Received September 29, 1987; revised February 17, 1988

A systematic study has been conducted on the evolution of phases in chromia-promoted  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> catalysts prepared under a wide range of conditions using different instrumental techniques, viz., DTA, XRD, TEM, IR, and Mössbauer spectroscopy. The structural parameters have been correlated with the reaction properties of the catalysts for the water gas shift reaction. It has been revealed that  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> prepared by precipitation techniques has an imperfect spinel structure. In the wet mixing method of preparation of the catalyst, the interaction between  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> and Cr<sub>2</sub>O<sub>3</sub> is found to be insignificant, while for the coprecipitated method, the interaction takes place by the incorporation of Cr<sup>3+</sup> ions into the octahedral vacant sites of the  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> lattice where chromia concentration remains below 15%, above which the crystallization of the mixed phase is hindered and the activity of the catalyst tends to decrease. The reverse coprecipitation technique with a chromia concentration of nearly 10% is found to be most effective for imparting higher CO conversion activity. © 1988 Academic Press, Inc.

### INTRODUCTION

Chromia-promoted iron oxide is widely used as a water gas shift reaction catalyst in which iron oxide mass initially exists in any of the crystalline forms, viz.,  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub>,  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>, or hydrated iron oxide, and chromia is used as a structural promoter (1–3). The incorporation of Cr<sup>3+</sup> ions into  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> lattice occurs readily by a continuous cationic interdiffusion process (4, 5). But the same is not true for  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> which differs in structural symmetry from  $\alpha$ -Cr<sub>2</sub>O<sub>3</sub>. Both  $\alpha$ - and  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> are reduced to Fe<sub>3</sub>O<sub>4</sub> to obtain the active catalytic mass for the water gas shift reaction. Since the reduction of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> into Fe<sub>3</sub>O<sub>4</sub> is effected by topotactic transformation (6), sintering of the active phase is greatly reduced in catalysts consisting of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> compared to that of  $\alpha$ -Fe<sub>2</sub>O<sub>3</sub> under identical operating conditions. Because of this property,

$\gamma$ -Fe<sub>2</sub>O<sub>3</sub> is preferentially used for the commercial production of high-temperature shift catalysts (7–11). However, no systematic study has been reported so far for the identification of the nature of Cr<sup>3+</sup> species in the catalytic system consisting of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>/Cr<sub>2</sub>O<sub>3</sub>. Only limited information is available in published literature (7, 12).

$\gamma$ -Fe<sub>2</sub>O<sub>3</sub> possesses an imperfect spinel structure in which Fe<sup>3+</sup> ions are distributed in tetrahedral and octahedral positions with cation vacancies preferentially located at octahedral lattice sites (13–15). Because of the preferential distribution of vacancies at octahedral sites, Fe<sup>3+</sup> ions are more strongly bound at the tetrahedral lattice points (13, 16). According to Verwey (14) and Kordes (15) the structure of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> can be represented as (Fe<sub>1</sub><sup>3+</sup>)<sub>tetr.</sub>(□<sub>1/3</sub>Fe<sub>5/3</sub><sup>3+</sup>)<sub>oct.</sub>O<sub>4</sub>, where □<sub>1/3</sub> denotes nearly 11% cation vacancies per molecule. It therefore seems possible that in the chro-

chromia-promoted  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> catalysts, Cr<sup>3+</sup> ions can be incorporated into the octahedral vacant sites of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub>.

With this goal in mind, in the present investigation, a systematic study has been carried out on the identification of the nature of incorporation of Cr<sup>3+</sup> ions and the evolution of phases in chromia-promoted  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> catalysts prepared under different conditions as well as the structural parameters and their effects on the catalytic activities for water gas shift reactions.

#### EXPERIMENTAL

Three series of samples were prepared for this study and will be denoted as A, B, and C.  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> was prepared by oxygenation of iron hydroxide slurry in alkaline medium. The precipitated mass was washed to free it from SO<sub>4</sub><sup>2-</sup> ions and calcined at 473 K for 1 h. This sample was designated A. The three samples in this series were prepared by kneading (incipient wet mixing)  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> with chromium(VI) oxide solution to have nearly 10, 15, and 20% Cr<sub>2</sub>O<sub>3</sub> by weight after calcination and were designated A1, A2, and A3, respectively. B series samples were prepared by the coprecipitation of ferrous sulfate and chromium(III) sulfate solutions (0.1 M each) with 0.25 M NaOH solution under an inert atmosphere, followed by oxygenation

of the hydroxide slurry in an alkaline medium. The precipitated mass was washed to free it from sulfate ions and was oven dried at 383 K. Three samples, namely B1, B2, and B3, were prepared with nearly 10, 15, and 20% Cr<sub>2</sub>O<sub>3</sub> by weight, respectively. Samples C1, C2, and C3 with about 10, 15, and 20% Cr<sub>2</sub>O<sub>3</sub> by weight in the calcined product, respectively, were prepared by a reverse precipitation technique, i.e., by the addition of mixed ferrous and chromium(III) sulfate solution to sodium hydroxide solution. The other treatments were the same as those used for the B series. The difference between the B and the C series is that in the B series the metal hydroxides are precipitated one after another depending on the solubility products, whereas in the C series both hydroxides are precipitated simultaneously. Another sample designated D was prepared by mechanical mixing of  $\gamma$ -Fe<sub>2</sub>O<sub>3</sub> with 10% Cr<sub>2</sub>O<sub>3</sub>. The chromia-incorporated samples were calcined for 1 h at respective temperatures as shown in Table 1. The chemical analyses for iron and chromium in all the samples were performed using standard analytical methods.

Differential thermal analysis was carried out in a DTA instrument fabricated in PDIL Workshop. The heating rate was maintained at 10 K/min, and  $\alpha$ -Al<sub>2</sub>O<sub>3</sub> was used as standard. The preheat treatment of the

<sup>a</sup> Amorphous.

kneaded samples was carried out at 573 K because of the hygroscopic and corrosive nature of free chromic acid for DTA studies.

X-ray diffraction studies were carried out with a standard Guinier camera and X-ray diffractometer using  $\text{CuK}\alpha$  radiation.  $\theta$ -values were corrected by comparison with  $\alpha\text{-Al}_2\text{O}_3$  diffraction lines. Crystalline phases were determined by the JCPDS method and lattice parameters were determined from the  $\theta$ -values using a suitable computer program. The crystallite sizes were measured by a line broadening technique using the Scherrer formula.

Electron micrographs of the samples were obtained using a transmission electron microscope (JEOL-JEM-100 CX). The samples were soaked in acetone to remove entrapped air and dispersed in isopropyl alcohol by means of an ultrasonic probe.

Infrared spectra were recorded in a SPECORD JR-75 IR spectrometer and a Bruker IFS Fourier transform IR spectrometer. The sample pellets were prepared using a CsI matrix.

The Mössbauer spectra of the samples were recorded in an NF-640 spectrometer at 295 and 77 K. Analyses of the Mössbauer spectra and the decomposition into Lorentz components were performed with the aid of an E-666 computer and SK-2 curve synthesizer.  $\text{Co}^{57}$  (Pd) with an activity of some 20 mCi at room temperature was used as a source.  $\gamma$  quanta were registered by a proportional counter with resolution  $\Delta E_{14.4 \text{ keV}} = 15\%$ . All chemical shifts were measured relative to  $\alpha\text{-Fe}$ . Sample weights were varied within 10–25 mg/cm<sup>2</sup> depending upon the content of Fe in mixed oxides. The samples were placed in Teflon cuvettes having a flat parallel Be window of 0.05 mm thick.

The CO conversion activities of the samples were measured in a glass reactor in the temperature range 518–573 K using a gas composition (dry) around 8%  $\text{CO}_2$ , 20% CO, 60%  $\text{H}_2$ , 4%  $\text{CH}_4$ , and steam:gas = 1.0, overall space velocities being varied in

the range 10,000–30,000 h<sup>-1</sup>. The volume of the catalyst taken in each case was 1 cm<sup>3</sup> of –10 to +12 mesh size (B.S.). All experiments were conducted under isothermal conditions far removed from equilibrium (maximum conversion 10%). The surface areas of the samples were measured by the BET method. The samples were reduced with the same gas composition at a temperature of 523 K before activity measurements. The activities per gram catalyst sample were expressed as a first-order rate equation given by Laupichler (17).

## RESULTS AND DISCUSSION

The DTA curves of the samples are shown in Fig. 1. In the DTA curves of samples A1, A2, and A3, an endothermic peak appears at 723 K whereas this peak is absent in sample A. This is due to formation of the  $\text{Cr}_2\text{O}_3$  phase from the interme-

FIG. 1. DTA curves of  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  samples. A,  $\gamma\text{-Fe}_2\text{O}_3$ ; A1, A2, and A3, wet mixed  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10, 15, and 20%, respectively; B1, B2, and B3, direct coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10, 15, and 20%, respectively; and C1, C2, and C3,  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10, 15, and 20%, respectively.

diate oxides of chromium, which are formed during calcination of the samples at 573 K. The intensity of the endothermic peak increases with increasing chromia concentration. This implies that free  $\text{Cr}_2\text{O}_3$  is present in the samples of the A series and therefore, practically no interaction between  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Cr}_2\text{O}_3$  takes place in these samples. In the case of B and C series samples, no exothermic peak around 723 K was observed in the DTA thermogram. This peak has been attributed by several workers (18, 19) to be due to the transformation of amorphous chromium hydroxide to crystalline chromium oxide. The absence of such a peak, therefore, indicates that in these samples, chromium hydroxide loses its identity under the present preparative conditions, thus implying the formation of a mixed hydroxide phase, which is converted into chromium-substituted  $\gamma\text{-Fe}_2\text{O}_3$  upon oxidation.

The exothermic peaks, appearing in the DTA thermograms of all the samples, are accounted for by the transformation of  $\gamma\text{-Fe}_2\text{O}_3$  into the  $\alpha\text{-Fe}_2\text{O}_3$  phase. In sample A, this peak appears at 823 K which is somewhat higher than the values reported elsewhere (20). In the samples of the A series, this peak is shifted to 893 K and in the samples of the B and C series, the same is further shifted to 913 K. A similar increase in the  $\gamma \rightarrow \alpha$  phase transition temperature in the presence of chromia has been reported by Danielezyk and Haber (9). The increase in the phase transition temperature suggests that in the presence of chromia,  $\gamma\text{-Fe}_2\text{O}_3$  becomes thermally stable, and the thermal stability of the coprecipitated samples is more than that of the wet mixed samples. In the case of samples C1 and C2, the exothermic peak becomes weak and broad and disappears in sample C3. This observation reveals that the incorporation of higher concentrations (more than 15%) of chromia by the reverse coprecipitation technique, as in the case of sample C3, hinders the crystallization of  $\gamma\text{-Fe}_2\text{O}_3$ .

X-ray investigation results are presented

in Table 1. The estimated standard deviations of the lattice parameter ( $a_0$ ) values are shown in parentheses. In the case of kneaded samples (A1 to A3),  $\gamma\text{-Fe}_2\text{O}_3$  is the predominate phase at the early stage of calcination, and a free  $\text{Cr}_2\text{O}_3$  phase is present in all the samples calcined at 723 K only. The formation of a single corundum-type  $\alpha\text{-Fe}_2\text{O}_3$  phase has been observed at 873 K. In the case of samples B1 to B3, the crystalline  $\gamma\text{-Fe}_2\text{O}_3$  phase is formed at 623 K. The transformation from the  $\gamma$ - to the  $\alpha$ -phase starts around 873 K and is completed at 973 K. In samples C1 to C3,  $\gamma\text{-Fe}_2\text{O}_3$  crystallizes in samples C1 and C2 at 623 K whereas sample C3 is amorphous up to 723 K. The transformation from the  $\gamma$ - to the  $\alpha$ -phase takes place as in samples of B series (Table 1).

Pure  $\gamma\text{-Fe}_2\text{O}_3$  (sample A) starts to transform into  $\alpha\text{-Fe}_2\text{O}_3$  at 723 K and is completed at 873 K. In the presence of  $\text{Cr}^{3+}$  ions this transformation temperature is elevated. The elevation of temperature is greater in coprecipitated samples than in the kneaded samples, which indicates that the thermal stability of  $\gamma\text{-Fe}_2\text{O}_3$  is greater in coprecipitated samples. In the case of kneaded samples the measured lattice parameter values of  $\gamma\text{-Fe}_2\text{O}_3$  at 723 K show an insignificant decrease in  $a_0$  values (Table 1) after incorporating  $\text{Cr}_2\text{O}_3$  into  $\gamma\text{-Fe}_2\text{O}_3$ . The crystallite size of  $\gamma\text{-Fe}_2\text{O}_3$  (Table 1) also does not change with an increase in chromia concentration. The insignificant change in  $a_0$  values and the presence of free  $\text{Cr}_2\text{O}_3$  reveal that there is little interaction between  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Cr}_2\text{O}_3$  in the kneading process. In coprecipitated samples, the change in  $a_0$  values of  $\gamma\text{-Fe}_2\text{O}_3$  from that of sample A is significant (Table 1). Moreover, the crystallite sizes of  $\gamma\text{-Fe}_2\text{O}_3$  are found to decrease monotonically with increasing chromium concentration (Table 1) and the X-ray diffraction lines gradually become broad and diffuse, particularly below 723 K. This is more pronounced in the C series samples; initially, at low chromia concentration, the composite oxide is crystalline

but with an increase in  $\text{Cr}^{3+}$  content a monotonic transition from a crystalline to an amorphous state occurs. The X-ray studies, therefore, reveal that in coprecipitated samples  $\text{Cr}^{3+}$  ions can enter the  $\gamma\text{-Fe}_2\text{O}_3$  lattice up to a certain concentration which is below 15%; consequently a lattice distortion takes place as is evident from the lattice parameter change. Furthermore, with the increase in  $\text{Cr}^{3+}$  content, a monotonic decrease on a long-range order of the  $\gamma\text{-Fe}_2\text{O}_3$  lattice seems to occur as inferred from the gradual broadening and diffuseness of the diffraction lines. However, further studies are necessary to substantiate this.

The results obtained from X-ray diffraction were further corroborated by electron microscopic studies. The electron diffraction pattern of sample A corresponds to the  $\gamma\text{-Fe}_2\text{O}_3$  phase. Free  $\text{Cr}_2\text{O}_3$  was noted in the electron diffraction patterns of samples A1 to A3 in addition to the  $\gamma\text{-Fe}_2\text{O}_3$  phase. The existence of free  $\text{Cr}_2\text{O}_3$  was also indicated in the electron micrographs by the appearance of plate-like particles over the  $\gamma\text{-Fe}_2\text{O}_3$  particles. However, no free  $\text{Cr}_2\text{O}_3$  was noted in the coprecipitated samples (B and C series). Electron diffraction patterns also indicated a distortion of  $\gamma\text{-Fe}_2\text{O}_3$  structure in the case of samples B3 and C3. This suggests that an interaction between  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Cr}_2\text{O}_3$  has taken place in coprecipitated samples. The incorporation of  $\text{Cr}_2\text{O}_3$  in the samples prepared by kneading does not show any major influence on the particle size of the  $\gamma\text{-Fe}_2\text{O}_3$  phase. However, the  $\gamma\text{-Fe}_2\text{O}_3$  particle sizes in the B and C series samples have been found to decrease appreciably by increasing incorporation of  $\text{Cr}_2\text{O}_3$ . This shows that an increase in chromia concentration in the coprecipitated samples hinders the crystal growth of  $\gamma\text{-Fe}_2\text{O}_3$ .

Infrared spectra of the samples of A, B, and C series, shown in Fig. 2, correspond to an imperfect spinel of  $\gamma\text{-Fe}_2\text{O}_3$ . This conclusion is based on the remarkable splitting of absorption bands in the regions 800–500

FIG. 2. Infrared spectra of  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  samples. A,  $\gamma\text{-Fe}_2\text{O}_3$ ; A1 and A3, wet mixed  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10 and 20%, respectively; B1 and B3, direct coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10 and 20%, respectively; and C1 and C3, reverse coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10 and 20%, respectively.

and 500–350  $\text{cm}^{-1}$  into several components (720, 640, 575  $\text{cm}^{-1}$  and 440, 410  $\text{cm}^{-1}$ , respectively). According to Preudhomme and Tarte (21), these bands are due to  $\nu_1$  (800–500  $\text{cm}^{-1}$ ) and  $\nu_2$  (500–350  $\text{cm}^{-1}$ ) modes of the  $\text{FeO}_6$  vibrations. However, Ishii *et al.* (22) ascribed the  $\nu_1$  mode to vibrations of both octahedra and tetrahedra and  $\nu_2$  to those of octahedra. The latter interpretation seems to be more reasonable. It can be observed from Fig. 2 that for the samples of the A series, the absorption bands are not affected significantly in the region 800–500  $\text{cm}^{-1}$ ; only the absorption bands in the region 500–350  $\text{cm}^{-1}$  are affected nominally with respect to their relative intensities and positions (shift from 440 to 450 and 410 to 415  $\text{cm}^{-1}$ ). This suggests that in the A series samples,  $\text{Cr}^{3+}$  is not incorporated into the

<sup>a</sup> For superparamagnetic doublet.

$\gamma$ -Fe<sub>2</sub>O<sub>3</sub> lattice, rather it is present as a free Cr<sub>2</sub>O<sub>3</sub> on the surface. For the B and C series samples, the absorption bands are sig-

nificantly affected in both regions (Fig. 2);  $\nu_2$  bands are perturbed more than  $\nu_1$  bands. The absorption bands at 440 and 410 cm<sup>-1</sup>

as well as 640 and 575  $\text{cm}^{-1}$  are gradually diminished in intensity and broadened appreciably with an increase in the  $\text{Cr}^{3+}$  concentration. Also, the absorption band at 720  $\text{cm}^{-1}$  disappears. These observations are more pronounced for samples of the C series than for those of the B series. In view of the perturbation of the absorption bands in both regions, it is evident that  $\text{Cr}^{3+}$  ions are incorporated into the  $\gamma\text{-Fe}_2\text{O}_3$  lattice and a lattice distortion has also taken place. Considering the structure of  $\gamma\text{-Fe}_2\text{O}_3$ , it is suggested that in the case of coprecipitated samples,  $\text{Cr}^{3+}$  ions occupy mostly the octahedral vacant sites of the  $\gamma\text{-Fe}_2\text{O}_3$  lattice. It is also revealed that after filling up of the vacant sites, the  $\gamma\text{-Fe}_2\text{O}_3$  lattice tends to be distorted further by the inclusion of more  $\text{Cr}^{3+}$  ions as observed from the maximum broadening of the IR bands of sample C3.

Parameters of the Mössbauer spectra from samples of the A, B, C, and D series are shown in Table 2. The representative spectra are shown in Fig. 3. The spectrum of pure  $\gamma\text{-Fe}_2\text{O}_3$  (sample A) has a sextet of lines ascribed to iron oxide which is close

FIG. 3. Mössbauer spectra of  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  samples. A,  $\gamma\text{-Fe}_2\text{O}_3$ ; A2, wet mixed  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having a  $\text{Cr}_2\text{O}_3$  content of about 15%; B2, direct coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having a  $\text{Cr}_2\text{O}_3$  content of about 15%; and C2, reverse coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having a  $\text{Cr}_2\text{O}_3$  content of about 15%.

to the imperfect spinel of  $\gamma\text{-Fe}_2\text{O}_3$ . A distinct feature of these modifications of Fe(III) is a small value of quadrupole splitting. However, the value of  $\delta$  is somewhat lower in than that of  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Fe}_3\text{O}_4$ , and  $H_{\text{eff}}$  varies over wider ranges with temperature (23), which can be accounted for by the imperfection of the  $\gamma\text{-Fe}_2\text{O}_3$  lattice. Some asymmetry in the first and sixth most intense components of the  $\gamma\text{-Fe}_2\text{O}_3$  may be due to the formation of  $\alpha\text{-Fe}_2\text{O}_3$  in traces. In samples of series A, the presence of  $\text{Cr}^{3+}$  ions has little effect on Mössbauer spectral parameters which remain essentially the same as those in imperfect  $\gamma\text{-Fe}_2\text{O}_3$ . In the Mössbauer spectra of the B series samples, a doublet appears along with the sextet from the imperfect  $\gamma\text{-Fe}_2\text{O}_3$  (or spinel). This doublet can be interpreted as a superparamagnetic doublet as a result of the incorporation of  $\text{Cr}^{3+}$  ions into octahedral vacancies of the spinel. In this case, part of spin density of  $\text{Fe}^{3+}$  ions is not available for exchange. The monotonic decrease in the  $\gamma\text{-Fe}_2\text{O}_3$  particle size (Table 1) with increasing  $\text{Cr}^{3+}$  concentration and the decrease in the relative spectral area of this doublet at low temperatures are consistent with superparamagnetic relaxation (24). Thus the appearance of doublet (Fig. 3, spectrum B2) is an indication of the interaction between  $\text{Fe}^{3+}$  and  $\text{Cr}^{3+}$  in the spinel lattice. The presence of line broadening also supports this fact, since line broadening increases with the increasing concentration of  $\text{Cr}^{3+}$  to 15% in the sample and then decreases somewhat (Table 2). The same features are characteristic for samples of the C series as well, but in this case the doublet is more intense, and line broadening is even more pronounced. This observation indicates the greater extent of the interaction between  $\text{Fe}^{3+}$  and  $\text{Cr}^{3+}$  ions in the spinel lattice. In view of the fact that parameters of the sextet remain unchanged within experimental error ( $\pm 0.03$  mm/s), one may conclude that except for the filling of cation vacancies in the spinel, no other mechanisms of interaction between Cr and Fe in mixed ox-

FIG. 4. Arrhenius plot of  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  samples. A1, A2, and A3, wet mixed  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10, 15, and 20%, respectively; B1, B2, and B3, direct coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10, 15, and 20%, respectively; and C1, C2, and C3, reverse coprecipitated  $\gamma\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  having  $\text{Cr}_2\text{O}_3$  contents of about 10, 15, and 20%, respectively.

ides are realized, and excess Cr is present in the form of free  $\alpha\text{-Cr}_2\text{O}_3$ . In sample C3 the sextet is not observed and all iron is in a superparamagnetic state.

The relative CO conversion activities of A, B, and C series sample are presented in Fig. 4. The measured apparent activation energies for all samples lie in the range 18–23 kcal  $\cdot$  mol $^{-1}$ . Figure 4 indicates that samples A1, B1, and C1 containing nearly 10%  $\text{Cr}_2\text{O}_3$  have better CO conversion activities than others. Of these three samples, sample C1, in which the cationic interaction is most prominent, shows the highest CO conversion activity. However, the surface area values (Table 1) of samples B2, B3, C2, and C3 are comparatively higher than those of samples A1, B1, and C1, indicating an increase in surface area with increasing chromia content in the composite oxide. This shows that the surface area has no direct relationship with the CO conversion activity, which has also been reported by

others (25, 26) for commercial catalysts containing  $\gamma\text{-Fe}_2\text{O}_3$  and  $\text{Cr}_2\text{O}_3$ . A decrease in the activity with increasing chromia content has been observed in all series of samples. This occurs mainly due to the presence of free chromia which seems to cover the iron oxide surface. This is more prominent in the case of samples B2, B3, C2, and C3. The lattice disruption in the case of sample C3 is also an important factor for reducing its catalytic activity to the lowest value.

The studies of conversion activities reveal that the incorporation of about 10%  $\text{Cr}_2\text{O}_3$  by weight is sufficient for preparing an effective chromia-promoted iron oxide catalyst. A similar dependence of catalytic activity on the optimum concentration of  $\text{Cr}_2\text{O}_3$  in the case of  $\alpha\text{-Fe}_2\text{O}_3/\text{Cr}_2\text{O}_3$  catalyst has been reported by Markina *et al.* (2) and Sen *et al.* (27). The results also indicate that a favorable cationic interaction seems to be necessary for enhancing the catalytic activity of chromia-promoted  $\gamma\text{-Fe}_2\text{O}_3$  catalyst for the water gas shift reaction. The catalytic activity remains stable until the filling up of the octahedral vacant sites of  $\gamma\text{-Fe}_2\text{O}_3$  lattice by  $\text{Cr}^{3+}$  ions. However, the presence of excess chromia causes a deterioration in catalytic activity.

#### SUMMARY

The incorporation of  $\text{Cr}^{3+}$  ions in the  $\gamma\text{-Fe}_2\text{O}_3$  lattice increases the thermal stability of  $\gamma\text{-Fe}_2\text{O}_3$  as is evident from DTA and XRD studies.

In a wet mixed method of preparation of catalysts,  $\text{Cr}_2\text{O}_3$  has little interaction with  $\gamma\text{-Fe}_2\text{O}_3$  and exists as a separate phase on the surface as revealed by the different studies.

$\gamma\text{-Fe}_2\text{O}_3$  is a defect spinel having nearly 11% cation vacancies per molecule at octahedral sites. The present investigation suggests that in the case of coprecipitated samples less than 15%  $\text{Cr}^{3+}$  ions are incorporated into these octahedral vacancies. The inclusion of more than 15%  $\text{Cr}^{3+}$  ions

hinders the crystallization of the mixed phase.

The catalytic activities of the coprecipitated samples having a chromia content less than 15% are found to be greater than those of the kneaded samples. With an increase in chromia concentration, catalytic activity decreases. The surface area has no direct relationship with the conversion activity. The catalyst sample prepared by a reverse coprecipitation technique having a chromia concentration of nearly 10% shows maximum catalytic activity.

#### ACKNOWLEDGMENTS

The authors express their sincere thanks to Professor L. M. Plyasova, Dr. S. V. Ketchik, and Dr. E. A. Paukhstis of the Institute of Catalysis for their cooperation and valuable discussions. Thanks are also due to Mr. K. C. Banerji, General Manager (R&D), Projects & Development India Limited, for his encouragement.
