(Received for publication May 10, 1976)

Efrotomycin is a narrow spectrum antibiotic. Among the genera tested for susceptibility *in vitro* it is most active against isolates of *Moraxella*, *Pasteurella*, *Yersinia*, *Haemophilus*, *Streptococcus* and *Corynebacterium*. The drug is as active by oral administration as by the subcutaneous route. Blood levels rise rapidly to high concentrations, after oral dosing, and are prolonged. Two peaks occur which may indicate biliary excretion and reabsorption. Urinary excretion is minimal. The high blood concentrations explain, in part, the *in vivo* activity against pathogens such as *Bordetella bronchiseptica* which are relatively insensitive *in vitro*. Oral activity of efrotomycin is an advantage over the related antibiotics, X-5108 and mocimycin.

Three related antibiotics X-5108<sup>1)</sup>, mocimycin<sup>2,3)</sup>, and kirromycin<sup>4)</sup>, were described in 1972~1973. Mocimycin and kirromycin are identical and antibiotic X-5108 is their N-methylated form<sup>5)</sup>. Efrotomycin<sup>6)</sup> belongs to this family of antibiotics. It is a disaccharide derivative of antibiotic X-5108 (DEWEY, R. S. and G. ALBERS-SCHONBERG, personal communication). The absolute structure of efrotomycin will be presented in a forthcoming paper. In the present communication, we report some *in vitro* and *in vivo* activities of efrotomycin (greater than 90% pure), and some comparisons with antibiotic X-5108 and mocimycin are made.

### *In Vitro* Activity

#### Antibacterial Spectrum

Initial tests showed efrotomycin to have a limited but interesting spectrum in that it was active *in vitro* and *in vivo* against some important animal pathogens. The *in vitro* testing was then extended to a series of human and animal pathogens. In these studies, the test bacteria were grown for 16 hours in brain-heart broth (including 5% horse serum when necessary), diluted to  $10^{-8}$  in fresh medium and spot-inoculated onto the surface of 100 mm plates containing 10 ml of brain-heart agar with various concentrations of the antibiotic. The number of viable cells inoculated onto the plates varied from  $3 \times 10^8$  to  $7 \times 10^8$  per spot, depending on the test organism. The plates were scored visually after 24 and 48 hours.

The results in Table 1 show that efrotomycin is not very active *in vitro*. Strains of *Moraxella*, *Pasteurella*, *Yersinia*, *Haemophilus*, *Streptococcus* and *Corynebacterium* are the most sensitive. The limited data with X-5108 and mocimycin show these two antibiotics to have a spectrum similar to efrotomycin but to be more active than efrotomycin *in vitro*.

#### Bactericidal Activity

The question as to whether efrotomycin was bactericidal or bacteriostatic was answered by the following experiments. Test bacteria were grown for 16 hours in brain-heart broth, diluted in fresh broth and added to tubes of brain-heart broth containing the antibiotic. The final concentration of cells varied from  $1.8 \times 10^6$  to  $1.9 \times 10^7$  per ml, depending on the test organism. The tubes were examined visually after 24 hours incubation at 37°C. The minimal inhibitory concentration (MIC) was taken as the lowest

level which prevented visible growth. One-tenth ml portions were removed from the tubes showing no growth and plated in 9.9 ml of brain-heart agar. After 72 hour incubation at 37°C, the colonies were counted. The minimum lethal concentration (MLC) was taken as the lowest efrotomycin concentration which killed 99.9% of the cells<sup>7)</sup>. Data are summarized in Table 2.

It is clear that efrotomycin is bactericidal with the -static and -cidal concentrations being much the same. Studies on the kinetics of the bactericidal action of efrotomycin have yielded some interesting results. In these experiments, the test bacteria for preparing the inoculum were grown in shaken culture

\* c.f.u.=colony forming units.

in brain-heart broth for 16 hours at 37°C, the same conditions used for the inoculum in the antibacterial spectrum and bactericidal studies. Two test organisms, *Moraxella bovis* 418 and *Pasteurella multocida* 86, were used at two dilution levels in brain-heart broth. Cultures with and without antibiotics were incubated and sampled at intervals, and plate counts were made for survival determinations.

Effective killing of *M. bovis* 418 depends on the inoculum concentration and requires 6~8 hours at a concentration of 0.8 µg of efrotomycin/ml. At an efrotomycin concentration of 0.4 µg/ml the bacterial counts are fairly level for 6 hours before dropping for a short period (~2 hours) prior to recovery and multiplication (Figs. 1 and 2). The relatively slow rate of kill by efrotomycin is also clear from the experiments with *P. multocida* 86 (Figs. 3 and 4). Most interesting is the observation that the bacteria can grow for several hours in efrotomycin concentrations that eventually kill most of the population. Concentrations of 1.56, 3.12 and 6.25 µg/ml in Fig. 3 and concentrations of 3.12 and 6.25 µg/ml in Fig. 4 show this phenomenon.

The only published data on the mode of action of this class of compounds are those of WOLF *et al.*<sup>8)</sup> on kirromycin. This antibiotic is a potent inhibitor of bacterial protein synthesis by interfering with peptide transfer reactions associated with the elongation factor Tu. If this is the mechanism of action of efrotomycin as well, the effect is not immediately lethal except at relatively high concentrations of the drug.

### In Vivo Activity

#### Efficacy against Mouse Infections

Mice were injected intraperitoneally with cultures grown for 16 hours at 37°C in brain-heart broth. Efrotomycin, antibiotic X-5108 and mocimycin were dissolved in ethanol and diluted with 1% Tween 80 in water (v/v). The other drugs were administered as sonicates in 1% Tween, except for penicillin which was an aqueous solution. Five-tenths ml of drug was given by gavage or subcutaneously at the time of infection and 6 hours post infection. Groups of five CFl female mice were used for each level and were observed daily for 7~14 days after infection. The ED<sub>50</sub> and LD<sub>50</sub> were calculated by the method of KNUDSEN and CURTIS<sup>9)</sup> as mg/dose/mouse. The results are summarized in Table 3.

Clearly, efrotomycin is rapidly absorbed after oral administration since it is as active by the oral route as by the subcutaneous route. The *in vivo* efficacy against *Bordetella bronchiseptica* is interesting in relation to the relative *in vitro* insensitivity of *B. bronchiseptica* isolates to the antibiotic. Moreover, efrotomycin is active against sulfamethazine-resistant *B. bronchiseptica* strains and is equal to chlorotetracycline. It is less active than penicillin G against strains of *P. multocida* and *M. bovis*.

Supplies of antibiotic X-5108 and mocimycin were adequate for comparison with efrotomycin in only one infection. Both antibiotic X-5108 and mocimycin had lower MIC's than efrotomycin against *B. bronchiseptica* F1728.

Fig. 5. Plasma levels in mice following single oral administration of 200 mg efrotomycin per kg.

However, two 6-mg doses of antibiotic X-5108 were not effective either by gavage or subcutaneously against an infection with *B. bronchiseptica* F1728. This dose, the highest tested, did give a statistically significant prolongation of mean survival time by both routes but lower doses had no effect. Moci-mycin was completely ineffective by either route at two doses of 6 mg/mouse. The ED<sub>50</sub> of efrotomycin in this test was 1.81 mg per dose by the oral route and 1.24 subcutaneously. Efrotomycin is well tolerated following either oral or subcutaneous administration. The oral LD<sub>50</sub> is greater than 4 g/kg and the subcutaneous LD<sub>50</sub> is greater than 2 g/kg.

#### Plasma Concentrations

The oral efficacy of efrotomycin against *B. bronchiseptica*, which is relatively insensitive *in vitro*, indicates that the antibiotic may be absorbed rapidly and reach and maintain high blood concentrations. This possibility was tested experimentally.

Randomized groups of CFI female mice were dosed by gavage with 4 mg of the sodium salt of efrotomycin per 20 g mouse. Blood was taken from the hearts at intervals using heparinized syringes and the plasma from each group was pooled and frozen until assayed. A microbiological cylinder agar plate diffusion assay was developed using *M. bovis* 418 as the test organism. Known concentrations of efrotomycin were prepared in normal mouse plasma and test samples were assayed against this standard. The data are presented in Fig. 5. The rapid absorption and prolonged high plasma levels of efrotomycin are evident. The two peaks of activity are most interesting. They have not been explained experimentally. However, biliary excretion of the drug followed by reabsorption is one possibility.

#### Serum Binding

Two ml volumes of 200  $\mu$ g efrotomycin per ml of horse serum or saline were dialyzed in rotating chambers against 2 ml volumes of saline at 5°C for 48 hours. The test was performed in quadruplicate. Dialysates and dialysants were assayed for antibiotic content using appropriate standards and the *M. bovis* assay. Efrotomycin was 30% bound by horse serum under the conditions described.

#### Urinary Excretion

One reason for the prolonged blood levels of efrotomycin is the poor urinary excretion of the drug. This was shown experimentally as follows: Five Marland Farms female rats, varying in weight from 190 to 210 g each was given efrotomycin by gavage at a dose of 400 mg/kg body weight. A control group of rats received an equal volume of diluent and was held under the same test conditions. Food and water were available during the test except that water was withheld for the first 6 hours after dosing. Urine was collected from 0~6 hours and from 6~24 hours. Samples from five rats were pooled and frozen until assayed. Standards were prepared in normal urine. Only about 2% of the dose was recovered during the 24-hour test period with approximately 4/5 of this during the last 18 hours. The volume of urine was considerably less from the efrotomycin dosed rats than from the control group, particularly during the first 6 hours. Other studies have shown that continued dosing with high oral levels of efrotomycin have not caused the test rats to show urinary retention (H. M. PECK, personal communication).

### Discussion

Efrotomycin is a narrow spectrum antibiotic with poor *in vitro* activity. However, the drug shows a number of favorable characteristics. It is quite active against several important animal pathogens. Indeed, its *in vivo* activity is greater than one would predict from *in vitro* potency. It is rapidly absorbed after oral administration and produces high prolonged blood levels; however, this is probably not the

only reason for the unexpected *in vivo* potency. It is not cross-resistant with other drugs used as feed additives or therapeutically in veterinary medicine. It offers promise as a growth permittant in the presence of disease complexes. Data on animal trials will be forthcoming from other investigators.
