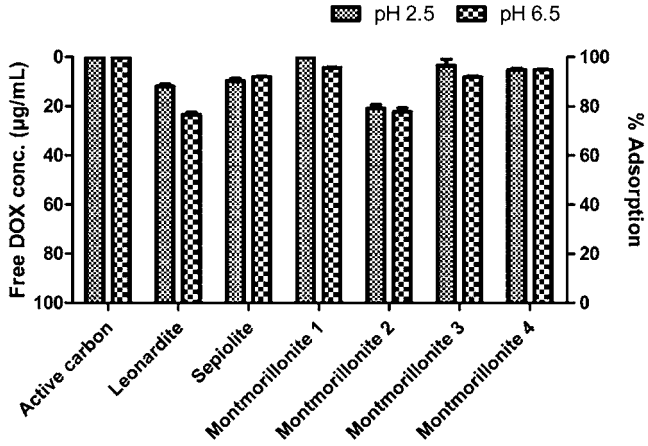

Figure 1. Doxycycline (DOX, 100 μg/mL) was incubated for 4 h at 37 °C with 20 mg of one of following binders in 5 mL of PBS buffer at pH 2.5 and 6.5: activated carbon (positive control), leonardite, sepiolite, and four different montmorillonites. The free DOX concentration (μg/mL) is presented on the left y-axis as the average of three independent measurements + standard deviation (SD). The percent adsorption is presented on the right y-axis. No significant differences were observed between the binders and activated carbon; however, all of the tested binders differed significantly (p < 0.001) from the negative control samples.

The plasma concentration−time profiles of DOX after a single oral bolus administration of the tetracycline whether or not combined with one of the binders are presented in Figure 2. Mean plasma concentration of DOX in the negative control group reached a first maximum at about 2.5 h and a second at 6 h. The area under the plasma concentration−time curves of the test groups are clearly lower compared to the control group, and the curves display only one maximum at the same time of the second maximum of the control group (at about 6 h). The PK parameters of DOX are presented in Table 1. Significant differences between the negative control group and test groups can be seen for the AUC_{0-inf}, AUC_{0-24h}, and C_{max} (p < 0.001). The absorption rate constant (k_a) was calculated using the curve-stripping method as described by Gabrielsson and

DOI: 10.1021/acs.jafc.5b00832
J. Agric. Food Chem. 2015, 63, 4370−4375

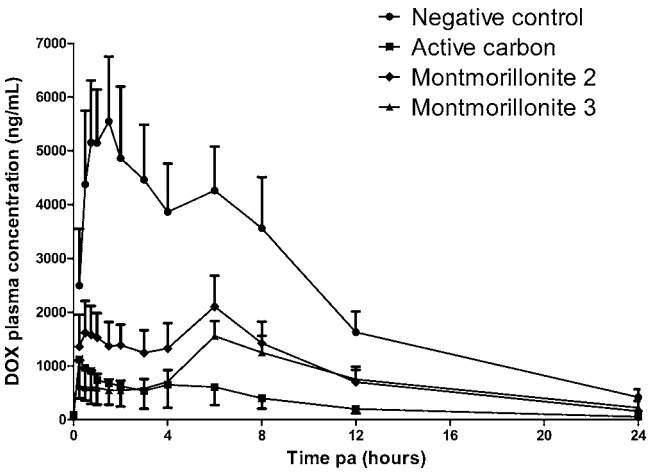

Figure 2. Four groups of eight broiler chickens were given an oral bolus containing water (negative control), activated carbon (positive control), montmorillonite 2, or montmorillonite 3 directly followed by an oral bolus containing doxycycline (DOX) at 20 mg/kg body weight. Plasma concentration−time profiles of DOX are presented as means of eight observations + standard deviation.

Weiner.[33] However, variance of the calculated k_a values did not allow meaningful comparison; therefore, this parameter was omitted from Table 1.

DISCUSSION

The aim of this study was to investigate the interactions between DOX and different feed additives used as mycotoxin binder. First, an in vitro adsorption screening study was performed. Therefore, an in vitro model as reported by De Mil et al.[7] and based on the model used by Sabater-Vilar et al.[25] was applied. This model uses PBS at pH values of 2.5 and 6.5, which represent, respectively, the gastric and duodenal pH conditions of monogastric animals. Less than 25% of the initial concentration could be detected as free DOX after 4 h of incubation at 37 °C in all groups, indicating that the majority of DOX is adsorbed by the additives. Deng et al.[10] described the binding mechanism between AFB1 and montmorillonite clays; the adsorption is facilitated by the exchangeable cations that form hydrogen bonds with AFB1. Along with the exchangeable cations, AFB1 can then be "trapped" between the silicate sheets of the montmorillonite and effectively bound. A similar mechanism might apply here because DOX has many sites suitable for hydrogen bonding.

When used as a mycotoxin binder, most recommendations mention an inclusion rate in the feed of 0.1−0.5% (w/w); however, when used as pelletizing, or binding, agent, inclusion rates up to 2% are recommended. A ratio of DOX/binder of 1:40 (w/w) is representative for the in vivo application of both substances when considering a clay inclusion rate of 1% (w/w); this ratio was the same in both the in vitro and in vivo trials.

The in vitro models used for the assessment of the efficacy include static[34,35] and dynamic[36,37] GI models, construction of adsorption isotherms,[38] and single-concentration studies.[25] Although the simple setup in this study cannot provide the same information as the complex dynamic and isotherm models, by using representative buffers and binder−drug ratios, this setup still can provide relevant information regarding the safety of the feed additives, which can be directly extrapolated to the in vivo situation. To verify the latter, in vivo experiments have to be carried out. An in vivo oral bolus model was applied to study the interactions from a PK perspective;[39] this is in accordance with EFSA guidelines for the safety testing of these group of additives.[12] Concerning the DOX PK parameters in the negative control group, the reported $T_{1/2,el}$ values are between 5.69 h[40] and 7.93 h[41] in broiler chickens, whereas this study found a $T_{1/2,el}$ of 8.22 h, which can be considered to be in the same range. The reported T_{max}, C_{max}, and AUC_{0-inf} values for most references are also in the same range as found for the control group in this study, namely, between 1.73 h[42] and 2.9 h[43] for T_{max}, between 3.18 μg/mL[40] and 7.84 μg/mL[41] for C_{max}, and between 39.84 μg·h/mL[40] and 97.6 μg·h/mL[41] for AUC_{0-inf}. The appearance of a second maximum in the plasma concentration−time profile is likely to be due to an enterohepatic recycling; this means excretion of DOX from the blood to the GI lumen by both hepatic/biliary or direct passive un-ionized diffusion from blood to gut, followed by reabsorption. This phenomenon, seen for most tetracyclines, has been described for many species such as pigs,[44] humans,[45] and sheep.[46] Pharmacokinetic analysis of DOX of the test groups clearly indicates that AUC_{0-inf} and C_{max} are decreased when AC or the tested montmorillonites are used simultaneously with DOX. Table 1 shows a somewhat delayed T_{max} of DOX in the montmorillonite test groups. However, this T_{max}

Table 1. Four Groups of Eight Broiler Chickens Were Given an Oral Bolus Containing Water (Negative Control), Activated Carbon (Positive Control), Montmorillonite 2, or Montmorillonite 3 Directly Followed by an Oral Bolus of Doxycycline (DOX) at 20 mg/kg Body Weight[a]

coincides with the second absorption maximum of DOX in the control group (Figure 2), which indicates that this shift is rather due to the absence of the first maximum than a delayed absorption. Differences in Vd/F and Cl/F can be explained by a difference in bioavailability, although the latter cannot be calculated with the given data. As expected, no differences in elimination kinetics were seen, because k_{el} and $T_{1/2el}$ were similar in both control and test groups. The 60% decrease in AUC_{0-24h} in the test groups results in a lower AUC/minimal inhibitory concentration (MIC) ratio, which is of major importance for the clinical outcome.[47] Therefore, a decrease in treatment efficacy can be expected because a decrease in oral bioavailability F is linearly correlated to a decrease in AUC[48] and therefore also to the AUC/MIC ratio. Antimicrobials for which the efficacy depends on the time the plasma concentration is above the MIC, such as TYL, might even be more sensitive to a decrease in oral bioavailability because the time above MIC decreases in a logaritmic manner as a function of F. Moreover, subtherapeutic concentrations of tetracyclines can induce microbial resistance.[18] This interaction is in line with previously reported interactions of montmorillonite-based feed additives with the macrolides TIL[13] and TYL[15] in broiler chickens.

On the basis of the in vitro adsorption and in vivo pharmacokinetic results, it can be concluded that AC and the tested montmorillonite clays can substantially diminish the oral absorption of DOX in broiler chickens, and this is most likely due to the adsorption of DOX to the clay additives. Therefore, when DOX is orally administered to chickens that are also fed montmorillonite-based feed additives, a possible interaction needs to be carefully considered. Further research is needed to investigate the safety of other additives when used simultaneously with other veterinary medicinal products.

ABBREVIATIONS USED

AC, activated carbon
ACN, acetonitrile
AFB1, aflatoxin B1
AUC, area under the curve
AUC_{0-24h}, AUC from time zero to the 24 h point
AUC_{0-inf}, AUC from time zero to infinity
BW, body weight
Cl/F, clearance relative to the absolute bioavailability
C_{max}, maximum plasma concentration
DMCTC, demethylchlortetracycline
EFSA, European Food Safety Authority
ESI+, electrospray ionization in the positive mode
F, bioavailability
GI, gastrointestinal
HPLC, high-performance liquid chromatography
k_{el}, elimination rate constant
LC-MS/MS, liquid chromatography−tandem mass spectrometry
LOQ, limit of quantification
MIC, minimal inhibitory concentration
MON, monensin
pa, post administration
PD, pharmacodynamic
PK, pharmacokinetic
relative F, relative bioavailability
SAL, salinomycin
SD, standard deviation
SRM, selected reaction monitoring
$T_{1/2,el}$, elimination half-life
TFA, trifluoroacetic acid
TIL, tilmicosin
T_{max}, time to reach C_{max}
TYL, tylosin
Vd/F, volume of distribution relative to the absolute bioavailability
XRD, X-ray diffraction

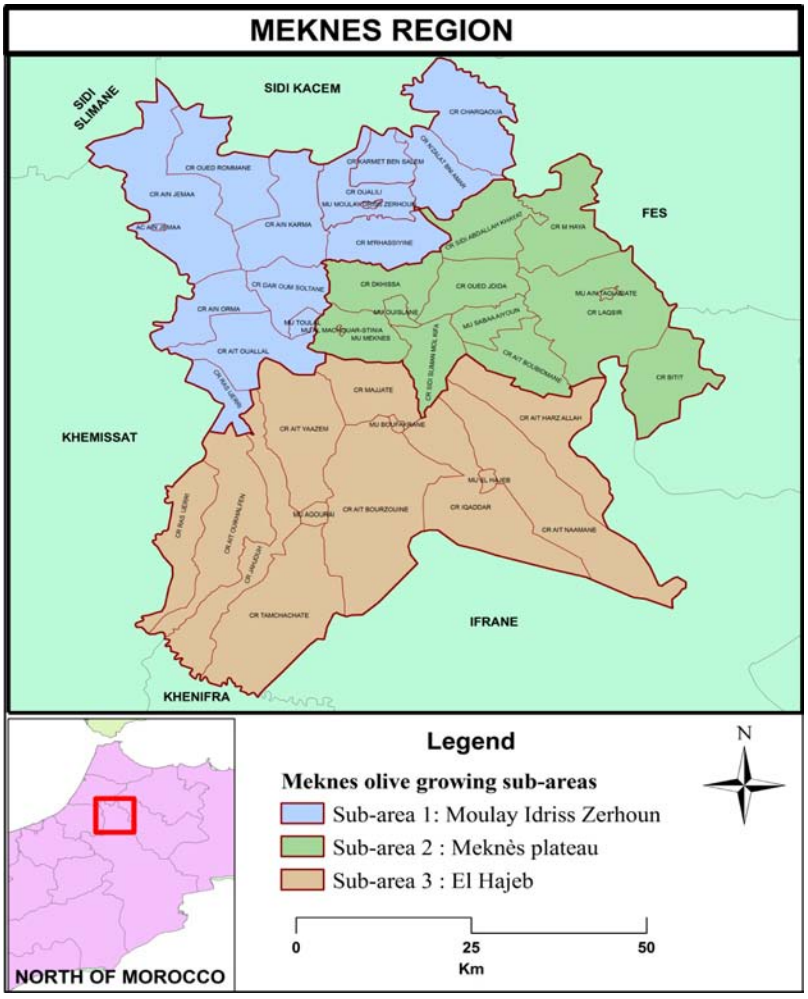

Figure 1. Map of the Meknès region showing the three subareas considered in the current study.

However, despite the importance of VOO production in the above-mentioned Meknès region, there is practically no detailed pluri-annual qualitative and quantitative characterization of the phenolic fraction of VOOs produced in this region.

Therefore, the aim of this work was to solve the lack of information in this regard by carrying out the comprehensive characterization and evolution of the phenolic fraction of Meknès VOOs over three consecutive seasons. A powerful LC-MS (using different analyzers) was used, and a total of 142 samples (from three diverse areas) were analyzed. The possible effect of interannual and intraregional variations on the content of the identified phenolic compounds was also evaluated. To our best knowledge, this work represents the first pluri-annual study reporting data on the phenolic fraction of VOOs from a Moroccan region.

MATERIALS AND METHODS

Olives Sampling. Monovarietal virgin olive oils from the most relevant Moroccan cultivar, Picholine marocaine, were considered. A total of 142 olive fruit samples were collected over three consecutive seasons (harvesting periods 2011−2013) from three subareas of the Meknès region (Figure 1). Sampling was carried out from the middle of October until the end of December. Olive samples (one sample is approximately 35 kg of olives) were handpicked in olive groves located in the three selected subareas belonging to the Meknès region. Only good-quality, fresh, and healthy fruits were selected. Ripening stage, being a parameter with great influence on olive oil characteristics, was evaluated by determining the ripening index following the method developed at the Agronomic Station of Jaén, based on the evaluation of the olive skin and pulp colors.[18] After harvesting, the olive fruit samples were immediately transported to the laboratory in ventilated rectangular plastic crates, and the oil was extracted within 24 h.

Oil Extraction. Oil extraction was carried out in a laboratory instrument, SPREMOLIVA C30 Oliomio (Oliomio, Italy) with a work capacity of 30 kg/h, and equipped with a knife crusher, a horizontal malaxator, and a two-phase decanter. Fruits were processed as follows: olives were washed to eliminate any foreign material and poured into the receiving hopper, where a screw feeds the crusher that is equipped with fix hole grid and grooved knife impeller at a temperature of 25−27 °C. The paste produced falls into the malaxing part; malaxing was carried out for 45 min at 28−30 °C. The resulting olive paste was decanted at a temperature of 23−27 °C without the addition of any water. All of the samples were subsequently filtered, placed in amber glass bottles, and stored in the dark at 4 °C.

Physicochemical Quality Indices. Determination of free fatty acids content (given as a percentage of oleic acid), peroxide value (expressed as milliequivalents of active oxygen per kilogram of olive oil (mequiv O_2/kg)) and K_{232} and K_{270} extinction coefficients calculated from absorption at 232 and 270 nm, respectively, was carried out by using the analytical methodologies described in the European Union Standard Methods Regulations 2568/91 and the subsequent amendments.[19] All of the parameters were determined in triplicate for each sample.

Phenolic Compound Analysis. *Chemicals and Reagents.* All of the reagents were of analytical grade and used as received. Methanol and *n*-hexane of HPLC grade supplied from Panreac (Barcelona, Spain)

DOI: 10.1021/jf506097u
J. Agric. Food Chem. 2015, 63, 4376−4385

were used for the extraction of the phenolic compounds from the olive oil samples. Acetonitrile from Lab-Scan (Dublin, Ireland) and acetic acid from Panreac were used for preparing the mobile phases. Water was deionized using a Milli-Q-system (Millipore, Bedford, MA, USA). Several phenolic standards were used for identification and quantification purposes, namely, hydroxytyrosol, tyrosol, luteolin, apigenin, and *p*-coumaric, quinic acid, ferulic, and caffeic acids supplied by Sigma-Aldrich (St. Louis, MO, USA), and (+)-pinoresinol was purchased from Arbo Nova (Turku, Finland). Oleuropein was acquired from Extrasynthese (Lyon, France). 3,4-Dihydroxyphenylacetic acid (DOPAC) was used as internal standard and supplied by Sigma-Aldrich.

Stock standard solutions of individual compounds at a concentration of 500 mg/L were prepared by exact weighing of the appropriate amount of the pure compound and dissolving it in methanol. These solutions were stored at −20 °C in the dark. Multianalyte working standard solutions at different concentration levels within the range of 0.5−250 ppm were prepared by appropriate dilutions of the stock solutions and stored in screw-capped glass tubes at −20 °C in the dark.

Phenolic Compound Extraction. The extraction of the phenolic compounds was carried out as previously described by Bajoub et al.,[16] with little modification. Briefly, 2 g of olive oil and 0.025 mL of internal standard solution (at a concentration of 500 mg/L) were extracted (repeating the same process three times in a row), adding every time 1 mL of *n*-hexane and 2 mL of methanol/water (60/40); the extract was centrifuged at 3500 rpm for 6 min. The combined extracts were evaporated to dryness using a rotary evaporator under reduced pressure and a temperature of about 30 °C. The residue was reconstituted up to 1 mL with methanol and filtered through 0.20 μm membrane (nylon) filters.

Chromatographic Separation. In a first step and for initial characterization purposes of the phenolic fraction of the studied samples, the analyses were carried out on a Waters LC Acquity system (LC, Acquity H-Class) (Milford, MA, USA) equipped with a Waters Acquity quaternary solvent manager (QSM), an Acquity sample manager (SM), a column heater, a degassing system, a diode array detector, and an ESI-time of flight MS detection system. Afterward, an Agilent 1260-LC system (Agilent Technologies, Waldbronn, Germany) equipped with an autosampler, degasser, quaternary pump, thermostated column compartment,diode array detector, and an ESI-ion trap MS detection system was used for further identification and quantification purposes. In both cases, the analysis of phenolic compounds was performed by following a previously reported methodology.[16] Separation was achieved on a Zorbax C18 analytical column (4.6 × 150 mm, 1.8 μm particle size), protected by a guard cartridge of the same packing. The injection volume was 10 μL in every case. The binary mobile phase consisted of water with acetic acid (0.5%) (phase A) and acetonitrile (phase B) and was delivered at a flow rate of 0.8 mL/min. Gradient elution was performed using the following solvent gradient: 0−10 min, 5% B; 10−12 min, 30% B; 12−17 min, 38% B; 17−20 min, 50% B; 20−23 min, 95% B. Finally, the B content was decreased to the initial conditions (5%) in 2 min and the column re-equilibrated for 2.5 min. As stated before, the separated compounds were monitored in sequence first with DAD (240, 280, and 330 nm) and then with a mass spectrometry detector (ESI-TOF MS or ESI-IT MS).

ESI-TOF MS and ESI-IT MS Conditions. To avoid the introduction of humidity into the system and achieve stable electrospray ionization and reproducible results, the flow delivered into the MS detectors from LC was reduced to 0.2 mL/min using a flow divisor 1:4. MS detection was first performed in a Synapt G2 time-of-flight (TOF) mass spectrometer (Milford, MA, USA) equipped with an electrospray interface. Spectra were recorded in negative mode, operating within the range of 50−1200 Da and at a scan speed of 240 ms. The source temperature was set at 100 °C with a cone gas flow of 800 L/h, a desolvation gas temperature of 500 °C, and a desolvation gas flow of 100 L/h. The capillary voltage was set at 2.2 kV. Internal calibration was performed using sodium formate cluster by using a solution containing 5 mM sodium hydroxide in the sheath liquid of 0.2% formic acid in water/isopropanol 1:1 v/v. The calibration solution was injected at the beginning of the run, and all of the spectra were calibrated prior to carrying out the compound identification. The accurate mass data of the molecular ions were processed through the software MassLynx 4.1 (Waters), which provided a list of possible elemental formulas, giving a Fit Conf (%) parameter that shows the prediction confidence.

After characterization of the phenolic fraction of the samples under study by TOF MS, a Bruker Daltonics Esquire 2000TM ion trap (Bruker Daltonik, Bremen, Germany) was used. The phenolic extracts were injected using the chromatographic conditions described above and both full scan (for quantitation purposes) and auto MS/MS (for further characterization purposes, in both negative and positive polarities). As far as MS/MS conditions are concerned, two methods were used: in the first one, the selected fragmentation energy (using nitrogen (N_2) as collision gas) was automatically applied to all of the ions that overtook the threshold intensity of 15000; in the second method, however, the analytical window was divided into two segments, and different threshold intensities were fixed for each one (the first one up to 12.5 min with an intensity threshold of 10000 and the second one, from 12.5 min until the end of the run, with a threshold intensity of 27000). Full scan mass spectra (m/z 50−800) were recorded in negative mode using a capillary voltage of 3.2 kV. The nebulizer gas was set at 30 psi, dry gas at 9 L/min, and drying gas (N_2) temperature at 300 °C. MS data were processed through Data Analysis 4.0 software (Bruker Daltonics, Bremen, Germany).

Phenolic Compound Identification and Quantification. Peak identification was done bearing in mind retention time, spectral data, and ESI-TOF MS and ESI-IT MS/MS information obtained from olive oil samples and pure standards. We also used the previously reported information.[12] The linearity of the detector response was verified with standard solutions at 11 different concentration levels over the range from the quantification limit to 250 ppm (0.5, 1, 5, 12.5, 25, 35, 50, 100, 150, 200, and 250 mg/L). Each point of the calibration graph corresponded to the mean value from three independent replicate injections. Calibration curves were obtained for each standard by plotting the standard concentration as a function of the peak area obtained from LC-ESI-IT MS analyses. The following equations were obtained for each calibration curve: apigenin ($y = 298095x + 53202$; $r^2 = 0.999$); caffeic acid ($y = 121649x + 45541$; $r^2 = 0.995$); ferulic acid ($y = 69884x + 26610$; $r^2 = 0.992$); hydroxytyrosol ($y = 117686x - 12928$; $r^2 = 0.998$); luteolin ($y = 259366x + 17767$; $r^2 = 0.999$); oleuropein ($y = 20535.20x + 5444.60$; $r^2 = 0.995$); *p*-coumaric acid ($y = 82728x + 23247$; $r^2 = 0.997$); pinoresinol ($y = 79815x + 44395$; $r^2 = 0.997$); quinic acid ($y = 77315x - 6950.41$; $r^2 = 0.997$); and tyrosol ($y = 33975x + 9524.70$; $r^2 = 0.995$). The compounds for which pure standards were not available were quantified on the basis of other analytes with similar chemical structures. In particular, secoiridoids were quantified in terms of oleuropein and lignans in terms of pinoresinol, and oxidized hydroxytyrosol was quantified by comparison with hydroxytyrosol.

Statistical Analysis. As the number of samples selected in the current study was considerably high (142 samples from different areas over three seasons), the quantitative data have been reported as mean ± standard deviation (SD) values of triplicate experiments and were analyzed using SPSS 20.0. One-way analysis of variance (ANOVA) and Tukey's test (with a significance level of 0.05) were used to determine the significance of the difference among the studied parameters regarding the subarea and crop season.

RESULTS AND DISCUSSION

Ripening and Quality Indices. Table 1 summarizes the mean ± standard deviation and maximum and minimum values of the ripening index and the regulated quality criteria (free fatty acids, peroxide value, K_{232}, and K_{270}) for all of the olive oil samples extracted from fruits of Picholine marocaine cultivar population grown in the areas considered within the current study. As can be seen, the ripening index values of the olive fruits used for the extraction of the olive oils were between a minimum value of 1.14 (crop season 2013) and a maximum

[a]Significant differences in the same row are indicated with different upper case letters (comparison between subareas at the same crop season, $p < 0.05$). Significant differences in the same column are indicated with different lower case letters (comparison among crop seasons, $p < 0.05$). [b]In this table and Table 3 the mean values are those calculated for all of the samples from the same area; therefore, SD gives to the reader an idea about only the variability of the olive oils in terms of composition and obviously not about the repeatability of the analytical methods used.

value of 6.78 (crop season 2012). This wide range allowed evaluation of the phenolic composition of the olive oil samples at three main maturation stages: green, spotted, and ripe. Furthermore, the ripening index was practically unaffected by the olive cultivation subarea or the crop season over the studied period. Therefore, the effect of the maturity stage on the differences found for the other studied parameters (in particular, for the phenolic composition) can be dismissed.

As far as the quality indices are concerned, and taking into account the limits set by the Commission of the European Community for olive oil classification,[19] 97.18% of the studied samples fell within the "extra virgin" category, and the rest (2.82%) were within the "virgin" category. This result is not surprising because the raw material was carefully selected, picked, and processed. Thus, as shown in Table 1, mean values for free fatty acid content (expressed as percentage of oleic acid) ranged from 0.18 to 0.46%. Only four olive oil samples showed a value >0.8%, which is the upper threshold limit established for the extra VOO category; none exceeded the limit of 2% for the VOO category.[19] The peroxide value was lower than the upper limit of 20 mequiv O_2/kg established for the extra virgin category for every sample, ranging from 5.55 to 9.17 mequiv O_2/kg. Likewise, all of the values of spectrophotometric UV absorption at 232 nm (K_{232}) and 270 nm (K_{270}) were below the limits of 0.22 and 2.25, respectively, established for the extra virgin category. Their mean values ranged from 1.24 to 1.61 and from 0.13 to 0.15 for K_{232} and K_{270}, respectively. Results of ANOVA test revealed that no statistically significant differences were observed for the quality indices according to production subarea. These results are in good agreement with the findings of other authors,[20,21] who claimed that these analytical parameters are mainly affected by factors causing damage to the fruits, such as olive fly attacks or inappropriate harvesting practices, transport, and storage of olives.

Phenolic Compound Profiling. *Qualitative Characterization.* Figure 2 shows a typical LC-ESI-TOF MS profile of a phenolic extract of Picholine marocaine, where the extract ion chromatograms (EICs) of the determined compounds are shown. The identification of these compounds was performed considering the information provided by the TOF MS detector, the information collected from MS/MS experiments in negative and positive modes, and the use of commercial pure standards (when available). The components were efficiently separated, and it was possible to identify 29 peaks, corresponding to a polar nonphenolic compound (quinic acid) and 28 phenolic substances (belonging to five different chemical categories) (see Table 2). The phenolic profile of Meknès olive oil samples was dominated by the presence of a high number of secoiridoids, mainly oleuropein aglycone (Ol Agl), ligstroside aglycone (Lig Agl), and six and three isomers of each one, respectively, decarboxymethyl oleuropein aglycone (DOA), dehydro oleuropein aglycone (Dehydro Ol Agl), methyl oleuropein aglycone (Methyl Ol Agl), methyl decarboxymethyl oleuropein aglycone (Methyl D-Ol Agl), decarboxymethyl ligstroside aglycone (D-Lig Agl), dialdehydic form of decarboxymethyl elenolic acid (D-Ald-D EA), desoxy elenolic acid (Desoxy-EA), and elenolic acid (EA). Besides, it was also possible to determine various simple phenols (hydroxytyrosol (Hyt), oxidized hydroxytyrosol (O-Hyt), and tyrosol (Ty)), lignans ((+)-pinoresinol (Pin), (+)-1-acetoxypinoresinol (Ac-Pin), and syringaresinol (Syr)), flavonoids (luteolin (Lut) and apigenin (Apig)), and a phenolic acid (*p*-coumaric acid).

Variation of the Phenolic Compounds Content over the Studied Period. It is well established that phenolic content in olive oil widely depends on intrinsic (genetic) and extrinsic

(geographical, seasonal, agronomic, environmental, maturation stage, processing and storage conditions) factors.[22−25] In the current study, the effect of the harvest season and production subarea on the composition of monovarietal olive oil from Meknès region (in terms of phenolic compounds) was evaluated (Table 3). Moreover, the total content for each chemical class (expressed in mg/kg) was calculated as the sum of the content of the individual phenols belonging to that chemical category (Table 3). It is possible to highlight the existence of an important intra-sub-zone variability, as attested by the wide range of obtained values. This variability can be the result of the genetic diversity of the cultivar Picholine marocaine. Indeed, several studies carried out to determine the comprehensive genetic characterization of this cultivar have reported that it includes several distinct clones and local genotypes, all known under the common name Picholine marocaine.[26,27]

Even if the qualitative phenolic compositions of all the analyzed olive oil samples from Meknès over the studied period were quite similar, the abundance of the analytes under study (in terms of both individual phenol concentration levels and global content by chemical categories) widely differed as illustrated by Figure 3 and Table 3. In general, *secoiridoids* were the most abundant group of phenolic compounds in every sample regardless of the subarea of origin and the harvest season, a fact that is in good agreement with the findings of other authors for various monovarietal olive oils.[12,28,29] This type of phenolic compound is of great importance because, for instance, it contributes to the organoleptic characteristics of VOO, by conferring bitterness and pungency.[10] The highest mean concentration value of secoiridoids (1106.96 mg/kg) was observed for olive oil samples from subarea 3 during crop season 2011, whereas the lowest mean concentration was found for samples from subarea 2 in crop season 2013, at 540.12 mg/kg. With regard to individual secoiridoids, the most abundant one over the evaluated period was DOA, with mean concentrations of 165.86, 168.34, and 101.39 mg/kg (for subarea 3), respectively, during the first, second, and third crop seasons. Other secoiridoids found at relatively high concentration levels were Ol Agl, with amounts ranging from 47.40 mg/kg in oils from subarea 2 for the third crop season to 155.45 mg/kg in olive oils from the same subarea for crop season 2011; Lig Agl, with mean values ranging from 70.42 to 111.23 mg/kg, respectively, in olive oils from subarea 1 (for the second crop season) and subarea 2 (for the third crop season); and EA, the lowest concentration of which was found in oils from subarea 3 at the third crop season (36.83 mg/kg) and the highest concentration value was registered in oils from subarea 2 during the first crop season (109.46 mg/kg). Isomers, of both Ol Agl and Lig Agl, were also determined at relatively high concentration levels. Indeed, in the case of Ol Agl, over the crop season 2011, isomers 5 and 2 showed the highest mean concentration level (60.79 and 55.95 mg/kg) in olive oils from subarea 3, whereas isomer 6 showed the highest mean concentration value (57.17 mg/kg) for samples from subarea 2. As far as Lig Agl isomers are concerned, isomer 1 remains the prevailing one in all of the analyzed samples over the three crop seasons with mean concentrations ranging from 33.20 mg/kg in oils from subarea 1 (for the first crop season) to 40.25 mg/kg in olive oils from the same subarea over the 2013 crop season. Besides the above-mentioned compounds, other secoiridoids were found at relatively lower amounts: Dehydro Ol Agl, which showed mean concentration values ranging between 3.06 mg/kg (found in oils from subarea 2 during the second crop season) and 15.02 mg/kg (found in oils from subarea 1 for crop season 2011); D-Ald-D EA, with mean concentration levels fluctuating from 0.39 mg/kg in oils from subarea 3 during the second crop season to 37.60 mg/kg in olive oils from subarea 1 over the crop season of 2011; Desoxy-EA, which was found at mean concentration levels between 8.23 mg/kg (in oils from subarea 1 in 2011) and 23.70 mg/kg (in olive oils from subarea 3 in 2012); D-Lig Agl, at concentrations ranging between 36.96 mg/kg (for oils from subarea 1 in 2012) and 157.90 mg/kg (in 2013, for oils from subarea 3); Methyl D-Ol Agl, in amounts between the following values, 15.80−27.27 mg/kg for oils from subarea 2 in 2012 and samples for subarea 1 over the first crop season, respectively, and Methyl Ol Agl, for which the lowest concentration was determined in oils from subarea 2 at the second crop season (1.28 mg/kg) and the highest one was registered in oils from the subarea in 2011 (4.15 mg/kg).

Simple phenols constitute the second group of phenols in terms of abundance in Meknès olive oil samples, with a total average amount that varies between 6.90 mg/kg (subarea 3, crop season 2013) and 13.07 mg/kg (subarea 2, crop season 2011). Within this group, Ty was the predominant substance, with levels found between 4.84 mg/kg, in oils from subarea 3 over the third crop season, and 7.80 mg/kg, in oils from subarea 1 during the second crop season. In terms of relative abundance, Ty was followed by Hyt, which showed mean concentration values oscillating between 1.07 mg/kg (subarea 3 for crop season 2013) and 5.62 mg/kg (subarea 2 afor crop season 2011); O-Hyt that was also found in relatively lower amounts, its mean values varying between 0.16 mg/kg (subareas 1 and 3, crop season 2013) and 1.02 mg/kg (subarea 3, crop season 2011). If these results are compared with those achieved in previous studies about the phenolic composition of monovarietal olive oils from different Mediterranean countries,[12,30] some particular characteristics can be highlighted for Meknès olive oils. The first feature is that Ty concentration levels in the evaluated oils are, in general, higher than Hyt concentration values; the second characteristic is that Hyt levels are lower than the previously published concentration values for other Mediterranean monovarietal olive oils. Both factors could be potentially considered as markers or discriminative characteristics of Meknès oils when compared with olive oils from other different Mediterranean locations.

Lignans were another relevant group of phenolic analytes determined in the selected samples; in terms of abundance, they were the third group, with average contents ranging from 1.43 to 5.34 mg/kg. The highest value was observed for oils from subarea 1 for the first crop season, whereas the lowest mean concentration level was found for oils from the same subarea over the 2013 crop season. When the concentration levels of individual compounds are taken into account within this group, we observe that Ac-pin levels were found between 0.91 mg/kg (subarea 1, crop season 2013) and 3.28 mg/kg (subarea 2, crop season 2012); Syr concentration values fell within the range between 0.17 mg/kg (subarea 1 and crop season 2013) and 2.42 mg/kg (subarea 1 and crop season 2011); and concentration values for Pin fluctuated within the range of 0.30−1.15 mg/kg, defined by the mean value obtained for the samples from subareas 1 and 3, respectively, over the 2011 season.

With regard to the *flavonoids* family, in terms of total content, average values were found within the range from 1.10 to 3.23 mg/kg, levels observed, respectively, in oils from subarea 3

[a]Significant differences in the same row are indicated with different lower case letters (comparison among crop seasons, $p < 0.05$) and with different uppercase letters (comparison among subareas at the same crop season, $p < 0.05$). [b]Quinic acid, Hyt, Ty, Pin, Lut, Apig, and p-Cou were quantified in terms of their commercial pure standards. O-Hyt was quantified in terms of Hyt. Lignans were quantified in terms of Pin. Secoiridoids were quantified in terms of oleuropein.

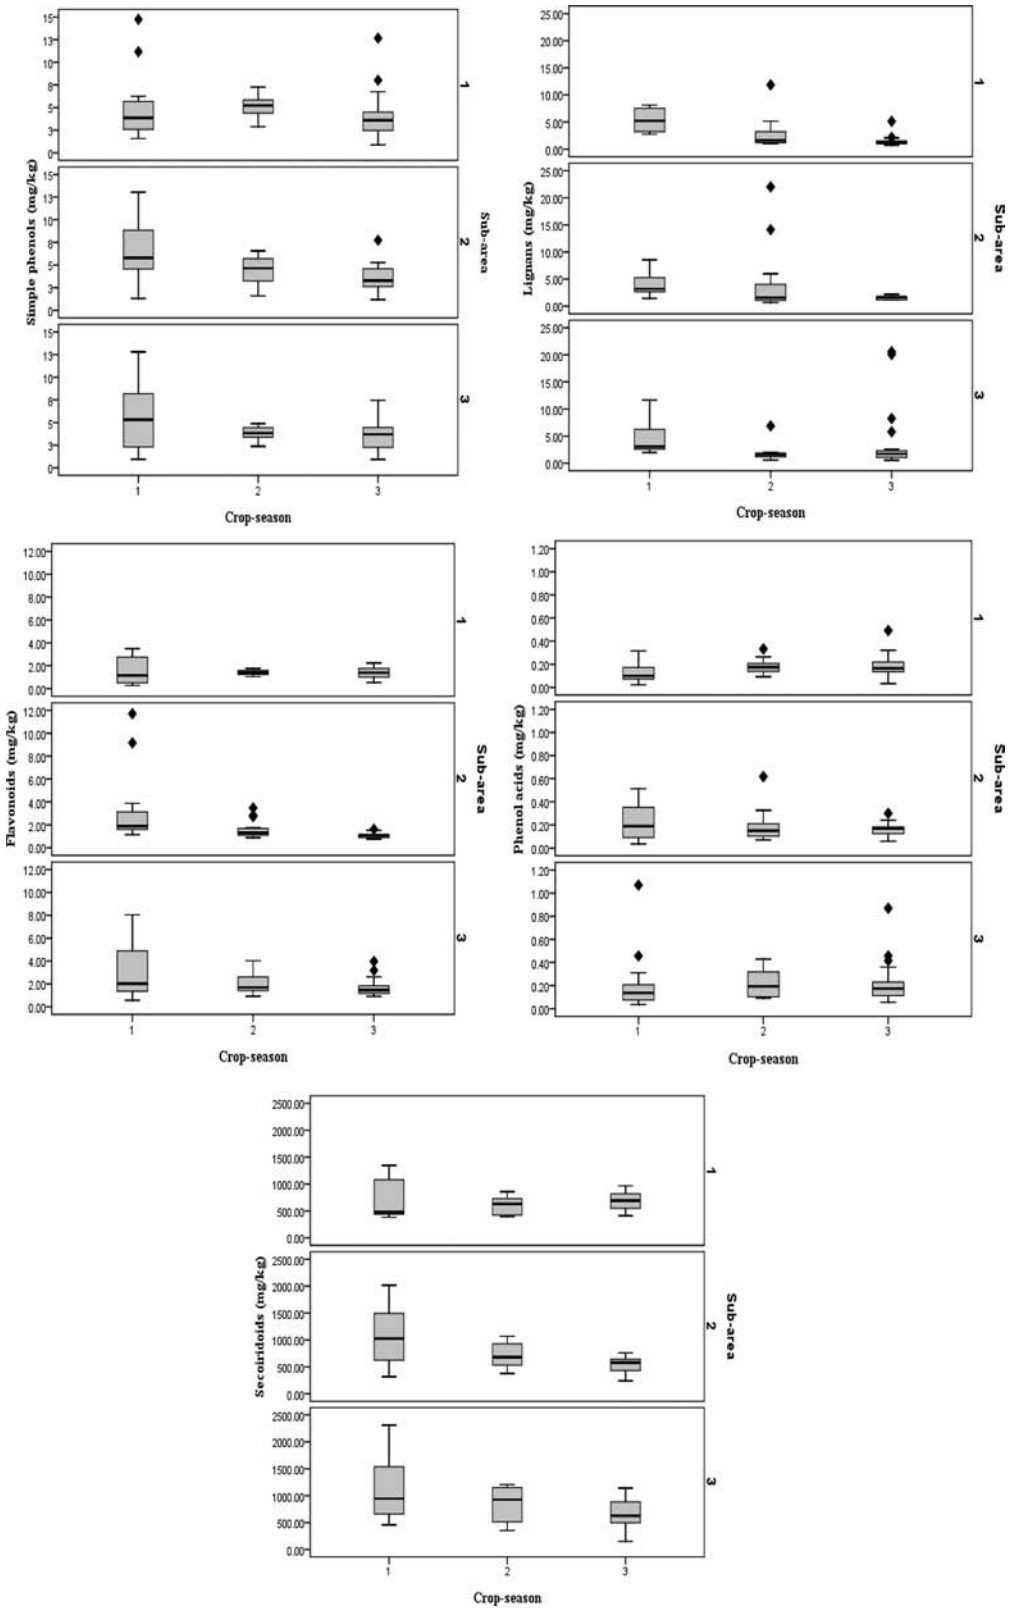

Figure 3. Box and whisker plots of total content of simple phenols, lignans, flavonoids, phenolic acids, and secoiridoids determined on Meknès VOOs. For box-plots, the line within the box indicates the median; the box boundary marks the 25th and 75th percentiles; percentiles and whiskers above and below the box indicate the 90th and 10th percentiles. Outlier data are shown as ♦.

during crop season 2013 and subarea 2 in 2011. Lut and Apig are the most relevant compounds within this group; Lut, which was the most abundant flavonoid occurring in the analyzed olive oil samples, was found at mean concentration levels ranging from 1.02 mg/kg (subarea 2, crop season 2013) to 2.63 mg/kg (subarea 2, crop season 2011), and Apig was found at lower concentration levels than those of Lut, with amounts oscillating between 0.08 and 0.65 mg/kg, observed for samples from

subarea 2 over the third crop season and olive oils from subarea 3 in 2011.

In the group composed by *phenolic acid*, p-Cou was the most abundant analyte. Its values (mean concentration) were found from 0.13 (in olive oils from the subarea 1 during the first crop season) to 0.22 mg/kg (which was a common concentration value for samples from subareas 2 and 3 in 2011 and those from subarea 3 in 2012).

The results obtained in this study are in good agreement with those achieved in a previous work in which the phenolic fractions of VOOs from seven north Moroccan olive growing areas were compared.[16] Also, some distinctive features of the phenolic fraction of Picholine marocaine VOOs, when compared to other Mediterranean VOOs, revealed by the mentioned work could be confirmed by the present study.

Furthermore, the study of intraregional and interannual variability of both the total and individual concentrations of the determined phenolic compounds in Meknès VOOs was carried out to evaluate the possible influence of the subarea and crop season factors on the phenolic fraction of the samples under study. Thus, an analysis of variance (ANOVA) was performed on the obtained quantitative data; the results are reported in Table 3.

Among the studied compounds, it should be pointed out that Ty, Lig Ag, and one of its isomers (isomer 3) were the analytes unaffected by both subarea and year of production factors. Furthermore, considering the influence of the subarea of origin, the examination of the results obtained by applying a post hoc test (Tukey's) showed that the total amount of the considered chemical classes seems to be unaffected by the subarea factor over the three crop seasons. However, as far as individual phenolic compounds content is concerned, we observed that in 2011, analytes such as O-Hyt, Syr, Pin, DOA, and D-Lig Agl were influenced by the subarea of origin. In 2012, the effect of subarea factor was observed for O-Hyt, D-Ald-D EA, EA, DOA, and D-Lig Agl. The third crop season, 2013, was the period with the highest number of compounds affected by the subarea factor, finding 10 compounds significantly affected ($p < 0.05$) by it, including O-Hyt, D-Ald-D EA, DOA, Methyl Ol Agl, and the six Ol Agl isomers. Despite these differences, there was no compound that could differentiate samples according to the subarea of origin, because the mean values for each variable were not significantly different ($p < 0.05$) at the same time for the three studied subareas (Table 3).

When the effect of crop season was evaluated, the ANOVA test revealed that this factor shows most pronounced influence in both the global amount of phenols (determined by families) and the content of individual phenolic analytes. Thus, olive oil samples from subarea 1 showed statistically significant differences ($p < 0.05$) for the following compounds: O-Hyt, Hyt, D-Ald-D EA, Desoxy-EA, EA, DOA, Syr, Pin, Ac-pin, Methyl D-Ol Agl, D-Lig Agl, Apig, Dehydro Ol Agl, Ol Agl, Ol Agl isomers 1, 3 and 6, and Methyl Ol Agl. When the same was made to evaluate the effect of harvest season factor on the samples from subarea 2, significant differences were found for O-Hyt, Hyt, D-Ald-EA, Desoxy-EA, EA, Syr, DOA, Lut, Ac-pin, Dehydro Ol Agl, Apig, D-Lig Agl, Ol Agl, Ol Agl isomers 2−6, and Methyl Ol Agl; in olive oils from subarea 3, crop season significantly affected O-Hyt, Hyt, D-Ald-EA, p-Cou, EA, DOA, Syr, Lut, Pin, Methyl D-Ol Agl, Dehydro Ol Agl, Apig, D-Lig Agl, Ol Agl, and Ol Agl isomer 5.

In conclusion, the work conducted here demonstrates that Picholine marocaine VOOs produced in the Meknès region could be considered as potential sources of phenolic bioactive compounds, because a total of 28 phenolic compounds (and quinic acid), belonging to five chemical classes, were identified and quantified in all of the analyzed samples. Differences were observed for the phenolic compounds under study as a function of the subarea of origin and harvest season, the latter being the most relevant variation factor. As a matter of fact, Picholine marocaine is the dominant olive cultivar in Moroccan olive-growing regions. We believe that our approach might be reasonably adopted in future studies for the comprehensive characterization of the selected variety (or any other), as well as for comparative studies of the composition of olive oils from a particular cultivar obtained in different growing areas.

	2	23 Sep 2007	silage, grain

including blocks from three batches of one-year-aged, three batches of two-year-aged, and two batches of three-year-aged Cheddar. Table 1 provides the date each block was produced, which is also the date the aging process began for each batch of cheese, and the herd's feed at the time the milk was collected. The cheese blocks were stored in vacuum-sealed packaging shielded from light at 4 °C until testing. The cheese samples were prepared for analysis by cutting off ∼50 g of each 2-lb block and removing the exterior 1 cm of cheese. The remaining 30 g piece was cut into approximately 1 cm × 1 cm × 1 cm cubes (1 g each), which were stored at −20 °C until the day of analysis (3 days maximum). Five grams of Cheddar in a 100 mL sample bottle were used for each SESI-MS analysis. Two technical replicates of each block were tested per day over a period of three consecutive days for a total of six SESI-MS measurements for each block in positive-ion mode. Additional samples were prepared for negative-ion mode SESI-MS analysis following the same procedure. In total, 48 positive-ion and 48 negative-ion SESI-MS spectra were collected.

Secondary Electrospray Ionization-Mass Spectrometry (SESI-MS). *Tuning and Standardization.* SESI-MS fingerprints were collected as previously described on a modified SCIEX API 3000 triple quadrupole mass spectrometer (for a schematic of the SESI modifications and sampling apparatus, see ref 25). To control for potential fluctuations in ionization efficiency, we used mixtures of semivolatile compounds (Table 2) for tuning the SESI operation voltage to maximize the match score between replicate spectra of the standards mixtures at the beginning and periodically throughout sample testing. For instrument tuning only, the declustering potential (DP), focusing potential (FP), and entrance potential (EP) were set at 50, 375, and 10 V, respectively, in positive-ion mode, and −50, −300, and −10 V in negative-ion mode to induce in-source fragmentation of the standard molecules. Generating multiple fragment ions from the standards mixtures provided more coverage over the mass range that was tested and created overlapping groups of ions whose relative intensities were more dependent on the operation voltage and less dependent on the gas-phase concentration of any single compound to compensate for small changes in the relative concentrations of the three individual standards in each mixture. Table 2 provides the mass-to-charge ratios (m/z) for the molecular and fragment ions that were monitored for each component of the standards mixtures, which had a minimum of 10% relative intensity in positive-ion mode and 5% relative intensity in negative-ion mode. The intensities of these fragments, relative to each other and to background peaks (m/z = 129, 149, 185 in positive-ion mode, and m/z = 42, 61, 79, 123, 185 in negative-ion mode), were recorded to measure intraday and interday variability in the SESI-MS fingerprint. Interday replicates of the positive-ion mode standards spectra had an average match score of 964 (±20), which is statistically indistinguishable from the intraday variation (969 ± 24).

Cheddar SESI-MS Volatile Fingerprinting. Cheddar samples were allowed to warm to room temperature prior to analysis. The cheese volatiles were introduced into the mass spectrometer by displacing the sample bottle headspace with CO_2 (99.99%; 2 L/min) for 2 min. Formic acid (0.1% (v/v)) and methanol (5% (v/v)) in water were used as an electrospray solution in positive-ion mode, and ammonium hydroxide (0.03% (v/v)) and methanol (25% (v/v)) in water were used for negative-ion mode, which provided the optimal ionization efficiency and stability in our system. The electrospray solutions were delivered at a flow rate of 5 nL/s through a nonconductive silica capillary (40 μm ID) with a sharpened needle tip. The DP, FP, and EP were set at 5, 350, and 2 V, respectively, in positive-ion mode and −5, −300, and −2 V in negative-ion mode to minimize in-source fragmentation for volatile fingerprints of the Cheddar samples. The operation voltage of the electrospray was ∼2.2 kV in positive-ion mode, and approximately −2.2 kV in negative-ion mode. Spectra were collected over 2 min as an accumulation of 40 scans over 20−200 m/z in single quadrupole mode. Deionized water (30 mL) at room temperature was used as the blank. The system was flushed with CO_2 between samples to prevent carryover. Tandem mass spectrometry (MS/MS) fragmentation spectra were collected for a selection of positive-ion mode peaks as an accumulation of 10 scans using 50, 375, and 10 V for DP, FP, and EP, respectively, 25−40 eV collision energy, and N_2 collision gas.

Data Analysis. Analyst 1.4.2 software (Applied Biosystems) was used for data collection and raw data processing. SESI-MS spectra were blank-subtracted and normalized to the peak of highest intensity. Spectral matching was calculated using Spearman's rank correlation analyses for the Cheddar SESI-MS fingerprints, and with NIST MS search V 2.0 software (National Institute of Standards and Technology) for the standards mixtures and MS/MS fragmentation spectra. Presence/absence analyses on a year-by-year basis were performed with the criterion that a SESI-MS peak had to have a signal-to-noise (S/N) greater than 2 in at least 50% of all of the samples in an aging category (i.e., at least 9 replicates for 1- and 2-year-aged Cheddars, at least 6 replicates for 3-year-aged Cheddars) to be considered as present. Presence/absence analyses on a batch-to-batch basis was performed with the criterion that a SESI-MS peak had to have a S/N > 2 in at least 3 (50%) of the replicates for a batch.

JMP version 10, SAS version 10 (SAS Institute Inc., Cary, NC), and MATLAB version 8.2 (MathWorks Inc.) were used for statistical analyses in this study. Principal component analyses (PCA) were performed using all experimental replicates as observations, and the

absolute intensities of the SESI-MS peaks 20−200 m/z with S/N > 2 as variables. The data were mean centered, and the range was scaled prior to PCA analysis; then, the statistical significance of the separations in PCA were calculated on a pairwise basis using two-sided Student's t tests of the principal component scores. The loading scores in principal components 1−3 were analyzed for each SESI-MS peak, and peaks with at least one loading score with an absolute intensity ≥0.7 (|LS| ≥ 0.7) were considered significant drivers of the PCA separation. To identify SESI-MS fingerprint peaks that can be used to predict the age classification of Cheddar cheeses, we performed partial least-squares-discriminant analysis (PLS-DA) of the normalized SESI-MS volatile fingerprints using all of the data for model building. In addition, PLS-DA leave-one-out cross validation was performed for the eight batch groups using all 48 samples. The correct classification rate was calculated by dividing the number of correctly classified samples by the total number of samples.

Two-sided nonparametric Mann−Whitney U-tests were carried out to identify SESI-MS fingerprint peaks that are significantly different between pairs of aging categories using a 5% significance level cutoff. The U-test z-scores were used as criteria for categorizing peaks as increasing or decreasing on a year-to-year basis. Increasing peaks have at least one z-score that exceeds the 5% cutoff (≤−1.96) for any two-year comparison, and all other z-scores for that peak must also be negative (i.e., must be less than zero; Table S2 in the Supporting Information). Decreasing peaks have at least one z-score that exceeds the 5% cutoff (≥1.96) for any two-year comparison and all other z-scores for that peak must also be positive (i.e., must be >0).

RESULTS AND DISCUSSION

SESI-MS Fingerprinting of Aged Artisanal Cheddar. *SESI-MS Volatile Fingerprints are Descriptive of Cheddar Cheese Aging.* The SESI-MS volatile fingerprints (m/z = 20−200) of one-, two-, and three-year-aged artisanal Cheddar cheeses were collected in both positive- and negative-ion modes (Figure 1) and were comprised of cheese volatiles that are Brønsted−Lowry bases and acids, respectively. Although there are volatile molecules that can be protonated or deprotonated depending on the electrospray solution, and therefore would be represented in both the positive- and negative-ion mode spectra, the information in these two spectra were considered to be complementary and have been combined into a single volatile fingerprint for each Cheddar sample. By visual inspection, the volatile fingerprints of aged Cheddar appear quite similar year-to-year, as the majority of the dominant SESI-MS peaks are present in all three ages. To quantify the similarity of the volatile fingerprints, the average Spearman's rank correlation coefficient (ρ) was calculated for the total SESI-MS fingerprint (positive- and negative-ion mode spectra) of all of the Cheddar samples. The fingerprints are well correlated within each aging period (ρ > 0.70; Table S1 in the Supporting Information), demonstrating that the SESI-MS fingerprints for the Cheddar samples are similar and reproducible.

It was hypothesized that the SESI-MS fingerprint of each aged Cheddar is unique and indicative of its aging period. A qualitative analysis of the spectral fingerprints indicates that 39% of the total peaks are uniquely present or uniquely absent in one of the aging categories (Figure 2a; Table S2 in the Supporting Information), and the unique peaks are consistently found in every batch of cheese tested in each category (Figure 2b-d; Table S2 in the Supporting Information). On the basis of these observations, it was posited that principal component analysis (PCA) could be used to cluster the Cheddar samples by their SESI-MS fingerprints (i.e., combined positive- and negative-ion mode spectra; Figure 3). Indeed, using all of the

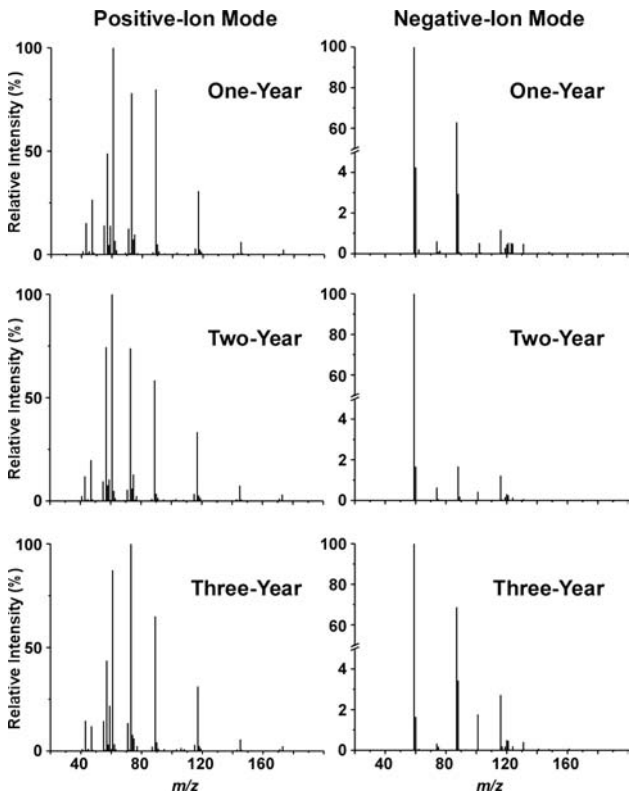

Figure 1. SESI-MS fingerprints from one-, two-, and three-year-aged Shelburne Farms Cheddar cheese in positive-ion mode (left column) and negative-ion mode (right column). The spectra are averages of 18 replicates for 1- and 2-year-aged Cheddar, and 12 replicates for 3-year-aged Cheddar, and normalized to the peak of greatest intensity in each spectrum.

SESI-MS peaks as variables and the 48 cheese samples as observations, it was found that all of the samples within an aging category clustered together and could be separated from the other aged Cheddars using the first three principal components (p < 0.0001; Table S3 in the Supporting Information). Partial least-squares discriminant analysis (PLS-DA) of the SESI-MS fingerprints was used to build a model for classifying the Cheddars by their aging periods and to identify any peaks that contributed significantly to the separation (i.e., VIP > 1.5; Table S2 in the Supporting Information). Surprisingly, it is not the peaks that are unique to an aging category that are responsible for the majority of the separation. Of the 35 peaks uniquely present or uniquely absent in the three aging groups, only 8 peaks (23%) have PCA loadings with an absolute value greater than 0.7, and 16 peaks (46%) have VIP scores greater than 1.5 (Table S2 in the Supporting Information). Looking at the data from the perspective of the 20 significant peaks in the PCA (loading absolute values ≥0.7) and the 27 peaks significant in the PLS-DA, 40% and 59% are uniquely present or uniquely absent in an aging category, respectively (Table S2 in the Supporting Information). Therefore, a large portion of the separation is generated by peaks that are shared by all of the aged Cheddars.

It was hypothesized that the shared SESI-MS peaks contribute to the statistical separation of the Cheddars due to nuances in peak intensity between the aging categories. The Mann−Whitney U-test was utilized on a peak-by-peak basis to identify SESI-MS peaks that are significantly different between each group (Figures S1 and S2 and Table S2 in the Supporting

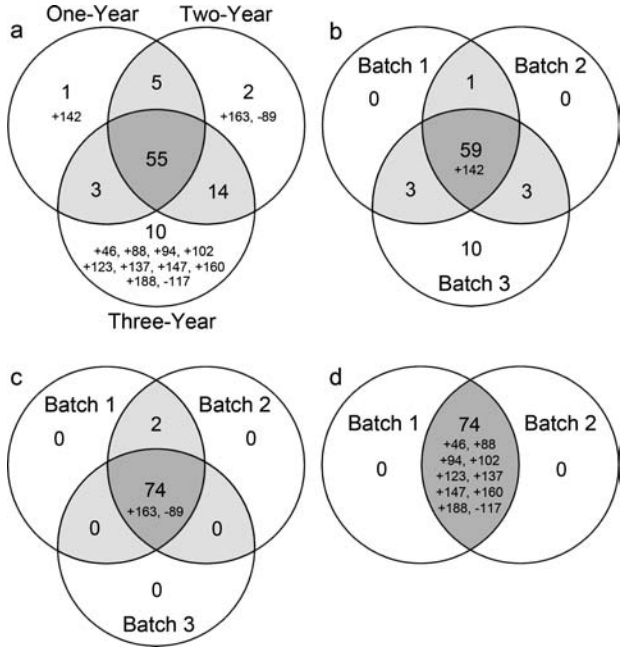

Figure 2. Number of SESI-MS peaks shared among artisanal Cheddar cheeses aged for 1−3 years. (a) Peaks shared by one-, two-, and three-year-aged Cheddars; (b) 1-year-aged Cheddar, batches 1, 2, and 3; (c) 2-year-aged Cheddar, batches 1, 2, and 3; and (d) 3-year-aged Cheddar, batches 1 and 2. Peaks were included if they were detected in at least half of the replicates for a given aging group. The mass-to-charge ratios (m/z) of peaks that are unique to a given age are listed.

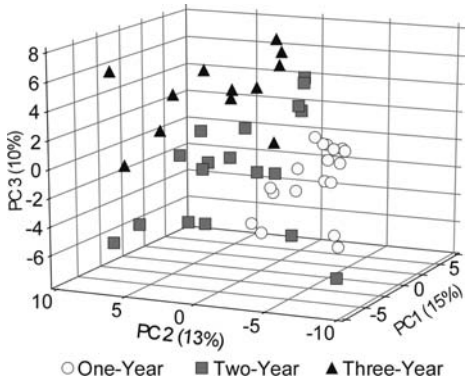

Figure 3. Principal component analysis of the SESI-MS volatile fingerprints of 1-, 2-, and 3-year-aged Cheddar cheeses. A total of 48 samples are included: 18 replicates of 1-, 18 replicates of 2-, and 12 replicates of 3-year-aged Cheddar.

Information). Of the 55 peaks in common with samples from all three Cheddar aging periods, 35 peaks (64%) have z-scores that exceed the 5% significance cutoff (≥1.96 or ≤−1.96) in at least one year-to-year comparison, eight of which also had significant loadings in the PCA and 11 of which have VIP > 1.5 in the PLS-DA (Table S2 in the Supporting Information). These data confirm that the presence and absence of SESI-MS peaks are not solely responsible for the characterization of aged Cheddars by their volatile profile. To utilize the differences in shared peaks, it is necessary to robustly measure the peak intensity (absolute or relative) in each sample day to day, and these data confirm that SESI-MS has this capability.

Peaks in the SESI-MS Volatile Fingerprint Correlate to Cheddar Cheese Aging. SESI-MS volatile fingerprints have utility beyond descriptively or predictively categorizing the Cheddar cheeses by aging period and can also be used to explore the impact of aging on the subtleties of the volatile profile. As Cheddars are aged, certain flavored components increase in intensity (e.g., sulfurous compounds) and others decrease (e.g., fresh milk-related flavor compounds);[28] therefore, it was hypothesized that a subset of SESI-MS peaks would trend over time. Of the 77 peaks in positive- or negative-ion modes that were different between any two ages of Cheddar (i.e., Mann−Whitney z-scores ≥1.96 or ≤−1.96; Figures S1 and S2 and Table S2 in the Supporting Information), we identified 26 peaks that were increased during the aging process and 11 peaks that were decreased (Table 3). For the majority of peaks, increasing intensity also correlated with increasing prevalence in the batches that were tested (or vice versa for decreasing peaks); that is, peaks that increase in intensity with age are also more likely to be measured in samples of three-year-aged Cheddars. One peak that increases with age, m/z = 95, may represent known aging-related flavor compounds in Cheddar (e.g., dimethyl disulfide (94 g/mol) and dimethyl sulfone (94 g/mol));[28] however, many of the aging-correlated SESI-MS peaks that were observed are likely not related to flavor. The flavorless compounds may still be valuable to cheesemakers, as they can be used as markers of the aging process.[29] All of the increasing and decreasing peaks that were observed contribute to the classification of Cheddars by aging period using PLS-DA (i.e., VIP > 0.8) and one-third of these peaks make very strong contributions to the classification (i.e., VIP > 1.5) and/or to the descriptive categorization of the Cheddars by PCA (i.e., |LS| ≥ 0.7; Table S2 in the Supporting Information).

There are an additional 40 peaks that have different intensities between two aging periods but do not demonstrate an increasing or decreasing trend (e.g., m/z = 101; Figure S1 and Table S2 in the Supporting Information). In some cases, the peak intensity variance is too great among these eight batches of Cheddar to confirm trends, and repeated longitudinal samples on several batches of Cheddar may be required to identify additional aging-related peaks. In other cases, it is postulated that several different compounds of the same nominal mass with unique aging-associated processes are being reported as a single peak in the SESI-MS fingerprints. MS/MS was performed on 29 positive-ion peaks (12% of the total peaks), and match scores between the fragmentation spectra indicate that the SESI-MS peaks represent the same compound(s) in >90% of the cases (Table S2 in the Supporting Information). However, the fragmentation spectra of the higher mass peaks do indicate mixtures of isobaric compounds (data not shown), and in two cases (m/z = 95 and 115), the relative abundances of the isobars appear to change year-to-year, which is reflected in the relatively low year-to-year match scores for m/z = 115 (Table S2 in the Supporting Information). Cheesemakers may find it beneficial to obtain additional information on isobaric compounds, as some will be flavored, and the nonflavored compounds may enhance or abrogate the sensory experience of the flavor volatiles of aged Cheddar.[30] Performing high resolution mass spectrometry (HRMS) or tandem mass spectrometry (MS/MS) will facilitate monitoring of additional aging-related compounds while preserving the nondestructive, rapid-analysis characteristics of SESI.[14,31]

Batches of Artisanal Cheddar Cheese Can Be Discriminated Using SESI-MS Fingerprints. The batches of aged Cheddars that were analyzed by SESI-MS are highly

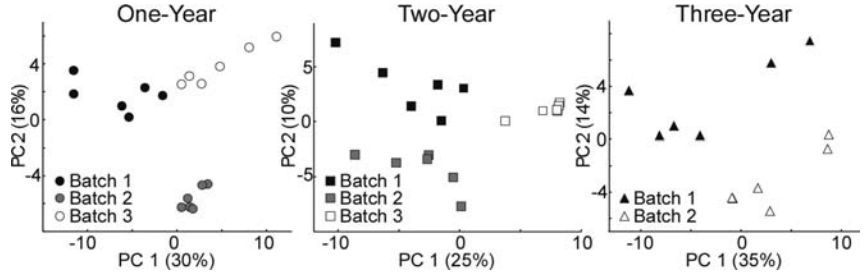

Figure 4. Principal component analysis (PCA) of the SESI-MS volatile fingerprints of batches of aged artisanal Cheddar cheeses. The two PCs providing the best separation for each age category are displayed. (a) Three batches of 1-year-aged Cheddar cheese ($p < 0.0001$). (b) Three batches of 2-year-aged Cheddar cheese ($p < 0.0001$). (c) Two batches of 3-year-aged Cheddar cheese ($p < 0.005$). Six replicates are included for each batch.

similar in their volatile fingerprint within each aging period (Figure 3; Table S1 in the Supporting Information) as well as in their flavor profiles, which met the age characteristics set forth by the cheesemakers (Table 1). However, subtle differences in the SESI-MS fingerprints of batches of the same age (Table S2 and Figure S3 in the Supporting Information) were observed, which were hypothesized to be statistically significant. Using PCA to evaluate the SESI-MS fingerprints within each age category, we observed that the six technical replicates of each batch cluster together and are statistically different from other batches of the same age (Figure 4; Table S4 in the Supporting Information). Whether the SESI-MS fingerprint could be used to identify the Cheddar samples by batch was also tested. PLS-DA leave-one-out cross validation was performed for all 48 samples in eight batch groups and obtained 100% correct batch assignments, confirming that the batches have unique volatile profiles and that SESI-MS fingerprints have the sensitivity and reproducibility necessary to discriminate highly similar samples with complex matrices. It must be noted that by testing only one sample per batch in this pilot study, it cannot be concluded whether the discrimination that was observed is on a batch-to-batch or sample-to-sample basis. However, other results from our lab indicate that SESI-MS volatile fingerprinting data can be used to correctly classify independent samples from closely related specimens.[32−35] From these previous studies and the observations presented here, it is posited that batch fingerprinting of Cheddar would be possible. Batch-to-batch variation is inherent to artisanal food production, and several variables in the milk and in the cheesemaking process impact the development of the Cheddar's flavor.[28] The cheesemakers at Shelburne Farms measure salinity, moisture, and pH and assess the overall milk quality and composition to predict the optimal aging time for each batch of Cheddar, balancing the time required to develop favorable flavor characteristics while diminishing less desirable ones. Prospectively monitoring volatile fingerprints for individual batches, and correlating early and final aging volatile fingerprints using rapid mass spectral fingerprinting techniques

J. Agric. Food Chem. 2015, 63, 4386−4392

such as SESI-MS may improve cheesemakers' ability to accurately forecast the aging time for every batch.

Through this pilot-scale study of the volatiles associated with aged artisanal Cheddar, it has been observed that SESI-MS is a robust and sensitive method for characterizing volatile mixtures arising from complex matrices. SESI-MS volatile fingerprints contain a wealth of data, and when coupled with chemometrics, the fingerprints can be mined for a variety of information on the samples' characteristics. The data suggest that SESI-MS can be employed to descriptively and predictively categorize artisanal Cheddar cheeses by their aging period, measure batch-to-batch differences in volatile profiles, and identify volatile components that are correlated with aging. Because SESI-MS is a rapid, nondestructive method for volatiles analysis, it is proposed that this technology is well-suited for quality analysis in food production and could be extended to the production of other artisanal aged products with complex flavor profiles, such as wines, spirits, and cured meats.

Marie Cook of FDACS. She described how to improve sampling quality and accuracy and elaborated on the techniques used to obtain good representative samples for analysis. After the symposium, she was invited to give a webinar for ACS-AGRO, which can be found at www.agrodiv.org/webinars/nov2014/1.html. Robert Gooding from BASF presented results from the use of microtechnology in high-throughput analysis of soil and plant samples. He emphasized factors of particle size, matrix, and analyte when choosing sample size for analysis. Kari Lynn from Dow AgroSciences presented the results from a round-robin study to assess the feasibility of a two-stage homogenization process that maintains homogeneity down to milligram level subsamples. This was independently performed by four laboratories, including Monsanto. The results demonstrated that each subsampling process (from kg to g and from g to mg) retained a comparable accuracy and precision, demonstrating 75 mg subsamples that adequately represented the original field samples processed using the advanced protocol for four analytes in six matrices tested.

The symposium concluded with a very interactive open question and discussion period, and several experts from the audience described their diverse range of experiences and findings. A main conclusion was that all milling approaches, including microtechnologies in residue analysis, should be evaluated for a given application to demonstrate acceptable performance before the protocol is applied in practice. The posters on sampling and combined uncertainties presented by Zsuzsa Farkas, who won a poster award in the IUPAC Congress, were prominently mentioned during the discussion, as were practical sample processing approaches used in regulatory monitoring laboratories in The Netherlands, United Kingdom, United States, China, India, and elsewhere.

Although the presentation rooms and poster floor were filled to capacity during the presentations, the compilation of the submitted papers published in this special section can benefit a great many residue chemists and other interested parties for years to come. The reader may not feel the same excitement from the lively discussions at both symposia, but the information in the papers should still benefit those in the pesticide analytical field who are interested in improving quality of results while saving time and cutting operating costs in the process.

needs in an efficient manner, but great caution and care are required to ensure that sample processing is properly done to provide meaningful results that lead to better conclusions and decisions.

SAMPLING

Why should laboratories care about sampling? It is easy for laboratory personnel to justify that sample collection is not their concern, but the quality of work suffers if expensive analyses are blindly conducted with no regard for the correctness of the sample and how it was obtained. Too often the sampling plan and its manner of execution are thought to be of no importance to laboratory personnel, but the final reports are often signed by laboratory staff who become liable for the quality of the findings. Just as an analyst cannot hide from the quality of his/her results when confronted with quality control (QC) findings, laboratory chemists should take ownership of their results with a holistic perspective. They should test the validity and determine uncertainties of all aspects in the process, and those responsible for sampling plans and sample collection should be held accountable to the same degree of oversight and verification to which the analysts are held accountable for their results. The tide of importance in pesticide residue analysis is rising, and analytical practices that can be likened to sand castles on the beach will not last long.

As food safety becomes increasingly complex due to far-reaching global food supplies, pesticide manufacturers are seeking to register pesticides in multiple countries and have their residue data accepted by regulators in the European Union, United States, Japan, Australia, Brazil, and many other countries. To demonstrate environmental and human health impacts, as well as the anticipated food residues, expensive field trials must be conducted. It is important that residue data generated from these studies yields acceptable trueness and precision for use in complex risk assessment calculations and statistical analyses. Regulators who enforce maximum residue levels (MRLs) must have confidence that the reported analytical results represent the true residue concentrations. Millions of dollars of perishable food shipments may be needlessly lost, causing much economic hardship to farmers and importers/exporters, if sampling leads to a false violation, or environmental and consumer safety may be compromised if actual violations are missed.

Due to the high stakes involved, food safety regulatory agencies can no longer afford to ignore the contribution of sampling to total analytical uncertainty. When data are shared between far-reaching organizations, there should be transparency and understanding of what, when, where, and how the sample was taken, and the degree of uncertainty in the analytical findings needs to be known when making inferences about the population from which the sample was taken.

CURRENT SAMPLING PRACTICES

Actually, studies involving pesticide application field trials have shown current practices to be acceptably precise (<25% RSD) if carried out according to common regulatory standards (e.g., EPA, OECD, FAO/WHO, Codex).[26−29] Similarly, sampling studies for regulatory monitoring have shown similarly good precision if enough replicate samples (≥6 from 8−12 lots) are taken, but this has been shown to depend significantly on analyte/commodity pairs.[30−33] Ambrus has recommended collecting 10−25 increments per sample, which has been shown to yield 16−25% uncertainty.[29] For a typical field trial of fruit trees, this translates into collecting samples from at least half of the trees dispersed randomly within a given plot and compositing 24 fruits per sample.[34] Sample weight can be reduced to 2−3 kg (or 4−6 lb) by taking alternate or single quarters from each fruit. Sample reduction is already taking place in the field, which makes sample transport, storage, and processing much easier in the laboratory. However, further reports in the scientific literature involving additional analytes/commodities to evaluate sample correctness and integrity would provide more confidence in whether this convenience should be followed more widely or not.

When sampling a crop from the field, U.S. Food and Drug Administration (FDA) recommends superimposing an imaginary grid on the field, dividing it into approximately 100 areas, randomly selecting 10 areas, and collecting 1 lb portions from each section. This yields 10 increments in the composite, which is typical for medium-sized crops.[35] Would it be better to take 30 increments of one-third pound each? In many cases, more increments are more representative, but this requires more effort and may or may not provide significant benefit depending on the crop and pesticide analytes. Ambrus and Soboleva found in a study of medium-size crops that increments of 5, 10, and 25 yielded RSDs of 37, 25, and 16%, respectively.[29]

Recommendations in monitoring programs for collection of fruits and vegetables range from 2 to 5 lb composites in accordance with FDA, Codex, European Commission, and Pesticide Data Program guidelines.[35−38] FDA recommends collection of 1 kg (10 units) for tomatoes, 2 kg (5 units) for cabbage, 0.5 kg for herbs, and 0.1 kg for spices. Whereas spices and herbs may warrant smaller masses, should the mass of the vegetable determine the number of increments collected (i.e., only 5 units of cabbage)? In the case of aflatoxin, FDA recommends sampling collection of twenty 1 lb units if the lot consists of fewer than 200 bags of grain, 40 units if fewer than 800 bags, and 60 units if fewer than 2000 bags. Should the size of the lot determine the number of increments, or should the number of needed increments be determined by the heterogeneity of the food being sampled and the error that can be tolerated?

Currently, most sampling plans/collections are assumed to be acceptable on the basis of theory and only a few studies, but little is done to verify the validity of the procedures in practice. At a minimum, laboratory personnel and sample collectors should meet each other and learn about their roles in the overall sampling/analysis chain and open lines of communication. Laboratories should also include the collection of replicates in their sampling protocols and periodically send a QC officer to the field to observe collection technique and collect duplicate (or more) samples of the same lots in the same way as the sample collector. The results from the duplicates can be compared to empirically measure sampling error. Just as proficiency testing results were quite poor to start (e.g., 50% RSD), current sampling practices may lead to embarrassingly high variability at first. However, recent interlaboratory proficiency test results often yield <25% RSD,[39] and the same motivations to instill better practices and performance due to peer pressure and personal responsibilities will take root with respect to sampling. Data quality improvement incentives can blossom only if the plan designers and sample collectors are held accountable in a similar way that laboratories have been held accountable for their operations.

RECENT DEVELOPMENTS INVOLVING SAMPLING

In 2011, the United States passed new food safety legislation known as the Food Safety Modernization Act (FSMA).[40] This law mandates the creation of an integrated food safety system to both prevent food safety problems (Title 1) and determine and respond to food safety problems (Title 2). Such an integrated system would require U.S. federal, state, territorial, and local food safety agencies, as well as food producers, to share information and analytical data. The law includes emphasis on the importance of sampling. The guidance to laboratories encourages laboratory accreditation, including standards for both sampling and testing (Section 202). For sampling, it mandates sampling procedures, QC systems, and trained, qualified sample collectors (Section 202 (a) (6)). The writers of the legislation recognized the need for scientifically defensible sampling as part of the goal to achieve a truly integrated food safety system.

In 2010, the FDA convened the Partnership for Food Protection to provide guidance on the many different sections of the new law. Drafted by members of federal, state, and local food and feed safety agencies across the country, the Laboratory Task Group drafted the Food and Feed Laboratories Best Practices Manual, which was published on the FDA Web site in 2013.[41] Sampling is discussed in Chapter 4, which states "Uniformity in sample collection is essential to achieve consistent laboratory analytical results between multiple federal, state and local food/feed safety agencies." The authors identified four critical elements about sampling: (1) the sampler must have policies, procedures, and records in place to ensure sample integrity security, accountability, and chain of custody; (2) the sampler must have a statistically appropriate sampling plan; (3) the sampler must undergo a training program; and (4) the sampler must be prepared to develop "incident specific" sampling plans prior to beginning collection. Note that the guidance recommends documented policies and procedures that would be consistent with any accredited program. But how are agencies to develop such plans?

In short, greater care must be taken than currently applied to sampling. Current practices are largely unchecked and lead to no guarantees. Much care is taken to collect samples that yield statistically valid results for risk assessment purposes in the Pesticide Data Program, which is conducted by several states in the United States and managed by the USDA Agricultural Marketing Service.[42] However, monitoring programs conducted by the FDA and USDA Food Safety and Inspection Service have recently been criticized by the U.S. Government Accountability Office for inadequate sampling plans and execution.[43] The USDA and FDA agreed with the report findings and will seek to address the limitations in their pesticide monitoring programs in the future. To provide more guidance and foster implementation of FSMA mandates, FDA awarded a cooperative agreement[44] jointly to three professional organizations: Association of Public Health Laboratories (APHL); Association of Food and Drug Officials (AFDO); and American Association of Feed Control Officials (AAFCO). One of 14 working groups is preparing a document, "Guidance on Obtaining Defensible Samples" (GOOD Samples), to address issues of sampling and sample processing.

GY'S THEORY OF SAMPLING

Just as a chain is only as strong as its weakest link, accuracy in sampling and laboratory sample processing is equally essential as all other aspects in the overall analytical workflow. Pierre Gy developed an extensive theory of sampling in his work with mining ores, and he literally wrote the book on the subject.[45] Pitard further explained Gy's theories and their application in practice.[46] The concepts Gy developed are universal when it comes to sampling and sample comminution for any application. Gy's theories have been applied in the cases of relatively dry food samples, such as grains and feeds, but less work has been done in other food types such as fruits, vegetables, and animal tissues. The general tenants that Gy developed apply to collections of primary samples from the agricultural fields as well as laboratory processing to produce an analytical test sample. Pitard tells us that "Sampling is correct when it gives all elements, in the batch to be sampled, a uniform probability of being selected".[46] Incorrect sampling may be responsible for large, undetected biases. Sampling theory describes the sources of variability (heterogeneity) that must be considered in the development of sampling and sample processing plans to ensure that the test portion analyzed is representative of the lot sampled and sources of error and uncertainty are reduced.

Gy asserted that both constitutional (compositional) and distributional heterogeneity are important in sampling. The greater the chemical and/or physical differences (such as density, proportion, reactivity, stability, bound state, particle shape, and range of sizes) between each fragment making up a particular analyte/matrix lot of interest, the greater the potential sample heterogeneity (both types), whether it be for the primary sample collected from the lot or the sample processed in the laboratory. Compositional (or constitutional) heterogeneity is due to the difference in composition of each fragment of the lot. Distributional heterogeneity is the manner in which separate and distinct particles or units are scattered or segregated within the lot. Distributional heterogeneity is the difference in composition of the increments (groups of particles). The greater the difference in composition of each fragment (the compositional heterogeneity), the greater is the possible distributional heterogeneity. The error that results from the compositional heterogeneity is called fundamental error (FE). Gy states that FE may be small but only zero "if the material is composed of one completely pure constituent",[45] which the residue chemist knows is rarely, if ever, true. The error that results from the distributional heterogeneity includes grouping and segregation error (GSE). One of the main components of GSE is segregation due to gravity. In residue chemistry, large compositional (relativity small test aliquot mass) and large distributional heterogeneity (segregation due to density differences) leads to large errors that must be measured and controlled.

To express the variance of FE as s^2, Gy derived the equation $s^2 = Cd^3/m$, in which d is the diameter of the largest particles (in cm), m is mass (in g) of the sample collected (or comminuted), and C is a constant (in g/cm^3) that is specific to the nature of the analyte/matrix in the lot.[45] Gy's constant is fixed by the nature of the material in the lot and refers to the compositional characteristics that cannot always be easily measured in food and feed samples but can be empirically estimated for particular analyte/matrix sample types. In practice, Gy's equation tells us that, for a particular analyte/matrix lot with a fixed C, the variance of FE due to sampling may be reduced by decreasing the size of the units (particles) within the sample and/or by increasing the mass of the sample collected. Laboratory sample reduction processes (such as

DOI: 10.1021/jf5056985
J. Agric. Food Chem. 2015, 63, 4395−4404

cutting, blending, chopping, and/or cryogenic grinding/cryomilling) all fall under the umbrella of "sample comminution".[35] Comminution is the process of reducing the particle size of a sample by grinding, blending, or other forms of pulverizing and is also commonly, but inaccurately, referred to as homogenization. We make this distinction because sampling theory states that "A set of units is homogeneous when all its units are strictly identical to each other."[46] The essence of comminution is to yield test sample portions of smaller particle size and reduce the FE. Comminution of laboratory samples never results in an entirely homogeneous sample and may, in fact, increase the distributional heterogeneity of the sample. In chemical residue analyses, the goal of the sample comminution process and the selection of a test portion is to reduce FE and provide an analytical test portion that accurately represents the original sample, composed of multiple increments, collected from a defined portion of product such as a lot of food or feed in commerce (e.g., store, slaughterhouse, warehouse, shipping container, field, crop).[16−25]

However, the relationship of density and mass changes with respect to matrix, analyte, and other sample characteristics such as analyte concentration and size/shape of fragments that are expressed by *C* in Gy's equation. Uncertainty also depends on the variability of the analyte(s) between the different fragments of the original sample. For example, aflatoxin in corn is typically less evenly distributed than common pesticides because it is more common that only a few kernels of corn are contaminated with aflatoxin, whereas applied systemic or nonsystemic pesticides tend to be present in many kernels. Thus, there must always be sufficient sample mass collected for comminution and subsampled for analysis to adequately represent the varying composition of analytes of interest in the sample.

Gy also described distributional heterogeneity, which corresponds to GSE. As an example, this can be likened to granola. Pesticides are not typically distributed evenly between the oatmeal, pecans, and crispy honey clusters (compositional heterogeneity). The small grains of crushed cereal and peanut dust also drop to the bottom. Distributional heterogeneity is changed by mixing (i.e., when you shake a cereal box, the crumbs fall to the bottom, but when you mix applesauce, the apples and liquid are more evenly dispersed.) GSE from distributional heterogeneity is reduced by correctly sampling multiple increments and combining into a single sample. An increment is the group of particles collected with one operation of a sampling tool. Each of the increments (groups) within the lot should have the same probability of being selected, and multiple increments should be taken from randomly chosen portions of the lot. The role of sampling tools is very critical to avoid sampling bias. The sampling tool must be capable of choosing all of the different fragments/particles of the lot without excluding particular particles such as clusters too large to be sampled or introducing additional bias such as missing the smaller particles or denser materials in a product sinking to the bottom or the oil on top of water being pushed to the side by a scoop. Thus, each sample should have the same relative amounts of each component (oatmeal, pecans, clusters, and crumbs) as in the lot.

Just as smaller particles settle to the bottom in a silo of grain, test samples may have differently sized particles dispersed in a container. For example, a blended slurry of tomatoes may contain liquid with more dense fragments of skin (containing the pesticide of interest), pulp, and seed in various sizes, shapes, composition and densities, resulting in a mixture of units that are more unalike than the whole tomatoes from which they were derived. The test portion that has very uniform particle size, such as may be achieved with cryomilling, may have less distributional heterogeneity and less GSE. How often do we just mix and scoop to take a test portion from a blended material? Mixing may or may not reduce distributional heterogeneity, but Gy's theory indicates that taking several smaller increments would yield a more representative test portion.

Thus, Gy's theories urge us to learn more about the physical characteristics and analyte distribution of our collected and comminuted samples. Reducing particle size and increasing mass reduce FE, and increasing the number of increments reduces GSE, but only if we have tools and techniques that allow us to achieve sample correctness.

EVALUATING SAMPLING ERROR

In multiclass, multiresidue methods for diverse commodity types, representative pesticides and matrices can be used in spiking experiments, but incurred residues in real samples provide more realistic results to validate appropriate sampling/processing standard operating procedures. To evaluate the degree of uncertainty in the overall analytical process, Lyn et al.[24] described a nested replicate design in which replicate strawberry samples were collected, each processed in duplicate, and each replicate was analyzed in duplicate. This enabled the use of analysis of variance (ANOVA) statistics to estimate the error due to sampling, sample processing, and analytical testing. This work not only demonstrated the significant contributions of sampling (38−99%) and processing (7−50%) to overall analytical uncertainty but also showed that these errors varied with respect to analyte and the source of strawberries.

Just as we conduct routine QC of our analytical methods, we can also determine the error contributed by our laboratory methods by analyzing a replicate test portion with each batch of 10−20 samples, reanalyzing samples with positive findings or analyzing multiple replicates of an incurred residue using different processing methods and analytical sample sizes during validation. Over time, these QC procedures will provide us with valuable information about the uncertainty in our procedures and help us to minimize the errors due to the sampling steps prior to our instrumental analyses.

In his chapter "Sampling for Trace Constituents", Pitard pointed out that when measuring trace level analytes, both constitutional and thus distributional heterogeneity are often very high. He stated that "analytical subsamples may be affected by a fundamental sampling error that is so high that data often show only the fraction of a constituent of interest that is finely disseminated everywhere within the product".[46] In determining whether we have achieved appropriate sample mass to control FE, Pitard describes an experiment in which 50 samples of at least 10 increments each are collected from a lot and analyzed using their whole mass. This same experiment is repeated with 50 samples of at least 10 increments each but totaling at least 10 times greater mass. If the variance is acceptably small (16−25%) when either the small or large mass is analyzed, then we have more confidence that the appropriate sample mass was collected. This same type of experiment may be performed to evaluate the appropriate mass for new processing and analysis methods. Whereas these very large experiments may be outside the capacity of many individual laboratories, it is hoped that, over time, more work will be conducted and reported in the

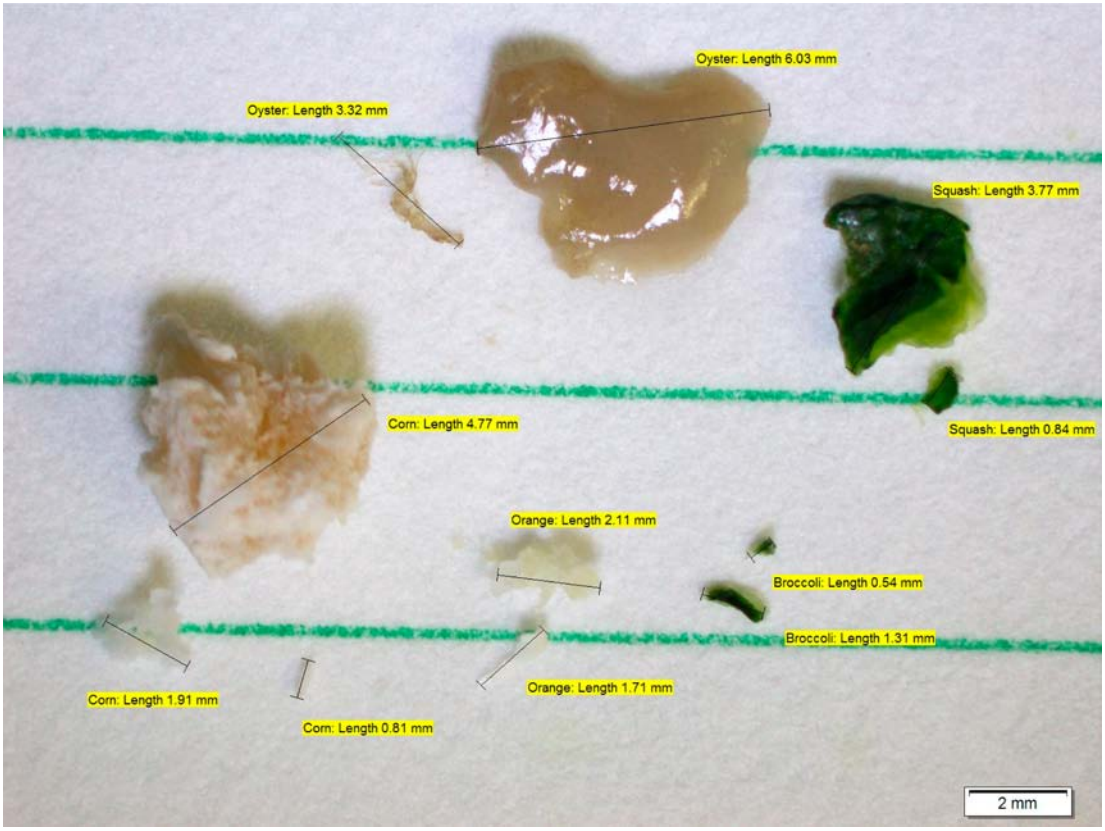

Figure 1. Example particle sizes of broccoli, corn, zucchini, squash, oranges, and oysters after room temperature blending.

literature that will inform residue chemists of sampling errors and how they may be minimized. The reader is encouraged to become more familiar with the Theory of Sampling[2,3,45,46] and incorporate it into the development of their sampling plans and comminution procedures.

■ COMMINUTION PROCEDURES IN PRACTICE

What is the smallest analytical test portion that can achieve results that represent the original sample? Before the quick, easy, cheap, effective, rugged, and safe (QuEChERS) approach to residue analysis,[48] most laboratories analyzed subsamples of 50−100 g.[47,49,50] Young et al.[23] demonstrated that ≈25 g subsamples can be representative of typical composite samples using standard FDA practices at the time.[40] On the basis of additional studies,[16,17,21] Ambrus has recommended that 30 g test samples are acceptable if traditional single-step comminution is conducted using common choppers. However, de Kok et al.[51] in the Dutch pesticide monitoring program have been using 15 g test samples since the 1980s in the mini-Luke method, a modification of the FDA PAM 302 method.[47] They still use this process and method, in which a simple two-step comminution procedure is followed: the 1−2 kg composite sample is comminuted at room temperature as in common practices,[16,17,21,23,47] and then a ≈200 g subsample is taken and thoroughly comminuted with a probe blender (e.g., Ultra-Turrax). A 15 g test portion is easily representative of the ≈200 g subsample, which is easily representative of the original 1−2 kg collected sample from the field. Meanwhile, the ≈200 g subsample is stored frozen for further analysis if needed for confirmation of a violative finding.

Similarly, QuEChERS calls for 10−15 g test samples for wet samples, and 2−5 g portions for dry samples to which water (e.g., 10 mL) is added. From the beginning, the developers have emphasized the importance of proper sample comminution when QuEChERS is employed, not only to obtain meaningful results from representative test samples but also to generate fine particles to allow better access of the extraction solvent to the pesticide analytes in the test sample.[43] For these reasons, some laboratories that use QuEChERS conduct comminution of frozen samples integrated with dry ice using vertical, s-blade choppers (e.g., Robot Coupe). Fussell et al.[19−21] evaluated cryogenic comminution for different pesticides/matrices, and their results show that in some cases, 2 g samples are sufficiently representative in a one-step process, but 10−15 g test portions are more appropriate to cover the gamut of common pesticides/matrices analyzed.

Pesticide monitoring programs in the United Kingdom and Germany have adopted the cryogenic comminution procedure and QuEChERS sample preparation. Another advantage of using frozen sample conditions is that fewer losses of analytes occur through degradation and volatilization.[18−20] However, cryogenic comminution also has disadvantages. For one, composite samples need to be frozen in chunks before comminution with dry ice, or else an eruption of CO_2 gas will occur when the dry ice is exposed to the sample at room temperature. It often takes an extra day to cut and freeze the composite samples for cryogenic processing and much freezer space depending on sample-throughput needs. Samples comminuted at room temperature in the FDA and Dutch approaches can be processed within the same day. In the case of cryogenic sample processing, there is an art in finding the right balance in the amounts of dry ice and sample, as well as the size of frozen sample chunks, in the chopper container. The amount of time given is also critical to achieve a flowing, homogeneous

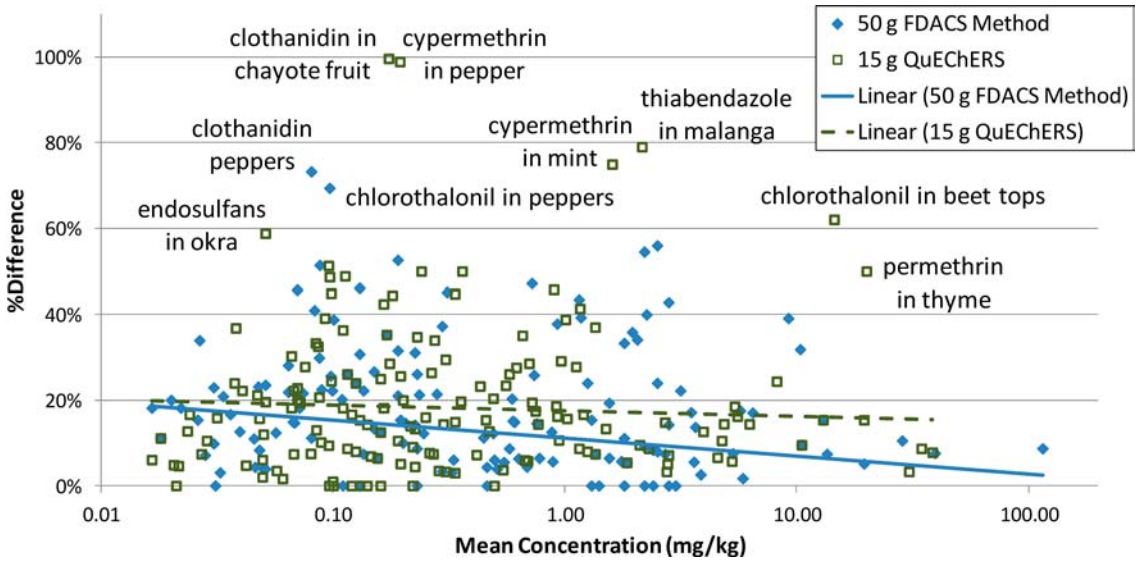

Figure 2. Absolute percent difference in results versus mean concentrations in reanalyses of 15−50 g duplicate test samples that were subsampled from ≈1 kg samples comminuted at room temperature and stored frozen until confirmatory reanalysis of potentially violative samples on a different date.

sample powder in the chopper. In a humid environment, the moisture from the atmosphere will condense in the sample to cause a low bias in the results due to added sample weight. Similarly, enough time must be given for all of the dry ice to sublime, which is typically done by placing the samples in a freezer in another time- and space-consuming step. Finally, frozen samples should be thawed prior to extraction, which allows greater access and solubility of the analytes in the extraction solvent, but to allow thawing during a longer extraction is also possible.

Disadvantages of the Dutch two-step method also include the need for worker skill/experience, particularly during the probe blender step. Cleaning of the blender and containers is more difficult when using wet samples, and care must be taken to avoid cross-contamination or introduction of water/solvent if the surfaces are not dry. Worker safety is a concern in either approach, but use of the probe blender is very noisy and requires ear protection, as well as care to avoid cut fingers, broken glass containers, and spraying of sample.

REAL-WORLD RESULTS

The aspects to consider in laboratory "sampling" (comminution) are the same as described for the field sample: more mass, smaller particle sizes, and more increments lead to less uncertainty. Unfortunately, the type of food and the analyte greatly affect the uncertainty. For example, a systemic pesticide distributed in oranges may allow 10 g highly representative test portions, but using the same comminution procedure for nonsystemic pesticides in tomatoes may need 30 g to yield the same degree of accuracy. We propose that the comminution protocol should be validated in the laboratory in a similar manner as the analytical method via replicate analyses of spiked and incurred precomminuted samples to determine pesticide recoveries and repeatabilities of test portions.

In the Florida Chemical Residue Laboratories, fresh fruits and vegetables are blended at room temperature in one step akin to the FDA protocol.[23,47] Microscopic examination of broccoli, corn, oranges, zucchini, and oysters (from Gulf Oil Spill samples) demonstrated that the particle sizes ranged from 0.5 to 6.0 mm (see Figure 1). Each sample type was quite different in consistency. For example, zucchini had two distinct layers of skin and pulp. Corn was very spongy, broccoli gave small oblong pieces, and oyster was a mixture of slimy gelatin and fibrous strings.

When screening >300 pesticides in 30 or more different types of samples in a single batch, are 10−15 g test portions adequate? Without replicate analyses of subsamples from the processed samples, the degree of uncertainty from the comminution step is unknown, but this issue is largely ignored in quality assurance programs and laboratory operations. Routine addition of replicates to a laboratory sampling, processing, and analytical scheme would allow the regulatory agency to estimate the total uncertainty in their measurement and make better decisions.

In regulatory analyses, samples indicated to be violative in the first analysis need to be reanalyzed for confirmation purposes. For indicated violative samples in the Florida laboratory, reanalyses were conducted of stored, frozen, duplicate test portions taken from the same processed samples after a period of days to weeks. Using the equation to calculate percent difference from the mean $|A - B|/[(A + B)/2] \times 100\%$, where A and B are the determined concentrations of the same analyte in the duplicate test portions, the reanalyses can be used to estimate uncertainty of the processing step in the laboratory (for the diverse range of analytes and samples monitored). Unfortunately, possible analyte degradation over time or changes in the matrix (cell disruptions, moisture gain/loss, freeze/thaw factors) also affect the consistency of results. Furthermore, the duplicate analyses were conducted on different days potentially by different analysts using different instruments. On the basis of proficiency testing results,[39] we assume that reproducibility is ≈25% RSD due to analytical and storage factors.

In all, 309 samples covering 70 different foods and 79 different analytes were reanalyzed, and determined concentrations ranged from 0.017 to 110 mg/kg. During the time period evaluated, the laboratory switched from analyzing 50 g subsamples by the Florida Department of Agriculture and

DOI: 10.1021/jf5056985
J. Agric. Food Chem. 2015, 63, 4395−4404

Consumer Services (FDACS) method[49] to their modified version of the QuEChERS method using 15 g test portions.[48] All together, 147 pesticide/matrix pair 50 g duplicates were analyzed by the FDACS method, which yielded 18 ± 15% differences, and 15 g test portions using the QuEChERS approach gave 20 ± 18% differences in the reanalyses. Figure 2 shows all percent difference results versus mean concentration in the duplicate analyses for each method. The 2% observed difference in precision did not significantly affect overall quality of results, but it reinforces the previous findings on sample comminution.[16−25]

Overall, the average percent difference was 19 ± 16% (n = 309), which can be compared with results for specific pesticides and commodities shown in Tables 1 and 2, respectively. The pesticide/matrix pairs that gave particularly variable results are listed in Figure 2, and the trend lines show the typical relationship of increasing precision versus concentration. In any case, the average 19% difference is less than the expected 25% RSD observed in interlaboratory trials for replicate analyses of proficiency test samples.[34] In general, the overall findings for many fruits and vegetables indicate that sample comminution at room temperature using common choppers to generate as little as 15 g test portions does not significantly contribute to overall uncertainty in pesticide residue analyses at violative levels. However, instances of higher variability can be observed in Figure 2 and Tables 1 and 2, which are due to a variety of factors including sample comminution.

Table 1. EVALUATION OF COMMINUTION VIA QUALITY CONTROL SPIKES

In other assessments that included sample processing, Lehotay has led two successful AOAC International Collaborative Studies (interlaboratory trials) for multiclass, multiresidue analysis of pesticide residues in fruits and vegetables.[47,48] In the first study involving supercritical fluid extraction (AOAC International Official Method 2002.03), cryogenic processing of 1−3 kg frozen chunks of apple, green bean, and carrot was conducted with dry ice, and test samples of 10 g were sent to collaborators, who further mixed the test portions with Hydromatrix for extraction and analysis of 1.9−2.6 g equivalent subsamples.[47] Similar sample processing with dry ice was conducted for AOAC International Official Method 2007.01 (QuEChERS) for grapes, lettuces, and oranges, which were subsampled into 15 g test portions.[52] In each case, Lehotay added a QC spike to determine the uncertainty of the sample processing (and subsequent) steps.

DOI: 10.1021/jf5056985
J. Agric. Food Chem. 2015, 63, 4395−4404

The sum of squares equation was used to calculate total and individual uncertainties for each step in the methods for each collaborating laboratory and matrix: $RSD_{total} = \sqrt{(RSD^2_{processing} + RSD^2_{extraction} + RSD^2_{cleanup} + RSD^2_{analysis})}$, or $RSD_{processing} = \sqrt{(RSD^2_{total} - RSD^2_{extraction} - RSD^2_{cleanup} - RSD^2_{analysis})}$. This empirical approach using QC spikes added to each step in the method can be used routinely by any laboratory to assess measurement uncertainties in method performance and pinpoint the source of problems leading to poor results. In both collaborative studies, the sample comminution step with dry ice and subsampling of 10−15 g test samples did not measurably contribute to the overall uncertainty in the methods (average $RSD_{processing} \approx 0\%$) for the given matrices and QC spikes (and incurred pesticides). In AOAC International Official Method 2002.03, average $RSD_{analysis} \approx 7\%$, $RSD_{extraction} \approx 8\%$, and $RSD_{mixing} \approx 10\%$ for average overall method RSD ≈ 15% for 16 laboratories.[47] In AOAC International Official Method 2007.01, average $RSD_{analysis} \approx 11\%$, and $RSD_{QuEChERS} \approx 9\%$ for average overall method RSD ≈ 14% for 13 laboratories.[53]

CRYOMILLING TO MINIMIZE SIZE OF TEST SAMPLES

At the IUPAC symposium, Gooding presented three case studies to demonstrate "How to verify that your comminution technique is adequate for your demands."[54] Miniaturization of test sample sizes in the laboratory eases sample preparation and analysis. In particular, agrochemical companies are striving for improved overall efficiency of operations without suffering loss of analytical quality in field trials by implementing high-throughput microextraction methods using analytical test portions of ≈0.1 g, thus enabling automation in the 96-well plate format, reduced solvent use, and reduction in time, costs, and labor.

In Gooding's Case Study 1, comminution to produce soil sample particles <350 μm was essential to microextract pesticides at 10 ng/g from three soil types. When using dry ice, it was necessary to first blend and then mill the samples to obtain a uniformly fine particle size. Milling the same original soil sample size with liquid nitrogen reduced the processing procedure to a single step. For triplicate analyses of ≈0.1 g subsamples, the %RSD values for the pesticide in sandy loam and loamy sand soils were about 25−35%, but silty loam gave RSD >100%. A small difference in matrix made a big difference in the test sample repeatability. These findings stress how important it is to validate miniaturized methods with incurred samples and validate the sample processing method as well as the analytical method. Results for microsamples should be compared with results from proven macro-sampling methods to demonstrate validity before implementation. Furthermore, we believe this should be done for every analyte/matrix pair to be analyzed.

In Case Study 2, Gooding demonstrated that when cryomilling high water content foods such as oranges, if the homogenate is warmed to room temperature before weighing, the 0.1 g test portion's measured pesticide concentration repeatability was 35−50% RSD. For cryomilled subsamples of peaches, blueberries, grapes, and plums weighed while still frozen, determined repeatabilities were <15% RSD. He cautioned that a fine and uniform particle size was not the only criteria for good results, and analyte/matrix dependency was observed.

In Case Study 3, Gooding noted the drawback when extracting microsamples that highly sensitive and precise instruments are needed to detect the concomitantly lower amount of analyte present at a given concentration. Smaller test samples translate to less analyte and greater difficulties in manipulating microvolumes. He gave an example of soil extracted in the 96-well plate format that required additional concentration of the extracts to achieve 1 μg/kg detection limits in liquid chromatography−tandem mass spectrometry (LC-MS/MS). Gooding concluded that microextraction methods increased throughput from 120 to 280 samples per person per week, but processing to a uniformly fine particle size was essential, and not all analytes/matrices met validation criteria for 0.1 g test sample sizes.

INTERLABORATORY ASSESSMENT OF CRYOMILLING

In the symposium's next presentation, Lynn detailed how three independent laboratories prepared samples using a two-step comminution procedure first entailing conventional blending of large composite samples followed by secondary cryomilling of 20 g subsamples for six matrices (soybean grain, cotton seed, whole oranges, and corn grain, stover, and forage).[55] High-throughput LC-MS/MS analysis involved 96-well plates for four different analytes (spinosyns A and D, glyphosate, and its AMPA metabolite) spiked ($n = 6$ for each laboratory) into the 20 g subsamples for each matrix. Replicate cryomilled samples were shipped to the source laboratory on dry ice for analysis of 75 mg test portions. The mean recoveries for spinosyns A and D in corn and soybean grains ranged from 87 to 123% with 6.1−7.6% RSD. Recoveries for oranges were 93−102% with 11−12% RSD. The accuracy of results was similar to analytical QC results for method spikes. Recoveries for glyphosate and AMPA ranged from 76 to 105% (6−14% RSD) for cotton seed and corn forage and stover, except for high recoveries of glyphosate in cotton seed (304 ± 24% SD) and stover (122 ± 10% SD) in cryomilled subsamples from one laboratory. Recoveries of incurred glyphosate and AMPA in corn forage ranged from 93 to 115% (8−13% RSD). In conclusion, cryomilling was reproducible across three laboratories, enabling the automation of microextraction using 96-well plates with an estimated 3−10-fold reduction in overall costs.

Pesticide registrants and contract laboratories have shown that new, 96-well plate analyses may be used in the analysis of pesticide residues in field trials, but only when validated to meet regulatory acceptability standards. To be acceptable for risk assessment and regulatory monitoring purposes, it must be demonstrated that the small test samples correctly represent the real situation in the sampled lot.

SUMMARY OF RECOMMENDATIONS

To summarize, we urge scientists conducting pesticide residue analyses to engage their samplers and include QC measures in their sampling protocols. Analysts should ensure that they are fully aware of parameters of sample heterogeneity with the goal to avoid incorrect sampling and comminution and reduce the uncertainty introduced to test samples. Validation of sampling and sample processing protocols and ongoing QC should be implemented in monitoring programs, just as such data quality assurances are required for analytical methods. If the state-of-the-art two-step comminution process using cryomilling can be demonstrated to yield acceptably accurate results for given

DOI: 10.1021/jf5056985
J. Agric. Food Chem. 2015, 63, 4395−4404

analytes/matrices of interest, then the automated high-throughput methods involving microsubsampling may be used just as any other validated protocols. The reports described above have shown this to be possible in some cases, but not in others. In any case, the dearth of publications in the scientific literature on the subject does not instill confidence among residue chemists and regulators that the described practices are ready for wider implementation. Just as the agrochemical industry led the way when LC-MS/MS was first introduced to help convince others of its attributes and validity, the analytical chemists conducting field trials for pesticide registrations are the early adopters to assess the new cryomilling and automated high-throughput approaches. For ongoing evaluations, we suggest that laboratories add QC spikes to samples prior to each step in the analytical process (comminution, cryomilling, sample preparation, and analysis) and thereby isolate these steps to assess the degree of uncertainties and help with troubleshooting if problems occur. The expenditure of so much time, effort, and expense in residue monitoring programs warrant assurances that the analytical results are meaningful for the intended purposes of regulatory registrations, enforcement, risk assessment, and other needs.

[a]This set of samples has a significantly high bias in recovery. This anomalous result was repeated across all subsamples of the site with consistent precision, and therefore it was concluded that this result is not an artifact of poor homogenization, but is more likely an error in fortification. [b]Average recovery is not within 70−120%. [c]Concentration determined by using a low-throughput method that uses 10 g of sample.

various models). Ten 20 ± 1 g aliquots of each of the primary milled tissues were weighed into plastic tubes. Four of these tubes were retained by the company laboratory, and three were sent to each of two external laboratories along with fortification solutions prepared by the company laboratory. The subsamples were fortified and secondary milled by the procedure described above and then returned to the company laboratory. A single subsample of each matrix was fine-milled without fortification to serve as batch quality controls.

For field-treated residue samples, a primary milled corn forage sample with known levels of glyphosate and AMPA was aliquoted into nine 20 ± 1 g subsamples. Three subsamples were retained by the company laboratory, and three were sent to each of two external laboratories.

After the secondary milling procedure was completed by each study site, the samples were returned to the company laboratory (either Monsanto or DowAgroSciences) for analysis by LC-MS/MS. Multiple 75−100 mg subsamples of each fine-milled sample were dispensed for analysis.

Dispensing Secondary Milled Samples. Samples that have undergone fine-milling were maintained in a frozen state to ensure homogeneity and prevent stratification. This was particularly important for higher water content samples such as forage and

oranges. Sets of samples were placed at the dispensing station on dry ice. Plastic disposable spatulas (VWR, Radnor, PA, USA) used for transferring were also chilled on dry ice prior to use. Subsamples of 75 ± 10 mg (for glyphosate/AMPA) or 100 ± 5 mg for spinosyn A/D were transferred to tared 1.4 mL polypropylene Matrix tubes (Thermo Scientific, Waltham, MA, USA). The exact sample mass was recorded and used to apply the appropriate factor for correcting sample concentration.

Analytical Methods. After homogenization and dispensing into 96-well format tubes, matrix samples were extracted and processed using validated methods. An overview of the workflow is shown in Figure 1. Within-set quality control samples assured the performance of the methods. Samples were analyzed by LC-MS/MS using electrospray ionization (ESI), and the mass spectrometer was operated in multiple reaction monitoring mode using two transitions for each analyte. Glyphosate and AMPA were analyzed in negative ionization mode, whereas spinosads A and D were analyzed in positive mode.

RESULTS AND DISCUSSION

The capability of the two-stage milling process to provide milligram scale subsamples that are representative of the field was tested by examining replicate subsamples in three phases of this round-robin study: (1) field-treated residue samples; (2) fortified samples; and (3) comparison with large-scale (5 g) samples.

The field-treated residue sample phase utilized corn forage as model RAC with field-applied glyphosate. Glyphosate and AMPA residues were previously determined at a 10 g scale using a validated analytical method. These same samples were bulk homogenized, and replicate 20 g subsamples were fine-milled using the secondary process by three independent laboratories. Six 75 mg subsamples of the fine-milled product were analyzed from each independent laboratory preparation. The results from the scaled-down assay are summarized in Table 1. The glyphosate and AMPA concentrations determined according to the new method were compared to those of the previous assay and were nearly identical (91−115%) In addition, the variability obtained using the scaled-down method ranged from 8 to 13%, well within SANCO's acceptable margin of <20%. These results demonstrate that 20 g subsamples are suitable for the secondary fine-milling to represent original primary milled bulk taken from the field in this RAC.

The fortification experiment enabled systematic examination of additional matrices across crop grouping categories using analytes that ranged in molecular weight, polarity, and charge (Table 3) to determine the effectiveness of sample comminution. The fortification approach represents the worst-case scenario, where all of the residue of the 20 g sample is fortified within a very small region, creating a "hotspot". The even distribution of this hotspot is performed solely by the secondary fine-milling process. Precision and recovery data from this interlaboratory study are summarized in Table 2.

Precision for glyphosate and AMPA ranged from 8.7 to 13.6% in corn forage, from 5.8 to 9.1% in cottonseed, and from 7.8 to 11.4% in corn stover across the three laboratories (Table 2). The recoveries of glyphosate and AMPA in cottonseed (oily matrix), corn forage (wet matrix), and corn stover (dry matrix) were mostly within the acceptable range of 70−120%. One result, the glyphosate data from the cottonseed samples prepared by laboratory B, had a significantly high bias in recovery. This anomalous result was repeated across all subsamples from that site with consistent precision (8% CV), and therefore it was concluded that this high result is not an artifact of poor homogenization.

A second pair of analytes, spinosads A and D, were chosen for testing on the basis of their dissimilarity to glyphosate and AMPA (Table 3). The fortification and milling processes were identical to those used for glyphosate and AMPA. The resulting mean recoveries of spinosads A and D in corn grain (dry matrix), soybean grain (oily matrix). and oranges (acidic matrix) were mostly within the acceptable range of 70−120%. There was a small amount of positive bias in the recoveries observed for spinosads A and D in the corn grain samples prepared by laboratory B. However, the precision values for spinosads A and D across all of the matrices tested were all <13%.

Low variability was observed in samples evaluated across laboratory sites, matrices, and analytes. Fortifying a hotspot is a worst-case scenario, yet uniformity in the sample results was still observed when a 75 or 100 mg aliquot was analyzed. Across laboratories, the % RSDs were very consistent, demonstrating the robustness of the technique across laboratories with varying degrees of experience.

The spinosad A and D recoveries and RSDs from samples analyzed in 10 g or 75 mg aliquots were compared to determine if additional variability was observed with the scaled-down assay. The 10 g aliquot samples were prepared by fortification of spinosads A and D into a 10 g aliquot of control matrix that had been primary-milled only. The 75 mg aliquot samples were prepared as described above with primary milling of the control matrix, followed by fortification of a 20 g aliquot of the matrix prior to the secondary milling step. The % RSD obtained at the 10 g scale ranged from 2.9 to 8.1 for spinosads A and D in soybean grain and was comparable to the % RSD obtained from

DOI: 10.1021/jf505249y
J. Agric. Food Chem. 2015, 63, 4405−4408

the 75 mg scale assay of 6.1−7.6%. In addition, the % RSD obtained at the 10 g scale ranged from 9.1 to 11.0% for spinosads A and D in oranges, which, again, was comparable to the % RSD obtained from the 75 mg scale assay of 10.5−12.4%. This similarity in RSD values across sampling size and milling procedure demonstrates that additional variability was not observed in the 75 mg samples beyond the innate inconsistency of the assay.

The advantages of the fine-milling and scaled-down sample size methods are a significant increase in throughput, improved quality due to a reduced risk of contamination and reduced variability, and a decrease in costs due to fewer FTE hours required due to automating the extraction, reduced reagent use, and reduced reagent disposal. The increase in throughput observed with the milligram-scale sample methods was 10 times for glyphosate and AMPA and 3 times for spinosads A and D when compared to the traditional gram-scale methods. Thus, there is a significant increase in the number of samples that can be processed in the same time interval utilizing the milligram-scale methods.

In conclusion, analysis of the field-treated samples demonstrated that the 10 g scale method and the 75 mg scale method that included a second processing step, fine-milling, gave comparable results in terms of calculated concentrations and variability. The fortified samples were prepared using analytes chosen for their dissimilar physicochemical properties, matrices that encompass the four main crop groupings (wet, dry, oily, and acidic), and laboratories with various degrees of experience with the secondary fine-milling technique. When the resulting concentration data were compared across these variables, excellent agreement in the recovery and variability values obtained was observed. Additionally, the fine-milling technique has significant advantages in increasing throughput, decreasing cost, and increasing assay quality.

sampled commodity, which indicates that the results of modeling are applicable regardless of the characteristics of the residue distribution in the sampled population. Knowledge of the uncertainty of sampling enables the calculation of combined uncertainty of residue concentrations measured in composite samples, which then can be used to test compliance with maximum residue limits as part of the premarketing self-control program of the producers.

The objective of this study is to utilize the extensive pesticide residue data obtained from supervised trials for estimation of average sampling uncertainty for all groups of fresh fruits and vegetables, primary feed commodities, and semiprocessed plant products included in the Codex Commodity Classification,[16] as well as for some individual crops for which sufficient residue data were available.

MATERIALS AND METHODS

Selection of Residue Database. For the evaluation of the within-field variability of pesticide residues of different crops and crop groups, supervised residue trials reported by the JMPR between 1997 and 2010 [8] were considered. In some of the trials, replicate samples were taken (duplicate samples in >99.95% of the cases) from the single-trial plots to get more accurate information on the average residue concentration of the treated field, according to the requirements of U.S. EPA.[17] These residue data were collected and used in our study. The selected data set contained altogether 12087 replicate sample sets (25876 individual ones), comprising 706 pesticide−crop combinations formed from 66 different pesticides and 106 commodities, referred to as "crops" in the study.

The Codex Classification of Foods and Animal Feeds,[16] developed within the framework of the Codex Committee on Pesticide Residues (CCPR), was primarily used for grouping the various crops. It takes into account, among other things, the nature of the crops and expectable level of pesticide residues; therefore, fresh and dry foods and semiprocessed foods and feeds were classified into different groups. It is intended to ensure the use of unambiguous description of various crops and to classify food commodities into groups for the purpose of establishing group maximum residue limits based on the

residues in/on representative commodities, which then can be extrapolated to the so-called minor commodities belonging to the group. In addition, we also took into account the sampling aspects in grouping of crops: for example, small-, medium-, and large-sized fresh fruits and vegetables.

The crops included in the supervised trial residue database belonged to 24 groups having similar characteristics. In addition to the determination of sampling uncertainties for individual crops, the typical sampling uncertainty was also calculated for crop groups aiming to provide initial estimates for the expectable sampling uncertainties for minor commodities, belonging to the given group, for which supervised trial residue data are not available.

Estimation of Sampling Uncertainty. The characteristic within-field variation of the residues in/on a crop is expressed as the relative standard deviation, CV. The use of CV values is more suitable than the standard deviation of the residues because the variability of pesticide residues in different data sets, expressed with their CV value, is comparable regardless of their average concentration. Previous studies revealed that the relative frequency distributions of pesticide residues are very similar and independent from the type of the pesticide (Figure 1); therefore, the average of the CV values of different data sets is considered to be the best estimate for the uncertainty of the measured residues.[18]

From the combined uncertainty of the measured residues (CV_R) and the uncertainty of the laboratory phase of the determination of residues[19] (CV_L), the uncertainty of sampling (CV_S) can be calculated as

$$CV_R = \sqrt{CV_S^2 + CV_L^2} \rightarrow CV_S = \sqrt{CV_R^2 - CV_L^2} \quad (1)$$

As the database used contained replicate samples, range statistics[20] was applied to calculate the relative standard deviation of the measured residues in one replicate sample set (CV_1), and their average was considered as the characteristic uncertainty of measured residue values in a given crop (CV_{R1}).

For replicate samples from one trial

$$CV_{R1} = \left(\frac{R_{max} - R_{min}}{\overline{R}}\right)/d_2 \quad (2)$$

where R_{max}, R_{min}, and $\overline{R}$ are the maximum, minimum, and mean residue values in replicate samples taken from one trial site and d_2 is the corresponding factor of 1.128, 1.693, or 2.059, for two, three, or four replicate samples, respectively.[21] Because the d_2 values are different, the CV values were calculated separately for replicate sample sets consisting of two, three, or four residue values, and their average was calculated afterward.

For a single *i*th commodity from k_i trials

DOI: 10.1021/jf5055112

$$CV_{Ri} = \frac{\sum_i CV_{R1}}{k_i} \quad (3)$$

The supervised trial reports include the validation data, but the details of concurrent recoveries obtained during the analysis of samples are usually not included in the FAO evaluations. Therefore, we collected the recovery data obtained during the validation of the methods used for analyzing samples from supervised trials by the specialized laboratories reported in the FAO evaluations.[8] The recovery studies were generally conducted at spike levels from 0.01 to 10 mg/kg with three to eight replicates. The CV_A obtained from the recovery studies generally ranged between 2 and 12%, with higher values up to 20% occurring in very few cases. There was no observable correlation between the spike level and the CV_A values of recoveries of various pesticide residues of different chemical structures and physicochemical properties from different sample matrices. Therefore, the weighted average of reported CV_A values was considered as the best practical estimate for the expectable variability of the results derived from the analysis phase. The results are summarized in Table 2. The grand weighted average (CV_{Aw}) of CV_A of recoveries obtained from various pesticide−crop combinations was calculated as

$$CV_{Aw} = \sqrt{\frac{\sum (df_i \times CV_{Ai}^2)}{\sum df_i}} \quad (4)$$

where df_i is the degree of freedom for the CV_{Ai} of the ith pesticide residue−crop combination.

The chopping and grinding of sample materials and their homogenization are generally carried out very carefully in the presence of dry ice, and the consequent sample processing error is usually negligible compared to CV_A.

The uncertainty of the analytical results varied from trial to trial; therefore, on the basis of the typical performance characteristic of analytical methods applied, we assumed an average value of 0.1 for the uncertainty of the laboratory phase (CV_L) and used eq 1 to get the uncertainty of sampling (CV_{S1}) from each calculated CV_{R1} value of a crop. In cases when the uncertainty of the measured residues (CV_{R1}) was lower than the assumed CV_L of 0.1, as a conservative approach, 0.1 was considered as the uncertainty of sampling. Because the sampling uncertainty was usually much larger, this assumption did not practically affect the results of our calculations.

The sample sizes (number of individual crop units or sample increments) making up a composite sample) were not systematically reported by the JMPR (Table 1). The mass of the sample is often indicated instead of the number of primary samples making up a composite sample. We assumed that the protocols of pesticide manufacturers, specifying typically large samples (24 units for small- and medium-sized and 12 for large-sized crops), were generally followed, but at least the minimum sample sizes recommended by the FAO guidelines were satisfied.[22] For official control, taking a minimum of 10 primary samples for small- and medium-sized and 5 for large-sized crops, respectively, is recommended according to the relevant Codex standards;[14] therefore, the CV_{S1} values calculated for each crop in supervised residue trials were adjusted with a factor of 1.55 ($f = \sqrt{24}/\sqrt{10} = \sqrt{12}/\sqrt{5} = 1.55$) based on the central limit theorem (eq 5), which is applicable for the far from normal distributions of residues in primary crop units (CV_{prim}) according to the study of Horváth et al.[23]

$$CV_n = \frac{CV_{prim}}{\sqrt{n}} \quad (5)$$

The adjusted CV_{S1} values (CV_{S1adj}) were calculated as

$$CV_{S1adj} = CV_{S1} \times f \quad (6)$$

The characteristic sampling uncertainty, CV_S, of a crop group consisting of i crops is calculated from the pooled variances of the CV_{S1adj} values of the crops belonging to one group, without excluding any $CV_{S1adj,i}$ values. For instance, for the group of small fruits (sf)

$$CV_{Ssf} = \sqrt{\frac{\sum (df_i \times CV_{S1adj,i}^2)}{\sum df_i}} \quad (7)$$

Calculation of Confidence Limits with Chi² Distribution. The confidence intervals of the sampling uncertainties, the upper and lower confidence limits of CV_S and CV_{S1adj} values were calculated by applying the Chi^2 distribution:

$$LCL = \sqrt{(df \times CV_S^2/\chi_{0.975})} \quad (8)$$

$$UCL = \sqrt{(df \times CV_S^2/\chi_{0.025})} \quad (9)$$

df, the degree of freedom, is the number of replicate sample pairs of a crop or a crop group, and $\chi_{0.975}$ and $\chi_{0.025}$ are the tabulated values for the 97.5th and 2.5th percentiles of the χ^2, distribution, respectively. The χ^2 values were calculated with linear interpolation in cases where they were not available to the corresponding df. [24]

Calculation of Confidence Limits by Using the Results of Modeling Experimental Data. According to the results of our previous study,[15] the 95% relative confidence interval of the sampling uncertainty is independent from the relative standard deviation of the measured residues in the sampled commodity, and it decreases with the increasing number of lots sampled. The modeling was carried out with only up to 20 independent lots to determine the confidence intervals of the CV_{S1adj} values. However, in the case of supervised residue trials, the number of trial sites from which replicate samples were taken amounted to over several hundred; therefore, the modeling has been performed again with the same methodology utilizing 182 primary residue data sets obtained from commercial lots[12] or specifically designed field trials: (1) 19 residue data sets,[15] each consisting of 104−120 residue values, comprising the combinations of 7 different pesticide active ingredients present in carrot or parsley leaves. (2) 68 lots, assumed to contain crops of the same origin, imported from various countries or grown locally in the United Kingdom were selected in logistic centers, and 100−100 individual fruits were randomly taken from each lot. The fruits were analyzed with multiresidue methods to detect all residues present in the fruits. The 68 data sets comprised apple, banana, kiwi, orange, peach, plum, potato, and tomato.[12] 24 different pesticide residues were detected in the samples. (3) 95 data sets were obtained from a coordinated research program, including field studies, to determine residues in individual items of leafy vegetables, small and large crops in 13 countries, representing the actual agricultural practice worldwide. Twenty-five pesticide active ingredients were analyzed from black currant, cherry, cabbage, chicory, kale, cucumber, grape, lettuce, mango, papaya, strawberry, and zucchini samples.[13]

10−10 residue values were selected with random sampling procedure with replacement 1000 times from each of the 182 primary residue data set. The average of the 10 randomly selected residue values were calculated and considered as the residue concentration in one composite sample. The procedure was repeated two times to obtain two databases for assessing the effect of taking duplicate samples to reflect the situation of the supervised trials database, containing mostly duplicate samples. The CV values were calculated from the composite samples with eq 2, applying the corresponding factor of 1.128.

Calculation of 95% Confidence Limits. The P0.025 and P0.975 percentiles of ranked CV values calculated from 1000 duplicate samples drawn from each of the 182 individual primary residue populations and the corresponding average CV values were taken to calculate the relative confidence intervals from one data set:

$$CI_{rel,i} = \frac{CV_{P0.975} - CV_{P0.025}}{\overline{CV_i}} \quad (10)$$

As shown in our previous study, the calculated confidence intervals are independent from the CV value of the parent population.[15] Figure 2 shows the fitted curve for the 95% relative difference of the CV values obtained from the 1000 duplicate composite samples generated from the 182 lots. The regression equation obtained was ($R^2 = 0.981$)

[a]N, number of commodities considered. [b]k, number of replicate sample sets used for estimation of CV_S. [c]CV_S, relative standard deviation of residues in composite samples meeting the minimum sample size requirements of the Codex sampling procedure. [d]UCL_{mod}, upper 95% confidence limit of the estimated sampling uncertainty (CV_S) calculated with the new approach.

$$CI_{rel,i} = 2.4679k^{-0.439} \quad (11)$$

Equation 10 was used for the estimation of the relative confidence intervals for the calculated CV_{S1adj} and CV_S values taking into account the number of trial sites (number of replicate sets, k). The absolute confidence intervals, CI_{na}, were calculated by multiplying the relative confidence limit values with the estimated average CV_{S1adj} and CV_S values. The estimated relative confidence intervals, obtained from the modeling experiment, were somewhat larger than those calculated with eqs 8 and 9. The upper confidence limit based on modeling (UCL_{mod}) was calculated proportionally to that obtained from Chi^2 distribution to take into account that CV_S-LCL < UCL-CV_S due to the asymmetrical nature of Chi^2 distribution. The calculation of UCL described above is called the "new approach".

To evaluate the effect of the number of lots randomly selected for estimation of the sampling uncertainty and its upper confidence limit as well as to assess the reliability of the estimated relative confidence intervals, an additional modeling has been made. From the 182 primary sample data sets, 4, 8, 16, and 20 were chosen independently 15 times, and the CV_S values and their relative confidence intervals were calculated from each of the duplicate composite samples drawn from them. In the cases of 16 and 20 lots, when the 182 data sets of CV values were not enough to get 15 repetitions, the 16 and 20 lots were selected following a random order of the data sets.

RESULTS AND DISCUSSION

The grand average of 8.56% calculated from 6467 recovery studies (Table 2) covering the most frequently occurring residue ranges of 0.01−10 mg/kg and the five typical commodity categories recommended for performing recovery studies as part of the method validation[25] can be considered as a good estimate for the expectable uncertainty of the analysis (CV_A) of residues. The average CV_L of 10% used for the calculation of CV_S from CV_R (eq 1) includes an allowance for sample processing CV_{SP} of 5.17%, which generally covers the contribution of sample homogenization procedures applied by the specialized laboratories analyzing samples from supervised trials.

The uncertainty of sampling was determined for 106 individual crops (Table 3) and 24 different crop groups

DOI: 10.1021/jf5055112
J. Agric. Food Chem. 2015, 63, 4409−4417

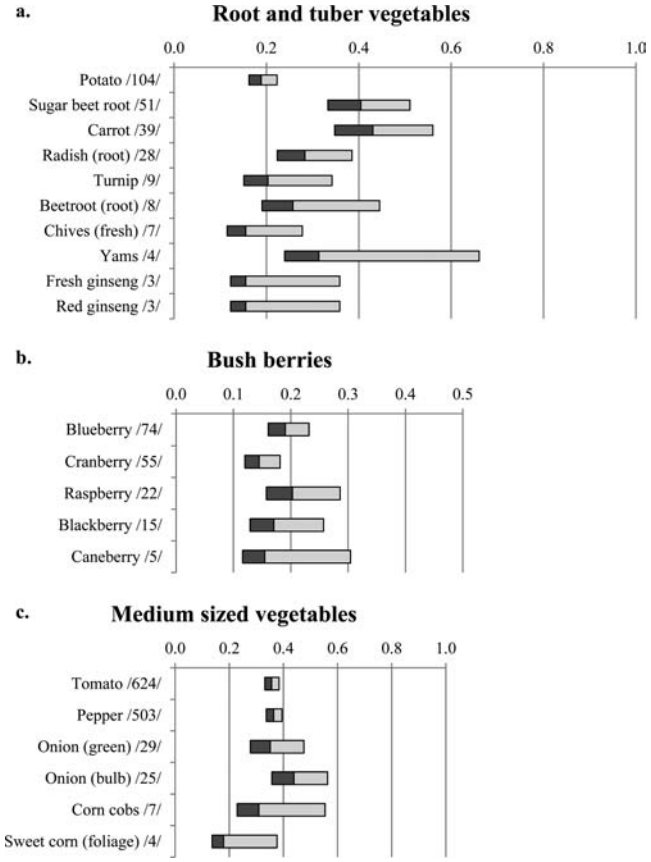

Figure 3. Confidence intervals of CV_{S1corr} values calculated with the new approach of crops belonging to root and tuber vegetables, bush berries, and medium-sized vegetable crop groups. (Number of samples sets is given within slashes.)

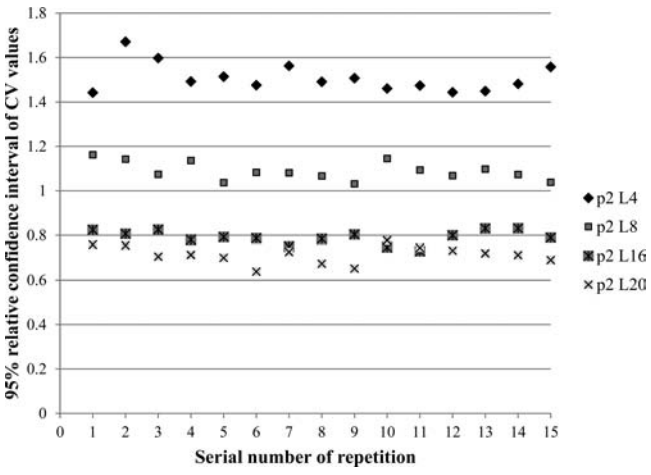

Figure 4. Variation of relative confidence intervals of the CV values calculated from two replicate samples (p2) from 4, 8, 16, or 20 lots independently selected up to 15 times.

(Table 4) based on the supervised residue trial data by applying the methods described above. The lower and upper confidence limits calculated on the basis of Chi^2 distribution and with modeling using 182 independent primary residue data sets are very similar, but the confidence intervals obtained with the new approach are somewhat larger as can be seen in Table 4. Examples of CV_{S1adj} values and confidence intervals of crops belonging to various crop groups calculated with the new approach can be seen in Figure 3. The range of the confidence intervals depends on the number of replicate sample sets, and it is increasing with decreasing number of sample sets used for calculation of CV_S (Figure 3).

The modeling experiments carried out for assessing the effect of data sets on the estimated sampling uncertainty and their confidence limits revealed (Figure 4) that they are robust and only minimally affected by the concentration level and distribution of residues in the lots from which the samples were taken. The relative standard deviations of the calculated confidence intervals from 15 repetitions were 4.3, 3.8, 3.9, and 5.5% in the cases of 4, 8, 16, and 20 lots, respectively, with an average value of 4.4%. This finding is in agreement with the previous experiments[15] showing that the relative confidence interval is practically independent from the variability of the parent population.

Taking into account the potentially serious consequences of an underestimated sampling uncertainty, as the largest contributor to the combined uncertainty, and to get reliable results when testing the compliance of a product in at least 95% of the cases, we recommend using the upper confidence limit of the estimated sampling uncertainties calculated with the new approach in practical applications.

Previous studies[15,26] indicated that sampling uncertainty values calculated from a minimum of eight lots can be considered as a borderline for acceptable estimate, as below that the confidence interval is getting very large. Therefore, where the number of sampled lots was <8, the estimated CV_S values are not indicated in Table 3; however, they were taken into account in the calculation of CV_S value of the corresponding crop group (Table 4). It is noted that, due to the small value of k, they practically do not affect the weighted average CV_S value.

In view of the large confidence intervals in cases when the number of tested lots is between 8 and 20, the sampling uncertainty results should be considered as temporary estimates, and they should be refined and revised when more information is available. In such borderline cases, the risk manager or other responsible person may decide whether to use the sampling uncertainty value belonging to an individual crop (Table 3) or a crop group (Table 4), but taking the UCL as the sampling uncertainty is recommended in all cases.

ACKNOWLEDGMENTS

We greatly appreciate the invitation of S. Lehotay, M. Krolski, J. Sandahl, J. Jenkins, and C. Harris, organizers of the *Poster Session on Residues in Food and Feed Monitoring Results and Dietary Risk Assessment* of the 13th IUPAC International Congress of Pesticide Chemistry, to publish the detailed results of our work in this special issue.

ABBREVIATIONS USED

CV, coefficient of variation (relative standard deviation); CV_R, combined relative uncertainty of the measured residues (in general); CV_L, relative uncertainty of the laboratory phase of the determination of residues including subsampling, sample

DOI: 10.1021/jf5055112
J. Agric. Food Chem. 2015, 63, 4409−4417

processing and the analysis phase of the determination [16]; CV_A, relative uncertainty of the analysis phase of the determination of residues including, for instance, extraction, cleanup and quantitative determination; CV_{Aw}, weighted average of relatives standard deviations of replicate recovery sets; CV_S, relative uncertainty of sampling (in general and in case of crop groups); CV_1, relative uncertainty of the measured residue values calculated from replicate samples from one trial; CV_{R1}, combined relative uncertainty of the measured residue values regarding one crop; CV_{S1}, relative uncertainty of sampling regarding one crop; CV_{S1adj}, relative uncertainty of sampling in case of composite samples meeting the minimum sample size requirements of the Codex sampling procedure; CV_{Sprim}, relative sampling uncertainty of residues in primary (incremental samples); CI, confidence interval; CI_{rel}, 95% relative confidence interval; CI_{na}, confidence interval calculated from the results of modeling experiments (called "new approach"); *k*, number of replicate sample pairs; LCL, lower confidence limit (2.5th percentile); UCL, upper confidence limit (97.5th percentile); UCL_{mod}, upper confidence limit calculated from the results of modeling experiments ("new approach")

authorities are generally the same or very similar to those given in the relevant Codex Standards, such as for pesticide residues.[6]

The objective of this paper is to show that available data on the uncertainty (variability) of pesticide residue measurement results may be used in the process of certification of compliance with MRLs. The principles described are also applicable for other chemical contaminants.

EXPERIMENTAL METHODS

Estimation of Combined Uncertainty of the Measured Residues. The combined relative standard uncertainty (expressed as relative standard deviation or coefficient of variation) of the residues measured in composite samples (CV_R) can be expressed as[25]

$$CV_R = \sqrt{CV_S^2 + CV_{SS}^2 + CV_{SP}^2 + CV_A^2} \quad (1)$$

It incorporates the uncertainties of sampling (CV_S), subsampling (CV_{SS}), sample processing (CV_{SP}) (chopping, mincing, and homogenization of analytical sample), and analysis (CV_A). The methods for estimation of sampling uncertainty have been described in detail in previous publications;[7,8,26] therefore, they are not repeated here. When the contribution of uncertainty of subsampling and sample processing is included in the estimated uncertainty of the laboratory phase of measurement (CV_L), the two phases of the process can be distinguished as

$$CV_R = \sqrt{CV_S^2 + CV_L^2} \quad (2)$$

$$CV_L = \sqrt{CV_{SS}^2 + CV_{SP}^2 + CV_A^2} \quad (3)$$

It is noted that the CV_L should always be determined either from retained test portions of the laboratory samples that contain incurred residues[10] or after treatment of the surface of the individual crop units with the test compound.[14] Furthermore, the results of collaborative studies or proficiency tests can provide information only on the uncertainty of the analytical procedure (CV_A) from the point of extraction and not for the combined uncertainty of the analytical results (CV_L), as the appropriate homogeneity of those samples had been carefully checked before distribution to the participants.

Principles of Control of Compliance of Food Commodities with the Legal Limits. As the consequence of the definition of MRLs, there are two distinctly different situations in the control of compliance of food commodities with the legal limits. Different sampling plans are required for testing compliance with MRLs of pesticide residues in commodities before and after marketing.

Control of Commodities on the Market (Enforcement or Monitoring Program). As the permissible maximum concentrations of residues and chemical contaminants apply to the average concentration of the substances in the bulk/laboratory sample, the combined uncertainty of the laboratory phase of the determination of the residue concentration (CV_L) shall be taken into account in deciding on the compliance or noncompliance of the sampled product. If the samples taken satisfy the minimum requirements for the number of primary samples and the mass of the laboratory/bulk sample,[6] the average residue determined in the sample provides the basis for deciding on the acceptability of the sampled lot. To make regulatory action in accordance with the relevant ISO and Codex guidelines,[27,28] among other regulatory agencies, the European Commission (EC) regulations clearly indicate that a lot is considered noncompliant if the measured analyte concentration corrected for recovery, when it should specifically be considered, minus 2 times the expanded uncertainty of the results is above the legal limit. For pesticide residues the default combined relative uncertainty reflecting the CV_L value (eq 3) is defined as 25%.[29] This means that a lot could be rejected if the residue measured in the composite sample taken from the lot would be >2 × MRL. We call this concentration the decision limit (DL). Figure 1 illustrates the situation when the MRL is 0.2 mg/kg and the apple lot (mean of 0.1 mg/kg and CV_R of 0.35) would be tested on the market applying the decision limit of 0.4 mg/kg (0.4−2 × 0.25 × 0.4 = 0.2 mg/kg) as defined by the EC. Under this condition a testing laboratory would reject a lot containing residues ≤0.2 mg/kg in 2.3% of the cases, because the dispersion of analytical measurement results can be considered normal.[30]

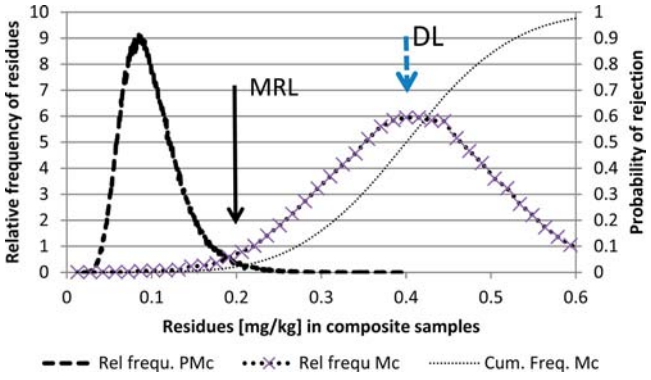

Figure 1. Distribution of residues in composite samples taken as part of the premarketing self-control (PMc) and distribution of analytical measurement results assuming a CV_L of 0.25 and measured residue of 0.4 mg/kg (decision limit, DL). The cumulative frequency of analytical measurements (Cum. Freq. Mc) indicates the probability of rejection of the lot based on the random error of the analysis.

Premarketing Self-Control. When the product is tested before it is placed on the market, it should be certified that at least a specified proportion of the product in terms of the minimum size and mass of bulk/laboratory sample complies with the legal limit. In this case the combined uncertainty (CV_R) including sampling uncertainty shall be taken into account, and the measured value should not be directly compared to the MRL as it may allow a product to be placed on the market with a substantial proportion containing the contaminant above the permitted limit. Let us assume that the MRL is 0.1 mg/kg and the average concentration of a pesticide residue is also 0.1 mg/kg in the sampled lot. If the measured residue in the sample taken from the given lot is <0.1 mg/kg, the sampled lot would be declared to be compliant. However, the decision would be correct only in about 56% and would be wrong in 44% of the cases as indicated by the cumulative frequency distribution curve in Figure 2. Therefore, a lower concentration must be selected as the action limit (AL), which should not be exceeded by the residue measured in the sample. The AL can be calculated by taking into account the combined relative uncertainty of the measured value (CV_R) (eq 1) and the targeted level of compliance.

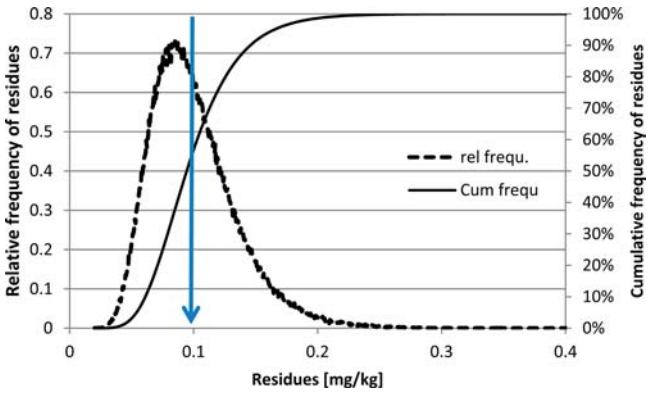

Figure 2. Distribution of residues in apple composite samples with a true mean of 0.1 mg/kg and CV_R of 0.35. MRL = 0.1 mg/kg.

The relationship of AL and MRL can be described with the following equations:

$$AL + k \times CV_R \times AL = MRL \quad (4)$$

DOI: 10.1021/jf505512h
J. Agric. Food Chem. 2015, 63, 4418−4428

$$AL = \frac{MRL}{1 + k \times CV_R} \quad (5)$$

The value of k depends on the agreed acceptable violation rate (P_V) or the compliant proportion of the lot, P_C, relative to the minimum sample size specified in the corresponding regulation ($1 - P_V = P_C$). For normal distribution, which may approximately be assumed with samples of size ≥25 for fruits and vegetables, k is equal to the corresponding standard normal variate, Z. A normal distribution may also be assumed for liquid materials and processed products, such as tomato puree. It is pointed out that in other cases the relative frequency distribution of pesticide residues can be best described with a log-normal distribution.[1]

Calculation of AL for Given Acceptance Probability at MRL. If the distribution of x_i can be described by the log-normal function, then the transformed variable $y_i = \mathrm{Ln}(x_i)$ is normally distributed. If the distribution of x_i has a mean (m) and standard deviation (s), then the distribution of the transformed variable y_i has a mean (M) and standard deviation (S). M and S can be calculated from m and s using the equations

$$M = \mathrm{Ln}\left(\frac{m^2}{\sqrt{(s^2 + m^2)}}\right) \quad (6)$$

$$S^2 = \mathrm{Ln}\left(\frac{s^2}{m^2} + 1\right) \quad (7)$$

Because y_i is normally distributed, the probability P_i (0.0−1.0) for any value y_i occurring from a distribution with mean M and standard deviation S can be calculated from normal distribution tables using the standardized equation

$$Z = \frac{(y_i - M)}{S} \quad (8)$$

$$y_i = M + Z \times S \quad (9)$$

In the sampling domain, m takes on the value of the legal limit MRL and x_i takes on the value of the AL. Typically $x_i \leq m$ (AL ≤ MRL); therefore Z will vary from zero to a negative value usually between 0.0 and −3.5 based upon the specified acceptance probability (acceptable violation rate), P_V. Once m and s are transformed into M and S and the acceptance probability (that will define Z) is specified, y_i can be determined from eq 9. Then x_i can be calculated by transforming y_i back to x_i.

$$x_i = \exp(y_i) \quad (10)$$

x_i is the AL in the linear scale.

RESULTS AND DISCUSSION

Comparison of Sampling Uncertainties Estimated from Supervised Trials and Commercial Field Samples. On the basis of the limited data available, the average sampling uncertainty for primary samples, CV_{Sprim} of 0.78, 0.81, 0.74, and 0.45, were estimated for residues in crop units of a small-, medium-, and large-size crops and *Brassica* leafy vegetables, respectively.[7] Additional residue data measured in carrot and parsley enabled the estimation of CV_{Sprim} values of 0.59 and 0.60, respectively.[8] Duplicate samples taken from 12087 supervised trials carried out in 106 different crops treated with 66 different pesticides provided the best available database for estimation of uncertainty of sampling.[31] The supervised trials are carried out usually on small scale with strictly controlled conditions for the application of pesticides. They aim to provide information on the maximum residues that can occur on treated crops under the critical use conditions [shortest interval between last application and harvest (preharvest interval), highest permitted dose, and application frequency] specified in the registration or use permit documents.[32] Consequently, these trials may not reflect the within-field residue distribution that occurs when the pesticides are applied according to the general agricultural practice. Table 1 summarizes the estimated sampling uncertainties obtained from the databases consisting of residues in/on primary samples, which were taken from fields treated according to normal farming practice and from supervised trials. The CV_S values were calculated for the minimum size of composite samples (12) specified by the Codex Standard for sampling plant products.[6] In Table 2 the sampling uncertainties calculated from residues in samples taken from commercial fields and from supervised trials are compared. The relative sampling uncertainty of residues in field composite samples (CV_{CS}) was calculated from four replicate samples and for supervised trials mostly from duplicate samples with range statistics.[8] The same tendency was observed in both cases. As the number of data sets from which the CV values were calculated greatly varies and the sample sizes in supervised trials had only sometimes been reported, precise comparison of the variability of residues in supervised trial and field samples could not be done. Therefore, the averages of CV ratios (1.15 and 1.19) are considered to be the best indicator of the difference in the variability of residues. Exceptions are papaya, strawberry,

[a]Data sets: 1, wheat, barley straw pyraclostrobin; 2, tomato endosulfan; 3, cucurbits propamocarb; 4, potato aldicarb; 5, soybean glyphosate; 6, propamocarb lettuce; 7, cereal grains prochloraz; 8, MLE fitted prochloraz in wheat and barley straw; 9, synthetic log-normal distribution with mean of 50.41 and CV of 0.29; 10, synthetic log-normal distribution with mean of 1.01 and CV of 0.69; 11, synthetic log-normal distribution with mean of 1.03 and CV of 1.39. The selected data sets contained no residue below the LOQ value, except data set 8 in which the 27 values below the varying LOQs of 0.1 mg/kg (6), 0.05 mg/kg (19), and 0.02 mg/kg (2) were replaced with the maximum likelihood procedure assuming log-normal distribution provided by Villanueva.[34]

cabbage, carrot, and parsley for which the ratios of relative sampling uncertainty of composite samples taken from supervised trials and relative sampling uncertainty of residues in field composite samples (CV_{CS}/CV_{Stcs}) are within the range of 0.44 and 0.70. The low variability in field trials cannot be explained on the basis of the available information. As it is quite unlikely that supervised trials lead to higher variability of residues than field trials, these values were disregarded.

Taking into account the uncertainties of the estimations, a rounded correction factor of 1.2 is used to account for the larger variability of residues in field samples.

Effect of Number of Residue Values below the LOQ on the Estimated Sampling Uncertainty. The range of residues in primary samples taken from a single field is typically hundred-fold. Depending on the average residue and the limit of quantification (LOQ) of the analytical method, various proportions of the primary samples may not contain detectable residues. The proportion of residues below LOQ is not known. The effect of the LOQ values in relation to the average of residue data population was studied with experimental supervised trial data[1] and synthetic log-normal distributions, as it was found that the within-field distribution of residues in crop units (primary samples) can be best described with log-normal distribution.[2] Of the supervised trial residue data sets, compiled by the FAO WHO Joint Meeting on Pesticide Residues for estimation of MRLs, those were selected that contained a relatively large number of data points. The descriptive statistical parameters of the selected data sets are summarized in Table 3. The selected data sets contained no residue below the LOQ value, except data set 8, in which the 27 values below the varying LOQs were replaced with the maximum likelihood estimation (MLE) procedure assuming log-normal distribution provided by Villanueva.[33] The residue values were also normalized by dividing them with the corresponding average residues of their data set to assist comparison of the spread of residues in the data sets with different mean residues.

For studying the effect of LOQ (mg/kg) values on the CV of the data population, the selected data sets were arranged in increasing order. The lowest number of residue values

corresponding to the selected percentage of the original data population (10−90%) was replaced with various LOQ values ranging from 2 times the reported LOQ to 0.7 average residues in the data set. These data sets are called adjusted data sets. For instance, in the case of data set 1, the lowest 11 values (0.03, 0.06, 0.07, 0.09, 0.09, 0.1, 0.1, 0.11, 0.12,0.12, and 0.12) were replaced with 0.04, 0.2, ..., 1.16) and then the descriptive statistical parameters were recalculated for each adjusted data set. The process was repeated with 20% of the residue values in the original data set and so on.

The percentage of residue values below the LOQ and the value of LOQ affect the average and the relative standard deviation of the original residue population (CV_O). The relationships of the corresponding CV and average residue of the adjusted data sets are complex, and they are best illustrated graphically. Figure 3 shows the ratios of the CVs of adjusted

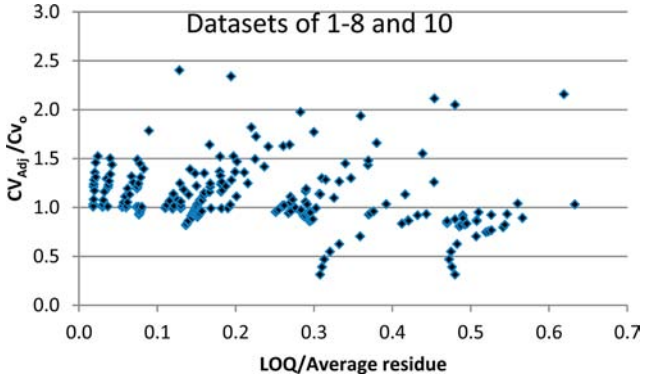

Figure 3. Relationship of the ratio of the CV values of adjusted (CV_{Adj}) and original (CV_O) data sets and the LOQ/average residue in the adjusted data sets 1−8 and 10.

data set (CV_{Adj}) and the original data set (CV_O) as the function of the ratio of LOQ and the average residue ($\overline{R}$) of adjusted data set ($LOQ/\overline{R}$). Figure 4 illustrates the CV_{Adj}/CV_O relationship as the function of the $LOQ/\overline{R}$ residues and the percentage of residues at or below the LOQ obtained from the data set 8 (Table 3, MLE fitted prochloraz residues). As similar $LOQ/\overline{R}$ residues could be obtained from various combinations of LOQ values (Figure 4) and their percentage proportion in the adjusted data sets, the CV_{Adj} values corresponding to $LOQ/\overline{R}$ ranges from ≤0.03 to ≤0.7 were grouped and the averages of $LOQ/\overline{R}$ and the CV_{Adj}/CV_O values being in the given ranges were calculated. The results obtained from the supervised trials and synthetic data sets are shown in Table 4. The results

indicate certain variation among data sets, which is attributed to the distribution of residues within the individual data sets and sampling uncertainty. As the typical sampling uncertainties were obtained from data sets with detectable residues, they do not represent the situations where the various proportions of the treated crops may contain residues below the LOQ. The probability of finding primary samples with nondetectable residues increases as the $LOQ/\overline{R}$ increases. However, no general tendency in the relationship between the $LOQ/\overline{R}$ and CV_{Adj}/CV_O could be established. The grand averages of CV_{Adj}/CV_O up to $LOQ/\overline{R}$ < 0.45 and <0.7 were 1.08 and 1.12, respectively (Table 4). Therefore, it is recommended that an adjusting factor of 1.1 be applied to account for the potential nondetects in the primary units of the sampled crop.

Effect of Mixing Commodities with Different Average Residues. Mixing commodities containing contamination above the legal limits with lots containing no or low level of contamination is not permitted by law.[34] However, it often

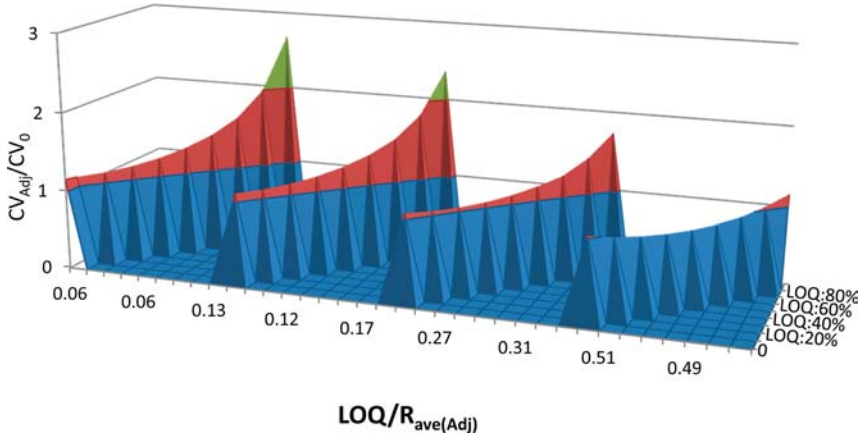

Figure 4. Relationship of CV_A/CV_O as a function of $LOQ/R_{av(A)}$ and percent of residues at LOQ in the case of data set 8 (prochloraz residue in cereal grains).

J. Agric. Food Chem. 2015, 63, 4418−4428

occurs or might occur in practice. Figure 5 illustrates the residue distribution in mixed and not-mixed products. It can be clearly seen that mixing substantially increases the spread of residues.

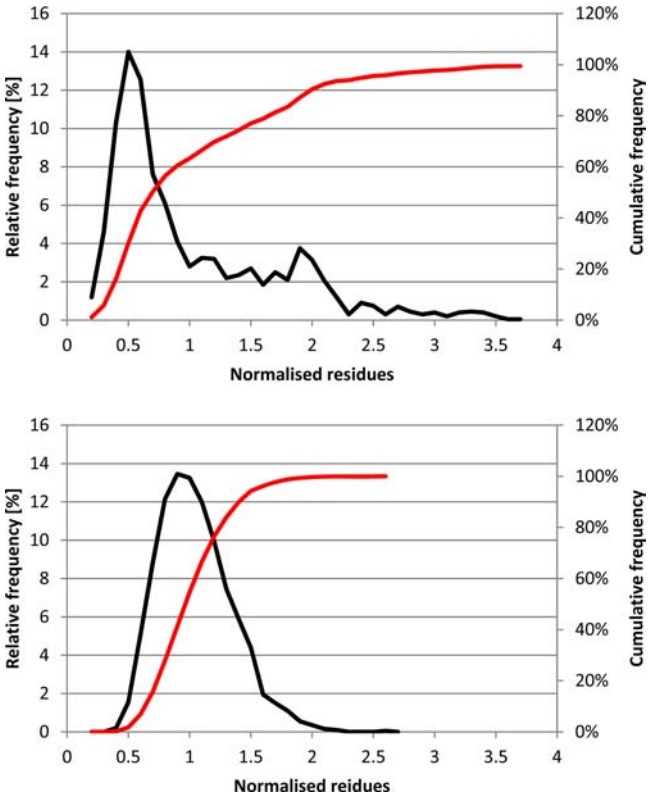

Figure 5. Relative and cumulative frequency distributions of phosalone residues in plum fruit samples taken from mixed (upper chart) and not mixed (lower chart) lots.

To examine the effect of mixing of commodities with substantially different average residues, model experiments were carried out with data set 9 (Table 3) in its original form (average residue 50.41 mg/kg, CV = 0.29) and its normalized version having an average of 1 and the same CV as the original data set. Random samples of 100, 200, 300, 400, and 500 were drawn from the normalized residue data population (representing the low-contaminated lot) and 900, 800, 700, 600, and 500 samples were drawn randomly from the original population (representing the contaminated lot). The residue values obtained from the two data sets were mixed, and the descriptive statistical parameters of the mixed data sets are summarized in Table 5. The same procedure was repeated with data set 8 and the normalized data set 9 to model the effect of the different average and CV values of the lots to be mixed. The results are shown in Tables 6 and 7.

The mixing reduced the average residue in the mixed lot but at the same time substantially increased its CV value. The change of the ratios of the average residues of the "contaminated" and "noncontaminated" data sets from 50.4 to 278 did not change the tendency of increase of CV values in the mixed data set. The large difference of the CV values (1.12 for the noncontaminated data set and 0.29 for the contaminated data set, Table 6) did not affect either the dependence on mixing ratio or the increase of CV_M/CV_O values shown in Tables 6 and 7, where CV_M is the relative standard deviation of residues in the mixed data set. The percentage of the noncontaminated samples (x%) in the mixed data set and the ratio of the CV_M of the mixed lot and the CV_O of the contaminated lot have a linear relationship, and the linear regression lines practically overlap for the two combinations:

original and normalized data set 9:

$$CV_M/CV_O = 0.0518x + 0.9874;\ R^2 = 0.9973 \quad (11)$$

original data set 8 and original data set 9:

$$CV_M/CV_O = 0.05413x + 0.9734;\ R^2 = 0.9967 \quad (12)$$

average regression equation:

$$CV_M/CV_O = 0.05527x + 0.9803;\ R^2 = 0.995 \quad (13)$$

In practice, the effect of mixing a contaminated lot with a noncontaminated one can be taken into account in compliance assessment only if the producer reveals the mixing ratio. In this case, the appropriate adjusting factor can be calculated with eq 13, and it should be used to multiply the recommended practical sampling uncertainties given in Tables 8 and 9. It should be emphasized that the presented principle is valid and applicable only if the effective mixing of the two lots is possible and it has been done. In practice, only liquid products and small grains can be properly mixed, other commodities cannot. Furthermore, it is re-emphasized that mixing a contaminated lot with a noncontaminated one is illegal in many countries.

Recommended Sampling Uncertainties for Control of Pesticide Residues in Food. Due to the large variability of residues in raw agricultural commodities (e.g., fresh fruits and vegetables), the sampling uncertainty cannot be determined reliably from a few measurements. Therefore, to ensure that the calculated AL values are correct in at least in 95% of the cases, it is recommended that the upper 95% confidence limits of the

[a]Number of replicate sample sets used for estimation of CV_{Stcs}. [b]Crops are grouped according to the size of crop units specified by the Codex Sampling procedure[6] or [c] by the Codex Commodity Classification.[40]

supervised trials and the potential effect of nondetectable residues on the relative standard deviation of residues, a combined multiplying factor of 1.3 is incorporated in the CV_{Sprim} values recommended for use under practical conditions. The CV_{Sprim} values are given to enable convenient determination of the expectable sampling uncertainty for various sample sizes (n) with eq 14, when sampling plans are designed for premarket self-control.

$$CV_n = \frac{CV_{prim}}{\sqrt{n}} \quad (14)$$

Farkas and co-workers demonstrated that the relative range of the 95% confidence limits around the sampling uncertainty, estimated from duplicate samples taken from different lots, rapidly decreases up to eight lots and the range gradually decreases with increasing number of lots. The gain above 20 lots is marginal.[8] This finding is in line with the ISO Standard,[35] which recommends a minimum of 20 lots to be tested for determination of sampling uncertainty of bulk materials with as many replicate samples as feasible. Therefore, when the number of trials providing the basis for the calculation of sampling uncertainty is <20 but ≥8, the estimated CV_S values should be used with caution. In case of doubt, it is recommended to use the typical sampling uncertainties estimated for the corresponding crop group. Likewise, CV_S values estimated for crop groups (Table 9) should be used when the database consists of <8 trials to concord with the conclusions of Lyn and co-workers.[36]

Optimization of Sampling and Testing Plan. *Consideration of the Uncertainty of the Laboratory Phase (CV_L) for Determination of Pesticide Residues.* Although the combined relative uncertainty of subsampling and sample homogenization can be at the same magnitude as that of the uncertainty of sampling,[11,15] laboratories generally pay very little attention to controlling the variability of these two steps, and the repeatability and reproducibility of the measurements are usually reported on the basis of the recoveries obtained with spiked samples.[37−39] The determination of CV_L is especially important when only 1−2 g portions are analyzed from the laboratory sample, which may amount to 1−>15 kg for small- and medium-size and large-size fruits (e.g., cabbage, watermelon), respectively. As the variability resulting from the test portion and particle size reduction depends on the laboratory equipment used and the sample materials analyzed, no typical values can be estimated. Therefore, the CV_L should be determined by each laboratory regularly as part of the routine operation by reanalysis of retained test portions[25] taken from samples containing incurred residues at well detectable concentration. An alternative option is the surface treatment method suggested by Maestroni and co-workers[11,12] and applied successfully in other studies.[13,14] It is especially important when the test portion size is reduced below 15 g.

[a]Number of test portions withdrawn from the homogenized laboratory sample for extraction. [b]Number of replicate analyses performed from the extract of the test portion.

DOI: 10.1021/jf505512h
J. Agric. Food Chem. 2015, 63, 4418−4428

It should be noted that simple recovery studies with spiked test portions before extraction do not provide any information on the efficiency of sample processing and its consequences on the CV_L. Furthermore, neither proficiency test nor collaborative study results provide information on CV_L.

Minimizing Combined Uncertainty of the Measured Residues. Applying eqs 1 or 2, the combined uncertainty of the measured result can be simply calculated with an Excel spreadsheet taking into account the best estimates for the sampling uncertainty (Tables 8 and 9) and the reproducibility CV values of the individual steps of the determination of the residues, which had been obtained from the method validation. The analysts can test the effect of various combinations in advance and select those that fit the purpose of the analyses. As a first step, the largest contributors to the total variance of the results should be reduced if possible. On the other hand, practically no improvement can be achieved by improving the procedure which contributes to the total variance with <30% of the largest contributor. Table 10 provides some examples to illustrate the application of the principle.

If the task of the laboratory is to test the compliance of the marketed products with the MRL, then only the CV_L value should be taken into consideration. It should be noted that the default CV_L of 25% specified by the EC[29] can be comfortably achieved with a CV_A of <20% determined with recovery studies, provided that the CV_{SP} of ≤10% can be maintained. It is pointed out that if a 1 g test portion is extracted instead of 15 g, applying the same sample processing (homogenization) procedure, which is increasingly getting into practice, the CV_L can be as large as 150% and the EC requirement cannot be met.[29] It should also be noted that the relevant minimum mass and sample size requirements must be met for market control. With smaller samples justified legal actions cannot be made.

For premarketing control, the sampling uncertainty should always be taken into account. The sampling uncertainty can be reduced with increasing sample size, provided that the sample processing equipment is suitable for efficiently handling and comminuting a large quantity of materials. Alternately, a sample size reduction step to obtain a sample mass that then can be further processed shall be included in the determination process, and its uncertainty shall be determined and taken into account for the calculation of CV_L. The latter option is not shown in Table 10.

Calculation of Action Limits and Operation Characteristic Curves. Using the combined uncertainty calculated from the recommended practical sampling uncertainties, CV_{Sprim} listed in Tables 8 and 9, and the actual CV_L of the laboratory phase of the residue analysis, the AL and the operation characteristic (OC) curves can be calculated on the basis of the underlying theory described with eqs 8−10. To facilitate premarketing control of pesticide residues, an MS Excel template was developed following the basic principles elaborated by Whitaker and co-workers.[41,42] The template calculates the AL, which should not be exceeded by the measured residues to achieve the desired compliance level. If replicate samples are taken, the residues measured in each sample should be below the calculated AL.

Figure 6 illustrates the calculated OC curves assuming CV_{Sprim} = 0.985, CV_L = 0.16 (15 g test portion), and CV_L = 1.5 (1 g test portion; one and three replicate extractions) and 2% acceptable violation rates. The corresponding AL concentrations of <0.065, <0.011, and <0.025 mg/kg clearly show the disadvantage of indiscriminate reduction of test portion size

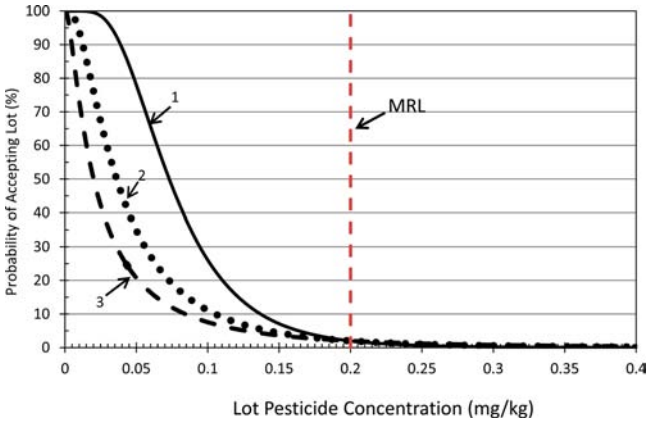

Figure 6. Operation characteristic curves indicating 2% violation rate at the MRL if the residue concentration in the sampled lot was ≤ALs of 0.065, 0.011, and 0.025. The CV_L values and number of test portions in parentheses for curves 1, 2, and 3 were 0.16 (1), 1.5 (1), and 1.5 (3), respectively.

(the residue concentration measured in a 1 g test portion should not be larger than 0.011 and 0.025 mg/kg when the MRL is 0.2 mg/kg) for the sake of reduction of the amount of chemicals required. Figure 7 illustrates the relationship of

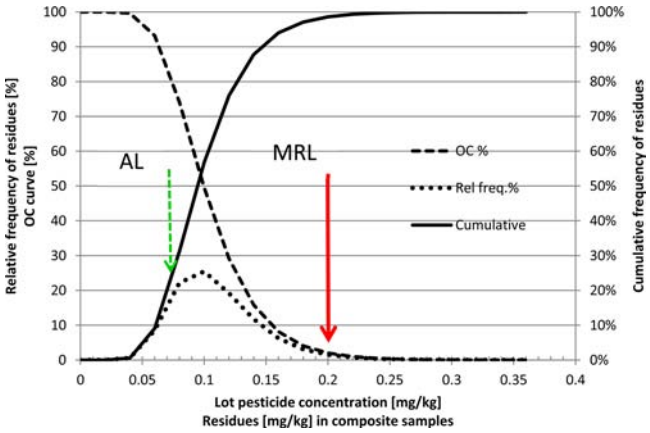

Figure 7. Relationship of relative and cumulative frequencies of residues in samples taken from a lot and the calculated operation characteristic curve assuming 98% compliance of the sampled lot.

relative and cumulative frequencies of residues in samples taken from a lot and the calculated OC curve. It can be seen that in the given case 98% of the samples contain residues below the MRL and the residues in 2% of the samples would exceed it.

It is emphasized that if a crop has been treated with a pesticide, 100% compliance cannot be certified. At present, there is no information available on an officially acceptable violation rate from any country. To enable the design of a sampling plan, which specifies the number and size of samples to be taken and the corresponding AL, an acceptable violation rate should be declared by the responsible national agencies. The BASELINE project carried out within the EU seventh research framework program recommended 98% compliance with the MRLs with 95% probability,[9] as performance objective for chemical contaminants if they do not impose any health risk to consumers. This criterion might be considered as a starting point to establish official acceptable violation rates.

ACKNOWLEDGMENTS

We greatly appreciate the invitation of S. Lehotay, M. Krolski, J. Sandahl, J. Jenkins, and C. Harris, organizers of the Poster Session on Residues in Food and Feed Monitoring Results and Dietary Risk Assessment of the 13th IUPAC International Congress of Pesticide Chemistry, to publish the detailed results of our work in this special issue.

ABBREVIATIONS USED

CV	coefficient of variation (relative standard deviation)
CV_A	relative uncertainty of the analysis phase of the determination of residues including, for instance, extraction, cleanup, ..., and quantitative determination
CV_{Adj}	relative standard deviation of residues in data sets in which the original residue data were replaced with various LOQ values
CV_L	relative uncertainty of the laboratory phase of the determination of residues including subsampling, sample processing and the analysis phase of the determination
CV_R	combined relative uncertainty of the measured residues (in general)
CV_O	relative standard deviation of residues in the original data set
CV_S	relative uncertainty of sampling in general
CV_{SS}	relative uncertainty of the subsampling of a large crop or a large bulk (aggregate) sample
CV_{SP}	relative uncertainty of sample processing including chopping, grinding, mincing, mixing the laboratory sample or part of it
CV_{Sprim}	relative sampling uncertainty of residues in primary (incremental samples)
CV_{CS}	relative sampling uncertainty in the case of composite samples
CV_{S1corr}	relative uncertainty of sampling in case of composite samples meeting the minimum sample size requirements of the Codex sampling procedure;[5]
CV_{Stcs}	relative sampling uncertainty of composite samples taken from supervised trials
CV_M	relative standard deviation of residues in mixed data set
LCL	lower confidence limit (2.5th percentile)
UCL	upper confidence limit (97.5th percentile)
LOQ	limit of quantification of an analyte in a sample matrix
MLE	maximum likely hood estimation procedure
MRL (ML)	maximum concentration of pesticide residues (contaminants) which is legally permitted in/on food and feed
n	sample size (number of primary samples in a composite sample)
$\bar{R}$	average of residues in a data set
M_{TP}	mass of portion of sampled material removed for extraction
DL	decision limit, the concentration of pesticide residue in a sample above which the sampled lot can be considered noncompliant
AL	action limit, also called accept/reject limit; the maximum residue concentration in a random sample satisfying the minimum requirements of laboratory sample, which can be present if the sampled lot is expected to comply with the MRL at specified probability level
P_V	violation rate; the percentage of the sampled lot that does not comply with the MRL; it is also called acceptance probability
P_C	proportion of the sampled crop complying with MRL

followed by gel permeation chromatography (GPC) or column chromatography with sorbents to remove lipids and other interfering components from fish extracts.[9] Nonpolar solvents, such as hexane, acetone, dichloromethane, and ethyl acetate, are commonly used for extraction. Similar techniques may be used to prepare fish samples for ELISA. For example, PLE with hexane and dichloromethane was used for extraction of fish tissues, followed either by cleaning with sulfuric acid or an acidified silica gel column to prepare fish samples for ELISA.[10,11]

PBDEs and DDTs are lipophilic and therefore accumulate in fatty tissues, such as in fish. In most method development studies, laboratory-spiked samples are used to assess method performance, but analytes are not internally integrated into the fat; thus, spiking is not necessarily acceptable to determine true extractability of the analytes from within fatty tissues. In incurred samples, contaminants are bound into cells and absorbed by fat and may not be readily available to the extraction solvent compared to spiked samples. The extractability of incurred contaminants is an important topic, but it is not given enough attention in method validation guidelines or in the scientific literature. A previous report on sample preparation for many POPs and pesticides in incurred fish with lipid content 3−10% showed acceptable total extractability and method performance using analysis by low-pressure gas chromatography−tandem mass spectrometry (LPGC-MS/MS).[12] This method should also be applicable to ELISA and provide superior ease, lower cost, and other benefits compared to PLE and GPC as described in the literature.[9,11,13]

The goal of this study was to evaluate a simple, rapid, and cost-effective sample preparation method, previously developed and validated for the analysis of diverse POPs in various fish tissues using LPGC-MS/MS, for the analysis of PBDEs and DDTs by commercial ELISA kits using incurred fish samples with various lipid content. Additionally, we sought to estimate matrix effects affecting the accuracy of measurements in the ELISAs for both contaminant groups. Comparison of ELISA and LPGC-MS/MS was also possible for the same samples, taking cross-reactivities of the ELISAs for individual analytes into account.

MATERIALS AND METHODS

Samples of Pacific white croaker (*Genyonemus lineatus*) and salmon (unknown species) were received from the National Institute of Standard and Technology (NIST) Marine Environmental Specimen Bank in Charleston, SC, USA. The croaker was collected in 2002 from Palos Verdes Shelf Los Angeles Sanitation District Zone 1 EPA Superfund site in Palos Verdes, CA, USA. Croaker samples were received as a frozen, homogenized powder. The salmon was contributed to the specimen bank by Axys Analytical, Sidney, BC, Canada (collection location was unknown). The salmon was received frozen as a whole-body fish and was thawed, filleted into skinless and boneless chunks, refrozen, and then homogenized with dry ice using a Robot Coupe (Ridgeland, MS, USA) RSI 2Y1 chopper. It was stored in glass containers at −18 °C until portions were thawed for analysis. The measured moisture content was 63% for salmon and 79% for croaker, respectively. Reported average lipid levels were 3−4 and 5−10% for croaker and salmon, respectively.[14] Standard Reference Material (SRM) 1947 (Lake Michigan Fish Tissue) was purchased from NIST (Gaithersburg, MD, USA), and contained 73% moisture and 10% fat content. SRM 1947 contains PBDE congeners and DDT pesticides with certified/reference concentrations. In addition, samples of Pacific white croaker and salmon were purchased from local grocery stores as "clean" matrices for use in matrix-matched calibration. They were homogenized with dry ice as described above and stored in glass containers in a −18 °C freezer.

Standards of PBDE congeners (28, 47, 99, 100, 153, 154, and 183) and DDT pesticides (*o,p′*-DDE, *p,p′*-DDE, *o,p′*-DDD, *p,p′*-DDD, *o,p′*-DDT, and *p,p′*-DDT) were purchased from AccuStandard (New Haven, CT, USA). All standards were ≥98% purity, and all solvents were of HPLC grade. Acetonitrile (MeCN), ethyl acetate, and hexane were from Fisher Scientific (Pittsburgh, PA, USA) and methanol (MeOH) was from VWR International (Radnor, PA, USA). Deionized water of 18.2 Ω-cm was prepared with an E-Pure model D4641 from Barnstead/Thermolyne (Dubuque, IA, USA). Primary−secondary amine (PSA) and C18 sorbents were purchased from UCT (Bristol, PA, USA). Z-Sep sorbent, which incorporated zirconium dioxide, was from Supelco (Bellefonte, PA, USA). Ammonium formate was from Sigma-Aldrich (St. Louis, MO, USA). PVDF 0.2 μm filter vials were from Thomson Instrument Co. (Oceanside, CA, USA). ELISA kits, 96-well microliter plates for PBDE and DDE/DDT, were from Abraxis (Warminster, PA, USA).

Sample Preparation. The sample preparation procedure was based on the quick, easy, cheap, rugged, effective, and safe (QuEChERS) approach including the recently reported filter-vial d-SPE cleanup technique.[15] Homogenized fish samples (4 g) were placed into 50 mL polypropylene tubes, and after the addition of 4 mL of MeCN, the tubes were shaken for 10 min on a pulsed-vortexer (Glas-Col, Terre Haute, IN, USA) at 80% setting with maximum pulsing. Water (4 mL) was used as a reagent blank. After extraction, 2 g of ammonium formate was added to induce the phase separation,[16] and the samples were shaken for 1 min on the pulsed-vortexer and centrifuged for 2 min at 3700 rcf. Extracts (0.5 mL) were transferred into the shell (bottom) portions of 0.2 μm PVDF filter-vials containing 75 mg of anhydrous $MgSO_4$, 25 mg of PSA, 25 mg of C18, and 25 mg of Z-Sep sorbents. The filter-vial plungers (top pieces) were partially depressed, and the extracts were shaken by hand for 30 s in an autosampler vial tray. Then the plungers were fully depressed into the filter-vial shells, forcing the cleaned-up extract through the filter membrane. Filtered extracts (200 μL) were transferred to glass autosampler vials containing inserts for LPGC-MS/MS analysis. Another set of filtered extracts (200 μL) was transferred to glass tubes for ELISA analysis. These extracts were evaporated to dryness with nitrogen and reconstituted in 200 μL of 1:1 (v/v) MeOH/water for ELISA analysis. Different fish extracts were prepared in four replicates (except for SRM 1947) on different days for separate ELISA and LPGC-MS/MS analysis. The equivalent fish tissue concentration was 1 g/mL in all final extracts.

Determination of Coextractives. Four types of fish tissues (croaker and salmon each from the specimen bank and from grocery stores) were extracted with MeCN, hexane, and ethyl acetate. Each solvent (15 mL) was added to 15.0 g each of the four fish tissues in 50 mL polypropylene tubes, and the tubes were shaken on the pulsed-vortex shaker for 10 min as described above. In the case of MeCN, two replicate extracts were prepared (one was used to determine coextractives, and the other was to estimate d-SPE cleanup efficiency). Additional MeCN extracts were prepared in the same manner for store-purchased salmon and croaker to generate matrix-matched (MM) calibration standards. For MeCN extracts, 7.5 g of ammonium formate was added to induce phase separation. The tubes were then centrifuged for 2 min at 3700 rcf, and 10 mL of each corresponding solvent extract was transferred into a preweighed glass tube, evaporated to dryness, and dried in an oven at 120 °C, after which the glass tubes with residues were reweighed.

d-SPE Removal Efficiency. Aliquots (10 mL) of MeCN extract for each fish type were placed into 50 mL tubes, to which 1500 mg of anhydrous $MgSO_4$ and 500 mg each of PSA, C18, and Z-sep were added for d-SPE cleanup. The tubes were shaken for 30 s and centrifuged for 2 min at 3700 rcf. The treated extracts (5 mL) were placed into preweighed glass tubes and evaporated to dryness. After drying in the oven at 120 °C, the glass tubes with residues were weighed again.

To prepare MM calibration curves for the ELISA procedure, another set of MeCN extracts after d-SPE of store-bought salmon and

DOI: 10.1021/jf505651g
J. Agric. Food Chem. 2015, 63, 4429−4434

croaker (5 mL of each fish extract) were transferred into glass tubes, evaporated to dryness, and reconstituted in 5 mL of 1:1 (v/v) MeOH/water. Aliquots of 0.45 mL of the corresponding fish extracts were placed into autosampler vials, and PBDE 47 standard solution was added to yield concentrations of 0, 0.1, 0.25, 0.5, 1, 2, and 4 ng/g, as was *p,p′*-DDE standard solution to yield concentrations of 0, 0.625, 1.25, 2.5, 5, 10, and 25 ng/g in a final volume of 0.5 mL.

LPGC-MS/MS. Low-pressure vacuum outlet GC was carried out using an Agilent 7890 GC system with a multimode inlet (MMI) interfaced to a 7000B triple-quadrupole MS/MS. The GC instrument was upgraded with a 220 V rapid heating oven device. A capillary column (15 m × 0.53 mm i.d. × 1 μm film thickness) Rti-5 ms (Restek, Bellefonte, PA, USA) was coupled to a restriction capillary (5 m × 0.18 mm i.d.) (Restek HydroGuard). High-purity He was the carrier gas at a constant flow rate of 2 mL/min. The MMI was initially set at 80 °C for 0.31 min with vent at 50 mL/min, then ramped at 420 °C/min to 320 °C, and held until 9.5 min. Injection volume was 5 μL. The oven temperature started at 70 °C for a 1.5 min hold, followed by a ramp at 80 °C/min to 180 °C, then at 40 °C/min to 250 °C, and then at 70 °C/min to 290 °C, at which it was held until 9.5 min. The transfer line and ion source were set at 280 and 320 °C, respectively, and the quadrupole was at 150 °C. Two MRMs per each analyte were used with a dwell time of 2.5 ms.

Calibration curves for PBDE congeners 28, 47, 99, 100, 153, 154, and 183 and *p,p′*-DDD, *o,p′*-DDT, *o,p′*-DDD, and *p,p′*-DDT were constructed at 0, 0.1, 1, 5, 10, 50, 100, 250, and 500 ng/g in MeCN. To quantify the high concentrations of DDE in the croaker, an additional calibration point of 1000 ng/g was added for *o,p′*-DDE. For *p,p*-DDE, the least intense MRM transitions were selected to avoid detector saturation and still achieve linear calibration with additional calibration points at 500, 1000, 2500, 5000, 7500, 10000, and 15000 ng/g of *p,p′*-DDE.[12]

ELISA Procedure. Because the analyte concentrations in the incurred samples were known, croaker and SRM 1947 extracts were diluted 1:50, 1:100, and 1:1000 times with MeOH/water (1:1 v/v) to fall within the calibration curve range.

The ELISA procedure described in the commercial kit instructions was followed.[17] For PBDE analysis, 50 μL of the final extracts and MM and solvent calibration standards (in MeOH/water (1:1 v/v) were placed into the wells, and 50 μL of PBDE antibody solution was added. After careful mixing and 30 min of incubation time at room temperature, 50 μL of PBDE enzyme conjugate solution was added. After further mixing, the solutions in the wells were incubated for another 30 min at room temperature. Then, the solutions were removed from the wells, which were rinsed with the washing buffer (provided with the commercial kit) four times. Afterward, 100 μL of color solution (hydrogen peroxide and 3,3′,5,5′-tetramethylbenzidine) was added, mixed, and allowed to incubate again for 30 min. Finally, 100 μL of stopping solution (0.5% of sulfuric acid) was added, and the optical density (OD) was read at 450 nm using the 96-well plate reader Synergy HT from Bio-Tek Instruments (Winooski, VT, USA). Quantification was based on MM calibration curves for croaker and salmon.

For the DDE/DDT pesticide assay,[18] 25 μL of final extracts and MM and solvent calibration standards were incubated in wells with 50 μL of DDE/DDT antibody solution at room temperature for 30 min, after which 50 μL of enzyme conjugate solution was added, mixed, and incubated again for 30 min. After the incubation, all wells were emptied, rinsed four times with washing buffer, and 150 μL of color solution was added. Following another 30 min of incubation, 100 μL of stopping solution was added, and the OD was measured as before. Measured OD was converted to ng/g concentrations using semilog calibration curves after normalization to the OD control values (%B/B_0). In initial experiments, measured ODs from replicated wells were within 1% RSD; thus, only one well per sample was used for subsequent analyses.

RESULTS AND DISCUSSION

Sample Preparation. In our sample preparation method, MeCN was used as an extraction solvent, providing acceptable recoveries for relatively nonpolar and polar organic contaminants from fish tissues without extracting significant amounts of lipids and other possible interferences. For instance, hexane and ethyl acetate are commonly used for extraction of lipophilic POPs from fish and other fatty tissues.[19,20] On the basis of studies using spiked samples, both solvents were shown to provide excellent recoveries. However, because hexane and ethyl acetate are rather nonpolar, they tend to extract significant amounts of lipids and similar coextractive components, creating a need for extensive cleanup to remove interfering coextractive components prior to analysis. Figure 1A demonstrates the

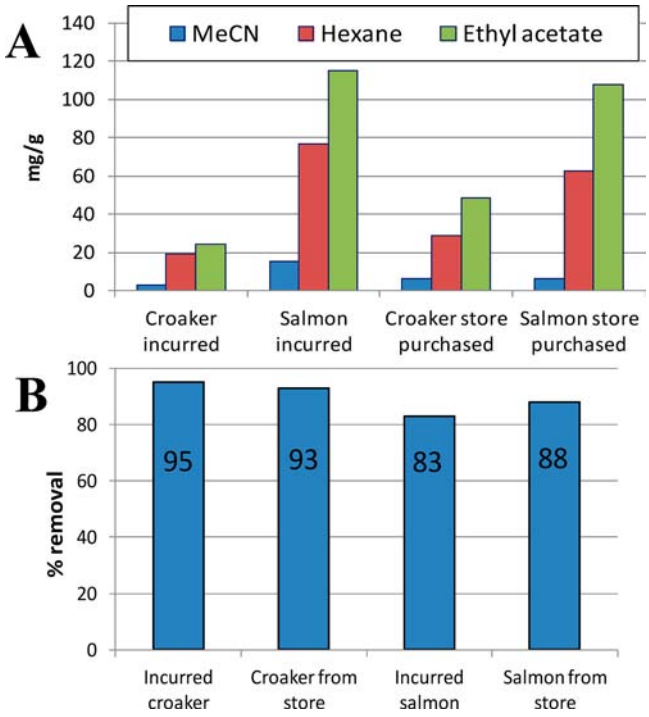

Figure 1. Comparison of matrix coextractive amounts (mg/g): (A) initial extraction; (B) coextractive removal efficiency (%) of MeCN extracts by d-SPE in the method.

difference in amounts of coextracted materials in four fish types in this study using hexane, ethyl acetate, and MeCN as extraction solvents. Hexane and ethyl acetate extracts contained up to 11 and 18 times, respectively, more coextractives compared to MeCN extracts. Furthermore, the filter-vial d-SPE approach with the selected combination of sorbents (C18, PSA, and Z-Sep) removed 83−95% of coextracted matrix from the salmon and croaker extracts (Figure 1B), providing relatively clean extracts for analysis. This new QuEChERS-based sample preparation method is simple and rapid, enabling preparation of a batch of 10 prehomogenized fish in 1 h by one analyst, and it can be implemented in any laboratory or even in the field if shaking is done vigorously by hand and time is given for the salted-out MeCN layer to separate from the water. The cost per sample is approximately $3 for materials.

The final MeCN extracts could be directly injected in GC-MS. However, MeCN is not typically suitable for ELISA, and our experiments using 10, 25, and 50% MeCN in aqueous solutions for final extracts in analysis of PBDEs by ELISA failed

Table 1. Average Measured Concentrations of Incurred PBDEs and DDT Pesticides in Croaker and Salmon by LPGC-MS/MS, Measured Concentrations of Contaminants in SRM 1947, and Accuracy of Measurements versus Certified/Reference Concentrations

	av ± SD (ng/g) (n = 4)		SRM 1947	
analyte	croaker	salmon	ng/g	accuracy (%)
p,p'-DDD + o,p'-DDT	457 ± 63	1.64 ± 0.15	57.7	94
o,p'-DDD	26 ± 2		3.9	119
o,p'-DDE	1210 ± 110		2.9	87
p,p'-DDE	10200 ± 670	9.8 ± 1.1	753	105
p,p'-DDT	23 ± 2		57.5	97
PBDE 28	1.9 ± 0.2		1.95	86
PBDE 47	173 ± 8	1.9 ± 0.1	68.3	93
PBDE 99	7.8 ± 0.9		14.5	76
PBDE 100	34.7 ± 1.7		11.9	70
PBDE 153	4.0 ± 0.6		3.8	100
PBDE 154	6.5 ± 0.2		8.3	122

Table 2. Comparison PBDEs and DDTs Concentrations between LPGC-MS/MS and ELISA Methods

	PBDE 47 equivalents, av ± SD (ng/g)		p,p'-DDE equivalents, av ± SD (ng/g)	
	calcd from LPGC-MS/MS data	measured by ELISA, (n = 4)	calcd from LPGC-MS/MS data	measured by ELISA, (n = 4)
croaker	181 ± 8	195 ± 28	10450 ± 670	6800 ± 2400
salmon	1.9 ± 0.1	2.1 ± 1.0	11 ± 1	9 ± 2
SRM 1947	82	89	786	560

to produce a dose−response curve, which is consistent with findings from a previous study.[21] Therefore, the fish extracts had to be evaporated to dryness and reconstituted in 50% aqueous MeOH solution prior to ELISA. When aqueous solutions containing <50% MeOH were tested, the amounts of measured contaminants were orders of magnitude lower compared to LPGC-MS/MS results, most likely because highly aqueous solutions failed to dissolve DDTs and PBDEs, which have rather high log K_{ow} values.

Comparison of LPGC-MS/MS and ELISA Results. The results of LPGC-MS/MS analyses of incurred PBDE congeners and DDT pesticides are presented in Table 1. PBDE 183 was not detected. Large amounts of PBDEs and DDTs in croaker tissues may be attributed to its origination to the Palos Verdes location, an EPA Superfund site.

To compare the results of PBDEs measured by both methods, equivalent amounts of PBDE 47 (analyte by which cross-reactivity in the ELISA is measured) were calculated from LPGC-MS/MS data. The cross-reactivity values for PBDE congeners 28, 47, 99, 100, and 153 were 0.15, 1, 0.9, 0.025, and 0.014, respectively.[10] Calculated PBDE 47 equivalents were 2.1 ng/g in salmon, 181 ng/g in croaker, and 82 ng/g in SRM 1947 (Table 2). Similarly, p,p'-DDE equivalents were calculated on the basis of cross-reactivity coefficients reported for its metabolites in the kit instructions. Concentrations were 10500, 11, and 786 ng/g p,p'-DDE equivalents for croaker, salmon, and SRM 1947, respectively, on the basis of concentrations measured by LPGC-MS/MS, as shown in Table 2. ELISA calibration curves ranged from 0.04 to 4 ng/g for PBDEs and from 0.625 to 25 ng/g for DDTs; thus, fish extracts prepared for ELISA underwent appropriate dilution factors to fall within the calibration curves.

The results by both methods agreed well (see Table 2) for the three types of fish and both contaminant groups, despite fundamental differences in the chemical nature of the analyses. ELISA is susceptible to altered responses due to indirect and direct matrix effects from chemicals in the extracts. PBDE 47 equivalent concentration calculated from LPGC-MS/MS data was 181 ng/g compared to 195 ng/g PBDE in croaker measured by ELISA. Croaker was the leanest fish with a lipid content of 3−4%. Repeatability, expressed in RSD for four replicates, was 14% for the PBDE assay, which was comparable to 3−15% RSDs for individual PBDE congeners measured by LPGC-MS/MS. DDT pesticides were measured at high concentrations in croaker samples. p,p'-DDE equivalent concentration measured by ELISA was 65% of the concentration measured by LPGC-MS/MS with RSD = 39%. In contrast, LPGC-MS/MS RSDs were 7−14% for individual DDT pesticides. For salmon, with 5−10% lipid content, the average of both techniques agreed within 11% for PBDEs (1.9 vs 2.1 ng/g) and 19% for DDTs (11 vs 9 ng/g), but the results were rather variable for the replicates. For SRM 1947, the results agreed within 9% (82 vs 89 ng/g) for PBDEs and within 29% for (786 vs 560 ng/g) for DDT pesticides.

To estimate the limit of detection by ELISA, average OD and standard deviation (SD) for salmon and croaker control samples (B_0) were calculated. $\%B/B_0$ corresponding to the LOD was calculated as previously described:[21] $\%B/B_{0\,LOD} = [B_0 - (3 \times SD)]/B_0$ (converted to ng/g using semilog calibration curves). LOD for both salmon and croaker was 1 ng/g PBDE equivalent. To compare this with LPGC-MS/MS, PBDE congeners 28, 47, 99, and 100 gave a method detection limit (MDL) of 1 ng/g each, whereas PBDEs 153 and 154 had MDL of 2 ng/g each. LODs for DDT pesticides calculated in the same manner yielded 0.4 ng/g p,p'-DDE equivalent in fish, which are quite similar to the MDLs for individual DDT pesticides measured by LPGC-MS/MS (0.5 ng/g). The LODs for each individual PBDE congener and DDT-type analyte are proportional to their cross-reactivities in ELISA. A significant advantage of the LPGC-MS/MS approach is the ability to identify and quantify each analyte individually.

Matrix Effects (MEs). It is well documented that coextractives from complex biological samples may cause MEs and inaccurate quantification in instrumental analysis,

DOI: 10.1021/jf505651g
J. Agric. Food Chem. 2015, 63, 4429−4434

including GC-MS.[22] However, MEs in ELISA are not as commonly characterized. A study on PBDEs in fish and comparison with GC-MS results suggested that higher concentrations of PBDEs in fish measured by ELISA in comparison to GC-MS may be explained by MEs.[10]

To compare the effect of coextracted matrix components for analysis of PBDEs and DDTs by ELISA, two sets of MM calibration standards (croaker and salmon) were prepared for each ELISA experiment. Figure 2 shows solvent-only (50% aqueous MeOH) and MM calibration curves for croaker and salmon in the PBDE ELISA. Both MM curves have similar slopes, which are different from the solvent-only calibration. Calculated MEs were −53 and −60% for salmon and croaker, respectively. These findings are similar to a study investigating MEs for microcystins in catfish with ELISA, in which −63% MEs were obtained.[21] This finding emphasizes a need for MM calibration in ELISA to obtain accurate results.

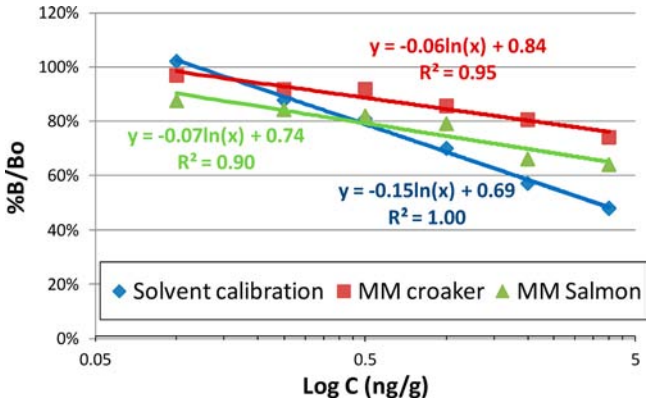

Figure 2. ELISA calibration curves for PBDE 47 in solvent only (50% aqueous MeOH) and matrix-matched (MM) fish extracts.

In the case of DDTs in ELISA, there was no difference for solvent versus MM calibration curves for croaker, nor in the case of salmon (Figure 3). Three calibration curves were identical, suggesting no direct/indirect interfering components in the extracts affecting the ELISA measurement for DDTs.

In conclusion, a simple and fast method for sample preparation of fish tissues previously developed for LPGC-MS/MS was evaluated for use in ELISAs of PBDEs and DDTs employing incurred fish with lipid content of 3−10%. In ELISA sample preparation, an additional solvent exchange step is needed prior to analysis. This method can be adopted in any typical laboratory and probably in the field. Matrix effects were estimated for croaker and salmon and were significant (up to −60%) in the PBDE ELISA, suggesting that MM calibration is essential for accurate quantification of PBDEs in fish extracts. Conversely, MEs in the DDTs assay were not observed. The method proved to work well for the three diverse fish matrices, and the results obtained by both measurement techniques were within reasonable agreement. Orthogonal confirmation is often required in many applications, and results of initial ELISA screening may be confirmed by the developed LPGC-MS/MS method using an alternative chemical mechanism.

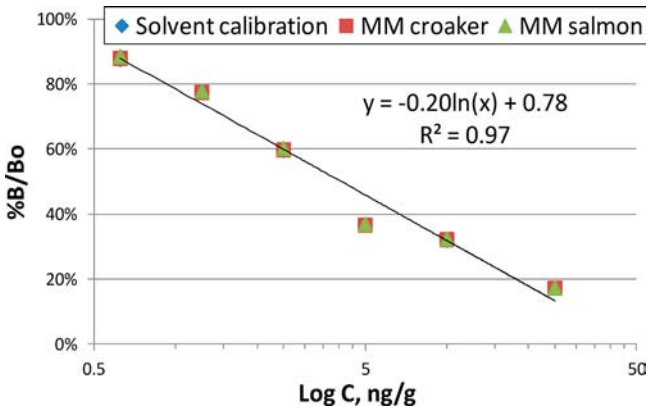

Figure 3. ELISA calibration curves for *p,p′*-DDE in solvent only (50% aqueous MeOH) and matrix-matched (MM) fish extracts.

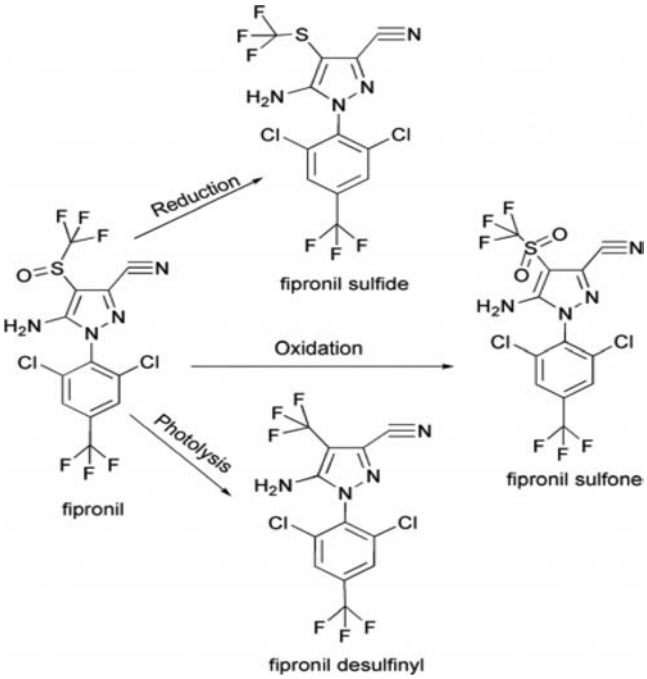

Figure 1. Degradation process of fipronil in the environment.[7]

peanut products and the environment. However, no studies are described in the literature about residue analysis and dissipation dynamics of fipronil and its metabolites in peanuts.

Due to the high toxicity and extensive use of fipronil in agriculture, a few scientific studies on the determination of fipronil in water, soil, and food samples have been reported. Fipronil was detected in soil and water samples by gas chromatography with mass spectrometric detection (GC-MS),[12] liquid chromatography (LC)−UV,[13] and GC with electron-capture detection (ECD).[14] Due to its toxicity to bees, there are also studies about its residue determination in honeybees, honey, and pollen samples by GC with nitrogen−phosphorus detection (NPD),[15] LC with tandem mass spectrometry (MS/MS),[16] GC-ECD/MS,[17] and LC-UV.[18] Methods to determine fipronil in cabbage,[19] tomato,[20] pepper, and Chinese cabbage[21] using GC-ECD were also reported.

Other papers describe the simultaneous determination of fipronil and its metabolites in environmental samples such as soil and water. In the study of Sunayana et al.,[22] soil samples were extracted using matrix solid-phase dispersion (MSPD) and analyzed by GC-MS. Dang et al.[23] detected paddy water samples by solid-phase extraction (SPE) and LC. Recently, the quick, easy, cheap, effective, rugged, and safe (QuEChERS) method was used for the determination of fipronil and its metabolites in cabbage, cauliflower, okra, tomato, grapes, and soil samples;[24] the samples were extracted with ethyl acetate and cleaned up by dispersive-SPE and then were quantified and identified by GC-MS.

A few papers appear concerning the residues and dissipation of fipronil and its metabolites in maize. Wang et al.[25] used a three-step method that consisted of liquid−solid extraction followed by liquid−liquid partitioning and florisil SPE for cleanup and, finally, detection with GC-ECD. Cheng et al.[26] applied the QuEChERS method for extraction and C_{18}, C_{18}/PSA, and PSA/GCB absorbents for cleanup for soil, maize grain, and straw, respectively; samples were detected by ultrahigh-performance (UHP)LC-MS/MS. There are other reports involving the residues and dissipation of fipronil and its metabolites on sugar cane leaves and juice[27] and grape leaves and berries,[28] but the methods used were time-consuming and solvent-intensive.

Because no paper has yet reported on the dissipation and residues of fipronil and its three metabolites (fipronil-sulfone, fipronil-sulfide, and fipronil-desulfinyl) in peanut, the overall aim of this project was to establish a simple and effective residue analysis method for fipronil and its three metabolites in peanut matrices and soil and then to investigate the dissipation trend and final residue levels in peanut plant and soil under field conditions.

MATERIALS AND METHODS

Chemicals and Standards. The fipronil (98.5%), fipronil-sulfone (99%), fipronil-sulfide (99.5%), and fipronil-desulfinyl (10 mg/L) standards were purchased from Dr. Ehrenstorfer GmbH Company (Augsburg, Germany), and the formulation (seed treatment microcapsule suspension containing 3% fipronil) was obtained from Beijing Yanhua Yongle Pesticide Ltd. (Beijing, China). High-performance (HP)LC-grade acetonitrile was supplied by Fisher Scientific (Pittsburgh, PA, USA). Ultrapure water was obtained from Aquapro Ultrapure Water System (Chongqing, China). Analytical grade NaCl and Cleanert florisil were purchased from the Beijing Reagent Co. (Beijing, China). PSA (primary−secondary amine), GCB (graphitized carbon black), C_{18}, and MWCNT (multiple-walled carbon nanotubes) were purchased from Agela Ltd. (Tianjin, China).

Fipronil, fipronil-sulfone, and fipronil-sulfide stock standard solutions of 1000 mg/L were prepared in acetonitrile, and the working standard solutions required for fortification and quantification were prepared from stock solution by dilution with acetonitrile. All standard solutions were stored at −20 °C before use. The stability of the four compounds in acetonitrile was reported to be stable at −20 °C for >15 months.[29]

Field Experiments. In normal agricultural practice, a 3% fipronil seed dressing formulation was recommended to be used on peanuts at a ratio of 1:50 (formulation weight/seed weight). In this study, field experiments (including the dissipation and terminal residue experiments) were conducted in 2012−2013 at three places that have different climate conditions, namely, Hebei province (in northern China, 116.51 E, 39.32 N), Hubei province (southern China, 113.45 E, 30.36 N), and Shandong province (eastern China, 117.07 E, 36.68 N). Each treatment field consisted of three replicate plots, and each plot had an area of 30 m^2 and was separated by irrigation channels. The organic matter contents of soil at Hebei, Hubei, and Shandong province were 15.7, 16.7, and 15.8 g/kg, and the pH values were 5.8, 6.2, and 7.5, respectively.

For the dissipation experiments, the peanut seeds were mixed evenly with fipronil formulation before sowing. To get the residue data during the growing process of the peanut seedlings, the treatment dosage was set as 1:25 (formulation weight/seed weight), which was 2 times the recommended dosage. When the peanut seedling reached 10−15 cm, the peanut seedling samples (about 1 kg) were randomly collected at 0, 1, 3, 5, 7, 14, 21, 28, 35, and 40 days (the first day of the sample collection was recorded as day 0). All collected samples were stored in a freezer at −20 °C until analysis.

To investigate the residue levels of the target pesticides in harvested peanut products, the terminal residue experiments were performed at the 1:50 recommended dosage as well as a higher dosage of 1:33 (1.5 times of the recommended dosage). The growth season of peanut was about 100−150 days (from June to October) at the experimental sites. At harvest time, samples of peanut, peanut shell, peanut straw, and soil (all about 1 kg) were randomly collected from each plot. Then the samples were shattered and analyzed to get the final residue data.

For the purpose of getting the dissipation curves of fipronil and its metabolites in soil, an experiment was applied in loam soil (organic matter content of 2.2%) with different pH values of acidic (pH 5), neutral (pH 7), and alkaline (pH 8) conditions. The soil samples were

J. Agric. Food Chem. 2015, 63, 4435−4443

Table 1. Parameters for Analysis of Fipronil and Its Metabolites

analyte	retention time (min)	qualitative ion transition (m/z)	quantification ion transition (m/z)	fragmentor (V)	collision energy (V)
fipronil	0.64	435/330	435/330	120	8
		435/250			25
fipronil-sulfide	0.67	419/382	419/382	130	8
		419/314			15
fipronil-sulfone	0.66	451/415	451/415	130	8
		451/282			25
fipronil-desulfinyl	0.64	387/350	387/350	100	8
		387/282			25

treated with fipronil standard solution to yield the concentration of 1.5 mg/kg. Then, the individually mixed samples (100 g in each container) were exposed to natural sunlight and were watered every day to keep the water content relatively constant at ≈15% in the soil. Then, the soil sample boxes were randomly collected at 0, 1, 3, 5, 7, 14, 21, 35, and 60 days. All collected samples were stored in a freezer at −20 °C until analysis.

Sample Preparation. Harvested peanut samples were separated into peanut kernels and peanut shell and were comminuted with an IKA (Staufen, Germany) grinder. Peanut seedling and peanut straw were also comminuted in the same way before analysis. All samples (including soil) were placed in polyethylene bags and stored at −20 °C until analyzed.

Samples (10 g of soil, 5 g of peanut kernels, 5 g of peanut shell, 5 g of peanut straw, 5 g of peanut seedling) were put into 50 mL centrifuge tubes, and then 5 mL of aqueous solution of formic acid (0.1%) and 20 mL of acetonitrile were added (except 10 mL of acetonitrile for soil samples). After the tubes were vortexed for 2 min, NaCl (3 g) was put into each tube. Then, the samples were vortexed again for 1 min and centrifuged at 3800 rpm (2260 rcf) for 5 min.

For the peanut straw samples, the extract (supernatant) was filtered through a 0.22 μm nylon filter into an autosampler vial for LC-MS/MS analysis. For the other samples (soil, peanut kernel, shell, and seedling), 1 mL of extract was transferred into a 2 mL centrifuge tube with 50 mg of PSA, and the tube was vortexed for 1 min. Afterward, each tube was centrifuged at 10000 rpm (4472 rcf) for 1 min, and the extract was filtered through a 0.22 μm nylon filter into an autosampler vial for LC-MS/MS analysis.

Analytical Procedure. All samples were detected with an Agilent 1200 HPLC and an Agilent 6410 B triple-quadrupole MS/MS. The separation was performed using a reverse-phase C_{18} HPLC column (50 mm × 2.1 mm × 3.5 μm particle size), which contains a dense monolayer of dimethyl-*n*-octadecylsilane stationary phase and an ultra-high purity ZORBAX Rx-SIL porous silica support. The mobile phase was isocratic and consisted of acetonitrile/water (90:10 by volume, containing 0.1% formic acid), with a flow rate of 0.3 mL/min. The MS/MS system gas was nitrogen at a constant flow of 8.0 L/min, and the source temperature was 350 °C. The nebulizer was 35.0 psi, and the injection volume was set at 5 μL.

The spectral acquisition was conducted using the mode of negative electrospray ionization for all four analytes, and multiple reaction monitoring (MRM) was utilized. The data acquisition parameters are listed in Table 1.

Statistical Analysis. The dissipation curves of fipronil were analyzed using nonlinear regression with Microsoft Excel software. The degradation kinetics followed first-order kinetics, $C = C_0e^{-kt}$, where C is chemical concentration (mg/kg) at time t (days), C_0 is initial concentration (mg/kg), and k is the first-order rate constant (day^{-1}) independent of C and C_0. The correlation coefficient (R^2) is used to represent the congruence between the data and the first-order dynamic equation. The dissipation of those compounds has been generally expressed in terms of DT_{50}, that is, the time after which 50% of the pesticide has disappeared, which can be calculated using Hoskins formula ($DT_{50} = (\ln 2)/k$). In this work, the curves from the simulation experiment on soil were fit to the best-fit first-order kinetics equation, but the curves for peanut seedling did not fit to the first-order kinetics very well, so the DT_{50} in seedling was estimated by measuring the time when fipronil degraded to half of the initial concentration. The terminal residue level was the total residues (the sum of fipronil, fipronil-desulfinyl, fipronil-sulfone, and fipronil-sulfide, expressed as fipronil), and the highest total residues (HR) in each matrix were calculated, which could be used for the dietary intake risk assessment of fipronil in peanut.[29]

RESULTS AND DISCUSSION

Optimization of the LC-MS/MS Conditions. GC analysis with various detectors (ECD, NPD, MS, and MS/MS) are usually used for the detection of fipronil and its metabolites. However, the analysis time in GC is normally longer than in LC methods. In this study, LC-MS/MS detection parameters for the four compounds were investigated, and sensitive responses were achieved using negative electrospray ionization (ESI−) mode. Mobile phases with different proportions of acetonitrile/water containing 0.1% formic acid were compared to obtain optimal instrument response, better peak shapes, and satisfactory separation efficiency. When the mobile phase was isocratic and consisted of acetonitrile/water (90:10 by volume, containing 0.1% formic acid), with a flow rate of 0.3 mL/min, we obtained optimal responses and peak shapes.

MS/MS conditions of the four target compounds were first optimized in both positive and negative ESI modes. The ionization efficiency was obviously higher in ESI− than in ESI+ for the analytes. Two product ions with the highest sensitivity and optimal selectivity were selected for each compound for establishment of the multiple reaction monitoring (MRM) parameters. The ion with higher response was used for quantification, whereas the less intense one as well as the retention time were used for qualification. The optimal MRM parameters including precursor ions, cone energies, product ions, and collision energies are shown in Table 1.

Development of the Residue Analysis Methods. Taking advantage of the high selectivity and sensitivity of the LC-MS/MS detection, we applied and modified the QuEChERS method[30] for sample preparation. Acidic aqueous acetonitrile was used as the extraction solvent, and the recoveries of 66−116% were satisfactory at four spiking levels for all of the matrices.

As a fast and efficient cleanup procedure in the QuEChERS method, dispersive SPE was also used in this study. Different sorbents such as 50 mg of florisil, 50 mg of PSA, 30 mg of GCB, 50 mg of C18, and 15 mg of multiwalled carbon nanotubes (MWCNT) were compared in the dispersive SPE

[a]Average of five replicates.

procedure at a spiking level of 0.01 mg/kg. Although the recoveries were consistent when the different sorbents were used, different response levels (peak areas) were obtained. The responses of the target compounds cleaned up by different sorbents are shown in Figure 2. From the histogram, we can observe that PSA achieved the highest response in most cases, except for fipronil-desulfinyl and fipronil in peanut straw. For peanut straw samples, there was no significant difference between the five sorbents and no-cleanup samples, except that fipronil got a much higher response without cleanup. To get high sensitivity for fipronil, no cleanup was chosen for the peanut straw samples. For the other four matrices (peanut kernel, shell, seedling, and soil), although PSA did not get the highest response for fipronil-desulfinyl, it achieved the best responses for the other three compounds, so PSA was chosen

DOI: 10.1021/jf5054589
J. Agric. Food Chem. 2015, 63, 4435−4443

as the cleanup sorbent for the determination of the four compounds in the four matrices.

MWCNTs constitute a new carbon-based nanomaterial that has been widely used in the analysis of metals, veterinary drugs, and other pollutants.[31] However, the performance of MWCNTs in this study was not outstanding (almost the same as GCB) and did not improve the response of fipronil and its metabolites.

Method Validation. To evaluate the repeatability and trueness of the method, the fortification experiment was carried out at levels of 0.001, 0.005, 0.01, and 0.1 mg/kg with five replicates at each level. Recovery and precision tests were performed by spiking the standard solutions into the noncontaminated samples. After being set aside for 30 min at room temperature, the samples were analyzed as described under Sample Preparation. The fortification recoveries were calculated by using the equation

$$\%R = [\text{residue found } (\mu g/g)/\text{added concn } (\mu g/g)] \times 100\%$$

All quantitative analyses were conducted using matrix-matched calibration curves. The recoveries are listed in Table 2, and the data show that the average recoveries of fipronil and its three metabolites in all five matrices (peanut kernel, shell, straw, seedling, and soil) range from 66−116% with relative standard deviations (RSDs) of 1−19%, which illustrates that the proposed method meets typical validation requirements for pesticide residue analysis.[32]

For the LC-MS/MS analysis, the presence of matrix components may result in a matrix-induced enhancement or suppression effect. With the aim of evaluating the matrix effects of the method, both reagent-only and matrix-matched calibration curves were produced. The calibration curves were linear in the concentration range of 0.001−0.5 mg/kg for the four compounds in different peanut matrices with correlation coefficient above 0.99. The matrix effect was evaluated by the equation:

$$\%ME = [(\text{slope of matrix-matched calibration curve} - \text{slope of reagent-only calibration curve}) / \text{slope of reagent-only calibration curve}] \times 100\%$$

If the %ME fell in the range of ±10%, the matrix effect was considered negligible.[33] As shown in Table 3, the %ME data are

Table 3. Matrix Effect (%ME) of the Different Matrices in LC-MS/MS Analysis

compound	peanut	shell	seedling	straw	soil
fipronil	−86	−84	−91	−92	−95
fipronil-sulfone	−71	−73	−88	−81	−80
fipronil-sulfide	−91	−91	−95	−96	−96
fipronil-desulfinyl	−96	−86	−98	−98	−97

in the range from −98 to −71%, which indicates a strong matrix suppression for the four compounds in the five matrices, without noticeable difference among the peanut matrices. Consequently, matrix-matched calibration standards were necessary for accurate quantification of fipronil and its metabolites in all samples in this study.

The limits of detection (LODs) were calculated at 3 times the signal/noise ratio at the retention time of the peak of interest, and the limit of quantification (LOQ) was taken as the minimum concentration of a substance that can be quantitatively measured in the specific matrix with acceptable precision. The LOD of fipronil and its three metabolites was 0.3 ng/g, and the LOQ of these four compounds was 0.001 mg/kg in all matrices.

Residue Dynamics of Fipronil and Its Metabolites in Soil. The fipronil active ingredient in the seed dressing formulation was poorly mobile in soil, and at the end of the cultivation period, it was mostly concentrated in the soil layer close to the seed.[3] Due to the unique application approach, we did not get the normal dissipation curve in soil under field conditions. There are many factors influencing the degradation fate of fipronil in soil, such as mineral clay content[34] and organic matter.[35] Understanding how pH influences the dissipation of fipronil in the soil is important for ensuring the safe use of fipronil. Therefore, the degradation dynamics of fipronil in soil of different pH values were investigated in a simulation experiment in the laboratory.

The dissipation trends of fipronil and its metabolites in acidic, neutral, and alkaline soil are illustrated in Figure 3. The dissipation curves show that the degradation of fipronil in soil

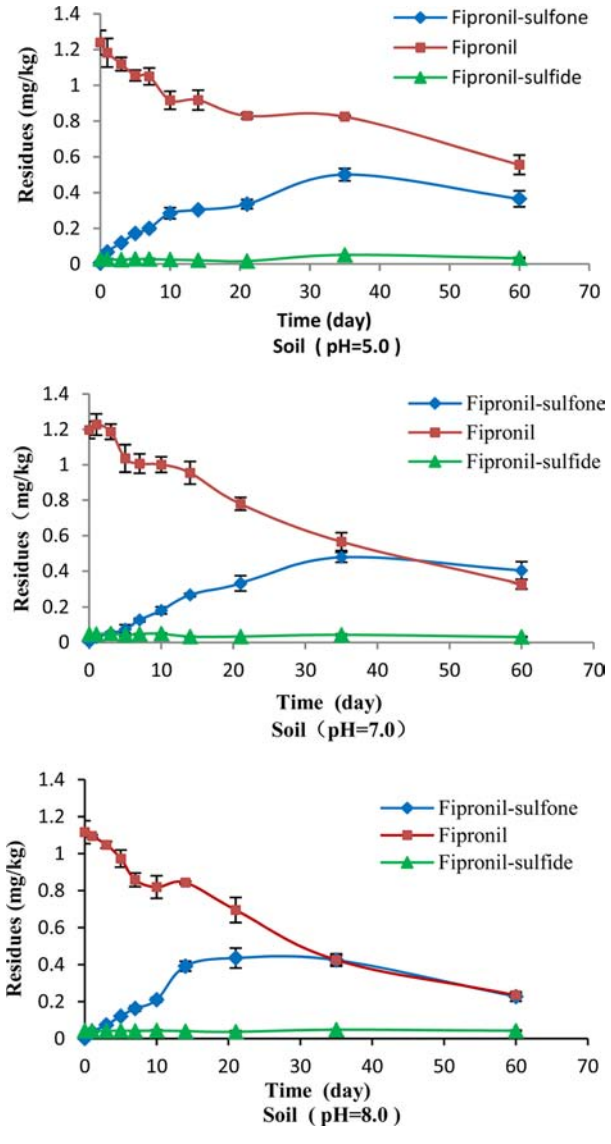

Figure 3. Dissipation curves of fipronil and its metabolites in soils of different pH values.

DOI: 10.1021/jf5054589
J. Agric. Food Chem. 2015, 63, 4435−4443

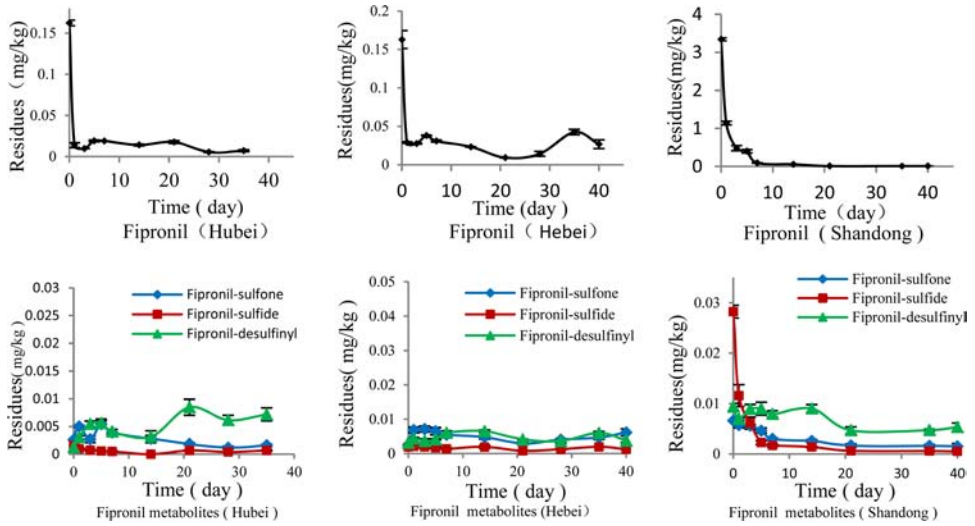

Figure 4. Dissipation curves of fipronil and its metabolites in peanut seedling at each trial site.

under different pH values (5, 7, 8) had a similar tendency. The residue of the parent fipronil gradually decreased, whereas the concentration of fipronil-sulfone increased gradually at first and then decreased over time. Fipronil-sulfide was also detected, but remained at a very low concentration (<0.04 mg/kg) during the entire dissipation process. Almost no photolysis product (fipronil-desulfinyl) was detected in the experiment, which was likely due to the total absence of light in the soil compartment. Therefore, the presence of fipronil-sulfone in a significantly higher amount compared to the other metabolites clearly demonstrates that the oxidation process played the major role in the metabolism of fipronil in the soil.

Considering the first-order kinetics equations, the half-lives of fipronil in acidic, neutral, and alkaline soils were calculated as 57, 32, and 27 days, respectively, which indicated that fipronil dissipated more rapidly in alkaline than in acidic soil. The degradation of fipronil in soil was also studied by Zhu et al.,[36] who found that the half-lives of fipronil in nonsterile clay loam soil were 9.7 and 8.8 days at 25 and 35 °C, respectively, whereas they were 3 times longer (about 33 days) in sterile soil. This means that microbial degradation had a significant influence on the half-life of fipronil in soil. In our work, the soil was almost sterile due to the pretreatment with acid or alkaline solutions, which might be the main reason for the relatively long half-lives of fipronil in the soil.

Dissipation of Fipronil in Peanut Seedling. The dissipation curves of fipronil and its metabolites in peanut seedling in Hebei, Hubei, and Shandong are illustrated in Figure 4. The dissipation curves show that fipronil dissipated rapidly in peanut seedling with estimated half-lives of <1 day at all three sites. The residues of fipronil dropped quickly and were <0.05 mg/kg in about 1−5 days. However, fipronil was still the highest residue compound versus the metabolites during all stages of dissipation.

From the dissipation curves of the three metabolites in peanut seedling (Figure 4), all three metabolites were detected during the dissipation of fipronil, although the concentrations were very low (all <0.01 mg/kg). Among the three metabolites, fipronil-desulfinyl had the highest concentration overall, especially at Hubei and Shandong, and fipronil-sulfide had the lowest. Fipronil-desulfinyl was found to be the major photodegradation product after the application of fipronil to corn, pea, and pear crops and, thus, is proposed to be the primary persistent residue on foliage-treated crops.[8] In our work, although peanut was treated with seed-dressing formulation, photolysis was also the relatively main degradation route in peanut crop other than oxidation and reduction.

Terminal Residue Analysis. After the peanut seeds were treated with the seed-dressing formulation at two dosages (1:50 and 1:33 formulation/seeds, in weight), the peanut and soil samples were collected at harvest time. Table S1 (see the Supporting Information) lists the terminal residue data of fipronil and its three metabolites in the harvested peanut and soil samples. For the purpose of dietary intake risk assessment, the total residue (the sum of fipronil and its three metabolites, expressed as fipronil) was calculated, and the total residue ranges are listed in Table 4. The results show that the final total residues in peanut shell and straw were relatively high, with the highest total residues of 0.99 and 0.30 mg/kg, respectively, whereas the residues were much lower in peanut kernels (<0.02 mg/kg) and in soil (0.003−0.15 mg/kg).

Table 4. Final Total Residues of Fipronil in Harvested Peanut and Soil Samples

	final residue (mg/kg)		
matrix	low dosage	high dosage	final total residue (mg/kg)
peanut kernel	0.003−0.014	0.003−0.020	0.003−0.020[a]
peanut shell	0.009−0.91	0.011−0.99	0.009−0.99[a]
peanut straw	0.061−0.30	0.055−0.20	0.055−0.30[a]
soil	0.014−0.15	ND[b]−0.011	0.003−0.15[a]

[a]Highest residue (HR) data. [b]ND means <0.0005 mg/kg.

The residues of the high-application experiment were a little higher than in the low-application experiment for peanut kernels and shells. Residues of the low-dosage experiment were even higher than in the high-dosage experiment in peanut straw and soil, which is likely due to the inhomogeneous distribution of the seed-dressing formulation in soil.

To demonstrate the residue distribution of fipronil and its three metabolites in harvested peanut samples, the final residues (see Table S1) are illustrated in Figure 5. In general, the parent compound fipronil had the highest residues in

DOI: 10.1021/jf5054589
J. Agric. Food Chem. 2015, 63, 4435−4443

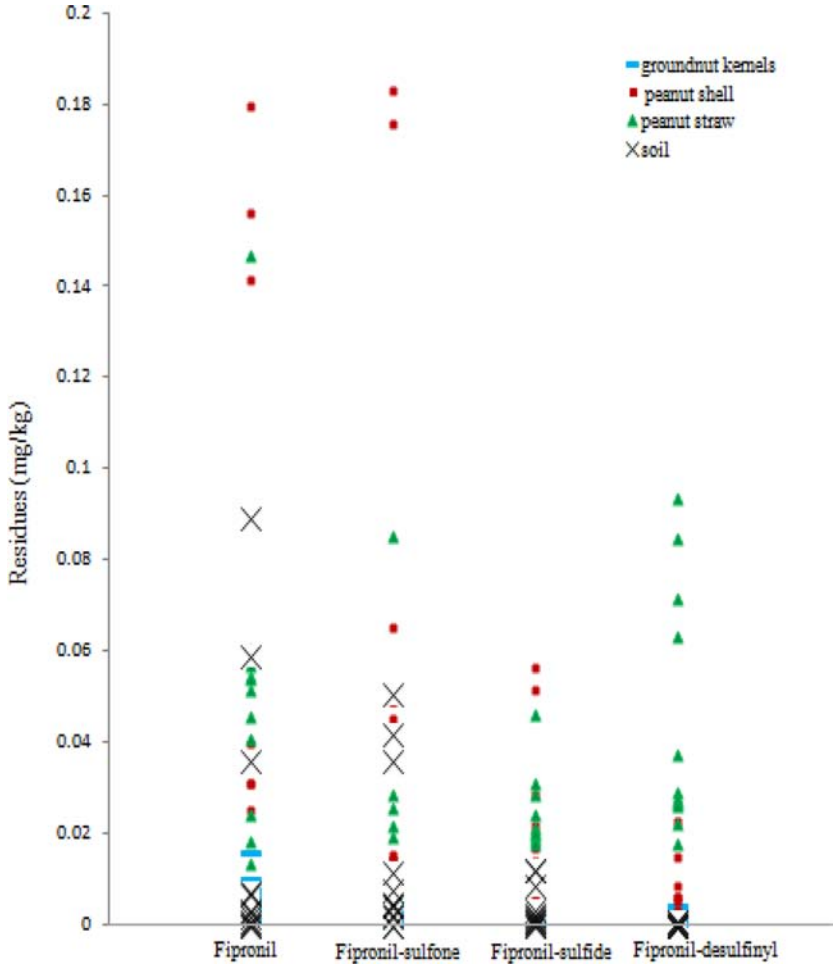

Figure 5. Distribution of the final residue data of fipronil and metabolites.

almost all four matrices (peanut kernel, shell, straw, and soil), whereas the residues of the three metabolites were a little different. The oxidation product (fipronil-sulfone) was the main metabolite found in peanut kernels, whereas in peanut straw, residue of photolysis metabolite (fipronil-desulfinyl) was the highest one and almost higher than fipronil. In the soil samples, fipronil-sulfone was also the highest, and there was also no detectable fipronil-desulfinyl in the terminal soil samples. This result is consistent with the residue distribution of the three metabolites in peanut seedling and soil in the dissipation experiment.

Until now, no MRL has been established for fipronil in peanut in other countries except for Japan, which set the MRL of fipronil in dried peanut as 0.01 mg/kg. Compared with the highest total residue data of 0.02 mg/kg in peanut kernels in our study, there would be some potential risks in the use of fipronil in peanut crops. However, the dietary intake risk assessment of fipronil leads to an acceptable daily intake (ADI) of fipronil as 0.0002 mg/kg body weight.[37] In China, assuming that the average adult body weight is 60 kg, then the ADI of fipronil for each person is 0.012 mg (0.0002 mg/kg bw ×60 kg bw). According to the dietary guideline in China,[38] the dietary intake of nut (including peanut) is 0.0039 kg each day, and based on the highest total residue of 0.02 mg/kg fipronil in harvested peanut kernels, the dietary intake of fipronil for each person would be <0.000078 mg (0.0039 kg × 0.02 mg/kg). Therefore, compared with the ADI of 0.012 mg, the acute risk quotient of fipronil was only 0.65%. This result indicates that the recommend dosage of fipronil would be safe in peanut for human health. The terminal residue data provides a basic evaluation for the safe use of fipronil as a seed-dressing formulation in peanut crops.

In conclusion, a residue analysis method for the simultaneous determination of fipronil and its three metabolites in peanut kernel, shell, straw, seedling, and soil samples was established using a modified QuEChERS sample preparation and LC-MS/MS analysis. The method was simple and fast, and the recoveries and LOQs were satisfactory for all matrices tested. The results of experiments demonstrated that fipronil dissipated rapidly in peanut seedling with a half-life of <1 day and degraded slowly in soil with half-lives of 27−57 days depending on soil pH values. The simulation experiment showed that fipronil degraded more rapidly in alkaline than in acidic soil, and oxidation was the main degradation route in soil samples, whereas no photolysis product fipronil-desulfinyl was detected. The final residues at harvest peanut kernels were all <0.02 mg/kg, whereas in peanut shell and straw the total residues were up to 0.99 and 0.30 mg/kg, respectively. Among the three metabolites, fipronil-sulfone was the highest residue compound in peanut kernels and soil samples, whereas fipronil-desulfinyl was the highest in peanut straw. The residue distribution of the metabolites is consistent with the results in dissipation experiments, which means that the photolysis metabolite fipronil-desulfinyl and the oxidation product

DOI: 10.1021/jf5054589
J. Agric. Food Chem. 2015, 63, 4435−4443

fipronil-sulfone were the highest residue metabolites in peanut plant (seedling and straw) and soil samples, respectively. The final total residue data in peanut kernels were used to evaluate the dietary intake risk of fipronil in peanut consumption, and results showed that the acute risk quotient of fipronil was only 0.65%, which provides an evaluation for the safe use of fipronil as a seed-dressing formulation in peanut crops. The data would also be helpful for the establishment of MRLs of fipronil in peanut.

Table 1. Treatments Performed in the Trial

control (C)	without application of agrochemicals
glyphosate (GL)	3 L ha^{-1} of glyphosate, commercial product
phosphorus (P)	100 kg ha^{-1} of calcium triple superphosphate
phosphorus + glyphosate (P+GL)	100 kg ha^{-1} of calcium triple superphosphate + 3 L ha^{-1} of glyphosate, commercial product

Table 2. Rainfall Simulation Dates

1 (Nov 7, 2012)	24 h after application
2 (Nov 11, 2012)	5 days after application
3 (Nov 14, 2012)	8 days after application

(phosphonomethyl)glycine potassium salt), 66.2 g, + inert ingredients and adjuvants, csp 100 cm^3) and phosphate fertilizers (calcium triple superphosphate, dissolved in distilled water; composition: 0−46−0, with 14% of calcium) were applied with manual spraying over the ground and without incorporation. Although glyphosate as foliar systemic herbicide in normal use is not applied on the soil, in this experiment we tried to generate conditions to analyze directly the interaction with P in the soil surface, avoiding crop canopy and residue interception by removing them before starting the treatment. The trial plots were preserved with nylon until the last simulation date to avoid possible variations in soil moisture.

Rainfall simulations at the field were performed using a small portable simulator designed by Irurtia and Mon.[17,18] The microsimulator consists of a metallic angle iron square prism. It is 1.5 m high and 0.25 m per side, holding clear acrylic walls that act as windbreaks (Figure 1). At the top there is a box holder with 49 plastic tubes that produce droplets. This box has a water feed from a reservoir placed in one of the edges of the structure. The reservoir is graduated in millimeters (laminar) of water applied to the microplots. In turn, the reservoir base can be varied in height, providing different pressures to form drops. The droplets formed have average diameters of approximately 4.7 mm. For a 1.5 m drop height the calculated kinetic energy of the microsimulator is 12.7 kJ m^{-2} m^{-1}, representing approximately 32.6% of the energy of natural rainfall.[18] In working position the device is attached to an iron frame, previously driven into the ground. This framework defines the microplot of 0.25 × 0.25 m where the measurements are made. The runoff is received through a funnel into a graduated (mm) container on one side of the bottom framework. With this device constant rainfall intensity is applied between 10 and 130 mm h^{-1} for each test site.

Measurements. Once the simulation process was initiated, sampling started when runoff began, collecting runoff water at the graduated reservoir at 5 min intervals, until constant runoff was verified, when three consecutive constant measurements were obtained (approximately 1 h), meaning that the basic infiltration rate was achieved. The total water volumes collected through the experience ranged from 1.5 to 2.5 L and were used to calculate infiltration and runoff rates. Samples were filtered and chemically analyzed for soluble phosphorus, glyphosate, and AMPA. The soluble phosphorus in the runoff water was determined using a colorimetric method.[19]

Glyphosate and AMPA Analyses.[20,21] Glyphosate (98%), AMPA (98%), glyphosate-FMOC (98.5%), AMPA-FMOC (97%), and isotopically labeled standards (ILS) [1,2-$^{13}C_2{}^{15}N$]glyphosate (98%) and [$^{13}C^{15}N$]AMPA were obtained from Dr. Ehrenstorfer (Augsburg, Germany). All other supplies used were of the best commercially available analytical grade.

Water sample aliquots of 3 mL, previously homogenized and filtered with 0.45 μm regenerated cellulose membrane filters, were placed in 15 mL Teflon centrifuge tubes and acidified with 6 M HCl to pH 1 (to maximize the dissociation of possible analyte−cation complexes). The samples were then spiked with internal standard (40 μL of ILS 1 mg L^{-1}) and neutralized to pH 6−7 with 6 M KOH. The derivatization

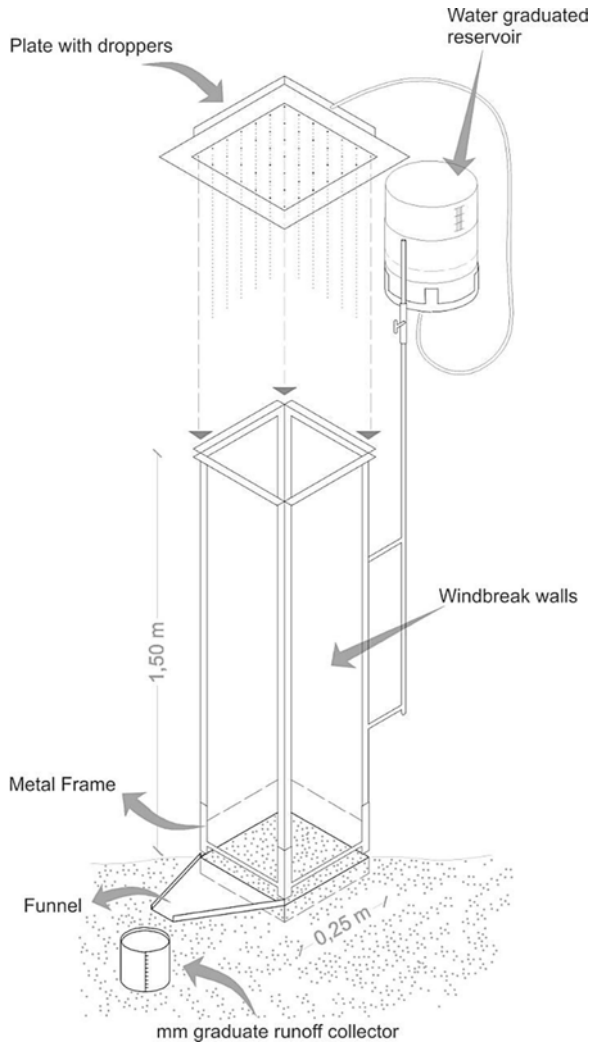

Figure 1. Scheme of portable rainfall simulator.

step was initiated with the addition of 0.5 mL of borate buffer (pH 9), FMOC-Cl (6 g L^{-1}), and acetonitrile. After overnight reaction at room temperature, the derivatization step was quenched by acidification to pH 3 with formic acid (FA).

After filtering with 0.45 μm regenerated cellulose filters, the derivatized extracts were passed through Oasis HLB (200 mg, Waters, Milford, MA, USA) cartridges. Cartridges were conditioned with 5 mL of MeOH, followed by 5 mL of 0.1% FA. Eluates were discarded, and the cartridges were washed with 3.5 mL of dichloromethane. The analytes were eluted with 9 mL of MeOH. The methanol aliquots were evaporated and reconstituted with the mobile phase (H_2O/MeCN 98:2 + 0.1% FA). Following 0.2 μm nylon syringe filtering, the extracts were ready for injection.

Liquid chromatography−tandem mass spectrometry (LC-MS/MS) analyses were performed using an Acquity UPLC liquid chromatograph (Waters) coupled to a triple-quadrupole mass spectrometer equipped with an ESI source (TQD, Waters Micromass, UK). Separations were performed at 40 °C using an Acquity UPLC HSS C18 column (1.8 μm particle size, 2.1 × 100 mm) at a flow rate of 0.35 mL min^{-1}. Standard and/or sample extract aliquots of 10 μL were introduced by means of an autosampler (Waters). The mobile phase consisted of H_2O/MeCN (98:2 + 0.1% FA; A1) and MeCN (+ 0.1% FA, B1), operated with a 10 min gradient run time.

Ionization was performed in positive-ion mode using nitrogen as the desolvation and cone gas at 600 and 15 L h^{-1}, respectively. A 1 kV capillary voltage was applied, and the source temperature was set at 140 °C. The desolvation temperature was 500 °C. Argon (1.32 × 10^{-5} mbar) was used at the collision cell to produce the respective ion

J. Agric. Food Chem. 2015, 63, 4444−4448

fragments, and acquisition was performed in MRM mode. The precursor and fragment m/z values for each specific compound, along with their respective cone voltages, collision energies, and dwell values, were optimized (Table 3). Chromatography and mass spectrometry data management was performed using MassLynx software v 4.1 (Waters).

The main parameters from our validation studies are shown in Table 4. Calibration curves from spiked nanopure water standards with concentration levels of 0.1, 0.5, 1, 10, 100, and 500 $\mu g\ L^{-1}$ were used for quantification purposes.[22]

Concentrations of glyphosate + AMPA ($\mu g\ L^{-1}$) and phosphorus (mg L^{-1}) were multiplied by the total volume of runoff water in 60 min to obtain the amount of glyphosate + AMPA and phosphorus lost in grams per hectare and kilograms per hectare, respectively.

Statistical Analyses. Data statistical analyses were realized through sampling variance and Tukey's test at a 5% significance level.[23]

RESULTS AND DISCUSSION

Runoff Analyses. The treatments applied had no influence on water dynamics. Thus, no significant differences were observed between either the runoff of different treatments or between the dates of simulation.

Phosphorus (P) in Runoff Water. *P Concentration.* The concentration of P in runoff water ranged between 0.3 and 5.9 mg L^{-1}. These values are similar to those obtained in runoff plots in fallow periods of a no-till Aquic Argiudoll.[24] Statistical analysis indicated that no significant interaction between treatment and date ($p < 0.05$) was observed, but significant differences between treatments and simulation dates were observed.

On the first simulation date, the P concentration in water was higher than and different from the third date (Table 5), indicating that nearby rainfall 1 day after the application of fertilizer favors the loss of P by superficial runoff to a representative dose of that used in the region.

With regard to treatment (Figure 2), no significant differences were found between the fertilized treatments, but there were differences with the treatments not fertilized with P. This behavior demonstrates that the higher P concentrations observed in runoff water were influenced by the practice of fertilization and not by the effect of the herbicide.

Table 5. Variance Analysis of Phosphorus Concentrations from Different Simulation Dates

date	concentration of P[a] (mg L^{-1})

2	2.1 ab
3	1.6 b

[a]Different letters indicate significant differences (Tukey $\alpha = 0.05$).

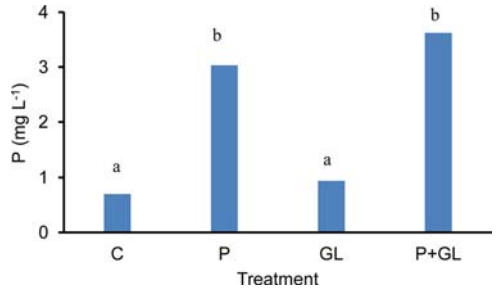

Figure 2. Variance analysis for phosphorus concentration (mg L^{-1}). Different letters indicate significant differences (Tukey $\alpha = 0.05$).

Amount of P in Runoff Water. The amount of P in runoff water ranged between 0.02 and 1.9 kg ha^{-1}. A significant interaction between treatment and date was found. Greater losses of P were observed with phosphate fertilizer treatment.

Treatments with P after a rainfall of approximately 1 h with 60 mm h^{-1} intensity lost 4% of the P applied by fertilization. These losses reduced the efficiency of the fertilization and consequently increased the pollution risk. Austin et al.[25] and Gaynor and Findlay[26] also reported on superficial phosphate transport and the eventual losses of the system under the dissolved or particulate shapes produced by rainfall or irrigation.

Glyphosate and AMPA in Runoff Water. *Glyphosate and AMPA Concentrations.* The glyphosate concentration in runoff water ranged between 18.6 and 1552.9 $\mu g\ L^{-1}$. This finding highlights the presence of glyphosate in all treatments, including the control, most likely because 2 months before the installation of our trial, the plot was sprayed for weed control in fallow with a 3 L ha^{-1} dose of the same commercial product used in the present trial.

A significant interaction was observed between the simulation dates and different treatments (Table 6). Treatment with P+GL on the first simulation date presented a higher concentration of glyphosate in water (19 times that of the control). On the same date, treatment with the same dose of herbicide without P exhibited approximately half the concentration of glyphosate in runoff water. The concentration was

diminished during the days after application, and the treatments without glyphosate were not different on any of the dates.

The concentration of AMPA also presented a significant interaction between treatment and date (Table 7). With P+GL

Table 7. Variance Analysis of AMPA Concentration

[a]Different letters indicate significant differences (Tukey α = 0.05).

treatment, no significant differences between dates were observed, implying that the degradation of the glyphosate molecule was immediate upon application, presenting no differences between the first and eighth days after application. With GL treatment, the first simulation date presented higher concentrations with respect to the others, and no significant difference was observed compared to P+GL.

Glyphosate + AMPA Concentration. Analysis of glyphosate + AMPA concentration presented a significant interaction between treatment and date. In Figure 3, P+GL

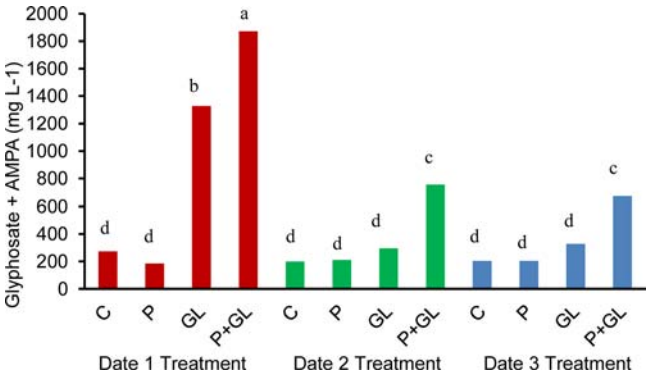

Figure 3. Variance analysis for glyphosate + AMPA concentration (μg L^{-1}). Different letters indicate significant differences (Tukey α = 0.05).

treatment presented a higher concentration on the first date, which was significantly different from GL treatment on the same date. For the other simulation dates, P+GL treatment was different from the other treatments.

Amount of Glyphosate + AMPA. Table 8 represents the analysis of the amount of glyphosate + AMPA lost in 1 h of rainfall simulation, 60 mm h^{-1} above bare soil. There were significant differences for the interaction between date and treatment; treatment with P+GL on the first simulation date was significantly higher than the other treatments.

The analysis of the first 5 cm of soil prior to the rainfall simulation indicated that no significant differences were

observed in the total P concentration between treatments (data not shown). Nevertheless, differences in glyphosate concentration were evident (Figure 4). No difference was

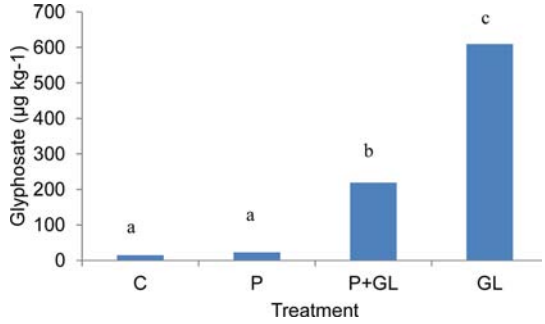

Figure 4. Variance analysis for glyphosate concentration (μg kg^{-1}) in the first 5 cm of the soil prior to each rainfall simulation. Different letters indicate significant differences (Tukey α = 0.05).

observed between the treatments that were not sprayed with glyphosate, and GL treatment had the highest concentration, confirming that 24 h after spraying, P occupied the exchanging sites in P+GL.

After P+GL treatment, 28% of the applied glyphosate was lost in the runoff water. In the case of GL treatment at the same dose, the losses were 2.5-fold less than those of the P+GL treatment, indicating that the practice of phosphate fertilization and the application of glyphosate significantly increase the loss of glyphosate by runoff.

Morillo et al.[27] reported that glyphosate can act in the soil in a similar way to phosphate, possibly through the phosphate group. According to the results obtained by Zhao et al.,[28] the effect of the phosphate application on glyphosate mobility in different soils is due to the combination of reduced pH produced by the addition of acidic phosphate solution and the repulsion between the glyphosate and preabsorbed phosphate.

A significant interaction between P and glyphosate in common sorption sites of no-till Aquic Argiudoll soil was verified in the field conditions. The application of phosphate fertilizer increased the loss of glyphosate with the runoff caused by rain a day after its application.

The rain simulators were useful for analyzing the effect of the time elapsed between application and rainfall, demonstrating competitive adsorption and transport of P and glyphosate on soil exchange sites.

The relationship between the application of glyphosate and phosphate fertilizers and their contribution to pollution by runoff had not been identified using field conditions before this work. Some authors have studied this subject under laboratory conditions and in other parts of the world where the lack of tillage does not have the same importance as in the Argentinean Humid Pampa. As a consequence, the environmental impact of

DOI: 10.1021/jf505533r
J. Agric. Food Chem. 2015, 63, 4444−4448

the interaction of those two practices, the most commonly used under no-tillage conditions, was unknown. As such, our results strengthen the necessity to pursue further studies aimed at understanding phosphorus−glyphosate interactions in soils under real conditions to establish an optimized time and conditions in current practice to reduce the risks of pollution by runoff. These results are of great importance for minimizing the environmental impact in the Argentinean setting, where no-tillage practices are extended to >20 Mha.

MATERIALS AND METHODS

Chemicals. Certified reference standards of all test compounds were of >97% purity and purchased from Ehrenstorfer GmbH (Augsburg, Germany) and Sigma-Aldrich (Steinheim, Germany). All of the solvents were of analytical reagent (AR) or ultragradient HPLC grade and obtained from J. T. Baker (Center Valley, PA, USA). All other reagents were of AR grade and purchased from Thomas Baker (Mumbai, India) and Merck India Ltd. (Mumbai, India). The dispersive solid phase extraction (dSPE) sorbent, namely, primary−secondary amine (PSA), was received from Agilent Technologies (Santa Clara, CA, USA). Ultipor Nylon-6,6 membrane filters (0.2 μm pore size and 13 mm diameter) were purchased from Pall Life Sciences (Ann Arbor, MI, USA). HPLC grade water was obtained through Sartorius water purification system (Göttingen, Germany).

Apparatus. For sample preparation a mixer with grinder (0.5 and 2 L capacity, model GX7, Bajaj India Ltd., Mumbai, India), vortex mixer (Genie 2T, Imperial Biomedicals, Mumbai, India), ultrasonic bath (Oscar Electronics, Mumbai, India), low-volume concentrator (TurboVap LV; Caliper Life Sciences, Russelsheim, Germany), high-speed refrigerated centrifuge (Kubota 6500, Kubota Corp., Tokyo, Japan), and a microcentrifuge (Microfuge Pico, Kendro D-37520, Osterode, Germany) were used. A pH meter (Thermo Orion, Chelmsford, MA, USA) was used after calibration using buffer solutions of pH 4 and 7. Residue analysis was performed using an LC-MS/MS [Shimadzu UFLC XR connected to API 5500 QTrap (AB Sciex, Toronto, Canada) mass spectrometer], supplied by Labindia Instruments Pvt. Ltd. (Mumbai, India).

Selection of Matrices and Sample Homogenization. Fruit and vegetable matrices were selected considering their importance for export and domestic consumption. The selected matrices were grape (*Vitis vinifera* L.), mango (*Mangifera indica* L.), capsicum (*Capsicum annuum* L.), okra (*Abelmoschus esculentus* L.), curry leaf (*Murraya koenigii* L.), drumstick (*Moringa oleifera* L.), and bitter gourd (*Mormordica charantia* L.). The method was initially optimized in grape and then extended to other commodities. The control matrices were obtained from the organically grown local farms and used after ensuring absence of any of the target incurred residues. About 0.5−2 kg sample sizes of different matrices were selected (0.5 kg for curry leaf, 1 kg for other vegetables, and 2 kg for grape and mango) to obtain a homogenized representative sample. The samples were chopped (except grape) after removal of stalks, caps in the case of vegetables, and stone in the case of mango, followed by crushing in a mixer−grinder. In the following step, about 0.1−0.4 kg of this crushed material (0.1 kg for curry leaf; 0.2 kg for bitter gourd, drumstick, and okra; 0.4 kg for grape, mango, and capsicum) was again homogenized in a smaller jar (0.5 L capacity) to obtain a finely crushed homogeneous sample with or without addition of water. In the case of bitter gourd, okra, and drumstick, water was added in the proportion of 1:1 w/w, and for curry leaf, the ratio was 1:3 w/w. The proportion of water added was based on the inherent moisture content of the matrices and was optimized through separately conducted experiments to achieve the desired level of homogeneity (RSD < 10% when analyzed in six replicates).

Selection of Agrochemicals. The study included 296 multiclass agrochemicals (including selective metabolites) with different biological activities such as insecticides, acaricides, fungicides, herbicides, and plant growth regulators, which were either neutral, acidic, or basic by chemical nature. The compounds were selected considering the MRL database of the European Union[2] and Food Safety Standards Authority of India.[3] Details of the test analytes are presented in Supplementary Table 1 of the Supporting Information.

Preparation of Standard Solutions. The stock solutions of individual certified reference standards (CRS) were prepared by accurately weighing 10−20 mg of each analyte in volumetric flasks (certified A class) and dissolving in 10 mL of methanol (stored at −20 °C). Intermediate standard mixtures of 10 μg/mL and a working standard mixture of 1 μg/mL were prepared by diluting the stock solutions in methanol. From this, the calibration standards within the range of 0.2−40.0 ng/mL were prepared by serial dilution with methanol/20 mM ammonium formate in water (1:1 v/v) or control matrix extracts.

Existing Method. Homogenized samples (10 g) were extracted with ethyl acetate (10 mL) per the procedure reported earlier.[4]

Optimization of Buffer Concentration. Homogenized grape (10 g) spiked at 10 ng/g was extracted with 10 mL of ethyl acetate either using no buffer or in the presence of acetic acid (1% v/v) plus variable amounts of sodium acetate (0, 0.1, 0.5, 1, and 2 g; $n = 6$) along with 10 g of sodium sulfate. No PSA cleanup was employed to avoid resultant pH-dependent effects on the recovered analytes. The average recoveries were compared against the respective matrix-matched standards employing single-point calibration.

Effect of Dispersive SPE Cleanup Using PSA. For this, two sets of homogenized control grape samples (10 g) were extracted with the existing method[4] and optimized sodium acetate buffer method, each in six replicates. The resultant extracts were spiked at 10 ng/g level and treated as (1) no cleanup, (2) cleanup with 25 mg of PSA per 5 mL of extract, and (3) cleanup with 125 mg of PSA per 5 mL of extract. The cleanup efficiencies in each case were evaluated by gravimetric comparison of the residual matter. At each variable amount of PSA, the pH of the corresponding ethyl acetate extract was measured after dilution with water and under continuous stirring with a magnetic stirrer. The average concentration of the analytes at different treatments were estimated as accuracy (%) against solvent standards and compared.

Optimization of DEG Quantity. Two milliliters of ethyl acetate extract of control grape and pure ethyl acetate solvent were taken in six different sets of 10 mL evaporation tubes and spiked with a mixture of pesticides at 10 ng/mL. DEG (10% in methanol) was then added in each tube at different volumes of 0, 10, 25, 50, 100, and 200 μL, respectively. After evaporation under a gentle stream of nitrogen at 35 °C, the residues were reconstituted in methanol/water (50:50) and injected into LC-MS/MS after passing through a Nylon-6,6 membrane filter (0.2 μm). The area (%) responses of the test analytes were compared. Full-scan analysis of selective samples was done using information dependent acquisition (IDA) functionalities of a QTrap LC-MS/MS system.

Proposed Method. The sample (10 g) was extracted with 10 mL of ethyl acetate (+ 1% acetic acid) in the presence of sodium acetate (0.5 g) and anhydrous sodium sulfate (10 g) by means of vortexing (2 min) and subsequent centrifugation at 5000 rpm for 5 min. An aliquot of the upper ethyl acetate extract (5 mL) was drawn and treated with PSA (25 mg) by means of vortexing for 30 s. The cleaned supernatant extract (2 mL) was placed in a 10 mL test tube, and to it 10% DEG (10 μL) was added. This mixture was subsequently evaporated to dryness under a gentle stream of nitrogen (in a low-volume concentrator) at 35 °C. The residue was dissolved in 1:1 methanol plus 20 mM ammonium formate in water (2 mL) by ultrasonication (1 min) followed by vortexing (30 s). This solution was centrifuged at 10000 rpm for 5 min. The extracts were analyzed by LC-MS/MS after passing through a Nylon-6,6 membrane filter (0.2 μm).

LC-MS/MS Analyses. Chromatographic separation of the test compounds was achieved on an Ultra AQ C18 column (3 μm, 100 mm length, 2.1 mm i.d.; Restek Corp., Bellefonte, PA, USA). The mobile phase composition was (A) water with 10 mM ammonium formate and (B) methanol with 10 mM ammonium formate, each with 0.1% formic acid, at flow rate of 0.5 mL/min with a gradient profile.[15] The column oven temperature was maintained at 40 (±1) °C. The injection volume was 10 μL. Measurements were done with electrospray ionization (ESI) in positive polarity with optimized multiple reaction monitoring (MRM) transitions. The source parameters, namely, ion source voltage (5500 V), nebulizer gas (30 psi), heater gas (60 psi), ion source temperature (550 °C), and curtain gas (40 psi), were maintained throughout the analysis.

Residue estimation was performed by retention time dependent "scheduled multiple reaction monitoring" (sMRM) with two mass transitions for each test molecule, one for quantification and the other for confirmation. The MRM detection window (MRM DW) was 90 s with the target scan time of 1 s. The ion ratio for the two mass transitions was used for unambiguous identification of each pesticide

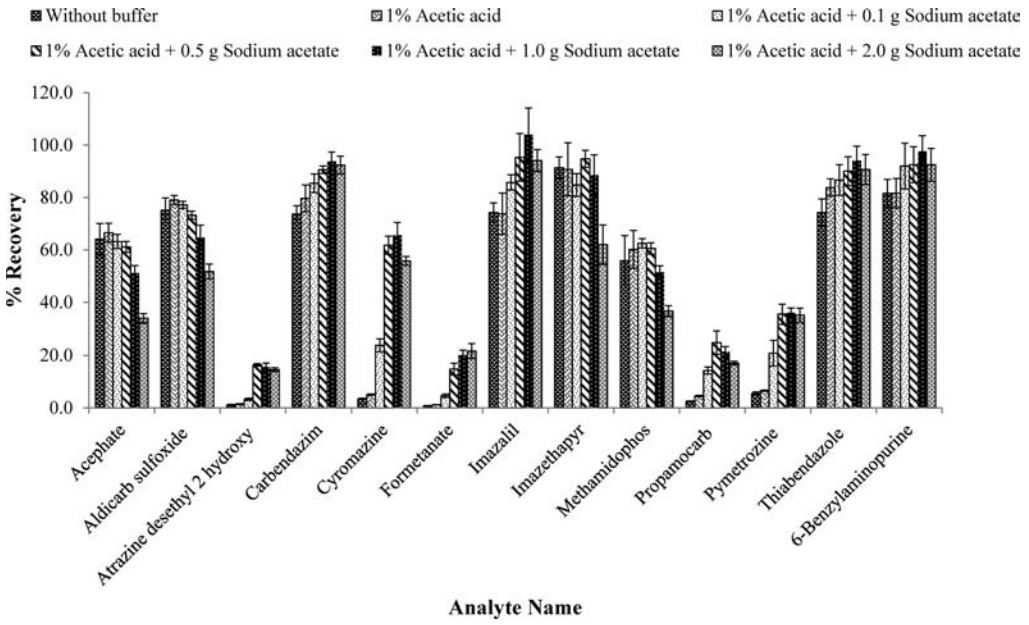

Figure 1. Effect of buffering on recovery of analytes.

per the criteria of the SANCO guideline.[14] A representative LC-MS/MS chromatogram is given in Supplementary Figure S1 in the Supporting Information.

Method Validation. The performance of the analytical method was assessed per the SANCO guideline.[14] Standard calibration was established on the basis of solvent and matrix-matched standards in the concentration range of 0.2−40 ng/mL. Limits of detection (LOD) and quantification (LOQ) were determined by considering signal-to-noise ratios (S/N) of 3 and 10, respectively, for the quantifier MRM ensuring that the qualifier MRM has S/N of ≥3:1 at LOQ. For the recovery experiment, at first the samples were spiked at the desired level from a standard working solution of 1 μg/mL and then thoroughly homogenized. Ten grams of homogenized mass was weighed in a 50 mL polypropylene tube and then extracted per the proposed method. The recovery experiments were carried out in grape at five spiking levels, that is, 1, 2.5, 5, 10, and 40 ng/g (n = 6). For all other matrices three spiking levels were selected, which were equivalent to 1, 5, and 10 ng/g for mango and capsicum; 2, 10, and 20 ng/g for bitter gourd, okra, and drumstick; and 4, 10, and 40 ng/g for curry leaf on an actual weight basis. Recoveries (%) were calculated against the respective matrix-matched calibrations. The precision in terms of repeatability in recovery was estimated as % RSD. The results were summarized in different categories, namley, I, recovery (70−120%), RSD ≤ 20%; II, recovery (60−140%), RSD ≤ 20%; III, recovery (60−140%), RSD > 20%; IV, recovery (<60%), RSD ≤ 20%; V, recovery (<60%), RSD >20%; VI, other (include the compounds below LOQ or those suffering from matrix-specific degradation and thus not included in categories I−V).

Dilution and Matrix Effect. Cleaned ethyl acetate extracts (control) of all test commodities were aspirated in evaporation tubes in the volumes of 2, 0.4, 0.2, and 0.1 mL (n = 6) and made up to 2 mL with appropriate quantities of ethyl acetate, which resulted into corresponding dilution of 0, 5, 10, and 20 times (v/v). After fortification (at the level of 10 ng/mL), they were evaporated to near dryness under a gentle stream of nitrogen in the presence of DEG solution (10 μL, 10%). The residue was dissolved in 1:1 methanol plus 20 mM ammonium formate in water (2 mL). The percent accuracy of each analyte response in undiluted or diluted matrix was compared to that of solvent standard, and the results are summarized in distinct groups: I, accuracy 0−30% (very high matrix induced signal suppression); II, accuracy 30−60% (high signal suppression); III, accuracy 60−80% (moderate signal suppression); and IV, accuracy 80−130% (low or no signal suppression or enhancement).

Comparison of Proposed Method with Existing Ethyl Acetate[4] and Buffered QuEChERS[10] Method. The proposed method was compared against the existing ethyl acetate[4] and buffered QuEChERS[10] methods (n = 6), and the method performances were evaluated in terms of recovery (%).

RESULTS AND DISCUSSION

In a highly acidic matrix suc as grape (pH ∼4), with the existing ethyl acetate method[4] the recoveries of certain basic pesticides (such as cyromazine, pymetrozine, atrazine desethyl 2-hydroxy, and propamocarb) were poor (<6%) as against the matrices with relatively higher pH such as okra (pH >5). Similar poor recoveries were also recorded in other acidic matrices, for example, plum (pH ∼3). Poor recoveries of such pesticides in highly acidic matrices could be attributed to their poor partitioning into the ethyl acetate phase, which might have occurred due to their ionization in acidic pH (in grape and plum) and the greater affinity of the ionized forms toward the aqueous phase.[16,17] Considering the role of pH adjustment explained in the buffered QuEChERS method[10] and with the optimized quantities of acetate buffer (i.e., 1% acetic acid + 1 g of sodium acetate per 10 g of sample), the pH of grape and plum matrix was adjusted to 5−6. Use of acetate buffer was cost-effective and easy to handle, and being in solid form, it avoided efforts for preparing and maintaining buffers in solution forms. With this approach, the recoveries of the above-mentioned compounds could be improved significantly. However, at the same time, the recoveries of certain compounds such as acephate, aldicarb sulfoxide, and methamidophos were decreased substantially as against the non-buffered method. Therefore, we decided to evaluate the best concentration of acetate buffer to obtain overall acceptable recoveries for the entire range of the test compounds.

Optimization of Buffer Concentration. With the addition of acidified ethyl acetate (1% acetic acid) and 0, 0.1, 0.5, 1, and 2 g of sodium acetate, the initial pH of the lower aqueous layer was changed from 3.9 (without buffer) to about 3.8 (1% acetic acid), 4.9, 5.7, 5.9, and 6.3, respectively. Recoveries of weakly acidic pesticides such as acephate and aldicarb sulfoxide showed about 15% loss in recovery when the

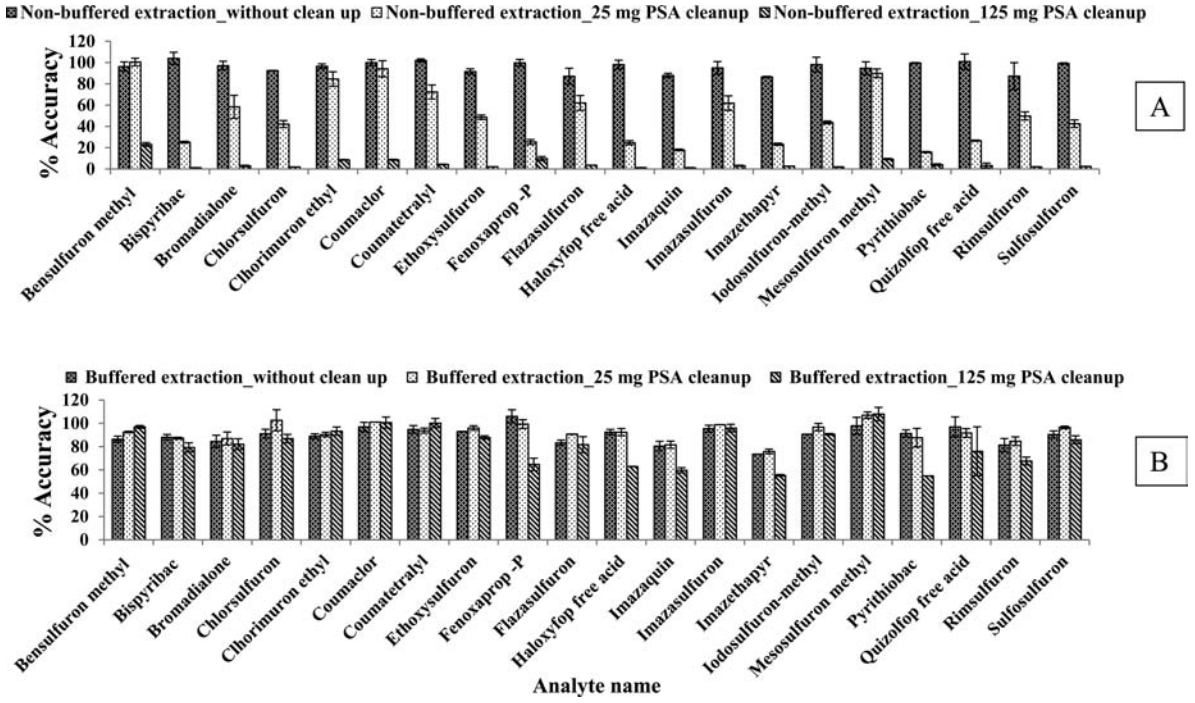

Figure 2. Effect of PSA cleanup in nonbuffered (A) and buffered (B) ethyl acetate extraction.

quantity of sodium acetate was increased from 0.5 to 1 g. A decreasing trend in recoveries (up to 28% loss in recovery) was observed with further addition (2 g) of sodium acetate for these compounds. For imazethapyr (acidic in nature) with increase in pH above 6, the recovery loss was about 30% (Figure 1). These acidic pesticides tend to form negatively charged ions as the pH increases with corresponding increase in water solubility and reduced partitioning into the ethyl acetate phase. In the case of methamidophos (basic in nature), a similar decreasing trend in recoveries was observed probably due to its hydrolysis with increase in pH toward neutral. In contrast to this, in the case of basic analytes, namely, atrazine desethyl 2-hydroxy, propamocarb, formetanate, cyromazine, and pymetrozine, the recoveries were enhanced by 10−25 times after adjustment of the pH above 5 as against the nonbuffered method. Although the recoveries of these compounds were comparatively low (15−65%) due to their highly polar nature and low extractability into ethyl acetate, buffering enhanced their extractability and facilitated accurate quantification. Other basic compounds such as carbendazim, thiabendazole, imazalil, and 6-benzylaminopurine (6-BA) also showed improved recoveries with buffering at pH >5 due to better partitioning into ethyl acetate.

To achieve the best compromise for optimum extraction of acidic and basic analytes, for the final method, 0.5 g of sodium acetate + 1% acetic acid was selected as the optimized quantity for buffering. The pH of all the test commodities was effectively adjusted within the range of 5−6 irrespective of the initial matrix pH (Supporting Inforamtion, Supplementary Figure S2).

Effect of Dispersive SPE Cleanup Using PSA. In the existing ethyl acetate method[4] 25 mg of PSA per 5 mL of extract had been used for dispersive cleanup to remove matrix coextractives such as fatty acids and sugars. In the initial studies, with this unbuffered method, we found that the PSA cleanup resulted in severe losses of certain acidic pesticides in all test matrices. Therefore, we decided to evaluate the effect of PSA cleanup in the optimized buffered ethyl acetate extraction. The quantities of PSA were selected per the existing ethyl acetate method,[4] that is, 25 mg/5 mL of extract, and per the original version of the QuEChERS method,[18] that is, 125 mg/5 mL extract (equivalent to 25 mg/mL).

Gravimetric estimation of the residual matrix showed that, in the existing method,[4] 56% residual matrix was removed as against 38% in buffered method using 25 mg of PSA; that is, the efficiency of PSA cleanup was reduced to 66% in the buffered extraction. This was attributed to partitioning of acetic acid (used during buffering) in the organic layer (ethyl acetate), which probably saturated the binding sites of PSA and was indicated by acidic pH of the ethyl acetate extract. The reduced cleanup efficiency of PSA due to transfer of acetic acid in the organic phase was also reported earlier in the buffered QuEChERS method.[10] It was observed that there was no significant difference in the residual matrix using 25 or 125 mg PSA and, therefore, 25 mg was chosen as the optimum quantity for cleanup.

The percent accuracy of test analytes against solvent standards in the existing and buffered methods without and with PSA cleanup (25 and 125 mg PSA/5 mL extract) revealed interesting results. In the unbuffered method, after PSA cleanup, many acidic urea herbicides (pyrimidinylsulfonylurea, triazinylsulfonylurea, aryloxyphenoxypropionic acid, imidazolinone, pyrimidinyloxybenzoic acid compounds) had significant recovery losses, which ranged between 25 and 83% with the cleanup using 25 mg of PSA and 73−98% with the cleanup using 125 mg of PSA per 5 mL of extract (Figure 2). Similar observations were reported in the literature recommending no PSA cleanup during extraction of acidic compounds to protect against recovery loss.[19,20] In buffered extraction, practically there were no losses with respect to the treatment with 25 mg of PSA, although 13−41% losses in recovery were recorded in the case of 125 mg of PSA. The probable reasons for this result could be related to the presence of acetic acid in the ethyl

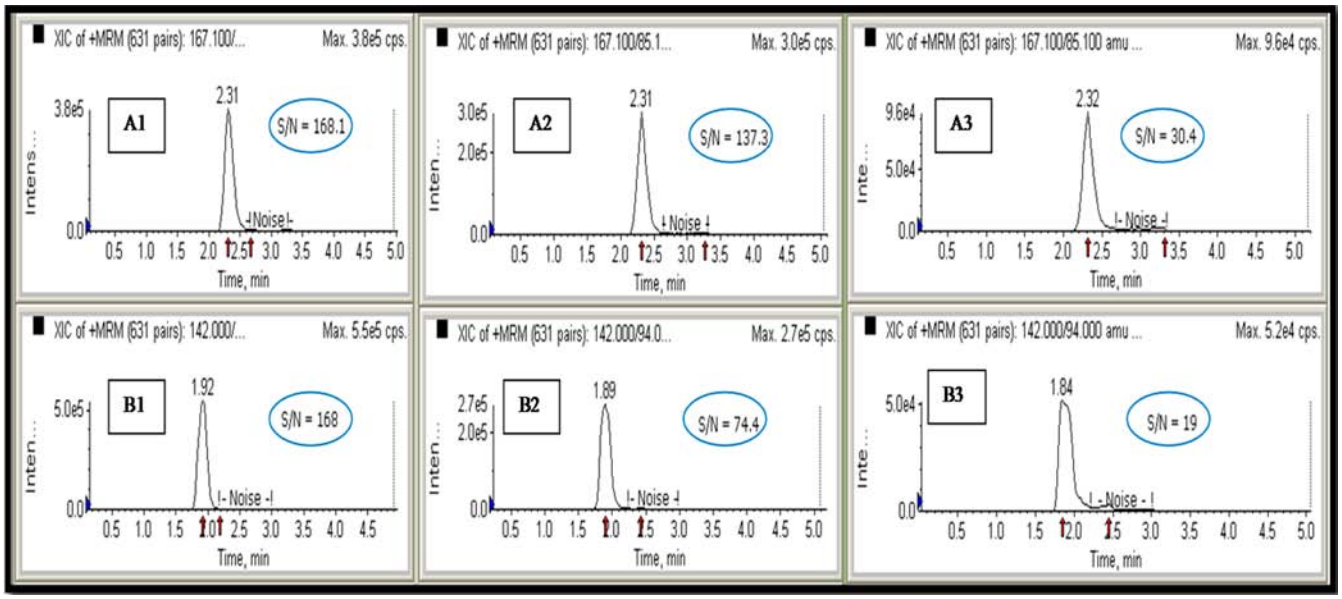

Figure 3. Signal suppression of (A) cyromazine and (B) methamidophos (10 ng/mL) corresponding to (1) no DEG, (2) 10 μL of DEG, and (3) 200 μL of DEG.

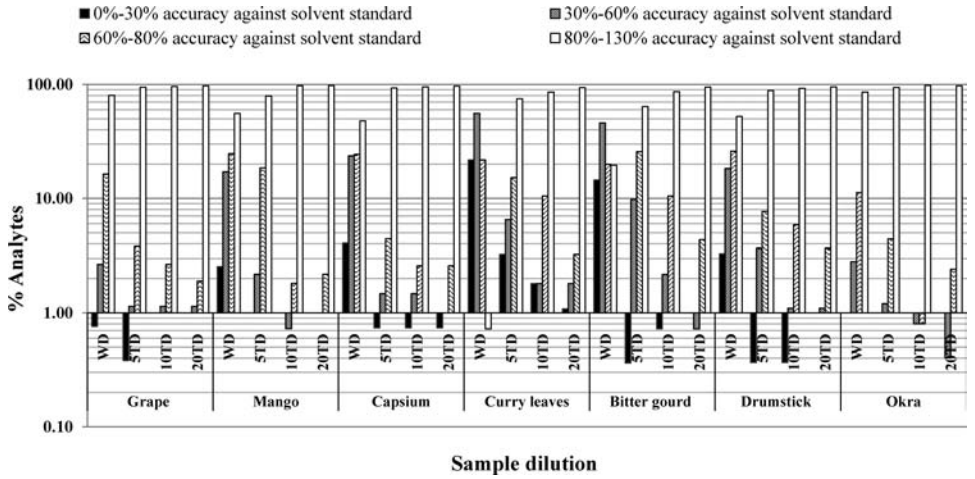

Figure 4. Demonstration of dilution approach for reducing matrix effect in different commodities.

acetate phase, which reduced direct interaction of PSA with the acidic analytes. This was another important and favorable aspect of buffering, and thus there was no need to omit PSA cleanup; good recoveries of acidic compounds could still be achieved. Furthermore, with this optimum quantity, signal suppression was significantly reduced by 20−50% for compounds, namely, dodine, bupirimate, fenpropimorph, imazalil, mexacarbate, methoprotryne, pirimicarb, prometon, prometryne, spiroxamine, and 6-BA.

Optimization of DEG Quantity. In the existing ethyl acetate based extraction method,[4] 200 μL of DEG (10% solution in methanol) for 2 mL of final extract is employed as a keeper during the solvent evaporation step. The significance of the use of DEG solution is explained by Mol et al.[21] In brief, addition of this high boiling, viscous liquid in the extract protects against loss of analytes during evaporation and avoids hard drying of the residual matrix, which otherwise may trap analytes and make their solubilization difficult. In our routine analysis, it was observed that the early-eluting compounds (t_R 2−5 min) suffer serious signal suppressions (>50%) irrespective of the matrix examined. Considering its polar nature and early elution, we assumed that DEG might be contributing to matrix effect, and hence its impact was investigated further. During the DEG optimization experiment, it was observed that the early-eluting compounds such as methamidophos, acephate, atrazine desethyl, atrazine desethyl 2-hydroxy, cyromazine, and dinotefuran showed significant signal suppressions (30−80%) as the quantity of DEG was increased from 0 to 200 μL (Supporting Information, Supplementary Figure S3). The trend in signal suppression of these analytes was similar in the case of pure solvent and matrix, which demonstrated that DEG rather than the matrix coextractives was responsible for signal suppressions. The effect was most prominent in the case of methamidophos, the earliest eluting compound (t_R 1.9 min), which had almost 40% signal suppression with 10 μL of DEG and almost 80% suppression after the addition of 200 μL of DEG. Figure 3 shows how signal suppression due to the addition of DEG resulted in lower signal-to-noise ratios (S/N) and, thus, increased LOQs of cyromazine (by 5 times) and methamidophos (by 8 times).

J. Agric. Food Chem. 2015, 63, 4449−4456

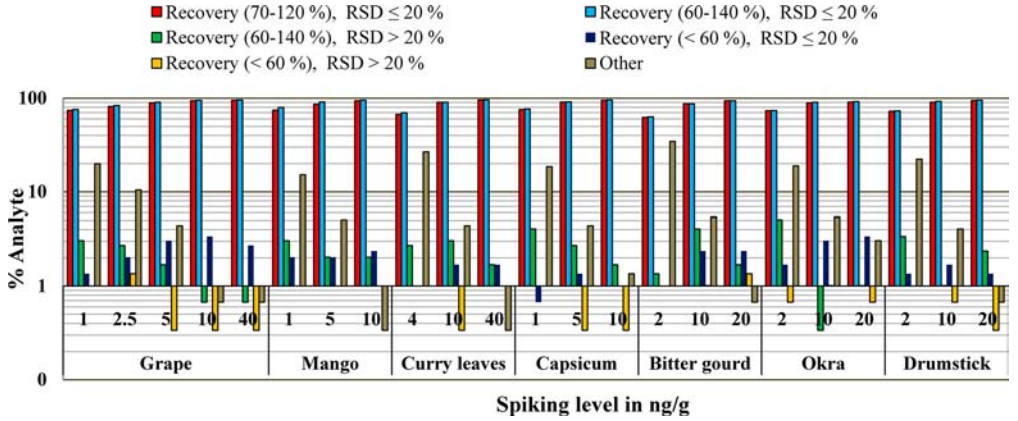

Figure 5. Summarized data on the performance of the buffered ethyl acetate method for 296 compounds in all test matrices.

To evaluate this further, DEG solution (equivalent to 200 μL of 10% DEG solution/2 mL) along with methamidophos (10 ng/mL) in methanol was injected in the same chromatographic system and analyzed in full-scan mode using QTrap functionalities. Analysis was performed using enhanced mass spectra (EMS) as "survey scan" and enhanced product ion (EPI) as "dependent scan". The extracted ion chromatogram of DEG (m/z 107.0) and enhanced product ion spectra revealed prolonged elution of DEG within 1−5 min (Supporting Information, Supplementary Figure S4), which could be the main reason for signal suppression of early-eluting compounds. The spectral confirmation was obtained by comparing the same with the earlier reported spectrum of DEG.[22] Due to relatively higher viscosity and boiling point (245 °C) DEG might be incompletely evaporated and reduce ionization of early-eluting compounds. Volatile or semivolatile compounds such as dichlorvos, molinate, and isoprocarb suffered higher recovery losses (20−60%) in the case when no DEG was used in the evaporation step, which could be avoided when 10 μL of DEG solution was added. Therefore, considering the role of DEG to avoid hard drying of residues, instead of completely omitting its use, its volume was optimized to 10 μL in place of 200 μL[4]

Dilution and Matrix Effect. In Figure 4, the results corresponding to "without dilution" (WD) indicate matrix effect of the respective test matrix. In the case of grape, mango, capsicum, okra, and drumstick, 72−97% of the test compounds had moderate to low matrix effect (groups III and IV). In the case of bitter gourd and curry leaf, 40 and 23% of the compounds suffered from moderate to low matrix effects, whereas 46−56 and 15−22% of compounds belonged to the high (group II) and very high (group I) matrix effect categories, respectively, in terms of signal suppressions. Hence, quantification of the residues of these compounds was performed on the basis of matrix-matched calibration standards.

Dilution led to cleaner extracts, reducing signal suppressions significantly.[9] In recent publications,[23,24] a similar approach has been demonstrated with reference to QuEChERS extraction. From the comparative study (Figure 4), it was concluded that 5−10 times dilution of the final extract effectively reduced matrix-induced signal suppression for most of the compounds. After dilution of the bitter gourd extract by 5 and 10 times, the percentage of compounds falling into groups I (very high matrix effect) and II (high matrix effect) came down from 60 to 10 and 3%, respectively. Similarly, for curry leaf, the dilution of extract by 5 and 10 times reduced the proportion of compounds falling into groups I and II from 77 to 10 and 3%, respectively. This study will thus help employ appropriate dilution for quantification against solvent standard and nullify the requirement of control matrix for preparation of matrix-matched standards.

Method Validation. Calibration linearity employing linear or quadratic regression equation was established with $r^2 \geq 0.995$ for all of the test analytes in solvent and matrix-matched standards within the range of 0.2−40 ng/mL with a weighting factor of $1/x$. The method LOD and LOQ values of all the analytes were determined in grape matrix based on S/N ratio and specified in Supplementary Table 2 in the Supporting Information. Results showed that, of 296 test compounds, 79.3% of the compounds had LOQs in the range of 0.2−1 ng/g whereas for 16.2 and 3.7% compounds, the LOQs were in the ranges of 1−5 and 5−10 ng/g, respectively. As about 80% of compounds could be easily quantified at the 1 ng/g level, it was selected as the lowest spiking level (LOQ) for recovery study in grape matrix. Per the SANCO guideline,[14] recovery study at minimum two levels (at LOQ and another higher level) need to be performed and thus, considering the entire range of LOQs, that is, 1−10 ng/g, the recovery study was performed at five spiking levels, 1, 2.5, 5, 10, and 40 ng/g in grape matrix. Once the method was validated for grape matrix, it was extended to other matrices and corresponding LOQs were estimated. Recoveries at LOQ were estimated for all matrix−chemical combinations, and the lowest level at which recovery is reported is the method LOQ for that particular matrix (Supplementary Table 2).

Figure 5 shows summarized method performance data classified into categories I−VI for all of the matrices. Of the 296 test compounds, 61.2−75.7% had recoveries in the range of 70−120 (±20)% at the lowest spiking level across the commodity matrices. At the regulatory default LOQ level of 10 ng/g, the recoveries for 87.1−94.9% of the compounds were within 70−120 (±20)%. Only 1−3.7% of the total compounds had recoveries <60 (±20)% at the 10 ng/g level, which could, however, be correctly quantified after the application of a recovery correction. Around 0.33−4% of compounds had good recoveries (60−140%) but with high RSDs (>20%) and about 0−1% of compounds had lower recoveries (<60%) with higher RSDs (>20%) at the 10 ng/g level. Of the 296 test analytes, 15−34% at the lowest spiking level and 0.33−3% at the highest spiking level (in all matrices) fell into category VI, which included the compounds below the LOQ or compounds that suffered matrix-specific degradation. Low recoveries were observed for compounds such as propamocarb and atrazine

DOI: 10.1021/jf505221e
J. Agric. Food Chem. 2015, 63, 4449−4456

desethyl 2-hydroxy due to poor extraction in ethyl acetate as discussed earlier, although their RSD (%) values were acceptable. Lower and variable recoveries were recorded for alanycarb in grape, mango, drumstick, and okra; cycloxydim in grape, bitter gourd, capsicum, and okra; thiophanate methyl in all of the matrices except okra and bitter gourd; bifenazate in all of the matrices except mango, capsicum, and drumstick; benfuracarb and formetanate in all of the matrices except capsicum and bitter gourd; and ethoxyquin in all the matrices except drumstick, okra, and mango, probably due to their degradation in matrix. Some compounds showed matrix-specific recovery problems, which could be due to different reasons, including metaflumizone degradation in bitter gourd, low recoveries (50−69%) of bromadiolone and quinoxyfen, conversion of quizalofop-*p*-ethyl, haloxyfop, and fenoxaprop-*p*-ethyl into their metabolites, namely, quizalofop free acid, haloxyfop free acid, and fenoxaprop-P, respectively, in okra matrix. However, it was possible to achieve sufficiently low LOQs for most of these compounds for effective screening and quantification at or less than the regulatory MRLs. In the case of bitter gourd and curry leaf, the lowest numbers of compounds falling within the acceptable performance criteria (recovery = 70−120 ± 20%, at the lowest spiking level) were mainly due to very high matrix-induced signal suppressions.

Comparison of the Proposed Method with the Buffered QuEChERS Method[10] and the Existing Ethyl Acetate Method.[4] The comparative method performances of the proposed method vis-a-vis the buffered QuEChERS method[10] are shown in Supplementary Figure S5 in the Supporting Information for the grape matrix. For the basic compounds such as imazalil, thiabendazole, and cyromazine, the performances of both methods were comparable. For atrazine desethyl 2-hydroxy, formetanate, propamocarb, and pymetrozine, the recoveries for the proposed method were less as compared to acetonitrile extraction because of the comparatively less polar nature of ethyl acetate, but they showed acceptable RSDs (<20%). For acidic pesticides such as imazethapyr and imazosulfuron, the results for the proposed method were superior as compared to the buffered QuEChERS method,[10] probably due to the lower quantity of PSA (25 mg/5 mL) required in the ethyl acetate method as against the buffered QuEChERS method (50 mg/mL), which is mainly responsible for the adsorption losses of these compounds. For most of the other analytes, the proposed method showed comparable results with the buffered QuEChERS methodology. In view of the lower unit price of ethyl acetate as compared to acetonitrile and the lower amount of cleanup sorbents used, the proposed method offers a cheaper alternative to the buffered QuEChERS method with comparable proficiency.

As shown in Supplementary Figure S6 in the Supporting Information, the recoveries of acidic and basic compounds were much improved after buffering at the time of extraction as compared to the unbuffered ethyl acetate method.[4] The basic compounds, namely, cyromazine, atrazine desethyl 2-hydroxy, propamocarb, and pymetrozine, and the acidic compounds, namely, bispyribac, imazaquin, and imazosulfuron, which were pH dependent, showed improved recoveries due to optimum extraction conditions in the buffered method as compared to the earlier one.

The improved method is a common platform for the analysis of a large number of agrochemicals including acidic, basic, and neutral compounds with polar or midpolar nature. The buffered approach has improved the multiresidue analytical performance by offering stability and extractability to a wide range of compounds, especially those the stability of which is dependent on matrix pH. Use of a single extraction protocol for multiple matrices with minimum cleanup makes the method suitable for routine analysis in a commercial testing laboratory setup. The LC-MS/MS method enabled quantitative screening of a large number of target analytes at 1 ng/g and lower traces. Even the pesticides with problematic nature could be satisfactorily screened with sufficiently low LOQs (≤10 ng/g). The method has a good potential for implementation as a regulatory generic method for quantitative screening of residues in fruits and vegetables.

agricultural products in terms of more than 400 pesticides has not been validated (e.g., analytical sensitivity of the pesticides, evaluation of sample matrix effect for multiple pesticides, and recovery of the multiple pesticides from sample matrix). Moreover, high-polarity pesticides such as diquat dibromide ($\log P_{ow}$ = −4.6) need a special analytical method using hydrophilic interaction chromatography (HILIC)[13] or ion-pair LC.[14] Therefore, it is difficult to analyze both high-polarity and low-polarity pesticides simultaneously under the same LC conditions. In addition, because analytical times for multiresidue pesticide analysis by LC/MS or LC/MS/MS are longer than 30 min, an improved throughput without reduction in chromatographic resolution is one of the technical issues that must be overcome.

Supercritical fluid chromatography (SFC) is a chromatographic technique that uses a supercritical fluid (SF) as a mobile phase. Because the temperature and pressure of a SF exceed the critical point, the SF also has certain physicochemical properties such as low viscosity and high diffusivity. By using SFC, one can achieve a high-throughput analysis without reduction in chromatographic resolution.[15,16] Supercritical carbon dioxide ($SCCO_2$) is the most frequently used mobile phase for SFC, because carbon dioxide can be easily converted to its supercritical state (critical temperature, 31.1 °C; and critical pressure, 7.38 MPa). $SCCO_2$ also exhibits favorable properties because it is chemically inert, nonflammable, relatively nontoxic, easy to handle, and inexpensive. Although $SCCO_2$ has relatively low polarity, the polarity of the mobile phase in SFC can be changed considerably by adding a polar organic solvent such as methanol as a modifier.[17] Therefore, SFC can be used in the analysis of chemical compounds with a wide range of polarities.[18,19] In previous works, we presented the potential of SFC coupled to triple-quadrupole mass spectrometry (QqQMS) under MRM for the high-throughput and simultaneous analysis of pesticides using 17 selected pesticides with a wide range of molecular weights (112.1−888.6) and polarities ($\log P_{ow}$ = −4.6 to 6.9).[20] A column screening study determined that the GL Sciences Inertsil ODS-EP column, containing polar embedded reverse phase particles, was suitable for the simultaneous SFC analysis of a wide variety of pesticides. Consequently, high-polarity pesticides (e.g., fosetyl, $\log P_{ow}$ = −2.7, and diquat dibromide), and low-polarity pesticides (e.g., cypermethrin, $\log P_{ow}$ = 6.6, and tralomethrin, $\log P_{ow}$ = 5.5) could be analyzed simultaneously by performing a single-run SFC/MS/MS method with a 20 min run time. However, our previous analytical system was composed of an SFC and a QqQMS. Although QqQMS-based methods provide highly sensitive and robust quantitative measurements, this approach has drawbacks and limitations, which are inherent to the targeted acquisition involved in the MS measurement: (i) usage limited only to targeted pesticide analysis; (ii) requirement of a complicated setup for the determination of the optimized MRM transition settings for every individual pesticide; and (iii) limitation in terms of the number of pesticides detected in a single-run experiment due to limitations regarding instrument performance (i.e., scanning speed).[21] Meanwhile, high-resolution mass spectrometry (HRMS) has attracted attention as a new promising tool for multiresidue pesticide analysis.[12,21]

The objective of the present research was to develop a practical and high-throughput simultaneous analytical system for multiple pesticides using SFC coupled to HRMS, (i.e., Q Exactive, a high-performance benchtop quadrupole Orbitrap mass spectrometer) (SFC/Q Exactive) and an automated library-based detection. The SFC/Q Exactive system provides high chromatographic separation, high mass resolution (a value of $m/\Delta m$ = 70000), and high mass accuracy (<5 ppm) with positive/negative polarity switching. The SFC/Q Exactive system was used in the screening of 508 pesticides, which have been previously analyzed by a combination of GC/MS and LC/MS. Together with the evaluation of the effect of the biological matrix on multiple pesticide analysis using a QuEChERS-based spinach extract without dispersive solid phase extraction (d-SPE), we have also addressed the performance of the recently developed automated HRMS software (ExactFinder) in multiresidue pesticide analysis.

MATERIALS AND METHODS

Chemicals, Reagents, and Materials. Ammonium formate was obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). MS grade methanol was purchased from Kanto Chemical Co., Ltd. (Tokyo, Japan). All other chemicals and reagents were of the highest analytical grade available. Carbon dioxide (99.99% grade, Nerikigasu, Osaka, Japan) was used as the SFC mobile phase. All standards of pesticides (pesticide mix solutions for food analysis) were purchased from Hayashi Pure Chemical Ind., Ltd. (Osaka, Japan) and are listed in Table S1 of the Supporting Information. A total of 17 standard mixtures with 7−56 targeted substances were used for the development of an analytical method for multiresidue pesticides using SFC/Q Exactive (see Table S1). Each standard mix solution was diluted with methanol to 0.02, 0.05, 0.1, 0.2, 0.5, 1, 2, 5, 10, 20, 50, 100, 200, 500, and 1000 $\mu g\ L^{-1}$, and these mixture solutions were used to validate the performance of our analytical system. Spinach was purchased from the local markets in Miyazaki, Japan, and used for sample purposes.

Sample Preparation. The extraction method for spinach used the QuEChERS procedure (without d-SPE protocol) using an Agilent Bond Elut QuEChERS EN 15662 kit (Agilent Technologies, Santa Clara, CA, USA).[22] Spinach was homogenized using a Retsch Grindomix GM200 (Retsch, Haan, Germany). Homogenized spinach (10 g) was placed in a 50 mL centrifugation tube, and 10 mL of acetonitrile was added. The tube was shaken manually for 1 min. Anhydrous NaCl (1 g), anhydrous $MgSO_4$ (4 g), sodium citrate (1 g), and disodium citrate sesquihydrate (0.5 g) were added in the tube. The tube was shaken using a vortex mixer for 30 s. Subsequently, the mixture was centrifuged for 5 min at 1500*g* using an LX-120 (Tomy Seiko Co., Ltd., Tokyo, Japan). The supernatant (the final spinach extract) contained the equivalent of 1 kg sample L^{-1}. For the evaluation of sample matrix effect, 7 standard mixture solutions with 47−106 targeted substances (see Table S2) were added individually to the extract. The final concentration of each standard mixture was adjusted to 1, 10, and 100 $\mu g\ kg^{-1}$. The prepared mixtures were used as samples to validate the system sensitivity and selectivity in the presence of contaminants.

SFC/MS Analysis. The SFC/MS analysis was performed using an Analytical SFC Method Station (Waters, Milford, MA, USA) coupled with a Q Exactive, a high-performance benchtop quadrupole Orbitrap mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA). The SFC system was equipped with a binary pump, a temperature-controlled column component, an autosampler, and a refrigerator. The mass spectrometer was equipped with an electron spray ionization (ESI) source. The SFC conditions were as follows: mobile phase, $SCCO_2$ (solvent A) and methanol with 0.1% ammonium formate (solvent B); injection volume, 5 μL; flow rate, 3 mL min^{-1}; column temperature, 35 °C; and column, Inertsil ODS-EP (250 × 4.6 mm i.d., particle size = 5 μm, GL Sciences, Tokyo, Japan). The gradient conditions were as follows: 5% B, 0−1 min; 5−10% B, 1−2 min; 10−20% B, 2−12 min; 20−30% B, 12−14 min; 30% B, 14−18 min; 30−5% B, 18−19 min; and 5% B, 19−20 min. The MS analysis conditions were as follows: polarity, positive and negative ionization; sheath gas flow rate, 20 arb; auxiliary (Aux) gas flow rate, 5 arb; spray voltage, 3600 V for both positive and negative ionization; capillary temper-

DOI: 10.1021/jf5056248
J. Agric. Food Chem. 2015, 63, 4457−4463

ature, 360 °C; S-lens level, 50; heater temperature, 200 °C; mass resolution, 70000; automatic gain control (AGC) target, 1,000,000; maximum IT, 250 ms; and scan range, 100−1500 (m/z). The SFC and MS analyses were controlled using the software SuperCrom (Waters) and Xcalibur 1.4 (Thermo Fisher Scientific), respectively.

Data Analysis. ExactFinder ver. 2.0 software (Thermo Fisher Scientific) was used for acquisition and data processing. Using this software, we developed a components database, searched for compound peaks, and calculated the peak area for each compound. The optimized automatic filter criteria for peak picking and compound identification were as follows: allowed mass deviation, 5 ppm; allowed intensity deviation of all expected isotopic ions, 10%; isotopic pattern matching score, >70%; retention time (RT) width, <30 s; and response threshold, 5000. The main criteria are that the mass deviation for each ion should be <5 ppm between the measured m/z and the theoretical m/z and that the relative intensity deviation should be <10% between the measured and theoretical values. However, the experimental and theoretical intensities are different for each ion. The spectral noise threshold is used to decide which peaks will be monitored in the experimental data. The theoretical noise threshold is calculated using the noise label, the theoretical intensity, and the experimental intensity of the monoisotopic ions. The ions having intensities are above the theoretical noise threshold are expected to be identified in the measured spectrum. These are the ions the program focuses on afterward, during the calculation of the isotopic score. The number of these ions indicates the number of expected isotopic pattern peaks based on the Fourier transform noise in the spectrum. However, the actual number of expected ions in the measured spectrum can be different from the theoretical one, due to variations in concentration or ionization efficiency. Therefore, ExactFinder uses the isotopic pattern to obtain a score value from a combination of the mass and intensity deviations between the theoretical and experimental spectra. The score is calculated using each ion's expected fit and the individual fit score weighted by its expected intensity. The normalized difference in mass and intensity between the theoretical and experimental spectra of each ion is summed by vector addition. The weighting contribution of each individual ion to the final isotopic pattern score is proportional to its intensity. The weighting factor of each ion is shown as the ratio between the intensity of each ion and the sum of the intensities of all the expected ions. The weighted deviation for each individual ion is computed by multiplying the vector form deviation by the weighting factor. The final isotopic pattern matching score is calculated as the percentage of the weighted deviation of each individual ion minus the sum of all weighted deviation value (ExactFinder ver. 2.0). All processing data were saved in CSV format, and then Microsoft Excel 2007 was used to calculate the average and relative standard deviation values of RT or peak area and linearity.

RESULTS AND DISCUSSION

Optimization of SFC and Q Exactive Conditions. To develop a practical and high-throughput simultaneous analytical method for multiple pesticides using a full-scan SFC/Q Exactive system, we used 508 agricultural chemicals covering a wide polarity range (logP_{ow} from −4.2 to 7.7) and a wide molecular weight range (from 99.0 to 872.5) as analytes. For the separation of multiple pesticides using SFC, we selected an Inertsil ODS-EP column, which contained polar embedded reverse phase particles. This column offered an effective separation of pesticides with a wide range of chemical properties in our previous investigation.[20] The modifier concentrations were changed from the 5% customary in SFC analyses to 30% to adjust to the various degrees of solubility of the targeted pesticides. Several compounds that were expected to exhibit weak retention on the stationary phase were also included in the target components. Therefore, the modifier percentage was increased slowly from 5 to 10%, stepwise from 10 to 20%, and dramatically from 20 to 30% and was maintained at 30% for 4 min to wash out any remaining hydrophilic compounds.

The Q Exactive operating parameters including sheath gas flow rate, Aux gas flow rate, spray voltage, capillary temperature, and heater temperature were optimized to separate a set of selected pesticides with a wide molecular weight range (i.e., aldicarb, MW 190.3; acibenzolar *S*-methyl, MW 210.3; clothianidin, MW 249.7; carpropamid, MW 334.7; indanofan, MW 340.8; tebufenozide, MW 352.5; and novaluron, MW 492.7). The variations in peak area for each of the seven pesticides was monitored using different parameter settings, which were as follows: sheath gas flow rate, from 20 to 50 arb; Aux gas flow rate, from 5 to 10 arb; spray voltage, from 1 to 5 kV; capillary temperature, from 200 to 400 °C; and heater temperature, from 200 to 350 °C. Accordingly, the operating conditions for Q Exactive were set as follows: sheath gas flow rate, 20 arb; Aux gas flow rate, 5 arb; spray voltage, 3,600 V; capillary temperature, 360 °C; and heater temperature, 200 °C.

Finally, we evaluated the effective mass resolving power (a value of $m/\Delta m$ = 70000) and mass accuracy (<5 ppm) under the optimized SFC and MS conditions using two sets of isobaric pesticides with a mass difference of <0.01 Da (group 1, tolyfluanid metabolite, m/z 215.0848, and metribuzin, m/z 215.0960; group 2, isoxathion m/z 314.0607, triazophos, m/z 314.0710, and hexaconazol m/z 314.0827). Our optimized full-scan SFC/Q Exactive system achieved discrimination among very similar isobaric pesticides through a combination of high mass resolution, high mass accuracy, and highly efficient separation by SFC (Figure 1).

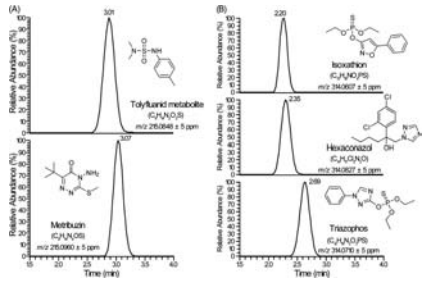

Figure 1. Separation of two sets of isobaric pesticide standards using the optimized full-scan SFC/Q Exactive system: (A) extracted ion chromatograms of tolyfluanid metabolite $(M + H)^+$ (m/z 215.0848 ± 5 ppm, RT 3.01 min) and metribuzin $(M + H)^+$ (m/z 215.0960 ± 5 ppm, RT 3.07 min); (B) extracted ion chromatograms of isoxathion $(M + H)^+$ (m/z 314.0607 ± 5 ppm, 2.20 min), hexaconazol $(M + H)^+$ (m/z 314.0827 ± 5 ppm, 2.35 min), and triazophos $(M + H)^+$ (m/z 314.0710 ± 5 ppm, 2.69 min).

Development of a Multiresidue Pesticide Database Using the SFC/Q Exactive System and ExactFinder Software. The workflow for the development of the pesticide database using the SFC/Q Exactive system and ExactFinder software is shown in Figure 2. To create the pesticide database, the compound name, the molecular formula, and all expected molecular ions [i.e., $(M + H)^+$, $(M + NH_4)^+$, $(M + Na)^+$, $(M - H)^-$, $(M + HCOO)^-$, and $(M + CH_3COO)^-$] of the targeted 508 psticides were stored in the ExactFinder database. Subsequently, 17 kinds of standard mixture solutions at a concentration of 1 mg L^{-1} were analyzed individually using the optimized full-scan SFC/Q Exactive method with high-throughput performance (20 min run time). Peak picking

J. Agric. Food Chem. 2015, 63, 4457−4463

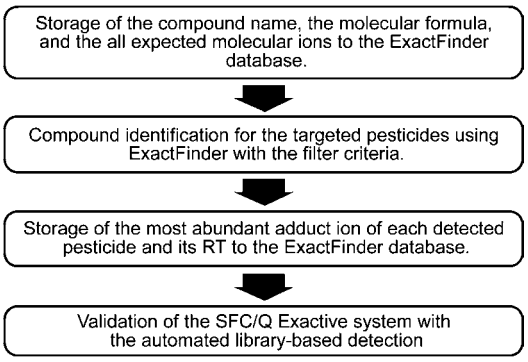

Figure 2. Workflow for the development of the pesticide database using the SFC/Q Exactive system and ExactFinder software in the present study.

and compound identification for the targeted 508 pesticides were carried out using ExactFinder with the filter criteria (i.e., allowed mass deviation, 5 ppm; allowed intensity deviation of all expected isotopic ions, 10%; isotopic pattern matching score, >70%). The main criteria are that the mass deviation for each ion should be <5 ppm between the measured m/z and the theoretical m/z and that the relative intensity deviation should be <10% between the measured and theoretical values. The isotopic pattern matching score, which is a vector sum approach based on a combination of the exact mass and the predicted intensity of each expected isotopic ion, was also used to determine the targeted pesticides (see Materials and Methods for details). In total, 444 pesticides were identified and the information on their RT and the most abundant adduct ion of each detected pesticide were added to the database; 64 chemicals were not confirmed by ExactFinder (see Table S1). We considered that this was due to the fact that either those chemicals were not solvated in $SCCO_2$ or methanol or were not efficiently ionized by electrospray ionization (ESI). Also, three sets of structural isomers, butachlor and pretilachlor, iprodione and iprodion metabolite, and promecarb and fenobucarb, coeluted. However, the separation of a large number of geometric isomers (i.e., fenpyroximate, phenothrin, cypermethrin, cyfluthrin, permethrin, bitertanol, pyriminobac methyl, metominostrobin, diclobutrazol, ferimzone, triadimenol, pyrifenox, and bromoconazole) and structural isomers (i.e., aldicarb and butocarboxim; esfenvalerate and fenvalerate; bioresmethrin and resmethrin; phenmedipham and desmedipham; haloxyfop and oxyfluorfen; acetochlor and alachlor; trifluralin and benfluralin; phoxim and quinalphos; ethiofencarb and methiocarb; 2,3,5-trimethacarb, 3,4,5-trimethacarb, and isoprocarb; bendiocarb and dioxacarb; prometryn and terbutryn; and MPMC and XMC) was enhanced by using high resolution in SFC (Figure 3). Our SFC/Q Exactive system also allowed simultaneous detection of both cationic (positive ion) and anionic (negative ion) species owing to their positive/negative fast polarity switching function.

A validation test for the 444 pesticides was performed to evaluate the system. Diluted stock solutions (0.02−1000 μg L^{-1}) were used to estimate the limit of detection (LOD), the linear dynamic range, its linearity (R^2 values), and repeatability. All of the experiments were repeated five times. The Q Exactive system removes the low-intensity regions, which are regarded as noise during the storage of raw data, to reduce the huge amount of data obtained from Fourier transform. Therefore, noise intensity was very low, and the signal-to-noise (S/N) ratio cannot be calculated in many cases. An S/N = 3 or 10 as a reference for the calculation of LOD or limit of quantification (LOQ), respectively, was not available. In this study, the LOD was defined as the actual detected concentration with the repeatability of peak area value. The threshold of the repeatability was set at a relative standard deviation (RSD) <25%. The linear range was calculated as that interval where the R^2 was >0.99. All data including pesticide name, molecular formula, polarity, adduct ion, RT, RSD for RT and peak area at LOD, linear range, and R^2 are presented in Table S1. The LOD for 391 pesticides (88.1% of the 444 pesticides investigated) was <10 μg L^{-1} (as shown in Table 1). The peak intensities for 53 chemicals were too low, even when their concentrations in the sample were high. This was due to the fact that almost all of these chemicals are usually analyzed using GC/electron ionization (EI)-MS^{2-5} because ESI is not considered as a suitable ionization technique for these compounds. However, the results above showed anew the wide coverage that SFC has and its usefulness in the rapid analysis of a wide variety of chemicals with logP_{ow} ranging from −4.2 to 7.7. The number of analytes was increased from the 17 chemicals analyzed in our

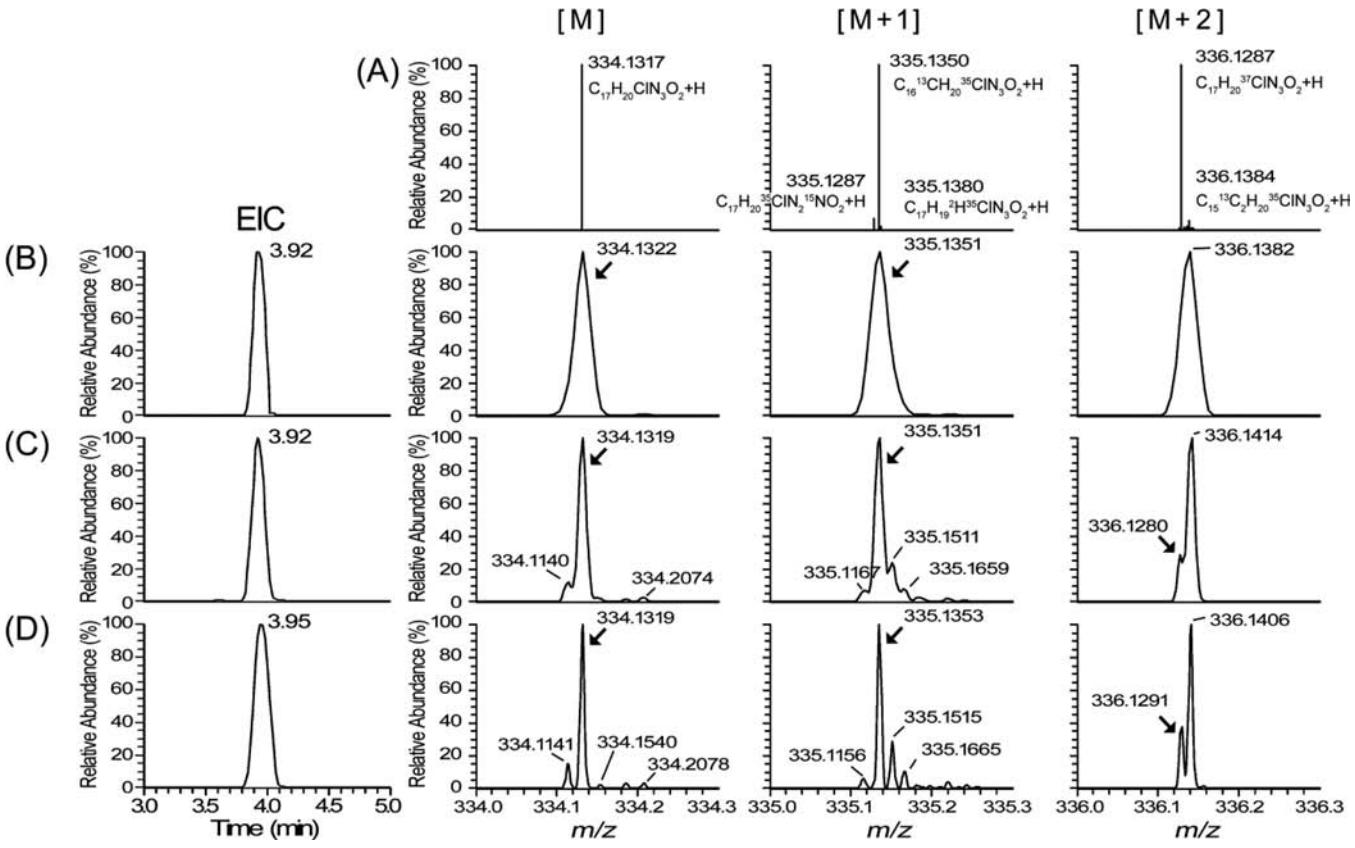

Figure 4. Influence of mass resolution on pesticide screening in the presence of contaminants: (A) theoretical monoisotopic ion and isotopic ions derived from furametpyr; extracted ion chromatograms and spectrum of furametpyr in spinach extract at different mass resolutions of 17500 (B), 35000 (C), and 70000 (D).

previous study to 444. Furthermore, these results indicated that not only the separation technique but also the ionization technique must be improved to construct a simultaneous analytical system for agricultural chemicals.

Validation of the SFC/Q Exactive System and ExactFinder Software Using Spinach Extracts Spiked with Pesticide Standards. The use of isotopic ions with both high mass accuracy and high mass resolution was considered useful to reduce the number of false positives in compound identification using the HRMS full-scan data.[12,23] However, too strict criteria may result in analytes going undetected (false negatives) if mass assignment obtained during the measurement proves to be insufficient or unreliable. For this reason, a thorough evaluation of mass assignment errors in complex samples and understanding of the parameters causing them is essential for automated wider scope screening methods.[21] Thus, we considered the influence of mass resolution on pesticide screening in the presence of contaminants (i.e., false-negative response). QuEChERS spinach extracts without d-SPE spiked with the seven different standard mixtures at the 10 μg kg^{-1} level were used as samples. The SFC/Q Exactive analyses were performed at different mass resolutions, that is, 17500, 35000, and 70000, and the raw data were analyzed using ExactFinder with the optimized automatic filter criteria (see Materials and Methods). The presence of 308, 349, and 373 chemicals was confirmed when using 17500, 35000, and 70000 mass resolutions, respectively (Table S2). These differences were caused by insufficient resolution, which made the contaminants hard to separate. For example, the extracted ion chromatogram and the spectra of the proton adduct of furametpyr (theoretical monoisotopic mass, m/z 334.1317) in spinach extract are shown in Figure 4. Furametpyr was not confirmed by ExactFinder at mass resolutions of 17500 and 30000. However, a peak derived from the monoisotopic ion of furametpyr was present in the case of both mass resolution settings (Figure 4B,C). The reason furametpyr could not be confirmed at mass resolutions of 17500 and 30000 was that its isotopic pattern matching score was not above the threshold value. In Figure 4D, the experimentally observed isotopic mass (M + 2, m/z 336.1291) could be discerned for the contaminant (m/z 336.1406) near the target mass, when using a mass resolution of 70000. The separation of target and contaminant in the spectrum becomes more difficult with a decrease in mass resolution. These results suggested that an analytical system with high mass resolution (a value of $m/\Delta m$ = 70000) and high mass accuracy (<5 ppm) must be used to distinguish between the target and the noise spectrum in the full-scan analysis to reduce false positives and negatives.

Figure 5 shows the number of confirmed pesticides at 1, 10, and 100 μg kg^{-1} using the optimized SFC/Q Exactive system

DOI: 10.1021/jf5056248
J. Agric. Food Chem. 2015, 63, 4457−4463

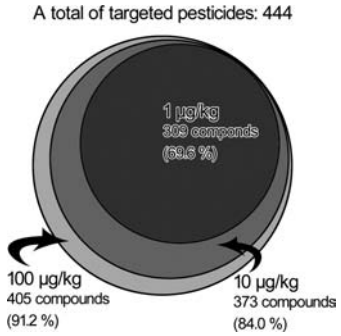

Figure 5. Comparison of the number of confirmed pesticides in QuEChERS spinach extracts at 1, 10, and 100 μg kg^{-1} using the SFC/Q Exactive system and ExactFinder software.

with a mass resolution of 70000 and the automated library-based detection (see Table S2 for details). The overall detection rate was 1 μg kg^{-1} for 69.6%, 10 μg kg^{-1} for 84.0%, and 100 μg kg^{-1} for 91.2% of the 444 pesticides investigated. In the range of 1−100 μg kg^{-1} levels, a large number of pesticides was detected, despite the lack of solid-phase purification; 39 pesticides were not identified regardless of their concentration. These included 24 chemicals considered to have poor sensitivity even when analyzed only in the absence of contaminants. Other pesticides (i.e., 15 chemicals) were easy to detect even at concentrations below 10 μg L^{-1}. Therefore, strong ion-suppressing effects of the biological matrices were considered as the main reason these chemicals were not found. This indicated that there could be other reasons, such as a decrease in the isotopic pattern score caused by contaminants. However, reducing the threshold of the isotopic pattern score may carry a significant risk of increasing the false positives because the threshold of the isotopic pattern score is an important criterion in the screening of target chemical ions from the full-scan analysis data. Fragment ion information is expected to be effective in solving this problem.

These results indicated that it is possible to get an accurate result rapidly in the presence of contaminants by using the SFC/Q Exactive (time for data acquisition, 72 samples per day) and ExactFinder software for data processing (time for data processing of 72 samples, approximately 45 min). On the other hand, the purification procedure is unavoidable to reduce the ionization suppression. Therefore, it might be a new challenge to attempt to optimize the purification conditions to purify more agriculture chemicals simultaneously.

In conclusion, the SFC/Q Exactive system developed in this study has sufficient sensitivity and accuracy for the practical analysis of multiresidue pesticides. The advantage of SFC is that it can achieve a high-throughput multiple pesticide analysis without reduction in chromatographic resolution, because a total of 444 chemicals including isomers were analyzed simultaneously by performing the single-run SFC/Q Exactive method with a 20 min run time. In addition, the effect of the biological matrix on multiple pesticide analysis using a QuEChERS-based spinach extract without d-SPE was evaluated using the SFC/Q Exactive system and ExactFinder software with the optimized automatic filter criteria. Using this system, we demonstrated that the use of both monoisotopic ion and isotopic ions with high mass accuracy (a value of $m/\Delta m$ = 70000) and high mass resolution (<5 ppm) was considered useful to reduce the number of false positives and negatives in compound identification using the HRMS full-scan data. Finally, we demonstrated that a total of 373 pesticides were confirmed in QuEChERS spinach extracts at 10 μg kg^{-1} levels (provisional MRLs in Japan), despite the lack of solid-phase purification. Taking all of the present results into account, our developed analytical system is a promising new tool for the accurate multiresidue pesticide screening with high throughput (time for data acquisition, 72 samples per day, and time for data processing of 72 samples, approximately 45 min).

The aforementioned facts and limitations led to the development of a matrix-compatible SPME fiber coating.[18] The same authors have employed the matrix-compatible coating to develop and validate an automated direct immersion−solid-phase microextraction−gas chromatography−time-of-flight mass spectrometry (DI-SPME-GC-ToFMS) method for the determination of triazole pesticides in grapes and strawberries. Rewarding results were achieved, as LOQs ranged from 0.25 to 5 ng/g for both matrices.[19]

To date, the application of SPME has not been considerably established for multiclass analysis of contaminants in food samples, given the limitations and challenges encountered concerning coating suitability toward complex matrices. In light of the good performance achieved by the developed matrix compatible coating, in this work, a DI-SPME-GC-ToFMS method for multiresidue analysis of pesticides in grapes is presented. The main goal was to develop a detailed protocol for the analysis of multiple pesticides comprising several different classes in grapes based on direct SPME extraction of grape sample matrix by employing a matrix-compatible SPME coating. Several factors that could influence method efficiency were carefully evaluated, from GC-ToFMS (GC oven program rate, MS acquisition rate, and ion source temperature) to parameters such as choice of internal standard, matrix modifications (salt addition, dilution factor), and extraction conditions (temperature and time). It is important to emphasize that the acquisition of high-quality analytical methods in combination with SPME requires optimization of the parameters that affect the extraction efficiency, namely, extraction phase chemistry, extraction mode, agitation method, sample modification (pH, ionic strength, organic solvent content), sample temperature, extraction time, and desorption conditions. Therefore, multivariate approaches such as Plackett−Burman and Central Composite Design (CCD) were employed to screen the most important parameters affecting extraction efficiency and to find optimum values for the most important parameters, respectively. To the best of our knowledge, this is the first time that the matrix compatible SPME coating has been used in a multiresidue pesticide determination.

MATERIALS AND METHODS

Solvents and Materials. All solvents used were of HPLC grade. Acetonitrile (MeCN), acetone, methanol (MeOH), dichloromethane (DCM), and isopropyl alcohol were purchased from Fisher Scientific. Glacial acetic acid, sodium sulfate, and sodium chloride were purchased from Supelco (Bellefonte, PA, USA). PDMS/DVB 65 μm Stableflex fibers were purchased from Supelco. Sylgard 184 (PDMS prepolymer and curing agent) was purchased from Dow Corning (Midland, MI, USA). Green seedless grapes were purchased at local markets in Waterloo (ON, Canada). Deionized water was obtained from a Barnstead/Thermodyne NANO-pure ultrawater system (Dubuque, IA, USA).

Standards. Pesticide standards (see Table S-1 in the Supporting Information for a list of all analytes) of purity of 95% or higher were purchased from Supelco, Accustandard, C/D/N Isotopes, and Restek. Details pertaining to the chemical structures and physicochemical properties of each analyte used in this work are described in the Supporting Information (Figure S-1 and Table S-1).

Individual solutions of standards were prepared in acetone, methanol, dichloromethane, and acetonitrile at 10 mg/mL (except chlorothalonil, which was prepared in dichloromethane, and folpet, which was prepared in toluene). A composite mixture was prepared, containing each contaminant at 100 μg/mL in acetonitrile (0.1% acetic acid).

Internal standard (quintozene, triphenylphosphate, trifluralin-d_{14}, terphenyl-d_{14}, 2-fluorobiphenyl, 2,4-dichlorophenol, phenol-d_5, and nitrobenzene-d_5) solutions were prepared at 1 mg/mL, except for parathion-d_{10} and α-HCH-d_6, which were purchased from Restek as 40 μg/mL solutions in acetonitrile. All standard solutions were stored in a freezer at −30 °C.

During method development, spiking standard mixtures were prepared containing target analytes at either 20 or 100 μg/mL, and internal standards were prepared at 50 μg/mL. The concentration of each analyte was carefully chosen to guarantee enough sensitivity for all analytes (final sample concentrations of 20, 100, and 50 ng/g).

To calculate the amount extracted by SPME for each analyte, a stock standard mixture containing all analytes of interest was prepared at 100 ng/μL in acetonitrile. This stock solution was used for successive dilutions to obtain calibration solutions ranging from 0.25 to 50 ng/μL (eight levels). Liquid injections of calibration solutions were carried out in quadruplicates.

Preparation of PDMS-Modified Coating. PDMS-modified coatings were prepared in-house employing a procedure described elsewhere.[18] All coatings were prepared at least in triplicate. Prior to their use, each coating was conditioned at 250 °C for 1 h and visually evaluated for uniformity and smooth surface coverage. If any defect was noted, coatings were discarded and new coatings were prepared.

SPME Procedure. Green seedless grapes, purchased at local markets in Waterloo (ON, Canada), were manually stemmed, washed with nanopure water, and dried. Next, grapes were crushed, homogenized using a blender, transferred to 200 mL amber glass flasks, and then stored in a freezer at −30 °C until analysis. Organically

grown fruits were obtained for method development and validation steps (previously analyzed for the absence of the target pesticides), whereas conventionally grown fruits were obtained for real sample analysis.

During initial SPME method development, 8 g of whole fruit pulp was weighed in a 10 mL vial, fortified with 8 μL of a spiking standard mixture to achieve the appropriate analyte concentration, and pre-incubated for at least 60 min prior to extraction to allow for the binding of the analyte to the matrix to occur. Once dilution occurred, the samples were thoroughly vortexed and allowed to stand for 1 h prior to extraction. A 5 min pre-extraction incubation of the sample was performed in the agitation unit at 500 rpm and at 30 °C, followed by a 30 min extraction in direct immersion mode at 30 °C while stirring at 500 rpm. Following extraction, the fiber was rinsed in deionized water and then desorbed for 10 min at 260 °C.

For Plackett−Burman experiments, 200 g of grape pulp was weighed into a 250 mL jar and spiked with an appropriate amount of standard mix. The sample was then allowed to stand in the agitation table for 1 h. Subsequently, appropriate amounts of salt (Na_2SO_4), followed by spiked grape pulp amounts, were weighed into each vial. Next, appropriate amounts of DI water and isopropyl alcohol were added to each vial, corresponding to each experiment, as defined by the Plackett−Burman design matrix.

For the CCD experiments, sample preparation was similar to that performed for Plackett−Burman, except that no isopropyl alcohol was added.

The levels tested for each factor during Plackett−Burman and CCD are presented in Tables 1 and 2, respectively. For the final SPME method, 4 g of whole fruit pulp was weighed in a 10 mL vial, followed by 4 mL of a Na_2SO_4 aqueous solution at 15% (w/w) (1.2 g of Na_2SO_4/vial). The mixture was thoroughly vortexed to ensure homogeneity. A 5 min pre-extraction incubation of the sample was performed in the agitation unit at 750 rpm and at 55 °C, followed by a 30 min extraction in direct immersion mode at 55 °C while stirring at 750 rpm. Following extraction, the fiber was rinsed in deionized water and then desorbed for 10 min at 260 °C.

SPME matrix-matched calibration curves were obtained in grape matrix to establish the linear dynamic range, LOQs, and method precision and accuracy.

Instrumentation. Sample pH was measured by a Metter Toledo MP220 (Schwerzenbach, Switzerland) pH meter. For centrifugation of samples, a Thermo Jouan BR4i (Waltham, MA, USA) centrifuge was used.

GC-ToFMS analyses were carried out using a Pegasus 4D instrument consisting of an Agilent 6890N gas chromatograph equipped with a split/splitless injector (Agilent Technologies, Palo Alto, CA, USA), an MPS2 autosampler for automated SPME (Gerstel, Mülheim and der Ruhr, Germany), and a Pegasus III high-speed time-of-flight mass spectrometer (Leco Corp., St. Joseph, MI, USA). Chromatographic separation was performed in a Restek Rxi-5Sil MS capillary (30 m, 0.25 mm i.d., 0.25 μm film thickness) with a 5 m integra-guard column. Helium was used as carrier gas at 1.2 mL/min. Oven temperature was initially set at 70 °C for 1.5 min, ramped at 40 °C/min to 210 °C for 1 min, and then ramped at 10 °C/min to 280 °C, at which it was held for 10 min, resulting in a total run time of 23 min. The injector was maintained at 260 °C (0.75 mm i.d. insert used for SPME and 4 mm i.d. insert packed with glass wool at the bottom used for liquid injections) in splitless mode (split was opened for SPME method after 10 min; for liquid injections, the split was opened after 1.5 min). MS operational conditions were as follows: electron ionization (EI) at 70 eV; ion source temperature, 240 °C; transfer line temperature, 280 °C; mass range, m/z 35−550; acquisition rate, 50 Hz; detector voltage, −1700 V. Retention times, as well as the selected quantifier and qualifier ions, are presented in Table S-2.

Data Processing. ChromaTOF (Leco Corp.) software (v. 4.24) was used for GC-ToFMS instrument control, data acquisition, peak deconvolution, and data preprocessing. Library searching was performed using the commercial NIST library. Data were further processed using Microsoft Excel (2010) and GraphPad Prism 5 (version 5.01, 2007, GraphPad Softwate, San Diego, CA, USA). The Statistica 8.0 (2007, StatSoft, Tulsa, OK, USA) program was used to construct experimental design matrices and for evaluation of results.

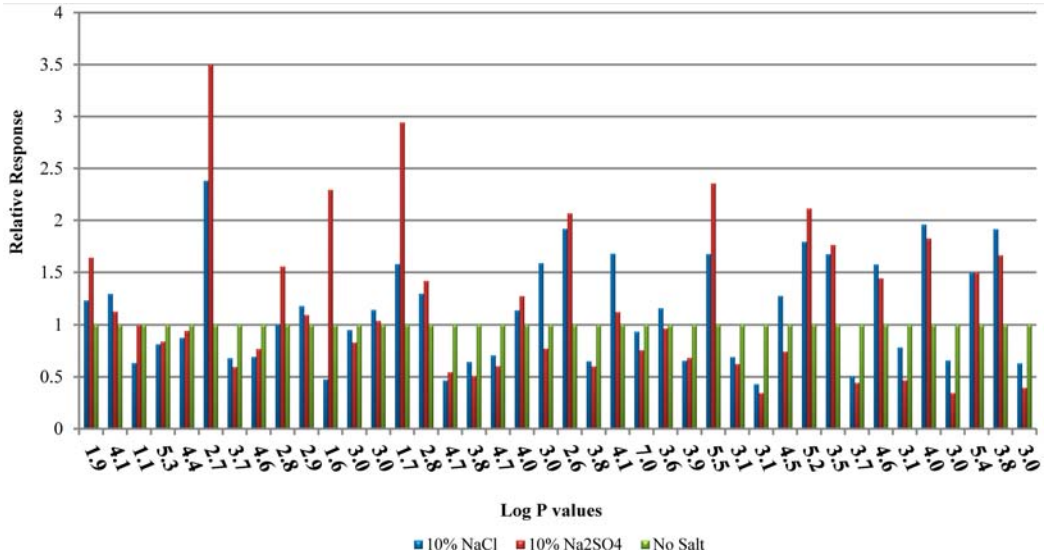

Figure 1. Influence of salt addition on extraction efficiency. Results are normalized for the response obtained without salt addition.

RESULTS AND DISCUSSION

The GC-ToFMS method was optimized to achieve chromatographic separation of the target pesticides with good peak shape, minimum matrix interferences, and increased sensitivity (S/N) within the shortest possible run time. Detailed discussion regarding the GC-ToFMS method optimization is presentated in the Supporting Information (section S-1).

SPME Method Development. *Preliminary Tests.* Once the GC-ToFMS method was developed, some preliminary DI-SPME studies in spiked water and grapes were carried out. Due to the addition of new analytes to the method, the time used for rinsing the fiber in water before desorption was reassessed. The predetermined time of 10 s[19] did not cause any statistically significant loss of analytes as compared to nonrinsing (data not shown).

Next, preliminary extractions in spiked grape pulp were performed to assess the optimum concentration level to be used during SPME method development. To establish such a level (analyte-dependent) the following factors were taken into account: (i) instrument response; (ii) SPME extraction efficiency; (iii) MRLs in grapes; and (iv) solubility of analytes. According to this assessment, pesticides were divided by low, medium, and high levels (10, 50, and 100 ng/g). Internal standards were kept at 50 ng/g. Regardless of the increased sample concentration of 100 ng/g, more polar pesticides such as acephate (log P = −0.85), omethoate (log P = −0.74), and dimethoate (log P = 0.704) could not be detected.

Because a multiresidue method should competently analyze both polar and nonpolar pesticides, different strategies were assessed to improve method sensitivity toward polar analytes (salting-out and water dilution).

A preassessment of the salting-out effect on extraction efficiency, determined by literature review, together with this author's previous findings, was carried out for two salts, NaCl and Na_2SO_4, at 10% (w/w). In agreement with our previous study,[19] the addition of NaCl did not yield satisfactory results. Interestingly, Na_2SO_4 not only provided better extraction efficiencies as compared to NaCl but also provided better repeatability of the data (assessed as RSD%, n = 3). Figure 1 shows the obtained results for selected pesticides (assigned according to their log P values). As expected, extraction efficiencies for pesticides bearing log P < 3 were positively affected by the addition of salt. It is important to note, however, that the addition of salt also improved the extraction of endogenous matrix compounds, such as organic acids (Figure S-5).

Screening of Influential Factors: Plackett−Burman. Plackett−Burman designs are used to obtain qualitative information, such as to detect which factors have the greatest influence on extraction efficiency in SPME. However, this saturated design assumes that there are no interactions between the different extraction variables, with each variable being tested at two experimental levels: a high level (+) and a low level (−).[21,22]

As presented in Table 1, in the current study, eight factors were studied, namely, (1) extraction time (15 and 60 min), (2) sample temperature (30 and 60 °C), (3) incubation time (5 and 15 min), (4) Na_2SO_4 addition (0 and 10%, w/w), (5) isopropyl alcohol addition (0 and 10%, v/v), (6) sample dilution (0 and 50%, w/w), (7) stirring rate (250 and 750 rpm), and (8) pH (natural grape pulp pH levels of 3.8 and 9). The ranges of the considered factors were chosen according to preliminary tests.

The rationale behind the selection of these factors was (1) extraction time affects the extraction efficiency; when extraction time increases, extraction efficiency also increases, until a maximum is reached (equilibrium). (2) An increase in sample temperature decreases sample viscosity, increasing analyte diffusivity in the medium, which in turn increases the amounts extracted in pre-equilibrium conditions. Increasing sample temperature may also favor the release of matrix-bound analytes into their free form in aqueous media. Conversely, an increase in temperature negatively affects the K_{fs}; however, this will be an issue only for equilibrium extractions. (3) Sample pre-incubation is closely related to sample temperature, although this parameter is more relevant in HS extraction than in DI; in DI mode, to avoid reproducibility problems, pre-incubation time must be sufficient to ensure uniform temperature throughout the whole sample. (4) The addition of salt modifies the ionic strength of the medium and can improve the extraction of more polar analytes via the salting-out effect. However, as a possible adverse effect of salt addition,

J. Agric. Food Chem. 2015, 63, 4464−4477

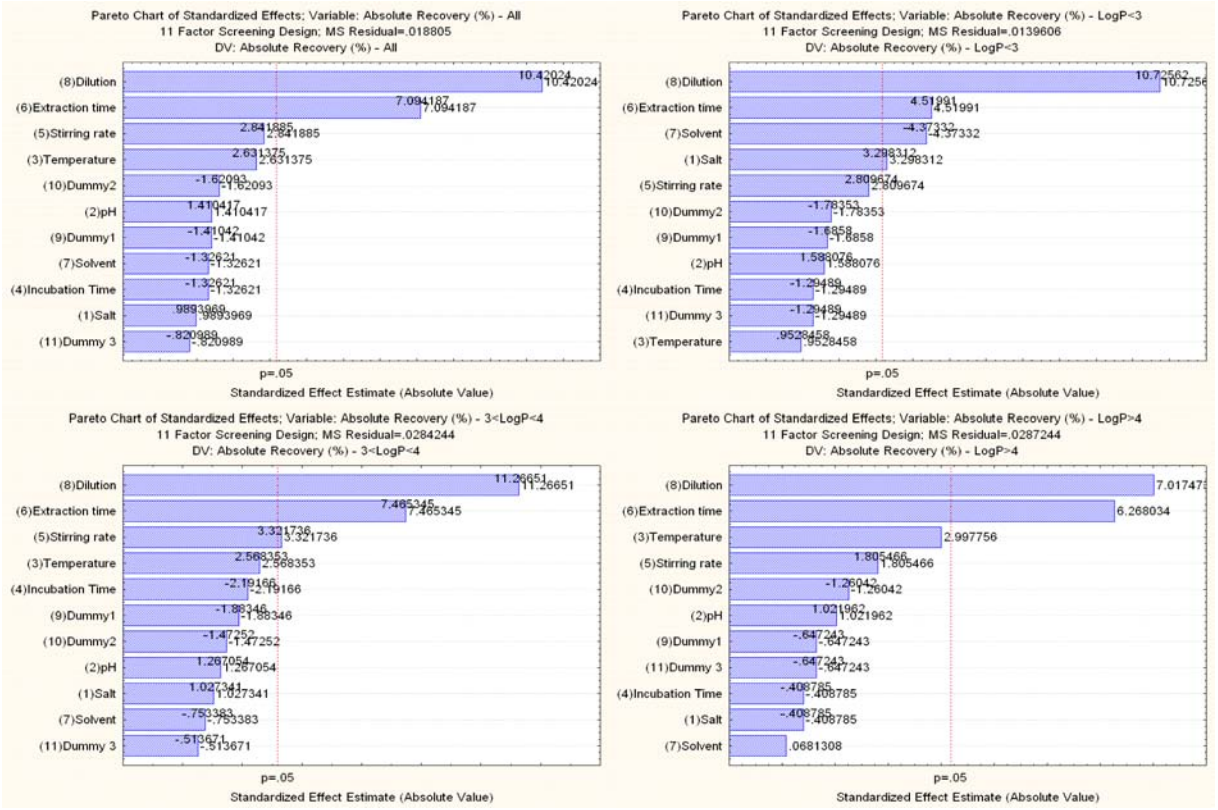

Figure 2. Pareto chart showing significant variables obtained in the Plackett–Burman design as a function of the average absolute recovery of pesticides studied: for all pesticides, dilution and extraction time were significant variables ($P < 0.05$); for the most polar pesticides (log $P < 3$), dilution, extraction time, solvent addition (negative), and salt were significant variables ($P < 0.05$); for the midpolarity pesticides ($3 < \log P < 4$), dilution, extraction time, and stirring rate were significant variables ($P < 0.05$); for the most hydrophobic pesticides (log $P > 4$), dilution and extraction time were significant variables ($P < 0.05$).

free-form analytes may be driven into matrix binding. When biological matrices are used, the addition of salt may aid in the natural normalization of occurring variations in salt content. (5) An addition of modifier (organic solvent) should be avoided, or kept at minimum, not exceeding 1–5%.[23] However, in some cases, the addition of organic solvent may help release matrix-bound analytes. (6) In general, dilution with water improves method performance in several ways, such as by minimizing the effect of the matrix and augmenting the release of analytes bound to matrix components to the aqueous phase (free concentration). Water addition may also minimize the attachment of matrix macromolecules onto the coating and decrease matrix viscosity, which increases the diffusion coefficients of the analytes, allowing higher extraction efficiencies in pre-equilibrium conditions. (7) Increasing the stirring rate, that is, agitation, assists the mass transport of the analytes between the sample and the fiber coating, which improves pre-equilibrium extraction and can shorten equilibration time. (8) Sample pH is important for analytes possessing pH-dependent ionizable groups, as only the nonionized form of the analyte is extracted by the coating.

Three "dummy" factors were also added to the design. These were fictitious factors, representing no procedural changes, and were used as a quality control measure for the design. If these factors appeared to influence the results, then the method was affected by variables other than the defined experimental parameters. The use of three central points also effectively accounted for experimental errors that could be associated with instrumental drifts.

Results were evaluated by calculating the amounts extracted and then calculating the absolute recovery for each analyte in each experiment. Analysis of variance (ANOVA) was used to evaluate results, and effects were deemed statistically significant at a 95% confidence level ($P < 0.05$). Because of the physical–chemical diversity of the analytes, results were analyzed as the average absolute recovery for all analytes, as well as per range of log P values. Absolute recovery (%) was selected to evaluate the processes, because analytes were present in different concentrations, and different amounts of spiked matrix were used for the experiments.

The results presented in Figure 2 showed that responses obtained for all three "dummy" factors, representing no procedural changes, showed no significant effect on the recovery of analytes. If these factors had appeared to influence the outcome, the method would be affected by variables other than the defined experimental parameters and should have been redesigned. The obtained data confirmed that this was not the case, indicating that all appropriate factors were considered.

As can be seen in Figure 2, when the average absolute recoveries for all pesticides were taken into account, the factors dilution and extraction time were significant, in a positive direction. This means that increasing sample dilution from 0 to 50% (4 mL of water) caused an increase in the amount extracted. In SPME, when additional phases are present in the sample, partitioning of the analytes in complex matrices occurs among all of the phases present in the system. Therefore, in the case of complex matrices, such as grapes, sample dilution may improve the partitioning of analytes between the sample and

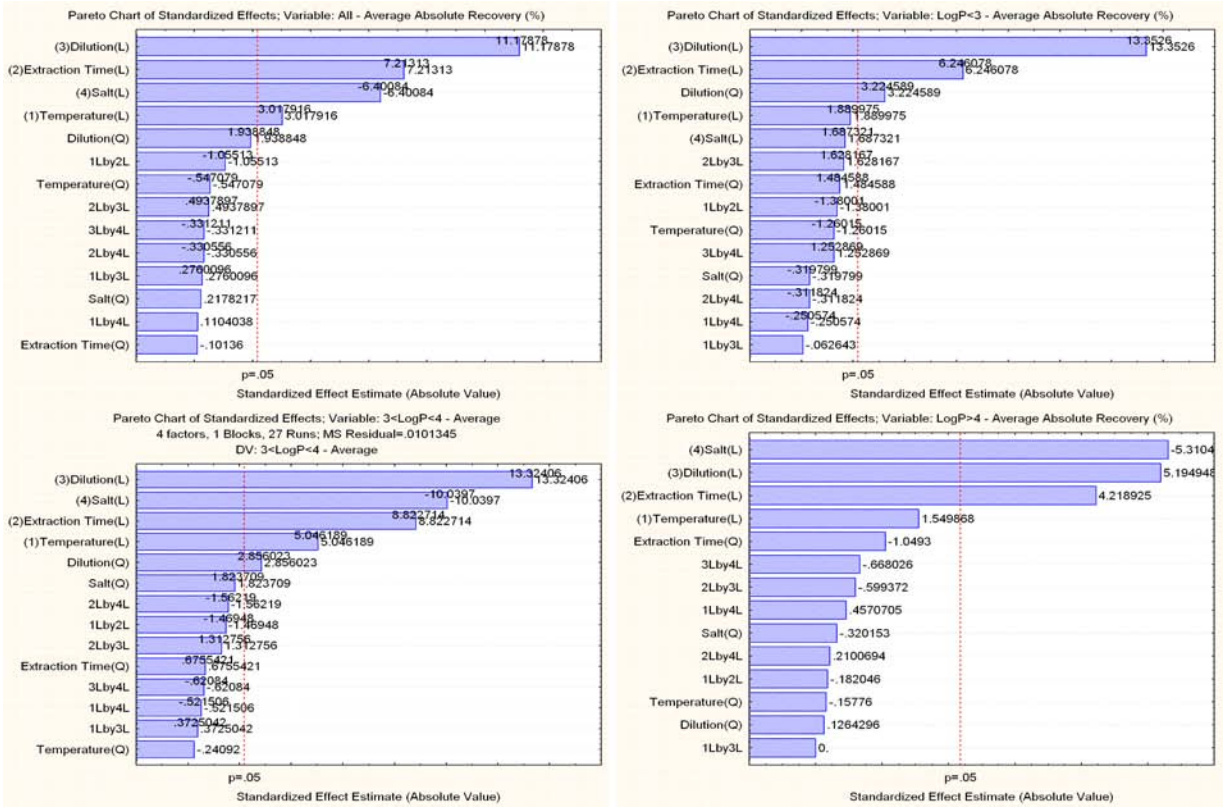

Figure 3. Pareto chart of effects showing significant variables obtained for central composite design as a function of the average absolute recovery of pesticides studied.

the coating as analyte competition between the other phases is diminished.[23−25] Extraction time and sample dilution were positively significant factors in the examination of all subgroups. The addition of organic solvent was negatively significant for most polar analytes (log P < 3). The addition of isopropyl alcohol decreased the polarity of the aqueous medium, causing the equilibrium between free-form and matrix-bound analytes to be shifted toward matrix binding, which in turn decreased the extraction efficiency. The addition of salt was shown to be significant (positively) only for more polar analytes, as the salting-out effect increased their extraction efficiency. Stirring rate was significant (positively) only for midpolarity pesticides (3 < log P < 4), possibly due to the improved extraction efficiency obtained as a function of the enhanced mass transfer through a thinner boundary layer. It is important to note that this is significant only for this group of analytes, taking note of their molecular size together with diffusion their through the PDMS overcoating. For more polar analytes, diffusion through the PDMS layer would still be the major limiting step in mass transfer, which explains why stirring rate does not play a significant role for these analytes. Conversely, stirring rate would be expected to play a significant role in the pre-equilibrium extraction efficiency of more hydrophobic pesticides. A possible explanation for the result herein obtained could be associated with the high matrix binding of these compounds, as well as the inherent limitation of a Plackett−Burman design that evaluates only main factors, with all interactions being cofounded. Therefore, keeping in mind that faster agitations lead to enhanced mass transfers, 750 rpm was chosen for all subsequent experiments. Surprisingly, extraction temperature did not have a significant effect on any subgroup assessed, because it is known that an increase in sample temperature may lead to improved extraction efficiency, as explained before. Even though sample temperature presented no effect on the outcome, it was still chosen for the following optimization step due to another limitation of the Plackett−Burman design; it evaluates only two levels, and no information regarding the behavior of a given factor in small increments comprising the range between these two levels can be acquired. To summarize, the factors chosen for optimization via surface response were extraction time, sample temperature, salt addition, and dilution.

Optimization of Factors: Central Composite Design. Once the significant variables were identified, an optimization of these variables was conducted to find the optimum values that can lead to a maximum signal. For this purpose, a CCD was employed for optimization of dilution ratio (% of water added), extraction time (min), extraction temperature (°C), and salt addition (% of Na_2SO_4). All other parameters were kept constant, as follows: stirring rate at 750 rpm; pre-incubation time of 5 min; and no pH modification (natural pH of ∼3.8).

In short, a CCD for k factors has three groups of design points: (1) two-level full factorial design points, containing a total of $n_{factors} = 2^k$ with coordinates $x_i = -1$ or $x_i = 1$, for $i = 1, ..., k$; (2) axial points ("star" points), formed by $n_{axial} = 2k$, with all factors set to coded level 0 (the midpoint) and the value $+\alpha$; and (3) central points, which are points with all levels set to coded level 0, the midpoint for each factor range. These points at the center serve two purposes: they provide an estimate of experimental error and determine the precision of an estimated response at and in the proximity of the central point.[21,26]

In the present study, the CCD consisted of four factors, with rotatability $\alpha = 2$ (the choice of α value will determine the predictability of the model) and three central points. To

summarize, all four factors were evaluated at five levels ($-\alpha$, −1, 0, +1, $+\alpha$), resulting in 27 experiments. The summarized conditions utilized for each experiment are presented in Table 2.

The data obtained for CCD experiments were also calculated as absolute recoveries (%). The Pareto charts of effects for all pesticides, as well as for subgroups, are presented in Figure 3.

By investigating the Pareto charts of effects in Figure 3 together with the profiles for predicted values and desirability, it could be seen that, overall, the most important factor leading to improved extraction efficiencies is the dilution of the matrix with water, with optimum results obtained at dilution percentages as high as 50%. Similarly, the effect of extraction time also led to improved extraction efficiencies, as expected.

Sample temperature effects were observed only for midpolarity analytes, and the temperature effect in the extraction efficiencies for these analytes have already been discussed. However, a closer inspection at surface responses generated between extraction time and sample temperature (Figure 4) shows that for a given extraction time, an improved extraction efficiency should be expected with an increase in sample temperature. Obviously, the effect varies among the subgroups, but in general, to differing extents, analyte recovery increases as temperature is increased (within the scope of the present study). Possible reasons are likely associated with decreased sample viscosity, as well as unbinding of analytes from the matrix.

The addition of salt seems to worsen analyte extraction, especially for midpolarity and more hydrophobic pesticides. This result was expected; as previously stated, the addition of salt might drive these analytes into matrix binding. However, the most surprising outcome of salt addition was obtained for the most polar pesticides: according to the Pareto chart of effects, salt addition had no significant effect in the recovery of these pesticides. Nonetheless, the surface responses generated between salt addition and sample temperature for these most polar analytes show that for a given sample temperature, improved extraction efficiency should be expected when salt is added to the sample (Figure 5). Accordingly, due to the salting-

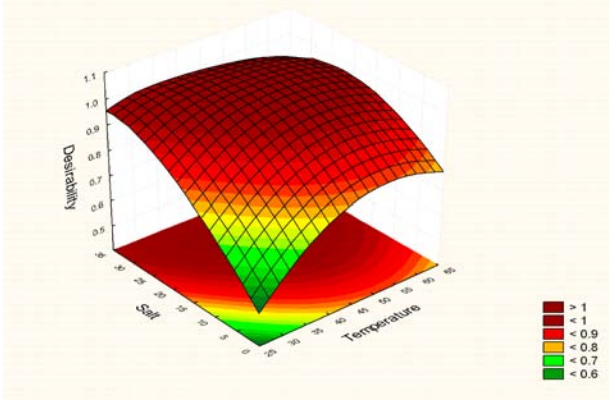

Figure 5. Response surface plot for desirability versus salt addition (%, w/w) and sample temperature (°C) for most polar analytes.

out effect, water molecules would form hydration spheres around the ionic salt molecules, reducing the concentration of water available, thus driving analytes into the fiber coating. However, if the salt concentration is increased past a certain extent, then a concurrent effect that reduces the ability of the analytes to move into the coating takes place, where the

analytes participate in electrostatic interactions with the salt ions in solution. To further investigate this effect, a closer look was taken at individual data for most polar analytes, which at this point may be considered the weak link in developing such a multianalyte SPME method. Dimethoate (log P = 0.704) displayed optimum results for sample temperatures above 43.5 °C and salt (%, w/w) above 20%. Similarly, pirimicarb (log P = 1.55) displayed little sample temperature effect and optimum extraction efficiency at values above 19.5% of salt added.

In summary, the effect of each factor in the extraction efficiency seen for each subgroup of analytes is as follows:

- For compounds characterized by log P < 3, sample temperature and extraction time had little effect; salt addition (%, w/w) yielded optimum results above 18%; sample dilution with water (%, w/w) yielded optimum results above 48%.
- For compounds characterized by 3 < log P < 4, extraction time had little effect; sample temperature yielded optimum results above 54 °C; salt addition (%, w/w) yielded optimum results below 4.5%; sample dilution with water (%, w/w) yielded optimum results above 42.5%.
- For compounds characterized by log P > 4, sample temperature and extraction time had little effect; salt addition (%, w/w) yielded optimum results below 7.5%; sample dilution with water (%, w/w) yielded optimum results above 45%.

The development of an SPME method aiming at simultaneous extraction of numerous analytes covering a broad range of polarities cannot succeed without a compromise in "optimum" values. Indeed, a multiresidue pesticide method, such as the one proposed here, must focus on the overall quality of data, keeping in mind method sensitivity. Therefore, rather than choosing the "optimum" values proposed by the CCD computation of all pesticide recoveries, the "optimized" method has the following conditions:

- An extraction time of 30 min represents a good compromise between good sample throughput with the GC run time and method sensitivity.
- A sample temperature of 55 °C provides enhanced mass transfer.
- Fifty percent dilution (4 mL of water) also improves mass transfer, increases coating lifetime, and broadens method linear dynamic range.
- The 15% of Na_2SO_4 (1.2 g) represents the main compromise of this method. Even though it does not help the extraction efficiency of most hydrophobic analytes, it does provide better results for the most polar analytes. Because more hydrophobic analytes display good extraction efficiency by SPME, a sacrifice was made here to improve the extraction efficiency of the more polar analytes (which typically yield low GC responses, together with a low affinity by the SPME coating) while keeping the response for all other analyte groups ≥75% of the optimum value.
- Other parameters already defined are a stirring rate of 750 rpm, a pre-incubation time of 5 min, a desorption temperature of 260 °C, and a desorption time of 10 min.

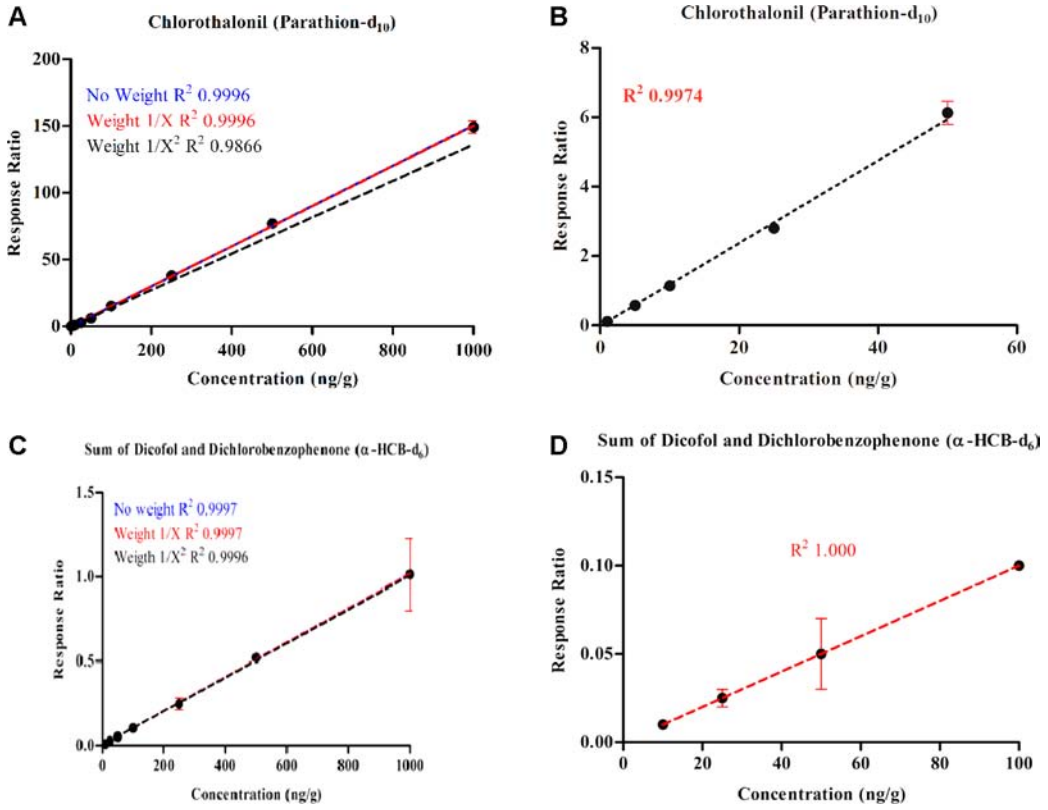

Figure 6. Representative calibration plots comparing different weights for regression curve (A, C) and inspection at lower concentration levels using weight $1/X$ (B, D), for chlorothalonil using parathion-d_{10} as internal standard (A, B) and for dicofol using α-HCH-d_6 as internal standard (C, D).

Internal Standard (IS) Selection. In quantitative determinations of multiresidue pesticides in food, the utilization of internal standards is of utmost importance, as they are used to correct for possible drifts in instrumental responses, as well as to account for losses during sample preparation steps.

A literature review of the most recent publications regarding GC-based multiresidue analysis in food shows that the vast majority of methods employ a solvent extraction step, as is the case for QuEChERS and its modifications.[2,4,27−32] In such cases, most of the published work reports an addition of internal standards (surrogates), such as parathion-d_{10} and α-HCH-d_6, before extraction to account for losses during sample preparation steps. Triphenylphospate (TPP) is then added to the final extract to correct for any instrumental drift. In short, given the exhaustive nature of such extraction methods, these three internal standards are successful in ensuring adequate quantitative data.

Because of the nonexhaustive nature of SPME, the application of these widely employed internal standards, generally used for exhaustive methods, would not be advisible without a previous investigation of their applicability. In SPME, internal standards should resemble, as closely as possible, the behavior of the analyte in the system matrix/coating; in other words, the IS should be able to mimic the partition of the analyte for the extraction phase and any competing phase.

For this reason, 10 compounds (Figure S-6), widely used as internal standards and surrogates in pesticide determinations by various methods, were investigated for their applicability as internal standards in the SPME method. Employing the previously optimized conditions, a matrix-matched calibration curve ranging from 1 to 1000 ng/g (eight points, quadruplicate) was performed with the addition of the mixture of internal standard (each IS at 50 ng/g).

The obtained data were processed by computing the ratio between the peak area of the analyte and that obtained for the internal standard (A_{an}/A_{IS}). This process was accomplished for each analyte and each IS candidate. For each analyte/IS pair, the data were analyzed according to a linear range that yielded a correlation coefficient (R^2) ≥0.995. The data are summarized in Table 3. Tribromophenol was excluded from the evaluation at the data processing stage due to its poor ionization in EI. Nitrobenzene-d_5 and 2,4-dichlorophenol were also eliminated from the IS selection because their extraction efficiencies were far superior to those displayed by the targeted pesticides. These small polar molecules are less prone to matrix binding and, as such, are more available in their free form in the aqueous phase of the matrix. Due to a mismatched extraction efficiency, 2-fluorobiphenyl was also eliminated from further assessment. The areas obtained by this IS were 1 order of magnitude higher than those obtained by the target analytes (at the same concentration of 50 ng/g).

In the analysis of complex matrices, where a significant and variable competing phase is present in the sample, the selection of internal standard is critical. If the internal standard has a different affinity for the competing phases from that of the analyte of interest, the amounts of internal standard and analyte bound to the matrix may not correlate linearly, and peak ratio analysis will not yield an adequate quantification.

The internal standards most used in the QuEChERS methods, parathion-d_{10} and TPP, resulted in very similar performances, as they both corrected well for approximately 70% of the analytes. Trifluralin-d_{14}, quintozene, and α-HCH-d_6 exhibited similar behaviors among themselves and were able to

DOI: 10.1021/jf506212j
J. Agric. Food Chem. 2015, 63, 4464−4477

correct well for approximately 20% of the analytes. Interestingly, these three IS candidates corrected analytes that were not corrected well by parathion-d_{10} and TPP. Most importantly, it has been determined that using only one pair of internal standards (parathion-d_{10} or TPP + quintozene or α-HCH-d_6) is sufficient to ensure reliable correction not only for instrumental drifts but also for variations that could occur when one is dealing with natural matrices. Moreover, the choice of TPP/quintozene as internal standards would render significant economic savings, because these compounds are significantly less expensive than the isotopically labeled ones.

Whereas terphenyl-d_{14} showed good correlation, the linear range was significantly shortened for all corrected analytes. Terphenyl-d_{14} presented the lowest extraction efficiencies among all tested IS candidates, as it was expected to be more strongly bound to the matrix. One hypothesis is that as the concentration of more hydrophobic compounds increased (in the calibration), more competition took place for adsorption onto the solid matrix. As such, more terphenyl-d_{14} would be available in its free form, which could account for the loss of linearity analyte/IS. This explanation is in line with the plot of instrumental response for terphenyl-d_{14} as a function of calibration level. For comparison, and to ensure that no mistakes were made during the spiking of the IS mixture, quintozene is also plotted in Figure S-7.

The more hydrophobic pyrethroid pesticides did not yield linear responses throughout the evaluation. It is possible that due to their low solubility in water and high hydrophobicity, these compounds adsorbed onto the vial walls during the duration of the sequence run. However, this hypothesis must be further investigated. At this point, the proposed method moves forward to the validation steps without the inclusion of these troublesome pesticides.

Method Validation. After establishment of the extraction conditions, the method obtained was validated in fortified samples by evaluating linearity, sensitivity, accuracy, and precision.

Linearity and Limit of Quantification. Method linearity was studied by means of matrix-matched calibration curves, using relative area versus adequate IS. Calibration levels were prepared at 1, 5, 10, 25, 50, 100, 250, 500, and 1000 ng/g. Linearity was assumed when the correlation coefficient (R^2) was >0.995 with randomly distributed residuals lower than 20%.

For each pesticide, the results were analyzed for hetero- or homoscedasticity using no weight, weight $1/X$, and weight $1/X^2$ (X = concentration). In addition, as shown in Figure 6, the obtained curves were also inspected at the lower range to ensure the validity of the regression model.

The results for method validation are summarized in Table 4. As can be seen, the method showed good linearity for all 40 pesticides in the entire calibration range selected for each analyte, with $R^2 > 0.995$. Even though calibration ranges were chosen to include concentration levels bracketing the EU MRL, when "relatively high", the proposed method did not meet the linearity requirement at the MRL concentration. For example, as the MRL for boscalid was 5000 μg/kg, the present method was validated and linear for boscalid in the range of 1−1000 μg/kg. In effect, the greatest strength of the proposed method also leads to one disadvantage. On the one hand, owing to the preconcentration capabilities of this method, admirably low limits of quantitation can be attained. On the other hand, the same preconcentration power causes the proposed SPME method to have a "relatively low" upper limit of linearity. For example, for the QuEChERS method, without solvent exchange or large volume injection, 1 g of sample will generate 1 mL of extract, of which only 1−3 μL will be injected in the GC. Conversely, in the present method, the totality of analytes extracted by the coating will be transferred to the GC. In the QuEChERS method, if the analyte is present in the sample in concentrations above the upper limit of linearity, the sample can be simply diluted so that a concentration within the linearity range is attained. In SPME, as discussed previously, the analyte will partition between the coating and all competing phases present in the sample. Dilution of the sample may cause significant differences in the content of these competing phases, which could lead to the unsuitability of the calibration data for the diluted sample. Matrix effects caused by further dilution of samples were not investigated in this work; however, it is an important point to be validated in future work.

In the present study, the LOQ objective is defined according to SANCO guidelines (SANCO/12571/2013) as the lowest assessed concentration of an analyte that yields a reproducible response that is both accurate (according to the expected value using the linear regression equation) and precise (≤20% RSD). Excellent LOQs were achieved for 38 pesticides (LOQ ≤ 10 ng/g, except dimethoate (LOQ = 50 ng/g), and pyridaben (LOQ = 25 ng/g)). By comparison of the LOQ values obtained with the proposed method with recent publications reported for GC-based multiresidue pesticide analysis in grapes, it is evident that the LOQs obtained in this study are in a similar range or better than those reported.[30,33−38] Furthermore, the LOQ values validated in this study are far below the MRL set for grapes.[39] The only exception is dimethoate, which has the MRL set as 20 ng/g and a presented LOQ value of 50 ng/g.

Precision and Accuracy. Precision as intraday repeatability was determined for grape samples spiked at three concentrations, 10, 50, and 500 ng/g. Data from five analyses for each concentration level performed in the same day were used for calculations (n = 5), with the data expressed as relative standard deviations (RSD, %). As presented in Table 4, good results were obtained for nearly all pesticides (RSD ≤ 20%).

Intermediate precision as interday reproducibility was also determined for grape samples spiked at three concentrations, 10, 50, and 500 ng/g. Data obtained from three analyses for each concentration level performed on three nonconsecutive days (n = 9) was used for calculations, with the data expressed as RSD (%). As in the case of repeatability, good results were obtained for nearly all pesticides (RSD ≤ 20%).

Accuracy was assessed by fortifying blank samples of grapes at three concentration levels (n = 5 intraday, and n = 9 interday). Results obtained were back-calculated by means of "estimated concentration values" to estimate accuracy.[40] For all pesticides, accuracy ranged from 82 to 120%.

It is worth highlighting the excellent performance obtained by the proposed method for pesticides such as chlorothalonil, dicofol, and folpet, which are considered the weak link in QuEChERS-based multiresidue methods.[5,20]

Commercial Samples. The validated method was applied for the analysis of six commercial samples of conventionally grown green seedless grapes purchased at local markets in Waterloo (ON, Canada).

Twelve pesticides, all pertaining to the so-called new generation of pesticides, were detected in the commercial samples (Table 5). These pesticides are preferred for applications in grape crops because they are considered

somehow more innocuous than, but just as effective as, the older pesticides.[41] Pyrimethanil was detected in four of the six samples analyzed. The highest concentration was found for fenhexamide. Despite these findings, all pesticides were present at concentrations much lower than their respective MRLs.

In summary, the validated method yielded good accuracy, precision, and sensitivity. Taking into account the method's performance by using an environmentally friendly and automated technique, the proposed method is considered appropriate for the determination of 40 pesticides, comprising 21 different classes, in grapes, with a performance similar or superior to that of exhaustive extraction methods based on solvent extraction. Furthermore, the method was successfully applied for multiresidue determination of pesticides in the incurred samples. Therefore, the present method could be satisfactorily applied in routine monitoring of pesticides in agricultural commodities, provided that proper optimization is carried out.

With regard to the limitations of the proposed method, the DI-SPME method did not meet a satisfactory performance toward more polar pesticides (e.g., acephate, omethoate, dimethoate) due to the low affinity of these compounds toward the fiber coating in conjunction with their impaired GC responses. Another limitation of this method was its inability to provide reliable results for highly hydrophobic pesticides, such as pyrethroids. In this case, further investigation is currently underway to avoid losses due to the interaction of these compounds with labware.

Despite the challenges and limitations encountered by this method, the practical aspects of the PDMS-modified coating demonstrated here create new opportunities for the application of SPME in food analysis.

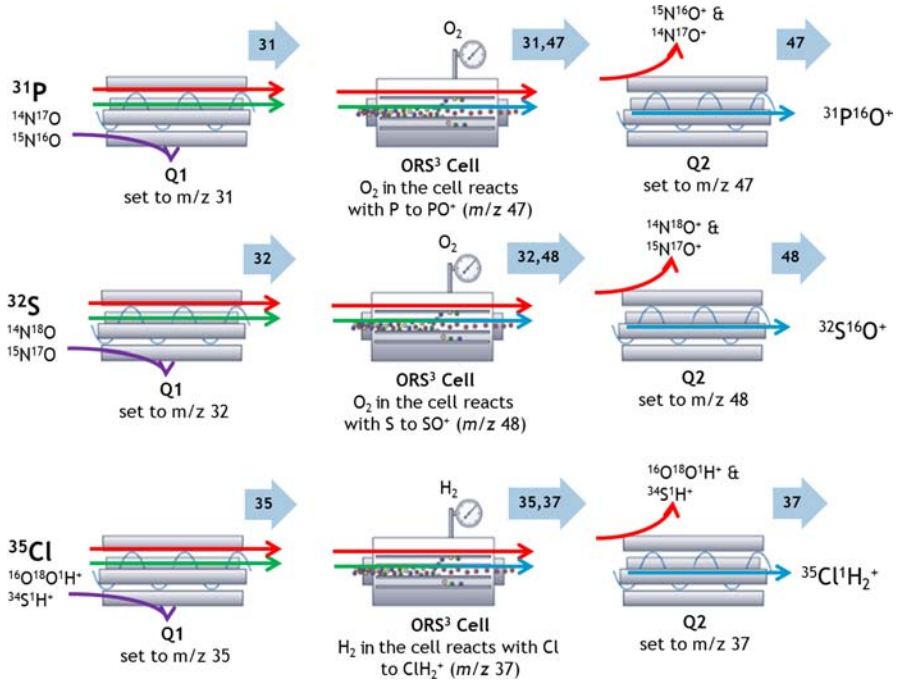

Figure 1. MS/MS mass shift mode using oxygen cell gas for the measurement of P and S. Q1 is set to m/z 31 and 32, allowing $^{31}P^+$ and $^{32}S^+$ and any other ions at m/z 31 and 32 to enter the CRC. All other ions are rejected. In the cell, P and S react with oxygen to form PO^+ at m/z 47 and SO^+ at m/z 48. Q2 is set to m/z 47 and 48, allowing PO^+ and SO^+ to pass to the detector. Because no NO^+ ions react with oxygen, they are rejected by Q2.

However, if these elemental interferences could be overcome, element-specific detection has the potential to further improve the pesticide detection limits by lowering the background chemical noise. The recent combination of tandem MS detection with inductively coupled plasma (ICP-MS/MS or ICP-QQQ) is a way to address this challenge. Similar to GC or LC-MS/MS, in ICP-MS/MS the first quadrupole (Q1) acts as a mass filter. In the collision reaction cell (CRC) that follows, analytes or interferences react with various gases in a very selective way to produce a product ion, which is then accepted (analyte) or rejected (interference) by the second quadrupole (Q2) prior to detection (Figure 1). Using this approach, background levels are dramatically reduced, thus increasing the sensitivity of the detection.

Presented here is the first application of a GC-ICP-MS/MS method for the selective and sensitive detection of heteroatom-containing pesticides in various food matrices. For the detection of organophosphorus pesticides, oxygen was used in the reaction cell to convert P (m/z 31) to PO^+ (m/z 47). Similarly, SO^+ (m/z 48) was monitored after the reaction of S (m/z 32) with oxygen for the detection of organosulfur pesticides. To detect chlorine pesticides, Cl (m/z 35) was reacted in the CRC with H_2 to form ClH_2 (m/z 37).

The developed method is an attractive alternative to existing highly sensitive and selective organophosphorus detection methods, with detection limits comparable to, or even slightly lower than, those of GC-MS/MS. The GC-ICP-MS/MS method is easy to set up and does not require retention time based acquisition conditions such as selected ion monitoring windows or the development of multiple reaction monitoring (MRM) settings. Due to the detection of heteroatoms instead of compounds, GC-ICP-MS/MS allows the quantification of unknown peaks by compound-independent calibration (CIC). The use of the MS/MS mode dramatically reduces background levels for interference-prone elements such as P, S, and Cl, thereby increasing the sensitivity of the method significantly compared to single-quadrupole ICP-MS detection.

Although this paper focuses on the analysis of pesticides by GC-ICP-MS/MS, it is understood that this system is unlikely to replace conventional GC-MS/MS approaches for the analysis of pesticide residues. Most pesticide residue laboratories have already invested in GC-MS/MS and LC-MS/MS equipment and, in most cases, these instruments provide more than adequate sensitivity. Furthermore, such methods have already been validated by the laboratory, a process that can be time-consuming. However, pesticides are a good model for other organophosphorus compounds (e.g., fire retardants and polymer additives) and sulfur compounds that can have a significant influence on flavor and aromas at trace levels. This GC-ICP-MS/MS approach may be useful when extremely low detection limits are desirable, such as for the analysis of pesticides in drinking water or baby food.

MATERIALS AND METHODS

Materials. A variety of food matrices were tested for their pesticide content including baby food fruit purees, green onions, tea (three types), green peppers, and yellow onion. The baby food purees were purchased in São Paulo, Brazil; the fresh vegetables were purchased at various produce markets in San Francisco, CA, USA; and the loose tea was purchased in various locations in China. All food matrices were extracted in triplicate using the AOAC 2007.1 QuEChERS method before analysis by GC-ICP-MS/MS. HPLC grade acetonitrile was purchased from J. T. Baker (Center Valley, PA, USA). Calibration was performed using three standard pesticide mixes obtained from Ultra Scientific (Kingstown, RI, USA) and Agilent Technologies (Santa Clara, CA, USA). The three mixed standard solutions were diluted with acetonitrile to form intermediate solutions, which were then used to prepare calibration standard solutions following serial dilutions in acetonitrile. QuEChERS kits were obtained from Agilent.

Sample Preparation. Apart from the prehomogenized baby food purees, all samples were ground in a food processor to obtain a homogeneous sample (NutriBullet, LLC, Porcomia, CA, USA).

DOI: 10.1021/jf506372e
J. Agric. Food Chem. 2015, 63, 4478−4483

Approximately 15 ± 0.1 g of sample (5 ± 0.1 g in the case of the tea samples due to their low density) were weighed into 50 mL centrifuge tubes, and then 15 mL of acetonitrile and two ceramic bars were added. This mixture was homogenized for 1 min on a vortex mixer. Then, prepackaged amounts of $MgSO_4$ and NaCl were added, and the system was agitated for 1 min again. The mixture was centrifuged at 2600*g* for 5 min. An 8 mL aliquot of the upper acetonitrile layer was transferred to 15 mL centrifuge tubes containing the dispersive and cleanup agents (PSA, $MgSO_4$). The tube was homogenized for 1 min and centrifuged at 2600*g* for 5 min. The resultant upper layer was transferred to an amber glass vial (Agilent Technologies) for analysis.

Instrument Setup. All measurements were carried out using an Agilent 7890 GC (Agilent Technologies, USA) coupled via an Agilent GC-ICP-MS transfer line (Agilent Technologies, Japan) to an Agilent 8800 ICP-QQQ instrument (Agilent Technologies, Japan). The chromatographic separation parameters were used as previously published.[12] The GC system was equipped with fast oven heating (240 V), a split/splitless inlet, a 7693A autosampler, auxiliary electronic pressure control (aux EPC), and a column backflushing system based on a purged union. Two columns were configured in an arrangement that allowed the first column to be backflushed shortly before the run had ended or during a postrun period.[13] The first column was a 5 m × 0.25 mm i.d. × 0.25 μm film thickness DB-5MS UI capillary column (cut from a 30-m DB-5MS UI column obtained from Agilent), which was installed between the inlet and one end of the purged union. The second column was a 15 m × 0.25 mm i.d. × 0.25 μm film thickness DB-5MS UI capillary column (Agilent Technologies) installed between the other end of the purged union and the transfer line connection inside the GC oven. Injections (1 μL) were made under splitless conditions with the inlet held at 280 °C. The GC oven temperature program started at 60 °C (held for 1.5 min), followed by a 50 °C/min ramp to 150 °C, then 8 °C/min to 240 °C, then 50 °C/min to 280 °C (2.5 min), and finally 100 °C/min to 290 °C (held for 2.05 min). The helium carrier gas was controlled in constant flow mode. The flow rate settings for analysis and backflushing mode were used as described previously.[12] Helium makeup gas (0.7 mL/min, controlled by an aux EPC module on the ICP-MS/MS) was passed through a metal tube placed in the GC oven and connected to the transfer line interface. The preheated makeup gas was used to sweep the GC column effluent efficiently into the plasma.

During ICP-MS/MS tuning, the helium carrier gas supplying the GC inlet and aux EPC module was replaced by argon containing H_2S at 100 ppm. The oxygen flow rates in the reaction cell and the quadrupole energy settings of the ICP-MS/MS were optimized by manually following the $^{32}S^+$ signal from the H_2S-spiked Ar gas. As discussed below, this resulted in a high sulfur background for several days after the switch back to pure helium, so an alternative position to feed the tuning gas into the ICP-MS/MS is recommended. The optimal operating conditions for the ICP-MS/MS are shown in Table 1.

The ICP-MS/MS includes an octopole reaction system (ORS^3) that is positioned between two quadrupole analyzers, as shown in Figure 1. The width of the bandpass of the first quadrupole analyzer can be varied from "fully open" to a unit mass filter, restricting the ions entering the CRC to a single mass to charge ratio (m/z) at any given time. For this study, two separate time-resolved analysis (TRA) methods were run simultaneously. P and S were analyzed using the same method as they both react spontaneously ($\Delta H_{reaction} < 0$) with oxygen:

$$^{31}P^+ + {}^{16}O_2 \rightarrow {}^{31}P^{16}O^+ + {}^{16}O \quad \Delta H_{reaction} = -3.17 \text{ eV}$$

$$^{32}S^+ + {}^{16}O_2 \rightarrow {}^{32}S^{16}O^+ + {}^{16}O \quad \Delta H_{reaction} = -0.34 \text{ eV}$$

For the determination of P and S, Q1 was set to transmit m/z 31 (for ^{31}P) and m/z 32 (for ^{32}S). O_2 was used as a reaction gas in the CRC. Q2 was set to monitor m/z 47 and 48 so that the product ions $^{31}P^{16}O^+$ and $^{32}S^{16}O^+$ could be detected free of any interferences. Besides the single oxides, the PO_2^+ and SO_2^+ masses at m/z 63 and 64 were monitored. Both P and S show high isotope purity (P, 31 (100%); S, 32 (94.99%), 33 (0.75%), 34 (4.25%), 36 (0.01%)[14]); thus, only the major isotope of each element was monitored.

Table 1. ICP-MS/MS Settings for the Two Different Detection Modes (Oxygen for P and S and Hydrogen for Cl Detection)

cell mode	O_2	H_2
scan mode	MS/MS	MS/MS
RF Power	1600	900
sampling depth (mm)	3	3
dilution gas (L/min)	0.6	0.5
octopole bias (V)	−0.5	−0.5
octopole RF (V)	150	150
KED (V)	−13	−13
cell gas	O_2	H_2
cell gas flow rate (%)	20	7
cell entrance (V)	−50	−30
cell exit (V)	−70	−70
deflect (V)	10	10
plate bias (V)	−60	−60
monitored masses	Q1 ≫ Q2	Q1 ≫ Q2
	31 ≫ 47	35 ≫ 37
	32 ≫ 48	

An illustration of the theory of the mass shift method using oxygen reaction gas is shown in Figure 1.

Even though the reaction between Cl^+ and O_2 is exothermic ($\Delta H_{reaction} = -0.91$ eV), the dominant process in the CRC under the conditions used is charge transfer ($Cl^+ + O_2 \rightarrow Cl + O_2^+$). Consequently, H_2 was used as the cell gas for the analysis of the Cl based pesticides based on the following theoretical reactions:

$$^{35}Cl^+ + {}^1H_2 \rightarrow {}^{35}Cl^1H^+ + {}^1H \quad \Delta H_{reaction} = -0.17 \text{ eV}$$

$$^{35}Cl^1H^+ + {}^1H_2 \rightarrow {}^{35}Cl^1H^1H^+ + {}^1H \quad \Delta H_{reaction} = -0.39 \text{ eV}$$

Q1 was set to m/z 35, where ^{35}Cl reacts with H_2 in the CRC to form $^{35}Cl^1H^1H^+$.[15] The Q2 was set to m/z 37, allowing the product ion ClH_2^+ to pass to the detector. Chlorine shows high isotopic purity (Cl, 35 (75.78%), 37 (24.22%)[14]); thus, only the major isotope was monitored.

RESULTS AND DISCUSSION

It has been shown previously that GC is an excellent sample introduction system for the ICP-MS detection of organophosphorus compounds.[10,16−21] Compared to liquid sample introduction into the ICP-MS, the GC delivers dry helium carrier gas containing relatively little matrix. However, GC-ICP-MS is limited to the determination of heteroatom-containing compounds that are volatile and thermally stable or can be converted to a volatile form by derivatizaton before injection into the GC-ICP-MS. Tuning of the GC-ICP-MS/MS was done by substituting the helium carrier gas with 100 ppm of H_2S spiked in Ar. As has already been discussed in the literature,[16] the optimal instrumental parameters for GC-ICP-MS are different from those required under wet plasma conditions. Thus, tuning for optimal parameter settings is required. For this study, optimization of the GC-ICP-MS/MS instrumental settings was carried out manually following the $^{32}S^+$ signal from the Ar gas spiked with 100 ppm of H_2S. The optimized plasma parameters are shown in Table 1.

In retrospect, introducing the Ar/H_2S tuning mixture through the EPC modules and carrier gas lines of the GC was problematic. H_2S contaminated the flow system and

continued to bleed out for the duration of these experiments. A better choice would be to introduce the H_2S/argon mixture as close to the ICP torch as possible, thereby minimizing the contact area for H_2S adsorption. This approach will be tested in future studies.

Once the GC-ICP-MS/MS was optimized for S sensitivity, the same instrument conditions were used for both S and P. The limits of detection were calculated on the basis of the standard deviations ($3 \times \sigma$, where σ is the standard deviation) from seven replicate blank samples, as shown in Table 2. Compound LODs and element specific LODs results are summarized in Table 2.

Careful optimization of the GC-ICP-MS/MS instrumental setup provides improved elemental detection limits compared to previously published GC-ICP-MS methods shown in Table 3.

Currently, one of the best ways to analyze GC-amenable pesticides is by GC-MS/MS with electron impact ionization.[29] This approach has largely replaced the use of traditional element-selective detectors such as the NPD, ECD, and FPD. GC-MS/MS offers high selectivity based on molecular fragmentation and the ability to detect any pesticide using a single detector. Detection limits for pesticides using current GC-MS/MS instrumentation typically vary from about 0.1 to 10 $\mu g\ kg^{-1}$ depending on the pesticide and instrument used.[22,23] The data in Table 2 would suggest that the GC-ICP-MS/MS is about an order of magnitude more sensitive than GC-MS/MS for organophosphorus pesticides. Using S or Cl, detection limits are similar to those achieved by GC-MS/MS. It is likely that detection limits using S will improve if the instrument can be tuned without contaminating the GC with H_2S. With one exception (dioxathion using S), all of the

DOI: 10.1021/jf506372e
J. Agric. Food Chem. 2015, 63, 4478−4483

pesticides in Table 2 could be detected well below 10 μg L^{-1}, which is the LOQ required by most food safety laboratories.

After instrumental conditions were optimized, mixtures of the three Ultra Scientific standard solutions were diluted with acetonitrile. Figure 2 shows chromatograms showing the heteroatom traces for P, S, and Cl of the calibration standard with identified pesticide compounds. The chromatogram for P and S was run in the same TRA run, and the Cl chromatogram trace was run in a separate TRA run and overlaid.

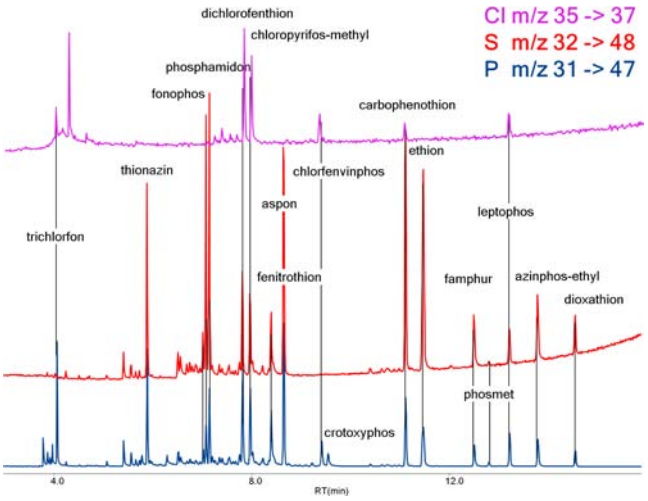

Figure 2. Chromatograms showing the heteroatom traces for P, S, and Cl of the calibration standard with identified pesticide compounds.

For a real-world application, real food samples (baby food purees, fresh vegetables, loose tea) were screened for their pesticide content. Every real-world food sample that was tested showed positive traces of pesticides in the chromatograms. Figure 3 shows an example of the P chromatogram of some of the analyzed food samples, together with a 200 ppb calibration standard.

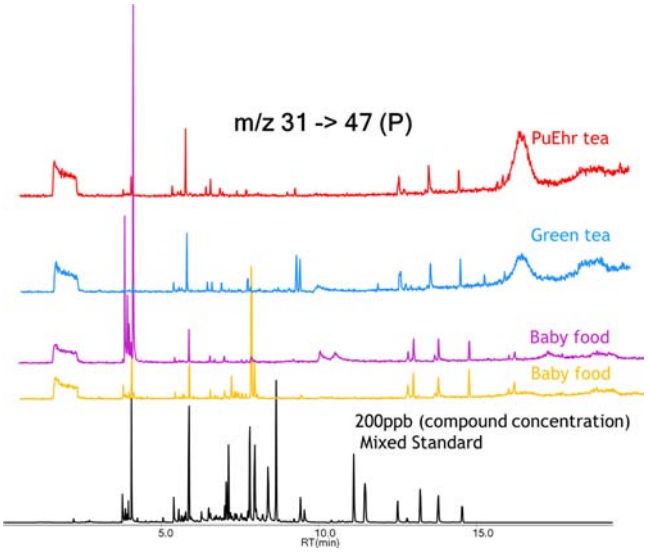

Figure 3. Example chromatogram showing the P trace of the analyzed food samples, together with a 200 ppb calibration standard. Baby food purple line or baby food 1, papaya + orange purée; baby food yellow line or baby food 3, grape purée.

This work clearly shows the potential of GC-ICP-MS/MS to be used for the ultratrace analysis of P-, S-, and Cl-containing compounds such as the pesticides in our test samples. GC-ICP-MS/MS optimization is essential to achieve the ultratrace LODs achieved in this study. There is also the possibility of using a CIC heteroatom method for quantification without the need for individual pesticide standards as shown by Bouyssiere et al.[24] and González-Gago et al.[25] Calibrating with pesticide mixes containing all analytes in the method is both time-consuming and expensive, especially as the analyte lists grow. In theory, one could calibrate for a long list of pesticides using a single compound containing the heteroatoms common to the target pesticides. However, this approach does not account for the behavior of individual pesticides (adsorption, degradation, etc.) during the chromatographic analysis. Future investigations will also target the application of GC-ICP-MS/MS for other matrices that would benefit from ultratrace detection limits and will look at ways of tuning the GC-ICP-MS/MS instrument that do not result in sulfur contamination.

honey.[2,7,10−13] The methods comprise the use of different strategies for the elimination of coextractives; for example, in the case of bees a hexane partition of the acetonitrile (MeCN) extraction solution is used to remove lipids from the extract.[11] Recently, our group reported an optimized combination of sample amount, extraction temperature, and cleanup methodology using freeze out, PSA, C18, and GCB as sorbents for beeswax pesticide residues analysis.[14] This approach was more effective than matrix solid phase dispersion (MSPD), which gave a high load of coextractives that spoiled the chromatographic system after a few injections. Pesticide residues in bees were analyzed using the MeCN-based extraction followed by different combinations of sorbents that optimized the performance of the method for the investigated analytes.[10,14] Compared with pollen, bees, and wax, honey is a simpler matrix, and due to its importance as food, it has been widely analyzed following different protocols. CEN 15662 QuEChERS has been smoothly applied to pesticide residue analysis in honey by our group.[15] As pointed out above, extensive surveys of pesticide residues in bees and beehives in North America and other parts of the world, looking for possible causes of bee decline,[2−8] have shown the presence of important amounts of pesticide residues in beehives. The major pesticide classes found were insecticides and fungicides, the latter being the most ubiquitous among North American apiaries. Chlorothalonil and strobilurins as well as some azoles accounted for the more frequent findings. The relationship of these pesticide cocktails to bee health is an open question that deserves a multiple-faceted approach to solve it, but at the same time, the vast array of residue findings in beehives supports the idea that bees collect what is in the environment, an ideal characteristic for an environmental monitor.[3,16−24]

In the present paper, the application of QuEChERS protocols for pesticide residue analysis in bees and bee products is reported. After the data gathered had been studied, a novel, first approach to check the recording of season variations in pesticide residues profiles in beehives within an agroecosystem is explored along with other statistical analysis to check the viability of beehives as environmental monitors.

MATERIALS AND METHODS

Chemicals and Standards. MeCN and *n*-hexane of HPLC quality were from Pharmco Products Inc. (Brookfield, CT, USA). Water was deionized in the laboratory using a Thermo Scientific (Marietta, OH, USA) EASYpure RoDi Ultrapure water purification system. Magnesium sulfate anhydrous, reagent grade, was from J. T. Mallinckrodt Baker Inc. (Phillipsburg, NJ, USA), and formic acid p.a. 88% was purchased from Macron Chemicals (Deventer, The Netherlands). A solution of 5% formic acid (v/v) was prepared in MeCN. The bulk amino sorbent (PSA, 40−60 μm), RP-C18, and graphitized carbon black (GCB) were from Scharlab (Barcelona, Spain). Analytical standards, of purity ≥95%, were from Dr. Ehrenstorfer (Augsburg, Germany).

Stock standard solutions of 1 mg/mL were prepared in MeCN, and working standard mixtures were prepared by appropriately diluting multiple stock solutions with MeCN. The pesticides studied were all LC amenable pesticides; no GC amenable pesticides were included. They were selected among the most used in extensive plantations in Uruguay aiming to check the model suitability. All working solutions were stored in the dark at 4 °C.

Apparatus. LC-MS/MS was performed with an Agilent 1200 LC system coupled to a 4000 QTRAP LC-MS/MS System from AB SCIEX run in the Scheduled MS/MS mode. LC separation was performed on a ZORBAX Eclipse XDB-C18 (150 mm × 4.6 mm, 5 μm) column. The operation of the LC gradient involved the following elution program: (A) water/HCOOH 0.1% (V/V); (B) MeCN. It was run at 600 μL min^{-1} starting with 10% component B at injection time during 1 min and gradually changing to 100% B over 15 min. This mobile phase was kept for 10 min and then shifted back to the starting conditions (10% component B) and kept there until 35 min after injection. The injection volume was 5 μL. MS/MS detection was performed in the multiple reaction monitoring (MRM) mode using an ESI interface in the positive ion mode. The ionization voltage was 4500 V, the nebulizer gas was synthetic air at 70 psi, and the curtain gas was nitrogen at 30 psi. The solvent evaporation in the source was assisted by a drying gas (heated synthetic air at 425 °C/50 psi). The optimal MRM transitions, collision energies, and declustering potentials for each investigated compound were determined by directly infusing with a syringe the standard solutions to the instrument at a constant flow. The MS/MS settings used in this study are listed in the Supporting Information.

Methodology. *Sampling Design.* Seven apiaries located in different production zones of Uruguay were selected on the basis of their health history and management. All of the apiaries have at least 20 beehives. From each apiary, samples of bees and honeycombs were taken randomly from five beehives in fall, winter, and spring. Then the samples were driven to the laboratory where they were joined, obtaining one composed sample per beehive product representing each apiary. The beehive matrices were obtained by allowing honey to drain. Once the wax was honey free, the pollen inside the cells was collected by digging into them one by one.

Sample Preparation. (a) Pesticide Residue Analysis in Beeswax. The methodology employed for the pesticide residue analysis in beeswax was that already described in a previous work by our group.[8] Briefly, 2 g of beeswax is extracted with 10 mL of MeCN at ∼80 °C. Then, the extract is frozen-out and cleaned up with 25 mg of primary−secondary amine (PSA) and 25 mg of C18 sorbent per milliliter of extract. Finally, the extract is acidified with 5% formic acid solution in MeCN (v/v) (10 μL/mL extract) and injected in LC-MS/MS.

(b) Pesticide Residue Analysis in Honey. The methodology employed for the pesticide residue analysis in honey was that already described in a previous work by our group.[9] Briefly, 5 g of honey is extracted with 10 mL of water and 10 mL of MeCN. Then the mixture of citrate buffer salts is added. The extract is cleaned up with PSA, 25 mg/mL, and $MgSO_4$, 150 mg/mL. Finally, the extract is acidified with 5% formic acid solution in MeCN (v/v) (10 μL/mL extract) and injected in LC-MS/MS.

(c) Pesticide Residue Analysis in Bees. Fifty grams of frozen honeybees weas thoroughly comminuted and homogeneized with a hand blender, and then 2 g was weighed in a 50 mL centrifuge tube and 5 mL of water; 10 mL of MeCN was added and shaken vigorously for 1 min; 0.5 g of disodium hydrogencitrate sesquehydrate, 1 g of trisodium citrate dihydrate, 4 g of anhydrous magnesium sulfate, and 1 g of sodium chloride were added and the mixture was shaken again; then the tube was centrifuged for 5 min at 3000 U/min. The extract was frozen out overnight and cleaned up by dispersive solid phase extraction: PSA and C18, 25 mg/mL, and $MgSO_4$/GCB (59:1), 150 mg/mL; vortexed for 30 s; and centrifuged for 5 min, 3000 U/min. The aliquot for LC-MS/MS analysis was acidified with 5% HCOOH in 10 μL/mL MeCN.

(d) Pesticide Residue Analysis in Pollen. Pollen isolated from the sampled portions of honeycomb was thoroughly comminuted and homogeneized with a hand blender, and then 5 g was weighed in a 50 mL centrifuge tube, and 5 mL of water and 10 mL of MeCN were added and shaken vigorously for 1 min; 1 g of sodium acetate, 4 g of anhydrous magnesium sulfate, and 100 μL of acetic acid were added, and the mixture was shaken again; then the tube was centrifuged for 5 min at 3000 U/min. The extract was cleaned up with dispersive solid phase extraction: PSA and C18, 25 mg/mL, and $MgSO_4$, 150 mg/mL; vortexed for 30 s; and centrifuged for 5 min, 3000 U/min. Finally, the cleaned extract was transferred into a screw-cap vial and injected in LC-MS/MS.

Statistical Analysis. Statistical analysis were performed using R, which is a free software environment for statistical computing and graphics.[25]

Besides the statistical description by average values and standard errors, two kinds of statistical analysis were done: a multiple factorial analysis (MFA, Escofier and Pages)[26,27] and the calculation of the Gower[28] distance. The MFA is done in two steps: first, a principal components analysis (PCA) is made per group of variables (groups being bees, wax, pollen, and honey), and the original values are standardized by the square root of the first eigenvalue from each group analysis; second, a new global PCA is made using the standardized values. That kind of analysis allows the relationship between concentration of products per group to be shown in a two-dimensional figure in such a way that the groups near one another in the figure are more similar in concentration of products.

The Gower distance is a distance based on the absolute values of differences between statistical samples,; in this case the samples are the apiaries in each season, and what is compared is the pesticide residues profile obtained in the four matrices analyzed. Calculus: (value − minimum)/range.

This distance allows the presence of missing values in some comparisons, and results are in the 0−1 interval, allowing an easy interpretation.

For all of the calculations, the concentration of coumaphos found for the different apiaries was not considered as the acaricide is an agrochemical commonly employed in apiculture and has no meaning in the consideration of the agroecosystem under study.

RESULTS AND DISCUSSION

The extracts produced had a significant load of coextractives. To overcome this difficulty and obtain low LODs, an LC-MS/MS using the scheduled option in the MRM mode with optimized transitions, collision energies, and declustering potentials for the 19 LC-amenable currently employed pesticides in Uruguayan agroecosystems was used, as continuous scanning of the whole mass range led to higher LODs and LOQs.

Methods Validation. In agreement with the analytical quality control procedures document by DG-SANCO,[29] five replicates of spiked blanks of bees at different levels (0.2, 0.1, 0.05, 0.01, 0.001, 0.0001 mg/kg) and of pollen (0.05, 0.01, 0.001, 0.0001 mg/kg) were analyzed to assess accuracy (% recovery) and repeatability (% RSD) of the procedure (Tables 2 and 3). Limits of quantification (LOQs) were considered as the lowest successfully validated levels, that is, the levels at which acceptable recoveries (70−120%) and RSDs (<20%) were achieved. For every pesticide, its LOQ is lower than the corresponding reported LD_{50}.[30] If we consider the weight of a bee is approximately 100 mg, a factor of 10 is needed to convert μg/bee to mg/kg. Very low LOQs (0.0001 mg/kg) were obtained for several pesticides, particularly azoxystrobin and dimethoate in both matrices, which is important if we consider that the concentrations found in the real samples were around this level.

Calibration curves were constructed using both solvent-based and matrix-matched standards at five concentration levels: 0.002, 0.01, 0.02, 0.05, and 0.1 mg/L for bees and 0.005, 0.01, 0.025, 0.05, and 0.1 mg/L for pollen. Linear correlation coefficients were >0.999 for bees and >0.991 in pollen for all of the studied analytes. Linear ranges were fit for purpose considering the concentrations found in real samples.

Matrix effects were calculated as the percentage difference in the best-fit slopes of the matrix-matched calibration curves versus the respective best-fit slopes of the solvent calibration curves.

Matrix effects were quite pronounced and variable from analyte to analyte (Tables 1 and 2), particularly in the case of pollen analysis. This is explained by the fact that matrix effects depend on whether a target analyte coelutes with coextracted matrix components, affecting the yield of free analyte ions generated within the ESI-ion source and thus the detection signals.

Where matrix effects remain strong, the use of matrix-matched calibration standards (prepared from extracts of blank matrix so far available) or the method of standard additions are

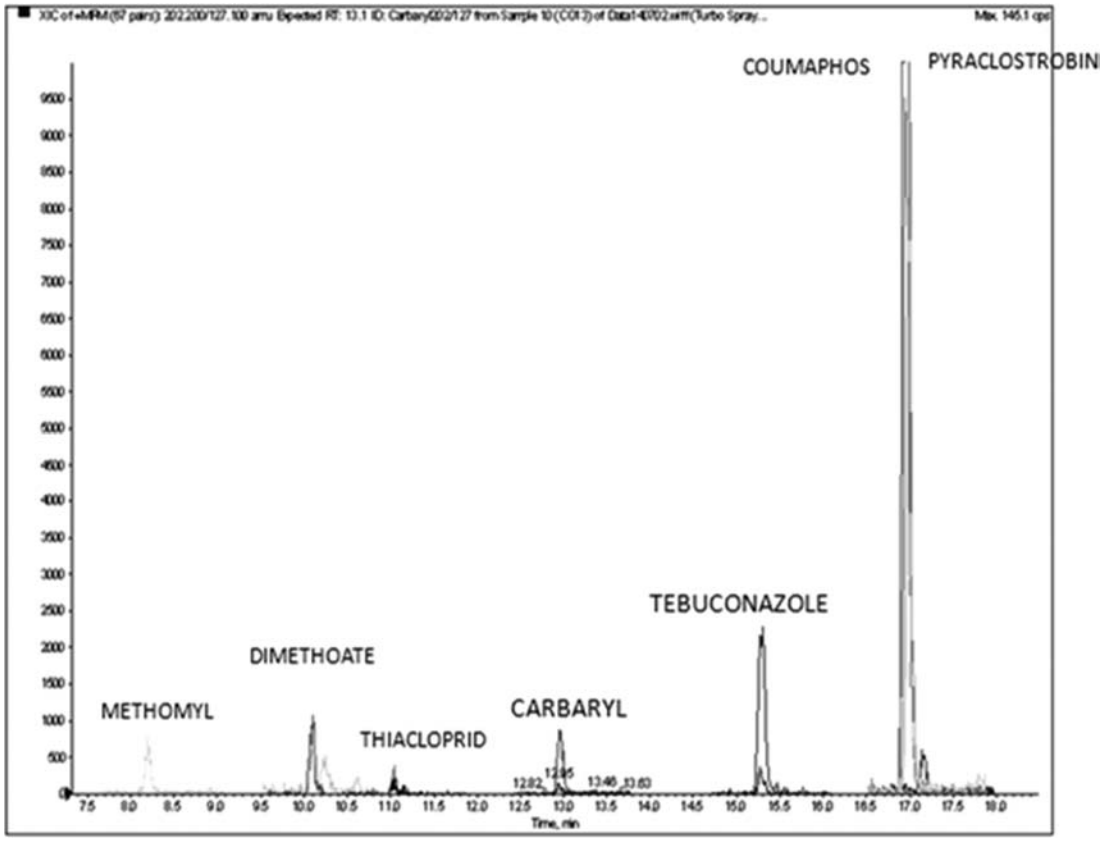

Figure 1. LC-MS/MS chromatogram showing multiple positive findings in a real beeswax sample.

recommended to obtain reliable quantification. Matrix-matched calibration was used during this study.

Beehive Samples Analysis. Pesticide residue analysis of the different samples of bees, pollen, beeswax, and honey yielded results similar to those found in North America and Europe.[5,10,19] Multiple findings in a single sample were frequent as shown in Figure 1, particularly in beeswax and pollen. Figure 2 shows a detailed graph of the frequency of positive findings

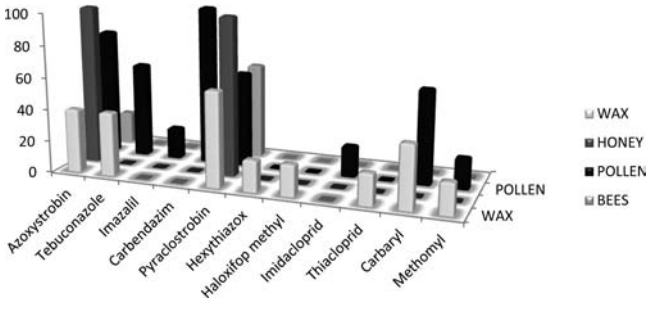

Figure 2. Frequency of positive findings in the four analyzed hive matrices.

for each matrix where the prevalence of fungicides is observed. However, the concentrations found were low, within the range of 0.0001−0.01 mg/kg. Mullin et al.[5] found a high occurrence of chlorothalonil in North American apiaries. In our case, all of the samples contained strobilurins as azoxystrobin and pyraclostrobin. The peculiarity of the high occurrence of fungicides in bee products has not been properly explained yet. Fungicides have intermediate pK_a and pK_{ow} on which the basis to understand their ubiquity in the different bee matrices, wax, pollen, and honey, could be built. The occurrence of pesticides in pollen is originated directly from what was applied over the crops. Depending on their physicochemical properties, residues can diffuse to other beehive compartments; the most remarkable ones are wax and honey. Either due to a dilution effect or slow solubility in them, their detection is hampered. Pesticide residues in honey are less frequent, probably because honey is an aqueous matrix, whereas most pesticides are lipophilic. Diffusion from a lipophilic matrix such as pollen to an aqueous one is not favored. Pesticides found in bees are those that they were directly exposed to; therefore, residue findings in bees could vary with time.

Taking advantage of the plasticity of the QuEChERS template coupled to modern analytical instrumentation, the validated analytical methodologies described, developed specifically for pesticide residue analysis in bees, honey, beeswax, and pollen, were applied to real sample analysis from beehives placed in Uruguayan agroecosystems: Insecticides (e.g., thiacloprid, imidacloprid, methomyl, carbaryl), fungicides (e.g., azoxystrobin, pyraclostrobin, tebuconazole, hexythiazox), and herbicides (e.g., haloxyfop-methyl) have been detected at 0.0001−0.01 mg/kg levels (Table 3).

Beehives as Environmental Monitors of the Application of Pesticides in Agroecosystems. The type of pesticide residues could be relatively similar within each matrix (bees, wax, honey, and pollen), independent of the agroecosystem due to its intrinsic chemical composition. Therefore, different residue profiles are expected per matrix. To check this assumption, a MFA of pesticide residue findings from all analyzed samples in bees, honey, pollen, and beeswax was performed. None of the four matrices is too close (Figure 3). This indicates that each matrix gives different information. If we

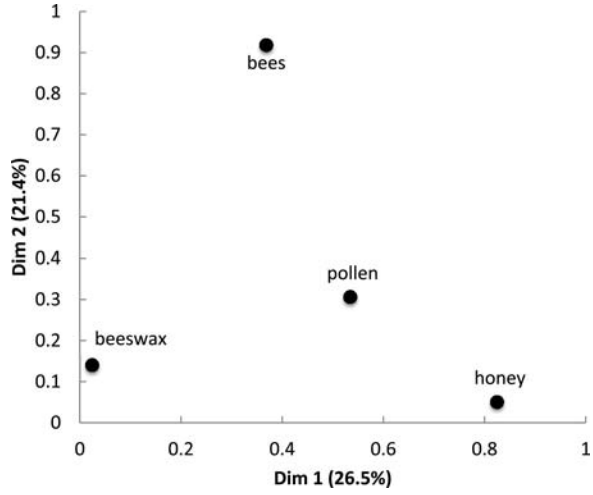

Figure 3. Multiple factorial analysis of pesticide residue findings from all analyzed samples in bees, honey, pollen, and beeswax.

consider how the residues reach the hive, more valuable information is gathered when each matrix is analyzed separately. Whereas the wax is an historic reservoir of the collected pesticides, residues in pollen are more diverse and represent what has been directly sprayed over the crops. A higher number of insecticides were detected in it: imidacloprid, carbaryl, and dimethoate. On the other hand, pesticide residues in bees tell us about the latest pesticide applications to which bees were exposed. In samples from the apiaries under study, bees carried mostly fungicides and the only herbicide detected, haloxyfop-methyl. Honey is a hydrophilic matrix, and lipophilic pesticides are expected to occur at low concentrations if at all, and more hydrophilic pesticides should be present. In our case, only the strobilurins were detected in this matrix.

An agroecosystem's monitor should be stable but capable of recording the baseline variations that occur in a definite environment. To assay the usefulness of the beehive as a monitor, we have to check the range of variability of the load of residues within the hive in an agroecosystem and if the differences found have some significance. Table 4 shows the evaluation of the Gower distances (G-distances) for five of the apiaries between two sampling seasons. For the other two, samples of only one season were taken, making the comparison impossible. The first conclusion is that the values of pesticide residues have to be compared within the same apiary. The lowest value was for apiary E, located near forestation and native wood, meaning that the change in pesticide residues content between the two seasons was low. This result could be explained as no pesticide is applied over the native crop and pesticide residues came from the forestry activities. Going up in

G-distances, apiary D, near a natural prairie, has a slightly higher G-distance as no pesticide is applied over the natural field. On the other hand, for apiary A, located also in a dairy basin where lotus and clover prairies, two very visited species by foraging bees, were planted, a higher G-distance was obtained, showing that the monitor is also capable to distinguish between different agricultural practices, although the same production activity is being developed in the hive surroundings. The G-distance found between apiaries A and D, bred in different dairy basin environments in spring, is 0.21 (Table 5), proving that the hive detected the different managements of the agricultural environment. Apiary B, located in the middle of eucalyptus forest plantations, showed the same G-distance as apiary A, which indicates that both apiaries were able to record the same change in their pesticide residues profile between autumn and spring. These findings confirm also the beekepers' observation that bees prefer to visit the natural forest due to its diversity rather than the cultivated one, usually a monospecies, either eucalyptus or pines. The highest G-distances were obtained for a complex environment where mixed production activities were being developed. The rotation from rice to cattle breeding is characteristic of the Uruguayan rice production, and apiary C located in such environment registered this variation. The differences in the pesticide residue loads observed between the two seasons in the apiaries located in all of the environments studied sustain the idea of the beehive as an environmental monitor. They are the first objective observations that the incorporation of pesticide residues, although low, is characteristic of each agroecosystem and the cropping practices developed in it. The apiaries in the different environments showed significant seasonal variations in the load of pesticide residues, which were characteristic for these environments. Figure 4 shows the change in the pesticide residues profile of an apiary located near soybean plantations, before and after the cropping season. The amount and type of residues found are higher at the end of the agricultural period, showing again that the beehive is sensitive to the seasonal changes that occur in the environment.

The data presented show that the work hypothesis is valid. However, more work is needed to understand the dynamics of bees' pesticide collection and residue storage in the beehive compartments to properly evaluate the hive as a monitor of an agroecosystem. The separate study of the different bee matrices gives richer insights into this problem. The information yielded by the pesticide residues profile of each matrix contributes to a wider picture of the situation. The analytical methodologies described allow gathering an enormous amount of information in a fast and effective way that makes feasible the idea of monitoring agroecosystems through the analysis of complex bee products.

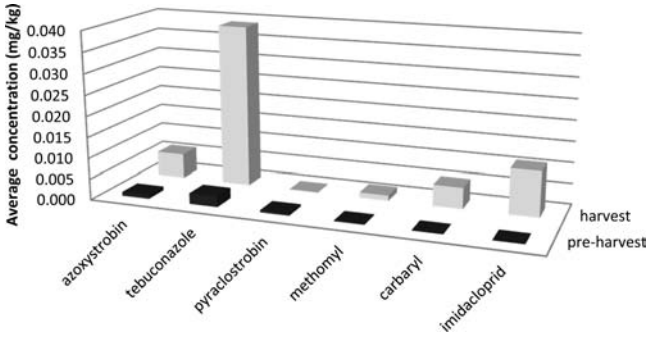

Figure 4. Average concentrations of the residues found in an apiary located in a soybean plantation sampled at pre- and postharvest.

Several methods using LC-TOF-MS that monitor veterinary drug and pharmaceutical residues in food products have been published.[19−23] However, having MS data only for the precursor ions is not considered sufficient for residue identity confirmation, even with high mass accuracy. In some methods in-source fragmentation was performed (in-source CID) to generate fragment ions that could provide additional data for compound identification.[22] However, the in-source CID fragmentation has significant drawbacks compared to tandem mass spectrometry. Matrix interferences could preclude its use, and large amounts of impurities can significantly complicate the analysis process.[24] A hybrid quadrupole TOF (QTOF) has the additional ability to obtain MS/MS spectra that can be used to further characterize drug residues. QTOF MS allows working under broad-band collision-induced dissociation (bbCID) (or MS^E) mode, switching alternately between low (LE) and high collision energy (HE) in the collision cell Q2, at the same run. The low-energy data set provides information for molecular (precursor) ions corresponding to a given retention time, whereas the second set contains their fragment ions.[25] The information provided, along with the isotopic distribution observed in the spectra, allows the reliable identification of the compounds detected in the samples.

In multiresidue analysis the LC part is responsible for some limitation as well, mainly due to the large number of target analytes that need to be separated simultaneously. Ultrahigh-performance liquid chromatography (UHPLC) can eliminate these limitations, providing additional chromatographic resolution and significantly lowering analysis times using sub-2-μm particulate column packing material.[21]

With the demand for high-throughput analysis constantly increasing, the development and application of generic extraction procedures, able to extract a wide range of compounds with different physical/chemical properties, have become essential. A wide array of the proposed methodologies for analyzing veterinary drug residues in food products employs liquid−liquid extraction (LLE) or solid−liquid extraction (SE), with solid-phase extraction (SPE) being the most widely used technique for the cleanup of the extracts.[26] The combination of solid−liquid extraction or liquid−liquid extraction followed by the SPE cleanup step has been satisfactorily applied to the analysis of several antibacterials in milk,[19] meat,[20,23] and eggs and fish.[23] An effort was made to omit cleanup steps by performing a single-solvent extraction in fish and feed matrices,[27] but matrix effects proved to be problematic leading to reduced sensitivity in some cases. To conclude, for an accurate and efficient multiresidue screening method, both a sensitive full scan technique and a comprehensive sample preparation are required.

So far, the number of applications of LC-QTOF MS determination of veterinary drug residues in food and feed matrices is quite limited.[5,27−35] Some of these studies cover a single class of drugs such as macrolides and quinolones in fish[29,30] or fewer than 30 compounds in milk[28,31] and aquaculture species.[32] Two of them cope with feed matrices: Boix et al. presented a qualitative screening of 116 veterinary drugs, validated on the basis of a previously reported validation protocol,[5] and Aguilera-Luiz et al. developed a wide-scope multiresidue method able to cover the analysis of >200 pesticide and veterinary residues.[33] As Aguilera-Luiz et al. stated in the conclusions of their study,[33] the developed method showed some limitations because some families of drugs, such as tetracyclines, quinolones, and penicillins, were not properly extracted, and low sensitivity made the detection of some compounds and fragments at low concentrations unfeasible. Deng et al. presented a multiresidue/multiclass quantitative screening approach for 105 veterinary drugs in meat, milk, and egg with UHPLC-QTOF MS/MS,[34] and Nácher-Mestre et al. described the development, qualitative validation, and application of a screening method for the detection and identification of about 70 organic compounds, including antibiotics, pesticides, and mycotoxins, in fish feed and fish fillets.[27] Most recently, Turnipseed et al. presented an LC-QTOF MS/MS method for the screening of about 200 veterinary drugs in milk, providing experimental retention time and product ion information.[35]

The objective of this work is the development of a reliable, sensitive, and modern screening methodology for the detection and identification of 143 veterinary drugs and pharmaceuticals in milk and fish samples based on the use of an advanced UHPLC-QTOF MS technique. Generic sample extraction procedures were used, and their efficiency was evaluated. A qualitative validation of the screening method was performed, and levels of detection and identification were specified for all target analytes in both matrices. Subsequently, the method was applied to the analysis of different milk and fish samples to test its applicability. Experimental data including retention times, product ion spectra, and precursor and product ion mass accuracy as well as precursor−product ion ratios were obtained and presented for all target compounds.

MATERIALS AND METHODS

Reagents and Chemicals. All veterinary drug and pharmaceutical standards were of high-purity grade (>90%). The majority of them were purchased from Sigma-Aldrich (Steinheim, Germany). Sulfadoxine (SDX) and sulfaclozine (SClZ) were donated by the National Laboratory of Residue Analysis of Food of Animal Origin of the Hellenic Ministry of Rural Development and Food. Bacitracin, halofuginone, arprinocid, salinomycin, semduramicin, manduramycin, nigericin, narasin, albendazole sulfone, carprofen, diclofenac, flunixin, mefenamic acid, meloxicam, niflumic acid, and tolfenamic acid were donated by the Veterinary Drug Residues Laboratory of the State General Laboratory of Cyprus.

Acetonitrile (ACN) and methanol (MeOH) of LC-MS grade were purchased from Merck (Darmstadt, Germany), whereas 2-propanol of LC-MS grade was from Fisher Scientific (Geel, Belgium). Sodium hydroxide monohydrate (NaOH) for trace analysis ≥99.9995% and formic acid 99% were purchased from Fluka (Buchs, Switzerland). Hexane (pesticide analysis grade, 95%) was purchased from Carlo Erba (Milan, Italy), and distilled water was provided by a Milli-Q purification apparatus (Millipore Direct-Q UV, Bedford, MA, USA). The ethylenediaminetetraacetic acid disodium salt (EDTA) and the trichloroacetic acid (TCA) were of analytical grade and were purchased from Panreac (Barcelona, Spain) and Fisher Scientific (Loughborough, UK), respectively. Regenerated cellulose (RC) syringe filters (15 mm diameter, 0.22 μm pore size) were provided from Phenomenex (Torrance, CA, USA). Solid phase extraction cartridges were Oasis HLB 3 cc (60 mg) from Waters (Milford, MA, USA).

Stock standard solutions of individual compounds (1000 μg mL^{-1}) were prepared in methanol and stored at −20 °C in brown glass to prevent photodegradation. Penicillins, cefalosporines, and metformin were dissolved in Milli-Q water and stored at 4 °C. In quinolone standard solutions, 100 μL of formic acid was added to enhance solubility. Four intermediate standard solutions containing the analytes were prepared by dilution of the stock solutions with methanol. The final concentration of these multicomponent solutions was 10 μg mL^{-1}, and they were also stored at −20 °C. New intermediate standard solutions were prepared every month. Working solutions and

J. Agric. Food Chem. 2015, 63, 4493−4508

calibration standards, containing all of the target analytes, were obtained by gradient dilution of the intermediate solutions, in concentrations varying from 1 μg mL^{-1} to 1 ng mL^{-1}. The working solutions were kept at −20 °C and renewed weekly.

Instrumentation. An ultrahigh-performance liquid chromatography (UHPLC) system (Dionex UltiMate 3000 RSLC, Thermo Fisher Scientific, Germany) interfaced to a QTOF mass spectrometer (Maxis Impact, Bruker Daltonics, Bremen, Germany) was used for the screening analysis.

The chromatographic separation was performed on an ACQUITY UHPLC BEH C18 column (2.1 × 50 mm, 1.7 μm) from Waters (Ireland), thermostated at 30 °C. The mobile phases were (A) MeOH and (B) an aqueous solution with 0.01% formic acid. The flow rate was 0.1 mL min^{-1} despite the fact that UHPLC allows higher flow rates (<0.2 mL min^{-1}) because electrospray ionization is more compatible with low flow rates and thus sensitivity of the detection is increased. The gradient elution program started with 5% MeOH (A), increased to 100% in 7 min, and kept constant for 3 min. Then, the initial conditions were restored, and the system was allowed to re-equilibrate for the next injection for 7 min (17 min total run time). Although the re-equilibration step is rather extended for a 50 mm length column, it is necessary to ensure retention time stability, which is indispensable for the adequate detection of target compounds. The injection volume was set to 5 μL.

The QTOF MS system was equipped with an electrospray ionization interface (ESI), operating in positive mode, with the following operation parameters: capillary voltage, 2500 V; end plate offset, 500 V; nebulizer pressure, 2 bar (N_2); drying gas, 8 L min^{-1} (N_2); and drying temperature, 200 °C.

The QTOF MS system was operating in broadband collision-induced dissociation (bbCID) acquisition mode and recorded spectra over the range m/z 40−1000 with a scan rate of 2 Hz. The Bruker bbCID mode provides MS and MS/MS spectra at the same time (as MS^E mode described in a previous study[5]). It works at two different collision energies; at low collision energy (4 eV), MS spectra were acquired, where all of the ions from the preselected mass range m/z 40−1000 are heading toward the flight tube without isolation at the quadrupole and there is no collision-induced dissociation at the collision cell. At high collision energy (25 eV), no isolation is taking place at the quadrupole, and the ions from the preselected mass range m/z 40−1000 are fragmented at the collision cell.

A QTOF external calibration was daily performed with a sodium formate solution, and a segment (0.1−0.25 min) in every chromatogram was used for internal calibration, using a calibrant injection at the beginning of each run. The sodium formate calibration mixture consists of 10 mM sodium formate in a mixture of water/isopropanol (1:1). The theoretical exact masses of calibration ions with formulas $Na(NaCOOH)_{1-14}$ in the range of 40−1000 Da were used for calibration. The instrument provided a typical resolving power of 36000−40000 during calibration (39274 at m/z 226.1593, 36923 at m/z 430.9137, and 36274 at m/z 702.8636).

Samples. Pasteurized whole bovine and ovine milk samples were purchased from local retail food outlets and supermarkets. Samples were stored at 4 °C before analysis (within 10 days). Cultured fish samples, consisting of gilthead sea bream (*Sparus aurata*) and sea bass (*Dicentrarchus labrax*) samples, were obtained from aquaculture and local fish markets. The fillets were homogenized with a high-speed blender and stored at −23 °C until analysis. One sample of each matrix was tested to ensure that it did not contain any analytes, and it was used for negative control and fortified with target compounds. Milk and fish samples contain different amounts of fat (2−3.5% for milk and 5−10% for fish tissue), so the method can be used to analyze different categories of food products with different fat contents.

Sample Preparation. Two different sample preparation protocols were developed and used for the extraction of veterinary drugs and pharmaceuticals from fish and milk samples. A schematic representation of the extraction and cleanup procedures is presented in the Supporting Information (Figure S1).

The sample preparation method for the fish tissue samples has been developed in a previous study from our group. It consists of a generic extraction of the analytes from the tissue using a mixture of analytes and further low-temperature and hexane cleanup. A 1 g portion of fish tissue sample is weighed and placed into a 15 mL polypropylene centrifuge tube. For fortified fish tissue samples, aliquots of 20 and 200 μL of a working solution standard containing all of the analytes at a concentration of 1 μg mL^{-1} were added. Spiked levels obtained were 20 and 200 μg kg^{-1}, respectively. When fortified, the samples are vortex-mixed for 30 s and allowed to stand for 10−15 min. Two milliliters of H_2O containing 0.1% formic acid (v/v) and 0.1% EDTA (w/v), 2 mL of MeOH, and 2 mL of ACN are added in all samples, subsequently. After the addition of each solvent, the tube is vortex-mixed for 30 s. The sample set is placed in an ultrasonic bath at 60 °C for 20 min, the samples are centrifuged at 4300g for 10 min, and the supernatant is decanted into a new polypropylene centrifuge tube. The tubes are placed in −20 °C for 12 h to precipitate the lipids and remaining proteins. After centrifuging and discarding the precipitate, defatting with hexane completes the sample cleanup. The extracts are evaporated to dryness under a nitrogen stream and reconstituted in 0.5 mL of methanol/aqueous solution of formic acid, 0.05% (25:75 v/v), achieving a two-time preconcentration of the analytes in the samples. Finally, the extracts are filtered through a 0.22 μm pore size RC filter (to remove matrix interferences).

Milk samples are allowed to thaw, and a quick homogenization of the fat is performed by shaking before taking up the test portion of 2 g for the analysis. The samples were extracted with a mixture of aqueous TCA 5% (w/v)−ACN (3:1, v/v) and were then subjected to cleanup with hydrophilic−lipophilic balance (HLB) SPE cartridges. In particular, 2 mL of whole milk is transferred in a 50 mL polypropylene centrifuge tube. For fortified milk samples, aliquots of 30 and 300 μL of a working solution standard containing all of the analytes at a concentration of 1 μg mL^{-1} were added to 2 mL milk samples. Spiked levels obtained were 15 and 150 ng mL^{-1}, respectively. When fortified, the samples are vortex-mixed for 30 s and allowed to stand for 10−15 min. After the addition of 12 mL of aqueous TCA solution 5% (w/v) and 4 mL of ACN, the samples are vortexed for 1 min and shaken for 60 min using a mechanical shaker in medium speed (approximately 1000 rpm). Then, the sample tube is centrifuged at 4000g for 5 min, and the supernatant is decanted in a new polypropylene tube and diluted to 50 mL with Milli-Q water. The diluted sample extract is adjusted to pH 5.5 by dropwise addition of ammonia hydroxide 15% (w/v) and measurement of the pH value with a pH meter. Afterward, the extract is loaded onto an Oasis HLB cartridge (60 mg, 3 mL) previously conditioned sequentially with 6 mL of MeOH and 6 mL of H_2O. The sample is passed through the cartridge at a flow no faster than 1 drop/2 s, and then it is vacuum-dried for 30 min. No washing step was applied to minimize analyte loss. The elution is carried out with 2 × 3 mL of MeOH, and the eluent is collected and evaporated to dryness under a stream of nitrogen at 40 °C. The residue is redissolved in 0.5 mL of MeOH/aqueous solution of formic acid, 0.05% (25:75 v/v), and filtered through a 0.22 μm RC filter. The preconcentration factor achieved with this method is 4-fold.

Qualitative Validation. Validation of the screening method was performed for qualitative purposes following the strategy described in the literature,[5,27,36] which is in part based on the SANCO/12571/2013 guideline.[37] Two sets of six fish samples (2 × 3 sea bream and 2 × 3 sea bass) and two sets of six milk samples (2 × 3 bovine milk and 2 × 3 ovine milk samples) were spiked at two concentration levels (20 and 200 μg kg^{-1} for fish samples and 15 and 150 ng mL^{-1} for milk samples). The samples were analyzed in four sets during four different laboratory days. Each set of samples consisted of seven samples of each matrix (six spiked samples, three at the low concentration level and three at the high concentration level, together with their respective nonspiked blanks) and one reagent blank to ensure that no laboratory contamination was held during the analysis.

The main validation parameters investigated were the screening detection limit (SDL) and the limit of identification (LOI). The lowest concentration level in which a target compound was detected in all samples is defined as the SDL, whereas the lowest concentration in which a target compound was satisfactorily identified in all spiked samples is defined as the LOI. The detection criterion was the

presence of the most abundant ion (most frequently, the protonated molecule) in the LE function at the expected retention time (±2.5% tolerance) measured at its exact mass with a maximum mass error of 2 mDa. For identification at least two m/z ions (for example, the precursor and one product ion) are required (in either the LE or HE function).

According to Commission Decision 2002/657/EC, a minimum of three identification points (IPs) is required for authorized substances and four for banned compounds.[38] For HRMS, 2 IPs are earned for the precursor and 2.5 IPs for each product ion. Consequently, when a compound is successfully identified (at LOI) 4.5 IPs are earned, in agreement with the EU requirements.

RESULTS AND DISCUSSION

UHPLC-QTOF MS Method Development. Data analysis and evaluation were processed with Data Analysis 4.1 and Target Analysis 1.3 (Bruker Daltonics). An in-house database of 143 pharmaceutical compounds and veterinary drugs was built including information on the analytes' retention time, molecular formula (to extract the accurate mass of the corresponding pseudomolecular ion and adducts $[M + H]^+$, $[M + Na]^+$, and $[M + NH_4]^+$), isotopic fit, and qualifier ions. All aforementioned data were obtained after injection into the UHPLC-QTOF MS of solvent standard solutions for all target analytes in a concentration of 0.5 μg mL^{-1}. From the LE and HE operation modes, two chromatograms were acquired, a MS and MS/MS chromatogram. LE provided the MS spectra and chromatograms, and thus it was used for the retention time and the molecular formula and mass accuracy of the precursor ions and adducts. From the HE operation the MS/MS spectra and chromatograms were obtained and, thus, information on the molecular formula and mass accuracy of the fragment ions used for the identification of the analytes. Mass spectra obtained from the injection of a standard solution of sulfamethoxazole, in both LE and HE modes, are presented in Figure S2. All TOF data obtained were evaluated against this database.

The addition of retention time and product ion data for target compounds in the database renders the analysis of samples much more efficient as many false-positive detects are precluded. Elemental compositions of the product ions were investigated, and the proposed formulas have arisen using the experimental m/z and Bruker's Data Analysis Smart Formula Tool, which proposes formulas based on the number and type of atoms found in the precursor ion. Many of these structures have been previously reported in the literature.[35,39,40] Table S1 shows the compound name, retention time (minutes), elemental compositions, and theoretical exact mass for precursor and main fragment ion.

For some compounds, the $[M + H]^+$ did not appear to be the most abundant ion. Ionophores, such as monensin, narasin, nigericin, and salinomycin, formed ammonium adducts; the same applied for amphenicols and some nonsteroidal anti-inflammatory drugs (tolfenamic acid and vedaprofen). Erythromycin presented a very abundant $[M - H_2O + H]^+$ ion, because it is very unstable in acidic conditions and is rapidly subjected to a loss of H_2O.[29] Finally, some penicillins were monitored as their $[(M + H_2 - CO) + H]^+$ degradation products. Penicillin G, penicillin V, cloxacillin, dicloxacillin, and oxacillin are subjected to a β-lactam ring-opening that leads to the formation of these products. Amoxicillin and ampicillin, due to their structure ($-NH_2$ at the R ring), are stable even in very acidic conditions.[41]

After internal calibration, specific criteria thresholds were set to screen the chromatograms for identified compounds and optimized to prevent false-negative results, but also with an acceptable percentage of false-positive results. Initially, retention time tolerance threshold was set at 0.15 min, which is lower than 2.5% RT deviation tolerance for all of the compounds eluting after 6 min. As can be seen in Table S1 only 5 of 143 compounds elute in a RT< 6 min (amoxicillin, melamine, metformin, sulfaguanidine, and piperazine). Thus, the EU requirements that set <2.5% RT deviation tolerance are practically fulfilled. All dRT are presented in Table 1.

The mass accuracy of the precursor ion, as well as of the qualifiers, should be <2 mDa compared to standard solutions for the compound to be considered as positively detected and identified. This threshold is quite strict, but it contributes significantly to reduce the number of false-positive results. Average mass accuracy values obtained in fortified milk and fish samples in both concentration levels examined are presented in Table 1. Ion intensity ratios (IIRs) were also calculated for all samples, and the average values in each matrix and each spike concentration level are presented in Table 1. However, the compliance of IIRs was not used as a criterion for identification.[36]

The isotopic fit is an additional criterion for the identification of a compound.[23] The isotope pattern matching algorithm (SigmaFit) is a feature of Bruker Daltonics software. Smaller values show better isotopic fit; however, in less abundant peaks, the mSigma values are relatively high, and thus no filtering is carried out for this parameter. Moreover, thresholds for the area and the intensity of the chromatographic peak are set, according to validated experiments, at levels of 2000 and 500, respectively. These thresholds were set, as a compromise of false-positive and false-negative results, bearing in mind the total number of features of a full scan chromatogram. These optimization results will be presented in detail in a future study from our group.

Sample Preparation Optimization. Finding suitable extraction conditions for a large range of target analytes displaying different chemical properties (lipophilicity, hydrophilicity, alkaline and acidic characteristics, etc.), along with keeping the procedure as short and simple as possible is a great challenge. Having a look at the literature in the field of veterinary drug residue analysis, it becomes apparent that acetonitrile extraction is the most common extraction route used for many veterinary drugs including antibiotics, anthelmintics, and coccidiostats.[9,11,14,42] Acidic extraction with trichloroacetic acid was found to be suitable for quinolones, lincomycin, and tetracyclines.[10,43,44]

Two different sample preparation procedures were followed in this study for the simultaneous extraction of 143 veterinary drugs and pharmaceuticals from fish and milk samples. The first method involves a simple generic solid−liquid extraction step of the analytes from fish tissue. The extraction is performed with 0.1% formic acid in an aqueous solution of EDTA 0.1% (w/v −ACN−MeOH (1:1:1, v/v), and additional ultrasonic-assisted extraction ensures the effective release of the analytes from the matrix. Precipitation of lipids and proteins was promoted by subjecting the extracts at very low temperature (−23 °C) for 12 h, and further cleanup with hexane ensures fat removal from the matrix. This method was developed, optimized, and validated in a previous study by our group and proved to be suitable for the efficacious extraction of veterinary drugs and pharmaceuticals from fish tissue. The second protocol consists of a generic extraction of the analytes from milk samples with a combination of ACN/5% aqueous

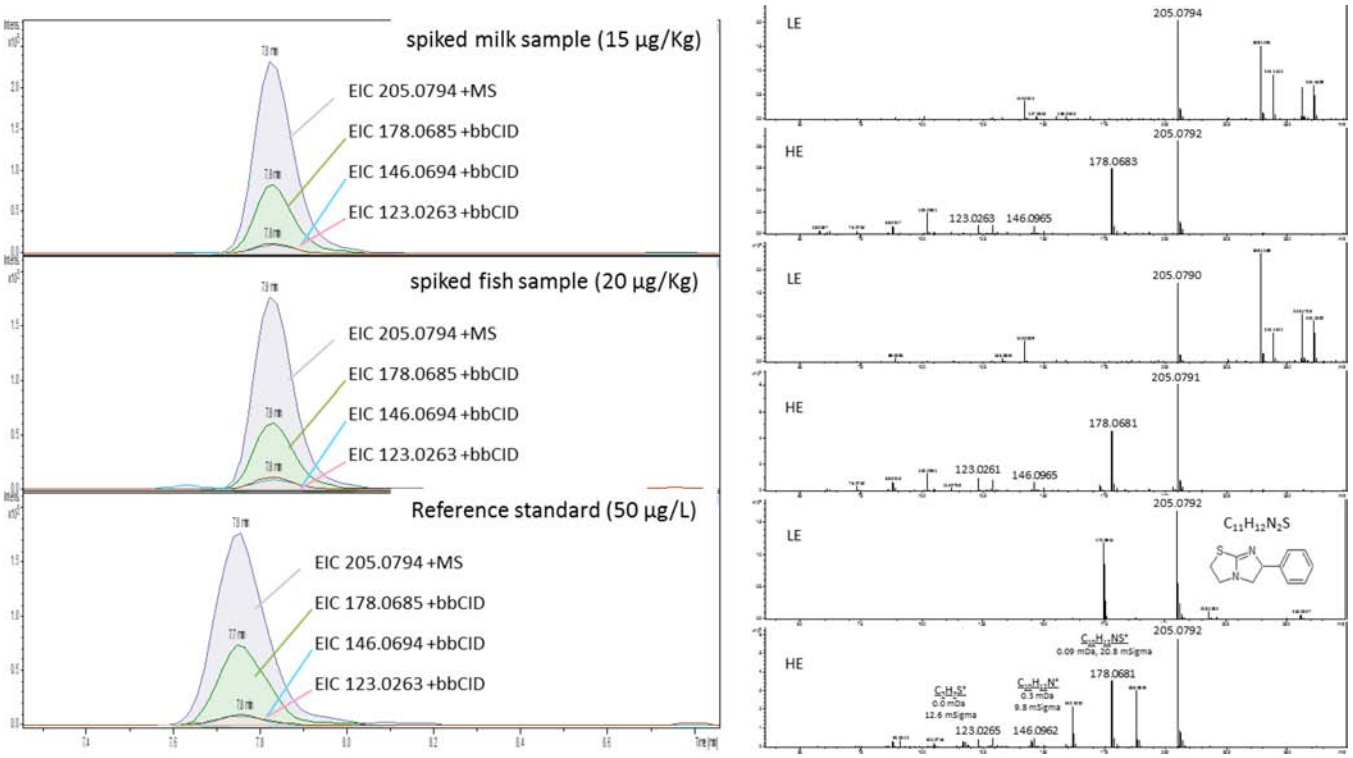

Figure 1. nw-XICs of levamisole corresponding to the protonated molecule at LE and to its fragment ions at HE for 50 ng mL^{-1} reference standard, 15 ng mL^{-1} spiked milk sample, and 20 ng g^{-1} spiked fish sample.

TCA solution 5% (1:3, v/v). Further cleanup with SPE (Oasis HLB cartridges) was performed to remove interfering proteins and provide clean and stable extracts. Extraction with ACN−TCA is a well-established sample preparation approach for food samples.[9,43] Because the screening method is intended to be used only as a qualitative method, there were no requirements with regard to recovery of the analytes.

The development of a generic SPE procedure can present some difficulties. If carefully designed, reversed phase SPE can recover most analytes from polar extraction solutions but may lead to losses of some (very polar) analytes.[4,21,23] Mixed-mode materials exhibiting both hydrophobic and ion-exchange properties have become a valuable alternative. One of the most widely used sorbents is a copolymer of divinylbenzene and vinylpyrrolidone, which has been commercialized under the trade name Oasis HLB by Waters. It has become the prime sorbent for multiresidue methods of veterinary drugs and pharmaceuticals due to its broad applicability spectra.[4,19,21,23,34]

The primary extracts had to be diluted in water to decrease the percent content of ACN (<10%) in the sample that will be loaded in the SPE. This is a practice that many researchers employ to avoid breakthrough of analytes during the SPE step due to a moderate amount of ACN in the extracting solution.[19,23,44] Proper adjustment of sample pH is necessary to avoid deprotonation of acidic compounds and protonation of basic compounds as well as to enhance extraction efficiency.[4] As analytes belong to different classes with different pK_a values, it is extremely difficult to establish a SPE protocol that is efficient for all of the target compounds. The extract pH was adjusted to 5.5 with ammonium hydroxide solution, according to the method of Kaufmann et al.,[25] who clearly state that this value constitutes a compromise and might not be the optimum for some very acidic and strongly basic analytes. Neutral pH values of the extract loaded in the SPE have been reported in cases when the extraction was held with water,[19,23] whereas a pH value of 4 was selected by Bohm et al.,[45] who used McIlvaine buffer as the extraction solvent.

Finally, the effectiveness of MeOH and ACN as elution solvents was evaluated. Elution with MeOH achieved higher responses of β-lactams and tetracyclines from the milk samples, because MeOH is a more polar solvent than ACN. On the contrary, less polar compounds, like some macrolides (tiamulin, tylosin) and some ionophore coccidiostats (semduramycin, narasin), presented better results when the elution was performed with ACN. However, MeOH was deemed to be the most suitable elution solvent because it revealed satisfactory results for the majority of the target analytes.

Qualitative Validation. The aim of a qualitative validation is to verify the presence of an analyte in a sample at a certain concentration level. As no quantitation is necessary, method recovery, accuracy, and precision were not examined.[36] Two different milk matrices (ovine and bovine milk) and two

DOI: 10.1021/acs.jafc.5b00962
J. Agric. Food Chem. 2015, 63, 4493−4508

different fish matrices (sea bream and sea bass) were tested at method validation at two concentration levels, 20 and 200 ng g^{-1} for fish samples and 15 and 150 ng mL^{-1} for milk samples. To consider the method fully validated for a given compound, the compound should be detected and identified according to the established criteria in all of the samples tested at a certain concentration level (6 of 6 for each matrix). Table 2 summarizes the SDLs and LOIs obtained for each analyte in milk and fish samples.

More compounds could be detected and identified in milk samples as compared to fish, although milk samples were prepared at lower concentration levels. This could be due to the higher preconcentration achieved with the sample preparation protocol used for milk, which succeeds in an increase in sensitivity. The more effective cleanup of milk samples, using SPE, could also lead to reduced matrix effects and enhanced sensitivity.

The majority of the compounds in both milk and fish samples were detected at the lowest concentration level (78% in milk samples and 60% in fish samples). What is of great significance is that, practically, the same number of compounds was also identified at this level: 74% in milk samples and 60% in fish samples, indicating the wide effectiveness and applicability of the proposed methodology. In relation to MRLs, as can be seen in Table 2, several of the target compounds are regulated in milk and fish tissue. On average, the method can be considered suitable for screening veterinary drug residues in milk and fish samples because both the SDLs and LOIs were below the established MRLs in most of the cases. More than 85% of the target analytes are identified in concentration lower than their MRLs in both matrices. Oxytetracycline, oxacillin, and tolfenamic acid could only be detected at regulatory levels in milk samples. For some compounds, the lowest concentrations tested were above their established MRLs, mainly in milk samples. However, according to our results, for some of these compounds, such as penicillin G, fenbendazole, oxfendazole, monensin, and clembuterol in milk samples and lasalocid in fish samples, their detection at the MRL levels would be quite probable considering their signal observed at the lowest concentration level examined.

Overall, for milk samples, the reliable identification using two accurate-mass ions was feasible for 74% of compounds at 15 ng mL^{-1} and for 87% at 150 ng mL^{-1}. For the remaining 13% of the compounds, LOIs could not be calculated with this method due to unsatisfactory fragmentation or insufficient sensitivity of fragment ions. Only 8% of the compounds could not be detected at 150 ng mL^{-1}. For fish samples, as mentioned above, 60% of the compounds were detected and identified at 20 ng g^{-1}. SDLs for the 29% of the compounds and LOIs for the 24% were calculated at 200 ng g^{-1}, whereas 11% of the compounds could not be detected and 16% could not be identified at the concentrations examined. The identification of the anthelmintic levamisole in a spiked milk sample (15 ng mL^{-1}) and in a spiked fish sample (20 ng g^{-1}) is shown in Figure 1.

Two compounds (tolfenamic acid and febantel) presented poor or no fragmentation as a result of the collision energy value applied, which was the result of a compromise for all compounds. For these compounds no fragments could be obtained and, therefore, the screening method was limited for detection, because no identification could be performed. Cefaclor, amoxicillin, and clarithromycin were not detected or identified in any of the spiked milk samples, whereas in fish, cefapirin, cefazolin, and febantel could be neither detected nor identified at the levels tested. This could be due to ineffective ionization of the compounds in the selected conditions, especially for cephalosporins. Another reason is that these compounds might not be stable under the extraction conditions assayed and that they are metabolized.[29,46] Matrix effects could also highly affect the determination.

Application to Milk and Fish Samples. To evaluate the applicability of the proposed method in routine analysis, five milk samples (four bovine and one ovine) and five fish samples (three sea bream and two sea bass) were tested. No positive results were found in any of these samples. The results reported by QTOF MS were confirmed by LC-MS/MS analysis in MRM mode, monitoring two transitions per compound, revealing the absence of any of the target analytes in the samples examined. The absence of false-positive results, even in this quite limited set of samples, is indicative of the adequate selectivity of the proposed methodology.

In conclusion, the qualitative validation of a wide-scope screening method including 143 veterinary drugs and pharmaceuticals has been carried out in two types of milk and two types of fish samples. Using this method, data including retention times, as well as accurate mass measurements for precursor and product ions, have been collected for all analytes. Detection, based mainly on the presence of the protonated molecule, as well as identification using a second accurate-mass fragment ion, was feasible in many cases at the lowest level tested (20 ng g^{-1} for fish samples and 15 ng mL^{-1} for milk samples). Finally, the applicability of the method was examined, and no false-positive results were revealed in a limited number of blank samples.

esters, and fatty acid ethyl esters by capillary gas chromatography.[6] This wide range of possible standard methods is sometimes perceived as a disadvantage by newcomers to the olive oil sector instead of an advantage when selecting a method for their own needs. As there are several standard methods to solve the same problem (i.e., to detect the same adulterant or to identify and quantify the same chemical compounds), the analysts often have difficulties establishing which standard method is the most suitable for their purposes. The extensive collection of standard methods is partially due to the fact that the regulatory bodies add the new methods to the list of the standard methods, keeping the previous ones. This additive—instead of substitutive—policy seems to imply that not all of the standard methods satisfy completely the requested expectations. Consequently, a considerable investment in optimizing current methods and developing new ones is important to keep pace with changing technologies and sophisticated adulterations. These new methods should be easy to implement and robust, have an adequate precision, be amenable to being validated, and be capable of detecting any fraud and malpractices in olive oil production.

In addition to the difficulties of analysts in choosing the most adequate standard method, they may have problems in applying the methods due to lack of experience. For example, they may have problems in the identification of the chemical compounds, due to possible shifts in the retention time, small changes in column composition, temperature program, or low resolution of peaks. Thus, in the particular case of analysts that work with olive oil for the first time, they often need to discuss their results with other analysts, expert in the field, to identify any problem and to confirm that they are working properly.

Not only is the expertise of the analyst a critical issue but there are also other factors such as the quality of equipment, reagents, environment (e.g., temperature, humidity, air pollution), among others, that can make the results difficult to reproduce. Validated analytical methods are thus essential for the quality performance of analytical laboratories. Today, analysts must be aware of the important role of quality assurance of their laboratories. The results of the laboratories are directly related to the use of validated and accredited methods. With regard to laboratory accreditation, the complexity of the standard methods is again a problem. A better justification for the existing methods through a detailed description of their application and the avoidance of any overlap between them is desirable to facilitate the accreditation of laboratories.

Understanding all of the drawbacks associated with the considerable complexity of standard methods, the olive oil sector is demanding the development of a rapid and universal method that can be used for all of the determinations required to confirm olive oil authenticity and/or quality. Despite the difficulties implementing the current standard methods, certain improvements have been achieved. For example, the compilation of information about the validation of the standard

methods[7] has allowed a better monitoring of the reproducibility and robustness of the methods. Additionally, the optimization of some standard methods has been carried out by improving columns, using different solvents, changing chromatographic conditions, and reducing the pretreatment of samples.

The improvement of the standard methods requires time, and the alternative to the current situation could be the design of a global procedure that allows the detection of different adulterations. Thus, the strategy of some current research studies is to combine standard methods and emerging technologies—including fingerprinting approaches—into a single comprehensive analytical strategy. The analytical techniques that have been suggested to achieve this aim are spectroscopic techniques—near-infrared (NIR) spectroscopy,[8] Fourier transform mid-infrared spectroscopy (FTIR),[9] FT-Raman spectroscopy,[10] fluorescence spectroscopy[11] nuclear magnetic resonance (NMR) spectroscopy[13]—spectrometric techniques—isotope ratio mass spectrometry[12]—and "omic" techniques.[14] In these areas, the fraudsters do not have much information on how to avoid being detected, but analysts may have problems in interpreting the information with plausible chemical explanations. These techniques can be helpful if they are combined with multivariate statistical techniques. Even then, the conclusions obtained from the analysis ideally should be supported by chemical or biochemical explanations. These new techniques, which provide a wide range of information about different chemical compounds in only one analysis, need to be validated with blind samples prior to being proposed as standards.

In this paper the standard methods have been analyzed from a point of view of the analysts and the potential problems that they may have when applying them. The practical aspects and the possible alternatives (nonstandard methods) for each determination have been discussed as well. A critical review of the chemical compounds analyzed by these methods and the concentration range of these compounds in olive oil is presented, together with the utility of these determinations in the characterization and authentication of olive oil.

METHODS FOR THE CONTROL OF OLIVE OIL PURITY AND AUTHENTICITY

The chemical compounds used for determining olive oil authenticity are numerous, and to explain their analytical methods, the compounds have been clustered into the sets of major and minor compounds. The group of major compounds is primarily made up of triacylglycerols (TAGs) or glycerol esters of fatty acids (FAs); fatty acids account for 94−95% of the total weight of TAGs. Table 2 shows some examples of applications of these major and minor compounds in detecting adulterations.

The broad and heterogeneous set of minor compounds includes several series of chemical compounds with a lipid structure (e.g., waxes), compounds that are not related to lipids from a chemical structure viewpoint (e.g., pigments, volatiles), and compounds that have the common characteristic of being obtained from unsaponifiable matter. The compounds that are present in unsaponifiable matter, which rarely represent >2% by weight of total olive oil, are regarded as the olive oil fingerprint. Thus, this fingerprint is very useful in authentication and geographical identification of olive oil, among other applications.

Olive Oil Major Compounds. *Fatty Acid Methyl Esters and Trans Fatty Acids.* Fatty acids (FAs) are the main components of olive oil. They are not generally present, however, as free fatty acids; when they are, they occur only in small amounts. Fatty acids are usually forming part of glycerides (mono-, di-, and triacylglycerols) and phospholipids through ester bonds. FAs present in olive oil are linear chains of 16−24 carbon atoms. FAs, which were some of the very early compounds to be analyzed by gas chromatography (GC), were of maximum importance in the detection of adulterants until the end of the 1960s. At that time seed oils with a modified fatty acid composition similar to that of olive oil appeared. The analytical performance, however, was improved and made the method suitable to determine *trans* isomers of fatty acids (TFAs) because TFAs appears as a result of certain manipulations, for instance, isomerization reactions that occur during the heating processes of olive oil.[15] The interest in determining the TFAs is explained by the fact that their determination allows the detection of refining oils in VOO.

Table 3. Most Common Methods for Quantifying Fatty Acids and Derived Acyl Lipids

compound	technique	sample pretreatment	reference	method details
fatty acids; *trans* fatty acids	GC-FID[a]	purification with silica gel extraction cartridge; cold methylation with KOH	COI/T.20/Doc No. 17.[113]	column: capillary 50−100 m × 0.25−0.32 mm ×0.1−0.3 μm stationary phase: cross-linked cyanopropylsilicone carrier gas: hydrogen or helium temperature program: 165 °C (15 min) to 200 °C at 5 °C/min injection mode: split
triacyglycerols	HPLC-RI[b]	0.12 g of oil in 0.5 mL of hexane is charged into column (SPE[c] cartridge: 1 g of Si) and solution pulled through then, eluted with 10 mL of hexane/diethyl ether (87:13 v/v); the purified oil is dissolved in acetone at 5%	COI/T.20/Doc No. 20.[16]	oven temperature: 25 °C mobile phase: acetone/acetonitrile (1:1 v/v) or propionitrile (flow rate = 0.6−1.0 mL/min) column: RP-18 (25 cm × 4 mm i.d.) (5 μm) with 22−23% carbon in the form of octadecylsilane detector: RI
	HPLC-RI	purification by SPE (IUPAC method 2507);[29] the purified oil is dissolved in acetone at (5%)	COI/T.20/Doc No. 25.[17]	oven temperature: 20 °C mobile phase: propionitrile (flow rate = 0.6 mL/min) column: RP-18 (25 cm × 4.5 mm i.d.) (4 μm) detector: RI
triacylglycerols; diacylglycerols	GC-FID	requires silylation; gives information clustered into their carbon numbers	COI/T.20/Doc No. 32.[39]	capillary column: 3−7 m × 0.25−0.32 mm ×0.10−0.15 μm; C58 and C60 loss by thermal degradation can be avoided by short column, 5 m should be enough phase: SE52, SE54 (5% diphenyl-dimethyl polyxilosane) carrier gas: hydrogen or helium temperature program: 80 °C, 1 min; to 220 °C at 20 °C/min to 340 °C, 10 min, at 5 °C/min injection mode: on-column
2-glyceryl monopalmitate (%)	GC-FID	GLC or SPE separation after hydrolytic reaction with pancreatic lipase; silylation should be applied	COI/T.20/Doc No. 23.[26]	capillary column: 12 m × 0.32 mm ×0.10−0.30 μm phase: methylpolisiloxane or 5% phenyl-methyl-polysiloxane carrier gas: hydrogen or helium temperature program: e.g., 60 °C, 1 min to 180 °C at 15 °C/min, to 340 °C, 13 min, at 5 °C/min injection mode: on-column
waxes	GC-FID	fractionation by LC on hydrated silica gel column (15 g of silica)	COI/T.20/Doc No. 18.[5]	capillary column: 8−15 m × 0.25−0.32 mm × 0.1 −0.3 μm phase: 5% phenyl-methyl-polysiloxane, liquid phase SE52, SE54 carrier gas: hydrogen or helium temperature program: e.g., 80 °C, 1 min, to 240 °C at 20 °C/min to 325 °C, 6 min, at 5 °C/min to 340 °C, 10 min, at 20 °C/min injection mode: on-column

Furthermore, GC analysis of FAs is also carried out as a tool for the calculation of the theoretical composition of TAGs with the final objective of determining the value of the theoretical ECN42 (equivalent carbon number)[16] and for the detection of the presence of hazelnut oil by means of the global method.[17]

The first step of FA analysis is derivatization by forming methyl esters (FAMEs), because they are more volatile and nonpolar than free fatty acids, and this makes them easier to elute through chromatographic columns. Among the methods for preparing FAMEs[18] the transesterification with methanolic solution of potassium hydroxide at room temperature[19,20] is the most commonly used. However, another method is suggested for VOOs with acidity >3.3% and crude olive pomace, which is based on the esterification and transesterification with sodium methylate in methanol in acid conditions at high temperature.[18] Perhaps the first method can be also suggested for the determination of *trans* fatty acid and the determination of ECN42 if samples are always first purified through a silica gel solid-phase extraction cartridge, and the sample spiked with hexane—olive oil/hexane (1:4); for example, 0.15 g of olive oil in 0.6 mL of hexane—is pulled down with hexane/diethyl ether (87:13) as in other standards.[18]

GC analysis can be undertaken with chromatographic columns with diverse characteristics. For instance, phases with the highest polarity allow excellent separations of polyunsaturated FAs. Phases with lower polarity are used for the separation of saturated and monoenoic compounds with the same chain length, although it may produce peaks that interfere in the determination of *trans* isomers of linolenic acid. An HP-88 capillary column, coated with 88% cyanopropyl aryl siloxane (100 m × 0.2 mm i.d. × 0.2 μm film thickness), or a Varian Chrompack CP-Sil 88 column, coated with cyanopropyl polysiloxane (100 m × 0.25 mm i.d. × 0.2 μm film thickness), can provide an accurate quantification of TFAs previously derivatized as methylesters. These columns are too long for FAs and can be substituted by others of 50 m × 0.20−0.32 mm i.d. 0.1 × 0.2 μm film thickness with a cross-linked stationary phase of cyanopropylsiloxane allowing also the *trans* fatty acid determination (Table 3). However, columns shorter than 50 m allow determining FAs but with loss of *trans* fatty acids.

The stationary phase polymerizes in aged columns, and the variation of retention times for the esters of FAs is observed. Better peak resolution is obtained if the carrier gas is hydrogen instead of helium. Furthermore, no silver ion prefractionation of TFA (by TLC, SPE, or HPLC) is required prior to the GC analysis.[21]

The use of WCOT columns of fused silica introduced remarkable improvements in separations with higher resolution, higher precision in analysis in both quality and quantity, higher sensitivity, a shorter analysis time, reduction in the preparation of analysis procedures, etc. Most phases are now chemically bonded to tube walls, which decreases loss in the column and, in turn, increases duration and temperature resistance and improves the resolution.

The determination of *trans* fatty acids can present a problem of overestimation. Small quantities of *trans* oleic acid could be formed when the sample is introduced into the gas chromatographic injector. This problem is more pronounced when automatic samplers with packing materials are used. To minimize this problem, it is necessary to replace the injector insert by a clean insert, deactivate the inset, lower the injector temperature from 250 to 30−50 °C, or remove the packing materials if the injection is manual.

Alternative methods based on spectroscopic techniques have been developed to analyze FAs and *trans* fatty acids, although they cannot determine individual FAs and TFAs as the GC method does. Thus, ^{1}H NMR methodology shows a good performance for FA quantification despite the fact that results for individual saturated compounds often deviate from GC results because of the sensitivity of ^{1}H NMR (400 MHz) integration; total amounts of saturates are, however, accurately determined.[22] Quantification of the sum of saturated fatty acids (SFAs), the monounsaturated oleic acid (MUFA), and the polyunsaturated linoleic and linolenic acids (PUFAs) can be obtained by means of mathematical equations using appropriate signal intensities as variables.[22] Additionally, linolenic acid can be quantified from the signal of the methyl protons of the linolenyl chain at δ 0.96.

TFAs can also be determined by IR spectroscopy, which is a rapid tool for detecting isomers.[23] The intensities of Raman spectroscopy bands near 1656 and 1670 cm^{-1} have also been related to the content of *cis* and *trans* isomers.[24]

Triacyglycerols (TAGs). TAGs consist of a glycerol moiety with each hydroxyl group esterified to a fatty acid. Each individual TAG species has three characteristics: (i) the total carbon number (CN), which is the sum of the alkyl chain lengths of each of the three FAs; (ii) the degree of unsaturation in each FA; and (iii) the position and configuration of the double bonds in each FA.[25] Twenty TAGs have been identified and independently quantified in olive oil, but only five are present in significant proportions.[18]

One of the main aims of TAG analysis is identifying TAGs that are biosynthesized and those that are synthesized by means of FFA esterification with glycerol. The analytical approach is based on the use of pancreatic lipase, an enzyme that has the ability to hydrolyze the 1- and 3-positions of natural TAGs, thereby producing 2-monoacylglycerols. The initial determination of palmitic and stearic acids at the 2-position has been currently substituted by determination of the content of 2-glyceryl monopalmitate.[26,27]

Thus, the possible combinations of FA molecules and their positions on the glycerol backbone of TAGs make the analysis of the TAG composition a very challenging task with either gas−liquid chromatography (GLC) or reversed phase liquid chromatography (RP-HPLC). Table 3 summarizes the RP-HPLC conditions (column dimension, stationary and mobile phases, kind of detector, and flow rate) and GLC conditions (columns, detectors, and chromatographic conditions) used for the determination of olive oil TAG profiles.

TAG separation is based on the number of carbon atoms and their unsaturation when RP-HPLC is used because of the good resolution of the RP-18 column. In the case of the presence of oxidized compounds, which interfere in the trilinolein (LLL) determination, samples should be purified by means of silica gel. Thus, in the case of olive pomace oil, the EC recommends using the SEP-PAK silica cartridge (Waters).[28] The IOC recommends making the purification by SPE according to IUPAC 2.507.[29]

This procedure, however, implies checking FA compositions in the oil after its purification in a long and tedious process during which mistakes can occur. This test is recommended by the EC in the case of the olive pomace oil and the IOC recommends this test in the determination of the 2-glyceryl monopalmitate.[26]

The purified oil is resolved in acetone, but sometimes the impurities of acetone can produce disturbances in the baseline

DOI: 10.1021/jf5062265
J. Agric. Food Chem. 2015, 63, 4509−4526

of the chromatogram (region 12−15 min); if this happens, a good solution is using another source of acetone or a mixture of propionitrile/acetone (25:75 v/v).

The RP-18 column resolution depends on the particle diameter. Experience shows that columns with 3 μm have no loss of resolution while saving time and solvents. Another empirical aspect concerns samples of raw olive pomace oils, which should be resolved in acetone and then filtered, with 0.2 μm pore size, to remove precipitates that would shorten the column life.

With regard to the mobile phase, critical peaks are effectively separated with acetone/acetonitrile in isocratic elution, although with this phase, saturated long-chain TAGs are not sufficiently resolved. As a consequence, some researchers[30,31] carried out experiments on isocratic elution with propionitrile as previously investigated.[32] Although propionitrile (HPLC grade) is expensive and highly toxic, it reduces dramatically the baseline drift when compared with the methods based on an acetone/acetonitrile mixture. The result is a better separation of TAGs clustered as ECN42, and it is used for the detection of the admixture of hazelnut oil to olive oil.[33]

The refractive index (RI) is the most appropriate detector, despite its drawbacks of low sensitivity and different responses toward saturated and highly unsaturated TAGs and the numerous external variables that affect baseline stability.[34] In comparison to other detectors, the UV detector, which has not been very widely used because it presents problems with isomerization and conjugation of double bonds, has good sensitivity and allows the use of elution gradients that improve the resolution.

The alternative of using GLC (Table 3) is scarcely applied today despite the fact that it also offers attractive possibilities as an efficient separation method, good quantitative recovery and reproducibility, an adequate time for analysis, and the availability of a flame ionization detector (FID), a simple but universal linear response detector. However, the GLC technique is not free of problems such as, for example, the injection system and the column deterioration. Selectivity in GLC depends on the length and chemical nature of the column stationary phase. For example, columns with phenyl-methyl-silicone phase are capable of reaching temperatures of about 360−370 °C for a long time and of separating TAGs by carbon atom number; unsaturated positional isomers cannot be separated by this phase unless sample derivatization followed by a reduction had previously been done.[18]

Another alternative is the analysis by HPLC-MS because MS can identify partially resolved HPLC peaks,[35] giving much more information on the position of the three fatty acid molecules at TAGs. Although few ionization techniques can be coupled to HPLC, the identification of positional isomers[36] can be carried out by atmospheric pressure chemical ionization (APCI) coupled to HPLC, whereas the identification of individual acyls can be done without electrospray ionization (ESI) without reference materials. A rapid and simple sample preparation—no analyte purification, chemical modification, or derivatization is required[37]—has increased the interest in applying matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS), LDI-TOF-MS being proposed for detecting the presence of sunflower oils in olive oil.[38]

Olive Oil Minor Compounds. As already mentioned, the set of minor components, which are used for the determination of purity and authenticity of olive oil designations, consists of compounds that derive from TAGs and other liposoluble compounds and the compounds that derive from the unsaponifiable matter.

Diacylglycerols (DAGs) and Monoacylglycerols. DAGs, which are present in a range of 1−3% in olive oils, are found as 1,2- and 1,3-isomers, 1,2-isomers being attributed to the incomplete biosynthesis of TAGs (Kennedy pathway), whereas 1,3-isomers are attributed to enzymatic or chemical hydrolysis of TAGs.

The official method[39] allows the determination of DAGs and TAGs together. TAGs are clustered on the basis of their carbon atom number, whereas in the case of DAGs the peaks are resolved according to their carbon atom number and their structure, the 1,2-isomers having lower retention time than 1,3-isomers. The method does not require particular experience of the analyst. Thus, 1 mL of the internal standard (dinonadecanoine 0.1% w/v in methyl *tert*-butyl ether) is added to a sample of 100 mg. Later, a dried aliquot of 20−30 μL is silylated with 200 μL of the silylation reagent, consisting of a 9:3:1 (v/v/v) mixture of anhydre pyridine/hexamethyl disilazane/trimethylchlorosilane. After a complete silylation, 2 mL of *n*-heptane is added, and 0.5−1.0 μL is injected into a GC instrument equipped with a capillary column of 3−7 m length × 0.25−0.32 mm i.d. (coated with SE52 or SE54 stationary phase). Experience has taught that it is advisible to purify the sample by column chromatography or SPE prior to addition of the internal standard that could also be 1,3-dipalmitoyl *rac*-glycerol. The silylation process can be critical. The solution of silylation reagent should be freshly made. It is not easy to detect the end of the reaction; it takes about 20 min. If a slight opalescence is observed after the silylation, it does not mean any anomaly. However, the formation of a white floc or the appearance of a pink color is indicative of the presence of moisture. A rapid warming applied to the bottom of the conical flask to the GC detector can eliminate the moisture. If the floc is not eliminated, the silylation reagent is deteriorated and the test must be repeated.

The method for the determination of the percentage of 2-glyceryl monopalmitate (Table 3) has some drawbacks such as the fact that it is a lengthy and tedious method (e.g., when sample acidity is >3%, it has to be previously neutralized). The neutralization of the oil is necessary because the activity of the pancreatic lipase depends on the pH, which should be adjusted to 8.3. Furthermore, the separation between phases after lipase pancreatic digestion is not automatic; it should be taken into account that lipase pancreatic is not stable and may lose activity easily. The thick interface between phases (diethyl ether and aqueous phase), after the centrifugation step, makes it difficult to collect an aliquot of the organic phase for preparing the silanized derivatives. Moreover, on-column injection shows well-known problems such as a large broad solvent front, low repeatability, and tailing peaks.

Waxes. The waxes, which are usually referred to wax esters because they are fatty acids esterified to long-chain alcohols,[20] contain even numbers of carbon atoms from C36 to C46 in olive oil. Because waxes are in the epidermal cells of olives,[40] their concentration characterizes olive oil pomace categories.

The official method for determining waxes[5] uses lauryl arachidate in hexane as internal standard and on-column GC injection. The standard method also suggests using palmityl palmitate or myristyl stearate as internal standards. Aragón et al.[41] propose to use these internal standards in heptane to avoid the impurities that can be present in some commercial hexane and to increase the time of its evaporation. With regard to

sample purification, SPE cartridges have replaced silica gel columns because the former requires smaller amounts of sample that reduce the elution solvent volume. SPE cartridges, however, need much more attention from the analyst. On the basis of this change, new methods have been proposed as alternatives to the standard method.[42] They are more rapid with lower consumption of organic solvents and no difference concerning the recovery factors. However, there is not much information about the precision and limits of quantification yet. With respect to the chromatographic column, the standard method suggests using semipolar columns with phenyl-methyl-silicone because this allows for a high resolution but is resistant at high temperatures. Columns, however, should be conditioned, prior to being used, with a gradual heat until a temperature of 350 °C is reached. It is important to note that in the last standard method[43] the sum of the contents of waxes is computed from C42 to C46, excluding C40, unlike previous norms.[5,6]

Unsaponifiable Fraction. As mentioned earlier, the unsaponifiable matter fails to react with sodium hydroxide and potassium hydroxide to produce soaps but remains soluble in classic solvents (e.g., hexane, petroleum ether, diethyl ether) after saponification. Thus, any method for determining unsaponifiable matter involves olive oil saponification and unsaponifiable matter separation by means of extraction with an appropriate solvent, such as diethyl or petroleum ether. Although the determination of unsaponifiable matter seems simple, this type of analysis still presents problems because of the lack of accuracy and precision in the results. Some difficulties are the impossibility of extracting all of the unsaponifiable matter and the formation of emulsions due to a too vigorous shaking. These emulsions can be destroyed by adding small quantities of ethanol. Other problems are soap hydrolysis, loss of unsaponifiable matter during solvent drying, evaporation, and incomplete saponification.

Although diethyl ether is the preferred solvent, it has a number of limitations. For example, if soaps pass into the solvent together with the unsaponifiable matter, it is wise to separate the soaps by washing the ether extract with an aqueous solution of sodium hydroxide, which can provoke soap hydrolysis and liberate acids. After solvent evaporation at a low temperature and reduced pressure, it is necessary to dry the unsaponifiable residue to ensure the elimination of any traces of solvent and water. A drying process should be carried out to avoid possible volatile compounds being present in the unsaponifiable fraction. Water elimination is usually performed by treating the unsaponifiable extract with water-free sodium sulfate followed by filtration. Finally, any remaining moisture traces are eliminated by vacuum drying with acetone or benzene. Sometimes incomplete saponification may occur,[44] in which case, error can be introduced due to the saponifiable portion of TAGs soluble in ether and hexane. When incomplete saponification is thought to have happened, the unsaponifiable residue containing the nonsaponified segment has to be saponified and extracted again following the same procedure.

Fractionation of the unsaponifiable components into several groups of constituents (e.g., hydrocarbons, tocopherols, and sterols) can be carried out by several procedures, most of them being chromatographic such as column chromatography and thin layer chromatography (TLC) with two different supports, alumina and silica gel (Table 4). The latter, which has traditionally been the method chosen for the complete fractionation of the unsaponifiable matter, can be applied to unsaponifiables extracted from petroleum ether and containing FFAs. In this case, first the silica gel must be treated with diluted potassium hydroxide to retain the FFAs and avoid interference with the other fractions. In the separation by TLC, the temperature is an important factor to have a good separation; the optimum temperature is 20−25 °C.

Currently HPLC has been described to carry out the fractionation of the unsaponifiable components, as described in the section focused on Sterols.

Hydrocarbons. The hydrocarbons, which are present in olive oils, include from high amounts of squalene ($C_{30}H_{50}$), an unsaturated linear triterpenic polymer of isoprene, to small quantities of saturated, linear (from C-15 to C-35), branching and terpenic compounds. Steroidal hydrocarbons (sterenes or steradienes) with two double bonds in the ring system are present in refined olive oils (ROOs), whereas small quantities of polycyclic aromatic hydrocarbons (PAHs) have been quantified in olive pomace oils.

The need to detect the presence of refined edible oils in VOOs resulted in a standard,[45] Lanzón[46] being the pioneer in suggesting stigmasta-3,5-diene (derived from β-sitosterol) as a marker for detecting admixtures of VOOs with refined vegetable oils. The method is based on the isolation of unsaponifiable matter, separation of steroidal hydrocarbon fraction with a 15 g silica gel chromatography column, and analysis by on-column GC with a column of 25 m coated with 5% phenyl-methyl silicone phase, as first proposed by Lanzón.[46] The separation by silica gel chromatographic can result in chromatograms with interfering peaks because the silica has low acidity. If this occurs, the silica gel should be treated by heating for a minimum of 4 h at 550 °C, or extra pure silica gel 60 (Merck, ref 7754) could be used.

Technological advancements have allowed for the preparation of fraudulent mixtures of desterolized vegetable oils in refined olive oil. In 2001 the IOC published the method to determine sterenes (campestadienes and stigmastadienes)[47] to detect desterolized seed oils in refined oils. This determination is based on the isolation of unsaponifiable matter, separation of sterene fraction with silica gel chromatographic column impregnated with silver nitrate, and analysis by capillary GC. The critical part of this determination is the optimization of the volumes used to extract each fraction (three different fractions are extracted from the silica gel column). The chromatograms obtained from each fraction can be used for identification if the volumes have been optimized correctly. Another problem with this determination is that in some cases 2,4- and 3,5-diene isomers are separated into two different peaks, which entails the computation of the sum of area to know the total concentration. In these cases the column should be changed with another that is less polar or has bigger internal diameter. This method can be applied to the quantification of stigmastadiene only if the concentration is >4 mg/kg. If the concentration of stigmastadiene is within 0.01 and 4 mg/kg, the IOC method[45] should be used. The presence of PAHs in olive pomace oils—arising from pyrolysis processes and environmental and natural sources—compelled IOC[48] to set up an analytical method with suitably sensitive, selective, and accurate analytical parameters for routine analysis to determine the PAHs concentration, expressed as benzo(*a*)pyrene on wet weight. It consists of an extraction step (e.g., saponification with alcoholic KOH and liquid−liquid partitioning) followed by one or more purification procedures (column chromatography, TLC, SPE) to end with the analytical determination by GC

DOI: 10.1021/jf5062265
J. Agric. Food Chem. 2015, 63, 4509−4526

coupled to flame ionization detection (FID) or mass spectrometry (MS), or by HPLC with spectrofluorometric detection. The last has proven to successfully separating PAHs from the other hydrocarbons (PAHs coelute with other hydrocarbons in silica TLC) with a good quantitative response.[49,50]

Sterols. The major chemical series of the olive oil unsaponifiable matter is that of sterols, which are usually grouped into 4-demethylsterols or phytosterols, 4,4-dimethylsterols or triterpenic alcohols, and 4-monomethylsterols or methylsterols; all of them have analogous chemical structures.

The fact that the concentrations of some sterols are characteristic of the genuineness of vegetable oils made them of interest for purity and authenticity control olive oil designations. Thus, for example, brassica seed oils have a high content of brassicasterol, whereas olive oils are characterized by a high concentration of Δ^5-avenasterol. These differences induced IOC to set up a method that allowed for their quantification. Results are expressed as percent of the total area of sterols, although the illegal process of removing sterols without forming fatty acid *trans* isomers[51] suggests giving the information in absolute concentration. In addition to qualitative differences in the sterol profiles of vegetable oils, some researchers[52,53] have pointed out that the pedoclimate (soil, climate, etc.) of the orchards and the cultivars affects the olive oil sterolic composition up to the point that some authentic olive oils can be qualified as nongenuine. The current proposal of decision trees[2,54] has been approved to be applied in those anomalous oils to overcome the number of wrong classifications by means of the implementation of equations that combine values of several chemical parameters.

The chromatographic methods are mostly devoted to determining the composition of 4-demethylsterols or phytosterols. Generally speaking, the determination of sterols comprises the sum of both possible forms (free and esterified) as their sterol acetates[55] as shown in Figure 1. Nevertheless, there is a method for determining the individual concentration of free and esterified sterols independently with the particular objective of detecting the presence of hazelnut oil.[56] For the determination of both forms together, the unsaponifiable material is usually purified by TLC on silica gel with hexane/diethyl ether (65:35 v/v). The experience has demonstrated that two developments must take place to obtain a satisfactory separation. The plate can be impregnated with alcoholic KOH for the purpose of retaining the FFAs in the unsaponifiable fraction. Three large bands would appear on the TLC plate. The first one contains 4,4-dimethylsterols or triterpenic alcohols, some phytols, and aliphatic alcohols. The second is composed of the remaining phytols and methyl sterols, and the third band contains sterols, erythrodiol, and uvaol. However, the individual separation of sterols is not exempt from difficulties as the amount of the unsaponifiable fraction in diethyl ether to be deposited on TLC exceeds 200 μL. An inadequate development of TLC and defective scraping on TLC of the sterol band are other habitual problems the analysts deal with.

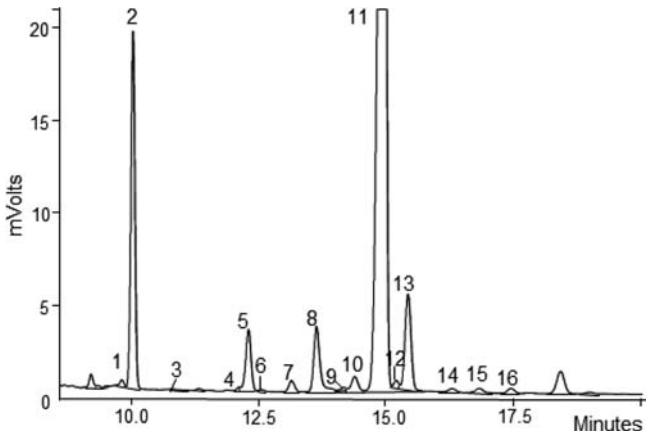

Figure 1. Chromatogram of 4-demethylsterols of a sample of virgin olive oil. Peaks: 1, cholesterol; 2, internal standard; 3, brassicasterol; 4, 24-methylenecholesterol; 5, campesterol; 6, campestanol; 7, stigmasterol; 8, Δ^7-campesterol; 9, $\Delta^{5,23}$-stigmastadienol; 10, chlerosterol; 11, β-sitosterol; 12, sitostanol; 13, Δ^5-avenasterol; 14, $\Delta^{5,24}$-stigmastadienol; 15, Δ^7-stigmastenol; 16, Δ^7-avenasterol.

4,4-Dimethylsterols or triterpenic alcohols, the first fraction, are analyzed by saponifying olive oil with KOH after the addition of an internal standard such as C-20 or C-21 and by extracting the unsaponifiable matter with diethyl ether and later purifying it on a plate. No analytical problems have been observed for their GC determination in a nonpolar column (100% dimethylpolysiloxane or a 5% phenyl−95% dimethylpolysiloxane).[57]

The methyl sterols, the second fraction, are separated on TLC with a mobile phase of cyclohexane/ethylic acetate (85:15, v/v). GC analysis of methyl sterols can be carried out under the same conditions as for 4-demethylsterols or phytosterols (EC 1991[1] and henceforth). These compounds are quantified together with triterpenic alcohols in the same chromatogram.[57]

Erythrodiol and uvaol (triterpene dialcohols) are determined by scraping their TLC band with the band of 4-demethylsterols or phytosterols,[58] the third fraction, and subsequent GC analysis. The use of capillary columns yields a significant chromatographic resolution of those diols. Results are still given in percentages, whereas absolute values (concentrations) are preferred as they would diminish substantially the current high number of false positives (genuine VOO classified as adulterated).

Analysts, however, have simplified the analysis because of the problems of using TLC. Thus, the most reliable and widely used technique is the off-line HPLC-GC coupling that comprises separation of the fractions of sterols or other unsaponifiable components (e.g., branching and terpenic hydrocarbons) by HPLC with a silica gel column, collection of the fraction, elimination of the solvent, further derivation, and injection onto GC. Figure 2 shows a typical HPLC chromatogram in which the peaks assigned to the different sterol fractions are shown.[59] Figures 3 and 4 display the correct separation and peak resolution of the compounds named 4,4-dimethylsterols and 4-monomethylsterols after application of the described HPLC-GC-based method.

Aliphatic Alcohols. Free and esterified aliphatic alcohols are a linear chain made of even and odd numbers of 20−32 carbon atoms. It is important to note that phytol (present in VOOs at low concentrations) is an artifact generated from chlorophyll decomposition by alkaline treatment during saponification. The standard method[60] begins by adding the internal standard (1-eicosanol) to 5 g of the sample prior to the saponification with ethanolic KOH and then extraction with ethyl ether. The alcoholic fraction is separated from the unsaponifiable matter by depositing it on a silica gel plate, or in a column of the same

J. Agric. Food Chem. 2015, 63, 4509−4526

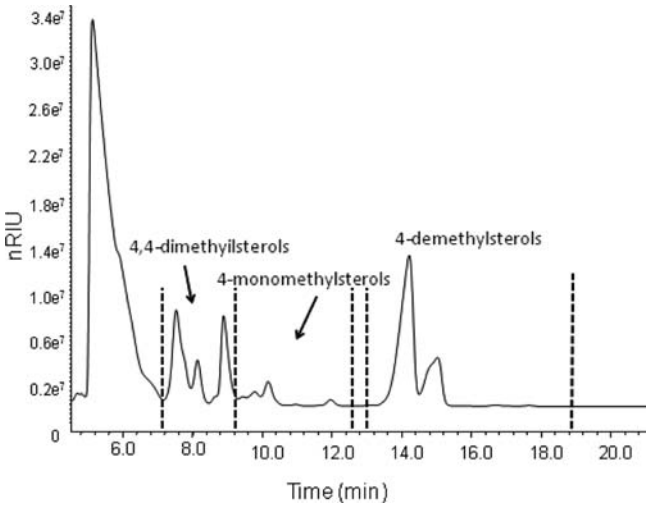

Figure 2. Sterols obtained in fractionation of the unsaponifiable matter by HPLC.[59]

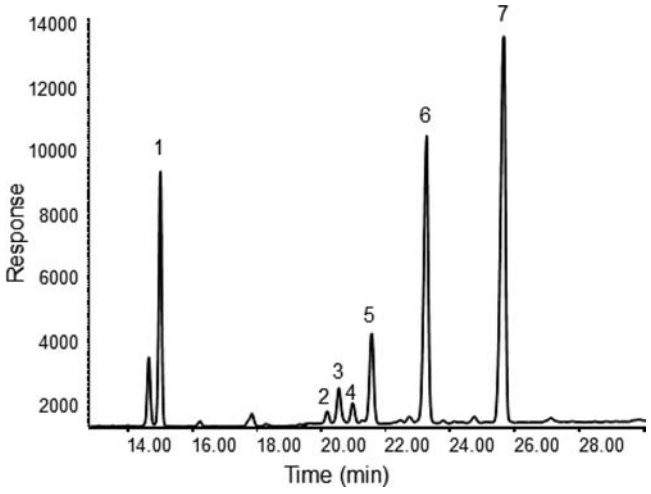

Figure 3. Chromatogram of 4,4-dimethylsterols of a sample of virgin olive oil. Peaks: 1, internal standard (5-α-cholestanol); 2, taraxerol; 3, dammaradienol; 4, β-amyrin; 5, butyrospermol; 6, cycloartenol; 7, 24-methylenecycloartanol.

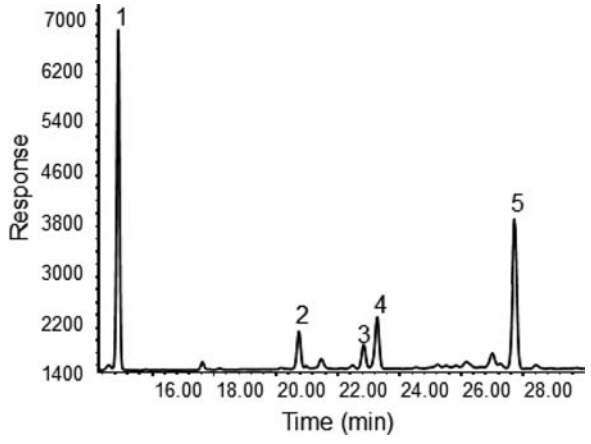

Figure 4. Chromatogram of 4-monomethylsterols of a sample of virgin olive oil. Peaks: 1, internal standard (5-α-cholestanol); 2, obtusifoliol; 3, gramisterol, 4, cycloeucalenol; 5, citrostadienol.

material, and eluting with hexane/diethyl ether (60:40 or 70:30, v/v). The silylized derivatives can be analyzed with SE-30 or SE-54 or SE-52 capillary nonpolar columns. Because EU regulations[61] (and followings) proposed the determination of wax content as an alternative to the quantification of aliphatic alcohols, the analytical method has not been modified since it became a standard method.

Tocopherols. Tocopherols (heteroaromatic acid compounds with high molecular weight) are lipid-soluble compounds easily oxidized in the presence of light, oxygen, alkaline pH, or traces of transition metal ions. The detection method[62] employs the direct analysis using normal-phase HPLC and fluorescence or UV detection. Tocopherols are directly analyzed through olive oil injection, dissolved in a hexane/isopropanol (99.8:0.2, v/v) mobile phase, in a Si-60 5 μm LiChrosorb column with a length of 250 mm and an internal diameter of 4 mm. The fluorescence detector characteristics are λ_{ext} = 290 nm and λ_{em} = 330 nm.[63] SPE has also been reported as an adequate procedure for sample preparation prior to HPLC analysis of tocopherols in VOO.[64] Luminescent methods have also been used for the determination of total tocopherols in VOO without prior separation.[65] IOC[2] recommends using the ISO 9936 method[66] to determine α-tocopherol. A portion of oil is dissolved in *n*-heptane, and the individual tocopherols are separated by HPLC-fluorescence or HPLC-UV. The content of each tocopherol is calculated by using calibration curves.

METHODS FOR OLIVE OIL SENSORY QUALITY CONTROL

Virgin olive oil stands out as a gourmet product because of its rich flavor, and its classification into quality categories basically relies on the sensory assessment, together with some chemical indices that do not provide information about aroma or taste. The sensory assessment by panel test is not, obviously, a chemical method, but some analytical techniques attempt to analyze the chemical compounds actually responsible for flavor and give objective chemical information that can explain the sensory perception.

Numerous problems make the sensory interpretation of instrumental analysis difficult to accomplish. This sensory interpretation can be even harder if those analyses do not provide information on the compounds that cause a particular attribute. Thus, instrumental approaches can be grouped as those that have a casual relationship with sensory quality (henceforth, apparently causal relationship) and those that have a causal relationship. The former methods do not analyze flavor compounds that are responsible for attributes, but compounds whose concentrations are, or seem to be, mathematically correlated with some sensory parameters. Mathematical correlation, however, can fail under certain circumstances, and in those cases, the relationship between sensory and chemical information would be dissociated.

Apparently Causal Methods for Sensory Quality Control. Although methods are validated prior to being proposed as standards, the validation step is not always carried out under the strictest conditions, which can result in overstated and overly optimistic analytical parameters (e.g., reproducibility, robustness) that usually present many exceptions when the method is widely applied by analysts. The problem is circumscribed not only to methods based on multivariate information but also to methods based on parameters with a weak or casual relationship with sensory quality. The fact is that a successful control of olive oil

DOI: 10.1021/jf5062265
J. Agric. Food Chem. 2015, 63, 4509−4526

adulteration by means of statistical procedures encouraged some analysts to think that a strong mathematical relationship can prevail over the lack of any scientific evidence explaining the relationship between sensory assessment and chemical compounds (e.g., pyropheophytins, ethyl esters).

Pigments. Although pigments are related to VOO color,[67] the determination of some of their compounds has been proposed as a method for determining VOO quality and adulteration,[68,69] although its fundamentals in this application are not quite clear.

In analytical terms, the method can be focused on determining a particular compound (pyropheophytin *a*) in a rapid way[69,70] or the maximum number of pigments.[71] In the first case, the analyst can use two methods,[69,70] although one is more focused on the determination of pheophytins[70] than pyropheophytins,[69] because both methods use a reverse-phase solid-phase extraction (RP-SPE). The first, however, elutes with petroleum ether (65−95 °C) and the second with petroleum ether (40−60 °C)/ethyl ether (9:1) for removing lipids. Acetone is used in both methods to collect the pigments. The critical point in both methods is the collection of the analytes in 0.2−0.3 mL of acetone and later the injection in the HPLC instrument because the high volatility of acetone suggests making this step as rapid as possible.

When the objective is to have information on a complete profile of pigments, SPE packs can be responsible for the degradation of some pigments—mostly carotenoids—despite their well-known ability in cleanliness and free acidity removal. In that case, it is suggested to employ a method that is lengthy and tedious but excellent and well-tested: liquid−liquid extraction, with hexane and dimethylformamide (DMF).[71]

Diacylglycerols. The difference in the formation of DAG isomers has not only been proposed for olive oil authenticity but also for distinguishing VOOs from extra-VOOs (EVOOs),[72] despite the fact that the relationship of DAGs with sensory quality is merely a result of casual with the apparent causal relationship in the case of VOO defects resulting from hydrolytic processes, for example, before processing of olives (e.g., fusty) or when vertical containers are used for decanting, among others.

The method proposed by Gertz and Fiebig[72] uses a silica gel column chromatograph to which 100 mg of the olive oil spiked with 1 mL of toluene is transferred, and then the column is washed with isooctane/diisopropyl ether (0.85:0.15) in a first step. In a second step the DAGs are eluted with diethyl ether and the solvent is removed with a rotary evaporator prior to being silylated at room temperature. Then 1 mL of acetone is added to the solution, and 1−2 μL is injected into a gas chromatograph. Pérez-Camino et al.,[73] however, suggested using SPE to which an aliquot of 500 μL of the dehydrated olive oil solution in hexane (0.2 mg/mL) and 200 μL of the internal standard are transferred. The method provided by IOC[39] allows separating the 1,2-isomer from the 1,3-isomer of diacylglycerols although saturated and unsaturated DAGs are eluted together.[74] This method suggests analyzing the olive oil sample by GC once it is purified. The suggested chromatographic conditions consist in a direct on-column injection with a capillary column fused silica 3−7 m coated with SE 52 or SE 54 liquid phase (5% diphenyl-dimethyl polysiloxane) (Table 3).

Fatty Acid Alkyl Esters. Alkyl esters are made up of methyl and ethyl esters of fatty acids previously present in their free form. They are a consequence of inappropriate practices in the harvesting and storing of the olives prior to olive oil extraction because of the rupture of the olive drupe and its contact with microorganisms (yeasts) and lipolytic and pectolytic enzymes. Consequently, it seems that the presence of the ethyl esters of fatty acids (FAEEs), which are present in the waxy fraction of olive oils,[75] indicates that olive oil could have been obtained from unhealthy olives when harvested or because of inadequate processing of the olives. However, the relationship of fatty acid alkyl esters with soft-deodorized oil[76] is casual as well as its relationship with sensory quality.

The method COI/T.20/DOC. No. 31,[43] which allows the determination of waxes as well (Table 3), is based on solid−liquid chromatography (LC) by traditional glass column for isolating the fraction containing alkyl esters and waxes. The method, although very simple—it requires only the addition of a suitable amount of internal standard to 500 mg of the sample prior to transfer into LC—may pose problems in its implementation because of the difficulty in having similar packing of the silica gel columns in repeatability studies. The difficulty becomes greater with the change of LC packed with 15 g of silica gel[6] to 3 g of silica gel,[43] which reduces the sample preconcentration. Furthermore, the flow rate of hexane/diethyl ether (99:1) of about 15 drops every 10 s is not an easy matter for inexperienced analysts. Experience also suggests that 15−20 mL of hexane should be added instead of 10 mL immediately after the sample is transferred into the column, which helps to achieve a better chromatogram resolution. Furthermore, in samples with low concentration of alkyl esters, they can be masked by the peak tail of the solvent (*n*-heptane or isooctane), which suggests using *n*-hexane, which is much more volatile.

An interesting alternative is the use of a method based on GC-(EI)MS/[77] in which there is no sample preparation and FAAEs are directly thermo-desorbed and cryo-focused in the cooled injector of a GC-MS (EI) instrument. The detection limit of the method competes with the standard, but the new one is faster and simpler, requires a lower amount of organic solvents, and significantly enhances method repeatability. However, it is a new method that requires further studies to fully understand its performance parameters and potential problems.

Free Fatty Acids (FFAs). FFAs arise from of the separation of fatty acids from TAGs in the olive because of the action of enzymes, further stimulated by light, water, and heat. Thus, FFA content is a marker of TAG hydrolysis, and hence it indicates how fresh and how well handled the olives were before being milled. The content of FFAs or free acidity is usually determined by titration following well-established standards,[78,79] although the amount of sample[1] seems to be high (i.e., 20 g when acidity is <1.0%) and could be reduced to half. There is also the alternative of substituting the solvents for others that are much more amicable, such as ethanol/water (1:1).[80]

Determination can be carried out by GC as FAMEs as well. FFA methyl esters are prepared by derivatization with trimethylsilyldiazomethane because methylation enhances the volatility and reduces the activity of FFAs, although methylation can be omitted if a highly polar capillary column (e.g., coated with 88% cyanopropyl-aryl-siloxane or 100% cyanopropyl polysiloxane) is used. The procedure also requires the addition of an internal standard (e.g., tridecanoic or nonadecanoic FAs) and a purification step by SPE filled with an amino stationary phase. Medium-polarity thermostable columns (e.g., coated 65% phenyl−35% dimethyl-polysiloxane) have also been used with success.

J. Agric. Food Chem. 2015, 63, 4509−4526

Although FFA determinations can be easily and rapidly achieved by FTIR, this approach is not an official method yet. Lanser et al.[81] used peaks near 1745 and 1711 cm^{-1} to construct a model allowing the determination of the free fatty acid content in crude oils. The C═O carbonyl groups of esters absorb at ∼1746 cm^{-1}, whereas the carboxylic acid group of FFAs has its characteristic band at 1711 cm^{-1}. Later, an FTIR instrument and ATR accessory were successfully used to determine FFA content in oils and fats.[82] However, it is FTIR with transmission cells that has been much more successful.[83] In this procedure the FFAs that are present in the sample are derivatized to the corresponding free fatty acid salt after reacting with sodium carbodiimide (a weak base) in methanol. The resulting salt presents a measurable spectroscopic band in a region without interference, and consequently this band is very easy to measure and calibrate.[84,85]

Oxidation Products. The peroxide value (PV) is an indicator of the primary oxidation status of olive oil, mainly because of the presence of hydroperoxides.[86] Despite the importance of PV as a quality index, the standard method (ISO 2009)[78] is laborious and time-consuming and requires the use of organic solvents and, even more importantly, its accuracy depends strongly on the experience of the analyst.[88] Its relevance justifies the need for reliable methods that use amicable solvents (i.e., isooctane) that do not perturb the interpretation of the results and can also be fast and nondestructive, with a high degree of automation to provide near-real-time measurements for assessing olive oil quality. In this context, vibrational spectroscopy offers alternative analytical tools;[87] for example, disposable IR cards have successfully been applied to determine PV of edible oils.[89,90]

A shift in double-bond configuration occurs during the formation of peroxy radicals and hydroperoxides because the normal methylene-interrupted configuration is transformed into a conjugated form. The absorbance in ultraviolet light of secondary oxidative compounds (conjugated dienes and trienes) is determined according to standard methods,[91] which can be easily implemented by analysts. New instrumentation, however, has better characterized the exact wavelengths at which the conjugated dienes and trienes absorb, 232 and 268 nm when using isooctane and 232 nm and 270 when cyclohexane is the solvent.

Causal Methods for Sensory Quality Control. The sensations perceived when a VOO is consumed are evaluated by sensory assessment implemented in the so-called panel test.[92] The official method, however, is questioned by numerous VOO sectors, because the difference between virgin and extra-virgin olive oils depends on the presence of defects, whatever their level of perception. It is there where the method fails: when the panel test analyzes oils that could not have any defect for some panel tests whereas others have been able to detect defects at very low intensity of the sensory perception, which is enough to qualify olive oils as virgin instead of extra-virgin. Reasons can be found in many aspects—limit of detection, subjectivity, inadequate training, too high sensitivity of some assessors for some odors—but none of them is convincing by itself to explain the errors in the analysis. Therefore, an objective measurement of VOO sensory quality should follow another strategy based on analytical chemistry.

From a chemical perspective, the flavor of VOO is explained by the occurrence of a series of minor chemical compounds that have a significant sensory impact. Thus, "I smell, therefore there are volatiles" is the sentence, which, emulating Descartes' phrase, summarizes the scientific support explaining that there is a causal relationship between volatile compounds and aroma, and, for a similar reason, between phenols and VOO taste. The methods for quantifying those chemical compounds have as their main objective to contribute to the explanation of what the assessors perceive when they smell and taste VOOs.

Phenols. The prevalent classes of phenols found in VOOs are phenolic alcohols, phenolic acids, flavonoids, lignans, and secoiridoids, some of them having antioxidant properties.[93] However, and despite, the interest of these compounds from sensory and health viewpoints, no harmonized and widely accepted analytical method exists today because their results are not comparable.[94] There are several approaches, one of them being supported by IOC,[95] whereas another[96] is still under evaluation. The first one is based on the individual separation of phenols by HPLC, and the second one provides the total content of *o*-diphenols by a more rapid and cost-effective colorimetric method. Their results, however, do not seem to be comparable. The colorimetric method has a low specificity, as the color reaction can occur with any oxidizable phenolic hydroxyl group.[97] However, it could be a valid method to determine the concentration of total phenols as required in the recent health claim on polyphenols[98] once the method is improved and corrected.

Regardless of the method applied, the first step is the extraction of the phenol fraction from the oil matrix removing the interfering components (e.g., lipids, pigments). The extraction of the phenol fraction can be carried out by SPE (e.g., C18 or diol) or liquid−liquid extraction (LLE). If SPE is used, the addition of hexane or other organic solvents to the oil before extraction[99] makes the sample flow through the SPE cartridge more easily with no effect on the recovery of phenols. However, the IOC method[95] uses a LLE with methanol/water (80:20, v/v). Some authors[100,101] have pointed out that the recovery of "bitter" phenolic compounds increases as follows: SPE C18 (with methanol) < SPE diol (with methanol) < LLE (60% aqueous methanol). LLE also seems to be more appropriate for the extraction of oxidized phenolic compounds.[102]

In the separation step, reversed-phase HPLC has been the most successful approach despite the fact that the elution time is generally long, >40 min. Separation is carried out using a column RP C18 (250 × 4 or 4.6 mm i.d.) with water/methanol or water/acetonitrile mixtures enriched with acetic, phosphoric, or sulfuric acid (up to 3%, pH <2) to suppress phenol dissociation and improve peak asymmetry. Analysts, however, should pay attention to the various pK_a values of individual phenols. Furthermore, degassing should be constant to avoid bubbles that disrupt the long runs. The starting composition of eluent should use a small amount of organic phase (approximately 5%). By the end of the run, this amount is usually rather high, although it should never reach 100%. The water quality used for the analysis is essential for avoiding higher backpressures expected at certain ratios. The conditioning times from run to run that are needed to ensure reproducible retention data are long.

Ultrahigh-performance liquid chromatography (UHPLC), with columns packed with 1.7 μm particles, coupled to MS/MS (LLE-UPLC-MS/MS) has been applied with success up to the point that its analytical parameters, as LOD and LOQ, are better than HPLC-DAD and HPLC-FLD with the exception of vanillic acid and pinoresinol.[103] Although it is much more rapid (18 min) than the IOC standard method and methodologies

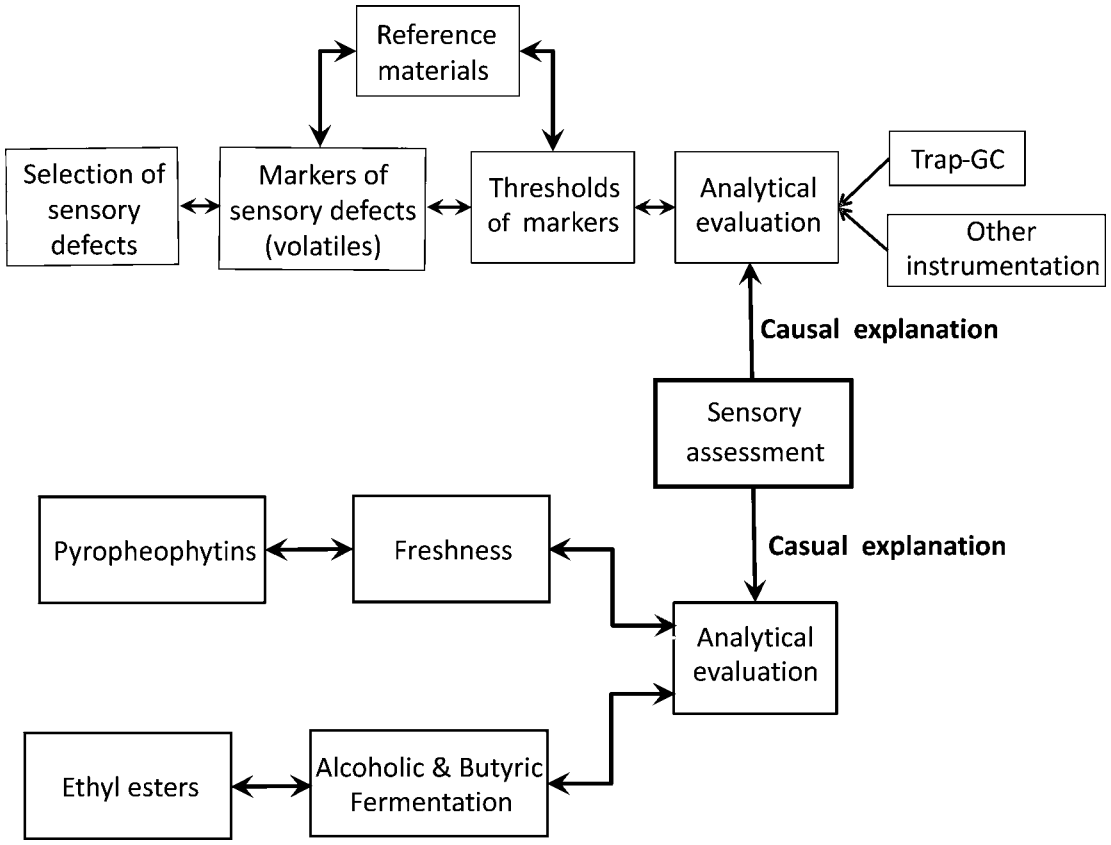

Figure 5. Different approaches to explain the sensory assessment from chemical compounds.

under evaluation by IOC, the instrumentation is not affordable for most laboratories.

The identification and quantification techniques depend on the aim of the study and available facilities. In the past decade LC-MS techniques have found extended application, although routine analysis is still less demanding regarding instrumentation. Thus, a good detection system can be an in-tandem diode array detector (DAD) with fluorescence detector (FLD). It is well-known that UV detection at 280 nm is the standard wavelength, although others (225, 240, and254 nm) are also useful for constituents of olive oil polar fractions, whereas flavonoids are detected at higher wavelengths (340 nm).

UV spectrophotometry (spectrum region between 200 and 290 nm) is extremely helpful in the identification of phenols and monitoring the purity of HPLC peaks, although hydroxycinnamic acids have a characteristic maximum at 310−332 nm. Differences in maximum wavelength and molar absorption values among the various phenols affect quantification.[93] Spectrofluorometry, in-tandem or not with DAD, is a valuable tool as it is more specific and sensitive than spectrophotometric detection.[104,105] However, there is a certain interest in modifying the IOC standard by adding a step of hydrolysis prior to the quantification with HPLC-DAD and suggesting the colorimetric method under revision[96] as a routine method for determining the phenolic content for verifying health claims.[98] This, once again, increases confusion among analysts because it does not produce comparable results and it is contrary to the current demand of analysts for a reduced number of standard methods.

Other alternatives to quantify the phenolic fractions have been studied. Mass spectrometry (MS), for its part, offers a high volume of data on fragments derived from phenolic compounds. Thus, MS can be also used to perform quantitative analysis of phenol composition on the basis of fragment abundance. Finally, nuclear magnetic resonance (NMR) and NMR-MS are powerful tools for the structural elucidation of isolated phenolic compounds that are not detectable by other means,[106] although NMR cannot yet be used in routine analysis.

Volatile Compounds. Any proposal to replace sensory assessment with an analytical procedure presently has two challenges. The first is the determination of the chemical compounds responsible for VOO aroma from the large set of currently identified compounds.[107,108] The second challenge is to explain those important VOO sensory attributes that are described with considerable vagueness such as fruitiness and green. Therefore, the establishment of the relationship between VOO chemical compounds and sensory attributes is the most complex aspect of the global study of olive oil flavor. However, the relationship between volatile compounds and sensory defects is already well-established.[109] Once the markers for a sensory defect are identified, a series of tasks should be implemented: (i) calculate the thresholds of the markers; (ii) select the better analytical evaluation (e.g., Trap, SPME); (iii) produce reference materials to facilitate the implementation of the method for analytical evaluation. All of these tasks (Figure 5) should be carried out to develop an analytical method for aroma authentication.

The separation and quantification of volatiles is usually carried out by GC, although aroma sensors,[110] which do not require a sample preparation step, are gaining in popularity. The sensors are applicable within a screening context, because aroma sensors do not supply individual information on volatiles but instead produce a response curve resulting from all of the

Table 5. Advantages and Disadvantages of Most Common Analytical Techniques, Chemical Phases, and Sensors Used To Study the Sensory Attribute of VOO

technique	description	advantages	disadvantages
dynamic headspace gas chromatography with Tenax	inert gas (e.g., N_2) sweeps headspace of sample, which is stirred or bubbled	high adsorption capacity	less sensitive to some acids
	volatiles are trapped in Tenax	useful for almost all kinds of volatiles	temperature and flow rate must be controlled
	trap is thermally desorbed in GC; heating the trap to a high temperature while passing a current of inert gas through it	good recovery factors	possible impurities of the adsorbent
		good repeatability	analysis per sample
		no artifacts	
static headspace gas chromatography with SPME	SPME fiber is exposed to sample vapor phase; volatiles adsorbed on fiber are desorbed in GC injection port	rapid, cheap, easy to use all steps in a single process when using automatic injector various kinds of fibers good repeatability	differences in quantification of low molecular weight molecules
			lower number of volatiles at low concentrations
			some of the disadvantages of the static headspace
			competitive effect between volatiles in SPME absorption
metal oxide semiconductor (MOS)	ceramic former heated by wire and coated with a metal oxide semiconducting film	robust	sensitivity affected by humidity
n-type (oxidizing compounds)		quite good sensitivity	temporary blinding effect
p-type (reducing compounds)		simple signal processing	sensor drifts
		low cost	poor specificity and selectivity with compounds with high molecular weight
		can be doped with metals to improve sensitivity and selectivity and diminish humidity and temperature dependence	nonlinear response to some chemical compounds
conducting polymer (CPSs)	based on a measurable change in electrical conductivity when are exposed to volatile compounds	easy to manufacture	nonreproducible
polypyrroles		low power consumption	too long response time (20−40 s)
polyanilines		robust	drift over time or changes in temperature
		can work at room temperature	extremely sensitive to moisture
		can be doped, producing sensors to specific series of volatiles or to a particular application	
acoustic sensors	based on the propagation of acoustic waves produced by piezoelectric materials in a multilayer structure	high sensitivity	temperature and humidity dependence
surface acoustic wave (SAW)		short response time	poor reproducibility in the deposition of the coating material
bulk acoustic wave (BAW)		low power consumption	certain level of noise because of the oscillator high frequency
		small size	
		robustness

DOI: 10.1021/jf5062265

volatiles present in a static headspace.[111] Table 5 describes the analytical techniques, chemical phases, and sensors that are commonly used in the analysis of volatiles. In addition to the described methods, in-tandem GC-olfactometry (GC-O) is a valuable tool for the selection of aroma-active components. In GC-O human subjects (assessors) assign the sensory properties of the different peaks/zones of the chromatogram when sniffing GC effluents. Many key aroma compounds occur at very low concentrations but still have sensory relevance due to low odor thresholds,[108] and they are perceived by panelists and consumers.[112,113]

UNIFYING METHODS

Researchers have always looked for unifying methods that allow reduction of the tremendous laboratory workload, given that the current methods offer partial solution for determining the presence of adulterants in olive oil. A difference between theoretical and empirical TAGs is an indication of a mixture of different oils and hence of the presence of an extraneous edible oil in olive oil. The practical implementation of this theory is the so-called global method, in which an analytical step for determining FAMEs and TAGs is followed by a mathematical procedure that makes this standard[17] different from the other previously approved methods to date.

Another proposal of a unifying method was provided by Mariani and co-workers in 1991,[114] in which sterols, triterpenic alcohols, squalene, and tocopherols are quantified simultaneously. This method is based on the concurrent determination of these compounds, avoiding the use ofTLC for separating the unsaponifiable fraction, which is tedious. The procedure is something similar to that already described for the simultaneous determinations of waxes, FAMEs, and FA ethyl esters.[6]

With regard to the unifying method for the sensory quality assessment, a recent method based on the quantification of ethyl esters has been proposed. However, the relationship between ethyl esters and VOO quality is casual. Furthermore, there is no kinetic equation that explains the formation of ethyl esters in VOO. This method has also raised the interest in quantifying ethanol, which is involved in the formation of ethyl esters but it is important to note that the odor threshold of ethanol is so high in a lipidic matrix that it does not contribute to VOO aroma.

The aforementioned unifying methods satisfy one of the requirements of analysts working on olive oil control, that is, to obtain complete chemical information from an oil without use of extensive resources. Therefore, such methods will presumably be welcomed by control laboratories. However, these methods still need to be fully validated, and experience is currently insufficient to propose amendments or detect potential problems. It is also unclear whether these methods should be proposed as alternatives to the current standard methods or as additional options for more experienced analysts.

FURTHER RESEARCH IN PERFECTING METHODS

The described methods have solved many problems and have made olive oil one of the most protected foodstuffs, although they still need to be improved with further research. The required improvements need to take into account current problems, which are somewhat different from those encountered in the past, and to be stricter in repeatability and reproducibility considering the recent technical advances. The greater ability of current techniques for identifying compounds in olive oil also sets the stage for the evaluation of new purity and quality parameters in addition to validating the current ones. Searching new parameters is of particular interest in quality assessment, where the development of alternative methods based on volatile compounds for the assessment of sensory characteristics is required. New research based on chemical and sensory approaches would make the current sensory assessment dispensable to some extent, alleviating the workload associated with panel tests. Researchers also strive to develop methods for assessing health benefits of virgin olive oil (e.g., analyzing phenols) to respond to the current demands of industry and consumers. Another challenge is to develop rapid approaches that may serve as alternatives to lengthy chromatographic methods. Thus, spectroscopic techniques may provide effective solutions in cases of complex analytical tasks such as identification of geographical origins. The establishment of open databank and data-sharing platforms fed with spectroscopic and chromatographic data is also being pursued to facilitate the implementation of practical and standardized applications. This task is arduous, requires time, and needs to keep pace with the development of new accurate methods and the rise of new challenges.

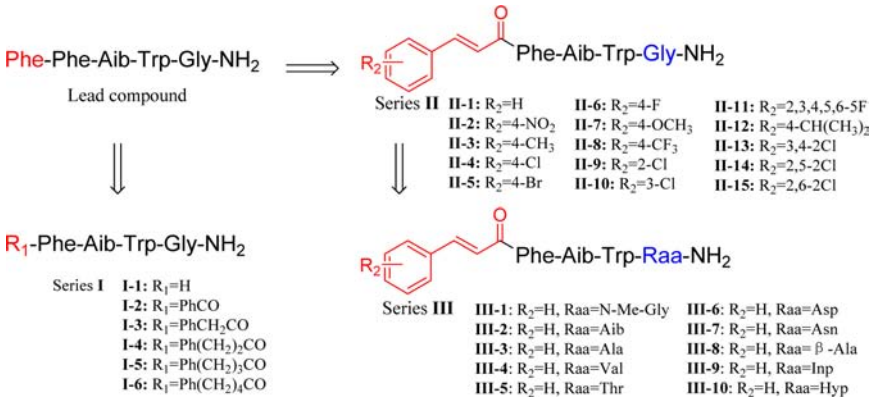

Figure 1. Design strategy of the insect kinin analogues using the peptidomimetic approach.

insect kinin sequence. These analogues not only maintain their activity *in vitro* in *A. domesticus* and *A. aegypti* Malpighian tubule fluid secretion assays and activity *in vivo* in *M. domestica* diuretic assay but also retain their resistance to hydrolysis of ACE and NEP endopeptidases. In addition, these analogues showed a response in receptor-expressing systems of tick *Boophilus microplus* and *A. aegypti*.[10,18,19,28] Among these analogues, the double Aib-containing kinin analogue (**K-Aib-1**: Aib-Phe-Phe-Aib-Trp-Gly-NH_2) was first reported to exhibit good aphicidal activity against pea aphid *Acyrthosiphon pisum*.[13] However, this analogue is still not suitable for use as an insecticide as a result of its longer peptide chain, higher molecular weight, and lower aphicidal activity. Further studies need to be undertaken to discover better kinin analogues with simpler structure and higher activity.

In our previous work, we designed and synthesized a series of analogues using **K-Aib-1** as the lead compound, modifying the N-terminal by replacing the N-terminal Aib with different substitutes or completely removing the N-terminal Aib. The sequence-simplified pentapeptide analogue Phe-Phe-[Aib]-Trp-Gly-NH_2, which was first synthesized and reported by Nachman et al.[18] to show resistance to an insect angiotensin converting enzyme and potent diuretic activity, also showed higher aphicidal activity than the **K-Aib-1**.[29] In the present work, we used the structure-simplified pentapeptide analogue Phe-Phe-[Aib]-Trp-Gly-NH_2 as the lead compound, and we further incorporated peptidomimetics to this structure, in an attempt to find (a) new analogue(s) with higher activity to employ as (a) new lead(s) for novel eco-insecticide candidates (Figure 1). Three series, comprising 31 analogues, were designed and synthesized by replacing/modifying the positions that played an important role in bioactivities.

MATERIALS AND METHODS

Synthesis. *Materials.* Rink Amide-AM resin (0.56 mmol/g), *O*-benzotriazole-*N*,*N*,*N*′,*N*′-tertramethyl uronium hexafluorophosphate (HOBt), 1-hydroxybenzotriazole anhydrate (HBTU), *N*,*N*′-diisopropylethylamine (DIEA), *N*,*N*′-dissoprophlcarbodiimide (Dic), trifluoroacetic acid (TFA), Fmoc-protected amino acids, Fmoc-Gly-OH, Fmoc-*N*-Me-Gly-OH, Fmoc-*L*-Phe-OH, Fmoc-*L*-Trp(Boc)−OH, Fmoc-*L*-Aib−OH, Fmoc-*L*-Ala-OH, Fmoc-*L*-Val-OH, Fmoc-*L*-Thr-OH, Fmoc-*L*-Asp(OtBu)-OH, Fmoc-*L*-Asn-OH, Fmoc-Inp-OH, and Fmoc-*L*-Hyp(tBu)-OH were purchased from GL Biochem, Ltd. (Shanghai, China). High-performance liquid chromatography (HPLC)-grade *N*,*N*-dimethylformamide (DMF), dichloromethane (DCM) and methanol were purchased from Dima Technology, Inc. (Richmond Hill, Ontario, Canada). Thioanisole, phenol, (substituted) cinnamic acids, phenylacetic acid, hydrocinnamic acid, 4-phenylbutyrilc acid, and 5-phenylpentanoic acid were purchased from Alfa Aesar, U.S.A.

General Synthesis Procedure. F[Aib]WG and F[Aib]W-[Raa] with Resin was synthesized from Rink Amide-AM resin (536 mg, 0.3 mmol) using the standard Fmoc/*t*Bu chemistry and HBTU/HOBt protocol.[30] Incoming amino acids were activated with HOBt (164 mg, 1.2 mmol), HBTU (456 mg, 1.2 mmol), and DIEA (210 μL, 1.2 mmol) in DMF (5 mL) for 5 min, and the couplings were run for 2 h. Removal of the N-terminal Fmoc group from the residues was accomplished with 20% piperidine in DMF (5 mL) for 20 min.

The lead compound and analogues were cleaved from the resin with TFA (9 mL) containing 5% phenol, 2.5% thioanisole (0.5 mL), and 5% water (0.5 mL) for 2 h after the mimic acids were coupled to the F[Aib]WG with resin (0.3 mmol) with HOBt (164 mg, 1.2 mmol), HBTU(456 mg, 1.2 mmol), and DIEA (210 μL, 1.2 mmol) in DMF (5 mL) for 3 h at room temperature. Removal of the protective group Boc and tBu was also accomplished in the cleavage procedure. To avoid the generation of OBt esters, some analogues containing a carboxylic acid group were synthesized using Dic as the coupling reagent instead of HBTU/HOBt. The general synthesis procedure is shown in Figure 2.

Purification and Characterization. The crude compounds were purified on a C_{18} reversed-phase semipreparative column with a flow rate of 10 mL/min using different ratio of acetonitrile/water (v/v) from 30/70 to 70/40 containing 0.1% TFA as an ion-pairing reagent. The wavelength of UV detection was set at 214 nm. The purified compounds were run again on HPLC to ensure that the purity was higher than 95%. The structures of the analogues were confirmed by high-resolution mass spectrometry (HRMS) using an Agilent Accurate-Mass-Q-TOF MS 6520 system equipped with an Electro Spray Ionization (ESI) source. All the MS experiments were detected in the positive ionization mode. For Q-TOF/MS conditions, fragment and capillary voltages were kept at 130 and 3500 V, respectively. Nitrogen was supplied as the nebulizing and drying gas. The temperature of the drying gas was set at 300 °C. The flow rate of the drying gas and the pressure of the nebulizer were 10 L/min and 25 psi, respectively. Full-scan spectra were acquired over a scan range of m/z 80−1200 at 1.03 spectra s^{-1}.

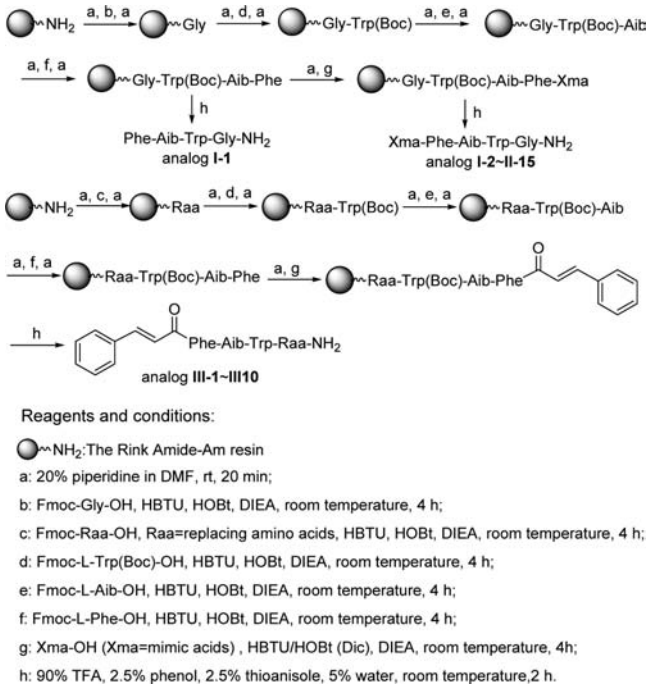

Figure 2. General synthesis procedure.

Aphicidal Bioassay. The aphicidal activity of the insect kinin analogues against *Aphis glycines* was determined using the reported procedure.[31]

Compounds were dissolved to a concentration of 2000 mg/L and then diluted to lower concentrations with 0.05% Triton X-100. Soybean leaf discs of about 3 cm diameter were dipped into the test solution for 15 s. The discs dipped into 0.05% Triton X-100 were set as the negative control. After air-drying, the treated leaf discs were placed individually into bioassay plates with 1% agar to keep moist. The discs were infested with 20 ± 3 3-day old aphids and kept in an incubator with constant temperature (25 ± 1 °C) for 48 h. The number of dead aphids was then counted, and the mortality rates were corrected using Abbott's formula.[32] Each experiment was performed three times. The standard deviations of the tested aphicidal values were ≤10%. The LC_{50} values were calculated using the SAS 9.0 (SAS Institute Inc., U.S.A.).

RESULTS AND DISCUSSION

Design and Synthesis of Analogues. Members of the insect kinin family are inactive *in vivo* as a consequence of hydrolysis by both hemolymph and tissue-bound peptidases in insects.[16,33,34] The two susceptible hydrolytic sites of the kinin core pentapeptide have been reported.[10] Analogues with modification and replacement of amino acids at the hydrolysis sites not only showed resistance to peptidases but also retained their bioactivities.[7,14,20,27,28] Our previous work demonstrated that the N-terminal Aib of the secondary hydrolysis site of analogue **K-Aib-1** did not play an important role in aphicidal activity.[29] Removing the N-terminal protective group might not only simplifies the structure but also maintains or even increases the aphicidal activity of analogues. Thus, the simplified analogue Phe-Phe-[Aib]-Trp-Gly-NH_2 could be a good lead compound. In this work, we replaced the terminal Phe of the lead compound with different mimics, which was also modified by Nachman et al.[35,36] in the N-terminal region of the insect kinin core pentapeptide to discover active diuretic analogues, expecting to find (a) new analogue(s) with higher aphicidal activity. As shown in Figure 1, the first step of the strategy is replacing the N-terminal Phe with H, aromatic carboxylic acids with different carbon chain lengths (Series **I**) and substituted phenyl cinnamic acids (Series **II**), which have been demonstrated to be good mimics of Phe in our previous work to obtain the optimal mimic of Phe. The result of aphicidal bioassay showed that the optional carbon chain length was 3-C and analogue containing the cinnamic acid group exhibited improved bioactivity. We subsequently used the optimal analogue (**II-1**) as the second lead, and we performed modifications at the C-terminal Gly, the site shown to enhance inhibition of weight gain and induce significant mortality in *Helicoverpa zea* larvae when modified with terminal aldehyde or with hydrophilic/hydrophobic natural/unnatural amino acids to assess its importance to bioactivity (Series **III**). The aphicidal activity against the soybean aphid *Aphis glycines* of all analogues was evaluated.

The analogues were synthesized using the solid-phase peptide synthesis (SPPS) employing the Fmoc protecting group strategy. For avoiding the generation of OBt esters, some analogues containing (substituted) cinnamic acid group were synthesized using Dic as the coupling reagent instead of HBTU/HOBt.[37] The purity and high-resolution mass spectrometry (HRMS) data of all target compounds are shown in Table 1.

Aphicidal Activity. The aphicidal activity of the lead compound, the analogues, and pymetrozine against *A. glycines* are shown in Table 1. The preliminary bioassay results (at a concentration of 200 mg/L, 48 h) indicated that all the analogues exhibited aphicidal activity. The aphicidal activity of analogue **I-4**, **I-5**, **I-6**, **II-1**, **II-3**, **II-10**, **III-2**, **III-3**, **III-6**, and **III-9** are comparable to or even better than that of the lead compound Phe-Phe-[Aib]-Trp-Gly-NH_2. On the basis of the primary experimental results, analogues showing a mortality rate higher than 70% were chosen to determine the LC_{50} values. As shown in Table 1, **I-4**, **II-1**, and **III-9** exhibited higher aphicidal activity against soybean aphid with LC_{50} values of 0.039, 0.019, and 0.034 mmol/L, respectively, compared to the lead compound (LC_{50} = 0.045 mmol/L). In particular, **II-1** was the most toxic compound to the soybean aphid with an LC_{50} of 0.019 mmol/L, even higher than the commercial insecticide pymetrozine with an LC_{50} of 0.034 mmol/L. However, the aphicidal activity of analogue **II-1** is not statistically significant and still needs to be improved in the further work.

Removing the terminal Phe (**I-1**) significantly decreased the ahpicidal activity, indicating that the N-terminal Phe group was important to maintain the bioactivity of the analogues. Thus, we retained the hydrolysis site Phe, but we modified it with other mimics. Analogues **I-4** and **II-1**, with 3-carbon mimetic aromatic carboxylic acids on the Phe[1] position, exhibited higher aphicidal activity than other analogues, suggesting that the optimal carbon chain length of mimetic aromatic carboxylic acids was 3-carbon, whereas the optimal mimic of Phe was the cinnamic acid. We surmised that the C═C bond of cinnamic acid might play an important role, such as forming a $\pi-\pi$ stacking effect, in the interaction of the mimetic insect kinin analogues with target receptors.

Recently, the widely accepted active conformation of an insect kinin C-terminal pentapeptide core region in the interaction of the analogue with the receptor is a 1-4 β-turn. The aromatic side chains of the critical residues Phe[1] and Trp[4]

interact to form a selective aromatic surface that interacts with the receptor site.[38] Analogues of series **II** were designed to determine the substituent effect of the benzene ring of cinnamic acid with different substitutes and they exhibited decreased aphicidal activity to varying degrees compared with **II-1**. We speculate that substitutions in the benzene ring affected the formation of the aromatic surface and thus interfered with interaction of analogues with the receptor site as a result of their steric stabilization, which led to the decreased bioactivity. Therefore, the side aromatic group without substitution of Phe played a critical role in bioactivity. Further studies on the effect of different side heterocyclic groups without substitution will also be useful to assess. In series **III**, analogues were designed based on **II-1** to assess the importance of the C-terminal Gly. The bioassay result showed that all the analogues were less toxic to the soybean aphid than **II-1**, which demonstrated that the C-terminal Gly site should be conserved.

In summary, three series of novel insect kinin analogues were designed and synthesized. The aphicidal bioassay results showed that most analogues exhibited considerable aphicidal activity against *A. glycines*, especially analogue **II-1** with an LC_{50} of 0.019 mmol/L, which exhibited improved aphicidal activity compared with the lead compound (LC_{50} = 0.045 mmol/L), and comparable activity to the commercial insecticide pymetrozine with an LC_{50} of 0.034 mmol/L. Therefore, analogue **II-1** could be used as a new lead for further chemical modifications and simplifications to discover eco-friendly insecticides.

the resulting glycoconjugates were then hydrolyzed during winemaking, that is, in a manner analogous to that observed in smoke-affected grapes and wine.[14]

Oak lactone, that is, the *cis*- and *trans*-isomers of 5-*n*-butyl-4-methyl-4,5-dihydro-2(3*H*)-furanone **1a** and **1b** (Figure 1), is an

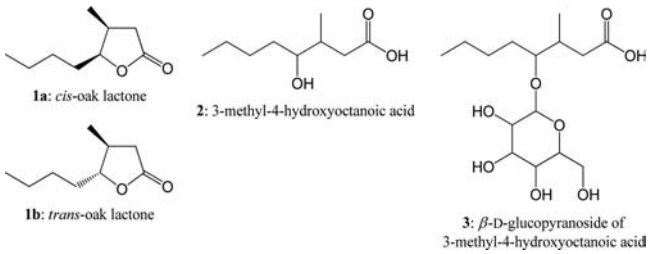

Figure 1. Chemical structures of *cis*- and *trans*-oak lactone **1a** and **1b**, 3-methyl-4-hydroxyoctanoic acid **2**, and the glucoside of 3-methyl-4-hydroxyoctanoic acid **3**.

important oak-derived volatile compound that typically imparts "coconut" and "vanilla" attributes to wine, following its extraction from oak chips or oak barrels.[15,16] Oak lactone occurs in green (i.e., unseasoned) oak wood,[16] but glycoconjugates of 3-methyl-4-hydroxyoctanoic acid (i.e., the ring-opened form of oak lactone **2**, Figure 1) have been identified in extracts of French and American oak wood,[17−20] including the β-D-glucopyranoside **3** (Figure 1). Oak lactone has also been detected in wines made with fruit from grapevines treated with oak extract or oak lactone,[7,8,21] and although increased glucosyl-glucose (G-G) levels were observed in grapes, suggesting glycosylation of oak derived volatiles,[21] it is not clear if glycoconjugate precursors of oak lactone accumulated, because this would necessitate a ring-opening step to generate the hydroxyl group required for glycosylation. The aim of this study was therefore to determine whether or not glycoconjugates of 3-methyl-4-hydroxyoctanoic acid accumulate in the fruits, leaves, and shoots of Monastrell grapevines following foliar applications of either oak extract or oak lactone, using qualitative and quantitative liquid chromatography−tandem mass spectrometry analysis.

MATERIALS AND METHODS

Chemicals. Chemicals were purchased from Sigma-Aldrich. Solvents were of HPLC grade from Merck (Darmstadt, Germany). Reference compounds included racemic *cis*- and *trans*-oak lactone and γ-hexalactone. [$^2H_4$]-(3*S*,4*S* and 3*R*,4*R*)-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid was synthesized in-house as previously reported.[19]

Grapevine Treatments. Field trials were conducted during the 2012 growing season and involved the application of oak lactone or oak extracts to grapevines (*Vitis vinifera* cv. Monastrell) grown in the experimental vineyard of the BSI winery, located in Jumilla, Spain (latitude, 38°28′ N; longitude, 1°18′ W). The plot covered an area of 1.09 ha and comprised loam soil. Vines were planted in 2002, with 2.8 m row and 1.5 m vine spacing, and were trained on a cordon trellis system and drip irrigated. The mean annual temperature was 16 °C, with a minimum temperature of −15 °C (in January) and a maximum temperature of 40 °C (in August).

Treatments were imposed on grapevines located in edaphologically homogeneous parts of the vineyard (excluding those located on vineyard edges), with buffer rows between treated and control vines to avoid contamination. Treatments comprised (i) the application of an aqueous solution of commercial toasted oak extract (Protea France S.A.S., Gensac la Pallue, France; comprising 231 μg/L *cis*-oak lactone and 247 μg/L *trans*-oak lactone) to grapevines (300 mL/vine, 16 vines per treatment) with and without bunches covered with plastic bags; and (ii) the application of a 0.6% aqueous solution of oak lactone (Sigma-Aldrich, Sydney, Australia) to grapevines (300 mL/vine, 16 vines per treatment) with and without bunches covered with plastic bags with 0.05% (v/v) adjuvant Fluvius (BASF, Germany) added to each solution as a wetting agent. All treatments were applied from a portable backpack sprayer. The placement of bunches in plastic bags was intended to prevent direct contact of fruit with oak lactone or oak extract solutions, but bags were removed immediately after solutions had evaporated (i.e., when droplets were no longer visible on leaves), typically 1 h after treatments were applied. Sixteen untreated grapevines were also selected as the control. Treatments were imposed in the early morning when ambient temperatures were <20 °C, at approximately 7 days postveraison.

Berry, leaf, and shoot samples were then collected from control and treated vines at three time points, designated as $t = 1$, being 10 days after foliar applications were applied; $t = 2$, being 20 days after application; and $t = 3$, being 36 days after foliar applications were applied (i.e., at maturity). For berry samples, approximately 15−20 grapes were randomly sampled from four clusters per vine per treatment (ensuring bunches from different locations within a vine were sampled). For leaf samples, four leaves per vine per treatment were randomly selected (ensuring different locations within a vine were sampled). For shoot samples, four shoots per treatment were randomly selected at $t = 1$ and $t = 2$, with one shoot per vine per treatment collected at $t = 3$. Samples were combined (within each treatment and at each time point) and then stored at −20 °C prior to analysis.

Quantitation of Oak Lactone by Gas Chromatography−Mass Spectrometry (GC-MS). Whole berries (50 g, in triplicate) were homogenized (T18 Ultra Turrax, IKA, Staufen, Germany), and the resulting homogenate was macerated for 2 h prior to centrifugation (3000*g* for 5 min). The resulting juice was then analyzed by stir bar sorptive extraction (SBSE)-GC-MS to determine *cis*- and *trans*-oak lactones according to previously reported methodology.[7] The SBSE analysis was performed using an automated thermal desorption unit (TDU, Gerstel, Mülheim and der Ruhr, Germany) mounted on an Agilent 7890A gas chromatograph (GC) coupled to a quadrupole Agilent 5975C mass spectrometry detector (Agilent Technologies, Palo Alto, CA, USA) operated in electron ionization mode. Separation was achieved with a fused silica capillary column (BP21 stationary phase, 30 m × 0.25 mm i.d. × 0.25 μm film thickness, SGE, Ringwood, Australia). The carrier gas was helium with a constant column pressure of 20.75 psi. The stir bars, coated with PDMS (Gerstel), were thermally desorbed in a stream of helium carrier gas at a flow rate of 75 mL/min with the TDU programmed from 40 to 295 °C at a rate of 60 °C/min (held for 5 min). The analytes were focused in a programmed temperature vaporising injector (PTV) (CIS-4, Gerstel), containing a packed liner (20 mg of tenax TA), held at 25 °C with Peltier cooling prior to injection. After desorption and focusing, the CIS-4 was programmed from 25 to 260 °C at 12 °C/s (held for 5 min) to transfer the trapped volatiles onto the head of the analytical column. The TDU was operated in the splitless desorption mode, whereas the CIS-4 was operated in the PTV solvent vent mode (purge flow to split vent of 80 mL/min, vent of 75 mL/min, and pressure of 20.85 psi). The initial GC oven temperature was 40 °C (held for 2 min); this was raised to 150 °C (at 10 °C/min, held for 5 min) and then to 230 °C (at 10 °C/min, held for 2 min). The MS was operated in scan mode (27−300 amu) with an ionization energy of 70 eV. The temperature of the MS transfer line was maintained at 230 °C. Identification of the *cis*- and *trans*-oak lactones was confirmed using the NIST library and by comparison of mass spectra and retention indices with oak lactone standards (Sigma-Aldrich, Steinheim, Germany). To avoid matrix interferences, MS quantitation was performed in single ion monitoring (SIM) mode using m/z 99 and was based on a five-point calibration curve of the oak lactone standards, using 200 μL of internal standard γ-hexalactone (Sigma-Aldrich, Steinheim, Germany) solution at 1 μL/mL in absolute ethanol (Merck, Damstadt, Germany).

Quantitation of Oak Lactone Glucoside by Liquid Chromatography−Tandem Mass Spectrometry (UHPLC-MS/MS). Extracts of fruits, leaves, and shoots sampled from control and treated

DOI: 10.1021/acs.jafc.5b01043
J. Agric. Food Chem. 2015, 63, 4533−4538

grapevines were analyzed by UHPLC-MS/MS to identify or determine oak lactone glycoconjugates.

Preparation of Fruit Extracts. Grape extracts were prepared according to methodology described previously.[22] Briefly, aliquots (2 mL) of juice (prepared as above) were loaded onto C18-HF solid phase extraction (SPE) cartridges (Grace, Australia), and each cartridge was washed with 10 mL of Milli-Q water. The retaining compounds were eluted with 2 mL of methanol and concentrated to semidryness under nitrogen at 40 °C. The resulting residue was reconstituted with 500 μL of 50% aqueous methanol and deuterated oak lactone glucoside, that is, [$^2H_4$]-**3** added (10 μg/mL) as an internal standard; the preparation of both glucoside **3** and its isotopically labeled derivative [$^2H_4$]-**3** is described elsewhere.[19,23] Samples were then filtered through a 0.45 μm GHP membrane (Acrodisc, PALL Life Sciences) prior to analysis.

Preparation of Leaf and Shoot Extracts. Extracts of leaves and shoots were also prepared according to previously described methodology.[13] Frozen plant material (cut in small pieces) was ground in a small grinder, and then a subsample (1 g, in triplicate) was extracted in 5 mL of Milli-Q water with shaking for 1 min and ultrasonication for 10 min. The resulting mixture was centrifuged (3000*g* for 5 min) and the supernatant collected. The remaining pellet was further extracted in another 5 mL of Milli-Q water as above. The supernatants were then combined and aliquots (5 mL) taken for SPE (as per the preparation of fruit extracts)

Instrument Analysis. An Agilent 1290 Infinity UHPLC combined with the 6490 QQQ LC/MS with iFunnel technology was used for identification and/or quantitation of oak lactone glycoconjugates. Data acquisition and processing were performed using MassHunter software version B.06.00 (Agilent, Palo Alto, CA, USA). Aliquots (10 μL) of each fruit, leaf, and shoot extract were injected and the components separated using a 150 mm × 2 mm i.d., 4 μm, Synergi Hydro-RP 80 Å column with a 4 mm × 2 mm i.d. guard column packed with the same material (Phenomenex, Lane Cove, NSW, Australia). The column temperature was maintained at 25 °C. A binary gradient was used with the mobile phases comprising 0.1% acetic acid in water (v/v) (eluent A) and 0.1% acetic acid in acetonitrile (v/v) (eluent B). Using a flow rate of 0.3 mL/min, the elution gradient was as follows: 0−10 min, 10% B; from 10 to 70% B in 1 min; then held at 70% B for 5 min (total runtime was 16 min). The column was re-equilibrated for 10 min prior to the next injection. The mass spectrometric analysis was performed using APCI in negative mode. The following source conditions were used: gas temperature, 290 °C; vaporizer, 370 °C; gas flow, 12 L/min; nebulizer pressure, 35 psi; and capillary voltage, 2500 V. Nitrogen was used as the nebulizer and collision cell gas. Quantitative analysis was performed in multiple reaction monitoring (MRM) mode, and the following mass transitions were monitored: *m*/*z* 335 → 119, 89, for unlabeled glucoside **3** and *m*/*z* 339 → 119, 89, for the internal standard, that is, [$^2H_4$]-**3**. The underlined ions were used as the quantifier ion, whereas the other ions were used as qualifiers. The transitions were monitored using a dwell time of 50 ms, a collision energy of 20 V, and a cell accelerator voltage of 4 V. The linear calibration range (LNR) was from 10 to 1000 μg/L in matrix-matched standards. The limit of detection (LOD) was 1 μg/L with a signal/noise ratio of 3, and the limit of quantitation (LOQ) was 10 μg/L with a signal/noise ratio of 10. Qualitative analyses of selected control and treated leaf samples were also performed, using full scan and selective ion monitoring (SIM) modes. Full scans ranged from *m*/*z* 50 to 600, with a step size of 0.1 amu. In SIM mode, the parent ion and acetate adducts of gallateglucoside, glucosylglucoside, and rutinoside glycoconjugates were monitored, with dwell times of 200 ms.

RESULTS AND DISCUSSION

Fruits, leaves, and shoots were collected for chemical analysis at three different time points, including at maturity and following treatment of grapevines with foliar applications of either oak extract or oak lactone. The oak lactone content of fruit was determined by GC-MS (Table 1), whereas the concentrations of a β-D-glucopyranoside of 3-methyl-4-hydroxyoctanoic acid in fruits, leaves, and shoots were determined by UHPLC-MS/MS (Table 2).

Table 1. Concentrations of *cis*- and *trans*-Oak Lactone (1a and 1b) in Fruit from Grapevines Treated with Oak Extract or Oak Lactone

Neither of the oak lactone isomers was detected in fruit sampled from control grapevines, as expected. Similarly, oak lactone could not be detected in fruit from grapevines treated with oak extract, but this most likely reflected the relatively low application rate, being equivalent to approximately 70 μg of oak lactone per vine. In contrast, the dose rate for the treatment comprising the direct application of oak lactone to grapevines was several orders of magnitude higher, at approximately 1500 mg of oak lactone per vine. Similar concentrations of *cis*- and *trans*-oak lactones were detected in fruit corresponding to this treatment, albeit only when bunches were exposed. A decline in oak lactone concentrations was observed as fruit ripened, which could in part be explained by increasing berry volume and water content[24] and possibly also volatilization (evaporation), but would also be expected if oak lactone were indeed being absorbed and assimilated by the grapevine in glycoconjugate precursor forms.

The earlier development of a quantitative method for the determination of the β-D-glucopyranoside of 3-methyl-4-hydroxyoctanoic acid **3**,[19] hereafter referred to as "glucoside", enabled the accumulation of glycoconjugate forms of oak lactone in different parts of the grapevine, that is, fruits, leaves, and shoots, to be investigated (Table 2). The oak lactone glucoside was not detected in fruit harvested from control grapevines, again as expected, albeit trace levels, that is, approximately 10 μg/kg, were detected in control leaves and shoots collected at maturity. In contrast, treatments involving foliar applications of either oak extract or oak lactone yielded glucoside **3** in fruits, leaves, and some shoot samples, with the highest concentrations being observed in leaves sampled at t = 1 from grapevines treated with oak lactone. The marked differences observed between the glucoside **3** content of samples derived from grapevines treated with oak extract versus oak lactone can again be explained by the different oak lactone dose rates associated with these treatments. Moderate glucoside levels, up to 261 μg/kg, were observed in leaves from grapevines treated with oak extract, whereas low levels, $\leq$5 μg/L, were observed in fruit, but only where bunches were uncovered and thus also exposed to the treatment. Glucoside **3** was not detected in the shoots of grapevines treated with oak extract.

Extremely high levels of glucoside **3** were observed in leaves from grapevines treated with oak lactone. Indeed, the concentrations far exceeded the working range (1−1000 μg/L) for which the stable isotope dilution assay used for quantitation was originally developed.[19] As such, the values reported for these samples are considered to be approximations, rather than absolute concentrations. Nonetheless, these results clearly demonstrate the accumulation of large quantities of glucoside **3** in the leaves of grapevines treated with oak lactone. The oak lactone glucoside was also observed in both the fruits and shoots of these grapevines, albeit at much lower levels than for leaves, that is, at levels up to 349 μg/L and 269 μg/kg (for fruits and shoots, respectively). When fruit was placed in plastic bags to prevent direct exposure to the oak lactone solution, glucoside **3** was still detected, but at concentrations approximately 1 order of magnitude lower than for fruit that remained exposed, at between 20 and 40 μg/L. The differences observed in glucoside **3** concentrations between covered and uncovered bunches might be explained by translocation of either oak lactone or the glucoside from leaves to fruit, but the higher amounts observed in uncovered grapes indicate oak lactone was directly absorbed by grapes, albeit to a lesser extent than by leaves.

An authentic sample of **3** was analyzed by UHPLC-MS/MS in MRM mode as a reference compound, and its retention time (Figure 2a) and product ion spectrum (Figure 3a) compared

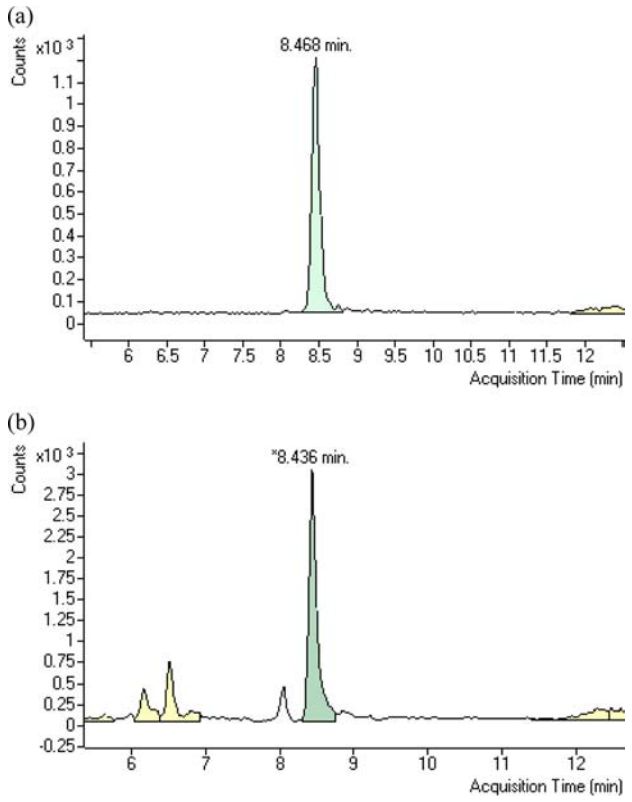

Figure 2. UHPLC-MRM chromatograms of (a) the glucoside reference compound **3** and (b) an extract of fruit taken from grapevines treated with oak lactone.

with those obtained for an extract of fruit corresponding to grapevines treated with oak lactone (Figures 2b and 3b). The reference compound eluted at a retention time of 8.47 min, which was close to that of the predominant peak present in the fruit extract, being 8.44 min. Furthermore, the mass transitions

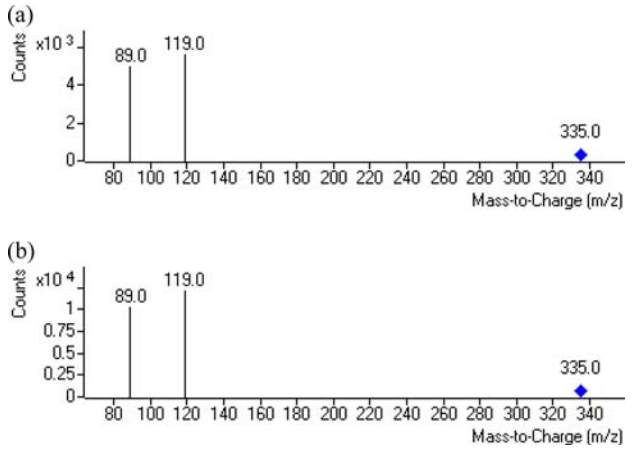

Figure 3. Product ion spectra of m/z 335 obtained by UHPLC-MS/MS of (a) the glucoside reference compound **3** and (b) an extract of fruit taken from grapevines treated with oak lactone.

J. Agric. Food Chem. 2015, 63, 4533−4538

m/z 336 → 119 and 89 obtained for the reference compound also matched those of the peak observed in the fruit extract. Together, these results validate the presence of glucoside **3** as a component of fruits and leaves of grapevines treated with oak extract and of fruits, leaves, and shoots of grapevines treated with oak lactone. This was in fact a somewhat unexpected result, because for glycosylation to occur, oak lactone must first undergo a ring-opening step to form 3-methyl-4-hydroxyoctanoic acid **2**, that is, an intermediate possessing the free hydroxyl function group required for glycosylation. Although the presence of glucoside **3** in fruits and leaves of grapevines treated with oak extract could conceivably be attributed to its presence as a constituent of the original oak extract (which was not measured), the accumulation of such large quantities of **3** in samples, leaves especially, derived from grapevines treated with oak lactone can only be explained by ring-opening and glycosylation of oak lactone post-treatment. Besides, in oak wood, the predominant oak lactone glycoconjugate precursor is the gallateglucoside, (3*S*,4*S*)-3-methyl-4-*O*-(6′-*O*-galloyl)-*β*-D-glucopyranosyloctanoic acid.[20] Leaf samples taken from grapevines treated with oak lactone (and from control grapevines) were analyzed by UHPLC-MS/MS in scan and SIM modes, in an attempt to identify mass transitions corresponding to the gallateglucoside, but there was no evidence to suggest its presence in the samples analyzed. The gallateglucoside derivative of **2** may therefore be a precursor that is unique to oak wood. In contrast, mass transitions corresponding to a glucose-glucose disaccharide, that is, m/z 557 → 497, were identified in extracts of leaves collected at t = 3 from grapevines treated with oak lactone, but not in extracts of leaves from control grapevines (Figure 4), suggesting further derivatization of glucoside **3** occurred. Without authentic reference compounds, the exact nature of this disaccharide cannot be confirmed; that is, it was not clear if the second sugar moiety was bound as a glucosylglucoside or as an ester via glycosylation of the carboxylic acid functionality. However, semiquantitation of the disaccharide using the standard curve for glucoside **3** suggested it accumulated at several-fold higher concentrations than the glucoside, which provides a plausible explanation for the declining concentrations of glucoside **3** observed in extracts of leaves with ripening (Table 2), that is, between t = 1 and t = 3 (maturity).

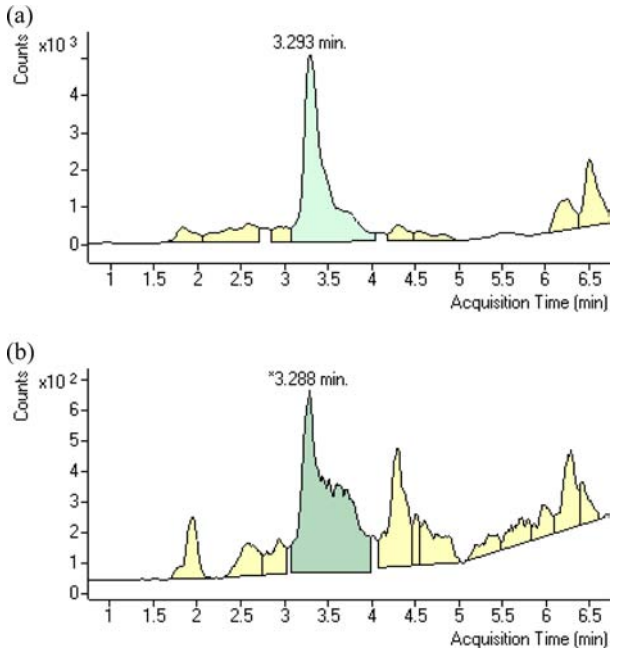

Figure 4. UHPLC-SIM chromatograms obtained for mass transitions corresponding to a glucose-glucose disaccharide, that is, m/z 557 → 497, in extracts of leaves taken from (a) grapevines treated with oak lactone and (b) control grapevines.

The rates of lactonization of the *threo*- and *erythro*-isomers of 3-methyl-4-hydroxyoctanoic acid **2** have been shown to be distinctly different, with lactonization of the *erythro*-isomer (to form *trans*-oak lactone **1b**) occurring at higher rates than lactonization of the *threo*-isomer (to form *cis*-oak lactone **1a**).[25] In the current study, the depletion of *cis*- and *trans*-oak lactones observed in fruit with ripening (Table 1) occurred at similar rates, suggesting stereochemistry did not influence the biochemical pathway responsible for the ring-opening step.

These results demonstrated the presence of oak lactone glycoconjugates in fruits, leaves, and shoots of Monastrell grapevines following foliar applications of either a commercial oak extract or an oak lactone solution, with both ring-opening and glycosylation occurring after oak lactone was absorbed by grapevines from the surrounding environment. This explains why in previous studies oak lactone could be detected in wine made from fruit from grapevines that were treated with oak extract or oak lactone, but not in the fruit itself; that is, the oak lactone was likely present in one or more glycoconjugate forms.

several authors.[20−24] First introduced by Lanaud et al. working at CIRAD (Centre de Coopération Internationale en Recherche Agronomique pour le Développement), most of the microsatellites are designated as "mTcCIR" (microsatellite *Theobroma cacao* CIRAD plus continuous numbering. All 10 SSR markers originated from this microsatellite collection database.

If numerous variations at microsatellite loci are detectable within CCN-51, it can be assumed that it is no pure clone that is propagated exclusively vegetatively. In this case, it is most likely that cross-breeding occurred during cultivation of CCN-51.

MATERIALS AND METHODS

Plant Material. Solely authentic leaf material from CCN-51, Arriba, Criollo, and two samples of beans removed from fresh fruits of CCN-51 (C15 and C16) were used (Table 1). Plant materials were obtained from the INIAP (Instituto Nacional de Investigaciones Agropecuarias, Guayaquil, Ecuador), Botanical Garden Hamburg (Hamburg, Germany), CATIE (Centro Agronómico Tropical de Investigación y Enseñanza, International Cocoa Collection, Cartago, Costa Rica), and from the ICGD (International Cocoa Germplasm Database, University of Reading, England). A total of 14 samples were picked freshly and stored at −20 °C.

DNA Extraction, Purity, and Concentration. The DNA was extracted using DNeasy Plant Mini/Maxi Kit (Qiagen, Hilden, Germany) following the manufacturer's instructions. The purity and concentration of DNA extracts were determined by spectrophotometry (260/280 nm; NanoDrop, Thermo Fisher Scientific Oy, Finland).

Qualitative PCR. A panel of 10 microsatellite markers (mTcCIR1, mTcCIR6, mTcCIR8, mTcCIR11, mTcCIR12, mTcCIR15, mTcCIR18, mTcCIR24, mTcCIR25, and mTcCIR60) was employed (Table 2).[20,23,25] Only primer pairs were chosen that were supposed to produce clearly discriminable PCR product lengths for Arriba EET and CCN-51 clones according to SSR profiles deposited by ICGD (http://www.icgd.rdg.ac.uk/). Forward primers were fluorescence labeled with 6-FAM (Sigma Life Science, Hamburg, Germany).

The SSR analysis was carried out four times with each primer pair to ensure reproducibility. The PCR conditions previously published by Cryer et al.,[23] Lanaud et al.,[20] Saunders et al.,[26] and Irish et al.[25] had to be adjusted to the sample set. For successful amplification, both template concentration and annealing temperatures had to be increased over those previously published.

The optimized PCR conditions were as follows: For qualitative PCR, 20 ng of the extracted DNA was used. The PCR reaction mix consisted of 1× buffer (10× buffer: 1 mM $MgCl_2$, 5 mM Tris, 25 mM KCl, 1% Triton X-100 (m/v)), 0.8 mM dNTPs (Bioline GmbH, Luckenwalde, Germany)), 1 μM of each Primer (Invitrogen, Darmstadt, Germany), 0.3 U Taq polymerase, and 2 μg BSA (10 mg/mL, New England Biolabs GmbH, Frankfurt am Main, Germany) in a final volume of 20 μL. The PCR started with a 5 min denaturation step at 94 °C, followed by 35 cycles of 94 °C for 40 s, an annealing at 50 °C (for primer pair mTcCIR11)/55 °C (all other primer pairs) for 40 s, 72 °C for 40 s, and a final elongation step at 72 °C for 1 min.

Fragment Analysis. Amplified PCR products were diluted (1:20) with ddH_2O, and 1 μL of the diluted fragments was mixed with 1 μL of GeneScan-500-LIZ size standard (Life Technologies, Darmstadt, Germany) and 10 μL of Super-Di formamide (Nimagen, Nijmegen, Netherlands). The amplicons were denatured at 97 °C for 5 min and

[a]For each microsatellite, the up to five observed different alleles are individually designated by letters (A−E). Allele size (bp) is given below each letter, "+" = allele present; "−" = allele absent. Differences within CCN-51 are highlighted. In most cases, two fragment lengths are representing the two alleles (heterozygote). In some cases, both alleles show the same fragment length (homozygote).

immediately quenched on ice. For the separation and visualization of the PCR products, the eight-capillary sequencer 3500 Genetic Analyzer (Life Technologies, Darmstadt, Germany) was used with Nano POP 7 (Nimagen, Nijmegen, Netherlands) as a gel matrix. Default running conditions for fragment analysis were used according to the manufacturer's instructions. The allele sizes were estimated with GeneMapper Software 5 (Applied Biosystems/Life Technologies, Carlsbad, Germany). The correct base calling of the PCR products was checked manually. After obtaining the amplicons by the gene-mapper, a 1−0-matrix (1: amplicon present; 0: amplicon absent) in Excel-file format was created. The further statistical analysis was carried out by PAST. Within the cluster analysis, the neighbor joinings of Simpson, Jacard, Jukes, and Euclidean were used for the evaluation. The results for all four methods were identical. For the presentation, the evaluation by Simpson is shown.[27]

RESULTS AND DISCUSSION

In the present study, 14 cocoa samples, including 10 CCN-51, two Arriba, and two Criollo plants were analyzed with a set of 10 SSR markers. The estimated sizes of the PCR products correspond to the published allele sizes for these markers (Table 2).[20,23,25] In the following, amplicons with identical lengths of basepairs were expected and named as one homologue allele in a microsatellite locus.

Within this sampling set, the 10 microsatellites exhibited two to five alleles (A−E) per locus (Table 3). As expected, most microsatellite loci of CCN-51 and Arriba samples differed in allele sizes (e.g., mTcCIR8: CCN-51 with the alleles A and C, Arriba with alleles A and B) allowing a discrimination between the two cocoa types. However, the microsatellite patterns of the 10 CCN-51 samples also showed differences in allele sizes, which would not be expected for pure clones.

All samples from Ecuador (C1−C3) showed an identical microsatellite pattern. In these samples, eight SSR loci were heterozygote, showing two alleles of different fragment lengths; only two microsatellites (mTcCIR15 and mTcCIR 24) were homozygotes. In most cases, the same alleles were detected for C5, C6, C7, and C15, though in some cases only one of the two allels is present (e.g., C5 mTcCIR6, mTcCIR12, and

mTcCIR25), showing a loss of heterozygosity in this locus. For some microsatellite loci, no amplicons were detected (e.g., C15 mTcCIR1, mTcCIR11, and mTcCIR15). These observations of differences in allele pattern might be explained by the occurrence of somaclonal variation, a common phenomenon in trees, observed among others in coffea or Populus trees.[28−30] The slight genetic variability also is well in line with the results from the previous published chloroplast analyses, where the samples C1−C3, C5−C7, and C15 showed identical results for the $(TAAAG)_n$ repeat (all $n = 14$) and for the restriction analysis (all CCN-51 typical).[11] A detailed summary of the chloroplast differences is given in Table 4.

But, the samples C4, C8, and C16 exhibit diverse different genetic patterns. These samples revealed both a reduced number of alleles but also the presence of complete different alleles in several SSR loci (Table 4). Whereas C8 and C16 showed three, respectively two different amplicons, the ICGD sample (C4), showed the most distinct differences among the CCN-51 samples. For example, for the microsatellites mTcCIR6, mTcCIR11, mTcCIR12, mTcCIR15, mTcCIR18, and mTcCIR24, one allele differs from the Ecuadorian CCN-51 pattern, whereas for mTcCIR8, mTcCIR25, and mTcCIR60, only one allele is present, indicating a loss of heterozygosity as demonstrated above.

It should be noted that for these three samples, the results from the chloroplast analyses also showed a different picture (Table 4). Whereas the results for C8 and C16 were completely identical to classical Arriba samples ($(TAAAG)_6$ and Arriba typical restriction pattern), for C4 only a slightly shortened $(TAAAG)_n$ repeat was detected ($n = 12$). Furthermore, the restriction pattern of this sample only differed at one restriction site from the Ecuadorian CCN-51 pattern.

According to the microsatellite results (Table 3), a manual scoring shows that samples can be divided into four types: C1, C2, and C3 (type I); C5, C6, C7, and C15 (type II); C8 and C16 (type III); and C4 (type IV). This grouping seems to reflect the geographical origin of the cocoa. Type I originates from Ecuador; samples of types II (C15) and III (C16) originate from Costa Rica, where they are already traded as CCN-51 type I (C15) and CCN-51 type II (C16). The ICGD sample behaves as fourth type. Comparing this presumption with the dendrogram of the cluster analysis (Figure 1), it was observed that samples from types I and II form one cluster (group I). The samples of type III, C8 and C16 from Costa Rica, form a second group (group II) basically separated from group I. Again, the ICGD sample C4 (type IV) is situated at the basis of all other investigated CCN-51 individuals and forms a

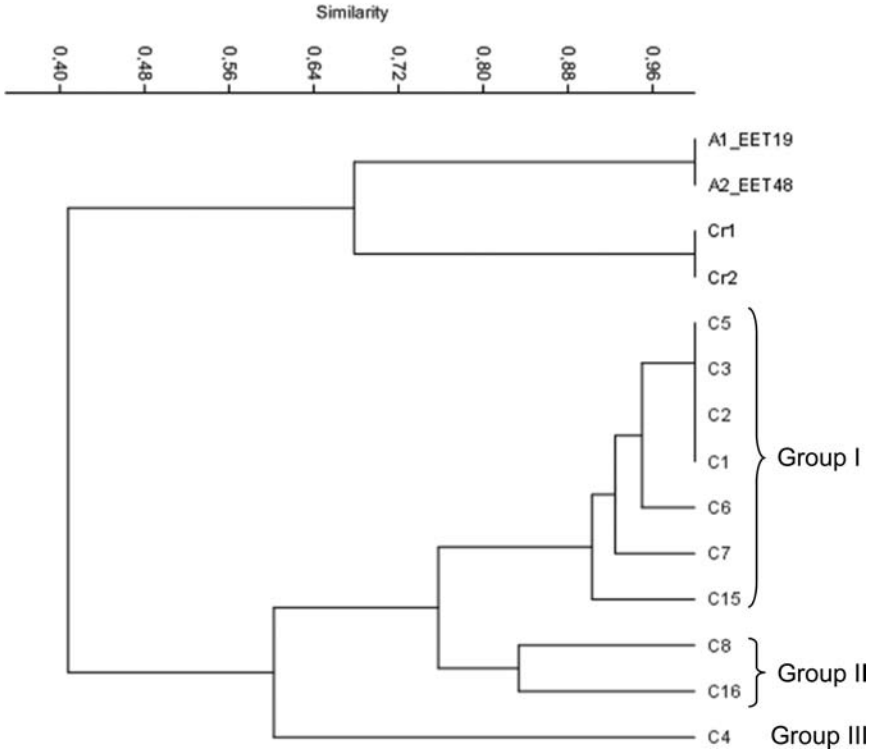

Figure 1. Dendrogram of the cluster analysis of the CCN-51, Arriba, and Criollo samples. Similarity measure by Simpson's index. The grouping of the CCN-51 samples suggests that there are three groups within this cocoa type.

DOI: 10.1021/acs.jafc.5b01462
J. Agric. Food Chem. 2015, 63, 4539−4544

distinct branch (group III). This individual shows different allele patterns in eight out of 10 SSR loci.

This grouping is well in line with the recent observations based on the chloroplast analysis ($(TAAAG)_n$ repeat and SNP analysis).[11] Taking these results into account, the same samples would be similarly grouped together: C1−C3, C5−C7, and C15 as one group; C8 and C16 as a second group; and C4 as a third group (Table 4).

Besides the CCN-51 samples, two Arriba and two Criollo were analyzed to classify the results in comparison to other cocoa types. The analysis of the microsatellite patterns of the two Arriba samples demonstrated a relatively high level of similarity. An apparent difference in Arriba was observed in the SSR locus mTcCIR12 (Table 3), which can be explained by sexual reproduction of the plant. The two Criollo samples showed nearly identical results but differed compared to the Arriba sample. This could be demonstrated by the microsatellites mTcCIR1, mTcCIR6, mTcCIR11, mTcCIR24, and mTcCIR25.

The previously published results of chloroplast marker analysis already gave reason to suggest that CCN-51 is not a pure clone. The present SSR analysis confirmed this by additional variations in the nuclear genome. This hypothesis is verified by different marker systems in two different genomes.

A possible explanation for these genetic variations within CCN-51 could be mistakes during propagation, including the growth of a seedling rootstock rather than the scion clone after grafting. Furthermore, in some cases, seed propagation rather than clonal propagation cannot be excluded. Moreover, mislabeling and misidentification in plant collections and arboreta cannot be ruled out. Misidentification of cocoa samples in germplasm collections was already observed earlier by other research groups.[31,32]

But, regarding the eight different SSRs of sample C4 in detail, it is striking that one of each microsatellite allele is a typical CCN-51 allele, whereas the second one is differing (Table 3). So, for C4 it is most likely that two different genomes were combined by a recent outbreeding event.

In the present study, various differences in the microsatellite pattern of CCN-51 could be detected. These genetic differences vary from slight differences in one to three SSR loci and a loss of heterozygosity up to complete different allele patterns in eight out of 10 microsatellite loci (CCN-51 sample C4 in Table 3). According to the statistical cluster analysis (Figure 1), the samples originating from Ecuador and some of those delivered from Costa Rica form one group, the two samples delivered from Costa Rica form a second group, and the ICGD sample forms an individual group. Hence, the suspicion is confirmed that one can differentiate between various types of CCN-51. Some of this genomic variation might be explained by somaclonal variation, but in other samples—especially in C4—outcrossing events probably occurred. The samples C4, C8, and C16 should be analyzed in more detail to clarify the doubtful classification into the CCN-51 type identified by different SSR patterns in the nuclear genome.

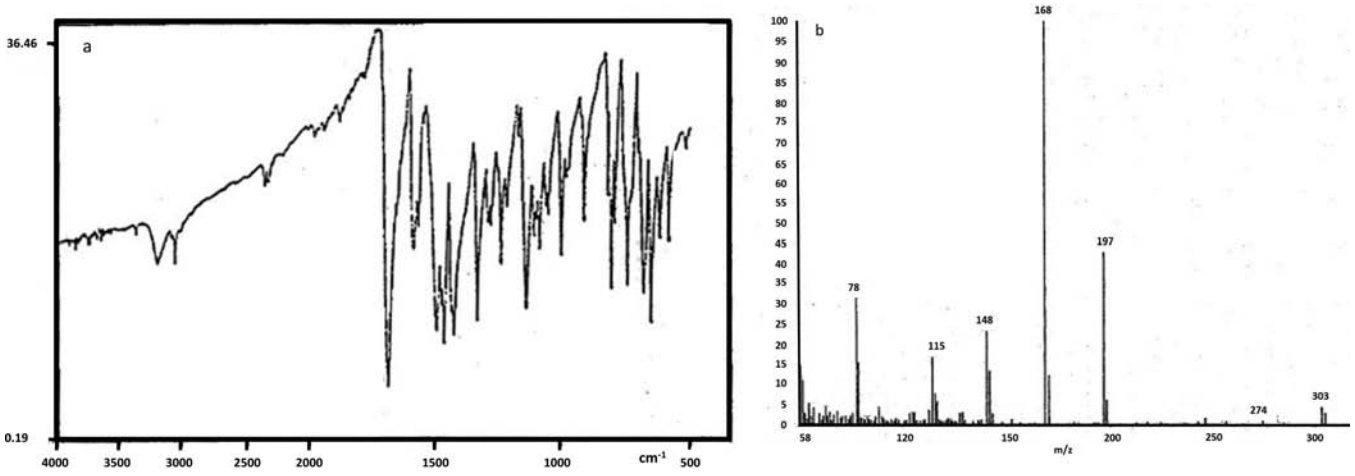

Figure 1. (a) Mass spectrum of DPKPH (electronic impact ionization); (b) IR spectrum of DPKPH.

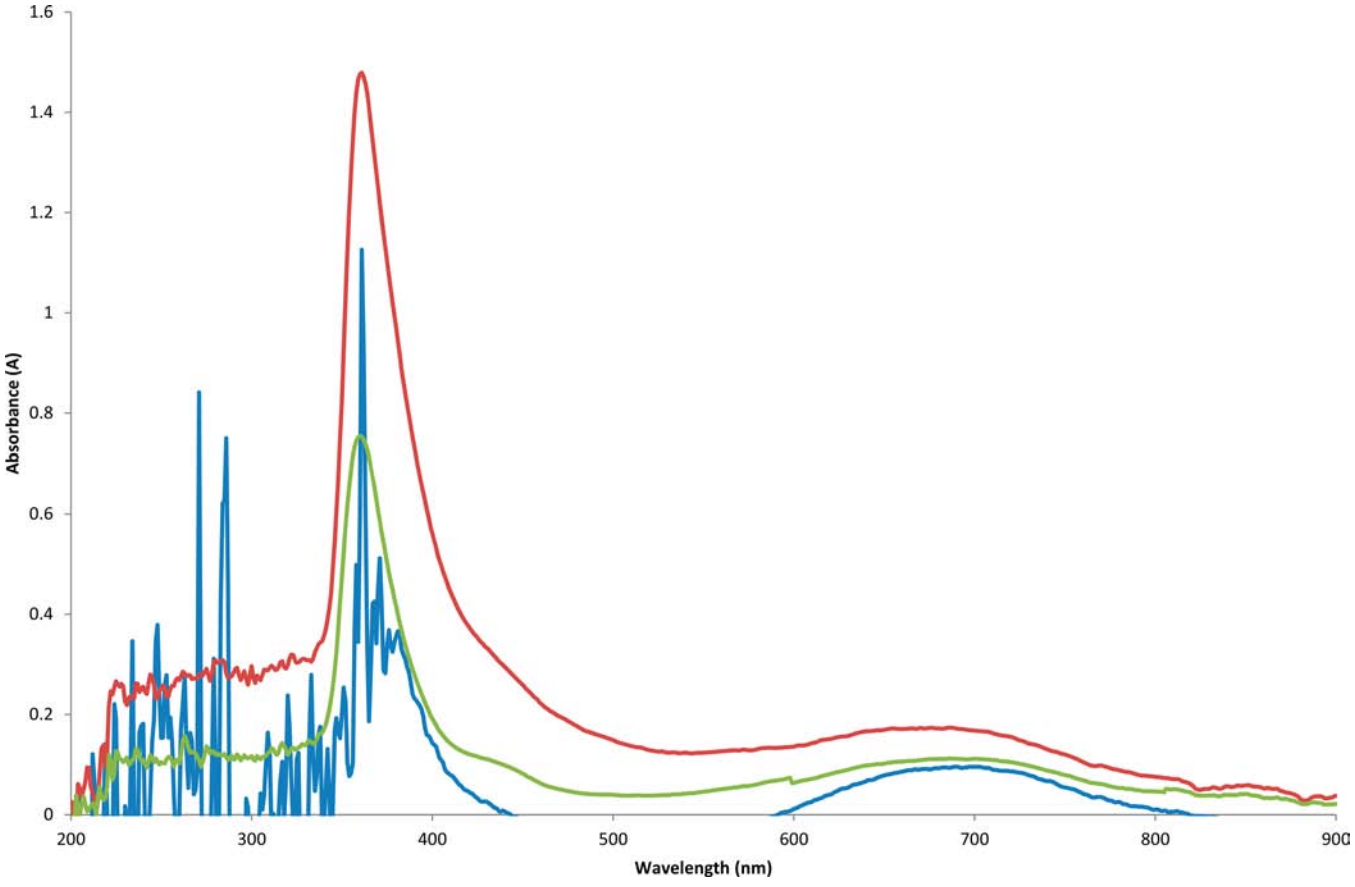

Figure 2. UV−vis spectra of Fe−DPKPH complex in water solution (spike of 1 mg L^{-1}), white wine (spike of 0.5 mg L^{-1}), and red wine (spike of 0.5 mg L^{-1}) samples. [DPKPH] = 1.25×10^{-4} mol L^{-1}.

EXPERIMENTAL PROCEDURES

Reagents and Solutions. Unless otherwise noted, all reagents were of analytical reagent grade. Picolinic acid ethyl ester (99.0%), 2,2′-dipyridylketone (97.0%), hydrazine (98.0%), NaOH (99.0%), ethanol absolute (96.0% v/v), acetic acid (97.0%), sodium acetate (98.5%), Br-ADAP, and ascorbic acid (99.0%) were purchased from Merck (Darmstadt, Germany). Solutions were prepared using high-purity deionized water with resistivity <18.2 MΩ cm (Milli Q, Millipore, Bedford, MA, USA). Standards of Fe(II) for calibration and to spike samples were prepared daily, by dissolving $FeSO_4 \cdot 7H_2O$ in 2% HCl from Merck.

Solutions of ascorbic acid dissolved in deionized water were prepared fresh daily. Finally, acetic acid/acetate buffer was used to control the pH in the sample during analysis. Buffer solution was prepared by dissolving equimolar proportions of acetic acid and sodium acetate in distilled water.

Wine Samples. Wine samples used in this study were purchased from the manufacturers. White wines with designation of origin (D.O.) *Jerez-Xéréz-Sherry* produced from Palomino fino grapes, Tio Pepe (Tío Pepe, Spain, 2008), and Romate (Sánchez Romate, Spain, 2009), as well as other white wines such as Casón Histórico, Don García, Don Simón (García Carrión, Spain), and Elegido (Viña Tridado, Spain) were analyzed. Rose wines Mateus Rose (Sogrape, Portugal, 2009)

DOI: 10.1021/acs.jafc.5b01571
J. Agric. Food Chem. 2015, 63, 4545−4550

with *D.O. Portugal* produced from a mixture of Portuguese red grapes Braga, Rufete, Tinta Barroca, and Touriga Franca, and, additionally, Carrefour (López Morenas, Spain), and Don Simón (García Carrión, Spain) were selected. Finally, the method was applied for the analysis of iron in the following red wines: Rincón (Marqués de Griñón, Spain, 2008) with *D.O. Dominio de Valdepusa* produced from Syrah and Garnacha grapes; Beronia Crianza (Spain, 2008) *D.O. Rioja* made from Tempranillo, Garnacha, And Mazuelo Grapes; and Río Mayor (Valero Winemakers, Spain, 2008) *D.O. Cariñena* produced from Garnacha, Tempranillo, And Cariñena grapes. Additionally, red wines Elegido (Viña Tridado, Spain) and Carrefour (García Carrión, Spain) were analyzed.

Synthesis of 2,2′-Dipyridyl Ketone Picolinoylhydrazone (DPKPH). The spectrophotometric reagent DPKPH was synthesized by condensation of equimolar amounts of the 2,2′-dipyridylketone and picolinoylhydrazide (PH) dissolved in ethanol, as reported by Mánuel-Vez and García-Vargas.[18] Reaction was quantitative, and the product was filtered and dried overnight at 80 °C to be stored dried. A purity of 99% was determined by elemental analysis. The product, DPKPH, was identified by mass spectrometry, and the following fragments were obtained: 303/197/168/148/115/78. The following bands were observed in an infrared spectrum for a sample supported on a KBr disk: 3200−300 cm^{-1} (ν_{N-H}), intramolecular hydrogen bond; 3050−3010 cm^{-1} ($\nu_{=C-H}$); 1690 cm^{-1} (amide I); 1490 cm^{-1} (amide II) (Figure 1). Finally, when dissolved in ethanol, the product presented maximum absorbance at 321 nm. The product was stored dry, and it was shown to be stable for up to 1 month in ethanolic solution at 4 °C.[19]

Apparatus. A pH-meter Jenway model 4330 was used during sample preparation, and spectrophotometric determination of Fe(II) was carried out in a Jenway 6300 spectrophotometer (Jenway, Stone, UK) using plastic cuvettes. Solaar series (UNICAM, UK) flame atomic absorption spectrometer (FAAS) was used for analysis of total Fe in validation studies as a reference method Commission Regulation (ECC) No. 2676/90 of September 1990 determining European Community methods for the analysis of wines for Fe analysis.[20] Identification of DPKPH was carried out using an IR spectrophotometer PerkinElmer 1600 FT-IR Series (PerkinElmer, Boston, MA, USA) and a VG 12250 mass spectrometer (VG Analytical Ltd., Wythenshaw, UK) using electronic impact as a source of mass fragments.

Procedure. The complexation of iron with DPKPH presents maximum yield at pH 4.9;[19] for this reason sample pH was adjusted prior to analysis using a small volume of 2 M NaOH that depended on the wine sample, so dilution of the sample was negligible. Maximum absorbance was observed at λ = 380 nm ($\varepsilon = 3.24 \times 10^4$ L mol^{-1} cm^{-1});[19] however, some interferences can also be detected at 380 nm associated with wine matrix components.[21] Consequently, a secondary maximum at 700 nm ($\varepsilon = 6.7 \times 10^3$ L mol^{-1} cm^{-1}) was selected for measuring $Fe(DPKPH)_2$ due to its better selectivity (Figure 2). Fe determination was in all cases carried out at room temperature after the samples had been filtered through a 0.45 μm pore sized nylon filter.

Formation of the green-blue complex $Fe(DPKPH)_2$ was directly conducted in a volumetric flask. This reaction takes place immediately after shaking the flask to homogenize the mixture. Conditions for application of the method were as follows in the case of total Fe analysis: 5 mL of sample or standard was placed into a 10 mL volumetric flask, 2 mL of 1 mol L^{-1} acetic acid/acetate buffer was added, followed by 1 mL of ascorbic acid 2×10^{-3} mol L^{-1} ascorbic acid and 2 mL of 6.24×10^{-4} mol L^{-1} DPKPH. Absorbance was measured at 700 nm. In the case of Fe(II) analysis, ascorbic acid was substituted by ultrapure water.

In the case of total Fe analysis, ascorbic acid was also added to ensure that Fe is in the form of Fe(II); the sample and all reagents were added in the following order: 5 mL of sample, 1 mL of ascorbic acid, 2 mL of acetic acid/acetate buffer, and 2 mL of DPKPH dissolved in ethanol. The signal was again measured at 700 nm.

To enhance the analytical signal due to Fe complexation, univariate optimization of DPKPH concentration and concentration of acetate buffer were carried. Furthermore, addition of ascorbic acid for analysis of total Fe was also studied.

Statistics. The extent of matrix effects on Fe determination was evaluated by comparing the slope of calibration curves and the analyzed total Fe concentration obtained by direct calibration using aqueous standards and by the standard additions method (SAM). In the case of direct calibration blank samples were prepared using an ultrapure water solution containing the reagents, and the standards were prepared by addition of a known concentration of Fe by dilution of a 1000 mg L^{-1} standard of Fe(II). SAM was applied by the addition of known spiked concentrations of Fe to the samples to build a calibration curve in which the blank was the sample itself without any spike. Concentration of Fe in the sample is estimated, by the standard additions method, as the intercept of the curve in the x axis. If the slope of the calibration curve using aqueous standards is comparable with that obtained by the SAM method, the method can be considered free of interferences.[22] Results were compared by a t test after three replicates of each sample were analyzed (t_c = 2.78). In the cases that t value was smaller than t_c, the null hypothesis that there is no evidence of significant difference between the results of the two methods was accepted with a 95% level of confidence.[22]

The limit of detection was calculated as the concentration that offered a response equal to the average of 10 independent blank samples plus 3 times its standard deviation. The limit of quantification was calculated as the concentration that offered a response equal to the average of 10 independent blank samples plus 10 times its standard deviation. The linearity of the method was evaluated using the criterion that the addition of a new standard of higher concentration resulted in a deviation of 5% between the measured and the theoretical concentration.[22]

To evaluate the accuracy of the method, three replicates of every sample were analyzed In the case of total Fe analysis, results were compared with those obtained by the reference method of Commission Regulation (ECC) No. 2676/90 of September 1990 determining Community methods for the analysis of wines for Fe analysis. For Fe(II) analysis results were compared with those obtained by the spectrophotometric determination of Fe(II) with Br-ADAP.[17] Comparisons were carried out by a t test for comparison of average experimental data (n = 4, α = 0.05, t_c = 2.78).

RESULTS AND DISCUSSION

Optimization of Fe(II) Complexation by DPKPH and Spectrophotometric Determination. Univariate optimization of the method was carried out using the analytical signal at 700 nm as a response factor. Fe(II) analysis was optimized by studying the effect of DPKPH and acetic acid/acetate buffer concentration in the presence of ascorbic acid to ensure that Fe was as Fe(II). The effect of ascorbic acid on the signal for total Fe was also evaluated.

Formation of the Fe(II)−DPKPH complex presents maximum yield at pH 4.9, in aqueous solutions containing up to 15% v/v ethanol.[21] For this reason the pH in the samples was buffered at pH 4.9 using acetic acid/acetate buffer during the whole study. All experiments were carried out using a 10 mL flask in which 5 mL of sample was placed. Concentrations of reagents are referred to the volume of the flask.

First of all, the effect of DPKPH concentration on the instrumental signal was studied. This study was conducted using water samples with an Fe concentration of 1 mg L^{-1} prepared by dilution of a standard of 1000 mg L^{-1} prepared by solution of $FeSO_4$. Ascorbic acid was added at a concentration of 30×10^{-4} mol L^{-1} during DPKPH optimization, and 0.5 mol L^{-1} acetic acid/acetate pH buffer was used. As can be observed in Figure 3, the absorbance due to the formation of the $Fe(DPKPH)_2$ complex was enhanced by an increase of the ligand concentration until it stabilizes at 1.25×10^{-4} mol L^{-1}. This concentration was used for further experiments.

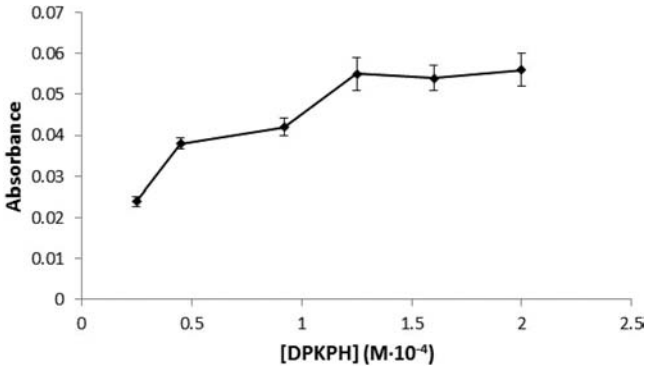

Figure 3. Optimization of DPKPH in 15% v/v ethanolic solution dissolved in water. Sample pH, 4.9; Fe concentration, 1 mg L^{-1}. Error bars represent the standard deviation of the average.

Thus, acetic acid/acetate buffer concentration to keep pH 4.9 in the sample was optimized. Figure 4 shows that absorbance

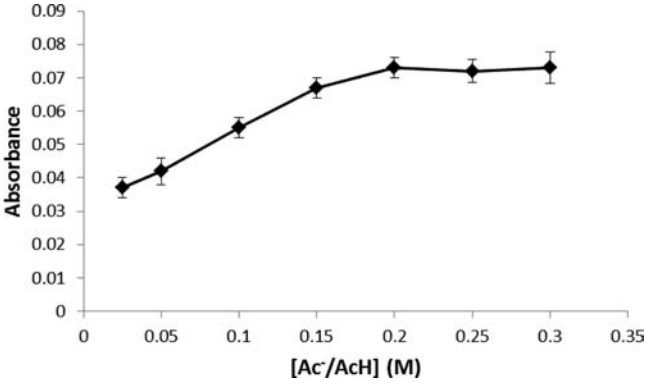

Figure 4. Optimization of acetic acid−acetate buffer (pH 4.9) for Fe concentration 1 mg L^{-1} and 1.25 × 10^{-4} mol L^{-1} DPKPH concentration. Error bars represent the standard deviation of the average.

was increased from buffer concentration 0.025 mol L^{-1} to 0.2 mol L^{-1}, being constant for higher concentrations. For this reason, 0.2 mol L^{-1} was selected as optimum concentration.

Finally, ascorbic acid concentration was optimized by keeping constant the optimized value of DPKPH and buffer concentration. Results showed that the analytical signal was increased with the addition of ascorbic acid up to 20 × 10^{-5} mol L^{-1} (Figure 5). This way the total concentration of Fe could be analyzed.

Effects of Wine Matrix on the Spectrophotometric Determination. Due to the complexity of the wine samples matrix, the effect of interferences that may appear in the samples affecting the Fe(II) complexation by DPKPH has been evaluated (Figure 2). This study has been performed for analysis of total iron. First, the effect of the presence of foreign ions that could compete in $Fe(DPKPH)_2$ formation was studied in white wine Tío Pepe (D.O. Jerez-Xéréz-Sherry, Spain, 2008) and red wine Río Mayor (D.O. Cariñena, Spain, 2008). For this study, wine samples were spiked with 1 mg L^{-1} of Fe(II). Cationic interferences were added as their chloride, nitrate, or acetate salt, and anionic interferences were added as sodium or potassium salts. Interference concentration was considered to have a negative effect on the method response if a variation of the analytical signal >4% was observed. As can be seen in Table 1, most anionic species are tolerated at relatively

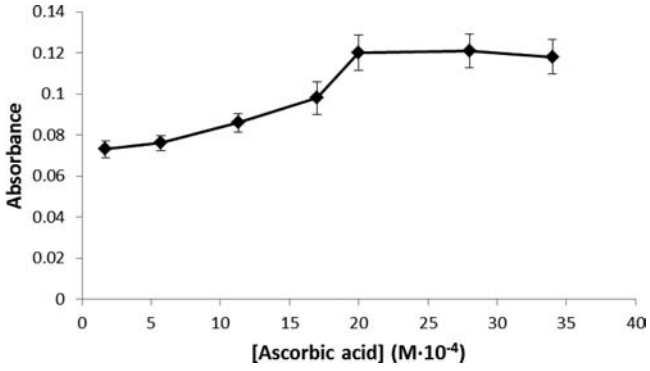

Figure 5. Effect of ascorbic acid concentration on the analytical signal. Fe concentration, 1 mg L^{-1}; sample pH, 4.9; buffer concentration, 0.2 mol L^{-1}; DPKPH concentration, 1.25 × 10^{-4} mol L^{-1}. Error bars represent the standard deviation of the average.

Table 1. Tolerance Limits of Chemical Interferences on Fe(II) Determination in White and Red Wine Samples

interference	concentration tolerated (mg L^{-1})
Cl^-, NO_3^-	10000[a]
CO_3^{2-}, Ca(II), Mg(II), Al(III)	950

high concentration. Furthermore, the main cationic species that coexist with Fe in wine, Ca(II), Mg(II), K(I), Na(I), Zn(II), Cu(II), Mn(II), and Se(II), do not affect signal due to Fe(II) in the concentrations at which they are normally found. This fact proves that the proposed method is highly selective for measuring Fe in wines.

However, the complexity of the wine matrix is not restricted to the aforementioned interferences. To contrast the robustness of the method against wine matrix, including ethanol concentration, results obtained by direct calibration and by the standard additions method were compared.[22] In particular, the slope of calibration curves and the analyzed total Fe concentrations using both methods were compared. This study was carried out on wine samples of different nature and ethanolic concentration, after the addition of 1 mg L^{-1} Fe: one white wine, Tío Pepe (D.O. Jerez-Xéréz-Sherry, Spain, 2008), and one red wine, Río Mayor (D.O. Cariñena, Spain, 2008). Slopes of direct calibration and standard additions method were compared by a t test. As shown in Table 2, there were no significant differences between the slopes for the direct calibration and the standard additions method (n = 4, α = 0.05). Finally, results of total Fe concentration analysis using both methods were compared, showing that there were no significant differences between the results due to matrix sample (Table 2). Thus, direct calibration could be used for analysis of Fe in white, rose, and red wines free of interferences of sample matrix, including ethanol concentration up to 15% v/v ethanol.

Analytical Features. Prior to application of the method to commercial wine samples, analytical features were evaluated. Limits of detection and quantification were calculated after

measurement of 10 reagent blank samples containing ultrapure water and the optimized concentrations of DPKPH, ascorbic acid, and acetate buffer. In these conditions, the method offered a limit of detection of 0.005 mg L^{-1}, a limit of quantification of 0.017 mg L^{-1}, and a linear response of up to 6 mg L^{-1}; for this reason samples containing higher concentrations were diluted before analysis. These analytical features allowed the use of this method in the analysis of Fe at the concentration level in which it normally appears in wine samples.

Application to Commercial Wine Samples. Finally, the capability of this method to selectively determine Fe(II) in wines was evaluated using different wine samples. In particular, five red wines, six white wines, and three rose wine were analyzed. In this section, results for Fe(II) and total Fe are discussed.

In the case of total iron concentration results were compared with those obtained by the reference method Commission Regulation (ECC) No. 2676/90 of September 1990 determining Community methods for the analysis of wines for Fe analysis.[20] Comparisons were carried out using a t test for three independent replicates of each sample. Results for total concentration of Fe by both methods were in good agreement in the two types of wine used (Table 3). This confirms the applicability of the spectrophotometric analysis of Fe in wine samples using DPKPH as a ligand, free of sample matrix effects for white, rose, and red wines.

Although some Fe(III) could be measured as Fe(II), the broadly accepted method of spectrophotometric determination by complexation of Fe(II) with Br-ADAP has been used as a reference method for selective analysis of Fe(II).[17] Results obtained by DPKPH complexation were compared with the reference method using a t test for three independent replicates of each sample (Table 3). Results confirmed the suitability of DPKPH for selective analysis of Fe(II) in wine samples.

In all cases the concentration of Fe(III) was smaller than the Fe(II) concentration. This can be explained by the reductive conditions of wine samples that prevents oxidative damage. Similar distribution of Fe ions has been observed for other wines such as sweet wines from Brazil, which could be explained by reductive characteristics of the wines.[17] Additionally, higher levels of Fe(III) were observed in the case of red wines if compared with rose and white wines.

For these reasons, spectrophotometric determination of Fe(II) and Fe using DPKPH as a colorimetric reagent appears as a simple and fast alternative to existing analytical methods for iron speciation in wine samples.

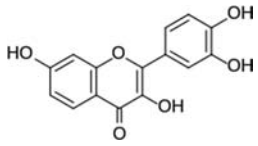

Figure 1. Structure of fisetin (3,7,3′,4′-tetrahydroxyflavone).

and facilitate the reparation of wrinkles in the skin.[24] Development of MMP inhibitors is a potential strategy for photoaging therapy.[5,25,26] In the literature, it had been reported that fisetin inhibited UV-induced ROS and activation of NF-κB and MAP kinase in lens epithelial cells.[27] However, few studies exist on the effect of fisetin against UV-induced photodamage in human skin and the related mechanisms. Therefore, this study investigates the potential mechanisms by which fisetin counteracts UVB-induced overexpression of MMPs/MAP kinases, COX-2, AP-1, and MMPs, the degradation of IκB and translocation of NF-κB, and the reduction in type I procollagen levels in human skin fibroblasts.

MATERIALS AND METHODS

Materials. Fisetin, DL-dithiothreitol, phenylmethylsulfonyl fluoride (PMSF), and Triton X-100 were purchased from Sigma-Aldrich Chemicals Corporation (St. Louis, MO). Collagenase was purchased from Calbiochem, Merck (Darmstadt, Germany). Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum (FBS), penicillin−streptomycin, and trypsin−ethylenediaminetetraacetic acid (EDTA) were purchased from Gibco, Invitrogen (Carlsbad, CA). Coomassie Blue R-250, dibasic sodium phosphate, lgepal CA-630, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), tris-(hydroxymethyl)aminomethane (Tris), and sodium dodecyl sulfate (SDS) were purchased from USB Corporation (Cleveland, OH). c-Jun, phosphor-c-Jun, NF-κB p65, and IκB antibodies were purchased from Cell Signaling Technology (Beverly, MA). Donkey anti-goat p38, p-p38, IgG-HRP, cAMP response element-binding protein (CREB), phosphor-CREB, ERK1, p-ERK 1/2, JNK1, p-JNK, MMP-1, MMP-3, and MMP-9 antibodies were purchased from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA).

Cell Culture. Human foreskin fibroblasts (Hs68) were purchased from the Bioresources Collection and Research Center, Food Industry Research and Development Institute, Hsinchu, Taiwan. The cells were cultured in DMEM, which contained 10% FBS, 100 units/mL penicillin, and 100 units/mL streptomycin and were maintained at 37 °C in a humidified, 5% CO_2 incubator.

UVB Irradiation Dose. Cells were washed with phosphate-buffered saline (PBS) and covered with PBS for UV irradiation using a UV lighter (302 nm, CL-1000M, UVP, Upland, CA). The UVB irradiation dose was 40 mJ/cm^2 (exposure time was 15 s) according to the previous studies.[6,28] This dose equates to about 23 s exposure at the noontime on July in the middle of Taiwan measured by a UV meter (UVP, Upland, CA). At this UV dose, the cell viability does not reduce considerably, whereas the protein expression is induced. After UVB irradiation, PBS was replaced with a serum-free medium and then incubated for 24 h for the MTT and various assays.

Cell Viability Test. A MTT assay was performed to examine the viability of the cells as previous studies described.[25,29] After being irradiated with UVB, the cells were incubated with various concentrations of fisetin for 24 h and the culture medium was replaced with MTT solution (0.5 mg/mL) and incubated. The MTT solution was then removed, and 10% SDS−HCl was added. The absorbance of the dissolved formazan crystals was then determined at 570 nm using a spectrophotometer (Tecan, Grodig, Austria).

Measuring Intracellular ROS. Intracellular ROS generation was measured using a 2′,7′-dichlorodihydro fluorescein diacetate (DCFH-DA) fluorescence dye assay as a previous study described, with slight modification.[6,30] Fibroblasts were seeded into 24-well plates and irradiated with UVB. Subsequently, various concentrations of fisetin (5, 10, and 25 μM) were added and then incubated for 2 h. The cells were incubated with 10 μM DCFH-DA for 30 min. The fluorescence intensity was determined at 488 nm excitation and 520 nm emission using a fluorescence microplate reader (Thermo Electron Corporation, Ratastie, Vantaa, Finland), and images were observed under a fluorescence microscope (Leica DMIL, Wetzla, Germany).

Measurement of Total Collagen Synthesis. Total collagen synthesis in fibroblasts after UVB exposure was measured using the Sircol soluble collagen assay kit and modified on the basis of a previous study.[6,25] Briefly, a cell culture medium was collected and mixed with Sircol dye reagent and incubated. After centrifugation, ice-cold acid−salt washing reagent was added to the precipitate and then the mixture was centrifuged. The precipitate was dissolved using alkali reagent, and the absorbance was determined at 555 nm using an enzyme-linked immunosorbent assay (ELISA) reader (Tecan, Grodig, Austria).

Western Blot Analysis. The cells were harvested at the indicated time and washed twice with ice-cold PBS for western blot analysis. The cells were lysed in a cold lysis buffer; the lysates were centrifuged; and an aliquot of the lysate was used to determine the protein content by conducting a Bradford assay (Bio-Rad Laboratories, Hercules, CA). Equal amounts of proteins (30 μg) were separated using SDS−polyacrylamide gel electrophoresis (SDS−PAGE) and blotted onto polyvinyl difluoride membranes. The membranes were blocked with non-fat milk in a Tris-buffered saline and Tween 20 (TBST) buffer and then incubated overnight with specific antibodies. These were goat polyclonal antibodies, which are used against MMP-1 and type I procollagen, and mouse polyclonal antibodies, which are used against phosphor-CREB, CREB, MMP-3, MMP-9, ERK, p-ERK, JNK, p-JNK, p38, p-p38, c-Jun, phosphor-c-Jun, and NF-κB p65. The membranes were incubated with the corresponding horseradish-peroxidase-conjugated secondary antibody after washing with PBS buffer. Immunoreactive proteins were detected using the ECL western blotting detection system (Fujifilm, LAS-4000, Tokyo, Japan), and the signal intensity of each band was quantified using a densitometer system (Multi Gauge V2.2) and then normalized with the internal control (actin).

Immunofluorescence Staining. For immunofluorescence staining, 1 × 10^5 cells were cultivated on glass coverslips overnight. The medium was removed, and the cells were washed twice with a PBS buffer. The cells were fixed with 4% paraformaldehyde in PBS for 30 min. The fixed cells were blocked with 5% non-fat milk with 0.3% Triton X-100/PBS buffer for 40 min and incubated overnight, separately, with the primary antibody. After washing, cells were incubated with the Alexa Fluor 488 anti-rabbit IgG secondary antibody for 2 h (Invitrogen, Carlsbad, CA). The unbound secondary antibody was removed by washing the cells 3 times with a PBS buffer. Thereafter, the samples were counterstained with ProLong Gold antifade reagent with DAPI and observed using a microscope.

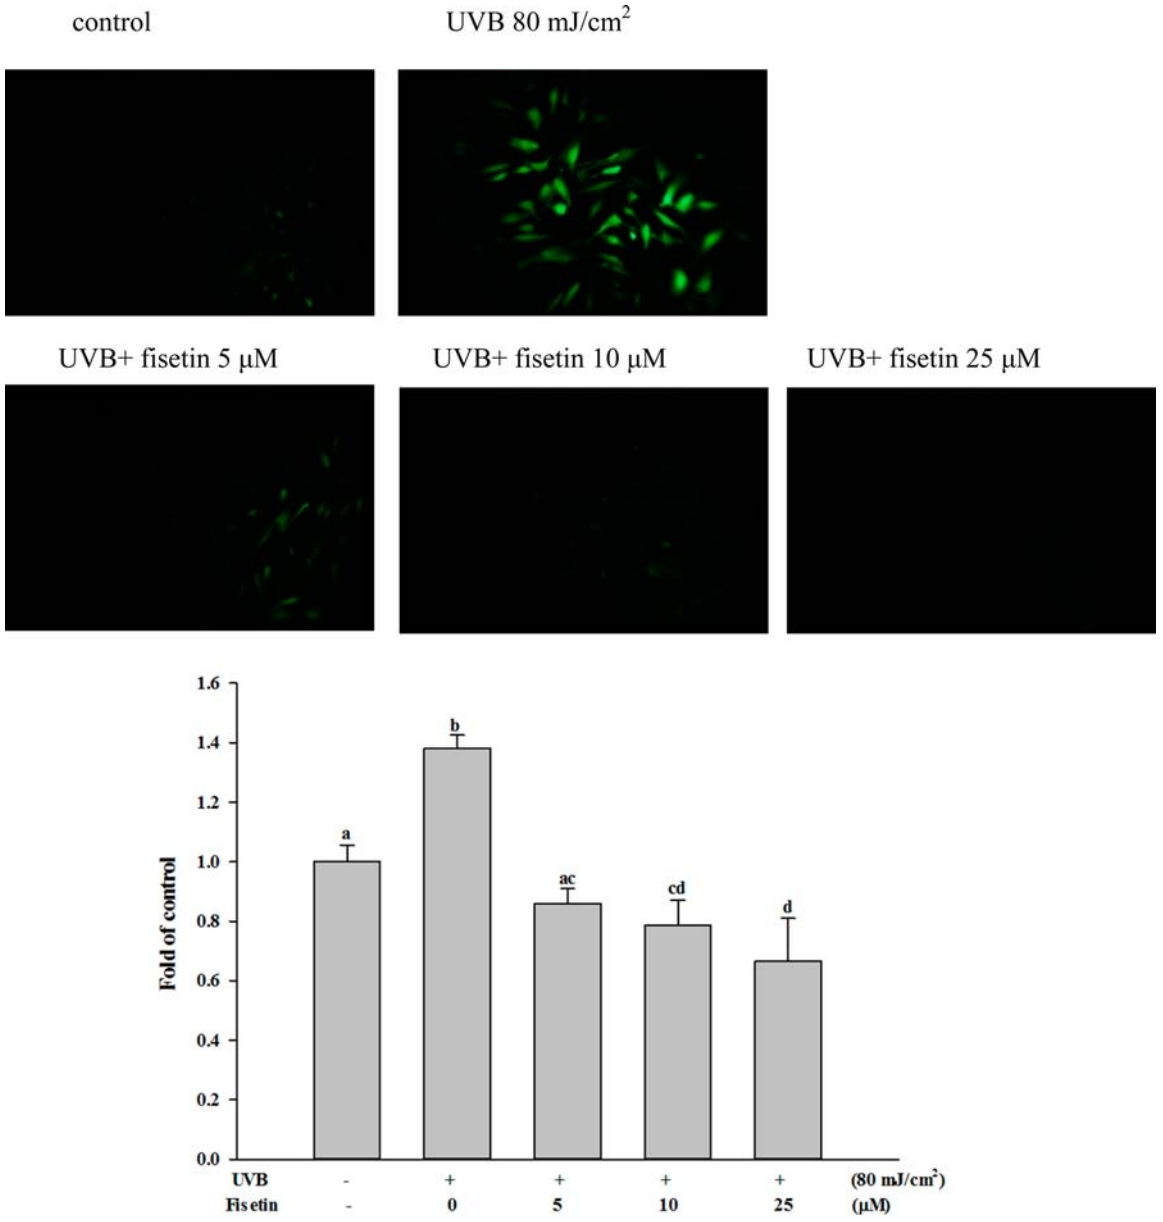

Figure 3. Repressive effect of fisetin on UVB-induced intracellular oxidative stress in human fibroblasts. Groups sharing the same letter are not significantly different ($p > 0.05$) as revealed by LSD post-hoc tests.

NO Measurement. The measurement of NO generation in human skin fibroblasts was by a previous study, with slight modification.[25] Cells were grown in a 6 well plate for 24 h before treatment. After UVB irradiation, cells were treated with different concentrations of fisetin for 24 h. Cell culture medium was then collected and mixed with Griess reagent (Promega, Madison, WI), and the absorbance of azo compound was determined at 540 nm using a spectrophotometer (Tecan, Grodig, Austria).

Quantitation of Prostaglandin E_2 (PGE_2). PGE_2 levels in cultured medium were determined using the protocol provided by the manufacturer of the kit (Cayman, Ann Arbor, MI). The cell culture and treatments were as described for the NO measurement.

Statistical Analysis. All measurements in the present study were obtained as averages of experiments that were at least three independent experiments performed in triplicate and are expressed as means ± standard deviation (SD). Differences between groups in experiments were analyzed for statistical significance using analysis of variation (ANOVA) with least significant difference (LSD) post-hoc tests or the Student's t test. $p < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Effect of Fisetin on the Cell Viability and UVB-Induced Phototoxicity. Safety is the primary criterion for skin-care products. Hs68 cells were treated with various concentrations of fisetin, and cell viability was measured using the MTT assay. The resulting survival curve indicated that fisetin (5−50 μM) did not exhibit cytotoxic effects on the proliferation of cells (Figure 2). After UVB irradiation (40 mJ/cm^2), the cell viability was significantly decreased to 82.7 ± 1.9% ($p < 0.001$). At 15−25 μM, fisetin did not significantly influence the cell viability of fibroblasts after UVB irradiation but decreased the cell viability to 64.8 ± 0.9% at 50 μM (Figure 2). Fisetin does not recover UVB-induced fibroblast mortality; indeed, the highest dose of fisetin (50 μM) even increases UVB damage. Therefore, 5−25 μM fisetin was used in the study of its anti-photoaging activity and mechanism.

Fisetin Reduced UVB-Induced Intracellular ROS. DCFH-DA staining and fluorescence microscopy were used

DOI: 10.1021/jf502500t
J. Agric. Food Chem. 2015, 63, 4551−4560

to qualitatively characterize the degree of ROS generation. ROS are potential inducers of skin-photoaging-related proteins and cause intracellular oxidative damage in human skin fibroblasts. Fibroblasts were exposed to UVB and then treated with various concentrations of fisetin for 2 h in a 24 well plate. After the fisetin-containing medium was removed, the cells were washed with PBS and incubated with 10 μM dichlorofluorescin diacetate (DCFDA) for 30 min. In this study, treatment with UVB significantly increased ROS generation 1.4-fold compared to control cells, whereas treatment with 5, 10, and 25 μM fisetin reduced UVB-induced ROS generation to 0.9-, 0.8-, and 0.7-fold, respectively (Figure 3). The results of fluorescence and immunofluorence staining indicate that fisetin protected Hs68 cells from the damage of UVB-induced ROS.

UV irradiation induced ROS generation in living organisms, causing oxidative stress, especially when ROS is not scavenged by an antioxidant defense system. Antioxidants, such as *N*-acetyl cysteine, scavenged ROS to protect skin from UVB-induced oxidative stress and cell death.[31,32] In this study, fisetin suppressed UV-induced intracellular ROS formation, protecting skin cells from oxidative damage and related diseases. In a previous study, fisetin exhibited 1,1-diphenyl-2-picrylhydrazyl radical scavenging activity.[33] It has been reported that the presence of a catechol group in the C-2 position and the number of hydroxyl substituents and their location in the molecule (especially at C-3, C-5, and/or C-7) are determinant structural factors for their ability to scavenge free radicals.[33,34] Fisetin, which has C-2 catechol and hydroxyl groups at C-3 and C-7, is an excellent free-radical scavenger. Therefore, its protective effect on skin against UV damage may contribute to its ability to scavenge UV-induced radical generation.

Anti-inflammatory Effect of Fisetin. *Fisetin on UVB-Induced COX-2 Expression.* The levels of COX-2 were 8.31-fold higher in fibroblasts exposed to UVB (40 mJ/cm^2) than in control cells (Figure 4a). In addition, fisetin (5, 10, and 25 μM) exhibited a dose-dependent reduction in UVB-induced COX-2 expression and a reduction of the UVB-induced expression of COX-2, which were 3.57-, 2.94-, and 1.06-fold compared to the control, respectively. The effect was significant when the dose was higher than 5 μM (Figure 4a). Epigallocatechin gallate (EGCG, 1 μM; positive control) significantly suppressed UVB-induced COX-2 expression (from 8.31- to 2.66-fold of the control).

Fisetin on UVB-Induced iNOS Expression. The result of fisetin on iNOS expression in fibroblasts is shown in Figure 4b. iNOS expression was increased to 1.6-fold after exposure to UVB; however, fisetin treatment (5, 10, and 25 μM) did not considerably reduce the levels of iNOS.

Effect of Fisetin on NO and PGE$_2$ Generation. As shown in Figure 5a, UVB exposure induced NO to 3-fold of the control and fisetin treatment reduced UVB-induced NO generation in human skin fibroblasts. UVB elevated PGE$_2$ in human skin fibroblasts, and fisetin at 10 and 25 μM would significant reduce PGE$_2$ production induced by UVB (Figure 5b).

UV irradiation leads to direct or indirect DNA damage and the formation of ROS, which induces an inflammatory response (induced COX-2 and iNOS) and damages the integrity of the extracellular matrix.[35] Our studies have shown that fisetin possesses anti-inflammatory activities by inhibiting UVB-induced PGE$_2$ and NO. The results of this study indicated that fisetin reduced UVB-induced COX-2 expression but not iNOS. The suppressive effect on COX-2 induction might be an independent process or an indirect phenomenon via reduced NO production. In addition, NO was controversially reported

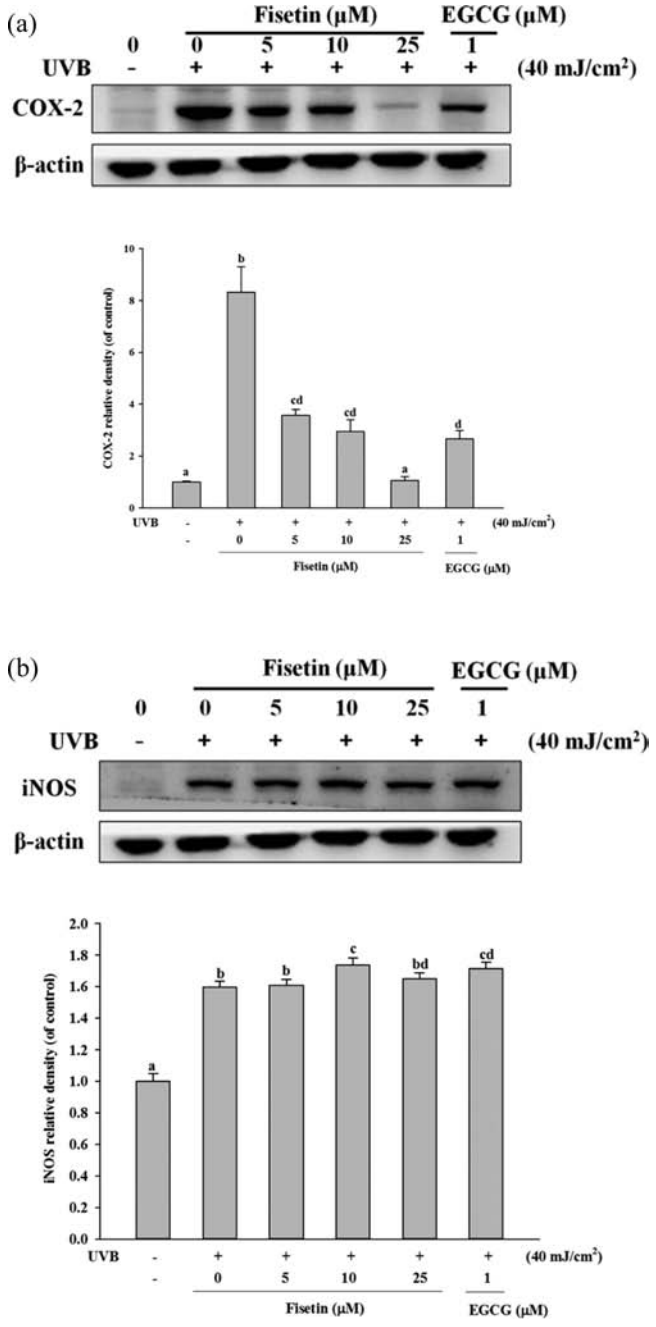

Figure 4. (a) Effect of fisetin on the UV-induced expression of COX-2 in human fibroblasts. (b) Effect of fisetin on the UVB-induced expression of iNOS in human fibroblasts. Groups sharing the same letter are not significantly different ($p > 0.05$) as revealed by LSD post-hoc tests.

to affect the level of COX activity and/or COX-2 expression.[36] It had been reported that flavonoids might directly affect COX-2 activity and/or expression, for example, wogonin, which was a direct COX-2 inhibitor but not an iNOS inhibitor.[37] Therefore, fisetin might directly inhibit COX-2 but not iNOS. The effect mechanism of fisetin on iNOS and COX-2 needs further study.

Effects of Fisetin on UVB-Induced Photodamage and Photodamage-Related Protein Expression. *Fisetin Attenuated UVB-Induced Reduction in Total Collagen Synthesis.* Fibroblasts were pretreated with fisetin (5−25 μM) for 1 h, exposed to UVB, and then treated with fisetin for 24 h. As shown in Figure 6a, fisetin treatment resulted in a dose-dependent

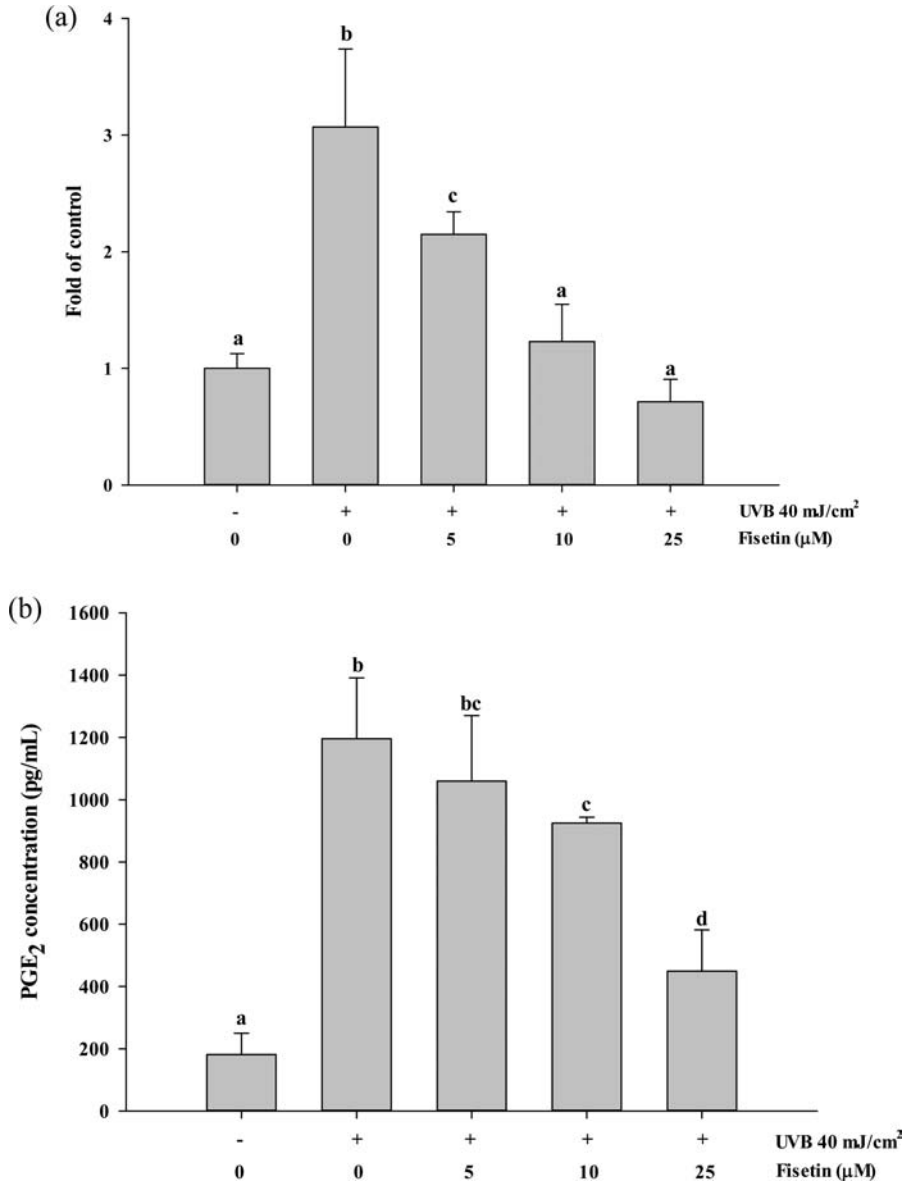

Figure 5. (a) Effect of fisetin on NO generation in human skin fibroblasts. Human fibroblasts were treated with/without UVB of 40 mJ/cm^2 and fisetin of 5, 10, and 25 μM. Groups sharing the same letter are not significantly different ($p > 0.05$) as revealed by LSD post-hoc tests. (b) Effect of fisetin on PGE_2 generation in human skin fibroblasts. Human fibroblasts were treated with/without UVB of 40 mJ/cm^2 and fisetin of 5, 10, and 25 μM. Groups sharing the same letter are not significantly different ($p > 0.05$) as revealed by LSD post-hoc tests.

restoration of collagen and fisetin at 25 μM would significantly increase total collagen synthesis.

Effect of Fisetin on MMP Expression. To examine the anti-damage effects of fisetin on UVB-irradiated human skin fibroblasts, we measured cellular MMP-1, MMP-3, and MMP-9 protein expressions. As shown in Figure 6b, UVB caused significant elevation of MMP-1, MMP-3, and MMP-9 protein expression (1.33-, 1.42-, and 1.53-fold compared to the control, respectively), whereas fisetin attenuated MMP expression. As shown in Figure 6b, the UVB-induced MMP-1 expression was reduced to 0.64-, 0.51-, and 0.42-fold when using 5, 10, and 25 μM fisetin, respectively, and 1 μM EGCG reduced MMP-1 0.54-fold compared to the control. Fisetin (5, 10, and 25 μM) suppressed UVB-induced MMP-3 expression 1.22-, 1.19-, and 0.92-fold compared to the control, respectively, and EGCG decreased 0.93-fold (Figure 6b). Furthermore, fisetin (5, 10, and 25 μM) inhibited UVB-induced MMP-9 expression 1.41-, 1.38-, and 1.43-fold, respectively, and EGCG decreased 0.8-fold compared to the control (Figure 6b). These results provide evidence that fisetin prevents the UVB-induced elevation of MMP-1, MMP-3, and MMP-9 levels, thus protecting UVB-induced skin damage and photoaging.

Effect of Fisetin on MAP Kinase Phosphorylation. In Figure 6c, the phosphorylation of ERK was increased after UVB irradiation, pretreatment with a high dose (25 μM) of fisetin diminished the effect (from 2.2- to 1.7-fold compared to the control), but pretreatment with lower doses (5 and 10 μM) did not. The results of the phosphorylation of JNK resembled those of the phosphorylation of ERK, whereas fisetin (10 and 25 μM) significantly reduced the phosphorylation of p-38 expression (Figure 6c).

Effect of Fisetin on c-Jun and p-c-Jun Expression. As Figure 7a shows, UV induced p-c-Jun expression (3.28-fold compared to the control), whereas fisetin treatment reduced

the c-Jun phosphorylation level in a dose-dependent manner. c-Jun expression was increased after UV irradiation, whereas fisetin inhibited the effect at 25 μM but not at 5 and 10 μM.

Effect of Fisetin on the IκB/NF-κB Pathway. Western blot analysis revealed that the protein levels of IκB were inhibited after the cells were treated with UVB irradiation, whereas fisetin significantly increased IκB expression in a dose-dependent manner (Figure 7b). In addition, the level of the NF-κB subunit, p65, was reduced 0.66-fold compared to the control in cytoplasma, whereas fisetin treatment significantly increased the expression of p65 in a dose-dependent manner (Figure 7b).

Immunohistochemistry Assay of NF-κB. The immunohistochemistry staining assay of NF-κB was conducted in fibroblast cells to determine the degree of NF-κB activation. As shown in Figure 7c, UVB induced the translocation of NF-κB to the nucleus, whereas fisetin suppressed the translocation of NF-κB induced by UVB.

Effect of Fisetin on the PI3K/AKT/CREB Pathway. Treatment of skin fibroblasts with UVB irradiation resulted in a

(c) Fisetin inhibits UVB-induced NF-κB activation by fluorescein isothiocyanate (FITC) immunofluorescence labeling.

2.21-fold increase in p-CREB Ser-133 levels (Figure 8). This showed the intense effect of UVB irradiation on the content of p-CREB Ser-133 in skin fibroblasts. This increase in p-CREB Ser-133 expression was significantly suppressed by fisetin treatment at 25 μM ($p < 0.001$). CREB expression was unchanged after either UVB or fisetin treatment and, similarly, was obtained after co-treatment of these two factors.

UV irradiation has been shown to upregulate the expression of iNOS, producing NO, and to react with superoxide, resulting in peroxynitrite and other ROS formations.[11] These ROS then induce an MAP kinase transcription factor, AP-1, phosphorylation of IκB, and then degradation, subsequently activating NF-κB and inducing COX-2 expression.[38,39] Furthermore, UV exposure activates MAP kinase and PI3K/AKT pathways, leading to upregulation of CREB Ser-133 and the subsequent transcriptional activation of the COX-2 gene.[40] In previous studies, the activation of p-38 resulted in AP-1 transcription, NF-κB expression and activation in the cytoplasma, and

DOI: 10.1021/jf502500t
J. Agric. Food Chem. 2015, 63, 4551−4560

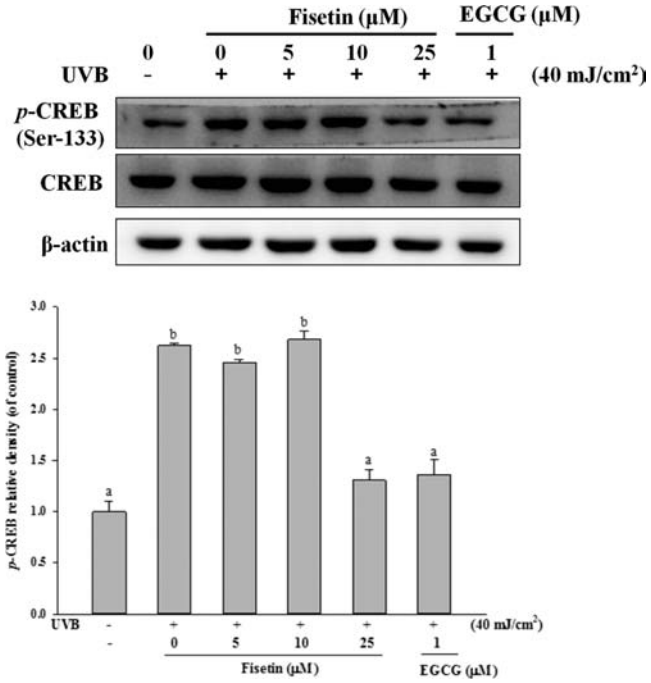

Figure 8. Effect of fisetin on the UVB-induced CREB phosphorylation at Ser-133. Groups sharing the same letter are not significantly different ($p > 0.05$) as revealed by LSD post-hoc tests.

p-CREB Ser-133 expression.[41] Results from this study indicated that fisetin attenuated the UV-induced overexpression of COX-2, p-CREB Ser-133, and MAP kinases and restored UV-induced IκB degradation, resulting in NF-κB down-regulation. In addition, fisetin inhibited UVB-induced NF-κB activation by inhibiting the translocation of NF-κB into the nucleus. Fisetin also inhibited UVB-induced NO and PGE_2 production. The inhibition of the phosphorylation of p-38, NF-κB transcription, and reduction of p-CREB Ser-133 by fisetin may contribute to the suppression of COX-2 expression. Inhibition of the MAP kinase pathway, therefore, prevents the phosphorylation of ERK, thereby enhancing the expression of type I procollagen.

The scavenging of ROS by fisetin may lead to a blockage of the MAP kinase pathway, which, in turn, may inhibit the activation of NF-κB and AP-1 and, therefore, inhibit the expression of MMP-1, MMP-3, MMP-9, and COX-2. MMPs play a vital role in UV-induced skin aging and degrade ECM in the dermis, resulting in the structural dysfunction of the skin. MMP-1 is a major enzyme that degrades collagen; MMP-3 activates proMMP-1; and MMP-9 degrades collagen fragments already degraded by MMP-1.[3] It has been shown that MMP-1 is expressed when the skin is exposed to UV, which induces a decrease of collagen and wrinkle formation.[5,6,42,43] Therefore, fisetin-inhibited MMP-1, MMP-3, and MMP-9 attenuated collagen degradation, thereby protecting skin from aging and photoaging. With regard to MMP expression, MAP kinase signaling cascades activate AP-1, a transcription factor and a complex containing c-Fos and c-Jun, and activate AP-1-dependent gene expression. The results indicate that fisetin suppressed the overexpression of UVB-induced MAP kinase/AP-1/MMPs and increased collagen content in human fibroblasts.

In summary, our results demonstrate that fisetin attenuated UVB-induced oxidative stress, photodamage, and inflammation

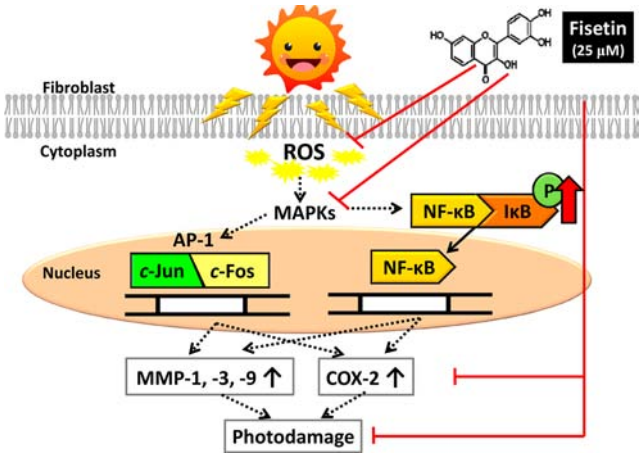

Figure 9. Schematic diagram showing inhibitory effects of fisetin in UVB-induced skin damage.

by modulating the expression of MMPs, MAP kinases, AP-1, COX-2, and p-CREB Ser-133 (Figure 9). In addition, fisetin effectively restored UV-induced IκB degradation, resulting in NF-κB inhibition. Therefore, fisetin is a potential agent used on UV-induced skin damage.

extracellular matrix. Therefore, the MMPs play an important role in the invasion process.[6]

Integrins are receptors located between the cell surface and adhesion. They are not only involved in adhesion of cell and extracellular matrix but also active in the downstream cell signaling transduction pathways. They are heterodimers constituted of α- and β-subunits by noncovalent bonds; the α-subunit has 18 types, and the β-subunit has 8 types.[7,8] In addition, integrin $\alpha v\beta 3$ has been shown to be overexpressed in multiple cancer cell metastasis processes. Some studies demonstrate that integrin $\alpha v\beta 3$ can bind with urokinase plasminogen activator (uPA) receptor and transfer plasminogen into plasmin that will then activate pro-MMPs and lead to the degradation of extracellular matrix by MMPs. Integrin $\alpha v\beta 3$ can directly bind to MMP-2 as well and help the degradation of MMP-2.[9]

FAK is the main controller of integrin-mediated cancer cell signaling transduction pathway. When FAK and integrin mix together to form a focal adhesion complex, the whole structure will be changed. The steroid receptor coactivator (Src) will phosphorylate FAK; the activated p-FAK will in turn activate the signaling transduction pathway of PI3K/AKT, MEK/ERK, and JNK and regulates the adhesion, migration, and invasion of cancer cells. Therefore, the protein expression and phosphorylation of FAK are usually recognized as one of the biomarkers of cancer metastasis.[9]

MATERIALS AND METHODS

Chemicals and Reagents. Basswood-cultivated *A. cinnamomea* (BCRC930103) mycelial powder was provided by PO-ZO Co., Ltd. (Taipei, Taiwan). Ethyl acetate (EA) was added to 500 g of *A. cinnamomea* dry powder to a total volume of 4 L and stirred for 3 days. The extract was then decanted and solvent removed by a rotary evaporator at 50 °C. The extraction was repeated. A silica gel column was used to fractionate the extracted sample and consecutively eluted with 10, 15, 20, 30, 50, 70, and 100% EA/hexane. The fraction with 100% EA/hexane contained the highest amount of antcin K. The purity of antcin K was >90% as determined by an HPLC analysis. The yield of antcin K from *A. cinnamomea* is about 0.5% in dry weight.

Bromophenol blue and sodium dodecyl sulfate were purchased from Bio-Rad Laboratories (Hercules, CA, USA). Antibiotic−antimycotic, Dulbecco's modified Eagle's medium, fetal bovine serum, and nonessential amino acids were purchased from Invitrogen (Carlsbad, CA, USA). Immobilon-P membrane (PVDF transfer membranes for Western blotting), Immobilon Western chemiluminescent HRP substrate (ECL), Millicell hanging cell culture insert (transwell), and dimethyl sulfoxide (DMSO) were obtained from Merck Millipore (Billerica, MA, USA). BD Matrigel Matrix High Concentration was purchased from BD Biosciences (San Jose, CA, USA). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), Brij 35, gelatin, bovine serum albumin (BSA), HEPES sodium salt, TritonTM X-100, trypan blue, Tween 20, crystal violet, and other analytical grade reagents were purchased from Sigma-Aldrich (St. Louis, MO, USA). Forty percent acrylamide/bis (29:1) solution, dithiothreitol (DTT), ammonium persulfate (APS), Coomassie brilliant blue R-250, glycerol, Tris base, and prestained protein ladder were purchased from Bioman (Taipei, Taiwan). Culture inserts (for wound-healing assay) were obtained from ibidi (Munchen, Germany). PRO-PREP protein extraction solution was purchased from Boca Scientific (Boca Raton, FL, USA). Trypsin−EDTA was obtained from Caisson Laboratories (North Logan, UT, USA). Acetic acid and methanol were purchased from Macron Chemicals (Center Valley, PA, USA). Phosphatase inhibitor cocktail tablet and protease inhibitor cocktail tablet were purchased from Roche (Basel, Switzerland). An SDS-PAGE kit was purchased from Bionovas Biotechnology (Toronto, ON, Canada). Anti-β-actin antibody and other secondary antibodies were obtained from Cell Signaling Technology, Inc. (St. Louis, MO, USA).

Cell Culture. Hep 3B cells were cultured in Dulbecco's modified Eagle's medium with 10% FBS, 1.5 g/L sodium bicarbonate, 2.38 g/L HEPES, 1% nonessential amino acids, and 1% antibiotic−antimycotic (100 units/mL penicillin, 0.1 μg/mL streptomycin, and 0.25 μg/mL amphotericin B) at 37 °C in a 5% CO_2 incubator.[10]

Determination of Cell Viability MTT Assay. Liver cancer cells at a concentration of 5×10^3 cells/well were seeded in 96-well plates and incubated for 24 h, followed by treatment with 0 (0.02% DMSO), 5, 10, 15, 20, and 40 μM antcin K and incubated for a further 24 h. At the end of the stipulated period, 100 μL of MTT solution (0.5 mg/mL) was added and incubated at 37 °C for 4 h. The resulting MTT formazan was dissolved in 100 μL of DMSO and the absorbance recorded at 570 nm using a PowerWave HT Bio-Tek microplate spectrophotometer (Winooski, VT, USA).[11]

Detections of Cell−Matrigel Adhesion Assay. Hep 3B cells with 5×10^4 cells/mL were seeded into 6-well plates and incubated for 24 h, and the medium was then removed. After two washings, the medium was changed to 2 mL of 0, 5, 10, 15, and 20 μM antcin K with 2% FBS and incubated in 5% CO_2 at 37 °C for 24 h. At the same time, matrigel (10 μg/30 μL) was coated into 96-well plates, 20 μL of BSA (2%) was added, and the mixture was incubated in 5% CO_2 at 37 °C for 1 h. Next, Hep 3B cells with 5×10^4 cells/mL were put into 96-well plates with 0, 5, 10, 15, and 20 μM antcin K in 2% FBS medium for 1 h. After removal of medium and two washings with PBS, 100 μL of 0.5 mg/mL MTT in 2% FBS medium was added. The following steps are the same as described in the cell viability MTT assay.[12]

Wound-Healing Assay. Putting ibidi culture-insert on the battle of 24-well plates, and Hep 3B cells with 3.5×10^4 cells/70 μL/well were seeded into other space and incubated in 37 °C at 5% CO_2 for 24 h. The next step was taking of fthe culture insert and adding 500 μL/well 0, 5, 10, 15, 20 μM antcin K in non-FBS medium incubation. Three pictures were taken by 100× microscopy at 0, 24, and 48 h randomly. Data were analyzed by ImageJ software to show the cell migration percentage compared with the control group.[13]

Cell Migration Assay. One transwell was set into 1 mL of PBS in 24-well plates and the unleakage transwell chosen after 30 min. To open the permeability of the transwell, 200 μL of PBS was added into the transwell and incubated for 18 h. PBS was removed next, and 1 mL of 10% FBS was added into the bottle of a 24-well plate seeded with Hep 3B cells (2.5×10^4 cells/100 μL/well, non-FBS medium) into the transwell. Then it was treated with 100 μL/well 0, 5, 10, 15, and 20 μM antcin K within non-FBS medium. After incubating in 37 °C at 5% CO_2 for 24 h, the cells were fixed by methanol in 15 min, dyed for 45 min by 2% crystal violet, and washed out by PBS. Finally, five pictures were taken by microscopy (200×), and cell number was analyzed by ImageJ software to demonstrate the ability of cell migration (cell migration percent of control).[14]

Matrigel Invasion Assay. Most steps were similar to the cell migration assay; the only different step was we would coat 4 μg/μL matrigel into the transwell to avoid bubble formation.[15]

Gelatin Zymography. Hep 3B cells (5×10^4 cells/mL) were seeded into 24-well plates at 37 °C in 5% CO_2 and incubated for 24 h, and the medium was removed and washed out with PBS twice. After treatment with various doses of antcin K, the upper medium was taken and mixed with 2× sample buffer (0.125 M Tris-HCl, 20% glycerol, 10% SDS, and 0.32% bromophenol blue). It was then loaded into 0.1% gelatin and 10% SDS-PAGE, run 100 V within 2 h, and 1× renaturing buffer (2.5% Triton X-100) was used to wash the gel twice; the gel was put in developing buffer (50 mM Tris-base, 200 mM NaCl, 5 mM $CaCl_2$, 0.02% Brij 35, pH 7.5) fpr incubation at 37 °C in 24 h. It was then dyed with Coomassie blue solution (2.5% Coomassie blue, 10% acetic acid, and 50% methanol) in 20 min. Finally, the destaining solution (10% acetic acid and 30% methanol) was used to remove color. After the gel had dried, it was analyzed by ImageJ.[16]

Western Blotting. For Western blotting, the cells (5×10^4 cells/10 mL/dish) were seeded in 10 cm^2 dishes for 24 h. After 24 h of incubation, the cells were treated with 10 mL of medium containing 0, 5, 10, 15, and 20 μM antcin K for 24 h. After 24 h of treatment, total

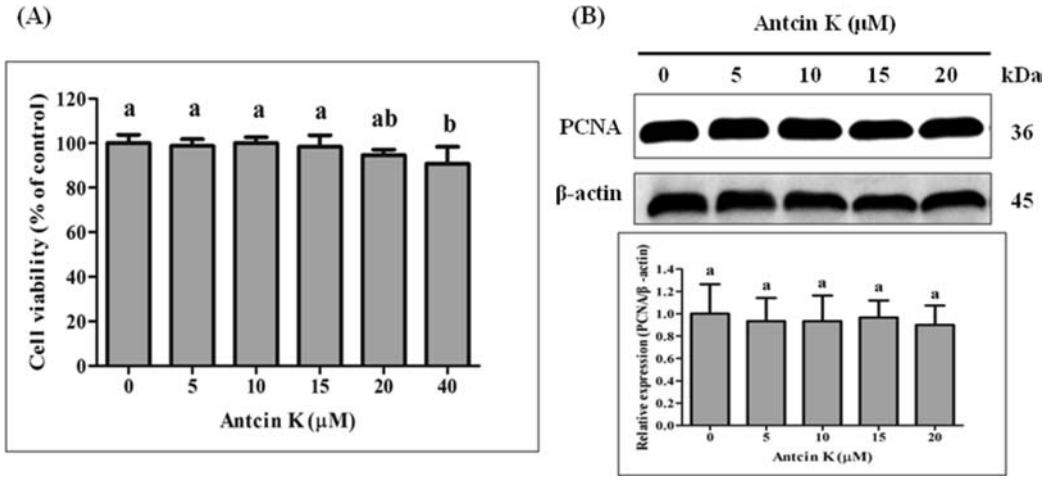

Figure 1. Effects of antcin K on cell viability and proliferation in Hep 3B cells. (A) Effect of antcin K on the cell viability in Hep 3B cells was determined by MTT assay. Data are expressed as the relative percentage to control (0.02% DMSO) and mean ± SD from three independent experiments (n = 3). (B) Effect of antcin K on the expression of proliferating cell nuclear antigen in Hep 3B cells was assessed by Western blotting. Protein levels are expressed as multiple of control (0.02% DMSO) by β-actin-normalized densitometry. Columns represent the mean ± SD from three independent experiments (n = 3).

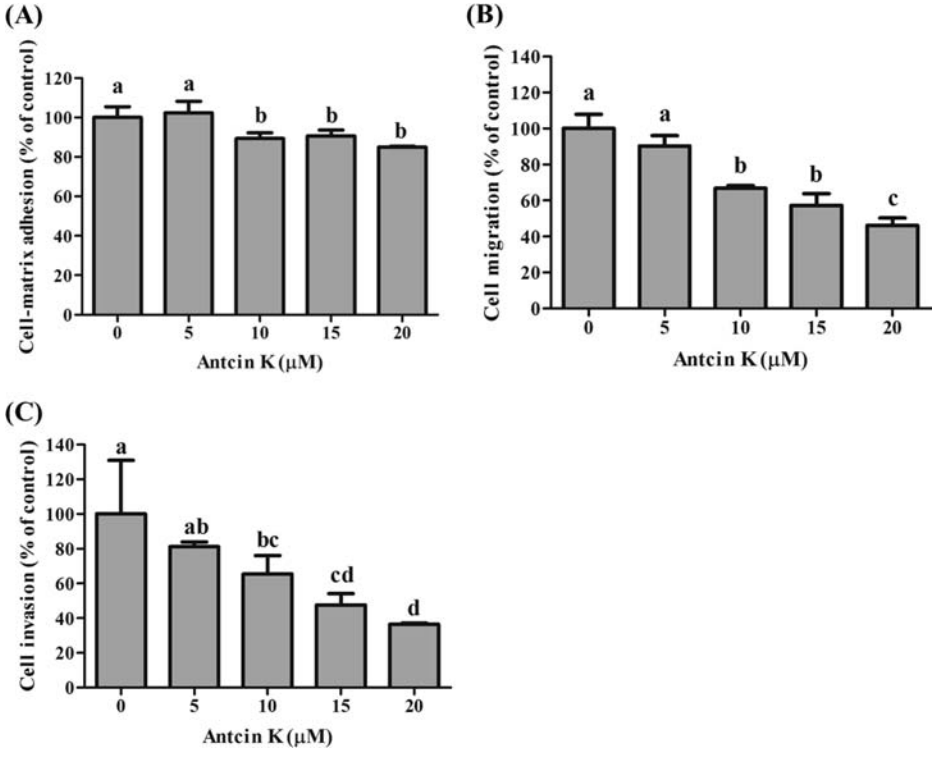

Figure 2. Changes by antcin K on the cell−matrix adhesion, migration, and invasion in Hep 3B cells. (A) Effect of antcin K on the cell−matrix adhesion in Hep 3B cells was determined by MTT assay. Data are expressed as the relative percentage to control (0.02% DMSO) and mean ± SD from three independent experiments (n = 3). (B) Effect of antcin K on the cell migration in Hep 3B cells was measured by Boyden chamber assay. The cells that migrated to the lower surface of the filter were stained with crystal violet and were photographed under a light microscope at 200×. Columns represent the mean ± SD from three independent experiments (n = 3). (C) Effect of antcin K on the cell invasion in Hep 3B cells was measured by Matrigel invasion assay. The cells that penetrated through the Matrigel to the lower surface of the filter were stained with crystal violet and were photographed under a light microscope at 200×. Columns represent the mean ± SD from three independent experiments (n = 3).

cell extracts were prepared in protein extraction solution, which contains 1 mM phenylmethanesulfonyl fluoride, 1 mM ethylenediaminetetraacetic acid, 1 μM pepstatin A, 1 μM leupeptin, and 0.1 μM aprotinin. The cell lysates were sonicated and cleared by centrifugation, and the protein concentration in the lysates was measured according to Lowry's method.[17] Fifty micrograms of proteins was loaded over 8% SDS-PAGE gels, transferred to polyvinylidene fluoride membranes, blotted with specific primary antibodies, and then labeled by horseradish peroxidase-conjugated secondary antibody according to the manufacturer's instructions. The membranes were performed using the enhanced chemiluminescence and EC3300 Corning UVP biospectrum AC system (Corning, NY, USA), and the relative density of each band after normalization for β-actin was analyzed using ImageJ 1.45 software.[18]

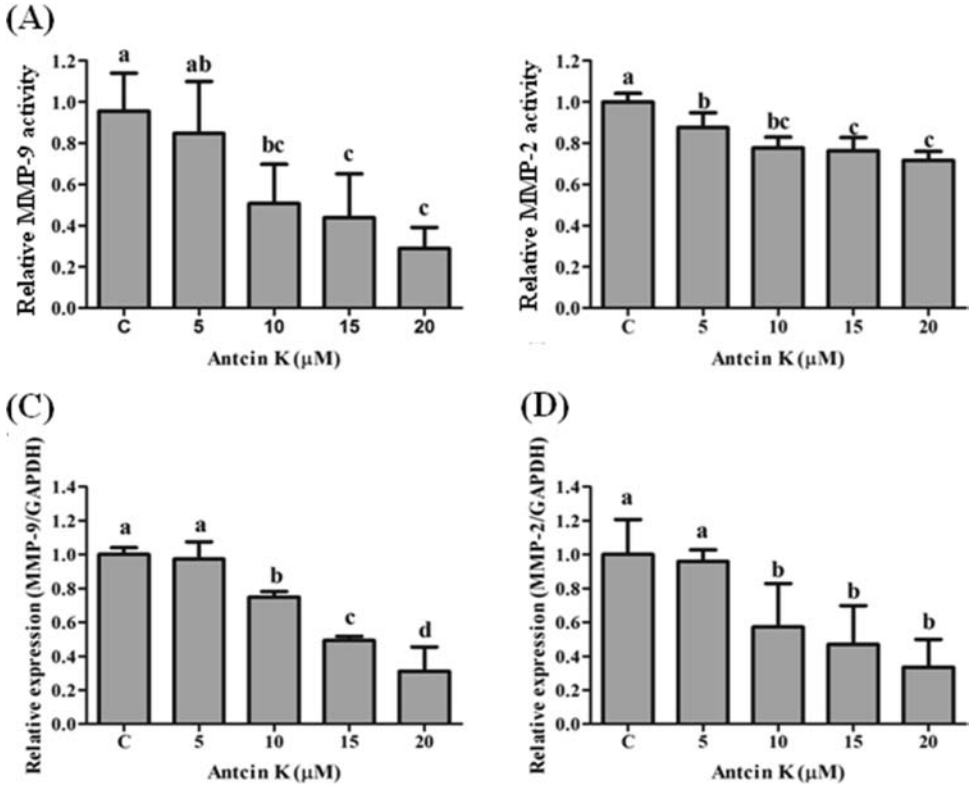

Figure 3. Effects of antcin K on the activity and protein expressions of MMP-2 and MMP-9 in Hep 3B cells. (A, B) Changes by antcin K on the activity of MMP-2 and MMP-9 in Hep 3B cells were assessed by gelatin zymography. Columns represent the mean ± SD from three independent experiments (n = 3). (C, D) Changes by antcin K on the expression of MMP-9 and MMP-2 in Hep 3B cells were assessed by Western blotting. Protein levels are expressed as multiple of control (0.02% DMSO). Columns represent the mean ± SD from three independent experiments (n = 3).

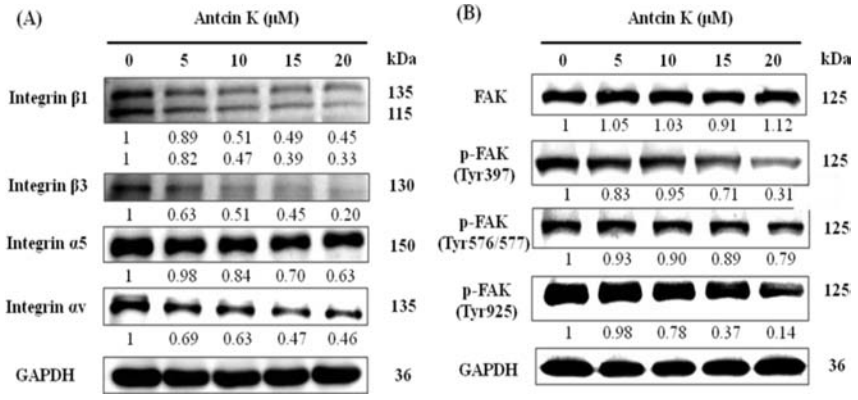

Figure 4. Effects of antcin K on the protein expression of integrin family and FAK-related protein in Hep 3B cells. (A) Effects of antcin K on the expression of integrin β1, integrin β3, integrin α5, and integrin αv in Hep 3B cells were assessed by Western blotting. The experiments were repeated at least three times with similar results (n = 3). Protein levels are expressed as multiple of control (0.02% DMSO) by GAPDH-normalized densitometry. (B) Effects of antcin K on the expression of FAK, p-FAK (Tyr397), p-FAK (Tyr576/577), and p-FAK (Tyr925) in Hep 3B cells were assessed by Western blotting. The experiments were repeated at least three times with similar results (n = 3). Protein levels are expressed as multiple of control (0.02% DMSO) by GAPDH-normalized densitometry.

Statistical Analysis. All results are reported as the mean ± SD, and the differences between the antcin K-treated and control groups were analyzed by one-way analysis of variance ANOVA and Duncan's multiple-comparison tests (SAS Institute Inc., Cary, NC, USA) to determine significant differences among treatments, $p < 0.05$.

RESULTS AND DISCUSSION

Effects of Antcin K on Cell Viability in Hep 3B Cells Measured by MTT Assay. The MTT assay was used to assess the nontoxic dose of antcin K in Hep 3B cells. Treatment with 0, 5, 10, 15, 20, and 40 μM antcin K for 24 h in Hep 3B cells showed that, except for the 40 μM antcin K treatment, there was no significant difference of antcin K treatment in Hep 3B cells compared with the vehicle control group (0.02% DMSO, viable cells = 100%, $p < 0.05$) (Figure 1A).

Protein Expression of PCNA on Antcin K in Hep 3B Cells. After treatment with 0, 5, 10, 15, 20, and 40 μM antcin K for 24 h in Hep 3B cells, the protein expression of proliferating cell nuclear antigen (PCNA) was not significantly different from the control group ($p < 0.05$). Therefore, 0−20 μM antcin

J. Agric. Food Chem. 2015, 63, 4561−4569

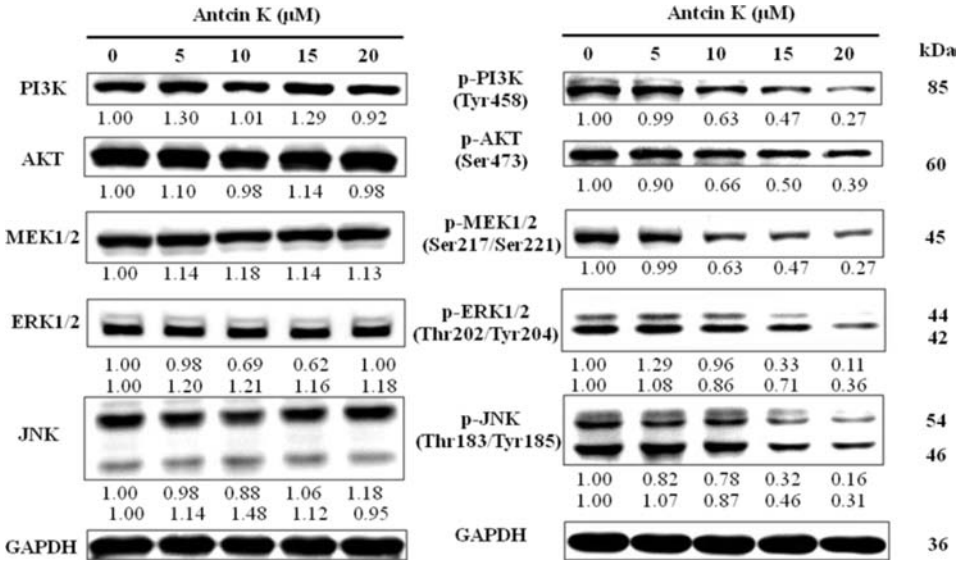

Figure 5. Total and phosphorylated protein expression of FAK's three downstream signaling transduction pathways, PI3K/AKT, MEK/ERK, and JNK. After incubation of the cells with 0−20 μM antcin K for 24 h, the expressed proteins were assessed by Western blotting. The experiments were repeated at least three times with similar results (n = 3), and GAPDH was used as loading control. Protein levels are expressed as multiple of control (0.02% DMSO) by GAPDH-normalized densitometry and shown on the bottom of each band.

K would not affect the cell proliferation (Figure 1B) or the cell viability of Hep 3B cells (Figure 1A).

Effects of Antcin K on Cell Adhesion in Hep 3B Cells. Hep 3B cells were pretreated with antcin K for 24 h and then seeded on 96-well microplates with matrigel. After 1 h, the medium was taken off, and the cells unattached on matrix were removed. The MTT assay was used to analyze the viable cells attached on matrigel to determine whether antcin K could inhibit the adhesion ability of Hep 3B cells. From Figure 2A, treatment of Hep 3B cells with 10 μM antcin K for 24 h could significantly inhibit Hep 3B cells' attaching on matrigel compared with the control group (0.02% DMSO, adhesion rate = 100%). Furthermore, the inhibition rates of 10, 15, and 20 μM antcin K were 10.9 ± 2.9, 9.3 ± 3.0, and 15.0 ± 0.5%, respectively.

Effects of Antcin K on Cell Migration in Hep 3B Cells. As shown in Figure 2B and Supplementary data 2, a Boyden chamber assay was used to analyze the migration effect of antcin K in Hep 3B cells. It showed that Hep 3B cells treated with 10, 15, and 20 μM antcin K for 24 h inhibited the migration of Hep 3B cells (p < 0.05), and the situation was similar to that in Supplementary data 1. It demonstrated that antcin K has significant migration inhibitory ability in human liver cancer cells.

Changes by Antcin K on Cell Invasion in Hep 3B Cells. Invasion is an important step of metastasis processing. Matrigel invasion assay was used to assess the effect of antcin K on invasion of Hep 3B cells in 24 h (Figure 2C and Supplementary data 3). It was found that 10 μM antcin K treatment significantly decreased Hep 3B cells invasion compared with control group (0.02% DMSO, invasion rate = 100%, p < 0.05), and the inhibitory rates of 10, 15, and 20 μM antcin K in Hep 3B cells were 34.7 ± 10.7, 52.4 ± 6.4, and 63.5 ± 0.7%, respectively. From the data of cell adhesion, wound-healing assay, and migration and invasion assays, antcin K not only decreased the adhesion of extracellular matrix but also inhibited the migration and invasion of Hep 3B cells in 24 h (Figure 2). Therefore, antcin K could be considered to decrease the activity of metastasis in human liver cancer cells. However, there are many reasons for metastasis, so additional experiments were designed to clarify the detailed mechanism of antcin K inhibiting Hep 3B cell metastasis.

Effects of Antcin K on the Activity and Protein Expressions of MMP-2 and MMP-9 in Hep 3B Cells. MMPs belong to a large family of proteases, which are calcium-dependent and zinc-containing endopeptidases. They are capable of degrading the composition of extracellular matrix and basal membrane such as collagens, laminin, fibronectin, and proteoglycans.[19] There are at least 20 types of MMPs known. MMP-2 and MMP-9 are considered the most related to the invasion of cancer cells.[9,10]

The activities of MMP-2 and MMP-9 were analyzed by gelatin zymography as shown in Figure 3A,B.[20] It was found that 10, 15, and 20 μM antcin K could inhibit the activity of Hep 3B cells (p < 0.05). The protein expressions of MMP-2 and MMP-9 had the same trends as activity (Figure 3C,D and Supplementary data 4). The data showed that antcin K could inhibit the protein hydrolysis of extracellular matrix and metastasis ability in Hep 3B cells. In addition, some researchers have shown that EMT-related proteins have a close relationship with MMP-2 and MMP-9.[21,22] Therefore, we inferred that antcin K might inhibit the metastasis ability of Hep 3B cells via decreasing MMP-2 and MMP-9 protein expressions. Then the EMT-related proteins were also regulated by MMP-2 and MMP-9.

EMT-Related Protein Expression of Antcin K in Hep 3B Cells. From Figure 6A, Western blotting was used to investigate the protein expression of E-cadherin and vimentin. Compared with the control group (0.02% DMSO), Hep 3B cells treated with 10−20 μM antcin K for 24 h, the protein expression of E-cadherin increased but the protein expression of vimentin decreased significantly (p < 0.05). These data supported our hypothesis about EMT-related proteins regulating metastasis ability after antcin K treatment in Hep 3B cells.

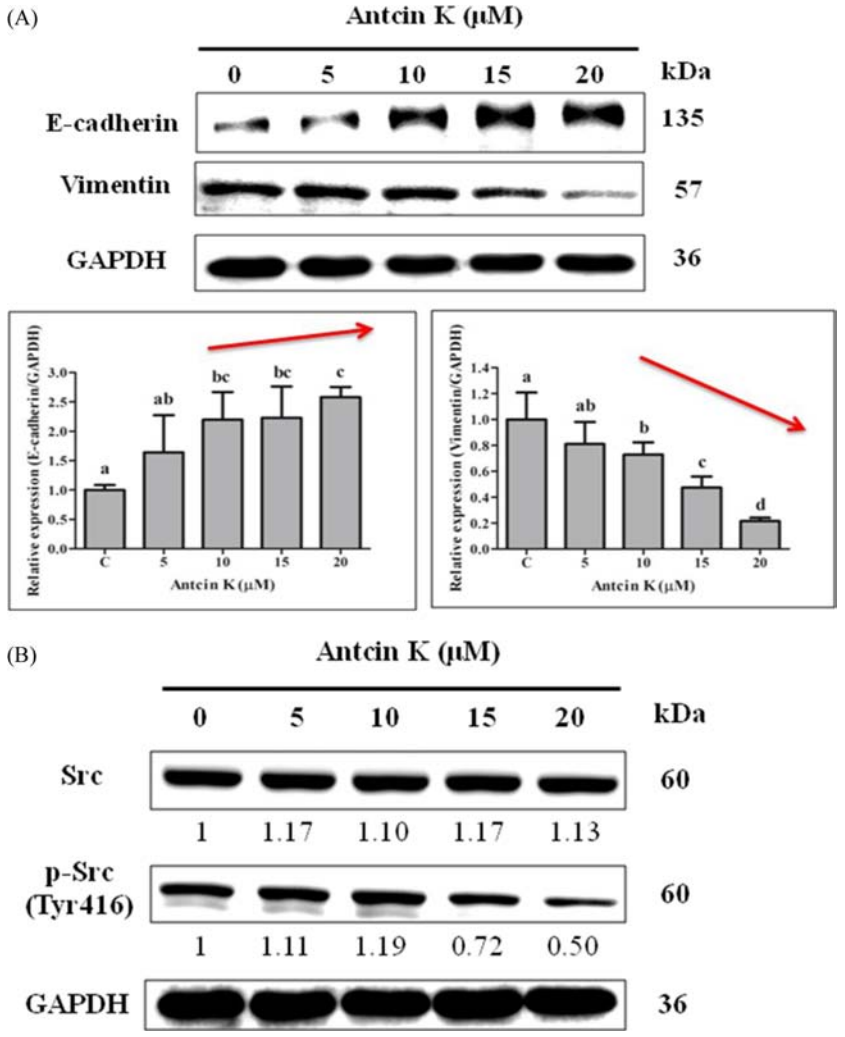

Figure 6. Effects of antcin K on the expression of E-cadherin, Src, and vimentin in Hep 3B cells were assessed by Western blotting: (A) effects of antcin K on the expression of E-cadherin and vimentin in Hep 3B cells; (B) effects of antcin K on the expression of Src and p-Src (Tyr416) in Hep 3B cells. The experiments were repeated at least three times with similar results (n = 3). Protein levels are expressed as multiple of control (0.02% DMSO) by GAPDH-normalized densitometry.

Protein Expression of Integrin of Antcin K in Hep 3B Cells. Integrin is the receptor protein that mediates cell adhesion, involving the interaction of extracellular matrix and regular migration and invasion of cancer cells. Previous studies have shown that some integrin subunits such as β1, β3, α1, α2, α3, α4, α5, and αv have been detected in Hep 3B cells.[23,24] However, various expressions of integrin are related to basal membrane, extracellular matrix-remodeling, adhesion, migration, invasion, and growth of cancer cells, and it is involved in the metastasis of multiple cancers.[24] In 2002, integrins β1, β3, α5 and αv were found in different liver tumors from liver cancer patients. In 80 cases of liver cancer patients, 77 patients had overexpression of integrin β1, 44 patients had overexpression of integrin αv, 15 patients had β3 overexpression, and 70 patients had overexpression of integrin α5. These findings demonstrate that integrin β1, β3, α5, and αv are indeed involved in the development and metastasis of liver cancer.[23]

In addition, Ly et al. showed that the expression of integrin $\alpha5\beta1$ could regulate integrin $\alpha v\beta3$-mediated adhesion or migration.[25] For specific and functional property, integrin $\alpha5\beta1$ only binds with fibronectin (F_n) of the extracellular matrix, which is the major component of the vascular wall. Fransvea et al. indicated that the expression of integrin $\alpha5\beta1$ could regulate the migration of the vascular wall.[26] To determine whether antcin K inhibiting metastasis was linked with the integrin family in Hep 3B cells, Western blotting was used to assess the integrin expression on antcin K treatment in Hep 3B cells. From the results, 10 μM antcin K could significantly decrease the protein expression of integrin β1, β3, α5, and αv in Hep 3B cells (Figure 4A). The data could explain that the antimetastasis ability of antcin K might be through the regulation of integrin receptor proteins in Hep 3B cells.

Protein Expression of FAK and Src of Antcin K in Hep 3B Cells. FAK is one of the major controlling proteins of adhesion. Migration and invasion are partially mediated by integrin and FAK regulation. Compared with the control group, the total protein expression of FAK after treatment with antcin K did not change in Hep 3B cells (Figure 4B), but the protein expression and phosphorylation of FAK of 15 and 20 μM antcin K treatment decreased significantly within FAK (Tyr^{397}), FAK ($Tyr^{576/577}$), and FAK (Tyr^{925}). In addition, the phosphorylated protein expression of Src decreased after antcin K treatment, but the total protein expression of Src did not change (Figure 6B). These data indicated that p-Src and p-FAK could mediate the antimetastasis mechanism of antcin K in Hep 3B cells.

Protein Expression of PI3K/AKT, MEK/ERK, and JNK of Antcin K in Hep 3B Cells. To confirm whether the expression of FAK downstream was changed like FAK and Src, the signaling transduction proteins PI3K/AKT, MEK/ERK, and JNK were investigated. As shown in Figure 5, when Hep 3B was treated with various concentrations of antcin K for 24 h, the total protein expressions of PI3K, AKT, MEK, ERK, and JNK were not changed compared with the control group, but the phosphorylated protein expressions decreased in dose-dependent manners. This demonstrated that antcin K treatment could decrease the phosphorylation of protein expression of FAK's three downstream signaling transduction pathways such as PI3K/AKT, MEK/ERK, and JNK. Our data proved that antimetastasis of antcin K was truly via the activation of PI3K/AKT, MEK/ERK, and JNK. Those results were agreeable to our data of viability and PCNA (Figure 1). For example, PI3K/AKT also controls the survival pathway.[27] Antcin K treatment changed only the phosphorylation protein expression of PI3K/AKT, which meant that 20 μM antcin K indeed inhibited the metastasis of Hep 3B cells and had no toxicity effect in Hep 3B cells.

From our results, the integrin family could interact with cellular molecular, transfer the extracellular signaling into cytosol, and then affect the expression of nuclei DNA and cytoskeleton. Moreover, the receptor tyrosine kinases (RTKs), β1 integrin cytoplasmic domains, integrin-linked kinase (ILK), and other adaptor proteins such as focal adhesion kinase (FAK) of cell membrane might interact with integrin, forming a focal adhesion complex. In addition, the Ras/Raf/MEK/MAPK signaling pathway could be involved in multiple functions such as cell proliferation, invasion, angiogenesis, extracellular matrix remodeling, and anti-apoptosis, which was regulated by the integrin−actin−RTK network.[28]

Antcin K is the most abundant triterpenoid from the fruiting bodies of basswood-cultivated *A. cinnamomea*. Most studies use the ethanol extracts of *A. cinnamomea* as material,[29−32] and previous study showed that the ethanol extracts of *A. cinnamomea* could inhibit the metastasis of human lung cancer CL1-0 cells through decreasing the phosphorylated protein expression of FAK, PI3K/AKT, JNK, and p38.[33] Our data demonstrated that antcin K acted through a similar mechanism as ethanol extracts of *A. cinnamomea* in antimetastasis of cancer treatment; it is therefore reasonable to assume that antcin K plays a major role in ethanol extracts of *A. cinnamomea*.

In conclusion, antcin K might inhibit the activation of PI3K/AKT, MEK/ERK, and JNK by decreasing the protein expression of integrind β1, β3, α5, and αv and activating FAK. Then antcin K decreased protein expression and activation of MMP-2 and MMP-9 to affect EMT (Figure 7) and inhibited the metastasis in human liver cancer Hep 3B cells.

phenols in the olive oil process without the impact of different plant material, different sample preparation/extraction procedures, and chromatographic conditions which can hamper such phenol studies. To our best knowledge, this work is the most comprehensive study on the quantitative behavior of olive fruit phenols entailed in olive oil production, providing insight into the origin, degradation, and evolution of each throughout the processing, with novel transfer/partition calculations and transformative relationships established.

MATERIALS AND METHODS

Reagents and standards. All reagents and standards were obtained and prepared as described.[13]

Sampling and samples pretreatment. Olive fruits of Istrska belica *cv.* were harvested in Gradno (Goriška Brda, Slovenia), stored overnight and processed to olive oil the next day using a laboratory-scale Abencor olive mill (Seville, Spain). Prior to that, a lot of fruits were randomly chosen as a representative starting fruit material, weighed and frozen with liquid nitrogen before subjected to freeze-drying. Then, fruits were manually destoned and rebalanced in order to obtain the pulp/stone average mass ratio, ground separately into homogeneous powder with a liquid nitrogen and stored at −25 °C until analysis. Other olive oil process-derived matrices (pomace, wastewater and oil) were sampled at the end of processing with an exception of paste, which was collected immediately after fruits crushing. The samples were prepared as previously described,[14−16] where destoned fruits, stones, paste and pomace were frozen with liquid nitrogen, freeze-dried, homogenized and stored at −25 °C until analysis, while the wastewater was primarily acidified (HCl, pH = 2.0) and defatted with *n*-hexane prior to freeze-drying and storage at −25 °C. The olive oil sample was solely stored in the dark at room temperature until extracted. The dry matter measurements of freeze-dried samples were performed gravimetrically,[17] providing the basis for phenols transfer/partition calculations.

Olive oil processing. A laboratory-scale olive oil processing trial was carried out as described elsewhere.[13] First, olives were ground to a paste by the hammer mill and homogenized in order to reduce the potential differences in the starting fruit material. Then, the paste (∼700 g) was put into a metallic pitcher and 100 mL of water (25 °C) added to improve its rheology. Afterword, the paste was malaxed in thermo-malaxer (30 min, 25 °C) and centrifuged (1400 g, 1 min) in order to obtain the three final products, i.e. oil and two wastes (wastewater and pomace). While the yield of pomace, which remained in a centrifuge was calculated, the masses of two liquid phases (oil + wastewater) separated by decantation process were balanced in order to assess the mass balance of the process trail. All the procedure was performed in duplicate.

Phenols extraction. *Destoned fruits, stones, paste, pomace and wastewater.* Phenols were extracted at room temperature according to a previously published ultrasound-assisted solid liquid extraction (USLE) method,[14,15] where a freeze-dried sample (1.5 g) was sonicated (3 × 20 min) with 25 mL of methanol. The homogenates of each extraction step were centrifuged (2515 *g*, 5 min) and combined supernatants diluted with methanol to 100 mL.

Olive oil. Extraction (at room temperature) was carried using ultrasound-assisted liquid liquid extraction (US-LLE) method previously described,[16] where a 10 g of olive oil was dissolved in *n*-hexane (10 mL) and sonicated (3 × 10 min) with pure methanol (5 mL). The homogenates of each extraction step were centrifuged (2515 *g*, 2 min), combined and defatted with a freeze-based fat precipitation (for 20 min at −80 °C). Afterward, the remaining extract was reconstituted to 25 mL with methanol and stored in the screw-capped dark glass containers at −25 °C until analysis.

U(H)PLC-DAD analysis. Prior to analysis, the aliquots of extracts were rotary concentrated 10-fold and the dry-residue redissolved in a mixture of U(H)PLC eluents A (water: acetic acid =95:5, v/v) and B (methanol) (A:B = 90:10; v/v). The extracts were filtered through 0.22 μm/13 mm PVDF filters from Carl Roth GmbH+Co. (Düren, Germany) and immediately analyzed by U(H)PLC-DAD analysis.

A Dionex Ultimate 3000 U(H)PLC liquid chromatograph (Thermoscientific, CA, USA) equipped with UV−vis diode-array (DAD) detector was used for the quantification. The extracts of 10 μL (except for oil; 20 μL) were injected and the DAD signals were recorded at 280, 320, and 365 nm, presenting a compromise for individual phenolic class detection. Chromatographic separation was achieved by using gradient elution on Kinetex PFP column (2.6 μm, 100 mm × 4.6 mm) attached to a PFP security guard (2.1 mm × 4.6 mm) both from Phenomenex (Sydney, Australia) under the analysis conditions previously described.[13]

Flavonols were quantified at 365 nm, while simple phenols and secoiridoids at 280 nm with an exception of unknown A, uknowns 408 MW, caffeoyl-6′-secologanoside and comselogoside quantified at 320 nm along with the group of cinnamic acids and flavonoids. When authentic standards were available, phenols were quantified based on their calibration curves, whereas others were expressed as equivalents; hydroxytyrosol glucosides and hydroxytyrosol acetate as hydroxytyrosol, tyrosol glucoside as tyrosol, all verbascoside derivatives as verbascoside, luteolin rutinosides as luteolin-7-*O*-glucoside, luteolin-3′-*O*-glucoside and luteolin-4′,7-*O*-diglucoside as luteolin-4′-*O*-glucoside, and all secoiridoids as oleuropein with an exception of caffeoyl-6′-secologanoside expressed as caffeic acid, and unknown A, unknowns 408 MW and comselogoside, which were expressed as *p*-coumaric acid equivalents. The identification strategy of all is in depth described elsewhere.[13]

U(H)PLC method validation. Prior to quantification, the suitability of U(H)PLC-DAD system was checked in terms of injector's reproducibility and linearity using commercially available standards.

The linearity of method was evaluated by serial dilution of standard stock solutions over broad concentration ranges using ten-point calibration curves.

The LODs and LOQs were calculated from y-intercept standard deviations (S_b) and slopes (a) of calibration curves using signal-to-noise ratio criteria of 3.3 (LOD = 3.3 x Sb/a) and 10 (LOQ = 10 × Sb/a) in the concentration ranges close to LOQs expected for each phenolic compound in prepared extracts (μg/mL): 0.33−1.67 (vanillin), 0.35−1.73 (vanillic acid), 0.33−1.65 (*p*-coumaric acid), 1.24−7.44 (caffeic acid), 1.44−5.76 (hydroxytyrosol), 1.40−3.93 (tyrosol), 1.00−2.99 (oleuropein), 0.39−0.97 (verbascoside), 0.24−1.20 (rutin), 0.23−1.17 (quercitrin), 0.25−1.23 (luteolin-4′-*O*-glucoside), 1.62−5.85 (apigenin), 0.48−2.87 (apigenin-7-*O*-glucoside), 0.56−4.49 (luteolin), 1.26−3.78 (luteolin-7-*O*-glucoside) and 0.79−4.76 (pinoresinol).

Extraction efficiencies of USLE and US-LLE methods were checked prior to application to olive matrices in terms of phenol yield recoveries obtained via consecutive five-step extraction. The extracts of destoned fruits, stone, paste, pomace and wastewater were submitted to a complete USLE method (3 × 20 min) using 25 mL of pure methanol. Then, the remaining solid residue was re-extracted twice and analyzed by U(H)PLC for a potential phenols presence in the fourth and fifth extraction step, where the summation of phenol yields from a five-step extraction was considered as 100%. Analogously, the efficiency of US-LLE method (3 × 10 min, 5 mL 100% meOH) has been checked for the oil sample.

Phenols partition and transfer percentages. The phenols partition and transfer percentages from fruits to paste and to final products (pomace, wastewater, oil) were calculated considering the mass balance according to eq 1:

$$\%P_{matrix} = (P_{matrix}/P_{fruit}) \times (m_{matrix}/m_{fruit}) \times 100 \quad (1)$$

where P is the concentration of individual phenolic compound in particular matrix expressed in mg/kg per fruit FW and m the mass of selected matrix and fruit FW (g) in press experiment.

Additionally, the percentages of their increases/decreases during crushing and malaxation were calculated using eqs 2 and 3:

Increase/decrease during crushing is presented with parameter c_c (in %):

[a]Expressed as mean ± SD (mg/kg fruits FW); Σ = total initial fruit content (destoned fruit + stone); t = 0, paste obtained immediately after crushing. [b]Expressed as mean ± SD (mg/kg fruits FW × e^{-2}). [c]Crushing; Sign t: total initial fruit and paste means separated by t-test (***, $P \leq 0.001$; **, $P \leq 0.01$; *, $P \leq 0.05$; ns, not significant, $P \geq 0.05$), c_c = % of increase/decrease with respect to fruits (eq 2); (−) value could not be calculated. [d]Malaxation Sign t; paste and total output means separated by t-test (***, $P \leq 0.001$; **, $P \leq 0.01$; *, $P \leq 0.05$; ns, not significant, $P \geq 0.05$); c_m = % of increase/decrease with respect to paste (eq 3); (−) value could not be calculated. [e]Compound is described as not detected (nd), not quantified (nq) due to trace amount (tr), inconsistent UV−vis spectrum (ins), coelution problems (co). [f]Numbers of peaks are referring to Figures S1−S6 in the Supporting Information. [g]Σ TP = sum of U(H)PLC-DAD quantified phenols.

J. Agric. Food Chem. 2015, 63, 4570−4579
DOI: 10.1021/jf506353z

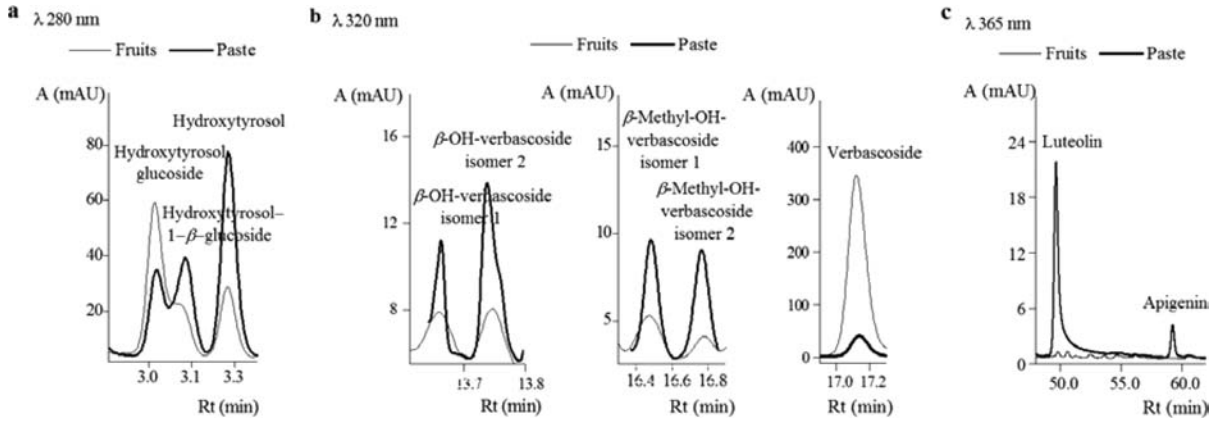

Figure 1. U(H)PLC-DAD phenolic profiles of olive fruits and olive paste.

$$c_c = (P_{paste} \times 100/P_{fruit}) - 100 \quad (2)$$

Increase/decrease during malaxation is presented with parameter c_m (in %):

$$c_m = ((P_{pomace} + P_{wastewater} + P_{oil}) \times 100/P_{paste}) - 100 \quad (3)$$

The initial fruit phenolic content was considered as the available (100%) pool derived from destoned fruit and stone marked as input (Table 1), while the term TP (total phenols) refers to a sum of U(H)PLC-DAD quantified phenols.

Statistical analysis. All results were expressed as means ± SD obtained from at least triplicate analyses and tested by ANOVA or *t* test (*, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$; n.s., not significant) using Costat Statistics Software 6.4 (CoHort Software, CA, USA). When ANOVA was significant, means were separated using Tukey's HSD test ($P < 0.05$).

RESULTS AND DISCUSSION

Method validation. The suitability of the U(H)PLC-DAD system was satisfactory, where the linearity of the injector was always above 99% and the reproducibility of ten replicates has never exceeded 0.5% of RSD, respectively.

The linearity of the method was excellent with high correlation coefficients (R^2) obtained for all standards over their broad concentration ranges (μg/mL) tested as follows; vanillin (y = 0.6348x; R^2 = 0.9933; 0.33−64.83), vanillic acid (y = 0.2899x; R^2 = 0.9957; 0.35−67.26), *p*-coumaric acid (y = 0.7863x; R^2 = 0.9946; 0.33−64.21), caffeic acid (y = 0.6081x; R^2 = 0.9982; 1.24−99.19), hydroxytyrosol (y = 0.1488x; R^2 = 0.9970; 1.44−524.19), tyrosol (y = 0.0993x; R^2 = 0.9937; 1.40−219.00), oleuropein (y = 0.0359x; R^2 = 0.9963; 1.00−7953.12), verbascoside (y = 0.2403x; R^2 = 0.9991; 0.39−1013.12), rutin (y = 0.2368x; R^2 = 0.9952; 0.24−312.40), quercitrin (y = 0.2329x; R^2 = 0.9925; 0.23−121.44), luteolin-4′-*O*-glucoside (y = 0.1775x; R^2 = 0.9976; 0.25−896.56), apigenin (y = 0.2293x; R^2 = 0.9988; 1.62−232.80), apigenin-7-*O*-glucoside (y = 0.3362x; R^2 = 0.9999; 0.48−274.56), luteolin (y = 0.2684x; R^2 = 0.9928; 0.56−483.12), luteolin-7-*O*-glucoside (y = 0.2487x; R^2 = 0.9962; 1.26−765.24), pinoresinol (y = 0.1429x; R^2 = 0.9975; 0.79−285.76).

The sensitivities of the DAD detector were determined by calculating the LODs/LOQs for each standard expressed in μg/mL and were as follows: 0.36/1.09 (vanillin), 0.23/0.69 (vanillic acid), 0.22/0.67 (*p*-coumaric acid), 2.46/7.44 (caffeic acid), 2.55/7.74 (hydroxytyrosol), 1.75/5.29 (tyrosol), 1.57/4.76 (oleuropein), 0.19/0.58 (verbascoside), 0.03/0.01 × e^{-1} (rutin), 0.01/0.04 (quercitrin), 0.12/0.36 (luteolin-4′-*O*-glucoside), 1.20/3.87 (apigenin), 0.17/0.52 (apigenin-7-*O*-glucoside), 0.53/1.60 (luteolin), 0.16/0.49 (luteolin-7-*O*-glucoside), and 0.04/0.11 (pinoresinol).

The extraction methods for the phenol isolation from olive matrices entailed in the olive oil processing trial were adopted from our earlier reports performed as a preliminary step toward a high-yielding TP analysis in fruits, wastewater, and olive oil.[14−16] However, prior to application in this experiment and evaluation with U(HPLC)-DAD, their efficiencies had to be rechecked, owing to introduction of new olive matrices of richer quali- and quantitative profiles and novel ones for which the recovery optimizations have not yet been performed (paste, pomace, and stone). Even so, our results confirmed that both USLE and US-LLE extractions are efficient for the quantitative phenol analysis, where a three-step extraction provided recoveries superior to 98% on average for all six matrices (US-LLE for the oil and USLE for others), again testifying to high powerful US extracting abilities

Quantification results. Table 1 presents detailed insight into olive fruit phenols transfer, transformation, and partition trail behavior during olive oil processing as affected by two operational steps, i.e. crushing and malaxation (30 min/25 °C). The process itself has two inputs, i.e. destoned fruit and stone, one middle/intermediate product (paste), and three outputs, i.e. pomace, wastewater, and oil, allowing us to follow the origin, evolution, and disappearance of each phenolic compound throughout the processing. The identification of all compounds presented in this study is described elsewhere.[13]

Impact of crushing. The relative contribution of the crushing step to a phenols reduction during olive oil processing has been rarely quantified in the existing literature. Similarly, little scientific information is available regarding its role in their transformative process, as the range of phenols analyzed so far has been limited.[6−9,18] A direct comparison of olive fruits initial phenolic composition (destoned fruit + stone) with the corresponding paste obtained directly after crushing (t = 0) is the first approach to such an estimation. Looking quantitatively, a significant TP drop was observed immediately after crushing (46%), confirming the previous postulation of being the most critical step in the overall process.[4] A similar TP loss (50−60%) has already been reported before for industrial-scale trials.[6,9] Although brief, this technological operation has also induced several transformative changes arriving from the mechanical mixing action, chemical and/or biochemical reactions, i.e. enzymatic and nonenzymatic hydrolyses, and oxidations.[19] As seen from results, crushing implied a rise of

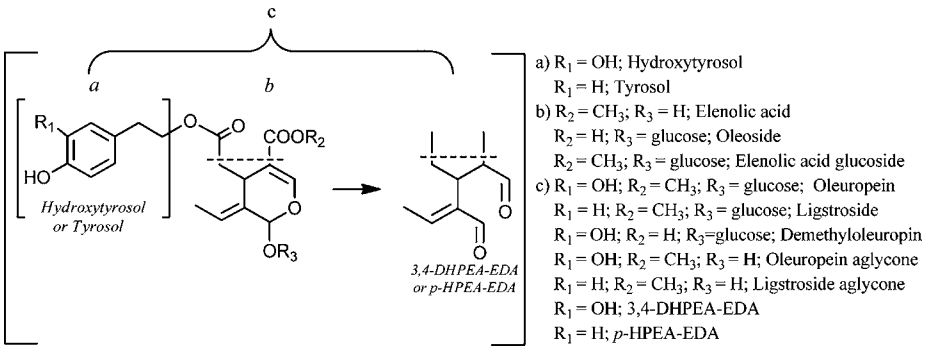

Figure 2. Possible interconversions of selected secoiridoids containing tyrosol and hydroxytyrosol in their structures.

simple phenols and benzoic acids, but decreased the yields of other classes with an exception of lignans, which were not involved/affected by the milling process. At the level of individual phenols, 13 out of 51 initially quantified fruit phenols have irrevocably disappeared after crushing (mainly those from stone) and eight newly appeared in the paste, indicating their technologically induced formation and/or release. The phenol profile of olive paste thus seems to be a result of all the transfer, liberation, and transformation phenomena with none, partial, or total hydrolysis/degradation of olive fruits native phenols, leading to a formation of new respective derivatives. A visual comparison of fruits' and paste's phenolic profiles (Figure 1) reflects some of the potential interconversion changes discussed below.

The highest decrease was observed for the main olive fruit secoiridoid glucosides, i.e. oleuropein, demethyloleuropein, and ligstroside, which is in line with previous reports.[6−9] While the content of oleuropein decreased for 94%, its demethylated form was almost completely degraded (traces of demethyloleuropein), whereas ligstroside could not be detected by DAD anymore. According to the mechanism of Servili et al.,[4] these glucosides can be transformed into their respective aglycones, primarily to oleuropein or ligstroside aglycones and further to their decarboxymethylated forms, i.e. 3,4-DHPEA-EDA or *p*-HPEA-EDA. Indeed, both of the potential (demethyl)-oleuropein transformants were found in olive paste after crushing; their first interconversion product eluted as three (oleuropein aglycone isomers), while the second as two peaks (3,4-DHPEA-EDA isomers), together accounting for 35 and 12% of fruits initial demethyloleuropein + oleuropein content together. This could indicate that crushing accelerated an enzymatic degradation of both glucosides, which already began in the fruit and would likely progress during maturation. Such an assumption is supported by the previous MS trace detection of oleuropein aglycones in destoned fruits[13] and the fact that 3,4-DHPEA-EDA has already been found in the fruits before.[20] Analogously, these transformants could also arrive from oleuropein diglucoside isomer 2, whose complete degradation was observed after crushing, while the rise of its isomer 1 (+64%) is thus far unexplained and warrants further investigation. Nevertheless, the transformation of these native fruit secoiridoid glucosides could also yield some other oleuropein structurally correlated phenols whose yields have increased after crushing, such as dihydro-oleuropein isomer 1 or others of lower molecular weight (MW) phenols. Indeed, there are many cleavage products possible upon the degradation of oleuropein, demethyloleuropein, and ligstroside, of which some are illustrated in Figure 2.

By contrast, the degradative mechanism of ligstroside was more ambiguous, as none of its two potential transformants (ligstroside aglycones and *p*-HPEA-EDA) could be detected in paste by DAD, but instead could easily be quantified in the oil at the end of the processing. The relationship that quantitatively explains such vague interconversion remains unclear and may indicate that (i) ligstroside was completely transformed into both, but the complexity of the paste's structure restricted their detection in paste, as its composition immediately after crushing is known to strongly differ from that after malaxation,[21] or (ii) these two transformants could have formed the complexes with polysaccharides released only after malaxation,[22] or (less likely) (iii) ligstroside was completely oxidized and/or transformed into other products, while its respected aglycones found in olive oil are the hydrolysis products of others, but structurally related compounds.

However, beyond the knowledge of fruits' prime secoiridoid glucosides behavior, the degradative mechanism of stone's main secoiridoid glucosides, *i.e.* nüzheonide and its esterified forms with methoxy group and 11-methyl oleoside, has not yet been established. Interestingly, only two out of ten quantified representatives were increased upon olives crushing (nüzhenide isomer 2 for 21% and nüzhenide 11-methyl oleoside isomer 4 for 258%), most likely due to improved release and/or the mill prompted hydrolysis of higher MW phenols such as nüzhenide (di)esters giving rise to their formation. All the other nüzhenide representatives have totally diminished throughout the milling operation due to either low oxidation resistance and/or crushing-induced degradation. Nevertheless, based on their chemical structures they could all yield a tyrosol glucoside, whose significant rise in paste (134%) should be marked after crushing.

Crushing also implied a rise of other simple phenols (Figure 1a, Figure 2a); hydroxytyrosol has increased for 170%, owing to degradation of hydroxytyrosol-containing compounds, while tyrosol for 107% due to the hydrolysis of tyrosol-containing phenols. This could have occurred via cleavage of the ester bond by the action of endogenous esterases splitting secoiridoid glucosides or their aglycones (Figure 2c), giving rise to elenolic acid glucoside, oleoside, or elenolic acid (Figure 2b). Until now, the release of simple phenols from aglycones was considered to ensue only during oil storage[23] and never during the course of its production. Alternatively, hydroxytyrosol could also be released from the fruits native hydroxytyrosol glucoside (−29%) and/or verbascoside (−31%) by the activity of glucosidases, analogously as tyrosol from nüzhenide and its esters. Owing to such complexity, it was not possible to assign their exact origin, as no obvious increase of the corresponding

DOI: 10.1021/jf506353z
J. Agric. Food Chem. 2015, 63, 4570−4579

cleavage compounds could be observed in olive paste. Another remarkable fact is also a distinct behavior of the two hydroxytyrosol glucosides displaying a rise (70%, hydroxytyrosol glucoside-1-β-glucoside) and a drop (29%, hydroxytyrosol glucoside) after olives crushing. Such a discrepancy clearly indicates their different chemical structure and for the first time experimentally supports (during the course of olive oil production) what has only been proposed before;[1] hydroxytyrosol glucoside-1-β-glucoside is a hydrolysis product of verbascoside enhanced by both the crushing and malaxation, while the formation of hydroxytyrosol glucoside appears not to be technologically prompted; instead it rather contributes to its degradation.

The appearance of vanillic acid in olive paste after crushing raises an issue of its origin. The fact that it was absent in both input matrices but present in all olive oil process-derived products suggests that is a formation product of the technological process. Possible explanations include a crushing-induced hydrolysis of lignin from stone once already proved to yield vanillic acid under acid stem explosion,[24] although there is always a possibility that a lab-milling of stone in a sample preparation was not efficient as the mill crushers of the Abencor system, hampering its expected detection in this fruit compartment. Interestingly, its quantitative yield was further unaffected by the malaxing conditions, which seems to only be facilitated its full distribution among the final products. By contrast, vanillin was detected in olive stone, but not in the corresponding paste, which could be attributed to a brief duration of crushing step, suffering less tissue damage, and hence a limited release immediately after it. The subsequent malaxation apparently induced its extractability, which allowed its quantification in olive oil, though in a much lower amount with respect to its original content in stone (3%).

Among cinnamic acids, only verbascoside has diminished after fruits crushing (−31%), whereas all of its derivatives have considerably increased (>150%, Figure 1b). It is of interest to add that their accumulation has further proceeded also during malaxation; thus, it is very likely that verbascoside derivatives had originated from any of the fruits' native unknown compound(s) hydrolyzed upon crushing and malaxation. Moreover, their initial presence in olive fruits suggests that the technology has only hastened the biosynthetic interconversion that would likely occur also at the fruit level; however, such a hypothesis undoubtedly warrants further investigation and is beyond the scope of the present study.

Crushing also contributed to a loss of glycosylated flavonoids with an exception of luteolin 3′-*O*-glucoside, which seemed to be resistant to any or all enzymatic and/or nonenzymatic degradations, transformations, or oxidations. The appearance of two new flavonoidal aglycones in olive paste, i.e. luteolin and apigenin (Figure 1c), indicates that some of them were hydrolyzed by the endogenous glucosidases, released, and/or activated by crushing, but a firm relationship could only be established for apigenin, whose formation in olive paste was collaborated with a drop of apigenin-7-*O*-glucoside. Luteolin, on the other hand, may have arisen from any or all of the six luteolin glycosides, rutin, and/or quercitrin.

In spite of several quali- and quantitative induced changes by crushing, a small portion of phenols remained unaffected, including luteolin-3′-*O*-glucoside, comselogoside, and caffeoyl-6′-secologanoside. A remarkable fact is that all of their yields have further remained constant also during malaxation, indicating their high technological resistance, which could have a wide potential in a forward design of TP enriched food products.

Impact of malaxation. Although phenols yield behavior during the course of malaxation has not been separately monitored, their levels in the output matrices yet permitted reliable insight into their further transformation/partition trail from paste to the final products, especially if it is considered that the time of the paste's span in the centrifuge is too short to allow important modifications to happen.

In general, the behavior of phenols during malaxation continued the trend initiated by the crushing, though quantitatively to a lower extend; a positive yield rise kept an increasing trend due to improved releases and/or transformative reactions, while the yield losses were followed by a further drop owing to enzymatic and/or nonenzymatic hydrolyses and oxidations. However, there were also a few exceptions; for example, luteolin rutinoside isomer 1 showed a rise after initial drop, while some of the potential transformants have decreased, i.e. elenolic acid glucoside isomer 1, 3,4-DHPEA-EDA isomer 1, nüzhenide isomer 2, oleuropein aglycone isomer 1, and nüzhenide 11-methyl oleoside isomer 4. This could indicate that the hydrolysis of their parent compounds has finished and their oxidative degradation prevailed due to operative conditions and/or enzymatic activities. By contrast, some other potential transformants (dihydro-oleuropein isomer 1 and oleuropein aglycone isomer 3) remained rather unaffected, similarly as most of the flavonoidal representatives. Moreover, the evolution of some new phenols could be evidenced in the final products; both representatives of lignans and some of secoiridoids (all unknown 484 MW isomers, *p*-HPEA-EDA, ligstroside aglycones, and the acetal of 3,4-DHPEA-EDA) have appeared in the oil or in the wastewater, while not in pomace, though some traces could still be previously detected by MS as well.[13] It is thus possible to deduce that only malaxation conditions were efficient enough to induce their formation and/or release due to prolonged mixing and/or enzymatic actions. However, there is always a possibility that the extraction method for these compounds was not equally efficient for all matrices, owing to structural specifics, requiring other approaches as previously demonstrated for lignans in fruits.[25]

Looking from a TP yield perspective, no losses could be observed during malaxation at 30 min/25 °C conditions, indicating a balanced degradation/formation equilibrium of the phenolic compounds quantified. In other words, the available pool of phenols detected in olive paste after crushing could also be quantified at the end of the process via a TP sum of output products (∼54%). This is somewhat in line with previous reports,[9] demonstrating no significant losses of phenol constituents during the malaxation process, though this operation has often been associated with major quantitative loss.[8] However, as further evident from results, only 0.53% of the available fruit phenols have ended up in olive oil and nearly 6% in the wastewater, while others have remained entrapped in the solid (48.12%). Such a partition distribution is rather different from our earlier industrial-scale results[6] (0.3−1.2% oil; 38.2−46.2% wastewater; 4.5−47.4% pomace), but not surprising as the latter is govern by the quantity of final products formed. In a present lab-scale study, pomace was clearly the predominant byproduct formed (82.3%), while the yielding indexes of liquid matrices were much lower, i.e. 8.9% for oil and 8.8% for the wastewater, most likely due to a less efficient

DOI: 10.1021/jf506353z
J. Agric. Food Chem. 2015, 63, 4570−4579

phases separation system in the Abencor mill. A similar components' yield distribution has been observed elsewhere.[11]

A high retention of phenols in pomace further suggests that the process conditions applied (30 min/25 °C) have not fully induced their transfer to liquid phases, yet constituting a challenge for some potential improvements. Our results also confirmed that a major proportion of fruit phenols is indeed lost with wastes, but some also owing to their technological destruction. This, however, is not in full agreement with the available results in the literature,[5] showing no TP losses during olive oil processing, but rather their unsuited yield distribution among the final products, i.e. 1−2% oil, 53% wastewater, and 45% pomace. However, it is rather uncommon that processing would quantitatively yield all the phenols confined in the initial fruit material (100% TP pool), especially not due to a well-known phenomenon of their oxidative catabolism.[4]

Partitioning model. The majority of phenols have originated from the pulp and/or peel, together accounting for 95% of the fruits initial TP content, while stone confined only a minor fraction (∼5%). Secoiridoids were the predominant class in both input matrices and maintained their prominent role also in the process-derived matrices, though represented by different individuals. With the exception of olive stone, the class distribution in solid matrices has decreased in the order secoiridoids > flavonoids > cinnamic acids > simple phenols. By contrast, in the wastewater, simple phenols constituted the second largest class, evidencing their hydrophilic nature, analogous to lignans in olive oil showing high tendency for the oily matrix. Interestingly, none of the fruit flavonoid glycosides were transferred to the oil above their trace amounts, but instead were largely confined in both of the waste matrices. Similarly, all cinnamic acids from fruits were lost with the byproducts, though one has scarcely been transferred to the oil as well, *i.e. p*-coumaric acid. The partition behavior of secoiridoids was rather similar to flavonoids, where apart from the two known glucosides (secologanoside and elenolic acid glucoside isomer 2), only aglycones were partitioned to the oil, while the other glucosides have ended up in the wastes (e.g., comselogoside and caffeoyl-6′-secologanoside). Such a partitioning model is quite similar to one previously reported at the industrial-scale level using different starting fruit materials,[6] which indicates that their qualitative distribution pattern among the final products is rather more common than unique.

The research interest in redesigning current technological approaches to provide higher extractability of olive oils with richer phenol yields and with lower ecological footprints has been great in recent years and is still significant due to increasing demands for functionally and sustainability in the olive oil industry. The results of the present study have provided us a deeper insight into phenols quantitative behavior during laboratory-scale olive oil processing, their tendency for individual matrices, and resistance to the technologically induced modifications, which are important in the recognition of their quality and value to mankind. Moreover, they provided us a better understanding of the relationship between the initial and final products, which could benefit any further industrial-scale trials.

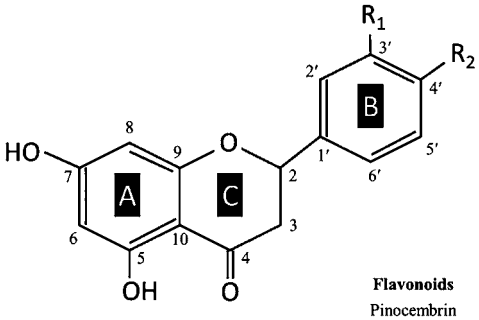
Previous reports have revealed that flavanone had better antioxidant ability than flavone because the single bond between C2 and C3 in flavanone had more flexibility than the double bond in flavones, which allowed cells to easily take up the compound.[20] Therefore, this study further focuses on their antioxidant activity as affected by the hydroxyl group found on the B-ring of flavanone structures. In this study, macrophage cell (RAW264.7), the main producer of superoxide, was used as cell model. Phorbol ester, phorbol 12-myristate 13-acetate (PMA), was used to stimulate superoxide production. Pinocembrin, naringenin, and eriodictyol, containing no, one, and two hydroxyl groups on their B-ring (Figure 1), respectively, were investigated for their antioxidant activity



Flavonoids	R_1	R_2
Pinocembrin	H	H
Naringenin	H	OH
Eriodictyol	OH	OH

Figure 1. General molecular structure of flavanone. Numbers reflect position of carbon skeleton. A, B, and C indicate the name of carbon rings of flavonoid molecular structure. Pinocembrin, naringenin, and eriodictyol have different numbers of substituting hydroxyl groups to R_1 and R_2 position on the B-ring.

by various in vitro assays including scavenging activity, reactive oxygen species (ROS) inhibition, and protein immunoblotting. Finally, in silico analysis was introduced to this research to simulate interaction between the flavonoids and PKCδ phorbol ester binding site. Altogether, the results would indicate the influence of flavonoid structure on antioxidant activity at the molecular level and serve as a further guide on how to improve the efficiency of flavonoids.

MATERIALS AND METHODS

Chemicals. Pinocembrin, naringenin, eriodictyol, PMA, 2′,7′-dichlorodihydrofluorescein diacetate (DCFH-DA), dimethyl sulfoxide (DMSO), 2,2-diphenyl-1-picrylhydrazyl (DPPH), and butylated hydroxyanisole (BHA) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Fetal bovine serum (FBS) and antibiotics were obtained from Biological Industries (Haemek, Israel). Dulbecco's modified Eagle's medium (DMEM) and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were bought from Gibco BRL (Grand Island, NY, USA) and AppliChem (Saxony-Anhalt, Germany), respectively.

Cell Culture and Treatments. Macrophage RAW264.7 cells were purchased from Bioresource Collection and Research Center, Taiwan. DMEM, supplemented with 10% FBS and 0.5% antibiotics (v/v), was used to culture the cells in a 10 cm Petri dish (Corning, New York, USA). The cells were incubated in a humidified incubator at 37 °C under 5% CO_2 and 95% air and subcultured every 2 days. Cell culture preparation before treatments was done by seeding cells at 1×10^6 cells/well into 96-well plates for cell viability assay or into 6-well plates for other assays. The seeded cell culture was allowed to acclimate for 12 h at 37 °C under 5% CO_2 before the flavonoid treatments.

Cell Viability Assay. MTT assay was used to investigate cytotoxicity effects of the flavonoids. RAW264.7 cell culture was prepared in 96-well plates as described under Cell Culture and Treatments. Each flavonoid at final concentrations of 10, 50, 100, and 200 μM in an appropriate amount of DMSO was added to the cell culture. After 24 h of the flavonoid treatments, the medium was discarded and MTT solution was added into each well. The plate was placed in the dark at room temperature for 3 h. Finally, DMSO was added to dissolve the purple formazan compound for 30 min, and the optical density (OD) was observed at 570 nm by ELISA reader (VersaMax microplate reader, Molecular Devices, San Francisco, CQA, USA). Ten replicates from each experiment were measured for the OD, and each experiment was repeated three times.

Measurement of DPPH Radical Scavenging Activity. The method to determine the scavenging activities of the flavonoids was adapted from that of Chao et al.[21] Briefly, 250 μL of 1 mM DPPH solution in methanol was added to 2 mL of 10 μM flavonoid solution. The mixture was shaken vigorously, allowing the reaction to proceed for 30 min in the dark, after which the absorbance was measured at 517 nm. The calculation of the scavenging activity was done by using the following formula where A_B and A_S are the absorbance of blank and sample, respectively. BHA was used as standard in this assay. The DPPH scavenging activity of each flavonoid was determined in triplicate.

$$\text{radical scavenging activity (\%)} = \left(\frac{A_B - A_S}{A_B}\right) \times 100$$

Reactive Oxygen Species (ROS) and IC_{50} Determination. Flow cytometer (FACSCaliburTM, BD Biosciences, Canada) was used to analyze ROS inhibition by the flavonoids. After 12 h of cell culture acclimation in 6-well plates, each flavonoid was added into each well (final concentration = 10 μM) for 24 h. PMA (final concentration = 100 ng/mL) was added at the last 30 min of the flavonoid treatment to induce the ROS production. Cells were washed twice by phosphate buffer saline (PBS) and harvested by using a cell scraper. Cell suspension was centrifuged at 500g (4 °C) for 5 min to obtain cell pellet. Cell pellet was incubated with 10 μM DCFH-DA at 37 °C in the dark for 30 min. After that, fluorescent intensity of dichlorodihydrofluorescein (DCF) was observed under FL-1 mode of the flow cytometer. Area gating was done in dot plot under E-1 mode, where >90% of cells were located inside the gated area. Data were collected from 10000 gated cells. The definition of IC_{50} is the flavonoid concentration required to inhibit half or 50% of PMA-induced ROS production. The IC_{50} was calculated using linear regression of ROS inhibition (%) from three different concentrations of each flavonoid. This assay was repeated five times for each experiment.

Proteins Immunoblotting Assay. RAW264.7 cells were treated with the flavonoids as described under Reactive Oxygen Species (ROS) and IC_{50} Determination. The cells were harvested and membrane proteins were collected and quantified using Mem-PER Plus Membrane Protein extraction kit and BCA protein assay kit (Thermo Scientific, Rockford, IL, USA), respectively, with bovine serum albumin as standard. Equal amounts of protein (30 μg) were loaded into each lane of 8% SDS–polyacrylamide gel, and protein separation was done by applying 110 V for 110 min. Polyvinylidene-fluoride (PVDF) membrane (PerkinElmer, Boston, MA, USA) was used to embed proteins from the gel through transfer process at 250 mA for 1 h. The membrane was blocked with blocking buffer and subjected to primary target antibodies (1:1000), phosphor-PKCδ Thr505, β-actin, (Cell Signaling, Beverly, MA, USA), and phosphor-p47 (Assay Biotech, San Diego, CA, USA), for 16–18 h at 4 °C. After that, the membranes were washed by TBST buffer for 1 h and subjected to diluted 1:5000 secondary antibodies (Merck Millipore, Bedford, MA, USA) for 1 h at room temperature. The membranes were washed again by TBST buffer for 1 h, and the protein bands were revealed with enhanced chemiluminescence reagent (ECL, Advansta, Menlo Park, CA, USA).

Molecular Docking. Docking study was performed in Accelrys Discovery Studio Visualizer version 3.0. Phorbol binding site, C1B domain, of PKCδ at 1.95 Å resolution and ligands were downloaded from RCSB Protein Data Bank (PDB code 1PTQ) and National

DOI: 10.1021/acs.jafc.5b00312
J. Agric. Food Chem. 2015, 63, 4580–4586

Center for Biotechnology Information (NCBI), respectively. All small molecules surrounding PKCδ structure including water molecules and phorbol ester ligand were removed for docking preparation. Molecules' energy was minimized by CHARMm program. Binding site of C1B domain was defined by using glycine 253 coordinate (*x*, 7.104; *y*, 24.326; and *z*, 27.682). The docking process was done by using the docking optimization CDOCKER tool in the software. The best 10 poses based on -CDOCKER_energy were obtained from docking, and hydrogen bond interactions between the ligands and amino acids in the receptor were sequentially visualized.

Statistical Analysis. Experimental results were used for analysis of variance using the Statistical Package for the Social Sciences (SPSS) computer program version 19. Significant differences between means were determined by Duncan's multiple-range test or Student's *t* test ($p < 0.05$).

RESULTS AND DISCUSSION

Cytotoxicity of Pinocembrin, Naringenin, and Eriodictyol in RAW264.7 Cells. Macrophages are well-known for their involvement in the immunological responses by producing superoxide compounds. Besides, it was reported that macrophages are targeted for oxidative stress therapeutic approaches.[22] Thus, murine macrophage RAW264.7 cells were used as cell model to evaluate oxidative stress level in this study. The influence of three flavonoids, pinocembrin, naringenin, and eriodictyol, on RAW264.7 cell viability was evaluated (Figure 2). After 24 h of exposure to the test compounds, it was found

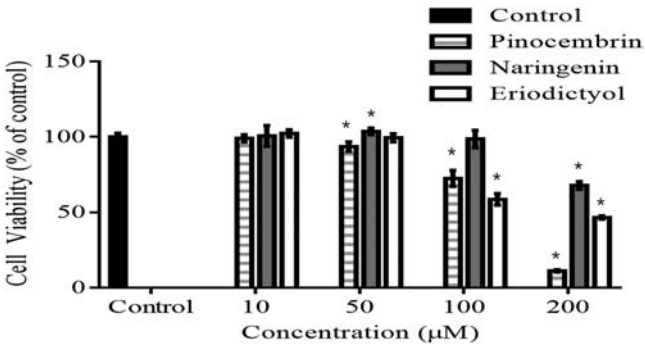


Figure 2. Cytotoxicity of pinocembrin, naringenin, and eriodictyol in RAW264.7 macrophage cells. RAW264.7 cells were treated with 0−200 μM of the flavonoids for 24 h. MTT was used to determine the viability of the cells after treatments. Optical density was measured at 570 nm. The experiments were performed with 10 replicates and were repeated three times. The values are expressed as mean ± standard deviation, and asterisks (∗) mark significant difference between each treatment and control group by Student's *t* test ($p < 0.05$).

that the highest concentrations of pinocembrin, naringenin, and eriodictyol, which did not significantly affect cell viability of in RAW264.7 cells, were 10, 100, and 50 μM, respectively. Previous literature reported similar results with different cell lines in which the highest concentrations of pinocembrin, naringenin, and eriodictyol were 10, 100, and 50 μM, in Y-79, microglia, and U937 cells, respectively.[23−25] In addition, it was also found that naringenin was the least toxic compound to RAW264.7 cells. Naringenin exhibited higher numbers of live cells than other flavonoids at concentrations between 50 and 200 μM, especially at 100 μM where the other two flavonoids significantly ($p < 0.05$) caused cell death. Finally, it was found that all flavonoids at 10 μM did not significantly affect cell viability. Therefore, the other assays in this research were conducted with flavonoid concentration at 10 μM.

Radical Scavenging of the Flavonoids. Pinocembrin, naringenin, and eriodictyol at 10 μM were tested for their scavenging activity. As shown in Figure 3, naringenin performed slightly higher scavenging activity than pinocembrin, but significantly higher activity ($p < 0.05$) was exhibited by eriodictyol over both pinocembrin and naringenin. The results from this assay were similar to those of Ye et al.,[26] where the number of hydroxyl groups on the B-ring was increased through the hydroxylation of naringin by *Trichoderma harzianum*. Adding one hydroxyl group to the B-ring of naringin could reduce the concentration of the compound by 40 times, whereas the DPPH scavenging activity remained at the same level.[26] Moreover, when two hydroxyl groups were added to the naringin, the scavenging activity was higher than when only one hydroxyl group was added.[26] Besides, the positions of hydroxyl groups on the B-ring also greatly contributed to the scavenging activity. Thavasi et al.[27] and Zhang et al.[28] illustrated that the addition of a hydroxyl group to the ortho position of phenol reduced O−H bond dissociation enthalpy (BDE) by 17.5 and 30.1 kJ/mol, respectively. On the other hand, addition to the meta position did not reduce the BDE.[27] Therefore, the greater number of hydroxyl groups and their ortho arrangement on the B-ring both made eriodictyol superior over pinocembrin and naringenin with regard to their scavenging ability.

Flavonoids Reduced ROS Production in PMA-Activated RAW264.7 Cells. Inhibition of ROS production in RAW264.7 was determined on the basis of the DCFH-DA principle. In brief, deacetylated DCFH-DA reacts with ROS compounds resulting in DCF, which can be detected by the FL-1 channel of flow cytometer. From this experiment, activated cells, treated with eriodictyol, had the lowest ROS level, followed by naringenin and pinocembrin, respectively (Figure 3). Furthermore, statistical analysis indicated that the three flavonoids could significantly reduce ($p < 0.05$) the ROS production compared with PMA-induced RAW264.7 cell (positive control). In addition, comparing the inhibition activity of each flavonoid, pinocembrin and naringenin showed similar ROS reduction. On the other hand, the inhibitory efficiency of eriodictyol was significantly higher ($p < 0.05$) than that of pinocembrin and naringenin. This implied that the two hydroxyl groups on the B-ring of eriodictyol had remarkable effects on the ROS reduction when compared to the lower number of hydroxyl groups on pinocembrin and naringenin. The reason was because the hydroxyl group on the B-ring acts as a hydrogen donor to stabilize radical species;[29] however, the presence of one hydroxyl group on the B-ring provides only little benefit to the antioxidant activity.[30] Thus, one hydroxyl group on the B-ring of naringenin could not importantly enhance ROS inhibition compared to pinocembrin. IC_{50} values of pinocembrin, naringenin, and eriodictyol were 44.9 ± 0.57, 30.2 ± 0.61, and 17.4 ± 0.40 μM, respectively (Supporting Information).

Flavonoids Reduced Oxidative Stress by Inhibiting Phosphorylation of PKC-δ and p47 in RAW264.7 Cells. From this assay, phosphor-PKCδ and phosphor-p47 expression at lipid raft were observed. PKCδ, a member of novel PKCs group originally located in cytoplasm, was found to be heavily phosphorylated compared to other PKC isoforms[31] and translocated to cell membrane when RAW264.7 cells were activated by PMA.[32] In addition, NADPH oxidase regulatory subunit, $p47^{phox}$, was found to be activated by phosphorylated PKC isoforms.[33] Overactivation of NADPH oxidase is one of

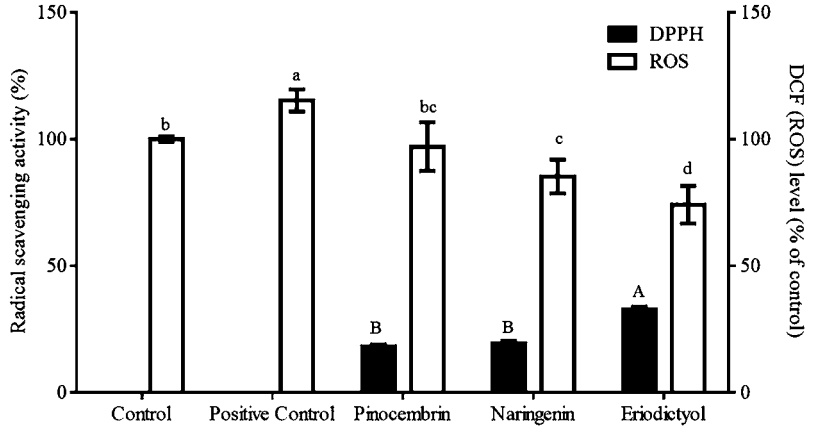

Figure 3. Radical scavenging activity of pinocembrin, naringenin, and eriodictyol at 10 μM concentration (black bars) and their reduction of ROS production in PMA-activated RAW264.7 cell (white bars). Cells were treated with the flavonoids for 24 h prior to 30 min of PMA activation. Cells without flavonoid treatment prior to PMA activation were named as positive control. The values were expressed as mean ± standard deviation from at least three individual experiments. Different letters indicate the significant difference in each group with other treatments ($p < 0.05$, Duncan test).

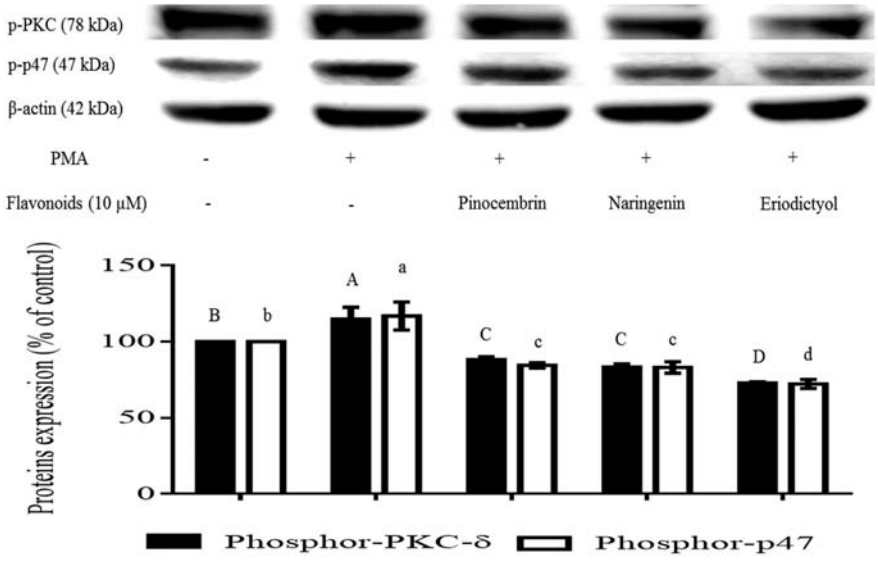

Figure 4. Flavonoids inhibited PKCδ activation to cell membrane. Pinocembrin, naringenin, and eriodictyol at 10 μM concentration were treated to 1×10^6 cells RAW264.7 macrophage cells for 24 h prior to 30 min of PMA activation. The values were expressed as mean ± standard deviation. Three replicates were done for each treatment. Different letters indicate the significant difference in each group with other treatments ($p < 0.05$, Duncan test).

the oxidative stress sources,[34] so the expression of phosphor-p47^{phox} at cell membrane is useful to determine the oxidative stress level. The results showed that all three flavonoids could significantly reduce ($p < 0.05$) phosphor-PKCδ and phosphor-p47^{phox} expressions in PMA-activated RAW264.7 cell membrane (Figure 4). Pinocembrin and naringenin inhibited the phosphorylation of both proteins at similar efficiencies, whereas eriodictyol performed significantly higher ($p < 0.05$) inhibition activity than pinocembrin and naringenin. The PKC inhibition activity of two hydroxyl groups on the B-ring over one hydroxyl group was similar to previous studies in which luteolin and quercetin showed higher PKC inhibition levels than apigenin and kaempferol for flavones and flavonols, respectively.[35]

Binding Mechanisms of the Flavonoids to PKCδ Phorbol Ester Binding Site. The phorbol ester binding site of PKCδ was well-defined at Tyr-238, Met-239, Ser-240, Pro-241, Thr-242, Phe-243, Leu-250, Leu-251, Trp-252, Gly-253, Leu-254, and Gln-257 of the C1B domain.[36] Phorbol esters bind and activate PKCδ function by forming three hydrogen bonds between C3 oxygen and hydrogen atom of Gly-253, between C4 hydroxyl group and the oxygen atom of Gly-253, and between the C20 hydroxyl group and Thr-242 and Leu 251.[36,37] Gly-253 is a key amino acid for phorbol ligand,[37] so Gly-253's coordinate was set up to be used as binding site for docking with ligands in this study. After the computational calculation, the best poses of pinocembrin, naringenin, and eriodictyol docking with the binding site had -CDOCKER_-energy values of 15.22, 16.95, and 21.49, respectively (Table 1). From the results, all flavonoids could bind with the phorbol ester binding site of PKCδ in which eriodictyol was the most favorable flavonoid in this study, and pinocembrin, on the other hand, had the poorest interaction. As shown in Table 1, all three flavonoids had different hydrogen bonding characteristics with the PKCδ C1B domain. Pinocembrin could form a hydrogen bond only between the hydrogen atom of the hydroxyl group at C7 and the oxygen atom of Ser-240.

Table 1. Hydrogen Bonding Characteristics from Docking Simulation between Phorbol Ester or the Best Pose of Each Flavonoid with C1B Domain of PKCδ at Phorbol Ester Binding Site

		hydrogen bonding	
ligand	-CDOCKER_energy	amino acid residue	distance (Å)
phorbol ester[a]	N/M[b]	Gly-253	N/M
		Leu-251	N/M
		Thr-242	N/M
pinocembrin	15.22	Ser-240	2.22
naringenin	16.95	Gly-253	2.21
		Leu-251	1.84
eriodictyol	21.49	Gly-253	2.1
		Leu-251	1.92
		Ser-240	2.24

[a]Reported by Majhi et al.[36] and Zhang et al.[37] [b]N/M, not measured.

Naringenin had a similar interaction by forming two hydrogen bonds between the oxygen atom in the carbon backbone of the C-ring and Gly-253 and between the C7 hydroxyl group and Leu-251. The single hydroxyl group on the B-ring of naringenin did not form any interaction with PKCδ. For eriodictyol, three hydrogen bonding bridges were built. The first bridge was the same as the first hydrogen bond in naringenin. The second and the third bridges were created between hydrogen atoms from two hydroxyl groups on the B-ring with Leu-251 and Ser-240 (Figure 5A). Interestingly, when two hydroxyl groups were available on the B-ring, the ligand (eriodictyol) turned the B-ring side to bind with the binding site (Figure 5D) rather than the A-ring as occurred with pinocembrin and naringenin (Figure 5B,C). This allowed the two hydroxyl groups to form hydrogen bonds with the kinase and strengthened the interaction. Although the catechol structure (B-ring) was reported to have lower hydrogen-bonding donor parameter than resorcinol ring (A-ring),[38] it was probably the distance between two hydroxyl groups of the resorcinol ring that did not

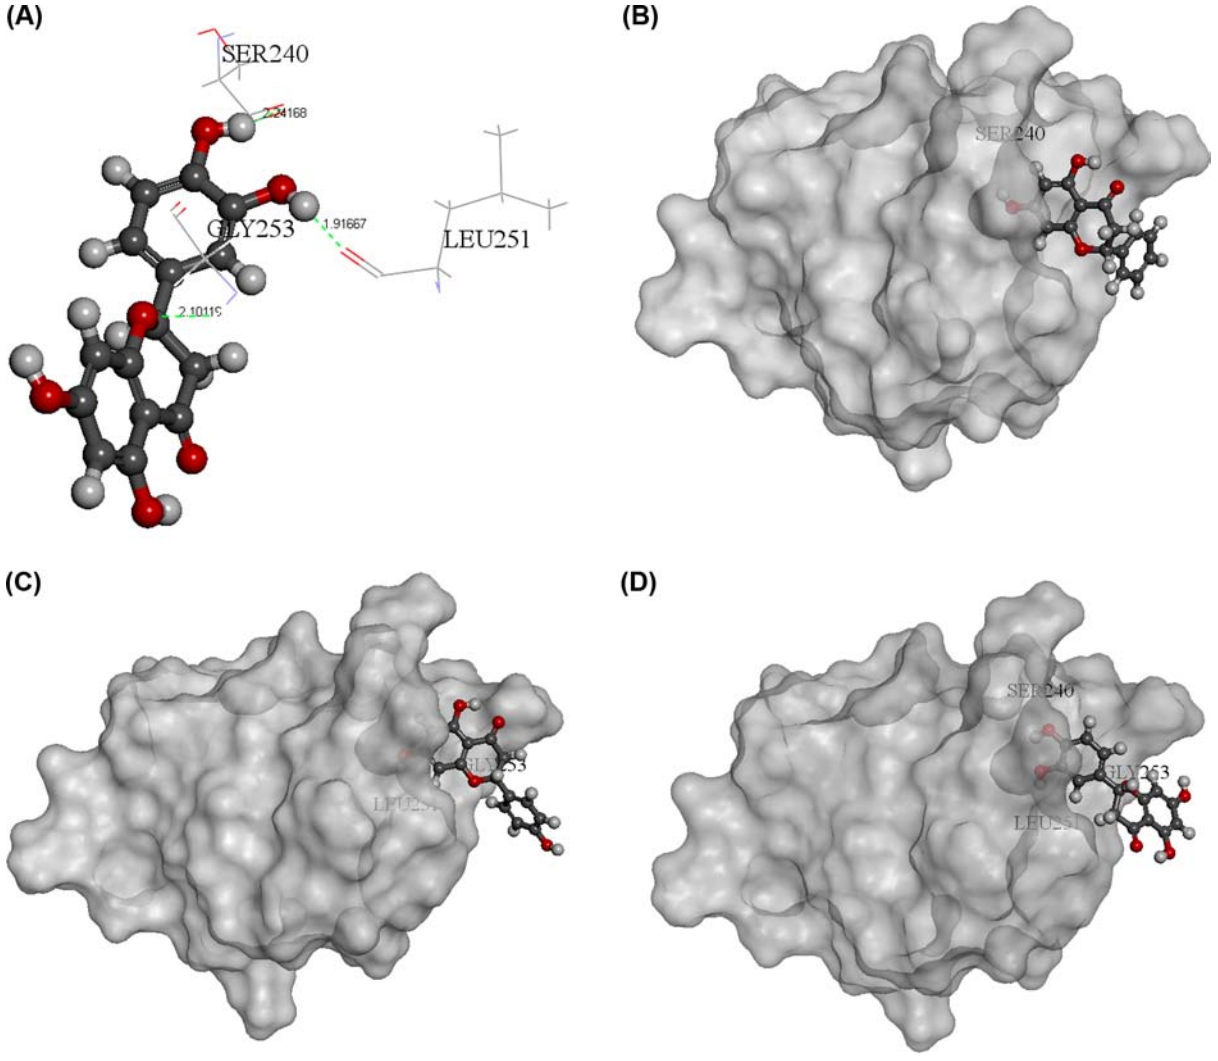

Figure 5. Docking simulation between flavonoids; pinocembrin, naringenin, and eriodictyol and C1B domain of PKCδ at phorbol ester binding site by Accelrys Discovery Studio Visualizer software. All flavonoid structures are represented in ball and stick type. Carbon, oxygen, and hydrogen atoms are colored in dark gray, red, and light gray, respectively. (A) Hydrogen-bonding interaction (green dashed lines) between the best pose of eriodictyol and PKCδ C1B domain amino acids (light gray lines). Numbers indicate hydrogen bonding lengths. (B, C, D) Illustrations of the best pose of pinocembrin, naringenin, and eriodictyol, respectively, docking with surface of PKCδ C1B phorbol ester binding site (painted with transparent gray) from -CDOCKER_energy values.

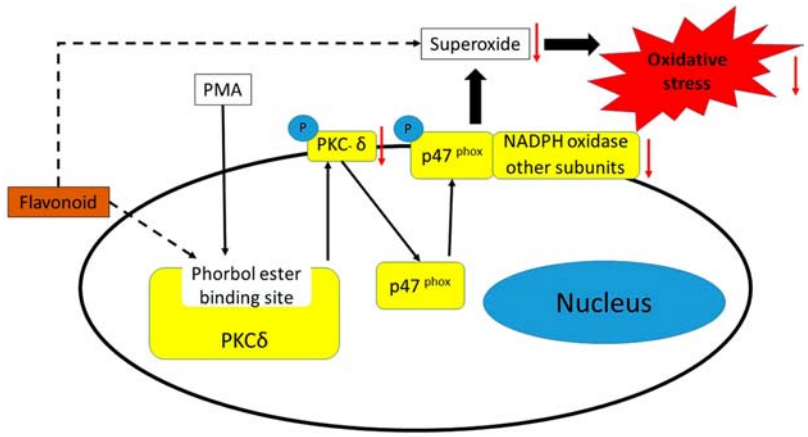

Figure 6. Flavonoid reduced oxidative stress in PMA-activated RAW264.7 by two approaches (dashed lines): neutralizing superoxide molecules and occupying PKCδ phorbol ester binding site.

fit with the amino acid residue arrangement at the binding site. Moreover, results also showed that the the C5 hydroxyl group of pinocembrin and naringenin could not form any hydrogen bond with the site. Thus, two ortho hydroxyl groups on the B-ring played a crucial role in forming a strong interaction with the binding site. The docking results correlated with the protein immunoblotting assays in which eriodictyol inhibited PKCδ activation better than pinocembrin and naringenin. Therefore, all three flavonoids could reduce oxidative stress by two ways (Figure 6, dashed lines). First, flavonoids directly neutralized the superoxide molecules. Second, the flavonoids could reduce the activation of PKCδ by phorbol esters by blocking the phorbol ester binding site. On the basis of both approaches, the number of substituted hydroxyl groups on the B-ring positively affects the antioxidant activity of the flavonoids.

study showed that SWE reduced oliec acid (OA)-induced hepatic lipid accumulation in HepG2 cells.[23] Therefore, in this study, we further investigated the anti-obesity effect of SWE in rats fed a high-fat diet (HFD). Adding caffeic acid (CA) and hesperetin (HPT), which are the main ingredients of SWE, also inhibit OA-induced lipid accumulation. In addition, animals fed with a HFD could serve as a model to attenuate hepatic lipid accumulation and evaluate the methods for healthcare foods for prevention of a fatty liver. The lipogenesis inhibitors could promote catabolism by downregulation of the activity of key enzymes of metabolism that account for the effect of healthcare foods.

MATERIALS AND METHODS

Materials. Fresh *S. edule* shoots and leaves were collected in Nantou county, located in central Taiwan. GPx, SOD, SREBP-1, SREBP-2, HMGCoR, PPARα, and carnitine palmitoyltransferase-1 (CPT-I) antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA). Anti-pThr172-AMPK, anti-AMPK, and FAS antibodies were purchased from Cell Signaling Technology (Beverly, MA). Anti-β-actin and anti-catalase antibodies were purchased from Sigma-Aldrich.

Preparation of SWE and Functional Polyphenol Extract from SWE. The fresh leaves were minced, air-dried under shade, and powdered for used. The extract prepared from 20 g of powder immersed in 1000 mL of distilled water under 4 °C for 24 h was filtered and lyophilized as the SWE with a yield of 17.24%. A total of 100 g of dried SWE powder was drenched with 300 mL of 50 °C methanol for 3 h. After refining 3 times, the extract was filtered and the solvent was removed from the combined extract using a vacuum rotary evaporator. The residue was dissolved in 500 mL of distilled water, removed the pigment with 200 mL of hexane, purified with 180 mL of ethyl acetate 3 times, and removed the solvent by a vacuum rotary evaporator. The residue was redissolved with distilled water and lyophilized to yield the powder as the polyphenol extracts of SWE (SWPE). The SWPE were analyzed for the presence and proportion of functional compounds by high-performance liquid chromatography (HPLC).

HPLC Analysis. HPLC was performed with a Hitachi HPLC system (Hitachi, Danbury, CT), which consisted of a pump (L-6200A), an ultraviolet detector (L-4250), and a Hitachi D-7000 HPLC system manager program. A systemic procedure for analyzing the phenolic acids contained a Mightysil RP-18 GP 250 column (Kanto, Tokyo, Japan), mobile phase solvent A [acetic acid/water (2:98, v/v)], and solvent B [0.5% acetic acid in water/acetonitrile (50:50, v/v)]. The flow rate was 1 mL/min. The gradient for the separation was 100% solvent A at 0 min, 70% solvent A and 30% solvent B at 5 min, 65% solvent A and 35% solvent B at 50 min, 60% solvent A and 40% solvent B at 55 min, and 0% solvent A and 100% solvent B at 60 min, followed by a 5 min post-run with HPLC-grade water. Phenolic acids were detected at 260 nm.

Animals and Treatment. The male Wistar rats (weight of 150 ± 10 g) obtained from the National Laboratory Animal Breeding and Research Center (Taipei, Taiwan) were housed and acclimated in laboratory conditions (23 ± 2 °C, 60 ± 5% relative humidity, and 12 h light/dark cycle) for at least 1 week before study. Different treatments of rats were divided into four groups (n = 10 per group) as follows: (A) normal meals (control), (B) HFD, (C) HFD + 0.5% SWE, and (D) HFD + 1.0% SWE. The composition of the HFD was 40% beef tallow, 26% casein, 15% corn starch, 9% sucrose, 5% cellulose, 4% mineral mixture, and 1% vitamin mixture.[24−28] The ratio of mineral and vitamin mixtures was according to AIN-93.[29] The metabolized energy of the control and HFD-fed rats, with or without SWE supplement, was 3.85 and 5.60 kcal/g, respectively. All rats, except the control group, were fed with the HFD for 12 weeks. The food intake of each rat was controlled as equal as possible. All rats were weighed every week. After the end of the experiment, animals were sacrificed to collect the blood sample and liver tissue. Serum was prepared and stored at −80 °C for further investigations, which were completed within 2 weeks. All animal experimental protocols used in this study were approved by the Institutional Animal Care and Use Committee of the Chung Shan Medical University (IACUC, CSMU), Taichung, Taiwan (IACUC Approval Number 885).

Hepatic Pathological Analysis. Liver tissues were fixed in 4% buffered paraformaldehyde overnight and embedded in paraffin. Consecutive paraffin sections were examined by hematoxylin and eosin (H&E) staining. Frozen sections were stained with Oil Red O and Sudan III reagents.[30,31] Then, the samples were analyzed by light microscopy (Nikon Eclipse, Nikon, Japan).

Blood Sample Analysis. Blood samples were collected into heparin tubes and immediately centrifuged at 3000g for 5 min at 4 °C. The serum was decanted and stored at 4 °C. Serum levels of total cholesterol, TGs, aspartate transaminase (AST), and alanine transaminase (ALT) were measured using clinical chemistry reagent kits (Randox Laboratories, Ltd., Antrim, U.K.). A free fatty acid (FFA) quantification kit (BioVision, Inc., Mountain View, CA) was performed to detect the FFA level of serum according to the protocol of the manufacturer.

Determination of Total Cholesterol and TGs in Liver. Fresh liver was collected for the extraction of liver lipids. Liver lipids were refined as described previously. Briefly, liver was homogenized with chloroform/methanol (1:2, v/v), and then chloroform and distilled water (1:1, v/v) were added to the homogenate and mixed well. The lipid extract was centrifuged at 1500g for 10 min, and the lower clear organic phase solution was transferred into a glass tube and then lyophilized. The lyophilized powder was dissolved in chloroform/methanol (1:2, v/v) as the liver lipid extract and stored at −20 °C. TGs and cholesterol in the lipid extracts were measured by enzymatic colorimetric methods using commercial kits (Human, Wiesbaden, Germany).

Preparation of the Protein Extract. The protein extracts of cultured cells or liver tissues were harvested in a cold RIPA buffer [1% NP-40, 50 mM Tris−base, 0.1% sodium dodecyl sulfate (SDS), 0.5% deoxycholic acid, and 150 mM NaCl at pH 7.5] containing proteinase inhibitor (17 μg/mL leupeptin and 10 μg/mL sodium orthovanadate). The cell lysates were vortexed at 4 °C for 4 h, and the liver tissues were homogenized on ice for 3 min. All protein extracts were then centrifuged at 10 000 rpm at 4 °C for 20 min. The protein concentration was measured with Coomassie blue (Kenlor Industries, Inc., Santa Ana, CA) using bovine serum albumin as a standard.

Western Blot Analysis. Protein samples (80 μg) were subjected to SDS−polyacrylamide gel electrophoresis and electrotransferred to nitrocellulose membranes (Millipore, Bedford, MA). Membranes were blocked with 5% non-fat milk powder/0.1% Tween-20 in Tris-buffered saline (TBS) and then hybridized with the primary antibody at 4 °C overnight. After washing with TBS 3 times, the secondary antibody was hybridized and conjugated to anti-mouse horseradish peroxidase (HRP) (GE Healthcare, Little Chalfont, U.K.) at room temperature for 1 h. HRP was activated by enhanced chemiluminescence (ECL) using ECL western blotting detection reagents and exposed ECL hyperfilm in Fujfilm LAS-3000 (Tokyo, Japan). Protein quantity was determined by densitometry using Fujfilm MultiGauge, version 2.2, software.

Cytotoxicity Assay. HepG2 cells were seeded at a density of 5 × 10^5 cells/mL in 24 well plates and incubated with OA, SWE, CA, or HPT at various concentrations. After 24 h, the medium containing (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (MTT) reagent (0.5 mg/mL) was replaced and incubated for 4 h. Formazan was produced by viable cells, which was dissolved with isopropanol. The absorbance was read at 563 nm by a spectrophotometer (Beckman DU640).

Nile Red Stain. HepG2 cells were seeded in 6 well plates (2 × 10^6 cells/mL) and treated with 600 μM OA and the indicated concentration of SWE, CA, or HPT for 24 h. The cells were washed twice with phosphate-buffered saline (PBS) and fixed with 4% formaldehyde for 30 min. Cell were stained with 40 μg/mL Nile red at room temperature for 30 min. Lipid-bound Nile red fluorescence was

[a]ND, normal diet group; HFD, rats fed a HFD-induced group; HFD + 0.5% SWE, rats fed a HFD with 0.5% SWE group; and HFD + 1.0% SWE, rats fed a HFD with 1.0% SWE group. [b]Data = [(week x − week 0)/week 0] × 100%. Each value is expressed as the mean ± standard deviation (SD) (n = 10/group). Results were statistically analyzed with a one-way ANOVA. [c]$p < 0.05$ compared to the ND group. [d]$p < 0.05$ compared to the HFD group.

measured and quantified the lipid content in cells by flow cytometry (Becton Dickinson, Mountain View, CA).

Statistical Analysis. Overall differences among groups were analyzed by one-way analysis of variance (ANOVA). When overall analysis demonstrated the presence of significant differences among all of the different groups studied, the differences between specific groups were tested using Duncan's multiple range test. All statistical analyses were performed using SigmaStat software (SPSS, Chicago, IL). $p < 0.05$ was considered statistically significant.

RESULTS

Functional Components of SWE. The presence and proportion of the main functional constituents of SWE were analyzed by HPLC. The HPLC results revealed that SWPE contained the presence of protocatechuic acid (PCA, 3.56 ± 0.11%), gallocatechin gallate (GCG, 1.18 ± 0.12%), caffeic acid (CA, 26.53 ± 0.28%), *p*-coumaric acid (*p*-CA, 7.32 ± 0.24%), hesperetin (HPT, 23.44 ± 0.18%), resveratrol (RV, 0.61 ± 0.04%), quercetin (Q, 4.18 ± 0.09%), and naringenin (N, 13.72 ± 0.14%) (Figure 1).

Effect of SWE on Body Weight of Rats Fed with a HFD. The effect of SWE on lipid homeostasis was examined. By feeding rats with HFD and the indicated concentration of SWE for 12 weeks, we compared relative body weight changes. In Table 1 and Figure 2, the rats fed with a HFD increased in weight in the entire experimental duration. In the termination of this experiment, the weight increased to 101.23%. Rats fed with 0.5 or 1.0% SWE decelerated the weight gain significantly at weeks 11 and 12. The results showed that feeding with SWE decreased weight gain in HFD-fed rats.

Effect of SWE on Body Fat Deposition. We further detected the lipid content of the liver in rats fed with a HFD or SWE (Table 2). First of all, we compared the weight of liver differences among different groups. The liver weight of rats fed a normal diet was 24.22 ± 3.08 g, and the liver weight of rats in the HFD group increased to 27.07 ± 2.09 g. After treating with 0.5 and 1.0% SWE, it was reduced to 23.54 ± 2.05 and 23.55 ± 3.21 g, respectively. Supplement of SWE significantly reversed the liver weight gain. The study also conducted weight variation of adipose tissue to evaluate whether SWE affected fat deposition. In Table 2, the results reveal that a HFD caused a significant increase in epididymal fat (23.27 ± 6.17 g), perirenal fat (40.01 ± 10.62 g), retroperitoneal fat (29.00 ± 10.70 g), and mesenteric fat (9.24 ± 2.53 g) in surrounding accumulation of adipose tissue compared to a ND, which means an increase in adipose tissue. However, 0.5 and 1.0% SWE showed a significant decrease in adipose tissue. The relative total fat was increased, while SWE reduced it even lower than the control. These results indicate that SWE inhibited adipose tissue fat deposition and obesity (Table 2).

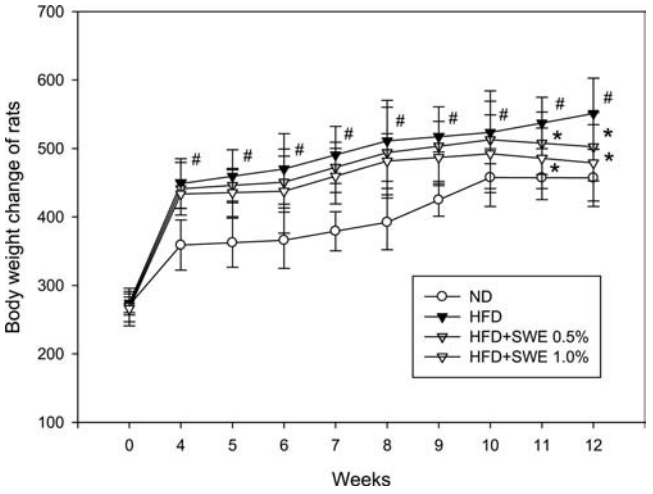

Figure 2. Effects of SWE on the body weight change of rats with obesity induced by a HFD. Body weight change versus time in rats fed various diets. All values are the means ± SD (n = 10). ND, normal group (rats fed normal chow); HFD, rats fed with 40% beef tallow. (#) $p < 0.05$ compared to the ND group. (∗) $p < 0.05$ compared to the HFD group.

Effects of SWE on the Serum Lipid and Hepatic Lipids of Rat Induced by a HFD. Because liver plays a critical role in metabolic regulations, we analyzed the hepatic content of cholesterol and TGs. After feeding SWE with both a HFD and 0.5 and 1.0% SWE for 12 weeks, animals were sacrificed and then the serum content of cholesterol, TG, and FFA were analyzed. As shown in Table 3, serum glucose, cholesterol, and FFA levels were elevated by a HFD. SWE reversed the serum levels of glucose and lipids, especially FFA. Merely 0.5% SWE exerted a profound effect of lowering of FFAs elevated by a HFD. A HFD increased low-density lipoprotein-cholesterol (LDL-C) and decreased high-density lipoprotein-cholesterol (HDL-C) and, thus, enhanced the LDL-C/HDL-C ratio. Supplementation of SWE effectively reversed the lipoprotein profiles. Noticeably, the analysis of AST, ALT, blood urea nitrogen (BUN), creatinine (CRE), electrolyte, and ketone

liver TG (mg/dL)	229.29 ± 23.04	622.86 ± 18..97[b]	444.18 ± 20.01[c]	429.27 ± 51.74[c]

[a]Each value is expressed as the mean ± SD (n = 10/group). Results were statistically analyzed with a one-way ANOVA. [b]$p < 0.05$ compared to the ND group. [c]$p < 0.05$ compared to the HFD group.

body showed that SWE did not burden the liver or affect kidney functions.

Next, we analyzed the cholesterol content of liver tissues. The results (Table 3) showed that the cholesterol content of rats fed with a normal diet was 223.60 ± 18.10 mg/dL. The cholesterol content of rats fed with a HFD alone was 661.24 ± 90.81 mg/dL. The cholesterol content of rats fed with 0.5 and 1.0% SWE was 544.04 ± 77.07 and 471.48 ± 54.19 mg/dL, respectively. As shown in Table 3, the TG and cholesterol contents of liver in rats fed with SWE were lower than the TG and cholesterol contents of liver in rats fed with a HFD alone. We also observed the TG content in liver tissues. The results showed that the TG content of rats fed with a normal diet was 229.29 ± 23.04 mg/dL. The TG content of rats fed with a HFD alone was 622.86 ± 18.97 mg/dL, while the TG content of rats fed with 0.5 and 1.0% SWE was 444.18 ± 20.01 and 429.27 ± 51.74 mg/dL, respectively. It showed the reduction of fatty metamorphosis in livers of SWE-supplemented rats (Figure 3 and Table 3). SWE reduced the contents of cholesterol, TG, and FFA to inhibit lipid accumulation.

Effect of SWE on the Hepatic-Lipid-Metabolism-Related Protein in HFD-Fed Rats. Previous studies showed that activation of AMPK-p could inhibit lipid accumulation and the activation of FAS and acetyl-CoA carboxylase (ACC).[32,33] In an animal model, we examined the protein level in lipid metabolism. In panels A and B of Figure 4, the results showed that the rats fed with 0.5 or 1.0% SWE had lower lipid accumulation.

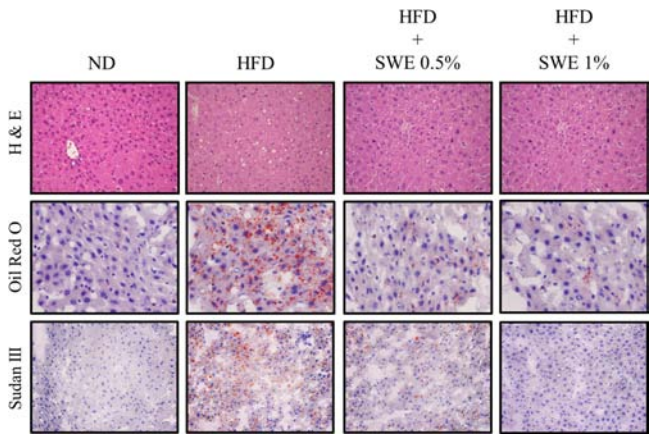

Figure 3. Histopathological examination of liver tissue in rats fed a control diet and HFD. Animals were fed a normal diet (control group), HFD, or HFD pair feeding with a 0.5 or 1% SWE diet for 12 weeks *ad libitum* (n = 10). Rats in all groups were sacrificed after 12 weeks of experiments. Liver tissues were obtained immediately after sacrifice and stained with H&E (100×, top), Oil Red O stain (400×, middle), and Sudan III stain (100×, bottom).

Effect of SWE on the Hepatic-Lipid-Oxidation-Related Protein in HFD-Fed Rats. In addition to the lipid synthesis, the hepatic lipid oxidation was also analyzed. PPARα was decreased in the HFD group, while SWE dose-dependently increased the PPARα (Figure 4C). SWE also increased the

DOI: 10.1021/acs.jafc.5b00346
J. Agric. Food Chem. 2015, 63, 4587−4596

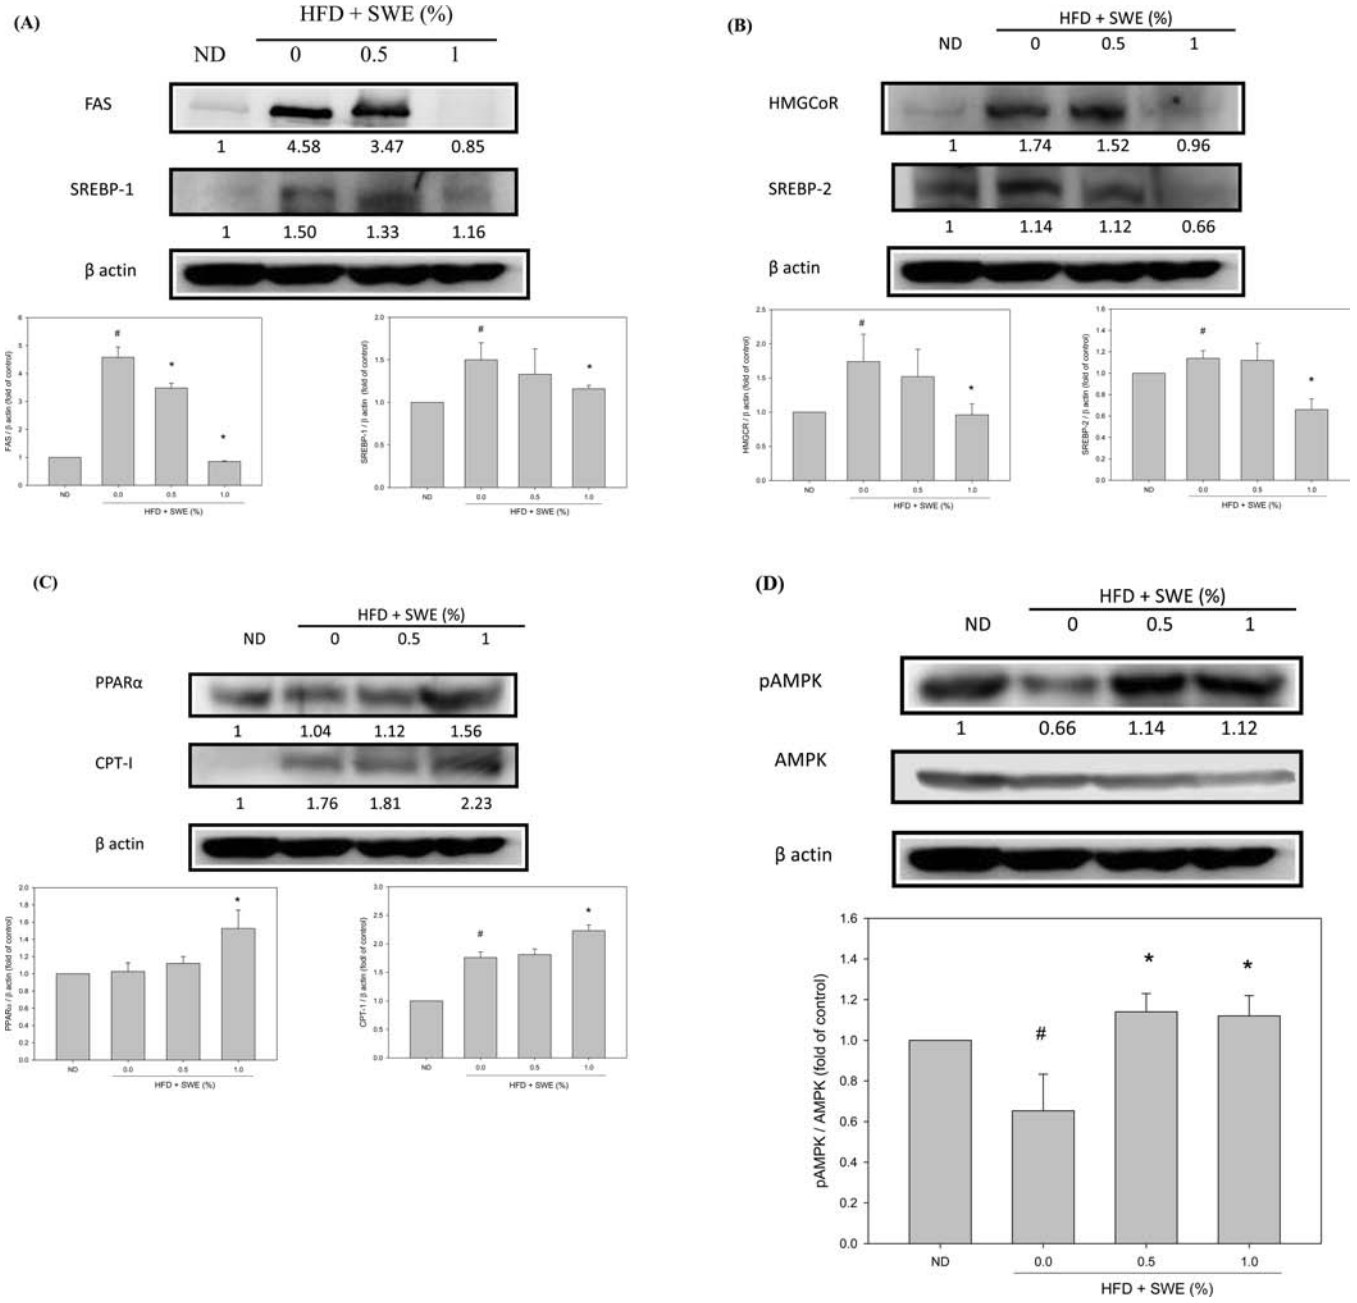

Figure 4. SWE treatment reduced fatty-acid-synthesis-related protein expression in rats fed a HFD. Animals were fed a normal diet, HFD, or HFD pair feeding with a 0.5 or 1% SWE diet for 12 weeks *ad libitum* (n = 10). Protein extracts from rat liver were subjected to western blotting to detect FAS, SREBP-1, HMGCoR, SREBP-2, PPARα, CPT-I, phosphorylated AMPK, and AMPK. β-actin was used as a loading control. The numbers below the panels represent quantification of the immunoblot by densitometry. Data are presented as means ± SD from three independent experiments. (#) $p < 0.05$ compared to the ND group. (∗) $p < 0.05$ compared to the HFD group.

expression of CPT-I and the activation of AMPK. In comparison to the control, 0.5 or 1.0% SWE significantly increased the AMPK phosphorylation (Figure 4D). Neither CPT-I nor AMPK was altered by a HFD. Hence, it was demonstrated that SWE inhibited lipid synthesis, stimulated lipid oxidation, and lowered hepatic lipid content.

Effect of CA and HPT on the OA-Induced Lipid Accumulation by SWE in HepG2 Cells. The main polyphenols of SWE are CA and HPT. The effects of CA and HPT on the intracellular lipid accumulation of HepG2 cells were conducted by OA. This experiment was focused on the change of intracellular lipid accumulation but did not cause cytotoxicity in HepG2 cells.[34,35] The cell cytotoxicity was not found under 4 mg/mL SWE, 200 μM CA, or HPT treatment (Figure 5A). SWE (1−2 mg/mL), CA (100−150 μM), and HPT (100−150 μM) can indeed reduce OA-induced lipid accumulation in HepG2 cells (panels B and C of Figure 5). Taken above, they showed that SWE, CA, and HPT have the ability to reduce the lipid accumulation in the liver.

DISCUSSION

The liver plays an important role in lipid homeostasis via regulation of lipogenesis and oxidative stress.[36] Recent studies on obesity in the field of food science have focused on the

DOI: 10.1021/acs.jafc.5b00346
J. Agric. Food Chem. 2015, 63, 4587−4596

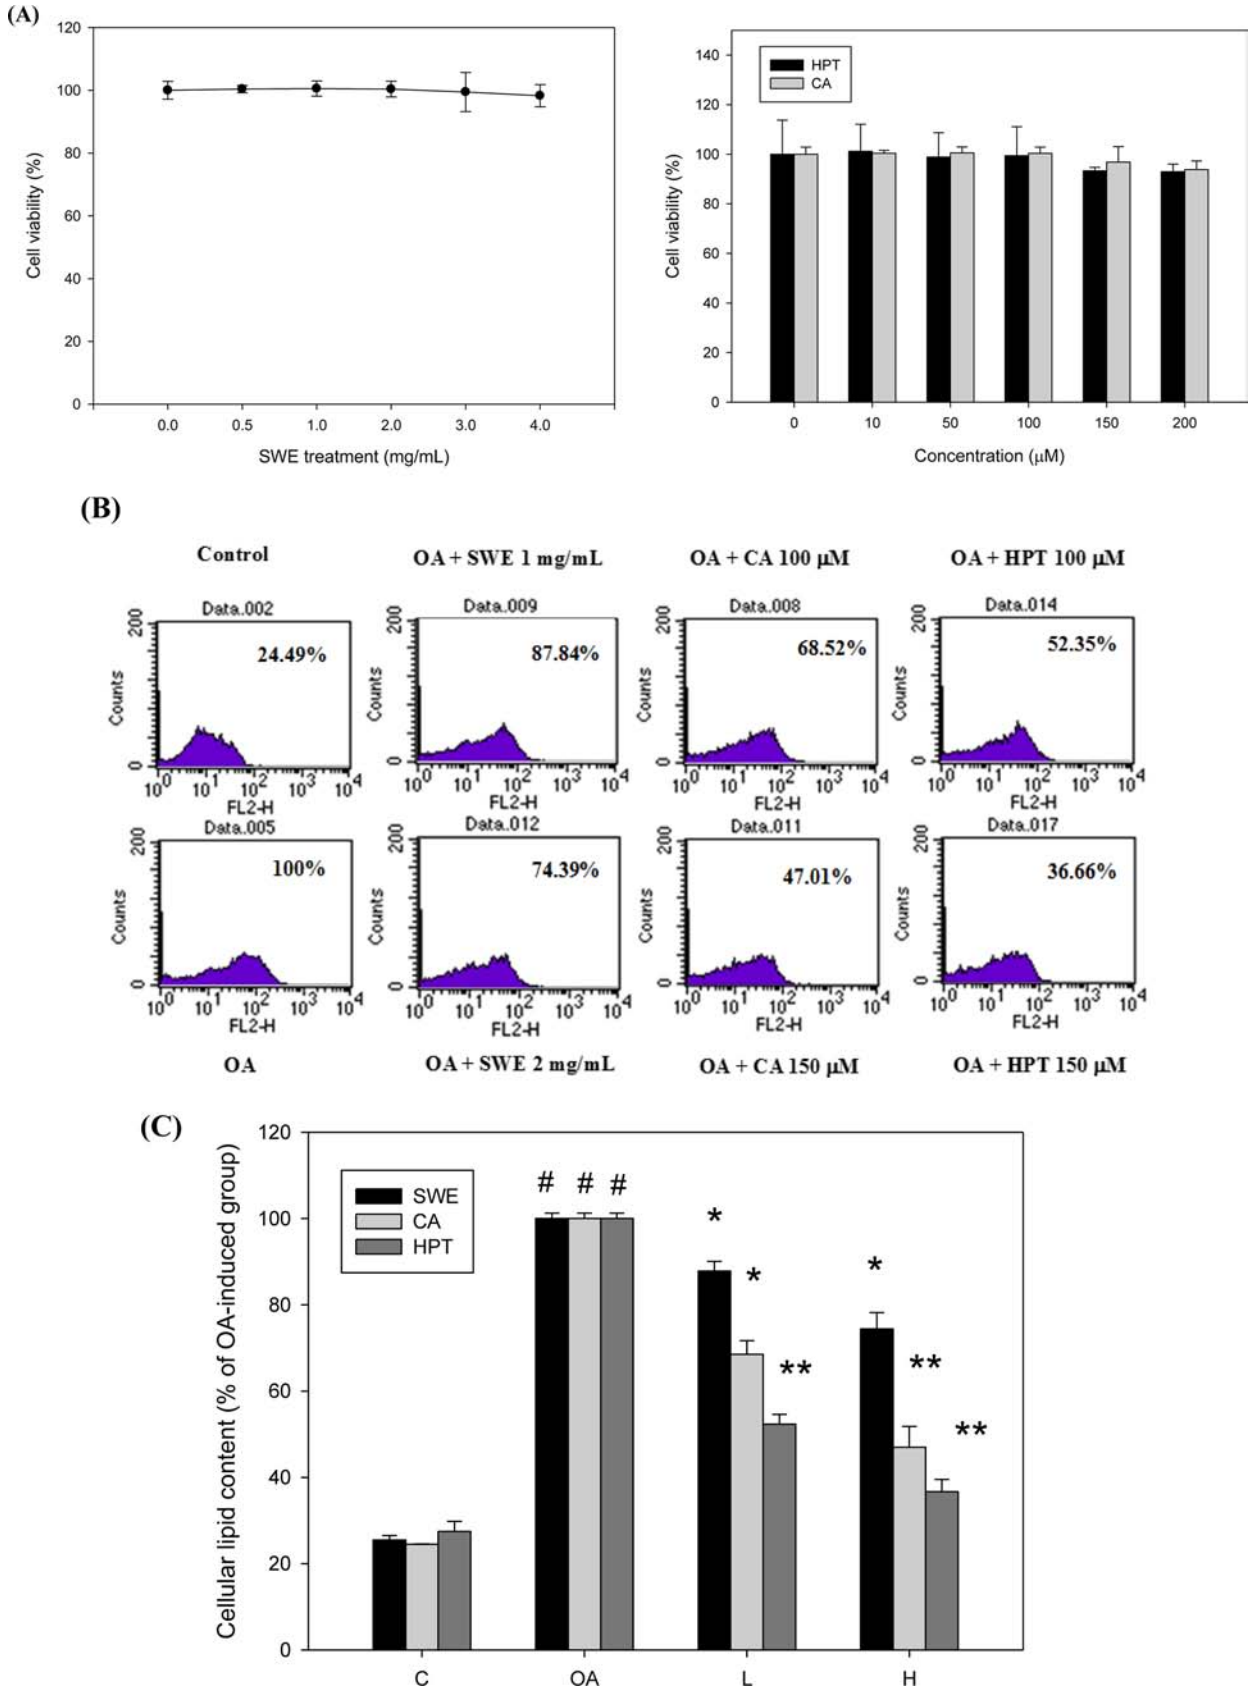

Figure 5. SWE, CA, and HPT attenuated OA-induced lipid accumulation in HepG2 cell. (A) SWE, CA, and HPT had no cytotoxicity effect on HepG2 cells. (B and C) Lipid accumulation was induced by 0.6 mM OA. Cells were co-treated with OA and the indicated concentrations of SWE, CA, or HPT for 24 h. Lipid-bound Nile red fluorescence was detected, and quantification of lipid in cells was immediately analyzed by flow cytometry. SWE-L, cells were treated with 1 mg/mL SWE as a low-dose SWE; SWE-H, cells were treated with 2 mg/mL SWE as a high-dose SWE; CA-L, 100 μM caffeic acid; CA-H, 150 μM caffeic acid; HPT-L, 100 μM hesperetin; and HPT-H, 150 μM hesperetin.

DOI: 10.1021/acs.jafc.5b00346
J. Agric. Food Chem. 2015, 63, 4587−4596

search for functional food ingredients or herbal extracts that can mend the body weight and body fat.[3,37−39] SWE suppressed OA-mediated lipid accumulation via regulating lipogenesis and lipolysis in an *in vitro* study.[23] The present investigation verified that SWE improved HFD-induced obesity by decreasing cellular lipid accumulation and increasing lipolysis via activation of AMPK in rats.

We first examined the effects of SWE on total cholesterol and TG contents in HFD-fed rats with respect to weight decrease (Figure 1) and serum cholesterol and TG reduction (Table 3). Our observations agree with other reports, which showed that polyphenols could significantly reduce the levels of total cholesterol and also availably diminish body weight in animals with a HFD.[39] In addition, there are other polyphenols, such as PCA, *p*-CA, and naringenin, existing in SWE. In 2010, Liu et al. pointed out that CA and *p*-CA possess the potential to reduce TGs.[40] Yoshida et al. showed that the administration of HPT and naringenin can reduce the FFA secretion in mouse adipocyte and improve lipolysis.[41] The previous study also showed that naringenin can effectively decrease body fat.[42] Hsu et al. revealed that PCA, *p*-CA, and CA have the potential to inhibit the differentiation of adipocytes.[43] In a previous report, Hsu et al. also showed that the flavonoid and polyphenol can reduce body weight and fatty liver formation in beef-tallow-induced rat obesity. In our result, we found that the rat body weight increases under a similar induction and SWE decelerates the weight gain and a fatty liver via reducing the accumulation of liver fat and increasing the fatty acid oxidation.[28] A previous study showed that CA (0.08%, w/w) or HPT (0.02%, w/w) exhibited the potential as an anti-obesity agent in an animal model.[44,45] After the analysis of HPLC, SWE contained 26% CA and 23% HPT. Accordingly, it was evaluated that the usage of SWE in 0.5 or 1% would be efficacious to improve obesity and fatty liver formation in our model. The present results showed that SWE has the potential role to reduce obesity in rats. Actually, the duration of 12 weeks is not long enough to confirm the efficacy. In a future study, we will extend the experimental duration to observe the results.

The synthesis of fatty acids and reduction of fatty acid oxidation are important events in regulating lipid accumulation of NAFLD.[46,47] We suggested that SWE may inhibit the synthesis of fatty acid and cholesterol. FAS is the primary enzyme involved in lipogenesis and serves as a marker of the treatment effect in obesity.[32] In the results, we found that SWE inhibited the expressions of FAS and HMGCoR in rats (panels A and B of Figure 4).

AMPK has high attention-getting importance to modulate the homeostasis of fatty acids in the research of lipometabolism.[48] Previous research indicated that polyphenolic components from many plants can activate AMPK.[49] In fact, our previous *in vitro* study and other research works showed that AMPK can be activated by polyphenol extracts.[23] We also investigated the effect of SWE on AMPK activity and the protein expression of SREBP-1. In this study, we found that SWE increased the activation of the AMPK pathway to regulate the lipid accumulation *in vivo* (Figure 4D). It is consistent that there are several reports demonstrating that AMPK plays an important role in regulating carbohydrate and lipid metabolism, serving as a metabolic master switch responsible for alterations in liver energy homeostasis.[50] It also agrees with previous studies that polyphenol extracts from plenty of plants can activate AMPK.[33] Activation of AMPK suppressed FAS expression because it prevents SREBP-1 translocation from the nuclei[49] and inhibits SREBP-2 activity to attenuate hepatic steatosis,[50] whereas SREBP-2 primarily controls cholesterol homeostasis by activating genes required for cholesterol synthesis and uptake.[51] In this study, we found that SWE can activate AMPK, reduce SREBP-1 expression (Figure 4), and lead to inhibition of hepatic lipogenesis, along with the other studies. Similarly, AMPK inhibits *in vitro* lipogenesis in hepatocytes through the downregulation of the cleavage processing and transcriptional activity of SREBP.[50] In another study, the protein levels of CPT-I and PPARα were ascertainable participating in the process of lipolysis.[52] In this study, we found that SWE had the same ability to activate PPARα and CPT-I expressions (Figure 4C). Others have also reported that activation of AMPK reduced fat storage while also increasing fatty acid oxidation.[53]

In our previous study, polyphenols were found in SWE at the level of about 7.73%.[23] SWE and CA augmented AMPK activation and mediated a decrease in SREBP-1, FAS, and HMGCoR in HepG2 cells.[23,34] In this study, we further demonstrated that SWE effectively improved various lipid-related parameters (body weight, adipocyte tissue, and serum-related parameters) in the HFD-induced rat model. It agrees with our previous study that CA exhibited potential as an anti-obesity agent by suppressing lipogenesis enzymes[44] or enhancing adipocyte glucose uptake, insulin secretion, and antioxidant capacity.[54] HPT intake alone at a dietary level of 0.02% showed a decrease in the plasma level cholesterol and TGs and reduced the activity of relative lipogenesis enzymes in high-cholesterol-diet-fed rats.[45] Meanwhile, in this study, we used CA and HPT, which are main ingredients of SWE, to show the effectiveness of reducing lipid accumulation in cells. Results in Figure 5 show that CA and HPT reduced the lipid accumulation in the liver. This is consistent with the CA-enhanced activity of AMPK to accelerate lipolysis.[34] In addition, CA inhibited OA-induced hepatic lipid accumulation and promoted the lipolysis via upregulation of AMPK. In conclusion, we showed that SWE can reduce lipid accumulation and elicit the fatty acid oxidation in the liver of HFD-induced rats. SWE would be developed as a potential therapeutic treatment to reduce the progression of a fatty liver and obesity.

chemical reagents were of analytical grade and manufactured by Sinopharm Chemical Reagent Co., Ltd. Methanol and acetonitrile were of HPLC grade and purchased from Shanghai Lingfeng Chemical Reagent Co., Ltd. The extraction procedure was conducted in an apparatus of USCCE that was designed by our laboratory to be suitable for industrial production, and its operation is clarified in Figure 1. The model of ultrasound probe is JY92-IIDN, purchased

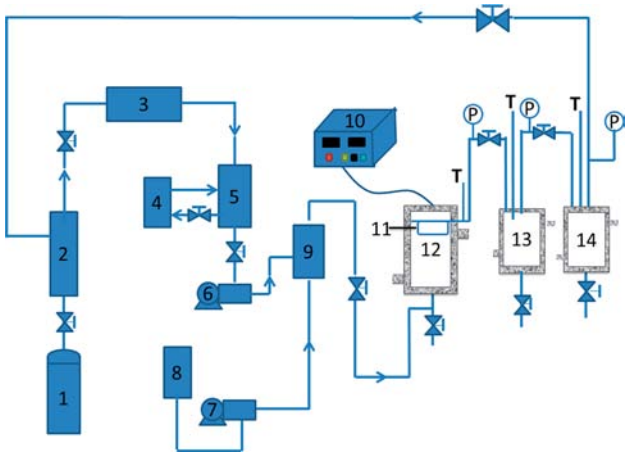

Figure 1. Scheme of ultrasound-enhanced subcritical CO_2 apparatus: 1, CO_2 cylinder; 2, bus-bar; 3, purifier; 4, refrigerator; 5, condenser; 6, main pump; 7, auxiliary pump; 8, cosolvent cylinder; 9, mixer; 10, ultrasonic generator; 11, ultrasonic transducer; 12, extraction kettle; 13, separation kettle I; 14, separation kettle II; T, temperature probe; P, pressure gauge.

from Ningbo Xinke Instrument Co., and its main technical parameters are operating frequency of 20−24 kHz and ultrasonic power of 20−900 W (adjustable), and the ultrasonic system is composed of a piezoelectric transducer (ultrasonic intensity range of 0−19 W cm^{-2}) and an ultrasonic generator. The generator comprises a power piezoelectric impedance-matching box and a power generator unit. The power generator unit consists of two parts: a power amplifier and a resonant frequency control system to maintain constant power to the transducer during the USCCE process. The transducer was placed in the extractor of the USCCE equipment, whereas the generator was located outside to control the ultrasonic intensity.

The operation of the apparatus of USCCE is as follows: CO_2 goes from the cylinder to the purifier to filter out possible liquid and particulate impurities in the gas, and then goes into the condenser and is cooled; after that, it is pumped into the mixer by a high-pressure pump and mixed with cosolvent pumped by the auxiliary pump; the mixture is pumped into the 5 L extraction kettle; under ultrasound, the mixture makes full contact with the material inside the extraction kettle; the extracted substances dissolve in supercritical CO_2 and flow into separation kettles I and II, in which case CO_2 goes back into the gaseous state and extracted substances sink to the bottom of separation kettle. Collected with plastic bottles, CO_2 flows out to the purifier and recycles again. During the extraction process, the pressure of the extraction kettle and separation kettle is controlled by the valves; the temperature is adjusted by the water bath outside the reactor.

Ultrasound-Enhanced Subcritical CO_2 Extraction. Extraction was carried out in the self-designed apparatus shown in Figure 1. *C. pyrenoidosa* (100.00 g) in the size of 4.5−5.5 μm was dried by spray-drying and then soaked in absolute ethanol and extracted at the designated extraction temperature, extraction pressure, CO_2 flow cosolvent, extraction time, and ultrasonic power conditions. Every experiment was in triplicate; 100.00 g was charged into the extract holder every time. The single-factor experiment can, on the one hand, investigate the effects of various factors on the law of USCCE and, on the other hand, lay the foundation for optimization design. The lutein dissolved in the subcritical CO_2 was separated from the carbon dioxide and collected in the separator. For the determination of lutein, chromatographic conditions used a Dionex HPLC system determination, Dikma C-18 (250 × 4.6 × 5 μm) separation column; the mobile phase was methanol/acetonitrile (90:10 by volume), the column temperature was 30 °C, the flow rate was 0.8 mL/min, the injection volume was 20 μL, and the detection wavelength was 450 nm. The lutein yield was determined gravimetrically as displayed in

$$\text{TLY}\ (\%) = \frac{E}{\text{FM}} \times 100\% \quad (1)$$

where TLY represents total lutein yield, E represents extracts (mg), and FM represents feed materials (g). Factors that affect ultrasound-enhanced subcritical CO_2 extraction methods are mainly extraction temperature, extraction pressure, CO_2 flow, cosolvent, extraction time, and ultrasonic power. To study the impact of various factors on the extraction yield of lutein, a single-factor experiment was designed, and then significant factors were chosen; orthogonal experiments were designed to optimize the extraction process parameters. The independent variables were pretreatment (absolute ethanol soaking and enzymatic pretreatment), temperature (18, 21, 24, 27, and 30 °C), pressure (9, 13, 17, 21, 25, and 29 MPa), flow rate (20, 25, 30, 35, and 40 kg/h), amount of cosolvent (0, 0.5, 1.0, 1.5, and 2.0 mL/g absolute ethanol), extraction time (0, 0.5, 1, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, and 5.0 h), and ultrasound power levels (0, 250, 500, 750, and 1000 W). Three pretreatment methods were investigated: no treatment, cosolvent was 2.0 mL/g absolute ethanol; ethanol soak, 100 mL of absolute ethanol was added, and soaked for 18 h, cosolvent was 1.0 mL/g absolute ethanol; enzymatic broken, 150 mL of absolute ethanol was added, 5% citric acid solution was used to adjust the pH value of the enzyme solution to 5.0, 2.0 g of cellulose was added to the enzyme solution and stirred for 3 h at 50 °C, and after completion of enzymatic hydrolysis, *C. pyrenoidosa* together with enzyme solution put into the kettle, cosolvent was 0.5 mL/g absolute ethanol. On the basis of single-factor results, four factors that had a significant impact on the lutein yield were determined: extraction pressure, temperature, amount of cosolvent ethanol, and ultrasonic power, L9 (3^3); orthogonal experimental design was used to determine their influence on the extraction of USCCE process of lutein *C. pyrenoidosa* experiments.

Comparison with Other Extraction Methods. In Soxhlet extraction (SE), *C. pyrenoidosa* powder was wrapped with a paper tube and then added to the Soxhlet extractor; 100 mL of petroleum ether was added, extraction was at 43 °C reflux for 18 h, petroleum ether was removed by rotary evaporation, and the concentrated solution was dissolved with ethanol and then transferred to a brown volumetric flask and stored in a cold and no-light environment. The whole process is under weak light. In subcritical water extraction (SWE), 100.00 g of dried *C. pyrenoidosa* was extracted by deionized water in the extraction tank, the same as in USCCE; extraction at pressure 5 MPa and temperature of 150 °C for 20 min, collected when cooled to room temperature, and NaCl as emulsification. Dichloromethane was added to the extract at a 1:1 ratio and mixed thoroughly; the separated liquid was allowed to stand for 1 h and stratified. The dichloromethane part was added to anhydrous sodium sulfate and then filtered, and the filtrate was collected. In supercritical CO_2 extraction (SCE), 100.0 g of dried *C. pyrenoidosa* was extracted in the extraction apparatus the same as in USCCE; extraction at pressure 25 MPa, flow of CO_2 30 kg/h, temperature of 50 °C for 4 h, cosolvent dosage of 1.5 mL/g ethanol; separation kettle I temperature of 35 °C and pressure of 6.5 MPa; separation kettle II temperature of 30 °C and pressure of 5 MPa.

In subcritical CO_2 extraction (SCCE), 100.00 g of dried *C. pyrenoidosa* was extracted in the extraction apparatus the same as in USCCE. SCCE involved an extraction pressure of 21 MPa, a CO_2 flow of 30 kg/h, a temperature 27 °C for 4 h, and a cosolvent dosage of 1.5 mL/g ethanol; separation kettle I temperature of 35 °C and pressure of 6.5 MPa; separation kettle II temperature of 30 °C and pressure 5 MPa. In the SCCE with pretreatment, the ultrasonic process was not used and the other conditions were in accordance with the optimal

process of orthogonal experiment. USCCE with pretreatment was based on the optimal process of the orthogonal experiment.

Kinetic Model Validation. The kinetic model can not only help us explore the subcritical fluid extraction process and predict the experimental results but also help budget before the investment, therefore effectively reducing the investment risk. However, studies on the kinetic model are complex; to reduce the load of work, only the extraction kinetic model established by our group was studied.[25] The ultrasound-enhanced subcritical CO_2 extraction kinetics equation for *C. pyrenoidosa* lutein is established as

$$E = E_\infty(1 - e^{-kt}) \quad (2)$$

wherein E_∞ is the lutein extraction yield when time tends to infinity, mg/100 g *C. pyrenoidosa*; k is the ratio of the solute concentration gradient descending rate; t is the extraction time, h; and E is lutein yield when the extraction time is t, mg/100 g *C. pyrenoidosa*.

For different extraction conditions, values of E_∞ are different, because the ultrasound, pretreatment, and entrainment agents will make a difference in equilibrium of the active component in solid particles.[26] For example, adding of cosolvent will increase the solubility of polar substances in subcritical CO_2, and ultrasound and pretreatment will destroy the cell structure and affect the absorption−desorption equilibrium in the solid particles. To obtain E_∞ and k values with and without ultrasound conditions, appropriate experi-

J. Agric. Food Chem. 2015, 63, 4597−4605

ments were needed. The experimental data were simulated in order that the yields calculated from the mathematical model have the smallest deviation with the lutein yields obtained under different experimental conditions.

The analysis of variance (ANOVA) was performed using origin 7.0, release 10 (OriginLab Corp., Northampton, MA, USA). Multiple-range tests were used to compare means of the estimated kinetic parameters. Evaluations were based on the $p < 0.05$ significance level.

Scanning Electron Micrographs (SEM). To further reveal the mechanism of USCCE, the present study investigated the effects of various extraction methods on *C. pyrenoidosa* powder microstructure. *C. pyrenoidosa* powders obtained with different extraction methods (Soxhlet extraction, subcritical CO_2 extraction, USCCE without pretreatment, USCCE with pretreatment) were observed by SEM. The control was dried in a vacuum oven at 45 °C for 12 h. The surface characteristics of dried cell were observed and recorded by using a Japanese Electronics Corp. JSM-6490LV scanning electron microscope. The samples were placed in a preparation chamber, and the morphology of the samples was magnified and digitally recorded.

RESULTS AND DISCUSSION

Effect of Pretreatment on Lutein Yield. The parameters remained constant as the effects of the different factors on the "ultrasound enhanced subcritical CO_2 extraction" of lutein were investigated. After enzymatic and soaking treatments of the *C. pyrenoidosa*, the yields of lutein were 85.05 and 69.02 mg/100 g *C. pyrenoidosa*, respectively. The better pretreatment method was enzymatic treatment; therefore, in subsequent experiments enzymatic treatment was adopted as the pretreatment method of *C. pyrenoidosa*.

Table 2. Variance Analysis between Factors Levels of Extraction Yield

error	15.03	2			

C. pyrenoidosa has a tough cellulose layer cell wall; it is not conducive for the solvent to penetrate into the cells to extract intracellular substances, so without any pretreatment, the extraction effect of lutein is poor. After soaking in high concentrations of polar solvents, its cells swelled, the structure loosened, and ingredients were released; the extraction became more conducive, so after soaking treatment the yield of lutein significantly increased. This effect has also been reported by the study conducted by Fang and others;[27] they studied the supercritical CO_2 extraction technology on the extraction of the colchicine roots. After enzymatic treatment, the cell wall of *C. pyrenoidosa* was degraded by cellulose, and the material in the cell can be better exposed to the solvent, thereby accelerating the release and extraction of the active ingredients and improving the yield of lutein.

Effect of Temperature on Lutein Yield. The results are shown in Figure 2A, when the extraction pressure was 17 MPa and the optimum temperature 27 °C. When the temperature was <27 °C, with the increase of extraction temperature, the yield increased; when the temperature was >27 °C, the yield began to decrease.

The effect of temperature on the extraction efficiency was mainly reflected in two aspects. On the one hand, when the temperature rises, the pressure of solute vapor increases, and the thermal motion of molecules becomes faster, the chance of colliding with each other increases, and the opportunity of subcritical fluid associating with lutein increases. On the other hand, an elevated temperature under a certain pressure will decrease the density of the CO_2 and the ability to dissolve, resulting in the lutein yield reducing. This phenomenon has been reported elsewhere when some natural components were extracted by supercritical CO_2.[28,29] Lutein having the highest yield at 27 °C is a combined effect of these two aspects.

Effect of Pressure on Lutein Yield. The results are shown in Figure 2B: with the extraction pressure increasing, lutein yield increases, and when the pressure exceeds 21 MPa, increasing the extraction pressure makes the yields decline, so the best extraction pressure is 21 MPa.

The ability of subcritical CO_2 to dissolve a substance is closely related to its density; changing the extraction pressure can make the subcritical CO_2 density change, thereby increasing or reducing its ability to dissolve lutein. When the temperature remains constant, extraction pressure rising leads to an increase in density, so there will be two opposite effects: increasing the ability of CO_2 to dissolve a substance, but reducing the diffusion of the substance.[30] At relatively low temperature, the ability of CO_2 to dissolve a substance is the dominant factor, so with pressure increasing, lutein yield increases; however, when the pressure exceeds 21 MPa, the diffusion of lutein was assumed to be inhibited, and this effect is greater than the positive effects brought about by the increased ability of CO_2 to dissolve the substance, and therefore yields begin to decline.

Effect of Flow Rate of CO_2 on Lutein Yield. The CO_2 flow rate also has some influence on the extraction capacity. It works mainly in two ways: when the fluid flow increases, CO_2 goes through the material layer more quickly, the agitation and contact with the material are enhanced, and the mass transfer coefficient and contact area are increased accordingly and promote the solubility of the fluid, thereby increasing the extraction speed. On the contrary, excessive flow decreases the relative retention time of the fluid in the extractor, so the solute and fluid cannot work sufficiently and the yield is limited. In addition, excessive velocity will also lead to subcritical fluid

Table 3. Comparison between Different Extraction Technologies of Lutein

extraction method	temperature (°C)	pressure (MPa)	ultrasound power (W)	time (h)	lutein yield (mg 100 g^{-1})

carrying the solute into the circulation system before complete separation in the separation kettle, thus reducing the yield rate. Experimental results are shown in Figure 2C: with the increase of the fluid flow, lutein yield first increased and then decreased. The optimum fluid flow rate was 30 kg/h.

Effect of Cosolvent on Lutein Yield. Adding an appropriate amount of suitable cosolvent can significantly improve the solubility of certain extracted components in subcritical fluid and the selectivity of subcritical fluid. CO_2 is a nonpolar substance, whereas lutein is a polar material, its dipole moment being 1.863.[31] High pressure can increase lutein's solubility in subcritical carbon dioxide, but this effect is limited. Ethanol is the only organic reagent that is permitted for use in functional food and pharmaceutical processing.[32] As a cosolvent, ethanol can increase the density of a subcritical fluid, and its penetration ability is strong in the matrix diffusion, so after the addition of a cosolvent, the yield of lutein greatly improved. However, the positive effect of cosolvent on the extraction of lutein is limited; besides increasing the subcritical fluid solubility, it would also weaken the selective ability of an extraction system, resulting in an increase of total extracts. This phenomenon has been reported in a study by Wu;[23] before the addition of ethanol, lutein and other substances could be well separated in separation kettles I and II, respectively, but after the addition of ethanol, most of the extracts were brought into separation vessel II, resulting in lutein not being separated out. Experimental results are shown in Figure 2D: the yield of lutein increases as cosolvent increases rapidly in the range of 0−1.0 mL/g, but when the amount is >1.0 mL/g, the effect of cosolvent started to slow; considering the cost, the amount of cosolvent was chosen as 1.0 mL/g.

Effect of Extraction Time on Lutein Yield. The results are shown in Figure 2E: with the extension of the extraction time, yield also has a corresponding increase, but the slope of the yield curve is gradually reduced and eventually levels off. A similar result was presented in research by Deenu et al.,[11] in which when the temperature was fixed, the lutein yield increased until a certain amount of time (approximately 5 h) and then decreased. This could be explained as the chemical decomposition of the bioactive compound present in the extract may occur as the extraction time prolongs, resulting in a decrease in the extraction yield. Considering the technology and production cost, the preferred time for the extraction of lutein is 4 h.

Effect of Ultrasound Power on Lutein Yield. The results are shown in Figure 2F: with the introduction of ultrasound,

2.5	102.06	74.36	6	127.77	97.39
3	113.01	83.85			

lutein yield rises rapidly. Because of the increase in sound power, sound intensity and the effect of ultrasonic vibration increases, leading to accelerated movement of solute molecules and the enhancement of the mass transfer inside the material, thereby improving the yield of lutein. This result is consistent

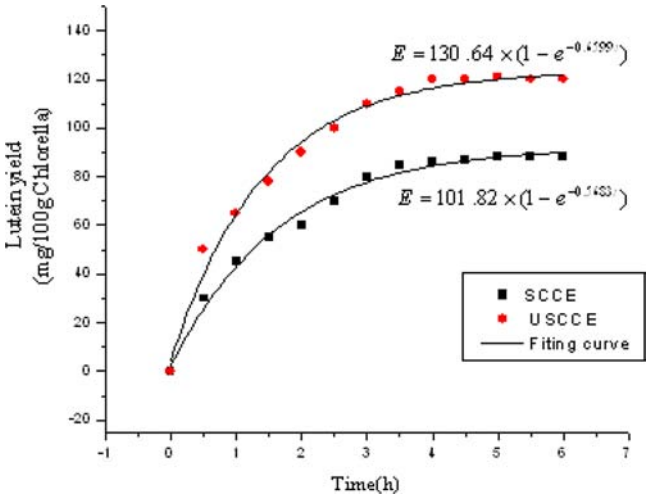

Figure 5. Model fitting curve of lutein extraction yield for USCCE and SCCE. The k value of USCCE was 0.6599, and the k value of SCCE was 0.5683.

with the findings of many other researchers on natural product extraction.[11,14,33−35] In research conducted by Riera et al.,[33] mass transfer enhancement in supercritical fluids extraction (SFE) by means of power ultrasound was calculated; at the end of the extraction time (8.5 h), the yield of the oil was significantly increased when the SFE was ultrasonically assisted. The improvement was about 20%. At the same time the process was accelerated by using ultrasound. Similar extraction yields were obtained in about 30% shorter time.

Optimization of Extraction Conditions of Lutein. Experiments were performed to determine the importance order of the factors influencing ultrasound-enhanced subcritical CO_2 extraction of lutein and calculate the optimum process parameters; according to the result of the orthogonal test, range analysis and variance analysis of factors are made. The orthogonal experiment results and the analysis results are shown in Tables 1 and 2, respectively.

Table 1 shows that in the four factors, extraction pressure had the maximum effect; extraction temperature had the minimum effect. According to Table 1, the importance order of each factor on lutein yield was $B > D > C > A$, and the optimization of process parameters of USCCE was $A2B2C3D3$ in which extraction temperature was 27 °C, extraction pressure was 21 MPa, dosage of ethanol was 1.5 mL/g, and ultrasonic power was 1000 W. Experiments were performed under the optimal conditions to verify the credibility of the best level combination, and results showed that the yield of lutein, 124.01 mg/100 g *C. pyrenoidosa*, was even higher than the highest yield in the orthogonal experiment, 117.75 mg/100 g *C. pyrenoidosa* (Table 1), so the best conditions were determined as $A2B2C3D3$.

As can be seen from the results of the analysis variance in Table 2, when $\alpha = 0.05$, the effects of extraction pressure (factor B) on the yield of lutein in broken *C. pyrenoidosa* reached a significant level, whereas the effects of the ultrasonic power (factor D) and cosolvent dosage (factor C) were not significant. The effect of ultrasonic power, by contrast, is more significant than that of cosolvent dosage, and with the increase of ultrasonic power, lutein yield increases. The extraction temperature (factor A) has a smaller effect on extraction; in the horizontal range of the experiments, the significance of factor A was the least, considering the production cost, and compared

with other research, the temperature could be chosen as room temperature.[11]

Comparison of USCCE with Other Extraction Methods. It can be seen from Table 3, in terms of the extraction temperature, the temperature of USCCE and SCCE with or without pretreatment was room temperature, which was lower than the other three methods. In terms of the extraction pressure, the pressure of USCCE and SCCE is lower than that of SCE; therefore, the former two methods have a relatively low requirement for the equipment. In terms of extraction time, supercritical and subcritical CO_2 extraction needed at most 7 h, compared with 18 h for Soxhlet extraction. We assume efficiency as extraction rate per unit time; the least efficiency of supercritical and subcritical CO_2 extraction was 9.8, whereas the efficiency of Soxhlet was 3.04. Extraction time could be greatly reduced and still achieve higher efficiency.

Compared with SCCE without pretreatment, the extraction yield of lutein after pretreatment is greatly improved, pretreatment being more conducive to the extraction of effective constituents in *C. pyrenoidosa*. Because of the introduction of ultrasound and pretreatment, USCCE with pretreatment had a much higher yield than the other four methods; yield had a 100−200% increase. Compared with the SCCE with pretreatment, the yield also had a 34.5% increase. To sum up, the USCCE with pretreatment is the best to extract lutein; the yield of SCCE was slightly higher than the SCE; Soxhlet extraction yield is medium, but it was so time-consuming that its efficiency is not high.

The HPLC conditions achieved baseline separation of lutein from the total extract, the retention time of lutein was in the vicinity of 8.35 min, and in Figure 3A lutein typical strong shoulder peak can be seen at 445 and 474 nm. Except for the subcritical water extracts, the other five extracts have the other two substances detected at retention times of 10.06 and 10.93 min; the two substances were full wavelength scanned, and the results are shown in Figure 4B,C. The main absorption band profile of these two substances was in the 400−500 nm range and has a shoulder peak or even three absorption peaks of typical carotenoid,[36] so these two substances were inferred as carotenoids, too, but their specific structure needs more analysis.

Extraction Kinetics. The results of USCCE and SCCE are shown in Table 4. According to the experimental data, we used the nonlinear fitting method to get the E_∞ and k values in Origin7.0 software. As is shown in Figure 5 and Table 4, the kinetic model and experimental data have a rather good fitting

DOI: 10.1021/acs.jafc.5b00461
J. Agric. Food Chem. 2015, 63, 4597−4605

degree. The k value of USCCE was 0.6599, larger than that of SCCE 0.5683, suggesting that ultrasound can increase the diffusion coefficient of internal solute and material; E_∞ increased significantly after using ultrasound, suggesting that ultrasound had an effect on the adsorption/desorption balance of solute between the interface of solid and liquid phases, and it made the balance tilt in the desorption direction. This conclusion is consistent with research conducted by Romdhane.[30] Overall, E_∞ and k increase at the same time, suggesting that ultrasound can enhance subcritical CO_2 extraction.

Microstructure of *C. pyrenoidosa* Powder. The images of *C. pyrenoidosa* treated by ultrasound with or without enzymatic pretreatment and conventional extraction are shown in Figure 6. The microstructure of the microalgal cell by SD (Figure 6B) had a lot of holes and interspaces because of a long time soaking (18 h). Part of the microalgal cell surface by SCCE (Figure 6C) floated up and had stepped lamella, which was because 4 h is not enough for CO_2 to penetrate into the interior. The microstructure of the microalgal cell by USCCE (Figure 6D) had more interspaces and holes than the microalgal cell by SCCE. This was the same as the results of Li et al.[37] and Zhao et al.,[38] in which ultrasound treatment disrupted tissues and cell walls. Moreover, the physical disruption of *C. pyrenoidosa* cells by ultrasound, together with enzymatic pretreatment, was the most efficient method to destroy microalgal cell walls (Figure 6E). Enzymatic pretreatment has recently been shown to be another alternative method, which opens up cell walls through biodegradation and releases bioactive compounds from microalga.[39] The cell walls were damaged by the application of ultrasound and enzymatic pretreatment, which resulted in the greater penetration of solvent into the sample matrix and increased the contact surface area between the solid and liquid phase, and, as a result, the solute quickly diffused from the solid phase to the solvent. Hence, USCCE with pretreatment is much more efficient and rapid for the extraction of the bioactive compound. Therefore, the sonication played an important role in breaking up the microalgal cell walls to enhance the extraction yield.

The extraction conditions for USCCE with enzyme pretreatment of lutein were evaluated and optimized with regard to the extraction efficiency. Results indicate that lutein was successfully extracted using USCCE with enzyme pretreatment due to its high efficiency, especially compared to other extraction methods. Among the four significant factors that affect USCCE with enzyme pretreatment (extraction temperature, extraction pressure, cosolvent dosage, and ultrasonic power), extraction pressure has maximum effect and extraction temperature has minimum effect. The optimal parameters of USCCE with enzyme pretreatment are extraction temperature of 27 °C, extraction pressure of 21 MPa, ethanol dosage of 1.5 mL/g, and ultrasonic power of 1000 W. Experiments performed under the optimal conditions reached 124.01 mg/100 g *C. pyrenoidosa*. Kinetic models of USCCE and SCCE in *C. pyrenoidosa* were established; different E_∞ and k values illustrate that ultrasound could strengthen the subcritical CO_2 extraction, and the model can also be a significant guide to the study of the amplification of the extraction process.
