**Abstract** In this work, effects of drying temperature, pH of aqueous electrolyte and current density on capacitive performance of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  material were firstly investigated.  $\text{VO}_x \cdot n\text{H}_2\text{O}$  powders were prepared by a melt quenching method. The samples were characterized by X-ray diffraction analysis (XRD) and Fourier transform infrared (FTIR). The capacitive properties of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples were examined by cyclic voltammetry and galvanostatic charge/discharge test.  $\text{VO}_x \cdot n\text{H}_2\text{O}$  sample which was obtained at the drying temperature of 80 °C, delivers a maximum specific capacitance of 227.3 F g<sup>-1</sup> and exhibits excellent capacity retention in the potential range of -0.3 to 0.7 V at a current density of 200 mA g<sup>-1</sup> in NaNO<sub>3</sub> solution with pH 2.

**Keywords**  $\text{VO}_x \cdot n\text{H}_2\text{O}$  · Capacitive properties · Drying temperature · pH

## 1 Introduction

Supercapacitors are very interesting charge-storage devices with high energy density and high power density. Recently, they have attracted worldwide attention due to their potential applications in hybrid electric vehicles, back-up

power storage, peak power sources, and so on [1, 2]. Based on the charge-storage mechanism, supercapacitors are classified as: electric double-layer capacitors (EDLCs) that store charge by utilizing the double-layer capacitance at an electrode/electrolyte interface; and pseudo-capacitors that store charge by utilizing the pseudo-capacitance arising from fast and reversible Faradaic reactions of electroactive materials with several oxidation states [3, 4]. Compared with EDLCs, more research has been focused on pseudo-capacitors which have higher specific capacitance. Traditionally, hydrous ruthenium oxide ( $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ ) has been an ideal electrode material for pseudo-capacitors since it exhibits excellent pseudo-capacitive behavior with great specific capacitance and good reversibility in strong acidic electrolyte [5–8]. Unfortunately, its large-scale application is unfeasible owing to its high cost and rarity in natural resource. Therefore, more economical transition-metal oxides (such as MnO<sub>2</sub>, NiO, and V<sub>2</sub>O<sub>5</sub>, etc.) are considered as promising alternative electrode materials for supercapacitors [9–14].

Among these transition-metal oxides, V<sub>2</sub>O<sub>5</sub> is an attractive electrode material because of its low-cost, modest electronic conductivity, easy preparation, as well as several stable oxidation states. The application of V<sub>2</sub>O<sub>5</sub> in Lithium-ion rechargeable battery has been widely recognized and well studied [15–17], but there are few reports about V<sub>2</sub>O<sub>5</sub> as electrode material for pseudo-capacitor. Lee et al. [18] firstly reported that amorphous V<sub>2</sub>O<sub>5</sub> displayed 350 F g<sup>-1</sup> between -0.2 and 0.8 V in an aqueous KCl electrolyte with pH 6.67. After 100 cycles, the specific capacitance rapidly declined to about 200 F g<sup>-1</sup>. Later, Reddy et al. [19] prepared nano-porous V<sub>2</sub>O<sub>5</sub> with crystalline structure, which delivered an initial specific capacitance of 214 F g<sup>-1</sup> and exhibited poor cycling life in 2 mol L<sup>-1</sup> KCl solution. Jayalakshmi et al. [20] applied a

thermal decomposition method to synthesize crystal  $V_2O_5$  powders that showed a fairly low specific capacitance of  $12 \text{ F g}^{-1}$  in  $0.1 \text{ mol L}^{-1}$  KCl solution. Therefore, further research is still needed to improve capacitive performance of vanadium oxide. In this article,  $VO_x \cdot nH_2O$  samples were prepared by a melt quenching method. The effects of drying temperature, pH of aqueous electrolyte, and current density on capacitive behavior of  $VO_x \cdot nH_2O$  were firstly discussed, and then the optimum conditions were obtained.

## 2 Experimental

### 2.1 Preparation of $VO_x \cdot nH_2O$ powders

$VO_x \cdot nH_2O$  powders were prepared by a melt quenching method. Crystalline  $V_2O_5$  powders were melted at  $800^\circ\text{C}$  in a muffle furnace. After being heated for 20 min, the melt was quickly quenched into distilled water with stirring. After 2 h, the formed brownish sol was filtered to remove a small quantity of insoluble impurities. The sol was constantly stirred until gels were formed. Finally, the gels were dried at  $40, 80, 120, 160, 200, 240^\circ\text{C}$  under vacuum, respectively. The obtained  $VO_x \cdot nH_2O$  samples were correspondingly labeled as VO-1#, VO-2#, VO-3#, VO-4#, VO-5#, and VO-6#.

### 2.2 Characterization of $VO_x \cdot nH_2O$ samples

The samples were characterized by X-ray diffraction (XRD) using a D/max-rA diffractometer with  $\text{Cu K}_\alpha$  radiation operated at  $40 \text{ kV}$  and  $100 \text{ mA}$  in the range of  $10\text{--}70^\circ$  ( $\lambda = 0.15418 \text{ nm}$ ). Fourier transform infrared (FTIR) spectra were obtained by Perkin-Elmer 16 pc. The samples were mixed with KBr and examined in the wave number range of  $400\text{--}4000 \text{ cm}^{-1}$ .

### 2.3 Electrochemical measurements

The  $VO_x \cdot nH_2O$  electrode was prepared by mixing  $VO_x \cdot nH_2O$  powders with acetylene black and polyvinylidene fluoride (PVDF) binder (in a weight ratio of 70:25:5) and grinding the mixture with *N*-methyl-2-pyrrolidone (NMP) as the solvent. The formed slurry was dried in air with infrared lamp to evaporate the NMP solvent. The resulting mixture powders were pressed onto stainless steel mesh (diameter is 5 mm), and then dried at  $60^\circ\text{C}$  under vacuum to remove the residual solvent. The typical mass of active material on a  $VO_x \cdot nH_2O$  electrode was approximately 1.5 mg.

The cyclic voltammetry (CV) was conducted in a three-electrode system comprising a  $VO_x \cdot nH_2O$  electrode, a platinum electrode and a saturated calomel electrode (SCE)

that serve as the working, counter, and reference electrode, respectively. The tests were carried out with LK2005 electrochemical workstation system in  $1 \text{ mol L}^{-1}$   $\text{NaNO}_3$  solutions with various pH values.

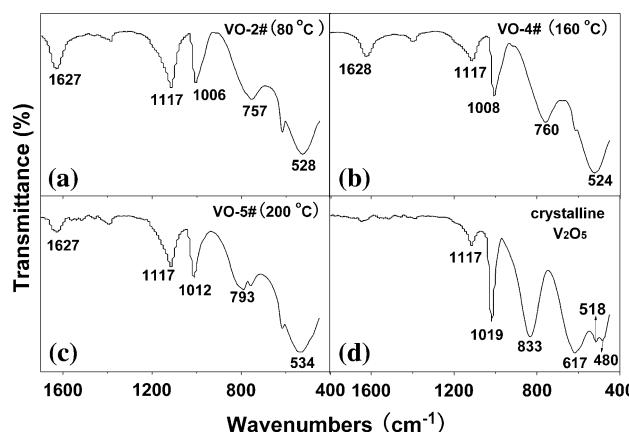

The charge/discharge test was performed in a two-electrode cell fabricated with two  $VO_x \cdot nH_2O$  electrodes which were separated by a Teflon gasket (inner-diameter of 5 mm, thickness of 3 mm). The experiments were carried out by Neware battery program-control testing system in  $1 \text{ mol L}^{-1}$   $\text{NaNO}_3$  solutions with pH 7 and pH 2.

## 3 Results and discussion

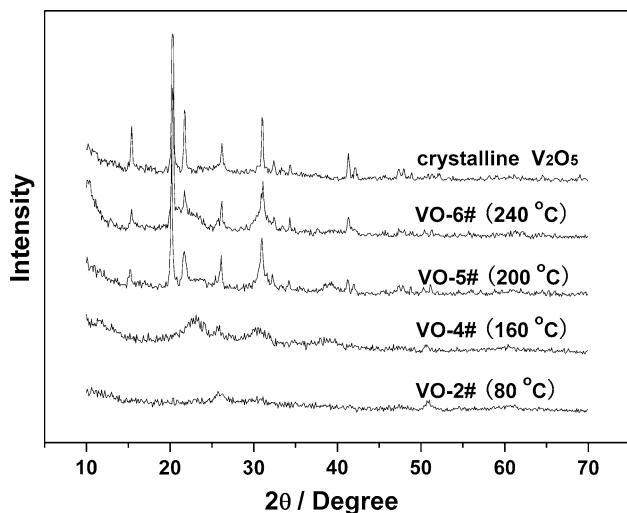

### 3.1 IR and XRD analysis

The IR spectra of VO-2#, VO-4#, VO-5#, and pure crystalline  $V_2O_5$  powders as starting material are shown in Fig. 1. The weak absorbance peak at  $1627 \text{ cm}^{-1}$  is assigned to the bending vibration of O-H, confirming residual water within these samples. In Fig. 1a, the strong peaks at 1006, 757, and  $528 \text{ cm}^{-1}$  are the IR signature of  $V_2O_5$  xerogel, which are assigned to the stretching vibration peak of V=O, the asymmetric and symmetric stretching vibration peaks of V—O—V, respectively [21]. Similarly, the three strong peaks corresponding to  $V_2O_5$  xerogel are also observed in Fig. 1b and c. These data indicate that the main ingredient in  $VO_x \cdot nH_2O$  samples is  $V_2O_5$ , in which vanadium oxidation state is V(V).

Compared to pure crystalline  $V_2O_5$  (Fig. 1d), the V=O absorbance peaks of VO-2#, VO-4#, and VO-5# shift to lower frequency, which should be resulted from the existence of V(IV) in  $VO_x \cdot nH_2O$  [22, 23]. The formation of V(IV) could be attributed to two factors: (i) the decomposition of the melting  $V_2O_5$  [24, 25]; (ii) the interaction of water with  $V_2O_5$  xerogel [26]. As we know,  $V_2O_5$  is *n*-type

**Fig. 1** IR spectra of  $VO_x \cdot nH_2O$  samples prepared at different drying temperatures

**Fig. 2** XRD patterns of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples prepared at different drying temperatures

semiconductor, and its charge transport proceeds via electron hopping along  $\text{V}^{4+} \rightarrow \text{O} \rightarrow \text{V}^{5+}$ , so the  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples would have higher electronic conductivity than pure crystalline  $\text{V}_2\text{O}_5$  because of the existence of V(IV) [27, 28].

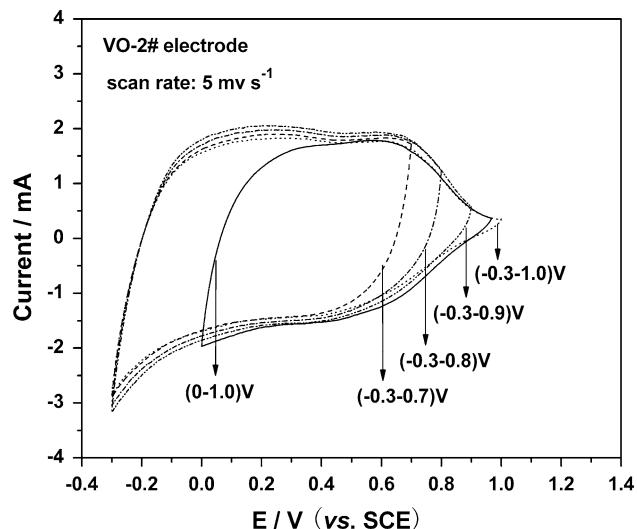

One can also observe in Fig. 1 that the V=O peak of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  sample shifts to higher frequency with increasing temperature, which should be caused by the decrease of V(IV) concentration. Liu et al. [23] have found that the oxidation of V(IV) to V(V) occurs at high temperature, resulting in the V=O bond length shortening and its absorbance peak blueshift. Of course, the declining content of V(IV) would lead to lower electronic conductivity and worse capacitive performance.

Figure 2 displays XRD patterns of the  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples prepared at different drying temperatures. No distinct diffraction peaks are noted for the samples prepared below 160 °C. Instead, some peaks appear for the samples prepared above 160 °C. The XRD results suggest that  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples are amorphous when dried below 160 °C, and become crystalline at higher temperature.

### 3.2 Electrochemical analysis

#### 3.2.1 Cyclic voltammetry test

In order to find out the optimal potential range of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  material, VO-2# electrode was examined with cyclic voltammetry (CV) in various potential ranges. Figure 3 presents the measured CV curves of VO-2# electrode in neutral  $\text{NaNO}_3$  solution at a scan rate of 5 mV s<sup>-1</sup>. Obviously, the output current evidently declines when the charge voltage is above 0.7 V (vs. SCE). The VO-2# electrode still exhibits good capacitive performance

**Fig. 3** CV curves of VO-2# electrode in various potential ranges in neutral  $\text{NaNO}_3$  solution

when discharge voltage is declined to -0.3 V (vs. SCE). Hence, the suitable working potential window is between -0.3 and 0.7 V for  $\text{VO}_x \cdot n\text{H}_2\text{O}$  material.

The pH value of aqueous electrolyte is another crucial factor in determining the capacitive behavior of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  powders. VO-2# electrode was also examined with cyclic voltammetry in alkaline and acid  $\text{NaNO}_3$  solution. The pH value of  $\text{NaNO}_3$  solution was adjusted with  $\text{HNO}_3$  or  $\text{NaOH}$  solution.

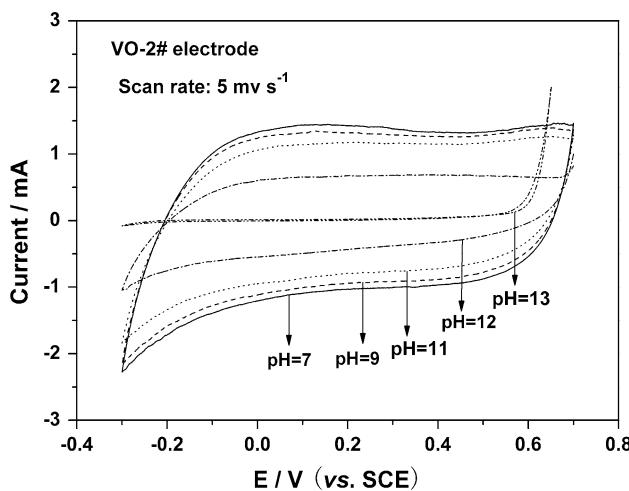

The CV curves of VO-2# electrode in alkaline  $\text{NaNO}_3$  solutions with various pH values are shown in Fig. 4. The output current rapidly decreases with the pH value increasing from 7 to 13, revealing that the capacitive properties of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  become worse.  $\text{V}_2\text{O}_5$ , as the main ingredient of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  sample, is amphoteric oxide, so  $\text{VO}_x \cdot n\text{H}_2\text{O}$  can be easily dissolved in alkaline solution (shown in reaction 1), which would result in poor capacitive performance:

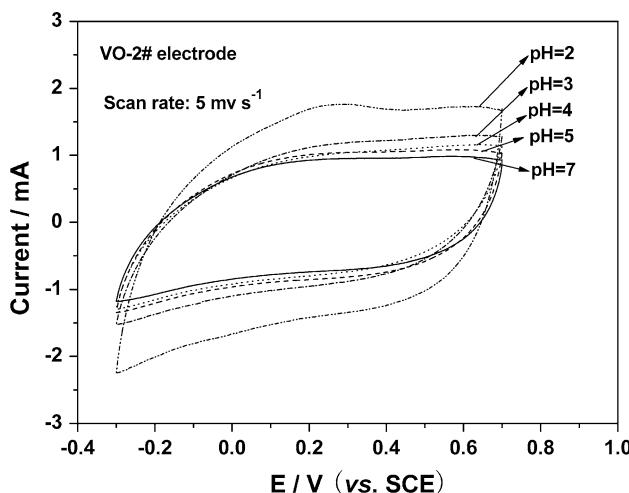

Figures 5 and 6 give CV curves of VO-2# electrode in acid  $\text{NaNO}_3$  solutions with various pH values. It can be found in Fig. 5 that the output current slightly increases with the pH value dropping from 7 to 3, and evidently increases at pH 2. However, the current remarkably decreases with increasing cycle number at pH 1 (Fig. 6), indicating that an irreversible reaction occurs. The acidity of  $\text{V}_2\text{O}_5$  is slightly stronger than its alkalinity, so  $\text{VO}_x \cdot n\text{H}_2\text{O}$  can be dissolved in the strong acid solution with pH 1 (shown in reaction 2).

According to the above results and discussion, the pH value of the aqueous electrolyte for  $\text{VO}_x \cdot n\text{H}_2\text{O}$  material should be controlled between 7 and 2.

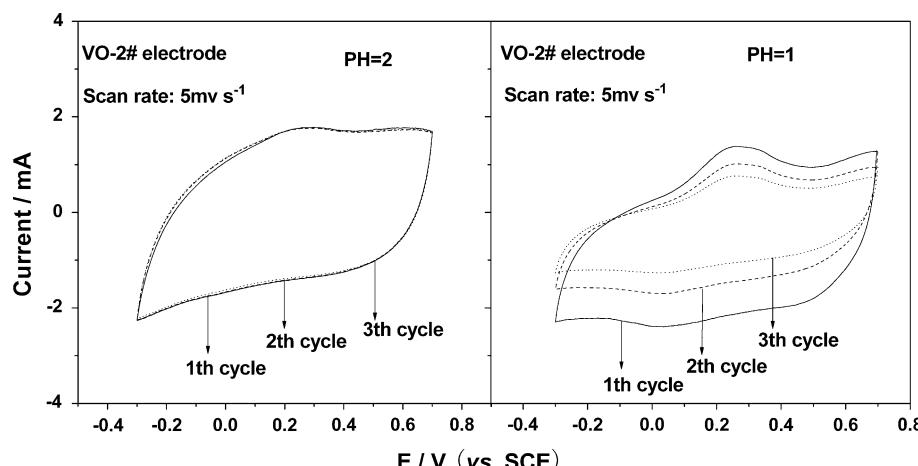

**Fig. 4** CV curves of VO-2# electrode in alkaline NaNO<sub>3</sub> solutions with various pH values

**Fig. 5** CV curves of VO-2# electrode in acid NaNO<sub>3</sub> solutions with various pH values

**Fig. 6** CV curves of VO-2# electrode in acid NaNO<sub>3</sub> solutions with pH 2 and pH 1

### 3.2.2 Charge and discharge test

The charge/discharge curves of VO-1# to VO-6# in neutral NaNO<sub>3</sub> solution at a current density of 200 mA g<sup>-1</sup> are presented in Fig. 7. All charge/discharge curves are almost linear and the coulombic efficiency is 99–100%, implying that VO<sub>x</sub>·nH<sub>2</sub>O material has an ideal capacitive behavior. Based on the discharge curves, the specific capacitance (C) can be calculated as:

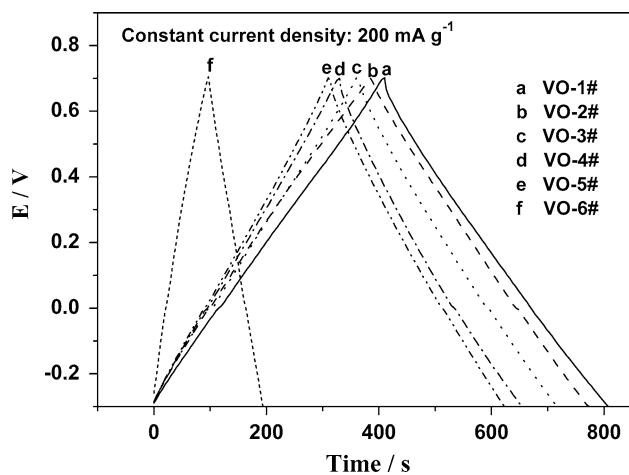

$$C = \frac{2 \times I \times \Delta t}{m \times \Delta V} \quad (3)$$

where  $I$ ,  $\Delta t$ ,  $m$ , and  $\Delta V$ , are the current density, discharge time, the active mass of the single electrode and potential window, respectively.

The initial specific capacitance of VO-1# to VO-6# is listed in Table 1. VO-1# delivers a maximum specific capacitance of 229.2 F g<sup>-1</sup>, while VO-6# delivers the minimum specific capacitance of 115.6 F g<sup>-1</sup>. Obviously, the specific capacitance declines with increasing temperature.

Figure 8 gives cycling life of VO-1# to VO-6# in neutral NaNO<sub>3</sub> solution at a current rate of 200 mA g<sup>-1</sup>. VO-1# and VO-6# have poor cycling performance, but the other samples exhibit relatively good cycling life. Therefore, the most appropriate drying temperature is 80 °C in consideration of specific capacitance and cycling performance.

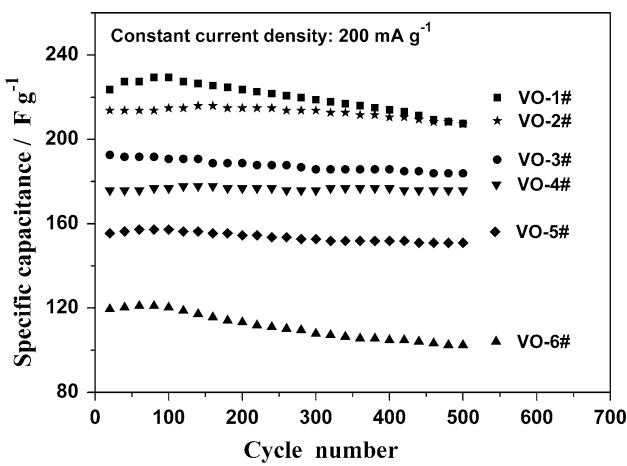

It can be concluded from Figs. 7 and 8 that VO<sub>x</sub>·nH<sub>2</sub>O samples obtained at different drying temperatures exhibit different specific capacitance values and cycling performance, which should be associated with the structure and water content of VO<sub>x</sub>·nH<sub>2</sub>O samples. XRD analysis reveals that VO-1# to VO-4# is amorphous, but VO-5# and VO-6# are crystalline. Zheng et al. [5, 6] found that amorphous RuO<sub>2</sub>·nH<sub>2</sub>O exhibited better capacitive performance than crystalline RuO<sub>2</sub> did. In our study, VO-6# with well-developed crystalline structure also shows the minimum specific capacitance and the poorest cycling performance.

**Fig. 7** Charge/discharge curves of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples obtained at different drying temperatures in neutral  $\text{NaNO}_3$  solution (1#: 40 °C; 2#: 80 °C; 3#: 120 °C; 4#: 160 °C; 5#: 200 °C; and 6#: 240 °C)

**Table 1** The water content and specific capacitance of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples prepared at different drying temperatures

| $\text{VO}_x \cdot n\text{H}_2\text{O}$ sample | Drying temperature (°C) | Water content (wt%) | Discharge specific capacitance ( $\text{F g}^{-1}$ ) |
|--|-------------------------|---------------------|--|
| VO-1#  | 40                      | 17.2                | 229.2  |
| VO-2#  | 80                      | 13.5                | 215.9  |
| VO-3#  | 120                     | 11.9                | 192.8  |
| VO-4#  | 160                     | 10.8                | 177.6  |
| VO-5#  | 200                     | 8.1                 | 141.2  |
| VO-6#  | 240                     | 4.7                 | 115.6  |

**Fig. 8** Cycling life of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples obtained at different drying temperatures in neutral  $\text{NaNO}_3$  solution (1#: 40 °C; 2#: 80 °C; 3#: 120 °C; 4#: 160 °C; 5#: 200 °C; and 6#: 240 °C)

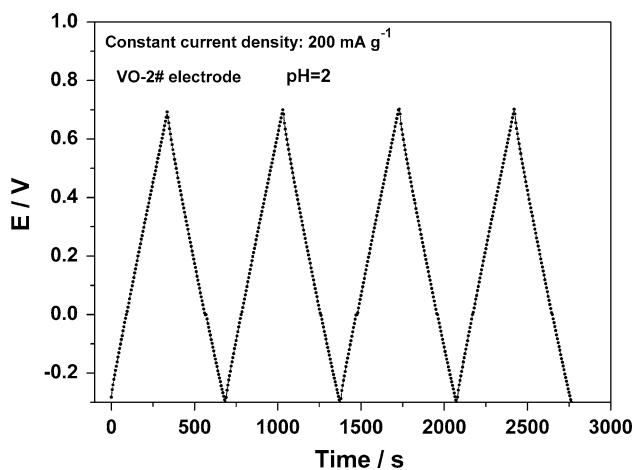

The  $\text{VO}_x$  content in the  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples was analyzed by oxidation-reduction titration, and then the water content was calculated (Table 1). It can be noted that the

water content declines with increasing temperature. The suitable water content not only enhances electronic conductivity (see Sect. 3.1), but also improves ionic adsorption/desorption and protonic diffusion in the bulk [5, 6, 9]. However, excessive water content is unfavorable for cycling life because it would make  $\text{VO}_x \cdot n\text{H}_2\text{O}$  be easily dissolved in aqueous solution. The water content of VO-1# prepared at 40 °C is up to 17.2 wt%, bringing about its poor cycling performance. The water content of VO-6# prepared at 240 °C is reduced to 4.7 wt%, resulting in the minimum initial specific capacitance. Therefore, the drying temperature of 80 °C is optimum in view of specific capacitance and cycling performance. In the subsequent experiments, VO-2# prepared at 80 °C is selected to investigate other capacitive properties of the  $\text{VO}_x \cdot n\text{H}_2\text{O}$  material.

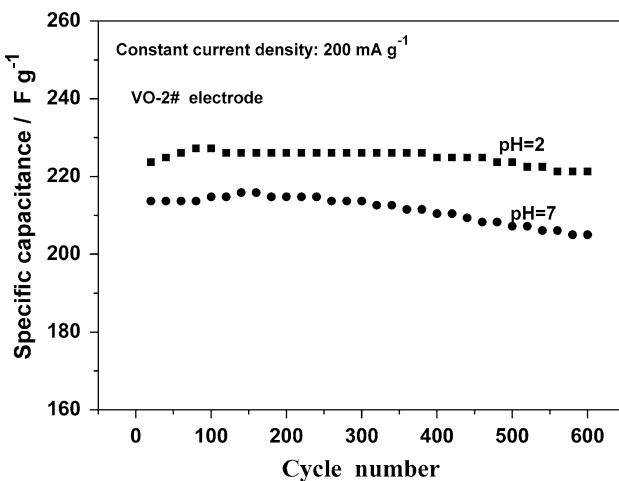

Figs 9 and 10 present the charge/discharge curves and cycling life of VO-2# electrode in  $\text{NaNO}_3$  solution with pH 2, respectively. The relationship between potential and time is quite linear (Fig. 9). The discharge specific capacitance is firstly 227.3  $\text{F g}^{-1}$  and keeps 221.3  $\text{F g}^{-1}$  after 600 cycles in  $\text{NaNO}_3$  solution with pH 2 (Fig. 10). VO-2# electrode delivers higher specific capacitance at pH 2 than that at pH 7, which is related to the energy storage mechanism of  $\text{VO}_x \cdot n\text{H}_2\text{O}$ . It has been found that  $\text{MnO}_2 \cdot n\text{H}_2\text{O}$  has two kinds of energy storage mechanism in aqueous electrolyte, proton-electronic mechanism, and ionic adsorption/desorption mechanism [9–11]. We here-with propose a similar energy storage mechanism for  $\text{VO}_x \cdot n\text{H}_2\text{O}$  (shown in reactions 4 and 5).

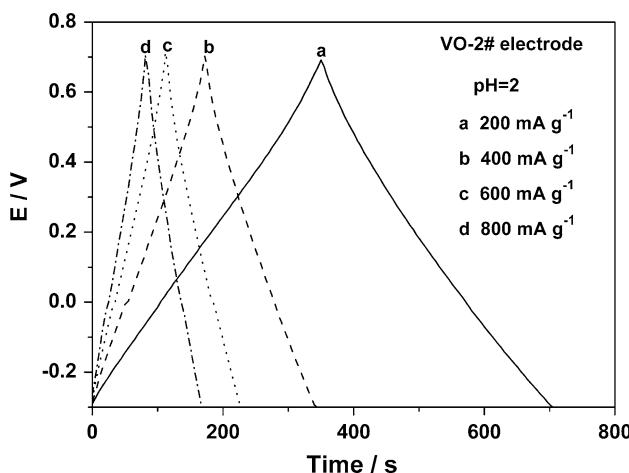

When pH drops from 7 to 2, it becomes easier for reaction 4 to take place because of increasing  $\text{H}^+$

**Fig. 9** Charge/discharge curves of VO-2# electrode in  $\text{NaNO}_3$  solution with pH 2 at a current density of 200  $\text{mA g}^{-1}$

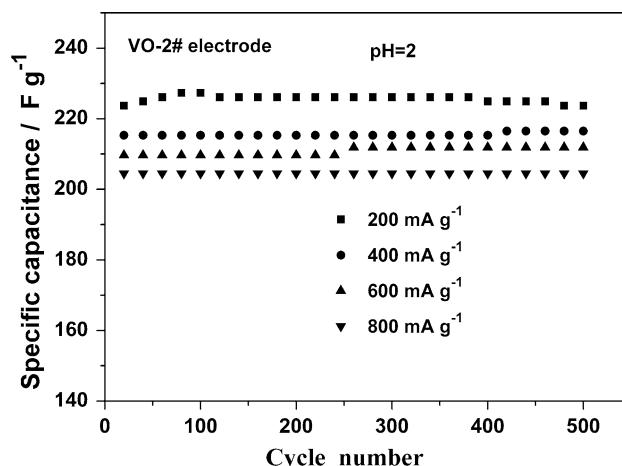

**Fig. 10** Cycling life of VO-2# electrode in  $\text{NaNO}_3$  solutions with pH 2 and pH 7 at a current density of  $200 \text{ mA g}^{-1}$

**Fig. 11** Charge/discharge curves of VO-2# electrode at different current densities in  $\text{NaNO}_3$  solution with pH 2

concentration, which would lead to greater specific capacitance.

An ideal electrode material for supercapacitors is able to be charged/discharged at high current density. Figures 11 and 12 show charge/discharge curves and cycling performance of VO-2# electrode at various current densities in  $\text{NaNO}_3$  solution with pH 2, respectively. A good linear variation of potential versus time is observed in Fig. 11. At the lowest current density of  $200 \text{ mA g}^{-1}$ , VO-2# electrode delivers the highest specific capacitance of  $227.3 \text{ F g}^{-1}$ . When current density is increased to  $800 \text{ mA g}^{-1}$ , the specific capacitance remains  $204.5 \text{ F g}^{-1}$ . It is obvious that the specific capacitance slightly decreases with increasing current density. In addition, the specific capacitance value is essentially unchanged after 500 cycles at  $800 \text{ mA g}^{-1}$  (Fig. 12), indicating that VO-2# electrode

**Fig. 12** Cycling performance of VO-2# electrode at different current densities in  $\text{NaNO}_3$  solution with pH 2

still exhibited good cycling performance at high current density in  $\text{NaNO}_3$  solution with pH 2.

#### 4 Conclusions

$\text{VO}_x \cdot n\text{H}_2\text{O}$  powders were prepared by a melt quenching method. The capacitive properties of  $\text{VO}_x \cdot n\text{H}_2\text{O}$  samples were strongly affected by drying temperature, pH of aqueous electrolyte, and current density. The optimum drying temperature is  $80^\circ\text{C}$ , and the pH value of aqueous electrolyte should be controlled between 7 and 2.  $\text{VO}_x \cdot n\text{H}_2\text{O}$  sample which was obtained at  $80^\circ\text{C}$ , delivers a maximum specific capacitance of  $227.3 \text{ F g}^{-1}$  and exhibits excellent capacity retention in the potential range of  $-0.3$  to  $0.7 \text{ V}$  at  $200 \text{ mA g}^{-1}$  in  $\text{NaNO}_3$  solution with pH 2. The specific capacitance slightly decreases with increasing current density, indicating that  $\text{VO}_x \cdot n\text{H}_2\text{O}$  powders could be charged/discharged at high current density.
