Slow Luminescence Emission from Polymers with a Hyperbolic Decay Law. A Survey of Commercial Materials With an Apparatus of Wide Aperture

G. D. MENDENHALL and H. K. AGARWAL, Department of Chemistry and Chemical Engineering, Michigan Technological University, Houghton, Michigan 49931

Synopsis

A survey of 98 commercial polymers with an apparatus responding to a sample area of 20 cm² revealed luminescence in about a third of them with a characteristic, hyperbolic decay extending over several minutes after brief irradiation with an incandescent source. The time dependence of the intensity was described well by the Debye–Edwards equation, of the form $I = At^{-m}$, with m between 0.67 and 1.17 except for polyvinylcarbazole, with m = 1.76. In a few cases studied in more detail, the emission could be stimulated by wavelengths extending into the visible region, showed a negligible temperature dependence (6-40° C), and was little affected by removal of oxygen or water from the atmosphere around the samples. The source of the emission is ascribed to charge recombination of photoejected electrons from chromophores in the polymer structure or (in most cases) present as adventitious impurities which were not extractable in two cases. Nylon 6, which showed little emission alone, gave well-defined hyperbolic curves after heating in air or after addition of the fluorescent dye Benzoxanthene Yellow H2495.

INTRODUCTION

Some time ago one of us¹ pointed out that weak light emission, stimulated by an incandescent source, was observed on a time scale of minutes from a variety of organic materials and could be fitted to an expression $1/I \equiv dt/dhv$ = kt for t > 0, corresponding to the Debye-Edwards equation² with m = 1. The parameters describing the decay have been empirically correlated in unpublished studies carried out by one of us (G. D. M.) to the composition, processing variables (e.g., degree of cure), age, or state of deterioration of edible or fabricated materials. Since those studies were largely proprietary and involved complicated systems, we have undertaken a survey of singlecomponent polymers in order to establish the scope of the luminescence. In addition to empirical applications, the nonexponential emission is important because it will contribute an apparent background signal to the exponential luminescence decay that is usually sought in polymers at much shorter observation times. A third interest in the phenomenon arises from its possible association with single electron transfer processes leading to polymer oxidation.³

We have used the term charge recombination luminescence to describe the emission by analogy to a number of other studies which have shown that a power function describes phenomena associated with diffusive electron-cation

recombination⁴⁻⁸:

$$C \xrightarrow{\mu\nu} C^* \to C^{*+} + e^- \tag{1}$$

$$C^{*+} + e^{-} \xrightarrow{\text{slow}} C^* \to h\nu^1$$
 (2)

where C = chromophore and $C^* =$ electronically excited C. We prefer the term Debye-Edwards luminescence (DEL) to describe the curves, since these workers were among the first to describe the hyperbolic decay curves in terms of electron recombination.

EXPERIMENTAL

The apparatus (Fig. 1) was a very simple device which allowed one to irradiate a thin layer of polymer with a conventional, 100 W incandescent light. A 1 cm layer of water in a Pyrex dish absorbed a large portion of the IR emission, and direct measurement of the sample surface with a thermocouple showed that the transmitted photons of all wavelengths produced no significant temperature rise. An irradiation time of 10.0 s was found to be sufficient to give a photostationary steady state. Following the irradiation, the sample was manually slid into a light-tight chamber under a photomultiplier tube-housing and the decay recorded for several minutes. This procedure gave good reproducibility ($m \pm 0.05$, ln $A \pm 0.2$), and the irradiating source was more stable and less damaging to samples than conventional laboratory lamps of higher power.

Data were collected in the photon-counting mode with a computer system described earlier.⁹ Parameters for the Debye–Edwards law were made by optimizing the *F*-statistic of the least-squares analysis of log–log plots by subtracting out a constant background counting rate which was usually small in comparison to the recombination luminescence. The values of $\ln A$ (intercept) and m (-1*slope) so obtained are given in Table I. The magnitude of A so evaluated depends on the sampling time interval and other factors (see Appendix).

For the experiments at 6° C the entire apparatus was moved into a cold room at that temperature. For experiments at 40° C, two horizontal 150 W heaters were attached to the sides of sliding device, and the input voltage was adjusted to give the desired temperature.

Polymer samples were taken from a collection available from SP2, Inc. (Kit no. 205) and examined initially without further treatment. A few samples from other sources are indicated parenthetically or in footnotes in Table I. Polyvinylcarbazole (PVK) was purchased from Polysciences, Inc. All samples were in the form of powders or granules. A sample of nylon 6 (4.9 g) was allowed to stand in a methanol solution $5.95 \times 10^{-6}M$ in Benzoxanthene Yellow H2495 (Hoechst 2495, from Aldrich Chemical Co.), the solvent was decanted, and the yellow polymer was dried. The concentration of the dye in the polymer was calculated as 7.9×10^{-4} % from the change in optical density of the methanol solution.

MENDENHALL AND AGARWAL

Fig. 1. Apparatus for detection of DEL.

An unsuccessful attempt was made to see unpaired spins by brief irradiation of a sample of nylon 11 in a 6 mm ID pyrex tube in the cavity of a Varian E9 electron spin resonance spectrometer. Unfiltered light from a 200 W high-pressure mercury lamp, focused with quartz lenses, was the excitation source for this experiment.

RESULTS

General Characteristics of DEL. The apparatus shown in Figure 1 is extremely simple and unsophisticated, and, in combustion with the high precision of the photon counting capability, it is very useful for characterization of a wide variety of natural and artificial materials. The sliding device is actually unnecessary for many substances, since the generality of the phenomenon was recognized when attempts to measure thermal chemiluminescence in a number of samples were frustrated by a slowly decaying component of the emission, which was traced to stimulation by fluorescent room lights.

About a third of the samples that we studied showed luminescence persisting for minutes after irradiation. The nonexponential nature of the decay is apparent in the curve shapes in Figure 2, in which the optimized fits according to the Debye–Edwards equation are plotted for three representative examples.

There is some ambiguity in the selection of the parameters in Table I due to the presence of a background signal, which is composed of inherent tube noise (usually < 7 cps with a cold tube) and chemiluminescence emission from the polymer. This appeared to be a serious problem only when the DEL was very weak, or when color filters were used to filter the exciting or emitted light. In two cases (Table I, samples 15 and 16) the fit was equally good with background levels ranging over factors of 3 and 6, respectively. In most

Fig. 2. Exemplary plots of DEL from polymers, as photons per 5-s interval vs. time. The fitted curves are drawn through (selected) experimental points.

examples, however, the best parameters led to a very close visual fit of the curve to the data, although systematic deviations were usually still apparent on examination of the residuals.

A list of polymers which did not show long-lived luminescence is given in Table II. In some cases we are able to detect the tail end of short-lived luminescence from these samples, but we were not able to collect sufficient data with this apparatus to distinguish between hyperbolic and exponential decay.

The mean exponential term of those given in Table I was 0.88 ± 0.13 . The calculated counting rates 30 s after the end of the irradiation varied from 120 (soluble starch) to 35,400 (polycaprolactone). Extrapolation to unit times $(I_0 \cong A/\Delta t)$ gave an estimate for the steady state intensities of the DEL during irradiation, which vary over about two orders of magnitude in representative examples (Table III).

The effect of other variables was examined in a few cases. In Table IV, decay parameters are given for a sample of nylon 11 which was examined after successive irradiations in the usual way. Aside from minor systematic trends which may be due to characteristics of the irradiation system, the parameters are very similar.

We also selected four samples of representative polymers for the study of atmospheric dependence (Table V). The decay parameters showed minor differences in ambient air, dry air, or nitrogen.

- 62. Vinylidene chloride/vinyl chloride copolymer

The sample temperature had little systematic effect on the parameters derived from the curves of DEL obtained from three representative polymers (Table VI). The exponential term m showed less change than the values of A, which displayed slightly larger values at 25°C than at higher or lower temperatures. At lower temperatures, charge-recombination kinetics have been found to be independent of temperature in some cases^{4,5} and to show irreversible changes associated with annealing in others.⁶

Spectral Distribution. Color filters were used in separate, rough experiments to determine the significant wavelengths for excitation and emission. In

TABLE IV Effect of Multiple Irradiations on DEL from Nylon 12

Table VII the exciting wavelengths for nylon 11 are seen to extend well into the visible region. The emitted light (Table VIII) appears to be concentrated between 400 and 490 nm, although there is some uncertainty because the manufacturer's curves for the photomultiplier tube indicate a decline in sensitivity from 20% at 400 nm to about 6.7% at 590 nm. In both types of experiments the effect of the filter should be only a diminution in the value of A from the subsequent data analysis (see appendix). This appears to be the case for the first three examples in Table VIII, but the last two filters removed so much light that there was a great deal of scatter in the data, and the fitted exponential term was anomalously low.

We attempted to extract chromophores from nylon 11 and the polysulfone resin with isopropanol-dichloromethane without success (Table IX). The polysulfone congealed into a hard lump during the extraction process, and was subsequently compression-molded into a sheet which showed DEL parameters virtually identical to those of the original resin.

Polyvinylcarbazole. After the original survey was completed, we became aware of work⁶ on laser-induced excitation in PVK, which gave emission corresponding to a power law over the range 0.05–lms. Unfortunately, it is not possible to calculate the value of the exponential term from the data given in this paper. Since photoconductivity via electron-hole formation is very well established for PVK, we examined a commercial sample in our apparatus and found the DEL to be the most intense by far of any polymer studied, with $\ln A = 17.99 \pm 0.02$ and $m = 1.792 \pm 0.007$ (average of 5 decays). In the previous work,⁶ signal averaging was necessary to obtain sufficient data for analysis. Although the source of the PVK, of course, may have been different

than ours, the sensitivity of our apparatus is indicated by the observation of measurable DEL an hour after the original 10 s irradiation of this polymer.

DISCUSSION

Decay Kinetics. The hyperbolic decay curves from the polymer samples distinguish them from simple fluorescence or phosphorescence emission, although the actual DEL from the short-lived excited states may correspond to one of the latter. The exponential terms (m) in our experiments are in the same range as those found in other systems. Debye and Edwards, for instance, obtained values of m between 0.83 and 1.61 in UV-irradiated p-toluidine in frozen glasses.² The values for many of our polymers are close enough to unity

1270 MENDENHALL AND AGARWAL

that the reciprocal formula applied earlier¹ would be satisfactory, although during initial attempts to use it in this study we found that a more general equation with an adjustable exponential term was preferable.

Stochastic models to account for the time dependence of hole-cation recombination processes have been advanced by a number of investigators recently.⁶⁻⁸ For instance, Stolzenberg et al.⁶ used a Monte Carlo simulation of geminate recombination with site hopping between i and j described by jump rates of

$$\begin{split} \nu_{ij} &= \nu_0 e^{-2\gamma |r_{ij}|} e^{-(\epsilon_j - \epsilon_j)/kT}, \qquad \epsilon_j > \epsilon_i \\ \nu_{ij} &= \nu_0 e^{-2\gamma |r_{ij}|}, \qquad \epsilon_j < \epsilon_i \end{split}$$

With one particular set of parameters γ (wave function overlap) and ν_0 , the simulated rate of electron-hole recombination followed a power function with m = 1.13, which is in the range of the exponential terms found in our study.

The use of short-wavelength excitation to produce a slowly decaying emission has been used previously by ourselves¹⁰ and others,¹¹ and ascribed without further evidence to *radical* recombination luminescence from an initially formed population of peroxyl radicals:

$$\mathbf{P} \xrightarrow{h\nu} 2\mathbf{R} \cdot \xrightarrow{\mathbf{O}_2} 2\mathbf{R}\mathbf{O}_2 \cdot \tag{3}$$

$$2\mathrm{RO}_2 \cdot \xrightarrow{k_t} \to \mathrm{nonradical \ products} + h\nu' \tag{4}$$

$$(P = precursor, R = alkyl)$$

For a homogeneous initial distribution of radicals, the above mechanism leads to the prediction¹⁰ of a decay of the light intensity (I) according to the equation

$$1/I^{1/2} - 1/I_0^{1/2} = 2k_t t/f \tag{5}$$

where f is the efficiency factor and I_0 is the initial intensity. For large I_0 , the equation reduces to

$$I = (f^{2}/4k_{d}^{2})t^{-2} = At^{-2}$$
(6)

In the presence of a background level of free-radical initiation giving rise to a nonstimulated luminescence I_{∞} , the equation takes on a more complicated form:

$$\ln\left[\left(I_{\infty}^{1/2} + I^{1/2}\right) / \left(I^{1/2} - I_{\infty}^{1/2}\right)\right] = 4k_{i} [\operatorname{In}] k_{i} t / f$$
$$-\ln\left[\left(I_{0}^{1/2} - I_{\infty}^{1/2}\right) / \left(I_{\infty}^{1/2} + I_{0}^{1/2}\right)\right] \quad (7)$$

where I_{∞} is the "thermal" chemiluminescence produced by the background initiation rate $2k_i$ [In].

In our samples all but one of the exponential terms was below 1.2, which precludes the simple formula (4), and application of eq. (5) to several examples gave substantially worse fits to the data.

The temperature-independence of the parameters for the DE (Table VI) is an expected characteristic of a process involving diffusion of a small particle such as an electron, although we would expect *a priori* that significant differences might be found in polymers in temperature ranges where they undergo phase transitions, or above a critical temperature for electron transport as discussed by Hamill.⁴ The apparatus was designed only for a general survey, however, and we have not made a systematic study of this possibility over an extended range of temperature.

Bässler has predicted⁶ a temperature dependence of the recombination rate proportional to $e^{-(T_0/T)^2}$, where T_0 is the width of the assumed Gaussian distribution of trapping sites. The absence of a temperature dependence of the decay parameters in the experiments described in Table VI would therefore suggest relatively large values of T_0 .

We anticipated that water might plasticize the polar polymers and change the DEL decay characteristics, but the data in Table V do not show very pronounced difference between samples in humid vs. dry atmospheres. The decay characteristics in nitrogen vs. oxygen also do not show much change, although oxygen is an effective quencher for triplet states in polymers,¹² and can scavenge electrons to form superoxide ion with different diffusional characteristics. These results are consistent with trapping of photoejected electrons in relatively rigid or at least inaccessible sites of the polymer, followed by hopping between lattice sites in competition with slow recombination with the original cationic center as described.⁶

The emission from our samples in all cases was relatively weak, and the design of our apparatus with a wide collection area was necessary to measure the emission with satisfactory precision. The weakness of the signal, however, is partly a simple consequence of the slow decay. Although it is not possible to characterize the DEL fully because the concentrations and quantum yields of the emitting species are not known, we can estimate roughly from the data of Tables III, VII, and VIII that for nylon 11, about 5×10^{-7} of the incident photons in the active region of the spectrum are emitted as DEL. Since not all of the incident energy is absorbed by the sample, the quantum yield is probably larger than this value.

Nature of the Chromophore. We had expected that irradiation in the short end of the visible spectrum would be effective, but it was a little surprising that light even with wavelengths beyond 500 nm (< 57 kcal/mol) was able to give an easily measurable luminescence (Table VII). Several pieces of evidence indicate that adventitious chromophores are responsible for this DEL. First, except for poly(*p*-phenylene sulfide) and PVK, none of the polymers contain chromophoric groups in their normal repeating units which absorb appreciably in the visible region. Second, many polymers of similar structure appear in both the luminescing and nonluminescing categories (Tables I and II). In one instance (polycarbonate) the material from one source showed DEL but a sample from a different source did not. Third, the absence of DEL from polycaprolactam, in contrast to other polyamides, may be associated with its commercial synthesis by a ring opening rather than a

high-temperature condensation process. Finally, we have been able to stimulate long-lived luminescence (average of 5 decays: $\ln A = 7.61 \pm 0.2$, $m = 1.06 \pm 0.08$) in nylon 6 with a typical hyperbolic decay curve by addition of $7.9 \times 10^{-4}\%$ of a dibenzofuran dye which is known to complex strongly with proteins.

Several authors^{13,14} have proposed that photochemical damage to polymers is caused by adventitious chromophores including peroxidic and catalyst residues, polyaromatic hydrocarbons, and titanium compounds. While the connection between the chromophores responsible for degradation and the ones causing the DEL is not established, the latter cannot be aromatic hydrocarbons in nylon 11 and in the polysulfone, because we could not extract them with organic solvents. Peroxidic residues alone do not appear to be the chromophores because they are transparent in the visible region. It is unlikely that the same, added impurity would be responsible for the DEL in all of the samples we examined, since egg albumin and nylon 6/9, for instance, have obviously divergent origins, even though their hyperbolic decay parameters are quite similar.

Evidence that the chromophores in the nylon series are introduced by high-temperature processing was obtained by an experiment in which polycaprolactum was examined for DEL in the usual way after heating in air at 100 °C for different times. A well-developed hyperbolic curve was apparent

Fig. 3. DEL from poly(ϵ -caprolactam) at 25°C after heating at 100°C for the indicated times. The plotting is carried out as for Figure 2.

after 16 h, although the sample initially showed little luminescence (Fig. 3). A very slight discoloration was apparent in this sample after the heating period, when it was placed next to unheated material for comparison.

Electron Spin Resonance Experiment. The absence of a significant signal on irradiation of nylon 11 in an ESR cavity suggests that the number of unpaired spins is relatively small. From the data on nylon 11 in Table I and the integrated form of the Debye–Edwards equation, we estimate that the total number of photons emitted in the DEL experiment with this polymer was about 10^{9} . Since the sample size in the ESR experiment was much smaller, it is not surprising if the free spins present were below the ESR detection limit of about 10^{13} , provided that the quantum yield of emission from the chromophore was above about 10^{-4} .

This work has been generously supported by 3M Co. and by a fellowship to H. K. Agarwal from Himont U.S.A., Inc.

APPENDIX

Cutoff Filters. For a decay of the form $I = At^{-m}$, interposing an optical filter between the sample and the detector will reduce the observed instantaneous intensity by a fraction f to a new value I':

$$I' = \int I = \int dhv/dt = \int At^{-m}$$
(8)

Evaluation of the decay curve obtained with the filter in place will give a new preexponential factor A' = fA; hence f = A'/A (Table VIII). The value of the slope of the log-log plot remains unchanged.

Similarly, self-absorption of emitted light from a sample, use of a detector with different sensitivity, or changing the distance from the sample to the detector will change the evaluated A factor but not m.

Normalization Correction. The data from our experiments were collected as the total photons during successive intervals Δt vs. the number of time intervals. In terms of the Debye expression given above, what we actually evaluated in the logarithmic transform of the raw data is therefore

$$\ln(I \cdot \Delta t) = \ln A' - m' \ln(t/\Delta t)$$
⁽⁹⁾

where I is approximated as an average intensity over the time interval. By comparison of this equation with the normalized form $\ln I = \ln A - m \ln t$, with I in counts/s and t in s, it can be shown that

$$m = m' \tag{10}$$

$$\ln A = \ln A' + (m' - 1) \ln \Delta t \tag{11}$$

Since the magnitude of A has no special significance, and is subject to proportionate increases due to the geometry of the apparatus and PMT response as well, the directly evaluated preexponential terms (i.e., A') are given in Table I without correction. The correction in any case is a small one and vanishes for m = 1.
