# Heat-Resistant Polymers Containing the Low Molecular Weight *closo*-Carboranes. III. The Preparation of Polycarboranesiloxane Polymers by Alcoholysis

R. E. KESTING, K. F. JACKSON, and J. M. NEWMAN, Chemical Systems Incorporated, Santa Ana, California 92705

#### Synopsis

A new synthesis for carboranesiloxane polymers has been discovered. It involves the alcoholysis of the bischlorodimethylsilylcarborane monomers and the generation of the HCl catalyst in situ. Alcoholysis is applicable to the synthesis of most carboranesiloxane polymers, with the probable exception of the SiB-1 homopolymers of the larger carboranes. The attack of the B—H moieties in the carborane cage can be minimized both by the utilization of a tertiary alcohol and by the addition of excess acid when a primary alcohol is employed.

#### **INTRODUCTION**

Crystalline carboranesiloxane polymers of the 5-SiB-1 type,

+SiR<sub>2</sub>CB<sub>5</sub>H<sub>5</sub>CSiR<sub>2</sub>O $+_n$ 

prepared by the FeCl<sub>a</sub>-catalyzed bulk condensation of the chloro- (i.e., ClSiR<sub>2</sub>CB<sub>5</sub>H<sub>5</sub>CSiR<sub>2</sub>Cl) and the methoxy- (i.e., CH<sub>3</sub>OSiR<sub>2</sub>CB<sub>5</sub>H<sub>5</sub>CSiOCH<sub>3</sub>) monomers, have been reported.<sup>1,2</sup> Amorphous copolymers, made by the incorporation of small quantities of larger carborane (--CB<sub>8</sub>H<sub>8</sub>C-- or m-CB<sub>10</sub>H<sub>10</sub>C—) into the predominantly —CB<sub>5</sub>H<sub>5</sub>C— siloxane backbone have also been prepared.<sup>3,4</sup> The 5-SiB-1 polymers, therefore, encompass a wide range of materials bounded at one extreme by homopolymer waxes and on the other by copolymer elastomers. These polymers are of considerable interest because of their high thermal and oxidative stability.<sup>5</sup> Simplified routes to replace the high temperature and vacuum syntheses hitherto employed are currently being investigated. The present paper describes a study initiated in December 1970 which appears to be applicable to the preparation of all carboranesiloxane polymers with the probable exception of the SiB-1 homopolymers of the large carboranes. It is a simple alcoholysis procedure which employs ambient temperatures, atmospheric pressure, and a catalyst generated in situ.

## **EXPERIMENTAL**

#### **Polymer Synthesis**

The new synthesis involves the addition of an alcohol to the 5-chloro monomer (i.e., 2,4-bis(chlorodimethylsilyl)-2,4-dicarba-*closo*-heptaborane-7) or mixtures thereof with the *m*-10-chloro monomer (i.e., 1,10-bis(chlorodimethylsilyl)-1,10-dicarba-*closo*-decaborane-10). In a typical example, 100 millimoles of 5-chloro monomer were placed in a flask to which 50 ml of an anhydrous alcohol was added. In another example, 50 ml of an alcohol was added to a flask containing 80 millimoles of 5-chloro monomer and 20 millimoles of the *m*-10-chloro monomer. After standing for periods varying between 20 and 200 hr, the precipitated polymers were extracted with solvent, precipitated, washed with water, and dried in a vacuum oven. This synthesis should be generally applicable to the preparation of SiB-1 polymers from the other small carboranes. The higher SiB polymers (i.e., SiB-2, -3, etc.) of C<sub>2</sub>B<sub>5</sub> and C<sub>2</sub>B<sub>10</sub>, and most intermediate *closo*-carboranes (with the possible exception of C<sub>2</sub>B<sub>9</sub>H<sub>11</sub>) are also accessible by this technique.

### Analysis

Number-average molecular weights  $\overline{M}_n$  were determined in chloroform utilizing a vapor pressure osmometer (Mechrolab Model 201A). They are accurate to  $\pm 10\%$ . Melting point ranges were determined on a Fischer-Johns melting point apparatus. Infrared analyses were obtained utilizing a Perkin Elmer Model 21 spectrophotometer.

#### **RESULTS AND DISCUSSION**

During the course of the methanolysis<sup>1,2</sup> of a large amount of 5-chloro monomer to produce 5-methoxy monomer, it was noticed by one of us (J.M.N.) that a white solid precipitate formed in the methanol phase after standing for several days. This precipitate was subsequently shown to be a partially soluble linear polymer whose infrared spectrum exhibited absorption (not present in the case of the 5-SiB-1 homopolymer prepared by anhydrous FeCl<sub>3</sub>-catalyzed condensation) in the 7.2–7.9  $\mu$ m range (maximum at 7.63  $\mu$ m). This absorption is attributable to B—O stretching from B—O—R groups. The latter are the result of the alcoholysis of the B—H groups in the carborane cage.

A study was then made of the effects of the nature and concentration of the R radical in ROH upon polymer properties (Table I). Where R is H or a primary or secondary alkyl group, the B—H moieties in the carborane cage are attacked after standing for several days at ambient temperature to an extent sufficient to cause a substantial amount of B—OR group formation (polymers 1 to 6). Attack of the carborane cage is most severe when water and methanol are employed (polymers 1 and 2). The polymers produced in these cases were also found to be covalently crosslinked and

hence incompletely soluble polymers. Broad melting ranges were therefore characteristic of these species. Interestingly, the addition of concentrated  $H_2SO_4$  to methanol dramatically decreased the B—O absorption in the product (polymer 8). (Protonated methanol should, of course, be less nucleophilic than unprotonated methanol, and hence less likely to attack the electrophilic carborane cage.) However, when R was a 3° radical such as *tert*-butyl or *tert*-amyl (polymers 9 to 14), a lesser amount of B—O absorption was observed, and the products were linear, completely soluble polymers with a molecular weight of about 2700 (i.e., a *DP* of about 12). For the latter, an oversimplified reaction scheme can be envisioned as follows:

$$CH_{3} CH_{3} CH_{3}$$

$$CI - Si - C_{2}B_{6}H_{6} - Si - CI + ROH \Longrightarrow$$

$$I$$

$$CH_{3} CH_{3}$$

$$I$$

$$CH_{3} CH_{3} CH_{3} CH_{3} CH_{3} CH_{3} CH_{3}$$

$$CI - Si - C_{2}B_{5}H_{5} - Si - OR + RO - Si - C_{2}B_{6}H_{5} - Si - OR + HCI (1)$$

$$CH_{3} CH_{3} CH_{3} CH_{3} CH_{3} CH_{3}$$

$$II I$$

$$ROH + HCI \rightleftharpoons RCI + H_{3}O^{+} + CI^{-} (2)$$

$$CH_{3} CH_{3} CH_{3} CH_{3} CH_{3}$$

$$II Or III \xrightarrow{H_{3}O^{+}} HO - Si - C_{2}B_{6}H_{5} - Si - OH + HCI + ROH + RCI$$

$$CH_{3} CH_{3} CH_{3} CH_{3} CH_{3} CH_{3}$$

$$II OF III \xrightarrow{H_{3}O^{+}} HO - Si - C_{2}B_{6}H_{5} - Si - OSi - C_{2}B_{2}H_{2} - Si - OH + HCI + ROH + RCI$$

$$IV$$

Equation (1) suggests that if compound II were the more important intermediate, a maximum in MW should occur when 1 mole of alcohol is reacted with 1 mole of chloro monomer, since such is required for stoichiometry. However, because of the side reaction indicated in eq. (2) (a reaction particularly likely when tertiary alcohols are employed), a somewhat higher concentration of alcohol would be required to achieve this maximum value. However, the fact that greater than stoichiometric quantities of alcohol can be added without lowering the MW of the product indicates that compound III may be more prevalent. In either case, the possible deleterious effect which an excess concentration of alcohol can have by virtue of a possible attack of the B—H moieties in the carborane cages (polymer 9) remains an important consideration.

(3)

It is significant that, although alcoholysis is applicable to the entire range of 5-SiB polymers, including the 5-SiB-1 homopolymers (Fig. 1a) and 5-SiB-1 copolymers containing 20 mole-% m-C<sub>2</sub>B<sub>10</sub> (Fig. 1b), the 10-SiB-1 homopolymers (Fig. 1c) do not appear to be accessible by this method. This appears to be primarily attributable to steric hindrance.

An examination of idealized molecular models (regular polyhedra) of the above species shows that the carbon atoms in the  $C_2B_5H_7$  chloro monomer

are encountered at the apex of two relatively small angles within the cage: a wide angle of 108° and a narrow angle of 63°. In both cases a large exterior angle results which can be expected to contribute to flexibility in the C—Si bond. Both carbon atoms in the m-C<sub>2</sub>B<sub>10</sub> chloro monomer, on the other hand, are situated at the apex of wide internal angles of 124.5°, with the result that the exterior angle is much smaller and hence the C—Si bond more restricted than is the case for the 5-SiB polymers. This suggests that two m-C<sub>2</sub>B<sub>10</sub> moieties cannot be made to adjoin one another in a SiB-1

Fig. 1. Polycarboranesiloxane polymers of the SiB-1 type.

polymer unless forcing conditions are employed. Copolymers incorporating both  $C_2B_5$  and  $C_2B_{10}$  monomers apparently represent a situation intermediate between 5-SiB-1 and 10-SiB-1 homopolymers, since the MW of the polymer containing 20 mole-% m-C<sub>2</sub>B<sub>10</sub> (polymer 14) is lower than that of the 5-SiB-1 homopolymer and higher than that of the 10-SiB-1 homopolymer, which does not appear to form under the present set of conditions. In other words, a m-C<sub>2</sub>B<sub>10</sub> monomer can be joined to a C<sub>2</sub>B<sub>5</sub> monomer, but less readily than one C<sub>2</sub>B<sub>5</sub> monomer to another of its own kind. This situation contributes to isolation of C<sub>2</sub>B<sub>10</sub> monomers which in turn acts to maximize randomness and hence elastomeric behavior on the copolymer.

Although low molecular weight polymers are obtained by alcoholysis, it is obvious that, where high molecular weight is desired, further polymerization can be effected by other techniques. The authors gratefully acknowledge the support of this study by the Office of Naval Research. They would also like to express their gratitude to their colleagues Dr. R. E. Williams and Dr. J. F. Ditter for helpful critical discussions.
