LC-MS/MS Method. The analysis of the dipeptide Pyr-Phe was performed with an ultraperformance liquid chromatographic (UPLC) system, consisting of vacuum degasser, refrigerated autosampler, and binary pump (Acquity UPLC system; Waters, Milford, MA, USA) equipped with a reversed phase Waters Acquity UPLC CSH C18 analytical column of 2.1 × 10 mm and 1.7 μm particle size. The gradient (solvent A, water 0.1% formic acid; solvent B, acetonitrile 0.1% formic acid) was as follows: 0 min, 0% B; 0−4 min, linear increase to 50% B; 4−4.5 min, 99% B; 4.5−5 min, isocratic; 5−5.1 min, return to initial conditions 0% B; total run time = 6 min. The flow was 600 μL min^{-1}, with the column oven at 60 °C. The UPLC system was connected to a triple-quadrupole mass spectrometer model XEVO TQ-S (Waters) equipped with an electrospray interface operating in the positive ion mode. The MRM transitions acquired for Pyr-Phe were obtained from the infusion of the dipeptide standard in acetonitrile/water 10:90 (v/v): 277.1 → 120.2, 277.1 → 166.2, 277.1 → 231.1. The collision energy for each MRM transition was set at 20, 10, and 10 eV, respectively. Capillary voltage was set at 3.20 kV, cone voltage at 40 V, source temperature at 150 °C, and desolvation temperature at 650 °C.

A targeted method was developed to confirm the presence of Pyr-Phe in the serum and plasma samples. The performance of the analytical method was evaluated by checking the performance criteria in samples: the S/N ratio ≥3 for all of the monitored MRM transitions and the retention time of the analyte within the tolerance limit of 2.5%. The analyte area of the samples was normalized every day by using the mean peak area of a standard solution of Pyr-Phe at a level of 10 μg L^{-1} (peak area in the sample/peak area of standard solution), injected at the beginning and the end of the series of samples. Hence, the abundance of Pyr-Phe in the serum/plasma was expressed as area ratio. Additionally, linearity was checked by constructing standard calibration curves and calibration curves using spiked serum samples (bovine serum from Sigma), at concentration levels in the range between 0.25 and 10 μg L^{-1}. Calibration curves were calculated daily by least-squares linear regression analysis of the peak area of the dipeptide.

Statistical Analysis. All descriptive statistical analysis and calculations were carried out using the Microsoft Excel software package version 2010 (Microsoft Corp.). Mean and standard deviation of peptide levels in samples from estradiol-treated animals and from nontreated animals were calculated to evaluate the biomarker effect in different age groups.

RESULTS AND DISCUSSION

Recent studies have focused on the measurement of various biomarkers that may be able to indicate treatments with estrogenic hormones in cattle.[34,35,38−41] In this research area, samples collected in vivo, on farms, appear convenient options for biomarker determination. The major advantage of samples as urine, blood, or hair is that routine controls may be performed while the animal is still at the farm. Some researchers have highlighted the superiority of serum in comparison to plasma for mass spectrometry-based metabolomics and biomarker discovery, due to the higher metabolite concentrations in serum.[42,43] For the present work, both kinds of matrices have been used. As long as the same sample preparation is used, either matrix should generate similar results when using targeted analysis.

Animal Age. The up-regulation of the biomarker in estradiol-treated adult females can be seen in Figure 1. The box plot summarizes the data obtained for these 13 animals. A clear age effect was observed when the levels of the biomarker in adult cows were compared with those obtained for prepubertal females. In the older animals the area ratios of Pyr-Phe were 0.5 ± 0.1 for control and/or progesterone-treated females and 2.8 ± 1.1 in treated animals. The basal serum concentrations in cows resulted in almost twice the plasmatic levels found in young animals. This group showed plasmatic levels below or at 0.4, except in the case of samples from treated individuals. Figure 2 shows a box plot of the plasma levels of Pyr-Phe in young females. The 2-week-old females exhibited inconsistent and short-lasting responses in some cases, whereas the 6-month-old female showed a delayed but clear increase on the biomarker level 2 weeks after the first EB dose. A possible reason for the missing and/or reduced response in young females could be the age and sexual development of the animals. The age of the animal plays an important role in the establishment of acceptable reference thresholds of biomarkers, as it influences the endogenous levels of the sex steroids.[44] Even though puberty onset will differ between animals, rather accurate age ranges may be established for a specific species and breed. In a study performed with 39 Holstein-Friesian heifers, the puberty onset was detected in a range of 38−55 weeks of age.[44] These data indicate that the young females included in this work can be considered as prepubertal animals. The latter was expected to be more responsive as it was closer to puberty onset.

It has already been suggested that prepubertal animals behave differently from adult animals in their response to anabolic treatments. In 2011, Becker et al. conducted two transcriptomics studies in parallel, one with postpubertal 24-month-old Nguni heifers and other one with prepubertal female 2−4-week-old Holstein-Friesian calves.[39] The animals were administered combinations of estrogenic and androgenic compounds. No successful results were obtained for prepubertal heifers. In a study by Cacciatore et al. female and

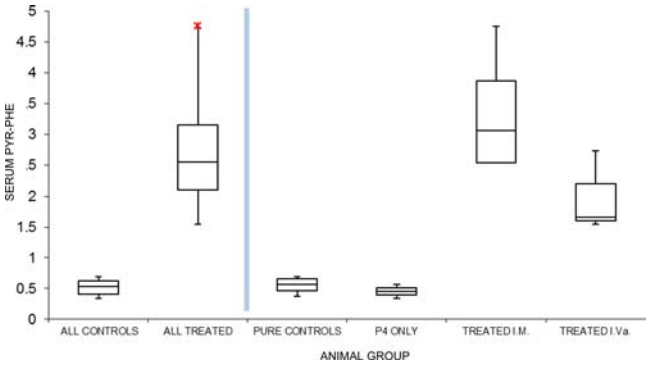

Figure 1. Overview of the presence of Pyr-Phe in the serum of adult cows treated or not with estradiol preparations (P_4, progesterone; IM, intramuscular; IVa, intravaginal). Box plot shows serum levels of the marker; the box limits are in the 25th and 75th percentiles, and the band in the middle of the box is the median; the whiskers are in the 1.5 interquartile range. Data not included between the whiskers are plotted as an outlier with a small cross.

male crossbred Holstein-Friesian × Fries-Hollands calves at an age of 10 weeks[34] were treated with a combination of EB and 19-nortestosterone decanoate intramuscularly. Among the nine plasma potential biomarkers measured, only one of the analytes (ir-inhibin) was down-regulated in males under hormonal treatment, but unaffected in females.

Administration Route, Dose, and Other Anabolic Compounds. The treatments applied in this study included several carrier solvents, anabolic combinations, doses, and routes of administration (see Table 1). All of the adult animals were treated with relatively low doses of estradiol, but a clear effect was observed in the levels of the selected biomarker, regardless of the route of administration and the drug (free estradiol or benzoate) (Figure 1). A smaller effect was noted for the intravaginal treatment. However, the mechanism of diffusion via vaginal mucosa is different and slower, and also the simultaneous administration of progesterone may have influenced the expression of the marker. A recent study by Wasowska and Krzymowska indicated that exogenous progesterone in porcine females affected the secretion of androgens and estrogens, resulting in a negative feedback for estradiol.[45] This feedback could lead to an altered response of the biomarker. The most evident up-regulation of Pyr-Phe was observed in the animal treated with estradiol-17β (lowest dose of estrogen), suggesting a stronger response to the free form. A possible reason is that esters need to be hydrolyzed before binding to receptors. Females under treatments with only progesterone (no estrogens) showed no significant differences in the levels of the dipeptide in comparison to "pure" control females.

For the 2-week-old heifers, the levels of Pyr-Phe in the control group, including the animals treated with carriers only, were measured at different points. No significant modifications could be observed, suggesting no influence of the carriers on the biomarker. The detected levels in plasma had an area ratio below 0.4 (0.2−0.4). For the treated animals, both pour-on and intramuscular administrations yielded inconsistent results, with short-term peaks in the levels of the dipeptide in some of the cases. In the pour-on group, a mild response of the marker could be observed only in one animal (Figure 3). A noticeable up-regulation (ratio 0.5) was expressed around day 21 in animal 179, treated three times (Figure 3C). The increase corresponds to 7 days after the last administration (of three consecutive doses), when some degree of steroid accumulation in the subcutaneous fat may be expected. The levels of the marker rapidly decreased to basal/control conditions. A mild effect was observed in animal 183, also around day 21 (Figure 3B). In this case, it was still in the range of the control animals. This animal received only one dose, and the initial basal levels of the dipeptide were very low (below 0.3) in comparison to the rest of the group. Pour-on formulations cannot be considered a topical route of administration in cattle under normal husbandry conditions.[46] In a natural environment, cattle lick themselves (allolicking) and lick other cattle (heterolicking). Thus, part of the drug may pass through the digestive tract, and not only in the treated animal but also in animals from the same herd or group. Additionally, different carrier solvents were applied per animal, possibly leading to different administration efficiencies. The highest levels of Pyr-Phe after treatment were observed for DEGMBE preparations, matching the results for hair analysis reported by Stolker et al.[15] At day 7, animal 178 (treated once) showed a response of 0.6 in the same range as animal 179 (treated three times) at day 21, both treated with formulas based on DEGMBE. In the intramuscular treatments, a clearer effect was observed in both females, even though the response was different in each animal (Figure 4). A single administration resulted in a late effect on the biomarker, reaching the maximum (measured) level almost 1 month after the administration (Figure 4A). The animal injected three times showed the same level after the second dose, suggesting some kind of accumulative effect (Figure 4B). Unfortunately, plasma from every time point was not available for analysis to obtain a complete pattern of the biomarker throughout the treatment.

Figure 2. Overview of the presence of Pyr-Phe in the plasma from young bovine females, grouped by age and treatment (IM, intramuscular; EB, estradiol benzoate; DROM, dromostanolone). Box plot shows plasma levels of the marker; the box limits are in the 25th and 75th percentiles, and the band in the middle of the box is the median; the whiskers are in the 1.5 interquartile range. Data not included between the whiskers are plotted as an outlier with a small cross.

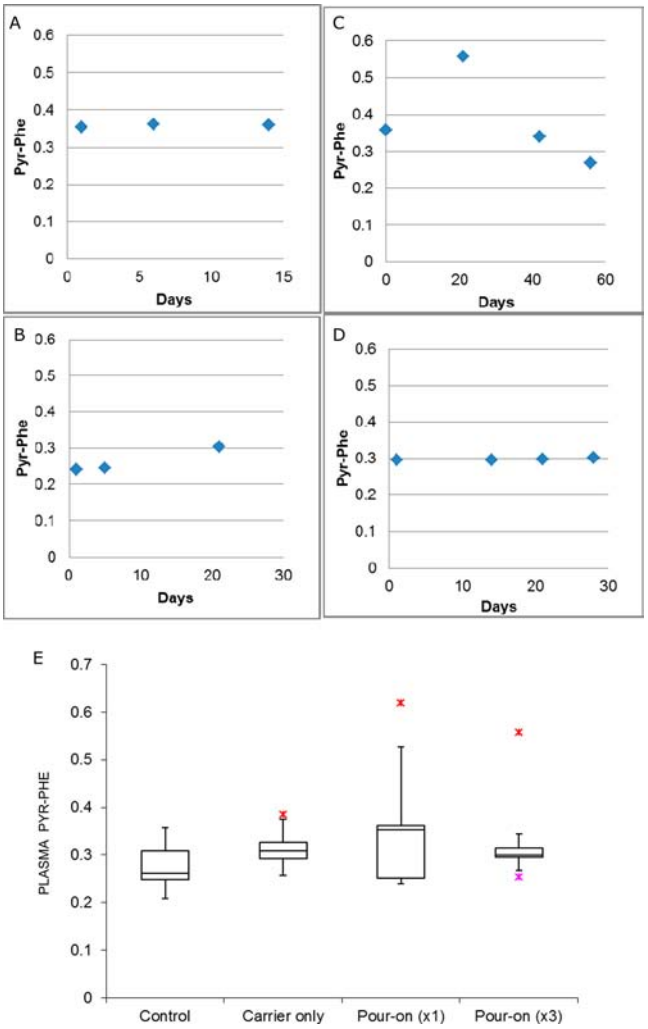

Figure 3. Evaluation of Pyr-Phe levels in the 2-week-old control females treated via pour-on and comparison to their respective control animals. The four upper plots represent the evolution of the marker in four individual animals treated once (A, B) or three times (C, D). The box plot (E) shows the serum levels of the marker in all the pour-on and control cases; the box limits are in the 25th and 75th percentiles, and the band in the middle of the box is the median; the whiskers are

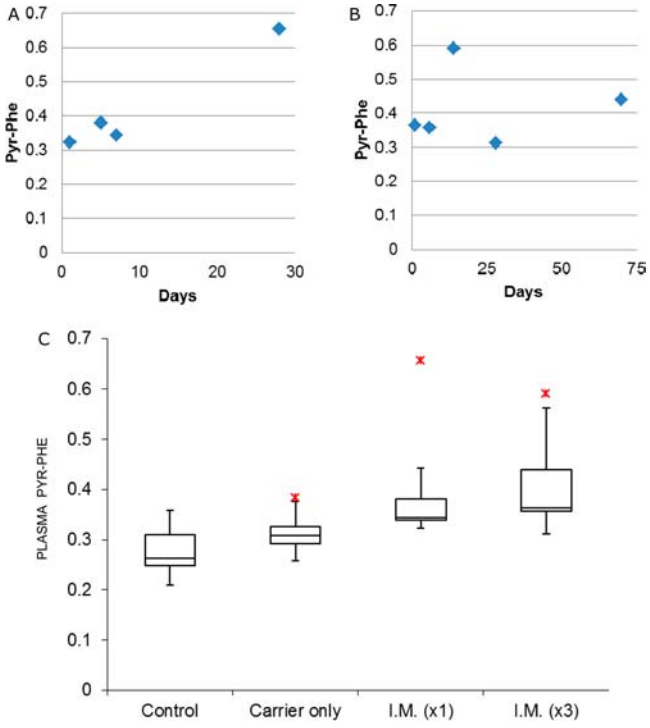

Figure 4. Evaluation of Pyr-Phe levels in the 2-week-old control females treated intramuscularly (IM) and comparison to their respective control animals. The two upper plots represent the evolution of the marker in two individual animals treated once (A) or three times (B). The box plot (C) shows the serum levels of the marker in all the IM samples and in control cases; the box limits are in the 25th and 75th percentiles, and the band in the middle of the box is the median; the whiskers are in the 1.5 interquartile range. Data not included between the whiskers are plotted as an outlier with a small cross.

Although it is difficult to draw conclusions, it is pertinent to make a few remarks. On the one hand, the doses applied may not have been high enough to raise an effect in the biomarker, especially in the case of pour-on treatments. On the other hand, the possibility exists for the androgenic compounds (TD and TC) to have an antagonistic effect on this biomarker. Hemmer et al. selected four peptides in the plasma of male and gravid female fish, as potential estrogenic biomarkers.[47] Afterward, they performed experiments with 17β-trenbolone to investigate possible effects of the synthetic androgen. All four peptide biomarkers were significantly reduced in females exposed at the highest treatment level, which corresponded with significant reductions in fecundity and changes in ovarian morphology. Other researchers have reported similar problems when using a combination of estrogenic and androgenic drugs in bovine animals.[34,39]

For the 6-month-old female, four different steroids were administered (DHA, MPA, EB, and DROM), reaching a total dose per compound of 250 mg. Whether due to the higher estrogenic dose or the difference of age, the changes in the peptide concentration were clearer in this prepubertal animal (Figure 5). The samples collected before the first injection appeared within basal levels, similar to those found in the 2-week-old animals. The first two samples collected (12 and 24 h) after the first EB injection showed decreased levels in comparison to the initial control samples (1 month earlier). However, the effects and/or feedback that the previous administration of DHA and MPA may have on the response of this biomarker remain unknown. DHA is a potent androgen with anabolic properties, and MPA is a synthetic glucocorticoid or corticosteroid. The possible interference of androgenic drugs has been previously discussed. Additionally, glucocorticoids can also inhibit endogenous production of sex steroids and can affect protein synthesis within the liver.[48,49] This last fact is especially relevant when one is working with protein or peptide makers. Unfortunately, no samples were collected during DHA and MPA administration. In the days following first EB injection, the biomarker came back to initial concentrations and exceeded them 2 weeks later, reaching levels closer to those found in treated adult females (Figure 5A). The last compound administered was DROM, a less potent synthetic derivative of dihydrotestosterone with enhanced anabolic activity and with certain antiestrogenic activity. Its administration did not lower the expression of the marker. It is difficult to draw tight conclusions for this range of age as there was only one animal.

Other Factors. The results suggest that both the protocol of administration and sampling and the variability of farm animals could affect the reliability of the method. However,

dx.doi.org/10.1021/jf503773u | J. Agric. Food Chem. 2015, 63, 370−378

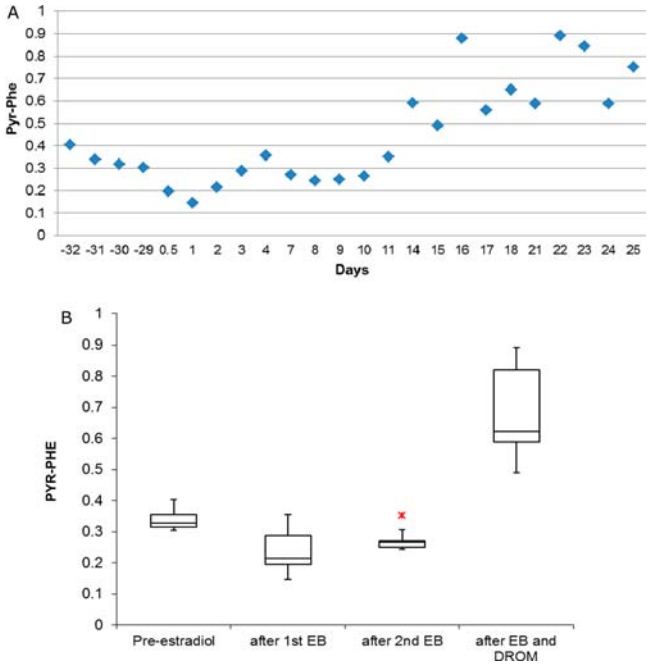

Figure 5. Evaluation of Pyr-Phe levels in the 6-month-old female treated intramuscularly with EB and other drugs. The point-to-point graph (A) shows the evolution of Pyr-Phe during the animal experiment, day 0 being the day of the first injection of EB. The box plot (B) shows the serum levels of the marker at different stages of the experiment; the box limits are in the 25th and 75th percentiles, and the band in the middle of the box is the median; the whiskers are in the 1.5 interquartile range. Data not included between the whiskers are plotted as an outlier with a small cross.

other factors such as origin, gender, breed, health status, and feed may also influence the expression of Pyr-Phe in estradiol-treated animals. In addition, it is essential to differentiate between genders when one is dealing with biomarkers and profiling methods for the detection of hormonal treatments.[13,21,34] In future studies, the presence of this dipeptide should be assessed in adult and prepubertal males. The feeding should not be excluded as a source of variability. In the present study, the prepubertal population followed a diet completely different from adult cows. On the other hand, experimental animals may not give the same results as animals living on real farms due to stress factors and differences in the management and environmental conditions. Finally, the possible classification of this biomarker as a marker of effect instead of exposure should not be excluded. That would mean that its presence is correlated to an estrogenic effect rather than to an administration or exposure to a specific compound (estradiol). Therefore, observational data about its presence and amount in bovine animals exposed to estrogen-like substances, such as mycotoxins and phytosterols, should be considered and explored soon as it would enhance the significance of this work. Also, these kinds of studies are necessary to facilitate the translation of this biomarker into practice.

No definitive solution has been found yet to solve the problem of the illegal administration of estradiol in cattle. A strong influence of age in effect-based detection approaches has been reported,[35,50] as well as a potential contribution of other drugs and individual variations. Results reported suggest that it is necessary to establish different biomarkers for specific treatment regimens and different age/gender classes of animals. The capability of Pyr-Phe to identify adult cows that are "highly suspicious" of estradiol treatments was proven. A potential threshold is established at a ratio of 1.0 because all of the samples from treated cows were above it. In the case of prepubertal animals, a threshold of 0.4 may be concluded from this study and proposed, but the screening ability would be clearly lower for these animals.

The introduction of new powerful tests is still required for prepubertal heifers. Combining multiple biomarkers in a panel might be beneficial, along with other options such as hair analysis or steroid profiling. The ultimate confirmation would rely on GC-C/IRMS. The matrix of choice for this powerful technique is urine. The use of different matrices for screening and confirmation is an obstacle to their implementation into routine. For this reason, the ultimate screening tool would preferably be urine-based. Moreover, the detection frame of screening and confirmation needs to be compatible.

Critical Evaluation of Changes in the Ratio of Insoluble Bound to Soluble Phenolics on Antioxidant Activity of Lentils during Germination

ABSTRACT: A new indicator, the ratio of insoluble bound phenolics (IBPs) to soluble phenolics (SPs), is suggested as an effective means to monitor changes in the antioxidant activity of lentils during germination. This indicator may be used to monitor other process-induced changes in antioxidant potential of food phenolics in other foods. The antioxidant activity of SPs, IBPs, and total value, the sum of both free and esterified phenolics, of germinated CDC Richlea lentil variety was evaluated for 4 days. Total phenolic content (TPC), total flavonoid content (TFC), 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical, and 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) radical cation scavenging ability were employed to record antioxidant activities. An incremental increase in IBPs was found in TPC, TFC, DPPH, and ABTS radical cation scavenging ability, whereas SPs showed a declining trend in TFC, DPPH, and ABTS, except TPC during 4 days of germination. The ratio of IBPs to SPs increased using most methods, and this may be possibly due to the changes of phenolic compound formation from soluble into insoluble bound form during germination process. The ratio can be used as a novel method for monitoring process-induced changes in the antioxidant activity of foods.

KEYWORDS: *lentil, germination, insoluble bound phenolics, antioxidant activity*

INTRODUCTION

Lentils have attracted much interest from food scientists and consumers alike as they serve as an excellent dietary source of legumes that are rich in dietary fiber, carbohydrates, protein, various vitamins, minerals, and several health-beneficial fatty acids.[1] Some epidemiological studies have reported their effects in lowering cholesterol and reducing colon cancer, heart diseases, and type-2 diabetes.[2]

Germination is an efficient and economical bioprocess for improving the nutritional quality and functionality of seeds and legumes and is well-studied in the plant physiology area. Reactive oxygen species (ROS) play a key role in seed development, dormancy breaking ability, and regulation of germination processes such as signaling molecules.[3] Meanwhile, phenolic compounds are responsible for controlling ROS that stimulate production of phenolic compounds by activating enzymatic or nonenzymatic pathways.[4] This complex reaction process affects the composition and quantity of phenolic compounds, leading to changes in nutritional and functional quality of seeds.

The reason for alteration of antioxidant activity of soluble phenolics (SPs) and insoluble bound phenolics (IBPs) induced by germination has not been fully explored. For this reason, we tested the ratio of IBPs to SPs to see if it would provide a useful tool for better understanding and monitoring of changes in antioxidant activity by predicting the localization and molecular transportation mechanism of phenolic compounds in plant cells during germination. Most phenolic compounds are synthesized in the intracellular space, especially in the endoplasmic reticulum, and are stored in vacuoles as SPs.[5] On the other hand, IBPs are transported from intracellular space and localized in cell walls by forming covalent bonds with insoluble macromolecules such as cellulose, arabinoglycan, and proteins or by self-polymerization. Therefore, changes in the ratio of these phenolics may provide a useful tool for predicting localization and transportation mechanisms of phenolic compounds and alteration of antioxidant activity upon processing, as exemplified for germination of lentils in this study. Thus, we monitored changes of antioxidant activity of SPs and IBPs procured from germinated lentils and used the ratio of IBPs to SPs to explain the results.

MATERIALS AND METHODS

Germination of Lentils. Fifty grams of CDC (Crop Development Center) Richlea lentils was washed thoroughly with distilled water and then placed on aluminum plates covered with a wet paper towel and allowed sufficient oxygen at 24.5 ± 0.8 °C. The germination process was followed on days 1, 2, 3, and 4. Water was supplied every 12 h to sustain adequate humidity. After germination, samples were dried in a forced air oven at 55 °C for 24 h and then stored at 4 ± 1 °C.

Extraction of Soluble Phenolics and Insoluble Bound Phenolics. Extraction of SPs from germinated lentils was followed as described by Wettasinghe and Shahidi with slight modification,[6] and IBPs were extracted as described by Naczk and Shahidi.[7]

Total Phenolic Content (TPC). TPC of germinated lentils was determined as described by Singleton and co-workers and as explained by Chandrasekara and Shahidi.[8,9]

Total Flavonoid Content (TFC). TFC was measured as described by Chandrasekara and Shahidi.[9]

2,2-Diphenyl-1-picrylhydrazyl (DPPH) Radical Scavenging Ability. DPPH radical scavenging ability was conducted as described as Sekhon-Loodu with slight modification.[10] Briefly, 1.9 mL of DPPH solution (0.1 mM) was mixed with 0.1 mL of sample, which was then allowed to react for 30 min at room temperature in the dark; the absorbance was then read at 517 nm.

2,2′-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) Radical Cation Scavenging Ability. ABTS radical cation was produced as described by Miller and Rice-Evans using ABTS and potassium persulfate.[11]

Statistical Analysis. Statistical analysis was conducted using IBM statistics version 21 (IBM Corp., Armonk, NY, USA). Duncan's test

RESULTS AND DISCUSSION

Total Phenolic Content. TPCs of SPs and IBPs in germinated lentils were determined using Folin−Ciocalteu's assay, and results are shown in Table 1. The germination process led to increase of TPC in both SPs (from 3.35 to 4.25 mg gallic acid equivalents (GAE)/g of defatted weight (DW)) and IBPs (from 4.78 to 6.45 mg GAE/g of DW). In agreement with this result, TPC of SPs isolated from germinated green lentils (*Lens esculenta*) showed increase of TPC during 7 days.[12]

The sum of SPs and IBPs, expressed as total value, showed an increasing pattern from 8.13 to 10.69 mg/g, and this result might indicate gradual synthesis of phenolic compounds during the germination process. In addition, the ratio of IBPs to SPs increased from 1.43 to 1.52.

Total Flavonoid Content. The influence of germination on changes in TFC in SPs and IBPs is presented Table 1. TFC of SPs decreased from 2.49 to 1.96 mg catechin equivalents (CE)/g of DW during the 4 days of germination, whereas that of IBPs increased from 2.98 to 3.85 CE mg/g. Decrease of TFC in SPs may be related to the degradation of flavonoids by oxidants such as ROS, which are produced in cells, especially in the mitochondria, during electron transfer chain reaction.[13,14] ROS play a key role as signaling molecules and affect cell division and growth. In doing so, the concentration of ROS is controlled by phenolic compounds, which act as regulators in plant metabolism by scavenging ROS, resulting in degradation of phenolic compounds. On the other hand, decrease of SPs can also be caused by their transport from intracellular space to cell wall and transformation from SPs into IBPs. This argument gains support from the previous findings of Strack et al.,[15] who reported that the increase in cell wall flavonoids during aging of Scots pine leaf paralleled a decrease in soluble flavonoids. They concluded that vacuolar efflux of these metabolites and deposition in the cell wall had occurred and that quercetin and kaempferol derivatives were also found in the cell wall of epidermal cells in lisianthus flowers petals.[16] Phenylpropanoids, particularly hydroxycinnamic acid derivatives, contribute to cell wall formation through esterification with complex carbohydrates.[17] These endoplasmic reticulum synthesized compounds were reported to be released in small vesicles that fuse in larger bodies and migrate to cell wall, after fusion with the plasma membrane.[18]

The ratio between IBPs and SPs is also shown Table 1. The ratio was increased significantly from 1.19 to 1.96 ($p < 0.05$), and this indicates that the decrease of SPs is more likely due to transportation of flavonoids from intracellular to cell walls rather than degradation by ROS. This is because the decreased value (0.53) of SPs from 2.49 to 1.96 is comparable with the increased value in IBPs (0.87), and the difference (0.34) is similar to the increase of total value (0.35) from 5.47 to 5.82, which might be related to the synthesis of phenolic compounds

DOI: 10.1021/jf505632p
J. Agric. Food Chem. 2015, 63, 379−381

during germination. Thus, both transportation and synthesis of flavonoids may occur at the same time during germination; further confirmation of this would benefit from more detailed study using HPLC methodology.

DPPH Radical Scavenging Ability. The DPPH radical scavenging ability of SPs and IBPs in germinated lentils is presented in Table 2. The germination process decreased the DPPH radical scavenging ability of SPs from 61.3 to 53.5%, whereas an increase from 47.1 to 76.1% was found for IBPs.

The continuous increase of total values induced by germination process was from 111.5 to 122.8%, and this increment may be associated with the synthesis of phenolic compounds during the germination process. The ratio of IBPs to SPs significantly increased by approximately 2-fold from 0.78 to 1.42. This is most likely related to the enhancement of IBPs, possibly due to transportation of SPs into cell wall as discussed in the case of total flavonoids.

ABTS Radical Cation Scavenging Ability. The ABTS radical cation scavenging ability of SPs and IBPs of germinated lentils is shown in Table 2. Enhancement of ABTS radical cation scavenging ability of IBPs was observed in germinated lentils compared to the control (from 48.2 to 65.3%); a decreasing trend was found in SPs from 63.3 to 57.6% during 4 days of germination. A moderate increase in the total and ratio of IBPs to SPs was found in germinated lentils from 111.5 to 122.8% and from 0.76 to 1.13, respectively. The reason for this change may be the same as that discussed for TPC, TFC, and DPPH results.

In short, a novel indicator, the ratio of IBPs to SPs, was proposed for the reasoning on the alteration of phenolic formation in lentils during the germination process. In all measurements tested, the ratio showed increasing trends, allowing speculation such as transportation of phenolic compounds from vacuole into cell wall followed transformation into insoluble bound phenolics by forming covalent bond with insoluble macromolecules. Although only one type of processing was given in this study, the ratio can be applied to many other types of process-induced phenolic changes in foods for the fundamental reasoning.

Supporting Information

ABSTRACT: The potential toxicity and accumulation of engineered nanomaterials (ENMs) in agricultural crops has become an area of great concern and intense investigation. Interestingly, although below-ground vegetables are most likely to accumulate the highest concentrations of ENMs, little work has been done investigating the potential uptake and accumulation of ENMs for this plant group. The overall objective of this study was to evaluate how different forms of cerium (bulk cerium oxide, cerium oxide nanoparticles, and the cerium ion) affected the growth of radish (*Raphanus sativus* L.) and accumulation of cerium in radish tissues. Ionic cerium (Ce^{3+}) had a negative effect on radish growth at 10 mg $CeCl_3$/L, whereas bulk cerium oxide (CeO_2) enhanced plant biomass at the same concentration. Treatment with 10 mg/L cerium oxide nanoparticles (CeO_2 NPs) had no significant effect on radish growth. Exposure to all forms of cerium resulted in the accumulation of this element in radish tissues, including the edible storage root. However, the accumulation patterns and their effect on plant growth and physiological processes varied with the characteristics of cerium. This study provides a critical frame of reference on the effects of CeO_2 NPs versus their bulk and ionic counterparts on radish growth.

KEYWORDS: *cerium oxide, nanomaterials, nanoparticles, radish, phytotoxicity, plant uptake*

INTRODUCTION

Nanotechnology is a rapidly expanding global industry. Engineered nanomaterials (ENMs) with their size smaller than 100 nm in at least two dimensions are increasingly found in commercial products. Due to their small size and large specific surface area, ENMs exhibit novel and different physical, chemical, and biological properties from their bulk or ionic counterparts. These unique properties provide new opportunities to fight diseases, enhance energy efficiency, and improve the environment.[1−3]

Although the synthesis of ENMs adds desirable physical and/or chemical properties over the bulk or ionic forms, the potential environmental health and safety implications of ENM use have become a serious concern. Previous research has shown that some ENMs used in consumer products are released into the environment, and many of these materials are detected in wastewater streams.[4−6] As one of the most commonly employed nanomaterials, cerium oxide nanoparticles (CeO_2 NPs) have attracted great attention. The potential toxicity of CeO_2 NPs (6−40 nm, unmodified) to bacteria, fish, and mammalian cells has been reported.[7,8] Plants play a critical role in maintaining ecosystem health and function and as a food source for humans. Plant uptake of ENMs represents an important pathway for human exposure to these nanoparticles through food consumption.[9] Consequently, investigation of the uptake and accumulation of ENMs by agricultural crops is not only warranted but also critical to food safety and human health. However, there are only a small number of studies in the literature that have addressed the interactions of CeO_2 NPs with terrestrial plants.[10−16] In one study, Wang et al.[10] found that uncoated CeO_2 NPs (<25 nm) at 0.1−10 mg/L had a slightly positive effect on tomato (*Solanum lycopersicum* L.) growth and yield (e.g., increased production of tomato fruit at 10 mg/L). However, cerium was reportedly transported from roots to shoots and accumulated in edible tissues, although the chemical form of Ce was not determined. These authors further investigated the transgenerational effect of CeO_2 NPs and found that second-generation seedlings grown with seeds from parental plants treated with 10 mg/L CeO_2 NPs were significantly smaller and accumulated more cerium as compared to seedlings generated from control plants.[11] Ma et al.[12] studied how rare earth oxide NPs affected root elongation and found that bare CeO_2 NPs with an average diameter of 7.2 ± 0.7 nm had no effects on rape (*Brassica napus* L.), radish (*Raphanus sativus* L.), wheat (*Triticum aestivum* L.), cabbage (*Brassica oleracea* L.), tomato (*Lycopersicon esculentum* L.), and cucumber (*Cucumis sativus* L.) at 2000 mg/L. Rico et al.[13] demonstrated that exposing rice seedlings to bare CeO_2 NPs with an average size of 231 ± 16 nm up to 500 mg/L for 10 days caused no visible signs of toxicity. However, CeO_2 NPs induced a

concentration-dependent modification of the oxidative stress and antioxidant defense system in the rice seedlings. Several studies have reported the uptake and accumulation of CeO_2 NPs by agricultural crops. For instance, Zhang and colleagues[14] showed that 7 and 25 nm bare CeO_2 NPs were detected in cucumber tissues, but the transport of cerium from roots to shoots was limited. Zhao et al.[15] investigated the effects of bare and alginate-coated CeO_2 NPs on corn plants and reported that surface coating and soil organic matter could promote the translocation of cerium in higher plants. A recent study demonstrated that intact CeO_2 NPs (7 nm) were taken up by soybean roots.[16] In summary, CeO_2 NPs can be taken up by plants and accumulated in plant tissues, but the majority of the NPs appeared to remain in the root tissues, raising concerns on the heightened accumulation of ENMs by root vegetables.[17]

Interestingly, even though the edible tissues of below-ground vegetables often have direct contact with soilborne ENMs and present the highest potential for ENM accumulation in food crops, little attention has been paid to this important group of food plants. In this study, radish (*R. sativus* L.) was adopted as a model plant in that it is a popular vegetable with high global consumption. In addition, radishes mature rapidly in full sun and light and can be harvested in 3−4 weeks, making it an ideal plant to study the fate and impact of environmental chemicals on the development of below-ground vegetables. The objectives of this study were twofold: (1) How does cerium in different chemical forms (e.g., ionic cerium vs cerium particles) and physical sizes affect the growth of radish? (2) How extensively and differently will the radish tissues take up and accumulate cerium in different forms and sizes? With these two objectives, we aimed to fill some of the current knowledge gap on the possible differential accumulation of cerium with different forms and particle sizes by plants. Even though detailed studies on the cerium effect of essential physiological and biochemical processes are not the concern of this study, their interactions are important for mechanistic understanding of the interactions of plants and nanoparticles and warrant further investigations.

MATERIALS AND METHODS

Chemicals. Dispersions of CeO_2 NPs (10 wt % in H_2O) and cerium chloride powder were purchased from Sigma-Aldrich (St. Louis, MO, USA). The bulk powder of CeO_2 was obtained from Strem Chemicals, Inc. (Newburyport, MA, USA). Hoagland solution (one-fourth strength) was prepared by dissolving an appropriate amount of the modified Hoagland basal salt mixture (Phytotechnology Laboratories, Lenexa, KS, USA) with deionized water. The size and morphology of CeO_2 NPs and the bulk suspensions were characterized by transmission electron microscopy (TEM). The hydrodynamic size and zeta potential of CeO_2 NPs in one-fourth strength Hoagland solution were measured with a dynamic light scattering instrument (Malvern Zetasizer Nano-ZS90, NY, USA).

Seed Germination and Growth Conditions. The radish seeds [Cherriette (F1)] were obtained from Johnny's Selected Seeds (Winslow, ME, USA). Seeds were surface sterilized with 1.25% sodium hypochlorite solution for 10 min and then rinsed with deionized water three times. The sterilized seeds were germinated on moist filter paper in a Petri dish for 7 days. Healthy young seedlings of similar size (7.5−8 cm in height from the root tip to the tip of cotyledons) and stage of development were transferred to 50 mL polypropylene centrifuge tubes containing one-fourth strength Hoagland solution and were incubated in a growth cart with a 16 h light/8 h dark cycle (28 °C) to allow the seedlings to further develop. The growth cart was equipped with four T5 fluorescent tubes, providing a light intensity of approximately 104 μmol m^{-2} s^{-1} of visible light (400−700 nm) at the height of plant leaves. After 7 days, the seedlings were transferred from the centrifuge tubes to 100 mL glass jars containing 10 mg/L of bulk or nanosized cerium oxide (CeO_2) or cerium chloride ($CeCl_3$). Each jar had a floating lid made by Hareline 2 mm thin fly foam (Fishwest, Sandy, UT, USA) so that the plant roots were constantly submerged in the treatment solutions. Due to the scarcity of information on the potential adsorption of cerium on foam surface, it was assumed that the potential impact of foam on cerium bioavailability was insignificant in this study. Four treatments were prepared, all in one-fourth strength Hoagland solution: (1) control (no cerium treatment); (2) 10 mg/L CeO_2 NPs; (3) 10 mg/L CeO_2 bulk; and (4) 10 mg/L $CeCl_3$. The concentration of 10 mg/L was chosen because this value is considered environmentally relevant[18] and our previous studies also showed that CeO_2 NPs at this concentration slightly enhanced plant growth.[10,11] Each treatment had 12 replicates. The solutions in the jars were replenished every other day with the same treatment solution to compensate for evapotranspiration, with the assumption that Ce would be taken up concurrently with water by plants. However, if plants preferably take up water, it is possible that cerium would accumulate in the growing solution. Plants were harvested 35 days after germination (i.e., 21 days after treatment). Additionally, a separate set of radish plants were grown and treated exactly as above. The harvested tissues from these plants were used to determine the distribution of cerium across the fine root tips and storage roots microscopically (see below for details).

Plant Physiological Responses. For the first batch of plants, daily transpiration rate was recorded for each seedling after it was transferred to 100 mL glass jars by measuring the water surface drop before the solution replenishment. The cumulative transpiration of each treatment was then calculated by summing the daily transpiration over the 21 day treatment period. Relative chlorophyll content was measured with a SPAD 502 Plus Chlorophyll Meter (Spectrum Technologies, Inc. Aurora, IL, USA) 1 day prior to harvest and was expressed as a percent of control. An OS 1p chlorophyll fluorometer (Opti-sciences, Inc., Hudson, NH, USA) was used to measure the yield of quantum efficiency of PSII (light-adapted Y(II)) and the photochemical efficiency of PSII (dark-adapted F_V/F_M) on the same day the relative chlorophyll was measured. Five of the 12 replicates from each treatment were used in a leakage test to assess root membrane integrity. The leakage test followed the published procedures with some modifications.[19] Briefly, the entire fine root system was submerged in 50 mL of deionized water and the initial conductivity C_w was measured immediately (Orion ROSS Ultra pH/ATC Triode Orion Star A325 Thermo Fisher Scientific, Waltham, MA, USA). The conductivity of the solution was measured again as C_0 after 3 h of incubation at room temperature. The entire fine roots were then autoclaved at 121 °C for 20 min with a Tuttnauer Brinkman 3850 M autoclave to release all electrolytes. The final conductivity C_t was measured after the samples cooled to room temperature. The percentage of electrolyte leakage was calculated as $EL = (C_0 - C_w)/(C_t - C_w) \times 100$.

Uptake, Accumulation, and Distribution of Cerium. At harvest, radish plants were separated into fine roots, storage roots (the edible radish bulb), and shoots. The tissues were then dried in an oven at 75 °C for 7 days and their dry weights determined. For each treatment, the 12 storage roots and 12 shoot tissues were divided into four groups, respectively. The shoot and storage root tissues in each group were then ground together into fine powders, from which 0.25 g of the ground tissues was weighed and digested in 4 mL of 70% nitric acid and swirled to mix. For the fine roots, the remaining seven replicates (five replicates used for the electrolyte leakage test were excluded) were divided into three groups, and each group contained either two or three of the fine root systems. Due to the smaller biomass of the fine roots, all ground tissues from each group were used for the digestion. The nitric acid digest was heated at 95 °C for 20 min and then at 45 °C for 4 min, and the cycle was repeated five times until all of the dry tissues were dissolved. Afterward, 2 mL of hydrogen peroxide was added to the mixture and heated using the same temperature cycle until the solution was clear. The digest solution was

then analyzed by inductively coupled plasma–mass spectrometry (ICP-MS) to obtain the concentration of cerium in each sample.

The radish roots used to determine the localization and distribution of cerium in their fine roots and storage roots were harvested at day 21 after treatment. To obtain a reference for the anatomy of the radish storage root, a cross section of the radish storage root taken at the equator was cut with a razor blade and observed under a Kruss MBL3000 light microscope (A.KRÜSS Optronic, Hamburg, Germany) (Supporting Information, Supplementary Figure 1). The radish fine root tips and sections of the storage roots from each treatment were also examined using a Zeiss LSM 510 META confocal microscope. A laser excitation wavelength of 543 nm was used, and an emission filter band-pass was set between 530 and 590 nm to collect both the laser reflection and autofluorescence in this region. To image the storage root, the root was first cut in half horizontally from the thickest point, and then a thin slice (~1 mm) of the storage root was cut from the bottom half of the storage root. That slice was then divided into four pieces and one of the pieces was randomly selected to determine the radial distribution of cerium toward the midpoint of the storage root. A schematic illustration of the slices preparation is shown in Supplementary Figure 1 in the Supporting Information. For each sample, a serial scanning along the z-axis of the sample was conducted, and the numbers of scanning planes varied from 8 to 11. The distance between two optical planes was approximately 10.2 μm.

Data Analysis. A one-way ANOVA was performed in this study for data analysis. The Duncan test was conducted for post hoc comparisons.

RESULTS

Characterization of CeO_2 NPs and the Bulk. Supplementary Figure 2 in the Supporting Information shows the TEM images of CeO_2 NPs and bulk CeO_2 in one-fourth strength Hoagland solution. The nanoparticles displayed variable shapes and sizes. Individual nanoparticles possessed triangular, rectangular, and other irregular shapes. The images indicate that the average diameter of individual CeO_2 NPs ranged from 10 to 30 nm. The nanoparticles aggregated considerably in the Hoagland solution, due to the high ionic strength. The hydrodynamic diameter of the nanoparticle aggregates was ~600 nm as measured by DLS. The zeta potential of CeO_2 NPs in the Hoagland solution was approximately −11.9 mV, suggesting that the nanoparticles were not stable. Bulk CeO_2 NPs were mostly at the micrometer scale, but the sizes were not uniform. Particles at the nanoscale were also detected in the bulk solutions. The sizes of bulk CeO_2 NPs ranged approximately from 100 to 4000 nm.

Plant Physiological Status. The radish exposed to CeO_2 bulk had the highest total dry biomass, which was significantly greater than all other treatments (Figure 1a). The biomass of the nanoparticle treated plants was not significantly different from the control plants. The plant biomass exposed to cerium ions was significantly lower than that of all other treatments. When the plant tissues were examined separately, the bulk cerium treated radishes, which had similar shoot biomasses as CeO_2 NPs treated radishes, had significantly higher dry shoot biomass than control and cerium ion treatment (Figure 1b). The dry weight of storage roots across the treatments exhibited patterns similar to those of the total dry biomass (Figure 1c), but the dry biomass of fine roots did not differ significantly as a function of treatment (Figure 1d). In addition to the total biomass, the distribution of the biomass between the root (fine + storage root) and shoot compartments was significantly different in response to treatment. The shoot/root ratio of dry biomass of cerium ion treated radish (1.34 ± 0.11) was significantly higher ($p < 0.05$) than all other treatments, which had similar ratios (control, 1.00 ± 0.10; bulk CeO_2, 0.95 ± 0.06; CeO_2 NPs, 1.07 ± 0.07). Visually, there was no apparent adverse effect of any of the cerium treatments on the growth and development of the radish plants except for the size differences (Figure 1e).

In addition to the root biomass, the fine root membrane integrity was significantly affected by different forms of cerium. Figure 2 indicates that 10 mg/L of CeO_2 NPs and ionic cerium resulted in significantly greater electrolyte leakage when compared to the control roots. Leakage from bulk cerium treated roots was not significantly different from control roots. The accumulative transpiration of radish for all treatments was comparable until day 21, then the accumulative transpiration of cerium ion treated radish became significantly lower than for other treatment groups (Supporting Information, Supplementary Figure 3). The relative chlorophyll content expressed in percentage is shown in Table 1. Although all treated radishes had lower chlorophyll content, only the bulk CeO_2 and CeO_2 NPs treated leaves had significantly lower chlorophyll content compared to the controls. The average quantum yield of photosystem II (Y(II)) and the F_V/F_M ratio for plants from different treatments are also shown in Table 1. The results indicated that the Y(II) was unaffected by the treatments. In contrast, only bulk CeO_2 treated radishes displayed an F_V/F_M ratio significantly lower value than the control. No significant differences were observed between the other cerium treatments.

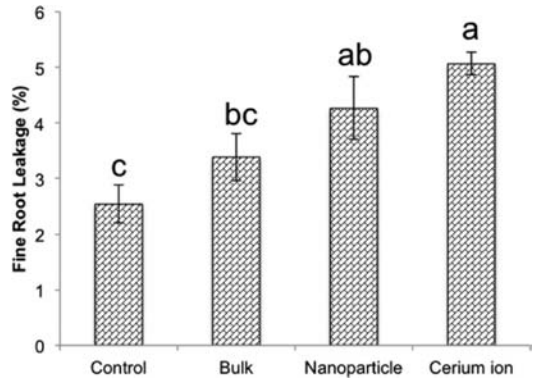

Figure 2. Electrolyte leakage from radish fine roots grown hydroponically in different solutions. The reported values are the average of five replicates in each treatment, and the error bars represent standard error. Different letters represent significant differences between the treatments ($p < 0.05$).

Cerium Uptake and Accumulation. Not surprisingly, exposure to cerium resulted in significantly greater concentrations of this element in plant tissues. For the treated plants, the cerium concentration and content were significantly higher in the fine roots than in other tissues (Figure 3). Among different treatments, the concentration of cerium in the storage root was not significantly different between cerium treatments (Figure 3A). In the shoot tissues, cerium ion treated radish had highest cerium concentration, followed by bulk cerium and then CeO_2 NPs treated radish (Figure 3A). The fine roots of CeO_2 NPs treated radish had significantly higher concentration of cerium than the bulk and ion treated radish (Figure 3B). When the cerium content rather than the concentration in different tissues was compared, cerium content in the storage roots of different treatments was still similar. The shoot cerium content of bulk and ion treated radishes was not significantly different but was markedly higher than that of nanoparticle treated radishes (Figure 3D). In the fine roots, the cerium content demonstrated patterns similar to the cerium concentration for different treatments (Figure 3D).

Cerium Localization and Distribution in Radish Root and Storage Root. For the fine root tips, the confocal microscopic images were captured both on the surface and at different depths from the surface. The control had some weak signals either from the cerium content in control tissues or from background excitation (Figure 4a). In contrast, plant roots from treated plants all generated stronger signals (Figure 4b–f). However, the signal patterns were noticeably different. On the bulk CeO_2 treated root, the signals were only detected from the mucilage surrounding the root tip in both surface and deeper scanning images (Figure 4b,c). CeO_2 NPs were detected on larger areas of the root surface as well as the mucilage on the root tip of the nanoparticle treated plants (Figure 4d). The signal was even more prominent in the deeper scanning planes (Figure 4e). For cerium ion treated radish root, the signals were predominantly detected in the surrounding areas. Neither the surface scan nor the deep scan detected significantly stronger signals than the controls within the root itself (Figure 4f).

Figure 5 shows the confocal images of cut slices of radish storage roots. The control storage root showed little signal (Figure 5a). In comparison, storage roots from treated plants had strong signals. For bulk CeO_2 treated radish, all signals

came from the pigmented periderm with a random pattern (Figure 5b). For CeO_2 NPs treated radish, stronger signals were observed in the pigmented periderm. In addition, the nanoparticles appeared to penetrate further into the storage root (Figure 5c). Cerium was detected not only in the periderm but also in the secondary vascular tissues in the storage root of cerium ion treated radish (Figure 5d,e).

DISCUSSION

Accompanying the ever-expanding applications of engineered nanomaterials are the increasing concerns about their toxicity to humans and the environment. A major question scientists are trying to ascertain is whether the reduction of microsized particles to nanosized particles will significantly increase their toxicity. Several previous studies have shown that nanoparticles typically exhibit stronger effects on plants than their bulk counterparts.[20,21] For example, following a 15 day hydroponic exposure, the biomass of zucchini plant exposed to silver nanoparticles was 75% less than that of plants treated with the same concentrations of bulk silver powder.[21] For CeO_2 particles, it is well accepted that the presence of highly mobile lattice oxygen on the surface will cause oxygen vacancy on the surface.[22] With the decrease of nanoparticle size, the specific surface area and consequently the density of the oxygen vacancy increase. The separation of oxygen from the lattice structure generates electrons, which can be used to reduce Ce^{4+} to Ce^{3+}. With increasing oxygen vacancy, the ratio of Ce^{3+}/Ce^{4+} will increase on the surface of nanoparticles.[23] Because Ce^{3+} is about 14% larger than Ce^{4+},[22] the conversion of Ce^{4+} to Ce^{3+} will strain the lattice structure and increase the reactivity and uperoxide dismutase (SOD) mimetic activity of the CeO_2 particles.[24] Therefore, particle size is an important consid-

eration in the assessment of the environmental toxicity of CeO_2. Unfortunately, information on the size effect of CeO_2 particles on plant development in the literature is very limited.

Due to the potential dissolution of some metallic nanoparticles, another major question actively investigated in the scientific community of nanotoxicology is the comparative toxicity of nanoparticles and the ionic form of the particles. Because of the general acceptance that CeO_2 NPs are stable in liquid solutions, ionic cerium was generally not included in the treatment paradigms.[13−16] However, the broad applications of different forms and sizes of cerium require a comprehensive understanding and comparison of their fate and phytotoxicity. Our investigation provides an assessment of the differential fate and phytotoxicity of cerium in its ionic, nanoscale, and bulk particle forms. Several physiological parameters including the root membrane integrity photosynthesis-related measurements, and biomass parameters were affected by certain forms of cerium at the tested concentration.

Whereas the specific mechanisms by which cerium compounds may compromise membrane integrity are not known and may differ, all forms and sizes of cerium resulted in some damage to root membrane integrity as indicated by an increase in electrolyte leakage. However, the effect was significant only for the nanoparticle and ionic forms. The changes in the integrity of root membrane could also alter the membrane potential and potentially the function of the membrane.[24] It has been reported that altered plasma membrane integrity and potential are associated with changes in the ion fluxes into plant roots.[25] Whether this alteration of membrane integrity influenced the concentration of any essential macronutrients or micronutrients in radish was not examined, but would be a reasonable question for future studies. For the bulk CeO_2 and CeO_2 NPs, in addition to their impact on the membrane, physical adsorption on root surface and blockage of nutrient uptake by plant roots may also occur. It is possible that such impacts on the roots may have affected the uptake of elements such as magnesium or iron, two nutrients associated with the synthesis of chlorophyll. A decrease in the concentration of either of these essential nutrients might have contributed to the decrease in relative chlorophyll content observed in some treatments. Other aspects of chlorophyll synthesis or degradation could have been affected as well, and a more detailed study will be required to understand the extent or severity of effects of cerium on chlorophyll metabolism. The significantly lower F_V/F_M values observed for the bulk cerium treatment as compared to the control plants suggested that photosynthetic electron transport associated with photosystem II was stressed in those plants, but not for the other cerium treatments. These results differ from a study with plantlets of *Medicago arborea* in which nanoceria was found to have a more negative effect on the F_V/F_M ratio than the same concentrations of bulk cerium.[25] Other studies have shown that the influence of cerium compounds on plant photochemistry differs depending on factors such as plant Mn status[26] and the presence of salt stress.[27] Definitive conclusions about the comparative phytotoxicity of the cerium ion and nanoceria cannot be made without further investigation. Even so, the overall effects of all treatments on the two photo-

synthetic parameters measured were modest and perhaps not indicative of a significant stress imposed on the plants, particularly given that there were no overt visible effects observed for any treatments, including the ionic cerium and the CeO_2 NPs treatments. The only other indication of a negative effect of treatment with cerium was the decrease in biomass observed for the cerium ion treatment.

The shoot/root ratio of radish was also affected by cerium, primarily through the change of the biomass of the storage roots. Because the root thickening is a result of the combined cell division and enlargement of secondary xylem and phloem cells that depends on the activity of the vascular cambium,[28] it is possible that different forms cerium of have different impacts on the activity of the vascular cambium. One could speculate that the bulk CeO_2 might have enhanced the activity of the vascular cambium, whereas ionic Ce inhibited it. Metabolically, according to the "sink capacity" theory, the storage root represents a major reservoir for radish, and sucrose transported within radish is the main carbohydrate for the growth of sinks. As such, photosynthate distribution into different tissues is heavily affected by the activity of sucrose synthase (SuSy).[29−33] If future studies examined the expression of SuSy genes and/or measured the activity of this enzyme in the radish hypocotyl in response to different forms of cerium, it might be possible to ascertain whether the changes in the mass of the storage root in response to bulk or ionic cerium treated radish plants were due to changes in sink strength. The specific mechanisms by which these cerium compounds influence the biomass of radish storage roots have implications for the agricultural production of radish and related vegetable species and are therefore worth further attention.

It should be pointed out that the concentration of $CeCl_3$ used in this study was very low, and the impact of chloride ion is not expected to be substantial. Parida and Das[34] investigated plant salt tolerance and salinity effects on plant growth and reported that under 100 mM NaCl (3.55 g/L Cl^-), chloride demonstrated limited influence on the osmotic adjustment of cell membrane. Scialabba and Melati[35] also reported that sodium chloride up to a concentration of 0.1% positively affected radish growth. The Cl^- in the ionic cerium solution used in this study was significantly lower than those reported values and was not expected to significantly contribute to the negative effect observed in the ionic treatment group. Consequently, the negative effect observed in the ionic treatment should be attributed to the ionic cerium. Another caveat about the results is that 10 mg/L was the concentration of the compounds of CeO_2 and $CeCl_3$, not the concentration of cerium as an element. Due to the different molecular weight percentage of cerium in CeO_2 and $CeCl_3$, the actual concentration of cerium as an element was 8.14 mg Ce/L in CeO_2 NPs and the bulk and was only 5.68 mg Ce/L in the ionic form. Cerium in CeO_2 was 43.5% higher than in the ionic form. If the equivalent concentration of cerium as an element was used, the ionic cerium may display an even stronger effect on plant physiology.

In addition to the yield of edible storage root, the potential accumulation of cerium was examined. Exposed plants had detectable cerium in all plant tissues, including the edible

DOI: 10.1021/jf5052442
J. Agric. Food Chem. 2015, 63, 382−390

storage roots and leaves, even though the forms of cerium in these tissues are unknown. However, the forms of cerium in plant tissues may affect both their toxicity and potential availability to humans, and they deserve detailed investigation in future studies. In the current study, the significantly higher cerium detected in the shoot tissues of exposed plants indicated that cerium translocation from roots to shoot had occurred. The upward transport of bulk cerium to radish shoots was unexpected given the size of the particles and the low dissolution rate of bulk CeO_2. It is most likely that the cerium content detected from the bulk treated shoot tissues was from the nanoscale particles present in the bulk mixture (Supporting Information, Supplementary Figure 2). The upward transport of CeO_2 NPs and ionic cerium from roots to shoots was expected and has been reported in the literature.[10,14,35,36] Interestingly, however, when the cerium localization in the storage root was investigated with the confocal microscope, signals of cerium in the vascular tissues were observed only in cerium ion treatment, suggesting that active transport may function as an important pathway of cerium accumulation only for ion treated radishes. In contrast, signals from the CeO_2 NPs and bulk treated radish roots were mainly located on the periderms. The results suggest that adsorption and diffusion of particulate cerium along the radial direction might be a more important pathway for CeO_2 NPs and bulk accumulation in radish storage roots. The diffusion may possibly occur from the lenticels on the periderm, but more precise techniques are needed to confirm this assumption. From the food safety point of view, the cerium accumulation in the edible storage root is more concerning, and our results showed that although cerium concentration and content were similar across the cerium treatment, the distribution of cerium in the storage roots varied and, consequently, its availability to humans would vary. For example, the majority of particulate cerium accumulated in the edible tissue could be removed in the food preparation process, whereas ionic cerium in the storage roots is more likely to be consumed by humans with the storage root.

In closing, our results suggested that 10 mg/L cerium as cerium oxide or cerium chloride could affect the growth of radish and could accumulate in the edible storage root and shoot tissues. However, the impacts and accumulation patterns varied significantly by the size and chemical form of cerium. Ionic cerium displayed the strongest impact on radish root membrane integrity and growth, followed by CeO_2 NPs and then the bulk. Whereas different forms cerium of all accumulate in radish tissues, their accumulation potential and distribution patterns varied greatly. As a result, potential exposure and risk to human health through diet exposure to different sizes and forms of cerium may vary, and these differences should be considered when the food safety of cerium in the environment is evaluated.

ABSTRACT: In this study, the photo-Fenton process was combined with a sequencing batch reactor (SBR) for the treatment of synthetic samples of citrus wastewater (CWW). An experimental design based on the surface response methodology was applied to assess the individual and combined effects of several operating parameters ($COD_{initial}$, Fe_3^+ concentration and H_2O_2 concentration) on the photo-Fenton treatment efficiency (DOC removal) with the aim of optimizing the process. The experimental results obtained under optimal conditions for CWW with high $COD_{initial}$ (10000 mgO_2/L) showed a partial degradation of organic matter of around of 61% (measured as DOC). Thereafter, the photo-Fenton effluent was neutralized and clarified before being subjected to the SBR reactor. The results show degradation yields up to 93% of the initial DOC removal without producing undesired side effects, using a hydraulic retention time (HRT) of 1.59 d. The final effluent contained a concentration of organic matter (measured as COD) of 120 mg O_2/L.

KEYWORDS: *citrus, wastewater, photo-Fenton, SBR*

INTRODUCTION

Citrus cultivation (mainly oranges) is a major industry and a significant economic sector in the United States, Brazil, Mexico, China, India, Iran, and most Mediterranean countries including Spain and Greece.[1] According to the Statistical Database of the Food and Agriculture Organization of the United Nations (FAOSTAT), world orange production in 2012 was estimated to be 68.2 million tons. For the fiscal year 2011, FAOSTAT estimated a citrus production of 0.27 million tons in Cuba. A high percentage of this produce (~84%) is used to manufacture products such as juice and essential oils, among others byproducts.

The citrus processing industry generates significant quantities of wastewaters, waste, and atmospheric emissions. Appropriate technology is therefore required to ensure the efficient management of all the resources involved. Citrus processing plants require large amounts of water and consequently produce large volumes of wastewater,[2] generating around 1.96 m^3 of wastewater/t of fruit.

Citrus wastewater derives from the production of citrus juice, the extraction of essential oils as byproduct, and the cleaning operations of equipment and industrial installations.[3] The organic load of this effluent can reach 26000 mgO_2/L (measured as COD) and suspended solids (TSS) 700−1000 mg/L. Furthermore, they usually present high conductivity and an acidic pH. The organic matter present in the effluent is composed by carbohydrates, organic acids, pectin, cellulose, hemicellulose, proteins, and traces of essential oils, which are inhibitors and toxics of biological treatments (the main process used to treat these effluents). The toxicity of citrus wastewater can be due to the high concentration of organic compounds, including the terpenes, the major constituents of essential oils.[4] The most important terpene present in essential oil from citrus is *R*-(+)limonene (90% of the total) and is found in high concentrations in actual industrial effluents. It is known that values of 0.008% (v/v) *R*-(+)limonene are toxic and have an inhibitory effect.[5]

The processes commonly used to treat this wastewater are biological processes such as activated sludge treatment. The main difficulties in the implementation of these processes are associated with space required, high hydraulic retention times, and the economic costs due to the high demand for energy in the process of aeration if the process is aerobic. Moreover, as in other food industries,[6] the majority of these treatments operate unsatisfactorily because of seasonal variability, the composition, and the high organic matter concentration of these effluents.

Previous studies carried out by our research group with citrus wastewater show that when the activated sludge process is directly fed with citrus effluents containing a concentration of organic matter higher than 2150 mg O_2/L, the proliferation of filamentous bacteria appears within a few hours. This growth produces undesirable side effects such as foams and bulking phenomena, which interfere with the treatment efficiency. These operational problems are very common in food industry plants, given the high content of colloidal and dissolved organic matter of low molecular weight which is easily biodegradable and which creates a situation of nutritional stress that leads to bulking.[7]

A possible alternative could be the application of advanced oxidation processes (AOPs) as a pretreatment in order to produce a partial degradation of the organic matter and to decrease the concentration of inhibitor compounds in aerobic biological treatments. In recent years, AOPs have been used to treat refractory wastewaters because they are effective for the

degradation of most of the pollutants.[8] However, there are few references to the treatment of effluents generated in citrus industries with advanced oxidation processes. Caudo et al.[9] tested copper-pillared clays in wet hydrogen peroxide catalysts oxidation of citrus wastewaters. After 4 h of oxidation reaction, the total organic carbon (TOC) decreased 50% and the biodegradability of the effluent (BOD_5/COD) increased from 0.05 to 0.4.

Among the different AOPs, the Fenton process is a promising alternative wastewater treatment. The Fenton oxidation process is based on the use of a combination of hydrogen peroxide and ferrous ion to form active hydroxyl radicals in acidic solutions.[10] This technique is highly effective for removing organic substances and color from wastewater.[11] In the photo-Fenton process (FF), additional reactions occur in the presence of light that produce hydroxyl radicals or increase the production rate of hydroxyl radicals,[12] thus increasing the efficiency of the process.

The combination of photo-Fenton processes and biological treatments for wastewater decontamination has attracted more attention in recent years as a result of various studies.[13] The photo-Fenton process is usually applied as a pretreatment to increase biodegradability and/or to decrease concentration of organic matter in order to improve the degradation of effluents by a biological process. Previous studies carried out by our research group[6,14,15] show that the application of photo-Fenton−biological processes is appropriate for the treatment of effluents in the wine industry.

The sequencing batch reactor (SBR), based on the principles of the activated sludge process, is typically used in combined systems owing to its simplicity, flexibility of operation, small floor space requirements, and good removal efficiency.[16] The SBR operation treatment cycle can be divided into the following five stages: filling, reaction, settling, decantation, and idle. All these stages occur in a single reactor.[17] In addition, the hydraulic retention time (HRT) can be adjusted by varying the decanted volumes after a settling period.[18]

In recent years, the combined Fenton−SBR process has been used to treat refractory wastewaters such as dyestuff,[19] landfill leachate,[20] textile effluent,[21] antibiotic wastewater,[11] agro-industrial effluents,[22] and other types of recalcitrant wastewater.[23] However, citrus wastewater treatment with this combined process has not been reported to date.

The aim of this study is to examine the degradation of synthetic samples of citrus wastewater by means of the photo-Fenton process combined with the SBR system. Furthermore, the effects of different factors such as the concentrations of Fe, H_2O_2, and initial organic matter on DOC removal by the photo-Fenton treatment are investigated. A three-level factorial statistical experimental design and surface response methodology were used in the experimental study. Optimal reagent doses maximizing DOC removal was determined.

MATERIALS AND METHODS

Wastewater. Owing to the seasonal character of citrus juice production, which generates wastewaters for about 6 months of the year, it was necessary to reproduce citrus effluents by means of synthetic samples of citrus wastewater (CWW). These samples were prepared by diluting natural orange juice in distilled water, taking into account the characteristic of real effluent generated in a citrus industry from Cuba (Table 1). The natural orange juice was obtained from fresh fruits: oranges (*Citrus sinensis* L.) var. Valencia, selected in a state of optimum ripeness, uniform size, and without apparent physical damage. The oranges were washed with water at room temperature and symmetrically cut in half to obtain the juice by manual squeezing in the laboratory.

Photo-Fenton Process. The reagents used for the photo-Fenton experiments were iron salt ($FeCl_3{\cdot}6H_2O$, Probus) and commercial hydrogen peroxide (30% (v/v), Carlo Erba). Predetermined amounts of commercial H_2O_2 and $FeCl_3$ were added to the sample in the reactor at the beginning of each experiment. The iron salt was mixed with the synthetic sample before the addition of hydrogen peroxide.

The photo-Fenton experiments were carried out using 100 mL flasks placed inside an ATLAS SUNTEST CPS+ solar chamber air-cooled at 35 °C. A xenon lamp emitted 5−6% of the photons in the 290−400 nm spectral range. The profile of the photons emitted between 400 and 800 nm followed the solar spectrum with a light intensity of 500 W/m^2, corresponding to 50% of AM1 (AM1 representing the light intensity of midday equatorial solar radiation).[24,25] The aqueous solutions were magnetically stirred (45 rpm). All experiments were conducted at the natural pH of the synthetic samples during 30 min, which ensured total consumption of the H_2O_2 concentration employed.

J. Agric. Food Chem. 2015, 63, 391−397

To detect possible interferences, a control sample without the addition of H_2O_2 and iron salt was used in each photo-Fenton experiment to quantify losses by volatilization and other causes. Each experiment was carried out in triplicate.

A three-level factorial statistical experimental design and the response surface methodology (RSM)[26] were used to investigate the effects of the three independent variables on the response factor and to determine the optimal conditions for maximizing the yield of the removal of organic matter (measured as DOC), defined as $Y_{DOC} = [(DOC_i - DOC_f)/DOC_i] \times 100$, where DOC_f is DOC in the sample after treatment and DOC_i is the initial value of DOC in the sample. The independent variables were the H_2O_2 concentration (established as a percentage of the stoichiometric weight ratio between the H_2O_2 and the COD, $R = H_2O_2/COD = 2.125$), the Fe^{3+}concentration (as mass ratio $[Fe^{3+}/H_2O_2] = 0.02-2.0$), and the organic matter concentration (1000−10000 mgO_2/L, measured as COD) present in the sample. The levels chosen for these variables followed those given in the bibliographic references.[5,27] The low, center, and high levels of each variable are designated as −1, 0, and +1, respectively, as shown in Table 3. A total of 27 experiments were carried out.

Table 3. Levels of Variables in Three-Level Factorial Statistical Experiment Design

		code variable level		
		low	center	high
parameter	variable	−1	0	+1
X_1	Fe^{3+} (mg/L)	85	510	850
X_2	H_2O_2 (mg/L)	425	2550	4250
X_3	$COD_{initial}$ (mg/L)	1000	6000	10000

The program used was the Windows version of Statgraphics Plus 5.1. This is a statistical software package both for the design of experiments as well as for obtaining graphs and statistical parameters, reduced models, and the tools necessary for data processing in general such as optimization tools.

After the different assays, the samples were filtered by means of 0.45 μm cellulose filters (Millipore) to remove suspended particulates before the analytical measurements. The DOC analysis was performed with a Shimadzu TOC-VCSH analyzer (detection limit: 5 mg C/L), carried out by method 5310B.[28] The concentration of H_2O_2 was monitored with Merckoquant peroxide analytical test strips (0−25 mgH_2O_2/L, 0−100 mgH_2O_2/L, and 0−1000 mgH_2O_2/L) and using the metavanadate method.[29] The concentration of total and dissolved iron was analyzed with the phenanthroline method 3500-B[28] using a multiparameter Hanna HI 83099 photometer in order to check the iron precipitation.

SBR Experimental Process. The aerobic degradation process was conducted in a SBR reactor. The reactor (4 L) was equipped with an air pump and air diffuser to guarantee the necessary dissolved oxygen for the degradation process and mixing. The cycle procedure was divided into four stages as follows: filling (0.25 h), aerobic reaction, settling (1 h), and idle (0.5 h). The seeding sludge was taken from the secondary sedimentation tank of a municipal wastewater treatment plant.

Aerobic degradation experiments of pretreated citrus wastewaters by the photo-Fenton process were performed with the synthetic samples that contained the highest concentration of organic matter (10000 mg/L, measured as COD). Sodium hydroxide 25% (w/v) ($CaOH_2$, Panreac) was added to pretreated samples to neutralize the pH; the sludge produced in the reaction was allowed to settle for approximately 0.5 h.

The citrus wastewaters showed a low content of nutrients (phosphorus, 4.5 mg/L; total nitrogen, 17.7 mg/L). The specialized literature reports that a stoichiometric nutrient ratio of COD:N:P

equal to 100:5:1 is required in order to give a suitable growth of microorganisms.[30] Therefore, the nutrient content was increased by dosing appropriate amounts of phosphate (KH_2PO_4, Panreac) and urea ($(NH_2)_2CO$, Panreac) salts in the influent prior to being fed to the SBR.

The treated synthetic sample was added to the SBR. The microorganisms were previously acclimatized, using diluted photo-treated samples as a feed, during a period of 30 days. The biomass concentration in the reactor was maintained in the range 3−4 g/L (measured as volatile suspended solids (VSS)), and the sludge retention time (SRT) was selected at 20 d with the aim of maintaining a high biomass concentration within the reactor. In addition, the dissolved oxygen concentration (DO) was maintained at values higher than 2 mg/L during the aerobic stage. For each batch performed in this work, the bioreactor continued operating until the %COD removal did not vary notably with time. The cycle was repeated 6−9 times in order to obtain repetitive results. The reactor was maintained at 25 °C (laboratory temperature) during the operation period.

The COD, DOC, volatile acidity, ammonium nitrogen (NH_3-N), phosphorus, dissolved iron, SST, turbidity, and color of the effluents were measured at the end of each process. In addition, during each cycle of the SBR, the sludge volume index (SVI) and settled sludge volume (V30) were measured according to the standard methods for the examination of water and wastewater (methods 2710D and 2710C). The microorganisms were observed with an optical microscope (Axiostar Plus Zeiss) using fresh preparations.

RESULTS AND DISCUSSION

Influence of Concentration of Organic Matter, Fe^{3+}, and H_2O_2 in the Photo-Fenton Process. Table 4 shows the RSM design matrix applied in this study, the measured values, and the responses predicted by the model for the DOC removal for each experiment. It can be seen that for the majority of experiments carried out with CWW with $COD_{initial}$ 10000 mgO_2/L (higher concentration of organic matter content) achieved lower DOC removal values (Y_{DOC}) than samples with $COD_{initial}$ in the range of 1000−6000 mgO_2/L. Degradation maxima of 94% is achieved for CWW with 1000 mgO_2/L (measured as COD) and 18% for CWW with 10000 mgO_2/L (measured as COD). This indicates that the initial composition of the samples has an important influence on the degradation performance.

Increasing the initial concentration of H_2O_2 produces higher degree of degradation. However, increasing the Fe^{3+} concentration results in a decrease in the degradation yields, except for treatment of samples with highest organic matter concentration (Table 4). Finally, the same percentage of the stoichiometric weight ratio between the H_2O_2 and the $COD_{initial}$ produces similar average values of yields of organic matter (Y_{DOC} = 16−22).

Figure 1 (main effect plot) and Figure 2 (Pareto diagram) show a statistical analysis of the results obtained in this research

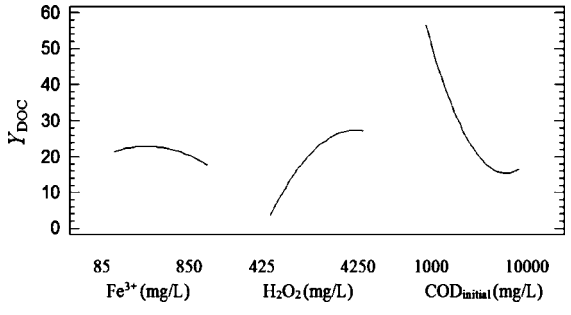

Figure 1. Main effects plot for photo-Fenton process.

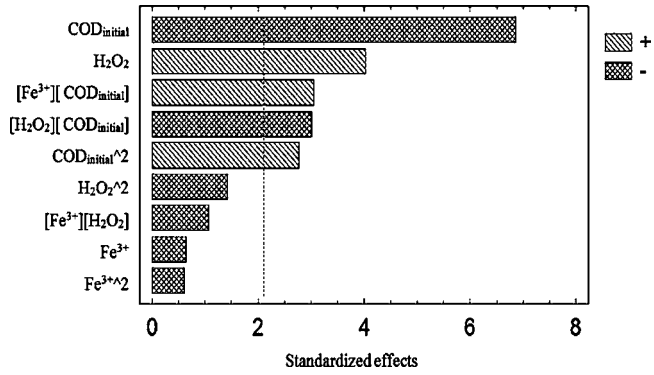

Figure 2. Pareto chart for synthetic samples of citrus wastewater.

to see the influence of the variables on the response factor (Y_{DOC}). The main effects plot in Figure 1 represents the effect of each variable on the response factor. As can be observed, an increase in both the initial concentration of the organic matter (measured as COD) and the iron concentration leads to a decrease in the degree of degradation of the organic matter. However, an increase in the H_2O_2 concentration has a positive effect on the degree of degradation of the organic matter. The slope of the plot is indicative of the importance of the variable on the response factor. It can be observed that the most influential variables are the initial concentration of organic matter in the CWW and the H_2O_2 concentration.

A Pareto graphic is used to draw conclusions about which of these variables and interactions are most significant. This graphic shows both the magnitude and the importance of the effects (variables and interactions). All the standardized effects were given in absolute values, and those which overpass the significance line (vertical line) exert a statistically significant influence on the response factor. The Pareto chart for CWW (Figure 2) shows that the variables and interactions that can be considered important in photo-Fenton processes are $COD_{initial}$, H_2O_2, and the interactions $[Fe^{3+}][COD_{initial}]$ and $[H_2O_2]$-$[COD_{initial}]$.

The application of RSM offers an empirical relationship between the response function and the independent variables. The mathematical relationship between the response factor and the variables can be approximated by a quadratic polynomial equation and represented by contour plots. Response surface plots provide a method for predicting the optimum conditions for treatment of CWW by the photo-Fenton process.

The coefficient of the response function for selected variables was determined by correlating the experimental results with the response factor by using the Windows version of Statgraphics Plus 5.1. The study was done for a confidence interval of 95%. The response function with the determined coefficients for DOC removal (Y_{DOC}) is presented by eq 1. The response factor predictions were in good agreement with the experimental data ($R^2 > 0.85$). This can be seen by comparing the measured values against the responses predicted by the model for Y_{DOC} (Table 4).

$$Y_{DOC} = 22.49 - 1.88X_1 + 11.77X_2 - 20.07X_3 - 3.83X_1X_2 + 10.94X_1X_3 - 10.77X_2X_3 - 3.08X_1^2 - 7.17X_2^2 + 14.03X_3^2 \quad (1)$$

Figure 3 shows the contour plots of the response factor (Y_{COD}) for CWW with 1000, 6000, and 10000 mgO_2/L of

DOI: 10.1021/jf505377a

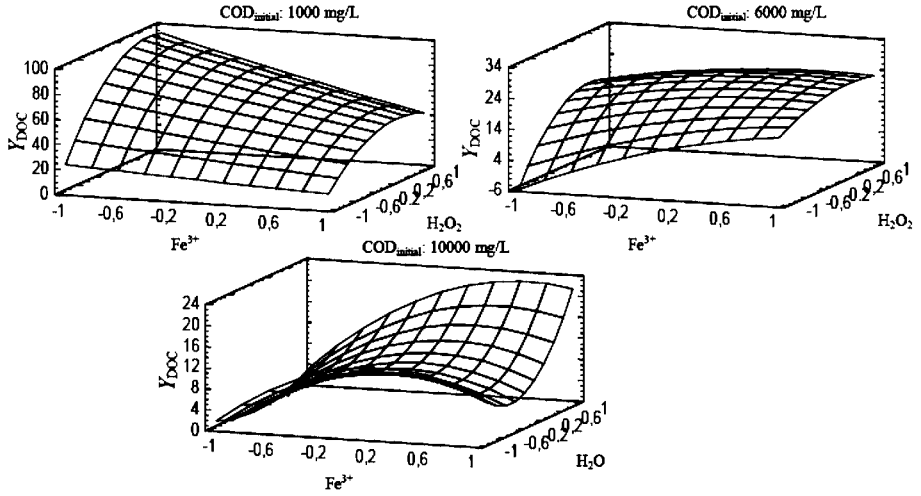

Figure 3. Contour plots for synthetic samples of citrus wastewater.

$COD_{initial}$. For the treatment of CWW with 1000 mgO_2/L, it can be seen that the operating conditions employed to achieve the maximum value in the response factor (i.e., values close to 100% organic matter removal (DOC removal)) come within the region of the experimental design.

On the other hand, samples with an organic matter concentration of 6000−10000 mgO_2/L show an optimum of Fe^{3+} concentration using a H_2O_2 concentration in the range of 425−4250 mg/L, in which the response factor reaches a maximum value. For these conditions, the maximum H_2O_2 concentration needed to reach values close to 100% of DOC removal falls outside the region of the experimental design. While it is true that this region should be considered with caution, the results suggest that there would be a higher response factor with the use of higher H_2O_2 concentrations than those considered in the study (obtained from an increase in the percentage of the stoichiometric ratio H_2O_2/COD) and intermediate values of Fe^{3+}.

Using the model reflected in eq 1, the most suitable conditions for decreasing the concentration of organic matter present in CWW with $COD_{initial}$ of 10000 mgO_2/L were calculated by considering the photo-Fenton process as a previous stage to the SBR process. The selected doses were as follows: $[H_2O_2]$ = 15938 mg/L (75% of stoichiometric value) and $[Fe^{3+}]$ = 510 mg/L for 61% COD removal.

The CWW ($COD_{initial}$ of 10000 mg/L) was treated by the photo-Fenton process using the following reagent doses: $[H_2O_2]$ = 15938 mg/L and $[Fe^{3+}]$ = 510 mg/L. The results are shown in Table 5. It can be observed that under these operating conditions a good level of degradation of organic matter was achieved. After 30 min of treatment, the final concentration of organic matter was 1818 mgC/L (measured as DOC) and 2225 mgO_2/L (measured as COD). Therefore, the photo-Fenton process is a technique capable of partially decreasing the concentration of organic matter present in citrus wastewaters with high organic load.

The evolution of the pH during the treatment shows a decrease mainly due to the formation of intermediate compounds such as organic acids (acetic acid, malic acid, etc.) which are difficult to oxidize. In the presence of these organic ligands, the Fe(III) can form stable complexes or associated ion pairs which exhibit charge transfer bands of ligand to metal in the UV−visible spectrum that are photochemically active and generate Fe(II) by irradiation. The irradiations of these complexes improve the photocatalytic properties for degrading organic compounds.[31] Consequently, approximately 63.5% of the catalyst remains in solution after the treatment. However, in these pH conditions (pH < 2), the absorption coefficient of the iron complexes decreases and Fe^{3+} appears as $Fe(H_2O)_6^{3+}$,[32] which is much less effective at absorbing light and in the production $^{\bullet}OH$,[33] resulting in an inefficient use of the peroxide.[31,34,35]

Degradation of Pretreated CWW by the SBR Process. The synthetic samples used to study the viability of the combined photo-Fenton/SBR process for the treatment of wastewater from the citrus industry were those samples with the highest concentration of organic matter (10000 mg/L of $COD_{initial}$). First, the CWW was treated by the photo-Fenton process using the previously selected conditions.

After the photo-Fenton process, the pretreated samples were conditioned by neutralization and sedimentation. In this stage, dissolved iron was mainly precipitated because the concentration in the clarified effluent was 0.7 mg/L and the pH was adjusted to 7−8. The concentration of organic matter decreased until 1000 mgC/L (measured as DOC) or 1634 mgO_2/L (measured as COD), amounts which can be

pretreated CWW	1634	1.59	0.3	120	71	310	115

assimilated by the microorganisms present in the biological reactor.[6,14,15]

After the acclimatization process, the pretreated CWW were treated by SBR. Table 6 shows the control parameters and the features of the final effluent.

A yield of 93% in the degradation of organic matter (measured as DOC) was achieved by the SBR process. The average organic matter concentration in the final effluent was 120 mg O_2/L (measured as COD). The total yield of organic matter degradation by the combined photo-Fenton process and biological treatment was 96% (measured as COD). Furthermore, the concentration of SST, turbidity, and color in the final effluent were 111 mg/L, 59 NTU, and 116 CPU, respectively. According to the Cuban legislation currently in force concerning wastewater discharge, the effluents of the citrus industry treated by this sequence of processes can be discharged into the wastewater collecting system.[36]

For these operating conditions in the SBR process, a significant decrease in the concentration of volatile acids (24%) measured as acetic acid was obtained during the first half hour of treatment. At the same time, a significant reduction in COD and DOC and an important consumption of nutrients was observed. The presence of a significant fraction of readily biodegradable compounds in the effluent, mainly organic acids of low molecular weight, accelerates the efficiency of the aerobic metabolism of biomass.

Furthermore, the analyses of NH_3^+-N, P_{total} and volatile acidity in the final effluent showed a concentration of 2.6, 2.9, and 370 mg/L, respectively. The high concentrations of volatile acids indicate the presence of a fraction of volatile organic compound which is more complex to degrade. These results are obtained for hydraulic retention times (HRT) of 1.59 d. For complete elimination of these compounds, a higher HRT is required, around 3 d of biological treatment.

Microbiological analyses showed a balance between the different types of microorganisms detected in the biological reactor (bacterium, protozoes, filamentous microorganisms, etc.), producing a correct flocculation and a good settleability of sludge. During the SBR process, the settleability and compactibility of sludge were very good. This is due, among other factors, to an appropriate F/M ratio.[30,37] The average values of the sludge volume index (SVI) and settled sludge volume (V30) parameters were 115 mL/g and 310 mL/L, respectively.

The results suggest that a combined system composed of the photo-Fenton process and biological treatment based on the SBR process is an effective and attractive alternative for the treatment of citrus processing wastewater, particularly during the period when effluents with a higher organic load are generated, although more studies on how system characteristics enhance or limit the individual and global efficiencies, and eventually, the overall treatment cost, must be performed.[13]

Supporting Information

ABSTRACT: Veterinary antibiotics can be released to environment by the animals' excretions, which thereby poses human health and ecological risks. Six antibiotics (tetracycline, oxytetracycline, chlortetracycline, sulfamethazine, sulfamethoxazole, and sulfadimethoxine) at three concentrations (5, 10, and 20 mg kg^{-1} soil) were employed in pots filled with a loamy sand upland soil. Three types of vegetable seedlings, including cucumber (*Cucumis sativus*), cherry tomato (*Solanum lycopersicum*), and lettuce (*Lactuca sativa*), were also cultivated during 45 d in the greenhouse. All antibiotics taken up by tested plants showed negative effects on growth. Relatively high levels of tetracyclines and sulfonamides (SAs) were detected in the nonedible parts, roots, and leaves of cucumber and tomato, but fruit parts accumulated them lower than acceptable daily intake. Indeed, cucumber roots accumulated SAs by up to 94.6% of total addition (at 5 mg kg^{-1} soil).

KEYWORDS: *bioaccumulation, emerging contaminant, pharmaceuticals, phytoavailability, risk assessment, veterinary antibiotics*

INTRODUCTION

Contamination of agricultural soils with agrochemicals, such as pesticides and fertilizers, and its potential accumulation in the crop tissues are well investigated. Adamo et al.[1] studied the uptakes of Zn, Cr, Cu, and Pb by lettuce plant from metals-contaminated soils and reported the order of transfer factor from soil to vegetables, Zn > Cu > Cr ≥ Pb. They revealed that the Pb contents in all collected samples were below the maximum levels of Pb in edible vegetables set by the European Union.[2] Babu et al.[3] also studied the uptake of organochlorine pesticides (DDT and HCH) by Basmati rice (*Oryza sativa*) from the soil. Residues of both pesticides were found in all soil and plant samples except for a few grain samples. Maximum and minimum levels of residue were observed in husk and grains, respectively, and the levels of DDT and CHC in grains were quite below the regulation by the government of India and WHO/FAO. Similarly, Waliszewski et al.[4] investigated DDT and HCH isomer levels in soil and carrot root and leaf. Their results revealed the organochlorine pesticide diffusion from agricultural soils to growing carrot plants and its vapor-adsorption by leaves.

Residues and metabolites of antibiotics are very important organic pollutants in our surrounding environments. Antibiotics are widely used for therapeutic purposes to treat or control infectious diseases in humans and animals. Antibiotics in veterinary practice are also used to increase feed efficiency and to promote growth in food producing animals at subtherapeutic levels.[5−7] Tetracyclines (TCs) and sulfonamides (SAs) as the most popular antibiotics groups that are active against a broad spectrum of Gram-positive/negative bacteria, some obligate anaerobes, protozoa, parasites, and fungi.[8,9] In Korea, TCs and SAs antibiotics are most commonly used in veterinary medicine, where the Korean Food and Drug Administration[10] reported that TCs have been used the most among antimicrobials in veterinary medicine (470.9 t) followed by penicillins (170.7 t) and SAs (157.4 t).[11−13] In European countries, including Spain, France, Germany, United Kingdom, Poland, and Italy, TCs are also most commonly used in veterinary medicine followed by penicillins and SAs and show the annual consumptions of 205−658 t of TCs, 83−567 t of penicillins, and 45−174 t of SAs.[14] The overuse of antibiotics in the field of livestock industry may lead to occurrence of antibiotics' residue due to animal excretions and animal products having a high concentration of antibiotics.[7,12,15−17] Excretion is the major means by which human and veterinary antibiotics are introduced into the environment. The application of manure to agricultural soils mainly leads to the release of residual antibiotics into soils through leaching and runoff, which thereby threatens groundwater and surface water quality.[12] Some leftover livestock feeds that contain therapeutic agents may also be discarded as waste or lost along with the runoff during watering and rainfall episodes.[18,19] In addition, significant amounts of antibiotics are discharged into the environment from wastewater treatment facilities, septic systems, and agricultural waste storage structures. Awad et al.[11] comprehensively monitored the occurrence and seasonal variations of TCs and SAs in water, sediment, and soil. They

observed higher levels of TCs and SAs in water, sediment, and soil during winter than summer season due to lower degradation rate in winter season. Ok et al.[13] also found the highest concentration of TCs and SAs in water, sediment, and soil at a site adjacent to the composting facility than at a site far away from that facility. As a result, the residual antibiotics in soil and water can be taken up by plants.[18,20−22]

Few studies investigated the uptake of antibiotics by plants. Sulfadimethoxine was found in root and leaves of barley with concentrations of 1.2 and 1.1 mg g^{-1}, respectively (on dry weight basis), when the barley was cultivated in soils treated with 300 mg L^{-1} sulfadimethoxine.[23] Kumar et al.[22] reported that the maximum amount of chlortetracycline recovered in plant tops was found in corn followed by cabbage and green onion. The amount of accumulated chlortetracycline in plant tissues was small (0.002−0.017 mg kg^{-1} fresh weight), but it increased with increased rate of chlortetracycline into the manure. Dolliver et al.[21] reported that the highest amount of sulfamethazine was detected in lettuce followed by potato and corn. Michelini et al.[24] also evaluated the effects of sulfadiazine on willow (*Salix fragilis* L.) and maize (*Zea mays* L.) plants. They found that the high concentration of sulfadiazine caused serious stress in willow (e.g., reduced C/N ratio and total chlorophyll content) and the death of maize, which thereby shows a strong potential to impair plant performance and biomass.

Because of consumption of agricultural products containing antibiotics' residues, public health could be threatened. Especially, continuous exposure to antibiotics could lead to allergic reactions and chemical poisoning by the development of resistant bacterial strains.[25,26] Several regulatory authorities had set maximum residue limits (MRLs) for antibiotics in foods of animal origin, for example, the European Union set MRLs for TCs that ranged between 0.1 mg kg^{-1} in milk and meat and 0.6 mg kg^{-1} in kidney, while it was set at 0.1 mg kg^{-1} for SAs in all livestock products.[27] However, no limit was set for food crops.

Previous studies focused on the presence and prevalence of antibiotics in environmental compartments as well as the impact of antibiotics on seed germination and plant growth. Some studies focused on the uptake of antibiotics by edible and nonedible plants and calculated the antibiotics contents in the different parts of nonripened plants. However, no study was found related to the accumulation and distribution patterns of antibiotics in the ripened plants' parts, especially the edible parts, through the exposure to different concentrations of antibiotics. Moreover, the previous studies did not focus on the safety assessment of those edible parts for human consumption with the successive increasing of antibiotics' dosage. Therefore, in this study, we hypothesized that the antibiotics of TCs and SAs accumulated in different parts of cucumber, tomato, and lettuce plants. In addition, the accumulation or plant uptake of antibiotics may show different distribution or patterns depending on the antibiotics' types or plant species. Consequently, this study was conducted (i) to reveal the effect of TCs and SAs on the growth of cucumber, tomato, and lettuce plants by measuring growth parameters including plant height, number of leaves, chlorophyll content, shoot weight, root weight, total root surface area, and fruit weight; (ii) to quantify the absorbed antibiotics in the different plant parts for food safety assessment; and (iii) to trace the distribution and cumulative patterns of various antibiotics.

MATERIALS AND METHODS

Antibiotics. Target antibiotic compounds were selected based on frequency of use in Korea.[10] Target antibiotic standards, including 97.5% tetracycline hydrochloride (referred to as TC in this study), 97% oxytetracycline hydrochloride (OTC), 97% chlortetracycline hydrochloride (CTC), 99% sulfamethazine (SMT), 99.7% sulfamethoxazole (SMX), and 98.5% sulfadimethoxine (SDM), were obtained from Sigma-Aldrich (St. Louis, MO, USA). The physicochemical characteristics of these antibiotics are shown in Table S1 of the Supporting Information. Acetonitrile, methanol, acetone, hexane, formic acid, and water of HPLC-grade were also obtained from LiChrosolv Co. (Merck, Germany). The solid-phase extraction (SPE) cartridges and 3 mL/60 mg of HLB (hydrophilic−lipophillic−balanced) were purchased from Waters Oasis Co. (Milford, MA, USA).

Stock solutions of antibiotics were prepared at a concentration of 100 mg L^{-1} as follows: 10 mg of individual standard (corrected by purity) was accurately weighed, dissolved in small amount of methanol, diluted to 100 mL with deionized water, and then stored at −20 °C.

Experimental Procedure. Each of 36 plastic pots (200 mm diameter × 190 mm tall) was filled with a loamy sand upland soil obtained from experimental field at Kangwon National University, Chuncheon, Korea. Each pot contained 3.7 kg of dry soil. Three kinds of plant seedlings, including cucumber (*Cucumis sativus*, 45 d old), tomatoes (*Solanum lycopersicum*, 45 d old), and lettuce (*Lactuca sativa*, 30 d old), were used for the cultivation experiment. Each of 12 pots was used for each cultivation of cucumber, tomato, and lettuce plants. The plants were individually transplanted as one plant in each pot and then irrigated by antibiotics' free water and kept for 2 weeks for adaptation before the addition of subjected antibiotics. Antibiotics, including TCs and SAs at the levels of 5, 10, and 20 mg kg^{-1} soil, were collectively spiked through the irrigation water at four doses (one dose per week) along with no antibiotics' addition as the control. All pots were irrigated twice a week with 50 mL of water containing antibiotics and 100 mL of water containing fertilizers, in order. To ensure the effects of antibiotics on plant growth only, the essential fertilizers of common plants were provided except phosphate fertilizer because of its negative effect on TCs adsorption by plants.[28] Plant seedlings were grown in a greenhouse, which was completely controlled at 25 °C and 70% humidity for 45 d of cultivation period. During cultivation, the growth parameters, such as plant height (cm), number of leaves, and leaf chlorophyll content by a chlorophyll meter (Minolta, SPAD-502, Japan), were measured weekly, and other parameters, such as weights of root, shoot, and fruit, and total root surface area, were determined after harvest (or 45 d of cultivation).

Plant Samples Preparation. After 45 d of cultivation, all seedlings had completely become ripened. The harvested shoots of each plant were washed with tap water and dried using an adsorbent paper for weighing. The fruits of each plant were also weighed. To remove the moisture completely, the harvested leaves and fruits were chopped and then subjected to a freeze-drier (OPERON, FDB-5503, Korea). For the measurement of root's surface area, the adhered soil was removed carefully, washed using the tap water, and then dried using an adsorbent paper. The Epson 10000XL scanner equipped with the WIN MAC RHIZO V 2009c program (Regent Instruments Inc., Canada) was employed for the morphological characterization of roots.[29] Briefly, the roots were placed in a tray (300 mm width × 400 mm length × 20 mm thickness) with water for separating out roots and moisturizing, and then the surface area of roots was determined.

Antibiotics' Uptake by Plants. The antibiotics' extraction from plant samples was done using the modified procedures of Migliore et al.[23] and Dolliver et al.[21] Specifically, 500 mg of dried and crushed plant sample was extracted with 8 mL of methanol:HCl (95:5), mixed for 30 s using a vortex (Vortex-2 genie, Scientific Industries, USA), sonicated for 10 min using an ultrasonic (JAC−1505, Korea), and centrifuged for 10 min at 4500 rpm, and then the supernatant was collected. The residue was extracted again with 5 mL of acetone using the same procedure. The supernatants were mixed and dried under N_2

gas at 40 °C. The residue was resuspended in 5 mL of methanol:nanopure water (50:50) and defatted with 5 mL of hexane three times. Hexane (the upper layer) was removed each time after the liquid–liquid partitioning. The remaining liquid extract was dried under N_2 gas at 40 °C up to 2.5 mL, which was subjected to the cleanup step using SPE.

The SPE cleanup procedure was performed according to Kim and Carlson[30] using an OASIS HLB 60 mg cartridge (Waters Corp., Milford, MA, USA). The cartridge was preconditioned with 3 mL of methanol, 3 mL of 0.5 N HCl, and 3 mL of nanopure water. The sample was passed through the cartridge at a flow rate of 2 mL min^{-1}, and then the SPE cartridge was washed twice with 3 mL of nanopure water and dried under depression for 5 min. The antibiotics were then eluted from the cartridge twice with 2.5 mL of methanol. The methanol extract was dried under N_2 gas at 40 °C until the volume reached ~150 μL and was then transferred to a 500-μL degraded Eppendorf tube. The final volume of eluate was completed to 400 μL using the mobile phase A solution (0.1% formic acid in HPLC-grade water, pH 2.6) and then mixed and filtered through a 0.22-μm cellulose acetate filter. The eluate was transferred into an amber vial equipped with 250 μL of a glass insert vial for HPLC–MS analysis.

The concentration of antibiotics was determined by the procedures of Kim and Carlson[30] using a HPLC–MS (Agilent 1260 series, Agilent Technologies, Palo Alto, CA, USA) equipped with a variable wavelength UV detector. Electrospray ionization (ESI) was used to detect the target antibiotic, and a positive mode was adapted. For the chromatographic separation of antibiotics, the same mobile phases (A, 0.1% formic acid in HPLC-grade water, pH 2.6; and B, 0.1% formic acid in HPLC-grade acetonitrile) of a study by Kim and Carlson[30] were used; however, a different HPLC column and pump program for the gradient elution of the mobile phases were employed. The used column was a YMC-Pack Pro C18 RS reversed-phase column (150 mm long × 2.0 mm i.d., 3-μm pore size) instead of an Xterra C18 column (50 mm long × 2.1 mm i.d., 2.5-μm pore size). A C18 guard column (Phenomenex, Torrance, CA, USA) was used to filter any particulates from the sample. The gradient program for the mobile phases started by a volume of 96:4 (A:B), which ramped to 88:12 (A:B) in 15 min and to 80:20 (A:B) in 10 min and then went back to the initial conditions in 5 min and remained isocratic for 5 min. The column temperature was maintained at 25 °C. Injection volume was 20 μL with a flow rate of 0.2 mL min^{-1}.

A Thermo Finnigan LCQ Duo ion traps mass spectrometer (Thermo, Woburn, MA, USA), equipped with a heated capillary interface and ESI, was used to perform the mass spectrometric analysis. Ultrapure N_2 gas was used for drying and nebulizing. Spray voltage was set to 4.5 kV, and the capillary voltage was autotuned to 3.5 kV. Drying gas temperature was set to 350 °C, and a flow rate was 10.0 L min^{-1}. Average concentration in triplicate of the individual antibiotics was calculated. Calibration curves established for the six antibiotics ranged from 100–5000 μg L^{-1}. When sample concentration exceeded the highest calibration point, the injection volume was reduced.

Statistics. Data were analyzed using SAS v.9.3 software (SAS Institute Inc., Cary, NC, USA). Mean separations were calculated using Duncan's multiple range test at a 0.05 significance level.

RESULTS AND DISCUSSION

Analysis of Antibiotics. Calibration was done for the six antibiotics and showed excellent linearity in the concentration ranges of 100−5,000 μg L^{-1}, with $R^2 \geq 0.996$ (Table S2 and Figure S1, Supporting Information). The extraction method and HPLC−MS conditions proved to enable a good simultaneous separation for the six antibiotics without neither overlapping between antibiotics nor interfering with the plant matrix as shown in the HPLC−MS chromatograms (Figure S2, Supporting Information).

Antibiotics Effects on Plant Growth. The growth parameters, including plant height, number of leaves, leaf chlorophyll content, shoot weight, fruit weight, root weight, and total root surface area, were determined to evaluate the effects of TCs and SAs on plant growth (Table 1). The results revealed that the antibiotics negatively affected all growth parameters for tomato except the fruit weight, which was no different with the control. This result may be due to the low retained quantities of antibiotics in tomato's fruits, which did not affect the fruit weight of treated plants; meanwhile, the other negatively affected growth parameters concerning roots and leaves of tomato may be due to their high contents of antibiotics as seen in the following results of Figures 1 and 2. The highest level of antibiotics (20 mg kg^{-1} soil) had the worst effects on the growth parameters of tomato. For cucumber, the antibiotics showed the negative effects on the growth parameters except the values of leaves' number, because the negative effect for antibiotics on cucumber's leaves was not observed in leaves' number but in the leaves sizes, which were reduced compared to the control (leaf size data not shown). Interestingly, the antibiotics' concentrations of 5 and 20 mg kg^{-1} had similar and negative effects on the plants' growth parameters compared to those of 10 mg kg^{-1}. Generally, our results showed that the antibiotics of TCs and SAs had negative effects on the plant growth of cucumber, tomato, and lettuce.

Different toxic effects between antibiotic compounds are due to their different behavior in the soil via sorption, degradation, and chelating with metals.[35] SAs have been known as antibiotics with higher bioavailability for plants than TCs because of their higher mobility in soils.[31−34] Furthermore, SMX and SMT in the SAs group were found to be toxic to plant growth in the soil as reported by Liu et al.[35] whereas CTC and OTC in the TCs group enhanced the growth of radish and wheat and also reported no negative effects on the growth of corn.[36] Those previous findings support our results concerning the growth negative effects for antibiotics on the three treated plants at the levels of 5 and 20 mg kg^{-1}; this negative effect could be due to the fact that the negative impact of SAs on plants was higher than the enhancing impact for TCs at those levels (5 and 20 mg kg^{-1}). Meanwhile, at the level of 10 mg kg^{-1}, the absorbed amount of TCs may have had a growth enhancing effect equivalent to the growth inhibiting effect for the absorbed amount of SAs. Therefore, some growth parameters for the 10 mg kg^{-1} treated plants were not negatively affected and statistically equal to those of the control plants. We believe that those obtained results are very important and considered a very interesting phenomenon; however, our data and analysis were limited to explain this phenomenon. Further work should be done to reveal the possible mechanism using more various levels of antibiotics.

Antibiotics Uptake by Cucumber, Tomato, and Lettuce. *Tetracyclines (TCs).* Accumulations of TCs were found in parts of leaves, fruits, and roots for each cucumber, tomato, and lettuce, as shown in Figure 1. For the cucumber, the increasing levels from 5−20 mg kg^{-1} of OTC, TC, and CTC led to the higher uptake by leaves, fruits, and roots (Figure 1). The accumulation of OTC and CTC was higher in the fruits and roots of cucumber than that of TC in the same parts, whereas the OTC showed the highest accumulation in leaves at 20 mg kg^{-1}. All TCs were highly accumulated in parts of leaves and roots rather than in parts of fruits.

The accumulation of OTC was the highest in all parts of tomato over all levels of OTC (Figure 1). Moreover, as the level of OTC increased, its accumulation by tomato was accelerated. No difference in accumulation was found between TC and CTC, and the accumulation of TC and CTC was much less than that of OTC.

For the lettuce, CTC showed the highest accumulation in all parts compared to other TCs over all levels of addition (Figure 1). In particular, the roots of lettuce accumulated the highest concentrations of CTC over all levels of addition, which were 0.249, 0.624, and 1.160 mg kg^{-1} fresh weight at 5, 10, and 20 mg kg^{-1}, respectively. These values of accumulation in the roots indicated up to 5.6-times higher than those in the leaves when the same level of CTC was treated. No difference of TC accumulation in the roots was found, and the OTC accumulation was fluctuated over all levels of addition. In brief summary, the accumulations of TCs by the subjected plants were higher in leaves and roots than in fruits and were gradually increased as the level of addition increased. The accumulations of OTC and CTC were generally higher than that of TC and maximized in tomato and lettuce, respectively. These obtained results were in accordance with Kumar et al.[22] who stated that the absorbed level of CTC by corn, cabbage, and green onion increased as the level of CTC increased in the manure−soil mixture. Hu et al.[37] also reported that the applied groups of antibiotics, including TCs and SAs, to the cultivated vegetables of radish, rape, celery, and coriander were biologically accumulated in vegetables through water transport and passive absorption.

Sulfonamides (SAs). With increasing level of SAs, the accumulating trend was very similar to that of TCs in all parts of tested plants including cucumber, tomato, and lettuce; however, the levels of accumulation were much higher than TCs (Figure 2). For cucumber and tomato, the accumulation of all SAs in leaves and roots was generally higher than that in their fruits, and it was increased as levels of SAs increased to 20 mg kg^{-1}. Especially, the accumulation of SMT was the highest in the leaves of cucumber and tomato over all levels. For the roots of cucumber, no difference of accumulation was found at the same level of SAs; however, as the level of SAs increased, the accumulation was gradually increased. At the level of 5 mg kg^{-1}, the accumulations of SAs in all parts of cucumber were not different, and those were relatively lower than at the higher additive level of SAs. For the fruits of tomato, the accumulation of SDM was the most, and that of SMX was the lowest at all the levels of addition. In other words, the accumulation of SDM was 68.9, 64.7, and 57.2% higher than that of SMX at 5, 10, and 20 mg kg^{-1}, respectively. For lettuce, all types of SAs were highly accumulated in roots rather than leaves. The accumulations of SMT in leaves of lettuce indicated the

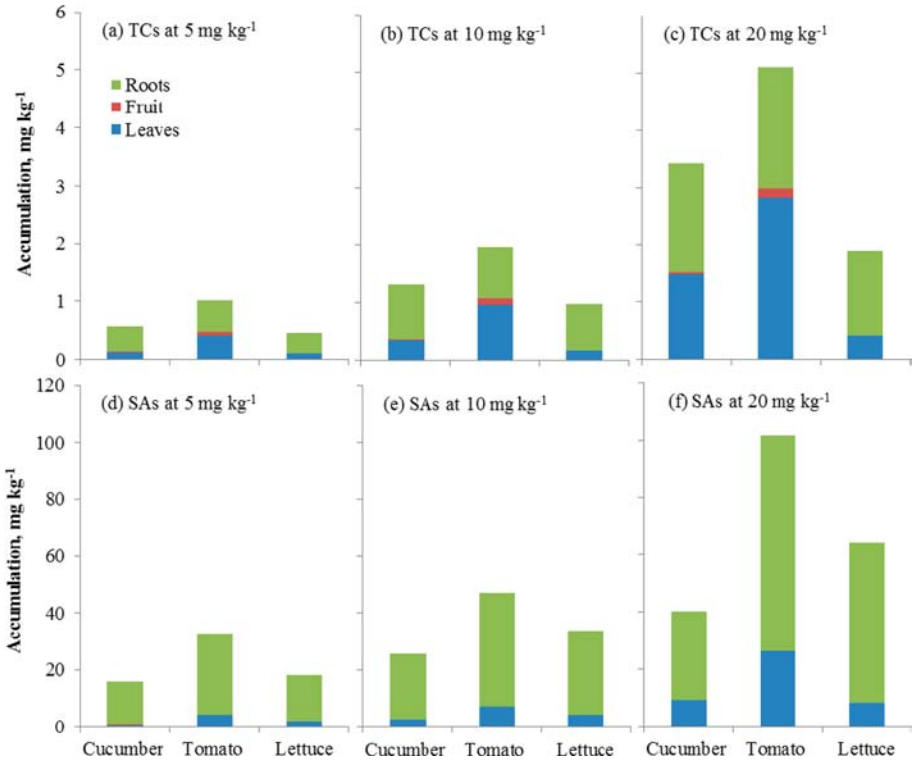

Figure 3. Distributed ratios of absorbed tetracyclines (TCs) and sulfonamides (SAs) between the different plant parts of roots, fruit, and leaves.

highest values of 1.02 and 2.34 mg kg^{-1} at 5 and 10 mg kg^{-1}, respectively, among SAs; however, the accumulation of SMT was not extended at 20 mg kg^{-1} compared to at 10 mg kg^{-1}. SMT and SMX showed rapid and linear increases of their accumulation by adding higher levels in the roots of lettuce, whereas SDM was slightly increased as its level increased. In general, the amounts of accumulated SAs were increased as the levels of each SA increased, and the accumulations of SAs were the least in the fruits for cucumber and tomato in this study.

Migliore et al.[23] reported that relatively high concentrations of 1.234 and 1.063 mg g^{-1} SDM were detected in the root and leaves of barley, respectively, grown in the soils treated with 300 mg L^{-1} of SDM. Dolliver et al.[21] found that the highest amount of SMT was taken up by lettuce, followed by potato and corn. On the basis of the results of TCs and SAs uptake by cucumber, tomato, and lettuce in this study, the accumulation of SAs was markedly higher than that of TCs. It can be explained with the low molecular weights of SAs, which are water-soluble and not strongly sorbed to soil particles; therefore, SAs may facilitate the uptake or accumulation by plant tissues.[21,31,37,38] On the contrary, because TCs have opposite characteristics to SAs, TCs are relatively stable and strongly sorbed to soil particles and thus not easily taken up by plants from the soil.[37,39]

Safety Assessment. The acceptable daily intake (ADI) values for TCs and SAs had been established by JECFA[40] and are defined as 0–30 μg kg^{-1} body-weight d^{-1} for TCs and 0–50 μg kg^{-1} body-weight d^{-1} for SAs. Because body weight is typically assumed to be 60 kg as an adult, the ADI values of TCs and SAs are 1.8 and 3.0 mg d^{-1}, respectively. In this study, the concentrations of TCs in edible parts of all plants were between 0.002 mg kg^{-1} (OTC in cucumber fruit at 5 mg kg^{-1}) and 0.204 mg kg^{-1} (CTC in lettuce leaves at 20 mg kg^{-1}). For the SAs, the concentrations in edible parts of all plants were between 0.013 mg kg^{-1} (SMX in tomato fruits at 5 mg kg^{-1}) and 3.240 mg kg^{-1} (SMX in lettuce leaves at 20 mg kg^{-1}). On the basis of the report estimated by WHO,[41] a typical adult in the eastern countries consumes fresh vegetables about 233 g d^{-1} including 81.5, 4.8, and 2.3 g d^{-1} of tomato, cucumber, and lettuce, respectively. Therefore, the amounts of TCs and SAs accumulated from the edible parts of tested plants were in the safe limit.

Distribution of TCs and SAs in Different Parts of Plants. Figure 3 shows the distribution of TCs and SAs in roots, fruits, and leaves of cucumber, tomato, and lettuce. For the cucumber, the total amounts of accumulated TCs to plant bodies (including leaves, fruits, and roots) were 0.574, 1.309, and 3.418 mg kg^{-1} at the concentrations of 5, 10, and 20 mg kg^{-1}, respectively (Table 2). It was linearly increased as the concentration of TCs into soils increased (Figure S3, Supporting Information). The amount of accumulated TCs in the leaves of cucumber at 5 mg kg^{-1} was 22.1% of the total accumulated TCs in all parts of plant body, but it was sharply increased to 43.9% at 20 mg kg^{-1}. On the contrary, the

Table 2. Total Absorbed Amounts of Tetracyclines by Plants

	20	0.211	0.318	1.364	1.892

DOI: 10.1021/jf5034637
J. Agric. Food Chem. 2015, 63, 398–405

amounts of accumulated TCs in the fruits and roots of cucumber were decreased as the level of TCs addition increased (2.3 to 0.8% for fruits and 75.5 to 55.3% for roots). In the case of SAs for the cucumber, the total concentrations of SAs were also linearly increased as the concentrations of SAs into soils increased (Table 3; Figure S4, Supporting Information).

Table 3. Total Absorbed Amounts of Sulfonamides by Plants

		total absorbed amounts (fresh weight basis; mg kg^{-1})			
plants	treatments (mg kg^{-1})	SMT	SMX	SDM	total
cucumber	5	5.359	5.633	4.924	15.916
	10	8.725	8.295	8.546	25.566
	20	16.319	11.330	12.692	40.341
tomato	5	9.573	17.193	6.113	32.879
	10	13.106	20.963	13.011	47.080
	20	42.445	38.467	20.887	101.799
lettuce	5	7.813	8.582	1.773	18.169
	10	16.776	12.790	4.377	33.943
	20	25.993	30.589	7.876	64.458

Moreover, the highest accumulation of SAs was detected in the roots up to 94.6% (at 5 mg kg^{-1}) compared to other parts of plant body. Interestingly, the smallest accumulation of SAs was found in the fruits of cucumber (<0.5%) compared to other parts of the plant body.

For the tomato, the total amounts of TCs were 1.021, 1.959, and 5.104 mg kg^{-1} at the concentrations of 5, 10, and 20 mg kg^{-1}, respectively (Table 2). The accumulation of TCs increased as the level of TCs addition increased (Figure S3, Supporting Information). The proportions of TCs accumulation in the leaves and roots were similar, which ranged from 40.2−55.2% of total accumulation of TCs in the all parts of plant body, and the accumulation of TCs in the fruits was the smallest, which ranged from 5.5% out of 1.02 mg kg^{-1} (the total content of TCs at 5 mg kg^{-1} spiking) to 3.3% out of 5.10 mg kg^{-1} (the total content of TCs at 20 mg kg^{-1} spiking) compared to other parts (Table 2). For the SAs, the roots of tomato accumulated the SAs the highest (up to 86.8% of total amount of SAs accumulated) compared to the leaves and fruits. Especially, the accumulation of SAs in the fruits of tomato as an edible part was less than 0.3% of the total amount of SAs accumulated.

For the lettuce, each TCs/SAs accumulation was not altered as the level of their addition increased from 5−20 mg kg^{-1} (Tables 2 and 3). The values of accumulation of TCs and SAs in the leaves were 0.413 and 8.392 mg kg^{-1} at 20 mg kg^{-1} spiked and equal to 21.8 and 13.0% occupied of total amount of TCs and SAs accumulation in the plant body, respectively.

Our results of TCs and SAs accumulated in plant bodies showed that the distributions of TCs and SAs were roots > leaves > fruits in general. These results agree with a study by Migliore et al.[23] who stated that the concentration of antibiotics in the roots was higher than other parts of wheat and corn. Similarly, Liu et al.[42] concluded that the distribution of all antibiotics in the wetland plant (*Phragmites australis*) followed the sequence root > leaf > stem. On the other hand, Hu et al.[37] found that the distribution of antibiotics in various tissues of the vegetables was leaves > stems > roots. They also insisted that the types and growth stages of vegetables would affect the distribution of antibiotics. The differences of antibiotics uptake and the distribution on plant, which occurred in the different studies, are due to the limited understanding of the interactions of antibiotic concentrations in manure/soil, antibiotic chemical characteristics, specific crops, plant growth stage, and plant physiology.[21]

We conclude that the growth of cucumber, tomato, and lettuce was relatively inhibited by the TCs and SAs accumulated from soils spiked at the levels of 5, 10, and 20 mg kg^{-1}. The accumulation of OTC was the highest in the cucumber and tomato, while CTC was the highest accumulated among TCs in the lettuce. The accumulation of SAs was the smallest in a part of fruits for cucumber and tomato that equals < 0.5% and 0.3%, respectively, from the total absorbed amounts of SAs. Moreover, the total amounts of TCs and SAs accumulated in the plant bodies were significantly increased as the level of their additions increased . Adding to that, the descending order for the total TCs contents in plants was tomato > cucumber > lettuce, while for SAs, it was tomato > lettuce > cucumber. In general, the relatively high level of TCs and SAs was detected in the nonedible parts (roots and leaves) of cucumber and tomato, and the fruits of these plants also contained a lower level than the ADI of antibiotics.

ABSTRACT: Pastures with diverse botanical composition may enhance animal-derived product quality. A recent study demonstrated high vitamin concentrations and yields in some forb species. The objectives of the present study were to investigate interrelations between herbage yields, vitamin concentrations, protein and fiber contents and analyze the effect of harvest date. We hypothesized that interrelations would be similar across investigated forage species. Four nonleguminous forbs: salad burnet (*Sanguisorba minor*), caraway (*Carum carvi*), chicory (*Cichorium intybus*), and ribwort plantain (*Plantago lanceolata*), three legumes: yellow sweet clover (*Melilotus officinalis*), lucerne (*Medicago sativa*), and birdsfoot trefoil (*Lotus corniculatus*) and a perennial ryegrass (*Lolium perenne*)−white clover (*Trifolium repens*) mixture were sown in a field trial with two replicated and randomized blocks. Forage in 1.5 m × 9 m plots was grown in two consecutive years and cut four times per year (May−October). Analyses of variance were performed. In most herbages, α-tocopherol and β-carotene were positively correlated as were β-carotene and lutein; all vitamins were negatively correlated with fiber content and herbage yield. β-Carotene was positively correlated with protein content. α-Tocopherol and β-carotene contents were generally highest in October and lowest in July. Our results showed similar interrelationships in most investigated species, and we suggest that these species may be mixed when designing novel biodiverse mixtures for particular product quality characteristics.

KEYWORDS: *herb, forb, forage legume, vitamin, α-tocopherol, β-carotene, lutein, seasonal pattern*

INTRODUCTION

Change is needed in the design and management of our food systems in order to enhance natural resource use. Fresh herbage is an important natural source of protein, fiber, fatty acids (FA), and vitamins in ruminant diets. Although synthetic vitamins are cheap and widely used in animal production, there is interest in naturally occurring vitamins, particularly in organic farming systems where use of synthetic or nonorganic feed and supplements has to be minimized. Fresh forage contains fat-soluble vitamins with antioxidative properties, e.g., α-tocopherol and β-carotene (pro-vitamin A),[1] and antioxidants like lutein. Tocopherols (vitamin E) and carotenoids, such as lutein and β-carotene, can be directly transferred from fresh grass into milk.[2] Vitamins in forage species are thus important for the vitamin concentration as well as the oxidative stability of animal-derived foods such as dairy[3] and meat products.[4] Several factors affect concentrations of α-tocopherol and β-carotene in plant species.[1,5]

Both α-tocopherol and β-carotene are quenching singlet oxygen and thereby protecting against photo-oxidative stress, but they act at different locations. The β-carotene counteracts the chlorophyl-photosensitized formation of singlet oxigen, whereas α-tocopherol captures free radicals and protects the membranes.[6] Excessive concentrations of α-tocopherol may be harmful to the plant because it increases the rigidity of membranes. However, this may be counteracted by changes in the FA profile of the membranes and elevated concentrations of β-carotene and other antioxidants.[7]

Concentrations of vitamins and FA in plants depend on factors such as regrowth stage, nitrogen (N) availability, temperature, day length, and leaf proportion in the harvested herbage.[8,9] Tocopherols are located in the photosynthetic parts of plants, in the chloroplasts.[7] Thus, leaves contain more tocopherol than stems.[10]

Herbaceous species of grasslands in temperate-climate zones mainly comprise three broad plant functional groups: grasses, forage legumes and nonleguminous forbs; the latter are generally not included in seeds mixtures for agricultural grasslands, except for special situations such as for organic farms.[11]

In many forb species, antioxidant properties have been reported.[12,13] Pastures with a more diverse botanical composition, including forbs, may enhance oxidative stability of milk. However, there is an agronomic knowledge gap in terms of quantitative data on the yield and quality of forbs in lowland regions with intensive systems. Few studies on vitamin concentrations in forages have been carried out with grass-

[a]Defined value.

legume mixtures (e.g., ref 14). Data on vitamins, yield, dry matter (DM) content, FA, protein, and fiber content in nonleguminous forb species are scarce, however, data from a field experiment with nonleguminous forbs, legumes, and a perennial ryegrass−white clover mixture has been recently published by us.[11,15]

Insight into the relationship between agro-ecological and environmental aspects for these traits that are important for food quality is lacking and could help to develop management guidelines and design novel biodiverse pastures for particular product quality characteristics such as higher unsaturated FA contents or flavours (e.g., refs 16 and 17). The aims of this study were to examine interrelations between herbage yield, vitamin concentrations, and protein and fiber contents as affected by harvest date during the growing season. We hypothesized that those interrelations would be similar for the investigated forages.

MATERIALS AND METHODS

Experimental Design, Plant Material, and Sward Management. The experiment was established in spring 2008 at the Research Farm Foulumgaard, Aarhus University, Denmark on a loamy sandy soil with pH (KCl) 5.9. Experimental details on establishment were reported earlier.[11] Pure stands were sown of four nonleguminous forb species, three legumes, and a mixture of perennial ryegrass (*Lolium perenne* L.) and white clover (*Trifolium repens* L.). The nonleguminous forbs were: salad burnet (*Sanguisorba minor* Scop.), caraway (*Carum carvi* L.), chicory (*Cichorium intybus* L.), and ribwort plantain (*Plantago lanceolata* L.). The legumes were yellow sweet clover (*Melilotus officinalis* (L.) Pall.), lucerne (*Medicago sativa* L.), and birdsfoot trefoil (*Lotus corniculatus* L.). The experimental design was a randomized block with two replications. Net plot size was 1.5 m × 9 m and there were 8 plots in each block.

Agronomic Management. One replicate was fertilized with cattle slurry which was applied with hoses in spring (17 April 2009 and 15 April 2010) and after the second cut (10 July 2009 and 15 July 2010) at 40.5 and 30.8, 23.9, and 20.5 t ha^{-1}, respectively. These dates and amounts reflect typical slurry applications on nonorganic farms in the region. The other replicate received only potassium sulfate in amounts that provided K comparable to that in the slurry: 200 kg ha^{-1} K was applied on 10 July 2009, and 100 kg ha^{-1} K on 7 April 2010 and 16 July 2010 (after the second cut). As P was not limiting, no P was applied. Thus, the main difference between this and the slurry-treated plots was additional N in slurry (ca. 190 kg ha^{-1} y^{-1} total N in slurry, of which ca. 114 kg ha^{-1} was NH_4−N). As replicate was confounded with slurry, a model was chosen with replicate (slurry) as fixed effect.

In this experiment, which was carried out on agricultural soils with high fertility, amounts of available N, P, and K were apparently not limiting.[11] The N-delivery capacity of the experimental site was at least 200 kg N ha^{-1} in 2009 and 140 kg N ha^{-1} in 2010, approaching the amounts of total N provided in slurry (185 and 195 kg N ha^{-1} of which 60% was NH_4−N). The loss of slurry N due to ammonia volatilization may explain the absence of a response to the additional N provided in slurry. Yields were presented earlier[11] and were similar in slurry-fertilized and mineral-K fertilized replicates, as were CP contents and other compounds in the harvested herbage. Replicate plots had generally similar digestibility values and there were no significant block differences for any of the measured traits.

Swards were cut with a forage harvester (J Haldrup A/S, Løgstør, Denmark) to a residual stubble height of 7 cm. Prior to cutting, visual observations were made on species development and leaf proportion but no phenological data were recorded.

Harvest Dates and Weather. Cutting dates in 2009 were 29 May, 9 July, 21 August, and 23 October, and in 2010, 31 May, 13 July, 19 August, and 21 October. These dates corresponded with standard dates for grass harvesting of typical 4-cut systems in Denmark, which are based on calendar date. The duration of the regrowth intervals of the herbages that were cut in harvests two to four (July 9/13, August 21/19 and October 23/21 in 2009/2010) was rather similar in both years: 41, 43, and 61 days in 2009 and 43, 37, and 61 days in 2010, respectively. Irrigation was applied on 9 and 29 June 2009 (38 and 54 mm respectively) and on 15 July 2010 after the second cut (15 mm following slurry application) to prevent drought stress.

Weather data were recorded daily at the Foulumgaard weather station within 500 m of the plot area. The winter of 2009/2010 was characterized by low temperatures and late frosts, and spring growth started late. The average temperature in April 2010 was only 6.5 °C whereas in April 2009 it was 9.4 °C (Table 1). Means of monthly air temperatures from April to October varied between 7.0 and 16.5 °C in 2009 and between 6.5 and 17.8 °C in 2010. On average, temperatures were higher in 2009 than in 2010, except during July and October. Means of monthly rainfall from April to October varied between 0 and 82 mm in 2009 and between 21 and 113 mm in 2010; total growing season rainfall was 367 and 445 mm, respectively. April 2009 was very dry (0 mm) and also in later months the rainfall in 2009 was lower than in 2010, except in June. There was a dry period though in 2009 from June 21 until July 7, with high temperatures. The total global radiation was much higher in 2009 than in 2010: from April to August,

DOI: 10.1021/jf503658n
J. Agric. Food Chem. 2015, 63, 406−414

total growing season radiation was 3252 and 2970 MJ m^{-2}, respectively.

Sample Processing and Chemical Analyses. After cutting, the herbage was weighed and samples were taken. One *ca.* 200 g sample was dried at 60 °C for 48 h in an air-forced oven, and used to determine DM content and for all chemical analyses. Ash was determined after combustion for 6 h at 525 °C, and N content was determined.[18] A Fiber-Tec system was used to determine neutral detergent fiber (NDF),[19] acid detergent fiber (ADF), and acid detergent lignin (ADL).[20] A second sample of ca. 500 g was taken from each cut in both years, immediately frozen in a plastic bag at −20 °C, freeze-dried and subsequently stored in an airtight plastic bag at −20 °C until analysis. Samples were later lyophilized and milled through a 1 mm screen. Of this material, 2 g was saponified in alcohol and the vitamins were subsequently extracted into heptane, analyzed by HPLC and quantified for α-tocopherol, ß-carotene (the sum of all isomers) and lutein.[21] Fatty acids were extracted in a mixture of chloroform, methanol, and water[22] after acidification by boiling in 3 mol L^{-1} of HCl for 1 h. Methyl esters were synthesized from alkaline methanol with BF_3 as catalyst and analyzed on gas liquid chromatography as methyl esters with C17 as internal standard. Unsown species (that comprised <5% of herbage DM) were excluded from the samples used for chemical analyses. In the October harvest of 2010, no herbage samples could be collected of salad burnet and yellow sweet clover due to low yields; in the latter species also one replicate sample was lacking in three other harvests.[11] In addition to absence of data in 5 plots, in 4 herbage samples no vitamins could be measured for yellow sweet clover because low yields prevented taking a 500 g sample, so vitamin data were only available in 7 out of 16 potential samples.

Statistical Analysis. Analysis of variance procedures were applied using the MIXED procedures of SAS (Version 9).[23,24] There were eight "species" (the seven forb species plus the mixture) and four harvests per year. Crude protein (CP) was calculated as 6.25 × N. The category "other compounds" was calculated as 1,000 − (NDF + CP + FA + Ash), lignin as ADL, cellulose as ADF − ADL and hemicellulose as NDF − ADF. For each species, mean, standard deviation and coefficient of variation were calculated for each parameter. The experimental design was a randomized block with two replications that were, however, confounded with management; hence statistically, sample size was n=1. Therefore,[25] yield and quality parameters were evaluated with a model that included fixed main effects of species, cut and replicate (block = slurry) (λ_b) to account for differences in fertilization regime and possible effects of N and P on yield and quality:

$$Y_{bscy} = \mu + \alpha_s + \beta_c + (\alpha\beta)_{sc} + \delta_b + A_y + B_{bs} + C_{bsc} + D_{sy} + F_{bsy} + E_{bscy}$$

where Y_{bscy} = the recorded value for species s in cut c of replicate (block) b in year y.

Greek letters denote fixed effects. Capital Latin letters denote random effects. Lower case Latin letters identify the effects and observations. E_{bscy} represents the random error.

The following effects were considered to be random effects: year (A_y), replicate × species (B_{bs}), replicate × species × cut (C_{bsc}), species × year (D_{sy}) and replicate × species × year (F_{bsy}). Because in an earlier model[11] the year × replicate effect $(\delta\lambda)_{yb}$ was not significant for any of the parameters, this interaction term was not included. The interaction species × cut $(\alpha\beta)_{sc}$ was significant and was kept in the model as a fixed effect. Interactions including replicate were generally small and kept in the model as random effects in order to take into account the random variation between plots and to take into account certain correlations that must be expected because of the design structure (e.g., same plot measured in both years). When analyzing experiments with a sample size n=1, ANOVA can be performed if some relevant interaction terms are random or absent and assuming that those random or absent terms have no true fixed effect.[25] These assumptions were met.

Differences detected among main effects and interactions were assessed using the PDIFF option in the least-squares means statement. All tests of significance were made at $P = 0.05$. First, overall covariance analyses were carried out to test the effect of species. Then, for each species simple regression analyses were conducted between vitamin concentrations and 1) yield, 2) NDF, and 3) CP, as well as among vitamin concentrations. Finally, multiple regression analyses were conducted with α-tocopherol, β-carotene, or lutein as dependent variables, and yield, concentrations of chemical compounds and weather parameters as independent variables. Starting with the full model, nonsignificant variables were successively dropped from the model until only significant variables remained. Temperature, rainfall and radiation were calculated for each regrowth interval (Table 1) and also for periods of 10, 7, 5, and 2 days before cutting.

Earlier Findings. Yield and concentrations of vitamins and other compounds differed among species[11,15] as summarized in Table 2.

Table 2. [a]Data summarized from Elgersma et al.[11,15]. [b]Other =100 − (NDF + CP + Ash) − mainly water-soluble carbohydrates and other components. [c]100(ADF-ADL)/NDF. [d]100(NDF-ADF)/NDF.

Averaged across harvests and years, yields were lower in yellow sweet clover, salad burnet and caraway (3.9, 4.6, and 5.6 t DM ha^{-1} $year^{-1}$, respectively) than in the grass−clover mixture and lucerne (12.5 and 15.4 t DM ha^{-1} $year^{-1}$, respectively). Lucerne, chicory, ribwort plantain, and birdsfoot trefoil had similar DM yields to the perennial ryegrass−white clover mixture. Ribwort plantain and lucerne had the highest concentrations of NDF (402 and 383 g kg DM^{-1}, respectively), ADF (339 and 321 g kg DM^{-1}, respectively), and ADL (78 and 67 g kg DM^{-1}, respectively). Birdsfoot trefoil had low NDF (328 g kg DM^{-1}) and ADF (272 g kg DM^{-1}) concentrations but a high ADL concentration (62 g kg DM^{-1}), as well as a low ash content (91 g kg DM^{-1}). The highest ash concentration was found in chicory (143 g kg DM^{-1}). CP concentrations were highest in legume

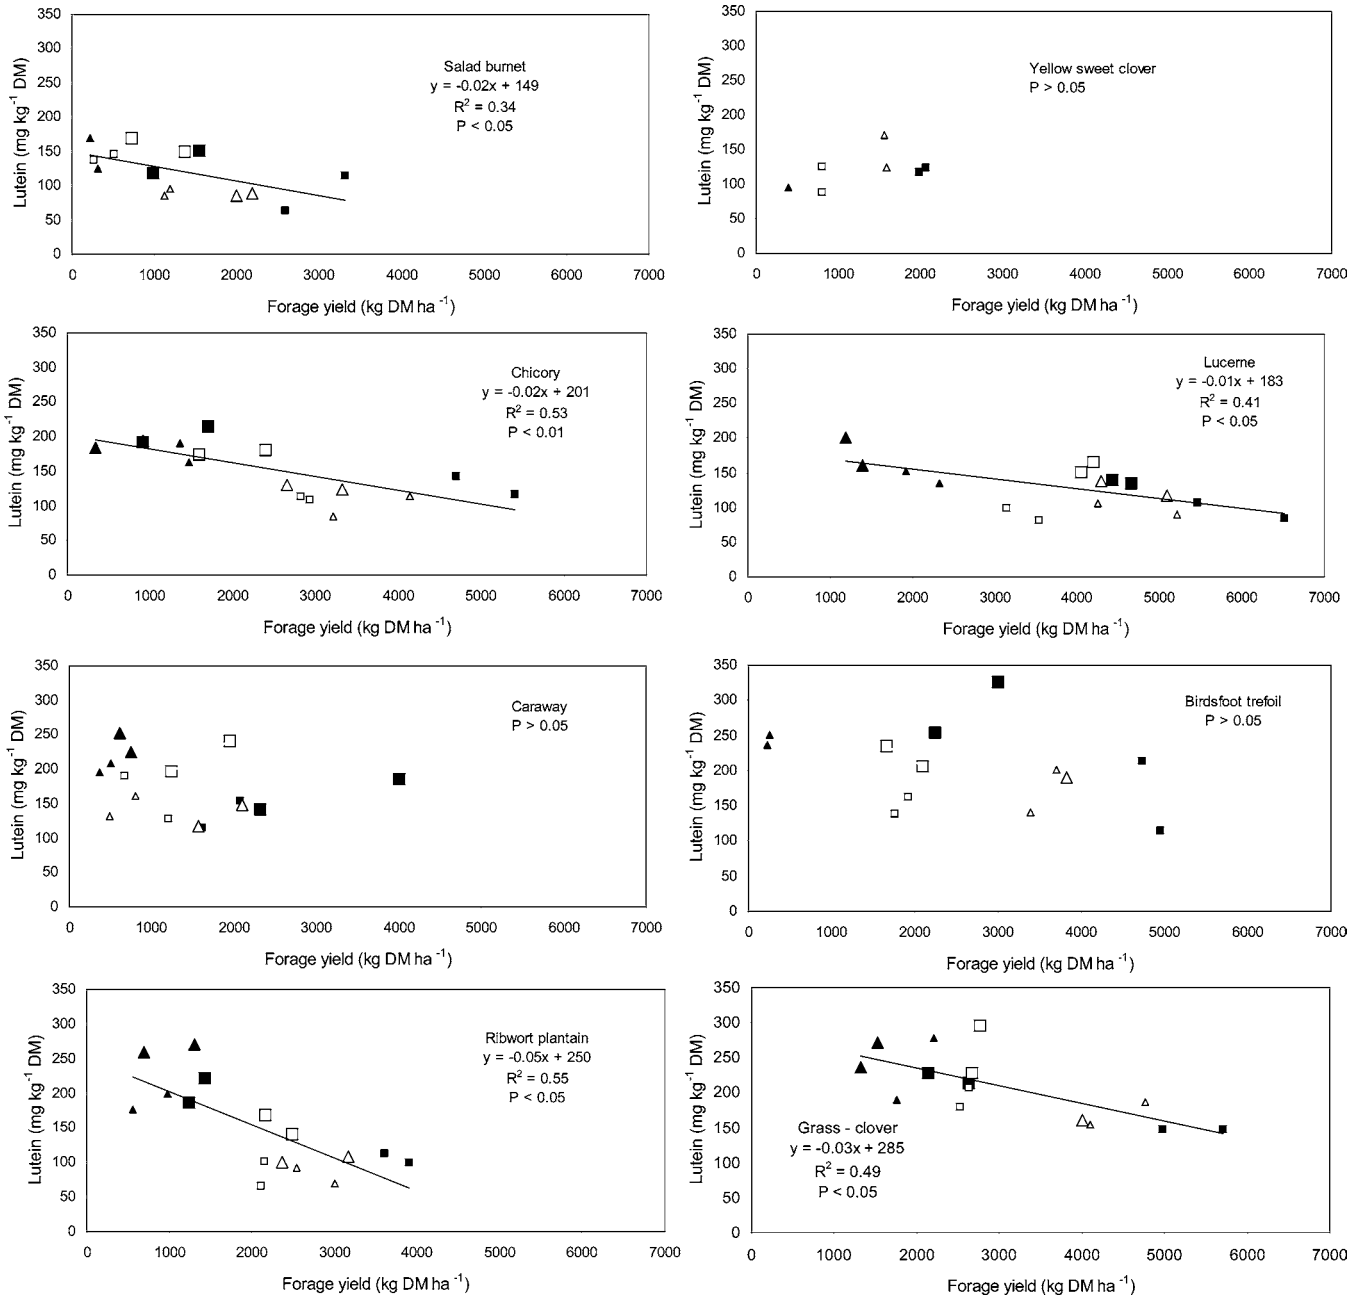

Figure 1. Relationships between concentrations of lutein and dry matter yield during four harvests (■ late May, Δ early July, □ mid/late August, ▲ mid/late October) in 2009 (small symbols) and 2010 (large symbols) yield in (left) salad burnet, chicory, caraway, and ribwort plantain, and (right:) yellow sweet clover, lucerne, birdsfoot trefoil, and a perennial ryegrass−white clover mixture.

species (198−206 g kg DM^{-1}) and in the grass−clover mixture (199 g kg DM^{-1}), and lowest in chicory and ribwort plantain (102 and 115 g kg DM^{-1}, respectively). The concentration of "other compounds" (i.e., not being ash, CP, fiber, or FA) including water-soluble carbohydrates, was significantly higher in salad burnet (452 g kg DM^{-1}) than in all other species; it was also higher in chicory and caraway (406 and 400 g kg DM^{-1}, respectively) than in the legume species (306−349 g kg DM^{-1}) and the mixture (320 g kg DM^{-1}).[11] Fatty acid concentrations were lowest in lucerne, ribwort plantain, chicory and yellow sweet clover (15.9, 17.1, 19.2, and 19.3 g kg^{-1} DM, respectively) and highest in birdsfoot trefoil and caraway (24.5 and 27.0 g kg^{-1} DM, respectively)[15]

α-Tocopherol concentrations were on average lowest in lucerne and yellow sweet clover (21 and 23 mg kg^{-1} DM) and highest (and exceeding those of the grass - clover mixture) in ribwort plantain and salad burnet (77 and 85 mg kg^{-1} DM, respectively). β-Carotene concentrations were lowest in lucerne, salad burnet and yellow sweet clover (26, 30, and 33 mg kg^{-1} DM) and highest in grass-clover, ribwort plantain, birdsfoot trefoil and caraway (48, 56, 59, and 61 mg kg^{-1} DM, respectively). Lutein concentrations were lowest in lucerne, salad burnet, yellow sweet clover, ribwort plantain and chicory (129, 129, 131, 149, and 152 mg kg^{-1} DM) and highest in birdsfoot trefoil, the grass−clover mixture, and caraway (206, 195, and 174 mg kg^{-1} DM, respectively).

Species × cut interactions were not significant for yield and most chemical compounds (Table 2), except for concentrations of CP and ash ($P < 0.05$),[11] β-carotene ($P < 0.001$), and total FA ($P < 0.01$).[15] Species × cut interactions that were significant were relatively small compared to main effects. There was no effect of year, except for concentrations of lignin ($P < 0.05$), FA ($P < 0.01$), and lutein ($P < 0.001$) (Table 2).

RESULTS

Seasonal Variation in Herbage Dry Matter Yield, Chemical Composition of the Forage, and Vitamin Contents. Lutein concentrations are shown in relation to DM yield in Figure 1. Herbage yields were generally lowest in the fourth harvest ($P < 0.001$) as can be seen in Figure 1. The seasonal growth patterns differed between years: in 2009, the first cut yielded most whereas in 2010, the second cut was most productive, except for caraway. During the fourth cut, yields were comparable in both years (caraway, ribwort plantain) or slightly higher in 2009 (chicory, lucerne, grass−clover mixture). Annual yields were numerically lower in 2010 than in 2009 for most species except caraway but averaged across species, there was no statistically significant effect of year (Table 2). For most species, the DM yield of the first cut was much higher in 2009 than in 2010: e.g., that of grass−clover produced 5.3 and 2.4 t DM ha^{-1} and birdsfoot trefoil yielded 4.8 and 2.6 t DM ha^{-1}, respectively. Leaf proportions of all species (not shown) were highest in the fourth harvest when all species were in the vegetative stage. Lucerne, yellow sweet clover, and chicory had a high proportion of stems during summer. Stems in birdsfoot trefoil were small, thin and green in both years, in contrast to stems of other forb species. Caraway had few stems that occurred already early May when other forbs were still vegetative; they started flowering after the first cut. Grass was in the heading stage at the time of the May harvests. Caraway had in the first cut of 2009 more stems and flowers than in the first cut of 2010.

Averaged across all species, large differences were found for ash and CP contents between harvest dates (Table 2). Ash concentrations were lower ($P < 0.001$) in cuts 1 and 2 than in cuts 3 and 4, whereas CP concentrations were higher ($P < 0.001$) in the first than in the second cut and then increased to become highest in cuts 3 and 4 (not shown). There were large differences ($P < 0.001$) between harvest dates in the concentration of "other compounds" including water-soluble carbohydrates, which were highest in the first cut and lowest in the third cut. The fiber contents (i.e., concentrations of NDF, ADF and ADL) differed between harvests ($P < 0.001$) and were lowest in the fourth harvest for all species, coinciding with low

[a]Values in brackets have a P value of 0.06.

yields. The concentrations of ADF and its components (hemicellulose and lignin) were generally higher in 2010 than in 2009 ($P < 0.05$).

Vitamin concentrations differed significantly ($P < 0.001$) among harvests (Table 2) and were generally lowest in the second cut, and highest in the fourth cut (Figure 2). The fourth cut showed high vitamin concentrations in both years, but α-tocopherol levels were higher in 2010 than in 2009. Interactions between species and cut were not significant for α-tocopherol (Table 2).

The ranking order for coefficients of variation of the species differed for the various parameters. The extent of variability in relation to the mean was generally highest for herbage yield, followed by contents of β-carotene, ADL, hemicellulose, α-tocopherol, cellulose and lutein; ash had the lowest value (not shown). The coefficients of variation for β-carotene ranged from 27 to 44%, for α-tocopherol from 27 to 33% and for lutein from 22 to 29% with ribwort plantain (44%) as outlier.

Relations between α-Tocopherol and β-Carotene, Lutein, Herbage Dry Matter Yield, and Chemical Composition. Covariance analyses of all data with vitamin contents as dependent variables showed large effects of species ($P < 0.001$) and yield ($P < 0.001$), therefore analyses were carried out for each species to investigate interrelations among vitamins contents, and between vitamins, yield, chemical compounds and weather parameters.

Figure 2 shows the relationship between α-tocopherol and β-carotene across harvest dates (four cuts in two years) for all species. Seasonal and annual fluctuations in vitamin contents can also be seen in Figures 1 and 2; harvests in May when most and October when all herbage was in the vegetative stage are depicted in black symbols and harvests during summer, when most species were in the generative stage, with open symbols. There was a positive correlation between α-tocopherol and β-carotene concentration in all species, except in salad burnet and yellow sweet clover where no relationship was found. Both vitamins were negatively correlated with yield in the non-leguminous forbs caraway, ribwort plantain ($P = 0.08$ for α-tocopherol), and to a lesser extent chicory; in salad burnet, β-carotene showed a negative relation with yield but there was no relation between α-tocopherol and yield (Table 3). In the grass−clover mixture, the negative relation between yield and β-carotene was stronger than that for α-tocopherol; in lucerne a similar pattern was found. Correlations in lucerne were less strongly negative than in grass−clover. In yellow sweet clover, no relations between yield and vitamin concentrations were found. In birdsfoot trefoil, only β-carotene was negatively correlated with yield. The correlation between β-carotene and yield was generally more negative than that between α-

DOI: 10.1021/jf503658n
J. Agric. Food Chem. 2015, 63, 406−414

tocopherol and yield, except in chicory. Salad burnet, caraway, birdsfoot trefoil and chicory had a low NDF content relative to grass−clover. Negative correlations between NDF and β-carotene were found in most forb species and with α-tocopherol in the legumes (Table 3).

In most herbages, lutein and β-carotene were positively correlated (not shown) but lutein and α-tocopherol were not correlated. Lutein was neither correlated with protein or NDF content (not shown). There was a negative correlation between lutein and herbage yield in salad burnet, chicory, ribwort plantain, lucerne, and the grass−clover mixture (Figure 1).

Multiple regression analyses (Table 4) revealed that across all species (n = 128), the variation in β-carotene was in part explained (R^2 = 0.36) by yield and temperature (mean of 7 days before cutting); the variation in α-tocopherol by yield (R^2 = 0.25); and the variation in lutein by temperature (R^2 = 0.22). The average temperature of 10, 7, or 5-day intervals prior to harvest had stronger correlations in the regressions than temperature during the entire growth interval (Table 1). Therefore, we chose the 7-day interval. Radiation and rainfall did not have significant effects; therefore, only temperature was included in the models.

In most species, temperature had more effect on β-carotene than on α-tocopherol (Table 4). Adding chemical compounds to the model did not improve the outcome. For example, there were significant simple correlations (Table 3) between β-carotene and NDF or CP but significance of those compounds was lost when temperature or yield were included in the models (Table 4).

DISCUSSION

Main Variation Factors of Vitamin Contents; Effect of Harvest Date. Concentrations of vitamins and FA in plants depend on factors such as regrowth stage, N availability, temperature, day length, and leaf proportion in the harvested herbage.[8,9] The main variation factors of vitamin contents are species c.q. botanical composition,[26] stage of maturity,[26,27] point in the growing season,[27] leaf/stem ratio,[10] and environmental factors.[28]

The stage of maturity of a species at harvest is determined by the duration of the preceding regrowth period, the daylength and weather conditions during the regrowth period. In this experiment, all species were cut at similar dates. The primary growth period may have differed according to species-specific temperature thresholds for growth. From the second harvest onward (July until October), regrowth periods, and associated temperature sums and radiation during each of these periods, were the same for all species. Radiation had no effect and temperature only explained part of the variation in β-carotene and lutein concentrations. In most species, temperature had more effect on β-carotene than on α-tocopherol.

In this experiment, leaf proportions of species were highest in October, which coincided with generally high concentrations of vitamins. This is in line with Brown[30] who found four times more α-tocopherol in grass leaves than in stems, and three times more α-tocopherol in clover leaves than in petioles. As tocopherols are located in the photosynthetic parts of plants, in the chloroplasts,[7] leaves contain more tocopherol than stems.[10] Higher contents of β-carotene have also been found in plants containing a higher proportion of leaves.[9] Unfortunately, in this study grass and clover leaves and stems were not separated; levels of α-tocopherol in mixed grass-clover herbage were 35, 48, and 35% higher in October (when both species were in the vegetative stage) than in May (when grass was heading), July, and August (when white clover had most flowers), respectively, and β-carotene levels were 70, 140, and 30% higher (Figure 2). Vitamin concentrations were thus generally lowest in July, which is in line with results from another Danish findings[31] reporting that β-carotene contents in grasslands with red clover (*Trifolium pratense* L.), white clover, lucerne and chicory, were lower in July than in May.[14] We also found 1.2−1.7 times higher contents of β-carotene in May than in July for all species except caraway and yellow sweet clover. Lucerne and yellow sweet clover had 1.3, and birdsfoot trefoil 1.5 times more α-tocopherol in May than in July (Figure 2).

Legumes flower most abundantly in summer. Levels of α-tocopherol were 71 and 69% higher in birdfoot trefoil, and 61 and 74% higher in lucerne in October than in July and August, respectively; figures for β-carotene were 195 and 220%, and 111 and 61%. Also chicory, salad burnet and ribwort plantain showed this pattern (Figure 2). In general, the concentration of β-carotene fluctuated more within each species than that of α-tocopherol, while lutein showed least variation. Lutein and β-carotene are found in association and the reason for the lower variation in lutein concentrations across the various harvest dates is not clear.

In pastures, species are mixed but here single-species stands of forbs were studied. Caution should be taken when intrapolating yield and chemical composition data, as plant species can interact differently with each other when grown in a mixture than when grown in monoculture. Interspecific interaction can affect canopy structure and leaf/stem ratio of species. Stress factors such as pests may cause increased α-tocopherol levels;[7] however, no pests or diseases were observed in our study.

Differences between Species; Relationships with Chemical Compounds. In this experiment, species differences were significant: α-tocopherol concentrations were on average lowest in lucerne and yellow sweet clover and highest in ribwort plantain and salad burnet; β-carotene concentrations were lowest in lucerne, salad burnet and yellow sweet clover and highest in grass-clover, ribwort plantain, birdsfoot trefoil and caraway; and lutein concentrations were lowest in lucerne, salad burnet, yellow sweet clover, ribwort plantain and chicory and highest in birdsfoot trefoil, the grass−clover mixture and caraway. Concentrations in pure stands of ribwort plantain and salad burnet (on average 77 and 85 mg α-tocopherol kg^{-1} DM, respectively), grass-clover and ribwort plantain (48 and 56 mg β-carotene kg^{-1} DM, respectively), and grass−clover and birdsfoot trefoil (195 and 206 mg lutein kg^{-1} DM, respectively) were comparable with reported data[29] from Southern Norway of 76−83 mg kg^{-1} DM α-tocopherol, 44−48 mg kg^{-1} DM β-carotene, and 193−244 mg lutein kg^{-1} DM in two mixed pastures with similar herbage proportions of nonleguminous forbs; however, these were mainly annual and biannual weeds.

This study demonstrated in a range of forb species a negative correlation between herbage yield and concentrations of β-carotene (6 out of 7 forbs), lutein (4 out of 7 forbs) and α-tocopherol (3 out of 7 forbs). In a perennial ryegrass−white clover mixture, negative correlations between herbage yield and all 3 vitamins were found; this was also the case in lucerne and chicory. Yellow sweet clover was the only forb where no correlation between herbage yield and vitamin contents occurred which may in part have been caused by missing values for this species.[11]

DOI: 10.1021/jf503658n
J. Agric. Food Chem. 2015, 63, 406−414

In all forbs except yellow sweet clover the β-carotene content was negatively correlated with NDF and positively with N contents; both correlations were significant for salad burnet, chicory, lucerne and birdsfoot trefoil. In caraway, there was a numerically negative correlation with NDF and a significant positive correlation with N content and in ribwort plantain, there was a significant negative correlation with NDF and a numerically positive correlation with N content; both numerical trends were not significant due to outliers. These correlations are in line with our expectation because herbage in a vegetative stage, i.e., in the October harvests, has a high leaf proportion which is associated with lower fiber and higher protein contents compared with herbage in a generative stage. Indeed, in autumn the yields were lowest and herbage contained most protein, least fiber (lignin, cellulose, hemicellulose), had a high ash content[11] and the highest concentrations of vitamins.[15] Correlations between α-tocopherol and NDF were only present in the 3 legumes, and between α-tocopherol and N only in chicory (Table 3); for this we do not have an explanation. There was no indication that interrelations of herbage yield, NDF and N with vitamin contents differed among legumes and nonleguminous forbs; however, numbers of species were rather low which hampers a general comparison of functional groups. Within most species, concentrations of α-tocopherol and β-carotene were positively correlated. In line with our results, positive correlations between chlorophyll and carotenoid pigments have been reported for several species.[32,33] With exception of salad burnet and yellow sweet clover, this study confirmed our hypothesis that interrelations between vitamins, yield, and quality compounds were rather similar for the investigated species.

Effect of Weather. The weather may provide an explanation for the fact that in 2010, vitamin concentrations in the first harvest were much higher than in 2009, which was very evident in e.g. chicory. The winter of 2009/2010 was severe and spring growth started late (Table 1). During the 20 days preceding the date of the first cut, the average air temperature was 9.6 °C in 2010 compared to 10.6 °C in 2009[11] which implies that in 2010 the forage was less mature during the first harvest. There was also a cold period after the third cut in 2010, which might have caused a delay in regrowth resulting in physiologically younger forage in the fourth cut compared to 2009. However, the higher vitamin concentrations in October of 2010 might also partly reflect differences between first-year swards and second-year swards, in combination with different daily mean temperatures and solar radiation during the growth intervals.

As in October daylength is shorter than in May, July, and August, yield levels in autumn were confounded with low radiation (Table 1). However, radiation did not explain variation in yield or vitamins when included in models. Concentrations of α-tocopherol and β-carotene in forage species grown in Southern Sweden generally had higher concentrations than from plants grown in Northern Sweden[14] but differences in daylength and temperature were confounded with other factors. In a controlled environment, β-carotene concentration in leaves increased with temperature after 3 to 4 weeks in kale (*Brassica oleracea* L.) and decreased in spinach (*Spinacea oleracea* L.) on a fresh mass basis,[32] but no temperature effects on caroteinoid contents were found when expressed on a dry matter basis. Similarly, in our study no direct relationship was found between mean air temperature during regrowth and concentrations of α-tocopherol, β-carotene, and lutein in herbage of the various forage species. Temperature during the last week before harvest did have an effect, which was greater than that of temperature during the last 2 days before harvest. This knowledge may be used in prediction models.

Relevance to Practice and Future Perspectives. The increasing interest of consumers in environment, animal welfare and the origin and method of food production is reflected in growing preference for food products of, i.e., pasture-based systems of production. For example, in the USA organic dairy markets are growing and the demand for milk and dairy products from pasture-fed cows has increased in recent years.[34,35] A substantial body of information is now available on the differences in composition and sensory properties of products from pasture-based and concentrate-based production systems. For milk, there has been less focus on grassland than for beef, presumably because in many regions forage represents a smaller proportion in feed rations of lactating compared to growing animals. Emerging data indicate that milk and meat produced from botanically diverse pastures have higher concentrations of specific (groups of) FA such as CLA and n-3 FA and antioxidants, which may be benefial for human health.[17] Our results indicate that yield and high temperature both had a negative effect on β-carotene and lutein concentrations. These compounds would be prone to decline in view of possible higher temperatures due to climate change. In our study, α-tocopherol content was not affected by variables other than yield. In the summer period the vitamin content is lower due to higher temperature. This knowledge can be included in decision support systems, when trying to reach specific goals for herbage quality; this is especially important for high producing dairy cows or for production of special products. Taking early cuts in spring and autumn, when the temperature is lower, would be a cultivation strategy when aiming for forage with high contents of β-carotene and unsaturated FA[15] and a high nutritive value, but is associated with a lower yield. Cutting at a greater stubble height or taking off animals before the sward is grazed down could be another way to increase leaf proportion and thus enhance vitamin contents in animal diets. Choice of species combination for a mixture when establishing a new sward is another issue that warrants further research and preferably on-farm testing. The high vitamin concentrations in most nonleguminous forbs in our study compared to those in major forages such as grass−clover and particularly lucerne, may encourage adoption of these species by farmers but would in practice require a number of challenges to be overcome, including development of optimal seed mixtures and management practices that can increase persistency of forbs in mixed swards under cutting and/or grazing.[36]

ABSTRACT: Co-formulations of 1,3-dichloropropene (1,3-D) and chloropicrin (CP) are commonly used for preplant fumigation in the production of high-value crops. Various ratios of 1,3-D to CP are available in these co-formulations. Collation of previous field data suggested that when the two fumigants were co-applied, the emissions of CP were significantly lower than when CP was applied singly. However, none of these previous studies had a control treatment with CP applied alone, alongside a treatment where CP was co-applied with 1,3-D under the same climatic and edaphic conditions. This work aimed to address this issue by measuring emission fluxes from soil columns maintained under controlled conditions in which 1,3-D and CP were applied alone and as four commercial co-formulations with various 1,3-D:CP ratios. A strong positive relationship between CP emissions and CP percentage in the formulation was observed. Furthermore, strong positive relationships between CP degradation half-life and CP percentage in the formulation and between CP degradation half-life and total column emissions suggested that the lower emissions were due to faster CP degradation when the CP percentage (and hence initial application mass) in the formulation was low. The presence of 1,3-D did not significantly affect the degradation rate of CP, and, therefore, it is hypothesized that co-application was, in itself, not a significant factor in emission losses from the columns. The findings have implications for the accurate modeling of CP because the effect of initial mass applied on CP degradation rate is not usually considered.

INTRODUCTION

The use of chemical fumigants is critical in agricultural areas of states such as California and Florida, where high-value crops, requiring efficacious pest control, are commonly grown.[1] Although they provide excellent plant pest control, fumigants are highly volatile, making them prone to evaporation into the atmosphere. In addition to the toxic nature of these volatile chemicals, they also have the potential to contribute to the formation of near-surface ozone if sufficient NO_x is available for reaction. Therefore, degradation of air quality and associated inhalation health risks in agricultural workers and local populations are potential hazards associated with fumigant application[2] that warrant management via mitigation strategies such as emission reduction (e.g., tarps and irrigation) and buffer zones. The ban on the use of methyl bromide, together with the recent withdrawal of methyl iodide in the United States, has limited the options for growers requiring the high degree of pest control offered by soil fumigants. 1,3-Dichloropropene (1,3-D) and chloropicrin (CP) are broad-spectrum fumigants with fungicidal, herbicidal, insecticidal, and nematicidal properties; however, weed control with these products is limited.[3,4] Often, 1,3-D and CP are applied together to enhance pest control. For example, commercial products of 1,3-D are often combined with CP to enhance the control of fungi.[5] These fumigants can be applied using shank injection or drip application, with or without tarps. The aerobic soil half-life of 1,3-D is given as 1.7−53 days.[3] For CP, half-life is reported as a few hours to several days[6] but is commonly considered to be approximately 4.5 days in sandy loam soil.[7]

In California, fumigant use is increasing. Pesticide Use Reports published annually by California Department of Pesticide Regulations (CDPR)[8] indicate that CP use increased from 2.49×10^6 kg in 2007 to 4.09×10^6 kg in 2012, and that 1,3-D use increased from 4.35×10^6 kg in 2007 to 5.57×10^6 kg in 2012. Indeed, 1,3-D and CP were ranked the first and third most used fumigants (based on mass applied) in California in 2012, respectively. In the same year, they were ranked the third and fifth most used pesticides (based on mass applied), respectively. Strawberry production is an important, and increasing, user of fumigants. According to CDPR[9] the fumigated land area for this commodity increased by 16% from 2011 to 2012. The majority of the 2011−2012 increase in fumigant use in strawberry production was due to the fumigants metam sodium (72% increase), 1,3-D (24% increase), and CP (11% increase).

Given their increasing use and importance, it is necessary to consider the emissions behavior of 1,3-D and CP. These fumigants can be applied separately or as co-formulations with

[a]Maximum CP flux normalized to an application rate of 112 kg ha^{-1} (100 lb acre^{-1}). Application types were either shank (S) or drip (D). [b]Data from Chloropicrin Manufacturers Task Force (CMTF) study, reported by Cryer and Van Wesenbeeck.[27]

various 1,3-D:CP ratios. However, there appears to be an effect of using co-formulations on the total emission losses of CP measured. We collated data (Table 1) from several field experiments in which CP was applied either alone or as the 1,3-D:CP co-formulations Telone C-17 (~17% CP, 83% 1,3-D), Telone C-35 (~35% CP, 65% 1,3-D), and Inline (~33% CP, 61% 1,3-D). Meta-analysis of these data showed that, on average, total CP emissions (% of applied) were ~4.5 times lower when CP was applied as a co-formulation with 1,3-D compared to being applied singly. Such observations have not been made for 1,3-D. These data are discussed in more detail later in this paper, but ostensibly suggest that when added as a co-formulation with 1,3-D, percentage emissions of CP are significantly lower than when it is applied singly. In fact, in some field studies, zero, or an extremely low amount of, detectable CP was emitted from the soil.[10] A possible explanation for these findings is that the presence of 1,3-D enhances the degradation of CP. There is evidence in the literature[11] showing that the degradation rate of CP increased by approximately 15% in soil containing 1,3-D compared to that in soil with no 1,3-D.

A major limitation of this collated emissions data, as it is used for this comparison, is that these previous studies were not designed specifically to test the effect of co-application of 1,3-D

DOI: 10.1021/jf506010b
J. Agric. Food Chem. 2015, 63, 415−421

and CP on CP emissions. Therefore, none of these studies had a control treatment with CP applied alone alongside a treatment in which CP was co-applied with 1,3-D under the exact same climatic and edaphic conditions. The goal of this work was to address this issue by measuring emission fluxes from soil columns maintained under controlled conditions in which 1,3-D and CP were applied alone and at various 1,3-D:CP ratios. Our hypothesis was that co-application of 1,3-D and CP would result in lower total emissions of CP than when CP was applied alone due to increased (or changes in) fumigant degradation kinetics when CP concentrations in soil are reduced.

MATERIALS AND METHODS

Chemicals, Sampling Tubes, and Soil. The commercially available 1,3-D and CP formulations used in this study were Telone II (1,3-D only), Tri-Clor (CP only), Telone C-17 (~17% CP, 83% 1,3-D), Telone C-35 (~35% CP, 65% 1,3-D), Pic-Clor 60 (~60% CP, 40% 1,3-D), and Pic-Clor 80 (~80% CP, 20% 1,3-D). Telone II, C-17, and C-35 were donated by Dow Agrosciences (Indianapolis, IN, USA) and Tri-Clor, PC-60, and PC-80 by TriCal Inc. (Hollister, CA, USA).

Sodium sulfate (anhydrous), *n*-hexane, and ethyl acetate were obtained from Fisher Scientific (Fair Lawn, NJ, USA). Acetone was obtained from Burdick and Jackson (Muskegon, MI, USA). XAD-4 (2 section 400/200 mg) and Anasorb CSC charcoal (2 section 400/200 mg) sorbent tubes were purchased from SKC Inc. (Eighty Four, PA, USA). Deionized water was used in the preparation of solutions.

Sandy loam soil (75% sand, 18% silt, 7% clay; 0.92% organic matter; Arlington soil series) was collected from the plowed, upper 30 cm of field 2B of the University of California Riverside Agricultural Station. This field has been used in numerous field and laboratory fumigant emission studies performed by the U.S. Salinity Laboratory (see, e.g., refs 12−14); however, the soil for this study was collected from an area of the field that had not been previously fumigated. The soil was sieved to 5 mm and stored in sealed plastic bags in a cool environment. The gravimetric moisture content of the soil used in the experiments was between 4 and 5%.

Soil Column Study. Stainless steel soil columns (12 cm diameter × 150 cm length) were used to study the surface emissions of co-formulations of 1,3-D and CP, following a simulated shank injection at 46 cm soil depth. The general design and setup of the columns has been described previously.[15,16] Soils were packed into the columns in 5 cm intervals to a dry bulk density of 1.5 g cm^{-3}. The top of each column was sealed with a stainless steel flux chamber. The columns were housed in a controlled temperature room where the ambient temperature was maintained at 25 °C.

Approximately 177 mg of a fumigant formulation was injected into the center of a soil column at 46 cm depth (equivalent field application rate of approximately 156 kg ha^{-1}). Specifically, the amounts of 1,3-D and CP applied for each formulation were as follows: Telone II, 177.1 mg of 1,3-D, 0 mg of CP; Telone C-17, 143.1 mg of 1,3-D, 29.0 mg of CP; Telone C-35, 115.2 mg of 1,3-D, 62.8 mg of CP; Pic-Clor 60, 71.4 mg of 1,3-D, 106.6 mg of CP; Pic-Clor 80, 35.1 mg of 1,3-D, 142.9 mg of CP; and Tri-Clor, 0 mg of 1,3-D, 176.4 mg of CP. Immediately after application, a vacuum (100 mL min^{-1}) was applied to the outlet of the flux chamber to sweep clean air across the soil surface. In this way, headspace gas vapors were collected on in-line sorbent tubes (XAD-4 filter media) that were sampled every 4 h throughout the experiment. Backup sorbent tubes were used to check for fumigant breakthrough. All sampled tubes were capped on both ends and stored in a freezer at −19 °C. Background air within the controlled column environment was sampled daily by pulling the air through an XAD-4 sorbent tube for 24 h periods. In addition, at the start of the experiment, blank XAD-4 and charcoal tubes were placed in the sample storage freezer (i.e., storage blanks). Analysis of all storage blank and background air sampling tubes yielded nondetectable levels of each fumigant, and so no correction was required for these potential sources of contamination. At the end of the experiment (10 days), XAD-4 tubes were cut into their A and B sections and each was placed into separate glass vials. After the addition of 4 mL of *n*-hexane, the vials were immediately capped and shaken for 1 h, and then 1 mL of supernatant solvent was removed for gas chromatography (GC) analysis. For the charcoal backup tubes, the procedure was the same except that the entire charcoal medium was removed into a glass vial, and 4 mL of acetone was used for the extraction.

Each co-formulation treatment was performed in triplicate, although for the PC-80 treatment, one of the three replicates yielded data that were deemed unreliable since they were very different from the other two replicates and also outside the trend observed across the experimental data set as a whole. This replicate was therefore excluded. When appropriate, one-way analysis of variance (ANOVA) was used to statistically compare emission losses between treatments at the 95% confidence level. This analysis was performed in Microsoft Office Excel 2007.

Degradation Study. Degradation kinetics of 1,3-D and CP in each formulation were also determined for the Arlington soil. Moist (5% gravimetric moisture content) soil (10 g) was placed into a 20 mL glass vial and 200 μg of fumigant added (total amount of 1,3-D plus CP) for each treatment/replicate. The vials were immediately capped (Teflon-faced butyl caps) and placed at 25 °C. At times 0 (immediately after adding fumigant), 2, 4, 8, 24, 48, 72, 144, and 240 h triplicate vials were removed and placed at −19 °C. At the end of the experiment, 10 g of anhydrous sodium sulfate and 10 mL of ethyl acetate were quickly added to each frozen vial before immediate recapping, shaking for 1 h, and subsequent removal of 1 mL of supernatant to an amber GC vial for GC analysis. Extraction efficiencies were determined as ~80% for both chemicals. Degradation loss of 1,3-D and CP from the soil was fitted with a first-order kinetic model to calculate the degradation rate constant and half-life for each chemical in each treatment.

Analysis. Analysis of sorbent tube and soil solvent extracts was carried out using an Agilent Technologies 7890C GC, equipped with a microelectron capture detector. The column was a DB-VRX 122-1534 with dimensions of 30 m × 0.25 mm × 1.4 μm (Agilent Technologies) running at a flow rate of 1.4 mL min^{-1} and with He as the carrier gas. The inlet temperature was 240 °C and the detector temperature, 290 °C. The GC oven temperature was maintained at 45 °C for 1 min after sample injection, increasing to 80 °C at a rate of 2.5 °C min^{-1} and then to 120 °C at a rate of 30 °C min^{-1}, before being held at this temperature for 2 min. Under these conditions, retention times of *cis*-1,3-D, *trans*-1,3-D, and CP were 11.0, 12.3, and 13.8 min, respectively. Sets of eight standards encompassing the range of concentrations of the samples were prepared from the Telone II (1,3-D only) and TriClor (CP only) formulations. Standards were prepared in the same solvent as the samples. 1,3-D data are reported as total 1,3-D (i.e., the sum of the *cis* and *trans* isomers).

RESULTS AND DISCUSSION

Figure 1 shows total emission losses of 1,3-D and CP (as a percentage of the amounts added) for each formulation. Total emissions of 1,3-D (~30−35% across all treatments) were broadly consistent with previously published values for both field[17−19] and laboratory[15,16] studies. One-way ANOVA testing showed no statistically significant differences ($p > 0.05$) in 1,3-D emissions across the treatments. The relative consistency of 1,3-D total emissions across the treatments indicates that co-formulation of this fumigant with CP did not affect 1,3-D emission behavior from the columns, consistent with previously published work (Table 1). Conversely, total CP emissions varied widely across the treatments, increasing monotonically from 0.018 to 14% as the amount of CP in the formulation increased (Figure 1).

In general, emission flux curves followed the expected trend of a peak in emissions shortly after application, followed by a gradual decline and tailing of the curve over time (data not

J. Agric. Food Chem. 2015, 63, 415−421

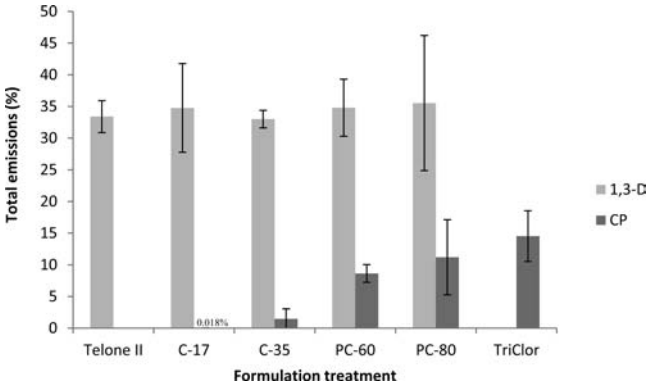

Figure 1. Total 1,3-D and CP emission losses (as percentage of amount added) for each treatment. Average CP emissions for the C-17 treatment were 0.018% (standard deviation = 0.018%).

shown). For formulations containing both 1,3-D and CP, this tailing occurred over a longer period for 1,3-D than for CP, probably due to the longer degradation half-life of the former.[15] Of significance in the assessment of the effects on air quality and risk assessment of fumigant operations is the maximum flux, in terms of both its magnitude and its timing. For each treatment, these variables are shown in Table 2. Peak emission flux generally occurred very rapidly after fumigant application, typically within 12 h. Compared to each fumigant applied singly, peak fluxes across the treatments generally declined in response to decreasing percentage (or mass) of each fumigant in the treatment. However, this relationship was not proportional as is particularly noticeable for the treatments with low CP levels. For example, the peak CP flux in the C-17 treatment was only 0.07% of the peak flux in the CP-only treatment despite containing 17% of the total CP level of this treatment. Similarly, the value for the C-35 treatment was just 6.3%, despite containing 35% of the CP amount in the CP-only treatment. Such dramatically disproportional differences were not observed across the 1,3-D treatments. Overall, CP again showed very different emission flux behavior from 1,3-D.

These experiments were conducted in an attempt to elucidate observations made during a meta-analysis of a number of published field studies in which co-application of 1,3-D and CP as the commercial product C-17, C-35, or Inline (a commercial drip application product with 33% CP and 61% 1,3-D), or as CP applied singly, was performed (Table 1). This meta-analysis, where the data from a number of independent studies were combined in a weight-of-evidence approach, suggested a hypothesis that chloropicrin emissions are reduced in the presence of 1,3-D. For example, on average, for this data set as a whole, co-application across 22 studies yielded approximately 4.5 times lower CP emissions (8% total emissions) than single CP application across 18 independent studies (36% total emissions). If only shank applications are considered (the same as emulated in the present study), the difference in CP emissions between co-formulation (10% total CP emissions) and single application (53% total CP emissions) is even greater. For drip applications, the difference in total CP emissions is lower but still marked (7% for co-application and 14% for single CP application). Clearly, emission reduction strategies, such as tarping, may be an important factor affecting emission levels across the collated studies, some of which were tarped whereas some were not. However, large differences in CP emissions between co-application and single CP application are similarly observed if tarping is removed as a potential factor. For example, for tarped shank applications, CP emissions averaged 8% with co-application and 50% with single application. With nontarped shank applications the values were 11 and 57%, respectively. In addition to an apparent effect on total CP emissions, the maximum emission flux of CP also seemed to be affected by co-formulation of CP with 1,3-D across these studies (Table 1). The maximum CP emission flux (normalized to an effective application rate of 112 kg ha^{-1} (100 lb acre^{-1})) for shank applications was reduced by >5 times from 52 μg m^2 s^{-1} with a single application to 8 μg m^2 s^{-1} with co-application. On the basis of anecdotal evidence, these results are also consistent with the experience of growers and applicators in the field, who have observed that chloropicrin is rarely detected (by olfactory sense or lachrimation) in Telone C-17 applications in the Pacific Northwest.

Overall, these collated field data broadly concur with our soil column studies in suggesting that when CP is co-applied with 1,3-D, total CP emissions and emission fluxes are reduced compared with CP applied alone. However, our column studies allow for a more detailed analysis of the relationship between the percentage of CP in a co-formulation and CP emissions. Indeed, for the column data, one-way ANOVA testing revealed that CP percentage in the formulation was statistically a highly significant (p = 0.008) factor affecting total CP emissions. We further observed a strong positive relationship (R^2 = 0.99) between CP percentage in a formulation and CP emissions (Figure 2), indicating that as CP levels decreased (and, consequently, 1,3-D levels increased) in the co-formulation, a process occurred to limit CP emissions from the soil. However, this relationship was not linear, but was rather best fitted with a

Table 2. Average Peak Emission Flux and Its Timing, Degradation Rate Constant, and Half-Life for 1,3-Dichloropropene (1,3-D) and Chloropicrin (CP) across All Treatments

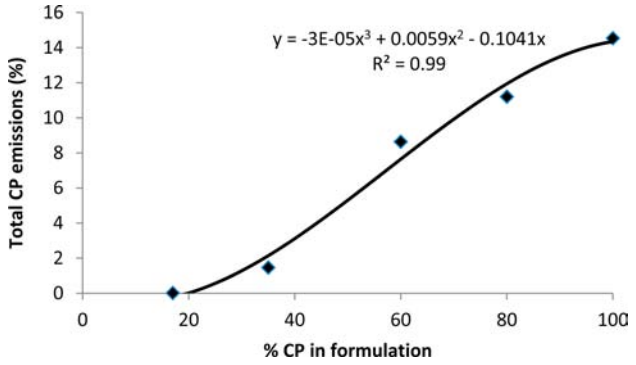

Figure 2. Relationship between percentage CP in the formulation and total CP emissions (percentage of amount added). Fitted line is a third-order polynomial.

third-order polynomial equation, which suggested a disproportional relationship between total CP emissions and CP percentage in the formulation (similar to the CP emission flux data). We are not aware of any previously published data that report this relationship.

In the column system, two processes are considered to dominate fumigant fate and transport, emissions and degradation. Because determining in situ degradation rates within the column is not possible, a separate degradation study was performed to quantify this parameter for each formulation product. In this degradation study, the total fumigant mass (1,3-D + CP) addition at the start of the experiment was the same for each formulation treatment. Subsequent loss of fumigant was attributed to soil degradation. Fitting a first-order kinetic model to the loss of fumigant over time yielded the degradation rate constants and half-lives shown in Table 2. At the lowest level of CP addition (C-17), CP half-life was just 2.5 h and at the highest level (CP only), was 66.6 h. As shown in Figure 3, a

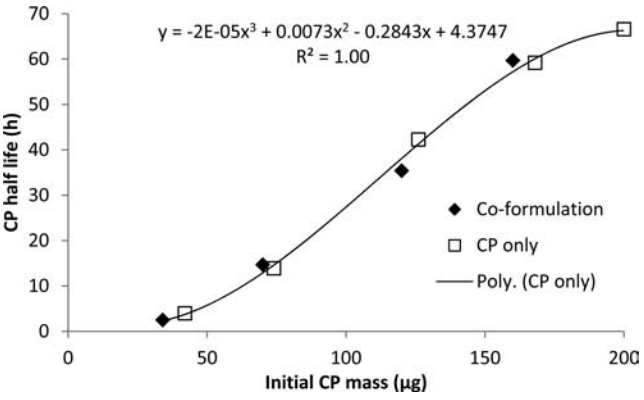

Figure 3. Relationship between initial CP mass added and CP degradation half-life in the presence (co-formulation data points) and absence (CP-only data points) of 1,3-D. The co-formulation data points are, from left to right, C-17, C-35, PC-60, and PC-80. Fitted line is third-order polynomial.

strong positive relationship between initial CP mass added in the formulation and CP half-life was observed across all treatments. For 1,3-D, across the six formulation products, half-lives ranged from 144 to 231 h, and no consistent relationship between half-life and percentage of 1,3-D in the formulation was observed. Therefore, in contrast to CP, it was concluded that the initial mass of 1,3-D was not significant in dictating the half-life of this fumigant. To determine whether the degradation of CP was related to the co-presence of 1,3-D, half-lives for various initial CP masses were determined in a separate degradation study in which approximately equivalent initial amounts of TriClor (CP only) were added to soils (i.e., in the absence of 1,3-D). The strong overlap between the data sets for CP degradation both in the presence and in the absence of 1,3-D (Figure 3) indicates that CP degradation rate was not affected by the presence of 1,3-D.

Because the total amount of fumigant (1,3-D + CP) added to each treatment of the degradation study was the same, the amounts of applied CP varied across the treatments. As shown in Figure 3, the initial CP mass controlled its degradation rate within the soil, with smaller masses degrading more rapidly. The dependency of fumigant degradation upon initial mass or concentration has been previously observed,[20,21] and rapid degradation (half-life of 2.9 h) of CP in sandy loam soil has also been reported when the initial concentration was low (10 μg^{-1}).[15] With a lower initial concentration, the number of biological and chemical sites available for degradation is greater per unit mass of fumigant. At higher initial concentrations, competition for such sites is likely greater, leading to a lower degree of degradation. Although this process may explain the degradation behavior of CP, it does not explain why 1,3-D was not affected in a similar way. However, Zheng et al.[11] noted that for soil collected from the same field as the current study, autoclave sterilization led to a >6 times increase in CP half-life from 9 days to 57 days when compared to control soil, demonstrating the significant influence microbial populations have on CP degradation rates. For 1,3-D, however, the increase due to sterilization was much less marked, from 139 to 193 days (averages of *cis* and *trans* isomers). This apparently strong dependence upon biological processes suggests that the suppression or death of soil microbes at high CP concentrations may induce slower CP degradation. The observed differences in CP degradation rate across the formulations provide a highly probable explanation for the observed trend in column CP total emissions and emission fluxes. A positive linear relationship (R^2 = 0.97) was observed between CP half-life and total emissions across the formulations. This strongly suggests that dramatically faster degradation in formulations with lower levels of CP resulted in relatively low amounts of CP available for emission to air. The degradation studies further suggested that this effect occurred irrespective of 1,3-D presence. Therefore, although there were significant differences in CP emissions across the formulations, this cannot be attributed to a 1,3-D/CP co-formulation effect. This suggests that we would expect the same CP emissions as those observed in the current column experiment if it was carried out using equivalent initial application masses of CP alone.

From an air quality perspective, the low CP emissions from certain co-formulations are clearly beneficial. The results have implications for volatility and environmental fate modeling of CP because its degradation rate is not often considered in relation to its initial application mass. The calculation of buffer zone sizes around fumigated fields is based on a linear scaling of empirically derived emission losses from studies utilizing the maximum labeled application rates. Therefore, the relationship between emission flux and application rate is assumed to be linear and have a slope of 1; that is, doubling the application rate would double the emission flux. Translating the current work into this broader context can be achieved by regressing maximum CP flux (commonly used as the primary indicator of fumigant impact on local air quality) against CP application rate

DOI: 10.1021/jf506010b
J. Agric. Food Chem. 2015, 63, 415−421

(Figure 4). In this case, although the relationship is linear, the slope is <1 (i.e., 0.22), indicating a disproportional effect of

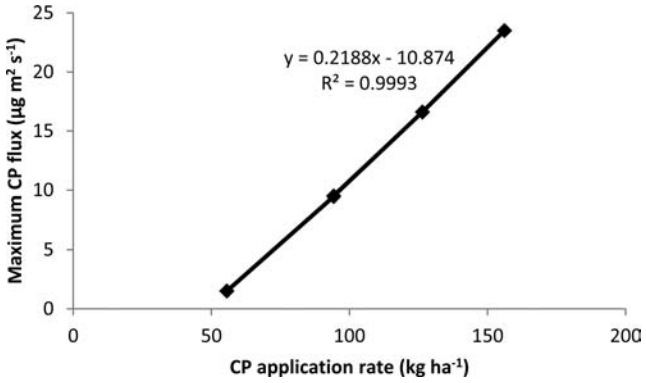

Figure 4. Relationship between CP application rate and CP peak emission flux from soil columns. The data points are, from left to right, C-35, PC-60, PC-80, and TriClor (CP only). The data point for C-17 did not fit the linear trend.

application rate on emission flux within this range of application rates. For example, Table 1 indicates that with C-35 application to the soil columns (CP application rate equivalent to 55.6 kg ha^{-1}) the peak flux was 1.5 $\mu g\ m^2\ s^{-1}$, whereas Figure 4 indicates that with a doubling of this application rate, the peak flux would more than double to 13.5 $\mu g\ m^2\ s^{-1}$, that is, a 9 times increase. Overall, this work suggests that at low CP application rates, smaller buffer zones may be adequate to protect public health because, due to more rapid degradation of CP in the soil, emissions would be disproportionately lower than suggested by a linear scaling approach. The observations presented in this paper may help to more accurately predict such emissions.

ABSTRACT: Solid lipid nanoparticles (SLN) containing the herbicides atrazine and simazine were prepared and characterized, and in vitro evaluation was made of the release kinetics, herbicidal activity, and cytotoxicity. The stability of the nanoparticles was investigated over a period of 120 days, via analyses of particle size, ζ potential, polydispersion, pH, and encapsulation efficiency. SLN showed good physicochemical stability and high encapsulation efficiencies. Release kinetics tests showed that use of SLN modified the release profiles of the herbicides in water. Herbicidal activity assays performed with pre- and postemergence treatment of the target species *Raphanus raphanistrum* showed the effectiveness of the formulations of nanoparticles containing herbicides. Assays with nontarget organisms (*Zea mays*) showed that the formulations did not affect plant growth. The results of cytotoxicity assays indicated that the presence of SLN acted to reduce the toxicity of the herbicides. The new nanoparticle formulations enable the use of smaller quantities of herbicide and therefore offer a more environmentally friendly method of controlling weeds in agriculture.

KEYWORDS: *environmental nanotechnology, herbicides, nanoparticles, herbicidal activity*

INTRODUCTION

The growing demand for food to sustain the global population has resulted in increased efforts to maximize agricultural production.[1] However, the presence of weeds that directly compete with crops for light, water, and nutrients can adversely affect productivity.[2] Herbicides that are widely used to control weeds offer advantages such as rapid action, flexibility in terms of the timing of application, and the ability to treat extensive areas.[3] Atrazine (2-chloro-4-ethylamine-6-isopropylamine-*s*-triazine) and simazine [2-chloro-4,6-bis(*s*-ethylaminotriazine)] are members of the triazine family of herbicides that have low solubility in water (30 and 5 mg/L, respectively) and a mechanism of action based on the inhibition of photosynthesis (due to their action on photosystem II); they are used in the pre- and postemergence control of weeds.[4]

A disadvantage associated with the use of herbicides lies in the fact that these substances have a wide range of different molecular structures and properties, which influences their behavior in the environment in terms of persistence, mobility, and toxicity.[5] Repeated applications are often required in order to achieve the desired results, which can increase adverse effects on the environment and nontarget organisms.[6]

The use of nanotechnology in agriculture has received increasing attention, with the development of new formulations containing active compounds.[6−8] The main objectives of these formulations are to (i) increase the solubility of active compounds, (ii) provide slow release, and (iii) provide protection against premature degradation. The use of carrier systems offers advantages, compared to conventional systems, because they can increase the biological activity of active substances, reduce the quantities necessary, and diminish the risk of contamination of hydric resources due to leaching.[9,10]

A wide range of different particles can be used, obtained from a variety of matrices and preparation procedures.[11] Solid lipid nanoparticles, whose matrices consist of lipids that are solid at ambient temperature, are particularly useful as carrier systems for nonpolar substances. They possess good physicochemical stability, promote sustained release of the active principle from the solid matrix, and can be metabolized by a variety of organisms.[12,13]

Many different types of carriers have been developed for the modified release of agricultural pesticides, including cyclodextrins,[14,15] clays,[16,17] silica,[18] lignin,[19] polymeric microparticles,[20−24] and nanoparticles.[25−27] Recent review articles have described advances in the use of modified release systems for active agents of interest in the agricultural sector.[28,29]

In a previous study,[26] nanoparticles of poly(ε-caprolactone) were developed as a carrier system for atrazine, and the results obtained with target organisms (*Brassica* sp.) showed the effectiveness of these formulations of nanospheres and nanocapsules, compared to a commercial formulation.

The objective of the present work was to prepare and characterize solid lipid nanoparticles used as a carrier system for a combination of the two herbicides atrazine and simazine. The use of a combination of two herbicides is a technique widely used in weed control, and in association with other procedures is an effective strategy for the control of vegetation. The

presence of more than one herbicide can broaden the range of target weeds, reduce costs, and help to prevent the emergence of plants resistant to the herbicides.

The advantage of using solid lipid nanoparticles loaded with two different herbicides lies in improved efficiency of the formulation, while at the same time helping to reduce toxicity to nontarget organisms and the wider environment. Concerning the use of polymeric nanoparticles,[26] lipid nanoparticles were selected for use in the present work, because they offer high colloidal stability as well as competitive production costs and ease of scale-up.

Evaluation of the characteristics and stability of the nanoparticles was performed by measurements of particle size (by means of dynamic light scattering), ζ potential, pH, polydispersion index, and encapsulation efficiency, as a function of time (up to 120 days). Particle morphology was investigated by transmission electron microscopy (TEM), and nanoparticle tracking analysis (NTA) was employed to measure the concentration and size distribution of the particles. The profiles of release of the herbicides from the SLN were investigated, and cytotoxicity of the formulations was evaluated via cellular viability assays with 3T3 cells. The effectiveness of the formulation was determined in herbicidal activity assays with pre- and postemergence treatment of the target species *Raphanus raphanistrum*. The same assays were repeated with *Zea mays* in order to determine the effects of the formulation on a nontarget organism. The goal was to develop a formulation suitable for future use in agriculture that provided increased effectiveness, while using smaller quantities of herbicides and reducing possible adverse impacts on the environment and human health.

MATERIALS AND METHODS

Materials. The reagents atrazine, simazine, poly(vinyl alcohol) (PVA; 30−70 kDa), and glycerol tripalmitate were obtained from Sigma−Aldrich. The solvents chloroform and acetone were acquired from Labsynth. Acetonitrile and methanol (HPLC-grade) were obtained from J. T. Baker. Seeds of *Raphanus raphanistrum* and *Zea mays* were purchased from ISLA Sementes. The substrate used to cultivate the plants was obtained from Hortaliça Mix.

Production of Solid Lipid Nanoparticles Containing Herbicides. SLN were prepared according to the method of emulsification with solvent evaporation, described in a previous report.[30] The lipid phase was prepared from 5 mL of chloroform, 250 mg of glycerol tripalmitate, and 5 mg each of atrazine (ATZ) and simazine (SMZ). After preparation, the lipid phase was inserted into an aqueous phase composed of 1.25% (m/v) PVA and the mixture was sonicated (Unique DES500) for 4 min at a power of 40 W. The pre-emulsion formed was then submitted to high-speed Ultraturrax homogenization (Tecnal TE-102) at 14 000 rpm for 7 min. After this step, the chloroform was removed by evaporation in a rotary evaporator and the sample was concentrated to obtain final concentrations of ATZ and SMZ of 0.5% (m/v).

Quantification of Atrazine and Simazine and Determination of Encapsulation Efficiency. The herbicides were quantified by high-performance liquid chromatography (HPLC) employing a Varian ProStar instrument (Agilent Technologies) fitted with a model PS 210 pump, a UV−vis detector operated at a wavelength of 225 nm, and a Phenomenex Gemini C^{18} reverse-phase column (5 μm, 250 × 4.6 mm) kept at a temperature of 25 °C. The mobile phase was composed of acetonitrile and deionized water (50:50 v/v), at a flow rate of 0.8 mL/min. Both herbicides were quantified in the same chromatographic run. The limits of detection and quantification, respectively, were 0.21 μg/mL and 0.71 μg/mL (atrazine) and 0.18 μg/mL and 0.60 μg/mL (simazine).

Determination of the efficiency of encapsulation of herbicides in nanoparticles was performed by the ultrafiltration/centrifugation technique, employing ultrafiltration devices containing a cellulose membrane with a molecular exclusion pore size of 10 kDa (Microcon, Millipore). The filtrate was collected, and the concentrations of the nonencapsulated herbicides were quantified by HPLC. The encapsulation efficiencies could then be determined by the difference between total amounts (100%) of the herbicides and the amounts found in the filtrate. The measurements were performed in triplicate after 0, 15, 30, 60, and 90 days.

CHARACTERIZATION OF NANOPARTICLES

Measurements of Size Distribution (by Dynamic Light Scattering) and ζ Potential. Hydrodynamic diameter and polydispersion of the particles were determined by the dynamic light scattering technique, on a Zetasizer ZS 90 instrument (Malvern Instruments). The ζ potential was determined by microelectrophoresis, on the Zetasizer ZS 90. Nanoparticles (with and without herbicides) were diluted in deionized water (1:1000 v/v) and analyzed at 25 °C, with the detector at a fixed angle of 90°. Results were expressed as the average of three determinations. In order to determine the stability of the system as a function of time, the samples were analyzed after 0, 15, 30, 60, and 90 days.

Nanoparticle Morphology Determined by Transmission Electron Microscopy. SLN morphology was evaluated by use of a Zeiss-LEO microscope (Model 906). The samples were prepared from droplets of a suspension of nanoparticles (with or without herbicides), which were deposited onto 200-mesh copper grids and allowed to dry for 15 min. After this period, a droplet of uranyl acetate solution (2%) was added to each grid, as a contrast agent, and the excess solution was removed with tissue paper. After drying, the samples were analyzed by use of the microscope operated at a voltage of 80 kV.[31]

Determination of Particle Size Distribution and Concentration by Nanoparticle Tracking Analysis. Concentration and size distribution of the solid lipid nanoparticles was investigated by the nanoparticle tracking analysis technique. Equipment comprised a NanoSight LM 10 cell (green laser, 532 nm) and a sCMOS camera controlled via NanoSight v.2.3 software. The SLN suspensions were diluted 11 000 times, and each sample was analyzed in triplicate. In order to ensure that different particles were analyzed, each replicate used 1 mL of sample suspension injected into the volumetric cell in order to displace the contents that had been measured previously. Each repetition consisted of five measurements, with approximately 2000 particles counted in each analysis. The final result was the size-distributed number concentration of the particles.[32]

Evaluation of Interaction of Herbicides with Nanoparticles by Differential Scanning Calorimetry and Fourier Transform Infrared Spectroscopy. In differential scanning calorimetry (DSC) analyses, 5 mg portions of each sample (herbicides, nanoparticles, and lipids) were weighed on an analytical balance, placed in sealed aluminum pans, and analyzed on a model Q20 instrument (TA Instruments). The thermal program consisted of a heating ramp from 5 to 250 °C, at a rate of 10 °C/min, under a flow of nitrogen (50 mL/min). An empty pan was used as a reference. These measurements were performed for all the sample materials (atrazine, simazine, tripalmitin, a tripalmitin/atrazine/simazine physical mixture, SLN alone, and SLN containing atrazine and simazine).

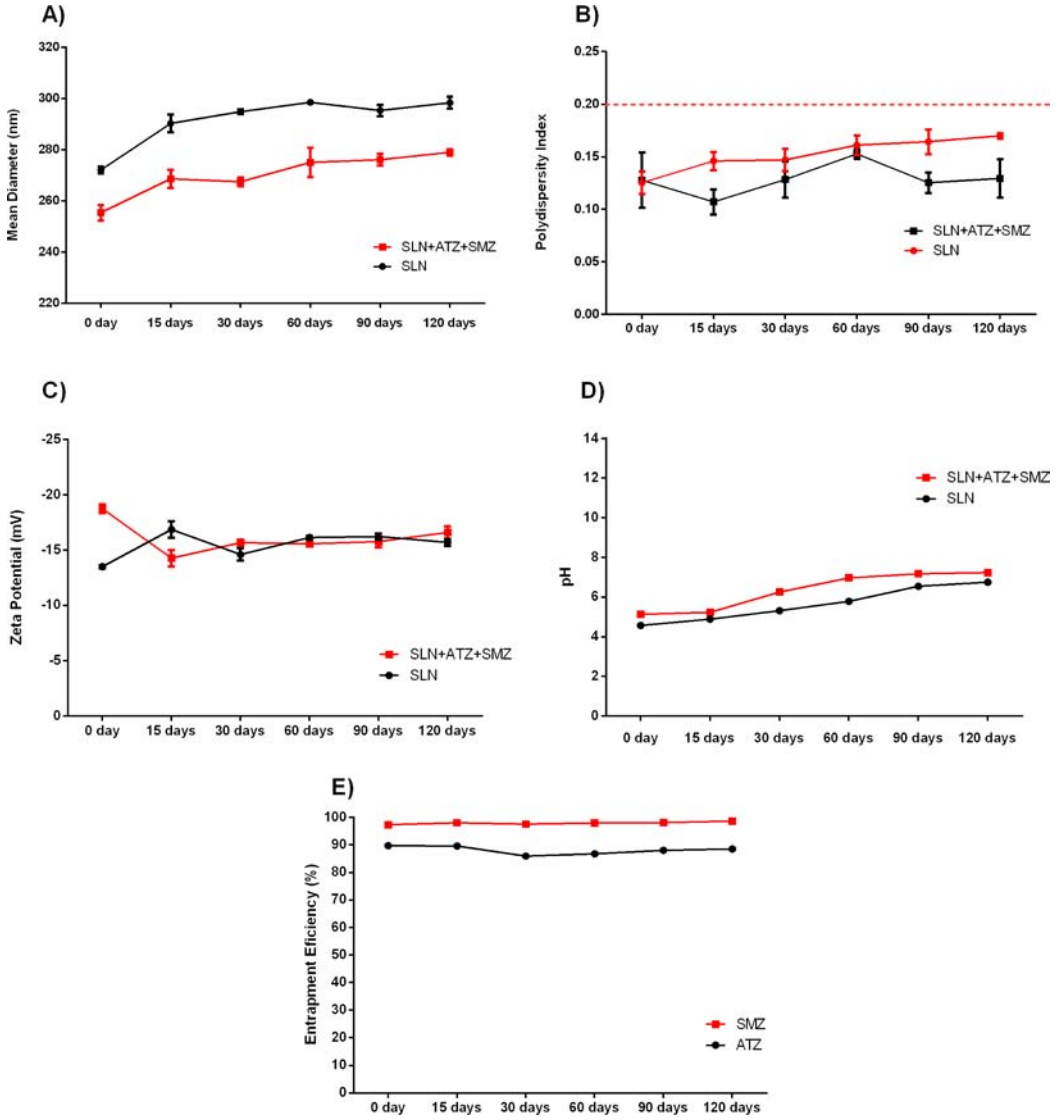

Figure 1. Stability of nanoparticles over a period of 120 days. SLN, solid lipid nanoparticles; SLN + ATZ + SMZ, solid lipid nanoparticles containing atrazine and simazine. (A) Hydrodynamic diameter of nanoparticles; (B) polydispersity index; (C) ζ potential; (D) pH; (E) encapsulation efficiency.

Fourier transform infrared (FTIR) analyses were performed on a Model 660 (Varian) spectrometer fitted with an attenuated total reflectance accessory (GladiATR, Pike Technologies) equipped with a diamond crystal (2.2 × 3.0 mm). The wavenumber range used was from 4000 to 400 cm^{-1}, the incidence angle was 45°, and 32 scans were collected for each sample, at a resolution of 8 cm^{-1}. The types of samples analyzed were the same as those used in the DSC analyses.

Release Kinetics Assays and Mathematical Modeling of the Data. Kinetics of release of ATZ and SMZ, free or encapsulated in SLN, was investigated in a two-compartment system with donor and acceptor compartments. The donor compartment contained 2 mL of the formulation and was separated from the acceptor compartment by a Spectrapore cellulose membrane with a molecular exclusion pore size of 1 kDa. The system was constantly agitated under "sink" conditions. Aliquots of 1 mL were collected at intervals of 15, 30, and 60 min during the first 7 h, after which a further two aliquots were collected at 24 h intervals, up to a maximum time of 55 h. The analyte concentrations were determined by HPLC and used to determine the percentage release of the herbicides. The experiments were performed in triplicate.[26]

The results of the release experiments were used to calculate the apparent flux values (J_{app}), according to Fick's first law (eq 1), using the slope of the linear section of the plot of the values:

$$M_t = M_0 - SJt \quad (1)$$

where M_t is the cumulative amount of the active agent released through the membrane of area S, as a function of time t, and M_0 is the total quantity of the active agent.[33,34]

The type of mechanism governing the release of herbicides from nanoparticles was elucidated by use of the Korsmeyer–Peppas model (also known as the power law).[35,36]

Evaluation of Cytotoxicity of Nanoparticles Containing Herbicides. Assessment of cytotoxicity was performed by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. Balb-c 3T3 mouse fibroblast cells were kept in continuous culture at 37 °C, under a humid atmosphere containing 5% CO_2. The culture medium used was Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum, 100 units/mL penicillin, and 100 μL of

streptomycin sulfate. The cells were plated out and, after a period of 48 h, were exposed for 24 h to a commercial formulation of herbicides (Primatop, Syngenta) and to nanoparticle suspensions (with and without herbicides). The herbicide concentrations tested were 0, 15.6, 31.25, and 62.5 μg/mL. Cellular viability was determined by the mitochondrial reductase activity of live cells, which causes conversion of the yellow tetrazolium salt to blue/purple crystals of formazan. After the 24 h period, the cells were incubated with MTT (0.5 mg/mL) for 3 h at 37 °C, followed by dissolution of the formazan crystals by agitation for 30 min in ethanol. The number of viable cells was then determined by colorimetric analysis (at a wavelength of 570 nm) employing a microplate reader (Multiskan MS, Labsystems).[37,38]

Herbicidal Activity Assays. Herbicidal activity was evaluated by means of pre- and postemergence treatments employing the target species *Raphanus raphanistrum* (wild radish) and nontarget species *Zea mays* (maize). Applications were made of commercial formulation (Primatop, Syngenta) and SLN containing herbicides, at concentrations equivalent to the recommended dosage (3 kg/ha). Control treatments consisted of nanoparticles without herbicides, applied at the same dilutions as the suspensions of nanoparticles containing herbicides, as well as water alone. The plants were cultivated in containers with a height of 17 cm and an upper diameter of 5.2 cm, which were completely filled with the substrate (Hortaliça Mix). One seed was planted in each container. For the preemergence treatment, the formulations were applied to the substrates by spraying soon after planting the seeds. After 13 days, the plants were collected and washed, and measurements were made of the fresh aerial parts and roots. For the postemergence treatment, the formulations were applied in the form of a spray 7 days after planting, and measurements of the aerial and root parts were made after a further 7 days of cultivation. The treatments were repeated for 1:10 (v/v) dilutions of the formulations (equivalent to application of herbicides at a rate of 0.3 kg/ha). Each test (pre- and postemergence) was performed with triplicates of five containers. The values obtained for the masses of the plants were calculated as means and standard deviations, and statistical evaluation employed analysis of variance (ANOVA) with the Tukey–Kramer test. These analyses were performed with GraphPad Prism v6 software.

RESULTS AND DISCUSSION

The purpose of this work was to develop solid lipid nanoparticles as a carrier system for the two herbicides (simazine and atrazine), offering an alternative technique for weed control. In earlier work by our research group,[26] polymeric carrier systems were developed for atrazine, and good results were obtained in terms of effectiveness of formulations. Meanwhile, in the present work, we use the strategy of associating two different herbicides in order to achieve more effective weed control, reducing costs, and helping to avoid the development of plant resistance.[39,40] Combinations of the herbicides atrazine and simazine are available commercially under various brand names (Controller 500 SC, Extrazin SC, Herbimix SC, Primatop SC, and Triamex 500 SC), and all are specifically registered for use in maize cultivations. The products are indicated for use at the preemergence stage, or after emergence, with weeds at the stage of 2–4 leaves, at dosages varying from 1.75 to 3.5 kg/ha^{-1}

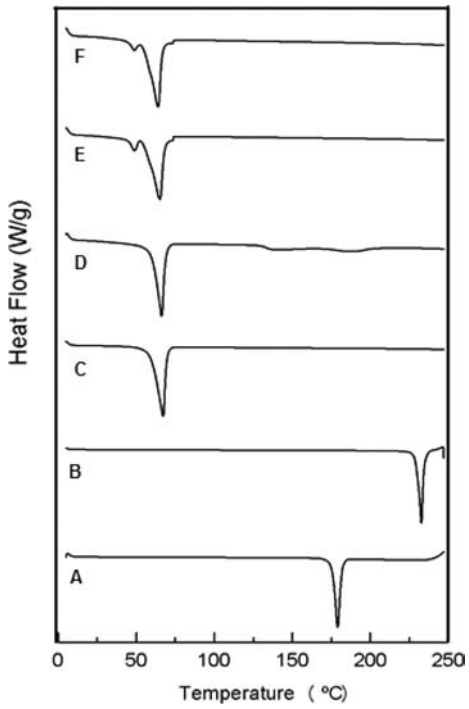

Figure 3. Differential scanning calorimetry evaluation of interaction between herbicides and components of the SLN formulation: Thermograms for (A) ATZ, (B) SMZ, (C) tripalmitin, (D) physical mixture, (E) SLN, and (F) SLN + ATZ + SMZ.

(equivalent to 3.5−7.0 L/ha of the commercial products). The dosage applied varies according to manufacturer and soil type, with smaller quantities used in the case of light soils, and greater quantities with clay soils or in the presence of high levels of organic matter.[41]

When the relative merits of solid lipid nanoparticles and polymeric nanoparticles of poly(ε-caprolactone) are considered, the great advantage of the former lies in their lower production costs, which makes them commercially attractive for use in agricultural applications. The following discussion describes the results obtained for this new formulation containing two herbicides.

Stability of Solid Lipid Nanoparticles. The stability of the nanoparticles was investigated over a period of 120 days, by measurements of hydrodynamic diameter, ζ potential, polydispersion index, pH, and encapsulation efficiency (Figure 1). At the beginning of the period, the hydrodynamic diameter of SLN without herbicides was 272.2 ± 1.35 nm, while nanoparticles loaded with herbicides showed a hydrodynamic diameter of 255.43 ± 3.01 nm. Hydrodynamic diameters of all the formulations increased significantly after 15 days of storage (Figure 1A). After this period, the SLN without the herbicides then remained stable up to the end of the trial (120 days).

The polydispersity index provides an indication of the homogeneity of size distribution of the particles. Values below 0.2 are considered to be indicative of good stability, with the particles present within a narrow size range.[42] Soon after preparation, the formulations showed polydispersity index values below 0.15 (Figure 1B). The values then increased

formulation	F_{app} (mg·m^{-2}·h^{-1})
ATZ	428.0 ± 43.74
SMZ	322.8 ± 31.5
SLN + ATZ + SMZ: ATZ	50.9 ± 0.69
SLN + ATZ + SMZ: SMZ	13.8 ± 1.04

Table 2. Values of Release Constant k, Release Exponent n, and Correlation Coefficient r Obtained by Mathematical Modeling

formulation	k (min^{-1})	n	r
SLN + ATZ + SMZ: ATZ	0.40 ± 0.03	0.76	0.9829
SLN + ATZ + SMZ: SMZ	0.31 ± 0.05	0.83	0.9814

over the period of the trial, but remained below 0.2, indicating satisfactory stability of the formulations as a function of time.

The ζ potential is a parameter that can be used to evaluate the stability of colloidal systems. However, in the present work, the PVA surfactant used during preparation of the formulations was adsorbed on the surface of the particles, creating a layer that provided steric stabilization. Hence, the measured ζ potential values reflected the charges on the particles, while here the stability of the particles was related to steric hindrance caused by the presence of PVA molecules on the surfaces of nanoparticles and not by the surface charge, as reported previously.[43] The SLN formulations showed negative ζ potential values that were not affected by encapsulation of the herbicides (Figure 1C). After 30 days of storage, an average value of −15 mV was obtained, which remained stable up to the end of the trial.

Figure 1D shows the profile of variation of pH as a function of time, for all the formulations. The observed changes were the same for all the particles, probably due to the occurrence of hydrolytic processes in the medium (such as the hydrolysis of tripalmitin), as well as modification of the lipid matrix of the particles, including phenomena such as crystallization or recrystallization, which altered the ionic equilibrium of species present in the medium.[44] Another possible contributing factor was the degradation of PVA by hydrolytic processes, which could cause changes in the medium leading to an increase in pH. However, further work will be needed in order to obtain a better understanding of these phenomena.

Joint encapsulation of the herbicides resulted in encapsulation efficiencies of 89.7% ± 0.02% (atrazine) and 97.3% ± 0.05% (simazine), which remained stable over time. This indicated the effectiveness of SLN for encapsulation of herbicides, because despite the variations in particle size, pH, and ζ potential, the encapsulation efficiency remained

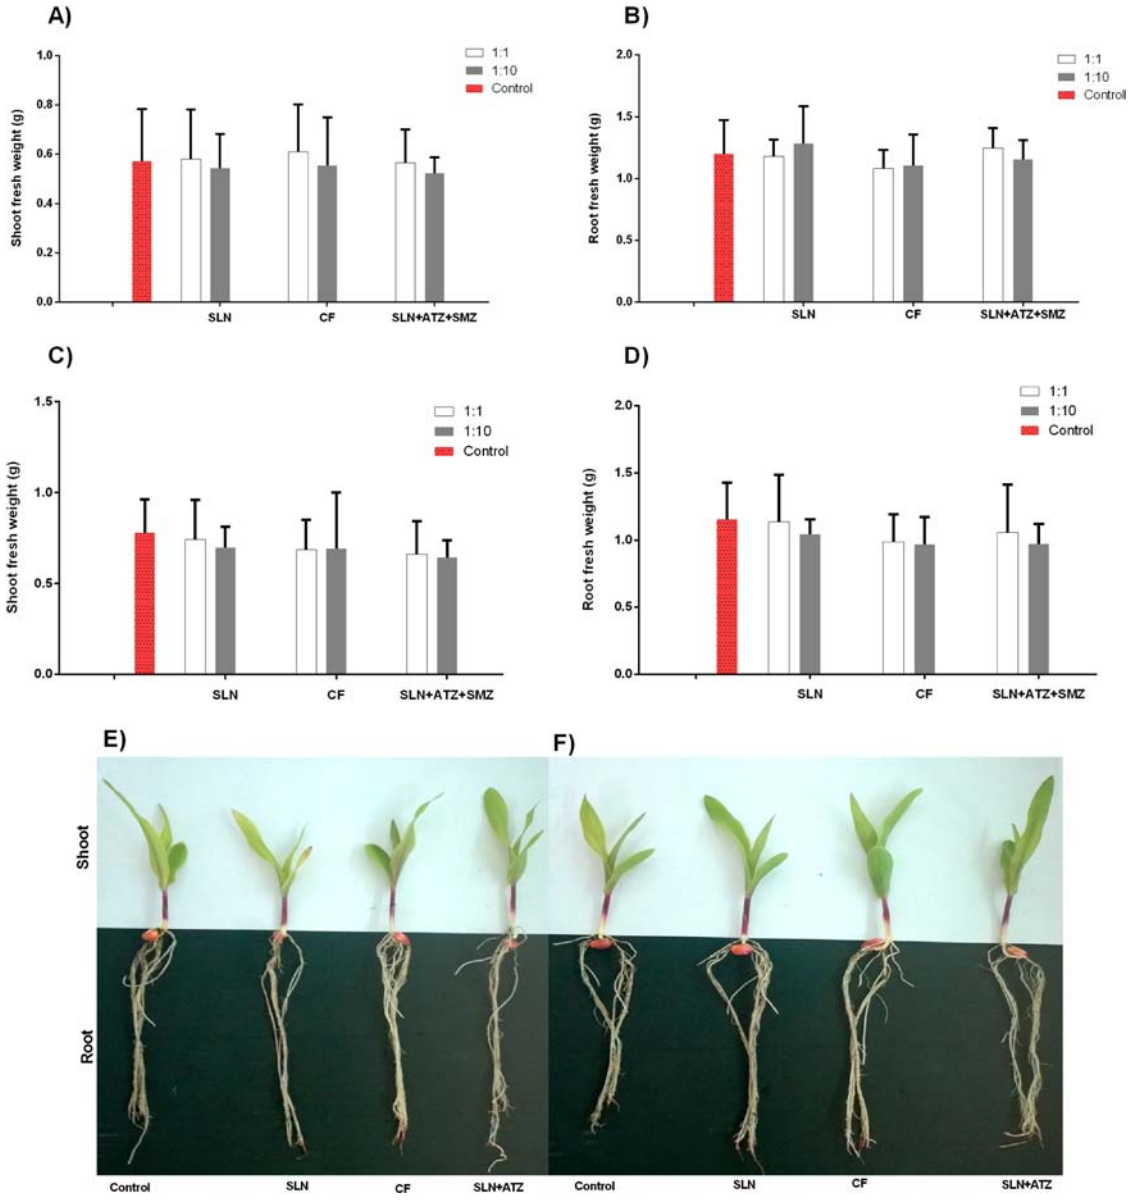

Figure 8. Effects of solid lipid nanoparticles (SLN), commercial formulation (CF), and solid lipid nanoparticles loaded with herbicides (SLN + ATZ + SMZ) on plant growth (nontarget species), at dosages equivalent to 3 and 0.3 kg/ha: (A) fresh masses of aerial parts after pre-emergence treatment; (B) fresh masses of roots after pre-emergence treatment; (C) fresh masses of aerial parts after postemergence treatment; and (D) fresh masses of roots after postemergence treatment. (E, F) Images of *Zea mays* plants after pre-emergence treatment at dosages equivalent to 3 and 0.3 kg/ha, respectively.

unaffected. The high values obtained can be explained by solubility of the herbicides in the lipid matrix, which is supported by their low solubility in water (30 mg/L for atrazine and 5 mg/L for simazine).[45]

Nanoparticle Morphology (Transmission Electron Microscopy). TEM micrographs of the SLN are shown in Figure 2. The particles obtained immediately after preparation were spherical, with average sizes of 111 ± 2.3 nm and 178 ± 3.1 nm in the presence and absence of herbicides, respectively (Figure 2A,B). These values were smaller than those obtained by photon correlation spectroscopy (PCS), which can be explained by the fact that the PCS technique measured the hydrodynamic diameter of the particles, while the TEM analyses employed dried samples.[27] Microscopic analyses performed at the end of the storage period showed that in the absence of herbicides, SLN remained spherical (Figure 2C), while SLN containing herbicides showed deformations (indicated by arrows in Figure 2D). This was reflected in the appearance of a new particle population with low intensity (Figure 2E) but high volume (Figure 2F), which corroborated the results obtained for hydrodynamic diameter, where a significant increase in particle size was observed after 120 days.

Interaction between Herbicides and Nanoparticles. Analyses employing differential scanning calorimetry (Figure 3) and infrared spectroscopy (Figure 4) were used to investigate the interactions of herbicides with SLN, as well as to determine whether the preparation process caused any changes in the components of the formulations.

DSC results revealed the presence of two narrow endothermic peaks, at 179 and 232 °C (Figure 3A,B), corresponding to the fusion points of atrazine and simazine, respectively. Figure 3C shows a peak at 64 °C, corresponding

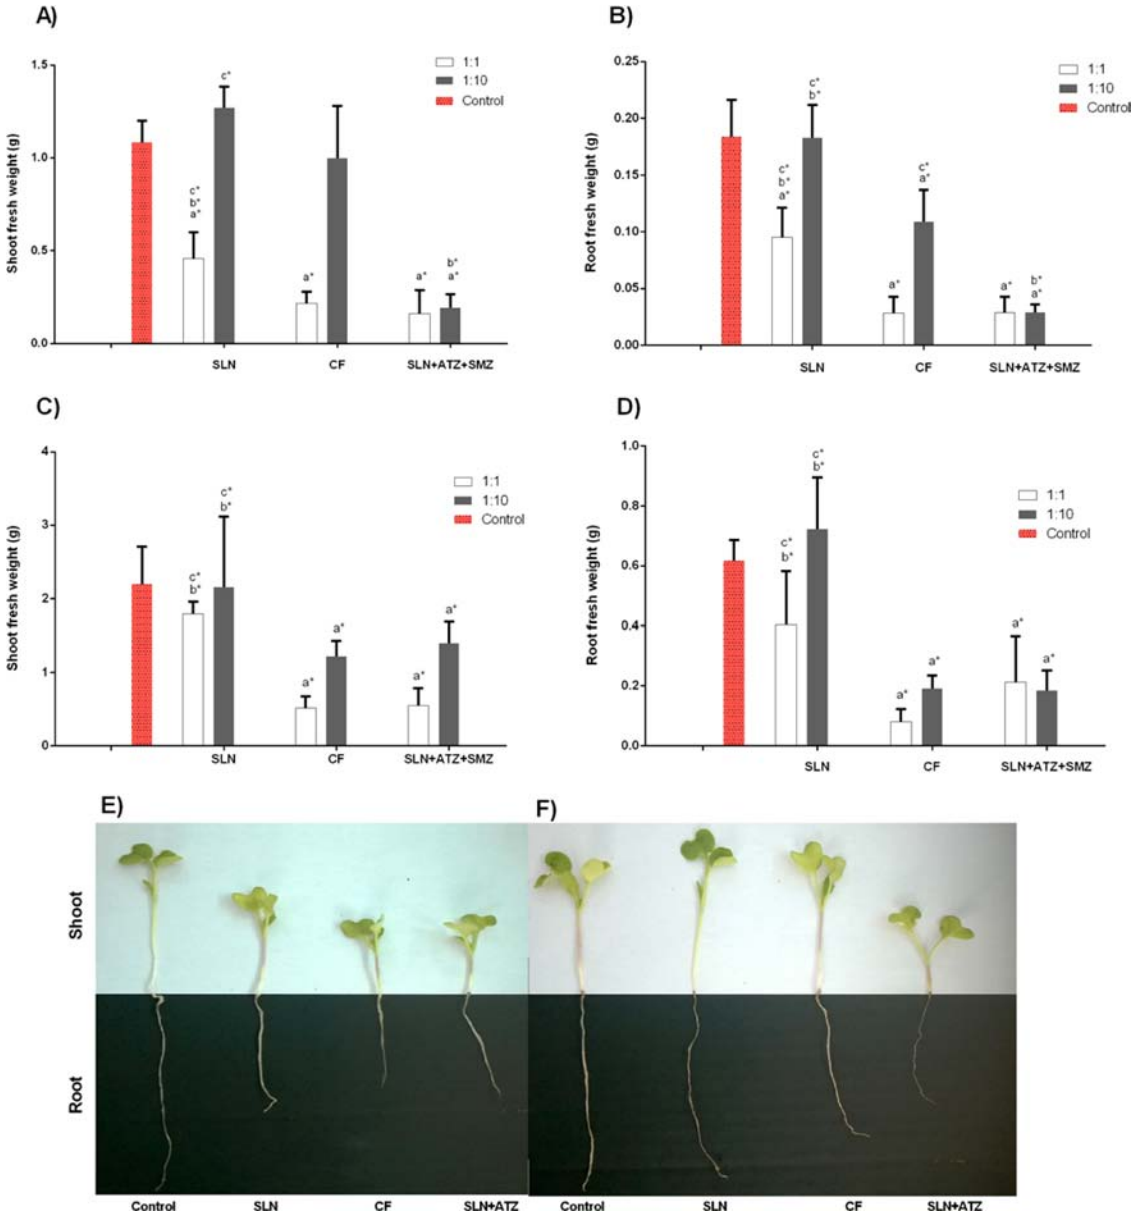

Figure 9. Effects of solid lipid nanoparticles (SLN), commercial formulation (CF), and solid lipid nanoparticles loaded with herbicides (SLN + ATZ + SMZ) on plant growth (target species), at dosages equivalent to 3 and 0.3 kg/ha: (A) fresh masses of aerial parts after pre-emergence treatment; (B) fresh masses of roots after pre-emergence treatment; (C) fresh masses of aerial parts after postemergence treatment; and (D) fresh masses of roots after postemergence treatment. (E, F) Images of *Raphanus raphanistrum* plants after pre-emergence treatment at dosages equivalent to 3 and 0.3 kg/ha, respectively. A significance level of $p < 0.05$ was considered for the differences obtained between groups, at the same application level, where a* indicates significant difference relative to the control; b* indicates significant difference relative to the commercial formulation; and c* indicates significant difference relative to SLN loaded with herbicides.

to the fusion point of the β form of pure tripalmitin lipid.[46] Results for the physical mixture of the components (Figure 3D) revealed two broad herbicide peaks, which were shifted due to interaction with tripalmitin. Analysis of SLN without herbicides (Figure 3E) showed a symmetrical peak at 64 °C, due to fusion of the β form of tripalmitin, and another peak at 48 °C, corresponding to recrystallization of the α form of tripalmitin.[47] In colloidal suspensions, lipids can show changes in crystallization and polymorphism, which consequently affect the fusion point.[47,48] In the case of SLN containing herbicides (Figure 3F), peaks characteristic of the fusion of forms α and β of tripalmitin were observed, but there were no symmetrical herbicide peaks at around 179 and 232 °C, indicating that the herbicides were dispersed throughout the nanoparticle matrix and were not present in the form of crystals.

The infrared spectra obtained for atrazine and simazine are shown in Figure 4 panels A and B, respectively. Similarities can be seen in the spectra, because both compounds belong to the triazine herbicide family, with specific bands at 3251 cm^{-1} corresponding to symmetrical and asymmetrical axial deformation of N−H, at 2972 cm^{-1} due to aliphatic C−H stretching and at 1616 and 1546 cm^{-1} due to deformation of C═C and C═N bonds, respectively. The spectrum of tripalmitin (Figure 4C) shows specific bands at 2914 cm^{-1} corresponding to stretching of alkyl group C−H, at 1733 cm^{-1} corresponding to stretching of ester C═O, and at 1173 cm^{-1} due to angular

DOI: 10.1021/jf5059045
J. Agric. Food Chem. 2015, 63, 422−432

deformation of C−O. The spectrum for the physical mixture (Figure 4D) shows the characteristic bands of tripalmitin, together with deformation of the C═C and C═N bonds of the herbicides. The spectrum for SLN without herbicides (Figure 4E) shows most of the bands corresponding to tripalmitin, together with a band at around 3340 cm^{-1} indicative of the presence of the −O-H group in the structure, which probably resulted from the use of the water and poly(vinyl alcohol) as stabilizers during preparation of the nanoparticles. Another characteristic −O-H deformation band of water can be seen at 1640 cm^{-1} in this spectrum. Figure 4F shows the spectrum for SLN loaded with atrazine and simazine, with the presence of characteristic bands corresponding to poly(vinyl alcohol), tripalmitin, and (indicated by the arrows) shifted lower intensity bands at 1629 and 1561 cm^{-1} associated with deformation of C═C and C═N bonds of the herbicides. These features indicate that the herbicides were encapsulated and/or had interacted with the nanoparticles. In previous work, de Melo et al.[49] used changes in FTIR spectra to show that the bioactive compound articaine interacted with nanospheres of alginate/chitosan, as well as with nanocapsules of PCL/PEG, confirming that both types of nanoparticle were suitable for loading with articaine.

Nanoparticle Tracking Analysis. The nanoparticle tracking analysis technique was used to characterize SLN suspensions immediately after their preparation. Figure 5 shows the concentrations of nanoparticles as a function of particle size. For SLN without herbicides, the particle number concentration was $(9.09 \pm 0.70) \times 10^{12}$ particles/mL and the average hydrodynamic diameter was 240.37 ± 95.54 nm. Encapsulation of the herbicides resulted in a concentration of $(11.75 \pm 0.64) \times 10^{12}$ particles/mL and an average hydrodynamic diameter of 252.18 ± 91.56 nm. It can be seen that use of DLS and NTA techniques resulted in similar average hydrodynamic diameter values, as well as particle number concentrations that were in the same range, evidencing the satisfactory conditions used to prepare the formulations. An important point is that the formulations showed the monomodal size distributions associated with only one population of particles. This type of homogeneity is desirable in modified release formulations, because there are therefore likely to be fewer interferences in the process of release of the active agents.[50]

Release Kinetics Assays and Mathematical Modeling. Release kinetics assays were conducted in order to obtain further information concerning the interactions between herbicides and nanoparticles, as well as the mechanisms involved in herbicide release. Figure 6 shows the curves obtained for cumulative release of the herbicides as a function of time. In these experiments, the herbicide molecules were able to traverse the 1 kDa pores of the cellulose membrane separating the donor and acceptor compartments, enabling observation of the progressive release of herbicide into solution. The results (Figure 6) showed that the presence of SLN modified the release profiles, which were slower compared to those of the free herbicides. For the free herbicides, 50% release was obtained in 2.5 h (ATZ) and 5.3 h (SMZ). When the compounds were encapsulated together in SLN, 50% release of the same quantities of the herbicides was obtained in 52.9 h (ATZ) and 51.1 h (SMZ).

The apparent fluxes (F_{app}) for the free and encapsulated herbicides are listed in Table 1. The data showed that the mass flux of simazine was lower than that of atrazine, for both free and encapsulated forms. When the herbicides were encapsulated, atrazine showed an initial release that was faster than that of simazine. This can be explained by the lower encapsulation efficiency obtained for atrazine, with initial fast release of the fraction of the herbicide that was not encapsulated. However, after the initial release, the release profiles for the two herbicides were very similar, indicating that the compounds had interacted in similar ways with the hydrophobic cores of the nanoparticles.

Release profiles of the herbicides were analyzed by use of the Korsmeyer−Peppas mathematical model. Linear regression was used to calculate the values of release exponent n, release constant k, and correlation coefficient r (Table 2).

Use of the Korsmeyer−Peppas model enables prediction of the mechanism of release of active compounds from nanostructured systems, which can essentially be by either Fickian diffusion and/or case II transport.[36] Here, the values obtained for the release exponent were in the range $0.45 > n > 0.85$, indicating that the kinetics could be described by anomalous transport, which involves a combination of the two different mechanisms. The values of the release constants k showed that atrazine was released faster than simazine, in agreement with the results obtained in kinetics and apparent flux experiments. Grillo et al.[25] also obtained higher release constant values for atrazine when the Korsmeyer−Peppas model was used to investigate the mechanisms of release of the herbicides atrazine, simazine, and ametryn from nanocapsules composed of poly(ε-caprolactone).

In Vitro Cytotoxicity Assays. The MTT reduction test employing 3T3 fibroblast cells was used to determine whether encapsulation of the herbicides altered their cytotoxicity. The results (Figure 7) showed that in the absence of herbicides, SLN were not cytotoxic in the concentration range tested, since cellular viability remained at around 100%. When herbicides were incorporated into SLN, cellular viability of 80% was obtained for the highest concentration tested, while greater cytotoxicity was observed for the commercial formulation, with a value of 64% obtained at the same concentration. These findings confirmed that encapsulation of the herbicides in the solid lipid nanoparticles resulted in a decrease in cytotoxicity.

Herbicidal Activity Assays. Effects of nanoparticle formulations, with and without herbicides, as well as the commercial formulation, were investigated for pre- and postemergence treatments applied to a target species (*Raphanus raphanistrum*) and a nontarget species (*Zea mays*), at concentrations equivalent to 0.3 and 3 kg/ha.

Atrazine and simazine are used together to increase the spectrum of action in controlling weeds in maize plantations. Maize is resistant to these herbicides because of the presence in this species of a soluble enzyme, glutathione S-transferase, that detoxifies both atrazine and simazine.[1,4] For the nontarget species (for pre- and postemergence treatments), none of the formulations showed any phytotoxic effects on the aerial and root parts of plants when compared with the control (Figure 8).

For the target species, in the case of pre-emergence treatments, all the formulations showed effects on both the aerial and root parts of plants, compared to the control treatment (Figure 9). At the 3 kg/ha concentration level, effects of the commercial formulation and herbicides encapsulated in SLN were significantly greater, compared to SLN without herbicides, which could be attributed to the presence of the active agents. However, when the formulations were diluted 10 times (0.3 kg/ha), SLN without herbicides showed no

DOI: 10.1021/jf5059045
J. Agric. Food Chem. 2015, 63, 422−432

phytotoxicity, compared to the control, and the commercial formulation showed a significant effect only on the roots. On the other hand, SLN containing herbicides caused greater effects on both the aerial parts and roots of plants, compared to the commercial formulation. This provided evidence of the effectiveness and agricultural potential of SLN containing herbicides, since when applications were performed at the recommended concentrations, all the formulations caused inhibition of growth, while at 10 times lower concentrations, the effect of the commercial formulation decreased, while SLN containing herbicides remained effective (Figure 9E).

In the case of postemergence treatment, SLN without herbicides showed no phytotoxic effects on aerial parts or roots, at either concentration, compared to the control. However, the commercial formulation and SLN loaded with herbicides showed phytotoxic effects on aerial parts and roots at both concentrations. No significant differences were observed between these phytotoxic effects.

The phytotoxic effects of SLN in pre- and postemergence assays could have been due to interactions of SLN with roots of *R. raphanistrum*, resulting in changes in the processes of absorption of water and/or nutrients. It is also possible that absorption of nanoparticles by the roots caused toxic effects and reduced growth rates. There have been several reports of interactions between nanoparticles and plants.[51−53] Meanwhile, it should be highlighted that the interaction of SLN with *R. raphanistrum* (Figure 9E,F) appeared to be species-specific, because no toxic effects of SLN were observed in assays with *Z. mays*, at the same concentration range (Figure 8E,F).

The greater effectiveness of SLN containing herbicides could be explained by reduced soil sorption of the active agents, as well as physicochemical and microbiological protection provided by encapsulation and sustained release of herbicides provided by the nanoparticles. Similar findings were reported previously[26] for encapsulation of atrazine in PCL nanoparticles (nanocapsules and nanopheres) and evaluation of the effects on mustard plants (*Brassica* sp.).

In conclusion, the herbicides atrazine and simazine were successfully incorporated into solid lipid nanoparticles, with encapsulation efficiencies of around 90% for atrazine and 98% for simazine. SLN showed hydrodynamic diameters between 255 and 300 nm and remained stable over a period of 120 days. DSC and FTIR analyses confirmed that the herbicides were encapsulated and interacted with the lipid matrix. The use of TEM and NTA techniques demonstrated that the nanoparticles were spherical, with an average concentration of 12×10^{12} particles/mL. Encapsulation resulted in modification of the herbicide release profiles, with slower and more sustained release compared to the free forms of the herbicides. Evaluation of cytotoxicity by the MTT test showed that SLN provided a protective effect and acted to decrease the toxicity of the active agents. In herbicidal activity assays, postemergence treatment with SLN containing the two herbicides was as effective as use of the commercial formulation. In the case of pre-emergence treatment, SLN loaded with herbicides were more effective, compared to the commercial product, indicating the potential of these formulations for use in agriculture. An important finding was that the formulations of SLN containing two active agents were more effective, compared to the commercial formulation, and caused no toxicity in nontarget organisms (*Z. mays* plants and mouse fibroblast cells). The findings illustrate one of the ways in which nanotechnology can be used to develop effective systems for modified release of herbicides, providing greater efficiency in weed control, reducing the quantities of active agents required, and at the same time decreasing toxicity toward nontarget organisms.

ABSTRACT: The objective of this study was to investigate how dosages of high-amylose modifier (HAM) gene(s) affected the structure of maize *amylose extender* (*ae*) mutant starch. GEMS-0067 (G), a homozygous mutant of *ae* and the HAM gene(s), and H99*ae* (H), an *ae* single mutant, were self-pollinated or inter-crossed to produce maize endosperms of G/G, G/H, H/G, and H/H with 3, 2, 1, and 0 doses of HAM gene(s), respectively. Endosperm starch was fractionated into amylopectin, amylose, and intermediate component (IC) of large and small molecular weights using 1-butanol precipitation of amylose followed by gel-permeation chromatography. Increases in the dosage of HAM gene(s) from 0 to 3 decreased the amylopectin content. The HAM-gene dosage significantly changed the branch chain-length of small-molecular-weight IC, but had little effect on the branch chain-length distributions of amylopectin and large-molecular-weight IC and the molecular structure of amylose.

KEYWORDS: *high-amylose maize starch, high-amylose modifier gene, starch structure, resistant starch*

INTRODUCTION

Starch is the major energy reserve of green plants and widely exists in seeds, tubers, roots, stems, leaves, and fruits.[1] Starch is composed of mainly amylopectin and amylose molecules. Amylopectin molecules consist of chains of (α1→4)-linked D-glucopyranose units, which are connected by (α1→6) glycosidic branch linkages. Amylose molecules are primarily linear chains of (α1→4)-linked D-glucopyranose units; amylose molecules with large molecular weight possess a few branches.[2−5] In addition to amylose and amylopectin, high-amylose maize starch also consists of intermediate components (IC) that have branched structures with branch chains longer than amylopectin but molecular weights smaller than amylopectin and similar to amylose.[6−11]

Amylopectin molecules are synthesized through cooperative reactions catalyzed by enzymes including starch synthases, starch branching enzymes (SBEs), and starch debranching enzymes.[12−16] SBEs include SBEI and SBEII. SBEII prefers to cleave, transfer, and form shorter branch-chains, whereas SBEI prefers to transfer and form longer branch-chains.[17] There are two isoforms of SBEII identified in maize endosperm, SBEIIa and SBEIIb. SBEIIb plays a major role in the biosynthesis of amylopectin molecules in maize endosperm.[14] Maize *ae* mutants, deficient of SBEIIb activity in the endosperm, produce high-amylose maize starch with greater contents of amylose and IC and longer branch chain-lengths of amylopectin than the normal maize starch.[3,11,18,19]

A public high-amylose maize line registered as GEMS-0067 has been developed from USDA-ARS Germplasm Enhancement of Maize (GEM) Project by selectively crossing the exotic line of GUAT209:S13 to a hybrid OH43*ae*×H99*ae*.[20] The GEMS-0067 maize line is a homozygous mutant of *amylose-extender* (*ae*) and high-amylose modifier (HAM) gene(s).[20] Preliminary results showed that the HAM gene(s) in the GEMS-0067 included the *sbeI* allele.[21] Starch of the GEMS-0067 maize consists of 39.4−43.2% resistant starch (RS) determined using the AOAC Method 991.43 for total dietary fiber, which is much greater than that of maize *ae* single mutants of H99*ae*, OH43*ae*, B89*ae*, and B84*ae* (11.5−19.1%).[11] Structures of the RS have been characterized as long-chain double-helical crystallites of amylose and IC, which maintain the B-type semicrystalline structures at 95−100 °C and, thus, are highly resistant to enzymatic hydrolysis.[6,11,22,23]

The gene-dosage effects, non-allelic interactions, and heritability of high amylose content of the GEMS-0067 maize were studied using maize samples grown in two locations (Kirksville, Missouri, and Brookings, South Dakota) and two years (2005 and 2006).[24] Results showed that the dosage of HAM gene(s) had an additive effect on the amylose content of starch produced by maize *ae* mutant. On the basis of the results reported by Wu et al.,[24] we selected two sets of the maize samples with different HAM gene(s) dosages grown in Kirksville, MO and Brookings, SD in summer of 2006 to characterize fine structures of the starches. In this study, we aimed to investigate effects of HAM gene(s) dosage present in maize *ae* mutants on the contents and structures of amylopectin, IC, and amylose and, in turn, the RS content of the starch.

MATERIALS AND METHODS

Materials. All the chemicals used for the study were reagent grade, used as received, and were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO) or Fisher Scientific (Pittsburgh, PA). Crystalline *Pseudomonas* isoamylase (EC 3.2.1.68) was purchased from Hayashibara Biochemical Laboratories, Inc. (Okayama, Japan) and used for debranching amylopectin and IC molecules.

Preparation of Maize Samples. GEMS-0067 and H99*ae* plants were grown in Kirksville, MO, and Brookings, SD, in summer 2006, and planted in a completely randomized design as described by Wu et al.[24] Each plot consisted of one row containing 20 individual plants of the same genotype. Rows were 4.5 m long and 0.75 m wide. There were six plots for each maize endosperm genotype. Through self-pollination and inter-crossing between GEMS-0067 (G) and H99*ae* (H), four maize endosperm genotypes, GEMS-0067×GEMS-0067 (G/G), GEMS-0067×H99*ae* (G/H), H99*ae*×GEMS-0067 (H/G), and H99*ae*×H99*ae* (H/H) with 3, 2, 1, and 0 doses of HAM gene(s), respectively, were produced. Individual samples were composed of 100 kernels from each ear in a genotype.

Starch Isolation. Endosperm starch was isolated from maize kernels using a wet milling method and protein present in the starch

DOI: 10.1021/jf504099x
J. Agric. Food Chem. 2015, 63, 433−439

was removed using an aqueous toluene solution as described by Li et al.[11]

Fractionation of Starch Components. Starch was fractionated into amylose and a mixture of amylopectin and IC using 1-butanol precipitation method.[11,13] Purity of the fractionated amylose and the mixture of amylopectin and IC was determined using Sepharose CL-2B gel-permeation chromatography (GPC),[11] and the collected fractions were analyzed for contents of total carbohydrate (phenol-sulfuric acid)[26] and amylose iodine blue staining.[27]

Amylopectin, IC, and Amylose Contents of Starch. Amylopectin, amylose, and IC contents of starch were determined using GPC and calculated on the basis of the total carbohydrate contents of the GPC peaks of native starch and the mixture of amylopectin and IC following the method of Li et al.[11]

RS Content of Starch. The RS content of starch was measured using AOAC Method 991.43 for total dietary fiber.[28]

Branch Chain-Length Distributions of Amylopectin and IC. Amylopectin and IC of different molecular weights were separated using a Sepharose CL-2B column as described by Li et al.[11] The collected fractions of amylopectin and IC of large and small molecular weights were each dispersed, debranched, and labeled with 8-aminopyrene-1,3,6-trisulfonic acid following the method of Morell et al.[29] with modification by Jiang et al.[6] Branch chain-length distributions of amylopectin and IC of large and small molecular weights were determined using a fluorophore-assisted capillary electrophoresis (FACE) (P/ACE MDQ, Beckman Coulter, Fullerton, CA) following the method of Morell et al.[29] with modification.[6]

Molecular-Size Distribution of Amylose. Molecular-size distributions of amylose molecules, before and after debranching, were determined using high-performance size-exclusion chromatography (HPSEC) following the method of Jiang et al.[6] with modifications. Shodex SB-804 and SB-803 analytical columns with a Shodex OH pak SB-G guard column (Showa Denko K.K., Tokyo, Japan) were used to analyze the molecular-size distribution of amylose. The amylose molecules were dispersed and debranched following the method of Li et al.[11] The debranched amylose was precipitated using absolute ethanol (20×). The collected debranched-amylose was dispersed in 90% DMSO in a boiling-water bath for 1 h, mechanically stirred at room temperature for 16 h, precipitated with absolute ethanol (20×), collected, and dispersed in hot water in a boiling-water bath for 30 min. The dispersed debranched-amylose (100 μL, 2 mg/mL) was filtered through a membrane (pore size of 5.0 μm) and injected into the HPSEC column as described earlier. Maltose, maltotriose, maltotetraose, maltoheptaose, and pullulan standards (P-5, P10, P20, P50, P100, P200, and P400, Showa Denko K.K., Tokyo, Japan) were used as reference standards for determining molecular size of amylose.

Statistical Analysis. All analyses were performed in duplicate. The mean values were analyzed using the method of Analysis of Variance (ANOVA) with the General Linear Model Procedure in SAS (Version 9.2, SAS Inst. Inc., Cary, NC). Differences between samples were evaluated by the *t*-test using Tukey's adjustment with the significance level set at $p < 0.05$.

RESULTS AND DISCUSSION

Contents of Amylopectin, Amylose, and IC. The GPC chromatograms of the starches isolated from maize *ae* mutants with different HAM-gene dosages are shown in Figure 1A. All the GPC profiles of the starches showed two peaks. The first peak (fractions 11−18) was amylopectin that had much larger molecular size, and the second peak (fractions 19−45) contained a mixture of amylose and IC (Figure 1A).

Amylopectin contents of the starches, calculated on the basis of the total carbohydrate content shown in the first peak of the GPC profile (Figure 1A), are shown in Table 1. Although the amylopectin contents of the starches harvested in Kirksville, MO, were higher than that of the starches harvested in Brookings, SD, the amylopectin content of the starch grown in the both locations increased with the decrease in the HAM-gene dosage (Table 1). The amylose and resistant starch contents of the starch samples, in general, decreased with the decrease in the HAM-gene dosage. The amylopectin contents were negatively correlated with the RS contents of the starches. These were consistent with previously reported results showing that amylose and IC contributed to the RS content of the maize *ae* mutant starch.[6] The G/H (2 doses of HAM gene) starch had moderately larger content of amylose and IC than the H/G (1 dose of HAM gene) starch; the G/H starch, however, displayed greater content of RS than the H/G starch (Table 1). This difference suggested that the HAM-gene dosage in the maize *ae* mutant not only increased the contents of amylose and IC but also altered the structures of IC, resulting in a substantially greater RS contents.

H/H	22.3 ^{A}	36.6 ^{C}	18.1 ^{A}	23.0 ^{A}	20.0 ^{D}

[a]Amylopectin, amylose, and IC contents were determined using normal butanol precipitation method and Sepharose Cl-2B gel-permeation chromatography followed by total carbohydrate content analysis. [b]Large-molecular-weight IC molecules were in fractions 19−30 (Figure 1B); small-molecular-weight IC molecules were in fractions 31−45 (Figure 1B). [c]Resistant starch content of the starch was measured using AOAC Method 991.43 for total dietary fiber. RS data of Kirksville, Missouri are adapted from Jiang et al. (2010d). [d]G/G, G/H, H/G, and H/H contained 3, 2, 1, and 0 doses of HAM gene(s), respectively. Data in the same column with different superscript letters are significantly different ($p < 0.05$).

The GPC chromatograms of the mixtures of amylopectin and IC after the amylose was removed using 1-butanol are shown in Figure 1B. The absence of amylose molecules in the mixture was evidenced with the reduced blue value between fractions 19 and 45 (Figure 1B). The contents of amylose, large-molecular-weight IC, and small-molecular-weight IC are summarized in Table 1. Although the amylose contents of the starches harvested in Kirksville, MO were higher (except G/G) than that of the starches harvested in Brookings, SD, the order of the changes were the same and the amylose contents of the G/H and H/G starches were similar. Variations were observed for the contents of the large- and small-molecular-weight IC between samples with different HAM-gene dosages, but there were no clear trends associated with the HAM-gene dosage. Because of the same order was observed in both locations, we only used the starch samples harvested in Kirksville, MO for fine structure analyses to understand the effect of HAM-gene dosage on starch structures.

Branch Chain-Length Distributions of Amylopectins. Branch chain-length distributions of amylopectin molecules of

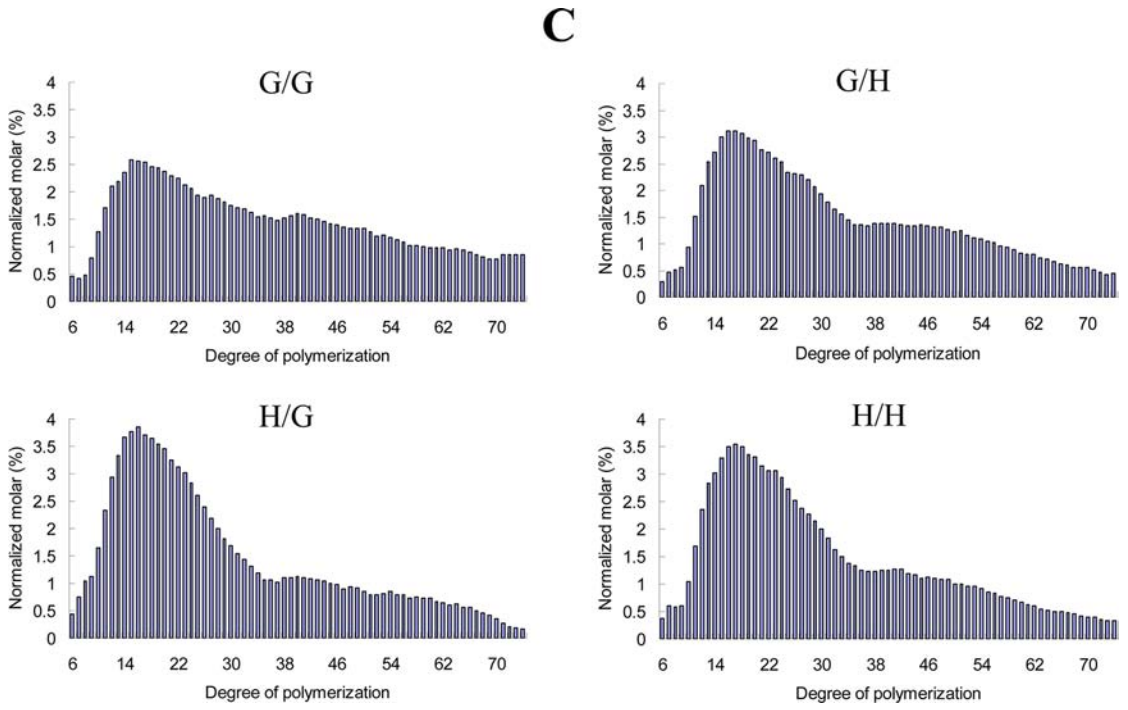

Figure 2. Branch chain-length distributions of amylopectins (A), large-molecular-weight IC (B), and small-molecular-weight IC (C). G/G, G/H, H/G, and H/H contained 3, 2, 1, and 0 doses of HAM gene(s), respectively. Fluorophore-assisted capillary electrophoresis was used for the analysis. The amylopectin, large-molecular-weight IC, and small-molecular-weight IC were collected from GPC fractions 11−18, 19−30, and 31−45, respectively (Figure 1B).

starches with different HAM-gene dosages are shown in Figure 2A. The branch chain-length profiles of the amylopectin molecules showed bimodal distributions with the peak chain-lengths at DP 14−15 and DP 46−49 (Figure 2A). The G/G amylopectin had slightly more short chains of DP ≤ 12 (16.2%) than other amylopectins (~13.5%). The percentages of branch chains with DP 13−24, DP 25−36, and DP ≥ 37 and average branch chain-lengths, however, were similar (data not shown). These results suggested that the HAM-gene dosage had little effect on the branch chain-length of amylopectin of the maize *ae* mutant starch.

Branch Chain-Length Distributions of Large-Molecular-Weight IC. Branch chain-length distributions of the large-molecular-weight IC of different HAM-gene dosages are shown in Figure 2B. The branch chain-length profiles of the large-molecular-weight IC also showed bimodal distributions (Figure 2B), similar to that of the amylopectins (Figure 2A). The large-molecular-weight IC of the starches having different HAM-gene dosages also displayed similar branch-chain-length distributions. These results showed that HAM-gene dosage also had little effect on the branch chain-length of large-molecular-weight IC of the *ae* mutant maize starch. The large-molecular-weight IC had average branch chain-lengths of DP 27.6, 27.3, 27.9, and 27.6 for G/G, G/H, H/G, and H/H, respectively, which were slightly longer than the amylopectin counterparts (DP 26.2, 26.3, 26.9, and 27.1 for G/G, G/H, H/G, and H/H, respectively). The similar branch-chain length distribution and average branch chain-length of amylopectin and large-molecular-weight IC of starch having different HAM gene dosage suggested that the large-molecular-weight IC and amylopectin had little or no contribution to the RS formation in maize *ae* mutant starch.

Branch Chain-Length Distributions of Small-Molecular-Weight IC. Branch chain-length distributions of the small-molecular-weight IC are shown in Figure 2C. The branch chain-length profiles of the small-molecular-weight IC showed a well-defined peak at chain-lengths of DP 15−17 and a shoulder at the chain-lengths of DP ≥37 (Figure 2C). The H/H sample (0 dosage) had a slightly larger percentage of long branch-chains (DP ≥ 37, 31.5%) and larger average branch chain-length (DP 30.8) but less percentage of branch-chains of DP 13−24 than the H/G counterpart (Table 2). As the HAM-gene dosage increased from 1 to 3, the percentages of branch-chains of DP ≥37 increased from 28.2 to 37.2 and 43.8% for the H/G, G/H, and G/G, respectively; and the average branch chain-lengths of the small-molecular-weight IC increased from DP 29.1 to DP 32.6, and DP 35.4 for the H/G, G/H, and G/G, respectively (Table 2); However, the percentages of branch-

Table 2. Molar-Based Branch Chain-Length Distributions of the Small-Molecular-Weight IC Separated from Starches of Self-Pollinated and Inter-crossed Lines of GEMS-0067 (G) and H99*ae* (H)[a]

sample	average CL (DP)[c]	DP ≤ 12 (%)	DP 13−24 (%)	DP 25−36 (%)	DP ≥ 37 (%)
G/G[d]	35.4 ^{A}	7.2 ^{B}	28.2 ^{D}	20.8 ^{C}	43.8 ^{A}
G/H	32.6 ^{B}	7.1 ^{B}	33.6 ^{C}	22.1 ^{B}	37.2 ^{B}
H/G	29.1 ^{D}	10.3 ^{A}	41.2 ^{A}	20.3 ^{D}	28.2 ^{D}
H/H	30.8 ^{C}	7.1 ^{B}	38.4 ^{B}	23.0 ^{A}	31.5 ^{C}

[a]The branch chain-length distribution of the small-molecular-weight IC was determined using a fluorophore-assisted capillary-electrophoresis. The small-molecular-weight IC was collected from GPC fractions 31−45 (Figure 1B). [c]CL = chain length; DP = degree of polymerization. [d]G/G, G/H, H/G, and H/H contained 3, 2, 1, and 0 doses of HAM gene(s), respectively. Data in the same column with different superscript letters are significantly different ($p < 0.05$).

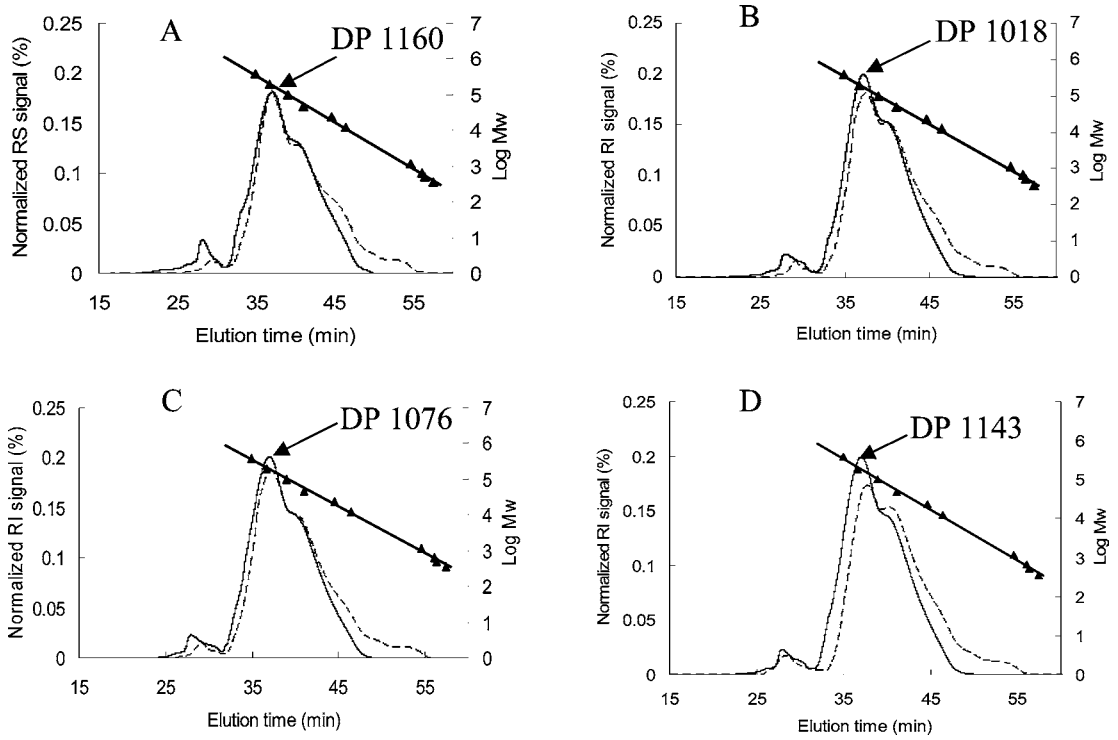

Figure 3. Molecular-weight distributions of amyloses separated from starches of self-pollinated and inter-crossed lines of GEMS-0067 (G) and H99*ae* (H). The separation was conducted using Shodex SB-804 and SB-803 analytical columns (Showa Denko K.K., Tokyo, Japan). (A) G/G with 3 doses of HAM gene(s); (B) G/H, 2 doses; (C) H/G, 1 dose; and (D) H/H, 0 dose. Solid lines, before isoamylase-debranching; dashed lines, after isoamylase-debranching; and linear line, a standard curve with molecular sizes of DP 2, 3, 4, 7, 75, 141, 292, 617, 1148, and 2346.

chains of DP 13−24 decreased from 41.2% to 33.6% and 28.2% for the H/G, G/H, and G/G, respectively. There were no clear trends observed for branches of DP ≤ 12 and DP 25−36 associating with the HAM-gene dosage (Table 2). The long branch-chains (DP ≥37, Table 2) increasing with the increase in the HAM-gene dosage facilitated the starch to develop more long-chain double-helical crystallites, which were resistant to enzymatic hydrolysis and resulted in the larger RS content of maize *ae* mutant starch (6). Small-molecular-weight IC of the H/G had a larger proportion of short chains with DP ≤ 24 (51.5%) than that of the H/H (45.5%, Table 2), which resulted in a lower resistant starch content of the H/G starch (12.9%) than that of the H/H starch (15.7%, Table 1). The greater concentration of short-branch chains of the H/G sample made the H/G sample more susceptible to enzymatic hydrolysis and resulted in less resistant starch content.

Molecular Structure of Amylose. The purity of the fractionated amylose was 98.6−99.8% examined using GPC. There was a very small amount of amylopectin shown at a peak between fractions 11 and 18, which displayed a typical low blue value of amylopectin (data not shown).

High-performance size-exclusion chromatograms of amylose molecules, before and after isoamylase-debranching, are shown in Figure 3. All the amyloses fractionated from starch samples of different HAM-gene dosages showed similar molecular weight distributions. There were three peaks shown on the chromatograms of amyloses, including a small peak (eluted between 25 and 32 min) with peak molecular sizes at DP 16502−17699, a major peak with peak molecular sizes at DP 1018−1160, and a shoulder-like peak with peak molecular sizes at DP ∼ 472 (Eluted at ∼40 min) (Figures 3A−D). The amyloses had average molecular sizes of DP 731−817 (Table 3), which were in agreement with the molecular sizes of amyloses isolated from high-amylose maize starches reported by Takeda et al.[30] After the amylose samples were subjected to an enzymatic debranching, similar molecular weight distributions were observed for all the debranched amylose samples obtained from starches of different HAM-gene dosages; the intensity of the small peak eluted between 25 and 32 min was reduced for the G/G, G/H, and H/G but not for the H/H (Figure 3A−D). These results suggested that the HAM-gene dosage of the maize *ae* mutant had little effect on the amylose molecular structure. There was no clear trend observed between the size of debranched amylose and the HAM-gene dosage (Table 3).

Table 3. Average Molecular Weights of Amyloses Separated from Starches of Self-Pollinated and Inter-crossed Lines of GEMS-0067 (G) and H99*ae* (H)

sample	before debranching (DP)[a]	after debranching (DP)
G/G[b]	817 ^{A}	452 ^{B}
G/H	731 ^{D}	445 ^{B}
H/G	795 ^{B}	487 ^{A}
H/H	756 ^{C}	417 ^{C}

[a]DP = degree of polymerization. [b]G/G, G/H, H/G, and H/H contained 3, 2, 1, and 0 doses of HAM gene(s), respectively. Data in the same column with different superscript letters are significantly different ($p < 0.05$).

In conclusion, the HAM-gene(s) dosage of *ae* mutant maize had little effect on the branch chain-length distributions of amylopectin and large-molecular-weight IC and on the molecular structure of amylose; but it increased the branch chain-length of small-molecular-weight IC and the content of

Changes in the Content of Free and Conjugated Polyamines during Lettuce (*Lactuca sativa*) Growth

Edgar Pinto* and Isabel M. P. L. V. O. Ferreira

REQUIMTE/Department of Chemical Sciences, Laboratory of Bromatology and Hydrology, Faculty of Pharmacy, University of Porto. R Jorge Viterbo Ferreira 228, 4050-313 Porto, Portugal

ABSTRACT: Polyamines (PAs) in plant foods are relevant due to the association of these bioactive nutrients with health and disease. The scope of the present study was to monitor the content of free, conjugated, and total (free + conjugated) putrescine (Put), spermidine (Spd), and spermine (Spm) at five stages of lettuce growth in three different greenhouses. The daily intake of PAs from lettuce consumption was estimated since its consumption represents about 7.2% of vegetables intake. Results showed that the content of free Put, Spd, and Spm decreased during plant growth, while the content of conjugated Put, Spd, and Spm increased. Nevertheless, the total PA content remained fairly constant. Significant differences were observed in the PAs content in lettuces grown in different greenhouses. The conjugated fraction of PAs in mature lettuces has an important contribution to the total PAs and will certainly influence the bioavailability and/or bioactivity of dietary polyamines.

KEYWORDS: *lettuce, polyamines, growth, daily intake, human health*

INTRODUCTION

Putrescine (Put), spermidine (Spd), and spermine (Spm) form a group of low molecular and aliphatic nitrogen polycations known as polyamines (PAs). These are commonly found in higher plants in free, soluble conjugated, and insoluble bound forms. Soluble conjugated PAs are mainly conjugated to small molecules such as phenolic compounds, whereas insoluble bound PAs are bound to macromolecules such as nucleic acids and proteins.[1] Put, Spd, and Spm usually have been included within the group of biogenic amines. However, due to their specific biological roles in plants they have become a peculiar group. In plants, PAs have been found in both the cytoplasm and other organelles (e.g., vacuoles, mitochondria, and chloroplasts).[2]

The biosynthetic pathways of PAs is highly conserved through evolution and starts from the two amino acid precursor molecules, L-arginine and L-methionine.[3] Two alternative biosynthetic pathways have been characterized. Put is synthesized through either arginine decarboxylase (ADC, EC 4.1.1.19) via agmatine (Agm) or ornithine decarboxylase (ODC, EC 4.1.1.17). Conversion of Agm into Put requires two distinct enzymes: *N*-carbamoylputrescine amidohydrolase (CPA, EC 3.5.1.53) and agmatine iminohydrolase (AIH, EC 3.5.3.12). Spd is synthesized by spermidine synthase (SPDS, EC 2.5.1.16) through the addition of an aminopropyl group, transferred from the decarboxylated *S*-adenosylmethionine (dcSAM), to Put. Spd can be aminopropylated at either Spm or thermospermine by the action of spermine synthase (SPMS, EC 2.5.1.22).[4,5] With regard to PAs catabolism, both Spd and Spm can be converted back to Put. Spermine oxidase (SMO, EC 1.5.3.16) mediates the back-conversion of Spm to Spd. Moreover, the enzyme polyamine oxidase (PAO, EC 1.5.3.11) catalyzes the conversion of Spd and Spm to 4-aminobutanal and *N*-(3-aminopropyl)-4-aminobutanal, respectively. Put is catabolized by diamine oxidases (DAOs) in a reaction that converts Put into Δ^1-pyrroline and generates NH_3 and H_2O_2 as byproducts.[3]

The amount of PAs present at a certain time within the human body is the result of three sources: (i) endogenous supply, (ii) through intestinal microorganisms, and (iii) exogenous supply through the diet.[6] The exogenous dietary source provides a much larger quantity of PAs than the other two sources. Thus, diet plays a key role controlling the body pool of these compounds and, consequently, in the regulation of several physiological mechanisms within the human body.[2] The dietary intake of PAs influences human health.[7] It has been suggested that a PA-rich diet could have several health benefits such as decreasing age-associated pathologies and increasing longevity.[8] However, a reduced intake of exogenous PAs through diet has also been proposed as an efficient nutritional strategy for several human conditions.[9−11]

In humans, PAs are involved in the regulation of many basic cellular processes, such as DNA replication, transcription, translation, cell proliferation, modulation of enzyme activities, cellular cation−anion balance, and membrane stability.[4,5] This occurs due to the inherent physicochemical properties of PAs that enable them to interact with negatively charged macromolecules such as nucleic acids, phospholipids, and proteins.[6] The importance of PAs in cellular growth and proliferation is well-established and has been related to their role in stabilizing the negative charges of DNA and of the chromatin structure, the regulation of several transcriptional factors, and protein synthesis.[7] PAs do not trigger cancer, but their increased availability enhances cell growth. However, it has been also documented that excessive accumulation of PAs induces apoptosis.[2] PAs play a vital role in the maintenance of intestinal

function and gut maturation. When damaged, the intestinal mucosa is able to repair itself, and PAs are essential for these repair processes. Moreover, PAs are widely described as essential growth factors for small intestinal and colonic mucosal growth and maturation.[6,7] PAs also show antioxidant activity and seem to be engaged in the reduction of cell membranes and DNA damage. At physiological levels, PAs can act as potent scavengers of reactive oxygen species (ROS).[2]

Although dietary PAs have been known as an important factor of health and disease, data on PA contents in foods are limited. Put, Spd, and Spm are present in variable amounts in various foods.[6,12] Regarding plant foods, very low levels, ranging from a few milligrams to less than a 100 mg/kg, are usually found.[2] Some work has been done in quantifying the PAs content in several plant foods.[13,14] However, no studies have addressed the PA content during the plant food growth period. Moreover, information concerning the content of conjugated PAs in food is scarce. Since in the last years an increased number of papers have been published encouraging the consumption of plant foods at their initial stages of growth (known as microgreens),[15,16] information regarding the PAs content of plant foods during their growth period is of great importance for consumers.

Lettuce is known to be an important source of mineral nutrients and phytochemicals that benefit human nutrition.[17] Additionally, it is one of the most consumed vegetables, accounting with a mean daily consumption in Europe of 23.4 g, which represents about 7.2% of the total dietary intake of vegetables.[18] Its global production was around 25 million tons in 2011.[19]

The aim of this study was to monitor the free and conjugated Put, Spd, and Spm content of a test plant food (*Lactuca sativa*) at five growth stages produced in three greenhouses as well as to estimate the daily intake of these compounds from lettuce consumption.

MATERIALS AND METHODS

Lettuce Cultivation, Sampling, and Sample Preparation. Lettuce (*Lactuca sativa*) plants (n = 100) with 2 weeks of growth were transferred on the same day to three different greenhouses: A_1 (41° 26.991 N, 8° 46.335 W), A_2 (41° 25.249 N, 8° 44.936 W), and A_3 (41° 27.435 N, 8° 45.377 W) located in NW Portugal, in a small region between Esposende and Vila do Conde. These three greenhouses were chosen because they were located in an intensive agriculture area, which is known to be the main supplier of vegetables to the city of Porto, Portugal. The experiments were conducted from December to February. All plants were exposed to the same conditions: light intensity, a total of 334 h of sunshine duration; photoperiod, on average 11.16 h; and temperature, average minimum temperature, 7.6 °C and average maximum temperature, 20.5 °C. Inorganic fertilizers were dissolved in 50 L water tanks and injected by an electric pump in long dripper pipes, from where the plants were fertigated. The nutrient elements provided (per plant and per fertigation) were as follows: 0.126 g N, 0.042 g K, 0.03 g P, 0.21 mg Fe, 0.051 mg Mn, and 0.013 mg Zn. The irrigation water used had the following characteristics: pH 6.91, electrical conductivity (EC) 401 mS/cm (at 25 °C), total dissolved solids (TDS) 201 mg/L, Ca^{2+} 70.2 mg/L, Mg^{2+} 19.2 mg/L, K^+ 5.2 mg/L, Na^+ 25.2 mg/L, Cl^- 83.4 mg/L, NO_3^- 37.4 mg/L, and SO_4^{2-} 66.8 mg/L.

Samples collection was always performed during the same period of the day (9–12 am). One kilogram (or at least 10 units) of lettuce was randomly harvested at five growth stages (2, 4, 6, 8, and 10 weeks hereinafter referred to as T_1, T_2, T_3, T_4, and T_5). After 10 weeks, lettuces reach their commercial maturity stage (T_5). Plant samples were placed into plastic containers, previously rinsed with diluted nitric acid (10% v/v) and deionized water, and kept at 4 °C on the way to the laboratory.

Soil was also sampled from the same locations using a stainless steel auger. In order to generate a representative sample, individual samples (n = 25) were combined to generate a composite sample.

At the laboratory, plant samples were cleaned and washed with deionized water to remove soil contamination. Afterward, inedible leaves were removed, and the remaining lettuce leaves were frozen at −80 °C and then freeze-dried. The dried samples were homogenized by grinding in a blender and sieved through a nylon sieve of 150 μm mesh size. Soil samples were spread in plastic trays, oven-dried for 24 h at 40 °C, crushed and sieved through a 2 mm nylon sieve, and stored at 4 °C until analysis.

Chemicals and Standard Solutions. Putrescine dihydrochloride, spermidine trihydrochloride, 1,7-diaminoheptane (internal standard, IS), spermine tetrahydrochloride, hydrochloric acid, acetonitrile, and 3,5-dinitrobenzoyl chloride (DNBZ-Cl) were purchased from Sigma–Aldrich (St. Louis, MO). Boric acid, sodium hydroxide, potassium chloride, ammonium nitrate and sodium chloride were from VWR (Radnor, PA). Perchloric acid ($HClO_4$) and carbon tetrachloride were both obtained from Merck (Darmstadt, Germany).

Standard stock solutions of PAs were prepared by dissolving each standard in 0.1 M HCl to provide a final concentration of 1000 mg/L. Working standard solutions (in the 0.5 to 10 mg/L interval range) were prepared daily from the stock solutions by adequate dilution with 0.1 M HCl. Sodium borate buffer was prepared from H_3BO_3 and KCl in water (0.5 M each) followed by titration with NaOH (0.5 M) to pH 10. DNBZ-Cl (56 mM) was prepared by dissolving a proper amount of the solid compound in acetonitrile.

Multielement calibration standards were prepared from 1000 mg/L single-element standard solutions (Sigma, MO) of Ca^{2+}, Mg^{2+}, K^+, and Na^+ for AAS and Cl^-, NO_3^-, PO_4^{3-}, and SO_4^{2-} for ion chromatography.

Instrumentation and Chromatographic Conditions. A Telstar (Terrassa, Spain) Cryodos-80 freeze-dry system was used to lyophilize lettuce samples. The moisture content was determined using HR73 Moisture Analyzer from Mettler Toledo (Greifensee, Switzerland). Water pH, electrical conductivity, and total dissolved solids were measured in situ by the IQ170 waterproof portable pH/conductivity/TDS meter (IQ Scientific Instruments, Carlsbad, CA). A PerkinElmer (Überlingen, Germany) 3100 flame (air-acetylene) atomic absorption spectrometer (AAS) was used for the determination of Ca^{2+}, Mg^{2+}, K^+, and Na^+. A PU-2089_{Plus} pump (Jasco, Tokyo, Japan) was used in conjunction with an IC-PAK anion-exchange column (10 μm, 50 × 4.6 mm) for Cl^-, NO_3^-, PO_4^{3-}, and SO_4^{2-} determination. Detection was done by a Waters Model 431 conductivity detector. The eluent was a 1.3-mM sodium gluconate/1.3-mM borax buffer solution adjusted to pH 8.5.

Chromatographic analysis of PAs was performed with an analytical HPLC unit (Jasco, Tokyo, Japan) equipped with Jasco PU-2080 HPLC pumps, Column Heater (Model 7981; Jones Chromatography, Hengoed, UK), and an MD-2010 Plus multiwavelength detector. The column was reversed-phase Ultracarb ODS (30) C18 (5 μm, 250 × 4.6 mm) (Phenomenex, Milford, MA). Borwin PDA Controller Software (JMBS Developments, Le Fontanil, France) was used for system control and data acquisition. Chromatographic separation was carried out by gradient elution with a mixture of two solvents and at a 1 mL/min flow rate. Solvent A consisted of 10 mM aqueous sodium formate/formic acid buffer at pH 3, and solvent B consisted of acetonitrile. The linear gradient program was as follows: 0–5 min, 40% B; 5–11 min, 58% B; 11–15 min, 58% B; 15–20 min, 65% B; 20–23 min, 65% B; 23–28 min, 95% B; 28–30 min, 95% B; 30–40 min, column rinse and re-equilibration. Column temperature was set at 35 °C. Detection was carried out at 250 nm.

Soil Analysis. Soil pH was measured in the supernatant of a 1:5 (w/v) suspension made up with ultrapure water. Organic matter content was determined based on its oxidation with a potassium dichromate (0.27 M) and sulfuric acid (98% v/v) mixture at 135 °C. CEC and particle size distribution were determined according to ISO methods.[20,21]

J. Agric. Food Chem. 2015, 63, 440–446

The extraction of Ca^{2+}, Mg^{2+}, K^+, and Na^+ from soil samples was performed following ISO 19730:2008.[22] Ten grams of air-dried soil and 25 mL of 1 M NH_4NO_3 solution were added to a 50 mL centrifuge tube and shaken for 2 h at 20 °C. Afterward, the solution was centrifuged at 5000*g* for 10 min and analyzed by AAS. The extraction of Cl^-, NO_3^-, PO_4^{3-}, and SO_4^{2-} from soil samples was conducted following ISO/TS 14256−1:2003[23] with some modifications. Briefly, soil samples were extracted with ultrapure water at a ratio 1:5 (w/v) at 20 °C. After 1 h of extraction, the solution was centrifuged at 5000*g* for 10 min. The above-mentioned anions were determined in the supernatant by ion chromatography.

Extraction and Analysis Of PAs. Lyophilized lettuce samples (100 mg) were homogenized in 2.5 mL of 5% (v/v) cold $HClO_4$ and incubated at 4 °C for 1 h. After centrifugation at 17000*g* for 30 min, the supernatant was collected and used as the sample extract to determine the content of free PAs.

In order to extract $HClO_4$-soluble conjugated PAs, a suitable portion of the previous extract was mixed with 12 M HCl (1:1, v/v) for 18 h at room temperature in centrifuge tubes as proposed by Fontaniella et al.[24] After acid hydrolysis, NaOH (10 M) was added to the centrifuge tubes to neutralize the HCl in excess, and the volume was made up to 2 mL with ultrapure water. This solution was used as a source of $HClO_4$-soluble conjugated PAs and free PAs.

PAs recovered from the nonhydrolyzed supernatant (free PAs) and the hydrolyzed supernatant (free + conjugated PAs) were quantified, after derivatization with DNBZ-Cl, by HPLC-DAD according to Pinto, Melo, and Ferreira.[14] Representative chromatograms of free and conjugated PAs are shown in Figures 1 and 2, respectively. Results are presented on a fresh weight (fw) basis. The detection limit (LOD) for Put, Spd, and Spm was 0.018, 0.034, and 0.042 μg/g, respectively, while the quantification limit (LOQ) was 0.062, 0.115, and 0.141 μg/g for Put, Spd, and Spm, respectively.

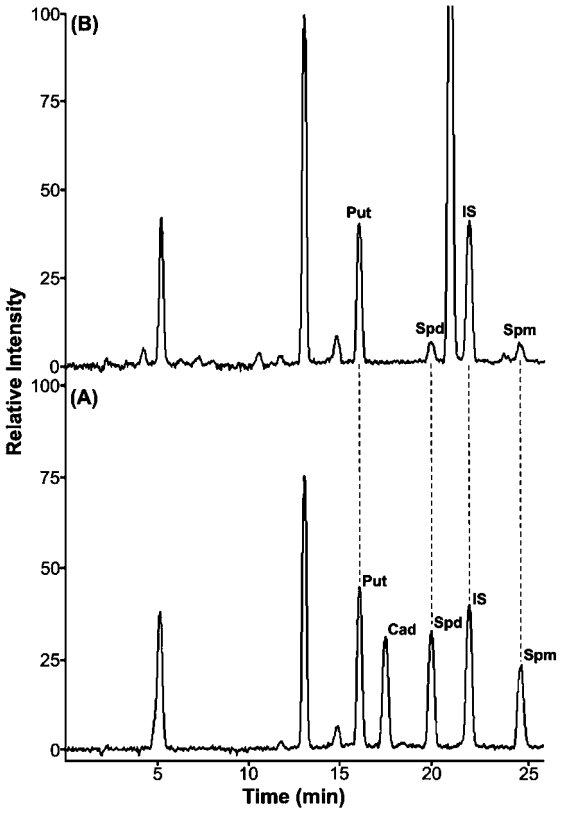

Figure 1. Representative chromatograms of free PAs: (A) mixed standard solution of 5 mg/L and (B) lettuce. Peaks: Put, putrescine; Cad, cadaverine; Spd, spermidine; IS, internal standard; and Spm, spermine.

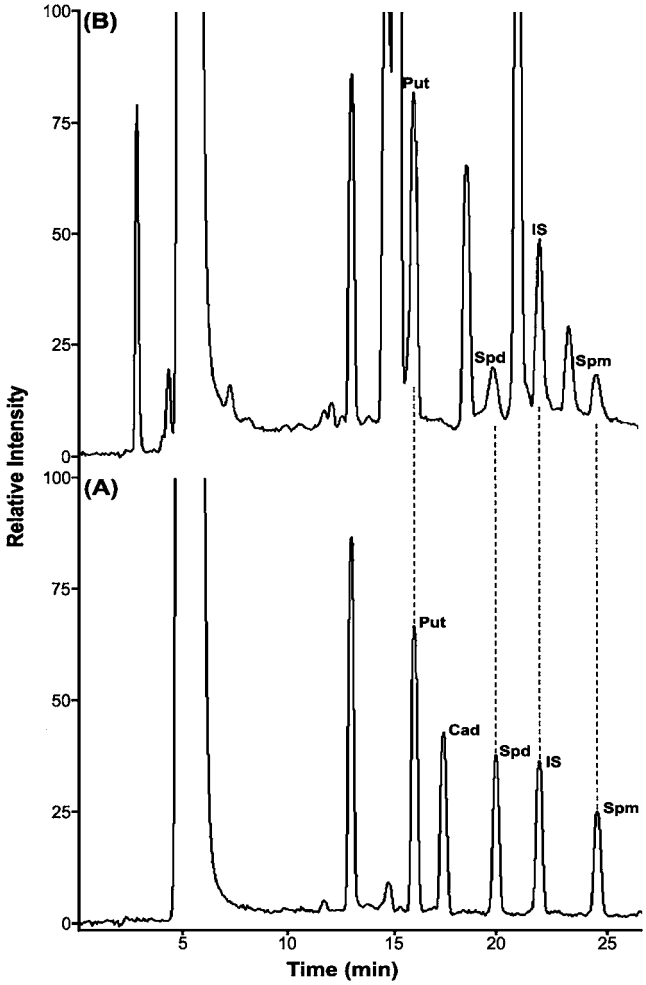

Figure 2. Representative chromatograms of conjugated PAs: (A) mixed standard solution of 5 mg/L and (B) lettuce. Peaks: Put, putrescine; Cad, cadaverine; Spd, spermidine; IS, internal standard; and Spm, spermine.

Estimated Daily Intake of PAs from Lettuce. The estimated daily intake (EDI) of Put, Spd, and Spm resulting from lettuce consumption was calculated. The EDI, which is dependent on both the PAs content of the edible part of the plants ($C_{polyamine}$; μg/g fw basis) and the average daily intake of lettuce ($DI_{lettuce}$), was calculated using the following formula:

$$EDI = DI_{lettuce} \times C_{polyamine}$$

where EDI is expressed as μmol/day, and DI was assumed to be 23.4 g/day for adults.[18]

Statistical Analysis. Data exploration, descriptive statistics calculation, and ANOVA were performed with IBM SPSS Statistics for Windows, version 22.0 (IBM Corp, Armonk, NY). Statistical significance was assumed for $p < 0.05$.

RESULTS AND DISCUSSION

Lettuce Leaf Biomass and Moisture Content. Lettuce leaf biomass at the 5 growth stages in the three greenhouses (A_1, A_2, and A_3) is shown in Table 1. A similar increase of leaf biomass was observed during lettuce growth in A_1, A_2, and A_3 greenhouses. No significant differences were observed between lettuce leaf biomass at T_1 and T_2. However, the increase of lettuce biomass was significant among T_3, T_4, and T_5 growth stages. Only at T_5 did A_2 lettuces show significantly higher biomass content compared to that of A_1 and A_3 lettuces.

Table 1. Lettuce Leaf Biomass (g FW/Plant) during the Five Stages of Lettuce Growth in the Three Greenhouses (A_1, A_2, and A_3)[a]

	lettuce ID		
growth stage	A_1	A_2	A_3
T_1	1.91 ± 0.04 a	1.85 ± 0.03 a	2.13 ± 0.09 a
T_2	6.69 ± 0.25 a	6.84 ± 0.31 a	8.23 ± 0.53 a
T_3	24.42 ± 1.45 b	24.08 ± 1.96 b	23.7 ± 1.75 b
T_4	56.68 ± 3.53 c	58.39 ± 4.36 c	59.54 ± 4.31 c
T_5	173.96 ± 6.94 d	186.85 ± 12.31 d	169.28 ± 8.17 d

[a]Data are presented as the mean ± SD (n = 5). In a column, different letters (a, b, c, and d) indicate significant differences between growth stages at $p < 0.05$.

No significant differences were found for the mean moisture content (94.3 ± 0.1%) of lettuces grown in the A_1, A_2, and A_3 greenhouses at the five growth stages.

Spatial Variation of Free and Conjugated PA Content in Lettuce Leaves. Significant differences were observed depending on the greenhouse where the lettuce was grown. A_1 lettuces showed significantly higher levels of all free PAs, while A_2 lettuces showed the lowest levels (Figures 3A, 4A, and 5A). For the conjugated PAs, this difference was not so clear for Put and Spd. However, A_2 lettuces showed a significantly higher level of conjugated Spm (Figures 3B, 4B, and 5B). For the total PAs, A_1 lettuces showed significantly higher levels of Put and Spd at all growth stages, whereas A_2 lettuces showed the lower levels of these PAs (Figures 3C and 4C).

A great body of evidence supports that abiotic stresses, such as metal toxicity, oxidative stress, drought, low temperature, and salinity, modulate the production of PAs in plants.[5] In order to understand the influence of soil properties in the PA content of lettuces, the analysis of soils from the three greenhouses was performed. A_2 soil showed a significantly higher pH, CEC, OM, and EC than the other two soils (A_1 and A_3). Moreover, A_2 soil was classified as a loamy sand soil, while A_1 and A_3 soils were sandy soils (Table 2). These characteristics are very important with regard to the bioavailability of essential and toxic elements to plants.[25] In Table 3 is shown the extractable content of Ca^{2+}, Mg^{2+}, K^+, Na^+, Cl^-, NO_3^-, PO_4^{3-}, and SO_4^{2-} of each of the three greenhouse soils. A_2 soil had the highest extractable content of Ca^{2+}, Mg^{2+}, K^+, NO_3^-, PO_4^{3-}, and SO_4^{2-} and the lowest extractable content of Na^+ and Cl^-. On the contrary, A_1 soil had the highest extractable content of Na^+ and Cl^- (Table 3). Given these results, it is hypothesized that the higher bioavailability of Na^+ and Cl^- in A_1 and A_3 soils is indicative of higher soil salinity. Since PAs are involved in salinity stress, these results can explain the highest amount of PAs (mainly in the free form) in A_1 and A_3 lettuces. The highest NO_3^- content in A_2 soil may have also influenced the PA content of lettuces, limiting the accumulation of Put in A_2 lettuces. Houdusse et al.[26] found that NO_3^- nutrition limited Put accumulation in wheat and pepper. The same authors also showed that the effect of salinity on PA content is highly dependent on nitrogen nutrition. Since the environmental conditions light intensity, temperature, photoperiod, and drought that can greatly influence the PAs content in plants were controlled in the present study, it seems that mineral nutrition and salinity were the factors responsible for the variation observed in the PA content among lettuces grown in different greenhouses.

Temporal Variation of Free and Conjugated PA Content in Lettuce Leaves. The free, conjugated, and total (free + conjugated) Put, Spd, and Spm contents at the five growth stages of lettuce (T_1, T_2, T_3, T_4, and T_5) in the three greenhouses (A_1, A_2, and A_3) are shown in Figures 3, 4, and 5. Regardless of the PA, a general trend was observed in all greenhouses: the content of free Put, Spd, and Spm decreased during plant growth (Figures 3A, 4A, and 5A), while the content of conjugated Put, Spd, and Spm increased (Figures 3B, 4B, and 5B). Despite the fluctuations observed in the content of free and conjugated PAs, total Put, Spd, and Spm content showed lower differences between different growth stages (Figure 5).

In plant foods, higher levels of free PAs are usually found in actively growing tissues.[5] Therefore, it is understandable that, in our study, higher levels of free Put, Spd, and Spm were obtained in the initial growth stages of all lettuces. Moreover, in plants, PAs are present not only as free molecules but also in the form of conjugates.[1] Similar to the free forms of PAs, conjugated PAs play key roles in plant survival, including cell division, flowering, and response to biotic and abiotic stresses. However, evidence suggests that these conjugates serve mainly as a reserve of PAs that can become available.[1,27] In the present study, higher levels of conjugated PAs were observed in the later stages of lettuce growth. This may be the reflex of a steady reduction of cell division during the lettuce growth period that results in an increase of the conjugated PA pool in plants. Sood and Nagar[28] also found an increase of conjugated Put, Spd, and

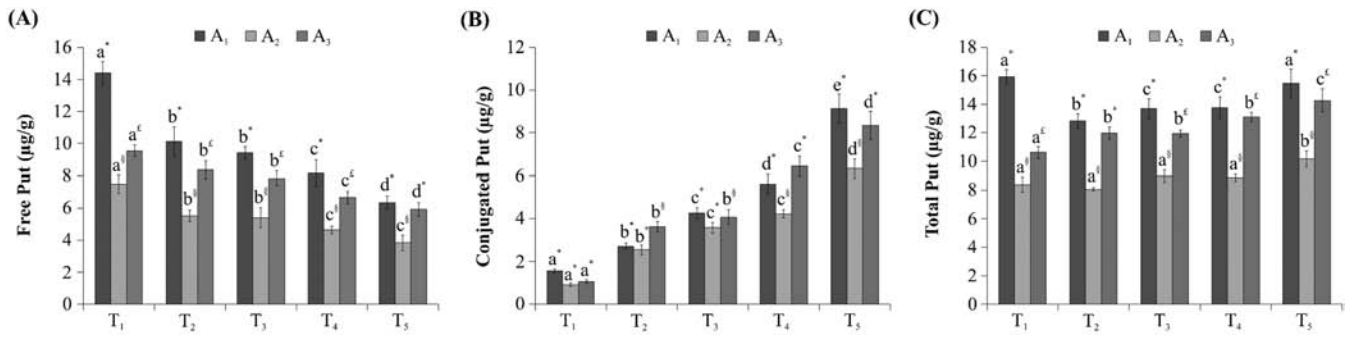

Figure 3. Free (A), conjugated (B), and total (C) putrescine (Put) content at five stages of lettuce growth (T_1, T_2, T_3, T_4, and T_5) in the three greenhouses (A_1, A_2, and A_3). Data are presented as the mean ± SD (n = 5). At a growth stage, different symbols (*, §, and £) indicate significant differences between greenhouses at $p < 0.05$. For a greenhouse, different letters (a, b, c, d, and e) indicate significant differences between growth stages at $p < 0.05$.

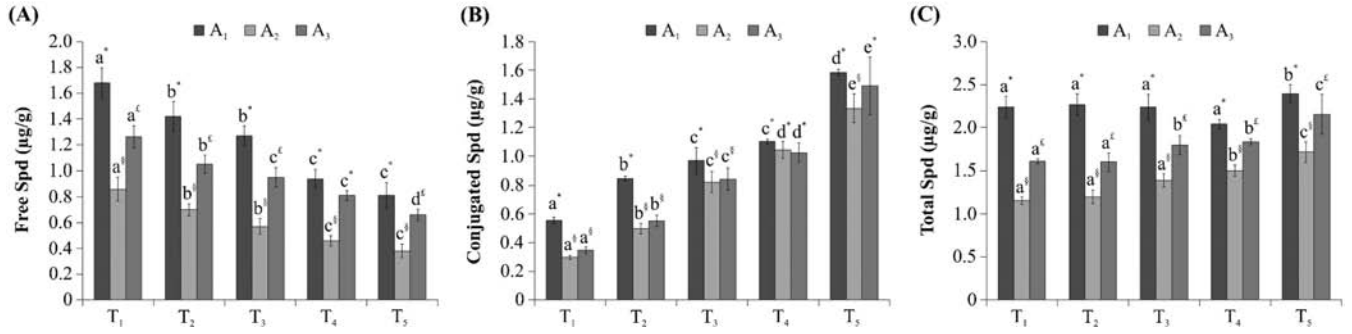

Figure 4. Free (A), conjugated (B), and total (C) spermidine (Spd) content at five stages of lettuce growth (T_1, T_2, T_3, T_4, and T_5) in the three greenhouses (A_1, A_2, and A_3). Data are presented as the mean ± SD (n = 5). At a growth stage, different symbols (*, §, and £) indicate significant differences between greenhouses at $p < 0.05$. For a greenhouse, different letters (a, b, c, d, and e) indicate significant differences between growth stages at $p < 0.05$.

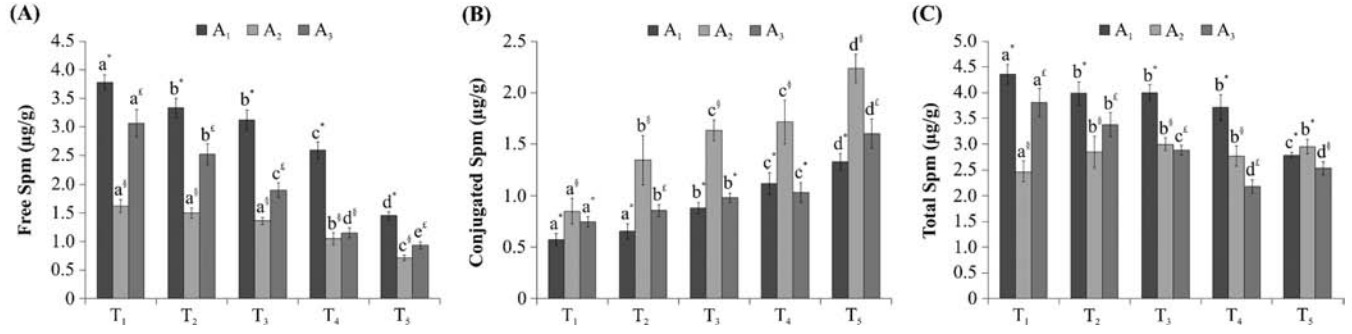

Figure 5. Free (A), conjugated (B), and total (C) spermine (Spm) content at five stages of lettuce growth (T_1, T_2, T_3, T_4, and T_5) in the three greenhouses (A_1, A_2, and A_3). Data are presented as the mean ± SD (n = 5). At a growth stage, different symbols (*, §, and £) indicate significant differences between greenhouse at $p < 0.05$. For a greenhouse, different letters (a, b, c, d, and e) indicate significant differences between growth stages at $p < 0.05$.

Table 2. Main Physicochemical Properties of the Three Greenhouse Soils (A_1, A_2, and A_3)[a]

	A_1	A_2	A_3
pH	6.5 ± 0.2 a	6.8 ± 0.1 b	6.6 ± 0.1 a
CEC (cmol/kg)	8.0 ± 0.5 a	18.1 ± 0.8 b	7.4 ± 0.6 a
OM (%)	53.1 ± 4.1 a	73.2 ± 2.8 b	21.3 ± 1.9 c
EC (μS/cm)	297 ± 49 a	645 ± 84 b	162 ± 19 c
clay (%)	1.9 ± 0.3 a	12.6 ± 0.4 b	2.3 ± 0.5 a
silt (%)	2.7 ± 0.4 a	12.8 ± 0.2 b	1.8 ± 0.3 a
sand (%)	94.9 ± 2.3 a	74.2 ± 2.0 b	95.4 ± 4.2 a
soil classification	sandy soil	loamy sand soil	sandy soil

[a]Data are presented as the mean ± SD (n = 15, i.e., triplicate analysis in each of the 5 sampling time points). Differences were tested according to ANOVA followed by Tukey's test. In a line, different letters (a, b, and c) indicate significant differences ($p < 0.05$) between the greenhouse soils.

Table 3. Extractable Content (mg/kg) of Chemical Species in the Three Greenhouses Soils (A_1, A_2, and A_3)[a]

	A_1	A_2	A_3
Ca^{2+}	784.0 ± 111.1 a	1285.3 ± 161.3 b	885.9 ± 99.5 c
Mg^{2+}	85.2 ± 11.9 a	199.8 ± 10.1 b	115 ± 20.2 c
K^+	167.1 ± 19.3 a	397.7 ± 35.7 b	109.8 ± 21.0 c
Na^+	194.4 ± 22.9 a	40.3 ± 13.7 b	76.5 ± 7.9 c
Cl^-	335.7 ± 50.9 a	16.2 ± 3.8 b	126.9 ± 27.4 c
NO_3^-	174.7 ± 44.0 a	411.0 ± 63.3 b	102.1 ± 31.5 c
PO_4^{3-}	50.9 ± 3.0 a	101.4 ± 3.1 b	63.5 ± 4.5 c
SO_4^{2-}	188.2 ± 27.7 a	485.3 ± 95.8 b	217.1 ± 64.6 a

[a]Data are presented as the mean ± SD (n = 15, i.e., triplicate analysis in each of the 5 sampling time points). Differences were tested according to ANOVA followed by Tukey's test. In a line, different letters (a, b, and c) indicate significant differences ($p < 0.05$) between greenhouses.

Spm during flower development of two species of rose (*Rosa damascena* and *Rosa bourboniana*).

Regardless of the greenhouse where lettuces were grown, free Put was always the most abundant PA, while free Spd was the least abundant. In particular, at T_5, free Put content was 6.4, 3.8, and 5.9 μg/g in A_1, A_2, and A_3 lettuces, respectively. These values are in close agreement with the 4 to 7.9 μg/g interval range described in the literature for lettuce.[2,13] For free Spd, the obtained levels in A_1, A_2, and A_3 lettuces at T_5 were 0.81, 0.38, and 0.66 μg/g, respectively. These values are significantly lower compared to the ones described by Ali et al.[13] in lettuces (6.2 to 9.1 μg/g). For free Spm, the obtained content at T_5 was 1.5, 0.7, and 0.9 in A_1, A_2, and A_3 lettuces, respectively, which are very similar to those reported in the literature (0.8 to 1.2 μg/g) for lettuce.[2,13] Similar to free Put, conjugated Put was the most abundant conjugated PA (9.1, 6.3, and 8.4 μg/g at T_5 in A_1, A_2, and A_3 lettuces, respectively), while conjugated Spd and Spm showed very similar contents. Since most studies carried out to date only determine the content of free Put, Spd, and Spm, data comparison between the content of conjugated PAs in our lettuces and other plant foods was impossible to perform.

Estimation of the PA Daily Intake from Lettuce Leaves. The EDI values of free, conjugated, and total (free + conjugated) PAs were calculated at each of the five growth

DOI: 10.1021/jf505453s
J. Agric. Food Chem. 2015, 63, 440−446

stages of A_1, A_2, and A_3 lettuces. Overall, the EDI values of free PAs were the highest in the first growth stage of lettuce (T_1), decreasing until the last growth stage (T_5). With regard to conjugated PAs, the inverse was observed: the first growth stage of lettuce (T_1) showed the lowest content, steadily increasing until the last growth stage (T_5).

Regarding the relative contribution of each PA for the dietary intake, Put was the most abundant PA (70% of the total PA fraction), followed by Spm (19%) and Spd (11%). Nishibori et al.[29] determined the content of PAs in several foods groups (e.g., vegetables, fruits, meat, cheese, cereals, nuts, eggs, and dairy) and estimated the daily intake of PAs from each food group. These authors found that vegetables are the main source of Put and Spd and that Put was responsible for almost half of the total PA intake considering all food groups. Other studies have also addressed the importance of vegetables as an important source of PAs in the human diet.[11,30,31]

Both free and conjugated PA content should be considered in the dietary intake estimation; thus, the total (free + conjugated) Put, Spd, and Spm mean content was calculated and discussed. A general trend was observed: A_1 lettuces contributed to the highest daily intake of PAs (3.81, 0.36, and 0.44 μmol/day for Put, Spd, and Spm, respectively), while A_2 lettuces contributed to the lowest daily intake of PAs (2.36, 0.22, and 0.32 μmol/day for Put, Spd, and Spm, respectively).

Several studies have estimated the daily intake of PAs; however, great variation is described depending on the type of food as well as on regional dietary habits. Among these studies, the lowest total PAs intake was obtained in Japan (200 μmol/day)[29] and the highest in European countries (316 μmol/day).[32] Considering this low and high total PA intake, it was observed that lettuce only contributes between 1.5 to 2.3% of the low total PA intake (200 μmol/day) and between 0.9 to 1.5% of the high total PA intake (316 μmol/day). It should be highlighted that most studies that deal with dietary PA intake consider only the free form of PAs present in foods.[2,13,31] Until now, it is not clear if the form in which PAs are present in foods influences their bioavailability and/or bioactivity. However, evidence suggests that this aspect is of major importance when studies are carried out with the aim of assessing the potential implications of dietary PA intake in human health since it is hypothesized that the toxicokinetics (absorption, distribution, metabolism, and excretion) of free, conjugated, and bound PAs will greatly differ among them.[6]

In recent years, increased consumption of plant foods at their initial growth stages (known as microgreens or baby leaf vegetables) has been observed due to their higher nutritional value, intense flavors, attractive colors, and tender textures.[16,17] According to our results, lettuce at the initial growth stages showed a higher content of free Put, Spd, and Spm than the conjugated form of these PAs. However, when lettuces are consumed in their mature stage (T_5), a higher contribution of conjugated Put, Spd, and Spm is observed. This information is very important considering the differences that are likely to exist between the bioavailability and/or bioactivity of free and conjugated PAs. Thus, it emphasized that due to the high contribution of the conjugated form of Put, Spd, Spm in the last stage of lettuces growth (maturity stage), conjugated PAs must be considered in studies evaluating the daily intake of PAs.

Until now, studies monitoring the PA content in plant foods have not detailed the form in which these compounds are present. This study describes relevant information about the evolution of free and conjugated Put, Spd, and Spm content during lettuce growth in three different greenhouses. Free PA content is significantly higher at the initial stages of lettuce growth, while at later growth stages conjugated PAs predominate. Despite these fluctuations, the total (free + conjugated) PA content remained fairly constant during the studied period. Data described here should be included in food databases to enable a reliable estimation of PA intake and how this intake can affect human health. The form in which a certain PA is present in foods will certainly influence its toxicokinetics. Thus, more studies in this field are required.

Supporting Information

ABSTRACT: The chemical compositions of essential oils obtained from four species of genus *Salvia* were analyzed by gas chromatography with a flame ionization detector (GC-FID) and gas chromatography−mass spectrometry (GC-MS). The main compounds identified from *Salvia* species essential oils were as follows: 1,8-cineole (71.7%), α-pinene (5.1%), camphor (4.4%), and β-pinene (3.8%) in *Salvia apiana*; borneol (17.4%), β-eudesmol (10.4%), bornyl acetate (5%), and guaiol (4.8%) in *Salvia elegans*; bornyl acetate (11.4%), β-caryophyllene (6.5%), caryophyllene oxide (13.5%), and spathulenol (7.0%) in *Salvia leucantha*; α-thujene (25.8%), viridiflorol (20.4%), β-thujene (5.7%), and camphor (6.4%) in *Salvia officinalis*. In biting-deterrent bioassays, essential oils of *S. leucantha* and *S. elegans* at 10 μg/cm^2 showed activity similar to that of DEET (97%, *N*, *N*-diethyl-*m*-toluamide) in two species of mosquitoes, whereas the activities of *S. officinalis* and *S. apiana* essential oils were lower than those of the other oils or DEET. Pure compounds β-eudesmol and guaiol showed biting-deterrent activity similar to DEET at 25 nmol/cm^2, whereas the activity of 13-*epi*-manool, caryophyllene oxide, borneol, bornyl acetate, and β-caryophyllene was significantly lower than that of β-eudesmol, guaiol, or DEET. All essential oils showed larvicidal activity except that of *S. apiana*, which was inactive at the highest dose of 125 ppm against both mosquito species. On the basis of 95% CIs, all of the essential oils showed higher toxicity in *Anopheles quadrimaculatus* than in *Aedes aegypti*. The essential oil of *S. leucantha* with an LC_{50} value of 6.2 ppm showed highest toxicity in *An. quadrimaculatus*.

KEYWORDS: *Salvia species, β-eudesmol, guaiol, 13-epi-manool, biting deterrent, larvicide, Aedes aegypti, Anopheles quadrimaculatus*

INTRODUCTION

Mosquitoes are vectors for many pathogens that cause human diseases such as malaria, dengue fever, yellow fever, Rift Valley fever, and Chikungunya.[1] When significant levels of transmission occur, epidemics can result in high rates of human morbidity and mortality. Insecticides from various chemical groups are the basic tools used for management of mosquito populations. Due to extensive and indiscriminate use of insecticides, mosquitoes have developed resistance against these chemicals.[2] Plant essential oils have been suggested as alternative sources for insect control because they are selective, biodegrade to nontoxic products, and have minimal effects on nontarget organisms and the environment.[3] The search for new strategies for natural products to control vectors of these diseases is desirable because this can help in managing resistance to synthetic insecticides and reducing the use of toxic chemicals.[3] Much effort has, therefore, been focused to identify the effectiveness of plant essential oils against mosquito larvae because of their broad-spectrum activity against target insects, low mammalian toxicity, and biodegradability in the environment.[4−7]

The genus *Salvia* L. (Lamiaceae) contains more than 750 species of herbs, subshrubs, and shrubs of worldwide distribution, with many of the species commonly used in local folk medical practices and in cosmetics.[8−11] The name of the genus *Salvia* means "safe" or "well", from the Latin word *salvere*, referring to the curative properties of the known culinary and medicinal herb *Salvia officinalis* L.[12] Members of this genus are reported to produce many useful secondary metabolites including terpenes, phenolics, and their derivatives that have been central to the pharmacopoeias of many countries.[13] The healing reputation of *Salvia* species can be traced back to Roman times, and a well-known sage, *S. officinalis*, is particularly known for this.[14] *Salvia* species are

[a]RRI, relative retention indices calculated against *n*-alkanes on polar column. [b]Percent calculated from FID data for polar column; tr, trace (<0.1%). [c]Identification method: t_R, identification based on the retention times (t_R) of genuine compounds on the HP Innowax column; MS, identified on the basis of computer matching of the mass spectra with those of the Wiley and MassFinder libraries and comparison with literature data.

used to treat diarrhea, gonorrhea, hemorrhoids, and eye diseases and as an antiseptic, antispasmodic, and stomachic.[15] Phenolic compounds of this genus have also shown excellent antioxidant property.[16] Four *Salvia* species, *Salvia apiana* Jeps., *Salvia elegans* Vahl, *Salvia leucantha* Cav., and *Salvia officinalis* L., were investigated in the present study.

S. apiana (white sage, bee sage, sacred sage) is a coarsely branched shrub growing up to 1.5 m. This species is native to California. Silvery white leaves of *S. apiana* are highly aromatic,

DOI: 10.1021/jf504976f
J. Agric. Food Chem. 2015, 63, 447−456

stems are hollow, and the flower stalks rise 1 m above the foliage, producing white to pale lavender flowers.[8,17,18] Some California Indian tribes consider *S. apiana* to be sacred and burn the leaves as incense for purification ceremonies[17] A tea made from the leaves is reported to relieve colds and congestion and was used by Native Americans as a shampoo, dye, and hair straightener.[18,19] Seeds are sold as a natural food that are soaked and added to water, fruit juice, and cereals, whereas the leaves are used in cooking.[20]

S. elegans (pineapple sage; syn. *S. rutilans* Carrière) is a perennial subshrub native to the high mountains of central Mexico and Guatemala.[8,18,21] Plants grow to 1 m in height, produce bright red flowers in the fall and winter, and are grown either as summer annuals in cold regions or outdoors year-round in mild climates.[8,18] The aromatic leaves may be added to fruit salads, desserts, and cold drinks and used for making tea.[20]

S. leucantha (Mexican bush sage, velvet sage) originates in tropical and subtropical conifer forests of central and eastern Mexico. Flowers produced from summer until frost typically consist of a purple calyx and a purple or white corolla, both covered with fine, velvety hairs.[20] Leaves are aromatic with a slight roasted nut or chocolate scent, but are not used for culinary purposes.[22]

S. officinalis (common sage) originates from the northern shores of the Mediterranean and has been cultivated for centuries in Europe.[18] Sage has also been used in herbal medicine against acne, cancer, cramps, diabetes, diarrhea, flatulence, gingivitis, headache, inflammation of the mouth and throat, insect bites, upset stomach, and many other ailments.[23,24] Leaves have the highest content of essential oils just prior to bloom.[18]

Previous research indicates that some species of *Salvia* have larvicidal and repellent activity against mosquitoes. Amer and Mehlhorn[25] reported repellent activity of clary sage (*Salvia sclarea*) essential oil against *Aedes albopictus* Skuse and *Culex* species. Conti et al.[26] reported the repellent effect of *S. dorisiana*, *S. longifolia*, and *S. sclarea* essential oils against *Ae. albopictus*, whereas Mathew and Thoppil[27] reported larvicidal activity of the essential oils of *S. elegans* and *S. splendens* against *Ae. albopictus* larvae. Considering the diversity of compounds present in *Salvia* species and their potential to be used in integrated management of these disease vectors, it is important to study the chemical composition and biological activity of essential oils of different species of *Salvia*. This study reports the chemical composition and larvicidal and biting deterrent activities of essential oils of *S. leucantha*, *S. elegans*, *S. officinalis*, and *S. apiana* against yellow fever mosquito, *Ae. aegypti* L., and malaria mosquito, *Anopheles quadrimaculatus* Say.

MATERIALS AND METHODS

Chemicals and General Experimental Procedures. NMR spectra were obtained on a Bruker DRX-500 spectrometer (chemical shift values are in ppm, ^{1}H NMR at 500 MHz and ^{13}C NMR at 125 MHz). Optical rotations were measured at ambient temperature using a Rudolph Research Analytical Autopol IV. Thin layer chromatography (TLC) was carried out on aluminum-backed plates precoated with silica gel F_{254} (20 × 20 cm, 200 μm, Merck & Co. Inc., Whitehouse Station, NJ, USA). Visualization was made by spraying with vanillin–H_2SO_4 (1% ethanolic vanillin with 10% ethanolic H_2SO_4) followed by heating. Preparative TLC was conducted on glass-backed plates precoated with silica gel F_{254} (20 × 20 cm, 500 μm, Sorbent Technologies, Inc., Norcross, GA, USA). Authentic standards borneol (CAS Registry No. 464-45-9), bornyl acetate (CAS Registry No. 5655-61-8), guaiol (CAS Registry No. 489-86-1), β-eudesmol (CAS Registry No. 489-86-1), β-caryophyllene (CAS Registry No. 87-44-5), and caryophyllene oxide (CAS Registry No. 1139-30-6) were all purchased from Sigma-Aldrich Co., St. Louis, MO, USA.

Plant Material. Plants of *S. apiana* and *S. officinalis* 'Extrakta' used in this study were propagated from seed obtained from Johnny's Selected Seeds (Winslow, ME, USA). Plants of *S. elegans* and *S. leucantha* were propagated by cuttings obtained from stock plants originating from commercial nursery sources. Plants of *S. apiana* were grown in field rows in a sandy loam soil, and plants of *S. elegans*, *S. leucantha*, and *S. officinalis* 'Extrakta' were grown in 3 gal containers in a pine bark-based substrate in controlled-environment greenhouses at the South Mississippi Branch Experiment Station (SMBES) in Poplarville, MS, USA (30°50′26″ N, longitude 89°32′46″ W; USDA hardiness zone 8b). Voucher specimens 510 (*S. apiana*), 14 (*S. elegans*), 101 (*S. officinalis* 'Extrakta'), and 6 (*S. leucantha*) were deposited at the SMBES for future reference.

Aerial parts were harvested from 6-month-old plants of *S. elegans* and *S. leucantha* in April 2009, from 9-month-old plants of *S. apiana* in February and March 2010, and from 6-month-old plants of *S. officinalis* 'Extrakta' in March and May 2010. Harvested plant material was air-dried for 3 weeks inside an air-conditioned building (25 °C maximum). Dried plant material was packed loosely into cardboard boxes and stored in the same building until shipment to the National Center for Natural Products Research in Oxford, MS, USA, in September 2009 (*S. elegans* and *S. leucantha*), March 2011 (*S. officinalis* 'Extrakta'), and April 2011 (*S. apiana*).

Isolation of the Essential Oils. Aerial parts of *S. apiana*, *S. elegans*, *S. leucantha*, and *S. officinalis* were separately subjected to hydrodistillation for 3 h using a Clevenger-type apparatus according to the procedure published in European Pharmacopea. The oils were dried over anhydrous sodium sulfate and stored in sealed amber vials in a freezer. Essential oils were obtained from *S. apiana*, *S. elegans*, *S. leucantha*, and *S. officinalis* with 0.6, 0.04, 0.03, and 0.24% yields, respectively.

Gas Chromatography (GC) and Gas Chromatography–Mass Spectrometry (GC-MS) Analysis of Essential Oils. *Salvia* essential oils were analyzed by GC with a flame ionization detector (FID) and GC-MS using an Agilent GC–mass selective detector (MSD) system. The GC-MS analyses were done with an Agilent 5975 GC-MSD system. An Innowax fused silica capillary (FSC) column (60 m × 0.25 mm, 0.25 μm film thickness) was used with helium as the carrier gas (0.8 mL/min). The oven temperature was kept at 60 °C for 10 min, then programmed to 220 °C at a rate of 4 °C/min, then maintained constant at 220 °C for 10 min, and finally programmed to 240 °C at a rate of 1 °C/min. The injector temperature was set at 250 °C. The split flow was adjusted at 50:1. Mass spectra were recorded at 70 eV with the mass range m/z 35–450. The GC analyses were performed using an Agilent 6890N GC system. FID detector temperature was set to 300 °C, and the same operational conditions were applied to a duplicate of the same column used in GC-MS analyses. Simultaneous autoinjection was done to obtain equivalent retention times. Relative percentages of the separated compounds were calculated from integration of the peak areas in the GC-FID chromatograms (Table 1).

Individual components were identified by comparison of retention times with authentic samples or by comparison of their relative retention index (RRI) to a series of *n*-alkanes[28] and by computer matching with commercial mass spectral libraries (Wiley GC/MS Library, MassFinder 3 Library) and in-house "Baser Library of Essential Oil Constituents" built from authentic samples, known oils, and mass literature data.[29−32] These identifications were accomplished by comparison of retention times with authentic samples or by comparison of their RRI to a series of *n*-alkanes.[28]

Isolation of (+)-13-*epi*-Manool. *S. officinalis* (500 mg) essential oil was subjected to high-performance flash chromatography (HPFC) using a Biotage SI instrument with a 25 M silica column (flow rate = 5.0 mL/min) and eluted with hexanes (100%, 420 mL), hexanes/acetone mixtures (99:1 to 98:2, 210 mL; 98:2 to 93:7, 180 mL; 97:3 to 96:4, 180 mL; 96:4, 120 mL; 96:4 to 95:5, 120 mL; 95:5 to 90:10, 120 mL, 90:10 to 80:20, 90 mL; 80:20 to 70:30, 90 mL) and finally washed

DOI: 10.1021/jf504976f
J. Agric. Food Chem. 2015, 63, 447−456

with acetone (100%, 240 mL). Portions of 12 mL volume were collected in 16 × 100 mm test tubes. Fractions with similar TLC profiles (hexanes/acetone 98:2, 95:5, and 90:10 v/v) were combined to give three fractions. The last subfraction C (50 mg) was purified by preparative thin layer chromatography using hexanes/acetone (99:1, v/v) with R_f value 0.34 to afford (+)-13-*epi*-manool (>98%, 10 mg). $[\alpha]_D^{25}$ = +59.2 (*c* 1.0, $CHCl_3$); ^{1}H NMR (500 MHz, $CDCl_3$) δ 0.99 (td, *J* = 13.5, 4.2 Hz, H-1a), 1.72 (H-1b), 1.46 (tt-like, *J* = 13.5, 3.5 Hz, H-2a), 1.55 (H-2b), 1.14 (td, *J* = 13.5, 4.1 Hz, H-3a), 1.37 (H-3b), 1.05 (dd, *J* = 12.6, 2.7 Hz, H-5), 1.28 (H-6a), 1.68 (H-6b), 1.94 (td, *J* = 13.0, 5.2 Hz, H-7b), 2.35 (br d, *J* = 13.0 Hz, H-7a), 1.53 (H-9), 1.30 (H-11a), 1.51 (H-11b), 1.22 (H-12a), 1.71 (H-12b), 5.88 (dd, *J* = 17.4, 10.7 Hz, H-14), 5.02 (d, *J* = 10.7 Hz, H-15a), 5.17 (d, *J* = 17.4 Hz, H-15b), 1.27 (s, 3H, H-16), 4.49 (br s, H-17a), 4.79 (br s, H-17b), 0.84 (s, 3H, H-18), 0.77 (s, 3H, H-19), 0.65 (s, 3H, H-20); ^{13}C NMR (125 MHz, $CDCl_3$) δ 39.1 (t, C-1), 19.4 (t, C-2), 42.2 (t, C-3), 33.6 (s, C-4), 55.6 (d, C-5), 24.4 (t, C-6), 38.4 (t, C-7), 148.7 (s, C-8), 57.4 (d, C-9), 39.9 (s, C-10), 17.7 (t, C-11), 41.5 (t, C-12), 73.4 (s, C-13), 145.3 (d, C-14), 111.5 (t, C-15), 27.6 (q, C-16), 106.5 (t, C-17), 33.6 (q, C-18), 21.7 (q, C-19), 14.4 (q, C-20); EIMS, *m/z* 290 [M^+] $C_{20}H_{34}O$, 272 (7), 257 (43), 244 (9), 229 (6), 216 (6), 203 (11), 189 (19), 177 (20), 161 (16), 147 (15), 137 (87), 139 (23), 123 (45), 121 (41), 115 (6), 109 (52), 107 (54), 95 (92), 93 (68), 66 (45), 81 (100), 79 (69), 71 (40), 69 (71), 67 (49), 55 (59), 43 (42), 41 (61).

Gas Chromatography–Mass Spectrometry Analysis for Isolated Compound 13-*epi*-Manool. The purity of 13-*epi*-manool was analyzed using an HP 5890 series gas chromatograph linked to an HP 5970 mass spectrometer system using a DB-1 capillary column (20 m × 0.18 mm with 0.25 μm film thicknesses). Helium (1 mL/min) was used as carrier gas. The GC oven temperature was held at 50 °C for 2 min and then ramped to 280 °C at a rate of 5 °C/min. The scanned mass range was from *m/z* 40 to 550, and the ion source was operated in electron ionization (EI) mode with an electron energy set to 70 eV.

Mosquito Bioassays. *Insects.* *Ae. aegypti* and *An. quadrimaculatus* larvae and adults used in these studies were from a laboratory colony maintained at the Mosquito and Fly Research Unit at the Center for Medical, Agricultural and Veterinary Entomology, USDA-ARS, Gainesville, FL, USA. For biting-deterrence bioassays, eggs were hatched and the insects were reared to the adult stage in the laboratory and maintained at 27 ± 2 °C and 60 ± 10% relative humidity with a photoperiod regimen of 12:12 h (light/dark). Adult females (8–13 days old) were used. For larval bioassays, the eggs were hatched and the larvae were maintained at the above temperature.

Mosquito Biting Bioassays. Experiments were conducted by using a six-celled in vitro Klun and Debboun (K&D) module bioassay system developed by Klun et al.[33] for quantitative evaluation of biting-deterrent properties of candidate compounds. Briefly, the assay system consists of a six-well reservoir with each of the 3 × 4 cm wells containing 6 mL of blood. As described by Ali et al.,[34] a feeding solution consisting of CPDA-1 (citrate–phosphate–dextrose–adenine) and ATP was used instead of blood. Green fluorescent tracer dye (www.blacklightword.com) was used to determine feeding by the females. Essential oils of *S. leucantha*, *S. elegans*, *S. officinalis*, *S. apiana* and individual compounds were tested in this study. Essential oils were applied at concentrations of 10 μg/cm^2, pure compounds at 25 nmol/cm^2, and DEET (97%, *N*, *N*-diethyl-*m*-toluamide) (Sigma-Aldrich, St. Louis, MO, USA) at 25 nmol/cm^2 as positive control. All treatments were freshly prepared in molecular biology grade 100% ethanol (Fisher Scientific Chemical Co., Fair Lawn, NJ, USA) at the time of bioassay. The temperature of the solution in the reservoirs was maintained at 37 °C by continuously passing warm water through the reservoir using a circulatory bath. Reservoirs were covered with a layer of collagen membrane (Devro, Sandy Run, SC, USA). Test compounds were randomly applied to six 4 × 5 cm areas of organdy cloth and positioned over the membrane-covered CPDA-1 + ATP solution with a Teflon separator placed between the treated cloth and the six-celled module to prevent contamination of the module. A six-celled K&D module containing five female mosquitoes per cell was positioned over the cloth treatments covering the six CPDA-1 + ATP solution membrane wells, and trap doors were opened to expose the treatments to these females. The number of mosquitoes biting through cloth treatments in each cell was recorded after a 3 min exposure, and mosquitoes were prodded back into the cells to check the actual feeding. Mosquitoes were squashed and the presence or absence of green fluorescent tracer dye in the gut was used as an indicator of feeding. A replicate consisted of six treatments: four test materials, DEET (a standard biting deterrent), and ethanol-treated organdy as solvent control applied randomly. Two sets of five replications each with five females per treatment were conducted on two different days using a newly treated organdy and a new batch of females in each replication. Treatments were replicated 10 times.

Larval Bioassays. Bioassays were conducted to test essential oils of *S. leucantha*, *S. elegans*, *S. officinalis*, and *S. apiana* for their larvicidal activity against moquitoes by using the bioassay system described by Pridgeon et al.[35] Five 1-day-old *Ae. aegypti* and *An. quadrimaculatus* larvae were added in a droplet of water to each well of 24-well plates (BD Labware, Franklin Lakes, NJ, USA) by use of a disposable 22.5 cm Pasteur pipet. Fifty microliters of larval diet (2% slurry of 1:1 beef liver powder (Now Foods, Bloomingdale, IL, USA) and brewer's yeast (Lewis Laboratories Ltd., Westport, CT, USA) was added to each well by using a Finnpipette stepper (Thermo Fisher, Vantaa, Finland). All chemicals tested were diluted in ethanol. Eleven microliters of the test chemical was added to the labeled wells, whereas 11 μL of ethanol was added to control treatments. After the treatment application, the plates were swirled in clockwise and counterclockwise motions and front and back and side to side five times to ensure even mixing of the chemicals. Larval mortality was recorded 24 h after treatment. Larvae that showed no movement in the well after manual disturbance of the water were recorded as dead. A series of five concentrations ranging between 125 and 1.95 ppm were used in each treatment to obtain a range of mortality. Treatments were replicated 10 times for each essential oil.

Statistical Analyses. Proportion not biting was calculated as described by Ali et al.[34] As the K&D module bioassay system can handle only four treatments along with negative and positive controls, in order to make direct comparisons among more than four treatments and to compensate for variation in overall response among replicates, biting-deterrent activity was quantified as biting deterrence index (BDI). The BDIs were calculated using the formula

$$[\mathrm{BDI}_{i,j,k}] = \left[\frac{\mathrm{PNB}_{i,j,k} - \mathrm{PNB}_{c,j,k}}{\mathrm{PNB}_{d,j,k} - \mathrm{PNB}_{c,j,k}}\right]$$

where $\mathrm{PNB}_{i,j,k}$ denotes the proportion of females not biting when exposed to test compound *i* for replication *j* and day *k* (*i* = 1–4, *j* = 1–5, *k* = 1–2), $\mathrm{PNB}_{c,j,k}$ denotes the proportion of females not biting the solvent control "*c*" for replication *j* and day *k* (*j* = 1–5, *k* = 1–2), and $\mathrm{PNB}_{d,j,k}$ denotes the proportion of females not biting in response to DEET "*d*"(positive control) for replication *j* and day *k* (*j* = 1–5, *k* = 1–2). This formula makes an adjustment for interday variation in response and incorporates information from the solvent control as well as the positive control.

A BDI value of 0 indicates an effect similar to that of ethanol, whereas a value significantly greater than 0 indicates biting-deterrent effect relative to that of ethanol. BDI values not significantly different from 1 are statistically similar to DEET. BDI values were analyzed using the ANOVA procedure of SAS [single factor: test compound (fixed)] (SAS Institute, 2007), and means were separated using the Ryan–Einot–Gabriel–Welsch multiple-range test. To determine whether confidence intervals included the values of 0 or 1 for treatments, Scheffe's multiple-comparison procedure was used with the CLM option in SAS. LC_{50} values for larvicidal data were calculated by using the PROBIT procedure of SAS. Control mortality was corrected by using Abbott's formula.[36]

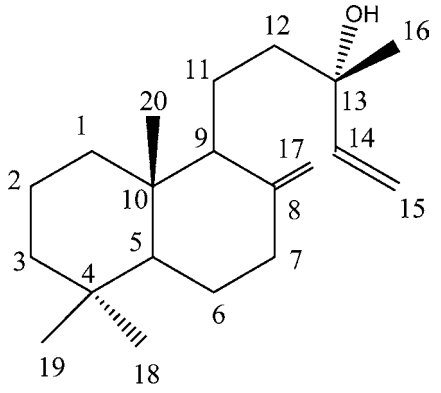
RESULTS AND DISCUSSION

The composition of four *Salvia* species was investigated in the present study. Identified compounds ranged between 90 and 99% (Table 1). *S. apiana* essential oil contained 1,8-cineole

DOI: 10.1021/jf504976f
J. Agric. Food Chem. 2015, 63, 447–456

(71.7%) as a major constituent followed by monoterpene hydrocarbons α-pinene (5.1%), camphor (4.4%), and β-pinene (3.8%). *S. elegans* essential oil had high content of borneol (17.4%), β-eudesmol (10.4%), bornyl acetate (5%), and guaiol (4.8%). Major constituents of *S. leucantha* oil were bornyl acetate (11.4%), caryophyllene oxide (13.5%), β-caryophyllene (6.5%), and spathulenol (7.0%). *S. officinalis* oil was rich in monoterpene hydrocarbon α-thujene (25.8%) and had high content of oxygenated sesquiterpene viridiflorol (20.4%).

Many studies have reported the composition of essential oils of these *Salvia* species. Chemical composition data on the essential oil of *S. apiana* showed 1,8-cineole as a major compound.[37,38] Mathew and Thoppil[27] reported spathulenol (38.73%) and β-caryophyllene (10.32%) as the major compounds of the *S. elegans* essential oil in samples extracted from the plant material collected from Ooth, southern India. Data on *S. elegans* essential oil differ from the above study where spathulenol (1.3%) is a minor compound and β-caryophyllene is totally absent. On the other hand, the *S. elegans* essential oil obtained from the cultivated species from Eboli, Italy, contained *cis*-thujone (38.7%), δ-cadinene (11.5%), geranyl acetate (6.9%), and geraniol (6.5%).[39] Data on the composition of *S. leucantha* essential oil corroborate the findings of Rondon et al.[40] Negi et al.,[41] and Upadhyaya et al.,[42,43] who reported bornyl acetate as the major compound followed by sesquiterpene hydrocarbons such as β-caryophyllene, α-guaiene, β-gurjunene, *cis*-muurola-3,5-diene, germacrene D, and bicyclogermacrene. In earlier investigations of the *Salvia* essential oils, we studied *S. leucantha* volatiles obtained by microdistillation technique, which showed limonene (34.6%), α-pinene (16.7%), and borneol (16.5%) as the major compounds, whereas β-caryophyllene (5.6%) and caryophyllene oxide (5.4%) were the major sesquiterpenes with low content of oxygened monterpenene bornyl acetate (0.1%).[44] These differences in chemical composition could be due to distillation technique used or growing conditions of the plants. The essential oil of *S. officinalis* was characterized by α-thujone (25.8%), β-thujone (5.7%), camphor (6.4%), and 1,8-cineole (4.4%) as major components, which also determine their chemotypes. The presence of thujone isomers in the essential oils is important because of their neurotoxic and hepatotoxic effects.[45] Thujone is banned as a food additive in the United States and Europe. The most common consumption of thujone is in dietary supplements such as sage-flavored products, teas, and drops and alcoholic beverages.[46] Oelschlagel at al.[46] found that *S. officinalis* 'Extrakta' contained the highest levels of α-thujone. They also reported low α-thujone in the essential oils of *S. officinalis* subsp. *major*, *S. officinalis* 'Berggarten', and *S. officinalis* 'Aurea'. In the present study, the 'Extrakta' variety of *S. officinalis* essential oil showed a high percentage (25.8%) of α-thujone and therefore cannot be recommended for use in the production of sage supplements. During the GC-MS analysis, the peak at RRI 2679 of the *S. officinalis* oil was not identified by the in-house "Baser Library of Essential Oil Constituents"; however, its mass spectrum was similar to that of 13-*epi*-manool according to the Wiley GC/MS Library and MassFinder 3 Library. To ensure its identity, this compound was isolated and characterized by 1D and 2D NMR spectroscopic data analyses (Figure 1). The chemical shift of H-17a (δ 4.50 for 13-*epi*-manool and δ 4.46 for manool) is the key to distinguish 13*S* and 13*R* isomers.[48] In our case, the ^{1}H NMR chemical shift of H-17a was observed at δ 4.49 and could be concluded for 13-*epi*-manool. Moreover, the specific rotation that we found in this study {$[\alpha]_D^{25}$ = +59.2 (*c* 1.0, $CHCl_3$)} also supported the identity as 13-*epi*-manool {$[\alpha]_D^{24}$ = +28 (*c* 1.5, $CHCl_3$ for manool.[49]



13-*epi*-manool

Figure 1. Structure of 13-*epi*-manool.

The in vitro K&D system used in this study specifically quantified the mosquito biting-deterrent properties of *Salvia* essential oils and the pure compounds. Essential oils of *S. leucantha* (BDI value = 1.01) and *S. elegans* (BDI value = 0.87) showed biting-deterrent activity similar to that of DEET, whereas the activity of essential oils of *S. officinalis* (BDI value = 0.63) and *S. apiana* (BDI value = 0.48) demonstrated low biting-deterrent activity against *Ae. aegypti* (Figure 2). The major compounds of the active oils *S. elegans* and *S. leucantha* were individually investigated. Among the pure compounds, (+)-β-eudesmol (BDI value = 0.81) and (−)-guaiol (BDI value = 0.82) showed the highest biting-deterrent activity, which was similar to that of DEET at 25 nmol/cm^2, whereas the activities of (−)-borneol (BDI value = 0.69) and (−)-borneol acetate (BDI value = 0.52) were significantly lower than that of DEET. The sesquiterpenes (−)-β-caryophyllene, (−)-caryophyllene oxide, and (+)-spathulenol were high in *S. leucantha* oil, and we previously reported their biting-deterrent activity with BDI values of 0.54 and 0.66 against *Ae. aegypti*, respectively.[50] Spathulenol has been reported to show good biting-deterrent activity against *Ae. aegypti* and *An. stepheni*,[51] and similar response of high biting-deterrent activity was observed in our laboratory against *Ae. aegypti* (A. Ali, unpublished data). The oxygenated diterpene 13-*epi*-manool was also investigated for mosquito activity in a search of new mosquito-deterrent agents. The biting-deterrent activity of (+)-13-*epi*-manool (BDI = 0.75) was lower than that of (+)-β-eudesmol and (−)-guaiol against *Ae. aegypti*. In *An. quadrimaculatus*, essential oils of *S. elegans* (BDI value = 0.9) and *S. leucantha* (BDI value = 0.86) also showed higher biting-deterrent activity that was similar to that of DEET, whereas the activities of essential oils of *S. officinalis* (BDI value = 0.6) and *S. apiana* (BDI value = 0.56) were lower than that of DEET (Figure 3). Pure compounds (+)-β-eudesmol (BDI value = 0.82) and (−)-guaiol (BDI value = 0.82) showed activity similar to that of DEET at 25 nmol/cm^2. (+)-13-*epi*-Manool demonstrated higher biting-deterrent activity than (−)-caryophyllene oxide, (−)-borneol, (−)-bornyl acetate, and (−)-β-caryophyllene; however, its activity was significantly lower than those of (+)-β-eudesmol, (−)-guaiol, or DEET in both species.

Previous research papers show repellent activity of essential oils of various *Salvia* species against different species of

J. Agric. Food Chem. 2015, 63, 447−456

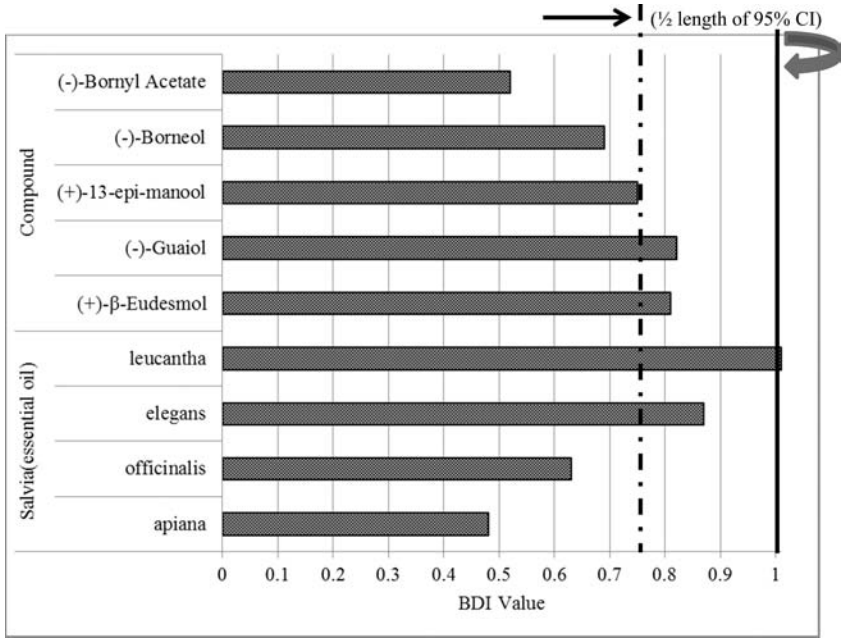

Figure 2. Biting-deterrent index (BDI) values of the essential oils extracted from samples of aerial parts of four species of *Salvia* and individual compounds against female *Ae. aegypti*. Essential oils were tested at 10 $\mu g/cm^2$ and the pure compounds were tested at 25 nmol/cm^2. Ethanol was the solvent control, and DEET at 25 nmol/cm^2 was used as positive control.

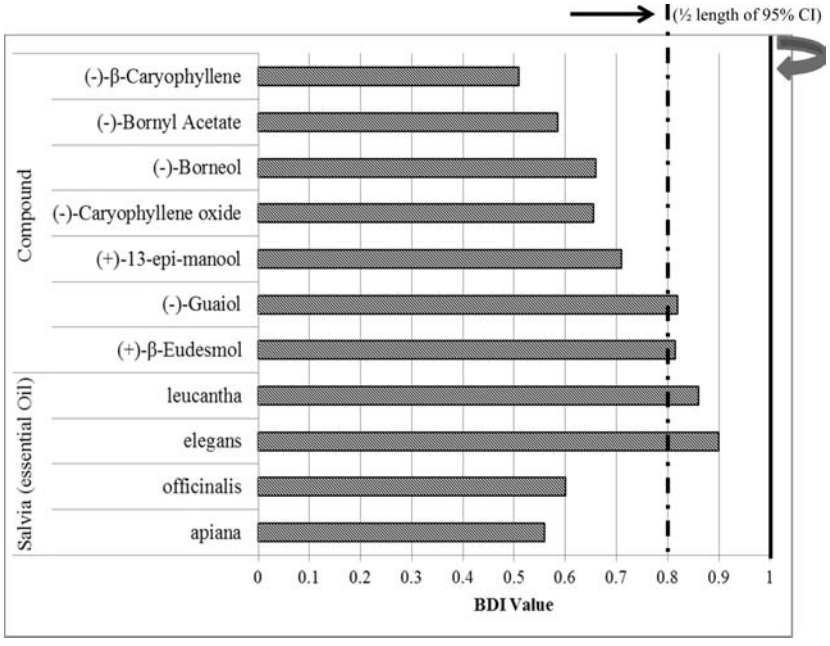

Figure 3. Biting-deterrent index (BDI) values of the essential oils extracted from samples of aerial parts of four species of *Salvia* and individual compounds against female *Anophelese quadrimaculatus*. Essential oils were tested at 10 $\mu g/cm^2$, and the pure compounds were tested at 25 nmol/cm^2. Ethanol was the solvent control, and DEET at 25 nmol/cm^2 was used as positive control.

mosquitoes. Conti et al.[26] reported that essential oils of *S. dorisiana*, *S. longifolia*, and *S. sclarea* have significant but variable repellent activity against *Ae. albopictus*. Essential oils of *S. dorisiana* with protection efficacy of 91−95% and protection times of 9.2 to 92.4 min were most active, whereas protection times of essential oils of *S. longifolia* and *S. sclarea* ranged between 3.2 and 60 min and between 3.6 and 64.2 min, respectively.[26] Amer and Melhorn[25] reported good repellent activity of essential oils of *S. sclarea* against mosquito species of *Ae. aegypti*, *An. stephensi*, and *Culex quinquefasciatus*. Kang et al.[52] showed low activity of essential oil of *S. officinalis* against *Culex pipens pallens* Cosquillett.

Ali et al.[50] reported significantly lower activity of (−)-*β*-caryophyllene and (−)-caryophyllene oxide than that of DEET against *Ae. aegypti*. Data of biting-deterrent activity of these compounds show a similar trend against *An. quadrimaculatus*. These data corroborate the finding of Paluch et al.,[53] who reported high repellent activity of (+)-*β*-eudesmol against *Ae. aegypti*.

[a]95% confidence interval. [b]df refers to degree of freedom. [c]NA (not active), showed <50% mortality at the highest screening dose of 125* ppm for essential oil and 100** ppm for pure compounds. [d]NT (not tested), ** compounds were not tested against *An. quadrimaculatus*. [e]Data from Ali et al.[47]

In larval screening bioassay, all of the essential oils showed larvicidal activity except *S. apiana*, which was inactive at the highest tested dose of 125 ppm against both mosquito species. Essential oil of *S. elegans* with LC_{50} and LC_{90} values of 14.4 and 27.2 ppm, respectively, showed the highest toxicity followed by the *S. leucantha* essential oil with LC_{50} and LC_{90} values of 29.5 and 51.8 ppm, respectively, against *Ae. aegypti* (Table 2). The toxicity of *S. officinalis* essential oil with LC_{50} and LC_{90} values of 56.9 and 92.4 ppm, respectively, was significantly lower than that of *S. leucantha* or *S. elegans* essential oils. In *An. quadrimaculatus*, essential oil of *S. leucantha* with LC_{50} and LC_{90} values of 6.2 and 15.8 ppm, respectively, showed the highest toxicity, which was significantly higher than those of *S. elegans* and *S. officinalis* essential oils (Table 2). The toxicity of *S. elegans* and *S. officinalis* essential oils was similar. In general, mortality was higher for *An. quadrimaculatus* with all of the oils tested than for *Ae. aegypti*. Of the tested pure compounds, only (−)-β-caryophyllene and (−)-caryophyllene oxide showed larvicidal acyivity with LD_{50} values of 26.0 and 29.8 ppm, respectively, against *Ae. aegypti*.[48] All other pure compounds tested in this study (borneol, bornyl acetate, guaiol, β-eudesmol, and 13-*epi*-manool) showed very weak or no activity at the highest dose of 100 ppm in the larvicidal screening bioassays against *Ae. aegypti* and *An. quadrimaculatus* larvae. Therefore, LD_{50} values were not calculated. The LD_{50} value of permethrin, which was used as positive control, was 0.0034 ppm.

Several studies have evaluated the toxicity of essential oils from various species of *Salvia* against mosquito larvae. Mathew and Thoppil[27] reported larvicidal toxicity of essential oils from aerial parts of *S. elegans*, *S. dorisiana*, *S. splendens* 'Blue Ribbon', and *S. splendens* 'Scarlet Sage Red' against larvae of *Ae. albopictus*. Essential oils of *S. elegans* and *S. splendens* 'Blue Ribbon' with LC_{50} values of 46.4 and 59.2 ppm, respectively, showed higher toxicity than *S. dorisiana* and *S. splendens* 'Scarlet Sage Red'. The essential oil of *S. dorisiana* showed insignificant toxicity against 4-day-old larvae of *Ae. albopictus*,[26] whereas the ethanol extract of *S. dorisiana* showed toxicity against the fourth-instar larvae of *C. pipiens* L. (LC_{50} = 62.7 ppm).[54] Pavela[55] reported larvicidal activity of essential oils from six species of *Salvia* against *C. quinquefasciatus* Say larvae. In addition, *S. sclarea* and *S. officinalis* essential oils showed larvicidal activity against *Spodoptera littoralis* Boisduval in both topical and fumigation trials,[56] whereas in topical and fumigation trials *S. officinalis* essential oil showed toxicity against *Musca domestica* L. adults.[57] Guaiol is reported to show larvicidal activity against larvae of *Mythimna separata* and *Plutella xylostella* and fumigant activity against larvae of *My. separata* and adult *Mu. domestica*.[58] However, this is the first report of larvicidal activity of guaiol against mosquitoes, and very low activity was found.

In conclusion, essential oils of *S. leucantha* and *S. elegans* showed biting-deterrent activity similar to that of DEET in both species of mosquitoes. *S. leucantha*, *S. elegans*, *S. officinalis*, and *S. apiana* essential oils contained 65.4, 38.5, 30.8, and 3.3% sesquiterpenes, respectively. Essential oils of *S. leucantha* and *S. elegans* were rich in sesquiterpenes. The biting-deterrent activity of these essential oils appears to follow the pattern of various sesquiterpene levels present in the individual oils. Essential oils of *S. leucantha* and *S. elegans*, with their high levels of sesquiterpenes, showed biting-deterrent activity similar to that of DEET. This is the first report on biting-deterrent activity of these oils against mosquitoes. Results indicate that essential oils of *S. leucantha* and *S. elegans* can be useful for preventing mosquito bites because of their demonstrated activity and, in general, most essential oils are considered to be minimum risk products. The diterpene 13-*epi*-manool was investigated for the first time against mosquitoes. The pure compounds β-eudesmol and guaiol show promise for development as mosquito deterrents. Essential oils of *S. leucantha*, *S. elegans*, and *S. officinalis* also showed larvicidal activity against both species of mosquitoes. Essential oils of these *Salvia* species are an important source of compounds that can be useful in developing selective, biodegradable, and naturally produced mosquito deterrents. However, further research is needed to identify activity of individual sesquiterpenes present in these oils and in mixtures of these sesquiterpenes to develop formulations for use as mosquito biting deterrents.

[§]Department of Agricultural Sciences, Biotechnology and Food Science, Cyprus University of Technology, 3603 Lemesos, Cyprus

ABSTRACT: Plant pathogenic fungi are considered of significant economic importance for adversely affecting both quantitatively and qualitatively fresh and processed produce. Extracts of *Salvia fruticosa* were initially screened for their antifungal activity, and the ethyl acetate fraction, being the most active, was further analyzed using HPLC-SPE-NMR hyphenation. The methoxylated flavones hispidulin, salvigenin, and cirsimaritin and the diterpenes carnosic acid, carnosol, and 12-methoxycarnosic acid were identified as the major components of the extract. In addition, the concentration levels of all identified components were determined using q-NMR. The antifungal activity of the crude extract and selected phytochemicals was estimated against the fungal species *Aspergillus tubingensis*, *Botrytis cinerea*, and *Penicillium digitatum*. The estimated MIC and MFC values of the ethyl acetate extract of *S. fruticosa*, as well as three of its major constituents, carnosic acid, carnosol, and hispidulin, support their antifungal activity, especially against *B. cinerea* and *P. digitatum*, suggesting their potential use in food and agricultural systems.

KEYWORDS: *Aspergillus tubingensis, Botrytis cinerea, diterpenes, flavonoids, Greek sage, Penicillium digitatum, phytochemicals, q-NMR*

INTRODUCTION

The genus *Salvia* is one of the largest genera in the Lamiaceae family. It comprises approximately 900 species that grow throughout the world, some of which are economically important considering their extensive use as spices, flavoring agents, and herbal drugs.[1,2] Ethnopharmacological studies reported that *Salvia* species have been used for more than 60 different ailments ranging from aches to epilepsy and mainly to treat colds, bronchitis, tuberculosis, hemorrhage, and menstrual disorders.[3] *Salvia officinalis* L. (sage), *Salvia miltiorrhiza* (red sage), *Salvia divinorum*, and *Salvia fruticosa* (Greek sage) are the most well-known and studied *Salvia* species.[3−6]

S. fruticosa is cultivated and/or grows wild in macquis and phrygana ecosystems in the Mediterranean basin.[4] Traditionally, aerial parts of *S. fruticosa* were used to treat many diseases such as malaria, fever, pneumonia, gastrointestinal tract disorders, cholera, plague, and common cold.[7] Numerous studies have revealed several physiological responses to *S. fruticosa*, which may be relevant to the promotion of health and the prevention or treatment of some chronic diseases. Antiproliferative activity against cancer cells,[8] cholinesterase inhibitory activity,[9] protection from oxidative damage of DNA,[10] and anti-inflammatory[11] and antimicrobial activities[1,2] of *S. fruticosa* have been highlighted. Furthermore, research has manifested the inhibitory effect of *S. fruticosa* against plant pathogenic fungi, such as *Aspergillus terreus*, *Fusarium oxysporum*, *Penicillium expansum*, *Verticillium dahliae*, *Botrytis cinerea*, *Alternaria solani*, *Rhizoctonia solani*, and *Sclerotinia sclerotiorum*. It is noteworthy that the antifungal potency of *S. fruticosa* has been mainly focused toward the efficacy of its essential oils, whereas their polar extracts have not been studied yet.[12−15]

Salvia species are known to be rich in a number of natural products such as essential oils, diterpenoids, triterpenoids, and flavonoids.[16] Phytochemical studies showed that *S. fruticosa* extracts are complex mixtures of diterpenes, phenolic acids, and flavonoids, but their phytochemical composition has not been studied thoroughly yet. Previous works on *Salvia* focused on targeted phytochemicals, using mainly chromatographic techniques highlighting the characteristic presence of carnosic acid, carnosol, and flavonoids.[17−21]

Direct crop losses caused by plant pathogenic fungi, as well as indirect product deterioration imposed by such contaminants, pose significant health and economic problems. In the agricultural sector, an array of approaches is employed to encounter the causal agents, with the use of conventional fungicides as the core component. However, concerns about environmental and human health risks associated with fungicide residues, in addition to issues regarding fungicide resistance due to their overuse, emphasize an increasing need to find and implement an alternative to synthetic fungicides approach, such as biofungicides.[22] Natural products, crude or isolated from aromatic and medicinal plants, can be envisaged as new antifungal ingredients.

In the search for naturally occurring antimicrobial agents, the antifungal activity of *S. fruticosa* extracts against the plant pathogenic fungi *Aspergillus tubingensis*, *B. cinerea*, and *P. digitatum* was assessed. The ethyl acetate extract of *S. fruticosa* was studied for the first time using HPLC-SPE-NMR set-up and q-NMR to reveal its phytochemical composition. Then, the antifungal activity of the major identified phytochemicals, namely, carnosic acid, carnosol, and hispidulin, was determined against plant pathogenic fungi using disk diffusion and broth microdilution assays because there are no data on their antifungal potency.

MATERIALS AND METHODS

Plant Material, Chemicals, and Fungal Microorganisms. *S. fruticosa* Mill. was collected from the Athalassa botanical gardens in Nicosia, Cyprus (Department of Agriculture, Ministry of Agriculture, Natural Resources and Environment) and was air-dried and pulverized into fine powder. Carnosic acid (≥91%), carnosol (≥98.0%), and hispidulin (≥98.0%) were obtained from Sigma-Aldrich to test their antifungal potency. Formulated fungicides containing the active ingredients fenhexamid (Teldor© 50WG; Bayer CropScience) and fludioxonil (Geoxe 50WG; Syngenta Crop Protection) were purchased from local authorized suppliers. Analytical grade solvents were obtained from Acros Organics. Water was prepared by reversed osmosis (Rios, Millipore), and for HPLC Milli-Q water (Millipore) was used. CH_3CN d_3, 99.8%, was purchased from Sigma-Aldrich.

Pure cultures of *A. tubingensis*, *B. cinerea*, and *P. digitatum* on Sabouraud agar, identified by molecular and standard microbiological methods, were used in the antimicrobial assays. Culture media, Sabouraud dextrose agar (SDA) and Sabouraud dextrose broth (SDB) were obtained from Oxoid.

Extraction and Sample Preparation. The extraction was carried out on a semi-automated Soxtec system 2055 (Foss Analytical, Hilleroed, Denmark) as described in previous work.[23] Three grams of plant material was placed into extraction thimbles, and 80 mL of ethyl acetate was transferred into each Soxtec extraction cup. Phytochemicals were extracted by setting the unit at the boiling position for 30 min and then at the rising position for 1 h. The ethyl acetate extracts were allowed to cool at room temperature and evaporated to dryness in a rotary evaporator at 45 °C. The dry extracts were stored at −20 °C until needed.

The ethyl acetate sage extract (27.2 mg) was dissolved in 1.5 mL of acetonitrile/water (2:1, v/v) and centrifuged. The supernatant was subjected to HPLC-SPE-NMR analysis.

HPLC-SPE-NMR. HPLC-SPE-NMR measurements were carried out on a chromatographic separation system consisting of an Agilent 1200 series HPLC with an in-line solvent degasser, quaternary pump, autosampler, column compartment with thermostat, and a diode array detector. The optimized HPLC-SPE-NMR parameters were used to analyze *S. fruticosa* extracts.[24] The Bruker/Spark Prospect 2 solid phase extraction unit (Bruker BioSpin and Spark, Emmen, The Netherlands) was used to trap the chromatographic peaks on Hysphere General Phase cartridges (2 mm i.d., 10−12 μm) after post-column addition of water by a Knauer K 120 HPLC pump (Berlin, Germany). The chromatographic peaks were multiply trapped from repeated HPLC injections on the same cartridge to increase their concentration, dried with dry nitrogen gas, and eluted with acetonitrile-d_3 into 3 mm NMR tubes using a Gilson Liquid Handler 215. 1D and 2D NMR spectra were recorded on a Bruker DRX-400 MHz instrument equipped with a 3 mm inverse broadband (BBI) probe using standard Bruker pulse sequences. The NMR system was controlled by software TopSpin 1.3 (Bruker BioSpin, Rheinstetten, Germany). Chemical shifts were expressed in parts per million (ppm) referenced to the solvent peak (1.94 ppm for CD_3CN).

The chromatographic separation was carried out a Luna C_{18}, 5 μm, analytical column (25 cm × 4.6 mm i.d., Phenomenex). The flow rate was 0.6 mL min^{-1}, and the injection volume was 50 μL. Gradient elution was performed using 0.1% formic acid (solvent A) and acetonitrile (solvent B) with the following linear gradient combination: at t = 0 min A = 90%, at t = 10 min A = 70%, at t = 20 min A = 50%, at t = 35 min A = 20%, at t = 50 min A = 0%, at t = 55 min A = 0%, and at t = 60 min A = 90%.

Quantitative NMR for Major Phytochemicals. For the quantitative analysis three independent samples were prepared by weighing 5 mg of the extract, adding 300 μL of acetonitrile-d_3, and transferring the mixture to 3 mm NMR tubes. All chemical shifts were measured with reference to the internal standard, 3-trimethylsilyl-2,2′,3′,3′-tetradeuteropropionic acid (TMSP-d_4) (δ_H = 0.000 ppm), of known concentration (0.3 mmol L^{-1}). NMR measurements were recorded on a Bruker DRX400 MHz instrument equipped with a 3 mm inverse broadband (BBI) probe (BrukerBiospin). The following acquisition parameters were used: $\pi/2$ excitation pulse; spectral width, 4006.4 Hz; 32K real data points; acquisition time, 4 s; relaxation delay, 15 s; number of transient accumulations, 256. Data were processed by using Topspin 1.3 (Bruker) software including manual phase correction and baseline correction over the entire spectral range.

Antifungal Properties. *Disk Diffusion Assay.* The inhibitory activity of the *S. fruticosa* extract and its main constituents on the mycelial growth of the plant pathogenic fungi *A. tubingensis*, *B. cinerea*, and *P. digitatum* was assessed by the disk diffusion assay.[25] The ethyl acetate extract of *S. fruticosa*, as well as its pure carnosic acid, carnosol, and hispidulin, was dissolved in 2 and 5% aqueous dimethyl sulfoxide (DMSO) solutions, respectively, and stock solutions of 1000 μg mL^{-1} were prepared. Conidial suspensions (10^6 conidia mL^{-1}) of each fungus were evenly distributed on the surface of SDA Petri dishes and were allowed to dry. Subsequently, sterile 6 mm in diameter Whatman filter paper disks were impregnated with 20 mL of each antimicrobial agent and were placed in the center of the inoculated Petri dishes. The natural products were tested at concentrations of 400 and 200 μg mL^{-1}, whereas aqueous solutions of synthetic fungicides were used as positive reference standards at the concentration of 10 μg mL^{-1}. More specifically, the hydroxyaniline fenhexamid was used as a reference botryticide, whereas the phenyllpyrole fludioxonil was used against *A. tubingensis* and *P. digitatum*. Negative controls were prepared using the solvents employed to dissolve the antimicrobial agents at their highest concentration. The plates were then sealed and incubated in the dark for 72 h at 25 °C. Mean inhibition zone diameters (IZD) were calculated against each microorganism by means of a ruler. Experiments were conducted three times, with two replicates per experiment.

Broth Microdilution Assay. A serial broth microdilution method was used to determine the minimum inhibitory concentrations (MIC) values of the ethyl acetate extract of *S. fruticosa* and its major constituents against the aforementioned plant pathogenic fungi.[25,26] Briefly, stock solutions of the natural antimicrobials were prepared in DMSO and serially diluted to obtain the desired final concentrations ranging from 300 to 10 μg mL^{-1}. The final DMSO content was 5% (v/v), and this solution was used as negative control. It is noteworthy that the DMSO controls did not show any inhibitory effects on the growth of the microorganisms tested (data not shown). One hundrend microliters of each tested concentration was added per well (96-well microplate) containing 80 μL of SDB and 20 μL of inoculum (10^6 conidia mL^{-1}). The final volume in each well was 200 μL. Aqueous solutions of fenhexamid and fludioxonil were used as standard fungicides for positive control (0.5, 0.1, 0.05, 0.01, 0.005, and 0.001 μg mL^{-1}). For each microorganism a sterility control that contained only the culture medium and a growth control for the respective conidial suspension without the tested antimicrobial agents were included. The plates were covered with a sterile plate sealer and incubated at 25 °C for 72 h in an orbital shaking incubator at 120 rpm. The assay was conducted three times, with two replicates per experiment. MIC was defined as the lowest concentrations of the compound that completely inhibited visible growth of the tested fungi. After the MICs were estimated, 20 mL samples from all of the optical clear wells, plus one negative control that showed growth, were spread onto the surface of SDB Petri dishes and incubated at 25 °C for a minimum of 72 h until mycelial growth was visible in the control plates. The minimum fungicidal concentration (MFC) value was determined as the lowest

DOI: 10.1021/jf5050734
J. Agric. Food Chem. 2015, 63, 457−463

concentration of the antimicrobial agent resulting in no growth on subculture, indicating 99.5% killing of the original inoculum.[26,27] Each experiment was repeated three times, and mean MFC values were calculated.

Statistical Analysis. The relative inhibition data for each fungal microorganism were compared using analysis of variance (ANOVA) and least significant difference (LSD) separation procedures of SAS version 9.1 (SAS Institute, Cary, NC, USA).

RESULTS AND DISCUSSION

Phytochemical Analysis of *S. fruticosa* Extract. Solvents of different polarities such as hexane, ethyl acetate, methanol, and water were used to prepare extracts of *S. fruticosa*. Preliminary data showed that ethyl acetate extract had the most potent antifungal potency among the tested extracts (data not shown). Therefore, the ethyl acetate extract of *S. fruticosa* was selected to be further analyzed. The chromatographic separation of the ethyl acetate extract of *S. fruticosa* was optimized and displayed six major peaks. The first three chromatographic peaks showed a UV spectrum (UV maxima at 260−270 and 340−350 nm) similar to those of flavonoids.[24] Their ^{1}H NMR spectra confirmed the flavonoid skeleton due to the presence of a deshielded signal in the region of 12−13 ppm attributed to hydroxyl proton OH-5 and the distinctive spin system in the aromatic region.[28] All three compounds exhibited an AA′XX′ pattern with two doublets resonating at the regions of ∼7.9 and 6.9 ppm, respectively, with a *J* coupling of 8.8 Hz and a number of singlets at the region of 3.7−3.9 ppm indicating the presence of methoxy groups. By comparison of the data obtained herein with those previously reported, compounds **1**, **2**, and **3** were identified as hispidulin (4′,5,7-trihydroxy-6-methoxyflavone), cirsimaritin (4′,5-dihydroxy-6,7-dimethoxyflavone), and salvigenin (5-hydroxy-6,7,4′-trimethoxyflavone).[29−31] The identified flavones differ in the degree of methylation of their hydroxyl groups. All compounds were unambiguously identified using 2D NMR experiments (COSY, HSQC, and HMBC), and their structures are described in Table 1 and Figure 1. Hispidulin and cirsimaritin were found for the first time in *S. fruticosa*, although they had been detected in other *Salvia* species.[32,33] The salvigenin in *S. fruticosa* has been recently identified.[34]

Compound **4** showed a methyl singlet at 0.85 integrating to six protons, two methyl doublets at 1.15 and 1.16 ppm, respectively, integrating to six protons, a 1H multiplet at 3.18 ppm, a 1H doublet at 5.39, and 1H singlet at 6.75 ppm. This combination of signals indicates a carnosol type diterpene. A comparison with literature NMR data allowed the identification of compound **4** as carnosol. The lack of signals in the region of 4−6 ppm and the similarity observed in almost all signals indicated the presence of carnosic acid (**5**). Compound **6** was easily attributed to 12-methoxycarnosic acid, due to the additional signal at 3.64 ppm integrating to three protons that suggested the presence of a methoxy group. All results are in agreement with previously reported NMR data and listed in Table 1 and Figure 1.[35,36] Carnosic acid and carnosol are the most well-known diterpenes in *Salvia* species, and they have been found in *S. fruticosa*.[19] The methoxy derivative of carnosic acid (compound **6**) is widely distributed in *Salvia* species,[37] but its presence in *S. fruticosa* has not been reported.

Quantitative ^{1}H NMR (q-NMR) is an extremely useful tool for the quantification of constituents in complex plant extracts without the need of laborious and time-consuming fractionation and isolation procedures. The area (referred to as the

[a]The minimum inhibitory concentration (MIC) was evaluated using the broth microdilution method in Sabouraud dextrose broth. MICs were defined as the lowest concentrations causing no visible growth. Results were read after 72 h of incubation at 25 °C. [b]After the MIC values were determined, samples from all optically clear tubes (complete growth inhibition), plus a negative control showing growth, were subcultured on Sabouraud dextrose agar. The dishes were incubated at 25 °C for 3 days, until growth was clearly visible in the control, and the minimum fungicidal concentration (MFC) value was determined as the lowest concentration with no visible growth. [c]Ethyl acetate extract of *S. fruticosa* in 2% (v/v) DMSO. [d]Stock solutions of the pure compounds of the main constituents of *S. fruticosa* tested in 5% (v/v) DMSO. intensity or the integral) of a NMR signal is directly proportional to the number of corresponding nuclei and thus, at variance with other techniques, the response factor is not dependent on the molecular structure. To date, q-NMR is considered to be at least as reliable and precise as the more commonly used chromatography-based techniques while providing several advantages such as simple method development, easy sample preparation, relatively short analysis time, and multiple calibration options without the need for identical reference materials.[38] The quantification of polyphenols and terpenes in complex plant extracts using q-NMR has been described comprehensively.[39,40] In Table 1, the concentration levels of the identified phytochemicals are displayed and show that carnosic acid and its 12-methoxy derivative were the main components of plant extract. Carnosol and hispidulin derivatives were found at lower concentrations ranging from 8.0 to 27.1 mg g^{-1}. Overall, the amount of diterpenes (381.3 mg g^{-1}) was significantly higher than that of flavonoids (45.6 mg g^{-1}) in *S. fruticosa* extract.

Antifungal Potential of *S. fruticosa* Extract and Its Constituents. It is difficult to correlate the antimicrobial activity of an extract to a specific compound due to their complexity and variability. Nevertheless, researchers have reported on the relationship between the chemical composition of the most abundant components of the extracts and their antimicrobial activity.[41] In addition, a structure−activity relationship for antimicrobial activity on a plethora of chemical classes is well documented.[42,43] Among the six major phytochemicals described in the present study, the selection of those that were further assessed for their antifungal activity was based on their abundance in the extract and their structural attributes. Thus, the diterpene carnosic acid was selected, because it was the predominant compound of the extract, and carnosol, for its structural dissimilarity among the other diterpenes found. With regard to the flavonoids, hispidulin was chosen because the other two, cirsimaritin and salvigenin, are hispidulin methoxy derivatives. The antifungal activity of *S. fruticosa* was initially qualitatively assessed against *A. tubingensis*, *B. cinerea*, and *P. digitatum*. The IZD was measured and the percent relative inhibition (RI) was estimated as the quotient of each antimicrobial agent of natural origin to that of the synthetic fungicide used per microorganism, considering the inhibition caused by each synthetic fungicide to be 100%. Overall, the inhibitory effect of all tested compounds was better at the concentration of 400 μg mL^{-1}, whereas among them the *S. fruticosa* extract was the most active against all fungal species, exhibiting moderate to high antifungal activity (Table 2). The least inhibited species by the extract was *A. tubingensis* with an RI of 49%, whereas for *B. cinerea* and *P. digitatum* the RI values were 74.3 and 76.7%, respectively. With regard to the natural compounds present in the extract, carnosic acid was the only one that caused inhibition across all tested microorganisms, ranging from the high 62.3% RI for *B. cinerea* to the lower 31.7% RI for *A. tubingensis*, whereas hispidulin performed the best against *P. digitatum*. Their antifungal potency was also quantitatively evaluated by means of MIC and MFC values (Table 3). The results confirmed that overall *A. tubingensis* was the least inhibited among the tested fungal species, as shown by the disk diffusion assay, with MIC values of 300 μg mL^{-1} for all *S. fruticosa* compounds, but carnosic acid had an MIC value of 200 μg m^{-1}. Similarly, MFC values recorded were ≥300 μg mL^{-1}. On the other hand, MIC values of *B. cinerea* and *P. digitatum* in the presence of the extract after 72 h were 100 and 150 μg mL^{-1}, respectively. On the basis of the MIC values of the pure phytochemicals, it can be suggested that overall *B. cinerea* was better inhibited (Table 3). *P. digitatum* MIC values were also in the same range. *B. cinerea* and *P. digitatum* exhibited the lowest MIC values in carnosol (100 μg mL^{-1}), followed by carnosic acid and hispidulin.

Cos et al. defined stringent end point criteria for "activity", suggesting that plant extracts should be considered efficacious if they exhibit IC_{50} values ≤100 μg mL^{-1}.[44] Considering that for the same active ingredient/microorganism system the MFC values, indicating 99.5% killing, should be by definition lower than its IC_{50} values, the ethyl acetate extract of *S. fruticosa* possesses antimicrobial properties worthy of further investigation, because the calculated MFC values for *B. cinerea* and *P. digitatum* were not far from the cutoff "activity" value.

The calculated MFC values for carnosic acid, carnosol, and hispidulin are in the same range as the extract itself, suggesting that probably its antifungal activity cannot be solely attributed to a single constituent. The antifungal potency of the extract also cannot be correlated with cirsirimatin, salvigenin, and 12-methoxycarnosic acid, because they were found at low concentrations and their chemical structures are closely similar to the tested phytochemicals.

DOI: 10.1021/jf5050734
J. Agric. Food Chem. 2015, 63, 457−463

A plethora of experimental studies have documented the promising biological activities of diterpenoids isolated from *Salvia* species, showing that most of them possess cytotoxic activity.[45] Carnosic acid and carnosol, as well as rosmanol and ferruginol, have been considered to be responsible for the biological activity of *Salvia* spp.[46] Collins and Charles manifest the significant inhibition of a range of food spoilage bacteria and yeasts by carnosol,[47] whereas carnosic acid and carnosol have been suggested to be responsible for the antimicrobial activity of *Rosmarinus officinalis* leaf extract against selected oral, cariogenic bacteria. The potent antifungal activity of carnosic acid against an array of yeast and molds was also documented by Gigante and co-workers.[48] With regard to hispidulin, no strong antimicrobial activity against *Staphylococcus aureus*, *Bacillus cereus*, *Escherichia coli*, *Salmonella typhimurium*, and *Candida albicans* was found because its MIC was >250 $\mu g\ mL^{-1}$.[49] The antifungal activity of cirsimaritin and salvigenin is maybe weaker than that of hispidulin as these compounds contain only one hydroxyl group on ring A, whereas a high antifungal activity of flavones is guaranteed by at least two hydroxyl groups on ring A.[50]

The action of different classes of natural products with diverse modes may be responsible for the antifungal activity of an extract. With regard to their mode of action, carnosic acid has exhibited the capacity to act as a natural free radical scavenger with a potential chemopreventive activity, whereas diterpenoids with antifungal activity on *B. cinerea* have been reported to induce permeabilization of the fungal cell membrane.[51,52] Flavonoids inhibit the growth of *Fusarium* spp. by different mechanisms, such as cross-linking of microbial enzymes; inhibition of microbial cellulases, xylanases, and pectinases; chelation of metals necessary for enzyme activity; and/or formation of a hard, almost crystalline, structure as a physical barrier against pathogen attack.[53]

Overall, the results obtained herein suggest the ability of the ethyl acetate extract of *S. fruticosa* to control a panel of fungal species, particularly responsible for postharvest fruit spoilage. In addition, MIC and MFC values of this extract meet the end point criteria for "activity". Research could be conducted toward the application of the extract alone or in combination with synthetic fungicides in the food industry, because it could be incorporated to edible coatings to control decay in organic production of horticultural crops. In addition, the documented antifungal activity of the *S. fruticosa* presented in this study should be explored also in other pathosystems to further elucidate its promising antimicrobial potential. HPLC-SPE-NMR and q-NMR experiments showed that diterpenes (carnosol, carnosic acid, 12-methoxycarnosic acid) and flavonoids (hispidulin, cirsimaritin, salvigenin) are the main constituents of the ethyl acetate extract. Although the antifungal potencies of carnosic acid, carnosol, and hispidulin could be characterized as moderate, they could be used as lead compounds toward the discovery of new antifungal agents.

Enantioselective Syntheses and Sensory Properties of 2-Methyl-tetrahydrofuran-3-thiol Acetates

Yifeng Dai, Junqiang Shao, Shaoxiang Yang, Baoguo Sun, Yongguo Liu, Ting Ning, and Hongyu Tian*

School of Food Chemistry, Beijing Key Laboratory of Flavor Chemistry, Beijing Technology and Business University, Beijing 100048, China

ABSTRACT: The enantioselective synthesis of four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate was achieved. The two enantiomers of the important intermediate *cis*-2-methyl-3-hydroxy-tetrahydrofuran were obtained by Sharpless asymmetric dihydroxylation (AD), whereas the two enantiomers of *trans*-2-methyl-3-hydroxy-tetrahydrofuran were derived from the corresponding optically active *cis*-isomers by Mitsunobu reaction. Each stereoisomer of 2-methyl-3-hydroxy-tetrahydrofuran went through mesylation and nucleophilic substitution to afford the corresponding product with specific configuration. (2*R*,3*S*)- and (2*R*,3*R*)-2-methyl-tetrahydrofuran-3-thiol acetate were obtained in 80% ee, whereas the (2*S*,3*R*)- and (2*S*,3*S*)-isomers were in 62% ee. The odor properties of the synthesized four stereoisomers were evaluated by gas chromatography−olfactometry (GC−O), which revealed perceptible differences among stereoisomers both in odor features and in intensities.

KEYWORDS: *2-methyl-tetrahydrofuran-3-thiol acetate, Sharpless AD, Mitsunobu reaction, enantioselective synthesis, sensory properties, GC−O*

INTRODUCTION

The olfactory properties of over 1400 enantiomers have been reported[1] since Rienäcker and Ohloff published the first data regarding the enantioselective perception of β-citronellol in 1961.[2] It is now well recognized that stereoisomers of many chiral chemical compounds are perceived differently as odorants by the human nose.[3] In addition to the differences in sensory properties, the stereoisomers of chiral odorants, such as Galaxolide and Tonalide, also have been found to be metabolized in living beings at different rates.[4] Therefore, it is significant to identify the desired odor-active isomers and further fulfill their commercial application from the prospective of improving odor qualities and reducing potential toxicological risks. Many research interests have been focused on the enantioselective preparation and organoleptic properties of chiral aroma compounds in recent years.[5−11]

Sulfur-containing compounds are an important category of flavor compounds due to their low odor thresholds and their unique odor features.[12,13] They are identified widely in volatile components of many foods and make significant contribution to food flavor,[14−18] especially to meat aroma.[19−23] 2-Methy-tetrahydrofuran-3-thiol is a representative sulfur-containing compound having meat aroma, which exists in four stereo-isomers due to the two chiral centers in the molecule. It is well-known that (±)-*trans*-isomer possesses stronger meaty and roasted notes while (±)-*cis*-isomer is weaker and has more sulfury and musty notes. Goeke prepared the four stereo-isomers by resolution and found their remarkable differences in odor features and intensities.[24] In comparison, the information about its acetylated form, 2-methyl-tetrahydrofuran-3-thiol acetate, is far more retarded, which was not been approved as a flavor compound in the United States by the Flavor Expert Panel (FEXPAN) before 2011 and appeared on the FEMA (Flavor and Extract Manufactures' Association) GRAS (generally recognized as safe) list 25 under no. 4686.[25] In our previous work, (±)-*trans*- and (±)-*cis*-isomers of 2-methyl-tetrahydrofuran-3-thiol acetate were prepared, and the odor properties were evaluated.[26] The results indicated that the diastereoisomers presented some organoleptic differences. However, as far as we know, the sensory properties of the four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate **1** (Figure 1) are still unknown. Therefore, the aim of this work

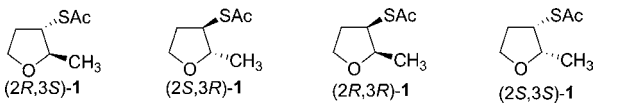

Figure 1. Four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate.

was to synthesize the four stereoisomers enantioselectively and investigate their sensory properties. In Goeke's work, the racemic diastereoisomers of 2-methyl-tetrahydrofuran-3-thiol were prepared by an iodocyclization approach starting from (3*Z*)- and (3*E*)-pent-3-en-1-ols, respectively. Also, (±)-*cis*-thiol was resolved via the camphanic acid thioesters to give the two enantiomers separately, whereas the two enantiomers of *trans*-thiol were produced via enzymatic resolution of *cis*-2-methyl-3-hydroxytetrafuran using the lipase *pseudomonas fluorescence*. Our present work tried a different way to prepare the four stereoisomers of **1** via chemical asymmetric catalytic approach (Figure 2).

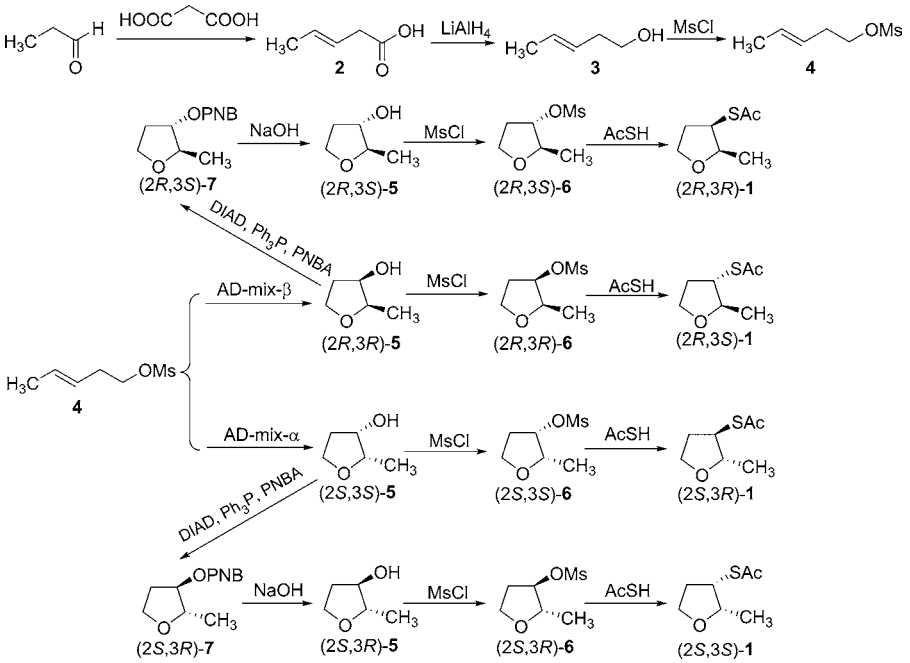

Figure 2. Synthetic routes leading to the optically active 2-methyl-tetrahydrofuran-3-thiol acetates.

MATERIALS AND METHODS

Chemicals. Triphenylphosphine (Ph_3P), diisopropyl azodicarboxylate (DIAD), and $LiAlH_4$ were purchased from Beijing Bailingwei Science and Technology Co. (Beijing, China), AD-mix-*α* and AD-mix-*β* were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO), and the others were purchased from Beijing Huaxue Shiji Co. (Beijing, China).

Syntheses. *(3E)-Pent-3-enoic Acid* ***2****.* The procedure for the preparation of **2** was adapted from the literature.[27] To a 1 L round bottomed flask equipped with a condenser and a bubbler connected to the exit of the condenser was added a solution of malonic acid (1 mol, 104 g), piperidinium acetate (from 0.85 g of piperidine and 0.6 g of acetic acid, 0.01 mol), and propionaldehyde (0.5 mol, 36.3 mL) in DMSO (400 mL). The reaction mixture was stirred at 40 °C for 2 h. Next, the solution was heated in an oil bath at 100 °C. A rapid evolution of carbon dioxide was observed. Heating was maintained until the evolution of carbon dioxide ceased. The solution was cooled to room temperature, poured into cold water (1 L), and extracted with diethyl ether. The combined extracts were washed with water, brine, dried over anhydrous $MgSO_4$, and evaporated under reduced pressure. The residue was distilled under vacuum (0.4 kPa, 60−65 °C) to give (3*E*)-pent-3-enoic acid **2** as a colorless oil (30 g, 60% yield). The product was used without further purification for the next step. ^{1}H NMR (300 MHz, $CDCl_3$): *δ* 1.68 (3H, d, *J* = 6.0 Hz, H-5), 3.05 (2H, d, *J* = 5.7 Hz, H-2), 5.54 (2H, m, H-3, H-4), 10−12 (1H, br, −COOH). ^{13}C NMR (75 MHz, $CDCl_3$): *δ* 17.9 (C-5), 37.8 (C-2), 121.9 (C-4), 130.0 (C-3), 179.0 (C-1). The spectral data of the obtained product were consistent with those as described by Thibonnet.[28]

(3E)-Pent-3-en-1-ol ***3*** *and (3E)-Pent-3-en-1-yl Mesylate* ***4****.* These two compounds were prepared according to our previously published procedures.[26] **3** was obtained by reduction of **2** with $LiAlH_4$ (88% yield), and then reacted with MsCl to give **4** (92% yield).

Data of **3**, ^{1}H NMR (300 MHz, $CDCl_3$): *δ* 1.65 (3H, d, *J* = 6.3 Hz, H-5), 2.22 (2H, m, H-2), 3.59 (2H, t, *J* = 6.3 Hz, H-1), 5.38 (1H, m, H-4), 5.57 (1H, m, H-3). ^{13}C NMR (75 MHz, $CDCl_3$): *δ* 18.0 (C-5), 35.9 (C-2), 62.0 (C-1), 127.2 (C-4), 128.1 (C-3).

Data of **4**, ^{1}H NMR (300 MHz, $CDCl_3$): *δ* 1.64 (3H, d, *J* = 6.3 Hz, H-5), 2.39 (2H, q, *J* = 6.9 Hz, H-2), 2.96 (3H, s, Me (mesyl)), 4.17 (2H, t, *J* = 6.9 Hz, H-1), 5.36 (1H, m, H-4), 5.57 (1H, m, H-3). ^{13}C NMR (75 MHz, $CDCl_3$): *δ* 17.5 (Me (C-5), 31.9 (C-2), 36.8 (Me (mesyl)), 69.4 (C-1), 124.5 (C-4), 128.7 (C-3).

(2R,3R)- or (2S,3S)-cis-2-Methyl-3-hydroxy-tetrahydrofuran ***5****.* The procedure for the Sharpless AD was adapted from the literature.[29] To a well-stirred mixture of AD-mix-*β* or AD-mix-*a* (11.05 g) in *t*-butyl alcohol−water (50 mL/50 mL) at room temperature was added **4** (1.312 g, 8 mmol). The reaction mixture was stirred at 5−10 °C overnight in the dark. Next, solid sodium sulfite (4 g) was added, and the mixture was stirred for an additional hour. Methylene chloride (30 mL) was added to the reaction mixture, and after separation of the layers, the aqueous phase (upper layer) was further extracted with CH_2Cl_2. The combined organic extracts were dried over anhydrous $MgSO_4$ and concentrated to give an oil, which was purified by column chromatography (silica gel, petroleum ether/ethyl acetate, 3/1) to afford (2*R*,3*R*)- or (2*S*,3*S*)-**5** as a light yellow oil.

*Data of (2R,3R)-****5*** *(from AD-mix-β).* 88% yield; purity, 95% by GC; 80% ee; $[\alpha]_D^{20}$ = −30.6° (*c* 4.80, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$): *δ* 1.27 (3H, d, *J* = 6.3 Hz, Me), 1.93 (1H, m, H-4a), 2.22 (1H, m, H-4b), 3.73 (2H, m, H-3, H-5a), 4.03 (1H, dd, *J* = 15.9, 8.1 Hz, H-5b), 4.17 (1H, m, H-2). ^{13}C NMR (75 MHz, $CDCl_3$): *δ* 13.7 (Me), 35.4 (C-4), 65.5 (C-5), 72.8 (C-3), 78.6 (C-2).

*Data of (2S,3S)-****5*** *(from AD-mix-α).* 85% yield; purity, 96% by GC; 62% ee; $[\alpha]_D^{20}$ = +23.7° (*c* 4.50, $CHCl_3$). The ^{1}H NMR and ^{13}C NMR spectra of (2*S*,3*S*)-**5** were the same as those of the antipode.

(2R,3R)- or (2S,3S)-cis-2-Methyl-3-mesyloxy-tetrahydrofuran ***6****.* (2*R*,3*R*)- or (2*S*,3*S*)-**6** was prepared according to our previously published procedures.[26] (2*R*,3*R*)- or (2*S*,3*S*)-**5** reacted with MsCl to give (2*R*,3*R*)- or (2*S*,3*S*)-**6**.

*Data of (2R,3R)-****6****.* 89% yield; purity, 98% by GC; 80% ee; $[\alpha]_D^{20}$ = −19.7° (*c* 5.23, $CHCl_3$). ^{1}H NMR (300 MHz, $CDCl_3$): *δ* 1.33 (3H, d, *J* = 6.6 Hz, Me-2), 2.34 (2H, m, H-4), 3.05 (3H, s, Me (mesyl)), 3.80 (1H, td, *J* = 8.4, 5.4 Hz, H-5a), 4.08 (1H, q, *J* = 8.1 Hz, H-5b), 3.95 (1H, qd, *J* = 6.3, 3.6 Hz, H-2), 5.13 (1H, ddd, *J* = 5.4, 3.6, 2.1 Hz, H-3). ^{13}C NMR (75 MHz, $CDCl_3$): *δ* 14.4 (Me-2), 34.0 (C-4), 38.5 (Me (mesyl)), 65.8 (C-5), 77.2 (C-2), 81.9 (C-3).

*Data of (2S,3S)-****6****.* 90% yield; purity, 96% by GC; 62% ee; $[\alpha]_D^{20}$ = +15.5° (*c* 5.06, $CHCl_3$). The ^{1}H NMR and ^{13}C NMR spectra of (2*S*,3*S*)-**6** were in line with those of the antipode.

(2R,3S)- or (2S,3R)-trans-2-Methyl-tetrahydrofuran-3-thiol Acetate ***1****.* (2*R*,3*S*)- or (2*S*,3*R*)-**1** was prepared according to our previously published procedures.[26] (2*R*,3*R*)- or (2*S*,3*S*)-**6** reacted with AcSH to give (2*R*,3*S*)- or (2*S*,3*R*)-**1**.

*(2R,3S)- or (2S,3R)-trans-2-Methyl-3-hydroxy-tetrahydrofuran **5***. To a solution of NaOH (6.4 g, 160 mmol) in methanol/tetrahydrofuran (124 mL, 30:1) was added (2*R*,3*S*)- or (2*S*,3*R*)-**7** (12 g, 48 mmol) at room temperature. The mixture was stirred at room temperature for 5 h. The reaction mixture was concentrated under reduced pressure. The residue was diluted with water, and the mixture was extracted four times with diethyl ether. The combined organic phases were washed once with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by column chromatography (petroleum ether/ethyl acetate, 6/1) to give (2*R*,3*S*)- or (2*S*,3*R*)-**5** as a light yellow oil.

*Data of (2R,3S)-**5***. 90% yield; purity, 97% by GC; 80% ee; $[\alpha]_D^{20}$ = +35.5° (*c* 2.74, MeOH) [lit.[30] $[\alpha]_D^{23}$ +11.7° (*c* 2.5, MeOH, 27% ee)]. ^1H NMR (300 MHz, $CDCl_3$): δ 1.76 (3H, d, *J* = 6.3 Hz, Me-2), 1.84 (1H, m, H-4a), 2.16 (1H, m, H-4b), 2.23 (1H, br, −OH), 3.82 (1H, m, H-3), 3.87−4.01 (3H, m, H-2, H-5). ^{13}C NMR (75 MHz, $CDCl_3$): δ 18.8 (Me-2), 34.3 (C-4), 66.0 (C-5), 76.7 (C-3), 81.7 (C-2).

*Data of (2S,3R)-**5***. 87% yield; purity, 96% by GC; 62% ee; $[\alpha]_D^{20}$ = −26.8° (*c* 4.28, MeOH) [lit.[30] $[\alpha]_D^{23}$ = −29.9° (*c* 2.5, MeOH, 70% ee)]. The NMR data were consistent with those of (2*R*,3*S*)-**5**.

*(2R,3S)- or (2S,3R)-trans-2-Methyl-3-mesyloxytetrahydrofuran **6***. (2*R*,3*S*)- or (2*S*,3*R*)-**5** was converted to the corresponding mesylate (2*R*,3*S*)- or (2*S*,3*R*)-**6** by the same procedure for (2*R*,3*R*)- or (2*S*,3*S*)-**6**.

*Data of (2R,3R)-**6***. 91% yield; purity, 97% by GC; 80% ee; $[\alpha]_D^{20}$ = +20.0° (*c* 6.00, $CHCl_3$). ^1H NMR (300 MHz, $CDCl_3$): δ 1.26 (3H, d, *J* = 6.6 Hz, Me-2), 2.18 (1H, m, H-4a), 2.24 (1H, m, H-4b), 3.04 (3H, s, Me (mesyl)), 3.89 (1H, td, *J* = 9.3, 6.6 Hz, H-5a), 4.01 (1H, td, *J* = 8.4, 3.3 Hz, H-5b), 4.12 (1H, m, H-2), 4.82 (1H, m, H-3). ^{13}C NMR (75 MHz, $CDCl_3$): δ 18.5 (Me-2), 32.5 (C-4), 38.4 (Me (mesyl)), 66.3 (C-5), 79.7 (C-2), 85.1 (C-3).

*(2R,3R)- or (2S,3S)-cis-2-Methyl-tetrahydrofuran-3-thiol Acetate **1***. (2*R*,3*S*)- or (2*S*,3*R*)-**6** was converted to the corresponding acetate (2*R*,3*R*)- or (2*S*,3*S*)-**1** by the same procedure for (2*R*,3*S*)- or (2*S*,3*R*)-**1**.

*Data of (2R,3R)-**1***. 85% yield; purity, 97% by GC; 80% ee (t_R 21.939 min); $[\alpha]_D^{20}$ = +10.7° (*c* 4.95, $CHCl_3$). ^1H NMR (300 MHz, $CDCl_3$): δ 1.19 (3H, d, *J* = 6.3 Hz, Me-2), 1.93 (1H, m, H-4a), 2.48 (1H, m, H-4b), 2.34 (3H, s, Me (Ac)), 3.75 (1H, td, *J* = 8.4, 6.3 Hz, H-5), 3.90 (1H, td, *J* = 8.4, 6.3 Hz, H-5), 4.13 (1H, m, H-2), 4.05 (1H, m, H-3). ^{13}C NMR (75 MHz, $CDCl_3$): δ 16.8 (Me-2), 30.6 (Me (Ac)), 33.5 (C-4), 46.3 (C-3), 65.9 (C-5), 76.5 (C-2), 195.4 (C═O).

*Data of (2S,3S)-**1***. 84% yield; purity, 98% by GC; 62% ee (t_R 22.265 min); $[\alpha]_D^{20}$ = −8.09° (*c* 4.37, $CHCl_3$). The NMR data were consistent with those of (2*R*,3*R*)-**1**.

Analytical Methods. *Enantioselective Analysis.* An Agilent 6890 GC with a flame ionization detector (FID) was used for GC analyses (Agilent Technologies, Santa Clara, CA). The columns used included a B-PM chiral capillary column (50 m × 0.25 mm × 0.25 μm), and a G-TA (50 m × 0.25 mm × 0.125 μm) from the ASTEC Co. (Chattanooga, TN). The analytical conditions for **1** and **5** (G-TA, 50 m) were as follows: injector temperature 250 °C, detector temperature 250 °C, N_2 as carrier gas, constant flow mode 0.8 mL/min, split ratio 50/1. The oven temperature was programmed from 50 to 170 °C at a rate of 5 °C/min, and held at 170 °C for 10 min. A different oven temperature program used for *cis*-**6** (B-PM, 50 m) was as follows: raised from 50 to 140 °C at a rate of 20 °C/min, and held at 140 °C for 2 min; raised to 155 °C at 0.2 °C/min, and was held at 155 °C for 5 min, then raised to 200 °C at 20 °C/min, and was held at 200 °C for 2 min. For *trans*-**6** (B-PM, 50 m), the conditions were as follows: raised from 50 to 120 °C at a rate of 5 °C/min, and held at 120 °C for 10 min; raised to 200 °C at 8 °C/min, and was held at 200 °C for 2 min. The concentration of samples was about 0.5 wt % in ethanol, and the injection volume was about 0.6 μL.

Chiral HPLC Analysis. HPLC analyses were conducted by an Agilent 1200 HPLC apparatus (column, Chiralcel OD-H or OB-H column (0.46 cm, ϕ × 15 cm) (Daicel, Japan); solvent, *n*-hexane-*i*-PrOH (9/1); flow rate, 0.5 mL/min; UV detection, 254 nm).

Chiral GC−O Analysis and Evaluation. Chiral GC−O analysis was carried out using an Agilent 6890N gas chromatograph installed with a chiral capillary column G-TA (50 m × 0.25 mm × 0.25 μm), a FID, and a sniffing port (Sniffer 9000; Brechbühler Scientific Analytical Solutions, Schlieren, Switzerland). The analytical conditions were the same as those in the determination of ee values by GC analysis. The column effluent was divided (ratio 1:1) between the FID detector and the sniffing port through one Y-shaped glass splitter. The effluent to the sniffing port was enclosed with a stream of humidified air of 16 mL/min and transferred to the glass detection cone by one length of capillary column at the temperature of 250 °C.

Sensory Panel. The panel consisted of 5 healthy, nonsmoking judges, 2 males and 3 females, aged 23−29. All panelists belong to the Beijing Key Laboratory of Flavor Chemistry, Beijing Technology and Business University. The judges were selected for their experience in assessing volatile flavor compounds of foods. A verbal description of the odor was obtained from the panelist when the peak appeared at the GC at the same time.

General Conditions for Odor Thresholds. Odor thresholds were determined according to the procedure described by Ullrich and Grosch.[31] The defined amounts of samples and the internal standard *trans*-2-decenal, the odor threshold of which in air is 2.7 ng/L,[32] were dissolved in EtOH and diluted stepwise by a factor of 1:1 (v/v). The aliquots were analyzed by GC−O until no odor was detectable.

NMR Spectroscopy. ^1H NMR and ^{13}C NMR spectra were recorded at 300 and 75 MHz, respectively, with an Avance 300 spectrometer. The experiments were done in full automation using standard parameter sets of the TOPSPIN 2.0 software package (Bruker). The compounds were dissolved in deuterated chloroform. The spectra were recorded at 25 °C.

Optical Rotations. Optical rotations were measured on an Autopol IV digital automatic polarimeter (Rudolph, Hackettstown, NJ).

RESULTS AND DISCUSSION

Preparation and Configuration Assignment of the Four Stereoisomers of 2-Methyl-tetrahydrofuran-3-thiol Acetate. The substrate for Sharpless AD, (3*E*)-pent-3-en-1-yl mesylate **4**, was easily prepared by the Knoevenagel condensation of propanal and malonic acid, followed by reduction with $LiAlH_4$ and mesylation. The procedure for Knoevenagel condensation was modified according to the

DOI: 10.1021/jf503866x
J. Agric. Food Chem. 2015, 63, 464−468

literature using DMSO as solvent instead of xylene,[27] which led to the remarkable improvements of both chemical selectivity and yield as compared to the results we published earlier.[26] (3*E*)-Pent-3-enoic acid **2** was obtained in about 60% yield with only 2% byproduct (2*E*)-pent-2-enoic acid.

The chiral centers of the four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate **1** were originated from Sharpless AD of (3*E*)-pent-3-en-1-yl mesylate **4**. 2-Methyl-3-hydroxy-tetrahydrofuran **5** was produced by Sharpless AD of **4** followed by an intramolecular S_N2 nucleophilic substitution in situ. The relative configuration of **5** was determined to be *cis* by comparing the ^{1}H NMR data with those of 2-methyl-3-hydroxy-tetrahydrofuran synthesized by oxidation of (3*E*)-pent-3-en-1-yl mesylate with H_2O_2/HCOOH or $KMnO_4$.[26] Also, the absolute configuration of **5** was tentatively assigned according to an empirical model developed by Sharpless et al.[33] (2*R*,3*R*)-*cis*-**5** was obtained using AD-mix-β as an oxidant, whereas (2*S*,3*S*)-*cis*-**5** was obtained from AD-mix-α. The specific rotation value of optically active (2*R*,3*S*)- or (2*S*,3*R*)-*trans*-**5** derived from the above obtained (2*R*,3*R*)- or (2*S*,3*S*)-*cis*-**5** by Mitsunobu reaction was consistent with the literature data,[30] which confirmed the aforementioned tentative assignment of absolute configuration. The chiral GC analysis of *cis*-**5** was carried out on G-TA (50 m × 0.25 mm × 0.125 μm) using trifluoroacetyl γ-cyclodextrin as chiral stationary phase, which enabled the separation of the two enantiomers of *cis*-**5**. (2*R*,3*R*)-**5** from AD-mix-β was obtained in 80% ee, whereas (2*S*,3*S*)-**5** was found in a relatively lower ee of 62%. (2*R*,3*R*)- or (2*S*,3*S*)-**5** was converted to the target compound (2*R*,3*S*)- or (2*S*,3*R*)-**1**, respectively, through S_N2 substitution of the corresponding mesylate by AcSH. The ee values of the intermediate mesylates were determined on B-PM (50 m × 0.25 mm × 0.125 μm), and the target compounds were analyzed by the same way as **5**. The obtained results of optical purity were consistent with those of **5**.

To obtain the two enantiomers of *cis*-**1**, (2*R*,3*R*)- or (2*S*,3*S*)-**5** produced by the Sharpless AD was subjected to Mitsunobu reaction, which gave (2*R*,3*S*)- or (2*S*,3*R*)-*trans*-2-methyl-3-*p*-nitrobenzoyloxy-tetrahydrofuran **7**. The determination of the ee values of the obtained benzoates failed by HPLC analyses on different columns, such as Chiralcel column OD-H and OB-H. The benzoates were then hydrolyzed to produce the two enantiomers of *trans*-**5**, respectively, which went through mesylation and nucleophilic substitution to afford the two enantiomers of *cis*-**1**, that is, (2*R*,3*R*)- and (2*S*,3*S*)-**1**. The ee values of (2*R*,3*R*)- and (2*S*,3*S*)-**1** were in accord with the starting material (2*R*,3*R*)- and (2*S*,3*S*)-**5**, which indicated no racemization occurred in Mitsunobu reaction, mesylation, and nucleophilic substitution.

Determination of Odor Properties. The enantiomers of *cis*- or *trans*-**1** were separated completely by a chiral GC column G-TA (50 m × 0.25 mm × 0.25 μm), on which the peak resolution R_s for two enantiomers of *cis*- or *trans*-**1** was 1.5 and 4.0, respectively. The odor properties of the four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate **1** were evaluated by the panel via chiral GC−O (Table 1). Among the four stereoisomers, both enantiomers of *trans*-**1** were found to possess meaty aroma as a top note, whereas the two enantiomers of *cis*-**1** were described to present mainly a top note of pungent smell of raw garlic and onion. In addition, the odor discrepancy between the two enantiomers of *trans*-**1** or *cis*-**1** also exited. For the enantiomers of *trans*-**1**, (2*S*,3*R*)-**1** smelled like roasted meat with an undernote of burnt and fried onion; in comparison, (2*R*,3*S*)-**1** smelled meaty with an undernote of sesame paste, fried onion and garlic, sweet, and sulfurous. Also, the former smelled more pleasant. For the enantiomers of *cis*-**1**, (2*R*,3*R*)-**1** presented additional savory and musty notes as compared to (2*S*,3*S*)-**1**.

Table 1. Odor Descriptions and Odor Thresholds of the Four Stereoisomers of 1

stereoisomers	odor description	odor thresholds in air[a] (ng/L)
(2*R*,3*S*)-**1**	meaty, sesame paste, fried onion and garlic, sweet, sulfurous	18.6
(2*S*,3*R*)-**1**	roasted meat, burnt, fried onion	7.3
(2*R*,3*R*)-**1**	raw garlic and onion-like, savory, musty, sulfurous	3.8
(2*S*,3*S*)-**1**	raw garlic and onion-like, sulfurous	5.7

[a]Mean values of duplicates, differing not more than ±10%.

Determination of Odor Thresholds. The odor thresholds of the four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate **1** were determined following the procedure described by Ullrich and Grosch.[31] Ethanol was used as solvent instead of diethyl ether because it was difficult to guarantee the accuracy of the sample concentration due to the high volatility of ether solution. For each stereoisomer, the sensory evaluations were performed in duplicate, and two stock solutions with similar concentration were prepared for each stereoisomer. The samples were evaluated by one judge, and the lowest concentration was double-checked by three consecutive GC−O runs. The odor thresholds of the two enantiomers of *trans*-**1**, that is, (2*R*,3*S*)- and (2*S*,3*R*)-**1**, were determined to be 18.6 and 7.3 ng/L air, respectively. In comparison, the odor thresholds of *cis*-**1**, that is, (2*R*,3*R*)- and (2*S*,3*S*)-**1**, were slightly lower, which were 3.8 and 5.7 ng/L air, respectively. The (2*R*,3*R*)-isomer was observed to have the lowest threshold, whereas the (2*R*,3*S*)-isomer had the highest threshold. Both isomers with relatively lower thresholds of *cis*- and *trans*-**1** were found to be (3*R*)-configuration. As compared to the odor thresholds of four stereoisomers of the corresponding thiol reported by Goeke,[24] the acetates had much higher thresholds. We tried to use the same procedure to determine the odor thresholds of the thiols prepared by hydrolysis of the corresponding stereoisomers of acetates. However, the separation of stereoisomers of thiols failed on chiral GC columns we have in our lab.

In conclusion, the four stereoisomers of 2-methyl-tetrahydrofuran-3-thiol acetate were prepared by application of Sharpless AD in conjunction with the Mitsunobu reaction. The GC−O data revealed that the four stereoisomers presented perceptible differences in odor properties. It looked as though the corresponding thiols had much lower odor thresholds. However, further work is needed, such as the preparation of enantiomerically pure stereoisomers, to determine the odor thresholds of these pure samples in water or air accurately.

High Enantiomeric Excess of the Flavor Relevant 4-Alkyl-Branched Fatty Acids in Milk Fat and Subcutaneous Adipose Tissue of Sheep and Goat

Stefanie Kaffarnik, Carolina Heid, Yasemin Kayademir, Dorothee Eibler, and Walter Vetter*

University of Hohenheim, Institute of Food Chemistry (170b), Garbenstraße 28, 70593 Stuttgart, Germany

ABSTRACT: Volatile 4-alkyl-branched fatty acids are characteristic flavor compounds of sheep and goat. Due to the methyl branch, the carbon C-4 represents a stereogenic center with the possible presence of one or both enantiomers in the respective samples. In this study, we used enantioselective gas chromatography to study the enantiomeric composition of 4-methyloctanoic acid (4-Me-8:0) and 4-ethyloctanoic acid (4-Et-8:0) in milk and dairy products from sheep and goat as well as in goat subcutaneous tissue. Different columns coated with modified cyclodextrins were tested to resolve racemic 4-alkyl-branched fatty acid methyl ester standards. The best enantiomer resolution was obtained on 25% *octakis*(2,3,6-tri-*O*-ethyl)-γ-cyclodextrin (γ-TECD) diluted in OV-1701. For analysis of the food samples, the lipids were extracted and fatty acids in the extracts were converted into fatty acid methyl esters. Non-aqueous reversed-phase high-performance liquid chromatography was used to fractionate the samples in order to gain one solution enriched in 4-Me-8:0 methyl ester and one solution enriched with 4-Et-8:0 methyl ester. Subsequent analysis by enantioselective gas chromatography with mass spectrometry allowed only the detection of one enantiomer of 4-Me-8:0 and 4-Et-8:0 in the samples. By means of a non-racemic standard of 4-Me-8:0, it was found that the predominant enantiomer was (*R*)-4-Me-8:0.

KEYWORDS: *alkyl-branched-chain fatty acids, enantioselective analysis, modified cyclodextrins, goat, sheep, milk*

INTRODUCTION

The 4-alkyl-branched fatty acids, 4-methyloctanoic acid (4-Me-8:0), 4-ethyloctanoic acid (4-Et-8:0), and 4-methylnonanoic acid (4-Me-9:0), were found to be responsible for the characteristic sweet, goaty and sheepy aroma of sheep and goat.[1−4] The carbon at the branching point (i.e., C-4) represents a stereogenic center, due to its substitution with four chemically different moieties. Accordingly, 4-alkyl-branched fatty acids may occur in both *S*- and *R*-forms in nature. In such situations, enantioselective studies may contribute to the understanding of the impact because enantiomers of the same molecule may have different properties including flavor notes. In addition, enantioselective analyses can provide insights into the biosynthesis of chiral compounds.

Different modified cyclodextrins have been used for the enantiomer separation of chiral compounds by gas chromatography (GC). Cyclodextrins (CD) are cyclic oligosaccharides composed of six (α-cyclodextrin), seven (β-cyclodextrin), or eight (γ-cyclodextrin) (1,4)-linked α-glucopyranose units which have the three-dimensional shape of a hollow torus.[5−7] Each glucopyranose unit of the cyclodextrin has hydroxyl groups in the 2-, 3-, and 6-positions which need to be modified for their applicability in GC. Suitable substituents are alkyl groups, acetyl groups, or silyl groups (especially *tert*-butyldimethylsilyl substituents).[8,9] Unfortunately, the potential of a chiral stationary phase (CSP) for a successful enantiomer separation cannot be predicted and has to be tested individually. Previous research has shown that the enantiomer separation of chiral fatty acids becomes more difficult if the stereogenic center is remote from the functional carboxylic group. For instance, the food relevant *anteiso*-fatty acids (fatty acids with a methyl branch on the antepenultimate carbon which is the stereogenic center) 12-methyltetradecanoic acid (*a*15:0) and 14-methylhexadecanoic acid (*a*17:0) have 10 methylene groups or more between the headgroup and the methyl branch and are difficult to enantioseparate.[10] By contrast, the enantioseparation of racemic standards of free 2-, 3-, and 4-alkyl-branched fatty acids has been achieved on *heptakis*(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin (β-TBDM) as well as on *octakis*(2,3-di-*O*-methyl-6-*O*-*tert*-butyldimethylsilyl)-γ-cyclodextrin (γ-TBDM).[11−14]

The aim of this study was to analyze the enantiomer composition of 4-Me-8:0 and 4-Et-8:0 in sheep and goat samples. For the enantioselective analysis of racemic standards of 4-Me-8:0, 4-Et-8:0, and 4-Me-9:0 methyl esters, we tested four CSPs and finally applied a CSP consisting of 25% *octakis*(2,3,6-tri-*O*-ethyl)-γ-cyclodextrin (γ-TECD) diluted in OV-1701. For the analysis of samples, volatile fatty acids had to be enriched because they are present only as minor components in milk fat of goat and sheep as well as in sheep subcutaneous adipose tissue.[15−19] For this purpose, the lipid phase was isolated and the fatty acids in the fraction were transferred into fatty acid methyl esters which were fractionated by non-aqueous reversed-phase high-performance liquid chromatography (RP-HPLC) similarly to the method of Hauff et al.[10] Enriched fractions of the fatty acids were then analyzed by GC with mass spectrometry operated in the selected ion monitoring mode (GC/MS-SIM).

MATERIALS AND METHODS

Chemicals. Methanol (purity >95%), *n*-hexane (purity >95%), and acetonitrile (purity 99.9%) were from Th. Geyer (Renningen, Germany). Concentrated sulfuric acid (>98%) was from BASF (Ludwigshafen, Germany), whereas sodium chloride was from Carl Roth (Karlsruhe, Germany). Helium (purity 5.0) and nitrogen (purity 5.0) were from Westfalen (Münster, Germany). Racemic standards of 4-methyloctanoic acid (4-Me-8:0), 4-ethyloctanoic acid (4-Et-8:0), and 4-methylnonanoic acid (4-Me-9:0) were from Endeavor Specialty Chemicals Ltd. (Daventry, U.K.). Racemic 4-methylhexanoic acid (4-Me-6:0) was from Sigma-Aldrich (Steinheim, Germany). Two different standard mixtures were prepared and used in this study. The racemic standard mixture 1 consisted of the methyl esters of 4-Me-6:0, 4-Me-8:0, and 4-Me-9:0, whereas the racemic standard mixture 2 consisted of the methyl esters of 4-Me-8:0, 4-Me-9:0, and 4-Et-8:0. The concentration of each compound in the mixtures was 10 ng/μL. Because pure enantiomer standards were not commercially available, a non-racemic standard of free 4-methyloctanoic acid was produced as follows. Racemic 4-Me-8:0 was derivatized with (−)-menthol to give the corresponding 4-Me-8:0 (−)-menthyl ester (i.e., a mixture of two diastereomers). The diastereomers were separated by reversed-phase HPLC using four serially linked columns (similarly to the method shown below for the isolation of individual fatty acids) and 100% acetonitrile as the mobile phase.[20] From 80 to 100 min, 40 fractions were taken every 0.5 min and the (−)-menthyl esters were saponified with KOH, the solutions acidified with HCl, and the free 4-Me-8:0 extracted with *n*-hexane. Enantioselective analysis of the RP-HPLC fractions allowed selecting one solution showing a distinct non-racemic composition of 4-Me-8:0. Aliquots of this fraction were also transferred in the corresponding methyl ester.

Samples. In a recent study, we developed a method for the direct quantitation of volatile 4-alkyl-branched fatty acid methyl ester in sheep and goat samples.[18] The samples with quantitative data for 4-Me-8:0, 4-Et-8:0, and 4-Me-9:0 were used in the present study for enantioselective determinations.[18,19] In brief, we used two goat milk and two sheep milk samples and nine cheese samples made from goat or sheep milk. These samples were bought in retail stores close to Stuttgart (Germany) in 2013/2014. In addition, two samples of homogenized sheep subcutaneous adipose tissue were analyzed in this study. The milk and cheese samples were lyophilized and extracted by accelerated solvent extraction before transesterification, as previously described,[19] while the sheep subcutaneous adipose tissue was directly subjected to transesterification.[18]

Transesterification Procedure. An aliquot of 3 mL of the milk fat extract (fat content ∼1 g, solvent evaporated thereafter) or ∼1 g of subcutaneous adipose tissue and 50 mL of 1% sulfuric acid in methanol was placed in a 100 mL round flask. The sample solution was stirred and refluxed for 2 h at 80 °C. After cooling the mixture on ice, it followed the addition of 20 mL of distilled water, 30 mL of saturated aqueous sodium chloride solution, and 500 μL of *n*-hexane. The two-phase system was vigorously shaken, and the upper organic phase was separated for RP-HPLC enrichment.

Non-Aqueous Reversed-Phase High-Performance Liquid Chromatography (RP-HPLC). The fractionation was based on the method of Hauff et al.[10] developed for *anteiso*-fatty acids with modifications. About 0.2 mL of acetonitrile was placed in a 1.5 mL GC vial, and 0.2 mL of the sample extract in *n*-hexane was added. After shaking, the upper *n*-hexane phase was evaporated by a gentle stream of nitrogen at 30 °C. The fatty acid methyl esters remained in the more polar acetonitrile phase. This solution could directly be used for RP-HPLC analysis, because acetonitrile is miscible with the mobile phase methanol. Enrichment of 4-methyl-branched fatty acid methyl esters was performed with a Waters HPLC system (Milford, USA) consisting of a 717 plus auto sampler, a 616 pump, a 996 photodiode array detector (DAD), and a 600S controller. Sample solutions (20 μL) were injected at room temperature (24 °C). The flow rate of the mobile phase methanol was set to 0.5 mL/min. Three serially linked columns were used for separation, i.e., two Supelcosil LC-18-DB columns of 16 and 25 cm length, 4.6 mm inner diameter, and 5 μm particle size from Supelco (Taufkirchen, Germany) and one 25 cm length × 4.6 mm inner diameter C_{30}-RP-HPLC column with 5 μm particle size from Trentec (Gerlingen, Germany). Because methyl esters of saturated fatty acids do not provide a response in UV or fluorescence detectors, the samples were fractionated without a detector. For this reason, 14 fractions were collected in intervals of 4 min (corresponding to a 2 mL volume). Subsequently, 0.5 mL of water and 0.5 mL of saturated aqueous sodium chloride solution as well as 200 μL of *n*-hexane were added to each fraction for extraction. The organic phase containing the fatty acid methyl esters was separated and analyzed by GC/MS. Further concentration of fractions 5 and 6 by a factor of 2 was carried out as follows. In order to prevent loss of the volatile analytes, 15 μL of methanol was added to 40 μL of the sample and the resulting azeotropic mixture of *n*-hexane and methanol (72:28; v/v) was carefully evaporated with a slight stream of nitrogen until the final volume was 20 μL.

Column Testing by Gas Chromatography with Flame Ionization Detection (GC/FID). Enantioseparations of racemic standards of 4-methyl-branched fatty acid methyl esters on different CSPs were performed with a Hewlett-Packard 5890 series II GC equipped with a flame ionization detector (GC/FID), a 7673 auto sampler, and a split/splitless injector. The injection volume was set to 1 μL. Four columns with modified cyclodextrins were tested. The first two contained the same amount of the same modified cyclodextrin dissolved in two different polysiloxanes, i.e., 20% *heptakis*(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin (β-TBDM) in (i) SE-52 or (ii) PS086 (30 m length, 0.25 mm inner diameter, 0.1 μm film thickness, BGB Analytik, Adliswil, Switzerland). In addition, we used (iii) 66% *heptakis*(6-*O*-*tert*-butyldimethylsilyl-2,3-di-*O*-methyl)-β-cyclodextrin (β-TBDM) in OV-1701 (30 m length, 0.25 mm inner diameter, 0.1 μm film thickness, BGB Analytik, Adliswil, Switzerland) and (iv) 25% triethylated-γ-cyclodextrin (γ-TECD) in OV-1701 (12 m, 0.25 mm inner diameter, film thickness not specified). The γ-TECD column (Table 1) was prepared in the laboratories of Prof. Dr. Michael Oehme (University of Basel, Switzerland).[21−23]

Nitrogen was used as the carrier gas with a column head pressure of 10 psi (30 m columns) or 6 psi (12 m γ-TECD). For enantioselective analysis on the β-TBDM column, the oven program started at 60 °C for 10 min, ramped 0.5 °C/min to a final temperature of 80 °C (β-TBDM: method A). The performance on the γ-TECD column differed from that on the β-TBDM column. On γ-TECD, the isothermal temperature oven program was at 40 °C for 280 min (γ-TECD: method B).

Enantioselective GC/MS-SIM Analysis of 4-Alkyl-Branched Fatty Acids as Methyl Esters in Samples. Enantioselective analyses were performed with a CP-3800/1200 GC/MS system equipped with a CP-8410 auto sampler (Varian, Darmstadt, Germany). The split/splitless injector was heated to 250 °C and used in splitless mode (split opened after 2 min). The injection volume was 1, 2, or 3 μL, depending on the fatty acid concentration. Helium was used as the carrier gas with a flow rate of 1.2 mL/min. Electron ionization was carried out with 70 eV. The transfer line temperature was set at 40 °C, while the temperature of the ion source was 200 °C. The GC column (iv) (γ-TECD) was installed in the GC oven using a retention gap (1 m, 0.25 inner diameter). The analyses were performed isothermally at 40 °C. After the elution of the analytes, a second run was started for the elution of less volatile compounds in the sample solution. This run started for 8 min at 40 °C before the temperature was raised at 10 °C/min to 150 °C (hold time 1 min). The new injection also served to rinse the injector by the injection and volatilization of the solvent. This program was repeated three times in order to elute higher boiling compounds from the column. During the third run, we could not observe peaks anymore in the chromatogram. In the selected ion monitoring (SIM) mode, m/z 74, 87, 99, 115, 129, 141, and 172 (M^+ of 4-Me-8:0 methyl ester) were measured from 10 to 60 min followed by m/z 74, 87, 113, 115, 129, 155, and 186 (M^+ of 4-Me-9:0-ME and 4-Et-8:0-ME) from 60 to 90 min (method C). The limit of quantitation (LOQ) was determined to be 0.34 mg/g for 4-Me-8:0-ME as well as 0.78 mg/g for 4-Et-8:0-ME and 4-Me-9:0-ME. The limit of detection (LOD) was 0.10 mg/g for 4-Me-8:0-ME and 0.23 mg/g

[a]Analyzed by GC/MS (all other measurements were performed by GC/FID); mean values (racemic standard) $n = 10$.

for 4-Et-8:0-ME and 4-Me-9:0-ME. These concentrations were ∼100-fold higher compared to the nonchiral measurements.[18] This loss of sensitivity on the γ-TECD column was due to broader peaks at longer retention times as a consequence of the low isothermal oven temperature required for the resolution of the enantiomers. The quality of the enantiomer purity was expressed by the enantiomeric excess (ee) (eq 1):[10]

$$\text{ee} = (\text{E1} - \text{E2})/(\text{E1} + \text{E2}) \text{ in \%} \quad (1)$$

As will be shown later, in all cases, only one enantiomer could be detected in the samples. Due to the low concentrations of the 4-alkyl-branched fatty acids in the sample, we could not generally rule out the presence of trace amounts of the undetected enantiomer in the sample solutions (which would have been the requisite for ee = 100%). For this reason, the limit of detection (LOD) had to be determined and formed the basis to conclude on the minimum ee of the predominant enantiomer in the samples. Accordingly, ee was calculated by assigning the LOD to the nondetected enantiomer according to the literature.[24] Then, it was noted that the ee was larger than the resulting ee value.

Enantioselective GC/MS-SIM Analysis of Free 4-Alkyl-Branched Fatty Acids and the Corresponding Methyl Esters in a Non-Racemic Standard. Analyses were performed with a G1800B GCD-Plus system (Hewlett-Packard) equipped with a HP6890 autosampler and a split/splitless injector operated in splitless mode. Helium was used as the carrier gas with a constant flow of 1.0 mL/min. The temperatures of the injector and the transfer line were set to 250 °C and 280 °C, respectively. β-TBDM (ii) (see above) was used. The oven program for the enantioselective analysis of the free 4-Me-8:0 started at 50 °C for 1 min; then, the temperature was increased at 1 °C/min to 200 °C (10 min hold time). In the SIM mode, m/z 57, m/z 73, m/z 83, m/z 85, m/z 99, m/z 101, and m/z 158 (M^+) were recorded throughout the run. In addition, 4-Me-8:0-ME was analyzed with the following program: 50 °C for 1 min, then at 10 °C/min to 65 °C and after 150 min at 10 °C/min to 200 °C (10 min hold time). Seven ions (m/z 74, m/z 87, m/z 99, m/z 115, m/z 129, m/z 141, and m/z 172) were measured in SIM mode.

Analysis of the enantioenriched 4-Me-8:0 standard (see above) on the β-TBDM column (ii) showed an enantiomer ratio of the first to second enantiomer of 3:1 (ee = 50%). In a previous study of Dietrich et al., who synthesized both enantiomers, it was found that the (*R*)-enantiomer of 4-Me-8:0 eluted first from β-TBDM.[25] Transferred on our measurements on β-TBDM, the non-racemic standard showed an enantiomeric excess of (*R*)-4-Me-8:0. An aliquot of the non-racemic standard was converted into the corresponding methyl ester and used for the determination of the elution order of the methyl ester on the CSPs.

Determination of the Efficiency of the Enantiomer Separation and Statistical Analysis. The efficiency of the enantiomeric separation was evaluated by means of the separation factor α (eq 2) and the percentage valley between the two enantiomers (eq 3).

$$\alpha = t'_{R2}/t'_{R1} \quad (2)$$

with α = separation factor; t'_{R1} = reduced retention time of the first eluting enantiomer, and t'_{R2} = reduced retention time of the second eluting enantiomer.

$$V\ (\%) = \frac{\frac{1}{2}(H_{E1} + H_{E2}) - H_V}{\frac{1}{2}(H_{E1} + H_{E2})} * 100 \quad (3)$$

with V (%) = valley between the two enantiomers, H_{E1} = peak height of enantiomer 1, H_{E2} = peak height of enantiomer 2, and H_V = height of the valley between the two peaks.

The statistical analysis was performed by one-way analysis of variance (ANOVA), using $\alpha = 0.05$. Evaluation by means of the p-value which describes the level of significance was based on $p < 0.05$ for statistical significance and $p < 0.001$ for high statistical significance.

RESULTS AND DISCUSSION

Enantioseparation of Racemic Volatile Branched-Chain Fatty Acid Methyl Esters on Modified Cyclodextrins. Three CSPs coated with β-TBDM were tested first because similar CSPs (15% β-TBDM or γ-TBDM in PS-268) were successfully used by Karl et al. for the enantiomer resolution of racemic standards of free alkyl-branched fatty acids.[13] Columns i and ii were coated with the same amount of the CSP dissolved in a nonpolar (SE-52) or medium polar (PS086) polysiloxane. Column i with the nonpolar polysiloxane showed slightly but not significantly better separation factors α and valleys between the peaks ($p > 0.05$) for the methyl esters of the three 4-methyl-branched fatty acids (Table 1). Similar observations were also made by Dietrich et al. for free 4-Me-BCFAs.[25,26] In contrast to *anteiso*-fatty acids,[10] the use of a high percentage of β-TBDM in the stationary phase could not really improve the enantioseparation of the 4-methyl-branched FAMEs (Table 1). Moreover, the enantiomers of the racemic 4-Et-8:0-ME standard could not be resolved on the β-TBDM columns (Table 1). For this reason, we also tested another CSP in form of a 12 m column coated with γ-TECD installed in the GC/MS system (Table 1). While a racemic standard of 4-Me-6:0-ME could not be enantioseparated on this column, separation factors α of >1.028 and valleys of >77% between the peaks were obtained for 4-Me-8:0-ME ($p < 0.01$ for the valley between the peaks; $p < 0.05$ for α) and 4-Me-9:0-ME ($p > 0.05$ for the valley between the peaks; $p > 0.05$ for α). Accordingly, the enantiomer resolution of 4-Me-8:0-ME was better than that on the β-TBDM columns (Table 1). Moreover, the enantioseparation of 4-Et-8:0-ME, i.e., the key-flavor compound for sheepy and goaty flavors,[2,3] was also resolved on the 25% γ-TECD column with similar success as for the 4-methyl-branched FAMEs (Table 1). Accordingly, the 12 m γ-TECD column was selected for studying the enantiomeric composition of the flavor relevant 4-Me-8:0, 4-Me-9:0, and 4-Et-8:0 as methyl esters in food samples.

Enrichment of 4-Alkyl-Branched Fatty Acid Methyl Esters from Sheep and Goat Samples by RP-HPLC Fractionation. Previous quantitation of the 4-alkyl-branched fatty acids in the samples resulted in concentrations of 0.1−185 μg/g fat in sheep and goat samples (Table 2).[18,19] These low levels were in agreement with data reported in the literature.[2,15−17,27] Due to the higher LOQ and LOD compared to nonchiral GC/MS measurements (see the Materials and Methods), these minor fatty acids were enriched by non-aqueous RP-HPLC by at least a factor of 20 prior to the enantioselective GC analysis. Nonchiral GC/MS analysis of the HPLC fractions verified that 4-Me-8:0-ME eluted into fraction 5 (16−20 min), while 4-Et-8:0-ME was detected in fraction 6 (20−24 min). In the samples with the highest amounts of 4-Et-8:0 (especially in goat samples), a share of 20−54% of this compound already eluted into fraction 5 (Figure 1). In agreement with the previous study, 4-Me-9:0 was only present in the sheep subcutaneous adipose tissue and could not be detected in milk and dairy products of goat and sheep.[18,19] In sheep subcutaneous adipose tissue, 4-Me-9:0-ME eluted into fraction 6, i.e., together with its isomer 4-Et-8:0-ME (Figure 2).

According to Hauff et al., this method eluted FAMEs mainly in dependence of length of the longest acyl chain while methyl branches had only a small effect on the retention.[10] Hence, the 4-alkyl-branched FAMEs could be completely separated from the major fatty acids in the samples (i.e., the methyl esters of 16:0, 18:0, 18:1*n*-9). However, the methyl esters of octanoic acid (8:0-ME), nonanoic acid (9:0-ME), as well as decanoic acid (10:0-ME) were also enriched by the procedure and presented the most abundant fatty acids in fraction 5 (Figure 1). The GC/MS chromatogram of fraction 6 was dominated by 9:0-ME, 10:0-ME, and undecanoic acid methyl ester (11:0-ME). However, this RP-HPLC enrichment step proved to be sufficient for enantioselective analysis of the 4-alkyl-branched fatty acids as methyl esters by GC/MS-SIM.

Enantiomeric Distribution of Volatile 4-Alkyl-Branched Fatty Acids in Sheep Subcutaneous Tissue and Ruminant Milk Fat. The GC/MS-SIM analysis of the RP-HPLC fractions 5 and 6 on γ-TECD resulted in the exclusive detection of a peak at the retention time of the first eluting enantiomer when compared to the racemic standard (Figure 2). This finding was in contrast to Karl et al., who

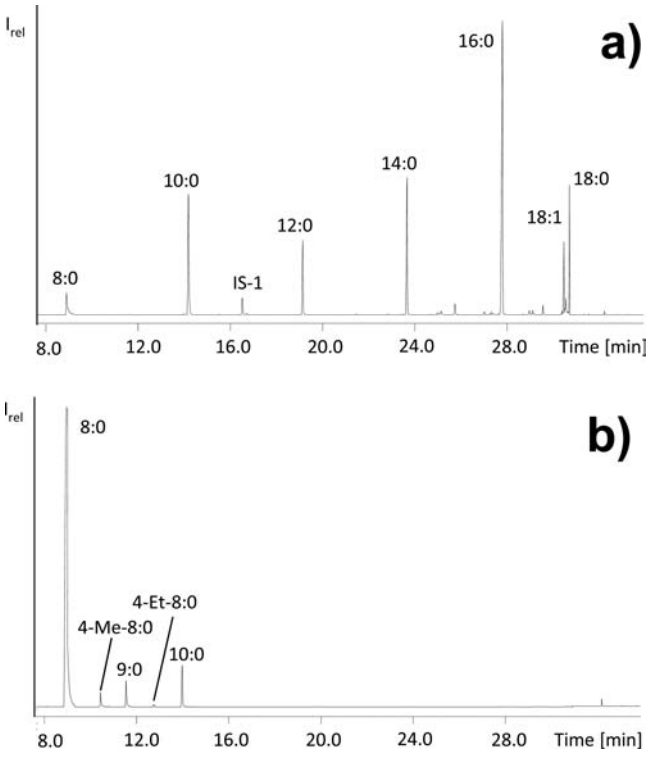

Figure 1. GC/MS chromatograms (HP-5ms column) of the fatty acid methyl esters (a) from the unfractionated goat milk sample and (b) in fraction 5 of the RP-HPLC fractionation.

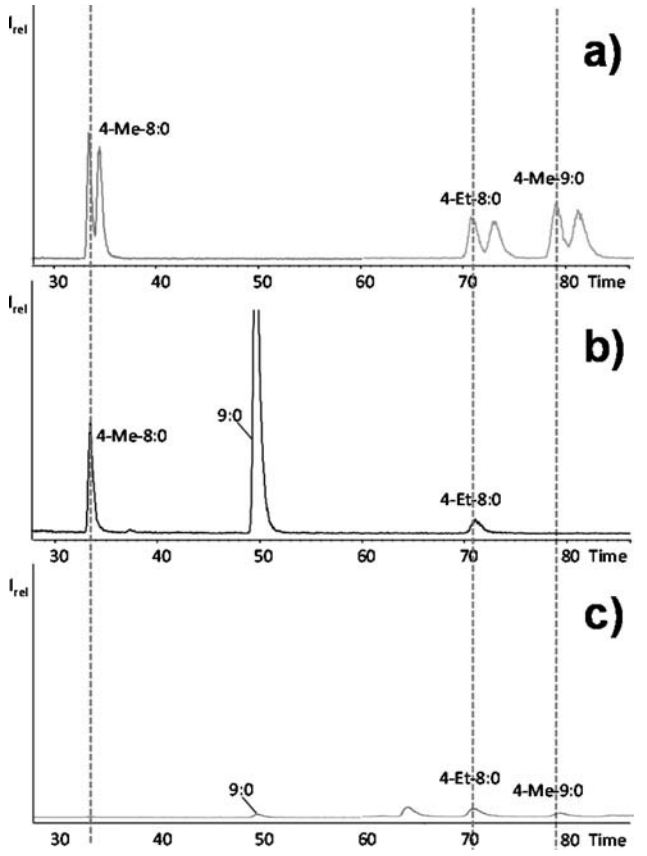

Figure 2. GC/MS chromatograms (25% γ-TECD in OV-1701) of the enantioseparations of (a) a racemic standard mixture of the methyl esters of 4-Me-8:0, 4-Et-8:0, and 4-Me-9:0, (b) RP-HPLC fraction 5 of a goat fresh cheese sample, and (c) RP-HPLC fraction 6 of a sheep subcutaneous adipose tissue sample.

reported a racemic distribution of 4-Me-8:0 in two sheep fat samples.[13] In order to exclude artifacts in our analysis, the results were verified by spiking the samples with similar amounts of racemic standards (methyl esters of 4-Me-8:0, 4-Et-8:0, and 4-Me-9:0) as present in the samples. After the standard addition, the peak height of the first eluted enantiomer (i.e., the one detected in the unspiked sample) had increased, while an additional peak was detected at the retention time of the second eluted enantiomer (Figure 3a). Moreover, the added amount in both nonchiral and chiral GC/MS chromatograms corresponded with the increase of peak area for the two peaks due to the spiking. This measure verified that the peaks detected in fact originated from the 4-alkyl-branched FAMEs and not from other FAMEs eluting at the same retention time from the γ-TECD column. Finally, normalization of the GC/MS-SIM ions m/z 74 and m/z 87 on the same height according to the method of Thurnhofer et al.[28] showed no difference in abundance for the two enantiomeric peaks in the spiked sample (Figure 3b). Thus, it was ultimately verified that for both 4-alkyl-branched fatty acids only one enantiomer could be detected in the sheep and goat samples.

By means of standards enriched in (*R*)-4-Me-8:0 and (*R*)-4-Me-8:0-ME (see the Materials and Methods), we could show that (*R*)-4-Me-8:0 (free acid) eluted first from β-TBDM (Figure 4a), while the elution order of the enantiomers was reversed for 4-Me-8:0-ME (Figure 4b). Moreover, (*R*)-4-Me-8:0-ME eluted first from γ-TECD, i.e., the reversed order as observed for the methyl ester on β-TBDM (compare Figures 3 and 4). Accordingly, the peak detected in all samples using the γ-TECD column originated from (*R*)-8-Me-8:0. For final verification, we also analyzed an HPLC fraction of a cheese sample on the β-TBDM column and this also verified the dominance of (*R*)-(4)-Me-8:0-ME, i.e., the second eluting enantiomer in our sample (Figure 4c).

Although only the (*R*)-enantiomer was detected in our sample, the LOD obtained for 4-Me-8:0 and 4-Et-8:0 did not allow enantiopurity to be verified. On the basis of an S/N ratio of 3 and by considering a concentration of the (*S*)-enantiomer corresponding to $S/N = 3$, the resulting ee of 4-Me-8:0 was between >98.2 and >87.5%. That means that the (*R*)-enantiomer represented in the worst case 93.25% and in the best case 99.1% of 4-Me-8:0 in the samples (Table 2). Note that these ee values should not be mixed up with identification of the (*S*)-enantiomer in our samples. Similarly, the ee of 4-Et-8:0 ranged from >93.4 to 82.35% (Table 2). In this case, the dominant enantiomer in the samples could not be identified.

Biosynthesis Pathway of 4-Me-8:0. Our measurements verified that 4-Me-8:0 was predominantly (if not enantiopure) present in the form of (*R*)-4-Me-8:0. This is remarkable because another class of chiral methyl-branched fatty acids, i.e., *anteiso*-fatty acids, were found with a clear dominance of the (*S*)-enantiomer in bovine milk fat (interestingly, *anteiso*-fatty acids eluted in reversed order, i.e., $R < S$, from the β-TBDM compared to 4-Me-8:0).[10,28] The different configurations of the predominant enantiomer indicated generally different biosynthetic pathways for both classes of compounds. While the *anteiso*-fatty acids are predominantly biosynthesized by using the amino acid isoleucine and malonyl-CoA as starters,[29,30] the primer for the biosynthesis of 4-alkyl-branched chain fatty acids is in all probability propionyl-CoA.[31] Propionyl-CoA, a

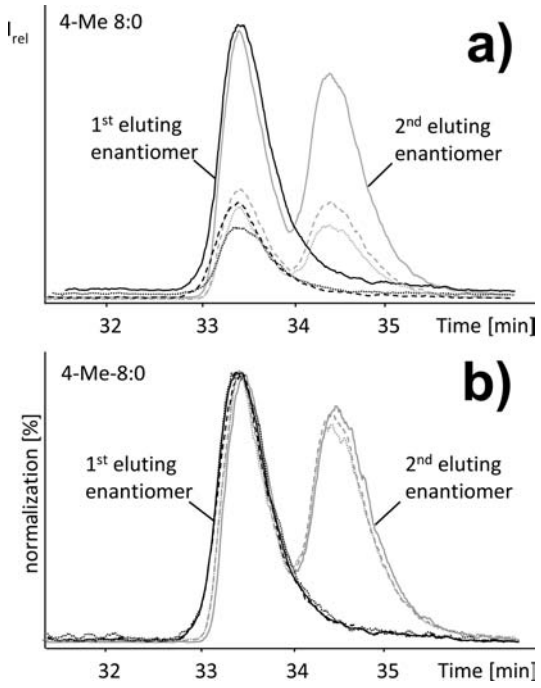

Figure 3. Overlay of the GC/MS-SIM chromatograms (25% γ-TECD in OV-1701) showing the total ion current (TIC) of the enantiomer separation of 4-Me-8:0-ME of sheep milk fat (fraction 5, black line) and a racemic standard of 4-Me-8:0-ME (gray line). Part a additionally shows the relative intensities of m/z 87 (dashed line) and m/z 74 (dotted line), whereas, in part b, the peaks of the TIC, m/z 87 and m/z 74, were normalized to the same abundance for the first eluted enantiomer.

degradation product of thymine and valine, is then carboxylated to give D-methylmalonyl-CoA (*S*-configuration). D-Methylmalonyl-CoA is then converted into L-methylmalonyl-CoA (*R*-configuration) by a methylmalonyl-epimerase. This step is important because only L-methylmalonyl-CoA can be reacted to succinyl-CoA, which is a component of the citrate-cyclus.[32]

In the biosynthesis of the 4-methyl-branched fatty acids, L-methylmalonyl-CoA is then activated by acetyl-carrier-protein (ACP)-transacylase into L-methylmalonyl-ACP which is merged with activated butyryl-ACP to give L-methyl-3-keto-hexanoyl-ACP. In the following, the keto function is reduced to give L-methyl-hexanoyl-ACP.[32] In the case of classic/common fatty acids, the ketone is reduced to the alcohol; then, water is eliminated, and the resulting double bond is hydrogenated.[32] For 4-Me-8:0, this step has not been investigated. However, our results verify that the conversion of L-methyl-3-keto-hexanoyl-ACP into L-methyl-hexanoyl-ACP is occurring enantioselectively, i.e., under maintenance of the *R*-configuration. Finally, (*R*)-4-Me-8:0 is formed by chain elongation with malonyl-CoA followed by elimination of the activation group. The biosynthesis of 4-Et-8:0 follows the same pathway except that butyryl-CoA is used as the primer instead of propionyl-CoA.[31] This also explains the formation of one enantiomer which is most likely the (*R*)-enantiomer.

Impact of the Enantiomeric Excess on the Flavor Perception. This pronounced enantiomeric excess of the chiral alkyl-branched fatty acids in the food samples resembles the one of other principal food compounds such as amino acids and monosaccharides.[33] Likewise, the high relevance of (*R*)-4-Me-8:0 in the goat and sheep samples could have an impact on the contribution of these compounds to the sheepy and goaty flavor because flavor thresholds had been previously determined with the help of racemic standards in different studies.[3,4] However, literature data on the flavor impression of the pure enantiomers of 4-Me-8:0 is equivocal. Karl et al. noted similar flavor impressions but a 2 times higher flavor intensity for the (*S*)-enantiomer of 4-Me-8:0 (and other 4-alkyl-branched fatty acids).[13] By contrast, Heinsman et al. reported that (*R*)-4-Me-8:0 showed the typical mutton smell and taste at a 5−10-fold higher intensity than the (*S*)-enantiomer.[34] The reasons for these differences in flavor perception of 4-Me-8:0 enantiomers remain unclear, and they had no practical relevance as long as it was thought that 4-Me-8:0 was racemic in sheep and goat samples. However, the new finding of the predominant presence of (*R*)-4-Me-8:0 in sheep and goat samples supports the relevance of enantioselective evaluation of the impact of this and further 4-alkyl-branched fatty acids on the sheepy and goaty flavor. It is noteworthy that two studies reported very similar sensorial qualities for the enantiomers of 4-Me-8:0.[13,34] In this context, it is worth noting that this similar impression of humans must not necessarily be valid as well for sheep and goats (which are bioproducing the compounds). In either case, the enantioselectivity of the 4-alkyl-branched fatty acids should be taken into account in the investigation of the characteristic flavor of goat and sheep samples.

Supporting Information

ABSTRACT: Distillers Dried Grains and Solubles (DDGS) are an animal feed containing varying levels of sulfur. As ruminants are susceptible to high sulfur diets, sulfur content is of major interest to the parties involved. The variation in levels of sulfur in DDGS is mainly due to sulfate derived from the addition of sulfuric acid during the production. ATR/FT−IR spectroscopy was used to determine sulfate levels in 90 DDGS samples from various origins (Canada, China, EU, and U.S.A.). Specific absorption bands for sulfate at 615 and 1107 cm^{-1} enabled the analysis of sulfate in the DDGS matrix. Besides direct quantification (using band at 615 cm^{-1}), PLS regression was applied for the prediction of sulfate using FT−IR spectra and calibration with reference values analyzed by capillary electrophoresis. An extended calculation on the total sulfur estimated that 11% of the DDGS samples analyzed in this study featured sulfur contents higher than 0.80%.

INTRODUCTION

The animal feed sector is affected more than ever by the rising lack of protein sources. The involved business has forced efforts to find alternative sources for animal nutrition, and novel feed materials are considered for entry into the market. Also, by- or coproducts from food production or industrial processes based on natural raw materials are considered and already used in the rearing of livestock. For example, Distillers Dried Grains and Solubles (DDGS) as byproducts of the bioethanol industry recently have gained importance in the animal feed sector. As such, the ethanol industry is primarily interested in the production of ethanol by fermentation of cereals (i.e., corn, wheat, barley, and sorghum), while at the same time obtaining a byproduct of high nutritional value (rich in proteins, raw fiber, fat, and minerals). However, it is of the utmost importance that animal feed materials derived from industrial processes or novel sources comply with legal requirements and that feed safety as well as food safety can be guaranteed in terms of the farm-to-fork principle.

With regard to DDGS, consistency in the nutritional value and quality of the feedstuff is particularly relevant, as sources of production are manifold and variation in the products composition is not only present among but also within production plants.[1,2] Besides the nutritional composition, one of the most important aspects regarding DDGS is its content of sulfur (S), which is strongly affected by the process of ethanol production. First, the concentration of sulfur-containing amino acids is increased by a factor of approximately three compared to the grain during the production process,[3] resulting in a content of S about 0.30 to 0.40 mass percent of endogenous origin depending on the raw material (corn or wheat). Second, sulfuric acid is used in many plants to control the pH of the cereal mash during fermentation and/or as a cleaning agent and can lead to high sulfate/sulfur levels in DDGS.[4] Many studies have already paid attention to the presence of S in DDGS and as Shurson, Tilstra, and Kerr (2012)[5] indicated, sulfur levels in DDGS can range from 0.31 to 1.93% (average 0.69%) on a dry matter (DM) basis. In addition, the sulfur content of Distillers Grains was reported to vary typically, showing a within-plant coefficient of variation from 6.4 to 40.8%[1] and 2.2 to 12.8%[6] respectively.

The particular interest in the sulfur content of DDGS is linked to the fact that ruminants are susceptible to high sulfur-containing diets. Although microbes present in the rumen require sulfur for their normal growth and metabolism, high S intake can decrease the bioavailability of trace minerals (e.g., copper, iron, zinc) and also lead to the production of H_2S by sulfate reducing bacteria (e.g., *Desulfovibrio* spp. and *Desulfotomaculum* spp.).[7] In ruminants, the major part of H_2S from the rumen will be eructated and inhaled during rumination and after entering the pulmonary vein in the lung, the H_2S consequently reaches the brain of the animal. As Schoonmaker and Beitz (2012) summarized, high concentrations of H_2S decrease cellular respiration and limit the rate of ATP generation causing necrosis of the cerebral cortex and softening of the brain tissue.[7] Severe cases of H_2S intoxication can result in polioencephalomalacia (PEM) and if not treated with thiamine, in the death of the animal.[7]

Risk for steers contracting PEM was reported to increase when the dietary S levels and the rumen available S levels in the diet increased; this was observed most clearly at dietary S levels above 0.6% and low levels of forage NDF in the diets.[8] However, Schoonmaker and Beitz (2012) mentioned that PEM incidence correlates not only with dietary S contents, but also with variation in the S content from day to day.[7] Therefore, consistency of the S content of DDGS but also of the whole diet must be regarded as a crucial factor in rearing of ruminants. According to the U.S. National Research Council,[9] the maximum tolerable dietary S level is 0.4% (DM basis) for beef cattle. For example, this dietary level could be exceeded if DDGS with sulfur content greater than 0.80% (DM basis) were fed to ruminants at high inclusion rates (DDGS: 40% of DM intake) in addition to corn and corn silage, assuming low sulfate levels in drinking water.[5,10]

In addition, inorganic forms of sulfur (i.e., sulfate) are described to be better available for ruminal bacteria.[7,8,11] In this context, Schoonmaker and Beitz (2012) mentioned that DDGS could show high sulfate levels of 0.5 to 1.7%, which can cause a dramatic increase in H_2S production in the rumen.[7] Moreover, Sarturi et al. (2013) observed greater ruminal H_2S concentrations for steers fed with Wet Distillers Grains with Solubles (WDGS) and sulfate-enriched diets compared with conventional or organic sulfur-enriched diets.[11] Therefore, great attention has to be devoted not only to sulfur levels, but also especially to sulfate levels in DDGS preventing ruminants of H_2S intoxication. Besides the risk of PEM, there is also a general interest in reducing sulfate levels (and sulfur levels) in DDGS because both ruminants and nonruminants show decreased feed intake and gain at high dietary S levels.[12,13] Sulfate levels in DDGS could be reduced most easily, if the use of sulfuric acid would be avoided and phosphoric acid or hydrochloric acid would be used instead for pH control in the production process.[14] Alternatively, the analysis of sulfate and/or sulfur levels in DDGS could enable the selection of feeds and batches of feed with acceptable S levels, and diets could also be kept to a more consistent S level in this way.[7]

Thus, the quantitative information on sulfur and/or sulfate in DDGS is of major interest to parties involved and certainly improves the quality and safety of DDGS. Traditionally, quantitative analysis of sulfur in animal feed has been performed by gravimetric analysis ($BaSO_4$) after oxidation of S-containing compounds to sulfate (e.g., AOAC Method 923.01).[15] Nowadays, X-ray fluorescence spectroscopy or inductively coupled plasma mass spectrometry (ICP-MS) are commonly used for this purpose. In the current study, the application of ATR/FT−IR spectroscopy for the determination of sulfate levels in DDGS as a rapid screening method is highlighted. The application targets the screening of sulfate levels in different batches of DDGS and was developed to easily preselect batches of DDGS with prominent sulfate levels. The technique itself could be used routinely in the field as laboratory expenses are limited and it could also serve as a process-oriented solution to control the sulfate content in DDGS on-site.

MATERIALS AND METHODS

DDGS Samples and Sample Preparation. 90 DDGS samples were collected in the frame of the EU project QSAFFE from reliable sources in the years 2011−2013. In this study, DDGS samples are defined as feed materials according to the numbering of the EU feed catalogue (Commission Regulation No. 68/2013):[16] either (a) number 1.12.10 (Distillers' dried grains) or (b) number 1.12.11 (Distillers' dried grains and solubles/Distillers' dark grains). The samples were produced from the bioethanol industry or the alcoholic beverage industry (whiskey, vodka) and were obtained from different geographical origins as stated by the provider. They were produced mainly from corn or wheat; details of the samples are provided as supplementary table (Supporting Information, SI). All samples were ground with a centrifugal mill (ZM 200, Retsch, Germany, mesh size 0.5 mm) and subsequently homogenized in plastic containers (filling level ∼2/3) for 6 h using a drum hoop mixer (RRM 100, Engelsmann, Germany). The DDGS samples were stored at 4 °C in the dark until analysis.

One preground DDGS sample without substantial sulfate level [#40, cf. SI], named sample A in this study, was spiked with different amounts of anhydrous sodium sulfate (analytical grade; ≥ 99.0%; Merck KGaA, Darmstadt, Germany) to levels of 1% to 5% sodium sulfate, in triplicates (each of 0.500 g) for FT−IR spectroscopy and in triplicates (each of 4.000 g) for capillary electrophoresis (CE). Also, one preground DDGS sample with medium sulfate content (1.44%) [#29, cf. SI], named sample B in this study, was analyzed to estimate precision of (1) FT−IR spectroscopy in the spectral range of interest, and (2) CE. In order to demonstrate the effect of Na_2SO_4-spiking to sulfate-containing DDGS, one further preground DDGS sample with medium sulfate content [#33, cf. SI], named sample C in this study, was spiked with 3% sodium sulfate.

FT−IR Spectroscopy. Prior to FT−IR spectroscopy, the preground DDGS samples were finely ground using a ball mill (MM 301, Retsch, Germany; 5 mL steel cylinders and 2 steel balls with 7 mm diameter, 30 Hz, 4 min) to achieve small-sized particles (more than 99% between 10 to 200 μm), as described before.[17] FT−IR spectra were collected with a Nicolet 6700 series spectroscope (Thermo Fisher Scientific, Waltham, MA, U.S.A.) equipped with a Smart Performer Accessory (single-bounce-ATR with diamond crystal), a micrometric pressure device enabling a standardized pressing force, a KBr beamsplitter, and a deuterated triglycine sulfate (DTGS) detector. In general, FT−IR spectroscopy of the DDGS samples was carried out as described in a previous study.[17] The spiked mixtures of sample A and sample C were ground with a ball mill (instrument setup specified above) for 4 × 1 min and mixed manually using a spatula after each grinding to improve homogeneous distribution of the sodium sulfate in the sample, which led to equal particle sizes as mentioned above. For estimation of precision, 10 replicates of sample B underwent fine grinding, triplicate FT−IR spectra of each replicate were collected, peak areas and sulfate contents (cf. following sections) were calculated. Then relative standard deviation (coefficient of variation) of the averaged sulfate contents of the triplicates (n = 10) was calculated.

Extraction of Sulfate and Capillary Electrophoresis. The extractable sulfate content of the DDGS samples was analyzed by capillary electrophoresis (CE). Sulfate was extracted out of the DDGS by weighing exactly 4.000 g of the preground sample material into a 50 mL Polypropylene Conical tube (30 × 115 mm; BD Biosciences, San Jose, U.S.A.) and adding 40.00 mL deionized water (18.2 MΩ; purified by Milli-Q Reference A+ System; Millipore, Schwalbach, Germany). The tube was capped and vigorously shaken until the sample material was dispersed in the water; then homogenized with an overhead shaker for 10 min, followed by 5 min supersonic wave treatment (35 kHz) and centrifugation for 10 min at an average of 7020g (8000 rpm, J2-HS Centrifuge with rotor JA-10, Beckman Coulter, U.S.A.). The supernatant was first filtered through an ashless filter paper (589/3, Whatman, Dassel, Germany) and subsequently through a 0.2 μm syringe filter (Perfect-flow Nylon membrane, WICOM, Heppenheim, Germany).

For capillary electrophoresis, 1000 μL of the filtered sample extract and 1000 μL of an internal standard solution of 2000 mg/L sodium chlorate (ACS reagent, ≥ 99.0%; Sigma-Aldrich, St. Louis, MO, U.S.A.) were diluted with deionized water to a final volume of 50 mL (using 50 mL glass flasks). Finally, 500 μL of this solution was pipetted to a 1 mL polypropylene vial and used for electrophoresis. Organic Acids Buffer (Agilent Technologies, Waldbronn, Germany) was used for electrophoretic separations. Three independent sulfate stock

solutions of 500 mg/L were prepared by dissolving appropriate amounts of anhydrous sodium sulfate (analytical grade; ≥ 99.0%; Merck KGaA, Darmstadt, Germany) in deionized water to a volume of 1000 mL. Sulfate standard solutions (5, 20, 40, 60, and 80 mg/L) were prepared from these stock solutions for calibration and were run daily in the beginning, the middle and the end of each sample sequence. Calibration curves were calculated on the average results of the three independent sets of standard solutions and used for determination of the sulfate concentrations in the sample extracts. Also, sulfate concentrations in sample extracts (and in standard solutions) were corrected using the chlorate peak as internal standard in the respective electropherogram. Finally, sulfate contents in the solid DDGS samples were calculated from the sulfate concentrations of the sample extracts.

The CE system employed for the study was an Agilent 7100 system (Agilent Technologies, Waldbronn, Germany) equipped with a fused-silica capillary of 72 cm length and 75 μm I.D. and UV−vis detector (190−600 nm) for indirect detection of analytes. The capillary was initially activated with 0.1 mol/L $NaOH_{aq}$ and water, rinsed with buffer daily before analyses and for preconditioning (240 s) before each injection. Sample solutions were injected in the hydrodynamic mode for 2 s at 50 mbar and separations were performed at 30.0 °C and a constant voltage of −25 kV. Total run time (without preconditioning) was 10 min and detection was based on a wavelength of 254 nm using a reference wavelength of 200 nm. Fresh buffer solutions were used after every 6 samples, and the detector was autobalanced after 60 s.

The spiked mixtures of sample A were homogenized using a spatula and extracted as described above; extracts were analyzed by CE, and the results served for estimation of recovery. Sample B was extracted ten times and analyzed by CE accordingly for estimation of precision. Extraction of sample B was carried out consecutively during the extraction of the samples and CE analysis of the respective replicates went along with samples on the single days of measurement by means of quality control.

Data Analysis. *Univariate Calibration Using Corrected Peak Area.* FT−IR raw spectra were investigated using the OMNIC 7.4 software (Thermo Fisher Scientific). Raw spectra (triplicates) were imported into The Unscrambler X 10.2 software (CAMO Software, Oslo, Norway) and preprocessed by Savitzky-Golay smoothing (centered spectral window 11 points, third polynomial for fitting) followed by Standard Normal Variate (SNV) transformation. Preprocessed spectra were then exported to ASCII text files using semicolons as item delimiter, transcribed to csv-format using KNIME version 2.9.1 (KNIME, Zurich, Switzerland) and finally imported into the OMNIC software again. Here, a macro (written in the OMNIC Macros Basic 7.4) was used for the calculation of the corrected peak height and corrected peak area in the range of 653.750 and 586.246 cm^{-1} for all spectra and results were automatically saved as text file. Peak location for the calculation of the peak height was defined at 617 cm^{-1} (seek closest peak enabled) and a new linear baseline (in the range of 653.750 and 586.246 cm^{-1}) was used automatically to calculate the corrected values of height and area, respectively. The text file was finally imported into Excel 2010 (Microsoft, Redmond, WA, U.S.A.) to draw graphs and calculate regression equations.

Regression analysis was performed by fitting a linear model (least-squares approach) to the obtained data of DDGS sample A spiked with different amounts of sodium sulfate. The double sided confidence interval bands for prediction were calculated according to eq 1:

DOI: 10.1021/jf503704r
J. Agric. Food Chem. 2015, 63, 476−484

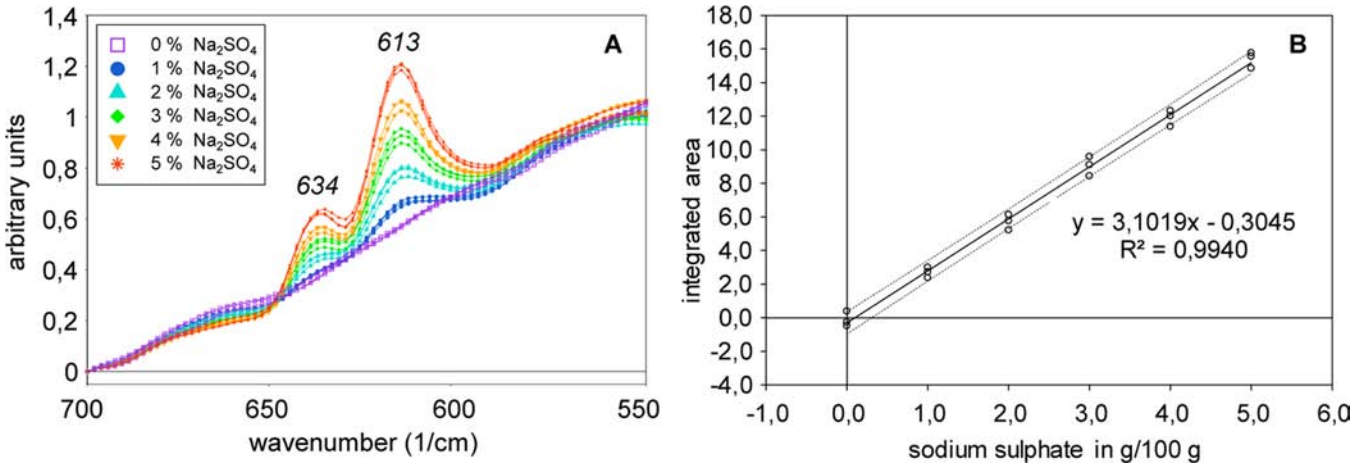

Figure 2. FT−IR triplicate spectra of DDGS sample A (SG smoothed, SNV transformed) spiked with different amounts of sulfate (A) and resulting calibration line with confidence intervals drawn by dashed lines (B). Spectra were zeroed to signal at 700 cm^{-1} in (A) for demonstration purposes (not conducted in actual data processing). Calibration was based on integration of bands between 654 and 586 cm^{-1}.

$$\hat{y} = (\hat{a} + \hat{b}x_i) \pm s_y t_{(p,df)} \sqrt{\frac{1}{m} + \frac{1}{n} + \frac{(x_i - \bar{x})^2}{Q_{xx}}} \quad (1)$$

where $\hat{a}$, $\hat{b}$, and x denote the intercept and slope estimated from calibration data and sulfate content respectively and s_y is the standard deviation of the residuals, calculated according to eq 2:

$$s_y = \sqrt{\frac{\sum (y_i - \hat{y}_i)^2}{n - 2}} \quad (2)$$

In eq 1, t is the student's t factor with p = 95% and degrees of freedom $df = n - 2$ are considering the number of samples (n) used for calibration. The number of replicates is indicated by m and Q_{xx} (sum of squared differences of contents) is calculated according to eq 3:

$$Q_{xx} = \sum (x_i - \bar{x})^2 \quad (3)$$

First, a calibration line was calculated for the sample spiked with different levels of sulfate and the respective corrected peak areas from the FT−IR spectra (matrix calibration). Then, this calibration was used to calculate the sulfate contents in all other samples analyzed in the study. Finally, these calculated sulfate contents were plotted against the sulfate contents analyzed by CE. The process coefficient of variation V_{x0}, based on the calibration using DDGS sample A, was calculated according to eq 4:

$$V_{x0} = \frac{s_y}{b \cdot \bar{x}} \quad (4)$$

Multivariate Calibration Using CE Reference Values (PLS Regression). For multivariate regression, FT−IR spectra were imported into The Unscrambler X 10.2 software, all sample triplicates were preprocessed by Savitzky-Golay smoothing (centered spectral window 11 points, third polynomial for fitting), then the triplicates were averaged, and finally SNV transformation was conducted. Partial least-squares regression (PLS regression) was calculated using the results from CE as reference values, based on NIPALS (Nonlinear Iterative Partial Least Squares) algorithm, mean centring and 7 requested latent variables (factors). Most important spectral variables of the calculated PLS models were consecutively selected three times (through the respective regression coefficients plot) and calculation of the new models with reduced number of variables was repeated accordingly. The PLS regression model was based on 2 latent variables (explaining 95.04% of the variance), a total number of 188 spectral variables (originally 1803, second step 568, third step 318, fourth step 188) and leave-one-out cross-validation was applied.

RESULTS AND DISCUSSION

Determining Sulfate by FT−IR Spectroscopy. FT−IR spectra of DDGS containing sulfate showed a unique band with local absorption maxima around 615 cm^{-1} (range: 640 cm^{-1} to 590 cm^{-1}) which were not present in DDGS without prominent sulfate levels (Figure 1). Also, a specific band around 1107 cm^{-1} was detectable in DDGS with high sulfate content (spiked with sodium sulfate). The band with the maximum around 615 cm^{-1} could be clearly attributed to one of the two fundamental IR active vibrations of the sulfate anion (SO_4^{2-}). In general, inorganic tetrahedral XY_4 molecules such as SO_4^{2-} show four normal modes of vibration; all are Raman-active, but only ν_3 and ν_4 are infrared-active.[18] For the sulfate anion in the free state, these vibrations appear at 1105 cm^{-1} (ν_3) and 611 cm^{-1} (ν_4) as it was described by Nakamoto.[18]

Addition of sodium sulfate to DDGS samples clearly increased the signal at 615 cm^{-1}, whereas the signal at 1107 cm^{-1} could only be detected at very high sulfate levels (Figure 1, red spectra: ∼4.2% sulfate) due to overlaying bands of compounds naturally present in the DDGS (e.g., C—O stretching vibrations of cellulose). In contrast to the maximum absorption signals reported in literature for pure sulfate salts,[18−20] the absorption maxima of ν_3 and ν_4 for sulfate in the matrix DDGS were sometimes found to be slightly shifted to lower or higher frequencies. The reason could possibly be the difference between the ATR technique and the transmission mode, as ATR generally introduces a shift to lower frequencies, or the DDGS matrix accounting for shifts in both directions of the frequency scale. Furthermore, the addition of sodium sulfate lead to an additional band at 636 cm^{-1} (Figure 1D) caused by the lowering of symmetry of the sulfate anion through coordination of the sodium cation. Possibly, coordination exists in the form of a bridged bidentate complex (C_{2v} instead of T_d), as it was previously reported for Na_2SO_4 and sulphato complexes.[21,22]

Recently, Zarrinbakhsh, Mohanty, and Misra (2013) reported on a water-soluble portion of DDGS which exhibits peaks at 1105 and 615 cm^{-1} only in the spectra of solid DDGS, but not in washed DDGS.[23] In consideration of the literature and our current study, their findings clearly indicate the presence of sulfate and their ascription of the major peak at

DOI: 10.1021/jf503704r
J. Agric. Food Chem. 2015, 63, 476−484

1105 cm^{-1} to the respective C—O vibrations of organic compounds should therefore be adjusted.

Quantification of Sulfate in DDGS by FT−IR Spectroscopy. In terms of quantification of sulfate, it was crucial to include both the signal of the normal sulfate anion at 615 cm^{-1} and the signal of the distorted sulfate anion at 636 cm^{-1}. Although for DDGS samples naturally containing sulfate simply the absorption at 615 cm^{-1} was noted, for all spiked DDGS samples linear relationship between band area and spiking level was only reached when integrating over both signals. This indicates that all distorted ions absorbing energy around the maximum of 636 cm^{-1} did not contribute to the absorption signal at 615 cm^{-1} anymore (due to band splitting). Hence, quantification of sulfate was based on the integration of the preprocessed FT−IR spectra of both spiked and nonspiked (native) DDGS samples between 654 and 586 cm^{-1} (Figure 1D). For calibration, DDGS sample A, derived from corn and without substantial sulfate level, was spiked with different amounts of sodium sulfate in levels of 1% to 5%, equal to 0.6% to 3.3% sulfate (Figure 2A). Integration of the respective preprocessed FT−IR spectra in the range of 654 cm^{-1} to 586 cm^{-1} resulted in a linear correlation of integrated area and sulfate content with superior confidence limits (Figure 2B). This matrix calibration was therefore used to calculate the sulfate contents in all other DDGS samples analyzed in the study. Generally, precision of FT−IR spectroscopic measurement in the spectral range of interest was good. Coefficient of variation of calculated sulfate contents (n = 10), based on DDGS sample B, was 2.4%, and the process coefficient of variation, based on the matrix calibration of sample A, was 5.6%.

It is also notable that the absorption maxima of the spiked DDGS (sample A) used for calibration (Figure 2A) compared to those of a spiked DDGS (sample C) with native sulfate content (cf. Figure 1D) were shifted two wavenumbers to lower frequency for both bands of the sodium sulfate vibrations (ν_3 and ν_4). However, this did not affect the integration, as the integration window was chosen broad enough to compensate for such shifts in the wavenumber scale. Furthermore, a quantification procedure aiming at the maximum height of the band around 615 cm^{-1} (using corrected absorbance values, data not shown), as it can generally be applied for quantitative IR spectroscopy,[24] was not as good as the approach by band/peak area demonstrated here. The procedure applied for calculation of the band/peak area included linear baseline correction of the spectra in the range of 654 to 586 cm^{-1}, before integration, and was carried out in the OMNIC Macros Basic 7.4 (Thermo Fisher Scientific). Although for the sample spectra, this resulted in slightly negative amplitudes around 640 cm^{-1} (Figure 3), the procedure was necessary in order to apply the calibration after addition of sodium sulfate using DDGS sample A (Figure 2) to the calculation of sulfate levels in all other samples. The main reason for choosing 654 cm^{-1} as the upper wavenumber for the baseline correction (Figure 3) was the additional signal of the distorted sulfate anion.

Comparison of FT−IR Spectroscopy and Capillary Electrophoresis. *Capillary Electrophoresis.* Sulfate content of DDGS samples was not only analyzed by the previously mentioned FT−IR approach, but also by the use of capillary electrophoresis (CE). The results served as reference values for comparison with FT−IR spectroscopy and also for multivariate calibration.

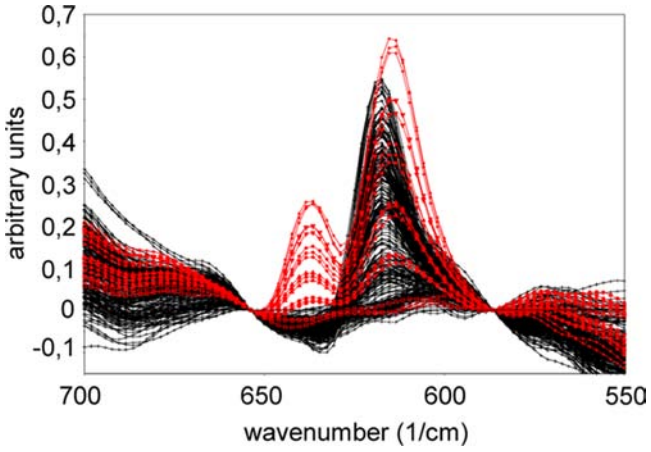

Figure 3. Linear baseline correction of preprocessed FT−IR spectra between 654 and 586 cm^{-1}. Shown are spectra of DDGS sample A, spiked with different amounts of sulfate (red) and spectra of all other DDGS analyzed in the study (black).

The vast majority of the sulfate present in DDGS is derived from sulfuric acid added in the production process and is probably not bound or located in the plant tissue, and therefore a preferably simple method for the extraction of sulfate out of the DDGS samples should work. In addition, several extraction methods for inorganic ions in plant materials had been reported before,[25−27] with sufficient extraction recoveries of sulfate and results indicating even quantitative extraction in comparison to reference methods.[28] Thus, extraction conditions and sample preparation procedure for CE were chosen in consideration of the methods for extraction of sulfate in these previous studies. Accordingly, the extractable sulfate contents analyzed in this study were considered to be capable to serve as reference values for comparison with the results achieved by FT−IR spectroscopy.

To support this assumption, DDGS sample A, without substantial sulfate content, was spiked with different amounts of sodium sulfate (1% to 5%) and analyzed for estimation of recovery. Also, DDGS sample B, with medium sulfate content (1.44%), was extracted ten times and accordingly analyzed by CE to underpin the precision of CE and its suitability as a reference method. Recovery ranged from 94% to 97% dependent on the amount of sulfate added to the sample, relative standard deviation of repetitive measurements (interday precision, n = 10) reached 1.7%. Sulfate was eluting about 3.5 min after the injection of the samples (Figure 4) and was identified by a separate standard addition procedure as well as all the identified peaks in the electropherogram (data not shown). Quantification of sulfate in all DDGS samples was based on correction of the peak area by an internal standard (chlorate) and calculation of the respective sulfate contents in the sample extracts using averaged calibration curves of the single working days.

Comparison of FT−IR and CE Based on Univariate Data. Regression of sulfate contents analyzed by FT−IR spectroscopy against the reference values determined by CE resulted in a linear relationship showing a slight overestimation of the sulfate content by FT−IR (Figure 5A). Although the results for DDGS samples which did not contain sulfate according to CE were leading to both positive and negative sulfate levels by FT−IR (e.g., due to integration of a negligible negative band), the offset in total was nearly zero indicating a good strategy for the

determination of sulfate by FT−IR. However, it was necessary to reintegrate 4 of the 90 samples that had been analyzed by FT−IR spectroscopy (by adjusting the right spectral wavenumber regions manually) as they were slightly shifted outside the region that had been selected for the automated calculation of the peak area (cf. above). In general, it was decided to include all DDGS samples that had been measured for the method comparison (elimination of outliers was omitted) to demonstrate the capability of the proposed strategy on a sample set of DDGS from various origins derived from corn and wheat (cf. SI).

Multivariate Calibration Using PLS Regression. The regression of the univariate results showed a rather high uncertainty for sulfate contents by FT−IR, especially for levels around 0.9% according to CE (cf. Figure 5A). In order to improve the significance of the approach and to overcome difficulties due to spectral window selection for peak area calculation, multivariate calibration was performed applying PLS regression. For this purpose, CE results were used as reference values and after subsequent selection of the most important spectral variables, PLS regression based on 2 latent variables (explained Y-variance: 95.0%) showed a reduced uncertainty with regards to the predictability of sulfate levels of DDGS using FT−IR spectra (Figure 5B). In this case, sulfate content was slightly underestimated by FT−IR spectroscopy, but was nearly unaffected when tested by leave-one-out cross-validation (explained Y-variance: 94.3%) indicating a robust calibration (Figure 5B). The most important finding with regard to the chemical information behind the data was, that the spectral variables used for the final PLS regression were consequentially correlated with the two fundamental IR active vibrations of the sulfate anion. The highest regression coefficients were found for the spectral regions from 1109 to 1088 cm^{-1} and from 623 to 599 cm^{-1} representing the S—O vibrations ν_3 (1105 cm^{-1}) and ν_4 (611 cm^{-1}) of the sulfate anion (Figure 6).

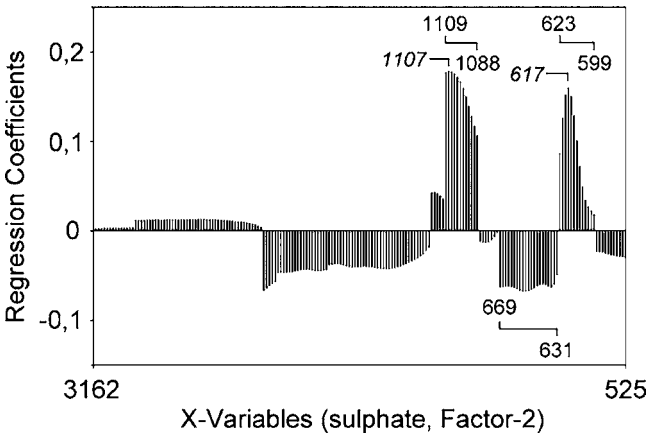

Figure 6. Most important spectral variables used for PLS regression and consistency with the fundamental S—O vibrations of the sulfate anion ν_3 (1105 cm^{-1}) and ν_4 (611 cm^{-1}). Scale of *X*-axis is not continuous.

Without a doubt, there is still a need to prove the robustness and validity of the calibration with an independent external sample set in the future. But in consideration of the sample set with a huge number of different origins included (cf. SI) and the strong correlation to the fundamental vibrations of the sulfate anion, the presented calibration is regarded as already solid at this stage. In general, improved specificity and the nonexisting influence of spectral window selection make the multivariate calibration advantageous, compared with the univariate procedure based on peak area calculation. First and foremost, the approach by FT−IR spectroscopy and subsequent multivariate data analysis could be used for the rapid

DOI: 10.1021/jf503704r
J. Agric. Food Chem. 2015, 63, 476−484

analysis of sulfate levels in DDGS (in terms of screening). By this, single batches of DDGS with high levels of sulfate could be identified and selected for further investigations. If the results indicate high sulfate levels, then verification of the results and analysis of the total sulfur levels (including sulfate) should consequently be carried out by reference methods, such as ICP-MS or X-ray fluorescence spectroscopy.

Estimation: Theoretical Calculation of Total Sulfur Contents. In general, quantitative information on sulfur and/or sulfate in DDGS is of interest to DDGS manufacturers, animal feed producers and farmers. Regarding DDGS, the total amount of sulfur (S) can be classified into S derived from organic compounds and S derived from inorganic compounds: S-rich organic compounds are mainly composed of amino acids containing S atoms or enzymes with S in the prosthetic group; inorganic compounds that contain S are mainly due to sulfate, derived mainly from sulfuric acid used in the production process of DDGS.

In the current study, it was shown that FT−IR spectroscopy could be used for estimation of sulfate levels in DDGS. However, organic forms of S, like S-containing amino acids and proteins, cannot be identified and thus will not be quantified by FT−IR spectroscopy. Nevertheless, the presented approach could be used for routine purposes, as the variability in the total S content of DDGS mainly depends on the inorganic form of S (i.e., sulfate) linked to the amount of sulfuric acid used in the production. In contrast, S-containing organic compounds mainly derive from the plant material (natural origin) and generally only a very low amount is added in the form of yeasts or nutrient salts during the production. Additionally, S derived from the plant material gives a relatively constant input to the production of DDGS, and the major part of it is organically bound with only about 10% of the S from natural origin being present in the form of sulfate.[29,30]

Bearing this in mind, the total S content of DDGS could be estimated, on the basis of a theoretical calculation, as the sum of: (1) the amount of S derived from sulfate (which could be determined by FT−IR spectroscopy) and (2) the amount of S derived from S-containing compounds which were already present in the natural plant material (and would in the main part be due to organic S-containing compounds). The amount of S naturally present in the plant material is dependent on the plant species but is well examined: based on the DM, corn contains an average of 0.12% S,[31] whereas for wheat, cultivated in the 1990s, a mean S content of 1.35 mg/g (0.14%) was reported.[30]

In the final product DDGS, all constituents are concentrated by a factor of approximately three compared to the grain and this would in theory, with regards to the above-mentioned mean S contents of the cereals, result in levels of 0.36% S for corn DDGS and 0.42% for wheat DDGS on a DM basis. However, for a final estimation of the total S contents in DDGS, one would have to consider the percentage of sulfate derived from the plant material, which is approximately 10% of the total S of plant-origin[29,30] and is already covered by the sulfate levels analyzed in this study. Therefore, the total S content of the DDGS samples was theoretically estimated as the sum of the sulfate content (based on the DM) and the "sulfate-corrected" mean S contents from the plant material (based on the DM) of 0.32% for corn DDGS and 0.38% for wheat DDGS (and DDGS of mixed origin). Finally, this resulted in estimated total S contents for the DDGS samples between 0.29% and 1.06% (median 0.63%) based on FT−IR spectroscopy using PLS regression, and consistently, in 0.32% to 1.08% (median 0.63%) when calculating with the reference values which have been analyzed by CE (Figure 7).

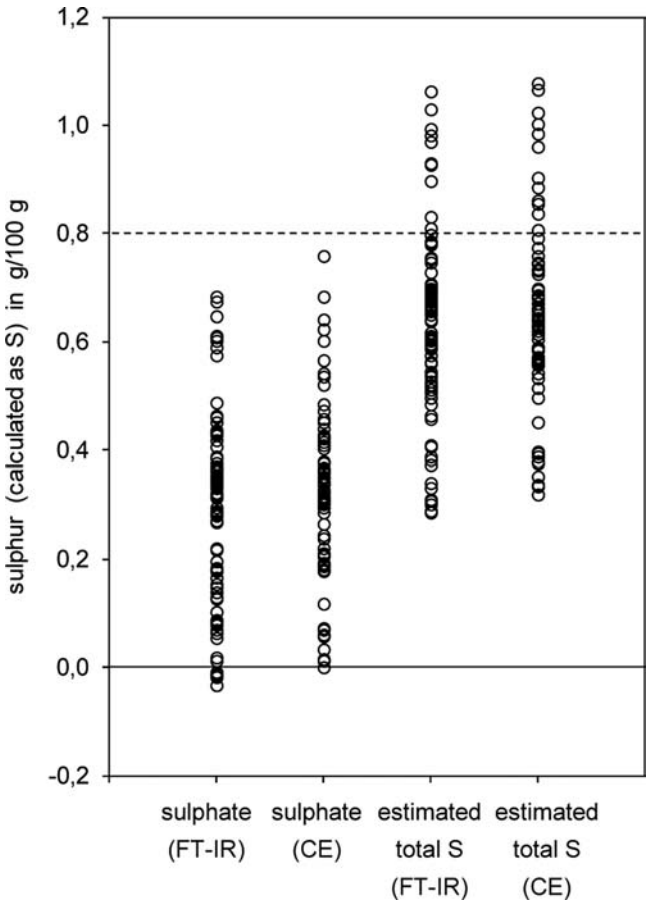

Figure 7. Distribution of sulfur contents of DDGS samples based on sulfate (from chemical analysis) and on estimation of total S contents (based on theoretical calculation). Sulfate (FT−IR) and sulfate (CE) are representing the sulfate levels (calculated as S) based on the DM of the samples; negative values are due to the multivariate calibration approach and should be regarded as zero/not detectable. Total S (FT−IR) and total S (CE) are estimated results of total S contents (calculated as S) additionally considering the theoretical input of plant-derived sulfur. The dashed line illustrates the maximum level of 0.8% S in DDGS discussed in literature.

With regards to the maximum tolerable dietary S level for beef cattle of 0.4% on a DM basis,[9] one has to consider that this dietary concentration could be exceeded if DDGS with a sulfur content greater than 0.80% (DM basis) were fed to ruminants at high inclusion rates (DDGS: 40% of DM intake), in addition to corn and corn silage assuming low sulfate levels in drinking water.[5,10] In such a scenario, 11% (based on FT−IR prediction), respectively 13% (based on CE results) of the DDGS samples analyzed in this study showed excessive sulfur levels on the basis of the theoretical calculation (Figure 7). However, such DDGS could still be fed at a lower inclusion rate or even mixed with batches of DDGS containing lower sulfur levels. This would not only protect ruminants of S toxicity and PEM, but could also show general advantages, because it has been reported that both ruminants and nonruminants show decreased feed intake and gain when feeding a high dietary S level.[12,13]

DOI: 10.1021/jf503704r
J. Agric. Food Chem. 2015, 63, 476−484

General Aspects and Future Perspectives. The study demonstrated that ATR/FT−IR spectroscopy can be applied to the determination of sulfate levels in the matrix DDGS. With regard to the maximum tolerable dietary S level for beef cattle of 0.4%, FT−IR spectroscopy could evaluate whether sulfate levels are low enough to use DDGS in high inclusion rates of the diet. It could serve as a prescreening method to select batches of DDGS with high sulfate levels before using techniques such as X-ray fluorescence spectroscopy or ICP-MS, especially if those are not affordable or FT−IR spectroscopy is already in use for other purposes. However, the final evaluation of sulfur levels in the study was based on an theoretical estimation combining the analyzed sulfate levels with the theoretical percentage of plant-derived sulfur in the form of organic S (as mean levels). Further investigation whether such an approach can be used in routine analysis should therefore be cross-validated with a complementary method (e.g., X-ray fluorescence spectroscopy) in the future. In conclusion, FT−IR spectroscopy can be applied for the comparison of DDGS batches regarding the sulfate content, which could be especially useful for blending of animal feed or adaption of process parameters in the production of DDGS.

Supporting Information

ABSTRACT: This paper presents a new analytical method for the determination of morpholine residues in citrus and apples using a novel dispersive micro-solid-phase extraction (DMSPE), followed by ultrahigh-performance liquid chromatography–high-resolution mass spectrometry (UHPLC–HRMS). Samples were extracted with 1% formic acid in acetonitrile/water (1:1, v/v) and then cleaned up using the DMSPE procedure. Morpholine from the extract was adsorbed to a polymer cation exchange sorbent and eluted with ammonium hydroxide/acetonitrile (3:97, v/v) through a 1 mL syringe with a 0.22 μm nylon syringe filter. All of the samples were analyzed by UHPLC–HRMS/MS on a Waters Acquity BEH hydrophilic interaction chromatography column using 0.1% formic acid and 4 mM ammonium formate in water/acetonitrile as the mobile phase with gradient elution. The method showed good linearity (R^2 > 0.999) in the range of 1–100 μg/L for the analyte. The limit of detection and limit of quantitation values of morpholine were 2 and 5 μg/kg, respectively. The average recoveries of morpholine from the citrus and apple samples spiked at three different concentrations (5, 20, and 100 μg/kg) were in a range from 78.4 to 102.7%.

INTRODUCTION

Morpholine, C_4H_9ON, has been widely used as an accelerant in rubber manufacturing, a sulfuration agent, a cleanser, a descaling agent, a surfactant, an agent in textile printing, and a fruit-preserving agent. It is added to some waxes as an emulsifier used in the preparation of wax coatings for fruits and vegetables.[1] In the presence of excess nitrite, morpholine can be chemically modified (nitrosated) to form *N*-nitrosomorpholine (NMOR), which has been proven to be a genotoxic carcinogen in rodents.[2]

Although morpholine as a component of the coating in fresh fruits is approved for use in China,[3] it is still under scrutiny by the European Union (EU) and has not been approved for use in the EU.[4] On the basis of a no observed adverse effect level [NOAEL, 96 mg kg^{-1} of body weight (bw) day^{-1}] in a chronic oral toxicity study for morpholine, an acceptable daily intake (ADI) of 0.48 mg kg^{-1} of bw day^{-1} was estimated by Health Canada.[2] However, there is no currently validated method to determine morpholine residues on waxed commodities, which caused residue data and estimated exposure for morpholine in citrus and apple fruits to not be obtained in China. It is well-known that gas chromatography–thermal conductivity detector (GC–TCD) and gas chromatography–mass spectrometry (GC–MS) or other methods [gas–liquid chromatography–thermal energy analyzer (GLC–TEA) and gas–liquid chromatography–mass spectrometry (GLC–MS)] could be used for analysis of morpholine residues in various matrix samples;[5−9] nevertheless, because of the high polarity and low molecular weight of morpholine, its response and sensitivity are not good enough for residue analysis in complex matrices. Recently, a liquid chromatography–mass spectrometry (LC–MS) method for the determination of morpholine in citrus and apples has been published,[10] but its affiliated extraction and no cleanup process resulted in a >20% ion suppression. The cleanup is considered to be a labor-intensive but effective process to overcome ion suppression. Currently, the cleanup methods, including solid-phase extraction (SPE) and dispersive solid-phase extraction (dSPE), are widely used to solve the matrix interferences in complex matrices for the residue analysis.[11−13] A dual SPE cartridge system was used as a pretreatment method for morpholine in pineapples by Gros et al., but it is time-consuming, laborious, and costly.[14] While a quick, easy, cheap, effective, rugged, and safe (QuEChERS)-based dSPE method for sample cleanup has been developed to improve sample throughput for residue analysis,[15,16] the purification effect is even worse than SPE.[17] On the contrary, dispersive micro-solid-phase extraction (DMSPE) can be categorized as a dSPE or SPE technique and exhibits some advantages over traditional dSPE (fewer matrix effects) and

SPE (such as without complex equipment, short time requirement, and less solvent consumption).[18−21] In the DMSPE cleanup technique, the solid sorbent is added directly to an extract and the cleanup procedure relies solely upon shaking and centrifugation. Graphene and carbon nanotubes (CNTs) are commonly used as solid sorbent materials for application in the sorbent phase of such processes. Polymer cation exchange (PCX), as a high molecular polymer, is a cation exchange sorbent material. PCX can adsorb the alkaline chemical substances directly and provide an effective separation. In the present study, all of those parameters that were supposed to affect the extraction efficiency in the DMSPE cleanup method, such as the amount of PCX, the adsorption time, and the type and volume of eluent, were carefully investigated and optimized. In analytical chemistry, optimization is a critical stage to find out the value that each factor could help to reach the best possible response.[22] Recently, the multivariate designs of experiments are accepted to obtain the optimal variable parameters.[23−26] The designs of experiments would not just significantly reduce the number of experiments, which can take less time, effort, and resources than the univariate studies, but also take the interactions between variables and nonlinear relations with the responses into account. Therefore, the central composite design (CCD) approach was used for studying the optimal variables in this DMSPE cleanup method.

MATERIALS AND METHODS

Chemicals and Reagents. Acetonitrile and methanol [high-performance liquid chromatography (HPLC) grade] were obtained from Fisher Scientific (Fair Lawn, NJ). Formic acid and ammonium formate (HPLC grade) was purchased from Tedia (Fairfield, OH). Ultrapure water was prepared from a Milli-Q reagent water system (Millipore, Bedford, MA). Cleanert PCX powder was obtained from Agela Technologies (Tianjing, China).

Morpholine was purchased from Supelco (Bellefonte, PA) and d_8−morpholine was obtained from Cambridge Isotope Laboratories (Tewksbury, MA). The purity of all of these standards was no less than 98.0%.

Standard stock solutions (1000 mg/L) were prepared by dissolving 10.0 mg of individual compounds in a 10 mL volumetric flask with methanol. The stock solutions were diluted in acetonitrile to prepare the intermediate standard solutions and the working standard solutions of 10 and 1 mg/L, respectively. All standard solutions were made in amber volumetric flasks and stored at −20 °C.

Sample Collection and Preparation. Apples and citrus were obtained from the local markets from Beijing, China. The apples were produced in Shandong and Gansu provinces in China as well as imported from Chile and the U.S.A. The citrus were transported from Jiangxi, Guangdong, Guangxi, Hubei, and Sichuan provinces in China as well as imported from South Africa and the U.S.A. All samples were cut into small pieces and homogenized using an electric grinder. One sample from 1 kg of apples/citrus was prepared and kept in 4 °C.

A total of 10 g of homogenized sample was weighed into a 50 mL polypropylene centrifuge tube, and a total of 40 μL of the internal standard (10 mg/L) was spiked into the sample. After 10 mL of 1% formic acid in acetonitrile/water (1:1 v/v) was added, the mixture was vortexed for 30 s, ultrasonicated for 10 min, and centrifuged at 8000 rpm for 5 min. The supernatant was poured off into a clean 50 mL polypropylene centrifuge tube and distilled to 20 mL with acetonitrile for the next purification. A total of 1 mL of the supernatant was transferred into a 2 mL eppendorf tube with 30 mg of PCX powder. The mixture was vortexed for 30 s for interaction between the analytes and PCX sorbent and then poured off into a 1 mL syringe with a 0.22 μm nylon syringe filter. The extracted solution was passed through the syringe and syringe filter manually and washed with 1 mL of acetonitrile again. Subsequently, the PCX enriched with the analytes was eluted with 2 mL of ammonium hydroxide/acetonitrile (3:97, v/v). The collected elution was prepared for ultrahigh-performance liquid chromatography−mass spectrometry (UHPLC−MS) analysis.

Chromatographic Conditions. UHPLC analysis was performed on a UHPLC Ultimate 3000 system (Dionex), using an Acquity BEH hydrophilic interaction chromatography (HILIC, 2.1 × 100 mm, 1.7 μm particle size) analytical column (Waters, Milford, MA) with the temperature maintained at 40 °C. The aqueous phase (A) consisted of a mixture of 0.1% formic acid and 4 mM ammonium formate in water, and the organic phase (B) was acetonitrile with 0.1% formic acid. The gradient started at 90% B for 2 min, reduced to 40% B in the next 4 min, followed by re-equilibration at 90% B for 3 min prior to the next injection. The flow rate was set to 300 μL/min, with a resulting overall runtime of 9 min. The injection volume was 10 μL.

Mass Spectrometry Conditions. A Q Exactive mass spectrometer (Thermo Fisher Scientific, Bremen, Germany) with heated electrospray ionization (HESI) was operated in the positive electrospray ionization (ESI^+) modes. The system was controlled by Xcalibur 2.2 (Thermo Fisher Scientific). The spray voltage was 3.5 kV for the positive mode. The temperature of ion transfer capillary, sheath gas, auxiliary gas, sweep gas, and S-lens radio frequency (RF) level were set to 325 °C, 30, 10, and 0 arbitrary units, and 55 V, respectively. The instrument was calibrated in the positive mode every 3 days using the calibration solutions, including caffeine, L-methionyl-arginyl-phenyl-alanylalanine acetate H_2O (MRFA), and a mixture of fluorinated phosphazines, Ultramark 1621, provided by the instrument manufacturer.

The Q Exactive detector was operated in targeted tandem mass spectrometry (tMS/MS) mode. The tMS/MS scan mode is similar to the SRM scan mode used in the triple quadrupole mass spectrometer. The mass spectrometer acquired a tMS/MS scan at a resolution of 70 000 full width at half maximum (fwhm) with 5.0×10^5 of automatic gain control (AGC) target (the number of ions to fill the C-trap) and 200 ms of maximum ion injection time (IT).

Design of Experiments. The software Design-Expert (version 8.0.5b, Stat-Ease, Inc., Minneapolis, MN) was used for experimental design, data analysis, and model building for response surface methodology (RSM).

The central composite design (CCD) approach was employed to identify optimum conditions in the DMSPE cleanup procedure. CCD requires an experiment number to meet $N = 2^k + 2k + c_p$, where k is the factor number and c_p is the replicate number of the central point.[22] In this study, the amount of PCX, the concentration of ammonium hydroxide in acetonitrile, and the volume of elute were set as three independent factors. A five-level three-parameter experimental design of the CCD approach was performed at random order with 20 run experiments, as shown in Table 1 and Table S1 of the Supporting Information. The full CCD was described as follows: (1) a full two-level (−1 and +1) factorial design, (2) center point (c_p = 5), and (3) two axial points on the axis of each design variable at a distance of α = 2.0 from the design center. The response Y (the efficiency of extraction) was established for the determination of optimum method conditions, and the recovery was selected as the indicator of the extraction efficiency. The optimal values of response Y were obtained by solving the regression equation and analyzing the three-dimensional response surface plot and contour plots.

Table 1. Variables and Levels Evaluated in the CCD

independent variable	unit	symbol	coded level

analyte	precursor ion (m/z)	fragment ion (m/z)	NCE (%)	linear range (μg/L)	linearity equation	R^2	LOD (μg/kg)	LOQ (μg/kg)
morpholine	88.0761	70.0658,[a] 68.0502	75	1−100	$Y = 0.10552X + 0.022816$	0.9997	2	5
d_8-morpholine	96.1259	78.1157,[a] 76.1035	75					

[a]Quantitative ion.

Method Validation. The selectivity of the method was performed by analyzing the blank samples, and matrix interferences were checked close to the elution zone of the analyte.

The calibration curve was constructed using working standard solutions and plotting the peak area ratio of the quantitative ion of the standard to the internal standard at concentrations of 1, 2, 5, 10, 25, 50, and 100 μg/L for morpholine. The concentration of the internal standard was 10 μg/L for d_8-morpholine.

The limit of detection (LOD) and limit of quantitation (LOQ) were estimated for the signal-to-noise (S/N) ratio of more than 3 and 10, respectively, from the chromatograms of samples spiked at the lowest concentration validated. Precision [intraday repeatability and interday reproducibility, in terms of percent relative standard deviation (RSD_r) and RSD_R, respectively] and recovery were estimated by spiked experiments in citrus and apple samples. Intraday repeatability of the method was evaluated by spiking the standard solutions to the six blank matrices at three different concentration levels (5, 20, and 100 μg/kg) and analyzing in the same run of the day on LC−MS. For interday reproducibility, the three concentrations were analyzed in three different days. Extraction recoveries of morpholine were measured in citrus and apples, which were fortified at three concentration levels (5, 20, and 100 μg/kg) with six replicates at each level. The recoveries were calculated from those measured in comparison to the expected concentrations.

The matrix effect (ME) was determined by constructing calibration curves in the blank extract and the pure solvent ($n = 3$). The effects were expressed in terms of signal suppression/enhancement (SSE) and calculated as follows: SSE = slope of spiked extract/slope of pure solvent standard.

Stability of the analyte in the matrix was determined by repeated analysis ($n = 3$) of spiked citrus and apple samples (5 and 20 μg/kg), which were stored at −20 °C. The samples were extracted and analyzed after 7, 14, and 21 days.

RESULTS AND DISCUSSION

Optimization of Chromatographic Conditions. The effects of different liquid chromatographic columns on the target compound separation and retention were initially studied. Three different types of analytical columns, namely, BEH C_{18} (2.1 × 100 mm, 1.7 μm), BEH HILIC (2.1 × 100 mm, 1.7 μm), and HSS T_3 (2.1 × 100 mm, 1.8 μm) were tested to their optimal elution conditions, which were shown in the Supporting Information. Figure S1 of the Supporting Information showed that morpholine had no good retention and weak MS response in C_{18} and T_3 columns because of its high polarity, which led to its co-elution with other impurities, while the HILIC column had a better retention effect and less interference from other impurities. As for the mobile phase, acetonitrile and water with a variety of modifiers were compared. A mixture of 4 mM ammonium formate and 0.1% formic acid solution was selected as the most suitable component for the mobile phase, in which a sufficiently good performance for ionization of morpholine was achieved with good peak symmetry under the optimized linear gradient mode.

MS/MS Optimization. *Optimization of Acquisition Modes.* Full-scan, targeted single ion monitoring (tSIM), and tMS/MS modes are three kinds of commonly used quantitative models for Q Exactive, and all were evaluated and optimized in the present study.

Full-scan mode is a full scan of all ions in the specified mass range. However, the precursor in the inclusion list (with retention times) can be selected in the quadrupole with a particular isolation width by tSIM mode. In tMS/MS mode, the precursor specified in the inclusion list is selected by quadrupole and fragmented in a higher energy collisional dissociation (HCD) cell with specific fragmentation energy. These three acquired modes were evaluated by the S/N ratios. The S/N ratios of morpholine (5 μg/L in a blank citrus extract) in different modes acquired within individual conditions are shown in Figure S2 of the Supporting Information. This figure highlights the fact that tMS/MS is more selective and specific than tSIM and full-scan modes because of complex matrices, which leads to better method detection limits. Therefore, the tMS/MS mode was selected as the quantitative model for morpholine in citrus and apples.

Optimization of the MS Condition in tMS/MS Mode. Using the Q Exactive tune application, the precursor ion was selected in the quadrupole and product ions were found by increasing the normalized collision energy (NCE) in tMS/MS mode. The actual HCD energy in electron volts is calculated on the basis of the chosen NCE, mass, and charge of the precursor ion.[27] After the product ions were chosen, fragmentation energy scans were carried out to obtain the optimal NCE for complete fragmentation of precursor ions. The optimal NCEs of the monitored ions are shown in Table 2.

MS Spectra of Morpholine and d_8-Morpholine. Using tMS/MS mode, the parent ions are selected in the quadruple (e.g., m/z 88.0761 for morpholine and m/z 96.1259 for d_8-morpholine) using a specified m/z window (4 Da) and subsequently fragmented in the HCD cell. A full scan of all fragmented ions originating from the parent ion was performed, and specific product ions were used for data analysis (m/z 70.0658 and 68.0502 for morpholine and m/z 78.1157 and 76.1035 for d_8-morpholine).

Optimization of the Extraction Procedure. Acidic methanol (1%) has been used to extract morpholine with water (0−2 mL), added for aid in the extraction.[10] Thus, the extraction efficiency was studied for the mixture of 1% acidic acetonitrile/water used as the extraction solution with different volumes in this study. Figure S3 of the Supporting Information showed that the extraction efficiency for morpholine was better at 1% formic acid than that at acetonitrile/water (1:1, v/v), and the 10 mL extraction solution was sufficient to extract morpholine completely. Moreover, ultrasound is of great help in the pretreatment of solid samples because it facilitates and accelerates the dissolution, fusion, and leaching.[28] Thus, the ultrasonic extraction was used to aid the extraction of morpholine from the citrus and apples.

During the DMSPE cleanup procedure, the parameters that affected the extraction efficiency, such as the amount of PCX, the adsorption time, and the type and volume of eluent were carefully studied. A one-factor analysis of the variable

preliminary experiment was performed first, and the preliminary study and results were shown in the Supporting Information. It was found that the adsorption of morpholine into PCX was a fast process, and the adsorption time greater than 30 s did not produce an extra enhancement of adsorption efficiency. As a result, a 30 s adsorption time was chosen for all subsequent experiments. As an analytical practice for SPE, it is well-known that alkaline substances are easily eluted from the strong cation exchange column in alkaline conditions. In addition, it is desirable to use a mobile phase for sample preparation to inject sample solutions into a LC system. Therefore, ammonium hydroxide in acetonitrile had been used to release morpholine from a PCX sorbent based on the ion exchange retention mechanism. Additionally, the detailed ion exchange retention mechanism including the structure of morpholine and PCX was provided in Figure S4 of the Supporting Information.

Design of Experiments. The one-factor analysis indicated that the amount of PCX, the concentration of ammonium hydroxide in acetonitrile, and the volume of eluent were the main effective factors for DMSPE but did not take into account interactions between factors. Therefore, the amount of PCX (10−50 mg, A), the concentration of ammonium hydroxide in acetonitrile (0.1−5%, B), and the volume of eluent (1−3 mL, C) were considered and optimized in CCD. After 20 run experiments described in Table S1 of the Supporting Information, the response Y was calculated on the basis of the efficiency of extraction for morpholine, and all statistical analysis were performed by Design-Expert software. The analysis of variance (ANOVA) for the response surface quadratic model showed that the model was significant, with a p value of less than 0.0001. The lack of fit of the model relative to its pure error showed a p value of 0.1663, which indicated that the fitted model was considered adequate to predict the efficiency of extraction under any set of the variable combination. Model coefficients for the response are shown in Table 3. The final equation in terms of coded factors was response = $87.18 + 3.69A + 11.81B + 7.94C - 2.87AB + 0.13AC - 3.12BC - 3.41A^2 - 6.16B^2 - 3.28C^2$. The three-dimensional (3D) surface response plots and their related counters, obtained using the fitted model, are shown in Figure 1. As shown in Figure 1, the concentration of ammonium hydroxide and the volume of eluent were two important factors that had a significant positive effect on the extraction efficiency. However, the amount of PCX affects the efficiency of the extraction process with the increasing of PCX from 20 to 30 mg, but it was almost unchanged above 30 mg. The optimum conditions were selected by the analysis data obtained from the response surface plots and the regression coefficient plots. The factor settings that maximize the efficiency of extraction were chosen in response optimization. Among these settings, the most desirable factor levels ranged as follows: 22−38 mg for the amount of PCX, 2.5−3.9% for the concentration of ammonium hydroxide, and 1.9−3 mL for the volume of eluent. To obtain the maximum response (Y = 90.7%; desirability = 0.994), the best combination was found to be 30 mg of PCX and 2 mL of 3% ammonium hydroxide in acetonitrile.

Under the above optimized PCX conditions for the DMSPE cleanup method, the pretreatment procedure was simple and fast and the cost of PCX for one sample is approximately 0.30 U.S. dollars. In addition, the total time required for the cleanup of one sample was only approximately 3 min.

Method Validation. *Selectivity.* With the high resolving power and accurate mass measurements of high-resolution mass spectrometry, no interfering peak at the retention time of morpholine was observed from citrus and apple samples. Extracted ion chromatograms for morpholine from the blank citrus, blank apple, and standard at 5 μg/L are shown in Figure 2.

Linearity, LOD, and LOQ. To obtain the internal calibration curves for the analyte, the peak area ratio of the quantitative ion of morpholine to d_8-morpholine was plotted at the concentration of 1−100 μg/L (Table 2). The coefficients of determination (R^2) of the calibration curve for morpholine were above 0.999, which indicated good linearity of the analytical range.

Here, the LOD and LOQ values of the complete method were calculated as 3 and 10 times the S/N ratio, which indicated 2 and 5 μg/kg, respectively.

Recovery and Precision. The results of the recovery, intraday repeatability, and interday reproducibility experiments are presented in Table 4. Overall, average recoveries, repeatability, and reproducibility varied from 78.4 to 96.2%, from 1.8 to 6.4% (RSD_r), and from 2.3 to 6.6% (RSD_R), respectively, for the citrus samples. However, the mean recoveries, repeatability, and reproducibility ranged from 85.4 to 102.7%, with RSD_r from 1.9 to 6.9% and RSD_R from 3.2 to 8.4% for the apple samples, which indicated that the established

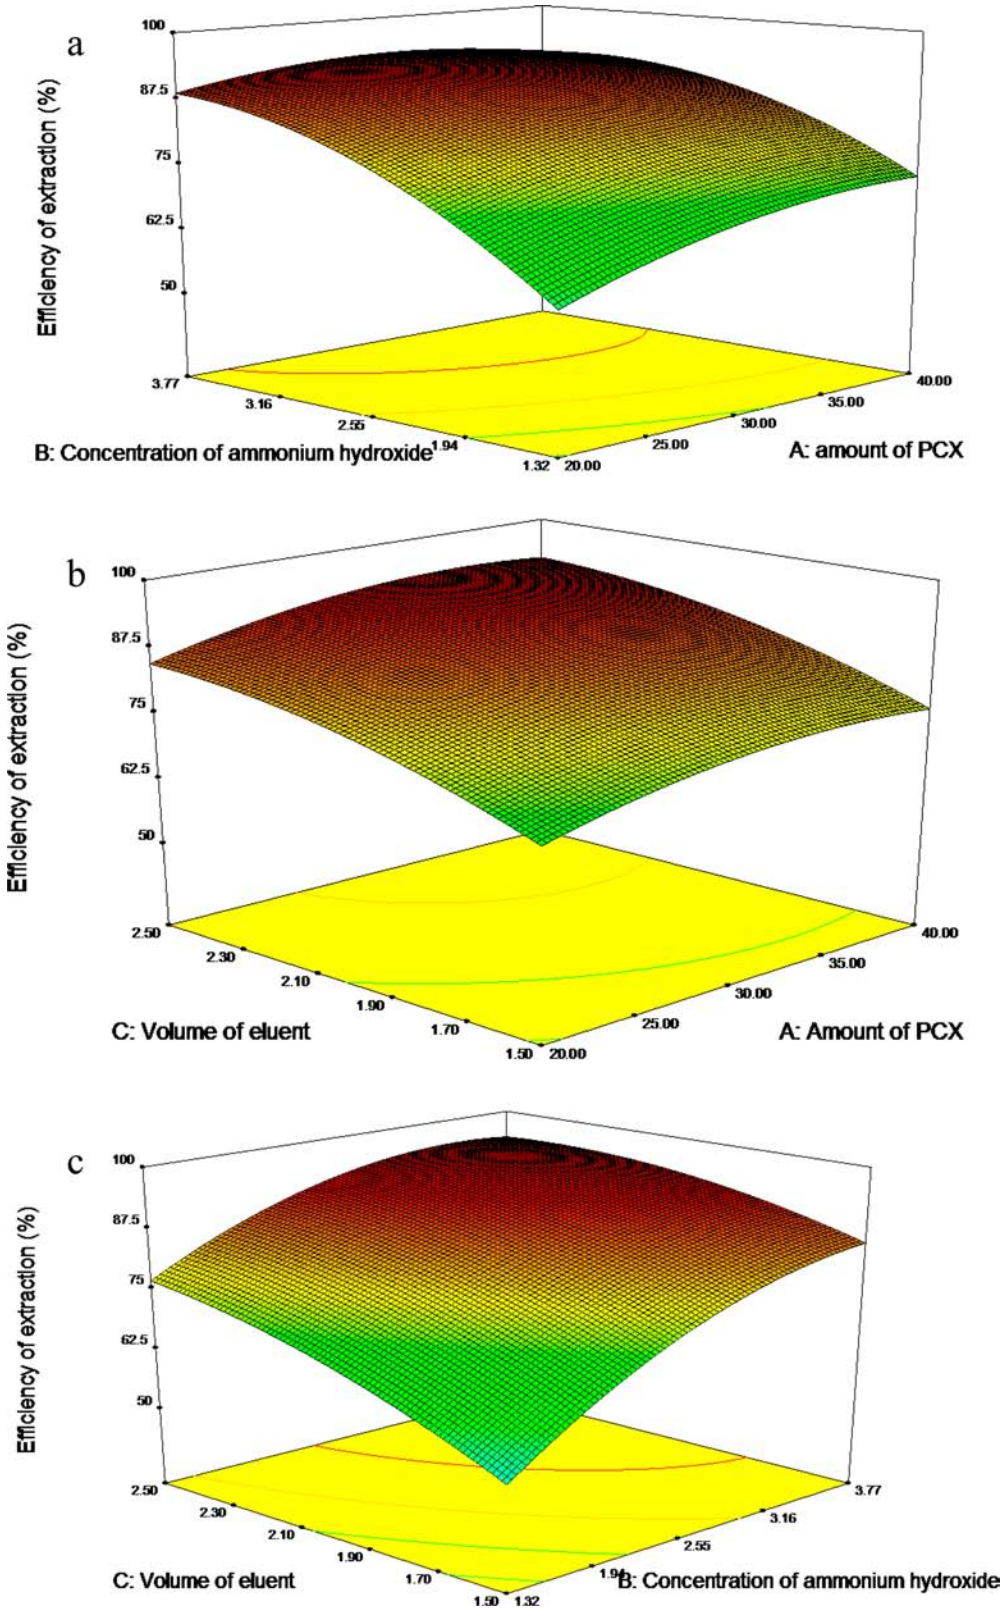

Figure 1. Three-dimensional graphs of the effects of the amount of PCX (A), the concentration of ammonium hydroxide (B) and the volume of elute (C) on efficiency of extraction: (a) fixed C = 2.0 mL, (b) fixed B = 2.55%, and (c) fixed A = 30 mg.

method was accurate enough and suitable for the determination of morpholine in citrus and apple.

Comparison on Matrix Effects. Removing the interference and minimization of the matrix effect in LC−MS is the key to have an accurate, robust, and sensitive quantitative assay.[29] In this study, matrix effects were evaluated by comparing slope ratios of matrix-matched standard calibration slopes with solvent standard calibration slopes (n = 3). It was found that

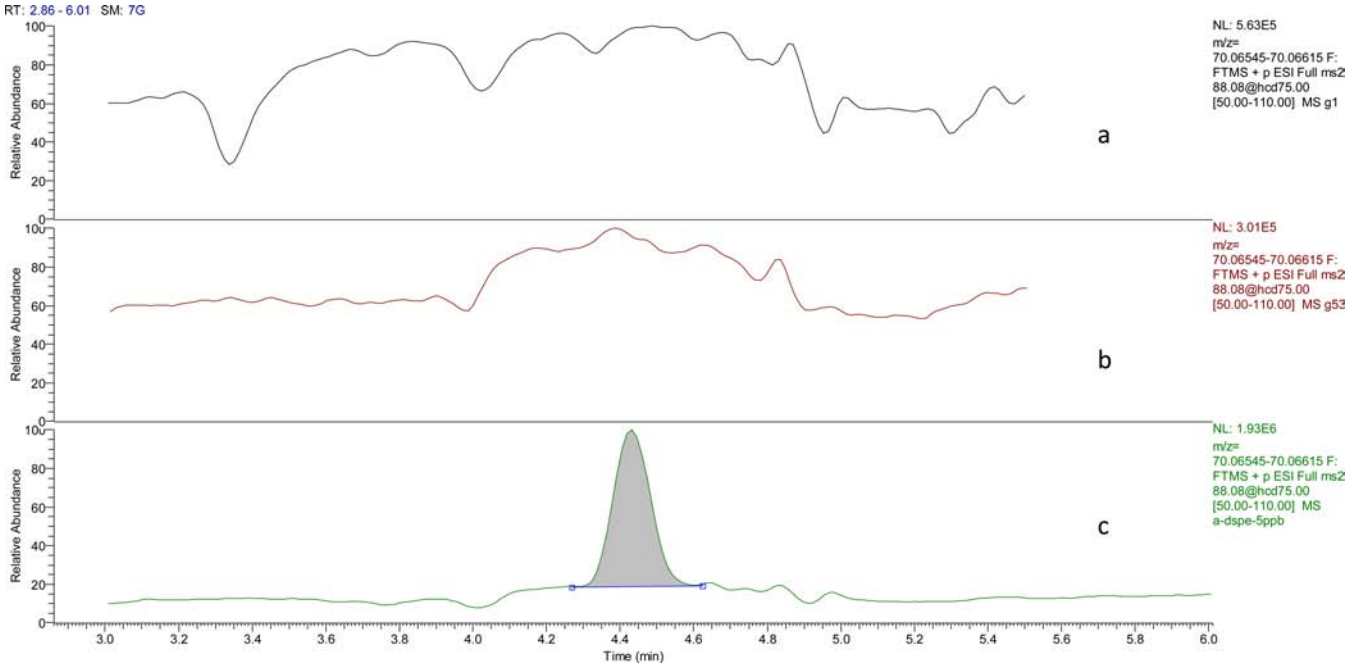

Figure 2. Extracted ion chromatograms for morpholine in the (a) blank citrus, (b) blank apple and (c) standard at 5 μg/L.

Table 4. Precision and Recovery of Morpholine

sample	fortified concentration (μg/kg)	average recovery (%, n = 6)	RSD_r (%)	RSD_R (%)	SSE (n = 3)
citrus	5	78.4	6.4	5.7	0.88 ± 0.03
	20	88.1	3.1	6.6	
	100	96.2	1.8	2.3	
apple	5	85.4	6.9	8.4	0.97 ± 0.02
	20	90.7	2.8	5.7	
	100	102.7	1.9	3.2	

slope ratios from the proposed method for citrus and apple samples were 0.88 ± 0.03 and 0.97 ± 0.02, which were in the range that Frenich et al. had put forward to consider tolerable if the value was between 0.8 and 1.2.[30] It was also observed that there was a slight matrix effect for morpholine in citrus and apple, and the citrus had a stronger matrix effect than the apple. To compensate for the matrix effects and quantify accurately for morpholine in different matrices, concentrations of morpholine in the samples should be calculated by the internal calibration curves.

Stability. The stability tests were performed among spiked samples (5 and 20 μg/kg) at different storage times (after 7, 14, and 21 days), and no obvious change for the recoveries (83.6−95.3%) were observed.

Application to Real Samples. A total of 10 citrus and 8 apples from local markets were analyzed for morpholine using the proposed method. A total of 5 citrus and 3 apples were positive for morpholine residues, with the concentrations of 80.5−598.7 μg/kg for citrus and 43.4−328.2 μg/kg for apples. Sen et al. had reported the contamination levels (0.25−7.7 mg/kg) of morpholine in 17 batches of apples coated with liquid waxes. They indicated that some citrus and apples from the local markets might have been processed with coating wax using morpholine. Further assessments should be conducted to determine whether the presence of contamination levels of morpholine in these samples pose a potential health hazard to humans based on the ADI (0.48 mg kg^{-1} of bw day^{-1}). Moreover, the proposed DMSPE method can be compared to other reported methods for the analysis of morpholine in citrus and apple samples. Table S2 of the Supporting Information compiles the comparison of the analytical features of the selected references. In comparison to the reported methods, fewer matrix effects with similar or better detection levels for the analysis of morpholine were achieved in this study.

In the present study, a new analytical method based on the DMSPE cleanup procedure was developed for the analysis of morpholine residues in citrus and apple samples. The proposed method was validated with fortified samples, and good recoveries were obtained. The LOD and LOQ were low enough to efficiently quantify morpholine in citrus and apple samples. To the best of our knowledge, this paper is the first to introduce application of PCX as a sorbent in DMSPE for sample preparations of alkaline substance and assumed to be widely used for alkaline contaminants at trace levels in the future.

Ultratrace LC-MS/MS Analysis of Segmented Calf Hair for Retrospective Assessment of Time of Clenbuterol Administration in Agriforensics

Wilco F. Duvivier,[†] Teris A. van Beek,[†] Thijs Meijer,[‡] Ruth J. P. Peeters,[†] Maria J. Groot,[‡] Saskia S. Sterk,[‡] and Michel W. F. Nielen*[,†,‡]

ABSTRACT: In agriforensics, time of administration is often debated when illegal drug residues, such as clenbuterol, are found in frequently traded cattle. In this proof-of-concept work, the feasibility of obtaining retrospective timeline information from segmented calf tail hair analyses has been studied. First, an ultraperformance liquid chromatography−tandem mass spectrometry (UPLC-MS/MS) hair analysis method was adapted to accommodate smaller sample sizes and in-house validated. Then, longitudinal 1 cm segments of calf tail hair were analyzed to obtain clenbuterol concentration profiles. The profiles found were in good agreement with calculated, theoretical positions of the clenbuterol residues along the hair. Following assessment of the average growth rate of calf tail hair, time of clenbuterol administration could be retrospectively determined from segmented hair analysis data. The data from the initial animal treatment study (n = 2) suggest that time of treatment can be retrospectively estimated with an error of 3−17 days.

KEYWORDS: *agriforensics, hair, β-agonist, mass spectrometry, liquid chromatography, veterinary control*

INTRODUCTION

Clenbuterol is a β-agonist approved for therapeutic use in some countries. However, it can also be used illegally, as a growth promoter for cattle. It increases the muscle-to-fat ratio and stimulates overall animal growth.[1−3] Clenbuterol-contaminated meat can cause food intoxication with severe consequences such as heart disorders,[4,5] and it has therefore been banned for use as a growth promoter in cattle in the European Union since 1988.[6] Many different methods for the analysis of clenbuterol and other β-agonist residues in different matrices have been published over the years.[1,2,7−24] Among these methods are approaches based on immunoassays,[7] receptor assays,[24] or biosensors,[1,8,9,21] but these methods lack either sensitivity or selectivity. To overcome these problems, gas chromatography−mass spectrometry (MS) and liquid chromatography (LC)−tandem MS (MS/MS) have been used to analyze a large range of β-agonists.[2,10−16,18−20,22,23] One of the difficulties that occurs when residues of a banned substance such as clenbuterol are found in animals, however, is the fact that animals are frequently traded. The owner can thus claim that a previous owner was responsible for the illegal administration of the detected substances. Current analysis methods are not sensitive enough to be used for estimated time of drug administration. To achieve this, human hair forensic techniques may be equally applicable in veterinary control and agriforensics.

Hair is a very interesting sample matrix because many compounds accumulate in hair via the bloodstream. Hair pigmentation can have an influence on the incorporation of compounds such as clenbuterol into the hair. Gleixner et al. found that more clenbuterol was accumulated into black hair compared to hair with less pigmentation; however, clenbuterol was detectable in hair samples regardless of the level of pigmentation.[25] The prolonged detectability of drugs in hair versus blood or urine makes it a powerful option for forensic investigations.[26,27] Because the average hair growth rate of human head hair is known, analysis of longitudinal segments can be applied to achieve a retrospective timeline of drug intake.[28,29] Longitudinal hair analysis enables correlation of, for example, drug-facilitated crime with the time of drug administration.[28] Typically, 1−3 cm longitudinal hair segments are used for drug analysis, corresponding to multiple months of hair growth.[30,31] Over the past 10 years, several attempts have been made to apply segmented hair analysis to animals, but primarily for horses.[32−40] Dunnett et al. published several papers describing segmented analysis of different drugs in horse hair, mainly focused on antibiotic residues. The distributions among tail hairs were consistent with the time of drug administration, although the used segment sizes (2.5−5 cm) were somewhat large compared to human forensic applications.[32−35] Similar approaches on horse hair have been reported by Anielski et al.[36] and Gray et al.[39] for the detection of anabolic steroids and related compounds. Furthermore, segmented hair analysis has also been used to retrospectively determine stress factors in the hair of bears[38] and orangutans.[40] The smallest segment length used in previous animal studies is 2 cm,[32−36,38−40] which does not allow a very accurate estimation of time of drug administration. Until now, segmented hair analysis has not been applied to bovine (calf) hair or to the illegal use of β-agonists such as clenbuterol.

In the current, preliminary, study, hair segments of approximately 10 mm were used to enable a more accurate retrospective timeline assessment, preferably with a margin of error on the order of weeks of hair growth (instead of months), which can be helpful in court cases when the time of illegal drug administration is critical in relation to animal ownership. For reliable retrospective timeline assessment, hair must be sampled following the forensic hair sampling protocol, as recommended by the Society of Hair Testing.[31] Sampling of a pencil-thick lock of hair by cutting as close to the skin as possible, in combination with the smaller segment sizes, results in much smaller amounts of hair, on the order of 25 mg instead of 50−1000 mg of hair, being available for analysis. Therefore, an ultratrace analysis method with a very low limit of detection was needed to be able to detect the very low residue levels in the much smaller samples. Apart from that, the average growth rate of bovine hair needed to be assessed, to convert the results of the segmented hair analysis to a retrospective timeline of drug administration. To this end, the analytical method of Nielen et al.[18] was adapted to achieve ultratrace detection of clenbuterol in segmented hair samples. Locks of bovine tail hair, obtained from a controlled treatment (n = 2) study, have been used to test the feasibility of the method and to obtain profiles of the clenbuterol distribution along locks of calf tail hair.

MATERIALS AND METHODS

Chemicals and Materials. All chemicals used were of (at least) analytical grade. Acetone, acetonitrile, ethyl acetate, and methanol were purchased from Actu-All Chemicals (Oss, The Netherlands). Acetic acid, ammonia, formic acid, hydrochloric acid, sodium acetate, and sodium hydroxide were purchased from Merck (Darmstadt, Germany). Chloroform was purchased from BioSolve (Valkenswaard, The Netherlands). Purified water was from a Milli-Q system (Millipore, Bedford, MA, USA). Clenbuterol hydrochloride was purchased from Sigma-Aldrich (St. Louis, MO, USA), and clenbuterol-d_6 internal standard was custom-synthesized previously at Wageningen University and Research Centre (Wageningen, The Netherlands).

Hair Samples. Blank hair samples were collected from the backs of different calves by shaving and were used for method development only. Incurred hair samples were collected from the tail of two male black-and-white Holstein Friesian calves of around 100 kg in a controlled treatment study performed at Ghent University (Ghent, Belgium). For ethical reasons, only two calves were dosed with clenbuterol, a banned substance, in this initial study. The calves were held in a separate stable, away from other cattle. The tails of the calves consisted of white hair only. During a 12 day acclimatization period, hair from the distal end of the tail of the two calves was sampled to obtain additional blank hair samples. Following the acclimatization period, the calves were treated for 14 days with clenbuterol. This animal study was approved by the Ethical Commission of Ghent University, under approval code EC2012/013, and took place from April until November. The treatment consisted of an oral dose of 1.2 μg clenbuterol (expressed as free base)/kg body weight dissolved in milk, once in the morning and once in the afternoon. Next, tail hair from the calves was sampled approximately once a month, for half a year. The detailed treatment and sampling schedule is shown in Figure 1A. At each sampling occasion, at least three pencil-thick hair samples were collected from the distal end of the tail of the calves, using the forensic hair sampling protocol recommended by the Society of Hair Testing.[31] Repeated sampling of the tail of the calves over the duration of the study caused differences in length of locks sampled on the same day, because some parts of the tail contained only shorter, newly grown, hairs due to previous sampling in that area. The resulting hair samples had a weight of approximately 30 mg/cm. For segmented analysis, hair samples were divided into 1 cm segments, starting from the proximal end.

Assessment of Hair Growth Rate. The average growth rate of calf tail hair was determined both for continued growth of existing hairs (length at start = 4.1 ± 0.5 cm), as well as for newly grown hair. Six female calves (black-and-white Holstein Friesian) were used, 1−3 weeks old (around 50 kg) at the start of the study. Continued hair growth was monitored by measuring the hair length of three locks of clearly marked tail hair during 8 weeks. To determine the average growth rate of newly grown hair, three other locks of tail hair from the same calves were cut as close to the skin as possible at the start of the study. The length of newly grown hair was also monitored during 8 weeks (one data point per week). From these results, average tail hair growth rates were determined per calf, which were then used to calculate the overall growth rate and standard deviation for the six calves. Finally, the average of the data from the first 26 days was used for all calculations regarding the theoretical position of the clenbuterol residues (see Results and Discussion).

Sample Preparation. The sample preparation of the hair samples was adopted from that of Nielen et al.[18] and adjusted to much smaller sample sizes. In short, 25 mg of hair were cut into small pieces (<3 mm), and 5.0 μL of internal standard was added (10 μg clenbuterol-d_6/L). One milliliter of 1.0 M sodium hydroxide was added, and the samples were heated for 2 h in a water bath at 65 °C. After the samples had cooled to room temperature, 1.0 mL of 1.0 M hydrochloric acid and 1.25 mL of 0.25 M sodium acetate buffer (pH 4.8) were added. Next, the samples were centrifuged for 10 min at 2000g, and the supernatant was transferred into a clean test tube. Prior to an additional centrifugation step, the pH of the supernatant was checked and, if necessary, adjusted to 4.8. The resulting supernatant was subjected to mixed-phase solid phase extraction (SPE) cleanup as described.[18] In short, the column was conditioned with 3 mL of methanol and 3 mL of sodium acetate buffer before the sample was introduced. After sequential washings with 1 mL of 1.0 M acetic acid, 6 mL of methanol, and 2 mL of acetone/chloroform (1:1), the retained compounds were eluted using 7.5 mL of 1% ammonia in ethyl acetate. After evaporation to dryness under a N_2 flow at 40 °C, the residue was reconstituted in 100.0 μL of 0.24% formic acid, and a 10.0 μL aliquot was injected in the LC-MS/MS system.

LC-MS/MS Method. The ultrahigh-performance liquid chromatography (UHPLC)-MS/MS analysis was carried out as follows. An Acquity UPLC system (Waters, Milford, MA, USA) was coupled to a Xevo TQ-S MS system (Waters), equipped with an electrospray ion source. The MS was used in positive ionization mode using the following conditions: capillary voltage, 3.0 kV; cone voltage, 20 and 25 V for clenbuterol and clenbuterol-d_6, respectively; source temperature, 150 °C; desolvation temperature, 400 °C; collision energy, 30 and 15 eV for clenbuterol and clenbuterol-d_6, respectively. Clenbuterol and clenbuterol-d_6 were analyzed in multiple reaction monitoring (MRM) mode using the following ion transitions: m/z 277.2 to m/z 132.1, 168.1, and 203.2 for clenbuterol and m/z 283.2 to m/z 204.1 for clenbuterol-d_6, respectively. Separation was achieved by using an Acquity BEH-C18 column (2.1 × 100 mm, 1.7 μm; Waters) at 40 °C and a flow rate of 0.4 mL/min. The mobile phases consisted of 25 mM formic acid in water (mobile phase A) and in acetonitrile (mobile phase B). The used gradient was as follows: isocratic elution for 1 min at 5% B, follwed by a gradient applied to 35% B in 8.5 min and then a steep gradient toward 100% B in 0.3 min. After 2.2 min at this condition, the system was re-equilibrated for 3 min at 5% B. Data analysis was performed using MassLynx V4.1 (Waters). Matrix-matched standards (MMS) were used for clenbuterol quantification in the hair samples. In short, clenbuterol standard was added to blank calf hair in concentrations ranging from 0.5 to 10 μg clenbuterol (expressed as free base)/kg hair. The resulting calibration curve was then used for concentration calculations in the hair samples. Throughout this work, all clenbuterol is expressed as the free-base basis.

Method Validation. The linearity of the MMS calibration curve was determined by analyzing the following clenbuterol concentrations in duplicate: 12.5, 25, 50, 100, and 250 pg per 25 mg of hair. The

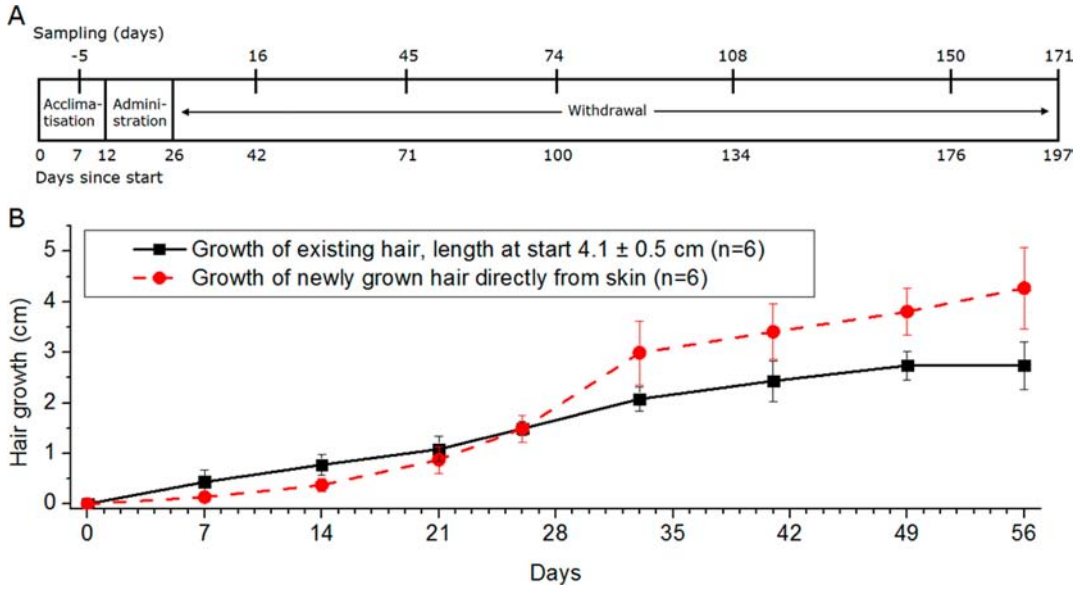

Figure 1. (A) Controlled animal treatment and sampling schedules. (B) Average hair growth rate of calf tail hair, both as continued growth from an existing lock and as new growth (after cutting as close to the skin as possible). Error bars represent intra-animal RSD (n = 6).

recovery was evaluated by spiking three blank hair samples with 50 pg clenbuterol/25 mg of hair. After sample pretreatment, 5.0 μL of internal standard was added just before injection instead of during spiking. Both experiments were executed on three different days. Further validation of the method regarding within-day repeatability, within-laboratory reproducibility, accuracy, decision limit (CCα), and detection capability (CCβ)[41] was performed using blank hair samples spiked at three concentration levels: 25, 50, and 100 pg per 25 mg of hair. A total set of 18 replicates for the 25 and 100 pg/25 mg concentration level and 21 replicates for the 50 pg/25 mg concentration level were analyzed on three different days. In addition, 21 blank hair samples were analyzed with the addition of internal standard only.

Data and Statistical Analysis. The hair growth data presented are mean values with corresponding relative standard deviations (RSD). Student's t test (two-sample assuming unequal variances) was used to assess significance of the difference between hair growth rates (P < 0.01). All validation data were evaluated using ANOVA. The analytical reproducibility of the method (10.6%) is shown as error bars in Figures 2−4.

RESULTS AND DISCUSSION

Ultratrace LC-MS/MS Method Development and Validation. The improved LC-MS/MS method for clenbuterol in hair allowed the analysis of hair samples as small as 25 mg, 2−40 times lower than in previously reported methods.[1,2,10,19,21,22] The within-day repeatability and within-laboratory reproducibility RSD were <9.6 and <10.6%, respectively, at all spike levels. Accuracy was 92−101% with an average recovery of 37%, which was slightly lower than the average recovery (49%) of the method by Nielen et al.[18] The incomplete recovery is possibly caused by incomplete reconstitution in only 100 μL, which volume is significantly lower than the 300 μL used by Nielen et al.[18] However, the lower reconstitution volume was necessary to obtain a final clenbuterol concentration high enough for LC-MS/MS analysis. Moreover, the added internal standard was capable of reproducibly correcting for the incomplete recovery, as shown by the accuracy and reproducibility data given above. Linearity of the MMS calibration curve was adequate in a range from 12.5 to 250 pg/25 mg hair (R^2 > 0.993). The resulting CCα and CCβ were 16.8 and 33.7 pg/25 mg hair, respectively. Compared to the CCβ reported in the previously described method[18] (<2500 pg/500 mg hair), we achieved a tremendous increase in absolute sensitivity, which was essential for the small sample amounts expected in this study. This sensitivity is similar to or better than that previously reported for clenbuterol in hair.[1,2,10,19,21,22]

Average Tail Hair Growth Rate. The average tail hair growth rate for calves has been determined for both continued growth on existing hairs and newly grown hair. For both types of hair, the locations were similar as used for sampling in the controlled treatment study. The length of three locks of tail hair and the length of newly grown hair on three other spots, after cutting as close to the skin as possible, were recorded over a period of 8 weeks. The resulting hair growth curves are shown in Figure 1. During the first 26 days, the growth rate was equal (P < 0.01) for both existing and new hair: 0.57 mm/day (± 0.05 and ± 0.10 mm/day for, respectively, continued and newly grown hair). After the first 26 days, the growth rate of existing hair plateaued, resulting in an average growth rate over 56 days of 0.49 ± 0.08 mm/day. During the 49 and 56 day time points, some of the locks became shorter or stayed the same length, indicating that the decreasing average growth rate was most likely caused by the breaking off of brittle tips of longer hairs. The latter hypothesis has been confirmed by dyeing tips of long tail hairs. After 2 weeks, the dyed part of the hair became shorter and new hair was formed at the proximal end of the hair, indicating that hair continued to grow, even though the total length did not increase. Hair zones containing drug residues will keep growing toward the distal end of the hair. The implications of breaking off brittle tips on the final retrospective timeline assessment should be investigated in more detail in future studies. The average growth rate at 26 days, 0.57 ± 0.08 mm/day, has been selected for further calculations, because both types of tail hair showed similar growth at this time point and later data points already showed plateauing of the hair growth rate for existing hairs (Figure 1). Few reference data on the hair growth rate of calves are available; the only data published report 0.20−0.23 mm/

day[42,43] but, unfortunately, these references do not provide experimental details, so it is unknown whether these reference data also relate to tail hair.

Segmented Hair Analysis for Retrospective Timeline Assessment of Clenbuterol Administration. The sampled locks of calf tail hair were analyzed after cutting into 1 cm segments. In view of the average hair growth rate as described above, each segment corresponded to approximately 17.5 days of hair growth. The resulting clenbuterol concentration profiles along the hair locks, prior to and up to 108 days after clenbuterol administration, are shown in Figure 2. Samples

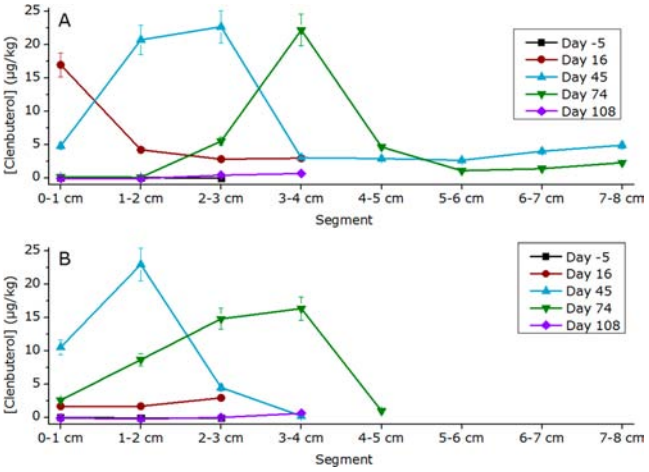

Figure 2. Clenbuterol concentration profiles versus hair segments from calf tail hair samples, taken at different time points (days before or after the end of the clenbuterol administration period of 14 days), of two different calves (A and B). Error bars represent the analytical reproducibility of the method (10.6%).

taken 108, 150, and 171 days after the end of the clenbuterol administration period did not contain clenbuterol in any hair segment. No clenbuterol was detected in the samples taken 5 days prior to clenbuterol administration (Figure 2), indicating that the calves did not come into contact with clenbuterol prior to the controlled administration and verifying once again that blank hair yields negative results. For the first calf (Figure 2A), peak clenbuterol concentrations were found in the 0−1 cm hair segment of the day 16 sample, in the 1−2 and 2−3 cm segments of the day 45 samples, and in the 3−4 cm segment of the day 74 samples. The longitudinal hair profiles from the samples obtained from the second calf (Figure 2B) showed peak clenbuterol concentrations in the 1−2 cm hair segment of the day 45 samples and in the 2−3 and 3−4 cm segments of the day 74 samples.

To establish the theoretical position of the clenbuterol residues in the hair lock samples, several issues have to be taken into account. First, clenbuterol was administered for 14 days (Figure 1A), theoretically resulting in incorporation into a longitudinal section of the hair of approximately 0.80 ± 0.11 cm, provided clenbuterol had been exclusively incorporated into hair via the hair root. The section in which clenbuterol was incorporated was, most likely, even larger because clenbuterol in cattle has a half-life time of 19 h during the distribution phase (first 3 days after administration) followed by a half-life time of 57 h during the elimination phase.[44] The majority (>95%) of the administered clenbuterol would have been metabolized or excreted from the body after 4 days. The additional days of unaltered clenbuterol in the blood circulation caused additional incorporation days in calf hair via the root. The prolonged presence of clenbuterol in the blood after withdrawal can add an extra 0.24 ± 0.03 cm to the length of the hair section containing clenbuterol. Furthermore, newly grown hair sections can be sampled only after clenbuterol reaches the skin surface. The skin thickness of calves is approximately 2.8 mm[42] and should be taken into account for the calculation of the theoretical position of the clenbuterol containing hair section. The theoretical positions of clenbuterol residues calculated using the average hair growth rate of 0.57 ± 0.08 mm/day and corrected for both the elimination time from the blood and the skin thickness are given in Table 1. The experimental data of hair segments containing clenbuterol peak concentrations were in good correlation with the calculated theoretical positions (Table 1). The theoretical position of the clenbuterol residues 108 days after administration would be around 5.5 cm, whereas the hair samples that could be taken at that time were of a maximum length of 4 cm. Thus, these 4 cm represent post-treatment hair only, in which clenbuterol could not have been incorporated. Besides the peak levels in the clenbuterol profiles along the hair segments, some segments showed some low residue levels of clenbuterol (e.g., day 16, 1−4 cm; day 45, 3−8 cm in Figure 2A). This is possibly caused by external contamination of hair via licking upon drinking the clenbuterol-containing milk[45] or by endogenous self-contamination via sweat, as described for human forensic practice by Henderson et al.[46] Another explanation for the low clenbuterol residue levels in segments not containing peak concentrations is

Table 1. Theoretical Position of Clenbuterol Residues in Calf Tail Hair, Calculated Using an Average Hair Growth Rate of 0.57 ± 0.08 mm/day, Experimental Position from Segmented Tail Hair Analysis, and Retrospective Assessment of the Time of Drug Administration

actual sample collection time after treatment	theor position of hair section containing clenbuterol residues (cm)	exptl position of clenbuterol peak concn in segmented tail hair samples (cm)	exptl retrospective time of clenbuterol admin (mean days ago and range)
day 16	0.28 ± 0.1 to 1.3 ± 0.2	0−1	13.5 4.8 ± 0.6 to 22.3 ± 3.0

axial diffusion of compounds along the hair, as described by Kintz et al.[47] However, both external contamination and axial diffusion will not interfere with the retrospective assessment of treatment time because in this preliminary trial only the position of the peak values in the clenbuterol concentration profiles along the hair segments was used. The peak values were much higher and could be easily distinguished from the slightly elevated levels caused by external contamination or axial diffusion. An initial attempt to remove external contamination by washing the hair segments with methanol prior to sample preparation did not reduce the detected traces of clenbuterol, in agreement with the findings of Hernández-Carrasquilla et al., who showed that methanol decontamination is insufficient to remove external β-agonist contamination from hair.[48] Because clenbuterol is a non-natural synthetic compound, residues in hair always indicate illegal use. Furthermore, the residue concentration following external contamination will be much lower compared to the peak concentration[45] and therefore not influence the assignment of the position of the clenbuterol peak along the hair.

In agriforensic practice, the time of drug administration will be unknown, and the segment of the hair in which the clenbuterol peak is detected must be converted to a timeline using an average hair growth rate. The skin thickness has been added to the start and end points of the segments, and the hair lengths have been converted to days of hair growth. The resulting retrospective estimations of time of clenbuterol treatment are included in Table 1. On the basis of this initial animal trial (n = 2), the retrospective estimations from segmented hair analysis were in good agreement with the actual period of clenbuterol administration. The accuracy of the retrospective estimation of the time of clenbuterol administration was 18 days when the clenbuterol peak concentration was detected in only one of the 1 cm long hair segments and approximately 35 days when detected equally in two subsequent hair segments (see, for example, the day 45 and 74 samples in panels A and B, respectively, of Figure 2). The experimental mean values for the retrospective time assessment show an error of only 3−17 days when compared to the actual time of clenbuterol administration (Table 1). It should be stressed that these results were obtained in a preliminary treatment (n = 2) study. Nevertheless, the results suggest that segmented hair analysis can be successfully used in agriforensics to obtain a retrospective estimation of the time of clenbuterol administration to calves.

Reproducibility of Longitudinal Clenbuterol Profiles. To test the reproducibility of the profiles, subsamples taken from the same lock of hair and duplicate locks of hair, sampled at the same time, were analyzed. A lock of tail hair sampled 45 days after the end of the clenbuterol administration period was divided into two subsamples, and 1 cm segments of these subsamples were analyzed. The conclusion with respect to the segments having the highest clenbuterol levels are comparable (Figure 3): both profiles show peak concentrations in the 1−2 cm segment, but for the second subsample, the peak clenbuterol concentration extended into the 2−3 cm segment. This may have been caused by uneven cutting of the hair due to bundling of the hair lock, which can result in slightly different sampling distances relative to the skin within a sampled lock. This phenomenon has been described in more detail by LeBeau et al.[49] and may result in two nonidentical subsamples after splitting of a lock of hair.

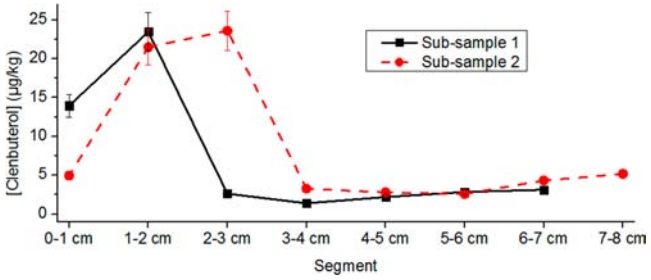

Figure 3. Clenbuterol concentration profiles versus hair segments from calf tail hair. Subsamples were obtained from a lock of hair sampled 45 days after the end of the clenbuterol administration period. Error bars represent the analytical reproducibility of the method (10.6%).

Figure 4 shows the concentration profiles of duplicate locks of hair, sampled at the same day. The duplicate samples, taken 45 days after administration (Figure 4A), show high clenbuterol

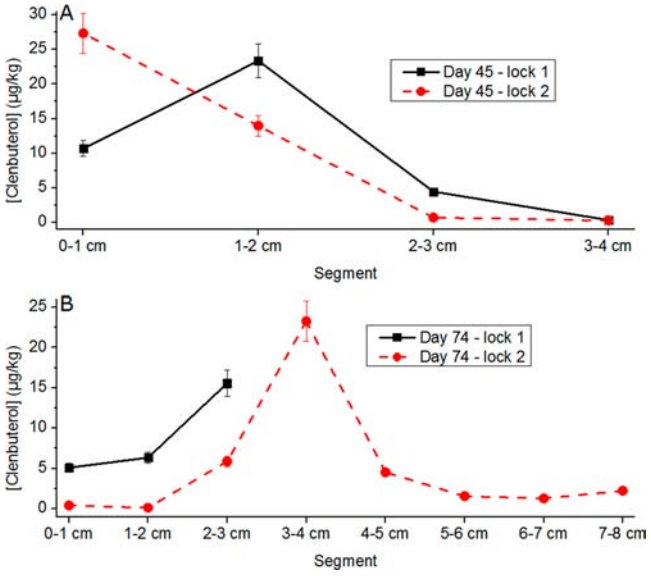

Figure 4. Clenbuterol concentration profiles versus hair segments from duplicate locks of calf tail hair, sampled (A) 45 and (B) 74 days after clenbuterol administration. Error bars represent the analytical reproducibility of the method (10.6%).

concentrations in the first two segments and lower in the distal segments, which is consistent with the calculated position of the clenbuterol residues (Table 1). For the analyzed duplicate samples collected 74 days after administration, a lock of 3 cm and a lock of 10 cm were analyzed (see Figure 4B). [Note: the difference in length of these locks is most likely caused by the repeated sampling of the tail of the calves. Some parts of the tail contained only shorter newly grown hairs, because those areas had been sampled before, whereas other parts still contained longer hairs on areas that had not been sampled before (see Materials and Methods).] An increase in clenbuterol concentration has been noted toward the 3−4 cm segment in both duplicate locks, and even though the length of the locks was not equal, the found trend is similar. A factor to be taken into account is the intra-animal variability: human hair forensics shows that the variation in residue concentrations between locks of hair from one person ranges from 14 to 62%. This can cause differences between and within locks of hair as also

DOI: 10.1021/jf5056437
J. Agric. Food Chem. 2015, 63, 493−499

observed in the present study (Figures 3 and 4). Note that the analytical variability of each data point is much lower (10.6%) according to the validation study. The position of the clenbuterol peak concentration, however, will not change by variation in the absolute concentration. In this respect, both samples showed comparable results: it can be stated that segmented hair analysis is reproducible in the assignment of the relevant segment position and, therefore, can result in a similar retrospective estimation of time of drug administration. It should be stressed, however, that inaccurate hair sampling can cause differences, even within a single lock of hair.[49] To reach the highest certainty about time of drug administration, multiple locks of hair should be sampled by cutting as close as possible to the skin and as straight as possible, in accordance with recommendations.[31]

FUTURE PERSPECTIVES

The LC-MS/MS method developed showed a CCβ value of 33.7 pg for as little as 25 mg of hair, which represents a major improvement compared to the previously described method (CCβ < 2500 pg for 500 mg of hair).[18] The resulting clenbuterol concentration profiles along the hair segments nicely shows the feasibility of retrospective estimation of the time of drug administration, with a mean error of 3−17 days, depending on the shape of the concentration profile of clenbuterol residues along the segments. To get a more precise retrospective estimation of the time of treatment, more reference profiles from different calves after controlled treatment should be analyzed and combined with more in-depth and longer lasting research toward differences in hair growth rates. In a follow-up study, both male and female calves and calves with different tail hair pigmentation should be included to gain more insight in the interanimal variation. Because many compounds accumulate in the hair of cattle, this method should be applicable to other banned substances as well, especially to other β-agonists. Extension of the scope can provide the agriforensics community with a powerful tool to estimate the time of illegal β-agonist administration. In many cases, an error on the order of a few weeks will be sufficient to support court cases in which (timelines of) illegal treatments are being challenged. Possibly, the retrospective timeline assessment could be improved further with trace analysis of even smaller segments. The latter may require entirely new analysis approaches such as longitudinal mass spectrometry imaging of intact hairs.[50]

Supporting Information

ABSTRACT: The *cis*−*trans* isomerism is a common phenomenon for acylated anthocyanins. Nevertheless, few studies reported effective methods for the preparation of isomeric anthocyanins from natural products. In this work, a high-performance liquid chromatography (HPLC) method was developed to efficiently purify anthocyanin isomers from *Lycium ruthenicum* Murr. based on a mixed-mode reversed-phase/strong anion-exchange column (named XCharge C8SAX). Four commercially available columns were evaluated with a pair of isomeric anthocyanins, and the results demonstrated that the XCharge C8SAX column exhibited improved selectivity and column efficiency for the isomers. The chromatographic parameters, including pH, organic content, and ionic strength, were investigated. Optimal separation quality for the anthocyanin isomers was achieved on the XCharge C8SAX column. Six pure anthocyanins, including two pairs of *cis*−*trans* isomeric anthocyanins with one new anthocyanin, were purified from *L. ruthenicum* and identified. All of the results indicated that this method is an effective way to separate anthocyanins, especially for *cis*−*trans* isomers.

KEYWORDS: *anthocyanins, cis*−*trans anthocyanin isomer, Lycium ruthenicum Murr., mixed-mode stationary phase, HPLC*

INTRODUCTION

Anthocyanins, a group of phenolic compounds, confer the characteristic colors to most fruits and vegetables. Increased evidence have proven their possible heath benefits in preventing chronic and degradative diseases, including heart disease and cancer.[1] At present, although more than 600 naturally occurring anthocyanins have been characterized, only a limited number of pure anthocyanin standards are commercially available with a steep price. Most bioassays on anthocyanins have to be conducted with crude anthocyanin extracts, likely resulting in the ambiguous explanation of the bioactivity of anthocyanins.[2] Therefore, preparation of pure anthocyanins is demanded for their bioactivity investigation.

Lycium ruthenicum Murr. is a kind of widespread nutritional food in the salinized desert of the Qinghai−Tibet Plateau. It is also a famous traditional herb recorded in the Tibetan medical classic "Jing Zhu Ben Cao". *L. ruthenicum* has been applied to treat many diseases, such as heart disease, abnormal menstruation, and menopause. Besides, the pigments of *L. ruthenicum* are demonstrated to possess good antioxidant activity,[3,4] and thus, anthocyanins in this plant have aroused great interest to many researchers. Recently, Zheng et al.[5] characterized anthocyanins in *L. ruthenicum* by high-performance liquid chromatography (HPLC) with electrospray ionization−mass spectrometry (ESI−MS), suggesting that most of them are acylated anthocyanins. Chen et al.[6] had identified and quantified seven main anthocyanins in *L. ruthenicum*. The results showed that the anthocyanins were mainly acylated with coumaric acid in both *cis* and *trans* configurations. Nevertheless, few anthocyanins in this plant have been isolated and identified by nuclear magnetic resonance (NMR). Information on their chemical structures is still incomplete. The purification of anthocyanins with enough purity and amount for structural elucidation is of great importance.

Column chromatography (CC) has been used extensively in the separation of anthocyanins from natural products.[7−10] Different columns are able to offer different separation selectivities for anthocyanins, which provide significant contribution to the preparation of anthocyanins.[11] Unfortunately, this technique will suffer from laboriousness and low efficiency, owing to consecutive column separation. Poor reproducibility is another drawback that hampers the application of CC in the purification. Alternatively, HPLC, one of the most effective

techniques to isolate compounds from complex samples, provides many advantages over other techniques, such as high efficiency and good repeatability. It appears to be a practical method for anthocyanin preparation.[12,13] Nonetheless, owing to limited separation selectivity, this technique has to be used in combination with CC and taken as a final purification to yield pure anthocyanins.[8,11] Preparation of anthocyanins, especially for *cis*−*trans* isomers, by HPLC remains to be further improved.

Structurally, anthocyanins are heterosides of an aglycone unit (anthocyandin) with the aromatic carboxylates, such as *p*-coumaric acid, coffeic acid, etc., bonded to the sugar in the molecule. Therefore, the acylated unit of anthocyanin easily generates *cis*−*trans* isomers (Figure 1). These stereoisomers

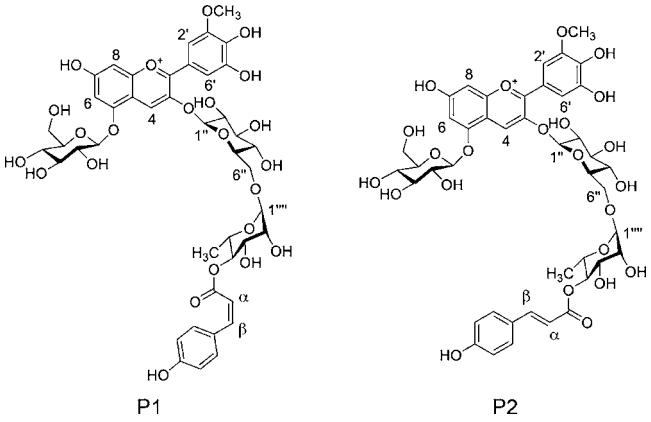

Figure 1. Structures of the *cis*−*trans* anthocyanin isomers from *L. ruthenicum*.

increase the difficulty in the isolation of anthocyanins from plants. The usual method for separating anthocyanins is almost exclusively performed on conventional C_{18} columns with aqueous acid/acetonitrile (ACN) as mobile phases.[14−16] This classic method shows good repeatability and efficiency for anthocyanin separation, but it has some limitations for isolating anthocyanin isomers. Multiple *p*-coumaric peaks for a given aglycone, attributed to the isomers, would occur, complicating the isolation and identification of anthocyanins.[17] In addition, the nearly co-eluted peaks are observed for some *cis*−*trans* anthocyanin isomers on reversed-phase (RP) columns, leading to difficulty in collecting compounds with good purity. Lately, Willemse et al.[18] have used hydrophilic interaction chromatography (HILIC) to separate anthocyanins for the first time. Co-elution of *cis*−*trans* acylated isomers, lower chromatographic efficiency, and higher organic solvent consumption restricted its application in the isomer purification. It is desirable to establish a HPLC method to achieve efficient preparation of isomeric anthocyanins.

The mixed-mode columns are capable of bringing interesting selectivity to separate complex mixtures and offer several advantages over conventional RP.[19−21] In recent years, Mccallum et al.[22] obtained improved separation of anthocyanins in grapes using a mixed-mode RP/anion-exchange column. Superior separation performance for acylated anthocanins was observed. Subsequently, Vergara et al.[23] published that different selectivities of the mixed-mode stationary phase were achieved in the separation of some wine anthocyanins probably based on the complex mechanisms of reverse chromatography and ion-exclusion chromatography. In the present work, we aimed to develop an efficient HPLC method to prepare *cis*−*trans* isomeric anthocyanins using a RP/strong anion-exchange column as well as to explore the effect of properties of stationary phases on selectivity toward the isomers. The potential of this approach will be demonstrated by the purification of anthocyanin isomers from *L. ruthenicum*.

MATERIALS AND METHODS

Plant Material. The fruits of *L. ruthenicum* were randomly sampled from Dulan (latitude, 36° 26′ N; longitude, 96° 31′ E; altitude, 2774 m). The fruits were ripe, hand-picked, and then preserved in 4 °C for subsequent experiments.

Apparatus and Reagents. Purification Factory is a preparative liquid chromatography (LC) system, which consists of two 2525 binary gradient modules (Waters, Milford, MA), an autosampler (Leap Technologies, Carrboro, NC), a 2498 ultraviolet (UV) detector (Waters), and MassLynx software (Waters, version 4.1).

Chromatographic separation and analysis were performed on an Alliance HPLC system consisting of a Waters 2695 HPLC pump and a 2489 UV−vis detector. Data acquisition and processing were conducted by Waters Empower software (Milford, MA).

Identification of pure compounds was carried out using mass spectrometry (MS) and NMR. MS was performed on a Q-TOF Premier (Waters MS Technologies, Manchester, U.K.). ^{1}H NMR and nuclear Overhauser effect spectrometry (NOESY) were measured on a Bruker DRX-400 spectrometer (^{1}H NMR at 600 MHz), with MeOH-d_4/TFA-*d* (95:5, v/v) as the solvent.

ACN was purchased from Merck of HPLC grade (Darmstadt, Germany) and from Yuwang Chemical Reagent Factory of industrial grade (Shandong, China). Methanol was purchased from Yuwang Chemical Reagent Factory of HPLC grade. Trifluoroacetic acid (TFA) and formic acid (FA) were purchased from J&K Chemical of HPLC grade (Hebei, China). Sodium biphosphate (NaH_2PO_4) was purchased from Sinopharm (Shanghai, China). Phosphoric acid was purchased from Tedia of HPLC grade (Fairfield, OH). Water for the HPLC mobile phase was reverse osmosis Milli-Q water (18.2 MΩ, Millipore, Billerica, MA). The references petunidin 3-*O*-[6-*O*-(4-*O*-(*cis*-*p*-coumaroyl)-*α*-L-rhamnopyranosyl)-*β*-D-glucopyranoside]-5-*O*-[*β*-D-glucopyranoside] (P1) and petunidin 3-*O*-[6-*O*-(4-*O*-(*trans*-*p*-coumaroyl)-*α*-L-rhamnopyranosyl)-*β*-D-glucopyranoside]-5-*O*-[*β*-D-glucopyranoside] (P2) were isolated in our laboratory. Their structures were characterized by MS and NMR. The structures of these two anthocyanins were displayed in Figure 1.

The columns used in this work are listed as follows: XTerra MS C_{18} (4.6 × 150 mm, 5 μm, Waters, Milford, MA), XUnion C_{18} (4.6 × 150 mm, 5 μm Acchrom, Beijing, China), XUnion C_8 (4.6 × 150 mm, 5 μm Acchrom, Beijing, China), and XCharge C8SAX (4.6 × 150 mm, 5 μm Acchrom, Beijing, China). The representative surface chemistry of the XCharge C8SAX stationary phase is shown in Figure 2. The detailed properties of the four columns are listed in Table 1.

Phosphate buffers were prepared using NaH_2PO_4 and adjusted to desired pH with H_3PO_4 solution at corresponding concentrations before the addition of organic solvent (pH values). The buffers were filtered through 0.22 μm membranes before use.

Table 1. Physicochemical Properties of the Columns

column	ligand	specific surface area (m^2/g)	average pore size	total carbon (%)	column efficiency
XTerra MS C_{18}	C_{18}	175	125	15.5% C load	74000
XUnion C_{18}	C_{18}	320	100	20.3% C load	73000
XUnion C_8	C_8	320	100	12.4% C load	80000
XCharge C8SAX	C_8	320	100	9.57% C load	75000

The dead time (t_o) of the columns was measured by uracil. The column efficiency of all of the columns used in this work was determined by naphthalene with a similar retention factor (k). All results are the average of triplicate determinations. The resolution (R) and selectivity (α) were used for the evaluation of separation quality. These data could be calculated from the system suitability software of the ChemStation.

Chromatographic Conditions. HPLC experiments were performed at the flow rate of 1.0 mL/min. The column temperature was maintained at 30 °C throughout using a thermostat. Detection was carried out at 520 nm, unless otherwise specified.

For column selection, the mobile phase was composed of NaH_2PO_4 (10 mM, pH 1.5) and ACN (85:15, v/v).

The preparation of fractions 6, 8, and 9 was conducted on an XCharge C8SAX column (4.6 × 150 mm, 5 μm). The mobile phase A was 0.2% TFA (v/v) in water, and the mobile phase B was 0.2% TFA (v/v) in ACN. Different isocratic elution conditions were adopted to separate three fractions. Isocratic elution for fraction 6 was 12% B; isocratic elution for fraction 8 was 14% B; and isocratic elution for fraction 9 was 15% B.

HPLC analysis of pure compounds was performed on an XTerra MS C_{18} column (4.6 × 150 mm, 5 μm). The mobile phase A was 0.2% TFA (v/v) in water, and the mobile phase B was 0.2% TFA (v/v) in methanol. Gradient elution steps were as follows: 0−30 min, 15−50% B; 30−40 min, 90% B.

Extraction of Anthocyanins. The fruit of *L. ruthenicum* Murr. was extracted triply with 20-fold of 70% ethanol for 2 h at pH 2.5 (adjusted with hydrochloric acid). Subsequently, three filtrates were combined and concentrated by rotary evaporation at 50 °C in vacuum. Then, the aqueous extract was prepared on the AB-8 macroporous resin (50 × 520 mm, Chemical Plant of NanKai University, Tianjing, China). The strong polar constituents were removed with aqueous acid (0.5% FA, v/v). Then, the target constituent was eluted with 70% ethanol. It was concentrated by rotary evaporation at 50 °C in vacuum and, finally, lyophilized.

Sample Preparation. The anthocyanin sample obtained from extraction described above was dissolved in aqueous acid and subjected to a SCX solid-phase extraction (SPE) cartridge (40 mL, 20 g of sorbent, Acchrom), preconditioned successively with MeOH and distilled water (0.5% FA). Non-anthocyanin compositions were collected with 3 vol of 5% ACN (0.5% FA). Subsequently, anthocyanins were eluted with 3 vol of 30% ACN (1 M NaH_2PO_4 at pH 2.0). Anthocyanin solution was dried by rotary evaporation at 50 °C in vacuum to remove organic solvent as much as possible and then loaded on the AB-8 macroporous resin. Phosphate was washed out by distilled water (0.5% FA). Anthocyanins were eluted with 70% ethanol. They were concentrated by rotary evaporation at 50 °C in vacuum. Fractionation of anthochanin constitutions was carried out on an XTerra MS C_{18} column (50 × 150 mm, 5 μm, Waters, Milford, MA) using methanol/water (0.2% TFA) as mobile phases, and in total, 14 fractions were collected according to UV absorption intensity (shown in the Supporting Information). Fractions 6, 8, and 9 were selected in this work to conduct further separation. A total of 100 mg of each fraction (fractions 6, 8, and 9) was dissolved in 2.5 mL of acid water and filtered through 0.22 μm pore size membranes to obtain an anthocyanin sample with a concentration at about 40 mg/mL.

RESULTS AND DISCUSSION

Column Selection. Column selection is one of the first principal factors for better separation in LC. In this work, four commercially available columns with different solid phases but the same particle size, diameter, and column length were tested to separate a pair of *cis*−*trans* anthocyanin isomers. The chromatograms for four different columns are shown in Figure 3. The selectivity (a), resolution (R), and column efficiency (N) values for the tested anthocyanins on each column are listed in Table 2.

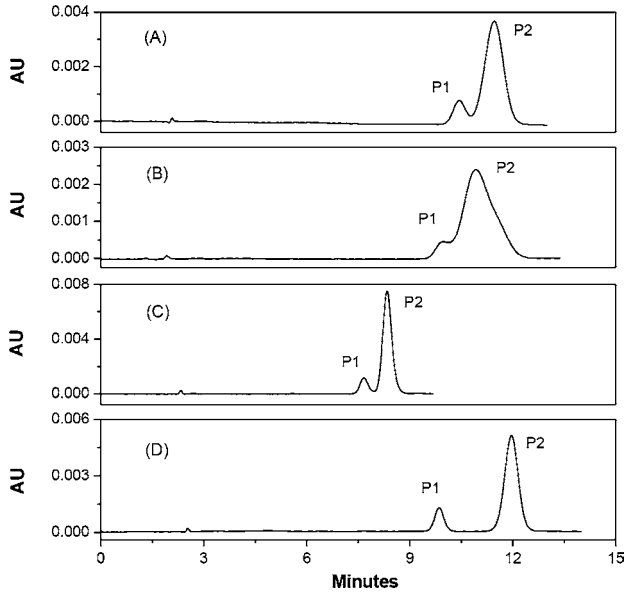

Figure 3. HPLC chromatograms of the anthocyanin isomers on (A) XTerra MS C_{18} (4.6 × 150 mm, 5 μm), (B) XUnion C_{18} (4.6 × 150 mm, 5 μm), (C) XUnion C_8 (4.6 × 150 mm, 5 μm), and (D) XCharge C8SAX (4.6 × 150 mm, 5 μm). Isocratic elution with NaH_2PO_4 (10 mM, pH 1.5) and ACN (85:15, v/v), with a flow rate of 1 mL/min, temperature of 30 °C, and wavelength of 520 nm.

Table 2. Column Parameters for the Separation of Isomeric Anthocyanins on the Four Columns

column	a	R	N
XTerra MS C_{18}	1.12	1.18	25000
XUnion C_{18}	1.12	*a*	*a*
XUnion C_8	1.11	1.43	30000
XCharge C8SAX	1.26	3.36	40000

[a]Could not be determined.

The XTerra MS C_{18} column, a hybrid-based C_{18} column, was chosen to separate the anthocyanin isomers for its good hydrophobic selectivity and excellent stability under high acidic conditions. The isomers were properly retained (P1 in Figure 1) with acceptable resolution for analytical purposes (R = 1.18; Table 2). Nonetheless, this analytical resolution seems inadequate for preparative application, because overlapping of the anthocyanin isomers might occur. It is necessary to separate them with satisfactory resolution. Selectivity has the greatest impact upon changing resolution, as compared to efficiency and retention (k). As a result, a column with better separation selectivity toward *cis*−*trans* anthocyanin isomers would be the

Other conditions are the same as those in Figure 3.

optimal choice for their preparation. It appeared interesting that properties of stationary phases would influence the selectivity to the isomers.

For RP columns, the hydrophobic interaction was regarded as the most important contribution to retention. Its effect on the selectivity to the anthocyanin isomers was investigated. XUnion C_{18} and XUnion C_8, two conventional RP columns with alkyl C_{18} and C_8 ligands, respectively, were investigated for separation of

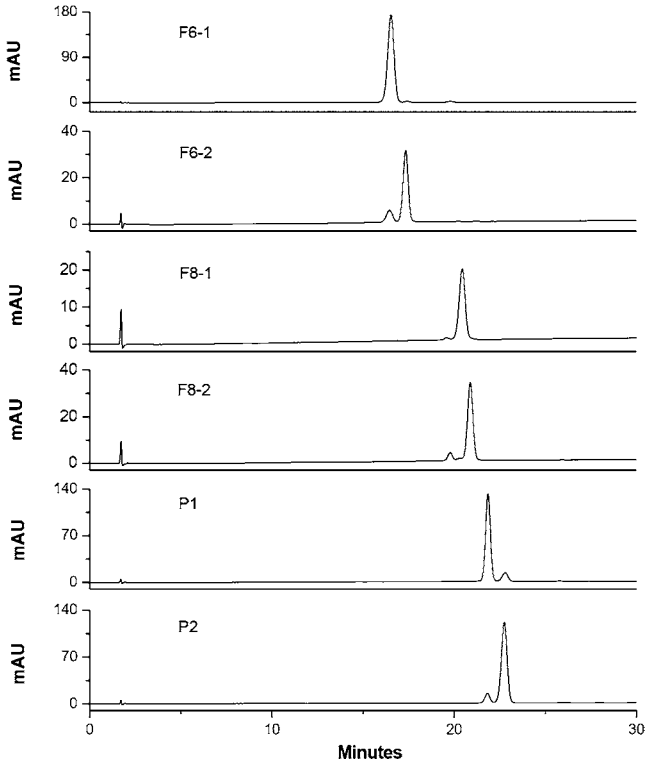

Figure 9. Purity evaluation of the isolated compounds on the XTerra MS C_{18} column (4.6 × 150 mm, 5 μm). F6-1 and F6-2 were isolated from fraction 6; F8-1 and F8-2 were isolated from the fraction 8; and P1 and P2 were isolated from fraction 9. Conditions: mobile phase A, 0.2% TFA aqueous solution; mobile phase B, 0.2% TFA in MeOH; gradient, from 15 to 50% B in 0−30 min. Other conditions are the same as those in Figure 3.

the anthocyanin isomers (panels B and C of Figure 3 for XUnion C_{18} and XUnion C_8, respectively). The results showed that the anthocyanins eluted earlier on XUnion C_8, indicating that the isomers experienced weaker hydrophobic interaction on XUnion C_8. However, selectivity values were similar on these two columns (a = 1.12 and 1.11 for XUnion C_{18} and XUnion C_8, respectively; Table 2). These data revealed that the contribution of the hydrophobic interaction to the selectivity for the *cis*−*trans* isomeric anthocyanins was quite limited. The XTerra MS C_{18} column, despite different bonding techniques, also had a similar selectivity value as either XUnion C_{18} or XUnion C_8. This phenomenon further confirmed the above deduction. The *cis*−*trans* isomerism is a form of stereoisomerism. Both of the isomers have exactly the same atoms joined up in exactly the same order. This means that their hydrophobicity might be analogical, and thus, conventional RP columns, which provided a single type of solute−sorbent hydrophobic interaction, would suffer from limited selectivity for the *cis*−*trans* anthocyanin isomers.

In addition, it was interesting to note that the XUnion C_8 column displayed much better resolution than XUnion C_{18}, as shown in Table 2. This could be primarily ascribed to the higher separation efficiency for the isomeric anthocyanins on XUnion C_8 than that on XUnion C_{18} (Table 2). It was reasonable to infer that stationary phases with C_8 alkyl ligands were more suitable for separation of the anthocyanin isomers.

In a highly acidic mobile phase, anthocyanins mainly exist in the falvylium cation form with a positive charge.[24,25] The *cis*−*trans* isomers of anthocyanin have a different spatial arrangement, probably resulting in a certain difference in electrostatic

interaction. Hence, the mixed-mode RP/ion-exchange stationary phase might be useful to provide improved selectivity. On the basis of the polar-copolymerized approach, the XCharge C8SAX column has both alkyl C_8 chains and quaternary ammonium groups on the silica surface, providing a hydrophobic interaction along with strong anion-exchange ability. As shown in Figure 3D, the anthocyanin isomers were completely separated on this mixed-mode column. Furthermore, XCharge C8SAX had better selectivity than the three other RP columns. It is possible that the presence of positively charged groups in the XCharge C8SAX column resulted in different extents of ionic repulsion with the isomeric anthocyanins and then provided a significant contribution to the improved selectivity. Accordingly, the resolution of the isomers on this mixed-mode column was superior to that on RP columns (Table 2).

Moreover, it is worth mentioning that, in previous papers, the mixed-mode column performed lower column efficiency and relatively longer analysis time for separation of anthocyanins in comparison to RP columns.[23] The XCharge C8SAX column exhibited high column efficiency to the anthocyanins, which was nearly twice as much as that on the XTerra MS C_{18} column (N = 40 000 and 25 000 for XCharge C8SAX and XTerra MS C_{18}, respectively; Table 2). Hypothetically, the strength of ionic

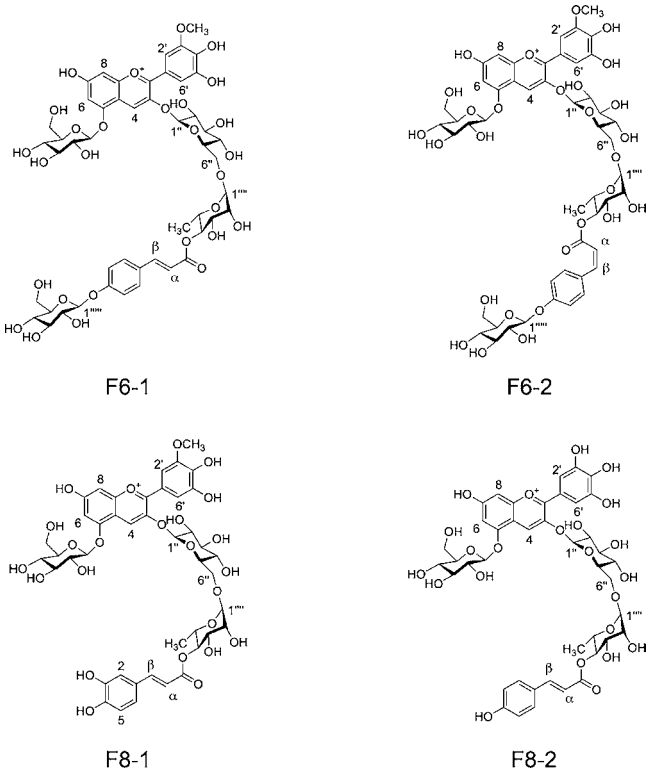

Figure 10. Chemical structures of the isolated anthocyanins.

repulsion between the positive charge on the stationary phase and falvylium cations could affect the separation efficiency.[21]

To summarize, benefiting from the presence of an appropriate level of positive charge on the surface of the solid phase, the XCharge C8SAX column displayed improved selectivity and better column efficiency for separation of the *cis*−*trans* anthocyanin isomers, which would be favorable for their preparation.

Mobile Phase Optimization. To obtain optimal separation performance on XCharge C8SAX, various mobile phase experimental factors, such as pH, organic content, and buffer concentration, were studied. The same experiments were also performed on the XTerra MS C_{18} column to further understand the retention mechanism of anthocyanins.

Effect of the pH. The pH value of elution has profound influence on the ionization of anthocyanins[25] and should be taken into consideration in the HPLC method development. As presented in Figure 4, separation of the anthocyanin isomers within the pH values of 2.32−1.56 was implemented on C_{18} and mixed-mode columns. The ionic strength and organic content were maintained constant at 15 mM and 15%, respectively.

On the XTerra MS C_{18} column (Figure 4A), the isomeric anthocyanins were co-eluted as one broad peak at pH ranging from 2.32 to 1.76 (panels a, b and c of Figure 4A). When pH decreased to 1.56 (panel d of Figure 4A), partial separation of the isomers was acquired. The secondary equilibria of anthocyanins, which would cause on-column band broadening,[26,27] was alleviated with a decreasing pH value. As a result, a highly acidic condition was of significance to ensure prevalence of the falvylium cations and improved chromatographic performance. However, the resolution for the isomers is still limited for preparative separation.

In contrast, the XCharge C8SAX column exhibited much better separation quality for the isomers than the XTerra C_{18} column. The resolution of the isomers was effectively improved on this mix-mode column with decreasing pH in the mobile phase (Figure 4B). At pH of 2.32, only one broad peak was observed (panel a of Figure 4B). When pH decreased to 2.06, a slight resolution of the isomers was achieved (panel b of Figure 4B). Baseline separation appeared at a pH value of 1.76 (panel c of Figure 4B), and better resolution as well as sharp peak shapes were obtained with pH of 1.56 (panel d of Figure 4B). This was due in part to the alleviation of the secondary equilibria effect by the decreased pH. More importantly, the electrostatic repulsion between the anthocyanin isomers and quaternary ammonium in the XCharge C8SAX column might provide remarkable contribution to the improvement of separation selectivity. The ionization of quaternary ammonium groups is barely changed within the studied pH values, whereas the charge of anthocyanins is pH-dependent. The percentage of flavylium cation species would increase with the decrease of pH. Meanwhile, the discrepancy in electrostatic force between the *cis*−*trans* isomeric anthocyanins became increasingly evident, leading to quite different strengths of ionic repulsion with positive charge in the XCharge C8SAX column. Thus, separation selectivity was improved constantly, as shown in Figure 4B.

Effect of the Organic Content. The XCharge C8SAX column has hydrophobic alkyl C_8 chains, and the anthocyanin isomers have some hydrophobic portions in the molecules. Two compounds could be retained through hydrophobic interaction. The linear solvent strength theory is often used to evaluate retention of a compound in reverse-phase liquid chromatography (RPLC)[28]

$$\log k = \log k_w - \frac{\phi_o}{2}(P_{H_2O} - P_o) \quad (1)$$

where P_{H_2O} is the polarity of water, P_o is the polarity of the organic solvent, Φ_o is the volume fraction of the organic solvent in percentage, and k_w is the retention factor of an analyte in water.

In this section, the influence of the organic modifier content in the mobile phase on the separation of the isomers was investigated under various ACN concentrations (from 14 to 15.5%). The ionic strength was kept constant at 15 mM, and the pH was fixed at 1.5. The log *k* versus the volume fraction of ACN was plotted in Figure 5. Obviously, the retention factor decreased linearly with the increase of the ACN content on these two columns. The correlation coefficients for the isomers were 0.9997/0.9998 on the XTerra MS C_{18} column and 0.9999/0.9999 on the XCharge C8SAX column. These results demonstrated that the anthocyanin isomers experienced RPLC retention behavior on both columns. The retention of the anthocyanins would be greatly susceptible to the change of the organic content on the XCharge C8SAX column.

Effect of the Buffer Ionic Strength. Given that the electrostatic repulsive interaction might be involved in the retention of anthocyanins on the XCharge C8SAX column, the influence of the ionic strength in the mobile phase on the separation of the isomers was further assessed under different buffer concentrations (from 1 to 15 mM). The organic content was kept at 15%, and the pH was fixed at 1.5. The plots of the retention time versus the ionic strength are presented in Figure 6. On the XTerra C_{18} column (Figure 6A), retention of the two isomers remained almost constant with the increase of the buffer concentration. Therefore, no obvious ion-exchange interaction existed. In comparison, the retention enhanced with an increasing buffer concentration on the XCharge C8SAX column

DOI: 10.1021/jf504525w
J. Agric. Food Chem. 2015, 63, 500−508

(Figure 6B), which is due to the reduction of Donnan exclusion between flavylium cations and positive quaternary ammonium groups in the stationary phase as a result of the electrostatic screen effect.[29]

From the above discussion, the XCharge C8SAX column provided a hydrophobic interaction along with an electrostatic repulsion for the separation of the anthocyanin isomers under the highly acidic conditions, which could be a reasonable explanation for its superior selectivity.

Effect of the Additive Types. Phosphate buffer has poor volatility and needs to be removed through the desalting process. Substitution of phosphate with other common acidic additives, including FA and TFA, was tested to separate the isomers on the XCharge C8SAX column. To maintain a pH value of the mobile phase around 1.5, 5% FA (pH 1.6−1.7) or 0.2% TFA (pH 1.5−1.6) was adopted. The organic content in the mobile phase was optimized to acquire a similar retention on the XCharge C8SAX column with different additives. As shown in Figure 7, FA and TFA could provide good chromatographic performance and, thus, were able to replace phosphate buffer. Moreover, as for preparative application, a satisfactory result was observed with TFA as the additive (as shown in the Supporting Information). The pH changed slightly for solutions containing TFA, even with large loading amounts, which could improve anthocyanin preparation. Hence, 0.2% TFA was recommended as mobile phase additives for separation of the isomers on the XCharge C8SAX column.

Purification of Anthocyanin Isomers from *L. ruthenicum* on the XCharge C8SAX Column. On the basis of the above results, a HPLC method was developed to separate the anthocyanin isomers using the XCharge C8SAX column. Three XTerra MS C_{18} purified fractions (fractions 6, 8, and 9) from *L. ruthenicum* were taken as examples for target purification. Chromatographic conditions for each fraction were optimized. The preparation chromatograms of fractions 6, 8, and 9 on the XCharge C8SAX column were presented in Figure 8.

Six compounds were yielded with sufficient amounts and dried by lyophilization. The purity of these compounds was checked by HPLC, which is shown in Figure 10. F6-2 is 85% pure, and other compounds are more than 90% pure. It was noticed that compounds F6-1 and F6-2 had close retention times on the XTerra MS C_{18} column (Figure 9). They were difficult to isolate and collect with favorable purity. However, these two compounds could be easily obtained with high purity on the XCharge C8SAX column. Similar results were observed for compounds F8-1 and F8-2 as well as compounds P1 and P2. These data demonstrated that this mixed-mode column could be used as the second-dimensional separation in anthocyanin preparation, because of its complementary separation selectivity.

Structure Elucidation. Identification of the pure compounds was performed by mass spectrum and NMR. The results of specific structural identification were as follows:

F6-1, red powder, $[M + H]^+$: m/z 1095.3169, calculated for $C_{49}H_{59}O_{28}$, m/z 1095.3187. ^{1}H NMR data are shown in Table 3. In comparison of the ^{1}H NMR and NOESY data to the literature,[8] F6-1 was identified as petunidin 3-*O*-[6-*O*-(4-*O*-(4-*O*-*trans*-(β-D-glucopyranoside)-*p*-coumaroyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-[β-D-glucopyranoside].

F6-2, red powder, $[M + H]^+$: m/z 1095.3169, calculated for $C_{49}H_{59}O_{28}$, m/z 1095.3187. ^{1}H NMR data are shown in Table 3. It was similar to F6-1. However, the olefinic proton signals of *p*-coumaric acids of F6-2 had smaller coupling constants (J = 12.5 Hz) than that of F6-1 (J = 16.0 Hz), indicating that its *p*-coumaric acid was *cis* configuration. In comparison of the ^{1}H NMR and NOESY data to F6-2 in the literature,[8] F6-2 was identified as petunidin 3-*O*-[6-*O*-(4-*O*-(4-*O*-*cis*-(β-D-glucopyranoside)-*p*-coumaroyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-[β-D-glucopyranoside]. To the best of our knowledge, it is a new anthocyanin.

F8-1, red powder, $[M + H]^+$: m/z 949.2598, calculated for $C_{43}H_{49}O_{24}$, m/z 949.2608. ^{1}H NMR data are shown in Table 3. In comparison of the ^{1}H NMR and NOESY data to the literature,[8] F8-1 was identified as petunidin 3-*O*-[6-*O*-(4-*O*-(*trans*-*p*-caffeoyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-[β-D-glucopyranoside].

F8-2, red powder, $[M + H]^+$: m/z 919.2469, calculated for $C_{42}H_{47}O_{23}$, m/z 919.2505. ^{1}H NMR data are shown in Table 3. In comparison of the ^{1}H NMR and NOESY data to the literature,[8] F8-2 was identified as delphinidin 3-*O*-[6-*O*-(4-*O*-(*trans*-*p*-coumaroyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-[β-D-glucopyranoside].

P1, red powder, $[M + H]^+$: m/z 933.2647, calculated for $C_{43}H_{49}O_{23}$, m/z 933.2659. ^{1}H NMR data are shown in Table 3. In comparison of the ^{1}H NMR and NOESY data to the literature,[8] P1 was identified as petunidin 3-*O*-[6-*O*-(4-*O*-(*cis*-*p*-coumaroyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-[β-D-glucopyranoside].

P2, red powder, $[M + H]^+$: m/z 933.2650, calculated for $C_{43}H_{49}O_{23}$, m/z 933.2659. ^{1}H NMR data are shown in Table 3. In comparison of the ^{1}H NMR and NOESY data to the literature,[8] P2 was identified as petunidin 3-*O*-[6-*O*-(4-*O*-(*trans*-*p*-coumaroyl)-α-L-rhamnopyranosyl)-β-D-glucopyranoside]-5-*O*-[β-D-glucopyranoside].

The chemical structures of P1 and P2 are shown in Figure 1, while others are shown in Figure 10. To the best of our knowledge, F6-2 is a new anthocyanin. Except for P2, all other anthocyanins were isolated from *L. ruthenicum* for the first time.

In summary, a HPLC method had been successfully developed to realize effective preparation of *cis*−*trans* isomeric anthocyanins from *L. ruthenicum* using the XCharge C8SAX column. Four commercially available columns were evaluated to separate a pair of anthocyanin isomers. The results indicated that the XCharge C8SAX column performed improved selectivity and better column efficiency in terms of separation of the isomers. Accordingly, discrimination of the isomers on this mix-mode column was superior to that on RP columns. Moreover, the mobile phases, including pH, organic content, and ionic strength, were investigated. The data explicitly demonstrated that combined mechanisms of the hydrophobic interaction and ionic repulsion were involved in anthocyanin retention on the mixed-mode column, which was a possible explanation for the improved selectivity to the isomers. On the basis of the established approach, six pure anthocyanins, containing two pairs of *cis*−*trans* anthocyanin isomers with one new anthocyanin, were isolated from *L. ruthenicum* and identified by MS and NMR. Five of them were purified from this plant for the first time. The overall results indicated that this method was feasible to efficiently separate anthocyanins, especially for *cis*−*trans* isomeric anthocyanins, benefiting from the improved separation selectivity.

ABSTRACT: Polymethoxyflavones (PMFs) have been known as a type of bioactive flavones that possess various beneficial biological functions. Accumulating evidence demonstrated that the metabolites of PMFs, that is, hydroxyl PMFs (OH-PMFs), had more potent beneficial biological effects than their corresponding parent PMFs. To facilitate the further identification and quantification of OH-PMFs in biological samples, the aim of this study was to develop a methodology for the simultaneous determination of 10 OH-PMFs using high-performance liquid chromatography (HPLC) coupled with electrochemistry detection. The HPLC profiles of these 10 OH-PMFs affected by different chromatographic parameters (different organic composition in mobile phases, the concentration of trifluoroacetic acid, and the concentration of ammonium acetate) are fully discussed in this study. The optimal condition was selected for the following validation studies. The linearity of calibration curves, accuracy, and precision (intra- and interday) at three concentration levels (low, middle, and high concentration range) were verified. The regression equations were linear ($r > 0.9992$) over the range of 0.005−10 μM. The limit of detection for 10 OH-PMFs was in the range of 0.8−3.7 ng/mL (S/N = 3, 10 μL injection). The recovery rates ranged from 86.6 to 108.7%. The precisions of intraday and interday analyses were less than 7.37 and 8.63% for relative standard deviation, respectively. This validated method was applied for the analysis of a variety of samples containing OH-PMFs. This paper also gives an example of analyzing the metabolites of nobiletin in mouse urine using the developed method. The transformation from nobiletin to traces of 5-hydroxyl metabolites has been discovered by this effective method, and this is the first paper to report such an association.

KEYWORDS: *hydroxyl polymethoxyflavones, HPLC, quantification, electrochemical detection, metabolites, nobiletin*

INTRODUCTION

Polymethoxyflavones (PMFs) are a unique class of bioactive flavonoids that are mainly found in citrus fruits such as sweet orange and tangerine, especially in their peels.[1] Increasing numbers of studies have demonstrated various beneficial biological functions of PMFs, for example, anti-inflammatory, anticarcinogenic, antiatherogenic, antiviral, and antioxidative effects.[2] We and others have identified several metabolites of PMFs after their oral administration in mice.[3−5] It was found that these metabolites are mainly hydroxyl PMFs (OH-PMFs). Interestingly, accumulating evidence has shown that OH-PMFs have potent biological activities,[6−13] and some of them were much stronger that those produced by their corresponding parent compounds.[3−5] OH-PMFs can be obtained by isolation from natural sources, such as citrus peels, and by chemical synthesis.[14] Several methods have been developed for the quantification of PMFs, including gas chromatography (GC),[15] supercritical liquid chromatography (SFC),[16] and high-performance liquid chromatography (HPLC) with UV detection.[17] However, there is no effective analytical method available for the simultaneous quantification of multiple OH-PMFs with quite similar chemical structures. With increasing interests in the beneficial bioactivities of PMFs, it is important to develop highly sensitive methods to analyze biological samples generated from animal and human studies that contain multiple OH-PMFs, for example, the metabolites of PMFs.

The electrochemical detection (ECD) is a powerful analytical method that can detect electric currents of less than nanoamps generated from oxidative or reductive reactions of test compounds.[18−20] OH-PMFs possess at least one phenolic group that is potentially reactive under electrical potential, which makes OH-PMFs good candidates for electrochemical detection. The aim of this study is to develop a fast, simple, and reliable HPLC coupled with ECD method for the assessment of 10 important OH-PMFs (Figure 1), namely, 4′-demethyltangeretin (**1**), 5-demethyltangeretin (**2**), 5,4′-didemethyltangeretin (**3**), 3′-demethylnobiletin (**4**), 4′-demethylnobiletin (**5**), 3′,4′-didemethylnobiletin (**6**), 5-demethylnobiletin (**7**), 5,3′-didemethylnobiletin (**8**), 5,4′-didemethylnobiletin (**9**), and 5,3′,4′-tridemethylnobiletin (**10**). Herein, we report a detailed validation of a HPLC-ECD method for the aforementioned 10 OH-PMFs, and we also successfully utilized this method to analyze urine samples containing multiple OH-PMFs and their metabolites generated from a mouse feeding study.

MATERIALS AND METHODS

Reagents and Chemicals. Organic solvents, including methanol (MeOH), acetonitrile (ACN), tetrahydrofuran (THF), and trifluoroacetic acid (TFA), were of HPLC grade and obtained from Fisher Scientific. Ammonium acetate was a product of EMD Chemicals Inc. (Gibbstwon, NJ, USA). 4′-Demethyltangeretin (**1**), 5-demethyltangeretin (**2**), 5,4′-didemethyltangeretin (**3**), 3′-Demethylnobiletin (**4**), 4′-demethylnobiletin (**5**), 3′,4′-demethylnobiletin (**6**), 5-demethylnobiletin (**7**), 5,3′-didemethylnobiletin (**8**), 5,4′-didemethylnobiletin (**9**), and 5,3′,4′-tridemethylnobiletin (**10**) were synthesized following previously published methods.[3,4] The purity of these 10 OH-PMFs was >98%, and their chemical structures have been confirmed by MS and NMR.[3,4]

Instrumentation and Chromatographic Conditions. The CoulArray HPLC system (Chelmsford, MA, USA) consisted of a binary solvent delivery system (model 584), an autosampler (model 542), and a CoulArray Multi-Channel EC detector (model 6210) (Waters, Milford, MA, USA).[21] Instrument control and data processing were performed with CoulArray 3.06 software. An Ascentis RP-Amide reversed-phase HPLC column (15 cm × 4.6 mm id, 3 μm) (Sigma-Aldrich, St. Louis, MO, USA) was used. Flow rate was 1.0 mL/min. The temperature of the autosampler was set to 4 °C. The injection volumes were between 10 and 50 μL. The optimal elution conditions were as follows: mobile phase A, 75% water, 20% acetonitrile, 5% THF, and 50 mM ammonium acetate; mobile phase B, 50% water, 40% acetonitrile, 10% THF, and 50 mM ammonium acetate (pH values of both mobile phases were adjusted to 3.0). The linear solvent gradient consisted of 10% B at the beginning, 50% B at 5.0 min, 70% B at 15.0 min, 90% B at 25.0 min, 100% B at 25.1 min, and 100% B at 30.0 min. Re-equilibration duration was 5 min between individual runs. Two EC detection cells (each contains four channels) were used, and the detecting potentials were set at 100, 200, 300, 400, 500, 600, and 700 mV.

Optimization of Chromatographic Conditions. *Elution Conditions.* To obtain optimal resolution of 10 OH-PMFs simultaneously, two complex mobile phases A and B were used: A, 75% water, 20% acetonitrile, 5% THF, and 50 mM ammonium acetate; B, 50% water, 40% acetonitrile, 10% THF, and 50 mM ammonium acetate. Both mobile phases were adjusted to pH 3.0. Four different elution conditions were compared, that is, (i) isocratic elution with 40% A and 60% B; (ii) isocratic elution with 50% A and 50% B; (iii) isocratic elution with 60% A and 40% B; and (iv) gradient elution, 0 min (10% B), 5 min (50% B), 15 min (70% B), 25 min (90% B), 25.1 min (100% B), 30 min (100% B), 30.1 min (10% B), and 35 min (10% B).

pH Values of Mobile Phases. The pH values of mobile phases A and B were adjusted to different values in the range of 2.0−7.0 by adding different volumes of TFA. The effects of pH on the sensitivity, retention time, and peak resolution of 10 OH-PMFs were determined and compared.

Concentrations of Ammonium Acetate. In the mobile phases, ammonium acetate was used as a buffer system that can affect the sensitivity of the ECD. Five different concentrations of ammonium acetate (0, 25, 50, 75, and 100 mM) were used to determine their effects on the ECD of 10 OH-PMFs.

Validation of HPLC-ECD Method. The stock solutions (10 mM) of each standard compound were prepared in DMSO and stored at 4 °C, and the final test solutions with a series of concentrations were prepared by diluting the stock solution with 50% methanol just before every experiment. Linearity, limit of quantification (LOQ), and limit of detection (LOD), and precision of the current method were determined. To assess the linearity of the method, calibration curves were constructed with eight concentrations of each OH-PMF (0.005, 0.01, 0.05, 0.5, 5, 10, 20, and 50 μM) in the test solutions. Calibration curves were obtained by plotting the responses (peak areas) of 10 OH-PMF standards against their respective concentrations using a linear least-squares regression. The slope, intercept, and correlation coefficient (r^2) were calculated for each OH-PMFs using a regression equation. The sensitivity of the method was determined by the LOD and LOQ. LOD and LOQ were the lowest measured concentrations with signal-to-noise (S/N) ratios of of 3 and 10, respectively. A known amount of standard OH-PMFs (at low, medium, and high concentrations of 0.05, 0.5, and 5 μM, respectively) was added to mouse urine, and overall recoveries were determined by the standard addition method. Intraday and interday precisions were determined for both retention time and peak area at low (0.05 μM), medium (0.5 μM), and high (5 μM) concentrations of OH-PMFs.

Quantification of OH-PMFs in Biological Samples. The optimized HPLC-ECD method was utilized to quantify OH-PMFs in the urine of mice after they were fed nobiletin, a polymethoxyflavone found in citrus fruits. Fifteen CF-1 male mice (7 weeks of age) were fed nobiletin at 500 ppm in standard AIN-93G powder diet for 1 week. The urine was collected using Tecniplast metabolic cages (5 mice per cage) during the last 12 h of feeding. Two hundred microliters of collected urine sample was extracted with 500 μL of ethyl acetate three times. The combined ethyl acetate extracts were

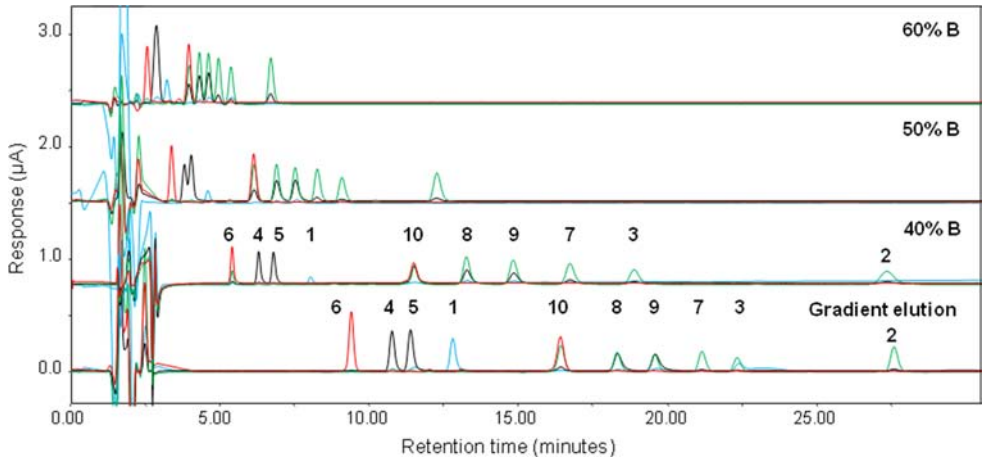

Figure 2. HPLC profiles of 10 OH-PMFs analyzed using four different elution conditions, that is, three isocratic elution conditions (i.e., 60, 50, and 40% mobile phase B) and one gradient elution condition (0 min, 10% B; 5 min, 50% B; 15 min, 70% B; 25 min, 90% B; 25.1 min, 100% B; 30 min, 100% B). The composition of mobile phase A was 75% water, 20% acetonitrile, 5% THF, and 50 mM ammonium acetate (pH 3.0); the composition of mobile phase B was 50% water, 40% acetonitrile, 10% THF, and 50 mM ammonium acetate (pH 3.0). Different EC potentials were used for detection (100 mV, in red; 300 mV, in green; 400 mV, in black; 600 mV, in blue). Each peak was labeled with corresponding OH-PMF **1**–**10** (injection volume = 10 μL; sample concentration = 0.5 μM).

[a]The peak cannot be separated with others from baseline. [b]The peak completely overlapped with another one.

dried under vacuum. Dried samples were dissolved in 1000 μL of 50% methanol for HPL-ECD analysis using the optimized method. The identities and concentrations of OH-PMFs (as metabolites of nobiletin) in mouse urine were determined by comparing the HPLC profiles of urine samples with those of OH-PMF standards and their corresponding standard curves.

Statistical Analysis. All analyses were performed in triplicate, and the results are presented as means ± standard deviation of three independent experiments.

RESULTS AND DISCUSSION

Optimization of HPLC-ECD Method. Different OH-PMFs may have different electrochemical reactivities and retention times under different chromatographical conditions. Therefore, it is necessary to determine the impact of multiple influencing factors (pH value, salt concentration, and polarity of eluents) to obtain optimal separation and sensitivity for all 10 OH-PMFs. The column was equilibrated for at least 2 h with new mobile phases when different mobile phases were used.

Optimization of Elution Condition. On the basis of our previous experience in analyzing PMFs by HPLC,[4,21] we developed two complex mobile phases A and B to optimize the elution conditions. Mobile phase A consisted of 75% water, 20% acetonitrile, 5% THF, and 50 mM ammonium acetate, and mobile phase B consisted of 50% water, 40% acetonitrile, 10% THF, and 50 mM ammonium acetate. In this section, the pH of mobile phases A and B was adjusted to 3.0. The effects of pH on the HPLC-ECD results are investigated in the following section. Four elution conditions were used to analyze a mixture of 10 OH-PMFs at 1 μM each. The HPLC profiles of 10 OH-PMFs under different elution conditions are shown in Figure 2, and the retentions times of OH-PMFs under different elution conditions are listed in Table 1. The isocratic elution with 60 or 50% of mobile phase B did not produce satisfactory separation of the 10 OH-PMFs, which was evidenced by overlapping peaks of different OH-PMFs, especially compounds **4** and **5**. In contrast, isocratic elution with 40% mobile phase B resulted in good separation of all 10 OH-PMFs. Nevertheless, the retention times of the 10 OH-PMFs were not evenly distributed, and compounds **1** and **4**–**6** were eluted within only 2.6 min when eluted with 40% mobile phase B. A potential drawback of the quick elution of compounds **1** and **4**–**6** is that any other compounds (e.g., contaminants or impurities) with similar retention times may have a good chance to interfere with one or more of them. The gradient elution (0 min, 10% B; 5 min, 50% B; 15 min, 70% B; 25 min, 90% B; 25.1 min, 100% B; 30 min, 100% B) produced the best separation of all 10 OH-PMFs within 30 min. Moreover, much better sensitivities can be obtained under gradient elution condition. For example, the sensitivity of compound **1** under gradient elution increased 8-fold in comparison with those under isocratic elution with 40% mobile phase B. Therefore, the gradient elution was selected as the optimal elution conditions.

Optimization of the pH of Mobile Phases. The pH of the mobile phase often significantly affects the nature of chromatograms, especially the sensitivity of ECD. In this section, we determine the effects of mobile phase pH on the retention time, sensitivity, and peak resolution of all OH-PMF. The initial pH values of mobile phases A and B were 7.15 and 7.34, respectively. Their pH values were adjusted to 2.0, 3.0, 4.0, 5.0, 6.0, and 7.0 by adding different volumes of TFA. The gradient elution condition was used in this section. As shown in Figure 3, varying pH values of the mobile phase had only

J. Agric. Food Chem. 2015, 63, 509–516

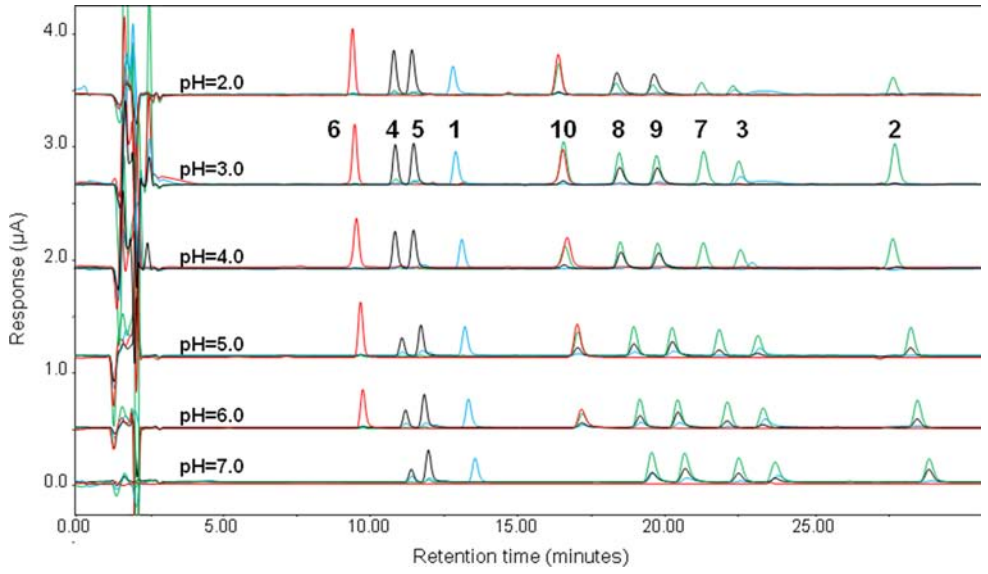

Figure 3. Effects of pH of mobile phases on HPLC profiles of 10 OH-PMFs. The pH values of both mobile phases A and B were adjusted to 2.0, 3.0, 4.0, 5.0, 6.0, or 7.0. Different EC potentials were used for detection (100 mV, in red; 300 mV, in green; 400 mV, in black; 600 mV, in blue). Each peak was labeled with corresponding OH-PMFs **1**−**10** (injection volume = 10 μL; sample concentration = 0.5 μM).

marginal effects on the retention times. To a certain extent, the peak symmetry and sharpness were improved when the pH decreased. Most importantly, the sensitivity of ECD was increased when the pH values of mobile phases were decreased. For example, as shown in Figure 4, at a potential of 400 mV,

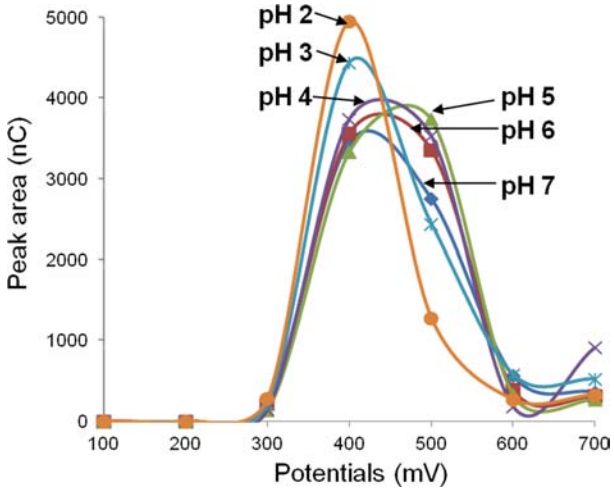

Figure 4. Effects of pH value on peak areas (nC) of compound **5** under different EC potentials (mV). The pH values of both mobile phases A and B were adjusted to 2.0, 3.0, 4.0, 5.0, 6.0, or 7.0. EC potentials were set at 100, 200, 300, 400, 500, 600, and 700 mV (injection volume = 10 μL; sample concentration = 0.5 μM; n = 3).

the mobile phase with pH 2.0 produced the highest sensitivity, followed by pH 3.0 and 4.0. A similar trend can be observed for other OH-PMFs. It is worth mentioning that at high pH, that is, pH 7.0, the sensitivity of ECD of compounds **6** and **10** became so low that they cannot be even detected at 1 μM concentration. Although pH 2.0 produced the highest overall sensitivity, we selected pH 3.0 as the optimal pH value for the mobile phases because high acidity of the mobile phase may cause damage to the stationary phase and therefore shorten the working life of the HPLC columns.

Optimization of Ammonium Acetate Concentration. For the mobile phase for use with EC detection, a buffered system that can provide ionic strength for good electron transfer is required in mobile phase.[22−24] In our study, ammonium acetate was used as a buffer system for EC detection.[25] The gradient elution condition was used in this section. Five different concentrations of ammonium acetate (0, 25, 50, 75, and 100 mM) were prepared in both mobile phases A and B with pH 3.0. As shown in Figure 5, the concentration of ammonium acetate did not have a significant effect on the retention times of OH-PMFs, but the addition of ammonium acetate greatly improved the symmetry and sharpness of peaks of OH-PMFs. Most interestingly, when the concentration of ammonium acetate increased from 0 to 25 mM and then to 50 mM, the sensitivity of EC detection was significantly enhanced. However, further increase of ammonium acetate concentration to 75 and 100 mM caused no further enhancement of sensitivity, and it even decreased sensitivity for some OH-PMFs. On the basis of these results, the optimal concentration of ammonium acetate was determined to be 50 mM, and this condition was used for the rest of the study described below.

Method Validation. Using the optimized chromatography conditions, we constructed the calibration curves for all 10 OH-PMFs by plotting the peak areas against a series of concentrations of prepared standards (0.005, 0.01, 0.05, 0.5, 5, 10, 20, and 50 μM, respectively; Figure 6). On the basis of the EC potential where the maximum sensitivities of different OH-PMFs were observed, we selected the potentials of 600, 300, 300, 400, 400, 100, 300, 300, 300, and 100 mV for analyzing OH-PMFs **1**−**10**, respectively. Satisfactory linearity was observed when the concentrations of OH-PMFs were within the range of 0.005−10 μM (Figure 6). The results on linear regression of standard curves of all 10 OH-PMFs (slope, intercept, correlation coefficient, and linear range) are reported in Table 2. The linearities of the standard curves for all 10 OH-PMFs were all >0.9992, suggesting good linearity within a relatively wide concentration range (0.005−10 μM, 2000-fold) for all 10 OH-PMFs. The limits of detection (LOD) and the limits of quantification (LOQ) were determined at signal-to-

DOI: 10.1021/jf505545x

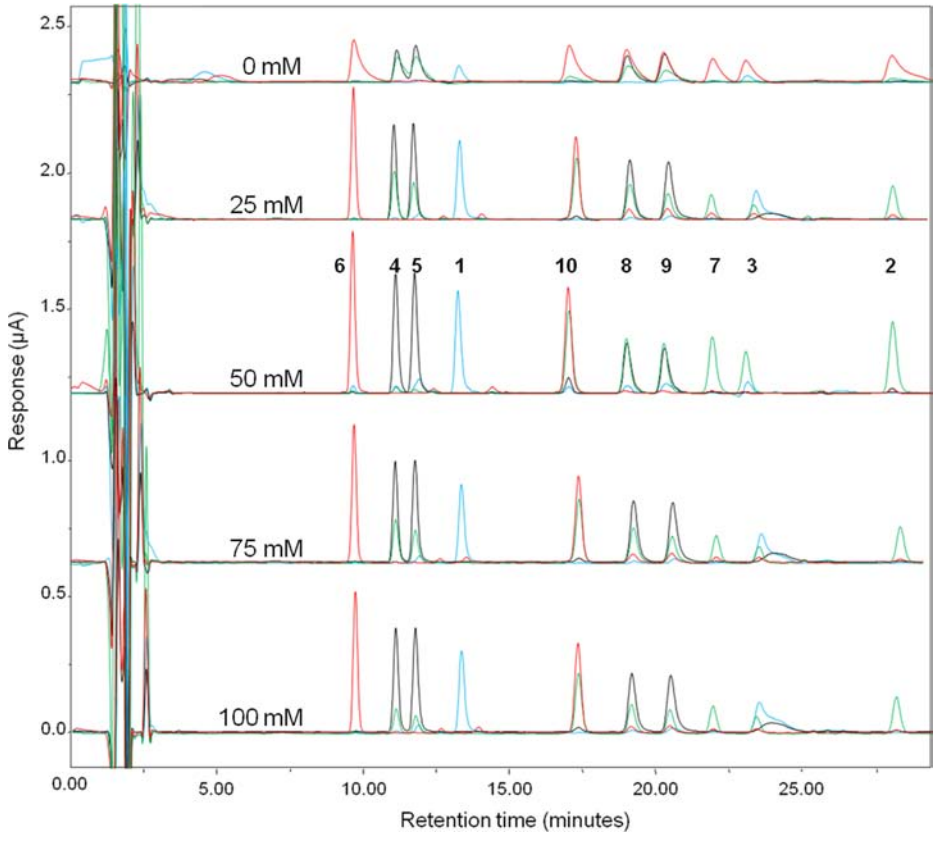

Figure 5. Effects of the concentrations of ammonium acetate (0, 25, 50, 75, and 100 mM) in the mobile phases on the HPLC profiles of 10 OH-PMFs. Different EC potentials were used for detection (100 mV, in red; 300 mV, in green; 400 mV, in black; 600 mV, in blue). Each peak was labeled with corresponding OH-PMFs **1**−**10** (injection volume = 10 μL; sample concentration = 0.5 μM).

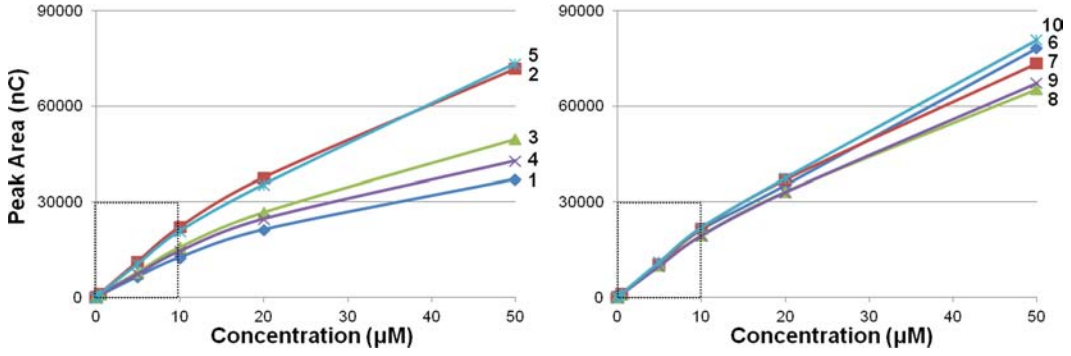

Figure 6. Calibration curves of OH-PMFs **1**−**10** (gradient elution; injection volume = 10 μL).

noise ratios (S/N) of 3 and 10, respectively. The results showed that the LODs of the 10 PMFs ranged from 8 to 37 pg per injection (10 μL) at a signal-to-noise ratio of 3:1, and the LODs ranged from 25 to 119 ng at a signal-to-noise ratio of 10:1.

Recovery rates of the extraction and detection method were obtained by analyzing the mouse urine samples that had been spiked with known amounts of OH-PMFs. As shown in Table 2, the recovery rates of different OH-PMFs ranged from 86.6 to 108.7% with the RSD (%, relative standard deviations) of <14.9% for all 10 OH-PMFs at 0.05, 0.5, and 5 μM that are representative of the low, medium, and high concentrations, respectively. Intraday and interday precisions (shown in Table 3) were determined at three different sample concentrations (0.05, 0.5, and 5 μM) by injecting the same sample solution three times a day for three consecutive days. Retention time and peak area were recorded and analyzed. Precision was expressed as RSD that was obtained from three repetitive injections of standard solutions of OH-PMFs. For intraday variation, the RSD of the retention time was between 0 and 0.88%, and the RSD of the peak area was between 1.03 and 7.37%. For the interday variation, the RSD of the retention time and the peak area were in the ranges of 0−1.46 and 0.70−8.63%, respectively. These results demonstrated that the method established in this study produced very good reproducibility. The RSD values for recovery and precision were the lowest at the concentration of 0.5 μM, which suggested that quantification of OH-PMFs by the method developed herein can produce the best repeatability when the concentrations of OH-PMFs are around 0.5 μM in the samples

to be tested. The high precision and low LOD of the method indicated that the proposed method was sensitive and reliable for analyzing OH-PMFs.

Quantification of OH-PMFs in Mouse Urine. Using the optimized and validated method developed in the previous sections, we quantified OH-PMF metabolites in the urine of mice fed nobiletin, a permethoxylated PMFs. Three batches of urine samples were analyzed, and their HPLC profiles under different EC potentials are shown in Figure 7. We confirmed the identities of seven OH-PMF metabolites by comparing their retention times and characteristic EC responses at different potentials with those of the synthesized standard of OH-PMFs. The OH-PMF metabolites identified in the urine were OH-PMFs **4**−**10**. Previously, three OH-PMF metabolites (**4**−**6**) were identified in the urine of mice fed nobiletin.[14] Recently, we identified three OH-PMF metabolites (**8**−**10**) in the urine of mice fed OH-PMF **7**.[4] It is known that nobiletin can be converted to OH-PMF **7** by acid hydrolysis that removes the methyl group at the 5-position in the A-ring. We propose that nobiletin may be converted to OH-PMF **7** by the acid found in the stomach after oral consumption of nobiletin (Figure 8). Nobiletin and OH-PMF **7** are then metabolized to produce their OH-PMF metabolites as reported previously.[4,14]

Utilizing the standard curves generated from synthetic standards of OH-PMFs, the concentrations of OH-PMF metabolites in the urine were quantified, and the results are listed in Table 4. To ensure the accuracy of the quantification, proper dilutions were made to the urine samples so that the

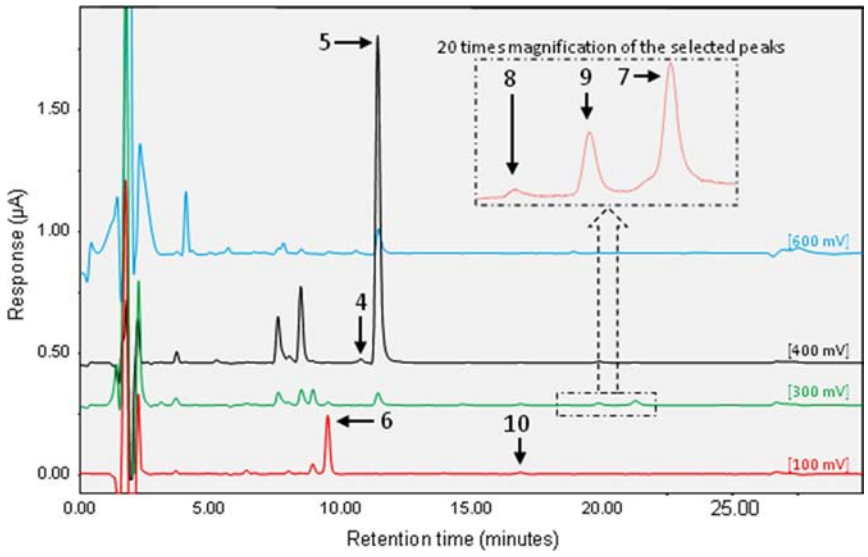

Figure 7. HPLC profiles of the OH-PMF metabolites of nobiletin in mouse urine. The urine samples were processed as described under Materials and Methods and then eluted with the optimized HPLC method. Different EC potential were used for detection (100 mV, in red; 300 mV, in green; 400 mV, in black; 600 mV, in blue). Each peak was labeled with corresponding OH-PMFs (injection volume = 10 μL; representative of three replicates).

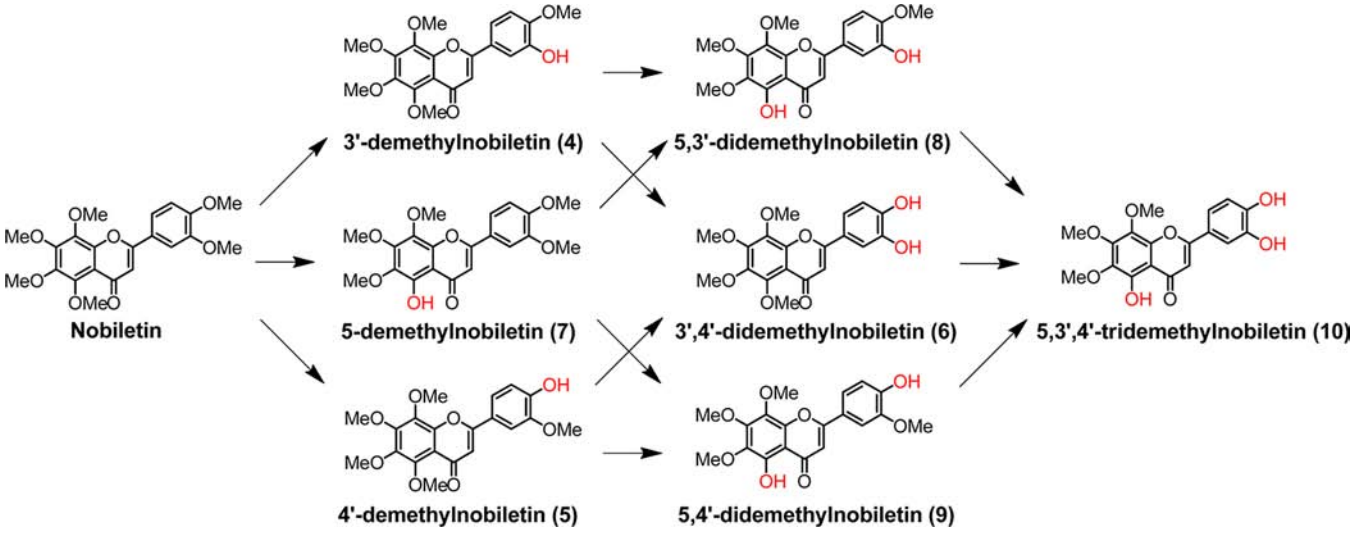

Figure 8. Proposed metabolism of nobiletin in mice.

Table 4. Concentrations (Nanomolar) of OH-PMF Metabolites of Nobiletin in Mouse Urine

batch	1	2	3	4	5	6	7	8	9	10
1				499	40988	6063	513	33	430	242
2				651	45063	6251	674	29	318	102
3				966	46021	6981	388	21	465	132

concentrations of OH-PMFs were within the linear range (0.005−10 μM) of the HPLC method. The results showed that OH-PMF **5** was the most abundant metabolite of nobiletin in mouse urine, followed by OH-PMF **6**. The concentrations of other metabolites (**4** and **7**−**10**) were much lower. Our results demonstrated that the HPLC-ECD method developed in this study can be used successfully to identify and quantify OH-PMFs in the biological sample (i.e., urine). Due to the high sensitivity and reproducibility of the method, it is expected that this method can be conveniently used to identify and quantify OH-PMFs in other biological samples such as blood, liver, kidney, and brain.

In conclusion, we have developed and validated a highly sensitive and reliable method for the simultaneous determination of 10 bioactive OH-PMFs by combining HPLC with EC detection. The HPLC profiles of these 10 OH-PMFs are significantly affected by different chromatographic parameters (i.e., organic solvent composition, pH, concentration of ammonium acetate of mobile phases). The optimal conditions were established to produce high sensitivity, linearity, accuracy, and recovery rate for 10 OH-PMFs within a wide concentration

DOI: 10.1021/jf505545x
J. Agric. Food Chem. 2015, 63, 509−516

range in a single HPLC run. The HPLC-ECD method established herein is expected to greatly facilitate the identification and quantification of OH-PMF metabolites in biological samples harvested from animal and human studies. The information on the bioactive metabolites in the biological samples will provide critical mechanistic insights into the molecular mechanism of PMFs and their metabolites.

Toll-like Receptor 4 Mediates the Antitumor Host Response Induced by *Ganoderma atrum* Polysaccharide

Qiang Yu, Shao-Ping Nie,* Jun-Qiao Wang, Dan-Fei Huang, Wen-Juan Li, and Ming-Yong Xie*

State Key Laboratory of Food Science and Technology, Nanchang University, 235 Nanjing East Road, Nanchang 330047, China

ABSTRACT: The aim of this study is to investigate the role of Toll-like receptor (TLR) 4 in *Ganoderma atrum* polysaccharide (PSG-1)-induced antitumor activity. In vitro, the apoptosis rate of S-180 cells was increased in PSG-1-induced peritoneal macrophage derived from C3H/HeN (wild-type) mice, but not from C3H/HeJ (TLR4-deficient) mice. In the S-180 tumor model, phagocytosis, NO and ROS release, phosphorylation of MAPKs and Akt, and expression of NF-κB were increased by PSG-1 in peritoneal macrophage derived from C3H/HeN mice. Furthermore, PSG-1 elevated Th1 cytokine production and enhanced the cytotoxic activity of CTL and NK cells in C3H/HeN mice. In addition, PSG-1 decreased the tumor weight and increased the apoptosis rate and caspase-3 and caspase-9 activities of tumor derived from the C3H/HeN mice. However, none of these activities were observed in C3H/HeJ mice. In summary, these findings demonstrated that the antitumor activity of PSG-1 is mediated by TLR4.

KEYWORDS: *Toll-like receptor 4, Ganoderma atrum polysaccharide, antitumor, innate immunity, adaptive immunity*

INTRODUCTION

Great efforts have been made in therapeutic treatments, including surgery, radiation, and chemotherapy; however, due to severe adverse effects, cancer is still the leading cause of death.[1] Recently, cancer immunotherapy that recruits the host immune response to exert an antitumor effect without harming the host is of great interest.[2]

Toll-like receptors (TLRs) are mammalian homologues of the *Drosophila* Toll receptor.[3] Ten and twelve functional TLRs have been identified in humans and mice, respectively.[4] Among them, TLR4 is expressed by various immune cells, including macrophages, neutrophils, and dendritic cells. Binding of ligands to TLR4 initiates signal transduction via recruitment of the adaptor protein myeloid differentiation protein 88 (Myd88) and the interleukin receptor-associated kinase (IRAK), which in turn activate tumor necrosis factor receptor-associated factor 6 (TRAF6). This is followed by the activation of downstream signals, such as mitogen-activated protein kinase (MAPK) and nuclear factor-kB (NF-κB), and leads to the activation of a wide spectrum of target genes.[5]

Emerging studies have shown that TLR4 agonists can serve as immunomodulating agents and exhibit promising therapeutic potential for cancer immunotherapy.[6,7] It is worth noting that natural polysaccharides, which have been safely used as ingredients of traditional medicines and functional food for a long time in oriental countries, are attracting more and more attention since they trigger the response of innate immunity and in turn induce adaptive immunity via TLR4 signaling.[8,9]

Ganoderma atrum has been used as a Chinese traditional medicine and functional food for thousands of years. In recent years, it has become more and more popular in developed countries as a dietary supplement.[10] The polysaccharides are regarded as the major bioactive substances in *G. atrum*. We recently isolated and purified a polysaccharide from *G. atrum*, named PSG-1, with a purity of >99.8%, whose primary structural features and molecular weight were characterized.[11,12] Our in vitro study has demonstrated that TLR4 is the major receptor involved in specific binding of PSG-1 to macrophages, and PSG-1 induces macrophage activation through the TLR4 signaling pathway.[13]

Interestingly, my colleagues showed that oral administration of PSG-1 could inhibit S-180 tumor growth and enhance the host immune system through the TLR4-mediated signaling pathway.[14] However, the research results were carried out just by measuring the protein expression of TLR4 in peritoneal macrophage from BALB/c mice, and then they suggested PSG-1 may exert its antitumor effect through TLR4. Strictly speaking, the role of TLR4 in PSG-induced antitumor host response has still not been fully determined. Therefore, in this study, we investigated the antitumor activity of PSG-1 in C3H/HeN (wild-type) and C3H/HeJ (TLR4-deficient) mice, especially focused on the contribution of TLR4 in PSG-1-mediated innate and adaptive immune responses. To the best of our knowledge, this is the first time transgenic mice have been used to establish a tumor model for exploring the effect of TLR4 on the antitumor activity induced by PSG-1 in vivo. The results presented in our study could provide powerful evidence to support the vital role of TLR4 played in PSG-1-induced antitumor activity.

MATERIALS AND METHODS

Materials and Reagents. 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and fluorescein isothiocyanate (FITC)−dextran were purchased from Sigma (St. Louis, MO). The NO assay kit was obtained from Beyotime Biotech Inc. (Jiangsu, China), carboxyl-2′,7′-dichlorofluorescein diacetate (CM-DCFH) was from Molecular Probes (Eugene, OR). Antibodies against phospho-ERK1/2 (p-ERK1/2), phospho-JNK1/2 (p-JNK1/2), phospho-p38 (p-p38), phospho-Akt (p-Akt), and NF-κB were purchased from Cell Signaling

(Beverly, MA). ELISA kits were from R&D Systems (Minneapolis, MN). Annexin V−FITC apoptosis detection kits were obtained from Becton Dickinson Biosciences (San Jose, CA). Caspase-3 and caspase-9 colorimetric assay kits were purchased from BioVision, Inc. (Palo Alto, CA). Cell culture products were from Life Technologies (Paisley, Scotland, U.K.).

Cells and Animals. The murine S-180 cell line and YAC-1 cells were purchased from the Type Culture Collection of the Chinese Academy of Sciences, Shanghai, China. Cells were cultured in RPMI-1640 medium containing 10% fetal bovine serum and maintained in a humidified incubator at 37 °C in a 5% CO_2 atmosphere.

Female C3H/HeN and C3H/HeJ mice (6−8 weeks old) were obtained from the Shanghai Laboratory Animal Center, China. The mice were housed eight per cage at 25 °C with a 12 h/12 h light/dark cycle. All mice were cared for in accordance with the Guidelines for the Care and Use of Laboratory Animals published by the National Institutes of Health, Bethesda, MD (NIH Publication 85-23, 1996). All procedures were approved by the Animal Care Review Committee, Nanchang University, China.

Isolation of Mouse Peritoneal Macrophages. Each mouse was intraperitoneally injected with 5 mL of cold PBS, and peritoneal macrophages were aseptically harvested from peritoneal exudates by peritoneal lavage. Cells were resuspended in RPMI-1640 containing 10% heat-inactivated FBS. After 24 h of incubation, the cells were washed by PBS to remove nonadherent cells. The resultant cells were collected as peritoneal macrophages.

Macrophage Cytotoxicity Assay. After incubation with PSG-1 (20, 40, 80, and 160 μg/mL) for 48 h, the mouse peritoneal macrophages from C3H/HeN or C3H/HeJ were washed with fresh medium and coincubated with S-180 cells at a ratio of 25:1 for 48 h. The MTT method was performed to measure the growth inhibition of S-180 cells. Cytotoxicity was calculated as follows: cytotoxicity (%) = $(OD_T - (OD_S - OD_E))/OD_T \times 100$, where OD_T, OD_S, and OD_E are the optical density values of the target cell control, test sample, and effector cell control, respectively.

Establishment of the S-180 Model. After 1 week of acclimatization, C3H/HeN and C3H/HeJ mice were randomly divided into three experimental groups (n = 8 per group). (i) Normal group: healthy mice without tumor inoculation were gavaged with 0.2 mL of saline. The S-180 model was established as previously reported.[15] Briefly, the S-180 mouse sarcoma cells with ascites were harvested under sterile conditions. A total of 2×10^6 cells suspended in 0.2 mL of sterilized saline were subcutaneously inoculated into mice in the left axillary region. (ii) Control group: after the day of inoculation, the mice were gavaged with 0.2 mL of saline for 10 consecutive days. (iii) PSG-1 group: the mice were gavaged with 0.2 mL of PSG-1 (100 mg/kg body weight) for 10 consecutive days. Twenty-four hours after the last treatment, all the mice were sacrificed by cervical dislocation. Tumors and spleens were extirpated and weighed in germ-free conditions.

Neutral Red Uptake. Phagocytosis of macrophages was determined by the neutral red uptake method as described with minor modification.[16] Briefly, peritoneal macrophages isolated from mice were seeded at a density of 5×10^5 cells/well in the 24-well microplates and cultured for 24 h. After being washed by PBS twice, the cells were incubated with neutral red (50 mg/mL) for another 3 h and washed twice by PBS. The plate was blotted dry, and then 50% ethanol containing 1% glacial acetic acid was added to each well. The absorbance at 540 nm was measured by a microplate reader.

FITC−Dextran Internalization. The FITC−dextran internalization of peritoneal macrophages was determined by flow cytometry. Briefly, peritoneal macrophages (1×10^6 cells/well) were seeded in the 24-well plate, and 1 mg/mL FITC−dextran was added to each well. After incubation at 37 °C for 1 h, the cells were washed three times and resuspended in 500 μL of PBS for flow cytometric analysis.

Measurement of ROS Generation. Peritoneal macrophages were harvested and seeded at a density of 1×10^6 cells/well in the 24-well plate. After incubation with 10 mM CM-DCFH at 37 °C for 30 min in the dark, the cells were washed three times, resuspended in 500 μL of PBS, and then analyzed by flow cytometry.

Measurement of NO Production. NO production was measured according to the manufacturer's instruction. Briefly, peritoneal macrophages (5×10^5 cells/well) were placed in a 96-well plate. After incubation for 48 h, the supernatants were collected and incubated with an equal volume of Griess reagent for 10 min at 25 °C. Nitrite concentrations were calculated by a standard curve.

Western Blot Analysis. The whole-cell protein or nuclear protein was prepared from peritoneal macrophages using a cell lysis kit or nuclear and cytoplasmic extraction kit (Beyotime, Shanghai, China) according to the manufacturer's instructions. A 40 μg mass of denatured protein was loaded onto 10% SDS−polyacrylamide gel by electrophoresis and transferred to a nitrocellulose membrane. Nonfat milk (5%) (prepared in TBS containing 0.1% Tween 20 (TBST)) was used to block nonspecific binding for 1 h at 37 °C. Then the membrane was incubated with specific primary antibodies at 4 °C overnight. After being washed three times with TBST, the membrane was incubated at room temperature for 1 h with secondary antibody, and the signal was analyzed by using a BeyoECL Plus kit (Beyotime, Shanghai, China). Densitometry of the band was analyzed by Quantity One.

Preparation of Splenocytes. The extirpated spleens were minced into small pieces in germ-free conditions. A single-cell suspension was prepared by filtering the suspension through a sterile sieve mesh. The cells were treated with lysis buffer (0.15 M NH_4Cl, 0.01 M $KHCO_3$, and 0.1 mM Na_2EDTA, pH 7.4) to get rid of red blood cells, followed by washing twice with cold PBS. Then the cells were adjusted to a concentration of 5×10^6 cells/mL in RPMI-1640 medium supplemented with 10% fetal calf serum and incubated for 3 h in Petri dishes. The suspended cell populations were collected.

Cytotoxicity Assays of Natural Killer (NK) Cell Activity. Splenocytes were used as the effector cells for splenic NK cell activity assay as described.[17] Briefly, effector cells (5×10^5 cells/well) were cocultured with YAC-1 cells in 96-well microplates at a ratio of 50:1 at 37 °C for 20 h. A 20 μL volume of MTT (5 mg/mL) was added to each well, and then the MTT assay was employed after 4 h of incubation. NK cell activity was calculated via the following equation: cytotoxicity (%) = $(OD_T - (OD_S - OD_E))/OD_T \times 100$, where OD_T, OD_S, and OD_E are the optical density values of the target cell control, test samples, and effector cell control, respectively.

Cytotoxicity Assays of Cytotoxic T Lymphocyte (CTL) Activity. The CTL activity was measured using a method similar to that described above except that S-180 cells and splenocytes were used as target cells and effector cells, respectively, at a ratio of 50:1. CTL activity was calculated via the same equation as described above: cytotoxicity (%) = $(OD_T - (OD_S - OD_E))/OD_T \times 100$.

Cytokine Measurement by ELISA. Levels of IL-2, IFN-γ, and IL-12 were determined by the ELISA kits according to the manufacturer's instructions.

Analysis of Apoptotic Cells. The tumors harvested from S-180-bearing mice were minced into small pieces in germ-free conditions. A single-cell suspension was prepared by filtering the suspension through a sterile sieve mesh. The suspension was washed twice with cold PBS and adjusted to a concentration of 1×10^6 cells/mL. Then the cells were stained with Annexin V−FITC and propidium iodide (PI) for 15 min in the dark and analyzed by flow cytometry (FACS Calibur, Becton Dickinson, United States).

Measurement of Caspase Activities. Caspase-3 and caspase-9 colorimetric assay kits were used to measure the activities of caspase-3 and caspase-9 in S-180 cells. Briefly, 1×10^5 cells/mL were treated with cell lysis buffer for 10 min on ice and centrifuged at 10000g for 8 min. Then the supernatants were incubated with caspase substrate LEHD-AFC for caspase-9 and DEVD-AFC for caspase-3 at 37 °C for 1.5 h. Chromophore p-nitroanilide was measured by a microplate reader at 405 nm.

Statistical Analysis. Values are expressed as means ± SEM. One-way analysis of variance followed by the Student−Newman−Keuls test was used to determine the statistical significance between various groups. A value of $p < 0.05$ was considered to be statistically significant.

RESULTS

PSG-1-Induced Macrophage Cytotoxicity in Vitro Is TLR4-Dependent. To examine the macrophage cytotoxicity induced by PSG-1, peritoneal macrophages from C3H/HeN and C3H/HeJ mice were treated with PSG-1 in vitro and then cocultured with S-180 cells. Cytotoxicity was measured by the MTT method. The cytotoxicity of macrophages derived from C3H/HeN mice was dose-dependently enhanced by PSG-1 ($p < 0.05$), but there was no significant change in C3H/HeJ mice (Figure 1).

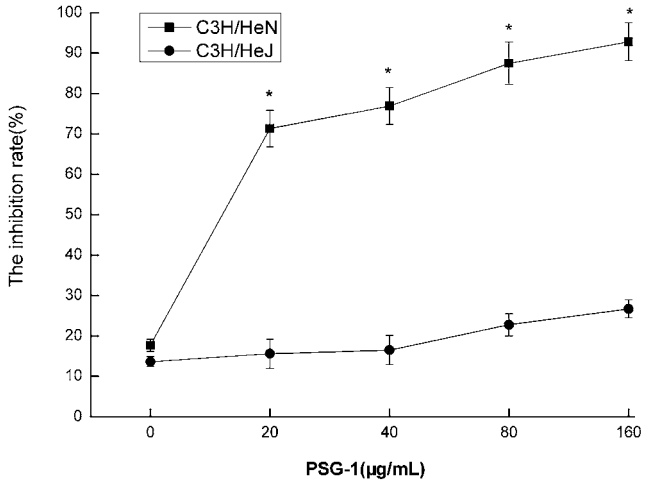

Figure 1. Effect of PSG-1 on macrophage-mediated cytotoxicity against tumor cells. Peritoneal macrophages were isolated from C3H/HeN (wild-type) or C3H/HeJ (TLR4-deficient) mice, cultured with various concentrations of PSG-1 in a 96-well plate for 48 h, and then cocultured with S-180 cells for another 48 h. The inhibition of S-180 cell proliferation was analyzed by the MTT method. These data are the means ± SEM of triplicate determinations. Key: *, $p < 0.05$ versus untreated cells.

Effect of PSG-1 on Macrophage Phagocytosis in TLR4-Deficient and Wild-Type Mice. Phagocytosis of peritoneal macrophages was measured by devouring neutral red. As shown in Figure 2A, there was a significant reduction in macrophage phagocytosis induced in both C3H/HeN and C3H/HeJ control groups compared with the normal groups. After PSG-1 administration, the phagocytic rate of the C3H/HeN mice was significantly increased compared to that of the control group ($p < 0.01$), but there was no significant increase in C3H/HeJ mice.

To confirm the effect of PSG-1 on the phagocytosis of peritoneal macrophages isolated from the S-180-tumor-bearing mice, flow cytometry was employed to analyze the FITC−dextran internalization. As shown in Figure 2B,C, PSG-1 markedly increased the phagocytosis of C3H/HeN mice ($p < 0.01$), but not that of C3H/HeJ mice, compared to that of the control groups.

Effect of PSG-1 on ROS and NO Production of Peritoneal Macrophage in TLR4-Deficient and Wild-Type Mice. As shown in Figure 3A,B the level of ROS in the control group was lower than that in the normal group. However, compared with that in the control group, ROS production was significantly increased in PSG-1-treated C3H/HeN mice. By contrast, no significant increase was recorded in C3H/HeJ mice. Moreover, peritoneal macrophages from C3H/HeN mice treated with PSG-1 exhibited an increase in NO production ($p < 0.01$), but the level of NO production in C3H/HeJ mice treated with PSG-1 showed no significant difference (Figure 3C).

Effect of PSG-1 on MAPK, PI3K/Akt, and NF-κB Pathways in TLR4-Deficient and Wild-Type Mice. To investigate whether the MAPK, PI3K/Akt, and NF-κB signaling pathways were involved in antitumor activity by PSG-1, we examined the effect of PSG-1 on the phosphorylation of ERK1/2, JNK1/2, p38, and Akt and expression of NF-κB in peritoneal macrophages by Western blotting. As shown in Figure 4, compared with those in the normal group, phosphorylation of ERK1/2, JNK1/2, p38, and Akt and expression of NF-κB were significantly decreased in the control group within both C3H/HeN and C3H/HeJ mice. However, significant enhancements in p-ERK1/2, p-JNK1/2, p-p38, p-Akt, and NF-κB levels were observed in C3H/HeN mice administrated with PSG-1, but not in C3H/HeJ mice.

Effect of PSG-1 on NK and CTL Activities in TLR4-Deficient and Wild-Type Mice. As shown in Figure 5A,B, compared with those of the normal group, NK and CTL activities of the control group were significantly decreased in C3H/HeN and C3H/HeJ mice. NK activity in the PSG-1-treated C3H/HeN mice was significantly higher than that in the control group ($p < 0.01$). However, the TLR4-defecient C3H/HeJ mice did not show any increase of NK activity. In addition, PSG-1 treatment enhanced CTL cytotoxicity in C3H/HeN mice compared with that in the control group, but not in C3H/HeJ mice.

Effect of PSG-1 on Cytokine Production of Spleen Lymphocytes in TLR4-Deficient and Wild-Type Mice. As compared to those in the normal group, IL-2, IFN-γ, and IL-12 levels were decreased in the control group in both C3H/HeN and C3H/HeJ mice. However, IL-2, IFN-γ, and IL-12 levels of PSG-1-treated C3H/HeN mice were significantly higher than those of the control group ($p < 0.01$) (Figure 5C). These data suggested that IL-2, IFN-γ, and IL-12 may contribute to the induction of antitumor activity mediated by PSG-1. Moreover, these treatments did not cause cytokine induction in C3H/HeJ mice.

Effect of PSG-1 on Tumor Weight and Apoptosis in TLR4-Deficient and Wild-Type Mice. The tumor weight of C3H/HeN mice treated with PSG-1 was significantly decreased compared to that of the control group ($p < 0.01$). However, no noticeable differences were found among the C3H/HeJ mice receiving different treatments (Figure 6A). Consistent with the above observation, the numbers of apoptotic cells were obviously increased in the tumors in PSG-1-treated C3H/HeN mice, but not in PSG-1-treated C3H/HeJ mice, compared to the control groups (Figure 6B).

Effect of PSG-1 on Caspase Activities in TLR4-Deficient and Wild-Type Mice. As shown in Figure 6C,D, both caspase-3 and caspase-9 activities increased after treatment with PSG-1 in the C3H/HeN mice ($p < 0.01$), but the activities of caspase-3 and caspase-9 were not significantly changed in C3H/HeJ mice.

DISCUSSION

Our previous studies have demonstrated that PSG-1 exerted an antitumor effect by boosting the host immune response.[18] However, the detailed underlying mechanism remains unclear. The present study first evaluated the effect of PSG-1 on macrophage-mediated cytotoxicity of S-180 cells by in vitro experiments using C3H/HeN (wild-type) and C3H/HeJ (TLR4-deficient) mouse-derived peritoneal macrophages. The macrophage cytotoxicity assay results showed that the percentage of apoptosis of S-180 cells was significantly increased

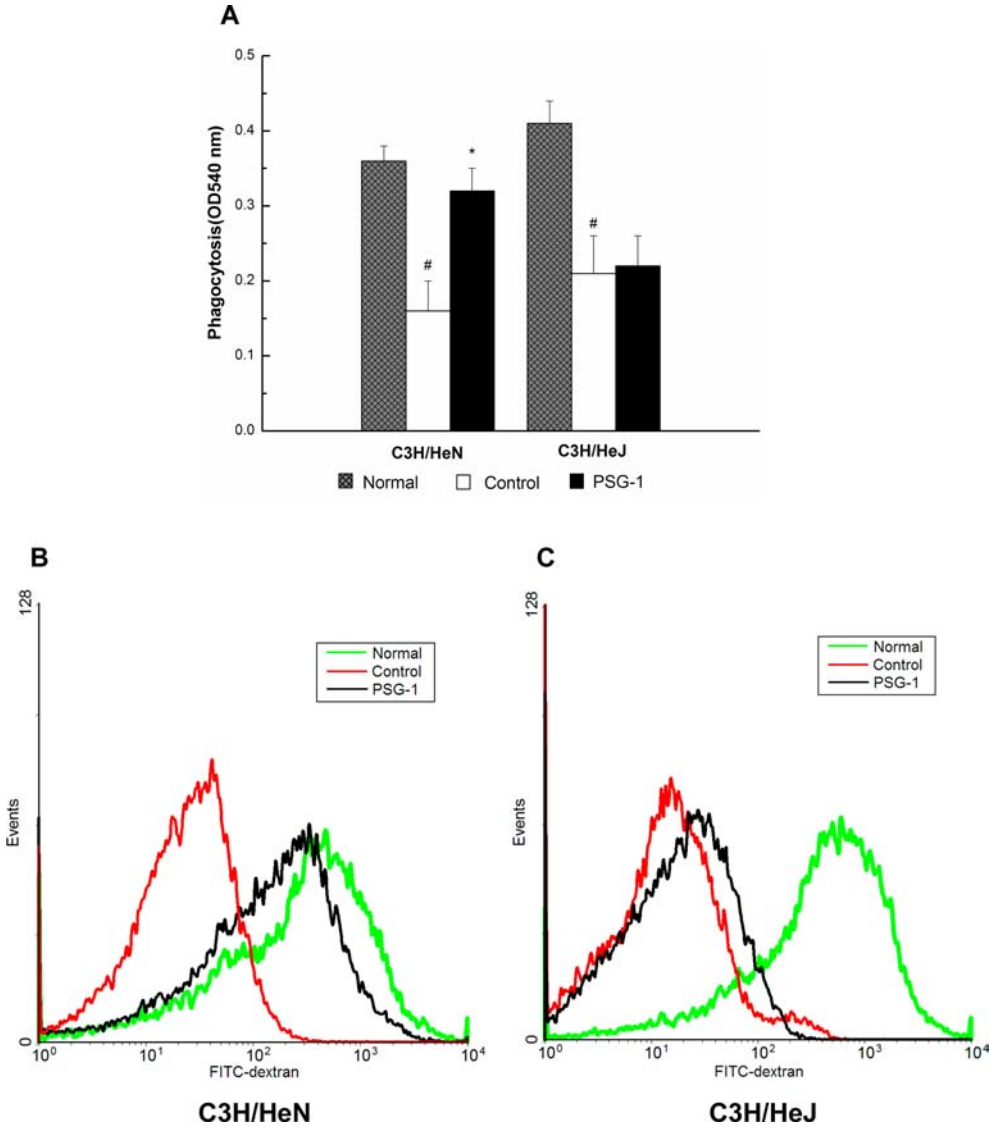

Figure 2. Effect of PSG-1 on macrophage phagocytosis in C3H/HeN (wild-type) and C3H/HeJ (TLR4-deficient) mice. (A) Phagocytosis of peritoneal macrophages was measured by devouring neutral red. Values are the means ± SEM of eight mice. Key: #, $p < 0.01$ versus normal group; *, $p < 0.01$ versus control group. (B, C) The extent of the phagocytic uptake of FITC−dextran was determined by flow cytometry.

in PSG-1-treated C3H/HeN mice but not in C3H/HeJ mice. On the basis of this observation, we hypothesized that TLR4 may be involved in the PSG-1-induced antitumor effect. To further elucidate the role of TLR4 in vivo, we established an S-180 tumor model in C3H/HeN and C3H/HeJ mice to explore the role of TLR4 in the antitumor immune response induced by PSG-1.

Macrophages play a vital role in host innate defense against microbial invaders and malignancies due to the nature of phagocytic, cytotoxic, and intracellular killing capacities.[19] Upon stimulation, the first reaction of macrophages is phagocytosis.[20] Meanwhile, as macrophages are highly secretory cells, they will produce large amounts of anticancer molecules such as NO and ROS, which can induce cytotoxicity of tumor cells.[21] Our data showed that the phagocytosis of peritoneal macrophages was markedly increased by PSG-1 in C3H/HeN mice, but not in C3H/HeJ mice, as evidenced by measuring neutral red uptake and FITC−dextran internalization. Similarly, the elevated release of NO and ROS was only detected in the peritoneal macrophages of C3H/HeN mice.

Given numerous studies have demonstrated that TLR4-mediated macrophage activation via a variety of intracellular signal transduction pathways,[22,23] we next sought to determine whether these pathways were also activated in vivo by PSG-1 administration. MAPKs are a family of serine/threonine protein kinases that include three major groups in mammalian cells, i.e., ERK1/2, JNK1/2, and p38.[24] PI3K and the downstream serine/threonine kinase Akt participate in mediating various cellular responses, such as cell growth, survival, and the trafficking of intracellular organelles.[25,26] Our previous study has demonstrated that MAPK and PI3K/Akt signaling pathways were simultaneously activated in PSG-1-stimulated macrophages. To study the putative effect of PSG-1 on MAPK and PI3K/Akt signaling pathways in S-180-tumor-bearing mice, we performed Western blot to detect the phosphorylation levels of total protein isolated from peritoneal macrophages. The results showed that the phophorylation levels of all three MAPKs and Akt were relatively high in C3H/HeN mice as compared to the control group, whereas no noticeable change was observed in C3H/HeJ mice. Furthermore, NF-κB is a universal transcription factor that regulates the transcription of numerous genes related to innate immunity.[27] Whether NF-κB was involved in the antitumor

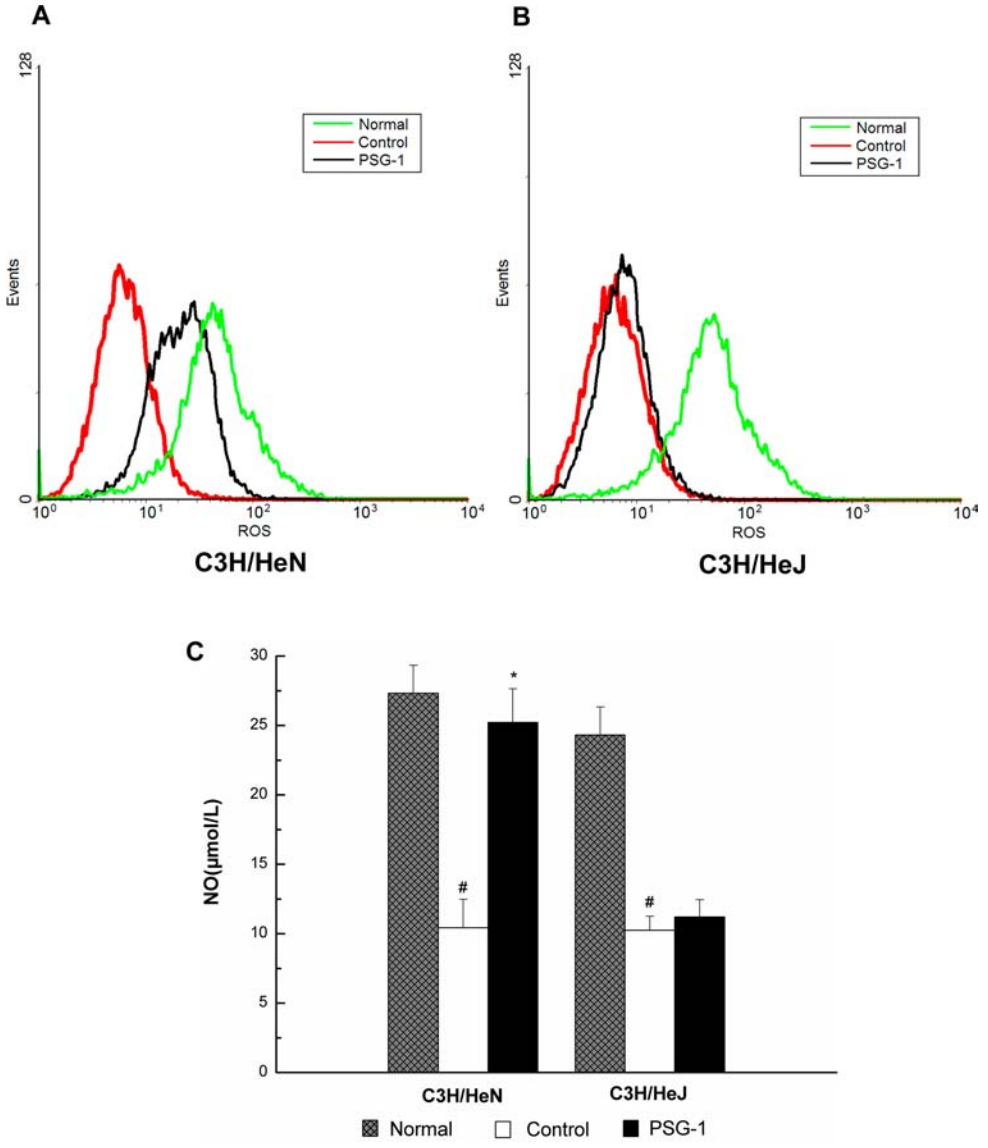

Figure 3. Effect of PSG-1 on ROS and NO production of peritoneal macrophages in C3H/HeN (wild-type) and C3H/HeJ (TLR4-deficient) mice. (A) The expression of fluorescence of 2′,7′-dichlorofluorescein (DCF) in peritoneal macrophages was analyzed by flow cytometry. (B) NO production was measured by the Griess method. Values are the means ± SEM of eight mice. Key: #, $p < 0.01$ versus normal group; *, $p < 0.01$ versus control group.

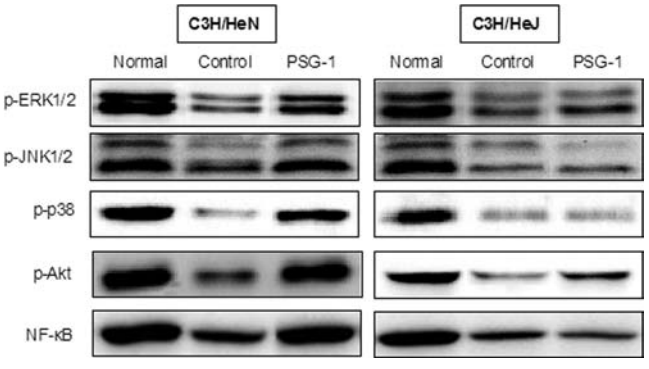

Figure 4. Effect of PSG-1 on the phosphorylation of ERK1/2, JNK1/2, p38, and Akt and expression of NF-κB in C3H/HeN (wild-type) and C3H/HeJ (TLR4-deficient) mice. The whole-cell and nuclear proteins isolated from peritoneal macrophages were analyzed by Western blot with anti-p-ERK1/2, anti-p-JNK1/2, anti-p-p38, anti-p-Akt, and anti-NF-κB antibodies.

immunity triggered by PSG-1 administration was investigated. As expected, enhanced NF-κB expression in the nucleus was detected in the peritoneal macrophage derived from C3H/HeN mice, but not C3H/HeJ mice. The above results indicated that PSG-1 elicited an antitumor effect by activating peritoneal macrophages and TLR4 was involved in antitumor innate immunity induced by PSG-1.

It is well documented that macrophages are the bridge cells between innate and adaptive immune responses.[28] After phagocytosis, macrophages will turn into antigen-presenting cells and then orchestrate the adaptive response by mediating lymphocytes.[29,30] Therefore, we focused on the effect of PSG-1 administration on spleen lymphocytes in S-180-tumor-bearing mice.

CTL and NK cells are known as two major populations of lymphocytes that are capable of killing tumor cells.[31] The cytotoxic activities of CTL and NK cells derived from spleen lymphocytes were analyzed. Although cytotoxic activities of C3H/HeN mouse-derived CTL against S-180 cells were

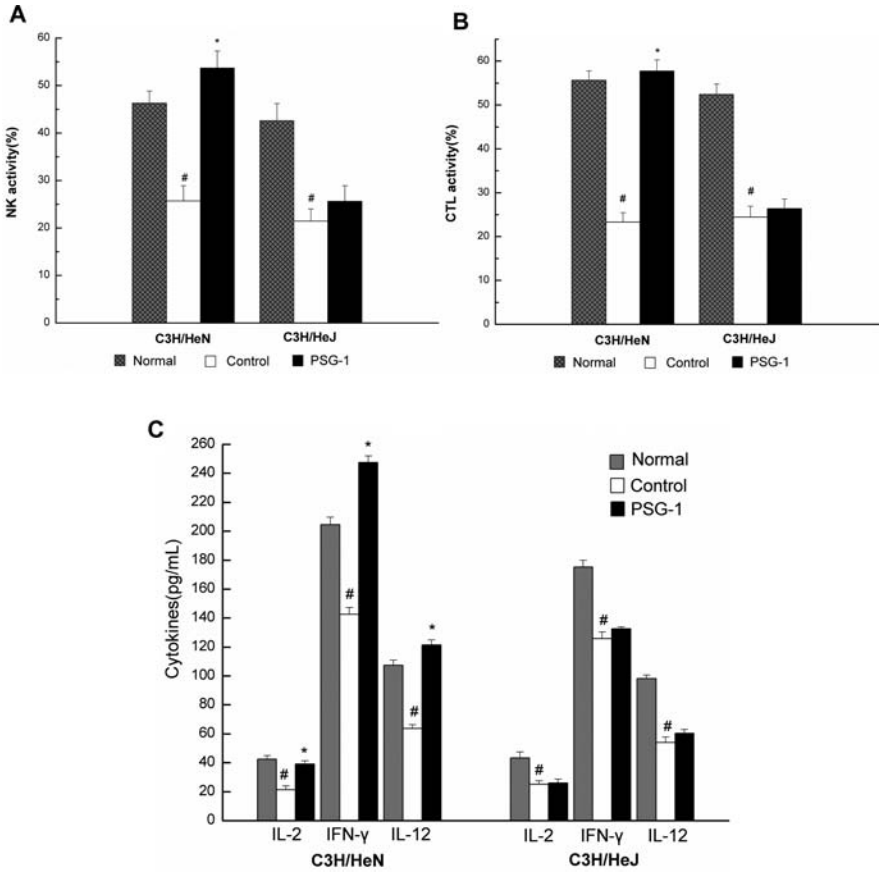

Figure 5. Effect of PSG-1 on NK and CTL activities and cytokine production of spleen lymphocytes in C3H/HeN (wild-type) and C3H/HeJ (TLR4-deficient) mice. (A, B) NK and CTL activities were evaluated by the cytotoxic activities of the spleen cells against YAC-1 cells (A) and S-180 tumor cells (B) ex vivo using the MTT method. (C) The production of cytokines was measured by ELISA. Values are the means ± SEM of eight mice. Key: #, $p < 0.01$ versus normal group; *, $p < 0.01$ versus control group.

significantly enhanced by PSG-1 treatment, the cytotoxic activities were not enhanced in C3H/HeJ mice. The function of NK cells is similar to that of CTL cells; however, unlike CTL, the killing by NK cells is nonspecific.[32] In the cytotoxic activities of NK cells, similar results were obtained. In nonspecific killing of the cells against YAC-1, cytolysis of C3H/HeN mouse-derived NK cells against YAC-1 was enhanced by PSG-1 treatment. Nonspecific killing activity of C3H/HeJ-derived NK cells was not increased by PSG-1 administration. These results displayed that NK and tumor-specific CTL activities were augmented by oral administration of PSG-1 via TLR4 stimulation.

Mounting evidence established that cytokines produced by T cells play an essential part in influencing the immune response toward protective antitumor immunity.[33] On the basis of the difference in secretion of cytokines, T helper (Th) lymphocytes are divided into Th1 and Th2 cells.[34] Hallmark Th1 cytokines, including IL-2, IFN-γ, and IL-12, are considered as characteristic of adaptive immunity.[35] The antitumor activities of IL-2, IFN-γ, and IL-12 have been extensively reported in murine tumor models.[36] Our present study showed that PSG-1 enhanced the production of IL-2, IFN-γ, and IL-12 and polarized the T-cell response to a Th1-dominant state in TLR4 wild-type mice, but not in TLR4-deficient mice, indicating that TLR4 plays an important role in the regulation of PSG-1-induced host antitumor adaptive immunity in tumor-bearing mice.

Apoptosis is the process of programmed cell death; it occurs normally as a homeostatic mechanism to maintain cell populations. Inappropriate apoptosis would promote carcinogenesis and tumor progression.[37] Caspases are a family of cysteine proteases that transduce the apoptotic signal cascade. Caspase-3 is known as a vital effector that is activated by caspase-9 via the mitochondrial pathway.[38] Our previous research has demonstrated that PSG-1 significantly inhibited tumor growth and promoted tumor apoptosis via mitochondrial pathways. Consistent with those findings, the current study found that C3H/HeN mice treated with PSG-1 had less tumor weight than the control mice. Moreover, the apoptosis rate and caspase-3 and caspase-9 activities of tumor derived from the C3H/HeN mice treated with PSG-1 were significantly increased compared with those of tumor derived from mice treated with vehicle. However, there were no significant differences in C3H/HeJ mice. We are therefore left with the important question of how TLR4 affects the tumor apoptosis triggered by PSG-1.

It is well-known that NO is a key effector molecule in macrophages.[39] However, there is accumulating evidence that NO not only plays a role in host defenses against tumor cells, but also is involved in the regulation of apoptosis. Apoptosis induced by NO occurs in diverse types of cells.[40−42] In addition, it has been demonstrated that caspase-3 and caspase-9 are central components in a cascade triggered by NO.[43] Considering our result has shown that PSG-1 induced NO release in peritoneal macrophages derived from the C3H/HeN mice, we speculated that NO released from PSG-1-activated macrophages may lead to an increase of caspase-3 and caspase-9 activities, resulting in

apoptosis of tumor cells. However, the potential mechanisms may be complex, so more detailed investigation is needed.

Overall, the results presented in this paper displayed that PSG-1 elicited antitumor activity in vivo in a TLR4-dependent manner, and TLR4-mediated activation of innate and adaptive immunity was involved in antitumor immunity induced by PSG-1. These observations revealed the therapeutic potential of PSG-1 as a novel compound for cancer immunotherapy.

Novel Insights into the Inhibitory Mechanism of Kaempferol on Xanthine Oxidase

Yajie Wang,[†] Guowen Zhang,*[,†] Junhui Pan,[†] and Deming Gong[‡]

[†]State Key Laboratory of Food Science and Technology, Nanchang University, Nanchang 330047, China

[‡]School of Biological Sciences, The University of Auckland, Auckland 1142, New Zealand

ABSTRACT: Xanthine oxidase (XO), a key enzyme in purine catabolism, is widely distributed in human tissues. It can catalyze xanthine to generate uric acid and cause hyperuricemia and gout. Inhibition kinetics assay showed that kaempferol inhibited XO activity reversibly in a competitive manner. Strong fluorescence quenching and conformational changes of XO were found due to the formation of a kaempferol−XO complex, which was driven mainly by hydrophobic forces. The molecular docking further revealed that kaempferol inserted into the hydrophobic cavity of XO to interact with some amino acid residues. The main inhibition mechanism of kaempferol on XO activity may be due to the insertion of kaempferol into the active site of XO occupying the catalytic center of the enzyme to avoid the entrance of the substrate and inducing conformational changes of XO. In addition, luteolin exhibited a stronger synergistic effect with kaempferol than did morin at the lower concentration.

KEYWORDS: *xanthine oxidase, kaempferol, inhibition mechanism, spectroscopy, molecular simulation*

INTRODUCTION

Xanthine oxidase (XO), a key enzyme in purine metabolism, is widely distributed in mammalian tissues.[1] Structurally, XO is a 290 kDa homodimer with each of the monomers acting independently during catalysis. Each subunit is composed of one molybdopterin cofactor, one flavin adenine dinucleotide (FAD) cofactor, and two distinct [2Fe−2S] centers.[2] The oxidation of xanthine occurs at the molybdopterin center (Mo-pt), and the electrons thus introduced are rapidly distributed to the other centers by intramolecular electron transfer.[3] Previous studies have shown that milk can inhibit the metabolic activity of *Escherichia coli* depending on the presence of XO,[4] but the excess of XO will lead to the oxidation and rancidity of milk in the processing process of dairy products.[5] On the other hand, XO catalyzes the terminal two steps in purine catabolism (hypoxanthine → xanthine → uric acid) in the human body, and the overproduction or underexcretion of uric acid plays a vital role in disorders such as hyperuricemia, which is a key cause of gout.[6] In addition, hyperuricemia has become an independent risk of chronic kidney disease and cardiovascular disease.[7] Obviously, maintaining uric acid in normal levels is the important therapy for the prevention of gout and other disorders.

For most patients with primary gout, uric acid overproduction is one of the major factors of hyperuricemia.[7] Increasing the excretion of uric acid or reducing uric acid production is the major therapeutic pathway for hyperuricemia.[8] Because of uric acid production resulting from the oxidation of xanthine by XO, the inhibition of XO activity has been regarded as one of the promising targets for the treatment of hyperuricemia.[9] As a powerful XO inhibitor, allopurinol has been widely used in clinic, but it also exhibits serious side effects such as hypersensitivity syndrome, impaired liver function, and renal toxicity.[8,10] Thus, finding new XO inhibitors with minor side effects as alternatives to allopurinol is of great importance.

Flavonoids are a large group of polyphenolic natural products that are widely distributed in various foods and beverages of plant origin.[11] These compounds are increasingly recognized as possessing a broad spectrum of biological activities and important therapeutic effects.[12−14] Interestingly, many biologically active flavonoids appear to have effects on various proteins, including enzymes.[15] Because of the low toxicity, XO inhibitory activities of flavonoids have attracted extensive attention. Kaempferol (3,5,7,4′-pentahydroxyflavone, structure shown in Figure 1A), a major flavonoid compound in the diet that contributes 22−29% of total flavonoid intake,[16] widely existed in daily food such as vegetables (pumpkin, snake gourd, bunga kantan, etc.) and fruits (chokeberry, strawberry, etc.) as well as teas and Chinese herbal medicine.[17,18] Investigations have shown that kaempferol exhibits a wide range of biological activities including antioxidant, anti-inflammatory, anticoagulant, and cardiovascular-protective effects.[19] Previous studies have also found that kaempferol possesses significant XO inhibitory activity in vitro;[20] this provides the basis for the application research of kaempferol as a XO inhibitor and a food functional ingredient; however, to the best of our knowledge, its inhibitory mechanism on XO is still obscure.

The main goal of pharmacotherapy using a combination of different drugs with similar effects is to increase the efficacy of the treatment while decreasing its toxicity. Fernández et al.[21] have reported that hesperidin and diazepam showed the synergy in terms of sedative and sleeping; thus, the use of hesperidin may decrease the effective therapeutic doses of diazepam. Both morin and luteolin are flavonoid compounds with a similar structure as kaempferol, and previous studies have shown that they exerted a significant inhibitory action on

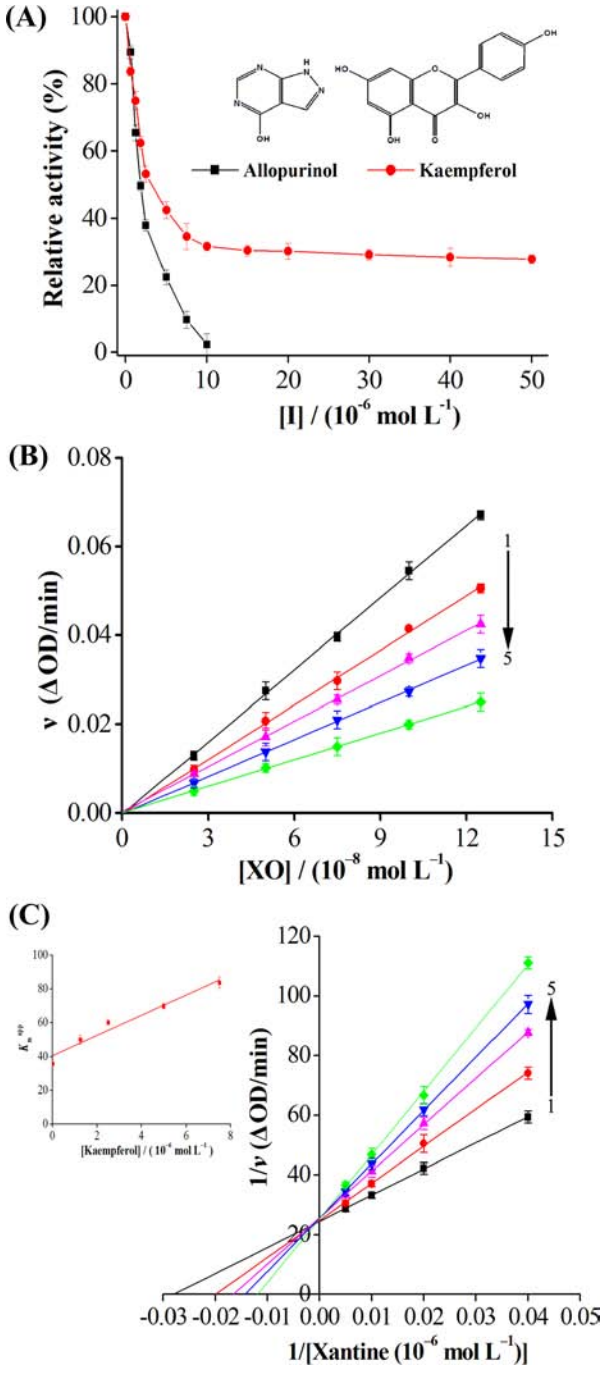

Figure 1. (A) Effect of kaempferol on XO activity (pH 7.5, T = 298 K). The inset shows the molecular structures of allopurinol and kaempferol. The final concentrations of xanthine and XO were 5.0 × 10^{-5} mol L^{-1} and 7.5 × 10^{-8} mol L^{-1}, respectively. (B) Plots of ν versus [XO]. c(xanthine) = 5.0 × 10^{-5} mol L^{-1}, c(kaempferol) = 0, 1.25, 2.5, 5.0, and 7.5 × 10^{-6} mol L^{-1} for curves 1 → 5, respectively. (C) Lineweaver–Burk plots. c(XO) = 7.5 × 10^{-8} mol L^{-1}, c(kaempferol) = 0, 1.25, 2.5, 5.0, and 7.5 × 10^{-6} mol L^{-1} for curves 1 → 5, respectively. The secondary plot represents the K_m^{app} versus [Kaempferol] (the upper left). Each value represents mean ± standard deviation (n = 3); $p < 0.05$ was considered to be statistically significant.

XO activity with a mixed type and a competitive manner, respectively.[22,23] Does each of them affect kaempferol inhibition on XO activity?

The aim of this work was to explore the inhibitory activity and type, explore the inhibitory mechanism of kaempferol on XO, and investigate the effects of morin or luteolin on kaempferol inhibiting XO activity in vitro using UV–vis absorption, fluorescence, circular dichroism (CD), and molecular docking methods. This study is expected to benefit further understanding of the inhibitory mechanism of kaempferol on XO and provide new insights into the applications of kaempferol as a XO inhibitor and a food functional ingredient.

MATERIALS AND METHODS

Materials. XO (EC 1.17.3.2, 35.7 units mL^{-1}) from bovine milk was obtained from Sigma-Aldrich Co. (St, Louis, USA). Xanthine was purchased from Sigma-Aldrich Co. (St, Louis, USA). Both of the stock solutions of XO (0.5 units mL^{-1}) and xanthine (5.0 × 10^{-4} mol L^{-1}) were prepared with 0.05 mol L^{-1} sodium phosphate buffer (pH 7.5). Kaempferol (analytical grade) was obtained from Aladdin Chemistry Co. (Shanghai, China), and its stock solution (5.0 × 10^{-3} mol L^{-1}) was prepared by dissolving its crystals in methanol and was diluted with the sodium phosphate buffer in the whole experiment process, but the contents of methanol were kept at less than 1% so that methanol had no effect on the activity and structure of XO. All stock solutions were stored at 0–4 °C and diluted to the required concentrations with the buffer. All other chemicals were of analytical reagent grade, and their aqueous solutions were prepared with freshly ultrapure water.

Enzyme Activity Assay. XO activity was measured by a UV–2450 spectrophotometer (Shimadzu, Japan) using a 1.0 cm quartz cell in a manner similar to that described by Tung et al.[24] with slight modifications. In the 2.0 mL reaction system, a series of assay solutions dissolved in 0.05 mol L^{-1} sodium phosphate buffer (pH 7.5) containing various amount of kaempferol and a fixed concentration of XO (7.5 × 10^{-8} mol L^{-1}) were incubated for 3 h at 37 °C to make the reaction equilibrium, and the assay was initiated by adding the substrate xanthine (the final concentration was 5.0 × 10^{-5} mol L^{-1}) to the complex solutions. The absorbance at 295 nm was then determined every 20 s at room temperature. Allopurinol was used as a positive control. The relative enzymatic activity was calculated as follows: the relative enzymatic activity (%) = (slope of reaction kinetics equation obtained by reaction with inhibitor)/(slope of reaction kinetics equation obtained by reaction without inhibitor) × 100.[25]

Kinetic Analysis for Inhibition Type. The assay was carried out in the absence and presence of kaempferol with varying concentrations of substrate xanthine using the same method as XO activity assay. The involved inhibition type was determined by the Lineweaver–Burk plot. For competitive inhibition, the Lineweaver–Burk equation can be written in double reciprocal form as follows:

$$\frac{1}{\nu} = \frac{K_m}{V_{max}}\left(1 + \frac{[I]}{K_i}\right)\frac{1}{[S]} + \frac{1}{V_{max}} \quad (1)$$

Secondary plot can be constructed from

$$K_m^{app} = \frac{K_m[I]}{K_i} + K_m \quad (2)$$

where ν is the enzyme reaction rate in the absence and presence of kaempferol. K_i and K_m represent the inhibition constant and Michaelis–Menten constant, respectively, and their values can be obtained from eqs 1 and 2. [I] and [S] are the concentrations of the inhibitor and substrate, respectively. K_m^{app} is the apparent Michaelis–Menten constant. The secondary plot of K_m^{app} versus [I] is linearly fitted, assuming a single inhibition site or a single class of inhibition site.[26]

Fluorometric Titration Experiments. A 2.0 mL sample of XO solution (4.0 × 10^{-7} mol L^{-1}) was added accurately to the quartz cell and then titrated by successive addition of 2.5 × 10^{-4} mol L^{-1} diluted kaempferol solution (to give a concentration range from 0–13.03 × 10^{-6} mol L^{-1}) with a microsyringe. Titrations were operated manually

DOI: 10.1021/jf505584m
J. Agric. Food Chem. 2015, 63, 526–534

and mixed moderately. These solutions were allowed to stand for 5 min to equilibrate, and then the fluorescence emission spectra were measured at 298, 304, and 310 K using a Hitachi spectrofluorimeter (Model F-7000, Hitachi, Japan) equipped with a 150 W xenon lamp and a thermostat bath. The excitation wavelength was 280 nm, and the excitation and emission bandwidths were both set at 2.5 nm. Appropriate blanks corresponding to the sodium phosphate buffer (pH 7.5) were subtracted to correct fluorescence background.

Synchronous fluorescence spectra were recorded by setting the excitation and emission wavelength interval ($\Delta\lambda$) at 15 and 60 nm over a wavelength range of 270−330 nm and 250−330 nm, respectively.

All the fluorescence data in this study were corrected for absorption of excitation light and reabsorption of emitted light according to the following relationship:[27]

$$F_c = F_m e^{(A_1+A_2)/2} \quad (3)$$

where F_c and F_m represent the corrected and measured fluorescence, respectively. A_1 and A_2 are the absorbance of kaempferol at excitation and emission wavelengths, respectively.

Circular Dichroism Analysis. The CD spectra of XO with increasing concentration of kaempferol were recorded at wavelengths between 190 and 250 nm on a Bio-Logic MOS 450 CD spectrometer (Bio-Logic, Claix, France) using a 1.0 mm quartz curet under constant nitrogen flush. The concentration of XO was kept at 1.0×10^{-6} mol L^{-1}, and the molar ratios of kaempferol to XO were varied as 0:1, 5:1, and 10:1. All observed CD spectra were measured in pH 7.5 sodium phosphate buffer at room temperature, and the buffer signal was subtracted. The online SELCON3 program was used to analyze the CD spectroscopic data to obtain the contents of different secondary structures of XO (http://dichroweb.cryst.bbk.ac.uk/html/home.shtml).

Molecular Simulation. The X-ray crystal structure of XO from bovine milk (PDB ID: 3ETR) was downloaded from the RCSB Protein Data Bank (http://www.rcsb.org/pdb).[28] The water molecules in XO were removed, whereas polar hydrogen atoms and Gasteiger charges were added to the macromolecule file for the preparation of docking running. The 3D structure of kaempferol was generated in Chem3D Ultra 8.0. The molecular docking studies were carried out by the MGL tools 1.5.6 with AutoGrid4 and AutoDock4. Docking calculations were performed using the default parameters, except for the number of GA runs (100 times) and the Lamarkian genetic algorithm with local search. To implement docking simulations, a grid box was defined with dimensions of 110 Å × 100 Å × 110 Å and a grid spacing of 0.403 Å. From the docking results, the best scoring docked model of a complex was chosen to represent its most favorable binding mode predicted by AutoDock. The outputs were further rendered with Pymol to obtain visible combination models.

Interaction Assay of Kaempferol with Morin or Luteolin on XO Activity. The interaction assay of kaempferol with morin or luteolin on XO activity was performed according to a previous report with slight modifications.[29] V_a and V_b are defined as the relative enzymatic activity in the presence of kaempferol and morin (or luteolin), respectively. V_{ab} represents the relative enzymatic activity in the presence of kaempferol and morin (or kaempferol and luteolin). If the inhibitory effect on XO of kaempferol with morin (or luteolin) is independent, the expected relative remnant activity of XO, V_c ($V_c = V_a \times V_b$) is equal to V_{ab}, and the combined effect is termed additive. In the data analysis for determining the type of interaction between kaempferol and morin or luteolin, only the values of $V_{ab} - V_c$ below −0.10 were regarded as synergistic (SY), and the values between −0.10 and +0.10 were considered as additive (AD).

Statistical Analysis. Data were analyzed using the SAS statistical package (version 8.1, SAS Institute, Cary, NC, USA). Obtained results including XO activity and inhibition type were expressed as means ± standard deviation (n = 3). One-way analysis of variance (ANOVA) was performed by using Origin 8.0 followed by multiple tests in order to determine the significant difference at $p < 0.05$.

RESULTS AND DISCUSSION

Inhibition of Kaempferol on XO Activity. As shown in Figure 1, panel A, the addition of kaempferol from 0−1.0×10^{-5} mol L^{-1} was found to dramatically decrease XO activity to approximately 30%, and then the decreasing tendency of XO activity was very slow with increasing amounts of the inhibitor. The concentration of kaempferol that resulted in a loss of 50% enzyme activity (IC_{50}) was determined to be $(2.18 \pm 0.02) \times 10^{-6}$ mol L^{-1} (allopurinol was $(1.79 \pm 0.02) \times 10^{-6}$ mol L^{-1}), which indicates that kaempferol was an effective XO inhibitor compared to allopurinol (positive control). This is due to the C-5 and C-7 hydroxyl groups in kaempferol that play an important role in inhibition.[30] As reported earlier, morin and luteolin with a similar structure as kaempferol have shown inhibition on XO activity with IC_{50} $(13.54 \pm 0.02) \times 10^{-6}$ mol L^{-1} and $(4.79 \pm 0.02) \times 10^{-6}$ mol L^{-1}, respectively.[22,23] It is likely that the meta-position hydroxyl groups on the B ring of flavonoid would decrease the electron cloud density of band I, which impacted the interaction of morin with XO negatively; thus, the inhibition of morin on XO was weaker than that of kaempferol. In contrast, the ortho-position hydroxyl groups on the B ring were in favor of the flavonoid−XO inteaction, which would enhance the inhibition of flavonoid on XO since luteolin showed better inhibition on XO than morin. The IC_{50} value of kaempferol was smaller than that of luteolin, this may be attributed to the 3-hydroxyl group of kaempferol, which was in favor of the distribution of the electron cloud and made the electronegativity of kaempferol increased.[31]

Reversibility. As shown in Figure 1, panel B, the plots of the ν versus [XO] at different kaempferol concentrations were constructed to confirm the reversibility of kaempferol mediated inhibition. The plots showed good linearity, and all passed the origin; moreover, the slope of the lines decreased with increased concentration of kaempferol, which indicates that the presence of kaempferol did not decrease the amount of efficient enzyme available, but it resulted in the inhibition of XO and an overall decrease of enzyme activity with respect to the oxidation of xanthine. These results suggested that the inhibition of kaempferol on XO was reversible and a noncovalent intermolecular interaction between kaempferol and XO.[32]

Inhibition Type. The Lineweaver−Burk double reciprocal plots were used to analyze the inhibition type of kaempferol on XO activity. The horizontal axis intercept ($-1/K_m$) increased and the vertical axis intercept ($1/V_{max}$) remained the same with increasing amounts of kaempferol (Figure 1C), which suggests that kaempferol caused a typical competitive inhibition[33] and that kaempferol may directly bind to the active site of XO competing with xanthine during catalysis. The inset of Figure 1, panel C showed the linear relationship between K_m^{app} and the concentration of kaempferol, which suggested that there was a single class of inhibition sites for kaempferol on XO. The value of inhibition constant (K_i) was calculated to be $(6.77 \pm 1.02) \times 10^{-6}$ mol L^{-1}.

Fluorescence Quenching of XO by Kaempferol. The above studies suggested that kaempferol may directly bind to the active site of XO to inhibit the enzyme activity. Therefore, fluorescence spectroscopy was further used to characterize the binding between kaempferol and XO. Figure 2, panel A shows the fluorescence emission spectra of XO with varying concentrations of kaempferol after being excited at a wavelength of 280 nm. The XO displayed a strong emission peak at

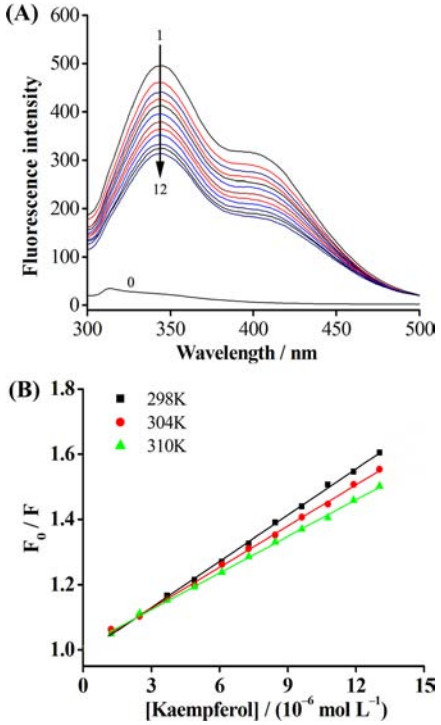

Figure 2. (A) Fluorescence spectra of XO in the absence and presence of kaempferol at different concentrations (pH 7.5, T = 298 K, λ_{ex} = 280 nm). c(XO) = 4.0 × 10^{-7} mol L^{-1}, and c(kaempferol) = 0, 1.24, 2.48, 3.69, 4.90, 6.10, 7.28, 8.45, 9.62, 10.77, 11.90, and 13.03 × 10^{-6} mol L^{-1} for curves 1 → 12, respectively. Curve 0 showed the emission spectrum of kaempfrol only, c(kaempferol) = 13.03 × 10^{-6} mol L^{-1}. (B) Stern−Volmer plots for the fluorescence quenching of XO by kaempferol at different temperatures.

342 nm, which resulted from the tryptophan and tyrosine residues of XO.[34] With increasing the amounts of kaempferol, the fluorescence emission peak of XO decreased significantly and regularly with no shift of the emission peak's position, which indicated that kaempferol interacted with XO and quenched the intrinsic fluorescence of XO.

Generally, fluorophore quenching can occur by different mechanisms, namely dynamic and static quenching processes. The static quenching is caused by the formation of the ground state complex, while the dynamic quenching is due to the collision between the fluorophore and the quencher. These two types of mechanisms can be distinguished by their different dependence on temperature or excited-state lifetime.[35] To determine the quenching mechanism of kaempferol binding to XO, the fluorescence quenching data were analyzed using the Stern−Volmer equation:[34]

$$\frac{F_0}{F} = 1 + K_{SV}[Q] = 1 + K_q\tau_0[Q] \quad (4)$$

where F_0 and F denote the steady-state fluorescence intensities of XO in the absence and presence of kaempferol, respectively. K_{SV} is the Stern−Volmer dynamic quenching constant, which was determined by linear regression of a plot of F_0/F against [Q]. K_q is the quenching rate constant of the biomolecule ($K_q = K_{SV}/\tau_0$). τ_0 is the average lifetime of the fluorophore without quencher, which is equal to 2.80 × 10^{-9} s.[36] [Q] is the concentration of kaempferol.

The plots of F_0/F versus [Q] at three different temperatures (298, 304, and 310 K) are shown in Figure 2, panel B, and the corresponding K_{SV} values for the complexation of kaempferol with XO are given in Table 1. A high linearity suggested that only one type of quenching process occurred, either static or dynamic quenching.[37] The K_{SV} values clearly displayed a decreasing tendency with increasing temperature, and the calculated K_q values at 298, 304, and 310 K were 1.69 × 10^{13}, 1.50 × 10^{13}, and 1.33 × 10^{13} L mol^{-1} s^{-1}, respectively, which were considerably greater than the maximum scatter collision quenching constant of various quenchers with biopolymers, 2.0 × 10^{10} L mol^{-1} s^{-1},[38] which indicates that the mechanism of the fluorescence quenching of XO was static and resulted from the formation of a kaempferol−XO complex.[39]

Then, the fluorescence titration data were further estimated to obtain the association constant (K_a) using the modified Stern−Volmer equation:[40]

$$\frac{F_0}{F_0 - F} = \frac{1}{f_a K_a[Q]} + \frac{1}{f_a} \quad (5)$$

where f_a is the fraction of accessible fluorescence. From the linear regression of $F_0/(F_0-F)$ versus $1/[Q]$, the values of K_a for the kaempferol−XO complex at three different temperatures are calculated (Table 1). The K_a values were in the order of 10^4 L mol^{-1}, which suggested that a moderate affinity existed between kaempferol and XO.

Thermodynamic Characteristics of Interactions. Generally, small ligands bind to biomolecules mainly through hydrogen bonds, van der Waals forces, hydrophobic interactions, and electrostatic forces. Determination of the thermodynamic parameters (enthalpy change $\Delta H°$, entropy change $\Delta S°$) can clarify the acting force of the binding interaction between kaempferol and XO, which was evaluated by the van't Hoff equation:

$$\log K_a = -\frac{\Delta H°}{2.303RT} + \frac{\Delta S°}{2.303R} \quad (6)$$

where R is the gas constant (8.314 J mol^{-1} K^{-1}), and T represents the experimental temperatures at 298, 304, and 310 K. By plotting log K_a versus $1/T$, $\Delta H°$ and $\Delta S°$ were determined. By knowing the $\Delta H°$ and $\Delta S°$ values, the free energy change ($\Delta G°$) can be calculated from the following equation:

$$\Delta G° = \Delta H° - T\Delta S° \quad (7)$$

Table 1. Quenching Constants K_{SV}, Modified Stern−Volmer Association Constants K_a, and Relative Thermodynamic Parameters for the Interaction between Kaempferol and XO at Different Temperatures

T (K)	K_{SV} (× 10^4 L mol^{-1})	R^a	K_a (× 10^4 L mol^{-1})	R^b	n	$\Delta H°$ (kJ mol^{-1})	$\Delta G°$ (kJ mol^{-1})	$\Delta S°$ (J mol^{-1} K^{-1})
298	4.72	0.9996	3.22	0.9992	1.04	49.45	−25.56	251.70
304	4.20	0.9993	3.90	0.9995	0.95		−27.07	
310	3.73	0.9994	6.99	0.9972	0.95		−28.58	

[a] R is the correlation coefficient for the K_{SV} values. [b] R is the correlation coefficient for the K_a values.

J. Agric. Food Chem. 2015, 63, 526−534

As shown in Table 1, the negative sign for ΔG° suggested that the kaempferol−XO binding interaction was spontaneous. The positive values of ΔH° and ΔS° indicated that the formation of kaempferol−XO complex was endothermic, and the values were frequently regarded as a typical evidence for hydrophobic interactions.[41] Thus, the kaempferol−XO complexation was driven mainly by hydrophobic forces.

Number of Binding Sites of Kaempferol on XO. For the static quenching interaction, when small molecules bind independently to a set of equivalent sites on a macromolecule, the number of binding sites (n) and binding constant (K_b) for the kaempferol−XO complex can be calculated from the slope and intercept of the regression curve of log $(F_0 - F)/F$ versus log$1/([Q_t] - (F_0 - F)[P_t]/F_0)$:[42]

$$\log \frac{F_0 - F}{F} = n \log K_b - n \log \frac{1}{[Q_t] - \frac{(F_0 - F)[P_t]}{F_0}} \quad (8)$$

where $[Q_t]$ and $[P_t]$ are the total concentrations of kaempferol and XO, respectively. As shown in Table 1, the values of n were approximately equal to 1, which suggested the existence of one binding site for kaempferol on XO, which was consistent with the results of inhibition-type studies. The K_b values of the kaempferol−XO complex were 4.79×10^4, 4.00×10^4, and 6.28×10^4 L mol^{-1} at 298, 304, and 310 K, respectivily, which were in accordance with the values of K_a at the corresponding temperatures.

Conformational Change of XO, Kaempferol Induced. Synchronous fluorescence spectroscopy can provide information about the alterations in the microenvironment around fluorophores of XO, which are related to the conformational changes of the enzyme. As shown in Figure 3, panels A and B, the maximum emission wavelength of both tyrosine and tryptophan residues had a slight red shift from 293−295 nm and from 285−286 nm, respectively, which suggest that the polarity around the tyrosine and tryptophan residues increased and the hydrophobicity decreased; namely, the fluorophores of XO were placed in a less hydrophobic environment and more exposed to the solvent with the addition of kaempferol.[43]

CD spectroscopy was performed to further monitor the conformational change of XO induced by kaempferol. As shown in Figure 3, panel C, the spectra of XO exhibited a negative band in the UV region at 216 nm, which is characteristic of β-sheet structure of protein.[44] The CD intensity of XO increased (shifting away from zero level) without any significant shift of peak's position upon increasing the concentration of kaempferol, which indicates that the secondary structure content of β-sheet increased and was also predominant in XO conformation after binding with kaempferol.[34] A similar phenomenon has been reported in the interaction of bixin with β-lactoglobulin.[45] The contents of different secondary structures of XO were analyzed with the use of the online SELCON3 program (Table 2). Compared with the free XO, it exhibited an increase in β-sheet and β-turn contents from 40.6% and 10.8% to 44.9% and 12.2%, respectively, and a decrease in α-helical and random coil structure contents from 13.2% and 35.4% to 9.5% and 33.4%, respectively, at a molar ratio of kaempferol to XO of 10:1. These results indicated that the binding of kaempferol to XO might have destroyed its hydrogen bonding networks[46] and induced minor unfolding of the polypeptides of the enzyme because of the loss of α-helical content.[27] It might be part of the mechanism of the enzymatic inhibition that the unfolding of

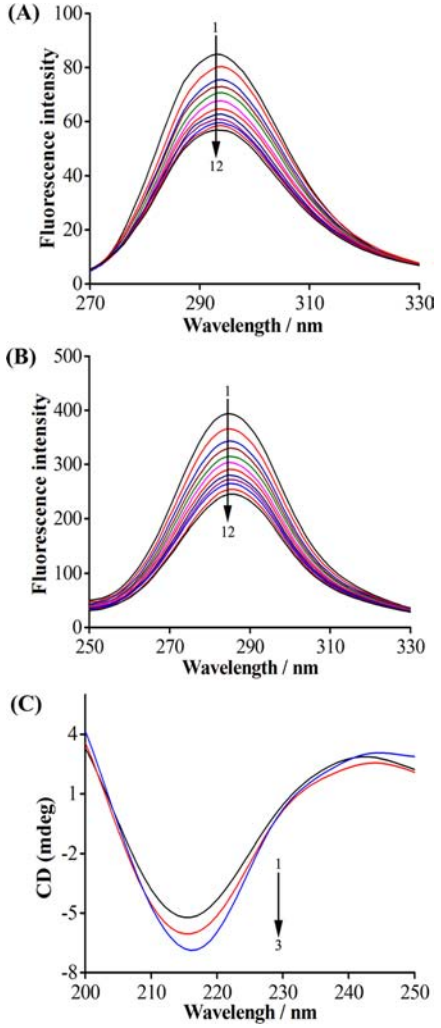

Figure 3. Synchronous fluorescence spectra of XO in the absence and presence of kaempferol (A) $\Delta\lambda$ = 15 nm, (B) $\Delta\lambda$ = 60 nm (pH 7.5, T = 298 K). c(XO) = 4.0×10^{-7} mol L^{-1}, and c(kaempferol) = 0, 1.24, 2.48, 3.69, 4.90, 6.10, 7.28, 8.45, 9.62, 10.77, 11.90, and 13.03×10^{-6} mol L^{-1} for curves 1 → 12, respectively. (C) The CD spectra of the kaempferol−XO system at pH 7.5. c(XO) = 1.0×10^{-6} mol L^{-1}, and the molar ratios of kaempferol to XO were 0:1(1), 5:1(2), and 10:1(3), respectively.

Table 2. Contents of Secondary Structures of Free XO and Kaempferol−XO Systems (CD Spectra) at pH 7.5

molar ratio [kaempferol]:[XO]	α-helix (%)	β-sheet (%)	β-turn (%)	random coil (%)
0:1	13.2	40.6	10.8	35.4
5:1	9.9	43.3	11.9	34.9
10:1	9.5	44.9	12.2	33.4

hydrophobic cavity was more conducive to kaempferol occupying the active site of XO. Moreover, since the helices are the most stable elements of secondary structure of protein, the decrease in α-helical content of XO induced by kaempferol probably led to a decline in its stability,[47] which thus resulted in a decrease in the catalytic activity of XO.

Computational Docking of the Kaempferol−XO Complex. Molecular docking was used to improve the understanding of the interaction between kaempferol and XO. The binding energy of conformational clusters was

[a]AD means additive interaction. [b]SY means synergistic interaction.

arranged according to the size of energy by performing the cluster analysis with the use of a root−mean−square deviation (rmsd) tolerance of 2.0 Å (Figure 4A). A total of 32 multimember conformational clusters was obtained from 100 docking runs. The cluster that possessed the most frequent locus (34 out of 100, the red bar in Figure 4A) and the lowest energy were the most optimal among all the clusters. The most energetically favorable binding gesture was selected for binding orientation analysis. From the docking results, the torsional energy and intermolecular energy were 1.49 kcal mol^{-1} and −6.20 kcal mol^{-1}, respectively; thus, the predicted binding energy ($\Delta G_{binding}$ = intermolecular energy + torsional energy) was obtained to be −4.71 kcal mol^{-1}, which was equal to the binding energy (−4.71 kcal mol^{-1}), which indicates that the docking result was credible.[48] The binding energy was slightly higher than $\Delta G°$ (−6.11 kcal mol^{-1}) obtained from above thermodynamic analysis at 298 K, which could be due to the lack of desolvation energy because the Autodock was performed under simulation of vacuum environment.

As shown in Figure 4, panel B, kaempferol inserted into the hydrophobic cavity of XO, the active site with molybdenum atomic (Mo) domain, and the only channel for the substrate xanthine to enter.[49] The bicyclic benzopyranone ring of kaempferol was sandwiched between amino acid residues Phe1009 and Phe914 and made aromatic interactions ($\pi-\pi$ effects) with the two phenylalanines, which were important for ligand−XO recognition.[24] Moreover, two hydrogen bonds were formed between kaempferol and several residues. One of the hydrogen bonds was constituted between the hydroxyl group in the B ring of kaempferol and Asn768, and the other was formed between the C3 hydroxyl group in the C ring of kaempferol and Luz1 (the coenzyme factor connecting with Mo atom), which suggests that weak hydrogen bond interaction between XO and kaempferol existed. In addition, it was found that the B ring of

DOI: 10.1021/jf505584m
J. Agric. Food Chem. 2015, 63, 526−534

kaempferol inserted into the hydrophobic region of XO interacted with residues Phe1013, Pro1076, Glu 802, Leu1014, Leu648, and Ser1075. The molecular docking supported and visualized the result that the binding of kaempferol with XO was driven mainly by hydrophobic interactions. These results suggested that the inhibitory mechanism of kaempferol on XO oxidation activity to xanthine may be due to the insertion of kaempferol into the active site of XO occupying the catalytic center of the enzyme, thus avoiding entrance of the substrate and causing conformational altertions in XO.

Effects of Morin or Luteolin on Kaempferol Inhibition of XO Activity. The XO inhibitory activities of kaempferol−morin and kaempferol−luteolin mixtures were determined to evaluate the possible synergistic effect. Synergistic effect means that the joint inhibitory ability of two inhibitors on the enzyme activity is greater than the sum of each inhibitor alone, which is different from the additive effect defined as the joint inhibitory effect of two inhibitors being equal to the sum of each inhibitor alone.[50] In this study, three different concentrations near the IC_{50} values of kaempferol, morin, and luteolin were selected. The obtained results are summarized in Table 3, where the remnant XO activity observed (V_{ab}) for kaempferol with morin or luteolin was compared to the remnant XO activity expected (V_c).

As shown in Table 3, the V_c value was calculated to be 0.55 when the remnant XO activity fractions were 0.61 (V_a) and 0.90 (V_b) (data not shown) at the individual added concentration of kaempferol and morin of 2.0×10^{-6} mol L^{-1}, respectively. However, the observed remnant of XO activity fraction (V_{ab}) was 0.30 when kaempferol and morin were added together. The ($V_{ab} - V_c$) value of −0.25 (<−0.10) suggested that these two flavonoids had a significant synergistic effect on the inhibition of XO activity. A similar phenomenon was observed when the concentrations of kaempferol and morin were 8.0×10^{-6} mol L^{-1} and 2.0×10^{-6} mol L^{-1} (or 1.4×10^{-5} mol L^{-1}), respectively. Because morin interacted with some amino acid residues located in the region near the hydrophobic cavity of XO,[22] while kaempferol bound to the active site, it can be thus deduced that the binding mode of the two flavonoids with XO strengthened the inhibition by occuping the entrance of the substrate xanthine and influencing the structure of XO. For the kaempferol−luteolin system, the concentration of luteolin was kept at 1.0×10^{-6} mol L^{-1}, and the different concentrations of kaempferol (0.5×10^{-6}, 2.0×10^{-6}, and 8.0×10^{-6} mol L^{-1}) were added to this solution. It was found that kaempferol and luteolin showed a synergistic effect on the inhibition of XO activity (Table 3). The synergistic inhibition of the kaempferol−luteolin mixture was also found when the concentration of luteolin was 5.0×10^{-6} mol L^{-1} and the concentration of kaempferol was 0.5×10^{-6} or 2.0×10^{-6} mol L^{-1}. These results indicated that luteolin may have a stronger synergistic effect with kaempferol on inhibiting XO activity than morin for the lower concentration required. The synergy mechanism could be conjectured that luteolin together with kaempferol bound to the active site of XO for its competetive manner by occupying the binding site of xanthine and inducing some conformational changes of XO.

In summary, the inhibitory mechanism of kaempferol on XO activity and its synergistic effect with morin or luteolin were investigated by multispectroscopic methods and molecular simulations. Taken together, the principal results of our study include the following: (i) kaempferol reversibly inhibited the catalytic activity of XO in a competetive manner with an IC_{50} value of $(2.18 \pm 0.02) \times 10^{-6}$ mol L^{-1} and K_i value of $(6.77 \pm 1.02) \times 10^{-6}$ mol L^{-1}; (ii) a strong fluorescence quenching of XO was observed due to the formation of a kaempferol−XO complex in a static procedure; (iii) the thermodynamic parameters, ΔH° and ΔS°, were calculated to be 49.45 kJ mol^{-1} and 251.70 J mol^{-1} K^{-1}, respectively, and ΔG° was negative, which suggests that the reaction between kaempferol and XO was a spontaneous process mainly driven by hydrophobic forces; (iv) there was a single class of binding site on XO for kaempferol, and the binding induced the conformational changes of XO; (v) it was predicted by molecular docking that kaempferol inserted into the hydrophobic cavity to interact with some amino acid residues Glu802, Leu873, Phe914, Arg880, Phe1009, Thr1010, Val1011, Leu1014, and Pro1076 located within the active site pocket; and (vi) kaempferol and luteolin or morin showed a significant synergistic effect on inhibiting the activity of XO, and luteolin exhibited a stronger synergistic effect with kaempferol at the lower concentration. As a consquence, the XO activity inhibited by kaempferol was probably due to the insertion of kaempferol into the active site of XO occupying the catalytic center of the enzyme to avoid entrance of xanthine and inducing conformational changes of XO. This study has provided new insights into the inhibition mechanism of kaempferol on XO and its joint effect with luteolin or morin. The results have shown that kaempferol could be a promising XO inhibitor, and the kaempferol−rich foods may be useful for the treatment of gout. Moreover, the ingestion of foods containing kaempferol and luteolin or morin may have a better therapeutic effect.

Structure Characterization of a Novel Polysaccharide from *Dictyophora indusiata* and Its Macrophage Immunomodulatory Activities

Wenzhen Liao,[†] Zhen Luo,[‡] Dan Liu,[†] Zhengxiang Ning,[†] Jiguo Yang,*[,†] and Jiaoyan Ren*[,†]

[†]College of Light Industry and Food Sciences, South China University of Technology, Guangzhou, Guangdong 510640, People's Republic of China

[‡]Research and Development Center, Infinitus (China) Company, Limited, Guangzhou, Guangdong 510665, People's Republic of China

ABSTRACT: A novel polysaccharide, here named DP1, was isolated from the fruiting body of *Dictyophora indusiata* using a water extraction method. Structure characterization revealed that DP1 had an average molecular weight of 1132 kDa and consisted of glucose (56.2%), galactose (14.1%), and mannose (29.7%). The main linkage type of DP1 were proven to be (1 → 3)-linked α-L-Man, (1 → 2,6)-linked α-D-Glc, (1 → 6)-linked β-D-Glc, (1 → 6)-linked β-D-Gal, and (1 → 6)-linked β-D-Man by periodate oxidation−Smith degradation and nuclear magnetic resonance analysis. The immunostimulating assay indicated that DP1 could significantly promote macrophage NO, TNF-α, and IL-6 secretion in murine RAW 264.7 cells involving complement receptor 3 (CR3). The immune activities of DP1 were quite stable under thermal processing (100, 121, and 145 °C). Besides, DP1 retained stability after acidic/alkline treatment (pH 4.0−10.0), which enabled it to be an ideal complementary medicine or functional food for therapeutics of hypoimmunity and immunodeficiency diseases.

KEYWORDS: *polysaccharide, Dictyophora indusiata, structure characterization, immunostimulating, complement receptor 3*

INTRODUCTION

Dictyophora indusiata, a member of the Phallaceae Corda family, is one of the most popular edible mushrooms consumed worldwide. Because of its attractive appearance, distinctive flavor, and high nutritive value, *D. indusiata* is also regarded as "queen of the mushrooms".[1] *D. indusiata* can also be used as a biopharmaceutical material with various therapeutic properties. In recent decades, many active compounds (e.g., polysaccharides, flavonoids, or proteins) from *D. indusiata* have been reported to possess immunoregulation, antioxidant, antityrosinase, anti-inflammatory, and neuroprotective activities.[2−4] Thereamong, the polysaccharides of *D. indusiata* received much more attention because of their multiple beneficial potency and relatively low toxicity.[5,6] To date, a couple of polysaccharides with various bioactivities have been purified from the fruiting body of *D. indusiata*, but rare information is available concerning their chemical structure and immunomodulatory activities.

Macrophage is one kind of the phagocyte that plays pivotal roles in the innate immune responses.[7,8] When the host is invaded by pathogenic organisms, macrophages can serve as antigen-presenting cells (APCs) that present antigen to T lymphocytes and, thus, induce the adaptive immune response.[9] Furthermore, macrophages also play important roles in embryogenesis, tumorigenesis, cutaneous wound healing, and hematopoiesis.[10−15] Thus, macrophages are usually used as ideal cell models to evaluate the immunomodulatory properties of bioactive compounds. Some botanical polysaccharides have been found to enhance the viability of macrophage against pathogenic microorganisms and tumorigenesis by increasing the secretion of nitric oxide (NO) and the production of cytokines, including tumor necrosis factor α (TNF-α) and interleukin (IL-1, IL-2, IL-6, IL-8, IL-10, and IL-12),[16−18] and it has been thought that polysaccharides can bind to specific membrane receptors of macrophage and activate the immune response through distinct signal transduction pathways.[19,20] However, the exact mechanisms involved in the activation of macrophages by polysaccharides are still not clear. For this sake, it is meaningful to explore the structural characterizations, biological functions, and molecular mechanisms of the polysaccharides from *D. indusiata*.

In the present study, a new polysaccharide, here called Dp1, with a purity of >97.5%, was separated from *D. indusiata*. The primary chemical structure and conformation of Dp1 were characterized. Also, its immunomodulatory activities and membrane receptors were examined using a murine RAW 264.7 macrophage model. The thermal stability of the Dp1 bioactivity against heat treatment was investigated, and its stability against acidic/alkali treatment at different pH conditions was studied as well. In addition, the possible signal transduction pathways involved in macrophage activation by Dp1 were discussed, and the results from this study might supply useful information to understand better the chemical structure and immunomodulatory activities of botanical polysaccharides.

MATERIALS AND METHODS

Materials and Reagents. *D. indusiata* was collected from Zhijin, Guizhou, China. The murine macrophage cell line RAW 264.7 was

obtained from American Type Culture Collection (ATCC, Rockville, MD). Dulbecco's modified Eagle's medium (DMEM), Fetal bovine serum (FBS), phosphate-buffered saline (PBS, pH 7.4), penicillin, and streptomycin were purchased from Gibco Life Technologies (Grand Island, NY). Anti-TLR2 antibody, anti-CR3 antibody, and anti-TLR4 antibody were obtained from Abcam, Inc. (Cambridge, MA). Laminarin and lipopolysaccharide (LPS) were obtained from Sigma Company (St. Louis, MO). Diethylaminoethyl (DEAE)-52 cellulose and Sephadex G-200 were purchased from GE Healthcare Life Science (Piscataway, NJ). A NO-detecting kit was purchased from Nanjing Jiancheng Institute of Biotechnology (Nanjing, China). Mouse IL-6 enzyme-linked immunosorbent assay (ELISA) kit and mouse TNF-α ELISA kit were acquired from Neobioscience Technology Co., Ltd. (Shenzhen, China). Standards of dextrans, uronic acid, phycite, glycerol, glycol reference, and monosaccharide references (e.g., glucose, galactose, xylose, mannose, and rhamnose) were purchased from Sigma Company (St. Louis, MO). The ultrapure water was obtained from a Milli-Q water purification system of Millipore (Bedford, MA). All of the other chemical reagents used in this study were of analytical grade.

Extraction and Purification of Polysaccharides from the Fruiting Body of *D. indusiata*. The fruiting body of *D. indusiata* was dried in a hot air-drying oven at 40 °C and crushed into powder using a tissue triturator. The powder of the fruiting body was extracted with boiling water at a ratio of 1:30 (w/w) for 2 h, and the obtained extract was centrifuged at 4000*g* for 15 min. The supernatant was then collected and concentrated at 60 °C. After that, the concentrated supernatant was deproteinated according to the Sevag method.[21] To remove the protein as much as possible, this deproteination process was repeated 10 times. The resulting solution was mixed with three volumes of absolute ethanol and kept overnight at 4 °C. The supernatant and precipitate were then separated by centrifugation at 5000*g* for 15 min. Finally, the precipitate was dried using vacuum freeze drying and collected as crude polysaccharides.

A total of 100 mg of crude polysaccharides was dissolved in 10 mL of ultrapure water and loaded onto a DEAE-52 anion-exchange chromatography column (2.5 × 60 cm). The elution was conducted using ultrapure water first and then by a series of NaCl solution in the sequence of 0.05, 0.1, 0.2, 0.3, and 0.5 M, at a flow rate of 0.5 mL/min. The eluent fractions were collected and analyzed by the phenol−sulfuric acid method.[22] Two fractions, DP1 (eluted by ultrapure water) and DP2 (eluted by 0.05 M NaCl) were obtained, dialyzed at 4 °C for 48 h, and lyophilized. In this study, we mainly focused the investigation on DP1, and the other fraction will be studied later.

After that, the DP1 fraction was further purified by Sephadex G-200 column chromatography. A total of 20 mg of DP1 was redissolved in 4 mL of ultrapure water and applied to a Sephadex G-200 column (2.5 × 60 cm). The sample was eluted with ultrapure water at a speed of 0.5 mL/min, and then the eluent was collected and detected using the phenol−sulfuric acid method for the determimation of 97.5% content.

Structure Characterization of DP1. *Molecular Weight Determination of DP1.* The weight-average molecular weight distribution of DP1 was analyzed by high-performance gel permeation chromatography (HPGPC, Waters, Milford, MA) on a Waters HPLC instrument with a TSK-GEL G-5000 PWXL column (300 × 7.8 mm inner diameter, 10 μm) and a TSK-GEL G-3000PWXL column (300 × 7.8 mm inner diameter, 6 μm, Tosoh Co., Ltd., Tokyo, Japan), using 0.01 mol/L KH_2PO_4 as the mobile phase at a flow rate of 0.6 mL/min.

Infrared (IR) Spectrum Analysis. The IR spectra of DP1 was analyzed according to the KBr disk method[23] using a Fourier transform infrared (FTIR) spectrophotometer (Bruker, Ettlingen, Germany) in the range of 400−4000 cm^{-1}.

Chemical Composition of DP1. A total of 20 mg of DP1 was hydrolyzed by 4 mL of trifluoroacetic acid (TFA) at 105 °C for 6 h. Excess of TFA was removed by rotary evaporation. Then, the residue was redissolved in methanol and dried by rotary evaporation. Finally, the residue was dissolved in ultrapure water and analyzed by ion-exchange chromatography (Dionex ICS-3000) equipped with an integrated amperometric detector and a Carbopac PA20 column (2 × 250 mm). The elution was conducted at a rate of 0.6 mL/min at a column temperature of 20 °C. Gradient elution was carried out according to the following process: 0−2 min, 100% 200 mmol/L NaOH; 2.1−20 min, 10% 20 mmol/L NaOH and 90% ultrapure water; and 20.1−40 min, 100% 200 mmol/L NaOH. The glucose, galactose, xylose, mannose, and rhamnose standards were derivatized as previously reported.[4] Acetyl inositol was used as the interior reference.

Periodate Oxidation−Smith Degradation. The periodate oxidation−Smith degradation method was taken out according to the report by Chi et al.,[24] with some modification. A total of 25 mg of DP1 sample was dissolved in 12.5 mL of ultrapure water and incubated with 12.5 mL of $NaIO_4$ (30 mmol/L) in the dark at room temperature. During the incubation period, 0.1 mL of the reaction liquid was taken out from the reaction system at different time intervals (0, 6, 12, 24, 36, 48, and 60 h), diluted into 100 mL with ultrapure water, and measured at 223 nm by an ultraviolet−visible (UV−vis) spectrophotometer (model UV-18000, Shimadzu, Japan) until the absorbance value became invariable. The process of periodate oxidation was stopped by the addition of 2 mL of glycol. Then, 2 mL of periodate product was titrated by 0.01 mol/L NaOH to quantify the production of formic acid. The rest of the periodate product was dialyzed in distilled water for 72 h and concentrated by rotary evaporation. Then, 70 mg of $NaBH_4$ was added to the residuary solution and kept in the dark for 24 h. The solution was adjusted to pH 5.0 with 0.1 mol/L acetic acid and dialyzed in distilled water for another 72 h. The solution was then concentrated and freeze-dried. A total of 10 mg of the residues was hydrolyzed by 4 mL of 2 mol/L TFA at 105 °C for 6 h. The lysate was acetylized with 1 mL of pyridine and 10 mg of hydroxylamine hydrochloride at 90 °C for 30 min. Then, 1 mL of acetic anhydride was added to the reaction system and continuously heating at 90 °C for another 30 min. The production of acetate derivative was analyzed by a gas chromatograph system (Aglient, 6890N, Agilent Technologies, Inc., Santa Clara, CA) with a DB-1701 capillary column (30 m × 0.25 mm × 0.25 μm, J&W Scientific, Fulsom, CA) and a flame ionization detector. The linearly heating program is from 80 to 220 °C at a speed of 2 °C/min, from 220 to 250 °C at a speed of 5 °C/min, and kept at 250 °C for 5 min. The temperature of the detector was set at 300 °C. Phycite, glycerol, glycol, rhamnose, arabinose, xylose, galactose, mannose, and glucose were used as standards.

Nuclear Magnetic Resonance (NMR). A total of 35 mg of DP1 was dissolved in 0.5 mL of D_2O in a NMR tube and then analyzed by a Bruker 600 MHz NMR apparatus (Bruker Corp., Fallanden, Switzerland).[25]

Thermogravimetric Analysis (TGA). The thermostability of DP1 was analyzed using TGA (Pyris Diamond TG−DTA, PerkinElmer Co., Waltham, MA). A total of 5 mg of DP1 sample was placed in the Al_2O_3 pan and heated from 60 to 600 °C with a heating rate of 10 °C/min. The analysis was conducted under a pure nitrogen gas atmosphere at a flow rate of 30 mL/min.

Immunomodulatory Activity and Stability Assay. *Cell Culture and Immunomodulatory Activity Test.* RAW 264.7 cells were cultured with DMEM plus 10% fetal bovine serum (FBS), 100 μg/mL streptomycin, and 100 units/mL penicillin and incubated at 37 °C with a 5% CO_2 humidified atmosphere in a carbon dioxide cell incubator. Cells were adjusted to a concentration of 1×10^6 cells/mL in the exponential phase, loaded onto the 96 well microplate (100 μL/well), and continuously incubated for 24 h. Then, the culture medium was changed to a new medium with DP1 samples and incubated for another 24 h. Antibodies (anti-TLR2, anti-CR3, and anti-TLR4, at a concentration of 5 μg/mL) and laminarin (500 μg/mL, the inhibitor of dectin-1) were added to cells to investigate the membrane receptors of DP1 on the RAW 264.7 cells. The cells were pretreated with antibodies and laminarin for 2 h prior to stimulation with different concentrations of DP1 (125, 250, 500, and 1000 μg/mL) and incubated for 24 h. LPS (50 μg/mL) was used as the positive control. After that, the supernatants of cells were collected and the levels of NO, TNF-α, and IL-6 were measured using a NO-detecting kit, mouse TNF-α ELISA kit, and mouse IL-6 ELISA kit, respectively, according to the instructions of the manufacturer.

Immunomodulatory Stability Assay. *Thermal Treatment.* DP1 was dissolved in PBS (pH 7.4) to make a final concentration of 500 μg/mL and subjected to different heat treatments (100 °C × 30 min, 121 °C

J. Agric. Food Chem. 2015, 63, 535−544

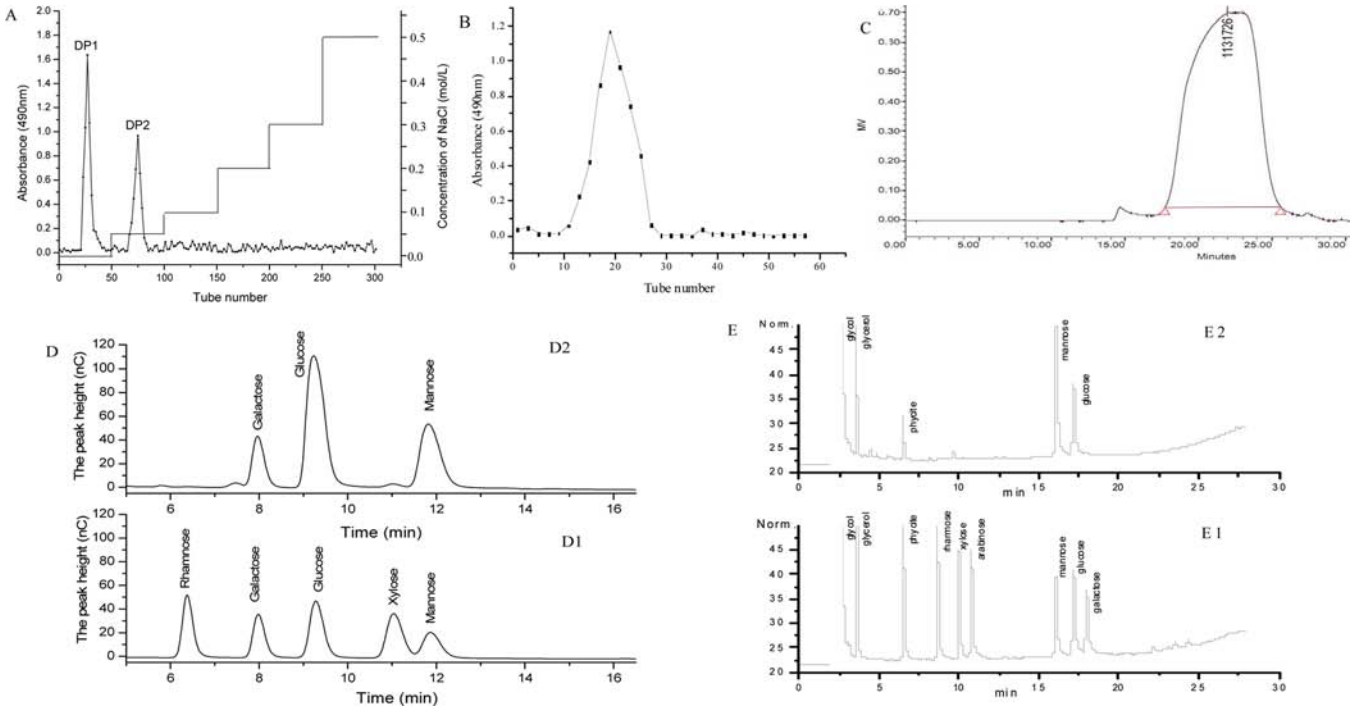

Figure 1. Chromatography of the polysaccharides from *D. indusiata* (DP1) by (A) DEAE-52 cellulose (DEAE-52), (B) Sephadex G-200, (C) HPGPC, (D) ion-exchange chromatography of the monosaccharide mixture (D1) and DP1 sample (D2), and (E) gas chromatography of the monosaccharide mixture (E1) and DP1 sample (E2).

× 30 min, and 145 °C × 30 min) and then cooled to room temperature. After that, DP1 was sterilized by a 0.22 μm microporous filtering film and then incubated with RAW 264.7 cells for 24 h. The changes of NO, TNF-α, and IL-6 levels were detected as described above.

Acidic/Alkaline Treatment. DP1 (500 μg/mL) was dissolved in different phosphate buffers to make final pH 2.0, 4.0, 6.0, 7.4, 8.0, and 10.0 and then kept overnight at room temperature. DP1 with different pH values was sterilized by 0.22 μm microporous filtering film and then incubated with RAW 264.7 cells for 24 h. The changes of NO, TNF-α, and IL-6 levels were detected as described above.

Combined Thermal Treatment and Acidic/Alkaline Treatment. DP1 (500 μg/mL) was dissolved in different phosphate buffers at pH 2.0, 4.0, 6.0, 7.4, 8.0, and 10.0. Then, the solution were heated at 121 °C for 30 min. All samples were sterilized by a 0.22 μm microporous filtering film and then incubated with RAW 264.7 cells for 24 h. The changes of NO, TNF-α, and IL-6 levels were detected as described above.

Statistical Analysis. Data were presented as the mean ± standard deviation (SD) for at least three replicates and analyzed by SPSS 16.0 (SPSS, Inc., Chicago, IL). Significance was determined at p values below 0.05 by analysis of variance (ANOVA). The difference between three or more groups was analyzed by one-way ANOVA multiple comparisons.

RESULTS AND DISCUSSION

Extraction and Purification of Polysaccharides from *D. indusiata*. Crude polysaccharides were isolated from the fruiting body of *D. indusiata* with a yield of 6.36%. The extracts were first purified by a DEAE-52 anion-exchange chromatography column (Figure 1A). Two independent peaks, DP1 (eluted by ultrapure water) and DP2 (eluted by 0.05 mol/L NaCl), were obtained. In the present study, we mainly focused on DP1, and the property of DP2 will be studied in our future work. The DP1 fraction was further purified by a Sephadex G-200 column. As shown in Figure 1B, a single peak of DP1 was observed. Finally, the DP1 fraction with a purity of >97.5% was obtained after dialysis and lyophilization.

Characterization of DP1. *Molecular Weight of DP1.* The weight-average molecular weight of DP1 was measured by HPGPC.[26] As shown in Figure 1C, a single peak was observed on the chromatogram and the molecular weight of DP1 was determined to be 1132 kDa. This result showed a great difference from the previous research by Hua et al.,[1] which indicated that the molecular weight of two polyacchrides from *D. indusiata* were 2100.99 and 18.16 kDa. The difference of the extraction method, the habitat, and the strain of *D. indusiata* may lead to the differences of molecular weights.

Monosaccharide Composition Assay. The monosaccharide composition of DP1 was analyzed using ion chromatography. As shown in Figure 1D, three monosaccharides, including galactose, glucose, and mannose, were identified according to the elution time of relative monosaccharide standards. The molar percentages of galactose, glucose, and mannose were 14.1, 56.2, and 29.7%, respectively. The results were different from that by Hua et al., who found that water-soluble polysaccharides from *D. indusiata* were composed of xylose, galactose, glucose, and mannose, with the molar percentages of 22.6, 18.6, 13.9, and 44.9%, respectively.[1]

Periodate Oxidation–Smith Degradation Analysis. The results for the periodate oxidation analysis of DP1 showed that 1.27 mol of periodate was consumed by every molar of sugar residues and 0.63 mol of acid was produced, indicating the existence of (1 → 2)- or (1 → 6)-linked glycosidic bonds. The periodate-oxidized DP1 sample was further analyzed by Smith degradation. Glycerol, erythritol, galactose, glucose, and mannose were observed after Smith degradation (Figure 1E). The presence of glycerol indicated the existence of (1 → 2)- or (1 → 6)-linked glycosidic bonds, while erythritol corresponded to the presence of (1 → 4)-linked glycosidic bonds. The presence of monosaccharides revealed the appearance of (1 → 3)-linked glycosidic bonds.

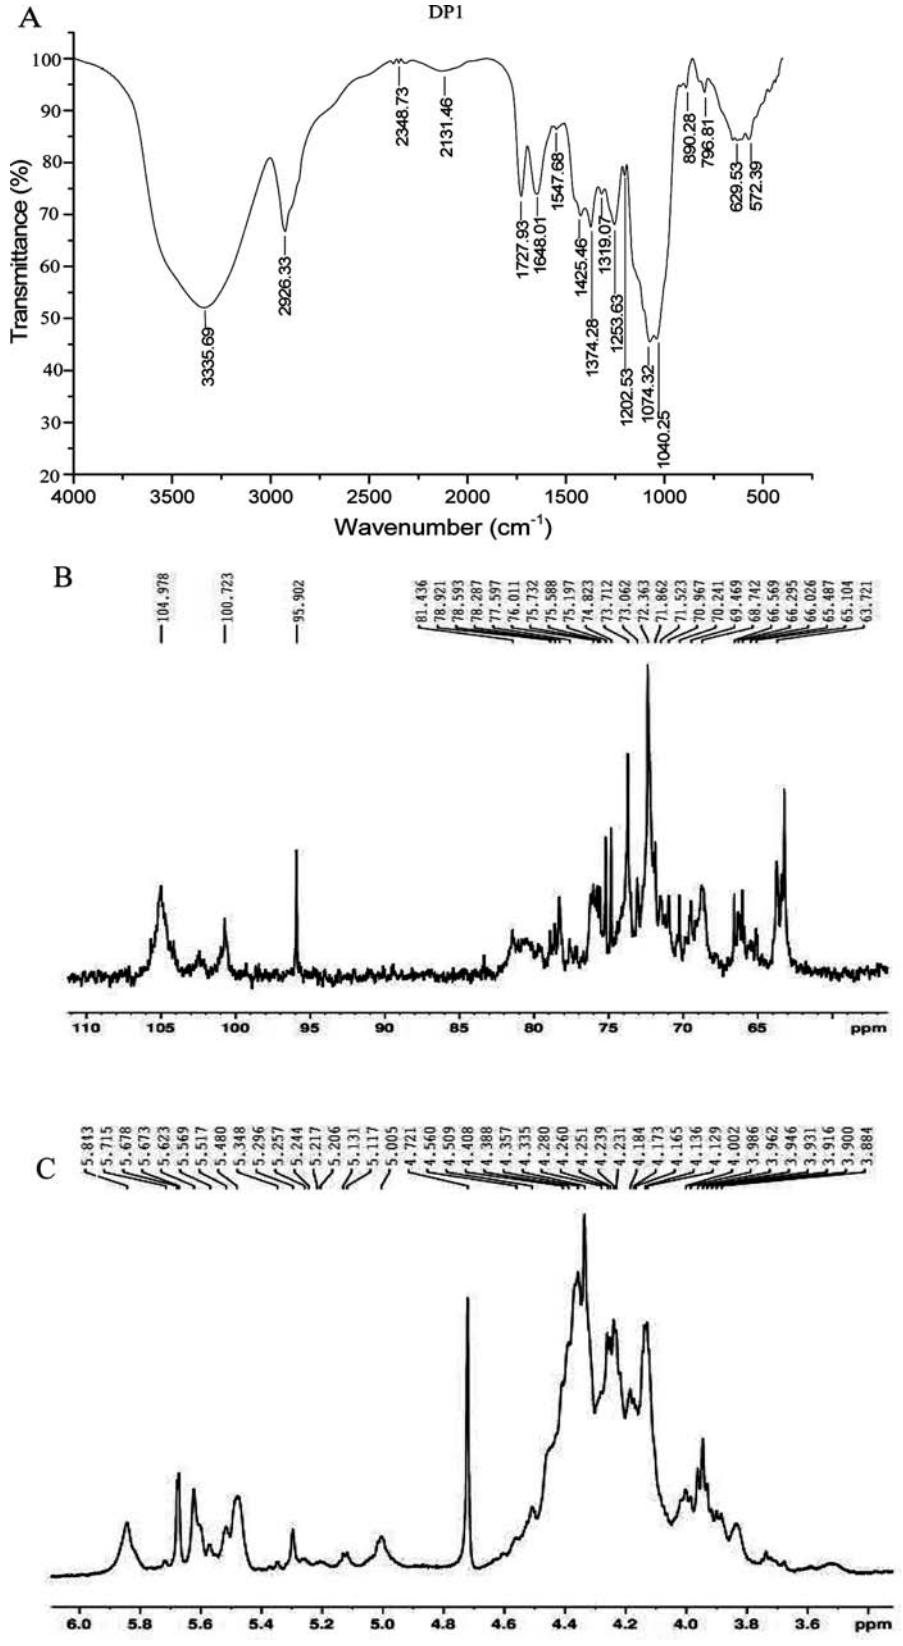

Figure 2. (A) FTIR spectrum, (B) ^{13}C NMR spectrum, and (C) ^{1}H NMR spectrum of the polysaccharides from *D. indusiata* (DP1).

IR Spectrum Analysis. The IR spectra of DP1 is shown in Figure 2A. The stretching intense characteristic peaks at 3335.69 cm^{-1} indicated the hydroxyl stretching vibration of the polysaccharide chains. The peak around 2926.33 cm^{-1} was attributed to the C−H stretching vibration.[27] The band at 1648.01 cm^{-1} may be due to the bound water. The absorption peaks between 1430 and 1200 cm^{-1} indicated the presence of the O−H deformation vibrations and C−O stretching vibrations,

DOI: 10.1021/jf504677r
J. Agric. Food Chem. 2015, 63, 535−544

respectively.[28] The bands at 1074.32 and 1040.25 cm^{-1} suggested that the skeletal modes of DP1 were pyranose rings. The absorption at 866 cm^{-1} indicated the β- pyranoside linkage in DP1. A characteristic peak at 796.81 cm^{-1} represented the presence of mannose.

NMR Analysis of DP1. The spectra of ^{1}H and ^{13}C NMR of DP1 are shown in panels B and C of Figure 2. The signals of DP1 in ^{1}H and ^{13}C NMR spectra were attributed on the basis of monosaccharide, glycosidic linkages, and chemical shifts.[29] The resonance signals of ^{13}C NMR between 95.0 and 110.0 ppm belonged to the anomeric carbon atoms of L-mannose, L-arabinose, D-galactose, D-glucose, and L-rhamnose.[29] The peak at 95.902 ppm suggested the presence of C-1 of a (1 → 3)-linked α-L-Man unit, and the peak at 100.723 ppm indicated the presence of C-1 of a (1 → 3)-linked α-D-Gal unit. Another peak at 104.978 ppm proved the presence of C-1 of a (1 → 2,6)-linked α-D-Glc unit, and the peak at 69.469 ppm corresponded to C-6 of a (1 → 6)-linked β-D-Glc unit. Besides, the peat at 68.742 ppm suggested the presence of C-6 of a (1 → 6)-linked β-D-Gal unit, and the peak at 66.569 ppm corresponded to the C-6 of a (1 → 6)-linked β-D-Man unit. The peaks in the region of 78.287−81.436 ppm (78.287, 78.593, 78.921, and 81.436 ppm) were attributed to the presence of (1 → 2)-, (1 → 3)-, or (1 → 4)-linked glycosidic bonds. The configuration of the glycosidic linkage of DP1 was analyzed by ^{1}H NMR spectra. The signals of ^{1}H NMR in the region of 5.400−5.843 ppm (5.483, 5.517, 5.569, 5.623, 5.673, 5.678, 5.715, and 5.843 ppm) indicated the presence of α-form furanose. The peaks at 5.000−5.400 ppm (5.005, 5.117, 5.131, 5.206, 5.217, 5.244, 5.257, 5.296, and 5.348 ppm) were attributed to the presence of α-form pyranose.

Immunomodulatory Activities of DP1. *Effects of DP1 on Macrophage NO, TNF-α, and IL-6 Production.* Modulation of the innate immune system can enhance the resistant ability of the host to exogenous pathogen threats.[30] It is thought that the stimulation of the immune system might be mainly through the activation of the macrophage and complement system.[31,32] Macrophage activation by immunomodulators is considered to be via the induction of NO expression and enhanced production of cytokines (TNF-a, IL-1, IL-6, IL-12, IL-10, etc.).[33] Thus, the effects of DP1 on macrophage NO, TNF-α, and IL-6 production were analyzed in this study. Untreated RAW 264.7 cells secreted very little NO, whereas the addition of DP1 in the medium significantly increased NO secretion in a dose-dependent manner (125−1000 μg/mL; Figure 3A). The concentration of NO reached 11.72 μmol/mL after treatment by 500 μg/mL DP1; this is higher than a polysaccharide from *Lentinula edodes* reported by Xu et al.[19] In the study by Xu et al., the concentration of NO was lower than 4 μmol/mL after treatment by 500 μg/mL of *L. edodes* polysaccharide. Meanwhile, DP1 had similar dose-dependent manner effects on macrophage TNF-α and IL-6 production (panels B and C of Figure 3). The macrophage IL-6 level (e.g., 1134 pg/mL IL-6 at 250 μg/mL DP1) treated by DP1 is higher than that of some polysaccharide fractions isolated from *Opuntia polyacantha*[14] (lower than 1000 pg/mL IL-6 at 250 μg/mL of some *O. polyacantha* fractions), whereas the TNF-α level (e.g., 588 pg/mL TNF-α at 250 μg/mL DP1) treated by DP1 is lower than that of a polysaccharide from *Ganoderma atrum* (over 1400 pg/mL TNF-α at 160 mg/mL *G. atrum* polysaccharide).[34] The results suggested that DP1 exhibited remarkable immunomodulatory activities by upregulation of NO, TNF-α, and IL-6 secretion in RAW 264.7 cells.

Roles of Complement Receptor 3 (CR3), Toll-Like Receptors (TLR2 and TLR4), and Dectin-1 on DP1-Induced Macrophage Immunomodulation. It has been proposed that macrophage activation is mediated primarily through the recognition of pathogen-associated molecular patterns (PAMPs) by pattern recognition receptors (PRRs) on the surface of macrophage cells. Stimulation of PRRs leads to the initiation of intracellular signaling pathways and eventually induces transcriptional activation and expression of cytokines. Recent evidence suggests that macrophages might bind polysaccharides and mediate immunomodulating effects mainly through CR3, TLR2, TLR4,

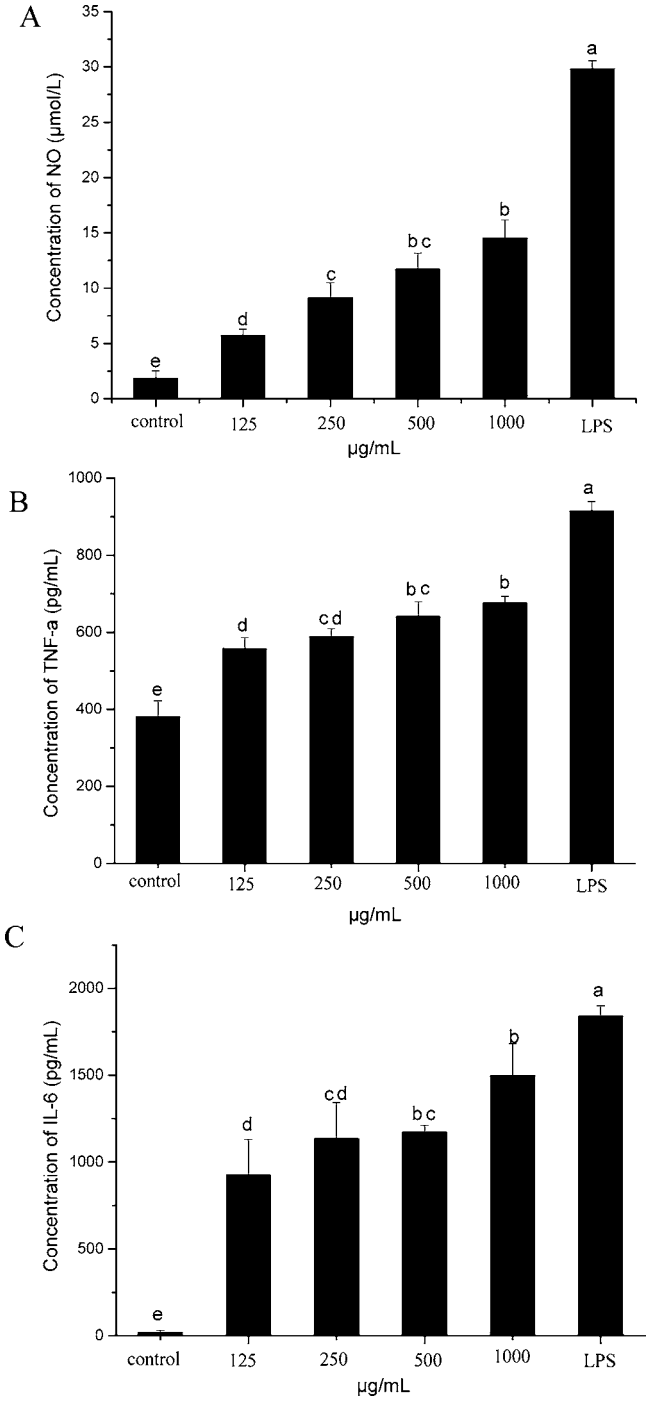

Figure 3. Effects of different concentrations of *D. indusiata* polysaccharides (DP1) on macrophage (A) NO, (B) TNF-α, and (C) IL-6 secretion in RAW 264.7 cells. The group without adding DP1 was used as the control, and LPS (50 μg/mL) was used as the positive control.

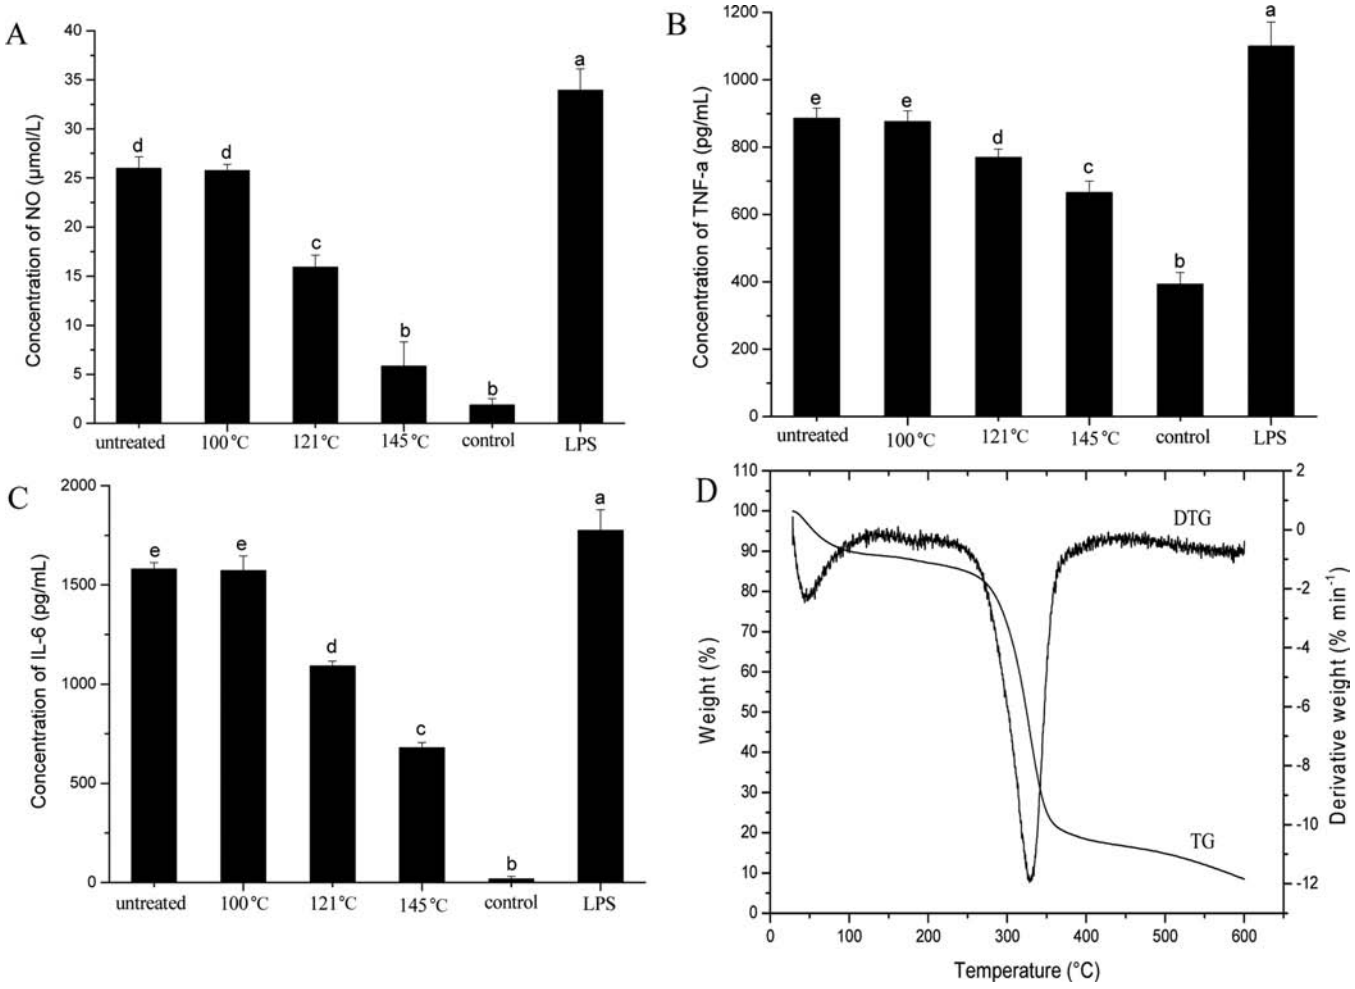

Figure 5. Effects of different temperature treatments on DP1 (the polysaccharides of *D. indusiata*)-induced (A) NO, (B) TNF-α, and (C) IL-6 secretion in RAW 264.7 cells. DP1 samples were divided into three groups and treated at 100, 121, and 145 °C for 30 min. Then, the cells were incubated with heat treatment DP1 samples for 24 h. (D) Thermogravimetry−differential therogravimetry (TG−DTG) curves of DP1.

or dectin-1.[35] In the present study, the roles of CR3, TLR2, TLR4, and dectin-1 on DP1-induced macrophage immunomodulation were investigated. Antibodies, including anti-CR3, anti-TLR2, anti-TLR4, and the inhibitor of dectin-1, laminarin, were preincubated with RAW 264.7 cells for 2 h and then incubated with DP1 for another 24 h. Laminarin is a β-glucan, which can specifically bind to dectin-1 and block the dectin-1-mediated immune responses.[36] The macrophage NO, TNF-α, and IL-6 productions were determined. As shown in panels A−C of Figure 4, after treatment of anti-CR3 and DP1, the levels of NO, TNF-α, and IL-6 were all visibly decreased in comparison to the group treated by DP1 only ($p < 0.05$). However, no decrease was found in the groups treated by anti-TLR2 and anti-TLR4. As for laminarin, it was even enhanced because of its own immunostimulating activity. These results indicated that CR3 was one of the receptors of DP1 on RAW 264.7. Previous studies have proven that CR3 possessed sugar specificity, and the polysaccharides containing *N*-acetyl-D-glucosamine or mannose in addition to glucose are most likely recognized by CR3.[34] Therefore, the mannose and glucose composition of DP1 may contribute to the specific binding of DP1 to CR3 on macrophage. Besides, there might be some other receptors of DP1 on the membrane of macrophage, because the NO level (Figure 4A), TNF-α level (Figure 4B), and IL-6 level (Figure 4C) in the treated group by anti-CR3 and DP1 were still higher than those in the group absent of DP1 treatment. CR3 has been proven to be involved in the activation of phosphoinositide-3-kinase (PI3K), phosphorylation of the downstream serine/threonine kinase Akt and mammalian target of rapamycin (mTOR), activation of the mitogen-activated protein kinase (MAPK), and nuclear factor-κB (NF-κB) signal transduction pathways. Activation of these signaling pathways ultimately leads to gene transcription and production of pro-inflammatory cytokines.[16] Therefore, we can infer that the possible molecular mechanism of DP1-induced macrophage immunomodulation was mainly through activation of the PI3K/Akt/MAPK/NF-κB signaling transduction pathways (Figure 4D), and these pathways will be characterized in our future study.

Effects of Thermal Treatment and Acidic/Alkali Treatment on DP1-Induced Macrophage Immunomodulation. It is well-established that severe environmental conditions, such as high tempreature, high pressure, and extreme pH, have great influence on the advanced structure of macromolecules.[37] In this study, the effects of different heat treatments and acidic/alkali treatments on the immunomodulation activity of DP1 were investigated. It was found that, with the increase of the temperature, DP1 exhibited a substantial decrease effect on macrophage NO, TNF-α, and IL-6 production, as shown in panels A, B, and C of Figure 5, respectively. It may be due to the fact that high temperatures (over 100 °C) can cause the breakdown of non-covalent bonds,

J. Agric. Food Chem. 2015, 63, 535−544

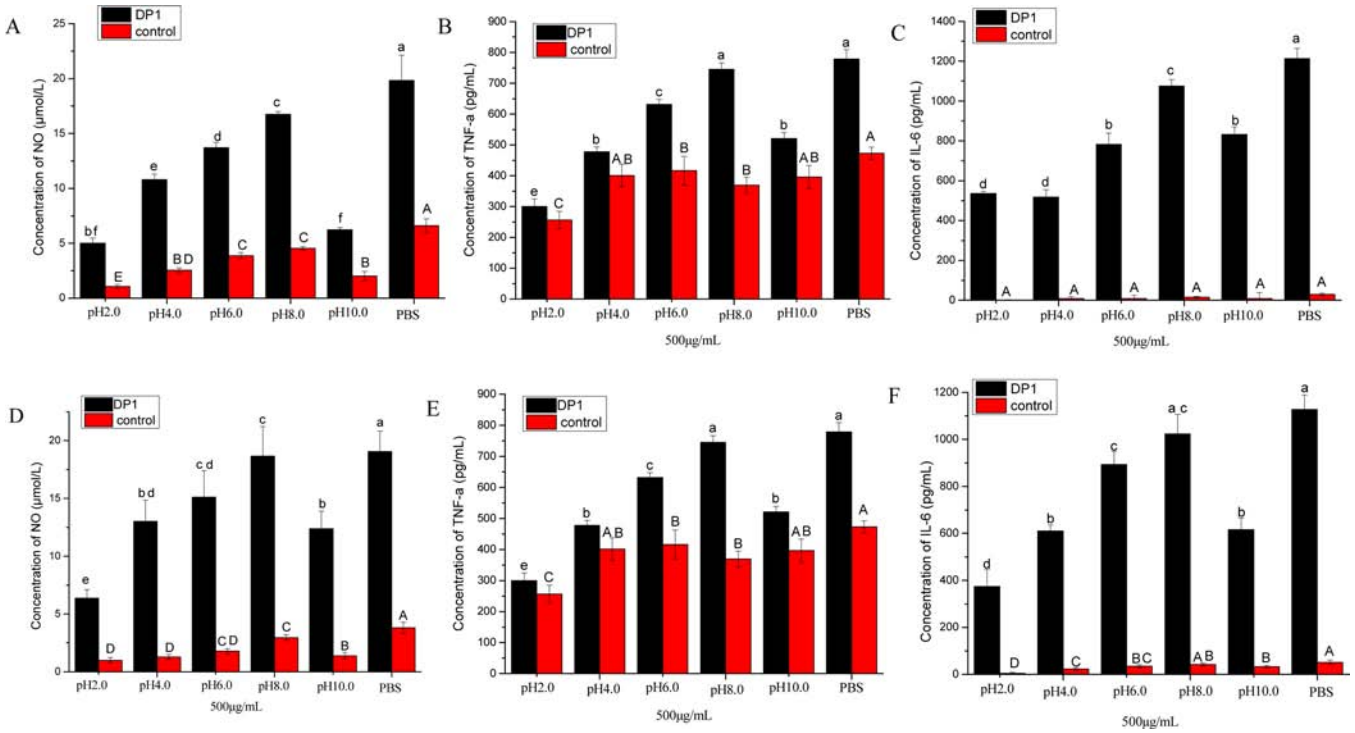

Figure 6. Effects of different pH treatments on DP1 (the polysaccharides of *D. indusiata*)-induced (A) NO, (B) TNF-α, and (C) IL-6 secretion in RAW 264.7 cells. Cells were incubated with DP1 at different pH values of phosphate buffers for 24 h. The cells of the control group were incubated at different pH values of phosphate buffers (without DP1) for 24 h. Co-effects of heat (121 °C) and different pH treatments on DP1-induced (D) NO, (E) TNF-α, and (F) IL-6 secretion in RAW 264.7 cells. Cells were incubated with heat treatment (121 °C) DP1 at different pH values of phosphate buffers for 24 h versus the control groups (without DP1).

such as ionic bonds, hydrogen bonds, and hydrophobic effects of DP1, and thus, in comparison to TNF-α and IL-6, the NO level was more sensitive to heat treatment and the 145 °C processing for 30 min destroyed 77.6% of its native activity. At this point, the immune activities of TNF-α and IL-6 were 24.9 and 57.0% of their native activities, respectively. Although being sensivity to heat treatment, DP1 was still able to upgrade the macrophage NO, TNF-α, and IL-6 levels after treatment at 145 °C. The reason for these results may be mainly because of the fact that thermal treatment just destroyed the higher structure (e.g., triple helical) of DP1. Recent evidence confirmed that the helix−coil transition of polysaccharide was induced by heat treatment at about 130−145 °C because of the breakage of hydrogen bonds.[38] The primary structure may not be damaged under the selected temperatures, although a higher structure may likely contribute much to the biological activity of DP1; the primary structure of DP1 also maintained a considerable part of its immune activity. The thermostability of DP1 was further analyzed using TGA. As shown in Figure 5D, neglecting the small weight loss at around 50 °C, attributed to the vaporization of retained moisture, the decomposition peak of DP1 was found at 329 °C. This degradation temperature of DP1 was much higher than that of the polysaccharides from haloalkalophilic *Bacillus* sp. I-450 (290 °C), as reported by Kumar et al.[39] These results further confirmed that DP1 exhibited good thermostability under extreme heat treatments.

Previous studies have also reported that the non-covalent bonds can also be destroyed in the strong acidic or alkline conditions.[40] Thus, the effects of pH changes on DP1 were investigated as well in the present study. The DP1 samples were pretreated by phosphate buffers with various pH (form 2.0 to 10.0) for 12 h. As shown in panels A−C of Figure 6, it was found that the cells without DP1 protection were very sensitive to different pH treatments, while the addition of DP1 remarkably enhanced the macrophage NO, TNF-α, and IL-6 secretion. Especially for IL-6, the protection effect of DP1 was more obvious. It turns out that, even at pH 4.0, DP1 could still protect the cells to recover 50% of their original NO, TNF-α, and IL-6 concentrations. It demonstrated that the structure of DP1 remained stable in a broad spectrum of pH levels. At alkline conditions (pH 10.0), DP1 showed less protection on the NO level of the cells but still contributed to the TNF-α and IL-6 secretion of macrophage.

The stability of DP1 against both heat treatment and acidic/alkline treatment was further explored. DP1 samples were dissolved in phosphate buffers with different pH values (from 2.0 to 10.0) and then heated at 121 °C for 30 min. The results demonstrated that DP1 still retained its immunomodulatory activities to enhance macrophage NO (Figure 6D), TNF-α (Figure 6E), and IL-6 (Figure 6F) secretion in RAW 264.7 cells. In this way, DP1 was proven to retain stable immunomodulatory activities, even undergoing combined heat treatment and acidic/alkline treatment. It was very interesting that, at pH 10.0, the results showed that the contribution of DP1 to the macrophage NO level was even enhanced after combined treatments (Figure 6D) than single alkline treatment (Figure 6A), and the reason was not yet clear. With the above results, we suggested the potential of DP1 as a novel immunomodulatory agent.

In this study, a new polysaccharide DP1 of 1132 kDa was purified from *D. indusiata*. DP1 consisted of (1 → 3)-linked α-L-Man, (1 → 2,6)-linked α-D-Glc, (1 → 6)-linked β-D-Glc, (1 → 6)-linked β-D-Gal, and (1 → 6)-linked β-D-Man. DP1 possessed significant immunomodulation activities by upregulating macrophage NO, TNF-α, and IL-6 secretion. One of the membrane

DOI: 10.1021/jf504677r
J. Agric. Food Chem. 2015, 63, 535−544

receptors of DP1 on RAW 264.7 was confirmed to be CR3. The PI3K/Akt/MAPK/NF-κB signaling pathways were thought to be involved in the immunomodulation function of DP1. DP1 retained stability across a broad spectrum of pH and thermal treatments. Thus, DP1 demonstrated the potential application as a complementary medicine for the hypoimmunity and immunodeficiency population.

Supporting Information

ABSTRACT: Two new bisabolane-type sesquiterpenoids, pleuroton A (**1**) and pleuroton B (**2**), and three clitocybulol derivatives, clitocybulol D (**3**), clitocybulol E (**4**), and clitocybulol F (**5**), were obtained from the mycelial culture of edible fungus *Pleurotus cystidiosus* O. K. Mill by repeated column chromatography over RP-18, Sephadex LH-20, and silica gel. Their structures were determined according to nuclear magnetic resonance data, high-resolution electron impact mass spectrometry, and circular dichroism spectra. These new sesquiterpenoids exhibited significant cytotoxicity against two human prostate cancer DU-145 and C42B cells in the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay. The median inhibitory concentration (IC_{50}) of compounds **1**, **2**, **3**, **4**, and **5** was 174, 28, 233, 162, and 179 nM, respectively, against the DU-145 cell and was 104, 52, 163, 120, and 119 nM, respectively, against the C42B cell. Especially, pleuroton B (**2**) exhibited the strongest cytotoxity among these sesquiterpenoids, which was confirmed by the colony formation assay. Furthermore, pleuroton B (**2**) could trigger the apoptosis of DU-145 cells through the detection of apoptosis cells using annexin V-FITC staining by flow cytometry, the observation of condensed nuclei in the apoptosis cells, and the western blot analysis for the expression of apoptosis-related proteins Bcl-2, Bak, and Bax. Analysis of structure−activity relationships of these sesquiterpenoids revealed that the unusual functional moiety of pleuroton B should contribute to its significant bioactivity. These results display the pharmacological potential of *P. cystidiosus*.

KEYWORDS: *edible fungus, Pleurotus cystidiosus, sesquiterpenoids, apoptosis inducing*

INTRODUCTION

Edible and medicinal fungi are a rich source of natural products with pharmacological potential; for example, davallialactone from *Inonotus xaranticus* could improve the aging process,[1] thelephantin O from *Thelephora aurantiotincta* could inhibit the proliferation of cancer cells,[2] etc. The genus *Pleurotus* is one of the major genera of edible fungi widely cultivated in China. Many different metabolites have been isolated from this genus. These include novel sesquiterpene pleurospiroketals[3] A−E and new monoterpenoids with inhibitory activity against nitric oxide production from *Pleurotus cornucopiae*,[4] diterpenoid eryngiolide A with cytotoxicity from *Pleurotus eryngii*,[5] ubiquinone-9 with an inhibitory effect on mammalian DNA topoisomerase I from *P. eryngii*,[6] and methane-type monoterpene pleurolactone from *P. eryngii*.[7]

Our recent experimental results indicated the ethyl acetate crude extracted from the mycelial culture of *Pleurotus cystidiosus* had shown significant inhibitory effects against prostate cancer DU-145 cells in the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay. To investigate new pharmacological constituents, the strain *P. cystidiosus* was cultured in dishes laid with potato dextose agar media on a large scale. As a result, two new bisabolane-type sesquiterpenoids, pleuroton A (**1**) and pleuroton B (**2**), and three clitocybulol derivatives, clitocybulol D (**3**), clitocybulol E (**4**), and clitocybulol F (**5**), were obtained from the mycelial culture of *P. cystidiosus* by repeated column chromatography over RP-18, Sephadex LH-20, and silica gel.

MATERIALS AND METHODS

General Procedures. Ultraviolet (UV) spectra were measured on Shimadzu UV2401PC (Tokyo, Japan). Infrared (IR) spectra were recorded on a Bruker Tensor-27 FTIR spectrophotometer (Ettlingen, Germany). Optical rotations were measured with Jasco P-1020 automatic polarimeter (Tokyo, Japan). Nuclear magnetic resonance (NMR) spectra were recorded at 500 MHz for ^{1}H NMR and 150 MHz for ^{13}C NMR on a Bruker AMX-500 spectrometer (Bruker BioSpin Group, Zurich, Switzerland). High-resolution electron impact mass spectrometry (HREI−MS) spectra were recorded on AutoSpec Premier P776 mass spectrometer (Milford, MA). Circular dichroism spectra were measured on a Chirascan Plus spectroscope (Applied Photophysics, Leatherhead, Surrey, U.K.). Column chromatography was performed on silica gel (Qingdao Marine Chemical Company, Qingdao, China), reverse-phase octadecyl-silica RP-18 (Merck, Darmstadt, Germany), and Sephadex LH-20 (Amersham Biosciences, Piscataway, NJ). Thin-layer chromatography was performed on the precoated silica gel GF_{254} plates (Qingdao Marine Chemical Company, Qingdao, China). Organic solvents used were from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). MTT, 4,6-diamidino-2-phenylindole (DAPI), RNaseA, and anti-β-actin were purchased from Sigma Chemical Co. (St. Louis, MO). Anti-Bcl-2, anti-Bax, and anti-Bak were purchased from Cell Signaling Technology (Danvers, MA). Annexin V-FITC Apoptosis Detection Kit was supplied by BD Biosciences, San Jose, CA.

Fungus Material and Fermentation. The strain was isolated from the basidiocarp of *P. cystidiosus*, which grew in the Qingyun mountains in Yongtai, Fujian, China. Inferred from the comparison of internal transcribed spacer (ITS) DNA sequences (GenBank accession number KP164598; see Figure S1 of the Supporting Information), the strain was identified as *P. cystidiosus* O. K. Mill[8] and has been deposited in the China Center for Type Culture Collection (CCTCC number 2014256). The strain *P. cystidiosus* was cultured in 750 dishes each containing ca. 20 mL of potato dextose agar media with the total volume of 15 L. These dishes were incubated at 28 °C for 43 days.

Extraction and Isolation. The fermented mycelia, some of which have formed the synnematous anamorph in black (see Figure S2 of the Supporting Information), together with the cultured substrate in these dishes, were merged and extracted with AcOEt/MeOH/AcOH (80:15:5, v/v/v). The organic crude extract was partitioned with AcOEt and double-distilled water. The AcOEt phase was dried over sodium sulfate (anhydrous) and concentrated under reduced pressure to afford 4.41 g of a crude organic extract. The crude extract was subjected to medium-pressure liquid chromatography (MPLC) over RP-18 silica gel (170 g) using a stepwise gradient of 30, 50, 70, and 100% (v/v) MeOH in water and to afford fraction 1 (154.8 mg) obtained from 30% MeOH in water and fraction 2 (495.7 mg) obtained from 50% MeOH in water. Fraction 1 was then subjected to a Sephadex LH-20 column eluted with MeOH to afford fraction 11 (48.4 mg). Fraction 11 was separated to fraction 111 (4.6 mg) and fraction 112 (15.4 mg) by MPLC over RP-18 silica gel (30 g) (from 25% MeOH in water). Fraction 111 was subjected to silica gel (1.0 g) chromatography using a $CHCl_3$/MeOH solvent gradient to yield compound **3** (1.7 mg). Fraction 112 was further subjected to a Sephadex LH-20 column (100 g) eluted with MeOH to afford fraction 1121 (3.0 mg). Fraction 1121 was subjected to silica gel (1.0 g) chromatography using a $CHCl_3$/MeOH solvent gradient to yield compound **5** (2.3 mg). Fraction 2 was divided to fraction 21 (222.9 mg) (from 35% MeOH in water) and fraction 22 (134.1 mg) (from

DOI: 10.1021/jf504931n
J. Agric. Food Chem. 2015, 63, 545−551

45% MeOH in water) by MPLC over RP-18 silica gel (30 g). Fraction 21 was continuously subjected to a Sephadex LH-20 (120 g) column eluted with MeOH and to silica gel (2.0 g) chromatography using a $CHCl_3$/MeOH solvent gradient to yield compound **1** (6.1 mg). Fraction 22 was further subjected to a Sephadex LH-20 (120 g) column eluted with MeOH and to afford fraction 221 (16.6 mg) and fraction 222 (49.0 mg). Fraction 221 was subjected to silica gel (1.0 g) chromatography using a $CHCl_3$/MeOH solvent gradient (200:1) to yield compound **2** (3.0 mg). Fraction 222 was also subjected to silica gel (1.0 g) chromatography using a $CHCl_3$/MeOH solvent gradient (50:1) to yield compound **4** (23.5 mg). The physical properties and spectroscopic data of five new sesquiterpenoids are as follows:

Compound **1**: colorless oil. $[\alpha]_D^{25}$: +51.7 (*c* 0.23, methanol). UV (methanol) λ_{max}, nm: 216. HREI−MS, *m*/*z*: 266.1521 (calcd for $C_{15}H_{22}O_4$, 266.1518). IR (KBr) ν_{max}: 3441, 1749, 1623 cm^{-1}. ^1H and ^{13}C NMR spectral data are shown in Table 1.

Compound **2**: colorless oil. $[\alpha]_D^{25}$: +79.7 (*c* 0.32, methanol). UV (methanol) λ_{max}, nm: 247. HREI−MS, *m*/*z*: 282.1461 (calcd for $C_{15}H_{22}O_5$, 282.1467). IR (KBr) ν_{max}: 3443, 1758, 1684, 1622 cm^{-1}. ^1H and ^{13}C NMR spectral data are shown in Table 1.

Compound **3**: colorless oil. $[\alpha]_D^{25}$: −50.0 (*c* 0.17, methanol). UV (methanol) λ_{max}, nm: 209. HREI−MS, *m*/*z*: 282.1465 (calcd for $C_{15}H_{22}O_5$, 282.1467). IR (KBr) ν_{max}: 3426, 1630 cm^{-1}. ^1H and ^{13}C NMR spectral data are shown in Table 2.

Compound **4**: colorless oil. $[\alpha]_D^{25}$: −45.8 (*c* 0.20, methanol). UV (methanol) λ_{max}, nm: 207. HREI−MS, *m*/*z*: 282.1466 (calcd for $C_{15}H_{22}O_5$, 282.1467). IR (KBr) ν_{max}: 3423, 1631 cm^{-1}. ^1H and ^{13}C NMR spectral data are shown in Table 2.

Compound **5**: colorless oil. $[\alpha]_D^{25}$: −51.3 (*c* 0.07, methanol). UV (methanol) λ_{max}, nm: 207. HREI−MS, *m*/*z*: 266.1517 (calcd for $C_{15}H_{22}O_4$, 266.1518). IR (KBr) ν_{max}: 3418, 1631 cm^{-1}. ^1H and ^{13}C NMR spectral data are shown in Table 2.

MTT Cell Viability Assay. MTT cell viability assay was used to evaluate the inhibitory effect of these compounds on two human prostate cancer DU-145 and C42B cells. DU-145 and C42B cells were cultured in Dulbecco's modified Eagle's media (DMEM) complemented with 10% fetal bovine serum and 2 mM L-glutamine. The cells were maintained at 37 °C in a humidified atmosphere of 95% air and 5% CO_2. DU-145 and C42B cells (1×10^5/well) were cultured for 72 h in 96-well plates (Falcon, CA) in the presence of various concentrations of compounds. All wells (100 μL each) were incubated with 20 μL of 5 mg/mL MTT solution for 3 h at 37 °C. Then, 100 μL of "triplex solution" [10% sodium dodecyl sulfate (SDS), 5% isobutanol, and 12 mM hydrochloric acid (HCl)] was added to each well and incubated overnight at 37 °C. Absorbance was read at 595 nm on a microplate reader (M-3350, Bio-Rad) with 655 nm as a reference.

Colony Formation Assay. DU-145 cells were cultured in 6 well plates (1000/well) overnight and with new medium replaced in the presence of compound **2**, and the plates continued to incubate at 37 °C with 5% CO_2 for 10 days. On the last day, the medium was removed, and after washing with phosphate-buffered saline (PBS) and fixing with methanol, the colonies were stained with crystal violet solution for 3 h at room temperature. The images were acquired with a scanner, and visible colony numbers were counted after washing and air drying.

Assessing Apoptosis by Annexin-V/Propidium Iodide (PI) Staining. Cells were seeded in a 6 cm dish 1 day before compound treatment. After treatment with compound **2** at 35 nM for 24 h, DU-145 cells were stained with annexin V and PI following the protocol of the manufacturer. Subsequently, cells were analyzed by a FACSCalibur flow cytometer and BD CellQuest Pro software under the examination of FL1 channel for FITC and FL3 detector for PI, as described elsewhere.

Assessing Apoptosis Using DAPI Staining. After treatment with compound **2**, cells were collected and washed once with 2 mL of ice-cold PBS, fixed with 1 mL of 4% paraformaldehyde for 20 min, and washed once again with 2 mL of ice-cold PBS. The cells were incubated in 1 mL of DAPI at 50 μg/mL containing 100 μg/mL RNaseA. This mixture was incubated for 30 min at 37 °C. After washing with 2 mL of PBS 3 times, the cells were observed using fluorescence microscopy at 340 nm (excitation) and 488 nm (emission).

Western Blot Analysis. After treatment with or without a compound for different time courses, cells were harvested and lysed in ice-cold lysis buffer [20 mM Tris−HCl at pH 7.4, 150 mM NaCl, 1 mM ethylenediaminetetraacetic acid (EDTA), 1 mM ethylene glycol bis(2-aminoethyl ether)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA), 1% Triton, 2.5 mM sodium pyrophosphate, 1 mM β-glycerolphosphate, 1 mM sodium orthovanadate, 1 mg/mL leupeptin, and 1 mM phenylmethylsulfonyl fluoride]. The lysate was mixed with an equal volume of 2× loading buffer (4% SDS, 10% 2-mercaptoethanol, 20% glycerol, and 0.2 mg/mL bromophenol blue in 0.1 M Tris−HCl at pH 6.8) and boiled for 10 min immediately. The boiled lysates were subjected to 8−12% SDS−polyacrylamide gels, developed under 100 V, and then transferred to Immobilon-P membranes (Millipore). After blocking with 5% skim milk in phosphate-buffered saline with 0.1% Tween-20 for 1 h and incubation overnight with the corresponding primary antibodies in the blocking solution at 4 °C, primary antibodies were detected using either a peroxidase-conjugated immunopure goat anti-rabbit IgG (H + L) or peroxidase-conjugated immunopure goat anti-mouse IgG (H + L) secondary antibody and enhanced chemiluminescence.

RESULTS AND DISCUSSION

Identification of New Sesquiterpenoids. Compound **1** was obtained as a colorless oil. The molecular formula of compound **1** was found to be $C_{15}H_{22}O_4$ (five degrees of unsaturation) based on the HREI−MS peak at *m*/*z* 266.1521 $[M]^+$ and ^1H and ^{13}C NMR data (Table 1 and Figure S3 of the Supporting Information). In the IR spectra, the prominent absorptions indicated the presence of hydroxyl (3441 cm^{-1}), carbonyl (1749 cm^{-1}), and unsaturated double bond (1623 cm^{-1}) groups. NMR data [^1H, ^{13}C, and distortionless enhancement by polarization transfer (DEPT)] revealed resonances for three methyls, three methylenes, including one terminal sp^2 methylene (δ_H 5.22 and 5.05, δ_C 106.9), five methines, including three oxygenated methines (δ_H 4.36, δ_C 85.1; δ_H 3.07, δ_C 75.7; and δ_H 4.77, δ_C 86.4) and one sp^2 methine (δ_H 6.44, δ_C 120.4), and four quaternary carbons, including one oxygenated carbon (δ_C 73.6), one carbonyl carbon (δ_C 199.8), and two sp^2 quaternary carbons (δ_C 149.3 and 161.0). One sp^2 methylene, one sp^2 methine, one carbonyl carbon, and two sp^2 quaternary carbons represented three double bond equivalents. Therefore, compound **1** must be bicyclic to account for five double bond equivalents required by the molecular formula. The cross-peaks of H-1 and H-2, H-1 and H-6, H-5α/β and H-4α/β, and H-5α/β and H-6 in the $^1H-^1H$ correlation spectroscopy (COSY) spectrum showed the spin system of H-1, H-2, H-4α/β, H-5α/β, and H-6. Further, the heteronuclear multiple-bond correlations (HMBCs) from H_3-14 to C-2, C-3, and C-4, from H_2-14 to C-6 and C-8, from H-1 to C-2, C-7, and C-8, from H-6 to C-7, and from H-8 to C-7 could be observed and allowed for the establishment of the octahydrobenzofuran moiety of compound **1**, together with the oxygenated nature of C-1, C-2, C-3, and C-8. HMBC correlations from H_3-12/13 to C-11, C-10, and C-13/12 and from H-10 to C-9 and C-12/13, together with the chemical shift of C-9 (δ_C 199.8 s), allowed for the establishment of another moiety of the carbonyl-substituted isoprene in compound **1**, which was connected to C-8 according to the key HMBC from H-8 to C-9. On the basis of the above data, the planar structure of compound **1** was formed. The relative configuration of compound **1** was established by nuclear Overhauser effect spectrometry (NOESY) experiments. The presence of NOESY correlations of H-1 with H-6 and H-6 with

DOI: 10.1021/jf504931n
J. Agric. Food Chem. 2015, 63, 545−551

H-5α indicated the α orientation of these protons. Further, the NOESY cross-peaks between H-2 and H_3-15 and H-2 and H-8 established the relative configuration at C-2, C-3, and C-8 and the β orientation of these protons (Figure 1). Therefore, the structure of compound **1** was established as a derivative of bisabolane-type sesquiterpenoid cheimonophyllons[9,10] and named pleuroton A.

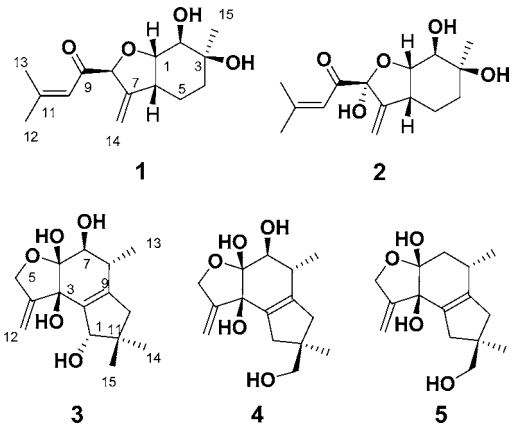

Figure 1. New sesquiterpenoids of *P. cystidiosus*.

Compound **2** was obtained as a colorless oil. The molecular formula of compound **2** was determined to be $C_{15}H_{22}O_5$ (five degrees of unsaturation) based on the HREI−MS peak at m/z 282.1461 $[M]^+$ and ^1H and ^{13}C NMR data (Table 1 and Figure S4 of the Supporting Information). NMR data (^1H, ^{13}C, and DEPT) displayed three methyls, three methylenes, including one terminal sp^2 methylene (δ_H 5.24 and 5.17, δ_C 110.4), four methines, including two oxygenated methines (δ_H 4.28, δ_C 84.6; δ_H 3.47, δ_C 77.7) and one sp^2 methine (δ_H 6.40, δ_C 119.7), and five quaternary carbons, including two oxygenated carbon (δ_C 73.8, 105.8), one carbonyl carbon (δ_C 196.8), and two sp^2 quaternary carbons (δ_C 152.0; δ_C 161.6). One sp^2 methylene, one sp^2 methine, one carbonyl carbon, and two sp^2 quaternary carbons represented three degrees of unsaturation. Thus, compound **2** must be bicyclic to account for five degrees of unsaturation required by the molecular formula. Comprehensive inspection of the NMR data [^1H, ^{13}C, heteronuclear single-quantum coherence (HSQC), HMBC, and $^1H-^1H$ COSY] revealed that compound **2** was similar to compound **1**, except that the oxygenated methine (δ_C 84.6) at C-8 in compound **1** was replaced by the dioxygenated quaternary carbon (δ_C 105.8) at the same position in compound **2** (Figure 1). The similar NOESY correlations of H-1 with H-6, H-6 with H-5α, H-2 with H_3-15, and H-2 with H-4β, established the relative configuration of compound **2**. Therefore, compound **2** was determined as an analogue of cheimonophyllons and named pleuroton B (**2**).

The molecular formula of compound **3** was assigned to $C_{15}H_{22}O_5$ based on the HREI−MS peak at m/z 282.1465 $[M]^+$ and NMR data (Table 2 and Figure S5 of the Supporting Information), requiring five degrees of unsaturation. The IR spectrum indicated the existence of hydroxyl (3426 cm^{-1}) and unsaturated double bond (1630 cm^{-1}) groups. Analysis of NMR data (^1H, ^{13}C, and DEPT) of compound **3** revealed 15 carbon signals attributed to three methyls, three methylenes, including one terminal sp^2 methylene (δ_H 5.27 and 5.13, δ_C 107.9) and one oxygenated methylene (δ_H 4.34 and 4.47, δ_C 68.4), three methines, including two oxygenated methines (δ_H 4.02, δ_C 88.5; δ_H 3.66, δ_C 76.9), and six quaternary carbons, including two oxygenated carbon (δ_C 77.7, 104.7 s) and three sp^2 quaternary carbons (δ_C 136.1, 150.7, and 141.5), indicating a tricyclic sesquiterpene backbone. HMBC correlations from the protons of two methyl groups at 0.97 (s, H-15) and 1.08 (s, H-14) to the corresponding carbons (C-1, C-11, and C-10) indicated the presence of *gem*-dimethyl groups and deduced the one 5-carbon moiety, including C-1, C-11, C-10, C-14, and C-15. According to HMBCs from H_3-13 to C-7, C-8, and C-9, from H-8 to C-6, C-7, C-9, and C-13, and from H-7 to C-3, C-6, C-8, C-9, and C-13, together with the $^1H-^1H$ COSYs of H-8 and H-7 and H-8 and H-13, and the consideration of the chemical shift of C-6 (δ_C 104.7 s), C-2 (δ_C 136.1 s), and C-9 (δ_C 141.5 s), a moiety of three hydroxy-substituted cyclohexenes could be recognized in compound **3**. Additionally, a furan moiety fusing with terminal alkene was assigned by analyzing the HMBC from H_2-12 to C-3, C-4, and C-5 and from H_2-5 to C-3, C-4, C-6, and C-12. Therefore, the planar structure of compound **3** was established (Figure 1).

Following a similar strategy, compounds **4** and **5** were recognized. Compound **4** has the molecular formula of $C_{15}H_{22}O_5$ based on the HREI−MS peak at m/z 282.1466 $[M]^+$ and NMR data (Table 2 and Figure S6 of the Supporting Information), requiring five degrees of unsaturation. The IR spectrum indicated the existence of hydroxyl (3423 cm^{-1}) and unsaturated double bond (1631 cm^{-1}) groups. Analysis of NMR data of compound **4** revealed 15 carbon signals attributed to two methyls, five methylenes, including one terminal sp^2 methylene (δ_H 5.27 and 5.13, δ_C 107.8) and two oxygenated methylene (δ_H 4.47 and 4.26, δ_C 68.4; δ_H 3.40, δ_C 71.3), two methines, including one oxygenated methine (δ_H 3.63, δ_C 76.0), and six quaternary carbons, including two oxygenated carbon (δ_C 77.7 and 104.6) and three sp^2 quaternary carbons (δ_C 131.5, 151.0, and 140.4). Compound **5** has the molecular formula of $C_{15}H_{22}O_4$ based on the HREI−MS peak at m/z 266.1517 $[M]^+$ and NMR data (Table 2 and Figure S7 of the Supporting Information), requiring five degrees of unsaturation. The IR spectrum indicated the existence of hydroxyl (3418 cm^{-1}) and unsaturated double bond (1631 cm^{-1}) groups. Analysis of NMR data of compound **5** revealed 15 carbon signals attributed to two methyls, six methylenes, including one terminal sp^2 methylene (δ_H 5.25 and 5.12, δ_C 107.5) and two oxygenated methylenes (δ_H 4.41 and 4.24, δ_C 67.9; δ_H 3.29, δ_C 71.3), one methine, and six quaternary carbons, including two oxygenated carbon (δ_C 77.8 and 105.2) and three sp^2 quaternary carbons (δ_C 132.1, 151.3, and 143.0). Detailed comparisons of NMR data (Table 2) of compounds **3**−**5** revealed that these compounds had a carbon skeleton similar to clitocybulols A and C.[11] However, the CHOH group at C-1 and the methyl group at C-14 in compound **3** were replaced by CH_2 at C-1 and a hydroxymethyl at C-14 in compound **4** (Figure 1). In addition, the CHOH group at C-7 in compound **4** was substituted for CH_2 at C-7 in compound **5** (Figure 1).

The stereochemistry of clitocybulols A and C was determined by applying the octant rule[12] and based on the circular dichroic spectra of these compounds.[11] The negative Cotton effects at 212 nm for compound **3**, 216 nm for compound **4**, and 216 nm for compound **5** (see Figure S8 of the Supporting Information) suggest that three compounds have the same configuration as clitocybulols A and C at C-3 and C-6. This configuration was further supported by the same sinistral optical rotations ($[\alpha]_D^{25}$, −50.0 for compound **3**; $[\alpha]_D^{25}$, −45.8 for compound **4**; $[\alpha]_D^{25}$, −51.3 for compound **5**; $[\alpha]_D^{25}$,

DOI: 10.1021/jf504931n
J. Agric. Food Chem. 2015, 63, 545−551

−80.0 for clitocybulol A; and $[\alpha]_D^{25}$, −57.7 for clitocybulol C) and NOESY experiments. NOSEY correlations between H-7 and H_3-13, indicating that they are directed on the same side of compound **3**, and between H-1 and H-8, which are pointed at the other side, were observed and deduced the stereochemistry of compound **3** (Figure 1). The presence of NOESY correlations between H-8 and H_2-15, between H_2-15 and H-10α, and between H-8 and H-1α indicated the α orientation of these protons in compound **4**. Further, the NOESY cross-peak between H-7 and H_3-13 revealed the β orientation of these protons in compound **4** (Figure 1). NOESY correlations between H-8 and H-1α and H-7α and between H_2-15 and H-5α, which showed the α orientation of these protons, and between H-1β and H-7β, between H-10β and H_3-13, and between H-10β and H_3-14, which showed the β orientation, were observed in compound **5** and supported its stereochemistry (Figure 1). Compounds **3**, **4**, and **5** were named clitocybulols D, E, and F, respectively.

Bioactivity Evaluation. The experimental results of the MTT cell viability assay indicated that these new sesquiterpenoids exhibit significant cytotoxicity against two human prostate cancer DU-145 and C42B cells. The median inhibitory concentration (IC_{50}) of compounds **1**−**5** against DU-145 and C42B cells are shown in Table 3. Consistently, the colony formation assay showed that the number of colonies formed in the cells treated with compound **2** significantly decreased in comparison to that of the control group (Figure 2). Furtherly, flow cytometric analysis revealed that the proportion of apoptotic cells after treatment with compound **2** was 13.36%, which was dramatically increased in comparison to 0.29% of the control cells (Figure 3A). Chromatin condensations induced by the treatment with compound **2** for 24 h could be observed by DAPI staining in DU-145 cells (Figure 3B). We observed that the expression levels of pro-apoptotic protein Bak and Bax increased significantly in the treated cells compared to the controls, but the anti-apoptotic protein Bcl-2 level was decreased (Figure 3C). Taken together, these results indicated that compound **2** triggered the apoptosis of the DU-145 cells.

Table 3. Growth Inhibition against DU-145 and C42B Cells of Compounds 1−5

	growth inhibition (IC_{50}, nM)	
compound	DU-145	C42B
1	174	104
2	28	52
3	233	163
4	162	120
5	179	119

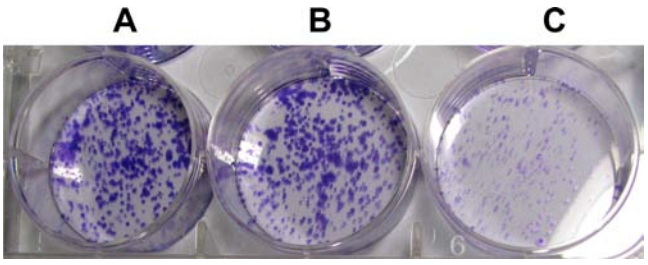

Figure 2. Colony formation assay (A, DU-145 cells were cultured in the medium not containing compound **2**; B, DU-145 cells were cultured in the medium containing compound **2** at 17.5 nM; and C, DU-145 cells were cultured in the medium containing compound **2** at 35 nM).

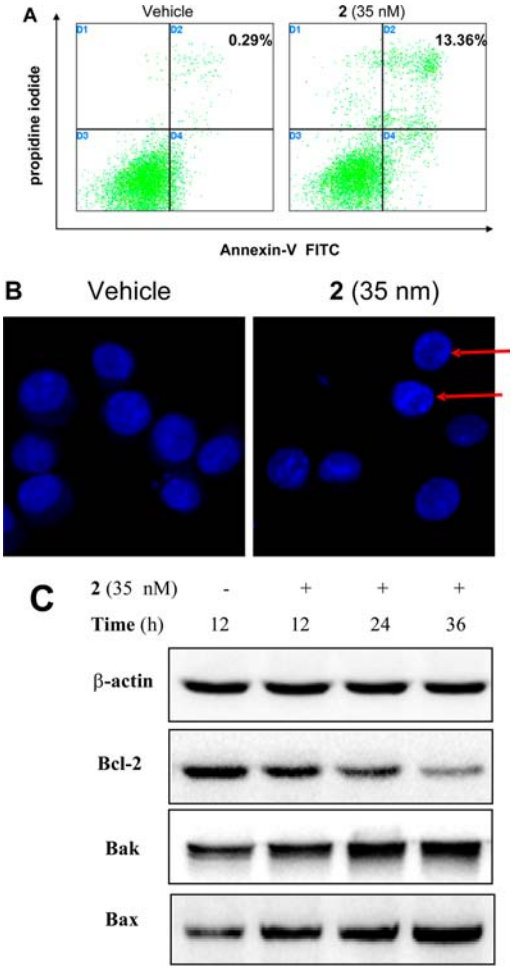

Figure 3. Analysis of apoptosis induced by compound **2**. (A) Detection of apoptosis using annexin V-FITC staining. After treatment with compound **2** at 35 nM for 24 h, DU-145 cells were analyzed by a FACSCalibur flow cytometer. The horizontal axis represents annexin V intensity, and the vertical axis shows PI staining. The lines divide each plot into four quadrants: lower left quadrant, living cells; lower right quadrant, early apoptotic cells; upper left quadrant, necrotic cells; and upper right quadrant, late apoptotic cells. (B) Microscopy of DU-145 cells treated with compound **2**. DU-145 cells were treated with compound **2** at 35 nM for 24 h. The images were captured using fluorescence (at 600×) for nuclear staining with compound **2** at 0 nM (vehicle) or 35 nM. Apoptotic cells with condensed nuclei were observed using nuclear staining, as indicated with red arrows. (C) Western blot analysis for the expression of apoptosis-related proteins in the DU-145 cells. The expression levels of Bcl-2, Bak, and Bax were determined by western blotting in the DU-145 cells after treatment for the indicated time with compound **2** at 35 nM. β-Actin was used for normalization and verification of protein loading.

Sesquiterpenoids **1** and **2** possess a bisabolane-type skeleton, whereas sesquiterpenoids **3**−**5** are clitocybulol derivatives. In the previous reports, cheimonophyllons A−E and cheimonophyllal, analogues of compounds **1** and **2**, exhibited nematicidal, cytotoxic, and antimicrobial activities,[9,10] but no activities were observed about clitocybulols.[11] In the present work, pleuroton B (**2**) exhibited significant cytotoxicity at a higher level than other sesquiterpenoids, pleuroton A (**1**), and clitocybulols D−F (**3**−**5**). In particular, although compound **1** possesses one α,β-

DOI: 10.1021/jf504931n
J. Agric. Food Chem. 2015, 63, 545−551

unsaturated carbonyl moiety and one exomethylene as compound **2**, compound **2** has one additional hydroxyl at C-8 compared to compound **1** and has ca. 2−6 times stronger cytotoxicity against the two prostate cancer cells than compound **1**.

Sesquiterpenoids are the major secondary metabolites of fungi, plant, algae, etc. The diversity of their structures is often beyond people's imagination. In recent years, many new sesquiterpenoids were discovered and possessed a wide variety of bioactivities, such as antidiabetic and anti-inflammatory,[13] anti-aging,[14] antimelanogenesis,[15] antineuroinflammatory,[16] antivirus,[17] antimicrobial,[18] acetylcholinesterase inhibitory activity,[19,20] protein tyrosine phosphatase,[21] antifouling,[22] etc. Moreover, the relationships between the structure and bioactivities of sesquiterpenoids have been summarized in several reviews[23−25] and revealed that the α,β-unsaturated carbonyl structural groups, including α-methylene-γ-lactones, α,β-unsaturated cyclepentanone, etc., are the active functional groups, which could react as Michael acceptors with nucleophiles by Michael addition and display promising cytotoxity, such as bigelovin,[26] ergolide,[26] kaunial,[27] germacranolide,[28] eudesmane derivative,[29] etc. Additionally, several studies in bisabolane-type sesquiterpenoids had revealed more interesting results about structure−activity relationships. The bisabolane-type sesquiterpenoid dihydro-ar-turmerone, which contains an oxidation functional group and the single bond moiety in its skeleton, has a higher acetylcholinesterase inhibitory activity than other analogues.[30] 3,6-Epidioxy-1,10-bisaboladiene (EDBD), the bisabolane sesquiterpenoid endoperoxide, showed stronger antitumor activity than α-curcumene, a bisabolane sesquiterpene that lacks the endoperoxide moiety of EDBD.[31] The additional hydroxyl at C-8 in compound **2** could act as an electron-withdrawing group and polarize the exomethylene, resulting in the susceptibility to nucleophilic attack and forming a bifunctional center, which plays a key role in the cytotoxity against the prostate cancer cells. Structure−activity relationship studies will contribute to the modification of new lead compounds.

Supporting Information

ABSTRACT: The berries of bilberry and black currant are a rich source of anthocyanins, which are thought to have favorable effects on nonalcoholic steatohepatitis (NASH). This study was designed to examine whether purified anthocyanins from bilberry and black currant are able to limit the disorders related to NASH induced by a methionine-choline-deficient (MCD) diet in mice. The results showed that treatment with anthocyanins not only alleviated inflammation, oxidative stress, steatosis, and even fibrosis but also improved depletion of mitochondrial content and damage of mitochondrial biogenesis and electron transfer chain developed concomitantly in the liver of mice fed the MCD diet. Furthermore, anthocyanins treatment promoted activation of AMP-activated protein kinase (AMPK) and expression of peroxisome proliferator-activated receptor-gamma coactivator-1α (PGC-1α). These data provide evidence that anthocyanins possess significant protective effects against NASH and mitochondrial defects in response to a MCD diet, with a mechanism maybe through affecting the AMPK/PGC-1α signaling pathways.

KEYWORDS: *AMP-activated protein kinase, anthocyanin, mitochondrial dysfunction, nonalcoholic fatty liver disease, oxidative stress*

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is currently the most prevalent chronic liver disease, largely due to the obesity epidemic.[1] It encompasses a spectrum of liver damage ranging from simple steatosis to nonalcoholic steatohepatitis (NASH), an advanced stage of disease comprising progressive steatosis, lobular inflammation, balloon degeneration, and even fibrosis.[2] The pathogenesis responsible for the development and progression of NASH is comprehensive and remains yet to be fully elucidated. Due to this available treatments remain unsatisfactory.

Hepatocytes are commonly enriched in mitochondria (~1000−2000 mitochondria/hepatocyte), signifying their critical roles within hepatocytes, such as the primary site for energy production and β-oxidation of fatty acids. Previous studies have shown that abnormal morphological changes in mitochondria and reduced mitochondrial DNA (mtDNA) copy number are observed in human subjects and animal models with NASH.[3,4] In addition, significantly decreased activity of the hepatic mitochondrial respiratory chain (MRC), particularly complex I and IV, was shown in NASH liver samples compared to controls.[5,6] Moreover, recent evidence has demonstrated impairment of mitochondrial β-oxidation in humans and animals with NASH.[7,8] These studies provide strong evidence to support the possibility that NAFLD might be a mitochondrial disease. They also support seeking therapies that improve mitochondrial function as a useful strategy for preventing NASH and its complications.

Interestingly, several polyphenolic compounds, such as curcumin,[9] quercetin,[10] anthocyanins (ACNs)[11] and green tea catechins,[12] have been demonstrated to have beneficial effects in NAFLD. Among them, ACNs are of great interest due to their abundance in a wide variety of plant foods and the fact that considerable amounts could be ingested from our plant-based daily diets. Existing in vitro data suggest that ACNs exert antisteatosis effects in hepatocytes by inhibiting lipogenesis and/or promoting fatty acid oxidation.[13−15] Mirroring the results obtained in vitro, ample evidence from animal models of NAFLD demonstrates that ACNs diminish hepatic lipid accumulation and inflammation.[16] Furthermore, ACNs are thought to promote antioxidant activity and eventually contribute to an overall positive gain in liver function.[17,18] Despite realizing these benefits, an understanding of the protective role of ACNs and the underlying mechanism of action in the progression of NASH remains unknown and requires further investigation in vivo.

Considering the potential capability of ACNs in NASH and the vital role of mitochondrial dysfunction in the progression of NASH, we set out to determine the influence of purified ACNs from bilberry and black currant on hepatic steatohepatitis and fibrosis as well as mitochondrial content and function in a methionine-choline-deficient (MCD) diet murine model of

NASH. The influence of ACNs on related signaling pathways was also investigated.

MATERIALS AND METHODS

Purified Anthocyanins. Purified ACNs were kindly provided by Polyphenol AS (Sandnes, Norway). As mentioned in our previous study,[19] the purified ACNs product consisted of 17 different natural ACNs from bilberry (*Vaccinium myrtillus*) and black currant (*Ribes nigrum*). Cyanidin 3-*O*-β-glucoside and delphinidin 3-*O*-β-glucoside are major components of the ACNs supplement. Detailed components and contents are listed in Supporting Information Table 1.

Reagents and Antibodies. Reagents for immunohistochemistry and immunofluorescence, such as serum blocking solution, hydrogen peroxide, and diaminobenzidine (DAB), were obtained from Zhongshan Jinqiao Biotechnology Co. (Beijing, China). Anti-AMP-activated protein kinase (AMPK) and antiphosphorylated AMP-activated protein kinase (p-AMPK) antibodies were purchased from Cell Signaling Technology Inc. (Danvers, MA, USA). Antibodies for cabamoyl phosphate synthase 1 (CPS-1), alpha smooth muscle actin (α-SMA), peroxisome proliferator-activated receptor-gamma coactivator-1β (PGC-1β), nicotinamide adenine dinucleotide dehydrogenase (Complex I), and cytochrome *c* oxidase (Complex IV) were purchased from Abcam (Cambridge, UK). Antibodies for peroxisome proliferator-activated receptor-gamma coactivator-1α (PPAR-α), peroxisome proliferator-activated receptor-1α (PGC-1α), glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and all secondary antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Fluorescent probe dihydroethidium (DHE) was purchased from Calbiochem (San Diego, CA, USA). All other reagents and kits were obtained from Sigma-Aldrich (St. Louis, MO, USA) and Invitrogen (Carlsbad, CA, USA) unless otherwise noted.

Animals and Diets. All animal procedures were approved by the Animal Care and Protection Committee of Sun Yat-Sen University (2013-10). Six-week-old male C57BL/6J mice purchased from the Experimental Animal Center of Sun Yat-Sen University (Guangzhou, China) were housed in standard cages within a room with a constant temperature and humidity, under a 12-h light/dark cycle, with free access to food and water. After 2-week adaptation, all mice were body-weight matched and randomly divided into three groups (n = 8 per group): (1) control group, mice were fed a control chow diet; (2) MCD group, mice were fed with a diet deficient in methionine and choline; (3) MCD + ACNs group, mice were fed with the MCD diet with addition of 1 g of purified ACNs per kilogram food. Both the control chow diet and MCD diet were purchased from Research Diets Inc. (New Brunswick, NJ, USA). The control diet was identical to the MCD diet but supplemented with D,L-methionine (3 g/kg) and choline chloride (2 g/kg). Food intake was measured every other day, and body weight was measured weekly.

Biochemical Analyses. At the end of the experiment, all mice were euthanized with sodium pentobarbital (50 mg/kg body weight) and sacrificed after overnight starvation. The serum and liver samples of each mouse were collected and stored at −80 °C for further analysis.

Serum alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were detected using commercial kits from Jiancheng Bioengineering Institute (Nanjing, China) according to the manufacturer's instructions. Serum triglyceride (TG), total cholesterol (TC), and hepatic TG/TC contents were determined using commercial detection kits (Applygen Technologies Inc., Beijing, China) according to manufacturer's protocols.

Histological Assessment. The liver samples were fixed in 10% phosphate-buffered formalin, embedded in paraffin, cut in 5 μm thickness, and applied to slides. The sections were stained with hematoxylin and eosin (H&E) and Sirius Red for histological analysis (NAFLD activity scoring (NAS) and collagen) under light microscopy (Leica, Bensheim, Germany). The Pathology Committee of the NASH Clinical Research Network[20] provided guidance and recommendations for the NAS study by semiquantitatively evaluating the following histological features: steatosis (<5% = 0; 5−33% = 1; 33−66% = 2; >66% = 3); lobular inflammation (none = 0; <2 foci = 1; 2−4 foci = 2; >4 foci = 3); and hepatocellular ballooning (none = 0; few = 1; prominent = 2). All features were scored blindly based on at least 5 samples per group and 10 fields of vision in each sample. Fresh liver tissue was embedded in Tissue Tek OCT, rapidly frozen in liquid nitrogen, and then stored at −80 °C for preparation of frozen sections (5 μm), which were used for staining with Oil Red O and immunofluorescence staining.

Immunohistochemistry and Immunofluorescence. The procedures for immunohistochemistry and immunofluorescence assays were performed as previously described.[21] Briefly, slides were incubated in serum blocking solution for 30 min and incubated overnight with either α-SMA or CPS-1 primary antibody. Then HRP-labeled or fluorescent secondary antibodies were used for immunohistochemistry (α-SMA) and immunofluorescence (CPS-1) analysis, respectively. DAB was applied for immunohistochemistry, and the samples were observed under light microscopy (Leica, Bensheim, Germany). DAPI (Roche, Germany) was utilized for immunofluorescence nuclear staining, and the samples were observed under an Inverted Fluorescence Microscopy (Nikon Eclipse Ti-E, Tokyo, Japan). The fluorescent intensity was analyzed using ImageJ software (Research Services Branch of the NIH, Bethesda, MD).

Western Blot. Liver tissues were homogenized, and 30 μg of total protein lysate were loaded onto 8−15% SDS polyacrylamide gels. After 90 min of electrophoresis, the proteins were transferred onto a polyvinylidene difluoride membrane in ice for 1−2 h. The membrane was blocked with 5% (w/v) bovine serum albumin dissolved in trihydroxymethyl aminomethane buffer salt containing 0.05% (v/v) Tween-20 (TBST). The membrane was then incubated at 4 °C overnight with primary antibodies for AMPK, p-AMPK, CPS-1, PGC-1α, PGC-1β, PPAR-α, Complex I, or Complex IV, followed by incubation with secondary antibodies conjugated with horseradish peroxidase for 2 h at room temperature. Signals were detected by enhanced chemiluminescence reagent (Thermo Fisher Scientific, Waltham, MA, USA). GAPDH was used for normalization. The density of the specific bands was quantified using ImageJ software.

Mitochondrial DNA Quantification. Total DNA was extracted from livers using a DNeasy Blood & Tissue Kit (Qiagen, Dusseldorf, Germany), and real-time PCR was performed using gene-specific primers amplifying mitochondrial DNA (mtDNA) and nuclear DNA (nDNA). The relative values of mtDNA content and nDNA content were used to assess mitochondrial copy numbers. The primer sequences are listed in Supporting Information Table 2.

RNA Extraction and Quantitative RT-PCR. Total RNA (1 μg) was extracted from liver tissues using Trizol reagent and transcribed into cDNA using the PrimeScript RT reagent kit (TaKaRa, Tokyo, Japan) according to the manufacturer's recommendations. Quantitative PCR was performed using a real-time PCR system (Applied Biosystems, Foster City, CA, USA), and reactions were performed using SYBR Green Master Mix (TaKaRa, Tokyo, Japan) with gene-specific primers. Each sample was normalized to β-actin, and the fold change in expression of each target gene relative to β-actin was assessed via the comparative CT ($2^{-\Delta\Delta CT}$) method. Primer sequences are listed in Supporting Information Table 3.

Detection of Hepatic Oxidative Stress. The total reactive oxygen species (ROS) levels in the liver tissues were detected using the fluorescent probe DHE. Briefly, frozen liver sections were incubated in DHE (10 μM) for 30 min in a dark and humidified chamber at 37 °C. DHE is oxidized by superoxide to ethidium bromide, bands to the DNA, and emits red fluorescence,[22] which was detected using inverted fluorescence microscopy. In addition, liver tissue homogenates were prepared to measure hepatic malondialdehyde (MDA) by following the commercial kit's instructions (Beyotime, Shanghai, China). The MDA concentrations were normalized by protein contents.

Statistical Analysis. All results were expressed as mean ± standard deviation (SD) and statistically analyzed with SPSS 16.0 for Windows (SPSS Inc., Chicago, IL, USA). Comparisons between all groups were evaluated using one-way analysis of variance (ANOVA). Differences were considered significant at $P < 0.05$.

RESULTS

Effects of ACNs on Animal Characteristics. As shown in Table 1, the initial body weight among the 3 groups showed little deviation ($P > 0.05$). After 4 weeks, the MCD mice with or without ACNs treatment displayed a significant reduction in body weight (~50%). Moreover, 1-fold increase in serum AST and more than 10-fold increase in serum ALT were observed in mice fed the MCD diet. Though ACNs did not attenuate the reduction of body weight induced by the MCD diet, their addition effectively decreased serum ALT and AST levels ($P < 0.05$). No significant changes in daily food intake among the 3 groups during the experimental period were observed (data not shown).

Table 1. Animal Characteristics and Serum Liver Enzymes of Mice in Different Study Groups[a]

	control	MCD	MCD + ACNs
initial body weight (g)	25.12 ± 1.30	25.09 ± 1.26	25.35 ± 1.20
final body weight (g)	27.39 ± 2.74	16.93 ± 0.73*	17.19 ± 0.42*
liver weight (g)	0.89 ± 0.13	0.54 ± 0.06*	0.56 ± 0.10*
liver to body weight ratio (%)	3.53 ± 0.62	3.20 ± 0.20	3.40 ± 0.34
serum ALT level (U/L)	6.03 ± 1.68	79.08 ± 36.54*	58.65 ± 25.03*/#
serum AST level (U/L)	23.43 ± 1.66	49.48 ± 3.17*	40.26 ± 2.07*/#

[a]All values are mean ± SD, $n = 8$. Statistical analysis of the data for multiple comparisons was performed by ANOVA. *$P < 0.05$ versus the control group; #$P < 0.05$ versus the MCD group.

Effects of ACNs on Lipid Accumulation. The histological features of Oil Red O staining illustrated a massive accumulation of neutral lipid droplets within the hepatocytes of MCD group, whereas only small lipid droplets were observed in mice treated with ACNs (Figure 1A). Quantitative determination of hepatic TG content further confirmed that a large quantity of TG accumulated in the livers of mice fed the MCD diet, which was significantly decreased by ACNs supplementation ($P < 0.05$) (Figure 1B). Conversely, the serum TG levels in both MCD diet group and MCD + ACNs group declined sharply compared with the control group, while were slightly up-regulated by ACNs though without significance compared with the MCD group ($P > 0.05$) (Figure 1C). This interesting phenomenon probably was

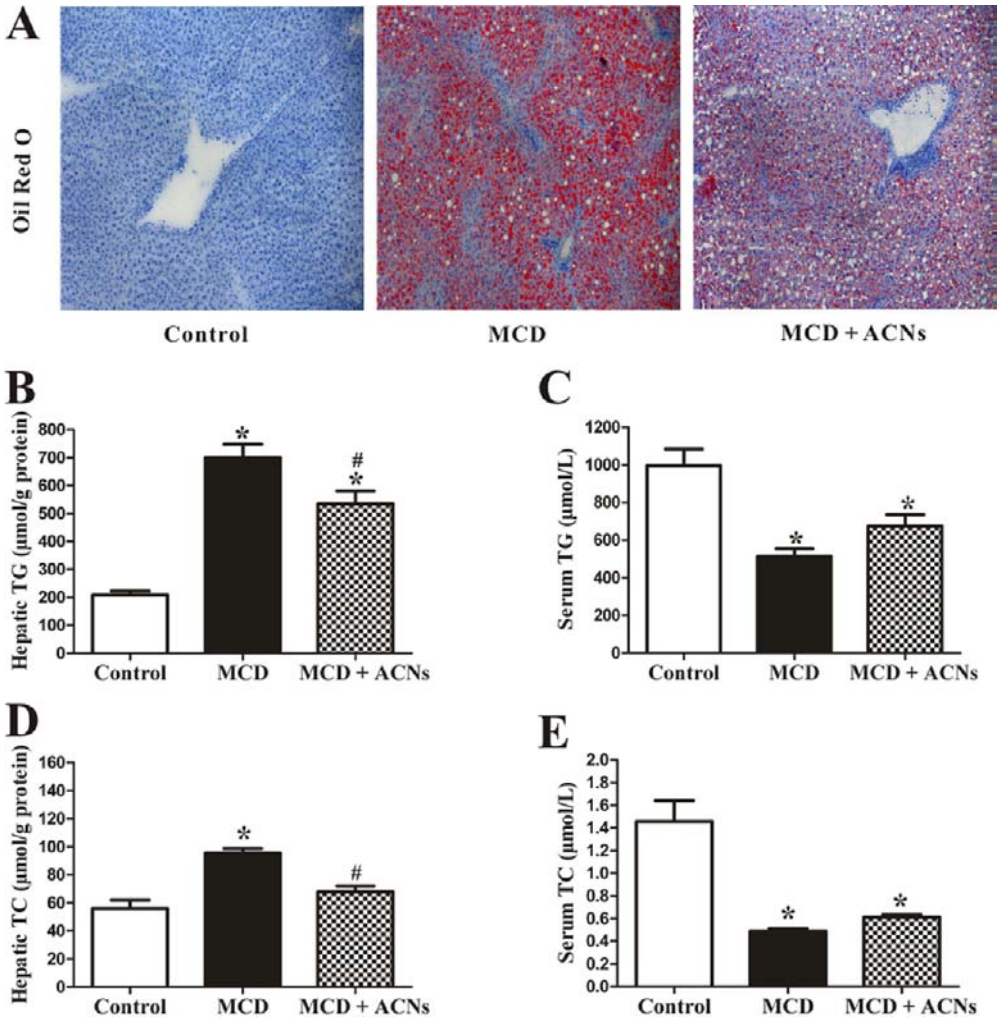

Figure 1. ACNs decreased lipid accumulation in mice fed the MCD diet. (A) Frozen sections (5 μm thick) were stained with Oil Red O, which marked neutral lipid. Representative micrographs (200× magnification) are shown. (B–E) TG and TC levels were measured from all frozen liver specimens and serum. Values are expressed as mean ± SD, $n = 8$. *$P < 0.05$ versus the control group; #$P < 0.05$ versus the MCD group.

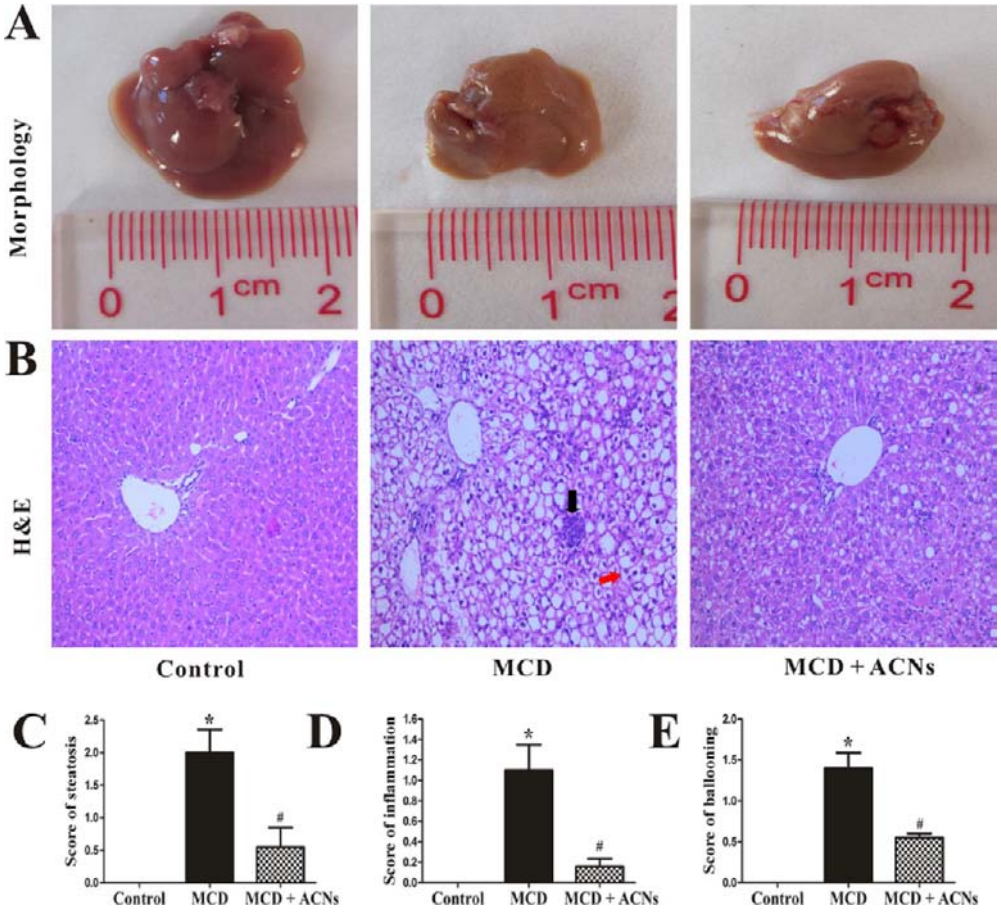

Figure 2. ACNs ameliorated steatohepatitis induced by the MCD diet. (A) Representative gross morphology images are shown. (B) Hepatic histological analysis of H&E staining (200× magnification). Inflammatory infiltration (black arrow) and hepatocyte ballooning (red arrow) were observed in liver sections from the MCD group which were improved in the ACNs-treated group. (C–E) Histological NAS scores of liver tissues. Values are expressed as mean ± SD, $n = 8$. *$P < 0.05$ versus the control group; $^{\#}P < 0.05$ versus the MCD group.

caused by hepatic TG potentially releasing into serum. Similarly, accumulation of hepatic TC was effectively alleviated by ACNs ($P < 0.05$) (Figure 1D). The serum TC levels in the MCD + ACNs group showed an increasing trend but no significant differences compared to the MCD diet only group (Figure 1E).

Amelioration of Steatohepatitis by ACNs. The gross morphology of the livers in the control group displayed red and smooth tissue surface. After 4 weeks feeding with MCD diet, the gross morphology of livers had an obvious increase in tawny and brittle appearance, which was improved greatly by ACNs treatment (Figure 2A). The NAS calculation system was applied to semiquantitatively evaluate the steatosis, inflammation, and ballooning. Indeed, the histological analysis of H&E staining indicated significant microvesicular steatosis, inflammatory cell infiltration, and hepatocyte ballooning in the MCD diet group. However, livers of the ACNs-treated group exhibited only mild hepatic steatosis and effectively ameliorated inflammatory infiltration with reduction by 50% in hepatocyte ballooning compared to the MCD diet only group (Figure 2B–E).

Inhibition of Liver Fibrosis by ACNs. To assess the effect of ACNs on hepatic fibrosis, we carried out a Sirius Red staining of collagen in liver sections. A substantial increase in collagen deposition was observed in the MCD group compared with the control group. However, an obvious decrease in the stained area percentage was observed in the MCD + ACNs group (Figure 3A). Activation of hepatic stellate cells (HSCs), the major effectors in collagen production during hepatic fibrogenesis, is another indicator of fibrogenesis. To further evaluate HSCs activation, immunohistochemical staining of α-SMA was performed. As displayed in Figure 3B, the data indicated that ACNs treatment reduced the expression of α-SMA, suggestive of inhibition of HSCs activation. Besides, both relative mRNA expression of collagen I and α-SMA confirmed that ACNs played a suppressive effect on fibrosis in NASH (Figure 3C and 3D).

Decrease of Oxidative Damage by ACNs. Mitochondria are the major sites for ROS production. Quantitative evaluation of hepatic ROS is also an indicator of mitochondrial impairment. In our present study, the 4-week MCD diet up-regulated ROS levels of liver tissues by approximately 6-fold compared with the control diet, and we unearthed that ACNs were able to significantly subdue ROS production induced by the MCD diet (Figure 4A and 4B). In addition, hepatic malondialdehyde (MDA) content, a widely used marker of oxidative stress, was increased by nearly 4-fold in the MCD group but only slightly increased in ACNs-treated mice (Figure 4C). The results of hepatic ROS and MDA levels clarified that ACNs played a suppressive effect on oxidative damage in NASH.

Attenuation of Reduced Mitochondrial Content and Function by ACNs. One of the common mitochondrial defects observed in NASH is depletion of mitochondrial DNA (mtDNA).[4] In our study, we first investigated the protective effect of ACNs on mtDNA. As shown in Figure 5A, mtDNA indeed displayed an apparent decrease in the MCD group, which was slightly improved through administration of ACNs ($P <$

DOI: 10.1021/jf504926n
J. Agric. Food Chem. 2015, 63, 552–561

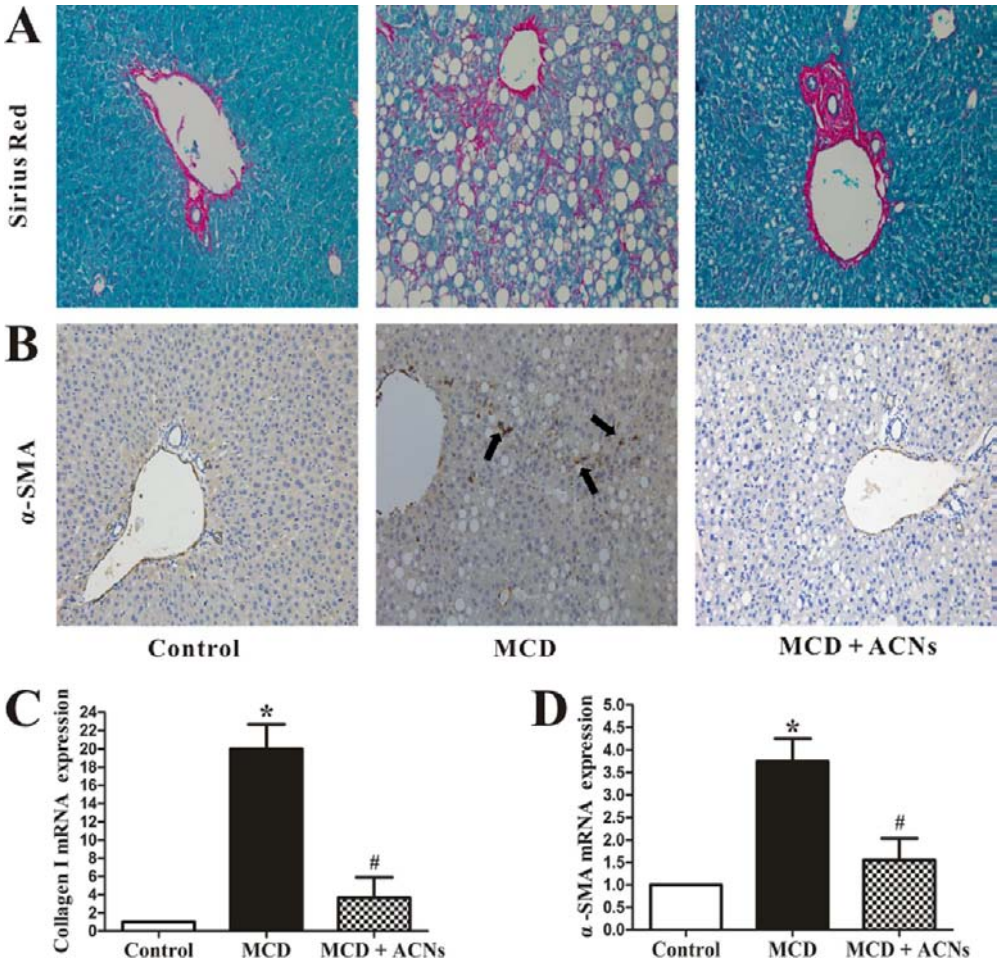

Figure 3. ACNs played an inhibitory role in progression of fibrosis in mice fed an MCD diet. (A) Paraffin-embedded liver specimens were stained with Sirius Red and observed by light microscopy. (B) Paraffin sections were immunoassayed for fibrosis markers, α-SMA (black arrows), to assess hepatic stellate cells activation. Representative photographs (200× magnification) are shown. (C and D) Total RNA was isolated from the livers, and genes expression of collagen I and α-SMA were subjected to RT-PCR analysis; the control group was set to be 1. Values are expressed as mean ± SD, $n = 8$. $^{*}P < 0.05$ versus the control group; $^{\#}P < 0.05$ versus the MCD group.

0.05), though it was still lower than the number observed in the control group. Moreover, CPS-1, a hepatic mitochondrial membrane specific marker and reflection of mitochondrial number and function in liver, declined in NASH but was significantly up-regulated by treatment of ACNs (Figure 5B−5D).

Enhancement of Mitochondrial Biogenesis by ACNs. To investigate whether ACNs are capable of increasing mitochondrial biogenesis, we determined the relative mRNA expression of peroxisome proliferator-activated receptor-gamma coactivator-1α (PGC-1α) and β (PGC-1β), nuclear respiratory factor-1 (NRF-1) and 2 (NRF-2), and mitochondrial transcription factor A (Tfam) (pivotal regulators of mitochondrial biogenesis). As displayed in Figure 6A and B, PGC-1α dropped in NASH ($P < 0.05$) but exhibited sharply increased expression after ACNs intervention, whereas PGC-1β was unaffected by either MCD diet or ACNs treatment. In addition, there was almost 50% reduction in PGC-1α-target genes NRF-1, NRF-2, and TFAM following a MCD diet, while the reduction was effectively suppressed with treatment of ACNs. Likewise, immunoblotting analysis revealed that ACNs reversed the reduction of protein abundance of PGC-1α induced by the MCD diet, while no significant difference in PGC-1β expression was observed among the three groups (Figure 6C). Together, these results indicate that ACNs may induce mitochondrial biogenesis through PGC-1α pathway.

Our previous research has demonstrated activation of AMPK by ACNs in hepatocytes,[14] which could result in phosphorylation of the transcriptional coactivator PGC-1α, thus leading to increased mitochondrial biogenesis.[23,24] Then, we determined the protein levels of p-AMPK and total AMPK and discovered an over 50% decrease in p-AMPK in the liver of NASH mice, which was rescued by ACNs with no change of total AMPK (Figure 6C).

Amelioration of Mitochondrial Electron Transfer Chain (ETC) Defects by ACNs. Mitochondrial ETC is constituted of four respiratory complexes (complexes I−IV).[25] To confirm the alteration of mitochondrial ETC and effects of ACNs on it at a functional level, the protein expression of two major sites of electron input into the electron transport system (complex I and IV) in total liver lysates was examined (Figure 6D). The mice fed the MCD diet had mitochondrial ETC defects, as shown by conspicuously diminished protein expression of mitochondrial complexes I and V, especially complex IV (approximately 4-fold). As expected, dietary ACNs intervention successfully intensified protein expression of mitochondrial complexes I and V, reflecting improvement of mitochondrial oxidative phosphorylation and enhancement of mitochondrial biogenesis and function.

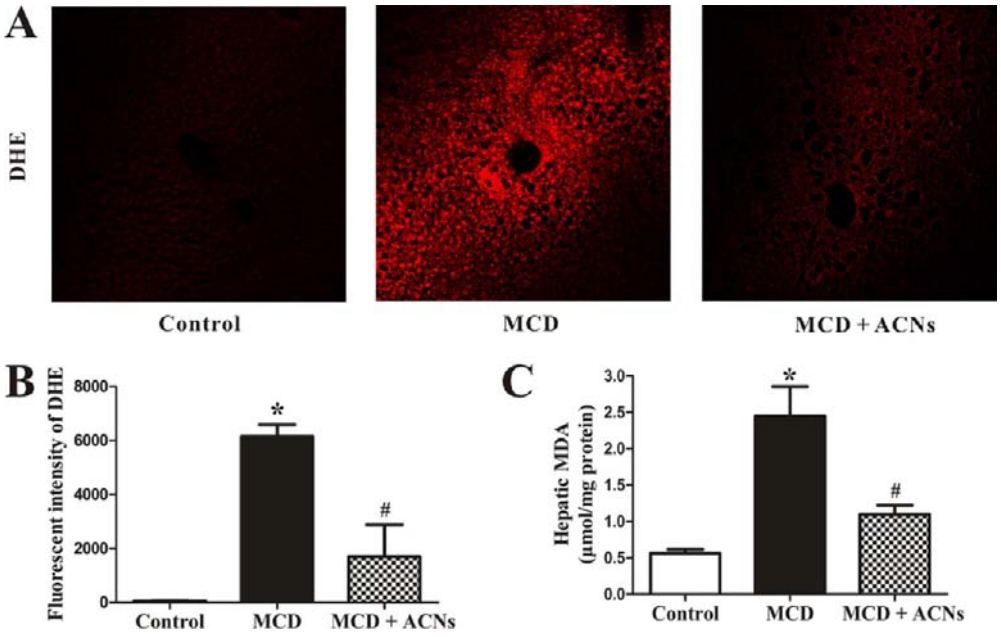

Figure 4. ACNs decreased oxidative damage in NASH. (A) Frozen sections of livers were stained with fluorescent probe DHE, showing red fluorescence in regions of ROS production. Representative fluorescence micrographs (200× magnification) are shown. (B) Fluorescent densitometry of DHE staining was quantified by ImageJ software. (C) MDA content in livers. Values are expressed as mean ± SD, $n = 8$. $^{*}P < 0.05$ versus the control group; $^{\#}P < 0.05$ versus the MCD group.

Improvement of Mitochondrial β-Oxidation by ACNs. Impairment of mitochondrial oxidative phosphorylation is often followed by inhibition of mitochondrial fatty acid β-oxidation. In the present study, we indeed discovered that both protein and mRNA expression of peroxisome proliferator-activated receptor-α (PPAR-α) were nearly halved in NASH but successfully restored by ACNs intervention (Figure 6C and E). PPAR-α is one of a superfamily of nuclear hormone receptors and able to transcriptionally up-regulate nuclear genes encoding mitochondrial fatty acid oxidation enzymes.[26] We then determined gene expression levels of carnitine palmitoyltransferase 1 (CPT-1) and medium chain acyl CoA dehydrogenase (MCAD), two rate-limiting enzymes of fatty acids β-oxidation. As illustrated in Figure 6E, relative mRNA expression of CPT-1 and MCAD dropped significantly in NASH ($P < 0.05$); however, both were augmented with administration of ACNs. These were accompanied by no distinction of fatty acid synthesis (FAS) between the groups. Thus, ACNs seemed to be able to stimulate hepatic lipid oxidation, leading to reduction of TG accumulation within hepatocytes.

DISCUSSION

Previously, we and others have shown that ACNs have hepatoprotective activities in obese and diabetic rodents.[16,27] In the present study, we demonstrated that purified ACNs from bilberry and black currant were capable of ameliorating hepatic steatosis, inflammation, oxidative stress, as well as signs of fibrosis and improving depletion of mitochondrial content and damage of mitochondrial biogenesis, ETC, as well as β-oxidation. To our knowledge, this work provides the first evidence that ACNs, the soluble flavonoids, alleviate complications of NASH and improve degeneration of mitochondrial function in mice fed a MCD diet.

Much research verifies that abnormalities in the number and quality of mitochondria are frequently observed in NASH and involved in its pathogenesis. These mitochondrial abnormalities include ultrastructural lesions, depletion of mtDNA, reduction of respiratory chain activity, impairment of mitochondrial β-oxidation, and induction of uncoupling and apoptosis.[28] As expected, our MCD diet-induced NASH model displayed a reduction in mitochondrial content as well as impairment of mitochondrial biogenesis, ETC activity, and β-oxidation function.

In our study, we discovered that dietary supplement of ACNs could ameliorate the depletion of mtDNA and decrease expression of CPS-1 (Figure 5). Mitochondrial DNA represents mitochondrial self-replication and is involved in mitochondrial biogenesis.[24] It is also crucial for mitochondrial oxidative phosphorylation, encoding 13 MRC polypeptides that embed within complexes I, III, IV, and V, and further for β-oxidation.[29] CPS-1, a hepatic mitochondrial membrane-specific marker, qualitatively reflects hepatic mitochondrial content and function in the liver and is a comprehensive marker of mitochondrial damage.[30] It could be concluded from our work that dietary ACNs mitigate the depletion of mitochondrial content and dysfunction in NASH.

Mitochondrial biogenesis plays a critical role in maintaining the dynamic equilibrium of proliferation and degradation of mitochondria in hepatocytes.[31] Activation of mitochondrial biogenesis is mainly reflected by the activation of NRF-1 and NRF-2, which conversely regulates the expression of Tfam, a protein essential for transcription, replication, and maintenance of the mtDNA. In our study, the mRNA expression of NRF-1, NRF-2, and Tfam was significantly decreased in mice fed the MCD diet, indicating damage to mitochondrial biogenesis. This effect was evidently ameliorated by administration of ACNs, especially with respect to NRF-2 and Tfam (Figure 6B). These data suggest that ACNs stimulate mitochondrial biogenesis in NASH.

As major sites for cellular respiration, mitochondria play a vital role in maintaining energy metabolism and function of hepatocytes, which includes the citric acid cycle and oxidative phosphorylation process. The oxidative phosphorylation process

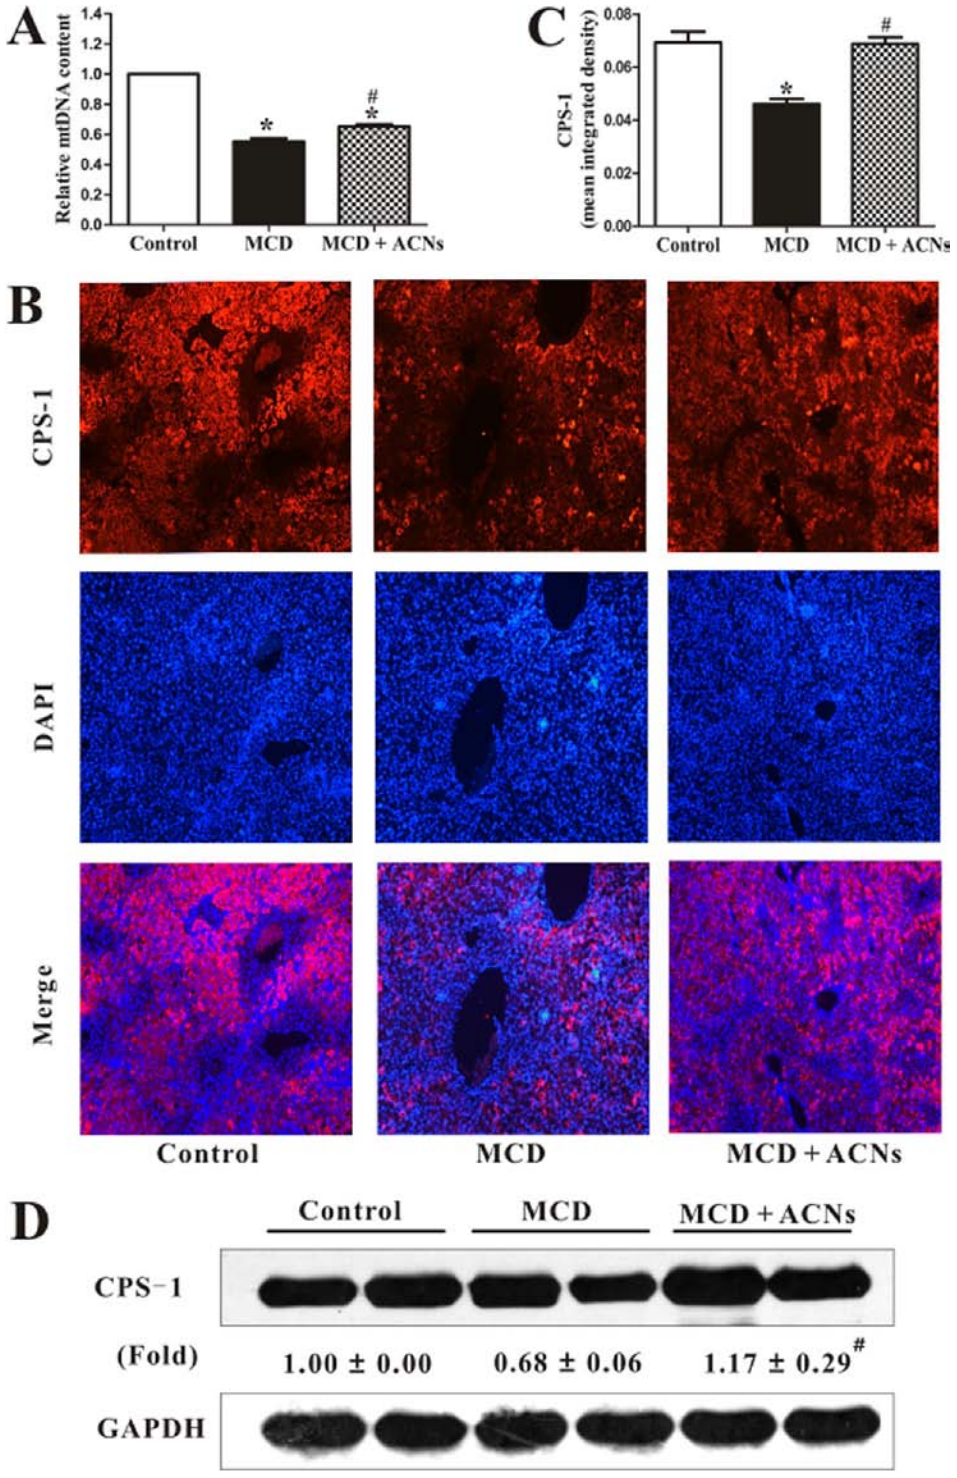

Figure 5. ACNs attenuated reduction of mitochondrial content and function in NASH. (A) Mitochondrial genome copy number was shown as the ratio of mtDNA to nDNA from purified liver DNA, which was determined by quantitative real-time PCR. The control group was set to be 1. (B) Representative immunofluorescent photomicrographs (200× magnification) for mitochondrial marker CPS-1 (red fluorescence) showed granular staining patterns in liver frozen sections. (C) Fluorescent staining of CPS-1 per field was quantified by ImageJ software and reported as mean integrated density. (D) Western blot analysis was performed to semiquantitatively assess expression levels of CPS-1 from liver homogenates. The control group was set to be 1. Values are expressed as mean ± SD, $n = 8$. $^{*}P < 0.05$ versus the control group; $^{\#}P < 0.05$ versus the MCD group.

of ETC is located on the inner membrane of mitochondrion and consisted of four large transmembrane protein complexes (mitochondrial respiratory complexes I–IV).[25] Complexes I and IV are two important and major protein complexes of the electron transfer chain among the four. Via determination of the two representative protein complexes, we ascertained that ETC defects happened in mice fed the MCD diet which, however, were visibly alleviated by ACNs administration (Figure 6D).

One of the most common hepatic cell injuries is the result of accumulation of various lipids, which further contributes to

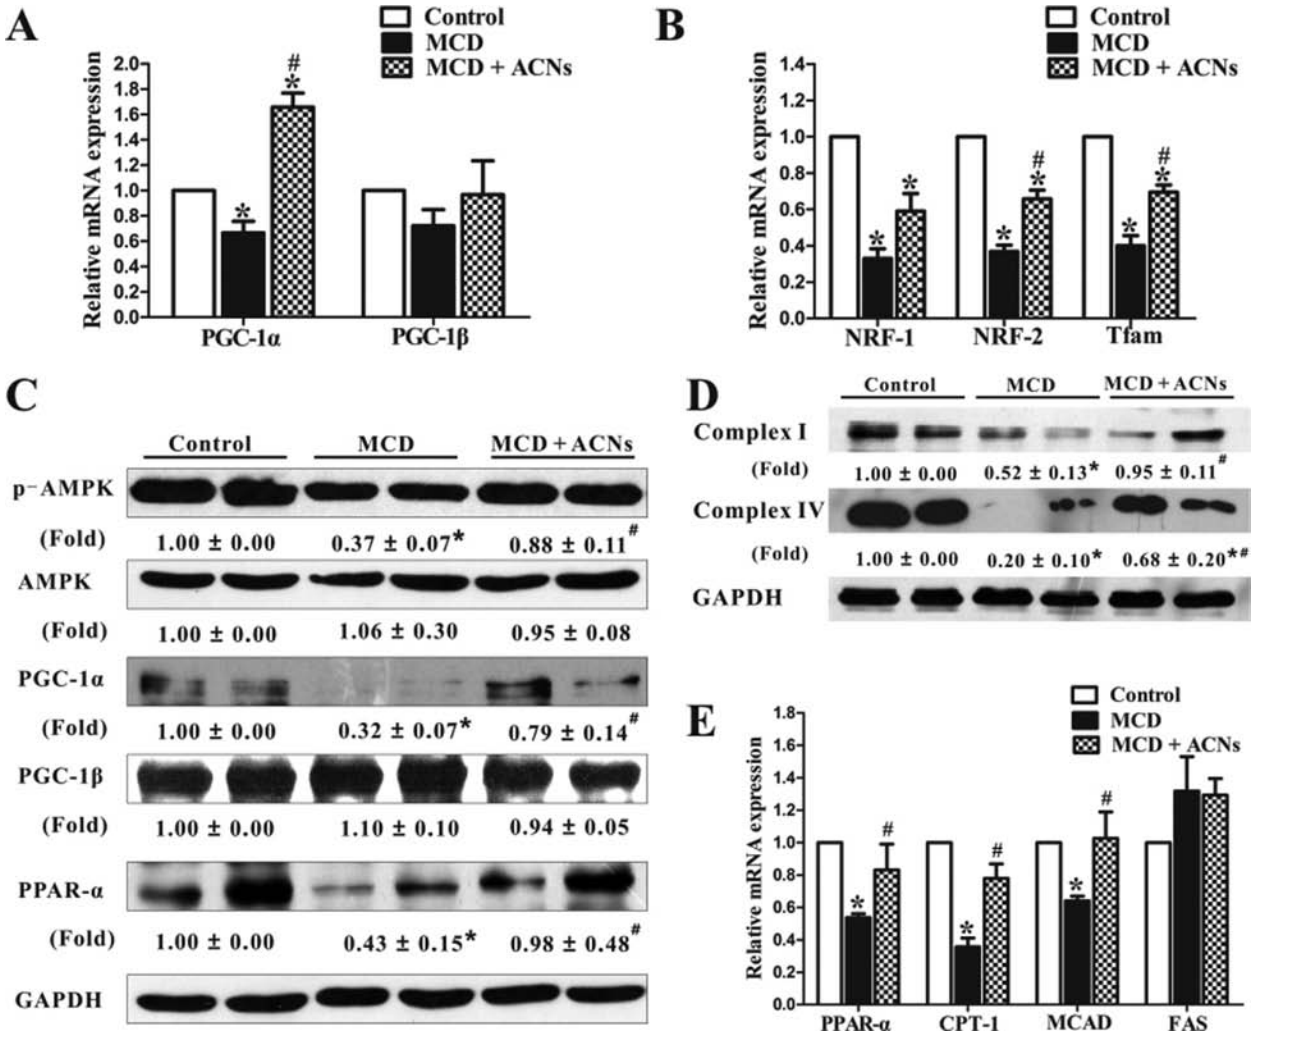

Figure 6. ACNs stimulated mitochondrial biogenesis and improved mitochondrial ETC defects as well as enhanced mitochondrial β-oxidation in NASH. (A and B) Real-time PCR was applied to measure mRNA expression of PGC-1α and PGC-1β (A) and genes related to mitochondrial biogenesis (NRF-1, NRF-2 and Tfam) (B). (C) Protein expression of p-AMPK, total AMPK, PGC-1α, PGC-1β, and PPAR-α in livers was measured by Western blot, quantified using densitometry, and normalized by GAPDH content. (D) Protein levels of complexes I and IV were examined by Western blot. (E) Genes related to fatty acid oxidation (CPT-1, MCAD, and PPAR-α) and lipogenesis (FAS) were subjected to RT-PCR analysis. The control group was set to be 1. Results are expressed as mean ± SD, $n = 6-8$. *$P < 0.05$ versus the control group; #$P < 0.05$ versus the MCD group.

development and progression of fatty liver. The main mechanisms are as follows: increased fatty acid uptake and de novo hepatic lipogenesis, decreased fatty acid β-oxidation and hepatic very low density lipoprotein-triglyceride (VLDL) secretion. One of the mechanisms of NASH induced by the MCD diet is decreased VLDL assembly and secretion, contributing to disturbance in phosphatidylcholine synthesis that is caused by deficiencies in methionine and choline.[32] In our study, we also observed that this model was accompanied by impairment of mitochondrial β-oxidation, manifested by a decrease in gene or protein expression of PPAR-α, CPT-1, and MCAD (Figure 6C and 6E), which consequently cooperated with decreased VLDL to result in the reduction of lipid clearance. Our data show that ACNs treatment significantly up-regulated protein expression of PPAR-α and gene expression of PPAR-α, CPT-1, and MCAD (Figure 6E). PPAR-α is predominantly expressed in the liver where it transcriptionally up-regulates nuclear genes encoding mitochondrial fatty acid oxidation enzymes CPT-1 and MCAD.[26] CPT-1 locates on the outer mitochondrial membrane and is a key rate-limiting enzyme of long-chain fatty acid β-oxidation, while MCAD is a key enzyme in the first step of medium-chain fatty acid β-oxidation. We conclude that ACNs can improve impairment of mitochondrial β-oxidation in NASH induced by the MCD diet, which further counteracts hepatocyte injury resulting from lipid accumulation by promoting TG clearance.

In line with existing research illustrating that ACNs are able to activate protein expression of AMPK in vitro[14] and in vivo,[16] we also found that ACNs could attenuate the reduction of p-AMPK expression induced by the MCD diet (but not total AMPK; Figure 6C). Moreover, emerging evidence showed that the activation of AMPK leads to increased expression of the downstream molecule PGC-1α,[33] which was demonstrated to be a potent stimulator of mitochondrial biogenesis in liver, heart, and skeletal muscle by contributing to activation of NRF-1, NRF-2, and Tfam.[34] In the present study, we showed that protein and gene expression of PGC-1α and its target genes were up-regulated by ACNs, which subsequently potentiated mitochondrial biogenesis. These data suggest that the improvement of mitochondrial dysfunction induced by ACNs treatment is

DOI: 10.1021/jf504926n
J. Agric. Food Chem. 2015, 63, 552−561

attributed to increased phosphorylation of AMPK, which subsequently increased expression of PGC-1α, rather than PGC-1β (Figure 6A and 6C).

In summary, our study shows that ACNs ameliorate liver disease in steatohepatitis progression and improve mitochondrial defects. Our previous study also showed that anthocyanin cyanidin 3-*O*-β-glucoside could notably improve mitochondrial function in high glucose-stressed hepatocytes.[35] Considering previous studies reporting that mitochondrial dysfunction takes precedence over insulin resistance and hepatic steatosis and leads to the natural history of NAFLD[30,36] and combining with our own results, we venture to conclude that administration of ACNs attenuated NASH due to the improvement of mitochondrial dysfunction in mice fed a MCD diet. The possible mechanism may involve activation of AMPK/PGC-1α signaling axis by ACNs, which subsequently contributes to improvement of depletion of mitochondrial mtDNA and mitochondrial biogenesis function, improves ETC activity and β-oxidation, and eventually attenuates lipid accumulation-induced hepatocyte injury by enhancing TG clearance. Due to limitations such as the animal model of NASH and lack of inhibitors or blockers in our current study, further research is needed to investigate the detailed molecular mechanisms and potential clinical applications of ACNs in NAFLD.

ABSTRACT: This is the first report concerning the selenium enrichment of *Catathelasma ventricosum* mycelia. The selenium-containing proteins present in selenium-enriched mycelia (Se-MC) were identified using size-exclusion chromatography−inductively coupled plasma−mass spectrometry (SEC-ICP-MS). The selenium-containing amino acids liberated by hydrolysis of these proteins were identified using anion exchange-ICP-MS. Se-MC was found to contain selenoproteins with molecular weights ranging from 1.7 to 60.5 kDa. The main selenium-containing amino acids within them were selenomethionine and selenocysteine. Furthermore, Se-MC possessed excellent antihyperglycemic and antioxidant properties. Se-MC normalized biochemical parameters like insulin level, blood glucose level, body weight, and antioxidant enzyme activity in streptozocin-induced diabetic mice. It also inhibited the α-amylase and α-glucosidase activities present in in vitro gastric and intestinal models. In conclusion, Se-MC has the potential to serve as a dietary supplement of selenium, an antioxidant, or an ingredient for the formulation of nutraceuticals.

INTRODUCTION

Diabetes mellitus, a chronic metabolic disease caused by insulin deficiency or dysfunction, is characterized by high blood glucose levels.[1] Hyperglycemia has been shown to increase oxidative stress through the overproduction of reactive oxygen species.[2] These oxygen radicals cause lipid oxidation and play a role in the development of diabetic complications. Oxidative stress is thought to link diverse mechanisms for the pathogenesis of diabetic complications.[3] Although several hypoglycemic drugs are available to treat diabetes mellitus, many of them have serious side effects.[4] Relatively low cost management of hyperglycemia with minimal clinical side effects remains a challenge for the medical system.[5] Phytochemicals from relatively low cost bioresources have relatively few side effects. Exploiting this resource offers a new approach for the treatment of various diseases, including diabetes.[6]

Catathelasma ventricosum, an edible fungus, is a delicious source of valuable nutrition. Its fruiting body provides an excellent source of nutrients because of its high protein, polysaccharide, and mineral content, as well as its low content of toxic metals, fat, and energy. A previous report has demonstrated that the fruiting body of wild *C. ventricosum* has antihyperglycemic and antioxidative effects.[7] Selenium (Se), a trace element important for human health, is a component of several selenoproteins that perform essential biological functions, including glutathione peroxidase (GSH-Px) and selenoprotein P. The Se-dependent enzyme GSH-Px reduces oxidized glutathione and minimizes lipid peroxidation by catalyzing the reduction of both lipid peroxides and hydrogen peroxide. Selenoprotein P, an extracellular antioxidant present in the vascular endothelium, lowers the level of peroxinitrile ($ONOO^-$), a reactive nitrogen species.[8] Se deficiency has been associated with several diseases, including hepatocyte damage, cardiovascular disease, and cancers.[9−11] Se supplementation using microorganisms may be an excellent solution to the problem of Se deficiency because organic Se compounds are generally believed to be better and safer dietary supplements than inorganic Se compounds. A variety of Se-enriched food supplements have been commercialized, including garlic, yeast, and lactic acid bacteria.[12]

Submerged basidiomycete culture is currently the preferred technique for producing stable, safe mycelia and mushroom biometabolites. Importantly, submerged culture is less time-consuming than mushroom cultivation and leads to the production of products with mushroom metabolite contents that are more consistent than those of products consisting of fruiting bodies.[1] Furthermore, based on our preliminary experiment, the capacity of *C. ventricosum* for selenium enrichment is greater than that of some famous mushrooms, like *Lentinula edodes, Pleurotus ostreatus, Ganoderma lucidum, Coriolus versicolor, Tremella fuciformis,* etc. (data not shown). In order to assess the suitability of Se-enriched mycelia from *C. ventricosum* (Se-MC) as a candidate for diabetes treatment, the

chemical composition and Se speciation in Se-MC was determined. The antihyperglycemic and antioxidant properties of Se-MC were also investigated.

MATERIALS AND METHODS

Chemicals. Sodium selenite and sodium selenate were obtained from Alfa Aesar (Ward Hill, MA, USA). Working solutions for the determination of total selenium were prepared daily by appropriate dilution of a 1 mg/mL Se (IV) standard solution (Merck, Darmstadt, Germany). Glibenclamide, streptozocin (STZ), 4-nitrophenyl-α-D-glucopyranoside (PNPG), selenocysteine (SeCys), selenomethionine (SeMet), and amino acid standards were purchased from Sigma-Aldrich Co. LLC (St. Louis, MO, USA). Reagent kits for the determination of catalase (CAT), maleic dialdehyde (MDA), superoxide dismutase (SOD), glutathione peroxidase (GSH-Px), and insulin were obtained from the Jianchen Bioengineering Institute (Nanjing, Jiangsu, China). The SXT Blood Glucose Monitoring System and Test Strip were from Sinocare Co., Ltd. (Changsha, Hunan, China). All other materials were of the highest grade commercially available and obtained from Sinopharm Chemical Reagent Co. Ltd. (Shanghai, China).

Se-Enriched Fermentation *C. ventricosum* Mycelia. The seed of *C. ventricosum* was purchased from Mianyang Edible Fungi Research Institute (Mianyang, Sichuan, China) and maintained on synthetic potato dextrose agar (PDA).

C. ventricosum was initially grown on PDA at 22 °C for 4 days. Aliquots (2.5 mL) of this 4-day-old liquid culture were then transferred to two hundred 250 mL flasks. Each flask contained 47.5 mL of Se-enriched fermentation culture medium (medium components were based on our previous reports[13]) and incubated at 22 °C on a shake platform at 100 rpm for 15 days. The harvest mycelia are referred to as Se-MC. *C. ventricosum* was also incubated in an otherwise identical fermentation culture medium without Na_2SeO_3 as a control. This control material is referred to as MC.

In Vitro Simulation of Gastrointestinal Digestion. Gastrointestinal digestion was simulated using a method based upon a published procedure that mimicks the physiological events taking place in the upper gastrointestinal tract (stomach and small intestine).[14] Three-gram samples of powdered *C. ventricosum* mycelia (Se-MC and MC were freeze-dried and ground to a fine powder (40 mesh)) were mixed with 18 mL of saline (140 mM NaCl, 5 mM KCl and 150 μM butylated hydroxytoluene (BHT)), acidified to pH 2 with 0.1 M HCl, and then mixed with 500 μL of pepsin solution. After incubation at 37 °C for 1 h in a shaking water bath, 0.1 M $NaHCO_3$ was added to increase the pH to 6.9. At this point, 2.5 mL of pancreatin-bile solution was added. After incubation at 37 °C for 2 h in a shaking water bath, the simulated gastrointestinal digestion (GI) extract was centrifuged, and then the supernatant was dried under nitrogen gas. The dried powder was used for the in vitro assay. The samples of Se-MC and MC were treated in triplicate.

Chemical Composition. *Proximate Analysis.* The crude protein, crude fat, moisture, ash, and total phenolic contents of Se-MC and MC were determined in triplicate using the Association of Official Analytical Chemists (AOAC) procedures (1995).[15] The determination of carbohydrate content (g) and energy content (KJ) were performed based on the methods of Liu et al. (2012).[7]

Amino Acid Analysis. Extracts were prepared according to the method of Ribeiro et al. (2008).[16] Amino acid analysis was performed using our previously published methods,[7] with slight modifications. Briefly, the amino acid composition was determined using a reversed-phase high-performance liquid chromatography (HPLC, Agilent 1100) system equipped with a 250 × 4.6 mm, 5 μm ODS HYPERSIL column (Agilent) (Santa Clara, CA, USA). The analysis was conducted using gradient elution at 40 °C and a flow rate of 1 mL/min. The mobile phase gradient was formed from buffer A (8 g of sodium acetate dissolved in 1000 mL of deionized water plus 225 μL of triethylamine and 5 mL of tetrahydrofuran; pH adjusted to 7.2 ± 0.05 with acetic acid) and buffer B (8 g of sodium acetate dissolved in 400 mL of deionized water plus 800 mL of acetonitrile and 800 mL of methanol; pH adjusted to 7.2 ± 0.05 with acetic acid). A/B ratios were 92:8, 40:60, 0:100, 0:100, 0:100, and 92:8, at run times of 0, 27.5, 31.5, 32, 34, and 35.5 min, respectively. Samples were derivatized with *o*-phthaldialdehyde (OPA, Sigma) (St. Louis, MO, USA) prior to HPLC; the detection wavelength was set to 338 nm, or 262 nm for proline. Stock solutions of individual amino acids, except for tryptophan, were prepared in 0.1 M HCl. Tryptophan solutions were prepared in water. The concentrations of the individual amino acids were approximately 1 mM. The samples of Se-MC and MC were analyzed in triplicate.

The Content of Se and Its Speciation. *Determination of Total Se.* Dried samples (approximately 0.1 g) were digested with a mixture containing 0.5 mL of H_2O_2 (30%) and 2 mL of HNO_3 (65%). After 24 h, the solutions were digested using a microwave system. A mineralization program was performed based on the method of Wrobel et al. (2004).[17] After digestion, the final solutions were diluted to a total volume of 25 mL with distilled water. The standard solutions and reagent blanks were digested using the same procedure. The samples of Se-MC and MC were treated in triplicate.

The total selenium concentration was determined using inductively coupled plasma mass spectrometetry (ICP-MS, Agilent 7500ce) (Tokyo, Japan). Isotopes ^{77}Se, ^{78}Se, ^{80}Se, and ^{82}Se were monitored. The instrument settings were as follows: forward power, 1590 W; carrier gas flow rate, 1.2 L/min; plasma gas flow rate, 15 L/min; and dwell time, 0.3 s per isotope. All samples were analyzed in triplicate.[18]

Investigation of Selenoproteins in Mycelia. Mycelia samples (1 g) were added to 100 mL of buffer containing 20 mM Tris-HCl (pH 7.5) and 150 mM NaCl. The mixtures were extracted with magnetic stirring at 37 °C for 24 h. After centrifugation (8000 rpm for 10 min), 1 mL of supernatant was transferred to 5 mL of acetone. This mixture was extracted with magnetic stirring at 4 °C for 24 h, and then placed at 5 °C for 24 h. After centrifugation (8000 rpm for 10 min), the supernatant was discarded and the protein precipitate was dried under nitrogen gas. The samples of Se-MC and MC were treated in triplicate.

The dry precipitate was resolubilized with 1 mL of mobile phase buffer for analysis by size exclusion chromatography (SEC)-ICP-MS. Chromatographic separations were performed using an Agilent 1100 liquid chromatograph (Palo Alto, CA, USA) equipped with a Superdex peptide 10-300 GL (300 mm × 10 mm × 15 μm) column. The mobile phase was composed of 20 mM Tris-HCl and 150 mM NaCl (pH 7.5), the injection volume was 50 μL, and the flow rate was 0.5 mL/min.[18] The SEC column was calibrated using a standard mixture of albumin (66 kDa), myoglobin (16 kDa), cytochrome *c* (12.5 kDa), methylcobalamin (1.34 kDa), and $(Gly)_6$ (0.36 kDa). All samples were analyzed in triplicate.

Se Speciation in the Mycelia. Enzymatic hydrolysis was performed to identify the species that possess covalent bonds between Se and proteins or peptides.[19] In this method, the precipitated selenoproteins were resolubilized with 1 mL of a solution containing 20 mM Tris-HCl (pH 7.5), 150 mM NaCl, and 0.03 g of trypsin. After incubation at 50 °C for 24 h in a shaking water bath, 0.03 g of proteinase K was added to the mixture described above, and the resulting solution was kept in a shaking water bath at 50 °C for an additional 24 h. After centrifugation (8000 rpm for 10 min) and filtration (0.45 μm polyvinylidene fluoride filter), the supernatant was passed through 5 kDa molecular weight cutoff filters (Ultrafree-0.5, Millipore) to remove high molecular weight proteins from the extracts before the analysis of the Se-containing species. The samples were treated in triplicate.

Se species were analyzed by anion exchange-HPLC-ICP-MS and identified by comparing their retention times with those of available standards (sodium selenite, sodium selenite, SeCys, and SeMet).[20] Chromatographic separations were performed using an Agilent 1100 liquid chromatograph (Palo Alto, CA, USA) equipped with a Hamilton PRP-X100 (250 mm × 4.1 mm × 10 μm) column. The mobile phase consisted of 5 mM ammonium citrate in 2% methanol (pH 5.2), the flow rate was 1 mL/min, and the injection volume was 50 μL. All samples were analyzed in triplicate.[18]

Antihyperglycemic Assays in Vitro. *α-Glucosidase Inhibitory Activity.* Inhibition of α-glucosidase activity was assayed using the

method of Palanisamy et al. (2011), with minor modifications.[3] Various dilutions of the GI extracts described above were mixed with α-glucosidase (0.4 IU) dissolved in 2 mL of phosphate buffer (0.1 M, pH 6.8) containing 50 μL of glutathione (1 mg/mL) and 50 μL of PNPG (0.1 M). These reaction mixtures were incubated at 37 °C for 15 min. The reactions were stopped with 10 mL of 0.1 M sodium carbonate, and the extent of reaction was determined by measuring the absorbance at 400 nm using a UV−visible spectrophotometer. Acarbose was used as the positive control, while the absence of sample was used as a negative control. The percentage inhibition was calculated as % inhibition = {1 − [(absorbance of sample)/(absorbance of negative control)]} × 100. The α-glucosidase inhibitory activity was expressed as an EC_{50} value (amount of sample causing 50% inhibition). All samples were analyzed in triplicate.

α-Amylase Inhibitory Activity. Porcine pancreatic α-amylase (1 IU) was dissolved in 0.5 mL of buffer (20 mM phosphate, pH 6.9) containing various dilutions of the GI extracts described above. These mixtures were incubated at 37 °C for 15 min. Each reaction mixture was subsequently added to 0.5 mL of soluble starch solution (1.5%) and incubated at 37 °C for 5 min. Each reaction was stopped at this point using 1.0 mL of 3,5-dinitrosalicylic acid reagent. The samples were then incubated in a boiling water bath for 10 min, cooled to room temperature, and diluted with distilled water. The absorbance was measured at 520 nm. Acarbose was used as the positive control, and reactions lacking sample were used as a negative control. The percentage inhibition was calculated as % inhibition = {1 − [(absorbance of sample)/(absorbance of negative control)]} × 100. The α-amylase inhibitory activity was expressed as an EC_{50} value (amount of sample causing 50% inhibition). All samples were analyzed in triplicate.

Animals. The male ICR mice (body weight 18 ± 2 g) used in this study were purchased from SLAC Laboratory Animal Company (Shanghai, China). The mice were acclimatized for at least 1 week before the experiment was started. Before and during the experiment, the mice were housed in a segregated air-conditioned room at 25 °C with a 12 h light and dark cycle. Mice were provided a basal diet (Shanghai Laboratory Animal Company) and free access to drinking water. This experiment was approved by the Institutional Animal Ethics Committee of Jiangnan University (Wuxi, China). All experimental animals were overseen and approved by the Animal Care and Use Committee of our Institute before and during experiments.

Establishment of a Diabetic Mouse Model. Diabetes was induced in mice by the intraperitoneal (ip) injection of a freshly prepared solution of STZ at a dose of 150 mg/kg body weight.[21] Mice displaying polydipsia and polyuria after 72 h were chosen for measurement of their fasting glucose levels using blood glucose test strips. Hyperglycemic mice (blood glucose level >16.8 mmol/L) were used as the diabetic mice for further studies.

Experimental Design. Based on a preliminary experiment (data not shown), the STZ-induced diabetic mice were randomly divided into five groups (6 mice per group). Group I: normal mice treated with saline solution as control. Group II: STZ-induced diabetic mice treated with saline solution as diabetic control. Group III: STZ-induced diabetic mice receiving oral glibenclamide (20 mg/kg/d) as a positive control. Group IV: STZ-induced diabetic mice receiving oral MC at a dose of 500 mg/kg/d. Group V: STZ-induced diabetic mice receiving oral Se-MC at a dose of 500 mg/kg/d. After 30 days of treatment, the animals were fasted overnight and sacrificed by cervical dislocation. Their blood glucose levels and body weight were measured. Blood collected from their eyes was immediately centrifuged for 5 min to obtain serum (stored at −70 °C). Kidney and liver tissues were excised from the animals, washed with saline solution, and stored at −70 °C.

Biochemical Analysis. Blood glucose levels were determined with blood glucose test strips using blood samples taken from the tail veins of overnight fasted mice. The serum insulin concentration was determined using commercially available kits according to the manufacturer's instructions. Liver and kidney homogenates were immediately assayed for SOD, CAT, GSH-Px, and MDA activities using the procedures described in the instructions contained in their corresponding assay kits.

Statistical Analyses. All of the assays described above were carried out in triplicate. The results are expressed as the mean ± SD. Data were analyzed using one-way analysis of variance (ANOVA) followed by Tukey's test. Statistical analyses were performed using SPSS software, version 16.0. Differences leading to values of $p < 0.05$ were considered statistically significant.

RESULTS

Chemical Composition. The proximate compositions of the investigated mushrooms are shown in Table 1. The order of the contents (g/100 g dry weight) was total carbohydrate > crude protein > ash > crude fat > total phenols. These data demonstrate that Se-MC contained slightly more protein and ash than the control MC, and slightly less total carbohydrate. The crude fat and total phenol contents of Se-MC were about half or less of those of the MC control. The total energy content of the Se-MC was slightly lower than that of the MC control.

The percentage composition of 17 amino acids was investigated in the mycelia of *C. ventricosum*; the results are presented in Table 2. Se-MC and MC were found to contain 13 and 12 amino acids, respectively. Se-MC contained seven of the essential amino acids, lacking only isoleucine. The ratios of the essential amino acids to nonessential amino acids were 0.87 and 0.80 in Se-MC and MC respectively.

The Content of Se and Its Speciation. The total Se contents of Se-MC and the MC control were determined by digesting samples and quantifying the Se by ICP-MS. The total Se content of Se-MC was 867.11 μg/g of dry mycelia. The mycelial yield was about 12.64 g of dry mycelia per L of culture. The conversion of organic Se was approximate 11%. No Se was detected in the MC control.

The SEC-ICP-MS chromatograms of the Se-MC extracts are presented in Figure 1a. The molecular weights (MW) of the three main Se-containing fractions were about 60.5, 11.2, and 1.7 kDa. Based on the description of Kapolna et al. (2007),[18] the fractions with high molecular weights (HMW; 60.5 and 11.2 kDa) represent Se-containing proteins, and those with the low molecular weight (LMW) of 1.7 kDa correspond to Se-containing peptides, while the molecular weights of selenoamino acids and inorganic selenium are less than 1.7 kDa.

A chromatogram of the Se species standards, obtained using anion exchange-HPLC-ICP-MS, is displayed in Figure 1b. The

species were identified by comparing their retention times to those of available standards. The selenium species profile of the Se-MC extracts is shown in Figure 1c. Selenomethionine (SeMet) was the predominant selenium species in the Se-MC extracts, comprising approximately 68% of the total selenium content. Other selenium species identified in Se-MC samples included selenocysteine (SeCys, 6%), selenite (Se−IV, 2%), and selenate (Se−VI, 5%).

Antihyperglycemic Activity in Vitro. The antihyperglycemic properties of Se-MC and MC were evaluated using two assays that measured the inhibition of α-glucosidase and α-amylase activities, respectively. Based on the results, the highest α-glucosidase inhibitory activity (EC_{50} = 8.3 μg/mL) was found in Se-MC, and the highest α-amylase inhibitory activity (EC_{50} = 19.4 μg/mL) was found in MC, while the α-glucosidase and α-amylase inhibitory activities of acarbose (positive control) were 15.9 and 26.7 μg/mL, respectively.

Effects of Se-MC and MC on Blood Glucose, Body Weight, and Insulin in STZ-Induced Diabetic Mice. Mice in the diabetic control group (group II) exhibited a severe decrease in insulin level and body weight and a significant increase in blood glucose level, compared with mice in the normal group (group I; $p < 0.05$) (Table 3). After administration of Se-MC, MC, or glibenclamide (positive control) for 30 days, the levels of blood glucose in groups III, IV, and V were much lower than that in group II. On the other hand, the insulin levels and body weights of the mice in groups III, IV, and V showed a significant increase compared with those of the mice in group II.

Effects of Se-MC and MC on MDA and Antioxidant Enzymes in Kidney and Liver of STZ-Induced Diabetic Mice. The MDA levels in the kidney and liver of untreated STZ-induced diabetic mice were significantly increased ($p < 0.05$), whereas the activities of antioxidant enzymes in the kidney and liver of untreated STZ-induced diabetic mice were significantly decreased ($p < 0.05$) compared with those of the mice in group I (Table 4). After administration of Se-MC or MC for 30 days, the MDA levels present in the mice in groups IV and V were significantly decreased ($p < 0.05$), while SOD, GSH-Px, and CAT activity were significantly increased ($p < 0.05$) in the kidney and liver, compared with those of the mice in groups II and III.

(b) Chromatogram of Se species standard obtained by anion-exchange ICP-MS. (c) Chromatogram of Se species profile in Se-MC obtained by anion-exchange ICP-MS.

DISCUSSION

The moisture content of mushrooms ranges from 86−94 g/100g fresh weight. The moisture contents of Se-MC and MC were 93.03 and 93.55 g/100 g fresh weight, respectively, which is higher than that of the fruiting body of *C. ventricosum*.[7] It seems that liquid culture conditions can increase the moisture content of *C. ventricosum*. Kalač (2009) indicated that low dry matter and lipid contents result in mushrooms with low energy values.[22]

The concentration order of the components in the proximate analyses of Se-MC and MC is consistent with that revealed in our previous report.[7] This indicates that the physical state of the culture medium (liquid state or solid state) may have a limited effect on the chemical composition of *C. ventricosum*.

The concentration of protein in Se-MC (31.22% of dry matter) is very high compared with those of most plants and mushrooms. The results are consistent with the conclusions of Belitz and Grosch (1999):[23] Se concentrations are positively correlated with protein content in food. Moreover, Pappa et al. (2006)[24] indicated that the Se concentration is negatively correlated with food fat content. The concentration of crude fat in Se-MC (2.17% of dry matter) is very low compared with those of most plants and mushrooms.[22] In a word, *C. ventricosum* is an ideal candidate for Se enrichment.

The content of crude protein in Se-MC, on the other hand, was 30% higher than that in MC. It seems that the presence of Se in the culture medium can affect protein metabolism in *C. ventricosum*. One possibility is that Se can replace sulfur in amino acids like selenomethionine (SeMet) and selenocysteine (SeCys), due to their physicochemical similarity, which may stimulate the synthesis of protein (especially Met and Cys). The results of the amino acid analysis also support this assumption. The concentration of methionine (Met) and cysteine (Cys) in Se-MC was much higher than that in MC. Moreover, Dumont et al. (2006)[25] indicated that most plants lack the ability to accumulate large amounts of Se (they rarely exceed 100 μg/g dry weight). However, some mushrooms have been recognized as Se accumulators. These mushrooms can take up a large amount of Se (>1000 μg/g dry weight) without exhibiting any negative effects because they increase their intracellular concentrations of SeCys and SeMet, which are normally incorporated into proteins.[8,25]

Although selenium is beneficial to normal biological function when supplied in appropriate quantities, excessive selenium intake can cause toxicosis.[26] The essential and toxic levels of Se are similar. The tolerable upper Se intake level for adults is set at 400 μg/day, while the recommended dietary allowance for Se is 55 μg/day for both men and women.[27] Therefore, determination of the total Se content of Se-MC is of great significance. The total Se content of Se-MC (867.11 μg/g of dry mycelia) is higher than that of some other Se-enriched plants and mushrooms, like *Allium schoenoprasum* (1.07 μg/g), *Lentinula edodes* (770.7 μg/g), and *Cordyceps militaris* (42 μg/g).[18,19,28]

The bioavailability of Se depends strongly on the chemical form of the Se that is ingested. Organic Se compounds are generally more bioavailable than inorganic Se compounds.[8] Ferri et al. (2007)[29] indicated there is a lack of information about the chemical forms of selenium in foods. This lack is mainly the result of the difficulties inherent in their identification. The application of different hyphenated techniques (HPLC-MS, HPLC-ICP-MS, etc.) has begun to change this situation. In this study, we employed HPLC-ICP-MS to analyze the Se species. Previous reports have identified selenate, selenite, SeMet, and SeCys as the primary selenocompounds in mushrooms.[19,28] These reports agree well with the results of this study. In addition, the ratio of organic Se to inorganic Se in Se-MC is 74:7, which is higher than the ratio seen in some Se-enriched foods.[20,28]

Two in vitro assays were carried out to evaluate the antihyperglycemic activity of a simulated gastrointestinal digestion extract of Se-MC and MC: an α-glucosidase inhibition assay and an α-amylase inhibition assay. α-Glucosidase, located in the brush-border surface membrane of intestinal cells, is a key enzyme of carbohydrate digestion. α-Amylase catalyzes the hydrolysis of the α-1,4-glucosidic linkages in glycogen, starch, and other oligosaccharides. Inhibition of the α-glucosidase and α-amylase activities in the human digestive tract can effectively control diabetes by diminishing the absorption of glucose derived from the degradation of starch by these enzymes.[30] There are two main concepts to explain the interaction mechanism between α-glucosidase/α-amylase and their inhibitor: (1) The inhibitor inhibits α-glucosidase/α-amylase activity by hydrolyzing them.[31] (2) α-Glucosidase/α-amylase and their inhibitor combine to form a soluble complex, which inactivates the enzymes.[32] Yasuda (2003)[33] indicated

DOI: 10.1021/jf5050316
J. Agric. Food Chem. 2015, 63, 562−568

that α-glucosidase/α-amylase inhibitor is not a competitive inhibitor that competes with α-glucosidase/α-amylase for starch, disaccharides, or various oligosaccharides. However, the inhibitor will combine with α-glucosidase/α-amylase directly and change their conformations, inactivating them. Acarbose, an inhibitor of a-glucosidase and α-amylase used in the treatment of diabetes mellitus, was chosen as the positive control.[3] The inhibitory activities of Se-MC and MC were significantly greater than those of acarbose ($p < 0.05$), which indicates that Se-MC and MC possess excellent antihyperglycemic activity. Inhibition of intestinal α-glucosidase and α-amylase activities is an important antihyperglycemic mechanism of Se-MC and MC. However, the antihyperglycemic activities of Se-MC and MC are very similar. It seems that adding Se into the culture medium does not have has much of an influence on the α-glucosidase and α-amylase inhibitory activities of *C. ventricosum* mycelium.

Animal models in which diabetes mellitus is induced by the administration of STZ or other chemicals have been reported.[21] The advantages of STZ are its greater stability and relative lack of extrapancreatic toxicity. In the present study, the diabetic mouse model was established by intraperitoneal injection of STZ, and all of the STZ-induced diabetic mice displayed polydipsia and polyuria.

Stapleton (2000)[34] reported that selenium has been found to have insulin-mimetic activities in vitro and in vivo. Based on the results presented here, Se-MC possesses better antihyperglycemic properties than MC. The levels of blood glucose and insulin in the mice in groups III and V were very close ($p > 0.05$), although they did not recover completely (compared with the normal group, $p < 0.05$). However, the body weight of the mice in groups IV and V was significantly lower than that of the mice in the positive control (group III) and normal mice (group I). It seems that both Se-MC and MC lack a strong ability to increase body weight in STZ-induced diabetic mice. Chen and Ianuzzo (1982)[35] suggested that the decrease in body weight observed in diabetic mice might be the result of protein wasting caused by the inability to use carbohydrates as an energy source. Zhao et al. (2011)[36] reported that administration of *Opuntia dillenii* polysaccharides significantly increased the body weight of STZ-induced diabetic mice.

Diabetes mellitus is associated with the generation of reactive oxygen species that cause oxidative damage to the liver and kidney.[37,38] Major antioxidant enzymes, including GSH-Px and SOD, are the first line of defense against the reactive oxygen species generated during oxidative stress in vivo.[39,40] In the present study, a significant increase in MDA levels and a significant decrease in GSH-Px, SOD, and CAT activity were found in kidney and liver of mice with STZ-induced diabetes (group II; compared with mice in group I), which suggests that severe oxidative stress occurred in liver and kidney tissues. However, after treatment with Se-MC (mice in group IV) or MC (mice in group V), MDA levels were significantly decreased ($p < 0.05$) and GSH-Px, SOD, and CAT activity were significantly increased ($p < 0.05$) in liver and kidney, compared with those of mice in group II. In particular, except MDA levels in kidney, activities of GSH-Px, SOD, CAT, and MDA in group V almost returned to their normal level, which indicated that Se-MC possesses a strong effect on increasing the synthesis of these antioxidant enzymes. MDA, the end product of lipid peroxidation, is used as an index of cellular damage and cytotoxicity. The MDA generated by high levels of free radicals can damage proteins and inactivate membrane-bound enzymes.[41] Chen et al. (2013)[39] indicated that decreasing MDA levels in diabetic rats may be associated with a drug's potential organ protective effect through improved glycometabolism and lipid metabolism. Therefore, it can be inferred that Se-MC probably exhibits its antihyperglycemic property by increasing these antioxidant enzymes in diabetic mice. These enzymes protect tissues from peroxidative damage and maintain their function, improving the sensitivity and response of target cells to insulin. Simultaneously, after the administration of glibenclamide, there was no difference among these biochemical parameters in group III compared with group II, which reveals that glibenclamide does not have an obvious ability to stimulate the synthesis of these antioxidant enzymes. This observation is consistent with those of a previous study, which found that glibenclamide is not capable of modulating antioxidant enzymes and diminishing STZ-induced damage to the liver, which is the main organ to synthesize antioxidant enzymes.[13]

In conclusion, the selenoproteins in Se-MC possess a wide range of molecular weights and SeMet and SeCys were identified as the main selenium compounds bound to these proteins. Moreover, Se-MC was found to be an effective antihyperglycemic and antioxidant. These results demonstrate that the mycelia of Se-enriched *C. ventricosum* can be used as a source of nutrients because of their high protein and carbohydrate content and their low fat and energy content. Mushrooms can also be uesd as a natural source of Se supplements for both animals and humans, especially in Se-deficient areas. Future studies may show that the Se-enriched mycelium of *C. ventricosum* is a source of new antidiabetic drugs, chemopreventive preparations, or food supplements.

Supporting Information

ABSTRACT: A new acidic polysaccharide (PLP) was isolated and characterized from *Plantago asiatic* L. seeds by hot alkali extraction and chromatographic purification using DEAE cellulose and Sephacryl S-400 columns. PLP has a molecular weight of 1.15×10^6 Da, and a monosaccharide composition of xylose (Xyl), arabinose (Ara), glucuronic acid (GlcA), and galactose (Gal) in a molar ratio of 18.8:7.2:6.1:1. The results of methylation analysis, FT-IR, and 1D and 2D NMR indicated that PLP was a highly branched heteroxylan of β-1,4-linked Xyl*p* backbone with three α-GlcA*p*-(1→3)-Ara*f* attached to the *O*-3 position and one α-T-linked-GlcA*p* and one α-Ara*f*-(1→5)-Ara*f* attached to the *O*-2 position every eight monosaccharide residues. PLP exhibited scavenging abilities against hydroxyl, peroxyl anion, and DPPH radicals in vitro and showed significant binding capacities against cholic and chenodeoxycholic acids, suggesting its possible cholesterol-lowering activity. The results demonstrated the potential use of PLP in functional foods and nutraceuticals.

KEYWORDS: *Plantago asiatic L. polysaccharides, monosaccharide composition, structure analysis, bile acid-binding capacity, antioxidant*

INTRODUCTION

Plantago L. (Plantaginaceae) is a perennial herb that has more than 270 species all over the world. Polysaccharides from *Plantago* L., such as psyllium, are important health components.[1−4] Psyllium is an arabinoxylan derived from the seed husk of *Plantago ovata* and is a commercial dietary fiber with a bile-acid binding activity, which might be important for its cholesterol-lowering activity.[5]

Psyllium is mostly produced in India. In China, *Plantago major*, *Plantago asiatic*, and *Plantago depressa* have been used in functional foods, and *P. asiatic* is most widely distributed.[6] The hot water extractable polysaccharides from *P.asiatica* L. seeds exhibited antioxidant activity in vitro[7] and were shown to promote defecation.[8] Polysaccharides may bind bile acids and enhance their intestinal elimination and consequently stimulate the conversion of cholesterol to bile acids in liver.[9] As a result, the levels of total plasma and low-density lipoprotein (LDL) cholesterol may be reduced, which may reduce the risk of cardiovascular diseases. Additionally, polysaccharides with antioxidant capacities could suppress LDL oxidation and consequently reduce the risk of cardiovascular disease.

Our previous studies showed that the physicochemical properties and bile acid-binding capacities of psyllium were closely related to its chemical and molecular structures.[9] Alkali-extractable polysaccharides may have bioactivities different from the water-extractable ones because the alkali-sensitive chemical bonds between polysaccharides and cell wall of plants could be broken during extraction, leading to the release of polysaccharide(s) with different chemical and molecular structures.[10,11] To date, little is known about the alkali-extractable polysaccharides of *P. asiatic* L. seeds.

The present study aimed to investigate the alkali-extractable *P. asiatic* L. seed polysaccharides. The ground seeds of *P. asiatic* L. were extracted with alkali and purified by column chromtographies. The chemical structures of individual polysaccharides were characterized by methylation, GC, HPLC, GC-MS, and 1D and 2D NMR spectroscopy analyses. In addition, their hydroxyl, peroxyl, and DPPH radical-scavenging capacities and bile acid-binding activity were examined. The results may serve as a scientific foundation for developing their possible application in functional foods and nutraceuticals.

MATERIALS AND METHODS

Materials. The seeds of *P. asiatic* L. were collected and identified by Dr. Haibo Yin (Liaoning University of Traditional Chinese Medicine) in 2012. Diethylaminoethyl (DEAE) cellulose was purchased from Whatman International Ltd. (Kent, UK). Sephacryl S-400 was purchased from GE Healthcare (Uppsala, Sweden). Dextrans with different molecular weights and standard monosaccharaides including arabinose, glucose, mannose, glucuronic acid, galactose, rhamnose, fucose, and xylose were purchased from the National Institute for Food and Drug Control (Beijing, China). Deuterated

water (D_2O) was purchased from Cambridge Isotope Laboratories, Inc. (Andover, MA, USA). Fluorescein (FL), iron(III) chloride, 6-hydroxyl-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox), dimethyl sulfoxide (DMSO), 2,2-diphenyl-1-picrylhydrazyl radical (DPPH•), cholic and chenodexycholic acids, diphorase, β-nicotinamide adenine dinucleotide, and 3-α-hydroxysterol dehydrogenase were purchased from Sigma-Aldrich (St. Louis, MO, USA). *myo*-Inositol, 2,2′-azobis(2-amidinopropane) dihydrochloride (AAPH), nitro blue tetrazolium (NBT), and 3-methyl-1-phenyl-2-pyrazolin-5-one (PMP) were purchased from J&K Scientific (Beijing, China). Acetic anhydride, pyridine, and sodium borohydride were purchased from Sinopharm (Beijing, China). Other reagents for isolation were of analytical grade without further purification.

Extraction, Isolation, and Purification of Polysaccharide (PLP). The dried seeds of *P. asiatica* L. (100 g) were ground into powder and then defatted by ethanol (95%, v/v) extraction for 9 h. The residues were extracted by hot water (1:30, m/v) three times at 80 °C for 2 h each time. After filtering, the residues were extracted by 0.5 M NaOH (1:25, m/v) twice at 80 °C for 2 h each time. The combined supernatants were neutralized by 37.5% hydrochloric acid and dialyzed with 3500 Da molecular weight cutoff membrane against distilled water for 72 h. The solution was deproteinized according to a Sevag method.[12] Fifteen milliliters of 30% hydrogen peroxide was added to 100 mL of solution to remove the pigment at 60 °C for 6 h. The resulting aqueous solution was collected after centrifugation at 4500 rpm for 10 min and then precipitated using 4-fold volumes of ethanol (95%, v/v). The precipitates were collected by centrifugation (4500 rpm × 10 min), rinsed with anhydrous ethanol, acetone, and ether, and dried with nitrogen (2 L/min, room temperature) to yield crude polysaccharides.

Three milliliters of crude polysaccharide solution (100 mg/mL) was applied to a DEAE column (2.5 cm × 30 cm, Whatman International Ltd.) and eluted first with distilled water at a rate of 0.2 mL/min for 24 h, followed by 0.62 M NaCl solution at the same rate. Fractions were combined according to the result of phenol−sulfuric acid determination. The eluent was concentrated, centrifuged, and loaded onto a Sephacryl S-400 column (1.6 cm × 100 cm, GE Healthcare). The column was washed with distilled water at a rate of 0.2 mL/min. Each eluting peak was collected, concentrated, and lyophilized to give the pure polysaccharide named PLP.

Purity and Molecular Weight Determination. The purity and molecular weight of PLP were determined using a high-performance size exclusion chromatograph (Agilent, Santa Clara, CA, USA) equipped with a gel filtration column (Shodex SUGAR KS-805, 8 mm i.d. × 300 mm, Showa Denko, Japan) and a refractive index detector. Deionized water as the mobile phase eluted at a flow rate of 1.0 mL/min. The molecular weight of PLP was calculated by the standard curve prepared with a series of dextran standards with different molecular weights (180, 2700, 5250, 9750, 13050, 36800, 64650, 135,350, 300,600, and 2,000,000 Da, respectively).

Monosaccharide Composition Analysis. PLP (5 mg) was dissolved in 1 mL of 2 M trifluoroacetic acid (TFA) and kept at 100 °C for 8 h. After being completely hydrolyzed, the excess TFA was removed by codistillation with the added 0.1% HCl−methanol. The residual was dissolved in 1 mL of distilled water for further derivatization.[13]

The hydrolysate was applied to monosaccharide composition analysis using a GC method.[14] Briefly, monosaccharide standards including arabinose, glucose, mannose, glucuronic acid, galactose, rhamnose, fucose, and xylose and the hydrolyzed polysaccharide samples were reduced by $NaBH_4$ at 65 °C for 30 min, followed by incubation with acetic anhydride and pyridine at 100 °C for 2 h. The resulting alditol acetates were applied to a GC (Agilent) equipped with a flame ionization detector and a HP-5 capillary column (30 m × 0.32 mm, 0.25 μm). The oven temperature was raised from 110 to 220 °C at 5 °C/min, held for 2 min, increased to 240 °C at 2 °C/min, held for 2 min, and finally increased to 280 °C at 10 °C/min.

Precolumn derivatization with PMP was used for the identification and quantification of the monosaccharides including uronic acid.[15] After mixing with 50 μL of 0.6 M sodium hydroxide, 50 μL of monosaccharide standard or the hydrolyzed polysaccharide sample solution was mixed with 50 μL of 0.5 M PMP in methanol. The reaction was carried out at 70 °C for 30 min and neutralized with 100 μL of 0.3 M hydrochloric acid, followed by extraction with chloroform (1.0 mL) three times. The aqueous layer was filtered through a 0.45 μm pore membrane filter for HPLC analysis (Agilent Technologies Co. Ltd., Santa Clara, CA, USA) at 250 nm with a Zorbax Eclipse XDB-C18 column (4.6 mm × 250 mm, 5 μm, Agilent, Palo Alto, CA, USA). The mobile phase was composed of ammonium acetate solution (pH 5.5) and acetonitrile at a ratio of 78:22 (v/v).

Infrared Spectral Analysis. The Fourier transform infrared (FT-IR) spectrum was determined on a FT-IR spectrophotometer with an ATR accessory (Nicolet 6700, Thermo Fisher, Waltham, MA, USA) in the range of 4000−400 cm^{-1}.

Methylation and GC-MS Analysis. Methylation analysis of polysaccharide was performed according to the method of Needs and Selvendran with minor modifications.[16] The dried PLP (10 mg) was dissolved in 5 mL of anhydrous DMSO with added NaOH powder (100 mg). CH_3I (2 mL) was added slowly into the solution. The methylated polysaccharide was extracted with chloroform. The methylation was repeated until the polysaccharide was methylated completely. The completion of methylation of PLP was confirmed by the disappearance of the OH band (3200−3700 cm^{-1}) in the IR spectrum.

The methylated polysaccharide was hydrolyzed in 3 mL of formic acid (88%, v/v) at 100 °C for 6 h and further hydrolyzed in 3 mL of 2 M trichloroacetic acid at 100 °C for 3 h. After being reduced with $NaBH_4$ at 60 °C for 1 h, monosaccharides were converted into the alditol acetates by reacting with pyridine and acetic anhydride at 100 °C for 1 h and subjected to linkage analysis using an Agilent 7890A-5975C GC-MS system (Agilent Technologies Co. Ltd., Santa Clara, CA, USA) equipped with a DB-5MS column (30 m × 0.25 mm, 0.25 μm, Agilent, Palo Alto, CA, USA). The oven temperature was from 100 to 190 °C at 20 °C/min, increased to 260 °C at 3 °C/min, and increased to 300 °C at 10 °C/min. The resulting peaks of alditol acetates were identified by their MS fragmentation patterns and the relative retention time in GC spectrum. Their relative amount was estimated as ratios of peak areas.

Nuclear Magnetic Resonance (NMR) Spectroscopy. PLP (50 mg) was dissolved in 0.5 mL of D_2O. The 1D and 2D NMR spectra, including ^1H NMR, ^{13}C NMR, HH COSY, HSQC, and HMBC, were recorded on a Bruker AV-500 MHz NMR spectrometer (Bruker, Rheinstetten, Germany) at 30 °C.

Relative DPPH•-Scavenging Capacity (RDSC). DPPH•-scavenging capacity was determined following a previously reported laboratory protocol[17] using a Synergy 2 Multi-Mode Microplate Reader (BioTek, Winooski, VT, USA). Trolox was employed as an antioxidant standard. Briefly, 100 μL of PLP, Trolox standard solution, or blank was added into each well, then 100 μL of 0.092 mM DPPH• solution was added to initiate the antioxidant radical reaction. The absorbance of the reaction mixture at 515 nm was recorded every minute for 1.5 h, and each sample was tested three times in parallel. The relative scavenging capacity (RDSC) was calculated as micromoles of Trolox equivalents (TE) per gram of PLP using the area under the curve (AUC) calculation.

Hydroxyl Radical-Scavenging Capacity (HOSC). A previously reported laboratory protocol[18] was applied to evaluate the HOSC value of PLP using a Synergy 2 Multi-Mode Microplate Reader (BioTek). Fluorescein (FL) prepared in 75 mM sodium phosphate buffer (pH 7.4) was used as the molecular probe and Trolox as the antioxidant standard. One hundred and seventy microliters of FL solution (9.28×10^{-8} M), 30 μL of PLP, standard, or blank, 40 μL of 0.199 M hydrogen peroxide, and 60 μL of 3.43 M $FeCl_3$ were added into each well successively to initiate the reaction. The fluorescence was recorded every minute for 6 h. The excitation wavelength was 485 nm, and emission wavelength was 528 nm. The experiment was conducted three times in parallel for each sample. The HOSC value was expressed as micromoles of TE per gram of PLP based on the AUC.

blank was added into 225 μL of 81.63 nM FL solution. After 20 min of preheating at 37 °C in a Synergy 2 Multi-Mode Microplate Reader (BioTek), 25 μL of 0.36 M AAPH was successively added into each well to initiate the reaction. The fluorescence was measured every minute for 2 h at 37 °C. The excitation wavelength was 485 nm, and emission wavelength was 535 nm. The ORAC value was calculated on the basis of AUC and reported as micromoles of TE per gram of PLP.

Bile Acid-Binding Capacity Assay. According to a previous laboratory protocol,[20] 25 mg of each sample was dissolved in 0.25 mL of 0.01 mol/L HCl to simulate gastric condition and then incubated at 37 °C for 60 min with continuous shaking. The solution was adjusted to pH 7.0 by adding 25 μL of 0.1 mol/L NaOH and mixed with 1.25 mL of bile acid stock solution (400 μM in 0.01 M phosphates buffer, pH 7.0) to simulate the intestinal condition. The mixture was incubated for another 60 min at 37 °C, followed by centrifugation at 4500 rpm for 15 min. The supernatant was collected to quantify the unbound bile acid. One hundred microliters of each sample or bile acid standard was mixed with 125 μL of 1.22 mmol/L nicotinamide adenine dinucleotide, 5 mmol/L NBT, 100 μL of diphorase (625 units/L), and 100 μL of 3-α-hydroxysterol dehydrogenase solution (625 units/L). After incubation at ambient temperature for 1 h, 100 μL of 1.33 mmol/L phosphoric acid was added to stop the reaction. The absorbance of each mixture was determined at 530 nm with cholestyramine resin as a positive control and the phosphate buffer without bile acid as the reagent blank. The bile acid-binding capacity (mg/g sample) was calculated according to the standard curves of cholic and chenodeoxycholic acids, respectively. Triplicate tests were conducted.

Statistical Analysis. Data were expressed as the mean ± standard deviation (SD) for each assay. Differences between means were determined by the analysis of one-way ANOVA and Tukey's test, using SPSS (SPSS for Windows, version rel. 16.0, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

RESULTS AND DISCUSSION

Isolation, Purification, and Molecular Weight of PLP. The crude polysaccharides were obtained from the dry seeds of *P. asiatic* L. by hot alkaline extraction and ethanol precipitation with a yield of approximately 5.45% (w/w). After purification with an ion exchange column (DEAE-32), the alkali-extractable polysaccharide PLP was further purified using a Sephacryl S-400 column chromatograph. No significant absorption band was observed at 260 or 280 nm in the UV spectrum, indicating that PLP contained no protein or nucleic acid (data not shown). PLP showed a single, sharp, and symmetric peak by HPLC analysis, and its purity was calculated as 99.2% (data not shown). The molecular weight of PLP was calculated 1.15×10^6 Da using a dextran standard curve.

Monosaccharide Composition. The result of GC analysis showed that the monosaccharide composition of PLP was

xylose, arabinose, glucose, and galactose at a molar ratio of 18.8:7.2:6.1:1 according to peak areas and response factors (Figure 1A,B). Considering that glucuronic acid could be reduced to glucose by $NaBH_4$ during acetylation and measured as glucose, a PMP derivatization analysis was further used to measure the possible uronic acid and glucose contents of PLP. The peaks of PMP-labeled monosaccharides in Figure 1D showed the presence of xylose, arabinose, glucuronic acid, and galactose without glucose. Taken together, these data indicated no presence of glucose in the alkali extractable polysaccharide

from *P. asiatic* L. seeds. The monosaccharide composition of PLP was xylose, arabinose, glucuronic acid, and galactose at a molar ratio of 18.8:7.2:6.1:1. It contained no protein or nucleic acid. The content of uronic acid was about 18.4%.

Structural Characterization of PLP. The FT-IR spectrum of PLP is shown in Figure 2. The assignments of functional groups were conducted according to previous literature.[14,21,22] The band centered at 3312 cm^{-1} arose from OH stretching vibrations of hydroxyl groups. The strong band at 2923 cm^{-1} was characteristic of C−H stretching vibrations of a CH_2 group. Moderate IR bands at 1600 and 1416 cm^{-1} arose from asymmetric and symmetric stretching vibrations of carboxylate generated by the reaction of KBr and carboxylic acid. They implied the presence of carboxylic acid, supporting the presence of glucuronic acid suggested by the result of PMP derivatization analysis. Strong overlapped IR bands at 900−1200 cm^{-1} corresponded to coupled C−O, C−C stretching, and C−OH bending vibrations. An IR band at 899 cm^{-1} was characteristic of β-anomeric configuration.

Methylation followed by GC-MS analysis was employed to obtain more structural information on PLP. Demonstrated by the FT-IR spectrum, PLP was methylated completely and then hydrolyzed under an acidic condition to form partially methylated alditol acetates followed by GC-MS analysis.

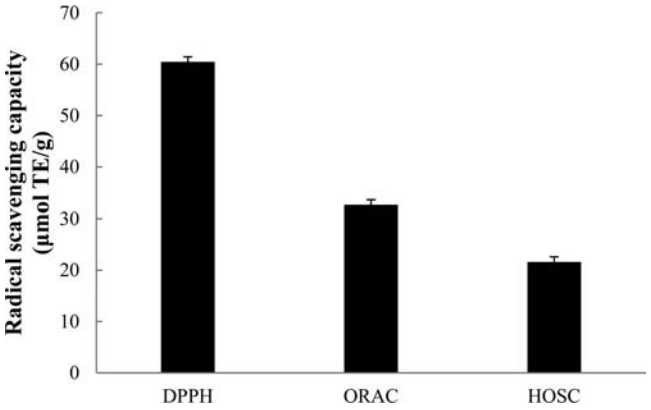

Figure 5. Free radical-scavenging activities of PLP. Data were expressed as Trolox equivalent (TE) in μmol TE/g. Free radical-scavenging activities were calculated using the area under the curve (AUC) against the Trolox standard. Vertical bars represent SD.

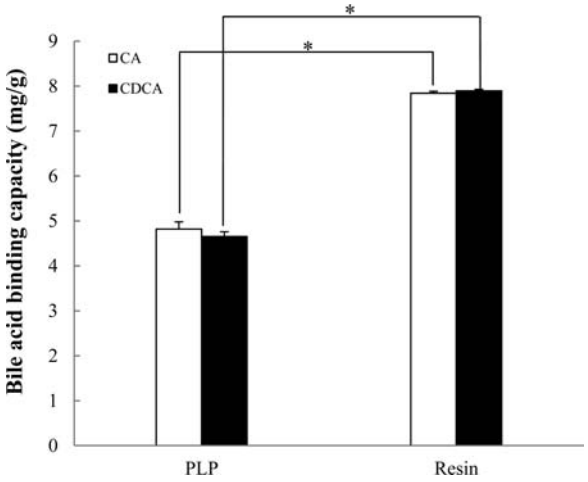

Figure 6. Bile acid-binding capacity of PLP. CA and CDCA represent cholic and chenodeoxycholic acids, respectively. Resin means cholestyramine resin, which is the positive control. Vertical bars represent the SD. * represents significant differences ($P < 0.05$).

According to the results in Table 1, seven homogeneous peaks were observed by GC analysis. According to their retention time, the peaks were identified as 2,5-di-Me-arabitol, 2,3-di-Me-arabitol, 2,3,5-tri-Me-arabitol, 3-Me-xylitol, 2,3-di-Me-xylitol, 2-Me-xylitol, and 2,3,4,6-tetra-Me-gluctiol with a molar ratio of 0.62:0.25:0.22:0.44:1.85:0.66:1, which was in good agreement with the monosaccharide composition. Due to its low content (3%) and possible structural damage during the methylation reaction, the galactose residues were not detected in the GC-MS analysis. The results implied that the possible structure of PLP was a highly branched araboxylan mainly composed of 1,4-linked Xyl*p* as the backbone with side chains

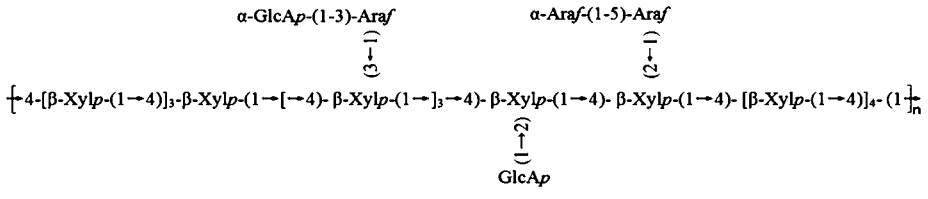

Figure 4. Proposed repeating unit of PLP.

DOI: 10.1021/jf505909k
J. Agric. Food Chem. 2015, 63, 569−577

attached to the *O*-2 or *O*-3 position.[23,24] The side chains consisted of 1,3-linked Ara*f*, 1, 5-linked Ara*f*, T-linked Ara*f*, and T-linked GlcA.

According to the ^{1}H NMR of PLP (Figure 3A), seven signals were displayed in the anomeric region between δ 4.4 and 5.5. Generally, the chemical shifts of α-linked Ara*f* and β-linked Xyl*p* were between δ 5.1 and 5.4 and between δ 4.4−4.8, respectively.[25−27] By comparison with the results of methylation analysis, the anomeric proton signals at δ 4.79, 4.55, and 4.46 and the anomeric carbon signals at δ 102.50, 101.41, and 100.85 corresponded with H-1 and C-1 of β-1,3,4-linked Xyl*p* (residue E), β-1,2,4-linked Xyl*p* (residue F), and β-1,4-linked Xyl*p* (residue G), respectively. The β-anomeric configuration was in a good agreement with the appearance of an FT-IR band at 899 cm^{-1} (Figure 2). The anomeric proton signals at δ 5.32, 5.18, and 5.16 and the anomeric carbon signals at δ 107.9, 104.75, and 105.87 (Figure 3B) could be attributed to H-1 and C-1 of α-1,3-linked Ara*f* (residue A), α-1,5-linked Ara*f* (residue B), and α-T-linked Ara*f* (residue C). The typical signal at δ 176 was ascribed to C-6 of the α-T-linked GlcA*p* (residue D).[28]

From the H−H−COSY spectrum (Figure 3C), the H-1 signal for α-1,3-linked Ara*f* at δ 5.32 might correlate with H-2 at δ 4.41. Similarly, H-3 (δ 3.99), H-4 (δ 4.46), H-5 (δ 3.83), and H-5′ (δ 3.79) were assigned successively. According to these results and the HSQC spectrum (Figure 3D), C-2, C-3, C-4, and C-5 of α-1,3-linked Ara*f* were assigned to δ 79.41, 83.44, 81.88, and 60.80, respectively. Signals of other residues were assigned by the same procedure. All carbon and proton signals are summarized in Table 2.[29] The signals of some terminal residues such as T-linked Xyl and T-linked Gal were not detected by NMR spectroscopy, possibly due to their low molecular ratio in PLP.

For polysaccharides, the HMBC spectra are considered an important tool to give information about the sequence of glycoside residues.[30] From the HMBC spectrum of PLP (Figure 3E), a cross peak was observed between H-1 (δ 5.32) of residue A and C-3 (δ 72.22) of residue E, which implied residue A was linked to *O*-3 of residue E. The cross peak D/F (H1/C2) was also found, indicating residue D was linked to *O*-2 of residue F. Other cross peaks were assigned by a similar procedure, and they are summarized in Table 3.

Taking all information together, PLP was a highly branched heteroxylan of β-1,4-linked Xyl*p* backbone possibly with three α-GlcA*p*-(1→3)-Ara*f* attached to the *O*-3 position and one α-T-linked-GlcA*p* and one α-Ara*f*-(1→5)-Ara*f* attached to the *O*-2 position every eight monosaccharide residues (Figure 4). Furthermore, the glucuronic acid content was greater in PLP compared to the hot water extractable *P. asiatic* L. polysaccharide.[31] The side chains of PLP were also different from that of water-extractable *P. asiatic* L. polysaccharides.

Antioxidant Activity of PLP in Vitro. The DPPH$^\bullet$-scavenging capacity was a widely accepted assay for evaluating the radical-scavenging capacity of natural compounds based on a single electron transfer (SET) mechanism.[14] PLP exhibited a strong scavenging capacity against DPPH$^\bullet$ with a relative DPPH$^\bullet$-scavenging capacity (RDSC) value of 60.5 μmol TE/g (Figure 5). It was much stronger than that of the tobacco seed flour and wheat grains at 2.65−4.37 μmol TE/g[32] and 0.91−1.53 μmol TE/g,[33] respectively. PLP had ORAC and HOSC values of 32.65 and 21.6 μmol TE/g, respectively. The ORAC value of PLP was comparable to that of the tobacco seed flour (25−53 μmol TE/g)[32] and wheat grains (15.7−35.8 μmol TE/g).[33] The HOSC value of PLP was comparable to that of wheat grains (18.6−24.5 μmol TE/g)[33] but lower than those of tobacco seed flour (44−74 μmol TE/g).[32]

Previous studies[19,34] have shown that polysaccharides possess a radical-scavenging effect due to their specific structure features. Their antioxidant effects are related to the number of available active hydroxyl groups in the polysaccharide structure. The results from this study suggested that PLP could effectively scavenge the three free radicals in vitro by either a hydrogen atom or an electron transfer mechanism. It was possibly dependent on the available active hydroxyl groups in its structure.

Bile Acid-Binding Capacity of PLP. Cholic acid (CA) and chenodeoxycholic acid (CDCA) are two primary bile acids synthesized in the liver from cholesterol. Binding bile acids to polymers may enhance their elimination through the gastrointestinal tract, which may promote the metabolism of cholesterol in liver and consequently lower the total plasma and LDL cholesterol levels.[9] As shown in Figure 6, the CA binding capacity for PLP was 65% of that for cholestyramine resin, whereas its CDCA binding capacity was 60% of that for cholestyramine resin on a per same weight basis. These data suggested the potential of PLP in reducing total plasma and LDL cholesterol levels because cholestyramine resin was a commercially used cholesterol-lowering agent. The mechanism of PLP binding bile acid might be similar to that for other psyllium-related and derived polysaccharides and might be related to its highly branched structure.[5] These results warrant additional research in investigating the cholesterol-lowering capacity of PLP from *P. asiatic* L. for its potential application in cholesterol-lowering functional foods.

Supporting Information

ABSTRACT: Carotenoid, flavonoid, and vitamin C concentrations were determined in fresh orange segments and a puree-like homogenate derived thereof, as well as freshly squeezed, flash-pasteurized, and pasteurized juices. Lutein and β-cryptoxanthin were slightly degraded during dejuicing, whereas β-carotene levels were retained. Vitamin C levels remained unaffected, whereas flavonoid levels decreased 8-fold upon juice extraction, most likely due to the removal of flavonoid-rich albedo and juice vesicles. Likewise, the presence of such fibrous matrix compounds during in vitro digestion was assumed to significantly lower the total bioaccessibility (BA) of all carotenoids from fresh fruit segments (12%) as compared to juices (29−30%). Mechanical disruption of orange segments prior to digestion did not alter carotenoid BA, whereas pasteurization of the freshly squeezed juice slightly increased BA by 9−11%. In addition to carotenoid BA, the stabilities of hesperidin, narirutin, and vitamin C including dehydroascorbic acid during in vitro digestion were monitored, and applied analytical methods were briefly validated.

KEYWORDS: *fruit matrix, bioavailability, dietary fiber, bioactive compounds, health and nutrition*

INTRODUCTION

Orange juice is the most popular fruit juice in the European Union and the United States.[1] Consumers perceive orange juice as a healthy and natural source of vitamins and other health-promoting nutrients, resulting in an increasing worldwide demand and production.[2] Additionally, the convenient packaging and long shelf life of juices are advantageous compared to fresh fruit. Recent intervention studies demonstrated the health benefits of long-term orange juice consumption, such as an increased total antioxidant status, lower total cholesterol levels, and the prevention of endotoxin increases after meals high in fat and carbohydrate.[3−6] However, greater consumption of orange juice has also been criticized because of its high intrinsic sugar level, being associated with a higher risk of type 2 diabetes and cardiovascular diseases.[7]

Oranges [*C. sinensis* (L.) Osbeck] and products thereof are rich sources of carotenoids, flavonoids, and vitamin C.[8−11] The carotenoid profile of oranges has been reported to be one of the most complex in fruits,[12] making its determination a popular research objective over the past few decades.[9] In addition to the provitamin A carotenoids β-cryptoxanthin, α-carotene, and β-carotene, oranges contain a large diversity of free and esterified xanthophylls, among them lutein and zeaxanthin. The latter compounds are believed to play an important role in preventing age-related macular degeneration and, possibly, cognitive impairment in elderly people.[13] Sufficient bioavailability is a prerequisite for their bioactivity in humans, that is, their liberation from the food matrix, incorporation into mixed micelles, and subsequent absorption by the enterocyte.[14] The term "bioaccessibility" refers to "the fraction of a compound that is released from its matrix in the gastrointestinal tract and thus becomes available for intestinal absorption". Because only micellarized carotenoids are potentially bioavailable, common in vitro digestion assays include analyses of the intestinal micellar fraction.[15] In vitro digestion models measuring the bioaccessibility of micro- and macronutrients in food by mimicking the physiological conditions in the intestinal tract have become a popular low-cost−high-throughput research tool.[15,16] Although presenting major drawbacks compared to in vivo studies, in vitro models allow the fast and inexpensive screening of a larger sample set, serving as a scientific basis for further in vivo studies.

Numerous reports have described the bioavailability and bioaccessibility of carotenoids from different food matrices.[14,17−19] Simultaneous intake of fat[20,21] as well as thermal and mechanical processing[22,23] were shown to favor carotenoid liberation and micellarization from tomatoes, carrots, and spinach, thus resulting in higher carotenoid bioavailability. Although some studies evaluated the effects of different orange juice production on carotenoid bioaccessibility,[24−26] comparative data regarding the bioaccessibility of unprocessed orange fruits and products derived thereof are lacking.

In addition to carotenoids, the flavanone glycosides hesperidin and narirutin represent potentially bioactive phytochemicals in oranges. In numerous epidemiological

studies, an inverse relationship between dietary flavonoid intake and cardiovascular diseases has been demonstrated, mainly due to the antioxidant properties of the flavanones.[11] Various other health-beneficial mechanisms have been reported, such as anti-inflammatory and chemopreventive activities.[11] The metabolism of hesperidin and narirutin involves the deglycosylation of the rhamnose moiety by the colon microbiota, their absorption by colonocytes, and their subsequent conjugation with hydrophilic compounds such as glucuronic acid.[10] The solubilization of flavonoids during processing and digestion is a key factor in this metabolism, thus strongly affecting their bioavailability.[27] In vitro models commonly used for the evaluation of carotenoid bioaccessibility include ultracentrifugation and microfiltration of the digesta,[18] thus also allowing the measurement of soluble flavonoids in the intestinal fluid.

Orange fruits and products thereof contain high amounts of vitamin C, with concentrations averaging 500 mg/L.[8,28] Although the bioavailability of vitamin C (comprising ascorbic acid and dehydroascorbic acid) ranges between 80% and 100% at doses normally ingested,[8] its oxidation and further degradation during processing, storage, and digestion might limit the nutritional value of a dietary source.

The first aim of this work was to evaluate the impacts of different steps of orange fruit processing on levels of carotenoids, flavonoids, and vitamin C. All test foods were produced from the same batch of navel oranges to ensure uniformity of analyte levels. The main objective was then to evaluate the in vitro bioaccessibility of nutritionally relevant carotenoids and flavonoids in these test foods. In addition, levels of vitamin C were monitored before and after in vitro digestion.

MATERIALS AND METHODS

Materials and Reagents. Fresh, untreated oranges [*Citrus sinensis* (L.) Osbeck cv. "Navel Lane Late"] were obtained from a wholesale market (Stuttgart, Germany). Ammonium oxalate (≥99.5%), calcium carbonate (98.5−100.5%), calcium chloride dihydrate (p.a.), dipotassium hydrogen phosphate (≥99%), ethanol (≥99.9%), aqueous hydrochloric acid (37%), potassium dihydrogen phosphate (p.a.), potassium chloride (p.a.), *N*,*N*-dimethylformamide (DMFA, ≥99.8%), sodium hydrogen carbonate (p.a.), sodium hydroxide (1 mol/L, Titrisol), 2-propanol (≥99.8%), methyl *tert*-butyl ether [MTBE, high-performance liquid chromatography (HPLC) gradient grade], and BIOQUANT total dietary fiber kits (1.12979.0001) were purchased from Merck (Darmstadt, Germany). Butylated hydroxytoluene (BHT) was from Merck Schuchhardt (Hohenbrunn, Germany). Ascorbic acid (Ph. Eur.), acetic acid (100%), sodium chloride (100%), potassium hydroxide (85.9%), magnesium chloride hexahydrate (Ph. Eur.), methanol (HPLC grade), metaphosphoric acid (GPR), and petroleum benzine (bp 40−60 °C, GPR rectapur) were purchased from VWR International (Leuven, Belgium). Porcine pancreatic α-amylase (46.4 U/mg), porcine bile extract, cholesterol esterase from porcine pancreas (42.9 U/mg), dehydroascorbic acid, disodium hydrogen phosphate, pancreatin from porcine pancreas, and pepsin from porcine gastric mucosa were obtained from Sigma-Aldrich Chemie (Steinheim, Germany). β-Carotene (≥97%), β-cryptoxanthin (≥97%), 3-*tert*-butylhydroxyanisol (BHA), and hesperidin (~90%) were from Fluka Chemie (Buchs, Switzerland), whereas antheraxanthin (95.0%), zeinoxanthin (97.7%), α-carotene (98.9%), lutein (99.9%), mutatoxanthin (95.5%), violaxanthin (99.3%), and zeaxanthin (99.8%) were purchased from CaroteNature (Ostermundingen, Switzerland). Narirutin (96%) was obtained from ChromaDex (Irvine, CA), and tris(2-carboxyethyl)phosphine hydrochloride (TCEP) was from Alfa Aesat (Karlsruhe, Germany). Ultrapure water (Milli-Q system, Millipore, Bedford, MA) was used for all analyses.

Production of Orange Test Foods. Figure 1 illustrates the processing steps used to obtain five different test products (fresh unprocessed orange segments, homogenized segments, freshly squeezed juice, pasteurized juice, flash-pasteurized juice). A minimum of 8 kg of oranges was used for the production of each test food to minimize the influence of raw-material heterogeneity. Unprocessed orange segments were manually peeled, and the adhering albedo and the columella were almost completely removed. A portion of the obtained segments was immediately frozen in liquid nitrogen, vacuum-sealed in plastic bags, and stored at −80 °C until further analyses. Residual segments were homogenized with a PUC colloid mill (Probst and Class, Rastatt, Germany) at 5050 rpm and a gap width of 1 mm. Subsequently, homogenization was repeated thrice with decreasing gap widths (350, 50, and 50 μm, respectively). The homogenized segments were filled into 20 mL plastic flasks, and the headspace was flushed with nitrogen prior to sealing. The plastic flasks were then immediately frozen in liquid nitrogen and stored at −80 °C until further analyses.

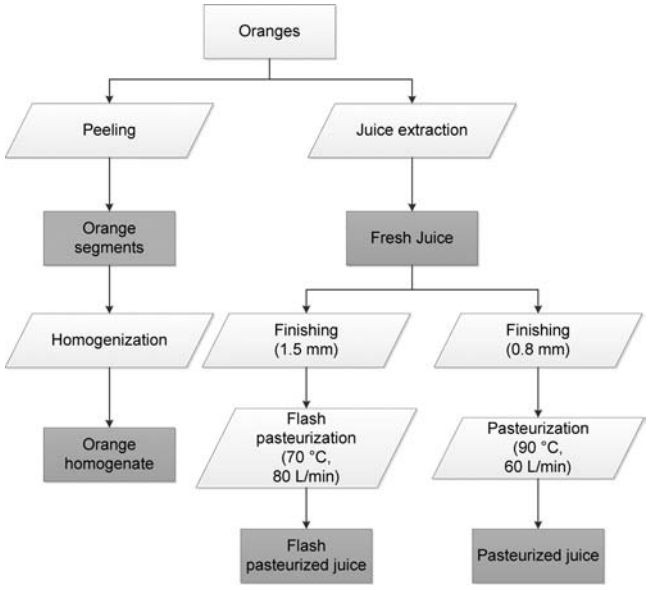

Figure 1. Production of the test foods (gray boxes) for in vitro digestion from the same batch of fresh "Navel Lane Late" orange fruits.

For orange juice production, oranges were washed with cold water and dejuiced using a semiautomatic Orange X-Press extractor (Brimato, Hilter, Germany). An aliquot of the freshly squeezed juice was filled into plastic flasks, frozen with liquid nitrogen, and stored at −80 °C until further use. The remaining freshly squeezed juice was finished using a commercial paddle pulper (PAP 0533, Bertuzzi, Brugherio, Italy) with mesh sizes of 1.5 and 0.8 mm for the production of the flash-pasteurized and pasteurized orange juice, respectively. As shown in Figure 1, the flash-pasteurized juice was continuously heated to 70 °C at a flow rate of 80 L/h using a tubular heater (Ruland Engineering & Consulting, Neustadt/Weinstraße, Germany), whereas the pasteurized juice was heated to 90 °C at 60 L/h. Subsequently, the juices were hot-filled into 500 mL glass bottles and cooled to room temperature in a water bath. The juices were filled into plastic flasks, and the headspace was flushed with nitrogen before sealing and freezing with liquid nitrogen. All samples were stored at −80 °C until further analyses. Product temperature was recorded throughout the process, and pasteurization values were calculated using *Bacillus coagulans* as the reference germ (T_{ref} = 93.3 °C, z = 8.9 K) according to the method of Hirsch et al.[29] Pasteurization values were 0.002 and 0.504 min for the flash- and conventionally pasteurized juices, respectively.

In Vitro Digestion Model. After being thawed at ambient temperature for less than 1 h, unprocessed orange segments were cut into cubic pieces of 5-mm length to mimic coarse comminution obtained by chewing. All other test foods were thawed and subjected

DOI: 10.1021/jf505297t
J. Agric. Food Chem. 2015, 63, 578−587

to the digestion model without further pretreatment. The in vitro digestion protocol was based on the method reported by Schweiggert et al.,[18] with the following modifications. During the oral phase, 10 mL (instead of 5 mL) of artificial saliva solution was used, and 7 mL (instead of 9 mL) of porcine bile extract/pancreatin solution was added at the beginning of the intestinal phase. After completion of the intestinal phase, 35 mL of the artificial intestinal fluid was centrifuged at 75000*g* for 60 min at 10 °C in a JA-25.50 rotor (Avanti J-26 XP/XPI, Beckman Coulter, Krefeld, Germany) to separate solids from the aqueous phase. The thus-obtained supernatant (~35 mL) was considered to contain the nutrients *liberated* from the solid food matrix. A volume of 5 mL of the supernatant was then filtered through a cellulose acetate-based 0.2-μm syringe filter (Klaus Ziemer, Mannheim, Germany) to yield the micellar fraction. Only micellarized lipophilic nutrients such as carotenoids are considered to be potentially available for absorption, thus representing the *bioaccessible* fraction. In vitro liberation and bioaccessibility were calculated as the percentages of the respective nutrient transferred from the test food to the supernatant obtained after centrifugation and to the micellar phase obtained by microfiltration of the supernatant, respectively, as described by Schweiggert et al.[18] The in vitro digestion was performed in triplicate.

Carotenoid, Flavonoid, and Vitamin C Analyses. *Sample Preparation.* Frozen orange segments and homogenized segments were milled under liquid nitrogen using a model 38BL41 blender (Waring, Torrington, CT) prior to analyses, whereas juices and digesta were analyzed without further pretreatment.

Carotenoids. An aliquot of 2.0 ± 0.1 g and 2.0 mL of test food and digesta, respectively, were combined with 50 mg of $CaCO_3$ and 3 mL of petroleum benzine/2-propanol (1:1, v/v), containing 50 mg of BHA and 50 mg of BHT/100 mL solvent mixture. Extraction was supported by a probe sonicator (Sonoplus HD 3080 with MS 72 sonotrode, Bandelin, Berlin, Germany) at 70% amplitude for 30 s. After centrifugation (3000 rpm, 3 min, Labofuge 200, Heraeus, Hanau, Germany), the upper organic layer was collected, and the sample was re-extracted twice with 2 mL of the above-mentioned extraction solvent. The combined organic phases were washed with 2 mL of aqueous NaCl (0.1 M) and dried under a stream of nitrogen at ≤25 °C. Subsequently, the dried extracts were redissolved in 3 mL of petroleum benzine, and saponification was started by adding 3 mL of ethanolic KOH (10%, w/v). After incubation for 3 h under continuous shaking using an orbital shaker at 130 rpm (Type A2, Edmund Bühler, Tübingen, Germany), the samples were washed with 2 mL of aqueous NaCl (0.1 M), centrifuged, and the upper organic layer was separated. The lower ethanolic phase was re-extracted with 1 mL of MTBE, and the combined organic phases were evaporated to dryness under a stream of nitrogen at ≤25 °C. Samples were redissolved in 400 μL of 2-propanol and filtered (0.45 μm) into amber vials prior to HPLC analysis. The extraction procedure was conducted in duplicate under subdued light.

Carotenoid identification and quantification were performed on a series 1100 HPLC instrument (Agilent, Waldbronn, Germany) equipped with a G1379A degasser, a G1312A binary gradient pump, a G1313A autosampler, a G1316A column oven, and a G1315B diode array detector (DAD) coupled to a Bruker 3000+ ion-trap mass spectrometer (Bruker Daltonics, Bremen, Germany). Carotenoids were separated on a YMC C30 reverse-phase column (150 × 3.0 mm i.d., 3-μm particle size, YMC Europe GmbH, Dinslaken, Germany) protected by a YMC C30 guard column (10 × 3.0 mm i.d., 3-μm particle size) and operated at 40 °C. The mobile phase consisted of methanol/water (90:10 v/v, eluent A) and MTBE/methanol/water (78:20:2 v/v/v, eluent B), both containing 1.5 g/L ammonium acetate. The following gradient was used (min/percentage of A): 0/98, 24/83, 28/54, 35/22.5, 35.1/0, 38/0, 41/98, 43/98. The total run time was 43 min at a flow rate of 1 mL/min. The injection volume was 20 and 80 μL for the analyses of test foods and digested samples, respectively. Carotenoids were monitored at 450 nm, and additional UV−vis spectra were recorded between 200 and 700 nm. Carotenoid identification was carried out by comparing the retention times, UV−vis spectra, and mass spectra of detected compounds with those of external standards and literature references.[30] To support the identification of carotenoid (*Z*) isomers, D_B/D_{II} ratios were determined according to the method of Britton.[30] Carotenoids were quantified by HPLC-DAD using linear calibration curves of external standards.

Vitamin C Analyses. Vitamin C analyses were conducted by HPLC-DAD based on the findings of Wechtersbach and Cigić.[31] A sample aliquot of 2.0 ± 0.1 g was transferred to a 20 mL volumetric flask containing 15 mL of metaphosphoric acid (1% w/v) adjusted to pH 3.8 with dipotassium hydrogen phosphate. A second aliquot of 2.0 ± 0.1 g was transferred to an identical buffer additionally containing 10 mM TCEP. The samples were made up to 20 mL with the respective buffer, vortexed, and allowed to stand for 30 min for the reduction of dehydroascorbic acid (DHAA) to ascorbic acid (AA) in the TCEP experiment. Subsequently, samples were membrane-filtered (0.45 μm) and analyzed by HPLC. For quantification of ascorbic acid by HPLC-DAD, the above-described HPLC system (series 1100 HPLC) was equipped with a reverse-phase C18 Sunfire column (250 mm × 4.6 mm i.d., 5-μm particle size, Waters, Eschborn, Germany) operated at 25 °C. The mobile phase consisted of aqueous metaphosphoric acid (1% w/v) adjusted to pH 2.6 with dipotassium hydrogen phosphate (eluent A) and methanol (eluent B). The following gradient was used (min/percentage of A): 0/100, 17/100, 20/0, 30/0, 33/100, 43/100. The total run time was 43 min at a flow rate of 0.8 mL/min. The injection volume was 20 μL. AA was monitored at 254 nm and quantitated by external linear calibration. DHAA concentrations were determined by subtracting the initial AA concentration from that obtained by the above-described TCEP experiment. The reported vitamin C levels represent the sum of AA and DHAA.

Flavonoids. Flavonoid extraction was performed according to method no. 58 of the International Federation of Fruit Juice Producers[32] with some modifications. Exactly weighed samples (2.0 ± 0.1 g of test foods and supernatant, 1.0 ± 0.1 g of micellar phase) were transferred into 50, 10, and 5 mL volumetric flasks for test foods, supernatant, and micellar phase, respectively. The following description refers to the experiment using the 50 mL volumetric flask. Experiments using 10 and 5 mL flasks were carried out identically using proportional amounts of reagents. After addition of 10 mL of ammonium oxalate solution (0.025 M) and 10 mL of DMFA, the samples were made up to 50 mL with deionized water and incubated in a type 461 water bath (Büchi Labortechnik, Flawil, Switzerland) at 90 °C for 10 min. Subsequently, samples were membrane-filtered (0.45 μm, Chromafil RC-45/15MS, Macherey-Nagel, Düren, Germany) into amber HPLC vials. Flavonoid separation was performed on the above-described series 1100 HPLC system, using a reverse-phase C18 Sunfire column (250 × 4.6 mm i.d., 5-μm particle size, Waters, Eschborn, Germany) at 25 °C. The mobile phase consisted of acetic acid (2%, eluent A) and methanol (eluent B) using the following gradient (min/percentage of A): 0/100, 10/100, 20/55, 30/55, 33/0, 40/0, 43/100, 50/100. The total run time was 50 min at a flow rate of 0.8 mL/min. The injection volume was 10 μL, except for supernatant and micellar phases of all juices (20 μL). Flavonoids were monitored at 287 nm and quantitated by external linear calibration curves.

Method Validation of Carotenoid, Flavonoid, and Vitamin C Determinations. *Repeatability.* The intra-assay precision and the time-dependent intermediate precision[33] of the methods described for analysis of the bioactive compounds were determined by analyzing a commercial orange juice in quadruplicate by the same person and with the same equipment on three different days within 1 month.[34] The orange juice was aliquoted and stored at −20 °C prior to the performance of the above-described determinations. Relative standard deviations (RSDs) for quantification of flavonoids and vitamin C were <0.7%. RSDs for quantification of carotenoids were <4.4%, except for the interday RSD of lutein (6.1%). The results illustrate the high precision of the methods applied. Further details are provided in Table S1 (Supporting Information).

Recovery. The accuracy of the methods described for analysis of bioactive compounds was determined by spiking different levels of the

analytes into orange juice.[33] Relative recovery was calculated based on the predicted and measured concentrations. Recovery rates were generally 98−100%, except for the addition of intermediate levels of *β*-carotene (95.3%) and high levels of *β*-cryptoxanthin (94.8%). Further details are provided in Table S2 (Supporting Information).

Limit of Detection (LOD) and Limit of Quantification (LOQ). LOD and LOQ were determined according to DIN 32645 from the respective calibration curves.[35] All measured concentrations of secondary plant metabolites were above the LOQ. Detailed information can be found in the Supporting Information (Table S2).

Quantitation of Pectin and Total Dietary Fiber. Pectin levels were quantitated spectrophotometrically according to IFU methods.[36] Pectin levels are expressed as milligrams of galacturonic acid (GA) per 100 g of test product. Dietary fiber levels were determined gravimetrically using a BIOQUANT total dietary fiber kit according to the supplier's instructions. Samples were analyzed in quadruplicate.

[a]Mean ± standard deviation, $n = 2$ for quantification of carotenoids in the test foods, $n = 3$ for in vitro digestion. Units of μg/100 g of FW. Different letters within rows indicate significant differences ($P \leq 0.05$). [b]Sum (C_P) = sum of lutein, β-cryptoxanthin, α- and β-carotene levels. [c]ZEA, zeaxanthin; (9Z)-ANT, (9Z)-antheraxanthin. [d]Obtained after centrifugation of the digesta. [e]Obtained after centrifugation and microfiltration (0.2 μm).

Statistics. Statistically significant differences of means were identified by Tukey's and Duncan's test, using SAS 9.1.3 (SAS Institute, Cary, NC). Differences were considered significant at $p < 0.05$. Normal distribution of the results was verified by the Shapiro–Wilk test. All reported data represent mean ± standard deviation. The standard deviation of the bioaccessibility was calculated by the Gaussian law of error propagation from the standard deviations of the levels in the test foods and of the total bioaccessible amounts of the respective analyte.

RESULTS AND DISCUSSION

Carotenoid Identification in the Test Foods. Figure 2 presents a chromatogram of a carotenoid extract from pasteurized orange juice, showing 26 detected carotenoids. Unambiguous identification of 9 carotenoids (peaks 6, 12–15_1, 17, 18, 25, 26) was achieved by comparing their retention times, UV–vis spectra, and molecular masses with those of authentic standards. Among them, lutein (14), zeaxanthin (15_1), zeinoxanthin (17), and β-cryptoxanthin (18) were the major ones, in accordance with previous studies.[9,28,37−39] The two enantiomeric forms (8*R*)- and (8*S*)-mutatoxanthin were also identified using authentic standards, although the assignment of the enantiomers to the respective peaks (12 and 13) was impossible. Using authentic standards (compounds 6, 25, and 26, respectively), violaxanthin and α- and β-carotene were unambiguously assigned.

Compound 9 was tentatively identified as (9Z)-violaxanthin. Its UV–vis spectrum was highly similar to that of all-*E*-violaxanthin (6), except for a characteristic hypsochromic shift of 2–4 nm (Table 1). In addition, the UV spectrum exhibited a cis peak at 328 nm with a D_B/D_{II} ratio of 0.078, and the compound eluted after its all-trans isomer, both being typical of (9Z)-carotenoid isomers. In agreement with the previous report of Dugo et al.,[40] a predominant quasimolecular ion was detected at m/z 601, thus supporting the identity of compound 9 as (9Z)-violaxanthin.

By analogy, compound 15_2 was tentatively assigned to (9Z)-antheraxanthin. It is noteworthy that this compound coeluted with zeaxanthin (15_1) and was detectable only in the flash-pasteurized and pasteurized orange juices, thus indicating its thermally induced formation. Meléndez-Martínez et al.[41] reported the presence of high amounts of *cis*-antheraxanthin in orange juice. Therefore, the zeaxanthin contents determined for pasteurized juices can be partly attributed to (9Z)- or (9′Z)-antheraxanthin. Because of the observed coelution, the fate of zeaxanthin during processing and digestion remains unclear.

Compound 16 revealed a slightly hypsochromic shift of the UV–vis spectrum similar to β-cryptoxanthin. In contrast to compounds 9 and 15_2, compound 16 eluted before its all-*E* isomer and had a D_B/D_{II} ratio of 0.459, which is characteristic of (13Z) isomers.[39] Therefore, compound 16 was tentatively assigned to (13Z)-β-cryptoxanthin.

Absolute Carotenoid Levels in Test Foods. Table 2 summarizes the carotenoid levels in the test foods, as well as the liberated and micellarized carotenoid fractions after in vitro digestion. Carotenoid epoxides such as violaxanthin and mutatoxanthin are not found in human plasma and thus are considered not to be bioavailable in humans.[42] Accordingly, we limited our bioaccessibility study to bioavailable carotenoids, because only such carotenoids would be relevant for the evaluation of assumed health-beneficial effects. Because of the coelution of the tentative (9Z)-antheraxanthin and zeaxanthin in both flash- and conventionally pasteurized juices, their carotenoid concentrations were apparently higher than those in the freshly squeezed juice. We therefore did not include these carotenoids in the sum of total (bioaccessible) carotenoids reported in Table 2 and Figure 3.

DOI: 10.1021/jf505297t
J. Agric. Food Chem. 2015, 63, 578–587

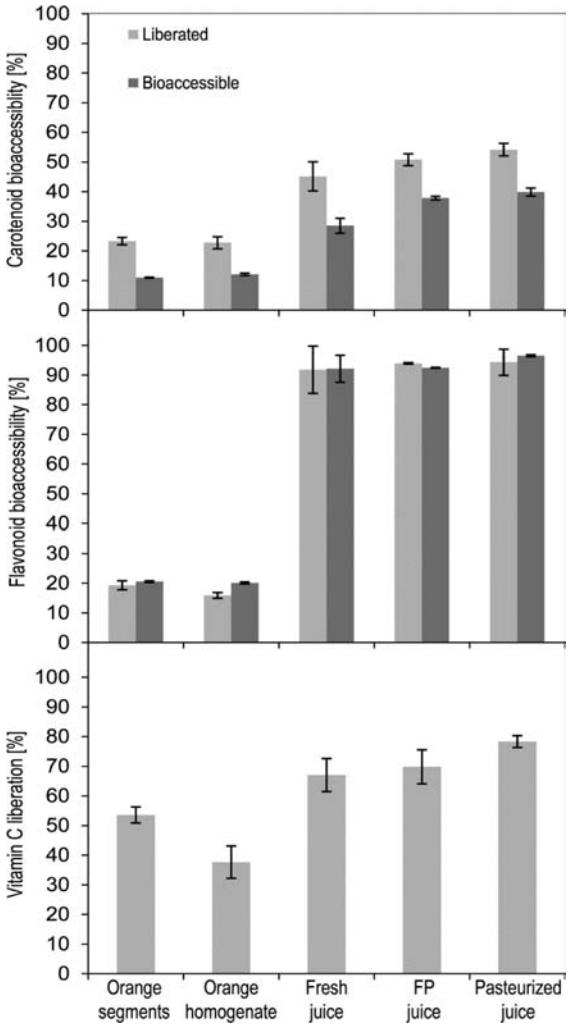

Figure 3. Bioaccessibility of potentially bioavailable carotenoids (lutein, β-cryptoxanthin, α- and β-carotene), flavonoids, and vitamin C from differently processed oranges (FP = flash-pasteurized). Liberated and bioaccessible fractions were calculated as the percentages of the respective nutrients transferred from the test food to the supernatant obtained after centrifugation and to the micellar phase obtained by microfiltration of the supernatant, respectively.

A decrease in total carotenoid levels (C_p) was noted during the processing of fresh oranges (224 μg/100 g of FW) into pasteurized orange juices (178−184 μg/100 g of FW, Table 2). However, the homogenized orange segments showed higher carotenoid levels (272 μg/100 g of FW), possibly due to the inevitable heterogeneity of the fruit or a slightly better carotenoid extractability during analyses. Among the nutritionally relevant carotenoids (Table 2), β-cryptoxanthin was predominant in fresh orange segments, homogenate, and freshly squeezed juice (102−151 μg/100 g of FW), being slightly lowered by 7−10% after pasteurization (92−95 μg/100 g of FW). According to the classification of Britton and Khachik,[43] β-cryptoxanthin levels of orange can be considered as being low (<100 μg/100 g of FW) to moderate (100−500 μg/100 g of FW), whereas papaya fruits (up to ca. 2500 μg/100 g of FW[44]) and red chili peppers (1834 μg/100 g of FW[45]) are among fruits and vegetables rich in β-cryptoxanthin. Lutein had the second highest concentrations in segments, homogenate, and freshly squeezed juice, reaching 82−96 μg/100 g of FW. Its contents were reduced by 17−19% after pasteurization (66−68 μg/100 g of FW, Table 2). Regarding the above-mentioned classification, lutein levels were considered as being low, particularly when compared to those of green leafy vegetables (>2000 mg/100 g of FW[43]). As mentioned above, the exact quantitation of zeaxanthin was hampered by the presence of (9*Z*)-antheraxanthin. Nevertheless, the sum of the aforementioned carotenoids more than doubled after processing of the freshly squeezed juice (51 μg/100 g of FW) to the pasteurized juices (115−117 μg/100 g of FW). This increase was ascribed to the heat-induced formation of the tentative (9*Z*)-antheraxanthin from yet-unknown precursors, because the practical absence of all-*E*-antheraxanthin in the fresh juice was verified using an authentic standard. For α- and β-carotene, degradation and isomerization were insignificant (Table 2), confirming their high stability at temperatures below 120 °C.[46]

Absolute Carotenoid Levels in Micellar Fractions and Bioaccessibility. After in vitro digestion, the so-called bioaccessible carotenoids are contained in the micellarized fraction resulting from microfiltration of the supernatant.[47] The lowest levels of bioaccessible carotenoids were found for orange segments (24.2 ± 0.4 μg of micellarized total carotenoids/100 g of test food). Hence, only 10.8% of the carotenoids contained in fresh orange segments was micellarized and thus bioaccessible (Figure 3). Although the micellarized carotenoid concentration after digestion of homogenized segments was higher (32.4 ± 1.1 μg/100 g), the bioaccessibility was similar (11.9%) to that of intact segments (Figure 3), thus indicating only a minor contribution of mechanical cell disruption to carotenoid BA in oranges. The previously reported supportive effect of comminution on carotenoid bioavailability from tomatoes by disrupting the cell matrix[22] might be less decisive for oranges, because of either the absence of large carotenoid crystals as reported for tomatoes[18] or the high intrinsic fiber levels of oranges (13.9 g/100 g, Table 3) as compared to tomatoes (1.2 g/100 g[48]). The amount of soluble fiber such as pectin can strongly affect micellarization of carotenoids in the duodenum, because previous studies demonstrated hindering of

β-carotene bioavailability in humans by dietary fibers and, particularly, citrus pectin.[49] In our study, pectin and soluble-fiber levels confirmed their inverse correlation with carotenoid BA. Whereas dietary fiber and bioaccessibility in fresh and homogenated oranges were 13.6−13.9 g/100 g and 10.8−11.9%, respectively, juices containing only 0.7−1.4 g of dietary fiber/100 g had a far higher BA of 28.3−39.5% (Tables 2 and 3).

Because of the diminished content of dietary fiber, micellar carotenoid levels increased to 57.9 ± 5.1 μg/100 g after the digestion of freshly squeezed orange juice, resulting in a 2.6-fold higher bioaccessibility (28.3%) when compared to carotenoids from orange segments. Highest concentrations of bioaccessible carotenoids were observed in the flash-pasteurized (67.1 ± 1.1 μg/100 g) and pasteurized (72.7 ± 2.4 μg/100 g) juices. The bioaccessibility of total carotenoids was significantly higher in the pasteurized juices (37.6−39.5%) than in the freshly squeezed juice (28.3%). Thermal processing and finishing of the fresh juice increased the BA of lutein, β-cryptoxanthin, α-carotene, and β-carotene, whereas the (9Z)-antheraxanthin/zeaxanthin BA decreased from 35% to 17% and 16% in flash-pasteurized and pasteurized juices, respectively. Note that this decrease might be attributable to the instability of epoxy carotenoids such as antheraxanthin during digestion. Higher pasteurization temperatures and intensified finishing with smaller mesh size did not result in significant changes of the carotenoid BA. Consequently, a moderate thermal treatment and finishing appear to be key factors in increasing carotenoid BA. The insignificant change in carotenoid BA from the flash-pasteurized to the pasteurized juice indicates a "saturation" of these processing effects, meaning that further heating or finishing beyond such an "optimum processing" does not further improve carotenoid BA. If this hypothesis is valid, the heat exposure during the production of the flash- and conventionally pasteurized juices (P values of 0.002 and 0.504 min, respectively) exceeded this optimum heating threshold. However, the definition of an "optimum thermal treatment" regarding carotenoid bioaccessibility is expected to be highly intricate because of the numerous interactions with other dietary factors, such as the amount of ingested dietary lipids. Unfortunately, we cannot differentiate whether the thermal treatment or the finishing step had the greater impact on carotenoid BA. Both treatments are assumed to contribute to the enhanced carotenoid bioaccessibility.

In comparison to this study, Stinco et al.[24] reported higher relative carotenoid absorption from simulated digesta, ranging from 34% in fresh hand-squeezed juice to 40% in industrially pasteurized juice and up to 52% in industrially squeezed and finished juice. According to their work, finishing resulted in a particle size reduction, thus improving carotenoid liberation, whereas thermal pasteurization apparently diminished carotenoid liberation during digestion. Note that Stinco et al.[24] did not separate the micellar fraction by microfiltration of the supernatant, which is rather more comparable to the liberated carotenoids displayed in Figure 3 than to the bioaccessible fraction. In agreement with our study, carotenoid liberation was 44.9−53.9% in freshly squeezed and pasteurized juices, thus being significantly higher than the respective bioaccessibility (28.3−39.5%). The observation of higher liberation as compared to bioaccessibility is in accordance with previous studies, which reported significantly lowered carotenoid levels after microfiltration of the aqueous supernatant.[18,47,50]

Flavonoid Levels in Test Foods and Digesta. Flavonoid contents in the orange juices were 8-fold lower than those of orange segments and homogenated segments (Table 4). According to previous studies, hesperidin levels in membranes and albedo of *Citrus sinensis* are between 8.5- and 16.0-fold higher than those in juice vesicles.[51] These findings correlate well with the hesperidin and narirutin levels determined in our test foods, because juice extraction resulted in the extensive separation of membranes and albedo. For instance, the hesperidin content decreased from approximately 240 mg/100 g in fresh orange segments to 30 mg/100 g of juice (Table 4). Despite the large differences in the test foods, the absolute hesperidin and narirutin levels in the supernatant and micellar fractions were similar after their in vitro digestion. Apparently,

DOI: 10.1021/jf505297t
J. Agric. Food Chem. 2015, 63, 578−587

their solubilization was dose-independent in our experiments, indicating a saturation of the intestinal fluid with soluble hesperidin and narirutin at 26−34 mg/100 g and 20−25 mg/100 g, respectively. Consequently, the bioaccessibility of hesperidin and narirutin increased significantly upon juice extraction (Figure 3). Whereas only 20.5% of the flavonoids were bioaccessible from orange segments, a total of 92.1−96.5% of the flavonoids occurring in the juices was bioaccessible, equaling a gain of almost 500% as compared to the orange segments. Comparing the digestion of intact and homogenized segments, differences in flavonoid BA were insignificant. Thus, homogenization of the orange segments turned out to be ineffective regarding flavonoid BA (Figure 3).

Our findings are in good agreement with those of a previous study by Vallejo et al., who found only the soluble fraction of flavonoids in orange juice to be bioavailable.[27] Supported by these findings, it is assumed that the higher hesperidin level in orange fruits compared to orange juice offers only a limited nutritional benefit, because differences in the hesperidin contents in the supernatant and micellar phase from the digested test foods were found to be insignificant. However, it is worth mentioning that our in vitro model did not include the simulation of colonic digestion, where hesperidin is deglycosylated by the microbiota to hesperetin 7-*O*-glucosid and hesperetin.[10] Insoluble hesperidin can thus be further solubilized, metabolized, and absorbed in the colon. Nevertheless, in an in vivo study, Brett et al.[52] found differences in flavonoid bioavailability to be insignificant based on total urinary hesperetin excretion of human subjects after consumption of orange fruit and juice.

Ascorbic Acid and Vitamin C in Test Foods and Digesta (Supernatant). When exposed to oxygen, ascorbic acid (AA) is reversibly oxidized to dehydroascorbic acid (DHAA), which also exerts vitamin efficacy. According to most reports, vitamin C efficacy is lost upon the irreversible degradation of DHAA to 2,3-diketogulonic acid.[31] Consequently, both AA and DHAA levels were monitored in our study (Table 4). AA levels in the fresh and flash-pasteurized juices (48.6 ± 0.5 and 45.5 ± 0.0 mg/100 g, respectively) were slightly higher compared to those in the orange segments (43.1 ± 0.6 mg/100 g) and the pasteurized juice (44.6 ± 0.1 mg/100 g). Although these slight differences might be due to unavoidable heterogeneities within the used batch of oranges, homogenization of the orange segments led to a significant loss of AA from 43.1 to 32.6 mg/100 g and, at the same time, to an increase in DHAA from 8.0 to 15.3 mg/100 g, possibly due to oxygen exposure during homogenization. However, the vitamin C values of all test foods ranged between 46.5 and 51.1 mg/100 g, confirming the stability of AA and DHAA at low pH.

The bioavailability of vitamin C ranges from 80% to 100% at doses normally ingested (≤180 mg).[8] Thus, the concentration in the intestinal digesta is rather a demonstration of vitamin C stability during digestion than of bioaccessibility. Whereas digestion of the orange segments resulted in residual vitamin C levels of 54% as compared to the test food, a level of only 38% was found after digestion of homogenized orange segments. The high input of air during homogenization probably favored further degradation of vitamin C during in vitro digestion. In contrast, the production of the pasteurized orange juice significantly improved vitamin C stability during digestion, resulting in a residual level of 78% as compared to the test food. Vitamin C levels in the digesta of the different juices did not differ significantly (Figure 3).

In conclusion, processing of the oranges into fresh and pasteurized juices slightly diminished carotenoid and vitamin C levels by 3−18%. However, flavonoid and dietary fiber levels were decreased to approximately one-tenth upon dejuicing. At the same time, carotenoid BA from orange segments was enhanced from 10.8% to 28.3% for freshly squeezed orange juice, whereas flavonoid BA was boosted by almost 5-fold to 96.5%. However, the total hesperidin levels in the digesta of all test foods were quite similar. The lower flavonoid levels in orange juices as compared to orange segments might be less relevant regarding their intestinal absorption, because low flavonoid solubility in the digestive fluids is considered to be the limiting factor. In contrast to dejuicing, homogenization of orange segments to a puree did not enhance carotenoid BA, thus indicating a minor role of cell disruption and comminution compared to the removal of fibers in orange products. To substantiate our findings, performing an in vivo bioavailability study is the next aim of our ongoing investigations.

ABSTRACT: MicroRNAs (miRs, miRNAs) play central roles in gene regulation. Previously, we reported that miRNAs from pasteurized, store-bought bovine milk have biological activity in humans. Here, we assessed the effects of milk processing, storage, somatic cell content, and handling by consumers on the degradation of miRNAs in milk; we also quantified miRNAs in dairy products. Pasteurization and homogenization caused a 63% loss of miR-200c, whereas a 67% loss observed for miR-29b was statistically significant only in skim milk. Effects of cold storage and somatic cell content were quantitatively minor (<2% loss). Heating in the microwave caused a 40% loss of miR-29b but no loss of miR-200c. The milk fat content had no effect on miRNA stability during storage and microwave heating. The concentrations of miRNAs in dairy products were considerably lower than in store-bought milk. We conclude that processing of milk by dairies and handling by consumers causes a significant loss of miRNAs.

KEYWORDS: *heating, miRNAs, milk, processing, storage*

INTRODUCTION

MicroRNAs (miRs, miRNAs) are small non-coding RNAs that play essential roles in the regulation of genes at the posttranscriptional level in plants and animals.[1] Mature miRNAs are about 22 nucleotides long and bind to complementary sequences in the 3′-untranslated region of mRNAs. Perfect or near perfect base pairing of the miRNAs and its target mRNAs typically results in mRNA degradation, whereas less perfect base pairing typically results in inhibition of mRNA translation.[2,3] Traditionally, miRNAs have been considered endogenous regulators of genes; i.e., miRNAs synthesized by a given host regulate the expression of genes in that host. Recently, our laboratory refuted this paradigm. We provided strong evidence that (1) humans absorb biologically meaningful amounts of miRNAs from nutritionally relevant doses of cow's milk, (2) physiological concentrations of milk miRNAs affect human gene expression *in vivo* and in cell cultures, and (3) endogenous synthesis of miRNAs does not compensate for dietary miRNA deficiency in mice.[4] Our discoveries were largely modeled on miR-29b and miR-200c but likely hold true for all miRNAs encapsulated in milk exosomes.[5,6] To the best of our knowledge, our previous paper is the first to provide unambiguous evidence that miRNAs can be transferred between distinct species through dietary means. In contrast, previous claims that miRNAs from plants affect human gene expression[7,8] are highly controversial and were met with skepticism by the scientific community.[4,9−12] On the basis of the above observations, milk miRNAs are a novel class of bioactive food compounds as defined by the National Cancer Institute in the United States.[13] The discovery that milk miRNAs are bioactive food compounds has broader implications because miRNAs play essential roles in gene regulation,[2,3] cell communication,[14,15] and human health.[16−23]

This study focused on determining the effect of milk processing, storage, somatic cell content, and handling by consumers on two miRNA, miR-29b and miR-200c, levels based on the following rationale. In bovine milk, miR-29b and miR-200c are among the most abundant miRNAs.[20] miR-29b is an important regulator of bone mineralization in humans, because it increases osteoblast differentiation[16] and decreases osteoclast differentiation and function.[17] miR-200c decreases cancer risk by targeting the transcription factor ZEB1, which induces E-cadherin expression, thereby limiting epithelial-to-mesenchymal transition, a key event in metastasis.[24,25] Also, the nucleotide sequences of miR-29b and miR-200c in bovine milk are identical to those of their human orthologues.[26] Our rationale for including the somatic cell count in our analysis was to assess whether an increase in milk cells, as seen in mastitis, might be a confounder in the analysis of milk miRNAs.

In Western societies, the majority of milk is processed prior to consumption. In fact, the production and sale of raw milk dairy products is illegal in many states in the United States, and pasteurization is required.[27] Moreover, while the per capita consumption of milk has declined from 236 pounds in 1982 to 195 pounds in 2012, total dairy consumption increased by 11% during the same time period.[28] Therefore, we considered it worthwhile to assess the effects of processing on the miRNA content in both milk and dairy products.

Little is known about the effects of processing and storage on milk miRNA levels. In two studies, synthetic miRNAs were added to bovine milk, and their stability after exposure to harsh treatments, such as acid and RNase, was assessed and compared to the stability of endogenous miRNAs in milk.[6,20] Synthetic miRNAs were rapidly degraded, whereas endogenous miRNAs were resistant to treatment. However, the harsh treatments applied in these studies are not representative of the treatments applied in commercial dairy production. In this study, we assessed the effects of pasteurization, fat content, cold storage, heating, and processing into dairy products on the content of milk miRNAs.

MATERIALS AND METHODS

Chemicals. Guanidinium thiocyanate and ethanol were purchased for use in the NucleoSpin miRNA plasma RNA extraction kit (Macherey-Nagel, Inc., Bethlehem, PA). TRIzol was purchased from Life Technologies (Grand Island, NY).

Milk and Dairy Products. Raw, whole, 2%, and skim cow's (*Bos taurus*) milk was obtained from the Pennsylvania State University Creamery (University Park, PA) from separate collections in three consecutive weeks in May 2014. A diagram illustrating the preparation of whole cow's milk is presented in Figure 1. Briefly, the milk was procured from the Penn State Animal Science Department's Holsteins breed herd, using raw milk and cream routinely supplied to the Penn State Berkey Creamery, University Park, PA. The milk was stored under intermittent agitation in a 22 712.5 L raw milk silo at 2.2 °C (Feldmeier Equipment, E-015-05, Little Falls, NY). The milk contained 3.25% fat and 12.15% non-fat solids (near-infrared method, CEM, Turbo Smart5, model 907990, Matthews, NC) and was pasteurized at 75.55 °C with a 28 s holding time (APV Paraflow, serial number 20053003000302, Goldsboro, NC). The milk was homogenized at 145 bar and 60 °C (APV Gaulin homogenizer, serial number 20052410702, Lake Mills, WI) and standardized using a Westfalia separator (MSE 55-01-177, Oelde, Germany), thereby producing whole milk (3.25% fat and skim milk). The 2% fat milk was prepared by mixing 3.25% milk and skim milk. After cooling, the product was transferred to a 7200 L refrigerated storage tank at 2.2 °C (Feldmeier Equipment, E-015-05, Little Falls, NY). The product was bottled on a filling machine (Federal Manufacturing, serial number 1/12.4GL843, Milwaukee, WI) and stored in a conventional cold-milk warehouse at 3.0 °C. On our initial collection dates, milk of all fat levels were stored at 4 °C for up to 15 days, and aliquots were taken and frozen at −80 °C every other day. In a separate experiment, bovine cells were removed from raw milk by centrifugation (500*g* for 10 min at 4 °C) to determine whether somatic cells are a meaningful confounder when analyzing the concentrations of miRNAs in milk from healthy cows. Samples were frozen at −80 °C and shipped on dry ice to Lincoln, NE, for miRNA analysis. Samples from all fat levels of milk on day 15 were heated in the microwave for 15 s and analyzed after cooling off to room temperature. Dairy products other than milk were purchased from grocery stores in Lincoln, NE. All samples were produced and analyzed as biological repeats in triplicate.

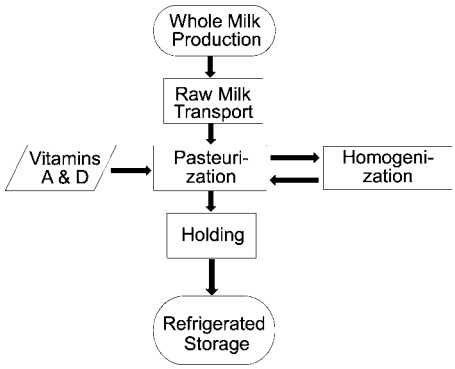

Figure 1. Schematic presentation of milk processing.

miRNA Analysis. Milk samples were spiked with a synthetic internal standard (25 attomoles) prior to extraction of miRNAs using miSPIKE synthetic RNA (IDT Technologies).[4] Dairy products (100 mg) other than milk were extracted using TRIzol prior to the addition of the synthetic internal standard. miR-29b and miR-200c were quantified using quantitative real-time polymerase chain reaction (PCR) as described previously.[4]

Statistics. Analysis by Bartlett's test homogeneity suggested that variances were homogeneous.[29] The paired *t* test was used for pairwise comparisons. One-way analysis of variance (ANOVA) and Fisher's protected least significant differences were used when comparing more than two groups. Repeated measures ANOVA was used for assessing the effects of storage time on the miRNA concentration. StatView 5.0.1 (SAS Institute, Cary, NC) was used for conducting statistical analyses. Means ± standard deviation (SD) are reported. Differences were considered statistically significant if $p \leq 0.05$.

RESULTS

Pasteurization and homogenization of raw milk resulted in a 63 ± 28% decrease of miR-200c in whole milk; effects were similar for 2% fat milk and skim milk (Figure 2A). The effect was less pronounced for miR-29b, for which a significant decrease (67 ± 18%) was observed only in skim milk (Figure 2B). Cold storage of milk did not affect the concentration of mir-29b and miR-200c in whole milk, 2% milk, and skim milk up to 15 days; 2% fat milk is shown as a representative example in Figure 3. Somatic cells are not meaningful confounds regarding the analysis of miRNAs in milk from healthy cows. When somatic cells were removed from raw milk by centrifugation and

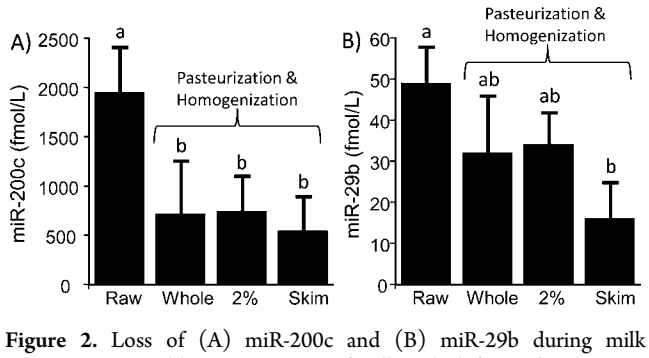

Figure 2. Loss of (A) miR-200c and (B) miR-29b during milk pasteurization and homogenization of milk with different fat contents. (a and b) Significantly different ($n = 3$ biological replicates; $p < 0.05$).

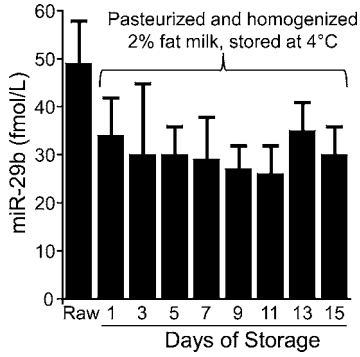

Figure 3. Storage at 4 °C did not affect the concentrations of miR-29b in pasteurized and homogenized 2% fat milk ($n = 3$ biological replicates; $p > 0.05$).

DOI: 10.1021/jf505526w
J. Agric. Food Chem. 2015, 63, 588−592

analyzed for miRNA content, the cellular miRNAs were found to contribute less than 2% of the total miRNAs present in raw milk before centrifugation: 1.1 ± 0.9% for miR-29b and 0.14 ± 0.08% for miR-200c.

Processing in the household has the potential to cause a considerable loss of some miRNAs in milk. For example, the concentration of miR-29b decreased by 40 ± 28% when processed milk was heated in the microwave and cooled to room temperature compared to milk before heating (Figure 4).

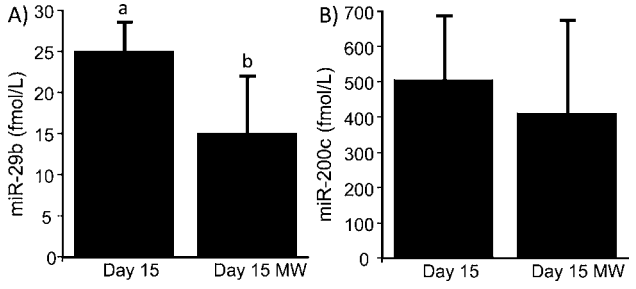

Figure 4. Loss of (A) miR-29b and (B) miR-200c during heating of whole milk in the microwave after 15 days of storage at 4 °C. Abbreviation: MW, microwaved. (a and b) Significantly different (n = 3 biological replicates; $p < 0.05$).

In contrast, when milk was heated in the microwave, the concentration of miR-200c was not statistically different compared to unheated controls. The concentrations of miRNAs varied considerably among the dairy products tested (Table 1) but were generally lower than the concentrations in pasteurized whole milk (compare to Figure 2). Fresco queso dip was a notable exception and contained higher concentrations of miRNAs than those observed in milk.

Table 1. Concentration of miRNAs, miR-29b and miR-200c, in Dairy Products[a]

	miRNA	
product	miR-29b (fmol/kg)	miR-200c (fmol/kg)
Best Choice yogurt	0.9 ± 0.10	37.6 ± 2.8
Fresco queso dip	36.1 ± 5.5	1029.8 ± 478.6
Greek yogurt	14.2 ± 3.9	462.3 ± 126.9
half and half	3.0 ± 0.17	513.3 ± 159.2
heavy whip cream	2.6 ± 1.3	342.0 ± 132.9
parmesan cheese	4.9 ± 1.9	232.0 ± 64.5
Upstate Farm yogurt	2.4 ± 1.0	216.9 ± 93.8

[a]Data are means ± SD; n = 3.

DISCUSSION

In a recent paper, we reported the importance of milk miRNAs for gene regulation in humans.[4] That report has major implications for the roles of milk and possibly other dairy products in human health. Cow's milk contains meaningful quantities of 245 miRNAs,[20,30] and 71.4% of these miRNAs are predicted to target about 11 000 human transcripts (unpublished observations). In addition to the roles of miR-29b and miR-200c in bone health and cancer prevention,[16,17,24,25] respectively, miRNAs have been implicated in various aspects of human health and disease, including hypertension, insulin resistance and diabetes, hyperlipidemia and atherosclerosis, reproduction, immune function, and Crohn's disease.[18,20,21,31−33]

We propose that milk has a meaningful effect on human health, mediated by miRNA-dependent gene regulation. The potential importance of dietary milk miRNA intake is supported by data suggesting that (1) Americans consume large quantities of milk and dairy products,[28] (2) a large proportion of milk miRNAs is encapsulated in extracellular vesicles, thereby providing protection against degradation[5,6] and a pathway for cellular uptake by endocytosis,[34,35] and (3) milk miRNAs are resistant against degradation during storage (this study).

Our previous studies of milk miRNAs in humans and mice were conducted using 1% fat milk from the grocery store.[4] On the basis of this study, the content of miRNAs is about 2 times higher in unprocessed milk compared to pasteurized, store-bought milk. Note that we have no intent recommending the consumption of raw cow's milk by humans, because of food safety concerns associated with raw milk. We observed that a loss of milk miRNAs occurred only during pasteurization, homogenization, and processing to dairy products other than milk. This observation is consistent with previous studies of milk miRNAs. For example, endogenous miRNAs were not degraded when milk was exposed to harsh treatments, such as low pH or treatment with RNase.[6,20] It is reasonable to propose that encapsulation of miRNAs in extracellular vesicles[5] prevents miRNA degradation based on the following lines of evidence: (1) When synthetic miRNAs are added to milk and subjected to low pH or RNase treatment, the miRNAs are rapidly degraded.[6,20] (2) When exosome membranes in milk were disrupted by sonication for preparing miRNA-depleted mouse diets in previous studies, miR-29b was rapidly degraded to concentrations below the detection limit.[4] Presumably, degradation was due to milk RNases gaining access to miRNAs released from exosomes. (3) When milk was fermented to produce yogurt, miRNA concentrations decreased to levels much lower than in milk (this study). We speculate that the decrease was due to the lysis of exosomes during fermentation and the large amounts of RNases produced by microbes. (4) When milk was homogenized, miRNA concentrations decreased by on average 50% (this study). We speculate that the decrease was caused by a disruption of exosome mebranes by shear forces applied during homogenization. Collectively, our studies suggest that milk and perhaps dairy products have the potential to contribute to the miRNA body pool in humans.

Some uncertainties remain to be addressed in future studies. For example, this study was modeled on the basis of miR-29b and miR-200c; however, there is a possibility that distinct miRNAs may be differentially metabolized.[8,36] Another layer of uncertainty is the possible effects of feeding regimens, season, and breed on the miRNA content in milk. Moreover, while this study suggests that somatic cells in milk from healthy cows do not contribute meaningful amounts to the total miRNA content in milk, it is possible that the increased somatic cell count in milk from cows suffering from mastitis[37] may cause an artificial increase in milk miRNA concentrations. Our previous studies suggest that plasma miRNA concentrations decrease by 61% in mice fed a milk miRNA-depleted diet for 4 weeks. This observation is consistent with milk miRNAs contributing meaningful quantities to the miRNA body pool but does not necessarily establish the essentiality of dietary miRNA intake. Clearly, this is an uncertainty that will need to be addressed in future studies. Finally, it is conceivable that miRNAs from foods

DOI: 10.1021/jf505526w
J. Agric. Food Chem. 2015, 63, 588−592

other than milk also contribute toward the total body pool of miRNAs.

There is precedent for degradation of milk compounds during processing. Examples include the thermal and non-thermal degradation of modified peptides[38] and DNA encapsulated in silica.[39] The immediate relevance of these previous publications for the stability of miRNAs in milk is uncertain.

Supporting Information

ABSTRACT: Alternative sources of natural rubber are of importance due to economic, biological, and political threats that could diminish supplies of this resource. Prickly lettuce (*Lactuca serriola* L.) synthesizes long-chain natural rubber and was studied to determine underlying genetic and phenotypic characteristics of rubber biosynthesis. Genotypic and phenotypic analysis of an F2 segregating population using EST-SSR markers led to the discovery of genetic regions linked to natural rubber production. Interval mapping (IM) and multiple QTL mapping (MQM) identified several QTL in the mapping population that had significance based on LOD score thresholds. The discovered QTL and the corresponding local markers are genetic resources for understanding rubber biosynthesis in prickly lettuce and could be used in marker-assisted selection (MAS) breeding. Prickly lettuce is an excellent candidate for elucidating the rubber synthesis mechanism and has potential as a crop plant for rubber production.

KEYWORDS: *EST-SSR, Lactuca serriola L., polyisoprene, prickly lettuce, QTL, rubber*

INTRODUCTION

Natural rubber (*cis*-1,4-polyisoprene) is a plant-derived bioproduct that has strategic importance due the number of products that utilize the polymer. Commercial quantities of natural rubber are supplied by the Brazilian rubber tree [*Hevea brasiliensis* (Willd. ex A. Juss.) Müll. Arg.], a native of the Amazon basin. Yearly rubber harvest has steadily increased since rubber was first commercialized. In 2011, worldwide natural rubber production reached 11,031,000 tonnes with consumption closely following at 10,981,000 tonnes.[1] Alternative sources of natural rubber are being investigated for their utilization in rubber production to alleviate the threat of supply shortages.[2,3] Prickly lettuce (*Lactuca serriola* L.) is one of the few rubber-bearing plant species able to produce high M_w rubber,[4] yet, to date, no research has been conducted to identify genetic influences of rubber biosynthesis or molecular markers linked to rubber trait development.

Prickly lettuce is closely related to, and most likely the progenitor of, cultivated lettuce (*Lactuca sativa* L.). It is believed the two species are conspecific[5] and are easily crossed to produce viable offspring. Cultivated lettuce is grown throughout the world and consumed for its nutritious foliage.[6,7] Cultivated lettuce has nine chromosomes and a genome size of approximately 2600 Mb. Prickly lettuce also has nine chromosomes and presumably a similar genome size. The Compositae Genome Project Database (CGPDB[8]) is the most comprehensive genetic resource for study of the Compositae family including cultivated and four closely related lettuce species, *L. serriola* L., *L. saligna* L., *L. virosa* L., and *L. perennis* L., ordered in proposed phylogenetic relatedness to cultivated lettuce. The genetic and genomic architecture of cultivated lettuce and its relatives has been well documented and includes a large inventory of molecular markers. Variable marker types include RFLPs,[9,10] RAPDs,[11] ISSRs,[12] genomic/EST-SSRs,[13−15] AFLPs,[5,16,17] TRAPs,[18] SNPs,[19] and SFPs.[20] The developed molecular markers have been effectively utilized for linkage mapping,[21] gene-tagging, QTL mapping,[16] and genetic diversity studies.[13,22] Although cultivated lettuce is the main research focus, many of the molecular markers are transferable and have been used between lettuce species. Most recently, the lettuce genome has been released[23] and will become a valuable asset in lettuce research as well as close lettuce relatives through sytenic genetic comparisons.

Prickly lettuce is important in lettuce breeding as donors of disease resistance genes[24−29] insect resistance,[30−32] and trait development such as carotenoid content,[33] bolting time,[34] and water use efficiency.[35] On the basis of the gene-pool concept,[36] *Lactuca* species were categorized into three gene pools based on their relationship to cultivated lettuce.[37] The primary gene pool is represented by numerous cultivars of cultivated lettuce, primitive landraces, and wild species where crossing barriers do not exist. Prickly lettuce is the primary representative as the progenitor species of this gene pool[38] and will be the greatest beneficiary of cultivated lettuce genetic advancements.

Prickly lettuce is a potential new crop plant for rubber production. Development of this species will require molecular tools that assist in breeding efforts for desired traits. Of equal scientific importance are the general mechanisms controlling rubber biosynthesis in all rubber-bearing plants. There are few studies that attempt to find genetic associations to rubber traits and no studies in prickly lettuce. The purposes of these studies were (1) to understand the genetic control of rubber traits in prickly lettuce and (2) to identify molecular markers or QTL

that would lead to a better understanding of the genes involved in rubber biosynthesis and allow for selection of prickly lettuce biotypes that have increased rubber-making potential.

MATERIALS AND METHODS

Plant Material and Population Development. In 2006, 20 eastern Washington prickly lettuce biotypes were collected and later screened for rubber content and quality. Preliminary screening of the collected biotypes for herbicide resistance and latex rubber revealed two with distinct rubber content and quality traits as well as contrasting visual phenotypes (Figure 1). Parent 6-9/13 (P1) had lobed leaves, was resistant to acetolactate synthase (ALS) targeting herbicides, was early to bolt, had average rubber M_w of 2.5×10^6 g mol^{-1}, and contained 4.9% rubber in the latex on average. Parent 4-10/6 (P2) had nonlobed oblanceolate leaves, no herbicide resistance, was late to bolt, an average rubber M_w of 1.1×10^6 g mol^{-1}, and contained an average of 2.2% rubber in the latex. Parental plants were grown in a greenhouse from seed in 16 cm round plastic pots into potting media (LC1Mix. Sun Gro Horticulture Distribution Inc., Bellevue, WA, USA) with temperatures kept at 26 °C daytime and 22 °C nighttime (±3 °C). Natural light was supplemented with sodium vapor lighting to give a 14 h photoperiod that coincided with the daytime portion of the temperature profile. Plants were subirrigated as needed. At anthesis, flowers were crossed using the clip-and-wash method.[39] Reciprocal crosses were made and F1 seeds collected. F1 seeds were planted and evaluated for potential self-pollination using the differential parental phenotypic traits of bolting time and leaf lobing, semidominant and dominant traits, respectively. Successfully crossed F1 plants had an intermediate bolting time between parental phenotypes and inherited leaf lobing traits (lobed in 4-10/6 × 6/9-13 crosses) that allowed for selection of nonselfed individuals. Cross efficiency was 81% with 13 of 16 successful crosses. One F1 plant with cross 6-9/13 female × 4-10/6 male was selected for creation of an F2 segregating population by collecting seed from the selfed F1 plant.

Figure 1. Leaf morphologies of the parents selected for generation of F2 segregating population.

Phenotypic Evaluation. In total, 250 F2 individuals were grown in a greenhouse from seed for 4 weeks prior to planting at Washington State University's Cook Agronomy Farm near Pullman, WA (GPS coordinates 46° 47′ 1.0854″, −117° 5′ 28.755″). Plants were started May 7, 2010, in a greenhouse under the same conditions as the parental and F1 plants but were planted in smaller 100 cm^2 square plastic pots. Plants were transplanted to the field June 7, 2010, at 2 m row spacing with 1 m distance between each plant. Two plants died, leaving a total of 248 individuals in the population. Throughout the growing season phenotypic data were collected from four main categories including latex extract components, rubber qualities, leaf measurements, and growth patterns. Flowering time phenotype was confounded by deer herbivory; however, deer appeared to graze preferentially on certain individuals within the population. Plants were scored with either herbivory or no herbivory. Lobing was scored as either lobed or not lobed. Leaf area and leaf perimeter values were calculated by scanning four fully expanded leaves on a flatbed scanner and using the ImageJ[40] convert to mask and wand tool functions to outline each leaf. Stem number was determined by counting the number of stems on each plant at 90 days after planting. Growth habit was scored on a scale of 1−5, where 1 represented the 6-9/13 parental phenotype, which consists of early bolting and multiple lateral shoots, and 5 represented the 4-10/6 parental phenotype that had a late bolt timing and few lateral shoots.

Latex from each individual was collected from the bolting stem for latex component and biochemical analysis. The percent of water, resin, rubber, and insoluble material from each plant was determined gravimetrically (% wt/wt). Latex was collected by making multiple diagonal incisions with a razor and catching the drips of latex into a tared microcentrifuge tube. Tubes were capped and reweighed to obtain weight of initial latex collection. Latex was then dried for 48 h under vacuum at 35 °C to remove all water. Tubes were reweighed to acquire total contained water. Dried samples were extracted three times with acetone by addition of 1 mL of acetone, vortexing, centrifugation for 5 min at 6822*g*, and collection of supernatant into a clean, tared vial. Acetone was dried under a stream of air, and vials were reweighed to determine resin content. Following acetone extraction, samples were extracted with hexane to dissolve rubber. One milliliter of hexane was added to each tube followed by vortexing and hand stirring with a spatula to dislodge the rubber pellet as needed. Samples were centrifuged, and supernatant was collected into a clean, tared vial. Latex was extracted three times with hexane, the third hexane addition being allowed to sit for 8−10 h before supernatant collection. Hexane was dried under air, and vials were weighed for total contained rubber. Original collection tubes

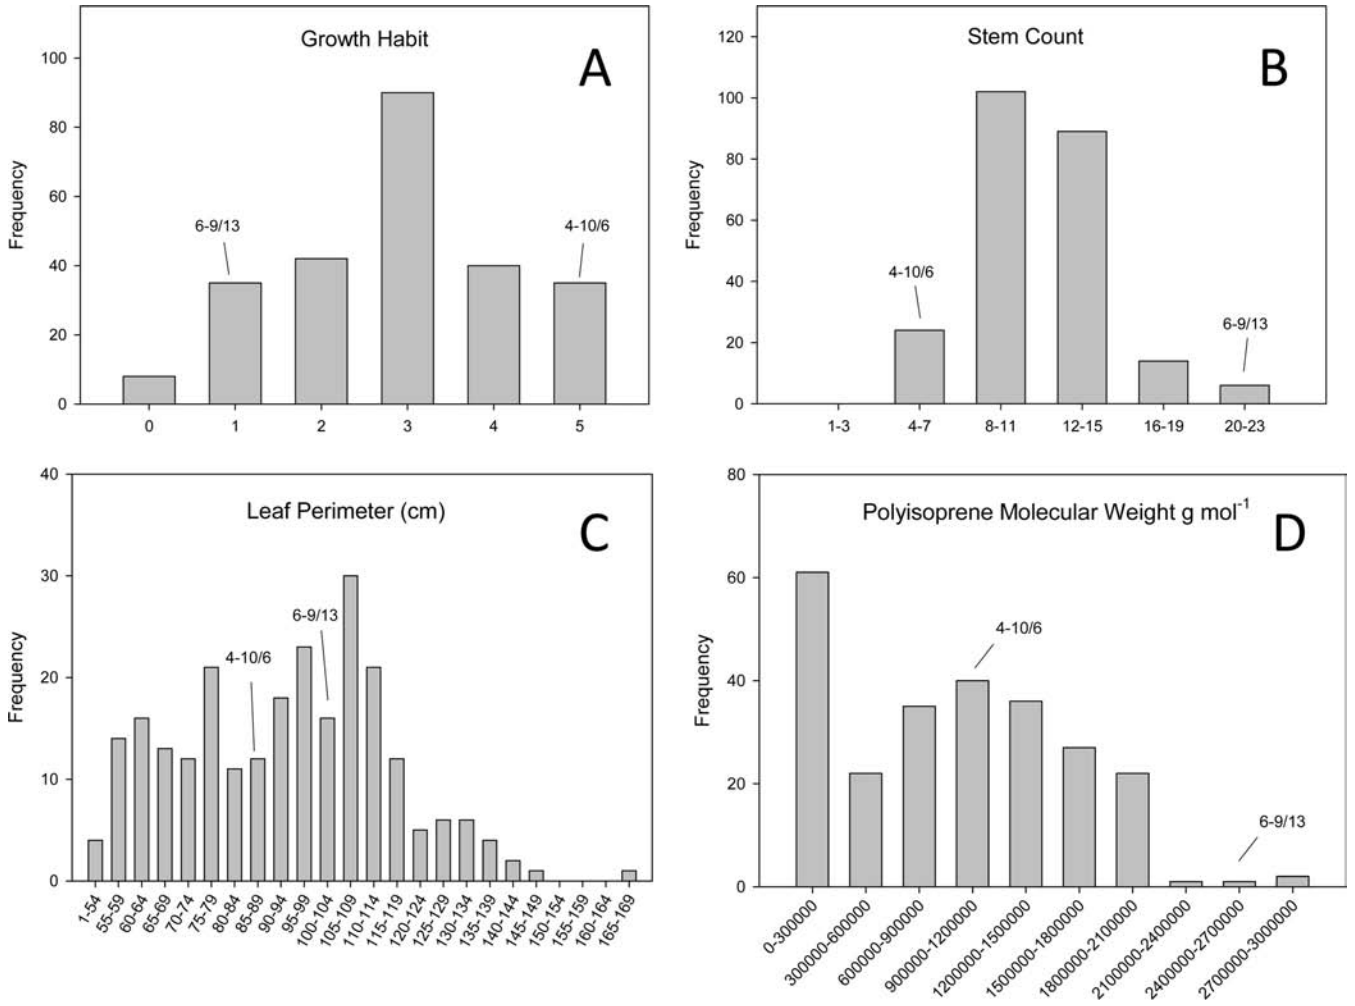

Figure 3. Distribution of selected traits growth habit (A), stem count (B), leaf perimeter (C), and polyisoprene weight (D) showing QTL on groups 4 and 8 from an F2 population derived from a cross of eastern Washington prickly lettuce biotypes 6-9/13 × 4-10/6.

containing insoluble latex material were dried and weighed to find the percentage of insoluble material.

The rubber fraction was further analyzed by high-performance liquid chromatography gel permeation/size exclusion chromatography (HPLC GPC/SEC), with refractive index (RI) detection to evaluate rubber (polyisoprene) polymer chain length (Figure 2). Dried rubber fractions were re-eluted in tetrahydrofuran (THF) to a concentration of approximately 5 mg mL^{-1}. Rubber was allowed to dissolve at room temperature overnight. A 100 μL portion of the dissolved rubber solution was removed from the top, without disturbing any nondissolved material at the bottom of the vial, and transferred to an HPLC vial with a 250 μL glass insert. An autosampler injected 40 μL of the dissolved rubber solution. Samples were analyzed with an Agilent 1100 series HPLC equipped with an Agilent G1362A refractive index detector. Polyisoprene polymers were separated with a Phenogel linear/mixed guard column (10 μM 7.5 × 50 mm), and a PLgel Mixed-B size exclusion column (10 μM 7.5 × 300 mm) using THF as mobile phase. Run time was 17 min with a flow rate of 1 mL min^{-1}. Column and detector were maintained at 40 °C. Molecular weights were extrapolated using polystyrene standards from Varian (EasiVial) to create a semilogarithmic standard curve (Figure 2C). A single standard of 1,4-polyisoprene (M_w 999,000 g mol^{-1}) (Polymer Standards Service) was added to the standard curve as a check against the polystyrene polymers. Agilent GPC software was used together with standards to generate a standard curve and estimate average molecular weight (M_n), weight-average molecular weight (M_w), and polymer dispersity ($Đ$). The values for polyisoprene characterization were determined by selecting the earliest eluting peak (longest polymer). Low $Đ$, a beneficial trait, is independent of polymer M_w but rather reflects the $Đ$ of the selected peak. In this study, the earliest eluting peak may have low M_w and low $Đ$.

Phenotypic values for the entire population were plotted versus frequency to generate histograms (Figures 3 and 4). Analysis of phenotypic frequencies over the population determined if traits were single-gene controlled having expected ratios of 3:1, 1:2:1, or multigenic (quantitative) with a normal distribution. Suspect single-gene traits were examined by chi-square analysis (X^2) and quantitative traits analyzed for QTL (Tables 1 and 2).

Prickly Lettuce Genetic Map. DNA from each individual in the F2 population and parents was extracted from young leaves that were frozen (−80 °C) and freeze-dried. Extraction was performed on approximately 30 mg of dried tissue using a Biosprint 96 DNA Extractor following manufacturer protocols. DNA concentrations were measured with a Nanodrop 2000 spectrophotometer and normalized to 50 ng μL^{-1}. A total of 400 EST-SSR derived primers that were previously mined from the CGPDB to analyze prickly lettuce genetic diversity were used for polymorphic screening.[13] An additional 61 EST-SSR primers developed by Simko[14] were added, giving a total of 461 EST-SSRs available to screen against the crossed parents. Polymorphism of the mined EST-SSRs was carried out using two genotyping platforms. The first employed 10% polyacrylamide gel electrophoresis (PAGE) denaturing gels with silver stain to visualize amplified fragments. Polymerase chain reactions (PCR) were carried out in 20 μL total volume mixtures each containing 100 ng of template DNA, 0.5 μM SSR primers, 250 μM dNTPs, 1.5 mM $MgCl_2$, 0.5× PCR buffer, and 1.0 U *Taq* DNA polymerase (MangoTaq, Bioline

USA Inc.). Reactions were carried out on a Techne TC-4000 thermocycler with the following PCR profile: initial denaturation at 95 °C for 3 min followed by 40 cycles at 95 °C for 30 s, 57 °C for 30 s, 72 °C for 25 s, and a final extension at 72 °C for 10 min.

Of the 461 primers 380 were further analyzed by a second genotyping platform utilizing an ABI 3730XL DNA analyzer (Applied Biosystems, Foster City, CA, USA). PCR amplifications were carried out in 12 μL reaction mixtures each containing 15 ng of template DNA, and three PCR primers [M13F primer (5′-CACGACGTT-GTAAAACGAC-3′) labeled with one of four fluorescent dyes (6-FAM, PET, VIC, or NED; Applied Biosystems), long forward primer with M13F-tail at its 5′ end and a reverse primer]. Primer concentrations were 0.25 μM reverse primer, 0.20 μM M13F, and 0.05 μM of the long, M13 tagged, forward primer. Other components

included 200 μM dNTPs, 1.0 mM $MgCl_2$, 1.0× PCR buffer, and 1.0 U of *Taq* DNA polymerase. PCR amplifications were done on a Bio-Rad C1000 or S1000 thermocycler using the following conditions: initial denaturation at 95 °C for 3 min followed by 42 cycles at 95 °C for 40 s, 57 °C for 60 s, 72 °C for 60 s, and a final extension at 72 °C for 10 min.

Segregation Analysis/Linkage Maps. Initially, 89 polymorphic EST-SSR markers were selected and used to create a genetic linkage map (Supporting Information, Supplementary Table 1). Of the 248 individuals in the F2 population, 186 were analyzed to facilitate 96 and 384 well formats. Fragment analysis of markers in the F2 population was carried out using an Applied Biosystems 3730XL DNA analyzer and GENE MARKER software version 1.5.[41] PCR conditions were the same as described for the parental screen in the second genotyping platform. Fragments were scored as either parent 1 (a), parent 2 (b), or heterozygous (h). Scored data were analyzed by JoinMap 4.0[42] using maximum likelihood algorithm with all other parameters set to default. The Haldane mapping function was used to calculate genetic distances. Maps were verified using Mapmaker 3.0b[43] at a LOD score of 3.0. The traits of leaf lobing and herbivory were scored bimodally as presence or absence phenotypes and analyzed by chi square (Table 1).

Polymorphism. Marker polymorphism was determined as the difference in nucleotide base pairs between parents as established by the ABI 3730XL DNA analyzer (Supporting Information, Supplementary Table 1). Fragment sizes were estimated by comparison to a size standard added to each well and tagged with fluorescent dye LIZ.

Trait Genetic Markers/QTL Analysis. F2 genotypic and phenotypic data were analyzed using MapQTL 6.0[44] to assist in identifying marker−trait correlations. Analysis was done using both interval mapping (IM) to allow for possible correlations with the unmapped markers and multiple-QTL model (MQM). Default parameters for IM were used and included algorithm, regression; test statistic, LOD; fit dominance for F2, yes; mapping step size, 1.0; neighboring markers, 5; number of iterations, 200; functional tolerance, 1.0×10^{-8}; and permutation, 1000. MQM model had the same default parameters. Chromosomes with associated QTL were made using MapChart 2.2[45] (Figure 5).

To determine the LOD score significance thresholds, a permutation test of 10000 iterations (p = 0.05) was performed over each chromosome.[46] QTL were considered significant if the output over the chromosome for the trait of interest exceeded the minimum threshold.

RESULTS AND DISCUSSION

Phenotypic Assessment. Phenotypes in the F2 population were quantitative in that they did not follow Mendelian segregation ratios with the exceptions of leaf lobing and low M_w. These traits segregated at a ratio of 3:1 (X^2 = 0 df 1) and (X^2 = 2.6 df 1), respectively (Table 1). Leaf lobing observed in this experiment is consistent with previous reports for inheritance of the trait, where lobing was reported as dominant to nonlobed leaves and controlled by a single gene.[47,48] The plant growth phenotypes growth habit and stem count had normal distributions with the majority of phenotypes intermediate between parents (Figure 3A,B). Leaf perimeter also had a less defined normal distribution pattern (Figure 3C). Leaf area in the F2 population had a normal distribution with the median closer to that of parent 6-9/13 and very few individuals sharing a large leaf area phenotype similar to that of 4-10/6 (Figure 4A). Rubber Đ values over the population were normally distributed (Figure 4B) and appear skewed to higher Đ; however, values cannot fall below the optimal Đ of one.

Normal distributions were observed for all latex components including the amount of rubber, resin, insoluble material, and water contained in the latex (Figure 4C−F). The M_w of the rubber from the F2 population was normally distributed; however, there was an enrichment of individuals with low M_w

Table 2. QTL and Associated Markers Found in an F2 Population Derived from a Cross of the Eastern Washington Prickly Lettuce Biotypes 6-9/13 × 4-10/6

J. Agric. Food Chem. 2015, 63, 593−602

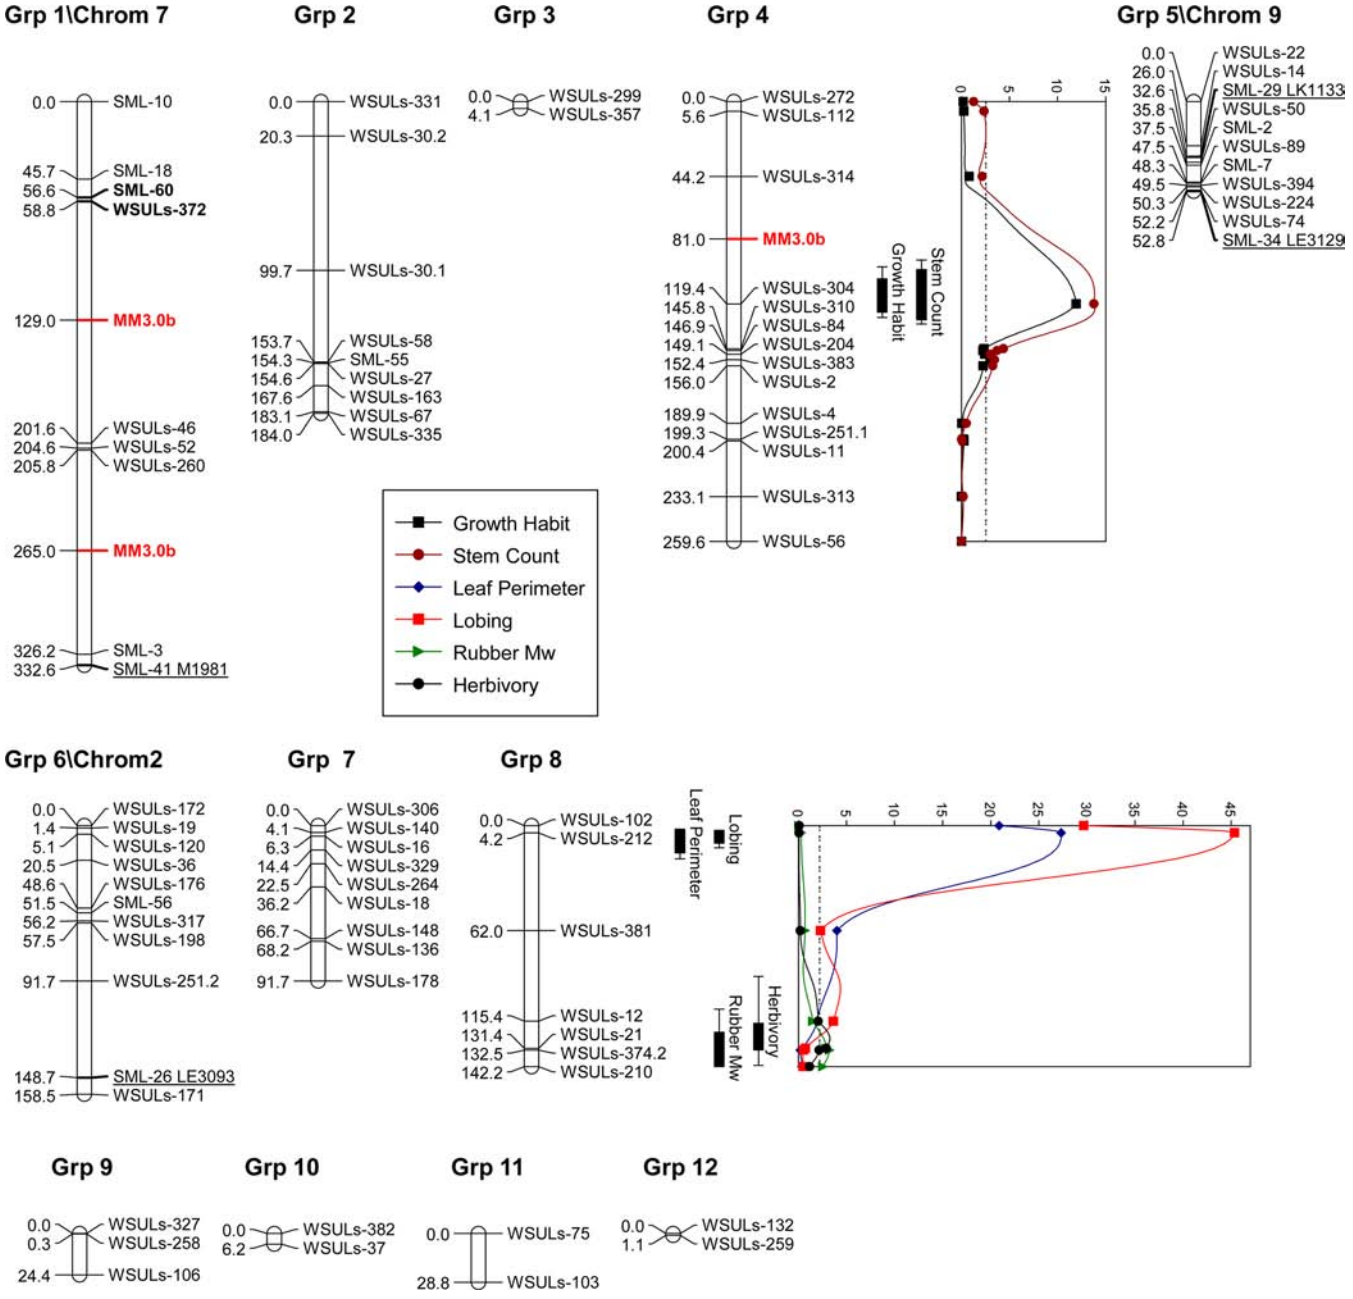

Figure 5. Linkage groups and QTL from eastern Washington prickly lettuce biotype cross (6-9/13 × 4-10/6). Group designations were derived from JoinMap 4.0 software. Bold, red markers with designation MM3.0b are further separation of linkage groups determined by MapMaker 3.0b. Chromosome designations were assigned on the basis of mapped EST markers found in CGPDB and are underlined. The bold markers SML-60 and WSULs-372 were derived from the same EST contig but found in independent SSR mining experiments. Significant QTLs are shown next to linkage groups as black bars with 1 and 2 LOD QTL intervals and corresponding QTL LOD graph.

rubber (Figures 2B and 3D). The reason for the elevated number of extremely low M_w phenotypes is unclear. Rubber from these individuals may have degraded at some point during collection, storage, or extraction. Alternatively, the individuals with low M_w rubber may have underlying genetic influences affecting polymer stability or determinant polymer length. Just under 25% of the F2 population had inferior, low M_w rubber (<100000 g mol^{-1}), suggesting the low M_w phenotype may be a single-gene trait (Table 1). Repeated studies from a recombinant inbred line (RIL) derived from the cross made for this study will assist in determining whether the low M_w phenotype is an artifact of sampling or a defined genetic trait.

Linkage Maps. Of the original 89 markers, 3 were not linked to any linkage group and 5 dominant markers did not map, leaving 81 mapped markers in 12 linkage groups (Figure 5). The chromosome number for lettuce and prickly lettuce is 9.[49] Discrepancies in chromosome number are most likely due to the low number of markers used in this study. A few of the markers previously mapped in the CGPDB and were used as anchors for assigning chromosome names for the associated linkage group. On the basis of maps generated in the CGPDB, some of the linkage groups made by JoinMap 4.0 in this study had distances longer or shorter than would be expected (Figure 5). For example, group 1 is anchored by SML-41 and corresponds to chromosome 7 in CGPDB, MAP 2 JMR2.

DOI: 10.1021/jf503934v
J. Agric. Food Chem. 2015, 63, 593−602

Chromosome 7 is 126.8 cM in length compared to 332.6 cM in this study. Group 5 is anchored by markers SML-29 and SML-34, both on chromosome 9 of MAP 2 JMR2. Chromosome 9 is 102.9 cM compared to our 52.8 cM distance. Group 6 is anchored by SML-26 to chromosome 2, which is 162.1 cM in MAP 2 JMR2, a much closer distance to 158.5 cM of this study; however, SML-26 is placed near the middle of MAP 2 JMR2 at 72.0 cM, whereas in our map SML-26 is nearer the end at 148.7 cM.

MapMaker 3.0b was used to verify grouping made by JoinMap. Mapmaker was more stringent in grouping of markers and further divided some of the linkage groups generated in JoinMap. The distinction is noted by bold, red markers designated as MM3.0b placed half the distance between the flanking mapped markers in the chromosome groupings. In general, JoinMap 4.0 and MapMaker 3.0b grouped markers similarly, lending confidence to the map structure.

Rubber Trait QTL. Of particular interest in this study are the markers and QTL linked to rubber traits. One QTL and one unmapped marker had significant correlations to rubber traits M_w and polymer Đ. Rubber M_w had a QTL associated with group 8 near markers WSULs-374.2 and WSULs-21. The rubber M_w QTL peaks near marker WSULs-374.2, at LOD 3.24, and accounted for 7.7% of the phenotypic variation in the population (Figure 5; Table 2).

Dispersity is a measure of polymer homogeny as measured by weight-average molecular weight divided by the number-average molecular weight (M_w/M_n) (Stepto 2009). An optimal ratio of 1.0 signifies uniform polymers. Dispersity is a beneficial trait if the rubber also has high M_w. The marker WSULs-374.1 had significant linkage to Đ with a peak LOD value of 4.79 and explained 11.2% of the phenotypic variation (Table 2) as determined by IM. It is important to note that the Đ and M_w values were based on the earliest eluting peak by HPLC-SEC/GPC and are therefore not necessarily correlated to one another. Low Đ does not mean high M_w. Review of the Đ and M_w values reveals that the majority of individuals with low Đ were more closely related to the low M_w individuals in the population. Interpretation of the marker is counterintuitive and suggests that the higher Đ values are representative of a beneficial trait. Although high Đ is less desirable, nearly all of the Đ values in the population from the earliest eluting peak would be considered acceptable for production purposes.[50]

The WSULs-374 markers are derived from the same primer yet generated distinct PCR products that segregated sufficiently to separate the two at a LOD threshold of 3.0. At LOD 2.0 WSULs-374.1 and WSULs-374.2 are grouped together; however, at this threshold they are separated by 122.1 cM. Both the rubber M_w QTL and Đ marker are derived from 6-9/13 alleles. This single marker could be used for selection and integration of prickly lettuce with acceptable Đ and high M_w rubber, the two most important traits in determining rubber end-use potential.[51]

Other Beneficial Traits. Cultivated lettuce cultivars have been developed to meet consumer and producer needs. Most have a delayed bolt time and, if allowed to bolt, have only a single stem. Cultivated lettuce produces copious leaf tissue and little latex during vegetative growth.[52] Many of these traits are in stark contrast to those desired in a rubber-producing cultivar. Anecdotal evidence suggests latex production increases with bolt initiation.[4] In this regard, early bolting with multiple stems would both be beneficial traits for rubber lettuce production. A strong growth habit and stem count QTL was identified in our study on group 4 that is highly correlated to marker WSULs-304 (Figure 5). The QTL significance continues at a lower level over a group of adjacent markers WSULs-310, WSULs-84, WSULs-204, WSULs-383, and WSULs-2 with the highest significance at marker WSULs-383 in this group. The growth habit phenotype was characterized by early bolt time with multiple lateral shoots. The growth habit QTL peaked at LOD 11.94 near marker WSULs-304 and LOD 2.98 near WSULs-383 and respectively explained 25.6 and 7.1% of the population phenotypic variation (Figure 5; Table 2).

As expected, stem count is strongly related to growth habit as a numerical reflection of the growth habit phenotype. The stem count QTL also peaked at markers near WSULs-304 and WSULs-383 with respective LOD values 13.84 and 3.43 and phenotypic variances 29.0 and 8.1% (Figure 5; Table 2). Growth habit associated markers will assist in selection of rubber lettuce cultivars that bolt early and have many stems. These traits may also facilitate multiple harvests over the season, increasing rubber yields. Alternative to harvesting fast-bolting multistem plants, crisphead lettuce cultivars possessing high latex and rubber content yet remain as compact heads would be ideal for current lettuce cultivation and harvest practices. Many of the head lettuce cultivars have high biomass (700−1000 g head^{-1}), disease resistance, and reduced chlorophyll content.[52] The crisphead lettuce cv. 'Salinas', released in 1975, is the most widely grown lettuce cultivar in the history of lettuce production.[52] Introgression of alleles that confer high rubber content and M_w in nonbolting head lettuce such as 'Salinas' lettuce leaf tissue would be well suited for current cultivation practices. The identified markers and QTL are useful tools for MAS and introgression of those traits into new rubber lettuce varieties. Further selection of prickly lettuce weedy traits, such as water use efficiency, would allow rubber lettuce to be grown on marginal lands, decreasing competition with existing lettuce production areas and other food crops.

In this study additional interesting marker−phenotype associations, not necessarily related to rubber lettuce development, have been identified. Leaf perimeter, a numerical expression of leaf lobing, and herbivory both had significant QTL on group 8 (Figure 5). As previously noted, lettuce leaf lobing has been identified as a dominant, single-gene trait.[47,48] Leaf perimeter QTL is associated with markers WSULs-102 and WSULs-212, which had respective peak LOD values of 20.87 and 27.32 and explained 40.3 and 49.2% of the phenotypic variation for the population (Figure 5; Table 2). The histogram for leaf perimeter is not normal and may be more indicative of epistatic interactions. The QTL for the lobing phenotype was stronger than the perimeter trait with peak LOD values of 29.7 and 45.4 at respective markers WSULs-102 and WSULs-212. Population phenotypic variance for the lobing trait was 52.0% near marker WSULs-102 and 67.5% at WSULs-212. Leaf lobing is an important horticultural trait in cultivated lettuce.[53] On an evolutionary level, lobed leaves may impart greater hydraulic efficiency and heat dissipative properties.[54,55] There are no reports of a leaf lobing gene in lettuce; however, a single large effect QTL has been identified on chromosome 3 through analysis of the core F7:8 RIL mapping population derived from a cross between *L. sativa* cv. 'Salinas' and *L. serriola* accession UC96US23.[53] The QTL found in this study is most likely the same found by Michelmore placing group 8 markers on chromosome 3 of the lettuce map.

DOI: 10.1021/jf503934v
J. Agric. Food Chem. 2015, 63, 593−602

On the basis of sequence similarity, the EST related to marker WSULs-102 resembles the *Arabidopsis thaliana* cyclin family protein AT5G67260 (CYCD3;2) (Supporting Information, Supplementary Table 1). In general, cyclin proteins act as transcription factors activating cyclin-dependent kinases during the cell cycle, in turn regulating key transitions during mitosis.[56] In *Arabidopsis*, CYCD3;2 is expressed in the shoot apical meristem and persists in young leaves. CYCD3;2 functions by determining cell number in developing lateral organs and mediating the effects of cytokinin on apical growth and development.[57] Leaf morphogenesis in tomato was dependent on cytokinin levels, and overexpression of a cytokinin biosynthesis gene IPK7 caused increased expression of CYCD3.[58]

The EST for WSULs-212 has similarity to AT4G14960 tubulin α-6 chain (TUA6) (Supporting Information, Supplementary Table 1). TUA6 encodes an isoform of tubulin necessary for right-handed helical growth.[59] It is interesting to find that both EST-SSRs markers associated with the leaf perimeter and lobing QTLs are involved in plant organ morphogenesis. Further study of these genes in lettuce would determine if either of the genes is the causal agent for leaf lobing in lettuce. Overexpression of the genes in a nonlobed lettuce background could help identify these candidate genes as the leaf lobing gene in lettuce.

A prickly lettuce herbivory QTL was found on group 8 and peaked at LOD 3.25 near marker WSULs-374.2. The population phenotypic variance for the QTL was 7.7% (Figure 5; Table 2). The phenotype was observed as preferential feeding of bolted stems in the F2 population by white tail deer (*Odocoileus virginianus* Zimmermann.). Evidence suggests latex is a beneficial adaptation to deter herbivory.[60,61] One example in lettuce was found where latex from an insect-resistant cultivar, 'Valmaine', prevented *Diabrotica balteata* (LeConte.) beetles from feeding on latex-painted lima bean leaves; however, feeding was not inhibited when latex from the susceptible cultivar 'Tall Guzmaine' was applied.[62] A follow-up study showed that differential compounds in the semipolar latex extract contained the inhibitory element(s).[63] Prickly lettuce contains an abundance of the sesquiterpine lactones lactucin and lactucopicrin.[64] Increase in the levels of these compounds was correlated to perceived bitterness by sensory analysis.[65] The compounds also have sedative and analgesic affects.[66] Chemical analysis of the resin extracts containing the sesquiterpines compared with plant feeding patterns will help determine if these compounds act as a deer herbivory deterrents or stimulants.

In summary, a set of polymorphic EST-SSRs have been used to generate a linkage map from a cross between two distinct eastern Washington prickly lettuce biotypes. Analysis of the map with phenotypic data has led to the discovery of QTL and markers useful in the development of rubber lettuce cultivars. The identified QTL and corresponding local markers could be used in a MAS breeding scheme to find individuals with high M_w rubber and multibolting traits or introgression of rubber-producing traits into current lettuce cultivars. Importantly, the QTL will allow further investigation of the genes that control these traits now that linked chromosomal regions have been identified. Additional QTL and markers related to lettuce leaf morphology and herbivory could be used in lettuce breeding for horticultural traits and understanding leaf ontogeny or lend evidence to latex herbivory relationships.

ABSTRACT: The structure of the lignin from brewer's spent grain (BSG) has been studied in detail. Three different lignin preparations, the so-called "milled-wood" lignin (MWL), dioxane lignin (DL), and cellulolytic lignin (CEL), were isolated from BSG and then thoroughly characterized by pyrolysis GC/MS, 2D-NMR, and derivatization followed by reductive cleavage (DFRC). The data indicated that BSG lignin presents a predominance of guaiacyl units (syringyl/guaiacyl ratio of 0.4−0.5) with significant amounts of associated *p*-coumarates and ferulates. The flavone tricin was also present in the lignin from BSG, as also occurred in other grasses. 2D-NMR (HSQC) revealed that the main substructures present are *β*-*O*-4′ alkyl-aryl ethers (77−79%) followed by *β*-5′ phenylcoumarans (11−13%) and lower amounts of *β*-*β*′ resinols (5−6%) and 5-5′ dibenzodioxocins (3−5%). The results from 2D-NMR (HMBC) and DFRC indicated that *p*-coumarates are acylating the *γ*-carbon of lignin side chains and are mostly involved in condensed structures. DFRC analyses also indicated a minor degree of *γ*-acylation with acetate groups, which takes place preferentially on S lignin (6% of S units are acetylated) over G lignin (only 1% of G units are acetylated).

KEYWORDS: *brewer's spent grain, lignin, Py-GC/MS, TMAH, HSQC, DFRC*

INTRODUCTION

Brewer's spent grain (BSG) is the solid waste generated during the brewing process and comprises the husk−pericarp−seed coat layers that covered the starting barley (*Hordeum vulgare* L.) grain.[1−4] BSG accounts for around 30% (w/w) of the barley grain, making it a readily available high-volume and low-cost byproduct within the brewing industry that can be regarded as a potentially valuable resource for the production of new added-value products.[1,2] Although BSG is produced in important amounts from brewing companies worldwide, with an estimated production of around 30 million tons per year,[5] the major part of these residues remains mostly underexploited.

BSG is a lignocellulosic material that is primarily composed of cellulose (17−25%), hemicelluloses (25−35%), protein (15−24%), lignin (8−28%), and lower amounts of lipids (10%).[1−6] Due to the high amounts of proteins and fibers, BSG has been predominantly used as animal feed. However, there is a trend nowadays for the more efficient utilization of the lignocellulosic residues generated from agro-forest and alimentary industries as feedstocks to produce new value-added products in the context of the so-called lignocellulosic biorefinery. In this context, the development of new techniques and procedures for a more appropriate valorization and industrial exploitation of this agro-industrial waste is of major importance because BSG is widely available at low cost and in large amounts.

Recent studies regarding the valorization and potential uses of BSG indicate that it could be considered as an important feedstock for the production of new products such as xylitol, lactic acid, and hydroxycinnamic acids or used as a growth medium for microorganisms and enzyme production, for paper manufacturing, or even for energy production, including the production of second-generation bioethanol, among others.[1,2,7,8] However, for an appropriate valorization of BSG as a source of added-value products and to explore newer applications and maximizing the use of existing technologies, a comprehensive characterization of the different components of BSG is of high interest. Previous studies have reported the composition of carbohydrates, proteins, lipids, and *p*-hydroxycinnamic acids in BSG.[4−6,9−11] However, studies regarding the composition of the lignin polymer in BSG have been insufficient and mostly restricted to its interactions with gastrointestinal microbiota[12,13] or to its recovery from the black liquors after alkaline pulping.[7] It is known that the content and composition of the lignin polymer play a decisive role in digestibility and delignification reactions and, therefore, the structural characterization of the lignin from BSG is an important step in the development of suitable methods for lignin depolymerization approaches. Moreover, detailed knowledge of the lignin polymer in BSG will help in the development of lignin-based high-added-value products from this waste material.

The lignin polymer is a complex macromolecule synthesized mainly from three *p*-hydroxycinnamyl alcohols, namely, *p*-coumaryl, coniferyl, and sinapyl alcohols, differing in their degree of methoxylation. These monolignols give rise to the *p*-hydroxyphenyl (H), guaiacyl (G), and syringyl (S) units, respectively, producing a variety of structures and linkages within the lignin polymer.[14,15] Moreover, *p*-hydroxycinnamates

(*p*-coumarates and ferulates) also occur in the lignins from grasses, such as barley, with *p*-coumarates acylating the γ-OH of the lignin side chain and ferulates and diferulates acylating cell wall polysaccharides and participating in both polysaccharide−polysaccharide and lignin−polysaccharide cross-coupling reactions, in the latter case mainly forming ether linkages similar to those existing between lignin units.[16]

In this study, an in-depth and comprehensive characterization of the lignin polymer in BSG has been performed. Because there is no universal method for the isolation of native lignin and due to the difficulties of isolating a representative lignin preparation from a material such as BSG, different lignin isolation methods were used. For this purpose, different lignin preparations that can be seen as representative of the native lignin due to their relatively low structural modification, namely, "milled-wood" lignin (MWL), dioxane lignin (DL), and cellulolytic lignin (CEL), were isolated according to traditional lignin isolation procedures.[17−19] The isolated lignin preparations were subsequently analyzed by using different analytical techniques, such as pyrolysis GC/MS (Py-GC/MS), in the absence and in the presence of tetramethylammonium hydroxide (TMAH) as methylating agent; 2D-NMR; and derivatization followed by reductive cleavage (DFRC). As far as we know, this is the first time that the detailed study of the structure of BSG lignin has been reported. Knowledge of the composition and structure of BSG lignin will help in maximizing the industrial utilization of this important agro-industrial waste.

MATERIALS AND METHODS

Samples. The BSG sample used in this study was taken from Adnams brewery (Southwold, UK) and was kindly provided by Prof. Craig B. Faulds (INRA, Marseille, France). The sample was the residue resulting from wort prepared from malted barley for ale brewing. Further information about the composition of this particular sample has been previously published.[20] The BSG sample was lyophilized and milled using an IKA knife mill (Janke & Kunkel, Staufen, Germany). Fifty grams of sample was successively extracted with acetone in a Soxhlet apparatus for 16 h and with hot water (100 mL, 3 h at 100 °C). The Klason lignin content was determined as the residue after sulfuric acid hydrolysis of the pre-extracted material according to TAPPI method T222 om-8.[21] The Klason lignin content was then corrected for proteins, determined from the N content obtained by CHN elemental analysis in a CHNS-932 Elemental Analyzer (LECO Corp., St. Joseph, MI, USA) and using a 6.25 factor,[22] and ashes. The acid-soluble lignin content was estimated, after the insoluble lignin was filtered off, by UV spectroscopy at 205 nm wavelength using an extinction coefficient of 110 L/cm/g. Holocellulose was isolated from pre-extracted BSG by delignification during 4 h using the acid chlorite method.[23] The content of α-cellulose was determined by removing the hemicelluloses from the holocellulose by alkali extraction.[23] Finally, the ash content was determined gravimetrically after 6 h of heating at 575 °C. Three replicates were used for each sample.

Isolation of "Milled-Wood Lignin". The MWL was isolated from the BSG sample according to the classical protocol.[17] Around 40 g of extractives-free sample was ball-milled in a PM100 planetary ball mill (Restch, Haan, Germany) at 400 rpm for 36 h in an agate jar and using agate balls (20 × 20 mm). The total ball-milling time was 5 h, with 5 min breaks after every 5 min of milling. The ball-milled powder was subsequently extracted with dioxane/water, 9:1 (v/v), using 20 mL of solvent/g of milled sample for 12 h under agitation, the solution was centrifuged, and the supernatant was evaporated to dryness in a rotary evaporator at 40 °C. The residue obtained (raw MWL) was then redissolved into a solution of acetic acid/water, 9:1 (v/v) (25 mL of solvent/g of raw MWL). The lignin was then precipitated into cold water and separated by centrifugation, milled in an agate mortar, and subsequently dissolved in 1,2-dichloroethane/ethanol, 2:1 (v/v). The mixture was centrifuged to eliminate any insoluble material. The lignin in the supernatant was precipitated in diethyl ether and recovered by centrifugation. This residue was then suspended in diethyl ether overnight, centrifuged, and finally suspended in petroleum ether. The final purified MWL sample was washed with *n*-hexane, recovered by centrifugation, and dried under nitrogen. The final yield was around 10% of the original Klason lignin content.

Isolation of Dioxane Lignin. The isolation of the DL was performed by acidolysis by the dioxane method according to a previously published procedure,[18] with some minor modifications. Fourteen grams of dry extractives-free (by Soxhlet extraction during 16 h with acetone and subsequent extraction with water at 100 °C) ball-milled BSG sample was refluxed for 40 min (3 times) with 150 mL of 0.05 M HCl in dioxane/water, 82:18 (v/v), under nitrogen. The lignin was then filtered and washed with dioxane/water, 82:18 (v/v). The filtrate was evaporated in a rotary evaporator at 40 °C, and then the lignin was precipitated in water. The precipitated lignin was then centrifuged and freeze-dried. After freeze-drying, the lignins were Soxhlet extracted with hexane for 8 h to remove lipid contaminants. The yield of DL was around 50% (based on the Klason lignin content).

Isolation of Cellulolytic Lignin. CEL preparations were isolated by enzymatically hydrolyzing the polysaccharides according to the protocol previously described.[19] For this purpose, we used Cellulysin (Calbiochem-Behring Corp., La Jolla, CA, USA), a crude cellulase preparation from *Trichoderma viride* that also contains hemicellulase activities. Its activity was ≥10000 units/g, estimated as reducing sugars (glucose equivalents) released from a paper filter at 40 °C, pH 4. The extractives-free ball-milled material (200 mg) was suspended in 20 mM NaOAc buffer (30 mL, pH 5.0) in a 50 mL centrifuge tube, 8 mg of Cellulysin was added, and the reaction slurry was incubated at 30 °C for 48 h. The solids were recovered by centrifugation (8000 rpm, 4 °C, 20 min), and the process was repeated twice with fresh buffer and enzyme. The lignin was finally recovered by filtration, washed with water, and then lyophilized. The yield of CEL was around 105% of the Klason lignin, indicating the presence of some contaminants in this lignin preparation.

Analytical Pyrolysis. The pyrolysis of the different lignin preparations (ca. 0.1 mg) was carried out in a 3030 microfurnace pyrolyzer (Frontier Laboratories Ltd., Fukushima, Japan) connected to a GC 7820A (Agilent Technologies, Inc., Santa Clara, CA, USA) and an Agilent 5975 mass selective detector (EI at 70 eV). The column used was a 60 m × 0.25 mm i.d., 0.25 μm film thickness, DB-1701 (J&W Scientific, Folsom, CA, USA). The pyrolysis was performed at 500 °C. The oven temperature was programmed from 45 °C (4 min) to 280 °C at a heating rate of 4 °C/min and held for 10 min. The carrier gas was helium at 2 mL/min. For Py/TMAH, around 0.1 mg of sample was mixed with 0.5 μL of TMAH (25%, w/w, in methanol), and the pyrolysis was performed as described above. The released phenolic compounds were identified by comparison of their mass spectra with those present in the Wiley and NIST libraries and those reported in the literature[24,25] and, when possible, by comparison with retention time and mass spectra of authentic standards. Peak molar areas for each lignin-derived phenolic compound were calculated, the summed areas were normalized, and the data for two repetitive analyses were averaged and expressed as percentages. The relative standard deviation was <5%. The response factors for most of the lignin-derived phenols released were practically identical, except for vanillin,[26] which is a minor peak here. Therefore, no attempt was made to calculate the response factor for every compound released.

NMR Spectroscopy. 2D-NMR spectra of the isolated lignin preparations were recorded at 25 °C on an AVANCE III 500 MHz instrument (Bruker, Karlsruhe, Germany) equipped with a cryogenically cooled 5 mm TCI gradient probe with inverse geometry. The lignin preparations (40 mg) were dissolved in 0.75 mL of dimethyl sulfoxide (DMSO)-d_6. The central solvent peak was used as the internal reference (DMSO, δ_C/δ_H 39.5/2.49). The heteronuclear single-quantum coherence (HSQC) experiment used Bruker's

DOI: 10.1021/jf505808c
J. Agric. Food Chem. 2015, 63, 603−613

"hsqcetgpsisp2.2" adiabatic pulse program with spectral widths from 0 to 10 ppm (5000 Hz) and from 0 to 165 ppm (20625 Hz) for the ^{1}H and ^{13}C dimensions. The number of transients was 64, and 256 time increments were always recorded in the ^{13}C dimension. The $^{1}J_{CH}$ used was 145 Hz. Processing used typical matched Gaussian apodization in the ^{1}H dimension and squared cosine-bell apodization in the ^{13}C dimension. Prior to Fourier transformation, the data matrices were zero-filled to 1024 points in the ^{13}C dimension. For heteronuclear multiple bond correlation (HMBC) acquisition experiments, the long-range *J*-coupling evolution time used was 80 ms.

2D-NMR correlation signals were assigned by literature comparison.[27−30] A semiquantitative analysis of the HSQC signals was performed using Bruker's Topspin 3.1 processing software. Integration of signals was performed separately for the different regions of the spectra corresponding to chemically analogous C−H pairs with similar $^{1}J_{CH}$ coupling values. The relative abundances of side chains involved in the different interunit linkages were estimated in the aliphatic oxygenated region from the C_α−H_α correlations, except for α-oxidized β-*O*-4 substructures (A_{ox}), for which C_β−H_β correlations had to be used. In the aromatic/unsaturated region, C_2−H_2 correlations from H, G, and S lignin units and from *p*-coumarates and ferulates were used to estimate their relative abundances.

DFRC (Derivatization followed by Reductive Cleavage). The DFRC degradation was performed according to the protocol previously developed.[31−33] Lignins (10 mg) were mixed with acetyl bromide in acetic acid, 8:92 (v/v), and stirred at 50 °C for 2 h. The solvents and excess of acetyl bromide were removed by rotary evaporation at reduced pressure. The products were then dissolved in dioxane/acetic acid/water, 5:4:1 (v/v/v), 50 mg of powdered Zn was added, and the mixture was stirred at room temperature for 40 min. After completion, the reaction mixture was transferred into a separation funnel with dichloromethane and saturated ammonium chloride. The aqueous phase was adjusted to pH <3 by adding 3% HCl, the mixture vigorously mixed, and the organic layer separated. The water phase was extracted twice more with dichloromethane. The combined dichloromethane fractions were dried over anhydrous Na_2SO_4, and the filtrate was evaporated on a rotary evaporator. The residue was then acetylated in 1.1 mL of dichloromethane containing 0.2 mL of acetic anhydride and 0.2 mL of pyridine for 1 h. The acetylated lignin degradation products were collected after rotary evaporation of the solvents and analyzed by GC/MS using mass spectra and relative retention times to authenticate the DFRC monomers and their *p*-coumarate conjugates as described in previous papers.[31−33] To investigate the occurrence of native acetylated lignin units, a modification of the standard DFRC method using propionylating instead of acetylating reagents (DFRC′) was used in the present study.[34−36]

The GC/MS analyses were performed with a GCMS-QP2010 Ultra instrument (Shimadzu Co., Kyoto, Japan). The column used was a 30 m × 0.25 mm i.d., 0.10 μm film thickness, DB-5HT (J&W Scientific). The oven was heated from 140 °C (1 min) to 250 °C at 3 °C/min, then ramped at 10 °C/min to 300 °C, and held for 10 min at the final temperature. The injector was set at 250 °C, and the transfer line was kept at 300 °C. Helium was used as the carrier gas at a rate of 1 mL/min. The DFRC compounds were identified on the basis of the mass spectra and relative retention times of authentic standards published previously.[31,32] Quantitation of the released individual (acetylated and propionylated) monomers was performed using tetracosane as external standard and by assuming response factors similar to those of the acetylated monomers reported previously.[30]

RESULTS AND DISCUSSION

The abundance of the main constituents (namely, water-soluble material, lipids, Klason lignin, acid-soluble lignin, polysaccharides, proteins, and ash) of the BSG sample analyzed in this work is indicated in Table 1. Previously published data of this sample are also shown for comparison. The Klason lignin content estimated in this work was relatively low (8.8%) compared to previous published data for the same sample (16−20.1%). One of the main reasons for this discrepancy is that previous works did not consider the high amounts of proteins and ashes when the Klason lignin content was quantitated gravimetically and presented an uncorrected value. In our case, the uncorrected Klason lignin content amounted to ca. 13%,

Table 1. Abundance of the Main Constituents (Percent Dry Weight) of the Brewer's Spent Grain Sample[a]

constituent	content[b]	Robertson et al. (2010)[4]	Faulds et al. (2008)[20]

[a]H, lignin *p*-hydroxyphenyl-type; G, lignin guaiacyl-type; S, lignin syringyl-type; PCA, *p*-coumarate; FA, ferulate; Pr, proteins. All G- and S-derived peaks were used for the estimation of the S/G ratio, except 4-vinylguaiacol (which also arises from ferulates), and the analogous 4-vinylsyringol.

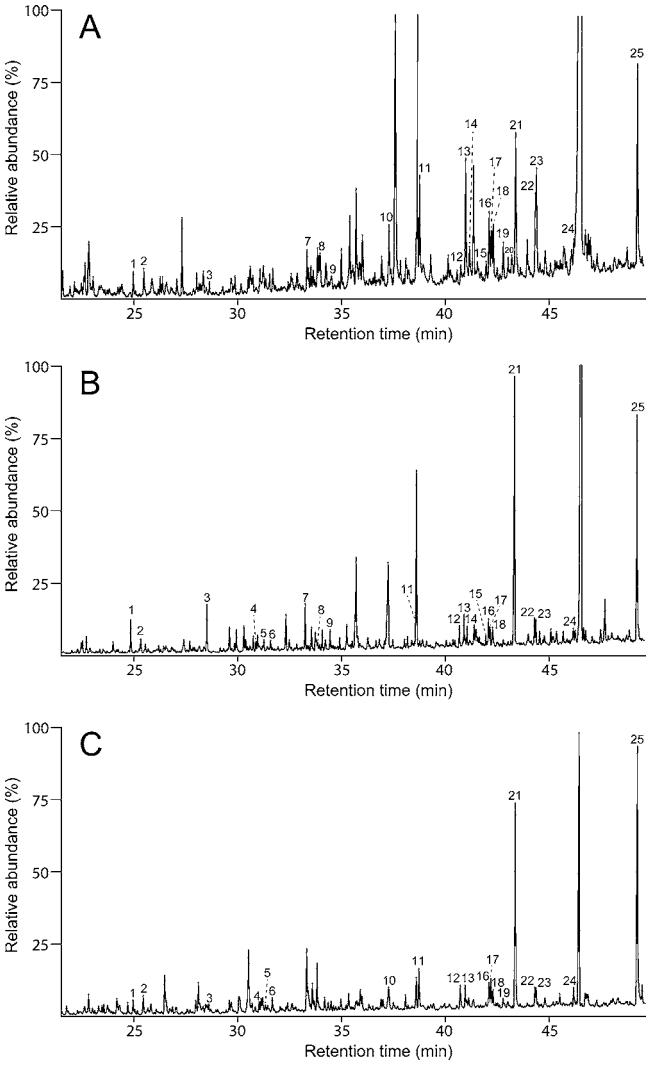

Figure 2. Py-TMAH-GC/MS chromatograms of the different lignin preparations isolated from BSG: (A) MWL; (B) DL; (C) CEL. The identities and relative abundances of the released lignin-derived compounds are listed in Table 3.

but contained appreciable amounts of ashes (ca. 10%) and proteins (ca. 20%) that needed to be corrected. Therefore, it is important to stress the importance of correcting the Klason lignin content in BSG (and related samples) for proteins and ashes to avoid presenting overestimated values.

In this work, we have thoroughly studied the composition and structure of the lignin polymer of BSG. For this purpose, different lignin preparations, MWL, DL, and CEL, were isolated from the BSG sample selected for this study according to traditional lignin isolation procedures.[17−19] However, it is well recognized that these lignin preparations, in particular MWL due to its low yield, represent only a part of the native lignin and may not be representative of the whole lignin present in the plant material.[19,37,38] Indeed, these lignin preparations can also undergo some structural modifications during isolation, especially during extended milling.[38,39] The yields of the lignin preparations isolated from the BSG sample varied from 10% (MWL) to 50% (DL) to 105% (CEL) of the Klason lignin content. However, and although these lignin preparations were purified as described, they still contained appreciable amounts of proteins (calculated from the N content), which accounted for 20% (MWL), 30% (DL), and 21% (CEL), that were difficult to remove and lipids, as shown in the NMR spectra. In any case, and despite the presence of impurities, it was still possible to get information about the structure of the lignin polymer. To obtain a detailed description of the structure of the BSG lignin, these lignin preparations were subsequently

[a]H, lignin *p*-hydroxyphenyl type; G, lignin guaiacyl type; S, lignin syringyl type; PCA, *p*-coumarate; FA, ferulate; Pr, proteins.

analyzed by different analytical methodologies, including Py-GC/MS, 2D-NMR, and DFRC.

Lignin Composition As Observed by Py-GC/MS. The different lignin preparations (MWL, DL, CEL) isolated from the BSG sample selected for this study were first analyzed by Py-GC/MS. The pyrograms are shown in Figure 1, and the identification and relative molar abundances of the released phenolic compounds are listed in Table 2. The pyrograms of the three lignin preparations were rather similar and released phenolic compounds that are derived from *p*-hydroxyphenyl (H), guaiacyl (G), and syringyl (S) lignin units as well as from *p*-hydroxycinnamates (*p*-coumarates and ferulates). The most predominant phenolic compounds released were 4-vinylphenol (**10**) and 4-vinylguaiacol (**11**), with important amounts of other compounds such as phenol (**1**), guaiacol (**2**), 4-methylphenol (**4**), 4-methylguaiacol (**6**), syringol (**15**), *trans*-isoeugenol (**19**), 4-methylsyringol (**20**), 4-vinylsyringol (**26**), guaiacylacetone (**27**), and *trans*-4-propenylsyringol (**32**). Compounds **10** and **11** coelute together in the same chromatographic peak, and their relative abundances in this peak were estimated on the basis of the relative abundance of their respective characteristic fragments ions (*m*/*z* 91 and 120 for 4-vinylphenol; *m*/*z* 107, 135, and 150 for 4-vinylguaiacol).

The high levels of phenol (**1**), 4-methylphenol (**4**), and 4-vinylphenol (**10**), together with the important amounts of 1*H*-indole released from the different lignin preparations, seem to indicate that the major part of these phenolic compounds does not arise from H-lignin structural units but from proteins, in agreement with the high content of protein impurities present in these lignin preparations as shown above. In addition, the high amounts of 4-vinylphenol (**10**) released upon pyrolysis from these lignin preparations, as also occurs in the lignins from other grasses, may also arise from *p*-coumarate esters that are acylating the lignin side chains and which decarboxylate efficiently under pyrolytic conditions.[28,29,40,41] Similarly, 4-vinylguaiacol (**11**), which is also present in high abundance among the pyrolysis products of the different BSG lignin preparations, might also arise from ferulates after decarboxylation upon pyrolysis.[28,29,40,41] Therefore, 4-vinylphenol and 4-vinylguaiacol cannot be used to determine the lignin H:G:S composition upon Py-GC/MS in the BSG lignin preparations because part of them does not arise from lignin structural units but from *p*-hydroxycinnamates or also from proteins in the case of 4-vinylphenol. An estimation of the S/G ratio was, however, obtained by using the molar areas of all the G- and S-derived compounds listed in Table 2, except for 4-vinylguaiacol, which also arises from ferulates, and its respective 4-vinylsyringol. The S/G ratios thus calculated for the different BSG lignin preparations indicated a predominance of G- over S-lignin units, with a S/G ratio in the range of 0.4−0.5.

As stated above, the high amounts of 4-vinylphenol and 4-vinylguaiacol released in the pyrograms point to the occurrence of important amounts of *p*-hydroxycinnamates (*p*-coumarates and ferulates) in the BSG lignin preparations, as usually occurs in all grasses. The occurrence of *p*-hydroxycinnamates in the BSG lignin preparations was therefore assessed by pyrolysis in the presence of TMAH as methylating reagent.[28,29,40,41] Py/TMAH induces transesterification of the *p*-hydroxycinnamate

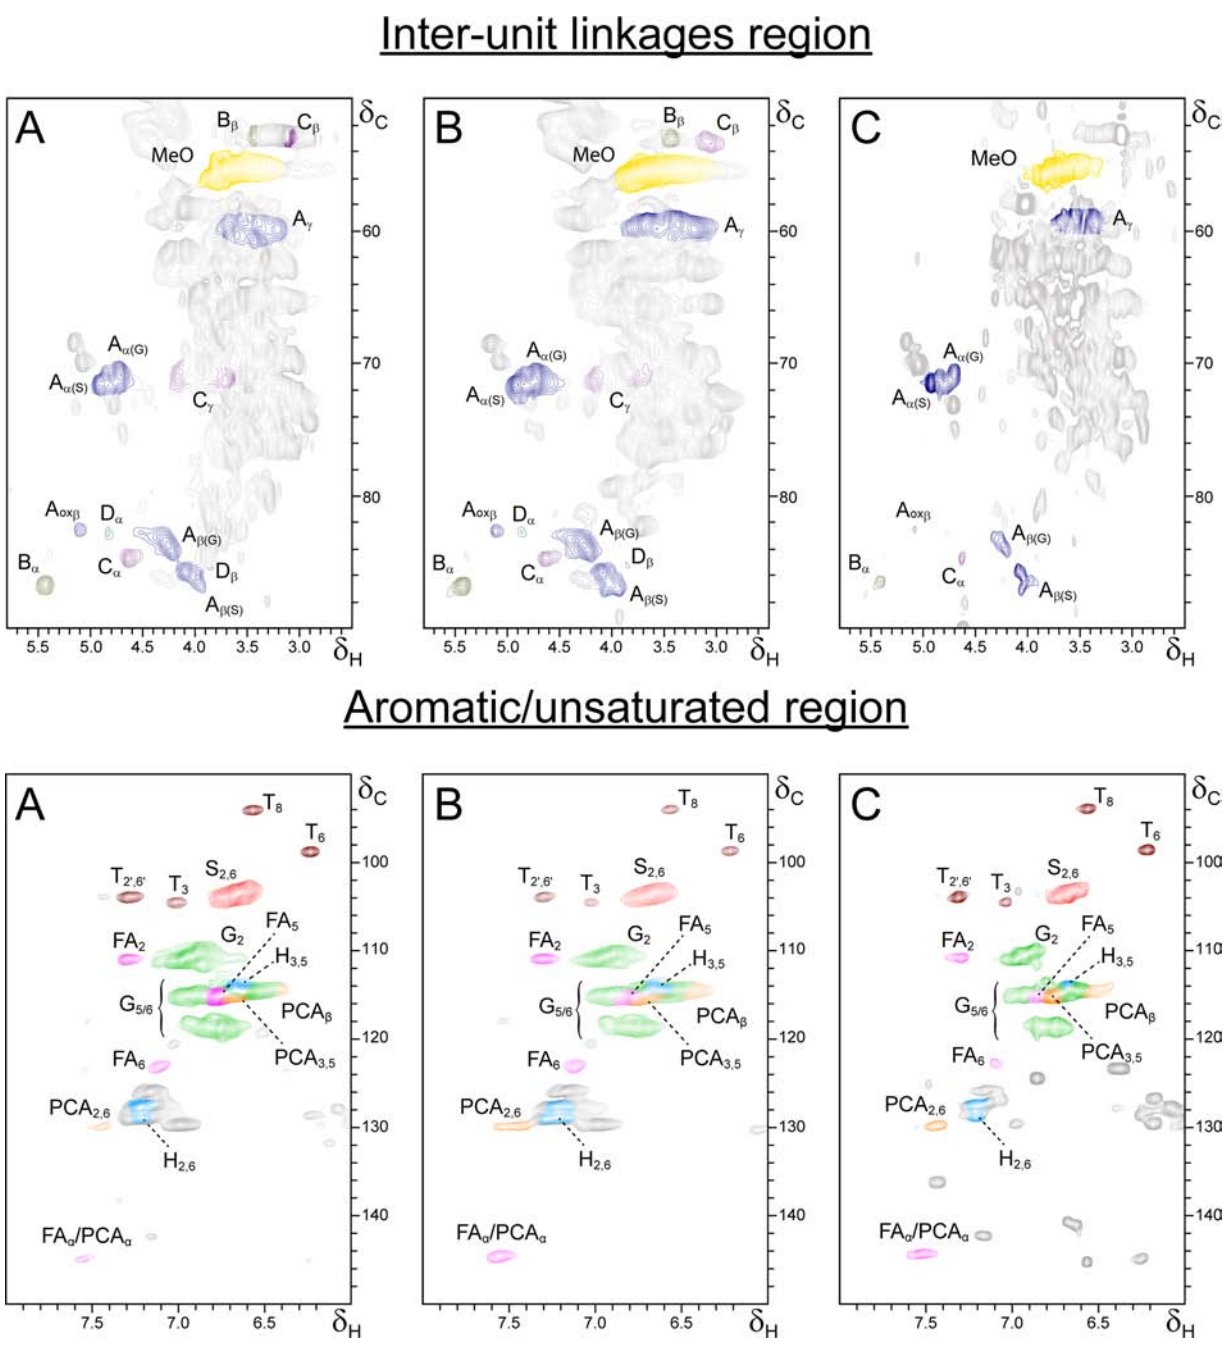

Figure 3. Side-chain (δ_C/δ_H 50–90/2.5–5.8) and aromatic/unsaturated (δ_C/δ_H 90–160/6.0–8.0) regions in the 2D (HSQC) NMR spectra: (A) MWL; (B) DL; (C) CEL. See Table 4 for signal assignments and Figure 4 for the main lignin structures identified.

esters and cleavage of ether linkages at C_4, with subsequent methylation of the formed phenolic groups. The Py/TMAH chromatograms of the BSG lignin preparations are shown in Figure 2. The identities of the compounds released and their relative abundances are listed in Table 3. It is clearly apparent that Py/TMAH of the different BSG lignin preparations released important amounts of the dimethyl derivatives of *p*-coumaric (**21**) and ferulic (**25**) acids, confirming the relatively high amounts of *p*-coumarates and ferulates present in the BSG lignin preparations, as also occurred in the lignin from other grasses. Previous studies have indicated that *p*-coumarates in grasses are acylating the *γ*-OH of the lignin side chains.[16,29,42] Ferulates, on the other hand, are an intrinsic part of the lignin structure in grasses, participating in coupling and cross-coupling reactions with other monolignols.[16,43,44] In all BSG lignin preparations, *p*-coumarates and ferulates were released in nearly similar abundances, with a *p*-coumarates/ferulates ratio around 0.8–1.0. An estimation of the lignin S/G ratio can now be performed upon Py/TMAH with more accuracy because *p*-hydroxycinnamates and lignin release clearly differentiated compounds (Table 3) and revealed a S/G value in the range 0.4–0.5, similar to that estimated upon Py-GC/MS, by ignoring 4-vinylguaiacol and its respective 4-vinylsyringol and confirming that BSG lignin is enriched in G-lignin units.

Lignin Structural Units and Interunit Linkages As Seen by 2D-NMR. To obtain additional information on the structure of BSG lignin, the different lignin preparations (MWL, DL, and CEL) were analyzed by 2D-NMR, which

provides information on the interunit linkages as well as the composition of the lignin units. The side-chain (δ_C/δ_H 50−90/2.5−5.8) and the aromatic/unsaturated (δ_C/δ_H 90−160/6.0−8.0) regions of the HSQC NMR spectra of the different lignin preparations are shown in Figure 3. The main lignin cross-signals assigned in the HSQC spectra are listed in Table 4, and the main lignin substructures present are shown in Figure 4.

The side-chain region of the spectra gives important information about the different interunit linkages occurring in the structure of the lignin polymer. The spectra of the different BSG lignin preparations show strong signals from lipids (including linoleic acid), proteins, and carbohydrates; however, they also show intense and characteristic signals for the lignin polymer. Thus, the spectra show prominent signals corresponding to β-O-4′ aryl-ether linkages (substructure A). The $C_\alpha-H_\alpha$ correlations in β-O-4′ substructures were observed at δ_C/δ_H 71.1/4.71 and 71.6/4.84 for structures linked to G or S lignin units, respectively. Likewise, the $C_\beta-H_\beta$ correlations were observed at δ_C/δ_H 83.7/4.26 for β-O-4′ structures linked to G units and at δ_C/δ_H 85.8/4.09 for β-O-4′ structures linked to S units. The $C_\gamma-H_\gamma$ correlations of β-O-4′ substructures were observed at δ_C/δ_H 59.4/3.40 and 3.72, superimposed to other signals. In addition, signals for phenylcoumaran substructures (B) were also found in the spectra of the BSG lignin preparations, the signals for their $C_\alpha-H_\alpha$ and $C_\beta-H_\beta$ correlations being observed at δ_C/δ_H 86.8/5.43 and 53.1/3.43, whereas the $C_\gamma-H_\gamma$ correlation overlaps with other $C_\gamma-H_\gamma$ signals around δ_C/δ_H 62/3.8. Resinol substructures (C) were also clearly observed in the spectra, with their $C_\alpha-H_\alpha$, $C_\beta-H_\beta$, and the double $C_\gamma-H_\gamma$ correlations observed at δ_C/δ_H 84.7/4.64, 53.5/3.05 and 71.0/3.83 and 4.19. Finally, small signals corresponding to dibenzodioxocin (5′-5″/α-O-4′/β-O-4″ linkages) substructures (D) could also be observed in the spectra, with the characteristic $C_\alpha-H_\alpha$ and $C_\beta-H_\beta$ correlations at δ_C/δ_H 83.0/4.82 and 85.2/3.85, as well as signals for the $C_\beta-H_\beta$ correlations of α-keto-β-O-4′-substructures (A_{ox}) at δ_C/δ_H 82.6/5.11.

The main cross-signals in the aromatic/unsaturated region of the HSQC spectra corresponded to the aromatic rings and unsaturated side chains of the different H, G, and S lignin units and to p-coumarates (PCA) and ferulates (FA) that are associated with the lignin. The S lignin units presented a strong signal for the $C_{2,6}-H_{2,6}$ correlation at δ_C/δ_H 103.7/6.68, whereas the G lignin units showed different correlation signals for C_2-H_2 (δ_C/δ_H 110.8/6.96) and C_5-H_5/C_6-H_6 (δ_C/δ_H 115.0/6.74 and 6.94 and δ_C/δ_H 118.8/6.79). Cross-signals corresponding to $C_{3,5}-H_{3,5}$ correlations of H lignin units were observed at δ_C/δ_H 114.5/6.62 overlapping with other lignin signals, whereas the $C_{2,6}-H_{2,6}$ correlations at δ_C/δ_H 128.3/7.22 overlapped with strong signals from proteins. Signals corresponding to p-coumarate structures (PCA) were clearly observed in the spectra of the isolated lignins. Cross-signals corresponding to the $C_{2,6}-H_{2,6}$ at δ_C/δ_H 130.0/7.46 and $C_{3,5}-H_{3,5}$ at δ_C/δ_H 115.5/6.77 correlations of the aromatic ring and signals for the correlations of the unsaturated $C_\alpha-H_\alpha$ at δ_C/δ_H 144.4/7.41 and $C_\beta-H_\beta$ at 113.5/6.27 of the p-coumarate units were observed in this region of the HSQC spectra. Signals corresponding to the C_2-H_2 and C_6-H_6 correlations of ferulate moieties (FA) were also observed at δ_C/δ_H 111.0/7.32 and 123.3/7.10 in the spectra. The signals corresponding to the unsaturated $C_\alpha-H_\alpha$ and $C_\beta-H_\beta$ correlations overlapped with those of the p-coumarate units. Moreover, the signals for the $C_\beta-H_\beta$ correlations of p-coumarates and ferulates indicated that the carboxylic groups were not in free but in ester form. Interestingly, in this region of the HSQC spectra, it was also possible to detect the two distinctive and typical signals at δ_C/δ_H 94.1/6.56 and 98.7/6.22 corresponding to the C_8-H_8 and C_6-H_6 correlations of tricin (T),[28] a flavone that is widely found and is apparently incorporated into the lignin structure in some grasses,[28,45,46] and that also occur in the lignin of other monocotyledons, such as coconut coir.[30] The HSQC spectra also show the C_3-H_3 correlation of tricin at δ_C/δ_H 104.5/7.03, whereas the correlations for $C_{2'}-H_{2'}$ and $C_{6'}-H_{6'}$ are observed at δ_C/δ_H 103.9/7.30. Tricin arises from a different pathway than the usual monolignols, but seems to act as a lignin monomer in grasses. Tricin cannot couple with other tricins, so it can only undergo cross-coupling with monolignols and must be present

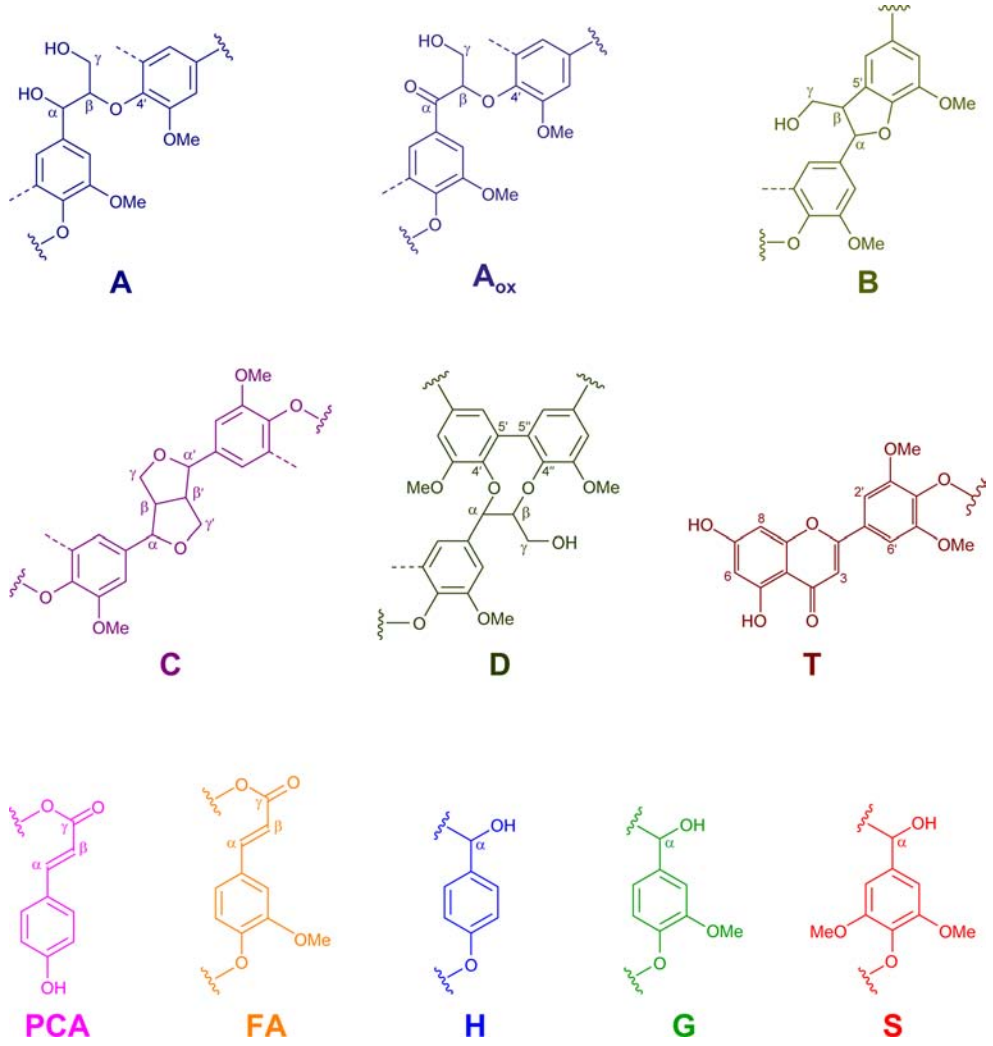

Figure 4. Main structures present in the lignin preparations from brewer's spent grain: (A) *β-O*-4′ alkyl-aryl ethers; (A_{ox}) C_α-oxidized *β-O*-4′ structures; (B) phenylcoumarans; (C) resinols; (D) dibenzodioxocins; (PCA) *p*-coumarates; (FA) ferulates; (H) *p*-hydroxyphenyl units; (G) guaiacyl units; (S) syringyl units; (T) tricin.

at the start of lignification acting as the initiation site. The incorporation of tricin into the lignin polymer through 4-*O*-*β* ether linkages has already been reported.[29]

The relative abundances of the main lignin interunit linkages and the molar abundances of the different lignin units (H, G, and S), *p*-hydroxycinnamates (*p*-coumarates and ferulates), and tricin, all estimated from volume integration of the corresponding cross-signals in the HSQC spectra, are shown in Table 5. The three lignin preparations gave similar results, indicating that they might be considered as representative of the native lignin in BSG. The main substructure present in the lignin of BSG was the *β-O*-4′ alkyl-aryl ether (A and A_{ox}), which accounts for 77−79% of all interunit linkages, followed by *β*-5′ phenylcoumaran substructures (B) that involved 11−13% of all linkages and lower amounts of *β-β*′ resinol substructures (C) with 5−6%, and dibenzodioxocins with 3−5%, depending on the lignin preparation. The exact determination of the H:G:S composition of the BSG lignin preparations was not possible due to the high amounts of proteins present in the lignin preparations, which impairs obtaining an accurate volume integral of the $C_{2,6}$−$H_{2,6}$ correlation of the H units. Therefore, the abundance of H lignin units is overestimated. However, and despite this limitation, the calculation of the S/G ratio can be performed with more accuracy because the characteristic signals are well resolved. The lignin S/G ratio determined upon 2D-NMR gave a value of 0.4, similar to that obtained upon Py-GC/MS and Py/TMAH, and confirmed that the BSG lignin is enriched in G units. With regard to the content of *p*-hydroxycinnamates, a higher abundance of ferulates than *p*-coumarates was observed in all lignin preparations, with *p*-coumarates accounting for 5−6% and ferulates accounting for 7−10% of the total lignin units. Finally, tricin units account for 5−8% of total lignin units, with the highest abundance in the CEL preparation.

Lignin Acylation with *p*-Coumarates and Acetates As Seen by 2D-NMR and DFRC. Whereas ferulates are an intrinsic part of the lignin structure in grasses, participating in coupling and cross-coupling reactions with other monolignols and producing a diversity of linkages, *p*-coumarates are always present acylating the *γ*-carbon of the lignin side chain.[16,28,42] However, the characteristic C_γ−H_γ correlations of *γ*-acylated lignin units at δ_C/δ_H 62.7/3.83−4.30 could not be clearly observed in the HSQC spectra of the different BSG lignin preparations due to overlapping with other signals. In this sense, and to prove that the *p*-coumarates present in BSG lignin are also acylating the *γ*-carbon of the lignin side chain, we

[a]Expressed as a fraction of the total lignin interunit linkage types A–D. [b]Molar percentages (H + G + S = 100). [c]Overestimated due to the presence of proteins. [d]Molar content as percentage of lignin content (H + G + S = 100).

performed HMBC experiments that correlate protons with carbons separated by two or three bonds. Figure 5 shows the section of the HMBC of the MWL preparation isolated from BSG with the correlations of the carbonyl carbons of the groups acylating the lignin *γ*-OH. The correlations of the carbonyl carbon at 166.0 ppm with the *α*-protons of *p*-coumarate esters (at 7.56 ppm) indicate that they belong to *p*-coumarate esters, but more important, the correlations of this carbonyl carbon with the protons at 4.08 ppm[28,42] definitively confirm that *p*-coumarates in BSG lignin are acylating the *γ*-position of the lignin side chains, as usually occurs in all grasses. However, the HBMC spectrum did not present any correlation for acetate groups (at 169.8 ppm) acylating the lignin side chain, despite the acetates having been widely found acylating the *γ*-OH in the lignins of many plants, including grasses.[28,29,34−36,47] This result seems to indicate that the extent of lignin *γ*-acetylation, if any, should be very low.

Further information about the acylation of the *γ*-OH of the lignin side chain was obtained from DFRC, a chemical degradative method that cleaves *α*- and *β*-ether bonds but leaves *γ*-esters intact.[31−33] The chromatogram of the DFRC degradation products of the MWL preparation is shown in Figure 6. The MWL from BSG released the *cis*- and *trans*-isomers of guaiacyl (*c*G and *t*G) and syringyl (*c*S and *t*S) lignin monomers (as their acetylated derivatives), arising from normal, non-*γ*-*p*-coumaroylated *β*-ethers in lignin. Only minor amounts of *γ*-*p*-coumaroylated syringyl (tS_{pc}) monomers could be detected in the chromatogram (<0.7% of the peak molar area of all lignin units) despite the significant amounts of *p*-coumarates present in this lignin (5% with respect to the total lignin aromatic units, as estimated by 2D-NMR in Table 5) and the fact that *p*-coumarates are acylating the *γ*-carbon, as observed by HMBC. No traces of *γ*-*p*-coumaroylated guaiacyl (cG_{pc} and tG_{pc}) lignin units could be found in the chromatogram despite this lignin being enriched in G lignin units, confirming that *p*-coumarates preferentially acylate S lignin units, as usually occurs in grasses.[16,29,42] Similar results were recently observed in the lignin from wheat straw, where neither traces of *γ*-*p*-coumaroylated syringyl nor guaiacyl conjugates were released, despite *p*-coumarates being attached to the *γ*-carbon, as clearly revealed by NMR.[28] This finding seems to indicate that, as also occurred in the lignin of wheat straw, *p*-coumarate groups are mostly attached to the lignin *γ*-OH in condensed lignin substructures that are not amenable to DFRC analysis.

The DFRC degradation method originally developed does not allow the analysis of natively acetylated lignin units because the degradation products are acetylated during the procedure. However, with appropriate modification of the original protocol by replacing acetylating reagents with propionylating ones, it is possible to obtain information about the presence of acetate groups originally acylating the *γ*-OH in lignin.[34−36] The results from this analysis indicated only a very minor extent of *γ*-acetylation of this lignin (undetectable by HMBC), which takes place predominantly on syringyl units (6% of S lignin units are acetylated), whereas only traces of acetylated guaiacyl units were detected (1% of G lignin units are acetylated).

In conclusion, the content and structure of the lignin from BSG have been thoroughly studied for the first time in the present work. Three different lignin preparations (MWL, DL, and CEL) were isolated and characterized in detail by different analytical methodologies (Py-GC/MS, 2D-NMR, DFRC). The

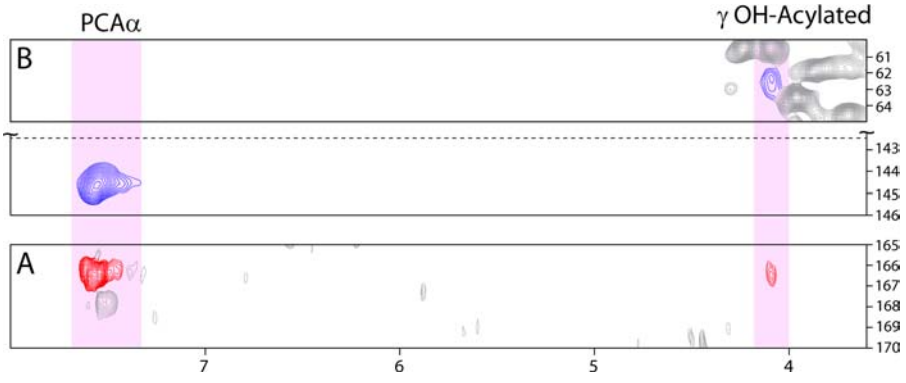

Figure 5. Section of the HMBC spectrum (δ_C/δ_H 165–170/3.5–8.0) of the MWL preparation isolated from BSG showing the main correlations for the carbonyl carbon of *p*-coumarates acylating the *γ*-position of the lignin side chain (A). Appropriate sections of the HSQC spectrum showing the $C_\gamma-H_\gamma$ correlations of the acylated lignin *γ*-carbon (δ_C 60–65) and the $C_\alpha-H_\alpha$ correlations of *p*-coumarates (δ_C 142–146) are also shown (B).

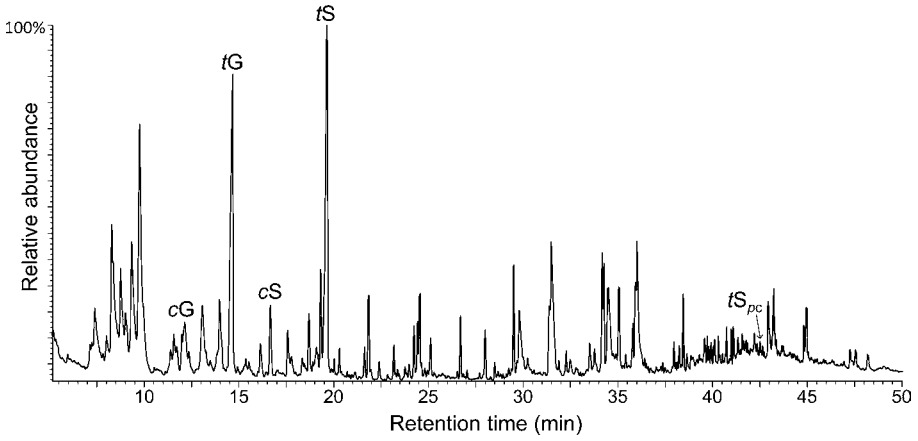

Figure 6. Chromatogram (GC-TIC) of the DFRC degradation products from the MWL preparation isolated from the BSG. *c*G, *t*G, *c*S, and *t*S are the normal *cis*- and *trans*-coniferyl and -sinapyl alcohol (guaiacyl and syringyl) monomers (as their acetate derivatives). tS_{pc} is the *trans*-sinapyl *p*-coumarate (as its acetate derivative).

analyses of these lignin preparations gave similar results and indicated that this lignin presents a strong predominance of G lignin units (S/G ratio of 0.4−0.5) with some amounts of associated *p*-coumarates and ferulates. The main lignin substructures present in BSG include *β*-*O*-4′ alkyl-aryl ethers (77−79% of all interunit linkages), followed by *β*-5′ phenylcoumarans (11−13%) and minor amounts of *β*-*β*′ resinols (5−6%) and 5-5′ dibenzodioxocins (3−5%). Finally, we also found that the flavone tricin is incorporated into the BSG lignin, as seems to occur in all grasses. The comprehensive understanding of the composition and structure of BSG lignin accomplished here will help development of lignin-based high-added-value products from this agro-industrial waste material and design of effective deconstruction strategies for biorefinery purposes.

Nonenzymatic Modification of Ubiquitin under High-Pressure and -Temperature Treatment: Mass Spectrometric Studies

Monika Kijewska, Karolina Radziszewska, Martyna Kielmas, Piotr Stefanowicz,* and Zbigniew Szewczuk

Faculty of Chemistry, University of Wrocław, Wrocław, Poland

ABSTRACT: The effect of high-pressure and/or high-temperature on the glycation of a model protein (ubiquitin) was investigated by mass spectrometry. This paper reports the impact of high pressure (up to 1200 MPa) on the modification of a ubiquitin using ESI-MS measurements. The application of glucose labeled with stable isotope allows a quantitative assessment of modification under the conditions of high-pressure (HPG) and high-temperature (HTG) glycation. A higher degree of modification was observed for the sample heated at 80 °C for 25 min under atmospheric pressure than for sample treated under high pressure. In samples treated at pressure below 400 MPa an insignificant increase of glycation level was observed, whereas high pressure (>600 MPa) has only a minor effect on the number of hexose moieties (Fru) attached to the lysine residue side chain.

KEYWORDS: *glycation, high-pressure glycation, Amadori products*

INTRODUCTION

High-pressure processing (HPP) preserves nutrients, natural flavor, and other sensory properties of food while extending the shelf life by preventing the growth of microorganisms by inducing structural changes to the cell membrane and inactivating important enzyme systems that disrupt metabolism of microorganisms.[1,2] Some bacteria show resistance[3] to pressures up to 800 MPa and or even higher. However, the application of high-pressure processing combined with increased temperature could be useful for sterilization of many products sensitive to high temperatures, such as food, cosmetics, and pharmaceuticals.[4]

HPP is a nonthermal preservation and pasteurization technique, which causes little or no changes in the sensory and nutritional attributes of the product being processed, unlike most conventional heat treatments.[5] HPP accomplishes this by application of high hydrostatic pressures (between 100 and 1000 MPa) to food products. High pressure to about 3000 MPa does not affect covalent bonds in the molecules; therefore, many vitamins and provitamins as well as dyes, drugs; or other pharmacologically active molecules retain their unique characteristics.[5,6]

Bristow et al.[7] and Moreno et al.[8,9] reported the impact of high-pressure and alkaline conditions on the formation of Maillard products. The condensation of glyceraldehyde with di- and tripeptides was hardly affected by a pressure increase (up to 500 MPa), and the reaction of glyceraldehyde, glycolaldehyde, or xylose with amino acids was slightly suppressed. For a glucose−lysine system, some stages of the Maillard reaction were affected differently.[10]

Staniszewska et al.[11] proved that advanced glycation end products (AGEs) formed under high pressure (850 MPa) differ from those obtained thermally. In general, after high-pressure glycation (HPG), the products have a lower molecular mass than after high-temperature glycation (HTG). Immunoblotting experiments showed that the epitopes of the cross-linked glycation products formed in solution under high pressure are not the same as those originating in dry conditions at high temperature. The antibodies against HTG products recognized HTG but not HPG products. This finding reveals that the biological properties of AGEs obtained by thermal treatment and high-pressure treatment may be different.[11]

The first investigations on the impact of pressure on modifications of proteinaceous amino acid residue side chains using glucose or more reactive dicarbonyl[12] compounds revealed an increased level of pentosidine,[13] whereas the observed formation of carboxyethylarginine from arginine did not occur at atmospheric pressure.[14] In contrast, the generation of other Maillard reaction products, such as pyrraline, is hindered with the application of pressure.[15]

The effect of combined heat and pressure on the Maillard reaction between bovine serum albumin (BSA) and glucose was investigated by Buckow et al.[16] The kinetic results showed that the protein−sugar conjugation rate increased with increasing temperature, but decreased with increasing pressure. However, five modified lysine residues were identified after 30 min of treatment at 200 MPa and 110 °C, that is, lysine residues K75, K204, K297/299, K548, and K557. Glycation of K548 was previously observed by Frolov et al.[17] The effects of pressure and temperature on the reaction kinetics are antagonistic as an increase in pressure at constant temperature leads to a decrease in the entropy of the system.[18] Considine et al.[19] reported that BSA is relatively resistant to pressure denaturation, whereas it is easily denatured by heat and combined heat and high-pressure treatment.

A similar investigation was performed on milk proteins in the absence and presence of different saccharides or dicarbonyl compounds.[20] Without carbohydrates, protein cross-linking of casein is enhanced by pressure through the formation of dehydroalanine-derived lysinoalanine. In contrast, saccharide or

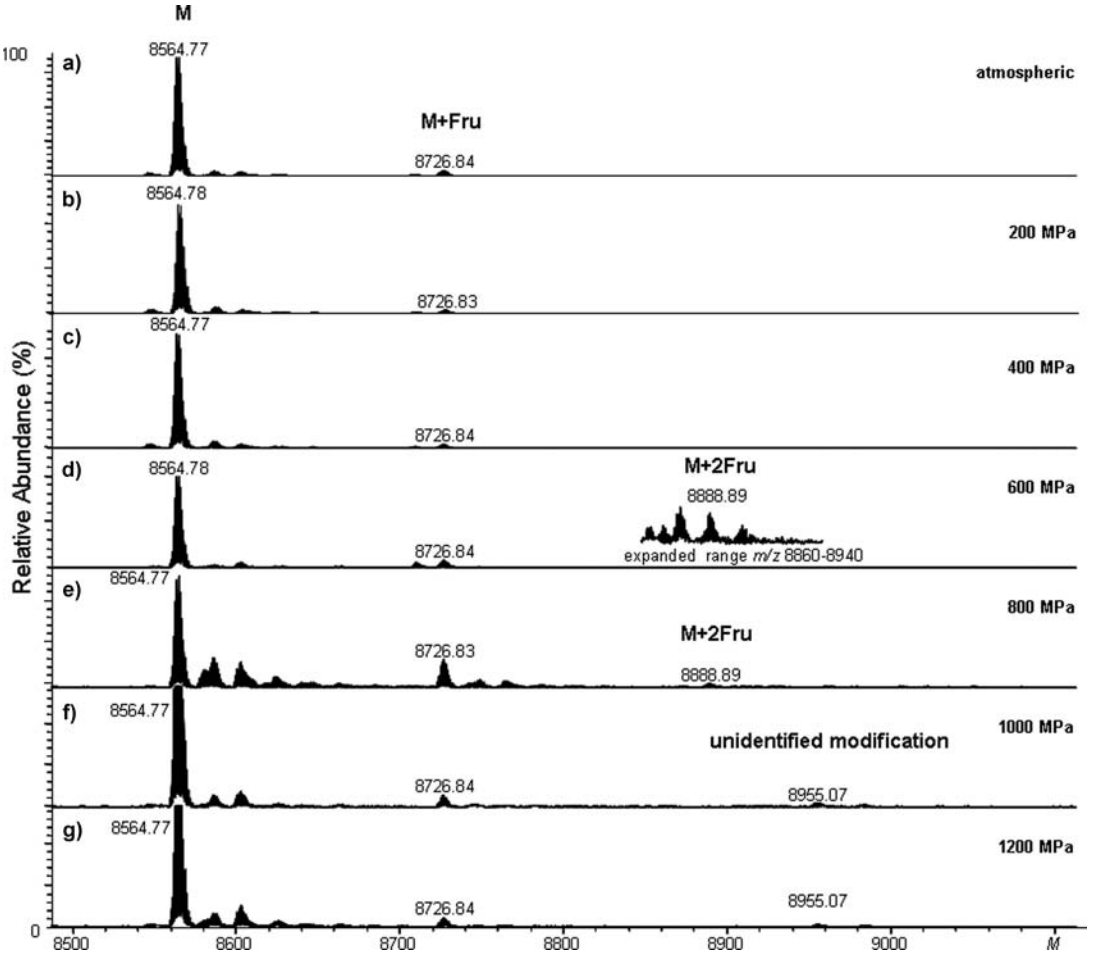

Figure 1. Deconvoluted ESI-MS spectra for ubiquitin glycated under high pressure in the range of 0.1−1200 MPa.

dicarbonyl compound-induced cross-linking is reduced at high pressures. The authors hypothesized that protein cross-linking is decelerated due to either degradation of sugars or carbonyl compounds or formation of early Maillard products.[20]

Our recent work has been focused on the reaction of the lysine moiety with reducing sugars. The Amadori products, including glycoconjugates, are potentially useful markers of some diseases: diabetes, Alzheimer's disease, or the aging process. We have reported an efficient method of synthesis,[21] as well as selective mass spectrometric (ESI-MS) detection based on the neutral losses, borate complex formation,[22,23] and isotopic (^{13}C, ^{18}O) labeling combined with enzymatic hydrolysis[24−26] and sequencing of glycoconjugates using various methods of fragmentation (ECD, CID).[27]

The utilization of high pressure, an emerging technology in the area of food processing, has been increasing over the past two decades. Herein we report the impact of high pressure (up to 1200 MPa) on the level of glycation of a ubiquitin using ESI-MS measurement. The quantification of the glycation level of ubiquitin was based on application of isotopic labeling [$^{13}C_6$].[23]

MATERIALS AND METHODS

Reagents. Reagents (including isotopically labeled [$^{13}C_6$]glucose; 99% ^{13}C and pepsin) and solvents (including formic acid (HPLC grade), acetonitrile (LC-MS grade), and ammonium formate (LC-MS grade)) were purchased from Sigma. Ubiquitin was purchased from Aldrich and D-glucose from Eurochem. The reagents were used without further purification.

High-Pressure Equipment. The high-pressure glycation experiments were carried out using a custom-made cylinder-piston type apparatus.[28,29] The stoppered polypropylene syringe, containing the protein sample, was placed in a high-pressure vessel filled with hexane as a transmission medium and compressed (0.1−1200 MPa).

High-Pressure Glycation. Ubiquitin (0.5 mg) and glucose (0.1 mg) were dissolved in 10 mmol/L aqueous ammonium formate (150 μL) at a 1:10 molar ratio and incubated at a given pressure (0.1−1200 MPa) for 24 h at room temperature (22 °C). After decompression, samples were diluted with 150 μL of a MeCN/H_2O/HCOOH mixture (50:50:0.1 v/v/v). The samples were directly analyzed by ESI-MS. Additionally, the modified ubiquitin treated under a pressure of 800 MPa was hydrolyzed according to the procedure described below.

High-Temperature Glycation. The high-temperature glycation of ubiquitin was performed according to Boratyński's method.[30,31] Briefly, ubiquitin and glucose or [$^{13}C_6$]glucose were dissolved in water at a 1:10 molar ratio and lyophilized. The dry lyophilisate was placed in an air oven at 80 °C for 25 min.[27] The resulting preparation was lyophilized and directly used for MS experiments.

Enzymatic Hydrolysis. Modified ubiquitin (1 mg) was dissolved in 5% aqueous formic acid (100 μL). Pepsin (10 μL of stock solution 1 mg/mL in water) was added, giving a 1:10 enzyme/substrate mass ratio. The reaction mixture was incubated for 5 h at 22 °C. The resulting digest was lyophilized and used for MS experiments.

ESI-MS Measurement. ESI-MS experiments were performed using an Apex-Qe Ultra 7T instrument (Bruker Daltonic, Germany) equipped with an ESI source. The obtained fragments were subsequently analyzed by the ICR mass analyzer. The instrument was operated in the positive-ion mode and calibrated with the Tunemix mixture (Bruker Daltonic). The mass accuracy was better than 5 ppm. Spectra were recorded for 5 μmol/L protein in a MeCN/

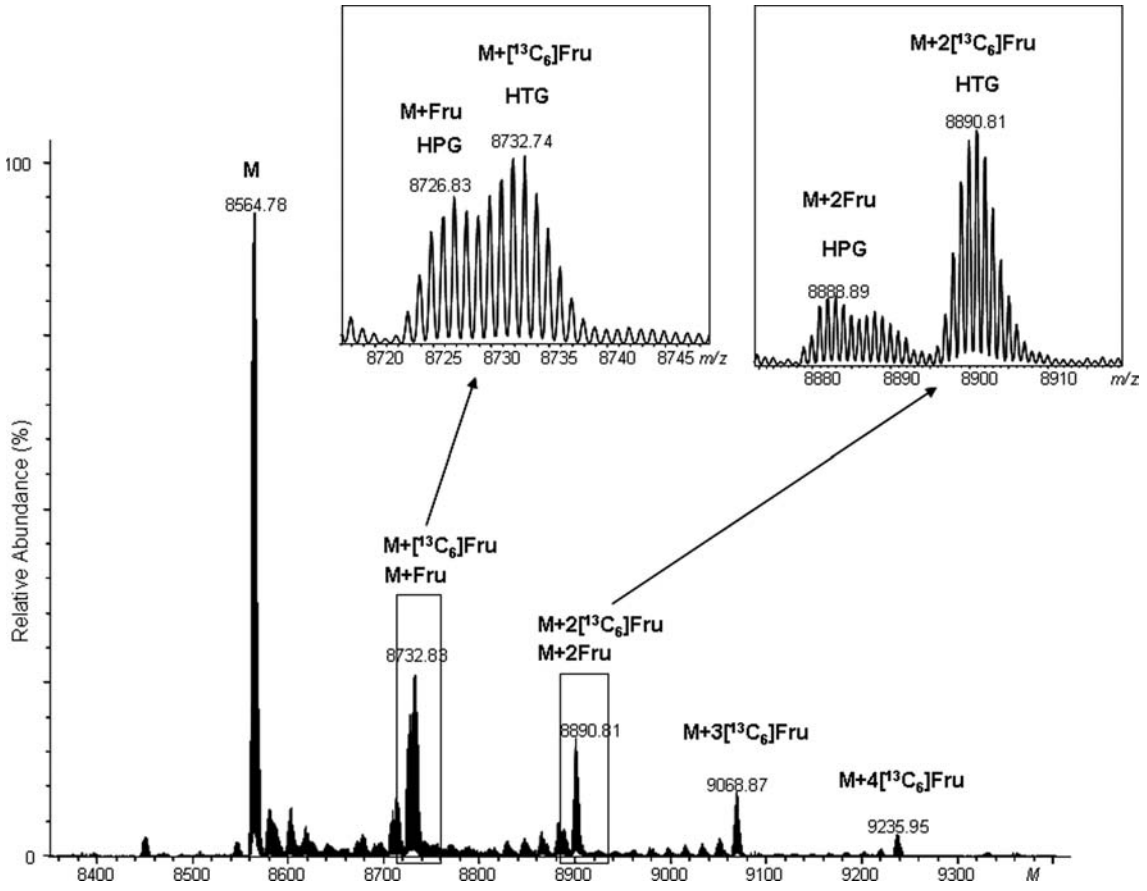

Figure 2. Deconvoluted ESI-MS spectrum of the mixture of ubiquitin modified thermally using [$^{13}C_6$]glucose and under high pressure (800 MPa) using standard glucose.

H_2O/HCOOH mixture (50:50:0.1 v/v/v). The sample was infused at a flow rate of 3 μL/min. The instrumental parameters were as follows: scan range, m/z 300−2500; drying gas, nitrogen; temperature of drying gas, 200 °C; potential between the spray needle and the orifice, 4.5 kV; source accumulation, 0.5 s; ion accumulation time, 0.5 s. The obtained mass spectra were analyzed using Bruker Data Analysis (Bruker Daltonic) software.

RESULTS AND DISCUSSION

High-Pressure Glycation. The effect of pressure on the Millard reaction between the model protein (ubiquitin) and a carbohydrate (glucose) was investigated. The series of experiments, including incubation of ubiquitin and glucose under high pressure in the range of 0.1−1200 MPa, were performed at isothermal conditions. The level of glycation was analyzed by ESI-MS.

The deconvoluted mass spectra (Figure 1) reveal the signals corresponding to mono- and diglycated ubiquitin, although the spectra are dominated by the nonmodified protein. A control sample was prepared using the same molar ratio of reagents and incubated under atmospheric pressure. The peak corresponding to monoglycated ubiquitin was observed for pressures of 0.1 MPa (atmospheric) and 200 and 400 MPa (Figure 1a−c). The average level of glycation calculated according to eq 1 equals 0.08. The approximate level of glycation of a particular Lys residue was calculated by comparing intensities of ions of protein differing by the number of hexose moieties.

$$\bar{n} = \frac{\sum n^* I_n}{\sum I_n} \quad (1)$$

n is the number of Fru and I_n is the intensity of the ion.

For protein samples incubated under pressure >600 MPa (Figure 1c−g), the signals corresponding to diglycated ubiquitin derivatives were observed. According to the literature, the critical pressure for denaturation of ubiquitin is approximately 600 MPa.[32−34] This may explain the appearance of the doubly modified protein under higher pressure (600−1200 MPa). The average level of modification was also calculated for 600 and 800 MPa pressures as 0.083 and 0.25, respectively. A further increase in pressure did not result in incorporation of another hexose moiety. The incubation of ubiquitin and glucose at 1000 MPa led to an additional modification, resulting in a 390.32 Da mass increase, which we were not able to identify accurately.

In Figure 2, the ESI-MS spectrum of the mixture of ubiquitin modified thermally using [$^{13}C_6$]glucose and by a high-pressure (800 MPa) using standard glucose is presented. The signals corresponding to mono- and diglycated ubiquitin confirm the presence of protein modification resulting from the reaction with both labeled and unlabeled glucose. The same experiments were conducted to compare the level of glycation under atmospheric and high pressure (800 MPa), using regular and [$^{13}C_6$]glucose, respectively.

In contrast to the results obtained for a high-temperature glycation using the same molar ratio of reagents as described previously,[27] the application of a high pressure has minor influence on the degree of glycation. However, after the high-pressure treatment, we observed additional signals in the MS spectra that were not observed after thermal treatment. We

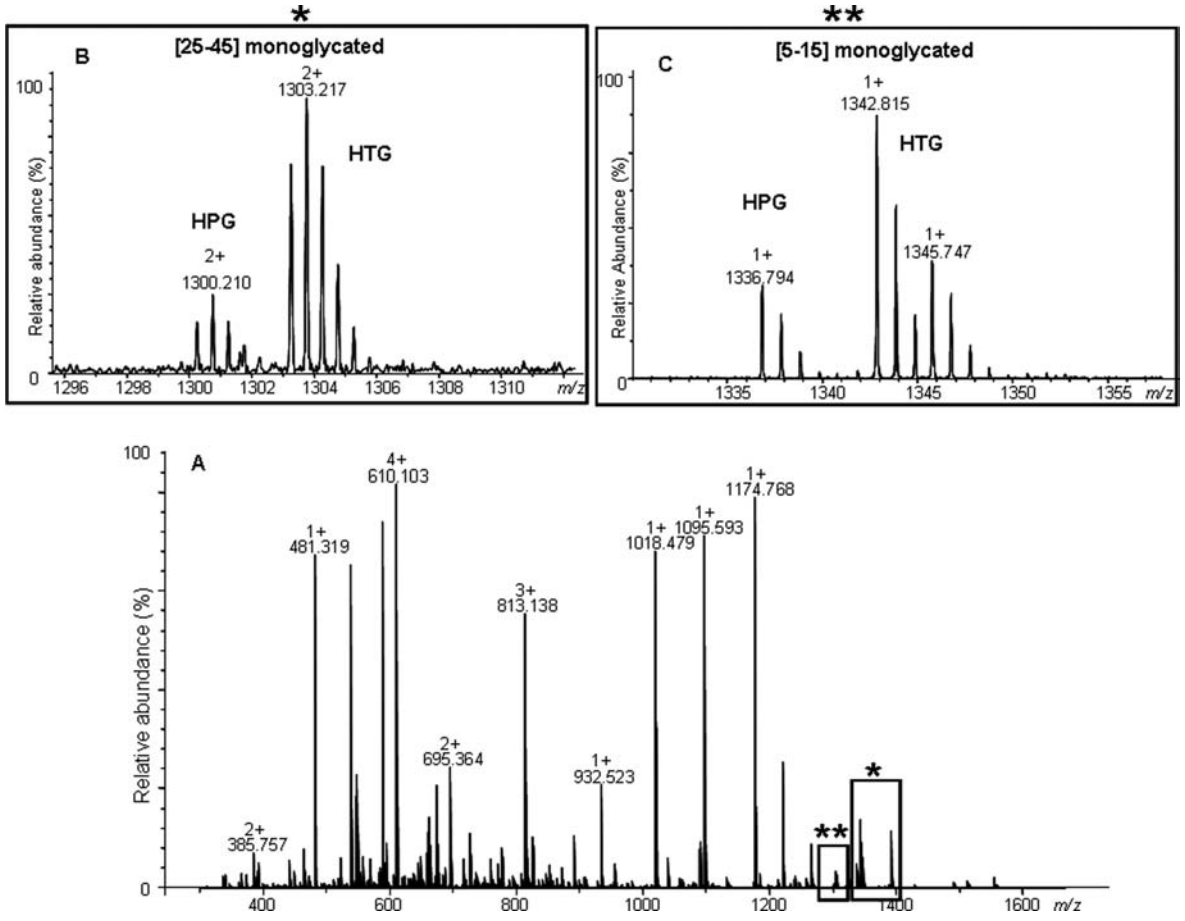

Figure 3. ESI-MS spectrum of the mixture of hydrolysates of ubiquitin glycated thermally (HTG) and under pressure (HPG, 800 MPa).

were not able to identify these byproducts. Further experiments are still needed to characterize these compounds and their mechanism of formation.

The regioselectivity of glycation of lysine moieties in ubiquitin was evaluated by enzymatic hydrolysis of the modified protein (incubated under pressure of 800 MPa) by pepsin followed by a direct ESI-MS measurement. Pepsin is a nonspecific protease, with the preference for peptide bonds at the C-terminus from Phe and Leu.[35] The crude hydrolysate was diluted with MeCN and then analyzed by ESI-MS. The glycation under high temperature and/or high pressure is relatively nonspecific. In the sequence of ubiquitin, there are seven lysine residues and the N-terminal amino group could be also glycated. Even though there are differences in the reactivity of the particular lysine moieties, every amino group may be glycated to some extent. Therefore, the sample of a glycated protein is an extremely complex mixture. In the analyzed hydrolysate, four peptides containing Amadori products, including residues 59−67, 5−15, 4−15, and 25−45, were found. The ECD fragmentation of modified peptide confirmed their sequence and the modification sites.[27] The analysis of the spectra allowed for identification of the glycated lysine residues as Lys6, Lys11, Lys27, Lys29, Lys33, and Lys63 within the sequences of ubiquitin fragments. The modifications of Lys48 and the α-amino groups, which according to the literature[27] are characterized by the lowest reactivity of all the potential glycation sites in ubiquitin, were not observed. In these studies, we received four identical peptide-derived Amadori products as in the case of thermally glycated ubiquitin.[23,27] Due to a much lower degree of modification under high pressure in comparison to the thermal modification of ubiquitin at the same protein/sugar molar ratio, the number of detected modified peptides was lower because of reduced concentration of glycated ubiquitin.

We tested the levels of glycation after the pressure and thermal treatment using isotopic labeling. High-temperature glycation was performed according to Boratyński's method using [$^{13}C_6$]glucose, whereas ubiquitin glycated under a high pressure was prepared using a standard glucose. The obtained modified proteins were mixed at a 1:1 weight ratio and then hydrolyzed in the presence of pepsin. The mixture of peptic fragments was analyzed directly, without a chromatographic separation, on an Apex-Ultra ESI-MS spectrometer. The same procedure was used to compare the efficiency of the glycation under atmospheric (APG) and high pressure (800 MPa) (HPG) using ubiquitin and glucose and [$^{13}C_6$]glucose, respectively.

The Amadori products obtained by the different treatments can be identified on the basis of mass difference caused by the use of [$^{13}C_6$] glucose. The search for glycated peptides can be performed automatically (in-house-designed spreadsheet) or by a visual inspection, recognizing the pairs of peaks with a defined m/z difference (m/z 6 for +1 ion, 3 Th for +2 ion, etc.). In the spectrum, signals corresponding to mixtures of hydrolysates of thermally and high-pressure glycated ubiquitin are presented. In the expanded range of this spectrum (Figure 3), a pair of signals corresponding to Amadori products 5−15 and 25−45 is shown. A significant difference in the signal intensity corresponding to

the modified peptides was observed. The intensities of signals corresponding to the peptide-derived Amadori products obtained by thermal methods are higher than for the same products obtained under a pressure of 800 MPa. The relative intensity of peaks corresponding to the same fragments containing [$^{13}C_6$]glucose and unlabeled glucose allows for the analysis of the degree of modification of the Amadori products obtained under a high pressure (800 MPa), atmospheric pressure, and thermal glycation. It also makes possible the determination of the distribution of sugar residues in the protein sequence and thus the comparison of the reactivity of individual lysine residues. The results, including only the pairs of modified peptides present after thermal and pressure treatment, are presented in Tables 1 and 2. For ubiquitin glycated according to Boratyński's method, more fragments were found.[23]

On the basis of relative intensities of the peaks we can conclude that the thermal glycation is 4 times as efficient as the glycation under 800 MPa pressure, whereas the glycation under 800 MPa pressure is twice as efficient as incubation at atmospheric pressure (Table 1). The analysis of hydrolysates shows that both thermal and pressure glycation are relatively nonselective.

To summarize, glycation under 800 MPa pressure caused a slight increase in the level of ubiquitin glycation as compared to the atmospheric pressure incubation. Using the same molar ratio in the experiments performed on ubiquitin glycated by Boratyński's thermal method, up to four molecules of sugar moieties can be introduced, in contrast to ubiquitin glycated under pressure, where only a disubstituted protein was obtained. The results of our studies indicate high-pressure processing is a potential method for the preservation of foods, because the analyzed sample treated with a high pressure (<800 MPa) compared with the pressure up to 600 MPa did not cause the formation of unidentified byproducts forming at higher pressure. Moreover, we also noted that the level of glycation of the model protein under high pressure may be compared with the degree of modification under atmospheric pressure for the same time of incubation. In both cases a slight increase of glycation was observed in contrast to thermal glycation. On the basis of the presented results we can conclude that high-pressure treatment, a new method of food preservation enjoying increasing popularity among customers, can reduce the degree of glycation of proteins in comparison to pasteurization. On the other hand, high-pressure processing cannot eliminate a commonly used method of food pasteurization because many advantages of AGEs formed at a high temperature are known, and this area of research is still a matter of dispute.

Remarkable Proanthocyanidin Adsorption Properties of Monastrell Pomace Cell Wall Material Highlight Its Potential Use as an Alternative Fining Agent in Red Wine Production

Ana Belén Bautista-Ortín, Yolanda Ruiz-García, Fátima Marín, Noelia Molero, Rafael Apolinar-Valiente, and Encarna Gómez-Plaza*

Supporting Information

ABSTRACT: The existence of interactions between the polysaccharides of vegetal cell walls and proanthocyanins makes this cell wall material an interesting option for its use as a fining agent to reduce the level of proanthocyanins in wines. Pomace wastes from the winery are widely available and a source of cell wall material, and the identification of varieties whose pomace cell walls present high proanthocyanin binding capacity and of processing methods that could enhance their adsorption properties could be of great interest. This study compared the proanthocyanin adsorption properties of pomace cell wall material from three different grape varieties (Monastrell, Cabernet Sauvignon, and Syrah), and the results were compared with those obtained using fresh grape cell walls. Also, the effect of the vinification method has been studied. Analysis of the proanthocyanidins in the solution after reaction with the cell wall material, using phloroglucinolysis and size exclusion chromatography, provided quantitative and qualitative information on the adsorbed and nonadsorbed compounds. A highlight of this study was the observation that Monastrell pomace cell wall material showed a strong affinity for proanthocyanidins, with values similar to that obtained for fresh grapes cell walls, and a preferential binding of high molecular mass proanthocyanidins, so these pomace cell walls could be used in wines to reduce astringency. The use of maceration enzymes during vinification had little effect on the retention capacity of the pomace cell walls obtained from this vinification, although an increase in the retention of low molecular mass proanthocyanidins was observed, and this might have implications for wine sensory properties.

KEYWORDS: *proanthocyanidins, tannins, cell wall material, grapes, pomace, phloroglucinolysis, size exclusion chromatography*

INTRODUCTION

The properties and characteristics of grape skin and flesh cell wall material (CWM) are closely related to some enological events and some observations concerning phenolic compounds in grapes and wines. In this way, previous studies have demonstrated that the composition and quantity of skin cell walls may determine the mechanical resistance, texture, and ease with which berries are processed, as well as anthocyanin extractability during fermentative maceration.[1,2]

Cell walls (CWs) are composed of polysaccharides, phenolic compounds, and proteins and are stabilized by ionic and covalent linkages. Among the polysaccharides, the presence of hemicellulose, cellulose, and pectins is important, and the last two account for 30−40% of the polysaccharide components of the cell wall.[3]

Cell wall polysaccharides contain hydroxyl groups as well as aromatic and glycosidic oxygen atoms that have the ability to form hydrogen bonds and hydrophobic interactions with some molecules,[4,5] including proanthocyanidins.[6] The existence of CWM−proanthocyanidin interactions may explain some experimental observations such as the decrease in grape proanthocyanidin (PA) extractability as ripening progresses,[7,8] which can be explained as a retention of PAs in the cell wall material,[9−11] and the reduced extractability of PAs during fermentative maceration,[12] which may be related not only to these PAs being retained in the solid parts but also to a substantial proportion of them being adsorbed by the CWM in suspension in the must and finally precipitated during settling. Moreover, some authors have stated that there are differences in the affinity of PAs for the different polysaccharides present in CWs, their affinity for covalently linked pectin being higher than that for xyloglucan and cellulose.[5] This observation may indicate that differences in the CW and PA composition among varieties may be the cause of the varietal differences in PA extractability observed in other experiments.[12]

Another enological practice that may be affected by these interactions is the use of enological tannins. The addition of exogenous commercial tannins to increase their levels in wine is a common practice for several reasons: they may help stabilize color, increase body, mask green characters, etc.[13] Depending on the final objective, they are used in the fermentative or postfermentative phase of winemaking. Their addition during fermentation may result in a large part of these exogenous tannins being eliminated by their interaction with the skin and pulp cell walls present in the must after crushing of the grapes, as reported by Bautista-Ortín et al.[14]

Another point of interest of the capacity of CWs to interact with PAs is their possible use as fining agents. Some red wines

present high levels of astringency and bitterness, due to an excessive extraction of tannins from grapes or an excessive addition of commercial enological tannins,[15] and may need a fining agent to reduce the concentrations of tannins in wines. Traditionally, proteins have been used for fining purposes, due to their high affinity for PAs. Most of the proteins commonly used are of animal origin, such casein, albumin, and gelatin.[16] Lately, those of vegetal origin (Arabic gum, pea protein) are becoming more popular, mainly due to the allergenic properties of some of the animal-derived proteins and the legal obligation to indicate their presence on the label (EU Directive 2007/68/EC November 27, 2007), a fact that may reduce their attraction for consumers. The ability of CWM to bind PAs makes them an interesting object of study for their possible use as new fining agents. Such studies were initiated by Bindon and Smith[17] and Guerrero et al.,[18] who studied the fining action of insoluble fibers prepared from fresh apple and different grape sources and compared them with commercial proteins, reporting that grape fibers may be considered as alternative fining agents for red wines. It is clear that fiber or purified CWM derived from fresh grapes would not be of commercial interest because grapes are a valuable product, but products derived from the pomace obtained after fermentation and devatting might be an interesting way of adding value to this byproduct, as also stated by Bindon and Smith.[17] However, compositional differences among different varieties, the possible compositional changes that flesh, but especially skin CWM may suffer during the fermentation process, and how these changes affect their binding capacity need to be considered. In fact, previous studies have shown that the fermentation process may alter the polysaccharide composition of the CWM, as may do the different treatments used during fermentative maceration as it is the use of maceration enzymes.[19,20] The use of maceration enzymes decreased the uronic acids and total sugar content of the cell wall due to their action on the pectin matrix[20] and that may change the level of CW−PA interactions.

In this study, the ability of purified CWM derived from pomace (from three different varieties and from two different vinification methods) to bind different types of PAs was studied, searching for a source of pomace material with a high adsorption capacity and clear selectivity for high molecular mass proanthocyanidins that could be used to reduce wine astringency.

MATERIALS AND METHODS

Chemicals. Chromatographic solvents were of high-performance liquid chromatography (HPLC) grade, and chemicals were of analytical reagent grade. Acetonitrile, acetone, methanol, ethanol, formic acid, and trifluoroacetic acid were from Merck (Darmstadt, Germany). The phloroglucinol reagent was sourced from Sigma-Aldrich (St. Louis, MO, USA). Sodium acetate was sourced from J. T. Baker (Deventer, The Netherlands). The standards (+)-catechin, (−)-epicatechin, (−)-epicatechin gallate, and (−)-epigallocatechin were obtained from Extrasynthese (Genay, France).

Instrumentation. The HPLC apparatus was a Waters 2695 (Waters, Milford, MA, USA) equipped with a Syrahstem autosampler and a Waters 2996 photodiode array detector.

Grapes and Pomace. *Vitis vinifera* L. cv. Monastrell, Cabernet Sauvignon, and Syrah grapes, cultivated in Murcia (Spain), were sampled at 23.8, 24.8, and 25.6 °Brix, respectively, and with a titratable acidity ranging from 2.9 to 3.3 g/L, expressed as tartaric acid.

Grapes from each of the three cultivars (90 kg) were destemmed and crushed. The crushed grapes were macerated in 100 L stainless steel tanks. Potassium bisulfite (8 g/100 kg grapes) was added. Fermentation was carried out with temperature control (25 °C); fermentations were initiated with Levuline Gala (commercial dry *Saccharomyces cerevisiae* yeast, OenoFrance, Bordeaux, France) inoculated at 10 g/hL. After 10 days of maceration, the wine was pressed at 150 kPa in a 75 L tank membrane press (Hidro 80L, Ausavil, Spain), and the pomace was recovered. The skins from pomace were separated from seeds and other solid parts, and they represented the pomace from the control vinification. Other vinification was carried out with the addition of a commercial enzyme preparation (3 g/100 kg, Enozym Vintage, Agrovin, Spain) just after crushing. The fermentation, pressing conditions, and pomace recovery were as described for the control vinification.

Cell Wall Material. Purified CWM was extracted from *V. vinifera* L. cv. Monastrell, Cabernet Sauvignon, and Syrah fresh skins and from the pomace obtained after 10 days of fermentative maceration. Cell walls were isolated according to the method of De Vries et al.,[21] as adapted by Apolinar-Valiente et al.[22] Briefly, the grape skin tissue or the pomace skin tissue (10 g) was suspended in 15 mL of boiling water for 5 min and then homogenized. One part of the homogenized material was mixed with two parts of 96% ethanol and extracted for 30 min at 40 °C. The raw alcohol-insoluble solids were separated by filtration on paper and extracted again with fresh 70% ethanol for 30 min at 40 °C. The washing treatment with fresh 70% ethanol was repeated several times until no sugars remained in the 70% ethanol phase. Then, the alcohol-insoluble solids (AIS) were washed twice with 96% ethanol and once with acetone and finally dried overnight under an air stream at 20 °C. The composition of the cell walls can be found in the Supporting Information (Figures S1−S4).

Proanthocyanidins Used in the Interaction Studies. Two purified PA fractions from ripened grape skin (sPA) and seed (sdPA) were selected for the experiment as well as two commercial samples, a skin-derived (T1) and a seed-derived (T2) enological tannin. The purity of the commercial tannins was estimated spectrophotometrically following the method of Riberau-Gayon et al.[23] after acid hydrolysis of the samples.

For the purified fractions, *V. vinifera* L. cv. Monastrell grape berries were used as the source material for grape skin and seed proanthocyanidins. A random sample (1 kg) was collected at technological maturity. Grape berries were kept at −20 °C until processed. For the proanthocyanidin isolation and purification, the skins and seeds were separated from the berry mesocarp and rinsed with distilled−deionized water, and the intact tissues were extracted in covered Erlenmeyer flasks with 2:1 acetone/water at room temperature for 24 h. To minimize proanthocyanidin oxidation, solutions were sparged with nitrogen and the extraction was carried out in the dark. Following extraction, the extract was concentrated under reduced pressure at 35 °C to remove acetone and then lyophilized to a dry powder.

The crude proanthocyanidins were purified using Toyopearl TSK HW 40-F size exclusion media (Sigma-Aldrich). The column (400 × 26 mm) was equilibrated with 1:1 MeOH/water containing 0.1% (v/v) trifluoroacetic acid. The proanthocyanidin powder was dissolved in a minimum amount of this mobile phase and then applied to the column. The column was then rinsed with 5 column volumes of the mobile phase to remove carbohydrate and low-molecular-weight flavan-3-ol monomer material. The proanthocyanidins were then eluted with 3 column volumes of 2:1 acetone/water containing 0.1% (v/v) trifluoroacetic acid. The eluent was concentrated under reduced pressure at 35 °C to remove acetone and then lyophilized to a dry powder.

For fractionation, the method proposed by Kennedy and Taylor[24] was used. Grape skin proanthocyanidin samples (2 g each) were dissolved in 50 mL of MeOH/water/formic acid (49.8:49.8:2.4) and quantitatively applied to a Sephadex LH-20 column (400 × 26 mm, Sigma-Aldrich) equilibrated with MeOH/water/formic acid (49.8:49.8:2.4). The column was then washed sequentially using different solvent systems and volumes. Eluted proanthocyanidin fractions were collected into test tubes. The fractions were rotary evaporated, lyophilized to dryness, and stored at −80 °C. One purified fraction from seed and another from skin were chosen for the experiments, on the basis of their quantitative availability and a mean degree of polymerization closer to that of red Monastrell wines.

Binding Reactions between Tannins and Cell Wall Material. Skin or pomace CWM was weighed into 3 mL tubes. CWM samples

DOI: 10.1021/jf503659y
J. Agric. Food Chem. 2015, 63, 620−633

were then combined with the four different proanthocyanidins: those contained in two different commercial enological tannins (a seed-derived and a skin-derived grape tannin) and the two purified skin- and seed-derived proanthocyanidins. They were dissolved in a model solution (12% ethanol at pH 3.6 adjusted with trifluoroacetic acid) to a concentration of 2 g/L. The reaction volume was 2.5 mL, and the CWM was 13 mg/mL. The different samples were shaken at 300 rpm in an orbital shaker at room temperature for 90 min. Each experiment (each tannin solution with each of the three different CWM, isolated from fresh grape skins and from the pomace of the two different vinifications) was made in duplicate and for each variety.

For each reaction, a blank without CWM and a blank without tannin were also included, the latter to monitor any possible desorption of CWM-bound tannin. After the binding reaction, samples were centrifuged at 13000 rpm, and the supernatant was transferred to a new tube. Samples were then dried under vacuum at 35 °C. Recovered tannin was reconstituted in 250 μL of methanol and then analyzed by phloroglucinolysis and size exclusion chromatography (SEC).

Analysis of Proanthocyanidins Using the Phloroglucinolysis Reagent. The proanthocyanidin content of the control sample (2 g/L) or those remaining in solution after the interaction with the CWs was analyzed using the phloroglucinol reagent, according to the method described by Kennedy and Jones[25] with some modifications described below. A solution of 0.2 M HCl in methanol, containing 100 g/L phloroglucinol and 20 g/L ascorbic acid, was prepared (phloroglucinolysis reagent). The methanolic extract was left to react with the phloroglucinolysis reagent (1:1) in a water bath for 20 min at 50 °C and then combined with 2 volumes of 200 mM aqueous sodium acetate to stop the reaction.

HPLC analysis followed the conditions described by Busse-Valverde et al.[26] Samples (10 μL injection volume) were injected on an Atlantis dC18 column (250 × 4.6 mm, 5 μm packing) protected with a guard column of the same material (20 mm × 4.6 mm, 5 μm packing) (Waters). The elution conditions were as follows: 0.8 mL/min flow rate; oven temperature, 30 °C; solvent A, water/formic acid (98:2, v/v); and solvent B, acetonitrile/solvent A (80:20 v/v). Elution began with 0% B for 5 min, linear gradient from 0 to 10% B in 30 min, and gradient from 10 to 20% in 30 min, followed by washing and re-equilibration of the column.

Proanthocyanidin cleavage products were estimated using their response factors at 280 nm relative to (+)-catechin, which was used as the quantitative standard. These analyses allowed determination of the recovery by mass of the total proanthocyanidin content, the apparent mean degree of polymerization (mDP), and the percentage of each constitutive unit. The mDP was calculated as the sum of all subunits (flavan-3-ol monomer and phloroglucinol adducts, in moles) divided by the sum of all flavan-3-ol monomers (in moles).

The percentage of conversion was calculated gravimetrically from the percentage of conversion of tannins to known proanthocyanin subunits.

To determine the naturally occurring proanthocyanidin monomers (catechin and epicatechin), the methanolic extract was analyzed without reaction with the phloroglucinolysis reagent.

Analysis of Proanthocyanidins by Size Exclusion Chromatography. An adaptation of the method described by Kennedy and Taylor[24] was used for SEC. The method used two PLgel (300 × 7.5 mm, 5 μm, 500 (effective molecular mass range of up to 4000 using polystyrene standards) by 100 Å (effective molecular mass range of 500−30000 using polystyrene standards) columns connected in series and protected by a guard column containing the same material (50 × 7.5 mm, 5 μm), all purchased from Polymer Laboratories (Amherst, MA, USA). The amount of sample injected was 40 μg. The isocratic method used a mobile phase consisting of *N*,*N*-dimethylformamide containing 1% glacial acetic acid, 5% water, and 0.15 M lithium chloride. The flow rate was maintained at 1 mL/min with a column temperature of 60 °C, and elution was monitored at 280 nm.

The SEC peak area results were calibrated to the gravimetric value (A_{280}/mg gravimetric) for each tannin type.

Statistical Analysis. All of the statistical analyses were made using Statgraphics Centurion XVI (Statpoint Technologies Inc., Warranton, VA, USA).

RESULTS AND DISCUSSION

Proanthocyanidins Used in the Experiment. Because it has been suggested that the composition, molecular size, conformational mobility, and shape influence the interactions between tannins and CWM,[4,5] PA samples with different characteristics were used for this study. We have worked with two commercial samples, a skin-derived (T1) and a seed-derived (T2) commercial tannin, and the results were compared with a purified PA fraction from ripened grape skin (sPA) or seed (sdPA). The phloroglucinolysis assay showed that the lowest conversion was observed in T1 and the highest in seed PA, with a conversion of 72% (Table 1). These results were expected because higher conversions are always found when working with seed tannins compared with skin.[7]

It is well-known that grape PAs slightly differ in their composition according to their origin in the berry. Seed proanthocyanidins contain greater levels of flavan-3-ols esterified to gallic acid, they generally have a lower degree of polymerization (mDP) than those from skins, and no trihydroxylation of the B ring has been observed.[25,27] However, and contrary to expectations, the mDP of the skin-derived commercial enological tannin was very low considering its origin (skin tannin sample), with values very similar to those obtained for seed-derived commercial sample. Higher mDPs were observed for the purified samples, the highest being found in sPA.

The maximum galloylation percentage was observed in the seed-derived tannins, especially in the purified samples, and lower values were found in the skin-derived samples, the lowest values in T1.

With regard to the subunit composition, commercial samples differed from purified samples mainly in the lower quantities of terminal units and higher percentage of extension epicatechin. Comparison of both purified samples showed the main differences were in the percentages of epicatechin gallate, both terminal and extension subunits (as was expected, given the higher percentage of galloylation) and the absence of epigallocatechin subunits in the seed samples. The composition of T1, labeled as skin tannin, showing a low mDP, relatively high galloylation percentage, and low percentage of epigallocatechin, may indicate that this sample is really a mix of skin and seed tannins.

The tannin samples and purified fractions were also analyzed using SEC. Given the relatively low conversion percentage of the phloroglucinolysis study, the use of SEC also allows the fraction that was not depolymerized by the phloroglucinolysis assay to be studied. This technique provides complementary information concerning the adsorption rate and molecular mass distribution of the tannins.

The profiles are shown in Figure 1, and differences were observed among the different samples. For the study of the molecular mass distribution, and unlike other studies that reported mass distribution information as a cumulative (% volume elution) molecular mass, in the current study the mass distribution is reported as elution time and the SEC chromatograms were divided in three areas representing the high (those eluting from minute 10 to 11.8, F1 (see Table 2)), medium (from 11.8 to 13.6 min, F2), and low molecular mass PAs (from 13.6 to 15.0 min, F3). The distribution of the eluted area showed that sPA and sdPA had the largest percentages of areas eluting at the first elution time range (67.8 and 66.9%, respectively), indicating a higher percentage of high molecular mass PAs, whereas in T1 and T2 the area in this fraction of elution time was lower

[c]This concentration corresponds to the real tannin content of a 2 g of the commercial sample T2, determined by acid hydrolysis.

(37.5 and 36.2%), which is in agreement with the differences in mDP. At the range of time between 11.8 and 13.6 min, corresponding to medium molecular mass PAs, the values were, this time, higher for T1 and T2 (48.2 and 49.3%) than for sPA (28.8%). Again, a substantial variation was observed at elution time from 13.6 to 15 min (low molecular mass PAs), the relative area being very low for sPA and sdPAs (1.7 and 0.7%) and higher for T1 and T2 (12.5 and 13.0%).

Effect of the Addition of the Different Cell Wall Materials to Model Solutions Containing the Different Proanthocyanidin Samples. The proanthocyanidin samples (commercial tannins and purified fractions) were combined with the purified skin CWM (gCW) from Monastrell, Cabernet Sauvignon, and Syrah grapes and their corresponding CWM from the pomace obtained after a control vinification (cmCW) or a vinification where a maceration enzyme was used (emCW). The different CWs were suspended in model solutions to determine the effect of the interaction in terms of PA concentration, composition, and molecular mass distribution. The effect of CWM additions on PAs was determined by observing the changes in the PAs that remained in solution compared with a control (Tables 3− 5 and Figures 2−5).

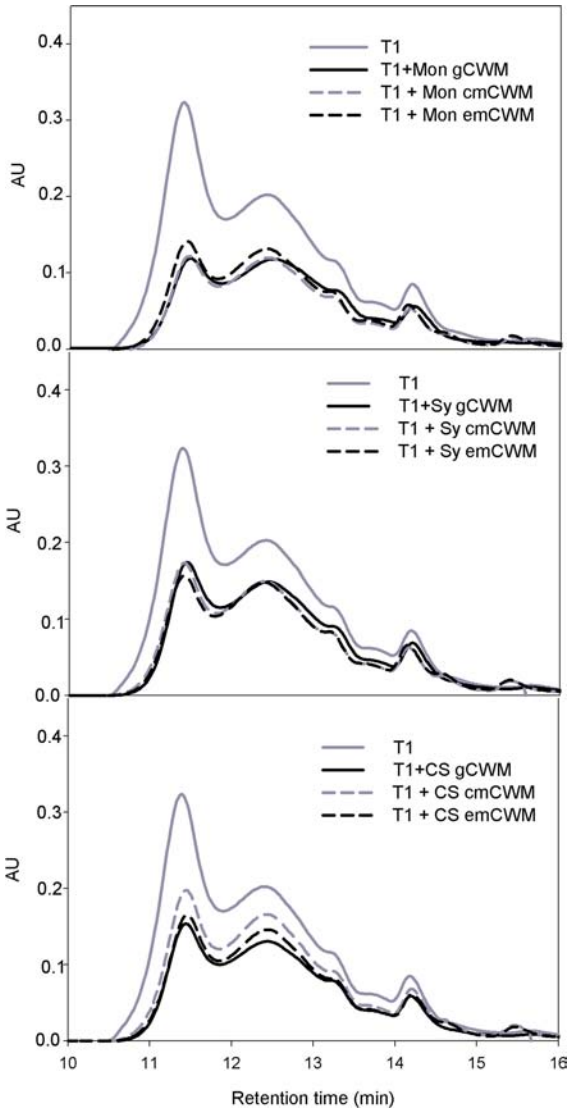

Figure 2. Comparison of the size exclusion chromatography of the commercial enological tannin T1 in solution and that for this remaining after the addition of different CWMs (gCWM, CWM from the skin of fresh grapes; cmCWM, cell wall material from the pomace obtained after a control vinification; emCWM, cell wall material from the pomace obtained after a vinification where a maceration enzyme was used).

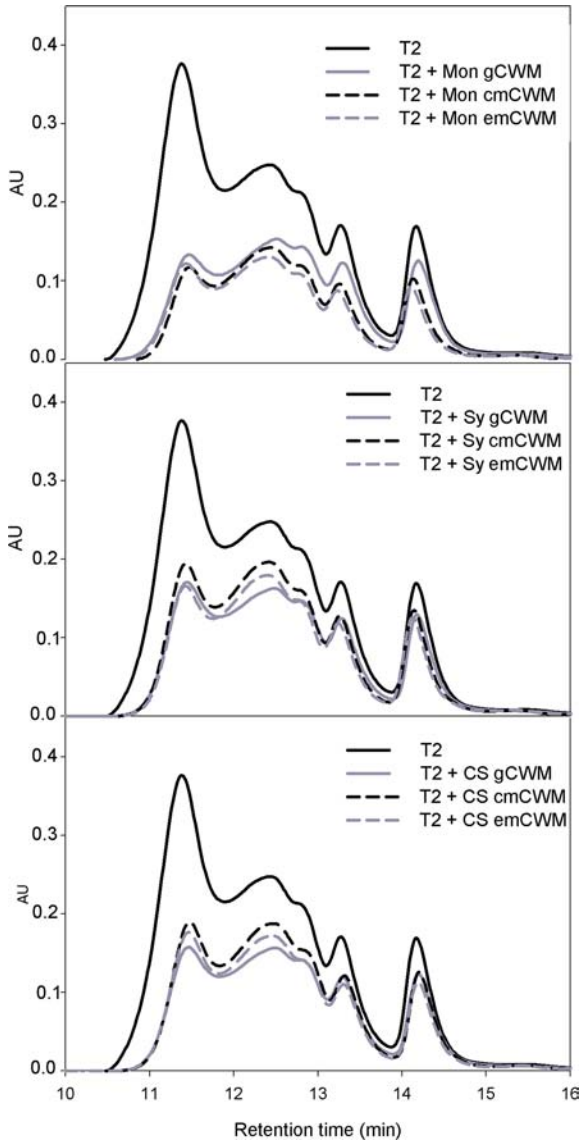

Figure 3. Comparison of the size exclusion chromatography of the T2 in solution and that for this remaining after the addition of different CWMs (gCWM, CWM from the skin of fresh grapes; cmCWM, cell wall material from the pomace obtained after a control vinification; emCWM, cell wall material from the pomace obtained after a vinification where a maceration enzyme was used).

The results of the phloroglucinolysis analysis showed that the addition of the different CWMs to the suspension containing the tannins produced, in all cases, a decrease in the quantity of tannins in the solution; that is, all of them could act as fining agents, reducing tannins in the wine. For Monastrell samples, this decrease ranged from 27.9% for the solution containing sdPA and cmCWM to 60.8% for sPA and cmCWM. The differences in the adsorption capacity of Monastrell fresh skin CWs compared with those of the pomace were not very large, being only slightly lower for cmCW with T1, T2, and sdPA. The data shown in the Supporting Information indicate that the percentual carbohydrate composition did not significantly change between fresh skin CWs and pomace CWs. In Monastrell CW samples, only the use of a maceration enzyme promoted a small decrease in the uronic acid proportion of the pomace CWs, the other sugars barely changing. Guerrero et al.[18] also reported that pomace CWs presented a chemical and polysaccharide composition quite similar to that of fresh grapes, although they seemed to present larger dry volume per unit mass and an increased expansion in hydroalcoholic solution. The potential contribution of an expanded surface area of the hydrated fiber, and therefore greater surface interaction, might well contribute to the high affinity of pomace CWs for PAs.

The adsorption capacity of Monastrell emCWs was always similar to that of fresh skin CWs, even when pectins (measured as uronic acids) were present at lower proportion. Le Bourvellec et al.[28] stated that the elimination of pectins decreased the apparent affinity values of cell walls and PA. However, the increase in cell wall porosity after pectin elimination may enhance the encapsulation of PA within a more open network and explain the very similar behaviors of gCW and emCWs.

Maximum adsorption was observed for purified skin PA samples, with lower values being observed for purified seed PA, the adsorption values of which were similar to those of the commercial samples, which, in turn, showed very similar behavior. Bindon et al.,[29] working with solutions containing different

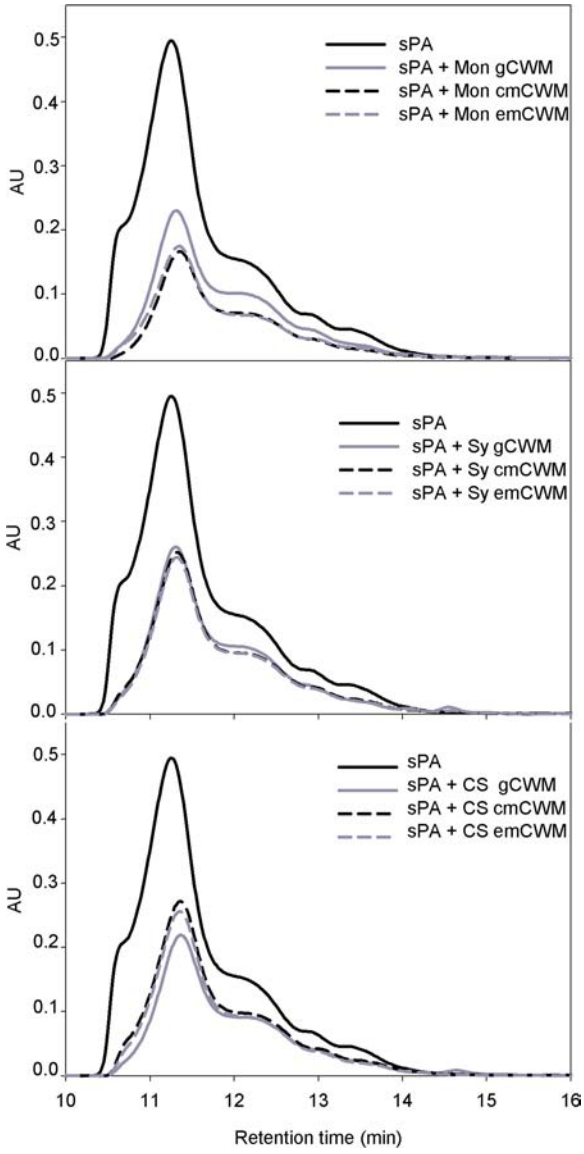

Figure 4. Comparison of the size exclusion chromatography of the purified skin tannin (sPA) in solution and that for this remaining after the addition of different CWMs (gCWM, CWM from the skin of fresh grapes; cmCWM, cell wall material from the pomace obtained after a control vinification; emCWM, cell wall material from the pomace obtained after a vinification where a maceration enzyme was used).

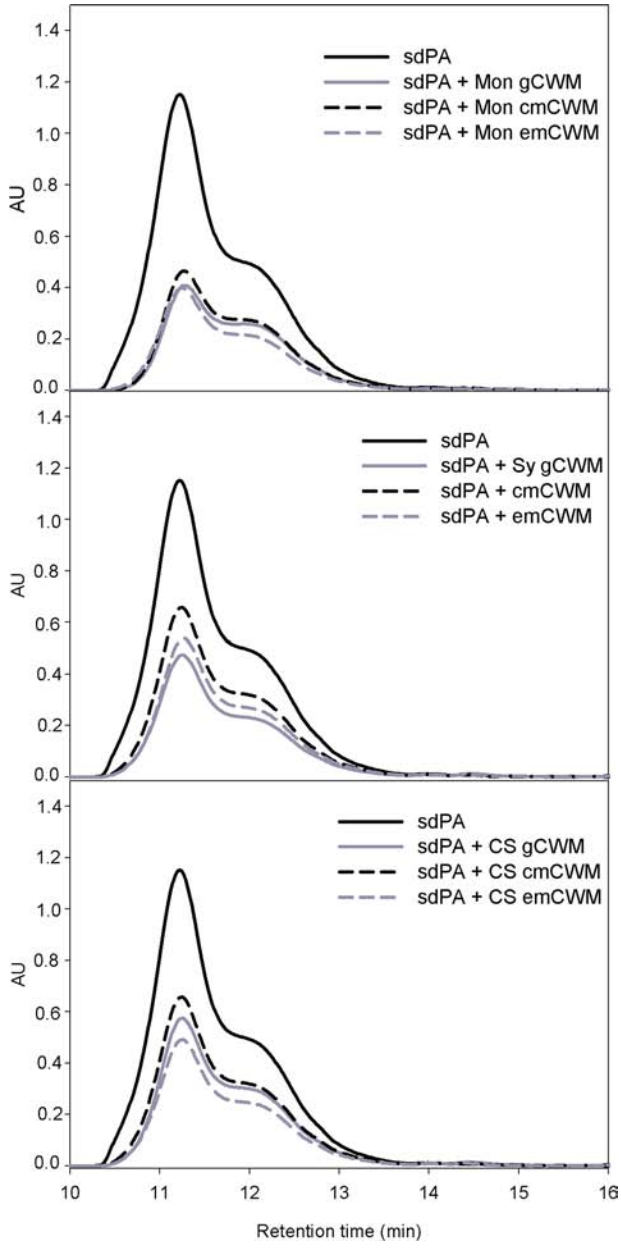

Figure 5. Comparison of the size exclusion chromatography of the purified seed tannin (sdPA) in solution and that for this remaining after the addition of different CWMs (gCWM, CWM from the skin of fresh grapes; cmCWM, cell wall material from the pomace obtained after a control vinification; emCWM, cell wall material from the pomace obtained after a vinification where a maceration enzyme was used).

percentages of skin and seed PAs, found that the total PA amount bound to flesh CWM gradually declined as the proportion of seed PA in the solution increased (from 57% removed for a solution containing 100% skin PA to 47% removed for a solution containing 100% seed PA), although, contrary to our results, they did not find any pattern of PA mass decrease when using skin CWs. The differences in adsorption between skin and seed PA are probably related to their different compositions. Haslam[6] reported that interactions between PAs and CWM increase as mDP increases (because each additional monomer increases the number of reactive sites, allowing the tannin molecule to bind simultaneously to more than one site in the cell wall), whereas the presence of epigallocatechin subunits in the skin tannin composition may also contribute to the differences because epigallocatechin has an additional hydroxyl group on ring B that provides another site for hydrogen bonding to occur.[5]

The percentage of galloylation (%G) slightly decreased in all of the nonadsorbed tannins (except in the case of the interaction of the pomace CWM with T2, where a small increase was observed). The mDP also tended to decrease in the fraction of nonadsorbed tannins, except for the samples where purified seed PA was used, when almost no changes were observed, and in the samples where skin PA was used, when the mDP of the remaining tannins slightly increased. In the case of purified samples, where large quantities of high molecular mass tannins are present, saturation of the available binding sites on the CWM surface might occur, whereas smaller PA molecules might still penetrate the interior of the CWM structure, therefore increasing the mDP of the remaining tannins, as also stated by Bindon et al.[11]

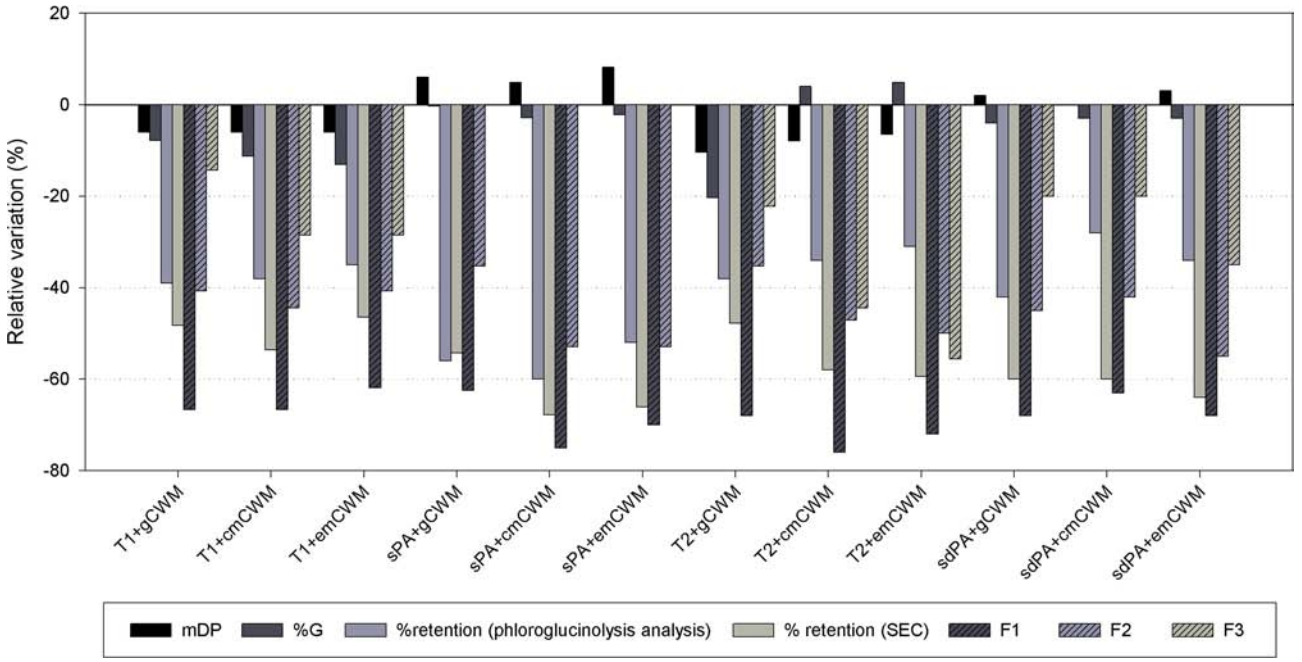

Figure 6. Percent changes in the main parameters when Monastrell CWs are used (T1, commercial enological tannin from grape skins; T2, commercial enological tannin from grape seeds; sPA, purified grape skin proanthocyanidin; sdPA, purified grape seed proanthocyanidin; gCWM, CWM from the skin of fresh grapes; cmCWM, cell wall material from the pomace obtained after a control vinification; emCWM, cell wall material from the pomace obtained after a vinification where a maceration enzyme was used; mDP, medium degree of polymerization; %G, percentage of galloylation; F1, F2, and F3, percentage of area of the size exclusion chromatogram corresponding to high (from 10 to 11.8 min), medium (from 11.8 to 13.6 min), and low (from 13.6 to 15 min) molecular mass PAs).

The terminal and extension subunits changed very little; a decrease in terminal epicatechin was always observed in sPA, concomitant with the increase in mDP.

When Cabernet Sauvignon CWM (Table 4) was used, the results showed that gCWM, in general, retained similar or larger quantities of tannins than Monastrell gCWM, which can be attributed to this variety presenting the highest content in pectins in their CWs, but this retention significantly decreased when the pomace CWM of this variety was used. The losses in sugars and pectins observed when the fresh skin CWs and the pomace CWs of this variety are compared might explain these differences. Also, another key structural difference that could reduce PA adsorption to Cabernet Sauvignon pomace cell walls could be, as suggested by Bindon et al.,[10] the endogenously higher concentrations of insoluble PA and lignin and lower cell wall-bound protein than in fresh skin cell walls. These differences may confer reduced flexibility and porosity to the pomace cell walls. In the case of T1, the retained quantities decreased by almost 50% compared with those retained in gCWM. The decrease was less pronounced when sPA was used, observing, in general, a higher adsorption of tannins when skin PAs (both commercial and purified) were used, similarly to that described for Monastrell. The behaviors of mDP and galloylation were exactly the same as those observed in Monastrell CWM, the observed increases in mDP in the nonadsorbed sPA being even higher.

In the case of Syrah, the retention of PAs on gCWM was the lowest of the three varieties studied, perhaps because the CW pectin content was the lowest and the cellulose content the highest (see Supporting Information, Figure S3). However, the adsorption capacities of gCWM and pomace CWM were almost the same, as in Monastrell, only a small decrease being observed (although much lower than that observed in Cabernet Sauvignon pomace CWM). The effect on mDP and the percentage of galloylation of the remaining PAs in solution was similar to that previously described for the other varieties, as was the higher affinity for skin PA samples.

These results suggest that, regarding binding capacity, important varietal differences exist and Monastrell pomace CWs could be the more interesting for reducing tannins and astringency in wines than pomace from other varieties.

The results of SEC analysis, comparing the PA profiles before and after the addition of CWM, are shown in Figures 2−5, whereas a comparison of the percentages of retention measured in the phloroglucinolysis analysis and SEC, including the retention of high, medium, and low molecular mass PAs, is shown in Figures 6−8.

As can be seen, the results were quite coincident with the phloroglucinolysis analysis, although the retention measured by SEC was greater than that observed by phloroglucinolysis for all of the varieties and all of the different PAs. This was probably due to the presence in the samples of some type of structures, such as oxidized tannins, that are not depolymerized by the phloroglucinol reagent but are measured by the SEC analysis.[30] This chromatographic analysis also showed that the intermediate (those eluting in SEC between 11.8 and 13.6 min) and especially the high molecular mass tannin fractions (those eluting from 10 to 11.8 min) were preferentially removed in all cases.

From a study of each individual tannin, the results for T1 (Figures 2 and 6) indicate that the highest retention was reported for Monastrell CWs. For Syrah (Figures 2 and 7) and Cabernet Sauvignon (Figures 2 and 8) CWs, the quantities of adsorbed tannin were lower when the pomace CWs were in the solution than with that of fresh grapes CWs and lower than that reported for Monastrell.

With regard to T2 (Figure 3), the behavior of Monastrell CWs was very similar to that reported for T1, the CWM of this variety

showing the highest adsorption compared with the results obtained in Cabernet Sauvignon and Syrah, the pomace CWs retaining even more tannins than fresh skin CW. For Syrah and Cabernet Sauvignon, the differences between gCWs and emCWs were almost nonexistent, whereas adsorption was lower in cmCWs.

DOI: 10.1021/jf503659y
J. Agric. Food Chem. 2015, 63, 620−633

In the purified samples, sPA (Figure 4) was highly retained by Monastrell CWs, reaching 67 and 65% in cmCW and emCWs. Also, high values of total adsorption were observed for Syrah and Cabernet Sauvignon CWs, the values being higher than that obtained with commercial tannins and, now, differences in the adsorption capacity between gCW and pomace CW were very small, especially in Syrah.

In the SEC profiles for sdPA (Figure 5), and contrary to the results observed in the phloroglucinolysis analysis, large differences were observed between varieties. The retention in Monastrell reached 64% for emCW, whereas for Cabernet Sauvignon the maximum value was only 38%, the use of pomace CWs leading to a retention of only 27 and 29%. Syrah showed intermediate values. It is clear that the SEC profiles of T1 and T2 and their behaviors were quite similar with regard to the retention properties (similar characteristics, especially the mDP, were observed in both commercial tannins, despite their different origins), whereas for purified samples, sPA and sdPA, behaved clearly differently, the higher adsorption being observed for sPA, as also found by Bindon et al.[29] for flesh CWs.

The results obtained by SEC are quite similar to the results observed with the phloroglucinolysis analysis and confirm that CWs from Monastrell pomace could be a really interesting material for wine tannin fining, being very effective in binding both nonpurified commercial tannins and native skin and seed tannins.

With regard to the molecular mass distribution of the retained tannins, the highest retention was always observed in the high molecular mass PAs, especially with Monastrell CWs, for which values of >70% were obtained for sPA + cmCW and T2 + cmCW. Bindon et al.[29] also found that for a 100% skin PA, the greatest PA-CW adsorption occurred in the higher molecular mass range, with less material removed by CWM in the lower molecular mass range. In general, emCW retained, percentually, lower quantities of high molecular mass PAs than gCW, perhaps due to a more linear structure, with slightly more affinity for low molecular mass tannins. Bindon and Smith[17] also observed that lower molecular PAs were preferentially bound when the Cabernet Sauvignon fibers were used.

These observations and differences can be much more clearly observed using a multivariate analysis of variance, which allows the different affinity properties of CWs (measured as the percentage of retained PAs calculated by phloroglucinolysis or SEC analysis) to be observed separately, taking into account their varietal or technological (fresh or processed skins) origin (Supporting Information, Figures S5 and S6). Monastrell CWs generally retained the highest quantities of PAs, especially when observed by SEC. It could be hypothesized that Monastrell CWs, due to their composition, have a higher capacity to bind oxidized tannins, which would explain the differences in percentage of retention observed between the phloroglucinolysis analysis and SEC. This would also explain why differences between varieties are much higher when the binding capacity is measured by SEC.

The same argument regarding varieties could be applied to the type of CW. Considering all of the data and for all of the varieties, gCWM showed a high PA affinity, in both phloroglucinolysis and SEC analyses. On the other hand, a large difference was observed in the binding capacity of emCWs, depending on the type of analysis. They were seen to retain a high quantity of PAs when the nonadsorbed PAs in solution were analyzed by SEC and much lower quantities when they were determined by the phloroglucinolysis analysis, which suggests that emCWs present a high affinity for oxidized and other nondepolymerized proanthocyanidins, which cannot be measured by the phloroglucinolysis analysis.

Finally, a discriminant algorithm was used to identify the specific variables potentially useful as predictors of discrimination between the three varieties and between the origins of the CWs. The discriminant analysis was based on a backward step algorithm (Table 6 and Figure 9). For the discrimination of varieties, the analysis was conducted with an *F*-to-enter = 2. This strategy resulted in a considerable reduction in the dimensionality of the information, because it led to the selection of very few variables that can be considered as the most important for the differentiation of the samples and which could indicate whether the various types of CWs could really be classified as different. When the variables were used to classify the CWs according to their varietal origin, a 72% correct classification was obtained. CWs from the Monastrell variety were well classified, only one sample being misclassified. CWs from Cabernet Sauvignon and Syrah showed slightly poorer separation, which is coincident with the experimental results, Monastrell CWs showing higher affinity for PAs than the CWs from Cabernet Sauvignon or those from Syrah grapes. The backward discriminant analysis allowed this separation to be reached with only two variables, the percentage of PA adsorbed to the CWs, measured as the percentage of decrease in the SEC area, and the mDP of the nonadsorbed tannins.

Table 6. Discriminant Functions Used To Predict to Which Group the Observations Belong

standardized coefficient	function 1	function 2
Variety		
SEC area	1.24	−0.22
mDP	0.94	0.84
CW Origin		
mDP	1.03	0.30
phloroglucinolysis area	0.75	1.02
% of retention at 90% elution time	−0.84	0.79

The classification obtained according to the technological origin of CW (from fresh skins or pomace from control or enzyme vinifications) was not very good (as low as 63%), indicating that the differences in their adsorption properties were not very different. The mDP of the nonadsorbed tannins, the percentage of adsorbed tannins measured by the area of phloroglucinolysis analysis, and the retention of the low molecular mass tannins were the variables used to discriminate the samples.

In conclusion, this study has confirmed that pomace CWs, a byproduct of the enology industry, present a high affinity for PAs and has demonstrated that this was especially remarkable in those of Monastrell grapes, for which pomace CWs present a very high adsorption capacity of all types of PA structures but especially for those of high molecular mass, and so their use in wines could reduce astringency. However, pomace cell walls present a slightly higher affinity for low molecular mass PAs than CWs from fresh skin grapes, and this might have implications for wine sensory properties such as astringency and bitterness and must be studied in greater depth. Moreover, and given that Guerrero et al.[18] observed that, in general, grape fibers not only reduced PAs but also reduced anthocyanins, total phenolics, and wine color density, to confirm the potential use of Monastrell pomace cell walls as an alternative fining agent to proteins, their role in the retention of other phenolic and volatile compounds in

Preparation and Characterization of Debranched-Starch/Phosphatidylcholine Inclusion Complexes

Weiwei Cheng, Zhigang Luo,* Lin Li, and Xiong Fu*

Carbohydrate Lab, College of Light Industry & Food Sciences, South China University of Technology, Guangzhou 510640, China

ABSTRACT: In this study, debranched-starch/phosphatidylcholine inclusion complexes were prepared. The effect of reaction parameters such as reaction temperature, reaction time, and addition amount of phosphatidylcholine on the phosphatidylcholine payload and inclusion rate was investigated. The phosphatidylcholine payload and inclusion rate prepared under the optimal conditions were 106 mg/g and 84.8%, respectively. The formation of debranched-starch/phosphatidylcholine inclusion complexes was confirmed by the results of XRD and FT-IR. Furthermore, the molecular, cluster, and fractal structures of the complexes were investigated using ^{13}C CP/MAS NMR and SAXS. The results indicated that the inclusion complexes were formed by hydrophobic interactions between alkyl chain of phosphatidylcholine and debranched-starch helix cavity. The complexes possessed a mass fractal structure, and a semicrystalline structure with a Bragg distance of 19.04 nm formed. After complexation, the stability of phosphatidylcholine was significantly improved, and phosphatidylcholine of the complexes can be gradually released with pancreatin treatment. This study revealed that debranched-starch can be used as an effective carrier of phosphatidylcholine for the purpose of improving its stability.

KEYWORDS: *debranched-starch, phosphatidylcholine, complexes, preparation*

INTRODUCTION

Phosphatidylcholine is a naturally occurring mixture with diverse fatty acid side chains such as stearic, oleic, and palmitic acids.[1,2] It is the best known kind of phospholipids.[2] Because of its outstanding physiological functionalities, such as slowing aging, enhancing memory, reducing blood fat, and preventing diabetes, and its surface activity, phosphatidylcholine has been widely used in food, pharmaceutical, and cosmetic industries.[3−5] However, due to its rich content of unsaturated fatty acids, phosphatidylcholine is sensitive to heat and light, and very easy to oxidize during manufacture, storage, and consumption, which restricts its applications in industries. Up to now, there are few reports on improving the stability of phosphatidylcholine.

Amylose, one of the two main fractions of starch, is a predominantly linear polymer, which is composed of α-D-glucose mainly linked by α-1,4 linkages. In the presence of ligands such as alcohols,[6] aroma compounds,[7] and lipids,[8] amylose can undergo a conformation change resulting in a single, left-handed helix that has a hydrophilic surface and hydrophobic inside helical channel. Hence, amylose can be used as a wall material to encapsulate hydrophobic guest molecules to form inclusion complexes, and meanwhile amylose single helices were arranged to form a V-type crystalline structure known as V-amylose.[9] Although the ability of amylose to form inclusion complexes with a wide variety of molecules has been known for several decades, only recently has amylose been systematically studied as a possible vehicle for bioactive compounds.[10−12] In view of the degradability and availability of amylose, the application of amylose as a food-grade delivery material has become a research hotspot in recent years.[13] Conventionally, amylose is obtained by separation of the two components of starch, mainly by methods of aqueous dispersion, aqueous leaching, selective retrogradation, or alcohol precipitation.[14] However, amylose obtained by these methods is often costly because of the complicated production process and the consumption of organic compounds such as alcohol, *n*-butyl, and pentanol.

In this study, to reduce the cost and achieve industrialization, amylose was obtained by hydrolysis of native potato starch with pullulanase, and the obtained debranched-starch (amylose) was used for the first time as wall material to encapsulate phosphatidylcholine by its single helical to improve the stability of phosphatidylcholine. The effect of reaction temperature, reaction time, and addition amount of phosphatidylcholine on the phosphatidylcholine payload and inclusion rate was investigated. In addition, the obtained debranched-starch/phosphatidylcholine complexes were characterized by X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FT-IR), ^{13}C cross-polarization/magic angle spinning nuclear magnetic resonance (^{13}C CP/MAS NMR), small-angle X-ray scattering (SAXS), and scanning electron microscopy (SEM), and the stability and digestibility properties of the complexes were also studied.

MATERIALS AND METHODS

Materials. Commercial food grade potato starch (amylose content 19.42%) was obtained from Qinghai Weston Co. Ltd. (Qinghai, China). Pullulanase (E.C. 3.2.1.41., activity 1000 ASPU/g) was supplied by Genencor (China) Bio-Products Co. Ltd. (Wuxi, China). One unit of pullulanase activity was defined as the amount of enzyme that liberates one glucose reducing equivalent from pullulan per minute at pH 4.5 at 60 °C. Phosphatidylcholine (phosphatidylcholine >95%, Epikuron 200) was obtained from Lucas Meyer (Hamburg,

Germany) and used without further purification. Pancreatin (8 × USP, from porcine pancreas) was purchased from Sigma-Aldrich (St. Louis, MO). All other chemicals used were of analytical grade.

Preparation of Debranched-Starch. Starch (50 g, dry basis) was mixed with 450 g of water in a 500 mL three necked flask. The slurry was adjusted to pH 4.5 with 0.5 mol/L HCl and gelatinized in a thermostatic water bath at 98 °C with stirring for 1 h. After gelatinization, the mixture was cooled to 60 °C and the debranching reaction was started by adding pullulanase (10 ASPU/g). To completely debranch starch, the solution was incubated at 60 °C, pH 4.5 for 4 h. The thoroughness of the debranched reaction was confirmed by ^{1}H NMR, which can distinguish α-1,6 from α-1,4 linkages of starch according to chemical shifts of 4.7−5.0 ppm for α-1,6 linkages and 5.1−5.4 ppm for α-1,4 linkages.[15,16] According to previous literature,[15,16] when the α-1,6 peak located at 4.7−5.0 ppm disappears altogether, all of the α-1,6 branch linkages are suggested to be completely hydrolyzed. In this study, when potato starch was hydrolyzed by pullulanase at the above reaction conditions, the α-1,6 peak located at 4.7−5.0 ppm disappears altogether, indicating that potato starch has been completely debranched. The hydrolysis percent and blue value of the debranched-starch were determined using the methods of Bruner[17] and Gilbert and Spragg,[18] respectively. Hydrolysis rate and blue value of the debranched-starch made under the above conditions were 15.11% and 1.12, respectively. The debranched-starch solution obtained was stored at 60 °C for further use.

Preparation of Debranched-Starch/Phosphatidylcholine Inclusion Complexes. Different amounts of tetrahydrofuran (10, 15, 20, 25, 30 g) containing 20 wt % phosphatidylcholine were added to the debranched-starch solutions, and after reacting in a thermostatic water bath at a certain temperature (40, 50, 60, 70, 80 °C) for 0.5, 1, 2, 3, and 4 h, respectively, the mixture was slowly cooled to ambient temperature and then stored at 4 °C for 18 h. Samples were centrifuged, washed to remove all tetrahydrofuran with deionized water, and dried in an oven at 40 °C overnight. The recovery of debranched-starch/phosphatidylcholine inclusion complexes is in the range of 35−40 g. The products prepared under the optimal conditions were used for further analysis. As control, a debranched-starch solution sample without phosphatidylcholine was slowly cooled to ambient temperature and then stored at 4 °C for 18 h. The mixture was centrifuged, washed with deionized water, and dried in an oven at 40 °C overnight. The obtained uncomplexed retrograded debranched-starch (URDS) product was used for further analysis.

Determination of the Phosphatidylcholine Payload and Inclusion Rate. The determination of the phosphatidylcholine payload and inclusion rate was done by phosphous molybdenum blue spectrophotometric method.[19] Debranched-starch/phosphatidylcholine complexes (0.5 g) and URDS (0.5 g) were accurately weighed and mineralized by HNO_3 and $HClO_4$, respectively. The mineralized liquid was transferred to a 50 mL flask and diluted with distilled water to volume. After being diluted to an appropriate concentration, the phosphous content of the complexes was determined by the phosphous molybdenum blue spectrophotometric method with URDS as blank, and the phosphatidylcholine payload was obtained by multiplying the phosphous content by a specific conversion coefficient. The phosphatidylcholine payload (X, mg/g) was calculated by the following equation:

$$X = (C \times N \times V_1 \times 25)/m_0 \quad (1)$$

where C (mg/mL) is the phosphous content of the mineralized liquid (after being diluted) determined from the phosphous standard curve, N is the dilution ratio of the mineralized liquid, V_1 (mL) is the total volume of the mineralized liquid, 25 is the conversion coefficient from phosphous to phosphatidylcholine, and m_0 (g) is the amount of the sample weighed.

The inclusion rate (Y) was calculated by the following equation:

$$Y = (m_1 \times X \times 100\%)/(m_2 \times 1000) \quad (2)$$

where m_1 (g) is the weight of the debranched-starch/phosphatidylcholine complexes obtained, X (mg/g) is the phosphatidylcholine payload of the sample, and m_2 (g) is the weight of phosphatidylcholine added.

Characterization of Debranched-Starch/Phosphatidylcholine Complexes. XRD analysis was performed on a D8 ADVANCE X-ray diffractometer (Bruker, Karlsruhe, Germany) operating at 40 mA and 40 kV by using Cu Kα radiation (λ = 0.1542 nm). The scattering angle (2θ) was varied from 5° to 60° with a scanning step of 0.04°.

FT-IR spectra of samples were acquired on a VECTOR 33 FT-IR spectrophotometer (Bruker, Frankfurt, Germany) using KBr disk technique. The samples were mixed with anhydrous KBr and then compressed into thin disk-shaped pellets. The spectra were obtained with a resolution of 2 cm^{-1} in a wavenumber range of 400−4000 cm^{-1}.

^{13}C CP/MAS NMR experiments were performed on a Bruker AVANCE AV 400 spectrometer (Bruker, Rheinstetten, Germany) equipped with a 4 mm MAS probe. Samples (ca. 100 mg) were packed in 4 mm zirconia rotor and spun at 6000 r/min. The spectra were obtained at ambient temperature with a sampling time of 17 ms and a relaxation delay time of 2 s. All chemical shifts were reported in parts per million (ppm).

SAXS measurements were performed using a SAXSess small-angle X-ray scattering system (Anton Paar, Graz, Austria), operated at an acceleration voltage of 40 kV and current of 50 mA. A Cu Kα radiation with a wavelength of 0.1542 nm was used as X-ray source. Prior to analysis, all samples used for the experiments were prepared by mixing the starch with distilled water and equilibrated at ambient temperature for 24 h; the total moisture content of each sample was 60%. Each sample then was filled into a capillary of 0.01 mm wall thickness, the sample-to-detecter distance was 261.2 mm, and the temperature was kept at 26 °C during the measurement. The data were collected by the IP reader softwware and read out by a Perkin-Elmer storage phosphor system. The background and smeared intensity were removed by applying the data to the SAXSquant 3.0 software. The average repeat distance (i.e., thickness of semicrystalline lamellae) of the amorphous and crystalline lamellar of each sample can be calculated as

$$d = 2\pi/q \quad (3)$$

where d (nm) is the lamellar repeat distance and q (nm^{-1}) is the scattering vector;[20] the relationship between q and θ can be calculated as

$$q = (4\pi \sin\theta)/\lambda \quad (4)$$

where λ (nm) is the wavelength of the X-ray source and 2θ is the scattering angle.

SEM observations were performed using a model 1530VP scanning electron microscope (LEO, Oberkochen, Germany). The accelerating voltage was 20 kV. The samples were mounted on an aluminum stub with a double sticky tape, and coated with gold in a vacuum before examination.

Stability of the debranched-starch/phosphatidylcholine inclusion complexes and URDS/phosphatidylcholine physical mixture (phosphatidylcholine payload106 mg/g) was evaluated by measuring peroxide value (POV) after the samples had been stored at 50 °C for 0, 3, 7, 13, and 20 days. The measurement of POV was according to ISO 3960:2001.

Digestion tests in simulated stomach condition and by enzymatic hydrolysis were performed according to previous literature[12] with little modification. The release of phosphatidylcholine from the complexes in simulated stomach conditions was tested by incubating the debranched-starch/phosphatidylcholine complexes (30 mg) with 2 mL of HCl (pH = 2) for 2 h at 37 °C under continuous stirring. The release of phosphatidylcholine from the complexes in simulated small intestine conditions was tested by incubating the debranched-starch/phosphatidylcholine complexes (30 mg) with 2 mL of pancreatin solutions for 24 h at 37 °C. The amount of phosphatidylcholine released following the simulated stomach and simulated small intestine conditions was measured by extracting the reaction substrate (after freeze-drying) with n-hexane, and the phosphatidylcholine payload was

measured by ultraviolet spectrophotometry according to our previous method.[4] The release rate (R) of phosphatidylcholine was calculated as

$$R = (m_1/m_0) \times 100\% \quad (5)$$

where m_1 (g) is the quantity of phosphatidylcholine released calculated according to the ultraviolet spectrophotometric method, and m_0 (g) is the phosphatidylcholine payload of the complexes calculated according to the phosphous molybdenum blue spectrophotometric method.

Statistical Analysis. All determinations were replicated three times, and mean values and standard deviations were reported. Analyses of variance (anova) were performed, and the mean separations were performed by Tukey's HSD test ($P < 0.05$) using SigmaStat version 2.0 (Jandel Scientific/SPSS Science, Chicago, IL).

RESULTS AND DISCUSSION

The complexation of phosphatidylcholine with debranched-starch is influenced by many factors. The effect of reaction parameters (reaction temperature, reaction time, and addition amount of phosphatidylcholine) on the phosphatidylcholine payload and inclusion rate was studied, and the results are shown in Figure 1.

Effect of Reaction Temperature. Reaction temperature had a great influence on the phosphatidylcholine payload and inclusion rate. As shown in Figure 1a, as the reaction temperature increased from 40 to 60 °C, the phosphatidylcholine payload and inclusion rate increased rapidly from 22 to 81 mg/g and 17.6% to 64.8%, respectively. However, when the reaction temperature was higher than 60 °C, a decrease in phosphatidylcholine payload and inclusion rate was observed. The reason for this phenomenon is probably that phosphatidylcholine is prone to deterioration when the reaction temperature is too high.[4] Thus, the optimal reaction temperature of 60 °C was selected for the following runs.

Effect of Reaction Time. As presented in Figure 1b, at the starting hours, the phosphatidylcholine payload and inclusion rate increased steadily with time increasing. However, when the reaction lasted for more than 2 h, an apparent reduction of phosphatidylcholine and inclusion rate was observed ($P < 0.05$). One reason for this phenomenon is probably the oxidative degradation of phosphatidylcholine after reacting at 60 °C for more than 2 h. Another reason might be that, similar to the complexation of cyclodextrin with guest molecules, the complexation of debranched-starch with phosphatidylcholine is also a dynamic process.[21] At the starting hours, phosphatidylcholine entered the hydrophobic cavity of debranched-starch by hydrophobic interactions. However, when the reaction time was too long, part of the phosphatidylcholine was released from the cavity.

Effect of Addition Amount of Phosphatidylcholine. The influence of addition amount of phosphatidylcholine on the phosphatidylcholine payload and inclusion rate was investigated, and the result is shown in Figure 1c. The phosphatidylcholine payload and inclusion rate increased with the increase in the addition amount of phosphatidylcholine at the first stage. As the addition amount of phosphatidylcholine solution increased from 10 to 20 g, the phosphatidylcholine payload increased rapidly from 43 to 86 mg/g, and the inclusion rate almost kept constant ($P < 0.05$). When the addition amount of phosphatidylcholine solution was further increased to 25 g, the phosphatidylcholine payload reached its maximum of 106 mg/g, while the inclusion rate slightly reduced. Therefore, the optimal addition amount of phosphatidylcholine solution was 25 g; that is, the mass ratio of phosphatidylcholine to native starch was 1:10.

J. Agric. Food Chem. 2015, 63, 634−641

XRD Analysis. X-ray diffraction was used to verify the formation of debranched-starch/phosphatidylcholine inclusion complexes. As shown in Figure 2a, the diffraction pattern of

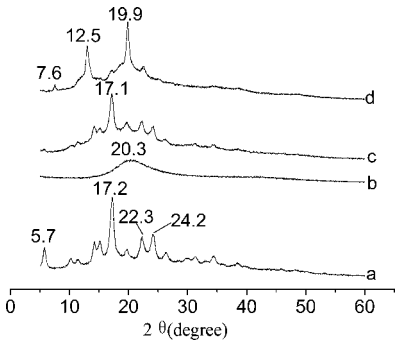

Figure 2. X-ray diffraction spectra. (a) URDS, (b) soybean lecithin, (c) URDS/soybean lecithin physical mixture, and (d) debranched-starch/soybean lecithin inclusion complexes.

URDS was a typical B-type crystalline structure with main diffraction peaks at 5.7°, 17.2°, 22.3°, and 24.2°.[22] The diffractogram of phosphatidylcholine (Figure 2b) exhibited a big and broad peak at around 20.3°, which indicated the amorphous characteristics of phosphatidylcholine.[23] As presented in Figure 2c, the diffractogram of URDS/phosphatidylcholine physical mixture (phosphatidylcholine payload 106 mg/g) was a simple superimposition of URDS and phosphatidylcholine, which remained the main diffraction peaks of URDS and showed the characterictics of phosphatidylcholine. As compared to URDS/phosphatidylcholine physical mixture, the diffractogram of debranched-starch/phosphatidylcholine inclusion complexes (Figure 2d) confirmed the formation of inclusion complexes, as inferred from the diffraction peaks at 7.6°, 12.5°, and 19.9°, which was a typical diffraction pattern of V-type amylose inclusion complexes.[10,24]

FT-IR Analysis. As a common analysis tool, FT-IR spectrum has been widely applied to confirm the formation of inclusion complexes.[25,26] Figure 3 illustrates the FT-IR spectra of URDS (Figure 3a), phosphatidylcholine (Figure 3b), URDS/phosphatidylcholine physical mixture (Figure 3c, phosphatidylcholine payload 106 mg/g), and debranched-starch/phosphatidylcholine inclusion complexes (Figure 3d). In the spectrum of URDS, the extremely broad band at 3384 cm^{-1} and the peak at 2930 cm^{-1} corresponded to the O−H and C−H stretching

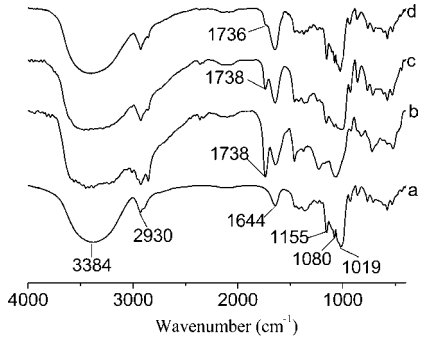

Figure 3. FT-IR spectra. (a) URDS, (b) soybean lecithin, (c) URDS/soybean lecithin physical mixture, and (d) debranched-starch/soybean lecithin inclusion complexes.

vibration, respectively. Three characteristic peaks at 1155, 1080, and 1019 cm^{-1} were assigned to the C−O stretching vibrations. The peak at 1644 cm^{-1} was attributed to the δ(OH) bending vibration.[27] As shown in Figure 3b, the spectrum of phosphatidylcholine was characterized by the absorption at 1738 cm^{-1}, which was attributed to the C═O stretching vibration.[4] The FT-IR spectrum of the URDS/phosphatidylcholine physical mixture showed approximate superimposition of the individual spectrum of URDS and phosphatidylcholine. Most of the absorption bands of phosphatidylcholine were covered by that of URDS, except the C═O stretching vibration located at 1738 cm^{-1}. The FT-IR spectrum of the debranched-starch/phosphatidylcholine complexes was almost the same as that of URDS except the shoulder peak (1736 cm^{-1}) corresponding to the C═O stretching vibration. However, as compared to the physical mixture, the C═O stretching vibration peak of phosphatidylcholine was apparently weakened; the reason is probably that part of the C═O bonds were covered by debranched-starch after the complexation of debranched-starch with phosphatidylcholine. Similar results were found by Yang et al.[25] who investigated the formation of inclusion complexes of amylose and conjugated linoleic acid. From the FT-IR spectra, the authors suggested that the driving force for self-assembly between amylose and conjugated linoleic acid is the hydrophobic interaction.

^{13}C CP/MAS NMR Analysis. The ^{13}C NMR spectrum and the peak data of (a) URDS, (b) URDS/phosphatidylcholine physical mixture (phosphatidylcholine payload 106 mg/g), and (c) debranched-starch/phosphatidylcholine inclusion complexes are presented in Figure 4 and Table 1. The serial

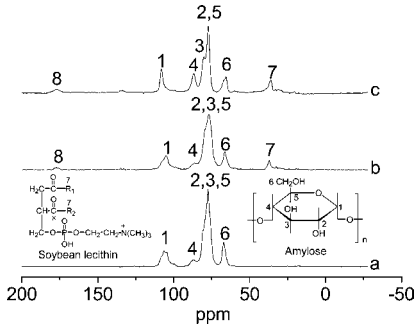

Figure 4. ^{13}C CP/MAS NMR spectra. (a) URDS, (b) URDS/soybean lecithin physical mixture, and (c) debranched-starch/soybean lecithin inclusion complexes.

number of the peaks in Figure 4 and Table 1 corresponds to the carbon atoms of the molecular formula presented in Figure 4. In the spectrum of URDS, the peaks were assigned as follows: 66.59 ppm, C6; 77.44 ppm, C2, C3, C5; 86.53 ppm, C4; and 106.46 ppm, C1.[28] The ^{13}C NMR spectrum of URDS/phosphatidylcholine physical mixture was almost the same as URDS, except two new peaks located at 37.09 and 176.89 ppm, which were attributed to the alkyl carbon and carbonyl carbon atoms, respectively.[29,30] In comparison with URDS and URDS/phosphatidylcholine physical mixture, the spectrum of debranched-starch/phosphatidylcholine inclusion complexes displayed typical characteristics of inclusion complexes, of which the C-4 peak at 86.46 ppm was better resolved from the combined C-2, C-3, C-5 peak and moved downfield, the C-3 peak was partially resolved from the C-2, C-5 peak, and the peak of C-1 was sharper and moved downfield.[31,32] The

J. Agric. Food Chem. 2015, 63, 634−641

Table 1. Characteristics of ^{13}C CP/MAS NMR Spectra

	ppm						
samples	C-7	C-6	C-3,5	C-2	C-4	C-1	C-8
URDS		66.59	77.44		86.53	106.46	
physical mixture	37.09	66.44	76.85		86.46	106.42	176.89
inclusion complexes	35.92	66.61	77.29	80.19	87.42	108.13	176.95

chemical shifts of C-1 and C-4 were more remarkable because α-1,4 linkages are more sensitive to conformational changes.[33] Morever, the peaks attributed to the alkyl carbon (35.92 ppm) and carbonyl carbon (176.95 ppm) atoms were also observed in the spectrum of the complexes. However, as compared to that of the physical mixture, the peak (35.92 ppm) corresponding to the alkyl carbon atoms of the complexes shifted upfield by 1.17 ppm. The chemical shift was caused by the combined trans and gauche conformation of the fatty acid chain of the lipids upon complexation with debranched-starch. Similar results were found by Lebail et al.[34] who investigated the complexation of amylose with fatty acids. Furthermore, according to Snape et al.[31] who demonstrated that all polar groups larger than carboxyl must lie outside the helix cavity of amylose, we can conclude that the debranched-starch/phosphatidylcholine inclusion complexes were formed by the hydrophobic interactions between the alkyl chain of phosphatidylcholine and the helix cavity of debranched-starch, with the rest of the parts of phosphatidylcholine lying outside the helix cavity.

SAXS Analysis. Characterization of the cluster and fractal structure of (a) native potato starch, (b) URDS, and (c) debranched-starch/phosphatidylcholine inclusion complexes was performed using SAXS, and the scattering patterns are presented in Figure 5. As shown in Figure 5a, native starch

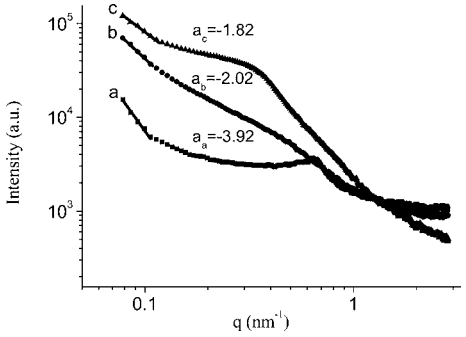

Figure 5. SAXS curves. (a) Native potato starch, (b) URDS, and (c) debranched-starch/soybean lecithin inclusion complexes.

showed one characteristic peak at about q = 0.66 nm^{-1}, which corresponds to a Bragg distance (d) of about 9.52 nm. This peak is thought to arise from the long periodicity occurring from the semicrystalline structure (i.e., alternating crystalline and amorphous lamellae structure) of the starch granules.[35,36] As can be seen from Figure 5b and c, after the gelatinization, enzymatic hydrolysis, and retrogradation process, the crystalline structure of native starch was completely destroyed, and the peak located at about 0.66 nm^{-1} disappeared. The SAXS pattern of URDS was smooth, and no distinct characteristic peak was observed within the testing range. However, after complexation with phosphatidylcholine, a new shoulder peak was observed in the SAXS curve of the complexes at about q = 0.33 nm^{-1}. This shoulder indicated that a semicrystalline structure with a Bragg distance (d) of about 19.04 nm existed in the complexes. In previous literature, similar results were found by Zabar et al.[37] who investigated the nano characteristics of the amylose/fatty acid complexes. In this study, the researchers suggested that interactions between fatty acid and amylose tend to form lamella of distinct nanometric dimensions. The structure of the debranched-starch/phosphatidylcholine complexes may be described as the crystalline regions of folded debranched-starch chains were separated alternately by regions of imperfections, chain ends, and probably residues of phosphatidylcholine, which lay outside the helix cavity of debranched-starch. It was worth noting that the semicrystalline structure in the complexes that was formed by crystallization of linear polymers from solution was different from that of native starch, of which the concentric regions of alternating amorphous and crystalline structures known as growth rings are formed by the radial orientation of the amylopectin molecules.[29]

In previous literature, SAXS data have also been used to analyze the fractal structure of native and modified starch.[19,36] The fractal structures can be characterized by the fractal dimension D, which can be obtained from the scattering power law equation:

$$I \propto q^{\alpha} \tag{6}$$

where I is the scattering intensity, and α is an exponent that can take the range from -1 to -4 and can be obtained from the slope between log I and log q.[20]

In case of $-4 < \alpha < -3$, the scattering can be judged as reflection from the surface, and the objects can be seen as possessing a surface fractal structure with the fractal dimension $D_s = \alpha + 6$, which indicates the irregularity of the surface. When the scattering surface is smooth, D_s becomes 2.[20] In case of $-3 < \alpha < -1$, the scattering objects can be seen as possessing a mass fractal structure (which means that the density profile of the scattering object has a self-similar nature) with the fractal dimension $D_m = -\alpha$, which indicates the degree of compactness of the physical arrangement of the mass.[20]

As can be seen from Figure 5a, native starch had an obvious surface fractal structure with $\alpha = -3.92$ and $D_s = 2.08$, indicating that native starch had a surface fractal structure and the surface of the granules was smooth. However, the slope of the scattering patterns of URDS and debranched-starch/phosphatidylcholine complexes was -2.02 and -1.82, respectively, indicating that both URDS and debranched-starch/phosphatidylcholine complexes possessed a mass fractal structure with D_m = 2.02 and 1.82, respectively. The D_m value of URDS was slightly higher than that of the complexes, which suggested that the molecules of URDS were arranged more tightly than that of the complexes.

SEM Analysis. Scanning electron microscopy was used to investigate the morphology of URDS and debranched-starch/phosphatidylcholine complexes at different magnification. The surface of URDS appeared to be smooth with no distinct features (Figure 6a,b). However, as shown in Figure 6c,d, after complexation with phosphatidylcholine, the complexes dis-

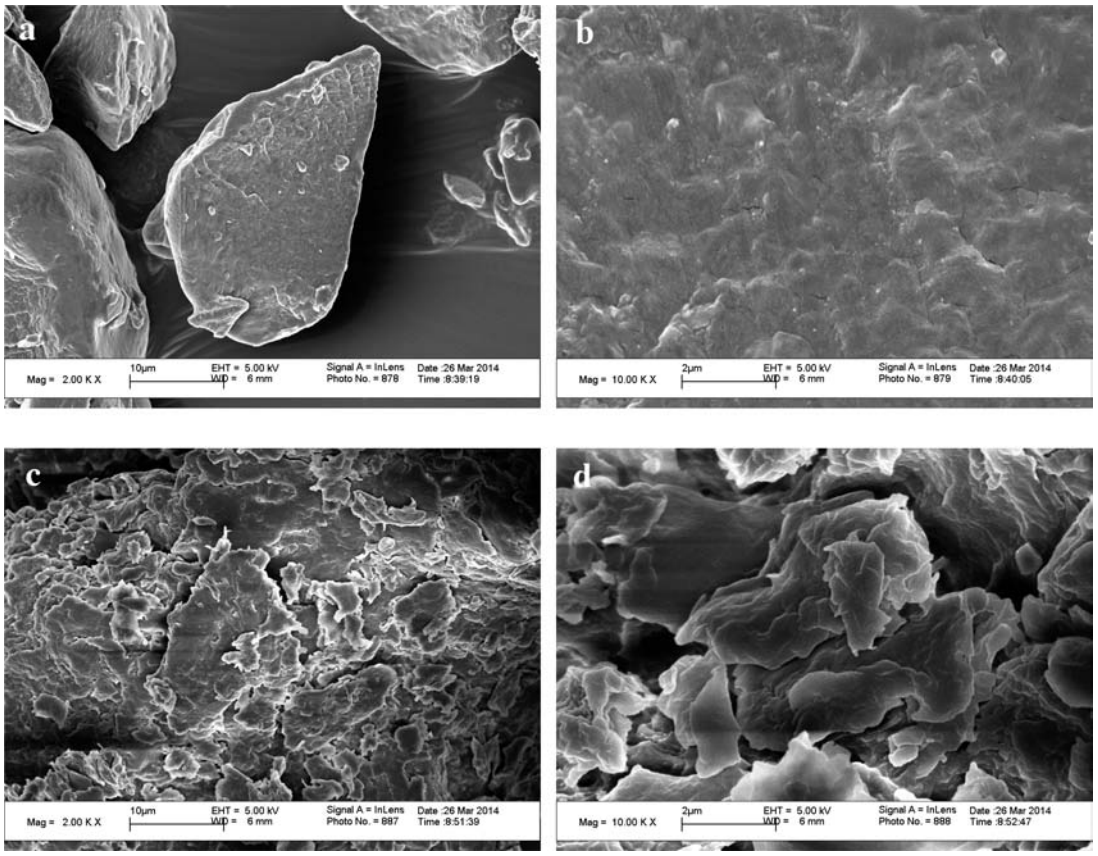

Figure 6. SEM images. (a) URDS ×2000, (b) URDS ×10 000, (c) inclusion complexes ×2000, and (d) inclusion complexes ×10 000.

played a rough appearance with thin lamellar structures embedded in the matrix. This phenomenon is probably due to the fact that the regular arrangement of debranched-starch was disrupted by the phosphatidylcholine molecules with alkyl chain encapsulated in the helix cavity of debranched-starch and the rest of the molecule parts of phosphatidylcholine lying outside the helix cavity. In previous literature, similar results were found in the amylose/fatty acid inclusion complexes.[29,37]

Stability Analysis. The determination of POV is a method that is widely used to evaluate the deterioration of lipids.[13] The higher is the value of POV, the severer is the deterioration of lipids. As can be seen from Figure 7, the POV of both the debranched-starch/phosphatidylcholine inclusion complexes and the URDS/phosphatidylcholine physical mixture increased with storage time increasing. However, the POV of the complexes was significantly lower than that of the physical mixture at any storage time. This result indicated that after complexation with debranched-starch, the stability of phosphatidylcholine was significantly improved. This result was in good agreement with other studies using amylose as embedding material of lipids.[12,13] Therefore, not only amylose extracted from native starch, but also debranched-starch can be used as wall material to improve the stability of lipids.

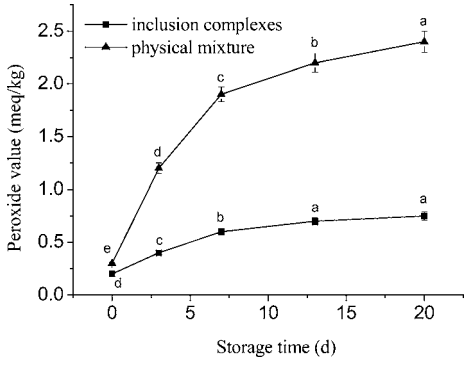

Figure 7. Stability of debranched-starch/soybean lecithin inclusion complexes and URDS/soybean lecithin physical mixture stored at 50 °C for 0, 3, 7, 13, and 20 days. Values in the same curve with different superscript letters are significantly different ($p < 0.05$).

Digestibility Analysis. The percentage of phosphatidylcholine released after the complexes were incubated under the simulated stomach condition and hydrolyzed by pancreatin is shown in Figure 8. As can be seen from Figure 8a, the complexes were relatively stable under stomach conditions, and only 5% of phosphatidylcholine was released after incubating for 2 h at the simulated stomach conditions. However, after being hydrolyzed by pancreatin for 24 h (Figure 8b), nearly all of the phosphatidylcholine was gradually released, which indicated that the debranched-starch/phosphatidylcholine inclusion complexes could be effectively hydrolyzed by pancreatin. Similar results were found by Lalush et al.[12] who studied the enzymatic digestion behaviors of amylose-conjugated linoleic acid complexes.

In conclusion, this Article described an exploratory study on the synthesis of debranched-starch/phosphatidylcholine inclusion complexes, which is a facile method to improve the stability of phosphatidylcholine. The optimum conditions for preparing the debranched-starch/phosphatidylcholine complexes were concluded as follows: reaction temperature, 60 °C; reaction time, 2 h; and the mass ratio of phosphatidylcho-

line to native starch (dry basis), 1:10. The phosphatidylcholine payload and inclusion rate measured under optimum conditions were 106 mg/g and 84.8%, respectively. The formation of debranched-starch/phosphatidylcholine inclusion complexes was confirmed by XRD and FT-IR. The debranched-starch/phosphatidylcholine inclusion complexes were formed mainly by the hydrophobic interactions between the alkyl chain of phosphatidylcholine and the helix cavity of debranched-starch, with the rest of the molecule parts of phosphatidylcholine lying outside the helix cavity. Moreover, a new semicrystalline structure with a Bragg distance of about 19.04 nm was formed in the complexes. The complexes possessed a mass fractal structure and displayed a rough appearance with thin lamellar structures embedded in the matrix. After complexation with debranched-starch, the stability of phosphatidylcholine was significantly improved, and the phosphatidylcholine encapsulated can be gradually released upon pancreatin treatment.

ABSTRACT: Cranberry is recognized for its many benefits on human health; however, its high acidity may be a limiting factor for its consumption. This study aimed to investigate the deacidification of cranberry juice using a two simultaneous step electrodialysis with bipolar membranes (EDBM) process. In step 1 (deacidification), during the 6 h treatment, the pH of the juice increased from 2.47 to 2.71 and a deacidification rate of 22.84% was obtained, whereas in step 2 (pH lowering) the pH of juice 2 was almost stable. Citric, quinic, and malic acid were extracted with a maximum of 25% and were mainly transferred to the KCl 2 fraction. A significant loss of anthocyanins in juice 2 (step 2) was observed, due to their oxidation by oxygen incorporated by the centrifugal pump. This also affected its coloration. The first step of the EDBM process was successful for cranberry juice deacidification and could be improved by increasing the number of membranes stacked.

KEYWORDS: *cranberry juice, deacidification, electrodialysis, bipolar membranes*

INTRODUCTION

Cranberry juice has a long history of scientific interest regarding its many positive benefits on human health. Particularly, it has a strong activity against *Helicobacter pylori*,[1] reduces urinary tract infection,[2] and can prevent gastrointestinal disorders.[3] All of these health benefits should attract consumers, but the high content of organic acids and low pH of cranberry juice are inconveniences that limit its consumption. The main acids present in cranberry juice are citric, malic, and quinic acids, and there is also the presence of benzoic and glucuronic acids, in lower quantities.[4] Those acids are responsible for the high titratable acidity of the juice and its astringency.

Different acidic juices such as mandarin orange juice,[5] pineapple juice,[6] passion fruit juice,[7] and tropical fruit juice[8] have already been deacidified by electrodialysis. Electrodialysis is an electrochemical process based on the migration of electrically charged species through selective membranes, under the influence of an electrical field. This electrical field is created by the application of a potential difference between the two electrodes present in the cell. This process is affordable, environmentally friendly as it does not use solvents, and easy to use. More recently, bipolar membranes (BM), which are membranes dissociating water molecules in protons (on the cationic side of the BM) and hydroxyls (on the anionic side) under the effect of electric field, were stacked in electrodialysis cells. Hence, electrodialysis with bipolar membranes (EDBM) has found applications in food systems regarding production or separation of organic acids,[9−14] production of hydroxide and hydrochloric acids,[15,16] inhibition of juice enzymatic browning,[17] and deacidification of fruit juices.[5,18]

A configuration already published for the deacidification of red wine[19] was preliminarily tested in the present study on cranberry juice (results not shown), but the results were not satisfying due to the difference in initial pH between cranberry juice and wine, influencing the migration of the acids according to their pK_a. A system more complex and more eco-efficient was then proposed here for cranberry juice deacidification.

The objectives of this work were (1) to use a two-step deacidification process to deacidify and then decrease the pH of the juice to its initial pH, which has never been performed to our knowledge; (2) to study the composition evolution of a cranberry juice deacidified during EDBM treatments; and (3) to study the EDBM parameters evolution and the potential fouling of the membranes during repetitive uses.

MATERIALS AND METHODS

Materials. Food grade Neosepta AMX-SB anion-exchange membrane, CMX-SB cation-exchange membrane, and BP-1 bipolar membrane from Tokuyama Soda Ltd. (Tokyo, Japan) were used. Solutions of 20 g/L NaCl and 2 g/L KCl (Mat Laboratory, Québec, QC, Canada) were prepared.

Treatments were carried out on a pasteurized and clarified cranberry juice produced by Fruit d'Or (Notre-Dame-de-Lourdes, QC, Canada). The juice was stored at −28 °C and thawed at 4 °C before each experiment.

Electrodialysis Cell. The electrodialysis cell was an MP type cell with 100 cm^2 of effective electrode surface (ElectroCell AB, Täby, Sweden) with two AMX-SB anionic membranes, two bipolar membranes, and two CMX-SB cationic membranes (Figure 1). Each membrane was placed behind two rubber gaskets, and there was one polypropylene spacer behind each membrane, representing the cell compartment. Food grade stainless steel cathode and a dimensionally stable anode (DSA-O_2) were used. The KCl and NaCl solutions were connected to their own external tanks and circulated in the compartments using two centrifugal pumps (Iwaki Magnet Pump,

Iwaki Co. Ltd., Tokyo, Japan). The flow rates were controlled using flowmeters (Aalborg Instrument and Controls, Inc., Orangeburg, NY, USA), whereas cranberry juice was circulated using a peristaltic pump (Kate, Barnant Co., Barrington, IL, USA) to avoid oxygen incorporation.

Protocol of Deacidification by ED. The deacidification was performed in two steps; the first was carried out to decrease the quantity of acids in the juice, as well as increase the pH of the juice. The second step was to reduce the pH of the juice previously deacidified to its initial value, in order to not affect its color, and to deacidify in the same time a new batch of juice to optimize the efficiency of the whole process.

Step 1 (Figure 1a). The volume of cranberry juice used in the first step was 750 mL. In the electrode compartment, 900 mL of 20 g/L NaCl was used, and 650 mL of 2 g/L KCl was put in KCl 1 and KCl 2 compartments. The flow rates were 1000 mL/min for the electrolyte (NaCl), 600 mL/min for the juice and KCl 1 (the flow is divided in two circuits in the cell, and consequently the flow rate is equal to 300 mL/min), and 300 mL/min for KCl 2. This study was carried out at room temperature. The first step was performed during 6 h.

During the electrodialysis treatment, the pH of the juice, KCl 1, and KCl 2 was recorded, as well as the conductivity of all those compartments. The current intensity, as well as the temperature of the compartment containing the juice, was also recorded. Samples (15 mL) were taken every hour to perform further analyses concerning the titratable acidity, total polyphenols, anthocyanins, organic acids, and degrees Brix.

After the experiment, the juice that was deacidified and KCl 1 were stored at 4 °C. KCl 2 and NaCl solutions were discarded as they were only necessary for beginning the first step of the process. Then the electrodialysis system was cleaned as follows: 10 min of circulation of hot water, then 30 min of alkaline solution, rinsing with water at 55 °C and circulation for 10 min, then circulation of acidic solution for 20 min. Finally, every compartment was rinsed with water at 55 °C for 4–5 min and then rinsed with distilled water.

Step 2 (Figure 1b). The objective of the second step was to deacidify the cranberry juice (juice 1) as in the first step, as well as to decrease the pH of the juice deacidified in the first step under the action of the bipolar membranes, to restore the initial pH of this juice, with a diminished level of organic acids.

Juice from the first step was reused as juice 2 in the second step. The KCl 1 in the first step was also reused as KCl in the second step, but 250 mL of new solution (2 g/L KCl) was added to the previous one to reach a volume of 550 mL. A new juice called juice 1 was used (Figure 1b). The volumes for juice 1, juice 2, and KCl were 550 mL, and the volume of NaCl remained identical to that in the first step. All flow rates were identical to those of the first step, and the experiments were also performed at room temperature. Every electrodialytic parameter was recorded according to the first step, and samples were also taken to proceed to further analyses.

At the end of the treatment, the electrodialysis system was cleaned as previously.

Analyses. *Conductivity.* A YSI conductivity meter, model 3100, was used with a YSI immersion probe (model 3252, cell constant K = 1 cm^{-1}; Yellow Springs Instrument, Yellow Springs, OH, USA) to measure the conductivity of all solutions.

Global System Resistance. The global resistance of the system was calculated using Ohm's law (U = RI). The values of voltage were read directly from the power supply indicators and the current passing through the electrodes from a multimeter (model 52-0060-2, Mastercraft, Toronto, Canada).

Membrane Electrical Conductivity. The electrical conductivity of the membrane was measured with a specially designed cell (conductivity clip) from the Laboratoire des Matériaux Echangeurs d'Ions (Créteil, France). The membrane's electrical conductivity κ (mS/cm) was calculated as

$$\kappa = \frac{l}{R_m A}$$

where l is the membrane thickness (cm), R_m the transversal electric resistance of the membrane (Ω), and A the electrode area (1 cm^2).

Membrane Thickness. The membrane thickness was measured using a Mitutoyo Corp. IDC type digimatic indicator with absolute encoder (model ID-C112EB, Kanagawa-Ken, Japan) with a resolution of 1 μm and a range of 12.7–0.001 mm. The membrane thickness value was averaged from four measurements at different locations on the membrane.

pH. The pH was measured using a VWR Symphony electrode equipped with an automatic temperature compensation device and connected to a VWR Symphony SP20 portable pH meter (Thermo Orion, West Chester, PA, USA).

Titratable Acidity. The titratable acidity was evaluated according to AOAC method 942.15. Forty milliliters of degassed distilled water was added to 4 mL of juice, and then 0.1 M NaOH was added drop by drop until pH 8.2 was reached. The pH was measured with the same electrode and pH meter as for the pH measurements. The titratable acidity was expressed as milliliters of NaOH (0.1 M) added.

Degrees Brix. The degrees Brix of cranberry juices was measured using a Digital Pocket Refractometer (model PAL-1, 0–53%, Atago, Tokyo, Japan).

Total Polyphenol Content. Total polyphenol content measurements in raw juice, juice step 1 (S1), juice 1–step 2 (S2), and juice 2–step 2 (S2) were performed using the microscale protocol for Folin–Ciocalteu colorimetry of Waterhouse.[20] The samples and the standards of gallic acid absorbances were measured at 765 nm using a UV–visible Agilent 8453 spectrophotometer (Agilent Technologies, Palo Alto, CA, USA). Concentration in total polyphenol was expressed as gallic acid equivalent per liter of juice (mg/L).

Anthocyanin Content. Total anthocyanin concentration was quantified by UV–visible spectroscopy following the method described by Giusti and Wrolstad.[21] Each sample of cranberry juice was diluted 10 times in two distinct aqueous buffers: 0.025 M potassium chloride buffer, pH 1.0; and 0.4 M sodium acetate buffer, pH 4.5. Diluted solutions were equilibrated for 15 min at room temperature before analysis. The absorbance of each diluted sample was measured at 520 and 700 nm using a UV–visible Agilent 8453 spectrophotometer (Agilent technologies, Palo Alto, CA, USA). Absorbance (A) due to the contribution of total anthocyanins was calculated as follows:

DOI: 10.1021/jf502824f
J. Agric. Food Chem. 2015, 63, 642–651

$$A = (A_{510nm} - A_{700nm})_{pH1.0} - (A_{510nm} - A_{700nm})_{pH4.5} \quad (1)$$

Concentration in total anthocyanins was expressed as milligrams of cyanidin-3-glucoside equivalent per liter of juice (mg/L) by applying the equation

$$\text{monomeric cyanidin-3-glucoside pigment (mg/L)} = (A \times MW_{Cyd\text{-}3\text{-}glu} \times \text{dilution factor} \times 1000)/(\varepsilon_{Cyd\text{-}3\text{-}glu} \times L) \quad (2)$$

with $MW_{Cyd\text{-}3\text{-}glu}$ = 449.2 g mol^{-1}, ε = 26900 L mol^{-1} cm^{-1}, and L = 1 cm.

Proanthocyanidins (PACs), Catechin, PAC-A_2, and PAC-B_1 Contents. The content of global PACs content of juices was determined by the BL-DMAC (4-dimethylaminocinamaldehyde) method, adapted from the method described from Prior et al.[22] The quantitative analysis of the global content of PACS of cranberry juices was carried out in triplicate for all three repetitions in 96-well plates. Prior to analysis, juices were freeze-dried to obtain dry residues. Standard calibration of PAC-A_2 controls was performed in methanol from 0.05 to 0.5 mg/mL. Seven microliters of control solution was added to 63 μL of methanol in each well. Dry residues obtained previously were solubilized in distilled water at a concentration of 15 mg/mL, then 20 μL of sample solution was added to 50 μL of methanol in each well. DMAC reagent was solubilized in acidified ethanol at 0.1%, and 210 μL of DMAC solution was added to each well before the reading. Plate readings were performed at 630 nm every 2 min for 20 min, on a Biohit Bp 800 microplate reader, and the DO values used were the ones obtained after stabilization around 16–18 min. A standard curve of PAC-A_2 was then drawn, and a polynomial regression was applied to provide an equation allowing the calculation of the PACs content of samples.

The contents of catechin, PAC-A_2, and PAC-B_1 of juices have been analyzed by densitometric HPTLC using a plate scanner at a wavelength of 225 nm according to the method developed by Boudesocque et al.[23] Dry residues of juices obtained prior to the PACs content analysis were solubilized in distilled water at 75 mg/mL. Stock solution of controls was prepared by solubilization of an appropriate amount of catechin, PAC-A_2, and PAC-B_1 to obtain the initial concentration of 1 mg/mL. Diluted solutions at 0.02, 0.035, 0.05, and 0.07 mg/mL were obtained from the stock solution. Ten microliters of each control and sample solution in triplicate was sprayed by a Linomat 5 Automatic TLC Sampler (CAMAG, Switzerland), at 30 nL/s under nitrogen flow. Plate migration was performed in an automatic ADC 2 tank (CAMAG), with dichloromethane/ethyl acetate/formic acid (6:10:1, v/v) eluent. Plates are then analyzed by a TLC Plate Scanner (CAMAG) at 200, 225, and 279 nm, and quantification was performed at 225 nm through the calibration curve for each standard.

Organic Acid Contents. Prior to analysis, organic acids were extracted from 1/5 diluted cranberry juices with a C18-SPE cartridge (6 mL, 500 mg, Silicycle, Québec, QC, Canada). The cartridges were previously conditioned with elution of 5 mL of methanol, then 5 mL of distilled water, and then 10 mL of acetonitrile/water (50:50 v/v) solution. After drying of the cartridges, 10 mL of sample was dropped off and the last 5 mL was kept for analysis. The individual organic acid contents of cranberry juices and KCl fractions were determined by HPLC based on AOAC method 986.13. The system used was a Waters 600 HPLC system (Milford, MA, USA) equipped with a UV detector (Waters, model 966). Organic acids were analyzed with an Allure Organic Acids column (300 × 4.6 mm, Restek, USA). Standards for all organic acids tested were used with external calibration. A solution of 0.2 M (v/v) KH_2PO_4 (pH 2.4) was used as solvent for elution at a 0.5 mL/min flow rate. The detection wavelength was 226 nm.

Cranberry Juice Color. The color parameters of the cranberry juice were determined with a chromameter (model Minolta meter CR-200, Konica Minolta Inc., Mississauga, ON, Canada). Results were reported as L^* (luminescence or lightness), a^* (intensity of color varying from red to green)m and b^* (intensity of color varying from yellow to blue).[24]

Statistical Analyses. Data obtained during treatments for pH, conductivity, titratable acidity, and organic acids content were subjected to a repeated-measures analysis of variance using SigmaPlot software (version 11.0) or for anthocyanin and total polyphenol content to an analysis of variance. Tukey tests were also performed on data using SigmaPlot software (version 11.0) to allow the determination of treatments that were statistically different from the other at a probability level of $P < 0.05$.

RESULTS AND DISCUSSION

Evolution of the Electrodialytic Parameters. *Global System Resistance.* According to the repeated measures analysis of variance, during the first step of electrodialysis the global system resistance remained almost constant ($P = 0.412$) around 44 Ω (Figure 2). During the second electrodialysis step,

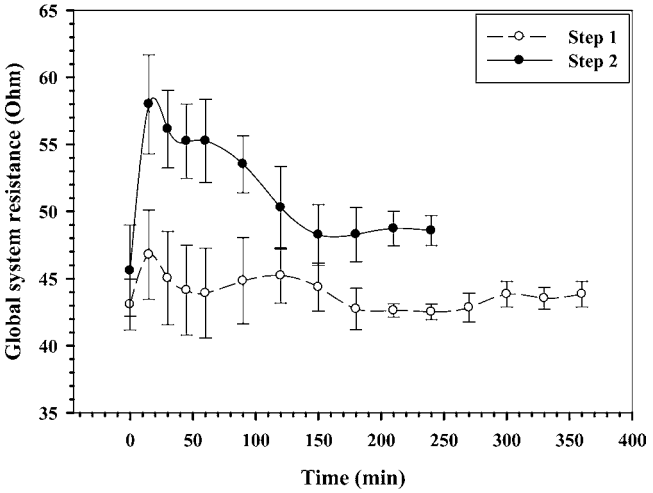

Figure 2. Results of the global system resistance (ohms) of the first and second electrodialysis steps.

the global system resistance increased from 45.60 to 58.00 Ω during the first 15 min and then decreased to 48.26 Ω after 150 min of treatment and reached a plateau until the end of the experiment ($P < 0.001$). The decrease could be due to water dissociation after 15 min of treatment at the surface of the monopolar ion-exchange membranes. Indeed, during water dissociation, the high conductivity of the H^+ ions produced facilitates the transport of the current, decreasing then the resistance.[25]

Membrane Parameters. Table 1 shows the thickness and electrical conductivity values of each membrane used for the EDBM treatments of the cranberry juices. The thickness was not significantly different after ED treatment for CMX-SB-1 membrane ($P = 0.184$) and for the two bipolar membranes ($P = 0.259$ and $P = 0.791$). For the other membranes, the thickness after the treatment was significantly higher ($P < 0.05$). However, the electrical conductivity of every CMX-SB membrane was not significantly different ($P > 0.05$) after use, meaning that their integrities were preserved, although they were in contact with the juice during the second step of the treatment. The electrical conductivity of AMX-SB membranes significantly decreased after the treatment ($P < 0.001$), as well as the conductivity of bipolar membranes ($P < 0.001$). During the two-step process, AEMs were in contact with raw juice in step 1 (see Figure 1a) and juice 1 in step 2 (see Figure 1b):

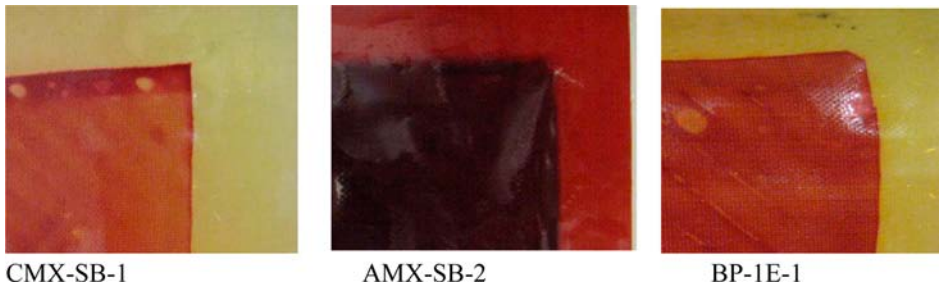

Figure 3. Photographs of anionic (AMX-SB), cationic (CMX-SB), and bipolar (BP-1) membranes.

organic acids and negative ions passed through this membrane during all of the process, but other negative molecules could have built up a deposit on the surface during the treatment, decreasing the conductivity of these membranes. As can be seen in Figure 3, the color of the CEM, AEM, and bipolar membranes changed (active and nonactive surface). These membranes may have interacted with a positively charged compound such as proanthocyanidin, anthocyanin, or other polyphenolic products, as well as negatively charged molecules such as organic acids and other molecules with high molecular weight such as pectin. All of these interactions could explain the difference of color of the membranes and their possible responsibity in fouling. This result is consistent with the literature. Indeed, a study demonstrated that the fouling appears in the AEM when this membrane transports the organic anion and that this fouling could appear when the current density is close to the limiting current.[8] It has been demonstrated in a previous study[26] that organic fouling can decrease the electrical conductivity of the ion-exchange membrane surface. Vera et al.[18] also observed a fouling on the anion-exchange membranes they used that were in contact with the treated passion fruit juice and attributed it to the colored compounds present in the passion fruit juice. Bipolar membranes were in contact with juice in step 1 and both juices in step 2, so that increased the risk of fouling at the surface of this membrane. Indeed, the fouling of membranes by charged compounds present in the juice is dependent on the position of the membranes in the configuration cell as well as the solution they are in contact with, as demonstrated before.[27]

Juice Parameter Evolution. *pH.* On the basis of the results obtained from the repeated measures analysis of variance, the first-step treatment had a significant effect on the pH ($P < 0.001$) of juice and both KCl fractions (Figure 4a). The pH of raw juice increased from 2.47 ± 0.02 to 2.71 ± 0.02 during the 6 h treatment ($P < 0.001$). The pH increase was higher in the first 75 min of treatment. At the initial pH of the juice, >60% of all acids were in the molecular and monoionized form, because the pH of the juice was below their first pK_a.[8]

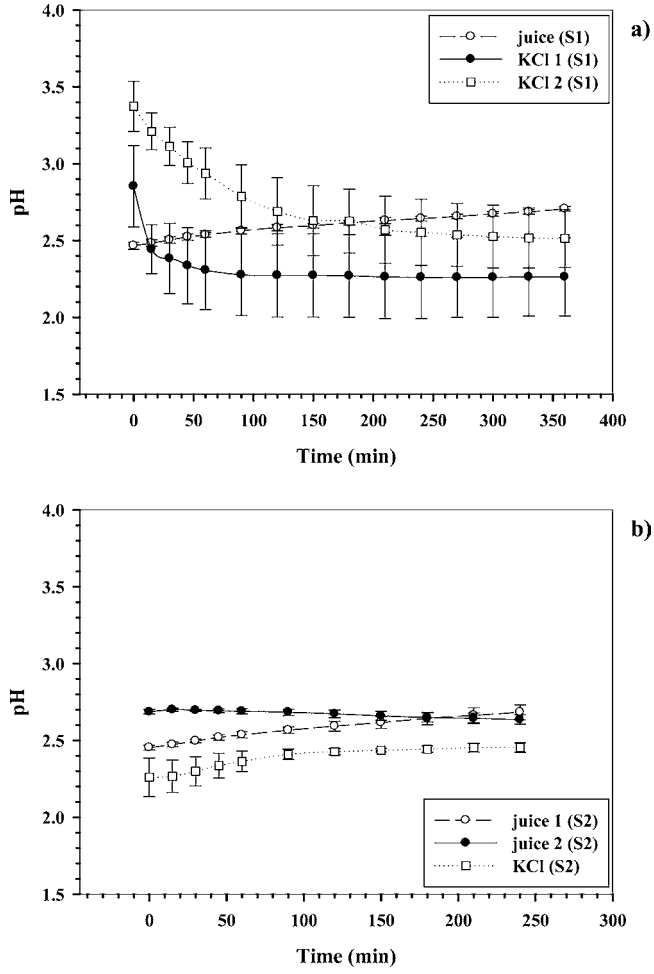

Figure 4. Evolution of the pH as a function of time for (a) the first electrodialysis step of juice 1, KCl 1, and KCl 2 and (b) the second electrodialysis step of juice 1, juice 2, and KCl.

DOI: 10.1021/jf502824f
J. Agric. Food Chem. 2015, 63, 642−651

The fact that a minority of the acids were charged did not help their migration through the anionic membranes. Concerning KCl 1, its pH decreased quickly from 2.85 ± 0.27 to reach a plateau around 2.26 ± 0.25 ($P < 0.001$) after only 55 min. The pH of KCl 2 decreased quickly in the first 75 min from 3.37 ± 0.16 to 2.51 ± 1.89 ($P < 0.001$), its final value. The pH decrease in the KCl 2 compartment followed closely the pH increase observed for juice (S1); the organic acids that left the juice were concentrated in the KCl 2 compartment, as expected with the cell configuration.

In step 2 (Figure 4b), the pH of juice 1 followed the same behavior as juice in step 1, with an increase from pH 2.46 ± 0.02 to 2.68 ± 0.05 ($P < 0.001$); meanwhile, the pH of juice 2 was almost stable during the first 75 min of the treatment and then decreased slightly ($P = 0.019$). Surprisingly, the pH of KCl in step 2 increased quickly from its initial value of 2.26 ± 0.13 to 2.45 ± 0.03 in the first 75 min and then continued to increase, but more slowly ($P = 0.033$).

With regard to the previously reported results obtained with passion fruit juices,[18,28] the pH variation obtained in our study was lower (0.3 pH unit versus >1.0 pH unit), which was explained by a lower initial pH in our study, far below the pK_a of the acids, corresponding to less charged species able to be extracted from the juice, so higher time or energy was required to achieve the transfer.

Conductivity. According to the repeated-measures analysis of variance, the electrodialysis treatment in step 1 had a significant effect on the conductivity values of juice and KCl fractions ($P < 0.001$). During the first step (Figure 5a), the conductivity of juice remained almost constant around 3152 ± 65 μS/cm for the first 75 min and then decreased quickly to 2856 ± 21 μS/cm at the end of the treatment ($P < 0.001$). This is explained by a demineralization of the juice, as well as a neutralization of the protons and the loss of organic acids and other charged molecules, phenomena already reported in the deacidification of passion fruit juices.[8] At the same time, the conductivity of KCl 1 followed a neperian logarithm increase: KCl 1 conductivity increased quickly from 3605 ± 73 μS/cm to reach a plateau at 4996 ± 219 μS/cm after 120 min of treatment ($P < 0.001$). The conductivity of KCl 2 fraction increased also from 3364 ± 22 to 4454 ± 110 μS/cm ($P < 0.001$), but the slope of the curve was slightly higher in the first 100 min compared to the last 300 min of the treatment. As expected, the conductivity of both KCl fractions increased due to the migration of organic acids as well as other charged molecules and ions from the juice into these compartments. To our knowledge, the conductivity of other KCl fractions during deacidification by electrodialysis has never been reported in the literature.

During the second step of electrodialysis (Figure 5b), the conductivity of juice 1 remained almost constant around 3046 ± 51 μS/cm during the first 60 min ($P > 0.05$) and then slightly decreased to reach 2801 ± 106 μS/cm at the end of the 240 min treatment. This behavior was similar to that of juice in step 1, due to the same movement of molecules. The conductivity of juice 2 (the juice obtained in the first step of the treatment) was not significantly different ($P > 0.05$) for the first 30 min and then decreased to reach a plateau at around 2264 ± 66 μS/cm. The conductivity of KCl in step 2 slightly decreased from 3711 ± 240 to 3476 ± 296 μS/cm during the first 90 min and then increased to reach 3929 ± 166 μS/cm at the end of the treatment ($P < 0.001$). In the second step, the KCl fraction seems to compensate for the decrease in conductivity of juice 1 according to step 1; moreover, juice 2 seems to be subjected to a demineralization because its conductivity decreased.

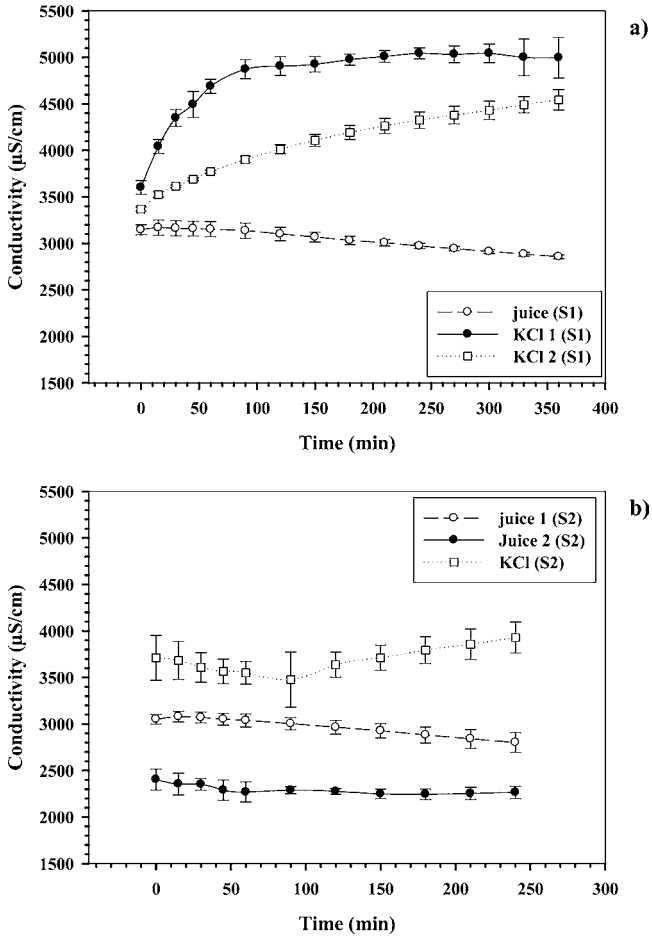

Figure 5. Evolution of the conductivity as a function of time for (a) the first electrodialysis step of juice 1, KCl 1, and KCl 2 and (b) the second electrodialysis step of juice 1, juice 2, and KCl.

Titratable Acidity. The titratable acidity of the juice in step 1 decreased during the 6 h of treatment from 15.90 ± 0.87 mL of 0.1 N NaOH to reach pH 8.2, to 12.27 ± 0.64 mL (Figure 6a), which corresponds to a 22.84 ± 0.22% deacidification. At the same time, the titratable acidity of KCl 1 fraction increased from 0.10 ± 0.00 mL to reach an almost stable value of 0.30 ± 0.00 mL of 0.1 N NaOH at 240 min. The titratable acidity of KCl 2 in the first step increased from 0.10 ± 0.00 mL to 2.85 ± 0.39 mL of 0.1 N NaOH: the KCl 2 compartment seemed to recover the acidity loss from the juice during the treatment. Vera et al.[28] have reported a deacidification of 70% of different clarified tropical fruit juices including passion fruit juices when they reached pH 4, using two electrodialysis cells with bipolar membranes of 20 and 200 cm^2 membrane areas, with various applied current densities between 50 and 400 A/m^2, but the duration of the ED treatment was not known. All of the juices used in this previous study had initial pH values higher than those of the cranberry juices (near pH 3.0), so citric and malic acids, both major acids in those juices, were mainly in their molecular form,[8,29] but at lower percentages than in cranberry juice, allowing a higher migration rate of these charged species.

In the second step (Figure 6b), the titratable acidity of juice 1 decreased from 15.97 ± 1.42 mL to 12.33 ± 1.46 mL of 0.1 N NaOH, corresponding to a deacidification of 22.78 ± 5.89%, comparable to the first step, with 2 h less treatment. During the

DOI: 10.1021/jf502824f
J. Agric. Food Chem. 2015, 63, 642−651

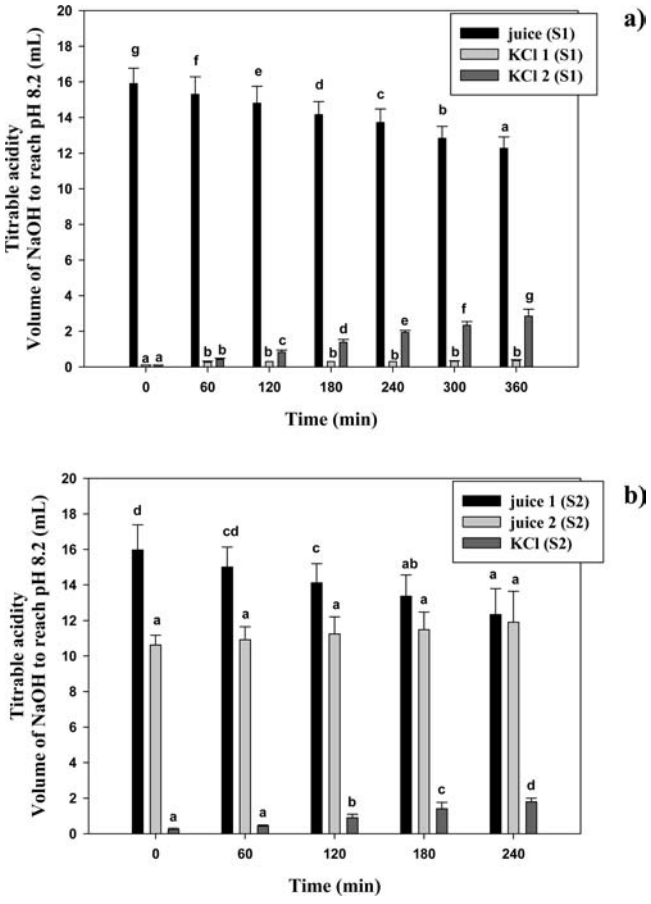

Figure 6. Evolution of the titratable acidity as a function of time for (a) the first electrodialysis step of juice 1, KCl 1, and KCl 2 and (b) the second electrodialysis step of juice 1, juice 2, and KCl.

same time the titratable acidity of juice 2 remained stable ($P > 0.5$) at a lower acidity than juice 1, whereas KCl increased from 0.23 ± 0.08 to 1.80 ± 0.20 mL, possibly compensating for the juice 1 acidity decrease.

Degrees Brix. The degrees Brix of juice in the first step (Figure 7) significantly decreased from 7.37 ± 0.06 to 6.87 ± 0.12 during the 6 h treatment ($P < 0.001$). During the 4 h treatment, the degrees Brix of juice 1−step 2 also decreased significantly ($P < 0.001$) following the same behavior as juice in step 1 ($P > 0.05$). Because the degrees Brix refers to the total soluble solids (primarily sugars and acids) and the titratable acidity decreased for the juice in step 1 and juice 1 in step 2, it was expected that the degrees Brix would decrease in these juices, as seen for the deacidification of tropical fruit juices.[28] However, juice 2 had a constant degrees Brix around 6.23 ± 0.15 during the 4 h treatment of step 2, lower than that of juice in step 1 and juice 1 in step 2 ($P < 0.001$), which is consistent with the titratable acidity results, because it was stable during the treatment for this juice.

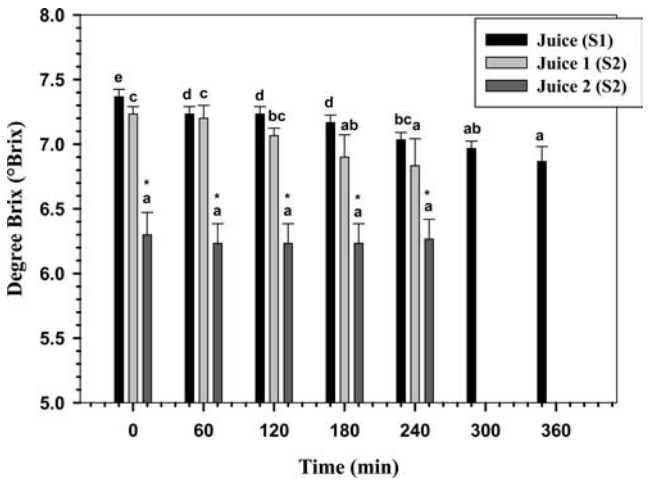

Figure 7. Evolution of the degrees Brix as a function of time for the first electrodialysis step of juice 1 and the second electrodialysis step of juices 1 and 2.

Total Polyphenol Content. On the basis of the results obtained from the analysis of variance, every electrodialysis-treated juice had a significantly lower total polyphenol content than the cranberry control juice ($P < 0.001$, Figure 8). Indeed,

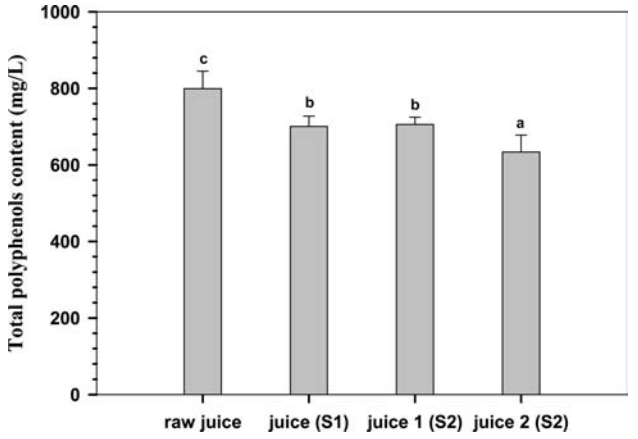

Figure 8. Results of total polyphenols content of the raw juice and the juices at the end of each treatment.

control juice had total polyphenol content of 799.15 ± 46.13 mg/L gallic acid equivalent, compared to around 703.10 ± 23.04 mg/L for juice−step 1 and juice 1−step 2 and 633.80 ± 44.01 mg/L for juice 2−step 2. Those results can be correlated to the fouling of membranes, because the coloration of the different membranes suggested a polyphenol/membrane interaction and a possible anthocyanins/membrane interaction.

Anthocyanin Content. Because the content of total polyphenol decreased for each juice treatment, the anthocyanin content was investigated. It appeared that this content was not significantly different ($P > 0.05$) for juice−step 1 and juice 1−step 2 at around 84.40 ± 1.14 mg/L cyanidin-3-glucoside equivalent before or after electrodialysis treatment, so those molecules did not migrate during the ED treatment. Otherwise, juice 2−step 2 had significantly lower anthocyanin content that other juices at the beginning of the experiment ($P < 0.001$) and even lower content at the end of the treatment ($P < 0.001$) (Figure 9). These results may suggest that there was a loss in anthocyanin between each step, due to storage (even for <3 days) at 4 °C. Indeed, this loss can be due to the oxygen present in the storage beaker used to keep the juice between the first and second steps[30] that may affect the anthocyanins during the storage. Furthermore, the significant loss during the second electrodialysis step could be due to the passage of juice 1 into a centrifugal pump, incorporating oxygen, whereas the peristaltic pump did not for juice−step 1 and juice 1−step 2.

DOI: 10.1021/jf502824f
J. Agric. Food Chem. 2015, 63, 642−651

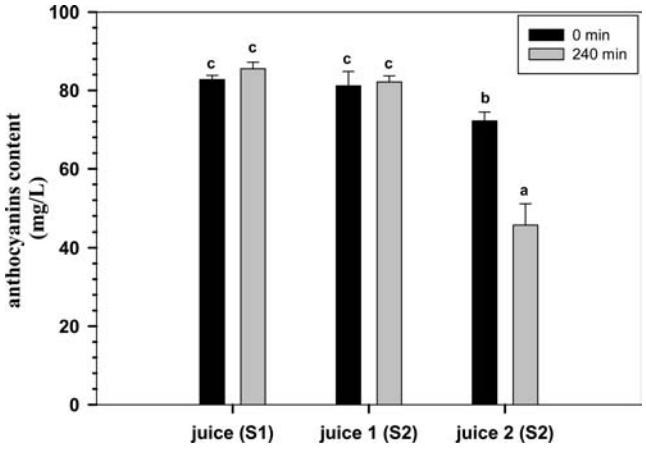

Figure 9. Results of total anthocyanins content at the end of each electrodialysis treatment.

Indeed, the decrease in total polyphenols for juice−step 1 and juice 1−step 2 was not due to anthocyanin degradation or fouling on membranes, contrary to what was suggested.

PACs, Catechin, PAC-A_2, and PAC-B_1 Contents. According to the analysis of variance, raw juice, juice−step 1, juice 1−step 2, and juice 2−step 2 were not significantly different ($P > 0.05$) with regard to their global PACs content, with values between 26.53 ± 3.11 and 28.60 ± 0.70 μg/mL, so these flavonoids were not degraded by the treatment (Table 2). However, this level of PACs was 16 times lower than what was already reported in the literature.[22,31] No catechin and PAC-B_1 have been observed by HTPLC. PAC-A_2 has been detected, but with values below the lower point of the standard curve applied, so its quantity in the different juices was below 0.02 mg/mL of PAC-A_2 standard. Those compounds were also not detected in cranberry juices by HPLC in another study.[32]

Organic Acid Contents. The major organic acids found in cranberry juices determined by HPLC analysis were citric acid (molecular weight (MW) = 192.12 g/mol), malic acid (MW = 134.09 g/mol), and quinic acid (MW = 192.17 g/mol).

The analysis of variance showed that the citric acid content of juice−step 1 (Figure 10a) was not significantly different ($P > 0.05$) throughout the treatment, but there was a tendency to decrease. Indeed, its concentration decreased from 3501.47 ± 215.75 mg/100 mL at 30 min to 2989.38 ± 355.41 mg/100 mL at the end of the treatment. On the other hand, the KCl 2 fraction had a content of citric acid that increased during the 6 h electrodialysis ($P < 0.001$) to reach 401.15 ± 36.58 mg/100 mL, compensating for the slight loss of citric acid in the juice, as expected with the cell configuration. Citric acid was produced in the KCl 2 fraction from citrate ion extracted from the juice and protons provided by BP-1 that went through CEM-1, as demonstrated in another study.[8] It is not visible in Figure 10a, but the content of citric acid in KCl 1 fraction increased slightly during the treatment to reach a 1.24 ± 0.30 mg/100 mL after 360 min. Juice 1 in the second step showed a behavior similar to that of the juice in the first step; indeed, even if there was no significant difference ($P > 0.05$) in the citric acid content as a function of time, there was a tendency to decrease, due to the migration of citrate ions through the AEMs membranes to produce citric acid in the KCl compartment. Indeed, as expected because of the cell configuration, the content of citric acid increased in the KCl compartment to reach 301.84 ± 39.55 mg/100 mL. Juice 2−step 2 remained stable for its content in citric acid during the 240 min of treatment ($P > 0.05$). Furthermore, the citric acid content of juice 2−step 2 was significantly lower than that of juice−step 1 and juice 1−step 2 from the beginning of the treatment until 120 min of electrodialysis, because of the migration of citrate ions during the first step of treatment.

These trends were similar for quinic acid (Figure 10b), except that juice 1−step 2 had a higher content of quinic acid at the beginning of the electrodialysis than at the end at 240 min ($P = 0.022$) and that the content of quinic acid of juice 2 in the second step was lower than for juice−step 1 and juice 1−step 2 during the 240 min of treatment. In that case, the quinic acid also concentrated in KCl 2−step 1 and the KCl−step 2, due to their same position in the cell. It has to be noted that the concentrations of quinic acid at times 0, 60, and 240 min were higher for KCl−step 2 compared to KCl 2−step 1. This can be due to the accumulation of quinic acid during the first passage in the electrodialysis, where the final concentration of KCl 1 was 17.43 ± 1.48 mg/100 mL.

The content of malic acid (Figure 10c) significantly decreased from 846.52 ± 54.13 to 635.13 ± 30.97 mg/100 mL during the treatment of juice−step 1 ($P < 0.001$), which corresponds to an extraction of 211.38 ± 54.65 mg/100 mL or 25% of this acid, whereas the KCl 2 fraction was enriched in this acid to reach a final content of 127.45 ± 22.98 mg/100 mL. A very little content of malic acid passed in the KCl 1 fraction to reach a final value of 1.24 ± 0.30 mg/100 mL. In the second step of the electrodialysis treatment, juice 1 and the KCl fractions had the same behavior as in the first step ($P < 0.001$), whereas juice 2 was not affected by the second electrodialysis treatment ($P > 0.05$), as for the other acids.

In their study, Bazinet et al.[27] also found a migration of citric and malic acid through an ultrafiltration membrane, when enriching a cranberry juice in antioxidants, confirming the migration ability of those acids during electrodialysis treatment. The most abundant organic acid found in the KCl 2−step 1 and KCl−step 2 recovery compartment was the citric acid. Among the acids present in the juice, citric acid was the most available to migrate at the pH of the juice, due to its high concentration (in comparison with other acids), its low molecular weight (192.12 Da), and its first pK_a (3.14), which was the lowest of all the acids.[8]

Table 2. Global Proanthocyanidins (PACs), Catechin, PAC-A_2, and PAC-B_1 Contents (μg/mL) in Cranberry Juices[a]

	raw juice	juice (S1)	juice 1 (S2)	juice 2 (S2)
PACs	26.77 ± 3.57a	26.53 ± 3.11a	28.60 ± 0.70a	28.00 ± 1.11a
catechin	nd[b]	nd	nd	nd
PAC-A2	bdl[c]	bdl	bdl	bdl
PAC-B1	nd	nd	nd	nd

[a]Data in the same row with different letters for the same parameter are significantly different at a probability level of 0.05. [b]nd, not determined (no peak corresponded to the peaks of the standards tested). [c]bdl, below detection level (below the lower point of the standard curve).

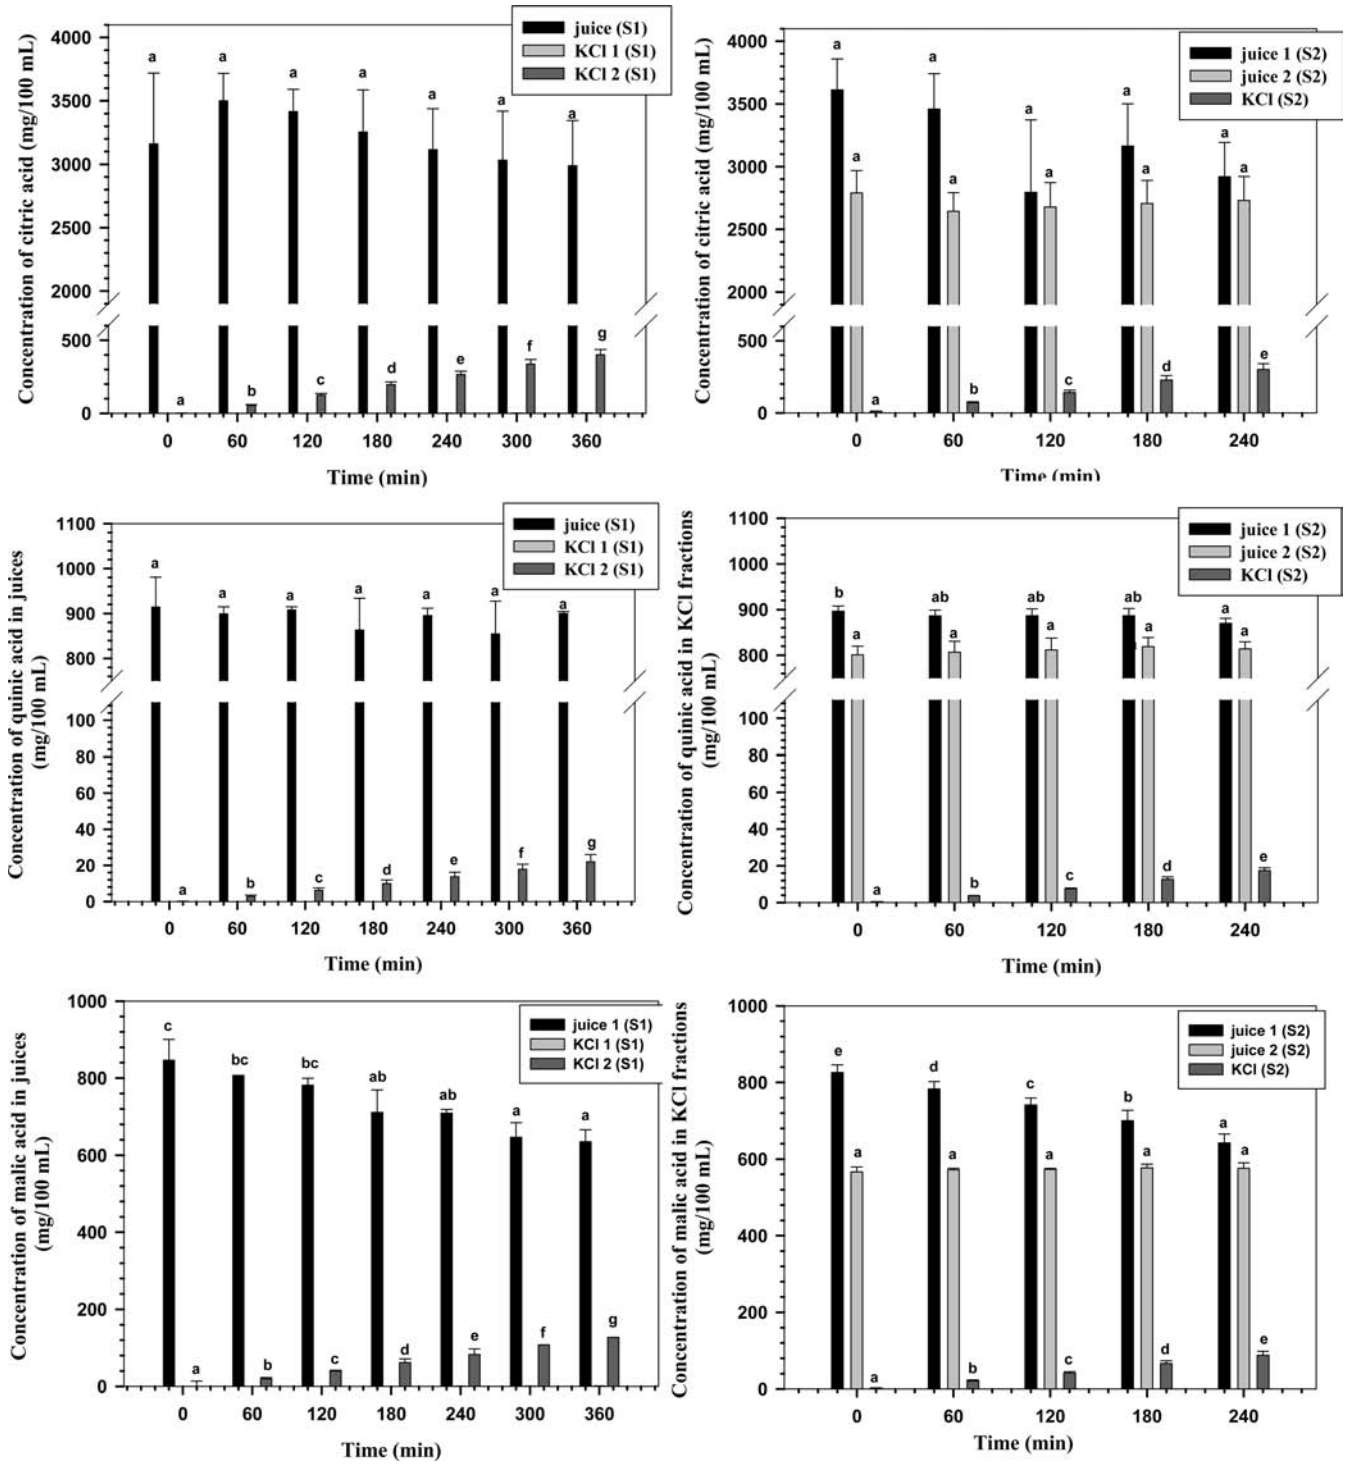

Figure 10. Evolution of (a, top) citric acid, (b, middle) quinic acid, and (c, bottom) malic acid contents of juice 1, KCl 1, and KCl 2 in the first electrodialysis step (6 h), as well as of juice 1, juice 2, and KCl in the second step (4 h). Data with different letters for the same parameter are significantly different at a probability level of 0.05.

Cranberry Juice Color. The cranberry juice color was studied on raw juice, final juice 1−step 2, and juice 2−step 2 because the volume required (30 mL) to do the analysis was not available for juice−step 1, because it was always used for the second step of electrodialysis (Figure 11). Considering that there were no significant differences ($P > 0.05$) for each L^*a^*b parameters between the control juice and juice 1−step 2, there should not be significant differences for juice−step 1. However, juice 2−step 2 was significantly different from other juices regarding component a^*. Indeed, this juice had a lower intensity of red and was visibly affected by the second electrodialysis treatment. Due to the presence of anthocyanins in cranberry juices, particularly cyanidin galactoside, peonidin galactoside, cyanidin arabinoside, and peonidin arabinoside, responsible for the red color of the juice,[33,34] and the variation of the intensity of ,a* parameter, already demonstrated to be correlated with anthocyanin content variation,[25] we can conclude that the significant degradation of anthocyanin in

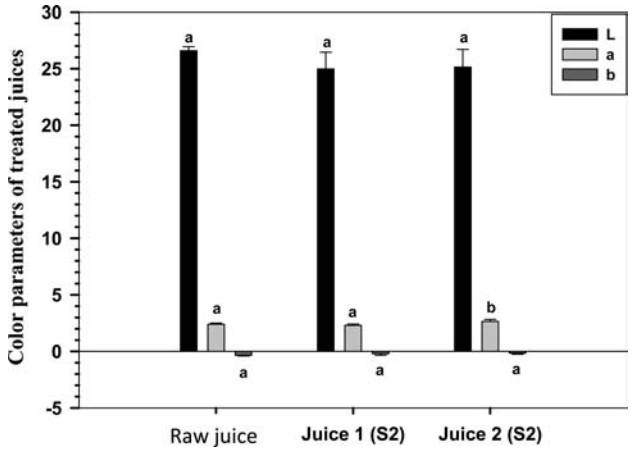

Figure 11. Results for the $L^*a^*b^*$ color parameters of the raw juice, juice 1, and juice 2 in the second electrodialysis step. Data with different letters for the same parameter are significantly different at a probability level of 0.05.

juice 2−step 2 during the electrodialysis treatment influenced its color and confirmed the decrease observed previously for the anthocyanins content.

This study demonstrated that it is possible to increase significantly the pH of a cranberry juice, as well as decrease its titratable acidity and organic acids contents by electrodialysis with bipolar membranes (EDBM). The first step of the treatment allowed better results than the second step concerning the polyphenols and anthocyanins content, as well as the color characteristics. The second step did not allow a pH decrease of juice 2 to recover its original characteristics; on the contrary, it seemed to deteriorate the cranberry juice. With regard to the electrodialytic parameters, the global system resistance decreased after each repetition, supported by the coloration of the different membranes and the diminution of the conductivity of the anionic and bipolar membranes due to the negatively charged molecules that passed through membranes or made a fouling at their surface.

To improve the results obtained in this study, the use of a configuration considering only the first step but with a higher surface of membrane obtained by increasing the number of membranes stacked would increase the rate of juice deacidification. Finally, this study proves that it is possible to remove organic acids with electrodialysis, a green technique using no solvent, even when the pH of the juice is far lower than the pK_a of the acids targeted.

Influence of Processing Parameters on Morphology of Polymethoxyflavone in Emulsions

Yuwen Ting, Colin C. Li, Yin Wang, Chi-Tang Ho, and Qingrong Huang*

Department of Food Science, Rutgers, The State University of New Jersey, 65 Dudley Road, New Brunswick, New Jersey 08901, United States

ABSTRACT: Polymethoxyflavones (PMFs) are groups of compounds isolated from citrus peels that have been documented with wide arrays of health-promoting bioactivities. Because of their hydrophobic structure and high melting point, crystallized PMFs usually have poor systemic bioavailability when consumed orally. To improve the oral efficiency of PMFs, a viscoelastic emulsion system was formulated. Because of the crystalline nature, the inclusion of PMFs into the emulsion system faces great challenges in having sufficient loading capacity and stabilities. In this study, the process of optimizing the quality of emulsion-based formulation intended for PMF oral delivery was systematically studied. With alteration of the PMF loading concentration, processing temperature, and pressure, the emulsion with the desired droplet and crystal size can be effectively fabricated. Moreover, storage temperatures significantly influenced the stability of the crystal-containing emulsion system. The results from this study are a good illustration of system optimization and serve as a great reference for future formulation design of other hydrophobic crystalline compounds.

KEYWORDS: *polymethoxyflavone, morphology, emulsions, crystal size*

INTRODUCTION

With the advances in medical sciences and informational technologies, people are more educated on disease pathologies. Instead of receiving therapeutic treatments after a disease has been diagnosed, engaging in preventive behavior has gained popularity among health-conscious individuals. The discoveries of many bioactive compounds from dietary sources have become the popular trend in research of disease prevention. The term nutraceutical is being used to identify these types of bioactive ingredients. Well-known examples of such bioactive compounds, including curcumin, quercetin, resveratrol, lutein, β-carotene, epigallocatechin gallate (EGCG), lycopene, etc., are widely investigated and documented on their ability to provide health-promoting benefits to living organisms. For chronic consumption, oral ingestion is the user-friendliest method for consumers to use the biofunctionalities provided by bioactive ingredients. However, many of those nutraceuticals are poorly absorbed when consumed orally because of their unfavorable chemical characteristics, which leads to fast degradation, low solubility, poor intestinal uptake and transport, extensive metabolism, and rapid excretion rate. For these reasons, various delivery systems have been developed to enhance their oral bioavailability.[1−4]

When consumed with lipids, the oral bioavailabilities of highly hydrophobic compounds were shown to be significantly improved.[1−3] Thus, many lipid-based delivery formulations have been developed for the oral consumption of nutraceuticals with poor aqueous solubility.[4] Emulsion, in this sense, has a long history of being applied as a convenient method to contain, protect, and facilitate uptake and transport of hydrophobic dietary ingredients. Because of this adaptable nature, many derivatives, supplemented with additional functional mechanisms, have been produced to broaden the applications of emulsion-based delivery systems for food and pharmaceutical uses. Moreover, because many studies have suggested an inverse relationship between the particle size and oral absorption of bioactive ingredients, the applications of technologies to physically reduce the emulsion particle to micro- or nanoscale have become a popular trend. However, with the reduction of the particle size, emulsion-based delivery systems face the challenge of low compound loading capacity and higher sedimentation rate because of the presence of highly crystalline hydrophobic ingredients.[5]

Polymethoxyflavones (PMFs), such as nobeletin, tangeretin, sinensetin, 3,5,6,7,8,3′,4′-heptamethoxyflavone (HMF), and others, contain multiple methoxy ($-OCH_3$) groups on their characteristic 15-carbon benzo-γ-pyrone structures and are categorized as a subgroup of flavonoids. PMFs and their hydroxylated derivatives have been proven to be potent therapeutic agents in preventing diseases, such as chronic inflammation, tumor development, atherosclerosis, thrombosis, and oxidation damage.[6−11] Multiple methoxyl groups on the structure of PMFs contribute to their highly hydrophobic nature, which results in a low aqueous solubility and poor oral bioavailability. The application of an emulsion-based delivery technology has been investigated for PMF oral ingestion with the interest of improving its bioavailability.[5,12,13] However, the high melting point and fast crystallization behavior of PMFs pose great challenges in designing, processing, storing, and applying emulsion formulations.[5,12−14] Because of their poor solubility in both oil and water at ambient temperatures, the loading capacity of PMF emulsion systems is generally unsatisfactorily low and the formula is subject to precipitation

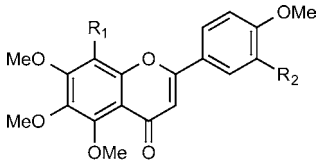
during storage. In our previous studies, a viscoelastic emulsion was designed to maximize the PMF loading capacity while maintaining a stable system, even if crystallization did occur.[13] During the process of optimizing the formulation, interestingly, the crystallization kinetics and the resulting crystal morphology were affected by the processing parameters. In the present study, we aim to systematically examine the effect of different processing conditions on the crystalline compound in an emulsion system. Moreover, the effect of various storage environments on the crystalline emulsion system was also included as a part of our discussion. Here, for the convenience of the study design, only tangeretin was selected as the model PMF compound in the emulsion system (Figure 1). The knowledge obtained from this study will serve as a useful reference for the future development of oral formulations targeting highly crystalline compounds.



Tangeretin R_1 = OMe R_2 = H

Figure 1. Structure of PMF with a detailed functional group of tangeretin.

MATERIALS AND METHODS

Materials. Tangeretin of 98% purity was purchased from Quality Phytochemicals, LLC (Edison, NJ). Rapeseed PC75 lecithin containing 75% phosphatidylcholine was a gift from American Lecithin Company (Oxford, CT). Neobee 1053 medium-chain triacylglycerol (MCT) was a sample requested from Stepan Company (Northfield, IL). Milli-Q water was used throughout the experiment.

Preparation and Processing of PMF Emulsion Samples. PMF emulsions were prepared according to a previously published method, with necessary modifications.[13] The distribution of each emulsion phase of the studied samples was kept constant at 46% aqueous phase, 1.5% emulsifier, and 52.5% oil phase. To evaluate the effect of the PMF loading concentration on the resulting crystal in the emulsion, various concentrations (0.3−2.0%) of the PMF compound were added to the carrier oil, composed of 100% medium-chain triacylglycerol (MCT), at 130 °C with continuous stirring until they were completely dissolved (Table 1). After PMF was dissolved in MCT, 0.45 g of lecithin was then added to the 130 °C PMF oil solution as the emulsifier and then stirred until fully solubilized. The aqueous phase [100% double deionized (DI) water] was preheated to 70 °C to prevent rapid PMF crystallization induced by impulsive temperature drops. To avoid excessive water loss, the disperse phase solution (MCT with solubilized PMF compound and lecithin) was adjusted to 70 °C immediately before mixing with the preheated aqueous phase. Once the aqueous phase had been added to the oil phase, the solution was maintained at 70 °C and continuously stirred until one phase of crude emulsion was formed. Because the crude emulsion formed was very viscous and could cause processing difficulty during high-pressure homogenization (EmulsiFlex-C6, AVESTIN, Inc., Ottawa, Ontario, Canada), the crude emulsion was then subjected to high-speed homogenization (ULTRA-TURRAX T-25 basic, IKA Works, Inc., Wilmington, NC) at 24 000 rpm. During high-pressure homogenization, all samples used for compound loading and storage studies were processed under 500 bar at 55 °C. However, samples used for comparing the effect of different processing parameters on the emulsion sample quality were produced at various combinations of temperatures (55, 65, and 75 °C) and pressures (500, 1000, and 1500 bar). Finally, approximately 25−30 g of emulsion sample was collected from each processing batch.

Table 1. Formulations for Emulsion Samples of Various Tangeretin (PMF) Loading

emulsion formulation compostion				
	oil phase (52.5%)		emulsifier (1.5%)	aqueous phase (46%)
PMF loading concentration (%)	PMF (g)	MCT (g)	lecithin (g)	DI water (g)
0.30	0.09	15.66	0.45	13.80
0.50	0.15	15.60	0.45	13.80
0.60	0.18	15.57	0.45	13.80
0.70	0.21	15.54	0.45	13.80
0.80	0.24	15.51	0.45	13.80
0.90	0.27	15.48	0.45	13.80
1.10	0.33	15.42	0.45	13.80
1.30	0.39	15.36	0.45	13.80
1.50	0.45	15.30	0.45	13.80
2.00	0.60	15.15	0.45	13.80

Particle Size Measurement. Because the particle size is an important quality parameter for an emulsion system, the average particle size was determined. A BIC 90 Plus particle size analyzer equipped with a Brookhaven BI-9000AT digital correlator (Brookhaven Instrument Corporation, New York, NY) was used for determining the average particle sizes from all emulsion samples produced. Emulsion samples were diluted in DI water by a dilution factor of 5000 to avoid multiple scattering effects. The light source was a solid-state laser operating at the wavelength of 658 nm with 30 mW of power, and a high-sensitivity avalanche photodiode detector was used for signal detection. Measurements were conducted at a fixed scattering angle of 90° at 25 ± 1 °C. Results were reported in triplicate (n = 3) as the mean particle size and size distribution.

Moisture Content Analysis. The moisture contents of emulsion samples were calculated as the percent sample weight loss when dried by an IR-200 moisture analyzer (Denver Instrument Co., Arvada, CO). To determine the moisture content, emulsion samples (≤0.2 g) were placed on a balanced aluminum weight pan (diameter = 100 mm) located on the scale section of the instrument. The samples were continuously heated by four parallel quartz infrared heaters at 200 °C until completely dried. The moisture content was then calculated using the following equation:

$$\text{moisture } (\%) = \frac{W_i - W_f}{W_i} \times 100 \quad (1)$$

where W_i is the initial sample weight being placed on the scale and W_f is the final sample weight after drying.

Crystal Size and Morphology Evaluation. To obtain higher loading concentrations of hydrophobic crystalline compounds, the resulting emulsion formulations are sometimes a system containing heterogeneous particles. In a mixed emulsion system, compounds are either solubilized within the emulsion droplet or present as entrapped small solid crystals. Variation of the processing parameters and storage conditions may result in different droplet and crystal characteristics. In this part of the study, crystal size and morphology were monitored using a direct microscopic observation. Undiluted emulsion samples were placed on a microscope slide and then mounted using a cover glass. An inverted optical microscope (Nikon TE 2000, Nikon Corporation, Japan) equipped with a charge-coupled device (CCD) camera (Retiga EXi, QImaging) was used for crystal morphology observation. All images were processed by C-Imaging software (SimplePCI, Compix, Inc.). The average sizes of the crystal (n = 100) were measured using Java-based image processing software (ImageJ) with corrected reference scaling.

X-ray Diffraction (XRD). The information on the crystal characteristics from emulsion samples containing various concentrations of PMF was studied using an XRD method. Powder X-ray

DOI: 10.1021/jf504465a
J. Agric. Food Chem. 2015, 63, 652−659

diffraction (PXRD) experiments were conducted using a D/M-2200T automated system (Ultima+, Rigaku) with Cu Kα radiation (λ = 1.5406 Å). The PXRD patterns were collected at 2θ angles from 3° to 40° at a scan rate of 2°/min. A graphite monochromator was used, and the generator power settings were 40 kV and 40 mA.

Study of Rheological Characteristics. The rheological properties of the emulsion samples were performed using an ARES rheometer (Rheometric Scientific, Piscataway, NJ) with parallel plate geometry (diameter of 25 mm) at room temperature (20.0 ± 0.2 °C). About 1 mL of the emulsion sample was deposited onto the plate geometry. Prior to each dynamic frequency sweep test, a dynamic strain sweep test ranging from 0 to 100% was performed at 2 rad/s angular frequency and the strain value of 5% in the linear viscoelastic region was adopted. The angular frequency ω ranged from 1 to 100 rad/s with 20 data points per decade. The gap between the two parallel plates was properly selected to prevent sample slip. A small amount of mineral oil was used to seal the sample edge to prevent solvent evaporation.

Storage Stability Evaluation. It is desirable to have a stable emulsion system for long-term storage. In this part of the study, the stability and quality changes under different storage conditions were evaluated. The emulsion sample quality was examined by monitoring the changes of the emulsion droplet size and crystal length over 30 days of storage at 4, 25, and 60 °C. All emulsion samples used in this study were processed in one single batch with a composition of 2.0% PMF, 50.5% MCT, 1.5% lecithin, and 46% DI water.

Statistical Analysis. A single-tailed student's *t* test was performed using Sigmaplot 10.0 software.

RESULTS AND DISCUSSION

Effect of the Tangeretin Loading Concentration on the Emulsion Property. For oral formulation, it is equally desirable to have adequate stability as well as sufficient loading of the active ingredient, so that a therapeutically meaningful dosage can be reached in a practical serving portion. Dependent upon the purpose and form of consumption, the requirements for a qualified oral formulation can vary significantly. For example, it is essential for an oral formulation to avoid creaming and precipitation when incorporated into a beverage product. On the other hand, when consumed as a soft gel or tablet, it is desirable for the oral system to have a higher concentration and sophisticated storage stability of the active ingredient. Therefore, it is necessary for investigators to explore the highest possible loading concentrations of the target compound in the designated oral applications. In our previously published paper, we had successfully developed a viscoelastic emulsion system to contain PMF with sufficient loading capacity and storage stability. Here, in this part of the experiment, we aim to systematically examine the effect of incorporating various tangeretin concentrations (0.3, 0.5, 0.6, 0.7, 0.8, 0.9, 1.1, 1.3, 1.5, and 2.0%) on the physical characteristics and related application potentials of the emulsion system. As suggested by previous studies, the particle size of oral formulation was a critical factor in determining the digestion, absorption, and bioavailability of hydrophobic active ingredients.[12,15−20] That is, smaller emulsion droplets often resulted in higher bioavailability because of faster digestion kinetics and potential direct uptake by gut wall and lymphatic systems. When the amount of emulsifier was held constant, the emulsion droplet size increased progressively (from 378.4 ± 5.3 to 565.2 ± 3.3 nm) as the percentage (from 0.3 to 2.0%) of tangeretin increased in the system, while no significant change in the moisture content was observed (Table 2). In general, the concentration of the emulsifier in the system was inversely related to the particle size. As the loading of PMF increased, the

larger particle size may have been the result of the various degrees of emulsifier consumed to support the PMF solubility of the system.

Moreover, the inclusion of crystalline hydrophobic compounds into emulsion formulations could sometimes result in a mixed system containing bioactives solubilized as dispersed droplets or present as entrapped crystalline particles. To maximize the loading of hydrophobic crystalline components in an emulsion system, the carrier oil was usually supersaturated using high processing temperatures. As a result, the reduction in temperature caused the compound to be expelled from the supersaturated oil phase and crystallized in the continuous phase. When the compound concentration (<0.6%) in the system was below the saturation concentration, no crystal formation was observed in the emulsion systems (panels a and b of Figure 2A). As the loading concentration increased to the

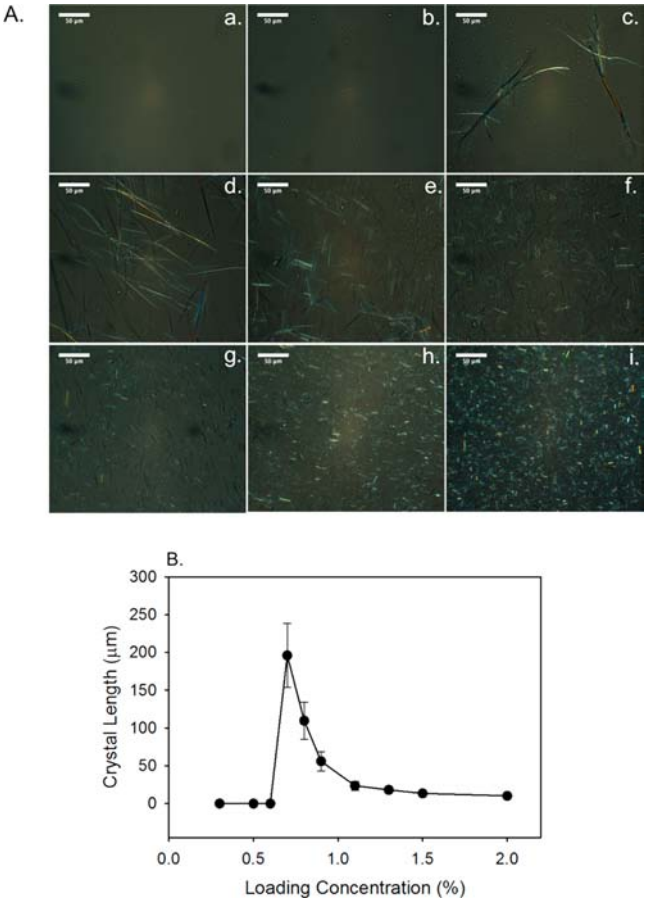

Figure 2. (A) Microscopic picture of emulsion samples with different tangeretin (PMF) loadings: (a) 0.5%, (b) 0.6%, (c) 0.7%, (d) 0.8%, (e) 0.9%, (f) 1.1%, (g) 1.3%, (h) 1.5%, and (i) 2.0%. (B) Quantitative plots of crystal lengths as a function of PMF loading concentrations.

critical concentration (0.7%), where it was only supersaturated, low amounts of tangeretin crystals appeared in bundles, with a maximum crystal size of 196.17 ± 42.44 μm scattered among the emulsion droplets. With the continuous increase in supersaturation, the number of tangeretin crystals increased (panels c–i of Figure 2A) as the size decreased (Figure 2B). As established by others, the size of a crystal produced is inversely proportional to the number of nuclei formed.[21−23] The number of nucleation sites considerably increased with a higher degree of supersaturation, because the number of molecules required for the formation of nucleating clusters decreased.[21] Therefore, smaller crystals were produced as the number of nuclei expanded more rapidly than the crystal growth. To be absorbed in the gastrointestinal (GI) tract, a hydrophobic crystalline compound has to be either solubilized or dispersed in the aqueous GI environment. Upon oral ingestion, large clusters of crystalline hydrophobic components are prone to gravitational precipitation, which causes them to be excluded from the body. On the other hand, the bioavailability of crystalline hydrophobic compounds may benefit from the smaller size. Small crystals are more advantageous for GI absorption because they are more easily incorporated into mixed micelles or directly absorbed by the gut wall.

Because of the crystalline structure, the variation in the PMF loading concentrations changed the physical characteristics of the viscoelastic emulsion systems, affecting the potential consumer applications. Specifically, the rheological properties of the viscoelastic emulsion are the most important factor in sustaining and stabilizing the PMF-incorporated system. Here, we explore the effects of different PMF loads on the rheological properties in relation to its crystalline characteristic. All of the samples containing different degrees of PMF loading had a higher storage modulus value ($G2$) than lost modulus value ($G2$), indicating a gel-like elastic behavior. Figure 3A shows G'

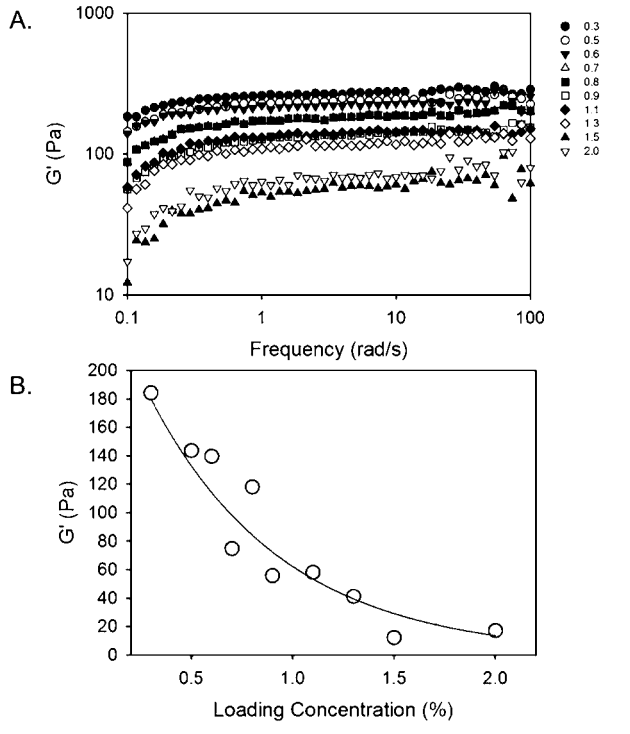

Figure 3. (A) Storage modulus ($G2$) versus frequency curve of emulsion containing various tangeretin (PMF) concentrations from 0.3 to 2.0%. (B) Plot of the $G2$ value at 0.1 rad/s frequency as a function of PMF concentrations.

as a function of the frequency for viscoelastic emulsion samples with PMF loading of 0.3, 0.5, 0.6, 0.7, 0.8, 0.9, 1.1, 1.3, 1.5, and 2.0%. To elucidate the effect of PMF loading on the $G2$ value, Figure 3B presents the changes to the $G2$ value at 0.1 rad/s frequency as a function of PMF concentrations. The increase in the PMF concentration from 0.3 to 2.0% in emulsion formulation is matched with a decreasing trend in $G2$ values. Because the $G2$ value is usually used as an indicator of the

DOI: 10.1021/jf504465a
J. Agric. Food Chem. 2015, 63, 652−659

network interaction, the lowering $G2$ values suggested the weakening of the gel-like structure in the emulsion. As reported in our previous investigation, the interactions between emulsion droplets contribute to the viscoelastic property of emulsion systems.[13] The weakening of the network interactions can be mainly attributed to the increasing number of crystals entrapped within the system. The increases of the emulsion crystalline structure were further confirmed by XRD analysis. In Figure 4, there was no characteristic peak observed in the

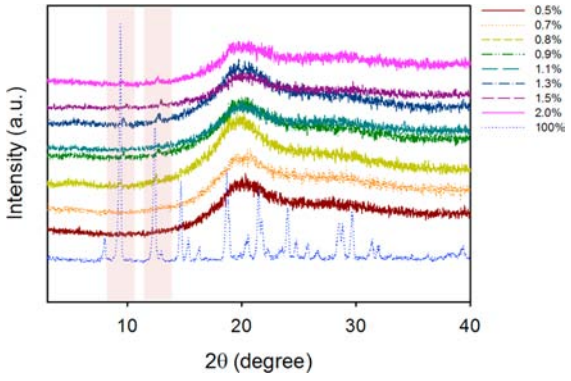

Figure 4. XRD pattern for emulsion samples with tangeretin (PMF) loading concentrations ranging from 0.5 to 2.0%. The pattern from 100% tangeretin crystal (blue dotted line) was also included as a characteristic peak reference.

emulsion sample with lower PMF concentrations (0.5 and 0.7%). However, the characteristic peak for PMF was detected in emulsion samples with higher PMF concentrations.

Effects of Processing Parameters on the Emulsion Property. Because smaller particles may have higher oral bioavailability, it is desirable to reduce the particle size in oral formulations containing hydrophobic components. High-pressure homogenization (HPH) is a common technique for reducing the droplet size in an emulsion-based system. As previously reported, smaller droplet sizes were obtained when higher processing pressure and temperature were applied.[24] To investigate the influence of HPH on the particle sizes of the crystalline emulsion system, different combinations of temperatures and pressures were used for producing PMF viscoelastic emulsions. Because PMF crystallization is sensitive to temperature variation, it is critical to maintain an elevated processing temperature during emulsion production. During HPH, temperatures lower than 50 °C promoted massive PMF crystallization and caused blockage of the HPH instrument. To prevent rapid crystallization, three temperatures (55, 65, and 75 °C) were selected for emulsion optimization trials. The three processing temperatures were applied in combination with three different pressure levels of 500, 1000, or 1500 bar, giving a total of nine production combinations. However, samples processed at 75 °C were excluded from the discussion, because it had excessive moisture loss and did not form a stable one-phase emulsion system (data not shown). Under all processing conditions, emulsion samples had an average droplet size of around ∼500 nm with no significant intersample deviation. However, the size of crystalline structures in the emulsion system was greatly influenced by different processing parameters. Under the same processing pressures, samples processed at 65 °C produced a larger crystal size than samples processed at 55 °C (Figure 5A). The results indicated that the rate of PMF crystallization in the viscoelastic emulsion was

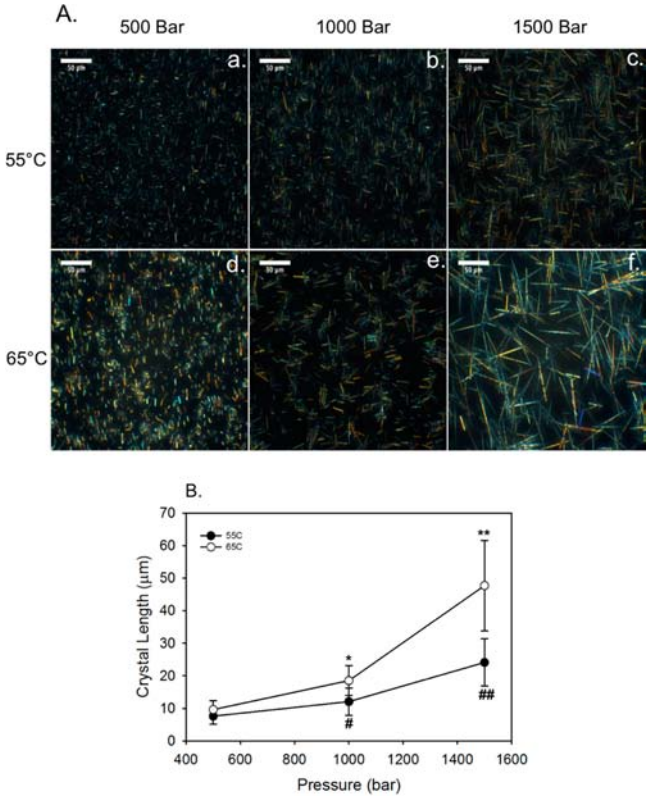

Figure 5. (A) Microscopic pictures of emulsion samples processed at different combinations of temperature/pressure level: (a) 55 °C/500 bar, (b) 55 °C/1000 bar, (c) 55 °C/1500 bar, (d) 65 °C/500 bar, (e) 65 °C/1000 bar, and (f) 65 °C/1500 bar. (B) Plot of the crystal length at 55 °C (○) and 65 °C (●) as a function of the processing pressure. (∗) $p < 0.05$: the crystal size of 55 °C/1000 bar is significantly different from the crystal size of 55 °C/500 bar and 65 °C/1000 bar. (∗∗) $p < 0.05$: the crystal size of 55 °C/1500 bar is significantly different from the crystal size of 55 °C/500 bar, 55 °C/1000 bar, and 65 °C/1500 bar. (#) $p < 0.05$: the crystal size of 65 °C/1000 bar is significantly different from the crystal size of 65 °C/500 bar. positively associated with the temperature ($\nu \propto T$). The production of larger crystals at higher processing temperatures is likely due to the higher temperature providing the system with more free energy (ΔG), which is required for nucleation as well as for fostering frequent collisions of crystalline molecules.[25,26] Besides processing temperature, the pressure under which the sample is produced also plays a critical role in determining the PMF crystal size. Under similar processing temperatures, crystal sizes became larger when the applied pressure increased (Figure 5B). The phenomenon of pressure application on the elevation of crystallization kinetics has been well-studied by previous investigations. Under high pressure, the melting temperature shifted toward a higher temperature, which increased the degree of undercooling and resulted in higher nucleation rates.[26−28] Moreover, the crystal growth was promoted because the physical distance of crystalline components was decreased under high-pressure conditions.[28,29] From our study, the crystal was smallest with a temperature/pressure combination of 55 °C/500 bar and largest at 65 °C/1500 bar with sizes of 7.58 ± 2.48 and 47.72 ± 13.94 μm, respectively.

The influence on the gel-like structure of the PMF viscoelastic emulsion by the pressure and temperature is given in panels A−C of Figure 6. For all pressure conditions, higher processing temperatures reduced the network interaction more than lower temperatures. While the network interaction of samples processed under 500 and 1000 bar was not significantly affected by temperature variation, the gel structure was greatly weakened when the temperature was raised at 1500 bar. The results from this study suggested that larger crystals in the emulsion system disrupt the gel-like

DOI: 10.1021/jf504465a
J. Agric. Food Chem. 2015, 63, 652−659

structure more by interfering with the emulsion droplet interaction. In Figure 7, the viscoelastic characteristics of emulsion samples under different pressure treatments are compared. Interestingly, the viscoelastic property of the emulsion system was not significantly changed by the pressure variation when the temperature was kept constant (55 or 65 °C). The results from the rheological study indicated that all emulsion samples sustained a viscoelastic structure, even though the network strength was variable.

PMF Emulsion Stability under Different Storage Temperatures. For the general population to benefit from oral formulations, it is important for products to have an adequate shelf life. In this part of the experiment, the storage stability of crystalline PMF viscoelastic emulsion was studied under three storage temperatures (4, 25, and 60 °C) over a 1 month period. Because the emulsion system was a mixed system, any change in the particle size of both emulsion droplets and crystalline components was monitored as indicators of potential instability. To minimize the variability, all emulsion samples were produced in one single batch, distributed between three bottles, and stored in the selected temperature environments. During the 1 month study, the emulsion droplets of all three samples remained stable one-phase systems and did not have noteworthy changes in particle size (Figure 8A). Upon closer examination of the droplet particle size, the droplet particles of the 25 °C sample were slightly larger than those of the other two storage conditions (panels a and c of Figure 8B). The results from this observation indicated that the stability of viscoelastic emulsion might not only benefit from storage in lower temperatures, where the molecular diffusion rate was limited, but also in higher temperatures, where the gel-like surface interaction was stronger. In Figure 9A, the observed microscopic crystal morphology under three storage conditions is presented in chronological order over a 1 month period. To clarify the effect of the storage temperature on the crystal growth, the crystal length from all temperature environments as a function of days elapsed is plotted in Figure 9B. According to our analysis, the crystal growth rate at 4 and 25 °C was minimal and showed no significant variability. However, at 60 °C storage temperature, the crystal growth rate was significantly accelerated. The growth rate of the crystalline structure is highly dependent upon the molecular diffusion rate and activation energy for the crystalline component to fit into the crystal lattice.[26] In this sense, higher storage temperatures provided all factors required for rapid crystal growth and, in our case, caused higher instability for the crystalline emulsion system.

In summary, we systematically optimized an oral formulation that included crystalline components. Formulations with PMF loading no more than 0.6% did not show the existence of crystal structures in the emulsion system. However, to achieve a higher PMF loading and smaller crystal sizes, PMF loadings higher than 1.5% should be selected. Processing parameters also play a critical role in determining the sample quality when a smaller particle size is desired. Because lower temperatures and pressures may create samples with a smaller crystalline structure, the processing temperature and pressure should be set at the optimum processing conditions. During storage, higher temperatures promoted faster growth in the size of both emulsion droplets and crystals. Therefore, to better preserve the quality, a sample containing a crystalline component should preferably be stored in cooler conditions. The results clearly illustrate that the loading concentration, processing parameters, and storage conditions are critical factors to produce crystals with desired sizes and specifications. The methods from this study can be used for future reference when designing oral delivery formulations for crystalline hydrophobic ingredients.

ABSTRACT: Inactivated yeast fractions (IYFs) can be used in enology to improve the stability and mouthfeel of red wines. However, information concerning the mechanisms involved and the impact of the IYF characteristics is scarce. Adsorption isotherms were used to investigate interactions between grape proanthocyanidin fractions (PAs) or wine polyphenols (WP) and a commercial yeast strain (Y), the inactivated yeast (IY), the yeast submitted to autolyzis and inactivation (A-IY), and the cell walls obtained by mechanical disruption (CW). High affinity isotherms and high adsorption capacities were observed for grape PAs and whole cells (Y, IY, and A-IY). Affinity and adsorbed amount were lower with wine PAs, due to chemical changes occurring during winemaking. By contrast to whole cells, grape PAs and WP adsorption on CW remained very low. This raises the issue of the part played by cell walls in the interactions between yeast and proanthocyanidins and suggests the passage of the latter through the wall pores and their interaction with the plasma membrane.

KEYWORDS: *inactivated yeast fractions, physicochemical properties, polyphenols, sorption isotherms*

INTRODUCTION

Inactivated yeast fractions (IYFs) are yeast derivatives produced from enological yeasts (*Saccharomyces cerevisiae*) previously inactivated to suppress their fermentative capacity. Depending on the treatment applied, inactivated whole yeasts, yeast autolysates, yeast extracts, cell walls, or mannoproteins can be obtained. IYFs are used in enology to improve fermentation steps,[1,2] to adsorb pigments,[3−6] or to enhance the safety,[7] the sensory characteristics,[8−11] the color and the colloidal stability of wines.[7,11−13] Regarding sensory properties and stability, the aim is to obtain characteristics similar to those of wines aged on lees.[3,14]

Despite their increasing use, there is limited information concerning the exact composition of IYFs and the mechanisms involved in their potential effect on the organoleptic properties and stability of wines. In fact, IYFs are usually complex products. Their impact can be related to the release of compounds that modify wine taste as well as to the removal of some wine components by parietal adsorption (insoluble fractions) or precipitation (soluble fractions). When dealing with red wines, this impact is mainly attributed to physicochemical interactions involving wine polyphenols and soluble or insoluble IYF components, especially mannoproteins[15,16] and cell walls.[17−19] However, the respective impact of IYF soluble and insoluble components and the exact mechanisms involved are not clearly established yet, and some contradictory results may be found in the literature[20,8] as well as in winemaking practice. This can be related either to the use of very different yeast derived products, obtained from different strains submitted to diverse treatments (thermal inactivation, autolysis, drying, etc.) and presenting different composition and structure, or to the variability of wine composition and initial characteristics.

The aim of the present work was to study interactions between polyphenols and yeast cells (parietal adsorption) and to compare the effect of different treatments (drying, autolysis, and mechanical disruption) on them. Interactions were studied by means of adsorption kinetics and isotherms established in a model winelike solution using grape seed and skin proanthocyanidins (PAs) with different average molecular weight and a pool of polyphenols purified from a red wine. This allowed evidencing (i) the impact of PA molecular weight on their adsorption and (ii) the impact of chemical changes that occur during winemaking. Indeed polyphenols, due to their high reactivity, undergo chemical changes once extracted from grapes. This leads to the formation of derived tannins and pigments, the properties of which are likely to be different from those of their precursors.[21−23] In addition, these derived products are poorly characterized using current analytical techniques.

MATERIALS AND METHODS

Yeasts, Inactivated Yeast Fractions, and Yeast Cell Walls. The yeast strain used in the present work is a commercial *Saccharomyces cerevisiae* strain (Lallemand, Montreal, Canada) commonly used in enology. Yeast was propagated aerobically at 32 °C in a fed-batch manner, with a growth rate of 0.18 h^{-1}, for a total of 17 h. Feed substrate was beet molasses diluted to allow suitable delivery of the molasses to the propagation, and ammonia hydroxide

(5%) was used as the nitrogen source. The yeast biomass (Y) was either frozen at −20 °C and conserved as such or submitted to further postharvesting treatments to obtain inactivated yeast fractions. The viability of frozen cells (Y) was determined prior interaction assays through flow cytometry associated with staining techniques and growth on Petri plates. Results (1 and 2.4% respectively) indicated that most cells were dead. A part of the biomass was inactivated by thermal treatment, achieved by holding the yeast cream at 70 °C for 15 min in a temperature controlled vessel. The inactivated yeast biomass was spray-dried in a Büchi B290 spray dryer (Büchi, New Castle, DE, USA). This enabled the inactivated yeast fraction (IY) to be obtained. Another part was submitted to autolysis. Autolysis was carried out by incubating the yeast biomass at a pH of 5.5 at 55 °C for 20 h. After autolysis the yeast was centrifuged at 15000*g* for 15 min in order to separate the soluble fraction from the insoluble fraction. The insoluble part (A-IY) was spray-dried.

A cell wall fraction (CW) was purified from the biomass Y at the laboratory scale by mechanical disruption, according to the protocol described by Dallies et al. (1998).[24] Before disruption, the yeast biomass was washed three times in a 5 mM phosphate buffer (pH 7.5) by successive resuspension and centrifugation steps (1000*g*, 5 min, 5 °C). Cells were then dispersed in the phosphate buffer at a concentration of 10^9 cells·mL^{-1} and 2 mL aliquots distributed in suitable glass tubes containing 5.3 g of 0.5 mm diameter yttria-stabilized zirconium oxide beads. Complete cell disruption was achieved with a tissue homogenizer (Precellys 24, Bertin Technologies, France) by the application of 13 periods of shaking of 20 s each at 5500 rpm, with 1 min intervals on ice between each period. Cell disruption was followed by optical microscopy. The cell suspension was then collected, and beads were extensively washed with the phosphate buffer. The supernatant and washing solution were pooled and centrifuged at 3800*g* for 5 min.[24] The pellet, containing the cell walls, was washed four times with phosphate buffer and twice with deionized water. The cell wall suspension was heated at 72 °C for 15 min to remove residual enzymatic activities, and sodium azide (0.02% w/v) was added to prevent any microbiological development. The suspension was then stored at 4 °C until use. The dry weight per milliliter of suspension, 4.4 mg·mL^{-1}, was determined by freeze-drying of aliquots. In accordance with literature data,[25,26] it was calculated that cell walls accounted for about 20% of the whole cell dry weight. Neutral sugars[24] and Kjeldhal analyses performed on CW indicated a neutral sugar content of 80% (w/w) and a nitrogen content of about 2% (w/w).

Physicochemical Characterization of Yeast and Inactivated Yeast Fractions. *Transmission Electron Microscopy (TEM).* TEM observations were performed to assess the impact of the process on yeast structure and integrity. Yeast and inactivated yeast fractions were washed three times in Milli-Q water before being dispersed in a 2.5% glutaraldehyde solution in Sorensen's buffer (0.1 M, pH 7.4) overnight at 4 °C. They were then washed twice in Sorensen's buffer and postfixed in a 0.5% osmic acid solution for 2 h in darkness and at room temperature. After two further washes in Sorensen's buffer, cells and cell walls were dehydrated in a graded series of ethanol solutions (30−100%). Samples were embedded in EmBed 812 using an automated microwave tissue processor for electronic microscopy (Leica EM AMW). Thin sections (70 nm; Leica-Reichert Ultracut E) were collected at different levels of each block. These sections were counterstained with uranyl acetate and observed using a Hitachi 7100 transmission electron microscope (Centre de Ressources en Imagerie Cellulaire de Montpellier, IURC, Montpellier, France).

Surface Hydrophobicity and Lewis Acid/Base Properties. Hydrophobicity and Lewis acid (electron acceptor)/base (electron donor) properties of the yeast and of the IYFs were determined by the microbial adhesion to solvents (MATS) method.[27] In aqueous media, polar acid/base forces usually occur under the form of hydrogen donor/hydrogen acceptor (Brønsted acid/base) interactions. However, the use of the Lewis model, more general, is preferable. The affinity of cells (Y, IY, A-IY) for two pairs of solvents of similar Lifshitz−van der Waals surface tension components was compared: (i) the apolar solvent hexadecane and its paired acidic monopolar solvent, chloroform, and (ii) the apolar solvent decane and its paired strongly basic, monopolar solvent, ethyl acetate. Because of the surface tension properties of these solvents, differences between the affinity for chloroform and hexadecane and the affinity for ethyl acetate and decane indicate electron-donor or electron-acceptor properties of the yeast surface, respectively. The hydrophobic/hydrophilic character is revealed by their affinity for apolar solvents.

Yeast biomass and yeast fractions were washed twice and suspended in 9 g·L^{-1} (155 mM) NaCl solution at pH 3.5 (adjusted with HCl) to get an optical density of about 0.7 at 620 nm. In a test tube, 0.4 mL of solvent was added to 2.4 mL of cell suspension. The mixture was vortex-mixed for 60 s and allowed to stand for 15 min to achieve the complete separation of the two phases. The aqueous phase was recovered, and the optical density at 620 nm measured. The percentage of cells bound to a given solvent (or the affinity) is expressed as

$$\%\ \text{affinity} = [1 - ((A - A_T)/A_0)] \times 100$$

A_0 and A being the optical density at 620 nm of the yeast suspension before and after contact with the solvent, respectively, and A_T the optical density at 620 nm of the control. Each assay was performed in triplicate.

Surface Charge. Yeast cells (Y, IY, A-IY) were rehydrated (IY and A-IY only), washed twice, and suspended in a 1 mM NaCl solution. Their electrophoretic mobility was measured at different pH, adjusted between 3 and 7 with HCl and NaOH, using a laser zetasizer (Zetasizer HS 3000, Malvern Instruments, Orsay, France). Each result represents a mean of at least 6 separate experiments.

Purification and Analysis of Polyphenols from a Red Wine. *Purification.* A wine polyphenol pool (WP) was purified from 9 L of a Merlot wine, produced in 2012 at the INRA Experimental Unit of Pech Rouge (Gruissan, France). Separation was achieved by applying the wine to a 7 L bed volume column filled with a styrene/divinylbenzene Diaion resin. The wine flow rate was of 4.2 L·h^{-1}. The resin was rinsed with two bed volumes of distilled water (flow rate 4.2 L·h^{-1}) to remove water-soluble compounds. The elution was followed by refractometry. The phenolic pool was finally eluted with 5 L of methanol and 12 L of 96/4 v/v ethanol/water, both solvents being acidified with TFA (0.05%). The ethanolic and methanolic extracts were pooled and the solvents removed by vacuum evaporation at 40 °C. The polyphenol pool was then freeze-dried and stored at −80 °C under argon atmosphere before further use. The total yield was 5 g of freeze-dried powder per 1 L of treated wine.

Polyphenol Analysis. The wine polyphenol pool WP was dissolved in a winelike medium at a concentration of 5 g·L^{-1}, giving an absorbance at 280 nm of 55.0 (total polyphenols index, TPI). The reconstituted wine had a color intensity ($A_{420nm} + A_{520nm} + A_{620nm}$, optical path 1 cm) of 16.1 and a color tint (A_{420nm}/A_{520nm}, optical path 1 cm) of 0.6. Spectrophotometric measurements were made with a SAFAS UV-MC^2 spectrophotometer (Monaco).

High performance liquid chromatography analyses on the reconstituted wine before and after phloroglucinolysis[28,29] were performed to obtain the composition of the pool. Before phloroglucinolysis, the wine was applied on a C-18 solid-phase extraction cartridge (Waters, Vac tC18 3 cm^3) to remove tartaric acid and salts.[30] The polyphenol composition of the fraction was (on a dry weight basis): 29.3 mg·g^{-1} anthocyanins, 7.7 mg·g^{-1} flavan-3-ol monomers, 32.7 mg·g^{-1} phenolic acids, 24.2 mg·g^{-1} stilbenes, 5.9 mg·g^{-1} flavonols, and 95.0 mg·g^{-1} tannins. The mean degree of polymerization of the tannins was 7.3 ± 1.1, with a % of epigallocatechin and of epicatechin-gallate units of 24.2 ± 2.3 and 3.3 ± 0.3, respectively. This low yield is related to the fact that most polyphenols in the wine pool consisted of derived pigments and tannins, formed by chemical reactions during winemaking and aging and resistant to the usual depolymerization methods.[22,23,31] The possible presence of residual nitrogenous compounds or polysaccharides in the wine pool was also assessed by the Kjeldhal method and the analysis of neutral sugars. Neutral glycosyl-residue composition of polysaccharides in the fraction was determined after hydrolysis with 2 M trifluoroacetic acid (120 °C, 75 min)[32] by converting the

DOI: 10.1021/jf504494m
J. Agric. Food Chem. 2015, 63, 660−670

monosaccharides into their alditol acetate derivatives.[33] Hydrolysis was performed on the reconstituted wine according to the procedure described previously.[34] Analyses indicated the presence of residual pectic polysaccharides, accounting for 2% of the dry mass, and of nitrogen (0.02 $g \cdot g^{-1}$). Assuming that nitrogen is related to peptides or proteins, this content would indicate the presence of about 12.5% peptides/proteins in the dried powder. Considering these results, it was considered that a TPI of 55.0 (obtained by dissolving WP in a winelike medium at a concentration of 5 $g \cdot L^{-1}$) corresponded to a whole polyphenol concentration of 4.275 $g \cdot L^{-1}$. This value was used to convert the TPI into adsorbed polyphenol amount.

Grape Seed and Skin Proanthocyanidin Fractions. Two proanthocyanidin (PA) fractions from *Vitis vinifera* grape seeds (variety Carignan) and a PA fraction from grape skin (variety Muscat), previously purified at the laboratory and stored at −80 °C under argon in sealed vials, were also used for sorption experiments. Grape seed PAs were purified as described by Ducasse (2010).[30] The first fraction, named thereafter Seed3, had a mean degree of polymerization of 3.0 ± 0.1 and a percentage of galloylation of 14.9 ± 0.2%, whereas the second one, named Seed12, had a mean degree of polymerization of 11.8 ± 0.5 and a percentage of galloylation of 26.0 ± 0.5%. The yields of the depolymerization reaction were 64.3 and 41.6% for Seed3 and Seed12, respectively. The grape skin PA fraction was purified from the skin of 1.25 kg of Muscat berries. PAs were extracted with 2.5 L of acetone/H_2O/methanol (51/34/15), under stirring and during 2 h.[35] The mixture was centrifuged for 20 min at 2000*g* and 20 °C. The solid phase was extracted again with the same solvent during one night at 4 °C, and the mixture was centrifuged. The supernatants were pooled, filtrated, concentrated under vacuum at 30 °C (final volume 200 mL), and stored at −80 °C before the following steps. Chlorophyll was removed by three extractions with hexane and the PA extract applied on a styrene/divinylbenzene Diaion resin in batch conditions. The resin was washed several times with H_2O acidified with trifluoroacetic acid (TFA, 0.05% v/v) to remove sugars and proteins (followed by refractometry), and PAs were recovered with MeOH acidified with TFA (0.05% v/v). Methanol was evaporated, and the samples were dispersed in distilled water and freeze-dried. This PA extract was dissolved in H_2O acidified with TFA (0.05% v/v) (5 mL, 47 $mg \cdot mL^{-1}$) and further applied on a Toyopearl TSK HW-50 (F) gel (Tosoh Corp., Tokyo, Japan) (diameter, 2.7 cm; 18 cm height) equilibrated with the same solvent. The column was then extensively washed with H_2O:TFA (0.05% v/v, 300 mL). Elution by 55:45:0.05 v:v:v EtOH:H_2O:TFA (450 at 10 $mL \cdot min^{-1}$) was performed first to remove low molecular weight polyphenols. High molecular weight proanthocyanidins were eluted with a 60:40:0.05 acetone:H_2O:TFA v:v:v mixture (450 mL). After concentration under vacuum (rotary evaporator at 30 °C), the high molecular weight PA fraction was freeze-dried and stored at −80 °C. This fraction, named Skin21, had a mean degree of polymerization of 20.1 ± 0.7, and its percentage of epigallocatechin units was 16.8 ± 1.2%. The yield of the depolymerization reaction was 73.9%.

Adsorption Experiments. Adsorption experiments were performed in a 12% v/v ethanol model winelike solution with 2 $g \cdot L^{-1}$ tartaric acid, the pH of which was adjusted to 3.5 with KOH 1 M. The ionic strength was set at 50 mM by NaCl (2.16 $g \cdot L^{-1}$). SO_2 (25 $mg \cdot L^{-1}$) was added to prevent polyphenol oxidation. Before experiments, the yeast biomass Y and the cell walls CW were washed twice in the winelike solution and resuspended at the final desired concentration in the same medium. Inactivated yeast IY and autolyzed−inactivated yeast A-IY, under the form of dried powders, were first rehydrated in water for 30 min at 37 °C, under stirring. Supernatant was removed by centrifugation (1500*g*, 5 min, 5 °C), and the pellets were washed twice and resuspended in the winelike solution, as described for Y and CW. All suspensions were dispersed properly in model wine using ultrasound (Branson Sonifier 250, 150 W, 40 s).

Adsorption Kinetics. In order to determine the contact time required to reach the adsorption equilibrium, experiments were performed first at different concentrations of the wine polyphenol pool using the yeast biomass at a concentration of 10^8 $cells \cdot mL^{-1}$. Samples were stirred continuously for 3 days, and an aliquot was taken at several time intervals. Yeast cells were removed by centrifugation (1000*g* for YC, 5 min, 5 °C) and the supernatants recovered for spectrophotometric measurements. The total polyphenol concentrations in the bulk were determined by absorbency measurements at 280 nm after adequate dilution. Total adsorbed polyphenols (TAP) were calculated from the difference in absorbance between the samples and the corresponding controls using

$$\mathrm{TAP} = \mathrm{TPI}^{\mathrm{PPcontrol}} - (\mathrm{TPI}^{\mathrm{sample}} - A_{280}^{\mathrm{Ycontrol}})$$

$\mathrm{TPI}^{\mathrm{PPcontrol}}$ being the total polyphenols index (A_{280} × dilution factor) of the polyphenol solution without yeast cells, $\mathrm{TPI}^{\mathrm{PPsample}}$ the total polyphenols index of the supernatant recovered after contact with yeasts, and A^{Ycontrol} the absorbance related to a possible release of compounds by yeasts. Indeed, Y, IY or A-IY may release compounds that absorb at 280 nm. Though very low, this absorbance affects the measurements at the lowest polyphenol concentrations. Therefore, yeast controls, i.e., 10^8 $cells \cdot mL^{-1}$ suspensions in the model wine without polyphenols, were also performed. With the wine polyphenol pool, absorbency measurements at 420, 520, and 620 nm were also performed to determine the impact of yeast and yeast fractions on color intensity and tint.[36]

Kinetics were repeated with the yeast biomass and the three tannin fractions, and then with the inactivated yeasts, the cell walls, and the WP and Skin21 tannins to confirm the contact time needed in sorption isotherm studies to reach equilibrium. Centrifugation conditions adopted to remove cells and cell walls for spectrophotometric measurements were 1500*g*, 5 min, 5 °C and 10000*g*, 5 min, 5 °C, respectively.

Adsorption Isotherms. From kinetic studies, a contact time of 24 h was chosen for adsorption experiments. Polyphenol stock solutions were prepared by dissolving the polyphenol fractions in the model wine at a concentration of 10 $g \cdot L^{-1}$. Dilution of these stock solutions was performed to get a final concentration range between 0.01 and 5 $g \cdot L^{-1}$. All sorption experiments were carried out by mixing equal volumes of a $2x$ $g \cdot L^{-1}$ polyphenol solution (x being the final desired polyphenol concentration) and of a 2×10^8 $cells \cdot mL^{-1}$ suspension (final concentration 10^8 $cells \cdot mL^{-1}$). For cell walls and considering that yeast walls account for 20% of the cell weight, the final concentration of the suspension was set at 0.44 $mg \cdot mL^{-1}$. Samples (2 mL) were placed in 2 mL tightly closed eppendorfs in order to minimize headspace and were stirred continuously (Stuart rotator SB3, 40 rpm) in darkness and at room temperature. After 24 h, samples were clarified by centrifugation (as above mentioned), and supernatants were recovered for spectrophotometric measurements and HPLC analyses (wine polyphenol pool only). Data represent a mean of at least two separate experiments.

Reversibility upon Dilution. The Y and IYF pellets obtained by centrifugation after adsorption were resuspended in 2 mL of model wine without polyphenols. Samples were stirred for 24 h and the supernatants recovered. The adsorption reversibility was evaluated through the quantity of polyphenols recovered in supernatants.

RESULTS AND DISCUSSION

Characterization of the Yeast Biomass and the Inactivated Yeast Fractions. TEM observations of Y, IY, A-IY, and CW are presented Figure 1. In the conditions adopted in the present work, neither the drying process nor the autolysis induced any detectable changes of the yeast ultrastructure (cell wall damage, release of the intracellular material, membrane collapse). All cells presented dimensions between 1.5 and 3 μm, and the measured thickness of the cell wall lay between 100 and 200 nm. The mechanical disruption procedure allowed close to complete removal of the intracellular material and the recovery of cell walls.

Though not visible by TEM, postharvesting processes significantly modified the surface physicochemical properties of cells, which reflects changes in their surface composition

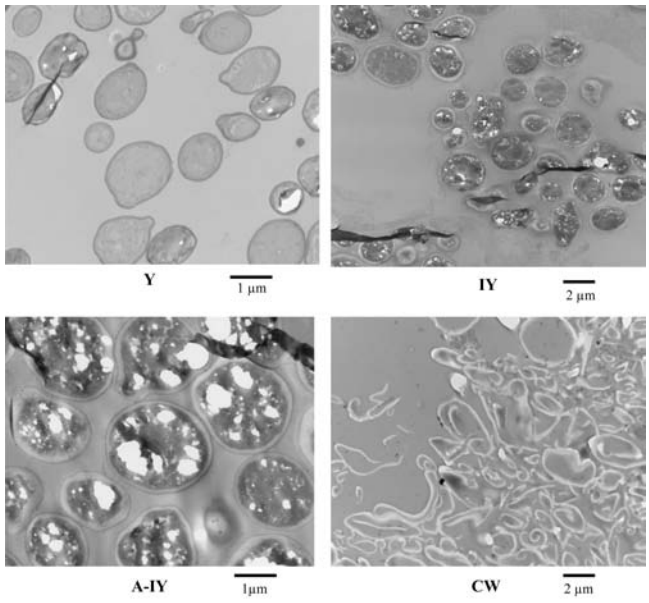

Figure 1. TEM views of the yeast biomass Y, the inactivated yeast IY, the yeast following to autolysis and inactivation A-IY and cell walls CW.

and/or structure (Figure 2). Indeed, IY and A-IY exhibited higher hydrophobicity than the untreated biomass Y, evidenced by their much higher affinity for apolar solvents hexadecane and decane (Figure 2B). All cells also exhibited a higher affinity for chloroform than for hexadecane, and a lower affinity for ethyl acetate than for decane. This allows their classification as basic (i.e., as electron donor), without any apparent electron-acceptor component. This electron-donor character was more pronounced for IY and A-IY than for Y, as shown by the greater differences in affinity observed with solvent pairs. Modification in surface polarity was coupled with a decrease of cell electrophoretic mobility and thus surface charge (Figure 2A). These results are in accordance with previous reports[37,38] and can be attributed to the drying process. Drying has been shown to modify the yeast cell wall structure, inducing changes that are not fully reversible upon rehydration and that are dependent on both the drying (heat-treatment, freeze-drying) and the rehydration procedure.[37,39] Electrophoretic mobility measurements and MATS experiments were not performed on cell walls because these latter present two very different surfaces in terms of composition (outer and inner surface). In addition, they are under the form of fragments of different size and shape. Thus, they cannot be easily compared to whole yeast cells.

Adsorption Kinetics. Kinetic studies were performed first with the wine polyphenol pool (WP) and the yeast biomass Y using different initial polyphenol concentrations. Polyphenol adsorption was followed during 64 h by the measurement of the total polyphenol index (TPI) and of the color parameters (Figure 3). After a rapid decrease of the TPI during the first hour, a plateau value was obtained for the two lowest polyphenol concentrations (0.5 and 1 $g{\cdot}L^{-1}$). This plateau value, indicating that the equilibrium was reached, was observed after 16 and 24 h at concentrations of 2.5 and 5 $g{\cdot}L^{-1}$, respectively. Maximum decrease in color intensity was obtained after 1 h of contact whatever the initial polyphenol concentration, and the color tint was not modified. The percentage of polyphenols fixed by yeast cells decreased from 30 to 16% when the polyphenol concentration in the model wine was increased from 0.5 to 5.0 $g{\cdot}L^{-1}$. In parallel, the decrease in color intensity varied from 33 to 17%. These results are comparable to those obtained by previous work,[17] where the interaction kinetic between yeast lees (1.35×10^8 $cells{\cdot}mL^{-1}$) and a pool of red wine polyphenols was studied in a model winelike solution. For a TPI of 23, close to the one measured in the present study at a WP concentration of 2.5 $g{\cdot}L^{-1}$, the loss in TPI at equilibrium was similar, on the order of 22% for a yeast population of 10^8 $cells{\cdot}mL^{-1}$ (instead of 23% here). In the above-mentioned study,[17] where samples were stirred once a day, much slower adsorption kinetics were obtained than those observed in the present work. This is likely related to the continuous agitation mode chosen in the present work, which favors contact between polyphenols and yeast cells. From these first results, the contact time for sorption isotherm experiments was set at 24 h. Kinetics were repeated with the yeast biomass and the tannin fractions, as well as with the inactivated yeasts and the cell walls, to check that equilibrium was reached (results not shown).

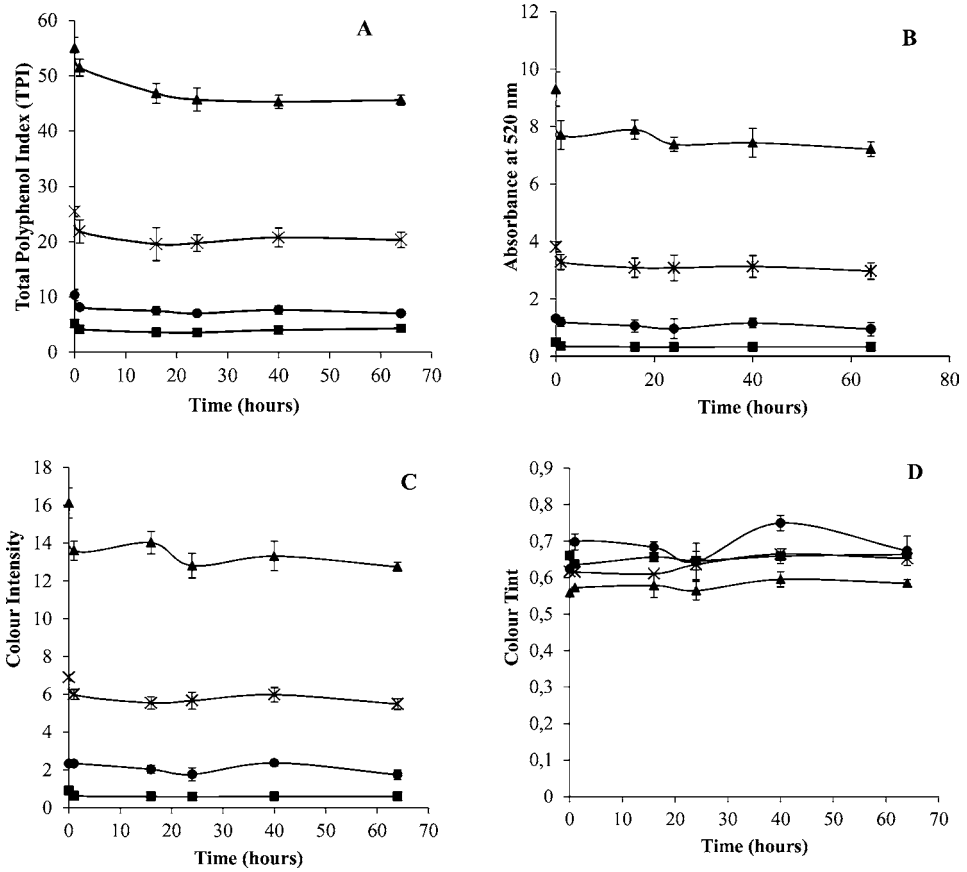

Figure 3. Adsorption kinetics of wine polyphenols on yeast biomass (Y, 10^8 cells·mL^{-1}) in model wine. The concentrations of the wine polyphenol pool were 5 g·L^{-1} (filled triangle), 2.5 g·L^{-1} (filled star), 1 g·L^{-1} (filled circle), and 0.5 g·L^{-1} (filled square). Polyphenol adsorption was monitored by the measurement of the total polyphenol index (TPI, A_{280nm} × dilution factor)) (A); the A_{520nm} (B); the color intensity (C); the color tint (D).

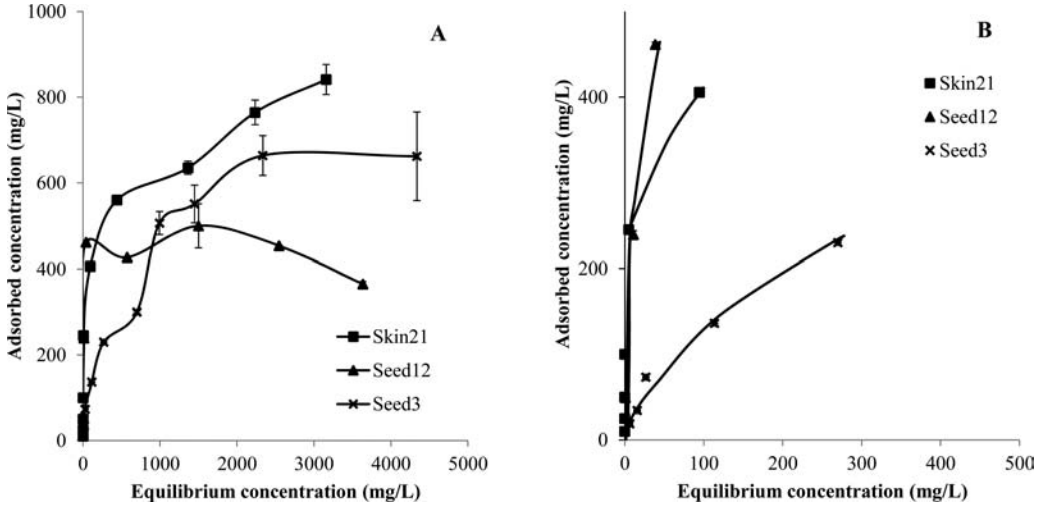

Figure 4. (A) Adsorption isotherms of grape skin (Skin 21) and grape seed (Seed 3 and Seed12) PA by the yeast biomass Y. (B) Enlarged view of the initial adsorption.

Adsorption of Grape Proanthocyanidins by the Yeast Biomass. Adsorption from solution is driven by a complex interplay between solute/solvent, solute/surface, surface/solvent physicochemical interactions, and solvent cohesion. The affinity for the surface (initial adsorption) as well as the maximum adsorbed amount will be dependent not only on the number of binding sites and accessibility to these binding sites but also on possible conformational rearrangements of the solute when dealing with polymers and on possible lateral interactions between adsorbed species. Adsorption isotherms (adsorbed concentration C_{sorbed} versus bulk equilibrium concentration C_{eq}) obtained on the yeast biomass with the grape seed (Seed3 and Seed12) and skin (Skin21) proanthocyanidin fractions are reported in Figure 4A. Skin21 and Seed12 exhibited very high affinity adsorption isotherms, with a complete adsorption at low concentrations, up to 0.5 g·

J. Agric. Food Chem. 2015, 63, 660−670

L^{-1} (Figure 4B and Table 1). This was followed by a continuous and very progressive increase of the adsorbed amount for Skin21, and no plateau value could be observed within the tested concentration range. With Seed12, a maximum plateau value was obtained from 0.5 $g \cdot L^{-1}$. A lower sorption was found for the lower aDP seed PA (Seed3) with an initial slope, calculated from the initial part of the curve of 2.62 and a progressive increase up to a plateau reached for an initial concentration of 3 $g \cdot L^{-1}$. There was no relationship between PA aDP and the maximum adsorbed amount. The lower affinity of Seed3 compared with Seed12 and Seed21 and the complete sorption of the latter at low concentrations suggest the involvement of multiple binding in their interactions with yeast cells.

Table 1. Initial Slopes C_{ads}/C_{eq} Deduced from the Initial Part of the Sorption Isotherms and Maximum Adsorbed Values (Q_{max}) Obtained with the Grape Seed and Skin Proanthocyanidin Fractions[a]

	C_{ads}/C_{eq}	C_{max} ($mg \cdot L^{-1}$)	Q_{max} ($mg \cdot g^{-1}$)	Q_{max}[b] ($mg \cdot m^{-2}$)
Seed3	2.62	664	352	221
Seed12	∞	500	265	167
Skin21	∞	840	445	280

[a] C_{ads}: sorbed concentration. C_{eq}: equilibrium concentration. Results are expressed in $mg \cdot L^{-1}$ and in $mg \cdot g^{-1}$ of dried yeast cells. [b] Yeast cells are considered as spheres with a mean diameter of 3 μm, so that 1 g (5.3×10^{10} cells) represents surface area of 1.47 m^2.

It is usually considered that polyphenol adsorption by yeast is related to their interactions with the cell wall components, and more especially mannoproteins. Yeast cell walls are composed of a network of β-1,3- and β-1,6-linked glucans, mannoproteins, and chitin.[25,26] Schematically, they can be described as two layered structures: an inner microfibrillar layer mainly composed of β-glucans cross-linked or not to chitin and an outer brushlike layer that mostly consists of mannoproteins. Mannoproteins present on the outer layer may be linked either to β-1,6-glucans by a remnant of their glycosyl phosphatidyl inositol (GPI) anchor or to β-1,3-glucans by an alkali-labile linkage.[40] Various proteins/mannoproteins are also attached to the cell wall outer network via disulfide bridges. Considering yeast cells as spheres with a radius of 1.5 μm, 1 g (5.3×10^{10} cells) represents a surface area of 1.47 m^2 (Table 1). This gives for whole cells adsorbed PA amount ranging from 167 to 280 $mg \cdot m^{-2}$, which is several tens to hundred times more than usually found on dense surfaces (in the order of few $mg \cdot m^{-2}$).[41] This result is consistent with PA location on several sites within the wall thickness. These sites can be mannoproteins, but also β-glucans and chitins. Unfortunately, information concerning PA interactions with mannoproteins remains scarce and is missing for β-glucans and chitins.

If polyphenol adsorption by yeasts is often attributed to cell walls,[7] it has also been suggested that small polyphenols may pass through the cell wall and interact with the plasma membrane lipids.[42] This hypothesis has been done to explain the protective effect of yeast lees toward polyphenol oxidation in white wines. In vitro experiments have evidenced that interactions between membrane sterols (ergosterol) and catechin or small (mainly dimers) oxidation reaction products are possible. We are working here with quite different polyphenolic structures (proanthocyanidins), with molecular weight ranging from 950 (Seed3) to 5840 Da (Skin21). The comparison of the adsorption isotherms does not evidence any impact of PA molecular weight on adsorbed amount. The question of the passage of these proanthocyanidins though the cell wall and interaction with the membrane will be further discussed later.

Impact of Postharvesting Treatments and Cell Disruption on Skin21 PA Adsorption by Yeast. The adsorption of polyphenols by the two inactivated yeasts (IY and A-IY) and the cell walls (CW) was compared to that of the yeast biomass (Y) using the Skin21 PA fraction (Figure 5A). Results evidenced very different adsorption behaviors between the whole cells on one hand and the purified cell walls on the other hand. On the whole, purified cell walls exhibited much lower adsorption capacity than the three others. At concentrations below 3 $g \cdot L^{-1}$, the adsorption of skin PA on CW was between 10 and 20 times less than that obtained with the whole cells. An unexpected and significant increase of the adsorbed amount was observed at the highest initial PA concentration, but it remains much lower than that observed with cells. These results are consistent with those of previous studies,[6] that showed a lower adsorption of oxidized phenolic compounds by cell walls than by whole yeast cells in white

[a]For cell walls, we assumed that yeast walls account for 20% of the whole cell weight and that the outer surface developed by cell walls is about twice that developed by whole cells. [b]This value could not be calculated due to the very low adsorption.

wine. As for the untreated biomass, a complete adsorption of Skin21 PA was noticed at low polyphenol concentrations with IY and A-IY, followed by a progressive increase of the adsorbed amount, with fluctuations at the highest tested concentrations. However, some differences were observed between the untreated biomass and the others, and cells could be classified by decreasing order of maximum PA adsorption as follows: Y > A-IY > IY (Figure 5A and Table 2). Though much less than cell disruption, heat treatment and yeast autolysis thus affected the adsorption of polyphenols by yeasts. The reversibility of PA adsorption was evaluated at different initial PA concentrations. Results are summarized in Figure 5B for concentrations of 1 and 4 g·L^{-1}. As can be seen, much higher reversibility was found with the cell walls than with the whole cells. This suggests higher interaction strength between PA and whole yeast than PA and cell wall, and indicates different interaction mechanisms.

Part Played by Cell Wall in PA Adsorption? The much smaller adsorption observed with CW by comparison to whole cells is quite unexpected if PA adsorption occurs only within the wall network thickness. Considering that the outer surface developed by cell walls is about twice that developed by whole cells (Table 2), PA amount adsorbed at initial concentrations below 3 g·L^{-1} fell to values on the order of 2 to 3 mg·m^{-2}. This much smaller adsorption by comparison to whole cells could first be due to a loss of some cell wall constituents involved in interactions with polyphenols during mechanical disruption and/or to an important alteration of their three-dimensional structure, affecting the accessibility to interaction sites and proanthocyanidin accumulation within the wall network thickness. However, these results also raise the question of PA passage through the CW to the periplasmic space and of their interaction with the plasma membrane. As stated before, such transfer and interaction have been hypothesized in the case of small polyphenols.[42]

The question here is the pore size of yeast cell wall and the possible transfer within the network of PA with aDP as large as 21. The pore sizes of yeast cell wall and their permeability to solutes can vary significantly with the strain as well as with growth and environmental conditions. Reports underline a large variability in the data, which can be attributed to cell wall and membrane dynamic behavior, to the very different structures and conformations of the molecules used to study this permeability and to the different treatments applied on cells.[43−45] Thus, if Scherrer and collaborators[43] stated that only molecules smaller than 700 Da and with a maximum Stokes radius of 0.85 nm could diffuse freely through the cell wall, it is known that high molecular weight secreted proteins such as invertase (53 kDa) are able to pass through the cell wall barrier. According to Gerhardt and Judge,[46] the maximum "pore" size of yeast cell walls is around 36 Å and polyethylene glycol or dextran polymers of 4.5 kDa and above are excluded. The average molecular weights of the studied PAs are 5.84, 3.98, and 0.95 kDa for Skin21, Seed12, and Seed3, respectively. Grape or apple tannins are wormlike chain polymers with gyration radius ranging from 2 nm for an aDP 9 grape seed tannin fraction to 5.6 nm for an aDP 40 apple tannin fraction,[22] the radius of the cross section being within the range 0.3 to 0.45 nm. In addition, dynamic light scattering experiments indicated a hydrodynamic diameter on the order of 3 nm for an aDP 28 apple proanthocyanidin.[47] Thus, the passage of the studied grape tannins through the cell wall pores is possible.

In that case, polyphenols may interact not only with cell wall constituents but also with the plasma membrane and/or accumulate in the periplasmic space. The hypothesis of tannin passage through the cell wall and interactions with the plasma membrane would account for the very different reversibility found between cell walls and whole cells. Indeed, if only a passive diffusion mechanism with PA accumulation in the periplasmic space was involved, the reversibility would be higher. Further specific studies will be needed to validate these hypotheses. It is also important to note that most of the data on cell wall permeability/porosity concerns living cells. We are dealing here with the biomass (Y) that presents a very low viability (2.4%) and with inactivated cells. This lack of viability, which is consistent with the context of wine aging and of the use of inactivated yeast, may induce differences in cell wall permeability.

Impact of Autolysis, Inactivation, and Drying on PA Adsorption by Whole Cells. Adsorption isotherm evidenced

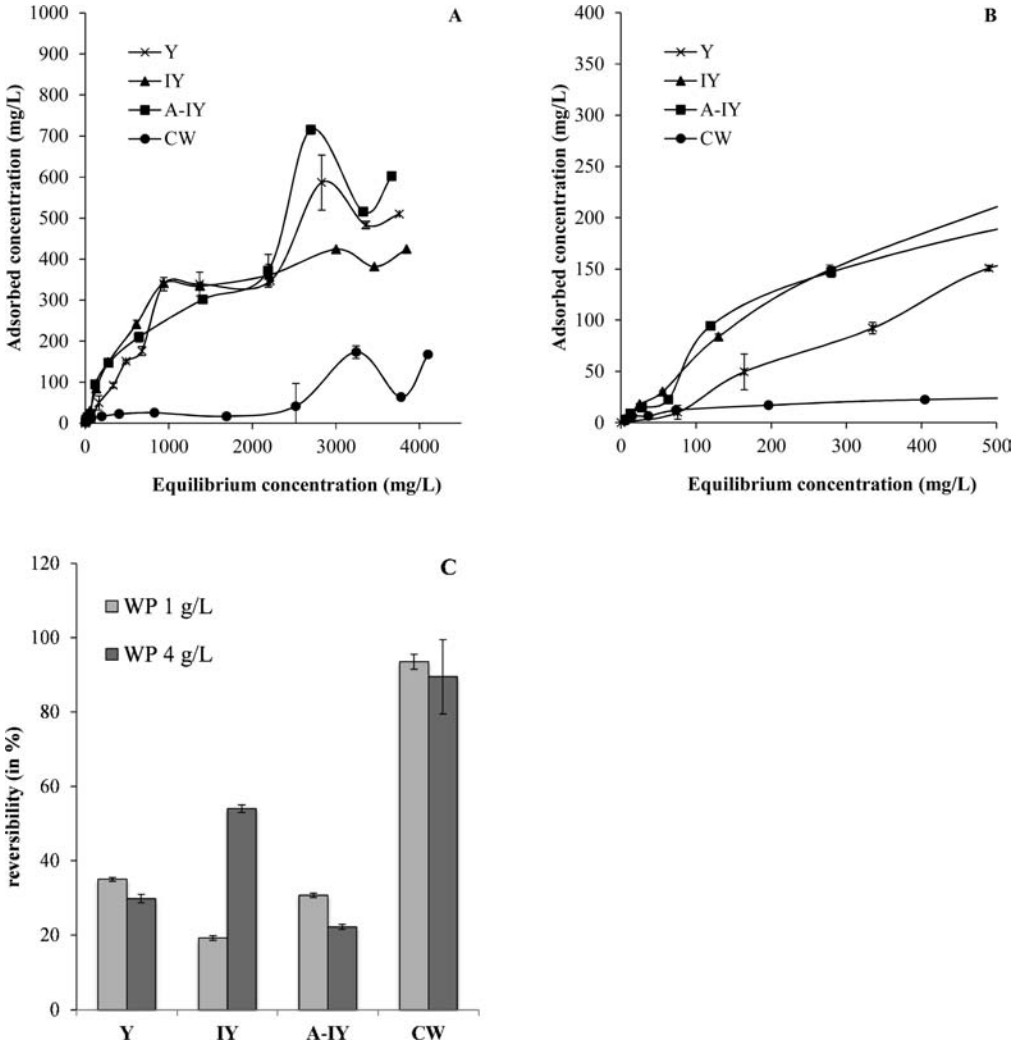

Figure 6. (A) Impact of postharvesting processes and cell disruption on the adsorption of wine polyphenols (WP): Y, yeast biomass; IY, inactivated yeast; A-IY, yeast submitted to autolysis and inactivation; CW, cell walls recovered from mechanical disruption. (B) Enlarged view of the initial adsorption. (C) Reversibility.

that autolysis, inactivation, and drying treatments decrease the maximum adsorbed amount of Skin21 PAs (Figure 5A). As stated before, maximum adsorbed amount on Y, IY, and A-IY indicates that PA adsorption is not limited to the outer cell surface but occurs within the cell wall thickness and may also involve the passage of PAs through the wall and accumulation in the periplasmic space. Thus, the composition and the three-dimensional structure of the cell wall will determine proanthocyanidin adsorption (affinity, adsorbed amount, and strength of the interactions) and wall permeability. Inactivation, autolysis, or spray-drying likely affect yeast cell wall characteristics,[37,38] and the MATS method, along with electrokinetic measurements, indicated an impact of these processes on the surface physicochemical properties of cells. The decrease in polarity observed for IY and A-IY by comparison to Y, which indicates a global decrease of sites for H-bond formation, could explain part of the observed differences between the untreated biomass and the two others. Indeed, proanthocyanidin adsorption on surfaces or complexation with other biopolymers (proteins, polysaccharides) in aqueous media have been shown to be mostly driven by hydrophobic attraction and H-bond formation, and thus by polar acid−base forces.[41,48−50] However, MATS and electrokinetic measurements provide information that only concerns the surface (outer mannoprotein layer). They provide neither any information concerning the three-dimensional organization of the cell wall network nor information about possible physicochemical changes inside this network. Thus, the greater adsorption capacity of Y by comparison to YI and AIY can also be related to a higher accessibility of PA to interaction sites. Especially, drying processes are known to affect the three-dimensional structure of biopolymer networks, inducing a collapse of their structure and a decrease of their porosity that are not fully reversible upon rehydration.[51]

Wine Polyphenols: Impact of Structural Changes on Tannin Sorption by Yeast Cells. Polyphenols from the wine pool WP exhibited much lower affinity than grape PA for the untreated and inactivated yeast cells, and maximum adsorbed amounts were also significantly lower (Figure 6 and Table 2). In agreement with that observed for PA, WP sorption on CW was about 15 times lower than on whole cells at concentrations below 3 $g{\cdot}L^{-1}$. With Y and A-IY, sorption curves presented a first plateau value for initial WP concentrations between 1.5 and 3 $g{\cdot}L^{-1}$, followed by a significant increase in adsorbed amount associated with strong fluctuations at higher concentrations. This increase at high WP concentrations was also

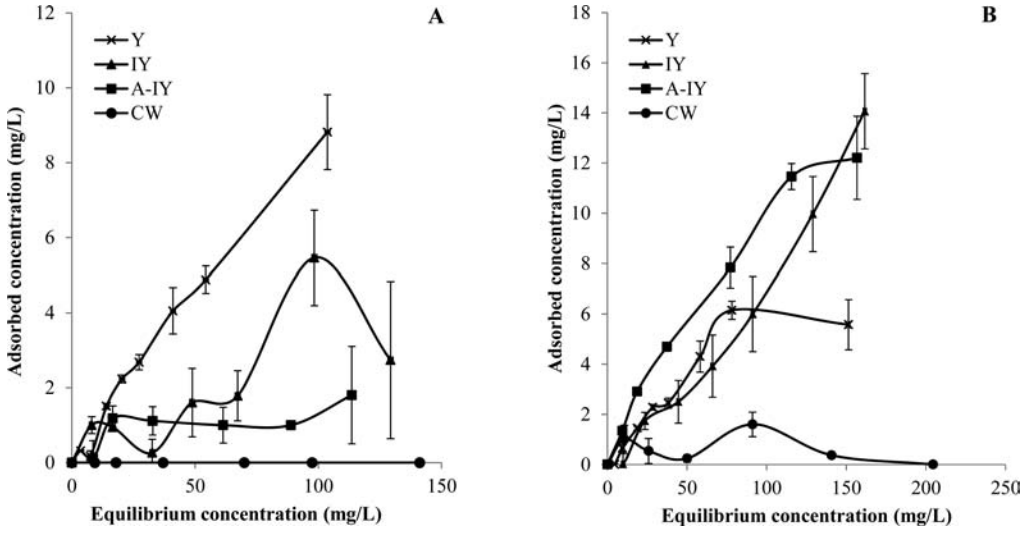

Figure 7. Adsorption of anthocyanins (A) and cinnamic acids (B) on the yeast biomass Y, the inactivated yeast IY, the yeast submitted to autolysis and inactivation A-IY; and the cell walls recovered from mechanical disruption CW.

noticed with cell walls, in accordance with that found with PA with this fraction, and was also associated with strong fluctuations. The exact origin of these fluctuations could not be identified in the present work.

The involvement of tannins and anthocyanins in oxidation reactions during winemaking and aging leads to the formation of a huge diversity of derived tannins and pigments, including polymeric pigments.[52] These structural changes result in the formation of modified units/subunits that cannot be easily analyzed, in a decrease of the yield of the acid-catalyzed cleavage reaction used for the analysis of oligomers and polymers, and induce bias in the determination of the average degree of polymerization of the latter.[53,22] This is the reason why adsorption was studied for WP using spectrophotometric measurements. HPLC analyses were however performed to distinguish between the adsorption of monomers (free anthocyanins and their derivatives, cinnamic acids, flavonols, flavanol monomers) and that of wine PAs and polymeric pigments. Among monomers, only anthocyanins and phenolic acids were adsorbed by yeast cells (Figure 7). This adsorption remained very low and nonspecific. Thus, adsorption of red wine polyphenols by yeast cells or yeast cell walls mainly concerns oligomeric and polymeric structures, and the lowest sorption of wine PAs by comparison to skin and seed PAs is not related to a competition with more simple phenols or to a different aDP but to structural changes. In addition, the higher reversibility found with WP by comparison to PAs indicates weaker interactions.

Structural changes related to oxidation reactions (intermolecular and intramolecular reactions) have been shown to induce an increase of the molecular weight of PAs, along with changes in their conformation.[22,31] This can first induce a lower accessibility of wine PAs to CW interaction sites and/or interfere with their diffusion through the cell walls. Moreover, changes in PA structure associated with winemaking and aging have been shown to modify their interactions with poly(L-proline). Isothermal titration calorimetry experiments indicated a decrease in hydrophobic attraction and hydrogen bond formation between PAs and poly(L-proline) for wine PAs by comparison to grape ones, a decrease that was enhanced with wine age.[31] This was attributed to fewer accessible PA interaction sites due to conformational modifications. However, it can also be due to chemical changes at the molecular level that modify their hydrophobic character and H-donor character. This is consistent with the higher affinity found at low concentrations for IY and A-IY by comparison to Y: postharvesting treatments increased the hydrophobicity and basic character of yeast surface by comparison to the untreated biomass.

This work allowed thus to evidence a very strong affinity of grape seed and skin proanthocyanidins for yeast cells, associated with high adsorption levels. Yeast cells in the context of this work were an untreated biomass with viability close to zero and inactivated yeast fractions. Wine polyphenols exhibited lower affinity for cells than grape PAs, attributed to structural changes that occur during winemaking and aging. A preferential adsorption of wine oligomeric and polymeric PAs and pigments was observed, while the adsorption of monomers remained very small. An important result here was the different adsorption behavior between whole cells and cell walls. Results raise the question of the exact part played by cell walls in the adsorption of wine polyphenols and suggest a quite easy diffusion of proanthocyanidins (up to an average DP of 21) and of wine PAs through this cell wall, accumulation in the periplasmic space, and interactions with the yeast cell membrane. This hypothesis needs to be confirmed, and future works will be devoted to the identification of polyphenol location in whole cells.

Complex Carbohydrates of Red Wine: Characterization of the Extreme Diversity of Neutral Oligosaccharides by ESI-MS

Thierry Doco,*[,†] Pascale Williams,[†] Emmanuelle Meudec,[‡] Véronique Cheynier,[†,‡] and Nicolas Sommerer[‡]

[†]Team BCP2, and [‡]Polyphenols Platform, UMR1083 Sciences pour l'Œnologie, INRA, 2 Place Viala, F-34060 Montpellier, France

ABSTRACT: The major neutral oligosaccharides of a Carignan red wine have been characterized for the first time. The oligosaccharides were prepared after removal of phenolic compounds by polyamide chromatography and of polysaccharides by alcohol precipitation and then were fractionated by anion exchange and size-exclusion chromatography. In a second step, the glycosyl composition and linkages of wine oligosaccharides were determined. Oligosaccharide fractions were analyzed by mass spectrometry (MS) with an electrospray ionization (ESI) source and an ion trap mass analyzer after separation by hydrophilic interaction liquid chromatography on a Nucleodur HILIC column (zwitterionic sulfoalkyl betaine stationary phase). Glycosyl residue composition analysis showed the predominant presence of arabinose, with galactose, rhamnose, and mannose in lower proportion. Neutral oligosaccharides were present at a concentration of 185 mg/L in this wine. The MS spectra in the negative ion mode of the oligosaccharide fractions showed a series of oligosaccharidic structures corresponding to oligo-arabinans often linked to the basic unit α-L-Rha*p*-(1 → 4)-α-D-Gal*p*A. The wine oligosaccharides identified correspond to arabino-oligosaccharides, rhamno-arabino-oligosaccharides, and different rhamnogalacturonan-arabino-oligosaccharides with DP ranging from 5 to 49, resulting from the degradation of grape cell wall pectins. Oligosaccharides have an extreme diversity, with more than 100 peaks detected in HPLC-ESI-MS spectra corresponding each to at least one oligosaccharidic structure.

KEYWORDS: *wines, oligosaccharides, HILIC, HPLC-ESI-MS/MS*

INTRODUCTION

Wine polysaccharides have been thoroughly studied because of their technological and sensory properties in wines. They have been shown to interact with tannins,[1,2] to decrease astringency,[3] to inhibit hydrogen tartrate crystallization,[4] to interact with wine aroma compounds,[5] to prevent or limit aggregation and flocculation and the formation of protein haze in white wine,[6−10] and to form specific coordination complexes with Pb^{2+} ions.[11,12] For sparkling wines, foam properties have been correlated with the type, the molecular weight, and the composition of polysaccharides.[13−16]

Although their presence in wine is known,[17−22] information on oligosaccharide composition is still limited, because of the difficulty in separating and characterizing them. Sucrose and other diholosides have been identified in wines,[22] and a global fraction of oligomers of homo- and rhamno-galacturonan was described and shown to decrease during wine aging.[23] The structure and amounts of polysaccharides and oligosaccharides released into the wines also depend on the grape varieties and the wine-making process and can be modified by enzyme treatment.[18,20,24−27]

Oligosaccharides can be found in various areas, in food, and in nonfood applications.[28] Their main applications include elicitation of plant defenses[29] and a role in prebiotics,[30] but they are also significant for their physicochemical properties such as chelations of cations[31] which can be important for wines. It is important to determine the exact composition of oligosaccharides in wines and to analyze their molecular structures in order to better understand the technological and organoleptic properties associated with them. Characterization of oligosaccharide structure has been classically performed by glycosyl and linkage analyses, by NMR, or by mass spectrometry techniques.[32] The direct analysis of oligosaccharide mixtures by MS has been made possible by the development of soft ionization techniques such as ESI (electrospray ionization).[33−35] The ion fragmentation patterns obtain by MS/MS or MS^n spectra provided information for structural characterization of oligosaccharides.[36] Acidic oligosaccharides have been identified previously,[17,18] and some neutral oligosaccharides have been characterized by high resolution and high mass accuracy matrix-assisted laser desorption/ionization Fourier transform ion cyclotron resonance mass spectrometry (MALDI-FTICR MS) in Grignolino and Chardonnay wines.[19]

We describe herein the purification of neutral and acidic oligosaccharides from a red wine of Carignan and the characterization of the main neutral oligosaccharides after chromatographic separation using a HILIC column by mass spectrometry coupled to an electrospray ionization source and an ion trap mass analyzer. The MS technique proved to be particularly efficient for the analysis of mixtures of wine oligosaccharides without prior derivatization.

EXPERIMENTAL SECTION

Wine Samples. Carignan red wine was made from the grapes of *Vitis vinifera* cv. Carignan grown at the INRA Experimental Unit Station (Gruissan, Southern France) and harvested in 2004 at

commercial maturity (21.8°Brix). A 100 kg amount of grapes was crushed and destemmed using a destemmer−crusher and put in 100-L stainless steel tanks. Alcoholic fermentation was carried out in tanks equipped with temperature control (28 °C), enabling regulation of fermentation kinetics. At the end of alcoholic fermentation, the must was pressed, the wine was stored in 50-L tanks, and lactic bacteria was subsequently added to induce malolactic fermentation. At the end of malolactic fermentation, the wine was racked in a 30-L inox tank and stored at low temperature (−4 °C) to induce tartaric stability. The wine was then bottled and stored in a cellar at 18 °C until analysis.[18,26]

Isolation of Oligosaccharide Fractions. As described in Figure 1, wines (500 mL) added to 1 M NaCl were partially decolorized on a column of MN Polyamide CC6 (28 × 2.8 cm) previously equilibrated with 1 M NaCl. Wine polysaccharides and oligosaccharides not retained on the polyamide column were eluted by two bed volumes of 1 M NaCl.[37] The wine complex carbohydrates were precipitated by ethanolic dehydration. This was performed by adding ethanol 95% acidified by 0.5% HCl to obtain a final concentration of 80% ethanol.[23,24] After one night at 4 °C, the supernatant, which contained the total oligosaccharide fraction, was recovered by centrifugation (30 min, 6288*g*, 4 °C) and dialyzed extensively against distilled water (MWCO 1 kDa), concentrated, and freeze-dried. Then a step of anion-exchange chromatography was performed. The solution containing oligosaccharides was loaded on a DEAE-MACROPREP column (17 × 5 cm; Bio-Rad, Hercules, CA) equilibrated with 50 mM sodium acetate buffer pH 4.8. An unbound fraction (nonretained fraction) was recovered, and a bound fraction (retained fraction) of oligosaccharides was eluted by 1 M NaCl in the same buffer. The unbound fraction and the bound fraction from DEAE-Macroprep were extensively dialyzed against distilled water (MWCO 1 kDa), concentrated, and freeze-dried.

The oligosaccharides of unbound (initial nonretained fraction) and bound (initial retained fraction) fractions were finally purified by size exclusion chromatography. The chromatography was performed by loading 2 mL of initial nonretained or initial retained fractions containing 30 mg of the freeze-dried fraction on a Superdex 30-HR column (60 × 1.6 cm, GE Healthcare, Uppsala, Sweden) with a precolumn (0.6 × 4 cm), equilibrated at 1 mL/min in 30 mM ammonium formate pH 5.6. The elution of oligosaccharides was monitored with an Erma-ERC 7512 (Erma, Tokyo, Japan) refractive index detector combined with Chromeleon software (Dionex, Sunnyvale, CA). Four and six fractions, according to elution time, were collected for the unbound DEAE fraction (initial nonretained fraction) and bound DEAE fraction (initial retained fraction), respectively. The isolated fractions, called nonretained fractions A, B, C, and D and retained fractions A, B, C, D, E, and F were freeze-dried, redissolved in water, and freeze-dried again four times to remove completely the ammonium salt (Figure 1). The molecular weight distribution of oligosaccharides present in the nonretained fractions A, B, C, D and retained fractions A, B, C, D, E, and F was determined by high-performance size-exclusion chromatography (HPSEC) using a LC-10 AS Shimadzu pump (Kyoto, Japan). HPSEC elution was performed on two serial Shodex Ohpak KB-803 and KB-805 columns (0.8 × 30 cm; Showa Denkko, Japan) connected to a ERC-7512 refractometer (Erma, Japan), at 1 mL/min flow rate in 0.1 M $LiNO_3$. The apparent molecular weights were deduced from the calibration curve established with a pullulan calibration kit (P-400, MW = 380 000 P-200, MW = 186 000; P-100, MW = 100 000; P-50, MW = 48 000; P-20, MW = 23 700; P-10, MW = 12 200; P-5, MW = 5800; Showa Denko K.K., Japan). The calibration equation was log MW = 27.746 − 1.03 × t_R (t_R = column retention-time at peak maximum, and r^2 = 0.997).

Neutral Sugar Composition as Alditol Acetates. Neutral sugars were determined as alditol acetates by GLC after TFA hydrolysis.[38] Separation was carried out on a DB225 column (30 m × 0.25 mm i.d.; 0.25 μm film; J&W Scientific, Agilent Technologies, Santa Clara, CA) with hydrogen as carrier gas (0.6 bar inlet pressure) on a Shimadzu GC-2010*plus* gas chromatograph. The alditol acetates were identified from their retention times by comparison with those of standard monosaccharides. Neutral sugars amounts were calculated relative to the internal standards. Allose and myo-inositol were used as internal standards.[39]

Neutral and Acidic Sugar Composition as Trimethylsilyl Derivatives. The neutral and acidic sugar composition was determined after solvolysis with anhydrous MeOH containing 0.5 M HCL (80 °C, 16 h), by GC of their per-O-trimethylsilylated (TMS) methyl glycoside derivatives.[40] The TMS derivatives were separated on two DB-1 capillary columns (30 m × 0.25 mm i.d., 0.25 μm film) (temperature programming 120−145 °C at 1.5 °C/min, then 145−180 °C at 0.9 °C/min, and finally−180−230 °C at 50 °C/min), coupled to a single injector inlet through a two-holed ferrule, with H_2 as the carrier gas on a Shimadzu GCMS-QP2010SE gas chromato-

graph. The outlet of one column was directly connected to a FID at 250 °C, and the second column via a deactived fused-silica column (0.25 m × 0.11 μm i.d.) was connected to a mass detector. Samples were injected in the pulsed split mode with a split ratio of 20:1. The transfer line to the mass was set at 280 °C. EI mass spectra were obtained from m/z 50 to 400 every 0.2 s in the total ion-monitoring mode using an ion source temperature of 200 °C, a filament emission current of 60 μA, and an ionization voltage of 70 eV.

Glycosyl-Linkage Determination. The glycosyl-linkage compositions were determined by GC-MS of the partially methylated alditol acetates. Two milligrams of polysaccharides in 0.5 mL of dimethyl sulfoxide were methylated using methyl sulfinyl carbanion and methyl iodide.[41] Only for the retained fractions A, B, C, D, E, and F, half of the methylated sample was then carboxyl-reduced with lithium triethylborodeuteride (Superdeuteride, Aldrich, Milwaukee, WI).[42] Both methylated and methylated-carboxyl-reduced samples were hydrolyzed with 2 M trifluoroacetic acid (75 min at 120 °C). The released methylated or carboxyl-reduced monosaccharides were converted to their corresponding alditols by treatment with $NaBD_4$ and then acetylated.[38] Partially methylated alditol acetates were analyzed by GC GC-EI-MS using a DB-1 capillary column (30 m × 0.32 mm i.d., 0.25 μm film); temperature programming 135 °C for 10 min and then 1.2 °C/min to 180 °C, with H_2 as the carrier gas on a Shimadzu GCMS-QP2010SE gas chromatograph.[43] Identity of each methyl ether was confirmed by EIMS, and their areas were corrected by response factors.

UPLC-ESI-MS^n. Separations of oligosaccharide fractions were performed using a Waters Acquity UPLC-DAD system (Milford, MA), on a (100 × 1 mm i.d.) Nucleodur HILIC column, 1.8 μm (zwitterionic sulfoalkyl betaine stationary phase, Macherey-Nagel, Düren, Germany), operated at 35 °C. The mobile phase consisted of acetonitrile/formic acid (99.5/0.5, v/v) (eluent A) and water/formic acid (99.5/0.5,v/v) (eluent B). Flow rate was 0.3 mL/min. The elution program was as follows: 1−40% B (0−20 min), 40−90% B (20−21 min), isocratic with 90% B (21−25 min), 90−1% B (25−26 min), isocratic with 1% B (26−33 min).

ESI-MS^n analyses were performed with a Bruker Daltonics Amazon (Bremen, Germany) mass spectrometer equipped with an electrospray source and an ion trap mass analyzer. The spectrometer was operated in the negative ion mode (capillary voltage, 4 kV; end plate off set: −300 V; temperature, 200 °C; nebulizer gas: 36 psi and dry gas, 7 L/min). Collision energy for fragmentation used for MS^2 and MS^3 experiments was set at 1. The mass spectra were acquired over a mass range of 300−2500 Da with target mass at 1200 Da, and 500−3000 Da with target mass at 2000 Da.

RESULTS AND DISCUSSION

Purification and Characterization of Oligosaccharide Fractions. Wine carbohydrates from Carignan were decolorized on Polyamide CC6 and then were precipitated by acidified alcohol in order to separate polysaccharides (mannoproteins, polysaccharides rich in arabinose and galactose (PRAGs), RGII, and glucans) from oligosaccharides (Figure 1). The passage of the supernatant through a column of anion exchange allowed us to separate wine oligosaccharides into two fractions, a first fraction not retained on the column and a second charged and retained on the column and then eluted by 1 M of NaCl. The glycosyl residue composition determined by GC after methanolysis and trimethysylilation,[40] is summarized in Table 1. The nonretained fraction contained low amounts of uronic acids, 2.7 mol % for galacturonic acid, and 1.1 mol % for glucuronic acid and is predominantly composed of arabinose (75.6%). In the retained fraction, galacturonic acid, rhamnose, and arabinose presented the highest molar percentages (29.2, 27.5, and 29.9, respectively). The total amount of oligosaccharides before the anion exchange represented a concentration of 446 mg per liter (184 mg for initial nonretained fraction and 261 mg for the initial retained fraction, Table 1). These results are slightly higher than those previously reported for Merlot and Carignan,[17,18] or Grignolino and Chardonnay wines,[19] but they were similar to those reported for Monastrell wine oligosaccharide fractions.[20]

The initial nonretained fraction and the initial retained fraction were finally separated by SEC on superdex HR30. The MW determined for the oligosaccharide fractions obtained by SEC are given in Table 1. The nonretained fraction and retained fractions yielded four and six subfractions, respectively, with molecular weight (MW) ranging from 8000 Da (fraction A) to 1000 Da (fractions D and F, respectively). Table 1 also shows the glycosyl residue composition of the oligosaccharide fractions obtain after solvolysis by GC of their per-O-trimethylsilylated (TMS) methyl glycoside derivatives. They contained most of the sugars known to take part in the composition of wine carbohydrates. Oligosaccharides of nonretained fractions A, B, C, and D and retained fractions A, B, C, D, E, and F included sugars such as rhamnose, arabinose, galactose, and galacturonic acid derived from the pecto-cellulosic cell walls of grape berries but also mannose and glucose released from yeast and/or bacteria polysaccharides.[17−21] The nonretained fractions A, B, and C were rich in arabinose (70.9%, 89.1%, and 82.1%, respectively), whereas nonretained fraction D contained similar proportions of arabinose and mannose (30%), and larger proportions of

[a]2,3,4-Rha: 1,5-di-*O*-acetyl-2,3,4-tri-*O*-methyl rhamnitol, etc. [b]Relative mole percent of each parent sugar family (sum of ethers from one sugar type) within total sugars. [c]Tr = trace, less than 0.5%. [d]6,6′-dideuterated ether only for the retained fractions.

rhamnose and glucose than the other three fraction, as well as xylose and galacturonic acid (6% each). In the retained fractions, the proportions of rhamnose and galacturonic acid increased from 15% to 50% in fractions A through F while that of arabinose decreased (48% in retained fraction A to 0% in the retained fraction F, Table 1). This composition indicated that the retained fractions with lower MW correspond to structures of the rhamnogalacturonan of type-I (RGI). The glycosyl-linkage compositions for nonretained and retained fractions are given in Table 2. Nonretained fractions A, B, C, and D are mainly constituted by arabinose linked at position 5 or arabinose linked at 3,5 (Table 2). Presence, after the methylation analysis, of these methyl ethers indicates the presence of a branched (1 → 5)-oligo-arabinan composed of the following repeating unit [→ 5)-Ara*f*-(1 → 5)[Ara*f*-(1 → 3)]-Ara*f*-(1 → 5)-Ara*f*-(1→], with more arabinosyl residues involved in the linear (1 → 5)-arabinan chain, and terminal arabinose linked in 3 on the (1 → 5)-arabinan chain. Analysis of glycosidic linkages (Table 2) indicates the presence of other oligosaccharides, in particular originating from mannoproteins, but at low levels in the nonretained fractions. Oligosaccharides from retained fractions are mainly constituted by rhamnose

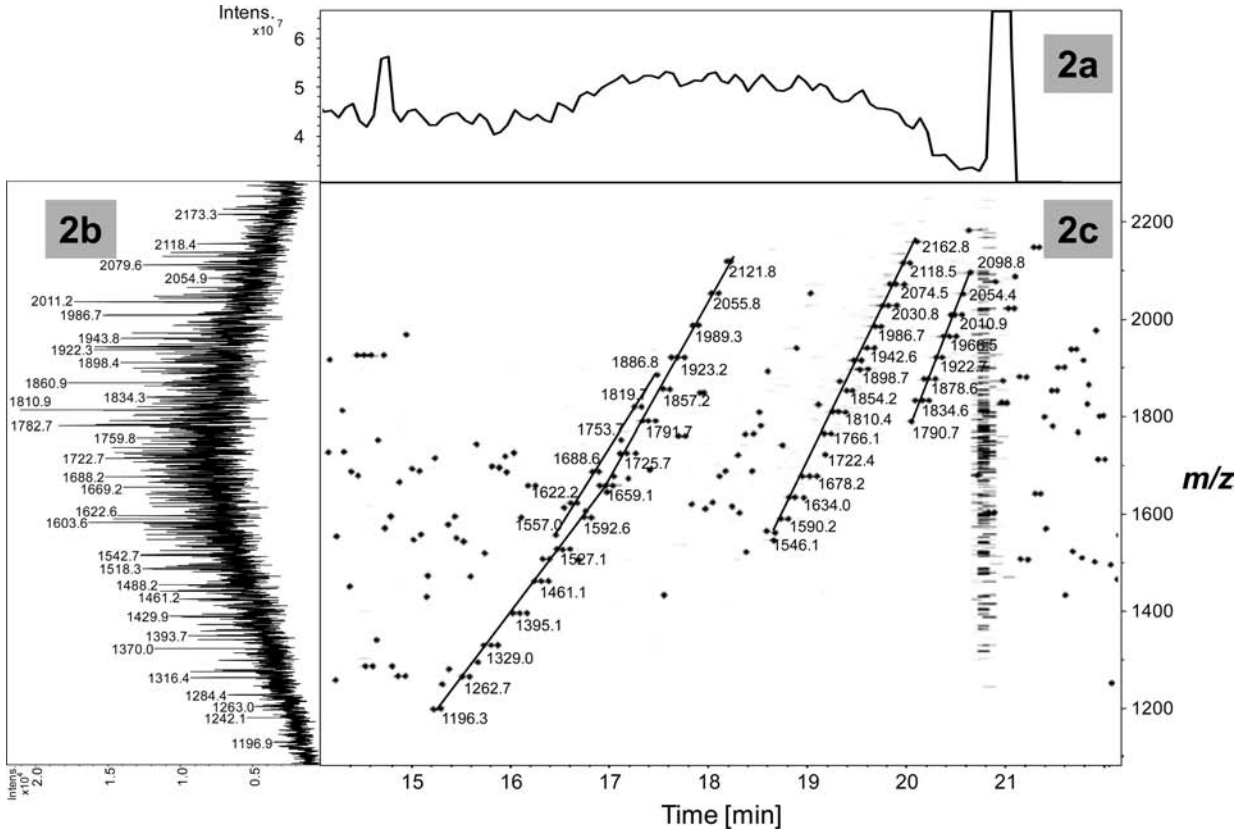

Figure 2. UPLC-MS analysis of nonretained fraction B: (a) total ion chromatogram; (b) full-scan mass spectrum of nonretained fraction B; (c) 2D projection of the full-scan mass spectra as a function of oligosaccharide retention times on the HILIC column.

linked at position 2 and 2,4, and by galacturonic acid linked at 4 (Table 2, per-O-methylated-6,6′-dideuterated ethers for uronic acids), indicating that fractions were oligo-rhamnogalacturonans organized with a repeat unit of [(→2)-α-L-Rha*p*-(1 → 4)-α-D-Gal*p*A-(1 →]$_n$.[44,45] The presence of 2,4-linked rhamnose along with methyl ethers from arabinose and galactose, obtained after methylation analysis (Table 2), indicated that side chains were attached to the oligorhamnogalacturonan backbone through the rhamnose moieties.[45] These oligosaccharides arise from the rhamnogalacturonan regions of pectins as a result of degradation of the grape berry cell wall by pectinases during grape maturation and/or wine making[46] and have been isolated for oligosaccharides of Carignan or Merlot wines.[17] Analysis of the glycosidic linkages enabled determination of the structure of oligosaccharides that were released into the wines but not their structural organizations, for example the degree of polymerization (DP) of the oligosaccharides.

UPLC-ESI-MS^n of the Nonretained Oligosaccharide Fractions. Figures 2a, 4a, and 5a show the total ion chromatogram of nonretained fractions B, C, and D on the HILIC column. HPLC coupled with mass spectrometry is a very powerful technique for oligosaccharide analysis and characterization, and ESI has been a good technique for the introduction of sugar components into an MS.[35,36] Recently, hydrophilic interaction liquid chromatography (HILIC), an alternative method for separation of highly polar compounds such as carbohydrates, and negative-ion ESI-MS^n were applied for structural analysis of oligosaccharides.[47−49]

The nonretained fraction A was also injected on the column but did not give a total ion chromatogram by MS. The masses of the oligosaccharides are too large (up to 8 kDa) to be analyzed in our ESI-MS spectrometer. Analysis of the full-scan mass spectra of nonretained fractions B, C, and D (Figures 2b, 4b, and 5b) show a multitude of mass signals between m/z 800 and m/z 2500 Da. The 2D projection of the full-scan mass spectra as a function of oligosaccharide retention times on the HILIC column (Figures 2c, 4c, and 5c) shows the separation as a function of the masses. Due to the low background noise in negative-ion mode, this 2D representation makes it possible to highlight oligosaccharides with different degrees of polymerization (DP). The negative ionization consists of a selective deprotonation of the anomeric hydroxyl at the reducing end of the oligosaccharide chain. Once the negative charge is localized at the reducing end, the ion fragmentation of the ring occurs rapidly and the mass losses observed are found to be diagnostic of the glycoside type. The signals obtained correspond to negatively charged oligosaccharides as deprotonated $[M - H]^-$, $[M - 2H]^{2-}$, and $[M - 3H]^{3-}$ ions determined by the isotopic distribution (1 for single deprotonated, 0.5 for doubly deprotonated, and 0.33 for triply deprotonated ions). In Figure 2c, a series of ions was observed at m/z 1557.0, 1622.2, 1688.6, 1753.7, 1819.7, and 1886.8, which correspond to a difference of 66 Da between the different ions (M = 3116 Da to M = 3776 Da). A second series of ions was observed at m/z 1196.3, 1263.0, 1329.0, 1395.1, 1461.1, 1527.1, 1592.6, 1659.1, 1725.7, 1791.7, 1857.2, 1923.2, 1989.3, 2055.8, and 2121.8 which also correspond to a difference of 66 Da. The ions of the two series correspond to oligosaccharide molecules detected as doubly deprotonated $[M - 2H]^{2-}$ ions. The difference of 66 Da (m/z 132 with z=2) between the first two series of ions corresponds to the presence of a pentose, likely an arabinose residue (Table

[a]The ions of the series correspond to negatively charged oligosaccharides detected as deprotonated $[M - H]^-$, $[M - 2H]^{2-}$, and $[M - 3H]^{3-}$ ions. The charge is indicated in parentheses.

1). The first series starting at m/z 1557.0 corresponds to the deprotonated oligosaccharides with the following structures: $[Ara]_n$-(1 → 4)-α-L-Rha*p*-(1 → 4)-α-D-Gal*p*A, where the number n of arabinose residue is between 21 to 26, and the first arabinose residue is linked at (1 → 4) on the rhamnose residue (Table 2). The second series starting at m/z 1196.3, 1263.0,.... corresponds to doubly deprotonated $[M - 2H]^{2-}$ oligo-arabinans with DP ranging from 18 (m/z 1196.3, M = 2396) to 32 (m/z 2121.8, M = 4246). A third series of ions at m/z 1546.1, 1590.2, 1634.0, 1722.4, 1766.1, 1810.4, 1854.2, 1898.7, 1942.7, 1986.8, 2074.5, 2118.5, and 2162.8 presented a difference of 44 Da between all the ions of the series. The difference of 44 corresponds of a triply charged arabinose residue (m/z 44 where m = 132 and z = 3), and this series of ions correspond to $[M - 3H]^{3-}$ ions of oligo-arabinans with a DP between 35 (m/z 1546.1, M = 4641) and 49 (m/z 2162.8, M = 6492). The separation on the HILIC column depends on the number of hydroxyl groups that each oligosaccharide has and the number of hydrogen bonds established with the stationary phase. Within a homologous series, e.g. oligo-

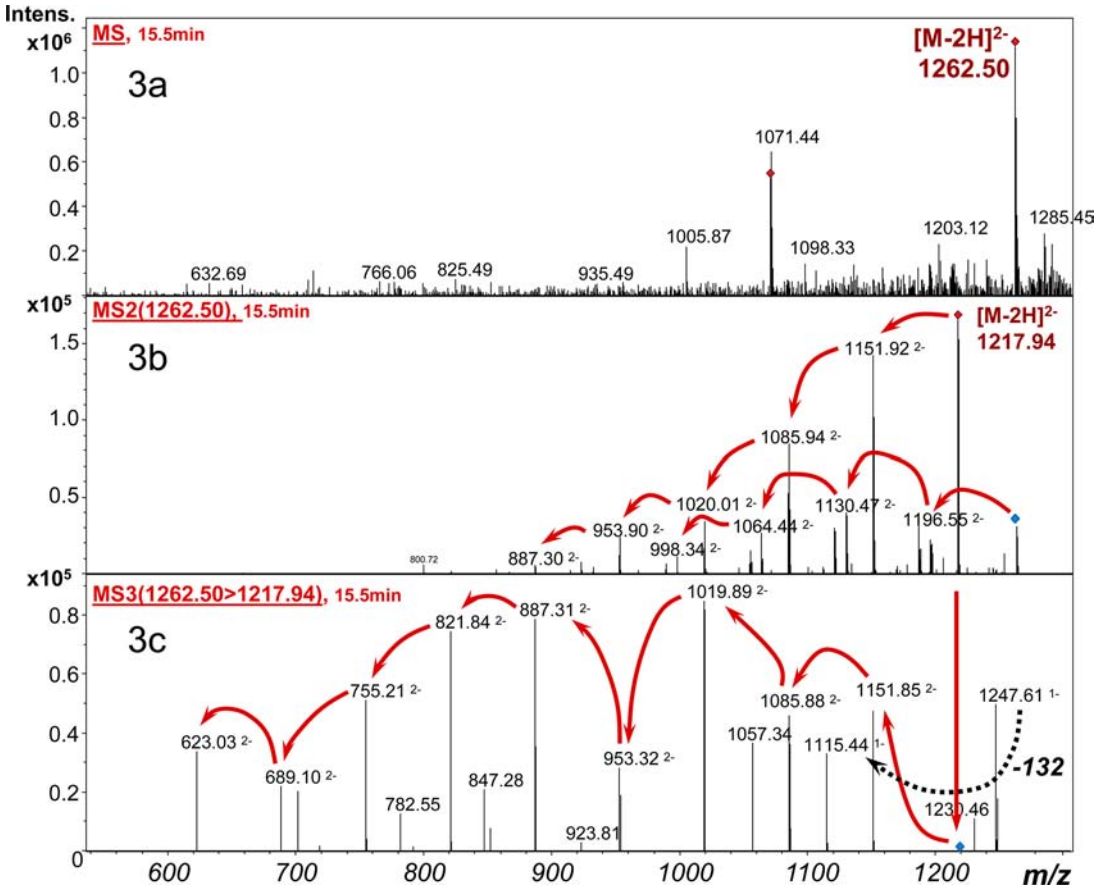

Figure 3. Spectra of MS^3 fragmentation by ESI-TI in negative mode of ion parent at m/z 1262.5 (a). MS spectrum of ion at m/z at 1262 $[M - 2H)^{2-}$. (b). MS^2 spectrum of the ion at m/z 1262.5 $[M - 2H)^{2-}$. (c). MS^3 spectrum of the ion at m/z at1217.94 $[M - 2H)^{2-}$ from the m/z 1262.5 ion $[M - 2H)^{2-}$. (red →) Loss of a fragment of m/z 66.

arabinans, this allows the prediction of elution positions as a function of DP. The oligo-arabinan of DP 18 (m/z 1196.3, M = 2396) has a retention time of 15.2 min, while the oligo-arabinan with a DP 49 (m/z 2162.8, M = 6492) has a retention time of 20.1 min. In this series, other oligo-arabinans with DP between 18 and 49 are eluted between 15 and 20 min on the column. The results of nonretained fractions B are summarized in Table 3.

The MS^n fragmentations of each oligosaccharide from nonretained fractions B, C and D, were performed by ESI-IT-MS^n in the negative ion mode. Figure 3 shows, as an example, the MS^n spectra of the $[M - 2H]^{2-}$ ion at m/z 1262.5 obtained from the nonretained fraction B. Under negative-ionization ESI-MS^n conditions, the fragmentation process of oligosaccharides involves the glycosidic cleavage between two sugar residues and cross-ring opening of sugar (cleavage of two bonds within the sugar ring). MS^n spectra of deprotonated oligosaccharides can be read "from right to left". The fragment ions observed in the MS^n spectra are usually named according to the nomenclature of Domon and Costello (1988).[50]

The MS^2 fragmentation (Figure 3b) of the parent ion at m/z 1262.5 showed the presence of a fragment ion at m/z 1196.5, due to the loss of an arabinose residue (m/z 66 where m = 132 and z = 2). This fragment ion at m/z 1196.5 loses a first arabinose residue to give the fragment ion at m/z 1130.5 and after successive losses of arabinose residues yields fragment ions at m/z 1064.4, 998.3,... Another point of the MS^2 spectra was the presence of a fragment ion due to the loss of 90 mass units (45 amu from the doubly charged parent ion), i.e. ion at m/z 1217.9 for parent ion at m/z 1262.5 (Figure 3b, MS^2 spectrum). The loss of this fragment corresponds to a fragmentation $^{0,2}X_n$ of a residue of arabinose in a nonreducing terminal position of the oligosaccharide studied.[50] Then from this ion, we observe a series of fragment ions produced by loss of arabinose residues: the fragment ion at m/z gives an ion at m/z 1151.9 and m/z 1085.9 and so on until a fragment ion at m/z 887.3 corresponding to the loss of five residues of arabinose from the ion at m/z 1217.9. All fragment ions obtained are doubly charged ions. In the same manner, the MS^3 fragmentation (Figure 3c) of the fragment ion at m/z 1217.9 showed the presence of fragment ions arising from successive losses of arabinose residues. The last fragment ion at m/z 623.1 corresponds to the loss of nine residues of arabinose from the fragment ion at m/z 1217.9. The fragment ion at m/z 623.1 corresponds to a doubly charged fragment, but it is also present as a singly charged fragment ion $[M - H]^-$ at m/z 1247.6. This fragment ion at m/z 1247.6 then loses an arabinose residue to give an ion $[M - H]^-$ at 1115.4 amu. All the ions present in the spectrum of the nonretained fraction B (Figure 2) were fragmented in MS^2 and MS^3 (data not shown). All ions identified on Figure 2C provide a MS/MS fragmentation spectrum similar to that of the ion at m/z 1262.5.

Figures 4c and 5c show mass spectra of wine oligosaccharides from the nonretained fractions C and D. We observe several series of oligosaccharides with different structures and degrees of polymerization. The results are summarized in Table 3. A

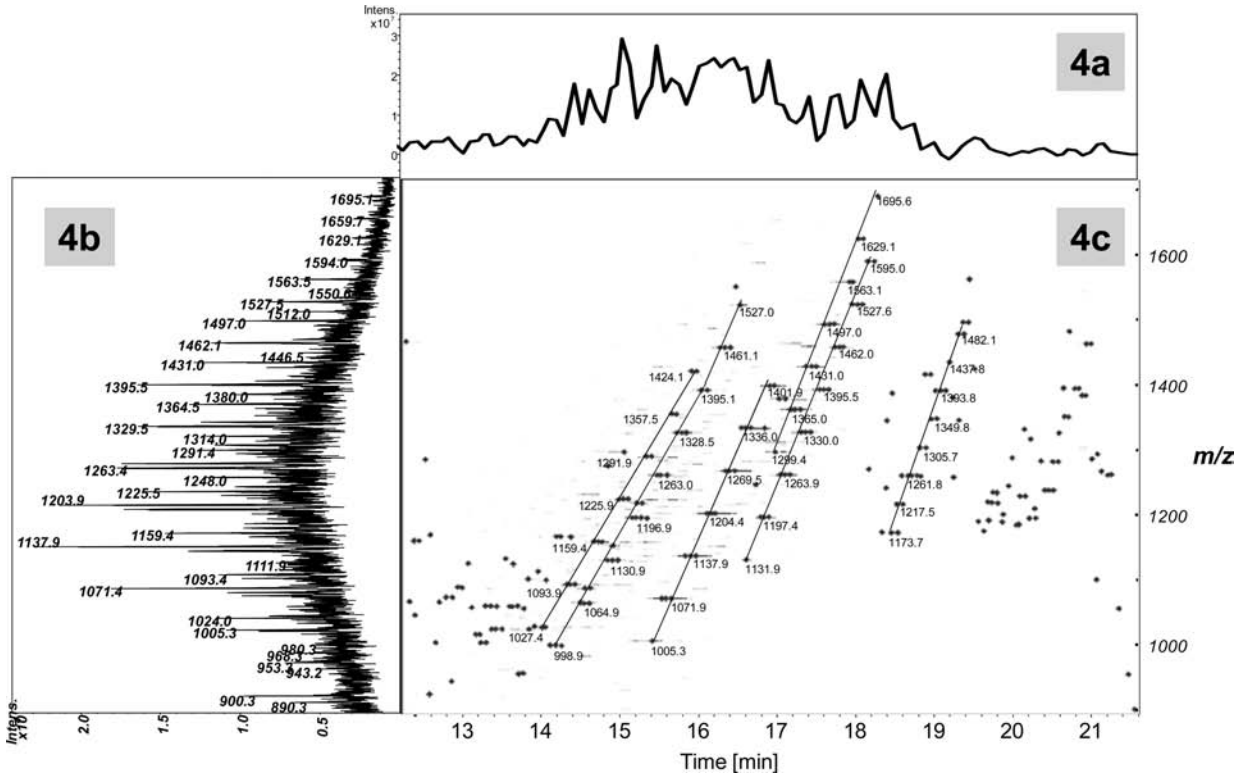

Figure 4. UPLC-MS analysis of nonretained fraction C: (a) total ion chromatogram; (b) full-scan mass spectrum; (c) 2D projection of the full-scan mass spectra as a function of oligosaccharide retention times on the HILIC column.

series starting from the $[M - 2H]^{2-}$ ion at m/z 1027.4 corresponds to the deprotonated oligosaccharides with the following structures: disaccharide α-L-Rha*p*-(1→4)-α-D-Gal*p*A substituted on the Rha by a lateral chain of arabinans. The first and last oligosaccharides of the series correspond to a DP of 15 and a DP of 21, respectively. The following two series, identified as $[M - 2H]^{2-}$ ions, correspond to the structure of oligo-arabinans with a DP ranging from 15 to 24, and rhamno-oligo-arabinans consisting of one residue of Rha substituted at the 4 position by arabinans of DP 15 to DP 21 (Table 3). The last series identified in the nonretained fraction C (Table 3) correspond to oligosaccharide molecules with the following structures: α-L-Rha*p*-(1→4)-α-D-Gal*p*A-(1→2)-α-L-Rha*p*, where one residue of rhamnose was substituted at (1→4) by *n* residues of arabinose with *n* between 16 to 30 (see Table 3). Our results indicated that these oligosaccharides are constituted by a core structure of degraded RGI, in which the oligo-rhamnogalacturonan backbone was substituted through the rhamnose moieties by (1→5)-arabinan branched at the 3-position by terminal nonreducing arabinose. These types of arabinan chains have been found in red wine as the side chains of RGI[51] while arabinans were rarely found.[22,52] RGI originates from grape cell walls. It is present in low amounts in wine,[22] presumably because it is hydrolyzed by glycoside hydrolases and/or "polysaccharidases" from grapes or from yeast used during the fermentation step. The detection of these oligosaccharides suggests that they have been released from grape cell wall polysaccharides under the action of rhamnogalacturonase, arabinanase, and α-arabinofuranosidase activities at least.

The oligosaccharide series identified in the nonretained Fraction D (Table 3) correspond to oligosaccharide with the following structures: One residue of rhamnose substituted by arabinan with a DP between 7 and 18, and oligo-hexose, where hexoses are galactose, glucose, or mannose (see Table 1) with a DP between 10 to 15.

UPLC-ESI-MS^n of the Retained Oligosaccharide Fractions. The retained fractions A, B, C, D, E, and F, corresponding to acidic oligosaccharides (Table 1), were also analyzed by LC-ESI-MS with the HILIC column. No mass signal was detected in retained fraction A, while retained fractions B and C provided mass signals of low intensity (Figure 6a–d) and the retained fractions E and F gave mass spectra corresponding to the oligosaccharides already identified.[17,18,20] The majority of masses could be assigned to an oligosaccharide structure. All oligosaccharide molecules were detected as the deprotonated $[M - H]^-$ and doubly deprotonated $[M - 2H]^{2-}$ ions. The predominant ions (the most intense) observed in the mass spectra were ions at m/z 485, 545, 661, 807, 837, 983, 1130, 1160, 1306, and 1452 for oligosaccharides from retained fractions E and F. The ion observed at m/z 661 corresponds to the deprotonated tetrasaccharide: [(→2)-α-L-Rha*p*-(1→4)-α-D-Gal*p*A(1→]$_2$, the ion at m/z 837 corresponds to the deprotonated pentasaccharide: α-D-Gal*p*A(1→[(→2)-α-L-Rha*p*-(1→4)-α-D-Gal*p*A(1→]$_2$, the ion at m/z 983 to the hexasaccharide: [(→2)-α-L-Rha*p*-(1→4)-α-D-Gal*p*A(1→]$_3$, the ion at m/z 1160 to the heptasaccharide and the ion at m/z 1306 to the octasaccharide: [(→2)-α-L-Rha*p*-(1→4)-α-D-Gal*p*A(1→]$_4$. The ions observed at m/z 485, 661, 807, 983, 1130, 1306, and 1452 correspond to the deprotonated rhamnogalacturonan oligosaccharides where the first oligosaccharide (m/z 485) has the following structure [α-L-Rha*p*-(1→4)-α-D-Gal*p*A(1→2)-α-L-Rha*p*]. The last ion of the series at m/z 1452 is an oligosaccharide of DP 9 with the following structure: [α-L-Rha*p*-(1→4)-α-D-Gal*p*A(1→2)-]$_4$α-L-Rha*p*. The ion at m/z 545 present in the MS spectrum of the

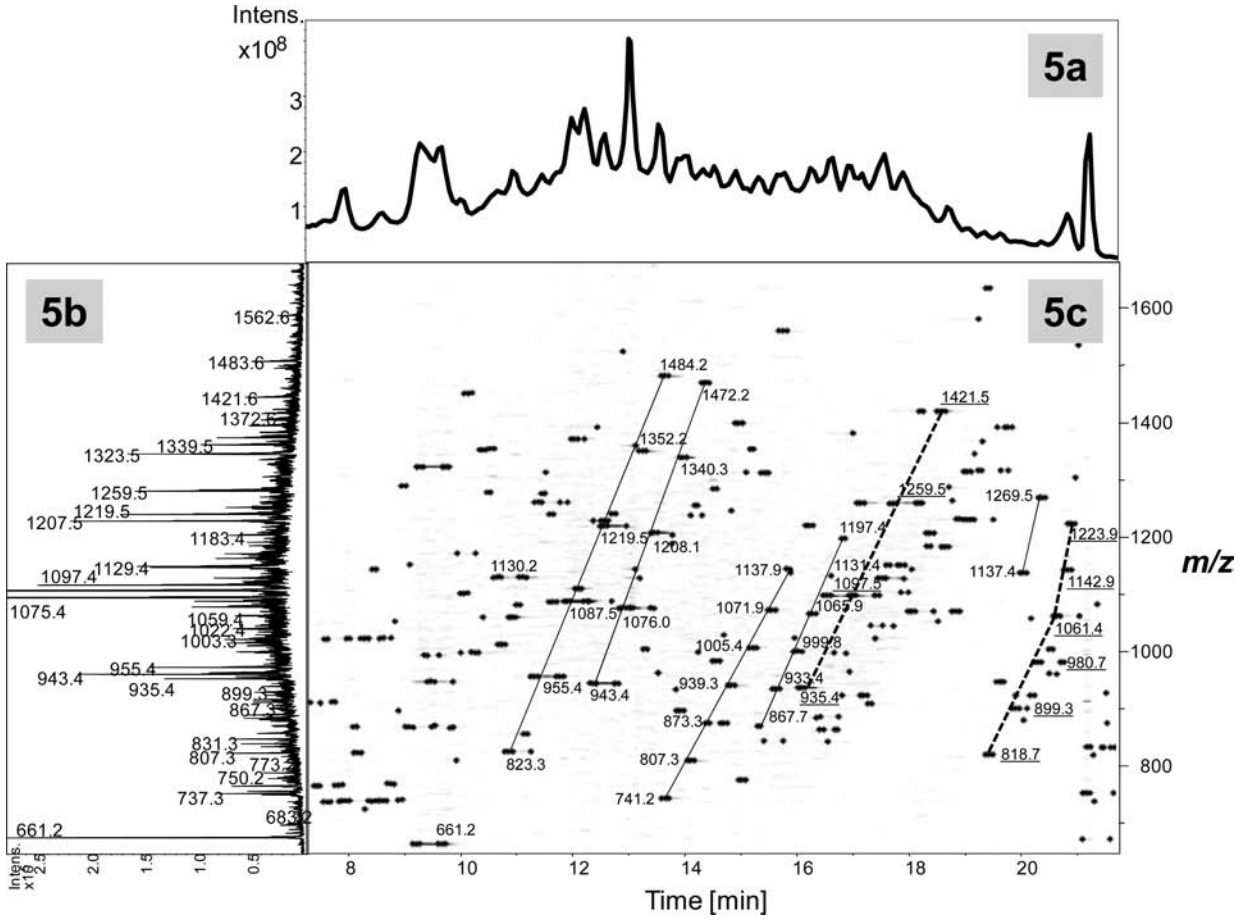

Figure 5. UPLC-MS analysis of nonretained fraction D: (a) total ion chromatogram; (b) full-scan mass spectrum; (c) 2D projection of the full-scan mass spectra as a function of oligosaccharide retention times on the HILIC column.

retained fraction F corresponds to the trigalacturonic acid coming from the homogalacturonan backbones of the pectins. These acidic oligosaccharides arise from the rhamnogalacturonan or homogalacturonan regions of pectins as a result of degradation of grape cell wall berries by pectinases during grape maturation and/or wine making.

In conclusion, we have isolated and characterized the neutral and acidic oligosaccharide fractions of Carignan red wines by complementary methods: glycosyl composition analysis, glycosidic-linkage analysis, and mass spectrometry. Mass spectrometry is a powerful tool used to identify and determine the structure of the oligosaccharides and in particular those coming from pectins.[36] Its use has enabled us to identify the various structures of oligosaccharides present in the fractions isolated from wines. We particularly focused on neutral wine oligosaccharide fractions (nonretained fractions A, B, C, and D), and for the first time, we have characterized by ESI-TOF MS a large number of neutral oligosaccharides rich in arabinose. We also found acid oligosaccharide structures previously characterized in our laboratory.[17,18,20] These molecules, neutral and acidic oligosaccharides identified in our previous works, and other oligosaccharides identified in Grignolino and Chardonnay wines by Bordiga et al.[19] (hexose-oligosaccharides, xyloglucans, and arabinogalactans), represent the degraded structures of polysaccharides originating from the grape berry cell wall, as a result of endogenous (present in grapes) or exogenous (added by the winemakers) enzyme activities present during the various stages of the wine making. The mass spectra of fractions of neutral sugars eluted from a HILIC column, used for the first time for separating wine oligosaccharides, showed a high variety of oligosaccharides (detected as $[M - H]^-$, $[M - 2H]^{2-}$, and $[M - 3H]^{3-}$ ions) corresponding to arabino-oligosaccharides composed of 8 to 49 arabinose residues, rhamnose substituted with arabino-oligosaccharides with a DP between 5 to 21, and different rhamnogalacturonan arabino-oligosaccharides composed of one or two residues of rhamnose, one residue of galacturonic acid, and side chains of 13 to 30 residues of arabinose. The oligosaccharides rich in arabinose are present in significant amounts (185 mg/L) in red wine, and are degradation products originating from the pectic polysaccharides of grape cell walls. Arabinans are known to participate in haze formation by self-aggregation when they have a low degree of branching. However, oligosaccharides rich in arabinan side chains isolated and identified in this study are highly branched with low molecular masses. It would be interesting to determine the impact of these structures on wines, especially their implications in haze development. Arabinans are known to be involved in clarification and stabilization problems of apple juices and concentrates.[53] No information is available on the properties of oligosaccharides rich in arabinose. However, our preliminary results show that in a wine model solution, oligosaccharides rich in arabinose can interact with purified tannins and form haze, but these results need to be confirmed. Knowledge of these oligosaccharides should allow us to study their physicochemical properties, their interactions with other

components present in wine (polyphenols, proteins, and aroma compounds), and possibly their beneficial health effects as prebiotics.

Supporting Information

ABSTRACT: Black garlic is a processed food product obtained by subjecting whole raw garlic to thermal processing that causes chemical reactions, such as the Maillard reaction, which change the composition of the garlic. In this paper, we report a nuclear magnetic resonance (NMR)-based comprehensive analysis of raw garlic and black garlic extracts to determine the compositional changes resulting from thermal processing. ^{1}H NMR spectra with a detailed signal assignment showed that 38 components were altered by thermal processing of raw garlic. For example, the contents of 11 L-amino acids increased during the first step of thermal processing over 5 days and then decreased. Multivariate data analysis revealed changes in the contents of fructose, glucose, acetic acid, formic acid, pyroglutamic acid, cycloalliin, and 5-(hydroxymethyl)furfural (5-HMF). Our results provide comprehensive information on changes in NMR-detectable components during thermal processing of whole garlic.

KEYWORDS: *black garlic, thermal process, Maillard reaction, NMR, multivariate statistical analysis*

INTRODUCTION

Garlic (*Allium sativum* L.) is widely used as a spice in many parts of the world, such as Asia, Europe, and the United States, because of its unique flavor and taste. Garlic has been reported to exert many health benefits, including antimicrobial,[1] anticancer,[2] and antioxidant[3] activities, and to improve the effects of hypoglycemic activity.[4] Among the chemical compounds of garlic, organosulfur compounds such as allicin are primarily responsible for its flavor,[5] and the derivatives of these compounds are responsible for its health benefits.[3,6]

Black garlic is a newly processed food that is made by subjecting whole raw garlic to thermal processing at approximately 70−80 °C under controlled humidity conditions for 1−3 months without any additives.[3] This processed food has a fruity taste and is edible without any cooking processes. The thermal processing induces many chemical reactions, such as the enzymatic browning reaction and Maillard reaction, which causes the color to change from white and yellow to dark brown. Compared with raw garlic, black garlic has a less pungent odor because of a decrease in allicin content,[7] whereas *S*-allylcysteine (SAC) contents have been reported to be increased.[7,8] SAC is a water-soluble sulfur compound with high antioxidant activity and shows at least a 5-fold increase in black garlic compared with raw garlic.[8] In addition, increments in the content of polyphenols and flavonoids[9] along with increments in antitumor effects in vitro[2] and immunostimulatory activity[10] are observed in black garlic after thermal processing. There are other reports that showed the potential health benefits of black garlic by chemical analysis,[11,12] cell culture experiments,[13,14] and animal experiments.[15,16]

Nuclear magnetic resonance (NMR) is a useful tool for studying the physicochemical state of foods and does not require the separation of their constituents, which may change the condition of the food samples; therefore, this technique has been applied in food science because of its simplicity and because it is a direct method to obtain comprehensive information about food products.[17−19] In addition, nondestructive NMR is commonly used to study the metabolome of many types of food, such as potato,[17] coffee,[20] mango juice,[21] and milk.[22,23] Although NMR is less sensitive than other analytical techniques, such as absorption spectroscopy and mass spectrometry combined with liquid or gas chromatography, it remains an indispensable and useful technique when combined with multivariate data analysis to provide a comprehensive observation of complex mixtures. Furthermore, the application of quantitative NMR (qNMR) was also reported on food due to the enormous potential in metabolomics profiling,[24] resulting from a feature of NMR techniques, that is, precise compound identification and quantification. NMR techniques are useful for monitoring composition changes during food processing such as fermentation, thermal processing, and ripening.[21,23−25] With untargeted multivariate statistical methods, such as principal component analysis (PCA), different origins,[25] cultivars,[21] processes,[23] or fermentations[24] in foods are clearly distinguished by the ^{1}H NMR spectra.

To date, metabolite changes in black garlic during thermal processing have not been reported. These changes could be detected by the one-dimensional (1D) and two-dimensional (2D) NMR spectra of black garlic with different degrees of thermal processing. Multivariate analyses are also used to obtain

comprehensive information regarding the compositional changes of black garlic from the NMR spectra. In this study, we report a ^{1}H NMR-based comprehensive analysis of raw garlic and black garlic extracts. The chemical compositional changes resulting from thermal processing are characterized using 1D ^{1}H NMR spectra, the signal assignment information is provided by analyses of 2D NMR spectra, and the resulting PCA is provided as score and loading plots.

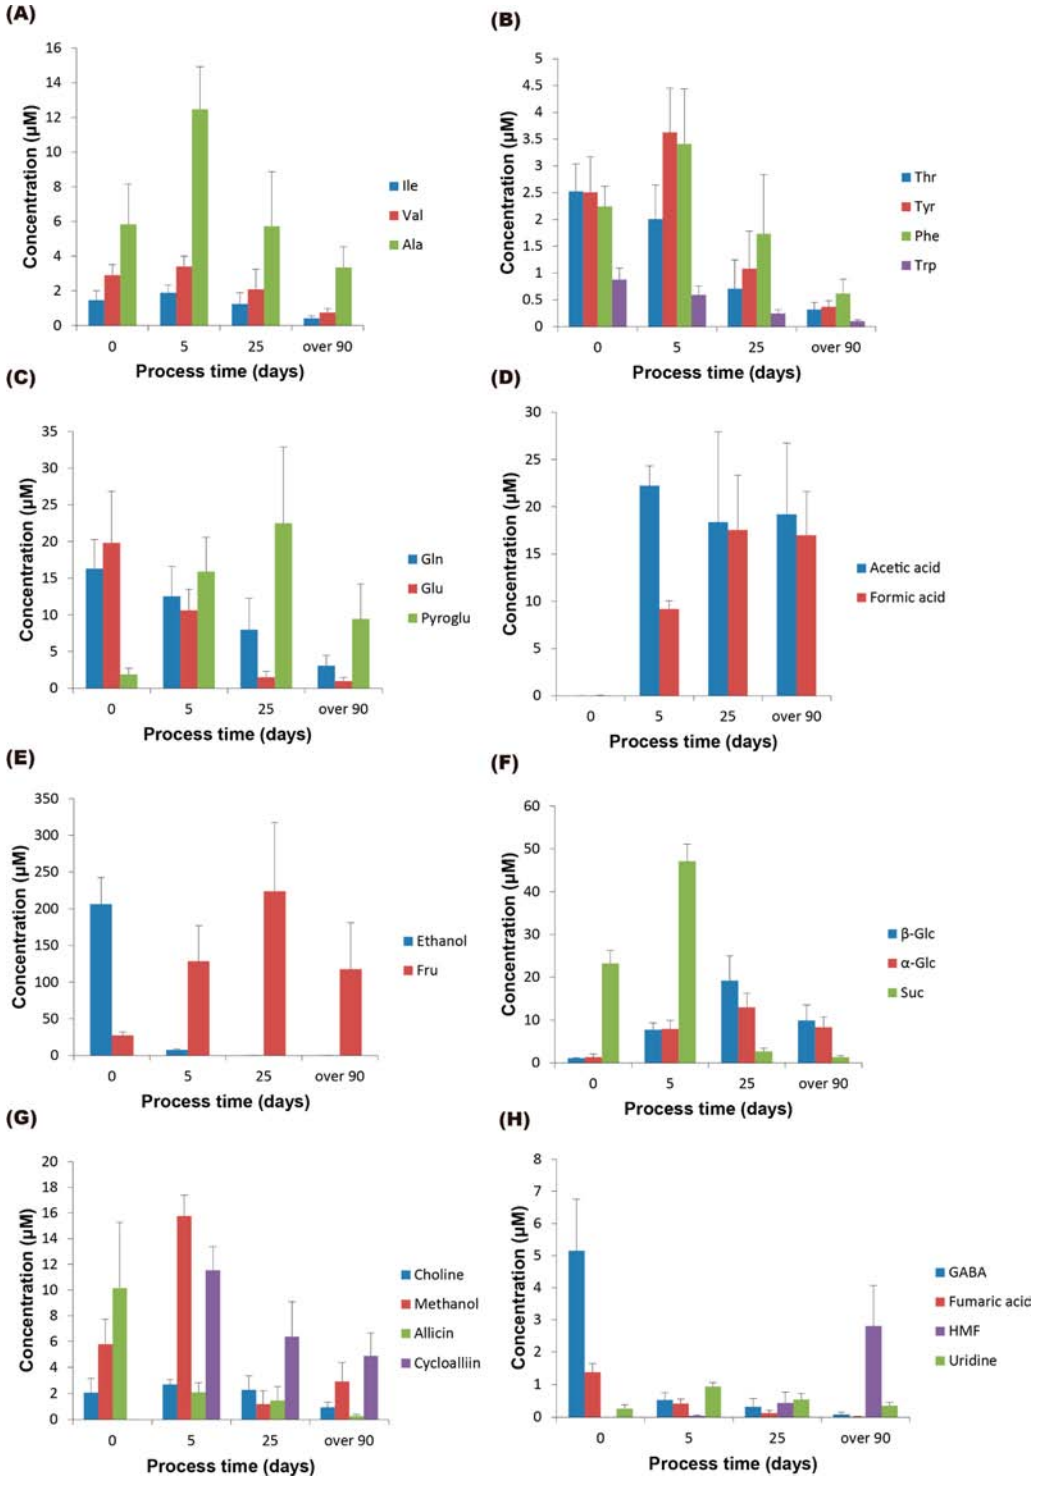

Figure 2. Changes in black garlic extract content during thermal processing: (A–C) amino acids, (D) organic acids, (E, F) ethanol and sugars, (G, H) other compounds. Abbreviations: Pyroglu, pyroglutamic acid; Fru, fructose; α-Glc, α-glucose; β-Glc, β-glucose; Suc, sucrose; GABA, γ-aminobutyric acid; HMF, 5-(hydroxymethyl)furfural. The L-amino acids are represented by the universal three-letter codes. The integral value of the DSS signal (trimethylsilyl protons) was set to unity. The integral values of the signals from the individual constituents were normalized to the value of a proton and then used to calculate the concentration. The data are the mean ± standard deviation (SD; n = 3).

MATERIALS AND METHODS

Materials. The raw garlic and black garlic samples were prepared by Salad Cosmo, Co., Ltd. (Japan) and stored at −30 °C until use. The garlic samples were divided into four groups including raw garlic and black garlic with three different degrees of thermal processing as follows: 5 day black garlic, which represents the early step of thermal processing, i.e., thermal processing of raw garlic at 75 °C for 5 days; 25 day black garlic, which represents the late step of thermal processing, consisting of subsequent thermal processing of the 5 day black garlic at 67 °C for 20 days; over 90 day black garlic, which represents the state offered for sale and is stored at room temperature for approximately 2 months after thermal processing of 25 day black garlic at 35 °C for 14 days.

DOI: 10.1021/jf504836d
J. Agric. Food Chem. 2015, 63, 683–691

NMR Samples. Samples of raw garlic and three types of black garlic (seven samples for each group) were peeled and sliced. The garlic samples (1 g) were soaked in 1 mL of 10% dimethyl sulfoxide-d_6 (DMSO-d_6; Cambridge Isotope Laboratories, Inc.)/90% D_2O (99.7%; Shoko Co., Ltd., Tokyo, Japan) for 1 h at room temperature. The extracts were centrifuged at 10000*g* at 4 °C for 10 min. The supernatants were removed and centrifuged again under the same conditions. Then 5 μL of 178 μM 4,4-dimethyl-4-silapentane-1-sulfonic acid, sodium salt (DSS; Wako Pure Chemical Industries, Ltd., Osaka, Japan) was added to the supernatants (600 μL) as an internal reference (final concentration of 1.47 μM),[21] with a chemical shift that was set to 0 ppm, and the solution was transferred into 5 mm NMR tubes.

NMR Spectroscopy. Quantitative ^{1}H NMR spectra were measured at 20 °C with a 600 MHz Agilent Unity INOVA-600 spectrometer equipped with a cryogenic probe. The signal of water was suppressed by the presaturation method, and the parameters of the measurements were as follows: number of data points, 64K; spectral width, 7764 Hz; acquisition time, 4.22 s; delay time, 30.0 s; number of scans, 32. The delay time was determined by the spin−lattice relaxation time (T_1) measurement, as used in a previous study.[20]

The ^{13}C NMR spectra were measured at 20 °C and 125.65 MHz on an Agilent Unity INOVA-500 spectrometer equipped with a 5 mm broad-band probe, and the parameters for ^{13}C NMR spectra were as follows: number of data points, 64K; spectral width, 31446 Hz; acquisition time, 1.04 s; delay time, 2.0 s; number of scans, 28128.

All of the 2D NMR spectra were measured at 20 °C on an Agilent Unity INOVA-500 spectrometer equipped with a 5 mm triple-resonance probe. For ^{1}H−^{1}H double-quantum-filtered correlation spectroscopy (DQF-COSY), the signal of water was suppressed by the presaturation method, and the acquisition parameters were as follows: number of data points, 2048 in F_2 (^{1}H) and 1024 in F_1 (^{1}H); spectral width, 5195 Hz in F_2 and F_1; acquisition time, 0.197 s; number of scans, 72. ^{1}H−^{13}C heteronuclear single-quantum coherence (HSQC) in the phase-sensitive mode was measured with the following parameters: number of data points, 2048 for ^{1}H and 512 for ^{13}C; spectral width, 5195 Hz for ^{1}H and 25141 Hz for ^{13}C; acquisition time, 0.160 s; delay time, 1.5 s; number of scans, 64. ^{1}H−^{13}C constant-time heteronuclear multiple-bond correlation (CT-HMBC) was obtained in the absolute mode with the following parameters: number of data points, 2048 for ^{1}H and 512 for ^{13}C; spectral width, 5751 Hz for ^{1}H and 30166 Hz for ^{13}C; acquisition time, 0.259 s; delay time, 2.0 s; number of scans, 512.

NMR Signal Assignments and Data Processing. The free-induction decay (FID) data were processed using ACD/NMR Workbook Suite V2012 (Advanced Chemistry Development, Inc., Canada). The signal assignments were performed as follows: (1) Certain signals in the 1D NMR spectra of the raw garlic extracts were assigned by comparison with the published data.[5,26] (2) For the assignments of the unreported signals in the 1D NMR spectra, we predicted candidate compounds using the Biological Magnetic Resonance Bank (BMRB)[27] and previous reports for the compounds of black garlic.[6,9] (3) We confirmed that the signals were correctly assigned to the candidate compounds using the 2D NMR spectra. The correlations between the carbons and their attached protons were confirmed by the ^{1}H−^{13}C HSQC spectra, and the ^{1}H−^{13}C CT-HMBC spectra were used to identify two- or three-bond coupling between the carbons and protons to detect linkages to the quaternary carbons. Couplings between two protons up to three bonds away were confirmed by the ^{1}H−^{1}H DQF-COSY spectrum. When the signals in the 1D NMR spectra were not distinguished or were undetectable in the 2D NMR spectra because of heavy overlaps or low sensitivity, respectively, spiking experiments[20] were performed in which analytical-grade chemicals were added to the NMR samples of the raw garlic or black garlic extracts to confirm the existence of the components. To observe the changes in metabolites in the garlic resulting from thermal processing, the integral values of the signals were calculated by the ACD/NMR Workbook Suite V2012. The integral value of the DSS signal at 0 ppm (the trimethylsilyl protons) was set to unity as an internal standard.

Multivariate Statistical Analysis. The ^{1}H NMR spectra were reduced into 0.04 ppm spectral buckets, the region of D_2O (4.8−5.1 ppm) was removed, and the ^{1}H NMR spectra from 0.8 to 9.5 ppm were then normalized. For the multivariate statistical analysis, the resulting data sets were imported into SIMCA-P, version 13 (Umetrics, Umeå, Sweden). PCA was performed to examine the variation in the data sets as an unsupervised classification method. The modeled variation in the score plot was defined with a 95% confidence interval, and the spectral data were Pareto scaled (Par). The goodness of fit (R^2x) and the predictability (Q^2) were described for the quality of the model.

RESULTS

^{1}H and ^{13}C NMR Spectra of Raw Garlic and Black Garlic Extracts. Figure 1 shows a representative 1D ^{1}H NMR spectrum of the raw garlic extract, 5 day, 25 day, and over 90 day black garlic extracts. On the basis of the 2D NMR analysis and the spiking experiments, 38 components were identified in the raw garlic and black garlic extracts (Table S1 in the Supporting Information). Among these components, 27 constituents of the raw garlic extracts, i.e., sucrose, α-glucose, β-glucose, fructose, L-alanine, L-valine, L-leucine, L-isoleucine, L-threonine, L-lysine, L-arginine, L-glutamine, L-glutamic acid, L-proline, L-asparagine, L-aspartic acid, L-tyrosine, L-phenylalanine, L-tryptophan, γ-aminobutyric acid (GABA), methanol, ethanol, citric acid, malic acid, fumaric acid, choline, and allyl organosulfur compounds such as allicin, have also been reported in previous studies on Italian raw garlic,[5] and all of these components were observed in the ^{1}H NMR spectrum of the raw garlic extract. In addition, uridine and lactic acid were detected in the raw garlic extract for the first time in this study. The following nine components were produced after thermal processing and were identified only in the black garlic extracts: pyroglutamic acid, cycloalliin, formic acid, acetic acid, succinic acid, 3-hydroxypropionic acid, glucosamine, 5-(hydroxymethyl)furfural (5-HMF), and 5-(hydroxymethyl)-2-furoic acid (5-HMFA). Four of the components observed in the raw garlic, i.e., GABA, L-tryptophan, ethanol, and fumaric acid, disappeared in the spectra of the black garlic extracts.

Changes in Garlic Components Resulting from Thermal Processing. To investigate the changes in the garlic components resulting from thermal processing, the contents of the garlic components were determined from the integral values of the ^{1}H signals corresponding to the individual components. Among the detectable components, 25 were quantitatively analyzed because their signals were separately observed (Figure 2).

Among the 17 detected amino acids, the contents of L-alanine, L-valine, L-leucine, L-isoleucine, L-lysine, L-arginine, L-proline, L-asparagine, L-aspartic acid, L-tyrosine, and L-phenylalanine increased in the 5 day black garlic extracts after the early step of the thermal processing and then decreased in the 25 and over 90 day black garlic extracts (Figure 2). Among the other detected amino acids, the contents of L-threonine, L-glutamine, and L-glutamic acid decreased with the progression of thermal processing. The pyroglutamic acid content increased in the 5 and 25 day black garlic extracts but decreased in the over 90 day black garlic extracts. The signals of GABA and L-tryptophan in the 1D ^{1}H NMR spectra nearly disappeared in the 5 day black garlic extract and showed a trace amount in the 25 and over 90 day black garlic extracts (Figure 1).

Among the four detected sugars, α-glucose, β-glucose, and fructose showed changes similar to those of pyroglutamic acid with the progression of thermal processing (Figure 2). The content of these sugars increased in the 5 and 25 day black garlic extracts and then decreased in the over 90 day black garlic extract. However, the sucrose content showed a 2.0-fold increase in the 5

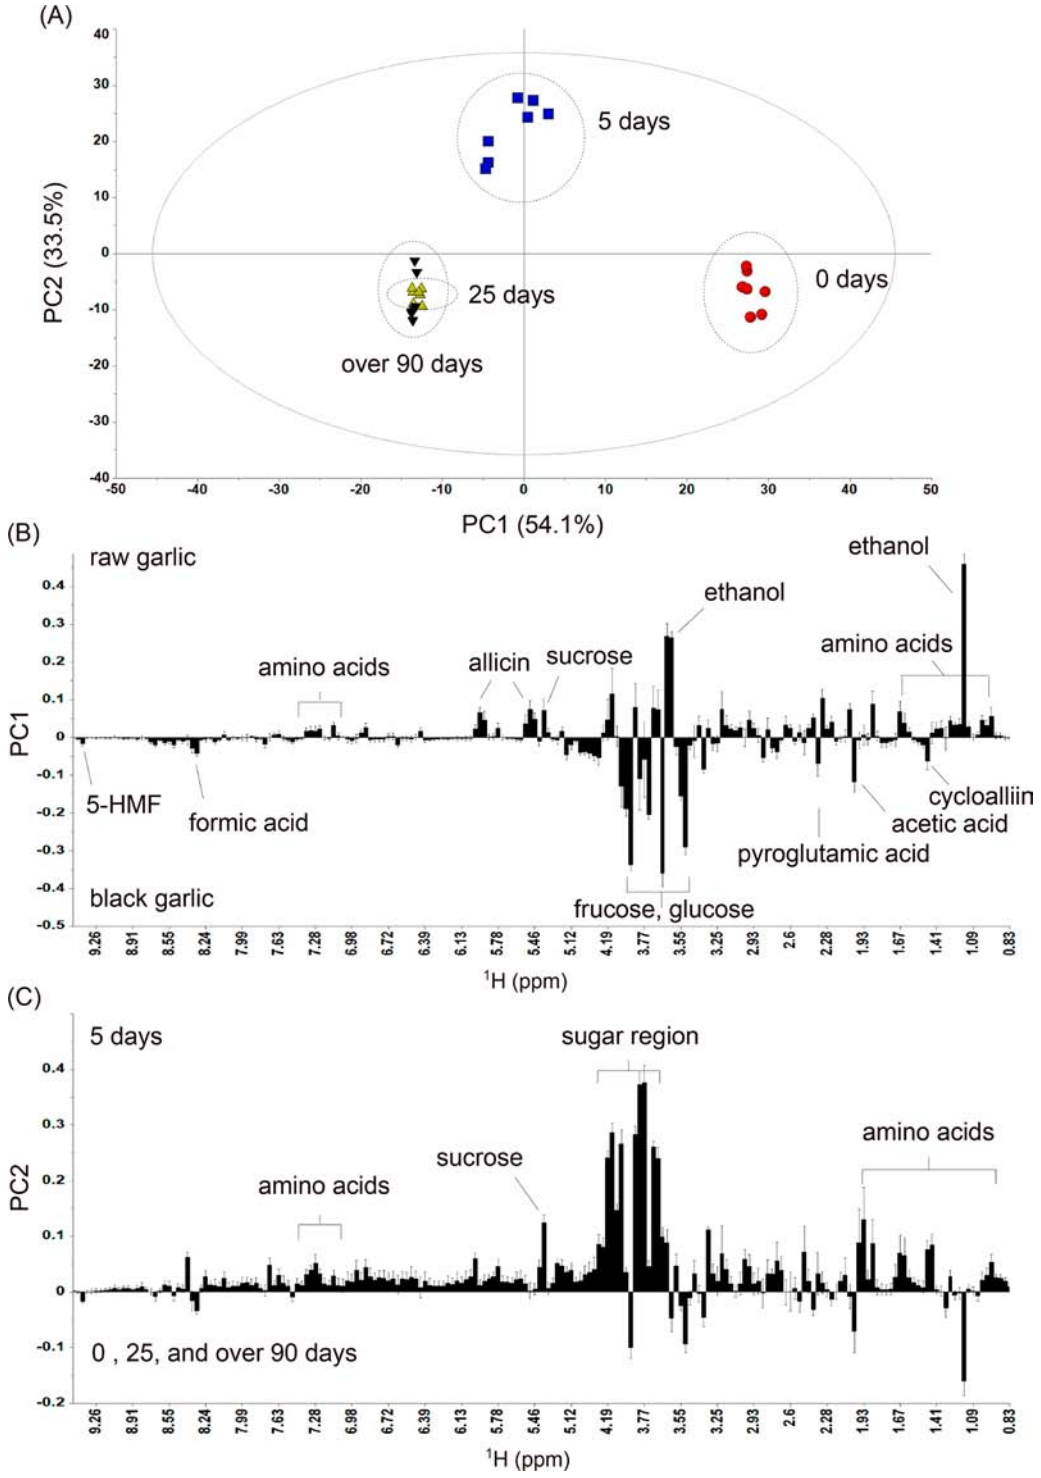

Figure 3. (A) PCA score plot, (B) loading plot for PC1, and (C) loading plot for PC2 for the extracts of raw garlic (0 days) and black garlic with different degrees of thermal processing (5, 25, and over 90 days). The PCA model with seven components was computed, and the goodness of fit (R^2x) was 54.1% and 33.5% for PC1 and PC2, respectively. The goodness of predictability was indicated by a Q^2 value of 0.95.

day black garlic extract compared with the raw garlic extract and significantly decreased in the 25 day black garlic extracts.

Among the observed organic acids, the ^{1}H signal of acetic acid was not observed in the raw garlic extract (Figure 1a), but it appeared in the 5 day black garlic extracts, and the content did not significantly change in the 25 and over 90 day black garlic extracts (Figure 2). The ^{1}H signal of formic acid also appeared in the 5 day black garlic extract and showed a small increase in the 25 and over 90 day black garlic extracts. The chemical shifts of acetic acid and formic acid changed in the ^{1}H NMR spectra during thermal processing (Figure 1), possibly as a result of changes in pH. However, the fumaric acid content decreased with the progression of thermal processing, and fumaric acid was not detected in the over 90 day black garlic extract. Succinic acid and 3-hydroxypropionic acid were detected only in the black garlic extracts (Figure 1). The contents of both of these

DOI: 10.1021/jf504836d
J. Agric. Food Chem. 2015, 63, 683−691

components increased in the 5 and 25 day black garlic extracts and then decreased in the over 90 day black garlic extracts.

Ethanol showed strong signals in the ^{1}H NMR spectra in the raw garlic extract but disappeared after thermal processing (Figures 1 and 2). Methanol showed a 2.7-fold increase in the 5 day black garlic extract compared with the raw garlic extract, and its content was significantly decreased in the 25 day black garlic extracts (Figure 2). However, a slight increase of methanol content was observed in the over 90 day black garlic extracts.

Among the other five detected components, the content of choline increased in the 5 day black garlic extracts and then decreased in the 25 and over 90 day black garlic extracts. The multiple signals at approximately 5.5 ppm in the ^{1}H NMR spectra of the raw garlic extracts were assigned to the allyl protons of allicin (Figure 1), and the content of allicin decreased during the thermal process (Figure 2). The multiplet signals at approximately 5.2 ppm were assigned to the allyl protons of organosulfur compounds. These signals increased in the 5 day black garlic extract and then decreased in the 25 day black garlic extract (Figure 1). Other compounds in the black garlic, such as cycloalliin, 5-HMF, and 5-HMFA, were detected in the 5 day black garlic extract (Figure 1). The content of cycloalliin decreased in the 25 and over 90 day black garlic extracts, whereas that of 5-HMF and 5-HMFA increased in the 25 day black garlic extracts. At the later thermal processing step of the over 90 day black garlic extracts, the content of 5-HMF was increased by more than 6-fold compared with that in the 25 day black garlic extracts.

Variations in Black Garlic Constituents Resulting from Thermal Processing. To determine the overall compositional changes in black garlic during thermal processing, PCA was performed on the quantitative ^{1}H NMR spectral data for all of the garlic extracts. As shown in Figure 3A, the raw garlic and 5 and 25 day black garlic extracts were clearly distinguished from one another on the PCA score plot with high statistical values of R^2x (54.1% for PC1 and 33.5% for PC2) and Q^2 (0.95). However, the over 90 day black garlic extracts were not distinguished from the 25 day black garlic extracts, indicating that the overall composition of the 25 day black garlic extracts was similar to that of the over 90 day extracts. The PCA loading plots demonstrated that the components in the raw garlic extracts and the black garlic extracts were different (Figure 3B). The PC1 negative loading indicated that the black garlic extracts contained higher amounts of fructose, glucose, acetic acid, formic acid, cycloalliin, pyroglutamic acid, and 5-HMF than the raw garlic extracts. On the basis of the PC1 positive loading, the raw garlic extract contained higher amounts of ethanol, amino acids, sucrose, and allicin than the black garlic extracts. However, the PC2 loading plot showed that the 5 day black garlic extract was chemically different from the raw garlic, 25 day black garlic, and over 90 day black garlic extracts. The differences were primarily observed in the amino acid and sugar contents.

DISCUSSION

Amino Acids. The ^{1}H NMR spectra showed that most of the amino acid content of garlic, except for that of GABA, L-tryptophan, L-threonine, L-glutamic acid, L-glutamine, and pyroglutamic acid, changed in a similar manner during thermal processing as follows: the content increased at the early step of thermal processing up to 5 days and decreased during the later thermal processing. The increased content of the amino acids, including L-alanine, L-valine, L-leucine, L-isoleucine, L-lysine, L-arginine, L-proline, L-asparagine, L-aspartic acid, L-tyrosine, and L-phenylalanine, in the 5 day black garlic most likely resulted from the degradation of proteins or peptides, which may result from enzymatic hydrolysis or nonenzymatic hydrolysis, such as pyrolysis. In addition, the pH value decreased from 7.1 for the raw garlic extract to 5.3 for the 5 day black garlic extract as thermal processing progressed, which may have led to further enzymatic hydrolysis of proteins under acidic conditions. However, additional data are required to verify that the increase in the amino acid content of garlic after 5 days of thermal processing is derived from proteins. In the 25 day black garlic extracts, the decrease in amino acids may have been caused by reactions with reducing sugars, such as the Maillard reaction. The amounts of glucose and fructose increased in the 25 day black garlic extracts, providing good conditions for the Maillard reaction, which frequently occurs during thermal treatment of foods such as coffee and chocolate.[28]

The decreased level of L-tryptophan in the black garlic extracts likely resulted from consumption of L-tryptophan in the chemical reaction to produce carboline, which has been reported in aged garlic extracts.[29] During this reaction, L-tryptophan reacts with an aldehyde or an α-oxo acid, such as pyruvic acid, which is produced from the Maillard reaction or from alliin metabolism, via Pictet−Spengler condensation to form tetrahydro-β-carboline derivatives (THβCs).[29,30] The THβCs exert high antioxidant activity in short-term-fermented black garlic and aged garlic extracts but were not detected in the ^{1}H NMR spectra in our study, likely because of the extraction method used. The THβCs in the aged garlic were extracted by ethanol or a relatively high ratio of an organic solvent in water solution.[29,30]

Levels of pyroglutamic acid increased in the 5 and 25 day black garlic extracts, most likely through conversion from glutamic acid or glutamine by enzymatic or nonenzymatic reactions.[31] The decrease in the contents of glutamic acid and glutamine supports their conversion to pyroglutamic acid during thermal processing. Pyroglutamic acid is a cyclic lactam of glutamic acid that is an agonist of glutamic acid and is beneficial for the prevention of amnesia or memory loss in rats.[32]

Sugars and Organic Acids. In the 5 day black garlic extracts, the sugars content, especially that of sucrose, glucose, and fructose, increased, possibly through the degradation of polysaccharides. The polysaccharides in garlic have been reported to include fructan and galactan.[33,34] The remarkable increase in fructose levels in the 5 and 25 day black garlic extracts may also have resulted from degradation of the abundant fructan in the garlic.[35] Degradation of the polysaccharides could occur under acidic and high-temperature conditions,[36] which have been well studied in food products such as coffee beans after thermal processing.[37,38] In plants, degradation of cell wall polysaccharides causes tissue softening; therefore, the texture of black garlic is more gumlike than that of raw garlic. The decrease in pH and the heat treatment during thermal processing could promote further hydrolysis of sucrose to glucose and fructose, which may also be supported by the increase in glucose and fructose contents accompanying the reduced sucrose levels in the 25 day black garlic extracts.

Signals of organic acids, such as acetic acid, formic acid, succinic acid, and 3-hydroxypropionic acid, were identified in the 1D ^{1}H NMR spectra and the 2D NMR spectra of the black garlic extracts. The contents of acetic acid were significantly increased in the 5 day black garlic extracts, as demonstrated by the differences between the raw garlic extract and the black garlic extracts in the PC1 loading plot. This change in acetic acid content may result from sugar fragmentation.[39,40] During

DOI: 10.1021/jf504836d
J. Agric. Food Chem. 2015, 63, 683−691

thermal processing, the production of short-chain carboxylic acid results from α-dicarbonyl and β-dicarbonyl cleavage of hexose or pentose.[39−41] These reactions may also produce formic acid, succinic acid, and 3-hydroxypropionic acid.[42] Fumaric acid was detected in the raw garlic extracts, but its content decreased after thermal processing, most likely because it was converted to other metabolites. Malic acid and citric acid were detectable in the 1D and 2D NMR spectra, but their signals in the ^{1}H NMR spectra were highly overlapped with other signals, which made it difficult to determine the integral values. The increased organic acid content reduced the pH of the solution, which thus affected the degradation of the proteins, peptides, and polysaccharides. In black garlic, the increased organic acid and sugar (fructose and glucose) contents most likely contribute to sourness and sweetness, respectively, which result in the fruity taste. The over 90 day black garlic may show better taste than 25 day black garlic due to the texture change after further thermal processing.

Other Compounds. Ethanol showed extremely strong signals in the 1D and 2D NMR spectra of the raw garlic extracts and was dominant in the PC1 positive loading. However, the ethanol contents were significantly decreased in the 5 day black garlic extracts and not detected in the 25 and over 90 day black garlic extracts. Because ethanol is a volatile compound, it may have been vaporized during the thermal treatment. Moreover, ethanol may be converted to acetaldehyde, which then reacts with L-tryptophan via Pictet−Spengler condensation to form THβCs.[29] The methanol signal in the ^{1}H NMR spectra increased in the 5 day black garlic extracts and then decreased during additional thermal processing. The changes in methanol content were unclear because similar changes have been reported only in plant growth.[43,44] In addition, the decrease in methanol content in the 25 day black garlic extracts may have occurred through evaporation, similar to the results observed for ethanol, because methanol is also volatile.

The content of allicin, a metabolite largely responsible for the strong odor of garlic, decreased with the progression of thermal processing in black garlic, as detected in the ^{1}H NMR spectra. Allicin could be converted from alliin by the enzymatic reaction of alliinase in raw garlic under conditions above pH 3.6.[7] In our experimental conditions, the pH values of raw garlic and 5 day black garlic extracts were around 7.1 and 5.3, respectively, and the pH value of over 90 day black garlic extracts was around 4.1. Therefore, allicin could be generated under these conditions. Although allicin is an unstable sulfur compound and it could be changed to other sulfur compounds by any processing, it was still detected in ^{1}H NMR spectra of raw and black garlic extracts with our extraction conditions and those described in the previous report.[5] The decrease in the allicin content results in a "smoother" taste of black garlic. However, the increased signal at approximately 5.2 ppm in the 5 day black garlic extracts suggests that other allyl organosulfur compounds may be produced from allicin at this stage. The 1D ^{13}C NMR and 2D NMR spectra showed that the signals were not from allicin but may represent other allyl organosulfur compounds described in previous studies, such as diallyl disulfide or other allicin derivatives.[1,5,7] As an important organosulfur compound in garlic, allicin has been studied for its health potential, including its antibacterial, antifungal, and antiviral activities.[45] However, allicin and other organosulfur compounds in garlic are eliminated by processing, such as long-time extraction and thermal processing.[7] Thus, allicin could not be the primary functional factor underlying the health benefits of black garlic. Processed garlic products, including aged garlic extract and black garlic, also showed higher antioxidant activity along with other potential health benefits compared with raw garlic.[46] These effects resulted from the formation of other functional compounds, such as SAC and THβCs. We have tried to assign the signals of major organosulfur compounds γ-glutamyl-*S*-alk(en)ylcysteines and *S*-alk(en)ylcysteine sulfoxides in garlic, but the existence of a cysteine structure, which is a methylene group linked to a sulfur atom ($-S-CH_2-$), was not detected in our NMR data. Signals of cycloalliin, a sulfur imino acid, appeared in the ^{1}H NMR spectra of the 5 day black garlic extracts. Although this organosulfur compound has been reported to exist in *Allium* species, such as onions and garlic,[47] it was not detected in the raw garlic extracts in our study or in a previous study[5] by NMR. Cycloalliin has been reported to have many biological effects, such as serum triacylglycerol-lowering effects[47] in rats and cancer risk reduction.[48] A previous report also indicated that cycloalliin could be generated from isoalliin by storage of raw garlic.[49] Because isoalliin is produced by γ-glutamyl transpeptidase and oxidase, the increased cycloalliin contents in black garlic extracts may result from thermal processing that enhances the enzymatic activity. Therefore, the increased amount of cycloalliin in the black garlic extracts may contribute to their higher functionality after thermal processing when compared with that of raw garlic.

In the thermal processing of foods, the Maillard reaction and caramelization products including 5-HMF and 5-HMFA[13,50] were also detected in the ^{1}H NMR spectra of the black garlic extracts. The increased contents of 5-HMF and 5-HMFA in the 25 and over 90 day black garlic extracts indicated that further thermal processing may have a positive correlation with the amount of 5-HMF in black garlic. 5-HMF and 5-HMFA were generated from fructose and glucose, which in turn were produced by sugar decomposition in the black garlic during the thermal treatments.

In summary, we characterized the compositional changes of black garlic through thermal processing using ^{1}H NMR spectra combined with multivariate statistical analysis. The PCA score plot indicated differences between the raw garlic extracts and black garlic extracts, although the 25 day black garlic extract was not clearly distinguished from the over 90 day black garlic extract. However, the amount of 5-HMF was different in the 25 day extract compared with the over 90 day black garlic extract as determined by detailed signal assignments. In total, 38 NMR-visible components in the raw garlic and black garlic extracts were identified by the present nondestructive NMR method, and the changes in the content of these compounds, including amino acids, sugars, organic acids, and other metabolites, were successfully monitored throughout the thermal processing. Thermal processing of garlic is important not only for generating a functional food but also for improving the taste of garlic as a processed food product. The insights into the changes in metabolite levels during thermal processing in the present study shed light on the changes in color, flavor, and taste of food products resulting from the Maillard reaction, browning reaction, and other reactions caused by thermal treatments.

ABSTRACT: Discrimination among the types of feeding regimes for Iberian pigs is currently a highly demanded challenge by the Iberian pig sector. In the present research, discrimination among feeding regimes has been achieved by the combination of two analytical methods (based on FAMEs analysis by GC−FID and determination of $\delta^{13}C$ by IRMS) previously used independently without success. In the present study, 80 samples of adipose tissue from Iberian pigs subjected to four different feedings were analyzed. The study of the variables more influenced by the feeding regime has allowed us to configure panels of markers with predictive power for the studied feedings by multivariate ROC analysis. The results provided values of specificity and sensitivity higher than 85% in most cases. The statistical combination of results from different analytical methods could be the key to develop models for the correct discrimination of Iberian pigs according to the feeding regime.

KEYWORDS: *Iberian pig, subcutaneous fat, IRMS, GC−FID, feeding regimes, ROC analysis, fatty acid methyl esters, stable carbon isotopes*

INTRODUCTION

The Iberian pig is well adapted to the environmental and ecological conditions of the dehesa, where it eats basically acorns, the fruit of the genus *Quercus*. Studies have shown that this feeding habit yields Iberian pigs with large amounts of monounsaturated fatty acids (MFAs), triglycerides, and phospholipids;[1,2] therefore, the fat composition in these animals is characterized by a content of polyunsaturated fatty acids (PUFAs) lower than that in those fed with prepared feeds.[3]

In the last 30 years, the increased demand for Iberian pork products has led to a rise in production, which has not been in-parallel with the available natural resources. The dehesa forest cannot support the density of animals demanded by consumers; therefore, Iberian pigs are most times fed with grains and prepared feeds,[4] and the obtained products are endowed with nutritional and organoleptical properties different from those of pigs subjected to the *montanera* feeding (traditional name for the feeding regime exclusively based on the natural resources of the dehesa). Differences in the feeding regime have a direct impact on the economic value of cured products obtained from slaughtered pigs. The high economic value of cured products from animals fed under the *montanera* regime has made mandatory regulation and identification of Iberian products. Therefore, legislation (a Royal Decree, RD) to regulate their quality according to animal feeding was promoted and approved in 2001.[5] Designation of the different types of feeding has undergone changes with time, which are defined according to the Spanish RD[6] as follows:

1. *Bellota* (*montanera*): feeding based on acorns, grass and other natural resources present in the dehesa without any contribution of prepared feeds (mainly composed by cereals and legumes).
2. *Recebo*: feeding up to a minimum weight in *montanera* conditions, then supplemented with prepared feeds.
3. *Cebo de Campo*: feeding based on prepared feeds but with a final stay in the dehesa for at least 60 days combined with prepared feeds.
4. *Cebo*: feeding based exclusively on prepared feeds.

Currently, some modifications in the new RD of 2014[7] have included the *Recebo* class into the *Cebo de Campo* class. Thus, the new *Cebo de Campo* class is a type of feeding based on prepared feeds but also, in some cases, on acorns and grasses of the dehesa.

Among the methods used for classification of products according to the feeding regime of Iberian pigs, the most common approach has been analysis of the relative proportions of fatty acids (FAs) in adipose tissues by gas chromatography (GC) separation and flame ionization detection (FID).[3,4] Analysis of FAs is of great interest in the meat industry because

of the technological, nutritional, and sensory aspects resulting from their composition. Nevertheless, the determination of FAs in the subcutaneous tissue related with the feeding regime of pigs has given rise to an increase of prepared feeds defined by a composition of FAs similar to that in acorns.[8] Therefore, the composition of the most important fatty acids in animals fed with prepared feeds is very similar to that in those fed by *montanera* regime, and the power of the analytical method to distinguish among the categories decreases as a result.[4]

The feasibility of using near-infrared spectroscopy (NIRS) for discrimination among subcutaneous fat from Iberian pigs reared on different fattening diets has also been evaluated in diverse studies.[9,10] This technology is based on the analysis of the spectra in the near-infrared region provided by direct determination of cured products or fresh meat. Nevertheless, the models developed so far do not allow successful discrimination of all types of diets.

It is clear that new and more specific analytical methods are needed at present to discriminate among feeding regimes. The application of isotope ratio mass spectrometry (IRMS) has become an interesting tool to analyze the quality and authenticity of food.[8] Some of the methods based on this technique have been adopted as official in the EU, for example, for the characterization of wine[11] and fruit juices.[12] Isotopic analysis of carbon and sulfur in adipose tissue has also led to an alternative method to discriminate between *Bellota* and *Cebo* regimes.[13,14] Pioneers in the study of the influence of diet on stable carbon isotope ratio in animals were De Niro et al.[15] Their results showed the possibility of performing dietary analysis based on the determination of the $^{13}C/^{12}C$ ratio. In the field of this research, González-Martin et al.[13] were pioneers in the determination of the isotopic $^{13}C/^{12}C$ ratio in subcutaneous fat of Iberian pigs to differentiate feeding regimes. Subsequently, other authors have studied the applicability of this technique in other fresh pig tissues, mainly muscle,[13] liver,[4,13−16] adipose tissue,[4,11,15] and intramuscular fat,[3,14,17−19] for the prediction of feeding regimes in Iberian pigs.[4] In general, the different techniques presented difficulty in discerning between other feedings and *Recebo*. The authors emphasized that application of only one method is not enough for the discrimination of four feeding categories; therefore, they combined several methods. Nevertheless, they did not combine their data to develop a unique discrimination model.

The aim of the research presented here was to combine the classical method for the determination of FAs based GC−FID and that for monitoring carbon isotopic abundances by IRMS to develop discrimination models and search for panels of markers with capability to classify slaughtered animals by their feeding regime.

MATERIALS AND METHODS

Samples. Eighty Iberian pigs were selected in different farms located North of the province of Sevilla (Spain) within an area delimited by 25 km from South to North and 50 km from East to West. Collection of samples was carried out in 2012 by personnel belonging to the National Institute of Agriculture and Food Research and Technology (INIA, Extremadura, Spain). The animals were classified into four groups according to the feeding regime as set by the official legislation[6]. Each group was composed of 20 samples. Subcutaneous fat samples from slaughtered pigs were collected following the established Spanish official method.[20] The fat tissues were cut and put into individual microwave-resistant glass containers, then heated in a domestic microwave oven (700 W power and 2450 MHz microwave frequency) for 5 min at the maximum power, after which the melted samples were homogenized prior to sampling 5 mL of the liquid fat.[21] The treated samples were then stored at −20 °C until analysis.

Reagents and Standards. *n*-Hexane from Scharlau (Barcelona, Spain) was used for fat solubilization. Commercial standards of FA methyl esters (FAMEs) were acquired from Fluka Analytical (Buches, Switzerland) and corresponded to the following acids: lauric (C12:0), myristic (C14:0), palmitic (C16:0), palmitoleic (C16:1n9), hepatadecanoic (C17:0), stearic (C18:0), oleic (C18:1n9), eicosanoic (C20:0), eicosenoic (C20:1), eicosadienoic (C20:2n6), eicosatrienoic (C20:3n6), eicosatetraenoic (C20:4n3), arachidonic (C20:4n6), eicosapentaenoic (20:5n3), behenic (C22:0), tetracosenoic (C24:0), docosatetraenoic (C22:4n6), docosapentanoic (C22:5n3), docosahexaenoic (C22:6n3), hexacosanoic (C26:0), and octacosanoic (C28:0). A mixture of cis/trans isomers of linoleic (C18:2) and linolenic (C18:3) FAMEs was from Supelco Analytical Sigma-Aldrich (St. Louis, MO, USA). Tridecanoic acid methyl ester (C13:0) was used as external standard (ES) in the determination step. The C13:0 methyl ester was selected as this FA is not present in the samples, and its physicochemical properties are similar to those of the target FAs. Individual stock standard solutions and multistandard solutions at different concentrations were prepared by dilution in *n*-hexane. The concentrations were selected according to those of the FAs in subcutaneous fat in pork, and the solutions were stored at −20 °C. The international isotopic standards (IIS) used for the determination of $\delta^{13}C$ values by IRMS were mineral oil (IAEA NBS22) and sacarose (IAEA CH_6), provided by the International Atomic Energy Agency (IAEA, Vienna, Austria).

Instruments. An Agilent 7820A GC System equipped with an FID was used to separate and determine the esterified FAs in each extract. The GC was furnished with an autosampler and a split/splitless injector. An SP-2380 fused silica capillary column (60 m × 0.25 mm I.D., 0.2 μm film thickness) provided by Supelco (Bellefonte, PA, USA) was used as the analytical column. EZ Chrom Elite Compact software (version 3.3.2 from Agilent Technologies, Santa Clara, CA, USA) was used for acquisition and processing of data in the GC−FID system.

A Delta V Advantage Isotope Ratio Mass Spectrometer from Thermo Fisher Scientific (Bremen, Germany) was also used. This system was equipped with a ConFlo IV Universal Interface for continuous flow analysis and a Flash 2000 HT elemental analyzer. A molecular sieve packed column (5 Å, 1 m × 1/8″ × 2 mm) from Thermo Scientific (Bremen, Germany) was used for sample cleanup. Isodat Gas Isotope Ratio MS Software (version 3.0 from Thermo Scientific, Bremen, Germany) was used to acquire and process the signal obtained by IRMS analysis.

Statgraphics Centurion XV, version 15.1.02 for Windows, and the Mass Profiler Professional (MPP) software package (version 2.0 from Agilent Technologies, Santa Clara, CA, USA) were used for statistical analysis of the generated data. Roccet software (version online, http://www.roccet.ca/) was used for data pretreatment and analysis of receiver operating characteristic (ROC) curves.

Preparation of FAMEs. Conversion of FAs into their more volatile FAMEs is mandatory prior to individual GC separation. Subcutaneous fat (0.1 g) was shaken with 2 mL of hexane and vortexed for 1 min to complete solubilization. Then, 0.2 mL of 2 M methanolic potassium hydroxide solution was added, and the byphasic system was vortexed for 1 min. The two phases were easily separated, and 1.5 mL of the upper phase, containing the esterified FAs, was pipetted in a glass vial. This solution was 1:100 (v/v) diluted in hexane, and the resulting analytical sample was spiked with the ES (40 μg/mL) prior to injection into the GC.

Determination of FAMEs by GC−FID. Two microliters of each analytical sample was injected into the GC−FID equipment for analysis of FAMEs. The injector and detector were maintained at 250 and 295 °C, respectively. All samples were prepared and analyzed in triplicate. The injection was 1:10 split, and the program of the temperature gradient was as follows: the initial oven temperature was kept at 50 °C for 2 min, then raised at 15 °C/min to a final temperature of 250 °C, which was held for 15 min. The equilibration time was 3 min. The mobile phase was helium at a flow rate of 1 mL/min. The corresponding standard was used to confirm identification of each FAME in the fat samples. Quantitative analysis was carried out by preparation of a

[a]RSD: relative standard deviation.

calibration model for each FA by using the multistandard solution at different concentrations spiked with the ES at 40 μg/mL. The concentrations of the target FAs were expressed as a percentage in relative terms.

Determination of $^{13}C/^{12}C$ Isotopic Ratio by IRMS. Sacarose ($\delta^{13}C$ −10.45 ‰) and NBS22-Oil ($\delta^{13}C$ −30.03 ‰) were used as IIS within the ranges 350−450 and 550−750 μg, respectively, to achieve a signal intensity of 7600 mV. Samples (within the range 320−420 μg) were weighed into a tin capsule (3.3 × 5 mm, IVA Analysentechnik e. K., Düsseldorf, Germany). The analyses were carried out in batches of 10 samples, sandwiched by standards as the internal control. The carrier and reference gases (He in both cases) were circulated at 80 and 200 mL/min, respectively. The temperatures of the elemental analyzer were set at 65 and 1020 °C for the oven temperature and combustion reactor, respectively. The results of the carbon isotope ratio ($\delta^{13}C$) analyses were reported as the per mil (‰) enrichment relative to the international standard, V-PDB (Vienna Pee Dee Belemnite) for carbon isotope ratio, according to the following equation:

$$X(‰) = [(R_{sample}/R_{reference}) - 1] \times 1000$$

where X is the ratio of the heavy to the light stable isotope (e.g., $^{13}C/^{12}C$) in the sample (R_{Sample}) and in the standard ($R_{Reference}$).[22] The fat samples were analyzed in duplicate with a variability less than 0.20‰ for $\delta^{13}C$ measurements.

Statistical Analysis. Raw data files were used to create a data set formed by samples (columns) and the quantitative variables (concentrations of FAs and $\delta^{13}C$ values). The data set, formed by 11 variables × 80 samples, was exported as comma separated value files (.csv) into the Roccet and MPP softwares for processing.

Normalization by logarithmic transformation was used as a preprocessing step since the data obtained from the two different analyses were combined. An ANOVA test was executed with the normalized data to evaluate the significance of each variable (p-value lower than 0.05). Statistical analysis was carried out by principal component analysis (PCA) and partial least squares discriminant analysis (PLS-DA). In the latter case, an N-fold cross-validation model was used. With this model, the classes of the input data are randomly divided into N equal parts; $N - 1$ parts are used for model training, and the remaining part is used for testing. The process is iteratively repeated N times using each time a different subset for testing. Thus, each row is used at least once in training and once in testing, and a confusion matrix is generated. This whole process can then be repeated as many times as specified by the number of repetitions. Ten repetitions and a fold number of three were selected in all PLS-DA models.

The ROC curves were individually obtained for different panels of variables in order to find discrimination trends between pairs of feedings.

RESULTS AND DISCUSSION

Development of Calibration Models for the Analysis of FAMEs. The calibration models were prepared from 25 FAMEs prior to analysis of the samples by using multistandard solutions at different concentrations as a function of the abundance of each compound in subcutaneous pork fat.[1,3,23] The most concentrated FAs, C16:0, C18:0, and, particularly, C18:1n9, ranged from 1.8 to 187.5 μg/mL; a second set (C14:0, C:16:1n9, and the C18:2 isomers) ranged from 0.90 to 93.75 μg/mL, and a third calibration range (from 0.48 to 48.75 μg/mL) was applied to C12:0, C17:0, C18:3 isomers, C20:1n9, C20:2, C20:3, and C20:4. Finally, the resting FAs were modeled from 0.125 to 12.5 μg/mL. Six dilutions (1:2, 1:5, 1:10, 1:25, 1:50, 1:100, and 1:250) of the multistandard stock solution, each injected in triplicate, were used to run the calibration curves. All the solutions at the different concentrations were spiked with the ES at 40 μg/mL. The calibration curves were obtained by plotting the ratio between the peak area for each FA and the peak area of the ES. The calibration equations and regression coefficients are listed in Supporting Information, Table 1. As can be seen, the regression coefficients were above 0.99 for all the compounds. It is also worth mentioning that the eight C18:3 isomers could not be independently quantified, except for the *t,t,t* and *c,c,c* isomers. A similar situation was found for C20:3 and C20:4 owing to the overlapping of their chromatographic peaks.

Analysis of FAs in the Target Samples by GC−FID and IRMS Characterization. Taking into account the variable concentration of the FAs in subcutaneous pig fat, different dilution factors were tested for analysis of the derivatized samples to obtain quantitative information on the maximum number of FAs. Thus, an 1/100 (v/v) dilution factor was adopted for

DOI: 10.1021/jf505189x
J. Agric. Food Chem. 2015, 63, 692−699

analysis of the 10 most concentrated FAs (C14:0, C16:0, C16:1n9, C17:0, C18:0, C18:1n9, *c,c* C18:2, *c,c,c* C18:3, C20:0, and C20:2); while the rest of FAs were detected at lower dilution factors at which quantitative analysis of the most concentrated FAs was compromised; therefore, they were discarded from the results obtained at dilutions lower than 1/100. Supporting Information, Figure 1 shows a GC−FID chromatogram obtained by analysis of subcutaneous fat from a *Bellota* sample.

After analysis, the data were processed to obtain the FA concentration profile from each sample. Table 1 summarizes the results provided by the 80 samples with information on the maximum and minimum concentrations found for each FA and the mean concentration and standard deviation for each target feeding. The $\delta^{13}C$ value is also included to show the variability of this parameter. As Table 1 shows, four FAs (C18:1n9, C16:1n9, C18:0, and *c,c* C18:2) clearly dominated the concentration profile of subcutaneous fat, which is in agreement with characterization studies previously reported.[1,3] The rest of the FAs were present at relative concentrations below 5%.

The comparison of the FA profile among the four types of samples grouped by feeding revealed that the content of major FAs was similar for *Cebo* and *Cebo de Campo* feedings (*p*-value above 0.0713), while samples from *Recebo* and *Bellota* also provided a similar profile (*p*-value above 0.1239); this is quite foreseeable behavior taking into account that these two feedings are the most similar among the four classes under study. It is also worth emphasizing that C18:1n9 was the most concentrated FA in the four groups of samples (about 50% of relative concentration), but mean values were higher for *Recebo* and *Bellota* (56.03 and 55.44%, respectively), which could be ascribed to similarity between these two feeding regimes. Animals subjected to the *Recebo* regime are fattened in *montanera* conditions up till they reach a cutoff weight, while *Bellota* animals are fed under *montanera* conditions up till they are slaughtered.

The only official method for discrimination of feeding regimes of Iberian pigs was based on GC−FID analysis of FA composition in subcutaneous adipose tissue.[6,18] This method was discarded as the official method in 2007 as it was not able to detect fraud imvolving Iberigan pigs fed with prepared feeds.[18] B.O.E. 2004[20] includes a summary of the criteria used for classification of the three defined feedings: *Cebo*, *Recebo*, and *Bellota*. The relative standard deviation (RSD %) was quite similar among the four groups under study (Table 1): below 10% for all FAs, except for the two most relevant, C16:0 and C18:1.

The $\delta^{13}C$ values (see Supporting Information, Figure 1, which shows an IRMS spectrum provided by analysis of a subcutaneous adipose *Bellota* sample) ranged from −28.01 to −24.54‰, with RSD below 3‰. Attending to this variability, the inclusion of $\delta^{13}C$ in classical discrimination models based on FAME analysis could aid in feeding classification. In this research, only carbon isotopic ratios were studied. The isotopic analysis of hydrogen and oxygen has been applied mainly for geographical discrimination of different types of food such as durum wheat semolina and potatoes.[4,16,24−30] Geographical discrimination is out of the scope of the present research as all samples were collected in a delimited area, as specified under Materials and Methods.

Influence of Feeding on the FA Profile and $\delta^{13}C$ Value. The data set was normalized by logarithmic transformation because of the two analytical methods used. The effect of this preprocessing step was proved by application of the Kurtosis and Skewness tests. Then, the normalized data set was analyzed by ANOVA to evaluate the influence of the feeding type on both the concentration of FAs and the value of the $^{13}C/^{12}C$ isotopic ratio (dependent variables). Table 2 summarizes the results provided by ANOVA of the 11 dependent variables as a function of the predictive factor, the feeding type. The variance is decomposed into two components: between-groups variability (intergroups) and within-group variability (intragroup). As can be seen, most of the variables reported a very high significance with *p*-values below 0.001, except for C17:0 and *c,c* C18:2 which did not show any level of significance. Therefore, the feeding factor exerted a noticeable influence on the FA profile and $^{13}C/^{12}C$ ratio. In fact, feeding was identified as the main variability source to explain the levels of the most concentrated FAs (C16:0, C18:0, C18:1n9, and C20:0) as well as the $^{13}C/^{12}C$ ratio, which was deduced by comparing the sum of squares between and within the target

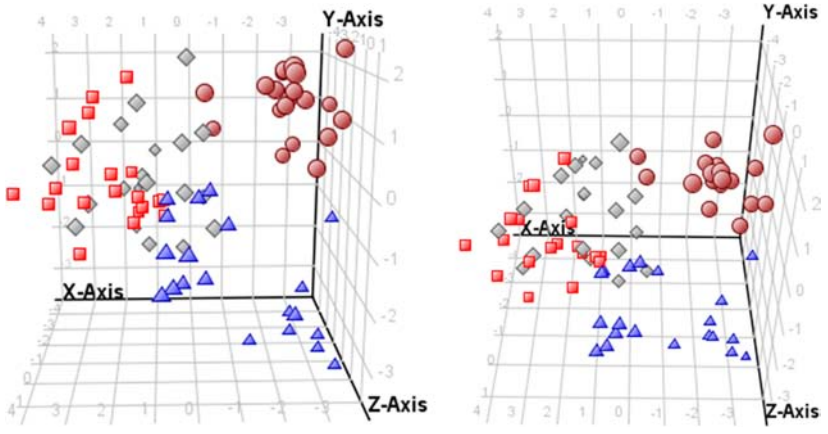

Figure 2. PLS-DA scores plot (different views) of samples from slaughtered pigs subjected to different feeding regimes. *X*-axis, t_0; *Y*-axis, t_1; *Z*-axis, t_2. Explained variability: *X*-axis, 40.95%; *Y*-axis, 19.56%; *Z*-axis, 9.65%. Square, *Bellota*; circle, *Cebo de Campo*; triangle, *Cebo*; rhombus, *Recebo*.

groups. Figure 1 shows the box-and-whisker plots obtained by normalized concentrations of the significant variables, which allowed us to detect some differences among the four groups. Thus, the $\delta^{13}C$ values revealed differences between *Cebo de Campo* samples and the other three feedings. However, C16:0, C16:1n9, and C18:0 were characterized by a similar trend since they were clearly more concentrated in *Cebo de Campo* and *Cebo* samples than in those from *Bellota* and *Recebo*. The opposite situation was observed with C18:1n9, which was more concentrated in animals subjected to the *montanera* regime during a given period. A different trend was observed for C20:0, which provided discrimination in concentration between *Cebo de Campo* and *Cebo* samples, while *Bellota* and *Recebo* samples gave levels between the two previous groups.

The influence of feeding on the FA profile and $\delta^{13}C$ values led us to apply multivariate analysis to find discrimination trends among groups. Thus, PCA was first applied to check the incidence of the breeding type on the FA profile and the $^{13}C/^{12}C$ ratio. The three-dimensional PCA scores plot with samples identified by symbols as a function of the type of feeding is shown in Supporting Information, Figure 2. The 3D-plot allowed us to explain 70.6% of the total variability. One cluster formed by *Cebo de Campo* samples can be clearly differentiated from the other three groups. Thus, the *Cebo de Campo* class was the feeding type providing the most discriminating pattern in the FA profile and the $^{13}C/^{12}C$ ratio. However, a partial separation can be observed for the other three feeding classes (*Cebo*, *Recebo*, and *Bellota*), which allows us to set differences. A particular behavior was

p-value	*Cebo de Campo* vs *Recebo*	*Cebo de Campo* vs *Bellota*	*Cebo de Campo* vs *Cebo*	*Bellota* vs *Cebo*	*Recebo* vs *Bellota*	*Recebo* vs *Cebo*
0.05−0.01			C16:1n9	C18:2	C18:3, C20:2	C14:0, C16:1n9
0.01−0.001	C20:2	C18:3, C20:2		δ^{13}C, C16:1n9	δ^{13}C	C18:3
<0.001	δ^{13}C, C16:0	δ^{13}C, C16:0	δ^{13}C, C18:3	C18:0, C18:1n9		C18:0, C18:1n9
	C18:0, C18:1n9, C14:0	C18:0, C18:1n9, C14:0	C20:0,, C20:2	C16:0, C18:3		C16:0, C20:0
	C20:0, C16:1n9	C20:0, C16:1n9		C20:0, C14:0, C20:2		

visualized for *Cebo* samples as two subclusters were found, one of them completely separated and a second subcluster that overlapped with *Recebo* and *Bellota* samples. No details were provided by farmers about this result, but it could be associated with differences in the provided feeding. The results obtained with PCA seem to be quite logical since the maximum overlap was detected between *Recebo* and *Bellota* samples that constitute the most similar classes since animals subjected to *Recebo* feeding must reach a minimum weight in the dehesa (*montanera* regime).

The next step was application of supervised statistical analysis by PLS-DA to evaluate the capability of the data set for development of predictive/discrimination models. Figure 2 shows the PLS scores plot that allows discrimination between *Cebo de Campo* and *Cebo* samples, while *Bellota* and *Recebo* samples overlapped. This behavior was checked in the confusion matrix provided by this PLS-DA model both in the training and validation steps, which were carried out by cross-validation. Thus, *Bellota*, *Cebo de Campo*, and *Cebo* were classified with accuracy above 90%, while the model failed in the classification of *Recebo* samples with a 45% of accuracy. In fact, the model confused 35% of the *Recebo* samples, which were erroneously classified as *Bellota* samples.

Multivariate Analysis between Pairs of Feedings. Since the variability in the concentrations of FAs and δ^{13}C values does not allow complete discrimination of the four groups of feedings, multivariate analysis was applied to pairs of feedings to precisely identify the patterns that differentiate them. For this purpose, one PLS-DA model was created for each pair of feedings, and then, ANOVA analysis revealed the main statistical differences in subcutaneous fat of animals subjected to each feeding (Supporting Information, Figure 3). Supporting Information, Table 2 shows the discrimination capability for training and cross-validation obtained from the six cases. As expected, high-discriminating models were found in all pairs of feedings, except for that involving *Bellota* and *Recebo* samples, which provided discrimination capabilities above 75% in the training step and 65% in the validation step. Supporting Information, Figure 3 shows the 3D-plots obtained by PLS-DA with clear separation between each pair of feedings. Therefore, if the variability study is focused on two types of feedings then the discrimination models gain in prediction capability, even for *Bellota* and *Recebo* samples, which seems to be the two most similar feedings.

After supervised analysis, an ANOVA test was independently applied to each pair of feedings to evaluate its influence on the concentration of FAs and δ^{13}C. Table 3 lists the variables that are significantly different by comparison of two feedings and the *p*-values obtained for them. As can be seen, the δ^{13}C value was significantly altered by the feeding in all cases, with a *p*-value below 0.001, except for the pair *Recebo* vs *Cebo*. The most concentrated FAs in subcutaneous fat, C16:0, C18:0, and C18:1n9, were significant in most of the evaluated pairs, except for *Cebo de Campo* vs *Cebo* and *Recebo* vs *Bellota*. It is worth mentioning that the significance level was quite high in all cases with *p*-values below 0.001. Only two FAs, C17:0 and *c,c* C18:2, were not significantly affected by the type of feeding.

Prediction Analysis by Multivariate ROC Analysis. The influence of feeding on the variability of FA concentration and δ^{13}C values in subcutaneous fat from Iberian pigs supports the assessment of predictive models based on panels formed by a combination of significant variables according to the ANOVA test. ROC curves are generally considered the method of choice for evaluating the performance of potential biomarkers associated with biological processes. In this research, panels were prepared by multivariate ROC analysis, which involves a preliminary study of the individual predictive capability of all the variables and, then, the combination of variables in panels to maximize the predictive capability. Taking into account that *Bellota* is the most appreciated class, prediction models were created for the classification of *Bellota* vs *Cebo de Campo*, *Bellota* vs *Cebo*, and *Bellota* vs *Recebo*. Other panels with commercial interest were also configured for discrimination between *Cebo* vs *Cebo de Campo* and *Cebo* vs *Recebo*. Predictive models were developed by dividing the set of samples into training and validation sets, which included 75% and 25% of the samples of each condition, respectively. The samples used for validation were not included in the training step, which means that this was carried out with an external set. The algorithm used for classification and selection of variables in the panels was PLS-DA with three latent variables. All of the panels were formed by three variables, except for *Bellota* vs *Recebo*, in which the best predictive behavior was provided by δ^{13}C, and no improvement provided the inclusion of additional variables. In the studies involving other combinations of feeding regimes, the sensitivity and/or specificity was not improved by inclusion of more variables either. It is also worth mentioning that all panels constituted by three variables were formed by δ^{13}C and the most concentrated FA, oleic acid. Additionally, stearic acid contributed to the prediction of *Bellota* vs *Cebo de Campo* and *Bellota* vs *Cebo*, while palmitic acid and eicosanoic acid improved the models for the discrimination of *Cebo* vs *Recebo* and *Cebo* vs *Cebo de Campo*, respectively. The models involving *Bellota* vs *Cebo de Campo* and *Cebo* reported high sensitivity and specificity, always above 90%, which led to quite good predictive models. The most complicated case was the model involving *Bellota* vs *Recebo*, based on a unique variable, δ^{13}C, which reported a specificity of 80%, while sensitivity decreased to 63%. This result agrees with that provided by the PLS-DA study for the same two feeding regimes. The efficiency of this model can be compared with that provided by previous studies based on IRMS analysis, such as that carried out by García Casco et al.,[4] who provided a model based on the analysis of stable isotopes of carbon (δ^{13}C) and sulfur (δ^{34}S) with lower discrimination capability than the model obtained in this research. The sensitivity and specificity of the models for the discrimination of *Cebo* vs *Recebo* and *Cebo* vs *Cebo de Campo* were 93% and 85%, respectively. The most compromised case was the model involving *Recebo* vs *Bellota* that reported a specificity of 80% and sensitivity of 63%. Thus,

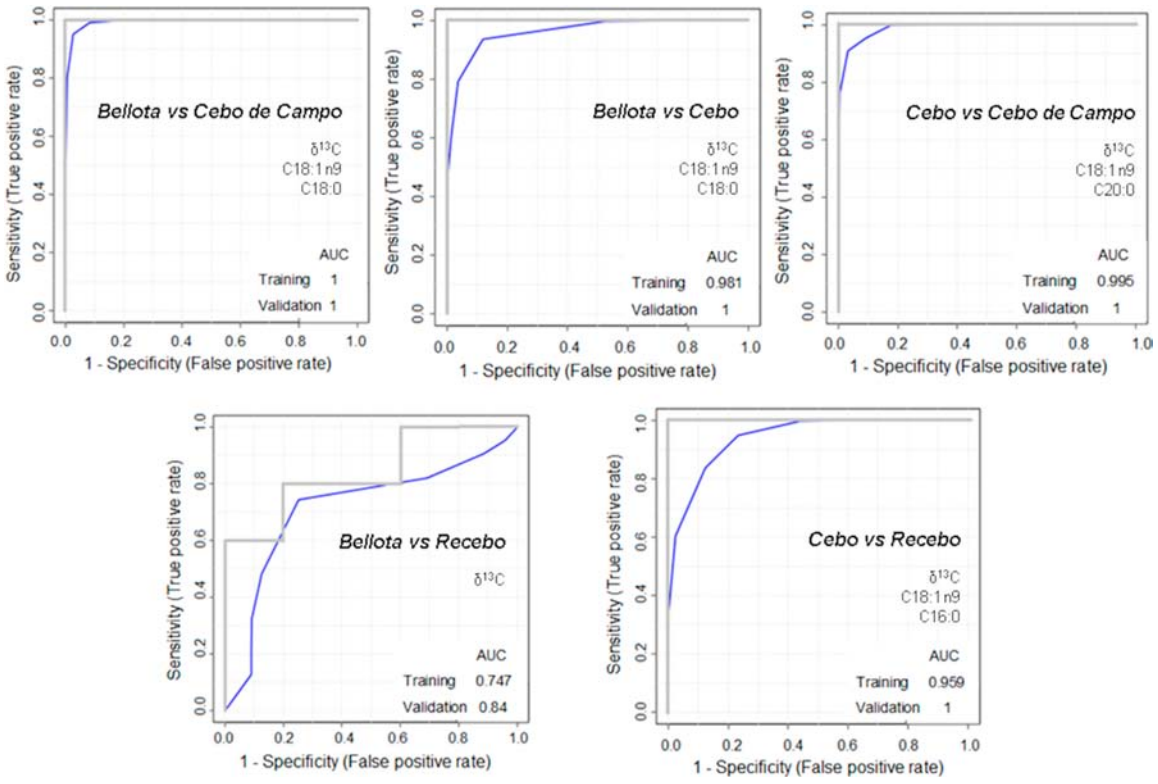

Figure 3. Individual ROC curves obtained from panels of biomarkers for discrimination between pairs of diets. The thick line corresponds to validation (external), and the fine line corresponds to training. *Bellota* vs *Cebo de Campo*: variables, δ^{13}C, C18:1n9, C18:0. *Bellota* vs *Cebo*: variables, δ^{13}C, C18:1n9, C18:0. *Cebo* vs *Cebo de Campo*: variables, δ^{13}C, C18:1n9, C20:0. *Bellota* vs *Recebo*: variables, δ^{13}C. *Cebo* vs *Recebo*: variables, δ^{13}C, C18:1n9, C16:0.

these models enabled us to classify samples according to their feeding regimes. These good prediction parameters can be explained by the ROC curves illustrated in Figure 3.

The results of sensitivity and specificity for each panel can be combined with the estimations of prediction capability for each class and the false positive rates listed in Supporting Information, Table 3. Thus, these values associated with the validation set were quite consistent with the results provided by the training set. As the validation set was formed by samples not included in the training set, the quality and statistical support are considerably enhanced.

At present, there are no discrimination methods able to identify the feeding regime used with capability to detect fraud. Different techniques have been independently assayed. However, no methods based on the application of different analytical techniques had been combined so far. In view of these results, the statistical combination of the results obtained by different analytical methods could be the key for the correct discrimination of feeding regimes in the sector of Iberian pigs. Taking into account the demand for methods to discriminate feeding regimes, this approach could be implemented in routine laboratories since the analysis of fatty acids is already carried out at this level, while IRMS analysis is frequently used in reference food laboratories.

Changes in the Levels of Off-Flavor Generation in Soybean through Biotic Elicitor Treatments

Sweta Kumari,*[,†] Anil Dahuja,[†] T. Vinutha,[†] Sanjay Kumar Lal,[‡] Abhijit Kar,[§] and Raj D. Rai[†]

[†]Division of Biochemistry, [‡]Division of Genetics, and [§]Division of Food Science & Post harvest Technology, Indian Agricultural Research Institute, New Delhi-110012, India

ABSTRACT: The nutritional benefits of soybean remain underutilized as the off-flavor present in it limits the consumption and acceptability among people. The aim of the present study was to unveil the effect of the phytohormones methyl jasmonate (MJ: 0, 50 μM, 1 mM, and 15 mM) and salicylic acid (SA: 0, 50 μM, 0.1 mM, and 10 mM) as elicitors on two contrasting off-flavor soybean varieties at different growth stages (1, bloom; 2, pod development; 3, seed development). The effects of two elicitors varied widely and were found to be dose dependent and growth stage independent. SA reduces the lipoxygenase (LOX) and hydroperoxide lyase (HPL) activity, which in turn resulted in reduction in the TBA number and carbonyl value in contrast to MJ. SA 0.1 mM is the most effective dose in reduction of off-flavor determining parameters and protein oxidation, and it reduces the LOX and HPL activity by 2.3- and 2.4-fold, respectively in "high off-flavor" cultivar 'Bragg' compared to "low off-flavor" cultivar 'DS 2706' which showed 1.4- and 2.1-fold, respectively. This reduction in protein oxidation is also supported by enhanced content of antioxidant enzymes. Thus, phytohormone SA can be used in reduction of off-flavor generation, more effectively than MJ treatments, in soybean.

KEYWORDS: *soybean, off-flavor, elicitation, protein oxidation, antioxidant enzymes*

INTRODUCTION

Soybean is fast emerging as one of the most important food crops in the developing countries, especially India, to cater to the needs for protein as well as oil. It has also been described as the "functional food of the century" for a plethora of nutraceuticals it possesses: anthocyanins, isoflavones, tocopherols, etc.[1] Indians are predominantly vegetarian, and the vegetable proteins have special significance. India has been struggling hard and importing oils and pulses to bridge the gap; the importance of production and consumption of soybean has, of late, gained the attention of the researchers and policy-planners. The consumption of soy protein as human food is being encouraged due to its economical source of high quality protein. Though soybean contains about 40% protein and 20% oil, it is classified as an oil crop. Although consumption of food products made from soybeans has registered steady increase during the past 30 years, the acceptance, popularity, and market of these products has, however, been limited due to "off-flavor"—beany, grassy—associated with soybean and its products.[2]

The off-flavor development in soybean seeds and its products is a serious problem. Soybean oil, in general, contains about 55% linoleic and 10% linolenic acid. Lipoxygenase (LOX), present in a relatively large amount (about 2%), is implicated as a major culprit in the peroxidation of lipids especially polyunsaturated fatty acids (PUFAs), containing *cis*,*cis*-1,4-pentadienes.[3] The products of this enzyme are subsequently acted upon by other enzymes like hydroperoxide lyase leading to the production of the off-flavor causing compounds such as pentanal, hexanal, heptanal, and even nonanal along with their unsaturated forms. These volatile and offensive smelling aldehydes are very reactive, bind covalently with proteins, and thus cause flavor problems both in protein and in oil products.[4] Out of three lipoxygenase enzymes (LOX1, LOX2, and LOX3) found in soybean seeds, LOX2 has been pinpointed to be largely responsible for generation of hexanal.[5]

Heat treatment is given to seeds before processing, to reduce LOX activity and production of volatiles, but the treatment may have undesirable effects on the texture. While processing methods for soymilk have considerably improved, processed soybean products often have undesirable chalky texture caused by processing. Breeders have, however, tried to reduce the off-flavor problem by developing varieties with low PUFA content/ratio[6] or by silencing/removing seed lipoxygenases.[5] This approach however is not without disadvantages as Lox is essential for formation of several important secondary products, including jasmonic acid, which plays a desirable role in various important physiological processes. Lox in soybean has also been reported to maintain the appropriate level of protease inhibitors which are vital for the protection of plants against insects and pests.[7] Hence, complete elimination of the lox isozymes from soybean may adversely affect plant defense mechanism. It has though been demonstrated that stacking mutations in all three LOX genes can reduce undesirable flavors, but these mutants still have been shown to contain considerable levels of off-flavor.[8] Furthermore, these mutations have not been incorporated into the elite breeding lines because of the technical difficulties in selecting for three recessive mutations that segregate independently.[9]

Inherent antioxidant potential in soybean seeds has been shown to reduce the off-flavor, and the effect is partially

mediated through secondary metabolites, especially tocopherol, anthocyanins, phenolics, etc.[3] Enhancement of desirable secondary metabolites by elicitation is an area of active investigation, and few strategies have found commercial application. It can, therefore, be explored to obtain soybean and its products with reduced off-flavor and enhanced consumer acceptability. Elicitors are chemical molecules which, when added in small amount to a living cell system, advance the biosynthesis of specific compounds and induce physiological changes in the plant.[10] Elicitors may be of biological or nonbiological origin, which upon contact with the higher plant cells trigger the increased production of the secondary metabolites like pigments, flavones, antioxidants, phytoalexins, and other related compounds. Biotic elicitors have biological origin and are commonly applied to enhance the phytochemical composition of plants.

Biotic elicitors (having biological origin) such as methyl jasmonate (MJ), salicylic acid (SA), etc. have been reported to increase production of secondary metabolites, isoflavonoid,[11] betalain,[12] saponin,[13] and glucosinolates,[14] through various mechanisms. They are natural plant growth regulator phytohormones playing key roles in the signal interplay during biotic and abiotic stresses.[15] In view of the above, it is quite apperent that biotic elicitors have a great potential to enhance the qualities, especially production of nutraceuticals, but this strategy has not been tried for the reduction of off-flavor in soybean. The main aim of this study is, therefore, to investigate the effect of the two most potent elicitors, namely, SA and MJ on the reduction levels of off-flavor generation in soybean. The approach was to determine the effect of concentration and stage of application of these elicitors on soybean genotype differing widely in their off-flavor generation potential.

MATERIALS AND METHODS

Chemicals. Salicylic acid and methyl jasmonate were purchased from Sigma-Aldrich Co. (Germany). Linoleic acid, 2,4-dinitrophenylhydrazine, and 5,5′-dithiobis(2-nitrobenzoate) [DTNB reagent] were obtained from Sigma-Aldrich Co. (USA). Ascorbic acid and glutathione were purchased from Sigma-Aldrich Co. (Bangalore, India). Lipoxygenase, Tween-20, tetraethoxypropane (TEP), riboflavin, methionine, nitro-blue tetrazolium chloride (NBT), and NADPH were purchased from Sisco Research Laboratory (Mumbai, India). Other chemicals and solvents used for estimation of various parameters were also of analytical grade.

Plant Materials and Elicitor Treatment. Two contrasting (high and low) off-flavor soybean varieties, viz., Bragg (high off-flavor) and DS 2706 (low off-flavor), were selected.[3] The field experiments were conducted in plots (size 1 m^2) in the research farm, IARI, New Delhi, following standard cultural practices. Treatments (sprays) were imposed at various growth stages of the crops, and three replications were maintained for each treatment. The total volume applied to one plot was 500 mL for high vegetative growth cultivar 'DS 2706' and 300 mL for low vegetative growth cultivar 'Bragg'. Different concentrations of the elicitors tried were as follows: MJ (0, 50 μM, 1 mM, and 15 mM) and SA (0, 50 μM, 0.1 mM, and 10 mM). Solutions of the elicitors were prepared by dissolving MJ in 0.01% (v/v) Triton X-100 and SA in distilled water. Elicitors were sprayed at three growth stages: GS-1 (beginning to full bloom), GS-2 (beginning to full pod), and GS-3 (beginning to full seed) with a hand sprayer. Spray was given to cover uniformly the whole plant. Seeds from the treated plants were harvested at full maturity in mid-November and were stored at room temperature for three months for off-flavor generation, after which seeds were processed for estimation of different parameters. Seeds from plants sprayed with only Triton X-100 or water were used as control. Soybean seeds were milled with a laboratory electric mill to make a fine particle size of 0.5 mm.

Assay of Lipoxygenase (LOX) Activity. The LOX activity in soybean extracts was assayed by a modified method of Axelrod et al.,[16] and the time course of the peroxide formation was measured by the increase in absorbance at 234 nm using a spectrophotometer. Overnight soaked soybean seeds (1 g) in distilled water were homogenized in 6 mL of ice-cooled extraction buffer (0.1 M phosphate buffer, pH 6.8) using a mortar and pestle. The homogenate was allowed to stand for 10 min at 4 °C and centrifuged at 15000*g* for 30 min at 4 °C. The resultant supernatant was kept at 4 °C for further estimations. To 2.99 mL of substrate was added 10 μL of enzyme extract, and the increase in OD was measured at 234 nm for 6 min at room temperature. A unit of enzyme was defined as the amount which produced a change in OD of 0.001 per min at 234 nm in 3 mL of reaction mixture. The peroxide identification in all solvents and extracts was done using the potassium iodide test and was found to be negative.

Assay of Hydroperoxide Lyase (HPL) Activity. In the present study HPL activity has been estimated by a coupled enzyme assay, which is conducted spectrophotometrically at 340 nm and measures the oxidation of nicotinamide adenenine dinucleotide, reduced form (NADH). It is based on the ability of hydroperoxide lyase products, aldehydes and ω-oxoacids, to serve as substrates for yeast alcohol dehydrogenase.[17] For the preparation of substrate for HPL, 3 mL of lipoxygenase (60 mg of lipoxygenase in 6 mL of 10 mM borate buffer, pH 8.9) solution was added to 35.5 mL of double distilled water and 7.5 mL of 8 mM linoleic acid. This solution was stirred on a magnetic stirrer for 20 min, to provide oxygen continuously to obtain fatty acid hydroperoxide. HPL was extracted from 1 g of soy flour by homogenizing in 6 mL of extraction buffer (50 mM potassium phosphate buffer, pH 7.0) through continuous stirring for 2−3 h on a magnetic stirrer. Supernatant was collected after centrifugation. In a 3 mL cuvette were taken 2600 μL of assay mixture (50 mL of 100 mM phosphate buffer, pH 6.0, 3.5 mg of NADH, and 6.6 mg of yeast alcohol dehydrogenase) and 200 μL of substrate (fatty acid hydroperoxide). To this was added 200 μL of enzyme extract, and the absorbance was measured at 340 nm at every 30 s interval for 6 min. A unit of enzyme was defined as the amount which produced a change in OD of 0.001 per min at 340 nm in 3 mL of reaction mixture. Total protein content of this extract was determined by Bradford method using bovine serum albumin as a standard.

Estimation of Thiobarbituric Acid (TBA) Number. TBA number is a measure of amount of malondialdehyde produced by the decomposition of various primary and secondary lipid peroxidation products. Its estimation was based on the reaction of TBA with malondialdehyde (MDA) to form a pink colored MDA−TBA adduct.[18] Overnight soaked soybean seeds (0.2 g), in distilled water, were homogenized with 2.0 mL of distilled water, and the homogenate was centrifuged at 15000*g* for 30 min. Thus, the extract obtained was filtered to obtain the clear extract through filter paper. Then, 0.2 mL of this extract was taken in a test tube, and 0.2 mL of 8.1% SDS, 1.5 mL of 20% acetic acid (pH 3.5), and 1.5 mL of 0.8% TBA were added. The final volume was made to 4.0 mL with distilled water and heated in a boiling water bath for 60 min. After cooling, 1.0 mL of distilled water and 5.0 mL of *n*-butanol−pyridine (15:1) was added and the tubes were shaken vigorously and centrifuged at 4000 rpm for 10 min. The pink color organic layer formed at the top was separated from the aqueous phase, and absorbance was taken at 532 nm. The standard curve was prepared using TEP ranging from 10 to 70 nmol and the level of lipid peroxides expressed as nmol of MDA/g fresh weight.

Estimation of Carbonyl Value. The carbonyls were estimated by the method described by Henick et al.[19] 2,4-Dinitrophenylhydrazine reacts with the lipids to form 2,4-dinitrophenylhydrazone derivatives that converted to wine red colored complex under alkaline conditions provided by KOH. The sample extraction for estimation of carbonyls was done in the same way as that for TBA number. For estimation, to a 2.5 mL centrifuge tube were added 0.5 mL of sample extract and 0.5 mL of 2,4-dinitrophenylhydrazine, and the mixture was heated in a water bath at 60 °C for 30 min. After cooling, 1.0 mL of KOH was added and a characteristic wine red color was appeared. Ten minutes

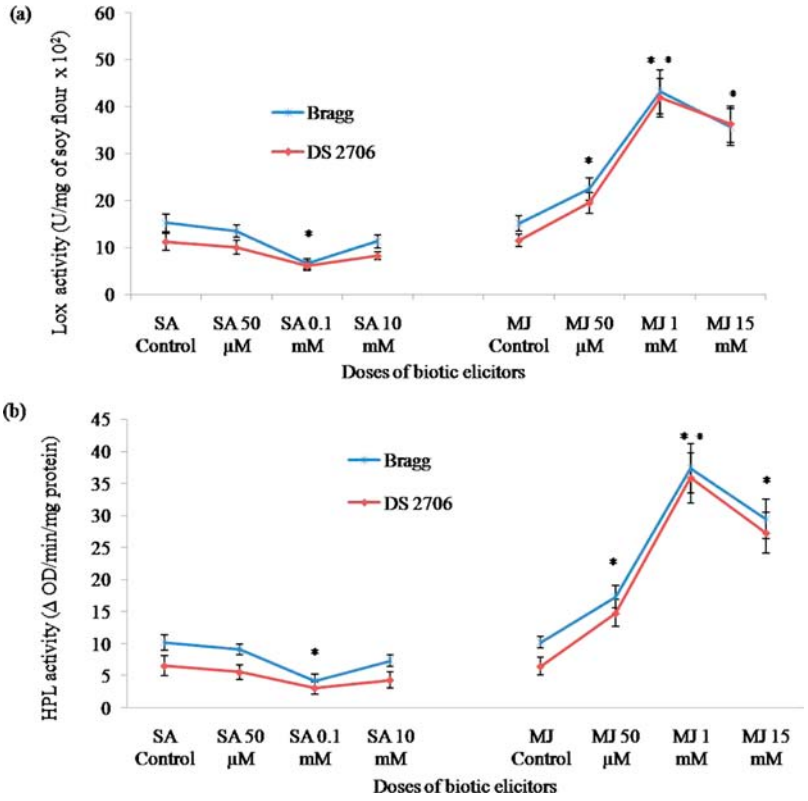

Figure 1. Effect of elicitors (SA and MJ) application at different doses in two soybean cultivars on (a) LOX activity and (b) HPL activity. Values are means ± SD of three determinations. *P* values as compared to control (* indicates that values are significant at $P < 0.05$, ** $P < 0.01$).

after the appearance of wine red color, absorbance was read at 480 nm. Amount of carbonyls was estimated by using the formula

$$A = \varepsilon CL$$

where A = absorbance; $\varepsilon = 2.72 \times 10^4$; C = concentration, and L = path length.

Estimation of Sulfhydryl Content of Protein. The sulfhydryl group of proteins were determined by titration with 5,5′-dithiobis(2-nitrobenzoate) (DNTB), using the general procedure of Ellman (1959).[20] Samples (75 mg) were suspended in 10 mL of 0.1 M phosphate buffer (pH 8.0), 1 mM EDTA, and 1% sodium dodecyl sulfate by stirring with a 1.25 cm stir bar in a 20 mL beaker on medium speed for 30 min at 20 °C. For SH determinations, to 3 mL of protein solution were added 3 mL of 0.l M phosphate buffer with EDTA and SDS and 0.1 mL of DTNB reagent, and the mixture was vortexed and incubated at 25 °C for 1.0 h. This mixture was centrifuged at 10000*g* for 30 min. Absorbance was measured at 412 nm vs reagent blanks. Calculations were based on extinction coefficient of 13,600 M^{-1} cm^{-1} for the thiolate chromogen according to the equation

$$\mu M\ SH/g = 73.53 A_{412} D/C$$

where A_{412} = the absorbance at 412 nm; C = the sample concentration in mg solids/mL; D = the dilution factor, 2.03 for SH; and 73.53 is derived from $10^6/(1.36 \times 10^4)$; 1.36×10^4 is the molar absorptivity (Ellman, 1959), and 10^6 is for conversions from the molar basis to the μM/mL basis and from mg solids to g solids.

Estimation of Antioxidant Enzyme Activity. Enzyme extract for superoxide dismutase (SOD), ascorbate peroxidase (APx), and glutathione reductase (GR) was prepared by homogenizing 1 g of overnight soaked soybean seed in 6.0 mL of extraction buffer (0.1 M phosphate buffer, pH 7.0, containing 0.5 mM EDTA). The homogenate was passed through four layers of muslin cloth, the filtrate was centrifuged at 16000 rpm for 30 min, and the supernatant obtained was used as the enzyme extract. Total protein content of this extract was determined by Bradford method using bovine serum albumin as a standard.

Superoxide Dismutase (SOD) Activity. SOD activity was assayed on the basis of its ability to inhibit photochemical reduction of nitro-blue tetrazolium (NBT) resulting in the decrease in optical density at wavelength 560 nm due to formazone formed by superoxide radical and NBT dye in the presence of the enzyme.[21] One unit of SOD activity was defined as the amount of enzyme that causes 50% inhibition of the initial rate of the reaction in the absence of enzyme, i.e., absorbance control.

Ascorbate Peroxidase (APx) Activity Assay. Ascorbate peroxidase (APx) reduces hydrogen peroxide to water with the help of ascorbic acid, which is oxidized to mono-dehydro ascorbic acid, which is spontaneously metabolized to dehydroascorbate. Hence, the assay is based on decrease in absorbance of ascorbic acid to mono-dehydroascorbic acid and dehydroascorbic acid.[22] The 3 mL reaction mixture contained 50 mM potassium phosphate buffer (pH 7.0), 0.5 mM ascorbic acid, 0.1 mM EDTA, 0.1 mM H_2O_2, and 0.1 mL of enzyme. The reaction was started with the addition of 0.1 mM hydrogen peroxide. Decrease in absorbance for a period of 30 s was measured at 290 nm in a UV−vis spectrophotometer. A unit of enzyme was defined as the amonnt which produced a change in OD of 0.01 per min at 290 nm in 3 mL of reaction mixture.

Glutathione Reductase (GR) Activity Assay. Glutathione reductase activity was assayed by recording the increase in absorbance in the presence of oxidized glutathione and DTNB (5,5-dithiobis-2-nitrobenzoic acid).[23] The reaction mixture contained 6.67 mM potassium phosphate buffer (pH 7.5) containing 33.33 mM EDTA, 0.5 mM DTNB in 0.01 M potassium phosphate buffer (pH 7.5), 66.67 mM NADPH, 0.1 mL of enzyme extract, and distilled water to make up a final volume of 2.9 mL. Reaction was initiated by adding 66.67 mM GSSG (oxidized glutathione). The increase in absorbance at 412 nm was recorded at 25 °C over a period of 5 min on a spectrophotometer. One enzyme unit is equivalent to 0.01 OD change per minute.

Statistical Analysis. All extractions and quantifications were carried out in triplicate ($n = 3$), and data are expressed as mean ± SD. The data were subjected to analysis of variance (ANOVA) Tukey test

to compare mean values, and the level of significance was set at 5% ($\alpha = 0.05$).

RESULTS AND DISCUSSION

Effect of Elicitor Application on Lipoxygenase (LOX) and Hydroperoxide Lyase (HPL) Activities. LOX and HPL are the two important enzymes of oxylipin pathway, which is responsible for the production of off-flavor causing volatile aldehydes and ketones. In the present study two elicitors, MJ (0, 50 μM, 1 mM, and 15 mM) and SA (0, 50 μM, 0.1 mM, and 10 mM), were used. With regard to MJ application, with increasing concentration an increase in the LOX and HPL activities was observed up to 1 mM application followed by a decline. The maximum increase (2.8-fold in Bragg and 3.6-fold in DS 2706 for LOX and 3.6-fold in Bragg and 5.5-fold in DS 2706 for HPL) was observed at 1 mM MJ application (Figure 1). However, the increase observed at 1.5 mM MJ was less compared to 1 mM MJ application. In SA application, with increasing concentration a decrease in the LOX and HPL was observed, further, the maximum decrease (2.3-fold in Bragg and 1.4-fold in DS 2706 for LOX and 2.4-fold in Bragg and 2.1-fold in DS 2706 for HPL) was observed at 0.1 mM SA application. However, the decrease observed at 10 mM SA was less compared to 0.1 mM SA application. A maximum decrease observed due to SA application at a dose of 0.1 mM and a maximum increase observed due to MJ application at a dose of 1 mM for LOX and HPL in both cultivars was significant at $P < 0.05$ compared to control. MJ has been found to effectively upregulate the LOX and HPL activity while SA has been found to effectively downregulate the LOX and HPL activity. SA and MJ appear to be important signaling molecules in plants, and they have been shown to be able to alter activity of plant proteins when applied exogenously. Hence, in the present study, it seems that a product of the oxylipin pathway, MJ derived from the linolenic acid, may have a positive feedback effect on one of the enzymes involved in its own production, LOX. Previously, a similar result has been obtained by Grimes et al.[24] wherein MJ has been shown to be regulatory for some enzymes directly involved in the oxylipin pathway, since it induces the accumulation of LOX in soybean. We also provide here evidence that MJ significantly increased levels of LOX and HPL associated with the oxylipin pathway. Similarly, Avdiushko et al.[5] also reported that the exogenous application of gaseous MJ effectively increased both LOX and HPL activity which was persistent and did not significantly change for at least 7 d after termination of MJ exposure.

In the present study, it seems that SA is acting antagonistically to MJ and decreases the activities of the off-flavor causing LOX and HPL that may be leading to reduced MJ biosynthesis and reduction of off-flavor generating volatile aldehydes and ketones as well. Previously, Leon-Reyes et al.[26] concluded that the antagonistic effect of SA on MJ signaling could be due to its action at a site that functions downstream of MJ biosynthesis. They also analyzed the MJ-responsive MJ biosynthesis genes LOX2, AOS, AOC2, and OPR3, and their results revealed that all were downregulated by exogenous application of SA, confirming their hypothesis that the MJ biosynthesis pathway could be a potential target of the antagonistic effect of SA on MJ signaling in *Arabidopsis*.

Effect of Elicitor Application on Thiobarbituric Acid (TBA) Number and Carbonyl Value. Estimation of the products of LOX and HPL action, i.e., peroxides, volatile aldehydes and ketones, and carbonylated proteins, were carried out in terms of TBA number and carbonyl value, respectively (Figure 2). In the present study, for change in the TBA number and carbonyl value, a pattern similar to the one obtained for LOX and HPL activity was obtained. With regard to MJ application, with increasing concentration an increase in the TBA number and carbonyl value was observed; further, the maximum increase (2.8-fold in Bragg and 4.4-fold in DS 2706

DOI: 10.1021/jf505199a
J. Agric. Food Chem. 2015, 63, 700−706

for TBA number and 2.4-fold in Bragg and 3.9-fold in DS 2706 for carbonyl value) was observed at 1 mM MJ application. However, the increase observed at 1.5 mM MJ was less compared to 1 mM MJ application. In SA application, with increasing concentration a decrease in the TBA number and carbonyl value was observed; further, the maximum decrease (3.1-fold in Bragg and 2.8-fold in DS 2706 for TBA number and 2.9-fold in Bragg and 2.2-fold in DS 2706 for carbonyl value) was observed at 0.1 mM SA application. However, the decrease observed at 10 mM SA was less compared to 0.1 mM SA application. The data presented here provide evidence that MJ directly or indirectly enhances certain enzymes of the oxylipin pathway (LOX and HPL) and SA inhibits the MJ responsive factors and thereby affects the direction the pathway takes and ultimately the type of fatty acid per oxidation products formed that leads to off-flavor generation in soybean. Hence, we may conclude that the MJ application mediated enhancement in LOX activity could lead to accumulation of the fatty acid oxidation product, i.e., hydroperoxides as indicated by high TBA number, which in turn may further stimulate the HPL activity thereby triggering the pathway toward the production of more volatile aldehydes and ketones. From this result one would expect to see a shift in the balance of oxylipin pathway products after MJ and SA application to increased production of fatty acid peroxidation products by MJ and decrease in fatty acid peroxidation products by SA from the HPL branch. Avdiushko et al.[25] compared the ability of MJ-treated tissues to evolve C_6 volatiles with that of control tissue in cucumber, tobacco, and *Arabidopsis* and found that all three plant species showed greater potential to form a variety of C_6 volatiles than controls. Hexanal, derived from linoleic acid, increased 2.5-fold in cucumber, 3-fold in tobacco, and 5-fold in *Arabidopsis*. Similarly, (*E*)-2-hexenal, derived from linolenic acid, increased above control plants by 80% in tobacco, 60% in cucumber, and 460% in *Arabidopsis*. Hence, if the levels of linoleic and linolenic acids available to LOX-catalyzed peroxidation are limiting in the pathway, the increase in HPL could shift the oxylipin pathway away from production of JA by allene oxide synthase. Hence, we can conclude that methyl jasmonate and salicylic acid selectively altered the activity of certain enzymes of the oxylipin pathway (lipoxygenase and hydroperoxide lyase) and increased and decreased the potential for greatly enhanced six-carbon-volatile production, respectively.

Effect of Elicitor Application on Antioxidant Enzyme Activity. Plants have developed enzymatic and nonenzymatic mechanisms to scavenge ROS. Among the active oxygen species, superoxide is converted by the SOD enzyme into H_2O_2, which is further scavenged by ascorbate glutathione cycle enzymes such as APx and GR.[27] The study on application of biotic elicitors on antioxidant enzyme activities showed that SA and MJ effectively influence the activity of SOD, APx, and GR in dose dependent manners in both of the cultivars 'Bragg' and 'DS 2706' (Figures 3 and 4). In the present study, both biotic elicitors SA and MJ increased the antioxidant enzyme activities maximal at 0.1 mM and 1 mM dose, respectively. However, declines in the antioxidant enzyme activities were observed in both of the cultivars at higher dose 10 mM and 15 mM, respectively. We also observed that high off-flavor cultivar 'Bragg' showed higher fold enhancement due to SA and MJ application (9.2- and 8.5-fold, respectively) in total antioxidant enzyme activity compared to low off-flavor cultivar 'DS 2706' (8.5- and 6-fold, respectively). Previously, Agarwal et al.[28]

showed that application of 1 mM SA on wheat seedlings resulted in significant increase in SOD, APx over control. Similarly, Manar et al.[29] reported increase in SOD and APx by 210% and 344%, respectively in egg plant embryos after MJ application. Ali et al.[30] also reported that methyl jasmonate and salicylic acid elicitation induces enzymatic and nonenzymatic antioxidant in suspension culture *Panax ginseng* roots in bioreactors and significantly induced the activity of the APx and GR and SOD.

Hence, application of biotic elicitors MJ and SA causes the generation of excessive reactive oxygen species (ROS) by

J. Agric. Food Chem. 2015, 63, 700−706

NADPH oxidase present in the membrane, which leads to oxidative burst in the cell.[31]

Effect of Elicitor Application on the Level of Protein Oxidation. The measurement of protein oxidation on the basis of sulfhydryl (−SH) group content revealed that protein oxidation is low in cultivar 'Bragg' compared to 'DS 2706' (Figure 5). SA 0.1 mM is the most effective dose in reduction

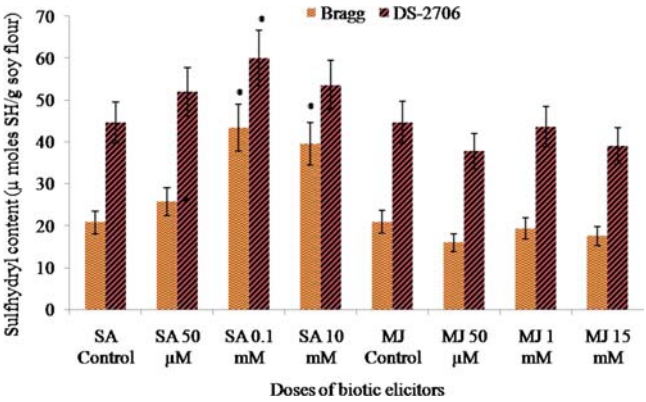

Figure 5. Effect of application of elicitors (SA and MJ) at different doses on levels of protein oxidation (measured in terms of −SH group) in two soybean cultivars. Values are means ± SD of three determinations. *P* values as compared to control (* indicates that values are significant at $P < 0.05$).

of protein oxidation in both of the cultivars while reduction is high in cultivar 'Bragg' (100%) compared to 'DS 2706' (36%). However, in the protein oxidation, application of MJ on the enhancement observed was not found to be proportionate. It could be due to increase in antioxidant enzyme system due to MJ application thereby providing protection to the proteins against oxidation. As Huang[32] showed, soybean protein oxidation and aggregation induced by lipoxygenase catalyzed linoleic acid oxidation. They suggested that linoleic acid oxidation products induced by LOX were very reactive substances that could react with soybean proteins, lead to its oxidation, and change the structural characteristics of soybean proteins. It seems that increase in antioxidant enzymes like superoxide dismutase, glutathione reductase, and ascorbate peroxidase by SA and MJ helps in reduction of protein oxidation and protection from oxidative stress. Previously, Dahuja and Madaan[3] also reported that presence of high levels of antioxidant enzymes and molecules in the soybean seeds leads to reduction in the lipid oxidation thereby resulting in low off-flavor generation in soybean.

Effects of Elicitors on the Growth Stage of Application. Considering the all important role of LOX in off-flavor generation, the effect of growth stage of the plant on its response to elicitors' application with regard to LOX2 activity was evaulated. Lipoxygenase from soybean seeds was extracted and its activity assayed from elicitor-treated and untreated plants of two varieties, viz., Bragg and DS 2706. The results of effect of growth stage of the plants on its response to both of the elicitors are depicted in Figure 6. The values of LOX2 concentrations from all treatments were compared with the untreated control. No significant variations were observed with respect to growth stages for both of the elicitors at all of the concentrations used in this study. Both of the genotypes of soybean exhibited a similar response to elicitors at all of the growth stages. Hence, our study suggested that, for a given

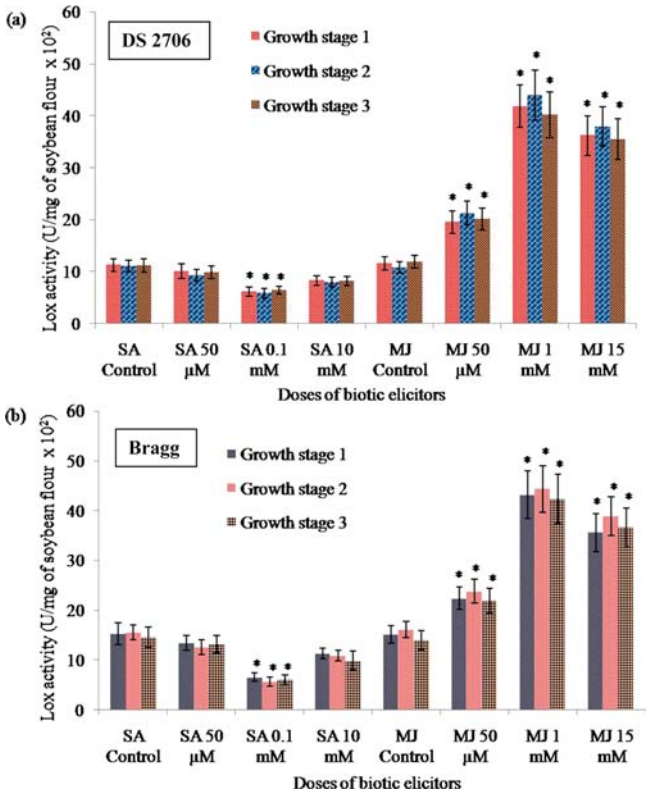

Figure 6. Effect of application of elicitors (SA and MJ) at different growth stages on LOX activity in soybean cultivars (a) DS 2706 and (b) Bragg. Values are means ± SD of three determinations. *P* values as compared to control (* indicates that values are significant at $P < 0.05$).

variety and elicitor, the concentration is an important factor for reduction of LOX2. Zhang et al.[11] while studying the effect of elicitor treatment on isoflavones also reported that, with all of the elicitors tested, concentration was a more important factor than growth stage Similarly, Eswaranandam et al.[13] reported that the overall effect of elicitor on total soy saponin content was not dependent on growth stage, however, elicitors sprayed at different growth stages showed differences among elicitors applied on soybeans.

Hence, biotic elicitors SA have the potential for reducing off-flavor content in soybean seeds when applied to plants in the field. The mechanism for off-flavor reduction as indicated by the results of the present study could be through reduction in LOX and HPL activity or due to enhancement in the levels of the antioxidant enzymes in response to oxidative burst caused by elicitors' treatments. We hereby propose a schematic model for representing the plausible sequence of events leading to off-flavor reduction in soybean after biotic elicitor treatments in abstract graphics. The effect of JA treatment on flavor quality of soybean seems to be contrasting to SA application. However, the dosage and duration of the elicitors' treatment need to be standardized further to get the optimal reduction in the level of off-flavor generation in soybean.

Supporting Information

ABSTRACT: Amaranth is a pseudocereal of high nutritional value, including a high dietary fiber content. Amaranth dietary fiber was suggested to contain large amounts of neutral rhamnogalacturonan I side chains. In this study, *endo*-arabinanase and *endo*-galactanase were used to liberate arabinan and galactan oligosaccharides from amaranth fiber. The liberated oligosaccharides were identified by high-performance anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD) and HPLC-MS^n using standard compounds, which were isolated from amaranth, sugar beet, potato, and red clover sprouts and characterized by one- and two-dimensional NMR spectroscopy. It was demonstrated that insoluble amaranth arabinans have linear and branched areas, with the *O*-3 position being the dominant branching point. Minor amounts of branches at position *O*-2 and double substitution were also found. Amaranth arabinans were also demonstrated to contain terminal α-(1→5)-linked L-arabinopyranose units. In addition, it was evidenced that galactans from amaranth seeds are composed of β-(1→4)-linked D-galactopyranose units, which can also be terminated with L-arabinopyranose units. In direct comparison to structural elucidation of amaranth fiber by using methylation analysis, the advantage of the enzymatic approach over methylation analysis was demonstrated.

KEYWORDS: *Amaranthus hypochrondriacus, dietary fiber, cell wall, arabinans, galactans, oligosaccharides, NMR, arabinopyranose, methylation analysis*

INTRODUCTION

Amaranth is a pseudocereal, which gained increasing interest by the food industry and consumers over the past decade. Due to their high starch content and their beneficial nutritional profile, amaranth seeds are used in many applications to replace common cereal grains. Amaranth seeds are reported to have a higher protein content than common cereal grains and a high protein quality because they are rich in lysine.[1] In addition, they are gluten-free, which makes them suitable for people suffering from celiac disease.[2] The seeds are usually used as whole grains, for example, in granola and cereal-based snacks. Thus, they also contribute to the intake of dietary fiber, which is mainly composed of cell wall polysaccharides and associated substances.[3] The seeds of *Amaranthus caudatus* are reported to have a total dietary fiber content ranging from 7.6 to 16.4%, depending on the variety.[4] Most recently, Lamothe et al.[5] analyzed monosaccharide units and glycosidic linkages of *A. caudatus* dietary fiber polysaccharides. They demonstrated that amaranth fiber contained high amounts of pectic substances such as homogalacturonan, arabinans, and galactans. In another study, ferulic acid esterified arabinan and galactan oligosaccharides were isolated from *A. caudatus*.[6] Arabinans and galactans are side chains of rhamnogalacturonan I, which is part of the pectic polysaccharides. Rhamnogalacturonan I consists of a backbone of repeating α-D-galacturonic acid and α-L-rhamnose units with neutral side chains being linked to the *O*-4-position of the rhamnose residues. Arabinans are composed of a backbone made up of α-(1→5)-L-arabinofuranose units, with potential branches at positions *O*-2 and/or *O*-3. Galactans have a backbone of β-(1→4)-D-galactopyranoses to which galactopyranoses and arabinofuranoses can be attached.[7] The structures of arabinans and galactans are important factors in plant physiology.[8] Also, depending on the structural elements present, different enzymes may be necessary for their degradation by human microbiota. Thus, the physiological properties of dietary fibers are greatly affected by their structural features.[9,10]

Because previous studies investigated only the main structural features of *A. caudatus* seeds by using methylation analysis,[5] the aim of this study was to obtain more detailed information on fiber polysaccharides of *Amaranthus hypochondriacus* seeds by using an enzymatic approach in addition to methylation analysis. Besides the isolation and characterization of novel arabinan and galactan structural elements, the focus of this study was to determine branched units as structural elements with potential impact on fiber fermentation.

MATERIALS AND METHODS

General. Thermostable α-amylase (EC 3.2.1.1, from *B. licheniformis*, 20000−60000 U/mL) (Sigma-Aldrich, Schnelldorf, Germany), protease (EC 3.4.21.14, subtilisin A from *B. licheniformis*, 300 U/mL) (Megazyme, Bray, Ireland), and amyloglucosidase (EC 3.2.1.3, from *A. niger*, 200 U/mL) (Megazyme) were used to analyze dietary fiber contents. The enzymes for preparative fiber isolation, Termamyl 120 L (EC 3.2.1.1, from *B. licheniformis*, 120 KNU/g), Alcalase 1.5 MG type FG (EC 3.4.21.62, from *B. licheniformis*, 1.5 AU/g), and AMG 300L (EC 3.2.1.3, from *A. niger*, 300 AGU/g) were kindly donated by Novozymes (Bagsvaerd, Denmark). *endo*-Arabinanase (EC 3.2.1.99, from *A. niger*, 9 U/mg) and *endo*-galactanase (EC 3.2.1.89, from *A. niger*, 408 U/mg) were purchased from Megazyme. Bio-Gel P-2 was from Bio-Rad Laboratories (Hercules, CA, USA). Amberlite FPA53 (OH^-) and Ambersep 200 (H^+) were purchased from Megazyme.

Materials. Amaranth seeds from *A. hypochondriacus* were grown and harvested in 2012 in Moersingen (Germany). The seeds were milled to a size <0.5 mm using an IKA MF10 basic mill and defatted with acetone. Arabinan from sugar beet and pectic galactan from potato were purchased from Megazyme. Red clover sprouts (*Trifolium pratense* L. cv. Rozeta) were grown and harvested in 2013.

Determination of Dietary Fiber Content. The defatted amaranth flour was analyzed for its dietary fiber content according to the method of Prosky et al.[11] using 1 g of flour, 100 μL of thermostable α-amylase, 100 μL of protease, and 200 μL of amyloglucosidase. The analysis was performed in duplicate, and fiber contents were corrected for ash (incineration for 5 h at 525 °C) and protein (determined as NH_4^+ according to the method of Willis et al.[12] after Kjeldahl digestion, nitrogen conversion factor = 6.25).

Dietary Fiber Preparation. Dietary fiber for preparative purposes was isolated by incubating 20 g of defatted amaranth flour or lyophilized red clover sprouts, suspended in 200 mL of 0.08 M phosphate buffer (pH 6.2), with 1.5 mL of thermostable α-amylase (Termamyl 120 L) at 92 °C for 20 min. After adjustment of the pH to 7.5 with sodium hydroxide, 1.12 g of protease (Alcalase 1.5 MG type FG) was added. The mixture was incubated for 30 min at 60 °C. The pH was adjusted to 4.5 with hydrochloric acid, 700 μL of amyloglucosidase (AMG 300L) was added, and the suspension was incubated for 30 min at 60 °C. The undigested residue was obtained through filtration, washed with water, ethanol (96%, v/v), and acetone and used as amaranth insoluble fiber. The soluble fiber was precipitated from the supernatant by adding 4 volumes of ethanol (96%, v/v), isolated by filtration, and washed with ethanol (96%, v/v)/water (4:1, v/v), ethanol (96%, v/v), and acetone. The soluble fiber was redissolved in water and dialyzed against water for 24 h (molecular weight cutoff = 3500 Da) to eliminate coprecipitated salts. The water was changed at least three times to ensure maximum dialysis.

Monosaccharide Analysis. The polymeric sugar composition of amaranth insoluble dietary fiber was analyzed after sulfuric acid hydrolysis according to the method of Saeman et al.[13] The fiber (100 mg) was swollen in 1.5 mL of 12 M sulfuric acid for 2.5 h, diluted with 9.75 mL of water, and hydrolyzed for 3 h at 100 °C. After filtration and dilution, the hydrolysate was analyzed by HPAEC-PAD as described below. Methanolysis was performed as described by De Ruiter et al.[14] with minor modifications. Hydrogen chloride in methanol (1.25 M, 2 mL) was added to 10−25 mg of sample, and hydrolysis was performed for 16 h at 80 °C. An aliquot (40 μL) was evaporated, and the 1-methylglycosides and 1-methylglycoside-6-methylesters were hydrolyzed with 500 μL of 2 M trifluoroacetic acid (TFA) at 121 °C for 1 h. After evaporation and coevaporation with ethanol, samples were dissolved in water. Samples were analyzed by HPAEC-PAD on an ICS-5000 System (Thermo Scientific Dionex, Sunnyvale, CA, USA) equipped with a CarboPac PA20 column (150 mm × 3 mm i.d., 6.5 μm particle size, Thermo Scientific Dionex) at 25 °C using a flow rate of 0.4 mL/min. The eluents used were (A) bidistilled water, (B) 0.1 M NaOH, and (C) 0.1 M NaOH + 0.2 M sodium acetate (NaOAc). Before every run, the column was rinsed with 100% B for 10 min and equilibrated for 20 min with 90% A and 10% B. After injection, the following gradient was applied: 0−1.5 min, from 90% A and 10% B to 96% A and 4% B; 1.5−22 min, isocratic, 96% A and 4% B; 22−32 min from 96% A and 4% B to 100% B; 32−42 min, isocratic, 100% C.

For monosaccharide analysis of oligosaccharides, an aliquot of the sample was hydrolyzed with 2 M TFA for 60 min at 121 °C and analyzed by HPAEC as described above. Determination of the D/L-configuration of the monosaccharides was performed by heating the evaporated TFA hydrolysate overnight at 130 °C with 150 μL of (*R*)-2-octanol and 5 μL of TFA.[15] Solvent was removed, and samples were silylated with 80 μL of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide and 20 μL of pyridine. Analysis was performed on a GC-MS system (GC-2010 Plus and GCMS-QP2010 Ultra, Shimadzu, Kyoto, Japan) equipped with an Rxi-5Sil MS column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Restek, Bad Homburg, Germany). The following conditions were used: initial column temperature, 150 °C; ramped at 1 °C/min to 200 °C; ramped at 15 °C/min to 300 °C. Injection temperature was 275 °C, and split injection was used at a split ratio of 10:1. Helium was used as carrier gas at 40 cm/s, and the transfer line was held at 275 °C.

Isolation of Standard Oligosaccharides. Red clover sprouts insoluble fiber (15 g) was extracted with 0.6 g of $Ca(OH)_2$ in 150 mL of water for 30 min at 95 °C. Polysaccharides were precipitated from the supernatant with 4 volumes of ethanol (96%, v/v), separated, redissolved in water, and dialyzed for 24 h (molecular weight cutoff = 3500 Da). For the isolation of oligosaccharide standards, 1−10 g of red clover sprout polysaccharides, arabinans from sugar beet, pectic galactans from potato, or amaranth insoluble fiber was dissolved or suspended in water (10 mg/mL) and incubated with *endo*-arabinanase or *endo*-galactanase (at least 1 U/100 mg sample) for 24 or 48 h. The hydrolysate was centrifuged, and the supernatant was freeze-dried and redissolved in water. The solution was fractionated by gel filtration using Bio-Gel P-2 as stationary phase (gel bed: 85 cm × 2.6 cm). Bidistilled water was used as eluent (1 mL/min), and the temperature was held at 45 °C. The oligosaccharides were detected using a Smartline RI detector 2300 (Knauer, Berlin, Germany). Fractions were collected every 2.5 min, combined according to the chromatograms, and freeze-dried. Fractions containing multiple compounds (as determined by HPAEC analysis) were further fractionated by HPLC (L-7100 pump, L-7490 RI detector, Merck/Hitachi, Darmstadt, Germany) using a semipreparative C18 column (250 mm × 8 mm i.d., 5 μm particle size, Eurosphere 100, Knauer). Water was used as eluent (1−1.5 mL/min) at various temperatures (5−35 °C). The fractions were collected according to the chromatograms and freeze-dried.

NMR Spectroscopic Characterization. After hydrogen−deuterium exchange, the samples were dissolved in D_2O, and spectra were collected on a Bruker Ultrashield 700 MHz NMR spectrometer (Bruker, Rheinstetten, Germany). Acetone was used as an internal reference (δ_H 2.22 ppm, δ_C 30.89 ppm).[16] The structures of the isolated oligosaccharides were identified by using ^{1}H, H,H-correlated spectroscopy (COSY), heteronuclear single-quantum coherence/heteronuclear multiple-quantum correlation (HSQC/HMQC), and heteronuclear multiple-bond correlation (HMBC) experiments. Standard Bruker pulse sequences were used (^{1}H, zg30; COSY, cosygpqf; HSQC, hsqcetgpsi2; HMQC, hmqcgpqf; HMBC, hmbcgplpndqf); spectra were acquired at 298 K.

Liberation of Oligosaccharides from Amaranth Fiber. Amaranth insoluble and dialyzed soluble fibers (10 mg/mL each) were incubated by using *endo*-arabinanase (2 U/100 mg fiber) for 24 h at 40 °C. Before *endo*-galactanase incubation, the insoluble fiber (400 mg) was suspended in 20 mL of water and heated to 90 °C. $Ca(OH)_2$ (28 mg) was added, and the mixture was heated for 90 min at 90 °C. After neutralization with hydrochloric acid, the supernatant was precipitated with 4 volumes of ethanol (96%, v/v). The precipitate was redissolved and desalted by passing over a column filled with 4 g of Amberlite FPA53 and 4 g of Ambersep 200. An aliquot (1 mL) of the eluate (20 mL) was incubated with *endo*-galactanase (4 U) for 24 h at 40 °C.

HPAEC-PAD Analysis of the Oligosaccharides. HPAEC-PAD oligosaccharide analysis was performed on an ICS-5000 system (Thermo Scientific Dionex) using a Carbopac PA100 column (250

DOI: 10.1021/jf505283x
J. Agric. Food Chem. 2015, 63, 707−715

mm × 4 mm i.d., 8.5 μm particle size, Thermo Scientific Dionex). The temperature was held at 25 °C, and a flow rate of 1 mL/min was applied using the following eluents: (A) bidistilled water, (B) 0.1 M NaOH, (C) 0.1 M NaOH + 0.5 M NaOAc. Before every run, the column was washed with 100% C for 10 min and equilibrated with 90% A and 10% B for 20 min. After injection, the following gradient was applied: 0−10 min, isocratic 90% A and 10% B; 10−20 min, from 90% A and 10% B to 100% B; 20−65 min, from 100% B to 50% B and 50% C; 65−68 min, isocratic 50% B and 50% C; 68−85 min, 100% C.

LC-MS Analysis of the Liberated Amaranth Fiber Oligosaccharides. The galacto-oligosaccharides were reduced according to the method of Pitson et al.[17] with minor modifications. In brief, after reduction with aqueous $NaBH_4$ (2 mL of 250 mM $NaBH_4$ per 5 mg of sample, 2 h at room temperature), the reaction was terminated by adding hydrochloric acid, and the samples were desalted using an ion-exchange column packed with 4 g of Amberlite FPA53 and 4 g of Ambersep 200. LC-MS analysis was performed on a Surveyor HPLC System, coupled to an LXQ linear ion trap MS^n system (Thermo Fisher Scientific, Waltham, MA, USA). Chromatographic separation was performed on a porous graphitized carbon (PGC) column (Hypercarb, 100 mm × 2.1 mm i.d., 3 μm particle size, Thermo Fisher Scientific) at 60 °C using a flow rate of 0.4 mL/min. The following gradient composed of 25 μM aqueous LiCl (A) and acetonitrile (ACN) (B) was used: 0−1 min, 100% A; 1−20 min, from 100% A to 90% A; 20−28 min, from 90% A to 30% A; 28−31 min, from 30% A to 20% A; 31−35 min, isocratic 20% A; 35−36 min, from 20% A to 100% A; 36−41 min, equilibration with 100% A.

Methylation Analysis. Methylation analysis was performed as described by Nunes and Coimbra[18] with minor modifications. Briefly, the sample was dissolved in 2 mL of dimethyl sulfoxide, and freshly ground sodium hydroxide (ca. 100 mg) was added. The solution was sonicated for 90 min and incubated at room temperature for 90 min. Methyl iodide (1 mL) was added, followed by 30 min of sonication and 30 min of incubation at room temperature. The solution was extracted with dichloromethane, and the organic phase was washed with 3 mL of 0.1 M sodium thiosulfate and twice with 3 mL of water. After evaporation and drying, the methylated polysaccharides were hydrolyzed by adding 2 mL of 2 M TFA and incubation at 121 °C for 90 min. After evaporation, 20 mg of $NaBD_4$ in 300 μL of an aqueous NH_3 solution (2 M) was added. After 1 h at room temperature, the reaction was terminated by adding glacial acetic acid. During cooling with ice, 450 μL of 1-methylimidazole and 3 mL of acetic anhydride were added, and the solution was incubated for 30 min at room temperature. After the addition of 3 mL of water, the partially methylated alditol acetates (PMAA) were extracted by using 5 mL of dichloromethane. The organic layer was washed three times with water, and residual water was removed by freezing overnight at −18 °C. The PMAAs in dichloromethane were analyzed by GC-MS (GC-2010 Plus and GCMS-QP2010 SE, Shimadzu) on a DB-225MS column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Agilent Technologies, Santa Clara, CA, USA) using the following conditions: initial column temperature, 140 °C, held for 1 min; ramped at 20 °C/min to 220 °C, held for 25 min. Helium was used as carrier gas at 40 cm/s. Split injection with a split ratio of 30:1 was used. The injection temperature was 220 °C. The transfer line was held at 220 °C, and electron impact mass spectra were recorded at 70 eV. The relative quantification of the partially methylated alditol acetates was carried out on a GC-FID system (GC-2010 Plus, Shimadzu) using a DB-225 column (30 m × 0.25 mm i.d., 0.25 μm film thickness, Agilent Technologies) and the same GC conditions as described for the GC-MS experiments, with the exception of a reduced split ratio of 10:1. FID temperature was 240 °C, and nitrogen was used as makeup gas. Molar response factors according to Sweet et al.[19] were used for semiquantitative calculations.

RESULTS AND DISCUSSION

Amaranth Dietary Fiber Content and Fiber Monosaccharide Composition. The insoluble and soluble dietary fiber contents of *A. hypochondriacus* seeds were 6.0 and 2.4%. These values are comparable with fiber contents of *A. caudatus* reported previously.[4,5] The monosaccharide compositions of the preparatively isolated insoluble and soluble fiber polysaccharides were analyzed after H_2SO_4 hydrolysis according to the method of Saeman et al.[13] and after methanolysis according to the method of De Ruiter et al.[14] (Table 1). Whereas sulfuric acid hydrolysis of the insoluble fiber underestimates uronic acids, methanolysis of amaranth insoluble fiber does not hydrolyze crystalline cellulose. The high contents of arabinose and galactose (sulfuric acid hydrolysis: 24.3% and 5.6% of the liberated monosaccharides) indicate high amounts of arabinans and galactans in the amaranth insoluble fiber. The low amount of rhamnose (2.0%) suggests long arabinan chains and rather short galactan chains. Comparable results were obtained from methanolysis. Methanolysis of the insoluble fiber demonstrated the galacturonic acid/rhamnose ratio to be 3.8:1 (H_2SO_4 hydrolysis: 1.7:1). Thus, amaranth fiber also contains significant amounts of homogalacturonan. Studies on the monosaccharide composition of *A. caudatus* insoluble fiber also reported high contents of pectic polysaccharides, however, with galacturonic acid as dominating monosaccharide.[4,5] The polymeric glucose and xylose units can be assigned to cellulose, xyloglucans, and xylans. Analysis of the soluble fiber yielded comparable proportions of the rhamnogalacturonan I sugars. The relatively high amount of mannose may indicate the presence of galactomannans in amaranth soluble fiber.

Table 1. Monosaccharide Composition (Percent) of Amaranth Insoluble Fiber after Sulfuric Acid Hydrolysis and Methanolysis and of Soluble Fiber after Methanolysis

monosaccharide	insoluble fiber (H_2SO_4)	insoluble fiber (methanolysis)	soluble fiber (methanolysis)
fucose	tr[a]	0.9	tr
rhamnose	2.0	5.9	4.5
arabinose	24.3	30.3	30.8
galactose	5.6	6.7	13.2
glucose	48.6	20.1	9.5
xylose	12.7	10.4	15.5
mannose	3.4	1.9	16.8
galacturonic acid	3.4	22.2	7.9
glucuronic acid	tr	1.7	1.7

Isolation and Characterization of Standard Compounds of Arabino- and Galacto-oligosaccharides. Preliminary studies showed that the hydrolysis of amaranth fiber with *endo* enzymes is not very effective, yielding only small amounts of some diagnostic oligosaccharides. The isolation of quantities sufficient for 2D NMR characterization of these diagnostic oligosaccharides would be an extremely time-consuming task. Thus, some standard compounds were isolated from sugar beet arabinans, potato galactans, and red clover sprout polysaccharides. These materials are more susceptible to arabinan and galactan hydrolysis by *endo* enzymes, yielding satisfactory amounts of the required diagnostic oligosaccharides. The purity of these oligosaccharides allowed for a detailed structural characterization by 1D and 2D NMR (structures shown in Figure 1). The oligosaccharides were hydrolyzed under acidic conditions, derivatized with (*R*)-2-octanol, silylated, and analyzed by GC-MS. This analysis showed that

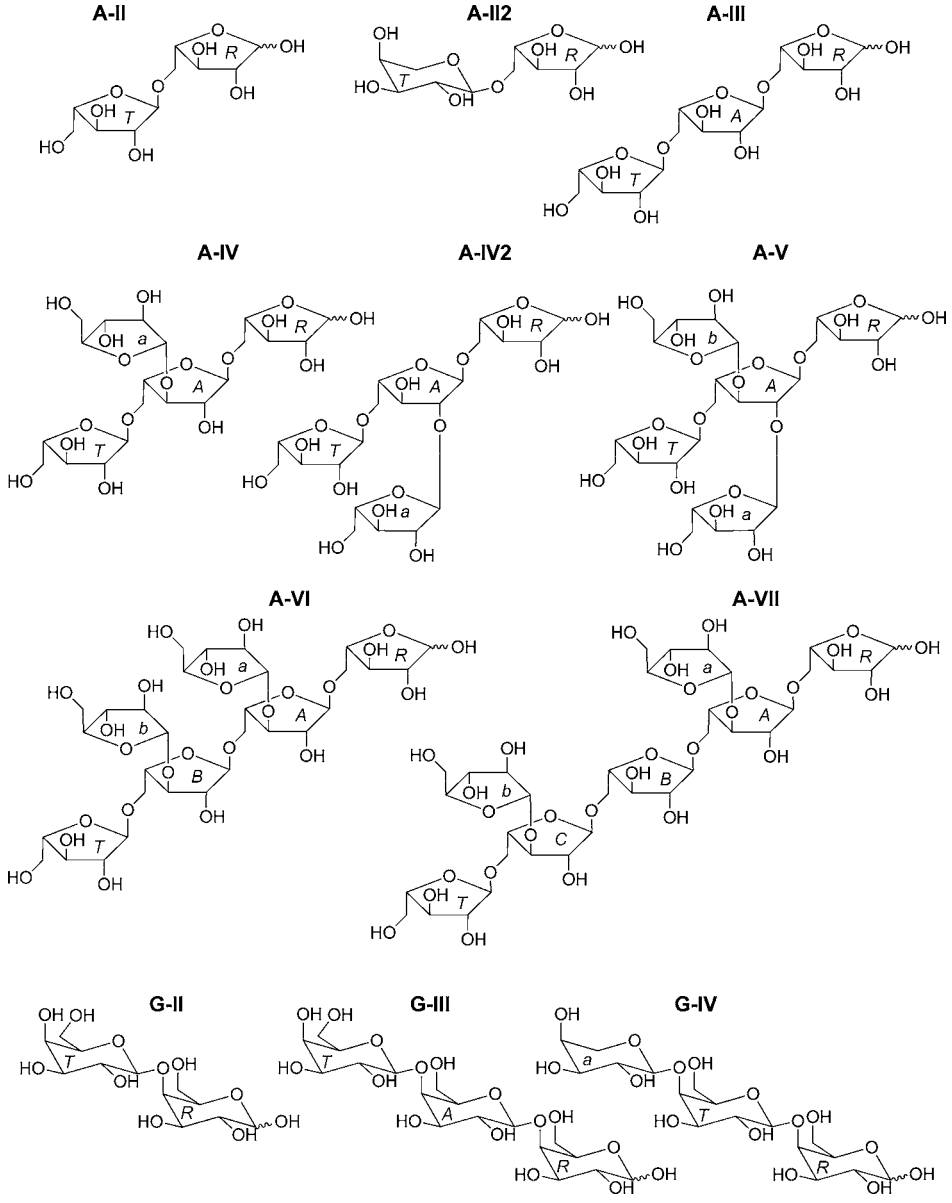

Figure 1. Structures of arabino-oligosaccharides isolated from sugar beet arabinan (**A-II**–**A-VII**), amaranth (**A-II2**), and red clover sprouts (**A-IV2**) and structures of galacto-oligosaccharides isolated from potato galactan (**G-II**–**G-IV**). Letters R, A, B, C, T, a, and b are used to describe the sugar units for the NMR spectroscopic assignment (Table 2 and Supporting Information).

arabinose was present in its L-form and galactose in its D-form in all oligosaccharides.

The isolated arabino-oligosaccharides represent many different substitution patterns of the arabinan backbone. These linear and branched arabino-oligosaccharides (Figure 1) with the exceptions of **A-II2** and **A-IV2** were previously isolated and characterized by Westphal et al.[20] The NMR spectroscopic data of the isolated oligosaccharides (Supporting Information) were in good agreement with data published by Westphal et al.[20]

The novel arabinan tetramer branched at position *O*-2 (**A-IV2**) was liberated in very low quantities from sugar beet arabinans and was also difficult to separate from the *O*-3 branched tetramer by RP18-HPLC. Thus, this tetramer was isolated from red clover sprout polysaccharides, where compound **A-IV2** was dominant over **A-IV**. It was possible to distinguish the *O*-2-branched tetramer from the *O*-3-branched tetramer by NMR spectroscopy analysis because their anomeric protons showed different ^{1}H chemical shifts. The other protons and carbons showed similar δ_C and δ_H values except H/C2 and H/C3 of the central arabinose unit A. The δ_C values were diagnostic because the C3 signal shifted downfield (83.10 ppm, Supporting Information) in the spectrum of compound **A-IV**, whereas the C2 signal shifted downfield (87.86 ppm, Table 2) in the spectrum of compound **A-IV2**. These values are in good agreement with literature data for *O*-3 and *O*-2 substituted arabinans.[20−23] The substitution at position *O*-2 was confirmed by an HMBC cross peak between H1 of the terminal arabinofuranose *a* and C2 of the central (1→5)-linked arabinose *A*.

Compound **A-II2**, which was isolated from an *endo*-arabinanase hydrolysate of amaranth insoluble fiber, contains an *α*-L-arabinopyranose attached to *O*-5 of an arabinofuranose. The ring form was unambiguously demonstrated by the ^{13}C chemical shifts (Table 2) and by an HMBC cross peak between C1 and H5. The (1→5)-linkage was evidenced by a long-range correlation between H1 of the arabinopyranose and C5 of the

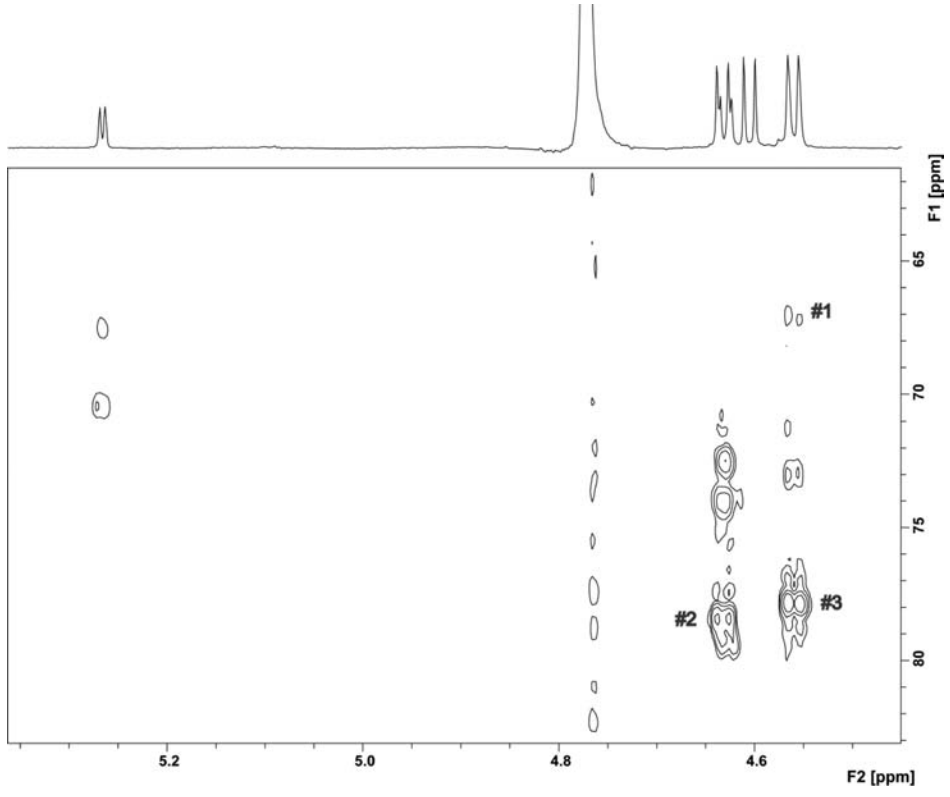

Figure 2. HMBC spectrum of compound **G-IV**. The marked cross-peaks show coupling of C5 and H1 of the arabinose (signal 1), coupling of C4 of the reducing galactose and H1 of the nonreducing galactose (signal 2), and coupling of C4 of the nonreducing galactose and H1 of the arabinose (signal 3).

arabinofuranose. Arabinopyranoses are rarely described as structural elements of arabinans. Ishii et al.[24] described the enzymatic transfer of a β-arabinopyranose to the *O*-3-position of an arabinan backbone. Swamy and Salimath[23] suggested the presence of terminal arabinopyranoses in an arabinan from *Cajanus cajan* cotyledons based on methylation analysis and ^{13}C NMR; however, the exact position in the arabinan backbone was not determined. The reported ^{13}C chemical shifts are comparable to those of **A-II2**, suggesting that a similar structural element was present in Swamy and Salimath's study. Besides demonstrating the occurrence of arabinopyranoses as structural elements of amaranth arabinans, the isolation of compound **A-II2** unambiguously demonstrates that arabinan chains can be terminated by arabinopyranoses.

Hydrolysis of the potato galactan yielded a heterogeneous mixture of oligosaccharides. Only structures relevant for this study are described here. As shown in Figure 1, linear β-(1→4)-linked galactopyranose dimers and trimers were isolated and characterized. The NMR data were in good agreement with previously published data (Supporting Information).[25,26] These structures are well-known as constituents of the galactan backbone.

J. Agric. Food Chem. 2015, 63, 707−715

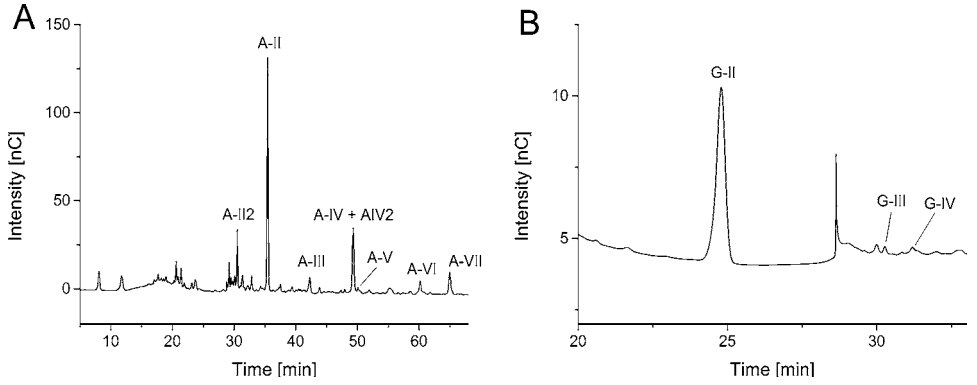

Figure 3. HPAEC chromatograms of the *endo*-arabinanase hydrolysate of amaranth insoluble fiber (A) and the *endo*-galactanase hydrolysate of the $Ca(OH)_2$ extract from amaranth insoluble fiber (B). A-II–A-VII and G-II–G-IV assign the signals to the structures shown in Figure 1 as evidenced by comparison of HPAEC and LC-PGC-MS retention times and MS^2 fragmentation patterns. The peaks around compound **A-II2** in the *endo*-arabinanase incubation were also present in an incubation mixture without enzyme.

The monosaccharide analysis of **G-IV**, however, revealed the occurrence of galactose and arabinose in a 2:1 ratio. Besides three anomeric proton signals for a reducing and a β-linked galactose, the ^{1}H NMR spectrum contained a signal at 4.56 ppm with a 7.4 Hz coupling constant (Table 2), suggesting the presence of an α-arabinopyranose. This hypothesis was confirmed by the ^{13}C chemical shifts, which were in good agreement with literature data for a terminal α-arabinopyranose,[27] and by an HMBC cross peak between H1 and C5 (signal 1 in Figure 2). A cross peak between C4 of the reducing galactose and H1 of the nonreducing galactose demonstrated the (1→4)-linkage between these residues (signal 2 in Figure 2). The long-range correlation between H1 of the arabinopyranose and C4 of the nonreducing galactose showed that the arabinopyranose is attached to *O*-4 of the nonreducing galactopyranose (signal 3 in Figure 2). Thus, **G-IV** contains a terminal arabinopyranose linked to the *O*-4-position of a β-(1→4)-linked galactan dimer. There have been few reports on such a structural element. Huisman et al.[28] demonstrated the presence of terminal arabinopyranoses in hydrolysates of soybean pectins by methylation analysis. Also, Ishii et al.[27] synthesized β-(1→4)-linked galacto-oligosaccharides containing terminal arabinopyranoses by using microsomal membranes from mung beans. However, NMR spectroscopic characterization of such an oligosaccharide isolated from plants has not been achieved yet. Because *endo*-galactanases should not be able to cleave glycosidic linkages between arabinose and galactose units, the liberation of this oligosaccharide strongly supports the hypothesis that arabinopyranose units terminate galactan chains, as previously suggested by Huisman et al.[28] and Ishii et al.[27]

Characterization of Amaranth Fiber Galactans and Arabinans via Liberated Galacto- and Arabino-oligosaccharides. To characterize structural elements of amaranth arabinans and galactans, the insoluble and soluble fibers were incubated with *endo*-arabinanase and *endo*-galactanase. No significant amounts of oligosaccharides were liberated from insoluble fiber by using *endo*-galactanase. This was probably due to an incorporation of the galactans into the complex cell wall matrix. Different pretreatments (extraction with hydrochloric acid, sodium hydroxide, $Ca(OH)_2$, or 1,2-diaminocyclohexane tetraacetic acid; enzymatic pretreatment with *endo*-polygalacturonase or cellulase) were tested to improve the enzymatic degradation. $Ca(OH)_2$ extraction of galactans was proven to be most efficient. As shown in Figure 3, several arabino-oligosaccharides and galacto-oligosaccharides were liberated by enzymatic hydrolysis of the insoluble fiber and the $Ca(OH)_2$ extract. Incubation of the soluble fiber liberated the same arabino-oligosaccharides (data not shown), but galacto-oligosaccharides were not detected. Thus, the polymeric galactose that was detected in amaranth soluble fiber after methanolysis is incorporated in linkages other than β-(1→4)-linkages or is part of galactomannans.

Identification of the liberated oligosaccharides was performed by HPAEC analysis (Figure 3) and comparison with the isolated standard compounds. However, because some of the oligosaccharides were present in very low amounts only, the LC-PGC-MS retention time and the fragmentation pattern of the lithium adducts were additionally used to confirm the presence of the oligosaccharides. Extensive peak broadening was obtained for the galacto-oligosaccharides on the PGC column. Thus, they were reduced with sodium borohydride to obtain sharp peaks and a good separation. Westphal et al.[29] described a coelution of the linear arabinotetraose with branched arabinotetraoses such as structure **A-IV** if analyzed by HPAEC. As also described by this group, the different tetramers can be separated on a PGC column. The mass trace of the lithium adduct of arabinotetraose (m/z 553) is shown in Figure 4 for the analysis of the hydrolyzed amaranth insoluble fiber, demonstrating the occurrence of both branched arabinotetraoses. The MS^2 fragmentation pattern yielded m/z

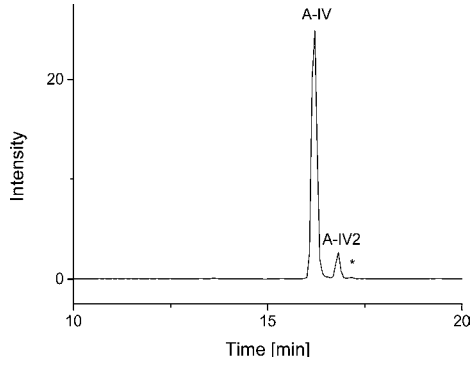

Figure 4. LC-PGC-MS mass trace of the lithium adduct of arabinotetraose (m/z 553) for the hydrolysate of amaranth insoluble fiber. The structures for **A-IV** and **A-IV2** are shown in Figure 1. The peak representing linear arabinotetraose is marked with an asterisk.

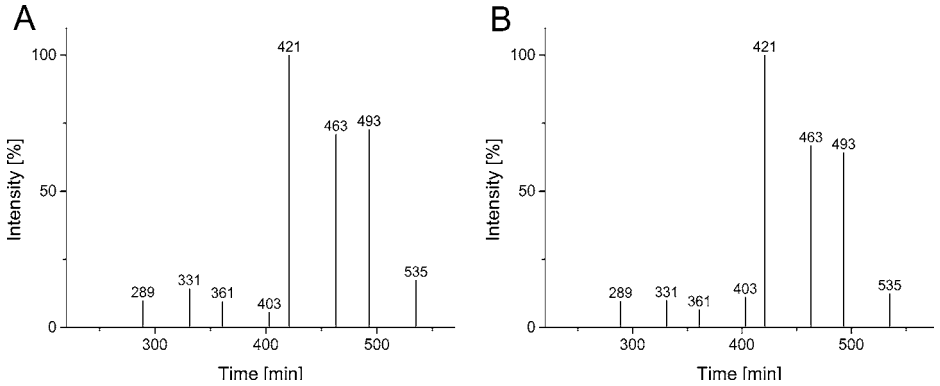

Figure 5. Fragmentation patterns of the lithium adducts of standard compounds **A-IV** (A) and **A-IV2** (B) (*m*/*z* 553).

421 as the main fragment ion in both peaks, which is typical for a branched arabinotetraose.[29] Compounds **A-IV** and **A-IV2** also showed *m*/*z* 421 as their dominating fragment. Due to their very similar structures, the fragmentation patterns of these branched arabinotetraoses showed only minor differences (Figure 5). Linear arabinotetraose was only found in traces, eluting after the branched arabinotetraoses (Figure 4). Because *endo*-arabinanase incubations were performed for 24 h, higher linear oligomers including linear arabinotetraose, which were initially liberated, were further degraded to yield mostly linear arabinobiose. Arabinotriose can also be cleaved by *endo*-arabinanase, but the conditions used here allow for their detection by HPAEC (Figure 3) and LC-PGC-MS. The amount of the trimer decreased with increasing incubation times. On the other hand, reduced incubation times favored the detection of the linear trimer (data not shown). This is in good agreement with previous findings by Dunkel and Amado.[30] A similar result was found for the galacto-oligosaccharides, with galactobiose and galactotriose being the only unsubstituted galacto-oligosaccharides detected. These are described as incubation end products.[31−33] Detection of these galacto-oligosaccharides confirms the occurrence of β-(1→4)-linked galactans in amaranth. The finding of the terminal arabinopyranoses (**G-IV**, Figure 1) suggests that this structural element may be a conserved one, because it was now demonstrated to exist in soybean, potato, and amaranth. The identification of compound **A-II2** demonstrates that arabinan chains in amaranth can also be terminated by arabinopyranoses. Because this structural element was only found to terminate the chains, there could be a special plant physiological function of this substituent. Also, degradation of these arabinans by human microbiota may be influenced in the absence of an arabinopyranosidase. The high abundance of arabinobiose suggests a high percentage of linear arabinans. However, the detection of the branched oligosaccharides shows some ramification with side chains mostly attached to the *O*-3 positions of the arabinan backbone. Double-substituted arabinan oligosaccharides (**A-V**) and areas with higher degree of branching at position *O*-3 (**A-VI** and **A-VII**) were found in small amounts only.

Methylation Analysis of Amaranth Dietary Fibers. The analysis of the PMAA obtained from methylation analysis (Table 3) confirmed these hypothesized structures. In insoluble fiber, there was a high amount of PMAA representing (1→5)-linked arabinose, whereas PMAA representing branched arabinoses were of lower abundance. The ratio of 1,3,5- and 1,2,5-substituted arabinofuranoses as determined by methyl-

ation analysis seemed to be comparable to that of the two branched arabinotetraoses as analyzed by LC-PGC-MS[2]. (1→4)-Linked galactose and terminal galactose were found in comparably low amounts. This supports the hypothesis of short galactan chains. Different from our enzymatic studies, terminal arabinopyranose units were not detected by methylation analysis, demonstrating the advantage of the enzymatic approach over methylation analysis. PMAA formed from (1→4)-linked glucose and terminal xylose represent cellulose and xyloglucans. However, a small part of the xylose may also be part of xylogalacturonan. The detection of (1→4)-linked xylose units suggests the presence of low amounts of xylans in the cell wall of the dicotyledonous amaranth seeds. Lamothe et al.[5] also detected a higher amount of linear arabinans in insoluble fiber of *A. caudatus*, but *O*-3 was the only branching position found. Also, the amount of PMAA representing galactans was significantly higher, and 1,4-substitued xylopyranoses were not detected. This may be due to species differences between *A.*

J. Agric. Food Chem. 2015, 63, 707−715

caudatus and *A. hypochondriacus*. The PMAA of amaranth soluble fiber (Table 3) suggest a high amount of arabinans, which are mostly composed of linear and, different from the insoluble fiber, *O*-2 substituted sections. However, **A-IV** was liberated in higher amounts than **A-IV2** from amaranth soluble fiber. Thus, the 1,2,5-substituted arabinofuranoses are probably involved in structural elements that are not cleaved by *endo*-arabinanase or liberated as oligosaccharides with a high degree of polymerization. For example, Eriksson et al.[34] already demonstrated that 1,2,5-substituted arabinofuranose can be part of complex arabinan side chains. The 1,3,6-substituted galactopyranoses demonstrate that (1→4)-linked galactans are not present, which is in good agreement with the results of the enzymatic digestion. These results are again different from the data for *A. caudatus* soluble fiber, where (1→4)-linked galactans and other arabinan structural elements were present.[5] Mannose is probably derived from structural elements other than mannans and galactomannans because it appears only in its terminal form.

By combining the results, it can be concluded that large amounts of neutral rhamnogalacturonan I side chains occur in amaranth seeds. As evident by our enzymatic approach and methylation analysis, they contain mostly linear arabinans, which are partially branched in position *O*-3 and/or *O*-2. The galactans, which are strongly incorporated in the cell wall matrix, are probably short and (1→4)-linked. We were also able to demonstrate that arabinan and galactan chains contain terminal arabinopyranoses. Our investigations showed that amaranth fiber is composed of arabinans and galactans with novel and unique structural features. The plant physiological functions of these structural elements as well as the consequences for human physiology and processing are difficult to deduce from our structural studies and may be part of future investigations.

ABSTRACT: Alpha-substituted derivatives of cinnamaldehyde (alpha-bromocinnamaldehyde, alpha-chlorocinnamaldehyde, and alpha-methylcinnamaldehyde) were used as inhibitors on mushroom tyrosinase. The result showed that three compounds can reduce both monophenolase and diphenolase activity on tyrosinase, and the inhibition was reversible. The IC_{50} values of alpha-bromocinnamaldehyde, alpha-chlorocinnamaldehyde, and alpha-methylcinnamaldehyde were 0.075, 0.140, and 0.440 mM on monophenolase and 0.049, 0.110, and 0.450 mM on diphenolase, respectively. The inhibition types and constants on diphenolase for these inhibitors were further studied. The molecular inhibition mechanisms of tyrosinase by the derivatives were investigated by UV-scanning study, fluorescence quenching, and molecular docking. These assays demonstrated that the derivatives could decrease the formation of *o*-quinones, and all derivatives were static quenchers of mushroom tyrosinase. Docking results implied that they could not form metal interactions with the copper ions of the enzyme, whereas they could interact with the amino acid residues of active site center. This research on alpha-substituted derivatives of cinnamaldehyde as tyrosinase inhibitors would lead to advances in the field of antityrosinase.

KEYWORDS: *tyrosinase, derivatives of cinnamaldehyde, fluorescence quenching, molecular docking*

INTRODUCTION

Tyrosinase (EC 1.14.18.1) is a copper-containing, mixed function oxidase widely distributed in animals, plants, and microorganisms.[1] It catalyzes two distinct reactions of melanin biosynthesis by hydroxylation of monophenols to *o*-diphenols and oxidation of *o*-diphenols to the corresponding *o*-quinones, which are the initial steps whereafter a series of highly reactive quinones are produced to initiate the pigmentation and excessive activation of tyrosinase can cause various dermatological disorders.[2]

Tyrosinase inhibitors are widely used in dermatological treatments and in cosmetics. Plenty of tyrosinase inhibitors are obtained from natural or synthetic sources, which have been further investigated.[3] Cinnamaldehyde, a low molecular weight cinnamic acid analogue with relatively broad distribution in plants, has shown various activities such as antitumor, cytotoxic, and mutagenic.[4,5] It has also been proven to have strong activity against a wide variety of wood decay fungi.[6,7] Cinnamaldehyde is considered to be a safe fragrant constituent without acute and chronic toxicity, and no case of mutagenecity or genotoxicity and carcinogenicity due to cinnamaldehyde has ever been reported in mammalian.[8]

In the previous study, Ikuyo et al.[9] reported that cinnamaldehyde inhibited the oxidation of L-DOPA by mushroom tyrosinase with an IC_{50} of 129 μg/mL (0.98 mM). Several kinds of derivatives of cinnamaldehyde have been reported. 2′-Hydroxycinnamaldehyde derivative isolated from *C. cassia* has been reported to have an inhibitory effect on farnesyl protein transferase activity and inhibited proliferation of several human cancer cell lines including breast, leukemia, ovarian, lung, and colon tumor.[10,11] Dimeric cinnamaldehydes strongly inhibited the growth of human tumor cells through the inducing of apoptosis in tumor cells and in vivo growth of human colon tumor xenograft in nude mice.[12] Yoshio et al.[13] reported that alpha-bromocinnamaldehyde has been used widely as an antifungal agent for optical, electric, and musical instruments, and they also proposed the metabolic pathway of alpha-bromocinnamaldehyde in rats.

Based on the above, we paid attention to the relationship between derivatives of cinnamaldehyde on alpha-substituted and mushroom tyrosinase. This research aims to understand the mechanism of the alpha-substituted derivatives on tyrosinase and to clarify molecular interaction between derivatives and enzyme structure.

MATERIALS AND METHODS

Materials. Mushroom tyrosinase (EC 1.14.18.1) from mushroom (*Agaricus bisporus*) was the product of Sigma-Aldrich (St. Louis, MO). The specific activity of the enzyme was 6680 U/mg. L-3,4-Dihydroxyphenylalanine (L-DOPA), L-tyrosine (L-Tyr), alpha-bromocinnamaldehyde (aBCA), alpha-chlorocinnamaldehyde (aCCA), alpha-methylcinnamaldehyde (aMCA), dimethylsulfoxide (DMSO), and $NaIO_4$ were also obtained from Sigma-Aldrich. Other reagents with standard analytical purity were acquired from Sinopharm (Shanghai, China). The water used was redistilled and ion-free.

Enzyme Activity Assay. Monophenolase and diphenolase activity assay were performed as previously reported.[14] In this reaction, L-Tyr and L-DOPA were used as the substrate for monophenolase and diphenolase activity assay, respectively. The reaction media (3 mL) for enzyme activity assay contained 1 mM L-Tyr or 0.5 mM L-DOPA in 50 mM Na_2HPO_4–NaH_2PO_4 buffer (PH 6.8) and 100 mL of different concentrations of inhibitor. The final concentrations of mushroom tyrosinase were 33.33 and 3.33 μg/mL for monophenolase and

diphenolase activity, respectively.[15,16] Enzyme assay was performed by following the increase of optical density at 475 nm (ε = 3700 M^{-1} cm^{-1}) accompanying the oxidation of substrates. The reaction was carried out at 30 °C. A Beckman DU800 spectophotometer was used for absorbance and kinetic measure.[17]

The inhibitor was dissolved in 3.3% DMSO and diluted to appropriate concentration. The controls without inhibitor but containing 3.3% DMSO in the reaction media were routinely carried out. The inhibitory effects of inhibitors on the enzyme were expressed as the concentrations that inhibited 50% of the enzyme activity (IC_{50}). The inhibition types were obtained by the Line-weaver Burk plot, and the inhibition constants were determined by the secondary plots of the apparent K_m/V_m or $1/V_m$ versus the concentrations of the inhibitors.[18]

UV Scanning Study. The experiment was carried out according to the method of Jiménez-Atiénzar et al.[19] with slight modifications. The oxidation of L-DOPA was carried out with and without the presence of inhibitor. The reaction media (3 mL) contained 0.5 mM L-DOPA in 50 mM Na_2HPO_4–NaH_2PO_4 buffer (pH 6.8) and 0.1 mL of inhibitor (dissolved in DMSO). The final concentration of the mushroom tyrosinase was 16.67 μg/mL. The UV spectra were recorded using a Beckman DU-800 spectrophotometer.

Nonenzymatic Generation of the Quinones. The experiment was carried out by methods of Espin and Wichers.[20] L-DOPA (100 μM) was oxidized by $NaIO_4$ (100 μM). The spectra in the absence and presence of the inhibitor (9, 18, 27, and 36 μM) were recorded with the DU800 spectrophotometer.

Fluorescence Spectrum Quenching. The experiment was performed with reference to Kim et al.[21] Fluorescence spectra were recorded using an Cary Eclipse fluorescence spectrophotometer. Fluorescence emission spectra were recorded at wavelengths of 300–420 nm upon excitation at 280 nm. The excitation and emission bandwidths were both 5 nm.[22,23] For each data point, 10 μL of inhibitor solution was added to 2 mL of tyrosinase solution to make sure each inhibitor was at the appropriate range of concentration. Each measurement was done thrice, and the means were calculated. The fluorescence quenching data were plotted as the fluorescence intensity against the inhibitor concentration. Fluorescence quenching was described by the Stern–Volmer equation[24]

$$F_0/F = 1 + K_q\tau_0[Q] = 1 + K_{SV}[Q]$$

where F_0 and F are the fluorescence intensities before and after the addition of the quencher, respectively, K_q is the bimolecular quenching constant, τ_0 (10^{-8} s) is the lifetime of the fluorophore in the absence of the quencher, [Q] is the concentration of the quencher, and K_{SV} is the Stern–Volmer quenching constant. Hence, the above equation was applied to determine the K_{SV} using linear regression of a plot of F_0/F against [Q]. For the calculation of bimolecular quenching constants, the data were plotted as F_0/F against [Q], with the bimolecular quenching constants calculated by linear regression.

There were two types of fluorescence-quenching mechanisms: static (by complex formation) and dynamic (by collisional processes).[25] When the type was static, the apparent binding constant (K_A) and the binding affinity (n) were estimated by plotting $\log[(F_0 - F)/F]$ against $\log[Q]$ with the following equation[26]

$$\log[(F_0 - F)/F] = \log K_A + n\log[Q]$$

where [Q] is the quencher concentration

Molecular Docking with Ligand. In this research, molecular operation environment 2010 software (MOE) was used for protein–ligand docking. The method was consulted with reference to Chen.[27] Before docking, the 3D structures of the inhibitors and tyrosinase were energy minimized. Hydrogens were added using the energy minimization module of the MOE. The parameters for molecular docking were as follows: the receptor and site were set to receptor atoms and dummy atoms, respectively; the refinement was set to force field; the retain of both the first and second scoring were set to 10; both the first and second rescoring were set to London dG; the MM/GBVI binding free energy scoring was used to rank the docking poses. A more negative value reflects a stronger interaction. Other parameters used were the default settings of the software. The docked conformation, which had the highest score, was selected to analyze the mode of binding.

RESULTS

Effects of Derivatives of Cinnamaldehyde on the Monophenolase Activity of Mushroom Tyrosinase. Taking aBCA, aCCA, and aMCA (see Figure 1 for structures) as the effectors, we probed the effects of these compounds on the activity of mushroom tyrosinase for the oxidation of L-Tyr. The lag time and characteristic of monophenolase activity were observed. The reaction system reached a steady state after the lag time. After the steady state, the curve of product increased linearly with increasing reaction time. The results are shown in Figure 2. Increasing concentrations of these effectors not only changed the lag time of the enzyme (Figure 2A-II, Figure 2B-II, and Figure 2C-II), but also the steady-state rates decreased obviously (Figure 2A-III, Figure 2B-III, and Figure 2C-III). When the concentrations of effectors were increased to 0.2 mM, the lag time was extended by aBCA, aCCA, and aMCA up to 115%, 75%, and 9%, respectively. As shown in Table 1, the concentrations for aBCA, aCCA, and aMCA leading to 50% enzyme activity (IC_{50}) were 0.075, 0.140, and 0.440 mM, respectively.

Effects of Derivatives of Cinnamaldehyde on the Diphenolase Activity. Effects of the derivatives on the oxidation of L-DOPA catalyzed by mushroom tyrosinase were investigated. The results showed that the inhibition was dose-dependent, while the relative activity of the enzyme reaction was reduced with increasing concentration of the inhibitors (Figure 3). The concentrations of aBCA, aCCA, and aMCA for leading to 50% enzyme activity loss (IC_{50}) were 0.049, 0.110, and 0.450 mM, respectively. The values are given in Table 1 as well.

Inhibition Mechanism of Derivatives of Cinnamaldehyde on the Diphenolase Activity. To ascertain the inhibition mechanism of derivatives of cinnamaldehyde, the oxidation of L-DOPA by derivatives was studied. Figure 4 shows that the plots of the remaining enzyme activity versus the concentrations of enzyme at different concentrations of aBCA gave a family of straight lines, which all passed through the origin. The slopes of the lines descended with an increase of the

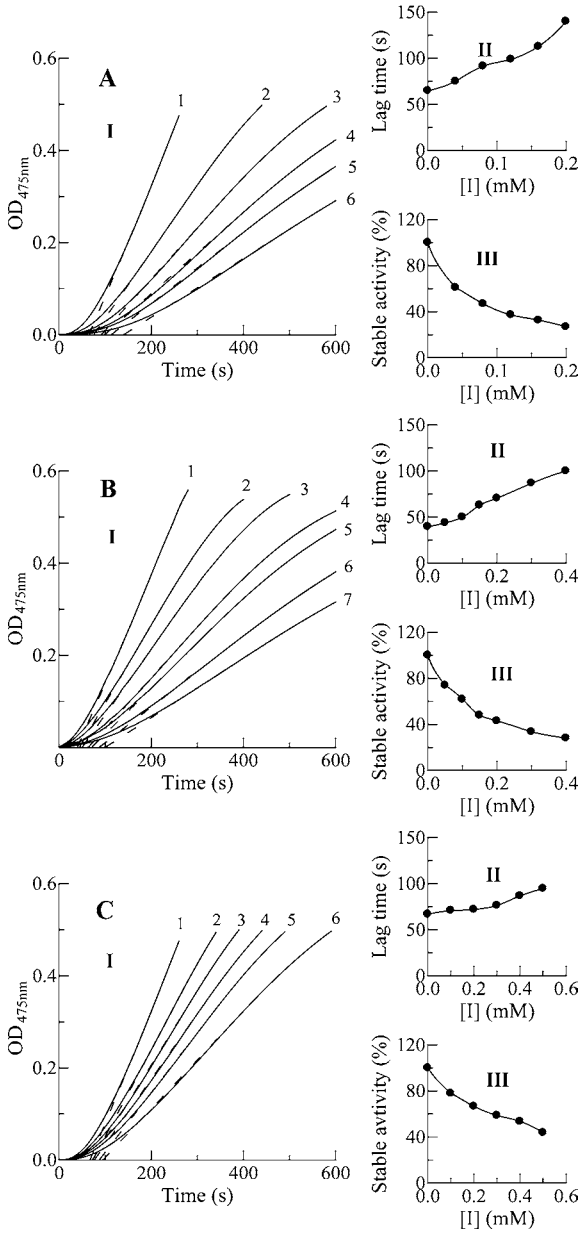

Figure 2. Inhibitory activity of the derivatives of cinnamaldehyde on monophenolase activity of mushroom tyrosinase. (I) Progress curves for the oxidation of L-Tyr by the enzyme. (II) Effects on the lag time of monophenolase. (III) Effects on the stable activity of L-Tyr by the enzyme. (A), (B), and (C) represent aBCA, aCCA, and aMCA, respectively. The concentrations of aBCA for curves 1−6 were 0, 0.04, 0.08, 0.12, 0.16, and 0.20 mM. The concentrations of aCCA for curves 1−7 were 0, 0.05, 0.1, 0.15, 0.2, 0.3, and 0.4 mM. The concentrations of aMCA for curves 1−6 were 0, 0.1, 0.2, 0.3, 0.4, and 0.5 mM.

concentrations of inhibitor, indicating that the presence of aBCA did not bring down the amount of active enzyme but just led to a decrease in the enzyme activity. Therefore, the inhibition of tyrosinase by aBCA was reversible. We also studied the inhibition mechanisms of aCCA and aMCA, as above. Results indicated that both aCCA and aMCA were reversible inhibitors of mushroom tyrosinase.

Inhibition Types and Constants on the Diphenolase Activity by Derivatives of Cinnamaldehyde. The plots of $1/v$ versus $1/[S]$ gave a family of straight lines indicating that aBCA was mixed type inhibitor (Figure 5A-I). Figure 5B-I indicated that aCCA was a noncompetitive inhibitor of the enzyme. As shown in Figure 5C-I, the result domenstrated that aMCA was an uncompetitive inhibitor of mushroom tyrosinase.

The inhibition constants (K_I) were obtained from the plots of the slopes versus the concentrations of the inhibitors (Figure 5A-II and Figure 5B-II), and the enzyme−substrate complexes (K_{IS}) were obtained from the vertical intercepts versus the concentrations of these compounds (Figure 5A-III and Figure 5C-II). The values obtained are summarized in Table 1 for comparison.

Oxidation of L-DOPA in the Presence and Absence of Derivatives of Cinnamaldehyde. The spectra obtained during the oxidation of L-DOPA in the absence (Figure 6A) and presence (Figure 6B, Figure 6C, and Figure 6D) of aBCA, aCCA, and aMCA by mushroom tyrosinase are given. In the absence of these compounds, the absorbance of the typical peak at 475 nm was 0.75. With the existence of aBCA, aCCA, and aMCA, at 10 min after the addition of the enzyme the peak intensity was reduced by 67%, 48%, and 24%, respectively. The results were consistent with the enzyme activity assay.

Interaction of Derivatives of Cinnamaldehyde with *o*-Quinones. Ultraviolet−visible scan was used to research the inhibitory mechanism of the compounds on mushroom tyrosinase. The *o*-diphenol (L-DOPA) was oxidized by sodium-periodate ($NaIO_4$) in the absence and presence of the inhibitors. Figure 7A, curve 1 shows spectrum of L-DOPA without any characteristic peaks. Curves 2−5 show the oxidation of L-DOPA by $NaIO_4$ for 1−4 min with a characteristic peak at 475 nm. Because the absorption did not increase as time goes by, L-DOPA (100 μM) was considered to be totally oxidized by $NaIO_4$ (100 μM).

Curves 1 in Figure 7B, 7C, and 7D are spectra of aBCA, aCCA, and aMCA, respectively. None of them showed characteristic peak at 475 nm. However, when the compounds were added to the mixture of L-DOPA and $NaIO_4$, a decrease of absorbance at the peak occurred (Figure 7B, Figure 7C, and Figure 7D curves 2−5).

Oxidation of L-DOPA by tyrosinase and $NaIO_4$ had the same typical peak at 475 nm indicating that they produced the same products. After addition of effectors, both the enzymatic and nonenzymatic reactions, the product peak became lower. The results indicated that effectors could bring down the oxidative product of L-DOPA, meaning that they prevented the formation of *o*-quinones, so the generation of melanin had

been reduced. This was the other process to restrain the activity of tyrosinase.

Analysis of Fluorescence Quenching of Tyrosinase with Derivatives of Cinnamaldehyde. Fluorescence quenching was applied to investigate the interactions of ligands and proteins.[28] The fluorescence emission spectra of tyrosinase in the absence and presence of aBCA are shown in Figure 8A. The fluorescence intensities of the emission peaks at 338 nm were inversely decreased with increasing concentration of aBCA (Figure 8B). Figure 8C is the Stern−Volmer plot which measured the Stern−Volmer quenching constants of aBCA. The results, shown in Table 2, suggested a good linear Stern−Volmer plot with K_q and K_{SV} values of 3.77×10^{12} M^{-1} s^{-1} and 3.77×10^4 M^{-1}, respectively. Due to the fact that the K_{SV} for dynamic cannot be larger than 100 L/M,[26] the K_{SV} we got demonstrated that the type of fluorescence-quenching mechanism between tyrosinase and aBCA was static.

Figure 8D shows the plot of $\log[(F_0 - F)/F]$ against $\log[Q]$ for tyrosinase with various concentrations of aBCA. From this graph, the values of K_A and n were obtained from the intercept and the slope. We obtain an equation of linear regression:

$$\log[(F_0 - F)/F] = 5.89 + 1.29 \log[Q], \quad R^2 = 0.9965$$

We have studied the fluorescence quenching of tyrosinase with aCCA and aMCA as well. Results were similar to aBCA, which indicated that both aCCA and aMCA were static quenchers of mushroom tyrosinase. All the values of K_{SV}, K_q, K_A, and n are shown in Table 2.

Molecular Docking Analysis. Docking simulations were further performed to understand the mechanism underlying the

aMCA	static	4.86×10^4	4.86×10^{12}	3.47×10	0.97

enzyme. whereas all of them could interact the amino acid residues in the center of active site. The oxygen for aBCA on the aldehyde group could directly act on His_{85} and His_{61}. Besides, aBCA could form intercations with tyrosinase residues, such $asAla_{286}$, His_{244}, Glu_{256}, Phe_{264}, Asn_{260}, Phe_{292}, His_{263},Val_{283}, His_{295}, and Ser_{282}. (Figure 9A).

The same analyses were carried out on aCCA and aMCA, which indicated the oxygen on the aldehyde group for aCCA and aMCA could directly act on His_{94} (Figure 9B) and His_{85} (Figure 9C), respectively. In addition, aCCA and aMCA could also interact with another 10 (Figure 9B) or 9 (Figure 9C) amino acid residues in tyrosinase. These interactions might enhance the inhibitory potency of derivatives on the enzyme.

DISCUSSION

This paper explained the relationship between the cinnamaldehyde derivatives and mushroom tyrosinase. For monophenolase activity, three derivatives could extend the lag time and inhibit the steady-state activity. Comparing the inhibitory effects of three derivatives, we found that aBCA was better than aCCA, and aMCA was weakest.

With respect to diphenolase activity, the IC_{50} showed the same results with the inhibitory effects of monophenolase.

J. Agric. Food Chem. 2015, 63, 716−722

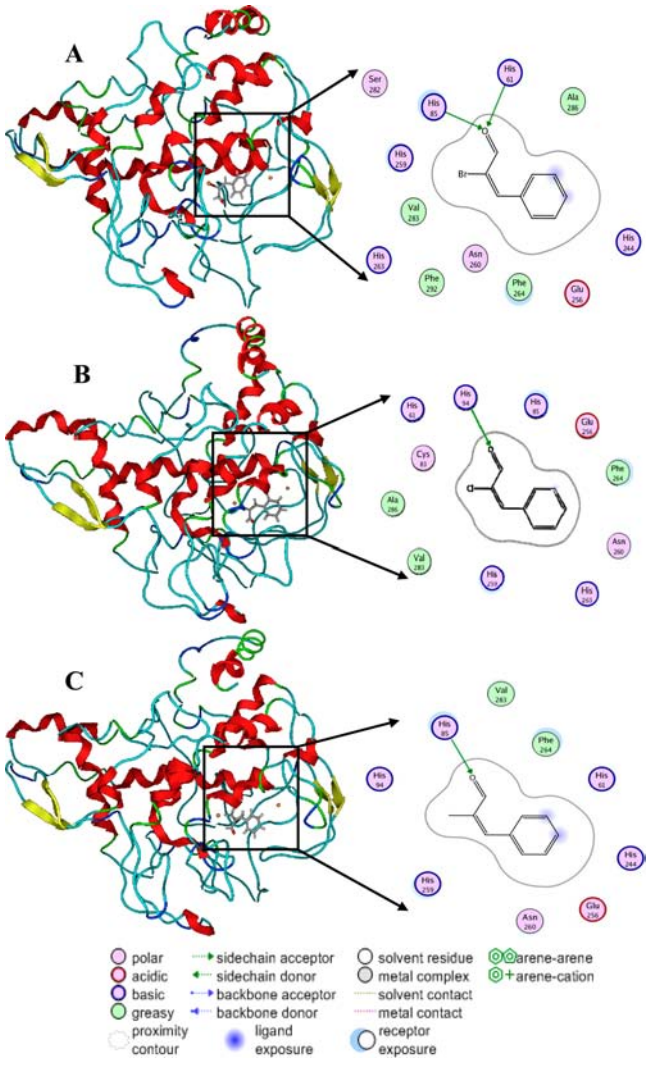

Figure 9. Binding mode of the ligands with tyrosinase residues. The receptor exposure differences were shown by the size and intensity of the turquoise discs surrounding the residues. (A), (B), and (C) represent aBCA, aCCA, and aMCA, respectively.

aBCA was the strongest inhibitor, and aMCA was the weakest. The inhibitions of three derivatives were reversible demonstrating that the effectors did not reduce the amount of the efficient enzyme, but just decreased the activity of tyrosinase.[29] It was interesting that each inhibition type of three compounds was different and this phenomenon may result in the different inhibitory capacities for derivatives. Compared with cinnamaldehyde, whose IC_{50} of diphenolase was 0.98 mM,[9] alpha-substituted derivatives showed better inhibitory effects. Due to the existence of alpha substituents, the terpenes on derivatives became unstable and easier to interfere with tyrosinase. Moreover, Xiao et al.[30] reported that alpha halogeno group can enhance cinnamaldehyde antibacterial ability greatly. Perhaps the substituents hindered the activity of enzyme and thus restrained bacterial growth.

Fluorescence quenching was used to investigate the interactions of ligands and proteins. The presented results showed that the tyrosinase fluorescence intensity decreased in the presence of derivatives; however, there was no apparent λ_{em} shift in the fluorescence emission spectra of tyrosinase with the addition of derivatives. Therefore, the interaction between effectors and tyrosinase only affected the microenvironment in close proximity to the fluorophore of tyrosinase, as no other changes in the immediate surroundings of the quenched residues were observed.[31] This mode was also observed by Mu et al.[32] in fluorescence quenching between 4-methoxycinnamic acid and tyrosinase. Moreover, tricin[30] and thiobarbituric acid[33] showed similar quenching mechanisms. Compared with the values in Table 2, for aBCA, aCCA, and aMCA, the K_{SV} increased in turn; meanwhile, the binding constant (K_A) and the binding affinity (n) decreased in turn. All the trends of the changes declared that tyrosinase and aBCA had the strongest interaction while the interaction between aMCA and enzyme was the weakest. The results were consistent with enzyme assay.

The results of molecular docking by MOE suggested that the inhibition on tyrosinase by three derivatives represented a different strategy for inactivating tyrosinase compared to simple copper chelators. They did not bind directly to the copper ions of the active site. An example of such inhibitor was 4-methoxycinnamic acid, which can occupy the position of CuA to suppress the monophenolase activity.[32]

The scores for aBCA, aCCA, and aMCA docking with tyrosinase were −9.59, −9.35,l and −8.84 kcal/mol, respectively. The score meant that the docking between tyrosinase and all compounds was successful. The molecular docking showed that aMCA could bind residues within free enzyme whereas the inhibition type demonstrated that aMCA could not interact with enzyme directly. L-DOPA may reduce the affinity of aMCA and enzyme, and aMCA prefers to combine with the complex rather than free enzyme.

Taken together, three derivatives of cinnamaldehyde could inhibit the acitvity of tyrosinase in two ways. First, the effectors combined with enzyme to affect the microenvironment in close proximity to the active site of tyrosinase. At the same time, alpha-substituent group enhanced the reciprocity between effectors and the residues within active site, which caused activity of tyrosinase to be restricted. The second way was enzyme, inhibitor, and the substrate to form ternary compound, and effectors could prevent the oxidative process of substrate, which brings down the formation of melanin. This was the other approach was to restrict the activity of tyrosinase. Among three derivatives, aBCA had the best inhibitory effect on tyrosinase. In addition, Lu et al.[34] reported that aBCA was a low toxical compound, with slight nonspecific inflammatory irritation effects on the skin and eye. The minimun effective dose of subacute toxicity experiment (oral) was 369 mg/kg body weight. In conclusion, aBCA was a good tyrosinase inhibitor and could be widely used as insecticide, bactericide, and so on.

Supporting Information

ABSTRACT: Determining the transfer rate of pesticides during tea brewing is important to identify the potential exposure risks from pesticide residues in tea. In this study, the transfer rates of 19 typical pesticides from tea to brewing were investigated using gas chromatography tandem mass and ultraperformance liquid chromatography tandem mass. The leaching rates of five pesticides (isocarbophos, triazophos, fenvalerate, buprofezin, and pyridaben) during tea brewing were first reported. The pesticides exhibited different transfer rates; however, this result was not related to residual concentrations and tea types. Pesticides with low octanol−water partition coefficients (Logkow) and high water solubility demonstrated high transfer rates. The transfer rates of pesticides with water solubility > 29 mg L^{-1} (or <15 mg L^{-1}) were >25% (or <10%), and those of pesticides with LogKow < 1.52 (or >2.48) were >65% (or <35%). This result indicates that water solubility at approximately 20 mg L^{-1} and LogKow at approximately 2.0 could be the demarcation lines of transfer rate. The results of this study can be used as a guide in the application of pesticides to tea trees and establishment of maximum residue limits of pesticides in tea to reduce pesticide exposure in humans.

KEYWORDS: *tea brewing, pesticides,transfer rate, water solubility, octanol−water partition coefficient*

INTRODUCTION

Tea made from dried leaves of *Camellia sinensis* is the second most widely consumed beverage worldwide after water.[1] Tea polyphenols and polysaccharides exhibit anticancer, anti-HIV, hypoglycemic, and immunological activities.[2,3] These active substances, along with harmful substances such as pesticides and heavy metals, are leached during tea brewing. Tea plants are treated with pesticides to prevent pests and diseases as well as achieve high yields. However, pesticide residues in fresh leaves are transferred from made tea to infusion during tea brewing. At present, the maximum residue limits (MRLs) of several hundred types of pesticides in tea have been regulated by China,[4] Japan,[5] the European Union,[6] and Codex Alimentarius Commission.[7] However, the pesticide MRLs have great differences in the formulation of the same pesticide. The absence of global unified pesticide MRLs makes pesticide management difficult. Thus, the establishment of unified and reasonable MRLs of typical pesticide residues in tea is urgently needed. The exposure level of toxic substances is crucial for risk assessment and establishment of MRLs. Therefore, the transfer rate of pesticides during tea brewing should be investigated because tea infusion is the most important pathway of pesticide exposure to humans during tea drinking.

Several studies have investigated the transfer rates of pesticides during tea brewing.[8−12] Neonicotinoid pesticides were easily leached into tea brewing. The transfer rates of acetamiprid, imidacloprid, and thiamethoxam are 78.3−80.6%, 62.2−63.1%, and 80.5−81.6%, respectively.[8] Wang et al.[9] determined 12 pesticide residue transfer rates during tea brewing using high-performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS). High transfer rates were found for quizalofop (44.5%), thiacloprid (49.7%), thiabendazole (61.3%), methidathion (65.4%), carbary (78.9%), carbendazim (83.4%), imidacloprid (84.9%), monocrotophos (87.4%), methomyl (92.4%), thiamethoram (92.6%), 3-hydroxucarbofuran (99.4%), and clothianidin (99.8%). Pyrethroid pesticides, such as cypermethrin, bifenthrin, deltamethrin, permethrin, and cyhalothrin, are prone to be retained in tea spent because their transfer rates are lower than 10% or even equal to 0.[10,11] Benzoylurea pesticides have low transfer rates of less than 10%, except for iflubenzuron (45.6%) and triflumuron (13.1%).[12] However, several pesticides, such as triazophos,[13,14] buprofezin,[15] fenvalerate,[16,17] and isocarbophos,[18,19] have been detected in tea samples. To the best of the authors' knowledge, the transfer rates of these pesticides have not been reported. The present study investigated the transfer rates of 19 typical pesticide residues from tea into brewing and analyzed the relationship between the transfer rate and the property of these pesticides. The results would provide important information for the establishment of pesticide MRLs in tea and help farmers select suitable pesticides with low transfer rates to reduce pesticide exposure to humans.

Figure 1. Tea brewing and sample preparation for GC-MS/MS and UPLC-MS/MS analysis of pesticide residues in made tea, infusion, and tea spent. Notes: (a) SPE column was conditioned with 5 mL of MeCN/tubene 3:1 (v/v) prior to sample. (b) Tea spent was directly extracted with 15 mL of MeCN but not addition of 5 mL of boiled water; the next steps of sample preparation were the same as "made tea".

MATERIALS AND METHODS

Selection of Pesticides. In this study, the selected pesticides have the following characteristics: (1) widely applied pesticides in tea plantations, such as bifenthrin, cypermethrin, cyhalothrin, fenpropathrin, carbendazim, difenoconazole, and propargite; (2) banned but detectable pesticides, such as dicofol, fenvelerate, and methomyl;[20,21] (3) ability to be substituted and highly detectable pesticides, such as imidacloprid, acetamiprid, buprofezin, and thiamethoxam; (4) non-authorized but detectable pesticides, such as isocarbophos, triazophos, chlorpyrifos, and pyridaben;[22] (5) newly applied pesticides in tea plantations, such as indoxacarb. The maximum residual levels (MRLs) of 11 of the 19 pesticides have been established by the Chinese government,[23] whereas those of the other 8 pesticides have yet to be established. Although the MRLs of 8 pesticides have been established by the European Union or Japan, these MRLs cannot be used because MRLs vary with different countries or organizations.[4−6] For example, the MRLs of imidacloprid established by China, Japan, and EU are 0.5, 10, and 0.05 mg kg^{-1}, respectively. The MRLs of 19 pesticides formulated by China, Japan, and the European Union are shown in Table S-1, Supporting Information. Determining the transfer rates and then accessing the exposure level of pesticides through tea brewing are beneficial for establishment of standard MRLs of pesticides in tea.

Materials. HPLC-grade acetonitrile (MeCN), acetone, methanol, dichloromethane (DCM), and toluene were purchased from Sigma−Aldrich (Merck, Germany). Primary secondary amine-bond graphite carbon black SPE columns (PSA/GCB, 500 mg/6 mL) were purchased from Varian (USA). A Milli-Q plus ultrapure water system from Millipore (Miford, USA) was used throughout the study to obtain HPLC-grade water. Analytical-grade NaCl, anhydrous Na_2SO_4, and anhydrous $MgSO_4$ (Zhejiang Medicine, China) were baked for 3 h at 650 °C prior to use. Certified pesticide standards and triphenyl phosphate (TPP) were purchased from Sigma−Aldrich (Steinheim, Germany).

Positive samples (including 22 green tea and 18 oolong tea) were selected from over 2000 samples that were collected from 2012 to 2014 from supermarkets, monopoly stores, wholesale markets, or field experiments for pesticide dissipation. Collected samples were stored in the dark at 1−4 °C and returned to room temperature before testing. Organic tea samples containing no pesticides were used as controls to prepare matrix-matched standard solutions.

Tea Brewing. Tea brewing was prepared with boiled water for certain times in duplicate or triplicate. To simulate the traditional green tea and oolong tea brewing, 3.0 g of tea samples was transferred into a sensory evaluation cup and added with 150 mL of boiled water. The cup was sealed with a cap and allowed to stand for 5 min. Tea soup was transferred into a baker and cooled to room temperature, which was the first soup. The boiled water (150 mL) was reinfused with tea spent and then collected as the second infusion.

Sample Preparations. The overall sample preparation is presented in Figure 1.

Made Tea. Approximately 250 g of each tea sample was ground into powder and then sieved through a membrane with a pore size of 200 μm. Tea power (4.0 g) was placed in a 50 mL centrifuge tube and then mixed with 10 mL of boiled water for 15 min. A 50 μL amount of 20 μg mL^{-1} internal standard triphenyl phosphate (IS TPP) surrogate standard solution in acetonitrile was added into the mixtures prior to extraction. Target pesticides were extracted with 20 mLof MeCN by homogenization at 12 000 rpm for 2 min. Approximately 5 g of NaCl and 2 g of $MgSO_4$ were added into a centrifuge tube, vigorously shaken for 1 min by hand, and then centrifuged at 10 000 rpm for 2

min. The supernatant (5 mL) was added in the GCB/PSA SPE column (SPE column was conditioned with 5 mL of MeCN/toluene 3:1 (v/v) prior to sample). Target pesticides were eluted from the SPE column with 25 mL of MeCN/toluene 3:1 (v/v). The elutes were evaporated into dryness and dissolved in 5 mL of acetone. Approximately 2 mL was filtered through a 0.22 μm membrane into an autosampler vial for GC-MS/MS analysis. Exactly 2 mL of the rest was solvent changed with 2 mL of methanol for UPLC-MS/MS analysis.

Tea Infusion. NaCl (10 g) was added into 100 mL of infusion and then transferred into a 250 mL separating funnel. IS TPP (50 μL) was added to achieve a concentration of 10 μg L^{-1} prior to extraction. DCM (100 mL) was used to extract the target pesticides from infusion by liquid−liquid extraction. The lower liquid (DCM phase) was filtered into a 150 mL heart-shaped bottle through a filter paper, which was filled with 15−20 g of Na_2SO_4. The infusion was re-extracted with 100 mL of DCM by LLE. Approximately 50 mL of DCM was used to wash Na_2SO_4 and then collected. The combined extractions (DCM phase from two LLE extraction) were evaporated into dryness at 40 °C and then dissolved with 5 mL of acetone. Approximately 2 mL of acetone solution was filtered through a 0.22 μm membrane into an autosampler vial for GC-MS/MS analysis. Exactly 2 mL of the rest was solvent changed with 2 mL of methanol for UPLC-MS/MS analysis.

Tea Spent. The tea spent (means all the solid residues of made tea after brewing twice) was cut into small pieces and then transferred into a 50 mL centrifuge tube. IS TPP (50 μL) was added to achieve a concentration of 25 μg kg^{-1} prior to extraction. Then, 15 mL of MeCN was added into the samples and then homogenized at 12 000 rpm for 2 min. The following steps were the same as the made tea in Made Tea section.

Preparation of Standard Solutions. Individual pesticide stock solutions at 1000 mg L^{-1} (200 mg L^{-1} for carbendazim) were prepared with acetone for 9 pesticides analyzed by GC-MS/MS and methanol for 10 pesticides analyzed by UPLC-MS/MS. IS TPP at 1000 mg L^{-1} was prepared with acetone. Intermediate mixed standard solutions at 40 mg L^{-1} and IS TPP solution at 20 mg L^{-1} were prepared by dilution of stock standard solutions with acetone (for GC-MS/MS) and methanol (for UPLC-MS/MS). All stock solutions and intermediate solutions were stored in the dark at −18 °C.

Matrix-matched standard solutions were prepared for quantification of 19 pesticides. A 5 mL amount of liquids obtained from blank sample (made tea, tea infusion, and spent tea) with the proposed treatment was evaporated to dryness. Afterward, 5 mL of solvent standard solutions (containing IS TPP at 50 μg L^{-1}) with concentrations ranging from 1 to 1000 μg L^{-1} for the pesticides analyzed by UPLC-MS/MS and 2 to 2000 μg L^{-1} for the pesticides analyzed by GC-MS/MS were added to produce solutions with final concentrations corresponding to the levels of matrix-matched calibration standards.

GC-MS/MS Analysis. Volatile and thermally stable pesticides, such as bifenthrin, chlorpyrifos, cyhalothrin, cypermethrin, dicofol (expressed as dichlorobenzophenone), fenpropathin, fenvalerate, isocarbophos, and triazophos, were analyzed by GC-MS/MS using a Bruker 450 GC coupled with a 300 MS. Separation was performed on a VF-5 MS column (30 m × 0.25 mm × 0.25 μm; Agilent, USA). The column temperature was maintained at 80 °C for 1.0 min and then ramped at 15 °C min^{-1} up to 180 °C, held for 2 min, and then at 5 °C min^{-1} up to 280 °C, held for 10 min. The injection volume was 1.0 μL, and splitless mode was adopted. Helium (99.99%) at a flow rate of 1.0 mL min^{-1} was used as the carrier gas and argon (99.99%) as the collision gas. The MSD transfer line, ion source, and manifold temperatures were 280, 230, and 40 °C, respectively. The triple-quadrupole mass spectrometer was operated in electron impact ionization mode. Two mass transitions were acquired for each

compound, the higher sensitivity of which was used for quantification. The GC-MS/MS parameters for nine pesticides are shown in Table 1.

UPLC-MS/MS Analysis. UPLC-MS/MS was used to analyze 10 pesticides (acetamiprid, buprofezin, carbendazim, difenoconazole, imidacloprid, indoxacarb, methomyl, propargite, pyridaben, and thiamethoxam). A Waters Acquity UPLC system equipped with an applied Biosystems 3200 QTRAP system (ABI, USA) and controlled Analyst 1.5 software was used. Chromatography was performed on an Acquity UPLC HSS T3 column (100 mm × 2.1 mm i.d., 1.8 μm particle size, Waters, USA). The mobile phase consisted of water (A) and methanol (B) containing 0.1% formic acid (v/v). Gradient elution was performed as follows: 90% A initially, 5% A for 1−10 min (held for 2 min), and then 90% A for 12−13 min (held for 1 min). The flow rate, autosampler temperature, and injection volume were 0.25 mL min^{-1}, 4 °C, and 3 μL, respectively. Analysis was performed in electron spray ionization mode, and analytes were detected by selective reaction monitoring. The UPLC-MS/MS parameters of the 10 pesticides are shown in Table 1.

Calculating the Transfer Rate of Pesticides. The transfer rate was calculated by two models. In one model, the rates of the first and second brewing are added (eq 1), whereas the other model involves indirect calculation of the residual rate of pesticides in tea spent (eq 2)

$$R_{in} = C_{in} \times V_{in}/C \times M \times 100\% \quad (1)$$

$$Re_{spent} = C_{spent}/C \times 100\% \quad (2)$$

where R_{in} is the transfer rate (%), C_{in} is the concentration of pesticides in tea infusion (ng mL^{-1}), V_{in} is the volume of tea infusion (mL), C is the concentration of pesticides in made tea (μg kg^{-1}), M is the mass of made tea (g), Re_{spent}(%) is the residual rate calculated by spent tea, and C_{spent} is the concentration of pesticides in tea spent (μg kg^{-1}).

RESULTS AND DISCUSSION

Method Validation. Method validation was evaluated with selectivity, linearity, accuracy, precision, and limits of

quantification (LOQs) (Table S-2, Supporting Information). Matrix-matched calibration solutions were used for quantification. No interfering peaks were observed for UPLC-MS/MS and GC-MS/MS because of the high selectivity of tandem mass (Figures 1 and 2, Supporting Information). The linearity obtained with $r^2 > 0.995$ for 10 pesticides analyzed by UPLC-MS/MS ranged from 1 to 1000 μg L^{-1} (except for methomyl, 8−2000 ug L^{-1}), whereas that obtained with $r^2 > 0.991$ for 9

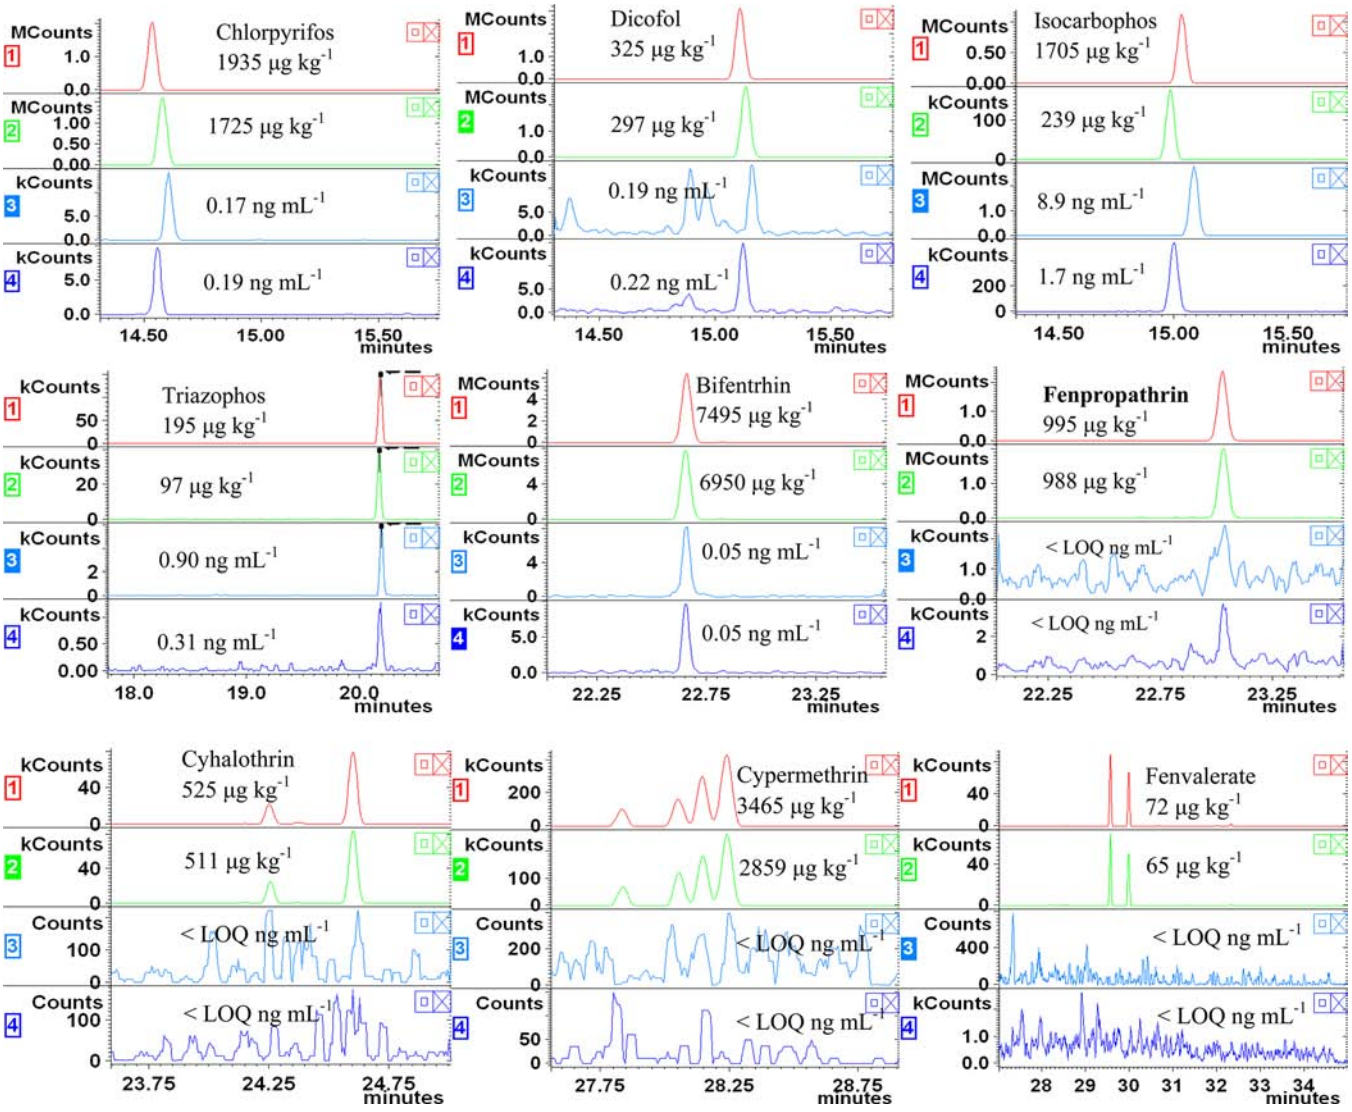

Figure 3. Typical GC-MS/MS chromatograms of 9 pesticides in made tea (1), tea spent (2), first soup (3), and second soup (4).

pesticides analyzed by GC-MS/MS was 2−2000 μg L^{-1} (except for cypermethrin, 4−2000 ug L^{-1}). The accuracy of the method was verified by measuring the recovery from blank samples of made tea, tea spent, and infusion spiked with the analytes at two concentrations of 80 and 400 μg kg^{-1} for both made tea and tea spent but 8 and 40 μg L^{-1} for tea infusion. For all matrices, satisfactory accuracy was achieved with a recovery of 80.4−119.3% for 10 pesticides analyzed by UPLC-MS/MS and 83.4−113.4% for 9 pesticides analyzed by GC-MS/MS. Method precision was determined five times (n = 5) at the two spiked levels. Good precision was obtained with relative standard deviations (RSDs) < 10% for all pesticides with two spiked levels. LOQs were defined when the signal-to-noise ratio was 10 times above the blank signal. The LOQs of 19 pesticides were 1−20 μg kg^{-1} in made tea and tea spent and 0.005−0.150 ng L^{-1} in tea soup.

Transfer Rate of Pesticides during Tea Brewing. The transfer rates of 19 pesticides are summarized in Table 2. The typical UPLC-MS/MS or GC-MS/MS chromatograms for 19 pesticides in made tea, spent, and infusion are shown in Figures 2 and 3, respectively. Compared with the pesticides analyzed by GC-MS/MS, those analyzed by UPLC-MS/MS were easier to leach into the infusion during tea brewing. The transfer rates of thiamethoxam, methomyl, carbendazim, imidacloprid, and acetamiprid were 90.4−90.6%, 89.5−91.3%, 79.6−81.2%, 76.5−77.3%, and 67.8−68.3%, respectively, which were much higher than those of the other 14 pesticides. These results were in accordance with previous studies by Hou et al.[8] and Wang et al.[9] but higher than the results from Gupta et al., where the transfer rates of acetamiprid and imidacloprid were lower than 50%.[24−26] This study is the first to report the transfer rates of pyridaben and buprofezin, which were all lower than 15%. Similar with the results from Cho et al.[27] the transfer rate of difenoconazole was found with nearly 8%. The lowest transfer rate of pesticides analyzed by UPLC-MS/MS was nearly 0% for propargite and indoxacart. Nearly no residues in tea infusion were observed for the pesticides (chlorpyrifos, dicofol, bifenthrin, fenpropathrin, cyhalothrin, cypermethrin, and fenvelerate) analyzed by GC-MS/MS. The results were in accordance with previous studies by Manikandan et al.,[10] Jaggi et al.,[11] and Tewary et al.[28] The transfer rates of isocarbophos (31.4−32.2%) and triazophos (27.1−29.6%) were also first reported in this study.

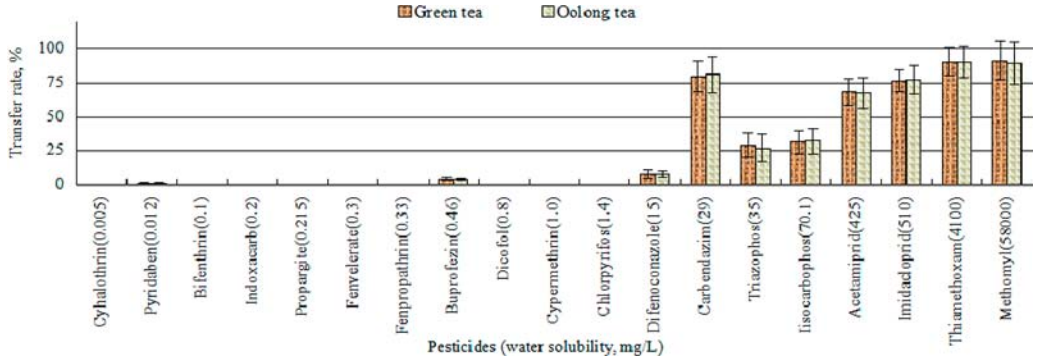

Figure 4. Relationship between water solubility and transfer rates of pesticides during tea brewing.

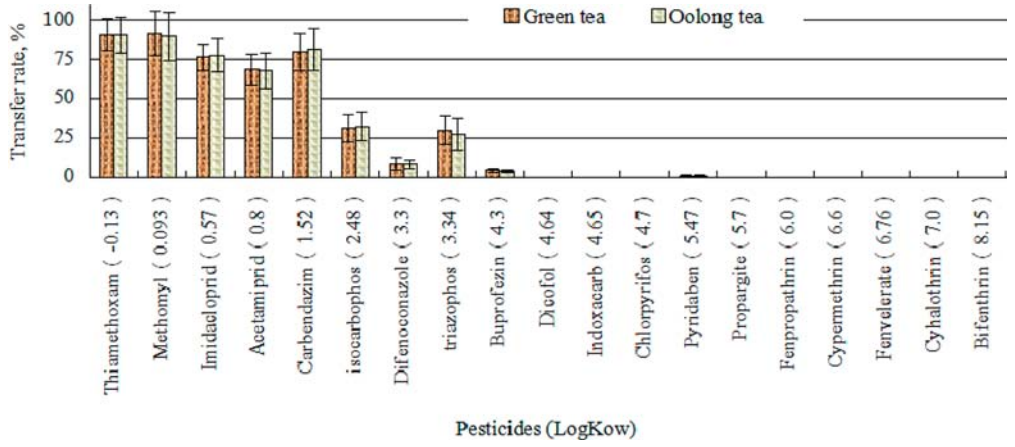

Figure 5. Relationship between octanol–water partition coefficient (Logkow) and transfer rates of pesticides during tea brewing.

In general, the transfer rates of 19 pesticides have no significant relation with their concentrations in made tea. For example, three tea samples containing acetamiprid at 43, 571, and 1150 μg kg^{-1} had transfer rates of 69.5%, 76.2%, and 72.1%, respectively. Similar to previous studies,[8] the present study found no significant difference between green and oolong teas. The deviations in the transfer rates from the same tea type were much higher than those between green tea and oolong tea samples.

Tea is usually brewed twice because its taste and aroma in the first and second infusions are favorable, but both taste and aroma rapidly decrease in the third or subsequent infusions. Thus, this study investigated the transfer rates of 19 pesticides during the first and second brewing. For pesticides with transfer rates higher than 20%, the ratios between the first and the second soups were 2:1–5:1. For the pesticides with transfer rates lower than 10%, transfer rates were similar during the first and second brewing. The transfer rates determined by indirect calculation of the residual rate in tea spent ($R_{in} = 1 - Re_{spent}$) were higher than the total transfer rates of the first and second infusions. This result indicated that suspended particles were leached into tea infusion and the mass of tea spent was lower than the original amount of made tea (3.0 g). The amounts of pesticides exposed to human during tea brewing should be indirectly calculated by the residual rate of tea spent since the suspended particles containing pesticides could also be adsorbed by humans during tea drinking.

Relationship between Transfer Rates and Physicochemical Properties of Pesticides. Water solubility is one of the crucial physical and chemical parameters that influences the transfer rates of pesticides from made tea to infusion because water is the most important carryover of pesticides during tea brewing. The relationship between transfer rate and water solubility of 19 pesticides is shown in Figure 4. The transfer rates increased as the water solubility of the pesticides increased. Low transfer rates of <15% were observed when the water solubility of pesticides was lower than 20 mg L^{-1}, but the rates increased from 22.6% (triazophos, 35 mg L^{-1}) to 90.6% (thiamethoxam, 4100 mg L^{-1}). This result indicated that the water solubility of certain pesticides at 20 mg L^{-1} could be a demarcation line of the transfer rate. However, carbendazim, methomyl, and buprofezin showed a different relationship between transfer rate and water solubility. Carbendazim with a low solubility of 29 mg L^{-1} exhibited a high transfer rate of 79.6–81.2%, whereas methomyl with an extrahigh solubility of 58 000 mg L^{-1} demonstrated a similar transfer rate of 89.5–91.3% to thiamethoxam at 4100 mg L^{-1} (90.4–90.6%). This result indicated that the transfer rate depended on other physicochemical properties of pesticides, such as Logkow.[29−32]

The relationship between the octanol–water partition coefficient (Logkow) and the transfer rate of 19 pesticides is shown in Figure 5. Obviously, the transfer rates of pesticides decreased with increasing LogKow. Five pesticides (thiamethoxam, methomyl, imidacloprid, acetamiprid, and carbendazim) with low LogKow values were mostly leached from made tea into infusion, whereas the pesticides (pyrethoid pesticides, dicofol, propargite, and indoxacarb) with high LogKow values were mostly retained in tea spent. The transfer rates dropped from approximately 80% to 30% when the LogKow value increased from 1.52 (carbendazim) to 2.48 (isocarbophos).

DOI: 10.1021/jf506103d
J. Agric. Food Chem. 2015, 63, 723–730

This result indicated that LogKow at approximately 2.0 can be a demarcation line of transfer rate.

Therefore, pesticides with low octanol−water partition coefficients (Logkow) or high water solubility were easily leached into tea infusion. The pesticides with LogKow at less than 2.0 and water solubility at higher than 20 mg L^{-1} are more exposed for human being by drinking tea because of their high transfer rates. The results from this study can be used as a guide in the application of pesticides to tea trees and establishment of MRLs of pesticides in tea to reduce pesticide exposure in humans.

Supporting Information

ABSTRACT: T-2 toxin is a trichothecene mycotoxin produced when *Fusarium* fungi infect grains, especially oats and wheat. Ingestion of T-2 toxin contaminated grain can cause diarrhea, hemorrhaging, and feed refusal in livestock. Cereal crops infected with mycotoxin-producing fungi form toxin glycosides, sometimes called masked mycotoxins, which are a potential food safety concern because they are not detectable by standard approaches and may be converted back to the parent toxin during digestion or food processing. The work reported here addresses four aspects of T-2 toxin-glucosides: phytotoxicity, stability after ingestion, antibody detection, and the anomericity of the naturally occurring T-2 toxin-glucoside found in cereal plants. T-2 toxin-β-glucoside was chemically synthesized and compared to T-2 toxin-α-glucoside prepared with *Blastobotrys muscicola* cultures and the T-2 toxin-glucoside found in naturally contaminated oats and wheat. The anomeric forms were separated chromatographically and differ in both NMR and mass spectrometry. Both anomers were significantly degraded to T-2 toxin and HT-2 toxin under conditions that mimic human digestion, but with different kinetics and metabolic end products. The naturally occurring T-2 toxin-glucoside from plants was found to be identical to T-2 toxin-α-glucoside prepared with *B. muscicola*. An antibody test for the detection of T-2 toxin was not effective for the detection of T-2 toxin-α-glucoside. This anomer was produced in sufficient quantity to assess its animal toxicity.

KEYWORDS: *mycotoxins, trichothecene, masked mycotoxins, ELISA, T-2 toxin, T-2 toxin-glucoside*

INTRODUCTION

Species of the genus *Fusarium* are among the most destructive fungal plant pathogens known and are responsible for major yield losses during cultivation of wheat, maize, barley, and soybeans.[1−4] Many species of *Fusarium* produce mycotoxins as they grow parasitically within the plant, and ingestion of contaminated grain and food products processed from this grain causes acute and chronic health problems for both humans and animals.[5,6] Some species of *Fusarium* produce trichothecenes, sesquiterpenoid mycotoxins that inhibit eukaryotic protein synthesis and other cellular functions in animals that ingest contaminated feed.[7] Type A trichothecenes (e.g., T-2 toxin, HT-2 toxin, diacetoxyscirpenol) are of particular concern because they are considerably more toxic than the type B group (e.g., deoxynivalenol and nivalenol). As part of their defense response to xenobiotics, plants can modify the structure of several mycotoxins, including trichothecenes, by conjugation to sugars, organic acids, or sulfates, which reduce their phytotoxicity and may facilitate their sequestration.[8−12] Whereas conjugation to sugars may protect plants from the ill effects of the toxins,[13] these so-called "masked mycotoxins" present a potential food safety concern because, although toxicological data are scarce, several studies highlight the potential threat to consumer safety from these substances.[9,14−17] In particular, the possible hydrolysis of masked mycotoxins back to their toxic parents during mammalian digestion is of considerable concern.

Structurally T-2 toxin, **1**, R = Ac (Figure 1) is (2α,3α,4β,8α)-4,15-bis(acetyloxy)-3-hydroxy-12,13-epoxytrichothec-9-en-8-yl 3-methylbutanoate, which in animals is known to be predominantly metabolized to the 4-*O*-deacetylated form known as HT-2 toxin, **1**, R = H (Figure 1).[10,11] Glucoside conjugates of T-2 toxin have been reported in *Fusarium*-infected grain and *Fusarium* culture material,[10,11] although to date the anomericity of the 3-*O*-linked glucosyl group is unknown. T-2 toxin-α-glucoside, **2**, and T-2 toxin-β-glucoside, **3** (Figure 1), are anticipated to have very different physical properties. More importantly, the relative toxicities of the two anomers are as yet unknown, and the ability to test the naturally occurring form needs to be addressed.

One of the most studied masked trichothecenes is deoxynivalenol-3-glucoside, which has been reported from

contaminated cereal crops[18] and in food products derived from these crops.[19] Nuclear magnetic resonance (NMR) studies have shown that the naturally occurring glucoside is deoxynivalenol-3-β-glucoside.[8,20] Plant glucosyltransferase genes that control the conversion of deoxynivalenol to deoxynivalenol-3-β-glucoside have been identified,[21−23] and a barley glucosyltransferase gene has been engineered into wheat to improve resistance to *Fusarium* head scab. In addition, a deoxynivalenol glucosyltransferase gene has been cloned and expressed in yeast.[21] As a result, deoxynivalenol-3-β-glucoside has been prepared using yeast expression and has been available for studies on its stability during food processing and the digestive fate of this masked mycotoxin.[17,24]

Although initial studies reported that deoxynivalenol-3-β-glucoside is relatively stable to gastric conditions,[17,24,25] it was recently reported that masked mycotoxins can be deconjugated by human colon microbiota, thus releasing their parent forms.[14,26] Because parent toxins may be absorbed in the intestine, this cleavage should be considered of toxicological relevance depending on the colonic absorption of the target compound.[14]

We have recently shown that three species of *Blastobotrys* are able to biotransform T-2 toxin to T-2 toxin-α-glucoside, **2** (Figure 1),[27] and these yeast species appeared to provide an efficient way to produce the material necessary to study the digestive fate or animal toxicity of T-2 toxin-glucoside and related compounds,[27] as well as develop methods for their detection.[28] It was first important to determine which anomeric form of T-2 toxin-glucoside was produced in *Fusarium*-contaminated cereals before proceeding with larger scale studies using the yeast biotransformation product. For this reason, T-2 toxin-β-glucoside, **3** (Figure 1), was chemically synthesized, and along with T-2 toxin-α-glucoside, **2** (Figure 1), the yeast biotransformation product, compared to the T-2 toxin-glucoside found in contaminated grain. We present here a comparison of the chromatographic and spectroscopic properties of the two anomeric forms, their relative reactivities to antibodies prepared with T-2 toxin-α-glucoside[28] or T-2 toxin, their relative phytotoxicities, the stabilities and bioavailabilities of these masked mycotoxins after ingestion, and the anomeric form of the naturally occurring T-2 toxin-glucoside. These results become particularly relevant if international standards are developed for the detection and quantitation of T-2 toxin and T-2 toxin-glucoside in cereal grains and products made from them.

MATERIALS AND METHODS

NMR Spectroscopy. NMR experiments were performed with acetone-d_6 as the solvent on a Bruker Avance AMX 500 spectrometer (Bruker BioSpin Corp., Billerica, MA, USA) operating at 500.11 MHz using a standard 5 mm *z*-gradient BBI probe at 27 °C. Chemical shifts are reported as parts per million from tetramethylsilane calculated from the lock solvent. The deuterated solvents used were obtained from Cambridge Isotope Laboratories (Andover, MA, USA). The pulse sequences used were those supplied by Bruker, and processing was done with the Bruker TOPSPIN software package (v. 1.3). Additional NMR experiments with tetra-*O*-TIPS-β-glucosyl T-2 toxin, **6**, and T-2 toxin-β-glucoside, **3**, were performed on an Agilent 600 MHz NMR spectrometer (Agilent, Santa Clara, CA, USA).

Naturally Contaminated Cereal Samples. One wheat and one oat sample were extracted for comparison with T-2 toxin-glucoside standards. Samples were finely ground with a Tecator Cyclotec 1093 (International PBI, Milan, Italy) laboratory mill equipped with a 500 mm sieve. Ten grams of each ground sample was extracted with 30 mL of acetonitrile/water (84:16 v/v) by orbital shaking for 2 h. After filtration through filter paper, 10 mL of extract was cleaned with a Mycosep 227 column (Romer Laboratories, Union, MO, USA). Purified extract (6 mL, equivalent to 2 g of sample) was dried under an air stream at 50 °C.

Liquid Chromatography−Mass Spectrometry (LC-MS) Analysis. Extracts of naturally contaminated cereals or T-2 toxin-glucoside standards were analyzed by LC coupled to tandem mass spectrometry (MS/MS) as previously described.[10,11] LC-MS/MS analyses were performed by a QTrap MS/MS system, from Applied Biosystems (Foster City, CA, USA) equipped with an electrospray ionization (ESI) interface and an 1100 series micro-LC system comprising a binary pump and a microautosampler from Agilent Technologies (Waldbronn, Germany). The column used was a 150 × 3 mm i.d., 4 μm, Synergi Hydro, with a 4 mm × 2 mm i.d., 10 μm, Aqua C18 guard column (Phenomenex, Torrance, CA, USA). The flow rate of the mobile phase was 200 μL/min, whereas the injection volume was 20 μL. Eluent A was water and eluent B was methanol, both containing 5 mM ammonium acetate. The elution was performed by changing the mobile phase composition as follows. Eluent B was increased from 20 to 40% in 3 min, then increased to 63% in 35 min, and kept constant for 9 min. For column re-equilibration, eluent B was decreased to 20% in 1 min and kept constant for 9 min. For MS analyses, the ESI interface was used with the following settings: temperature, 350 °C; curtain gas, nitrogen, 30 psi; nebulizer gas, air, 10 psi; auxiliary gas, air, 30 psi; ion spray voltage, +4500 V, positive ion mode.

The MS was operated in enhanced product ion (EPI) mode, applying a collision energy (CE) for stimulation of ion fragmentation of 10, or multiple reaction monitoring (MRM) mode to observe several distinctive ions produced upon fragmentation of the toxin with ammonium adduct $[M + NH_4]^+$ ion. For T-2 toxin-glucoside, the parent ion (m/z 646) and fragment ions were monitored to observe

DOI: 10.1021/jf504737f
J. Agric. Food Chem. 2015, 63, 731−738

elution of the separated T-2 toxin conjugates. Operation of the LC-MS/MS instrument and interpretation of the acquired data were done utilizing the Analyst (ABSCIEX) software provided by the MS instrument manufacturer.

Preparation of T-2 Toxin-glucosides. T-2 toxin-glucosides were prepared using T-2 toxin that had been isolated and purified from liquid cultures of *Fusarium sporotrichioides* strain 5493cos9-1#11 as described previously.[27] T-2 toxin-α-glucoside, **2** (optical rotation, $[\alpha]_D^{20}$ = +79.74, *c* 0.153, CH_3OH), was prepared by feeding T-2 toxin to *Blastobotrys muscicola* cultures as described previously.[27] T-2 toxin-β-glucoside, **3**, was synthesized as described below (Figure 2).

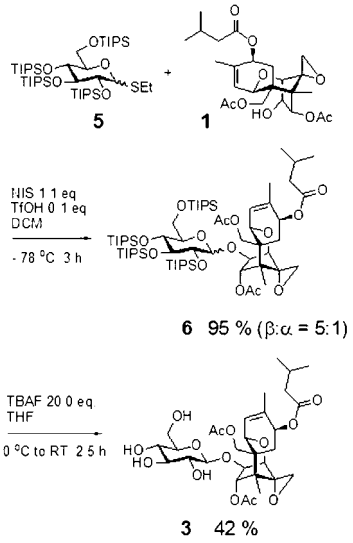

Figure 2. Synthesis of T-2 toxin-β-glucoside, **3**.

Ethyl 2,3,4,6-Tetra-*O*-acetyl-1-thio-D-glucopyranoside, 4.[29] Pentaacetyl-β-glucopyranose (1.0 g, 2.56 mmol) was dissolved in dichloromethane (20 mL), and ethanethiol (220 μL, 3.07 mmol) was added followed by BF_3OEt (1.6 mL, 12.8 mmol) at ambient temperature under an argon atmosphere. After 2 h, the reaction mixture was diluted with dichloromethane and washed with saturated sodium bicarbonate. The aqueous phase was extracted with dichloromethane, and the combined organic phase was washed with brine and dried over sodium sulfate. The filtrate was concentrated, and the residue was purified by column chromatography over silica gel (hexane/ethyl acetate, 1:1), giving 660 mg (67%) of a colorless oil in the form of a 1:1 α,β-mixture.

Ethyl 2,3,4,6-Tetra-*O*-triisopropylsilyl-1-thio-D-glucopyranoside, 5.[30] To a solution of **4** (660 mg, 1.68 mmol) in methanol (16.5 mL) was added sodium methoxide (10 mg, 0.17 mmol) at ambient temperature. After 1 h, the reaction mixture was neutralized with Amberlite 120. The resin was filtered off, and the filtrate was concentrated to give a colorless oil (340 mg),[31] which was dissolved in 2,6-lutidine (15 mL) (Sigma-Aldrich, St. Louis, MO, USA) and treated with triisopropylsilyl trifluoromethanesulfonate (2 mL, 4.9 mmol) (Sigma-Aldrich). The reaction mixture was heated to 130 °C, and after 1.5 h, further triisopropylsilyl trifluoromethanesulfonate (2 mL, 4.9 mmol) was added. The reaction mixture was maintained at 130 °C for 2 h, then further triisopropylsilyl trifluoromethanesulfonate (2 mL, 4.9 mmol) was added. After 2 h, the reaction mixture was cooled to room temperature, diluted with hexane, and washed with 0.1 M HCl until the water phase remained acidic. The organic layer was washed with brine and dried over sodium sulfate. The filtrate was concentrated and purified by column chromatography over silica gel eluting with hexane, a colorless oil (680 mg, 53%) as a 1:1 mixture of α,β-isomers.

Tetra-*O*-TIPS-β-glucosyl T-2 Toxin, 6. A solution of **5** (110 mg, 0.13 mmol) and T-2 toxin (40 mg, 0.086 mmol) was dissolved in dry dichloromethane (0.4 mL) with 3 Å acid-washed molecular sieves (Alfa Aesar, Ward Hill, MA, USA). The reaction mixture was cooled to −78 °C under an argon atmosphere, and then *N*-iodosuccinimide (26 mg, 0.15 mmol) (Chem-Impex Int. Inc., Wood Dale, IL, USA) was added. After 0.5 h, trifluoromethanesulfonic acid (2.3 μL, 0.04 mmol) (Sigma-Aldrich) was added to the cold solution. After 3 h, the reaction mixture was quenched with triethylamine (EMD, Philadelphia, PA, USA), and the molecular sieves were filtered off. The filtrate was concentrated and purified by column chromatography over silica gel (eluent, hexane/ethyl acetate 4:1) to give a colorless oil (100 mg, 95%) as a 1:5 mixture of α,β-isomers.

^{1}H NMR (600 MHz in $CDCl_3$) for β-isomer: δ 5.66 (d, *J* = 3.3 Hz, 1H, H-4), 5.63 (d, *J* = 5.9 Hz, 1H, H-10), 5.27 (d, *J* = 5.5 Hz, 1H, H-8), 4.91 (d, *J* = 5.9 Hz, 1H, H-26), 4.31 (d, *J* = 12.1 Hz, 1H, H-15a), 4.27 (dd, *J* = 4.8, 3.67 Hz, 1H, H-3), 4.10 (d, *J* = 5.5 Hz, 1H, H-11), 4.08 (overlapped with H-15b, 1H, H-28), 4.07 (d, *J* = 12.5 Hz, 1H, H-15b), 3.95 (d, *J* = 2.9 Hz, 1H, H-29), 3.90 (d, *J* = 5.9 Hz, 1H, H-27), 3.89 (d, *J* = 5.8 Hz, 1H, H-30), 3.84 (d, *J* = 5.1 Hz, 2H, H-31a,b), 3.73 (d, *J* = 4.8 Hz, 1H, H-2), 2.92 (d, *J* = 4.0 Hz, 1H, H-13a), 2.75 (d, *J* = 4.0 Hz, 1H, H-13b), 2.29 (dd, *J* = 15.0, 5.9 Hz, 1H, H-7a), 2.09 (m, 1H, H-18), 2.07 (s, 1H, H-23), 2.05 (m, 1H, H-19), 2.00 (s, H-25), 1.99 (overlapped with H-25, 1H, H-7b), 1.72 (s, H-16), 0.95 (d, *J* = 6.2 or 5.1 Hz, 1H, H-20), 0.94 (d, *J* = 6.2 or 5.1 Hz, 1H, H-21), 0.67 (s, H-14); ^{13}C NMR (150 MHz in CD_2Cl_3) δ 172.4 (C-17), 170.2 (C-22), 169.8 (C-24), 135.1 (C-9), 124.1 (C-10), 103.4 (C-26), 83.5 (C-30), 82.8 (C-3), 80.6 (C-4), 79.5 (C-2), 78.0 (C-28), 77.3 (C-27), 71.1 (C-29), 68.0 (C-8), 66.8 (C-11), 65.7 (C-31), 64.3 (C-15), 64.1 (C-12), 48.5 (C-5), 46.7 (C-13), 43.4 (C-18), 43.0 (C-6), 26.9 (C-7), 25.7 (C-19), 22.1 (C-20), 22.1 (C-21), 20.9 (C-25), 20.6 (C-23), 20.1 (C-16), 6.2 (C-14); HRMS-ESI (*m*/*z*) $[M + Na]^+$ calcd for $C_{66}H_{124}O_{14}Si_4Na$ 1275.7966, found 1275.7947.

T-2 Toxin-β-glucoside, 3. The above α,β-mixture of **6** (100 mg, 0.08 mmol) was dissolved in THF (1.0 mL) and treated at 0 °C with tetrabutylammonium fluoride (1.6 mL, 1.6 mmol) (Acros-Thermo Fisher Scientific Inc., Waltham, MA, USA). The reaction mixture was allowed to warm to room temperature and stirred for 2.5 h, after which it was concentrated and purified by column chromatography over silica gel (eluent, chloroform/methanol, 8:1) to give a colorless oil (42 mg, 84%) of a 1:5 α,β-mixture. Further purification of this mixture by C18 HPLC (water−acetonitrile 25−40%) and freeze-drying gave 21 mg (42%) of the pure β-isomer, **3**, as a white amorphous powder.

^{1}H NMR (600 MHz in CD_3OD) δ 5.96 (d, *J* = 3.0 Hz, 1H, H-4), 5.77 (d, *J* = 6.00 Hz, 1H, H-10), 5.31 (d, *J* = 5.6 Hz, 1H, H-8), 4.46 (dd, *J* = 4.9, 3.2 Hz, 1H, H-3), 4.43 (d, *J* = 7.7 Hz, 1H, H-26), 4.37 (d, *J* = 6.2 Hz, 1H, H-11), 4.36 (d, *J* = 12.7 Hz, 1H, H-15a), 4.08 (d, *J* = 12.5 Hz, 1H, H-15b), 3.81 (dd, *J* = 12.0, 2.2 Hz, 1H, H-31a), 3.70 (d, *J* = 5.0 Hz, 1H, H-2), 3.63 (dd, *J* = 12.0, 5.8 Hz, 1H, H-31b), 3.34 (t, *J* = 9.0, 8.9 Hz, 1H, H-28), 3.28 (t, *J* = 9.0, 9.0 Hz, 1H, H-29), 3.24 (dd, *J* = 9.0, 7.8 Hz, 1H, H-27), 3.19 (ddd, *J* = 9.6, 5.8, 2.2 Hz, 1H, H-30), 3.03 (d, *J* = 3.8 Hz, 1H, H-13a), 2.85 (d, *J* = 3.9 Hz, 1H, H-13b), 2.36 (dd, *J* = 15.2, 6.0 Hz, 1H, H-7a), 2.14 (dd, *J* = 7.6, 2.4 Hz, 1H, H-18), 2.07 (s, H-23), 2.05 (s, 1H, H-25), 2.05 (m, H-19), 1.92 (d, *J* = 15.2 Hz, 1H, H-7b), 1.73 (s, H-16), 0.95 (d, *J* = 6.6 Hz, 1H, H-20), 0.94 (d, *J* = 6.6 Hz, 1H, H-21), 0.72 (s, 1H, H-14); ^{13}C NMR (150 MHz in CD_2Cl_3) δ 174.1 (C-17), 170.8 (C-24), 170.7 (C-22), 137.2 (C-9), 125.2 (C-10), 103.8 (C-26), 83.9 (C-3), 81.3 (C-4), 80.6 (C-2), 78.4 (C-30), 78.2 (C-28), 74.9 (C-27), 71.6 (C-29), 69.4 (C-8), 68.6 (C-11), 65.9 (C-15), 65.4 (C-12), 62.8 (C-31), 50.2 (C-5), 48.0 (C-13), 44.6 (C-18), 44.5 (C-6), 28.9 (C-7), 27.0 (C-19), 22.9 (C-20), 22.8 (C-21), 21.3 (C-25), 20.9 (C-23), 20.6 (C-16), 7.2 (C-14); HRMS-ESI (*m*/*z*) $[M + Na]^+$ calcd for $C_{30}H_{44}O_{14}Na$ 651.2629, found 651.2618; optical rotation $[\alpha]_D^{20}$ = +7.51 (*c* 0.080, CH_3OH).

ELISA Tests. The responses of the T-2 glucoside anomers were evaluated in two immunoassay formats. The first of these was a competitive indirect enzyme-linked immunosorbent assay (CI-ELISA) based upon an antibody (Mab 2-13) developed against T-2 toxin-3-α-glucoside, conjugated to ovalbumin (e.g., T-2G−OVA), as described previously.[28] The second immunoassay format was a commercial test kit previously validated to detect T-2 toxin and HT-2 toxin (Veratox for T-2/HT-2) (Neogen Corp., Lansing, MI, USA). Assays were performed as described in the test kit instructions. For consistency with the methanol content indicated in the test kit instructions, the

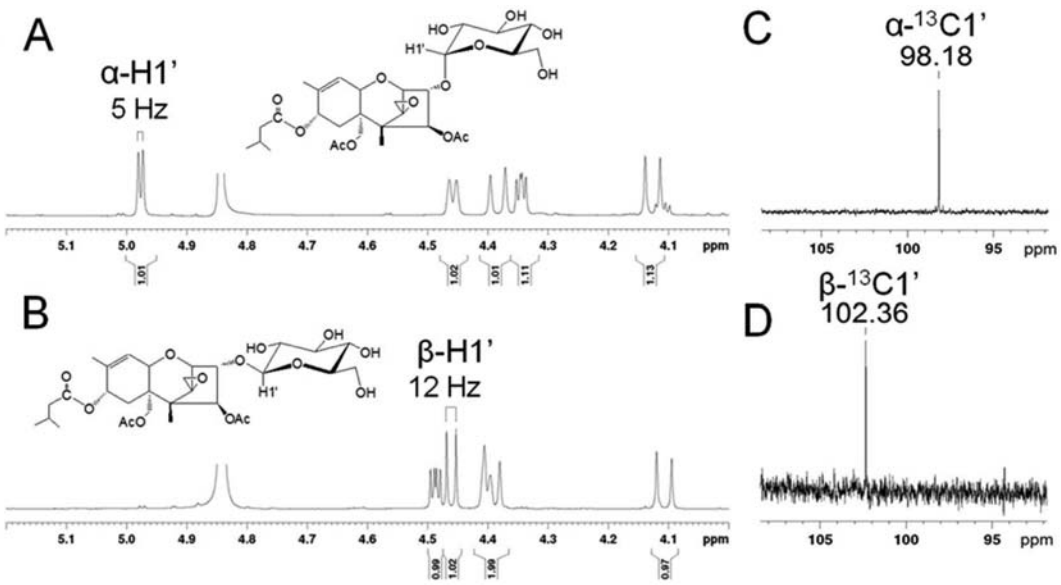

Figure 3. Proton NMR spectra of (A) T-2 toxin-α-glucoside, (B) T-2 toxin-β-glucoside with signals for the H1 anomeric proton indicated and ^{13}C NMR anomeric carbon signals of (C) T-2 toxin-α-glucoside (98.18 ppm) and (D) T-2 toxin-β-glucoside (102.36 ppm).

T-2 toxin-glucoside standards were prepared in 35% (v/v) methanol/water.

Phytotoxicity. The single-celled alga *Chlamydomonas reinhardtii* was used to assess the relative phytotoxicity of T-2 toxin, T-2 toxin-α-glucoside, and T-2 toxin-β-glucoside, as described previously.[27,32] Triplicate cultures (10 mL) were initiated with 10^5 cells/mL containing a 100 μM concentration of an individual trichothecene and grown for 6 days under fluorescent lights, with agitation of 200 rpm. Culture doublings were calculated as follows: (log of the final density − log of the initial cell density)/log 2.

Artificial Saliva Digestion Assay. The in vitro digestion experiment was performed as described previously.[16] Briefly, the main digestive juices were prepared by mixing salts and enzymes[33] and were preheated at 37 °C before use. A volume of 200 μL of a water/methanol (25:75, v/v) solution containing the target compounds was transferred in a 4 mL septum vial, and the solvent was evaporated under nitrogen. The in vitro digestion was started by adding 75 μL of artificial saliva to 200 μL of the water/methanol (25:75 v/v) solution containing the target analyte (500 μg/L). After 5 min of incubation at 37 °C, 150 μL of artificial gastric juice was added and the mixture was incubated again for 2 h. At the end of the gastric step, 25 μL of 1 M bicarbonate solution with 150 μL of artificial duodenal juice and 75 μL of artificial bile juice were added, and then a final incubation step of 2 h was performed. Finally, 25 μL of acetonitrile was added to stop the reactions, and the sample was centrifuged for 10 min at 10000 rpm, prior to direct LC-MS/MS analysis.

In Vitro Human Colonic Fermentation Assay. Human colonic fermentation of T-2 toxin-α-glucoside, T-2 toxin-β-glucoside, and T-2 toxin was carried out as described previously.[14] Fresh feces were collected from three different healthy and nonsmoker donors. These samples were immediately placed in an anaerobic environment and then mixed and weighed to obtain a 10% fecal solution in a phosphate saline buffer (PBS). For each sample 1.8 mL of growth medium, prepared as described previously,[14] and 1.8 mL of fecal solution were mixed and added to 0.4 mL of a toxin solution, at a final concentration of 500 μg/L. Each vial was then treated with a slight nitrogen flow to eliminate oxygen and perform fermentations under anaerobic condition. Samples were incubated in a water bath at 37 °C and shaken at a rate of 200 strokes/min. Fermentations were stopped immediately to have controls and then after 30 min and 24 h, by cooling samples to room temperature and adding 0.4 mL of acetonitrile. Samples were immediately centrifuged at 14000 rpm for 10 min and stored at −20 °C. At the same time, samples without added mycotoxin were prepared. All of the fermentations were performed in triplicate. Samples were diluted adding acetonitrile (1:2 v/v) and directly analyzed for T-2 toxin-glucoside, T-2 toxin, and HT-2 toxin by LC-MS/MS using MRM as described above.

RESULTS AND DISCUSSION

NMR Analysis of T-2 Toxin-α-glucoside, 2, and T-2 Toxin-β-glucoside, 3. NMR spectra were recorded for T-2 toxin-α-glucoside, obtained by yeast biotransformation (Figure 3A,C) and for chemically synthesized T-2 toxin-β-glucoside (Figure 3B,D). Both compounds are characterized by two spin systems due to a single glucopyranosyl ring and the trichothecene aglycone. The anomeric linkages are characterized by proton signals in the 4.5−5.5 ppm range and the ^{13}C signals by proton signals between 95 and 105 ppm. Consistent with expectations, T-2 toxin-α-glucoside gave a doublet at 4.98 ppm that integrates to a single proton (Figure 3A) and correlates to an adjacent ^{13}C signal at 98.18 ppm (Figure 3C). The observed $J_{1,2}$ coupling constant of 5 Hz is consistent with a small H1eq−H2ax dihedral angle that is characteristic for α anomers. The chemically synthesized T-2 toxin-β-glucoside is similarly characterized by a larger H1ax−H2ax bond angle, resulting in a definitive $J_{1,2}$ coupling constant of 12 Hz for the β-anomeric proton at 4.46 ppm (Figure 3B). This H-1 proton correlates to the β-C1 ^{13}C NMR anomeric signal at 102.36 ppm (Figure 3D). Hence, the T-2 toxin-glucoside anomers are defined by the observed ^1H and ^{13}C chemical shifts and by the characteristic $J_{1,2}$ coupling constants. These assignments were confirmed by HSQC and, together with HMBC, DEPT, COSY, and NOESY experiments, enable the complete NMR assignment of both epimers.

LC-MS Analysis of T-2 Toxin-α-glucoside and T-2 Toxin-β-glucoside Standards. The two epimeric standards, T-2 toxin-α-glucoside prepared with yeast and the synthetic T-2 toxin-β-glucoside, could be separated with LC (Figure 4). In EPI mode, T-2 toxin-α-glucoside and T-2 toxin-β-glucoside $[M + NH_4]^+$ ions were subjected to collision-induced dissociation. Under these conditions, T-2 toxin-α-glucoside more readily ionized to yield an $[M + H]^+$ ion than the T-2 toxin β-glucoside, as shown by the relative intensities of the

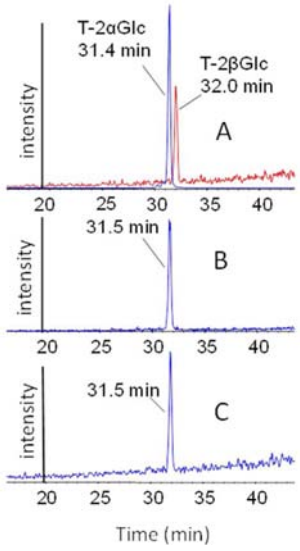

Figure 4. LC-MS/MS chromatograms of (A) T-2 toxin-α-glucoside (T-2αGlc) and T-2 toxin-β-glucoside (T-2βGlc) standards, (B) T-2 toxin-glucoside extracted from wheat, and (C) T-2 toxin-glucoside extracted from oats.

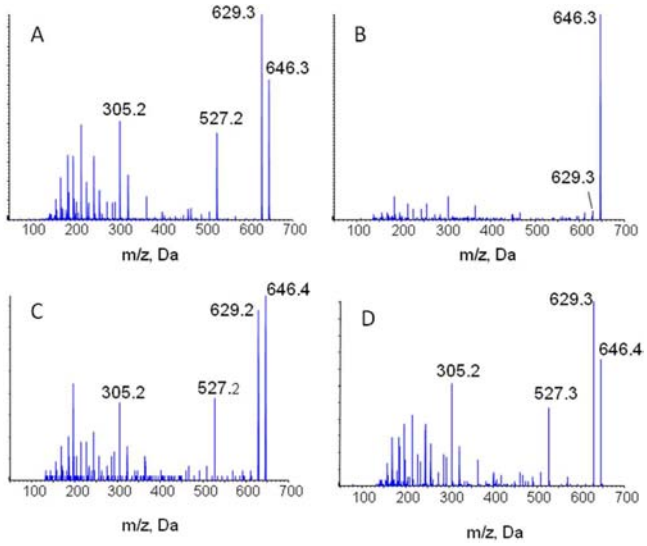

Figure 5. Tandem mass spectrum of the $[M + NH_4]^+$ ion of (A) T-2 toxin-α-glucoside, (B) T-2 toxin-β-glucoside, (C) T-2 toxin-glucoside from oats, and (D) T-2 toxin-glucoside from wheat.

residual $[M + NH_4]^+$ and $[M + H]^+$ ions (Figure 5). Other fragment ions were similar to those previously observed from *Fusarium*-infected grain.[10,11]

LC-MS Analysis of Naturally Contaminated Cereals. To determine the form of T-2 toxin-glucoside present in contaminated oats and wheat, extracts were analyzed with LC-MS/MS and compared to the standard T-2 toxin-α-glucoside and T-2 toxin-β-glucoside (Figure 4). Under the conditions used, T-2 toxin-α-glucoside eluted at 31.4 min and T-2 toxin-β-glucoside at 32.0 min. T-2 toxin-glucoside was detected at 31.5 min in oat and wheat samples, consistent with T-2 toxin-α-glucoside (Figure 4). In addition, there were differences in the mass spectra of the two isomers, showing the same fragment ions but with different relative intensities. Similar to T-2 toxin-α-glucoside, the yeast biotransformation product, the T-2 toxin-glucoside from oats and wheat, had the prominent $[M + H]^+$ product ion from the $[M + NH_4]^+$ ion (Figure 5).

Digestive Study on Anomeric Forms of T-2 Toxin-glucoside. In this study, the stability under in vitro gastrointestinal conditions and the catabolic fate of both T-2 toxin-α-glucoside and T-2 toxin-β-glucoside were tested in a human gut microbioma assay and compared to T-2 toxin. The simulated digestion assay used was developed to mimic the human gastrointestinal process.[14,16]

We found that the T-2 toxin-glucosides were unchanged after incubation with human artificial saliva. These results are similar to those reported for deoxynivalenol glucoside and zearalenone glucoside[14] and further demonstrate the stability of some α- and β-glucosidic bonds upon digestion.

In contrast to zearalenone glucoside, which was hydrolyzed in the first 30 min of colonic fermentation,[9] T-2 toxin and the T-2 toxin-glucosides were relatively stable for the first 30 min (Figure 6). There was significant degradation after 24 h (Figure 6). T-2 toxin was mainly transformed into its derivative HT-2 toxin (83% at t = 24 h). T-2 toxin-α-glucoside and T-2 toxin-β-glucoside were both strongly degraded after 24 h, with <30% of the starting material remaining. The degradation pathway is different between α- and β-forms. The latter was mainly cleaved to release its precursor T-2 toxin (58%) with a smaller percentage of HT-2 toxin (12%), whereas the former is converted into T-2 toxin (13%), HT-2 toxin (30%), and other metabolites of unknown structure and toxicity (33%).

Because smaller amounts of T-2 toxin remained following colonic fermentation with T-2 toxin-α-glucoside, it may pose less of a risk than T-2 toxin-β-glucoside, which is not known to occur in crops. However, T-2 toxin-α-glucoside was also converted into other, as yet uncharacterized, compounds (Figure 6). In addition to T-2 toxin and HT-2 toxin, other possible products of T-2 toxin-glucoside include HT-2 toxin-glucoside, T-2 triol, and T-2 tetraol. It is important to consider the toxicity of all of the products when the risk posed by T-2 toxin-α-glucoside in grain is assessed.

Phytotoxicity. The relative toxicity of T-2 toxin and the T-2 toxin-glucosides was tested with *C. reinhardtii* cultures. Previous studies have shown that T-2 toxin is quite phytotoxic[32] and T-2 toxin-α-glucoside is nontoxic.[27] In this study, cultures grown in 100 μM T-2 had only a slight increase in the number of cells, with 0.6 doubling after 4 days. In contrast, neither T-2 toxin-α-glucoside nor T-2 toxin-β-glucoside was phytotoxic, with 5.4 and

Table 1. Cross-Reactivity of ELISA toward T-2 Toxin-α-glucoside and T-2 Toxin-β-glucoside

analogue	av IC_{50} ± 1 SD (ng/mL)	cross-reactivity (relative to T-2 toxin, %)
Mab 2-13 ELISA		
T-2 toxin[a]	3.3 ± 0.1	100
T-2 toxin-α-glucoside	3.04 ± 0.16	108 ± 5.7
T-2 toxin-β-glucoside	5.80 ± 0.16	56.9 ± 1.6
Commercial T-2 Toxin/HT-2 Toxin Kit		
T-2 toxin	3.03 ± 0.13	100
T-2 toxin-α-glucoside	18.9 ± 2.4	16.0 ± 2.0
T-2 toxin-β-glucoside	6.65 ± 0.58	45.5 ± 4.0

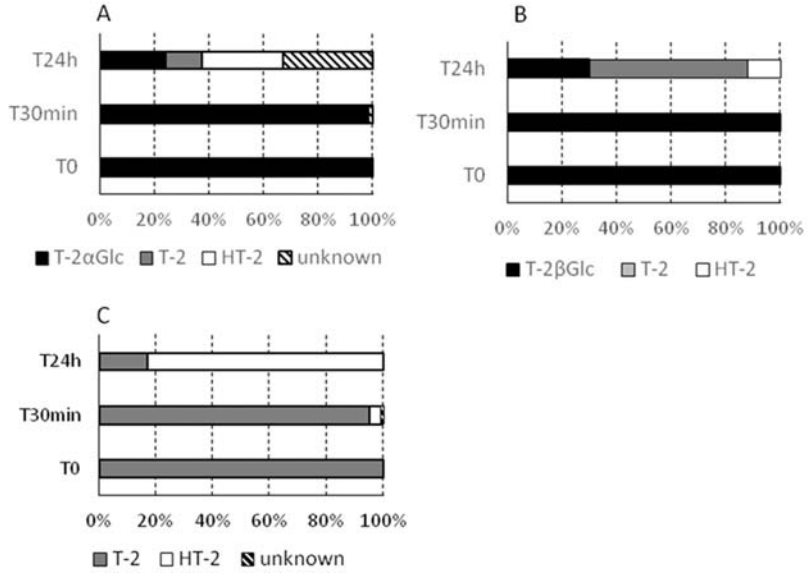

Figure 6. Degradation upon human colonic microbiota fermentation of (A) T-2 toxin-α-glucoside (T-2αGlc), (B) T-2 toxin-β-glucoside (T-2βGlc), and (C) T-2 toxin (T-2). HT-2 toxin (HT-2).

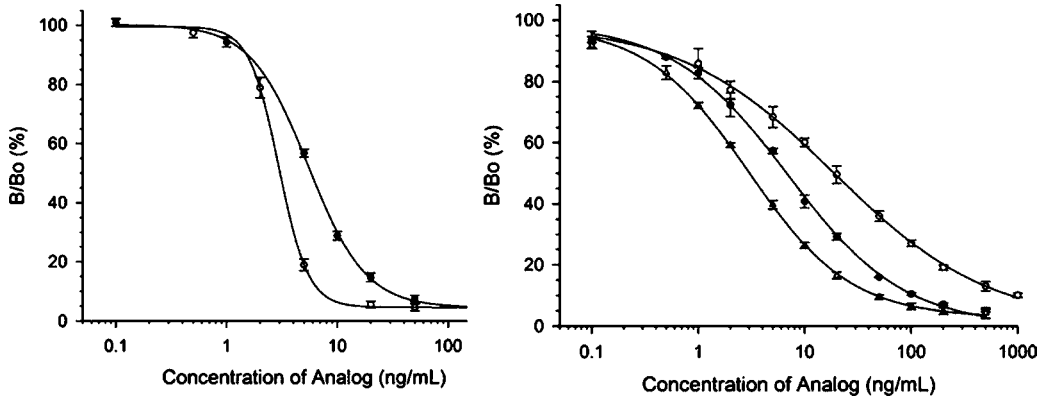

Figure 7. ELISA responses. (A) CI-ELISA responses of T-2 toxin-α-glucoside (open circles) and T-2 toxin-β-glucoside (solid circles) with Mab 2-13. Data shown are the averages from four plates, with six replicates per toxin concentration per plate (n = 24), ± 1 standard deviation. Curves represent the fit of a logistic dose−response equation over the indicated concentration range (0.1−200 ng/mL). (B) ELISA responses of T-2 toxin (open triangles), T-2 toxin-α-glucoside (open circles), and T-2 toxin-β-glucoside (solid circles) to Neogen Veratox T-2/HT-2 antibody. Data shown are the averages from three plates per toxin, with four replicates per toxin concentration per plate (n = 12), ± 1 standard deviation. Curves represent the fit of a logistic dose−response equation over the indicated concentration range (0.1−1000 ng/mL).

5.5 doublings, respectively, which are similar to the 5.3 doublings observed for cultures treated with acetone alone.

Antibody Detection of T-2 Toxin and T-2 Toxin-glucosides with Two Immunoassays. T-2 toxin-glucoside standards were each tested in two immunoassays. The first immunoassay was a competitive indirect ELISA format using Mab 2-13, an antibody developed with T-2 toxin-α-glucoside.[28] Mab 2-13 recognized T-2 toxin α-glucoside slightly better than T-2 toxin (cross reaction 108%), whereas T-2 toxin-β-glucoside was recognized more poorly, at about 57% relative to T-2 toxin (Table 1; Figure 7A). This makes this antibody-based test suitable for the detection of both T-2 toxin and the naturally occurring T-2 toxin-α-glucoside.

The second immunoassay was a commercially available T-2/HT-2 kit. This kit was used to determine if an ELISA, developed before the glucosides of T-2 and HT-2 toxins were even discovered, could detect these "masked" mycotoxins. The commercial ELISA test kit for T-2 toxin and HT-2 toxin detection performed very well for detecting T-2 toxin with good sensitivity and good reproducibility. In addition, the kit cross-reacted fairly well with the T-2 toxin-β-glucoside, but poorly with the T-2 toxin-α-glucoside (Table 1; Figure 7B). However, given that T-2 toxin-α-glucoside is the form found in naturally contaminated samples and that the cross-reaction with this anomer was only about 16%, this test kit would not be recommended for the simultaneous screening of T-2 toxin and T-2 toxin-α-glucoside.

The ability of plants to form trichothecene glucosides can be seen as a detoxification mechanism that plants use when infected with trichothecene-producing fungi. Because trichothecenes can be virulence factors in plant disease,[34] expression of trichothecene UGT genes in plants is a potential way to increase disease resistance to trichothecene-producing fungi. This approach may reduce disease and thereby decrease the amount of trichothecenes. However, both the trichothecenes and their masked forms need to be considered to accurately

DOI: 10.1021/jf504737f
J. Agric. Food Chem. 2015, 63, 731−738

assess the risk to human and animal health posed by plant material contaminated with trichothecenes.

Sufficient amounts of T-2 toxin-glucoside are needed to determine the risk posed by the masked form of T-2 toxin in cereals, to develop reliable methods for their detection, and to study the stability, digestive fate, and toxicity of T-2 toxin-glucoside formed in plant materials. Whereas the synthesis of deoxynivalenol-glucoside is relatively straightforward,[35] this method was not amenable to the preparation of T-2 toxin-glucosides because the isovaleryl and acetyl groups are labile during the synthesis. A synthesis employing a superarmed tetra-*O*-triisopropylsilyl protected donor[36] offered a way to selectively remove the protecting groups from the sugar portion of the glucoside without disturbing the isovaleryl and acetyl groups of T-2 toxin, thus providing a means to synthesize T-2 toxin-β-glucoside. Microbial T-2 toxin-α-glucoside was prepared as a single anomer with *B. muscicola* yeast cultures,[27] On the basis of LC and LC-MS chromatographic comparisons and MS/MS analyses, the T-2 toxin-glucoside occurring in contaminated wheat and oats was found to be identical to the yeast biotransformation product, T-2 toxin-α-glucoside.

It is notable that naturally occurring T-2 glucoside has an α-linked sugar, whereas naturally occurring deoxynivalenol glucoside has a β-linked sugar. Although β-linked sugars are more commonly found with xenobiotics and natural products including flavonoids,[37] there is a report of *Fusarium* cultures producing an α-linked glycoside, 15-monoacetoxyscirpenol-4-α-glucoside.[38] The *Blastobotrys* glucosyltransferase that converts T-2 toxin to T-2 toxin-α-glucoside has not been identified, but there may be substrate preferences between the UGT that lead to trichothecene α- or β-glucosides.

Although the focus of this study was the T-2 toxin-glucosides, HT-2 toxin-glucosides have also been reported in contaminated grain[11] and in culture material.[10] They may be formed either by hydrolysis of T-2 toxin-α-glucoside or by conversion of T-2 toxin to HT-2 toxin followed by glycosylation at C-3 or C-4. It is possible that the latter route may utilize different glucosyltransferases that result in a β orientation. To date, no plant UGT that converts T-2 toxin to T-2 toxin-α-glucoside has been identified. Numerous glucosyltransferases were screened to identify one that had good substrate specificity for deoxynivalenol.[23] Although the T-2 toxin-glucoside found in naturally contaminated oats and wheat was identical to the T-2 toxin-α-glucoside prepared with yeast cultures,[27] the anomericity of HT-2 toxin-glucosides has not been determined.

The present study has demonstrated that naturally occurring T-2 toxin-glucoside has an α-linked sugar and that T-2 toxin-α-glucoside can be prepared with *B. muscicola* in sufficient quantity to study its animal toxicity. The U.S. FDA has not provided guidance levels to the agricultural industry for T-2 toxin or related trichothecenes. The European Food Safety Authority (EFSA) established a group tolerable daily intake of 100 ng/kg body weight for T-2 and HT-2 toxins.[39] However, at present it is not possible to perform a proper risk assessment for masked mycotoxins in food, due to the lack of data on exposure and toxic properties. Masked mycotoxins may elude analysis because of altered physical properties or because of modification of an epitope recognized by antibodies used for the detection, leading to an underestimation of the total mycotoxin load. Possible release during food processing is also a concern, and EFSA currently has a working group on the public health risk of masked mycotoxins in food and animal feed. Research on masked mycotoxins is hampered by the nonavailability of analytical standards or calibrants, and only one compound, deoxynivalenol-3-β-glucoside, is commercially available.

The occurrence of T-2 toxin-α-glucoside in wheat and oat samples, and its metabolism by microbes during digestion, suggests that there is a risk in underestimation of the total T-2 toxin load and a need to monitor both mycotoxins and their conjugated forms in cereals and food products. To promote research efforts in the area of masked mycotoxins, T-2 toxin-α-glucoside has now been made available to the scientific community by the authors.

ABSTRACT: The fruit of *Ziziphus jujuba*, named as jujube or Chinese date, is used as a health supplement worldwide. Two kinds of jujubes are commonly found in the market: immature jujubes eaten as fruits, and mature jujubes employed as medicinal herbs. To study the variation of jujubes at two developmental stages, we investigated their chemical and biological properties by metabolic profiling and cellular assays. In NMR profiling, the levels of 11 metabolites were measured. Statistically differences in the levels of threonine, alanine, acetate, creatine, glucose, sucrose, and formate were found between mature and immature jujubes. In parallel, their neuro-protecting and erythropoietic activities were compared. The water extract of mature jujube possessed better effect in inducing neurofilament expression than that of the immature one, while immature jujube extract performed better in activating HRE-mediated transcriptional activity. These findings suggest the maturity of jujube has to be considered when it is being used for health food products.

KEYWORDS: *Rhamnaceae, Ziziphus jujuba, maturity, NMR, metabolic profiling, neurofilament expression, hypoxia response element*

INTRODUCTION

Jujube is the fruit of *Ziziphus jujuba* Mill. from the Rhamnaceae family, commonly named Chinese date or red date. According to ancient Chinese medical theory in *Shennong Bencao Jing* (300 BC−200 AD), one of the usages of jujube was to play a trophic role in our brain by calming down the mind and improving quality of sleep, as such, which prolonged one's life-span. In addition, the daily consumption of jujube-containing herbal decoction is also considered to enhance the "Qi" (the vital energy) and to nourish the "Blood" (body circulation) of individuals.

Current nutritional findings have reported that carbohydrates, minerals, vitamins, and amino acids are major ingredients in jujube.[1,2] Moreover, pharmacological data have shown that the fruit has abilities to perform antioxidant actions,[3,4] immunological activity,[5] a potential sedative effect,[6] treatment of jaundice,[7] and anti-inflammatory effects.[8] Previously, we have demonstrated the neuronal activity of jujube in defending cultured PC12 cells against oxidative stress,[9] and its beneficial roles in neuronal differentiation.[10] Jujube could stimulate the expression of neurotrophic factor in cultured astrocytes.[11] Besides, jujube water extract has abilities to stimulate the expression of erythropoietin (EPO) in cultured Hep3B cells[12] and to regulate cytokine expression in cultured RAW 264.7 cells.[13]

Two forms of jujubes are usually found in the marketplace: unripe jujubes eaten as fruits and ripe jujubes considered as medicinal herbs. However, it is unclear whether the unripe jujube is exactly the same as the ripe one in terms of chemical composition and pharmacological activity. Currently, metabolic profiling methods are employed increasingly to seek quality control of medicinal herbs.[14] Here, we aim to employ ^{1}H NMR (nuclear magnetic resonance) metabolic profiling to identify jujube water extracts at two stages of maturity. In addition, the pharmacological properties of two developmental stages of jujube were compared, which included: (i) the neuro-protecting activity by using the induction of neurofilament in cultured PC12 cells, and (ii) the erythropoietic activity by revealing the activation of the hypoxia response element (HRE) in cultured Hep3B cells.

MATERIALS AND METHODS

Preparation of Herbal Extract. The fruits of *Z. jujuba* cultivated in Hebei Cangzhou at two stages of maturity were collected in 2012. Classification of jujube: unripe jujube was collected in September 2012 with a yellow-green background having mahogany-colored spots. Ripe jujube was harvested in October 2012 when its appearance turned entirely red, and the fruit began to soften and wrinkle. The raw materials were authenticated by Dr. Tina Dong according to their morphological properties, having the voucher numbers voucher #12-09-A for immature jujube and voucher #12-10-A for mature jujube. The voucher specimens are kept at the Center for Chinese Medicine, The Hong Kong University of Science and Technology. After removing the kernel and chopping into slices, the fruits were dried by using a freeze-dryer. The dried fruits were powdered to

homogeneous size (40 mesh). Fifty grams of the dried powder was weighed accurately and extracted in 1 L of boiling water twice for 1 h. The extract was lyophilized to dryness and stored at −80 °C. The powder was redissolved with water, or other solvents, and vortexed at room temperature before use.[9]

NMR Metabolic Analysis. Sample preparation for NMR spectroscopy was performed as in previous studies.[14] Briefly, dried jujube extract (50 mg) was redissolved in 1000 μL of aquae, from which 550 μL was mixed with 50 μL of a D_2O solution with 0.2% TSP-d_4 and 3 mM sodium azide. All particulates were discarded by centrifugation at 13,000*g* for 1 min, and the supernatant was transferred to a standard 5 mm NMR tube. NMR spectra were acquired using a Bruker AV 400 MHz NMR spectrometer. Gradient shimming was employed to improve the magnetic field homogeneity prior to all acquisition. The ^{1}H NMR spectra of the samples were acquired on a ^{1}D NOESY pulse sequence to generate a spectrum with a reduced residual solvent peak. Each sample was performed around 5 min (64 scans). All spectral data were integrated using the rNMR program.[15] The data were then formatted in XML for importing into MATLAB version 2009b and SIMCA-P version 12.0. Each ^{1}H NMR spectrum was Pareto scaled and divided into 1300 bins. The summed intensity in each bin was used as a data point for Principle Component Analysis (PCA). Metabolites were identified and assigned using a Chenomx Profiler with input from online databases hmdb.ca,[16] bmrb.wisc.edu,[17] and literature data.[18] The statistical significance of the changes in the integrated area of these assigned peaks was evaluated using a two-tailed Student's *t* test.

Cell Cultures. PC12 cells were purchased from American Type Culture Collection (ATCC, Manassas, VA). The PC12 cells were cultured in Dulbecco's modified Eagles medium (DMEM) added with 6% fetal bovine serum (FBS), 6% horse serum (HS), 100 U/mL penicillin, and 100 μg/mL streptomycin. Cultures were placed in a water-saturated 7.5% CO_2 incubator at 37 °C. Medium was renewed every 2−3 days. Human hepatocellular carcinoma Hep3B from ATCC was maintained in DMEM added with 100 IU/mL penicillin, 100 μg/mL streptomycin, and FBS to a final concentration of 10%. For subculturing, cultures were rinsed with 5 mL of 1X PBS (phosphate buffered saline) having 1 mM EDTA twice, followed by adding 1 mL of tripsin/EDTA solution to detach the cells. Reagents for cell cultures were obtained from Invitrogen Technologies (Carlsbad, CA). Cobalt chloride ($CoCl_2$, ≥97%; an inhibitor of HIF-α degradation) was obtained from Sigma (St. Louis, MO). Nerve growth factor (NGF; PC12 cells differentiation inducer) was from Alomone Laboratories (Jerusalem, Israel).

Expression of Neurofilament 68. The determination of neurofilament expression in cultures was performed according to a previous method.[10] Briefly, cultured PC12 cells were plated into 12-well plates for 24 h and then transferred to low serum for 3 h prior to treatment with jujube extract. After 3 days of treatment, the cells were harvested. The concentration of total proteins was determined by Bradford assay. Equal amounts of total protein were separated on SDS-PAGE, transferred to a nitrocellulose membrane, and incubated with an antibody specific to neurofilament 68 (NF68; Sigma) using GAPDH (Abcam Ltd., Cambridge, U.K.) as loading control. The nitrocellulose was conjugated with horseradish peroxidase antimouse secondary antibody. The intensity of the protein bands was quantified using an image analyzer.

Determination of pHRE-Luc Activity. The DNA construct of HRE and the vector were generated as described previously.[12] Briefly, cultured Hep3B cells were seeded into 24-well plates and transfected with pHRE-Luc using Lipofectamine reagent (Invitrogen), according to the manufacturer's protocol. The luciferase activity in the cell lysates was evaluated in a Tropix TR717TM Microplate Luminometer (Bedford, MA), and the activity was expressed as absorbance (up to 560 nm) per mg of protein.

Statistical and Other Analyses. The amount of total protein was measured by Bradford's assay (Hercules, CA). Data were presented as Mean ± Standard Error of Mean (SEM). Statistical analyses were evaluated using *t* test (version 13.0, SPSS, IBM Corporation, Armonk, NY). $p < 0.05$ was considered as significant (*), $p < 0.01$ as more significant (**), and $p < 0.001$ as highly significant (***).

RESULTS

Metabolic Profiles of Jujubes at Two Stages of Maturity. Before NMR analysis and cell treatment, the water extracts of jujube were chemically standardized as reported previously.[9,10] The below chemical parameters were applied to the water extracts from both mature and immature jujubes. The contents of nucleobases, including uracil, xanthine, hypoxanthine, guanine, and/or adenine in water extract should be more than 45 and 80 μg/g of dried extract of jujube. The contents of nucleosides, including cytidine, uridine, and/or guanosine in jujube extract, should be more than 80 and 150 μg/g. The contents of cyclic nucleotides, including cGMP and cAMP, in the extract should be more than 85 and 100 μg/g. The amounts of flavonoids, including quercetin 3-O-rutinoside, quercetin 3-O-galactoside, quercetin 3-O-β-D-glucoside, and kaempferol 3-O-rutinoside, in jujube extract should be more than 50 and 35 μg/g. Thus, the jujubes extracts were chemically standardized, and only samples that met the standardization criteria would be selected for all below analyses.

Jujube samples at two stages of maturity were collected from Cangzhou of China (Figure 1). Morphologically, there was a considerable difference between mature and immature jujubes, i.e. color and texture. In order to investigate the metabolic profiling of jujube extracts, ^{1}H NMR was employed to measure their primary metabolites. The average spectra of the jujube extracts were obtained, as indicated in Figure 2. Visual observation demonstrated that the spectrum of mature jujube showed similarity with that of the immature one. The top intense peaks were found at between 3.3 and 4 ppm, which belonged to the sugar compounds. Among these peaks, the two highest concentrations were sucrose and glucose. In addition, we identified other primary metabolites (Table 1), such as amino acid and organic acid. PCA, the most basic and efficient approach for evaluating complex data in metabolic profiling, was applied for data analysis.[19] Here, PCA was performed to analyze the integrated peak areas of identified metabolites. Clear separation of immature jujube and mature jujube was successfully observed (Figure 3A). The corresponding loading plot indicated that jujube at the immature stage showed a greater concentration of sucrose, alanine, and formate, while the others were found to be higher in mature jujube (Figure 3B). All identified and integrated peaks were further analyzed (Figure 4). Sucrose was shown to be the highest intensity in jujube, and then glucose and creatine. The metabolites of mature and immature jujubes were compared. The levels of

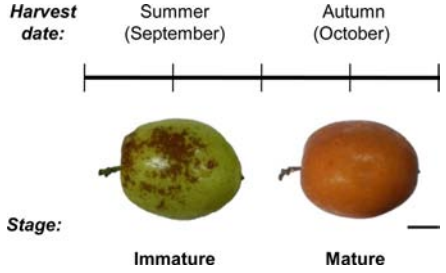

Figure 1. Morphology of mature and immature jujubes. Immature fruit was collected in summer with a yellow-green background having mahogany-colored spots (left panel). The mature fruit was collected in autumn when its appearance became entirely red and the fruit began to soften and wrinkle (right panel). Jujube samples were obtained from Cangzhou, Hebei. Bar: 1 cm.

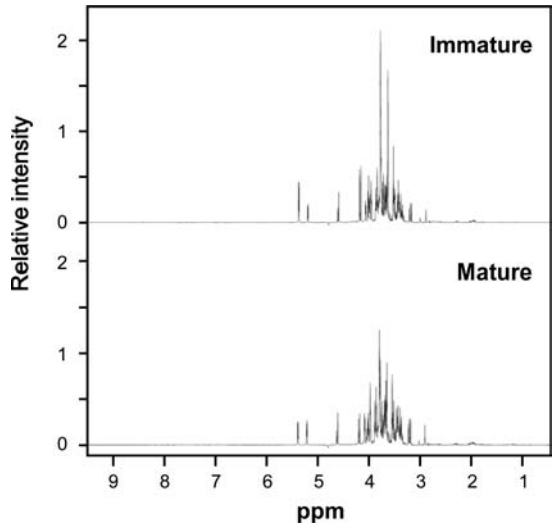

Figure 2. Average ^{1}H NMR spectra of mature and immature jujube water extracts. Each representative ^{1}H NMR spectrum of mature and immature jujube water extracts was the mean of five replicates (n = 5). The overall features for both spectra are indeed very similar. The NMR condition was described in the Materials and Methods. The experimental time for each sample was around 5 min (64 scans).

Table 1. Chemical Shifts of Metabolites Identified in ^{1}H-NMR Spectra of Jujube Extracts Used for Quantification

Metabolite	Chemical shift (ppm)[a]
Acetate	1.9 (s)[b]
Alanine	1.5 (d)
Asparagine	2.93 (m)
Choline	3.2 (s)
Creatine	3.9 (d)
Formate	8.4 (s)
Glucose	5.2 (d)
Isoleucine	1.2 (d)
Sucrose	5.4 (d)
Threonine	1.3 (d)
Valine	1.1 (d)

[a]Chemical shifts are determined by references, databases, and software described in the Materials and Methods section. [b]s: singlet; d: doublet; m: multiplet.

alanine, sucrose, and formate were higher in immature jujube than that of the mature one, while the levels of isoleucine, threonine, acetate, creatine, and glucose were higher in mature jujube than that of the immature one. The levels of valine, asparagine, and choline did not show a significant difference between mature and immature jujubes (Figure 4).

Pharmacological Properties of Jujubes at Two Stages of Maturity. PC12 cells are a commonly used model for the evaluation of neuronal differentiation.[20] The differentiation could be analyzed by a biochemical analysis in determining the expressions of neurofilaments that are the neuronal cell-specific cytoskeleton proteins, including NF68, NF160, and NF200. Our previous studies reported that jujube water extract stimulated the expressions of neurofilaments, especially NF68 in a concentration-dependent manner, and the submaximal concentration of jujube extract was revealed at ~2 mg/mL.[10] To compare the difference between mature and immature jujubes on NF68 expression, different jujube extracts at 2 mg/mL were applied onto cultured PC12 cells for 72 h. The results

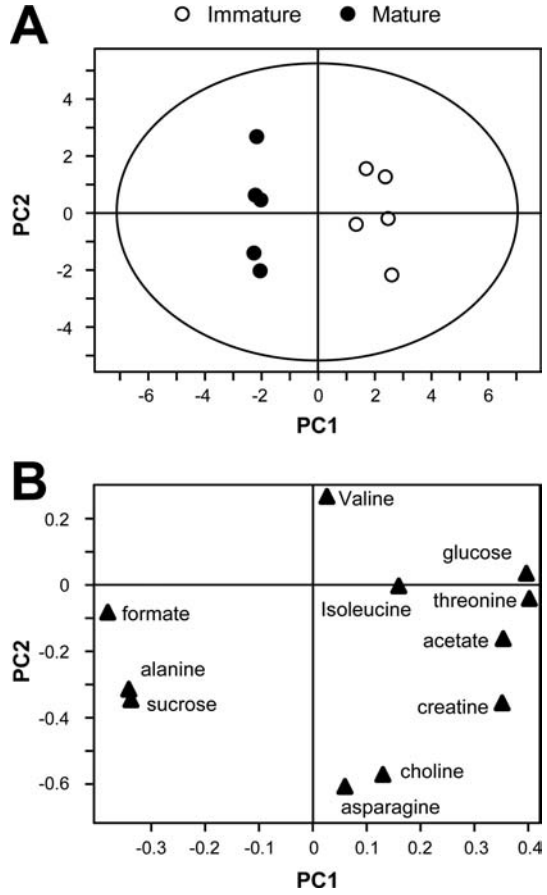

Figure 3. Chemometric analysis by PCA. (A) Scores from pattern recognition (PCA) of a selection of targeted molecules. (B) Loading plots from pattern recognition (PCA) of a selection of targeted molecules. Data are unit-variance scaled. The score plot can successfully discriminate mature and immature jujube. Loading plat shows which molecules contributed most to the discrimination. Immature jujube has a higher concentration in formate, sucrose, and alanine.

showed that both immature jujube and mature jujube possessed the ability to stimulate neurofilament expression (Figure 5A, upper panel). Moreover, the effect of mature jujube was ~60% higher than that of the immature one (Figure 5B, lower panel).

Jujube was reported to induce the expression of EPO, a specific hematopoietic growth factor, by activation of the transcriptional activity of HRE in cultured Hep3B cells, and the submaximal concentration of jujube was revealed at about 2 mg/mL.[12] To investigate the transcriptional activity of HRE, a luciferase-reporter construct (pHRE-Luc), having six HREs derived from the enhancer of EPO gene and tagged upstream of a luciferase gene, was transfected into cultured Hep3B cells (Figure 6, upper panel). Here, the HRE-mediated transcriptional activity of jujube at two stages of maturity was investigated. Different jujube extracts at 2 mg/mL were added onto HRE-expressed Hep3B cells. The data demonstrated that both immature jujube and mature jujube activated HRE-mediated transcriptional activity. And immature jujube possessed better effect, ~30% higher than that of mature jujube (Figure 6, lower panel).

J. Agric. Food Chem. 2015, 63, 739−744

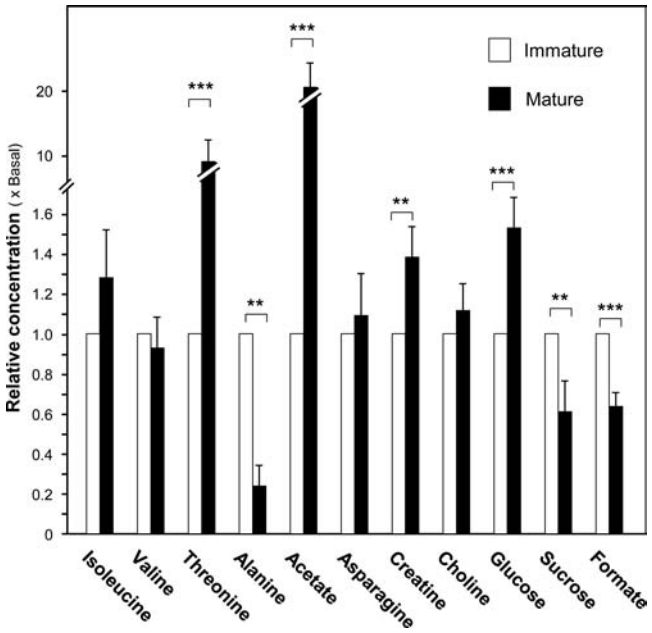

Figure 4. Quantification of identified metabolites between mature and immature jujube extract. Peaks associated with identified metabolites in all of the ^{1}H NMR spectra were integrated to yield the concentrations in the extracts relative to the mean value for immature jujube (basal level set at 1.0). The most noticeable feature was the concentration of sucrose and glucose; that of sucrose is higher in immature jujube, but mature jujube has a higher concentration in glucose. Values are expressed as mean ± SEM (n = 5). Statistical comparison was made between mature and immature jujubes; * p < 0.05; ** p < 0.01; *** p < 0.001, by student's t test.

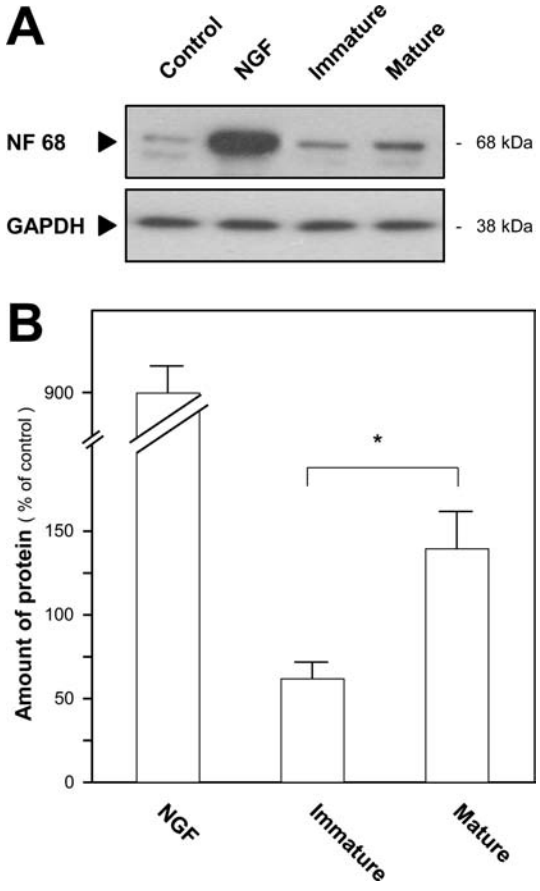

Figure 5. The inductive role of jujubes at two stages of maturity in neurofilament expression. (A) Cultured PC12 cells were treated with mature and immature jujube water extracts (2 mg/mL) for 72 h. The cell lysates were collected to determine the expressions of NF68 at ~68 kDa. NGF (50 ng/mL) served as a positive control. GAPDH at ~38 kDa served as loading control. (B) Quantification plot was shown in histograms. Data are expressed as the percentage of increase to basal reading (untreated culture), mean ± SEM, n = 4. Statistical comparison was made between mature and immature jujubes; *p < 0.05.

DISCUSSION

Jujube can be found all around the world today due to its health benefits both as food and herbal medicine. China has over 1.5 million hectares of total farm area and is the sole country known to be outputting jujube. The output of fresh jujube is about 400,000 tons, while 4,700 tons of jujubes are dried annually.[21] In China, jujube has been consumed into numerous products, i.e. juice, vinegar, and wine. In Korea, jujube is featured in the popular ginseng chicken dish. A candy called "jujube", being made from jujube paste, is available in America.[22] Among folk, dried jujubes have been commonly consumed as a snack or with tea. It can be further smoked to boost their taste.

Recently, the variation of chemical contents at different stages of the fruits was reported, indicating the specific usages of different stages of jujubes. In chemical analysis, the total phenolic content and total flavonoidic content rapidly decreased during maturity.[23−25] In good agreement with this notion, our studies revealed that the content of flavonoids fell sharply during maturity.[9] As for nucleotide and its derivatives, the contents of 7 compounds were higher in mature jujubes than that of immature ones, including xanthine, hypoxanthine, adenine, uridine, guanosine, cGMP, and cAMP.[9] The content of polysaccharide in jujube has not been significantly changed by the developmental stage.[9] In line with this, our current studies revealed that the total amount of sugars, including glucose and sucrose, did not show a significant difference between mature and immature jujubes. However, a report showed that the pectin contents increased during ripening.[26] Indeed, our data demonstrated that the content of glucose was higher in mature jujube than that of immature jujube, yet the sucrose amount was higher in immature jujube than that of the mature one. Choi et al. (2012) revealed that mature jujube had a lower level of protein than that of the immature one, while mature jujube contained higher amounts of free amino acids than that of the immature one.[23] Our NMR results showed that the total amount of tested amino acids was higher in mature jujube than that of the immure one, which was in line with the studies by Choi et al. (2012).[23] Fatty acid profiles of fruits were also reported to be affected by maturity.[27] Besides, we revealed that the total amount of organic acids including acetate and formate was higher in mature jujube than that of the immature one.

In biological analysis, the variation between mature and immature jujubes in antioxidative effect has been reported. Flavonoids were considered as one of the ingredients in jujube contributing to this effect, yet whether the levels of flavonoids were correlated with the activity is still debatable. Zhang et al. (2010) reported that the ferric reducing activity power (FRAP) effect was great related with the content of total flavonoids.[28] Immature jujube containing significantly higher amount of flavonoidic compounds showed better antioxidative activity

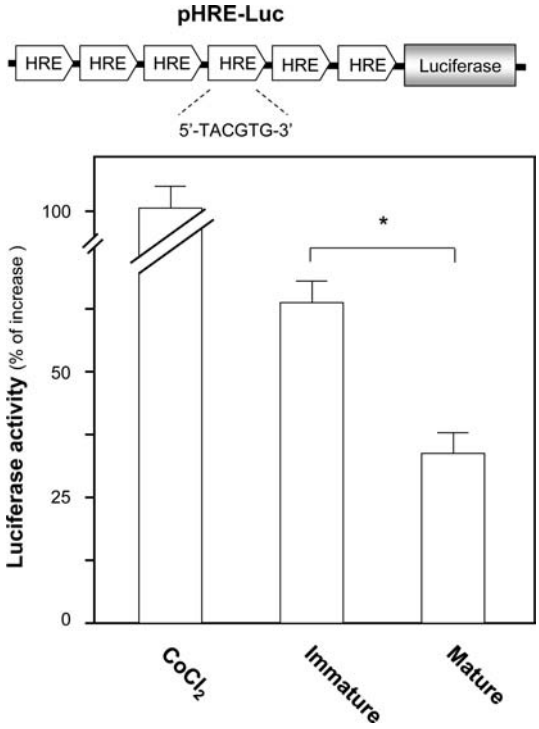

Figure 6. Comparison of HRE-mediated transcriptional activity on jujubes at two stages of maturity. A luciferase-reporter containing six HREs and a downstream luciferase-reporter gene, namely as pHRE-Luc, was used as a study tool (upper panel). Cultured Hep3B cells, transfected with pHRE-Luc, were treated with mature and immature jujube water extracts (2 mg/mL) for 24 h. The cell lysates were subjected to luciferase assay. $CoCl_2$ at 100 μM served as a positive control. Values are expressed as the percentage of increase to basal reading (untreated culture), and they are in mean ± SEM, where n = 4, each with triplicate samples. Statistical comparison was made between mature and immature jujubes; * $p < 0.05$.

than that of the mature one.[23] Zozio et al. (2014) proposed that, during ripening, the antioxidant activity may be more impacted by the flavonols and condensed tannins.[25] In contrast, other studies demonstrated that the antioxidative activity did not show significant correlation with the amount of flavonoids.[4,9] Here, immature jujube was shown to have higher levels of flavonoids, which performed better with regard to pHRE-Luc activity than that of mature jujube. However, our previous studies have shown that cAMP and polysaccharide, rather than flavonoid, in jujube could also achieve this activity.[12] This suggests that the pHRE-Luc activity of jujube does not relate to the content of flavonoids. In parallel to this notion, flavonoids derived from herbal medicines have been reported to be able to induce the expression of EPO,[29] suggesting that flavonoids may be one of the active ingredients for this action. In addition, we also revealed that mature jujube had a better effect in inducing neurofilament expression than that of the immature one: this higher induction could be an outcome of the higher amount of cAMP in mature jujube.[10] Besides, a report demonstrated that as the fruit matured, the activity of jujube in inhibiting Hel299 normal lung and A549 lung cancer cells declined.[23]

Novel Strategies To Enhance Lateral Flow Immunoassay Sensitivity for Detecting Foodborne Pathogens

Shan Shan, Weihua Lai,* Yonghua Xiong, Hua Wei, and Hengyi Xu

State Key Laboratory of Food Science and Technology, Nanchang University, Nanchang 330047, China

ABSTRACT: Food contaminated by foodborne pathogens causes diseases, affects individuals, and even kills those affected individuals. As such, rapid and sensitive detection methods should be developed to screen pathogens in food. One current detection method is lateral flow immunoassay, an efficient technique because of several advantages, including rapidity, simplicity, stability, portability, and sensitivity. This review presents the format and principle of lateral flow immunoassay strip and the development of conventional lateral flow immunoassay for detecting foodborne pathogens. Furthermore, novel strategies that can be applied to enhance the sensitivity of lateral flow immunoassay to detect foodborne pathogens are presented; these strategies include innovating new label application, designing new formats of lateral flow immunoassay, combining with other methods, and developing signal amplification systems. With these advancements, detection sensitivity and detection time can be greatly improved.

KEYWORDS: *lateral flow immunoassay, foodborne pathogens, sensitivity enhancement*

INTRODUCTION

Food safety is an important public health priority. Foodborne diseases are serious global problems and impose a significant burden not only on infected individuals but also on the economy. Although a majority of cases are mild, occasional cases can lead to serious or long-term conditions or even death. The Centers for Disease Control and Prevention estimated that each year roughly one in six Americans (or 48 million people) becomes adversely affected by foodborne diseases.[1] The World Health Organization estimated that approximately a million people suffered from foodborne diseases each year in the United Kingdom.[2] Foodborne pathogens contaminate food at some parts of the food chain from farm to fork. *Salmonella*, enterohemorrhagic *Escherichia coli* (EHEC), *Listeria monocytogenes*, *Staphylococcus aureus*, *Campylobacter*, *Cronobacter*, *Vibrio*, and *Shigella* are reported frequently. For instance, *Salmonella* is one of the most common causes of food poisoning in the world and can cause more serious illnesses in older adults, infants, and persons with chronic diseases. Every year, *Salmonella* is estimated to cause approximately 1.2 million illnesses in the United States.[3] Another case involves EHEC; this pathogen is often reported as one of the most common causes of foodborne outbreaks. For example, approximately 265,000 EHEC infections occur each year in the United States. EHEC O157 also causes approximately 36% of these infections, and non-O157 EHEC accounts for the remaining cases.[4] In other instances, *L. monocytogenes* primarily affects older adults, pregnant women, newborns, and adults with weakened immune systems. In the United States, *L. monocytogenes* causes nearly 2500 cases of listeriosis per year.[5] Foods that are most frequently associated with foodborne illnesses include meat, fish, poultry, vegetables, and fruits. These foods may cause illnesses when they are eaten.

In traditional methods, analytes are initially cultured in enrichment media for 18−24 h and then cultured in selective media for 18−24 h; biochemical and serological tests are subsequently performed to confirm suspected colonies for another 3−5 days. Conventional detection methods require 5−7 days to identify target bacteria. The methods of conventional isolation and culture are time-consuming and laborious. Therefore, a simple, specific, and sensitive method that can be used to detect pathogens should be developed. Several methods based on nucleic detection, such as real-time polymerase chain reaction (PCR),[6−8] multiplex PCR,[9−11] and loop-mediated isothermal amplification (LAMP) methods,[12−14] have been developed rapidly. Enzyme-linked immunosorbent assay (ELISA),[15−17] biosensing,[18−21] and electrochemical strategies[22,23] have also been extensively investigated. On the one hand, these methods are sensitive and specific; on the other hand, these methods require technical expertise, laborious procedures, and expensive instrumentation. In addition, these technologies are inappropriate for on-site tests. With these drawbacks, detection techniques have been developed and improved. For instance, lateral flow immunoassay (LFI) has been considered as a promising diagnostic tool extensively applied to detect drugs,[24−27] toxins,[28,29] hormones,[30,31] heavy metals,[32,33] pesticides,[34,35] and pathogens.[36,37] LFI provides several advantages, including rapid procedure, convenient operational requirements, sensitivity, and cost-effective equipment. Review papers have described the strengths, weaknesses, opportunities, and threats of LFI,[38] as well as its advanced ability to detect mycotoxins, phycotoxins, and pesticides.[39,40] In this paper, recent advances on LFI applied to detect foodborne pathogens are described. Furthermore, sensitivity enhancement methods are presented and discussed.

FORMAT AND PRINCIPLE OF TRADITIONAL LFI

Components of the LFI Format. Immunochromatography test paper technology, which was developed in the early 1980s,

involves rapid detection based on immunological techniques. A LFI device consists of a sample pad, a conjugate pad, a nitrocellulose membrane, and an absorbent pad. A test zone and a control zone are found on the nitrocellulose membrane (Figure 1A).

Sample pads are used to filter specific sample components; these pads can also change the pH of a sample and release analytes with high efficiency.
