parent compound was the major radioactive residue, but in similar extracts from psoralen-treated insects, a much greater percentage of the tritium residues was as psoralen metabolites. In the extracts of excreta (Table 3), little of the total tritium recovered was in the form of unmetabolized psoralen or isopsoralen, but it appeared that approximately twice the percentage of isopsoralen was eliminated unchanged in the excreta as was psoralen.

Characterization of Metabolites. Metabolites P1 and IP1 exhibited very similar TLC behavior, and metabolites P2 and IP2 likewise showed almost identical TLC properties. Furthermore, the TLC behavior of P1 and IP1 was quite similar to that of the monohydroxy acid metabolite of xanthotoxin previously identified by us from *P. polyxenes* (Ivie et al., 1983; Bull et al., 1984). The other major metabolite of xanthotoxin in the earlier *P. polyxenes* study was conclusively shown to be a dihydroxy acid, and the metabolites P2 and IP2 from this study closely share its chromatographic properties.

On the basis of our previous observations (Ivie et al., 1983; Bull et al., 1984), the structures in Figure 5 were proposed for metabolites P1, P2, IP1, and IP2. Mass spectral analysis of the small quantities of metabolites available supported these assignments. Treatment of each metabolite with diazomethane produced methylated products consistent with the proposed structures. The monomethyl derivative of P1 gave a molecular ion at *m/z* 234, with diagnostic ions at *m/z* 203 $[M-OCH_3]^+$, 202 (base peak) $[M-OCH_3,H]^+$, 175 $[M-CO_2CH_3]^+$, and 174 $[M-OCH_3,H\ CO]^+$. The dimethyl derivatives of both P1 and IP1 exhibited, as expected, very similar mass spectra, with the molecular ion at *m/z* 248, a $[M-OCH_3,CH_3]^+$ ion at 202, and the base peak at 189 $[M-CO_2CH_3]^+$. The monomethyl derivatives of metabolites P2 and IP2

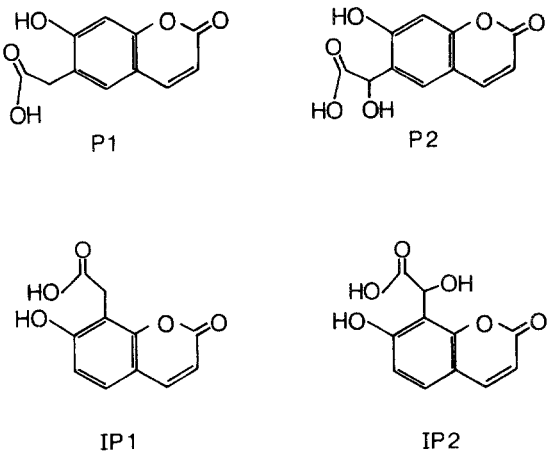

FIG. 5. Proposed structures for the major metabolites of psoralen (P1, P2) and isopsoralen (IP1, IP2) in *Papilio polyxenes* caterpillars.

likewise gave almost identical mass spectral data, with the molecular ion at *m/z* 250, and other diagnostic fragments as follows: *m/z* 202 $[M-OCH_3,OH]^+$, 191 (base peak) $[M-CO_2CH_3]^+$, 190 $[M-OCH_3,H,CO]^+$, and 174 $[M-CO_2CH_3,OH]^+$. The observed molecular ions and fragmentation products of these metabolite derivatives fully support the structural assignments shown in Figure 5; therefore, these structures almost certainly represent the major metabolic products for psoralen (P1, P2) and isopsoralen (IP1, IP2) in *P. polyxenes*. These findings are consistent with our earlier studies of the fate of xanthotoxin (8-methoxypsoralen) in this insect species (Ivie et al., 1983; Bull et al., 1984). It was not possible to conduct proton or [^{13}C]NMR studies with these metabolites due to their availability in only very limited amounts.

The chemical nature of the organic extractable tritium residues listed as "unidentified" in Tables 1–3 was not studied. This radioactivity consisted of several, generally, minor, products in most samples. That portion of each fraction shown in the tables as "water soluble/unextractable" almost certainly consisted, at least in part, of tritium released from the [^{3}H]furanocoumarin molecules as a result of metabolic transformations. Because tritium was incorporated into the double bond of the furan ring (as well as in the lactone ring double bond), the generation of metabolites P1, P2, IP1, and IP2 would certainly have resulted in some loss of label, presumably as tritiated water. The relative extent of labeling at each site of the two furanocoumarins studied is unknown, thus it is not possible to make firm conclusions regarding the extent of label loss to be anticipated as a result of the metabolic transformations observed.

The data in Tables 1–3 are expressed as percent of administered ^{3}H, and indicate 100% accountability of dosage. Calculated accountability of dosage actually ranged between 89 and 101%. This variation probably reflects experimental error. On the basis of these data, it seems clear that volatility or other loss of label did not occur to any major extent.

DISCUSSION

Our studies on the comparative metabolism of a linear furanocoumarin (psoralen) and an angular furanocoumarin (isopsoralen) by *Papilio polyxenes* caterpillars were designed to test the hypothesis that differences in the rate of metabolic detoxification might explain why *P. polyxenes* prefers psoralen-rich host plants rather than potential hosts that contain isopsoralens (Berenbaum and Feeny, 1981). We deliberately selected for study the parent unsubstituted compounds of each series to avoid possible complications in data interpretation that might arise as a result of substituent effects on metabolic phenomena.

Data obtained in the present studies on the metabolism of [^{3}H]psoralen by *P. polyxenes* are fully consistent, both qualitatively and quantitatively, with data gathered earlier by us in studies of the fate of a substituted psoralen, 8-

methoxypsoralen (xanthotoxin) in *P. polyxenes* caterpillars (Ivie et al., 1983; Bull et al., 1984). The present studies extend the data base on furanocoumarin interactions with *P. polyxenes* to show that isopsoralens are degraded in this insect by metabolic reactions analogous to those observed with psoralens. The isopsoralen detoxification and excretion rates documented here must be considered as very rapid by any standard, although it is clear that *P. polyxenes* caterpillars do metabolize isopsoralen at a slower rate than is observed with an identical psoralen dose. Table 4, which represents a partial summarization of data from Tables 1–3, indicates a consistent two- to threefold higher concentration of unmetabolized isopsoralen, as compared to psoralen, in almost all fractions. In body tissues in particular, the ratio of unmetabolized isopsoralen/psoralen appears to be at least 3.0 in samples analyzed within 1.5 hr after treatment. On the basis of these data, it seems reasonable to expect that under comparable conditions of constant dietary exposure, levels of intact isopsoralens within the body tissues (where toxicity would be expressed) would be at similarly higher levels (relative to psoralens) were the insects foraging on isopsoralen-containing host plants.

Berenbaum and Feeny (1981) have cited evidence that the biosynthesis of isopsoralens in plants has evolved more recently than that of psoralens. These workers have proposed that the biosynthesis of isopsoralens may be an evolutionary response, by plants that already produce psoralens, to the selective pressures of certain highly specialized insect herbivores such as *P. polyxenes* that are tolerant to the otherwise toxic effect of the linear compounds.

On the basis of data from earlier, limited studies on the interactions of unlabeled psoralen and isopsoralen with *P. polyxenes* caterpillars, we concluded that a reduced rate of metabolic detoxification of isopsoralens probably was not a factor in the relative sensitivity of these insects to isopsoralens (Bull et al., 1984). Considering the much more definitive data presented here, we now believe that our earlier conclusions were premature. Our present data do, in fact, appear to be compatible with the hypothesis that a reduced detoxification rate accounts at least in part for the susceptibility of *P. polyxenes* caterpillars to the deleterious effects of isopsoralens. If such be the case, however, our studies suggest that the "competitive edge" possessed by plants that synthesize isopsoralens as insect host plant resistance agents is a very slim one indeed, at least as regards herbivory by the black swallowtail.

IN VITRO METABOLISM OF A LINEAR FURANOCOUMARIN (8-METHOXYPSORALEN, XANTHOTOXIN) BY MIXED-FUNCTION OXIDASES OF LARVAE OF BLACK SWALLOWTAIL BUTTERFLY AND FALL ARMYWORM

DON L. BULL, G. WAYNE IVIE, ROSS C. BEIER, and NAN W. PRYOR

(Received May 28, 1985; accepted July 23, 1985)

Abstract—Studies were made of the comparative in vitro metabolism of [^{14}C]xanthotoxin and [^{14}C]aldrin by homogenate preparations of midguts and bodies (carcass minus digestive tract and head) of last-stage larvae of the black swallowtail butterfly (*Papilio polyxenes* Fabr.) and the fall armyworm [*Spodoptera frugiperda* (J. E. Smith)]. The two substrates were metabolized by 10,000*g* supernatant microsomal preparations from both species. Evidence gained through the use of a specific inhibitor and cofactor indicated that mixed-function microsomal oxidases were major factors in the metabolism and that the specific activity of this enzyme system was considerably higher in midgut preparations from *P. polyxenes* than in similar preparations from *S. frugiperda*. Aldrin was metabolized 3–4 times faster by *P. polyxenes*, and xanthotoxin 6–6.5 times faster.

Key Words—Aldrin, xanthotoxin, mixed-function oxidases, black swallowtail butterfly, fall armyworm, *Papilio polyxenes*, *Spodoptera frugiperda*, Lepidoptera, Papilionidae, Noctuidae.

INTRODUCTION

The results of recent studies of the in vivo metabolism of a linear furanocoumarin (xanthotoxin, 8-methoxypsoralen) by last-instar larvae of the black swallowtail butterfly (*Papilio polyxenes* Fabr.) and the fall armyworm (*Spodoptera frugiperda* J.E. Smith) gave convincing indirect evidence that the plant-derived

phototoxin was detoxified primarily via oxidative routes in both species (Ivie et al., 1983; Bull et al., 1984). The two predominant metabolites of xanthotoxin were both formed through cleavage of the furan ring moiety of the molecule; based upon mass spectrometry and nuclear magnetic resonance analyses these products were identified as monohydroxy and dihydroxy derivatives of xanthotoxin. More recent comparative studies by Ivie et al. (1985) demonstrated that analogous acidic products were formed during the in vivo metabolism of another related linear furanocoumarin (psoralen) and its angular analog (isopsoralen) by *P. polyxenes* larvae. In the case of xanthotoxin, metabolic formation of mono- and dihydroxy derivatives occurred in vivo following oral administration to *P. polyxenes* or *S. frugiperda* larvae, as well as in vitro when the compound was incubated with slices of midgut or body (carcass less digestive tract and head) tissues (Ivie et al., 1983; Bull et al., 1984). These studies also indicated that a profound difference in the rate of the in vivo metabolic degradation of xanthotoxin was most likely the major factor contributing to the tolerance of *P. polyxenes* and susceptibility of the *S. frugiperda* to the phototoxin.

A logical metabolic route to the formation of mono- and dihydroxy metabolites of furanocoumarins would include formation of a 2,3 epoxide at the furan ring moiety of the molecule as a result of oxidation by mixed-function microsomal oxidases (MFO) (Kolis et al., 1979) followed by ring cleavage to form the hydroxy derivatives. The purpose of the research described herein was to determine through in vitro techniques whether MFO enzymes were indeed responsible for the metabolic transformations of xanthotoxin that we previously observed in insects.

METHODS AND MATERIALS

Insects. Last-stage larvae of both species were obtained from colonies maintained in the laboratory at 27 ± 2°C and 60 ± 5% relative humidity under a photoperiod regimen of 14:10 hr light–dark. The *P. polyxenes* colony was reared on parsley (*Petroselinum sativum*) as described by Ivie et al. (1985). *Spodoptera frugiperda* larvae were from a colony maintained on a semidefined diet (Shaver and Raulston, 1971). In studies requiring parsley-reared *S. frugiperda*, third-stage larvae were selected from the stock colony and held individually in Petri dishes where they were allowed to feed on fresh parsley until they reached the desired stage of development.

Actively feeding larvae from groups of the same chronological age were selected on the basis of apparent similarity in physiological development. They were dissected in chilled (4°C) phosphate buffer (0.1 M, pH 7.5) with aid of a binocular microscope. Midguts were removed and emptied of their contents. These tissues and the remainder of the body (minus the head, foregut, and hindgut) were rinsed separately in 1.15% KCl and then returned to chilled phos-

phate buffer. During dissection, larvae were subjected to further selection for uniformity based upon the physical appearance of the midgut and fat bodies. Those with empty guts or that apparently were not actively processing ingested food were discarded. Dissected gut and body tissues were brought into brief contact with absorbent toweling to remove excess water and were then weighed and returned to cold buffer for further processing.

To obtain approximately equal amounts of tissue (wet weight) in samples of each species, we used three larval equivalents of *S. frugiperda* midguts or bodies for each one equivalent from *P. polyxenes*. These tissues were homogenized briefly in cold buffer (1.5 m and 0.5/ml for *S. frugiperda* and *P. polyxenes*, respectively) using a motor-driven Teflon pestle and glass tube apparatus, and the crude homogenate was filtered through cheesecloth. The filtrate was then centrifuged (Beckman L5-50 centrifuge) at $10{,}000g_{max}$ and 4°C for 15 min. Precipitated solids were discarded, and the supernatant was then filtered through glass wool and centrifuged again for 1 hr at $105{,}000g_{max}$ and 4°C. Immediately after centrifugation, the supernatant was decanted, the pellet was resuspended in the same volume of phosphate buffer containing 30% glycerol, and then preparations were used for different analyses. Protein content of different homogenate preparations was determined with the method of Bradford (1976).

Chemicals. Xanthotoxin radiolabeled with ^{14}C (specific activity of 9.86 mCi/mM) at the 8-methoxy position was prepared as described by Ivie et al. (1983). [^{14}C]Aldrin (2.6 mCi/mM) was purchased from California Bionuclear Corp., Sun Valley, California. Both radiolabeled compounds were >99% pure based upon thin-layer chromatography (TLC) analyses with methods described below. Radioactive samples of xanthotoxin or aldrin were diluted with pure unlabeled compounds so that each incubation mixture would contain a total of ca. 100,000 dpm of radioactivity. All other chemicals were obtained from commercial sources.

Enzyme Assays. Microsomal oxidase activity was determined with methods similar to those described by Yu (1982). Aldrin was included in all enzyme assays as a model to confirm that MFO activity was present or absent in different preparations.

Incubation mixtures were contained in standard 20-ml glass scintillation vials, and the incubations were carried out for 30 min in air in a water bath shaker maintained at 35°C. Each incubation mixture contained 2 ml of tissue preparation; a NADPH-generating system that included 1.8 μmol of NADP, 18 μmol of glucose-6-phosphate, and 1 unit of glucose-6-phosphate dehydrogenase; either 25 μg of [^{14}C]xanthotoxin or 100 μg of [^{14}C]aldrin; and sufficient buffer for a final volume of 5 ml. In all assays, an equal number of samples lacking the NADPH-generating system were included. Acetone solutions of [^{14}C]xanthotoxin were added first to the incubation vials and allowed to evaporate to form a thin film on the bottom surface. Preliminary tests indicated that

this method of addition resulted in greater metabolism of xanthotoxin than when it was added as a solution. The [^{14}C]aldrin was added first to the incubation vials as a solution (1 μg/μl) in ethylene glycol monomethyl ether. Each assay also included control samples containing all the above components except for tissue.

At the conclusion of the incubation period, the reaction was stopped by the addition of 0.5 ml of 6 N HCl and immediate partition (two times) with methylene chloride. Aqueous and organic fractions were radioassayed, the organic fraction was dried by filtration through anhydrous sodium sulfate, and then the sample volume was reduced under vacuum to ca. 0.5 ml and analyzed by thin-layer chromatography (TLC) as described below. This extraction procedure resulted in essentially complete recovery of radioactive materials associated with both substrates. All incubations were run in duplicate and replicated two or more times.

Analyses. Extracts containing radiocarbon were assayed by conventional liquid scintillation (LSC) procedures using a standard fluor (Permablend II®; Packard Instrument Co., Inc., Downers Grove, Illinois) in a solvent mixture of 2 : 1 (v/v) toluene and ethylene glycol monomethyl ether. Corrections were made as needed for quench and instrument efficiency.

TLC analyses of samples containing [^{14}C]xanthotoxin and its metabolities were done with precoated plates (Silplate F-254, 20 × 20 cm, 0.25-mm gel thickness, with fluorescent indicator; Brinkmann Instruments Inc., Westbury, New York) and a solvent mixture of 75 : 25 : 1 (v/v) ethyl acetate, methanol, and acetic acid [see Ivie et al. (1983) for R_f values of xanthotoxin and its metabolites]. Samples containing [^{14}C]aldrin and its metabolic products were analyzed with the same kind of TLC plates using a 1 : 1 (v/v) mixture of *n*-hexane and chloroform. This system provided good resolution of aldrin, its oxidative metabolite dieldrin, and minor amounts of polar radioactive material that were retained at the baseline.

Radioactive zones on TLC plates were located by autoradiography with X-ray film, and quantitated by LSC.

RESULTS AND DISCUSSION

Preliminary investigations indicated that the 105,000*g* supernatant was inactive against either [^{14}C]xanthotoxin or [^{14}C]aldrin, whether fortified or not with NADPH. Furthermore, there was no activity against either substrate in 10,000*g* supernatant or microsomal preparations that were boiled prior to addition to incubation mixtures.

The results of comparative studies (Table 1) indicated there was definite activity against both substrates in different homogenate preparations of the two species. TLC analysis demonstrated that the array of xanthotoxin metabolites

[a] Incubation mixture was 5 ml of phosphate buffer (0.1 M, pH 7.5) containing one *P. polyxenes* or three *S. frugiperda* equivalents, 25 μg of xanthotoxin or 100 μg of aldrin, 1.8 μM NADP, 18 μM glucose-6-phosphate, and (±) one unit of glucose-6-phosphate dehydrogenase.

produced in vitro was the same as that found with our previous in vivo studies (Ivie et al., 1983; Bull et al., 1984). Dieldrin was the only significant product of aldrin metabolism, although traces of radiocarbon (<0.1% of dose) were occasionally retained at the baselines of TLC plates.

That enzyme activity was appreciably greater in most tissue samples fortified with NADPH, especially the microsomal preparations, is good evidence that MFO enzymes were involved, However, there was essentially no activity in 10,000*g* supernatant preparations of *P. polyxenes* bodies against either substrate. This was somewhat surprising in view of our previous demonstration that incubation of xanthotoxin with preparations containing slices of body tissues resulted in substantial (>60%) degradation (Bull et al., 1984). The absence of activity in homogenates of *P. polyxenes* body tissue most likely can be attributed to the presence of endogenous inhibitors comparable to those that have been implicated by others in the unexplainable absence of MFO activity in certain insect tissue preparations (Nakatsugawa and Morelli, 1976).

Specific activities of NADPH-fortified 10,000*g* supernatant and microsomal (105,000*g* precipitate) preparations of *P. polyxenes* midguts were clearly higher against both substrates than those of *S. frugiperda* (i.e., 3.8 and 2.6× for aldrin and 6.5 and 6.1× for xanthotoxin, respectively). Concentrations of total protein in midgut preparations were only slightly higher in those from *P. polyxenes*. We also found (Table 1) that the specific activities of 10,000*g* supernatant preparations of either the midgut or body homogenates of *S. frugiperda* against aldrin were substantially higher in larvae reared on parsley than in those reared on artificial diets (ca. 2 and 43×, respectively, in NADPH fortified samples). At first appraisal, our data from tests with parsley-reared *S. frugiperda* seem to contradict a recent report by Yu (1984) that *S. frugiperda* larvae fed for two days on artificial diets fortified with xanthotoxin had enhanced levels of some MFO enzymes, but not aldrin epoxidase, which instead was diminished. Parsley does contain xanthotoxin and at least seven other linear furanocoumarins; together these phototoxins have a concentration of ca. 100–150 ppm based upon wet weight (R.C. Beier, unpublished information). In our study however, the *S. frugiperda* larvae were fed on parsley for a longer period of time (ca. 10 days) and, too, other chemicals in the plant may have been responsible for the observed induced activity of aldrin epoxidase.

Inclusion of the MFO inhibitor piperonyl butoxide in incubation mixtures containing 10,000*g* supernatant preparations fortified with the NADPH-generating system resulted in a definite reduction in the in vitro metabolism of aldrin and xanthotoxin by *P. polyxenes*, and of aldrin by *S. frugiperda* larvae (Table 2). This reduction in activity was directly proportional to the concentration of inhibitor. Our results, especially with aldrin, are very similar to those reported

TABLE 2. EFFECT OF PIPERONYL BUTOXIDE ON IN VITRO METABOLISM OF [^{14}C]ALDRIN AND [^{14}C]XANTHOTOXIN BY HOMOGENATES OF LAST INSTAR *P. polyxenes* AND *S. frugiperda* LARVAE[a]

Piperonyl butoxide concentration (M)	Enzyme activity (% of control ± SD)		
	P. polyxenes		*S. frugiperda*
	Aldrin	Xanthotoxin	Aldrin[b]
0	100.0	100.0	100
10^{-6}	99.6 (±3.0)	78.6 (±8.8)	78
10^{-5}	82.6 (±4.3)	51.3 (±0.6)	41
10^{-4}	38.4 (±8.3)	29.8 (±3.2)	22
10^{-3}	3.5 (±1.8)	18.1 (±1.2)	5

[a] Except for the addition of piperonyl butoxide in 50 μl of ethylene glycol monomethyl ether, incubation conditions were the same as noted in Table 1.
[b] Data for *S. frugiperda*/aldrin are from one replicate with duplicate samples per concentration.

by Yu et al. (1979) for the variegated cutworm (*Peridroma saucia* Hübner) and by Yu (1982) for *S. frugiperda*. These authors considered that such a response to piperonyl butoxide was good evidence that the enzyme inhibited was a typical microsomal monooxygenase.

The results of these in vitro studies substantiate our previous speculation (Ivie et al., 1983; Bull et al., 1984) that the extensive in vivo metabolism of ingested xanthotoxin that we found in *P. polyxenes* larvae was due largely to the action of MFO enzymes associated with midgut tissues. Moreover, the large differences between *P. polyxenes* and *S. frugiperda* larvae in the in vivo detoxification of xanthotoxin in the aforementioned studies can probably be attributed for the most part to the substantially greater levels of MFO activity found in *P. polyxenes*.

In nature, certain specialist members of the genus *Papilio* feed successfully and preferentially on plants from the families Umbelliferae and/or Rutaceae that are rich in linear furanocoumarins (Berenbaum, 1981a,b). Not only are linear furanocoumarins nontoxic to *Papilio* larvae, there is also evidence that they might stimulate feeding and enhance growth (Berenbaum, 1981a). In contrast, generalist feeders such as *Spodoptera* spp. tend to avoid plants that contain linear furanocoumarins; when forced to consume furanocoumarins such as xanthotoxins, both growth and survival are negatively affected (Berenbaum, 1978).

It is believed that a primary function of MFO enzymes in herbivorous insects is to detoxify naturally occurring chemicals that are repellent or toxic to the insect and that the capability for such inactivation of plant defensive chemicals can have a profound influence on the feeding strategies of different insect groups (Krieger et al., 1971; Brattsten et al., 1977). Our collective studies (Ivie et al., 1983, 1985; Bull et al., 1984; and the present work) therefore suggest that the evolutionary adaptation of *P. polyxenes* that allows that species to feed and thrive on furanocoumarin-rich plant groups is directly related to the development of a highly efficient MFO system in the digestive tract.

(Received May 28, 1985; accepted September 30, 1985)

Abstract—The botanical phototoxin, α-terthienyl (α-T) was spray applied to natural or artificial pools containing mosquito (*Aedes intrudens*) larvae and nontarget invertebrates (caddisfly, damselfly, midge, shrimp, *Daphnia*, snail) and one vertebrate (trout) at concentrations varying from 0.01 to 1 kg/hectare, under field and laboratory conditions. All field-treated nontarget invertebrates survived α-T treatment better than *A. intrudens* which can be controlled at doses as low as 0.01 kg/hectare within one week. Under laboratory conditions, snails and trout survived α-T and UV treatments up to 10 kg/hectare. These results compare favorably with organophosphates and pyrethroid insecticides currently used for mosquito control. The results confirm that α-T is a highly effective larvicide with acceptable nontarget effects.

Key Words—α-Terthienyl, *Aedes intrudens*, Diptera, Culicidae, caddisfly, Trichoptera, Limnephidae, damselfly, Odonata, Libellulidae, midge, Chaoboridae, shrimp, *Daphnia*, snail, Physa, trout, Salmo, thiophene.

INTRODUCTION

The thiophene α-terthienyl (α-T) was recently shown to have exceptional larvicidal activity to mosquitoes and blackflies in laboratory and field trials (Wat et al., 1981, Arnason et al., 1981, Philogène et al., 1985). The value of this naturally occurring compound from the tribe *Tagetae* (Asteraceae) as a commercially acceptable insecticide depends upon its efficacy towards target species and its toxicity level towards nontarget organisms. In the present paper, we

0098-0331/86/0400-0893$05.00/0

report on further field and laboratory experiments with the mosquito *Aedes intrudens* and some nontarget invertebrates and vertebrates and demonstrate that α-T is an efficient mosquito larvicide that is relatively nontoxic to nontarget species.

METHODS AND MATERIALS

Field Trials. Spray applications of α-T formulated in ethanol to large (20–40 m^2) natural breeding pools (temporary snow-melt ponds) were undertaken in the same way as described earlier (Philogène et al., 1985). Water temperature was in the range 10–14°C during the testing period.

The following organisms were field tested: *Aedes intrudens* (Diptera, Culicidae); caddisfly larvae (Trichoptera, Limnephidae), damselfly larvae (Odonata, Libellulidae), midge larvae (Diptera, Chaoboridae), the freshwater shrimp, *Chirocephalopsis bundyi*, and an unidentified ostracod (Crustacea).

Two tests were undertaken: one in early May with third- and fourth-instar *A. intrudens* larvae present and a second in mid-May with fourth-instar larvae and pupae. In the first test, eight pools were treated in applications of 0, 0.01, 0.1, and 1.0 kg/hectare, in duplicate. Intermediate application rates were used in the second test: 0.05, 0.1, 0.5 kg/hectare. Larval counts were made in 25 dips, and the percent reduction calculated according to the formula of Mulla et al. (1971).

To achieve a more precise evaluation of effective levels of control, applications were also made to 25 fourth-instar larvae (the most resistant instar) of *A. intrudens* in bioassay cages placed in 1-m-diameter wading pools containing pond water. The bioassay cages consisted of a cylindrical cage (12.5 × 15 cm) constructed of diamond-stamped aluminum surrounded by muslin held in place by rubber bands.

The pools were placed in a hardwood forest in partial shade, as in the preceding field trials, with 3 replicates for each application. Nontarget organisms (caddisfly, damselfly, and midge larvae) were also treated in the same way, but the pools were moved out of the canopy into full sunlight, adjacent to a permanent pond from which the nontarget organisms were taken.

EC_{50} and EC_{90} values were calculated on the basis of three concentrations giving intermediate survival of larvae.

The numbers of ostracods and freshwater shrimps present in temporary snow-melt pools did not permit observations in contained enclosures. These ecosystems were, however, treated with α-T in the same way as the bioassay cages.

Laboratory Tests. The water flea, *Daphnia magna* (Ostracoda), was obtained from Carolina Biological Supply and the snail, *Physa* sp. (Gastropoda), purchased from a local supplier. These organisms were treated at 23°C in Pyrex

crystallizing dishes (28 cm^2) containing 200 ml of water. Following α-T application, the preparation was maintained for 30 min in the dark and then treated with near-UV (5 W/m^2) from four 20-W Westinghouse blacklight blue tubes. UV treatment was 1 hr for snails and 15 min for *Daphnia* (the maximum near-UV exposure with limited effects on controls).

Toxicity tests with trout were based on guidelines outlined by Sprague (1973). Rainbow trout (*Salmo gairdneri*) were obtained from the Val des Bois Hatchery (Quebec) and held for two weeks in the lab prior to testing. Ten 5- to 8-cm fish were placed in each of six 10-gal aquarium tanks maintained at 14°C and equipped with an aeration tube, freshwater supply, and syphon. After 48 hr, air and water flow were arrested and α-T was applied. One hour later the aquaria were exposed to near-UV (5 W/m^2) from six 24-in. 20-W blacklight blue fluorescents for 1 hr. Following UV treatment, air and water supplies were resumed. Fish were held in aquaria for a further 72 hr or more.

RESULTS AND DISCUSSION

All the organisms treated in the field or in the lab under controlled conditions survived α-T and light exposure much better than the target mosquito *A. intrudens* (Table 1). Complete control of the latter was achieved within two days at 1 kg/hectare and within one week at 0.1 and 0.01 kg/hectare in the first field test (Figure 1). In the second test, where intermediate application rates were used, larvae were controlled in three days at all application rates, while pupae were only partially controlled at 0.05 kg/hectare, with substantial reductions in numbers at 0.1 and 0.5 kg/hectare (Figure 2). In the bioassay cages, at 72 hr after application time, an EC_{50} of 0.046 kg/hectare and an EC_{90} 0.104

TABLE 1. TOXICITY DATA FOR TARGET AND NONTARGET ORGANISMS[a]

Type of organism	Scientific name	Common name	EC_{50}	EC_{90}	Remarks
Insects					
Diptera	*Aedes intrudens*	Mosquito larvae	0.046	0.104	Outdoors/sunlight
	Chaoborus sp.	Midge larvae	0.178	0.280	Outdoors/sunlight
Trichoptera	*Limnephidae*	Caddisfly larvae	1.32	21.0	Outdoors/sunlight
Odonata	*Lestes* sp.	Damselfly larvae	0.38	1.52	Outdoors/sunlight
Crustacean	*Daphnia magna*	Water Flea	0.044	1.50	Indoors/near UV
Mollusc	*Physa* sp.	Snail	≥ 10	≥ 10	Indoors/near UV
Fish	*Salmo gairdneri*	Rainbow trout (5-8 cm)	≥ 10	≥ 10	Indoors/near UV

[a] EC_{50} and EC_{90} values are based on a probit analysis of two to three application rates with intermediate survival.

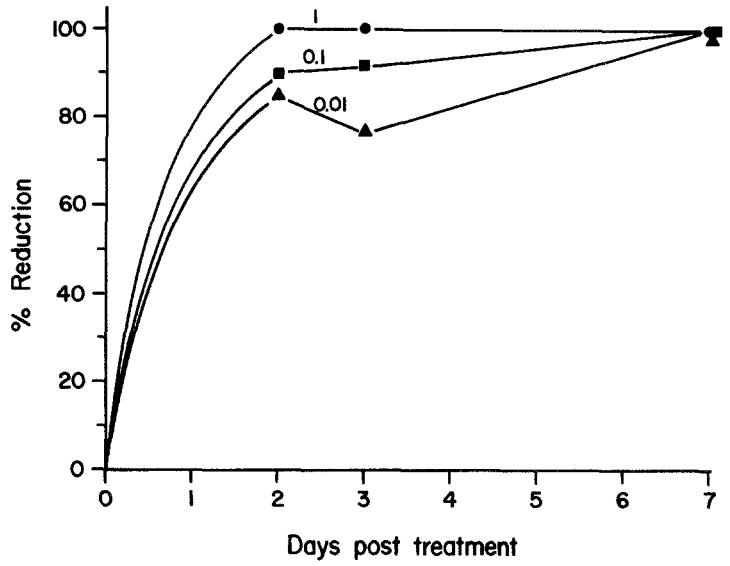

FIG. 1. Percent reduction in third- and fourth-instar larval counts following α-T treatment of natural breeding ponds on May 3, 1984. Application rates in kg/hectare. Results are average of duplicate trials.

kg/hectare were calculated, values that agree well with the results in natural pools.

Toxicity data for nontarget organisms under field conditions show that only midge larvae, which are close relatives of mosquitoes, would be adversely affected by the phototoxic properties of α-T, at application rates required to control mosquito larvae. The EC_{50} and EC_{90} values for caddisfly and damselfly larvae indicate that they would survive α-T treatment at mosquito larvicidal levels.

Of the other invertebrates observed in the field, the ostracod was unaffected at the highest application rate (1 kg/hectare), while the freshwater shrimp survived the 0.1 kg/hectare application but suffered 100% mortality at 1 kg/hectare.

Under laboratory conditions *Daphnia*, snails, and trout survived α-T and UV treatment without any significant or visible signs of intoxication.

The efficacy of α-T in the field is comparable to the organophosphate temephos which gave 100% control of *Psorophora* larvae at 18 g/hectare (Kottkamp et at., 1981) or pirimphos methyl, which gave 100% control of *Culex* larvae at 50 g/hectare (Mulla et al., 1973). Stream macroinvertebrates including amphipods, caddisfly larvae, and mayfly larvae show adverse reactions, including detachment and mortality to these two insecticides (Muirhead-Thompson, 1978).

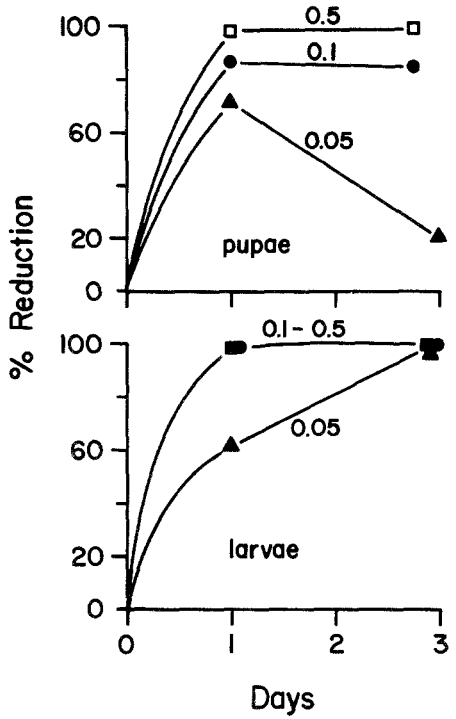

FIG. 2. Percent reduction of fourth instars and pupae in natural breeding pools treated on May 7, 1984.

Some pyrethroids are, however, more active than α-T or organophosphates. For example, cypermethrin controlled *Culex* larvae at 3–5 g/hectare (Mulla et al., 1982) and permethrin at 11 g/hectare in trials against *Psorophora* larvae (Thompson and Meisch, 1977). However, these materials reduced mayfly larvae to very low levels at mosquito larvicidal applications (Mulla et al., 1982). α-T has good efficacy and acceptable nontarget effects, which may therefore provide a new alternative to organophosphates and pyrethroids.

Acknowledgments—This work was made possible by a grant from the Department of National Defense (Canada).

(Received March 15, 1985; accepted August 16, 1985)

Abstract—At concentrations up to 6.7 ppm, 8-methoxypsoralen, sphondin, and khellin are not toxic to first-instar larvae of the mosquito *Aedes aegypti*. The irradiation of sensitized larvae with long-wavelength ultraviolet light did not always produce any immediate toxicity enhancement, but delayed effects were clearly visible. These were observed over the development of the organisms from first-instar larvae to adults. No adverse effects were noted when larvae were irradiated in the absence of sensitizers, or when they were placed in solutions of sensitizers which had been previously irradiated with the same light sources. 8-Methoxypsoralen was slightly more phototoxic than its isomer sphondin. Khellin, recently reported to undergo photoinduced cyclization with DNA components, showed minimal phototoxicity in the concentration range used.

Key Words—Phototoxicity, 8-methoxypsoralen, sphondin, khellin, *Aedes aegypti*, Diptera, Culicidae.

INTRODUCTION

8-Methoxypsoralen (8-MOP) is a natural product primarily found in plants belonging to the families Rutaceae, Umbelliferae, Leguminosae, and Moraceae. Its phototoxic properties have long been recognized, particularly in relation to

0098-0331/86/0400-0899$05.00/0

the treatment of dermatological disorders in man, notably vitiligo and psoriasis (Anderson and Voorhees, 1980).

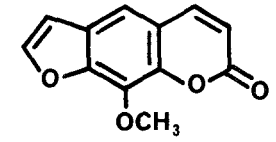
Numerous mechanistic studies have been performed, demonstrating the importance of cycloaddition reactions to pyrimidine bases of nucleic acids produced in the presence of long-wavelength ultraviolet light (Shim et al., 1984, and references cited). Either one or two double bonds in the furanocoumarin ring system can participate in the cycloaddition reactions. Less spectacular, but perhaps of comparable biological importance, the generation of singlet oxygen by 8-MOP has also been demonstrated (Joshi and Pathak, 1983; Kagan et al., 1984, and references cited).

The question of how insects interacting with plants producing 8-MOP deal with this phototoxic molecule has been raised. Camm et al. (1976) showed that linear furanocoumarins lacked toxicity to the aphids *Aphis heraclella* and *Cavariella pastinacae* feeding exclusively on Umbelliferae. Berenbaum (1978) discovered that the phototoxicity of 8-MOP was greater than its toxicity in the larvae of the Southern armyworm *Spodoptera eridania*, a generalist insect herbivore. Ivie et al. (1983) demonstrated a rapid detoxification of 8-MOP in larvae of the black swallowtail butterfly *Papilio polyxenes*. In contrast, the larvae of the psoralen-sensitive fall armyworm *Spodoptera frugiperda* metabolized 8-MOP at a much slower rate.

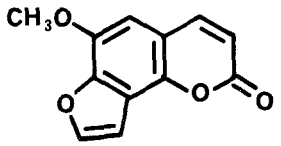
The phototoxicity of 8-MOP in insects whose diet is completely unrelated to plants producing this compound has apparently not been demonstrated, with the exception of the photoovicidal activity in *Drosophila melanogaster* (Kagan and Chan, 1983). However, its lack of photoinduced activity has been recorded in mosquito larvae (*Aedes aegypti*) and blackfly larvae (*Simulium vittatum*) by Wat et al. (1981), and in the larvae of *A. aegypti* and *Drosophila melanogaster* by Kagan et al. (1983).

The mosquito *Aedes aegypti* is a convenient organism for toxicity work in the laboratory. It is particularly valuable for phototoxicity studies since it can grow from egg to adult in the complete absence of light. The results of any light treatments on this organism are therefore easily determined by comparison with dark controls. A cursory screening had revealed the lack of acute phototoxicity of 8-MOP in second- and third-instar larvae of *A. aegypti* at a concentration of 0.78 ppm (Kagan et al., 1983) and 6.7 ppm. Prior studies of phototoxic effects in mosquito larvae have generally used late instars because their larger sizes made them more convenient to handle. However, we have frequently observed these later instars to be less sensitive to treatments with other sensitizers, and Arnason et al. (1981) also reported increased photosensitivity of first instars compared to older larvae. As illustrated in this report, delayed phototoxic effects can be readily demonstrated.

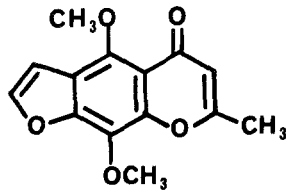
The phototoxicity of 8-MOP is compared to that of two natural products, sphondin and khellin (Figure 1). Sphondin is an isomer of 8-MOP characteristic of the genus *Heracleum*, where it has been detected in 30 species, usually in



8-METHOXYPSORALEN



SPHONDIN



KHELLIN

FIG. 1. Structures of 8-MOP, sphondin, and khellin.

the roots. There have been scattered reports of its occurrence in 10 other genera of the family Umbelliferae, and only one finding outside of this family, in the fruits of *Ruta pinnata* (Rutaceae), by Estevez Reyes and Gonzalez Gonzalez (1963). Sphondin is not commercially available but has recently become more readily accessible through chemical synthesis (Wulff and McCallum, manuscript in preparation). It is highly inhibitory to the growth of hypocotyl cuttings of cucumber seedlings, while accelerating their root formation (Shimomura et al., 1982). It also has mitotic activity in wheat-seedling roots (Zhamba et al., 1970) and inhibits seed germination and root growth in radishes (Komissarenko et al., 1971). Finally, sphondin has shown phototoxicity to the fungus *Penicillium expansum* (Van der Sluis et al., 1981), to *Candida albicans* (Kavli et al., 1983a), and has generated weak photoepicutaneous response (Kavli et al., 1983b).

Khellin is a furanobenzopyrone well known for its vasodilator properties (Hassan and Zubair, 1980), which is also of value in controlling atherosclerosis (Schurr and Day, 1981). It was originally isolated from the seeds of *Ammi visnaga*, family Umbelliferae (Fantl and Salem, 1930), and it has been shown to be phototoxic to three gram-positive organisms (*Bacillus subtilis*, *Staphylococcus aureus*, and *S. faecalis*) in a classic paper by Fowlks et al. (1958). It induced skin pigmentation in rabbits in the presence of sunlight (Kabilov, 1962) and was phototoxic to viruses (Cassuto et al., 1977). A more recent paper con-

firmed the phototoxicity of khellin against *B. subtilis* and *S. aureus*, but not against *S. faecalis*, and established its phototoxicity against *S. albus*, *Candida albicans*, and *Saccharomyces cerevisiae* (Abeysekera et al., 1983). These authors demonstrated that khellin and ultraviolet light induced 2 + 2 photoaddition to thymine and chromosomal changes in Chinese hamster ovary cells. In our earlier screenings, however, khellin induced no acute phototoxic effects in third- and fourth-instar *A. aegypti* larvae (Kagan et al., 1983).

A number of furanocoumarins, including 8-MOP, and related furanoquinolines and furanochromones, including khellin, display feeding inhibitory activity against the tobacco cutworm (*Spodoptera litura*), cockroaches (*Periplaneta americana*, *Stylopyga rhombifolia*, and *Blattela germanica*), and the housefly *Musca domestica* (Yajima and Munakata, 1979). Whether or not the magnitude of the effect depends on the presence of ultraviolet light is unknown. Unfortunately, this activity was not investigated in sphondin.

METHODS AND MATERIALS

Khellin and 8-MOP were purchased from Sigma. Sphondin (mp 191°C) was synthesized in the laboratory in four steps from furan via 2-furyl(methoxy)methylene pentacarbonyl chromium(0). The details of the synthesis will be reported separately. All three sensitizers showed a single peak on HPLC analysis. Sixfold serial dilutions from a stock solution containing 1 mg/ml of sensitizer in dimethyl sulfoxide provided the samples which were assayed. Prof. G. Craig, Jr., University of Notre Dame, provided the original eggs of *A. aegypti* (strain Rock) from which the laboratory colony was established. Eggs were placed in aged tap water in the morning, and first-instar larvae were collected in the afternoon. For each experiment, 10 larvae were transferred into a 6-ml vial, the excess water was pipetted out, and 3 ml of the appropriate sensitizer solution were added under very dim incandescent light. Between 8 and 12 replicates were usually prepared at each sensitizer concentration (Table 1). All samples were incubated overnight in the dark. The next morning all the larvae were still surviving.

One set of vials was then irradiated for 30 min, receiving 13.5 W/m^2, under a bank of eight light sources emitting above 320 nm, with a maximum at 350 nm (RPR-3500A from the Southern New England Ultraviolet Corp., Hamden, Connecticut). The contents of these vials and of an equivalent set continuously kept in the dark were transferred into Petri dishes containing 40 ml of water, to which 0.5 ml of a 16 g/liter liver powder suspension (ICN Pharmaceuticals, Cleveland, Ohio) was added. This was done in the dark room dimly lit through an amber Kodak OC Safelight filter. Control and irradiated larvae were then kept in a darkroom throughout the experiments. The surviving or-

ganisms were counted every day afterwards, and they were fed in the same manner three and six days after the irradiation.

In other control experiments, 3-ml samples of 6.7 ppm solutions of each sensitizer were photolyzed for 30 min and were then seeded with the first-instar larvae. These organisms, continuously kept in the dark, were transferred into Petri dishes the next day and handled as above to check for toxicity of photoproducts which might have been formed from the original sensitizers.

Table 1 summarizes the number of experiments performed with each sensitizer, as well as the mean cumulative adult emergence on day 11. Every day, the experimental points shown on Figures 1 to 4 were determined by comparing the total number of surviving organisms at each developmental stage in all the runs to the total number of original larvae.

The experiments with 8-MOP, in which the incubation time was only 1 hr, were performed identically. All the results discussed in the text were obtained from the average of six experiments, both in the dark and in light.

Besides the actual irradiations with UV light, the organisms had to be ex-

posed to light once a day for a few minutes while the survivors were counted. This was done in the dark room, about 20 cm from a 15-W incandescent bulb.

Statistical analyses were performed using SAS82.4 programs. Adult emergence on day 11 for irradiated samples and dark controls was compared by a two-tailed Mann-Whitney-Wilcoxon test for each concentration. LC_{50} values were determined by linear regression analysis.

RESULTS AND DISCUSSION

The highest concentration used in this work with the three sensitizers was 6.7 ppm. At this level, the irradiations for 30 min did not have any immediate lethal effect. Notable differences in behavior and survival between the dark controls and the organisms which had been irradiated began to appear later on, and these effects were also clearly dependent upon the concentration of sensitizer used in the experiment.

A dynamic picture of the development of the *A. aegypti* in our experiments was obtained by plotting on a single graph the percentage of surviving larvae, pupae, and adults recorded each day following the irradiation. Petri dishes are very convenient for housing sets of irradiated organisms, since they allow a count of the adults to be made very rapidly without providing them an opportunity to escape, and they minimize the space requirements for storing the large number of experiments in progress. One of the earlier studies on the toxicity of photodynamic compounds in *A. aegypti* was conducted in Petri dishes (Barbosa and Peters, 1970). The drawback of the technique is that the adults die rapidly, because flight space is limited, and it is difficult to feed them without allowing their escape. For these reasons the present work did not investigate the behavior of the adults and their reproductive ability, which will be the subject of a later study.

The effects of irradiation in the absence of any sensitizers are shown in Figure 2. The survival curves for the larvae, pupae, and adults corresponding to the fate of the irradiation controls (open squares) and the dark controls (solid circles) are practically superimposable. This proves that irradiation for 30 min with UV light alone caused no short-term developmental abnormalities. In these experiments the first pupae were visible on day 6 following the irradiations, they were at their peak on day 8, and less than 10% remained at the end of the experiments, on day 11. The percent [$\bar{X}$ (SEM)] of adults present in dark and light controls were 82.7 (3) and 80.9% (5), respectively.

Phototoxicity of 8-MOP. The experiments in which the sensitizer was irradiated prior to the introduction of the larvae were necessitated by the fact that 8-MOP is known to have a rich photochemistry at the wavelengths used in the experiments. For example, in addition to the photocycloadditions to pyrimidines already mentioned, 8-MOP can generate singlet oxygen, and this reagent

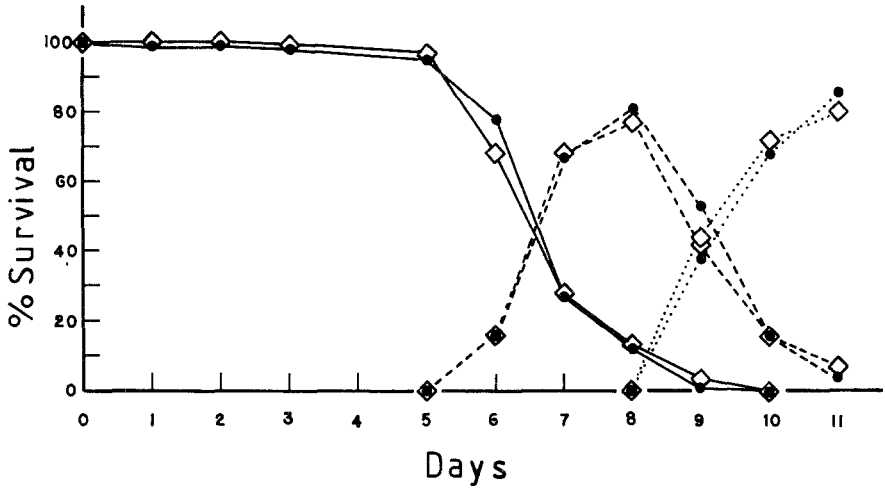

FIG. 2. Larvae (solid lines), pupae (broken lines), and adults (dotted lines) obtained from first-instar *A. aegypti*, as a function of time. The fate of the irradiated organisms (open squares) is compared to the dark controls (closed circles). See text for details.

has been shown by Logani et al. (1982) and by Wasserman and Berdahl (1982) to react with 8-MOP itself, resulting in oxidation products in which the furan ring had been opened, in a manner reminiscent of the enzymatic detoxification reported by Ivie et al. (1983). The biological activity of these products was unknown.

At a concentration of 6.7 ppm, 8-MOP in the dark had practically no effects on the development of *A. aegypti*, compared to the controls. The only noteworthy difference may have been that at the end of the experiments a few organisms had still not left the larvae stage. However, the peak concentration of pupae and the number of adults present at the end were essentially the same as in the controls. These results are presented in Figure 3A, which summarizes three different experiments performed at that same concentration. One shows the survival in the dark (solid circles), which is indistinguishable from the survival of organisms placed in a 6.7 ppm solution of 8-MOP which had been previously irradiated for 30 min (triangles). The third curve (open squares) shows the survival of the organisms which had been irradiated for only 30 min. While no acute toxicity could be detected the day of the irradiation, only 26% of the irradiated, sensitizer-exposed larvae were still alive the next day, and all were dead three days after the irradiation. The high phototoxicity of 8-MOP, which could not be detected on the day of the irradiation, was now clearly demonstrated. While consistent with DNA interference, this observation could not be interpreted unequivocally as a proof for it in the absence of supporting biochemical and genetic results.

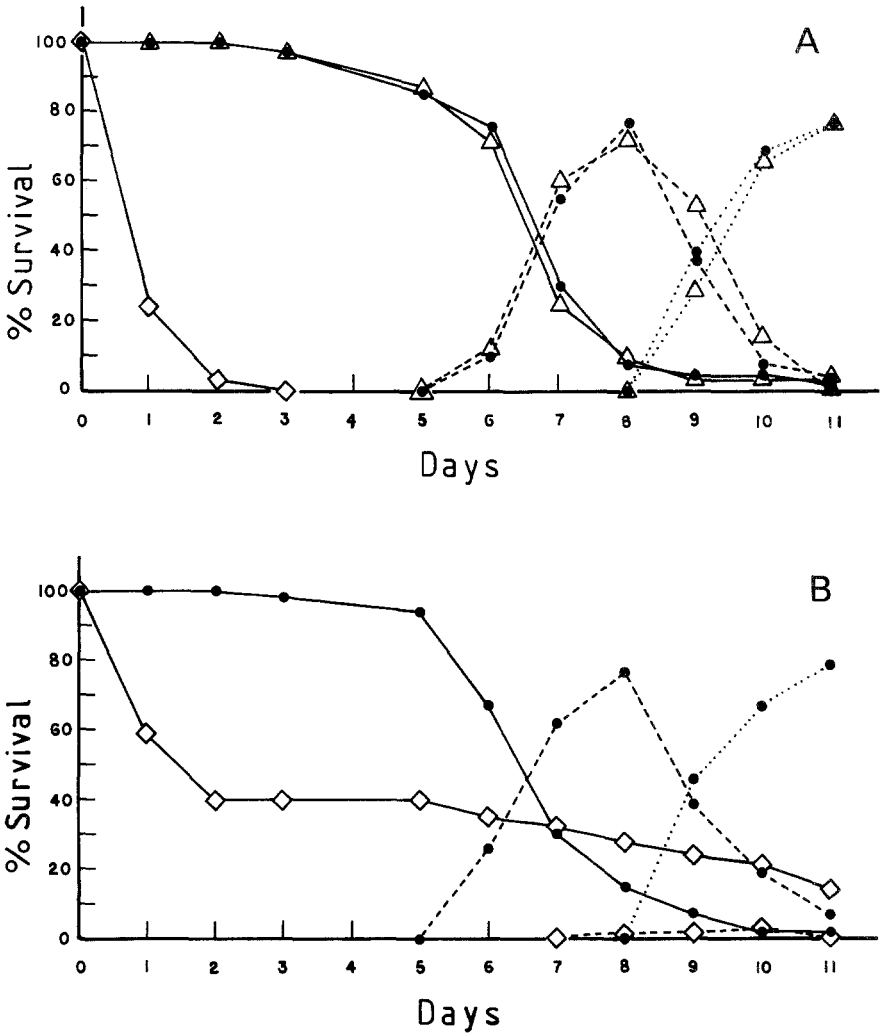

FIG. 3. Experiments with 8-MOP: larvae (solid lines), pupae (broken lines), and adults (dotted lines) obtained from first-instar *A. aegypti*, as a function of time. The sensitizer concentration was 6.7 ppm in A, 1.1 ppm in B and D, and 0.2 ppm in C. The survival of the dark controls is shown with solid circles, that of the irradiated organisms with open squares. The open triangles show the fate of the organisms kept in the dark in an identical solution which had been irradiated separately for the same duration. The irradiations took place after overnight incubation in the presence of the sensitizer, except in the case of D where only 1 hr of incubation was used. The appearance of 1% of adults from days 10 to 11 for the irradiated organisms in B is not visible on this graph. See text for details.

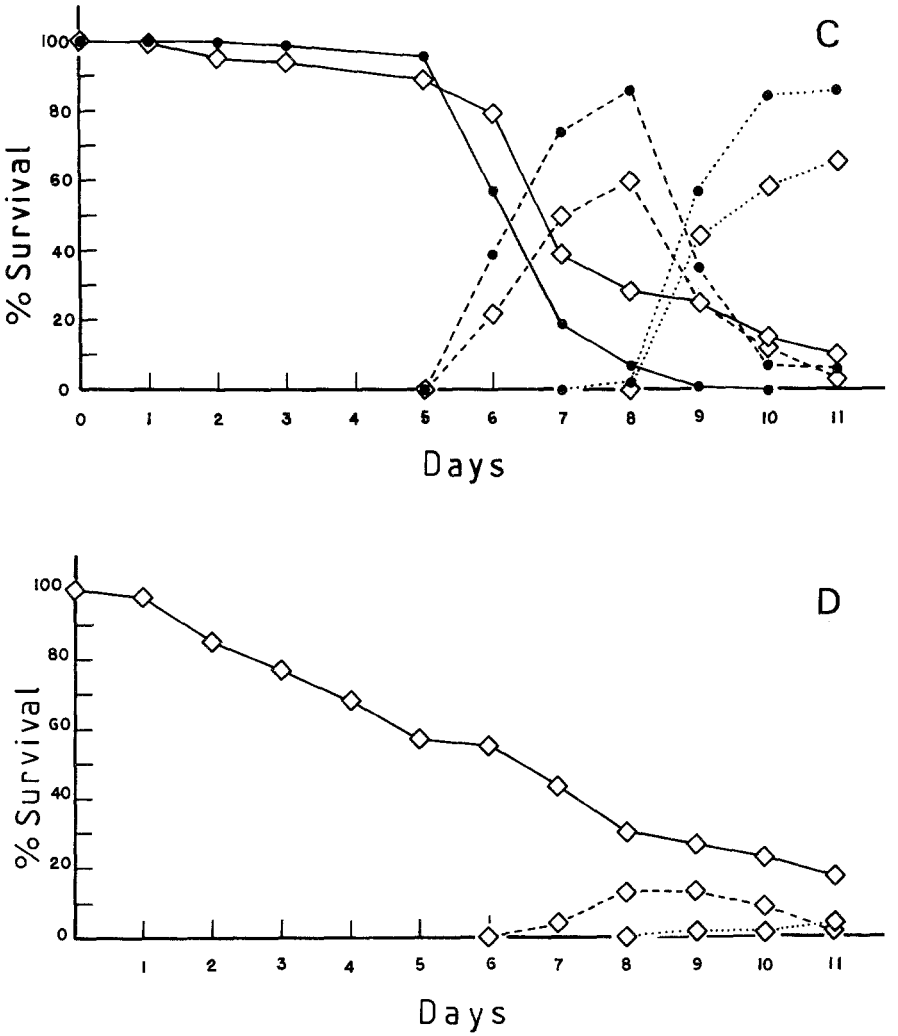

FIG. 3. Continued.

A sixfold dilution of the sensitizer solution (1.1 ppm) led to different results. As shown on Figure 3B, a precipitous drop in the larval survivorship occurred during the two days after irradiation, and most of the surviving organisms then failed to produce pupae and adults. Even though 57% of the larvae had survived on day 2, gradually decreasing to 40% over the next four days, only about 7% of the original pool yielded pupae. At the end of the experiment, only 2.7% of the original sample had turned into adults, while 12.2% were still

larvae. These had not gone beyond the second instar and died over the next days rather than develop normally. The adult emergence for irradiated larvae [2.7% (1)] was significantly lower than for dark controls (77.7% adults) ($Z = 3.7$; $P = .002$).

At this concentration (1.1 ppm), the dark controls showed a development practically identical to that of the controls which had not been treated with either light or chemical (see Table 1).

A further sixfold dilution of the sensitizer solution, to 0.2 ppm, resulted in diminished phototoxic effects (Figure 3C). Some larvae still failed to pupate. Consequently, there was a smaller proportion of pupae than in the controls, but most of those pupae turned into adults. At the end of the experiment, only 65% (7) of the original larvae had turned into adults, compared to 85% (6) in the dark controls ($Z = 1.5$; $P = 0.15$).

Finally, another sixfold dilution of the sensitizer solution, to 0.03 ppm, yielded survival curves identical to the controls, with a 77% conversion of the larvae into adults (not shown).

A linear regression analysis of the adult survival versus sensitizer concentration gave an LC_{50} of 0.41 ppm.

It is interesting to observe the diversity of the delayed phototoxic effects: death of all the larvae at 6.7 ppm; 40% survival on day 6 at 1.1 ppm, but inability for most of them to pupate; reduced ability to pupate at 0.2 ppm, but most pupae viable; and no detectable effects at 0.03 ppm. The etiology of these developmental irregularities is completely unknown.

The incubation time prior to irradiation is expected to be a significant parameter in photosensitizing experiments, although it may be difficult to predict how this parameter will affect the overall transformation of insect larvae into adults. One argument is that a shorter incubation time should result in more limited incorporation of a toxicant into the organisms, and their survival should therefore be greater. An equally plausible argument is that longer incubation times should allow more extensive metabolic inactivation of the sensitizers prior to photolysis. The target organisms should therefore be more seriously affected by the irradiations with shorter incubation times.

In order to help decide between these opposite viewpoints, a series of experiments was conducted with 8-MOP, in which the initial incubation time was reduced to 1 hr, the photolysis time being kept at 30 min. This experiment introduced at least two additional changes, namely that the organisms were younger and perhaps more sensitive at the time of the irradiations and that they were fed earlier than in the other experiments. However, the results were almost the same as those obtained with the overnight incubation time. At 6.7 ppm, all the larvae were dead two days after the irradiation. At 1.1 ppm, the survival curve (Figure 3D) for the larvae declined less steeply than shown on Figure 3B, and it was almost linear over the duration of the experiment. Two days after irradiation, for example, 71% of the larvae were still alive, compared to 57%

earlier, but on day 8 their survival was the same in both cases, about 30%. The mean proportion of adults observed at the end was not very different, 4.2% compared to 2.7% earlier. We must conclude, therefore, that *A. aegypti* larvae do not possess an efficient mechanism for the metabolic inactivation of 8-MOP.

Phototoxicity of Sphondin. Sphondin, an isomer of 8-MOP, was studied in the same manner. Figure 4A summarizes the behavior of the larvae in the presence of 6.7 ppm of sensitizer in the dark (closed circles), and in the presence of a solution of the sensitizer at the same concentration which had been first irradiated for 30 min (triangles). Both series of experiments yielded very similar results, demonstrating the absence of toxicity for the chemical and proving that no toxic products were formed when it was irradiated. The results of the irradiation of the larvae in the presence of sphondin at 6.7 ppm are also shown in Figure 4A (open squares). An immediate effect was detected, with only 40% of the larvae surviving the irradiation and 4% alive one day later. However, no further changes were found during the rest of the experiment. The development of the few surviving larvae was arrested, and no pupae were obtained.

At 1.1 ppm, the survival one day after exposure (61%) was greater than at 6.7 ppm (Figure 4B), but many of the surviving larvae failed to pupate. On day 11, when all the experiments were terminated, 16% of the original population had turned into adults, 6% were pupae, and 30% were still larvae. Dark controls had 82% adults, 12% pupae, and 0% larvae (adult emergence significantly different, $Z = 2.8$; $P = 0.02$).

At 0.2 ppm, the results of the experiments in the dark [81% (9) adult formation] and in the light [85% (3) adult formation], were no longer different ($Z = -0.15$, $P = 0.89$). A linear regression analysis on the data for survival to the adult stage gave $LC_{50} = 0.68$ ppm.

Phototoxicity of Khellin. Although khellin had been reported to be phototoxic, as summarized earlier, we did not observe any short-term acute phototoxic response at concentrations up to 6.7 ppm, using mosquito larvae, *Daphnia magna*, or the eggs of *Drosophila melanogaster* (unpublished results).

Figure 5 summarizes the studies with 6.7 ppm of khellin, and confirms our earlier observations. The results in the dark (closed circles) and in the light (open squares) are very similar. The curve for the irradiated pupae appears to be broader and to have a lower maximum than in the dark experiments, but the ultimate proportion of adults [$\bar{X} = 74$ (9)] is within the normal range observed in untreated larvae.

At 1.1 ppm, the results of the dark and light experiments [$\bar{X}$% (SEM) = 82 (5) and 81 (11), respectively] and that of the untreated controls are all within the normal range (not shown). Our results, showing that 8-MOP was more active then khellin, are in accord with those of Abeysekera et al. (1983) in a different system. They also conform with the results of experiments with the fungus *Penicillium expansum*, which showed that 8-MOP was very phototoxic, sphondin weakly phototoxic, and khellin not phototoxic (Van der Sluis et al.,

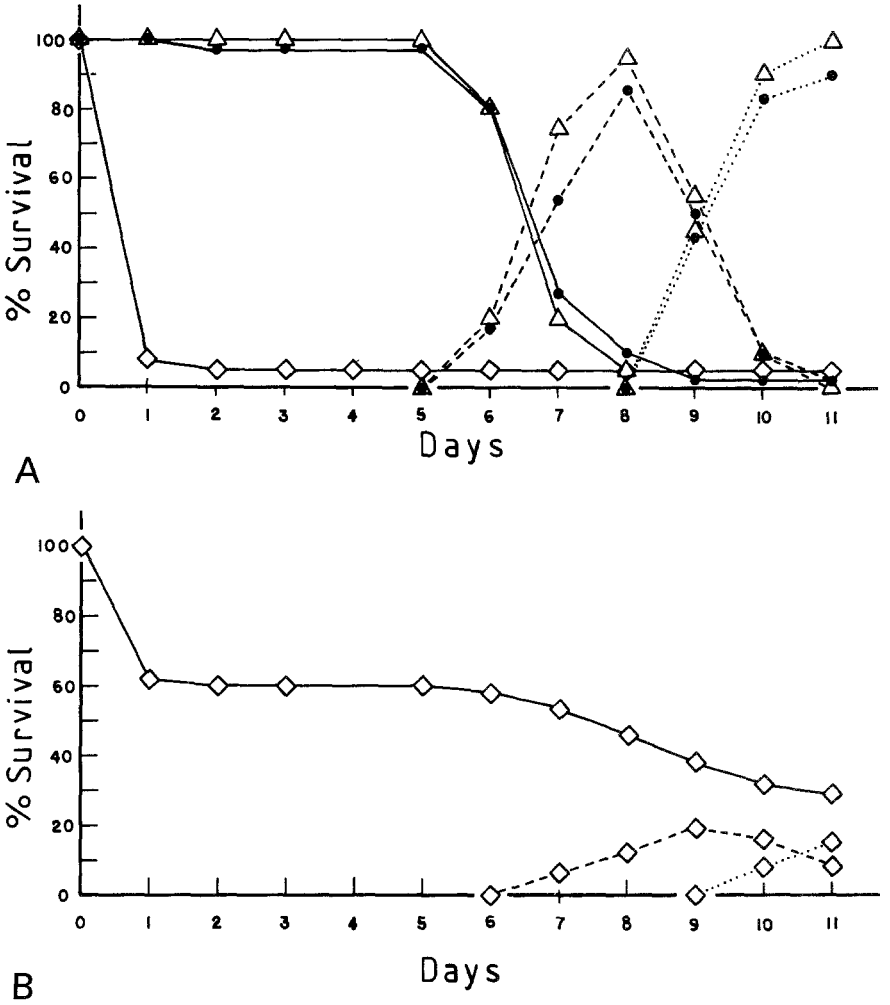

FIG. 4. Experiments with sphondin: larvae (solid lines), pupae (broken lines), and adults (dotted lines) obtained from first-instar *A. aegypti*, as a function of time. The sensitizer concentration was 6.7 ppm in A, 1.1 ppm in B. The survival of the dark controls is represented with solid circles, that of the irradiated organisms with open squares. The open triangles are for the organisms kept in the dark in an identical solution which had been irradiated separately for the same duration. The dark controls in B, identical to the results shown in A, have been omitted. See text for details.

1981). The same relationship was also observed in photosensitizing experiments on the skin of guinea pigs and rabbits (Khadzhai and Kuznetsova, 1965).

The diversity of the phototoxic responses described for khellin and, particularly, its phototoxicity observed in the earlier studies with microorganisms

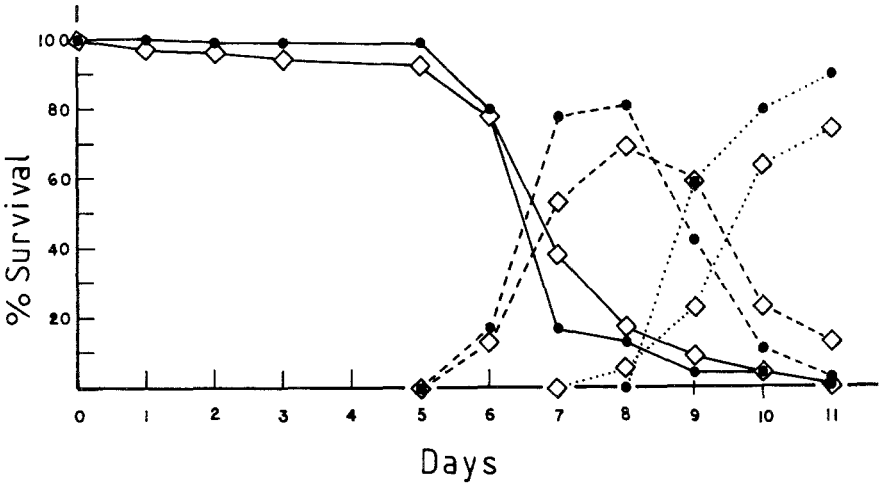

FIG. 5. Experiments with 6.7 ppm of khellin: larvae (solid lines), pupae (broken lines), and adults (dotted lines) obtained from first-instar *A. aegypti*, as a function of time. The survival of the dark controls (solid circles) was identical to that of the organisms in a similar solution which had been previously irradiated (not shown). The irradiated organisms are represented with the open squares. See text for details.

and viruses, could be the results of one or more of the following circumstances: (1) presence of phototoxic impurities in the samples, (2) strong dependence on the wavelength distribution of the irradiating source, and (3) strong dependence on the intensity of the source. With respect to the first hypothesis, it may be relevant to note that the seeds of *A. visnaga*, which contain khellin, and those of *A. majus*, which contain 8-MOP, cannot be unequivocally distinguished by their morphological characters. Only by germinating the seeds can their source be confirmed. While we do not have enough information for providing a specific conclusion, one must note that khellin appears to show a specificity in its photobiochemistry which is, to our knowledge, without precedent.

CONCLUSIONS

This paper illustrates a simple and convenient technique for observing phototoxic effects which are not immediately detectable. By following the development of the mosquito larvae from the first instar, rather than from later stages as was customary, one increases the opportunities either for seeing abnormalities or for gaining confidence that no phototoxic reactions are induced. The quantitative comparison of the phototoxicity for different compounds is greatly facilitated. For example, neither 8-MOP nor sphondin showed any immediate phototoxicity at concentrations of 6.7 ppm and below. The measurement of the

24-hr survival data for 6.7 ppm already produced different results (26% with 8-MOP vs. 4.2% with sphondin), but observations over a longer span (three days or more) clearly showed a greater survival of the larvae treated with sphondin than with 8-MOP. On the other hand, since no adults were produced from either experiments, both sensitizers could also have been viewed as having the same phototoxicity.

Toxicity assay of these compounds at 1.1 ppm shows equipotency at the time of the irradiations (100% survival), and possibly 24 hr later (72% and 61% survival for 8-MOP and sphondin, respectively). It is only afterwards that notable differences are detected, showing that only 3% of the organisms treated with 8-MOP are converted into adults, compared to 16% of those treated with sphondin. However, since low-level incandescent light was briefly used during the course of the experiments, the survival in both the dark controls and the irradiated organisms might have been slightly affected. We believe that the difference would have been insignificant, because of the short duration of the exposures and the low intensity of the lamps utilized.

It is interesting to note that the knowledge that a molecule can undergo photocycloaddition to DNA components is not sufficient for predicting that it will be an efficient photosensitizer in a complex biological organism, as witnessed here by the lack of photosensitization with khellin. While the mechanisms of the phototoxic reactions described in this article are completely unknown, the observation of fairly rapid results with 8-MOP and sphondin is consistent with processes which are not based on modifications of the genetic material. Oxygen-mediated reactions modifying membranes, proteins, or hormone systems via reactions with singlet oxygen, superoxide ion, or hydroxyl radicals are alternatives which deserve serious consideration. The slower results observed at lower concentrations would also be consistent with modifications of the genetic material, and 8-MOP is certainly known for exhibiting this duality of mechanisms, as reviewed in the Introduction. Perhaps oxygen-independent modifications of nucleic acids as well as oxygen-dependent biochemical changes occur in all cases. The latter, being lethal at higher concentrations, prevent the expression of the former ones, which would therefore be observable only at lower sensitizer concentrations.

Note Added in Proof: After presentation of these results on Dec. 12, 1984 at the Sympsoium on Insects and Photoactive Substances in Plants, during the National Meeting of the Entomological Society of America, other participants published a paper describing the effects of 8-methoxypsoralen and khellin on *A. atropalpus* (Philogene et al., 1985). Their results with khellin cannot be fully evaluated on the basis of the published data, but they appear to be quite different from those herein reported.

Acknowledgments—We are grateful to Prof. G. Craig, Jr., University of Notre Dame, for gifts of eggs of *A. aegypti* used in establishing our mosquito colony, and for advice. Prof. H.

Rösler, University of Maryland, called our attention to the problems associated with the identification of the seeds of *Ammi visnaga* and *A. majus*. The financial support by the Research Board of the University of Illinois at Chicago is gratefully acknowledged.

(Received May 28, 1985; accepted July 15, 1985)

Abstract—The application of an ultrasensitive photobiological assay which detects photosensitizing furocoumarins with sensitivities as high as 1×10^{-11} g is discussed in relation to these molecules as phytoalexins. Examples of the utilization of this technique, verified by both HPLC and TLC, are the analyses of healthy and diseased celery and carrots, dry seeds, plant extracts and oils, and whole plants and leaves. The usefulness of this method in following the metabolic detoxification of furocoumarins is also illustrated. The extreme sensitivity of the test has permitted the detection, for the first time, of both 5-methoxypsoralen and 8-methoxypsoralen in fresh carrot roots.

Key Words—Furocoumarins, psoralen, 5-methoxypsoralen, 8-methoxypsoralen, phototoxicity, photobiological assay, celery, carrot, analysis, umbelliferous seeds.

INTRODUCTION

The relationship between photosensitizing furocoumarins in a number of plant families and their properties as phytoalexins has been of considerable interest and comment (Scheel et al., 1963; Hahlbrock et al., 1981; Beier et al., 1983, Beier and Oertli, 1983). It is among members of the Rutaceae and Umbelliferae that the greatest variety and highest concentrations of furocoumarins have been reported, although these chemicals do occur in other families.

0098-0331/86/0400-0915$05.00/0

The occurrence and distribution of furocoumarins have been used in the chemotaxonomy of plants (Crowden et al., 1969; Heywood, 1971), although often only the presence or absence of these compounds has been used for classification. The absence, for example, of furocoumarins in carrot roots, although present in leaf wax (Stadler and Buser, 1984) has always seemed surprising. However, using new ultrasensitive biological photoassay, backed by HPLC analysis, we have since confirmed the presence of furocoumarins in carrots (Ceska, 1986). Furocoumarins increase in plants when they are subjected to stress. These stresses can take many forms, including exposure to UV radiation, changes in temperature, increases in metal ion content, and infection with bacteria or fungi (Beier et al., 1983). In parsley tissue culture cells the responses to stress are very fast, and the available evidence suggests that gene activation, followed by the synthesis of specific mRNA, precedes increases in enzymes associated with the synthesis of psoralen from umbelliferone (Hahlbrock et al., 1981). Psoralen, which can also be considered the representative furocoumarin molecule, is the precursor of the linear furocoumarins, 5-methoxypsoralen (5-MOP) and 8-methoxypsoralen (8-MOP). The structural formulas of key furocoumarins are illustrated in Figure 1.

The linear furocoumarins can form, in the presence of near UV (320–380 nm), both monoadducts with DNA and DNA interstrand cross-links; the angular furocoumarins such as angelicin can form only DNA monoadducts under normal circumstances (Ashwood-Smith and Grant, 1976). The consequences of these photoadditions to DNA are cell death and, in surviving cells, mutation, chromosome aberrations, and carcinogenicity in both animals and man (Ashwood-Smith et al., 1982; IARC, 1982). Berenbaum and Feeny (1981) have discussed the relative actions of angelicin and xanthotoxin in terms of toxicity to insects which feed on furocoumarin-containing plants. Ivie et al. (1983) and Ashwood-Smith et al. (1984) have both described insect larvae, the resistance of which to furocoumarins appears to be based on enzymatic detoxification.

In this paper we shall demonstrate how the application of an ultrasensitive and rapid photobiological assay for photosensitizing compounds can resolve problems of the occurrence, distribution, and metabolism of furocoumarins.

METHODS AND MATERIALS

The furocoumarins used in this study were carefully checked for purity by TLC, HPLC, and photobiological assay and were recrystallized from 95% ethanol before use. Stock solutions in methanol or ethanol were kept at 4°C in the dark. The sources for the furocoumarin standards have been described previously (Chaudhary et al., 1985). Conditions for both normal and reverse-phase HPLC are indicated in the figure legends together with details of tissue separation and preparation. TLC analysis was carried out on Merck K 60 silica

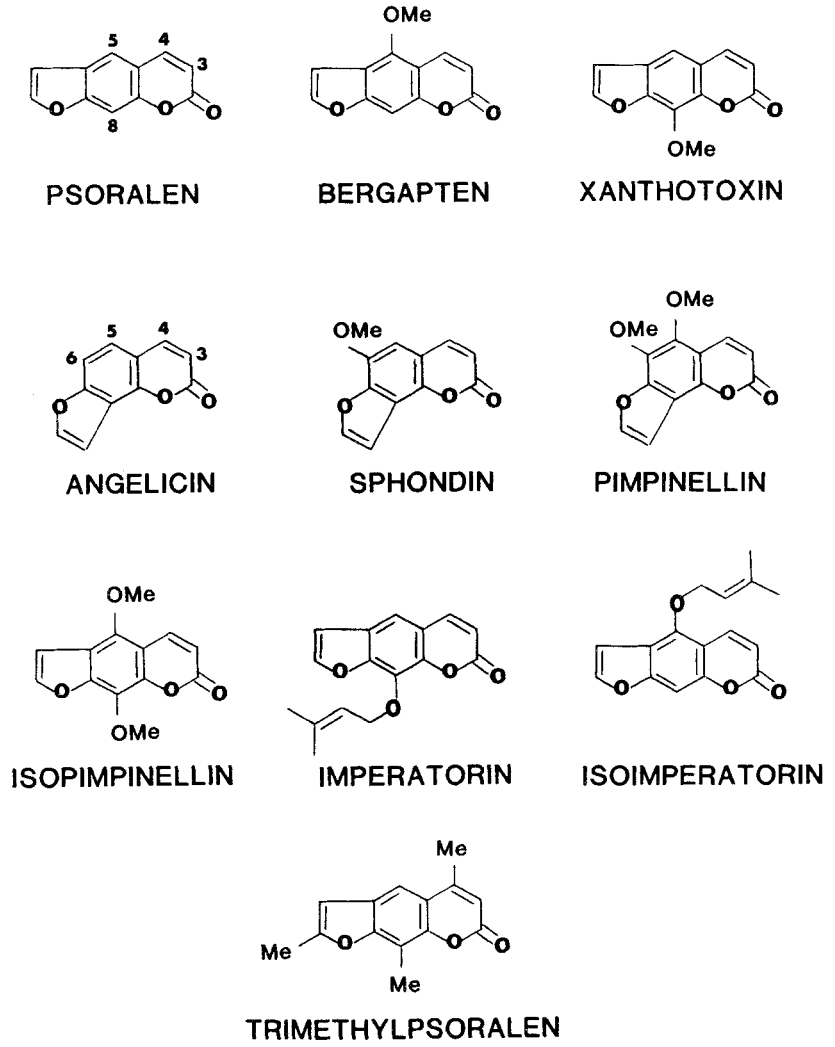

FIG. 1. Structure of furocoumarins; bergapten = 5-MOP; xanthotoxin = 8-MOP.

plates (without fluorescence indicator) and compounds, after development, were visualized with black light (300–380 nm).

Plant Materials. All vegetables and seeds were bought locally. Oil of bergamot was purchased from Sigma (St. Louis, Missouri), and the suntan preparation, Bergasol, specially formulated for the U.K. market and containing no 5-MOP was purchased in England.

Photobiological Assays. The detection of very small amounts of photosensitizing substances in plants, plant extracts, or plant products was carried out utilizing a photobiological assay introduced by Ashwood-Smith et al. (1983). The DNA-repair-deficient mutant *E. coli* B_{s-1} (rec^+, exr^-, hrc^-), which is extremely sensitive to ultraviolet radiation and to chemical alkylating agents (Igali et al., 1970) was grown to about 10^8/ml at 37°C in brain–heart infusion broth. This culture was used in the soft agar overlay which was prepared by dissolving 10 g of bacto-tryptone, 6 g bacto-agar, and 5 g of KCl in 1000 ml of distilled water. Square Petri dishes contained, as a base, commercial brain–heart infusion agar. Dried and developed TLCs were imprinted for 30 min onto the surface of the Petri dishes prior to the addition of the soft agar overlay (3.5 ml + 0.1 ml of the overnight bacterial culture). The seeds and plants themselves were added to the surface of the overlay after it had been poured onto the base agar. The complete details of these procedures are given by Ashwood-Smith et al. (1983).

TLC and HPLC Analysis. Merck precoated silica gel K 60 sheets were used (without fluorescence indicator), and two dimensional chromatograms were developed first with chloroform and second with hexane–pentane–ethyl acetate (35:35:30). Visualization was performed with near UV (300–380 nm). Samples for HPLC were processed as described by Chaudhary et al. (1985) after preliminary separation first through C18 Sep-Pak and then through Silica Sep-Pak cartridges. Normal phase analysis followed, in essence, the technique described by Berenbaum et al. (1984). Further experimental details are contained in the appropriate figure legends.

Enzymatic Detoxification of Furocoumarins. Both 5-MOP and trimethylpsoralen dissolved in methanol were added at a concentration of 5 μg/ml to a reaction mixture containing rat liver microsomes, NADP, and glucose-6-phosphate (Ashwood-Smith et al., 1984). The reaction was stopped after various incubation times at 37°C by the addition of an equal volume of ethyl acetate. After shaking, the ethyl acetate was spotted onto silica plates before one-dimensional TLC in hexane–pentane–ethyl acetate (35:35:30). After the TLC was dry, the normal imprinting procedure was followed by photobiological assay. Part of the top of the TLC was cut away before imprinting in order to fit into the square Petri dish (no active molecules were associated with this portion). The R_f for trimethylpsoralen was 0.58 and for 5-MOP, 0.43.

RESULTS AND DISCUSSION

Photosensitivity of E. coli B_s. It is important to check the sensitivity of the repair-deficient bacterium every week or so; otherwise contamination with a resistant wild-type microorganism could occur and decrease the inherent sensitivity of the assay procedures. The effect of irradiating two cultures streaked

onto the surface of a nutrient agar Petri dish is illustrated in Figure 2. Approximately 150 J/m^2 of UV (Mineralight UV S · 12 253.7 nm distributed by Fisher Scientific Ltd.) resulted in a complete inhibition of growth of the indicator bacterium and little apparent effect on the wild-type *E. coli B/r* (Ashwood-Smith et al., 1983).

Although no experiments are reported in this paper concerning the photosensitizing actions of non-DNA damaging agents such as polyacetylenes and α-terthienyl, the use of these two *E. coli* strains separately in photobiological assays can be very revealing. If the sensitivities with both bacterial strains is the same for any unknown chemical, then it may be inferred that the biological action is some target other than DNA, perhaps proteins or lipids. If there is a large difference, in that *E. coli* B_s is much the more sensitive of the two indicator strains, perhaps by a factor as large as 10,000, then it may be concluded that DNA is the primary target (Ashwood-Smith et al., 1983).

Analysis of Furocoumarins in Celery and Carrot Plants. The results of analyzing fresh, nondiseased celery plants by both normal and reverse-phase

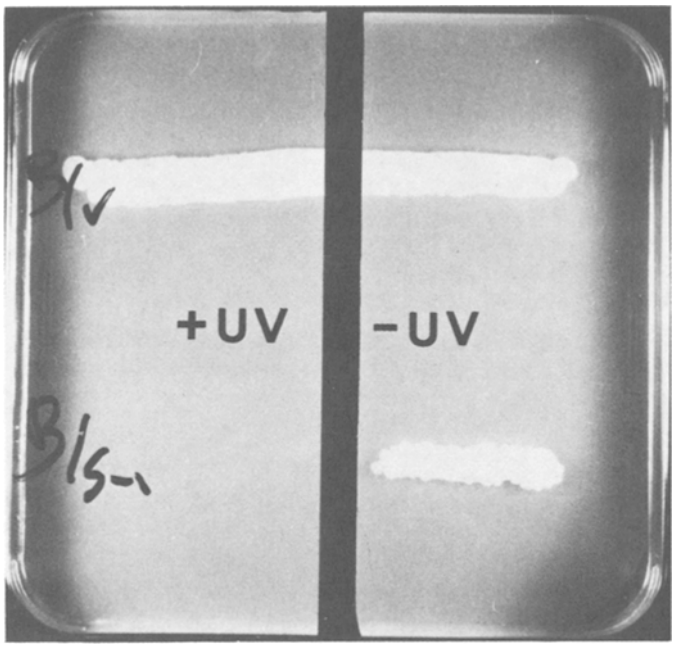

FIG. 2. Photosensitivity of *E. coli* B_s and *E. coli B/r*. Logarithmically growing cultures of the two bacteria (at 37°C in brain–heart infusion broth) were streaked onto the surface of nutrient agar plates and incubated for 24 hr at 37°C after a brief exposure to germicidal ultraviolet radiation (253.7 nm; 150 J/m^2). Half the plate was protected from the radiation.

HPLC are shown in Figure 3. The separation of psoralen, 5-MOP, and 8-MOP is good and was sufficient to demonstrate (Figure 4) the phytoalexin response of diseased celery (Ashwood-Smith et al., 1985). Results after photobiological assay of fresh and diseased celery are illustrated in Figure 5. The increase in furocoumarins, shown in diseased plants, of about 30-fold (Ashwood-Smith et

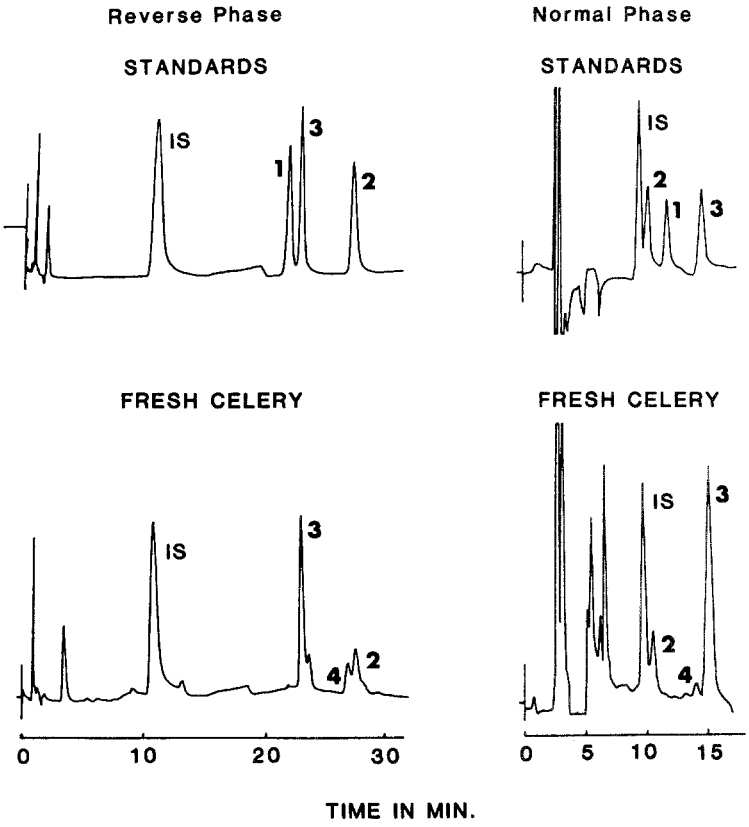

FIG. 3. Normal and reverse-phase HPLC analysis of healthy celery plants. Reverse-phase analysis was performed with a Varian MCH-10 column (4 mm × 30 cm) employing acetonitrile–water as a solvent commencing at 25:75 and remaining constant for 15 min before changing over a period of 5 min to 35:65 and remaining thus for 10 min. The flow rate was 2 ml/min. For normal phase analysis, a Varian Si-5 column (4 mm × 30 cm) was used with a solvent consisting of cyclohexane–isopropylether–*n*-amyl alcohol (15:4:0.5) with a flow rate of 1 ml/min. Detection for both methods was at 254 nm, and quantitation was done by peak area integration with a Hewlett-Packard 3390A integrator. All samples contained coumarin as an internal standard (IS) (30 μg/ml) and were injected as samples of 10 μl. The furocoumarin standards were used at 5 μg/ml. 1 = psoralen, 2 = 5-MOP, 3 = 8-MOP, 4 = isopimpinellin.

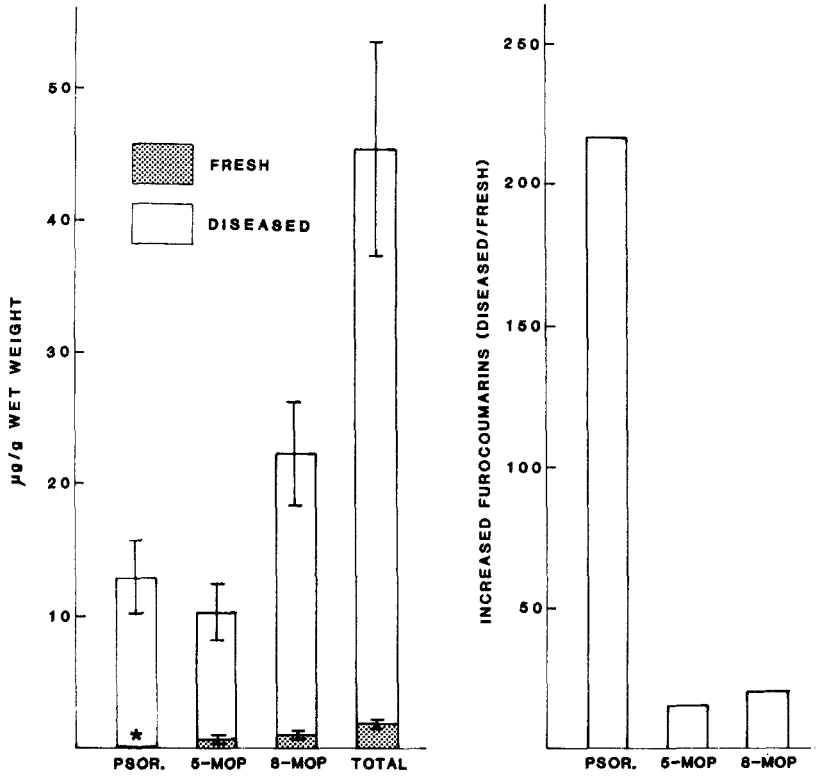

FIG. 4. Total and individual furocoumarin content of fresh and diseased celery. Samples were extracted with ethyl acetate and worked up according to the procedures recently published by Beier et al. (1983) and Chaudhary et al. (1985). Concentrations of furocoumarins are given ±SEM in µg/g wet weight. The control values for psoralen (*) were in a number of cases below reasonable detection limits. The analyses were carried out on 22 fresh samples and 12 diseased samples (in most instances the celery was infected with the fungus, *Sclerotinia sclerotiorum*). Tests for probability (*P*) by the Student's *t* test gave values of *P* greater than 0.001 for all comparisons. The right-hand graph illustrates increases, as ratios of diseased to fresh.

al., 1985) was sufficient to produce a very large area of bacterial kill in the indicator lawn (Figure 5B).

When fresh carrot plants were analyzed, 5-MOP and 8-MOP were, for the first time, shown to be present as constituents of the root. There has been one report (Stadler and Buser, 1984) of 5-MOP and 8-MOP being found in the outer wax of the carrot leaves. Analysis of diseased carrot (the fungal pathogen was not identified) which had been stored for several weeks in a dark, cool basement indicated that psoralen was present at a concentration of 0.87 µg/g, and 8-MOP

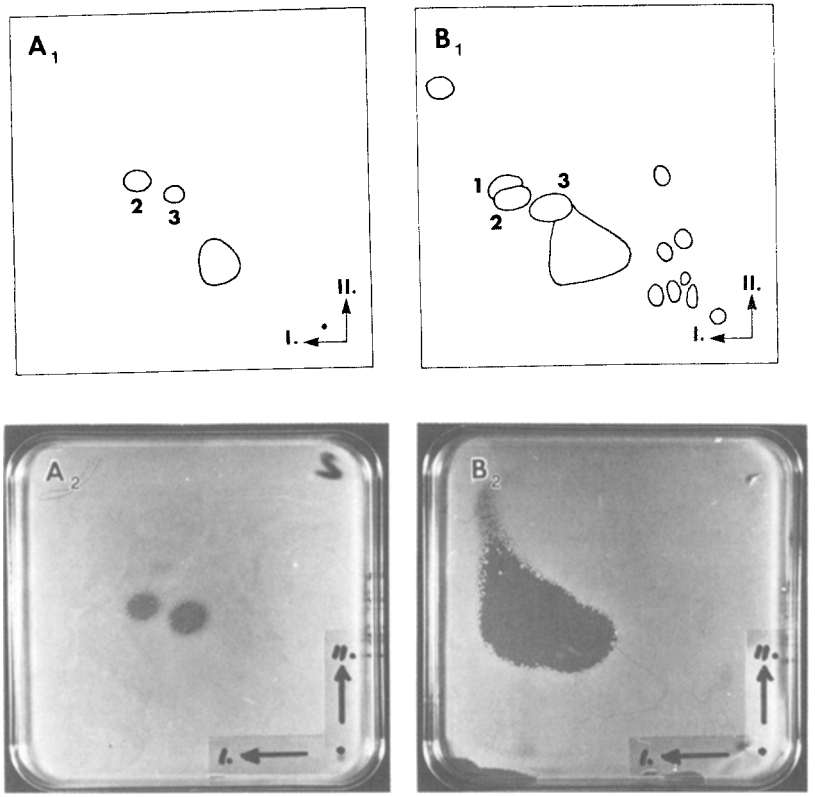

FIG. 5. Photobiological assay of fresh and diseased celery. Top left and top right illustrate the spots revealed by UV radiation (300–380 nm) after two-dimensional TLC of fresh and diseased celery, respectively. Bottom left and bottom right are imprints of the developed TLCs assayed photobiologically. The position of the photoactive spots is seen by the dark areas which, under the lighting conditions used, represent zones of no bacterial growth in an otherwise virgin lawn. Both samples are equivalent to 100 mg of celery (wet weight). 1 = psoralen, 2 = 5-MOP, 3 = 8-MOP.

at 1.55 μg/g; values are for wet weight. 5-MOP levels were also elevated, but HPLC analysis was hindered, even after purification by Sep-Pak, by the presence of other substances eluted from the diseased carrots in the same time interval. The levels of furocoumarins in fresh carrots were below the detectable limits of our HPLC methodology but were clearly seen in the photobiological assay (Figure 6). Only approximations were appropriate for estimation, by comparisons with standards and a knowledge of the sensitivity of *E. coli* B_s: values of about 1×10^{-8} g for both 5- and 8-MOP were obtained (Ashwood-Smith et al., 1983).

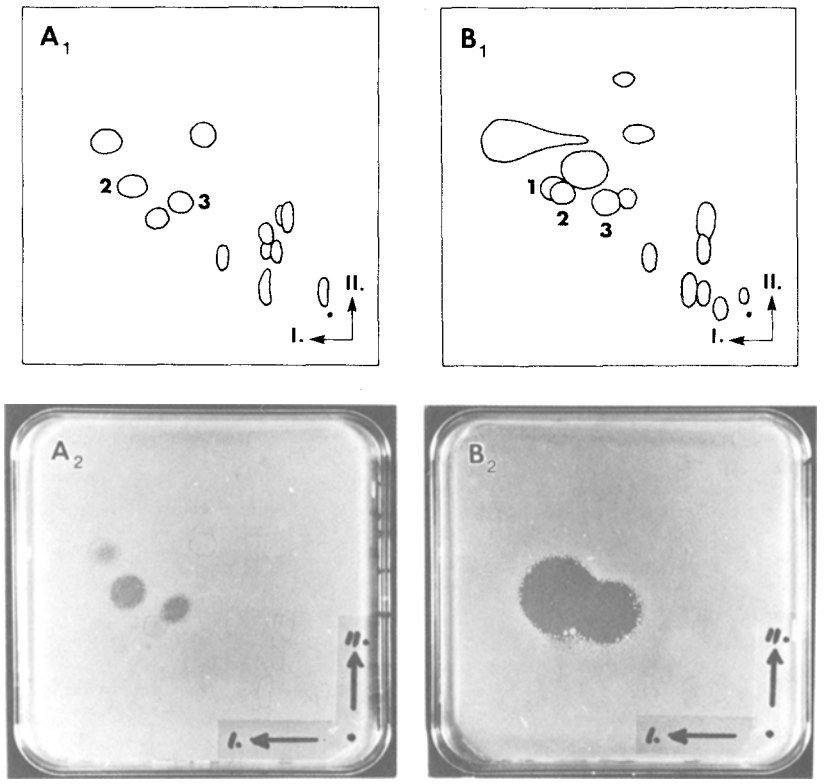

FIG. 6. Photobiological assay of fresh and diseased carrot. Details as for legend to Figure 5. Top left and bottom left are from fresh, healthy carrot; top right and bottom right from diseased carrot. Sample A, fresh carrot, represents 510 mg (wet weight) and sample B, disease carrot, 130 mg. 1 = psoralen, 2 = 5-MOP, 3 = 8-MOP.

Furocoumarin Content in Various Seeds of Umbelliferae. A number of vegetable and herb seeds were analyzed directly by photobiological assay and typical results are shown in Figure 7. Photosensitizing activity was seen with the seeds of *Angelica archangelica* L. (Figures 7, A5 and D6), two varieties of parsnip, *Pastinaca sativa* L. (Figures 7, C3 and C4), and slight activity with two different varieties of celeriac, *Apium graveolens* L. var. *rapaceum* (Miller) D.C. (Figures 7, D4 and D5). Seeds of four varieties of carrot, *Daucus carota* L. (Figures 7, A1–4), coriander, *Coriandrum sativum* L. (Figure 7, C1), anise, *Pimpinella anisum* L. (Figure 7, C2), vegetable fennel, *Foeniculum vulgare*

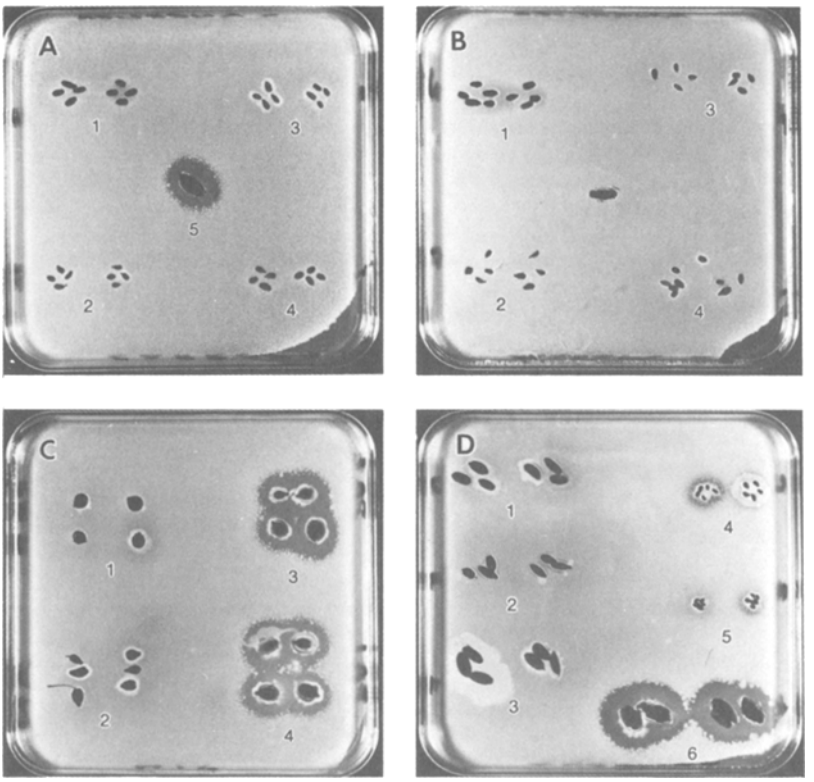

FIG. 7. Photobiological assay of various vegetable and herb seeds of the Umbelliferae. (A) Four varieties of carrot seed 1–4, exposed to near UV, showing no photobiological activity. The positive activity of one seed of *Angelica archangelica* is seen in the center. (B) As for (A) but without exposure to near UV; this plate is the negative control. (C) Seeds of coriander, 1; anise, 2; and two varieties of parsnip, 3 and 4; exposed to near UV. (D) Seeds of vegetable fennel, 1; coumin, 2; green fennel, 3; celeriac, 4 and 5; and angelica, 6; exposed to near UV. Negative controls were done in all experiments but are shown only in (B).

Miller var. *azoricum* (Miller) Thell. (Figure 7, D1), herb fennel, *F. vulgare* var. *vulgare* (Figure 7, D3) and cumin, *Cuminum cyminum* L. (Figure 7, D2) were negative. All seeds were also analyzed in the absence of near-UV radiation and showed no activity with the exception of a very small zone of growth inhibition with one variety of carrot seed (Figure 7, B1). However, for the sake of brevity, only one control plate is illustrated (Figure 7B).

The concentration of furocoumarins per seed was in some instances too low to be measured directly, and seed extracts had to be prepared. In Figure 8 the presence of photobiological activity in extracts from five varieties of parsley seeds, *Petroselinum crispum* (Mill.) A.W. Hill is shown (Figures 8, A1–5). Four seeds that gave negative results when analyzed directly gave weak positive results when extracts were used. These included cumin (Figure 8, B1), green fennel (Figure 8, B2), coriander (Figure 8, B3) and vegetable fennel (Figure 8, B4), together with the strong reaction to the seeds of *A. archangelica* (Figure 8, B5). Carrot seeds sometimes gave positive results but were equivocal. All analyses performed in the dark were negative.

The furocoumarin patterns of celery, *Apium graveolens* L. var. *dulce* (Miller) D.C., and parsnip seed extracts are illustrated in Figure 9A and 9B, respectively. Celery seed had a much lower furocoumarin content than parsnip seed and thus 9A represents 50 mg dry weight and 9B (parsnip) 10 μg weight.

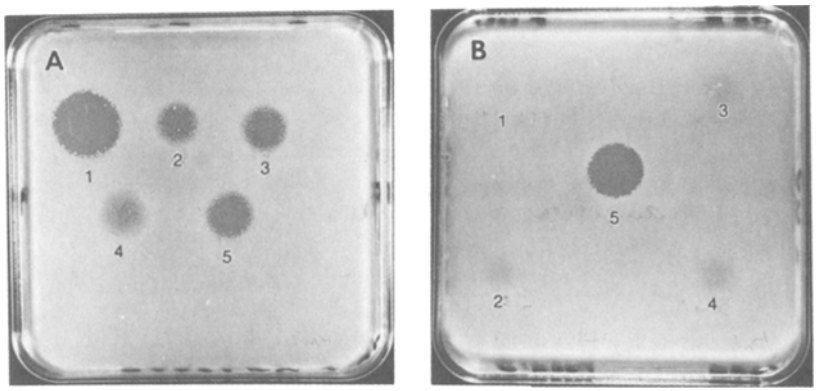

FIG. 8. Photobiological assay of seed extracts. (A) 1–5 are various varieties of parsley equivalent to 50 mg. (B) 1, cumin, 50 mg; 2, green fennel, 50 mg; 3, coriander, 50 mg; 4, vegetable fennel, 50 mg; 5, *A. archangelica*, 2 mg. All samples are tested as spots on silica TLC plates.

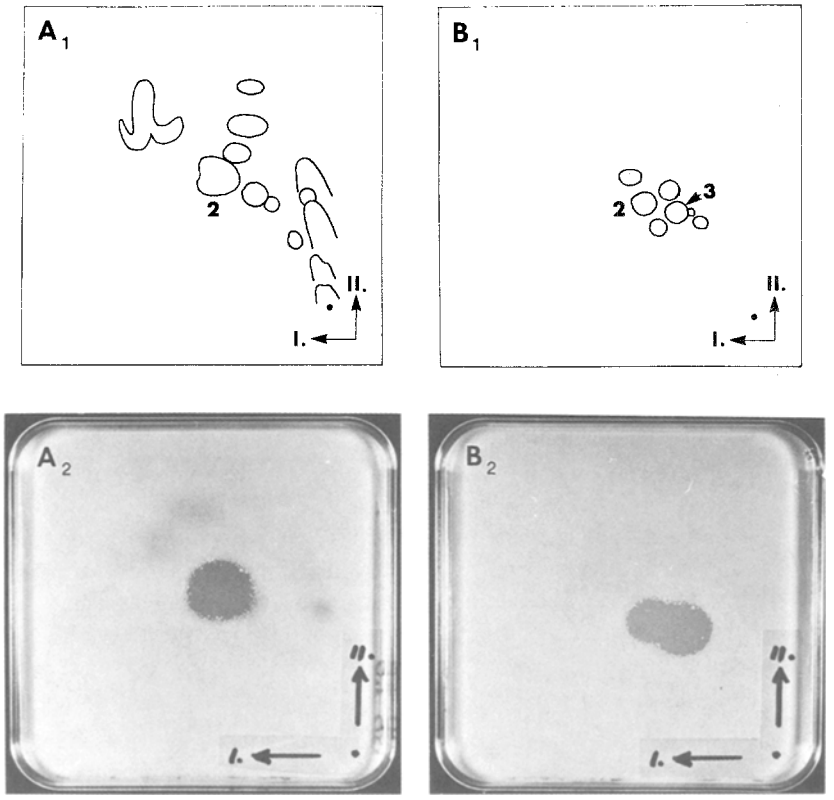

FIG. 9. Photobiological assay of celery and parsnip seed extracts. (A) celery (50 mg); (B) parsnip (10 μg). 2 = 5-MOP, 3 = 8-MOP.

Both seeds contained 5-MOP, but 8-MOP was only seen in parsnips. In addition, three and perhaps four other active molecules were present in celery seeds. Imperatorin was detected in parsnips by HPLC and TLC (compared with a standard). It is known to be phototoxic systemically (Ljunggren, 1977; Ljunggren and Möller, 1978) but not topically (Musajo, 1955); it was photoactive in our bioassay. However, as equivalent amounts of these two seeds were not used, the absence of a particular molecule could not be firmly established.

Application of Photobiological Assay to Detection of Photosensitizing Substances. Illustrated in Figure 10 are the results of the bioassay of extracts made from two rutaceous plants, *Thamnosma montana* Torr. et Frem. and *Skimmia japonica* Thumb. *Thamnosma montana* and *Skimmia laureola* Sieb. et Zucc. ex Walp, are known to cause skin photosensitivity upon contact (Michell and Rook, 1979). The presence of 5-MOP and 8-MOP plus two other unidentified compounds is clearly seen in *T. montana* extracts (Figure 10A, dried stem). The

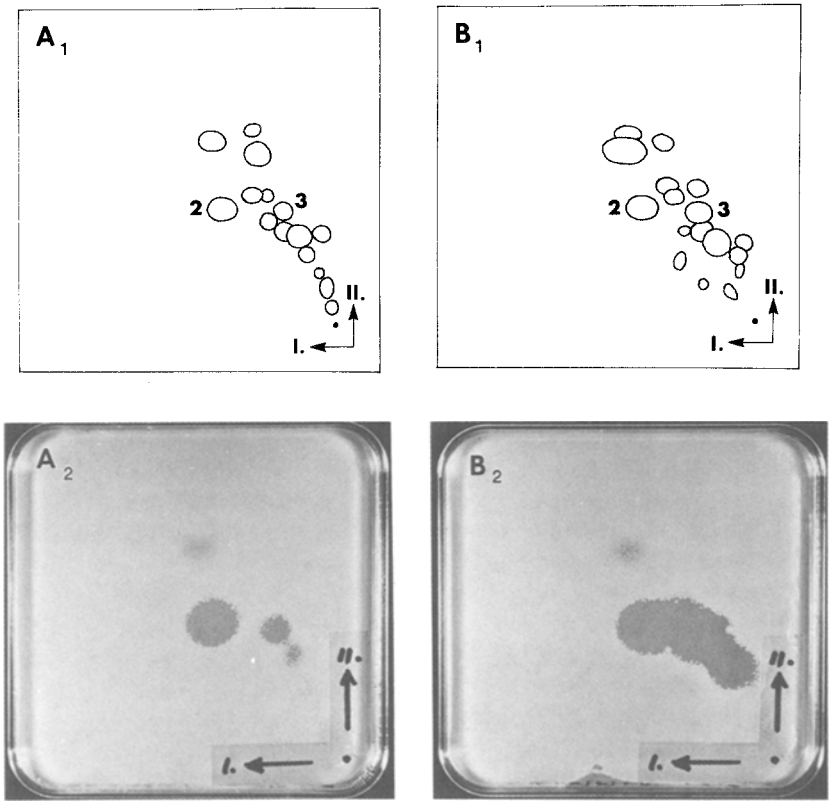

FIG. 10. Photobiological assay of crude plant extracts. (A) Chloroform extract of *Skimmia japonica* fresh leaf representing 1.35 mg wet weight. (B) Chloroform extract of *Thamnosma montana*. This was a two-year-old herbarium specimen representing 0.85 mg dry weight. The chromatographic procedures were as indicated in the legend for Figure 5 and the text. 2 = 5-MOP, 3 = 8-MOP.

fresh leaves of *S. japonica* (Figure 10B) contain 5- and 8-MOP plus four other unidentified photosensitizing molecules.

It is of some interest that the analysis of *T. montana* was performed on a two-year-old dry herbarium sample. The retrospective investigation of furocoumarin content is thus possible provided that herbarium samples have not been treated with chemicals to prevent decomposition and which may, therefore, interfere with the photobiological detection by killing the indicator bacterium.

Several plant oils and one cosmetic product were analyzed photobiologically after two dimensional TLC, and these results are given in Figure 11. Oil of bergamot before and after steam distillation is illustrated in Figure 11A and 11B, respectively, and shows the large reduction in 5-MOP content; dime-

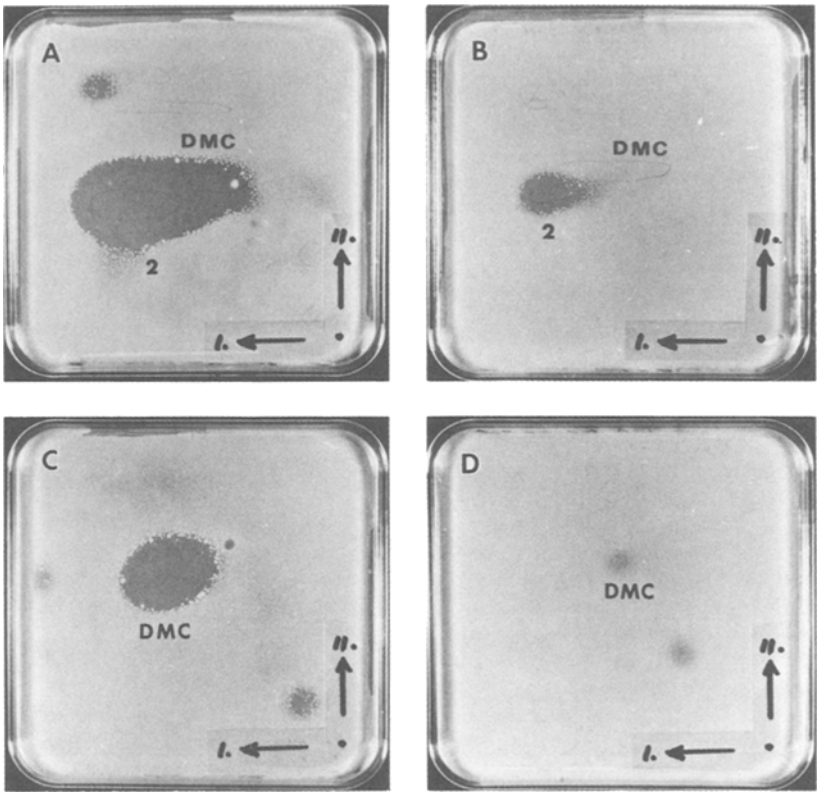

FIG. 11. Photobiological assay of plant oils and suntan lotion. (A) Oil of bergamot (crude); 5 μl. (B) Oil of bergamot (after steam distillation); 5 μl. (C) Refined oil of lemon; 10 μl. (D) Bergasol suntan oil, U.K., 1984 preparation made with citrus essence; 10 μl. The two dimensional TLCs were standard. The inhibition zones in oil of bergamot are due to 5-MOP and dimethoxycoumarin (DMC). Steam-distilled bergamot oil has a low 5-MOP content. Lemon oil contains large quantities of DMC plus two other unidentified components. Bergasol contains DMC plus one other photoactive chemical. There is no 5-MOP, a photocarcinogen found in this suntan oil, prior to changes in the U.K. formulation in 1982. 2 = 5-MOP.

thoxycoumarin is still detectable. An unidentified compound was removed by the steam distillation process. Analysis of lemon oil (10 μl) showed two unknown compounds plus a large amount of dimethoxycoumarin. The usefulness of this assay procedure to investigate cosmetics is demonstrated in Figure 11D in which the results of analyzing a commercial suntan preparation are shown. In this instance 10 μl of Bergasol (UK formulation 1984 with added lemon oil

and minus oil of bergamot) revealed the presence of dimethoxycoumarin and one other active substance but no 5-MOP.

Detection of Photosensitizing Compounds in Plants. The ease with which the presence or absence and, to some extent, the amount and spatial distribution of photosensitizing compounds can be detected in living plants is illustrated in two examples shown in Figures 12 and 13. Two 12- to 13-day-old parsnip seedlings were gently applied to the top surface of the soft agar and analyzed. Figure 12A is the result of the standard exposure to near-UV radiation and 12B the control which received no near-UV radiation. The diffusion of furocoumarins from all parts of the seedlings is obvious. The biological effect of furocoumarins as phytoalexins is well illustrated in the second example, in which the leaves of *Skimmia japonica*, cut in several places (indicated in Figure 13 by

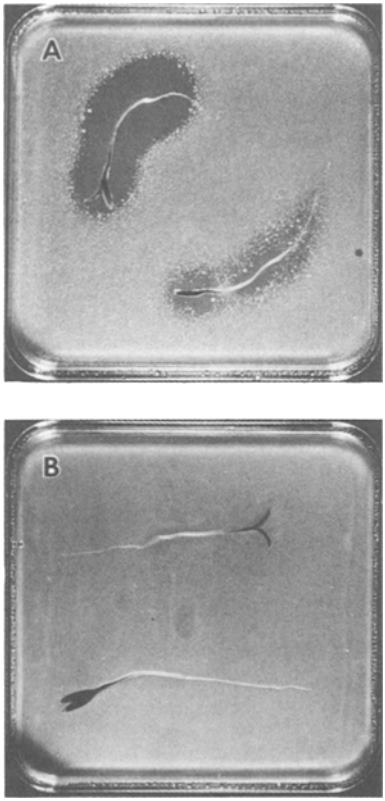

FIG. 12. Photobiological assay of parsnip seedlings. Parsnip seedlings (12–13 days old) assayed for furocoumarin activity (after surface sterilization with chlorine bleach) with (A) and without (B) exposure to near-UV radiation.

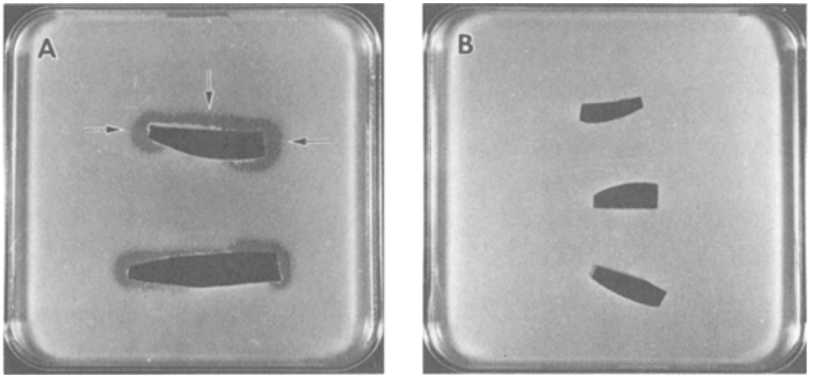

FIG. 13. Photobiological assay of a fresh leaf of *Skimmia japonica* showing effect of deliberate injury (cutting). The inhibition of bacterial growth associated with the cut edges (arrows) is clearly seen indicating the leakage of photoactive chemicals. Left photograph illustrates leaf after exposure to near-UV; right photograph without exposure to near-UV.

arrows), are leaking furocoumarins into the surrounding agar and thus the greatest area of bacterial inhibition is associated with the cut surfaces.

Detection of Metabolites following Enzymatic Detoxification. Microsomal enzymes (mixed-function cytochrome oxidases, P-450 and P-448) from mammalian liver S-9 mix (Maron and Ames, 1983) rapidly inactivate furocoumarins when a suitable source of electrons (NADPH) is present. The changes in photoactivity can easily be followed by one-dimensional TLC of the reaction mixture as a function of time. Illustrated in Figure 14 is the metabolic detoxification

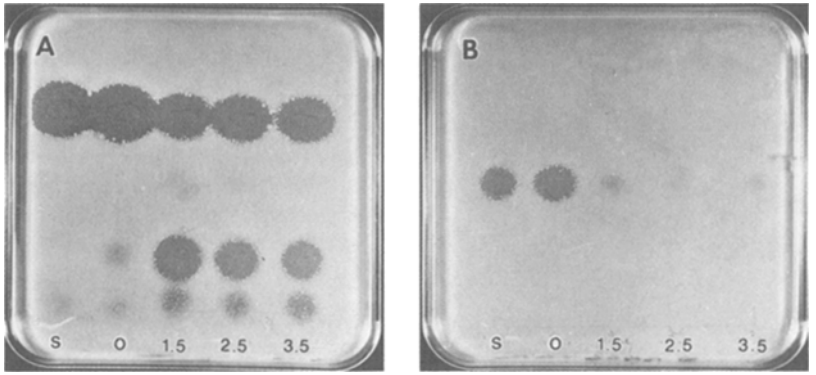

FIG. 14. Enzymatic detoxification of trimethylpsoralen and 5-MOP followed by photobiological assay. (A) Breakdown of trimethylpsoralen into two slower moving but active molecules. (B) Detoxification of 5-MOP and the disappearance of photosensitizing activity. Time is in hours of incubation.

of trimethylpsoralen (Figure 14A) and 5-MOP (Figure 14B). It will be noted that trimethylpsoralen is broken down into two other photoactive compounds in the course of its metabolism, while 5-MOP is detoxified without the formation of photoactive molecules. Other evidence (Ashwood-Smith, unpublished observations) indicates that psoralen, 8-MOP, and angelicin are also detoxified without the formation of active intermediates. The application of this methodology in studying the manner in which insects detoxify furocoumarins is apposite (Ashwood-Smith et al., 1984; Ivie et al., 1983).

Abstract—Four *Escherichia coli* strains carrying all the possible combinations of genes controlling sensitivity to near-UV (NUV; *nur* versus *nur*$^+$) and far-UV (FUV; *uvrA6* versus *uvrA*$^+$) were inactivated with broad-spectrum NUV together with specific phototoxins. The inactivation kinetics of the four strains are consistent with the previous reports that psoralen and angelicin inactivation is based on the formation of DNA adducts, while xanthotoxin (8-MOP) inactivation is based on the combined effects of DNA adduct formation and oxygen-dependent photodynamic action. At sufficiently high NUV fluences, xanthotoxol (8-HOP) induces lethal DNA lesions in an excision-deficient (*uvrA6*) strain. Inactivation by alpha-terthienyl plus NUV involves strictly membrane damage since the genes controlling the sensitivity to either NUV or FUV have no effect on inactivation kinetics. Using mutation to histidine independence (*his-4*$^+$) in the presence of NUV as a measure of mutagenicity by phototoxins, psoralen and xanthotoxin are mutagenic, angelicin is less mutagenic, and xanthotoxol and alpha-terthienyl are not mutagenic. None of the phototoxins tested in the presence of NUV were as mutagenic as FUV. Imperatorin and berberine were neither phototoxic nor mutagenic in this assay system. This assay thus provides a rapid qualitative screening procedure to identify the mode of action and mutagenicity of plant phototoxins with potential insecticidal properties.

Key Words—*Escherichia coli*, alpha-terthienyl, angelicin, xanthotoxin, xanthotoxol, psoralen, histidine independence, mutagenesis.

INTRODUCTION

Over the past 20 years cellular systems in *Escherichia coli* have been identified for the repair of DNA damage whether it is induced by far-UV (FUV; 200–290 nm), ionizing radiation, or chemicals (for reviews see Witkin, 1976; Walker, 1984). The systems which have been most thoroughly characterized are the excision and recombination repair systems, both of which are inducible (Radman, 1974; Kenyon and Walker, 1981). Mutants defective in DNA repair have been identified principally based upon their hypersensitivity to inactivation by radiation or chemicals. If a strain carrying a mutation in a repair pathway (e.g., *recA*, recombinational repair defective, or *uvrA*, excision repair defective) is sensitive to inactivation by a particular treatment, it can be assumed that the damage induced by the treatment is at the DNA level and is reparable in corresponding nonmutant strains (for review see Scott et al., 1976).

In addition to DNA repair by the recombination and excision systems, there exists in *E. coli* cells another repair system specific for oxidative damage (Demple and Halbrook, 1983) resulting from treatment of cells with H_2O_2 or near-UV (NUV). However, it remains controversial as to whether this repair system is inducible (Sammartano and Tuveson, 1985). As is the case for the excision and recombinational repair systems, mutants have been identified representing defects in the pathway for the repair of oxidative damage. *E. coli* strains with *xthA* mutations (exonuclease III defective) are sensitive to inactivation by H_2O_2 (Demple et al., 1983) and broad-spectrum NUV (Sammartano and Tuveson, 1983). The fact that inactivation by NUV is strongly oxygen-dependent (Peak et al., 1983) suggests that the damage induced by these wavelengths is oxidative and probably involves the generation of H_2O_2.

Another gene (*nur*; NUV resistance) sensitizes cells specifically to inactivation by NUV (Tuveson and Jonas, 1979), photodynamic action (acridine orange plus visible light) and sunlight (Tuveson and March, 1980). Significantly, the *nur* mutation sensitizes *E. coli* to inactivation by NUV, photodynamic action (presumably oxidative), or sunlight, independent of whether the strain carries mutations in either the recombinational (*recA1* or *recA13*) or excision repair systems (*uvrA6*; Tuveson and Jonas, 1979; Tuveson, 1980). Strains with the *nur* mutation are sensitive to inactivation by H_2O_2 (Sammartano, Tuveson and Davenport, in preparation), suggesting that the mutation determines sensitivity to oxidative damage. The identification of mutations which specifically sensitize *E. coli* cells to oxidative damage allowed for the construction of a set of strains responding differentially to DNA damage which is oxidative (presumably DNA base damage; Massie et al., 1972) and nonoxidative DNA damage (such as photoadducts). In this paper, we show that these *E. coli* strains exhibited the inactivation kinetics expected for phototoxins whose mechanisms of action have been deduced previously. These strains may thus be useful in determining the inactivating mechanisms which underlie previously uncharacter-

ized phototoxins. The possible mutagenicity of such phototoxins can be assessed since this set of strains carries a mutable auxotrophic marker as well (*his-4*).

METHODS AND MATERIALS

Bacterial Strains. The strains RT7h, RT8h, RT9h, and RT10h were derived from strains RT7, RT8, RT9, and RT10 (Tuveson, 1980) by P1 transduction of a Tn10 insertion located next to the *his-4* allele in strain AB1157 (Leonardo et al., 1984). The four strains have the following properties in common: F^-, *argA21, lysA22, malA1, str 104,* $\lambda^r\lambda^-$, *supE44, zee::Tn10, his-4.* The strains differ genetically as follows: RT7h, *thi-1, nur, uvrA6;* RT8h, *th-1*$^+$, *nur, uvrA*$^+$; RT9h, *th-1, nur*$^+$ *uvrA6*; and RT10h, *thi-1*$^+$, *nur*$^+$, *uvrA*$^+$.

Media. The complex medium used was Luria-Bertani broth (LB; Miller, 1972). The semienriched minimal medium (SEM) used to assess survival consisted of appropriately supplemented minimal A medium (Miller, 1972) plus casamino acids (Difco, 0.4 ml of a 10% solution per liter; Kato et al., 1977) solidified with 1.5% Bacto-agar (Difco). To detect histidine independent (*his-4*$^+$) mutants, cells were spread on each of three SEM plates lacking histidine. To assess plate mutants (Webb, 1978), unirradiated cells were spread on minimal A medium lacking histidine (but containing arginine and lysine) and SEM lacking histidine. For the calculation of *his-4*$^+$ mutants per survivor, net *his-4*$^+$ mutants in a cell population were assessed as the total *his-4*$^+$ mutants minus the *his-4*$^+$ plate mutants.

Chemicals. Berberine, xanthotoxin (8-methoxypsoralen, 8-MOP), and psoralen were purchased from the Sigma Chemical Company, St. Louis, Missouri. Alpha-terthienyl (α-T) was a gift from J.T. Arnason, Biology Department, Ottawa University, Ottawa, Ontario, Canada. Imperatorin and angelicin were obtained from Roth-Chemie (Nahrstedt, Germany; now Atomergic, Plainview, New York) and HRI Associates (Emeryville, California), respectively. Xanthotoxol (8-hydroxypsoralen; 8-HOP) was synthesized by E. Heininger and J. Sternberg using a modification of the procedure of Schönberg and Sina (1950).

Broad-Spectrum NUV-Fluence Response Curves in Presence of Presumptive Phototoxins. Cells were grown at 37°C with shaking in side-arm flasks (Belco) containing 50 ml of LB broth (Miller, 1972). Growth was monitored by measuring the change in absorbance with a Klett-Summerson colorimeter equipped with a red filter. A 5-ml aliquot of stationary-phase cells (2.5 hr after entering the transition from exponential to stationary growth phase) was removed, washed three times with saline, and diluted to approximately 5.0×10^8 cells/ml in cold saline (ice bath temperature) and placed in a 16 × 160-mm tube with a magnetic flea at the bottom. Appropriately diluted presumptive phototoxin in 10 ml of 95% ethanol was added to the cell suspension following

which a 1-ml aliquot was withdrawn and held in the dark as a check on light-independent toxicity. Viability of the cells in the aliquot held in the dark was assessed after all manipulations had been completed with the NUV-treated suspension.

The broad-spectrum NUV source is identical to that described previously (Tuveson and Jonas, 1979). Briefly, the source consisted of a parallel array of four lamps (General Electric, 40 W BLB, integral filter) which emit radiation between 313 and 425 nm, with a maximum emission at 350 nm. The fluence rate was approximately 30 W/m^2 as estimated using a UVX Digital Radiometer (UVP, Inc., San Gabriel, California). This fluence rate is three times the estimate previously published which had been made with a Blak-Ray UV intensity meter (model J-227; Ultraviolet Products, Inc., San Gabriel, California) equipped with a J221 long-wave UV sensor (Tuveson and Jonas, 1979). The long-wave UV sensor proved to be defective.

Bioassay for Phototoxins. Ashwood-Smith et al. (1983) have described a bioassay procedure for the detection of furocoumarins and other photosensitizers. We have used essentially the same procedure described by Ashwood-Smith et al. (1983) for carrying out the bioassay procedures with our strains. Two thin-layer chromatographic (TLC) plates (silica gel 0.25 mm, glass backed, Merck, Darmstadt, Germany) were spotted with 20 μl of psoralen (1 mg/ml) and 20 μl of α-T (1 mg/ml). The plates were placed in contact with LB agar in each of four Petri dishes for 2 min. Essentially, the phototoxins were replicated onto each of four plates of LB agar. The individual plates in the set of four were overlayed with 4 ml of LB soft agar (0.8%) containing about 10^5 cells/ml of one of the four *E. coli* strains (RT7h–RT10h). One set of four plates was placed in the incubator immediately, while the second set of four was exposed to 43.7 kJ of broad-spectrum NUV before being placed in the incubator.

RESULTS AND DISCUSSION

The four strains (RT7h, RT8h, RT9h, and RT10h) which carry all four possible combinations of genes controlling excision proficiency (*uvrA6* versus *uvrA*$^+$) and sensitivity to oxidative (photodynamic) damage (*nur* versus *nur*$^+$) can be used to distinguish between effects of phototoxins which result from oxygen-independent DNA photoadduct formation and photodynamic damage which is oxygen dependent. To establish that this is the case, it was necessary to inactivate the four strains with phototoxins for which the mechanism of lethal action has been established in other ways (Scott et al., 1976). As expected, the strains carrying the *uvrA6* mutation (RT7h and RT8h) were sensitive to inactivation by psoralen plus NUV, supporting the established fact that psoralen phototoxicity is based on cycloadditions to DNA (Figure 1). When these same strains were tested with xanthotoxin (8-MOP), three of the four strains proved to be sensitive to inactivation (RT7h, RT8h, and RT9h; Figure 2). This is the

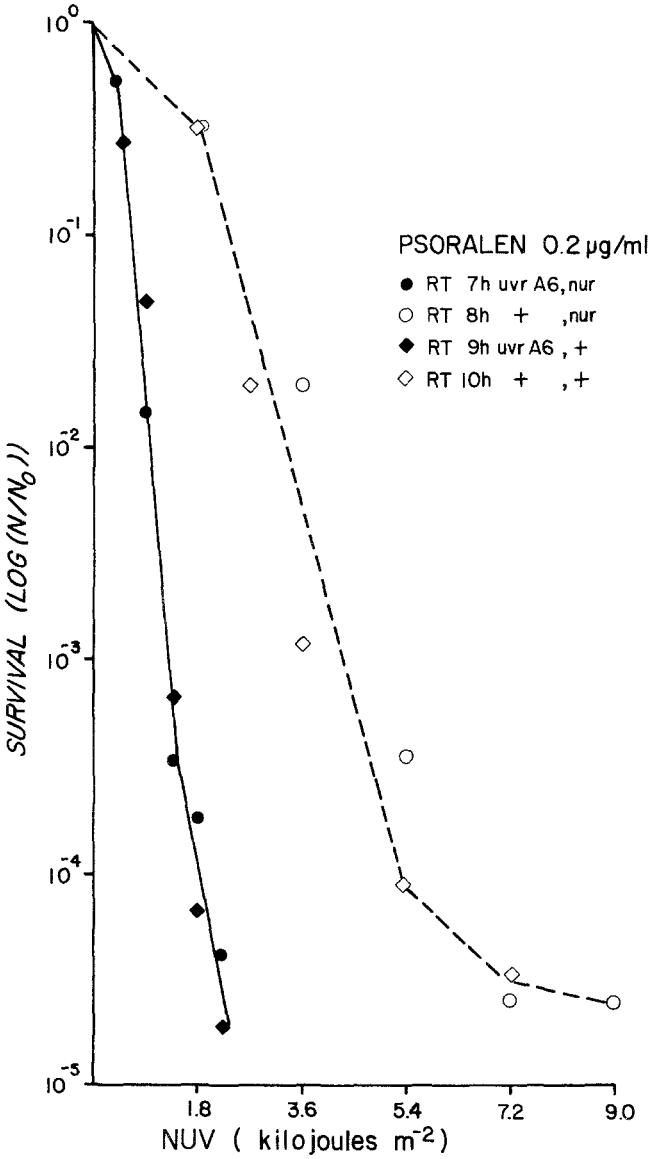

FIG. 1. Fluence–response curves for four *E. coli* strains treated with broad-spectrum NUV in the presence of psoralen.

result to be expected if xanthotoxin can act both as a classical photosensitizer and by DNA cycloadditions as has been suggested by Vedaldi et al. (1983). It should be noted that, although both psoralen and xanthotoxin were used at the rate of 0.2 µg/ml, the fluence of NUV required to obtain equivalent inactivation

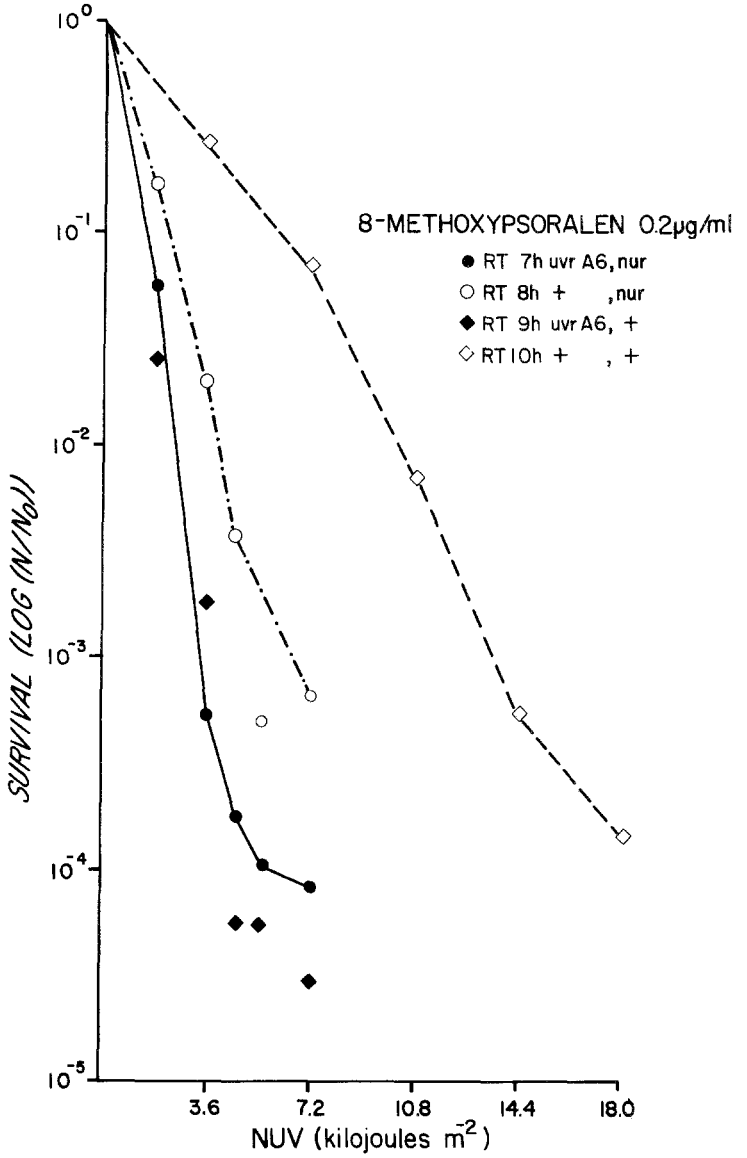

FIG. 2. Fluence–response curves for four *E. coli* strains treated with broad-spectrum NUV in the presence of 8-methoxypsoralen (xanthotoxin).

with xanthotoxin using the repair-proficient strain RT10h was greater than twice that required with psoralen. The reason for this difference is not apparent from these experiments since both chemicals produce cycloadditions to DNA.

When angelicin was used, the strains behaved as expected if its mode of

lethal action were based on monoadduct formation in DNA; the strains carrying the *uvrA6* mutation (RT7h, RT9h) were sensitive to inactivation by angelicin and NUV (Figure 3) (Scott et al., 1976). Consistent with the formation of monoadducts in DNA, the concentration of angelicin used in these experiments was five times that used with psoralen or xanthotoxin for equivalent toxicity, although the NUV fluences used were about the same with all three phototoxins. These results support the hypothesis that angelicin inactivates exclusively by monoadduct formation in DNA and does not act as a classical oxygen-dependent photosensitizer. The fact that angelicin inactivates by monoadduct formation in DNA is thought to reflect its angular configuration (Scott et al., 1976).

The addition of a hydroxyl group to the parent psoralen molecule at the 8 position (xanthotoxol or 8-hydroxyporalen) results in the loss of phototoxicity. We tested xanthotoxol as a phototoxin for the four strains used in our assay (RT7h–RT10h, Figure 4). The inactivation observed for three strains is that expected with NUV alone (Leonardo et al., 1984; Sammartano and Tuveson, 1984). The sensitivity of RT9h might be interpreted to mean that xanthotoxol at high NUV fluences (>18 kJ) induces damage which is reparable by the excision repair system (*uvrA*$^+$). However, in the RT7h strain, which also carries *uvrA6* mutation leading to excision deficiency, the NUV fluence tested was not sufficiently high to induce xanthotoxol excision-reparable lesions. The NUV sensitivity of the RT7h and RT8h is controlled by a gene (*nur*) which has been shown to be independent of either *recA* or *uvrA* mutations which sensitize cells to FUV (Tuveson and Jonas, 1979; Tuveson, 1980). We can speculate that, although RT7h carries the *uvrA6* mutation, it is not sensitive to xanthotoxol because the NUV fluences employed were insufficient to induce xanthotoxol lethal lesions but were more than sufficient to induce xanthotoxin lethal lesions (compare Figures 2 and 4).

When the four strains were treated with α-terthienyl (α-T) and NUV, the kinetics of inactivation for all the strains were indistinguishable (Figure 5). There is much evidence available suggesting that α-T acts as an oxygen-dependent (photodynamic) photosensitizer (Arnason et al., 1981), the principal lethal target for which is the membrane (Downum et al., 1982). Photochemical experiments with hydrophobic thiophenes, including α-T, suggest that these compounds, when irradiated with NUV, produce $^1O_2$ which might be expected to interact with membrane components (proteins and unsaturated fatty acids) to form peroxides and hydroperoxides that alter the hydrophobic character of the membrane, leading to leakage of cellular components and cell death (Reyftmann et al., 1985). The inactivation kinetics observed with our four strains are consistent with the membrane being the principal lethal target when *E. coli* cells are treated with α-T and NUV, since the mutations controlling NUV (*nur* versus *nur*$^+$) or FUV (*uvrA6* versus *uvrA*$^+$) sensitivity do not influence the inactivation kinetics. It has been shown that the *nur* gene sensitizes *E. coli* to photodynamic action when cells are treated with acridine orange plus visible light (Tuveson

TABLE 1. PROPERTIES OF PHOTOTOXINS INVESTIGATED WITH *Escherichia coli* STRAINS RT7H, 8H, 9H, AND 10H

Phototoxin[a]	Mutagenicity	Concentration (μg/ml) used for inactivation experiments (conc./maximum conc. used)	F_{37} kilojoules for strain RT10h[a] (F_{37}/maximum F_{37})
Psoralen (Ps)	+	0.2 (0.02)	1.62 (0.03)
Xanthotoxin (8-methoxypsoralen, 8-MOP)	+	0.2 (0.02)	3.24 (0.60)
Angelicin (An)	+	10.0 (1.0)	2.70 (0.05)
Xanthotoxol (8-hydroxypsoralen, 8-HOP)	−	10.0 (1.0)	54.0 (1.0)
α-Terthienyl (α-T)	−	10.0 (1.0)	7.2 (0.13)

[a]Relative efficiency of inactivation: Ps > 8-MOP > α-T > An > 8-HOP.
[b]RT10h was used to compare F_{37} (fluence resulting in 37% survival) since it is repair proficient.

and March, 1980). This observation suggests that the *nur* gene sensitizes cells to oxidative damage involving DNA. When α-T is used as a photosensitizer, however, the *nur* gene has no sensitizing effect, as would be expected if the lethal effects of this compound plus NUV are restricted to the membrane.

When either imperatorin (Fahmy and Abu-Shady, 1947) or berberine (Philogène et al., 1984) were tested as possible phototoxins with the four *E. coli* strains RT7h, RT8h, RT9h, and RT10h, inactivation beyond that which could be accounted for by the NUV light system alone could not be demonstrated. In this assay system neither imperatorin nor berberine is phototoxic.

In all of the experiments just described (Figures 1–5), selection was carried out for histidine independence at the *his-4* locus. The comparison of the mutational results is difficult since the concentration of photosensitizer and the fluence of NUV used differs for each photosensitizer (Table 1). It seems most appropriate to compare the mutational results at equivalent survival levels assuming, therefore, the same number of lethal lesions are being produced by the phototoxins being compared. As a standard for mutagenicity, we elected to use FUV, which is highly mutagenic for the *his-4* allele carried by strains RT7h–RT10h (Kato et al., 1977). The comparison of the mutagenic effects of the various phototoxins tested and FUV are presented in Figure 6. It is apparent that psoralen, xanthotoxin (8-MOP), and angelicin are capable of inducing *his-4*$^+$ mutations but are not as efficient as FUV for the induction of such mutations. Mutations to histidine independence were not detected in the experiments in-

FIG. 5. Fluence–response curves for four *E. coli* strains treated with broad-spectrum NUV in the presence of α-terthienyl.

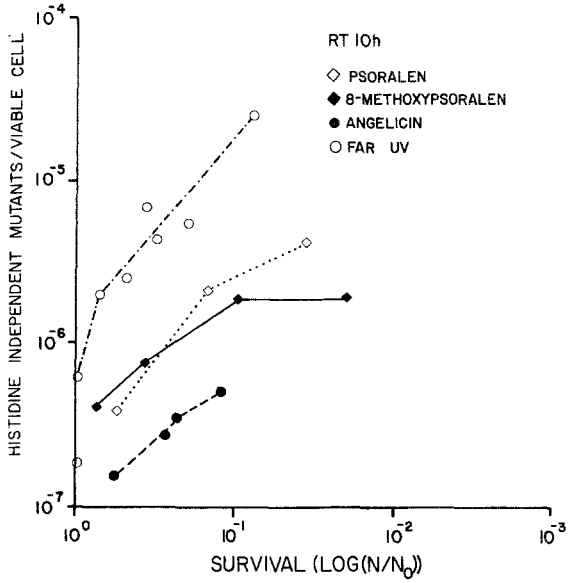

FIG. 6. Histidine-independent mutations per viable cells induced in strain RT10h with broad-spectrum NUV in the presence of phototoxins compared at equivalent survival levels.

volving xanthotoxol (8-HOP) or α-T. The mutation results with xanthotoxol were not unexpected since the inactivation observed with RT10h could be accounted for by the NUV radiation alone and NUV is not particularly mutagenic (Tyrrell, 1978; Leonardo et al., 1984). Even with RT9h, in which some fraction of the inactivation is the result of NUV and xanthotoxol, *his-4*$^+$ mutants were undetectable. The fact that *his-4*$^+$ mutants were not detectable with α-T plus NUV is what would be expected assuming the lethal target is the membrane rather than DNA.

In Table 1, the results are summarized and an evaluation of the relative efficiency of the phototoxins plus NUV for inactivation is presented. In this evaluation we have attempted to take into account the fact that the inactivation kinetics are determined by two variables: (1) the phototoxin concentration employed and (2) the fluence required to obtain 0.37 survival. As might have been expected, psoralen and xanthotoxin are the most efficient for inactivation and xanthotoxol the least efficient. In fact, the inactivation involving xanthotoxol is probably totally independent of the chemical and simply represents NUV inactivation.

The results reported here suggest that the four *E. coli* strains described (RT7h–RT10h) can be used to give a preliminary indication of the mechanism(s) by which a suspected phototoxin might inactivate cells. Furthermore, some indication of the mutagenicity of the presumptive phototoxin can be as-

sessed by selecting *his-4*$^+$ independent mutants in the same experiment in which inactivation kinetics are being assessed. Finally, identical inactivation kinetics for all four strains, as was seen with α-T (Figure 5), can be taken as preliminary evidence that the principal lethal target is the membrane.

Ashwood-Smith et al. (1983) have devised a method for assaying phototoxins involving transfer of presumptive phototoxins from TLC plates onto nutrient agar plates followed by overlaying the agar plates with soft agar (0.8%) containing bacteria (10^5–10^6 cells/ml). After the overlay solidifies, the plates are exposed to various NUV fluences. Where phototoxins were present on the TLC plate, a zone of inhibition will appear in the bacterial lawn on plates exposed to NUV before overnight incubation at 37°C. We ran an experiment to see whether similar procedures might be used with *E. coli* strains RT7h–RT10h. The results of this experiment are presented in Figure 7. It appears that the four strains described here can be used in a bioassay system comparable to that

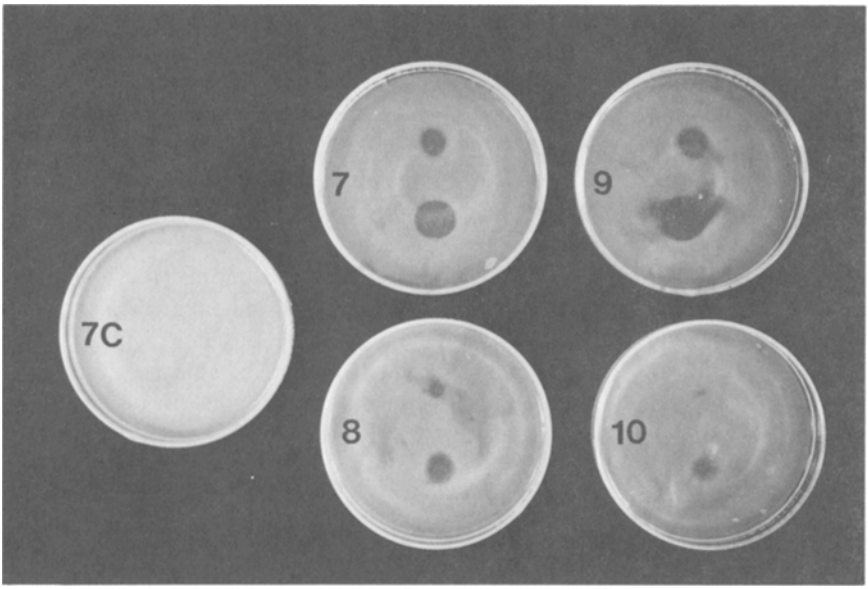

FIG. 7. Photograph of Petri dishes containing LB agar onto which TLC plates had been pressed for 2 min, following which a 4-ml overlay of LB agar seeded with indicator bacteria had been poured. 7 = RT7h, 8 = RT8h, 9 = RT9h, 10 = RT10h. Only a single unirradiated control is shown (7C = RT7h not exposed to broad-spectrum NUV). All other plates were exposed to broad-spectrum NUV. Upper clear zone in bacterial lawn = α-T; lower clear zone = psoralen.

described by Ashwood-Smith et al. (1983). The upper clear zone in the plates exposed to NUV marks the position of the α-T spot on the TLC plate and would be expected to be the same size for all four strains (Figure 5). However, R10h seems to be the least sensitive of the four strains to inactivation by α-T and NUV. The lower clear zone in the plates exposed to NUV marks the position of the psoralen spot on the TLC plate. Strains RT7h and RT9h exhibit larger zones of inactivation than do strains RT8h and RT10h, as expected, since these strains carry the *uvrA6* allele. These results imply that this qualitative bioassay can be used with the four strains described here to draw preliminary conclusions concerning the possible inactivation mechanism(s) characteristic of a particular phototoxin. However, firm conclusions concerning the inactivation mechanism(s) for such a phototoxin will require quantitative inactivation experiments.

The control of insect pests using synthetic chemicals is coming to a close. Alternative methods are needed to accomplish this objective. Clearly, there is not going to be any single method which will prove satisfactory under all circumstances. One possible method of control for insect pests would be to utilize the chemicals evolved by plants to control insect pests, such as phototoxins. These compounds, when ingested by insects feeding on plants, become toxic with exposure to sunlight. In principle, since these are "natural products," they are biodegradable and could be developed as ecologically sound "insecticides." To begin an evaluation of phototoxins, a rapid method is needed to evaluate the mechanism(s) by which the compound acts and its potential mutagenicity. Using the four *E. coli* strains we have constructed (RT7h, RT8h, RT9h, and RT10h), it should be possible within not more than two weeks to obtain some information as to the mode of action and the mutagenicity of newly isolated and purified phototoxic plant-derived compounds. This system is qualitative and reproducible, eliminating the need to do the initial phototoxicity assessment of new plant products with insect-feeding experiments. Should the bacterial experiments prove positive, then efforts to evaluate the efficacy of the new compound with insects could be undertaken. Since insect experiments are slow and exhibit high variability, the bacterial systems should accelerate the evaluation of potentially important compounds as phototoxins for insects.

Journal of Chemical Ecology, Vol. 12, No. 5, 1986

Editors' Note

The field of chemical ecology considers chemical–biological interactions in the context of the organism's surrounding environment. As techniques become increasingly sophisticated, we are able to probe more deeply into the chemical, biochemical, and genetic basis of these interactions. The International Society of Chemical Ecology, founded in 1983, is a forum for the discussion of the latest developments in this field: an area wherein the subject of chemical ecology is the focal point that brings together scientists regardless of the system in which they work (e.g., plant or animal, terrestrial or marine).

When the second annual meeting of the International Society of Chemical Ecology convened in Madison, Wisconsin on June 8–12, 1985, four symposia highlighted recent progress in various aspects of chemical ecology. These were: Marine Chemical Ecology, Chemical Aspects of Symbiosis, Behavioral Adaptations to Chemical Cues, and the Evolutionary Ecology of Chemical Defense in Insects. The *Journal of Chemical Ecology*, as the official journal of the society, is dedicating this issue to the proceedings of those symposia.

Each paper has undergone peer review in accordance with the standard review policy of the Journal. We are especially grateful to symposium moderators: D. Rittschof, D. Norris, W. Burkholder, and J. Pasteels; and to reviewers: E.A. Bernays, M.S. Blum, M.D. Bowers, W.E.S. Carr, L.S. Ciereszko, S.S. Duffey, W.B. Heed, T. Jermy, G.W. Ordal, J.G. Rodriguez, G.G.E. Scudder, and R.A. Werner.

We acknowledge the cooperation of Plenum Publishing Corporation in producing extra copies of this issue to accommodate registrants of the symposium and others interested in the proceedings under this single cover.

(Received July 29, 1985; accepted November 4, 1985)

Abstract—An overview of marine chemical ecology is presented. Emphasis is placed on antipredation, invertebrate–toxic host relationships, antifouling, competition for space, species dominance, and the chemistry of ecological interactions.

Key Words—Chemical ecology, ecological chemistry, defense, predation, antipredation, symbiosis, biological associations, fouling, biofouling, antifouling, communities, succession, dominance, competition, marine chemistry, medicine, toxin, noxin, venom, poison, marine natural products chemistry, natural products chemistry.

INTRODUCTION

The chemical ecology of marine organisms is described by a vast assemblage of papers and books, representing a wide variety of subdisciplines within biology and chemistry. Much of the recent interest in marine chemical ecology has developed historically as offshoots from natural products chemistry (i.e., novel compounds, Manes et al., 1985) and drug and health-related studies. Among some of the most interesting applied topics, in which considerable basic research has been and is being done, are health problems such as worldwide human marine poisonings, numbering over 20,000 cases and 150 deaths annually (Russell, 1984). Paralytic shellfish poisoning or PSP, including saxitoxin, annually numbers about 2000 cases and 33 deaths (Hashimoto, 1979;

0098-0331/86/0500-0951$05.00/0

Russell, 1984; Steidinger and Baden, 1984). Ciguatera or fish poisoning causes deaths in the Indo-Pacific region in particular (Randall, 1980). Poisonings from eating other dangerous seafoods (e.g., snails and crabs) number about 530 cases and 37 deaths annually; (Garth and Alcala, 1977; Yasumoto et al., 1983a,b; Russell, 1984).

Swimmer's itch from the blue-green *Lyngbya majuscula* (now *Microcoleus lyngbyaceus*), is caused by the inflammatory agent debromoaplysiatoxin, one of the most potent skin irritants known (Russell, 1984). Some 1.5×10^6 humans are stung every year as a result of contact with marine organisms (Kohn, 1958; Plessis, 1975; Russell, 1984). Dermatitis from haptens in bryozoans is also common (Russell, 1984). In addition to the above poisons and irritants, a variety of antibiotic (i.e., antibacterial, antifungal, antiviral) agents, antitumoral compounds such as didemnins or depsipeptides (Burkholder, 1973; Mynderse et al., 1977; Weinheimer et al., 1978; Rinehart et al., 1981a,b; Jacobs et al., 1985; Thompson et al., 1985), prostaglandins (Weinheimer and Spraggins, 1969; Ruggieri and Thoroughgood, 1985), and antiinflammatory agents such as potassium fluorosilicate are known to occur in marine species (Gregson et al., 1979).

Other topics of interest in chemical ecology include mutualism (Muscatine and Porter, 1977; Wilkinson and Vacelet, 1979; Glynn, 1983), chemical communication (Reiswig, 1970; Barbier, 1981; Liley, 1982), chemoreception (e.g., in larval settling, Hadfield, 1977; Hadfield and Ciereszko, 1978; Crisp, 1984; Morse and Morse, 1984; food recognition and detection of predators, Noakes and Ward, 1981; Croll, 1983), bioluminescence (Ruby and Morin, 1978; Morin, 1981), immunological responses such as the death of subordinate corals and graft acceptance in sponges (Hildemann et al., 1981; Jokiel et al., 1982; Neigel and Avise, 1983; Kaye and Reiswig, 1985), growth controls (Sullivan et al., 1983; Rinkevich and Loya, 1985), the use of marine pesticides (Padan or nereistoxin; Ruggieri, 1976), the weakening of calcareous structures by boring organisms (Goreau and Hartman, 1963; Anderson and Stonard, 1979; Young and Nelson, 1985), the use of marine bioactive substances in neurophysiology (McClure and Martin, 1983; Koenig et al., 1984), natural shark repellents (pardaxin, see discussion below; Bakus, 1983a; Bakus et al., 1983; Tachibana et al., 1985), natural antifouling agents (Riegle, 1982; Targett et al., 1983; Bakus and Kawaguchi, 1984), the stunning of fishes (Plessis, 1975), and chemotaxonomy (Bergquist and Wells, 1983; Gerhart, 1983; Bergquist et al., 1984; Lee and Gilchrist, 1985; Tymiak et al., 1985).

In addition, there are fascinating cases of symbiosis. For example, the clownfish, *Amphiprion clarkii*, that forms a mutualistic association with the sea anemone *Stechodactyla haddoni*, has a mucus layer of relatively inert glycoprotein that is three to four times thicker than that of many other reef fishes (Lubbock, 1980; Brooks and Mariscal, 1984). This mucus layer protects the fish from stings by nematocysts of the sea anemone. Another example is the

juvenile damselfish, *Abudefduf leucogaster*, that lives among the soft coral *Litophyton viridis* in the tropical Pacific. These fish are protected from potential predators by chemicals released by the soft coral which are noxious to most fish but to which the damselfish have developed a tolerance (Tursch, 1982).

An exhaustive review of marine chemical ecology is not possible at this time. Instead, we will provide an overview, concentrating on the following aspects of chemical ecology that represent our different principal interests, that is, antipredation, invertebrate–toxic host relationships, antifouling, competition for space, species dominance, and the chemistry of ecological interactions. The reader is referred to other recently published reviews for additional information (e.g., Herring, 1979; Fenical, 1982; Norris and Fenical, 1982; Faulkner and Ghiselin, 1983; Faulkner, 1983; 1984; Wright, 1984; Scheuer, 1985; Coll et al., 1985).

ANTIPREDATION

Predators (in the broad sense) are widespread in the marine environment. This is reflected in numerous types of offensive and defensive mechanisms among their prey. Protective and defensive mechanisms evolved by the biota against vertebrates and invertebrates include rapid growth and growth in wave-washed and cryptic areas by benthic algae, unpredictable occurrences in time and space, burrowing, boring, large size, structural defense, evasive movement, cryptic coloration and form, nocturnal activity, symbiotic associations, parental protection, and chemical defenses (Bakus, 1964, 1969, 1983b; Menge and Lubchenco, 1981, Norris and Fenical, 1982). Many interactions of attack, defense, and behavioral response involve not physical force but chemical agents. A great many of these chemical agents can be assigned two or three adaptive roles (Whittaker and Feeny, 1971; Janzen, 1979). For example, secretion of mucus may serve to clear a hard coral of sediment but may also provide a mechanism for concentration of allelochemicals, preventing excessive dilution by currents (Jackson and Buss, 1975; Sullivan et al., 1983). This may also be the case in Maldivian soft corals (e.g., *Dendronephthya* and *Sarcophyton*, Bakus, personal observation). The retention of pigments is a passive chemical defense mechanism, effective in cryptic coloration, warning coloration, and countershading. For example, juveniles of the burrfish *Chilomycterus antennatus* reportedly are Batesian mimics in shape and coloration of the sea slug *Aplysia dactylomela* (Norris and Fenical, 1982).

Consumer pressure is severe in tropical rocky intertidal communities, where most organisms are located in holes and crevices for protection from predators (Menge and Lubchenco, 1981). The ultimate in consumer pressure occurs on coral atolls (Bakus, 1967, 1969). However, chemical defenses are not limited to species occurring in low latitudes. The kelp *Alaria marginata* produces an-

tiherbivore phenolic compounds (Steinberg, 1984) as does the Caribbean brown alga *Stypopodium zonale*. The holothurian *Psolus chitinoides* in the San Juan Islands, Washington, is highly unpalatable to fish and has the highest saponin content of the four species of sea cucumbers examined (Bingham and Braithwaite, 1985). Many species of the green algae *Caulerpa* and *Halimeda* are ichthyotoxic (Gerwick and Fenical, 1981; Norris and Fenical, 1982; Russell, 1984). Genera within the Udoteaceae and Caulerpaceae are highly resistant to fish grazing (Lewis, 1985). In particular, certain *Halimeda* species contain halimedatriol, a diterpenoid trialdehyde, which shows antibiotic activity, inhibits cell division and sperm motility, and is ichthyotoxic (Paul and Fenical, 1984). Some *Halimeda* and *Caulerpa* species also produce diacetoxybutadiene-containing terpenes which deter fish feeding even when coated onto their preferred food, the seagrass *Thalassia testudinum* (Targett et al., 1986). However, the reef flat blue-green *Schizothrix calcicola* contains a major toxic metabolite (debromoaplysiatoxin) yet is consumed in large quantities by surgeonfishes at Enewetak Atoll (Bakus, 1967; Mynderse et al., 1977). This tends to support Lewis' (1985) conclusion that the susceptibility of tropical algal species to fish grazing is not clearly correlated with morphological (e.g., calcification) or chemical (e.g., allomones) characteristics that have been previously suggested as plant defenses against herbivory.

Similarly, toxic sponges and probably soft corals are consumed by certain fishes (Randall and Hartman, 1968; Anderson et al., 1981; Tursch and Tursch, 1982). The sponges *Neofibularia* spp. contain some of the most painful undescribed marine chemicals known to man (Hartman, 1967). Several flatworms including *Thysanozoon* spp. and even certain brittlestars secrete an acid, as do some opisthobranchs (Marbach and Tsurnamal, 1973; Cimino et al., 1983; Faulkner and Ghiselin, 1983; Russell, 1984). Opisthobranchs also release terpenes and a variety of other compounds which are thought to function in defense (Lewin, 1970; Faulkner, 1983; Mebs, 1985). Faulkner and Ghiselin (1983) believe that the loss of the shell in dorid nudibranchs and other opisthobranchs is correlated with defense chemicals, the chemical defenses being elaborated gradually as the shell was being lost.

Coelenterates employ nematocysts offensively and defensively. The most toxic are cubomedusae such as the sea wasp, *Chironex fleckeri*, which has been known to cause human death in less than five minutes (Russell, 1984; Halstead, 1985). Nematocysts in hydroids (*Lytocarpus* spp. and *Millepora* spp.) and some hard corals (*Acropora palmata*) are known to sting divers (Halstead, 1985). Zoanthids containing palytoxins are reportedly among the most toxic marine organisms known (Moore and Scheuer, 1971; Moore and Bartolini, 1981; Russell, 1984; Uemura et al., 1985). The sea anemone (*Stoichactis* spp.) contains polypeptides that are proteinase inhibitory, toxic, and hemolytic (Mebs and Gebauer, 1980). Many sea anemones have cytolytic toxins, principally proteins and peptides (Russell, 1984). However, not all cnidarian defenses are contained

within the nematocysts. For example, gorgonians (*Lophogorgia* spp., *Plexaura* spp.) have terpene and prostaglandin defense toxins (Fenical et al., 1981; Gerhart, 1984).

The polychaete *Eurythoe* has hollow, sometimes fluid-filled stinging chaetae; the sea hare *Aplysia brasiliana* produces antishark chemicals (Kinnel et al., 1979); and the blue-ringed octopus in Australia (*Hapalochaena maculosa*, which contains the venom maculotoxin, identical to the chemical poison tetrodotoxin) has caused human fatalities (Russell, 1984). Even the eggs and/or larvae of some seastars (*Asterias rubens*, *Acanthaster planci*) are protected by saponins or glycosides (Lucas et al., 1979). In fact, it is likely that the larvae of many asteroids may contain saponins that act against predators such as polychaete worms and fishes. Palytoxin also occurs in the eggs of the zoanthid *Palythoa tuberculosa* (Endean and Cameron, 1983).

Russell (1984) has questioned whether offensive sponge odors and taste play a defensive role. Green (1977) found that the sponge *Iotrochota birotulata* has a colored, strong-smelling exudate that, when released in water, is avoided by fishes. Green and Bakus (personal observation), in 1973 found that several species of foul-smelling gorgonians from the region of Veracruz, Mexico, were ichthyotoxic.

Aposematism is poorly studied in marine invertebrates. Some zooanthids are aposematically colored (Lewis, 1982), but sponges seem to display a large variety of colors whether toxic or not (Bakus and Thun, 1979). Some fishes have what appears to be warning coloration and erectile caudal spines as defensive mechanisms (surgeonfishes or Acanthuridae). Others secrete a mucus that prevents predaceous fishes from eating them (Kerstitch, 1984). Perhaps the most incredible case of antipredation occurs in the Moses sole found in the Red Sea. This diminutive flatfish secretes a milky toxin that in some instances paralyzes the jaws of a biting shark (Clark, 1983; Dr. Eugenie Clark, personal communication).

Many marine toxins appear to be feeding deterrents also. Echinoderm noxins and toxins appear to be the same chemically, that is, triterpenoid and steroidal saponins (Burnell and ApSimon, 1983; Dr. G. G. Habermehl, personal communication). Terpenoids in sponges may be unpalatable to predators (Manes et al., 1984, 1985; Russell, 1984; Bescansa et al., 1985). More than half of nontoxic soft corals are noxious to fishes, their chemicals causing 48–88% feeding deterrency in fish (La Barre et al., 1986b). Feeding deterrency is as common among nontoxic fish corals as among toxic soft corals. The herbivorous fish *Sparisoma radians* avoided the milky exudate released from injured tips of the green alga *Halimeda incrassata* (Targett et al., 1986).

A variety of marine organisms are venomous, including octopuses (via their salivary glands), snails (especially *Conus geographus* and *C. textile*), sea urchins (*Toxopneustes*), sea stars (*Acanthaster planci*), fishes (scorpaenids or rockfishes such as the turkeyfish, stingrays; Roche and Halstead, 1972), and of

course, all of the 51 species of sea snakes (Family Hydrophiidae, Voris, 1972). There are about 700 species of toxic (i.e., venomous and poisonous) fishes known. Rather few of the fishes (3%) on the Great Barrier Reef are venomous (Cameron, 1976). Many species are poisonous, either with toxic skin (about 50 species, e.g., crinotoxic soapfish, boxfish, puffers, and stonefish) or nocturnal mucus cocoons (wrasses and parrotfishes). There are even cases of fishes with toxic models (*Canthigaster*) and edible mimics (*Paraluteres*, Cameron, 1976). Recent summaries of information on venomous and poisonous marine organisms are found in Habermehl (1981), Sutherland (1983), Russell (1984), Russell et al. (1984), and Halstead (1985).

Defensive toxicity is prevalent in warm waters (Table 1). This high incidence in the tropics probably is an evolutionary response to a sessile or slow-moving habit, exposure coupled with high-diversity and high-intensity predation (especially by fishes), and rapid turnover rates (Bakus, 1969, 1983b; Cameron, 1976; Miller, 1982; Hay, 1984a,b). Recent findings indicate that the toxicity of sponges to fishes is relatively high in northern France and even the Antarctic (Hugsecom and van de Vyer, 1985; James B. McClintock, personal communication). This toxicity may represent adaptive responses to invertebrate predators, the broad spectrum toxins also affecting fishes.

What we do not know is often more interesting than what is known. Although exposed coral reef holothurians are toxic to fishes, and cryptic sea cucumbers in the same area are not, some cryptic sponges are toxic to fishes (Green, 1977; Bakus, 1981). Is this an accidental metabolic byproduct resulting from transposons, a feature selected in the past that has not yet been eliminated from the gene pool, or does this represent a species that occurs cryptically in some regions and exposed in others? Green (1977) found that most nontoxic sponges were unexposed in the tropics but exposed in cold temperate waters. As a general rule, opisthobranchs are both distasteful and cryptic (Faulkner and Ghiselin, 1983), the latter especially common in the tropics (Bakus, personal observation). Only seldom has it been demonstrated that even suspected toxins vary seasonally (e.g., saponins in the seastar *Asterias amurensis*, Yasumoto et al., 1966). How widespread is this phenomenon? Is it simply a Q_{10} response or could it be an adaptation to a seasonal increase in predation pressure, or both?

Bakus (1969) illustrated how the holothurian *Holothuria atra* secretes a toxin when disturbed. Parrish (1972) reported that the holothurian *Actinopyga agassizi* releases a noxious substance from the body surface when attacked by the snail *Charonia variegata*. Advanced hunger and periods of exposure in close proximity to the holothurian appear to give *C. variegata* sufficient resistance to the noxin to permit successful predation. Green (1977) suggested that sponge toxins may be released continuously into the surrounding water and serve as a warning deterrent to predators. Lucas et al. (1979) stated that saponins diffuse from starfish and are detected by their prey. They also serve as defense chemicals in asteroids and holothurians. The first chemically demonstrated release

of an allelochemical from a marine organism was from an Australian soft coral (Coll et al., 1982a). Toxins are secreted more or less continuously in several species of soft corals (Sammarco et al., 1982; Coll and Sammarco, 1983) and in at least two species of sponges from California (*Spongia idia* and *Aplysina fistularis*, Walker et al., 1980; Thompson, 1985). We know nothing about this phenomenon in hundreds of other species of toxic sponges, gorgonians, and holothurians. The intensity of fish grazing on the benthos certainly appears to be greater in the tropics in general than that of higher latitudes (e.g., note the high-standing crops of algae in the latter, Bakus, 1969; Choat, 1982). However, is the encounter rate between predators and prey also greater in the tropics? This has never been investigated. How does a fish learn that a species is toxic? Presumably by trial and error feeding and/or by chemoreception (Bakus, 1981). This interaction needs considerably more study in the field.

Some marine toxicity studies have examined whole organisms from diverse geographical areas and pooled results. Questions regarding variations in toxicity with geography, age, sex, body part, depth, and so forth, need to be addressed in more detail. Based on analogies with terrestrial systems, one would expect to find variations in quality and quantity of allelochemics over the range of some species in response to changes in the environment or shifting selection pressures (Whittaker and Feeney, 1971). Dr. Valerie Paul (personal communication) is currently studying these subjects in marine algae, but we know virtually nothing about this in marine benthic invertebrates. There do not appear to be significant changes in the toxicity of soft corals with latitude along the Great Barrier Reef of Australia (Coll and Sammarco, 1983). This suggests that there is no significant change in the intensity of predation as long as coral reef communities persist. Toxicity in holothurians is weaker in cold waters than in the tropics (Bakus, 1974). Sponges that are toxic in colder waters were moderately to highly toxic whereas those in the tropics ranged from slightly to highly toxic (Green, 1977). Certain species of sponges and holothurians apparently are toxic in some localities and nontoxic in others (Green, 1977; Bakus, 1981). A sample of two species of blue-greens collected from the seaward side of Enewetak Island was much more toxic than a specimen collected on the lagoon side of the island (Mynderse et al., 1977), perhaps an adaptive response to high intensity grazing on the outer reef flat (Bakus, 1967). Two antimicrobial metabolites occur in the intertidal sponge *Aplysina fistularis* but not in the same species at depths of 5–15 m (Thompson et al., 1983; Thompson, 1985).

Several different toxic saponins can be found within an individual holothurian (Dr. G. G. Habermehl, personal communication), yet we know almost nothing about the adaptive advantage of having several compounds. One suggestion is that saponins are important in reproduction, antipredation, and antifouling. Prostaglandin A_2 in the gorgonian *Plexaura homomalla* (representing about 10% of the dry weight) is one million times more concentrated than in most other marine invertebrates. It has emetic properties in a very wide range

TABLE 1. TOXICITY OF SHALLOW-WATER MARINE ORGANISMS AT VARIOUS LATITUDES[a]

Locality	Latitude	Taxonomic group	No. of Species		Species (%)	Source
			Tested	Toxic

[b] Organism toxic to humans.
[c] 73% of exposed benthic species.

of organisms, causes learned feeding aversion in fish, and is ichthyotoxic (Gerhart, 1984). Many other gorgonians are ichthyotoxic (see above and Bakus, 1981). Toxins in soft corals, principally terpenes, constitute about 1% of their dry weight (Dr. John Coll, personal communication). About half of soft coral species are ichthyotoxic (Coll et al., 1982b; La Barre et al., 1986b). Siphonodictidine, a sponge chemical that kills coral polyps around the sponge *Siphonodictyon* spp., represents about 1% of the dry weight of the sponge. A congeneric sponge contains the chemical siphonodictyal, a very different metabolite that also kills nearby coral polyps (Sullivan et al., 1983). To what extent do inquilines occur in toxic animals such as sponges? The mildly toxic (to fish) Caribbean sponge *Spheciospongia vesperium* is teeming with inquilines (Pearse, 1932, 1950; Bakus and Thun, 1979), but the more toxic sponge *Ircinia campana* seems to have far fewer (Bakus, personal observation).

There is a dearth of information on whether the compounds toxic to fishes also serve other adaptive roles, such as antifouling agents or species spacing allomones. Sammarco et al. (1982) suggest that toxic compounds from soft corals serve both an antipredator function and a role in competition for space. However, it is not known whether chemically identical terpenes are involved in multiple roles. Coral reef sponges, soft corals, and ascidians that lack allelochemicals have a hardened body or secrete copious amounts of mucus (Bakus, 1969, 1981; Green, 1977; Bakus and Thun, 1979; Dr. John Coll, personal communication). The behavior of fishes exposed to benthic invertebrate toxins suggests that the chemicals are interfering with oxygen transport across gill membranes and/or that a strong chemoreceptive response is occurring. Mackie et al. (1975) reported that the toxic effects of saponins are similar to those of synthetic surfactants. They damage the gill epithelium, reducing gas exchange across the gill surface. Pardaxin, a polypeptide of the size of about 3800 daltons in the Moses sole, is hemolytic and ichthyotoxic (Primor and Zlotkin, 1976; Dr. Samuel Gruber, personal communication). It is a potent gill ATPase inhibitor and clearly causes structural damage to gill tissues (Primor et al., 1980). It also acts as a surfactant (Primor et al., 1983; Gruber and Tachibana, 1986). These appear to be the only instances where the physiological effects of antipredatory toxins are known.

INVERTEBRATE-TOXIC HOST RELATIONSHIPS

Benthic marine organisms containing bioactive compounds, such as some sponges, cnidarians, mollusks, holothurians, and asteroids, are probably never completely devoid of either predators or symbionts. Because of this, it is necessary to examine how predators and symbionts (i.e., associated species) handle the toxic or noxious compounds that their hosts produce. A toxic compound is thought to provide general protection to the host; therefore, any associate would be expected to be specialized in their adaptations to the host. As an example of

this, Coll et al. (1983) briefly describe the relationship of the prosobranch mollusk *Ovula ovum*, an egg cowry, to the highly allelotoxic soft coral *Sarcophyton* spp. The prosobranch grazes on the corals' tissue without apparent harm. By way of a reduction–elimination reaction believed to be enzyme-mediated, the egg cowry transforms sarcophytoxide, the most abundant terpene in the soft coral, into a much less toxic, 7,8 deoxysarcophytoxide. This process probably occurs in the digestive diverticula/stomach region. Similarly, in a review article, Faulkner and Ghiselin (1983) discuss numerous cases in which nudibranchs selectively incorporate sponge toxins that are capable of acting as feeding inhibitors, the only exception being the *de novo* synthesis of polygodial in *Dendrodoris limbata* (Cimino et al., 1983). The secondary metabolites of the nudibranch *Cadlina luteomarginata* are found only in the dorsum and act as antifeedant chemicals to fish (Thompson et al., 1982). Additionally, herbivorous marine mollusks (e.g., *Aplysia*, saccoglossans) contain protective compounds dietarily derived from their algal food sources (Norris and Fenical, 1982; Faulkner, 1984).

In many other cases, however, the means by which an associate handles the toxins of its host are not well understood. Sponge-zoanthid associations appear to be of two distinct types in the central Caribbean. One group consists of dull-colored zoanthids, lacking toxicity, thus offering no protection to their sponge host. Brightly pigmented zoanthids, toxic in nature, comprise the second group, possibly representing a mutualistic association in which the toxic zoanthid reduces predation on host sponges (Lewis, 1982). It seems likely that sponge hosts are never exposed to zoanthid toxins. This may also be the case in zooxanthellae-coelenterate relationships. Many toxic alcyonaceans and gorgonians contain algal symbionts which contribute to the nutrition of the host (Muscatine, 1980). Kokke et al. (1984) present strong evidence that the zooxanthellae do not synthesize these bioactive compounds nor do they provide an immediate precursor to toxin (terpene) synthesis (e.g., a mevalonic precursor). Since these terpenes are probably stored in membranous vacuole-type structures similar to those proposed in sponges (Simpson, 1984), any toxin-resistance hypothesized from the mere existence of the algal–toxic host relationship might simply be explained by stating that the zooxanthellae are never exposed to these bioactive compounds (Dr. William Fenical, personal communication).

Other toxic host–associate interactions simply have not been examined in detail. A variety of animals (worms, sea urchins, crustaceans, and fishes) feed on the seastar *Acanthaster* in spite of its toxic saponins (Glynn, 1984). The prosobranch gastropods *Cyphoma* and *Neosimnia* feed on gorgonians containing bioactive compounds without deleterious effects (Dr. Eric Jordan, personal communication). Sundial shells (*Heliacus* spp.) eat some of the polyps of the zoanthid *Palythoa* (Endean and Cameron, 1983). The seastar *Evasterias troschelii* has a commensal polychaete, *Arctonoe fragilis*, that is immune to the hosts' saponin, whereas the noncommensal polychaete *Arctonoe pulchra* is not

(Patterson et al., 1978). Some tropical fishes feed on toxic sponges with no visible negative reactions (Randall and Hartman, 1968). These are only a few examples of the wide variety of interactions between an associate and its toxic host yet to be explored and understood.

In summary, a species that closely associates with (i.e., lives within in some manner or feeds on) a toxic host species may handle bioactive compounds by one of the following means: (1) excrete or secrete the toxins unchanged (e.g., some opisthobranchs), (2) incorporate the toxins or a derivative thereof, possibly for their own defensive benefit (e.g., many sponge-feeding nudibranchs; *Ovula ovum*), (3) be immune to any toxic effects yet forced to handle bioactive compounds in some manner, and (4) avoid contact with its host's toxins (e.g., possibly zooxanthellae).

ANTIFOULING AND SUCCESSION

The initial stages of marine community development involve several steps: (1) adsorption of biopolymers in water to a surface (Mitchell, 1977; Baier, 1984; Lewin, 1984), (2) chemical attraction of bacteria, (3) reversible adsorption of bacterial populations, the bacteria adhering within minutes after settling onto a surface (Colwell, 1984), (4) irreversible adsorption of bacteria involving macromolecular fibrils, the attachment occurring by flagella and other cellular structures (a typical adhesion polymer on a bacterial surface might be making at least 10,000 contacts with a surface; Robb, in Lewin, 1984), (5) agglomeration and colony formation, and (6) growth of a secondary bacterial population, pennate diatoms, protozoans, and adhesion of particulate matter (Cuba and Blake, 1983; Mitchell and Kirchman, 1984). Whether microfouling is a general prerequisite to subsequent settling has not been resolved (Little, 1984).

Larval settling behavior is dependent on substratum type, substratum rugosity, light intensity, existing surface films, host inductance, larval chemoreception and other factors (Meadows and Campbell, 1972; Birkeland, 1977; Chia and Rice, 1978; Costlow and Tipper, 1984; Crisp, 1984; Morse and Morse, 1984). Three ecological models have been developed to explain the causes of succession or the replacement of species over time. They include: (1) "facilitation" or alteration of conditions by early species that allow later species to replace them, (2) "inhibition," that is, early colonists inhibit the invasion of later species, and (3) "tolerance," that is, early colonists do not affect the recruitment and growth of later species. There is ample evidence to support both facilitation (Gallagher et al., 1983; Turner, 1983; Harris et al., 1984) and inhibition (Sutherland and Karlson, 1977; Sousa, 1979; Standing et al., 1982; Rittschof et al., 1985). Breitburg (1985) recently concluded that examples of all three models appear to occur in marine community development. She and Dean and Hurd (1980) showed that more than one mechanism may be present

in the same community. Inhibition seems to be more prevalent than facilitation, and tolerance appears to be relatively rare (Bergen, 1985).

Replacement of species during succession has been reported as orderly (Anger, 1978; Murray and Littler, 1978; Sousa, 1980; Sutherland, 1981) and disorderly (Fager, 1971; Osman, 1977; Sutherland and Karlson, 1977). Species composition in succession is affected by prior residents, grazing, temporal variability in recruitment and growth, small-scale differences in settlement, growth and/or survival of colonists, and the physical regime (i.e., disturbance ranging from mild to severe) under which they occur (Bergen, 1985; Breitburg, 1985). However, if successional studies are examined in detail, the actual mechanisms by which species growth is enhanced or inhibited are poorly known. To predict changes in species composition, interactions between the various pairs of early and late colonizers must be taken into account (Breitburg, 1985).

Woodin and Jackson (1979) suggested that different species of the same functional group (i.e., guild) may help each other in competition with species in different functional groups. This may be related in part to the fact that there is more evidence for competition between distantly related taxa than between closely related forms. Thompson (1984) proposed that communities develop by certain species secreting allomones in concert, preventing other species from settling. Thompson (1985) demonstrated that exudates from the sponge *Aplysina fistularis* inhibited metamorphosis of gastropod veliger larvae, reduced settlement of larvae, and caused behavioral modifications in five species of adult invertebrates, but were not toxic to dorid nudibranchs. They also reduced tissue damage from browsing animals by repelling them.

Walker et al. (1985) reported that the sponge *Aplysina fistularis* responded to a simulated injury by exuding 10–100 times more antimicrobial metabolites within about the first 5 min than normally. They found that marine sponges with clean surfaces exhibited greater antimicrobial activity than those with biofouled surfaces. This phenomenon was also reported from Australia (McCaffrey and Endean, 1985). Nakatsu et al. (1983) suggest that sterol sulfates may be responsible in part for the lack of fouling organisms on the sponge *Toxadocia zumi*. Crinoids contain polyketide sulfates which may serve not only as a defensive mechanism against fish (Rideout et al., 1979), but as antifouling agents. Even asteroids may discharge saponins into water in part to prevent fouling (Russell, 1984). Certainly one of the most unusual cases of antifouling occurs in the stonefish (*Synanceja horribilis*) which moves so seldom that it must shed its biofouled skin periodically (Cameron, 1976).

In addition to the above, evidence is beginning to accumulate which suggests that chemistry may play an important role in succession. Kirchman et al. (1983) proposed a lectin model system (i.e., proteins or glycoproteins with carbohydrate-binding specificity) to explain biochemical processes in the settling of fouling organisms (see also Lewin, 1984; Mitchell and Kirchman, 1984). Stoecker (1980a, b) showed that acidity and high vanadium contents are

defenses against fouling in some ascidian species. Targett et al. (1983) found that the growth of the diatom *Navicula salinicola* is inhibited by the substance homarine from gorgonians, a simple 2-carboxy *n*-methyl pyridine. A furanogermacrene isolated from the gorgonian *Pseudopterogorgia americana* inhibits both *N. salinicola* and *Nitzchia* spp. at naturally occurring concentrations in *in situ* experiments (Targett, 1985). Experiments conducted by Bakus et al. (1983) indicate that extracts from tropical gorgonians and sponges can inhibit, enhance, or not affect the settling of dominant marine fouling organisms. Preliminary evidence supports the suggestion that tropical marine organisms may show greater potential as antifoulers than do temperate latitude species (Bakus and Kawaguchi, 1984). Moreover, antibiosis in sponges near Cancun, Mexico, appears to be seasonal (Green et al., 1986; Batus et al., 1986).

The occurrence of clean-surfaced animals that lack appendages, such as sponges, ascidians, soft corals, gorgonians, and holothurians, suggests that antifouling allomones may be present. This is especially true of species on coral reefs, animals potentially exposed to a great variety of algal spores and especially invertebrate larvae. We are beginning to test this hypothesis, working on the assumption that tidy tropical species remain clean by preventing the initial irreversible adsorption of bacteria on their surfaces. Thus, experiments with antibiotics in the laboratory coupled with antifouling experiments in the field may answer some important questions in this regard.

We know very little about the interaction between species pairs during marine succession, especially on the chemical level. Laboratory experiments are needed to demonstrate chemical interactions, corroborated by field experiments. We need to determine how certain species maintain clean body surfaces. If chemicals are secreted, where are they produced and where are they stored; what controls their production and release?

COMPETITION FOR SPACE

Marine organisms, in competing for space, may crowd, undercut, crush, overshadow, overgrow, digest, or poison their neighbors (Quinn, 1982; Branch, 1984). Soft corals may leave trails by moving over hard corals and killing them, offering space susceptible to secondary colonization (Benayahu and Loya, 1981; La Barre and Coll, 1982). Kittredge et al. (1974) brought to attention the role of allelochemics in the sea. Recently, Bak and Borsboom (1984) demonstrated an allelopathic interaction between the giant sea anemone *Condylactis gigantea* and benthic algae. They emphasized that the widely differing results between their laboratory and field experiments were due to the considerable dilution of toxin released by the anemone into the sea. Sheppard (1979) suggested that a toxic secretion may be responsible for the gap between certain hard corals competing for space. Benayahu and Loya (1981) reported that although massive

soft corals (e.g., *Lobophytum, Sacrophyton, Sinularia*) inhibit hard coral growth, some hard corals can inhibit the growth of smaller soft corals. There is rapidly growing interest in the biological role of terpenes in hard corals.

The role that toxins might play in competition for space among cryptic coral reef species was suggested by Jackson and Buss (1975). They proposed competitive networks or a feedback loop in an otherwise hierarchical sequence of interference competitive abilities. For example, species 1 is dominant over species 2, species 2 over species 3, species 3 over species 4, yet species 3 dominates over species 1 (feedback loop). Later they suggested that where competitive networks exist, competition for space may increase diversity (Buss and Jackson, 1979), in comparison with the generally accepted theory of competitive hierarchies disturbance. Quinn (1982) found that the competitive organization of low intertidal rock faces in Washington was essentially hierarchical. Reversals in the outcome between pairs of competing species may occur seasonally or in response to changing physical conditions or even composition of the plankton. Russ (1982), in a long-term study, demonstrated that major groups or taxa are hierarchical (e.g., ascidians and sponges overgrow everything else), that species networks did not exist, that there was no single competitively dominant species, and that larger colonies often would win in competition for space between pairs of species. He also indicated that except in one case, Jackson and Buss had not demonstrated competitive networks. Other criticisms of Jackson and Buss were reported by Quinn (1982); Russ (1982); and Walker et al. (1985). Huston (1985) suggested that an alteration of competitive hierarchies by changing environmental conditions is an alternative mechanism that could produce a nonhierarchical competitive networks on the underside of coral shelves.

Porter and Targett (1985) have quantitative evidence that the proximity of the sponge *Plakortis zygomorpha* to the scleractinian coral *Agaricia lamarki* stressed the coral to the point where in situ P/R (productivity/respiration) ratios were less than 1. Sammarco et al. (1982) demonstrated that soft corals could retard the growth of hard corals, effectively competing with them for space. They considered the secreted compounds important in both antipredation and competition for space. These discoveries have clarified some perplexing problems concerning competition for space between these two major coral taxa (Sheppard, 1979; Benayahu and Loya, 1981) and showed that contact was not essential for inhibition. Birkeland et al. (1981) found that the coral *Mycetophylla aliciae,* strongly competitive for space among Caribbean hard corals, is apparently defenseless against overgrowth by ascidians. The movement of larger didemnids is a frequent source of small-scale (about 100 cm^2) disturbance of occupation of space by hard corals, yet sponges were overgrown but not damaged. Bakus (personal observation) found that ascidians were the only organisms growing over the living basal tissues of the Maldivian soft coral *Dendronephthya* spp. Space for recruitment may not be a limiting factor for the giant

sea anemone *Condylactis gigantea* in a supposedly space-limited environment, due to the toxins it secretes (Bak and Borsboom, 1984).

Lang (1973) concluded that a strict hierarchy of aggression (i.e., one species destroying another species by exocoelenteric digestion with extended mesenteric filaments) occurs in Caribbean corals. Sheppard (1979, 1981), however, found that such a rigid hierarchy was not characteristic of scleractinian corals in the Indian Ocean. Coral aggression was not related to general morphology, taxonomic position, or corallum shape. Wellington (1980) demonstrated that the previously reported hierarchy for some Pacific corals, based on extension of mesenterial filaments, was a short-term response. Aggression by corals also occurs by catch or sweeper tentacles (Sebens, 1984; Hidaka, 1985). However, Bradbury and Young (1981) and Cope (1981) maintain that physical factors (i.e., temperature, wave action, light) rather than competition or predation, explain the distributions of scleratinian corals. Many ecologists would agree that physical–chemical factors are most important because they determine which species have the physiological ability to survive in a new habitat.

Scleractinian corals are not alone regarding agonistic behaviors. Intraspecific agonistic behavior has been reported in the large temperate sea anemone *Anthopleura xanthogrammica* (Sebens, 1984). Nonneighbor anemones exhibit an acrorhagial response, producing vesicular extensions at the column margin over a period of up to about 10 min, damaging other anemones. The chemistry of this interaction is apparently unknown; it presumably involves the secretion of digestive enzymes. All anemones with acrorhagi reportedly use them agonistically, intra- or interspecifically, except for genetically identical clonemates (Sebens, 1984). Webb and Coll (1983) showed that hard corals die within 24 hr of exposure to soft coral terpenes at a concentration of $\geqq 10$ ppm. Finally, Theodor (1966, 1971, 1975) showed that tissue necrosis resulted from contact between gorgonians, and La Barre et al. (1986a) demonstrated that soft corals move apart to avoid tissue degradation resulting from tissue contact.

It is now known that community structure can be controlled by chemical interactions from direct contact, from the release of chemicals into surrounding waters, by overgrowth (nearly a kilometer of reef at Gaum was covered by the sponge *Terpios* sp., Bryan, 1973; Plucer-Rosario, 1983), by agonistic behavior, and by "sessile" species moving apart from one another (La Barre et al., 1986a, b). We do not know what the total pattern of these interactions is for any single community nor how these patterns vary with latitude.

COMMUNITY DOMINANCE AND BIOACTIVE SUBSTANCES

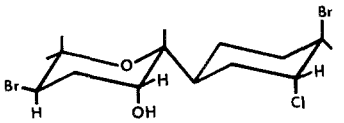
It has been accepted dogma that dominance is a distinguishing trait of species-poor ecosystems. However, Birch (1981) showed that dominance increases as marine benthic communities become more species-rich. Highly aggressive Caribbean corals reportedly are relatively minor components in all reef habitats

(why should this be?), whereas many of the most aggressive corals in the Indian Ocean are extremely dominant in certain zones (Stoddart and Yonge, 1971; Lang, 1973; Sheppard, 1979). Many ecologists have proposed that allelochemics may play an important role in contributing to the maintenance of high species diversity (e.g., Sammarco et al., 1982), but some of these chemicals may also be responsible for creating dominance in toxic tropical species (Birch, 1981). Endean and Cameron (1983) claimed that many coral reef animals that are well protected by toxins are normally rare but live long. However, Bakus maintains that many tropical species with defenses are dominant by biomass and/or number (e.g., the corals *Acropora* spp. and *Porites* spp., the surgeonfishes *Acanthurus* spp., the two-species scleractinian coral reefs of Cocos Island, off Pacific Central America, Bakus, 1967, 1975; Sheppard, 1979; Potts et al., 1985). Other species that are dominant and toxic include the algae *Halimeda* spp., *Caulerpa* spp., and *Laurencia* spp.; the sponges *Ircinia* spp. and *Terpios* spp.; the soft corals *Sarcophyton* spp. and *Dendronephthya* spp.; the stinging corals *Millepora* spp.; the sea cucumbers *Holothuria* spp.; and the diadematid sea urchins; to name but a few (Bakus, 1968; 1973; Bryan, 1973). Although these species may not reflect overall dominance, they dominate in patches. Patchy dominance, a phenomenon of scale, may be an ecologically significant factor in the tropics.

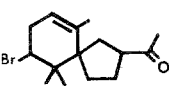
CHEMISTRY

Marine organisms often possess characteristic and/or unique chemical features. These components have served as the starting point for many chemical-ecological studies, although it has been shown that marine chemical–biological interactions are by no means restricted to uniquely marine compounds. The general classes of interest to marine chemical ecologists are outlined below.

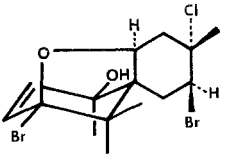
Terpenes. Terpenoid compounds have been isolated from algae, sponges, coelenterates, mollusks, and echinoderms. From algae alone more than 60 sesquiterpenes have been identified. These can be divided into 18 skeletal types, at least two thirds of which are new to science (Martin and Darias, 1978). More than 90 diterpenes have also been isolated from marine organisms. Of these, about 25% represent new skeletal classes (Fenical, 1978). Carbon–halogen bonds are characteristic of many marine terpenoids, particularly those isolated from algae. Bromine is the halogen most frequently incorporated into these marine secondary metabolites. Most typically, halogen-containing terpenes are found in algae in the genus *Laurencia* where they are thought to function in part as herbivore feeding deterrents (Figure 1) (e.g., Fenical, 1975; Erikson, 1983). The sea hare *Aplysia* spp. is one of the few herbivores adapted to grazing on *Laurencia* spp. Halogenated metabolites from the plant are concentrated in the sea hare and are thought to provide it with a means of defense against its own predators (Fenical, 1975). Other marine animals are capable of elaborating



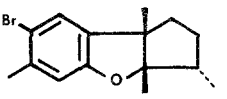
Isocaespitol



Spirolaurenone



Pacifenol



Aplysin

FIG. 1. Some terpenoid skeletal types typical of marine organisms include: the bisabolane, isocaespitol, from the red alga *Laurencia caespitosa* (Gonzalez et al., 1973; 1975); the chamigrane, spirolaurenone, from the red alga *Laurencia glandulifera* (Suzuki et al., 1970); pacifenol, a trihalogenated chamigrane from the red alga *Laurencia pacifica* (Sims et al., 1971); and the bromocuparane, aplysin, known from the opistobranch mollusk *Aplysia* and its algal diet, *Laurencia* (Yamamura and Hirata, 1963; Irie et al., 1969).

terpenoid metabolites de novo for use in chemical defense (Cimino et al., 1983). In sponges, terpenes represent the most abundant nonsteroidal metabolites; over 100 have been identified (Figure 2) (Minale, 1978). Sponge terpenes typically contain a multiplicity of prenyl units and furan rings (e.g., Cimino et al., 1971, 1975a,c). The naturally rare isonitrile function is also known from several sponge terpenoid compounds (e.g., Fattorusso et al., 1974, 1975). Sesterterpenes are also relatively abundant in sponges (Cimino et al., 1972; Fattorusso et al., 1972). In coelenterates, terpenes are known only from the Order Alcyonaria. These include sesquiterpenes and diterpenes. Most characteristic is the cembranolide skeleton (Figure 3) (Tursch et al., 1978). In general, terpenoid compounds are thought to function in antipredation, competition for space, and possible antifouling.

Steroids. The biosynthesis of steroids is intimately related to that of the higher terpenes, particularly the triterpenes. Marine organisms contain a far more diverse array of sterols than do terrestrial organisms. Marine organisms produce sterols with a remarkable variety of side chains, unconventional nuclear structures, and assorted hydroxylation patterns (Figure 4) (Schmitz, 1978). Sponges yield the most varied and biogenetically unprecedented array of sterols found among the invertebrate phyla (Goad, 1978). Dinoflagellate sterols are characterized by more heavily alkylated side chains and the presence of a 4-

Ircinin-1

FIG. 2. Terpenoids typical of marine sponges include sesquiterpenes with furan rings (pallescensin-1, Cimino et al., 1975a–c) which are often joined with linear prenyl groups (anhydrofurospongin-1, Cimino et al., 1971), sesquiterpenes with the rare isonitrile functional group (axisonitrile-1, Cafieri et al., 1973), and linear and cyclic sesterterpenes (ircinin-1, Cimino et al. 1972; scalarin, Fattorusso et al., 1972).

alpha methyl group (Withers, 1983). The gorganians are characterized by their content of gorgosterol and related sterols (Goad, 1978; Withers, 1983), which contain a cyclopropane group in the side chain. Sterols are of interest principally because of their role in the production of steroidal hormones such as ecdysones with which regulate molting in Crustacea (Goad, 1976). They also are known to play a role in the defense of certain species (Burnell and ApSimon, 1983).

Carotenoids. Carotenoids are encountered in bacteria, algae, fungi, inver-

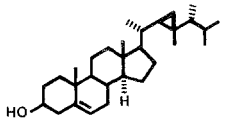
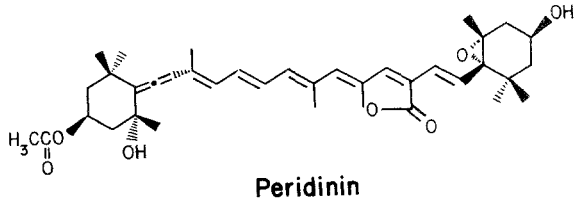
Dinosterol



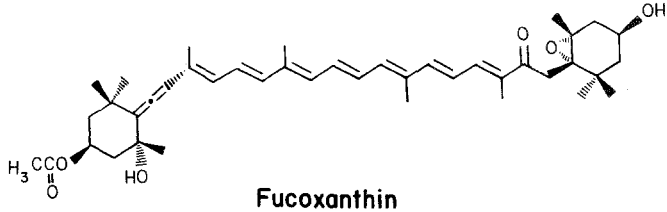
Gorgosterol

FIG. 4. Steroid types typical of marine organisms include: the A-norstanol and 19-norstanol skeletal modifications (Minale and Sodano, 1974a,b); dinosterol with the 4α-methyl group and additional side chain aklylation that is characteristic of many dinoflagellate sterols (Shimizu et al., 1976); and gorgosterol which shows the side chain with the cyclopropyl bridge typical of gorgonians and their dinoflagellate symbionts (Ciereszko et al., 1968).

tebrates, and vertebrates. More than 100 carotenoids have been isolated from marine sources and of these, about 40% are exlusively marine (Liaaen-Jensen, 1978). The most abundant are two carotenoids found in phlytoplankton, peridinin and fucoxanthin (Figure 5) (Strain et al., 1976). In general, marine carotenoids have more complex structures and more structural variation than do



Peridinin



Fucoxanthin

FIG. 5. Two exclusively marine carotenoids. Peridinin has a unique C_{37} skeletal structure bearing lactone, allenic, epoxy, acetoxy, and alcohol functions (Rapoport, 1971; Strain, 1976; Kjoesan et al., 1976).

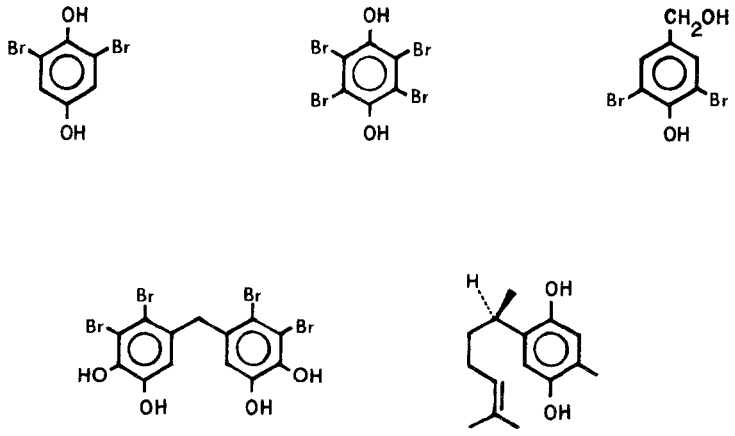


FIG. 6. Phenols arising from a variety of biosynthetic pathways are characteristic of many marine plants and invertebrates (Craigie and Gruenig, 1967; Kurata and Amiya, 1977; McEnroe and Fenical, 1978; Higa et al., 1980).

their terrestrial counterparts (Liaaen-Jensen, 1978). Marine carotenoids have a photoprotective role in photosynthetic bacteria and algae and play an important role in cryptic coloration and form (Burnett, 1976). The presence of oxygenated carotenoids is correlated with the tolerance of certain marine mollusks to environmental pollution, suggesting that they provide an intracellular reserve of oxygen (Karnaukhov et al., 1977). Carotenoids and carotenoproteins may also have a functional role in the reproduction of brown algae, crustaceans, and sea urchins (Lee, 1977; Hallenstvet et al., 1978). They are also useful in chemotaxonomy (Lee and Gilchrist, 1985).

Phenolics. Phenolic compounds occur in bacteria, algae, seagrasses, sponges, coelenterates, annelids, echinoderms, hemichordates, and protochordates. They are best known in brown and red algae, sponges, and echinoderms (Higa, 1981). More than 220 phenolics have been described from marine organisms (Figure 6). They arise via a variety of biosynthetic pathways. Their most obvious characteristic is the presence and abundance of halogenated substituents. Bromine is the halogen most frequently incorporated. Halogenated and nonhalogenated phenolics have been shown to have a multiplicity of potential ecological roles. For example, they are known to function as feeding deterrents in certain marine macrophytes (Valiela et al., 1979; Geiselman, 1980; Phillips and Towers, 1982a,b; Steinberg, 1984, 1985) thought to be responsible for defense or recognition in several species of enteropneusts (Higa, 1981).

Nitrogeneous Compounds. A wide variety of nitrogeneous compounds have been isolated from marine organisms, ranging from simple compounds such as tetramine to complex ones such as tetrodotoxin and saxitoxin (Figure 7). The latter are powerful neutrotoxins which inhibit sodium passage through axonal

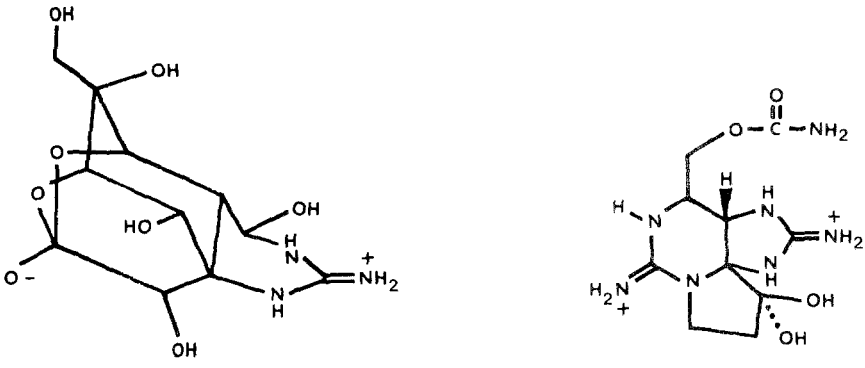

FIG. 7. Tetrodotoxin and saxitoxin are the two most widely known marine guanidino compounds (Woodward, 1964; Shimizu, 1978). Both have the high ratio of heteroatoms to carbon that is typical of many marine toxins.

membranes (Chevolot, 1981). Other simpler nitrogenous compounds play important roles in marine biological interactions. For example, gamma-aminobutyric acid (GABA), produced by encrusting algae (*Lithothamnium* and *Lithophyllum*), induces settlement and metamorphosis in abalone larvae (Morse et al., 1979; Morse and Morse, 1984). Alkaloids unique to the marine environment are being isolated and identified in growing numbers. They are often characterized by a bromine substituent. Haloindoles isolated from marine acorn worms (*Ptychodera flava* and *Glossobalanus* spp.) are responsible for the characteristic odor of these species and are thought to function as a chemical defense against micro- and macroorganisms (Figure 8) (Higa et al., 1980; Christopherson, 1983).

Compounds of Mixed Biogenesis and Miscellaneous Compounds. Many compounds are derived from the condensation of products arising from different biogenetic pathways (Figure 9). For example, asterosaponin A is an oligosaccharide with a steroidal aglycone. It is responsible for the pronounced avoidance behavior of numerous marine species when they are placed in the vicinity of a

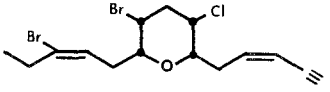
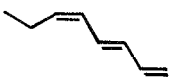
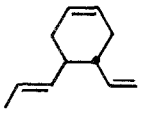
Cyclic polysulfides



Dactylyne



Fucoserratene



Aucantene

FIG. 10. Examples of miscellaneous compounds from marine organisms: Haloforms from the red alga *Asparagopsis* (Burreson et al., 1975, 1976); cyclic polysulfides from the red alga *Chondria californica* (Wratten and Faulkner, 1976); dactylyne, an enyne containing compound from the digestive gland of the sea hare *Aplysia dactylomela* (McDonald et al., 1975); and fucoserratene and aucantene, hydrocarbon pheromones from the brown algae *Fucus serratus* and *Cutlaria multifida*, respectively (Jaenicke et al., 1974).

starfish (Burnell and ApSimon, 1983). Miscellaneous compounds include compounds such as haloforms, acetylenes, sulfur compounds prostaglandins, and unusual lipids (Figure 10). To these compounds have been attributed a variety of roles, including chemical defense and species recognition (Jaenicke et al., 1974; Mueller, 1979; Gerhart, 1984).

Despite the considerable work on natural products chemicals since the early 1960s, many questions concerning the chemical nature of biological interactions remain unanswered. We need information on the origin of the compounds (de novo synthesis, diet, or symbiosis, e.g., Barrow, 1983; Catalan et al., 1985), whether the compounds are continuously produced or induced in response to an external stimulus, whether they are sequestered or free within their hosts, whether they are directly released into the sea, the nature of the released form compared with the stored form, and what the modes of action are. In an applied sense, we need to know more about the potential for these compounds as prototypes for antifoulants, pharmaceuticals, and agrichemicals (Colwell, 1983; Colwell et al., 1984).

CONCLUSIONS

For chemical ecologists, natural products chemistry has little meaning without a framework based on ecological and evolutionary theory. Similarly, understanding the fundamental mechanisms of many ecological interactions can be achieved only with an investigation of the chemistry involved. We are beginning to realize that current ecological theory may be too general or insensitive (e.g., in marine succession), that generalizations about populations will be made at a lower level of generality with much more detail and more restrictive conditions than previously anticipated (Krebs, 1985). It is also apparent that interdisciplinary studies between ecologists and chemists are rewarding because they seek the fundamental mechanisms behind ecological phenomena. Marine chemical ecology, an emerging discipline, seeks to create an interdisciplinary understanding of chemical–biological interactions occurring in the sea.

CHEMICALLY STIMULATED FEEDING BEHAVIOR IN MARINE ANIMALS
Importance of Chemical Mixtures and Involvement of Mixture Interactions

(Received June 27, 1985; accepted August 20, 1985)

Abstract—A review is provided of the chemical components in tissue extracts that elicit feeding behavior in marine fish and crustaceans. For most species, the major stimulants of feeding behavior in excitatory extracts are an assemblage of common metabolites of low molecular weight including amino acids, quaternary ammonium compounds, nucleosides and nucleotides, and organic acids. It is often mixtures of substances rather than individual components that account for the stimulatory capacity of a natural extract. Recent studies using a shrimp, *Palaemonetes pugio*, are described in which behavioral bioassays were conducted with complex synthetic mixtures formulated on the basis of the composition of four tissue extracts. These results indicate that synergistic interactions occur among the mixture components. The neural mechanisms whereby marine crustaceans receive and code information about chemical mixtures are also reviewed. Narrowly tuned receptor cells, excited only by particular components of food extracts such as specific amino acids, nucleotides, quaternary ammonium compounds, and ammonium ions, are common in lobsters and could transmit information about mixtures as a labeled-line code. However, since physiological recordings indicate that most higher-level neurons in the brain each transmit information about many components of mixtures, rather than about a single component, it is suggested that information about a complex food odor is transmitted as an across-fiber pattern, instead of a labeled-line code. Electrophysiological recordings of responses of peripheral and central neurons of lobsters to odor mixtures and their components reveal that suppressive interactions occur, rather than the synergistic interactions noted earlier in the behavioral studies.

0098-0331/86/0500-0989$05.00/0

Possible reasons for these differences are discussed. Evidence from the behavioral study indicates that the "direction" of a mixture interaction can be concentration-dependent and the synergism may occur at low mixture concentrations, while suppression may occur at high concentrations.

Key Words—Feeding behavior, chemoreception, mixture interaction, synergism, suppression, neural coding, chemical senses, crustaceans, fish, marine animals.

INTRODUCTION

Many marine animals have extremely well-developed chemical senses. The detection of external chemicals by the chemical senses affects many facets of the behavior of marine animals including the following: (1) elicitation of feeding behavior, including food recognition and ingestion, by scavengers (Carr, 1982), selective predators (Rittschof et al., 1984), and herbivores (Harada et al., 1984); (2) deterrence of feeding behavior (Sun and Fenical, 1979; Stoecker, 1980); (3) mate recognition and copulatory behavior (Dunham, 1978; Gleeson, 1980); (4) predator avoidance and alarm responses (Mackie and Grant, 1974; Sleeper et al., 1980); (5) selection of surfaces for settlement by larvae (Morse et al., 1979); (6) homing by migratory species (Stabell, 1984); (7) species recognition and social behavior (Liley, 1982); and (8) maintenance of symbiotic associations (Ache, 1974; Davenport, 1966).

In this presentation, we will focus upon studies of stimulants of aspects of feeding behavior in fishes and crustaceans. We will not attempt to review all of the earlier studies on feeding behavior in marine animals. For these, the reader should refer to the following: coelenterates (Lenhoff and Lindstedt, 1974); gastropods (Croll, 1983); crustaceans (Ache, 1982); fish (Hara, 1975; Atema, 1980, Carr 1982); general review (Mackie and Grant, 1974). More particularly, the focus will be upon studies of fishes and crustaceans in which quantitative bioassay procedures were employed to identify and to measure stimulatory chemicals that occur in the tissues of various prey organisms. We will show that, in most cases, the perceived "odors or tastes" of prey organisms are due to complex mixtures of chemicals. Recent behavioral data will then be presented to show that synergistic interactions occur among the components of several complex mixtures. Finally, we will discuss neural mechanisms identified in crustaceans for the reception and integration of information about complex odorants.

METHODS USED TO STUDY FEEDING BEHAVIOR

Several types of behavioral responses have been used with fishes to measure the stimulatory capacity of the active components of food odors or tastes.

These responses include the biting of an inert object emitting a chemical stimulus (Carr et al., 1976), ingestion of food pellets containing chemical stimulants (Mackie, 1982; Ohsugi et al., 1978; Ina and Higashi, 1978), attacking of food balls (Goh and Tamura, 1980; Hidaka, 1982), attraction and entrance into compartments containing stimulants (Hashimoto et al., 1968; Tsushima and Ina, 1978), and other aspects of behavior associated with food searches (Atema et al., 1980; Holland, 1978; Pawson, 1977). In crustaceans, the types of behavioral responses used to study food-related chemicals include the attraction to and grasping of a delivery device releasing a stimulant (Carr et al., 1984), movement toward the site of release of a stimulant (Ache et al., 1978); Mackie and Shelton, 1972; McLeese, 1970), and the onset of a series of components of behavior associated with the detection of food including antennular flicking, leg probing, movements of mouthparts, and locomotion (Derby and Atema, 1981; Pearson and Olla, 1977; Pearson et al., 1979; Zimmer-Faust and Case, 1983).

SUBSTANCES IN NATURAL EXTRACTS EVOKING ASPECTS OF FEEDING BEHAVIOR

Aqueous extracts prepared from the tissues of diverse organisms often prove to be highly excitatory stimulants of feeding behavior in marine animals. Several investigators have addressed the problem of fractionating and analyzing an excitatory extract in an effort to reproduce its activity with synthetic solutions. Table 1 summarizes the results of studies in fishes and crustaceans in which a substantial portion of the stimulatory capacity of an extract has been mimicked with synthetic solutions. The following three important generalities emerge from an inspection of the material presented in Table 1:

1. In the case of each extract described here, the principal stimulants of feeding behavior are common metabolites of low molecular weight that include amino acids, quaternary ammonium compounds, nucleosides and nucleotides, and organic acids. In some species of crustaceans, there are examples in which particular extracts or biological fluids contain attractants or feeding stimulants that are high-molecular-weight substances, such as proteins (Carr and Gurin, 1975; Zimmer-Faust et al., 1984). However, in most cases it is clear that the principal stimulants are low-molecular-weight substances of the sort cited in Table 1.

2. When a single excitatory extract is analyzed and tested behaviorally in more than one species, the different test species may respond to different substances in the same extract. Note in Table 1 that a similar squid extract was used in studies with the turbot (No. 3), rainbow trout (No. 4), and plaice (No. 11). With each fish species, the major stimulants in the squid extract were different. For the turbot, inosine was the major stimulant, whereas the rainbow

TABLE 1. STUDIES OF CHEMICALLY STIMULATED FEEDING BEHAVIOR IN FISH AND CRUSTACEANS IN WHICH A SUBSTANTIAL PART OF THE ACTIVITY OF AN EXTRACT WAS ACCOUNTED FOR WITH A SINGLE SUBSTANCE OR A MIXTURE OF SUBSTANCES

Animal studied[a]	Substances required to mimic activity of extract	Source of extract	Behavioral response
A. Fish	Single substances		
1. Dover sole	Betaine or betaine + glycine	Mussel	Ingest pellet
2. Pigfish	Betaine	Oyster	Biting response
3. Turbot	Inosine	Squid	Ingest pellet
	Mixture of substances		
4. Rainbow trout	Amino acids	Squid	Ingest pellet
5. Japanese eel	Amino acids	Clam	Attraction
6. European eel	Amino acids	Squid	Ingest ration
7. Red sea bream	Amino acids	Worm	Ingest pellet
8. Pigfish	Amino acids and betaine	Crab, shrimp	Biting response
9. Pinfish	Amino acids and betaine	Shrimp[b]	Biting response
10. Puffer	Amino acids and betaine	Clam	Ingest pellet
11. Plaice	Amino acids, quaternary ammonium compounds, nucleotides, nucleosides and lactate	Squid	Ingest pellet
B. Crustaceans			
12. Lobster	Amino acids, quaternary ammonium compounds, nucleotides, nucleosides and lactate	Squid	Attraction
13. Shrimp	Amino acids, quaternary ammonium compounds, nucleotides, nucleosides and lactate	Crab, shrimp	Grasp delivery device

[b] For the pinfish, a synthetic mixture or amino acids and betaine accounted for about 20% of extract's activity.

trout required a mixture of amino acids, and the plaice required an even more complex mixture of substances in the same extract.

3. The stimulatory capacity of most extracts is due to a mixture of substances acting in concert rather than to a single dominant substance. In 10 of the 13 examples cited in Table 1, mixtures were necessary to yield synthetic stimulants with stimulatory capacities similar to those of the natural extracts.

EVIDENCE OF MIXTURE INTERACTIONS IN RESPONSES OF SHRIMP TO MIXTURES OF FOOD COMPONENTS

Mixtures—Additive vs. Interactive Effects

Rifkin and Bartoshuk (1980) described the following two methods whereby a mixture of components could be treated in an additive manner by a chemosensory system: (1) addition of perceived intensities (referred to below as response summation), and (2) stimulus summation (= stimulus substitution). Response summation would be more likely when two or more stimulants activate different receptor sites. Stimulus summation would be expected to occur when two or more stimuli activate the same receptor sites.

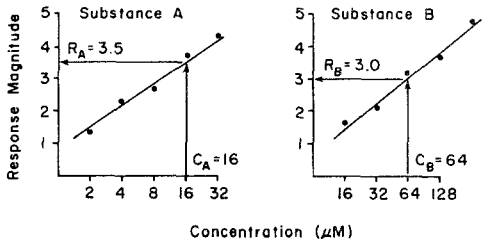
Figure 1 depicts the application of these additive methods toward predicting the effects of a mixture of two substances whose individual dose–response (D-R) functions have been measured. The response summation method (IIA in Figure 1) predicts that when the two substances are mixed at known concentrations, the response elicited will be equal to the simple sum of the responses elicited by the unmixed components. The stimulus summation method (IIB in Figure 1) treats the mixture as a higher concentration of one component and uses the D-R function of that component to predict the response to the "higher concentration" of that component.

A mixture interaction, which may express itself as either synergism or suppression, is considered to have occurred when a mixture of substances is observed to evoke a response that is different in magnitude than the response predicted by applying the additive methods described above (Rifkin and Bartoshuk, 1980; Derby and Ache, 1984b). Whereas the results of some of the behavioral studies cited in Table 1 suggest that mixture interactions may indeed be occurring, only the results of the following study with a marine shrimp have been subjected to the quantitative analyses required to document such an interaction.

Analysis of Effectiveness of Chemical Mixtures and Components

The synthetic chemical mixtures shown in Table 2 were used to study behavioral chemoattractants of the shrimp, *Palaemonetes pugio*. This shrimp is an opportunistic scavenger that feeds upon detritus (Welsh, 1975) and small

I. DOSE RESPONSE CURVES FOR SUBSTANCES A AND B.



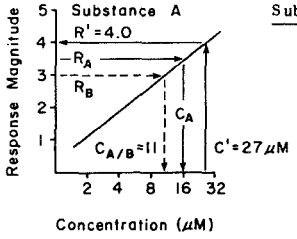
II. PREDICTING THE RESPONSE TO A STIMULATORY MIXTURE CONTAINING: 16μM A PLUS 64 μM B

A. Response Summation: Sum responses elicited by individual substances.

1. Concentration of A(=C_A) = 16 μM; Response to C_A = 3.5 (=R_A)
2. Concentration of B(=C_B) = 64 μM; Response to C_B = 3.0 (=R_B)

Sum of R_A + R_B = 6.5 =PREDICTED RESPONSE

B. Stimulus Summation: Use the response elicited by B (=R_B) to express the mixture as a higher concentration of A.



Substance	Response to Substance	Concentration of A Eliciting Same Response
A	3.5(=R_A)	16 μM (=C_A)
B	3.0(=R_B)	11 μM (=$C_{A/B}$)

Sum of C_A + $C_{A/B}$ = 27 μM (=C')

Response to C' = 4.0 (=R') = PREDICTED RESPONSE

FIG. 1. Using the methods of response summation and stimulus summation to predict the response to a mixture of substances whose effects are additive. See text for further explanation.

invertebrates (Bell and Coull, 1978) in the field and is attracted to and feeds upon the soft tissues of a broad array of organisms in the laboratory. For behavioral bioassays, groups of shrimp were tested in compartmented boxes into which solutions of defined concentrations were delivered at a controlled rate. Each solution was tested over a range of concentrations, and the number of animals giving a positive response was recorded. A positive response consisted of a shrimp moving to, and grasping, the delivery device within a 2-min period. The percentage of animals giving a positive response was then transformed to the percentage of the maximum response obtained during the study. Further procedural details are given in Carr and Derby (1986).

Table 2 shows the results of analyses of the amino acids, nucleotides and related substances, quaternary ammonium compounds, and organic acids in

aqueous extracts of crab, shrimp, oyster and mullet. These analyses were used to prepare synthetic mixtures containing substances at the same relative concentrations as present in the natural extracts. The "extracts" that were analyzed in the current study were prepared by the gentle shaking in cold water of diced tissue obtained from live organisms. Unlike extracts prepared by blending or homogenizing tissues, the extracts obtained by the current procedure include only those molecules that readily diffuse from recently injured tissues, thereby providing a stimulus that is potentially excitatory to an array of opportunistic scavengers such as *P. pugio*.

Figure 2 shows the dose–response (D-R) regressions obtained for the artificial mixtures based on the composition of oyster (AOM), shrimp (ASM), crab (ACM), and mullet (AMM), and for eight compounds that both occur in the mixtures and elicit behavioral responses when tested individually at concentrations of 1 mM or less. These stimulatory compounds were the nucleotides AMP, XMP, GMP, ADP, and IMP, the amino acids glycine and taurine, and a quaternary ammonium compound, betaine. Other than these eight compounds, only three compounds in Table 1 (the amino acids alanine, hydroxyproline, and phenylalanine) had measurable activities when tested individually. These latter substances were omitted from Figure 1 and from the analyses of interactions given below because they occur in the mixtures at subthreshold concentrations.

Evidence for Synergistic Interactions among Components of Synthetic Mixtures

Figure 3 depicts how the methods of response summation and stimulus summation described earlier are applied to provide predicted responses to a single dose of one of the complex mixtures cited in Figure 2. In the example (Figure 3), the stimulatory mixture is a 96 μM dose of ASM, a dose that evokes 90% of the maximum response. The figure shows the D-R functions for the only four components of ASM (AMP, Gly, Tau, and Bet) that are present at suprathreshold concentrations within the range of concentrations at which ASM was tested. The concentrations of AMP, Gly, Tau, and Bet in 96 μM ASM are 1.39, 26.72, 9.41, and 14.37 μM, respectively, and are represented in this figure as C_{AMP}, C_{Gly}, C_{Tau}, and C_{Bet}. The responses elicited by C_{AMP}, C_{Gly}, C_{Tau}, and C_{Bet}, as determined by their individual regression lines, are 43.0, 19.7, 3.8, and 0%, respectively, and are represented on the y axis as R_{AMP}, R_{Gly}, and R_{Tau}. (C_{Bet} is a subthreshold concentration and thus is not stimulatory by itself at the concentration found in 96 μM ASM.)

Response Predicted by Response Summation. The sum of the individual responses is 66.5% (ΣR in Figure 3), which is less than the measured response value of 90%.

Response Predicted by Stimulus Summation. The active components are expressed in terms of a higher concentration of AMP, the most contributory

[c] A blank space indicates the substance was not detected in the extract.
[d] L-Amino acids were used in artificial mixtures.

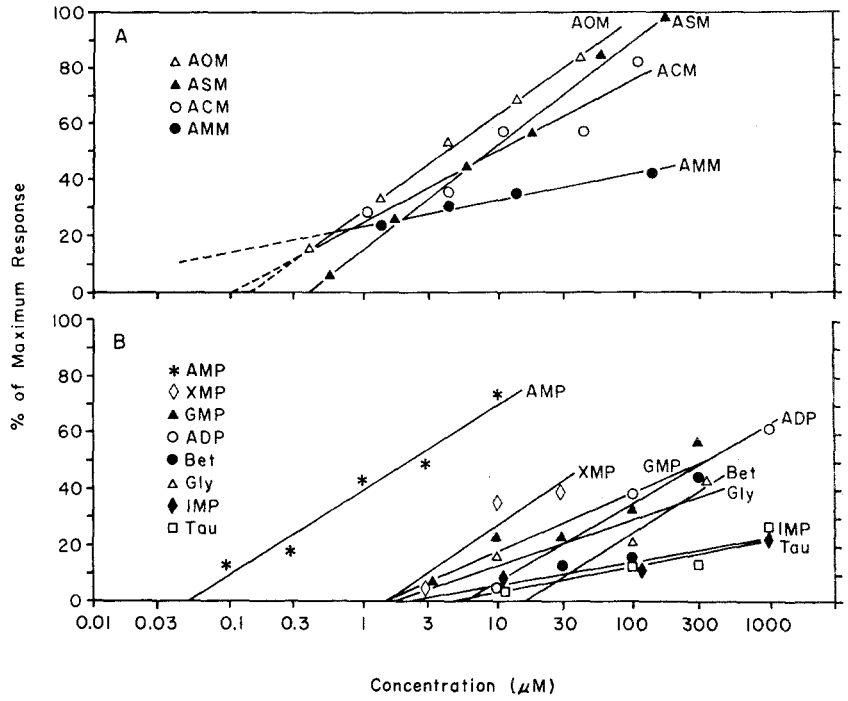

FIG. 2. Dose–response functions for mixtures and individual components tested with *P. pugio*. Responses are expressed as a percentage of the maximum response evoked by any stimulus. (A) Mixtures: artificial oyster mixture (AOM), artificial shrimp mixture (ASM), artificial crab mixture (ACM), artificial mullet mixture (AMM). (B) Components: AMP, XMP, GMP, ADP, IMP, betaine, glycine, taurine. In both A and B, regression lines of best fit for the data are shown for each mixture and component. Abbreviations for components are as shown in Table 2. Modified from Carr and Derby (1986).

component in the mixture. The AMP-equivalent concentrations for R_{AMP}, R_{Gly}, and R_{Tau} are 1.39, 0.24, and 0.07 μM, respectively (represented in Figure 3 by C_{AMP}, $C_{AMP/Gly}$, and $C_{AMP/Tau}$). The sum of these concentrations is depicted as C′ (= 1.70 μM). This represents a "mixture" of AMP at a total concentration equivalent in effect to the amounts of AMP, Gly, and Tau in a 96 μM dose of ASM. The response elicited by concentration C′ is determined from the AMP regression line to be 45.6% (ΣS) which is much less than the measured response of 90% that is actually evoked by a 96 μM dose of ASM.

Occurrence of Synergistic Interactions over a Range of Concentrations. In Figure 4, the D-R functions observed during the bioassays of the four artificial mixtures are compared with the predicted functions obtained by applying the additive methods of response summation (ΣR) and stimulus summation (ΣS). Synergistic interactions occurred over the entire response range at which the

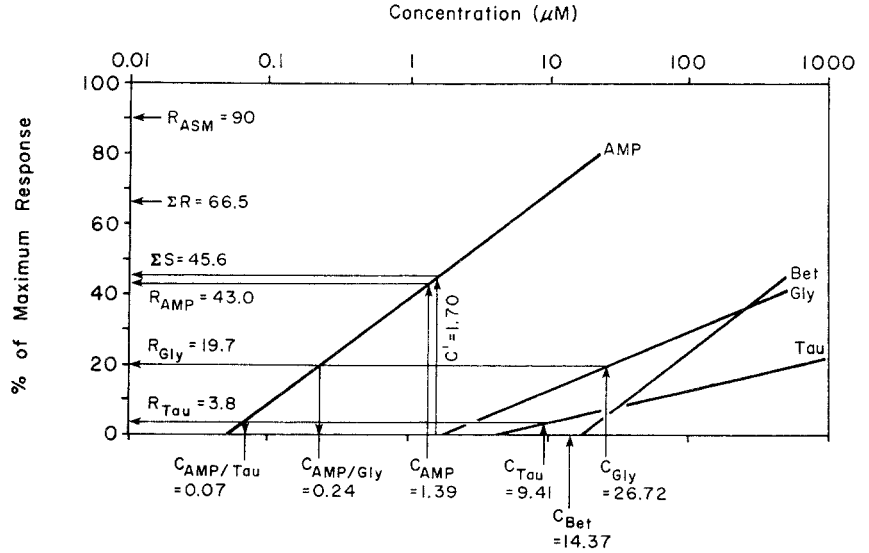

FIG. 3. Application of additive methods to calculate predicted responses to a mixture of components. The stimulatory mixture is 96 μM ASM (artificial shrimp mixture), a dose that evokes a 90% maximal response (see Figure 1). Magnitude of response to 96 μM ASM is shown as R_{ASM}. Calculations are based on D-R lines of best fit for each component as shown in Figure 2. See text for description of how methods are used to obtain a predicted response. Modified from Carr and Derby (1986).

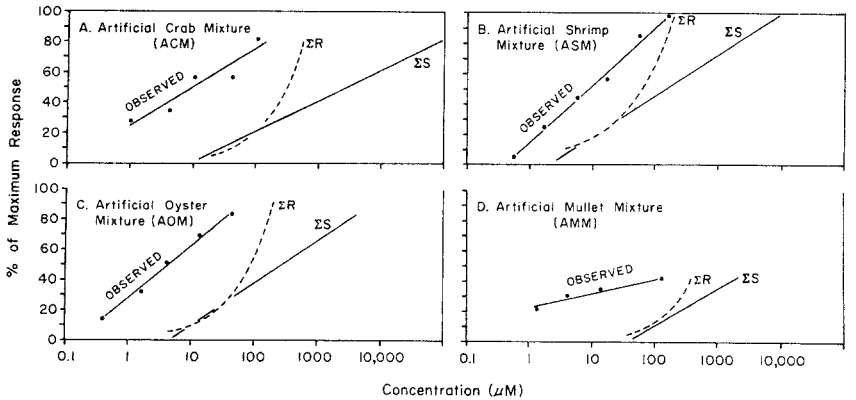

FIG. 4. Comparison of the observed and predicted D-R functions for four artificial mixtures tested with the shrimp, *P. pugio*. (A) Crab; (B) shrimp; (C) oyster; (D) mullet. For each mixture, the observed D-R curve is compared to the curves predicted by response summation (ΣR) and stimulus summation (ΣS). Modified from Carr and Derby (1986).

mixtures were tested since each mixture was far more effective than predicted by either of the additive models. In each of the four mixtures, the D-R function for the observed result is situated to the left of the functions for the predicted results. Hence, in each case the mixture concentration predicted to elicit a response of a particular magnitude is a greater concentration than that actually required to elicit such a response. A major consequence of synergistic actions such as those shown in Figure 4 is that they provide an organism with the capability for detecting and responding to mixtures at concentrations below the response thresholds for even the most stimulatory individual components in the mixture. Note that responses as high as 20–40% of the maximum response are elicited by mixture concentrations that are predicted by the additive D-R functions to be subthreshold.

NEURAL MECHANISMS IN CRUSTACEANS FOR EXTRACTING INFORMATION FROM CHEMICAL MIXTURES

Chemosensory Systems of Crustaceans

Chemosensory sensilla, sensory hairs containing chemoreceptor cells, are located on much of the body surface of aquatic crustaceans, including both pairs of antennae (antennules and antennae), the six pairs of mouthparts, and the claws and walking legs (Ache, 1982). The antennules, containing aesthetasc sensilla, are usually referred to as olfactory (smell) organs, whereas antennae, walking legs, and mouthparts are usually referred to as gustatory (taste) organs. The distinction between organs of olfaction and gustation in aquatic animals cannot be made on the basis of the carrier medium, as with terrestrial animals. Nonetheless, a distinction may be possible on the basis of other criteria, including differences in central projections of axons of receptor cells from different organs and differences in behavioral functions governed by different organs (Atema, 1977, 1980).

Neural Coding of Single Compounds

Because of their large size, lobsters have frequently been selected for electrophysiological studies of crustacean chemosensory systems. Electrophysiological responses given by chemosensory neurons have been recorded during the application of the individual components of excitatory mixtures onto sensilla on the antennules and walking legs. This provides a first approach to understanding how these systems encode and decode the information contained in chemical mixtures. Recordings from the antennules or the walking legs of the spiny lobster (*Panulirus argus*) and the American lobster (*Homarus americanus*) indicate that many of the chemoreceptor cells possess narrow excitatory response spectra (see Figure 5). Receptor cells with narrow excitatory response

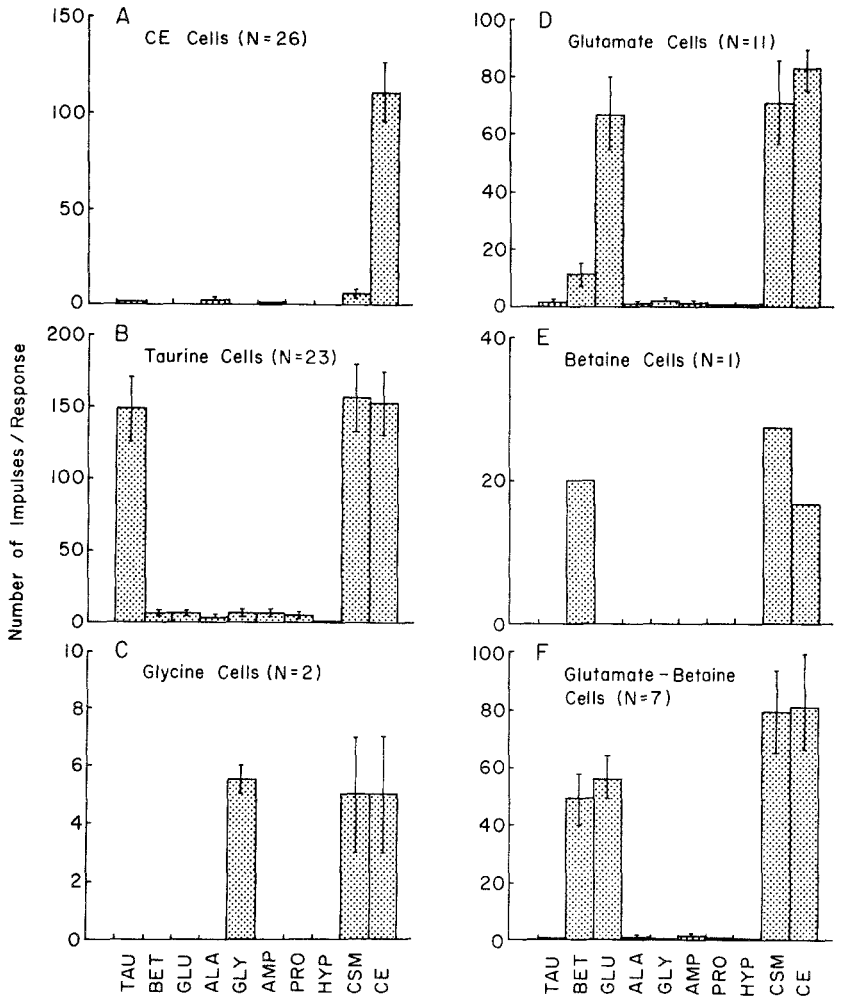

FIG. 5. Excitatory response spectra for six types of chemoreceptor cells in the antennules of the spiny lobster, *P. argus*. Responses are to taurine, betaine, glutamic acid, alanine, glycine, AMP, proline, hydroxyproline, artificial crab mixture (CMS, this mixture is similar but simpler than that in Table 1 and has a total concentration of 0.33 mM), and crab extract (CE). Each individual compound was tested at the concentration that it occurs in the mixture and extract. Each cell is excited primarily by only one (or, in the case of the glutamate–betaine cells, two) of the eight individual compounds, and the response to this compound is usually similar to the response to the complete mixture or extract. From Derby and Ache (1984a).

spectra are strongly excited by one or a very limited number of the many compounds tested. Several distinct classes of such narrowly tuned receptor cells are now known, including those excited only by a single amino acid (either taurine, glutamine, glycine, arginine, hydroxyproline, or glutamine), by nucleotides (adenosine 5′-monophosphate), by quaternary ammonium compounds (betaine), or by ammonium ions (Fuzessery et al., 1978; Derby and Atema, 1982; Derby and Ache, 1984a; Derby et al., 1984a; Johnson and Atema, 1983; Johnson et al., 1984). Other receptor cells having broader excitatory response spectra have also been identified, but they appear to be less numerous.

If one considers only the narrow excitatory response spectra of specific populations of chemoreceptor cells such as those described above for lobsters, then such populations of cells could theoretically function as labeled-line arrays in the detection of food chemicals. In a labeled-line system, the identity of a specific compound in the chemical environment is made on the basis of the activation of cells specifically sensitive to that compound. Those chemicals for which labeled lines exist presumably elicit specific behaviors.

A labeled-line code would be most advantageous if the labeled-line information is transmitted relatively unchanged to subsequent levels of the chemosensory neural pathway and eventually to motor neurons controlling the relevant behavior. An analysis of responses of olfactory interneurons in the brain of the spiny lobster reveals that this is not the case for most interneurons and for most chemicals that have been examined. Progressing inward from the olfactory receptor cells to successively higher neural levels, cells become increasingly more broadly tuned, with interneurons usually responding to many more than one chemical (Derby and Ache, 1984a; Derby et al., 1984b). This fact strongly suggests that stimulus quality for most chemicals is probably not encoded in the brain of the spiny lobster by labeled-line activity, but rather as the patterns of activity generated across a large population of neurons, a so-called across-neuron pattern code (Erickson, 1974). Indeed, statistical analyses indicate that the across-neuron patterns for different food-related chemicals can be quite distinct, indicating that these chemicals are probably discriminable (see Figure 6). Nonetheless, there exists a smaller number of brain interneurons in the spiny lobster that have response specificities nearly as narrow as those of the specialized receptor cells, suggesting that labeled-line information generated at the receptor level can be retained by some neurons in the brain, at least for some stimulants (Derby and Ache, 1984a; Derby et al., 1984b). The contribution of such narrowly tuned interneurons toward coding of odor quality in this system is presently unknown but is under investigation.

Neural Coding of Mixtures

The selection of compounds to be tested in experiments of quality coding, we believe, should be dictated by the natural history of the animal and not solely

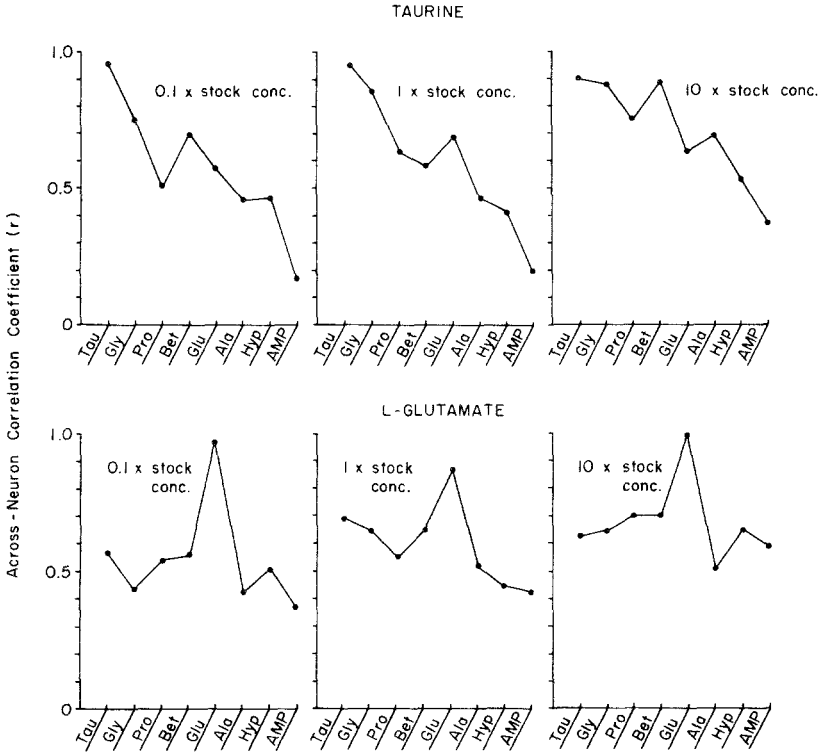

FIG. 6. Across-neuron pattern coding of chemical quality by olfactory neurons in the brain of *P. argus*. Shown are across-neuron correlation profiles for the responses of 45 neurons to taurine and glutamate, each at three concentrations. Each point represents the correlation coefficient (from Pearson's product moment correlation) between the responses of the 45 interneurons to the compound at the top (taurine or glutamate, at one of three concentrations) and the responses of the same neurons to one of the eight compounds tested. "Stock concentration" refers to the concentration that the particular compound is found in the artificial crab mixture used in this experiment (described in legend to Figure 5). The shapes of the six correlation profiles are representative of similarities and differences in across-neuron patterns for the six stimuli. Stimuli eliciting profiles of similar shape are less likely to be differentiated by these neurons; stimuli eliciting profile of different shape are more likely to be differentiated by these neurons. Thus, the three concentrations of taurine, which evoke similar across-neuron correlation profiles, are probably determined by this population of neurons to be of a similar sensory quality. On the other hand, taurine and glutamate, which have different across-neuron correlation profiles, are probably judged by these neurons to be of different sensory qualities. Hence, by using across-neuron patterns as a code for chemical quality, these neurons could differentiate chemical qualities (e.g., taurine vs. glutamate) in spite of changes in chemical quantity.

by the availability of chemicals or by other arbitrary means. Likewise, for studies of the neural coding of mixtures, it is most appropriate to utilize naturally occurring mixtures. The foregoing criteria are satisfied in the studies with lobsters cited below.

Neurophysiological studies reveal that the magnitude of the neural responses to particular mixtures cannot always be predicted from the responses to the individual components in that mixture. In a neurophysiological study of brain interneurons in the spiny lobster (Derby and Ache, 1984b), the observed responses to mixtures were compared to the predicted responses obtained by using additive models similar to those described earlier for behavioral studies with shrimp. Unlike the synergistic interactions described earlier for the shrimp behavioral studies, the lobster physiological study has shown suppressive mixture interactions to be most prevalent (Figure 7). Subsequent studies have shown

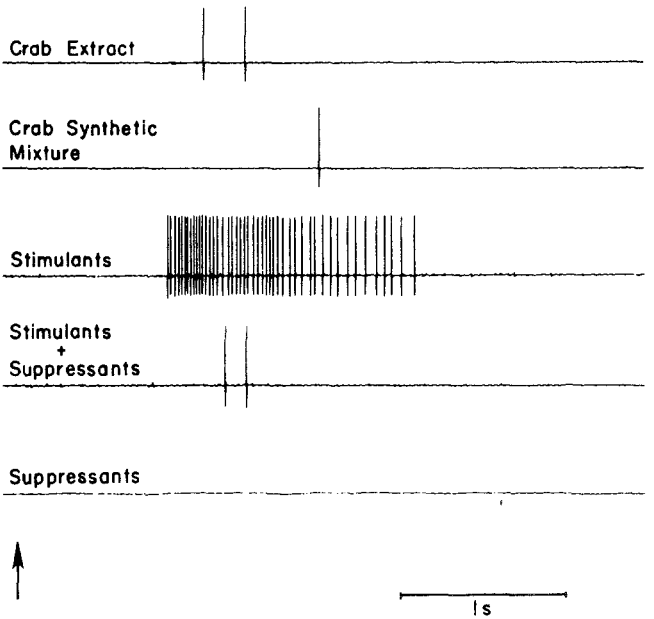

FIG. 7. Mixture suppression in an olfactory interneuron in the brain of *P. argus*. Responses are to the crab extract, the artificial crab mixture (Table 1, with a total concentration of 4.25 mM), a mixture of 12 stimulants in the artificial crab mixture (AMP, ADP, ATP, alanine, betaine, glutamic acid, glutamine, glycine, lactic acid, phenylalanine, taurine, trimethylamine oxide), a mixture of three suppressants in the artificial crab mixture (arginine, cysteine, proline), and a mixture of the 12 stimulants plus the three suppressants. These data show that addition of the suppressants to the stimulants results in a dramatic reduction in the ability of the stimulants to excite this interneuron, i.e., mixture suppression occurs. Arrow indicates stimulus introduction. Modified from Derby and Ache (1984b).

that suppressive mixture interactions also occur in several classes of receptor cells in lobsters (Derby et al., 1985; Gleeson and Ache, 1985; Johnson et al., 1985). Several of the suppressant substances present in natural mixtures have been identified for these receptor cells (Derby et al., 1985; Gleeson and Ache, 1985). However, not all receptor cells show mixture suppression at all mixture concentrations (Derby and Ache, 1984a; Derby et al., 1985; Gleeson and Ache, 1985). In fact, mixture synergism has been reported to occur at low mixture concentrations for some types of receptor cells (Johnson et al., 1985).

In an attempt to identify mechanisms responsible for mixture interactions in one class of olfactory receptor cell excited by taurine, Gleeson and Ache (1985) have performed a kinetic analysis of responses evoked by binary mixtures of stimulants and suppressants identified for the spiny lobster. This analysis requires the assumption that the frequency of action potential output from receptor cells is an accurate monitor of receptor–ligand binding. The results with this class of cells indicate that the mixture suppression is partly, possibly largely, a result of competitive inhibition among the components of the binary mixtures. Mixture interactions in other classes of receptor cells do not appear to conform strictly to either competitive or noncompetitive kinetics (Johnson et al., 1985).

Studies of olfactory interneurons in the brain of the spiny lobster have extended our understanding of the origin of mixture interactions. Not only is mixture suppression of peripheral origin manifested in brain interneurons, but some mixture suppression is even generated within the central nervous system, adding to that originating in the peripheral nervous system. This is supported by the observation that mixture suppression is expressed in some interneurons when stimulatory compounds and suppressive compounds are presented simultaneously to *separate* regions of the receptive field of a particular neuron (Derby et al., 1985).

In evaluating the significance of mixture interactions with respect to the coding of chemical quality, we must be aware of additional complexities inherent in this system. Firstly, although mixture interactions are known to occur, they probably are not expressed in all receptor neurons or in all neurons of higher order. Secondly, those neurons that do express a mixture interaction (e.g., suppression) may do so in a concentration-dependent fashion (Johnston et al., 1985). These complexities imply that coding by receptor cells, even those with narrow excitatory response spectra, may not be as simple as we originally thought. Thus, it is likely that even at the receptor level, chemical quality is coded as an across-neuron pattern. In fact, the added complexity of mixture suppression seen clearly in lobsters may make an important contribution to the coding of different chemical qualities. The superimposed effects of excitation and suppression could theoretically create even more distinct differences among across-neuron patterns for the numerous mixtures of chemicals likely to be encountered by animals in their natural chemical world (Derby, 1986).

ENIGMA OF CONTRASTING RESULTS OF BEHAVIORAL AND PHYSIOLOGICAL STUDIES

The results of the behavioral study described earlier in the section on synergistic interactions show clearly that synergistic interactions were expressed in the behavioral responses given by the shrimp, *P. pugio*, to four artificial chemical mixtures. One of the same artificial mixtures (artificial crab mixture) that expressed synergism in the behavioral study was found to express suppressive interactions when used in physiological studies with the spiny lobster, *P. argus*. In fact, the phyisological studies revealed mixture suppression at three levels of the olfactory system extending from receptor cells to brain-output interneurons (Derby and Ache, 1984a, b; Gleeson and Ache, 1985; Derby et al., 1985).

We do not yet understand why the behavioral studies revealed mixture interactions that were opposite in "direction" to those expressed by the physiological studies. One possible explanation is that the neurons expressing mixture suppression may not be part of the neural pathway mediating feeding behavior. The identity and behavioral function of the individual neurons showing suppression is unknown. However, since mixture suppression is expressed pervasively in several levels of the nervous system, it is very likely that at least some of these neurons influence walking, grasping, or other activities associated with the lobster's feeding behavior. A second possible explanation of the difference in the behavioral and physiological results is that the magnitude of a behavioral response may not be predicted by the magnitude of a physiological response that is generated solely by the olfactory system. The latter is supported by the following observations of lobster behavior.

In a behavioral trapping study done with spiny lobsters, an artificial crab mixture (similar to that used in the behavioral study with shrimp) was very effective at stimulating lobsters to enter a trap. However, two individual components of the mixture, taurine and AMP, each with marked physiological activity, did not stimulate trap entry. Furthermore, tests of submixtures containing either five or ten of the components, identified physiologically to be among the major olfactory stimulants in the complete artificial crab mixture, revealed that each submixture was either ineffective or less effective than the complete mixture in stimulating entry into traps (Carr, Ache and Milstead, unpublished results). The foregoing shows that physiological measurements of events occurring in the antennular chemosensory system are not necessarily reliable predictors of a behavioral response expressed by the whole animal. Behavioral responses of the sort observed in the shrimp or lobster may be evoked by a multimodal process that includes inputs from chemosensory cells in the antennae, legs, and/or mouthparts, in addition to those in the antennules. Synergistic interactions expressed by a multi-modal process may not be expressed when one examines only a single component of that process.

Another factor that may influence the apparent directionality of a mixture

interaction is the particular concentration(s) at which the mixture is tested. Behavioral data presented in Figure 8 show that the apparent direction of a mixture interaction can change dramatically when the mixture is tested over a broad range of concentrations. The figure shows that a biphasic D-R curve is obtained when shrimp are tested behaviorally with crab extract at concentrations higher than those depicted earlier (cf., Figure 4A). Note the convergence and intersection of the D-R curves for the observed behavioral responses and the responses predicted by the additive method of response summation. The extended curves imply that at mixture concentrations greater than ca. 800 μM, which is a saturating concentration, a zone of increasing mixture suppression is encountered in which the concentration predicted to elicit a response of a particular

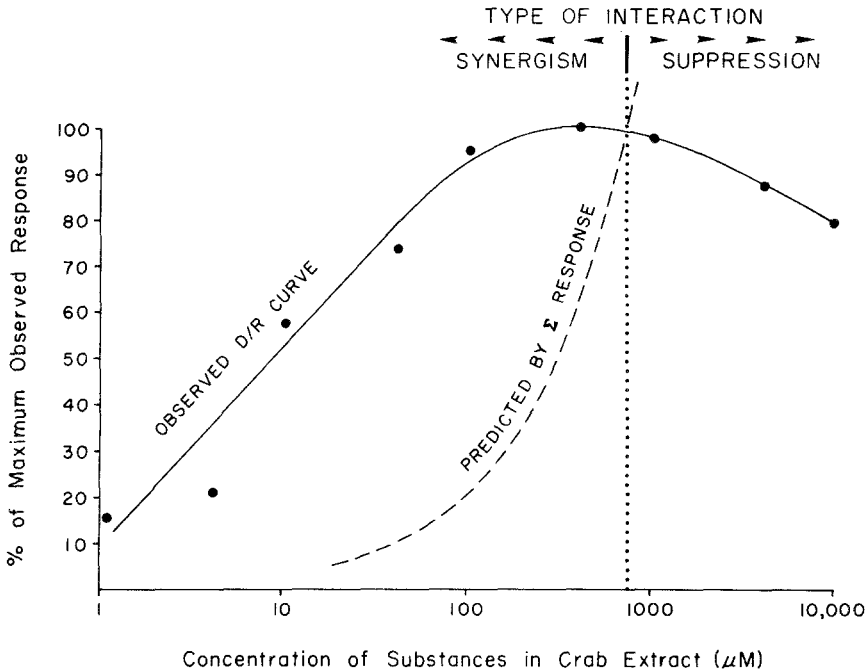

FIG. 8. Effect of concentration on the direction of mixture interactions as shown by behavioral responses of shrimp, *P. pugio,* to a crab extract tested over a wide range of concentrations (N = 756 shrimp). Concentrations given are based on the total concentration of all substances measured in crab extract as shown in Table 2. The predicted D-R curve obtained by the additive method of response summation is the same as that shown in Figure 4A for the artificial crab mixture (ACM). The convergence and intersection of the curves indicate that synergistic interactions occur at concentrations less than about 800 μM, whereas suppressive interactions occur at greater concentrations. The biphasic nature of the observed D-R curve is characteristic of all stimulants we have tested behaviorally over a wide concentration range (e.g., see Carr and Thompson, 1983).

magnitude is a lesser concentration than that actually observed to elicit such a response. In short, at high saturating concentrations the mixture is less effective than predicted by the method of response summation. This relationship at high mixture concentrations is in direct contrast to that of the synergism seen to occur at lower mixture concentrations where the mixture is more effective than predicted. Electrophysiological studies are currently in progress with the spiny lobster to determine if a change in the direction of a mixture interaction, similar to that observed behaviorally, does indeed occur when a mixture is tested over a broader range of concentrations (Ache and Herder, personal communication). It is noteworthy that evidence for synergism at low concentrations and suppression at high concentrations was reported recently by Johnson et al. (1985) in physiological studies of two classes of chemoreceptor cells in the American lobster.

FUNCTIONAL SIGNIFICANCE OF MIXTURE INTERACTIONS

Both synergistic and suppressive mixture interactions can play a significant role in increasing the effectiveness of the chemical senses whenever stimulants occur as mixtures. This is most evident in systems composed of cells with broad excitatory response spectra (see discussion in Derby, 1986). Synergism at low mixture concentrations provides an organism with a capacity to extend its range of sensitivity downward to odor concentrations that are subthreshold for individual components. On the other hand, suppression at high mixture concentrations may extend the range of responsiveness upward while avoiding either an overworking or a saturation of the system. Hence, the resultant effect of suppression could be similar to that noted earlier by Bartoshuk (1975), namely, to encode a broad range of potential concentrations into a much smaller range of potential response intensities.

Acknowledgments—The authors are grateful to Ms. Marsha Lynn Milstead for preparing the illustrations and Mrs. Louise E. MacDonald for typing the manuscript. We have also benefited greatly from the many discussions and collaborations with Drs. Barry Ache and Richard Gleeson, our colleagues in chemoreception at the Whitney Laboratory. Our work is supported in part by NSF grant BNS-84-11693.

MACROMOLECULAR CUES IN MARINE SYSTEMS

DAN RITTSCHOF and JOSEPH BONAVENTURA

Duke University Marine Laboratory and Marine Biomedical Center, Beaufort, North Carolina 28516

(Received June 26, 1985; accepted August 19, 1985)

Abstract—A review of the roles of biopolymers as marine chemical cues is presented. The goal of the review is to provide a context within which to view present research and to provide insight into future research potential for macromolecules in marine chemical ecology. The roles of peptides, proteins, glycoproteins, proteoglycans, lectins, and mucopolysaccharides are discussed. Biological events mediated include: larval settlement and metamorphosis, gamete attraction, predator-prey interactions, alarm responses, feeding responses, nonfood resource acquisition, trail following, and larval-release behavior. Molecular origins, transmission, modulation, and multifunctionality of cues are discussed and illustrated with specific examples. The advantages of biopolymers, especially peptides and proteins, as specific cues in marine systems derive from their solubility, specific information content (due to the asymmetric nature of the monomer and the wordlike information content of the primary structure of the polymer), distance transmission in water by bulk flow rather than diffusion, relatively high signal-to-noise ratio, and common occurrence as structural and metabolic components of all living organisms.

Key Words—Marine animals, macromolecules, peptides, glycoproteins, behavior, prey detection, site selection, metamorphosis, biopolymers.

INTRODUCTION

Chemical mediation of behavior is well known in virtually all groups of living organisms. Marine animals are no exception. Most reports describing the chemicals which mediate these behaviors in marine species have been concerned with feeding (reviews: Bardach, 1974; Scheuer, 1977; Dunham, 1978; Atema, 1982). Where known, these chemicals are primarily low-molecular-weight compounds such as amino acids. Only a few reports detail the mediation of marine organism behavior by macromoleculars such as peptides, proteins, gly-

0098-0331/86/0500-1013$05.00/0

coproteins, proteoglycans, lectins, and mucopolysaccharides. Although the total number of reports is small, the spectrum of documented macromolecule-induced responses is broad. The phyla of organisms displaying such responses include Polychaeta, Cnidaria, Mollusca, Ascidia, Echinodermata, and Crustacea. Macromolecules mediate aspects of: (1) larval settlement and metamorphosis [Crisp, 1984 (review); Morse, 1984 (review); Mitchell and Kirchman, 1984 (review); Burke, 1984]; (2) gamete attraction (Miller and Tseng, 1974); (3) predator–prey interactions (Rittschof et al., 1984); (4) alarm responses (Atema and Stenzler, 1977); (5) feeding responses (Gurin and Carr, 1971; Magnum and Cox, 1971; Carr et al. 1974; Carr and Gurin, 1975; Collins, 1975; Zimmer-Faust et al., 1984); (6) shell acquisition behavior in hermit crabs (Rittschof, 1980a); (7) trail following (Dimon, 1905; Hewatt, 1940; Crisp, 1969; Hall, 1972; Wells and Buckley, 1972; Cook and Cook, 1975; Trott and Dimmock, 1978) and (8) larval release behavior (Rittschoff et al., 1985).

Thus, macromolecules appear to play major roles in the transmission of information for the mediation of behavior and resource utilization in the marine environment. However, these roles are not the exclusive domain of macromolecules, and for the sake of perspective it is useful to note that other classes of substances function in similar roles and are equally important (for discussion, see Scheuer, 1977).

The nature of aquatic systems enables use of molecules of virtually any size as cues and signals (Wilson, 1970). In aquatic systems, solubility rather than volatility is of major importance (Atema, 1982). From a chemical point of view, macromolecular cues may not have the unique and interesting features that many secondary compounds from plants and animals have. However, they can exert considerable influence on biological activity. The biological activity of macromolecular cues is based upon the information content inherent in their polymeric structure. Polymer building blocks in specific sequences are high-information-containing macromolecules. Transformation and transduction into biological responses comes from polymers which have various levels of organization and structure, ranging from primary to quaternary.

Previous authors have discussed the tenuous distinction between smell and taste in aquatic organisms (Bardach, 1975; Atema, 1982). "Noses" and "tongues" appear either scattered indiscriminately or in highly complex patterns on virtually every conceivable external surface of marine organisms. Virtually every aspect of an organism's life cycle appears to be capable of being modulated through chemoreceptors. A recent and "delightful" complication is the growing need to distinguish between taste, contact chemoreception and touch with respect to the detection of and response to macromolecules adsorbed on surfaces. Thus, the three intuitively and anatomically distinct senses of taste, touch, and smell in terrestrial vertebrates form a continuum in marine sensory systems.

Equally delightful is the increasing evidence [specifically through the work of Morse's group at the University of California at Santa Barbara (Morse, 1984, 1985) and several groups at the University of Florida C.V. Whitney Marine Laboratory (Greenberg and Price, 1983; Derby et al., 1984)] that endocrine and neuroendocrine interactions which operate inside vertebrate bodies have external analogs that function at the interface between marine invertebrates and the environment. These analogs show great promise as model systems for the study of the effector–receptor interactions that are the basis of neuroendocrinology. This is another example of a simple model system shedding light on much more complex ones.

In the sections that follow we discuss the origins, transmission, information content, modulation, mechanisms of action, and the evidence for multifunctionality of marine macromolecular cues. Our goal is to give a brief overview of perspectives, research directions, as we see them, and insight into the complex nontoxic chemical networks that are fundamental to the daily life in the marine environment.

ORIGINS OF CUES

In instances where the origin of the chemical cue is known (Crisp and Meadows, 1962; Atema and Stenzler, 1977; Rittschof, 1980a; Kirchman et al., 1982; Larman et al., 1982; Forward and Lohman, 1983; Rittschof et al., 1983; Morse, 1985), the primary function of the anatomical source of the cue is as a component of the structural or metabolic machinery of the source organism. Sources are diverse: structural proteins, photosynthetic pigments, blood proteins, and exopolymers such as egg capsule proteins and mucopolysaccharides. Thus, interspecific information transmission may be a secondary function for the cue molecule, while the primary function may be structural or metabolic. Some examples of chemicals with secondary cueing functions are: (1) algal products which cue barnacle or gastropod settlement on substrates (Strathmann et al., 1981); (2) predation of a gastropod and potential shell availability to a hermit crab (McClean, 1974); (3) feeding responses (see Introduction for references); and (4) prey or predator location. Molecules with both intra- and interspecific cueing functions will be discussed in more detail in the section on multifunctionality.

Some of the more completely documented examples of origins of intraspecific molecular cues come from studies of larval settlement and feeding. Regarding cues for larval settlement, Kirchman et al. (1982) found that bacterial mucopolysaccharides promote settlement of polychaete larvae, whereas peptides associated with phycoerythrobilin, a photosynthetic pigment in red algae, promote settlement of abalone larvae (Morse et al., 1979; Morse, 1985). In

snail feeding studies, Carr and Gurin (1974, 1975) provided convincing evidence that glycoproteins of over 100,000 daltons derived from oyster flesh are involved in initial events of feeding stimulation.

In the other examples of intraspecific macromolecular cueing mentioned above (gametic attraction, alarm responses, predator–prey interaction, etc.), there is insufficient information to assign the cues a definite molecular type or origin. However, there is documentation that peptides originating from gastropod muscle proteins cue hermit crab shell acquisition behavior (Rittschof, 1980a). Also, there is evidence that heat-stable peptides of unknown origin are slowly released from living barnacles and cue their location to predatory snails (Williams et al., 1983; Rittschof et al., 1984). Likewise, heat-stable peptides may serve as sperm attractants in hydrozoans (Miller and Tseung, 1974).

Among the molecules cueing conspecific responses, the majority that have been described are glycoproteins. Heat-stable, high-molecular-weight substances found in the blood of mud snails function as an alarm substance when released by a catastrophic event (Atema and Stenzler, 1977). Natural catastrophic events include crushing or injury of the snail during predation. Experimentally, release of alarm substances is accomplished by any procedure that promotes bleeding. Over 16 species of gastropods display alarm reactions in response to crushed conspecifics (Snyder, 1967). Heat-stable proteins promoting settlement of conspecific larvae have been extracted from homogenates of adult barnacle tissues (Larman et al., 1982). Heat-stable peptides from living adult barnacles have similar effects on barnacle settlement (Rittschof, 1985). Finally, peptides from extracts of sand surrounding adult sand dollars (Burke, 1984) promote settlement and metamorphosis of larval sand dollars. However, the exact origin of any of the peptides in these examples has not been determined. The adhesive used by a colonial tube-building polychaete, which promotes settlement of conspecific larvae (Jensen and Morse, 1984), is an example of one interspecific larval settlement cue with a known origin. Peptide-cued conspecific larval release behavior is known in female mud crabs (Rittschof et al., 1985). In this case, small peptides released from hatching eggs (Forward and Lohman, 1983) cause female crabs carrying eggs to pump their abdomens. The precise origin of these larval-releasing peptides is uncertain.

Trail following in gastropods has received considerable attention at the ecological and behavioral level, but little attention has been given to this phenomenon at the molecular level. Many gastropods follow mucus trails laid down by conspecifics. The trails are known to have polarity, and in some instances they contain enough information for the discrimination of individuals of the same species from one another (Trott and Dimmock, 1978). The self/nonself recognition component has not been studied chemically, and the polarity appears to be a short-lived (hours) structural property of the mucus trail.

TRANSMISSION OF CUES

Because of the slow rate of diffusion of molecules in water, bulk water flow is important in the transport of chemical cues (Wilson, 1970; Atema, 1982). Three-dimensional odor trails (Atema, 1982) are a consequence of a slow rate of diffusion coupled to bulk water movement. These factors dictate that for most organisms detection of a chemical gradient and gradient search will not be involved in response to distant cue sources. Rheotaxis and searching in response to on–off type availablilty of cues (Van Haften and Verway, 1958; Derby and Atema, 1980; Rittschof, 1980b; Rittschof et al., 1983; Brown and Rittschof, 1984) is a more commonly demonstrated mechanism. In a careful study of chemically mediated rheotatic responses of oyster drills (Brown and Rittschof, 1984) neither the chemical cue nor the water flow alone were effective, while any combination of flow and cue, within a threefold range of each, elicited creeping responses by the drills.

Macromolecular cues function when in solution (Carr, 1967; Atema and Stenzler, 1977; Rittschof, 1980a) much the way that any other chemicals function. A more unique feature of macromolecular cues is that many are known to function when adsorbed to or part of a surface (Morse et al., 1980; Crisp and Meadows, 1982; Kirchmann et al., 1982; Jensen and Morse, 1984; Rittschof, 1985). Often, hydrolysis of the actual source of the cue can lead to extended cueing functions. For example, small molecules like amino acids which cue feeding for fish and blue crabs are released at effective concentrations for about 12 hr from a 15-g flesh source if it is protected from consumption. In contrast, the macromolecules which cue shell acquisition in hermit crabs are generated from that same source for at least three days (Rittschof, 1980b). Macromolecules adsorbed to surfaces after release from the blood of mud snails also function to prolong behavioral responses. It is not clear whether this effect is due to partitioning of the cue between the water and substrate, or a result of partial hydrolysis of the parent compound. Nevertheless, the result is a stimulation of a specific behavior for up to 24 hr (Atema and Stenzler, 1977).

In addition to macromolecules that can function as guides for trail following in snails, macromolecules implicated in larval settlement appear to function when they are adsorbed to or physically a part of a surface (Crisp and Meadows, 1962; Hidu, 1969; Morse et al., 1979; Kirchman et al., 1982; Rittschof, 1985). This particular phenomenon appears to be widespread among settling larvae. Documentation of specific surface contact requirements exists for larvae of mollusks, crustaceans, and polychaetes, ascidians (Woollacott, 1984), and bryozoans (Mihm et al., 1981). A surface mechanism of action is difficult to demonstrate experimentally because of the possibility of slow leaching or hydrolysis of the adsorbed cue. Minimally, the initial steps in the behavioral responses to

adsorbed molecules must be a molecular contact that intitates the response (Crisp and Meadows, 1962; Morse et al., 1979, 1980; Kirchman et al., 1982; Rittschof, 1985). This particular area of marine chemoreception is one which is at the interface between touch contact chemoreception and taste.

MODULATION OF MACROMOLECULAR CUES

Behavioral and physiological responses to macromolecular cues can be positively and negatively modulated by natural compounds. By themselves, modulators do not evoke responses at "natural" concentrations in the absence of the cue. For example, stimulation by the macromolecules associated with both abalone settlement (Morse, 1984, 1986) and location of prey by predatory snails (Williams et al., 1983; Rittschof and Brown, 1986) can be either facilitated or suppressed by modulatory compounds. These modulators appear to be low-molecular-weight compounds that are different in each specific instance.

Morse (1984) reviews information that his group gathered on modulators that facilitate settlement of abalone larvae. Facilitators are components common in "dissolved organic material" which aid all aspects of metamorphosis in response to low concentrations of the inducer [GABA-mimetic peptide (Morse, 1985)]. Facilitators all appear to be structural analogs of GABA, which themselves possess inducing activity only at high concentrations (Morse, 1984; Trapido-Rosenthal et al., 1985). Morse (1984) makes the argument that facilitators of abalone settlement, because of their structural analogy to natural inducers, may function in any of the steps in the normal induction pathways.

Facilitation (Williams et al., 1983) of responses of snails to soluble peptides from barnacles is due to micromolar concentrations of ammonium ion (Rittschof and Brown, 1985). Compounds suppressing chemotactic responses of snails to these peptides occur in the odors from the predatory snail's bivalve prey (Williams et al., 1983). Modulators with suppressant activity are poorly characterized because of the inability at this time to extract and concentrate them from seawater. However, it is known that suppressants are not amino acids or simple sugars, and that they have an apparent molecular size between 500 and 1000 daltons. Thus, chemical modulations of certain snail predator–prey interactions are expressed in several ways, including camouflaging (Fishlyn and Phillips, 1980), facilitation of the attractiveness of the odor of a prey species (Rittschof et al., 1983; Williams et al., 1983), and suppression of chemotactic behavior (Williams et al., 1983; Rittschof and Brown, 1986).

MULTIPLE FUNCTIONS

Evidence for multifunctionality of macromolecular cues in marine organisms is restricted at this time to preliminary investigations of peptides that orig-

inate from barnacles and oysters (Rittschof and Brown, 1986). These peptides were discovered and isolated by virtue of the creeping response evoked in predatory snails (Rittschof et al., 1983, 1984; Rittschof et al., 1986). Peptides originating from barnacles were isolated and purified from seawater containing live intact barnacles. Detection of biological activity was done with an assay which tested the creeping response observed in inexperienced predatory snails. Soluble peptides from water bathing intact oysters were isolated and purified. The bioassay used in this study measured the creeping response in snails that had been conditioned (Wood, 1968) to respond to peptides from oysters. Although the amino acid sequences of the peptides are not yet known, chromatographic, compositional, and biological properties indicate that several distinct peptides may be present (Rittschof and Brown, 1986; Rittschof et al., 1986).

In addition to their biological activity in predatory snails, the peptides isolated from barnacles and oysters have effects on the settling stage of larval barnacles. At concentrations that can be detected in field situations (2.5 μg/liter), barnacle peptides affect the behavior and induce metamorphosis in settling stage larvae. In this respect these peptides are similar to arthropodins (Crisp and Meadows, 1962). As is the case with arthropodins, soluble but "sticky" barnacle peptides affect larval behavior and induce metamorphosis when adsorbed onto surfaces. In contrast, "sticky" oyster peptides, presented at concentrations comparable to barnacle peptides, alter larval barnacle behavior but do not induce metamorphosis. Tests of effects of these oyster peptides on larval oysters are in progress in collaboration with researchers at the University of Maryland.

Thus, there is preliminary evidence that macromolecular cues may perform more than one cueing function. In the case of barnacle peptides, there is evidence for three functions: (1) prey location by predatory snails plus (2) site selection and (3) induction of metamorphosis by barnacle larvae. In the case of oyster peptides, there is evidence for two functions: (1) prey detection by predatory snails and (2) site selection in larval barnacles. It appears likely that future work will show that macromolecules that provide information concerning the presence of specific kinds of organisms are central to the physiological ecology of those organisms.

Whether adsorbed to surfaces or free in solution, macromolecular cues function to transmit specific information in marine environments. The fact that many cues are proteinaceous but heat stable suggests that higher-order macromolecular structure (secondary, tertiary, and quaternary) is less important than the covalent primary structure inherent in all biopolymers. In a peptide, for example, the "R" groups of each amino acid might function unambiguously, similar to strings of letters forming words. While odor bouquets (Bardach, 1975) of smaller molecules can perform the functions of single macromolecules, there is little evidence in marine systems other than in those areas entailing relatively

nonspecific responses (such as feeding) that mixtures of odors have specific cue functions. However, as is the case in insect pheromone systems, mixtures of marine secondary metabolites may have specific functions.

Advantages related to specific cueing functions are inherent in the primary structure of macromolecules, especially peptides. In many environments peptide cues have a high signal-to-noise ratio. This is because background levels of free peptides and amino acids (Mopper and Lindroth, 1982) are low due to the biological demand for and scavenging of organic nitrogen. Concomitantly, rapid biological uptake combined with dilution result in short signal duration. As the size of the peptide increases, the rapid decrease in the rate of diffusion increases the potential for transport of effective cue concentrations over relatively long distances. Should modulating molecules be present, the change in ratio of cue to modulator in the odor plume due to differences in rates of diffusion could be used by organisms to gain information about the distance to the source. The polar, amphoteric structure of peptides provides high solubility in water. The linear structure and polarity (amino terminal and carboxy terminal) of peptides provide potential for unambiguous information transmission. Should the peptide originate from a repeating structure such as a marine adhesive (Waite, 1983) or blood antifreeze protein (Komatzu et al., 1970), there is remarkable potential for extended slow release function. Finally, as proteins are major metabolic and structural components of all organisms, the intact molecules and their specific degradation products are available as raw materials for the evolution of information transmission.

(Received July 29, 1985; accepted November 19, 1985)

Abstract—Plant and fungal cell wall fragments produced by enzymic degradation during pest attacks are hypothesized to be activators of a universal recognition system for locally and systemically activating genes which control the synthesis of plant defense chemicals such as the antibiotic phytoalexins and antinutritive proteinase inhibitors. Proteinase inhibitor cDNAs have been prepared from wound-induced mRNAs, isolated, and characterized. The cDNAs have been utilized to quantify specific proteinase inhibitor mRNAs in leaves following wounding or simulated insect attacks. The cDNAs have also been utilized as hybridization probes to isolate and characterize proteinase inhibitor genes from tomato and potato genomic DNA. Proteinase inhibitor proteins have been induced in tomato leaves by chewing insects and shown to be highly correlated with a systemically mediated reduction in the nutritional quality of the leaves toward the larval noctuid *Spodoptera exigua*. Thus, the wound-induced proteinase inhibitors, whose genes in tomato leaves can be activated by wounding, insect attacks, and plant and fungal cell wall fragments, can significantly decrease the quality of the leaves for such herbivorous insects. This inducible set of biochemical reactions leading to the de novo biosynthesis of proteinase inhibitors is, therefore, considered to be a potentially important defense of plant leaves that should be considered both in developing general theories on insect-plant interactions and in selecting insect-resistant crop varieties.

INTRODUCTION

Current hypotheses concerning the chemical bases for plant defenses against predators include the concept that plants can respond to attacks of insects, microorganisms, and viruses by activating genes that produce defensive chemicals. In recent years, studies on the insect-induced proteinase inhibitors in plant leaves and of phytoalexin synthesis in cotyledons and seedlings have provided models to study the biochemical and molecular biological mechanisms that underlie induced defensive responses. Over the past 15 years, evidence has been accumulating to support a model in which plant and fungal cell walls contain, within their polysaccharide structures, informational components that can be released by attacking insects and microorganisms can subsequently act as signals to activate plant genes that produce defensive chemicals.

The first report of a cell wall polysaccharide with phytoalexin elicitor activity came from the laboratory of Dr. Peter Albersheim at the University of Colorado in the mid-1970's. A β-glucan fraction (glucose polymers containing β-1,3 and β-1,6 linkages) derived from fungal cell walls was found to contain powerful elicitors of the synthesis and accumulation of the antibiotic isoflavonoid phytoalexins in legume seeds (Ayres et al., 1976). Phytoalexins induced by such elicitors can eventually comprise several percent of the wet weight of the plant cells in which they accumulate. Elicitation of pyhtoalexins by fungi appears to be localized only in cells adjacent to and near the site of hyphal infection; hence, the effects of such elicitors, whether they be β-glucans or other chemicals, are not systemic. Recently, the structure of an active oligomeric β-glucan fragment from the cell walls of *Phytophthera megasperma* was identified as a hexaglucosyl hexitol (Sharp et al., 1985). Substitution of the hexitol unit with glucose did not diminish its activity in eliciting phytoalexin synthesis in soybean cotyledons. As little as 1 pmol of the elicitor per 1 ml tissue volume of cotyledon elicited phytoalexin synthesis (Sharp et al., 1985).

In 1980, Hadwiger and Beckman (1980) reported that another component of fungal cell walls, chitin (Figure 1, right) harbors structural components within its polymeric structures that, upon degradation and solubilization, can be potent elicitors of both phytoalexin synthesis and proteinase inhibitor synthesis. Chitin, a β-1,4-*N*-acetylglucosamine polymer, when deacylated and chemically or enzymatically fragmented, yields soluble oligo- and polysaccharides that elicit phytoalexin synthesis in tissues of a variety of plant species from diverse families (Hadwiger and Loeschke, 1981; Walker-Simmons and Ryan, 1984).

In the late 1970s, fragments from the cell walls of plants (Figure 1, left) were shown to activate defensive responses in plants. Pectic fragments were

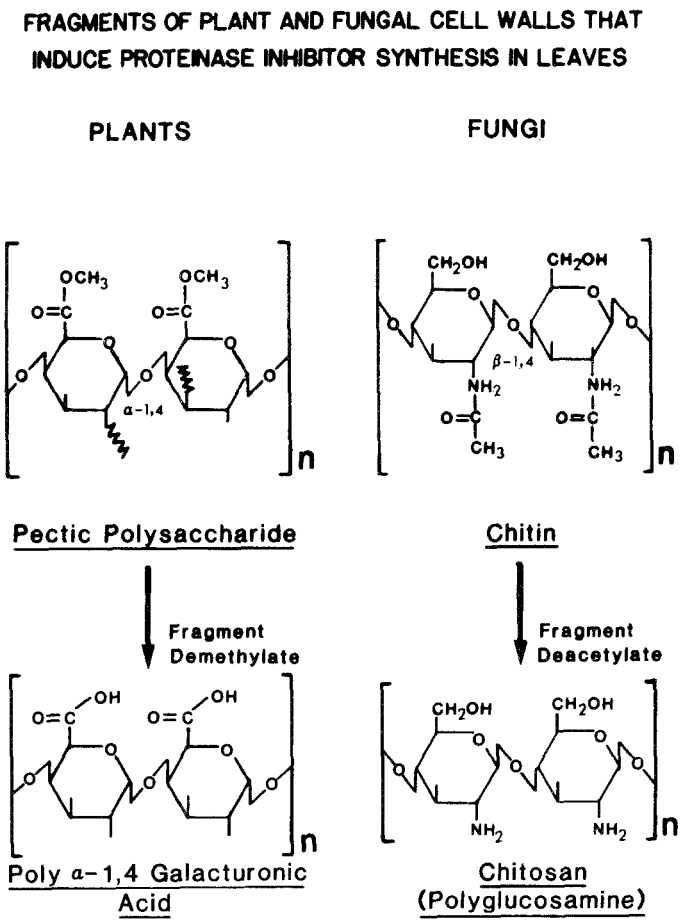

FIG. 1. Structures of the repeating units of fragments that can activate plant defensive responses. The fundamental sugar unit of chitin (right) is β-1,4-N-acetylglucosamine.

shown to induce proteinase inhibitor synthesis in plant leaves (Ryan, et al., 1981) and elicit phytoalexin synthesis in legume cotyledons and seedlings (Hahn, et al., 1981). Research on the systemically mediated insect- or wound-induced synthesis of proteinase inhibitors in plant leaves led to the isolation of a component of tomato leaves called the proteinase inhibitor inducing factor, PIIF, that was apparently the active inducer of synthesis of proteinase inhibitors in excised tomato leaves. In 1978, this component was tentatively identified as a pectin-like molecule from tomato leaves (Ryan, 1978), and in 1980, the activity was shown to reside in a well-defined fragment of sycamore cell walls

(Ryan et al., 1981). During this period, the laboratories of Dr. P. Albersheim in Colorado and Dr. C. West at UCLA, reached the same conclusion—that plant cell wall fragments contained biological activity and were elicitors of phytoalexin synthesis in legume seedlings and cotyledons (Hahn, et al., 1981; Jin and West, 1984). Thus, the concept of the potential role for fungal and plant cell wall fragments as initial signals for activating a variety of genes producing defense chemicals has evolved. A summary of the possible origins and actions of these carbohydrate signals in response to insect or microorganism attacks is shown in Figure 2.

As shown in Figure 2, the pectin fragments released by insect attacks, can be simulated in vitro by the mixing of cell walls with plant endopolygalacturonases released from compartments in the cell by the chewing action of attacking insects (or other animals). The fragments, or derivatives or adducts thereof, are thought to be transported throughout the plants where they can activate defensive genes.

On the other hand, microorganisms initiate attacks on plants (Figure 2) by releasing a variety of enzymes, including polygalacturonides that degrade the cell wall (Bateman, 1976). The cell wall fragments are released by the microorganism's endopoloygalacturonases (EPGases) (Lee and West, 1981) or pectic

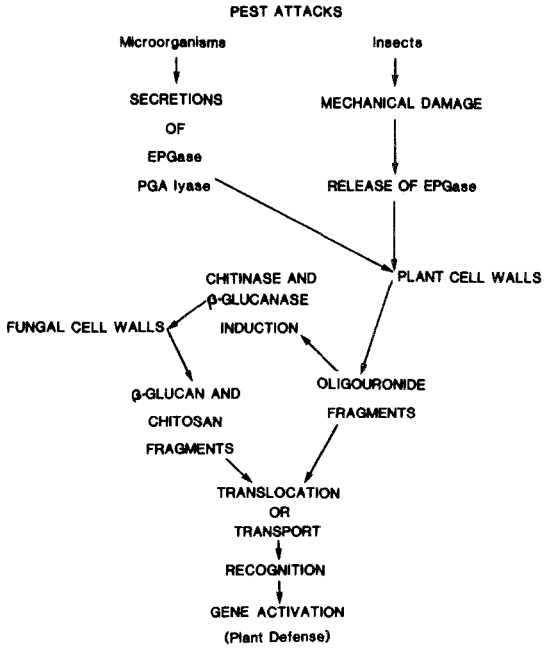

FIG. 2. Proposed scheme for the production and transport of cell wall fragments during attacks by microorganisms and insects.

lyases (PGAlyases) (Davis et al., 1984) and act as localized signals to elicit the synthesis of phytoalexins. Additionally, attack by microrganisms has recently been shown to induce localized synthesis of two plant enzymes, chitinase (Abeles et al., 1970) and β-glucanase (Boller et al., 1983). Since induced plant enzymes would be present in tissues adjacent to the sites of attacks, they could react with the cell walls of invading fungi, causing a release of active chitin and β-glucan fragments which could further amplify the induction of phytoalexin synthesis elicited intitially by the pectic fragments (Figure 2). As an infection proceeds, the fragments (signals) would continue to be released, and therefore cause continued phytoalexin synthesis. Nearly 20 examples of plants producing phytoalexins, proteinase inhibitors, or other defensive chemicals in response to cell wall fragments have now been reported in plants from genera in several plant families including the Solanaceae, Leguminosae, and Pinaceae. This distribution implies that a common recognition-gene activation system may be a fundamental component of all of these plants and may, moreover, serve as a universal regulator of resistance to a variety of detrimental external stimuli.

Based on knowledge of the pathways of pest-induced fragmentation of the plant and fungal cell walls, one can consider a number of potential regulatory processes governing the release of oligo- and polysaccharides. The quantity and specificities of both plant and microorganismal (and perhaps insect) cell wall-degrading enzymes could modulate the temporal and structural features of the released oligo- and polysaccharide fragments. The levels of chitinase and β-glucanase that are induced in plant tissues could be modulated by the promoter strengths of the genes, or by multiple gene copies. Finally, the efficiency of transport mechanisms and receptor responses could come into play in establishing a successful defensive response. Furthermore, both the phytoalexins and proteinase inhibitors are only a part of an array of defensive chemicals, both constitutive and inducible, with which they may act in concert. It is anticipated that a more detailed understanding of the induction of proteinase inhibitors and phytoalexins in response to attack by foreign organisms will emerge as we more incisively depict the identity of the signals that regulate induced defenses, unravel the recognition systems that regulate gene expression in response to these signals, and fully define the structures and organization of the genes and their pest-induced promoters that are regulated by cell wall fragments.

In this article we briefly review the background and status of research concerning the wound signal PIIF and the isolation of proteinase inhibitor genes. We will then describe recent experiments that strongly implicate the proteinase inhibitor proteins as induced defensive chemicals.

INSECT- OR WOUND-INDUCED PROTEINASE INHIBITORS

In 1972, localized wounding of tomato plants by chewing insects was found to induce the systemic accumulation of a proteinase inhibitor in leaves through-

out young tomato and potato plants (Green and Ryan, 1972). For several years, the research focused on the isolation and characterization of the wound-induced proteinase inhibitors and the inducing factor, PIIF. Current research on the response of these plants to wounding has been concerned with (1) and understanding of the intracellular mechanism by which cell wall fragments can activate proteinase inhibitor producing genes in plant leaves, (2) the isolation and characterization the proteinase inhibitor genes, and (3) the regulation of expression of the genes by the cell wall fragments. More recently, the question of the effectiveness of proteinase inhibitors as defensive chemicals against herbivores has also been addressed. Although the antinutritional properties of the inhibitors has indirectly implicated them as potential defensive chemicals, no research has been done until recently to study directly their possible roles in reducing the nutritional quality of plant tissues toward attacking insects.

Many parameters of wound-induction of proteinase inhibitors in tomato plants are now known. This response is easily quantified in young tomato plants (2–3 leaf stage) by crushing the lowest leaf across the midrib with a hemostat. Within 6 hr after wounding, two proteinase inhibitors, called inhibitors I and II (6), can be detected in the wounded leaf and, after an additional 60–90 min, the inhibitors can be detected in upper, unwounded leaves. The inhibitors accumulate in both wounded and unwounded leaves for several hours, although inhibitor I accumulates at about twice the rate of inhibitor II (Ryan, 1978). The inhibitors are compartmentalized in the central vacuole of the cell where they are apparently not degraded as are other intracellular proteins. Thus, even though only a small fraction of total foliar protein synthesis (about 1% of the total protein) is devoted to production of the two inhibitors, they accumulate fairly rapidly.

The pectic fragment, PIIF, was purified from tomato leaves by utilizing an assay system in which young plants, excised at the petioles, were supplied with aqueous extracts of tomato leaves (Ryan et al., 1985) containing tomato leaf cell soluble fractions, separated by conventional analytical techniques. When PIIF was present in a given solution, that solution induced the synthesis of the two inhibitors in leaf cells. The active inducer component was identified as a highly methylated pectic fragment with an average length of 30 residues (Ryan et al., 1981). The fragment, when hydrolyzed and analyzed, contained nearly 70% galacturonic acid, and its general composition closely resembled that of the pectic polysaccharides of plant cell walls (Ryan et al., 1981).

PIIF was partially hydrolized with trifluoric acid to remove neutral side chains, and an active, demethylated polygalacturonic acid polymer with an average chain length of 20 (Bishop et al., 1984) was recovered. Upon analysis, the polymer was found to contain 90% galacturonic acid. Further fragmentation of this polymer by enzymic degradation with tomato endopolygalacturonase and subsequent isolation and assay of the smallest fragments revealed that PIIF activity was present in dimers and in larger oligomers up through the hexamer,

the largest pure polymer tested. However, all of the fragments contained less activity than PIIF itself. A small polymer or oligomer that possesses the full activity of PIIF has not yet been recovered. By extrapolation of the increasing activities of the oligomers, the maximal activity was estimated to be present in about a nonomer. This estimate approximates the size of the polyuronides which are active in the phytoalexin systems (Lee and West, 1981; Nothnagel et al., 1983). However, in the localized phytoalexin response, oligomers less than about seven uronide units are inactive. It is possible that fragments with lengths of seven or less are transported and act systemically, whereas the larger ones may not be transported and act locally. The chemical nature of the factor(s) that is systemically transported and activates proteinase inhibitor synthesis is presently under investigation.

The molecular biology of the wound induction has also been extensively studied. Leaves of wounded tomato plants were found to contain mRNAs coding for both inhibitor I and II (Nelson and Ryan, 1980), identified using an in vitro translational system followed by immunoprecipitation and electrophoresis in polyacrylamide gels containing SDS. Little or no translatable inhibitor I or II mRNA was found in unwounded leaves.

Using partial amino acid sequence data from the *N*-terminal regions of both inhibitors, oligonucleotide sequences were deduced and probes for the two inhibitors were synthesized (Graham et al., 1985a,b). These probes were used in conjunction with hybrid selection techniques using in vitro translations to select cDNAs coding for inhibitor I and II from a library of wound-induced cDNAs prepared in the plasmid pUC9. Several cDNA clones were identified, and full-length cDNAs for both inhibitor I and II were isolated and characterized. These clones have been useful for deducing the entire open reading frames for the two inhibitors. These experiments revealed that both inhibitors are synthesized as preproteins with leader, or transit, sequences of about 20 amino acids at their *N*-terminals that are apparently necessary for posttranslational transport into the central vacuole where inhibitors are stored (Walker, Simmons and Ryan, 1977).

The cDNAs were also used in hybridization experiments to quantify inhibitor mRNA levels in leaves following wounding (J. Graham and C. A. Ryan, in preparation). After a single wound, inhibitor I and II mRNAs first appear at about 4 hr. By 8 hr, the maximum levels are found, the decline with a half-life of about 10 hr. Multiple wounding causes to mRNAs to appear sooner and the levels to increase significantly. For example, four wounds on a leaf, inflicted hourly, cause a doubling of mRNA. Thus, and insect constantly chewing on a leaf would probably produce maximal responses in the leaves. After multiple wounding, the levels of mRNAs for inhibitor I and II have been estimated to cumulatively comprise nearly 1% of the total mRNA of leaf cells.

The cDNAs were also employed to isolate genes for both inhibitors from a tomato genomic library. The characterization and organization of these genes are in progress.

The genes are currently being constructed into a shuttle vector that is a derivative of the Ti plasmid (An et al., 1985) to be used to transform plants to see if the wound-induced promoters are still functional in the isolated genes. If so, the structures of the promoters responsible for reacting to attack by foreign organisms can be resolved. Identification and synthesis of this promoter could be quite useful in further fundamental and applied research to understand and manipulate plant genes to improve natural plant defenses against attacking pests.

EFFECTS OF WOUND-INDUCED PROTEINASE INHIBITORS ON HERBIVORES

The hypothesis that wound-induced plant proteinase inhibitors have a detrimental effect on herbivores was tested by rearing larval *S. exigua* on leaf material from unwounded and wounded tomato plants (Broadway et al., 1985). Two commercial varieties of tomato, Ace 55 (Ace) and Castlemart (CM), were grown to the 7–8 leaf stage in sterilized soil inside fine mesh cages in a greenhouse to prevent wounding of the plant tissue by external agents. The plants were divided into two groups. One group was maintained as a control, and the other group was wounded by enclosing 3–4 fifth-instar larval *S. exigua* on the lower leaf of each plant via a gauze bag. The insects were allowed to feed for 24 hr. After this 24 hr period, the leaves from plants of both groups were removed, immediately frozen at −20°C, lyophilized, and pulverized.

The results of biochemical assays to determine total levels of foliar inhibitor I and II for the four samples of leaf tissue (Ace, Ace/wounded, CM, CM/wounded are shown in Figure 3. Tissues were also assayed for catecholic, phenolic, and protein content. When statistically comparing the four samples of leaf tissue using two-way analyses of variance followed by multiple comparisons of means at 5% level (95% CI), there is no significant relationship between wounding and the levels of total foliar phenolic or protein.

In contrast to the levels of foliar phenol and protein, the combined levels of inhibitor I and II in the tissue samples from both varieties of wounded plants were significantly higher than levels in the samples from both varieties of unwounded plants. In addition, wounding induced the production of a significantly higher level of inhibitor I and II in the tomato variety Castlemart (CM/w) than in Ace 55 (Ace/w). There was no significant difference between the two unwounded varieties, Ace and CM in their total inhibitor I and II content. Thus, among the chemicals investigated, only the levels of inhibitor I and II were elevated in response to wounding.

In order to assess whether this induced level of inhibitor had any effect on herbivorous insects, the following experiment was done. The four samples of lyophilized plant material (Ace, Ace/w, CM and CM/w) were reconstituted to 15% (wet wt) with a 1.6% agar solution and 0.05% sorbic acid and were provided as a diet for second-instar larvae of *S. exigua*. Experiments were termi-

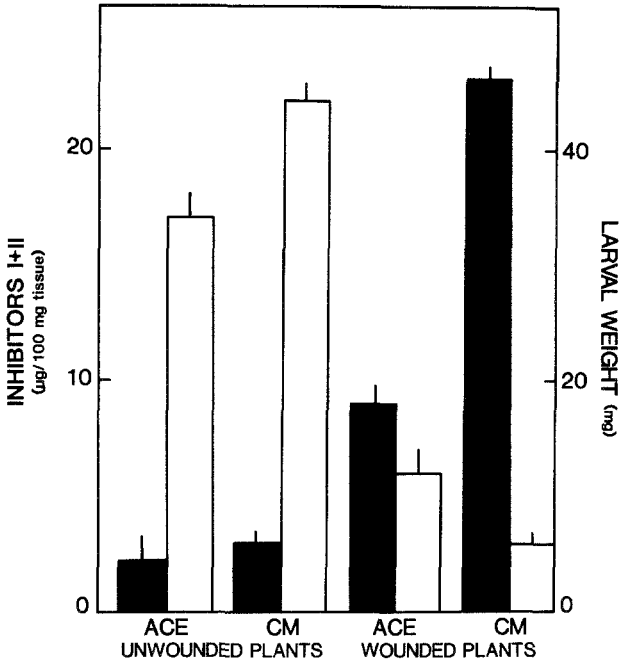

FIG. 3. The levels of proteinase inhibitors I and II in leaves of tomato varieties Ace and Castlemart. Leaves of unwounded and wounded plants (dark columns) are compared with the growth of *Spodoptera exigua* larvae (open columns) that subsequently fed on the leaves. Error bars fefer to 95& CM.

nated and all larvae were weighed when the larvae feeding on the control diets reached fifth (ultimate) instar.

These data indicate that the foliage from wounded palnts is a poorer food source than that from unwounded plants. When larval growth, as measured by weight gain, was examined in relation to the dietary inhibitor I and II, it was clear that there was a significant inverse relationship ($r^2 = 0.81$, $P = 0.05$) between the levels of inhibitor I and II in the leaf tissue and the means of the weight of larval *S. exigua*.

The alternation of the nutritional quality of plants by herbivory resulting in enhanced "resistance" (wound-induced resistance) of the plant, is a subject that has recently received much interest (Rhoades, 1983: Hare, 1983; Ryan, 1983; Kogan and Paxton, 1983). Wounding of a variety of plant species by either artificial or natural means can result in elevated levels of phytochemicals that are potentially strong antibiotic (Ryan, 1983; Kogan and Paxton, 1983; Haukioja and Niemela, 1976, 1977; Niemela and Haukioja, 1979), and artificially defoliated trees can subsequently produce foliage which is of reduced nutritional quality for herbivorous insects (Wallner and Walton, 1979; Werner,

1979). None of the factors that cause the decreased nutritional quality have been determined, and only a few studies have shown that insect herbivory will reduce the nutritional quality of foliage for future herbivores (Karban and Carey, 1984; Benz, 1977; Baltensweiler et al., 1977; Overhulser et al., 1972).

Previous to this research, there have been no studies to show either that insect herbivory induces specific phytochemicals in plants or that these phytochemicals subsequently confer resistance to the plant against pathogens or herbivores. Although the work relating the levels of plant proteinase inhibitors to larval growth and development is indirect, a recent study (Broadway and Duffey, 1986) showed that chronic exposure to purified potato inhibitors related to those induced in tomato leaf has a detrimental effect on the digestive physiology of larval *S. exigua* by inducing a pernicious hyperproduction of gut proteases. It appears that the chronic stress on the digestive enzyme-producing system is a major factor in depressing growth of lepidopterous larvae.

In summary, the systemic insect-induced synthesis of proteinase inhibitors in tomato leaves appears to be regulated by a universal recognition-communication system mediated by cell wall fragments of plants (or fungi) generated during attacks by foreign organisms. The large accumulation of the antinutrient inhibitors from the activation of proteinase inhibitor genes resulted in the synthesis of new mRNA and inhibitor protein. The levels of the inhibitors in the leaves induced by attacks of the larval noctuid *S. exigua* correlated with the reduction of the nutritional quality of the plant tissues as a food source for the insects. Proteinase inhibitors can therefore be seriously considered as potentially important induced defensive chemicals against herbivorous insects.

Abstract—The mutualistic interactions of cactophilic *Drosophila* and their associated yeasts in the Sonoran Desert are studied as a system which has evolved within the framework of their host cactus stem chemistry. Because the *Drosophila*–yeast system is saphrophytic, their responses are not thought to directly influence the evolution of the host. Host cactus stem chemistry appears to play an important role in determining where cactophilic *Drosophila* breed and feed. Several chemicals have been identified as being important. These include sterols and alkaloids of senita as well as fatty acids and sterol diols of agria and organpipe cactus. Cactus chemistry appears to have a limited role in directly determining the distribution of cactus-specific yeasts. Those effects which are known are due to unusual lipids of organpipe cactus and triterpene glycosides of agria and organpipe cactus. *Drosophila*–yeast interactions are viewed as mutualistic and can take the form of (1) benefits to the *Drosophila* by either direct nutritional gains or by detoxification of harmful chemicals produced during decay of the host stem tissue and (2) benefits to the yeast in the form of increased likelihood of transmission to new habitats. Experiments on yeast–yeast interactions in decaying agria cactus provide evidence that the yeast community is coadapted. This coadaptation among yeasts occurs in two manners: (1) mutualistic increases in growth rates (which are independent of the presence of *Drosophila* larvae) and (2) stabilizing competitive interactions when growth reaches carrying capacity. This latter form is dependent on larval activity and results in benefits to the larvae present. In this sense, the coadapted yeast community is probably also coadapted with respect to its *Drosophila* vector.

Key Words—*Drosophila*, Diptera, Drosophilidae, yeasts, cactus, community ecology, mutualism, coadaptation, evolution, alkaloids, fatty acids, sterols.

INTRODUCTION

Coevolution has been defined as an evolutionary change in a trait of the individuals of one population (or species) in response to a trait of the individuals of a second population (or species), followed by an evolutionary response by the second population (or species) to the change in the first (Janzen, 1980). The evolution of secondary compounds in plants, which are generally considered to be defense agents against herbivores and microorganisms (e.g., Whittaker and Feeny, 1971; Levin, 1973; Rosenthal and Janzen, 1979; Futuyma, 1983) and the counterevolutionary response of the herbivores and microorganisms is, therefore, viewed as a process of coevolution. Plant–herbivore or predator–prey relationships can also elicit the evolution of mutualistic interactions between species (Ricklefs, 1979). If the mutualism between species is accompanied by adaptations of both parties which increase the effectiveness of the association, the process is said to involve coadaptation (Roughgarden, 1978). We have been studying a biological system in which species of *Drosophila* feed and breed in the decaying tissue of cacti (Heed, 1978, 1982). The microbial community (various species of bacteria and yeasts) which decays the cactus transforms the tissue into food for these drosophilids. In turn, these drosophilids can vector microorganisms into new habitats (damaged tissue). This is particularly important for the yeasts, which do not disperse by wind and rely on insects such as *Drosophila* for transmission to new habitats (Gilbert, 1980). The nutritional benefits of the yeasts to the fly and the transmission benefits of the fly to the yeasts form an interdependent system, and thus create the potential for coevolution and coadaptation.

One feature of this system which makes it amenable to studies of coadaptation is that, although the secondary chemistry in the host cacti may have involved coevolutionary relationships with herbivores, it is essentially uncoupled from the evolution of the *Drosophila* and associated microorganisms. In essence, the saphrotrophic nature of the system precludes selective forces from the *Drosophila* microbiota on the host plants. Changes in the host chemistry due to selective pressure by pathogenic microorganisms and primary herbivores may exert selective forces on the saphrophytic system, but not vice versa.

In this paper, we will briefly review the chemical constituents of cactus tissue utilized by drosophilids and yeasts in the North American Sonoran Desert. In conjunction with this chemical description, we will focus attention on the yeasts, drosophilids, and yeast–*Drosophila* associations and review evidence which indicates that the chemistry of the host plants has played a role in determining what types of yeasts and drosophilids are present in particular plant species. In conclusion, we will present new data on yeast–yeast interactions in association with their fly vectors. These data will be used to evaluate various factors operating to determine yeast community structure and the coevolutionary or coadaptive features of the *Drosophila*–yeast community association.

CACTUS CHEMISTRY

Kircher (1982) has reviewed and outlined the major chemical constituents of several cacti found in the Sonoran Desert. His analysis (Table 1) includes representatives of two major systematic divisions of the columnar cacti [subtribe Pachycereinae: *Carnegiea gigantea* (saguaro) and *Lophocereus schottii* (senita); subtribe Stenocereinae: *Stenocereus thurberi* (organpipe) and *Stenocereus gummosus* (agria)]. Comparing the approximate chemical composition of the cacti, there is variation in the first two columns, percent H_2O and insoluble residue. Variance in the former, however, may primarily be due to differences in climatic conditions and water availability in the regions where the samples were collected. Although there is variability in amount, the composition of the insoluble residue fraction (cellulose, lignin, polysaccharides, and inorganic compounds) is similar among the four cacti. Major differences among the plants of the two subtribes reside in the lipid and methanol-water soluble fractions.

The major components of the lipid fraction of saguaro and senita are fatty acids (as esters), sterols, and alkaloids. The fatty acids in both species and the sterols in saguaro are considered typical for plants of this type. The sterols in senita are unusual in that this species apparently has an interrupted sterol biosynthetic pathway which leads to the accumulation of intermediate forms of sterols (Campbell and Kircher, 1980). The typical plant sterols, campesterol and sitosterol, are absent. Both species contain isoquinoline alkaloids: carnegine and gigantine in saguaro, lophocereine and its trimer, pilocereine, in senita (Brown et al., 1972; Djerassi et al., 1962). The concentration of alkaloids in senita (3–15% of the dry weight of the plant) is much greater than the concentration in saguaro (1–2% dry weight).

The lipid fractions of the congeners, agria and organpipe cactus, are chemically similar to each other and quite different from the other columnar cacti. The three main components of these fractions are neutral pentacyclic triter-

TABLE 1. APPROXIMATE COMPOSITION OF FRESH CACTUS TISSUE[a]

		Dry weight (%)				
Cactus[b]	H_2O (%)	Insoluble residue	Lipids	Alkaloids	MeOH-H_2O soluble	Triterpene glycosides
Saguaro	87	77	2.5	1.5	21	
Senita	81	71	6.5	3–15	25	
Organpipe	78	61	11		28	+
Agria	80	57	6.5		36	+

[b] Scientific Names: *Carnegiea gigantea* (saguaro), *Lophocereus schottii* (senita), *Stenocereus thurberi* (organpipe), *S. gummosus* (agria).

penes, sterol diols, and unusual fatty acids (Kircher, 1980; Kircher and Bird, 1982). The fatty acids are unusual in that they are predominantly C_8, C_{10}, and C_{12} chain lengths rather than the more typical C_{16}, $C_{18:1}$, $C_{18:2}$, and $C_{18:3}$. Most of the triterpenes and sterol diols are monoesterified to the fatty acids.

The methanol–water-soluble fraction of agria and organpipe cactus represents a large portion of the dry weight of these plants (up to 40% dry weight) and is composed mainly of triterpene glycosides (Kircher, 1977). This fraction of both saguaro and senita is a poorly defined mixture of substances, but triterpene glycosides are not present in either species. These compounds then, like alkaloids, are subtribe characteristics since this pattern of mutually exclusive distribution of the compounds extends to other members of the two subtribes (Gibson and Horak, 1978). Stem chemistry of this unusual nature is likely to have evolved as a result of various selection pressures from hervibores and pathogenic microorganisms, as well as adaptations to survive the extremes of desert climates (Gibson, 1982).

YEASTS

The distribution of yeasts in necrotic cactus tissue has been studied from both taxonomic viewpoints (Phaff et al., 1974, 1978, 1980, 1985; Miller et al., 1976; Starmer et al., 1978a, b, 1979, 1984; Miranda et al., 1982; Holzschu et al., 1983) and ecological and evolutionary analyses (Heed et al., 1976; Starmer et al., 1976, 1980, 1982; Starmer, 1980, 1981a, b, 1982a, b; Fogleman et al., 1981, 1982; Starmer and Phaff, 1983; Fogleman and Starmer, 1985). The distribution of yeast species over the four cacti is summarized in Table 2. A correlation analysis of these data shows that yeast communities of plants within subtribes have significantly higher correlations than yeast communities between plants of different subtribes (average correlation within is 0.76, average correlation between is 0.28). The extent to which the cactus stem chemistry has directly influenced the distribution of yeasts within the systematic hierarchy has been determined by studies of yeast growth on media (complete and minimal) which has been supplemented with chemical constituents of the cacti.

The general result has some explanatory power but is far from complete. First, the triterpene glycosides of the *Stenocereus* species do inhibit growth of some yeast taxa (i.e., *P. heedii*, *P. amethionina* var. *pachycereana*, and some strains of *Cr. cereanus*) and, thus, help explain why these species are relatively rare in *Stenocereus* stem necroses (Starmer et al., 1980). Several yeast species (e.g., *P. fluxuum*) not found in cacti are also sensitive to the triterpene glycosides (Starmer et al., 1980) and indicate that these chemicals may be functioning to restrict related yeasts that grow outside of the cactus yeast community from the *Stenocereus* habitat.

The medium chain fatty acids found as esters in agria and organpipe cactus tissue can inhibit yeast growth if they occur in the free undissociated form

(Suomalainen and Oura, 1958). The relative amount of yeast growth in the presence of the free undissociated fatty acids is dependent on pH and yeast taxa. The ability to grow in the presence of these compounds is apparently associated with the ability to utilize them as a source of carbon. *Candida ingens* is unique in this regard, as it can utilize the medium chain fatty acids as the sole source of carbon as well as tolerate them at concentrations which are inhibitory to other yeasts (Henry et al., 1976; Starmer, 1982a). Thus, the lipolytic activity of *C. ingens* might give this yeast an advantage in agria or organpipe cactus tissue

when the unusual lipids are hydrolyzed to free the medium chain fatty acids. The relatively high frequency of *C. ingens* in organpipe rots, where these compounds are in relatively high concentration, is in accord with this notion.

The alkaloids of saguaro and senita apparently have neither inhibitory nor stimulatory effects on yeast growth (Fogleman and Kircher, 1983) and are not likely to be directly responsible for the distribution of yeasts in cactus necroses. In fact, complete medium supplemented with the water-soluble extracts, whole tissue, or filter sterilized rot juices of senita or saguaro does not appear to cause qualitative differences in the growth of cactus yeasts.

In summary, there is some evidence that the chemistry of *Stenocereus* species does function to inhibit some yeasts and thus partially determine which yeast can grow in decaying stems of these cacti. However, there are no indications that chemicals of cacti in the subtribe Pachycereinae directly determine yeast distributions.

DROSOPHILA

The ecology and evolutionary biology of the *Drosophila* species of the Sonoran Desert have been the subject of several recent reviews (Heed, 1978, 1982; Heed and Mangan, 1985). The four endemic species are: *D. mojavensis*, *D. nigrospiracula*, *D. mettleri*, and *D. pachea*. Two major points have been put forth as a result of evolutionary studies of these four drosophilids. First, each species is thought to have evolved its own set of adaptations to desert conditions independently. This statement is supported by the observation that the geographic distribution of the closest relatives of each endemic species either lies entirely outside the desert or overlaps the desert only slightly. Second, in regard to phylogenetic trends, *D. pachea* and *D. mojavensis* are obviously derived species, and they show evidence of origin from the south along the coast of Mexico. On the other hand, neither *D. nigrospiracula* nor *D. mettleri* are clearly derived forms, compared to their relatives, and the route to their place of origin is not known with any certainty.

Twenty-five years of extensive collection data by W.B. Heed and his students and colleagues have firmly established the *Drosophila*–host plant relationship in the Sonoran Desert. Essentially, there is a one-to-one relationship between the flies and the cacti, in that each cactus has only one main resident fly species. The host plant relationships are as follows: *D. mojavensis*—agria and organpipe, *D. nigrospiracula*—saguaro and cardón, *D. pachea*—senita, and *D. mettleri*—soaked soils (mainly from saguaro and cardón).

There is ample evidence that the secondary chemistry of the cacti limits host plant utilization. For example, *D. pachea* has evolved a strict dependency on the unusual sterols present in senita, so that the more typical plant sterols are not adequate for female fertility or larval development (Heed and Kircher,

1965). Since senita is the only cactus that contains these sterols, *D. pachea* is effectively limited to this host plant. In addition, the alkaloids in senita have been shown to be toxic to *D. mojavensis* and *D. nigrospiracula*. Senita, therefore, cannot be used as a host plant by these two species (Kircher et al., 1967; Fogleman et al., 1982).

Another chemical interaction between cacti and *Drosophila* involves the medium chain fatty acids and sterol diols present in both agria and organpipe. The presence of either of these compounds in ecologically realistic concentrations produces a drastic reduction in the viability of *D. nigrospiracula* larvae (Fogleman et al., 1986). Thus, agria and organpipe necroses are not suitable substrates for this species.

Investigations into the chemical interactions between the cacti and the *Drosophila* have clearly demonstrated the important role that stem chemistry plays in host plant utilization. Approximately 60% of all possible combinations of cactus species and *Drosophila* which do not occur in nature are exclusions due primarily to chemistry. Despite the fact that the endemic *Drosophila* exhibit high degrees of behavioral specificity for their host plants, the chemical factors in host plant utilization are still important since they indicate the selection pressures which currently act to maintain the specificities or which historically acted to produce them.

YEAST-*DROSOPHILA* INTERACTIONS

It is well known that *Drosophila* larvae derive nutritional benefits from yeasts (Sang, 1956, 1978). However, almost any yeast is sufficient for growth and development of *Drosophila* larvae in the laboratory (Wagner, 1944, 1949), and in several studies, bacteria growing in the natural substrate are nutritionally sufficient (Robertson et al., 1968; Starmer, 1982a; Vacek, 1982). If coadaptations between *Drosophila* and associated yeasts have occurred, it must therefore be manifested in terms other than nutritional sufficiency.

Investigations on the effects of organpipe cactus chemical constituents on the larvae of *D. mojavensis* have shown the medium chain fatty acid and sterol diol components to be either lethal (Fogleman et al., 1985) or to slow development and reduce adult size (Starmer, 1982a). Because the medium-chain-length fatty acids of organpipe cactus are bound as esters, the realization of this detrimental effect requires hydrolysis during the decay process. Experiments (Starmer, 1982a) have shown that by inoculating fresh organpipe tissue with a bacterium (*Erwinia carnegieana*) and various cactus yeasts, *D. mojavensis* larvae develop faster and attain larger sizes if the yeast present has lipolytic activity (i.e., *Candida ingens* or *Pichia mexicana*). If the bacterium is not included and only crude lipids (with fatty acids as monoesters) are added to a complete medium, there are no differences in viability, development rate, or adult size

of *D. mojavensis* among yeast treatments. Furthermore, if the medium chain fatty acids are added into a complete medium with the yeast *C. ingens*, the fly is partially relieved of the toxic effect.

In summary, the experimental evidence indicates that the lipolytic yeast *C. ingens* can provide benefits to *D. mojavensis* larvae when the unusual lipids of organpipe tissue are hydrolyzed by other microorganisms. The faster developing and larger animals are then more likely to distribute *C. ingens* to other habitats, increasing the frequency of *C. ingens* in the organpipe yeast community. However, *C. ingens* is also found commonly in other cactus rots which do not contain unusual or toxic lipids. It is therefore possible that the production of extracellular lipases by *C. ingens* is irrelevant or may serve other functions in the cactus–*Drosophila*–microorganism system.

Other compounds which are not present in fresh cactus but appear during the decay process may also play a role in the coadaptive process. Decaying *Stenocereus* species are somewhat unusual in that they often produce volatiles such as 2-propanol and acetone (Heed, 1978; Vacek, 1979; Fogleman, 1982). These volatiles at moderate to high concentrations can be toxic to *Drosophila* adults and larvae of several species (David and Bocquet, 1975; Argues and Duarte, 1980; Daggard, 1981; Batterham et al., 1982). However, at lower concentrations, adults can benefit in terms of longevity when the volatile 2-propanol is present in the atmosphere (Batterham, et al., 1982; Sampsell and Latham, 1984). This benefit appears to be diet dependent in *D. mojavensis* since nonaxenic adults do not show comparable longevity as when tested under axenic conditions (Batterham et al., 1982). Controlled experiments utilizing known yeasts or other microorganisms have not yet been conducted with adults. However, experiments with larvae have domonstrated that common cactus yeasts, *Candida sonorensis* and *Cryptococcus cereanus*, which can tolerate and metabolize 2-propanol, provide benefits to three *Drosophila* species in the presence of 2-propanol as compared to another common cactus-associated yeast, *Pichia cactophila*, which has less tolerance and cannot metabolize 2-propanol (Starmer et al., 1986).

YEAST-YEAST INTERACTIONS AND YEAST COMMUNITY-*DROSOPHILA* INTERACTIONS

One perplexing observation in work on nutritional benefits of particular yeast to larvae is that sometimes the yeast of choice does not provide the best nutrition (Lindsay, 1958; Cooper, 1959; Ali and El-Helw, 1974). Given that yeasts rarely occur as monocultures in their natural habitats, it is thus reasonable to postulate that yeast–yeast interactions may be important in the nutrition of the *Drosophila* which might vector them.

Benjamin Metcalf (Syracuse University) has carried out a series of exper-

iments designed to answer the question: are yeast–yeast interactions important to the yeasts and flies? These experiments were conducted by seeding various numbers (0, 25, 50, 75) of axenic *D. mojavensis* first-instar larvae on sterile agria cactus tissue (10 g) inoculated with the bacterium *Erwinia carnegieana* in conjunction with given numbers (10^4 cells) of monocultures and most possible bicultures of five common agria cactus yeasts (*P. cactophila*, *C. sonorensis*, *Cr. cereanus*, *P. amethionina* var. *amethionina*, and *C. ingens*). Observations were then made on numbers of viable yeasts present at sequential time periods (0.5, 1, 3, 5, 7, and 11 days) as well as the percent emergence (viability) and size (thorax length) of adult *D. mojavensis* from treatment vials. Viable yeasts numbers were determined by removing small (approximately 0.1 g) amounts of decaying tissue and then dilution plating on complete or selective media (for bicultures) and growing at 25°C until colonies appeared. The initial growth rate (r) and carrying capacity (K) of each yeast was determined by fitting the observations (using nonlinear least squares) to the logistic growth curve. Coefficients of determination for these fits exceeded 0.90, and thus the logistic equation was a food predictor of yeast growth dynamics.

This experiment was replicated three times so that statistical comparisons could be conducted on yeast growth rates, yeast carrying capacity, fly viability, and size. These comparisons allow for determination of yeast–yeast interactions with and without *Drosophila* larvae present and also allow for comparisons of monoculture versus biculture effects on the fly. Tables 3 and 4 summarize the results for yeast effects on yeasts at various larval densities. It appears that the presence of larvae does not change the pattern of yeast effects on the initial growth rate of other yeasts (Table 3). The pattern is clear; yeasts of this community, in general, increase one another's growth rates, regardless of the presence of larvae.

The pattern for carrying capacity is qualitatively different (Table 4). When no larvae are present all yeast–yeast effects are positive, whereas when larvae are present various negative and positive–negative interactions appear. If one utilizes May's (1974) criteria for qualitative stability of communities, those yeast communities with larvae are qualitatively stable while those without larvae are unstable. These results are consistent with the findings of Heithaus et al. (1980), that the addition of a predator can lead to stable equilibrium for systems involving mutualism. Furthermore, analysis of several models of mutualism (Wolin and Lawlor, 1984; Addicott, 1979) indicates that mutualism that increases r, enhances stability. Because some of the bicultures were not carried out, the validity of this conclusion is not without question.

The results for yeast effects (monoculture vs. biculture) on thorax size and viability are depicted in Figures 1 and 2. The points on the graph in Figure 1 represent the average size of adults (sex and density separate) reared from each monoculture plotted against the size of adults from the corresponding biculture. It is apparent from Figure 1 that adults reared from bicultures are about the

culture yeast effects on *Drosophila* are compelling evidence for community coadaptation of the yeasts with respect to their fly vector. Members of the yeast community of agria cactus tend to facilitate one another's initial growth and, in the presence of larvae, experience competitive interactions which are stabilizing. In turn, the mixed cultures of yeasts provide viability benefits to the *Drosophila* and thus increase the likelihood of being transported to a new habitat.

The effects of monocultures and bicultures of yeast on *D. mojavensis* larvae growing in decaying agria cactus tissue has been demonstrated in another cactus–fly system. In this case, *D. buzzatii*, which breeds in decaying *Opuntia stricta* cladodes, where these species have been introduced in Australia, were

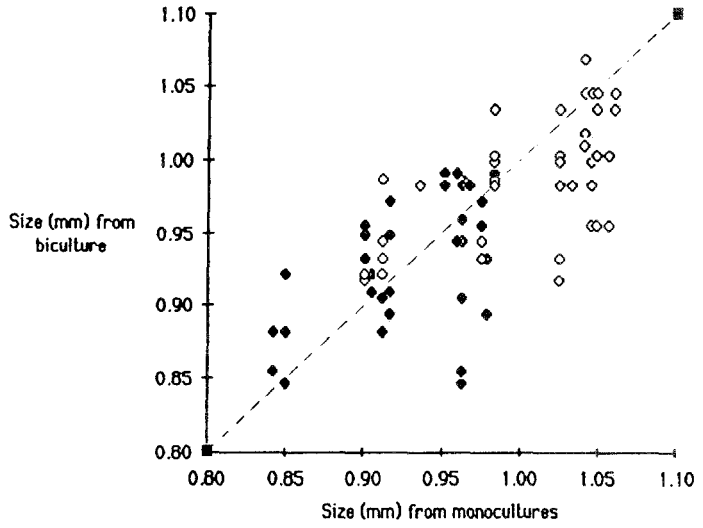

FIG. 1. Average thorax size (mm) of adult *D. mojavensis* reared from bicultures of yeasts plotted against the size of adults reared from each corresponding monoculture. Males are filled diamonds, while females are open.

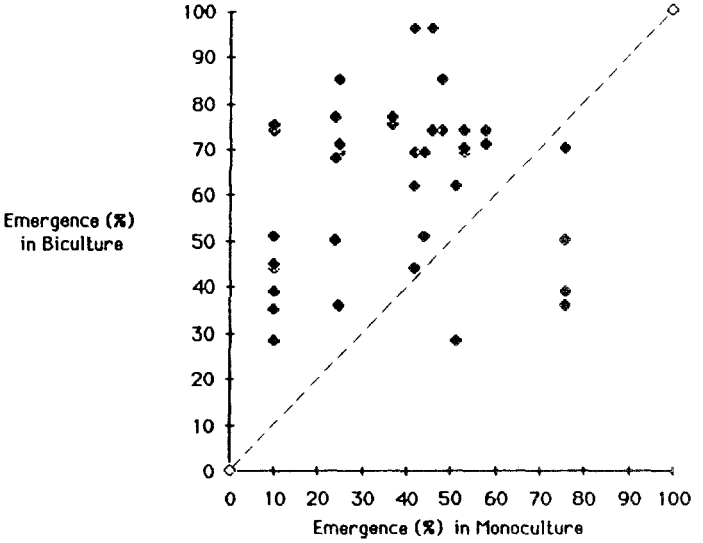

FIG. 2. Average emergence (%) of *D. mojavensis* larvae grown on bicultures of yeasts plotted against the emergence of larvae from each corresponding monoculture.

utilized. The yeasts associated with *O. stricta* rots (Barker et al., 1983) are similar to those found in columnar cacti. However, some species (e.g., *Clavispora* sp. "O") are more common in *O. stricta* necroses. Experiments were designed to measure the effects of monocultures and bicultures of four common yeasts (*P. cactophila*, *C. sonorensis*, *Clavispora* sp. "O," and *P. amethionina* var. *amethionina*) on the growth and development of three *Adh*-1 genotypes of *D. buzzatii*. Experiments were conducted by seeding 40 axenic first-instar larvae (10 *Adh*-1^b/*Adh*-1^b:20 *Adh*-1^b/*Adh*-1^c:10 *Adh*-1^c/*Adh*-1^c) onto 5 g of sterile, homogenized *O. stricta* cladode tissue in 30-ml vials. Ten yeast treatments (four monocultures and all six possible bicultures) were applied by inoculating 50 μl of an approximately 10^5 cells/ml suspension of each yeast. Bicultures received 25 μl of each suspension. Each treatment was replicated five times and incubated at 25°C. Adult sex, genotype, thorax size, and development time

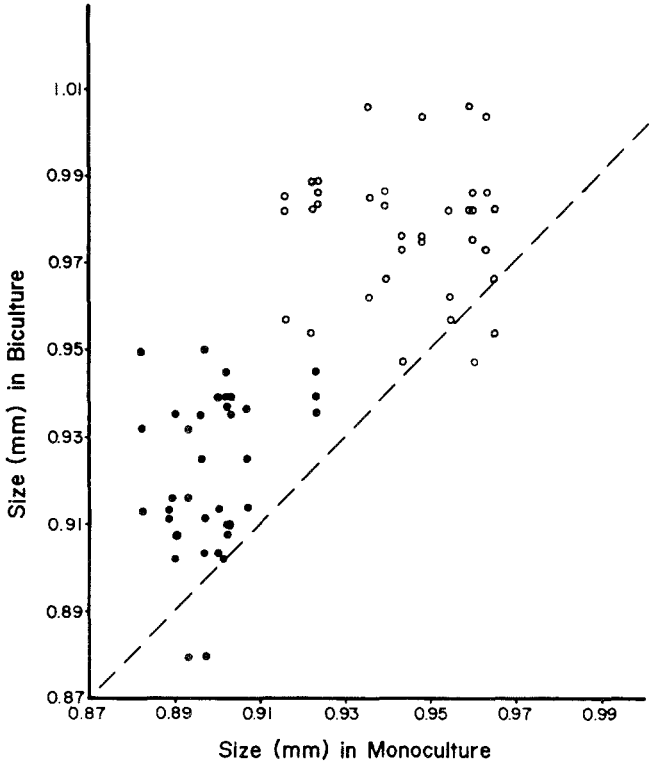

FIG. 3. Thorax length (mm) of *D. buzzatii* adults which grew as larvae on monocultures and all possible bicultures of four yeast species. Each point represents a monoculture against each biculture it is a member of for each *Adh*-1 genotype and each sex (female = ○) (male = ●) averaged over all animals of five replicate vials.

were observed. Because *Adh*-1 genotypic effects are not of interest here and genotype by yeast interactions were not statistically significant, we will only present the results for flies irrespective of genotype.

A priori contrasts of yeast monocultures versus bicultures showed highly significant effects for development time ($F = 44.8$, df = 237,6) and thorax length ($F = 14.1$, df = 237,6) but no significant effect on viability ($F = 1.7$, df = 120,6). These contrasts are depicted in Figures 3–5. It is apparent from these figures that larvae develop faster and reach larger sizes on bicultures as compared to monocultures. Once again, although for different reasons, mixed cultures of yeasts provide benefits to the *Drosophila* and thus increase the likelihood of being transported to a new habitat.

SUMMARY

The mutualistic interactions of cactophilic *Drosophila* and their associated yeasts are viewed as a system which has evolved within the framework of the host cactus stem chemistry. Because the *Drosophila*-yeast system is saphro-

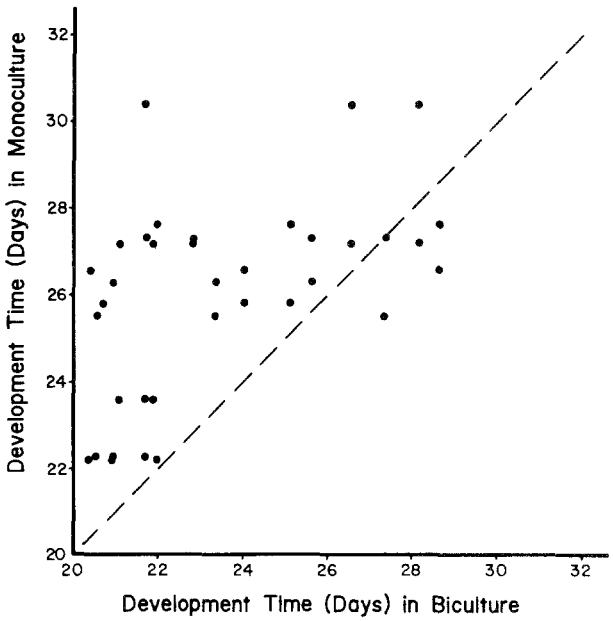

FIG. 4. Development time (days) of *D. buzzatii* larvae grown in monoculture and all possible bicultures of four yeast species. Each point represents a monoculture and the biculture combination it is a member of for each *Adh*-1 genotype averaged over five replicate vials.

phytic, their responses are not thought to directly influence the evolution of the host.

Host cactus stem chemistry appears to play an important role in determining where cactophilic *Drosophila* breed and feed. Several chemicals have been identified as being important: (1) sterols of senita cactus are required in the diet of *D. pachea*, (2) alkaloids of senita cactus are toxic to other *Drosophila* species, and (3) medium chain fatty acids and sterol diols of *Stenocereus* species are detrimental to *D. nigrospiracula* and thus restrict this species from utilizing organpipe and agria cactus.

Cactus chemistry appears to have a limited role in directly determining the distribution of cactus-specific yeasts, even though the yeast community composition does correspond to chemical groupings of the host cacti. Those effects which are known are due to triterpene glycosides and unusual lipids of *Stenocereus* species. These compounds can restrict yeast growth and thus eliminate some species of cactus yeasts from the *Stenocereus* habitats.

Drosophila–yeast interactions are viewed as mutualistic and can take the form of (1) benefits to the *Drosophila* by either direct nutritional gains (viability, increased size, or longevity) or indirect gains due to detoxification of harmful chemicals produced during decay of the host stem tissue (e.g., *C. ingens* can metabolize toxic medium chain fatty acids of organpipe cactus) and (2)

benefits to the yeast in the form of increased likelihood of transmission to new habitats.

Experiments on yeast–yeast interactions in decaying agria cactus provide compelling evidence that the yeast community is coadapted. This coadaptation takes the form of (1) mutualistic increases in growth rates, which is independent of the presence of *Drosophila* larvae, and (2) stabilizing competitive interactions when growth reaches carrying capacity. This latter form is dependent on larval activity and results in benefits to the viability (*D. mojavensis* on agria cactus) or increases in size and faster development (*D. buzzatii* on *Opuntia stricta*) when fed bicultures or resident yeasts.

Given that *Drosophila* may be the primary vector of the yeasts, any yeast or combination of yeasts which serve to benefit the *Drosophila* (greater viability, larger size, or faster development) will also benefit the yeast. In this sense the yeast community is probably coadapted with respect to its *Drosophila* vector.

Acknowledgments—We are grateful to William B. Heed and Herman J. Phaff for their ideas on and useful contributions to the subjects discussed here. We also thank Virginia Aberdeen, Phil Ganter, and Charlotte Stephenson for their capable assistance and support. CELLULOSE DIGESTION IN *Monochamus marmorator* Kby. (COLEOPTERA: CERAMBYCIDAE): Role of Acquired Fungal Enzymes

JEROME J. KUKOR and MICHAEL M. MARTIN

Division of Biological Science
University of Michigan
Ann Arbor, Michigan 48109-1048

(Received June 26, 1985; accepted August 13, 1985)

Abstract—Larvae of the balsam fir sawyer, *Monochamus marmorator* Kby. (Coleoptera, Cerambycidae), contain midgut digestive enzymes active against hemicellulose and cellulose. Cellulases from larvae fed on balsam fir wood infected with the fungus, *Trichoderma harzianum* Rifai (Deuteromycetes, Moniliales, Moniliaceae), were found to be identical to those of the cellulase complex produced by this fungus when compared using chromatography, electrophoresis, and isofocusing. When larvae are maintained on a fungus-free diet, their midgut fluids lack cellulolytic activity, and they are unable to digest cellulose. Cellulolytic capacity can be restored by feeding the larvae wood permeated by fungi. We conclude that the enzymes which enable *M. marmorator* larvae to digest cellulose are not produced by the larvae. Instead, the larvae acquire the capacity to digest cellulose by ingesting active fungal cellulases while feeding in fungus-infected wood.

Key Words—Cellulases, xylophagy, cellulolysis, acquired enzymes, nutritional ecology, *Monochamus marmorator*, *Trichoderma harzianum*, Coleoptera, Cerambycidae, Moniliaceae.

INTRODUCTION

The ability of wood-boring larvae of cerambycid beetles to utilize the structural polysaccharides in their food has been the subject of many investigations dating back to the early 1900s (Linsley, 1959). Cellulolytic enzymes have been detected in the gut fluids of many species (Dajoz, 1968; Chararas et al., 1971; Chararas, 1981), and approximate digestibility measurements have demonstrated that between 12 and 57% of ingested cellulose may be assimilated (Martin, 1983). At one time it was believed that intracellular symbionts might play

0098-0331/86/0500-1057$05.00/0

a role in cellulose digestion in these beetles (Buchner, 1928; Campbell, 1929; Uvarov, 1929), but this possibility has failed to receive confirmation (Mansour and Mansour-Bek, 1934a, b;, Parkin, 1940). The inability to demonstrate symbiont-mediated cellulolysis has led to the assumption that cerambycid larvae produce all of the enzymes necessary for cellulose digestion, although there is little evidence to support this assumption.

Cellulose digestion is generally accomplished by a collection of enzymes (the cellulase complex) consisting of three major classes of hydrolases: endoglucanases (C_x-cellulases), cellobiohydrolases (C_1-cellulases), and β-glucosidases (e.g., cellobiases) (Martin, 1983). In no study of any species of cerambycid beetle has compelling evidence been presented that all of the requisite enzymes of the cellulase complex are produced by the larvae themselves.

We have studied cellulose digestion in the balsam fir sawyer, *Monochamus marmorator* Kby. (Cerambycidae, Lamiinae). Larvae of this species tunnel extensively through the wood of moribund balsam fir (*Abies balsamea*) stems, frequently passing through patches of wood decayed by white rot fungi. The objective of this study was to determine whether the capacity of *M. marmorator* larvae to digest cellulose is due to fungal enzymes ingested by the larvae during feeding. Our research on *M. marmorator* is part of ongoing investigations into the roles of acquired fungal enzymes in the digestive processes and nutritional ecology of xylophagous insects (Martin, 1984).

METHODS AND MATERIALS

Collection and Maintenance of Larvae. M. marmorator larvae were collected from moribund stems of balsam fir at the University of Michigan Biological Station, Cheboygan County, Michigan. Larvae were maintained in the laboratory at 22°C in 150-ml wide-mouth polyethylene jars containing decayed balsam fir wood chips (BFWC), kept at a 30–50% moisture content. In experiments that involved larvae reared on a fungus-free medium, 40 *M. marmorator* larvae were reared for two to four weeks in 25-ml plastic cups containing small blocks of a wheat germ–casein artificial diet (Tobacco Hornworm Diet, Bio-Serv). Larvae have been successfully maintained on this diet for over nine months.

Isolation and Maintenance of Fungi. Fungi associated with the galleries of *M. marmorator* larvae in balsam fir stems were isolated by placing small wood chips, removed aseptically from the wood adjacent to larval galleries, onto plates of 1.5% malt extract agar, 4% potato dextrose agar, and 5% Czapek agar (Difco).

For the production and harvest of cellulase, *Trichoderma harzianum* was grown in 7-liter batches on a medium of the following composition (ingredients given in grams per liter): microcrystalline cellulose (Polysciences), 5.0; $(NH_4)_2SO_4$, 2.0; KH_2PO_4, 1.7; $K_2HPO_4 \cdot 3H_2O$, 0.5; $MgSO_4 \cdot 7H_2O$, 0.5;

$CaCl_2 \cdot 2H_2O$, 0.05; H_3BO_3, 2×10^{-4}; $CuSO_4 \cdot 5H_2O$, 3×10^{-4}; $ZnSO_4 \cdot 7H_2O$, 4×10^{-3}; $MnCl_2 \cdot 4H_2O$, 1×10^{-3}; $FeSO_4 \cdot 7H_2O$, 1×10^{-3}; $CoCl_2 \cdot 6H_2O$, 3×10^{-4}; $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, 2×10^{-4}. Incubation was on a rotary shaker at 22°C for two weeks.

Extract Preparation and Enzyme Assays. Midguts were dissected from *M. marmorator* larvae as described by Martin et al. (1980). Since the pH of the midgut fluid ranged between 6.2 and 6.9, extracts were prepared in 50 m*M* Bis-Tris-HCl buffer [bis(2-hydroxyethyl)imino-tris(hydroxymethyl)methane] (Sigma), pH 6.5. For enzyme assays, the pooled midguts from one to three larvae were prepared as described in Martin et al. (1981). For purification of the cellulase enzyme complex from *M. marmorator* gut fluid, the midguts from 30 larvae were pooled.

Total activity of the cellulase complex was determined by incubating 0.5 ml of suitably diluted extract with 0.5 ml of 0.5% microcrystalline cellulose suspended in 0.1 M sodium acetate buffer, pH 5.0, at 45°C for 2 hr. Carboxymethylcellulase and xylanase activity were determined with 0.5% carboxymethylcellulose, sodium salt (Sigma), or 0.5% larchwood xylan (United States Biochemical), in sodium acetate buffer, with incubation at 45°C for 1 hr. The incubation was terminated by the addition of 1.0 ml of alkaline dinitrosalicylic acid (DNSA) reagent (Bernfeld, 1955). Insoluble cellulose and xylan were removed by centrifugation at 3500*g* for 1 min. The supernatant solution was then heated at 110°C for 8 min, diluted with 1.5 ml of water, and the absorbance at 540 nm determined. Enzyme/reagent blanks were prepared using heat-denatured aliquots of extract.

Cellulase Purification and Analysis. The cellulase enzyme complex from *T. harzianum* was purified from 28 liters of two-week-old culture fluid as previously described (Kukor and Martin, 1983). The cellulase complex from *M. marmorator* larvae reared on *T. harzianum*-infected BFWC was prepared from the pooled midguts of 30 larvae, and the cellulase from artificial diet-reared larvae was prepared from the pooled midguts of 12 animals.

M. marmorator cellulase purification was achieved by an initial ammonium sulfate fractionation, with all of the cellulase activity contained in the 26–50% S ammonium sulfate fraction. Precipitated proteins were collected by centrifugation, dissolved in Bis-Tris buffer (pH 6.5), and the residual ammonium sulfate was removed by diafiltration in a stirred cell. Total protein was estimated by the dye-binding method of Bradford (1976).

The *Trichoderma* and *Monochamus* enzyme preparations were fractionated by high-resolution anion-exchange chromatography using a fast protein liquid chromatography (FPLC) system (Pharmacia). FPLC separations were carried out at a flow rate of 1.0 ml/min with an HR5/5 MonoQ column equilibrated with 50 mM Bis-Tris buffer (pH 6.5) containing 10 mM KCl. Proteins were eluted with a 10–500 mM linear KCl gradient, and 1.0-ml fractions were collected.

Discontinuous-SDS-gradient gel electrophoresis was performed on 7.5–15% polyacrylamide gels using the system of Neville, as modified by Piccioni et al. (1982). Gels were stained with brilliant blue R250 (Sigma). Analytical isoelectric focusing was performed on ultrathin polyacrylamide gels (Servalyt Precotes, Serva Fine Biochemicals), as previously described (Kukor and Martin, 1983).

[^{14}C]*Cellulose Utilization.* For [^{14}C]cellulose utilization experiments, individual larvae were placed in stoppered 25-ml scintillation vials. The bottom of each vial was coated with a thin layer of 2% agar in 0.1 N HCl, which provided moisture for the larva while it was feeding on the labeled cellulose. The headspace in each vial was periodically flushed with air at a flow rate of 30 ml/min for 15 min, and the $^{14}CO_2$ in the exit gas was bubbled through phenethylamine (1 : 1 v/v in MeOH) in ACS counting scintillant (Amersham). The trapping efficiency of this system was 90%.

Each animal was provided with a 100-mg food tablet made from α-cellulose fiber (Sigma) amended with 5% (w/w) [U-^{14}C]cellulose (ICN). The labeled cellulose was repurified before use according to the procedure of Rapson (1963), to ensure removal of any water- or alkali-soluble noncellulosic contaminants that might have been present. The specific activity of labeled cellulose in each food tablet was calculated from the amount of radioactivity in weighed portions of the tablets, which were digested in 67% sulfuric acid and diluted 10-fold with water before mixing with counting scintillant.

Counting efficiency was estimated by the H-number method or by internal standards, as appropriate.

Assimilation Efficiencies. For approximate digestibility determinations, larvae from two groups (those reared for four weeks on *T. harzianum*-infected BFWC and those reared for two weeks on artificial diet followed by two weeks on autoclaved BFWC) were placed in individual 150-ml polyethylene bottles containing 4–5 g (wet weight) of autoclaved BFWC. The jars, covered with Saran wrap, were incubated at 22°C, and the diet was kept at 30–50% moisture content by periodic addition of sterile distilled water. After seven days, uneaten food and fecal pellets were separated using a series of standard mesh sieves. Food fragments were retained on a 1-mm mesh screen, whereas the fecal pellets were collected on 0.5- and 0.4-mm mesh screens. The few small food fragments that passed onto the 0.5-mm and 0.4-mm mesh screens could be separated from the spherical fecal pellets by allowing the pellets to roll down an inclined metal pan subjected to moderate vibration by tapping with a pencil. Approximate digestibility was determined on a dry weight basis as AD (%) = 100 (food ingested − feces)/food ingested.

The cellulose content of BFWC and *M. marmorator* fecal pellets was estimated by the procedure of Updegraff (1969).

RESULTS

Digestive Enzymes of M. marmorator. The digestive fluids from the midguts of *M. marmorator* larvae, either collected from their natural galleries in balsam fir stems or cultured in the laboratory on balsam fir wood chips permeated by mycelium of the fungus, *T. harzianum*, contain enzymes that enable them to digest both cellulose and hemicellulose (Table 1). Activity toward microcrystalline cellulose indicates the presence of the entire cellulase complex required to degrade native cellulose, while activity toward carboxymethylcellulose (CMC) indicates the presence of endoglucanases (C_x-cellulases) which attack soluble degradation products of cellulose or amorphous regions of the predominantly crystalline structure of native cellulose. Activity toward larchwood xylan indicates the presence of enzymes required to degrade arabino-4-O-methylglucuronoxylans, which are a major class of hemicelluloses present in both hardwoods and softwoods. Although the assays were routinely conducted at a pH of 5.5, the cellulolytic and hemicellulolytic enzymes exhibit significant activity in the pH range 6.2–6.9 observed in the midgut fluids of these beetle larvae. Since cellulose and arabino-4-O-methylglucuronoxylans make up 42 and 9%, respectively, of the dry weight of extractive-free balsam fir wood (Côté, 1977), the presence of cellulases and xylanases in the gut fluid of *M. marmorator* larvae is of obvious adaptive value.

In contrast to larvae from natural galleries or reared on fungus-infected wood, larvae fed for two weeks on a fungus-free artificial diet have gut fluid in which activity toward microcrystalline cellulose is barely detectable (Table 1). CMCase and xylanase activity is still evident, albeit at somewhat reduced levels, in the larvae from the fungus-free diet. When cellulase-free larvae are transferred from the artificial diet to autoclaved fungus-infected balsam fir wood chips, they do not regain the enzymes of the cellulase complex. This finding demonstrates that the cellulolytic activity of the gut fluid of larvae reared on normal fungus-infected wood is not due to enzymes of insect origin, the secretion of which is induced by heat-stable components of the normal diet, but instead suggests that cellulolytic activity might be due to ingested fungal enzymes. CMCase and xylanase activity is increased in larvae transferred to autoclaved, fungus-infected wood.

Fungi Associated with M. marmorator *Galleries.* The galleries of middle- to late-instar *M. marmorator* larvae often pass through regions of wood decayed by white rot fungi. Although we have not conducted an exhaustive study to characterize all of the fungi associated with *M. marmorator* galleries, we did establish that *Hirschioporus abietinus*, *Stereum sanguinolentum*, *Amylostereum chailletii*, and *Trichoderma harzianum* are readily isolated from the wood adjacent to larval galleries. *T. harzianum* was the species most frequently isolated.

TABLE 1. ENZYMATIC ACTIVITY TOWARD CELLULOSE, CARBOXYMETHYLCELLULOSE, AND XYLAN OF EXTRACTS OF MIDGUTS OF *Monochamus marmorator* LARVAE, BALSAM FIR WOOD CHIPS (BFWC) AND THE FUNGUS, *Trichoderma harzianum*

Source of extract	Enzymatic activity [units/mg (dry weight) of dissolved solids in extract][a]

M. marmorator larvae			
Collected from natural galleries in balsam fir	0.55 ± 0.04 (5)	10.8 ± 0.7 (5)	22.5 ± 2.4 (5)
Cultured for 2 weeks on BFWC permeated by *T. harzianum*	0.45 ± 0.08 (10)	14.7 ± 0.7 (12)	17.7 ± 1.5 (12)
Cultured for 2 weeks on artificial diet	0.01 ± 0.005 (6)	8.0 ± 2.8 (6)	9.3 ± 3.4 (6)
Cultured for 2 weeks on artificial diet, then for 2 weeks on autoclaved, *Trichoderma*-infected BFWC	0.01 ± 0.005 (3)	16.4 ± 4.9 (3)	15.2 ± 5.1 (3)
BFWC			
Sterile	0.0 (1)	0.0 (1)	0.0 (1)
Permeated by *T. harzianum*	0.40 ± 0.01 (3)	1.5 ± 0.5 (3)	6.8 ± 2.4 (3)
Culture fluid from 2-week-old axenic culture of *T. harzianum*	2.3 ± 0.7 (3)	13.3 ± 6.6 (2)	8.2 (1)

[a] A unit of activity is the amount of enzyme required to liberate 1 μmol of maltose equivalents per hour under the conditions of the assay (45°C, pH 5.0, incubation volume 1.0 ml). Each value is the mean ± standard error of the mean for the number of replicates in parenthesis.

All of these fungi are cellulose digesters and hence are potential sources of cellulolytic enzymes. In agreement with the hypothesis that the beetle larvae are acquiring a capacity to digest cellulose through the ingestion of fungal cellulases, we demonstrated activity toward microcrystalline cellulose, carboxymethylcellulose, and larchwood xylan in an extract of balsam fir wood permeated by the mycelium of *T. harzianum*, as well as in the culture fluid of *T. harzianum* grown on microcrystalline cellulose in a defined medium (Table 1).

Purification and Comparison of Monochamus *and* Trichoderma *Cellulases.* When subjected to high-resolution anion-exchange chromatography (FPLC), 84% of the total activity toward microcrystalline cellulose in the gut fluid of larvae fed *T. harzianum*-infected wood eluted at 0.15 M KCl in a single large protein peak (Figure 1A). This peak was absent in the gut fluid of larvae cultured sequentially on an artificial diet and then on autoclaved *T. harzianum*-infected balsam fir wood chips (Figure 1B), although there was some activity toward carboxymethylcellulose and xylan associated with the various protein peaks in the elution profile. When the culture fluid from *T. harzianum* was subjected to a similar separation, a large protein peak eluted at 0.15 M KCl which accounted for 67% of the total activity toward microcrystalline cellulose (Figure 1C).

A comparison of the major cellulase peak from the insect and fungal preparations was made by discontinuous, denaturing-gel electrophoresis and isoelectric focusing. On an SDS-gradient gel, the FPLC cellulase fractions from *T. harzianum* culture fluid and from the gut extract of *M. marmorator* reared on *T. harzianum*-infected balsam fir wood chips show identical patterns of protein

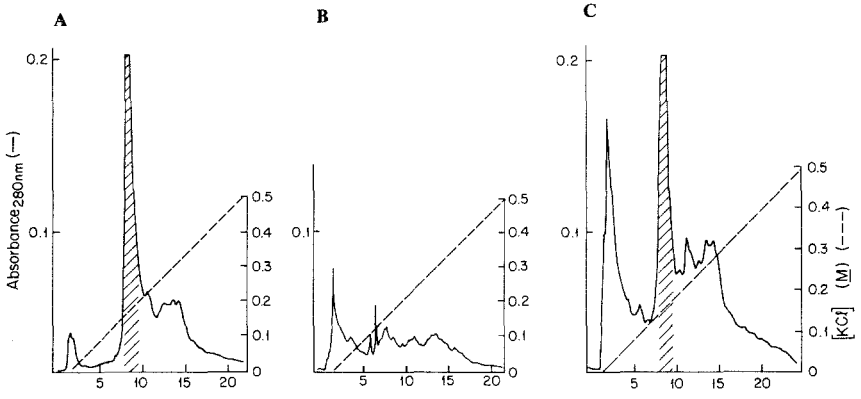

FIG. 1. FPLC elution profiles of *M. marmorator* midgut extracts and *T. harzianum* culture fluid. (A) *M. marmorator* reared on *T. harzianum*-infected BFWC. (B) *M. marmorator* reared on artificial diet and then on autoclaved *T. harzianum*-infected BFWC. (C) Fluid from an axenic culture of *T. harzianum* grown on a defined medium. Crosshatching indicates fractions with most of the activity against microcrystalline cellulose.

FIG. 2. SDS-gradient gel (7.5–15%) of the major FPLC cellulase peaks from *M. marmorator* reared on *T. harzianum*-infected BFWC (M), and culture fluid of *T. harzianum* grown on a defined medium (T). Apparent molecular masses of the major bands: 83.9, 80.0, 70.0, and 17.9 kD.

bands (Figure 2). The four major bands have apparent molecular masses of 83.9, 80.0, 70.0, and 17.9 kilodaltons. In an analytical isoelectric focusing gel (Figure 3), the fungal and insect FPLC cellulase fractions also have identical patterns, appearing as a broad band focused between pH 4.73 and 5.07, with the highest density of protein at pH 5.0. These comparisons of fungal and insect cellulases demonstrate that the enzymes responsible for activity toward microcrystalline cellulose in the digestive fluids of *M. marmorator* larvae reared on *T. harzianum*-infected wood are identical to the enzymes produced by this same fungus grown in a defined medium, and they confirm our hypothesis that the insects acquire essential digestive enzymes by the ingestion of fungi or fungal enzymes present in wood they consume.

[^{14}C]*Cellulose Utilization.* In order to demonstrate the importance of ingested fungal enzymes to cellulose digestion, we fed larvae [U-^{14}C]cellulose

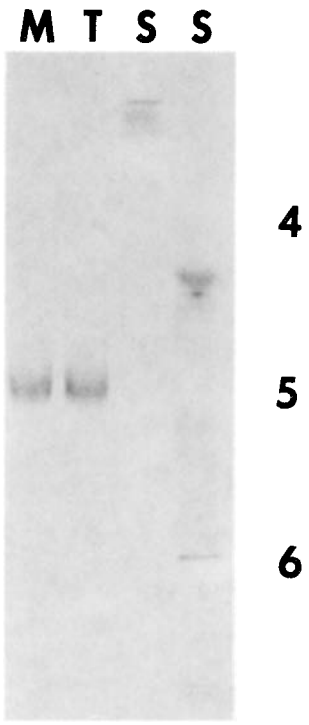

FIG. 3. Analytical isoelectric focusing on an ultrathin polyacrylamide gel (Serva Precote, nominal pH range 4–6) of the major FPLC cellulase peaks from *M. marmorator* reared on *T. harzianum*-infected BFWC (M), culture fluid of *T. harzianum* grown on a defined medium (T), and isoelectric point marker proteins (S). The marker proteins used and their corresponding pI values are pepsinogen, 2.80; amyloglucosidase, 3.50; glucose oxidase, 4.15; β-lactoglobulin, 5.34; conalbumin, 5.9.

and determined the percentage of ^{14}C from the food incorporated into respired carbon dioxide and body tissue (Table 2). The production of significant amounts of ^{14}C-labeled carbon dioxide by larvae reared on a fungus-containing diet (larvae 1, 2, 3) and the incorporation of ^{14}C into the fat body and integument (larva 1) clearly reveal the ability of these insects to digest cellulose, while the absence of any labeled carbon dioxide in the respiratory gases from larvae reared on a fungus-free diet (larvae 4, 5, 6, 7) shows that they are unable to digest cellulose. In this set of experiments it was also demonstrated that a larva that had lost its acquired cellulases by maintenance on a fungus-free diet for two weeks (larva 5) regained cellulolytic capacity after only 24 hr on a diet of fungus-infected wood. A second larva (larva 6) did not regain its cellulolytic capacity after feeding for 24 hr on fungus-infected wood that had been autoclaved in order to kill the fungus and deactivate any fungal enzymes that had been secreted into

TABLE 2. UTILIZATION OF [^{14}C]CELLULOSE BY *Monochamus marmorator* LARVAE CULTURED ON FUNGUS-CONTAINING AND FUNGUS-FREE DIETS

TABLE 3. APPROXIMATE DIGESTIBILITY OF AUTOCLAVED, FUNGUS-INFECTED BALSAM FIR WOOD CHIPS (BFWC) AND CELLULOSE IN BFWC BY *Monochamus marmorator* LARVAE

Larval diet immediately prior to experiment	Approximate digestibility (%)[a]	
	BFWC	Cellulose in BFWC
Four weeks on BFWC permeated by live mycelium of *Trichoderma harzianum*	52.2 ± 1.9 (4)	26.7 ± 4.0 (4)
Two weeks on artificial diet followed by 2 weeks on autoclaved, *Trichoderma*-infected BFWC	20.8 ± 5.4 (3)	3.7 ± 2.6 (2)

[a] Each value is the mean ± standard error of the mean for the number of replicates given in parenthesis. Duration of experiment was one week.

the substrate. These experiments confirm that larvae can digest cellulose only after they have fed on a substrate that contains active fungal enzymes.

Assimilation Efficiencies. When reared on fungus-infected wood, *M. marmorator* larvae assimilated over 50% of the dry matter and 25% of the cellulose in their food (Table 3). By contrast, larvae reared on a fungus-free artificial diet assimilated only 21% of the dry matter of balsam fir wood chips and a negligible portion of the cellulose in balsam fir wood (Table 3). These results clearly demonstrate that acquired fungal cellulases make a significant quantitative contribution to the ability of *M. marmorator* larvae to utilize their natural food.

DISCUSSION

In this study we have demonstrated that the ability of the larvae of *M. marmorator* to digest cellulose is due to fungal enzymes ingested by the larvae during the consumption of fungus-infected wood. The larvae do not secrete the full complement of enzymes required for cellulose digestion, and in the absence of a dietary source of fungal cellulases, they are unable to digest cellulose. The demonstration that the capacity for cellulose digestion by the larvae of this cerambycid beetle is due to the acquisition of fungal enzymes calls into question the often-stated but untested hypothesis that other xylophagous cerambycid larvae, as well as anobiid and buprestid larvae, secrete all of their own cellulases. While there is convincing evidence that many of these beetles do produce endoglucanases active against carboxymethylcellulose (Martin, 1983), there is no compelling evidence that any species secretes the entire cellulase complex, and

no evidence that rules out the possibility that cellulose digestion is mediated by ingested fungal enzymes.

The dependence upon ingested fungal enzymes to digest refractile polysaccharides has been demonstrated previously in the macrotermitine termites (Martin and Martin, 1978, 1979) and siricid woodwasps (Kukor and Martin, 1983). However, unlike the fungus-growing termites and siricid woodwasps, both of which have highly coevolved mutualistic associations with specific fungal symbionts, the cerambycid beetles are not known to maintain specific associations with particular species or strains of fungi, although cellulolytic fungi have been reported as surface contaminants on the eggs of *M. scutellatus* (Leach et al., 1937). Species of the genus *Monochamus* generally oviposit under the bark of sound timber, and the early larval instars feed in sound phloem and sapwood. It is only the later instars that expand their digestive capabilities by ingesting the enzymes of wood-rotting fungi that subsequently colonize the substrate. Finding that ingested enzymes derived from casual fungal associates play a vital role in the digestive processes of this wood-feeding beetle underscores the potential generality of a strategy for resource exploitation based upon the ingestion of microbial enzymes.

Fungal tissue plays an important role in the nutrition of a number of wood- and detritus-feeding invertebrates. Because of the chemical alteration of substrate brought about by fungi and because of the ability of fungi to concentrate nutrients, fungus-infected wood is a resource of higher nutritive quality than uninfected wood. Numerous studies of xylophagous anobiid and cerambycid beetles have shown improved performance (decreased larval mortality, increased growth rate, increased pupal weight, increased adult body size, and increased fecundity) of animals reared on fungus-infected substrate compared to fungus-free substrate (Campbell and Bryant, 1940; Fisher, 1940, 1941; Campbell, 1941, Becker, 1942, 1968; Bletchly, 1953). It is reasonable that the exploitation of ingested fungal enzymes for the digestion of refractile polysaccharides would evolve in a species with a preference for fungus-infected wood and gut conditions compatible with enzyme function. We predict that additional examples of the acquisition of digestive enzymes will be provided by further studies of the nutritional ecology of xylophagous insects.

Acknowledgments—We thank the staff of the University of Michigan Biological Station and the Matthaei Botanical Gardens for use of their facilities. Dr. Barry OConnor, University of Michigan Museum of Zoology, provided access to the museum's cerambycid collection. R. Vande-Kopple, D. Mercer, and G. Keevil assisted in the field work; and N. Alpiner assisted in the cellulase purification. Dr. C.F. Yocum instructed us in the use of his FPLC system. Dr. D.T. Wicklow, USDA, ARS, Northern Regional Research Center, Peoria, Illinois, identified our isolate of *T. harzianum*. This research was supported by NSF grant PCM-82-03537 to M.M. Martin.

(Received July 29, 1985; accepted October 23, 1985)

Abstract—Bacterial chemotaxis presents a model sensory system in which cells modulate the direction of rotation of their flagella in response to gradients of certain chemicals. The chemotactic machinery of *Escherichia coli* is currently being systematically reduced to its individual components through the accomplishments of behavioral, physical, genetic, molecular genetic, and biochemical analyses. Thirteen of the so called "MCP-related" class of chemotaxis gene products are known. Transmembrane methyl-accepting chemotaxis proteins (MCPs) are important for the chemical sensing, signal generation, and sensory adaptation processes. Soluble chemotaxis proteins relay information from these MCPs to structural components of the flagella referred to as switch proteins. Emphasis here is on the separate roles each of these groups of chemotaxis proteins perform, as well as their protein–protein relationships.

Key Words—Bacteria, chemotaxis, methyl-accepting chemotaxis proteins, molecular biology, signal transduction, switch proteins.

INTRODUCTION

Prokaryotic organisms have evolved a plethora of methods to sense and respond to each other and to their environment. For example, luminescent marine bacteria secrete small autoinducer molecules into their surroundings which, when present in sufficient concentration, induce the cells to produce light (Engebrecht and Silverman, 1984). Individual cells of the soil bacterium *Myxococcus xanthus* respond to chemical signals from one another and come together to form a fruiting body structure (Zusman, 1984). Blue-green algae respond to nitrogen

0098-0331/86/0500-1071$05.00/0

deprivation by developing specialized cellular compartments for nitrogen fixation (Golden et al., 1985). Many other prokaryotic chemical response systems also exist.

One of the most extensively studied bacterial response systems is that of chemotaxis. The chemotactic characteristics of a bacterial community often affect an entire ecosystem. Bacterial chemotaxis to oxygen in pond water may shield methane-producing bacteria from oxygen's toxic affects as well as provide carbon dioxide for the anerobic production of methane (Rosen, 1984). Soil bacteria chemotax to a wide variety of potential energy sources such as fungal propagules and plant exudates (Arora et al., 1983; Gitte et al., 1978). Marine bacteria may be attracted by coral and algal extracellular products and even rum distillery wastewater (Chet and Mitchell, 1976; Fuentes et al., 1983.). Chemotaxis is also believed to play an important role in certain human diseases, such as cholera wherein *Vibrio cholerae* must colonize the intestinal mucosa (Freter et al., 1979).

The focus for this review concerns a class of chemotaxis in *Escherichia coli* (*E. coli*) which is governed by transmembrane methylatable chemotaxis proteins (MCPs). The bulk of bacterial chemotaxis research has been performed on *E. coli* or *Salmonella typhimurium* (*S. typhimurium*). There is virtually complete functional homology among the flagellar, motility, and chemotaxis genes between these two enteric gram-negative species (Defranco et al., 1979; Kutsukake et al., 1980). Chemotaxis research on these organisms has provided an impressive array of behavioral, physical, genetic, molecular, and biochemical data. For information concerning the related subject areas of bacterial flagellar formation, energy transduction for motility, as well as additional taxis reviews, other sources are available (Silverman, 1980; Berg and Khan, 1982; Parkinson and Hazelbauer, 1983; Taylor, 1983; Macnab and Aizawa, 1984; Mizuno et al., 1984; Ordal, 1985).

BEHAVIOR

E. coli cells are 1–2 μm in length, peritrichous, and may, depending on environmental conditions, contain up to 10 flagella per cell, each approximately 10–15 μm in length (Hilmen and Simon, 1976). The regulation of the motion of the flagella governs the cells' chemotactic responsiveness. It has been conclusively demonstrated that the flagellum operates as a rotary engine with the flagellar filaments playing a passive role much like the propeller for a ship (Berg and Anderson, 1973; Silverman and Simon, 1974). This bacterial motor may rotate in either the counterclockwise or clockwise direction. Counterclockwise rotation (as viewed along the flagellum towards the cell) is typically associated with positive wave propagation of the filaments and straight swimming. In this mode the filaments are all in a stable left-handed helical conformation, and

together form a bundle of flagella which rotate in concert. During clockwise rotation, however, hydrodynamic forces induce the formation of right-handed filaments which cause the unwinding of the bundle (Macnab and Ornston, 1977). The net result is that the cell jerks about ("twiddles") until counterclockwise rotation is resumed and the flagellar bundle restored. In an isotropic environment, bacterial motility has been described as possessing a "random three-dimensional walk" which is characterized by a series of runs (the product of counterclockwise rotation), which are interrupted every 1–2 sec by twiddles (the product of clockwise rotation) (Berg and Brown, 1972).

Chemotactic behavior in *E. coli* consists of the ability to alter migration in response to gradients of chemicals. The response to attractant stimuli is a decreased probability of switching to tumbling, as well as an increased probability of switching from tumbling to smooth swimming (Khan and Macnab, 1980). The converse is true for repellent responses. These actions promote the net movement of a population of cells in a favorable direction. A diagram representing chemotactic behavior is shown in Figure 1. Because the cells do not actually modulate the angle of their turns, this is not a true taxis. Their responses have been more precisely described as klinokinesis, a biased random walk (Taylor, 1983). In addition to the movements of the cells, *E. coli* may also respond to certain attractants or repellents by increasing or decreasing the rate of its cell division, respectively (Sherman and Vorobyeva, 1983).

After the initial perception of an attractant or repellent (also called a chemoeffector), cells respond along two distinct pathways, beginning with a rapid sensory transduction or excitation phase, and followed by the adaptation phase during which the cells return to normal motility. Excitation requires approximately 0.2 sec (Segall et al., 1982; Block et al., 1982), while adaptation can be observed to last for several minutes.

E. coli can sense chemical differences of only one part in 10^4 over the length of its entire body (Dahlquist et al., 1972). How is such sensitivity achieved? Rapid mixing experiments with known chemoattractants or repellents and bacteria have shown that the chemotactic system operates as a time averaging system rather than a spatial sensory system (Macnab and Koshland, 1972). Chemoeffector information is integrated while the bacteria swim through their environment. Implied in this system is therefore some type of rudimentary memory.

che GENES, PRODUCTS, AND PRODUCT LOCATIONS

One of the advantages of studying sensory transduction in *E. coli*, especially as compared with higher organisms, has been the wealth of techniques available for genetic analysis. The study of mutants deficient in various aspects of chemotaxis has greatly aided the dissection of the individual processes in-

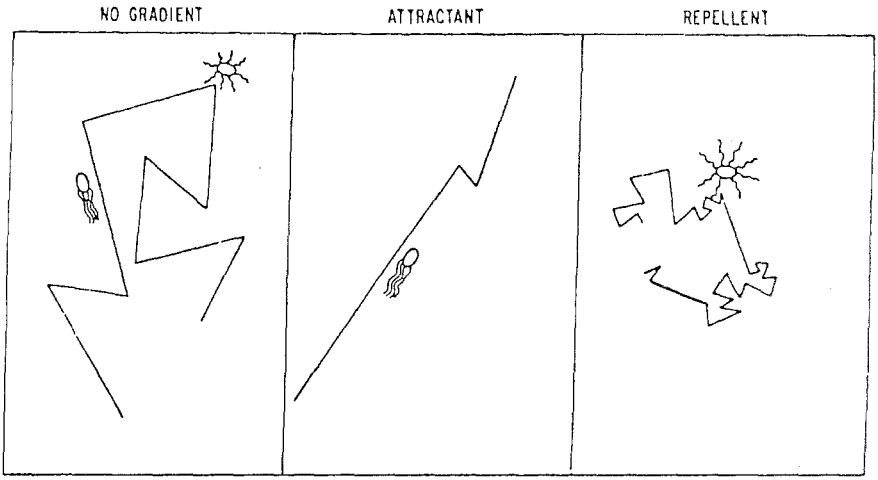

FIG. 1. Effect of chemoeffectors on bacterial motility. In the absence of an attractant or repellent, a cell exhibits smooth swimming interrupted every 1–2 sec with a tumble (left). Cells presented with an attractant spend a greater percentage of their time smooth swimming (middle), while those stimulated with a repellent bias their motility towards tumbling (right). Taken with permission from Silverman (1980).

volved. Furthermore, the availability of such mutants has provided the foundation for the recombinant DNA analyses which have since taken place. Nonchemotactic mutants (*Che*$^-$) have been isolated by a variety of techniques involving such characteristics of *Che*$^-$ mutants as their smaller region of growth on 0.4% agar plates (Parkinson, 1976) and their migration characteristics on preformed attractant gradients (Armstrong et al., 1967; Aswad and Koshland, 1975). These mutants contain flagella which rotate but exhibit altered swimming patterns. Some of these mutants tumble constantly, while others rarely tumble, and some will respond to no chemotactic stimuli, while others are only defective in responding to a particular class of chemicals. Thus, mutants blocked at various points along the flow of sensory information processing have been obtained.

The mapping of *che* (chemotaxis) genes in *E. coli* has been accomplished through Hfr × F$^-$ matings (Armstrong and Adler, 1969; Harayama et al., 1979) and deletion analysis in λ *che* transducing phage (Silverman and Simon, 1977b; Parkinson, 1978; Slocum and Parkinson, 1983). All but two *che* genes have mapped to areas near 42 or 43 minutes on the *E. coli* genetic map. Hand in hand with the advent of molecular biology, techniques were developed which allowed the definition of *che* operon structure, as well as *che* gene product identification. λ *che* transducing phage were used to direct the expression cloned *che* genes' products (Silverman et al., 1977). Also, *che* gene products have been identified using the minicell technique for selectively programming the *de*

novo expression of cloned *che* genes on plasmids (Matsumura et al., 1977). Altogether, 12 genes and gene products required for chemotaxis have been identified (Silverman and Simon, 1976; Silverman et al., 1977; Matsumura et al., 1977; Hazelbauer et al., 1981; Bartlett and Matsumura, 1984; Clegg and Koshland, 1985; Malakooti and Matsumura, in preparation). Most of these gene products have also been localized to the outer membrane, inner membrane, or soluble subcellular compartments (Ridgeway et al., 1977; D. Bartlett; PhD thesis, University of Illinois, Chicago; 1985; Clegg and Koshland, 1985). Table 1 lists the *E. coli che* genes, their map positions, product molecular weights, and product locations.

METHYL-ACCEPTING CHEMOTAXIS PROTEINS

A group of randomly situated transmembrane proteins, termed transducers, or methyl-accepting chemotaxis proteins (MCPs), play key roles in both the excitation and adaptation phases of certain chemotactic responses. MCPs have been found in enteric bacteria, *Caulobacter*, photosynthetic bacteria, *Bacillus*, and *Spirochaeta* (Kort et al., 1975; Goldman et al., 1982; Kathariou and Greenberg, 1983; Shaw et al., 1983). Each MCP is responsible for integrating infor-

TABLE 1. MCP-RELATED CHEMOTAXIS GENES, GENE PRODUCTS, PRODUCT LOCATIONS, AND PROPOSED FUNCTIONS

[a] IM = innermembrane localization, CYT = cytoplasmic localization.
[b] The *cheA* locus contains two overlapping genes whose products are 76 and 66 kd. The smaller cheA product is found exclusively in the cytoplasm, while the larger product is found in both the cytoplasm and the inner membrane.

mation pertaining to one or a few chemoeffectors. In the case of *E. coli* this is accomplished through direct interactions on the outer face of the inner membrane with specific amino acids or with occupied periplasmic binding proteins (Anraku, 1968; Adler, 1969; Hazelbauer and Adler, 1971; Kellerman and Szmelcman, 1974; Willis and Furlong, 1974; Hazelbauer, 1975; Clarke and Koshland, 1979; Kondoh et al., 1979; Hedblom and Adler, 1980; Wang and Koshland, 1980). After signaling a flagellar response, the MCPs undergo changes in methylation that correlate with sensory adaptation (Silverman and Simon, 1977b; Springer et al., 1977). The degree of occupancy of an MCP by one of its chemoeffectors is a measure of that cell's current environment. The level of methylation of the MCPs appears to reflect the cell's chemoeffector environment in the past and may participate in the memory process. Curiously, in *E. coli*, the MCPs become more methylated in response to an appropriate attractant stimulus, while in the gram-positive *Bacillus subtilis*, the MCPs become less methylated (Goy et al., 1977; Goldman et al., 1982). The methylation–demethylation reactions occur at several γ-glutamyl residues along each MCP (Kleene et al., 1977; Van der Werf and Koshland, 1977) and are catalyzed by chemotaxis-specific enzymes. The *cheR* protein is the methyltransferase and the *cheB* protein is the methylesterase (Springer and Koshland, 1977; Stock and Koshland, 1978). *S*-Adenosylmethionine (SAM) provides the methyl groups (Armstrong, 1972). Methanol is the hydrolysis product (Toews and Adler, 1979).

The *cheB* protein also performs a second modification: the irreversible deamidation of glutamine to glutamic acid residues on the MCPs that are then capable of being methylated (Rollins and Dahlquist, 1981; Sherris and Parkinson, 1981). The function of this process is unknown.

Four MCP genes are known to exist: *tar*, *tap*, *tsr*, and *trg* (Ordal and Adler, 1974; Silverman and Simon, 1977a; Springer et al., 1977; Hazelbauer et al., 1981; Krikos et al., 1983). The *tar* gene product mediates responses to the attractants aspartate and maltose and to the repellents Co^{2+} and Ni^{2+} (Clarke and Koshland, 1979). The *tsr* gene product mediates responses to the attractant serine and to the repellents acetate, leucine, benzoate, and indole (Hedblom and Adler, 1980). The *trg* gene product is responsible for attraction to ribose and galactose (Kondoh et al., 1979). As yet no known function exists for the *tap* gene product. MCP-mediated chemotaxis does not require transport (Adler, 1969). The *tar* product is methylated four times, *tsr* product six times, and the *trg* gene product more than five (Kehry et al., 1983).

MCP methylation is particularly interesting in view of its analogy with mammalian sensory systems. Both neurosecretion and macrophage chemotaxis have been found to involve reversible methylation (Odea et al., 1981; Aksamit and Backlund, 1983). Furthermore, these multiple MCP methylations are similar to the multiple phosphorylations of rhodopsin, a covalent modification associated with adaptation to light in vertebrates (Schichi and Sommers, 1978).

All of the *E. coli* MCP genes have been sequenced, as well as the *S. typhimurium tar* gene (Boyd et al., 1981; Krikos et al., 1983; Russo and Koshland, 1983; Bollinger et al., 1984). This has allowed the determination of their primary amino acid sequence as well as their predicted hydrophilic and hydrophobic domains. All of the MCPs appear to follow the same general configuration. At the *N*-terminal end is a very hydrophobic region which has been proposed to serve as a signal sequence that spans the membrane. This is followed by the receptor binding site which extends into the periplasmic space, followed by a second membrane-spanning domain and, finally, the bulk of the protein resides at the cytoplasmic face. Biochemical analysis of the *tar* and *tsr* products has determined two tryptic peptides which localize to the cytoplasmic regions of both proteins and which are methylated and show similarities in amino acid sequence (Wang and Koshland, 1980; Kehry and Dahlquist, 1982).

The extensive regions of nucleic acid sequence homology between *tsr*, *tar*, and *tap* genes have suggested that they comprise a gene family whose products might contain some functionally similar and some functionally different domains (Boyd et al., 1981). Indeed, two chimeric genes containing the 5′ end of the *tar* gene fused to the 3′ coding region of the *tsr* gene have been found to be chemotactically functional. In cells lacking both *tar* and *tsr* wild-type functions, the chimeric gene products were capable of triggering tactic responses to *tar* chemoeffectors (Krikos et al., 1985).

There have been two possibilities proposed for MCP mediation of initiation of signal transduction (Krikos et al., 1983). It may occur through the MCP polypeptide backbone, pushing or pulling its transmembrane segments, thereby altering the structure of the MCP carboxyterminal portion present in the cytoplasm. Alternatively, chemoeffector binding may influence the aggregation–disaggregation properties of monomeric MCP molecules.

ADDITIONAL CHEMOTAXIS PROTEINS

In addition to the receptors, transducers, methyltransferase, and methylesterase, additional chemotaxis proteins exist which are known to play a key role in the signal transduction and/or adaptation process. They do so by interacting between the transducer molecules and the flagella. These are the products of the *cheY*, *cheZ*, *cheA*, and *cheW* genes (Silverman and Simon, 1976; Parkinson, 1978). Mutations in any one of these genes, as well as the *cheR* and *cheB* genes result in a generally nonchemotactic mutant. By transcriptionally fusing the above genes to high level promoters, all of their gene products have been overexpressed to the level of detectability on SDS-polyacrylamide gels (Matsumura et al., 1984; Matsumura et al., unpublished data).

Complementation tests between *S. typhimurium* and *E. coli* have suggested that the *cheY* gene product and *cheR* product (methyltransferase) interact (De-

franco et al., 1979). Like *cheR* mutants, *cheY* mutants show a counterclockwise rotational bias. Reversion analysis of *cheY* and switch mutants (discussed in the section on switch proteins) suggest that they too interact (Parkinson and Parker, 1979; Parkinson et al., 1983). Hence, *cheY* appears to serve in some capacity to bridge the sensory and/or adaptation aparatus between the MCP–methyltransferase complex and the flagellar aparatus. The *cheY* protein is the first chemotaxis protein which has been purified to greater than 99% homogeneity and for which X-ray crystallographic data may soon be ready (Matsumura et al., 1984). *In vitro* it is eluted from cibacron blue columns with SAM (the methyl donor for MCP methylation) and SAM analogs in such a manner as to suggest that it is a noncatalytic SAM-binding protein rather than a catalytic methyltransferase. The *cheY* protein *in vitro* also inhibits EcoRI methyltransferase activity. Based on these results, it has been proposed (Matsumura et al., 1984) that a possible function for the *cheY* protein in chemotaxis is to negatively regulate *cheR* methyltransferase activity, either by interaction with the *cheR* product or *cheR* product–substrate complex. Since then, *cheY* protein has been shown to inhibit *cheR*-mediated methylation of MCPs, an effect which can be reversed if a chemoeffector such as 5 mM aspartate is present (Vacante and Matsumura; unpublished results). This is shown in Figure 2. Flagella from cell wall-containing cell envelopes, when energized, rotate exclusively counterclockwise; however, addition to *cheY* protein induces clockwise rotation (Eisenbach; personal communication). Likewise, overexpression of *cheY* protein has been noted to produce a clockwise rotational bias (Clegg and Koshland, 1984). For these reasons *cheY* has been designated the tumble regulator.

The *cheZ* product appears to close the circle of *che* protein interactions. Complementation tests between *S. typhimurium* and *E. coli* suggest that the *cheZ* and *cheB* (methylesterase) products interact (Defranco et al., 1979). Like *cheB* mutants, *cheZ* mutants possess a clockwise rotational bias. Revertants of *cheZ* often map to the same flagellar switch genes as *cheY*, which also suggests that the *cheZ* product interacts at the flagella (Parkinson and Parker, 1979; Parkinson et al., 1983). Because both *cheY* and *cheZ* interact with the methylation machinery as well as the motor, they may both serve as second messengers which convey information to the motors about the methylation state of the MCPs (Parkinson et al., 1983). For example, enhanced interaction of *cheY* protein with the switch might reflect an increased rate of dissociation of a *cheR–cheY* complex from the MCPs, resulting in a decrease in the rate of MCP methylation. Interestingly, the *cheZ* protein is methylated, but no function has yet been assigned to this modification (Silverman and Simon, 1977b).

The *cheA* gene has gained some notoriety due to the fact that it contains two overlapping genes: one which codes for a membrane-bound product, and a shorter cytoplasmic product formed by a later ribosome binding site (Matsumura et al., 1977; Smith and Parkinson, 1980). Both *cheA* products have been implicated with increasing demethylation of the MCP molecules (Springer and

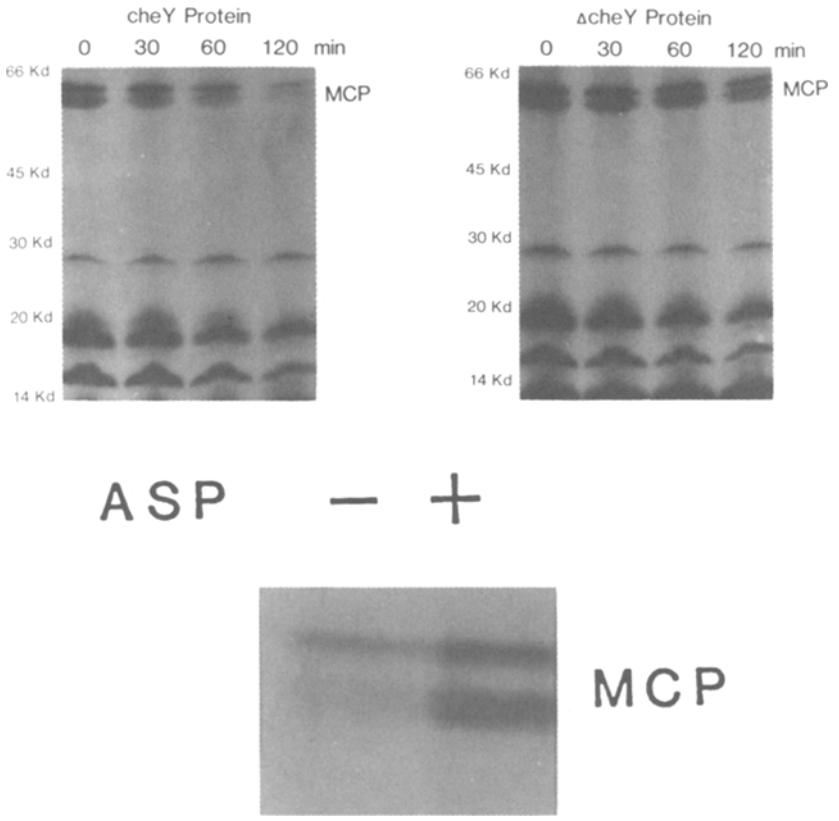

FIG. 2. Effects of *cheY* protein overexpression on MCP methylation in situ. The *cheY* gene has been placed under the transcriptional control of the high level *trp* promoter. The MCPs of cells which have been permeabilized to tritiated methyl SAM show a decrease in radioactive methyl group incorporation following the induction and overexpression of the *cheY* gene product (upper left). This effect is not observed when an internal deletion within *cheY* is introduced (upper right). This inhibition of methylation may be reversed if a chemoeffector such as 5mM aspartate is added (lower panel). A complete description of the effect of *cheY* protein on MCP methylation will be presented elsewhere (Vacante and Matsumura, in preparation).

Zanolari, 1984). However, reversion analysis of flagellar component genes implies that these gene products may associate with the flagellar motor (Parkinson, 1977). Because both the *cheA* and *cheW* genes are part of a known motility operon, and because related genes are often clustered, both *cheA* and *cheW* may act at the motor. This implies that the *cheA* role in demethylation may be an indirect one. The *cheA* gene product has also been demonstrated *in vitro* to bind to the *cheW* product. In the presence of *cheA* protein, *cheW* protein selectively

binds to affinity columns prepared with antibody directed against the *cheA* protein (MacNally and Matsumura, in preparation). Both *cheA* and *cheW* mutants possess a counterclockwise rotational bias, implying that they both have roles in tumbling (Parkinson, 1978).

SWITCH PROTEINS

In *E. coli* there exist three particular flagellar genes, each of which may be altered to impart Fla$^-$ (flagellar defect), Mot$^-$ (no flagellar rotation), or Che$^-$ phenotypes. These are the *flaBII*, *flaAII*, and *motD* genes (no *fla* designation for the *E. coli motD* gene currently exists). The fact that genetic defects within the same gene may express themselves so differently underlines the obviously close relationships of flagellar assembly, rotation, and chemotaxis. These genes' products are believed to be at the interface of the chemotactic machinery and the flagellar structure. Because of the central role these proteins play in modulating flagellar rotation in all types of taxes, they have been termed the switch proteins (Macnab and Aizawa, 1984). Most likely these products are structural components of the motor which are also essential for energization function and sensory reception.

These conclusions are based upon the facts that a class of chemotactic mutants, designated *scyB* (suppressors of *cheY* mutations) map to the *flaBII* gene (Parkinson et al., 1983; Bartlett and Matsumura, 1984), because the *cheC* gene maps within the *flaAII* cistron (Silverman and Simon, 1973; Clegg and Koshland, 1985), and by analogy with experiments in *S. typhimurium*, the *flaBII*, *flaAII*, and *motD* genes may acquire Mot$^-$ or Che$^-$ phenotypes in addition to their Fla$^-$ null phenotypes (Collins and Stocker, 1976; Warrick et al., 1977; Dean et al., 1983). Although no flagellar mutants mapping to the *E. coli flaBII* gene have been obtained through random mutagenic techniques, reversed genetic methodology (in which recombination between a cloned mutant gene and the corresponding wild-type locus occurs) has demonstrated that the null phenotype of the *flaBII* gene is indeed Fla$^-$ (Bartlett, PhD thesis).

All the switch genes are located within two flagellar operons mapping at about 43 minutes. The *flaBII* gene is located in an operon whose genes, transcribed from left to right, are *flaBI*, *flaBII*, *flaBIII*, *flaC*, *flaO*, and *flaE*. The *flaAII* and *motD* genes comprise part of the next downstream operon which is transcribed in the order *flaAI*, *flaAII*, *motD*, *flbD*, *flaR*, *flaR*, *flaQ*, and *flaP* (Silverman and Simon, 1973; Bartlett and Matsumura, 1984; Malakooti and Matsumura, in preparation). The *flaB* locus was divided into three complementary groups based upon the ability of various deletions and insertions with *flaB*-locus-containing plasmids to complement specific flagellar and chemotaxis mu-

tants, as well as code for polypeptides (Bartlett and Matsumura, 1984). The existence of three *flaB* genes has been confirmed through DNA sequence analysis (Frantz et al., unpublished data). Similar approaches have been used to subdivide the *flaA* locus into the *flaAI* and *flaAII* genes (Malakooti and Matsumura, in preparation). Although the phenotype of a *flaAI* mutant is unknown, it has been given a *fla* designation because of the previous *flaA* designation to this locus.

The switch proteins along with other flagellar components may comprise a portion of a structure located beneath flagellar basal bodies. Such a location would be consistent with their proposed roles of interacting with soluble *che* proteins as well as affecting flagellar rotation. They do not appear to be soluble proteins, as Ravid and Eisenbach (1984) have found that *E. coli* ghosts which contain energized flagella retain their rotational biases when prepared from strains bearing *che* mutations within the *flaAII* or *flaBII* genes. Similar ghosts prepared from cells with defects in soluble chemotactic products (such as *cheY* protein) do not retain such rotational biases.

A subflagellar basal body structure has never been observed during morphological examinations of *E. coli* flagella. However, these techniques have involved lysozyme digestion of the cell wall, and detergent solubilization of the cell membrane, in which case many components of the basal body or a subbasal body structure may have been lost (Depamphilis and Adler, 1971; Hilmen and Simon, 1976). Isolated flagellar organelles from the gram-negative *Aquaspirillum rubrum* reveal adherent fibrils emanating from the basal bodies (Coulton and Murray, 1978). Analyses in *Pseudomonas aeruginosa* and *Vibrio metchnikoviic* have revealed similar results. Thin-section electron micrographs in these organisms have demonstrated a dense cluster of "ribosome-like" granules at the cytoplasmic face of the flagellum, approximately 60 nm in diameter (Vaituzis and Doetsch, 1969).

Overexpression of *flaBII*, *flaAII*, and *motD* genes results in most of the switch proteins partitioning to the soluble cell fraction (Clegg and Koshland, 1985; Bartlett, PhD thesis; Malakooti and Matsumura, in preparation). This may reflect either a loose, or a site-limiting cytoplasmic membrane association. A glimpse into the tendency of flagella-associated proteins to associate with the membrane has been investigated from their overall hydrophobicity determined from their amino acid composition (Kyte and Doolittle, 1982). We have found a complete correlation between these hydrophobicity values determined for the switch/basal body proteins, and their overexpressed products' subcellular localization. The more hydrophobic *motA* and *flaAI* products do not show site-limited incorporation into the membrane fraction, while the less hydrophobic *flaBI*, *flaBII*, *flaBIII*, *motB*, and *motD* products do (Table 2). The derived amino acid sequence of the three *flaB* genes and *motD* gene provides no membrane spanning domain for the *flaBII* protein, while the *flaBI* protein possesses a pos-

TABLE 2. RELATIONSHIP BETWEEN HYDROPHOBICITY AND SITE-LIMITED INCORPORATION INTO INNER MEMBRANE AMONG MOTILITY AND BASAL BODY PROTEINS

	Average hydrophobicity	Site-limited membrane incorporation
motA	+0.353	No[a]
flaAI	+0.032	No
motD	−0.036	Yes
flaBIII	−0.402	Yes
flaBII	−0.429	Yes
motB	−0.434	Yes
flaBI	−0.474	Yes

[a] Data of Wilson and Macnab (personal communication).

sible membrane spanning region near its amino terminus, and the *flaBIII* and *motD* products contain possible membrane spanning sites near their carboxy termini (Frantz et al., unpublished results). One or both of these flagellar components, as well as others, may help to anchor the *flaBII*, *flaAII*, or *motD* proteins into their positions. It is noteworthy that in *S. typhimurium* the analogous gene to the *E. coli flaBI* gene appears to comprise the cytoplasmic membrane-bound M-ring of the basal bodies. This is based upon examinations of basal body proteins from temperature-sensitive flagellar mutants (Aizawa et al., 1985). Intergenic suppression analysis using the *mot* alleles of the switch genes suggests that all three of their proteins may interact together (Macnab and Aizawa, 1984). Figure 3 includes possible protein–protein relationships among the sensory transducers, additional *che* proteins, and switch/basal body complex.

In addition to the requirements for the above-mentioned chemotaxis proteins, there is also a role of phosphate in MCP-mediated chemotaxis. Cells depleted of methionine or ATP do not synthesize SAM, the methylation donor for MCP methylation. Tumbly *cheC* mutants which possess defects in the flagellar switch will not swim smoothly when depleted of methionine, but will when depleted of ATP, as do all cells (even when their proton motive force remains high enough for the flagella to switch to tumbly swimming) (Arai, 1980; Galloway and Taylor, 1980; Shioi et al., 1982). This indicates a role for ATP outside of SAM synthesis. In the presence of 5 mM phosphate, even with low ATP levels, smooth swimming may be restored (Arai, 1980). Therefore some other phosphorylated compound besides ATP appears to be involved in chemotaxis. Ordal (1985) has proposed that this compound may serve as a co-factor for the *cheY*, *cheA*, or *cheW* proteins for their flagellar interactions, or that kinase activity exists for one of the switch components.

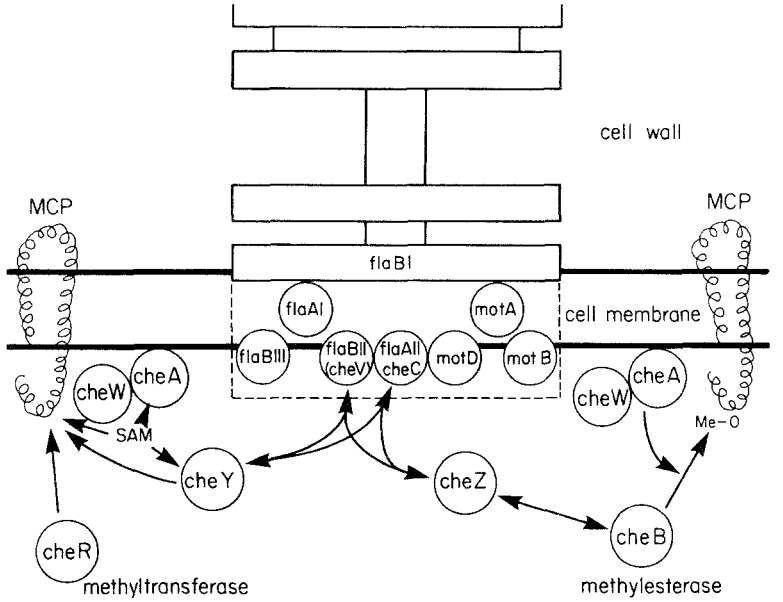

FIG. 3. Schematic representation of sensory flow in *E. coli* MCP-dependent chemotaxis.

A COMMON TAXIS SIGNAL?

Virtually nothing is known about the nature of the excitatory signal in chemotaxis or in any other taxis. The response system may simply involve a series of protein–protein, or protein–small molecule (such as Ca^{2+}) binding steps (Parkinson, 1977; Ordal and Fields, 1977; Ordal, 1985). In addition, there may be regulation of enzymes involved with the generation and degradation of this signal, such that magnitude amplification, allosteric cooperativity; or the newly discovered zero-order ultrasensitivity might be involved in a kinetic pathway (Koshland, 1984). There is some evidence for the role of both the *cheB* and *cheZ* gene products in signal transduction for a few different types of taxis. Thus it is possible that these different sensory systems may interface at one point along their signaling pathways. Impulse response studies in MCP-mediated chemotactic mutants have indicated that only *cheZ* mutants have an altered impulse response time (Block et al., 1982; Segall et al., 1982). $CheD^-$ mutants which map to the *tsr* gene and which may possess MCPI molecules locked into the signaling mode show defective *cheB* product activity (Callahan and Parkinson, 1985; Kehry et al., 1985). $CheB^-$ mutants appear to be defective in thermosensory excitation (Imae et al., 1984.). Furthermore, both *cheB* and *cheZ* mutants are defective in aerotaxis and the phosphotransferase-system-

mediated taxis, both of which proceed via MCP methylation-independent adaptation pathways (Niwano and Taylor, 1982).

FUTURE PROSPECTS

All of the *E. coli* MCP-related *che* genes have been cloned, and their products' primary amino acid sequence have either been determined, or are in the process of being ascertained (Boyd et al., 1981; Krikos et al., 1983; Bollinger et al., 1984 Matsumura et al., 1984; Frantz et al., unpublished data; Malakooti and Matsumura, in preparation; N. Mutoh and M. Simon, personal communication; J.S. Parkinson; personal communication). In the near future, site-directed mutagenesis and the determination of the nucleic acid sequences containing various *che* mutations will become important for more clearly defining structure and function relationships among these genes' products. Concerning the MCPs, such analyses may help the determination of chemoeffector binding sites, as well as domains on the proteins necessary for methylation, methylase binding, methylesterase binding, and signal transduction. Similar analyses may be directed towards discovering what moieties of the *cheY* protein bind SAM, *cheR* protein, or the flagellar switch. Furthermore, structure and function studies among the switch proteins may yield valuable information concerning their association with *cheY* protein, *cheZ* protein, and each other.

Does an elaborate submembrane basal body complex exist? A structure analogous to the *E. coli* ATPase can be envisioned (Downie et al., 1979; Cox et al., 1981). This analogy is strengthened by the fact that Mitchell (1985) has offered the fascinating ATPase rotating subunit hypothesis in which proton motive force drives rotation of the ATPase enzyme in a manner similar to that proposed for the bacterial flagellar motor. By examining the ability of switch or basal body products to fractionate into the membrane fraction in various switch or basel body mutants, a hierarchy of assembly into the basal body complex may be determined. In this way information concerning protein-protein interactions for these membrane-associated proteins may be determined.

A wealth of information relating to chemotaxis is *E. coli* already exists, and the future purification of all the *che* proteins promises to elucidate new biochemical properties.

Acknowledgments—We would like to thank N. Mutoh, M. Simon, J. S. Parkinson, B. Frantz, D. Vacante, J. Malakooti, D. Macnally, and J. Stader for their contribution of data prior to publication. (Received June 26, 1985; accepted August 21, 1985)

Abstract—Ticks and mites respond to a limited spectrum of stimuli in their search for hosts and mates. Airborne chemical signals include carbon dioxide, ammonia, organic acids, terpenoids, 2,6-dichlorophenol, and other phenolic compounds. These are detected primarily by sensilla in and adjacent to Haller's organ. Most ixodid species examined have one or more multiporose sensilla that detect such volatiles. These olfactoreceptors enable the ticks to respond to remote volatile chemicals from hosts and from the other ticks, e.g., sex pheromones. Other sensilla, probably mechanogustatory in function, also occur on the tarsi. Gustatory sensilla on the palps detect assembly pheromones that enable ticks and mites to respond to conspecific or heterospecific chemical stimuli in their environment. Responses to those stimuli in ticks result in clustering, i.e., arrestant behavior. Arrestant behavior also occurs in certain mites. Finally, cheliceral chemosensilla enable ticks to recognize specific phagostimulants in host blood, e.g., ATP and glutathione, that stimulate feeding. In *Dermacentor variabilis* and *D. andersoni*, these same cheliceral chemosensilla recognize species-specific genital sex pheromones in the vulvae of conspecific mates, without which they do not copulate.

Key Words—*Dermacentor variabilis*, *Dermacentor andersoni*, *Amblyomma* spp., semiochemicals, behavior, sensilla, Haller's organ, phenols, genital sex pheromone, 2,6-dichlorophenol.

INTRODUCTION

Acarines are a remarkably diverse group of animals, comprising tens of thousands of species that are found in an immense variety of terrestrial and freshwater habitats. Mites are major components of soils, where they feed on fungi, dead and decaying leaves and, occasionally, one another. Others are parasitic, attacking numerous mammals, birds, reptiles, and even insects. Many infest nests, burrows, and human habitations. Plant mites are notoriously destructive pests, affecting many of our most valuable fruits and ornamentals. As vectors of animal diseases, the ticks are without peer among the Acari in terms of the variety and sheer destructive potential of the pathogenic agents that they transmit.

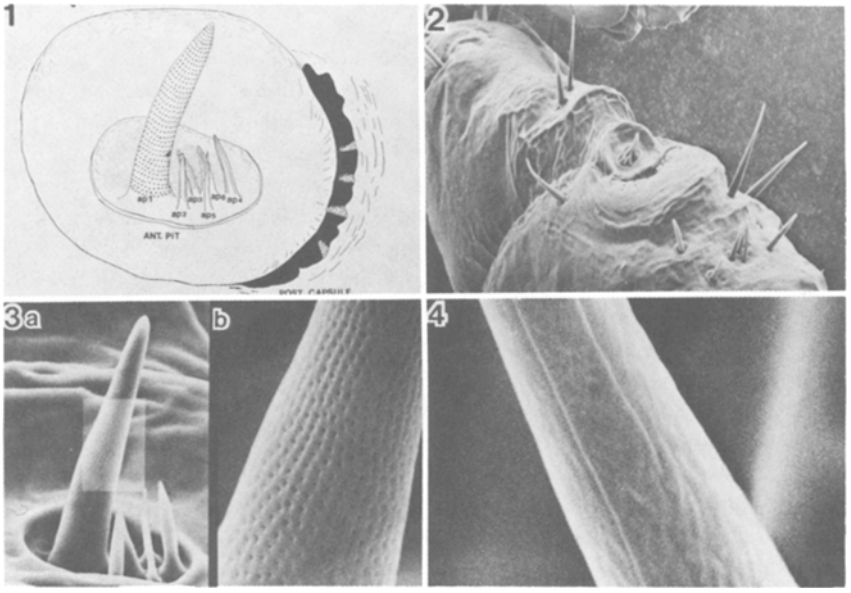
An assemblage of such diversity may be expected to have numerous semiochemicals and behavioral adaptations. However, relatively few such behavior-modifying compounds have been found to date, a fact which may reflect the paucity of our knowledge rather than a dearth of chemical communication in nature. Acarines produce a variety of arrestant pheromones, a limited spectrum of sex pheromones, several dispersal pheromones, and an unusual pheromone or pheromones, specific for the genus *Amblyomma*, for regulating attachment and clustering of feeding ticks. Absent are trail pheromones, food-finding pheromones, the innumerable defensive compounds (Staddon, 1979) and the great variety of androconia, hair pencils, and other devices for sexual display and pheromone dispersal. As Blum (1981) has noted, the insects "are remarkable chemists" and have evolved an incredible cornucopia of compounds to deal with the need to communicate information.

This review will examine the variety of acarine semiochemicals and the behavioral adaptations regulated by them. Special attention will be given to ticks, where the greatest amount of new knowledge has accumulated. We will limit ourselves almost entirely to chemoreceptors and the semiochemicals that they perceive, although the potential role of other receptor types can hardly be excluded.

PERCEPTION OF PHEROMONES AND HOST ODORS

Three organs are used for detection of chemical cues in ticks, (1) the Haller's organ on the first leg tarsi, (2) the terminal segment of the palps, and (3) the cheliceral digits. Little is known of the organs used for pheromone perception in mites.

Haller's Organ. This complex organ consists of an anterior trough with six or seven setiform sensilla, completely exposed to the atmosphere, and a posterior capsule with both setiform and pleomorphic sensilla, exposed only by a small pore or narrow slit (Figure 1). The anterior trough (Figure 2) in most



FIGS. 1–4. Haller's organ complex in ixodid ticks. Figure 1. Diagrammatic reconstruction of the Haller's organ illustrating the different types of sensilla. The open, anterior pit usually contains six sensilla that are visible when examined by SEM. Other sensilla on dorsal surface of the tarsus may also serve as chemosensilla, but are not physically located in the Haller's organ complex in most ixodid species that have been examined. The posterior capsule is represented by a narrow slit, shown in black, which serves as the opening to the underlying chamber, or posterior capsule. Four multiporose sensilla are depicted as protruding from the capsular cavity for purposes of illustration. Composite illustration based on study of the organ in *Dermacentor variabilis* and *D. andersoni*, as well as studies of other authors. ANT. PIT = anterior pit; POST. CAPSULE = posterior capsule; ap-1 through ap-6 = anterior pit sensilla. Figure 2. SEM view of the dorsal surface of the tarsus of leg I of a *D. andersoni* male illustrating the Haller's organ complex and other sensilla nearby. 213×. Figure 3. Split-screen view illustrating (a) the anterior pit sensilla, ap-1 through ap-6 and (b) high-magnification detail of the multiporose sensilla ap-1; 1349× for (a), 5396× for (b). Figure 4. Enlargement of one of the grooved sensilla, ap-2, 8410×.

ixodid species that have been studied (Foelix and Axtell, 1971, 1972; Hess and Vlimant, 1982a, b; Leonovich, 1977; Waladde and Rice, 1982) has at least four types of setiform sensilla: (1) a large, broadly based multiporose seta (ap-1) serving as a sensillum basiconica (Figure 2) (two such sensilla occur in *A. americanum*); (2) three grooved sensilla with perforations in the grooves (ap-2, 3, 4); (3) one smooth-walled sensillum (ap-5); and (4) a grooved sensillum without perforations (ap-6) (Figure 4). In addition, a group of setae on a ridge

or hump anterior to the trough contain one or more multiporose setae similar to ap-1 (=MD-3 of Waladde, 1982).

In *Amblyomma variegatum*, only one such seta occurs. In both cases, the multiporose sensilla have characteristic internal profiles. The pores are actually plugged, and contain branching dendrites with branches believed to be in physical contact with the plugged pores. In *A. variegatum*, the pores communicate directly with the interior lumen of the seta (single walled type). The pores are believed to be permeable to airborne odor chemicals, since dye molecules penetrate through the pores into the sensillum liquor (Foelix and Axtell, 1972). These sensilla are clearly olfactoreceptors, the functional capabilities of which will be discussed below. Olfactoreceptors with plugged pores have been identified in several mesostigmatid mites (e.g., *Dermanyssus & Mesonyssus*) (Davis and Camin, 1976; Moritsch et al., 1974). Thus, this type of receptor is probably widespread throughout the Acari. The grooved sensilla, with perforations in their grooves, are also olfactoreceptors. However, these sensilla typically have three or four unbranched dendrites in a central lumen that opens to the exterior via fine canals, providing the characteristic "spoke wheel" arrangement. In *A. variegatum*, they are described as double-walled sensilla, with radiating canals connecting the central lumen to the grooves. Their precise chemical sensitivities are unknown. The other sensilla in the anterior trough are probably not olfactoreceptors. Tip-pore sensilla also occur on the tarsus outside of Haller's organ as well as on other leg tarsi. They are probably mechanogustatory receptors, responding to water and salts (Hess and Vlimant, 1982a).

More is known about the function of the Haller's organ sensilla than any other tick or other acarine sensory system. Electrophysiological recordings from microelectrodes implanted below the anterior trough demonstrate that this structure will respond to crude animal odors, e.g., human breath, cattle body washings, etc. This type of study is useful as a sort of "electrotarsorgram," comparable to the electroantennograms used with insects. Precise measurements were initiated by Haggart and Davis (1979). These workers implanted uninsulated tungsten microelectrodes into the hemolymph space below the anterior trough and a group of tarsal seta anterior to Haller's organ to record extracellular action potentials in *Rhipicephalus sanguineus*. Using this method, they were able to demonstrate relatively specific responses of certain neurons in each test location to NH_3. The magnitude of the responses were similar to stimulus intensities. The responses were characteristic of sensory neurons, with an initial burst of impulses reaching 40 impulses/sec (phasic response), followed by a slow decline in impulse frequency (tonic response), with no significant decrement over the duration of stimulation. Removal and restimulation revealed the same pattern, indicating rapid recovery. The NH_3-sensitive neurons were relatively specific for this compound, with high sensitivities to NH_3 and slight sensitivity to several other acids. The authors suggested that the response to am-

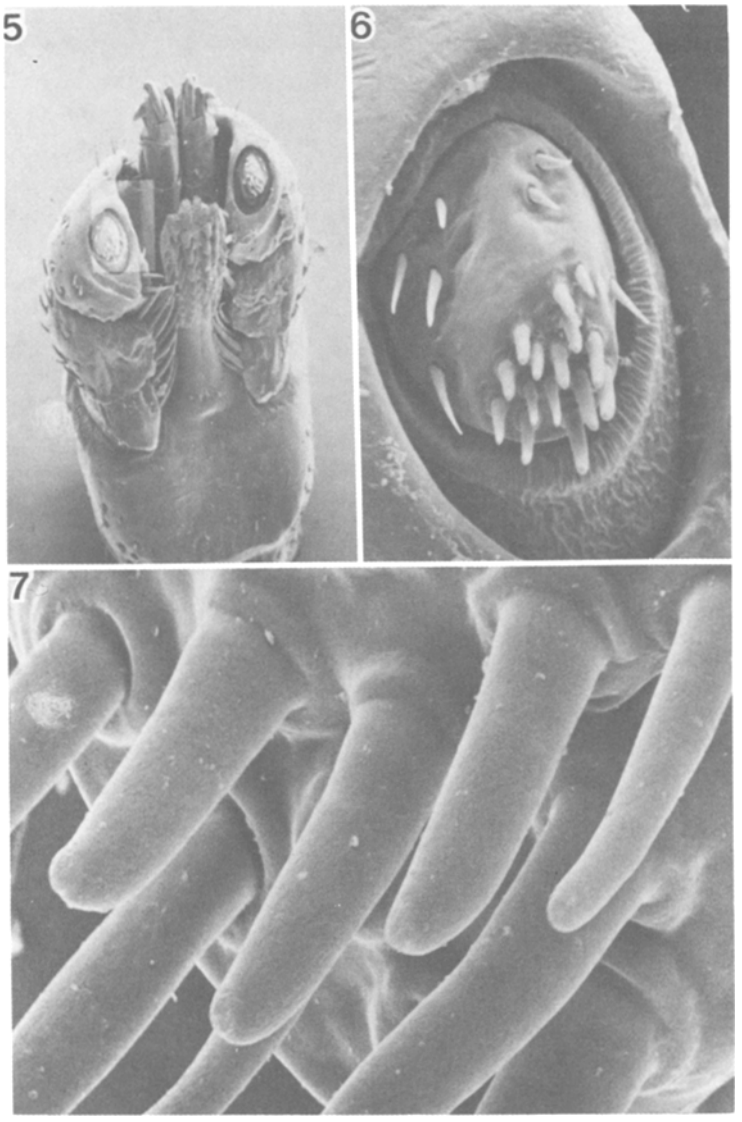
monia may be useful in host-locating behavior, e.g., along well used animal trails.

In further studies by these authors (Haggart and Davis, 1981) using the same methods, highly significant responses to 2,6-dichlorophenol (2,6-DCP) were found when the microelectrode was positioned below the ap-1 sensillum in *A. americanum*. They concluded that only one sensillum, ap-1, is the 2,6-DCP receptor. Unfed males, fed males, and unfed females responded to this pheromone. The response characteristics were similar to those described above for ammonia, but the tonic phase declined gradually with time. The response intensity was proportional to stimulus intensity over a relatively broad range. The 2,6-DCP-sensitive neurons were also found to respond to different cresol isomers; responses to NH_3 were also found, but this was believed to be due to action potentials from neighboring neurons. In view of the fact that unfed males and females as well as fed males detect the pheromone, Haggart and Davis concluded that the behavior responses to 2,6-DCP are based on integration of information in the central nervous system rather than at the level of peripheral neuron sensitivies.

A significant advance in selective recording of sensory responses was made by Waladde (1982), who used the tip recording technique to test the responses of individual sensilla in *A. variegatum* and *R. appendiculatus*. With this method, Waladde demonstreted that the two multiporose sensilla present in these species, ap-1 and MD-3, were able to detect 2,6-DCP in amounts as low as 0.04 ng/μl. The same sensilla were relatively insensitive to *p*-cresol or salicylaldehyde, while phenol was actually inhibitory. The sensilla were sensitive to hexane washings of larval and female ticks; moreover, ap-1 was capable of detecting NH_3. In contrast to *A. americanum*, two sensilla are used to detect the pheromone in this species, but the stimulus-response characteristics were otherwise very similar (although no decline in response intensity was seen in this species). These findings are remarkable because neither species has been found to contain 2,6-DCP. Moreover, these findings raise serious doubts about the role of phenol and *p*-cresol, reported to serve as the sex pheromone of *R. appendiculatus* by Wood et al. (1975).

The Haller's organ sensilla are also used to detect the male originated aggregation/attachment pheromone, but the specific sensilla used for this purpose are unknown. In view of the fact that two of the three components of this pheromone are also phenols (Schoni et al., 1984), it is probable the detection is accomplished by the same multiporose sensilla used to detect 2,6-DCP. Future research should be directed to determining this activity.

Palpal Organ. The fourth segment of the palp of ixodid ticks contains nine or more tip-pore sensilla at its distal margin that serve as mechanogustatory receptors, as well as mechanoreceptor sensilla along its lateral edges (Figures 5–7). None are known to serve as thermoreceptors. These are high-threshold



FIGS. 5–7. Scanning electron micrographs illustrating the palpal receptors in a *Dermacentor andersoni* male. Figure 5. Ventral view of the entire capitulum. High-lighted area enlarged (Figure 6), 38×. Figure 6. Enlargement illustrating the fourth article (segment) of the right palp, partially recessed in a cavity of the preceding third article. A total of 13 short, thick, and blunt sensilla, all similar in appearance to one another, occur at the tip of the fourth article (=palpal organ); nine others, including seven thinner, tapering sensilla, occur along the margins. Porelike depressions that appear at the tips of some of the sensilla represent contrast-related artifacts, as shown in the enlargement below, 306×. Figure 7. High-magnification view illustrating the blunt sensilla at the tip of the palpal organ. No pores are evident, 2490×.

receptors, requiring many times higher concentrations of each specific chemical to be stimulated than with olfactoreceptors. Two types of distal margin sensilla are known, the long, thin type A sensilla, and the much shorter and thicker type B sensilla. Both types exhibit only minute wall pores near the seta tip (Foelix and Chu-Wang, 1972; Ivanov and Leonovich, 1983) which are not evident when the sensilla are examined by scanning EM [(although Waladde and Rice (1982) illustrate what they believe to be much larger terminal pores in *B. microplus*]. The type A sensilla detect salts, glucose, and sucrose (Balashov et al., 1976); they probably detect compounds in sweat and other skin secretions and are believed to facilitate the selection of feeding sites. The type B sensilla do not respond to the same compounds as the type A sensilla. Rather, they are believed to perceive pheromones (Ivanov and Leonovich, 1983). The palpal organ is known to be used in the perception of assembly pheromones (Leahy et al., 1975; Graf, 1975) and may even participate in courtship behavior. Feldman-Muhsam and Borut (1971) reported that males of ixodid ticks would not copulate when their palps were amputated. However, *Dermacentor variabilis* are apparently unaffected by the loss of their palps and copulate readily. Observations of courting males indicate that they apply their palps to the female's body cuticle and may obtain unknown chemical signals which guide them to the female's venter and genital pore (Sonenshine, unpublished). The extent to which the palps are used in this role is unknown. Electrophysiological studies also suggest a generalized sensitivity to steroids (Taylor, unpublished). Further study of the palpal organ sensilla and their capabilities for detecting specific chemicals should be encouraged and may provide needed new knowledge of tick feeding behavior.

Cheliceral Digit Sensilla. Chemoreceptive, mechanoreceptive, and, most probably, even thermoreceptive sensilla occur on the digits of the chelicerae (Waladde and Rice, 1977, 1982; Sonenshine et al., 1984). In *Boophilus microplus*, two pores and a papilla occur on one of the denticles of the inner digit. Only one of these sensilla, the proximal pore, is a chemoreceptor, innervated by 11 chemosensory dendrites. Chemoreceptor dendrites also occur in the lumen of the outer digit, but the precise sensillum innervated is uncertain. Similar structures occur on the digits of *D. variabilis*, but the papilla is replaced by a cone-shaped cavity that probably serves as a proprioceptive sensillum. In *B. microplus*, electrophysiological records reveal selective responses to host blood, saline solutions, and the phagostimulants ATP and reduced GSH. Evidently, the cheliceral digit sensilla provided the final pieces of information needed to complete the food acquisition process, namely, the evaluation of the contents of fluids that are being sucked. Presumably, failure to detect the appropriate phagostimulants leads to detaching and reattachment elsewhere.

In *D. variabilis*, the cheliceral digit sensilla also respond to extracts of the female reproductive tract and 20-hydroxyecdysone, as well as 10^{-3} M ATP, 10^{-3} M reduced GSH, and physiological saline. In summary, these ticks have

the necessary morphological and physiological capabilities to respond to sexual excitants in the female genital pore, as well as to specific phagostimulants in host blood. This is not surprising, in view of the widespread use of the chelicerae in different acarines as sperm transfer devices, e.g., the spermatodactyls of parasitic mesostigmatid mites, in addition to their role in penetration of the host integument.

ARRESTANT BEHAVIOR

In ticks, this behavior is induced by assembly pheromones. Ticks encountering the pheromone cease ambulatory activity and become akinetic. Studies of Gothe and Kraiss (1982) implicate substances passed via the anus and, possibly, the coxal glands, as the excitant. Assembly pheromones are widespread among species of both Argasidae and Ixodidae. Moreover, interspecific and even interstadial responses to these chemical signals are common. This evidence strongly suggests a single class of compounds, perhaps even a single molecule, as the common assembly pheromone of ticks. Obenchain (personal communication) suggested that guanine and another, unidentified purine voided in tick feces probably serves this role (cited by Sonenshine et al., 1982a). Detection of this pheromone is accomplished by the palpal organ sensilla.

Assembly pheromones occur most frequently in species that inhabit arid environments, e.g., most Argasidae, rhipicephalids of tropical Africa, etc. Taylor and Sonenshine (unpublished), using a laboratory simulated "meadow environment" (Figure 8, Table 1), were unable to find evidence of assembly pheromones in *Dermacentor variabilis* and only weak responses to saline washings in *D. andersoni*. *D. variabilis* is a tick of the humid eastern deciduous forest biome of North America. These findings are consistent with the chemical characteristics of the pheromone, which is highly soluble in saline and other dilute aqueous salt solutions. Such solubility characteristics would favor its persistence in arid environments but not under the conditions of frequent rainfall, high humidity, and dew-covered vegetation that is characteristic of eastern North America. In Switzerland, however, an area with high rainfall, *Ixodes ricinus* assemble on vegetation in response to other ticks or tick extracts (F. Jigand, personal communication). Comparative evidence suggests that differences in perceptive abilities (i.e., chemoreception) rather than the actual presence of the pheromone may account for the differences in response to these compounds noted above.

Arrestant behavior has also been reported in mites, but for entirely different reasons. In the Tetranychidae and Phytoseidae, developing female nymphs (pharate females) emit the sesquiterpene alcohols farnesol, nerolidol, and geraniol, and the monoterpene citronellol. Mate-seeking males encountering such sexually active nymphs stop, palpate them, and remain akinetic nearby, a pose

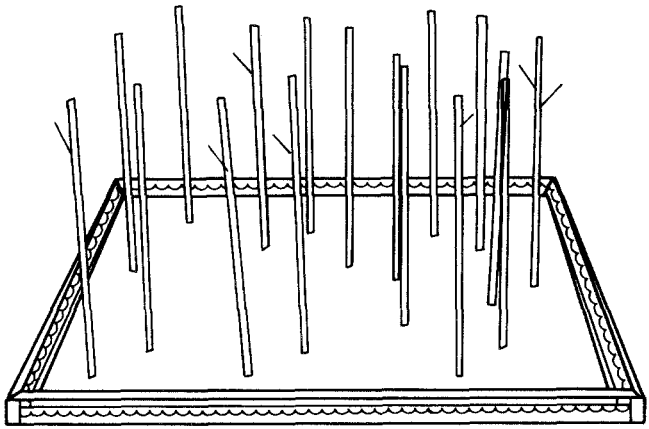


FIG. 8. Simulated "meadow" environment in which experiments on adult tick clustering behavior was done. Two identical environments were used, one of which served as the control. Each consisted of a 1.9-cm-thick acrylic (Plexiglas) base, 61 × 61 cm square, surrounded by a water filled moat, 1.8 cm wide. Acrylic rods, 1.3 cm. diam × 30 cm high, were placed at random throughout the acrylic base and cemented in place. Small secondary acrylic rods, 0.2 cm diam and 4 cm long, were attached at random heights to the upright rods to simulate branches. Ticks, *D. variabilis* adults, were released on the base and allowed to climb the rods.

TABLE 1. RESULTS OF SIMULATED "MEADOW" BIOASSAYS OF *Dermacentor variabilis* TO DETECT PRESENCE OF ASSEMBLY PHEROMONE[a]

Treatment	No. ticks in test	× No. ticks/rod[b]	× No. clusters[c]
1. Filter paper + tick extract	360	0.84	0.0a
2. Filter paper contaminated by female ticks	216	0.69	0.19b
3. Filter paper contaminated by male ticks	576	0.98	0.29
4. Rods contaminated by live ticks	864	0.94	0.36
5. Rods with other live ticks during test	576	1.02	0.42
6. Controls	2736	0.92	0.35

[a] Done in a controlled environment chamber at 27° ± 1°C, 80 ± 5% relative humidity, and uniform daylight fluorescent light.

[b] No significant difference in the mean number of ticks/rod due to the different treatments, $F = 2.169$, $P > 0.1$, *df*, 6, 13. There was significant added variance due to the position of the "meadow" environment probably related to air currents in only one of the positions tested, $F = 16.765$, $P = 0.001$, *df*, 2, 5737.

[c] Significant differences in the mean number of clusters/rod were observed, $F = 4.913$, $P < 0.001$, *df*, 6, 5737. However, those treatments that were significant were less than the controls. Using the least significant difference (LSD) test, a = significantly different from all other treatments except No. 2, b = significantly different from treatment No. 3.

known as "guarding" (Regev and Cone, 1980). Although akinetic, the males are not insensitive. Molting of the female deutonymphs arouses the male and copulation ensues. The nature of the pheromone and its mode of detection provide worthwhile problems for future study.

HOST-SEEKING BEHAVIOR

Despite the obvious importance of this behavior, little is known about the specific stimuli to which ticks respond, and even less about the receptors that perceive them. CO_2 and NH_3 are known host-originated stimuli to which ticks respond (Wilson et al., 1972; Haggart and Davis, 1980, 1981), and butyric acid is reputed to be an excitant (Waladde & Rice, 1982). No other host-originated chemical stimuli are known. Questing ticks also respond to vibrations. In *B. microplus*, questing larvae respond best to 80–800 Hz, the frequency range associated with sound made by cattle (Waladde and Rice, 1982). Radiant heat is another important stimulus. Few of these signals are likely to be important independently. The integrative value of different types of stimuli, demonstrated so effectively by Lees (1948), remains to be explored. Finally, while olfactoreceptors and thermoreceptors provide information that confirm the presence of the host's body, gustatory receptors are especially important in determining skin characteristics and selection of the feeding site. An extensive literature exists on this subject, reviewed most recently by Waladde and Rice (1982).

MATE-FINDING BEHAVIOR: PHEROMONES USED IN COURTSHIP

Courtship is the term used to describe a ritualistic sequence or hierarchy of behavioral events used by members of a species to identify and accept their prospective partners for mating. The complexity of this process varies greatly. In most acarines in which the process has been subjected to intensive study, a characteristic mating behavior is observed with one or more of these events regulated by pheromones. The best known examples are the ticks, especially the metastriate Ixodidae. Species of this group of ticks, comprising more than 600 species, occur in all continents except Antartica and infest various reptiles, birds and mammals. Despite this exceptional diversity of hosts and habitats, these ixodids are remarkably similar with regard to procedures used in their mating behavior. In all cases, the adults become sexually active only while feeding on a host, and the males must detach and search for females that have achieved sexual readiness. Males encountering receptive females mount their partners dorsally, then turn to the ventral surface, probe the body cuticle with their palps and chelicerae until they locate the gonopore, and commence cop-

ulation. Pheromones guide some, probably all, of these discrete behavioral events. (Sonenshine et al., 1982b; Sonenshine, 1985).

In *Amblyomma maculatum*, *A. variegatum*, and possibly three other African *Amblyomma* species, a male-originated, species-specific aggregation–attachment pheromone guides the attachment process, so that species-specific clusters are formed before the ticks are ready for mating. Males of these species attach readily even without the presence of other males, but they will also respond to the pheromone secreted by other males and attach beside them. Females, however, will attach only if conspecific males are present and have matured to the point that they are secreting this pheromone. In *A. variegatum*, a three-component blend of compounds guides different events in this process. *O*-Nitrophenol induces searching behavior and the aggregation response. The other two components, methyl salicylate and pelargonic acid, induce the attachment and clasping behavior that is characteristic of this species. These pheromone-regulated behavioral events explain the clustering observed on the hosts. However, it is not known how the males recognize when the females are sexually ready or even if such distinctions are necessary. *A. variegatum* males can detect 2,6-DCP (Waladde, 1982), a compound which is present in females of this species (Wood et al., 1975). In the Gulf Coast tick, *A. maculatum*, both males and females are found to contain 2,6-DCP. However, males respond to this compound, seeking out, mounting, and copulating with females emitting the pheromone. Sonenshine et al. (1982a) suggest that 2,6-DCP functions in these situations as a generalized excitant, stimulating males to detach and mate with any adjacent, sexually ready females already present in the conspecific feeding cluster. Thus, mate finding in these *Amblyomma* species of large ungulates commences with the attachment process, leading to the formation of conspecific clusters, followed by the secretion of 2,6-DCP one or two days later, exciting the males to detach, locate, and copulate with the pheromone-secreting females. No other pheromones are known in these large ungulate parasites and none appears necessary to ensure that mating will be accomplished only with partners of the same species.

In most other ixodid species that have been studied, males and females attach to hosts independently. Feeding females secrete 2,6-DCP, exciting males to detach and commence mate-seeking behavior. 2,6-DCP has been found in 14 species of ixodid ticks, representing five genera (Sonenshine et al., 1986). Although perhaps lacking in some species not thoroughly studied it is unquestionably the most common of the several ixodid sex pheromones. Many of these species are sympatric and often share the same hosts. This problem of species-specificity in the courtship behavior of ticks and the use of pheromones to regulate it was discussed in a previous review (Sonenshine, 1985). Consequently, the remainder of this paper will be devoted to examining examples of this process in the genera *Hyalomma* and *Dermacentor* in order to appreciate the dif-

ferent chemical and physical signals and their role in maintaining reproductive isolation.

In the camel ticks, *H. dromedarii* and *H. anatolicum excavatum*, the males exhibit a unique ability to discriminate differences in the concentration of 2,6-DCP (Khalil et al., 1983). *H. anatolicum excavatum* males respond readily to concentrations of this pheromone that are near threshold for *H. dromedarii*, while those concentrations that are highly attractive to *H. dromedarii* males actually repel *H. anatolicum excavatum* males. In a series of experiments with authentic 2,6-DCP administered to females (killed and washed, but still attached), the optimal concentration for attraction of *H. anatolicum excavatum* males was 15 ng/tick. Increasing the concentration to 30 ng repelled these males. In contrast, 15 ng elicited weak responses by *H. dromedarii* males whereas 30 ng was highly attractive to these ticks. Clearly, a marked difference in sensitivity is exhibited in responses of these two species. This ability to discriminate differences in concentration is consistent with natural differences in the occurrence of 2,6-DCP in the two species (Silverstein et al., 1983). In effect, the (relatively) high concentration of the compound emitted by *H. dromedarii* acts as a distinct pheromone, attractive to conspecific males, but repellent to *H. anatolicum excavatum* males, a sympatric species with a similar host range. The natural differences in the amounts of 2,6-DCP secreted by the two species and the differences in male response to these differences enable the same molecule to act as two separate pheromones, minimizing the need to generate separate molecules for this purpose.

Recent research suggests that 2,6-DCP may be the only sex pheromone required to elicit species-specific mating in *Hyalomma*, at least in *H. dromedarii*. Males of this camel tick readily respond to female *D. andersoni* and *D. variabilis*, orienting to and mounting them in almost all cases, resulting in numerous copulations; 40% of the trials with *D. andersoni* and 20% with *D. variabilis* were completed in this manner. When 13 *H. dromedarii* females were neutered and cleansed of surface chemicals, virtually all (78%) of *H. dromedarii* males deposited spermatophores in these females despite the neutering treatment (Sonenshine and Taylor, unpublished)! Several males even failed to distinguish the female genital aperture and deposited their spermatophore in the wound scar posterior to it. Coating the female genital pore with lacquer reduced copulation, but the males merely left without attempting to pierce this barrier, quite the opposite of the male response to similar challenges in *D. variabilis*. However, Khalil et al. (1983) did observe reduced mating success after severing the vagina from the gonopore.

In the North American *D. andersoni* and *D. variabilis*, a genital sex pheromone not only guides the courting males to the female gonopore, but provides species-specific information that enables the males to identify and copulate only with conspecific partners. *D. variabilis* males, excited by the general, interspecific attractant 2,6-DCP will court all pheromone-secreting females in a mixed

species population, mount them, and probe their genitalia; however, they will copulate only with conspecific females (Sonenshine et al., 1982b). Physical and chemical characteristics of the female body surface may also provide information which enables the males to confirm the females as prospective mating partners. Inanimate objects of the same general shape and size as partially engorged female tick, "pseudoticks," are ignored by sexually excited males, as are females that lack pheromone. However, adminstration of 2,6-DCP to the authentic female induces a vigorous courtship response, even if the treated female is dead. The males palpate these treated tick remnants, mount them, probe their genital pores, and many even copulate. However, males exposed to the 2,6-DCP "pseudoticks" orient to the pheromone source but fail to mount or copulate with these inanimate objects. When the texture and chemical characteristics of the cuticle are preserved, the males mount and probe these "pseudoticks" in the normal manner, and several males even copulate with these objects. Experiments are planned to determine whether physical characteristics, e.g., texture of the superficial folds on the female body, or chemical characteristics, e.g. cuticle waxes, or some combination of both physical and chemical features are essential to the mounting response.

Regardless of how they guide themselves to the female's ventral body surface, male *D. variabilis* and *D. andersoni* appear to require a genital sex pheromone to identify the gonopore and commence copulation. At least one component of this pheromone provides species-specific information which must be perceived or the male will not copulate. As has been discussed previously, the males bear gustatory receptive sensilla on their cheliceral digits. Males that have had the digits of the chelicerae removed are unable to form spermatophores, apparently because they are unable to identify the species-specific component of the genital sex pheromone. Thus, a multicomponent pheromone system appears to have evolved in the American *Dermacentor* species to provide precise mate-identifying information. As expected, *D. variabilis* males will not mate with females of any other species, since they appear to require the presence of the conspecific genital pheromone in order to form and release the spermatophore.

Further study of the genital sex pheromone was done by preparing an extract (in methanol) of the anterior reproductive tract (ART) tissues, fractionating it chemically, and assaying the different fractions to determine which ones were most active. Preliminary tests demonstrated that thorough washing of the female genital surface and cutting the vulva, thereby severing the reproductive tract from the gonopore, would prevent mating. Males were observed to mount and probe these "neutered" females, but few males would copulate, even though the appearance of the gonopore remained unaltered by this treatment. However, when an aliquot of the crude extract of the female ART was placed in the genital pore of these "neutered" females, the male response was restored; males copulated readily. These findings appear to meet the essential criteria for demon-

stration of chemical communication, i.e., a pheromone: removal of the material resulted in loss or at least extreme reduction of the response, while implanting the crude extract restored the response. Using gel permeation chromatography to separate the extract components by molecular size, Sonenshine et al (in press) demonstrated activity with at least two groups of fractions containing compounds of widely differing molecular weights. Their evidence suggests that the pheromone contains one or more compounds with a molecular weight of 600–700 atomic mass units (amus), and one or more compounds with molecular weights in the range of 400–500 amus. Further studies of the chemical identity of the genital sex pheromone are in progress.

The ability of the males to detect the genital sex pheromone was confirmed by electrophysiological methods. Davis and Sonenshine applied micropipets filled with solutions of the extract to the cheliceral digits of fed, sexually active male ticks (Sonenshine et al., in press). Rapid bursts of spikes indicating strong responses by the excited neurons were observed. The cheliceral digits were also responsive to physiological solutions of ATP, glutathione, and sodium chloride, i.e., similar to the responses observed by Waladde and Rice (1977) in *B. microplus*. Washings of the female vulva and genital pore were also stimulatory, although such extracts failed to elicit copulations in the bioassay. These studies were repeated by Taylor and Sonenshine (unpublished), with similar results (Figure 9).

Additional evidence of the existence of the genital sex pheromone in *D. variabilis* is demonstrated by the success of interspecific matings when *D. variabilis* were exposed to heterospecific females treated with *D. variabilis* female extract. Normally, *D. variabilis* males rarely if ever copulate with females of the camel tick, *H. dromedarii*. However, when the *H. dromedarii* females were neutered and extracts of *D. variabilis* females (anterior reproductive tract) were placed in their vulvas, the male response was restored. Although magnitude of the response (43%) was considerably less than in the conspecific assay (78%), such copulations between species are unusual; the frequency of this occurrence in the controls was only 10.6%.

These findings, summarizing evidence obtained by two different assay methods, argues persuasively for the existence of a genital sex pheromone in *D. variabilis* and *D. andersoni*, originating in the female reproductive tract and dispersed onto the external genital surface.

Although the chemical identity of the genital sex pheromone is unknown at this time, considerable evidence has accumulated implicating 20-OH ecdysone as one of the components of the pheromone in *D. variabilis*. Extracts of the anterior reproductive tract tissues gave a strong positive response when assayed by radioimmunoassay, 180 pg/tick (4.7 ng/mg) for *D. variabilis* as compared to only 12.5 pg/tick (0.3 ng/mg) in *H. dromedarii*. Bioassays also show a high proportion of successful mating responses when 20-OH ecdysone is implanted in the vulval remnant of neutered *D. variabilis*, or in the vulvae of

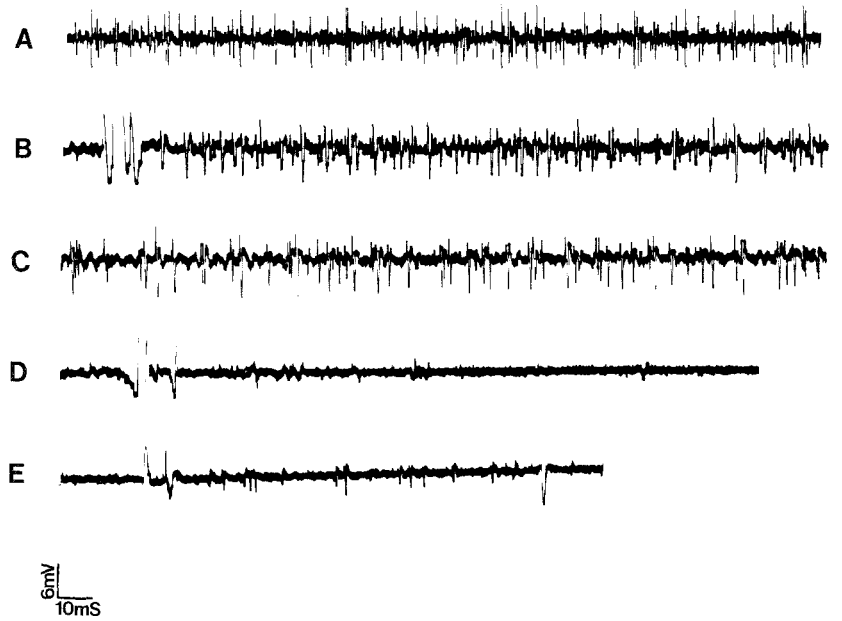

FIG. 9 Oscilloscope tracings illustrating the responses of *D. variabilis* chelicerae and palps to various chemical stimuli administered by capillary microelectrodes. (A) Response of the inner cheliceral digit sensilla to a 0.15 M NaCl solution. (B) Response of the inner cheliceral digit sensilla to 20-OH ecdysone (1×10^{-3} M). (C) Response of the inner cheliceral digit sensilla to ecdysone (1×10^{-3} M). (D) Absence of a response of the palpal sensilla to 20-OH ecdysone (1×10^{-3} M). (E) Absence of a response of the palpal sensilla to ecdysone (1×10^{-3} M).

"pseudoticks," i.e., remnants of conspecific females in which the interior contents have been replaced with wax. In contrast, similar tests with *D. andersoni* were unsuccessful. The natural hormone was also demonstrated in the *D. variabilis* ART extracts by HPLC (2.2 ng/tick), but not in the ART of *H. dromedarii*. Although 20-OH ecdysone is generally present in many species of ticks (Solomen et al., 1982), its occurrence in the ART of *D. variabilis* appears to be unusually concentrated. Soneshine et al. (in press) suggest, albeit with considerable caution, that 20-OH ecdysone plays a unique role in *D. variabilis*, perhaps by elevating the level of nervous excitation and, therefore, is one of the active components of the genital sex pheromone in that species.

SUMMARY

This review has emphasized the importance of acquiring and integrating knowledge of sensory organ structure, functional capabilities of the sensilla, and behavioral observations to assess the biological value of the incoming in-

formation. Special stress has been accorded to the chemical stimuli, although these are not the only stimuli important in tick activities, nor are they necessarily paramount in the performance of all necessary behavioral functions. Nevertheless, study and correlation of the ultrastructure, neurophysiology of acarine sensory systems, and behavioral responses to specific chemical cues have enabled biologists and chemists, working in concert, to make important advances in understanding host-finding, feeding, and mating behavior in these remarkably diverse arthropods. These include such important discoveries as the identification of 2,6-dichlorophenol as the common sex attractant of numerous ixodid species, the identification of a blend of *O*-nitrophenol, methyl salicylate, and pelargonic acid as the aggregation attachment pheromone of *Amblyomma variegatum*, the response of tarsal olfactoreceptors to various substituted phenols, the discovery of genital sex pheromones, and the detection of these secondary sex pheromones by olfactoreceptors on the cheliceral digits. New advances and increasing improvements in the sophistication of such tools as electron microscopy, electrophysiology, and gas chromatography offer promise of an even greater pace of discovery, leading to recognition of new or poorly known semiochemicals and a much better understanding of how these compounds influence acarine behavior.

COEVOLUTIONARY ADAPTATIONS OF ROOTWORM BEETLES (COLEOPTERA: CHRYSOMELIDAE) TO CUCURBITACINS

ROBERT L. METCALF

Department of Entomology
University of Illinois
Urbana-Champaign Illinois 61801

(Received June 26, 1985; accepted October 15, 1985)

Abstract—The cucurbitacins are oxygenated tetracyclic triterpenoids produced as secondary plant compounds by nearly all genera of Cucurbitaceae. The very bitter and toxic cucurbitacins are effective semiochemicals acting ecologically as allomones to protect the Cucurbitaceae from attack by a variety of invertebrate and vertebrate herbivores. For the Luperini (Coleoptera: Chrysomelidae: Galerucinae) the cucurbitacins have become kairomones for host selection, affecting the behavior of this large group of 1500 species of Aulacophorina (Old World) and Diabroticina (New World) by arrest and compulsive feeding. When feeding on bitter cucurbits these beetles sequester large amounts of cucurbitacins in their blood and tissues, and these act as allomones to deter predation. Specific detoxification and excretory mechanisms of the Diabroticina enable these beetles to avoid the toxic effects of the cucurbitacins.

Key Words—Rootworm beetle, *Diabrotica* spp., *Aulacophora* spp., Coleoptera, Chrysomelidae, *Cucurbita* spp., *Cucumis* spp., cucurbitacin, allomone, kairomone, Chinese mantis, *Tenodera aridifolia sinensis*, predator, Orthoptera, Mantidae.

INTRODUCTION

Coevolutionary adaptations between terrestrial plants and insect herbivores must have originated in the Carboniferous Period about 300 million years (BP) when land plants were diversifying and insects had begun to evolve from primitive segmented ancestors (Riek, 1970; Taylor, 1982). By the Permian Period 270 million years BP insects had segregated into modern orders, and the first fossil records of insect-damaged leaves are recorded. The first flowering plants oc-

0098-0331/86/0500-1109$05.00/0

curred in the Triassic Period about 225 million years BP (Smart and Hughes, 1973).

Over this vast stretch of evolutionary time, many of the estimated 100,000 secondary plant compounds appeared in response to evolutionary pressures for protection of plants from herbivore attack. Semiochemical communication has become the dominant force in coevolutionary relationships between plants and animals, by allomones that benefit the producer, kairomones that benefit the receiver, and synomones where both producer and receiver benefit. Fraenkel (1969) stated the profundity of the case for host plant selection by herbivores: "evidence for the importance of secondary plant substances in host selection is so overwhelming as to need no further proof."

The roles of the cucurbitacins of Cucurbitaceae as allomones and kairomones regulating herbivore attack provide a compelling example of the ecological and behavioral effects of secondary plant compounds (Chambliss and Jones, 1966; Sharma and Hall, 1973, Metcalf et al., 1980). The oxygenated tetracylic triterpenoid cucurbitacins (Cucs) are extremely bitter and toxic substances characteristic of the Cucurbitaceae (Metcalf et al., 1980). An appropriate scenario for the evolutionary and behavioral interactions between Cucurbitaceae and herbivores can be portrayed as follows (DaCosta and Jones, 1971a; Price, 1975; Metcalf, 1979): (1) ancestral Cucurbitaceae with *bi bi* genes for Cuc synthesis are heavily preyed upon by herbivores; (2) mutation in Cucurbitaceae to *Bi bi* forms bitter and toxic Cuc that deters herbivore attack; (3) strong selection pressure spreads *Bi bi* genes throughout evolving Cucurbitaceae species; (4) mutant Cucurbitaceae flourish in absence of herbivore attacks; (5) mutant ancestral Luperini rootworm beetles develop detoxification and excretion pathways to neutralize harmful effects of Cucs; (6) Luperini beetles expand into new ecological niches developing specific receptors for Cuc detection; and (7) Luperini beetles develop high blood and tissue levels of Cuc conjugates for defense against predators.

CUCURBITACINS AS ALLOMONES FOR CUCURBITACEAE

There is no ambiguity about the role of the Cucs as protective semiochemicals of the Cucurbitaceae and allied families against the attacks of herbivores. This is immediately apparent to anyone who has tasted a bitter squash, cucumber, or melon. The Cucs are the bitterest substances yet identified and can be detected by humans at dilutions as great as 1 ppb (Metcalf et al., 1980). The merest trace produces an almost paralytic response in lips and mouth and a persistent aftertaste. Moreover, the Cucs are extremely toxic to mammals with LD_{50} values to mice intraperitoneally of Cuc A, 1.2; Cuc B, 1.1; and Cuc C, 6.8 mg/kg (David and Vallance, 1955); and orally of Cuc I, 5 and Cuc E glycoside, 40 mg/kg (Stroesand et al., 1985).

Mice fed freeze-dried *Cucurbita texana* fruit at 10–20% of the diet died in 3–6 days. When fed this fruit at 1%, 40% died within 10 weeks, and the survivors had severe diarrhea and anemia (Stroesand et al., 1985). Sheep and cattle that consumed bitter fruit of wild *Cucumis leptodermus*, *C. africanus* and *C. myricarpus*, under drought conditions in South Africa were severely poisoned (Watt and Breyer-Brandwyk, 1962). Twenty-two cases of human poisoning from eating *C. pepo* (zucchini) fruits that contained about 1.1 mg Cuc E glycoside per gram occurred in Queensland, Australia, in 1982 (Ferguson et al., 1983a; Herrington, 1983). Symptoms included severe cramps, persistent diarrhea, and collapse occurring within a few hours after eating the zucchini fruits which were apparently mutant reversions to the *Bi* heterozygote (Rhymal et al., 1984).

Allomonal effects of Cucs have also been demonstrated on invertebrate herbivores including red spider mites (Tetranychidae) and the stem borer *Margaronia hyalinate* (DaCosta and Jones, 1971a). The presence of Cucs E and I has been shown to provide feeding deterrents to numerous insect herbivores including the leaf beetles *Phyllotreta nemorum*, *P. undulata*, *P. tetrastigma*, *Phaeodon cochliariae*, and *P. cruciferae* (Nielson et al., 1977). Cuc B applied to bean leaves prevented the feeding of the bean leaf beetle *Ceratoma trifurcata* (Metcalf et al., 1980).

Chemical Identity of Cucurbitacins. Approximately 20 chemically different Cucs have been characterized from plants (Lavie and Glotter, 1971; Guha and Sen, 1975) (Figure 1). Cuc B is the predominant form found in about 91% of all species characterized, followed by Cuc D (69%), Cucs G and H (47%), Cuc E (42%), Cuc I (22%), Cucs J and H (9%), and Cuc A (7%). Cucs C, F, and L were each found in only a single species (2%) (Rehm et al., 1957). It appears that the two primary Cucs are Cuc B and Cuc E and that the other Cucs are formed by enzymatic processes occurring during plant development and matu-

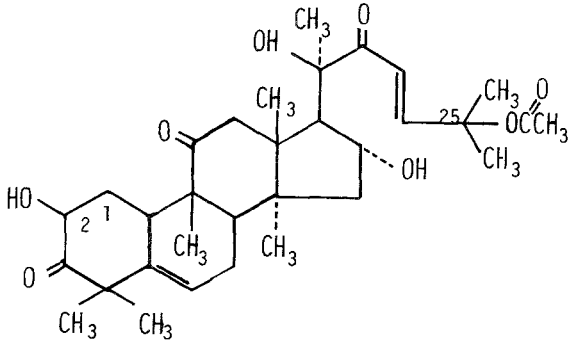

FIG. 1. Structure of cucurbitacin B. Cuc D is C_{25}—OH; Cuc E is C_1=C_2; Cuc I is C_1=C_2, C_{25}—OH; Cuc F is C_2—OH, C_3—OH, C_{25}—OH; Cuc G is C_{24}—OH, C_{25}—OH; Cuc L is C_1=C_2; C_{23}—C_{24}, C_{25}—OH.

ration. Cuc B can be metabolized to Cucs A, C, D, F, G, and H and is characteristic of *Coccinia*, *Cucumis*, *Lagenaria*, and *Trichomeria* (Rehm et al., 1957). Similarily Cuc E can be metabolized to Cucs I, J, K, and L and is characteristic of *Citrullus*. *Cucurbita* contains two groups of species characterized by either Cuc B or Cuc E (Metcalf et al., 1982). Cuc B is converted to Cuc E by Cuc Δ^1 reductase that produces the diosphenol grouping $C_1{=}C_2$, and Cuc Δ^{23} reductase converts the $C_{23}{=}C_{24}$ Cuc B and E series to the dihydro Cucs. Cucs B and E are converted to Cucs D and I by desacetylation by Cuc acetyl esterase (Schwartz et al. 1964, Schabort and Teijema 1968, Lavie and Glotter, 1971).

The Cucs in *Cucumis*, *Lagenaria*, and *Acanthosicyos* are present as free aglycones. However, in most species of *Citrullus* examined, the Cucs are present as glycosides (Rehm et al., 1957). In *Cucurbita* Cucs are present as aglycones in most species but glycosides are found in *C. cylindrata*, *C. foetidissima*, *C. palmata*, and *C. texana* (Metcalf et al., 1982). The presence of glycosides is related to the absence of β-glucosidase (elaterase) which may also be sequestered in intact plant tissues and released by crushing (Enslin et al., 1956).

Although the multiplicity of Cucs and their variable distribution in the Cucurbitaceae presents a complex situation for analysis, certain generalizations are valid: (1) Cucs B and E are the parent substances found most widely and the other Cucs, generally present in much lower quantities, are degradative products. (2) Cuc D is always associated with Cuc B and Cuc I is always associated with Cuc E. (3) Cucs G and H are always associated with Cucs B and D. (4) Cucs J and K are always associated with Cucs E and I. (5) Cuc A is always associated with Cuc B. (6) Cuc C is singular and occurs alone in *Cucumis sativus* (Rehm et al., 1957; Ferguson et al., 1983b). (7) Only Cucs B, C, and E sometimes occur alone.

Distribution of Cucurbitacins in Plants. Cucurbitacins, as the name suggests, are peculiarly associated with the family Cucurbitaceae where they have been characterized in at least 30 genera and more than 100 species (Rehm et al., 1957; Lavie and Glotter, 1971; Pohlmann, 1975). Cucs are also found in a few genera of the related plant families Begoniaceae, Brassicaceae (Cruciferae), and Datisceae, all of the superorder Violoflorae (Thorne, 1981). For example, Cucs have been identified in 16 species of *Iberis* (Brassicaceae) (Lavie and Glotter, 1971; Curtis and Meade, 1971). Cucs have also been identified in a few species of Euphorbiaceae, Scrophulariaceae and Rosaceae (Dryer and Trousdale, 1978).

Cuc synthesis in *Cucumis*, *Citrullus*, *Cucurbita*, and *Lagenaria* is initiated by a single dominant gene *Bi*. Nonbitter fruit may develop from bitter seedlings in the presence of a modifier gene *Su Bi* (Robinson et al., 1976). It is probable that a few major genes control the chemical nature of the Cuc formed and Cuc B is dominant over Cuc E (Ferguson et al., 1983b).

Cucs are found in all parts of the plant in the Cucurbitaceae: roots, stems, leaves, fruit, and occasionally in the seeds.

Roots. The concentration in the roots increases with age and can reach very high levels in perennial plants, e.g., 1.4% in *Citrullus naudinianus*, 1.1% in *Acanthosicyos horrida*, and 0.9% in *Colocynthis ecirrhosa* (Rehm, 1960). In 18 species of *Cucurbita*, Cucs B–D were detected in the roots of seven, up to 0.43% in *C. ecuadorensis*, and Cucs E–I were identified in six up to 0.38% in *C. palmata* (Metcalf et al., 1982).

Leaves. Although Rehm (1960) indicates that the leaves of Cucurbitaceae seldom contain Cucs even when the roots have very high concentrations, this generalization has many exceptions. Young rapidly growing leaves of *Colocynthis* (*Citrullus*) *vulgaris* and *C. ecirrhosa* have only about 0.01% Cucs, but this reaches 0.1–0.3% by the end of the vegetative season. Of 18 species of *Cucurbita* examined, Cucs B–D were found in seven species up to 0.059% in *C. lundelliana*, and Cucs E–I in six species up to 0.1% in *C. okeechobeensis* (Metcalf et al., 1982).

Fruits. The fruits of a variety of Cucurbitaceae contain high amounts of Cucs. Rehm et al., (1957) found Cuc concentrations of >0.1% in the fruits of *Citrullus colocynthis* and *C. ecirrhosis* (Cuc E), *Cucumis angolensis* and *C. longyies* (Cuc D), *C. myriocarpus* (Cuc A), and *C. sativus* (Cuc C). Of 18 species of *Cucurbita* examined, the fruits of seven contained Cucs B–D up to 0.31% in *C. andreana*, and the fruits of five contained Cucs E–I up to 0.23% in *C. foetidissima* (Metcalf et al., 1982).

Seeds. Cucs are not commonly found in the seeds of Cucurbitaceae. Rehm et al. (1957) reported that three of 45 species had bitter seeds, presumably from Cucs present in the surrounding tissue.

CUCURBITACINS AS KAIROMONES FOR ROOTWORM BEETLES

The ancestral association between the leaf beetles of the tribe Luperini (Coleoptera: Chrysomelidae: Galerucinae) and the plants of the family Cucurbitaceae seems to have been effected through the presence of the cucurbitacins acting secondarily as kairomone cues for host selection by the beetles. The scope of this association is presently worldwide. The Luperini is comprised of two very similar but geographically isolated subtribes, the Diabroticina of the New World, containing about 993 species all evidently radiating from tropical America, and the Aulacophorina of the Old World, containing about 535 species apparently radiating from tropical Australasia (Maulik, 1936; Wilcox, 1972). The Aulacophorina are presently all restricted to Asia except *Aulacophora foveicollis* whose range extends to Europe and *A. africanus* extending into Africa. Maulik (1936) cites the remarkable similarity between these two

large groups of phytophagous beetles: "In the Old World, Aulacophora represents Diabrotica . . . In larval, pupal and adult structures, in breeding habits and in food plants, there is a remarkable resemblance between the two genera." The present distribution of the two subtribes of the Luperini is shown in Metcalf (1985).

At least 50 species of Luperini, representing more than 80% of the available host records, have been recorded as feeding on Cucurbitaceae (Wilcox, 1972; Takizawa, 1978; Metcalf, 1985). The common names of notable pest species attest to the significance of this relationship:

Diabroticina (New World): *Diabrotica balteata*, the banded cucumber beetle; *D.* (*Paranapiacaba*) *connexa*, the saddled cucumber beetle; *D. picticornis*, the painted cucumber beetle; *D. speciosa*, the cucurbit beetle; *D. u. howardi*, the spotted cucumber beetle; and *A. vittatum*, the striped cucumber beetle.

Aulacophorina (Old World): *Aulacophora abdominalis*, plain pumpkin beetle; *A. femoralis*, cucurbit leaf beetle; *A. foveicollis*, red pumpkin beetle; and *A. hilaris*, pumpkin beetle.

The role of cucurbitacins in host selection by Luperini is exemplified by two recent studies relating Cuc content of *Cucurbita* cotyledons to damage by rootworm beetles, rated on a five-point scale. For *A. foveicollis* attacking *Cucurbita moschata* cultivars there was a substantial correlation between Cuc content and feeding damage, $r = 0.62$, $N = 32$, SD = 0.14[2], and it was concluded that "low cucurbitacin content appeared to impart resistance" (Pal et al., 1978). In a similar study of *D. u. howardi* and *A. vittatum* attacking *Cucurbita pepo* cultivars, the correlation between beetle damage and Cuc content was, $r = 0.77$, $N = 12$, SD = 0.20, and it was concluded that there was a "strong positive correlation between seedling cucurbitacin content and Diabroticina beetle attacks" (Ferguson et al., 1983b). Similar correlations were found between the average numbers of Diabroticina beetles feeding on crumpled leaves or sliced fruits of various *Cucurbita* spp. and their total Cuc content (Metcalf et al., 1982): with *D. u. howardi*, leaves $r = 0.74$, $N = 16$, SD = 0.20; fruits $r = 0.70$, $N = 11$, SD = 0.24. With *D. v. virgifera*, the correlations were leaves $r = 0.64$, $N = 16$, SD = 0.24; and fruits $r = 0.58$, $N = 11$, SD = 0.27.

The systematic relationships between Aulacophorina and Diabroticina and their common responses to Cucs indicate a common ancestral relationship with a Cucurbitaceae progenitor during a geologic period no later than the Miocene ca. 30 million years BP when continental land bridges were still present (Metcalf, 1979). This argument is supported by the presence of fossil *Diabrotica* spp. in Florisant shales of Colorado, ca. 25–30 million years BP (Wickham, 1914). Isozyme studies of the Diabroticina have produced evidence of the divergence of *Acalymma* from *Diabrotica* at about 2.7 genetic distances or approximately 45 million years BP (unpublished data).

[2] r = correlation coefficient, N = number of observations.

TABLE 1. LIMIT OF RESPONSE (LR) OF DIABROTICINA BEETLES TO PURE CUCURBITACINS ON SILICA GEL PLATES

Species	Cuc LR (μg)							
	B	D	E	F	G	I	L	E-gly
D. balteata	0.01			10	3	5		0.1
D. l. barberi	0.1		0.3					5
D. cristata	0.1	1.0	0.3	>10	3		>1.0	50
D. u. howardi	0.001	0.03	0.01	1.0	3.0	0.1	0.01	0.05
D. u. undecimpunctata	0.003		0.03					
D. v. virgifera	0.01	0.1	0.3	0.1	3	0.3	1.0	0.03
A. vittatum	0.3		10					50

Sensory Receptors of Diabroticina Beetles for Cucurbitacins. The high degree of sensitivity to the Cucs and the specificity of the behavioral responses of arrest and compulsive feeding induced by proximity to Cucs demonstrate that specific receptor organs are present in the beetles. Both sexes of *D. u. howardi*, *D. v. virgifera*, and *A. vittatum* responded to pure Cucs with identical arrest and feeding behavior. Amputation of the antennae of *D.u. howardi* beetles had little effect on the feeding response to Cucs but amputation of the maxillary palpi abolished arrest and feeding (Metcalf et al., 1980). Scanning electron microscopy of the maxillary palpi of the several species of Diabroticina studied (Table 1) has demonstrated *sensilla basiconica* arranged around the tip of the maxillary palpus that seem likely to contain the Cuc receptor. Detailed study of the comparative morphology in the several species is in progress (J.R. Larsen, in preparation).

Diabroticina Beetle Sensitivity to Cucurbitacins. Field observations of the mass attacks of various Diabroticina beetles on cotyledons, leaves, and fruits of Cucurbitaceae suggest that the Cucs present are effective at low concentrations in producing arrest and compulsive feeding of adult beetles.

Qualitatively, all the species of Diabroticina investigated (see Table 1) will feed to some degree on pure crystalline Cucs A, B, C, D, E, F, G, I, and L placed on filter paper or silica gel thin-layer chromatography (TLC) plates (Chambliss and Jones, 1966; Metcalf et al., 1980). The various beetle species produced identical spectra of feeding patterns on TLC plates developed from chloroform extracts of *Cucurbita andreana* (Cucs B–D), *C. okeechobeensis* (Cucs E–I), or *C. texana* (Cuc E glycoside) (Metcalf et al., 1982). These "beetle prints" (Figure 1) are valuable in characterizing the distribution of Cucs in the Cucurbitaceae. When the TLC plates developed from plant extracts were presented simultaneously, Cuc B was always fed upon before Cuc E and Cuc D before Cuc I, indicating the greater beetle sensitivity to the Cuc B–D compounds (Table 1). The beetle bioassay used in conjunction with TLC to separate

the individual Cucs is both qualitative and semiquantitative as the areas eaten from the TLC plates are proportional to the amounts of Cucs present.

Quantitatively, there are substantial differences in the threshold amount of the various chemically purified Cucs that produces a detectable feeding response and different species of beetles show different responses to the individual Cucs (Table 1). This quantity is the limit of response (LR) and is measured on silica gel TLC plates exposed to about 100 Diabroticina beetles for four days. The LR represents the relative degree of complementarity of the various Cucs to the maxillary palpi receptors of the Diabroticina (Metcalf et al., 1980). *D. u. howardi* and *D. u. undecimpunctata* beetles consistently responded to 1–3 ng of Cuc B under these standard conditions as shown in Table 1. This beetle bioassay is therefore about 250× more sensitive than HPLC (Ferguson et al., 1983b) and 1000× more sensitive than UV spectrophotometry (Metcalf et al., 1982).

Table 1 also shows that there are major differences in the LR values for the various Diabroticina beetles to the individual Cucs. These differences have evolutionary and behavioral significance. The conclusions that can be drawn from the data in Table 1 are: (1) Cuc B was consistently detected in the lowest amount and is probably the parent Cuc to which Diabroticina receptors are attuned, as it was found in 91% of the species characterized. (2) Cuc B was consistently detected at levels of about 0.1 that of Cuc E. (3) The acetoxy Cucs B and E were detected at levels about 0.1 those of the corresponding desacetoxy Cucs D and I, respectively. (4) Saturation of the desacetoxy Cucs at $C_{23}=C_{24}$ double bond (Cuc L) had little effect on level of detection. (5) Sensitivity to the 2-OH, 3-C=O Cuc D was greater than to the 2-OH, 3-OH Cuc F. (6) The *D. undecimpunctata* subgroup (*D. balteata*, *D.u.u.*, *D.u.h.*) is more sensitive to Cucs than the *D. virgifera* subgroup (*D.l. barberi*, *D. cristata*, and *D.v. virgifera*). (7) *A. vittatum* is substantially less sensitive to Cucs than the *Diabrotica* spp.

The range of variations in maxillary receptor sensitivity to the various Cucs (Table 1) is relatively consistent for all the species examined. It appears that Cuc B has maximum complementarity to the Cuc receptor. Receptor depolarization most probably results from allosteric changes in the conformation of the receptor protein resulting from interactions of the free paired electrons (dipoles) associated with the several oxygen atoms of the Cuc molecules (Metcalf et al., 1980). The structural change from Cuc B to Cuc E by introduction of a single C=C bond at C_1-C_2 in ring A (Figure 1) seems trivial, yet this change produces a 10-fold decrease in receptor affinity (Table 1). The introduction of the C=C bond into ring A changes the orientation of the three contiguous O atoms (C_3=O, C_2—OH, and C_{11}=O) from a staggered configuration on the cyclohexyl moiety of Cuc B to a planar configuration in Cuc E. From observations of molecular models, this change seems ample to decrease receptor affinity and depolarization. Cucs D and I exhibit about a 10-fold decrease in receptor affinity

as compared to the C_{25} acetoxy derivatives B and E (Figure 1). This suggests that the acetoxy C=O dipole must also be involved in complete binding to the receptor.

CUCURBITACINS AS ALLOMONES FOR DIABROTICINA BEETLES

The incredibly bitter taste of Cucs and their toxic effects on vertebrates after ingestion suggest a further role in the behavioral ecology of the Diabroticina beetles, i.e., as protective allomones against predators. Thus the ingestion of Cucs by Diabroticina species feeding on bitter Cucurbitaceae host plants may provide protection against birds and predaceous vertebrates, as first suggested by Howe et al. (1976).

Storage and Sequestration of Cucs. Diabroticina beetles can concentrate and sequester relatively large amounts of Cucs in free and derivatized form. A single elytron of *D. undecimpunctata* or *D. balteata* fed on bitter *Cucurbita andreana* × *C. maxima* cultivar (Rhodes et al., 1980), containing 1–3 mg Cuc B–D per gram fresh weight, had an extremely bitter taste and the numbing effect on lips and tongue was perceptible 2 hr later (personal observation).

Groups of *D. balteata* adults were fed on bitter *C. andreana* × *C. maxima* fruit for various periods of time and the Cuc content was measured in the hemolymph by UV spectrophotometry after isolation by TLC. The presence of a Cuc conjugate (R_f 0.4 in chloroform–methanol 1 : 1) was readily detected in 1 μl or less of insect hemolymph following TLC, after one and two days of feeding of the adult beetles on bitter squash (Ferguson et al., 1985). The concentration of the Cuc conjugate rapidly increased in the hemolymph of *D. balteata* and reached an apparent plateau level after 30–40 days when blood levels were about 30 μg/μl (3%). Similar blood measurements on *D. u. howardi* adults collected from bitter squash plants indicated hemolymph levels of Cucs of 20–26 μg/μl. This Cuc content is equivalent to about 15 mg Cucs per gram of body weight. No Cucs were detectable in *D. balteata* adults reared on pollen food (Ferguson et al., 1985).

Adverse Effect of Cucurbitacin Sequestration upon Predators. The Chinese mantis *Tenodera aridifolia sinensis* is an omnivorous insect predator and has been shown to acquire learned aversion to cardiac glycosides sequestered in the milkweed bug, *Oncopeltus fasciatus* (Berenbaum and Miliczky, 1984). Paired experiments where mantids were offered first Diabroticina beetles reared on pollen and then beetles reared on bitter squash fruit showed that 72% of *D. balteata*, 46% of *D. u. howardi*, and 24% of *D. v. virgifera* fed on bitter fruits were rejected. The results were highly significant ($P < 0.001$–$P < 0.05$) (Ferguson and Metcalf, 1985). No mantid ever rejected a beetle fed on pollen, but the rejection reaction of the Cuc-containing beetles typically consisted of the

mantid violently flinging away the beetle after a single bite on an elytron. Approximately 70% of the rejected beetles survived such encounters. The predator was obviously disturbed by the Cucs and underwent a period of excessive grooming, unsteadiness, and/or regurgitation. In some instances the mantis would fall from its perch and, after holding the bitter prey away from its body, would taste it one or two more times prior to discarding it.

Although the Chinese mantis consistently rejected *D. balteata*, *D. u. howardi*, and *D. virgifera* adult beetles fed on bitter squash in favor of those fed on pollen, the striped cucumber beetle, *A. vittatum*, was an exception, in that there was no significant difference in rejection rate between beetles fed pollen and those fed bitter squash (Ferguson and Metcalf, 1985). However, larvae of the *A. vittatum* beetles were reared on the roots of *Cucurbita maxima* (blue hubbard squash). The roots of this species contain relatively large amounts of Cucs, and taste and beetle bioassays showed the presence of large amounts of Cucs in both the pollen-fed and bitter-squash-fed adults. Thus, the larvae feeding on the bitter roots sequestered Cucs that were transferred to the adult beetles during metamorphosis. The larval sequestration of Cucs was effective and persistent, and *D. u. howardi* adult beetles fed as larvae on bitter *Cucurbita* and then placed as adults on a pollen diet for three months were still rejected by the Chinese mantid. Bioassay by TLC and beetle feeding demonstrated that the hemolymph of these beetles free from exposure to Cucs for six weeks still contained quantities of Cucs comparable to those fed continuously on bitter fruit (Ferguson and Metcalf, 1985).

The feeding deterrent effect of pure Cuc B was evaluated by topical application in acetone of 14 μg to the elytra of pollen fed beetles devoid of Cucs. Such treated beetles were consistently rejected by the Chinese mantid (Ferguson and Metcalf, 1985).

The protective effect of Cucs against predation of Diabroticina species appears to extend to larvae and to eggs. The larvae of several species reared on roots of bitter squash had hemolymph that was distinctly bitter. Females of *D. u. howardi*, *D. balteata*, and *A. vittatum* laid eggs that contained substantial quantities of Cucs as detected by beetle bioassay (Ferguson et al., 1985) (Figure 2). These "bitter" eggs could be effective in discouraging ant egg predators such as by *Solenopsis geminata* and *Pheidole* spp. (Risch, 1981).

Metabolism of Cucurbitacins by Diabroticina. The ability of Diabroticina beetles to grow, develop, and reproduce on host bitter *Cucurbita* containing as much as 0.32% fresh weight of Cucs (Metcalf et al., 1982) demonstrates the evolutionary development of effective metabolic mechanisms for disposition of these toxic triterpenoids. For example, groups of 25 *D. u. howardi* or *D. v. virgifera* adults completely consumed 1 mg of Cuc B in 72 hr without any perceptible ill effect. These insects weighed about 20 and 10 mg, respectively, so that the oral LD_{50} values for Cuc B are $>>2000$ mg/kg (Metcalf et al., 1980).

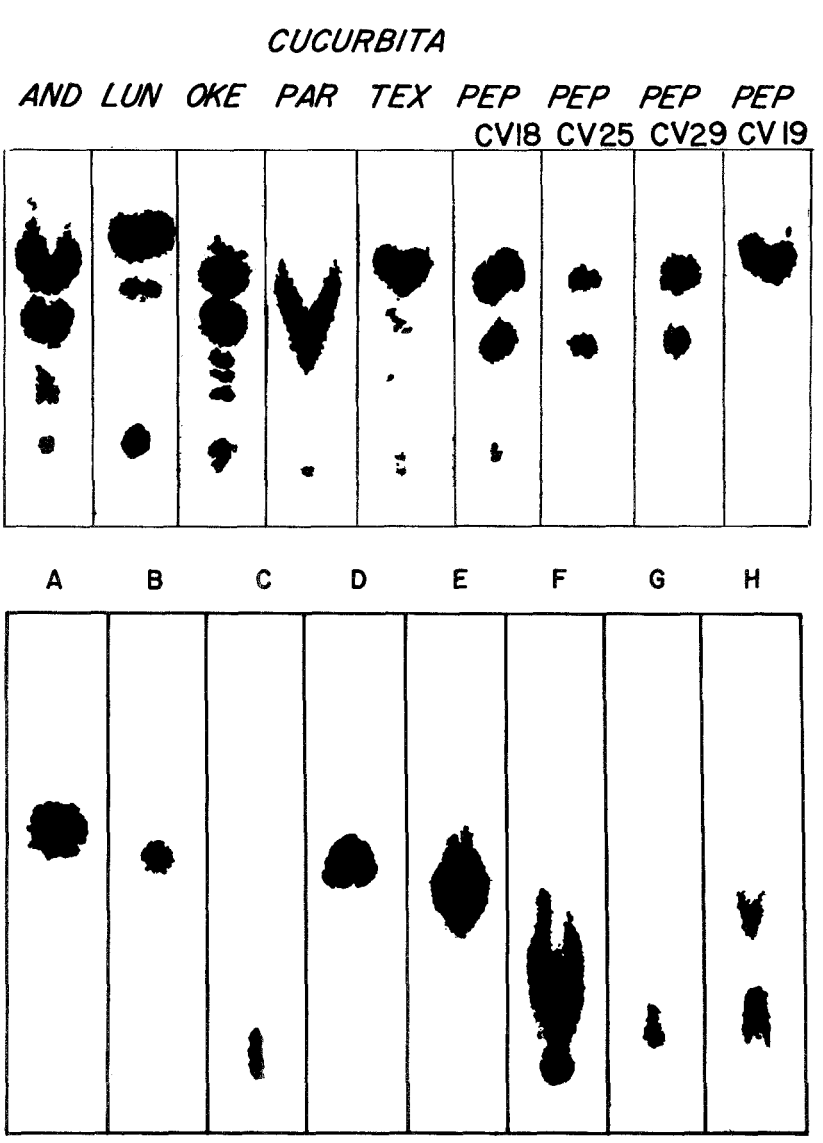

FIG. 2. Profiles of thin-layer chromatograms showing areas eaten from silica gel plates, "beetle prints," by feeding of adult *Diabrotica u. howardi*. Top: chloroform extracts of cotyledons of *Cucurbita* spp. and cultivars. AND = *andreana*, LUN = *lundelliana*, OKE = *okeechobeensis*, PAR = *palmeri*, TEX = *texana*, PEP = *pepo* cv. Ambassadore, Diplomat, Greenbay, and Black, respectively. (Ferguson et al., 1983b). Bottom: A, B = Cuc B and D standards, C = 0.75 μl of hemolymph from field collected *D. u. howardi*, D. = same hemolymph treated with pectinase, E = chloroform extract of excreta from *D. u. howardi*, F = chlorofrom extract of the body of *D. u. howardi* with no exposure to Cucs for six weeks, G = chloroform extract of 200 eggs from *D. u. howardi* adults fed on Cucs, and H = extract of 400 eggs of *A. vittatum* exposed to Cucs only as larvae (Ferguson et al., 1985).

[^{14}C]Cuc B was synthesized from DL-[2-^{14}C]mevalonate in seedlings of *C. maxima* and purified by preparative TLC to specific activity of 2.5 μCi/m mol. Approximately 1 mg of the [^{14}C]Cuc B was fed to groups of 20 one- to two-week-old Diabroticina beetles over a period of 48 hr. The disposition of ^{14}C-labeled products was examined in excreta, hemolympyh, gut, and body remainder after extraction and TLC. The total amounts of ^{14}C label excreted ranged from 67.2% for *A. vittatum* to 94.6% for *D. balteata*. Cuc B was identified in the excreta ranging from 1.7% in *D. u. howardi* to 30.0% in *D. v. virgifera*, but only traces of Cuc D were found, suggesting that deacetylation is not a major step in the formation of excretory products. Most of the ^{14}C was excreted in all five species of Diabroticina as three polar metabolites, R_f 0.0, 0.15, and 0.23 in TLC with chloroform–methanol 95:5. These polar metabolites comprised from 46.8% of the total excreted ^{14}C in *D. v. virgifera* to 91.0% in *D. balteata*. The major excretory metabolite in all five species, R_f 0.0, was a Cuc conjugate that comprised from 24.7% of the total excreted ^{14}C in *A. vittatum* to 43.8% in *D. cristata* (Ferguson et al., 1985). A small proportion of a Cuc-conjugate was permanently sequestered in the hemolymph, from 0.98 to 2.76% of the total ^{14}C. The remainder of the ^{14}C was retained, largely as conjugates, in the body and gut. In the five species examined, there were markedly different ratios of unmetabolized Cucs/polar metabolites, probably related to the present-day dietary habits of the beetles.

When *D. u. howardi* were fed ^{14}C Cucs B–D followed by two weeks on an artificial pollen diet, 93.9% of the total ^{14}C was excreted, but the hemolymph retained 1.12% of the total ^{14}C and 1058 eggs collected contained 0.21% (Ferguson et al., 1985). The characteristic polar metabolite of the hemolymph in all five species of beetle fed Cuc B had R_f 0.40 upon TLC in chloroform–methanol 1:1. This metabolite was further purified by HPLC (Ferguson et al., 1985), a fraction with retention time (RT) of 4.26 min eliciting strong beetle feeding on TLC plates (Figure 2). This Cuc conjugate was incubated overnight with pectinase to free the cucurbitacin which was extracted with chloroform. The cucurbitacin had an R_f 0.46 upon TLC with chloroform–methanol 95:5, and a RT on HPLC of 5.60 min, identical to that of Cuc D. Mass spectrometry by electron impact produced a fragmentation pattern identical to Cuc D (Audier and Das 1966). When beetles were fed *Cucurbita okeechobeensis* fruit containing Cuc E, or *C. texana* fruit containing Cuc E glycoside (Metcalf et al., 1982), hemolymph conjugates were formed that released Cuc I (R_f 0.52, blue-violet color with $FeCl_3$) after treatment with pectinase. Pure Cucs B and E, when incubated with pectinase, were not deacetylated to Cucs D and I as demonstrated by TLC. Thus, the deacetylation to produce the hemolymph conjugates was occurring in vivo in the beetles (Ferguson et al., 1985).

Consumption of Bitter Cucurbita and Diabroticina Longevity. Paired experiments were conducted where 50 newly emerged beetles were fed ad libitum on uniformly sized pieces of either bitter *C. andreana* × *C. maxima* F_1 hybrid

squash fruit containing 1–2 mg/g of Cuc B–D or on *Cucurbita* cultivars, *C. pepo* or *C. moschata*, devoid of Cucs (Ferguson et al., 1985). The total Cuc consumption was estimated over the lifetime of the beetles as 1–2 mg per beetle for *D. balteata*, 1.7–3.4 mg for *D. virgifera*, and 0.8–1.6 mg for *A. vittatum*. Beetle mortality was recorded daily, and the weekly mortality pattern and mean longevities for each species were determined (Ferguson et al., 1985). The lifespans of the adult beetles are remarkably long, up to 250 days. However, exclusive feeding on Cuc-containing fruit significantly decreased the mean longevity of *D. virgifera* from 126 days to 59 days ($P < 0.001$) and of *D. balteata* from 129 days to 70 days ($P < 0.001$). With *A. vittatum*, there was no significant difference in the longevity between the beetles fed on sweet fruits, mean 136 days, and those fed on bitter fruit, mean 122 days.

There were significant differences in the accumulated mortalities of male versus female beetles: the longevity of male *D. virgifera* was reduced 147% by feeding on bitter fruit as compared with only 39% for the female. With *A. vittatum*, feeding on bitter fruit decreased the male longevity by 27% ($P = 0.018$) but had no effect on the female longevity (Ferguson et al. 1985).

These effects on longevity can be interpreted in terms of the stress produced over the insects' lifetimes for energy requirements for metabolism, excretion, and tissue storage of the Cucs. These costs appear to be greatest in *D. virgifera*, whose normal life-style as a Poaceae feeder does not expose it to Cucs. The stress factor is less for *D. balteata* that commonly feeds on Cucurbitaceae and was barely perceptible for *A. vittatum* that is monophagous on Cucurbitaceae.

Incorporation of Cuc D into a pollen diet at 0.5 mg/g increased male food consumption substantially over that of females: *D. balteata* male 36%, female 3 %; *D. howardi* male 25%, female 1%; *D. virgifera* male 15%, female 9%; and *A. vittatum* male 24%, female 7% (Ferguson, 1985). This suggests that the male beetles in the longevity experiments may have consumed more Cucs, thus reducing their survival rate.

COEVOLUTIONARY IMPLICATIONS OF DIABROTICINA AND CUCURBITACEAE ASSOCIATION

The original coevolutionary strategy of the Cucurbitaceae to synthesize the intensely bitter and toxic Cucs as allomones to restrict herbivory has been very successful, as major herbivores are relatively few. This evolutionary strategy has produced three major variations in the structures of these Cuc allomones, (1) C_1-C_2 unsaturation, (2) acetylation at C_{23}, and (3) glucosylation.

A comparison of Cuc content of *Cucurbita* spp. with phyllogeny as constructed from genetic compatibilities and numerical taxonomy (Rhodes et al., 1968) suggests that the primitive form of Cucs was *B–D* and that Cucs *E–I* and the glycosides appeared as secondary modifications. These two modifications

each evolved at least twice independently in *Cucurbita*, i.e., $C_1 = C_2$ (E, I) in *C. martinezii* and *C. palmata* subgroups, and formation of glycosides in *C. texana*, *C. palmata*, and *C. cylindrata* (Metcalf et al., 1980, 1982).

All species of Diabroticina examined have specific Cuc receptors on the maxillary palpi that are structurally attuned to Cuc B. The presence of trace quantities of Cuc B elicits arrest and compulsive feeding in these Diabroticina species whether they are monophagous on Cucurbitaceae as *A. vittatum*, oligophagous on Cucurbitaceae as *D. balteata*, polyphagous as *D. u. howardi*, oligophagous on Poaceae as *D. l. barberi* and *D. v. virgifera*, or monophagous on *Andropogon* as *D. cristata*.

Stimulation of the Cuc receptors in Diabroticina beetles produces behavioral responses of arrest and compulsive feeding that are so fundamental as to override even the male response to the female sex pheromones, e.g., in *D. u. howardi* (Hummel and Andersen, 1982).

All species of Diabroticina examined have well-developed detoxification and storage mechanisms to partially metabolize, conjugate, and concentrate Cucs. Thus they appear to be immune to the general repellent and acutely toxic effects of Cucs. (Ferguson et al., 1985).

Major natural enemies of the Diabroticina appear to be few, and judged from the incredibly bitter taste of beetles fed on bitter *Cucurbita* and their repellent effect to a mantid predator (Ferguson et al., 1985), the coevolutionary strategy of the Diabroticina to conjugate Cucs and concentrate these bitter products in the hemolymph provides a successful survival mechanism.

Acknowledgments—The research reviewed was supported in part by Competitive Grants 5901-0410-8-0067-0 and 59-2171-1-1-6590 from the USDA, SEA Grants Office. Any opinions, findings, and conclusions or recommendations are those of the authors and do not necessarily reflect the view of USDA.

PHYTOCHEMICAL BASIS OF LEARNING IN *Rhagoletis pomonella* AND OTHER HERBIVOROUS INSECTS

DANIEL R. PAPAJ and RONALD J. PROKOPY

Department of Entomology
University of Massachusetts
Amherst, Massachusetts 01003

(Received July 23, 1985; accepted January 13, 1986)

Abstract—Examples of phytochemically-based learning of host preference in herbivorous insects are reviewed in the context of traditionally important issues: the number and kinds of chemicals involved; which sensory modalities are affected; whether peripheral or central nervous processing is altered; and whether learning is associative or not. A fifth issue addressed here—whether experience enhances a feeding or ovipositing insect's propensity to accept familiar chemical stimuli or to reject novel chemical stimuli—has been ignored in previous studies. Following the review, evidence is presented indicating that female apple maggot flies (*Ragoletis pomonella*) learn to reject both novel physical and novel chemical stimuli.

Key Words—Learning, phytochemistry, host preference, herbivorous insects, *Rhagoletis pomonella*, Diptera, Tephritidae.

INTRODUCTION

The location and selection of host plants by herbivorous insects has been portrayed historically as a simple, invariant behavioral sequence (Thorsteinson, 1960). In particular, responses to the secondary and nutrient chemical constituents of plants have been viewed generally as consequences of innate releasing mechanisms (*sensu* Tinbergen, 1969), stereotyped and relatively resistant to environmental factors. The continuing accumulation of evidence for learning of host preference in herbivorous insects (Jermy et al., 1968; Dethier, 1980; Prokopy et al., 1982; Rausher, 1983; Papaj and Rausher, 1983; Stanton, 1984; Papaj, 1986a, b) and saprophagous insects (Jaenike, 1982, 1983, 1986), as well as recent theoretical discussions of learning as a factor in the evolution of host discrimination (Rausher, 1983; Papaj and Rausher, 1983; Stanton, 1984), de-

0098-0331/86/0500-1125$05.00/0

mand a critical examination of the thesis that an insect's responses to phytochemicals are static and independent of prior feeding or egg-laying history. In this paper, we first review the evidence for learning involving plant chemicals and then introduce our own work on learning to chemical cues in fruit acceptance behavior by the apple maggot fly, *Rhagoletis pomonella.* We define "learning" as a reversible change in behavior with experience; we use "induction" synonymously with learning, but apply that term particularly to effects of diet on the feeding preference of lepidopterous larvae.

GENERAL REVIEW

Induction of Larval Feeding Preference. Yamamoto and Fraenkel (1960) and Jermy et al. (1968) can be credited with first showing convincingly that host preference depends on prior feeding history. Since then, feeding or oviposition preference has been altered by feeding or oviposition experience almost whenever the issue has been examined, predominantly in lepidopterous larvae (see reviews by Hanson, 1983; De Boer and Hanson, 1984), but also in adult Lepidoptera (Stanton 1984; Traynier 1984; Papaj 1986a–c), Diptera (Jaenike, 1982, 1983, 1985; Prokopy et al., 1982, 1986; Cooley et al., 1986) Orthoptera (Cassidy, 1978) and Coleoptera (Phillips, 1977; Rausher, 1983).

Most studies of so-called induction of feeding preference adopted the assay developed by Jermy et al. (1968) in which individuals reared on a particular host plant or artificial medium are presented simultaneously with an array of hosts, nonhosts, or artificial media. Preference was usually defined by the relative proportion of material of each type consumed after a certain time has elapsed or after a certain absolute amount of material is ingested. In the original work by Jermy et al. (1968), for example, larvae of the tobacco hornworm, *Manduca sexta,* were reared on tobacco (*Nicotianea* spp.), Jerusalem cherry (*Solanum* spp.), and tomato (*Lycopersicon* spp.); larvae were subsequently offered plant disks of all three species simultaneously. The assay was terminated when a larva had consumed approximately half of one disk. The results were unambiguous: larvae always consumed more leaf material of the plant species on which they were reared.

In other words, the order in which host species were preferred was altered by prior experience—in the sense of Papaj and Rausher (1983), a modification of the rank order of preference. In other cases the rank order of preference remained the same, but the degree to which different species were consumed still depended on feeding history—in the sense of Papaj and Rausher (1983), a modification of the specificity of preference. For example, when *Manduca* larvae were reared on certain nonhost species, those species were consumed more frequently than if the larvae were reared on host plants, but never more fre-

quently than the host plants themselves (De Boer and Hanson, 1984). In general, the outcome of induction, i.e., whether rank order or specificity is altered by experience, may depend upon the taxonomic relatedness of the test plant species (Wasserman, 1982; De Boer and Hanson, 1984).

The notion that host experience causes changes in an herbivorous insect's responses to host chemical stimuli was implicit in an important hypothesis about the processing of host-selection information advanced by Jermy et al. (1968). Presuming that induction of preference in lepidopterous larvae was mediated by changes in responses to phytochemicals, Jermy and colleagues argued that discrimination among plant species must involve, at least in part, assessment of qualitative differences in the profiles of phagostimulants and deterrents of different plant species. If quantitative differences only were important, e.g., if larvae discriminated among plants merely by measuring the level of a compound shared by those plants, then induction to one host should have enhanced the acceptability of all host species more or less equally. In fact, induction always resulted in increased consumption of the inducing plant relative to alternative plants. Qualitative differences among plants could reflect, for example, differences among plants in the kinds of compounds perceived by the insect or differences in the relative concentrations of more than one compound shared by those plants.

Evidence for Phytochemical Basis of Larval Induction. The assumption of a phytochemical basis of larval induction of feeding preference has been supported by a number of studies. In a study by Schoonhoven (1969), for example, the gustatory organs of *Manduca* larvae reared on tomato plants exhibited electrophysiological responses to saps from an array of host and nonhost species that differed from those of larvae reared on an artificial medium. Impulse rates from a gustatory organ, the medial maxillary sensilla styloconica, were generally higher for larvae fed on artificial diet than for those fed on tomato leaves. Similarly, the impulse rates generated by contact with a variety of pure chemicals (sodium chloride, salicin, solanin, and inositol) were greater after feeding on artificial diet lacking these compounds than after feeding on tomato.

The responses of larvae to single compounds can also be modified by rearing on media containing those compounds. Electrophysiological responses to the secondary compound, salicin, by *Manduca* larvae were altered by prior feeding on diets containing salicin (Schoonhoven, 1969). When salicin was incorporated into artificial medium or tomato leaves, the medial maxillary sensilla styloconica of larvae exposed to the salicin-laced diet fired less rapidly than the sensilla of larvae exposed to diet alone.

Induction of preference for diets containing particular compounds is not confined to secondary plant compounds only. The medial maxillary sensilla styloconica of *Manduca* larvae fed on artificial diet spiked with 0.01 M inositol (a weakly stimulatory sugar) fired at a lower rate upon contact with inositol than

did those of larvae fed on artificial diet alone (Schoonhoven, 1969). Similarly, Städler and Hanson (1978) induced successfully *Manduca* larvae to an artificial diet containing the nutrient linoleic acid. Larvae fed on a standard wheat germ diet and larvae fed on a similar diet lacking lineoleic acid and other nutrient compounds consumed proportionately more of their respective diets in choice tests. Städler and Hanson used choice tests featuring a variety of extracts of the diets as well as tests with pure lipid components to confirm that experience altered feeding responses to linoleic acid.

Components of Behavior Altered by Induction. Like most induction studies using natural foliage for testing, preference for a host chemical or host test extract has often been deduced from the relative amounts of chemically treated and untreated material consumed by larvae in choice assays. These so-called "cafeteria tests" facilitate a large number of replicates and experiments (e.g., Städler and Hanson, 1978; De Boer and Hanson, 1984), but compromise efforts to define which components of host-selection behavior are altered by prior experience. Saxena and Schoonhoven (1978, 1982), in sharp contrast, used behavioral assays in which individual insects were observed directly to elucidate the behavioral mechanisms underlying induction of larval preference.

Saxena and Schoonhoven (1978) reared a group of *Manduca* larvae on a wheat germ diet containing the terpene, citral, and another group on a plain wheat germ diet. Results of a tightrope choice test in which larvae walked along a wire or Plexiglas edge between two experimental disks revealed that citral-exposed larvae turned more frequently towards a citral-medium disk than a plain-medium disk. Moreover, induction to diet was symmetrical. Larvae reared on plain medium turned more frequently towards a plain-medium disk than a citral-medium disk. Larvae reared on citral medium consumed more citral medium than plain medium in both choice and no-choice presentations; larvae fed plain medium consumed more plain medium in both choice and no-choice presentations. Although differences in consumption between citral-experienced and citral-naive larvae presumably represent some unknown composite of differences in orientation, biting and feeding responses, and/or arrestment, Saxena and Schoonhoven contended that both orientational and contact feeding responses were altered by prior experience with citral medium or plain medium.

Saxena and Schoonhoven (1982) extended these assays using *Manduca* larvae reared and tested on natural foliage. As commonly found in such studies, prior experience with a plant species tended to increase the extent to which that species was consumed relative to other plants. In addition, larvae tended to turn more frequently towards the plant on which they were fed, in both choice and no-choice tests. Interestingly, the rank order of orientational preferences of larvae reared on different diets did not always correspond to the rank order of feeding preferences. This result suggests that some other behavior besides orientation is also altered by prior feeding history. Furthermore, the alteration in orientational preference was apparently olfactorily-based, at least in part. Lar-

vae reared on tomato, for example, chose tomato leaves over blank controls in the turning assay much more often than did larvae reared on an artificial diet. This effect of experience on orientation behavior disappeared entirely when test tomato leaves were presented behind a glass barrier.

Sensory Modalities and Multicomponent Chemical Basis of Induction. The contention that both orientation and contact behavior are affected by prior feeding history suggests that more than one sensory modality is involved in induction of larval preference. More direct and detailed information about the sensory modalities affected by induction was supplied by the ablation experiments of Hanson and Dethier (1973). After raising *Manduca* larvae on either tomato or Jerusalem cherry, they extirpated systematically the olfactory and gustatory organs of fourth- and fifth-instar larvae. Using standard leaf-disk choice tests, the relative consumption of tomato and Jerusalem cherry was measured for normal and operated larvae. Loss of either the gustatory organ (maxillary sensilla styloconica) or both olfactory organs (antennae and maxillary palps) reduced markedly the strength of induction, relative to unoperated larvae. A lesser but significant degradation of induction followed the removal of the antennae alone or the palps alone. The residual effect of prior experience on relative consumption of tomato and Jerusalem cherry after ablation of either the olfactory or gustatory systems suggested strongly that both systems were involved independently in induction of host preference.

This systemic redundancy in induction of preference was paralleled in Hanson and Dethier's studies by a redundancy in the number of discriminatory organs within each system: both discrimination and induction of discrimination persisted after the unilateral ablation of the maxillary sensilla styloconica, antennae, and palps. The unilateral extirpation procedure not only indicated that more organs of each type were present than were required to discriminate or to be induced to discriminate among food plants, but confirmed that the effects of the bilateral gustatory and olfactory ablations on induction were not merely the result of surgical trauma.

The activity of both olfactory and gustatory systems in induction of preference in lepidopterous larvae implies that responses to more than one class of chemical compound are modified by prior feeding history. This inference was supported by Städler and Hanson (1976, 1978), who recorded the behavioral and electrophysiological responses of larvae reared on tomato and Jerusalem cherry to host extracts prepared with a variety of solvents. Using a modification of the standard cafeteria test, larval preference was measured as the proportion of glass-fiber disks impregnated with a particular solvent extract that was consumed by a larva. While larvae discriminated among a number of extracts, only the nonpolar hexane and polar water extract carried the inducing activity. Thus, experience with a host plant apparently altered responses to more than one but less than all of the phytochemicals used in discrimination. The fact that responses to only a subset of the phytochemicals used to select hosts were appar-

ently altered by prior experience may help to explain the common observation (De Boer and Hanson, 1984) that the extent to which preference among particular plant species is induced in late-instar larvae is not necessarily coincident with the extent to which early-instar larvae discriminate among those species.

Adult as well as immature insects may be conditioned to more than one chemical in plant or plant-derived resources. A multicomponent chemical basis of learning of adult oviposition preference in *Drosophila* spp. was postulated by Jaenike (1983). After exposing larval and adult *D. melanogaster, D. pseudoobscura,* and *D. immigrans* to artificial media containing one of various substances (sodium chloride, ethanol, ethyl acetate, lactic acid, piperidine, and peppermint oil), Jaenike (1982) presented adults simultaneously with media with and without these substances. Rearing larvae on these media had no effect on the number of eggs laid by adults in various substrates, adding to the tremendous body of evidence that adult preference is rarely susceptible to larval conditioning (Papaj and Rausher, 1983). Exposure of adult flies to peppermint-containing food, however, significantly reduced the aversion of adults of all three species towards laying eggs in this medium. While this result may be a bonafide example of habituation to a deterrent substance (Manning, 1967; McGuire, 1984), Jaenike (1983) nevertheless questioned the extent to which learning of acceptance of individual deterrent compounds (particularly ones that were not present in natural food resources) reflected the kind of learning possible in natural breeding substrates.

Jaenike (1983) therefore exposed larval and adult *Drosophila melanogaster* to more natural breeding substrates derived from apple, tomato, squash, and banana. As before, adult preference did not depend on the type of food on which larvae developed. In two-choice tests, however, individuals laid a greater proportion of eggs in the particular substrate on which they fed as adults than did individuals that fed on the other substrate. In a second experiment, adult flies were exposed to either apple, tomato, orange, grape, or onion food and tested simultaneously on all five media. Adult exposure to a certain medium sometimes, but not always, induced a preference for ovipositing on that medium. Adults that fed on grape or tomato, for example, laid proportionately more eggs in grape or tomato, respectively, than did adults in the other treatments. Feeding on apple, orange and onion, however, did not increase the proportion of eggs laid on those substrates, relative to feeding on alternative food sources. In addition, exposure to one food source sometimes increased the relative acceptability of other foods. Flies kept on apple, for instance, laid proportionately more eggs on grape than flies kept on tomato, orange, or onion. This so-called "cross-induction" phenomenon was not reciprocal: flies maintained on grape medium did not show an enhanced propensity to accept apple medium.

A mechanism proposed by Jaenike (1983) to explain cross-induction assumed that prior experience with a given food resource influences responses to an array of repellent and attractive compounds. While details of this scheme

were entirely speculative, cross-induction itself is probably genuine. Enhancement of relative acceptibility of one host species upon experience with another is evident in a great number of studies on induction of preference (even though it was not usually acknowledged; e.g., Jermy et al., 1968; Yamamoto, 1974; Saxena and Schoonhoven, 1982; De Boer and Hanson, 1984). Indeed, its generality may be very much understated simply because induction experiments typically assay discrimination between only two plant species, conditions under which cross-induction cannot be deduced.

Effects of Experience on Peripheral and Central Processing. Presuming a multicomponent chemical basis of induction of lepidopterous larvae, Schoonhoven (1977) proposed alternative schemes in which experience with a food resource was accompanied by changes in either the central or the peripheral nervous system. Both models embrace the notion that discrimination is the outcome of comparison of the across-fiber firing pattern of sensory receptors with a centrally located template. The first model supposes that prior experience affects feeding behavior by changing the internal template of the phytochemical spectrum against which the across-fiber firing pattern of the sensory receptors is matched. The second model supposes that prior experience alters the across-fiber firing pattern of the sensory receptors itself.

Both Schoonhoven (1969) and Städler and Hanson (1976) reported evidence that changes in the sensitivity of the gustatory maxillary sensilla styloconica to particular chemicals accompany induction of host preference. While these studies clearly corroborate a hypothesis of peripheral control of induction, they do not exclude the possibility of correlative changes in the central nervous system.

A central nervous system component in conditioning of feeding behavior was emphasized in Szentesi and Bernays' (1984) study of the physiological basis of habituation to nicotine hydrogen tartrate (NHT) by grasshopper nymphs (*Schistocerca gregaria*). Habituation, defined as the waning of response to a stimulus with repeated exposure to that stimulus, is widely presumed to involve central nervous processes. While a number of investigators have defined effects of host experience on feeding (e.g. Schoonhoven, 1969; Gill, 1972, cited in Szentesi and Bernays, 1984) or oviposition (Jaenike, 1982, 1983) preference that could potentially be attributed to habituation (McGuire, 1984), few studies controlled for effects of resource deprivation on preference. In most procedures, food with and without deterrent was offered to groups of insects ad libitum for a specified period of time, after which responses to the stimulus were measured. No attempt was made to control for the effect of differences in consumption rate of the alternative diets on subsequent preference. Thus, a difference in preference among treatments could be due to the specific effect of repeated exposure to the deterrent or to the general effect of resource deprivation or to both. By ensuring that all locusts consumed food at the same average rate, regardless of the presence or absence of a deterrent in their diet, Jermy et al.

(1982) and Szentesi and Bernays (1984) verified that a depression of deterrency was due to repeated exposure to the deterrent and not to food deprivation.

Periods of sensory stimulation even without ingestion of the deterrent substance was sufficient to cause habituation to NHT by locust nymphs. Grasshoppers whose maxillary palp sensilla had been encapsulated with nicotine hydrogen tartrate (NHT) solutions ate more NHT-treated diet than control grasshoppers whose palps were encapsulated with water, even though both groups were reared on an NHT-free diet of fresh wheat (Szentesi and Bernays, 1984). An additional result demonstrated that habituation via sensory stimulation was associated with changes in the central nervous system. Before testing, the maxillary palps of groups of NHT-exposed and NHT-naive individuals were covered with a nylon sleeve and rendered inaccessible to sensory stimulation. Despite concealment of the palps, individuals whose palps were previously immersed in NHT solutions ate more NHT-impregnated food in the test period than did individuals whose palps were previously immersed in water.

Chemical Cues Involved in Associative Learning by Herbivorous Insects. Associative learning, defined as the association of a neutral stimulus with a nonneutral stimulus through the temporal pairing of those stimuli, is usually considered to entail changes in the central nervous system. Two instances in which a nonneutral host-selection chemical cue is associated with a neutral visual cue are known, both in adult papilionoid Lepidoptera.

Searching behavior of ovipositing cabbage butterflies, *Pieris rapae*, was altered by prior experience with particular varieties of their cabbage hosts (Traynier, 1984). Exposure of adult females to either Earlyball or Wongbok cabbage varieties for as short as 30 min predisposed individuals to land more frequently on those types in the first 5 min of a two-choice test. Efforts to reverse the effects of training in this experiment were unsuccessful, suggesting that short training periods induced relatively long-term changes in oviposition preference.

Taking advantage of the fact that paper disks wetted with sinigrin (a common component of cabbage and other crucifers) and water solutions elicited oviposition, Traynier (1984) next attempted to train female butterflies to disks of two shades of green, Shoalhaven Green and Great Green. Although females tended to land first on Shoalhaven Green disks regardless of prior experience, this preference in two-choice tests was greater for females preexposed to sinigrin-treated Shoalhaven Green disks than for females preexposed to sinigrin-treated Great Green disks. A single contact with a sinigrin-treated Shoalhaven Green disk—even without oviposition—altered significantly a butterfly's choice of colored disks. Thus, the visual cue (color or monochromatic hue) was apparently associated with the perception of sinigrin solution directly and not indirectly via the events corresponding to egg-laying.

Association of a visual cue with chemical releasers of oviposition behavior also occurs in pipevine swallowtail butterflies (Papaj, 1986a, b). In a large

outdoor screened enclosure, adult female *Battus philenor* butterflies were trained to search selectively in an array of host and nonhost plants for leaves of a shape (defined by maximum leaf length–maximum width ratio) similar to that of the *Aristolochia* host species to which they were exposed. Unlike cabbage butterflies, the effects of learning were reversed readily upon exposure to an alternative host species with a significantly different leaf shape. As in cabbage butterflies, contact with a host plant without oviposition was sufficient to induce a change in alighting responses.

Methanolic extracts of *Aristolochia macrophylla* applied to artificial substrates or to nonhost plants elicited oviposition by gravid females. When placed on nonhost plants sprayed with these extracts, butterflies alighted predominantly on leaves of a shape similar to that of the treated nonhost species. Contact with treated nonhost plants even without oviposition was sufficient to increase significantly a female's propensity to alight on leaves of a shape similar to that of the treated nonhost plant.

Many studies of associative learning (e.g., Traynier, 1984) neglect to control for the nonassociative effects of sensitization and pseudoconditioning. Sensitization is defined as a change in response coincident with repeated presentations of a neutral, conditioned stimulus whether or not that stimulus is paired with a nonneutral, unconditioned stimulus (McGuire, 1984; Tully, 1984). Cabbage butterflies, for example, may have come to prefer to land on green disks even if green disks without sinigrin treatment had been presented repeatedly. The fact that experienced *Pieris* butterflies often laid eggs on untreated disks in subsequent tests may be evidence of this nonassociative process.

The searching behavior of pipevine swallowtail butterflies, by contrast, provided an internal control for sensitization. *Battus* butterflies searching for a host plant on which to deposit eggs land periodically on leaves. Upon alighting, they drum their tarsi and presumably stimulate tarsal chemoreceptors (Feeny et al., 1983). If the leaf belongs to a nonhost species, the female immediately resumes search. If the leaf belongs to a host, the female often lays a small egg cluster and resumes search. The great majority of leaves on which a female alights are nonhost plants and, in fact, the standard assay for leaf-shape response (Rausher, 1978) records only the kinds of nonhost leaves on which an individual lands.

Whereas a single contact with a treated nonhost plant induced a search mode for leaves of a shape similar to that of that plant, repeated contacts with untreated nonhost plants in the enclosure array did not. Moreover, both in the enclosure (Papaj, 1986a) and in the field (Papaj, 1986b), a single contact with a host plant whose leaf shape differed from that for which an individual was searching originally often induced a new search mode for the leaf shape of the newly discovered host plant. Such abrupt switches in nonhost alighting behavior never occurred after "mistaken" contacts with a nonhost plant with the "wrong" leaf shape. The most parsimonious explanation for these host-re-

leased switches is that female butterflies associated the neutral shape stimuli of the host leaves on which they landed with positive host phytochemical stimuli.

Pseudoconditioning is defined as a change in response coincident with repeated presentations of the nonneutral, unconditioned stimulus whether or not that stimulus is paired with the neutral, conditioned stimulus (McGuire, 1984; Tully, 1984). Pseudoconditioning of leaf-shape response could have been possible if repeated contact with host extract (i.e., the unconditioned stimulus) resulted in search modes for particular leaf-shapes. Specifically, repeated contact with extracts prepared from the broad-leaved host species, *A. macrophylla*, should have induced preferences for broad leaves. In fact, search modes depended only on the leaf shape of the nonhost species (i.e., the conditioned stimulus) to which the extract was applied.

LEARNING IN APPLE MAGGOT FLY

Repeated oviposition in a particular fruit species alters the degree to which female apple maggot flies, *Rhagoletis pomonella* (Walsh), attempt to oviposit into various fruit species in future encounters (Prokopy et al., 1982, 1986). Females ovipositing successively in hawthorn fruits, for example, accepted subsequent hawthorn fruits more frequently than did females ovipositing successively in apples. The training effect was reciprocal: females exposed to apples accepted apples more frequently than females exposed to hawthorn fruits. The effect of experience on responses to alternative fruit species could be reversed by repeated exposure to a different fruit species. Although the effect of experience on apple maggot fly oviposition-site selection was previously described as associative learning (Prokopy et al., 1982), this assignation was premature. In fact, almost nothing was known at the time about the stimuli involved in learning. Hence, it was not possible to show that one cue was associated with another through prior experience.

Prokopy et al. (1986) established an alternative dimension along which to classify effects of experience on host preference. They pointed out that experience with a host type could alter the difference in acceptance of two host types in either of two ways. First, prior experience with a particular host type might act to enhance the likelihood of acceptance of that host type in subsequent encounters. Alternatively, experience with one host type might depress the tendency to accept alternative host types in subsequent encounters. Although previous studies of learning of preference failed to distinguish between "learning to accept" and "learning to refuse" a host type, most investigators have assumed that learning enhances the propensity to accept the familiar resource type. In fact, Prokopy et al. (1986) and Cooley et al. (1986) discovered that

both the apple maggot fly and another tephritid fly, the Mediterranean fruit fly (*Ceratitis capitata* Weidemann), learn to reject the novel fruit type.

This conclusion was reached by comparing the fruit acceptance of flies exposed to a single fruit species with that of flies that had never been exposed to fruit (i.e., naive flies) or with that of flies exposed alternately to more than one fruit species (i.e., untrained flies). A female apple maggot fly ovipositing successively into hawthorn fruit, for example, had no greater propensity to accept a test hawthorn fruit than did a female ovipositing alternately into hawthorn and apple. Instead, the female trained on hawthorn was simply less prone than the untrained female to accept an apple. Similarly, females exposed to apples were less prone than the naive or untrained females to accept a test hawthorn fruit. In short, females exposed to a particular fruit species were always more likely to reject the alternative fruit species than were naive or untrained females.

Whether learning to reject the novel fruit type is mediated by responses to chemical stimuli was not known previously. In the following study, we investigated two cues—fruit surface chemistry and fruit size—that could be involved in learning of fruit acceptance by ovipositing female *R. pomonella.* These stimuli were chosen because both are known to be important in discrimination of oviposition sites by naive females (Diehl and Prokopy, 1986). We asked the following questions: (1) Do females exposed to particular fruit species discriminate among models differing in size or in chemistry? (2) If females learn based on fruit size or chemistry, do they learn to accept familiar fruit stimuli or to reject the novel fruit stimuli? (3) Is an association between fruit size and chemistry formed through prior experience with host fruit?

METHODS AND MATERIALS

Adult female *R. pomonella* flies originated from puparia collected from infested apple fruit on Orchard Hill at the University of Massachusetts at Amherst. Adult flies were kept at 25°C, 16:8 light–dark photoperiod, and about 60% relative humidity. On day 1, 25 females and five males were placed in each of three 30 × 30 × 30-cm Plexiglas and aluminum screen cages. On day 7, two Red Delicious apples (ca. 60 mm diam) were hung with wire from the ceiling of cage 1. On the same day, 10 *Crataegus mollis* fruits (ca. 15 mm diam) were hung with wire from the ceiling of cage 2. Cage 3 received no fruit. Every two days, fruits were replaced with fresh fruit. This training regime was replicated three times. The number of eggs deposited in a single sample of used apples and hawthorn fruits was estimated by counting the number of oviposition punctures into the fruit surface.

On day 14, we began testing the propensity of experienced and naive flies to attempt to oviposit in a variety of fruit models. The models were prepared

by coating plastic and clay spheres of apple (65 mm in diameter) and hawthorn (15 mm in diameter) sizes, respectively, with ceresin wax dyed red. Ceresin wax in the form of hollow hemispheres is known to elicit relatively high rates of oviposition by apple maggot flies (Prokopy and Bush, 1973).

Models of each size were treated with surface fruit chemicals of either apple or hawthorn fruits, using the following procedure. Parafilm (American Can Co.) was stretched and wrapped around individual apples or groups of between six and eight hawthorn fruits. The parafilm was left on the fruits for between three and seven days at room temperature. The parafilm wrap was then removed and applied to wax models of each size category. The surface originally in contact with the surface of the fruit was always placed in contact with the wax surface of the model. The parafilm wrap was removed from the models after 2 hr, and the models were used immediately in testing. Each day, freshly treated models were used in testing. A preliminary study (Papaj, unpublished) revealed that ceresin wax domes pretreated with parafilm wrapped in host fruit received significantly more oviposition punctures and eggs than domes pretreated with blank parafilm.

Assay flies were selected by introducing, in alternating fashion, a large or small red ceresin wax sphere into each treatment cage. When a female flew or walked onto the model, she was placed in an empty test cage and allowed to rest for 5 min. Virtually all flies were eventually tested using these criteria. The fly was then allowed to walk onto the first model. An acceptance of the model was recorded if the female attempted to oviposit (i.e., bore into) in the model. A rejection was recorded if the female flew or walked from the model or if the female remained on the fruit 5 min without boring. Following acceptance (which was interrupted before egg deposition could occur) or rejection, the fly was permitted to rest 5 min before presentation of the next model.

The order of presentation of the models was randomized, changing each time a series of flies from each treatment was tested. Approximately 85 flies from each training regime were tested on each of the following four models: (1) apple size treated with apple-exposed parafilm, (2) apple size treated with hawthorn-exposed parafilm, (3) hawthorn size treated with apple-exposed parafilm, and (4) hawthorn size treated with hawthorn-exposed parafilm.

About 25 flies were tested on two additional models: one apple-sized and one hawthorn-sized model, each exposed to blank parafilm only.

RESULTS

Although flies in each fruit-exposure group were given equal opportunity to lay eggs in fresh fruit, apple-exposed flies laid many fewer eggs than hawthorn-exposed flies. In one sample three-day period, flies laid 234 eggs into one

set of 10 hawthorn fruit. Flies laid only 34 eggs into two apples in the same period (this difference is highly significant; $G = 167.35$, $P < 0.0001$). Casual observations suggested that flies had difficulty penetrating the apple skin with their ovipositor.

For all groups of females tested on models treated with blank parafilm, large, apple-sized models were accepted less frequently than small, hawthorn-sized models; this difference was significant for hawthorn-exposed and naive flies (Table 1). In addition, females exposed previously to hawthorn fruit exhibited an even greater difference in their propensity to bore into large vs. small models (0.12 vs. 0.36, respectively) than did naive females (0.27 vs. 0.54, respectively), but this trend was not significant. Previous experience with apple, by comparison, had no detectable effect on a female's propensity to attempt to oviposit in apple- vs. hawthorn-sized models.

Likewise, there was no effect of apple exposure on acceptance of models pretreated with parafilm wrapped previously around fruit. Females exposed to apples attempted to oviposit into apple- and hawthorn-treated spheres of either size as frequently as naive females (Table 2). Both apple-exposed and naive flies attempted to oviposit less frequently in large models compared to small models. Neither group of flies, however, exhibited a difference in propensity to bore into an apple-treated model or a hawthorn-treated model of a given size.

Females exposed to hawthorn fruits, by contrast, differed markedly from naive females in their acceptance of particular models pretreated with parafilm wrapped previously around fruit (Table 2). First, although each group attempted to bore more often into small models than large models of a given parafilm treatment, hawthorn-exposed females attempted to oviposit proportionately less frequently into apple-sized models of a given parafilm treatment than did naive females. Second, the training reponse to fruit model size was paralleled by a

TABLE 1. PROPORTION OF ACCEPTANCES BY FEMALES EXPOSED TO APPLE OR HAWTHORN FRUITS AND BY NAIVE FEMALES ON MODELS DIFFERING IN SIZE AND PRETREATED WITH BLANK PARAFILM

		Model type	
Exposure	N	Apple-sized[a]	Hawthorn-sized[a]
Apple	26	0.19 a1	0.38 a1
Hawthorn	25	0.12 a1	0.36 a2
Naive	26	0.27 a1	0.54 a2

TABLE 2. PROPORTION OF ACCEPTANCES BY FEMALES EXPOSED TO APPLE OR HAWTHORN FRUITS AND BY NAIVE FEMALES ON MODELS DIFFERING IN SIZE AND PARAFILM PRETREATMENT

Exposure	*N*	Apple-sized[a]	Hawthorn-sized[a]
A. Apple-treated model			
Apple	81	0.35 a1	0.63 a2
Hawthorn	84	0.14 b1	0.48 b2
Naive	86	0.43 a1	0.72 a2
B. Hawthorn-treated model			
Apple	81	0.39 a1	0.62 a2
Hawthorn	84	0.28 b1	0.69 a2
Naive	86	0.49 a1	0.69 a2

[a] Proportions within a column that are followed by the same letter are not significantly different by a two-way *G*-test at $P = 0.05$. Proportions within a row that are followed by the same number are not significantly different by a two-way *G*-test at $P = 0.05$.

training response to fruit model parafilm treatment. Naive females exhibited no difference in acceptance of hawthorn-treated and apple-treated models within a size category. Hawthorn-exposed females, by contrast, attempted to bore considerably less often into an apple-treated model than into a hawthorn-treated model of a given size category.

In summary, responses to both size and surface chemistry were altered by prior experience with hawthorn fruits. The hawthorn-exposed flies accepted least often an apple-treated and apple-sized model and most often a hawthorn-treated and hawthorn-sized model. Training was associated with the rejection of novel fruit stimuli: the propensity of hawthorn-exposed females to attempt to oviposit into the hawthorn-treated and hawthorn-sized models was no greater than that of naive females. Rather, the propensity of hawthorn-exposed females to attempt to oviposit into apple-sized and/or apple-treated models was consistently less than that of naive females.

Finally, a log-linear chi-square model (Bishop et al., 1975) was used to assess the interaction of learned responses to model size and chemistry. The analysis tested the independence of the following factors: response (accept vs. reject), exposure (hawthorn-experienced vs. naive), size (apple-sized vs. hawthorn-sized), and parafilm treatment (apple-treated vs. hawthorn-treated). The significant response × exposure × size effect ($G = 4.32$, $P < 0.05$) confirms statistically that flies exposed to hawthorn fruits differed from naive flies in propensity to bore into large and small fruits. The significant response × exposure × parafilm treatment effect ($G = 6.39$, $P < 0.01$) confirms that flies

exposed to hawthorn fruits differed from naive flies in propensity to bore into apple-treated and hawthorn-treated fruit. Most importantly, the lack of a four-way interaction (response × exposure × size × parafilm treatment effect, $G = 0.44$, $P > 0.05$) indicates that the effect of training on size discrimination did not depend on the chemical features of the fruit model. Conversely, the effect of training on discrimination of fruit chemistry did not depend on the size of the fruit model.

DISCUSSION

A fundamental dichotomy in learned responses to novel vs. familiar chemical stimuli has been ignored previously. In many investigations of induction of feeding preference, the proper controls by which to identify this kind of conditioning were not executed. "Naive" insects were typically first-instar larvae that had not yet fed on plants or older larvae that had fed on a "neutral" artificial medium. When naive insects are much younger than experienced insects, however, level of experience is necessarily confounded with developmental stage. Moreover, insects feeding on artificial diets are not "naive" because such diets are not "neutral": lepidopterous larvae can be induced to prefer particular artificial diets over others and even over natural foliage (Städler and Hanson, 1978; Saxena and Schoonhoven, 1982). Using "untrained" individuals that have been exposed to a mixture of host species or a mixture of artificial media is a viable, but rarely considered, alternative. Of course, feeding insects can be "untrained" only to the extent that they will consume alternative foods.

An additional methodological complication has afflicted most studies of induction of larval feeding preference. Although cafeteria tests have assayed adequately the relative consumption of alternative foods, the *absolute* consumption rate of alternative food items across control and experimental groups has rarely been measured. Without measuring absolute consumption rates, however, it is almost impossible to deduce whether experience with a particular host species causes an absolute increase in the tendency to consume that host or an absolute decrease in the tendency to consume novel hosts, or both.

Despite these difficulties, many investigators have assumed that prior host experience enhances the acceptability of familiar food. Schoonhoven (1969), for example, presumed that induction in *Manduca* larvae was associated with decreased deterrence of the familiar diet. Similarly, Jaenike (1982, 1983) and McGuire (1984) contended that exposing adult *Drosophila* flies to peppermint-oil medium reduced the flies' aversion to peppermint oil. Städler and Hanson (1978) stated that induction of *Manduca* larvae to particular artificial diets both increased consumption of the rearing media and decreased consumption of alternative media.

Our present results indicate that alteration of a female apple maggot fly's responses to both physical (i.e., model size) and chemical (i.e., parafilm treatment) cues took the form of learning to reject the novel model type, paralleling the results of previous experiments (Prokopy et al., 1986; Cooley et al., 1986) with tephritid flies tested on natural fruit.

Interestingly, the propensity of hawthorn-exposed flies to bore into the hawthorn-treated, hawthorn-sized model was identical to that of naive flies. This result could be interpreted in one of two ways. First, fruit size and the fruit chemical constituents extracted and transferred with the parafilm treatment may be the only characters which females learned. Hawthorn-experienced flies might have accepted the hawthorn-sized, hawthorn-treated model as frequently as did naive flies because all of the relevant stimuli with which they were familiar were present. If so, experienced flies may be attending either to the absence of familiar stimuli or to the presence of novel stimuli when they reject novel fruit models. Such a fortuitous result seems unlikely. Fruit size and parafilm-extracted chemicals probably represent only a subset of the stimuli.

Alternatively, experienced flies may not be attending to the absence of familiar stimuli at all when they reject novel fruit or fruit models. Rather, they may reject novel fruit or novel fruit models because of the presence of novel stimuli. Thus, even though the hawthorn-sized, hawthorn-treated model does not bear all of the stimuli learned by flies, it would still be accepted by the experienced flies as vigorously as by the naive flies because of the absence of any novel stimuli.

In this study, apple maggot flies clearly learned to reject models with novel chemical stimuli, but only when exposed to hawthorn fruit. Exposure to apples failed to alter the females' fruit acceptance pattern, relative to that of naive females. In fact, apples always receive many fewer oviposition attempts than do hawthorn fruit in laboratory assays (Prokopy et al., 1985) and have consistently yielded a weaker training effct than hawthorn with real test fruit in previous experiments (Prokopy et al., 1986). Nevertheless, we do not yet know if females trained successfully to apple learn to accept familiar chemical stimuli or to reject novel chemical stimuli.

We also do not know if learning in apple maggot flies constitutes associative learning. The lack of an interaction in training to models of different sizes and parafilm treatments implies that size and chemistry cues were not associated during learning. If size and chemistry became associated through experience, the hawthorn-exposed flies should have been proportionately less inclined to bore into an apple-sized, apple-treated model than was expected based on their responses to the models with mixed size and chemistry characteristics (i.e., the apple-sized, hawthorn-treated and hawthorn-sized, apple-treated models). This negative result does not, however, exclude an association between size and/or chemistry and some other unknown stimuli.

By using fruit models to train as well as to test female apple maggot flies, we hope to address these questions. We hope also to shed light on the principal issues outlined in our review: whether learning based on host chemistry involves one or more than one chemical constituent; which sensory modalities are involved in learning of preference; and whether changes in the central or peripheral nervous system accompany experience with particular host species.

Acknowledgments—We thank William Conner, Haruhiko Itagaki and Susan Opp for helpful comments. Lorelei Hoey and Sylvia Cooley provided excellent technical assistance. (Received June 26, 1985; accepted August 13, 1985)

Abstract—L-Canavanine manifests potent insecticidal properties in a canavanine-sensitive insect such as the tobacco hornworm, *Manduca sexta* (L.) (Sphingidae). Investigations of the biochemical basis for the antimetabolic properties of this arginine analog reveal that it is activated and aminoacylated by arginyl tRNA synthetase and incorporated into the nascent polypeptide chain. This creates structurally aberrant, canavanine-containing proteins that can possess altered physicochemical properties. Evidence is presented in studies with the tobacco hornworm; the canavanine-adapted bruchid beetle, *Caryedes brasiliensis* (Bruchidae) and the weevil, *Sternechus tuberculatus* (Curculionidae); as well as the canavanine-resistant larvae of *Heliothis virescens* [Noctuidae] to support the contention that formation of aberrant, canavanyl proteins produce deleterious biological effects and is a significant basis for canavanine's antimetabolic properties.

Key Words—L-Canavanine, *Manduca sexta*, Lepidoptera, Sphingidae, *Caryedes brasiliensis*, *Dioclea megacarpa*, Leguminosae, *Sternechus tuberculatus*, Coleoptera, Bruchidae, Curculionidae, *Heliothis virescens*, Noctuidae, allelochemicals, toxicology.

INTRODUCTION

L-Canavanine, L-2-amino-4-(guanidinooxy)butyric acid, is a potentially toxic allelochemical synthesized by hundreds of leguminous plants (Bell et al., 1978). This arginine analog (Figure 1) elicits potent antimetabolic properties in developing larvae of canavanine-sensitive insects such as the tobacco hornworm, *Manduca sexta* (L.) (Sphingidae). Of the various mechanisms whereby canavanine manifests its toxicity in insects, one of the most important is through

0098-0331/86/0500-1145$05.00/0

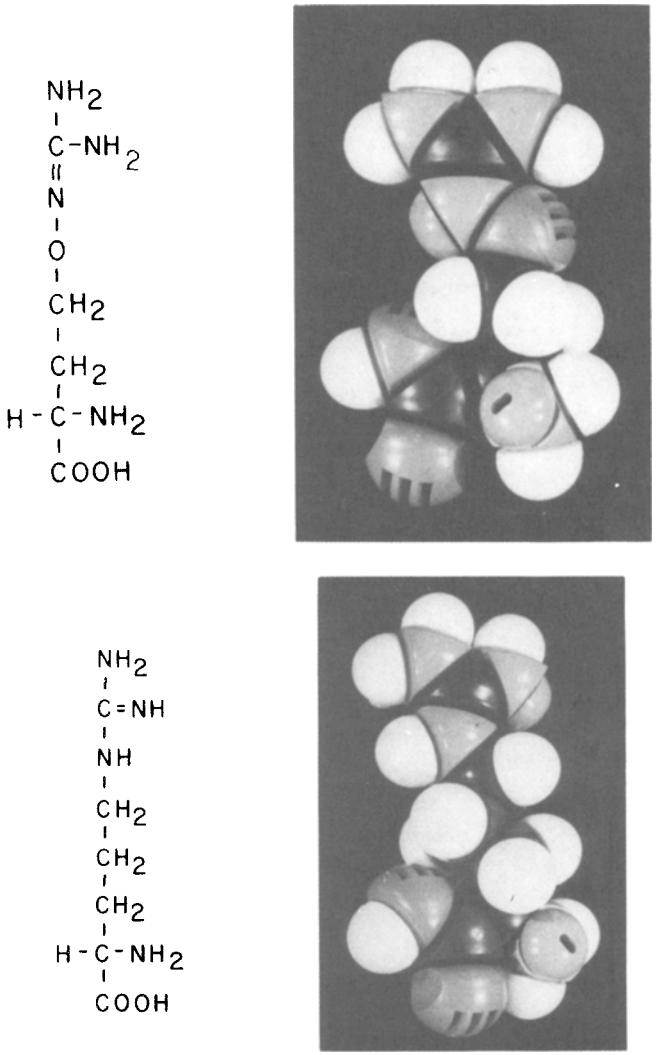

FIG. 1. CPK space-filling model of L-canavanine bottom and L-arginine top.

the formation of canavanine-containing, aberrant proteins. Due to the marked structural analogy between L-canavanine and L-arginine, arginyl-tRNA synthetase activates and aminoacylates L-canavanine, eventually linking it to the cognate tRNA for arginine (Allende and Allende, 1964). These reactions obligate the erroneous incorporation of canavanine into the nascent polypeptide chain.

CANAVANINE AND ABERRANT PROTEIN PRODUCTION

Administration of 1 g canavanine per kilogram fresh body weight (the LD_{50} larval dose) via parenteral injection to newly ecdysed fifth-instar larvae causes canavanine incorporation into the de novo-synthesized proteins of various larval tissues. Canavanine incorporation into hemolymph proteins is ascertained by precipitating the hemolymph proteins obtained from L-[*guanidinooxy*-^{14}C]canavanine-treated larvae with trichloroacetic acid (TCA). After exhaustively washing the TCA-precipitated materials, the hemolymph proteins are hydrolyzed with 6 N HCl and the hydrolysate canavanine separated from arginine by ion-exchange chromatography (Rosenthal and Thomas, 1985). The canavanine-containing fraction is treated simultaneously with arginase (EC 3.5.3.1) and urease (EC 3.5.1.5) to convert L-[*guanidinooxy*-^{14}C]canavanine to [^{14}C]urea and L-canaline prior to conversion to NH_3 and $^{14}CO_2$. The latter compound is trapped in hydroxide of hyamine and quantitated by liquid scintillation spectroscopy (Rosenthal and Janzen, 1983a).

About 0.4% of the parenterally injected L-[*guanidinooxy*-^{14}C]canavanine is recovered in the hemolymph proteins of *M. sexta* after 24 hr (Figure 2). Thus, canavanine-sensitive insects such as *M. sexta* can incorporate significant amounts of canavanine into newly synthesized proteins. Evidence for replacement of a residue other than arginine by canavanine has not been found.

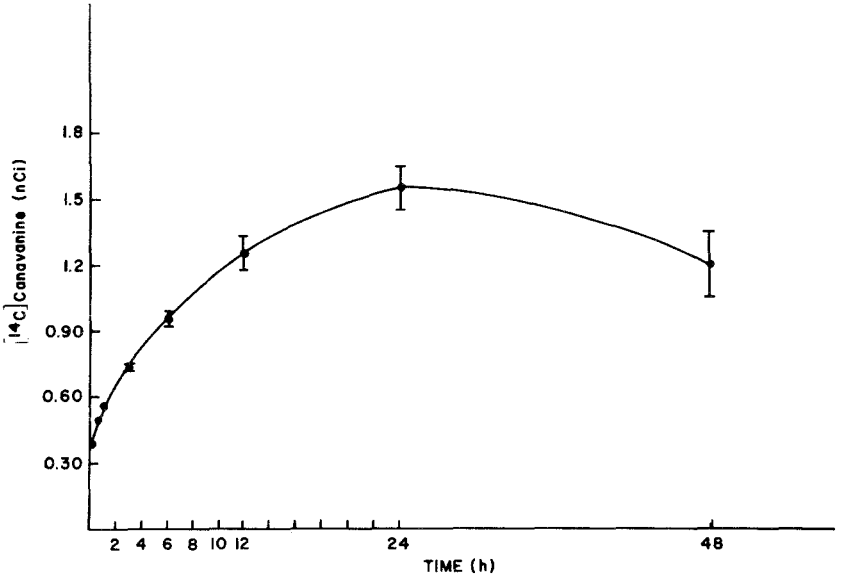

FIG. 2. Incorporation of L-[*guanidinooxy*-^{14}C]canavanine into de novo-synthesized hemolymph proteins of *M. sexta*. Each value represents the mean and SE of three samples. See original (Rosenthal and Dahlman, 1985) for additional experimental details.

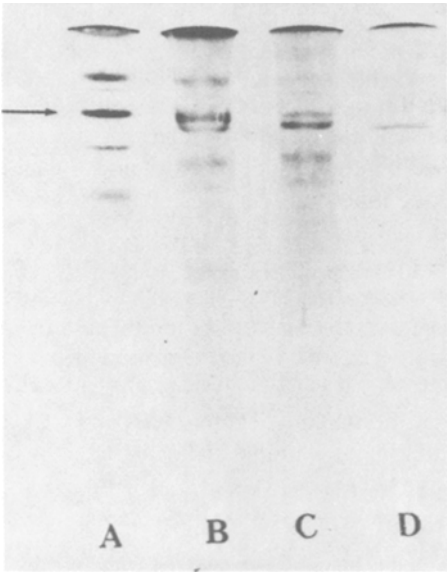

FIG. 3. Polyacrylamide gel electrophoresis of secreted fat body proteins of the migratory locust, *Locusta migratoria migratorioides*. Lane A, protein pattern from fat bodies maintained on arginine-free incubation medium for 3 hr at 30°C; lanes B, C, and D, from comparable materials maintained on 10 mM canavanine for 3, 6, and 9 hr, respectively (lane C, transfer to fresh incubation medium after 3 hr, lane D, transfer after 3 and 6 hr). In each instance, the incubation media from five fat body samples were pooled (2.5 ml) and 0.1 ml was applied to the gels. Arrow, position of vitellogenin; canavanyl vitellogenin is 1.5 mm below vitellogenin. See Pines et al. (1981) for additional experimental details; reproduced with permission.

A much more meaningful question, however, is that of the biochemical and biological ramifications of canavanyl protein production. This question has been addressed in studies of vitellogenin synthesis and secretion by the fat body of the adult migratory locust, *Locusta migratoria migratorioides*. Vitellogenin is the principal extraovarial protein; it is transported to the oocyte where it functions in vitellin formation, a key protein of the egg yolk. Isolated fat body of *Locusta* can be maintained in culture for 9 hr; during this time, the fat body produces vitellogenin and secretes it into the external medium. *Locusta* fat body maintained in complete medium produces appreciable vitellogenin (Figure 3, lane A). If the arginine of the culture medium is replaced by canavanine, both native vitellogenin and a novel canavanyl vitellogenin are produced over the first 3 hr (lane B). During the next hour, the proportion of canavanyl vitellogenin to the native molecule increases further (lane C). Lane D reveals the limited biosynthetic capacity of the fat body during the final 3-hr incubation

period. Of the detectable protein, only canavanyl vitellogenin can be discerned (Pines et al., 1981).

The shift in the electrophoretic mobility of canavanyl vitellogenin attests to the alteration that results from canavanine incorporation into this protein. It reveals that sufficient canavanine can be incorporated into vitellogenin to alter significantly its physicochemical properties. While these studies are of interest biochemically, they still leave unresolved the important biological question of whether canavanine incorporation into protein alters functional parameters of the macromolecule.

Work is in progress by Douglas Dahlman and the author to isolate enzymes from *M. sexta* and to compare these macromolecules with their canavanine-containing counterparts. These efforts are intended to provide the first direct experimental evidence on how canavanine replacement for arginine affects the functionality of a structurally aberrant insectan enzyme. The above biological question is also being addressed in a collaborative effort with Peter Dunn at Purdue University. Dunn is investigating the protein lysozyme and a group of peptides, known collectively as bacteriacidins, that are produced by the fat body of *M. sexta.* These hemolymph components function to protect the larvae against pathogenic organisms.

Incorporation of canavanine into these molecules diminishes significantly their biological activity and protective efficacy. Antibodies raised against lysozyme are immunoreactive with canavanyl lysozyme. This reactivity provides the means to determine the amount of lysozyme formed by canavanine-treated, cultured fat body. Under conditions in which canavanine inhibits about 50% of lysozyme's biological activity, no appreciable reduction in the amount of lysozyme produced relative to control fat body cultures occurs. Thus, canavanyl protein formation affects adversely the functionality of the molecule, not its synthesis. This point is most important, for addition of sufficiently high canavanine to the culture medium can terminate lysozyme formation.

Such direct experimental evidence addressing the question of canvanine incorporation and impaired functionality is still limited; however, convincing indirect evidence continues to accumulate. If, for example, one obtains an insect either able to use or resist canavanine, the capacity of such an insect to avoid canavanyl protein production can be evaluated. Development through evolutionary time of a significant preventive or avoidance capacity suggests that benefit is accrued from preventing aberrant protein production and therefore that such production carries deleterious biological consequences.

The bruchid beetle, *Caryedes brasiliensis* (Bruchidae) represents a canavanine adapted insect. *Caryedes brasiliensis* is the sole insect predator of *Dioclea megacarpa* (Leguminosae), a plant inhabiting the Neotropical forests of Costa Rica (Janzen, 1980). The seed of this legume is a veritable canavanine storehouse; as much as 13% of its dry weight is contributed by canavanine (average seed canavanine content may be closer to 9%). Canavanine can ac-

count for 55% of every nitrogen atom and more than 95% of the nitrogen allocated to free amino acids of the seed (Rosenthal, 1977). This stored canavanine undoubtedly creates a very formidable chemical defensive barrier that contributes to the significant freedom from insect predation that occurs in the seed.

Caryedes brasiliensis incorporates little [^{14}C]canavanine into total larval protein (Rosenthal et al., 1977). Comparable experiments with *M. sexta* result in the incorporation of 3 $\pm$ 0.5% of the administered canavanine into de novo synthesized proteins that constitute the musculature and body wall of the larvae (Rosenthal et al., 1976).

The appreciable capacity of this seed predator to avoid canavanyl protein production is revealed by direct comparison of the incorporation of radioactive arginine and canavanine, when the specific activity of each amino acid is equal. Under these conditions, the bruchid beetle incorporates into protein one canavanine molecule for each 365 molecules of arginine. This compares to one canavanine in 5.6 arginine molecules for *M. sexta* (Rosenthal and Janzen, 1983b). Comparable analyses with an array of arginine analogs indicates that *M. sexta* can incorporate all of the tested compounds into proteins. On the other hand, *C. brasiliensis* exhibits little ability to link these amino acids to arginyl tRNA (Table 1). These experiments provide evidence that *C. brasiliensis* may have evolved a discriminatory arginyl-tRNA synthetase that not only limits canavanine placement into protein, but also imparts a general resistance to the inclusion of such nonprotein amino acids into newly synthesized proteins.

A very important dimension is added to this research by the studies of John Bleiler, a graduate student in my laboratory. As part of his field work in Costa Rica, Bleiler discovered a weevil, *Sternechus tuberculatus* (Curculionidae) that is a seed predator of the legume, *Canavalia brasiliensis* (Figure 4). The female

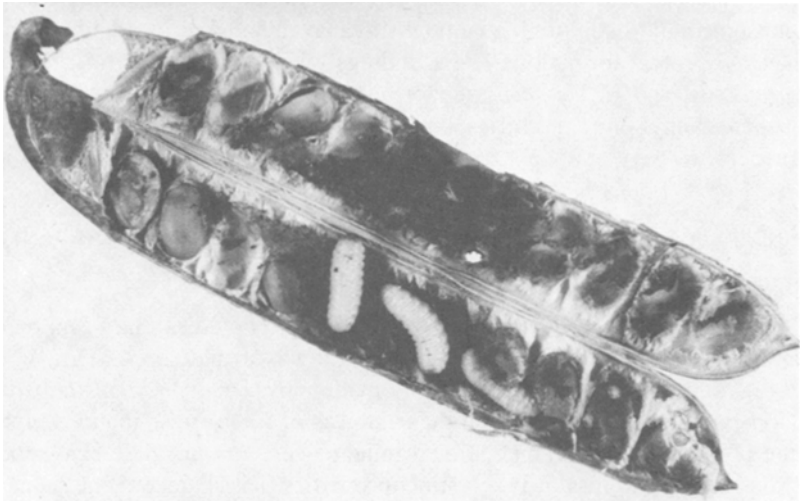

FIG. 4. Terminal instar larvae of the curculionid weevil, *Sternechus turberculatus*. The larvae are seen feeding on the canavanine-containing seeds of the legume, *Canavalia brasiliensis*.

weevil bores through the pericarp and deposits her eggs on the inside wall of the fruit; the larvae consume the seeds. Thus, in contrast to *Caryedes brasiliensis*, *Sternechus tuberculatus* develops within the fruit, not the seed.

Canavalia Brasiliensis stores about 8% of its dry matter as L-canavanine. Comparable analysis of the discriminatory capacity of *S. tuberculatus* reveals that so little canavanine is incorporated into larval proteins of this canavanine-utilizer that the arginine-to-canavanine ratio is in excess of 1:500. Thus, both of these canavanine-utilizing seed predators exhibit a pronounced ability to avoid the accumulation of canavanyl proteins.

The tobacco budworm, *Heliothis virescens* (Noctuidae), a generalist herbivore, is remarkably resistant to canavanine. Milan Berge, in my laboratory, determined the LC_{50} value for terminal instar larvae at 300 mM. High dietary levels of canavanine attenuate larval growth and the resulting pupae are depauperate, but the massive developmental aberrations noted with canavanine-fed *Manduca sexta* larvae are not observed. Since *Heliothis virescens* larvae are so canavanine resistant, it is relevant to ask if the larvae incorporate significant canavanine into their newly formed proteins. Such determinations indicate an amino acid incorporation ratio of canavanine to arginine of about 1 to 100, under the same conditions that this ratio is 1 to 5.6 for *Manduca sexta*. Moreover, comparison of canavanine incorporation into de novo-synthesized proteins reveals that while *Manduca sexta* places about 3.5% of the injected L-[*guanidinooxy*-^{14}C]canavanine into larval proteins of the body wall, the value for *He-*

liothis virescens is about 0.04%. Larvae of *Heliothis virescens* which are able to consume abnormally high quantities of canavanine, do so without significant canavanyl protein formation. These findings with *M. sexta*, *C. brasiliensis*, *S. tuberculatus*, and *H. virescens* support my contention that formation of anomalous, canavanyl proteins carries a marked potential for adverse biological consequences.

INDEPENDENT EVIDENCE FOR DYSFUNCTION IN INSECTAN CANAVANYL PROTEINS

Independent experimental evidence from insect studies that bears on canavanine incorporation and protein functionality is available. As part of their investigation of heat-shock protein formation by *Drosophila melanogaster*, DiDomenico et al. (1982) forced the synthesis of these stress-induced proteins in the presence of canavanine. Canavanine placement into these heat-shocked proteins causes the loss of two distinct properties that characterized them. The canavanyl heat-shocked proteins fail to concentrate in the nuclei of treated salivary gland cells (Figure 5A and B). These canavanyl proteins also lose the ability to bind RNA. This finding was established by treating normal heat-shock proteins with RNA-degrading enzymes. Removal of the RNA component results in a distinctive pattern that displays only the heat-shocked protein (Figure 5D) rather than the broad streaking characteristic of the RNA–heat-shocked protein complex (Figure 5C). Canavanyl heat-shocked proteins electrophorese as the normal, RNA-treated heat-shock proteins do (Figue 5D).

An equally dramatic effect of canavanine incorporation into heat-shocked proteins is indicated by electrophoretic analysis of *Drosophila* proteins from heat-shocked cells returned to 25°C (Figure 6). Heat-shock proteins gradually disappear and synthesis of normal proteins ensues concomitantly.

Canavanyl heat-shock proteins are not only not degraded, they actually increase. These canavanine-treated cells fail to resume production of the usual protein complement. Clearly, canavanine incorporation into these stress-induced proteins has a profound effect on normal cellular function. DiDomenico et al. (1982) concluded that their canavanyl heat-shock proteins are " . . . nonfunctional or, at the very least, to have profoundly disturbed function."

CANAVANINE AND INSECT PROTEIN SYNTHESIS

Another aspect of canavanine and insect protein synthesis and turnover emanates from investigation of canavanine and *M. sexta* conducted by the author and Douglas L. Dahlman. Our studies of canavanine and hemolymph protein synthesis in fifth-instar *M. sextra* larvae reveal that a parenterally injected, LC_{50} dose stimulates de novo protein synthesis. Yet, positive canavanine-me-

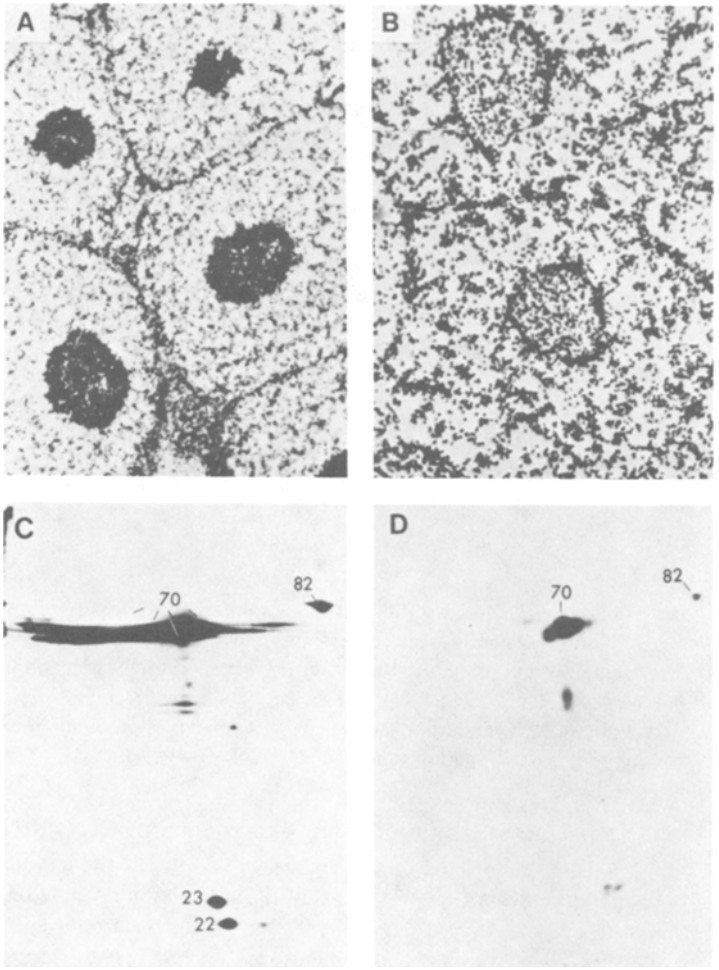

FIG. 5. The effect of L-canavanine on the heat-shock proteins of *Drosophila melanogaster*. (A and B) Salivary glands from a third stadium *D. melanogaster* larva were split and incubated under conditions that generated heat-shock proteins either in the presence of arginine or canavanine. (C and D) Analysis of heat-shock proteins by two-dimensional electrophoresis. See original (DiDomenico et al., 1982) for additional experimental details. Photo kindly supplied by S. Lindquist; reproduced with permission.

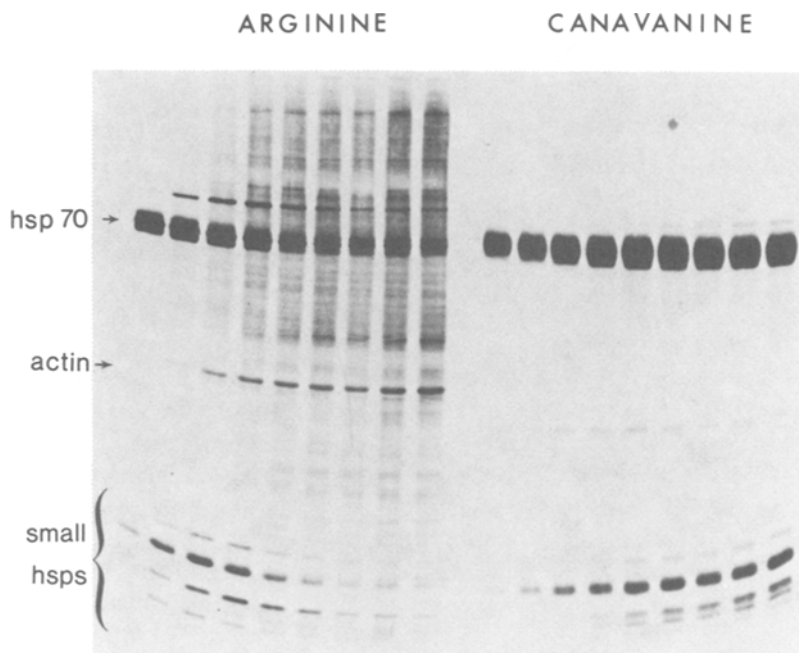

FIG. 6. Loss of heat-shock protein synthesis and resumption of normal protein production. Heat-shock proteins were synthesized in the presence of arginine or canavanine and placed under conditions where normal protein synthesis resumes. The proteins were pulse-labeled with tritiated leucine at consecutive 60-min intervals. See original (DiDomenico et al., 1982) for additional experimental details. Photo kindly provided by S. Lindquist; reproduced with permission.

diated stimulation of protein production is of short duration; it exists for between 1.5 and 3 hr (Table 2). While the biochemical basis for this enhancement is still under study, an explanation for the short duration of this effect may be known.

Manduca sexta possesses a very active system for the preferential degradation of aberrant, canavanyl proteins. Terminal instar larvae degrade erroneous hemolymph proteins several times faster than their normal counterparts, and there is evidence that the level of anomalous protein governs the rate of aberrant protein catabolism. The short period of canavanine-mediated stimulation of protein synthesis may represent the time required for these reactions to attain an equilibrium with those of preferential degradation (Rosenthal and Dahlman, 1985).

In a corollary experiment, *M. sexta* larvae were treated initially with canavanine for 24 hr, under conditions in which appreciable canavanyl hemolymph proteins are formed (as in Figure 2). These insects and control larvae were then

TABLE 2. INCORPORATION OF L-[^{3}H]LEUCINE INTO HEMOLYMPH PROTEINS

Time (hr)	[^{3}H]Leucine incorporation (nCi)[a]

12.0	1.21 ± 0.03	1.21 ± 0.03
24.0	1.88 ± 0.13	1.91 ± 0.05

[a] At the specified time after producing the canavanine-treated or control larvae, each larva received 2.0 μCi L-[^{3}H]leucine/g fresh body weight. Thirty minutes later, the hemolymph was collected. Each value is the mean ± SE of nine larvae. See original for further experimental details (Rosenthal and Dahlman, 1985).

injected with [^{3}H]arginine-containing hemolymph proteins. Careful monitoring of these normal, tritiated proteins indicated that they are degraded at the same rate by canavanine-treated and control larvae. This finding indicates that *M. sexta* larvae can distinguish effectively between normal and aberrant proteins. Even in a large excess of anomalous canavanyl protein, when very active protein degradation is occurring, normal proteins are not swept out in purging abnormal macromolecules.

ECOLOGICAL CONSIDERATIONS

The experiments conducted to date with representative canavanine-utilizing, canavanine-resistant, and canavanine-sensitive insects reveal the importance to canavanine-utilizing insects of avoiding the adverse biological consequences manifested by aberrant, canavanyl protein formation. If anomalous proteins are formed by an insect such as *M. sexta*, the larvae can respond by preferential degradation of their aberrant macromolecules without inadvertent destruction of functional proteins. This capacity of insects to respond to canavanyl protein formation is particularly critical in insect ability to cope with this potentially toxic allelochemical, because canavanine not only mediates the production of pernicious aberrant proteins, but stimulates the rate at which these deleterious macromolecules are built.

(Received August 19, 1985; accepted January 16, 1986)

Abstract—The majority (85%) of 394 monarch butterflies sampled from overwintering sites in Mexico contain the same epoxy cardenolide glycosides, including most conspicuously a novel polar glycoside with a single genin-sugar bridge (aspecioside), as occur in the milkweeds *Asclepias speciosa* and *A. syriaca*. This cardenolide commonality was established by isolating aspecioside and syriobioside from the wings of overwintering monarchs and the two plant species, and comparing chromatographic and NMR spectrometric characteristics of the isolates. When combined with the migratory pattern of monarchs and the distribution of these two milkweed species, this chemical evidence lends strong support to the hypothesis that *A. syriaca* is the major late summer food plant of monarchs in eastern North America. This finding may be of ecological importance, for *A. syriaca* contributes less cardenolide and cardenolides of lower emetic potency to monarchs than most milkweeds studied to date.

Key Words—*Danaus plexippus*, monarch butterflies, Lepidoptera, Danaidae, Asclepiadaceae, milkweeds, *Asclepias syriaca*, *Asclepias speciosa*, ecological chemistry, chemical defense, cardenolides, aspecioside, desglucosyrioside, syriobioside, overwintering.

INTRODUCTION

Monarch butterfly (*Danaus plexippus* L.) larvae sequester cardiac glycosides (cardenolides) from their milkweed (*Asclepias* spp., Asclepiadaceae) host plants, and there is much evidence that these emetic heart poisons defend the monarch from potential vertebrate predators in the larval, pupal, and adult stages (references in Brower, 1984; Seiber et al., 1983). Presumably this protection extends to adults during migration and in their overwintering aggregations in Mexico and along the California coast (Brower and Fink, 1985). The overwintering sites in the neovolcanic plateau of central Mexico are of particular interest, for these well-defined areas apparently serve as resting colonies for the bulk of the monarch population migrating from east of the Continental Divide—the majority of monarchs on the North American continent (Urquhart and Urquhart, 1976; Brower, 1985). Monarch specimens collected recently from the sites in Mexico were found to contain a broad quantitative spectrum of cardenolides, but it is unclear exactly how and to what extent these chemicals provide protection in the colonies from certain opportunistic avian and rodent predators (Brower and Fink, 1985; Fink and Brower, 1981; Fink et al., 1983; Brower et al., 1985; Brower and Calvert, 1985).

The sequestration and storage of milkweed-derived cardenolides by monarchs is a selective process. Monarchs reared as larvae on milkweeds low in cardenolide concentrate the chemicals, whereas those reared on cardenolide-enriched plants exclude more cardenolide than they store (Brower et al., 1982, 1984a, b). This suggests regulation to achieve a cardenolide capacity, at least for cardenolides in specific structural classes (Reichstein et al., 1968; Roeske et al., 1976; Seiber et al., 1980). Monarchs also selectively store just some of the array of cardenolides typically present in individual *Asclepias* plants. This qualitative regulation involves, at least in part, rapid larval metabolism of some cardenolides (generally the less polar ones) to other cardenolides (generally of intermediate polarity) which are stored (Reichstein et al., 1968; Roeske et al., 1976; Brower et al., 1982; Seiber et al., 1980; Marty and Krieger, 1984). The variation in cardenolide structures from one *Asclepias* species to another, along with the selective storage of just some of the cardenolides by each monarch reared on an individual plant, have led us to investigate the possibility of "fingerprinting" wild captured adults to their larval *Asclepias* food plant as reflected in their specific cardenolide thin-layer chromatography (TLC) profiles (Brower et al., 1982, 1984a, b).

Application of the TLC fingerprinting technique to adult monarchs collected from overwintering sites thus provides an opportunity for delineating which of the 108 known species of *Asclepias* are the major larval food plants in North America. With this goal in mind, we analyzed the cardenolide content of monarchs collected from various overwintering sites in Mexico (Brower et al., 1977). The majority of these individuals had the same major cardenolides,

thereby indicating a potential commonality of larval food plant species. This was in sharp contrast with our prior survey of overwintering monarchs collected in California coastal colonies, which showed several distinct cardenolide TLC patterns spanning a broad R_f range (Roeske et al., 1976). We here present evidence that the major cardenolides in the majority of individuals from Mexico are identical to two of the major cardenolides present in *Asclepias speciosa* and *A. syriaca*. At least one other, less prevalent, cardenolide in monarchs from Mexico also coincides with a third cardenolide constituent of these same two plant species. This chemical evidence, coupled with the known geographical and temporal occurrence of *Asclepias* species (Woodson, 1954), allow us to establish that *A. syriaca* is the most probable major food plant of fall migrant monarchs in eastern North America—a subject of copious speculation in the prior literature (Urquhart, 1960; Urquhart and Urquhart, 1978, 1979, 1980; Fink and Brower, 1981; Brower et al., 1984b).

METHODS AND MATERIALS

Butterfly and Plant

Whole live monarch butterflies of both sexes were collected from clusters on branches of the oyamel fir (*Abies religiosa*) in January and March, 1978, 1979, and 1980 from several overwintering areas in the states of Michoacan and Mexico (Calvert et al., 1979). They were individually packed in glassine envelopes and kept frozen until oven dried and prepared for analysis. For chemical isolation, wings were excised from an additional sample of approximately 8000 live monarchs collected in January, 1983, from Site Alpha. They were dried at 60°C for 16 hr, milled to a fine powder (166.7 g dry weight), and kept frozen until extracted.

Whole, above-ground *A. speciosa* plants were collected near state route 89 just south of Sierraville (Sierra County, California) on July 12, 1982. They were dried in a forced draft oven at 50–60°C for 48 hr, ground in a Wiley mill to pass a 2.0-mm screen, and then stored frozen until extracted. Leaves of *A. syriaca* plants collected in Hampshire County, Massachusetts, in August 1967, were dried at 60°C for 16 hr, similarly screened, and stored at room temperature. The validity of this *A. syriaca* plant sample was verified by comparing cardenolide TLC profiles with those from more recent collections of *A. syriaca* from the same general area.

Analytical Procedures

Gross Cardenolide Content. Plant and butterfly specimens were analyzed for gross cardenolide content by a spectrophotometric assay based upon the base-catalyzed reaction of cardenolide with 2,2′,4,4′-tetranitrodiphenyl (TNDP)

as described in Brower et al. (1972) and modified by Brower et al (1975). This assay provides results in micrograms of cardenolide (equivalent to digitoxin) per 0.1 g dry weight.

Thin-Layer Chromatography. The lead acetate precipitation method described in Brower et al. (1982) was used, with the modification described in Brower et al. (1984b), to clean up samples prior to TLC.

The conditions for analytical TLC development in the chloroform–methanol–formamide (CMF) primary solvent system or the ethyl acetate–methanol (EAM) solvent systems, visualization with TNDP, and photography of developed chromatograms were the same as described previously in Brower et al. (1982). Preparative TLC conditions were as noted in subsequent sections of this paper.

High-Performance Liquid Chromatography (HPLC). The HPLC consisted of two Altex (Berkeley, California) model 110a pumps, a model 410 solvent programmer, an LDC (Riveria Beach, Florida) Spectromonitor I variable-wavelength UV detector (set at 220 nm), with range = 0.08–0.64 Absorbance Units Full Scale (AUFS), a Rheodyne injector (model 7125, Cotati, California) with a 50-μl loop, and a Linear (model 155, Irvine, California) recorder with the chart speed set at 20 cm/hr. The column was a Partisil 10 column (Whatman, 10 μm, 25 cm $\times$ 4.6 mm ID) and the flow rate was 1.2 ml/min.

The sample was injected with 100% methyl *tert*-butyl ether as the eluting solvent, and immediately a gradient to 100% tetrahydrofuran (THF) was begun extending over 10 min. The THF was then held for 15 min. Fractions (2 ml) containing the major cardenolide components were collected. The usual elution time was ca. 15–20 min after injection. After the solvent program was completed, solvent was recycled to 100% methyl *tert*-butyl ether and held there for 30 min to allow for reequilibration.

Nuclear Magnetic Resonance (NMR) Spectrometry. NMR was run in $CDCl_3$–CD_3OD solvent on a Bruker WM 400 NMR at the University of Sydney.

Isolation of Cardenolides

Butterfly Wings. Butterfly wing powder (10 g) was soaked overnight in 150 ml 50% aq EtOH. The mixture was blended twice in a Polytron homogenizer for 2–5 min followed by standing 2 hr. The process was repeated with a second volume of solvent and the filter cake resulting from filtration of the first batch. The combined filtrates were concentrated to 100 ml and methanol (20 ml) added. The solution was partitioned with petroleum ether (3 $\times$ 50 ml), sodium chloride added to the aqueous solution to saturation, and then partitioning was carried out with 10% isopropyl alcohol in chloroform (3 $\times$ 40 ml). The isopropanol–chloroform extract was filtered through sodium sulfate and evaporated to dryness to give 85.8 mg of viscous liquid. TLC showed at least four cardenolide

spots, with one at R_{Dig} = 0.60 in CMF being the most prominent. The above residue was combined with another 56 mg from a second batch of wings similarly processed and the mixture fractionated by preparative TLC on two 2-mm silica gel G plates developed twice each with ethyl acetate–methanol (97:3). Six fractions were obtained: fraction 2 (8.8 mg) was enriched in the major component (R_{Dig} = 0.60 on an analytical TLC plate); fraction 4 (5.0 mg) had primarily syriobioside, by matching R_{Dig} (=0.67) with a syriobioside standard; fraction 6 (6.1 mg) had primarily desglucosyrioside, by matching R_{Dig} (=1.3) with a desglucosyrioside standard.

Preparative TLC fractions 2 and 4 were separately subjected to preparative HPLC yielding 1.8 mg of the major cardenolide from TLC fraction 2 (subsequently identified as aspecioside) and 0.75 mg of syriobioside from TLC fraction 4. Both collections were single components, by analytical TLC.

A. syriaca. Plant material (100 g) was processed similarly to monarch wings with the following exception: Prior to preparative TLC, the isopropanol–chloroform extract was chromatographed on 30 g of Biosil A silica gel eluted with chloroform (200 ml) followed by 1% increments of methanol in chloroform (100 or 200 ml/increment). The 6 and 7% methanol in chloroform increments contained the major cardenolide (R_{Dig} = 0.60), subsequently identified as aspecioside, and the 3 and 4% contained syriobioside. Completion of the isolation scheme yielded 1.9 mg aspecioside and 1.0 mg of syriobioside. Desglucosyrioside also appeared in TLC analysis of early Biosil A chromatographic fractions.

A. speciosa. Plant material (1800 g) yielded 21.5 mg of aspecioside, 9.7 mg of syriobioside, and amounts of desglucosyrioside and uzarigenin which were not isolated. The procedure, reported in detail in Cheung et al. (1986), was similar to that described for *A. syriaca*.

RESULTS

In order to demonstrate cardenolide commonality among *A. speciosa*, *A. syriaca*, and overwintering monarchs from Mexico, extracts of composite samples of each (dried, ground aerial plant parts or dried, ground wings) were carried through a multistep isolation scheme (Table 1). The stages varied with the sample, requiring more steps for the plants due to a higher level of coextractives than for the butterfly wings. Each sample type contained desglucosyrioside, based upon coincidence of TLC R_f in two solvent systems; this was a major cardenolide component in the two plant species but a minor one in the butterfly wing extract. Each sample type also contained two polar cardenolides by TLC analysis in two solvent systems; one had R_{Dig} = 0.37 (EAM) and 0.60 (CMF) while a second had R_{Dig} = 0.90 (EAM) and 0.67 (CMF).

Initial spectrometric measurements were made on the two polar compounds

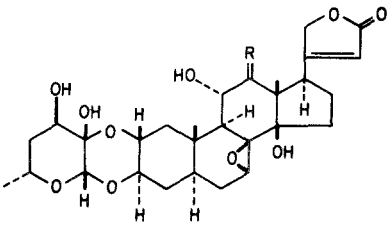
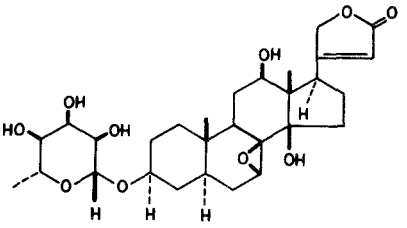
from *A. speciosa*. One (R_{Dig} = 0.67 in CMF) had a [^{1}H]NMR spectrum identical in its major features with those reported for syriobioside (Brown et al., 1979) and, in fact, coincided in TLC R_f (two solvent systems) with a syriobioside standard.

The second (R_{dig} = 0.60 in CMF) had a [^{1}H]NMR spectrum showing H-1′ as a doublet, indicating the presence of H at carbon 2′ in contrast to syriobioside and desglucosyrioside; the carbohydrate of this compound is thus linked to the aglycone through only one oxygen atom, as distinct from the doubly linked system of syriobioside and desglucosyrioside. The carbohydrate NMR signals identified it as 6-deoxy-D-allose. The stereochemistry of the protons on each carbohydrate carbon was determined with the aid of decoupling experiments. The mass spectrum of this compound (desorption chemical ionization and cesium FAB) had MH^+ = 551 amu, indicating a molecular weight of 550 (vs. 564 for syriobioside and 562 for desglucosyrioside). The molecular formula of $C_{29}H_{42}O_{10}$ takes into account the structure of the 6-deoxy-D-allose, requiring the aglycone to be $C_{23}H_{32}O_6$. The NMR spectrum had a doublet at 3.24 ppm (J = 6 Hz) which was assigned to the 7α-H of a β-7,8-epoxide. The position of the remaining oxygen functional group is 12β, based upon NMR decoupling experiments given in detail elsewhere (Cheung et al., 1986). The structure for this compound, for which we proposed the name "Aspecioside" (Cheung et al., 1986), along with the structures of desglucosyrioside and syriobioside, are

shown below:



R = O, Desglucosyrioside
R = α-OH, β-H, Syriobioside



Aspecioside

[^{1}H]NMR was employed to confirm the presence of aspecioside in *A. syriaca* plants and the monarch wing sample from Mexico. The spectra for corresponding isolates from the latter two sources were identical, except for extraneous impurity peaks, with that of aspecioside from *A. speciosa* (Figure 1).

Desglucosyrioside and syriobioside were originally isolated from *A. syriaca* (Bauer et al., 1961; Masler et al., 1962) along with syrioside, and β-D-glucose conjugate (at C-3′) of desglucosyrioside, the relatively simple cardenolide genins syriogenin and uzarigenin, and the uzarigenin conjugate desglucouzarin. The structures of desglucosyrioside, syriobioside, and syrioside were recently determined (Brown et al., 1979; Cheung and Watson, 1980).

We previously showed that *A. speciosa* also contains desglucosyrioside, syriogenin, and uzarigenin, along with TLC spots in the R_f range of syriobioside, syrioside, and aspecioside (Brower et al., 1984b). The only other *Asclepias* species known to contain cardenolide epoxides are *A. eriocarpa* and *A. erosa*, both of which are found only in California, and *A. labriformis*, which is found in a relatively restricted habitat in Utah (Seiber et al., 1978; Cheung et al., 1980).

In our earlier study of the sequestration of cardenolides by monarchs reared on *A. speciosa*, we showed that desglucosyrioside (TLC spot 19 in CMF) was present in freshly emerged adult monarchs along with several other cardenolide TLC spots, including two now identified as syriobioside (TLC spot 11) and aspecioside (TLC spot 10) (Brower et al., 1984b). The latter compound, which was particularly enriched (factor of ca. 2.5) in the adult butterflies relative to its concentration in *A. speciosa* leaves, was followed in order of spot intensity by syriobioside and desglucosyrioside. This order of intensity occurred also in the monarch wings sampled from the overwintering sites in Mexico. There was a total of 21 resolvable TLC spots in whole adult monarchs freshly emerged from *A. speciosa*-reared larvae (Brower et al., 1984b). Nine of these, including spots 10, 11, and 19, had probabilities of occurrence greater than 0.50 (i.e., half or more of the 111 butterflies examined from six geographical areas in California had these spots). For 10, 11, and 19, which were among the five most intense spots, the intensity values (most intense = 5.00) were 4.28 (spot

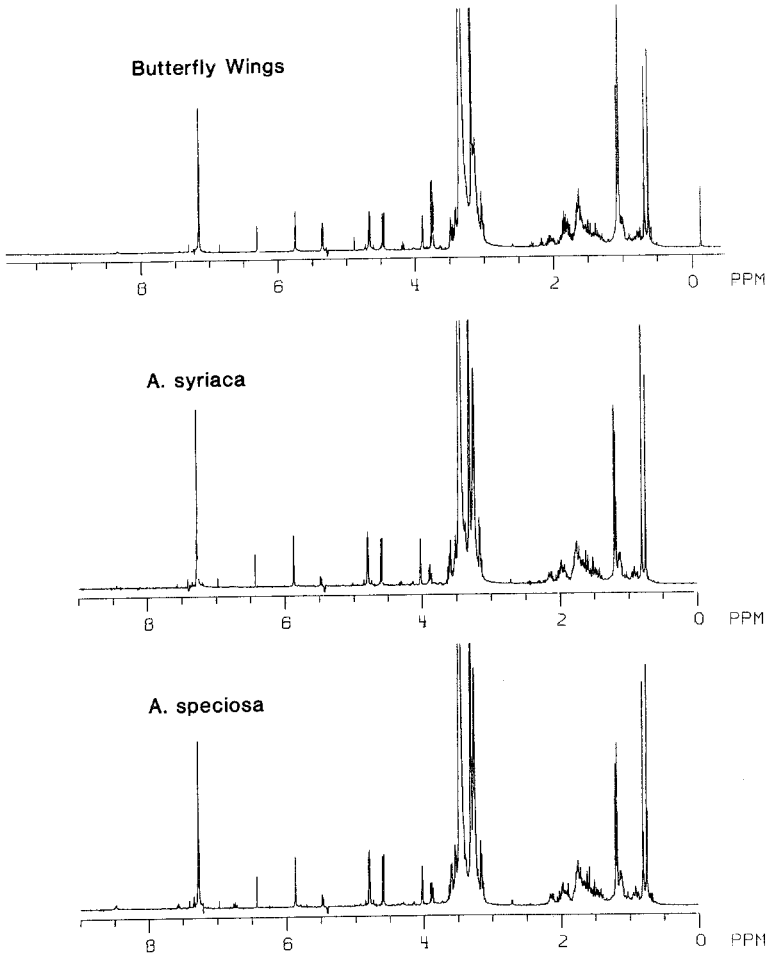


FIG. 1. [^{1}H]NMR spectra (400 MH_z) of aspecioside isolated from monarch wings collected from overwintering Site Alpha in Mexico, *Asclepias syriaca,* and *A. speciosa.* The NMR spectrum of the wing isolate is offset by approximately 0.15 ppm relative to the two other spectra.

10), 2.04 (spot 11), and 1.97 (spot 19), which is roughly in agreement with observations made on the monarch wing samples from Mexico.

A detailed analysis of the *A. syriaca* plant–butterfly cardenolide fingerprint is underway but not yet completed (Malcolm and Brower, in preparation). Enough *A. syriaca* plant–butterfly pairs have been analyzed by TLC to compare with the *A. speciosa* profile and that from overwintering butterflies (both whole specimens and wings only) from Mexico. This comparison is in the redrawn TLC channels in Figure 2. The four sample types are qualitatively similar, particularly in the predominance of aspecioside and, to a lesser extent, syrioside and desglucosyrioside in all four. Several other unidentified TLC spots

are common to the four sample types as well. From these preliminary data with *A. syriaca*-reared monarchs, we conclude that they provide a cardenolide profile very similar to the more extensively studied *A. speciosa* monarchs (Brower et al., 1984b). This is in keeping with the common cardenolide chemistry in the two plant species (Cheung and Watson, 1980; Cheung et al., 1986) as well as other similarities between the two species discussed further below.

The extent to which the *A. speciosa/A. syriaca* cardenolide TLC pattern was represented in the overwintering monarchs collected in Mexico was gauged in the following manner: Individual, whole monarchs (394) collected over a three-year period from Site Alpha were analyzed, and the cardenolide TLC patterns subjectively categorized in four groups (Figure 3): (1) Those having the greatest cardenolide spot intensity at the R_{Dig} of ca. 0.60 (aspecioside) and/

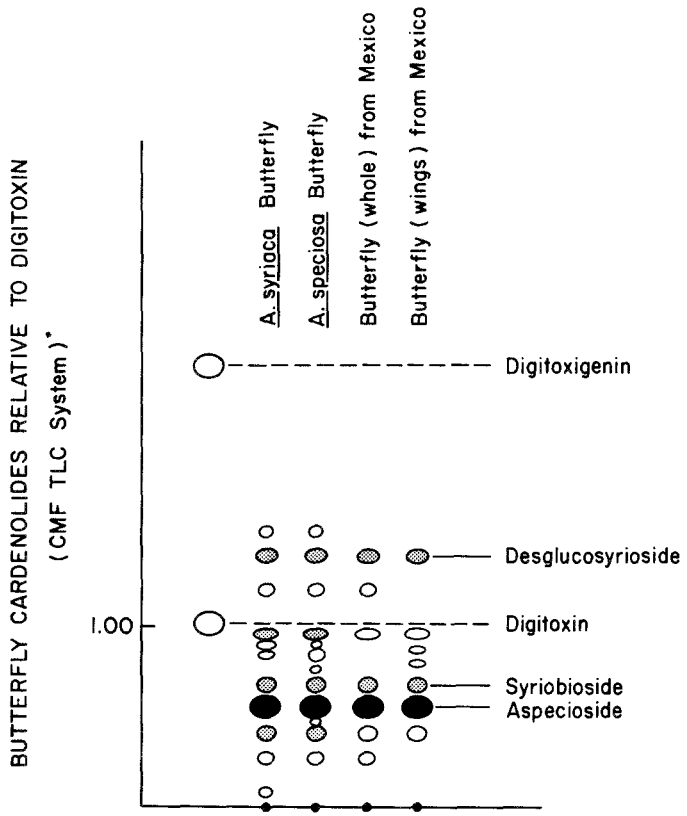

FIG. 2. Redrawn thin-layer chromatographic channels showing typical cardenolide profiles from *A. speciosa*- and *A. syriaca*-reared monarchs, Site Alpha monarch whole bodies and Site Alpha monarch wings. These channels are from plates developed four times in chloroform–methanol–formamide (90:6:1). The most heavily shaded spots were the most intense in the original chromatograms.

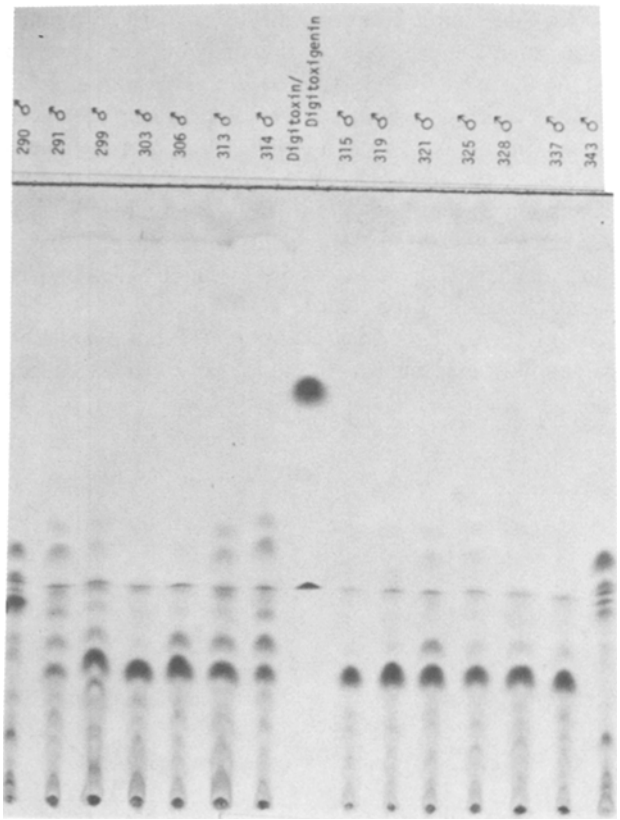

FIG. 3. Photograph of a thin-layer chromatography plate spotted with cleaned extracts of 14 individual whole monarch males collected on January 23, 1979, at Site Alpha N-15 in Mexico. Butterflies 290 and 343 show a pattern with more high R_f ($R_{Dig} > 1.0$) than low R_f cardenolides ($R_{Dig} < 1.0$). Butterfly 291 has approximately equal amounts of high and low R_f cardenolides. Butterflies 299, 303, 306, 313, 314, 315, 319, 321, 325, 328, and 337 show predominately aspecioside ($R_{Dig} = 0.6$) with lesser amounts of syriobioside ($R_{Dig} = 0.7$) and, in some cases, desglucosyrioside ($R_{Dig} = 1.3$); these represent the *A. syriaca* profile discussed in the text. Altogether 394 monarchs from Site Alpha were similarly analyzed. Chromatograms were developed as in Figure 2, with 75 μg digitoxin equivalents spotted for each butterfly.

or ca. 0.67 (syriobioside)—the most recognizable features of the *A. speciosa/A. syriaca* fingerprint pattern—included 337 individuals. (2) Those having their greatest cardenolide spot intensity at the $R_{Dig} > 1$, which probably had not been reared as larvae on *A. speciosa* and/or *A. syriaca*, included nine individuals. (3) Those having cardenolides of approximately equal intensity low ($R_{Dig} < 1$) and high ($R_{Dig} > 1$) included 40 individuals. This latter group may have included some individuals fed as larvae on either *A. speciosa* or *A. syriaca*, but the evidence was not clearcut. (4) Those lacking any observable cardenolide

spots at concentrations applied to the TLC plates included 10 individuals. In sum, 85% of the specimens examined conformed clearly to the *A. speciosa/A. syriaca* fingerprint.

DISCUSSION

The range of *A. syriaca* is reported to extend from Maine to Virginia, west to North Dakota and Kansas, and south to, roughly, 35° latitude (Figure 4) (Woodson, 1954). It is an abundant species—"the preeminent weedy species of the northeastern U.S." (Woodson, 1954)—whose frequency and range have been increased by agricultural and transportation activities (Marks, 1983; Brower, unpublished observations). Its range coincides closely with that of the major population of summer monarchs in North America (Urquhart, 1960), and it is readily available as a food plant into late summer when the last generation of monarchs which eventually migrates south is produced. *A. speciosa* shares many of these characteristics with the important exception that its range extends from Minnesota to Texas in the east westward to the Pacific coast, that is, approximately up to but only marginally overlapping with the range occupied by *A. syriaca* (Figure 4). In fact, the similarity of the two species is demonstrated by spontaneous hybridization in their overlapping range in Minnesota,

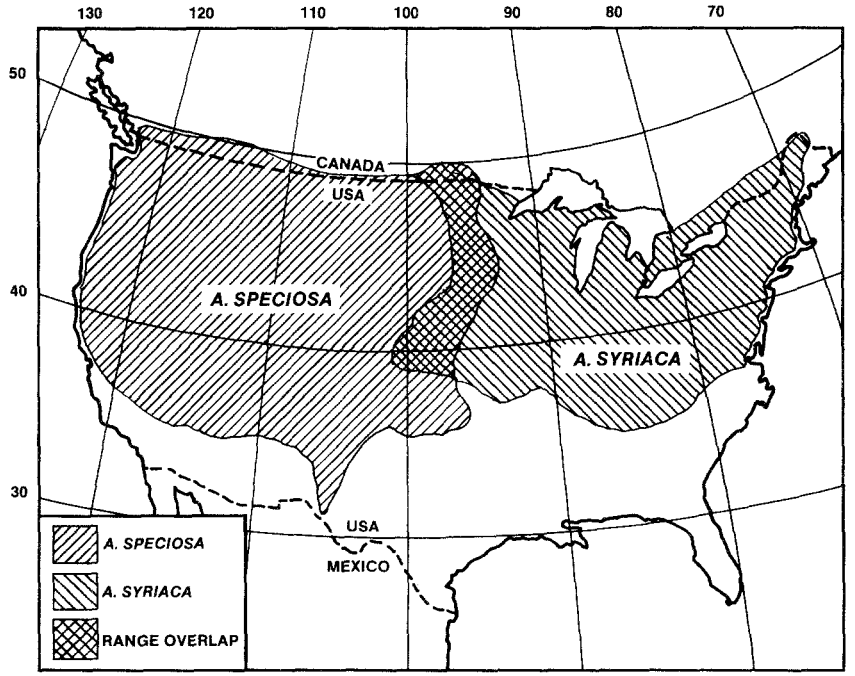

FIG. 4. Map showing approximate ranges of *Asclepias speciosa* and *A. syriaca* in North America (from collection data in Woodson, 1954).

Iowa, and the Dakotas (Woodson, 1954) as well as their very similar cardenolide chemistry. Because *A. speciosa* does not grow in the midwest–northeast U.S., it is clear that *A. syriaca* is the more likely late season host plant for monarchs which migrate to the overwintering sites in Mexico—that is, the major population in North America.

Several other *Asclepias* species which have a range similar to *A. syriaca* cannot be definitively excluded as potential contributors to the dominant TLC fingerprint observed in the sample from Mexico because their plant–butterfly fingerprints have been studied less extensively than those of *A. speciosa* and *A. syriaca* or have not been examined at all. Some speculation, however, may be offered on the potential contribution of these other species. Among those species which are relatively abundant and widespread within the *A. syriaca* range, *A. amplexicaulis, A. incarnata, A. tuberosa,* and *A. verticillata* have nil or very low cardenolide concentrations when compared with *A. syriaca* (Seiber et al., 1983) and are therefore unlikely candidates. *A. humistrata, A. quadrifolia, A. variegata, A. viridifolia,* and *A. viridis* are early season species (Woodson, 1954) which are not abundant late in the season when the fall migratory population is formed. Several other less-abundant species in similar geographical ranges cannot be excluded as minor contributors based upon available evidence.

If *A. syriaca* is, in fact, the principal late-season host plant for monarchs in North America, as others have suggested (Urquhart, 1960; Urquhart and Urquhart, 1978, 1979, 1980; Fink and Brower, 1981) and our cardenolide analyses strongly support, the finding may prove to be of much ecological importance. Historical changes in the eastern North American flora have apparently favored the adaptable and hearty *A. syriaca,* increasing its abundance relative to other milkweeds and thus increasing its availability as a monarch food plant (Brower et al., 1984b; Marks, 1983). We have previously shown that its botanical relative, *A. speciosa,* is a poor cardenolide source for monarchs relative to other *Asclepias* species we have examined (Brower et al., 1984b) and that the cardenolide concentration range of *A. syriaca* is similar to that of *A. speciosa* (Malcolm and Brower, in preparation). Moreover, as noted above, *A. syriaca* contains virtually the same cardenolides as *A. speciosa*. In addition, we have shown (Brower et al., 1984b) that the polar epoxy cardenolides now identified as syriobioside and aspecioside, which predominate in monarchs reared on *A. speciosa* and *A. syriaca,* have a markedly lower emetic potency than those of intermediate polarity which are sequestered from the California milkweed species, *A. eriocarpa* (Brower et al., 1982). This may account for the lower emetic potency of migrating monarchs collected in Massachusetts (Brower and Moffitt, 1974) and also in Mexico (Brower and Fink, 1985) than was observed in monarchs sampled from the overwintering sites in California, most of which probably fed on *A. eriocarpa* and other milkweeds contributing cardenolides of intermediate polarity (Brower et al., 1982). The consequence of an increase in abundance and distribution of *A. syriaca* plants may have been to lower the monarch's cardenolide content, as well as to diminish its emetic potency (Brower

and Fink, 1985) throughout the entire eastern range. This may account for the more extensive avian and rodent predation in the overwintering colonies in Mexico than occurs in the overwintering sites in California (Calvert et al., 1979; Fink and Brower, 1981; Fink et al., 1983; Brower et al., 1984b; Brower and Calvert, 1985).

The potential connection between an increasing abundance of a milkweed host plant, *A. syriaca,* which is a relatively poor source of cardenolide defensive chemicals, and the increased vulnerability of the major monarch butterfly population in eastern North America warrants further study.

(Received June 27, 1985; accepted September 23, 1985)

Abstract—The morphological and physiological adaptations associated with sequestration of cardenolides by the lygaeid *Oncopeltus fasciatus* are summarized and discussed. Cardenolides are efficiently accumulated in *O. fasciatus*; however, the insect does not appear to suffer any physiological cost as a result of handling large amounts of these plant toxins. Morphological adaptations of the insect include a modified integument composed of a double layered epidermis with an inner layer (the dorsolateral space) specialized for cardenolide storage. Special weak areas of the cuticle are found on both the thorax and abdomen, which rupture when the insect is squeezed, resulting in the cardenolide-rich contents of the inner epidermal layer being released onto the body surface in the form of discrete spherical droplets. Physiological adaptations include selective sequestration of food plant cardenolides, concentration of cardenolides in the dorsolateral space, passive uptake of cardenolides at the gut and dorsolateral space requiring little energy output, reabsorption of secreted cardenolides by the Malpighian tubules, high in vivo tolerance to cardenolides, and the presence of cardenolide-resistant Na,K-ATPases.

Key Words—Hemiptera Heteroptera, Lygaeidae, *Oncopeltus fasciatus*, Asclepiadaceae, cardenolides, sequestration, morphological adaptations, physiological adaptations.

INTRODUCTION

The Heteroptera, including the Lygaeidae, have adult metathoracic and larval abdominal scent glands (Staddon, 1979), that produce a diversity of chemicals

[1]Hemiptera-Heteroptera: Lygaeidae.

0098-0331/86/0500-1171$05.00/0

(Baggini et al., 1966; Calam and Youdeowei, 1968; Tsuyuki et al., 1965; Weatherston and Percy, 1978). These chemicals often function for defense (Remold, 1962, 1963; Calam and Youdeowei, 1968; Dazzini and Pavan, 1978).

Lygaeidae are generally brown, cryptically colored, and ground dwelling seed feeders. In contrast, members of the subfamily Lygaeinae are typically brightly colored arboreal plant feeders, with red and black aposemetic coloration (Scudder and Duffey, 1972). The coloration and off-ground habit in the Lygaeinae correlates with a reduced adult metathoracic scent apparatus (Schaefer, 1972), although scent glands persist and function in both larvae and adults (Games and Staddon, 1973a,b; Henrici, 1938, 1939; Johansson, 1957; Remold, 1962, 1963; Staddon, 1979).

Most of the Lygaeinae feed on Asclepiadaceae and Apocynaceae (Scudder and Duffey, 1972), and hence, the warning coloration in this taxon also appears to be correlated with the use of cardenolides for defensive purposes. This has been clearly documented in other insect species (Brower, 1969; Brower and Brower, 1964; Rothschild, 1966, 1972; Rothschild and Kellett, 1972; Rothschild et al. 1970, 1973).

Oncopeltus fasciatus (Dallas) is a typical member of the Lygaeinae, and a common research animal (Feir, 1974). It normally lives on species of Asclepiadaceae (Eggermann and Bongers, 1971, 1972), although it can also live on *Nerium oleander* (Klausner et al., 1980) and can be reared on peanuts (Frings and Little, 1955), sunflower seeds (Bongers, 1969), and on a mixture of cashew and sunflower seeds or pumpkin and sunflower seeds (Gordon and Loher, 1968).

While *O. fasciatus* clearly utilizes endogenously produced chemicals for its defense (Games and Staddon, 1973a, b), it is also able to sequester large quantities of cardenolides from its food plants thoughout its life cycle (Duffey and Scudder, 1974). It is assumed that these exogenous chemicals also have an antipredator defensive function (Duffey and Scudder 1974; Scudder and Meredith, 1982a).

This paper reviews the role of cardenolides in the complex defensive system of *O. fasciatus*. In it is summarized the morphological and physiological adaptations associated with cardenolide uptake and accumulation. These adaptations are discussed with particular reference to the high efficiency of cardenolide accumulation seen in *O. fasciatus* and the lack of any apparent physiological cost of cardenolide storage to the insect. Contrasts are made between cardenolide sequestration and deployment in *O. fasciatus* and that in the monarch butterfly (*Danaus plexippus* L.). Finally, comments are offered on predation experiments with this insect and other Lygaeinae.

MORPHOLOGICAL ADAPTATIONS

The Integument. The integument of arthropods characteristically has a single-layered epidermis bound by a basal lamina (Richards, 1951; Neville, 1975).

In *O. fasciatus* a double-layered epidermis is present in both males and females, regardless of diet, from late embryo through to the adults (Scudder and Meredith, 1982a). This unusual epidermal structure is a special morphological feature of *O. fasciatus* adapted for cardenolide storage and release.

The outer layer of the epidermis (Figure 1) is a typical epidermal monolayer (Ep), concerned with cuticle production and support. It is pigmented and nonvacuolated. In contrast, the inner epidermal layer (Ev) is extensively vacuolated and unpigmented. The irregularly shaped, membrane-bound vacuoles (v) are probably the site of cardenolide storage in *O. fasciatus*. The vacuolation of the inner cell layer becomes more and more extensive during development, until in the adult the cells are essentially fluid-filled.

In the adult integument, the inner cell layer is very fragile, and cells may lack lateral cell membranes. When the cardenolide compartments are expanded, the cytoplasm of the cells is drastically reduced, and persists only in the areas where the inner cells are attached to the basal lamina by hemidesmosomes. However, study of the nuclei of these cells shows that they are not necrotic, suggesting that these cells must be cardenolide resistant. Since the cells can be experimentally loaded with ouabain (Scudder and Meredith, 1982a), they would appear to be as resistant as mammalian cell lines that have been established in culture (Baker et al., 1974; Landolph et al., 1980; Mankovitz et al., 1974; Robbins and Baker, 1977).

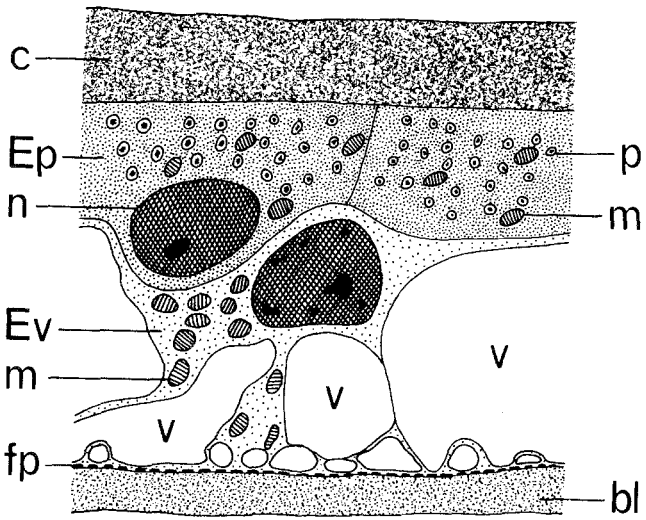

FIG. 1. Diagrammatic section through the integument of adult *O. fasciatus* showing the double layered epidermis. Abbreviations: Ep, pigmented epidermal cell layer; Ev, vacuolated epidermal cell layer; bl, basal lamina; c, cuticle; fp, foot processes; m, mitochondria; n, nucleus; p, pigment granule; v, vacuole.

The basal lamina (bl) underlying the inner epidermal cell layer in *O. fasciatus* thickens throughout development, and in the adult is 1.02 μm thick. This is at least twice the usual thickness (Ashurst, 1968) reported for the insect basal lamina. It is suggested (Scudder and Meredith, 1982a) that this thick basal lamina functions structurally to prevent the inner cell layer from rupturing internally, and releasing the contents into the hemocoel.

Thus, the integument of *O. fasciatus* is especially adapted in that (1) it has a double-layered epidermis with an inner layer specialized for cardenolide storage; (2) the inner layer is cardenolide and ouabain resistant; and (3) it has an especially thick basal lamina to provide structural reinforcement preventing the inner cell layer from rupturing internally.

Although a similar double-layered epidermis has been found in *Lygaeus kalmii* (Scudder and Meredith, 1982a), it is not known if it also occurs in other Lygaeinae. It is also not yet clear whether the cardenolides stored in the inner cell layer of immature stages are passed from one instar to the next.

Since the inner epidermal layer cells lack extensive membrane elaboration and abundant mitochondria, such as is seen in transporting tissues, it is suggested that the cardenolide uptake process into the cells is not an active process. (See section on physiological adaptations for further discussion).

In the adult *O. fasciatus*, injection experiments with India ink show that the cardenolide-containing areas of the integument appear to be continuous between the thorax and abdomen. The area which we have called the dorsolateral space is especially expanded in the epimeral lobes of the metathorax and the dorsolateral margins of the mesothorax and abdomen. The cardenolide-containing space occurs throughout the integument of the thorax and abdomen and is interrupted only in regions of muscle attachment and where the cuticle is modified as invaginations.

Thoracic Release Sites. In both the thorax and abdomen of *O. fasciatus*, cardenolide-rich fluids are released onto the surface of the body by integument rupture: there are no special pores or glands. Only when the insect is forcibly squeezed will discrete spherical droplets appear at precise points of weakness. Mere disturbance will not elicit release.

In the meso- and metathorax, these areas of weakness occur along the dorsolateral margins of the segment. In the mesothorax, droplets of cardenolide-rich fluid may form anywhere along the margin, where the cuticle is somewhat thinner (Scudder and Meredith, 1982a).

In the metathorax, there is a curved slit at the posterior, dorsolateral margin of the epimeral lobe. Here cuticular flanges abut and are underlayed by the epidermis. When pressure is applied, the flanges are forced apart, and the epidermal layer seal is broken to release the cardenolide-rich contents of the inner epidermal layer. Normally, the cardenolides will be released on the thorax before they will appear on the abdomen.

Abdominal Release Sites. On the abdomen, special weak areas of cuticle

occur in the lateral black pigment spots at the anterolateral corners of sterna II–VII. On the surface, this area of the cuticle is smooth and is surrounded by dense microtrichia. This smooth area of cuticle is about one fourth the normal thickness of the surrounding cuticle. This weak area and underlying epidermis is ruptured under pressure to release the cardenolide-rich contents of the inner epidermal layer. On release, these droplets are emphasized by their location on aposematic areas and are positioned such as to be immediately encountered by a predator.

These structural specializations seen in the abdomen of *O. fasciatus* are also present in other Lygaeinae, but are not a universal characteristic of the subfamily (Scudder and Duffey, 1972). In those taxa without structural weak points on the sterna, the mode of deployment of the cardenolides is not known.

PHYSIOLOGICAL ADAPTATIONS

Oncopeltus fasciatus sequesters and tolerates large amounts of cardenolides in its body tissues. A number of physiological adaptations are associated with this ability. We have studied sequestration of cardenolides from its natural food plants (*Asclepias* spp.), the distribution of cardenolides in body tissues, the uptake of cardenolides at the gut and into the dorsolateral space, the metabolism and excretion of cardenolides, and the tolerance of the insect and its Na,K-ATPases to the toxic effects of cardenolides. Since commercial preparations of host plant cardenolides are not available, two nonasclepiad cardenolides, ouabain and digitoxin, have been used as indicator cardenolides in many of the experiments we have undertaken. Ouabain and digitoxin are not found in the food plants of *O. fasciatus* and have a 5β *cis* A/B steroid ring juncture rather than the 5α *trans* A/B steroid ring juncture characteristic of asclepiad cardenolides. Ouabain and digitoxin were chosen owing to their contrasting polarities and to their availability in pure and radiolabeled forms. In addition, a number of the metabolites of these compounds have been identified and are also commercially available.

Uptake of Cardenolides from Natural Food Plants (Asclepias, *spp.). Oncopeltus fasciatus* sequesters cardenolides from the seeds and vegetative parts of its food plants (Duffey and Scudder, 1974; Feir and Suen, 1971; Moore and Scudder, 1985) with no apparent physiological costs (Isman, 1977; Chaplin and Chaplin, 1981; Jones et al., 1983). Several studies suggest that milkweed cardenolides are sequestered in proportion to the cardenolide content of the food source (Isman, 1977; Duffey et al., 1978; Vaughan, 1979). The wide range in the cardenolide contents detected in *O. fasciatus* (0–900 μg cardenolide per insect) reflects the large intra- and interspecific differences in the cardenolide contents of the insect's food plants (Isman et al., 1977a; Duffey et al., 1978; Vaughan, 1979; Isman, 1977, 1979, unpublished data). In contrast, a study by

Vaughan (1979) found quantitative regulation of the cardenolide content in *O. fasciatus*. A greater percentage of the seed cardenolide content was sequestered in insects reared on *A. syriaca* seeds of low cardenolide content than in insects reared on *A. syriaca* seeds of high cardenolide content. In general, females contain more cardenolide per insect than males (usually >50% more; Duffey and Scudder, 1974; Isman, 1977), possibly as a result of cardenolide accumulation in developing eggs, although in one study no sexual differences in total cardenolide content per insect was found (Moore and Scudder, 1985).

These results suggest that uptake of cardenolides in *O. fasciatus* is similar to that in the monarch in the following aspects: (1) neither insect suffers any apparent physiological cost because of the sequestration and storage of cardenolides, (2) both species usually exhibit sexual dimorphism in cardenolide contents, and (3) both species exhibit differences in cardenolide content which reflect interspecific differences in their food plants (Brower and Moffitt, 1974; Seiber et al., 1980; Brower et al., 1984).

Distribution and Selective Sequestration of Milkweed Cardenolides. The distribution of cardenolides in *O. fasciatus* has been determined in insects reared on two natural food plants, *Asclepias syriaca* and *A. speciosa* (Table 1 and Figure 2). The results of these experiments (Duffey and Scudder, 1974; Moore and Scudder, 1985) indicate that cardenolides are accumulated primarily in the dorsolateral space while low cardenolide levels are maintained elsewhere in the insect (Table 1).

Comparison of the cardenolide profiles of insects and their food plants shown in Figure 2 indicate that individual cardenolides are selectively sequestered and stored in *O. fasciatus*. Most, but not all, of the cardenolides detected

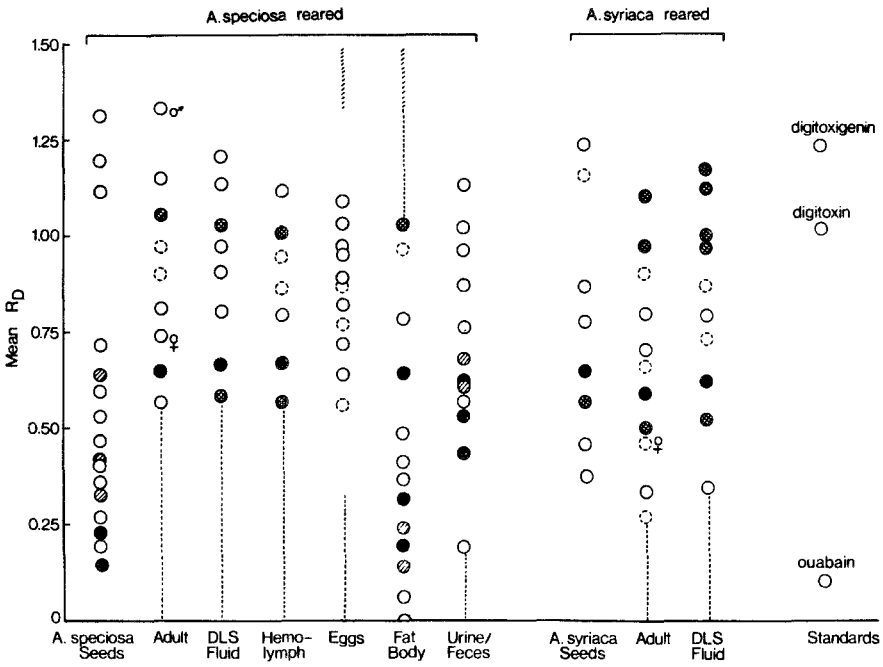

FIG. 2. Cardenolide profiles of *A. speciosa* and *A. syriaca* seeds and extracts of *O. fasciatus* adults reared on each seed. Each spot represents an individual cardenolide. The relative concentrations of the cardenolides of the different samples are not comparable. Symbols: $R_D = R_f$ spot/$\bar{X}$ R_f of digitoxin; ⊘, noncardenolide; ○, low concentration; ○, medium concentration; ⊗, high concentration; ●, highest concentration; ◐, high or highest concentration depending on the extract; ♂, seen in male only; ♀, seen in female only; ⁞, light tailing of cardenolides; ≡, light tailing of noncardenolides.

in the seeds were present in the insect, and many of the cardenolides that were highly concentrated in the insect did not correspond to highly concentrated cardenolides in these seeds (Figure 2; see also Moore and Scudder, 1985). Selective sequestration of food plant cardenolides has also been noted in *Danaus plexippus*, *Aphis nerii*, *Caenocoris nerii*, *Spilostethus pandurus*, and *Poekilocerus bufonius* (von Euw et al., 1967, 1971; Rothschild et al., 1970; Brower et al., 1982). Many of the cardenolides detected in *O. fasciatus* which do not correspond to seed cardenolides may represent products of metabolism.

The cardenolide profiles shown in Figure 2 also indicate that cardenolides of a wide polarity range were sequestered, as well as concentrated, in insects reared on either species of milkweed. These results indicate a further similarity between *O. fasciatus* and the monarch since the monarch also sequesters cardenolides covering a wide polarity range (Brower et al. 1982). This was unexpected since earlier studies indicated that polar cardenolides are preferentially

sequestered in *O. fasciatus* (Duffey and Scudder, 1974; Duffey et al., 1978; Scudder and Meredith, 1982b). The role of physical-chemical characteristics other than polarity in cardenolide sequestration in *O. fasciatus* is also suggested by the sequestration and concentration of intermediate and more polar cardenolides in the fat body of insects reared on *A. speciosa* (Figure 2). This result was also unexpected since the fat body often accumulates nonpolar compounds and toxins owing to their lipophilic nature (Kilby, 1963), and earlier observations indicated preferential sequestration of the nonpolar cardenolide digitoxin in the fat body of adult *O. fasciatus* (Duffey et al., 1978).

Uptake of Cardenolides by the Gut. Uptake of the polar cardenolide, ouabain, and the nonpolar cardenolide, digitoxin, by the gut of *O. fasciatus* has been investigated by Yoder et al. (1976) and Scudder and Meredith (1982b). The selective permeability of the gut to digitoxin seen in both experiments suggests that the gut may be more permeable to nonpolar cardenolides than to polar cardenolides. Uptake of ouabain and digitoxin was linearly related to concentration, was nonsaturable, and was not observed to occur against a concentration gradient, which suggests that gut uptake of cardenolides is probably passive and occurs by diffusion. The results of Yoder et al. (1976) also provide evidence that uptake of cardenolides by the gut may be sensitive to Na^+ levels and that uptake of individual cardenolides may not be affected by the presence of other cardenolides in the gut lumen.

Scudder and Meredith (1982b) demonstrated that the gut of two insects which do not normally encounter cardenolides in their diet, namely the locust *Schistocerca gregaria* and the cockroach *Periplaneta americana*, was not permeable to either ouabain or digitoxin. These results suggest that gut permeability to cardenolides may be one of the specializations that has allowed certain insects, such as *O. fasciatus*, to accumulate these plant toxins in their body tissues and defensive secretions.

Uptake of Cardenolides into Dorsolateral Space. The uptake of ouabain and digitoxin into the dorsolateral space has been investigated by Duffey et al. (1978) and Scudder and Meredith (1982b). The selective permeability of the dorsolateral space seen in these experiments (ouabain $>>$ digitoxin) is the reverse of that seen in the gut. This indicates that the accumulation of some cardenolides, i.e., ouabain, in *O. fasciatus* may be limited by their rate of uptake across the gut, whereas for other cardenolides, i.e., digitoxin, accumulation may be limited by their rate of uptake into the dorsolateral space (Scudder and Meredith, 1982b).

Uptake of ouabain and digitoxin by the dorsolateral space, is in proportion to the cardenolide content in the food source and the hemolymph, is nonsaturable, and displays first-order kinetics which suggests that the uptake of cardenolides into this epithelial layer is passive and occurs by diffusion (Duffey et al., 1978; Scudder and Meredith, 1982b). We have already noted ultrastructural characteristics of the inner epidermal layer that suggest uptake of cardenolides

into the dorsolateral space is passive (Scudder and Meredith 1982a). Estimated ratios of cardenolide concentration in the dorsolateral space to cardenolide concentration in the hemolymph (DLS/H) were as high as 73 in insects injected with ouabain (Duffey et al., 1978). In insects reared on natural host plants, DLS/H ratios up to 13,000 were found (Duffey and Scudder, 1974; Duffey et al., 1978; Moore and Scudder, 1985). Since diffusion of a compound can only occur along its electrochemical gradient, the cardenolides in the dorsolateral space must have a lower chemical activity than the cardenolides in the hemolymph. The chemical activity of the cardenolides in the dorsolateral space could be lowered by processes such as phase separation (i.e., an emulsion phase as suggested by Duffey et al., 1978), binding to proteins or binding to other cellular constituents; however, at this time the actual process involved is not known.

Some of the characteristics of ouabain uptake into the dorsolateral space suggest that this epithelial layer may function in the tolerance of *O. fasciatus* to cardenolides by maintaining low levels of these toxins in the hemolymph (less than 6.5×10^{-6} M, Moore and Scudder, 1985a). Uptake of ouabain can occur when cardenolide levels in the hemolymph are as low as 3.5×10^{-7} M (Duffey et al. 1978). In addition, rates of ouabain uptake increase as hemolymph concentrations of ouabain increase, aiding in rapid clearance of ouabain from the hemolymph (Table 2).

Metabolism of Cardenolides. Several studies have indicated that ouabain and digitoxin, as well as milkweed cardenolides, are metabolized in *O. fasciatus* adults (Duffey and Scudder, 1974; Scudder and Meredith, 1982b; Meredith et al., 1984; Moore and Scudder, 1985), and metabolism of digitoxin has been

TABLE 2. UPTAKE OF OUABAIN INTO DORSOLATERAL SPACE 3 HOURS AFTER HEMOLYMPH INJECTION[a]

Initial ouabain concentration in hemolymph after injection (M)[b]	Concentration in dorsolateral space fluid 3 hr after injection (pmol/μl)	Injected ouabain in dorsolateral space after 3 hr (%)[c]
4×10^{-8}	3×10^{-2}	17–26
4×10^{-7}	2×10^{-1}	8–13
4×10^{-6}	5	25–38
4×10^{-5}	100	50–75
4×10^{-4}	1000	50–75
4×10^{-3}	10000	50–75

[a] Calculated from data in Duffey et al., (1978).
[b] Calculated using hemolymph volume estimate of 10 μl (Duffey et al., 1978).
[c] Calculated using dorsolateral space volume estimate of 2–3 μl (Duffey and Scudder, 1974).

demonstrated in larval instars (Duffey and Scudder, 1974). Possible sites of cardenolide metabolism in adult insects were investigated using ouabain and digitoxin. To date, metabolism of ouabain has only been found in the Malpighian tubules of *O. fasciatus* (Meredith et al., 1984), whereas metabolism of digitoxin has been found in both the Malpighian tubules and the midgut (Scudder and Meredith 1982b). Digitoxin was not metabolized in isolated hemolymph or dorsolateral space fluid (Scudder and Meredith, 1982b).

Metabolism of cardenolides has also been indicated in a number of other insects and may serve to rid the insects of particularly toxic cardenolides, as well as provide the insects with cardenolides that are readily accumulated and especially effective for defense (von Euw et al., 1967; Scudder and Meredith, 1982b; Brower et al., 1982; Levey, 1983).

Excretion of Cardenolides by Malpighian Tubules. Meredith et al. (1984) investigated the excretion of ouabain by the Malpighian tubules under a variety of in vitro conditions. Their results demonstrated that ouabain was passively secreted and metabolized by the Malpighian tubules which suggests that the tubules are a potential site of cardenolide loss in *O. fasciatus*. The discovery, however, of a specialized tubule segment that actively reabsorbed ouabain indicates that the excretory loss could be minimized and that reabsorption of secreted cardenolides may be an important factor in the sequestration of cardenolides in *O. fasciatus*. Indeed, in situations of high ouabain secretion by the tubules, 84–93% of the ouabain that otherwise would be excreted was reabsorbed. Further investigation is necessary to establish the role in vivo of the Malpighian tubules in the overall process of sequestration of cardenolides in *O. fasciatus*.

Ouabain-Resistant Na,K-ATPases and Tolerance to Cardenolides. Two additional factors may function in the ability of *O. fasciatus* insect to tolerate and store cardenolides from its food plants: in vivo tolerance of the insect to large amounts of cardenolides injected into the hemolymph, and the presence of cardenolide-resistant Na,K-ATPases in the insects' nervous tissue (Moore and Scudder, 1986). The in vivo tolerance of *O. fasciatus* to ouabain was compared to that of *Schistocerca gregaria* and *Periplaneta americana*, two orthopteroid insects which do not encounter cardenolides in their diet. The results clearly show that *O. fasciatus* was highly resistant to the toxic effects of ouabain (Table 3); correcting for interspecific weight and hemolymph volume differences, *O. fasciatus* tolerated 1954× and 7288× the LD_{50} for *S. gregaria* and *P. americana*, respectively.

Cardenolides exert their toxic effects by specifically inhibiting the enzyme $Na^+ + K^+ - ATPase$ (Na, K-ATPase; E.C. 3.6.1.3), and among vertebrates, species differences in sensitivity to cardenolides are known to parallel differences in the sensitivity of their Na,K-ATPases (Akera, 1977; Bodeman, 1981; Schwalb et al., 1982). Our studies (Moore and Scudder, 1986) indicate that such differences may also account for interspecific sensitivities to ouabain in *O.*

TABLE 3. OUABAIN TOLERANCE OF *O. fasciatus*, *S. gregaria*, AND *P. americana*[a]

Insect	Ouabain injected (nmol/insect)	Ouabain injected (nmol/mg wet weight insect)	Initial ouabain concentration in hemolymph after injection (M)[b]
O. fasciatus, 100% survival	200.0	4.3	12.5×10^{-3}
S. gregaria, LD_{50}	6.1	2.2×10^{-3}	3.0×10^{-5}
P. americana, LD_{50}	0.9	5.9×10^{-4}	5.4×10^{-6}

[a] Adult females—*O. fasciatus* and *P. americana* random ages, *S. gregaria* 16–18 days after ecdysis. Survival after 24 hr (48 hr survival is the same).

[b] Calculated using the following hemolymph volume estimates: *O. fasciatus* and *S. gregaria* 11 and 200 μl, respectively (Meredith, unpublished results), *P. americana* 165 μl (Guthrie and Tindall, 1968), and assuming complete mixing of injected ouabain with hemolymph.

fasciatus and *S. gregaria* (Table 4); the ouabain concentration resulting in 50% inhibition of the Na,K-ATPase activity in nervous tissue lyophilates of *O. fasciatus* was 100× greater than that for *S. gregaria* brain and 200× greater than that for *S. gregaria* rectum. Thus, the presence of cardenolide-resistant Na,K-ATPases in *O. fasciatus* appears to be one more factor in the ability of this insect to tolerate and store cardenolides from its food plants.

Characteristics of Sequestration and Tolerance of Cardenolides in O. fasciatus: *Comparison to Monarch Butterfly.* Throughout this review, we have noted the similarities and differences in the sequestration and tolerance of cardenolides in *O. fasciatus* and the monarch. Of particular interest is the fact that neither insect appears to suffer ill effects from the sequestration of large amounts of cardenolides.

Our investigations suggest that the low physiological cost of sequestering cardenolides in *O. fasciatus* is the result, at least in part, of the following specializations: (1) high in vivo tolerance to cardenolide intoxication (Moore and Scudder, 1986); (2) passive uptake of cardenolides at the gut and dorsolateral space, requiring little energy output (Duffey et al., 1978; Scudder and Mere-

TABLE 4. INHIBITION OF NA, K-ATPASE ACTIVITY BY OUABAIN IN NERVOUS TISSUE OF *O. fasciatus* AND BRAIN AND RECTUM OF *S. gregaria*

Species	Tissue	I_{50} (M)[a]
O. fasciatus	nervous tissue	2.0×10^{-4}
S. gregaria	brain	2.0×10^{-6}
S. gregaria	rectum	1.0×10^{-6}

[a] I_{50} = the molar concentration resulting in 50% inhibition.

dith, 1982a,b); and (3) the presence of cardenolide-resistant NA,K-ATPases in the nervous tissue (Moore and Scudder, 1986).

It is of obvious interest to determine if these specializations are also found in the monarch and other cardenolide-accumulating insects. The work of Vaughan and Jungreis (1977) suggests that cardenolide-resistant Na,K-ATPases are a factor in the low physiological cost of cardenolide sequestration in the monarch. Further work is needed to determine the importance of cardenolide-resistant Na,K-ATPases, high in vivo tolerance, and the mode of cardenolide uptake in the storage and tolerance of host plant cardenolides in other insects.

Despite the similarities seen in the sequestration and tolerance of cardenolides in *O. fasciatus* and *D. plexippus*, there are some interesting differences between these two insects, particularly in the greater efficiency and apparent nonsaturability of cardenolide uptake in *O. fasciatus* and the different distribution of cardenolides in the body tissues of these insects (Tables 5 and 6). Table 5 demonstrates that *O. fasciatus* sequesters more cardenolides per g dry weight of insect than has been recorded for any other nonlygaeid insect species. This high efficiency in cardenolide uptake seems to be directly related to the presence of the dorsolateral space in the integument of *O. fasciatus* and the apparently nonsaturable accumulation of large amounts of cardenolides in the

TABLE 5. GROSS CARDENOLIDE CONTENT OF INSECTS FEEDING ON SPECIES OF *Asclepias*

Insect species	Host plant species	Cardenolide content (mg/g dry wt)[a]	Ref.[b]

TABLE 6. DISTRIBUTION OF CARDENOLIDES AMONG TISSUES OF THREE INSECTS FEEDING ON MILKWEED[a]

Insect	Cardenolide content			
	Hemolymph	Gut	Fat body	Wings
O. fasciatus (adult)	Low	Low	Low	Low
Danaus plexippus (adult)	High	Moderate	Low	High
Danaus plexippus (larvae)	High	High	?	—
Cycnia inopinatus (larvae)	High	Low	?	—
Cycnia inopinatus (adult)	?	?	?	High

[a] Data compiled from Brower and Glazier, 1975; Duffey and Scudder, 1974; Moore and Scudder, 1985; Nishio et al., 1983; Nishio, 1980.

highly specialized inner epidermal layer (Duffey and Scudder, 1974; Duffey et al., 1978; Scudder and Meredith, 1982b; Moore and Scudder, 1985).

Table 6 demonstrates that the tissue distribution of cardenolides in *O. fasciatus* differs from that of *Danaus plexippus* as well as the arctiid moth *Cycnia inopinatus*. This may reflect interspecific differences in maximizing the defensive use and minimizing the toxic effects of food plant cardenolides (see Blum 1981, 1983). High cardenolide concentrations in the wings of *D. plexippus* and *C. inopinatus* and the gut of *D. plexippus* larvae appear to be effective in defense against predators (Brower and Glazier, 1975; Nishio, 1980; Blum, 1983). In contrast, the low cardenolide content in the wings, gut, and other tissues of *O. fasciatus* probably reflects the greater effectiveness of concentrating cardenolides in the dorsolateral space for predator defense in this insect (Duffey and Scudder, 1974; Scudder and Meredith, 1982b; Moore and Scudder, 1985).

PREDATION EXPERIMENTS WITH LYGAEINAE

To date, few experiments have been carried out to investigate the effectiveness of cardenolides in *O. fasciatus* predator defense. Gelperin (1968) noted that *O. fasciatus* was rejected by mantids, and Feir and Suen (1971) mention that *O. fasciatus* is not acceptable to the common fence lizard, but these authors did not distinguish the effectiveness of cardenolides from the effect of the scent gland exudates. Similarly, the experiments of Abushama and Ahmed (1976) with *Spilostethus pandurus* failed to make this distinction. Sillén-Tullberg et al. (1982) reported that the great tit (*Parus major*) found adults of *Lygaeus equestris* more distasteful than larvae, and attributed the differences to the concentration of cardenolides, but noted the occurrence of scent glands in both stages. Sillén-Tullberg et al. (1982) found that many larvae and adults of *L. equestris* survived being seized and immediately dropped by the predator.

Endogenous defensive chemicals are certainly effective against many terrestrial predators (Staddon, 1979), and since these are released first by *O. fasciatus* when disturbed, this factor must be taken into account in any assessment of the function of cardenolides. There is some evidence to suggest that the cardenolides in *O. fasciatus* may be effective in some instances, but there is little experimental evidence for universal predator defense to vertebrates (unpublished data). However, Berenbaum and Miliczky (1984) indicate that cardenolides can be effective against mantids, although they are not effective against all insect predators (Sauer and Feir, 1972). Levey (1983) suggested that the cardenolides in *Spilostethus* may protect these insects from reduviids, but not from mantids. Jones (1932, 1934) found that *Oncopeltus sexmaculatus* and *Lygaeus kalmii* were left uneaten by birds and that *L. kalmii* (fresh and dried for up to 60 days) was refused by ants, although he drew attention to the fact (Jones, 1932) that the relative unacceptability of many insects to predators may depend on many factors, not only on the plant-derived deterrants.

(Received June 26, 1985; accepted September 3, 1985)

Abstract—Chemical defense in chrysomelid larvae (subtribe Chrysomelina and Phyllodectina) is reviewed. Most species secrete autogenous monoterpenes. The diversity of their secretion is interpreted as a mechanism to reduce adaptation by predacious arthropods. The consequences of a host plant shift to the Salicacae are explored. Salicin from these host plants is used as a precursor for the salicylaldehyde secreted by the larvae of many species. This offers several advantages. It provides the larvae with an inexpensive and efficient defense. The recovery of the glucose moiety of the salicin contributes significantly to the larval energy budget. Adults sequester salicin in the eggs at concentrations which are toxic to ants. Owing to this maternal provisioning, neonate larvae produce salicylaldehyde from hatching onwards, whereas other species secreting monoterpenes are not protected at hatching. The secretion of salicylaldehyde by different species is considered to be chemical mimicry reinforcing visual aposematic signals.

Key Words—Defensive secretion, egg defense, allomones, *Salix*, salicin, Coleoptera, Chrysomelidae, monoterpenes, salicylaldehyde.

INTRODUCTION

Chrysomelidae, or leaf beetles, are a family of phytophagous insects, often forming large aggregations on their food plants. This makes them particularly apparent to predators and parasitoids, and spectacular chemical, mechanical, and behavioral defensive mechanisms have evolved in this family (Deroe and Pasteels, 1982). Defensive glandular secretions of both larvae and adults are particularly prominent in the brightly colored Chrysomelini, a tribe of the subfamily Chrysomelinae.

0098-0331/86/0500-1189$05.00/0

In temperate regions, Chrysomelinae are often found in damp, open, relatively undisturbed habitats such as riversides, marshes, and meadows. There, the favored food plants include both herbs [docks (Polygonaceae), buttercups (Ranunculaceae) or mints (Labiatae)] and also some trees and shrubs [willows and poplars (Salicaceae) or alders (Betulaceae)]. The Chrysomelinae are monophagous or oligophagous on these plants.

Within the Chrysomelinae there is a fairly good parallel between systematic position and the distribution and chemical nature of chemical defense. This is true both in the larval and adult stages. At least in the larvae, the apparent exceptions can be explained by the influence of particular host plants. In the present paper, we will give an overview of larval chemical defense in this group and discuss in more detail the influence of host plant secondary chemistry.

DISTRIBUTION OF CHEMICAL DEFENSE IN CHRYSOMELINAE LARVAE

The larvae of the subtribe Chrysomelina and of the genus *Phratora* in the subtribe Phyllodectina all possess nine pairs of glands distributed over the meso- and metathorax and the first seven abdominal segments. The glands are eversible, and when the larvae are disturbed, a drop of secretion appears at the tip of the everted reservoirs. Most of this secretion can be withdrawn back into the reservoirs during the retraction of the latter into the body (Hollande, 1909; Garb, 1915). According to the descriptions of Cuénot (1896), Hollande (1909), Garb (1915), Berti (1968), and Renner (1970), there seems to be little morphological difference between the glands of the different genera.

The principal classes of compounds found so far in the larval secretions of Chrysomelini are listed in Table 1, together with the host plant of each species. Six different methylcyclopentanoid monoterpenes have been identified (Figure 1) (review in Pasteels et al., 1984). Many species secrete a mixture of these compounds which are most likely autogenously synthesized. The larvae producing them feed on a range of plants, and no direct host plant influence can be detected. The secretions of different species within a genus are, in some cases, more different than the secretions from species belonging to different genera. In addition quantitative and qualitative differences exist between geographically isolated populations of the same species.

In Table 2, the data for different populations of *Plagiodera versicolora* are summarized. The European samples are rather homogenous, characterized by the presence of plagiodial and plagiolactone. They differ strongly from both the Japanese and the previous North American samples. The Japanese *Plagiodera* is a different subspecies but *Pl. versicolora* was introduced into North America from Europe. The reader must be cautioned about possible artifacts; these monoterpenes are unstable, and, for example, plagiodial can be easily transformed

plagiolactone but no chrysomelidial. It has been reported that some populations of European *Plagiodera* larvae also produce salicylaldehyde (Hollande, 1909; Pasteels et al., 1984). In view of the relative homogeneity of the secretions from larvae originating from England to the south of France, this observation needs to be confirmed.

The significance of the diversity of chemical defenses between sympatric species or between allopatric populations of the same species is not clear. In most cases, no pheromonal function is known which could explain the specificity of the blends. The larvae are often gregarious, but defensive secretions do not have an aggregating function. Groups of mixed species are easy to obtain in the laboratory. Larvae experimentally made devoid of secretion remain grouped. It has been suggested that the secretion of the larvae of *Gastrophysa viridula* may lower intraspecific competition. Indeed, the larvae evert their glands at the approach of adults of the same species which are repelled (Renner, 1970). This epideictic function does not necessarily imply highly specific pheromones. Indeed, Raupp et al. (1984) suggested that the secretion might also lower interspecific competition by repelling other herbivores.

The diversity of defensive secretions could be due to genetic drift in the absence of selective pressure for uniformity. Tschinkel (1975), in his study of the defensive secretions of tenebrionids, suggested that their precise composition was not critical as long as the secretion met certain physical requirements. Variation on the theme would then be possible without any particular ecological significance. On the other hand, it is also possible that intraspecific variation between geographically isolated populations reflects adaptation to the different communities in which the beetles are living. If this is the case, secretions from

different species inhabiting the same food plant should be more similar to each other than those of species living in different habitats. This does not seem to be true. In nature, larvae of *Hydrothassa marginella* and *Prasocuris phellandrii*, for example, are often found together on *Ranunculus* spp.. They are probably exposed to the same set of potential predators and parasitoids, but they produce different mixtures of compounds.

Selection for diversity would be another possible explanation of the specificity of the defensive secretions in sympatric species. So far, the activity of the defensive compounds has only been demonstrated with "standard laboratory predators" such as ants, for which at least chrysomelidial and salicylaldehyde are deterrent (Blum et al., 1978; Sugawara et al., 1979; Pasteels et al., 1983). Using adult sawflies (*Tenthredo olivacea*), predator observed to feed on chrysomeline larvae in nature, Pasteels and Grégorie (1984) demonstrated that the sawflies can be conditioned and show a preference for the larvae producing the secretion they have already experienced. such behavior of predators favors the maintenance or evolution of diversity of defensive secretions in sympatric species. Especially for species feeding next to each other on a plant, a high diversity of defensive blends may be a good strategy to prevent adaptation by the predator. Similarly, interspecific and intraspecific diversity of plant secondary metabolites is thought to limit the adaptation of herbivores to these plants (Dolinger et al., 1973; Atsatt and O'Dowd, 1976).

The wide distribution of methylcyclopentanoid monoterpenes in the secretions of the larvae of Chrysomelina dnd *Phratora* suggests that these compounds represent their primitive defensive secretion. As already stated, these products are most likely synthesized de novo, since they have no obvious precursors in the food plants; for example, chrysomelidial is secreted by the larvae of different species feeding on *Alnus*, *Rumex*, *Ranunculus*, *Brassica*, *Nasturtium* and *Salix*, respectively.

The larvae of some species of Chrysomelina and *Phratora*, however, secrete not monoterpenes but aromatic compounds such as salicylaldehyde or benzaldehyde. These species feed on trees belonging to the Salicaceae or Betulaceae. In contrast to the situation described for the species producing monoterpenes, in at least some species producing aromatic compounds, the defensive secretion is derived from a host plant precursor. In these species there is no longer a chemical diversity in the defensive blends.

Pasteels et al. (1982) suggested that the secretion of aromatic compounds by chrysomeline larvae can be best explained as a consequence of a shift of food plant, associated with speciation, from herbs to Salicaceae or Betulaceae. The secretion of salicylaldehyde would then be an adaptation to the secondary chemistry of the Salicaceae.

In the remainder of this paper we will examine in more detail the mechanism of such adaptation and its consequence for the willow-feeding leaf beetles.

FOLIAR SECONDARY CHEMISTRY OF THE SALICACEAE

Among north temperate woody plants, the European Salicaceae are remarkable for the presence of phenolglycosides in their bark and in the leaves of some species. The leaves of the species containing phenolglycosides do not contain proanthocyanidins, a form of condensed tannins found in the leaves of the remaining salicaceous species (Hegnauer, 1973).

Salicaceous bushes and trees might have been particularly likely objectes of host plant switches of primitively herb feeding Chrysomelinae for various reasons. First, they are one of the most abundant woody plants in the biotopes favored by the beetles. Secondly, the leaves of these *Salix* species without proanthyocyanidins might be a less formidable evolutionary barrier for an herbivore adapted to digesting herbs (Rowell-Rahier and Pasteels, 1982) than those of most woody plants, which typically contain tannis.

Using published food plant lists for the weevils, the sawflies, and the caterpillers of the British moths, we searched for a correlation between the presence or absence of phenolglycosides in the leaves and the degree of dietary specialization of the insects feeding on these leaves.

The results showed that the *Salix* spp. with phenolglycosides (*S. babylonica*, *S. fragilis*, *S. incana*, *S. nigricans*, *S. pentandra*, *S. purpurea*, *S. repens* and *S. triandra*) tend to be the hosts of specialized herbivores and are avoided by generalists. Conversely, *Salix* spp. without phenolglycosides in their leaves (*S. alba*, *S. aurita*, *S. caprea*, *S. cinerea*, and *S. viminalis*) tend to be eaten by more generalist insects and are avoided by the more specialized ones. Moreover, the faunas of the different *Salix* species with phenolglycosides in their leaves are more similar to each other than to the faunas of the *Salix* species having no phenolglycosides in their leaves (Rowell-Rahier, 1984).

Salicin is one of the most frequently occurring of these glycosides. It is known to be toxic (Marks et al., 1961) and, together with the other phenolglycosides present in the leaves, may act as a wide-range feeding deterrent against nonadapted herbivores (Edwards, 1978; Tahvanainen, 1985). Salicin also proved to be deterrent and highly toxic for ants. In a toxicity test, 50% mortality was reached after two days of experimental regime, during which the LD_{50} may be estimated as 5 μg of salicin per ant in two days (Pasteels et al., in preparation).

INFLUENCE OF HOST PLANT ON DEFENSIVE SECRETION OF CHRYSOMELINE LARVAE

The best studied example within this group of beetles, whose defensive secretions are dependent on the host plant, is *Ph. vitellinae*, one of the species whose larvae secrete salicylaldehyde. It was suggested long ago that salicylal-

dehyde is derived from host plant phenolglycosides (Wain, 1943) such as salicin and populin. We tried to verify this hypothesis experimentally for *Ph. vitellinae* and *C. tremulae*, using two different approaches (Pasteels et al., 1983)

First, to confirm the role of salicin as a precursor of the salicylaldehyde secreted by the larvae of *Ph. vitellinae*, the consequences of a salicin-free diet on the defensive secretion of the larvae were examined. In nature, adult *Ph. vitellinae* are never seen on *S. caprea*, and the larvae do not normally accept these hairy leaves as food. After being denuded of trichomes, however, the leaves of *S. caprea* were readily accepted by the larvae of *Ph. vitellinae*. Larvae developed normally on "shaved" *S. caprea* leaves but did not secrete salicylaldehyde. Addition of salicin to *S. caprea* restored the secretion of salicylaldehyde. Salicin is thus a precursor for the larval defensive secretion, but it is not obligatory for food acceptance by the larvae. The hairiness of the leaves of *Salix* species containing no salicin is responsible for the mortality due to starvation of the young larvae reared on them.

Secondly, by feeding larvae of *C. tremulae* with labeled salicin, we demonstrated that also in this species salicylaldehyde is derived from salicin. This is most likely true for all species of the genus feeding on salicaceous plants.

After confirming the influence of the host plant secondary metabolite, we tried to establish the relationship between the quantity of precursor ingested and the quantity of defensive secretion produced and to determine where in the body this transformation occurred. The fate of the glucose moiety split from the original glycoside molecule was also examined.

The results show that the concentration of salicylaldehyde in the secretion is positively correlated with the amount of salicin in the food of the larvae. The transformation of salicin into salicylaldehyde probably occurs mostly in the defense glands, since the β-glucosidase activity is four times higher in the glands than in the gut (Pasteels et al., 1983).

The concentrations of glucose and of salicylaldehyde in the secretion are far from being equimolar, indicating that the glucose formed by salicin hydrolysis was in great part recovered by the larvae and transferred back into the blood (Pasteels et al., 1983).

WHEN A STRONG DEFENSE IS GOOD FOR THE ECONOMY

The energetic costs of defense are frequently referred to in discussions of the ecology and evolution of chemically defended organisms; it is generally assumed that any loss is fitness caused by these costs must be outweighted by the gain in fitness secured by an effective defense. However, there has been virtually no attempt to demonstrate these energetic costs or to measure them quantitatively, especially in animals (Blum, 1981).

Although no direct experimental data are available, it is very likely that

the methylcyclopentanoid monoterpenes secreted by the larvae of chrysomeline species (see above) arise from geranylpyrophosphate via mevalonic acid, as do other terpenes (Blum, 1981). This must involve finite, although perhaps small, costs. The salicylaldehyde secreted by other species is formed by the enzymatic hydroloysis of the glucosidic bond of salicin. A preliminary calculation shows that when the glands are emptied and refilled daily, this glucose could supply up to one third of the caloric requirements of the larva (see Table 3).

Both types of defense occur in closely comparable species of the same genera feeding on Salicaceae. This assemblage is thus very suitable for an investigation of the cost of defense, which would be expected to be maximal in those species synthesizing monoterpenes de novo and minimal in those secreting salicylaldehyde, which profit from the use of a plant precursor and also by gaining glucose.

Larvae of *Phratora tibialis*, *Ph. vitellinae*, *Plagiodera versicolora*, and *Chrysomela 20-punctata* were reared in the laboratory from egg to adult on appropriate *Salix* spp.; these, together with the chemical nature of the secretions of the beetles, are listed in the first three columns of Table 4. Each species sample was divided into control and experimental groups, which did not differ in population density, quantity, and quality of food provided, sex ratio, mortality during the experiment, or in time elapsed before eclosion as adults. Both groups were disturbed daily and induced to evert their glands: the exposed secretion was collected only from the experimental group, which then refilled their glands by the following day. The assumption is made that the control

TABLE 3. DERIVATION OF BENEFIT OF GLUCOSE RECOVERY IN *Ph. vitellinae* LARVAE[a]

A. Energy requirements
   Oxygen consumption: 0.5 ml O_2/g FW/hr
   1 ml O_2 consumed = 5.05 cal
   3.68 cal = 1 mg glucose, incorporating correction for energy loss during digestion.
   Mean weight of field-collected third-instar larvae: 8.54 mg; thus, one larva requires 140.65 μg glucose/day
B. Energy gain from salicin metabolism
   Daily salicin ingestion: 0.46 μM
   Daily glucose ingestion in form of salicin: 0.46 × 180 = 82.8 μg of which (0.46 − 0.20*) × 180 reach the glands = 46.8 μg
   [*: the glands only start to produce secretion after ingestion of 0.20 μM of salicin].
   99.9% of this glucose is recovered by the larvae; thus the larva recovers 46.7 μg glucose/day, covering 33.2% of the daily energy requirement.
   Rather than the correction marked with an asterisk above, one could also take into account the fact that 20% of the total glucosidase activity is found in the gut. This would suggest that 80% (= 65.5 μg/day) of glucose present in the original salicin is recovered from the glands, covering 46.6% of the larval daily requirement.

[a] Data from Pasteels et al. (1983) and Keister and Buck (1974).

TABLE 4. MEAN WEIGHTS OF ADULT CHRYSOMELINAE WHEN DEFENSIVE SECRETION OF LARVAE HAS (EXPERIMENTAL) OR HAS NOT (CONTROL) BEEN REMOVED DAILY[a]

Chrysomelinae species	Host-plant species	Defence nature	Mean weights (mg ± sd (*N*))		*P*
			Control	Experimental

Ch. 20punctata	*S. nigricans*	S + X	25.10 ± 5.19 (79)	25.60 ± 3.19 (26)	NS
Ch. 20punctata	*S. caprea*	X	25.20 ± 2.80 (8)	22.60 ± 3.70 (120)	*

[a] Means and standard deviations were calculated for each group (columns 4 and 5).

[b] Abbreviations: M, methylcyclopentanoid monoterpenes; S, salicylaldehyde; X, unidentiified compounds; *N*, sample size; *P*, probability levels of difference between experimental and control groups (Student's *t*-test); **, $P < 0.01$; *, $P < 0.05$; NS, $P > 0.05$.

group, which do not lose their secretion, will synthesize at a much lower rate than the experimental group.

Within 12 hr of eclosion, and before feeding, the resulting adults were weighed, and this value was used as a measure of larval growth and, by inference, of adult fitness. In those species secreting autogenous monoterpenes (*Ph. tibialis* and *Pl. versicolora*), the mean weight of the experimental group is significantly lower than that of the control: a daily renewal of the secretion is thus a drain on their metabolism. It is not excluded that this is due to the fluid lost occurring during collection of the secretion in the experimental group. In the species which secrete exclusively salicylaldehyde (*Ph. vitellinae*), the experimental group is significantly heavier than the control. This weight gain is probably associated with the extra glucose obtained from the hydrolysis of salicin. When the larvae of this species are completely deprived of salicin [by raising them on *S. caprea*, which does not contain this compound (Hegnauer, 1973)] or allowed only one fifth of their normal intake, the experimental imaginal fresh weights do not differ from those of the control group feeding on *S. nigricans*. Additionally, preliminary results suggest that when *Ph vitellinae* is reared undisturbed on *S. nigricans* leaves with added glucose, the adult weights are comparable to those of the experimental group on the same plant. The last species (*Ch. 20-punctata*) reared on *S. nigricans*, secretes a mixture of both salicylaldehyde and various compounds which are as yet unidentified but most likely not directly derived from the host plant. Here there is no difference betweeen the control and the experimental groups, suggesting that the glucose recovered from salicin degradation is balanced by the biosynthetic cost of the other compounds. This hypothesis is supported by the finding that in the same species raised on *S. caprea* (i.e., without salicin) the experimental animals weigh significantly less than the controls.

These results show, to our knowledge for the first time, that an autochthonously produced secretion entails an appreciable metabolic cost. This cost is expressed as a loss of weight of the adult, which in many other insects has been demonstrated to be associated with reduced fecundity and fitness (references in Raupp and Denno, 1984). These costs can be avoided by the use of an appropriate plant precursor: where this is a glucoside, as in the present example, the resultant glucose production can convert the loss into a profit. Leaves, because of their high fiber and cellulose content, usually have a low available calorific density (McNab, 1978), and this spin-off metabolic advantage could be of particular relevance to a folivorous insect. Plant glucosides are not, in general, available to herbivores as energy sources because of the potential toxicity of the aglycone; in chrysomeline larvae, it is the localization of the greater part of the degradation process in the external glands which makes this feasible. Lastly, larvae in the field are likely to be frequently disturbed by parasites and predators, or even by the movement of leaves in the wind, and will tend to lose

secretion by contact with these agents. If this is true, the laboratory situation, where the secretion is collected daily, may reflect the natural situation rather closely.

The transformation of salicin to salicylaldehyde does not only provide an inexpensive or even profitable defense for the larvae but also an effective one. Laboratory tests with a generalist predator such as the ant *Myrmica rubra*, often seen exploring the foliage of the host plants of various leaf beetles, show that salicylaldehyde is a potent deterrent, more active than salicin or its aglycone saligenin (Pasteels et al., 1983).

DEFENSE OF EGGS AND NEONATE LARVAE

At hatching, the larvae are clustered and immobile on the leaves. They are thus highly exposed to predation and also to cannibalism. An innate defense might therefore be critical. The observation that, on the one hand, the larvae of some species already produce secretion at hatching, before feeding, and that, on the other hand, some other species do not have "full" glands at the beginning of their larval life, is therefore very interesting. It is only the neonate larvae of those species secreting salicylaldehyde which have functional glands on hatching. No larvae of any species seem to be able to produce monoterpenes at eclosion. Indeed, chemical analysis demonstrated that, paradoxically, only those larvae which depend on salicin normally found in their food seem to be able to produce a defensive secretion before feeding. A possible explanation could be that salicin is sequestered in the eggs and used as a precursor by the neonate larvae. To test this hypothesis, we studied the occurrence of defensive allomones in chrysomelid eggs.

The eggs, often brightly colored, are laid in clusters on the foliage and are thus highly exposed to predation. In the field, survival of the eggs can be as low as 25% (Wade and Breden, personal communication). There might therefore be a strong selective pressure for the eggs to be protected. Indeed, chemical analysis showed that the two isoxazolinone glycosides characteristic of the adult defensive secretion (Pasteels et al., 1982) are present in the eggs of all species studied (Table 5). The occurrence of identical compounds in the eggs and in the adult defensive glands was already reported in the Chrysomelina producing cardenolides (Pasteels and Daloze, 1977) and could represent a general feature of the Chrysomelinae. However, these isoxazolinones were never detected in neonate larvae, and, at least in one species, it was found in the egg shells left after hatching.

Additionally, the eggs of some of the Salicaceae feeders contain salicin, and those species are also those whose larvae secrete salicylaldehyde. Since the salicin was no longer detected in the neonate larvae, it must have been trans-

formed into salicylaldehyde. The sequestration of salicin in the eggs explains the fate of this plant toxin in the adult females. It protects the eggs themselves and also provides precursor for protection of the neonate larvae at a very vulnerable life-stage when other species are not protected. The amount of salicin found, on average, in one *Chrysomela* egg is about the LD_{50} dose for an ant (Pasteels et al., 1985).

CONCLUSIONS

One of the challenges of chemical ecology is to interpret chemical results in an ecological context. Ecomones (semiochemicals) often appear as "wisdom" remaining from past history. The selective pressures from which they result are difficult to identify and might even be absent from the biotopes in which the organisms live today.

We would like to suggest a possible scenario for the evolution of chemical defense in the larvae of leaf beetles. The secretion of methylcyclopentanoid monoterpenes in species feeding on herbs could be a response to the pressure of numerous predacious arthropods (or parasitoids) exploring the foliage. These compounds, classified as volatile irritants, are well known ant repellents. The larvae of these beetle species are rather small and inconspicuous, feeding on the lower surface of the leaves. Larval defense is not associated with aposematism, and preliminary experiments suggest that birds are only slightly re-

pelled by their secretions. The chemical diversity of the secretion might prevent adaptation by predacious arthropods.

Shifts of host plants occurred during the evolution of chrysomeline beetles, and one of these shifts had a drastic influence on chemical defense: the shift to salicaceous species, with leaves rich in phenolglycosides. It has occurred at least three times (Pasteels et al., 1984), and it frequently results in the use of salicin as a precursor of the defensive secretion.

The utilization of salicin offers multiple advantages for chrysomelid beetles. First, it allows them to exploit a set of host plants otherwise well protected from generalist herbivores by phenolglycosides. Second, it provides the larvae with an inexpensive defense, an effective deterrent against generalist predators. Third, the recovered glucose contributes significantly to the larval energy budget and is positively correlated with an increased relative growth rate of the larvae. Fourth, the adults sequester salicin in the eggs at concentrations which are toxic for ants. Fifth, neonate larvae of the species producing salicylaldehyde are protected from hatching onwards, whereas other species secreting monoterpenes are not so protected.

The larvae of species feeding on Salicaceae produce a much larger volume of secretion than those synthesizing monoterpenes (three or four times larger for larvae of equal sizes). This is probably made possible by the relative availability of the salicylaldehyde derived from the host plant. Such abundant production of a volatile irritant deters predaceous birds as well as arthropods. These larvae (e.g., *Chrysomela* spp.) are large, gregarious, and aposematic, and several species feed on the upper surface of the leaf. The utilization of salicin has led to chemically homogenous secretions. This is probably advantageous against predacious birds. It reinforces the aposematic signal and can be considered as a case of chemical mimicry.

Acknowledgments—We thank H. Rowell, D. McKey, and L. Koechlin for fruitful discussions and comments on previous versions of the manuscript. J.C. Braekman and D. Daloze collaborated in the chemical analysis.

ALLELOPATHIC POLYACETYLENES FROM *Centaurea repens* (RUSSIAN KNAPWEED)

KENNETH L. STEVENS

Western Regional Research Center
U.S. Department of Agriculture
Berkeley, California 94710

(Received April 29, 1985; accepted August 16, 1985)

Abstract—The allelopathic weed Russian knapweed (*Centaurea repens*) was found to contain polyacetylenes VIII–XIV in the roots. Dose vs. response of the root length elongation against lettuce, alfalfa, barnyard grass, and red millet showed IX to be active. Closely related isomers were not active. Examination of the soil surrounding the Russian knapweed roots revealed the presence of IX in sufficient concentration to have an appreciable effect on the surrounding plant community.

Key Words—Allelopathy, polyacetylenes, Russian knapweed, *Centaurea repens, Compositae*

INTRODUCTION

It has been recognized for some time (Fletcher, 1963) that Russian knapweed (*Centaurea repens* L., Compositae), a rapidly spreading noxious weed, exhibits many of the characteristics of an allelopathic plant species. Earlier work (Stevens, 1982) showed the presence of a number of sesquiterpene lactones, many of which were shown to have some phytotoxic activity (Stevens and Merrill, 1985). However, both the concentrations of these sesquiterpene lactones in the plant and their toxicity to test species left some doubt as to whether these were responsible for the total phytotoxicity of Russian knapweed to the surrounding plant community.

Many polyacetylenic compounds have been isolated from composites (Bohlmann et al., 1973) but relatively few have been shown to be phytotoxic. Specifically, matricaria ester (I, ME), dehydromatricaria ester (II, DME), lachnophyllum ester (III, LE), and the two matricaria ester derivatives IV and V

0098-0331/86/0600-1205$05.00/0

have been shown to have activity against rice seedlings (Kawazu et al., 1969; Kobayashi et al., 1974, 1980; Numata et al., 1973; Ichihara et al., 1976, 1978) (Figure 1). Since some of these compounds were found in the soil, it was concluded that the C_{10} polyacetylenes are probably allelopathic substances of ecological importance (Kobayashi et al., 1980). With the exception of the two

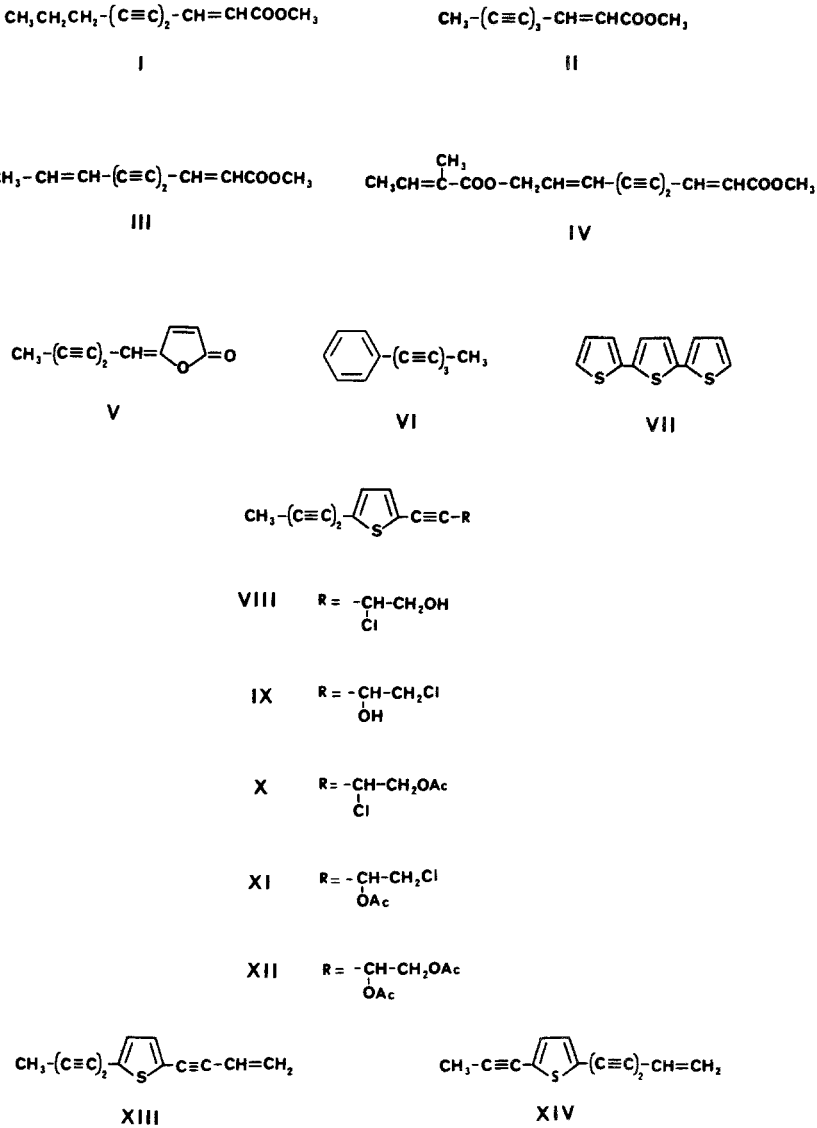

FIG. 1. Structures of Polyacetylenes

polyacetylenes phenyheptatriyne (VI, PHT) and α-terthienyl (VII), which have been found in the leaves of the tropical weed *Bidens pilosa* and the roots of common marigold *Tagetes erecta*, respectively (Campbell et al., 1982), there appear to be no data which would suggest that other polyacetylenes are phytotoxic. It must be recognized, however, that the vast majority of polyacetylenes described in the literature have never been tested for biological activity, particularly phytotoxicity.

METHODS AND MATERIALS

Extraction and Isolation. Roots of Russian knapweed were collected throughout its growing season near Discovery Bay (Hwy. 4 between Brentwood and Stockton), California. The severed roots were immediately placed on Dry Ice then ground in a rotating plate mill with Dry Ice to approximately $\frac{1}{8}$-in. particle size. The Dry Ice–root mixture was then slurried with ether–Skelly-F (1 : 2) in a larger beaker and allowed to warm to room temperature. Light was excluded to prevent any photodecomposition of the polyacetylenes. After warming to room temperature, the mixture was filtered and the solvent reduced in volume on a rotary evaporator at approximately 25°C.

Final separation of the polyacetylenes was accomplished by a combination of column chromatography on silica gel with benzene and preparative TLC (silica gel) using a variety of solvents, i.e., ether–Skelly-F (1 : 9), benzene, and cyclohexane–acetone (4 : 1). Polyacetylenes were collected from the preparative plates by scraping the bands from the plate and extracting the silica gel with ether. In all instances, care was taken to exclude light and keep the temperature of the solvents below 30°C.

Isolation of Polyacetylenes from Soil. Soil (375 g wet) from around the roots of Russian knapweed was sieved to remove organic material then placed in a chromatography column. Ether–Skelly-F (1 : 2) was percolated through the column and collected (2 : 1). The solvent was evaporated under reduced pressure and the residue chromatographed on preparative plates (20 × 20 cm. × 0.5 mm). Bands were scraped off and extracted with ether.

Identification of Compounds. Isolated compounds were analyzed by UV and [^{1}H]NMR spectroscopy and compared with reported values.

Bioassay. The seedling inhibition assays were carried out as follows: Seeds of lettuce (*Lactuca sativa*, black-seeded Simpson), barnyard grass (*Echinochloa crusgalli*), alfalfa (*Medicago sativa*), and red millet (*Panicum miliaceum*) were germinated on 0.5% agar (Bacto-Agar, Difco Laboratories, Detroit, Michigan) in a growth chamber set at 16-hr, 68°F days and 8-hr, 58°F nights. Twelve seedlings of each species were placed on 0.5% gels (20 ml agar/19 cm Petri dish) which had previously been slurried with the prescribed amount of polyacetylene in ether. In our tests, the concentrations were: 0, 5, 10, 20, 40, and

80 ppm. The polyacetylenes were added to the still-fluid gel at approximately 30°C to avoid thermal decomposition. Controls had only solvent incorporated into the gels. The seedlings were then placed in the dark at 20°C for 24 hr and root length measured to the nearest millimeter. Root growth studies with ME were carried out for 48 hr. Of the 12 seedlings whose root length were measured, the longest and shortest were discarded and the remaining 10 were used in the statistical analyses. In each case two replicates were run.

Data Analysis. The results of the seedling growth assays were analyzed separately using the Washington, D.C., Computing Center facilities and Statistical Analysis System (SAS Institute, Inc., Cary, North Carolina, 1982). The transformed data were subjected to Cochran's test for homogeneity of variances of all treatments and the least significant difference (LSD) test for differences between all treatment means.

RESULTS AND DISCUSSION

Five polyacetylenes, VIII–XII, obtained in pure form from Russian knapweed have been identified. Table 1 shows their respective UV and NMR spectra along with the literature reference. In addition to those listed in the table, com-

TABLE 1. UV AND NMR DATA OF POLYACETYLENES VIII–XII

Compound	UV(ether), λ_{max}[a]	NMR($CDCl_3$), 90 MHz, δ values(TMS)	Reference
VIII	344, 324, 270, 250, 206	2.04(s,3H,Me), 3.92(d,1H,J = 6), 3.97(d,1H,J = 5), 4.88(dd,1H, J = 5,6), 7.12(s,2H)	Bohlmann, 1965
IX	342, 322, 250, 236, 210	2.00(s,3H,Me), 3.70(d,1H,J = 6) 3.71(d,1H,J = 4), 4.79(dd,1H, J = 4,6), 7.02(d,1H,J = 3.5)	Bohlmann, 1970
X	342, 324, 270, 250, 236, 210	2.00(s,3H,Me), 2.08(s,3H,COMe), 4.37(d,1H,J = 6), 4.38(d,1H, J = 5), 4.91(dd,1H,J = 5,6), 7.08(s,2H)	Bohlmann, 1965

XII	342, 322, 248, 210	2.00(s,3H,Me), 2.07(s,3H,COMe), 2.09(s,3H,COMe), 4.22(dd,1H, J = 5,12), 4.34(dd,1H,J = 7,12), 5.80(dd,1H,J = 5,7), 7.02(s,2H)	Bohlmann, 1965

[a]Intensities were similar for all compounds [i.e., 342(2×10^4), 322(2.2×10^4), 250(8×10^3), 210(1.7×10^4)].

pounds XIII and XIV were isolated as a mixture. Lack of material, coupled with their instability, precluded separating the two isomers; however, they were readily identified by comparing the UV and NMR spectra of the mixture with those reported (Bohlmann et al., 1965).

Each of the isolated polyacetylenes is a C_{13} derivative, containing one thienyl group which can formally be envisioned (Bohlmann et al., 1973) as the addition of hydrogen sulfide across two triple bonds. These substances have not previously been found in other Composites. Compound VIII has been found in a number of *Echinops* spp. (Bohlmann et al. 1965) and *Pluchea dioscorides* (Bohlmann et al., 1973). Likewise, IX has been found in the roots of *Eclipta prostata* L. (Bohlmann et al., 1973) while X has been isolated from both *Echinops* spp. and *Centaurea cristata* (Bohlmann et al., 1966). Although a number of *Centaurea* species have been investigated for polyacetylenes (Bohlmann et al., 1973), VII, IX, and X represent new compounds to this genus. Bohlmann (Bohlmann et al., 1965) reported the presence of the diacetate XII in *Echinops sphaerocephalus* L.; however, it was only inferred to be present and was not isolated, nor were any data given. Its presence in Russian knapweed thus confirms it as a natural product.

The presumed intermediate oxidation products between the unsaturated compounds XIII, XIV, and the chlorohydrins and chlorohydrin acetates, viz., the epoxides, have not been found in spite of their presence in other *Centaurea* species (Bohlmann et al., 1973).

In all cases, with the exception of XIII and XIV, the isolated polyacetylenes are optically active, which rules out the possibility of their being hydrolysis products of XIII. As a typical example, IX showed $[\alpha]_{589}$ ($CHCl_3$) = +17.5°; $[\alpha]_{578}$ = +18.9°; $[\alpha]_{546}$ = +20.6°; $[\alpha]_{436}$ = +37.9°.

Root length assay of VIII–XII has shown activity for only IX, with the results of lettuce, alfalfa, barnyard grass, and red millet tabulated in Table 2. The mean root length of the control for lettuce seedlings was 10.6 mm (starting length was approximately 3 mm), while at 10 ppm the root length was 6.9 mm. Fifty percent reduction in root length occurs at 12 ppm. The results of alfalfa, barnyard grass, and red millet were all similar, indicating that IX effectively inhibits root length elongation of grasses as well as broadleaf plants.

The possibility of synergism among the isolated polyacetylenes was tested by comparing the activity of the crude extract with that of IX. Allowing for concentration differences, it was found that IX accounted for all of the activity with no synergistic effect from other compounds.

Matricaria ester (ME, I), the first reported phytotoxic polyacetylene, was likewise tested under the same conditions against lettuce seedlings. Matricaria ester closely approximates the activity of IX with a 50% reduction in root length elongation occurring at 10 ppm. Little is known of the mode of action of the matricaria ester polyacetylenes. In a review (Numata et al., 1973) it was stated that addition of 5 ppm of either indoleacetic acid (IAA) or gibberelin (GA_3)

TABLE 2. EFFECT OF IX ON ROOT GROWTH OF WEED AND CROP SEEDLINGS

Seedling	Conc. of IX (ppm)	Mean root length (mm)[a]	
Lettuce	0	10.6	a
	10	6.9	b
	20	4.8	c
	40	3.7	d
	80	3.2	d
Barnyard grass	0	20.7	a
	5	16.3	b
	10	8.7	c
	20	4.7	d
	40	6.0	d
	80	5.0	d
Alfalfa	0	17.8	a
	5	14.6	a
	10	14.4	a
	20	10.1	b
	40	5.0	c
	80	5.1	c
Red millet	0	15.4	a
	5	19.1	a
	10	13.3	a
	20	6.1	b
	40	5.2	b
	80	2.0	c

[a] Means associated with a given test seedling with different letters are significantly different at the $\alpha = 0.05$ level according to the Least Significant Difference (LSD) test performed on transformed values. Original values are given.

failed to nullify the effects of 20 ppm of an ME derivative. It was concluded that the inhibitory effects were not based on a hormonal mechanism. The mechanism of plant growth inhibition by both matricaria esters and the thienyl compounds must await further studies.

To lend credence to the hypothesis that IX participates in the allelopathic action of Russian knapweed, the soil immediately surrounding the plant was extracted and found to contain 4–5 ppm of this particular compound. The analysis was based on actual material isolated, and hence represents a minimum amount because of the instability of the compound. The actual concentration in

the soil may be considerably higher than 4–5 ppm. Extrapolation of the data from the bioassay to field conditions, gives a 30% reduction in root growth at 4 ppm. This is certainly sufficient to have an appreciable effect on the surrounding plant community (Kobayashi et al., 1974).

(Received May 17, 1985; accepted August 16, 1985)

Abstract—The cuticular hydrocarbons of *Locusta migratoria cinerascens*—larvae and adults, males and females, gregarious and solitaries—have been investigated by combined gas chromatography–mass spectrometry. The hydrocarbons comprise 52–78% of the cuticular lipids and are divided into *n*-alkanes (28.7–47.3%), 3-, 4-, and 5-methylalkanes (11.3–15.8%), internally branched monomethylalkanes (13.7–19.9%), and internally branched dimethylalkanes (19.8–35.9%) with seven or nine methylenes between the two branch points. While the sexual dimorphism does not seem to be reflected in the cuticular hydrocarbon composition, clear quantitative variations favoring the longest chain alkanes have been observed between gregarious and solitary locusts, thus revealing a new phase character in these insects.

Key Words—Locusts, *Locusta migratoria*, cuticular hydrocarbons, mass spectrometry, phase polymorphism, Orthoptera, Acrididae.

INTRODUCTION

The cuticular lipids play a part in the regulation of water evaporation in insects and also protect them from the penetration of insecticides and microorganisms (Beament, 1964; Ebeling, 1964; David, 1967; Hadley, 1981). These cuticular lipids contain a large proportion of hydrocarbons. Some of these hydrocarbons act as pheromones (Carlson et al., 1978; Blomquist and Jackson, 1979; Howard and Blomquist, 1982; Jallon, 1985) or can be factors of chemotaxonomic differentiation (Blomquist et al., 1976; Lockey, 1976, 1984; Jackson, 1981).

These are the reasons for researchers' sustained interest in the chemical analysis of cuticular hydrocarbons from numerous species (Nelson, 1978;

0098-0331/86/0600-1213$05.00/0

Blomquist and Jackson, 1979). Their reviews show that cuticular hydrocarbons are generally homologous series of *n*-alkanes and branched alkanes, mono-, di-, or trimethylated. Monomethylalkanes with terminal (2-, 3-, 4-, 5-methyl) and internal (7- to 23-methyl) branches, have been identified in three species of crickets (Hutchins and Martin, 1968), cockroaches (Tartivita and Jackson, 1970; Jackson, 1972), ants (Lok et al., 1975; Nelson et al., 1980), and bark beetles (Lockey, 1982). The 2-methylalkanes which do not occur in most of the insects already studied but are present in large proportions in three species of crickets (Blomquist et al., 1976) may permit taxonomic assignment. Di- and trimethylalkanes with isoprenoid spacing have been described in various insects (Nelson, 1978). Other polymethylalkanes with 1, 5, 7, 9, or 11 carbon atoms between branch points have also been identified (Nelson et al., 1980, 1981, 1984).

So far, the cuticular hydrocarbons of nine acridids have been studied: *Schistocerca vaga* (Nelson and Sukkestad, 1975), *Schistocerca gregaria* (Lockey, 1976), *Schistocerca americana* (Jackson, 1982), *Melanoplus sanguinipes* and *packardii* (Soliday et al., 1974) reanalyzed along with *differentialis* (Nelson et al., 1984), *Melanoplus bivittatus femurrubrum* and *dawsoni* (Jackson, 1981), and *Locusta migratoria* (Lockey, 1976). In 1976, Lockey suggested that the hydrocarbon compositions of different locusts are closer together if they belong to the same subfamily. Thus, a very fine chemical analysis appears to be the first condition for the use of the hydrocarbon profiles as additional characters in the insects' taxonomic grouping. Since Lockey (1976) has only studied the major components, we undertake here a new study of cuticular alkanes of a subspecies of the migratory locust: *Locusta migratoria cinerascens*.

The migratory locust is well known for its ability to change its kind of life, crowded or gregarious (gregaria) and isolated or solitary (solitaria) "phases." Thus it is interesting to know if the behavioral, morphological, and physiological changes of both phases (Uvarov, 1921, 1966) could lead to changes in the chemical composition of cuticular hydrocarbons.

Chemical stimulations can come into play at different ages of the locust's life (Gillett, 1975; Loher, 1960; Norris, 1970). However, the origin of these chemical pheromones is still under discussion and their nature remains to be specified.

In this study we decided to compare cuticular hydrocarbons at larval and adult ages of both sexes, from gregarious and solitary locusts of the *Locusta migratoria cinerascens* species.

METHODS AND MATERIALS

Insects Used. Last larval instar and mature adult, male and female, gregarious and solitary insects were used. They were raised at the Insect Biology Laboratory. The strain was *Locusta migratoria cinerascens* from Sardinia. Gre-

garious locusts were bred in groups of 200 individuals in cages 40 × 40 × 60 cm. Solitary locusts were maintained from birth in individual 1-liter containers in a separate breeding room. Each room was submitted to a regular change of air 12 times an hour. The photo- and thermoperiods were 12/12 hr with temperatures of 25 ± 1°C (night) and 35 ± 1°C (day). Separate evaluation of characters such as behavior (Nicolas, 1972; Gillett et al., 1972), morphometrics (Nicolas, 1973; Minato et al., 1973), pigmentation, and fecundity (Nicolas, 1972) had shown that, under our laboratory conditions, the locusts isolated from birth are conspicuously different from the crowded ones bred simultaneously.

All locusts were fed on fresh corn shoots and bran every day of the week with no interruption.

The same numbers of the animals of both sexes used were: 23 gregarious, last-instar larvae, two to three days old; 5 gregarious, mature adults, 34 days old; 10 solitary, last-instar larvae, two to three days old; and 21 solitary, mature adults, 21 days old.

All the solitary locusts used were light beige as this color was close to that of the white paper surrounding them to keep them separated. Each insect was killed by freezing at −20°C, then extracted by stirring during 10 min in hexane (5 ml/adult and 3 ml/larva). After evaporation of the solvent, hydrocarbons were separated from the weighed extracted cuticular lipids by thin-layer chromatography (Merck 10 × 20 plates of silica gel 60 F254 with concentration zones) and elution with nanograd hexane. From this weighed fraction of hydrocarbons, branched ones were separated with 5 Å Linde molecular sieves (as described by O'Connor et al., 1962).

Combined gas chromatography–mass spectrometry (GC-MS) was used to identify the components of the different extracts. Mass spectra were obtained on a Nermag R10-10 spectrometer associated with a PDP8 calculator (Digital Equipment Instrument) and coupled to a Girdel 31 chromatograph with a Ros injector. Fractions were temperature programmed from 200 to 300°C at 3°/min with isotherm at 300° on a capillary column either 10 or 25 m long, 0.32 mm wide, coated with CpSil 5 CB Chrompack. The carrier gas was helium and inlet pressure 0.25 bar. Fractions were analyzed by GC-MS either by electronic impact or by positive chemical ionization. In electronic impact, ionization voltage was 70 eV and the temperature of ion source was 110°C for hydrocarbons up to C_{40}. In these conditions, the molecular peak is always present. The temperature of the ion source was 290°C for more condensed hydrocarbons (C_{40} to C_{53}), but then only the ion M-15 is present. Mass scanning was carried out from atomic mass unit (amu) 100 to 600 or 750. In these conditions and without amplification (the sensitivity for the masses examined being better) spectra of branched hydrocarbons often have a base peak which corresponds to a characteristic fragmentation at a methyl branch. Positive chemical ionization was performed using methane generating an internal source pressure of 0.2 torr; ioni-

zation voltage was 90 eV, temperature of ion source 150°C, and mass scanning started at 100 amu.

The mass spectra of alkanes were interpreted according to the criteria proposed by McCarthy et al. (1968), Nelson et al. (1972), Nelson (1978), and Pomonis et al. (1978, 1980). Integration of chromatographic peaks was carried out with a Hewlett Packard integrator coupled to a Varian 3700 chromatograph with the 25-m column mentioned above (see GC-MS), programmed from 40 to 300°C at 4°/min and isothermal at 300° with a flow rate of helium being 18 cm/sec; an "on column" injector was used.

Retention indices (Ettre, 1964) were calculated with the 25-m column, using the *n*-alkanes from C_{22} to C_{37} identified without ambiguity by GC-MS and present in all total hydrocarbonated fractions.

All the bar charts (Figure 14–18) were constructed from the *n*-alkane percentage and the branched alkane percentage columns shown in Table 2 (%/N. and %/B.).

RESULTS

The hydrocarbons comprise 52–78% of all the cuticular lipids (Table 1). The smallest percentages were obtained for the solitary locusts. Our results, qualitatively in agreement with those of Lockey (1976) for the described compounds, exhibit quantitative differences; however, it must be mentioned that Lockey's analyses concern wings rather than total insect extracts. The chromatographic profile of a partial but complex hydrocarbon fraction (up to nonatriacontane) is presented in Figure 1 (25-m column).

Total (A) and corresponding branched (B) fractions (up to tripentacontane) are presented in Figure 2 (10-m column). Table 2 summarizes all the identified alkanes with their percentage for the eight groups of insects studied.

To perform analysis, correlations were carried out with results of electronic impact and chemical ionization in mass spectrometry on the one hand, and difference of retention index (*dI*) in gas chromatography between branched alkanes and *n*-alkanes with the same carbon number, on the other hand. It is known that *dI*s are related to the position of the methyl branch for a monomethylalkane (Mold et al., 1966) and to the number of methyl branches in a polymethylalkane (Nelson and Sukkestad, 1970). These correlations show, in agreement with Lockey (1976), that the fractions studied appear to consist of four classes of alkanes: class A, *n*-alkanes; class B, terminally branched monomethylalkanes; class C, internally branched monomethylalkanes; and class D, dimethylalkanes.

Class A: n-Alkanes. Their mass spectra are characteristic and their presence is in agreement with the comparison between the chromatographic profiles obtained before or after the separation on molecular sieves (Figure 2).

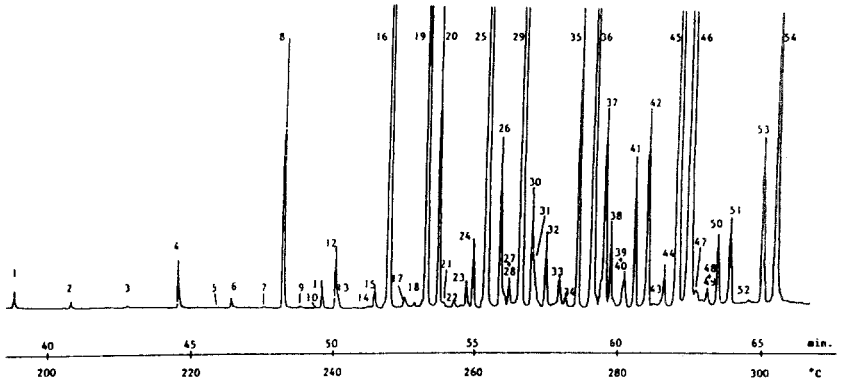

FIG. 1. Partial gas chromatogram of a hydrocarbon fraction of male solitary fifth-instar larvae of *Locusta migratoria cinerascens*. CpSil 5 CB Chrompack capillary column of 25 m × 0.32 mm, temperature programmed from 40 to 300° at 4°/min and held at 300°; "on-column" type injector.

In electronic impact conditions (70 eV, starting mass scanning: 100 amu), the molecular peak $M^{+}\cdot$ is base peak. Sixteen linear alkanes, from C_{22} to C_{37}, have been identified; *n*-nonacosane in gregarious and *n*-hentriacontane in solitary locusts are the most important. The percentage of these total *n*-alkanes decreases from larval to adult ages (Table 1) and more strongly in gregarious locusts.

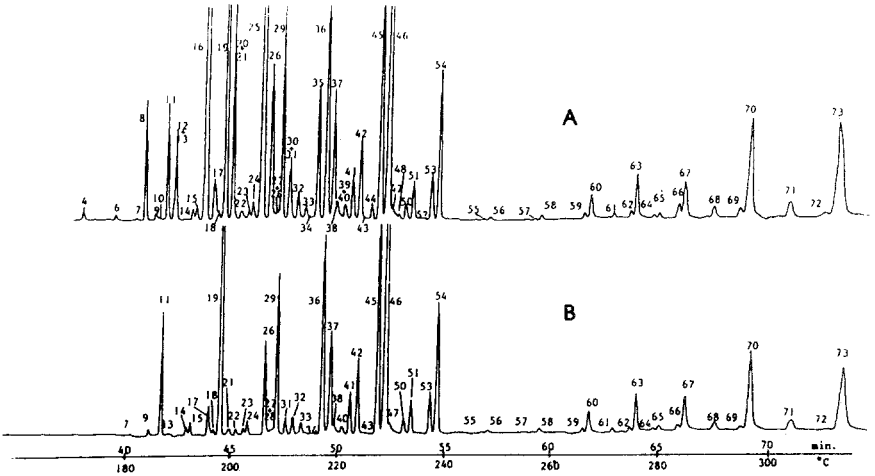

FIG. 2. Gas chromatographic analysis of the total (A) and branched (B) hydrocarbon fractions of male gregarious mature adults, *Locusta migratoria cinerascens*. Same conditions as Figure 1 with a column of 10 m × 0.32 mm.

[a] See footnote to Table 1 for abbreviations.

[b] %/T: percentages (±0.1%), scaled to 100, of total alkanes. %/N: percentages (±0.1%), scaled to 100, of normal alkanes. %/B: percentages (±0.1%), scaled to 100, of branched alkanes. tr.: <0.1%.

[c] °: major isomer. (1) 11- and 13°-methylheptacosanes for MGA and FGA. (2) The retention indice and the carbon number agree with a 3,X-dimethylalkane (Nelson et al., 1980), but the very small percentage of this product did not allow us to get a good spectrum. (3) 11°- and 13-methylnonacosanes for MSL and MGA; 9-, 11°-, and 13-methylnonacosanes for FGA. (4) 10-, 11°-, 12-, and 13-methyltrialontanes for MGA and FGA; 11°-, 12-, 13-, and 14-methyltriacontanes for FGL. (5) Branch points unidentified. (6) 12°-, 13-, and 14-methyldotriacontanes for FGL; 12-, 13°-, and 14-methyldotriacontanes for MSA; 11-, 12°-, 13°-, and 14°-methyldotriacontanes for MGA. (7) + 12,20-dimethyldotriacontane for MGA and MGA; + unidentified dimethyldotriacontane for the other insects. (8) 11-, 12-, 13°-, 14-, 15-, and 16-methyltetratriacontanes for FGL and FSL; 12-, 13°-, 14-, 15-, 16-, and 17-methyltetratriacontanes for MSL. (9) 13°-, 14°-, and 15-methylhexatriacontanes for MGL, FGL, and FSL; 12-, 13°-, 14-, 15-, 16-, 17-, and 18-methylhexatriacontanes for MSL. (10) The small percentage of this component did not allow us to identify it; present on the gas chromatograms after separation on molecular sieves, it is quite probably a branched alkane.

Class B: Terminally Branched Monomethylalkanes. 5-, 4- and 3-methylalkanes have been identified. The *dI*s between these alkanes and the *n*-alkanes with the same carbon number are, respectively, 50, 42, and 28. The first two series account for less than 1% of the different analyzed fractions. According to the biosynthesis of these compounds (Blomquist and Jackson, 1979), 5-methylalkanes are even hydrocarbons (5-methylnonacosane and 5-methylhentriacontane) and 4-methylalkanes are odd hydrocarbons (4-methyloctacosane and 4-methyltriacontane). 3-Methylalkanes are by far the most abundant products of this class: they account for 12% of the total hydrocarbon fraction with a little more for the male solitary adult locusts (15.8%). They range from 26 to 36 carbon numbers; among them, those with an even number of carbons are the most abundant. 3-Methylnonacosane is the major one of the series for gregarious locusts and 3-methylhentriacontane for solitary ones.

Their mass spectra (from 100 amu) give the following characteristic fragments: 5-methylalkanes: M-57 (base peak) and M-85; 4-methylalkanes: M-43 (base peak) and M-71; 3-methylalkanes: M-29 (base peak) and M-57.

Class C: Internally Branched Monomethylalkanes. They account for 13–20% of total hydrocarbon extracts and range from C_{28} to C_{38} (described here but probably up to C_{52}). The *dI* with same number linear hydrocarbons is 67. The predominant branch points are 11, 12, and 13 for odd methylalkanes (the minor ones) and 11 and 13 for even methylalkanes (the major ones).

In fact, each chromatographic peak corresponds to a mixture of odd or even monomethylalkanes, isomers for the position of the branch point. The mass spectrometry of these derivatives has been described by McCarthy et al. (1968) and Nelson et al. (1972). This has enabled us to establish the structures proposed in Table 2.

The mass spectrum of peak 41 of Figure 2 suggests a mixture of 12-, 13-, 14-, and 15-methyltetratriacontanes (Figure 3). In the same way, peak 45 of

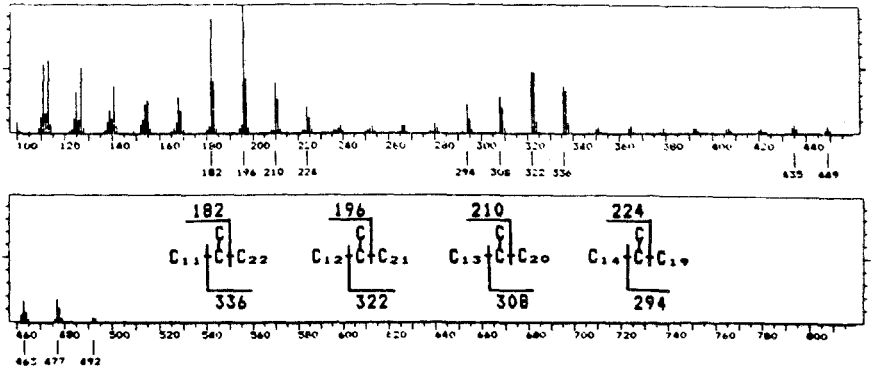

FIG. 3. Mass spectrum of GC peak 41 (Figure 2): 12-, 13-, 14-, and 15-methyltetratriacontanes.

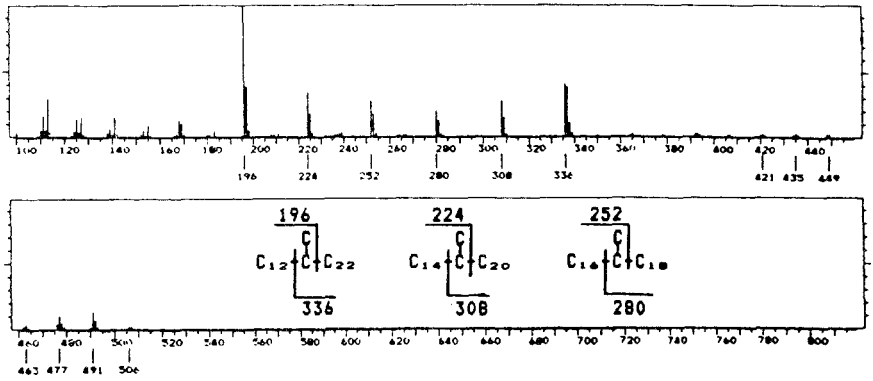

FIG. 4. Mass spectrum of GC peak 45: 13-, 15-, and 17-methylpentatriacontanes.

Figure 1 is interpreted as a mixture of 13-, 15-, and 17-methylpentatriacontanes (Figure 4). In all cases, the base peak of these spectra recorded from 100 amu is the secondary even ion of the weaker molecular mass of the major isomer (*m/z* 196 for 13-methyl isomer in Figures 3 and 4).

Some qualitative differences appear between insect categories. For example, to the isomers identified in peak 41 of Figure 2 (Figure 3), are added 16- and 17-methyltetratriacontanes in peak 41 of Figure 1 (Figure 5). Probably, these qualitative differences come from quantitative variations between monomethylalkanes inside the same chromatographic peak of the various insect categories analyzed.

Class D: Dimethylalkanes. The percentages of these products are close to those of monomethylalkanes (8–19% of total hydrocarbon extracts), and range from C_{33} to C_{53}. After C_{39}, only four odd dimethylalkanes, C_{47} to C_{53}, have been proposed, the others being minor ones. The *dI* of 140 and the molecular

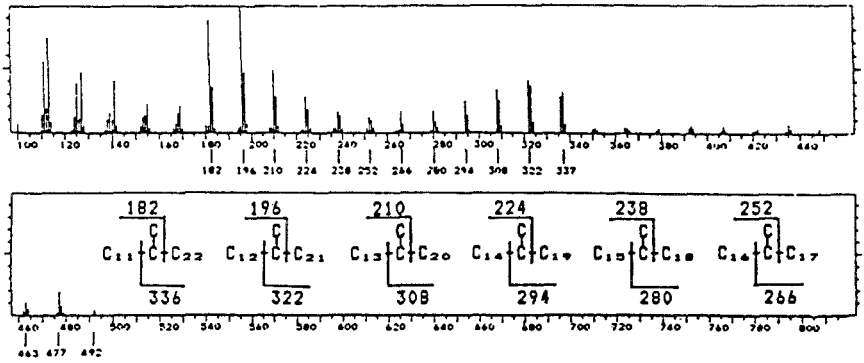

FIG. 5. Mass spectrum of GC peak 41 (Figure 1): 12-, 13-, 14-, 15-, 16-, and 17-methyltetratriacontanes.

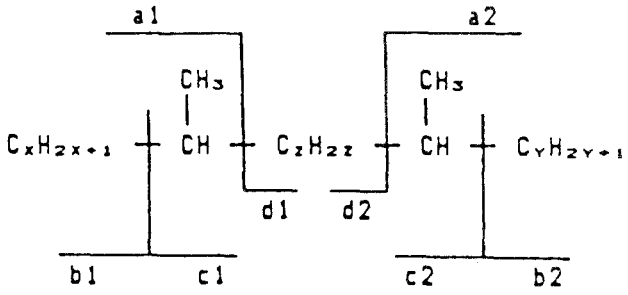

SCHEME 1.

masses, determined by chemical ionization, agree with internally branched dimethylalkanes.

The mass spectrometry, more complex than for monomethylalkanes, was used to suggest structures. According to the Nelson school (Nelson et al., 1972; Pomonis et al., 1978, 1980), internally dimethylalkanes undergo two more fragmentations than monomethylalkanes (Scheme 1).

The spectra of 15,19-dimethylpentatriacontane (Sonnet, 1976) (Figure 6) and 13,23-dimethylheptatriacontane (Carlson et al., 1984) (Figure 11B) are presented as examples. Note the relative importance in Figure 6 of m/z 266/267 (even ion major one) which correspond to a pair of ions $d - 1/d$. The other doublet $d - 1/d$ is superimposed with m/z 294/295. Pomonis et al. (1980) mention this rupture with a greater intensity and a major odd ion, $d >> d - 1$, for 9,14-dimethylheptacosane.

As in the case of the monomethylalkanes, each chromatographic peak of the dimethylalkanes corresponds to a mixture of isomers. We present here our suggestions for identifications and the corresponding spectra of some of them (Figures 7–11).

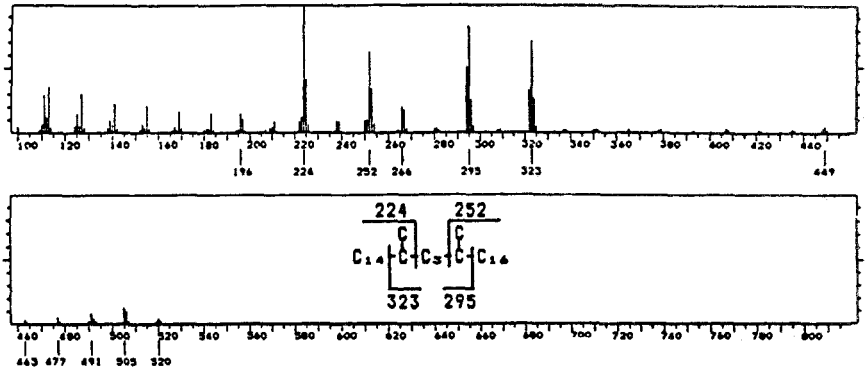

FIG. 6. Mass spectrum of 15,19-dimethylpentatriacontane.

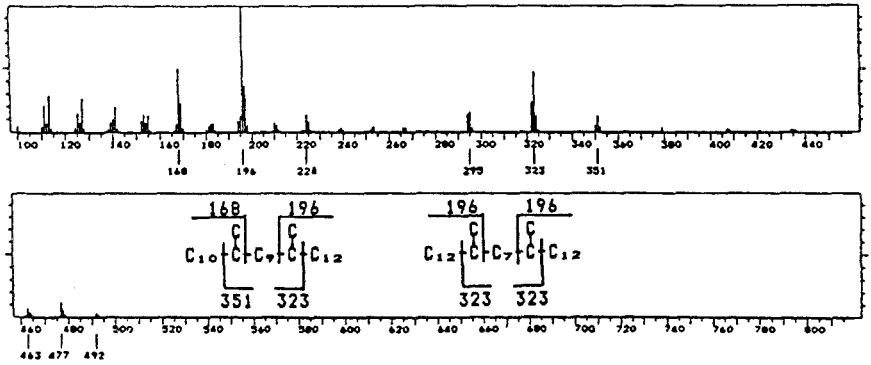

FIG. 7. Mass spectrum of GC peak 37: 11,21- and 13,21-dimethyltritriacontanes.

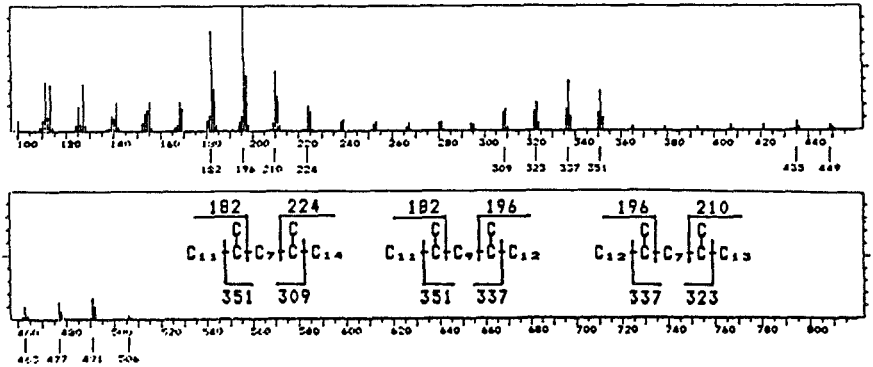

FIG. 8. Mass spectrum of GC peak 42: 12,20-, 12,22-, and 13,21-dimethyltetratriacontanes.

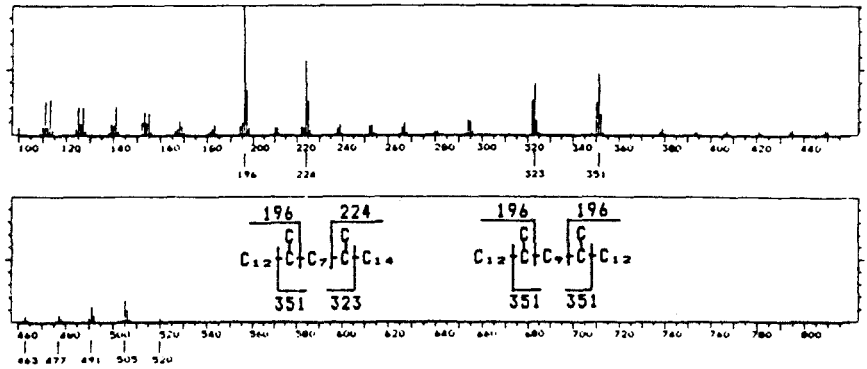

FIG. 9. Mass spectrum of GC peak 46: 13,21- and 13,23-dimethylpentatriacontanes.

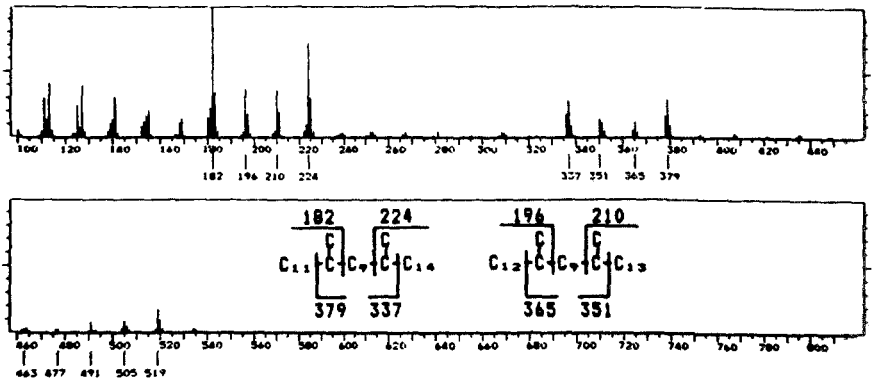

FIG. 10. Mass spectrum of GC peak 51: 12,22- and 13,23-dimethylhexatriacontanes.

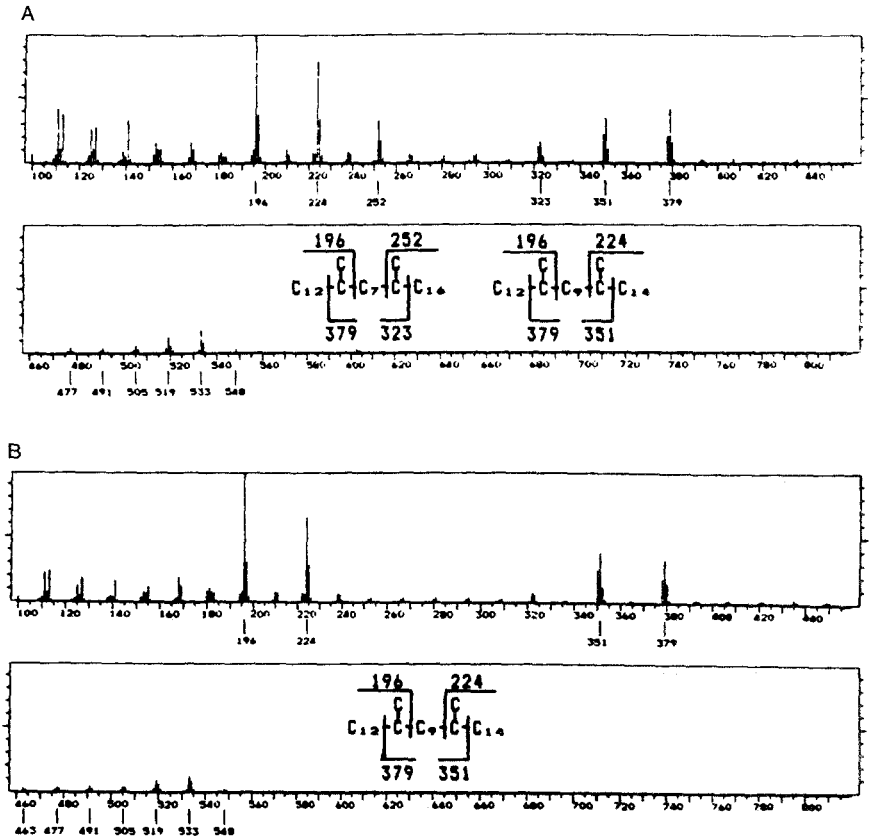

FIG. 11. (A) Mass spectrum of GC peak 54: 13,21- and 13,23-dimethylheptatriacontanes. (B) Mass spectrum of 13,23-dimethylheptatriacontane.

The spectrum of Figure 7 (chromatographic peak 37), corresponds to a mixture of dimethyltritriacontanes (M = 492). According to the pairs of ions **168**/169, **196**/197, 322/**323**, and 350/**351** (major ions in heavy type), we propose 11,21-dimethyltritriacontane. Moreover, the increased intensities of ions at *m/z* **196**/197 and 322/**323** suggest the presence of the symmetric 13,21-dimethyltritriacontane. Finally, the ions at *m/z* **224**/225 and 294/**295** suggest a third isomer with a branch point at carbon 19, but it is difficult to say if it is 11,19- or 13,19-dimethyltritriacontane. The results mentioned further on might be in favor of 11,19 (seven carbons between branch points). We must note that the ion at *m/z* 294 also corresponds to the ion $d - 1$ of the two precedent isomers.

The mass spectrum of Figure 8 (chromatographic peak 42) was interpreted as a mixture of 12,20-, 13,21-, and 12,22-dimethyltetratriacontanes. The two first isomers are sufficient for the attribution of the eight major fragments observed, but the fact that the ratios 351/309 and 337/323 are positive implies the presence of the third isomer.

In the same way, the mass spectrum of Figure 9 (chromatographic peak 46) agrees with the one of 13,21-dimethylpentatriacontane (first proposed by Lockey, 1976) but the ion at *m/z* 351 (>323) suggests the presence of symmetric 13,23-dimethylpentatriacontane (minor one).

For the mass spectrum of Figure 10 (chromatographic peak 51), if we put together the two major even ions at *m/z* 182 and 224 and the two odd ones at *m/z* 337 and 379, we suggest 12,22-dimethylhexatriacontane. The 13,23-dimethylhexatriacontane agrees with other even fragments at *m/z* 196 and 210 and odd fragments at *m/z* 351 and 365. It should be noted that the intensity of the ion at *m/z* 350, greater in this particular case than the ion at *m/z* 351, is partially due to an ion $d - 1$ of the isomer 12,22.

The mass spectrum of peak 54, Figure 11A, in comparison with the spectrum of 13,23-dimethylheptatriacontane (Figure 11B), proves the presence of this hydrocarbon in product 54. But the positive intensity ratio 379/351, on the one hand, and the presence of ions at *m/z* 323 and 252, on the other, can be interpreted as the fragmentation pattern of isomer 13,21.

It should be emphasized that all the dimethylalkane structures suggested here have seven or nine carbons between branch points. Such series are reported, among others, in the hemolymph of the Japanese beetle *Popilla japonica* Newman (Nelson et al., 1975), with seven methylene groups, and in the cuticular hydrocarbons of the house fly *Musca domestica* (Nelson et al., 1981) and of the grasshoppers *Melanoplus differentialis*, *sanguinipes*, and *packardii* (Nelson et al., 1984), with nine methylene groups.

DISCUSSION

The differential bar charts presented in Figures 12 to 16 concern the insect population described in the experimental part. However, similar analyses have

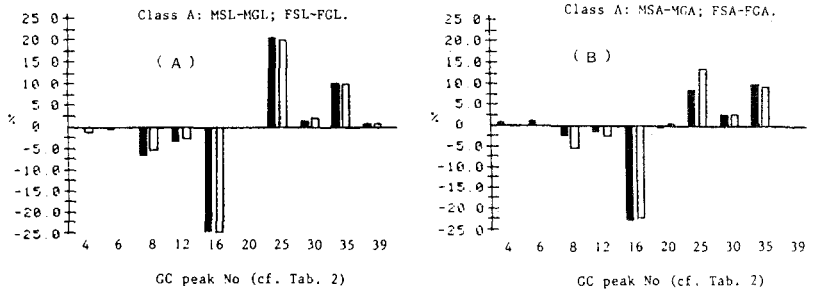

FIG. 12. (A) %MSL − %MGL (black bar chart); %FSL − %FGL (white bar chart). (B) %MSA − %MGA (black bar chart); %FSA − %FGA (white bar chart). MSL: male solitary larvae; MGL: male gregarious larvae; FSL: female solitary larvae; FGL: female gregarious larvae; MSA: male solitary adult; MGA: male gregarious adult; FSA: female solitary adult; FGA; female gregarious adult.

been carried out on at least one other insect population. In all cases, similar typical schemas are observed, even if slight variations in absolute identified hydrocarbon percentages occur from one population to another.

The differential bar charts in Figures 12 to 14 reveal that there is a general tendency for the cuticular hydrocarbons of solitary locusts to be more condensed than those of the gregarious ones. This emerges from the comparison of their hydrocarbon profiles and is valid for both ages and sexes. For the products belonging to classes A, B, and C, we can find a compound representing the variation mean: *n*-triacontane (No. 20) for class A (Figure 12A and B), 3-methyltriacontane (No. 24) for the 3-methylalkanes of class B (Figure 13A and B), and the methyltetratriacontanes (No. 41) for class C (Figure 14A and B). On the other hand, the relative percentages of dimethylalkanes are not modified much by phase changes.

Concerning the evolution of cuticular hydrocarbon composition during the locusts' transformation from larvae to adults, not many changes are observed

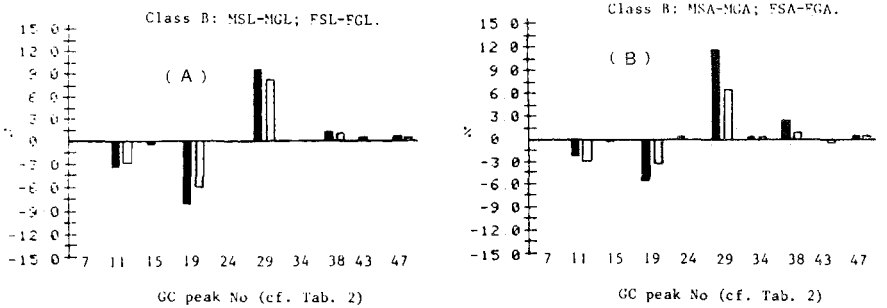

FIG. 13. (A) %MSL − %MGL (black bar chart); %FSL − %FGL (white bar chart). (B) %MSA − %MGA (black bar chart); %FSA − %FGA (white bar chart).

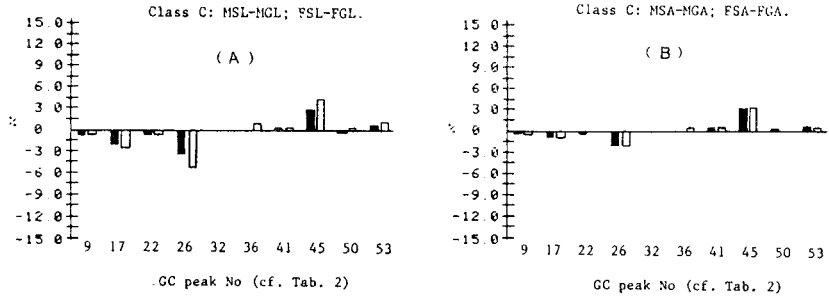

FIG. 14. (A) %MSL − %MGL (black bar chart); %FSL − %FGL (white bar chart). (B) %MSA − %MGA (black bar chart); %FSA − %FGA (white bar chart).

in the *n*-alkanes and the 3-methylalkanes. A decrease in the relative percentages of monomethylalkanes can be observed (Figure 15A and B) in both gregarious (−11.6% for the females and −11.1% for the males) and solitary insects (−8.5% for the females and −6.9% for the males). The variations of dimethylalkanes are presented in Figures 16A and B. They show a clear increase in these compounds in gregarious (+9.4%) and solitary (+8.5%) females. In the males, the tendency seems weaker (+3.0% for gregarious) or reversed (−2.3% for solitary ones). The presence of long-chain branched alkanes, in greater quantities in adults than in larvae, has already been described in *Schistocerca americana* (Jackson, 1982).

The differences between the sexes are slight but seem to be greater in the case of the solitary locusts, especially for dimethylalkanes. This very weak sexual dimorphism leads to the hypothesis of a probable absence of any sexual contact cuticular pheromone of a hydrocarbon nature in these insects.

The differences observed between gregarious and solitary insects show the importance of the role of the cuticle in phase dimorphism; this can be added to the underlying pigmentary tegumental phase dimorphism, which was the only one known until now (Uvarov, 1966; Albrecht, 1967). This new phase char-

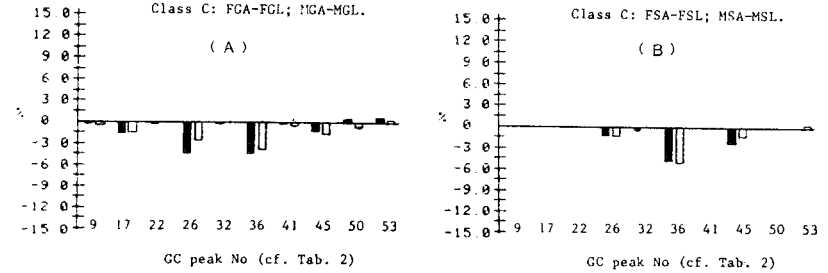

FIG. 15. (A) %FGA − %FGL (black bar chart); %MGA − %MGL (white bar chart). (B) %FSA − %FSL (black bar chart); %MSA − %MSL (white bar chart).

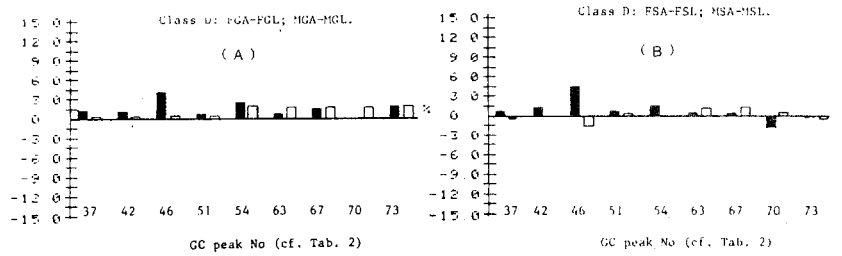

FIG. 16. (A) %FGA − %FGL (black bar chart); %MGA − %MGL (white bar chart). (B) %FSA − %FSL (black bar chart); %MSA − %MSL (white bar chart).

acter is now to be taken into account in biosynthesis problems, on the one hand, and in all taxonomic research with the aim of identifying species according to their hydrocarbon profiles, on the other hand: the kind of life—gregarious or solitary—quantitatively changes the chemical composition of the cuticle. Further research into the possible biological role of these phase change modifications remains to be done.

Acknowledgments—We thank D.A. Carlson for samples of 15,19-dimethylpentatriacontane and 13,23-dimethylheptatriacontane; we thank Professor J. Jullien and J.M. Péchiné for helpful discussions.

WESTERN AVOCADO LEAFROLLER, *Amorbia cuneana* (WALSINGHAM), (LEPIDOPTERA: TORTRICIDAE) Discovery of Populations Utilizing Different Ratios of Sex Pheromone Components[1]

J.B. BAILEY,[2] L.M. McDONOUGH,[3,4] and M.P. HOFFMANN[2]

[2]*Department of Entomology, University of California Riverside, California 92521*

[3]*Yakima Agricultural Research Laboratory Agricultural Research Service, USDA 3706 West Nob Hill Boulevard, Yakima, Washington 98902*

(Received July 19, 1985; accepted August 26, 1985)

Abstract—The most effective lure for male *Amorbia cuneana* (Walsingham) in Orange, Ventura, and Riverside counties of California was previously found to be a 1:1 ratio of (*E*,*E*)-10,12- and (*E*,*Z*)-10,12-tetradecadien-1-ol acetates. In subsequent field tests in San Diego and Santa Barbara counties, this lure was ineffective. Analysis of sex pheromone glands (SPG) of female *A. cuneana* from these two counties showed the *EE*:*EZ* ratio to be about 1:9 and synthetic lures of this composition were highly attractive in these areas. Analysis of the SPG of a number of females from both areas showed that there were three population types: two in the low ratio areas possessed 37 and 58% *EZ*, and the third in the high ratio areas possessed 89% *EZ*.

Key Words—*Amorbia cuneana*, *Amorbia essigana*, sex pheromone, sex pheromone component ratios, Lepidoptera, Tortricidae, (*E*,*E*)-10,12-tetradecadien-1-ol acetate, (*E*,*Z*)-10,12-tetradecadien-1-ol acetate.

INTRODUCTION

Amorbia cuneana (Walsingham) is a pest of avocados and citrus in California (Ebeling, 1959). It is native to North America (Walsingham, 1879). At one time it was thought there was another *Amorbia* species in California, *Amorbia essigana* (Busck) (Busck, 1929). Subsequently, *A. essigana* was placed in syn-

onymy with *A. cuneana* (Powell, 1983). In previous work, McDonough et al. (1982) reported the structure and synthesis of the sex pheromone of *A. cuneana*, a mixture of (*E*,*E*)- and (*E*,*Z*)-10,12-tetradecadien-1-ol acetates. Subsequently, field tests to determine optimum component ratios, dosages, lure longevity, and other parameters associated with use of the lure were carried out (Hoffmann et al., 1983). The field tests were conducted in Orange, Ventura, and Riverside counties of California. However, when the lure was later tested in San Diego and Santa Barbara counties, few or no male *A. cuneana* were captured even though light traps showed high populations were present. We therefore undertook this study to determine the reason for these results.

METHODS AND MATERIALS

Insects. Amorbia cuneana females analyzed in this study were collected as larvae or pupae from avocado groves in San Diego, Santa Barbara, and Ventura counties in California during the summer and autumn of 1981.

Pupae were sexed, and the females were sent to Yakima, Washington, where they were placed on moist vermiculite and kept at 17°C, 63% relative humidity in a photoperiod of 14 : 10 light–dark. Emerged females were caged daily and offered a diet of beer, sucrose, and ascorbic acid (Calkins and Sutter, 1976). Larvae were taken to the UC South Coast Field Station in Irvine, California, where they were reared on *Trichoplusia ni* diet (Shorey, 1963) at 26.7°C in a photoperiod of 14 : 10 light–dark. Upon pupation, the specimens were collected and sent to Yakima where they were treated in the same manner as previously described.

Females analyzed in the mating studies were the progeny of single adult pairs collected as pupae from a commercial avocado grove in Ventura County. Rearing and handling procedures were the same as previously described, with the exception that the progeny of each mated pair were kept separate, allowing for determination of the range in isomer ratios of the sex pheromone in single matings.

Determination of Ratio of Pheromone Components in Females and Field-Aged Septa. Females (2–4 days old) were collected ca. 8 hr after the beginning of scotophase and refrigerated 10–30 min before dissection. The abdomen was squeezed to extrude the terminal segments and the tip was excised so as to include all of the abdominal segment not covered by scales. Each tip was extracted separately in 10 μl of heptane for about 33 min.

The extracts of individual female abdominal tips were analyzed on a Quadrex glass capillary column (56 m × 0.25 mm ID) coated with methyl silicone (SE 30®) and operated in the splitless mode with the following program: 45 sec delay on inlet purge; 2 min at 80°C; 32°C/min to 190°C.

Septa from the field aging test were extracted in dichloromethane for 1 hr

by shaking with a mechanical shaker. The dichloromethane was evaporated, and the residue was dissolved in heptane and analyzed in the same manner as the abdominal tip extracts.

Preparation of Lures. The synthetic pheromone consisting of a mixture of *EE* and *EZ* isomers was prepared as reported previously (McDonough et al., 1982). Lures of given *EE:EZ* compositions in red rubber septa (West Co., Phoenixville, Pennsylvania) were prepared from the purified isomers. The isomers were purified by high-pressure liquid chromatography (Hewlett-Packard chromatograph model 1084B), using an ultraviolet detector and a 10-μm particle size silica with a bonded coating of octadecyl (RP-18) in a column 20 cm $\times$ 4.6 mm ID. Fractions were eluted with 77% MeOH in water.

Field Tests. Tests were conducted in commercial avocado groves in Santa Barbara and San Diego counties. Pherocon® 1C traps were used with an extra coating of Stickem Special® applied to the trap bases to improve trap efficiency. Lures were rubber septa impregnated with 0.2 mg of 98.5%, 90.0%, 80.0%, and 50.0% of the *EZ* component of the pheromone. These septa were impaled on No. 17 straight pins hung from the top inside center of the traps.

Traps were hung on peripheral branches of the trees 2–3 m off the ground and spaced no closer than 27 m within and between trap rows. A randomized complete block design was used. Four treatments replicated five times were used in the Santa Barbara County study. Traps were checked every two days and rotated one position within the block each time they were checked to minimize bias in trap-catch due to location. Traps were checked eight times so that each treatment was at each location twice during the study.

The test in San Diego County was conducted in a commercial avocado grove near San Luis Rey. It was conducted in the manner described above except that the distance between traps was about 50 m and four replicates were used.

Trap catch data were analyzed using ANOVA and DMRT ($P = 0.05$).

RESULTS AND DISCUSSION

Following our initial unsuccessful trapping experiments in San Diego and Santa Barbara counties, pupae of *A. cuneana* were obtained from these areas, reared to adults, and female sex pheromone glands (SPG) were extracted. An obvious difference in extracts of female SPG from those we had analyzed previously (McDonough et al., 1982; Hoffmann et al., 1983) was in the ratio of the (*E*,*E*)-10,12- and (*E*,*Z*)-10,12-tetradecadien-1-ol acetates.

Determination of the *EZ* isomer content (as a percent of the total of *EE* + *EZ*) from 16 virgin female *A. cuneana* from San Diego County gave an average value of 86.6 $\pm$ 5.1 SD%. All values except one were in the range 82.0–93.0%; the exception was 72.1%. The *EZ* content in 11 females from Santa

Barbara County averaged 89.7 ± 2.4% (range 86.7–92.7%). Accordingly, lures with high ratios were tested and compared with a low-ratio lure (50% *EZ*) in these areas.

The results of the Santa Barbara test are summarized in Table 1. At the termination of the test, the lures were extracted and the isomer content was determined. This procedure was necessary because of the ease with which conjugated dienes in rubber septa can isomerize outdoors (Davis et al., 1984; Guerin et al., 1983). After 19 days, *EZ* percentages had decreased to levels that were significantly different from the ratios found in females of this area. The final ratios found in the lures indicate that during the test those of initial values of 98.5 and 90.0% *EZ* were changing mainly throughout the range found in females, while the 80% lure would have been at best marginal at the beginning of the test and considerably below the values found in females during much of the test. From this standpoint then, the trap catches indicate a male preference only for those ratios found in the females of this region.

A similar field test was conducted in San Diego County (Table 2). The lures were not analyzed at the end of this test. Less isomerization would be expected here than in the first test because of the shorter test period (8 days). Again there was a preference for the higher ratios of *EZ*. The 50% isomer again caught very low numbers, while the catch of the other treatments increased with increasing percentages of *EZ*.

In our earlier study (Hoffmann et al., 1983), we reported that *EZ* percentages from individual female *A. cuneana* from Riverside County averaged 54.8 ± 10.2% *EZ* (range 33.7–69.6%). Subsequent examination of these data indicated that most of the values appeared to be grouped around two values. To determine if this were in fact the case, *EZ* percentages of female progeny from seven singly mated pairs were determined.

TABLE 1. TEST OF EFFECT OF (*E,E*)-10,12- AND (*E,Z*)-10,12- TETRADECADIEN-1-ol ACETATE RATIOS (PERCENT *EZ* AS PERCENT OF *EE* + *EZ*) ON TRAP CATCH OF MALE *A. cuneana* IN SANTA BARBARA COUNTY, CALIFORNIA[a]

Percent *EZ*		No. of males caught[b]	
Initial	Final	Total	Per trap–day
98.5	78.1 ± 1.6	1403	14.8 a
90.0	59.3 ± 2.7	926	9.7 a
80.0	55.9 ± 4.8	39	0.4 b
50.0	not analyzed	24	0.3 b

[a] Because the conjugated diene structure isomerizes, values of the percent *EZ* are listed both at the beginning and at the end of the test. Test was conducted from 8/24/82 to 9/11/82 (19 days). There were five replicates of each ratio.

[b] Means followed by the same letter are not significantly different; ANOVA and DMRT ($P = 0.05$).

TABLE 2. TEST OF EFFECT OF (*E,E*)-10,12- AND (*E,Z*)-10,12- TETRADECADIEN-1-ol ACETATE RATIOS (PERCENT *EZ* AS PERCENT OF *EE* + *EZ*) ON TRAP CATCH OF MALE *A. cuneana* IN SAN DIEGO COUNTY, CALIFORNIA[a]

Initial percent EZ	No. of males caught[b]	
	Total	Per trap–day
98.5	332	10.4 a
90.0	152	4.8 b
80.0	83	2.6 bc
50.0	14	0.4 c

[a] The test was conducted from 10/14/82 to 10/22/82 (8 days).
[b] Means followed by the same letter are not significantly different; ANOVA and DMRT ($P = 0.05$).

The ratios of the pheromone components in females from the singly mated pairs from a low ratio area are summarized in Table 3. The *EZ* ratios fall into two well-defined groups with small standard deviations: one at about 37% *EZ* and the other at about 58% *EZ*. It is noteworthy that the 37 and 58% *EZ* populations share the same geographical area while the 88% *EZ* population appears to inhabit its own distinct areas.

A summary of all *EZ* percentages determined in single females from this and our preceding study (Hoffman et al., 1983) is shown in Figure 1. The *EZ* values clearly occur in three groups: at 37.2 ± 3.9% *EZ* and 58.3 ± 3.0% *EZ* for the population responding to the low *EZ*% lure, and 88.5 ± 3.2% for the population responding to the high *EZ*% lure. The greatest number of individual females possessed the 37.2% *EZ* lure, and the distribution of values about the

G	16	16 (37.1 ± 1.3)

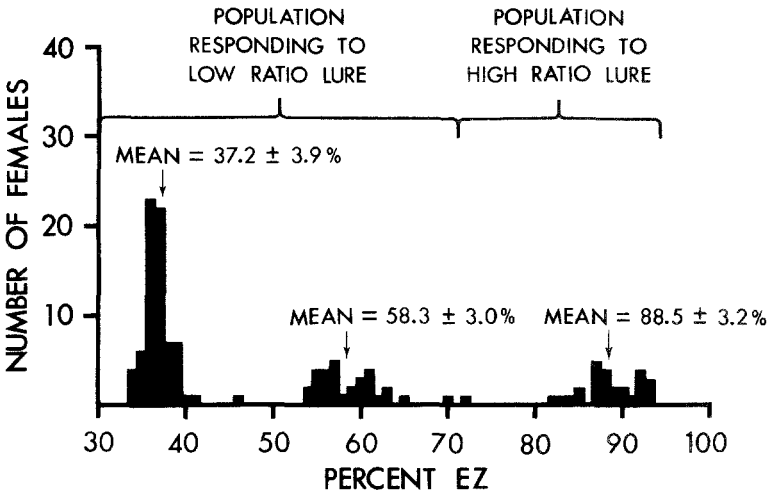

FIG. 1. Number of female *A. cuneana* having a given percent of *EZ* (as a percent of *EE* + *EZ*).

mean resembles a normal distribution. Presumably, the distribution about the 58.3 and 88.5 values would also resemble a normal distribution if a greater number of insects had been analyzed. The relative proportion of the females having the 37.2 and 58.3% *EZ* values (71 and 29 females, respectively) does not necessarily represent the actual relative proportions in field populations. The sampling was not extensive enough to ensure a statistical sample.

The phenomenon of three groups of values of *EZ*% in *A. cuneana* suggests a situation similar to the one found for the European corn borer, *Ostrinia nubilalis* (Hübner) as reported by Klun and Maini (1979), Klun et al. (1973, 1975), Kochansky et al. (1975), and Cardé et al. (1975). The sex pheromone of *O. nubilalis* is (*E*)- and (*Z*)-11-tetradecen-1-ol acetates. Originally two varieties of *O. nubilalis* were found to exist in nature: one in which females used a 4:96 *Z:E* ratio (New York strain), and the other in which they used a 97:3 ratio (Iowa strain). The males of each variety responded only to the ratios found in females of the same variety. Subsequently, geographic areas were discovered in which three varieties coexisted: males responded to *Z:E* ratios of 1:1 as well as 97:3 and 3:97. In those areas where males responded to the 1:1 ratio, native females were found that contained a 35:65 *Z:E* ratio. Laboratory breeding experiments between the 97:3 and 4:96 varieties yielded only the 35:65 variety. Breeding of the 35:65 variety gave the 97:3, 35:65, and 4:96 in an approximately 1:2:1 ratio. Klun and Maini (1979) concluded that the *Z:E* ratio was determined by a single pair of alleles with one allele exhibiting incomplete dominance. Although a similar situation might exist for *A. cuneana*, it is not possible to know, with our present information, which genotypes produce the

observed phenotypes of *A. cuneana*. Breeding experiments are needed to answer this question. From a practical standpoint lures containing a 1:1 *EE:EZ* and a 1:9 *EE:EZ* ratio should be adequate for monitoring the low and high ratio *A. cuneana* populations.

BENEFICIAL ARTHROPOD BEHAVIOR MEDIATED BY AIRBORNE SEMIOCHEMICALS
I. Flight Behavior and Influence of Preflight Handling of *Microplitis croceipes* (Cresson)[1]

Y.C. DROST,[2] W.J. LEWIS,[3] P.O. ZANEN,[2] and M.A. KELLER[4]

Insect Attractants, Behavior, and Basic Biology Research Laboratory

(Received June 13, 1985; accepted August 26, 1985)

Abstract—Oriented responses of *Microplitis croceipes* (Cresson) to airborne odors of actively feeding *Heliothis zea* (Boddie) larvae were observed in a flight tunnel. The behavior of *M. croceipes* prior to and during sustained, oriented flights was videotaped and analyzed in detail. Preflight exposure of the parasitoid to feces and other components of the plant–host complex were found to be vital in effective flight behavior, while maturation of the parasitoid had little effect. The increased frequency of oriented flight that resulted from preflight exposure of a plant–host complex persisted for at least 24 hr.

Key Words—Hymenoptera, Braconidae, *Microplitis croceipes*, parasitoid behavior, habitat location, *Heliothis zea*, Lepidoptera, Noctuidae, flight tunnel, female flights, preflight handling.

SERIES PREFACE[5]

Improved methods for harnessing beneficial entomophagous arthopods are considered of priority importance as a means of providing effective, safe, and eco-

nomically sound technology for combating the losses of agricultural products to insect pests. Current approaches for using these biological control agents include: (1) importing and establishing new species of beneficial parasitoids and predators from foreign countries; (2) encouraging maximum abundance and efficiency of these beneficial arthropods in crops or other target areas by providing food, shelter, attractive odors, etc.; and (3) mass production and release of beneficial arthropods into the target areas.

A central problem underlying all approaches for biological control is the inability to ensure retention and sustained activity of the biological agents in the target area. This problem exists in the case of many pests where the beneficial insects are naturally present in high numbers and/or technology for their mass production and release is available. A prerequisite for resolving this problem is a knowledge of factors and mechanisms governing the means by which they find and attack their hosts and prey.

Trail odors from the pest insects, cues from the host plants, and other biological communication mediators are vital to the host- or prey-finding process (Lewis et al., 1982a). A considerable amount of information has begun to accumulate regarding the role of these factors. For example, substantial progress has been made toward elucidating close-range foraging behavior of entomophages mediated by contact chemicals (Weseloh, 1981). However, major gaps in knowledge exist which seriously constrain employment of biological control (Greany et al., 1984). Of particular significance is the lack of information regarding the foraging behavior mediated by volatile semiochemicals. The work of Hagen et al. (1976) on the response of *Chrysopa carnea* Stephens to volatile tryptophan by-products from honeydew of aphids, the occurrence of volatile kairomones in prey searching by predatory mites (Sabelis and Van de Baan, 1983; Sabelis and Dicke, 1985), reports of Lewis et al. (1982b, 1985) and Noldus and van Lenteren (1985) regarding the use of moth sex pheromones by *Trichogramma* spp. to locate host eggs, and various reports regarding host plant and habitat preferences by entomophages (Altieri, 1983; Vinson, 1981) demonstrate the importance of airborne semiochemicals to host and prey selection by entomophages.

Volatile allelochemicals have been shown to be an important tool for beneficial arthropods in microhabitat selection and niche segregation (Vet, 1983, Vet and van Opzeeland, 1984; Vet et al., 1984) and distant prey selection (Dicke and Groeneveld, 1985). Yet, essentially no information is available about the behavioral mechanisms involved in entomophage responses to the volatile semiochemicals. Additionally, little is known about the chemical nature, role, or interactions of components from different sources (plants and host insects) that comprise the total semiochemical system. Only a few structures of volatile allelochemicals emitted from host plants or fermentation products of host-associated frass have been elucidated (Greany et al., 1977; Dicke et al., 1984; Elzen et al., 1984).

Natural-enemy foraging behavior, as mediated by volatile semiochemicals, is the subject of a set of collaborative studies planned by J.C. van Lenteren and coworkers at the Agricultural University, Wageningen, The Netherlands, and J.H. Tumlinson, W.J. Lewis and coworkers, ARS, USDA, Gainesville, Florida, and Tifton, Georgia, respectively. These investigations will be the subject of this series of reports. The studies are designed to involve both generalist and specialist entomophages and those attacking different stages of insect pests, especially the egg and larval stages. Also, the research will involve entomophages from the European and United States agricultural ecosystems. It is hoped that these joint investigations will provide an impetus for breaking through this central barrier to biological control.

INTRODUCTION

The primary constraint in deciphering long-range host-searching behavior of entomophagous arthopods has been the lack of effective bioassay techniques. Much research has been conducted with various olfactometers, but these systems confine the parasitoids, making flight and related behavioral expressions virtually impossible (Kennedy, 1977; Vet et al., 1983). Moreover, olfactometers are inappropriate for insects that only orient to odors after initiation of flight. Previous attempts to use greenhouses or flight tunnels for behavioral response studies of parasitoids to airborne semiochemicals also have generally failed because the insects typically exhibit disoriented behavior under captive conditions.

These characteristics have prohibited bioassays of oriented flight behavior and other responses of entomophages to airborne stimuli. Gross et al. (1975) demonstrated that preflight exposure to kairomones could be used to override the tendency of *Microplitis croceipes* (Cresson) to disperse. Preflight exposure of two *Trichogramma* spp. and *M. croceipes* to the respective kairomones from moth scales and larval feces of their common host *Heliothis zea* (Boddie) increased rates of parasitization. It was postulated that the higher parasitization resulted from more consistent orientation to the host. This paper reports behavioral responses of *M. croceipes* to airborne semiochemicals in a flight tunnel, describes their flight characteristics, and evaluates the influence of preflight handling.

METHODS AND MATERIALS

Insects. Larval *H. zea* were reared on artificial diet using the method of Burton (1969). The *M. croceipes* were obtained from the Insect Biology and Population Management Research Laboratory, Tifton, Georgia. Parasitoids of both sexes were allowed to emerge and mate in acrylic cages (30 × 30 × 17

cm) at 28°C, 50–70% relative humidity, and a 16-hr photophase (Lewis and Burton, 1970). Mating occurs as soon as both sexes are present (Bryan et al. 1969; Lewis and Burton, 1970). Age of females used for experiments varied between 1 and 5 days.

Odor Source. The following kind of target was prepared to approximate the composition of cues present in a natural plant–host complex. Larvae were placed on cowpea leaves in the late afternoon the day prior to experimentation to ensure that larval feces came from pea leaves only. A water-filled vial (9.5 cm height, 6 dm diam.) that contained a cowpea leaf with an eating and defecating *H. zea* larva (plant–host complex) was placed in the middle of the intake end of the test section of the flight tunnel.

Flight Tunnel. A variable-windspeed flight tunnel was constructed to study the flight behavior of parasitic Hymenoptera (Figure 1). The tunnel has a 50 × 50-cm cross-section and is an assembly of three sections: intake, test, and exhaust, which has a venturi shape. Air enters the intake made of 6-mm-thick plywood by passing through a standard dust filter. Inside is a honeycomb of plastic soda straws (197 mm length, 6 mm diam.) packed loosely in a regular linear pattern. Two sheets of aluminum window screen (7 × 7 mesh/cm^2) hold the straws in place.

The test section is 120 cm long with a glass top and cast acrylic walls and floor, all 6 mm thick. A black and white pattern on poster board is supported underneath the floor of the test section by a sheet of cast acrylic to provide a visual reference for flying insects. Nylon mosquito netting (13 × 13 mesh/cm^2) covers both open ends of the test section. One side wall is hinged at the top to allow access to the test section; foam weather-strip tape is used to seal this portal when closed. Aluminum angle braces (2 × 2 cm) reinforce the edge joints of glass and acrylic. In addition, these braces are mounted at the ends of each section as flanges to permit fastening tunnel sections together. Overhead

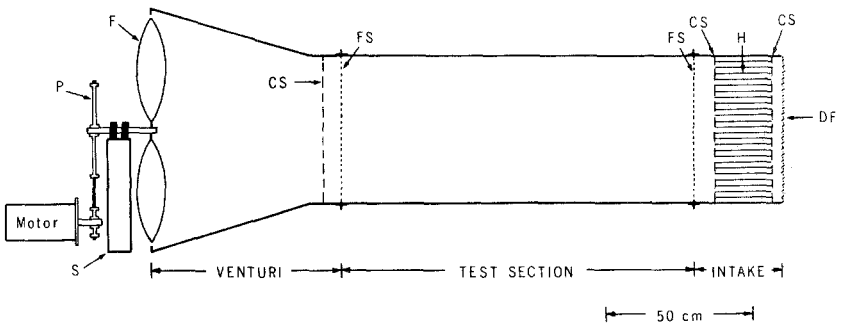

FIG. 1 Lateral section of the flight tunnel: H, honeycomb of 6-mm-diam. soda straws; CS, course screen (7 × 7 mesh/cm^2); FS, fine screen (13 × 13 mesh/cm^2); DF, dust filter; F, fan blade; and S, fan support.

lighting is provided by eight flood lamps arranged in two rows, or for video recording by two fluorescent bulbs. Light intensity in the flight tunnel varied between 3229 and 4090 lux for the flood lamps and between 2260 and 3014 lux for the fluorescent tubes.

The plywood venturi opens the cross-section from 50 × 50 cm to 80 × 80 cm over 55 cm, and internal baffles transform the section from a square to an octagon at the fan end. One sheet of aluminum window screen is mounted near the upwind end of the venturi. A three-blade aluminum fan, shrouded within 1 cm of the 76-cm-diam. blades, is powered by a variable-speed motor (model 4Z248A, 0.2 kW = $\frac{1}{4}$ hp, Dayton Electric Mfg. Co., Chicago, Illinois). The fan draws air through the intake into the test section. Screens and mosquito netting in the flight tunnel aid in achieving laminar air flow while the honeycomb removes some turbulence before air enters the test section.

Flight tunnel performance was assessed using both the smoke of a ventilation smoke tube (Mine Safety Appliance Co., Pittsburgh, Pennsylvania) and a hot-wire anemometer (model AB-27, Hastings Airmeter, Hastings Raydist, Hampton, Virginia). Air flow through the test section is approximately laminar as judged by viewing smoke plumes. Windspeed using the calibrated motor speed dial can be varied between 7 ± 1 cm/sec and 200 ± 3 cm/sec and was maintained at 23 ± 2 cm/sec, measured at the center of the flight tunnel during all experiments.

Flights were recorded on video tape from the center top with a RCA® TC 2055/C camera and a Panasonic® NV-8959 recorder. Tapes from sustained flights only were replayed in slow motion or frame by frame for analysis.

Preflight Handling. Standard exposure cups were prepared by placing one medium-sized cowpea leaf (ca. 3.45 cm^2) and one, third-instar *H. zea* larva in a 30-ml plastic cup in the late afternoon, allowing it to eat and defecate during the night. The next day, just prior to an experiment, each *M. croceipes* female was transferred with a clean 1-dram vial (6 cm height, 1.5 cm diam.) from the rearing cage and allowed to contact the material in the exposure cup during a 2-min period and sting the larva once. If a parasitoid could not find the host within 2 min, the larva was picked up carefully with forceps and presented to the female, which always resulted in a sting. If a female stung more than once, she was discarded. Immediately after this preflight exposure procedure, the parasitoid was transferred to the flight tunnel in a 1-dram vial. The vial was placed open end up at the downwind end of the flight tunnel, straight downwind from the target. Time from introduction into the tunnel until initiation of flight (latency), time from initiation of flight until landing on the target (navigation time), and type of flight were recorded for each female.

Observation time per individual was limited to a maximum of 10 min and stopped after a female landed on the target. Females that did not take off within 5 min were discarded. The number of no take-offs did not exceed 4% of the number of tested females for any experiment. For experiments in which a par-

asitoid was given a second flight trial immediately after landing, it was recaptured in the vial within 3 sec, before it could sting the larva. If oviposition could not be prevented, the parasitoid was excluded from the second trial and the target was replaced by one with an unparasitzed larva.

Flight Initiation and Orientation. The behavior of female *M. croceipes* exposed to the plant–host complex in the flight tunnel was observed. All females had the standard preflight exposure to a plant–host complex. Observations were restricted to the behavior expressed on the 1-dram release vial and in flight. During these observations, we defined a classification of discrete behavioral events. Relationships between these behavioral events during flights and on the 1-dram vial were described. Four categories of flight were used to evaluate the effect of different preflight exposures.

Next, characteristics of sustained flight toward a plant–host complex were determined and described. Video recordings were made only of the first flights of individuals, eight of which were used for the analysis.

Experiment 1. Flight responses to undamaged plants with and without associated infestation odors were observed. The responses of nine females provided with the standard preflight exposure were tested individually in three sequential trials. The female was recaptured after each trial and released at the introduction point for the next trial. The stimuli were given in the following order: (1) noninfested cowpea leaves, (2) noninfested cowpea leaves with the odor of a plant–host complex added, and (3) noninfested cowpea leaves again with infestation odors removed. The second treatment was achieved by placing the plant–host complex outside the flight tunnel, out of sight of the insects, at the intake end. In this way the insect perceived visual cues of the noninfested cowpea leaves in every trial, while it was exposed to additional olfactory cues of the plant–host complex only in the second.

Experiment 2. Five types of preflight exposure cups were used to determine the effect of preflight exposure to individual components of the plant–host complex on the initiation and characteristics of flight of *M. croceipes* females. In addition to the standard exposure cups containing a plant–host complex and empty control cups, these cups contained either an artificially damaged cowpea leaf, a larva, or larval feces. Leaves were artificially damaged by three pricks with a pair of forceps just prior to use so the damage would be fresh when presented to parasitoids. Larvae and larval feces were obtained from standard exposure cups and transferred to clean ones just prior to use. Latency, navigation time, and flight type were recorded for the first and second flights of each individual tested. Only females that landed on the target after the first flight were given a second trial. To determine whether maturation influenced the flight behavior of female *M. croceipes*, behavioral data of individuals with a preflight exposure to the larval feces or the plant–host complex were combined into three age groups.

Experiment 3. Retention of the effect of preflight exposure of a parasitoid to a plant-host complex was assessed. First flight responses were tested for females either 0 or 24 hr after their preflight exposure procedure.

Statistical Analysis. The number of females that exhibited a certain flight type after a given preflight exposure were analyzed with Chi-square test. Multiple comparisons of mean times spent to certain behavior were performed using the Duncan's multiple range test. A *t*-test was used when only two mean times needed to be compared. Latencies were transformed to log (x + 1) to stabilize variance. The 0.05 level was set for the rejection of all null hypotheses.

RESULTS AND DISCUSSION

Description of Behavioral Responses. The behavior of female *M. croceipes* was observed from time of introduction into the flight tunnel and first contact with the wind until landing on the target. The typical sequence of the behavioral events observed during these studies was diagrammed (Figure 2). The left side of the diagram represents the preflight behavior performed on the 1-dram release vial while the right side shows the behavior performed by *M. croceipes* in flight.

Responses of the females to the odor sources were defined using the following classification of behavioral events.

1. Standing still: standing still on the substrate without moving antennae.
2. Standing still while drumming: standing still while drumming the substrate with antennae.
3. Standing still while preening: standing still while preening antennae, legs, or both sides of wings.
4. Standing still upwind oriented: standing still while sticking antennae in a vertical plane perpendicular to the wind direction.
5. Walking while drumming: Walking while drumming the substrate with antennae.
6. Initiation of flight pose: sitting on hind legs while making "walking" movements with front legs in the air and sometimes temporarily spreading wings (Figure 3A).
7. Initial zigzagging: making sideways excursions mainly in the horizontal plane and perpendicular to the wind direction soon after take off.
8. Straight flight: flying directly into the main wind direction.
9. Recurrent zigzagging: sideways excursions recurring after a period of straight flight. These excursions are similar to the initial zigzagging, except the movements are less restricted to the horizontal plane.

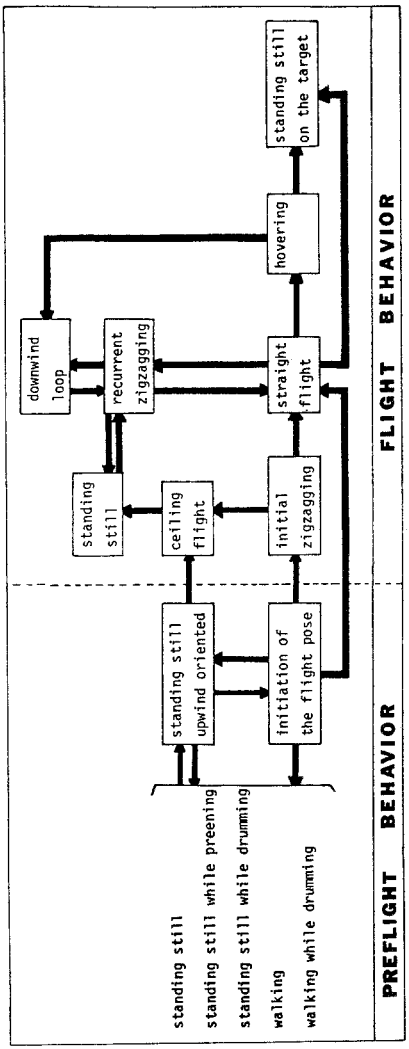

FIG. 2 Schematic representation of the behavioral events and transitions as exhibited by *Microplitis croceipes* responding to *Heliothis zea* larvae feeding on cowpeas.

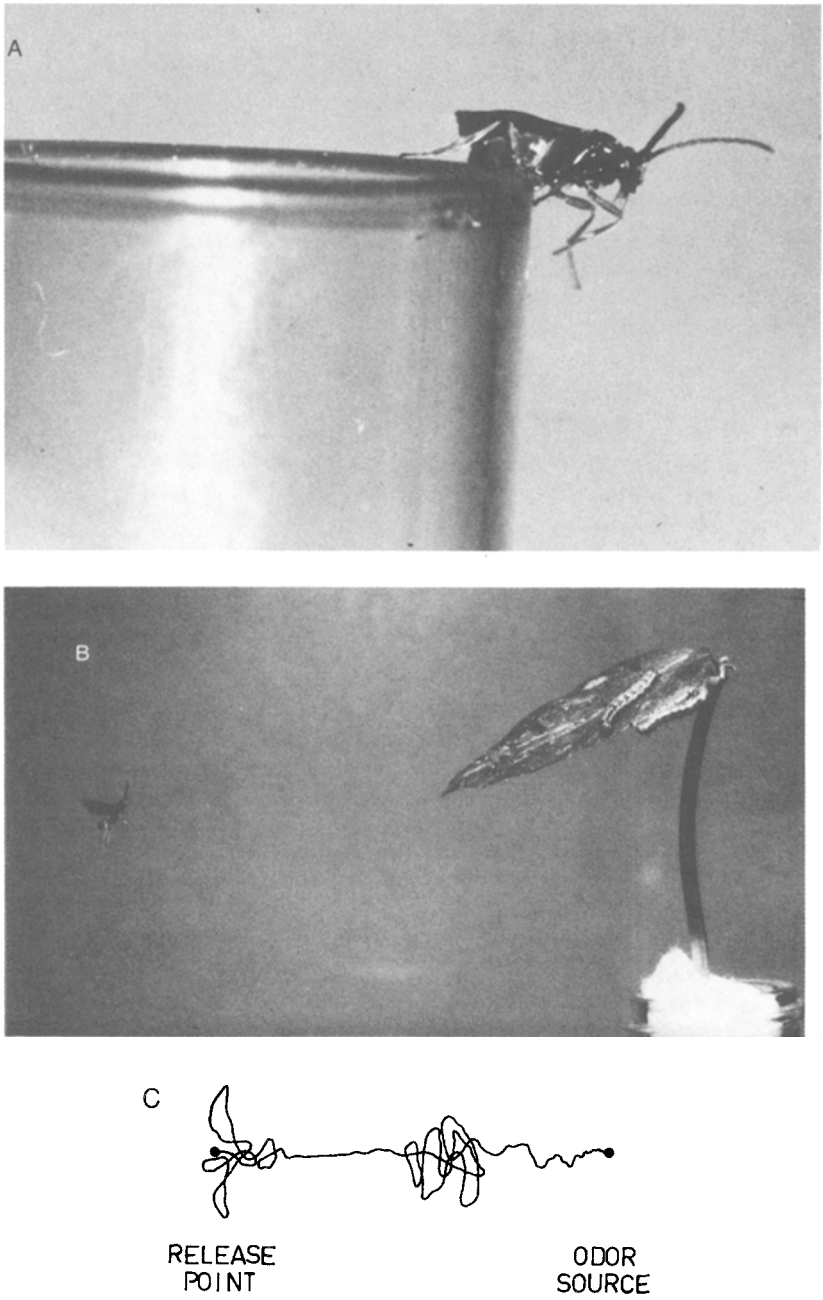

FIG. 3 Behavior of female *Microplitis croceipes* in the flight tunnel. (A) Initiation of the flight pose. (B) Hovering flight. (C) Top view of a sustained flight track.

10. Hovering: keeping stationary while flying at approximately 10 cm downwind from the target (Figure 3B).
11. Downwind loop: a looping maneuver, resulting in a return to an earlier downwind position.
12. Ceiling flight: a strong phototactic, "nonplume-oriented" response that results in the female being in contact with the ceiling of the flight-tunnel where she continues her wing beating.

Figure 2 represents the typical sequence of the described behaviors. Quantifications of these behaviors will be presented in subsequent reports of this series.

Preflight Behavior. Individuals that reached the open end of the 1-dram vial responded by taking an upwind oriented pose for several seconds. This action was followed either by walking, walking while drumming, or by the initiation of the flight pose. The process of intermittent upwind orientation and walking on the 1-dram vial was often repeated before flight was initiated

Flight Behavior. Four types of flight were distinguished; sustained flights, interrupted flights, temporary oriented flights, and non-target-oriented flights.

Sustained flights can involve all steps beginning with an initiation of the flight pose and ending with standing still on the target except a ceiling flight. A typical sustained flight (Figure 3C) begins with initial zigzagging, during which a little "ground" is lost and/or the parasitoid rises slightly above what is presumedly the odor plume. Subsequently there is a dramatic decrease in the extent of the sideways excursions followed by a straight approach toward the target. Sometimes this straight approach is interrupted by a brief recurrent zigzagging that occurred mostly at a 40-cm distance downwind from the target and consisted of sideways excursions smaller than the initial zigzagging. After resuming straight flight or continuing recurrent zigzagging, hovering takes place often at a 10-cm distance downwind from the target. From this point, quick darts were performed toward the target, ending with a landing on the target. Females allowed to fly a second time spent less time on both types of zigzagging.

Interrupted flights differ from sustained flights by the occurrence of a very wide recurrent zigzagging, which begins soon after the onset of straight flight, and sometimes include a downwind loop. These very wide zigzaggings lead to a landing on the sidewalls of the flight tunnel. Within a minute, an initiation of flight pose occurs again, after which flight continues first with a zigzagging and on to oriented flight.

Temporary oriented flights are the same as interrupted flights except that after the landing there is no further flight activity within 10 min.

Non-target-oriented flights include a ceiling flight that occurs immediately after release or after a brief initial zigzagging flight.

Experiment 1. No females had a sustained flight to undamaged plants only, compared to 89% that had one when the odor of a plant–host complex was added. Four of nine tested females flew beyond the cowpea leaves and landed on the screen at the upwind end of the flight tunnel when odor of a plant–host complex was provided behind the screen. Mean latencies of the first two trials (15.6 ± 2.8 sec ISE and 7.9 ± 3.7 sec ISE) were not significantly different. However, after response to the plant–host complex odors (second trial), there was a significantly longer mean latency in the third trial (102.0 ± 48.3 sec ± SE). Comparision of navigation times was not relevant, since sustained flights were only exhibited in second trials and not in the first and third.

Experiment 2. There are several factors in a plant–host complex that might contribute to the preflight experience of a female and hence influence the percentage of target-oriented responses in the flight tunnel. Contact with feces is known to elicit an intense searching response and initiate host-oriented flight (Lewis and Jones, 1971; Gross et al., 1975). When the female encounters a larva, she will generally oviposit. The deposition of an egg might have a different effect on searching behavior than contact with cues that give information about the presence of larvae. This experiment tested the respective effects of preflight exposures to individual components of a plant–host complex on subsequent flight behavior.

Exposures to larval feces or the full plant–host complex was the most effective preflight preparation, based on the percentage of resulting sustained flights. Preflight exposure to larval feces or a plant–host complex also significantly decreased the percentage of nontarget oriented flights (Figure 4). Stinging a larva without contacting other host-related cues did not increase the percentage of sustained flights as much as exposure to larval feces or a plant–host complex. After an *M. croceipes* female has parasitized a larva in a cup, there is usually a short postoviposition period (< 10 sec), during which the female does not search for other hosts. After this period, she continues walking and, upon encountering feces, she is reinforced to search. This reinforcement by feces apparently is important for the parasitoid to continue host searching. However, the effect of preflight exposure to a full plant–host complex reduced the percentage of non-target-oriented flights even more than feces, which suggests that the feces is not the only cue responsible for the behavioral change. Occurrences of temporary oriented flights did not differ significantly with the type of preflight exposure, whereas interrupted flights were observed only after preflight exposure to a larva, feces, or the plant–host complex.

Mean latencies of females exposed to feces or the plant–host complex were significantly longer than those of females exposed to either a damaged leaf, a larva, or nothing (control) (Table 1). This was mainly because females that were exposed to feces or the plant–host complex did not restrict themselves to an upwind orientation pose, they took off like the control group but searched

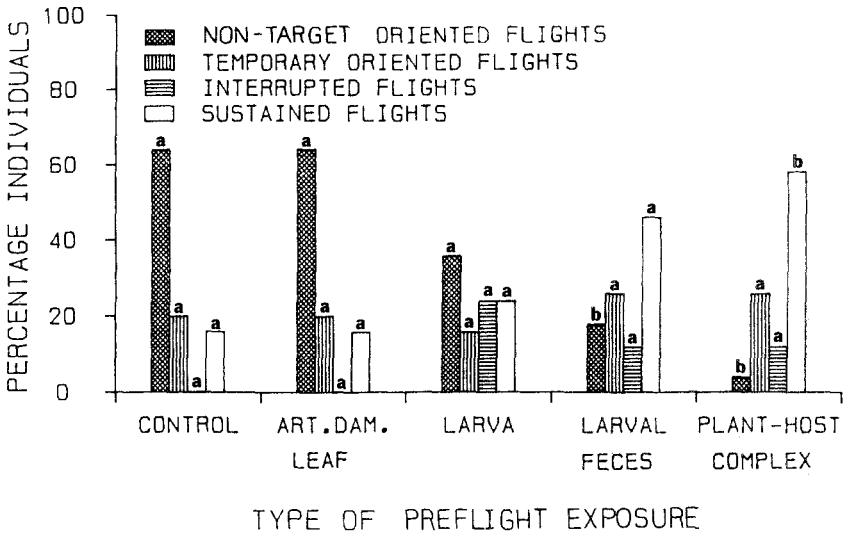

FIG. 4 Percentages of female *Microplitis croceipes* that exhibited various flight responses when provided the indicated preflight exposure. Bars within groups associated with different letters are significantly different (chi-square, $P < 0.05$).

TABLE 1. FLIGHT PERFORMANCE OF FEMALE *M. croceipes* PROVIDED VARIOUS PREFLIGHT EXPOSURES[a]

Preflight exposure	*N*	Sustained flights (%)	Flight characteristics	
			Mean latency ± SE (sec)	Mean navigation time (sec)
Control	25	16.0 a	30.6 ± 11.1 a	8.8 ± 3.2 a
Artificially damaged leaf	25	16.0 a	28.2 ± 11.7 a	10.0 ± 5.4 a
Larva	25	24.0 a	16.9 ± 3.4 a	11.0 ± 2.3 a
Larva feces	24	46.0 a	49.5 ± 12.7 b	15.9 ± 3.9 a
Plant-host complex	24	58.0 b	45.4 ± 11.8 b	12.3 ± 1.9 a

[a] Percentages (chi-square) and means (Duncan's multiple-range test) within columns not associated with the same letter differ significantly ($P < 0.05$).

the vial for a longer time. There were no significant differences in mean navigation times of females that had a sustained flight, which indicated that preflight exposure influences only the initiation of sustained flight.

If exposure to hosts and/or host-associated trail odors is vital for obtaining host-oriented responses of female *M. croceipes*, how do they find a host the first time under natural circumstances? Artificially reared parasitoids are separated from the host before they emerge and thus do not contact host cues before testing. In the field, however, *M. croceipes* emerge in close proximity to the host larva. Although these larvae are unsuitable for oviposition, they may give newly emerged female parasitoids basic information that increases their host selection efficiency significantly.

Second flights were more efficient than first flights. The percentage of sustained flights was significantly higher (74% vs. 52%) and the navigation times significantly shorter (2.6 ± 0.5 sec ± SE, $N = 31$ vs. 13.2 ± 2.1 sec ± SE, $N = 48$). Furthermore, second flights involved more straight flight than first ones. Little time was spent on initial zigzagging and only recurrent zigzagging was observed. Lewis (unpublished data) observed that *M. croceipes* females in field experiments repeatedly flew to visual structures associated with host cues, while Jones (personal communication) observed that *M. croceipes* males, when repeatedly responding to female sex pheromones, recognize visual structures in a flight tunnel. This might be a case of associative learning, and the results discussed above lend additional evidence in that direction.

Maturation did not influence the response of exposed females (Table 2). Data from females with a preflight exposure to larval feces and plant–host complex were pooled and rearranged in three age groups. There were no significant differences in the percentages of sustained flights among the three age groups.

TABLE 2. EFFECT OF AGE ON FLIGHT OF FEMALE *Microplitis croceipes*[a]

Flight characteristics	Response per age class		
	1–2 ($N = 29$)	3 ($N = 11$)	4–5 ($N = 8$)
Sustained flights (%)	68.9 a	45.5 a	75.0 a
Mean latency ± SE (sec)	50.9 ± 12.5 a	50.5 ± 15.9 a	30.9 ± 11.9 a
Mean navigation time ± SE (sec)	15.6 ± 2.8 a	8.6 ± 1.7 a	12.7 ± 2.7 a

[a]Observations of females with preflight exposure to larval feces and plant–host complex were pooled. Percentages (chi-square) and means (Duncan's multiple-range test) across columns not associated with the same letter differ significantly ($P < 0.05$).

TABLE 3. EFFECT OF 24-HR DELAY FROM PREFLIGHT EXPOSURE TO PLANT–HOST COMPLEX UNTIL TESTING ON RESPONSE OF FEMALE *Microplitis croceipes*[a]

	Preflight history and resultant response		
Flight characteristics	Control ($N = 15$)	Immediately after exposure ($N = 15$)	24 hr after exposure ($N = 15$)
Sustained flights (%)	20.0 a	73.0 b	66.7 b
Mean latency ± SE (sec)	7.6 ± 2.4 a	10.9 ± 2.3 a	10.8 ± 1.7 a
Mean navigation time ± SE (sec)	9.7 ± 1.8 a	10.1 ± 1.7 a	10.8 ± 1.7 a

[a] Percentage (chi-square) and means (Duncan's multiple-range test) across columns not associated with the same letter differ significantly ($P < 0.05$).

Experiment 3. Parasitoids exposed to a plant–host complex 24 hr before their first flight were more responsive than those that were not exposed (Table 3). This indicates that preflight exposure causes a prolonged behavioral change.

CONCLUSIONS

The results of this study demonstrate that oriented flight responses of *M. croceipes* to airborne host odors can be studied under laboratory flight tunnel conditions.

Characteristics of the behavioral responses prior to take off and during flight could be observed adequately. Thus, this system is efficient for elucidating behavioral mechanisms of parasitoids mediated by host-associated volatiles. Such experimental tests have not been developed previously for study of parasitoid host-searching behavior.

The nature of the flight responses of *M. croceipes* was strongly affected by preflight exposures to host-related materials. Prior exposure to host feces was the single most important experience for obtaining sustained flight responses to the target. However, preflight exposure to combinations of the plant–host complex was more effective than any of the single components. Influence of the preflight exposure on the flight characteristics lasts for at least 24 hr without any intermediate encounter to such materials. These findings demonstrate the importance of airborne, as well as contact, semiochemicals in the host-searching behavior of *M. croceipes* and show the value of the flight tunnel system as an approach for elucidating the mechanisms of the host-foraging behavior of *M. croceipes*.

(Received March 18, 1985; accepted September 4, 1985)

Abstract—(*E,Z*)-3,13-Octadecadien-1-ol (1a) was identified as the sex pheromone from the poplar twig clearwing moth, *Paranthrene tabaniformis*, females by gas chromatography–mass spectrometry analysis, synthesis, and laboratory bioassays. In the field tests, a trap baited with 200 μg synthetic 1a caught more male moths than two live female moths.

Key Words—*Paranthrene tabaniformis*, poplar twig clearwing moth, sex pheromone, Lepidoptera, Aegeriidae, (*E,Z*)-3,13-octadecadien-1-ol.

INTRODUCTION

3,13-Octadecadien-1-ol (1), its acetate, or the mixture of their geometrical isomers have been identified as sex pheromones, or shown to be sex attractants of many species of clearwing moth (Lepidoptera: Aegeriidae) (Tumlinson, 1979; Tumlinson et al., 1974). Exceptions are *Vitacea polistiformis* which uses (*E,Z*)-2,13-octadecadienyl acetate as its sex pheromone (Schwarz, et al., 1983), and *Synathedon tipuliformis*, for which this compound is a sex attractant (Voerman et al., 1984). Although it was reported (Du et al., 1981; Nielsen and Purrington, 1978) that males of the poplar twig clearwing moth *P. tabaniformis* were

[1] Studies on the identification and syntheses of insect pheromone XXI. Stereoselective synthesis of all the possible optical isomers of the mosquito oviposition attractant pheromone. 0098-0331/86/0600-1263$05.00/0

attracted by a synthetic compound (*E*,*Z*)-3,13-octadecadien-1-ol (1a) by screening tests, the structure of the sex pheromone of this insect remained undetermined. Since *P. tabaniformis* is a primary pest of forests in northern China, the structure determination of the sex pheromone of this insect would facilitate the use of traps for monitoring purposes and would be the first step in the exploration of a possible pest control method. We now describe the structure determination and synthesis of the sex pheromone of the poplar twig clearwing moth.

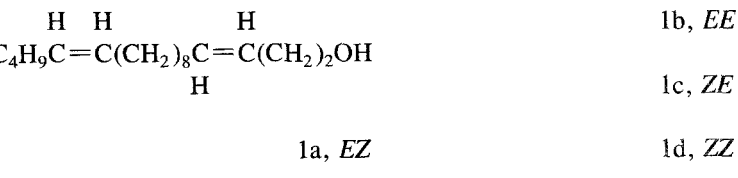
METHODS AND MATERIAL

Pheromone Collection. Moths used in this study were reared on an artificial diet. Details of the insect diet, rearing technique, and the bioassay procedure will be described elsewhere by some of the authors. The ovipositor areas of 1- to 2-day-old unmated females (50 FE) were clipped and extracted with CH_2Cl_2. The extract was filtered over glass wool to remove the solids and then most of the solvent was removed under dry N_2 to an appropriate small volume for analysis.

Instruments for Structure Analysis. Mass spectra were obtained on a Finnigan 4021 GC-MS instrument equipped with a SE-54 capillary column (30 m × 0.25 mm), split ratio 10:1. The column temperature was programmed from 100 to 200°C at 10°C/min. Helium was normally used as the carrier gas. Mass fragmentography was conducted on a Shimadzu QP-1000 GC-MS instrument, FFAP column (50 m × 0.3 mm), column temp 220°C, split ratio 50:1.

Bioassay. EAG (electroantennagram) equipment was home-made according to Roelofs and Comeau (1971). Field tests were conducted in the Beijing area during the adult flight seasons in 1983 and 1984. Delta-type adhesive traps were used and hung on trees about 1.5 m above the ground. Traps were charged with 200–600 μg synthetic lure, using red rubber sleeve stoppers as dispensers.

Synthesis



Many synthetic routes to (1) have been published (Uchida et al., 1978, 1979; Voerman, 1979; Ebata and Mori, 1979; Doolittle et al., 1980; Gardette et al., 1983; Abrams et al., 1983; Vinczer et al., 1984). In this paper, the triple-bond migration method (Zhang et al., 1983; Zhang and Zhou, 1983) was employed, and all the isomers (1a–d) were synthesized from propargyl alcohol (2) in an overall yield of 37%, as illustrated mainly by the preparation of 1a ac-

cording to Scheme 1. The geometric purities of 1a–d were all more than 95%, and these were used in EAG and field tests.

[^{1}H]NMR spectra were recorded in $CDCl_3$ solution with TMS as internal standard on Varian XL-200 and EM-360L spectrometers. Capillary gas chromatographic (CGC) analyses were performed on a Varian 3700 model instrument equipped with DEGS column (40 m × 0.28 mm) at a column temp of 180°C with split ratio of 40:1. Infrared spectra refer to films and were measured on a Perkin-Elmer 577 spectrometer. Mass spectra were obtained with Finnigan 4021 model mass spectrometer with electron impact source. All boiling points were uncorrected.

RESULTS AND DISCUSSION

Structural Determination

The pheromone extract was injected into a GC-MS (SE-54 column) followed by another injection of the synthetic compound 1a for comparison. The mass spectrum and the retention time (R_t) of the natural pheromone were found to be identical with those of the synthetic 1a (Figure 1), indicating the presence of 1 in the female ovipositor area extract. To determine the double bond configuration, the extract was mass fragmentographed (MF) on GC-MS using *m/z* 266 (M^+) and 248 (M-18) (Figure 2B). The four mixed geometric isomers 1a–d were also mass fragmentographed under the same conditions. The synthetic isomers 1a–d gave four virtually baseline-separated peaks on MF with R_t of 18.12, 17.40, 17.05, and 16.42 min for (*ZZ*), (*ZE*), (*EZ*) and (*EE*) isomers. The natural pheromone was shown to be identical to 1a with R_t of 17.05 min (Figure 2A, B). Other evidence was obtained by coinjection of the pheromone extract with 1a on MF. It showed that only the peak with R_t 17.05 min was enhanced (Figure 2C). Further support was obtained by bioassays. The EAG of the synthetic isomers 1a–d were determined at concentration of 1 and 0.1 μg, and the responses in mV were: 1a (1.5, 0.5), 1b (0, 0), 1c (0, 0), and 1d (1.5, 0.5) (Figure 3). Thus both 1a and 1d gave strong EAG responses, while the other two appeared rather weak. However, in the field tests, only 1a was shown to be very attractive to male moths. The trap baited with 200 μg of 1a captured more males than those baited with two live females. In one of the competition tests, traps baited with 200 μg of synthetic 1a captured eight males per trap, while traps baited with one or two females caught 1.5 males per trap (Table 1). The other three isomers are ineffective (Table 2) and seemed to have neither an inhibitory nor synergistic effect toward the sex pheromone in the preliminary binary system tests (Table 3). Thus 1a was established as the sex pheromone of *P. tabaniformis*.

c X = Br

SCHEME 1. *a*. Li-liq. NH_3, *n*-$C_7H_{15}Br$; *b*. NaH-1,2-PDA or 1,2-EDA; *c*. DHP, HCl; *d*. *n*-BuLi/*n*-BuBr; *e*. P-2 Ni, H_2; *f*. TsOH-CH_3OH; *g*. Py-TsCl, LiBr-acetone; *h*. LiC≡CCH_2CH_2OTHP-HMPT; *i*. LAH-Diglyme.

Synthesis

The procedure chosen to prepare 1a is outlined in Scheme 1.

Dec-3-yn-1-ol (3). Reaction of dilithio-2 [prepared from 2 (1.59 mol) and Li (3.18 mol)] with *n*-heptyl bromide (279 g, 1.56 mol) in liq. NH_3 (1500 ml) at −40°C for 3 hr gave 3 (190.2 g) in 80% yield, bp 78–86°C/2 mm.

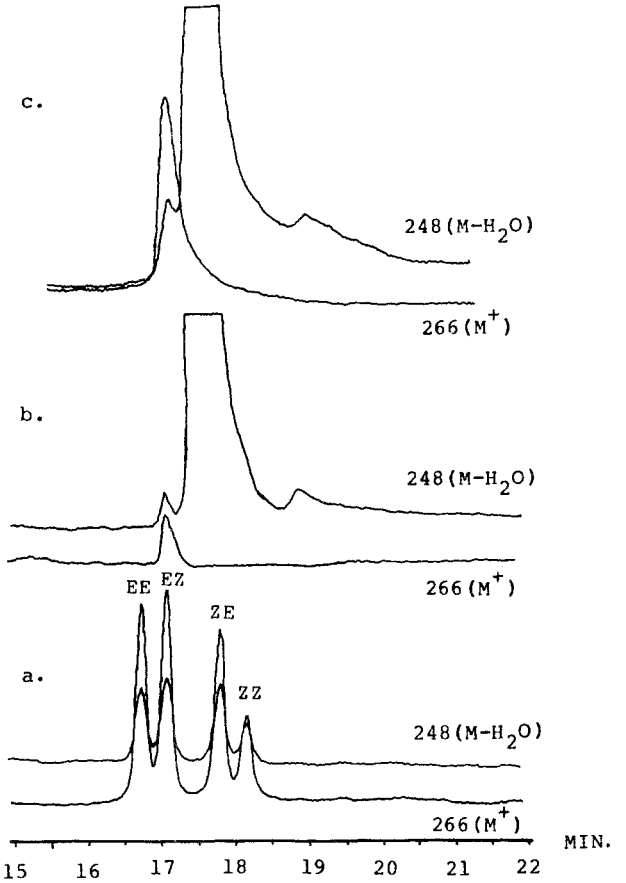

FIG. 2. MF of the sex pheromone of *P. tabaniformis* and synthetic compounds 1a–d. (A) Synthetic compounds 1a–d, (B) pheromone from the extract of the females, (C) coinjection of the pheromone from the extract and compound 1a.

Dec-9-yn-1-ol (4). 1,2-Propylenediamine (100 ml) was added dropwise to NaH (3.7 g, 154 mmol), followed by heating at 70°C for 1.5 hr. After addition of 3 (4 g, 30 mmol), the mixture was stirred at 70°C for 2 hr. The reaction was quenched by addition of aqueous saturated NH_4Cl and extracted with ether. After work-up, 4 (3.3 g) was obtained in 83% yield, bp 135–137°C/23 mm.

The migration of the triple bond in 3 to produce 4 could be monitored by GC (column SE-54, 40 m × 0.25 mm, 170°C, split ratio 70:1), R_t: 3.88 min (R_t: 2.90 min for 3), IR, ν_{max}: 3300(OH), 2130(C≡C) cm^{-1}. NMR, δ: 1.35[12H, br. $(CH_2)_n$], 1.91(1H, OH), 2.13(2H, m, $CH_2C\equiv$), 3.57(2H, m, $C\underline{H}_2OH$).

1-Tetrahydropyranyloxy-9-tetradecyne (5). To a stirred, ice-bath-cooled mixture of 4 (41 g, 0.266 mol) and 0.5 ml HCl, excess dihydropyran (27 g)

was added dropwise followed by stirring for 7 hr at ambient temperature. $NaHCO_3$ (4.5 g) was added, and the mixture was stirred for 1 hr. Upon filteration and evaporation of low boiling impurities, a quantitative yield of crude product was obtained. To the solution of tetrahydropyranyl ether of dec-9-yn-1-ol (30 g, 0.12 mol) obtained above in diglyme (100 ml), a solution of *n*-BuLi in ether (0.15 mol) was added dropwise at 0°C. After evaporation of the ether, *n*-butyl bromide (22 g, 0.16 mol) was added, and the stirred mixture was heated at 140°C overnight. The mixture was poured into ice-water, extracted with ether, and worked up in the usual manner to furnish 5 (29.5 g) in 83.6% yield, bp 137–141°C/0.01 mm.

(Z)-9-Tetradecen-1-ol (6b). Catalytic hydrogenation (Brown and Ahuja, 1973) of 5 (40.7 g, 0.137 mol) over P-2 Ni, and removal of the protecting group (with 11 g TsOH, 280 ml CH_3OH, stirred at room temperature for 8 hr) yielded 6b (33.4 g) in 92.1% yield, bp 107–110°C/0.01 mm. GC: SE-54 column (40 m × 0.25 mm), 180°C, split ratio 70:1, R_t 7.64 min. IR, ν_{max}: 3330(OH), 3010, 1660, 730 (*cis*-CH=CH) cm^{-1}. NMR, δ: 0.89 (3H, t, J = 7, CH_3), 1.31[16H, br, $(CH_2)_n$], 1.87–2.19 (4H, m, CH_2C=), 3.60 (2H, t, J = 6, $C\underline{H}_2OH$), 5.07–5.67 (2H, m, CH=CH).

*1-Bromo-*cis*-9-tetradecene (6c).* The crude tosylate of 6b [prepared from 6b (9 g, 42 mmol) by treatment with pyridine (50 ml) and TsCl (10 g) at 10°C for 2.5 hr] was refluxed with LiBr (6.2 g, 71 mmol) in acetone (60 ml) for 4 hr to afford the corresponding bromide 6c (9.3 g) in 94.4% yield, bp 88–96°C/0.01 mm.

(Z)-1-Tetrahydropyranyl-octadec-13-en-3-yne (7). To a solution of 6c (13.7 g, 47.9 mmol) in HMPT (50 ml), a solution of $LiC{\equiv}CCH_2CH_2OTHP$ (50.8 mmol) in THF (50 ml) was added. The temperature was kept at 0–10°C overnight to yield 7 (12.5 g) in 94.7% yield.

(E,Z)-3,13-Octadecadien-1-ol (1a). Decetrahydropyranylated 7 (4.9 g) was treated with $LiAlH_4$ (3 g) and diglyme (60 ml) (Rossi and Carpita, 1977) at 140°C for 9 hr to yield a crude product which was further purified by flash column chromatography over SiO_2 (eluted with 10% ethyl acetate–*n*-hexane) to give 1a (3.96 g) in 80.8% yield. The overall yield of 1a from 2 was 37%. Calcd. for $C_{18}H_{34}O$: C, 81.13, H, 12.86. Found: C, 81.00, H, 13.19. IR, ν_{max}: 3300(OH), 3010, 960, and 730 (*trans*- and *cis*-CH=CH) cm^{-1}. NMR, δ: 0.83 (3H, t, J = 7, CH_3), 1.26 [16H, br, $(CH_2)_n$], 1.47–2.3 (8H, m, CH_2C=), 3.60 (2H, t, J = 7, $\underline{CH_2}OH$), 5.24–5.6 (4H, m, CH=CH). MS, *m/z*: 266 (M^+, 1.6%), 248 (M-H_2O, 0.5%), 54 (100%). CGC(DEGS) analysis showed that 1a contained (*EZ*) 95.1%, (*EE*) 2.9%, (*ZZ*) 1.1%, (*ZE*) 0.9% with R_t of 25.25, 24.12, 27.68, and 26.36 min.

The other three isomers (1b–d) were synthesized in a similar manner to 1a with the only difference being the use of $LiAlH_4$-diglyme treatment in place of partial hydrogenation over P-2 Ni to introduce a *trans* double bond at C_{13} or to introduce the *cis* configuration at position C_3. Compound 1b contained (*EE*) > 95%, (*ZZ*) 3%, (*ZE*) 1%, (*EZ*) 1%; 1c, (*ZE*) 95.2%, (*EE*) 3.5%, (*ZZ*) 1.3%; 1d, (*ZZ*) 95.2%, (*ZE*) 2.7%, (*EZ*) 1.0%, (*EE*) 1.1%. All compounds (1b–d) were fully characterized by IR, NMR, and MS spectrometry.

CONCLUSION

The chemical and biological data presented in this paper are strong evidence that (*E,Z*)-3,13-octadecadien-1-ol (1a) is a sex pheromone of *P. tabaniformis*. In addition to 1a, all the other geometric isomers have been synthesized. The preliminary data indicated significant attractiveness of the *EZ* isomer alone; the other isomers were inactive and seemed to have neither inhibitory nor synergistic effects toward the *EZ* isomer. Synthetic 1a has been used for monitoring and in a large-scale control program for *P. tabaniformis* since 1983.

In the field tests, one of the synthetic isomers, 1d-(*ZZ*), although inactive toward *P. tabaniformis*, was highly attractive to the poplar large hornet moth *Aegeria apiformis* Clerk that also belongs to Aegeriidae. The structure identification of the sex pheromone of *A. apiformis* is under way in cooperation with Zhang Zhi-Yong and his coworker of Shan-Xi Agricultural University.

Acknowledgments—The authors are grateful to Professor Yang Ping-Lan of Shanghai Institute of Entomology for the suggestion to undertake this study.

FIELD STUDIES ON CHEMICALLY MEDIATED BEHAVIOR IN LAND HERMIT CRABS: Volatile and Nonvolatile Odors[1]

DAN RITTSCHOF and JOHN P. SUTHERLAND

Duke University Marine Laboratory
Beaufort, North Carolina 28516

T.H. Curran Marine Field Station
West Esterillos, Costa Rica

(Received July 1, 1985; accepted September 3, 1985)

Abstract—Land hermit crabs, *Coenobita rugosis*, were tested in the field in Costa Rica for behavioral responses to odors. Volatile odors associated with horse feces, fruit, and honey attracted crabs within minutes. Odors from dead gastropod flesh were not immediately attractive, but after aging, odors from a variety of flesh sources attracted crabs. Crabs fed actively upon the materials that attracted them. Feeding behavior was stimulated by components of fruit juice and fresh gastropod flesh juices of less than 10,000 daltons, honey, a 0.5 M sucrose solution, and a saturated solution of tyrosine. Twenty additional amino acid solutions tested at 0.1 M concentration were weak feeding stimulants at best. Chemical cues controlled feeding behavior, but not shell acquisition; *C. rugosis* were not differentially attracted to flesh odors or to living gastropods whose shells they occupied.

Key Words—Chemoreception, Crustacea, odors, *Coenobita rugosis.*

INTRODUCTION

With the exception of chemoreception studies using components of crude oil, kerosene, and drilling muds (reviews, Sutterlin, 1974; Atema, 1976; Epifanio, 1979; Pearson and Olla, 1979, 1980; Pearson et al., 1981) and ammonium (Carter and Steele, 1982; Zimmer-Faust et al., 1984a), there are few journal reports of responses of decapod crustaceans to volatile odors. In water, solubility rather than volatility is a major consideration (Atema, 1982). Separation

0098-0331/86/0600-1273$05.00/0

of responses to volatile and nonvolatile odors is especially difficult with aquatic organisms because water carries nonvolatile water-soluble cues as well as volatile water-soluble cues. In addition, volatiles may be transported absorbed to particulates, in miceles and crystals (Epifanio, 1979). Thus, in water, volatile and nonvolatile cues can function in distance chemoreception, while in air, under most atmospheric conditions, only volatile molecules can function in distance chemoreception.

Feeding responses of aquatic organisms in general (Bardach, 1975; Atema, 1982) and in crustaceans specifically (Bardach, 1975; Ache et al., 1976; Ache, 1977, 1982; Fuzessery et al., 1978; Pearson et al., 1979; Robertson et al., 1980, 1981; Zimmer-Faust et al., 1984a,b; Carr and Derby, 1986; Derby and Atema, 1982a–c; Derby and Ache, 1984) have focused on crude aqueous extracts, polar, nonvolatile compounds (proteins, amino acids, nucleotides, sugars) or secondary plant compounds (Derby et al., 1984). That volatile components contribute to crustacean feeding responses has been demonstrated, but not fully assessed.

Because air is the transport medium, responses of terrestrial crustaceans to volatile components can be easily separated from responses to nonvolatile compounds in complex mixtures. We chose the land hermit crab, *Coenobita rugosis*, for field studies because morphological, behavioral and natural history information suggested land hermit crabs might detect volatile substances. Studies of *Coenobita* antennules (crustacean sensory structures) indicate that they have arthropod olfactory reception morphology (Ghiradella et al., 1968). Antennal flicking, a way of maximizing sampling of the environment (Schmitt and Ache, 1979) is an obvious feature of land hermit crab behavior. Finally, in the field we observed the omnivorous nature (e.g., Hazlett, 1981; Page and Willason, 1983) and apparent olfactory abilities of land hermit crabs. Hermit crabs arrive at and feed upon distinct food islands such as feces, carrion, and fruit within minutes of their deposition. Kurta (1982) investigated first arrivals and total number of *C. compressus* coming within 12.5 cm of 30- to 35-mm-diameter turtle eggs and did not demonstrate olfactory ability. However, Kurta pointed out that the high density of crabs in the study area could have resulted in lack of sensitivity of his test measures and that social facilitation (Wilson, 1975) of responses confounded the interpretation of data with respect to olfaction. We designed our tests to minimize confounding variables and maximize assay sensitivity with respect to Kurta's observations.

The relative ease of chemical separation of volatile from nonvolatile substances in air, coupled with the omnivorous habits of land hermit crabs should provide information applicable to studies of olfaction in Crustacea in general. Understanding the chemoreceptive abilities of land hermit crabs as well as the chemistry of the volatile attractant compounds should broaden our perspectives on the potential for experimentation with volatile water-soluble compounds in olfaction studies with other terrestrial, semiterrestrial, and aquatic crustaceans.

Additionally, we can make comparisons of the factors of biological importance for aquatic and terrestrial hermit crabs. For example, shells are of major importance to intertidal and subtidal populations of most hermit crabs studied (for review see Hazlett, 1981). Populations are limited by shell availability (Vance, 1972) and fitness of individuals is affected by shell fit (Bach et al., 1976). Aquatic hermit crabs have highly specialized behaviors associated with locating and procuring shells (McClean, 1974; Hazlett, 1981; Rittschof, 1980a; Wilber and Herrnkind, 1982, 1984; Gilchrest, 1982). Specific shell acquisition behaviors are mediated by nonvolatile molecules released from the flesh of dead gastropods (Rittschof, 1980a,b), and these cues are instrumental in the location of new shells by crabs (Wilber and Herrnkind, 1984). In field tests, aquatic hermit crabs do not respond to food (McClean, 1975; Rittschof, 1980a; Gilchrest, 1982), although they do in the laboratory (Hazlett, 1971a,b). Thus, shell acquisition behavior is not associated with feeding. In this regard, we asked the general question: How do land hermit crabs compare to local aquatic hermit crabs with respect to responses to odor cues from flesh food sources and flesh sources associated with the potential availability of gastropod shells?

METHODS AND MATERIALS

Study Area. The study area was a 15 × 3-m crescent-shaped stretch of sand at the base of a bluff approximately 0.8 km west of West Esterillos, Costa Rica. The area is the mouth of a creek during the rainy season, but at the time of the study, April 1985, the creek was dry. The sand was damp at the base of the bluff due to slight seepage. The damp ground was covered with driftwood and the fallen trunks of several large trees. Three mature almond trees bearing and dropping fruit shaded the area after 0900 hr. Dry beach sand stretched from the fallen trees toward the Pacific Ocean for approximately 4 m to the mean high water mark. Land hermit crabs, *Coenobita rugosis*, were in evidence at all times. They were especially abundant in the daytime in the damp sand feeding on almonds. In the daytime, however, about 70% of the crabs could be found in refuges under and within the rotting logs.

At night, the crabs left the shelter of the logs and ranged between the bluff and the surf. Experiments (described below) were conducted near (olfactory tests) or in areas (taste tests) heavily traveled by crabs at all times. Most studies were conducted on dry sand along an irregular line 30 cm to the Pacific Ocean side of the fallen logs.

Tests of Attraction by Volatile Compounds. In tests for attraction of crabs by volatile odors, behavioral assays used pitfalls to eliminate touch and vision as means of sensory input about test substances. Attractive volatile odors were defined operationally as those that evoked investigation by crabs. Two types of assays were conducted. Pitfalls in both assays were 115-ml polypropylene bot-

tles with their tops cut off. The pitfalls were buried flush with the sand in a single line at approximately 1.0-m intervals along the line of logs mentioned above. Fallen almonds were removed from the vicinity within 2 m of the pitfalls. Daytime assays were conducted for 40 min each, between 1200 and 1700 hr. We reduced the likelihood that random movements by the crabs would be mistaken for positive responses by: (1) placing pitfalls in areas near to, but not directly in regions of, high crab activity and (2) by choosing a target diameter for determining a positive response of 5 cm. Visual cues were eliminated by placing odor sources in pitfalls. Social facilitation (Wilson, 1975; Kurta, 1982) was eliminated by collecting responding individuals immediately. Test substances were placed in every other pitfall (4–6 of each type), and every crab that touched a pitfall was captured, recorded, and held until the experiment was completed. Each test was repeated at least twice and on different days. Nighttime assays were initiated at 2000 hr and terminated at 0400 hr the following morning. Flesh responses and responses to living gastropods were tested at night. The number of crabs in control and experimental pitfalls (those containing potential attractants) were counted.

Different endpoints for the assays were used because crabs did not fall into the traps in the daytime and the crabs were disturbed by lights at night. We assumed vision was not a factor at night because crabs fell into traps. In both types of assays, the null hypothesis that there was an equal response to control and experimental pitfalls was tested with the G statistic with one degree of freedom (Sokal and Rohlf, 1981). Because of the relatively large number of tests performed, the null hypothesis was rejected only with probabilities of $P < 0.01$. Because of the large number of crabs in the area and the impossibility of individual marking, only within-test comparisons were made.

Test Substances—Volatile Odors. The origins of all test subtances containing volatile odors were complex mixtures of volatile and nonvolatile compounds. Separation of volatile from nonvolatile compounds was by the pitfalls described above. In all tests, winds were light, approximately 5.0 km/hr or less. Excreta, fermentation products, fruit, honey, living gastropods, and dead flesh odors were tested for attractiveness to crabs. Excreta included fresh horse feces (about 10 g/pitfall) and human urine (20 ml/pitfall). Fermentation products were a solution containing actively fermenting baker's yeast growing for 3 hr in a 0.25 M sucrose solution and a 5% acetic acid solution (20 ml/pitfall). Fruits included 5- to 10-g samples of banana, coconut, mango, and cashew fruit. Honey was diluted 1 : 5 with boiled sea water and tested at 20 ml/pitfall.

Living flesh included 0.1–0.3 g (wet tissue weight) of the coiled gastropods *Nerita scabricosta*, *Nerita funiculata*, and *Planaxis planicostata*. Living snails were kept from escaping and were protected from hermit crabs by small bags made of plastic screening. Dead flesh included 0.3- to 3.0-g samples of the coiled gastropods *Nerita scabricosta* and *Acanthina brevidentata*, the limpets *Siphonaria gigas* and *Fissurella virescens*, 0.1–0.3 g of the flesh of an

unknown aquatic hermit crab, and 4.0–5.0 g of an unknown holothurian. The coiled gastropods are utilized for protection by *Coenobita*, while the limpets are unsuitable for this purpose. Night observations at low tide revealed *C. rugosis* frequented the habitat of the living gastropods. All animals were killed by freezing for 4–8 hr prior to use. After thawing, the flesh was allowed to stand for 1 hr to "age" before using it in an experiment (see Rittschof, 1980b).

Tests of Feeding Stimulation. Tests of feeding stimulation used feeding movements (placement of chaelae to the mouthparts) as an endpoint. Test solutions including a boiled seawater control were presented to the crabs either soaked into paper towels (paper towel assay) or loaded into segments of dialysis tubing (10,000-dalton cutoff) which were placed along paths heavily traveled by crabs. In order to control for differences in crab distribution, three types of data were collected: (1) the number of crabs walking within 2.5 cm of the test solution but not contacting it, (2) the number of crabs walking within 1.5 cm of this solution and contacting it, and (3) whether or not a crab fed after contacting the test solution. The former data allow consideration of any volatile attractants in the test solution. The latter measures whether the test solution actually stimulated feeding. Experiments with honey, melon juice, and seawater were conducted for 40 min. All other tests were conducted until 15 crabs had contacted a particular test solution. In the latter, 20–30 min were required for a total of 15 crabs to contact a test solution.

Test Substances—Nonvolatile Odors. Sources of nonvolatile compounds were complex mixtures and seawater solutions of nonvolatile compounds. Mixtures included melon juice, honey, and homogenates of limpet flesh. Nonvolatile solutions were cane sugar and 21 L-amino acids (Sigma Chemical Corporation, St. Louis, Missouri, kit No. LAA-21). These were tested for induction of crab feeding responses. Melon (honeydew) juice was from the rind of a locally grown melon. Honey was local honey diluted 1 : 5 with boiled seawater. Sugar solutions were from locally processed cane sugar and were made up in boiled seawater at 0.1 and 0.5 M concentrations. Limpet homogenates were 3 g fresh limpet flesh (*Siphonaria gigas*) macerated in 18 ml of boiled seawater with stainless-steel dissecting scissors. The limpet macerate was mixed several times and allowed to stand for 5 min before the light brown solution was decanted and used in experiments. No more than 30 min elapsed between the killing of a limpet and the completion of testing of its juices. The 21 L-amino acids were dissolved in boiled seawater to a final concentration of 0.10 M.

Tests with Local Hermit Crabs. Tests of responses of *Clibinarius* spp. and tidal pool *Calcinius* spp. were performed to determine their responsiveness to flesh from coiled and uncoiled gastropods. Tests were patterned after Rittschof (1980b). Frozen and thawed gastropod flesh (5 g/container) were placed in perforated polypropylene bottles and the bottles with and without flesh placed at 1-ml intervals in tidal pools. Aquatic crabs touching the containers were removed and counted.

TABLE 1. RESPONSES OF *Coenobita rugosis* TO WASTE AND FERMENTATION ODORS

Odor source	Number responding		G	Significance
	Control	Treatment		
Horse feces	2	58	65.0	<.01
Human urine	7	15	2.9	NS
Yeast	8	17	3.2	NS
Acetic acid	4	0	—	NS

RESULTS

Responses to Volatile Odors. When tested with waste and fermentation odors, land hermit crabs responded significantly only to the odor of fresh horse feces (Table 1). Although fermenting yeast, human urine, and 5% acetic acid all have distinct odors to humans, crabs were not significantly attracted to these odors in the assay interval. In contrast, *C. rugosis* responded significantly to the odor of honey and several kinds of fruits (Table 2). *C. rugosis* did not respond to freshly killed *Siphonaria gigas* (Table 2).

In overnight assays, odors from the flesh of animals were highly attractive to hermit crabs (Table 3). This was true even when the flesh was of limpets and holothurians, organisms unsuitable as shell sources. In contrast, tests of two genera of intertidal hermit crabs showed these crabs responded specifically to odors of dead gastropods with shells of a type that could be occupied and not to odors from limpet flesh (Table 4). There was no evidence that *C. rugosis* was attracted to living snails (Table 5).

Tests of Feeding Responses. The distinction between attraction by volatile compounds and stimulation of feeding responses is illustrated by comparison

of the response of crabs to towels soaked in melon juice (a mixture of both types of stimulant) and to 0.5 M sucrose (Table 6). Every crab passing within 2.5 cm of the melon juice-soaked towels was attracted to the towel and stimulated to feed. More crabs actually passed within 2.5 cm of the towel soaked in the 0.5 M sucrose without touching it, than touched it. However, every crab that touched the more concentrated sugar solution showed feeding behavior. In total, 28 different solutions were tested for stimulation of land hermit crab feeding activity with the paper towel assay (Table 6). Two of the complex mixtures tested, melon juices and honey, contained both attractant and feeding-stimulant activity. Two other solutions, 0.5 M sucrose and complex mixture of fresh meat juices from the limpet, *Siphonaria gigas*, elicited feeding activity but did not attract crabs. Dilution of sucrose to 0.1 M resulted in a decrease in feeding stimulation from 100% in the case of 0.5 M to 6%, a level of feeding stimulation observed with several amino acid solutions. Of the 21 amino acid solutions, each tested at 0.1 M concentration, none gave evidence of attractant activity and only eight stimulated at least one crab to feed (Table 6). Tyrosine, not completely soluble in seawater at 0.1 M concentration, was the amino acid most notable as a feeding stimulant, evoking feeding in 5 of 15 cases. Histidine solutions appeared to elicit contact-dependent repellent activity. Every crab

contacting a towel soaked in histidine backed up immediately and did not touch the towel a second time.

The paper towel assay showed that juice from the flesh of *Siphonaria gigas* stimulated feeding responses in land hermit crabs when the crabs encountered the solution. Flesh juice prepared from freshly killed *S. gigas*, encased in 10,000-dalton cutoff dialysis tubing also elicited feeding responses from every crab touching the tubing (Table 7). There was no evidence of volatile attractants as crabs no contacting the tubing passed by it. As was the case with the paper towel assay, crabs were not attracted to the control tubing containing boiled seawater and did not show feeding responses when they contacted it (Table 7).

DISCUSSION

Coenobita rugosis is an omnivorous crab that detects volatile odors and nonvolatile odors of both plant and animal origins. It can use olfaction to locate fruits, honey, feces, and the flesh of dead animals from a distance. When crabs contact the materials emitting the odors (with either their antennules or dactyls), feeding is stimulated. Solutions of sucrose, fresh flesh juices, and saturated solutions of tyrosine were not attractive from a distance, but were feeding stimulants when contacted by crabs. This suggests nonvolatile components are sufficient to cue feeding responses. Unlike its tidepool counterparts that are attracted only to flesh of specific species of gastropods whose shells they occupy, *C. rugosis* are attracted to food and do not exhibit odor-oriented shell acquisition behavior (McClean, 1974). This observation is supported by the fact that *C. rugosis* are not differentially attracted to the flesh of gastropods which are potential shell sources. There is no evidence that *C. rugosis* are attracted to living gastropods.

The possibility that *C. rugosis* can detect conspecifics was not addressed directly in this study. The possibility has been suggested that numbers of crabs captured in nighttime pitfall assays are due to a combination of attraction to odor of test substance and to conspecifics. Examination of the total data set with respect to all control animals and to odor sources found not to be attractive suggests that this is not true (see Tables 3 and 5). Although it is obvious that

crab activity, as measured in control pitfalls, varies markedly from night to night (12–75 animals captured), it is also obvious that responses to empty pitfalls and to substances deemed unattractive (living snails) were similar and did not overlap with frequency of response to what we have concluded are attractive odors. This suggests that there is not a general olfactory attraction to conspecifics.

The terrestrial existence of *C. rugosis* dictates the types of substances that can transmit information over a distance. This is most dramatic in the case of nonvolatile compounds. Where polar, nonvolatile chemicals can transmit specific information over tens of meters to hermit crabs in the water (Rittschof, 1980a,b), these same compounds are only detected upon contact by *Coenobita rugosis*. A biological consequence is the elimination of distance detection of coiled gastropod shells using peptides from snail flesh (Rittschof, 1980b), a major way that aquatic hermit crabs normally acquire shells (Wilber and Herrnkind, 1984). Although it is thought that land hermit crabs obtain access to shells mainly as a result of storm action (Hazlett, personal communication), *C. rugosis* were observed at low tide at night walking in the immediate vicinity of the various species of gastropods used in this study. As shelter of some form is essential for hermit crabs (for review see Hazlett, 1981), the questions of how land hermit crabs find shells and if they use volatile cues in the process are salient ones. If aquatic hermit crabs are starved, it is difficult to separate their shell acquisition responses from feeding responses in the laboratory (Rittschof, unpublished data). Thus, one might expect that well-fed land hermit crabs might exhibit behaviors not observed in this study. In circumstances in which food is in abundance, *C. rugosis* may display chemoreception-dependent shell acquisition behavior as do many aquatic hermit crabs (McClean, 1975; Rittschof, 1980b; Gilchrest, 1982).

In contrast to nonvolatile compounds, volatile compounds can function similarly as distance cues in either aquatic or terrestrial environments. The effectiveness of a volatile molecule in water will be dependent upon the solubility of the compound in water and the sensitivity of the olfactory receptor (Atema, 1982). Given identical receptor sensitivity and because of scale considerations, transport by advection, the effective transmission distance (the distance from the source that the stimulus still evokes a response) of a water-soluble volatile molecule in air and in water would be dependent upon the specific molecule. Because of the greater than 1000-fold slower rate of diffusion in water, depending upon turbulence, the effective transmission distance in water can be greater in water than in air if solubility is high.

Because their feeding responses include frugivory, detritiverory, and carnivory, *C. rugosis* provide a model system for examining and dissecting the relationship between volatile and nonvolatile compounds in crustacean feeding responses common to aquatic crustaceans. In future investigations we will test the hypothesis that soluble volatile compounds that cue feeding responses in

land hermit crabs also function to cue feeding responses in semiterrestrial and aquatic crustaceans.

PROPAGANDA SUBSTANCES IN THE CUCKOO ANT *Leptothorax kutteri* AND THE SLAVE-MAKER *Harpagoxenus sublaevis*

ANTHONY B. ALLIES, ANDREW F.G. BOURKE, and NIGEL R. FRANKS

School of Biological Sciences, University of Bath
Claverton Down, Bath, Avon BA2 7AY, U.K.

(Received May, 17, 1985; accepted September 3, 1985)

Abstract—This paper reports the first discovery of "propaganda substances" in a workerless inquiline ant, the European myrmicine *Leptothorax kutteri* Buschinger. These substances are used by the parasite queen as a chemical weapon for defense against hostile workers of the host species *L. acervorum.* The substances also have an unusual behavioral effect: they cause host workers to attack each other, and they therefore appear to override nestmate recognition in host colonies. Laboratory experiments show that the source of these substances is the Dufour's gland of the *L. kutteri* queen. Our experiments also confirm the hypothesis that the closely related slave-making ant *Harpagoxenus sublaevis* uses its Dufour's gland secretions as a chemical weapon during slave raids and colony foundation. The behavioral effect of these slave-maker secretions is identical to that of *L. kutteri* queens.

Key Words—Dufour's gland, Formicidae, Hymenoptera, inquiline ant, slave-making ant, *Harpagoxenus sublaevis*, *Leptothorax kutteri*, *Leptothorax acervorum*, pheromone, nestmate recognition.

INTRODUCTION

Inquiline ants have the unusual ability to infiltrate colonies of ants of other species and to become accepted by their members. However, compared to our knowledge of the colony infiltration methods of myrmecophiles (e.g., see Hölldobler 1970, 1971; and review of Kistner, 1979), there is relatively little known about how inquiline queens accomplish these feats (see reviews of Wilson, 1971; Dumpert, 1981). For instance, it is not known how the inquiline ant *Leptothorax kutteri* (Buschinger, 1965) manages to infiltrate colonies of its host *Lep-*

0098-0331/86/0600-1285$05.00/0

tothorax acervorum. In laboratory introductions the parasite queens are usually attacked by *L. acervorum* workers from the target colony (Buschinger, 1965, and personal communication; Franks, unpublished observations). In such introduction experiments, *L. kutteri* queens display none of the behaviors previously recorded in inquiline foundresses (see Discussion). Instead, this paper demonstrates that they deploy a "propaganda substance" as a defense against the attacks of the target colony workers. *L. kutteri* is the first inquiline in which such substances have been found. Nevertheless, the manner in which the parasite queens follow up this strategem and come to be tolerated by their hosts remains an unsolved problem.

Propaganda substances were first described in slave-making *Formica* from North America (Regnier and Wilson, 1971). On slave raids these ants broadcast mimics of alarm pheromones among resisting host workers, causing them to panic and flee. The substances used by *L. kutteri* have a different behavioral effect. They cause host workers to attack each other, and they therefore appear to override nestmate recognition in host colonies.

In addition, this paper shows that the slave-making ant *Harpagoxenus sublaevis*, another parasite of *L. acervorum* and also a close relative of *L. kutteri*, possesses substances which have a similar effect on *L. acervorum* workers during conflicts between the slave-makers and host colonies, that is during slave raids by *H. sublaevis* workers and in colony foundation by the queens. The most obvious adaptation of *H. sublaevis* females for fighting is their possession of large and secateur-like mandibles, with which they dismember their opponents. The existence of chemical weapons in this species was first suggested by Buschinger (1974a) when he recorded that *L. acervorum* workers may attack each other following contact with slave-raiding or colony-founding *H. sublaevis* females. Similar phenomena have been observed by Alloway (1979) during slave raids by *H. americanus* on its North American *Leptothorax* hosts. We also observed an effect of this type in laboratory introductions of *L. kutteri* queens to *L. acervorum* colonies. In *H. sublaevis* it was suggested (Buschinger, 1974a) that the effect is due to a pheromone from the Dufour's gland which the slave-maker wipes onto its opponent with its sting. The Dufour's gland secretion of *H. sublaevis* has also been proposed to act as a repellent which the slave-makers smear over captured brood in order to deter would-be *L. acervorum* rescuers (Winter, 1979; Buschinger et al., 1980).

Remarkably, in both *H. sublaevis* and *L. kutteri*, the Dufour's gland is hypertrophied (Buschinger, 1974b). Therefore our first experiment was to test under standardized conditions whether or not contact with *L. kutteri* caused *L. acervorum* workers to be attacked by their nestmates. Following a positive result, our second experiment tested the hypothesis that it is the Dufour's gland secretions of *L. kutteri* and *H. sublaevis* that contain the parasites' propaganda substances.

METHODS AND MATERIALS

All the ants used in the experiments came from colonies collected in sourthern Sweden in July 1983. Both *L. acervorum* and *H. sublaevis* are widespread in central and northern Europe, but *L. kutteri* is known only from sites in West Germany, the Alpine region, and Sweden (Buschinger, 1965; Douwes and Buschinger, 1983). The colonies were found in pine forests in hollow dead twigs on the ground. They were maintained in the laboratory, and the experiments were carried out between October 1983 and June 1984.

Experiment 1. Single *L. acervorum* workers were removed from unparasitized colonies and confined in arenas (100 cm^2) with either (1) single newly inseminated *L. kutteri* queens, (2) single *L. acervorum* queens from another nest, or (3) single *L. acervorum* workers from another nest. The behavior of the pairs of ants was then observed. After 60 min the workers were returned to their own nests, and the behavior of their nestmates towards them was recorded.

Experiment 2. We tested the response of *L. acervorum* workers to nestmates treated with extracts of the Dufour's gland of *L. kutteri* queens, *H. sublaevis* females, and, as controls, queens of *L. acervorum*. The *H. sublaevis* females were not classified as workers or queens because in this species most queens are identical in external morphology to workers. The colonies tested in the trials were unparasitized colonies of *L. acervorum*. For every trial, a set of four replicate portions was made from each colony by selecting at random four groups of three workers and housing each group in its own small arena (4 cm^2). We then added to three of these replicate portions a nestmate treated with either (1) an extract of Dufour's gland contents, (2) an extract of poison vesicles, or (3) solvent alone.

The glandular extracts were prepared by first dissecting ants in distilled water. The glands were then removed and crushed whole in liquid paraffin (mineral oil). This solvent was used because, unlike hexane, for example, it was not toxic to the ants. Since the Dufour's gland volumes of *L. kutteri* and *H. sublaevis* are, respectively, about 40 and 60 times that of the *L. acervorum* queen, the *L. kutteri* Dufour's gland extracts contained 6 glands/10 μl of solvent (giving a concentration of 1.5×10^{-2} μl gland content/μl of solvent), and the *H. sublaevis* Dufour's gland extracts contained 4 glands/10 μl of solvent (concentration 1.6×10^{-2} μl gland contents/μl solvent). In the *L. acervorum* queen trials (since here the Dufour's gland is very small), we used single glands crushed in single paraffin droplets (concentration 1.3×10^{-3} μl gland contents/μl solvent). Poison extracts contained the same number of glands as corresponding Dufour's gland extracts. Poison extract was used in these trials as an additional control, to test whether other endogenous substances, in general, could induce hostility.

All the ants which were introduced to the groups of workers were first

marked with paint dots on their heads. The glandular extracts (or liquid paraffin alone) were then applied to the thorax with a pinhead. The average volume applied was 0.50 ± 0.15 μl (determined by weight). Therefore, in the case of the ants treated with Dufour's gland extract, each ant received the equivalent of either 0.29 of an average *L. kutteri* gland, or 0.21 of a *H. sublaevis* gland, or a whole queen *L. acervorum* gland (since here the whole paraffin droplet in which the gland had been crushed was applied). Sixty minutes after the addition of each treated ant to the arena of nestmates, we recorded whether or not it was being bitten. This we defined as an attack. The time interval guaranteed that any attack was not a temporary response to a new object in the arena. Finally, a worker from a different unparasitized *L. acervorum* colony was added to the fourth replicate portion of the trial colony. This worker was also marked with a paint dot, and its reception in the arena was recorded in the same way as that of the treated ants. Only the results from trials in which this alien was attacked were considered valid. This ruled out trials in which the unfamiliar surroundings of the test arena might have lead to a lack of hostility to any introduced worker.

RESULTS

Experiment 1. As regards response of workers to nestmates confined with *L. kutteri* queens or alien conspecifics: the *L. acervorum* workers always fought with the ant with which they were confined, whether it was a queen *L. kutteri*, an alien *L. acervorum* queen, or an alien *L. acervorum* worker. In these fights the *L. kutteri* queens were seen to daub the *L. acervorum* workers with a clear viscous fluid which they released from the tip of the abdomen. This behavior was not observed in *L. acervorum* workers or queens. When the *L. acervorum* workers which had been with the *L. kutteri* queens were returned to their home colonies, all of them were attacked by their nestmates (Table 1). Workers which had been with either worker or queen alien conspecifics were attacked only very rarely when returned to their own nests (Table 1). This suggests that a *L. kutteri* queen can contaminate a hostile host worker with a secretion which causes the worker to be attacked by its nestmates.

Experiment 2. As regards response of workers to nestmates treated with gland extracts: *L. acervorum* workers treated with extracts of the Dufour's gland contents of *L. kutteri* and *H. sublaevis* were significantly more likely to be attacked by their nestmates than were workers treated with either extracts of the contents of the poison vesicles or with liquid paraffin alone (Table 2, columns A and B). Furthermore, extracts of the Dufour's gland substances of *L. acervorum* queens did not induce attack by nestmates at a significantly greater frequency than did the control solvent (Table 2, column C). These results suggest that the hostility-inducing substances of *L. kutteri* and *H. sublaevis* originate in

the Dufour's gland and that the active agents in these secretions are either absent or present in only very small amounts in the Dufour's glands of *L. acervorum* queens.

DISCUSSION

The substances used by *L. kutteri* queens when they encounter foreign host colonies and their behavioral effects are, as far as we know, unique among inquilines. Other species of inquiline, in which single queens enter large, mature host colonies, use a variety of techniques, but none of them involve substances which cause host workers to fight one another. For example, the inquiline queen *Anergates atratulus* appears to play dead when met by a worker of the host species *Tetramorium caespitum*. She then clings with her jaws onto the worker's antenna and is dragged into the nest (Wheeler, 1910; Gösswald, 1954). *Epimyrma stumperi* either plays dead in a similar manner, or captures a *Leptothorax tuberum* host worker, rubs it with her forelegs, and grooms herself, apparently acquiring the host's colony odor in this way (Kutter, 1969). Another parasite of *Tetramorium caespitum*, *Teleutomyrmex schneideri*, employs a third type of entry method. She seems to appease the host workers with surface glandular secretions (Stumper, 1950; Gösswald, 1953).

How *L. kutteri* queens penetrate host colonies in the field has never been observed. The possibility cannot be excluded that the parasite queen enters colonies at the founding stage, as suggested in the inquilines *Strumigenys xenos* (Brown, 1955) and *Pogonomyrmex colei* (Rissing, 1983). It is also conceivable that *L. kutteri* queens transfer to daughter colonies during budding of the host colony, as may occur in *Plagiolepis xene* (Passera, 1964). However, the occurrence of single *L. kutteri* queens in isolated *L. acervorum* colonies (Buschinger, personal communication) suggests that at least some parasite colonies are founded by lone *L. kutteri* queens entering mature host colonies. From our

results, we would expect these invading queens always to be attacked by the target colony workers. In all of the 15 laboratory introductions of single *L. kutteri* queens to *L. acervorum* colonies we have performed to date, such attacks have proved fatal (Franks, unpublished observations). However, it is likely that the probability of successful colony foundation in nature is very low. When attacked by the target colony workers, the parasite could use its propaganda substances to confuse its aggressors, allowing it to escape immediate danger and to proceed to gain the acceptance of its hosts by means which are at present unknown. It could seek to enter a cavity in the host nest where it could remain undetected, in order to pick up the colony odor from the nest material. Or it may deliberately court attack in order to acquire the colony odor by cuticular contact, as does the myrmecophilous beetle *Myrmecaphodius excavaticollis* (Vander Meer and Wojcik, 1982), deploying the propaganda substance only if the attack becomes too severe. There is evidence that *L. acervorum* workers who have not met the parasite can pick up the propaganda substance from nestmates which have. This would speed up the spread of the substances through the defending force, potentially vital for a single parasite pitting itself against an entire colony.

The use of Dufour's gland secretions as chemical weapons in the penetration of host colonies may also occur in the inquiline *Doronomyrmex pacis*. Buschinger (1974b) discovered the Dufour's gland to be hypertrophied in this species as well. Intriguingly, it is also a close relative of *L. kutteri*, and parasitizes the same host species, *L. acervorum*. However, another related parasite of *L. acervorum*, *L. goesswaldi*, appears to have a Dufour's gland only slightly larger relative to its body than that of *L. acervorum* (Buschinger, 1974b).

In the slave-maker *H. sublaevis*, our results confirm the hypothesis (Buschinger, 1974a) that this ant possesses a chemical weapon produced in quantity by the Dufour's gland. In this species there is no difficulty in seeing how substances which provoke internecine battles in host workers serve the needs of the parasite, since both colony-founding *H. sublaevis* queens and workers on slave raids aim to drive all adult host ants from the brood of their target colonies. However, an explanation remains to be found for the strong similarity both in the behavioral effects of the propaganda substances of *L. kutteri* and *H. sublaevis* and also in their glandular origin. This similarity may be due to a convergent evolution, especially since the parasites share the same host. Alternatively, the close phylogenetic relatedness of these two parasites, and of both to their host (Buschinger, 1981), argues for common ancestry as the explanation. Chemical analysis of Dufour's gland secretions could be used to discriminate between these alternatives. Since these secretions appear to override nestmate recognition, the analysis of these substances may also provide special insights into the chemical basis of colony-specific odor.

Acknowledgments—We thank Per Douwes for his generous help in the field and many stimulating discussions, and Alfred Buschinger, Bert Hölldobler, Frances Judson, Nick Platt, and Stuart Reynolds for their advice and encouragement. This research was supported by a field grant from the Balfour-Browne Fund of the University of Cambridge and a University of Bath Studentship to A. Bourke; a Royal Society, Scientific Investigations grant; and a Nuffield Foundation award, to newly appointed science lecturers, to N. Franks. Laboratory facilities in Sweden were provided by the Ecological Station of Uppsala University on Öland.

PREDATOR DETERRENCE BY MANDIBULAR GLAND SECRETIONS OF BEES (HYMENOPTERA: APOIDEA)

JAMES H. CANE

Department of Zoology/Entomology
Auburn University, Alabama 36849

(Received April 23, 1985; accepted September 5, 1985)

Abstract—Volatile lipids from the mandibular gland secretions of bees (Hymenoptera: Apoidea) are potent olfactory repellents of foraging ants (*Formica, Crematogaster*) in biologically relevant contexts and quantities. In contrast, differential success in capture of bee and fly prey by predatory asilid flies (*Efferia*), reduviid bugs (*Apiomerus*), and arachnids (*Agelenopsis, Argiope*) is better explained by prey size than by chemical repellence, aposematism, or possession of a sting. Supernormal doses of some allomones, applied to worker honeybees (*Apis mellifera*) that were fed to *Argiope aurantia* spiders, elicted more frequent preenvenomation pauses following ensnarement but did not significantly increase other prey-handling times. These pauses merely delayed the bee's demise. Mandibular gland secretions of solitary bees augment their other secondary defenses in at least two contexts: (1) during intranest encounters when repelling intruding ants, and (2) retaliation delivered to their arthropodan predators which, if the bee is nearly too large for the predator to handle, may allow the bee to escape.

Key Words—Defense, allomone, bees, Hymenoptera, Apoidea, repellent, *Argiope, Apiomerus*, Asilidae, Diptera Formicidae.

INTRODUCTION

The 15,000+ species of nonparasitic solitary bees (Apoidea, excluding eusocial Apidae) are relatively k-selected "prudent" species sensu Hutchinson (1978) in that females generally produce fewer than 30 eggs during their 3- to 6-week adult life-spans (Michener, 1974). Concomitantly, their protective adaptations effectively lessen reproductive losses. Mass provisions of pollen and nectar/oil are both isolated from the elements and visually concealed from predators (anachoresis sensu Edmunds, 1974) within subterranean, pebble, resin, wood, or stem nests. Earthen nest cells are typically varnished with hydrophobic mem-

0098-0331/86/0600-1295$05.00/0

branes (Cane, 1981) that protect moisture-sensitive larvae and provisions; females may also fumigate these cells using mandibular gland volatiles prior to provisioning (Cane et al., 1983). Among the adult females' protective adaptations are two secondary defenses which may enhance their chances to repel or escape their arthropodan predators. These defenses are the sting and the mandibular gland secretion.

The mandibular glands, apparently possessed by both sexes of all Apoidea (Nedel, 1960), are the sole known sources of volatile repellents from solitary bees. This multifunctional secretion may also serve as a premating pheromone (Tengö, 1979; Cane and Tengö, 1981; Hefetz, 1983; Vinson et al., 1982) and nest cell disinfectant (Cane et al., 1983). To our noses, the bouquet of a bee's mandibular gland can resemble essences of citrus, garlic, banana, butter, melting styrene, etc. Both sexes release these volatiles during handling (e.g., Linsley and Zavortink, 1977). Their known molecular structures include various low-weight (<300 amu) aliphatic, isoprenoid, and occasionally aromatic hydrocarbons, alcohols, aldehydes, ketones, ketals, and acids. Quantification of a bee's potential glandular volume is available for *Colletes cunicularius* (10 μg linalool/bee) (Bergström and Tengö, 1978) and three species of *Exoneura* (40–80 μg total lipids/bee, 0.1–3.0 μg salicylaldehyde) (Cane and Michener, 1984).

Solitary bees of all life stages succumb to diverse predators and parasites. A few are as follows: kleptoparasitic "cuckoo" bee larvae (e.g., *Sphecodes*, Nomadinae, Melectini) consume the host bee's eggs, larvae, and provisions (Bohart, 1970). Some meloid beetles are parasites of larval bees (Erickson et al., 1976). Detrivorous or carnivorous ants may raid solitary bee nests (Schultz, 1977). The *Nomada* kleptoparasites rely upon kairomones for host nest assessment and selection (Cane, 1983). Foraging ants, of course, also respond to semiochemicals.

Adult solitary bees can be victims of arthropodan predators and parasitoids during mating, foraging, and nesting activities. Predatory arthropods include spiders (especially Araneidae and Thomisidae) (Bilsing, 1920; Bromley, 1948), robber flies (Asilidae) (Linsley, 1960; Dennis and Lavigne, 1975), assassin bugs (Reduviidae) (Usinger, 1958; Stephen et al., 1969; Weaver et al., 1975), ambush bugs (Phymatidae) (Caron, 1978), preying mantids (Mantidae) (personal observation), sphecoid wasps (especially Philanthini) (Evans and Lin, 1959), and occasional ants (Formicidae) (Schultz, 1977; Cane, personal observation). The kleptoparasites and ants contrast with the robber flies, spiders, and assassin bugs in that the latter groups are typically comprised of long-legged, swift-moving, sit-and-wait predators which seem to rely more upon visual or tactile rather than chemical information, as in the former group, for prey localization and recognition. The three latter taxa inject fast-acting toxins and/or digestive enzymes into their prey, thereby achieving rapid prey immobilization. Some of these arthropodan predators may be capable of associative learning for prey defenses and recognition (Gelperin, 1968).

Faced with sundry mortality factors and limited reproduction potential, solitary bees must bear adaptations that largely prevent or circumvent fitness losses. Other than the sting and mandibles, the mandibular gland secretion could serve a secondary defensive function in startling or repelling a predator or parasite. Given diverse predators, parasites, and contexts of encounter, the secretion is unlikely to confer effective defense against all adversaries at all times. This study characterizes some of these behavioral and ecological contexts for allomonal defenses of solitary bees.

METHODS AND MATERIALS

Reduviidae. Assassin bugs, *Apiomerus flaviventris*, were taken during 1980 and 1984 from flowering *Baccharis* shrubs growing about water tanks in the San Simon Valley near Rodeo, New Mexico. These bugs regularly feed upon bee, wasp, or fly prey. The bugs were housed in glass terraria in the insectory at the Southwest Research Station of the American Museum of Natural History (S.W.R.S.) near Portal, Arizona. Cut vegetation provided perches. Daily, an active, freshly caught bee was offered to each of five or six *A. flaviventris*, and the ensuing predation attempts recorded. Inconclusive experiments with particular prey species were repeated. Tested bees are ranked by body size and noted for observable aposematic colorations, sex (and so sting), and noticeable (by my nose) mandibular gland odors.

Asilidae. Both sexes of the abundant robber fly, *Efferia rapax*, prey upon bees and flies of the desert scrub and canyon meadows of the San Simon Valley. In these settings, live bees tethered with a long hair to the tip of a 2-m long stick were flown above perched robber flies. Lack of response (N), approach/inspection (A), and actual striking (S) responses were recorded for each *E. rapax* individual, following the criteria of Dennis et al. (1975).

Formicidae. Ants were tested in both the laboratory and field. At a nesting aggregation of *Colletes thoracicus* in Ithaca, New York, foraging *Formica glacialis* were baited to 10-cm^2 filter papers smeared with honey. This ant species preys upon nest contents and adults of *Andrena alleghaniensis* (Cane, personal observation). Foragers were then briefly presented, at antennal length, with a micropipet bearing either (1) dried extract of one, two, or four mandibular gland equivalents of *C. thoracicus*, (2) dried hexane solvent, or (3) a small aqueous sample of the bee's provisions. Hexane effectively extracts lipids like linalool from *Colletes* mandibular glands (Bergström and Tengö, 1978). Each ant's first response was classified as either feed (F), no response (N), jump back (J), retreat (R), or bite (B). The 440 responses of 87 foragers were compared using a G statistic for a 5×5 test of independence, followed by an a posteriori test by STP for homogeneity (Sokal and Rohlf, 1969).

In the laboratory, queenless colonies of *Formica subsericea* and *Crema-*

togaster cerasi were housed in 30 × 40 × 10-cm Plexiglas nesting boxes that connected, via short plastic tubes, with 50 × 75 × 10-cm Plexiglas foraging arenas. Although *Formica* will raid bee nests, *C. cerasi* is a small woodland species that likely tends aphids and coccids (M. DuBois, personal communication).

Colonies were fed for four consecutive days/week from 0900–1000 hr following 1 hr of illumination. Foragers were offered a microscope slide at the arena's center bearing 50-μl milk and honey droplets. As the first foragers returned to the nest, this bait was replaced by four cleaned slides (in two rows) placed equidistantly at the arena's end opposite the nest. Each slide bore a 4-cm^2 filter paper square saturated with two drops of milk and one of honey. Centered on each filter paper was a 1-cm^2 black velvet square, impregnated with 5 μl of test chemical, or hexane as a control. Thus, foragers were simultaneously presented both with the "allomone" (without physical contact) and attractive food, as might occur if confronted by a female bee while raiding her nest.

A weekly test consisted of three volatiles selected from the following: butyric acid, citral, citronellol, farnesol, geraniol, linalool, 2-octanone, salicylaldehyde, or skatole. Solids were dissolved in a minimum of hexane. Treatments were selected randomly each week, and distributed in a 4 × 4 Latin-square design, with days and feeding station positions randomized. These treatments represent a chemical diversity of known mandibular gland secretions of bees (see Discussion). This design controls for day and position effects, time of day, and order of experimentation. On the three nonexperimental days of the week, ants received water and dead cockroaches ad libitum in their nest boxes.

During the 1-hr experiments, ants at the feeding stations were counted every 3 min, resulting in 20 cumulative censuses. Actual totals of foraging individual ants were impossible without marking. Square-root transformations of these frequency data yielded normal distributions by rankits analysis. A 4 × 4 Latin-square ANOVA was applied to each week's tests for each ant species, using BMDP79 programs. Following a significant result, a posteriori Duncan's multiple-range tests were used to detect intraexperiment differences between the control and the three test lipids used during each week's trials.

Arachnida. Two species of spiders were tested—*Argiope aurantia* (Araneidae) and *Agelenopsis aperta* (Agelenidae). The latter were housed and fed similarily to the reduviids. Owing to their terrestrial habits, the funnelweb spiders (Agelenidae) are unlikely to encounter bees (Bilsing, 1920). In contrast, *A. aurantia* commonly ensnares flower-visiting insects such as bees (Bromley, 1948) in its orb webs. The diets of *Argiope* and *Araneus* (=*Epeira*) in Ohio typically consisted of 14–24% bees, particularly honeybees (Bilsing, 1920).

In 1982, three *A. aurantia* were individually housed in 1 × 1 × 0.1-m observation frames faced with removable glass and backed by window-screening to the outside. Freshly caught, live bees were tossed into the peripheral

halves of the spider's webs. The times until contact (A), duration of offensive silk wrapping (W), and time until feeding (F) were recorded, as was the anatomical point of envenomation (adopted from Robinson and Olazarri, 1971). Prey were offered sequentially until either a spider no longer responded or four prey had been consumed. Final offerings were dropped from analysis when the spider's refusal was due to satiation, which was tested by offering a muscid fly, being a known desirable prey item.

In 1984, six *A. aurantia* were individually caged outdoors in 30 × 30 × 60-cm screen enclosures. These were fed active *Apis mellifera* foragers which had been briefly (<5 min) chilled, perfumed with one synthetic mandibular gland lipid, and quickly (30–60 sec) revived in warm sunlight within their individual vials. Doses of 7–14 μg, 68–71 μg, 136–141 μg, or 860–1170 μg, diluted to 1 μl with hexane, were administered topically to the chilled bee's thorax. Control bees received either no chemical or merely 1 μl hexane. The treatments were butyric acid, citral, citronellol, 2-decanone, farnesol, geraniol, linalool, and salicylaldehyde. Butyric acid, 2-decanone, and linalool were only delivered at 7–14 μg owing to time constraints and interest in testing biologically relevant quantities (see Introduction). Each spider daily received one or two bees sequentially. Dosage, compound, and order of feeding were randomized across days and spiders. The six spiders were thus blocked as six replicates, each receiving each dose of each compound once. The spider's time until prey encounter following web contact, the duration of the spider's offensive silk wrap, and the duration if any of the spider's pause while astride the ensnared bee prior to envenomation were all recorded.

Statistical comparisons were necessarily nonparametric owing to excessive ties of 0- and 1-sec handling times that defied normalization. Runs tests (Sokal and Rohlf, 1969) were first performed for up or down trends for the two prey-handling times (median contact and wrap times) and the proportion of pausing behaviors for the experimental days ($N = 10$) to both assess the success of randomization and to check for either habituation or learning. Four Friedman tests (adjusted for ties) (Conover, 1980) were then applied, treating the six spiders as blocks and either the test volatiles or the dosages as treatments. Two tests compared median contact times, and two compared median wrap durations. Finally, a G statistic was applied to the frequencies of pausing to assess independence from the treatment dosage, followed by an STP a posteriori comparison of frequencies where justified (Sokal and Rohlf, 1969).

Standardization. Although the dosage of each compound applied to each bee prior to release was controlled, the initial quantity encountered by the spider upon contacting the captive bee is lessened during the bee's brief warming-up and flight into the web. The proportion of the original dosage remaining was assessed in the laboratory. Live, chilled bees were perfumed with 7, 68, 860, and 1720 μg of citral diluted to 2 μl with hexane. As in the field experiments, these bees were then warmed for 2 min and allowed to fly encaged for 1 min.

Each live bee was then captured and plunged into methylene chloride solvent containing an internal hydrocarbon standard. A dead bee with a matching dosage was handled identically. After 5-min of extraction, an 1 : 10,000 aliquot (1 μl) was drawn and injected onto a gas chromatograph (HP5710A GC with FID, 4.5 mm $\times$ 1 m, 10% UC-W98 packed column, 170°C isothermal, and HP3380 integrator). The extractable proportions of the original dosages on these live bees were compared with those from the dead bees using the integrated peak areas (adjusted to equilize the areas of the hydrocarbon standards).

RESULTS

Reduviidae. The assassin bug *Apiomerus flaviventris* handily takes offered prey representing all five apoid families as well as flies (Table 1). They are sit-and-wait predators, rearing up on their meso- and metathoracic legs with forelegs laterally outstretched. Bees are typically clutched mediodorsally across the thoracic dorsum. In this position, the bee's legs, sting, and mandibles are all incapable of contacting the reduviid. Prey were often initially pierced through their cervices or mediodorsally through other membranes. The reduviids' encounter times with prey in their glass terraria varied from 6 sec to over 30 min (N = 27 timed bouts, median = 5 min). Prey smaller than *A. argemonis* (intertegular width < 2.7 mm) were captured on the first lunge nearly 95% of the time. For prey larger than the honeybee (intertegular width >3.2 mm), only one of the 15 prey items offered was successfully captured despite 35 total lunges. Notably, the large black syrphid fly, *V. mexicans*, which lacks mandibles, sting, and any apparent defensive secretion, remained uncaught (Table 1). Conversely, honeybees, which possess these defenses, were victims of *A. flaviventris* 93% of the time (Table 1). The stalk and lunge of an *Apiomerus* was readily thwarted by resting bumblebees as they thrust it aside with a kick from the mesothoracic leg. The *Apiomerus* were unable to successfully grip many of these larger prey.

Asilidae. Perched *Efferia rapax* darted to meet 68% of the offered tethered insects (N = 76 bees and 5 flies) and attempted capture for 47% of these close approaches. Prey smaller than 2.5-mm intertegular width (*Melissodes* sp. 2) were invariably at least approached (N = 25 bouts) (Table 1). The brightly colored, strong-odored *A. argemonis* was frequently approached and struck, but in general, the flies responded less frequently to the larger (intertegular width >2.5 mm) potential prey.

Formicidae. Foraging *Formica glacialis* ants at the *Colletes thoracicus* nesting aggregation responded differentially to the extract presentations. The G test indicated significant differences among the treatments ($P < 0.001$). The a posteriori tests show significant differences ($P < 0.05$) between the ants' responses to provision extract, to hexane control, and to mandibular gland ex-

TABLE 1. RESPONSES OF REDUVIID, ASILID, AND AGELENID PREDATORS TO POTENTIAL BEE PREY

[a] The menu of insects includes both flies (*Volucella*, *Musca*, and *Calliphora*) and bees, the latter including social (*Bombus*, *Apis*), kleptoparasitic (*Triepeolus*), and solitary representatives drawn from 14 different tribes that bracket most of the available size range of bees (roughly *Drosophila*-sized to large bumblebees). Bees are subjectively classified as to having an odoriferous mandibular gland secretion (*), and exhibiting aposematic or mimicry patterns (+).

[b] Intertegular width, being the shortest distance across the thorax between the insect's wing tegulae (wing bases), is an excellent estimator of bee dry weight (Cane, unpublished).

[c] The number of offered (O) prey items captured (C) is reported as a capture success rate (success).

[d] The frequencies of no response (N), aerial approach to investigate within 10 cms (A), and actual striking (S) of the tethered bee or fly are reported.

[e] The number of prey items making web contact are classified as either escaped (E) or captured (C).

tracts. Responses to the three dosages of mandibular gland extract (1, 2, and 5 glandular equivalents) did not differ significantly from one another. The ants met provision extracts with either feeding responses with mouthparts extended (35%) or no observable response ($N = 74$ ants). Hexane generally (92%) elicited no behavioral responses ($N = 173$ ants). Mandibular gland extracts never elicited feeding responses ($N = 193$ ants), but, of the 94 tested ants, 69% gave

avoidance responses (jump or retreat) while the remaining 19 directed defensive sprays at the pipet bearing the volatilizing mandibular gland extract of the *Colletes* bees. This represents 90% of all of the retaliatory responses elicited. Provision extracts, then, generally elicit approach and feeding responses, the solvent alone elicits no response, and the mandibular gland extracts elicit avoidance, startle, or retaliatory responses from foraging ants in the field.

During the laboratory ant studies, the ranges of cumulative forager counts at any one feeding station for a day's experimentation ranged from 0 to 127, $\bar{X} = 23.5$ (*Formica subsericea*) and from 0 to 629, $\bar{X} = 105$ (*Crematogaster cerasi*). Neither day nor position affected forager distributions at the feeding stations ($P > 0.5$). In all experiments, the control attracted at least as many foragers as any bait with odor ($P < 0.05$). For both ant species, neither farnesol nor skatole were significantly repellent ($0.05 < P < 0.1$). Citral, citronellol, geraniol, and linalool were all effective repellents ($P < 0.01$) of both ant species. Salicylaldehyde was also strongly repellent (2% of foragers feeding) for *F. subsericea* ($P < 0.001$), but only mildly so for *C. cerasi* ($P < 0.05$). Butyric acid and 2-octanone were marginally repellent chemicals ($0.01 < P < 0.05$) for both ant species.

Arachnida. Agelenopsis aperta, the funnelweb spider, was reasonably successful in capturing bee prey (Table 1). Only one escape in eight bouts was seen. A large, chilled *Centris* bee was offered to the spider, which immediately began wrapping it in silk. After 1 min, however, the bee revived and ripped free from the webbing. The spider retreated to its funnel refugium. In contrast, the spider took *A. argemonis* females handily, despite these bees' mandibular gland secretions that were noticeably released from their spread mandibles when first contacted by the spider.

Among *Argiope aurantia*, the four largest bees (from three families) all successfully escaped from these spiders' webs, despite the spiders' attempts at prey immobilization with silk (Table 2). The *Megachile* lack any notable mandibular gland volatiles. Of the remaining 11 smaller prey bees, only one escaped. Median handling times for all 16 prey were 2 sec to contact, 10 sec spent silk wrapping, and 11 additional sec until steady feeding. The three flies were not wrapped in silk prior to envenomation.

During the 1984 experiments, none of the 135 perfumed honeybee workers escaped *A. aurantia* once contact was made. In neither this experiment, nor any of the above experiments, was a predator ever injured by either a bee's mandibles or sting. Median handling times (and 25–75% quantiles, range) were similar to the above experiments. Contact was made in 1 sec (1–6 sec, range 1–66 sec), and offensive silk wrapping persisted for a median of 8 sec (5–12 sec, range 1–47 sec). In 22% of all cases, the spider paused astride the wrapped bee for 1–300 sec following silk wrapping but prior to envenomation (median 10 sec). As for *Apiomerus*, venom was typically injected mediodorsally on the bee, but for *A. aurantia* it was more often in the thoracic dorsum.

TABLE 2. DURATION OF PREY-HANDLING SEQUENCES OF *Argiope aurantia* SPIDERS IN RESPONSE TO OFFERED ACTIVE BEE PREY TOSSED INTO WEB

[a] Spider approach time (A) following web contact, duration of offensive silk wrapping (W), and delay until actual feeding (F) are all reported in seconds. Some potential prey forcefully escaped (E) following attempted silk-wrapping by the spider. See Table 1 for explanation of * and +.

No significant habituation or learning trends across experimental days were detected with the runs tests. Comparing the nine compounds (including hexane controls) at the 7- to 14-μg dose ($N = 45$), neither median contact ($P > 0.25$) nor wrapping ($P > 0.25$) durations were significantly prolonged (one-tailed) using Friedman tests. Similarily, no significant increases were found for median silk-wrapping durations ($P > 0.25$) across the dosage gradient from 0 to 200 μl ($N = 125$). Only median contact time was significantly enhanced (from 1 to 3 sec) by increasing dosages of volatiles applied to the bees ($P < 0.025$) (neglecting momentarily the incrementing type I errors accrued by repeated tests on the same family of data).

The proportional frequency of post-wrap pausing behavior across dosages was significantly greater (18–27% of bouts) when compared with hexane or no-treatment controls (4%) ($G = 123.4$, $G_{P<0.005} = 14.86$), but no differences among dosages were detectable by STP analyses. There were no significant differences among the compounds for pausing frequencies.

The extractable dosages of citral remaining upon live bees following their brief warm-up and flight preceding web ensnarement varied considerably. From 39 to 100% of the original dosage was recovered from dead bee whole-body extracts. Relative to these figures, extractable citral remaining upon live bees

ranged from 1.3% to 80%, with proportionately more recovered from the larger initial dosages. Thus, dosages encountered by *Argiope* spiders upon first contact with their perfumed *Apis* prey ranged from aproximately 0.5 μg (7–14 μg initial dosage) to 950 μg (860–1170 μg initial dosage). This adequately brackets the known range of naturally occurring quantities of these volatiles from bees (see Introduction).

DISCUSSION

Insect exocrine lipid secretions can serve as allomones that deter attacks by their predators or parasitoids (Blum, 1981). To be an allomone, candidate exocrine lipids must repel known predators/parasitoids for biologically relevant contexts of encounter, all within the quantitative confines of the producing target-prey species. If synthetic allomones are used in the absence of the natural delivery system, then we must approximate the quantities encountered by the predator. If the secretion persists evolutionarily as a defensive adaptation, it must reduce the prey's probability of reproductive fitness losses (injury or death) despite the predator's counteroffensive adaptations. In short, an allomone is not merely a repellent per se, but a deterrent to predation as well.

The tested synthetics are present in a majority of known mandibular gland secretions of bees. Among 11 colletid species (*Hylaeus* and *Colletes*), citral is frequent, and linalool is common in the latter genus (Blum and Bohart, 1972; Bergström and Tengö, 1973, 1978; Hefetz et al., 1979b; Duffield et al., 1980). Citral is also known from andrenids, being reported from three species of *Calliopsis* and one *Nomadopsis* (Hefetz et al., 1982), *Panurginus potentillae* (Duffield et al., 1983) and *Andrena* (Bergström et al., 1982). Three species of *Andrena* also bear citronellol (Tengö and Bergström, 1976; Bergström et al., 1982) and ketones like methyl decanone (Tengö and Bergström, 1976, 1977). The oxaeid *Protoxaea gloriosa* secretes citral and geraniol (Cane and Buchmann, unpublished). So does the melittid *Dasypoda*, which also produces linalool and citronellol (Bergmark et al., 1984). A *Centris* bee produces geraniol and citral (Vinson et al., 1982). Among stem-nesting bees, *Ceratina* mandibular glands (three species) contain nerolic and geranoic acids and/or their acetates (Wheeler et al., 1977), *Pithitis* has the acetates plus salicylaldehyde (Hefetz et al., 1979a), and three species of *Exoneura* also produce salicylaldehyde (Cane and Michener, 1984). Butyric acid seems ubiquitous among worker *Bombus* (Cederberg, 1977), skatole and nerol have been isolated from *Melipona* (Smith and Roubik, 1983), and citral is common among both *Trigona* and *Lestrimellita* (Blum, 1966). Simple olfactory field evaluations suggest that these compounds will be found in more bee species.

Ants are effectively repelled by either authentic or synthetic mandibular gland components of bees, both in field and laboratory contexts. When present

in the airspace proximate to food, these volatiles render an otherwise attractive feeding station repellent or threatening. Prior experience with bees does not seem to influence repellence (comparing omnivorous *Formica* with aphid-tending *Crematogaster*). Repulsion is, to an extent, species-specific (comparative responses to salicylaldehyde), but some mandibular gland volatiles repel neither species. Mandibular gland equivalents are adequate to achieve significant repellence (experiments with linalool).

In what contexts do solitary bees encounter ants? Ants often share soil nesting aggregations with bees. Nesting tumuli of bees can contain odors of the provisions held within (Cane, 1981). Various ant genera opportunistically prey upon such ground nests (Cane, personal observation; Schultz, 1977). Ants raid stem-nesting bees both to consume the nest contents as well as to usurp the bee's hollow domicile. Michener (in Cane and Michener, 1984) notes that these nests are quickly taken over by ants if the resident bee is removed. A *Pithitis* or *Ceratina* female will smear her body with cephalic secretions upon encountering ants at her nest entrance. The mandibular gland secretions of a female bee, when released at her nest entrance, can repel marauding ants which might otherwise kill her or her progeny.

The arthropodan predators of flying insects (asilids, reduviids, arachnids) successfully counter the repellents and venoms of bees by virtue of combinations of hard exoskeletons, sit-and-wait tactics followed by rapid approaches, powerful long legs that facilitate prey handling and remotion of prey defenses, and rapid prey immobilization by injected venoms. Warning or mimicry patterns, volatile mandibular gland secretions, and/or stings are at best secondary to overall prey size and strength in determining outcomes of predator–prey conflicts for *Apiomerus flaviventris, Efferia rapax,* and *Argiope aurantia* (Tables 1 and 2).

Asilid prey records and the distribution of presumed allomones among prey taxa underscore these results. Linsley (1960) reported the hymenopteran prey from nine genera of southwestern U.S. asilids. Relatively large (his distinction) asilid species commonly take species of *Anthophora,* Apis, Bombus,* Centris,* Melissodes,* Protoxaea,** and *Xylocopa.** (The asterisk denotes my field observations of perceptable mandibular gland volatiles). Medium-sized asilids take various *Apis, Agapostemon, Colletes,* Exomalopsis, Halictus, Hesperapis,* Megachile, Melissodes,* Micranthophora,* Nomia,* Perdita,** and *Psaenythia.** Finally, the small asilids prey upon such bee taxa as *Colletes,* Exomalopsis, Lasioglossum,* and *Perdita.** Linsley (1960) noted distinct differences in prey selection for these asilids among the potentially available prey which he explained by the relative sizes of predator and prey. In Wyoming, Dennis and Lavigne (1975) found 10 species of robber flies to take prey averaging 40% of their own body lengths. Some taxa (*Mallophorina*) consumed up to 73% Hymenoptera. They captured most of the above genera plus *An-*

thidium, Dialictus, Dianthidium, Epeolus, Evylaeus, Nomada,* Pseudopanurgus,* Sphecodes,* and *Triepeolus.**

From the above lists and my own results (wherein the prey menu is controlled), it seems that bees emitting even copious amounts of supposed repellents do not escape the asilids' menus. Some asilid species even seem to prefer more colorful bees and wasps (Linsley, 1960). Lavigne and Holland (1969) and Dennis et al. (1975) demonstrated that asilids distinguish among artificial lures primarily by size. Size, then, outweighs olfactory repellence in these examples of asilid prey selection.

Less is known of the hymenopteran prey of reduviids, although some *Apiomerus* have earned the label "bee assassin" (Caron, 1978). Indeed, *A. pictipes* in Mexico seems to employ *Trigona* attractants to lure guard bees to their demise (Weaver et al., 1975). Like the asilids, *A. flaviventris* adults readily take bees regardless of the bee's scent, but fail to manage larger, although otherwise undefended insects. Their inability to capture the large syrphid fly *Volucella,* contrasted with their repeated success with smaller *Andrena argemonis* (which smells of burnt garlic) or the sting-endowed honeybee, illustrates this point. Contrasted with the asilids, the prey size assessment by *Apiomerus* seems to be accomplished only after repeated grappling attempts, rather than by close range inspection. Perhaps bees bearing repellent mandibular gland secretions may enjoy some enhanced predator deterrence when the bee is marginally large for a given reduviid (again, contrasting their lesser success with odoriferous *Andrena* vs. the somewhat larger *Apis*).

Bee predation by spiders presents a similar story. Spiders that might otherwise rarely encounter bees, owing to their web placement, such as *Lycosa, Agelina* (Bilsing, 1920), and *Agelenopsis* (Table 1), readily tackle offered bee prey. In Ohio, Bilsing (1920) found the webs of *Argiope, Neoscona,* and *Araneus* to contain enwrapped species of *Bombus,* Megachile, Melissodes,* Augochlora, Apis, Colletes,** and *Halictus* (again, * = scented). Bristowe (1941) reported that *Argiope* would occasionally be stung and temporarily paralyzed by a captive *Halictus,* and sometimes rejected *Nomada* bees. Neither response was ever observed in my experiments. In contrast, Suter (1978) noted that, among a diversity of offered prey, *Halictus* elicited the "least latency of first motion" and fewest pauses per approach, using thanatosis (playing dead) to minimize its web-borne vibrations. When Fabré (1912) fed large, odorous *Xylocopa* and *Bombus* to *Lycosa,* the spider often retreated. But, if it attacked, it never failed to immobilize the prey item. Again, the bee's mandibular gland secretion does not convey protection against spiders, even for arachnids whose diet rarely includes bees.

Although mandibular gland secretions of bees do not deter predation by spiders, they do alter aspects of the *Argiope* prey-handling sequence. Honeybees perfumed with various mandibular gland components did elicit signifi-

cantly more frequent preenvenomation pausing. Owing to prior "immobilization wrapping," however, the bee never escaped. Also, prior to envenomation, *Argiope* throws silk offensively from a distance for odoriferous *Trigona* bees (Robinson et al., 1969) and pentatomid bugs (Robinson and Olazarri, 1971). In their studies, these prey also elicited frequent "rest-on-prey" pauses, with intensive grooming, again suggesting that the spider finds these volatiles noxious but tolerable.

Clearly, mandibular gland lipids of bees are often olfactorily perceptable by both humans and the arthropodan predators of bees. While variably repellent to ants at the bee's nest entrance, these allomones are generally ineffective deterrents of the bee's arachnid, reduviid, and asilid predators.

Book Review

Insect Communication. (edited by Trevor Lewis (ed.)). New York, Academic Press 1984, $55.00, 414 pp.

This book is a collection of papers delivered at the 12th symposium of the Royal Entomological Society of London, in honor of the society's 150th year. The topic, insect communication, was chosen because it spans the subject of insect biology and has enjoyed a rapid expansion in the past decade. The volume covers a variety of topics, ranging from discussions of specific communication channels to the evolution of communication and the practical aspects of disrupting communication as a control tactic.

Two chapters address acoustic communication in insects. The chapter by Bennet-Clark is a thorough, but straight-forward, description of the physical aspects of insect hearing. Behavioral aspects of this modality are taken up by Ewing, with specific reference to sexual behavior. Ewing amply demonstrates the richness of song diversity and its complexity in a wide range of organisms with respect to both calling and courtship sequences. One of the important problems addressed in this chapter, and common to a number of others in the book, is that too often songs are characterized as being involved in calling or courtship without critical analysis of the precise components of the song that are important for the behavior in question. In addition, while songs are often characterized as species specific, the essential or optimal stimulus rendering the specificity is mostly undetermined, and in many cases there is little evidence that females utilize song in discriminating between males, although this is almost always presumed.

Visual communication is also covered in two chapters. The first is a description of the insect eye, by Wehner and Srinivasan, with emphasis on visual acuity. The second, by Case, is a comprehensive and well written account of visual communication in fireflies. Emphasis is placed on the behavioral strategies used to maximize the capabilities of the visual system in overcoming the problem of detecting a point source of light against a varied and often shifting background. Again, the richness and complexity of these displays are well documented, despite the fact that for many groups very little is known about their mating behavior.

Chemical communication is given the greatest coverage in the book (nine of 16 chapters). In a chapter on the chemistry of insect communication, Silver-

0098-0331/86/0600-1311$05.00/0

stein presents a discussion of the classification of compounds according to their functional group and three-dimensional structural properties (the chemist's view), and their behavioral activity as semiochemicals (the biologist's view). He correctly points out that, despite the pitfalls, the available technology and experience in chromatographic analysis, volatile collections, and behavioral assays allow (and demand) a greater precision in determinations of chemical structure and behavioral function of pheromonal compounds, and a greater degree of interaction between the chemist and behaviorist.

Chemical communication in bark beetles is one of the most complex systems known, and the chapter by Borden is an excellent critique of chemically mediated aggregation and dispersion in this group. He begins with a generalized discussion of the complex sequence of events in the aggregation of beetles on a host tree, emphasizing important relationships between host accessibility, beetle physiology, and the interactions between both that involve semiochemicals. This generalized scheme is then used to contrast three case histories, the mountain pine beetle, an aggressive attacker of trees; the elm bark beetle, which relies on a fungus to aid in weakening the host; and the ambrosia beetle that utilizes dead or dying hosts. A secondary theme of this chapter concerns the potential for disruption of the communication process as a method of controlling the beetles. Borden provides an extensive list of ways this might be accomplished, emphasizing the importance of basic biological information about the insect-host interaction in designing control strategies.

A number of chapters deal with chemical communication in the social Hymenoptera. Morgan reviews the variety of chemicals used by bees, wasps, and ants for recruitment and foraging. The theme of this chapter is that the richness of diversity in glands and their secretions (chemical "words") and the multiple use of these secretions in a variety of contexts (chemical "phrases") allows for greater complexity of chemical meaning. Ecological considerations are also central to the chapter by Howse on alarm and defense compounds in social insects, and in Koeniger's chapter on brood care and recognition of pupae in the honey bee and hornet. Howse shows how the tactics used in defense and alarm are intimately related to foraging strategies and to nest structure and colony size.

The electrophysiology of insect olfaction is covered by Boeckh. Whereas there is a great deal known about peripheral receptors and their activity, Boeckh points out that questions dealing with central processing are most pertinent to an understanding of two major problems in pheromone perception. The first concerns the sensitivity of males to the chemical stimulus and is partially answered by the tremendous degree of convergence of neural pathways that occurs in the macroglomerulus of the deutocerebrum. More perplexing, however, is the question of how insects discriminate odor quality or the precise ratio of

components in the multicomponent blends of most insects. The "labeled line" and "across-fiber pattern" hypotheses are both discussed as they relate to specific sex pheromones and food odors, respectively.

Boeckh is an acknowledged leader in the field of CNS studies of olfaction, and it is only in the past few years that extensive details of this area have become available. It is thus unfortunate that a major error of reference is made in this chapter. Boeckh refers to Roelofs and his collaborators (specifically the study by Baker et al., 1981) as proponents of the idea that individual chemical components play "different roles in the approach of a male (moth) to the female." In fact, this study as well as a number of others have shown clearly that in the Oriental fruit moth, the complete three-component blend acts as a unit to influence all stages of the behavioral sequence. Recent studies in our lab, involving identifications of more complete pheromone blends in the cabbage looper, red-banded leafroller, soybean looper, and European cornborer moths, support this idea as a general principle in pheromone perception (J. Chem. Ecol. *12*, 659). This correction is important because it relates directly to the question of how blend quality affects male behavior downwind of a source and how electrophysiological experiments can be designed to investigate the observed sensitivity of males to small amounts of minor components in the blend.

Olfactory sexual communication in the Lepidoptera is the subject of a chapter of Cardé and Charlton. Rather than a descriptive survey of the field, this chapter focuses on several challenging questions concerning the current debate over the functional role of multicomponent pheromone blends and the orientation of males flying in a windborne odor plume. The authors state in the introduction that the primary function of the chemical signal is the securing of a mate and that selection will favor factors that enhance the ability of males to rapidly detect and respond to the airborne signal. One important factor concerns the activity of males at the time females are releasing pheromone. The authors suggest that males are most probably in an active appetitive searching flight pattern rather than in a quiescent state. They then argue that wind-tunnel assays utilized to determine male sensitivity to the signal (a second important factor enhancing mate location) may not be valid because they involve male activation from a quiescent state rather than from appetitive flight and that the thresholds for these two steps (activation wind fanning vs. locking on to the odor plume) might be very different. As evidence, unpublished flight tunnel results with the gypsy moth are provided. The authors claim that whereas males are able to fly upwind in a plume of 2.6×10^4 molecules/cm^2/$\frac{1}{2}$ sec, activation from a quiescent state in a flux of 2.6×10^6 molecules/cm^2/sec takes an average of 16 sec. It is undoubtedly true that appetitive flight is an important aspect of male precopulatory behavior and should be a serious consideration for future studies. It should be noted, however, that the gypsy moth displays a much longer latency

for this behavior than several other moth species with which this reviewer is familiar, and thus the observations with this insect may not be of general application to other Lepidoptera.

The problems associated with male sensitivity lead directly to a discussion of discrimination of blend quality, and a shift from the gypsy moth to the Oriental fruit moth, which uses a three-component blend. The authors ask "are the thresholds for attraction (locking on the upwind flight) lowest for the entire blend, or do portions of the blend evoke these behaviors at the same concentration? [or]. . can there be more than one active space [for the pheromone]?" One of the presumptions leading to these questions is the idea that, since minor components are present in such low quantities relative to the major component, they cannot be detected at the same distance as the major component. Yet there are numerous examples showing that upwind flight is dependent on a precise ratio of isomers and that males are able to detect very slight changes in isomeric ratios. It has also recently been demonstrated in our lab for the Oriental fruit moth, red-banded leafroller, and cabbage looper moths, that addition of minor components results in significant levels of upwind flight to low dosages of the major component that alone elicit no locking on or upwind flight. Thus it can be argued that males do not perceive the blend as a sequence of individual components with different spheres of activity, but rather that the blend acts as a unit to effect male sensitivity and specificity. The fact that some males are able, at low concentrations of pheromone, to exhibit flight to partial blends or off ratios (at much slower flight speeds than to the same concentration of the optimal blend) may suggest that a portion of the population has a broad range of specificity and may not be representative of meaningful threshold behavior.

I would also take exception with the authors claim (based on their interpretation of the figure shown from Linn and Roelofs, 1983) that "discrimination of the ratio of components occurs during upwind flight, with specificity for the optimal blend most pronounced in later behaviors." In fact, the figure shows that specificity is most profoundly effected in the early orientation or locking on phase of the response. It is clear for this insect and a number of others that taking flight is not a discriminating behavior, but rather that this occurs in the locking on and initiation of upwind flight phases. In addition, since the Oriental fruit moth initiates a response very rapidly in the tunnel (flight and locking on taking less than 3 sec), it is unlikely that the thresholds for this behavior would be different for insects in flight.

The importance of addressing these arguments in some detail relates not only to the comparative data that allow an alternative view, but also to statements presented by the authors in the introduction concerning the functional role of the chemical signal. If it is true that the chemical signal is critical in mate location, then it can be argued that males would be selected to be tuned to the complete female released signal, a signal that enhances the sensitivity

and ability of males to discriminate odor quality in the earliest (downwind) stages of the response. The fact that certain components are present in smaller amounts should not preclude their importance at any stage in the male precopulatory response.

The remainder of the chapter by Cardé and Charlton deals with a discussion of orientation mechanisms. This area has enjoyed much attention over the past decade and a great deal is now understood about how flying insects orient to an odor source. The authors note, however, that recent studies have radically altered previous views about movement of a pheromone plume in a fluctuating wind flow and raised questions about how this relates to the movement of the insect. Future studies must concentrate on these problems as they relate to the field to determine if the principles discovered in the arena of the wind tunnel are correct.

As noted earlier, one of the unstated, but important, themes that occurs throughout this volume concerns the functional aspects of signals used in communication. The evolutionary aspects of this problem are dealt with in two chapters. In the first, West-Eberhard argues strongly that sexual selection is *the* driving force in the evolution of species-specific signaling and courtship displays, as opposed to these being primarily reproductive isolation mechanisms. She argues that many signals should be considered as competitive rather than cooperative, in that they lead to differential success in obtaining a resource. After discussing several properties of socially competitive traits (strength of selection, potential for change, diversity of sensory channels, and perpetuity), she shows that many sexual and nonsexual displays can be considered as competitive and thus influenced by sexual selection, including nonsexual communication in social insects, threat displays, territorial displays, courtship, male external genitalia, and possibly female calling. Sexual selection theory, however, involves both intraspecific competition (male–male) and intersexual selection (female choice). There is at present considerable controversy over the role of these two factors and, unfortunately, the problems associated with separating them in the analysis of a display are not dealt with in this chapter. Rather there is a more general emphasis on the potential for rapid signal divergence that can occur under social selection and its role in speciation.

In the other chapter dealing with evolutionary questions Hölldobler presents a more general view. He first notes that, to discuss the evolution of communication, one must decide what communication is. Ideas concerning a definition of communication vary from one extreme, that it must be mutually beneficial to both participants, to the other extreme, that communication is the manipulation of one member (usually the receiver) by another (the sender). Hölldobler adopts a central position and asserts further that the "comparative analysis of the mechanisms of animal communication provides the basis for understanding the adaptive significance and for reconstructing the evolutionary

history of communicative behavior." A discussion of sexual selection then follows that is somewhat more balanced and cautious than West-Eberhard's. While species-specific signals may mediate reproductive isolation, individual components of the signal promote mate assessment and mate choice. He points out that the available evidence from studies of geographic variation in mating signals suggests that species diversity occurs primarily in allopatry and that cases of character displacement are rare. This is in agreement with West-Eberhard, as is Hölldobler's analysis showing that significant variation can exist in the ability of males to display, thus allowing for sexual selection to be a strong selective force. He cautions, however, that separation of intrasexual and intersexual selections is very difficult in practice, as is determination of the genetic basis for female choice. These ideas are then developed in a comparative analysis of individual recognition, worker communication, division of labor, and recruitment in the social hymenoptera. This group certainly offers a vast store of material for testing the hypotheses proposed for the evolution of communication signals.

The only chapter, by Vinson, dealing with interspecific aspects of communication concerns parasitoid host location. As with several other chapters, this one is a discussion of the diversity of strategies utilized by parasitoids in locating a host. Emphasis is placed on the interaction of the host habitat and the use of multiple signals to locate the host. These include host habitat odors, host odors (or kairomones), and visual or tactile components.

The final chapter of this volume, by Wall, is a discussion of the exploitation of insect communication by man and is devoted entirely to chemical communication. Wall first discusses the imbalance in research and development in this area, with identification of compounds and use in detection far outstripping monitoring, mass trapping, or disruption. Neglected areas of research include population studies, behavioral studies in the field, formulations, and meteorological studies. It is clear that effective use of chemicals to monitor or disrupt insect communication demands greater attention to trap design, trap efficiency, the behavioral strategies of the insects in the field, and effective formulation of the appropriate compounds for monitoring and disruption.

The field of insect communication is indeed a broad one and would be difficult to cover adequately in one volume. In the present work, whereas the major modalities involved in communication are dealt with, the choice of some of the chapters seems puzzling. I question, for example, the need to discuss the physical or morphological aspects of an apparatus used in communication (chapters by Wehner and Srinivasan; Bennet-Clark) when there is no discussion of the relevance of the behaviors involved. These technical aspects could have been better handled by references to other reviews. In addition, the chapter by Boeckh is the only one that contains any discussion of electrophysiology as it relates to communication. There is also a lack of integration between chapters,

and the introductory chapter by the editor, Lewis, makes no attempt at a synthesis. Rather, he discusses insect communication as it might relate to several aspects of human language, and then proposes four areas of concern for future study. These include electromagnetic communication, recognition and perception of pheromone blends, applied exploitation, and additional modes of communication. I would agree with the second and third of these choices but would voice an opinion, shared by a number of the authors themselves, that one of the most pressing problems concerns the functional aspects of signaling as its relates to the ecology and evolution of mating and the social aspects of communication in the Hymenoptera. I also question whether the theories proposed by Callahan constitute a serious concern for future studies.

Finally, the volume is of high quality, well illustrated, and extensively referenced. While it is not complete in its coverage, and thus might not serve adequately as a text, many of the chapters provide excellent reviews for researchers in other disciplines, and perhaps a number of stimulating questions for those in a particular discipline, as indeed was the case with this reviewer.

PLANT ALLELOCHEMICALS AND INSECT PARASITOIDS Effects of Nicotine on *Cotesia congregata* (Say) (Hymenoptera: Braconidae) and *Hyposoter annulipes* (Cresson) (Hymenoptera: Ichneumonidae)[1,2]

(Received July 15, 1985; accepted September 11, 1985)

Abstract—Parasitoids developing within tobacco hornworms or fall armyworms exhibit significant differences in development and survival depending on whether their hosts fed on nicotine-free or nicotine-containing diets. The effects of nicotine were more severe on the relatively less adapted parasitoid, *H. annulipes* than the specialist parasitoid, *Cotesia congregata*. Labeled alkaloid originally placed in herbivore diet was incorporated in several parasitoid tissues. These results suggest that interactions between plant allelochemicals and parasitoids should be considered in the development of theory on insect herbivory and plant defense.

Key Words—Plant allelochemical, parasitoids, three trophic level interactions, nicotine, *Manduca sexta*, Lepidoptera, Sphingidae, *Spodoptera frugiperda*, Noctuidae, *Cotesia congregata*, Hymenoptera, Braconidae, *Hyposoter annulipes*, Ichneumonidae.

INTRODUCTION

The role of plant nutrients and allelochemicals on the ecology of insect herbivores has been the subject of a great deal of research. Relatively little emphasis

has been placed on the role of plant allelochemicals, within the tissues of herbivores, on the survival and ecology of secondary consumers such as insect parasitoids. Several researchers have speculated on the nature of these three trophic level interactions. Their conclusions were generally based on correlations between low levels of parasitism and the consumption by herbivores of plants with allelochemicals known to be toxic, the demonstration of the presence of an allelochemical within a parasitoid without an evaluation of its effects, or some other form of indirect or incomplete evidence (Narayanan and Subba Rao, 1955; Smith, 1957; Jones et al., 1962; Reichstein et al., 1968; Altahtawy et al., 1976; Rothschild et al., 1977; Smith 1978; Benn et al., 1979). Although many of the conclusions and speculations made in these studies are intuitively appealing, they remain speculations and assumptions to be fully and critically tested.

Morgan (1910) and Gilmore (1938a,b) suggested that nicotine might influence levels of parasitism of *Manduca sexta* (L.) (the tobacco hornworm) parasitized by *Cotesia congregata* (Say) (= *Apanteles congregatus*). Thurston and Fox (1972) found a significantly lower larval parasitoid emergence from hosts treated with nicotine. Development time of parasitoid larvae from nicotine-treated hornworms was longer, but the difference was not significant. Campbell and Duffey (1979, 1981) provided the most detailed and extensive investigations of the role of an allelochemical, within host tissues, on parasitoid survival and fitness. Campbell and Duffey (1979) showed that tomatine, a major alkaloid of tomato, caused prolonged larval parasitoid development, reduced pupal eclosion, reduced adult size and longevity, and caused morphological abnormalities in *Hyposoter exiguae* (Viereck), a parasitoid of *Heliothis zea* (Boddie) (corn earworm). Campbell and Duffey (1981) suggested that the detrimental influences of tomatine resulted from the possible disruption of sterol metabolism.

Our study attempted to confirm and extend the results of Thurston and Fox (1972). In addition to documenting other biological effects of nicotine, the study was designed to determine if nicotine was present at all three trophic levels and thus confirm the role of nicotine as the causal agent. A comparison was made of the outcome of interactions among a plant allelochemical, an herbivore, and its parasitoid using two herbivores, *Manduca sexta* and *Spodoptera frugiperda* (Smith) (the fall armyworm). The parasitoids of the hornworm and fall armyworm which were evaluated were *Cotesia congregata* and *Hyposoter annulipes*, respectively.

METHODS AND MATERIALS

M. sexta and *S. frugiperda* were reared on synthetic diets (Bio-Serv. Inc., Frenchtown, N.J.) which were either nicotine free or had nicotine incorporated. The concentration of nicotine in the fall armyworm diet (0.025% wet weight)

was $\frac{1}{4}$ that of the tobacco hornworm diet (0.1% wet weight) due to the higher sensitivity of the fall armyworm to nicotine toxicity. These concentrations are at the low end of the range of concentrations normally found in tobacco (Sisson and Saunders, 1983) and cause no significant mortality of host herbivores. To follow the low levels of nitocine incorporated into insect tissues, both diets were supplemented with 100 μCi/liter of generally labeled tritiated nicotine-*d*-bitartrate with specific activity of 1.27 μCi/mmol (Amersham Corp Arlington Heights, Illinois).

Newly enclosed tobacco hornworm and fall armyworm larvae, because of their sensitivity to manipulation, were left on nicotine-free diet before being used in experiments. Seven-day-old hornworm larvae (usually second instars) were individually parasitized and placed in 227-cm^3 (8-oz.) paper cups. Larvae of this age are the host stage preferred by *C. congregata*. Half the parasitized larvae were placed on nicotine-free diet and the other half on nicotine-containing diet. For *S. frugiperda*, half of a cohort of 3-day-old larvae were transferred to nicotine-containing diet while half were placed on nicotine-free diet. All larvae were parasitized on day 4, which is the preferred host stage of *H. annulipes*. Larvae were placed in 10-cm-diam. plastic Petri dishes with diet in batches of 18/dish and exposed to parasitoid females.

C. congregata is gregarious, and larvae emerge from their hosts and spin cocoons in which they pupate and from which adults emerge. After larval parasitoid emergence, all host larvae were dissected and unemerged parasitoids counted. *H. annulipes*, a solitary parasitoid which consumes all host tissues except for its integument, emerges as a larva and spins a cocoon from which the adult emerges.

Samples of synthetic diet, parasitoid adults, cocoons, and meconia were taken to isolate, identify, and quantify the labeled alkaloid. Samples were frozen, weighed, lyophilized, reweighed, and ground in a mortar and pestle with 40% (v/v) methanol containing 0.1% (v/v)1 N HCl. The homogenate was centrifuged at 10,000 *g* for 10 min and the supernatant filtered through 0.45 μ nylon 66 membrane filters. The samples were applied to an HPLC chromatographic system with a Waters automatic injector and a UV absorbance monitor with a Waters Model 440 detector. The specific radioactivity of each of the peaks in the eluant was monitored with a Radiomatic Model Flo-one HS radioisotope detector using Flow Scin II cocktail. Nicotine was separated and quantitated on a 10-μ C_{18} reverse-phase column using a mobile phase at 0.6 ml/min 60% (v/v) methanol containing 0.1% (v/v) phosphoric acid buffered to pH 7.0 with triethylamine. Total radioactivity in each sample was checked by measuring the level of radioactivity in an aliquot of the extract with a Packard Tricarb scintillation counter as described previously (Saunders et al., 1977). Specific quench curves for each type of biological sample were used to quantitate the concentration of labeled compound in tissues.

RESULTS AND DISCUSSION

Nicotine in the tissues of an herbivore can effect the development and survival of its parasitoids. In tobacco hornworms reared on nicotine-containing diets, the proportion of parasitoid larvae that failed to emerge from their hosts was significantly greater than those failing to emerge from hornworms on nicotine-free diets (Table 1). These data confirm the results of Thurston and Fox (1972). Of the parasitoid larvae which emerged from their hosts, a greater proportion failed to form cocoons if they had emerged from nicotine-fed hornworms. No statistically significant differences were demonstrated in pupal mortality, average number of larvae emerging, or the average total number of adults resulting per host (Table 1). Larval and pupal development as well as the size of adult *C. congregata* were unaffected by nicotine (Table 2).

The effects of nicotine on *H. annulipes* were similar to those on *C. congregata* but somewhat more severe on survival and development (Table 3). Of the fall armyworms reared on nicotine-containing diet and exposed to parasitism, only about 46% produced parasitoid larvae compared to almost 76% of the hosts reared on nicotine-free diet. These results are, at least in part, comparable but in sharp contrast to the lack of significant differences in the total number of *C. congregata* produced. Clearly, some of the difference may have been due to fewer nicotine-fed armyworm being parasitized. The extremely small size of 4-day-old larvae and the large size of *H. annulipes* relative to its host made accurate determination of individual parasitization, rather than random contact, impossible. As with *C congregata*, the ability of *H. annulipes* to

form cocoons is influenced by nicotine. Another important difference between parasitoid species is that while larval development in *C. congregata* is unaffected by nicotine, nicotine exposure prolongs larval development in *H. annulipes*.

Perhaps most important were differences in adult size. *H. annulipes* adults from hosts reared on nicotine-containing diet were significantly smaller than those produced from hosts free of nicotine. These results are in marked contrast to those with *C. congregata* where the slight numerical differences between nicotine and nicotine-free adults were not statistically significant. The decline

in adult parasitoid weight associated with the presence of nicotine in hosts may have important negative consequences for *H. annulipes* fecundity and overall fitness. Other developmental parameters were not affected by nicotine. Essentially identical results have been obtained in field experiments using low and high nicotine cultivars in which parallel observations were made (Thorpe and Barbosa, 1986, 1319–1328).

Determination of the presence and quantity of the labeled compound in parasitoid tissues confirms the transfer of a plant allelochemical from the diet of an herbivore to the herbivore and subsequently to its parasitoid (Tables 4 and 5). Campbell and Duffey's (1979) study was the first and this is the second to detect directly a plant allelochemical in the tissues of a parasitoid and simultaneously to demonstrate its deleterious effects.

Tables 4 and 5 show that the parasitoids of both the tobacco hornworm and the fall armyworm may deal with accumulated concentrations of a plant allelochemical by shunting the material to cocoon silk and meconium (waste

products remaining in the cocoon after adult emergence). The highest concentrations of radioactive alkaloid per gram dry weight were observed in the cocoon silk and meconium. Relatively little radioactivity remained in adult tissues. In *C. congregata*, a significantly greater concentration of alkaloid is shunted to the cocoon silk rather than into the meconium. This is an efficient mechanism since cocoon biomass is six times greater than that of meconia. No such efficiency is exhibited in *H. annulipes*. Nicotine may (1) be directly toxic to parasitoid larvae, (2) interfere with parasitoid nutrition, or (3) act indirectly by reducing host size beyond that caused only by parasitism. Host size and nutrition can also affect both parasitoid growth and development (Beckage and Riddiford, 1978, 1983). Regardless of the specific mechanism, the presence of nicotine in parasitoid tissues supports the role of nicotine as the causal factor in the biological changes observed.

In *C. congregata* the only aspects of development which are detrimentally affected are those changes occurring just prior to and just after larval parasitoid emergence. The fact that any detrimental changes were noted is somewhat unexpected since the parasitoid was exposed to very little of the ingested nicotine. Indeed the concentration of nicotine in the diet of the hornworm causes no significant hornworm mortality. Hemolymph is the principal food source of parasitoid larvae. Of the small amount of nicotine that remains in hornworm tissues, the lowest concentrations are found in the hemolymph. Self et al., (1964) demonstrated that the percent recovery of ^{14}C-labeled nicotine in hornworm larvae 4, 15, and 24 hr after ingestion was 5.2%, 4.1%, and 0%, respectively, while after 24 hr, 92.4% of ingested nicotine is recovered in the feces (Self et al., 1964). Both data sets suggest the rapid egestion of nicotine. Six hours after ingestion, the ratio of recovered nicotine in hemolymph, larva, and feces was 1:6:182. Although one might speculate that parasitoids may concentrate blood alkaloids, there is no evidence indicating that parasitoids possess such a capacity, and thus it is most reasonable to assume that the food consumed (blood) contains relatively little alkaloid. A second reason why, a priori, one would not expect any major effect due to nicotine is that the evolution of *C. congregata* is closely associated with that of *M. sexta* and thus closely associated with nicotine. Although *C. congregata* is recorded from other Sphingidae, the relative abundance of other hosts is scarcely comparable to that of *M. sexta*. In addition, whether or not the parasitoids emerging from these other sphingid hosts are actually *C. congregata* is a subject of debate (Krombein et al., 1979).

Hyposoter annulipes, on the other hand, is not routinely exposed to nicotine. It attacks a variety of noctuids which feed on a large number of plant families (i.e., a wide variety of plant allelochemicals). Tobacco (and thus nicotine) is not a prime or frequent host plant of any *H. annulipes* hosts. In the Maryland area, *S. frugiperda* attacks tobacco only when its populations reach relatively high densities on other crops like corn. These factors may, at least in

part, explain the more severe effects of nicotine on this parasitoid compared to those on *C. congregata*. However, since little is known of the metabolism of nicotine by the fall armyworm, intrinsic changes (i.e., metabolic alteration of nicotine) may be responsible for the modification of survival and development in *H. annulipes*.

Finally, data like these may have a significant effect on theories describing insect–plant interactions. Although the role of plant allelochemicals in host-habitat and host-finding has been extensively reviewed (Vinson 1975, 1976, 1977, 1981; Price, 1981; etc.), there has been less emphasis on the effects of plant allelochemicals within the tissues of herbivores on their natural enemies. This study, Campbell and Duffy's (1979, 1981), and others (see Introduction) suggest that the development of ecological theories on plant–insect interactions should consider the role of natural enemies. Issues that might be affected by such consideration include the role of insect herbivory in the evolution of certain forms of plant defense, the relationship between type of defense and growth forms of plants, the protection of "valuable" tissues at the potential expense of less important tissues, etc. We suggest that parasitoids (and other natural enemies) are critical participants in three trophic level interactions and may affect the evolution of plant and herbivore. Thus, theoretical predictions that include parasitoids (or other third-trophic-level organisms) may be quite distinct from those that exclude them from consideration and may be more parsimonious with ecological and evolutionary patterns (see Barbosa and Saunders, 1985; Schultz, 1983).

Acknowledgments—The authors would like to express their appreciation for the comments of Dr. Sean Duffey on an early version of this manuscript.

Abstract—The significance of nicotine in the three trophic level interaction involving tobacco (*Nicotiana tabacum*), the tobacco hornworm (*Manduca sexta*), and the parasitoid *Cotesia congregata* was investigated in field plots of two varieties of tobacco which had about a 10-fold difference in their nicotine content. While *M. sexta* mortality, rates of parasitism by *C. congregata*, and the total number of *C. congregata* larvae produced per host were similar on each of the two varieties, the number of parasitoids reaching adulthood on the low nicotine treatment was nearly twice that on the high nicotine treatment. This difference was due to the significantly greater proportion of parasitoid larvae which failed to emerge from the host or that died prior to pupation after emerging from hosts which fed on the high nicotine variety. A greater proportion of larvae from hosts which fed on the low nicotine tobacco died as pupae. No treatment differences occurred for either sex of the parasitoid in individual dry weight, longevity, or pupal development time, except that female pupal duration was prolonged in the high nicotine treatment. These results support the suggestion that plant allelochemicals, which may function to provide plant resistance against pest herbivores, can be detrimental to natural enemies of the pest.

Key Words—Plant allelochemical, parasitoid, three trophic level interaction, antibiosis, nicotine, tobacco, *Manduca sexta*, Lepidoptera, Sphingidae, *Cotesia congregata*, Hymenoptera, Braconidae.

INTRODUCTION

An extensive body of theory has been developed to explain the role of plant allelochemicals in plant–insect herbivore interactions (Feeny, 1975 1976; Rhoades and Cates, 1976; Rosenthal and Janzen, 1979). While early attention focused primarily on the effects of plant chemicals within a two trophic level system, emphasis has more recently expanded to include interactions with natural enemies, which occupy the third trophic level (Lawton and McNeill, 1979; Price et al., 1980; Schultz, 1983). Natural enemies consuming hosts which in turn are feeding on plants being defended by allelochemicals can be affected in a variety of ways. These compounds can increase a herbivore's susceptibility to natural enemies by prolonging development time (Feeny, 1976; Blau et al., 1978; Lincoln et al., 1982), increasing consumption (Aizawa, 1963; Doane and McManus, 1981), or increasing the duration of such noncryptic activities as feeding and intra- and interplant movement (Erikson and Feeny, 1974; Schultz, 1983). However, adverse effects of allelochemicals on natural enemies have also been demonstrated (Eisner, 1970; Campbell and Duffy, 1979; Price et al., 1980; Barbosa and Saunders, 1985).

Nicotine, an alkaloid found in tobacco (*Nicotiana tabacum* L.), is an allelochemical which has been shown to be highly toxic to insects (Self et al., 1964; Yang and Guthrie, 1969; Parr and Thurston, 1972). Thurston and Fox (1972) reported reduced emergence of larval *Cotesia congregata* (=*Apanteles congregatus*) (Say) from their *Manduca sexta* (L.) hosts after adding nicotine to the host's synthetic diet. Campbell and Duffey (1979, 1981) demonstrated that tomatine [a major alkaloid of tomato (*Lycopersicon esculentum* Mill.)] can cause prolonged development, reduced pupal eclosion, smaller size, and shortened adult longevity in *Hyposoter exiguae* (Viereck) when incorporated into its host's synthetic diet. Laboratory studies by Barbosa et al. (1986) showed that *C. congregata* developing in *M. sexta* reared on artificial diet containing 0.1% nicotine suffered higher larval mortality than those reared on hosts fed diet without nicotine. The nicotine treatment significantly reduced the number of *C. congregata* larvae that emerged from the host and those that did emerge spun fewer cocoons.

The effects of nicotine on *C. congregata* have never been experimentally tested in the field. Morgan (1910) and Gilmore (1938) observed that *M. sexta* parasitism appeared to occur at much lower levels on tobacco than on other nearby solanaceous plants and attributed this difference to the toxic effects of nicotine. Thurston and Fox (1972) sampled *M. sexta* larvae from field plots of dark and burley tobacco varieties (presumed to have high and low levels of nicotine, respectively), but found no difference between the varieties in percent emergence of *C. congregata* larvae. The objectives of this study were to test the effects of a high and a low nicotine variety on the survival of *M. sexta*, rates

of parasitism by an endemic population of *C. congregata*, and to evaluate the effects of the different host diets on parasitoid survival and development.

METHODS AND MATERIALS

A 0.14-hectare field of tobacco at the University of Maryland Tobacco Experiment Station, Upper Marlboro, Maryland, was divided into 25 blocks of 40 plants each. Row and interplant spacing were 1 and 0.6 m, respectively. Each block was subdivided into two treatment plots, each containing 20 plants of either NC-95, a flue-cured tobacco variety widely used in North Carolina which has an alkaloid level of 2.65% on a cured-leaf basis (Chaplin and Weeks, 1976), or LAFC-95, an experimental line created by back-crossing a low alkaloid line to NC-95 (Chaplin, 1975). This variety has an alkaloid level of 0.18%. Each block was separated from adjacent blocks by two rows of MD-201, a typical commercial variety used in Maryland. All treatment plants were started from seed in a greenhouse and then transplanted by hand on June 27, 1983. Metalaxyl and pendimethalin were incorporated into the soil prior to planting for disease and weed control, but no additional pesticides were used. Subsequent weed control was by mechanical cultivation.

The *M. sexta* used in this study were obtained as eggs from stock cultures (North Carolina State University). Larvae were transferred upon hatching to 2-liter plastic crispers containing strips of Bioserv® hornworm diet. When the treatment tobacco plants were ca. 50 cm tall, a population of *M. sexta* was established by transferring 1- to 3-day-old laboratory-reared larvae from diet to tobacco leaves at a mean density of one larva per treatment plant. The actual dispersion of the larvae was determined by sampling from the negative binomial distribution with $k = 4$ (Southwood, 1978). Borth and Harrison (1984) found that this distribution approximates that of endemic *M. sexta* populations in Maryland tobacco fields. Interplant migration does not occur at these densities (McFadden, 1968). Six hundred larvae were introduced on July 25 (cohort 1) and 400 on August 9 (cohort 2). All individuals were subsequently counted twice weekly. Missing larvae were assumed lost to predation (Lawson, 1959). Since the development of individual larvae was carefully monitored, any *M. sexta* found to be at an inappropriate growth stage were assumed to have originated from wild populations and were removed.

Rates of *C. congregata* parasitism over time were determined by sampling three or four larvae from each treatment in each of five blocks (cohort 1) or three blocks (cohort 2) twice weekly. (The actual number of larvae sampled is shown in Table 2). Sampled larvae were subsequently reared for two weeks on excised tobacco foliage and then dissected to determine parasitism. On August 10 and 25, all remaining larvae from cohorts 1 and 2, respectively, were collected and reared individually in the laboratory in 177-ml plastic cups on ex-

cised leaves of the same tobacco variety from which they were collected. All larvae were examined daily for parasitoid emergence. The number of *C. congregata* larvae that emerged and spun cocoons was recorded for each host. Three days after parasitoid emergence, all *M. sexta* larvae were frozen and later dissected to determine the number of *C. congregata* larvae which failed to emerge. All adult *C. congregata* were counted, sexed, and oven-dried at 60°C to a constant weight. *C. congregata* adult longevity and pupal development time were determined from samples of 10 cocoons from one host out of each treatment from each of 10 blocks (cohort 2 only). Each cocoon was isolated in a 27-ml plastic cup with a streak of honey and placed in a growth chamber under a regime of constant light and 27 ± 2°C. All cocoons were checked daily for adult emergence and death.

Unless otherwise indicated, all data were analyzed by analysis of variance, using the mean square error for the block × treatment interaction to test for differences between the two tobacco varieties. All data expressed as percentages were arcsine $\sqrt{\%}$ transformed prior to analysis.

Leaf samples were prepared for nicotine quantitation by cutting two veinless 0.5-g sections from the centers of randomly sampled leaves. One of these sections was dried at 50°C for 24 hr to determine percent moisture. The other was ground in 10 ml of 40% (v/v) methanol containing 0.1% (v/v) 1 N HCl with a Ten Broeck homogenizer. The homogenate was then centrifuged at 11,000 *g* for 15 min, and the supernatant filtered through a 0.45-μm Millipore filter prior to injection. The samples were processed and nicotine quantified using high-performance liquid chromatography. A description of the equipment and procedures used is given by Saunders and Blume (1981).

RESULTS

Table 1 shows the concentrations of nicotine found in samples of leaf tissue from each of the tobacco varieties on three dates. There was at least a 10-fold difference in nicotine concentration between the varieties on each sampling date. Chaplin and Weeks (1976) found a similar difference in alkaloid level between these two varieties.

The cumulative mortality of the *M. sexta* larvae placed in the field on the two varieties was not significantly different ($P = 0.66$; *t* test). The cumulative average number of larvae missing out of the 20 larvae initially established per plot increased linearly from 1.8 per plot on the third day after introduction to 9.3 per plot on the 14th day after introduction.

Rates of *C. congregata* parasitism (Table 2) were higher for the first cohort of *M. sexta* (July 25–August 8) than for the second (August 9–August 24), (60–100% and 18.2–88.9%, respectively). Rates of parasitism did not differ signif-

TABLE 2. TEMPORAL DISTRIBUTION OF PARASITISM OF *M. sexta* LARVAE BY *C. congregata* ON TWO TOBACCO VARIABLES

Cohort[a]	Tobacco variety	Parasitism (%) on day[b]			
		4	7	11	14
1	NC-95	60(15)	95(20)	100(18)	100(16)
	LAFC-53	73.3(15)	94.7(19)	100(19)	100(19)
2	NC-95	18.2(11)	54.5(11)	83.3(12)	80(5)
	LAFC-53	30(10)	83.3(12)	88.9(9)	80(5)

[a] Cohorts 1 and 2 were introduced on July 25 and Aug. 9, respectively.
[b] Number of days since larvae were introduced into the field. Values are % parasitism of (N) *M. sexta* larvae averaged across five (cohort 1) or three (cohort 2) blocks.

icantly between varieties ($P = 0.16$) (date and cohort effects were not partitioned or tested). Sixty-seven percent of the larvae in cohort 1 were parasitized by the fourth day after exposure in the field, and by the 11th day, 100% of the larvae were parasitized. The apparent drop in the percentage of larvae parasitized in cohort 2 from day 11 to 14 may be a sampling artifact, or it may indicate selective elimination of parasitized individuals from the population.

The effect of high and low nicotine varieties on *C. congregata* survival and development is shown in Tables 3 and 4. While the total number of *C. congregata* larvae which developed in *M. sexta* feeding on each of the two varieties was not significantly different, significantly more male and female *C. congregata* adults were produced from hosts feeding on the low nicotine variety (Table 3). This was because a significantly greater proportion of larvae failed to emerge from hosts on high nicotine tobacco, and a significantly higher proportion of those that did emerge died prior to spinning cocoons. A significantly greater proportion of the *C. congregata* which developed in hosts which fed on

the low nicotine tobacco died as pupae, but this source of mortality was low (<4%) in both treatments. Since the exact time of parasitization was not known, larval development time could not be measured. However, pupal development time was significantly greater for females under the high nicotine treatment (Table 4). There were no significant differences between treatments in longevity or dry weight of *C. congregata* adults.

DISCUSSION

Wilson and Huffaker (1976) state that plant resistance and biological control should form the core of integrated pest management programs. Campbell and Duffey (1979) and Barbosa et al. (1982) suggest that these tactics may be incompatible or even antagonistic if the mechanism of host plant resistance interferes with the biology of natural enemies. Some incompatibility appears to have occurred in this study since two tobacco varieties which differed in their levels of the allelochemical nicotine were found to affect the survival of *C. congregata* differentially.

The two tobacco varieties in this study differed significantly not only in their alkaloid level, but also in their levels of reducing sugars and total nitrogen (Chaplin and Weeks, 1976). Some of the difference in total nitrogen between the two varieties may be due to the difference in the levels of nicotine, which contains nitrogen; however, the reduction in the alkaloid fraction of the low nicotine variety cannot account for all of the reduction in total nitrogen (Chaplin and Weeks, 1976). While it is possible that some portion of the detrimental effects of the high nicotine tobacco variety on *C. congregata* were attributable to nutritional factors rather than toxicity, total nitrogen, which is considered to be a good index of nutritional quality (Mattson, 1980), is higher in the high than in the low nicotine variety, suggesting that the high nicotine variety is nutritionally superior. The close agreement between the results of this study and those of Barbosa et al. (1986), in which nutritional quality was controlled by using artificial diet, further supports the role of nicotine as the factor responsible for the reduction in *C. congregata* survivorship on hosts which fed on the high nicotine tobacco.

Acknowledgments—We are indebted to Dr. James Saunders for the HPLC analysis, Dr. Michael Jackson for providing the tobacco seeds, Dr. Ken Aycock for his assistance in growing the tobacco seedlings, and Dr. Clyde McCee and the University of Maryland Tobacco Research Farm for providing and maintaining the field plots of tobacco. We also thank Drs. Michael Raupp and Sean Duffey for critically reviewing an earlier version of the manuscript, and Mr. John Kemper and Ms. Jane Downing for technical assistance. The Computer Center of the University of Maryland provided computer time.

LASER MICROBEAM STUDIES OF ROLE OF AMPHID RECEPTORS IN CHEMOSENSORY BEHAVIOR OF NEMATODE *Caenorhabditis elegans*

BOWMAN O. DAVIS, JR.,[1] MARIAN GOODE, and DAVID B. DUSENBERY

(Received May 30, 1985; accepted September 12, 1985)

Abstract—Amphid sensilla, historically considered the primary chemosensory structures of nematodes, were found to be necessary for the detection of only one of the six chemical stimuli that were tested. Only the attraction to cAMP was eliminated by damaging the two lateral lips, which bear the amphid sensilla. The inner labial sensilla, one of which occurs on each of the six lips, are probably the primary receptor structures for the other chemical stimuli. Damaging all six lips, which should destroy all anterior chemosensory input, not only eliminted the attraction to sodium and chloride ions, but reversed the nematodes' response to them. Nematodes with all six lips destroyed showed reversal behavior when exposed to these attractants. Nematodes with damage to all six lips appeared to recover much of their normal chemosensory function within 24 hr after treatment.

Key Words—*Caenorhabditis elegans*, nematode, chemotaxis, chemoreception, amphid, laser microbeam.

INTRODUCTION

For many years, the amphids have been thought to be the major sense organs for reception of chemical stimuli by nematodes (Steiner, 1925). Evidence for this reasonable supposition is their location near the anterior end and their structure, which consists of nerve cell endings within a cavity that opens to the exterior (Coomans, 1979; Wright, 1980). Until recently, there was no experi-

[1] *Present address: Department of Biology, School of Science and Allied Health, Kennesaw College, Marietta, Georgia 30061.

0098-0331/86/0600-1339$05.00/0

mental evidence to support this presumed function. We have approached the question of amphid chemosensory function by using a laser microbeam to destroy the amphids in *Caenorhabditis elegans* and measuring their response to a variety of known stimulus chemicals.

Laser microbeams have previously been used to study the function of sensory structures (Samoiloff et al., 1973; Chalfie and Sulston, 1981). Since treatment with the laser microbeam requires the handling of individual specimens, a behavioral assay that works well with individual nematodes is desirable. The tail-tether technique (Dusenbery, 1980) appears to be the best available in this regard. In this technique, a nematode is held by the tail with a suction pipet, while a stream of water carrying chemical stimuli flows past. Its behavior is recorded by projecting its shadow on an array of photodetectors connected to a polygraph. Reversal bouts and other responses to adverse stimulation are readily determined. The distribution of these activities during repeated cycles of stimulation is used to determine the response score.

Detailed studies of the anterior end of *C. elegans* have been made by serial-section electron microscopy (Ward et al.,1975; Ware et al., 1975). It was demonstrated that the only anterior sensilla that open to the exterior are the amphids and the inner labial sensilla. The only other sensilla that are known to open to the exterior are the pair of phasmids located on the tail (Sulston et al., 1980). The amphids are relatively complex sensilla. Each amphid contains the endings of 12 neurons, eight of which appear to be exposed to the outside environment. Each inner labial sensillum contains the endings of two neurons, one of which is exposed to the exterior. Each phasmid contains the endings of two neurons, both of which are exposed to the exterior. The sensilla of other nematodes are basically similar, except that the number of neurons in each type of sensillum varies (Coomans, 1979; Wright, 1980).

The six inner labial sensilla are distributed radially around the mouth. One inner labial sensillum is associated with each of the six lips. Additionally, an amphid sensillum is located on each of the two lateral lips. Since each lip is only about 1 μm across, it is not practical to destroy a single type of sensillum on the lateral lips. However, one can exploit the fact that destruction of the lateral lips should inactivate both amphids but only one third of the inner labial sensilla. This pattern of damage allows the detection of chemosensory responses that are mediated by the amphid receptors.

METHODS AND MATERIALS

Unless otherwise specified, young adult nematodes were taken from standard cultures (Brenner, 1974). For microbeam treatment of the lateral lips, the nematodes were anesthetized with either 0.1% tricaine and 0.01% tetramisole (Kimble et al., 1982) in N buffer (100 mM NaCl, 25 mM potassium phosphate,

pH 6.0) or with sodium azide (Nelson, personal communication) at a final concentration of 100 μg/ml in N buffer. Anesthetized nematodes were transferred to an agar pad (Sulston et al., 1980) and oriented with their lateral lips in the same focal plane by placing a length of 6-O surgical silk across the nematode prior to addition of the cover glass. For treating all six lips, the nematodes were anesthetized in either tricaine/tetramisole or cold N buffer saturated with CO_2, or with sodium azide as described above. The tricaine/tetramisole-treated nematodes were allowed to recover from anesthesia overnight, whereas the CO_2- and sodium azide-treated nematodes recovered within 30–90 min. Unfortunately, the CO_2 treatment did not immobilize the nematodes sufficiently to use the orientation technique for treating the lateral lips.

The laser microbeam system was patterned after that of J.G. White (Sulston and White, 1980) and employed a Candella, model SLL-66 flashlamp-pumped dye laser focused through a Zeiss Universial microscope equipped with differential interference contrast optics. Using coumarin-2 dye, the microbeam system focuses on the order of 0.1 megawatt of 450 nm photons through an area about 1 μm in diameter for about 0.1 μsec. This extreme intensity leads to nonlinear, multiphoton processes, and no absorbing pigment is required. The laser intensity was sufficient to produce visible damage to target tissues as evidenced by coagulation which was visible with the differential interference contrast system. To ensure complete destruction of dendritic endings, target lips were subjected to multiple hits until the entire interior lip tissue was visibly coagulated. From those specimens which showed no alteration in chemotaxis behavior as a result of the laser treatment, representatives were heat killed and reexamined by differential interference contrast microscopy to confirm the extent of lip damage.

After recovery from anesthesia, treated nematodes were assayed for altered responses to sodium, chloride, carbon dioxide, D-tryptophan, high osmolarity, and cAMP. Responses were quantitated by the tethered worm technique (Dusenbery, 1980) which gives a graphic recording of the nematode's movement patterns. This assay technique allows for repeated, cyclic exposure of each nematode to alternate stimulus and control solutions. Both experimental and control solutions were prepared using one of three standard buffers. MOPS (morpholinopropane sulfonic acid) buffer contained 10 mM MOPS, 5 mM KCl, 1 mM $CaCl_2$, and 1 mM $MgSO_4$ adjusted to pH 7.0. MES [2(*N*-morpholino)ethane sulfonic acid] buffer was the same as the MOPS buffer with MES substituted for the MOPS and adjusted to pH 6.0. Finally, a phosphate buffer contained 5 mM Na_2HPO_4, 5 mM KH_2PO_4, and 50 mM Na_2SO_4 adjusted to pH 7.0.

For each assay, the test and control solutions were prepared as shown in Table 1. Nematodes were alternately exposed for 1-min intervals to test and control solutions. Both experimental nematodes and anesthetized controls were

TABLE 1. COMPOSITION OF BEHAVIORAL ASSAY SOLUTIONS

Assay	Test solution	Control solution
Na^+	100 mM NaCl in MOPS buffer	50 mM $CaCl_2$ in MOPS buffer
Cl^-	100 mM NaCl in MOPS buffer	50 mM Na_2SO_4 in MOPS buffer
D-Tryptophan	1 mM D-tryptophan and 100 mM NaCl in MOPS buffer	100 mM NaCl in MOPS buffer
Osmotic	200 mM NaCl in MOPS buffer	100 mM NaCl in MOPS buffer
CO_2	1 mM $NaHCO_3$ and 100 mM NaCl in MES buffer	100 mM NaCl in MES buffer
cAMP[a]	2 mM cAMP in phosphate buffer	Phosphate buffer alone

[a] Since Ward (1973) found that Cl^- inhibits the response to cAMP, no chloride was included in the test or control solutions.

observed for at least 10 cycles of stimulation. Controls were generally anesthetized with the experimentals and allowed to recover without microbeam exposure. However, controls for the sodium assay had one subdorsal and one subventral lip targeted in order to verify that the observed responses were not simply a result of the microbeam procedure.

For quantitation of each cycle, the solution in which the greater reversal activity occurred was determined. Each cycle of test and control solutions was designated as positive, negative, or even. A positive cycle was one in which reversal behavior was greater in the control solution. If reversal activity was greater in the stimulus solution, the cycle was scored as negative. Response values (R) were calculated by the formula:

$$R = \frac{N_+ - N_-}{N_+ + N_- + N_0} \times 100$$

where N_+ = positive cycles, N_- = negative cycles, and N_0 = even cycles in which reversal activity was either absent or equal in both solutions. This procedure produces a scale on which +100 corresponds to complete attraction, −100 to complete avoidance, and zero corresponds to no response. Mean response (R) values and standard deviations were computed for each experimental and control group. Rank-sum statistical analyses were performed on the mean R values of different experimental and control groups. In any comparison, if the probability that the two means were from the same population was less than 5% ($P < 0.05$), the two means were considered to be significantly different.

In experiments to evaluate the nematode's capacity to recover from laser damage, both young (3–4 days old) and old (6–7 days old) nematodes were

assayed twice for their responses to sodium. The first assay was performed immediately (2 hr) after recovery from anesthesia. Nematodes were then removed from the tail-tether apparatus and held overnight on separate, fresh bacterial plates. After 24 hr the same nematodes were assayed again for response to sodium to detect any recovery of chemosensory function.

RESULTS

If the amphids were the only receptors for sodium ions, damaging the lateral lips should eliminate the response to sodium. However, as seen in Table 2, nematodes treated in this way responded nearly 80% as strongly as untreated controls. Although lateral lip damage significantly decreased the response from that of untreated controls (Table 2 and Table 3, column L-0), the results of this procedure did not differ significantly from those obtained by destruction of a subdorsal/subventral lip pair (Table 2 and Table 3, column L-SD/SV). Bilateral lip damage eliminates all amphid-mediated sensory input while leaving four of the six inner labial sensilla unaltered and presumably functional. Thus, the data indicate that the inner labial sensilla, rather than the amphids, are of primary importance for the detection of sodium.

In order to test the involvement of inner labial sensilla, all six lips were targeted, and nematodes were tested for response to sodium and chloride. Interestingly, destruction of all six lips did not eliminate the responses as expected. Instead, this treatment reversed the responses so that avoidance behavior was greater in the sodium or chloride solutions (Table 2). Nematodes that were anesthetized with tricaine/tetramisole did not show the characteristic re-

TABLE 2. RESPONSES TO Na^+ AND Cl^-[a]

		Lips targeted			
		Twa			
Stimulus	Anesthetic	Lateral	SD/SV	Six	None
Na^+	Na azide	78 ± 18(6)	93 ± 11(6)	−70 ± 19(5)	100 ± 0(5)
Na^+	T/T[b]	82 ± 5(5)	89 ± 16(5)	66 ± 29(8)	99 ± 4(8)
Na^+	CO_2			−76 ± 17(5)	94 ± 5(7)
Cl^-	CO_2			−60 ± 35(5)	88 ± 16(6)

[a] Tabulated above is the mean response (*R* value) ± standard deviation and (*N*) for the following groups: lateral lips ablated (Lateral); one subdorsal and one subventral ablated (SD/SV); all six lips ablated (Six); and anesthetic controls with no lips targeted (None).

[b] With this anesthetic, a 24-hr delay occurred between microbeaming and assay to allow for recovery from anesthesia.

TABLE 3. STATISTICAL ANALYSIS

Stimulus	Anesthetic	*P* value of groups compared				
		L-SD/SV	L-6	L-0	6-0	SD/SV-0
Na^+	Na azide	0.066	0.002	0.015	0.002	0.094
Na^+	T/T	0.050	0.724	0.030	0.020	0.434
Na^+	CO_2				0.001	
Cl^-	CO_2				0.002	

[a] Rank-sum statistical tests were performed on data from the groups reported in Table 2. The probability that the groups compared were from the same population is tabulated above. Worms with lateral lip ablation (L) were compared with worms having all six lips ablated (6) and with control groups in which either two lips other than the laterals were ablated (SD/SV) or in which the worms were anesthetized and not ablated (0).

versal of response to sodium when all six lips were damaged. However, with this anesthetic, 24 hr were required for recovery. During this extended time, functional recovery from the laser damage is a possibility. Such recovery could return their responses toward normal by the time of the assay.

In order to test the possibility of recovery from laser damage, a separate battery of experiments was conducted in which nematodes were anesthetized with sodium azide. Since recovery from azide anesthesia was rapid, nematodes could be assayed for sodium detection within 2 hr of treatment. Each individual nematode could then be allowed to recover overnight and could be assayed a second time after 24 hr. Table 4 shows the results of these experiments. Young nematodes (3–4 days old) showed statistically significant recovery of chemosensory function over 24 hr. Interestingly, older nematodes (6–7 days old) showed no significant recovery over the same time period. Statistically, even the younger nematodes did not recover sufficiently to equal the ability of control nematodes in detecting sodium.

TABLE 4. AGE DEPENDENCE OF 6-LIP RECOVERY

Treatment group	Age (days)	2 hr postop[a]	24 hr postop[a]	Significance[b] (2 hr vs. 24 hr)
6-lip	3–4	$-70 \pm 19(5)$	$60 \pm 32(5)$	$P = 0.002$
control	3–4	$100 \pm 0(5)$	$100 \pm 0(5)$	
6-lip	6–7	$2 \pm 16(5)$	$26 \pm 40(5)$	$P = 0.09$
control	6–7	$98 \pm 5(5)$	$96 \pm 9(5)$	

[a] Mean (R) value $\pm$ SD(N).
[b] Experimental groups of both ages at 2 and 24 hr after ablation were significantly different from control ($P = < 0.01$).

[a] Mean response (R) value ± SD(N).

Since the experiments suggested that the inner labial sensilla, and not the amphids, were responsible for sodium detection, other known stimuli were tested to determine the role of amphid sensilla in their detection. The responses of young, lateral lip treated nematodes to CO_2, D-tryptophan, high osmolarity, and cAMP are shown in Table 5. Of the various stimuli tested, only the response to cAMP was impaired by damaging the lateral lips. The response of amphid-damaged nematodes to cAMP was significantly weaker than that of control nematodes and was similar to the behavior of nematodes receiving no stimulation.

DISCUSSION

The present findings indicate that the amphids are not essential for the response to most stimuli tested, but they may still play a minor role. The various experiments involving the response to Na^+ suggest that they might. Damage to the lateral lips had a greater impact on the response than damage to two of the other lips (Table 2), although, the difference is of marginal significance (Table 3). It may be that all anterior chemosensory sensilla participate to some extent in sodium detection. Thus, damage to the lateral lips would affect both amphids as well as two inner labial sensilla, while damage to any other pair would affect only two inner labials.

Since *C. elegans* responds to sodium as strongly and reproducibly as to any known stimulus, this finding is not a simple case of eliminating a weak or minor response. The only other experiments bearing on this surprising result are some previous genetic dissection studies on *C. elegans*. Lewis and Hodgkin (1977) described a strain of *C. elegans* that was defective in attraction to Na^+ and Cl^- and had anatomical defects in the inner labial sensilla but not the amphids. This result is entirely consistent with our microbeam studies. More recently, Albert et al. (1981) have described two strains as defective in attraction

to Na^+ and Cl^- but having anatomical defects in the amphids and not in the inner labial sensilla. This apparent contradiction can be explained by assuming that these strains have defects in the inner labial sensilla that were not observed by electron microscopy. However, when taken together, the studies of mutant strains are contradictory. The microbeam experiments described here are more convincing, and we conclude that several chemosensory responses of *C. elegans* are not dependent upon the amphids.

The reversal of response to soduim and chloride that occurred with young nematodes in which all six lips were damaged and tested within a few hours is difficult to explain. This phenomenon is further complicated by the fact that it rarely occurs with older nematodes. The reversed response could result from a mechanism by which the nematode normally compares stimulation at the head and tail and responds to the difference between them. Sensilla resembling simple amphids, the phasmids, are known to be located in the tail of most nematodes (Wright, 1980), including *C. elegans* (Sulston et al., 1980). Damage to all six lips eliminates chemosensory input from the anterior end of the nematode. If the nematodes compare anterior and posterior chemosensory input, destruction of the anterior sensilla could shift the balance of sensory input toward the tail receptors and lead to a reversed response.

The tail-tether apparatus is designed so that the tail of the nematode being tested is held in a pipet by vacuum and is probably not exposed to stimulus solutions. Younger nematodes are smaller in diameter and fit more loosely in the pipet. It is possible that stimulus solutions can "leak" around the younger nematodes and come into contact with tail receptors. Although highly speculative, this might explain the reversal of response to sodium that occurs in young nematodes. Further experiments will be necessary to answer this question.

Anatomy of the amphid sensilla has historically resulted in their being assigned the function of primary chemosensory structures of nematodes. Yet, of the six chemical stimuli tested, only cAMP detection appears to be significantly impaired by lateral lip damage. Possibly, the role of the amphid as a chemoreceptor has been overestimated. However, it is more likely that the stimuli that are normally detected by the amphids have not yet been tested or even discovered.

(Received February 11, 1985; accepted September 12, 1985)

Abstract—Five cuticular chemical components isolated from the green leaves of tobacco introductions (TIs) and a commercial tobacco cultivar were tested for their effects on tobacco budworm, *Heliothis virescens* (F), oviposition in cage bioassays, and field experiments. These chemicals were sprayed onto budworm-resistant TI 1112 tobacco which produces low levels of most cuticular components. Individual duvane diterpenes (α- and β-4,8,13-duvatrien-1-ols and α- and β-4,8,13-duvatriene-1,3-diols) increased tobacco budworm egg laying on sprayed TI 1112 plants. *cis*-Abienol, docosanol, and docosanyl myristate were inactive.

Key Words—Tobacco budworms, *Heliothis virescens* (F), Lepidoptera, Noctuidae, tobacco, *Nicotiana tabacum* L., diterpenes, duvanes, host plant resistance, oviposition.

INTRODUCTION

The leaves of commercially grown tobaccos, *Nicotiana tabacum* L., are covered by sticky exudates that are excreted onto the leaf surface from glanded

trichomes (Michie and Reid, 1968; Severson et al., 1984). The major cuticular components consist primarily of diterpenes (labdanes and duvanes), hydrocarbons, and sucrose esters (Enzell et al., 1977, Severson et al., 1984). *N. tabacum* varieties and tobacco introduction (TIs) produce primarily labdanes (some oriental and cigar tobaccos), primarily duvanes (many flue-cured and burley tobaccos), or a combination of both types of diterpenes (Reid, 1979, 1980; Sato et al., 1982; Severson et al., 1984). Tobaccos with simple (nonglanded) trichomes, such as TI 1112, produce only trace amounts of diterpenes and sucrose esters, and these tobaccos are resistant in the field to green peach aphids, *Myzus persicae* (Sulzer) (Johnson and Severson, 1982), and tobacco budworms, *Heliothis virescens* (F) (Elsey and Chaplin, 1978; Severson et al., 1983; Johnson and Severson, 1984), and tobacco hornworms, *Manduca sexta* (L.) (Chaplin et al., 1976, Johnson, 1978).

In controlled cage studies with tobacco budworm moths, Jackson et al. (1983) demonstrated that one mechanism of host plant resistance in TI 1112 is ovipositional nonpreference. The whole leaf wash (WLW) extracted from the budworm-susceptible commercial flue-cured variety, NC 2326, stimulated tobacco budworm oviposition when sprayed onto TI 1112 potted plants in cage and field experiments (Jackson et al., 1984). NC 2326 WLW was fractionated into a methanol–water-soluble (MWS) fraction, containing predominantly α- and β-4,8,13-duvatriene-1,3-diols (α- and β-diols), and a hexane-soluble (HS) fraction consisting of hydrocarbons, fatty alcohols, and wax esters. Only the MWS fraction stimulated tobacco budworm oviposition when sprayed onto TI 1112 plants (Jackson et al., 1984).

Other tobaccos, TI 1223 and TI 1341, with surface chemical compositions different from NC 2326, are also susceptible to tobacco budworm damage in the field (Johnson and Severson, 1984). TI 1223 produces the duvane diterpenes, α- and β-4,8,13-duvatrien-1-ols (α- and β-ols) and the labdane diterpene, *cis*-abienol. A mixture of duvanes, α- and β-ols and α- and β-diols, is present in the cuticular extractions of TI 1341 (Severson et al., 1984). In controlled cage studies, high levels of budworm ovipositional activity are observed on both TI 1223 and TI 1341 (unpublished data).

The research described herein was done to determine if duvane and labdane diterpenes stimulate tobacco budworm ovipositon when sprayed onto the budworm-resistant TI 1112. Docosanol and docosanyl myristate were also tested. Data from cage and field tests will be reported.

METHODS AND MATERIALS

The solvents used for plant extraction, component isolation, and spray application were Burdick and Jackson distilled-in-glass grade and were used as received. Docosanol [99+% by glass capillary gas chromatography (GC-2)]

and myristic acid (99+% by GC-2) were obtained from Sigma Chemical Company (St. Louis, Missouri).

Whole leaf cuticular components were extracted from tobacco grown under flue-cured conditions at Clemson University Pee Dee Research and Education Center, Florence, South Carolina; the Tobacco Research Station, Oxford, North Carolina; and the University of Georgia Coastal Plain Experiment Station, Tifton, Georgia, as described by Jackson et al. (1984). the NC 2326 WLW and MWS fractions were prepared from materials obtained in late May and early June at Tifton for that test year. The other diterpene components and mixtures were isolated from WLW extracts from various tobaccos obtained at all locations the previous crop year. All components and fractions were analyzed by GC-2 as described by Severson et al. (1984).

α- and β-Diol Mixture. NC 2326 MWS (2.5–3.0 g in $CHCl_3$) was placed into a 10-ml injection loop and was pumped onto a 2.5 × 58-cm liquid chromatography column (Laboratory Data Control) containing a 44-cm bed of Sephadex LH-20. Chloroform was pumped through the system at 2 ml/min, and 5-ml gel fractions (GF) were collected. After the collection of GF 45, the solvent was changed to 10% MeOH in $CHCl_3$ and pumped through the system for 3 hr. The column was reconditioned overnight using a 0.5 ml/min flow of $CHCl_3$. The fractions rich in diols (GF 35–42) were combined, and the solvent was removed from the sample on a rotary evaporator at 40°C under reduced pressure (100–150 mm Hg). The residue was placed in a desiccator under vacuum (~1 mm Hg) for 4 hr to yield 1.8–2.0 g of α- and β-diol mixture (71% α, 23% β by GC-2). The major impurities were oxidized diols (oxydihydroxy and trihydroxy duvanes).

α- and β-Ols. About 3 g of TI 1341 WLW in 10 ml of $CHCl_3$ was placed onto a Sephadex LH-20 column and eluted as above. Gel fractions rich in α- and β-ols (GF 25–32) were combined and the solvent removed. The residue was dissolved in hexane and placed on a 50-g basic alumina column (activity grade 1, slurry packed in hexane) and eluted with 0.5 liters of 1:3 CH_2Cl_2–hexane. The α- and β-ols were then eluted with 1.5 liters of 1:1 CH_2Cl_2–hexane. Solvent was removed as described above to yield about 650 mg of a colorless oil (98% by CG-2, α- to β-ol ratio 9:1).

α-Diol, β-Diol, cis*-Abienol, and Docosanyl Myristate.* α-Diol (mp 65–66°C, 99+% by GC-2) (mp 65–66°C, Roberts and Rowland, 1962), β-diol (mp 122–123°C, 99+% by GC-2) (mp 126°C, Roberts and Rowland, 1962), and *cis*-abienol, as a monohydrate (mp 63–65°C, with softening, 99+% by GC-2) (mp 65%C, with prior softening, Gray and Mills, 1964) were isolated as described by Severson et al. (1982). Docosanyl myristate was prepared from docosanol and myristic acid (mp 55.5–56°C; *m/e* 536, $C_{36}H_{52}O_2$; 98+% by GC-2).

Formulation of Spray Materials. A three-year average yield of about 55 mg of α- plus β-diols (α- to β-diol ratio approx 3:1) per plant was obtained

from 6-week-old NC 2326 plants. Therefore, the materials for spray applications were formulated at the following one-plant equivalent levels: NC 2326 WLW, NC 2326 MWS, and α- plus β-diol mixture at 55 mg of α- plus β-diol (as determined by GC-2 analyses); α-diol, α- and β-ol mixture, and *cis*-abienol at 41.2 mg; and β-diol at 13.8 mg. Docosanol and docosanyl myristate were formulated at 2 mg/plant which was 10–20 times their average levels on NC 2326 in the field. The above were dissolved in hexane–CH_2Cl_2 (3:1) at a concentration of one plant equivalent per 0.5 ml. The solutions, including a solvent blank (SB) of hexane–CH_2Cl_2 (3:1), were divided into 2-ml lots into vials and stored at $-17.8°C$ in the dark until needed. The vials were brought to ambient temperature before spraying and quantitatively transferred with carrier solution (3:1 acetone–H_2O) to yield 40 ml of spray solution. One plant equivalent of material (10 ml of mixture) was sprayed onto each test plant.

Ovipositional Cage Bioassays. A screen cage bioassay for tobacco budworm oviposition on potted tobacco plants was used for tests during 1980–1983 at the Tobacco Research Station, Oxford, North Carolina. Ten 3-day-old female moths were released shortly before dark into each 2.4 × 2.4 × 2.0-m screened cage located outside. Four test plants were placed in the corner opposite four control plants. The morning following each test all eggs were counted. Details of plant production, insect rearing, cage design, egg monitoring procedure, and spray application of cuticular isolates were described by Jackson et al. (1983, 1984). Spray treatments are given in Table 1.

Before individual analyses of variance for each experiment, data were transformed to a percentage of the total eggs counted per replication. Preference for egg laying on a particular treatment versus the control was evaluated by a paired *t* test.

To determine the efficiency of the spraying procedure, cuticular leaf chemical samples were taken from sprayed and unsprayed tobaccos. One 2-diam. leaf plug was taken from each plant as soon as they dried after spraying (day 0) and one and two days later. These leaf plugs were dipped eight times into 10 ml of CH_2Cl_2 in 20-ml scintillation vials. These samples were frozen immediately, shipped on Dry Ice to Athens, Georgia, and stored at $-17.8°C$. The cuticular chemical samples were analyzed by GC-2 as described by Severson et al. (1984).

Field Experiments. The activities of the cuticular diterpenes from tobacco on budworm oviposition were tested in the field at Oxford, North Carolina, and Florence, South Carolina, during 1983. Five replications of six treatments of 6-week-old tobacco plants were arranged in a cross pattern in fields isolated from other tobaccos. The six treatments were: TI 1112 with SB; TI 1112 with NC 2326 MWS; TI 1112 with α-diol; TI 1112 with β-diol; TI 1112 with α + β-ols; and NC 2326 with SB. The centers of adjacent replications were 10 m apart. Within a replication, the treatments were positioned at the points of an

equilateral hexagon with the nearest plants of different treatments being ca. 2.5 m apart. Four plants per treatment per replication were arranged in a square with 0.5 m between plants. The Oxford and Florence tests had similar designs, except that 6-week-old potted plants (two weeks in greenhouse and four weeks in shade outdoors) were used at Oxford and 6-week-old field-grown plants were used at Florence. One spraying per test was made by the same technique as described above for cage bioassays. The Oxford plants were sprayed starting at 1100 hr on August 23. After they dried, the plants were moved to a recently mowed stubble field of harvested wheat and arranged in the pattern described above. This field was over 500 m from the nearest tobacco field. Two hundred mated female budworm moths (40 per replication) were released per night for four successive nights. Eggs were counted and removed on four successive days.

The design at Florence was similar. Spraying of this test was begun at 1500 hr on July 7. However, after completion of these chemical applications, a large thunderstorm appeared. To prevent loss of this experiment, the plants were covered. A stake was driven into the ground in the center of each group of plants and they were covered with a tent of clear polyethylene. The rain prevented the release of moths that evening. The following morning the polyethylene was removed and a shade of a 1.2 × 1.2-m sheet of plywood was placed over each group of plants. These were removed just prior to moth release that evening. Therefore, day 0 for the Florence test was 24 hr after spray application. The field spray-back tests were sampled for chemical analyses as described above for cage tests.

Since the experimental designs were the same at the two locations, data from the Oxford and Florence tests were transformed to log $(x + 1.0)$ and combined prior to analysis of variance. Treatment means were separated by Duncan's new multiple-range test.

RESULTS

Ovipositional Cage Bioassays. As previously reported (Jackson et al., 1983, 1984), ca. 75% of the budworm eggs were deposited on unsprayed NC 2326 plants when moths were given a free choice between them and unsprayed TI 1112 plants (experiment 1, Table 1). Also, as previously shown (Jackson et al., 1984), both NC 2326 WLW and NC 2326 MWS were active in stimulating tobacco budworm oviposition onto TI 1112 plants (experiments 2 and 3, Table 1).

Tobacco budworm oviposition was significantly higher on TI 1112 plants sprayed with any of the individual duvanes or combinations of duvane isomers than it was on control TI 1112 plants sprayed only with the solvent blank (experiments 4–7, Table 1). This activity also persisted in experiments where du-

vane-treated TI 1112 were tested against control TI 1112 plants treated with NC 2326 WLW or NC 2326 MWS (experiments 8–14, Table 1). Neither docosanol, *cis*-abienol, nor docosanyl myristate stimulated budworm oviposition in the cage bioassays.

The levels of cuticular chemicals remaining on treated TI 1112 plants used in the cage bioassays declined over time after spraying. The α + β-4,8,13-duvatrien-1-ols and *cis*-abienol broke down most rapidly and significantly less (ca. 10%) of these compounds remained on the plants by two days after spraying (Table 2). Both the α- and β-4,8,13-duvatriene-1,3-diols applied individually or in NC 2326 MWS were more stable, with ca. 21–30% remaining after two days. Nearly 50% of the docosanol remained on the TI-1112 plants after two days (Table 2).

Field Experiments. All TI 1112 plants sprayed with duvane diterpenes or NC 2326 MWS had significantly ($P = 0.05$) more eggs deposited on them than TI 1112 plants sprayed only with solvent blank (Table 3). This trend continued for three days after spraying. Only the TI 1112 with NC 2326 MWS treatment had similar numbers of eggs as the NC 2326 control plants the first night after spraying. All of the treatments had significantly fewer eggs than NC 2326 by the second night after spraying.

However, as shown in Figure 1, all the diterpenes degraded rapidly in the field. This fast degradation explains the decrease in eggs found after the second night on these spray treatments relative to NC 2326. No changes were observed over time in the cuticular component profiles of NC 2326 and TI 1112 sprayed only with SB. The α- and β-ols disappeared at the fastest rate and were nearly absent two days after applications. The α- and β-diols were somewhat more stable, and they approached TI 1112 levels only after three days in the field.

DISCUSSION

Each of the duvanes tested in cage bioassays and field experiments stimulated tobacco budworm oviposition onto TI 1112 plants sprayed with these materials. None of the nonduvane cuticular components from tobacco increased egg laying. These data are evidence that the observed ovipositional nonpreference resistance of TI 1112 by *H. virescens* is due in part to the absence of duvane diterpenes which are major components of the leaf surface chemical profiles of commercial American tobaccos.

Our data indicate that β-diol may have a higher activity than the α isomer. The α:β ratio for NC 2326 MWS was ca. 3:1, and this ratio changed little over time (Table 2). Severson et al. (1984) reported an α:β ratio of 2.9:1.0 for NC 2326, and this ratio approximated 3:1 for 11 varieties of flue-cured, burley, Maryland, dark-fired, cigar wrapper, cigar binder, and Turkish tobaccos. Roberts and Rowland (1962) showed that α-diol is more heat and light labile than

[b] Data combined from Oxford, North Carolina and Florence, South Carolina; means in the same column followed by the same letter are not significantly different ($P = 0.05$); Duncan's multiple-range test.

β-diol. For our field tests we also saw a slightly more rapid decline of α-diol than β-diol when these materials were applied individually (Figure 1). When applied as part of the NC 2326 MWS these chemicals did not disappear as rapidly, but α-diol still declined more rapidly than β-diol. The α- and β-ols broke down very rapidly and were nearly gone by the second day after spraying (Figure 1).

The data indicate that the diterpenes are continuously synthesized and secreted onto the surface of the rapidly growing leaves, and then decompose (Table 2). They are believed to be converted to higher oxidation states by phytoxidation (Reid, 1975) which then further decompose to numerous volatile terpenes that may be important flavor and aroma components (Colledge et al. 1975; Enzell, 1977; Kawashima and Gamou, 1979; Wahlberg et al., 1977; Demole and Dietrich, 1977; Reid, 1979). Mass spectral analysis indicated that the oxidized duvanes are hydroxyepoxy, hydroxyoxy, and trihydroxy degradation products of the parent α- and β-ols and diols reported by Demole and Dietrich (1977), Enzell (1977), and Enzell and Walhberg (1980). A slight increase in the levels of the oxidized duvanes after three days in the field does not appear to account for all of the decreases in the parent duvanes. Thus, it would indicate the losses occur due to the formation of volatile components and/or degradation products that are not soluble in CH_2Cl_2 or are not GC volatile. The data presented here showed that the presence of duvane diterpenes is important in stimulating budworm oviposition. However, more studies are needed to determine

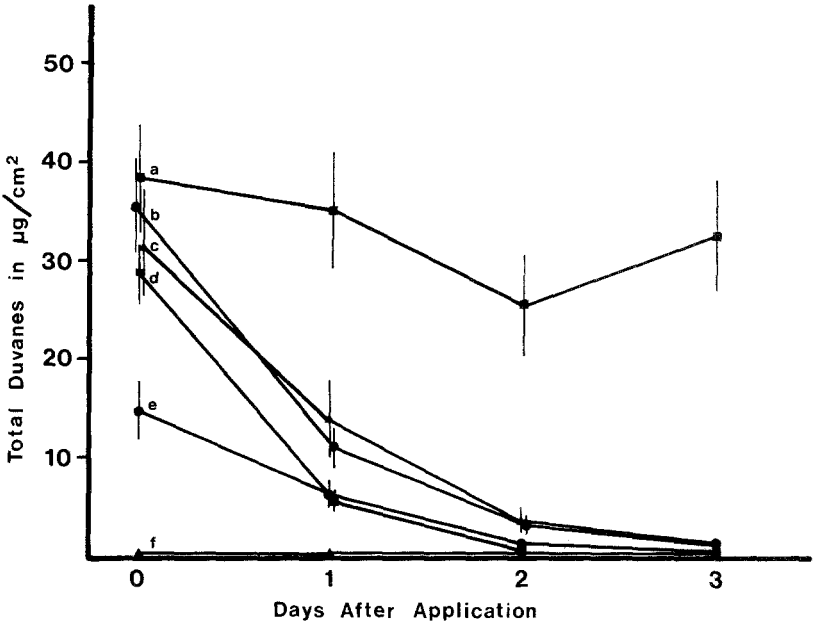

FIG. 1. Total duvane diterpenes on NC 2326 (a) and on TI 1112 plants sprayed with a solvent blank (f), the methanol–water-soluble fraction of NC 2326 whole leaf wash (c), α-4,8,13-duvatriene-1,3-diol (b), β-4,8,13-duvatriene-1,3-diol (e), or α- plus β-4,8,13-duvatrien-1-ols (d) in field tests with potted plants at Florence, South Carolina, and Oxford, North Carolina, 1983. Vertical lines indicate plus or minus standard error of the means; there were 10 samples per mean.

if oxidized duvanes or their volatile degradation products are also active in inducing budworm oviposition.

(Received June 3, 1985; accepted September 18, 1985)

Abstract—*Z*-8-Dodecenyl acetate (Z8–12 : Ac), *E*-8-dodecenyl acetate (*E*8–12 : Ac), *Z*-8-tetradecenyl acetate (Z8–14 : Ac), *Z*-10-tetradecenyl acetate (Z10–14 : Ac), and *Z*-8-dodecen-1-ol (Z8–12 : OH) were identified in the proportions 100 : 1 : 30 : 5 : 2 in female sex gland extracts of *Grapholita funebrana*, accompanied by saturated acetates from 12 to 20 carbons with tetradecyl acetate predominating. Z10–14 : Ac has not previously been described as a lepidopteran sex pheromone component. Best attraction of males is obtained with Z8–12 : Ac in the presence of a higher proportion of *E*8–12 : Ac than in the female. Inclusion of the 14-carbon acetates did not augment *G. funebrana* catches but inhibited *G. molesta*. On the other hand, addition of Z8–12 : OH at the level optimal for *G. molesta* reduced attraction of *G. funebrana*.

Key Words—*Grapholita funebrana*, plum fruit moth, *Grapholita molesta*, Lepidoptera, Tortricidae, *Z*-8-dodecenyl acetate, *Z*-8-tetradecenyl acetate, *Z*-10-tetradecenyl acetate, sex pheromone, delta-10-unsaturation.

INTRODUCTION

Grapholita funebrana Tr. (Lepidoptera, Tortricidae) is recorded as a pest on a wide variety of *Prunus* spp., especially plums across Eurasia (Bovey, 1966; Carter, 1984). After the identification of *Z*-8-dodecenyl acetate (Z8–12 : Ac; for

0098-0331/86/0600-1361$05.00/0

other short forms, see Table 1) as a sex pheromone component of *G. molesta* (Roelofs et al., 1969), this compound was also found to attract *G. funebrana* in the field (Granges and Baggiolini, 1971). Mating disruption in *G. funebrana* with this chemical has met with variable success (Arn et al., 1976; Mani et al., 1978; Charmillot et al., 1982); this is the first report on a chemical analysis of the sex pheromone of *G. funebrana*.

METHODS AND MATERIALS

Insects. Since *G. funebrana* is difficult to rear, we collected first-generation larvae from infected fruit in June and the diapausing generation in corrugated paper bands wound around tree trunks in September. The latter were held over winter in an insectarium. Adults were segregated according to sex on emergence at 24°C and 56% relative humidity in a 16:8 hr light–dark cycle (6000:1 lux) and held in polystyrene boxes supplied with sucrose solution.

Sex gland extracts of 150 2 to 4-day-old females were made midway through the scotophase by removing the everted ovipositor tips and placing them in hexane (ca. 1 μl/gland, Merck "for residue analysis").

Chemical Analysis. Gas chromatography (GC) with electroantennographic detection (EAD) (Arn et al., 1975) was made on a 25-m Silar 10c high-resolution glass capillary column (3 min at 40°C, 10°/min to 60°C, and 4°/min to 200°C). The detector species (Guerin et al., 1985), *Pammene rhediella* and *Spilonota ocellana*, were obtained from field traps baited with their respective attractants *Z*-8,*E*-10-dodecadien-1-ol and Z8–14:Ac.

Mass spectrometric (MS) analysis of 50 female equivalents (FE) was made with a Finnigan 4015 instrument using the Silar column. Dimethyl disulfide (DMDS) adducts from 20 FE were derived as described by Buser et al. (1983) and analyzed on a 50-m SP-1000 column (2 min at 80°C, 20°/min to 120°C and 5°/min to 240°C).

Field Trials. These were done in 6–10 replicates using rubber caps and traps as in Arn et al. (1979) in plum orchards in Switzerland and in peach orchards bordered by plums in Hungary. Separation of *G. molesta*, also caught at the latter location, from *G. funebrana* was done on the basis of genitalia.

RESULTS

Chemical Analysis. GC-EAD analysis of the female sex gland extract using the male *G. funebrana* antenna indicated biologically active components at the retention times of 12:Ac (weaker signal) and Z8–12:Ac. A systematic search with the key ions *m/z* 61 ($CH_3COOH_2^+$ and M^+-CH_3COOH indicated the presence of two dodecenyl acetates (*m/z* 166) in the gland extract, one at the retention time of Z8–12:Ac, the other, at a much smaller amount, matching *E*8–

TABLE 1. COMPONENTS IDENTIFIED IN *G. funebrana* SEX GLANDS[a]

Compound	Short form	Identified by	Amount (ng/FE)
Dodecyl acetate	12:Ac	GC-MS	0.08

[a]In order of elution on Silar 10c and SP-1000.

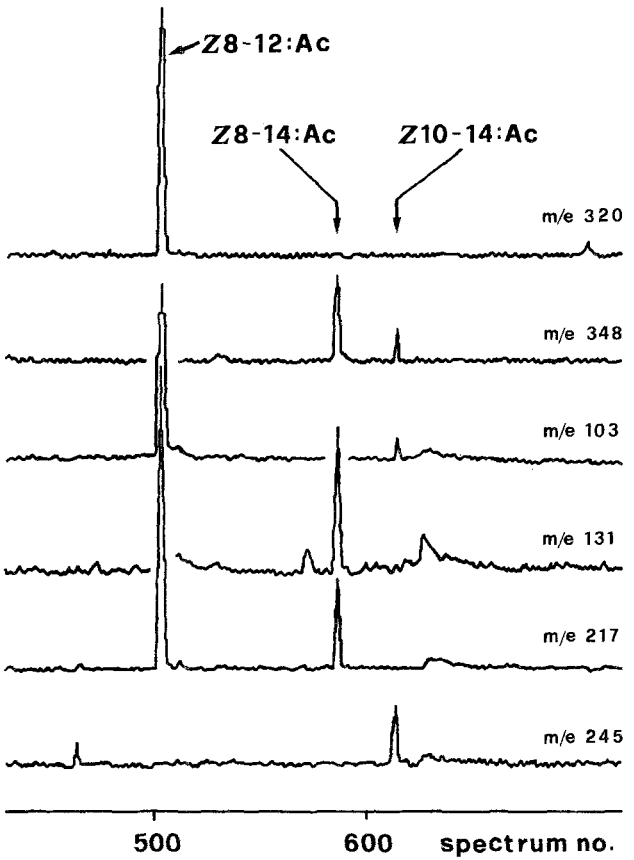

FIG. 1 Mass chromatograms of DMDS-derivatized *Grapholita funebrana* female extract on SP-1000 using the respective molecular ions 320 and 348 for dodecenyl and tetradecenyl acetates, the typical fragment ions 103 and 131 for omega-4 and omega-6 unsaturation, and those of 217 and 245 for delta-8 and delta-10 monoenic acetates.

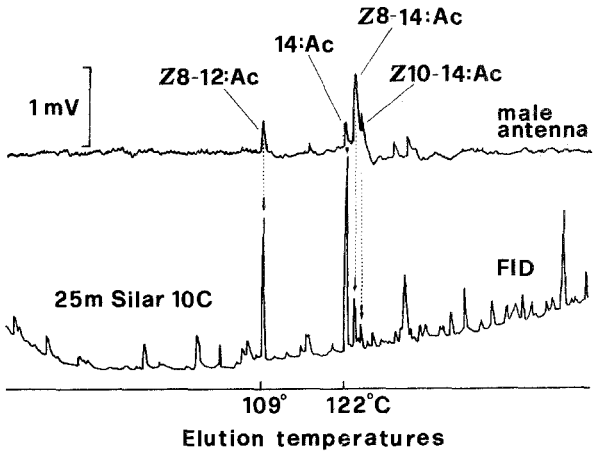

FIG. 2. GC-EAD analysis of *Grapholita funebrana* sex gland extract (10 FE) on 25-m Silar 10c using as detector a *Spilonota ocellana* male antenna most sensitive to Z8–14:Ac.

12:Ac. In addition, we found two tetradecenyl acetates (*m/z* 194) and saturated acetates from 12 to 20 carbons (Table 1).

Assignments of double-bond positions were made from DMDS adducts. The recorded mass spectra revealed one major peak at *m/z* 320 for dodecenyl acetate adducts with the diagnostic ions *m/z* 103, 217, and 157, for delta-8-unsaturation (Figure 1). The level of the *E*8–12:Ac derivative was below the detection limit. At *m/z* 348 for tetradecenyl acetates, two peaks with dissimilar mass spectra were obtained at the ratio seen in the underivatized extract, indicating positional isomers. Based on the fragment ions *m/z* 131, 217, and 157 for the first and 103, 245, and 185 for the second, they were assigned delta-8 and delta-10.

In GC-EAD (Figure 2) the antenna of *S. ocellana*, specifically sensitive to Z8–14:Ac (Arn et al., 1974), gave the strongest response to the early eluting tetradecenyl acetate with an intensity matching that of a synthetic Z8–14:Ac; the *E*8 isomer was comparatively inactive. Isomer assignment of the second tetradecenyl acetate was based on retention times. Although we did not detect Z8–12:OH in the extract by GC-MS, analysis with the antenna of *P. rhediella* indicated the presence of ca. 2.5% of this product (relative to Z8–12:Ac), matching both retention time and activity of the synthetic standard. *P. rhediella* is attracted to Z8,*E*10–12:OH but also is selectively sensitive to Z8–12:OH (Guerin et al., 1983); the closely eluting isomers on Silar 10c, Z7, *E*8, *E*9, and Z9 were relatively inactive.

Field Trials. In two tests in Switzerland, we varied the amounts of *E*8–12:Ac and the 14-carbon compounds identified (Table 2, A and B). Despite

our detecting only 1% *E*8–12:Ac in the female, better catch was obtained with 4%, confirming earlier findings (Arn et al., 1976; Biwer and Descoins, 1978). None of the tetradecenyl acetates added singly or in pairs, nor 14:Ac added to the four-component blend augmented catch.

Selectivity tests on *G. funebrana* and *G. molesta* were made in Hungary where both species flew simultaneously (Table 2, C). Blends containing Z8–12:Ac with 4 or 8% *E*8–12:Ac attracted both species. Addition of the three 14-carbon acetates in the proportions found in the females failed to improve attraction of *G. funebrana*. (In Switzerland these two treatments caught 2303 and 2244 males, respectively, in five replicates from May 17, to September 5,

1984). Furthermore, direct field observations in Hungary indicated that of those males orienting to the pheromone source, neither the percentage contacting the rubber cap nor those subsequently displaying hairpencils was augmented by inclusion of the 14-carbon acetates (in all 66 males were observed). However, *G. molesta* was inhibited in the presence of the 14-carbon compounds. On the other hand, addition of Z8–12 : OH to the binary blend at the level found in the *G. funebrana* sex gland reduced captures of the latter by a factor of three while enhancing those of *G. molesta*.

DISCUSSION

The identification of Z8–12 : Ac in the *G. funebrana* sex pheromone gland is not surprising considering its field activity on this and other *Grapholita* species. On the other hand, Z8–14 : Ac and Z10–14 : Ac, identified here, are not common as components of sex attractants. To our knowledge, Z10–14 : Ac has not been previously identified in Lepidoptera, although field trials have established it as an attractant component for moth species in the tribes Archipini and Olethreutini and the family Gracillariidae (Roelofs and Brown, 1982; Arn et al., 1974; Ando et al., 1977; Booij and Voerman, 1984). Reference to the occurrence of Z8–14 : Ac is only made for the tortricids *Ctenopseustis obliquana* (Young et al., 1985) and *Planotortrix excessana* (Galbreath et al., 1985) in New Zealand, and for *S. ocellana* based on GC-EAD retention time by Arn et al. (1975). Z8–14 : Ac is also attractive to *Spilonota laricana* (Priesner, 1977) and another Eucosmini species, *Pseudexentera spoliana* (Roelofs and Brown, 1982).

While the pathways leading to pheromone components with double bonds in odd-numbered positions are well established, less is known about the biosynthesis of unsaturated compounds of the type found in *G. funebrana*. A delta-10-desaturase, as claimed by Roelofs and Bjostad (1984), acting on both 14 and 16 carbon chains, in conjunction with chain-shortening, could account for the production of Z10–14 : Ac and Z8–/E8–12 : Ac on one hand, and Z8–14 : Ac on the other.

The occurrence of 14-carbon acetates in the Grapholitini is in itself novel (cf. Roelofs and Brown, 1982). Although not involved in attraction, these compounds may contribute to specificity of the *G. funebrana* attractant blend. Inhibition of *G. molesta* by 12 : Ac, another component of the *G. funebrana* sex gland, has already been established (Rothschild, 1974). On the other hand, Z8–12 : OH reduces *G. funebrana* catch at the optimum required for *G. molesta*. However, since *G. molesta* is sexually active in the afternoon and *G. funebrana* in the early morning, isolation by pheromone blend is less critical here than, for example, between *G. molesta* and *G. prunivora* (Baker and Cardé, 1979).

Further optimizations of the *G. funebrana* atttractant blend could include testing effects of lower amounts of Z8–12 : OH and the role of each of the 14-carbon acetates in inhibition of *G. molesta*.

(Received July 23, 1985; accepted September 16, 1985)

Abstract—Lactic acid has been identified in extracts of filter paper "conditioned" by the German cockroach, *Blattella germanica* (L.). One- to two-week old larvae aggregated on filter paper wetted with solutions of lactic acid.

Key Words—Aggregation, lactic acid, German cockroach, *Blattella germanica*, excreta, Dictyoptera.

INTRODUCTION

Ishii and Kuwahara (1967) first demonstrated the aggregation of larvae of the German cockroach, *Blattella germanica* (L.), on filter paper which had been "conditioned" by being placed in a culture of the cockroach. Similarly, Watler (1979) showed that conditioned substrates aggregated larvae of *Acheta domesticus* (L.). McFarlane et al. (1983) found volatile fatty acids on the papers conditioned by *A. domesticus* and showed that one of them, propionic acid, aggregated the larvae. In similar work with *B. germanica*, McFarlane (1984) found propionic, isovaleric, and valeric acids to be repellent; isobutyric acid to be slightly repellent; and acetic and butyric acids to be without effect.

In analyses of frass for volatile fatty acids by gas–liquid chromatography, lactic acid was frequently observed to be present. The demonstration of lactic acid on conditioned filter paper, and the effect of lactic acid on aggregation in *B. germanica*, are the subjects of the present article.

0098-0331/86/0600-1369$05.00/0

METHODS AND MATERIALS

German cockroaches were maintained on Ralston Purina dog chow at 30±1°C and 55±5% relative humidity and at a photoperiodic regime of 14:10 light–dark. Tests were carried out with DL-lactic acid, obtained from the Fisher Scientific Company, Montreal.

The method of testing was the same as used previously (McFarlane, 1984). The experiments were conducted at room temperature. The larvae were 2–12 days old; newly hatched larvae and older larvae tended not to settle under the conditions of the experiment. Two 14 × 3.8-cm strips of Whatman No. 1 filter paper folded twice (to form a W) were placed on edge and spaced evenly in a culture dish (diam. 19.2 cm). Lactic acid was tested by making serial dilutions and treating a filter paper strip with 0.68 ml of the solution. The control paper was wetted with 0.68 ml distilled water. Twenty larvae were introduced into the culture dish, and the dish was immediately covered with fine-mesh Tergal® which was secured with a rubber band. Each culture dish was then covered with a small cardboard box which maintained darkness for the test. If this was not done, the larvae would not settle on the papers. In fact, in nearly all trials, the great majority of the larvae came to rest on the papers, and these were counted. Larvae not on the papers were not considered in the analysis of results, as the normal response to the experimental situation was to come to rest on a paper; wandering larvae could not therefore be said to have been attracted or repelled. The few trials in which less than half the larvae came to rest on the papers were also not considered, for the same reason.

Where the solutions were tested immediately, i.e., while still wet, larvae were counted 1.5 hr after the experiment was set up, and thereafter at 0.5-hr intervals for 6 hr. Where the solutions were applied to the filter paper the previous day, and allowed to dry before testing, counts were made at 0.5-hr intervals after the experiment was set up for a total of 2 hr. Response to the dried papers was found to be quicker than to the wet papers in preliminary trials.

In the analysis of results, the previously found bias towards the left-hand paper (McFarlane, 1984) was taken into account, and statistical treatment was carried out independently for left and right papers. Student's *t* test was used to test for the significance of differences between mean numbers on treated and control papers.

Lactic acid has a pK of 3.08. Tests were also carried out with various organic and inorganic acids with similar pK values. Fumaric acid (pKs of 3.03 and 4.44), citric acid (pKs of 3.14, 4.77, and 639) and phosphoric acid (pKs of 2.12, 7.21, and 12.67) were tested.

Methods for Lactic Acid Determination in Conditioned Filter Papers. Two methods were used to analyze for lactic acid by gas–liquid chromatography; the identity of lactic acid was confirmed by mass spectrometry.

Method I. Filter paper strips (14 × 3.8 cm) were conditioned by placing two strips in a culture jar containing 40 adult and 40 larval cockroaches and leaving them in the jar for 1–25 days. On removal from the culture jar, the filter papers were tested (against untreated paper) for their ability to aggregate larvae.

The conditioned filter papers (6) were cut into small pieces (approximately 0.5 cm^2) and placed in a beaker (100 ml). A quantity (15 ml) of distilled water was added to the beaker, and the mixture was allowed to stand for 30 min with intermittent mixing. The liquid was squeezed from the paper and collected; an additional 5 ml of distilled water was then added to the beaker. The mixture was agitated and the liquid was once more squeezed from the paper and collected. A total of 10 ml of extract was collected; this extract was used for analysis of lactic acid.

The same procedure was followed for a sample of untreated filter paper.

For lactic acid determination by gas chromatographic analysis, the lactic acid was converted to benzyl lactate; clean-up and derivatization procedures for benzyl lactate were performed according to the method of Jones and Kay (1976). Conditions of gas chromatographic analysis were as follows: Varian gas chromatograph (model 3700) equipped with a flame-ionization detector; glass column (1.8 m long × 2 mm internal diameter); column packing material was 1% butane-1,4-diol succinate polyester on Chromosorb W, 80–100 mesh; nitrogen carrier gas (flow rate = 20 cc/min); temperature programming: initial temperature = 70°C, initial hold = 8 min, program rate = 4°C/min, final temperature = 150°C, final hold = 1 min. The benzyl lactate in the sample was identified by reference to a standard benzyl lactate preparation. Peak areas were calculated by means of a HP 3390A Reporting Integrator (Hewlett-Packard Co., Avondale, Pennsylvania).

Method II. Filter papers were conditioned by placing four strips (14 × 3.8 cm) in each of two jars with 40 adult males each, and four in each of two jars with 40 adult females each. The papers were removed after 21 days and tested immediately for attraction to larvae. As the male papers gave a quicker aggregation response than the female papers, only the male papers were used in the analysis for lactic acid (Table 1).

Whole papers were extracted as in method I. This does not give an accurate idea of the uniformity of lactic acid and the concentration on the papers, as excreta is spotted on the papers and not uniformly distributed. Hence, spotted areas were cut out with a cork borer (5 mm diameter) and independently analyzed, along with similar nonspotted areas of the same papers.

For lactic acid determination by gas chromatographic analysis, the method of Jones and Kay (1976) was used for preparation of the benzyl lactate derivatives. Conditions of gas chromatographic analysis were as follows: Varian gas chromatograph (model 3700) equipped with a flame-ionization detector; DB 17 (Chromatographic Specialties Ltd., Brockville, Ontario, Canada) capillary col-

Table 1. Rate of Aggregation of Larvae to Filter Papers Conditioned by Male or Female Adult Insects (Eight replicates/test. Mean ± SD)

Time after start (hr)	Males, number on		Females, number on	
	Treated	Control	Treated	Control

umn (30 mm × 0.25 mm ID); helium carrier gas (flow rate = 1 cc/min; makeup gas flow rate = 30 cc/min); temperature programming: initial temperature = 70°C, initial hold = 12 min, program rate = 4°C/min, final temperature = 180°C, final hold = 1 min. Identification and quantitation of the lactate was performed using the procedures described in method I.

The identity of the benzyl lactate peak was confirmed by mass spectrometry using a Kratos MS 50 TCTA mass spectrometer coupled to a Kratos DS 55 data system (Kratos, Manchester, England); conditions of mass spectrometry were: electron impact source, run at 79 eV; source temperature = 200°C.

Analysis of Frass and Conditioned Filter Paper for D- *and* L-*Lactic Acid.* Extracts of whole conditioned filter paper (eight papers conditioned for 17 days) were prepared using the procedure described previously. The extracts were analyzed for D-lactic and for L-lactic acids using the enzymatic assay method of Sigma Chemical Company, 1984, (Sigma Diagnostics, pyruvate/lactate; quantitative enzymatic determination in whole blood at 340 μm; procedure No. 820-Uv, St. Louis, Missouri).

RESULTS

Analyses of conditioned filter papers for lactic acid by method I, with six papers used for each analysis, gave the following results: conditioned for 1 day, 0.0072 mg lactic acid/filter paper; for 5 days, 0.0077; for 10 days, 0.0114; for 15 days, 0.0155; and for 25 days, 0.0280. The amount of lactic acid found increased with the duration of conditioning. All papers used in the analyses were first tested for aggregation of larvae and all gave positive results. No lactic acid was detected in extracts of untreated filter papers.

Analyses for lactic acid of conditioned filter papers from a culture of male adult cockroaches by method II showed 0.0329 mg lactic acid/filter paper, and 0.2098 mg/filter paper in the contaminated spots of filter paper. Lactic acid was not detected in uncontaminated areas of filter paper. It may be seen that the

[b] Significantly greater than control at $P = 0.02$.
[c] Significantly greater than control at $P = 0.01$.
[d] Significantly less than control at $P = 0.001$.
[e] Significantly less than control at $P = 0.05$.

amount of lactic acid/filter paper after conditioning for 21 days is similar to that for papers conditioned for 25 days in the analyses given in the preceding paragraph. It may also be seen that when contaminated spots were analyzed, the concentration of lactic acid was more than six times that of whole filter paper. Confirmation of the presence of lactic acid in these extracts was obtained from the mass spectrometric analysis. The results of the analysis for the isomers of lactic acid was as follows: 0.0563 mg D-lactic acid per conditioned filter paper, and 0.0623 mg L-lactic acid per conditioned filter paper.

The results of "wet" trials using lactic acid solutions are given in Table 2: 0.68 ml of 10^{-2} and 10^{-3} M lactic acid led to significant aggregation, whereas 10^{-1} and 10^{-4} M were repellent. Therefore, there is an optimal concentration for aggregation. The amounts of lactic acid on the filter papers ranged from 0.612 mg/paper at 10^{-2} M to 0.0612 mg/paper at 10^{-3} M. The amount of lactic acid actually found in contaminated spots is therefore within this range. The rate at which larvae responded to the filter papers in the experiments with 10^{-2} M lactic acid is given in Table 3.

When previously dried papers were tested, 10^{-2} M lactic acid was repellent, and lower concentrations had no effect.

Tests using fumaric acid showed repellency at 10^{-1} M and 10^{-2} M and no effect at 10^{-3} M, no effect with citric acid, and repellency at 10^{-1} M phosphoric acid and no effect at 10^{-2} M (Table 4).

DISCUSSION

Lactic acid aggregates larvae of *B. germanica* at concentrations of 10^{-2} to 10^{-3} M, when the larvae are exposed to filter paper wetted with 0.68 ml of the solution. This amount is greater than the amount found on whole con-

[a] "Response" indicates that 50% or more of 20 larvae had come to rest on the test papers; "no response" indicates that 50% had reacted to the test papers.

ditioned filter papers. However, the lactic acid on conditioned filter paper is concentrated in many small spots of excreta, and when these spots are analyzed, the concentration sensed by the larva is in the range 10^{-2}–10^{-3} M.

However, when the larvae are exposed to the dried paper, similar concentrations are either repellent or ineffective. This is the same kind of result which McFarlane et al. (1983) obtained with *A. domesticus* and propionic acid, where wet papers aggregated the larvae but dried papers repelled. The repellent effect

of 10^{-2} M lactic acid presented dry may be explained if drying of the filter paper leads to local increases in concentration which are repellent. Lower concentrations of lactic acid on dried paper do not seem to be detected by the larvae.

With wet papers, arrest of movement of the larvae begins while the paper is still wet, and aggregation follows. In fact, there seem to be two distinct aspects to aggregation. First there is the arrest of movement when conditions are favorable. Then there is the attraction of larvae for each other.

The fact that there is an optimal concentration range for lactic acid using wet papers may explain why a dry paper with an arrestant concentration was not found. For if, as was suggested, increases in concentration accompany drying, then there is no control of the distribution of lactic acid on the dried papers.

Inasmuch as no aggregation was obtained with fumaric, citric, and phosphoric acid, it is concluded that the attraction of lactic acid lies in the nature of the molecule itself, not its acidity.

Wileyto and Boush (1983), in a study of the attractancy of various food components for the German cockroach, state that "the dregs in a beer bottle have more attractive power than anything tested in the laboratory [unpublished data]. It is of interest that the lactic acid concentration of beer ranges from 65–450 mg/liter (Charalambous, 1981), which is similar to the concentrations we have found to aggregate the German cockroach.

THE FEMALE SEX PHEROMONE OF SUGARCANE STALK BORER, *Chilo auricilius* Identification of Four Components and Field Tests

BRENDA F. NESBITT,[1] P. S. BEEVOR,[1] A. CORK,[1] D. R. HALL,[1] H. DAVID,[2] and V. NANDAGOPAL[2]

[1]*Tropical Development and Research Institute, 56/62 Gray's Inn Road, London WC1X 8LU, England,*

[2]*Sugarcane Breeding Institute, Coimbatore 641007, India*

(Received June 27, 1985; accepted September 17, 1985)

Abstract—Four pheromonal components have been detected in ovipositor washings and volatiles from female sugarcane stalk borers, *Chilo auricilius* Dudgeon (Lepidoptera: Pyralidae), using combined gas chromatography–electroantennography. The components have been identified as (I) (*Z*)-7-dodecenyl acetate, (II) (*Z*)-8-tridecenyl acetate, (III) (*Z*)-9-tetradecenyl acetate, and (IV) (*Z*)-10-pentadecenyl acetate by comparison of their gas chromatographic behavior with that of synthetic standards. In field tests carried out in northern India during 1982–1984, a combination of II, III, and IV in their naturally occurring ratio (8:4:1) was shown to provide a highly attractive synthetic source for trap use. (*Z*)-7-Dodecenyl acetate was found to reduce catches of male *C. auricilius*, both when dispensed with the other three components and when released from dispensers surrounding a trap baited with the other three components.

Key Words—Sugarcane stalk borer, *Chilo auricilius*, Lepidoptera, Pyralidae, sex pheromone, sex attractant; (*Z*)-7-dodecenyl acetate, (*Z*)-8-tridecenyl acetate, (*Z*)-9-tetradecenyl acetate, (*Z*)-10-pentadecenyl acetate.

INTRODUCTION

Chilo auricilius Dudgeon (Lepidoptera: Pyralidae) is an important pest of sugarcane found in India, Southeastern Asia, Indonesia, and northern Australia. The larvae damage the cane by attacking shoots and by internode boring, which impairs growth and results in losses of weight of cane and sugar recovery; yield

losses of up to 30% have been recorded in India. Sorghum and rice are also attacked by this species. Its life history and factors affecting its incidence are described by Gupta et al. (1981), who also reported that no suitable and effective control measures were available. The presence of a female sex pheromone was demonstrated in northern India by trapping of male *C. auricilius* in virgin female baited traps (Kalra and David, 1971). Identification and synthesis of the female sex pheromone was undertaken with the aim of providing a control agent compatible with existing cultural practices in India.

METHODS AND MATERIALS

Insect Material. Pupae were field collected in northern India and sent by air freight to London. They were sexed and the sexes segregated and maintained in an environmental cabinet until adult emergence (conditions: reversed light–dark cycle, 12 hr:12 hr; temperature 26°C photophase, 24°C scotophase; relative humidity 85%). Adult moths were maintained under the same conditions with a supply of 10% sucrose solution.

Pheromone Collection. Ovipositor washings in carbon disulfide or heptane were usually prepared from virgin female moths 6–8 hr into the first dark period after emergence. Some extracts were prepared after $1\frac{1}{2}$, 3, 4, 5, and $10\frac{1}{2}$ hr and from 2- to 3-day-old females in attempts to obtain higher pheromone yields. Volatiles were collected from individual virgin female moths as described previously (Nesbitt et al., 1979).

Electroantennography (EAG). Recording of male moth antennal responses to GC column effluent (GC-EAG) was carried out essentially as described previously (Moorhouse et al., 1969). "Puff" tests were carried out as described by Nesbitt and et al. (1977), with a 7-min recovery period between stimulations.

Gas Chromatography (GC). For analyses on packed columns, with and without simultaneous recording of EAG responses to part of the column effluent, columns and conditions were as follows: glass columns (1.8 m × 2 mm ID) packed with (A) 2.5% SE30 and 0.5% Carbowax 20 M on Chromosorb G AW DMCS, programmed from 120 to 225°C at 4°C/min; and (B) 1.5% Carbowax 20 M on Chromosorb G AW DMCS programmed from 120 to 200°C at 4°C/min. Carrier gas for A and B was 25 ml/min nitrogen. For analyses on fused silica capillary columns, columns were as follows (except where otherwise stated): 50 m × 0.32 mm ID Chrompack columns coated with (C) CP Sil 5CB (chemically bonded methyl silicone), and (D) CP wax 57CB (chemically bonded, cross-linked polyethylene glycol). Carrier gas for C and D was helium 0.8 kg/cm^2. A Grob splitless injector was used. Columns were maintained at 70°C for 2 min at the start of each analysis (except for analyses of pentadecenyl isomers); subsequent temperature profiles were as follows: For dodecenyl isomers: C and D, 70–120°C at 20°C/min, then isothermal; for tridecenyl iso-

mers: C, 70–135°C at 20°C/min, then isothermal; D, 70–100°C at 20°C/min, then isothermal (25 m × 0.24 mm ID column). For tetradecenyl isomers: C, 70–145°C at 20°C/min, then isothermal; D, 70–140°C at 20°C/min, then isothermal. Conditions for pentadecenyl isomers were as follows: C, 80°C for 1 min, 80–120°C at 40°C/min, 120–200°C at 1°C/min; D 70°C for 2 min, 70–110°C at 20°C/min, isothermal for 34 min, 110–200°C at 2°C/min.

Synthetic Chemicals. (*Z*)- and (*E*)-6-tridecenyl acetate, (*Z*)- and (*E*)-7-tridecenyl acetate, and (*Z*)- and (*E*)-10-tridecenyl acetate were purchased from the Institute for Pesticide Research, Wageningen, The Netherlands. The other monounsaturated acetates were synthesized by standard Wittig or acetylenic routes. The pheromone components used in field tests were purified by liquid chromatography on silica gel impregnated with 20% silver nitrate so that they contained less than 0.1% of the opposite geometric isomer.

Field Tests. These were carried out at two centers in Uttar Pradesh, N. India, during 1982–1984. The traps used were large water traps (60 cm × 60 cm) on 75 cm legs, similar to those described by Campion et al. (1974) but without lids; pheromone dispensers were suspended centrally just above the water from a cross rod. Dispensers for the synthetic compounds were polythene vials (35 mm × 8 mm × 1.5 mm thick); an equal weight of 2,6-di-*tert*-butyl-4-methylphenol (BHT) was added to the synthetic materials as antioxidant. Synthetic pheromone sources were not renewed during experiments. Virgin female moths used to bait traps were caged singly in small mesh containers positioned in the same way as the polythene vials. The female moths were renewed every three days.

For attractancy experiments involving a small number of treatments (Tables 1 and 2), traps were set out randomly in a row, crosswind, approximately 30 m apart. For the experiment detailed in Table 3, treatments were placed randomly in an 8 × 5 grid with approximately 30 m between traps. For the experiment detailed in Table 4, a 6 × 6 lattice design was used with trap spacing within blocks 30 m and blocks at least 100 m apart. For communication disruption experiments, six vials containing the test chemical were placed evenly in a circle around a trap baited with synthetic attractant at 1 m distance and at the same height above the ground as the attractant vial. In the experiment detailed in Table 5, the "surrounded" traps and control traps were set out randomly in two parallel rows, with approximately 30 m between traps in each row and 60 m between rows. In the two-trap experiments (Tables 6 and 7) traps were approximately 30 m apart and replicates were at least 100 m apart. In the experiments summarized in Tables 1, 2, 3, and 5, treatments were randomized at the beginning of the experiment only.

Statistical analyses were based on a factorial random block design with treatments and nights as the two factors. Catches were converted to $(x + 0.5)$ and subjected to analysis of variance. Differences between treatment means were tested for significance by least significant differences (LSD) tests. The

experiment described in Table 4 was a Latin square design and treatments were rerandomized each night. In the disruption experiments (Tables 6 and 7), the positions of treatment and control traps were exchanged each night.

RESULTS AND DISCUSSION

Structure Determination

GC-EAG analyses of ovipositor washings and female volatiles on nonpolar and polar packed columns (A and B) showed four EAG responses. Equivalent chain lengths of the EAG-active compounds based on the retention times of *n*-alkyl acetates (ECLs) suggested that these compounds were C_{12}, C_{13}, C_{14}, and C_{15} monounsaturated acetates or C_{14}, C_{15}, C_{16}, and C_{17} monounsaturated aldehydes (column A ECLs 11.9, 12.9, 13.9, 14.9; column B ECLs 12.4, 13.3., 14.3, 15.4). The EAG-active compounds, assumed to be pheromonal components, were designated I–IV in order of elution; the largest EAG response was to component II. In ovipositor washings, the average ratio of the GC peak heights for components I, II, III, and IV was 4:8:4:1. Entrained female volatiles were enhanced in the more volatile components I and II, and the ratio of the four components was very variable. The best yield of pheromone was 6 ng/female from ovipositor washings; usually much lower yields were obtained. When male moth EAG responses to tridecyl acetate and pentadecanal were compared (GC-EAG link, 10 ng injected), a 1.0-mV response was recorded to the acetate and no response to the aldehyde, suggesting that component II at least, was an acetate rather than an aldehyde. When GC retention times of components I–IV were compared with those of the positional and geometric isomers of dodecenyl, tridecenyl, tetradecenyl, and pentadecenyl acetates, respectively, on fused silica capillary columns C and D, the results described below were obtained:

Component I. All dodecenyl isomers were available for comparison, and the only one with retention times consistent with those of component I on both columns was (Z)-7-dodecenyl acetate, (Z7–12:Ac) (Figure 1).

Component II. *Z*- and *E*6, 7, 8, 9, 10-tridecenyl acetates were available for comparison. Component II had retention times consistent only with the Z8 isomer, (Z8–13:Ac) (Figure 2). By analogy with the retention times of the full series of dodecenyl and tetradecenyl acetates, which both follow a similar pattern, the (Z)-8-tridecenyl acetate retention times are thought to be unambiguous.

Component III. All tetradecenyl acetate isomers were available for comparison. The retention times for component III fitted only with those of (Z)-9-tetradecenyl acetate (Z9–14:Ac) on both columns (Figure 3).

Component IV. The structural assignment for this component is more tentative than for I–III; it was the least abundant component in ovipositor washings and yields in entrained female volatiles were further reduced by its relative

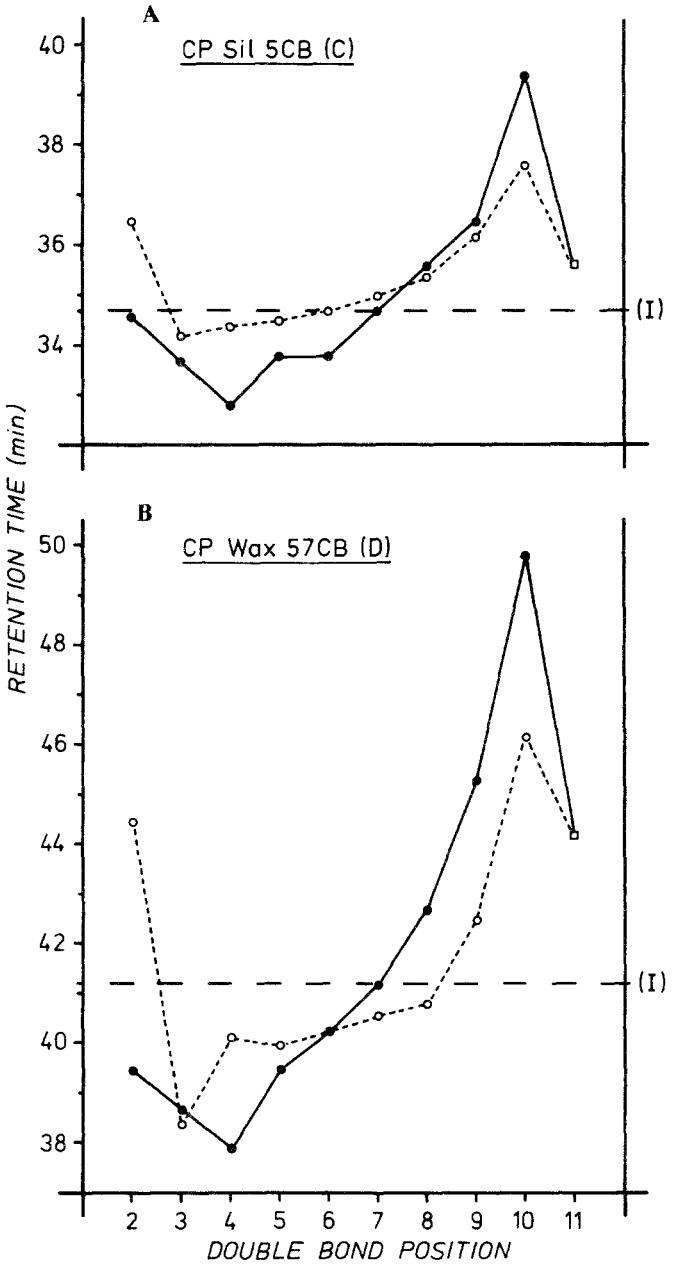

FIG. 1. Retention times of dodecenyl acetate isomers and pheromone component (I) on fused silica capillary GC columns coated with (A) CP Sil 5CB (column C) and (B) CP Wax 57CB (column D): ●—● *Z* isomers; ○- - -○ *E* isomers; □ no configuration. Retention times of dodecyl acetate on column C 37.37 min; column D 35.91 min.

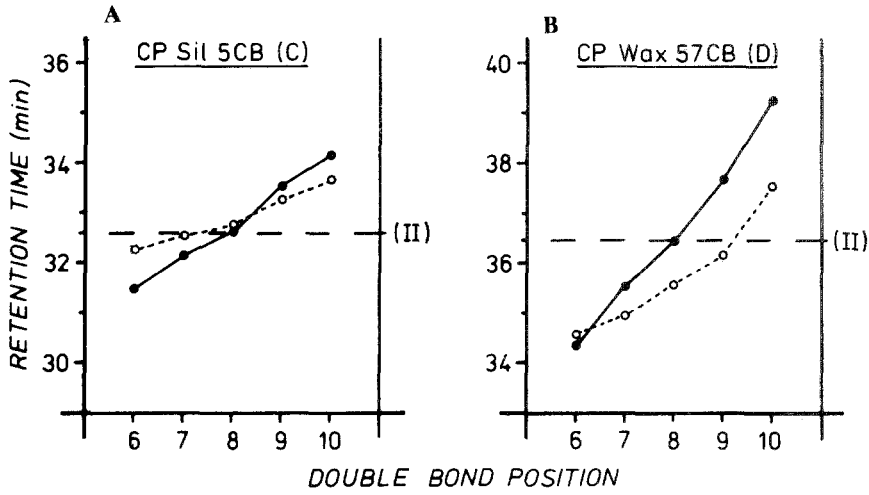

FIG. 2. Retention times of tridecenyl acetate isomers and pheromone component (II) on fused silica capillary GC columns coated with (A) CP Sil 5CB (column C) and (B) CP Wax 57CB (column D): ●—● *Z* isomers; ○- - -○ *E* isomers. involatility. At the time when GC-EAG analyses were carried out on the natural pheromone only (*Z*)-9 and (*Z*)-10-pentadecenyl acetate were available for comparison with component IV. The latter was found to cochromatograph with the *Z*10 isomer (Z10–15 : Ac) on both polar and nonpolar columns. Later, when the *E*9, *Z*8, and *Z*7 isomers were available, these were shown to be fully resolved from the *Z*10 isomer under GC conditions similar to those used originally on column D.

When EAG responses to *Z*7–12 : Ac, *Z*8–13 : Ac, *Z*9–14 : Ac and Z10–15 : Ac were compared by puff-testing at the 2-ng level, the following results were obtained: *Z*7–12 : Ac, 1.4 mV; *Z*8–13 : Ac, 1.9 mV; *Z*9–14 : Ac, 1.2 mV; Z10–15 : Ac, 0.9 mV (mean of duplicate tests). Using the same antennal preparation, 0.25 female equivalent (ovipositor washing) gave 1.1 mV (mean of single tests on four different samples).

Field Tests

In 1982 the four synthetic acetates, *Z*7–12 : Ac, *Z*8–13 : Ac, *Z*9–14 : Ac, and Z10–15 : Ac dispensed from polythene vials were tested in traps using two ratios, 1 : 1 : 1 : 1 and 4 : 8 : 4 : 1, respectively, and two loadings, 0.1 and 1.0 mg. The results indicated that the naturally occurring 4 : 8 : 4 : 1 ratio at the higher loading was significantly more attractive to male *C. auricilius* than the other treatments (Table 1). Early in 1983 the 4 : 8 : 4 : 1 mixture, 1 mg loading, was compared with traps baited with virgin female moths. Catches with the synthetic

mixture were very much higher than with the virgin female moth (Table 2); it is not known why the female moths performed so poorly. To determine whether all four acetates were necessary for attraction, an experiment was carried out in which each acetate was tested on its own, and Z8–13 : Ac, the most EAG-active and abundant component, was tested in binary combination with each of the three other components (in their naturally occurring proportions). The 4 : 8 : 4 : 1 four-component mixture was included for comparison. The results showed that the individual acetates were only weakly attractive, but the Z8–13 : Ac/Z9–14 : Ac and Z8–13 : Ac/Z10–15 : Ac binary mixtures were significantly more attractive than the Z8–13 : Ac/Z7–12 : Ac mixture or the four-component mixture (Table 3). The latter results suggested that Z7–12 : Ac might be reducing trap catches and, in 1984, a three-component mixture without this component (Z8–13 : Ac, Z9–14 : Ac, and Z10–15 : Ac, 8 : 4 : 1) was compared with the three binary mixtures tested previously and the four-component mixture. The results showed that the three-component mixture was significantly more attractive than the other treatments; the Z8–13 : Ac/Z9–14 : Ac mixture emerged as the best binary mixture in this experiment (Table 4).

Having defined an attractive mixture for trap use, experiments were carried out to determine whether any of the individual components was a potentially

useful mating disruption agent. This was done by testing the effect of surrounding a trap baited with synthetic attractant with six vials containing the individual components. In the first experiment, 1-mg vials containing the individual components were used, and the central traps and control traps were baited with the four component, 4 : 8 : 4 : 1, mixture (the most attractive source known at the time). "Surrounding" vials containing this mixture were included for comparison, although it was realized that such a complex mixture was unlikely to be an economic proposition for mating disruption. The results showed that only the Z7-12 : Ac vials and those containing the four-component mixture were effective in reducing trap catches. The traps surrounded by Z9-14 : Ac and Z10-15 : Ac vials caught significantly more male moths than the control traps (Table

5). The effect of the Z7–12 : Ac component on reducing trap catches was tested further in a replicated, two-trap experiment in which the surrounding vials were moved from one trap to the other each night. The results indicated a significant reduction (74%) in catch in the surrounded traps (Table 6). A similar experiment in which the loading of the Z7–12 : Ac vials was increased to 2 mg and the more attractive 8 : 4 : 1, Z8–13 : Ac, Z9–14 : Ac, Z10–15 : Ac mixture was used in the traps, resulted in a 95% reduction of catch in the surrounded traps (Table 7).

CONCLUSIONS

The analytical and field results reported indicate that Z7–12 : Ac, Z8–13 : Ac, Z9–14 : Ac, and Z10–15 : Ac are components of the female sex pheromone of *Chilo auricilius*. Moreover, a three-component mixture of Z8–13 : Ac, Z9–14 : Ac, and Z10–15 : Ac in an 8 : 4 : 1 ratio provides an effective synthetic attractant for trap use. The role of the Z7–12 : Ac component in the moth's reproductive behavior is obscure. Although a mixture of this component and the major component Z8–13 : Ac is more attractive than either component alone, Z7–12 : Ac added to a mixture of Z8–13 : Ac, Z9–14 : Ac, and Z10–15 : Ac in their natural ratio reduces trap catches. Moreover, Z7–12 : Ac released from vials surrounding a trap baited with the other three components also causes a reduction in trap catch. Pheromonal components which reduce trap catches have been reported in other lepidopterous species (Beevor and Campion, 1979; Mustaparta, 1984). In practical terms, Z7–12 : Ac is a potentially useful mating disruption agent for *C. auricilius* and disruption trials are in progress with a sprayable, microcapsule formulation of this chemical.

Although monounsaturated acetates are very common pheromonal components in Lepidoptera, odd-numbered chain lengths are rare, and a sequence of four acetates each differing in chain length by only one carbon atom is unique among pheromones identified to date.

Acknowledgments—We wish to thank the management of M/s Upper Doab Sugar Mills, Shamli, and Dr. K. V. Isaac, Cane Development Officer, for all the facilities provided for the field experiments. We also thank Miss Jane Mullings (TDRI) for skilled technical assistance in the laboratory work. This work was carried out under MAFF licence number PHF 211/51 issued under the Destructive Pests and Diseases of Plants Order 1965.

(Received July 12, 1985; accepted September 20, 1985)

Abstract—A volatile kairomone of the two-spotted spider mite, *Tetranychus urticae*, elicits a searching response of the phytoseiid predator *Amblyseius potentillae*, only when the predator is reared on a carotenoid-free diet. However, after addition of crystalline β-carotene or vitamin A acetate to the predator's rearing diet this searching response was absent. Because vitamin A and β-carotene are indispensable nutrients for diapause induction, the carotenoid-deficient predators increase their fitness by searching for two-spotted spider mites, when other spider mites are unavailable. Two-spotted spider mites, among others, contain the carotenoids required for diapause induction, but are an inferior prey due to the dense webbing they produce. When the predators have carotenoids at their disposal, they do better by searching for other spider mites that are more profitable in terms of reproductive success. Such a prey is the European red spide mite, *Panonychus ulmi*. The volatile kairomone of this prey elicits a searching response of the predator whether it has a carotenoid deficiency or not.

Key Words—*Amblyseius potentillae*, *Tetranychus urticae*, *Panonychus ulmi*, Acarina, Phytoseiidae, Tetranychidae, volatile kairomones, vitamin A, β-carotene, diapause induction.

INTRODUCTION

Amblyseius potentillae (Garman) (Acarina: Phytoseiidae) is a polyphagous predatory mite that can feed and reproduce on phytophagous spider mites (Acar-

0098-0331/86/0600-1389$05.00/0

ina: Tetranychidae) (Kropczynska-Linkiewicz, 1971; Overmeer, 1981) and pollen of several plant species (Overmeer, 1981). The predator is known to respond to volatile kairomones. In Y-tube olfactometer experiments it was shown that starved *A. potentillae,* when reared on two-spotted spider mites (*Tetranychus urticae* Koch), respond to a volatile kairomone of the European red spider mite [*Panonychus ulmi* (Koch)] but not to a kairomone emitted from leaves infested by the two-spotted spider mite, to which other predatory mites respond (Sabelis and Van de Baan, 1983). *Tetranychus urticae* is an unprofitable prey species for *A. potentillae*, as the predator is hindered by the dense webbing produced by this spider mite (Sabelis, 1981). The European red spider mite that also produces silk but not a dense webbing is a more profitable prey. These differences in values of these prey species for *A. potentillae* also are reflected in the ability of the predator to control populations of these mite species. The predator is able to control populations of *P. ulmi* Van de Vrie, 1973; McMurtry and Van de Vrie, 1973; Rabbinge, 1976), but it is unable to control those of *T. urticae* (Sabeis, 1981).

When animals search for food, they have to make decisions about where to search, how long to search at a specific site, and which type of food to eat. In optimal foraging theory, it is assumed that predators make decisions so as to maximize their genetic contributions to future generations. It is therefore assumed that animals maximize their net rate of food intake (Pyke et al., 1977; Krebs, 1978). Although it has received little emphasis in the literature, nutrient composition also is important and should be optimized. Examples are available for spiders (Greenstone, 1979) and moose (Belovsky, 1978). General dietary components like nitrogen, amino acids, and proteins are usually thought to be important (Greenstone, 1979; Slansky and Feeny, 1977; Moss et al., 1972). In this paper, a specific nutrient is taken into account: vitamin A, which is an indispensable nutrient for diapause induction in the eyeless mite *Amblyseius potentillae* (Veerman et al., 1983). Our work shows that a deficiency of vitamin A or its precursor β-carotene in the diet of *A. potentillae* affects its response to a kairomone of one of its prey species, the two-spotted spider mite. To our knowledge this is the first time that any single nutrient has been shown to be of crucial importance in prey selection.

METHODS AND MATERIALS

Predators. Amblyseius potentillae was reared on plastic plates (McMurtry and Scriven, 1965) in a climate room at 25 $\pm$ 1°C, 60 $\pm$ 10% relative humidity, under continuous fluorescent light on four different diets. Two-spotted spider mites have been used as prey for many years. The mites were brushed off the host-plant leaves onto the plastic plates to circumvent the adverse effects of the dense webbing of this prey. For about five years, predators from this culture

have been reared on broad bean (*Vicia faba* L.) pollen, a carotenoid-free diet for *A. potentillae* (Overmeer and Van Zon, 1983). For some experiments we added crystalline β-carotene or vitamin A acetate (Sigma Co., St. Louis, Missouri) to the pollen (1 mg β-carotene or vitamin A acetate per 5 mg pollen). Overmeer and Van Zon (1983) and Veerman et al. (1983) showed that *A potentillae* take up these crystalline carotenoids when mixed with pollen.

Prey. The two-spotted spider mite was reared in our laboratory for many years on Lima beans (*Phaseolus lunatus* L.) at 20–30°C under continuous fluorescent light that was added to the sunlight regime.

The European red spider mites were collected from an apple orchard. The leaves, on which 20–40 active *P. ulmi* stages were present, were used in the bioassay on the day collected.

Bioassay. We used an olfactometer that consisted of a glass tube with an iron wire in the center, both of which are Y-shaped. Odor-emitting objects may be placed in PVC cages at the ends of both arms of the Y-tube olfactometer. Air was sucked out at the base of the tube and led to the outside of the climate room in which the olfactometer was positioned. The airstream speeds in both arms of the olfactometer were measured with a hot wire anemometer and standardized at 0.7 ± 0.1 m/sec by inserting dry cotton wool in the inlet of the airstream and/or changing the total air speed with a valve. Female predators that had been deprived of food and water for 20 hr in a plastic tube were placed individually on the wire at the base of the basal tube and observed. Starved predators were used as these showed a response to the volatile kairomone of *P. ulmi*, unlike well-fed predators (Sabelis and Van de Baan, 1983). When the predator walked upwind and reached the far end of one of the arms, the experiment was terminated. The maximum experimental time was 10 min. Predators that did not walk to the far end of one of the arms were left out of the statistical analysis.

The results have been analyzed using a sign test. The null hypothesis is that the probabilities of the predators to walk to the far end of either arm are equal to 50%. For a more detailed description of the olfactometer, the experimental procedure and statistical analysis, see Sabelis and Van de Baan (1983). The experiments were performed at 26 ± 1°C and 60 ± 10% relative humidity.

RESULTS AND DISCUSSION

Results of experiments using the Y-tube olfactometer show that when *A. potentillae* were reared on broad bean pollen and then starved for 20 hr, they responded to the volatile kairomones of *T. urticae* and *P. ulmi*. However, when they were reared on *T. urticae*, they did not respond to the kairomone of *T. urticae*, but only to that of *P. ulmi* (Table 1). The difference in response between predators reared on the two different diets could be accounted for either

Predator reared on	Content of arm 1	Content of arm 2	N^a	$N(1)$	$N(2)$	$N(0)$	Critical level
T. urticae	9 bean leaves infested with *T. urticae*	9 clean bean leaves	40	21	19	0	NS[b]
	18 apple leaves infested with *P. ulmi*	18 clean apple leaves	40	31	9	0	$P < 0.001$[b]
V. faba pollen	9 bean leaves infested with *T. urticae*	9 clean bean leaves	60	44	15	1	$P < 0.001$
	18 apple leaves infested with *P. ulmi*	18 clean apple leaves	53	38	14	1	$P < 0.001$

[a] N = number of predators tested; $N(1)$ = number of predators that walked to far end of arm 1; $N(2)$ = number of predators that walked to far end of arm 2; $N(0)$ = number of predators that did not walk to far end of one of the arms.
[b] Results of Sabelis and Van de Baan (1983).

by a genetic difference due to different selection pressures in the two cultures or by a physiological difference due to different diets. No differences in fecundity, developmental time, and mortality have been observed between *A. potentillae* reared on *T. urticae* or *V. faba* pollen (Overmeer, 1981). The predators can be reared equally well on both diets. However, it has been reported that predators reared on broad bean pollen cannot enter reproductive diapause, while those reared on *T. urticae* can (Overmeer and Van Zon, 1983). Because β-carotene is known to affect diapause in the two-spotted spider mite (Veerman and Helle, 1978), this compound was added to the broad bean pollen or to carotenoid-free eggs of albino *T. urticae* that *A. potentillae* were reared upon. This addition restored the predator's ability to enter diapause (Van Zon et al., 1981; Overmeer and Van Zon, 1983). Adding vitamin A, a derivative of β-carotene, to the diet of *A. potentiallae* also has the same effect (Veerman et al., 1983). Thus, a physiological difference between predators reared on the two different diets might cause the difference in response to the *T. urticae* kairomone.

When *A. potentillae* were reared for several generations on broad bean pollen mixed with β-carotene or vitamin A or just on broad bean pollen to which the carotenoid was only added five days prior to the experiment, the predators showed no response to the kairomone of *T. urticae* (Table 2). However, the response to the kairomone of *P. ulmi* was still present when the predators were reared for several generations on broad bean pollen to which crystalline β-carotene was added. Thus, the response of *A. potentillae* to the kairomones of *T. urticae* and *P. ulmi* is identical for predators reared on either *T. urticae* or pollen plus crystalline β-carotene as carotenoid source. These results show that β-

carotene and vitamin A affect the response to the *T. urticae* kairomone. Predators respond to this kairomone when they lack these carotenoids. Because vitamin A is an essential nutrient for inducing diapause and hence for hibernation, it is thus worth foraging for, since the ability to enter diapause is of selective advantage. Predators being under stress conditions (in this case carotenoid-deficiency) would do better by broadening their diet, and the response to the *T. urticae* kairomone by carotenoid-deficient predators can be interpreted in this context.

Amblyseius potentillae is found in orchards, where it is unlikely that the pollen of *V. faba* would be an important food source. Therefore one wonders under what circumstances carotenoid shortage could occur in the field. This question cannot be answered yet, but is of importance in concluding how frequently carotenoids are a limiting factor, and thus how decisive their role is in natural selection.

There are several ways in which *A. potentillae* can obtain carotenoids, and it would be interesting to study how they are affected by depriving *A. potentillae* of carotenoids: (1) Predation on any seizable phytophagous prey. When deprived of carotenoids *A. potentillae* responds to the kairomones of more prey species than after consumption of these compounds (Dicke and Groeneveld, 1986; this paper). (2) Cannibalism, a phenomenon often observed in cultures of *A. poten-*

tillae on broad bean pollen, but not in those on *T. urticae* (Overmeer and Van Zon, 1983; own observation). This only helps the carotenoid lack when the conspecific contains cartenoids. (3) Consumption of the types of pollent that have carotenoids available to the predator. (4) Consumption of red yeasts that are present on the host plant leaf. The phytoseiid mite *Amblyseius finlandicus* (Oudemans) has been found to feed and reproduce on fungal spores (Kropczynska, 1970), but so far *A. potentillae* has not been found to feed on fungi. (5) Phytophagy, a phenomenon reported for the predatory mite *A. hibisci* (Chant) (Porres et al., 1976) that has recently been confirmed for *A. potentillae* as well (Dicke, in preparation).

Thus, it might seem that, in the field, *A. potentillae* usually should have no problem in obtaining carotenoids. Whether this is true should be investigated by sampling predators in the field and testing their ability to enter diapause. However, if obtaining carotenoids is indeed not a problem for *A. potentillae*, this might be the result of the development in evolutionary time of one or more of the five above-mentioned strategies to obtain carotenoids. As carotenoids are unstable under light conditions, this might mean that the transparent *A. potentillae* has to replenish its supply regularly. Still, the amount of carotenoids needed for diapause induction seems to be small; after switching from a diet with carotenoids to one without, the offspring do not loose the ability to enter diapause until in the second generation (Overmeer and Van Zon, 1983). However, a low amount of carotenoids may be insufficient to detect the photoperiodic signal under dim light conditions, as has been reported for larvae of *Bombyx mori* (Shimizu and Kato, 1984).

Whether other functions of carotenoids in *A. potentillae* exist is not known. In other organisms, only photofunctions have been demonstrated for carotenoids (Krinsky, 1971), although many hypotheses about other functions have been put forward (Krinsky, 1971; Karnaukhov et al., 1977). Based on their isolation from bovine olfactory epithelium and the brownish-yellow color of olfactory mucosa, it has also been suggested that carotenoids function as receptors for the energy from odorous molecules (Briggs and Duncan, 1961; Kurihara, 1967). It was thus postulated that smell is impaired by vitamin A deficiency (Briggs and Duncan, 1961). In *A. potentillae*, vitamin A deficiency results in response to the kairomones of an increased number of prey species. In Y-tube olfactometer experiments in which different prey species were offered in each olfactometer arm, carotenoid-deficient *A. potentillae* distinguished between the kairomones of these prey species (Dicke and Groeneveld, 1986). This indicates that olfactory discrimination in *A. potentillae* is improved. The hypothesis of Briggs and Duncan (1961) would predict, however, an impaired olfactory function, and thus this hypothesis cannot hold for olfaction in *A. potentillae*.

A response to kairomones of a larger number of prey species can be thought to occur under stress situations other than carotenoid deficiency. Severe star-

vation can be such a stress situation. A response to the volatile kairomone of *T. urticae* may therefore be present in *T. urticae*-reared *A. potentillae* after starvation for a longer time than the 20 hr of food deprivation used in this study.

Conditioning due to experience with a host species has been observed to affect host recognition by hymenopterous parasitoids (Arthur, 1971; Vinson et al., 1977; Vet, 1983). In the present case, predators that were reared on two-spotted spider mites for many years do not respond to the volatile kairomone of this prey species (Sabelis and Van de Baan, 1983). Only predators that were reared on broad bean pollen and never had any contact with two-spotted spider mites respond to the volatile kairomone of this prey. The response of *A. potentillae* to the volatile kairomone of *T. urticae* is not dependent on previous contact with this prey species, but on whether the predator has available nutrients that are indispensable for diapause induction. The eyeless predatory mite *A. potentillae* can identify a deficiency in β-carotene or vitamin A in its body. As a result, the predator responds to a volatile kairomone of an unprofitable prey species when the alternative is no prey at all. The result of this response is that after finding and consuming this prey species, the predator will have carotenoids available and thus will be able to enter diapause.

Acknowledgments—We thank J.C. van Lenteren for discussion and critically reading the manuscript, and A. Veerman for valuable comments on an earlier version of the manuscript. H. Snellen is thanked for rearing the two-spotted spider mites and Mrs. C. Hengeveld for improving the English text.

(Received May 8, 1985; accepted September 24, 1985)

Abstract—Loblolly and shortleaf pine growing on a single site in the North Carolina piedmont were examined to determine similarities and differences in their defensive mechanisms against the southern pine beetle, *Dendroctonus frontalis* Zimmermann, and its fungal associate, *Ceratocystis minor* (Hedgecock) Hunt. Both species responded to wounding and fungal inoculation by forming a hypersensitive lesion around the wound site. There were significantly less soluble sugars and more monoterpenes in the lesion tissue than in unwounded inner bark. The two species were similar in resin flow rate and inner bark soluble sugar content, but the loblolly pines had thicker bark, longer hypersensitive lesions, and a higher concentration of inner bark monoterpenes. Inner bark monoterpene composition was also significantly different between the two pine species. It is hypothesized that two different defensive strategies against southern pine beetle attack may be utilized.

Key Words—*Dendroctonus frontalis*, *Coleoptera*, *Scolytidae*, *Ceratocystis minor*, *Pinus*, bark beetle, fungus, defense, monoterpenes, soluble sugars, resin flow, hypersensitive lesion.

INTRODUCTION

The southern pine beetle (SPB), *Dendroctonus frontalis* Zimmermann (Coleoptera: Scolytidae), is a serious pest of pines throughout the southern United States. It is capable of attacking and killing all four of the major southern pine species: loblolly, *Pinus taeda* L.; longleaf, *P. palustris* Mill; shortleaf, *P. echinata* Mill;

0098-0331/86/0600-1397$05.00/0

and slash, *P. elliottii* Engelm.; but shortleaf and loblolly appear to be the two more susceptible hosts (St. George and Beal, 1929).

Upon attacking a tree, female SPB introduce several fungal species to the host phloem tissue (Bramble and Holst, 1935, 1940). One of these fungal associates is the blue-staining fungus, (*Ceratocystis minor* Hedgecock) Hunt (Rumbold, 1931). The role of this fungus in overcoming tree resistance is not fully understood, but it has been suggested to be a major factor in causing host mortality (Coulson, 1980). *C. minor* may overcome tree resistance by disrupting water movement within the tree (Caird, 1935; Bramble and Holst, 1940).

Berryman (1972) hypothesized a three-step defense sequence by which conifers defend themselves when attacked by bark beetles and their fungal associates. First, there is a wound cleansing step (primary resin flow), followed by an infection containment step (a hypersensitive reaction), and finally a wound healing step (periderm formation). In the southern pines, primary resin flow may act to slow down or prevent colonization by SPB, while the hypersensitive reaction may act to contain the associated fungi.

Primary resin flow may physically prevent successful bark beetle attack by "pitching out" the beetles (Vité and Wood, 1961). In the four major southern pines, tree resistance to SPB has been related to flow, viscosity, and crystalization time of the primary resins (Hodges et al., 1979).

The hypersensitive reaction has been more extensively studied in western conifers (i.e., Reid et al., 1967; Berryman, 1969). The reaction can be described as a rapid necrosis of cells surrounding the infection site, accompanied by the development of traumatic resin ducts and an increased concentration of monoterpenes and phenolics in the reaction zone (Reid et al., 1967). Shrimpton (1973) found a decrease in free-sugars and an increase in starch in the area surrounding a wound. The change in monoterpene composition may be an active defense against bark beetles by accumulating toxic, repellent, or inhibitory materials in the area of attack (Russell and Berryman, 1976). The change in carbohydrate composition may be an indirect defense by limiting a potential beetle/fungal nutrient (Wong and Berryman, 1977). Cook annd Hain (1985) have reported that a hypersensitive reaction also occurs in loblolly pine. They reported a change in monoterpene composition and a decrease in soluble sugars between unwounded phloem and phloem from the hypersensitive reaction zone. However, only qualitative data were presented for the monoterpenes, and the monoterpene and soluble sugar information were from different time periods after wounding. Thus, there was no quantitative measure of monoterpene accumulation in the hypersensitive lesion and no way to determine if monoterpene accumulation and soluble sugar decrease occurred simultaneously. The objective of this study was to quantitatively examine and compare the first two stages in host defense (resin flow and the hypersensitive reaction) of loblolly and shortleaf pine on a single study site in the North Carolina piedmont.

METHODS AND MATERIALS

Experimental work was conducted during the summers of 1983 and 1984 in the Hill Experimental Forest of North Carolina State University, located ca. 20 km north of Durham, North Carolina. The stand was predominantly pine, with loblolly, shortleaf, and virginia pine all being present. Equal numbers of loblolly and shortleaf pine (four in 1983 and eight in 1984) were examined beginning the first week of June, July, and August of each year. One shortleaf pine from the August 1984 sample was later infested with cerambycid larvae and was dropped from the analysis, making the total sample size 36 loblolly and 35 shortleaf pines. All trees used in this study were 50–65 years of age.

On the initial day of sampling during each month, tree physical characteristics (Table 1) were measured and inner bark samples removed for determination of soluble sugar and monoterpene content. The soluble sugar samples were removed with a No. 9 cork borer (13 mm diameter), wrapped in aluminum foil and placed on Dry Ice. The monoterpene samples were also removed with a No. 9 cork borer, placed in 2 ml of *n*-pentane or CH_2Cl_2 and placed on Dry Ice. Both of the inner bark samples were subsequently stored at −20°C until chemical determinations could be made. Also on this day, trees were wounded to the xylem at breast height with a No. 9 cork borer and inoculated with a 1 ml solution of *C. minor* in a 2.5% malt extract solution. The fungi were shake-cultured for 14 days prior to inoculation and were in the mycelial stage.

Two weeks later, the hypersensitive reaction resulting from the fungal inoculation was removed and the lesion length was measured. Two inner bark samples were removed from the hypersensitive lesion, one for soluble sugar determination and one for monoterpene determination. Samples were handled as described above. Also measured at this time was the resin flow rate. Flow was measured on an aspect of the tree perpendicular to the wound reaction. A 2-cm-deep hole with a diameter of 0.64 cm was made in the tree and a glass tube fit snugly into the hole. A calibrated receptacle was attached to the open end of the tube for capturing and measuring the amount of resin. Total flow was measured after 4–5 hr.

Inner bark samples were analyzed for soluble sugar content using the An-

TABLE 1. AVERAGE TREE PARAMETERS ±SD FOR LOBLOLLY AND SHORTLEAF PINES EXAMINED

Species	*N*	dbh (cm)	Height (m)	Bole ht (m)	Phloem (mm)	Bark (mm)
Loblolly	36	34.74 ± 4.56	25.85 ± 2.74	14.63 ± 2.63	1.38 ± 0.32	2.24 ± 0.55
Shortleaf	35	29.32 ± 4.46	24.05 ± 4.05	13.25 ± 2.72	1.26 ± 0.32	1.23 ± 0.29

throne colorimetric technique (Hodge and Hofreiter, 1962; Hazid and Neufeld, 1964). The inner bark samples were analyzed for monoterpenes using a modification of the gas chromatograph program used by Cook and Hain (1985). The program began with an initial temperature of 60°C which was held for 12 min. The temperature was then raised by 15°C/min until a final temperature of 200° was reached. This final temperature was held for 15 min. An internal standard of 1 μl ρ-cymeme was used in each sample. The monoterpene values reported herein are given as ρ-cymene equivalents.

The average resin flow rate (ml/hr), length of the hypersensitive reaction (mm), inner bark soluble sugar content (% dry wt), and inner bark monoterpene content (μl/g dry wt) and composition were calculated for each tree species. Student's t tests were conducted between species to determine if there were significant differences in resin flow or length of the hypersensitive reaction. A two-way analysis of variance was used to determine if differences existed between species or between unwounded and lesion inner bark tissue soluble sugar content. A two-way multivariate analysis of variance was conducted to determine if differences in inner bark monoterpene content or composition existed.

RESULTS

The loblolly pines examined had thicker bark ($t = 9.6163$, $df = 69$, $[P > t] \leq 0.0001$, two-tailed) than the shortleaf pines on this study site (Table 1). There was no significant difference in the average resin flow rate between the two species ($t = 0.9074$, $df = 69$, $[P > t] = 0.3674$, two-tailed); however, there was a large range in measurements within both species (Table 2). There was also a large range in the length of the hypersensitive reaction produced by the trees when wounded and inoculated with *C. minor* (Table 2), but overall, the loblolly pine produced a significantly longer lesion ($t = 2.2644$, $df = 69$, $[P > t] = 0.0267$, two-tailed) than did the shortleaf pines.

Unwounded inner bark soluble sugar content (percentage of the total inner bark dry weight) averaged 11.15 $\pm$ 5.08% ($n = 36$) in the loblolly pines and 10.36 $\pm$ 2.76% ($n = 33$) in the shortleaf pines. This was significantly greater

TABLE 2. MEASURES OF RESIN FLOW RATE AND LENGTH OF HYPERSENSITIVE LESION FOR LOBLOLLY AND SHORTLEAF PINES EXAMINED

		Resin flow rate (ml/hr)		Lesion length (mm)	
Species	N	$\bar{X} \pm$ SD	min, max	$\bar{X} \pm$ SD	min, max
Loblolly	36	0.29 $\pm$ 0.27	0.00, 1.11	100.8 $\pm$ 25.9	61.0, 150.0
Shortleaf	35	0.24 $\pm$ 0.20	0.00, 1.00	87.4 $\pm$ 24.0	47.0, 138.0

($F = 238.03$, $df = 1,125$, $[P > F] \leq 0.0001$) than the lesion soluble sugar content of the loblolly, $2.28 \pm 0.96\%$ ($n = 30$), and shortleaf, $2.09 \pm 1.37\%$ ($n = 29$), pines examined. The inner bark soluble sugar content was not significantly different between the two species ($F = 1.28$, $df = 1,125$, $[P > F] = 0.2596$).

The inner bark monoterpene concentrations (Table 3) were significantly higher in the hypersensitive lesion opposed to unwounded tissue ($\Lambda = 0.3286$, $F = 36.10$, $df = 6,106$, $[P > F] \leq 0.0001$) but, unlike the soluble sugars, there was also a significant difference between the monoterpene concentrations in loblolly and shortleaf pine ($\Lambda = 0.7657$, $F = 5.41$, $df = 6,106$, $[P > F] \leq 0.0001$). The between-species difference in inner bark monoterpene concentrations also represented a between-species difference in monoterpene composition ($\Lambda = 0.7254$, $F = 8.10$, $df = 5,107$, $[P > F] \leq 0.0001$). In loblolly pine, the change in inner bark monoterpenes from unwounded to lesion tissue resulted in a higher proportion of α-pinene being present and a lower proportion of β-pinene, while in shortleaf pine there was a lower proportion of α-pinene and a higher proportion of β-pinene in the lesion than in unwounded tissue (Figure 1). The monoterpene composition was significantly different between the unwounded and lesion tissue ($\Lambda = 0.6063$, $F = 13.90$, $df = 5,107$, $[P > F] \leq 0.0001$).

DISCUSSION

The loblolly and shortleaf pines responded similarly when wounded and inoculated with *C. minor*. Both species have well-developed resin canal systems and when severed, the resin flows down and out through the wound hole. Both species produced a necrotic lesion around the invasion site, and the lesion tissue contained significantly lower amounts of soluble sugars and higher concentrations of monoterpenes than was found in unwounded tissue. The results on the hypersensitive reaction agree with previous work on loblolly pine which reported decreases in reducing sugars following SPB introduction (Barras and Hodges, 1969) and in the hypersensitive lesion four weeks following fungal inoculations (Cook and Hain, 1985). The change in monoterpene content from unwounded to lesion tissue agrees with work by Cook and Hain (1985) on loblolly pine and Reid et al. (1967) on lodgepole pine. Russell and Berryman (1976) suggested that the change in monoterpene composition may be an active defense against bark beetles and their associated fungi. Based upon lethal dosage, Coyne and Lott (1976) ranked the toxicity of the six monoterpenes to SPB as limonene > myrcene > α-pinene > β-pinene > β-phellandrene > camphene. The increased concentration of all six of these monoterpenes in the lesion tissue and the changed composition of the monoterpenes appears to support the hypothesis of Russell and Berryman (1976).

TABLE 3. AVERAGE CONCENTRATIONS OF MONOTERPENES PRESENT IN UNWOUNDED TISSUE AND IN HYPERSENSITIVE LESIONS OF LOBLOLLY AND SHORTLEAF PINES EXAMINED

Species		N	Monoterpenes (μl/g inner bark dry wt $\pm$ SD)[a]					
			α-Pinene	Camphene	β-Pinene	Myrcene	Limonene	β-Phellandrene

[a] Monoterpene values are presented in ρ-cymene equivalents.

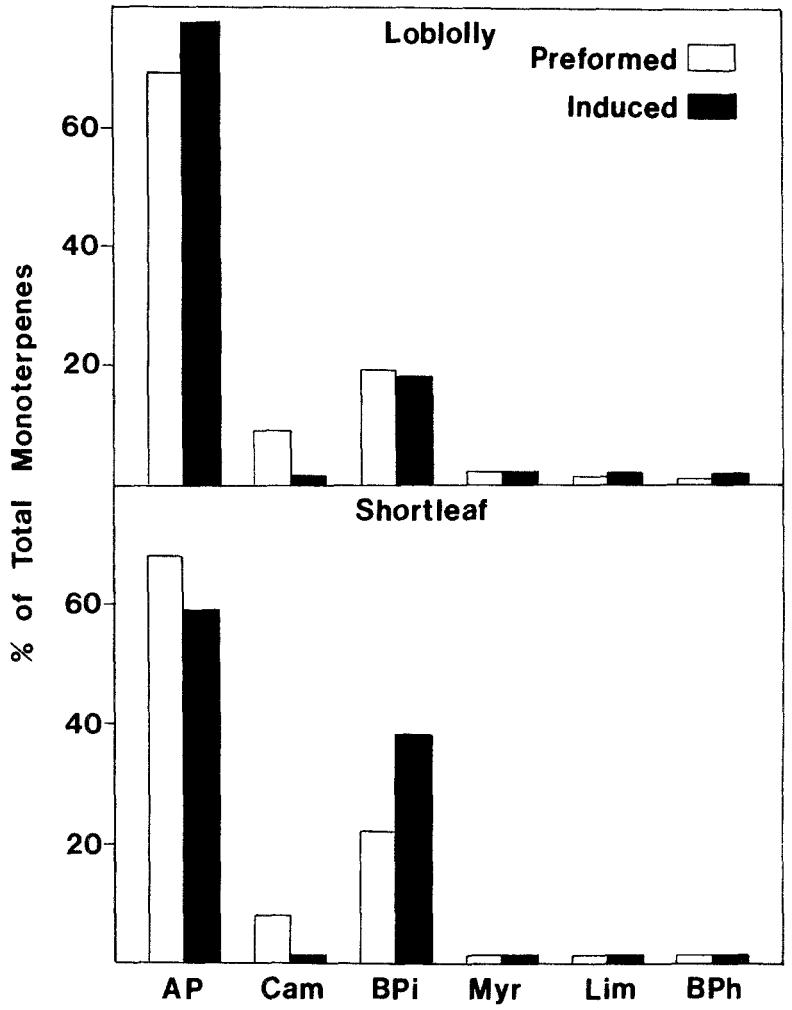

FIG. 1. Average composition of the inner bark monoterpenes from unwounded tissue (preformed) and the hypersensitive lesion (induced) for the loblolly and shortleaf pines examined. The monoterpenes were α-pinene (AP), camphene (Cam), β-pinene (BPi), myrcene (Myr), limonene (Lim), and β-phellandrene (BPh).

Preformed tree defenses against bark beetles and their associated fungi can be viewed as physical and/or chemical barriers which are present prior to attack and must be overcome by the invader. We examined two preformed physical barriers, bark thickness and resin flow rate, and one preformed chemical barrier, inner bark monoterpenes. Thicker fissure bark has previously been associated with SPB infestations where the preferred host was loblolly pine but not in areas

where shortleaf pine was the preferred host (Hicks, 1980). Although thick bark may constitute a physical barrier to attacking beetles and result in more intense predation (Franklin and Green, 1965), once attack is successful the SPB may benefit because bark thickness adversely affects some SPB parasitoids (Goyer and Finger, 1980). Also, if brood survival increases with bark thickness, the probability of adjacent trees, those that will be attacked next (Coster and Gara, 1968), being successfully attacked should increase because the number of potential attacking beetles would increase.

Resin flow rate was one of the variables used by Hodges et al. (1979) to separate resistant from susceptible southern pines. Higher flow rates can prevent beetles from becoming established in a tree and, even if the beetles are not "pitched out" (Vité and Wood, 1961), the rate of gallery construction is apparently related to the amount of resin encountered by the beetles (MacAndrews in Thatcher, 1960). Although not significantly different between species, the resin flow rates showed considerable tree-to-tree variation which may be a factor in an individual tree's susceptibility or resistance to SPB.

There were higher concentrations of α-pinene, camphene, β-pinene, and myrcene in the unwounded inner bark and higher concentrations of α-pinene, camphene, myrcene, and limonene in the hypersensitive lesion of loblolly compared to shortleaf pine. All of these substances are toxic to SPB (Coyne and Lott, 1976), and α-pinene, β-pinene, myrcene, and limonene are toxic to the western pine beetle, *D. brevicomis* LeConte (Smith, 1965). Along with being toxic, differences in monoterpene composition within the trees may be important. For example, Gollob (1980) suggested that loblolly pines with higher myrcene content may be viewed as nonhosts by SPB.

Host odors are important to attacking SPB populations, and α-pinene is believed to be the most important of these tree-produced volatiles (Renwick and Vité, 1969). By itself, α-pinene acts as a synergist for the SPB aggregation pheromone, frontalin (Kinzer et al., 1969; Renwick and Vité, 1969). Although turpentine appears to be a more effective pheromonal synergist (Payne et al., 1978), the lowered proportion of α-pinene in shortleaf tissue following attack may serve to slow mass aggregation of the beetle and allow the tree time to further respond with other defensive mechanisms. The decreased percentage of α-pinene is not large and possibly has no effect on the attacking SPB. However, we believe the hypothesis that the change does affect SPB attack behavior is plausible and could be tested.

The hypersensitive lesion produced in response to fungal inoculation was longer in loblolly than in shortleaf pine. The lesion area was resin soaked, high in monoterpene content, and low in soluble sugars in both host species. A larger reaction would force the beetles to expend more energy to reach suitable brood material and thus may be correlated with a higher probability of containing both the beetles and the associated fungi. Due to physiological differences between the two species, the difference in lesion size may or may not be important in

comparing species resistance to SPB attack. If the invading organisms are contained in the lesion, wound periderm will seal off the necrotic area, thereby protecting adjacent tissue from any possible adverse affects (Mullick, 1977).

Based upon the above information, we hypothesize two different strategies of host defense against SPB and its associated fungi. One strategy would be to rely upon strong quantitative defenses. The result would be a thick-barked tree with a high resin flow rate and a strong hypersensitive reaction. The second strategy would involve a qualitative defense. This may result in the production of nonattractive or less attractive host odors, as might be the result of a rapid change in monoterpene composition following beetle attack. Both loblolly and shortleaf pine possess characteristics within each defensive strategy. Both species have quantitative defenses of resin flow and a hypersensitive response with monoterpene accumulation, and both possess qualitative defenses as evidenced by the change in monoterpene composition. The loblolly pines examined appear to rely more heavily on a quantitative defense, while the shortleaf pines appear to have a better developed qualitative defense.

Acknowledgments—We would like to thank Udo Blum, Fred Gould, and John Monahan for their comments on an earlier draft of this manuscript; and W. Hobbs, P. Nappen, and E. Younan for technical assistance. Dr. J.R. Bridges furnished the fungal culture used in this study, and Dr. F.L. Hastings allowed us to conduct our chemical analyses in his laboratory. We also thank the North Carolina State University School of Forest Resources for allowing us to work in Hill Experimental Forest. This research was supported by the USDA-sponsored bark beetle IPM program. This is paper No. 9858 of the Journal Series of the North Carolina Agricultural Research Service, Raleigh, North Carolina.

(Received July 26, 1985; accepted September 30, 1985)

Abstract—Two compounds recently isolated from the defensive gland of *Necrodes surinamensis*, α- and β-necrodol, first representatives of a new category of monoterpenes (the necrodanes), are shown to be repellent to ants and other insects and irritating to cockroaches and flies. The compounds doubtless play a defensive role in *Necrodes*. The possible long-range applied significance of research on insect repellents is discussed.

Key Words—Coleoptera, Silphidae, *Necrodes surinamensis*, carrion beetle, monoterpenes, iridoids, necrodols, defensive secretion, insect repellent, insect irritant, bioassay.

INTRODUCTION

Monoterpenes, long recognized as major constituents of plant essential oils, play important roles as defensive agents and pheromones in the animal kingdom (Weatherston, 1973). The occurrence of over 30 acyclic, monocyclic, bicyclic, and tricyclic monoterpene skeletons, all enzymatically derived from geranyl pyrophosphate (1) (Figure 1), attests to the wide variety of functions served by these compounds (Devon and Scott, 1972; Iwasaki and Nozoe, 1974). Within this structural diversity, the iridoids, characterized by the 1-isopropyl-2,3-dimethylcyclopentane skeleton (2), first found in nepetalactone (3), are the only

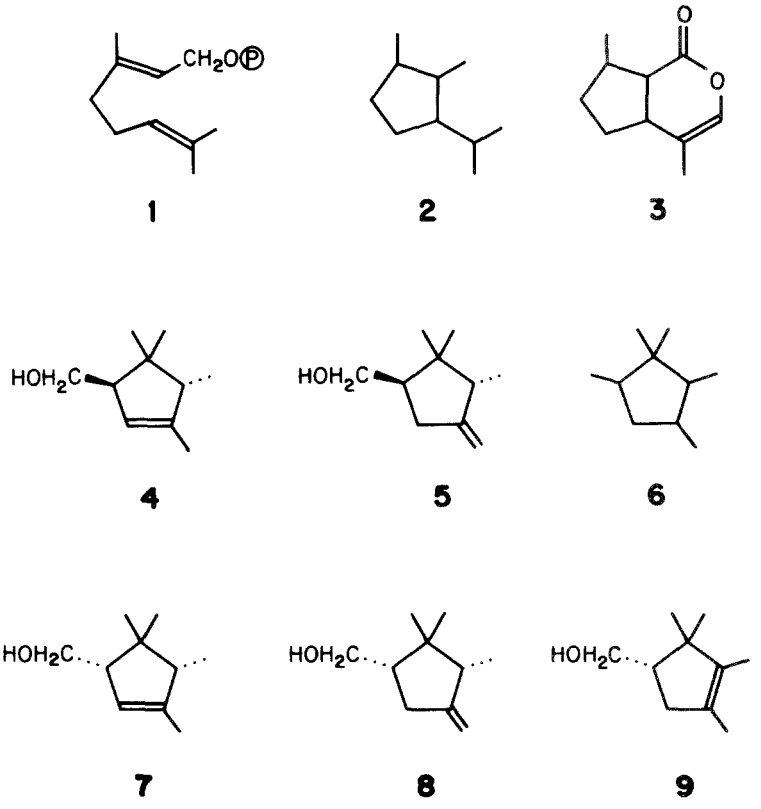

FIG. 1. Chemical structures

widely distributed monoterpenes based on the cyclopentane nucleus (Devon and Scott, 1972; Iwasaki and Nozoe, 1974).

In this context, the discovery of α- and β-necrodol (4, 5) from a silphid beetle, *Necrodes surinamensis*, is interesting (Eisner and Meinwald, 1982). These terpene alcohols appear to be the first representatives of a new family of cyclopentanoid monoterpenes, based on the 1,2,2,3,4-pentamethylcyclopentane nucleus (6), which we propose to call necrodanes. The necrodols are produced by the rectal gland of *Necrodes*. The products of this gland, together with enteric fluid, are ejected as an aimed spray when the beetle is under real or simulated attack. Predators such as ants are deterred by the discharges (Eisner and Meinwald, 1982). This in itself suggested a defensive role for the necrodols, but an insufficient quantity of the compounds was initially isolated from the beetles for biological testing. We have now synthesized milligram quantities of 4 and 5, together with some closely related structures, epi-α-necrodol (7), epi-β-necrodol (8), and γ-necrodol (9), and here present evidence that these compounds are repellent and topically irritating to insects.

METHODS AND MATERIALS

Syntheses of 4, 5, 7, 8, and 9 from (+)-camphoric acid, a readily available precursor of known absolute configuration (Beilstein, 1971), have been described (Jacobs, 1985) and will be published elsewhere. All compounds are liquids at ambient temperature.

In all the following tests, sample presentation was by way of capillary tubing of inner diameter = 619 ± 0.34 μm (mean ± SE; $N = 20$).

The general deterrency tests were carried out with β-necrodol only, the compound available in greater quantity. The tests were similar to those previously carried out with nepetalactone (Eisner, 1964) and consisted of observing the response of a variety of insects to the vapors emanating from the tip of a capillary tube filled with β-necrodol, presented to the insects manually at near contact range. The insects tested (Table 1) were a mixed array that had come to rest at night on an illuminated surface outdoors, on the grounds of the Archbold Biological Station, Lake Placid, Florida. The protocol involved initial presentation of a control (glass capillary tube filled with distilled water), first from one side of the body (5 sec), then the other (5 sec), followed by presentation of β-necrodol (5 sec on each side of body) if the response to the control was negative (no movement toward or away from capillary tube). A response was scored as aversive if the insect turned away from the necrodol both times. Respondents and nonrespondents were collected for subsequent identification.

The assay with ants (*Monomorium pharaonis*), also carried out at the Archbold Biological Station, involved testing for the repellency of β-necrodol vapors to workers feeding at a sugar bait. The tests were carried out near a natural colony of the ant, at a site to which foragers had laid a network of trails. The bait (10^{-1} M sucrose) was presented as a drop of fixed circumference (spread to the rim over the surface of a circular glass cover slip of 18 mm diameter). When ants had become tightly aligned to feed along the entire perimeter of the drop, a capillary tube with β-necrodol was abruptly swung into place with a mechanical arm that brought the tip of the capillary to a point 2 mm above ground just outside the margin of the drop. Presentation of the sample invariably induced dispersal of a substantial fraction of the feeding ants. The test was replicated eight times. For each test, counts of ants feeding at the drop were taken (from photographs) at 5-sec intervals, from 25 sec before to 25 sec after sample presentation, providing the basis for determination of the percentage of ants repelled as a function of time. Data for the five time transects prior to presentation of the sample showed no significant variability; these data were lumped for all tests ($N = 40$) for calculation of the base value of 0% repellency. Control presentations of empty capillaries, or of capillaries filled with inert chemicals (H_2O, glycerol), failed to induce ant dispersal.

Two tests were used for assessment of the topical irritancy of the necrodols, one with the cockroach *Periplaneta americana*, the other with the fly

[a] All tests based on single specimens, except where indicated by larger number in parentheses.

Phormia regina. The cockroach test was based on the observation (Eisner, 1961) that direct application of chemical irritants to *Periplaneta* induces preening reflexes. The responses are highly stereotyped, and the delay to their onset provides a measure of the irritancy of a sample. For assay purposes, late-instar decapitated nymphs are used, and the site of application of the chemical is the abdomen. We have used the test for assay of other chemicals (Eisner et al., 1961; Smolanoff et al., 1975), and the protocol is described in detail elsewhere (Eisner et al., 1976). Both α- and β-necrodol were assayed, as well as compounds 7–9, with 20 nymphs per sample. The compounds were tested in pure form, and stimulation was by near contact presentation (capillary tubing with sample held at less than 1 mm from the surface of the fourth or fifth abdominal tergite, to one side of midline). Delay to onset of scratching was timed to the nearest second.

The test with *Phormia* was also based on a preening reflex. When subjected to an irritant vapor, *Phormia* everts the proboscis, regurgitates a droplet onto its tip (the labellum), and proceeds to wipe the labellum against the substrate. In tethered flies, the substrate can be made inaccessible, and proboscis extension alone, either with or without regurgitation, can serve as an indication of the response. As with the *Periplaneta* test, delay to onset of extension provides a measure of the potency of the irritant. Details of the protocol are provided elsewhere (Eisner et al., 1976). Both α- and β-necrodol were tested, as well as compounds 7–9, with 20 flies per sample. Presentation was at close range (capillary tube held at 0.3–0.6 mm from labellum), and response was timed to nearest second.

Statistical comparisons were by the *K*-sample Smirnov test (Conover, 1971).

RESULTS

As is clear from Table 1, β-necrodol proved repellent to a diversity of insects (31 species), including Coleoptera (14 families), Hymenoptera (2 families), and Hemiptera (2 families). Among the Hymenoptera was *Monomorium pharaonis*, the ant also used in our feeding deterrency test. Unaffected by the compound were 18 species, comprising Coleoptera (three families), Hymenoptera (one family), Hemiptera (three families), Lepidoptera (three families), and Ephemeroptera (three families). Only three families, the Scarabaeidae, Lygaeidae, and Braconidae, are represented on both tables.

The potency of β-necrodol vis à vis *Monomorium* is evident from Figure 2. By 5 sec after presentation of the compound, the repellency had virtually peaked, indicating that it was essentially of immediate onset. Visual observation tended to confirm this. No sooner had the tube with the sample swung into place, than the ants turned away from the food and fled. Only ants positioned

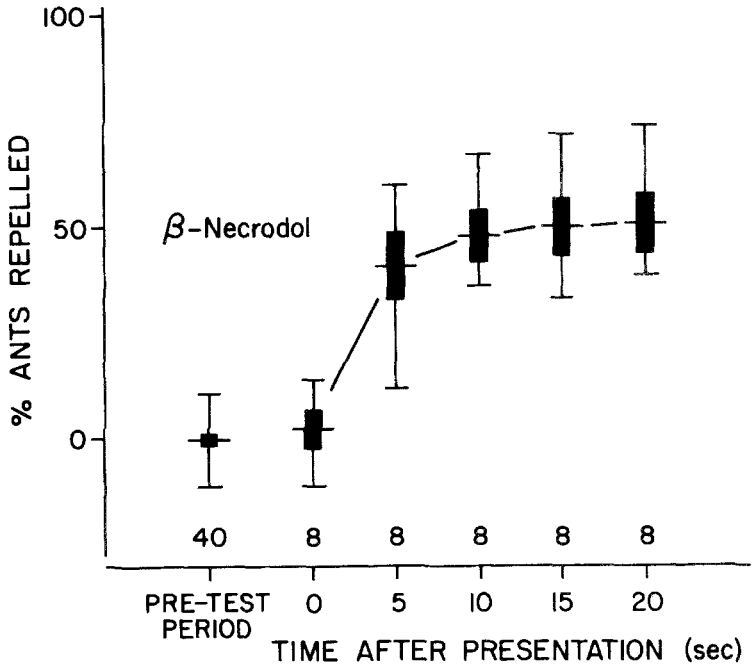

FIG. 2. Repellency of β-necrodol (vapor phase) to the ant *Monomorium*. Details in text. Horizontal lines, vertical lines, and vertical bars give means, ranges, and one standard error on each side of mean, respectively. Numbers above baseline give sample sizes.

furthest from the stimulus (those feeding from the drop across from the site of presentation of the tube) failed to respond.

The data on topical irritancy to roaches and flies are plotted for α- and β-necrodol only (Figure 3). The compounds proved equally active in each test ($P > 0.1$ for both cases). *Phormia* is more sensitive than *Periplaneta* to the compounds, a difference that we know to hold also for other topical irritants (e.g., *p*-benzoquinone, acetic acid, 2-hexenal; all tested in vapor form). Compounds 7, 8, and 9 (data not plotted) proved repellent in both tests. With *Periplaneta*, their activity matched that of the two necrodols ($P > 0.1$). With *Phormia*, 8 and 9 proved as active ($P > 0.1$), and 7 somewhat less active ($P < 0.05$), than the necrodols.

DISCUSSION

There seems little doubt that α- and β-necrodol contribute to the defensive action of the *Necrodes* spray. Although repellency data were obtained for β-necrodol only, one is tempted to presume α-necrodol to be similarly repellent,

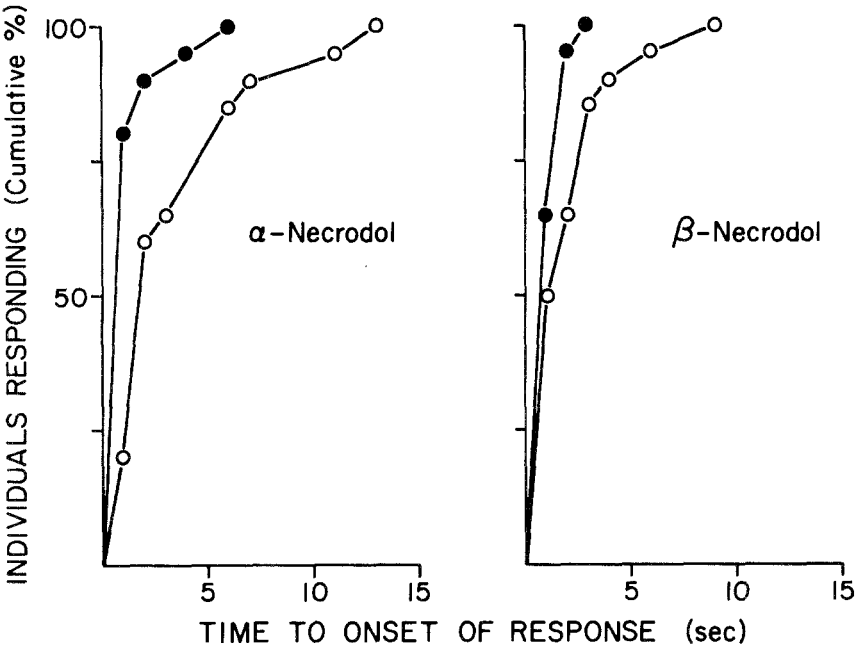

FIG. 3. Topical irritancy of α- and β-necrodol (vapor phase) to *Periplaneta americana* (open circles), and *Phormia regina* (closed circles). Details in text. Horizontal lines, vertical lines, and vertical bars give means, ranges, and one standard error on each side of mean, respectively; $N = 20$ for all four tests.

given the equal potency shown by the two compounds in the irritancy tests. To what extent the necrodols are supplemented or even synergized in their activity by some of the other components (Eisner and Meinwald, 1982) of the beetle's spray remains unknown. Certainly, one component, octanoic acid, has deterrent potential of its own. It is a proven topical irritant (*Periplaneta* test), and as part of the defensive secretion of another arthropod has been shown to have surfactant and penetration-promoting activity (Eisner et al., 1961). Another component, lavandulol, known also from essential oils of plants (Karrer, 1958), may be anti-insectan as well.

The fact that there were insects that failed to respond to β-necrodol should come as no surprise, since chemical repellents often have restricted rather than generalized activity.

The irritancy tests with *Periplaneta* and *Phormia* have become staples in our laboratories for the screening of natural products for insect deterrency. The cleansing responses elicited in these insects by chemical stimulation attests, we feel, to the existence in these species (as perhaps primitively in insects as a whole) of a "common chemical sense" (Keele and Armstrong, 1964; Mon-

crieff, 1944), a generalized, broadly attuned sensitivity to noxious chemical stimuli. The common chemical sense may, in fact, be the primary sensory input system that mediates insect repellency. The necrodols are not exceptional in being, at the same time, repellent to insects and effective in the *Periplaneta* and *Phormia* irritancy tests. We have extensive data on compounds (or chemical mixtures) of arthropodan and plant origin (for example, components of insect defensive secretions; plant essential oils) that support the contention that potency in the two irritancy tests correlates with repellency. The irritancy tests, therefore, provide a quick means for obtaining first-approximation quantitative data on the insect repellency of compounds.

Screening for repellency, fashionable before insecticides came into vogue, has long ceased to be a matter of priority. Naturally occurring repellents, one came to learn, are altogether too often ill-suited for purposes of insect control. For the chemical ecologist, the search for new repellents never lost its appeal, for with the characterization of novel compounds there often came the discovery of new biological roles for chemical factors in nature. But for use in conventional control programs, repellents were usually too volatile, unstable, or generally toxic. The prospects of biotechnological approaches to insect control put the search for insect repellents into new perspective. The possibility, for example, of conveying upon a plant the capacity to produce its own insect repellents, by transferring to that plant appropriate genes from another that already has the capacity, is no longer fanciful. Gene transfer from plant to plant is bound to become an applicable reality. The questions that will then arise are which genes and the capacity to produce which repellents. Chemical ecology, through discovery of appropriately active natural products, is now laying the groundwork that will help answer the second of these questions. Compounds such as cyclopentanoid terpenes, of which the necrodols are examples, which have evolved so often and proven themselves in so many different natural defensive contexts, may well be prime candidates for eventual exploitation in the context of biotechnological control.

Acknowledgments—This study was supported in part by NIH grants AI-02908 and AI-12020 and by a Fellowship from the International Paper Co. to R.J. We thank M. Eisner for technical help and D. Aneshansley for statistical calculations.

(Received July 29, 1985; accepted September 30, 1985)

Abstract—Sex gland extracts and washes of *Eupoecilia ambiguella* contain 10–20 ng/female of the primary sex pheromone component *Z*-9-dodecenyl acetate (*Z*9–12 : Ac), accompanied by a number of related compounds. These are *E*-9-dodecenyl acetate (*E*9–12 : Ac), *Z*-9-dodecen-1-ol (*Z*9–12 : OH), saturated acetates of 12, 16, 18, and 20 carbons, and traces of a doubly unsaturated acetate, tentatively identified as a 9,11-dodecadienyl acetate. Octadecyl acetate predominates among the pheromone-related components, making up 1–2, occasionally 20–30 times the amount of *Z*9–12 : Ac. The same compounds were also found in field-collected females and in effluvia. *Z*-9-Undecenyl acetate, which is a male attractant on its own, was also found in a sample of female effluvia. A hierarchy is observed in the ethological function of the pheromone components. *Z*9–12 : Ac is an attractant for *E. ambiguella* males. Dodecyl acetate (12 : Ac) is not attractive on its own but augments male catch when added to the main attractant. Addition of 18 : Ac augments attraction only when both *Z*9–12 : Ac and 12 : Ac are present. Wind-tunnel tests demonstrate that 18 : Ac also raises the disorientation threshold, as previously shown for 12 : Ac. Other compounds, with the possible exception of additional saturated acetates, had either no effect on trap catch or, in the case of *E*9–12 : Ac, *Z*9–12 : OH, and *E*-9,11-dodecadienyl acetate, were inhibitory above a certain level. A blend of roughly equal parts of *Z*9–12 : Ac, 12 : Ac, and 18 : Ac provides the best attractant blend for *E. ambiguella* known to date.

Key Words—*Eupoecilia ambiguella*, Lepidoptera, Tortricidae, sex pheromone, sex attractant, synergist, Z-9-dodecenyl acetate, dodecyl acetate, octadecyl acetate.

INTRODUCTION

The tortricid moths *Eupoecilia ambiguella* Hbn. and *Lobesia botrana* Den. et Schiff. are the most important insect pests of European vineyards (Bovey, 1966). Although they coexist in many regions, *L. botrana* predominates in the Mediterranean countries while *E. ambiguella* is mainly found in more Northern, humid climates, particularly along the Rhine valley. Sex pheromone research on these two species has a long history, highlighted by the invention of the clock trap (Götz, 1941b) and early claims of control by mass trapping (Götz, 1941a).

The identification of Z-9-dodecenyl acetate (Z9–12:Ac; for other short forms see Table 1) as a sex pheromone component and male attractant was reported by Arn et al. (1976) and Saglio et al. (1977). The synergistic effect of 12:Ac was demonstrated by Arn et al. (1979); wind-tunnel and field studies involving this compound and Z-10-tridecenyl acetate were presented by Rauscher et al. (1984). Various reports (Roehrich et al., 1979, Arn et al., 1981, Winkelmann-Vogt and Schropp, 1984) deal with communication disruption as a means of grape moth control. Here we present the results of more detailed analyses of the female blend and of field and wind-tunnel tests with the compounds identified.

METHODS AND MATERIALS

Insects. A continuous culture of *E. ambiguella* was maintained in the laboratory (Rauscher et al., 1984). About 100 wild females were obtained from collection of second-generation larvae which were kept in the insectarium until spring. Sexed pupae and adults (provided with 10% sucrose solution) were held in an 18:6 hr photoperiod at 24°C, 56% relative humidity with 3000–6000 lux in the photophase. Pheromone extracts were made from 3-day-old females in the middle of the scotophase.

Preparation of Extracts. Female wash was prepared in near darkness (4 lux) by sucking calling females through a vacuum tube into a flask containing 0.5–1 ml methylene chloride (Merck, analytical grade). Each collection lasted a maximum of 30 sec (10–20 females) after which the solution was transferred to another vial. Typically, an extract from 100–200 females was obtained in one session. The pooled solution was filtered and reduced to 100 μl. Sex gland extracts were prepared as described by Guerin et al. (1986) by excising ovipositor tips in a minimum of hexane (Merck, for residue analysis, 1 μl/tip). For collection of effluvia, 50–100 females were placed in a 1-liter glass bottle lined with nylon gauze as a resting site and supplied with synthetic air at ca. 50 ml/min through a metal-bellows regulator. The air from the bottle passed through a Pasteur pipet with ca. 1 ml glass beads (1 mm diam.) for ca. 3 hr. These were

then extracted with 0.5 ml hexane and the eluate concentrated at room temperature.

Gas Chromatography–Mass Spectrometry. GC-MS was carried out on a Finnigan 4015 instrument using 25- and 50-m Silar 10c high-resolution glass capillary columns. Spectra were recorded using electron-impact (EI, 70 eV, 240°C, *m/z* 35–535) and chemical ionization (CI, isobutane 0.4 torr, 180°C, *m/z* 85–585). For trace level analyses of acetates, selected ion monitoring was carried out using *m/z* 61 ($CH_3COOH_2^+$ and M^+-60 (CH_3COOH) ions. Typically, the columns were temperature programmed as follows: 60°C, 2 min, 20°/min to 100°C, 4°/min to 250°C.

For determination of double-bond positions, a sex gland extract of 100 females in 0.1 ml hexane was first reacted with 20 μl trifluoroacetic anhydride for 1 hr at 50°C in a sealed ampoule for esterification of alcohols. After blowing off the reagent with nitrogen, the sample was derivatized with dimethyl disulfide (DMDS) as previously described (Buser et al., 1983).

Gas chromatography with electroantennographic detection (GC-EAD) was done as described (Arn et al., 1975; Guerin et al., 1985).

Field Tests. These were made in various vineyards in Switzerland. Two most suitable locations where *E. ambiguella* was abundant were Yvorne VD and Maienfeld GR. The tetra trap (base 9.5 × 16.5 cm and 9.5 cm high, Figure 1A), which can be folded from a rectangular sheet of laminated paper, and the rubber cap used as dispenser have already been described (Arn et al., 1979).

Trap Placement. In numerous tests with orchard and vineyard tortricids we have observed a high variability in trap catch which appears to stem from at least four sources, (1) long-range differences, apparently connected with pop-

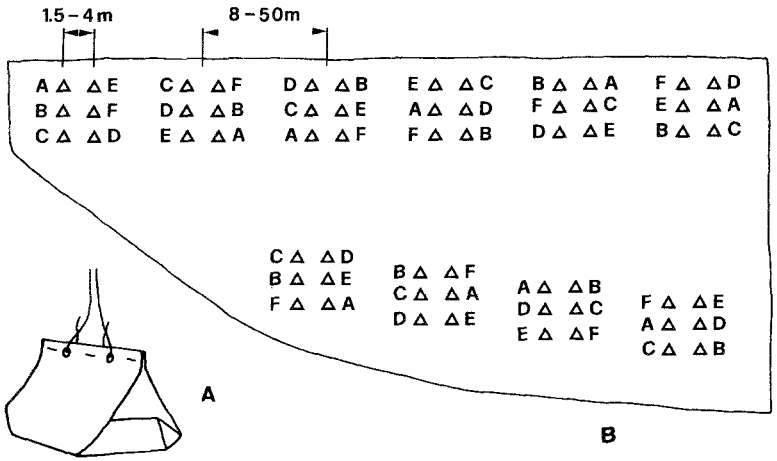

FIG. 1. (A) The tetra trap. (B) Arrangement of traps in a field test with six treatments and 10 replicates.

ulation distribution, often visible as a gradient across a given area and effective at distances as low as 5–10 m; (2) a border effect arising from a higher source of moths outside than inside the experimental area (competition effect); (3) effects of wind direction visible from the fact that traps closest to and farthest away from the wind receive the highest catch; and (4) microenvironment effects: some traps repeatedly attract many more insects than their neighbors, although their bait is the same and the surroundings supposedly identical.

In a replicated comparison of attractant blends, placing the treatments at the fairly large distances used by Perry et al. (1980) was not feasible due to lack of space and variations in moth density. On the other hand, rotation of traps during moth flight was impractical because of travel distances. We therefore adopted the following procedure: The traps to be compared (treatments) are placed in a group at distances of 1.5–4 m, but the groups of traps (replicates) are spaced apart as widely as possible (8–50 m) to make the best use of the moths available (Figure 1B). The position of a given treatment within replicates is systematically varied so that it occupies every position as often as possible. Neighboring of the same two treatments with respect to wind direction is kept to a minimum.

A convenient arrangement for a test with six treatments is shown in Figure 1B. Even with 10 replicates, differences in catch of a factor of two are often required for significance. As an alternative to the above design, we have, on occasion, placed all treatments and replicates in one long row. In this case, at least four buffer traps whose counts are disregarded are required at each end. Dose–response curves with individual compounds added to the main attractant or a blend were established with steps of factors of four to five or less. Trap catches were usually recorded once or twice a week; counts were transformed to log $(x + 1)$ and submitted to two-way analysis of variance followed by Duncan's multiple-range test ($P = 0.05$).

Wind-tunnel tests were made with laboratory-reared males as previously described (Rauscher et al., 1984).

RESULTS

Chemical Analysis

GC-EAD. All types of female extracts revealed one major product active on the *E. ambiguella* male antenna, coinciding with Z9–12 : Ac. Occasionally, with highly sensitive antennal preparations, small but reproducible responses were obtained at the elution times of 12 : Ac, *E*9–12 : Ac, and 18 : Ac (Figure 2).

GC-MS. The pheromone-related components identified in the female material are listed in Table 1. The main unsaturated component is Z9–12 : Ac, as

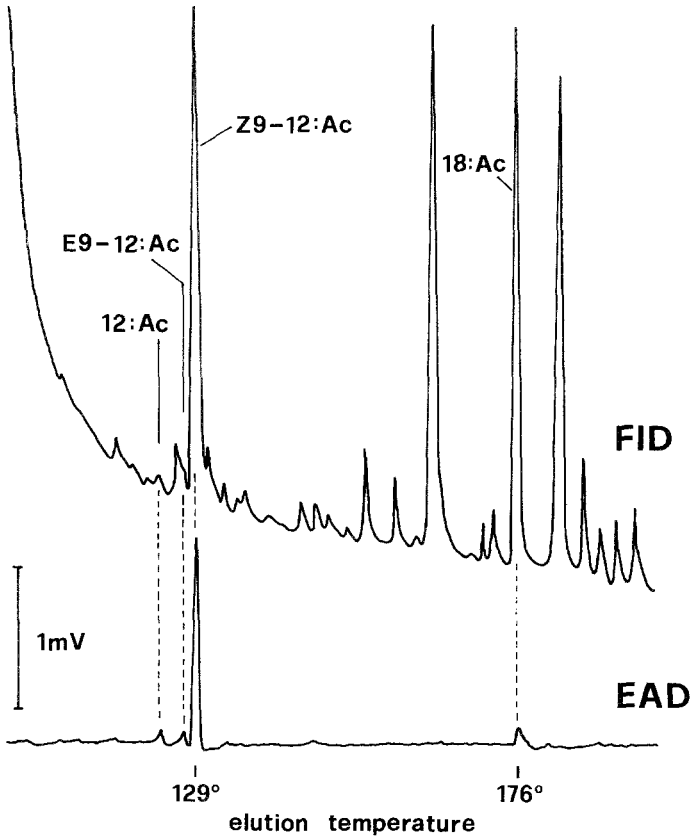

FIG. 2. Gas chromatogram of *Eupoecilia ambiguella* female wash (two female equivalents) using flame ionization (FID) and electroantennographic (EAD) detection with conspecific male antenna. Silar 10c glass capillary column (0.25 mm × 25 m); 2 min at 60°C, 20°/min to 100°C, 5°/min to 250°C.

reported previously (Arn et al., 1976, Buser et al., 1983). *E*9–12 : Ac was found in all preparations in amounts between 0.1 and 1% of *Z*9–12 : Ac. Its identity was confirmed by GC-EAD using a male antenna of *Sparganothis pilleriana* Den. & Schiff. which gave a response matching that of a similar amount of synthetic standard.

Saturated acetates were found in all samples with 18 : Ac predominating, followed by 20 : Ac, 16 : Ac, and 12 : Ac. There were indications for the presence of trace amounts of decyl acetate (less than 0.01% of *Z*9–12 : Ac); the level of tetradecyl acetate, if present, was below 0.002% of *Z*9–12 : Ac.

A compound with the mass spectrum and retention time of a 9,11-dodecadienyl acetate (*E* and *Z* not separated) was detected in most female extracts

TABLE 1. PHEROMONE-RELATED COMPOUNDS IDENTIFIED IN *E. ambiguella* FEMALES

Compound	Short form	Identification criteria	Female wash (ng/female)		Gland extract (ng/female)	Effluvia, (relative amount)
			Reared	Wild		
Z-9-Undecenyl acetate	Z9–11 : Ac	GC-MS	ND[b]	ND	ND	0.5
Dodecyl acetate	12 : Ac	GC-MS	0.2–1	0.4	3	0.8
Z-9-Dodecenyl acetate	Z9–12 : Ac	GC-MS, DMDS	15–30	10	100	100
E-9-Dodecenyl acetate	E9–12 : Ac	GC-MS, GC-EAD[a]	0.02–0.1	0.1	0.5	0.1
Z-9,11- or *E*-9,11-Dodecadienyl acetate or similar	Z9,11–12 : Ac	GC-MS	0.02	0.01	0.2	0.1
Z-9-Dodecen-1-ol	Z9–12 : OH	GC-MS, TFA-DMDS	1	ND	8	ND
Hexadecyl acetate	16 : Ac	GC-MS	2	1	10	0.2

[b] ND = not detected.

at a fraction of a percent of Z9–12 : Ac. While the 7,9 and 8,10 isomers showed significant differences in the lower mass range, the spectrum of the diene found in *E. ambiguella* closely matched that of Z9,11–12 : Ac.

An undecenyl acetate was detected in one sample of female effluvia at less than a percent of Z9–12 : Ac. From its elution just prior to 12 : Ac on the Silar column it was identified as Z9–11 : Ac.

Evidence for the presence of trace amounts (less than 0.01 % of Z9–12 : Ac) of hexadecenyl and octadecenyl acetates was obtained occasionally. Occurrence of Z-10-tridecenyl acetate, a synergist of male attraction (Rauscher et al., 1984), in the females could not be substantiated.

A novel approach was followed for the identification of a dodecenol found in all washes of laboratory-reared females. After trifluoroacetylation and DMDS adduct formation (TFA-DMDS) of a gland extract, we observed a component with the molecular ion $M^+ = 374$ corresponding to a bis(methylthio)dodecenyl trifluoroacetate. Prominent ions were at *m/z* 89 and 285, as expected for the two fragments A^+ and B^+, respectively, of a compound showing a double bond in position 9. Since other trifluoroacetates such as octadecyl were not observed, we concluded that this compound was a reaction product of the native alcohol and not a transesterification product of Z9–12 : Ac. It was assigned *Z* because the native product coeluted with Z9–12 : OH and gave no signal with the *S. pilleriana* antenna which is specifically sensitive to both *E*9–12 : Ac and *E*-9-dodecen-1-ol (Guerin et al., 1985).

Insects collected from the wild were found to contain the same components as the laboratory material except for Z9–12 : OH, which was below detection limits. Their Z9–12 : Ac content was reduced, possibly because they were less well adapted to our laboratory conditions.

The three methods of obtaining pheromone extracts provided similar results. Differences were obtained with the amount of 18 : Ac which was lower in the effluvia than in the wash, as expected from volatilities, and comparatively high in the gland extracts (20–30 times the amount of Z9–12 : Ac).

Other compounds identified in the gland extract were hydrocarbons of 23–29 carbons with the odd-numbered chains predominant, as reported from other insects (e.g., Descoins et al., 1985); saturated alcohols of 18, 20, and 22 carbons; saturated fatty acids of 14 and 16 carbons; and a monounsaturated 16-carbon acid.

Field and Wind-Tunnel Tests

Attractiveness of Z9–12 : Ac and Z9–11 : Ac. As previously reported, Z9–12 : Ac attracts *E. ambiguella* males in the field and the same was found true for Z9–11 : Ac, equally attractive at the same dose. Tests with mixtures of Z9–12 : Ac and Z9–11 : Ac at steps of 20% gave the same catches as the parent compounds, indicating simply an additive effect.

Effect of Saturated Acetates. In a first test series, 12 : Ac, 16 : Ac, 18 : Ac, and 20 : Ac were added singly to Z9–12 : Ac at levels between 0.2 and 5 times the proportion found in the females. An increase of catch was obtained with 12 : Ac at amounts of at least four times that found in the female blend as reported earlier (Arn et al., 1979, Rauscher et al., 1984). No such effect was found for the others. On the other hand, a significant improvement was obtained when Z9–12 : Ac was combined with all four saturated acetates even at the proportions found in the female wash. This indicated an interaction between the components. Systematic omission of each of the saturated acetates from the blend did not suggest that any component other than 12 : Ac was important for optimum catch (Table 2, test A). However, the 16- to 20-carbon acetates together augmented the catch significantly as long as 12 : Ac was present (Table 2, test B).

Combined Effect of 18 : Ac and 12 : Ac. Systematic tests of binary and ternary blends later revealed that addition of 18 : Ac alone to Z9–12 : Ac strongly augments *E. ambiguella* attraction provided that 12 : Ac is already present at a minimum of 20% (Figure 3). The optimized mixture from these tests, a 1 : 1 : 2 blend of Z9–12 : Ac, 12 : Ac, and 18 : Ac represents an improvement of a factor of two over our previous best (Rauscher et al., 1984).

E9–12 : Ac as an Inhibitor. As reported previously, presence of *E*9–12 : Ac in the lure inhibits grape moth catch (Arn et al., 1979). Further tests now show

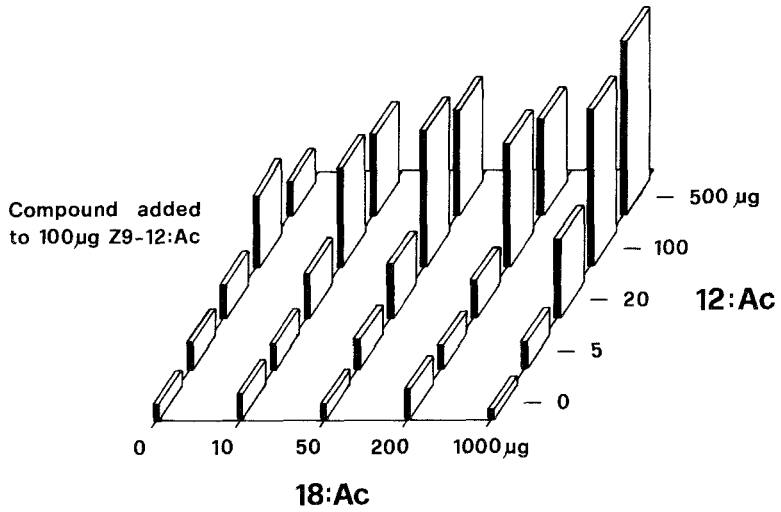

FIG. 3. Relative catches of *Eupoecilia ambiguella* with Z-9-dodecenyl acetate (Z9-12:Ac) and various amounts of dodecyl acetate (12:Ac) and octadecyl acetate (18:Ac) added. Combined results from four tests with overlap at (12:Ac/18:Ac) 0/0, 5/0, 100/0 and 100/200; total catch with the best treatment in a test with six replicates involving all 12:Ac and 18:Ac doses above 5 µg was 445 males. Data for 18:Ac = 0 are from Rauscher et al. (1984).

that 12:Ac reduces this sensitivity to the inhibitor. In a binary mixture, the presence of 0.2 to 2% *E* is sufficient for significant catch suppression of Z9-12:Ac; however, in a ternary blend containing 12:Ac and Z9-12:Ac at a 1:1 ratio, the threshold is 10% *E*. Adding more 12:Ac to a blend containing 20% *E* brought the attractiveness up to that of a sample with only 10% of the geometric isomer (Figure 4). From the dose-response curves obtained earlier (Rauscher et al., 1984) dilution by 12:Ac was not responsible for this change. This apparent desensitizing effect of 12:Ac against the inhibitor may be important when preparing formulations on a large scale where purification of isomers is impractical.

Other Components. Components detected or supposed at one point as part of the pheromone blend were tested at various levels in combination with Z9-12:Ac, the four saturated acetates, and Z9-12:OH (the latter at 5%). No positive effect on trap catch could be observed except as reported for Z10-13:Ac (Rauscher et al., 1984). No effect on catch was obtained from Z9,11-12:Ac (added at levels of 0.2-10% of the amount of Z9-12:Ac), Z9-14:Ac (0.5-10%), and Z11-16:Ac (5-100%), although *E*9,11-12:Ac was inhibitory at a level of 2% and above, and Z9-12:OH at 10%.

Diel Periodicity. Götz (1941b) reported that *E. ambiguella* males fly into female-baited traps in the early morning. We have found that, in line with ob-

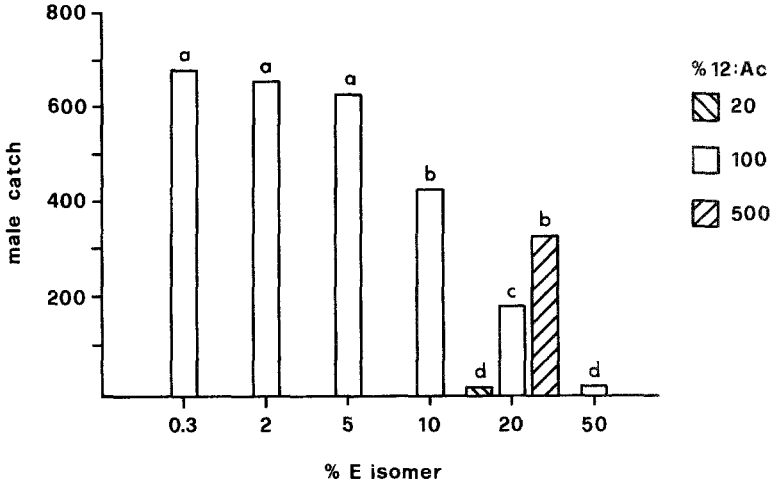

FIG. 4. Catches of *Eupoecilia ambiguella* with Z-9-dodecenyl acetate (1000 μg/cap) and varying amounts of *E* isomer and dodecyl acetate added. Totals of 10 replicates. Values marked with the same letter not significantly different at $P = 0.05$ (Duncan's multiple-range test).

servations in the laboratory (Arn et al., 1975; Rauscher et al., 1984), our populations fly during darkness; activity began before midnight (geographical time) and was over at 2:30 AM.

Wind-Tunnel Tests. These were done with the 1 : 1 : 2 blend of Z9–12 : Ac, 12 : Ac, and 18 : Ac which had given optimal field attraction. Compared with the previous results (Rauscher et al., 1984), addition of 18 : Ac to the binary blend results in a higher proportion of males reaching the source and increases the range over which caps are attractive (Figure 5).

DISCUSSION

Three components of the female secretion of *E. ambiguella* contribute to male attraction and can, at present, be considered part of the sex pheromone of this species: Z9–12 : Ac, 12 : Ac, and 18 : Ac. The type of hierarchy existing among the three compounds seems to be novel to the pheromone field: Z9–12 : Ac is required for attraction while addition of 12 : Ac augments male catch. Octadecyl acetate is neither attractive on its own nor does it augment the catch when added to Z9–12 : Ac unless 12 : Ac is present at a minimum level. As shown earlier in the wind tunnel (Rauscher et al., 1984), the effect of 12 : Ac is not so much to improve attractiveness—with Z9–12 : Ac alone at optimal dose about the same number of males reach the source as with calling females—as to raise the concentration level at which attraction to the source is still possible.

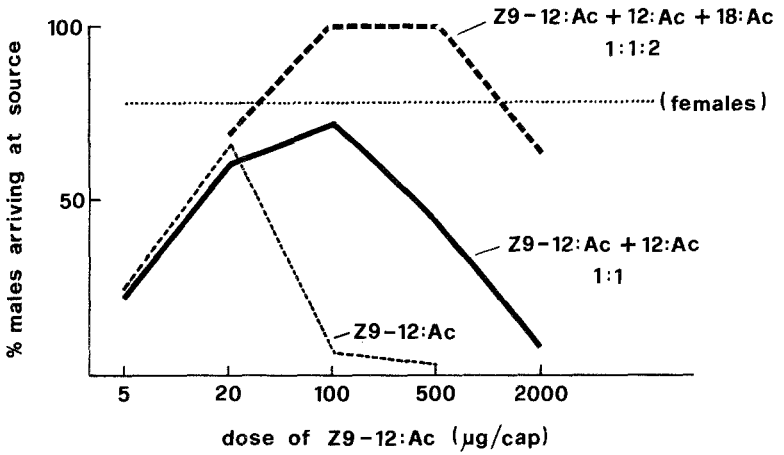

FIG. 5. Response of male *Eupoecilia ambiguella* in the wind tunnel to varying doses of *Z*-9-dodecenyl acetate in blends with dodecyl acetate and dodecyl plus octadecyl acetate; 25 males per data point. Differences between curves at doses of 100 μg and above significant at $P = 0.05$ (Duncan's multiple-range test). Results for Z-9-dodecenyl acetate alone and females are from Rauscher et al. (1984).

Octadecyl acetate appears to act in the same way by increasing the disorientation threshold even further.

The "best blend" of these three components contains a larger proportion of 12 : Ac than the female secretion. Although wind-tunnel and some field tests indicate that this blend is superior to calling females, other experiments were not quite conclusive. Since use of a suboptimal ratio by the females is unusual, we are left with the question if yet additional components, identified or unknown, contribute to male attraction by *E. ambiguella* females. Substitution of one pheromone component by another has been demonstrated in the cabbage looper (Linn et al., 1984). It is possible that 16 : Ac and 20 : Ac show a similar effect as the other saturated acetates. With complex interactions of blend components, behavioral experimentation is clearly becoming difficult and time-consuming.

No biological functions could be found for the other components of the female secretion, notably the *E* isomer and the parent alcohol of the main attractant which in many other tortricid pheromone blends act as coattractants. Equally unclear is the role of the other unsaturated products which were present in amounts too low for final identification, namely a dodecadienyl acetate showing characteristics of the 9,11 isomers.

Very curious also is the case of *Z*9–11 : Ac which was found in our sample of effluvia but neither in the sex gland extract nor in any of the numerous samples of female wash. The reason for this may be that its higher vapor pressure

raised its level just above detection limit. This chemical is as good an attractant for *E. ambiguella* males as its higher homolog and might be produced by an aberrant biosynthetic pathway. Fluctuation of pheromone blend composition with generations has been demonstrated in *Utetheisa ornatrix* (Jain et al., 1982). On the other hand, our laboratory culture, which has been inbred for over 100 generations, did not show any signs of altered or diminished pheromone production as was shown by Minks (1971) for *Adoxophes orana* F. v. R.

The practical use of pheromones for insect control has, in the past, been hampered by cost of chemicals. Additives such as the saturated compounds reported here enhancing biological activity and, as shown for 12 : Ac, permitting the use of attractants of technical purity could dramatically improve this situation. Further experiments will be needed to show if the effects we have demonstrated here for attraction are applicable to disruption.

Acknowledgments—We thank David Hall for generous samples of Z9–11 : Ac and the two dienic acetates, and Augustin Schmid for help with the field trials. This work was partly supported by the Swiss National Science Foundation.

ALLELOPATHIC RESEARCH OF SUBTROPICAL VEGETATION IN TAIWAN
III. Allelopathic Exclusion of Understory by *Leucaena leucocephala* (Lam.) de Wit[1]

CHANG-HUNG CHOU and YAW-LUN KUO

Institute of Botany, Academia Sinica
Taipei, Taiwan 11529, Republic of China

(Received February 25, 1985; accepted August 25, 1985)

Abstract—*Leucaena leucocephala* plantations in Kaoshu, southern Taiwan, exhibit, after several years of growth, a unique pattern of weed exclusion beneath *Leucaena* canopy. The pattern has been observed in many *Leucaena* plantations in Taiwan and is particularly pronounced in the area where a substantial amount of *Leucaena* litter has accumulated on the ground. Field data showed that the phenomenon was primarily not due to physical competition involving light, soil moisture, pH, and nutrients. Instead, aqueous extracts of *Leucaena* fresh leaves, litter, soil, and seed exudate showed significantly phytotoxic effects on many test species, including rice, lettuce, *Acacia confusa, Alnus formosana, Casuarina glauca, Liquidambar formosana*, and *Mimosa pudica*. However, the extracts were not toxic to the growth of *Leucaena* seedlings. The decomposing leaves of *Leucaena* also suppressed the growth of the aforementioned plants grown in pots but did not inhibit that of *Leucaena* plants. By means of paper and thin-layer chromatography, UV-visible spectrophotometry, and high-performance liquid chromatography, 10 phytotoxins were identified. They included mimosine, quercetin, and gallic, protocatechuic, *p*-hydroxybenzoic, *p*-hydroxyphenylacetic, vanillic, ferulic, caffeic, and *p*-coumaric acids. The mature leaves of *Leucaena* possess about 5% dry weight of mimosine, the amount varying with varieties. The seed germination and radicle growth of lettuce, rice, and rye grass were significantly inhibited by aqueous mimosine solution at a concentration of 20 ppm, while that of the forest species mentioned was suppressed by the mimosine solution at 50 ppm or above. However, the growth of *Miscanthus floridulus* and *Pinus*

[1] Paper No. 292 of the Scientific Journal Series of the Institute of Botany, Academia Sinica, Taipei, Taiwan. This study was supported in part by a grant to C.H. Chou. Part of this paper was a MS thesis submitted by Y.L. Kuo to the Department of Forestry, National Taiwan University, and presented at the Seminar on Allelochemicals and Pheromones, sponsored by the CCNAA and AIT on June 21–26, 1982.

0098-0331/86/0600-1431$05.00/0

taiwanensis was not suppressed by the mimosine solution at 200 ppm. The seedlings of *Ageratum conzoides* died in mimosine solution at 50 ppm within seven days and wilted at 300 ppm within three days. It was concluded that the exclusion of understory plants was evidently due to the allelopathic effect of compounds produced by *Leucaena*. The allelopathic pattern was clearly shown in the area with a heavy accumulation of *Leucaena* leaf litter, which was a result of drought and heavy wind influence.

Key Words—Allelopathy, weed exclusion, *Leucaena leucocephala*, phytotoxins, mimosine, phytotoxic phenolics, forest plantation.

INTRODUCTION

It is often asserted uncritically that a deleterious effect of one plant upon another is ascribable to competition for light, soil moisture, or mineral nutrients. Muller (1969) therefore emphasized additionally that allelopathy should be recognized as one of the environmental factors to be considered in analyzing the mechanisms of plant interactions. Under some circumstances allelopathy may also interact with other natural habitat factors (Muller, 1966, 1974; Gliessman and Muller, 1978; Börner, 1971; Koeppe et al., 1976; Anaya and del Amo, 1978; Rice, 1984; Chou, 1983; Chou et al., 1981; 1984).

Since 1972, Chou and his associates have demonstrated several cases of allelopathy in Taiwan (Chou and Chung, 1974; Chou and Chiou, 1979; Chou and Hou, 1981; Chou and Lin, 1976; Chou and Yang, 1982; Chou and Young, 1975). They have dealt with the mechanisms of autointoxication of *Oryza sativa*, the allelopathic exclusion of weeds and pasture grasses, comparative allelopathy of natural vegetation and agricultural plantations, and the roles of allelopathy in tropical and subtropical agroecosystems. More recently the authors have focused on forest plantations; for example, Chou and Yang (1982) reported that the regulation mechanism of understory species in stands of *Phyllostachys edulis* was primarily due to the allelopathic effect of the bamboo leaf and leaf litter. Additionally, the tree *Leucaena leucocephala* has been widely planted in Taiwan because of its high economic value for producing nutritious forage, firewood, and timber. Generally, after a few years, the floors of these plantations are relatively bare of understory plants, except *Leucaena* seedlings. This pronounced pattern of weed exclusion beneath *Leucaena* trees is particularly pronounced in areas having a drought season. Nakasuga and Yamada (1979) indicated that only a few weeds were able to grow beneath *Leucaena* plantations in Okinawa. The exclusion of weeds by *Leucaena* plants was thought to be due to either a physical competition or a biochemical inhibition by *Leucaena* leachate, or both. The aim of this study was thus to elucidate the mechanism of allelopathic interference of *Leucaena leucocephala* interacting with environmental stresses.

METHODS AND MATERIALS

Study Site. Leucaena plantations chosen for the present study are located at Kaoshu, Pingtung County of southern Taiwan. In the area, six varieties of Salvado-type, namely K8, K28, K29, K67, K72, and S1 and one variety of native Hawaiian-type *Leucaena* were planted in different densities: 2500, 5000, 10,000, 20,000, and 40,000 plants per hectare. The monthly mean weather data (1978–1982) in the Kaoshu area are given in Table 1. The monthly mean temperature ranges from 19.4°C (January) to 28.6°C (July) and the annual precipitation is 2578.1 mm, of which 90.9% of rainfall (2343.4 mm) is concentrated in the summer season, from May to October, and about 9.1% of rainfall (234.7 mm) is distributed in the remaining seasons. In Kaoshu, there is a severe drought and heavy wind in winter, from December to February, and less than 40 mm of precipitation during the period. Correlated with these weather patterns, there has developed a pronounced pattern of weed exclusion beneath *Leucaena* plants (Figure 1). The density and diversity of understory species on the *Leucaena* plantation floor varied with planting density. However, in the present study we selected a study site with a planting density of 10,000 plants per hectare.

Materials. Fresh leaves and litter of *Leucaena leucocephala* varieties (listed above) were collected from the Kaoshu study site. The plant materials were air-dried in the field in sunlight and further dried out in a laboratory hood. Soils were collected from the *Leucaena* and grassland control sites from the surface

TABLE 1. AVERAGE MONTHLY WEATHER DATA (1978–1982) IN KAOSHU STUDY SITE[a]

Month	Temperature (°C)	Precipitation (mm)	Sunny day (hr)

FIG. 1. Different understory patterns shown on the *Leucaena* floors at the Kaoshu site of Taiwan.

to 15 cm depth. The soils were air-dried and screened through a 2-mm sieve to remove all visible plant residues. For bioassay purposes, seeds of lettuce (*Lactuca sativa* var. Great Lakes 366), rice (*Oryza sativa* Taichung 65), and rye grass (*Lolium multiflorum*) were used. In addition, seedlings of *Acacia confusa, Alnus formosana, Casuarina glauca, Pinus taiwanensis, Liquidambar formosana, Miscanthus floridulus, Mimosa pudica*, and *Ageratum conzoides* were used for testing the phytotoxic effects of *Leucaena* leachates and extracts.

Field Measurements. Light intensity was measured under the canopy of *Leucaena* trees in different planting densities after three to four years of growth and in the open grassland control area in sunny days of September 1981, February 1982, and on May 1–3, 1985 in the Kaoshu study site. In the light measurement, at least 10 replications for each treatment were made. The biomass and litter on the *Leucaena* and the grassland control floors were sampled from plots of each treatment with three replications.

Preparation of Aqueous Extracts of Leucaena *Leaves, Litter, and Soil.* A 1% aqueous extract of air-dried leaves was prepared by soaking 2 g of air-dried leaves in 198 ml distilled water, shaking the mixture for 2 hr, and suction filtration. A 2.5% aqueous extract of leaf litter was prepared in the same way. However, soil extracts were prepared by shaking 150 g of each soil with 500 ml of distilled water for 2 hr and centrifuging the mixture at 3000 rpm

(2369 *g*). The aqueous extracts of leaves, litter, and soil were stored in a refrigerator at 4°C before assaying.

Physicochemical Analyses of Extracts and Soils. The aqueous extracts of *Leucaena* leaves, litter, and soil were subjected to osmotic concentration determination by using an osmometer (Fiske G-66). Other physicochemical properties, such as soil texture, soil pH, soil moisture, organic matter content, and percent of nitrogen and phosphorus were determined by methods described by Rice (1974).

Bioassay Techniques. Two bioassay techniques were employed to determine the phytotoxic potential of leaf, litter, and soil extracts. The sponge bioassay techniques described by Chou and Young (1975) and Chou and Lin (1976) were employed using the seeds listed in the Materials section. In every bioassay, distilled water served as a control. Tests and controls were set up in triplicate. The water culture bioassay was also used; it consisted of planting seedlings of *Ageratum conzoides* in aqueous mimosine solutions at concentrations of 50, 100, 200, and 300 ppm. The growth of seedlings was recorded every day until the 14th day. The bioassay data were subjected to statistical analysis by using the Student's *t* test.

Pot Experiment. Styrene plastic containers of 150 ml capacity were filled with about 150 g of air-dried soil intermixed with 1–2 g of *Leucaena* dried leaf. The soil without addition of *Leucaena* leaf served as control. Seedlings of *Acacia, Alnus, Casuarina, Pinus, Liquidambar, Miscanthus, Mimosa,* and *Ageratum* were planted in treatment and control containers, each replicated 30 times. The experiment was conducted in a phytotron with temperatures of 25°C for daytime and 20°C for nighttime.

Isolation and Identification of Phytotoxins. We hypothesized that mimosine and some phytotoxic phenolics were present in the leaves of *Leucaena.* The isolation and quantitative determination of mimosine in *Leucaena* leaves followed the techniques described by Brewbaker and Kaye (1981). In addition, 5 g of air-dried leaves of each *Leucaena* variety were extracted and the extracts analyzed for phytotoxic phenolics by using the techniques described by Chou and Young (1975). The extracts were further quantitatively analyzed by using high-performance liquid chromatography (HPLC) (Waters Associates, model 6000A) with a C-18 reversed phase column and solvent system of methanol–water–glacial acetic acid (20:80:1, v/v/v). The flow rate of solvent was 1.0 ml/min and chart speed was 0.2 in./min.

RESULTS

Field Measurements. In the summer period (July–September) in the Kaoshu study site, the average light intensity in an open grassland control area was 28,000 lux, while that under the canopy of *Leucaena* trees ranged from

4000 to 6000 lux (14.2–21.4% of the control). However, in the winter period (December–February), the average light intensity in the control area was 33,000 lux, while that under the canopy of *Leucaena* trees was 8000 lux (24% of the control). The relatively higher amount of light intensity in winter than in summer was primarily due to the *Leucaena* leaf fall as a result of a dry winter season and heavy wind. Additionally, the light intensity also differed with *Leucaena* varieties (Chou and Kuo, unpublished data).

The amount of solar radiation in a year is relatively high in the Kaoshu area (2020.8 hr), and the annual rainfall is also high (2578.1 mm). Since rainfall was particularly concentrated in the summer in the Kaoshu area (Table 1), the soil moisture was relatively higher in summer (usually above 15%) than in winter (below 11%) (Chou and Kuo, unpublished data). For example, in a recent field study during May 1–3, 1985, we found that the mean soil moisture of the *Leucaena* soil in the Kaoshu area was below 2%, indicating that the soil was very dry before the rainfall season. Nevertheless, the soil moisture content is not significantly different between the *Leucaena* soil and the control grassland soil during the drought season. Additionally, data of soil pH, soil texture, organic matter, and total nitrogen content were also not significantly different between the two soils (Table 2). However, the phosphate content was obviously higher in the *Leucaena* soil. An overall comparison of soil characteristics between the control grassland and the *Leucaena* soils showed that the latter provided better soil conditions for the growth of understory plants.

In the Kaoshu site, the biomass of ground cover beneath *Leucaena* plantations was relatively low as compared to the grassland control, being 9.3 g/m^2 on the *Leucaena* floor and 330 g/m^2 in the grassland control area, showing about 80% bare ground on the *Leucaena* floor. However, the amount of litter accumulated on the *Leucaena* floor was remarkably high (1027 g/m^2), being significantly higher than that of the biomass (Figure 2). The floristic composition in

TABLE 2. SOIL CHARACTERISTICS IN CONTROL GRASSLAND AND *Leucaena* PLANTATION AT KAOSHU STUDY SITE, PINGTUNG COUNTY, TAIWAN[a]

Characteristics	Grassland soil	*Leucaena* soil
Texture	Sandy loam	Sandy loam to loam
pH	5.9	6.5
Organic matter (%)	2.1	2.3
Total nitrogen content (%)	0.1	0.1
Total phosphate (meq/100 g)	61.0	68.0

[a] Data are the mean of 10 replicates of each soil analysis and are not statistically significant between the two soils.

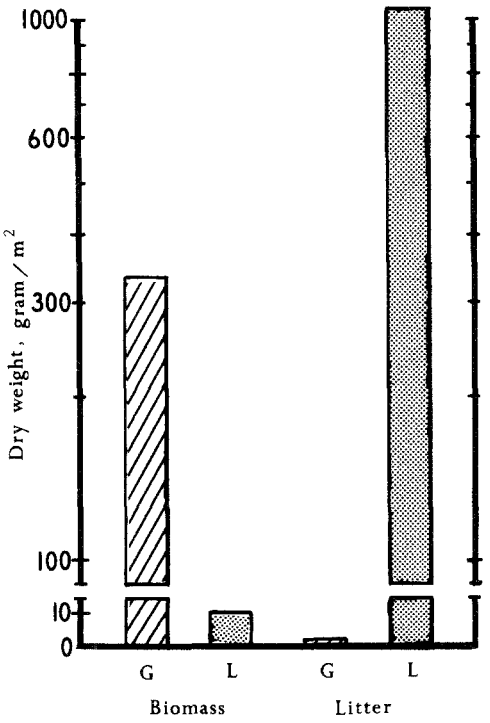

FIG. 2. Quantitative comparisons of biomass collected beneath the *Leucaena* trees (L) and in the open control grassland (G) and that of litter on the *Leucaena* floors in the Kaoshu study site.

the *Leucaena* understory at the Kaoshu site included eight species, and 16–23 species were found in the control grassland. The dominant species are different between the control and the *Leucaena* areas. The most abundant species in the control area are *Hyptis suaveolens, Paspalum* sp., and *Imperata cylindrica*, while those in the *Leucaena* plantation are *Leucaena leucocephala* itself, *Axonopus compressus*, and *Ageratum conzoides* (Kuo, 1983). It should be mentioned that *Ageratum conzoides* and *Rhynchelytrum repens* are shade-intolerant species. Their appearance in the *Leucaena* plantation may serve as an indication that low light intensity is not a causal factor of weed exclusion in this plantation. In addition, in the same area, *Acacia* plantations produce ground-level light intensity lower than that in *Leucaena* plantations; nevertheless the biomass production of understory plants is significantly higher in the former than the latter, indicating that the lower density of biomass under the *Leucaena* stand is likely not due to competition for light.

An overall review of the phenomenon occurring in the study site strongly indicates that the relatively lower density of weeds beneath the *Leucaena* plan-

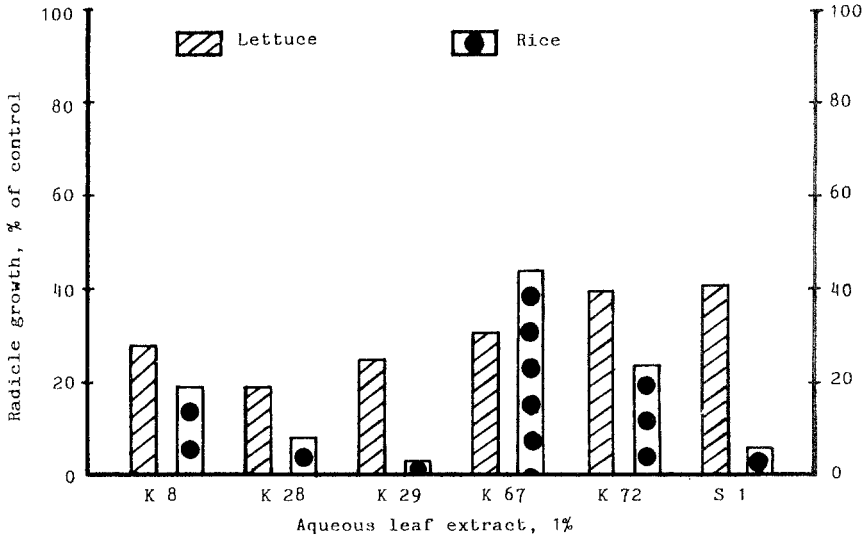

FIG. 3. Effects of 1% aqueous extracts of various *Leucaena* leaves on the radicle growth of lettuce and rice seedlings.

tation of the Kaoshu area is not due to the physical competition for light, soil moisture, and nutrients, but is rather due to severe winters of low precipitation and strong wind causing the leaves and other plant parts of *Leucaena* to fall. This difference may result from secondary plant metabolites leached from the *Leucaena* leaves and litter producing an allelopathic effect. This hypothesis requires further investigation.

Phytotoxicity of Aqueous Extracts of Plant Parts and Soils. The 1% aqueous extracts of *Leucaena* leaves significantly reduced the radicle growth of lettuce and rice (Figure 3). The phytotoxicity ranged from 60% to 96%, being significantly higher on rice than lettuce. Among six varieties, K29 and K28 generally gave the highest inhibition of radicle growth of the two tested plants. This inhibition is thought to be due to phytotoxic substances present in the extract instead of osmotic inhibition because the osmotic concentrations of the extracts (below 20 mosmol) are too low to cause any osmotic inhibition (Chou and Young, 1974). The phytotoxicity was not significantly different between varieties but was significantly reduced by the subsequent extractions. The second subsequent extracts of the leaves revealed no phytotoxicity, indicating that most of the phytotoxic substances present in the leaves were hydrophilic and easily leached out by water (Chou and Kuo, unpublished data).

Since there was a substantial amount of *Leucaena* litter accumulated on the floor, further bioassay of 2.5% aqueous extracts of litter of K8, K72, and

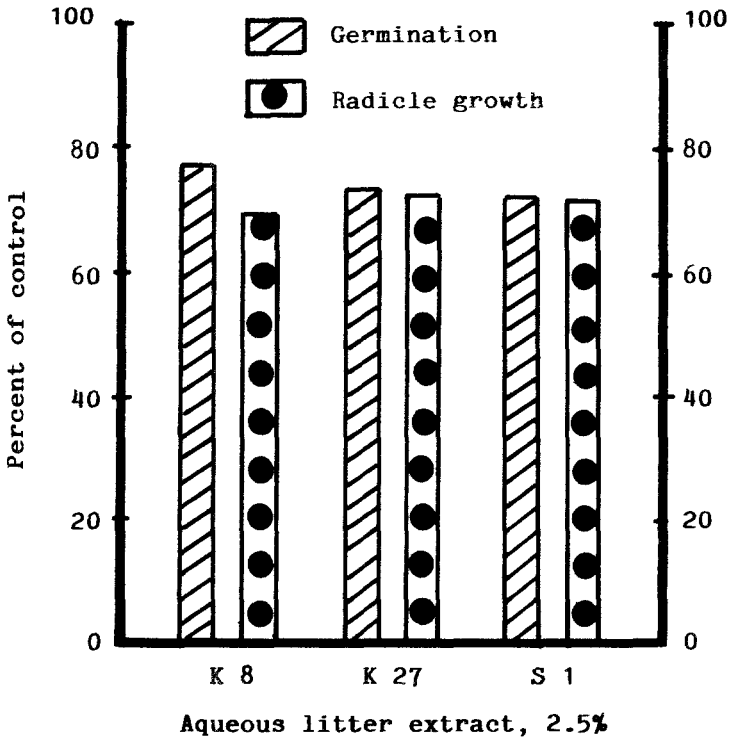

FIG. 4. Effects of 2.5% aqueous litter extracts of *Leucaena* on the seed germination and radicle growth of rye grass.

S1 was also conducted by using rye grass as the test plant. Seed germination and radicle growth of rye grass were inhibited by the extracts to 70% of the distilled water control, and the inhibition was not significantly different among *Leucaena* varieties (Figure 4). Furthermore, aqueous extracts of *Leucaena* soil (150 g soil/500 ml) and its grassland control soil were also bioassayed against lettuce. The original extract of *Leucaena* soil (1× solution) caused only a 20% inhibition, while the control soil exhibited 0%. However, when the 1× solutions were concentrated five times, the *Leucaena* soil extract caused 45% inhibition, indicating that the phytotoxicity was present in the *Leucaena* soil. However, the control soil showed 22% inhibition (the osmotic concentration of 5× solution is 30 mosmol) which was possibly due to an osmotic effect instead of phytotoxicity (Chou and Young, 1974).

We found that the *Leucaena* litter included *Leucaena* seeds also, and therefore we conducted an experiment to test the phytotoxicity of seed exudates. The exudates were obtained by soaking the seeds (200 *Leucaena* seeds in 100 ml of distilled water) for different time durations, such as 12, 24, 36, 48, 60, and 72

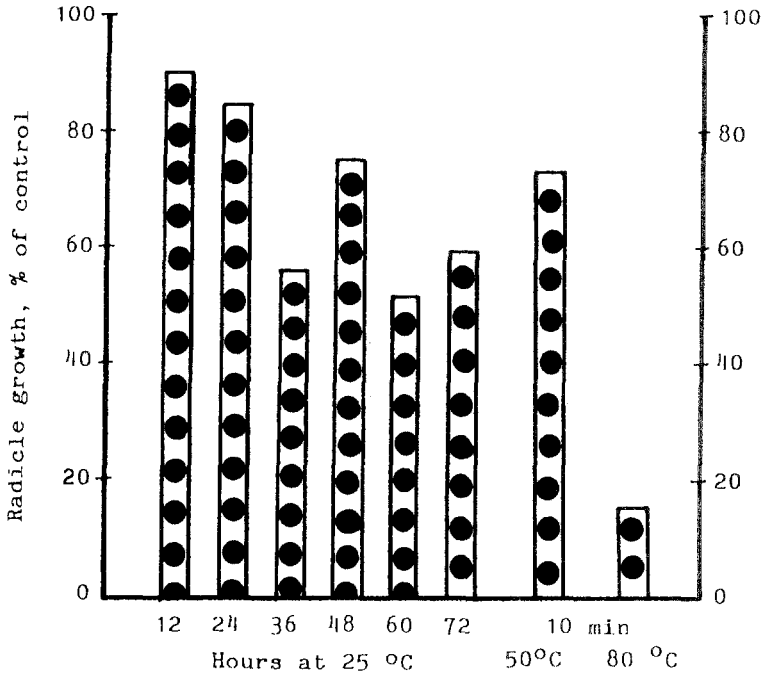

FIG. 5. Effects of aqueous exudates of *Leucaena* seeds on the radicle growth of lettuce seedlings. The exudates were obtained by soaking 200 *Leucaena* seeds with 100 ml distilled water for different time intervals and at various temperatures.

hr at room temperature, and for 10 min at 50°C and 80°C. No visible microorganism activity was found during the period of seed exudation. The bioassay results of lettuce showed that the phytotoxicity of seed exudate obtained at room temperature increased with increasing soaking time. The exudate obtained at the end of 24 hr caused 14% inhibition while that at 60 hr produced 47% inhibition. The toxicity of seed exudate was extremely high, above 80%, when seeds were soaked at 80°C for 10 min, while the toxicity was only 26% when the seeds were soaked at 50°C for 10 min (Figure 5).

It is concluded that the fresh leaves, litter, seeds, and soils of *Leucaena* exhibit significant phytotoxicity on the growth of lettuce, rice, and rye grass, indicating that phytotoxins are present in the plant parts and litter and that the phytotoxins are likely water soluble.

Effects of Aqueous Leaf Extracts of Leucaena *on Forest Species.* It is possible that *Leucaena* may be planted with other forest species. It was therefore desirable to evaluate the allelopathic inhibition of other forest species by *Leucaena*. Five forest species and an aggressive grass, *Miscanthus floridulus*, were

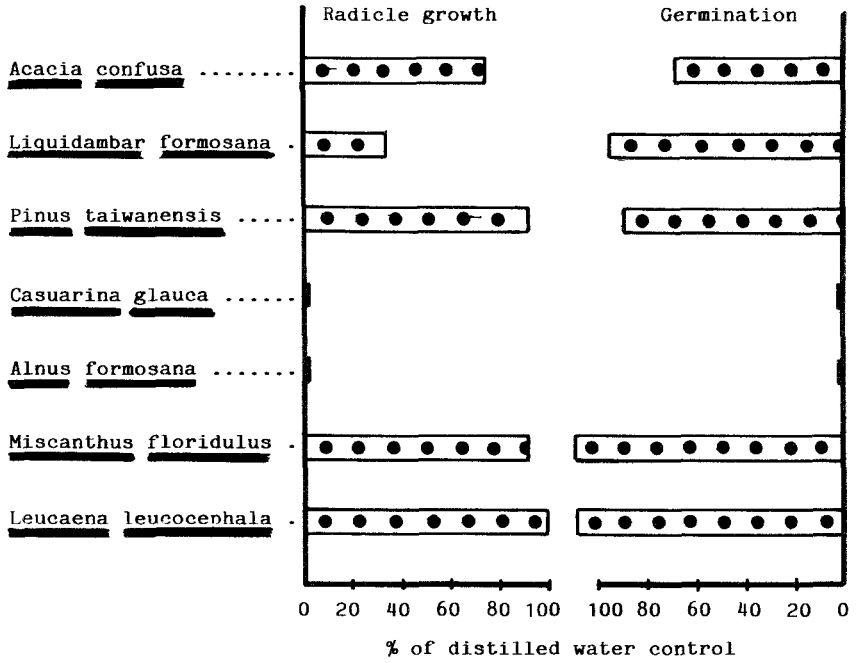

FIG. 6. Effects of 1% aqueous extract of *Leucaena* K28 leaves on the seed germination and radicle growth of seven plant species.

chosen for the study. The radicle growth of *Acacia confusa, Liquidambar formosana, Casuarina glauca*, and *Alnus formosana* were significantly inhibited by 1% aqueous extract of K28 leaves and that of *Pinus taiwanensis* and *Miscanthus floridulus* were not affected (Figure 6), indicating that these two latter species can tolerate the leached *Leucaena* metabolites. Moreover, in order to see whether *Leucaena leucocephala* was an autotoxic plant, its seeds were bioassayed by 1% *Leucaena* leaf extracts of varieties K8, K28, K29, K67, and S1. No inhibitory effect on the germination and radicle growth of *Leucaena* was found, indicating that *Leucaena leucocephala* can tolerate the leaching metabolites produced by itself. This finding agreed with field observations that *Leucaena* seedlings occur abundantly and are healthy under *Leucaena* canopy.

Effects of Decomposing Leucaena *Leaves in Soil on Growth of Plants.* Either 1 or 2 g of *Leucaena* leaves were mixed well with 150 g soil in a plastic container and planted with seedlings of *Leucaena leucocephala, Acacia confusa, Alnus formosana, Casuarina glauca, Liquidambar formosana*, and *mimosa pudica*. The survival rate of these seedlings at 60 days after transplanting is shown in Table 3. The results indicate that the seedlings of *Leucaena leucocephala* grow very well with 100% survival, while the seedlings of *Alnus formosana* and *Acacia confusa* did not grow so well and the survival rate was

TABLE 3. EFFECT OF *Leucaena* LEAF MIXED WITH SOIL OR MULCHED ON SOIL SURFACE ON GROWTH OF FOREST PLANTS[a]

	Survival (% of the control)		
	Leaf intermixed		Leaf mulched
Species	1 g	2 g	5 g
Leucaena leucocephala	100	100	86.7
Alnus formosana	72.2	44.4	36.8
Acacia confusa	29.6	18.5	14.0
Liquidambar formosana	4.5	9.0	30.6
Casuarina glauca	0	0	0
Mimosa pudica	0	0	0

[a] Data express the percent survival relative to survival in the soil alone.

about 50%. The remaining two species, *Casuarina glauca* and *Mimosa pudica*, were totally killed by the decomposing *Leucaena* leaves in soil. In addition, when the *Leucaena* leaves were deposited on the surface of pot soil instead of being mixed with soil, the results were similar to those of the former experiment (Table 3). This indicates that the decomposing *Leucaena* leaves mixed in soil produced some toxins that suppressed the growth of some forest species tested.

Quantitative Analysis of Phytotoxins in Leucaena *Leaves.* The mimosine content in different varieties was determined by spectroscopic analysis. The contents varied with *Leucaena* varieties, revealing that K29 had the highest mimosine content of 5.75%, followed by K28 (5.27%), K8 (4.95%), S1 (4.61%), K72 (4.42%), and K67 (2.77%). It is interesting to note that juvenile leaves contained higher amounts of mimosine than normal mature leaves. Harvested leaves exposed to sunlight at noon lost over 50% of total mimosine as compared to the air-dried leaves. The mimosine contents of *Leucaena* leaves significantly varied with season and location of *Leucaena* plantations (Yeh, 1983).

In addition to mimosine, phytotoxic phenolics present in *Leucaena* leaves were mainly identified by paper chromatography and HPLC. The HPLC spectrum of nine authentic phenolic acids is given in Figure 7A, which is used for the quantitative comparison of phenolic acids isolated from the *Leucaena* leaves (Figure 7B). The contents of phenolic acids in leaves of *Leucaena* K28 are given in Table 4. They are gallic, protocatechuic, *p*-hydroxybenzoic, *p*-hydroxyphenylacetic, vanillic, caffeic, *p*-hydroxycinnamic, and ferulic acids. The amount of these phenolic compounds was significantly higher in young leaves than in mature leaves. Of these, protocatechuic and *p*-hydroxycinnamic acids had higher concentrations than the remaining compounds. Moreover, quercetin

and 18 other flavonoids were found in seven varieties of *Leucaena* leaves (Kuo, 1983); some of those flavonoids might be phytotoxic in nature.

Inhibitory Effects of Mimosine on Plant Growth. The aqueous solutions of mimosine at concentrations of 10, 20, 30, 40, 50, 60, 70, and 80 ppm were bioassayed using lettuce and rice seeds as test materials. Results are shown in Figure 8. Mimosine exhibited significant suppression of the radicle growth of lettuce and rice at concentrations of 10 and 20 ppm. Above 50 ppm, mimosine almost prevented the growth of both kinds of seedlings and significantly suppressed the growth of *Acacia confusa* and *Casuarina glauca*. In addition, forest species such as *Acacia confusa, Casuarina glauca, Liquidambar formosana, Pinus taiwanensis*, and *Alnus formosana*, and an aggressive weed, *Miscanthus floridulus*, were also bioassayed. At the 200 ppm concentration, mimosine significantly inhibited seed germination and radicle growth of the tested plants, except *Pinus taiwanensis* and *Miscanthus floridulus* (Figure 9). This agrees with results shown in Figure 6, indicating that the inhibition of the forest plants is apparently due to mimosine and the phenolics mentioned. However, the *Leucaena* seedlings were not suppressed by either plant extracts or the mimosine solution at 200 ppm. Furthermore, seedlings of *Ageratum conyzoides* could sur-

vive in an aqueous mimosine solution at 50 ppm for six days, but died at 300 ppm within four days (Table 5). These findings of bioassays of known mimosine agree well with those of previous bioassays of the aqueous extracts of *Leucaena* plant parts, and overall bioassay findings strongly support the allelopathic hypothesis of weed exclusion by *Leucaena* plants.

DISCUSSION

It was hypothesized that *Leucaena leucocephala* plantations exhibit an allelopathic pattern of weed exclusion, and this hypothesis was supported by the findings of field observations and experiments, greenhouse pot experiments, and laboratory assays. The *Leucaena* leaves and litter contained a substantial quantity of mimosine, which showed strong phytotoxic activity on many species used in this study. However, the extracts of *Leucaena* leaves and aqueous solutions of mimosine at concentrations below 200 ppm had no phytotoxic effect on the growth of *Leucaena* itself. In addition to mimosine and quercetin, eight phytotoxic phenolics were also identified. Among 10 phytotoxins found in the plant, mimosine is the most toxic to the test species, of which some are excluded from *Leucaena* plantations. Mimosine is a well-known toxic nonprotein amino acid present in the seeds and foliage of the plant. The toxic effect of mimosine on animals has been reported by various authors (Hegarty et al., 1976; Jones, 1981; Reis et al., 1975). Mimosine can cause inhibition of mungbean (Ling et al., 1969; Smith and Fowden, 1966) and hypocotyl or radicle growth of lettuce (Wilson and Bell, 1978). Reisner and Bucholtz (1979) found

that mimosine completely inhibited cell division and synthesis of DNA, RNA, and protein in *Paramecium tetraurellia* at submillimolar concentration. It is an interesting question why mimosine significantly inhibits the growth of many plants tested yet hardly affects the growth of *Leucaena* seedlings. According to Smith and Fowden (1966), *Leucaena* may have a detoxification mechanism that degrades mimosine into 3,4-dihydroxypyridine and then converts 3,4-dihydroxypyridine into nontoxic metabolites. This might be the reason why the growth of young *Leucaena* seedlings was not retarded under mature *Leucaena* trees.

The allelopathic phenomenon has often been found in areas under a stress environment. It is possible in the present study that the differential field pattern of various study sites could be influenced by environmental conditions. Winter drought is common in the Kaoshu site but not in the other sites. The drought season caused a significant amount of *Leucaena* leaves to fall; consequently, the litter of *Leucaena* released phytotoxic phenolics and mimosine to the soil and suppressed the growth of understory plants. The suppression of understory plants by fallen *Leucaena* leaves was also seen locally in the Chialin site, where a *Leucaena* tree had died and fallen, leading to a significant amount of fallen leaves and to an allelopathic phenomenon. Thus, these ten allelopathic compounds of mimosine, quercetin, and phenolic acids present in the *Leucaena leucocephala* plant parts and other unidentified compounds are likely responsible for the allelopathic effects of *Leucaena* plantations.

ISOLATION AND CHARACTERIZATION OF GLUCOCAPPARIN IN *Isomeris arborea* NUTT.

MATTHEW J. BLUA and ZAC HANSCOM, III

Department of Biology, College of Sciences
San Diego State University
San Diego, California 92182

(Received August 19, 1985; accepted October 1, 1985)

Abstract—*Isomeris arborea* (Capparaceae), is the only woody caper endemic to southern California and northern Baja. Methylglucosinolate, also known as glucocapparin, was the only glucosinolate found in *I. arborea* organs by paper chromatography of the thiourea derivatives and was quantitatively determined by gas chromatography by hydrolytic products. The concentration of glucocapparin ranged from an average of 4.6 mg/g wet weight in mature leaves to 5.2 mg/g wet weight in immature leaves. Buds averaged 6.2 mg/g wet weight and capsule walls 1.8 mg/g wet weight. Seeds contained an average of 14.3 mg/g wet weight of glucocapparin. Glucocapparin concentration was found to vary significantly among the mature leaves of individuals within a single population. This compound is known to be deleterious to nonadapted herbivores and may be implicated in the chemical defense mechanism of *I. arborea*.

Key Words—Capparaceae, chemical defense, allelochemics, glucocapparin, glucosinolate, *Isomeris arborea*, caper.

INTRODUCTION

Glucosinolates are secondary metabolites most notably responsible for the flavors and pungent scents of cruciferous crops such as cabbage, mustard, and radish, among others (MacLeod, 1976). They also provide a degree of protection against fungal infection and nonspecialized herbivores (Stoessl, 1970; Feeny, 1977). However, their role in caper–insect interactions is unexplored at present.

Glucosinolates are found as cytoplasmic components of most, if not all, plant tissues and organs of the species containing them and are especially concentrated in seeds (Van Etten et al., 1979; Van Etten and Tooky, 1979). Glu-

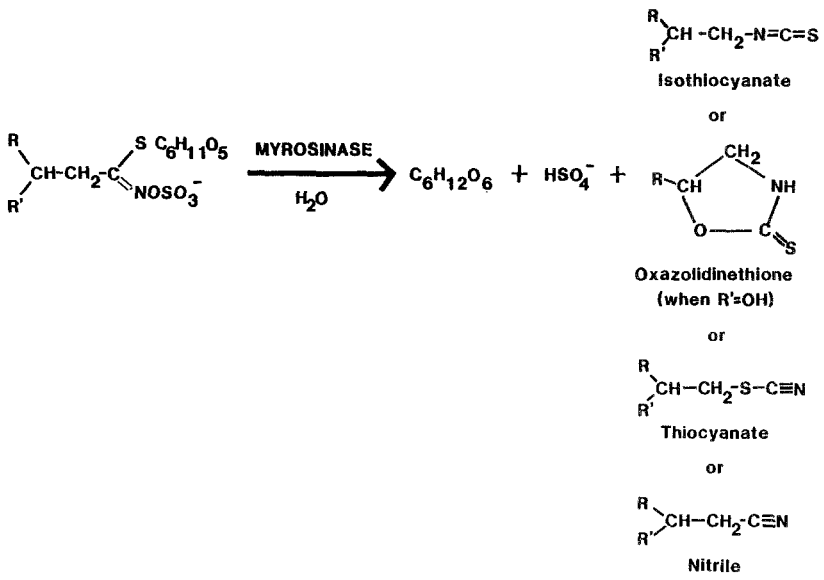

FIG. 1. Enzymatic hydrolysis of a generalized glucosinolate.

cosinolates undergo a hydrolysis reaction catalyzed by the enzyme myrosinase (thioglucosidase glucohydrolase, EC 3.2.3.1) to generate glucose, a sulfate ion, and a toxic nitrogenous hydrolytic product (Figure 1). The class of nitrogenous hydrolytic product generated depends on hydrolytic conditions as well as the "R" group of the reacting glucosinolate (Cole, 1976; Gil and MacLeod, 1980). It is generally accepted that isothiocyanates are the predominate class of toxin formed. Other toxins generated are oxazolidinethiones, nitriles, and thiocyanates (see Figure 1). Ingestion of these nitrogenous hydrolytic products and of the intact glucosinolates by nonadapted insects results in reduced growth and development (Erickson and Feeny, 1974).

Although glucosinolates and their nitrogenous hydrolytic products are known to be repulsive to generalist herbivores, they have also been shown to be oviposition and feeding stimulants to specialized herbivores having evolved mechanisms to circumvent the effects of these toxins (Feeny et al. 1970; Schoonhoven, 1972). *Isomeris arborea* Nutt. is a perennial shrub of the Capparaceae native to desert, valley grassland, and coastal sage scrub plant communities of southern and central California. *I. arborea* has high photosynthetic rates and contains levels of organic nitrogen which are as high as many cultivated plants and are higher than most shrubs in the plant communities in which it is found. Because of its high photosynthetic rates, high nitrogen levels, and a lack of any physical defense, *I. arborea* would be especially susceptible to exploitation by herbivores if endogenous secondary compounds (e.g., glucosinolates) did not impose a strong chemical barrier against herbivory.

The pattern of secondary compounds in *I. arborea* does not follow the scenario outlined by Rhoades and Cates (1976) and Feeny (1976). *I. arborea* individuals usually live in relatively dense populations, have a woody perennial growth form, and often support dense foliage throughout all seasons (Iltis, 1957). These characteristics lead us to expect quantitative defense compounds in *I. arborea*. However, *I. arborea* contains glucosinolate, which is a qualitative, physiological toxin. Generally toxins and other qualitative defense compounds are found in nonapparent plants. *I. arborea* has not been reported to contain quantitative defense compounds.

Rhoades (1979) points out that consumption by an adapted herbivore is limited to an amount that will not saturate the herbivore's ability to detoxify or otherwise tolerate the defensive chemical. In controlled experiments and field observations, *Murgantia histrionica*, an adapted herbivore, preferentially fed on *I. arborea* flower buds and capsules even though all plant parts were equally available (Nuss, 1983). *M. histrionica* had a much greater mortality rate when forced to feed on leaves rather than on buds only or capsules only (English, 1983). Based on these observations, we hypothesized that either some aspect of nutritional quality was lower in leaves than in buds or capsules, or that leaves, buds, and capsules contained different concentrations of defensive compounds. Perhaps both factors worked in combination to produce the observed pattern. Also, it is common to see some *I. arborea* individuals having as many as 150 herbivores while others in the same population have few or none (B. Collier, personal communication). These observations suggest that glucosinolate concentration among *I. arborea* individuals might vary significantly within a population.

In the first part of this study we identified the glucosinolate component of *I. arborea* and developed the methods necessary to accurately quantify glucosinolate in many small samples of *I. arborea* organs. In the second part of this study we analyzed for differences in glucosinolate complement among organs and among individuals within a population of *I. arborea*.

METHODS AND MATERIALS

Collection of Plant Material. Plant material from *Isomeris arborea* Nutt. was collected from Sorrento Valley, a coastal sage scrub plant community along Flint Kote Road, Torrey Pines State Preserve, San Diego County, California. Immature (not fully expanded) and mature leaves, flower buds, capsule walls, and seeds were collected from five plants for studies comparing glucosinolate concentration among organs. In a separate study to compare glucosinolate concentration in leaves among plants within the population, mature leaves were collected from three branches from each of 10 plants. In each case fresh plant material was picked and immediately stored on Dry Ice before being transferred to a freezer for storage prior to analysis.

Glucosinolate Identification. Preliminary spot test, in conjunction with paper chromatography (Rodman, 1978), were employed as the primary method of identification of glucosinolate in *Isomeris arborea*. Sinigrin (allylglucosinolate), a standard glucosinolate, was also tested as a control, because it produces an isothiocyanate upon enzymatic hydrolysis. In addition, glucosinolate was extracted from seeds of *Cleome spinosa*, a caper closely related to *I. arborea* reported to generate isothiocyanate and oxazolidinethione upon hydrolysis (Kjaer and Thomson, 1963); *Brassica napus*, known to generate isothiocyanate and oxazolidinethione upon hydrolysis (Youngs and Wetter, 1967); *Brassica oleracea*, known to generate all three types of aglucons (Van Etten et al., 1976); and pea (*Pisum sativum* L.), which does not contain glucosinolates.

Thiourea derivatives from the hydrolytic products of *I. arborea* glucosinolate were chromatographed in six different solvent systems on 30-cm^2 Whatman No. 1 chromatography paper spotted 4 cm from the bottom. Phenylthiourea and methylthiourea, derivatized with ammonia from methylisothiocyanate, a mustard oil common in the Capparaceae, were simultaneously chromatographed. The six solvent systems used for paper chromatographic studies were: (1) *n*-butanol–toluene–water (3 : 1 : 1); (2) chloroform–water (5 : 3); (3) toluene–ethanol–water (5 : 1 : 2); (4) toluene–*n*-butanol–water (3 : 1 : 2); (5) toluene–*n*-butanol–water (10 : 1 : 2); (6) toluene–acetic acid–water (5 : 2 : 4).

In each system the aqueous phase was used to condition the chromatography chamber. Ascending chromatography was terminated after the solvent front ran to ca. 5 cm from the top of the chromatography paper. After drying the paper, spots were made visible by spraying the paper with Grote's reagent and suspending it over steam. Resulting blue or violet spots were circled with pencil and their mobility calculated relative to that of the phenylthiourea standard.

Gas Chromatographic Analysis. Quantification of *I. arborea* isothiocyanate was done by comparing retention times and area counts to those of standard isothiocyanate (Pfaltz and Baur Inc., Stamford, Connecticut). Gas chromatographic analysis was done on a Varian Vista 6000 gas chromatograph using a 6-ft, 2-mm ID, glass chromatography column packed with 10% Carbowax 20 M on 100/120 mesh Chromosorb WAW. Injection and FID temperatures were set at 150°C and 200°C, respectively. Nitrogen flow was 30 ml/min. Oven temperature was programmed to maintain 60°C for 2 min and then increased to a final temperature of 120°C at a rate of 10°C/min.

An extraction procedure that proved to be adaptable to as many as 40 analyses per week was developed from the methods of other researchers (see Daxenbichler and Van Etten, 1977; MacLeod and MacLeod, 1977; Van Etten and Daxenbichler, 1977; Rodman, 1978). Typically, 50 ml of hot 70% methanol was blended with 0.30–1.00 g of frozen, crushed plant tissue for 1 min in a tissue homogenator (Sorvall Omni-Mixer No. 17150) at high speed. The mix-

ture was boiled and condensed to approximately 30 ml. The liquid was filtered through Whatman No. 2 filter paper, and the plant tissue was mixed with ca. 10 ml of distilled water followed by similar filtration with rinses. The combined liquid extract was then condensed by vacuum evaporation to < 10 ml. Water was added to a final volume of 10 ml. The 10-ml glucosinolate extract was decanted into screw-cap centrifuge tubes (Pyrex No. 8422) with 10 ml of 0.05 M sodium phosphate buffer, pH 7.5, 0.10 ml of 4.2% ascorbate in water, 15.0 ml methylene chloride, and 1.0 ml myrosinase extract, prepared as described by Rodman (1978). Caps with Teflon liners were fixed tightly to the tubes which were placed on a table top shaker set at approximately 50 oscillations per minute. The tubes were allowed to mix overnight (ca. 12 h) at room temperature.

After hydrolysis, the aqueous phase and the methylene chloride phase were cleanly separated by centrifugation for 20 min at 1500 rpm on a table-top centrifuge (Sorvall RT 6000). Twelve milliliters of the methylene chloride phase were removed by syringe for gas chromatographic analysis of nitrogenous hydrolytic products. An Evapo-Mix vacuum evaporator (Buchler Instruments) with an ice-water bath was used to gently concentrate the 12.0 ml methylene chloride extracts to approximately 1 ml each. The concentrated extracts were transfered with methylene chloride rinses to 2-ml vials having Teflon-lined screw caps. Next, undecane was added as an internal standard to make a final concentration of 0.05% before methylene chloride was added gravimetrically to a final volume of 1.50 ml. The concentration of glucosinolate is given in milligrams of glucocapparin per gram of plant material, fresh weight. Because milligrams of methylisothiocyanate per milliliter of methylene chloride is actually measured by gas chromatography, appropriate conversion factors are used. Standard solutions containing 0.50, 1.00, 5.00, 10.00, and 15.00 mg of sinigrin were used with an extract from 1.00 g of bean leaves to determine percent mean recovery and standard deviation for this method of quantitative analysis. In each case $N = 10$. Mean recovery ranged from ca. 103% for small amounts to ca. 97% for larger amounts of sinigrin analyzed (Table 1).

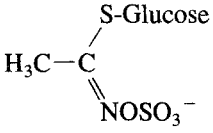
TABLE 1. RECOVERY OF ALLYLISOTHIOCYANATE UPON ENZYMATIC HYDROLYSIS OF SINIGRIN (In each case, $N = 10$)

Sinigrin hydrolyzed (mg)	Mean % recovery ± SD
0.50	103.3 ± 3.5
1.00	99.6 ± 1.5
5.00	96.7 ± 1.2
10.00	97.3 ± 2.3
15.00	97.0 ± 1.4

RESULTS

Glucosinolate Identification. The three major types of nitrogenous hydrolytic products generated by glucosinolates found in members of the Capparaceae are isothiocyanates, thiocyanates, and oxazolidinethione (Kjaer and Thomson, 1963; Gmelin and Kjaer, 1970; Kjaer and Schuster, 1971; Gil and MacLeod, 1980). Spot tests allowed us to determine which of these aglucons predominates in *Isomeris arborea*.

Paper chromatographic studies of the derivatized isothiocyanate showed that extracts from *I. arborea* leaves, flower buds, capsule walls, and seeds generated only one isothiocyanate, the thiourea analog of which has the same R_{Ph} values as methylthiourea. This indicates that *I. arborea* synthesizes the methylisothiocynate-generating glucosinolate known as glucocapparin (methylglucosinolate).



(1)

Gas chromatography confirmed identification of methylisothiocyanate and allowed quantitative determination of glucocapparin in the various plant parts of *I. arborea*.

Comparative Concentrations. A significant difference in glucocapparin concentration was found among immature and mature leaves, buds, capsule walls, and seeds ($P < 0.001$). Glucocapparin levels ranged from an average of 1.8 mg/g fresh weight of capsule walls to 14.3 mg/g fresh weight of seeds. Buds (6.2 mg/g), immature leaves (5.2 mg/g), and mature leaves (4.6 mg/g) had intermediate levels which were not statistically different (Table 2). These results confirm the hypothesis that there are quantitative differences in the glucocapparin content among organs fed upon by specialist herbivores, such as *Murgantia histrionica*.

TABLE 2. MEAN MILLIGRAMS OF GLUCOCAPPARIN PER GRAM FRESH WEIGHT OF PLANT ORGAN ± STANDARD DEVIATION OF FIVE *Isomeris arborea* INDIVIDUALS

Immature leaves	Mature leaves	Buds	Capsule walls	Seeds
5.2 ± 1.4ab	4.6 ± 0.8ab	6.2 ± 0.7b	1.8 ± 1.0a	14.3 ± 4.8c

[a] $F = 20.80$, $P < 0.001$. Means followed by the same letter are not significantly different at the 0.01 level (Student-Newman-Keuls test for multiple comparisons).

TABLE 3. MEAN MILLIGRAMS GLUCOCAPPARIN PER GRAM FRESH WEIGHT OF MATURE LEAVES FROM TEN *Isomeris arborea* INDIVIDUALS[a]

Plant number	Glucocapparin (mean mg/g fresh wt mature leaves ± SD)
1	4.7 ± 1.1
2	6.4 ± 0.4
3	4.3 ± 1.3
4	5.3 ± 0.6
5	3.6 ± 0.2
6	5.3 ± 0.8
7	4.1 ± 1.0
8	3.9 ± 0.3
9	3.3 ± 0.1
10	5.5 ± 0.6

[a] $F = 2.72$, $P < 0.025$. Samples were from three separate branches from each plant.

A comparison of glucocapparin concentration among the mature leaves of 10 individuals from the Sorrento Valley population showed a significant variability at $P < 0.025$ (Table 3).

DISCUSSION

In this study we used a method that allows simultaneous qualitative and quantitative analysis of glucosinolate and that is adaptable to a large number of samples, such as would be required by ecological studies. Because only one glucosinolate is quantified, involved derivatization like the analytical techniques of Olsen and Sorensen (1979) or time-consuming ion-exchange chromatography (Van Etten and Daxenbichler, 1977) is not required. The percentage of recovery of allylisothiocyanate from sinigrin when using this method was greater than 96% and standard deviation due to methodology was quite small (<3.5%).

Almost all capers studied contain glucocapparin as the most abundant glucosinolate (Kjaer and Thomson, 1963). Glucocleomin (2-hydroxy-2-methylbutylglucosinolate), which yields 5-ethyl-5-methyl-2-oxazolidinethione upon enzymatic hydrolysis, is usually found in conjunction with glucocapparin but was not found in *I. arborea*; glucocleomin is the second most common glucosinolate in the Capparaceae. Oxazolidinethione- and thiocyanate-producing glu-

cosinolates, compounds generally found in other capers, are notably lacking in *I. arborea*.

Surprisingly, the organs predicted to be the best defended in *I. arborea* do not have the highest glucocapparin concentration. Rhoades (1979) predicts that reproductive structures should be more highly defended than other organs because damage to them would represent a greater loss of plant fitness than similar damage to other organs. Also, McKey (1974) suggests that defense compounds are distributed and redistributed among plant parts according to a balance between vulnerability to attack by herbivores and the relative value of a plant part in terms of overall plant fitness. Of the organs studied, capsule walls always contained the lowest levels of glucocapparin (Table 2). Preliminary studies indicated that immature seeds contained glucocapparin levels which were one third to one half of the levels of mature seeds (Stillinger, unpublished data).

Glucosinolate is generally most concentrated in the mature seeds of plants equipped with this defense system (Rodman, 1978). The highest concentration of glucocapparin in *I. arborea* was found in mature seeds. As a further protection, mature seeds have a hard seed coat which generally present a physical barrier to phytophagus insects.

The difference in glucocapparin levels of mature leaves among plants (Table 3) is an important aspect of the defensive system of *I. arborea* and is currently being studied more extensively. Rhoades (1979) points out that quantitative variability of defensive chemicals among plants should be advantageous because it reduces the ability for herbivores to counteradapt.

The concentration of glucosinolate has been found to respond to environmental factors such as water stress, available nitrogen, soil sulfate, and soil type (Freeman and Mossadeghi, 1972, 1973; Josefsson, 1970; Ju et al., 1980; Louda et al., 1985). These factors are not expected to be identical for all individuals at any one time and may contribute, along with heritability, to the observed variation among plants in glucocapparin and vulnerability to insect herbivores.

Studies on the defensive "strategies" of plants typically consider only one aspect of a complex suite of characteristics that limit herbivory. Our observations suggest that glucocapparin is part of a defense system which alone restricts feeding by generalist herbivores, and in conjunction with other facets of defensive physiology, limits feeding by specialist herbivores. These other facets, which are under investigation, include fluctuations of nitrogen concentration, variability of individual phenology, and the possible presence of other defensive compounds in *I. arborea*.

Because *I. arborea* is a perennial plant with one easily quantifiable glucosinolate, it is an excellent candidate for studies which relate its physiology and phenology to such things as coevolution and plant defense theory.

Acknowledgments—The authors wish to thank Dr. Boyd Collier, Dr. Svata Louda, Dr. Steve Welter, and an anonymous reviewer, for their helpful criticism upon reviewing the original manuscript. We acknowledge the assistance of Dr. Dale Chatfield for help with the development of our gas chromatography technique. Torrey Pines State Preserve served as a convenient field study site. Our research was partially funded by the United States Department of Agriculture, grant 59-2069-0-1-4190, for which we are most appreciative.

(Received May 28, 1985; accepted September 25, 1985)

Abstract—Iridoid glycosides were found to be sequestered by natural populations of *Euphydryas anicia* after ingestion from the host plants *Besseya alpina*, *B. plantaginea*, and *Castilleja integra*. Both major iridoids of *B. alpina*, catalpol and aucubin, were found in butterfly populations where this was the only host plant. The catalpol–aucubin ratio was higher in the butterflies than in the host plant. An *E. anicia* population which uses both *B. plantaginea* and *C. integra* as host plants was found to sequester catalpol as well as another iridoid, macfadienoside. Macfadienoside was the major iridoid of *C. integra*, while catalpol esters were the major iridoids of *B. plantaginea*. Although it was a major sequestered iridoid, catalpol was a minor constituent in both host plants. The macfadienoside–catalpol ratio in the butterflies from this population was highly variable, and there appeared to be both sex and individual variation in host plant and/or iridoid glucoside utilization by *E. anicia*. Although other iridoids were present in the host plants, none was sequestered in more than trace amounts.

Key Words—*Euphydryas anicia*, Lepidoptera, Nymphalidae, *Castilleja integra*, *Besseya plantaginea*, *Besseya alpina*, iridoid glycosides, catalpol, macfadienoside, sequestration, plant-insect interactions, herbivory, ecological chemistry.

INTRODUCTION

Larval host plant specificity in checkerspot butterflies (*Euphydryas*, Nymphalidae) was interpreted in terms of the iridoid glycoside content of the host plant, and this was then definitely established as an important paradigm in a number of butterfly–host plant interactions (Bowers, 1981, 1983; Bowers and Puttick, 1986). The later work (Bowers and Puttick, 1986) showed sequestration of the bitter and presumably emetic iridoid catalpol by *Euphydryas phaeton* and a variety of iridoid glucoside fates in other herbivores.

Populations of *E. anicia* occur throughout the Colorado mountains where they are hosted by *Besseya* and *Castilleja* (Scrophulariaceae) species. We hypothesized that chemical analyses of *E. anicia* and its host plants would extend the generality of the iridoid glucoside paradigm for Scrophulariaceae utilization to natural *Euphydryas* populations and could provide data of value in studying the evolution of host plant specialization by *Euphydryas* butterflies. Various populations and species exhibit a range of behavior, from strict monophagy to utilization of as many as four host plants in a given population (Ehrlich et al., 1975; Singer, 1983).

In the long term, we also want to test the idea that host plant chemical factors might play an important part in providing differential selection pressures between populations at ecologically variant sites and that this could eventually lead to speciation among *E. anicia* populations.

No chemical studies have previously been reported on any of the host plants, and their analyses would be of value to our ongoing investigation of the Scrophulariaceae as well as to the plant–insect interaction. Detailed chemical results will be published at a later date, with the present report focusing on the establishment of iridoid ingestion by *Euphydryas* larvae and sequestration in the adult butterflies.

METHODS AND MATERIALS

Collections. For the first study we chose *E. anicia* using *Besseya alpina* as a larval host at three high-altitude (about 3700 m) sites (Cumberland Pass, Gothic Mt., and Bellview Mt.) and the same species using both *B. plantaginea* and *Castilleja integra* at a lower (2700 m) high-plains site (Red Hill). A detailed study on the ecology and population genetics of *E. anicia* at Cumberland Pass has been published (Cullenward et al., 1979). More recently, adult nectar source, larval host plant distribution, and adult butterfly distribution have been mapped for the Red Hill site (Odendaal, unpublished work). In addition, cross-breeding studies among *E. anicia* populations at each of the above sites have been carried out to study genetic differentiation and mate choice (Odendaal and Ehrlich, unpublished work).

B. alpina (Gray) Rydb. (FRS 239; CSU Herbarium No. 14530) was collected at Bellview Mt., Gothic Mt., and Cumberland Pass (all Gunnison County, Colorado); *B. plantaginea* (James) Rydb. (FRS 240; CSU No. 18338) and *C. integra* Gray (FRS 230A; CSU No. 66099) were collected north of highway 285 between Como, Colorado, and Red Hill Pass, Park County. Collections were all made in late June or early July 1984 and specimens were identified by Professor Dieter Wilkin, Department of Botany, Colorado State University. *E. anicia* Doubleday and Hewitson were collected at the same sites and identified by PRE and FJO. The *Besseya* species grow as broad-leaved rosettes, and entire above-ground material was used for the analyses, since the larvae are leaf consumers. With *C. integra*, leaves and bracts are the major portions consumed. Whole above-ground material was again used for the basic analyses. Separate TLC comparisons were performed on stems, leaves, bracts, and seeds and showed that they contained essentially the same iridoids, although there were some relative concentration differences. *Euphydryas* from each site were collected live in late June or early July, placed in methanol, and the mixture held in the freezer until isolation of iridoids and analysis, which were all carried out within six weeks. Individuals were collected, placed in killing jars briefly, removed, and stored at room temperature until analysis. Dried specimens were weighed, and the average weight was then used to establish a dry weight basis for the pooled *Euphydryas*, which were extracted fresh. Female weights were 34.2 ± 4.2 mg ($N = 3$) and males were 20.8 ± 3.0 mg ($N = 9$). The presence or absence of eggs in the females was not determined.

General Chemical and Analytical Methods. Thin-layer chromatography (TLC) was conducted on Silica gel with 6:4 $CHCl_3$–MeOH or 65:35:2 $CHCl_3$–MeOH–H_2O eluting solvents, both double developed. For visualization, plates were sprayed with a solution made up of 90 ml 50% EtOH, 10 ml of conc. H_2SO_4, and 0.5 ml of *p*-anisaldehyde, followed by heating at about 110° for 3–5 min. Iridoids without substitution at C-4 were gray, brown, or blackish, while those with acid, ester, or aldehyde functional groups at C-4 were pink. Iridoid detection limit was about 1 μg. Gas–liquid chromatography (GLC) of the iridoid trimethylsilane (TMS) ether derivatives was similar to that reported (Inouye et al., 1976). A 30-m DB-1 capillary column was used isothermally at 270° with a column head pressure of 18 psi, and FID detection. Under these conditions typical retention times were sucrose 7.0, aucubin 8.5, trehalose 8.6, catalpol 10.4, and macfadienoside 11.4 min. Macfadienoside was not quantitatively eluted from the column, but a reproducible detection of 40% was established by injection of known amounts as well as by comparison with TLC and, particularly, [^{1}H]NMR analysis. Analyses by [^{1}H]NMR were conducted on Bruker 270 or Nicolet 360 MHz spectrometers.

Plant Analysis. A detailed description will be given of the *B. plantaginea* iridoid isolation and analysis and others will then be summarized. Lab-bench

dried plant material (32 g) was stirred in 200 ml of MeOH for 6 hr, filtered, and the solution evaporated to dryness. The residue was triturated well with $CHCl_3$, the $CHCl_3$ removed, and the remaining residue triturated with H_2O. The aqueous solution was extracted with $CHCl_3$ and the aqueous portion evaporated to dryness to leave 2.5 g of a mixture of sugars and iridoid glucosides. This mixture was again triturated well several times with a minimum of methanol, concentrating the iridoids in the methanol and leaving much of the insoluble sugars behind. The methanol was evaporated to leave 1.0 g of crude iridoid–sugar mixture. The sugar content (mostly sucrose) was estimated at 10–15% from GLC and the isolation procedure below.

The iridoid mixture (500 mg) was separated into components using medium-pressure liquid chromatography (MPLC) on C_{18} reverse-phase Silica gel and 65:35 H_2O–MeOH elution. Ten fractions were obtained which were then evaporated, and the residues were further purified by an additional MPLC, prep. TLC, or crystallization. The pure iridoids were then identified by [^{1}H]- and/or [^{13}C]NMR and (in part) by comparison with standard samples.

Insect Analyses. Because of the high iridoid content and relatively low content of interfering polar compounds in the butterflies, a somewhat simplified extraction and isolation scheme was used, particularly in the single butterfly analyses. An example isolation is given here. One 35.2-mg air-dried *E. anicia* female collected at Red Hill (July 10, 1984) was crushed in 15 ml MeOH, and the mixture was stirred (magnetic stirrer) for 4 hr. The solution remaining after filtration was evaporated in vacuo and the residue triturated five times each with 0.5 ml $CHCl_3$, followed by four triturations (0.5 ml each) with MeOH. The MeOH solution was evaporated to yield a crude iridoid and sugar mixture, 4.0 mg, 11%. The total was then analyzed for iridoid content (about 30% of the mixture) by TLC, GLC of the TMS derivatives, and 360 MHz [^{1}H]NMR.

RESULTS

Each of the host plants was found to contain an array of iridoid glucosides, with the total content 1–2.5% of the dry weight. Catalpol, 1 (Figure 1) was a major iridoid (40–50%) of *B. alpina*, less so (10–15%) for *B. plantaginea*, but was a very minor iridoid (about 3%) of *C. integra*. Aucubin, 2, was present in *B. alpina* at only a slightly lower concentration than catalpol, but was not found in *B. plantaginea* nor in *C. integra*. The major iridoid (about 60%) of *C. integra* was macfadienoside, 3.

For the *Besseya plantaginea* isolation (see Methods and Materials), for example, the relative iridoid content of the plant was assessed from the ten original MPLC fractions (major iridoid underlined in a mixture): Fraction 1 (sugars, catalpol, and 8-epiloganic acid), 90 mg; 2 (8-epiloganic acid and mussaenoside), 10 mg; 3 (mussaenoside), 4 mg; 4 (mussaenoside and verproside),

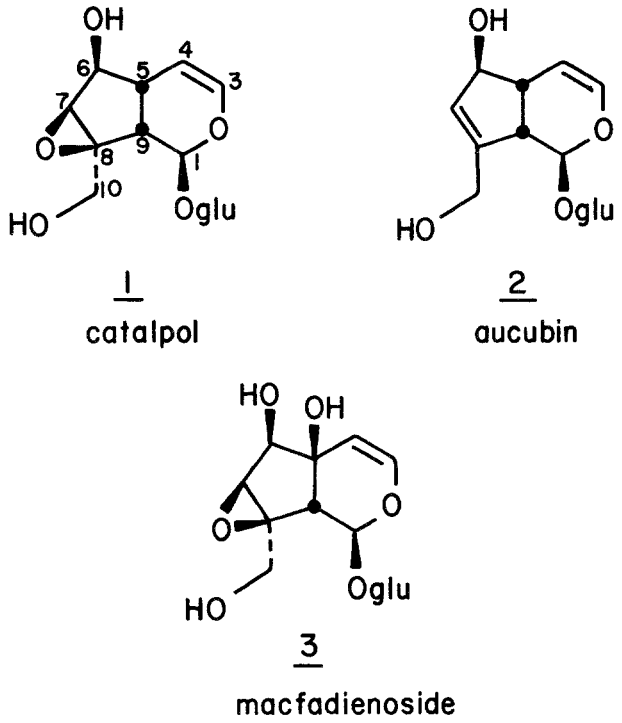

FIG. 1. Host plant iridoid glycosides.

24 mg; 5 (mussaenoside and verproside), 122 mg; 6 (verproside), 32 mg; 7 (verproside and amphicoside), 12 mg; 8 (amphicoside), 73 mg; 9 (amphicoside and veronicoside), 24 mg; 10 (veronicoside), 37 mg. These data, along with GLC of the crude TMS-derivative mixture indicated the following relative percentages: 8-epiloganic acid (5%), mussaenoside (5%), veronicoside (15%), amphicoside (20%), catalpol (12%), verproside (43%). Veronicoside is 6-benzoylcatalpol, amphicoside is 6-veratrylcatalpol, and verproside is 6-dihydroxybenzoylcatalpol. None of these was found in the analyzed butterflies. Details of structure determinations will be published elsewhere.

Complete iridoid analysis for the *B. alpina* and *C. integra* host plants is not as yet complete, but major components were determined. For *C. integra*, 75 g of dried above-ground plant material yielded 2.3 g of purified iridoid and sugar mixture, whose TLC indicated the presence of nine iridoids. Isolation work showed the mixture to consist of about 60% macfadienoside, with the second major iridoid being adoxoside. Catalpol represented about 3% of the iridoid content, and we could not identify aucubin as being present. Adoxoside represented about 15% of the total, but was not found in any of the adult butterflies. The *B. alpina* host plant yielded about the same quantity (1.5%) total

iridoids, and TLC of plants from each site showed them to be virtually identical in iridoid content (six spots observed). TLC and GLC data showed the major iridoids to be catalpol and aucubin. This combination represented about 80% of the total, with the remainder about equally distributed among four minor iridoids.

Iridoid content of the adult butterflies was about 1–4% of the dry weight of the insect. Analyses for individual iridoids revealed that catalpol, aucubin, and macfadienoside were sequestered in varying amounts by *E. anicia*. There was TLC and GLC evidence for the presence in minor amounts of some of the other iridoids from the host plants as well as iridoids (or metabolites) which were not noted in the host plants, but these were not investigated further. In order to compare insect utilization of host plants at the various sites, we determined relative amounts of the three major iridoids in the host plants and adult butterfly groups (along with a few individuals) and the data are presented in Table 1.

The NMR analyses were of particular value in accurately assessing the

TABLE 1. COMPARISON OF SEQUESTERED IRIDOID CONTENT OF *Euphydryas anicia* AND HOST PLANTS

Site	Iridoids (Catalpol = 1)	
	Aucubin–Catalpol	Macfadienoside–Catalpol
Cumberland Pass		
Besseya alpina host plant	0.92	no macfadienoside
Euphydryas anicia (31 males)	<0.10	no macfadienoside
E. anicia (6 females)	0.63	no macfadienoside
Belleview Mt.		
B. alpina host plant	0.68	no macfadienoside
E. anicia (27 males)	0.15	no macfadienoside
E. anicia (8 females)	0.18	no macfadienoside
Gothic Mt.		
B. alpina host plant	0.65	no macfadienoside
E. anicia (15 males)	0.29	no macfadienoside
Red Hill		
B. plantaginea host plant	no aucubin	no macfadienoside
Castilleja integra host plant	no aucubin	20
E. anicia (33 males)	no aucubin	0.15
E. anicia (31 females	no aucubin	0.70
E. anicia (1 male)	no aucubin	0.40
E. anicia (1 male)	no aucubin	0.44
E. anicia (1 female)	no aucubin	4.6
E. anicia (1 female)	no aucubin	2.9

butterfly aucubin–catalpol and macfadienoside–catalpol ratios of Table 1. The C-3 proton resonances (aucubin, dd, 6.21 ppm; catalpol, dd, 6.33 ppm; macfadienoside, d, 6.40 ppm) were sufficiently separate so that the relative iridoid content could be determined directly from integrals observed in the partially purified iridoid mixture. These ratios closely matched those for aucubin–catalpol and macfadienoside–catalpol established from the GLC method. In a typical example, the macfadienoside–catalpol ratio was determined to be 2.9 by the NMR analysis and 3.0 by the GLC analysis. The GLC showed the presence of small amounts of the insect sugar trehalose, as well as trace amounts of other iridoids, which were also detected by TLC. The total of these were estimated at less than 10% of the total purified iridoid mixture and could not be positively identified.

With the butterflies from the Gothic, Cumberland, and Belleview sites similar methods were used to determine aucubin–catalpol ratios. No macfadienoside was found in these butterflies. In the TLC analyses, all butterflies showed a diffuse gray iridoid-like spot more polar (lower R_f) than the major iridoids, which did not appear in any of the host plant analyses. This substance could not be correlated with any extraneous peaks in the GLC or [^{1}H]NMR analyses, and its genesis is unknown at this time. Collections and groupings were made prior to the analyses and hence are not those of an optimally designed experiment. They should, rather, be viewed as exploratory in nature. The results did yield initial data of value as well as information on which to build hypotheses to be tested in future field and laboratory studies.

DISCUSSION

The results clearly show iridoid ingestion and sequestration by natural populations of *E. anicia* hosted by three different plant species. In most cases, catalpol was the major iridoid of the insects, although aucubin and macfadienoside were also found; macfadienoside was, however, the major iridoid in two Red Hill females. In one case, that of female butterflies at Cumberland Pass, there was little, if any, selective sequestration of catalpol over aucubin. Male butterflies at Cumberland Pass and Belleview Mt. did selectively sequester catalpol, but somewhat less so at Gothic Mt.

Detailed conclusions cannot yet be drawn from all the data from the Red Hill population since *E. anicia* is known to use both host plants for pre- and postdiapause larval feeding (Odendaal, unpublished data). One immediate conclusion is that all the individuals analyzed spent part of their life cycle on *C. integra* since they all contained macfadienoside, which is not present in *B. plantaginea*. The two females were either less efficient at sequestering catalpol over macfadienoside than were the two males or else spent a greater part of their life cycle on *C. integra* than did the males. Although the total macfadien-

oside content of both sexes was lower in the population average than in the individuals, a female vs. male difference still was maintained. The low macfadienoside content of the pooled butterflies at Red Hill (as compared to the individuals) suggests that some do not use *C. integra* at all. A differential usage among pre- and postdiapause larvae in this univoltine species might also account for some of the variability. The data from the Red Hill population is perhaps most easily explained by both sex and individual variations in butterfly utilization of host plants and/or iridoid glucosides.

It is notable that the catalpol content of both the *B. plantaginea* and *C. integra* host plants is quite low compared to other iridoids, and hence a very specific sequestration appears to be taking place. The *B. plantaginea* does contain large quantities of esterified catalpol derivatives (veronicoside, amphicoside, and verproside), and the possibility remains that the insect is hydrolyzing these materials in order to obtain catalpol. Labeling or feeding experiments and frass analysis will be necessary to definitely establish or exclude the utilization of these catalpol esters. Since catalpol could be hydroxylated in the insect to yield macfadienoside, a likely biosynthetic step in the plant, the butterfly could be producing macfadienoside, rather than sequestering it. This seems unlikely, however, in view of the results at the Cumberland, Belleview, and Gothic sites. Catalpol was sequestered by all the butterflies analyzed, but in no case was macfadienoside found. It is not likely that *E. anicia* at Red Hill would metabolize catalpol to macfadienoside, while *E. anicia* at the other sites would not.

In summary, we have further established iridoid ingestion and sequestration as an important paradigm in the interaction of *Euphydryas* and their host plants and extended the work to some natural populations of *Euphydryas anicia*. It seems likely that iridoid utilization will be of general applicability in the Melitaeine group as has been suggested (Bowers, 1983). Preliminary results from our laboratory show that *E. editha* (*C. linariifolia* host plant) and *Poladryas arachne* (*Penstemon virgatus* host plant) also sequester catalpol. How far this paradigm can be extended to other lepidopteran taxa has yet to be determined, although its utility in understanding the feeding strategies of *Junonia coenia* (Nymphalidae) and *Certomia catalpae* (Sphingidae) has been established (Bowers, 1984; Bowers and Puttick, 1986).

The importance of iridoid glycosides in other plant–insect herbivore relationships is suggested by two further examples. Thus, the observed (Owen and Whiteway, 1980; Moran and Southwood, 1982) shift of three phytophagous insect specialists from their normal iridoid-containing *Verbascum* (Scrophulariaceae) host to the introduced *Buddleja davidii* (Buddlejaceae) need not in itself "support radical views on plant classification" (Strong et al., 1984). The shift is logical in that the Buddlejaceae are also know to contain iridoid glucosides, and the insects in question may simply be chemists rather than botanists. The second example deals with a white admiral butterfly, *Limenitis* (*Ladoga*) *cam-*

illa (Limenitinae), which is monophagous on *Lonicera periclymenum* in England and has a restricted range, although the host plant is ubiquitous. The restricted range was interpreted (Pollard, 1979) in terms of the increased relative importance of bird predation at cooler latitudes where larval and pupal populations are slow to develop. All *Lonicera* species have high iridoid glucoside content and, in view of the established relationship among iridoid glucosides, palatability, and bird feeding behavior (Bowers, 1981), it is possible that variations in host plant iridoid glucoside content and levels of sequestered iridoids could also play a role in the *Limenitis* range restriction. If iridoid glucoside content of larvae at cooler latitudes is low, this could account for increased predation.

Ingestion of iridoids does not automatically mean sequestration, but it may be worthwhile to test the hypothesis that all aposematic insects monophagous on iridoid-containing plants sequester these bitter substances. In view of the fact that iridoids appear to be stable in dry Lepidoptera specimens and are sequestered in reasonable concentrations, it should be possible to verify this hypothesis by analysis of individual insects from present collections.

Our results at this point are not sufficiently detailed or quantitative, and extensive comparisons cannot yet be made with the detailed studies on cardenolide sequestration by *Danaus plexippus* (Brower et al., 1984) and *D. gilippus* (Cohen, 1985). Some trends, however, can be noted. In the *Danaus* systems, cardenolide TLC profiles of the adult butterflies were generally comparable to those of the host plants. In one case, 20 of 23 cardenolides of the plant were also found in the adult butterfly. Our TLC and GLC iridoid profiles of adult *E. anicia* and its larval plants are markedly different from each other because of the propensity of the butterflies to preferentially sequester catalpol (and somewhat less so macfadienoside), while excreting or metabolizing other iridoids. The fortuitous occurrence of macfadienoside in only one of the host plants has, however, allowed us to determine something of plant usage based upon adult butterfly analyses. This was successful in the *D. plexippus* work since cardenolide profiles were different in different plant hosts, and these were reflected in the adult butterflies.

Acknowledgments—We thank Kristina N. Jones for assistance with butterfly collections, the Colorado State University Regional NMR Center (funded by NSF Grant CHE 78-18581) for high-field nmr assistance, and Deane Bowers for helpful comments on this paper.

(Received May 23, 1985; accepted October 15, 1985)

Abstract—A survey of 59 species of tropical legume seeds revealed high interspecific variation in proteinaceous capacity to inhibit bovine trypsin (a digestive enzyme) and to agglutinate human (type B, Rh positive) and laboratory rabbit red blood cells. The legume subfamily Mimosoideae was conspicuous for the absence of seeds with very weak trypsin inhibition. Congenerics sometimes differed strongly from each other with respect to both trypsin inhibition and phytohemagglutination. Half the species of seeds displayed no hemagglutinating capacity with one or the other kinds of red blood cells, and in only 27% of the 30 cases where there was some activity did the same species of seed actively agglutinate both species of red blood cells. A species of seed that had hemagglutinating capacity was almost invariably associated with moderate to high levels of trypsin inactivation. While it has been long known that a great diversity of small toxic and potentially defensive molecules occur in legume seeds and that one species of seed often contains several of them, we now feel that it is reasonable to consider legume seeds as also containing a high diversity of potentially toxic protein molecules. A single seed is likely to contain, at the least, three to four classes of defensive compounds, any or all of which, or some in combination, may be the cause of a seed being rejected by a potential seed predator.

Key Words—Seed predation, seed chemistry, lectins, protease inhibitors, phytohemagglutins, Costa Rica, seed defenses, Leguminosae.

INTRODUCTION

A seed is a bag lunch for a seedling. However, there has been strong selection for seed traits that lower the probability that the seed will become lunch for a seed predator. Since seeds are rich in nutrients of value to a wide variety of animals, we expect that natural selection will have led to each species of seed having a variety of defenses, some of which function against certain potential seed predators, and others that function against others. Some seed proteins, e.g., lectins or phytohemagglutinins (Liener, 1979; Rudiger, 1984; Janzen, 1981) and proteinase inhibitors (Ryan, 1979), are among these potential defense traits (e.g., Janzen, 1977, 1978, 1981; Janzen et al., 1976; Lee, 1979; Olsnes and Pihl, 1973; Laskowski and Kato, 1980; Gatehouse et al., 1979; Adam 1974; Stripe et al., 1976; Warsy et al., 1974; Jayne-Williams and Burgess, 1974; Tannous and Ullah, 1969; Pearch et al., 1979).

One important step in understanding the defenses of a seed is identifying the potentially toxic compounds in that seed. This is less simple that it would appear for three major reasons. First, "toxicity" is a dosage- and animal-specific trait, although, of course, certain classes of compounds (e.g., alkaloids, cyanogenic glycosides) have a higher chance of being toxic than do others. This means that simply identifying a compound in a seed does not disclose the seed's toxicity to animals (although some quite educated guesses are possible). Second, a given phytochemist tends to be specialized with respect to identification of a certain class of compounds. It is therefore almost impossible for the ecologist to send a bag of seeds to a single phytochemist and ask for a profile of all the potentially defensive compounds in that seed. Third, there are two major groups of potentially defensive compounds in seeds.

There are relatively small molecules that are generally straightforward to describe, identify, and isolate. Their mode of action on animal systems in generally very specific, and these compounds have a long tradition of examination by pharmacologists; caffeine, strychnine, L-dopa, canavanine, and cyanogenic glycosides are some well-known examples. If seed defenses were constituted only of compounds such as these, we would undoubtedly understand seed relationships with seed predators much better than we do. However, seeds also contain large molecules made up of repeating patterns of sugars, phenols, and amino acids. These carbohydrates, tannins, lignins, phytohemagglutinins (lectins), and protease inhibitors (to name but a few) are difficult to describe, identify, and isolate. Their mode of action on animal systems is often generalized (e.g., one may be a "digestion inhibitor," another "inhibit uptake of amino acids by the intestine," etc.). These large molecules have been known for a very long time in a general sort of way; tanning leather with polyphenols so as to prevent access to collagen by bacterial enzymes, and boiling beans to denature toxic phytohemagglutinins may be just as ancient to humans as is chewing plants for alkaloid pain-killers and mashing rotenone-rich foliage into streams

to stupefy fish. However, these large molecules have been largely the despair of phytochemists. An additional complication in interpreting large molecules is that they are often major parts of the biomass of a seed and clearly serve also as sources of raw biosynthetic construction materials for the developing seedling. However, given their physiological activity against animals, they are additionally a potential part of the defense repertoire of a seed.

One of the more profitable ways of determining the defense repertoire of a seed is to test the seed contents against potentially susceptible biological systems. In fact, two of the large and potentially defensive types of proteinaceous molecules found in seeds are traditionally recognized by their physiological activity against animal systems rather than by chemical characterization. Here we report for 59 species of tropical legume seeds the results of challenging trypsin, a protease enzyme, with the finely ground contents of live seeds. We also report the results of asking if the same seed contents will agglutinate red blood cells of the human (type B, Rh positive) and the laboratory rabbit (*Oryctolagus cuniculus*).

As will be discussed below, we wish to emphasize that in such a general screening only positive results are useful; protease inhibitors and phytohemagglutinins display a wide variety of specificities, and a seed that neither inhibits trypsin nor agglutinates rabbit or human red blood cells may still contain a very potent proteinase inhibitor or phytohemagglutinin. For example, *Phaseolus lunatus* seeds showed no hemagglutination with type B blood (Table 1) but contain a powerful hemagglutinating factor for type A human blood (anonymous reviewer). The species of seeds to be screened were chosen in great part because they are the subjects of intensive feeding tests against seed predators in the Costa Rican habitats where they grow (e.g., Janzen, 1981; Janzen et al., 1986) and because they are subjects of an intensive long-term effort to characterize the entire defense repertoire of certain species of seeds (e.g., *Dioclea megacarpa*, Rosenthal et al., 1982; Rosenthal and Janzen, 1983, 1985; *Lonchocarpus* spp., Fellows et al., 1979; Janzen et al., 1986).

METHODS AND MATERIALS

Seed Sources. All the seeds listed in Table 1 were collected by D.H.J. between 1965 and 1980 in the lowlands of Guanacaste Province, Costa Rica except as itemized below. Exceptions: *Entada gigans* and *Oxyrhynchus trinervius* were beach drift seeds and *Mucuna mutisiana*, *Parkia pendula*, and *Pterocarpus officinalis* were rainforest seeds, from Corcovado National Park, southwestern Costa Rica; *Adenopodia polystachya* and *Canavalia bicarinata* came from mangrove forest margins near Puntarenas, Costa Rica; *Erythrina* spp. came from the area around San Jose, Costa Rica; *Mucuna andreana* came from rainforest edges at Finca La Selva, Heredia Province, Costa Rica; *Leucaena glauca* from St. John's Island, British Virgin Islands, Caribbean; *Ormosia* spp. were

[h] Prepared as described in Uy and Wold (1977).

purchased in a native market in Merida, Venezuela; *Sophora macrocarpa* was collected to the north of Santiago, Chile.

These plant species are common, and the collections were unambiguously identified by D.H.J. Additionally, voucher specimens for all these species have been deposited in the herbarium of the Missouri Botanical Gardens, St. Louis, Missouri. All the Guanacaste plant names conform to Janzen and Liesner (1980) except that *Lysiloma seemannii* is now known as *Lysiloma divaricata*. D.H.J. identified all plants in the field and was certain that only mature and dormant seeds were collected for analysis.

Seed Treatment. Large seeds, those weighing more than 500 mg dry weight after removal of the seed coat, were ground and tested after removal of their seed coats. Smaller seeds were ground up entire for the tests. All seeds were living at the time of grinding and ranged between 5 and 10% water content (i.e., seemingly dry and hard). Seeds were finely ground in a Wiley mill before testing. This seed meal was not oven-dried before use or weighing for percentage determinations.

Proteinase Inhibitor Tests. Bovine trypsin was purchased from Worthington (Freehold, New Jersey) and was approximately 50% active as determined with the active site titrant *p*-nitrophenyl-*p'*-guanidinobenzoate (Chase and Shaw, 1967). Enzyme activity was determined by the method of Hummel (1959) using tosyl-L-arginine methyl ester as substrate. The powder from individual seeds was dissolved in 0.5 M KCl (50 mg powder per ml), soaked for 1 hr, and contrifuged at 10,000*g* for 10 min. The clear supernatants were employed for assays. Trypsin inhibitory activity was determined by the addition of increasing quantities of the extract to a standard quantity of trypsin and incubated for 5 min prior to assay. The data is reported as the quantity (dry wt) required to decrease the activity of 1 μg trypsin 50%.

Hemagglutinin tests. The finely ground seed was suspended in 10 volumes of physiological saline (0.9% NaCl) and vigorously shaken for 5 min. Any insoluble material was removed by centrifugation, and the hemagglutinating activity of the supernatant was determined by the photometric procedure of Liener (1955). In this method, serial dilutions of this extract (or a suitably diluted portion thereof) are added to an equal volume of a suspension of trypsinated rabbit or human red blood cells. The latter were prepared by prior treatment with glutaraldehyde, as described by Turner and Liener (1975), in order to increase their stability during storage. The mixture of each dilution with the red blood cell suspension was allowed to sit at room temperature for 2 $\frac{1}{2}$ hr, at which time the absorbance at 620 nm was measured in a Coleman Junior Spectrophotometer model 6A.

One hemagglutinating unit (HU) is arbitrarily defined as that amount of lectin which causes a 50% decrease in the absorbancy of the cell suspension under the conditions specified above. The reciprocal of the dilution (X) corre-

sponding to 1 HU may be calculated from the percentage of the cells remaining in suspension of those tubes having the closest values which are above (tube a) and below (tube b) the 50% endpoint. The following equation is employed:

$$\log x = \log c = (50 - b) \cdot \log 2$$

Where c = reciprocal of dilution in tube b, a = % of cells in suspension in tube a, and b = % of cells in suspension in tube b. The agglutinating activity of the seed extract is then calculated from the value of x and the weight of the seed material employed in making the original extract.

RESULTS

The results in Table 1 show clearly that trypsin inhibition among a large array of legume seeds can range from negligible (e.g., *Cassia leptocarpa*, *C. emarginata*, *Schizolobium parahybum*, *Ateleia herbert-smithii*, *Gliricidia sepium*, *Lonchocarpus acuminatus*, *L. costaricensis*, *L. minimiflorus*, *L. salvadorensis*, *Ormosia tovarensis*) to very intense (e.g., *Bauhinia glabra*, *Adenopodia polystachya*, *Erythrina berteroana*, *Pterocarpus officinalis*). Very intense activity was found in all three legume subfamilies, but the Mimosoideae are conspicuous for the absence of seeds with very weak trypsin inhibition. Congenerics may differ strongly from each other (e.g., different species of *Cassia* seeds ranged from very intense inhibition to virtually no effect) as well as be quite similar. Except for the two species of *Ormosia* (which are traditionally viewed as very rich in alkaloids that are toxic to vertebrates), all really large seeds showed inhibitor activity; small seeds display such a variety of intensity that no generalization can be made about the direction of their intensity.

Half the species of seeds displayed no hemagglutination activity against laboratory rabbit or human blood cells. The same seed was active against both kinds of red blood cells in only 27% of the 30 cases where there was some activity. Overall, there was more agglutination response by the rabbit than by the human red blood cells; this conforms with the direction of the "control" results with a purified hemagglutinin SBA. However, in both cases the response is relatively weak when compared with SBA. A high level of hemagglutinating activity against one kind of red blood cell is apparently randomly associated with the level of activity against the other.

A species of seed that showed hemagglutinating activity was almost invariably associated with comparatively moderate to high levels of trypsin inactivation. However, there were at least two cases of some hemagglutination by seeds that displayed virtually no trypsin inhibition (e.g., *Schizolobium parahybum*, *Ormosia tovarensis*).

DISCUSSION

The positive results listed in Table 1 are only the tip of the iceberg. It is likely that every legume seed contains one or more protease inhibitor and/or one or more phytohemagglutinin. However, demonstrating this will require screening against a wide variety of enzymes (and perhaps screening under a variety of environmental conditions such as different but biologically realistic levels of pH and temperature). Likewise, given the strong specificity of different kinds of phytohemagglutinins for different species of red blood cells, a seed will have to be screened against many kinds of blood cells and perhaps other sugar-containing substrates before it can be certified as free of phytohemagglutinins (lectins). For example, as mentioned earlier, lectins in *Phaseolus lunatus* seeds do not hemagglutinate type B human blood, but do hemagglutinate type A human blood.

Since virtually every species of seed listed in Table 1 contains one or more kinds of uncommon amino acid, alkaloid, or cyanogenic glycoside, the results of this screening add robustness to the hypothesis that each species of legume seed is likely to have a variety of defenses. For example, *Dioclea megacarpa* contains canavanine and canaline, and now it is clear that it also contains a trypsin inhibitor protein and a hemagglutinating protein. Conversely, when an animal refuses to feed on a seed, it is clear that one cannot automatically attribute such a refusal to the first potentially defensive compound that is easily isolated from the seed. For example, *Pterocarpus officinalis* seeds contain the alkaloid hypaphorine, a potent feeding deterrent to at least one species of small seed-eating rodent (Janzen et al., 1982). However, it is obvious from the results presented in Table 1 that the refusal of wild rainforest animals to harvest the large and abundant *P. officinalis* seeds may also be due to their strong trypsin inhibitor ability, strong lectin activity, or the combination of these obnoxious proteins with the alkaloid (or even with some as yet undetected other defensive compound).

When an animal bites into a seed, it gets the defensive compounds along with a large bulk of material that is either quite edible and digestible, or merely inert from the viewpoint of the animal. The material other than the defensive compounds plays two important roles in the context of this survey. First, when examining the defensive compound repertoire of a seed (or any other plant part), it is commonplace to think in terms of concentration (or activity) of the compounds in the seed contents. This quantitative measure is presumed to have some biological meaning. However, we must caution that concentrations (or intensity of activity) as measured by the biologist are extremely difficult to accurately interpret in terms that represent how the animal experiences them. Not only is there the problem that one beast's poison may be another beast's dinner, but additionally there may be strong threshold effects. For example, Gatehouse

et al. (1979) showed that the threshold level of trypsin inhibitor in *Callosobruchus*-resistant cowpeas (*Vigna unguiculata*) lies between 0.5 and 0.8%.

Furthermore, impact of the defense compound may simply be to lower the gain from the food being eaten, rather that do some direct damage to the animal. For example, if a trypsin inhibitor occurs at some low level, it may inactivate only part of the gut enzyme pool, leaving another portion of the gut's enzymes to function normally. If the seed happens to contain a large amount of the substrate, the remaining enzyme pool may be able to harvest so much resource that the trypsin inhibitory effect is inconsequential from the viewpoint of the potential seed predator; seed predators eat mouthfuls of seed content, rather than just the compounds being assayed. In the context of the present survey, the message is that high or low values of proteinase inhibitor or phytohemagglutinin activity may not translate well into the inedibility or toxicity of a meal of seeds, especially when one considers the highly positive gains that an animal may get from a bite of the seed. Of course, the greater the amounts and kinds of potential defense materials in the seed, and the lesser the amounts of traditional nutrients present, the greater the chance that a seed will be inedible or toxic to a seed predator that is not specialized on that species of seed. Equally, the larger the defense repertoire and the less the nutrient content, the more biochemically specialized is likely to be the specialist seed predator that regularly feeds on a seed that is toxic to other animals.

Second, the other portions of the seed affect the interpretation of our survey results. When a caterpillar takes a bite of a leaf, some of the defensive compounds in the leaf may function in making leaf material unavailable rather than hurting the caterpillar directly; likewise, the contents of the seeds surveyed here may affect the ability of the proteinase inhibitors and phytohemagglutinins to react with the test substrates. For example, when the seed is ground up and placed in a liquid medium, the trypsin inhibitors may well react with some of the other proteins in the seed rather than with the trypsin offered as an assay. Likewise, the phytohemagglutinins may cross-react with complex polysaccharides in the seed meal, and thus be prevented from participation in the bioassay. A number of such responses are to be expected if selection has operated to produce a seed whose nutrients become unavailable when the seed is eaten, rather than (or in addition to) to produce a seed that is actually toxic or otherwise inedible to the seed predator.

In other words, the positive results in Table 1 can be believed, but no result, including the zeros, can be taken to indicate the maximum amount of reactable proteinase inhibitors or phytohemagglutinins that may occur in the seed. As mentioned in the Introduction, it is even quite possible for there to be inhibitors present that do not react with bovine trypsin but will react with other enzymes. Likewise, the values obtained in Table 1 cannot be viewed as the maximum possible levels of reaction in the gut of an animal, since the gut adds

various other substrates and reactants to the mix, creating a reaction environment that is obviously different from that used in the screening for the data in Table 1 (see Becker, 1984, for a discussion of similar philosophies vis à vis tannins as digestion inhibitors for leaf-eating caterpillars).

It is tempting to expect an inverse relationship between the activities of the two quite different classes of proteins for which we assayed. However, the expectation disappears when one considers that these two classes of compounds are only two of at least three to five classes of potentially defensive compounds in a seed (and perhaps there are double that number of kinds of defensive compounds when one considers that it is commonplace for a single species of seed to contain several kinds of alkaloids or uncommon amino acids). Furthermore, the plant has other defenses such as seed hardness, seed number, phenology, dispersal mode, etc. (Janzen 1978). A seed that is short on any one these defenses may well be exceptionally well-endowed on some other defense axis (e.g., Janzen, 1969, 1977; Janzen and Higgins, 1979) rather than just increase one of the potential defenses that we happen to screen for here.

TOXICITIES OF HOST SECONDARY COMPOUNDS TO EGGS OF THE *Brassica* SPECIALIST *Dasineura brassicae*[1]

INGER ÅHMAN

(Received July 12, 1985; accepted October 15, 1985)

Abstract—The toxicities of selected host secondary plant substances to eggs of the *Brassica* specialist *Dasineura brassicae* were estimated in a laboratory test. Isothiocyanates (ITCs) and 1-cyano-2-phenylethane, autolysis products of glucosinolates, were more toxic than a "green leaf alcohol," *cis*-3-hexen-1-ol, found in numerous plant families. The most toxic compound, 2-phenylethyl ITC, occurs in all investigated *Brassica* hosts of *D. brassicae*. However, the less suitable *Brassica* hosts additionally release comparatively large amounts of allyl ITC. This suggests that even a crucifer specialist may be restricted in its use of particular hosts due to their compositions and concentrations of glucosinolate compounds.

Key Words—Secondary compounds, glucosinolate, isothiocyanates, toxicity, *Brassica*, Cruciferae, *Dasineura brassicae*, Diptera, Cecidomylidae.

INTRODUCTION

Glucosinolates are characteristic secondary compounds of cruciferous plants (Kjaer, 1976). Glucosinolate compounds (glucosinolates and/or their breakdown products) can have adverse effects on herbivores which, in nature, do not feed or feed only to a limited extent on crucifers (Feeny, 1977; Blau et al., 1978; Lerin, 1980). Deleterious effects have very seldom been shown against insects specialized for feeding on crucifers. However, very few experiments have been specifically designed for testing toxicities of glucosinolate compounds to crucifer specialists (Feeny, 1977). Much more information is available regarding their use of glucosinolate compounds as behavioral cues in connection with feeding and reproduction (Verschaffelt, 1911; Feeny, 1977; Lerin,

[1] Winn., Diptera: Cecidomyiidae.

0098-0331/86/0600-1481$05.00/0

1980). Although glucosinolates are ubiquitous in crucifers, plant species differ with regard to composition, concentrations and breakdown routes of these compounds (Kjaer, 1960, 1976).

Since cruciferous species can be characterized by their glucosinolate profiles (Rodman & Chew, 1980), tolerances of a particular crucifer specialist to the various substances may help explain the extent to which it uses individual cruciferous species as hosts. In this study, the toxicities of selected compounds to eggs of the *Brassica* specialist *Dasineura brassicae* Winn. were estimated. The selection of test compounds was based on knowledge about host plant suitability (Åhman, 1981) and plant chemistry (Cole, 1976).

Host Relationships of D. brassicae. In Sweden, *D. brassicae* infestations have only been reported on *Brassica* spp. (Sylvén, 1949). *D. brassicae* females deposit their eggs through holes in the pod walls with their telescopic ovipositor. The oviposition holes are, to a large extent, feeding and oviposition punctures made by the weevil *Ceutorhynchus assimilis* Payk. (Speyer, 1921; Sylvén and Svenson, 1975). Eggs normally hatch after four days, and larvae feed inside the pods until they are full-grown (Sylvén, 1949). In a host plant suitability test (Åhman, 1981), both egg survival and larval weights were significantly lower on *B. juncea* Coss & Czern (brown mustard; Chinese–eastern European origin) and *B. nigra* Koch (black mustard) than on *B. napus* L. (rape) and *B. campestris* L. (turnip rape). In intact cruciferous plants, glucosinolates occur within the parenchymal tissues (Kjaer, 1960), and only minute amounts are broken down and released from the plants (Cole and Finch, 1978). However, when plants are damaged, glucosinolates hydrolyze enzymatically, and both volatile and nonvolatile aglucones are released (Kjaer, 1960).

Since *D. brassicae* females oviposit in the vicinity of damaged plant tissue, the eggs are probably exposed to comparatively high concentrations of aglucones. Cole (1976) made a survey of volatile glucosinolate aglucones released after autolytic hydrolysis of numerous crucifers and found that concentrations of isothiocyanates (ITCs) in *B. juncea* and *B. nigra* were considerably higher than in *B. napus* and *B. campestris* (Table 1). There were also differences in aglucone compositions between the suitable and less suitable hosts for *D. brassicae* (Table 1). Since the composition and concentrations of glucosinolate compounds may vary within a species with plant age, plant part, environmental conditions, and plant genotype (Delaveau, 1952, 1958; Kjaer, 1960; Lichtenstein et al., 1964; Josefsson, 1967, 1971; Josefsson and Appelqvist, 1968; Cole, 1978, 1980; Louda and Rodman 1983a,b), only major patterns were considered during selection of test compounds.

METHODS AND MATERIALS

Test Compounds. The compounds selected for testing were: sinigrin, the "mother" glucosinolate of allyl ITC; allyl ITC, predominant in the less suitable hosts *B. juncea* and *B. nigra*; 2-phenylethyl ITC, present in all *Brassica* species

2-Phenylethyl ITC (% of total aglucones)	11	27	5	20	11
1-Cyano-2-phenylethane[d] (% of total aglucones)	11	9	19	0	0

[a]*B. juncea* shows polymorphism in glucosinolate composition (seed investigations) relative to geographical origin. Chinese–European forms contain mainly sinigrin, while gluconapin in the major glucosinolate in forms from Pakistan and India (Vaughan et al., 1963; Josefsson, 1972; Gland et al., 1981).
[b]Named *B. rapa* L. by Cole (1976); synonymous with *B. campestris* ssp. *rapifera*, turnip, a European form with swollen "roots."
[c]Named *B. chinensis* L. by Cole (1976); synonymous with *B. campestris* ssp. *chinensis*, an Asian leafy form.
[d]Named 2-phenylpropionitrile by Cole (1976).

investigated by Cole (1976); *n*-butyl ITC, which is not known to occur naturally; 1-cyano-2-phenylethane (i.e., the nitrile corresponding to the ITC, 2-phenylethyl ITC; Cole 1980), which was found in the suitable hosts but not in *B. juncea* and *B. nigra*, and finally, *cis*-3-hexen-1-ol, which occurs in *Brassica* spp. (MacLeod, 1976; Wallbank and Wheatley, 1976; Cole, 1978, 1980) and in numerous other plant species from various families (Visser et al., 1979). Relative concentrations of glucosinolate breakdown products to "green leaf compounds" (*cis*-3-hexenol and *trans*-2-hexenal) vary during plant development. In mature *B. campestris* plants, the ratio fluctuates around 1:1 (Cole, 1978, 1980).

The test compounds were obtained from various sources: sinigrin from Nutritional Biochemicals Corporation, Cleveland, Ohio; allyl ITC from Merck, Darmstadt, BRD; 2-phenylethyl ITC and *n*-butyl ITC from Maybridge Chemical Co. Ltd., Tintagel, Cornwall, UK; *cis*-3-hexen-1-ol from Northern Aromatics Ltd., Radcliffe, Manchester, UK, and 1-cyano-2-phenylethane was synthesized by the Department of Organic Chemistry, Royal Institute of Technology, Stockholm. The purity of the compounds was at least 95%.

Dilution Preparations. Series of 10-fold dilutions (v/v) of liquid test compounds in 0.09 M NaCl–water solution were prepared. Desired concentrations of the solid compound, sinigrin, were obtained by weighing and directly dissolving the compound in NaCl–water solution. Since most liquid compounds had low solubility in water, each dilution was homogenized just before pipetting, using an automatic shaker. Also, in some dilution preparations, the surfactant Tween 80 (0.1 ml/liter) was added to enhance mixing of the test compound with the NaCl–water solution. However, results from the bioassays with and without the surfactant were of the same order of magnitude. Preliminary tests were made to determine the approximate minimum lethal concentration for each compound. Dilutions with concentrations around this point were later tested in a standardized way.

Egg Treatments. Eggs were exposed to the compounds in the wells (volume: 300 μl) of polystyrene, microtiter plates. Into each of the 16 wells on a plate, 150 μl of one of the dilutions of a test compound or the control (NaCl–water solution) was pipetted. The fluid was soaked up by Sephadex G-25 Fine, which was carefully poured into the well. *D. brassicae* eggs were obtained from *B. napus* plants exposed to females in the field or in a cage in the laboratory. The egg transfer was carried out under a microscope, using a scalpel to open the pods. One egg at a time was picked up on a fine-tipped, moistened brush and placed on top of the Sephadex "bed" in a well. Eggs from each egg batch were distributed among the control plate and the plates with various concentrations of one of the test compounds. Afterwards, each plate was tightly wrapped in one layer of Parafilm and another of aluminum foil, isolating the wells from each other and from the surrounding air. The plates with eggs were kept at room temperature (20–22°C) for at least five days, after which egg mortality (i.e., proportion of eggs that had not hatched) was determined under a microscope.

Method Evaluation. Lethal doses determined by this method reflect not only the toxicities of the compounds, but also their transport characteristics such as their volatility and tendency to penetrate the egg. All the compounds other than the salt sinigrin may have a fumigant action. However, test conditions should be fairly similar to the natural situation occurring for eggs in pods. Furthermore, one must be aware that even if toxicity test results correspond to ITC release of the plants (Cole, 1976), other plant characteristics might have been responsible for the observed differences between *Brassica* spp. in *D. brassicae* mortality rates (Åhman, 1981).

RESULTS

All the tested breakdown products from glucosinolates and *n*-butyl ITC were lethal to *D. brassicae* eggs at doses lower than that of the "leaf alcohol" *cis*-3-hexen-1-ol (Figure 1). 2-Phenylethyl ITC had the lowest lethal dose of

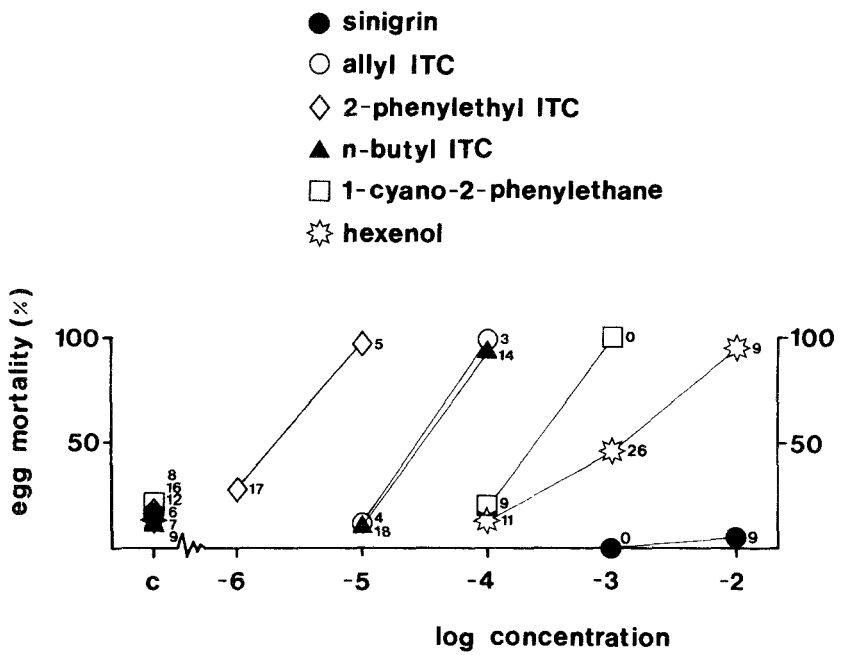

FIG. 1. Dose–mortality relationships for *Brassica* secondary compounds and *D. brassicae* eggs. Each point represents a mean from at least four replicates of 16 eggs each, except for sinigrin −2, −3 (two replicates). Concentrations of liquid compounds: v/v, and sinigrin: g/ml (c = controls). Figures represent ± standard deviations. Lines connect mean points.

all the test compounds. Lethal doses of allyl ITC and *n*-butyl ITC were lower than that of the nitrile 1-cyano-2-phenylethane, and no lethal effects were obtained with the glucosinolate sinigrin at the concentrations tested.

DISCUSSION

D. brassicae mortality rates were higher on *B. juncea* and *B. nigra* than on *B. napus* and *B. campestris* in a previous host suitability test (Åhman, 1981). Results from the present study imply that this differential mortality may have been due to the higher release of ITCs from *B. juncea* and *B. nigra* (Cole, 1976). The most toxic compound, 2-phenylethyl ITC, occurs in all four plant species, but *B. juncea* and *B. nigra* additionally release comparatively large amounts of allyl ITC (Table 1). However, female oviposition behavior might reduce egg exposure to potentially toxic hole exudates. For example, fewer eggs were laid on *B. juncea* and *B. nigra* than on *B. napus* and *B. campestris* in preference trials (Åhman, 1981, 1985b), implying that host use patterns may

be affected by the host's glucosinolate profile; however, differential oviposition behavior need not necessarily rely on such compounds as cues.

In addition, the female may reduce the exposure of her eggs to autolysis products from the damaged pods by using her long ovipositor to place eggs at a distance from the holes. Such behavior was suggested when two previous host suitability tests (Åhman, 1981, 1985a) using different egg transfer techniques were compared. In the study where mortality rates differed between *Brassica* spp. (Åhman, 1981), eggs in NaCl–water solution were injected into the pods with a syringe through small holes in the pod walls. In the other study, V-shaped scars were made in the pods, and the eggs were placed away from those scars with a fine-tipped brush (Åhman, 1985a). In this latter case, there was no significant difference in egg mortality between the two test species, *B. napus* and *B. juncea*. The eggs were probably more exposed to potentially toxic plant juices in the first injection-transfer than in the V-scar transfer. Furthermore, females may avoid oviposition in recently made holes, where concentrations of breakdown products are likely to be high.

2-Phenylethyl glucosinolate (or probably rather the ITC, produced when this glucosinolate is broken down) seems to be a particularly toxic compound to many insects, including crucifer specialists. It was one of the two glucosinolate compounds toxic to the crucifer specialist *Plutella maculipennis* Curtis when tested in diets at concentrations where other glucosinolates were not toxic (Nayar and Thorsteinson, 1963). Furthermore, in a field study, *Cardamine cordifolia* plants without crucifer-adapted chrysomelids on them were characterized by a particularly high content of that compound (Louda and Rodman, 1983a). Moreover, insecticidal actions of various macerated crucifer roots and root extracts, against insect species which do not feed on crucifers, have been attributed to the high release of 2-phenylethyl ITC from those roots (Lichtenstein et al., 1962, 1964; Lowe et al., 1971).

Not only was survival of *D. brassicae* eggs transferred to *B. nigra* and *B. juncea* lower than that of eggs transferred to *B. napus* and *B. campestris*, but larval weights were also lower on *B. juncea* and *B. nigra* (Åhman, 1981, 1985a). To ensure that the lower larval weights were not a result of delayed egg hatching, recently hatched larvae (instead of eggs) were transferred to *B. napus* and *B. juncea* using the V-scar technique. This test also showed larval weights to be significantly lower on *B. juncea* (I. Åhman, unpublished results). Thus, apart from being potentially lethal to *D. brassicae* eggs, *B. juncea* and *B. nigra* also have negative effects on larval growth. These adverse effects may be caused by their high ITC release and restrict *D. brassicae* from using them as hosts.

Acknowledgments—I thank chemists at the Department of Organic Chemistry, Royal Institute of Technology, Stockholm, for synthesizing the compound 1-cyano-2-phenylethane. I also thank Prof. J. Pettersson, Dr. C. Solbreck, and Dr. D. Tilles for commenting the manuscript. This work was partly refunded by Riksbankens Jubileumsfond.

(Received July 12, 1985; accepted October 15, 1985)

Abstract—A sex pheromone of the sweetpotato weevil, *Cylas formicarius elegantulus* (Summers), was obtained from collections of volatiles from virgin females, and pheromone was isolated by means of liquid and gas chromatography. The purification procedure was monitored by quantitative laboratory and field bioassays and the compound was identified as (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate by means of spectroscopic and microchemical methods. Synthesis, followed by laboratory and field bioassays, showed that the biological activity of the synthetic material was qualitatively and quantitatively indistinguishable from that of the purified natural product.

Key Words—*Cylas formicarius elegantulus*, sweetpotato weevil, sweet potato, (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate, sex pheromone.

INTRODUCTION

Sweet potato is the sixth most important crop in the world (Anonymous, 1981) and is surpassed in importance as a root crop only by the potato (Martin, 1983). Most sweet potatoes are grown in the tropics, and there the sweetpotato weevil, *Cylas formicarius elegantulus* (Summers), is the limiting factor to both production and storage of this crop. This pest occurs in all parts of the tropics where sweet potatoes are grown and in many temperate zones as well. Very low level pre- or postharvest infestations reduce both quality and marketable yield (Pros-

hold, 1983), and extremely bitter tasting and toxic sesquiterpenes produced by the potato tissue in response to insect feeding can render the commodity unfit for consumption (Akazawa et al., 1960; Uritani et al., 1975). Losses due to such infestations and diseases that often follow weevil attack are estimated at 35–95% (Anonymous, 1978).

Presently, there is no suitable method for the detection of low-level infestations; by the time insects are seen on the crop, considerable damage has already been done. The underground feeding habits of the larvae and the nocturnal activity of the adults make it difficult for farmers to make effective use of pesticides. Thus, there is a need for a sensitive detection tool to aid the grower in managing and controlling infestations of the sweetpotato weevil (Coffelt et al., 1978).

It is established that insect pheromones can often be used to locate, survey, or monitor pest populations at levels not otherwise detectable (see Klassen et al., 1982). We report here the isolation and identification of a sex pheromone, (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate, obtained from female sweetpotato weevils and the response of conspecific males to the synthesized pheromone in the laboratory and in the field.

METHODS AND MATERIALS

Insect Rearing and Handling. Insects were reared in the laboratory on commercially obtained sweet potatoes at 26 ± 1°C and 60 ± 5% relative humidity under a 14:10 (light–dark) photoperiod using the procedures described by Coffelt et al. (1978). Virgin insects were obtained (females for pheromone collection and males for use in bioassays) by separating male and female weevils within 24 hr of eclosion. Adults were maintained, prior to testing, for 5–7 days in groups of 50–75 in 100 × 15-mm glass Petri dishes with bottoms lined with Whatman No. 1 filter paper. During this period, males and females were kept in separate growth chambers with environmental parameters identical to those used for insect rearing. Adults were provided a small slice of sweet potato every 48 hr.

Pheromone Collection. Pheromone collections were made by drawing air over virgin female weevils that were confined in a 10.5-liter (24.5 × 22.2 cm diam.) glass jar. Each jar contained 1500–2000 females and one sweet potato. House vacuum (120mm Hg) was used to pull ambient air through the unit at 2 liters/min. The units were kept in a laboratory hood within a room maintained at 26 ± 1°C and 65 ± 5% relative humidity and a 14:10 (light–dark) photoperiod. Volatiles emanating from the unit were entrained using two glass adsorption traps (1.5 × 8 cm) each containing 2.0 g Chromosorb 102 (60–80 mesh). Prior to use, the adsorbent was eluted with 100 ml of reagent-grade diethyl ether.

Volatiles were collected continuously over a 30-day period for a given

batch of insects. Pheromone was collected at 48-hr intervals by eluting the entrained volatiles with 5–7 ml of pentane–ether (90:10). A fresh potato was placed in the unit at this time. During the course of this study, approximately 850,000 female equivalent days (FED) were collected.

Laboratory Bioassay. Samples were bioassayed using the procedure described by Coffelt et al. (1978). Briefly, 3–5 μl of test extract were pipetted onto the flattened end of a glass rod and then exposed to a series of ten males that were held individually in 1.6 × 5-cm Teflon-coated shell vials. The treated rod was suspended within 1 cm of the test insect for a period not greater than 15 sec. A positive response, defined as antennal elevation and locomotion, was taken as evidence of the presence of pheromone. Rods treated with solvent only served as controls, and exposure of a single rod to 10 males constituted one replication. This bioassay was employed only after initial studies revealed that only those fractions that elicited the above responses were attractive to males in the field. All laboratory bioassays were conducted under Cool-White fluorescent room lighting at 26 ± 2°C during the latter half of the photophase using males that were between 7 and 30 days of age. Pheromone units are expressed in terms of FED, one FED being the estimated quantity of pheromone obtained from one female per 24-hr period. The collected volatile material and all fractions obtained in the purification of the pheromone were bioassayed at 10^{-1}, 10^{-2}, 10^{-3}, and 10^{-4} FED.

Field Tests. Field bioassays were conducted in February–August 1984 in 0.2-hectare plots of sweet potato at the Federal Experiment Station, St. Croix, U.S. Virgin Islands.

In the first series of tests (February 1984), unpurified volatiles that contained pheromone, partially purified material (active fractions from HPLC) and purified material (from the Carbowax 20 M GC column) were compared to determine whether any loss of attractiveness to feral males occurred as a consequence of the indicated fractionations.

Doses of 0.0, 0.2, 2.0, and 20 FED in 50 μl hexane were applied to 22 × 22-mm glass cover slides. After solvent evaporation, the cover slides were placed in the center of a 100 × 15-mm Teflon-lined Petri dish (cover slides elevated 16 mm above floor of dish). Dishes were placed at the center of individual 50 × 50-cm wooden platforms raised to the plant canopy height (15–20 cm). The number of males on the platform and in the dish (< 15 mm from source) within 5 min of deployment of the sample were recorded and taken as evidence of response. All tests were conducted between 1930 and 2145 hr Atlantic ST at temperatures ranging from 20.5 to 22.2°C.

Platforms were deployed at 2-m intervals in a line approximately perpendicular to the prevailing easterly wind direction. Treatment locations were randomized within plots, and a total of nine replications were made in three different plots over several nights, with no plot being used for more than one replication per night. Cover slides treated with hexane only served as controls.

The second series of field bioassays was conducted in March and September 1984 to compare the relative attractiveness of the purified natural product with synthetic pheromone (>99% purity). Doses treated were 0.0, 0.08, 0.8, 8.0, and 80 ng/50 μl, and the material was formulated on glass slides. Additionally, the purified natural material was compared with synthetic pheromone when formulated on rubber septa (A.H. Thomas No. 8753-D22). The material was dissolved in 100 μl of hexane and pipetted into the large reservoir of the septum cap. Septa were loaded with 10, 30, 100, and 300 ng of material and aged a minimum of two days prior to use. Septa treated with hexane served as controls. Septa were positioned about 3 cm above the floor of the Petri dish with a paper clip. Test duration was 20 min. There were four replications at each dose in two different plots on different days. Within plots, treatment locations were randomized between replications. Treatments were randomized within plots, and two plots were used. Other parameters were as in the previously described field bioassay.

The third series of field bioassays was conducted in August 1984 to identify the nature of the relationship between the applied dose of synthetic pheromone (>99% purity) and the number of feral males attracted. Bioassays were similar to those previously described, and the pheromone was formulated on rubber septa in doses of 0, 1, 10, 100, or 1000 ng (eight replications).

Isolation. After excess solvent was removed from the collected volatiles at 25°C with N_2, the concentrate was chromatographed on a gravity-flow glass column (15 × 1 cm ID) prepared by slurry packing 5.0 g of 60–100 mesh silica (J.T. Baker Chemical Co., Phillipsburg, New Jersey). Solvents used for the gravity flow column included 5% ether–hexane (80 ml) and 10 and 20% ether–hexane (80 ml each). The active fractions from the gravity flow column were concentrated and injected onto a high-performance liquid chromatography (HPLC) column (250 × 4.4 mm ID) packed with 5 μm silica (Lichrosorb (Si-60). The HPLC column was eluted with 2% ether in hexane at a flow rate of 2.0 ml/min. Ten fractions (2 ml each) were collected. An additional 20 ml of 5% ether–hexane was used to remove the (inactive) polar material from the column. The active fractions from the HPLC column were combined, concentrated, and further purified by gas–liquid chromatography (GLC).

All micropreparative GLC was performed with a Varian model 1400 gas chromatograph equipped with a flame-ionization detector. The effluent from the packed columns was split with 2% of the effluent routed to the detector, and 98% collected in cooled, 30-cm glass capillary tubes (Brownlee and Silverstein, 1968).

The initial column used for further purification of the active material from HPLC was a 2 m × 2.3 mm ID glass column packed with 5% OV-101 on 80–100 mesh Chromosorb G-HP. Helium was used as the carrier gas at 20 ml/min, and the column temperature was programmed from 120 to 220° at 10°/min.

The active fraction collected from the OV-101 column was subsequently chromatographed on a 1.8 m × 2.0 mm ID glass column packed with 4.4% Carbowax 20 M on 120–140 mesh Chromosorb W operated isothermally at 180°C. Helium was used as the carrier gas at 20 ml/min.

All analytical GLC was performed with a Hewlett-Packard model 5790 gas chromatograph equipped with a flame ionization detector and a splitless capillary injector. Output from the detector was interfaced to a Nelson 4416 data system. The active fraction from the Carbowax packed column was analyzed on the following fused silica capillary columns: 50 m × 0.25 mm ID BP-1 methyl silicone (Scientific Glass Eng., SGE); 50 m × 0.25 mm ID Carbowax 20 M; 50 m × 0.25 mm ID CPS-1 (equivalent to SP-2340); and a 35 m × 0.25 mm ID soft glass column coated with cholesteryl-*p*-chlorocinnamate (Heath and Doolittle, 1983). Helium was used as the carrier gas for all columns at a linear flow of 18 cm/sec.

Identification. The active component was identified by chemical ionization mass spectrometry (CI-MS) and by Fourier transform proton nuclear magnetic resonance (FT-PMR). Additional structural information on the active compound was derived from the mass spectra of the products from microozonolysis.

Mass spectra were obtained with an upgraded Finnigan 1015/3200 chemical ionization mass spectrometer coupled with a Varian 1400 gas chromatograph and a user-designed splitless injector. Fused silica capillary columns used in the gas chromatographic inlet system included a 50 m × 0.25 mm (ID) methyl silicone (BP-1) and a 50 m × 0.25 mm (ID) Carbowax 20 M (Quadrex) column. Helium was used as the carrier gas at a linear flow of 18 cm/sec. Reagent gas, either methane or isobutane, was introduced as make up gas. The ['H]NMR spectra were obtained with a Nicolet 300-MHz Fourier transform spectrometer. Approximately 4 μg of the purified compound was placed in a 70-μl external capillary extension tube (Wilmad, Buena, New Jersey) containing 15 μl of deuterated benzene. Two thousand transients were collected over a 1-hr period using a 6-μsec pulse (90° tip angle). Proton decoupling was accomplished by standard decoupling techniques (decoupler power ca. $\frac{1}{2}$ watt) and 4000 transients spectra were obtained over a 2-hr period.

Microozonolysis of the pheromone (50 ng each experiment) was carried out in CS_2 or hexane at −70°C, and the ozonide was reduced with triphenylphosphine (Beroza and Bierl, 1967). The ozonolysis products were analyzed by CI-MS. Synthetic standards were used to confirm the ozonolysis products and also to verify the spectral data.

Synthesis The synthesis of (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate, I, was initiated with the preparation of 3-dodecen-1-ol from 1 decyne (Figure 1).

For the synthesis of 3-dodecyn-1-ol, n-butyllithium II, (9.3 ml of 2.7 M in hexane) was injected into a cooled (≤0°C) solution of 1-decyne (4.5 ml, 25 mmol), in dry tetrahydrofuran (THF, 36 ml) under nitrogen. Ethylene oxide

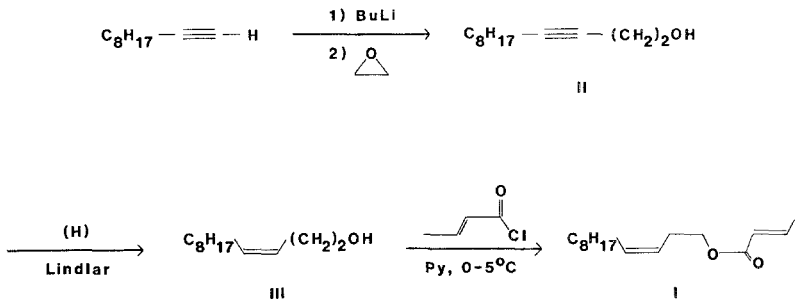

FIG. 1. Synthesis of (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate.

(1.5 ml, 30 mmol) was injected from a precooled syringe, and then hexamethylphosphoric triamide (9 ml, ca. 2 equiv.) was injected. The resulting mixture was stirred overnight at ambient temperature and then worked up by dilution with water and extraction with hexane. The product alcohol was distilled under reduced pressure to give 3.45 g (77.5%): bp 74–79°C/0.05 mm; IR (CCl_4) 3640 cm^{-1}; NMR δ 0.88 (3H, t, CH_3), 1.27 (CH_2 envelope), 2.18 (2H, m, $CH_2\underline{CH_2}C{\equiv}C$), 2.41 (2H, m, $HOCH_2\underline{CH_2}C{\equiv}C$), 3.67 (2H, m, $\underline{CH_2}OH$) ppm.

To synthesize (*Z*)-3-dodecen-1-ol, III, alkynol II (3.25 g, 17.9 mmol) was hydrogenated over 30 mg of Lindlar catalyst prepared according to Mozingo (1955). The reduction was carried out in pentane (35 ml) at atmospheric pressure and ambient temperature. The reduction was monitored by gas chromatography using a 25-m (0.25 mm ID) fused silica capillary column coated with CPS-1 (Quadrex Corp.). After filtration and concentration, the alkenol III was distilled under reduced pressure to give 2.87 g (88.3%): bp 67–70°C/0.05 mm, IR (CCl_4) 3300 broad, 1050 cm^{-1}; NMR δ 0.88 (3H, t, CH_3) 1.27 (CH_2 envelope), 2.05 (2H, m, $\underline{CH_2}C{=}C$), 2.33 (2H, m, $HOCH_2\underline{CH_2}C{=}$), 3.64 (2H, m, $\underline{CH_2}OH$), 5.38, 5.55 (2H, m's, *cis* olefinic H).

To synthesize (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate, I, crotonyl chloride (5.7 ml of 90% technical grade, 59.4 mmol) and alkenol III (8.75 g, 47.5 mmol) were dissolved in methylene chloride (CH_2Cl_2, 90 ml) and cooled in an ice bath. Pyridine (3.8 ml, 47.5 mmol) was added in CH_2Cl_2 (10 ml) dropwise. The resulting mixture was stirred cold for 1 hr and then worked up with water and CH_2Cl_2. The organic phase was dried ($MgSO_4$) and concentrated. The yield of crude ester (12.0 g) was nearly quantitative. Distillation of 6.0 g of crude product under reduced pressure gave 5.1 g (84%) of I containing less than 10% of the isomeric 3-butenoate ester: bp 105–109°C/0.1 mm; IR (CCl_4) 1720 (C = 0), 1660 (C = C) and 970 cm^{-1} (*trans* HC = CH).

The distilled synthetic material was purified on a 5-μm silica gel HPLC column (25 cm × 4.4 mm id) using 2% ether–98% hexane. This HPLC-purified material was then further purified using a 20% $AgNO_3$ silica gel HPLC

column, 25 cm × 1.25 cm OD and was eluted with toluene. This material was analyzed by capillary GC on the same columns mentioned earlier.

RESULTS AND DISCUSSION

Positive laboratory bioaassay responses were obtained only to volatile collections from females; males did not respond to volatile collections from empty containers, containers holding a sweet potato, containers holding male weevils (or males with potato). Females did not respond to any of these preparations. Additional studies showed that more pheromone was obtained from volatile collections from females plus sweet potato than from females only.

The isolation of the SPW female pheromone required a sequence of four chromatographic separations: (1) silica (gravity flow), (2) HPLC, (3) GLC (OV-101), and (4) GLC (Carbowax 20 M).

Beginning with the crude materials, and continuing through the purification, all materials (combined, active and inactive fractions) were bioassayed in serial dilution (6–10 replicates per concentration) in the laboratory (Fig. 2A) to ensure that no loss in activity had occurred. In addition, field bioassays of the crude, HPLC, and the GLC Carbowax samples were conducted to ensure that no loss of activity in the field occurred as a result of the separation performed. Results of these field bioassays are summarized in Figure 2B. The dilution series obtained for the gravity flow silica column and for the micropreparative GLC samples from the OV-101 column and the inactive fractions are omitted from Figure 2 for simplicity. For all comparisons, including the series not shown, there was no indication of loss of biological activity in either field or laboratory bioassays, and in all analyses, the regression data are significant at the 1 or 5% level.

Laboratory bioassays indicated all of the activity of the initial collections was recovered in the 5% ether–hexane eluant (80 ml) from the gravity flow silica column. No increase in activity was observed by the addition of the more polar components that were obtained by further elution with 10 and 20% ether–hexane. The active fractions from several gravity flow runs were combined and subsequently purified by HPLC. The biologically active fraction from HPLC eluted between a column capacity ratio (k') of 3.67 and 4.33. As shown in Figure 2, no loss of activity relative to the crude material was noted over a range of concentrations either in the laboratory or the field bioassay.

The active material that was obtained from the HPLC column was then further purified by GLC on a packed OV-101 column. All biological activity was contained within a 2-min fraction with a Kovats Index (KI) of 1780–1800 (Kovats, 1965). No increase or decrease in biological activity was observed when the active fraction was recombined with other GLC fractions and subsequently bioassayed over a range of 1×10^{-4} to 1×10^{-1} FED in the laboratory.

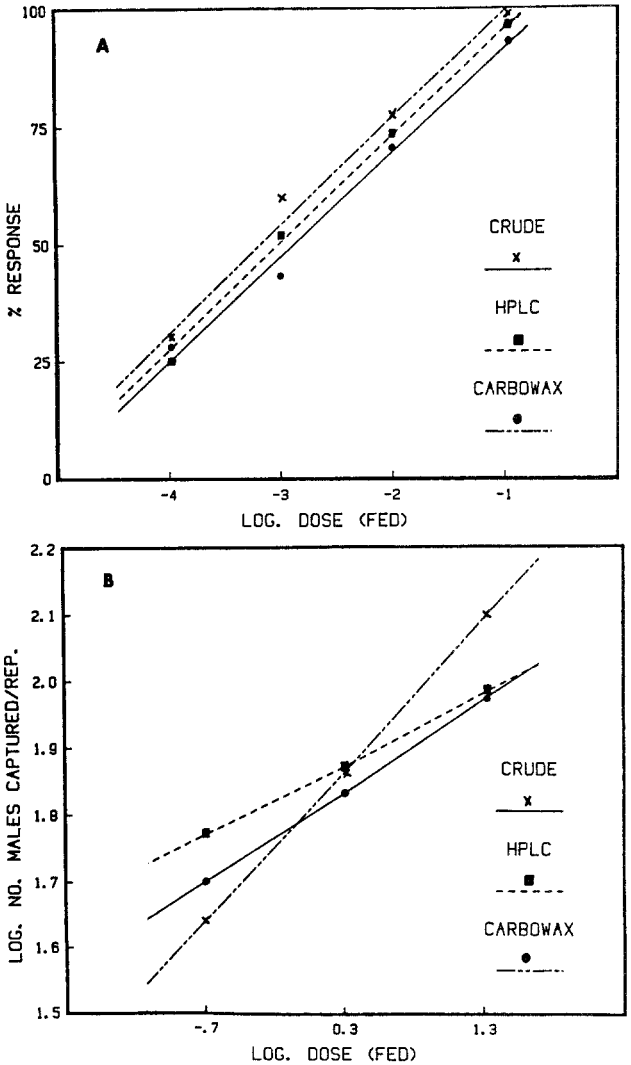

FIG. 2. Laboratory (A) and field (B) responses of *C. f. elegantulus* males to progressive isolates of female sex pheromone. (A) Average of nine replicates/point, (B) average of 6–10 replicates/point, February 1984, St. Croix, U.S. Virgin Islands.

Further purification on a Carbowax 20 M column yielded a single peak with KI = 2200 that produced full activity in laboratory and field bioassays (Figure 2A,B). Quantitative analysis of this material indicated that a FED was equivalent to ca. 4 pg. The active peak from the Carbowax 20 M column was found to be >99.8% pure when analyzed on the CPS-1, Carbowax 20 M, OV-101, and the cholesteryl-*p*-chlorocinnamate capillary columns.

The isobutane CI mass spectrum (Figure 3A) established that the molecular weight of the pheromone was 252 with diagnostic peaks at *m/e* 251 (M − 1), 253 (M + 1), and 254 (M + 2). The fragment ion at *m/e* 167 (M + 1 − 86) suggested the loss of butenoic acid ($C_4H_6O_2$) from the parent molecule. The methane CI mass spectrum (Figure 3B), in addition to showing a peak at (M + 1 − 86), provided a base peak at *m/e* 87 [$C_4H_7O_2^+$] consistent with protonated butenoic acid. Based on the mass spectral data the structure was proposed as a butenoate of a 12-carbon alcohol which contained one degree of unsaturation. Ozonolysis of the pheromone (ca. 50 ng/ozonolysis) produced two major products that were identified as nonanal and decanal (1 : 0.8, respectively) (see below) by comparison of their retention times on a 50-m CW-20M capillary column and their mass spectra with synthetic standards.

High-field 300-MHz PMR with decoupling experiments provided the spectral information needed for structure elucidation of the pheromone. The spectrum (Figure 4) indicated four olefinic protons. The proton giving rise to the signal at δ = 7.03 (1H sextet) was coupled (Table 1) to the olefinic proton at δ = 5.95 (1H, d, J = 15.6) and the methyl protons of δ = 1.43 (3H, d). Thus the crotonate moiety, $0{=}C{-}C\underline{H}{=}C\underline{H}{-}C\underline{H_3}$, was established. The olefinic proton δ = 5.41 (1H m) was coupled to the methylene protons at δ = 2.44 (2H, q), which also were coupled to the methylene protons at δ = 4.22 (2H, t), $CH{=}C\underline{H}{-}CH_2{-}C\underline{H_2}{-}0$. Thus the position of the olefinic bond in the alcohol chain was unequivocally established as being in the three position. The olefinic proton δ = 5.60 (1H, m) was coupled to the methylene protons at δ = 2.12 (2H, m) and the olefinic proton at 5.41 (1H, q, J = 1.01). The methylene envelope δ = 1.40 (12H, m) and the methyl protons δ = 1.05 (3H, t) are consistent with a heptyl moiety. Examination of PMR spectra of synthetic samples of (*Z*)- and (*E*)-3-dodencen-1-ol and the methyl esters of (*Z*) and (*E*)-2-butenoate indicated that the geometry of the olefinic bonds were (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate.

In addition to (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate, the other three possible geometric isomers were synthesized. All four isomeric forms are adequately resolved on a 50-m CPS-1 (Quadrex) capillary column and the isolated natural pheromone had a retention time identical to that of the synthetic (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate. The synthetic (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate was 99+% pure and identical to the natural material by all analytical procedures.

PMR and capillary GC data established that only one compound identical to the synthetic (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate had been isolated as the natural pheromone. Ozonolysis of the synthetic pheromone also produced the same two aldehyde products (nonanal and decanal) that were produced by ozonolysis of the natural pheromone material. We are currently investigating the source of the artifact aldehyde, decanal, that is reproducibly generated in this ozonolysis. Crotonate esters of alkenols in which the double bond is situated more remotely from the alcohol oxygen undergo ozonolysis to give the predicted aldehyde only.

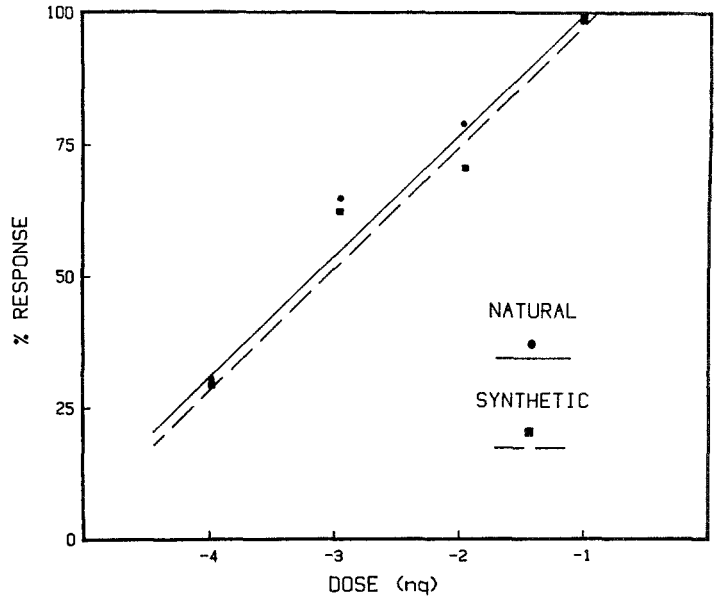

FIG. 5. Laboratory response of *C. f. elegantulus* males to purified natural pheromone and synthetic pheromone (6–10 replicates/point).

Quantitative bioassays comparing the relative activity of the purified natural product and the synthetic material were conducted in the laboratory and in the field. Figure 5 summarizes the results of the laboratory study (6–10 replications at four different dosages for each material). No measurable difference between the two materials was observed. The relative activity, in terms of male attraction in the field, is shown in Figure 6. Two release substrates, glass (Figure 6A) and rubber (Figure 6B), were used, and the similarity in response is shown in the figures. The response of feral males to septa loaded with a higher amount of the synthetic material is shown in Figure 7. Controls did not capture a significant number of weevils in any test.

The biological and chemical data presented in this paper provide evidence that (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate is the major component of the female-produced sex pheromone of *C. f. elegantulus*. Additionally, the similarities in male sweetpotato weevil response in the field to natural crude volatiles and synthetic material, at levels as low as 0.08 ng of this compound, demonstrated that (*Z*)-3-dodecen-1-ol (*E*)-2-butenoate is qualitatively and quantitatively equal to the pheromone volatilized by females. Although Coffelt et al. (1978) reported three areas of activity based on liquid chromatography of extracts of filter paper that had been exposed to female sweetpotato weevils, we found only one active compound in our analysis of volatiles collected from sweetpotato weevil females.

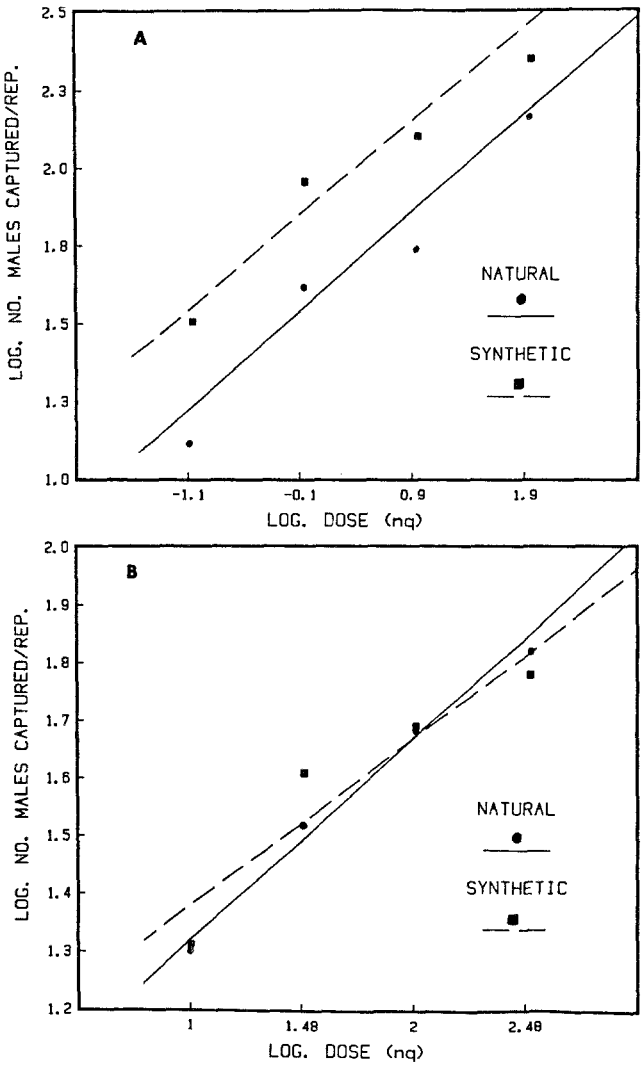

FIG. 6. Field bioassay—isolated natural vs. synthetic pheromone; (A) substrate is glass (nine replicates/point); (B) substrate is rubber septa (eight replicates/point). Tests done in March and September 1984, St. Croix, U.S. Virgin Islands.

Unlike pheromone components that have been described for many Coleoptera species, apparently the material functions as a sex pheromone in that it is produced by one sex and elicits an overt series of behaviors (activation, orientation, homosexual movements) only by the opposite sex. To our knowledge, this appears to be the first case of a crotonate ester being identified as an insect pheromone.

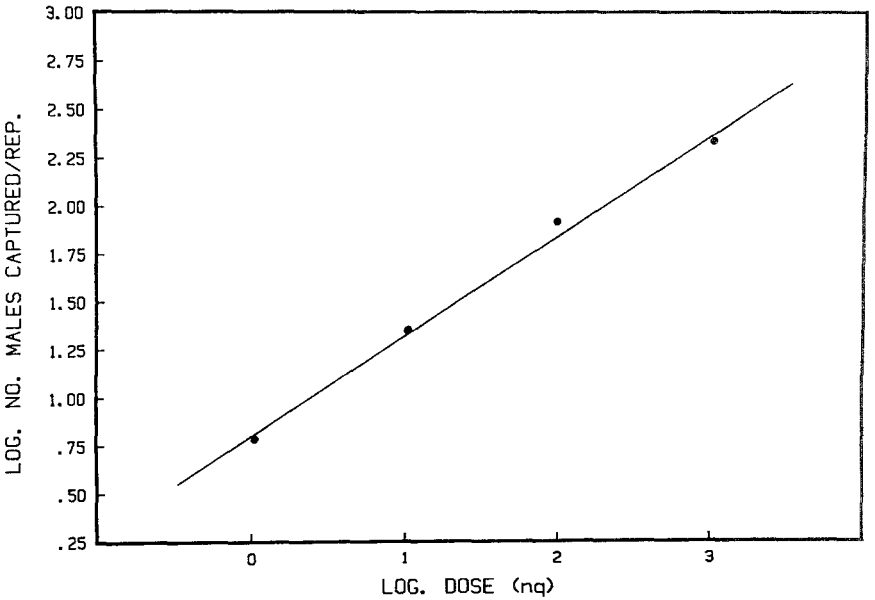

FIG. 7. Dose–response of *C. f. elegantulus* males to (Z)-3-dodecenol-1-ol (*E*)-2-butenoate formulated in rubber septa (eight replicates/point). Tests done in August 1984, St. Croix, U.S. Virgin Islands.

Finally, the availability of this material provides a tool that can be developed to monitor, detect, and perhaps manipulate populations in commercial plantings of sweet potato.

Acknowledgments—We express our thanks to A.T. Proveaux and Wayne McClellan of this laboratory for their assistance. We are also indebted to Cleofe Ascensio and Jose Gonzalez at the St. Croix Laboratory for their assistance in the field experiments.

Abstract—The responses of a sunflower specialist, *Homoeosoma electellum*, the sunflower moth, to the terpenoids produced by its host plant, *Helianthus*, were measured. Larvae were reared on synthetic diet containing one of three concentrations of the dominant sesquiterpene lactone found in glandular trichomes of *H. maximilliani*. Treatments were initiated at each of three larval ages. Pupal weight was significantly reduced, but the effect diminished as the larvae aged. Survival and development time were unaffected by various treatments. In behavioral tests, larvae showed no preference for untreated synthetic diet compared to diet containing the secondary compound at a concentration of 1% by dry weight. When the concentration was raised to 5%, all but last-instar larvae showed a significant preference for the untreated diet. A second behavioral test measured the damage done to whole florets and an array of floral parts offered to larvae of different ages. The damage pattern of floral tissues changed as the larvae grew older, demonstrating that the willingness of larvae to eat tissues contaminated with trichome contents increased with age. The value of the glandular trichome contents as a defense against *H. electellum* is discussed.

Key Words—Chemical defense, feeding behavior, glandular trichomes, *Helianthus*, herbivory, *Homoeosoma electellum*, Lepidoptera, Pyralidae, host-plant resistance, plant–insect interactions, sesquiterpene lactones, terpenoids.

INTRODUCTION

The ability of specialist herbivores to feed without apparent ill effect on plants containing toxic constituents is often attributed to specific physiological adaptation which enables them to ingest the toxic compounds of their hosts without being poisoned. For example, some specialized herbivores excrete, metabolize, or sequester various plant toxins (Dauterman and Hodgson, 1978; Brattsten, 1979; Duffey, 1980; Blum, 1983; Dowd et al., 1983; Rhoades, 1983), and it is frequently assumed that many other specialist herbivores possess similar abilities. The extent to which these herbivores use behavior rather than physiological mechanisms to avoid deleterious amounts of debilitating compounds has received comparatively less attention. There are a few reports showing that specialists feed preferentially on plant parts with relatively low toxin concentrations (Krischik and Denno, 1983; Schuh and Benjamin, 1984) and that behavior such as petiole or vein cutting prior to feeding on leaf tissue reduces mobilization of secondary compounds (Carroll and Hoffman, 1980; Rhoades, 1983). These reports suggest the need to characterize both behavioral and physiological mechanisms when investigating the relationship between a specialist herbivore and the secondary compounds of its host. Our study highlights the importance of behavior during the larval life of the sunflower moth, *Homoeosoma electellum* (Lepidoptera: Pyralidae), in the face of its changing ability to grow on a diet containing the secondary compounds of its host.

We designed a series of experiments to measure both behavioral and growth responses of *H. electellum* to a major group of secondary metabolites of *Helianthus* in order to discover how this insect is able to feed successfully on sunflowers without being poisoned. The sunflower moth specializes on the inflorescenes of several genera of the Asteraceae, including several species of *Helianthus*, the sunflower (Teetes and Randolph, 1969a; Schulz, 1978). This insect is a significant pest of the cultivated sunflower which is a variety of *H. annuus* (Carlson, 1967; Heiser et al., 1969).

Our experiments were designed to answer these specific questions: (1) Does the concentration of the major secondary compound in the diet have an effect on (a) larval fitness as manifested in survival, development time, and pupal weight or (b) larval behavior as expressed in feeding preference and damage patterns to various floral tissues? (2) Are these effects on fitness and behavior affected by the age at which a larva encounters a particular concentration of its host's secondary compounds? In brief, we found both dose-dependent and age-dependent effects in the larvae on pupal weight, feeding preference, and acceptability of floral tissue.

METHODS AND MATERIALS

Chemical Defenses in Helianthus. Species of *Helianthus* produce a variety of terpenoid secondary metabolites, including high concentrations of sesquiter-

pene lactones and diterpene carboxylic acids (Gershenzon et al., 1981). These compounds are often localized in glandular trichomes which are found on the surfaces of leaves, young stems, and parts of the inflorescence including the phyllaries, the ray corollas, and the terminal appendages of the anthers (Gershenzon, 1984). The florets of both *H. maximiliani* and *H. annuus* (wild), the two species used in our experiments, have a dense trichome area on the terminal appendages of the fused anthers. *H. maximiliani* has a density gradient of trichomes across three quarters of the anthers' length with the greatest density at the top (Figure 1). We did not directly measure the terpenoid concentrations at different points along this gradient. However, we know that in unopened florets (i.e., preanthesis) concentations of the major terpenoid, a sesquiterpene lactone, 8β-sarracinoyloxycumambranolide (8β-SC) (Figure 2a), approaches 10% at the anther tips and averages 0.01–1.0% (dry weight) on the rest of the anther.

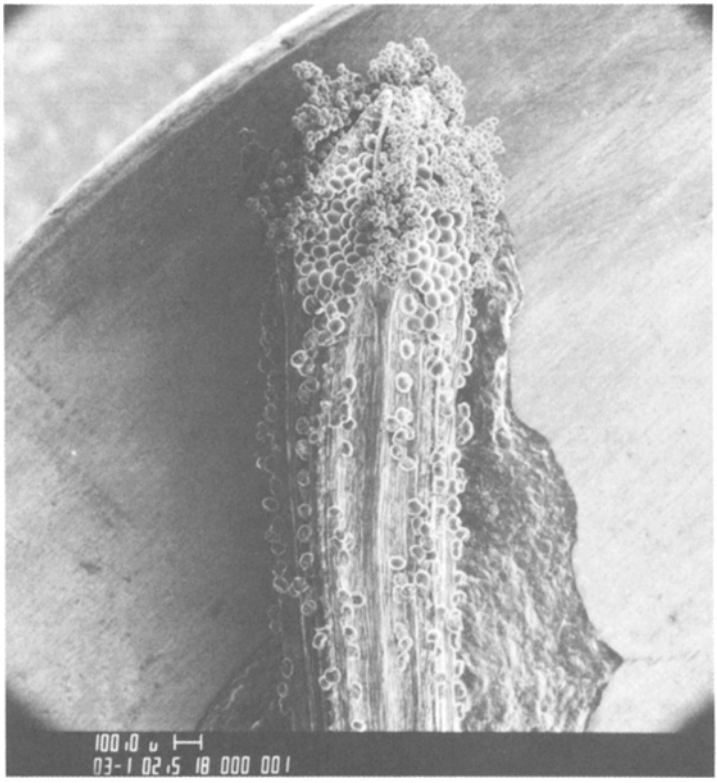

FIG. 1. Fused anther dissected from a preanthesis floret of *H. maximiliani* electron micrograph (SEM) of fresh, unfixed material, taken at 2.5 kV accelerating potential; 30×. Large spherical structures are trichomes, smaller spheres at the anther tip are pollen grains. Courtesy of G. Kreitner.

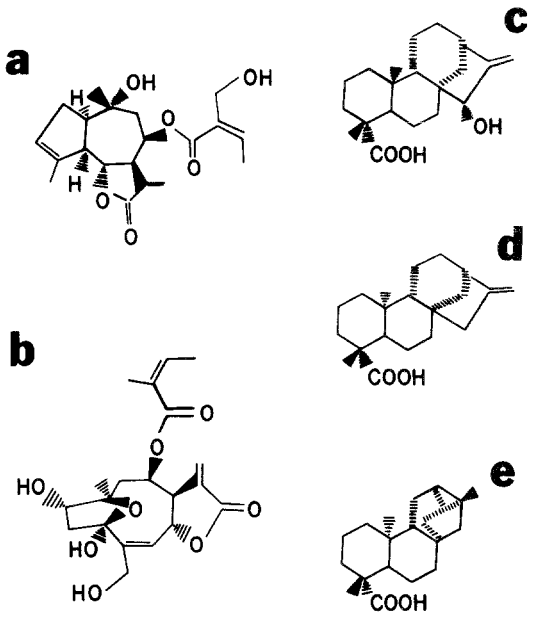

FIG. 2. Some sesquiterpene lactones and diterpene acids of *Helianthus*: (A) 8β-sarracinoyloxycumambranolide, *H. maximiliani*; (B) niveusin A, *H. niveus*; (C) grandifloric acid, *H. annuus*; (D) kaurenoic acid, *H. annuus*; (E) trachylobanic acid, *H. annuus*.

During anthesis, the contents of trichomes can be smeared down the sides of the fused anthers and also contaminate the inner tip of the corolla tube as the anthers push through the top of the corolla tube. This was verified with electron micrographs of florets (G. Kreitner, personal communication). In light of the density pattern of trichomes on the floret and the smearing of trichomes contents during anthesis, we infer that, after anthesis, the upper portion of the fused anthers holds concentration gradients of 8β-SC ranging from 10% at the tip reaching 0.01–1.0% near the bottom.

The glandular trichomes of *H. maximiliani* contain principally sesquiterpene lactones (Gershenzon and Mabry, 1984), while the constituents of *H. annuus* trichomes are principally diterpenoids, with sesquiterpene lactones present in lower quantities (Melek et al., 1985). Sesquiterpene lactones are bitter, colorless compounds found chiefly in members of the Asteraceae (Seaman, 1982). Previous work has shown them to be toxins, growth inhibitors, and feeding deterrents to a number of phytophagous insects (Burnett et al., 1974; Nakajima and Kawazu, 1978; Pettei et al., 1978; Picman et al., 1978; Jones et al., 1979; Doskotch et al., 1980; Ganjian et al., 1983; Nawrot et al., 1983). Diterpene acids, which are widely distributed in conifers, legumes, and composites have also been reported to act as insect toxins and growth inhibitors (Elliger et al.,

1976; Waiss et al., 1977; Singh et al., 1979; Rose et al., 1981; Wagner et al., 1983; Schuh and Benjamin, 1984).

Sunflower Infloresence and Life Cycle of Sunflower Moth. Maturation of a sunflower inflorescence begins at the outer ring of florets and spirals inward. The entire process requires 5–10 days in wild species (Knowles, 1978), and up to 16 days in cultivars depending on environmental conditions and head diameter (Griffiths and Erickson, 1983). The maturation of an individual floret, anthesis, proceeds from the male to female stage (see Figure 3). In the male stage, the fused anthers rise from the corolla, and pollen which has been shed inside the anther tube (formed from the fused anthers) is pushed up and out of the tube by the rising style. In the female stage, the style branches unfold, exposing the now-receptive stigmatic surfaces.

The female sunflower moth deposits one to a few eggs among disk florets after anthesis has begun on the inflorescence. On average, eggs hatch 48 hr later. The developing larva passes through five instars in 18–20 days. When reared on the cultivated sunflower, early second-instar larvae feed principally on pollen, while later second and third instars feed on a variety of floral parts including pollen, corollas, styles, and ovaries. Fourth and fifth instars feed mainly on the developing achenes, although they do considerable damage to other floral parts and the receptacle. Pupation occurs in the soil and lasts either eight days or through the winter, depending on season and latitude (Randolph et al., 1972; Rogers, 1978a; Archer et al., 1981).

Both the herbivore and the two sunflower species used in these experiments

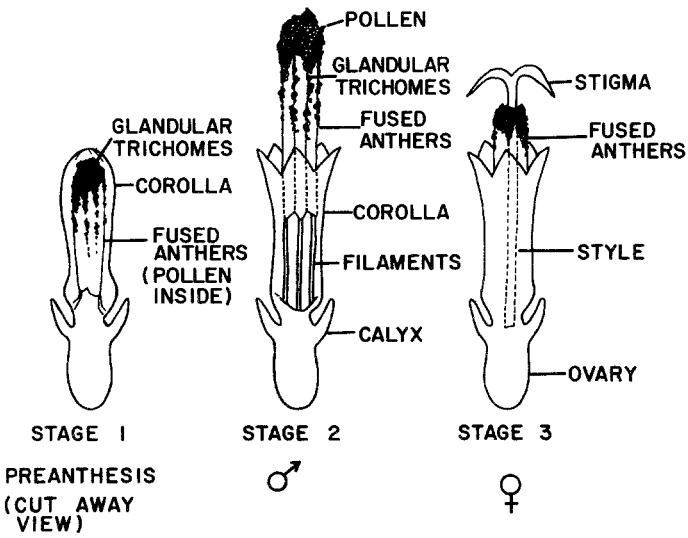

FIG. 3. Floret anatomy for three developmental stages of *Helianthus* species.

are native to North America and have sympatric ranges (Heinrich, 1956; Heiser et al., 1969).

A laboratory colony of *H. electellum* was maintained in a control chamber at 25°C, 70% relative humidity, and a photoperiod of 16 light hours per day. The colony was initiated from pupae obtained from a laboratory culture maintained by C.E. Rogers, USDA, Bushland, Texas. (This culture was originally started from adults collected from cultivated sunflower at Bushland, Texas.) The pupae were placed in screen cages until eclosion. Adults were sexed (Rogers, 1978b) and transferred in groups of 10 pairs to one-gallon jars which served as mating chambers. Jars held a 10% honey solution for adult feeding and cotton balls for ovipositional substrates. First-instar larvae hatched on the cotton balls and were transferred to 2-oz plastic containers (three per container) filled with a wheat germ-based synthetic diet modified from Vanderzant et al. (1962) by Randolph et al. (1972). Larvae were left in these containers until pupation. Young larvae fed primarily on the surface of the diet, while older larvae burrowed and constructed silk-lined tunnels.

Growth Responses. To investigate the tolerance of *H. electellum* larvae to the terpenoids of its host, the principal sesquiterpene lactone of the southern Texas *H. maxmiliani* was extracted as previously described (Gershenzon and Mabry, 1984). This sesquiterpene lactone, 8β-SC, makes up almost 50% of the terpenoid content of the glandular trichomes of *H. maximiliani* and was thus assumed to represent a valid test of the some of the physiological and behavioral capabilities of the herbivore. The use of a purified compound allowed us to interpret the response of the herbivore to a known substance. 8β-SC was incorporated into the synthetic diet and fed to larvae of different ages and at three different concentrations (per dry weight): 0.01, 0.1, and 1%. These levels span the range of concentrations for this sesquiterpene lactone in most plant tissues except the tip of the fused anthers where the concentration approaches 10% (Gershenzon, 1984).

8β-SC, which is highly lipophilic, was evenly distributed in a water-based synthetic diet by dissolving it in reagent-grade acetone and coating the resulting solution onto a cellulose powder (Alphacel, ICN Nutritional Biochemicals) by evaporating the solvent under water pump vacuum. The coated powder was then dried under high vacuum to a constant weight and thoroughly mixed with the agar-containing diet after the diet had cooled to 60°C. Because the acetone impurities could have left a residue on the cellulose powder, we tested two different control diets: one containing cellulose powder which had been soaked in acetone and vacuum dried as above and one containing untreated cellulose powder. The concentration of cellulose in all diets tested was identical.

Larvae of different ages were used in these tests because the feeding preferences of *H. electellum* have been shown to change during development (Rogers, 1978a; Archer et al., 1981). Experiments were carried out with three age

classes: neonates, second instars, and third instars. The latter two groups were reared on plain diet (with untreated cellulose) until tests were initiated. Measurements were made of survival to pupation, development time (hatch to adult emergence), and pupal weight. Indices of feeding efficiency (Waldbauer, 1968) were not calculated because removing *H. electellum* from their silk tunnels for repeated measures would have disrupted their normal behavior. Sample sizes varied between treatment groups as a function of availability of larvae in the appropriate developmental stage. Not all individuals which emerged as adults were weighed as pupae.

Behavioral Responses. The behavioral responses of *H. electellum* larvae to *Helianthus* terpenoids were investigated in two experiments: one using the purified sesquiterpene lactone and one using detached florets and floral parts. In the first experiment, each larva was presented simultaneously with diet containing sesquiterpene lactone and control diet to see which was the preferred food. The diets were prepared as above. Treated diet incorporated cellulose powder coated with 8β-SC to give final concentrations of either 1 or 5%, and control diet contained cellulose powder which had been coated with pure acetone. The 1% concentration was used for comparison with the growth response experiment and the 5% concentration was employed to approximate the high sesquiterpene lactone concentrations close to the tip of the anther appendages. Because preference often changes through development, 30 naive larvae (not previously exposed to sesquiterpene lactones) from each of five instars were tested at each concentration.

A single larva was placed in the center of a Petri dish holding two plugs of treated diet and two plugs of control diet. The configuration of treated and control plugs was alternated between dishes to eliminate any position effect. Larval position was recorded five times over a 24-hr period. Preliminary trials showed that larvae usually made and maintained a food choice within the first 12 hr. After diet selection, a larva spun a silken chamber around its body and affixed the silk to the diet plug. For each succeeding instar tested, the food plugs were spaced slightly further apart, so that the relative distance between them did not change as larval size increased (it approximated $1\frac{1}{2}$ larval lengths), and so that a larva could not affix its silken chamber to different food plugs simultaneously. The experiment was conducted under dim red light because larvae became agitated under white light and tended to locate themselves in a position of minimum exposure.

Our second behavioral experiment measured the damage done to an array of floral parts offered to *H. electellum* larvae of different ages. Wild *H. annuus* collected near Austin, Texas, was used in this experiment. The florets of *H. annuus* have approximately the same abundance and distribution of glandular trichomes as the florets of *H. maximiliani*, but there are differences in trichome terpenoid composition. The use of wild *H. annuus* allowed us to compare our

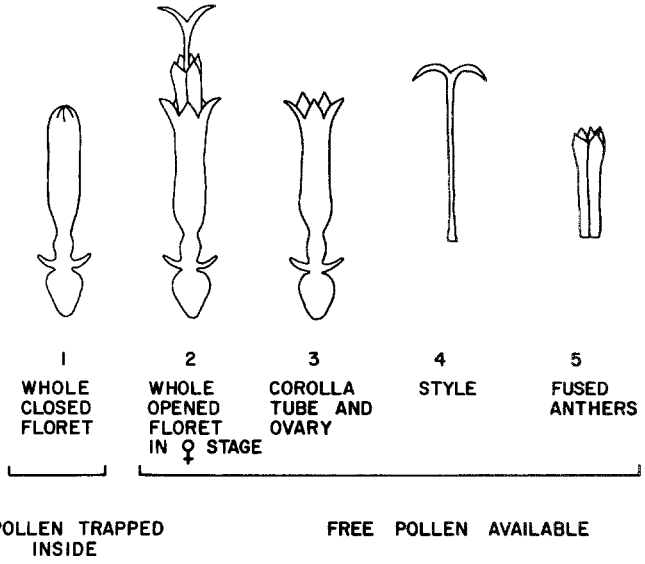

FIG. 4. Five food types, floral tissues of wild *H. annuus*, offered separately to larvae. In all but food type 1, free pollen was available.

results with previous observations on the feeding response of *H. electellum* to the cultivated *H. annuus*. (Rogers, 1978a).

Detached florets and floral parts of wild *H. annuus* were arranged in five treatments: (1) whole closed florets (preanthesis), (2) whole open florets just after style branches had opened, (3) corolla tubes and attached ovaries, (4) styles, and (5) anthers (Figure 4). In all but the first treatment, free pollen was available. Under natural conditions, developing achenes are also available to the larva; achenes are the favored food of fourth and fifth instars (Archer et al., 1981). However, the intent of this experiment was to determine which tissues were acceptable rather than preferable to larvae of different ages. Ten naive first instars and five naive larvae of each additional larval instar (reared on unadulterated synthetic diet) were introduced singly into a Petri dish holding one of five treatments and held under dim red light. Each dish held three representatives of the treatment group. Tissue damage was scored under red light 24 and 48 hr after a larva was placed in a Petri dish.

RESULTS

Growth Responses. Larvae of *H. electellum* reared on artificial diets containing the sesquiterpene lactone 8β-SC suffered significant reduction in pupal weight compared to larvae reared on control diets, but their survivorship and

TABLE 1. PUPAL WEIGHTS FOR DIFFERENT AGED LARVAE REARED ON TREATED AND CONTROL DIET (*N* given parenthetically)

Age at treatment initiation	Mean pupal weight[a,b] (mg)				
	Control diet[b]		Treated diet (% 8β-SC)		
	CC	C	0.01	0.1	1.0
First instar	351 a (150)	344 a (277)	333 a (112)	324 b (121)	315 b (106)
Second instar			341 a (57)	333 a (62)	316 b (57)
Third instar			340 a (43)	357 a (46)	348 a (48)

[a]Means followed by same letters within rows are not significantly different at 5% level (Tukey's studentized test). No interaction between 8β-SC dose and age of treatment initiation ($P = 0.26$).
[b]CC = with plain cellulose, C = with acetone-treated cellulose.

development time were not affected. The reduction in pupal weight was both age-dependent and dose-dependent (Table 1). Larvae that began feeding on 8β-SC treated diet as neonates had reduced pupal weights when 8β-SC concentration in the diet was $\geq 0.1\%$. Larvae that began feeding on treated diet as second instars had reduced pupal weights at 8β-SC concentrations $\geq 1\%$. The pupal weights of larvae that began feeding on treated diet as third instars were unaffected at the concentrations of 8β-SC tested.

The 8β-SC had no significant effect on larval survivorship regardless of concentration or the age at which larvae first encountered treated diet (Table 2). Similarly, 8β-SC had no effect on larval development time (Table 3). There were no significant differences between larvae reared on control diet containing cellulose powder upon which pure acetone had been dried and larvae reared on diet containing untreated cellulose powder. Thus, the solvent used to coat 8β-SC onto the cellulose powder prior to incorporation into the diet did not contribute to the treatment effects measured.

Behavioral Responses. The first through fourth instars showed a significant preference for control diet over a 5% 8β-SC diet; however, the fifth instars showed no preference (Figure 5). At a 1% concentration of 8β-SC there was no demonstrable preference for either control or treated food by larvae of any age class.

The results of the acceptability test based on feeding damage of whole florets and floral organs are illustrated in Figure 6. First instars ate only pollen, scavenging loose pollen from style branches or anthers or crawling down the corolla tube of open florets to graze. When only closed florets were available,

TABLE 2. PERCENT SURVIVAL UNTIL PUPATION FOR DIFFERENT AGED LARVAE ON TREATED AND CONTROL DIET (*N* given parenthetically)

Age at treatment initiation	Survival (%)[a]				
	Control diet[b]		Treated diet (% 8β-SC)		
	CC	C	0.01	0.1	1.0
First instar	84 (224)	82 (225)	83 (75)	89 (75)	77 (75)
Second instar			85 (75)	92 (75)	83 (75)
Third instar			78 (63)	92 (63)	90 (63)

[a] No significant difference in survival between treated and control diets, $G = 1.48$, or between larvae started on treated diet at different ages, $G = 0.82$ (test of independence with G compared to $\chi^2_{(0.05)(1)} = 3.841$.
[b] CC = with plain cellulose; C = with acetone-treated cellulose.

there was no tissue damage and larvae starved to death. Second instars also ate primarily pollen but, in addition, did some minor damage to the ovary. Besides scavenging loose pollen, this age class was also able to make a small entrance hole near the base of the corolla tube of the whole unopened floret to obtain pollen, and thus did not starve when only closed florets were available. Third instars ate pollen, ovaries, parts of the lower corolla and, occasionally, the style

TABLE 3. DEVELOPMENT TIME FOR DIFFERENT AGED LARVAE REARED ON TREATED AND CONTROL DIET (*N* given parenthetically)

Age at treatment initiation	Mean development time (days)[a]

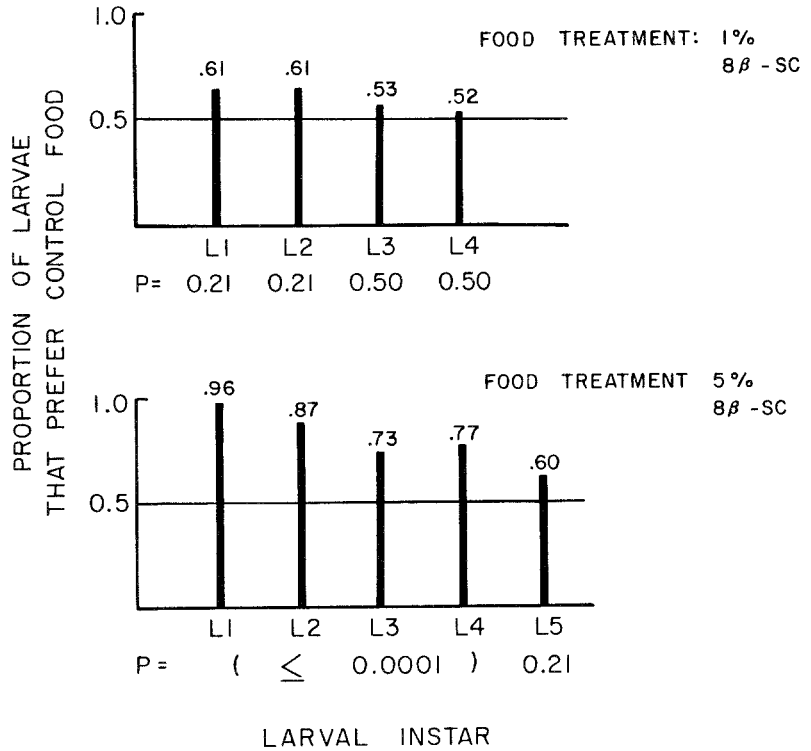

FIG. 5. Larval preference for control diet (with acetone-treated cellulose added) or diet treated with 8β-SC (1 or 5% by dry weight) for different aged larvae. In a binomial test, a P value ≥ 0.05 means that larvae showed a preference for control diet.

tube (but not the rough branches). Fourth instars ate pollen, ovaries, styles, the lower two thirds of the corolla tube, and occasionally the lower edge of the fused anthers. Fifth instars ate everything except the corolla tube tips and terminal appendages of the anthers.

DISCUSSION

Behavioral and Growth Responses. Our results show that the specialist herbivore *H. electellum* is essentially unaffected by the principal terpenoid of its host *H. maximiliani* at the concentrations tested. At concentrations of 1% and below, the sesquiterpene lactone 8β-SC had no influence on larval survivorship or development time and reduced pupal weight only slightly (an average of 5%), and only if consumed during the first two instars. Under natural conditions, *H. electellum* does not consume tissue contaminated with 8β-SC until

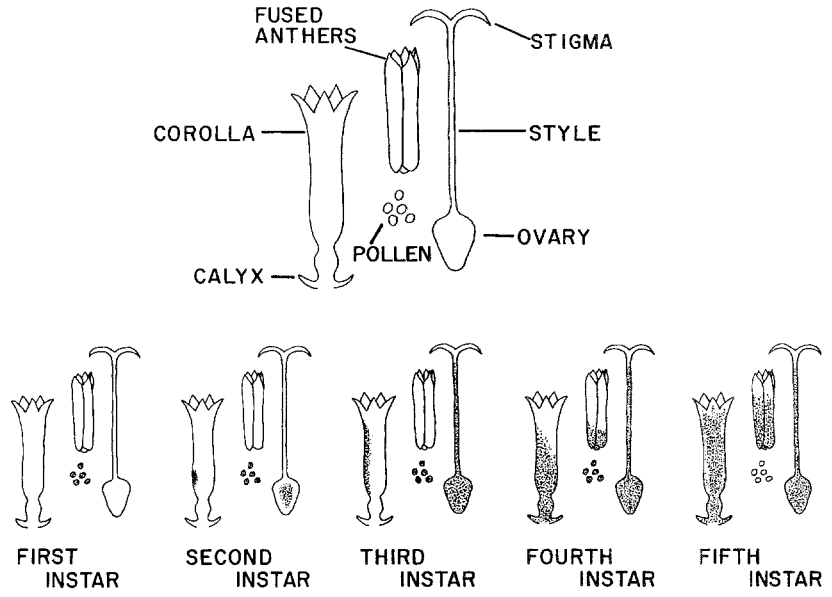

FIG. 6. Schematic diagram of patterns of tissue damage of wild *H. annuus* florets as larvae age. Stippled areas indicate the extent of damage.

the third instar. Therefore, both behavioral and growth responses of this specialist herbivore to the major secondary compound of its host are important in protecting it from ill effects.

8β-SC does have a negative effect on some herbivores. At 1% levels, the southern armyworm, *Spodoptera eridania* (Lepidoptera: Noctuidae), experienced significant depression in growth; when given a choice *S. eridania* also avoided the compound. *Melanoplus sanguinipes* (Orthoptera: Acrididae), occasionally a pest on the cultivated sunflower, also avoided the compound when given a choice (Gershenzon et al., 1985).

The effects on *H. electellum* of 1% concentrations of 8β-SC are comparable to the effects of other *Helianthus* terpenoids on this species. Two compounds, niveusin A, a sesquiterpene lactone from *H. niveus* (Figure 2B), and grandifloric acid, a diterpene from *H. annuus* (Figure 2C), had no significant effects on the growth, survivorship, or development time of *H. electellum* larvae at the 1% level or below (Rogers and Gershenzon, unpublished results). However, two diterpene acids from *H. annuus*, kaurenoic acid (Figure 2D) and trachylobanic acid (Figure 2E) were reported to reduce *H. electellum* growth significantly at concentrations of 0.5–2% (Elliger et al., 1976; Waiss et al., 1977).

Our behavioral experiments showed that *H. electellum* larvae are not significantly deterred from feeding on diet containing 1% 8β-SC. This result might

have been predicted from the growth tests, since *H. electellum* larvae ingest food containing 1% 8β-SC with minimal ill effect. However, higher concentrations of 8β-SC appear to deter feeding significantly. All larval instars, except the fifth, preferred control diet to diet treated with 5% 8β-SC. In addition, no larvae, regardless of age, would feed on the anther appendages, which contain terpenoid concentrations of up to 10%. This suggests that the acceptability of the anther tissue changes as a function of insect age and concentration of 8β-SC. This conclusion is corroborated by the behavior of larvae on wild *H. annuus* where the willingness to eat contaminated tissue increases with age.

In summary, the ability of *H. electellum* to survive on *Helianthus* is due to both behavioral and growth characteristics: mechanisms which allow *H. electellum* to ingest lower levels of terpenoids with impunity and which deter feeding on tissues containing levels of terpenoids that are detrimental. Both physiological and behavioral responses change with larval age.

These results suggest several further investigations. First, it would be valuable to repeat these experiments using a crude extract of the glandular trichome contents of *H. maximiliani* to look for an alteration of response due to other trichome components. Second, since we did not address the physiological mechanism(s) which have an impact on growth, it would be interesting to distinguish sensory responses (e.g., repellency) and digestive responses (e.g., toxicity) to understand why young larvae grow less when fed 1% 8β-SC and avoid diet containing 5% 8β-SC.

The shift in growth potential as a function of age of encounter with the secondary compound should prompt concern about the use of Waldbauer (1968) indices in assessing the nutritional value of a host plant for a particular herbivore during only one instar period. In such studies, a change in physiological capability during development would go undetected.

Sesquiterpene Lactones: Defensive functions? In general, the sesquiterpene lactones of *Helianthus* appear to serve as defenses against some herbivores because of their abundance, their location in glandular trichomes on the surface of the plant, and their toxicity and feeding deterrency to other herbivores (Jones et al., 1979; Gershenzon et al., 1985). Furthermore, the high concentrations of terpenoid-filled trichomes on the anther appendages suggest a role in defense against herbivores that feed on floral parts. The proximity of sesquiterpene lactones to the pollen (Figures 1 and 2) makes it tempting to postulate a role for these constituents in protecting the pollen from predation until the arrival of pollinators. Recently published micrographs show that the activity of some pollinators on *H. annuus* results in the removal of the anther's glandular trichomes (Griffiths and Ericson, 1983).

Our observations of *H. electellum* larval behavior indicate that the anther sesquiterpene lactones, in combination with tissue toughness, negative phototaxis of larvae, and inflorescence phenology, discourage pollen removal before

the arrival of pollinators and discourage severance of the style prior to the opportunity for fertilization.

Toughness and Trichomes. First-instar larvae are unable to reach the pollen in unopened florets because of tissue toughness and the presence of glandular trichomes. Avoidance of tough tissue by entry through the top of the unopened floret through suture lines of the closed corolla and closed anthers would result in contact with easily ruptured glandular trichomes. By the second instar, larvae are able to chew a small hole in the corolla base and crawl up into the anther tube from below, thereby avoiding contact with glandular trichomes or their contents.

Negative Phototaxis. Glandular trichomes do not appear to present a barrier to larval movement (Rossiter, personal observation). Therefore, pollen available at stage two of anthesis (extended above other disk florets by the rising styles) is most likely protected because of the larva's negative phototaxis.

Inflorescence Phenology. The majority of ovipositions on an inflorescence occurs when approximately one quarter of the florets have opened (Teetes and Randolph, 1969b; Depew, 1983). When larvae hatch (two days after oviposition), there is a ready supply of loose pollen which has fallen into the inflorescence due to wind or insect activity. First-instar larvae graze on loose pollen which has fallen onto the silk runways woven between the corolla tubes or into the open corolla tubes (Rogers, 1978a; Rossiter, personal observation). In wild *Helianthus* species, anthesis occurs over a 5- to 10-day period (Knowles, 1978). Oviposition begins one to two days after anthesis begins, and it is another six days before the first eggs laid produce second instars (Randolph et al., 1972), Therefore, by the time any larvae are able to enter unopened florets by chewing a hole in the base of the corolla tube, and remove new pollen or sever styles, most of the florets on the head have had the opportunity to carry out their reproductive function (pollen dispersal and fertilization). Thus, the phenology and habits of this floral specialist do not appear to impede the initial reproductive function of its host. We can speculate that the timing of oviposition has been affected by the necessity for young larvae to forage on pollen and avoid secondary compounds.

Later instars do injure floral organs and developing seeds of wild sunflowers, but the extent of this injury is considerably less than it is in cultivated sunflower (Rogers, 1980). Multiple factors undoubtedly contribute to the greater susceptibility of cultivated sunflower: (1) Cultivated *H. annuus* have lower densities of glandular trichomes on their anthers than either *H. maximiliani* or wild *H. annuus* (Gershenzon, 1984). (2) The period of anthesis, and therefore the opportunity for oviposition, is longer for the cultivar (up to 16 days) due to the increased number of florets on the very enlarged inflorescences (Griffiths and Erickson, 1983). (3) Tissue toughness and glandular trichome contents may differ between cultivated and wild sunflowers. (4) The monoculture habit can

enhance the abundance of an herbivore species (Stanton, 1983). Our data show that the use of floral tissues by larvae of different ages is dependent, at least in part, upon degree of contamination by glandular trichomes contents.

We compared our results for wild *H. annuus* with Rogers' (1978a) data for intact inflorescences of cultivated *H. annuus*. With wild sunflowers, larvae eat only pollen for the first two instars, with slight ovary damage by second instars. With cultivars, however, larvae eat not only pollen but occasionally anthers and styles during the first instar and anthers, pollen, corollas, and styles during the second instar. The type of injury sustained by cultivars is an impediment to the female reproductive function because styles can be damaged before fertilization occurs. Rogers (1978a) has pointed out that the greater the proportion of ovaries fertilized before style damage begins, the greater the seed set despite continued herbivory. The extent to which the abundance of glandular trichomes in wild *Helianthus* inhibits destruction of the style before fertilization is a topic for further investigation.

Acknowledgments—We thank Charlie Rogers for provision of the insect culture and information on laboratory rearing procedures, Gerald Kreitner for the electron micrograph, Carl Schlichting and Jack C. Schultz for comments on the manuscript, Clark Hubbs and the University of Texas Department of Zoology for laboratory space and computer facilities, Meredith Conoley for laboratory assistance, and Martha Richards for the graphics. (Received May 14, 1985; accepted October 16, 1985)

Abstract—Extracts prepared from elderberry, *Sambucus simpsonii* Rehd., leaves with either acetone, dichloromethane, distilled water, ethanol, hexane, or methanol deterred oviposition by *Heliothis virescens* (F.) on treated substrates in the laboratory. Doses of the aqueous extract equivalent to as little as 0.8 mg of leaves/cm^2 of oviposition substrate were effective in reducing egg deposition. There was no significant difference in the mean number of landings on extract-treated and untreated surfaces. When either the antennae, proboscis, or the metathoracic legs were removed from female moths, there was no significant effect on oviposition on paper towels treated with elderberry leaf–water extract in laboratory bioassays, but in field cages, moths without these appendages deposited significantly fewer eggs on treated leaves of tobacco plants, a preferred host. There was no evidence that elderberry leaf–water extract affected mating by *H. virescens*.

Key Words—*Heliothis virescens*, Lepidoptera, Noctuidae, oviposition behavior, oviposition deterrents, chemoreceptors, *Sambucus simpsonii*.

INTRODUCTION

As scientists become increasingly successful in isolating natural chemicals in plants and animals, interest in the utilization of plants or plant substances as insect oviposition and feeding deterrents in pest management systems has increased (Boddé, 1982). Tingle and Mitchell (1984) found that aqueous extracts from foliage of a variety of nonhost plants deterred oviposition by the tobacco budworm, *Heliothis virescens* (F.). Similarly, cabbage leaves, a host of *Tri-*

[1] Lepidoptera: Noctuidae.

choplusia ni (Hübner), produce chemicals that deter oviposition by this species (Renwick and Radke, 1981). Jermy and Szentesi (1978) reported that oviposition by *Acanthoscelides obtectus* Say, *Bruchus pisorum* (L.) and *Pieris brassicae* L. could be inhibited even on the most preferred substrates by substances of very dissimilar chemical structures. Their experiments showed that the acceptability of a given substrate was influenced substantially by the presence of alternative substrates and that both water- and hexane-soluble factors were involved. Mitchell and Heath (1985) determined that chemicals extracted with different solvents from pigweed, *Amaranthus hybridus* L., and from frass of pigweed-fed *Spodoptera exiqua* L. or *S. eridania* (Cramer) larvae deterred oviposition by *S. exigua* when the extracts were sprayed onto pigweed, a preferred host plant.

The objective of the present study was to define and correlate specific reproductive behaviors of *H. virescens* when exposed to extracts of elderberry leaves, *Sambucus simpsonii* Rehd., prepared with various solvents. This plant was selected because aqueous extracts of leaves are an effective oviposition deterrent for *H. virescens* (Tingle and Mitchell, 1984). Adult *H. virescens* females were observed during oviposition to note possible behavioral changes caused by the elderberry extracts. The effect of the extracts on mating and oviposition in both choice and no-choice situations also was determined. Various appendages were removed from moths in an attempt to determine the location of receptors involved in the perception of oviposition deterrent(s).

METHODS AND MATERIALS

Initially, extracts prepared from elderberry leaves with either of six solvents (acetone, dichloromethane, distilled water, ethanol, hexane, or methanol) were evaluated as oviposition deterrents in a Plexiglas assay tunnel in the laboratory (test 1). The holding compartment of the tunnel for the *H. virescens* moths was 25 × 25 × 51 cm long with four ports (7.5 × 20 cm) in the top that were covered with white Viva paper towels used routinely for egg-laying surfaces at this laboratory. Air was pulled through the ports of the compartment from top to bottom (covered with screen wire), at ca. 0.3 m/sec with 55 × 55-cm box fan. The exhaust side of the fan was covered with a fiberglass filter to collect insect scales.

Each extract was prepared by homogenizing 20 g fresh weight of elderberry leaves in a blender with 100 ml of the solvent, which was then filtered through a Viva paper towel. The solvent was removed with a rotary evaporator and the residue was reconstituted with 100 ml of a 3 : 1 acetone–water solution. The extract prepared with distilled water was not evaporated. In each assay, the paper towels were saturated with an extract prepared with one of the solvents at the rate of 6.7 mg equivalent/cm^2, and they were allowed to air dry. Treated and untreated towels were placed alternately on the ports of the assay tunnel.

Before the onset of the scotophase, 20 laboratory-reared 2- to 3-day-old females that had been confined with males for mating were released into the holding compartment and given a choice of laying surfaces. Prior to testing, the moths were held at 27°C on a reversed 14:10 light–dark photoperiod. Temperature in the test area was maintained at ca. 27°C.

Preliminary laboratory tests showed that of the total number of eggs laid by laboratory-reared females in a 10-hr dark period, 32% were deposited during the first hour, 14% during the second hour, and 4–9% during each of the following 8 hr. Therefore, we observed the moths during the first hour of the scotophase using a television monitor equipped with a remotely controlled low-light surveillance camera. The total number of eggs deposited on the two treated towels were counted and compared to the total number of eggs on the untreated towels. Overnight egg counts were made in some tests. All tests were replicated six times.

Next, dose–response experiments were conducted with elderberry leaf extracts prepared with distilled water (test 2). Each dose, ranging from 0.01 to 6.7 mg equivalents of leaf/cm^2 of paper towel oviposition substrate, was replicated six times. Towels saturated with 5 ml each of distilled water and air dried served as controls.

In the third test, extracts prepared from 20g elderberry leaves/100 ml of one of three solvents were tested separately on tobacco leaves (oviposition substrate). The leaves were obtained from mature potted plants and shaped to 7.5 × 20 cm to conform to the size of the ports on the assay tunnel. The extract was brushed onto both sides of the leaves to the point of runoff at the rate of 3.3 mg equivalents/cm^2. Control leaves were treated similarly with 5 ml each of the respective solvent.

In test 4, females were confined for oviposition in eight glass lamp globes (four sets of two) that were positioned above the ports of the assay tunnel so that air would be pulled through them. The globes tapered in diameter from 11.0 cm at the center to 7.5 cm at both ends and were 22.5 cm high. Two no-choice tests were conducted simultaneously. Paper toweling on top of the globes served as the laying surface. Two moths were confined in each globe. The top of one globe in each set was treated with 6.7 mg equivalents/cm^2 of elderberry leaf–acetone extract and air dried; the top of the other globe (control) in the set was treated with 2.5 ml of acetone. The number of eggs deposited on each top was recorded after 1 hr. In two sets of globes, the moths were prevented from contacting either the extract-treated surface or the acetone-treated control surface by separating these surfaces with wire mesh covered with untreated paper towels. Air was pulled over the treated surfaces through the globes. These tests were replicated 12 times. Moths were observed with a low-light television camera in six replicates. The number of landings on the paper towel tops during the first hour of darkness was recorded.

Either the antennae, proboscis, or the pro-, meso-, or metathoracic legs

were amputated from each test female moth in test 5 to determine if the chemoreceptors detecting the plant extract were located on these appendages. The amputations were made at ca. 21°C during the light period while the moths were relatively inactive. The extract used in these tests was prepared with 20 g elderberry leaves/100 ml water. Tests were conducted in both the laboratory and outdoors in Saran field cages (2.9 m diam and 1.2 m high) described by Tingle and Mitchell (1984). In the laboratory, five 3- to 5-day-old *H. virescens* females were confined overnight in glass globes that were positioned on top of the assay tunnel; half of each paper towel top was treated with 6.7 mg equivalents/cm^2 of extract, and half of each top was left untreated for a control (10 replicates).

Potted tobacco plants in the prebutton (prebudding) stage of growth, with all but four leaves removed, were used in the field cages. Using a Badger air brush, two leaves were sprayed on both upper and lower surfaces with extract at the rate of ca. 1.5 mg equivalents/cm^2 of leaf surface at ca. 1500 hr; two control leaves were left untreated. The control leaves were covered with a polyethylene bag to prevent the extract from settling on them during spray applications. Eight plants were spaced equally in a circular pattern in the cages. Twenty-five pairs of laboratory-reared 2- to 3-day-old moths were released and maintained in each cage. Each plant was considered a replicate. The total number of eggs deposited on the treated and untreated leaves were counted the following morning (24 replicates).

Test 6 was set up in two environmental chambers maintained at 27°C to determine if the presence of the oviposition-deterring extract prepared with elderberry leaves and water affected mating by *H. virescens*. Ten pairs of 3- to 5-day-old virgin moths were confined in a 3.8-liter Fonda paper carton that was lined with white paper towels. The linings in some of the cartons were first treated with ca. 7 mg equivalents/cm^2 of the extract (10 replicates). Females were dissected to determine mating status after overnight confinement; eggs deposited also were counted.

Test 7 was conducted to determine if the presence of the extract reduced the total number of eggs laid by an *H. virescens* female in her lifetime. One pair of newly emerged, virgin moths was confined in a 0.47-liter Fonda paper carton until both moths died. The cartons, which were held in an environmental chamber at 27°C, were lined with paper towels treated with ca. 7 mg equivalents/cm^2 of the elderberry leaf–water extract. The linings were changed daily. New towels also were placed in the control cartons daily (15 replicates). Eggs were counted daily, and the mating status was determined after the female died.

RESULTS AND DISCUSSION

In the first experiment, extracts prepared from elderberry leaves with each of the five solvents tested significantly reduced egg deposition by *H. virescens*

($P = 0.01$, paired t test). During the first hour of darkness, reductions in egg deposition ranged from 69% with dichloromethane to 89% with both distilled water and ethanol; the reductions attained with acetone and methanol extracts were 76 and 77%, respectively. Similarly, in overnight tests, significant reductions were attained ($P = 0.01$, paired t test): 90% (distilled water), 81% (acetone), 80% (dichloromethane), 78% (ethanol), 75% (methanol), and 40% (hexane). This suggests that more than one chemical may be involved in oviposition deterrence with extracts from elderberry leaves. From observations made during the first hour of darkness, there was a slight reduction in the number of approaches (within 7.5 cm) and landings on the treated surfaces; however, the differences observed were not significant statistically.

Doses of elderberry aqueous extract from 0.8 mg to 6.7 mg equivalents/cm^2 paper towel (test 2) reduced egg deposition by *H. virescens* significantly ($P = 0.01$, paired t test), while doses of 0.01, 0.1, and 0.4 mg equivalents/cm^2 had no significant effect on oviposition (Figure 1). These results are very similar to those reported by Mitchell and Heath (1985) and Williams et al. (1986) for *S. exigua* and *S. frugiperda* (J.E. Smith), respectively. The primary difference between the dose–response experiments in this study and those involving *Spodoptera* is the source of the oviposition deterrent(s). The deterrent chemicals for *S. exigua* and *S. frugiperda* were obtained from host plants, whereas the deterrent for *H. virescens* was obtained from a nonhost, elderberry.

Significant reductions in egg deposition also were attained (test 3) on to-

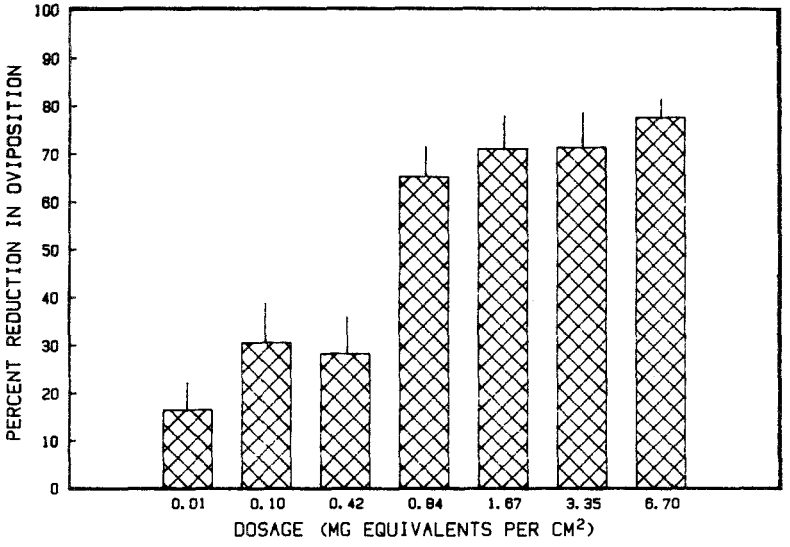

FIG. 1. Relationship between percent reduction of *Heliothis virescens* eggs deposited on extract-treated paper towels and dosage of elderberry leaf aqueous extract. Bars include standard error of means.

bacco leaves treated with extracts (3.3 mg equivalents/cm^2) prepared with either methanol (75% reduction), distilled water (71%), or dichloromethane (54%). Extracts prepared with other solvents were not tested on tobacco leaves.

When *H. virescens* females were confined in glass globes in a no-choice situation (test 4), there was no significant difference (unpaired *t* test) in the number of landings on the extract-treated and untreated surfaces, even when the moths were allowed to contact the treated surface. A significant reduction in egg deposition of 51% ($P = 0.05$, unpaired *t* test) on oviposition substrates was attained when moths were allowed to the contact the treated surface; however, there was no significant reduction in egg deposition when contact with the treated surface was prevented. These results indicate that the insects were not affected by odor from the elderberry extract.

In choice tests in the laboratory (test 5), there was no significant difference in the number of eggs deposited on toweling treated with elderberry leaf–water extract or the control half when moths had either antennae, proboscis, or metathoracic legs removed (Table 1). We did not test the effects of simultaneous amputation of the different appendages. However, in field-cage bioassays, moths with and without antennae, proboscis, or metathoracic legs laid significantly

TABLE 1. EFFECT OF ELDERBERRY LEAF–WATER EXTRACT ON OVIPOSITION BY *Heliothis virescens* WITH VARIOUS APPENDAGES REMOVED IN LABORATORY AND FIELD-CAGE TESTS

	Reduction in oviposition (%) and *t*-values[a]			
	Laboratory[b]		Field cage[c]	
Appendage(s)	With all appendages	Without appendage(s)	With all appendages	Without appendage(s)
Antennae	50.3 2.803*	24.3 1.812 NS	48.3 5.722**	56.3 5.309**
Proboscis	38.2 5.000**	23.0 1.739 NS	31.9 3.397**	59.4 14.532**
Prothoracic legs	32.5 3.596**	68.9 7.230**		
Mesothoracic legs	42.5 3.096*	50.1 4.295**		
Metathoracic legs	48.5 4.665**	21.7 1.772 NS	44.7 7.517**	45.9 4.668**

[a] Calculated by Student's paired *t* test from percent of eggs deposited in treatment and control: NS = nonsignificant; * = significant at $P = 0.05$; ** = significant at $P = 0.01$.
[b] 6.7 mg equivalents/cm^2 of extract on half of 7.5-cm-diam paper towel.
[c] 1.5 mg equivalents/cm^2 of extract on tobacco leaves.

fewer eggs on tobacco leaves treated with elderberry leaf extract than on untreated leaves on the same plant. The use of tobacco plants, a preferred cultivated host that produces an oviposition stimulant for *H. virescens* (Jackson et al., 1983), likely contributed to the difference in results obtained in laboratory and field-cage tests. Although the quantity of extract per cm^2 actually was greater on the towels (6.7 mg equivalents) than on the tobacco leaves (1.2 mg equivalents), moths without antennae, proboscis, or metathoracic legs did not perceive the extract as an oviposition deterrent in the laboratory, but they seemed to avoid it in the cages. Some receptors that were not being utilized in the laboratory may have been responding to the treated and untreated plant surfaces under the more natural conditions in the field cage. Also, if one receptor is missing, the insect may rely on other chemoreceptors. In the laboratory tests, we observed females probing the laying surfaces (i.e., toweling) with their ovipositors, but we did not attempt to correlate this probing with egg deposition.

The amputation of either the proboscis or metathoracic legs from the *H. virescens* females used in test 5 had no significant effect on the total number of eggs deposited (treated and control leaves combined) on tobacco plants in field cages. However, in the cage that contained females without antennae, there was a significant reduction of 76% ($P = 0.01$, unpaired t test) in the combined total number of eggs laid on tobacco plants as compared to the combined total egg counts on tobacco plants in the cage that contained females with antennae intact. Moths in both cages were active, but those without antennae tended to rest on the side of the cage instead of on the plants, as did moths with antennae intact. If the receptors that aid in locating host plants are present on the antennae, then it is reasonable to assume that the moths without antennae would have difficulty in locating the tobacco plants. This difference in behavior did not appear to be due entirely to injury since in the laboratory, females without antennae laid only 26% (not significant, unpaired t-test) fewer eggs than those with antennae when confined in 3.8-liter paper cartons lined with paper towels (Tingle, unpublished data).

Most olfactory and/or contact chemoreceptors of oviposition stimulants have been found on the head appendages and/or tarsi (David and Gardiner, 1962; Yamamoto et al., 1969; Benz, 1969; Yamada, 1971; Städler, 1974). However, Valencia and Rice (1982) found chemosensilla on the ovipositor of the potato moth, *Phthorimaea operculella* (Zell.), which may influence oviposition in this species.

When virgin *H. virescens* moths were confined in 3.8-liter paper cartons lined with paper towels treated with elderberry leaf–water extract (test 6), there was no significant difference in the frequency of mating between pairs of moths confined in treated containers and those in the untreated controls, nor did the leaf extracts have any toxic effect on the moths. However, there were significantly fewer eggs deposited (48% reduction; $P = 0.05$, unpaired t test) by moths confined overnight in the treated containers. Even when laying surfaces

were saturated with the extract and air dried, the females deposited some eggs on the extract-treated surfaces, particularly when they had no choice. Significantly fewer total eggs were laid (36% reduction; $P = 0.05$, unpaired t test) by individual female moths during their lifetimes when they were confined in 0.47-liter paper cartons lined with paper towels treated with elderberry leaf–water extract (test 7). Similarly, Jackson et al. (1983) found that in no-choice tests, *H. virescens* moths deposited less than half as many eggs on an insect-resistant cultivar of primitive tobacco than on a preferred flue-cured tobacco cultivar.

Contact chemoreception has been found to play an important part in the behavioral sequence leading up to oviposition in a number of phytophagous insects (Ma and Schoonhoven, 1973; Städler, 1978; Saxena and Goyal, 1978; Behan and Schoonhoven, 1978; Chadha and Roome, 1980). The presence of multiple receptors on female *P. brassicae* was indicated by Ma and Schoonhoven (1973). Perhaps mechanoreceptors and chemoreceptors (contact and olfactory) of *H. virescens* are utilized in a sequence to select the most suitable surfaces for oviposition. Insects using multiple receptors would be more likely to avoid unsuitable environments. Although the test insects used here responded similarly to extracts prepared with the various solvents, different chemoreceptor mechanisms may have been involved in the response to the chemical substances in each extract because substances of different chemical and physical properties could evoke the same response at the behavioral and presumably also at the receptor level (Jermy and Szentesi, 1978).

Research unraveling the intricate relationships that exist between the insect's ability to perceive the chemistry of a plant and integrate the sensory input into definable behavior could serve as the foundation of future breakthroughs in insect pest management technology. Although the reductions in oviposition on tobacco plants sprayed with elderberry leaf extract were not spectacularly high, the data do demonstrate the feasibility of using oviposition deterring chemicals on preferred hosts even though such plants may have a powerful oviposition stimulant, as does tobacco (Jackson et al., 1983). The extracts used here were in their crudest form. It is not unreasonable to assume, therefore, that the level of oviposition deterrency would improve with further purification of the active chemicals. Even modest reductions in the level of oviposition by *H. virescens* could have a significant impact on the quantity of pesticide used and the frequency of application now required to control this pest on crops such as tobacco and cotton. The combined effects of lower oviposition and less pesticide usage would, in turn, enhance opportunities for utilizing other means of control, especially parasitoids and predators.

Acknowledgments—The authors wish to thank J.F. Chaplin, A.H. Baumhover (retired), D.M. Jackson, J.N. Hobgood, and other personnel of the Tobacco Research Laboratory, Oxford, North Carolina, for supplying the test insects; and C.R. Artaud of the Florida Department of Agriculture and Consumer Services, Division of Plant Industry, Gainesville, Florida, for identifying the plant

species *Sambucus simpsonii* Rehd. Also, we thank M. McKoy of this laboratory for counting the eggs and sexing the insects used in this study.

ALLELOPATHIC INFLUENCE OF *Sorghum bicolor* ON WEEDS DURING GERMINATION AND EARLY DEVELOPMENT OF SEEDLINGS

OKSANA PANASIUK, DONALD D. BILLS, and GERALD R. LEATHER[1]

Eastern Regional Research Center[2]
Philadelphia, Pennsylvania 19118

(Received June 6, 1985; accepted October 23, 1985)

Abstract—The allelopathic interaction between sorghum [*Sorghum bicolor* (L.) Moench] and 10 species of grass and broadleaf weeds was investigated. Germination of weed seeds was slightly inhibited or stimulated, depending on species, when incubated in closed Petri dishes with germinating sorghum. Subsequent radicle and hypocotyl or coleoptile elongation of weeds was significantly inhibited by the germinating sorghum. For weeds interplanted with sorghum and grown under greenhouse conditions. The inhibitory effect on some weed species was still evident after 2 months of growth. Significant differences were found in the dry matter per weed plant grown in pots in proximity to sorghum vs. weeds grown in monoculture. Aqueous leachates from pots planted with sorghum alone or from a system in which sorghum roots protruded into water had strong allelopathic activity. These results indicate that water-soluble allelochemicals are produced by germinating sorghum seeds and that production of these substances continues during seedling growth.

Key Words—Allelopathy, *Sorghum bicolor*, weeds, weed control, agroecosystems, phytotoxins, seed germination.

INTRODUCTION

Residues of mature sorghum [*Sorghum bicolor* (L.) Moench] contain water-soluble allelochemicals that inhibit seed germination and seedling development of other species of plants (Lawrence and Kilcher, 1961; Guenzi and McCalla,

[1] Weed Science Research, Bldg. 1301, Ft. Detrick, Maryland 21701.
[2] Agricultural Research Service, U.S. Department of Agriculture.

1962; Guenzi et al., 1967; Lehle and Putnam, 1982). Johnson grass [*Sorghum halepense* (L.) Pers.] also produces phytotoxic substances (Abdul-Wahab and Rice, 1967; Nicollier et al., 1983). A number of phenolic acids have been implicated as phytotoxins that can be leached from sorghum residues, but there is insufficient evidence that these are the active or sole allelochemicals (Guenzi and McCalla, 1962). Sorghum and Johnson grass also produce two cyanogenic compounds, dhurrin and taxiphyllin, which upon hydrolysis yield HCN and *p*-hydroxybenzaldehyde, but their potential role as allelochemicals is likewise ambiguous (Nicollier et al., 1983).

While the allelopathic effect of residues of mature sorghum on other plants has been described, studies involving the cogermination of sorghum seeds with seeds of other species are lacking. Allelopathic activity expressed by a species in the earliest stages of development could confer a powerful advantage over other plants. The purpose of our investigation was to determine if sorghum exerts an allelopathic influence on selected weeds when cogerminated with them.

METHODS AND MATERIALS

Seeds. Sorghum seed (cv. Bird-a-boo) was obtained from the Taylor Evans Seed Company,[3] Tulia, Texas. Cress [*Lepidium sativum* (L.) cv. Curlycress] was obtained from the Burpee Seed Company, Warminster, Pennsylania. Weed seeds were collected from the following locations in the years indicated: barnyard grass [*Echinochloa crus-galli* (L.) Beavr.] (Arkansas, 1976), curly dock [*Rumex crispus* (L.)] (California, 1975), green foxtail [*Setaria viridis* (L.) Beavr.] (North Dakota, 1976), Johnson grass (Illinois, 1977), bigroot morning glory [*Impomea pandurata* (L.) G.F.W. Meyer] (Illinois, 1978), redroot pigweed [*Amaranthus retroflexus* (L.)] (Maryland, 1976), red sorrel [*Rumex acetosella* (L.)] (Illionis, 1974), velvetleaf [*Abutilon theophrasti* Medic.] (Mississippi, 1974), and wild mustard [*Sinapsis arvensis* (L.)] (North Dakota, 1976).

Cogermination in Petri Dishes. Seeds of sorghum, weeds, and cress (which was treated as a "weed" in this study) were surface treated with an 800 ppm solution of Roccal to minimize mold growth. Tween 20 (0.5%) was added to the solution to serve as a wetting agent. Seeds were agitated for 15 min with the Roccal solution and then rinsed 10 times with sterile water. Seeds were germinated in sterile plastic Petri dishes (9 cm diameter). The bottom of each dish was lined with a sterilized Whatman No. 3 filter paper disk, and 3 ml of sterile distilled water was added. Controls consisted of 20 evenly spaced weed seeds per dish. Treatments consisted of 20 weed seeds and 20 sorghum seeds, evenly and uniformly interspersed, per dish. For each weed tested, data were

[3] Reference to brand or firm name does not constitute endorsement by the U.S. Department of Agriculture over others of a similar nature not mentioned.

collected from five controls and five treatments. Since data was collected at three days and at seven days, the initial number of controls and treatments was doubled because the measurement made at three days was destructive. As a contingency, one additional control and one additional treatment were included for both the three-day and seven-day trials.

Petri dishes were placed on trays, 12 dishes per tray, so that paired dishes for controls and treatments were side by side. Trays were placed in an environmental growth chamber maintained at 25°C. and 80% relative humidity. The photoperiod was 8 hr per day, and the light intensity at the level of the trays was 9500 lux. Trays were rotated daily to compensate for any minor differences in temperature and light intensity at different locations in the growth chamber.

Daily observations were recorded for germination, leaf formation, root formation, and general health of the developing seedlings. Prior to collecting quantitative data at three days and at seven days, one control and one treatment were discarded from each tray. These were selected visually on the basis of being the least typical (low germination, mold growth, etc.) of the six controls and six treatments on the tray. If none was atypical, the paired treatment and control from the lower left-hand corner of the tray were discarded. For the remaining controls and treatments, the number of ungerminated seeds was counted and, for germination seeds, the length of hypocotyls or coleoptiles and radicals (or primary roots) was measured. Data was statistically analyzed by the Waller-Duncan K-ratio t test to determine the effects and interactions of weed variety, presence or absence of sorghum, and length of trial on three responses: length of hypocotyls or coleoptiles, length of radicles, and percent germination.

Sorghum Root Exudates. A 20-cm-diameter desiccator was autoclaved, and 350 ml sterile distilled water was added to bring the water level to the bottom of the perforated porcelain disk that conventionally holds samples above the desiccant. A layer of sterile, moist cheesecloth was placed on top of the porcelain disk, and 30 g (about 1000 seeds) of sorghum seed, which had been surface-treated with Roccal as described earlier, were evenly distributed on top of the cheesecloth. The lid was placed on the desiccator, and it was located under fluorescent light (about 9000 lux for 15 hr/day) at room temperature. As the sorghum seedlings grew to a height of 9–10 cm with roots of 3–5 cm length protruding into the water, the water was withdrawn from the desiccator and replenished at five-day intervals. Water collected from the desiccator was concentrated on a rotary evaporator to a volume of 30 ml, and 3 ml of this concentrate was tested for allelopathic activity against germinating weed seeds in Petri dish assays as previously described. For control assays, 3 ml of distilled water was used in place of the concentrated sample from the desiccator.

Interplantings in Clay Pots. Seeds of sorghum and selected weeds were planted in sand in 12.7-cm clay pots. Pots were maintained in a greenhouse under conditions of summer sunlight and were watered daily by immersing the

base of the pots in water. Plants were fertilized twice a week by immersing pots in Hoagland and Arnon (1950) nutrient solution with iron content increased to 1.6 times that of the standard solution. Control pots containing only sorghum or a weed and pots interplanted with varying ratios of sorghum and a weed were maintained for periods of up to 60 days. In some cases, leachate was obtained by watering pots planted with 25 sorghum seeds and collecting the runoff. The unconcentrated leachate was used to water an equivalent number of pots planted with weeds or interplanted with sorghum and weeds.

RESULTS

The data on the influence of sorghum on weeds cogerminated in closed Petri dishes is summarized in Table 1. Minor differences in percent germination of weed seeds between weeds germinated alone or in the presence of germinating sorghum seeds were noted. The greatest differences were in the growth and development of seedlings over a period of three or seven days.

Of the 10 species of weeds investigated, statistical analysis of data revealed that cogerminating sorghum in the Petri dish significantly influenced the development of all, except green foxtail and velvetleaf, at the 5% probability level by the seventh day. In several cases, statistically significant differences were noted by the third day. Cogermination with sorghum suppressed the elongation and development of hypocotyls or coleoptiles of weeds with one exception: green foxtail showed a slight but statistically significant increase in average length of coleoptiles. Morning glory, barnyard grass, and velvetleaf exhibited the greatest percent reductions in hypocotyl or coleoptile elongation in the presence of germinating sorghum. Cogermination with sorghum produced significant reduction in the average radicle length of all species tested.

In addition to effects on elongation, weeds germinated in the presence of sorghum generally were less healthy in appearance with higher incidences of necrosis, chlorosis, and retardation of development. Visual observations of differences other than measured growth are presented in Table 2.

Concentrated water samples obtained from desiccators in which the roots of young sorghum seedlings protruded into the water had general effects on the development of selected sprouting weed seeds that were comparable to the effects of proximity to germinating sorghum seeds. In three-day Petri dish assays, the average lengths of barnyard grass coleoptiles and radicles were reduced 30% and 20%, respectively, in comparison with controls. Pigweed hypocotyls and radicles were, on the average, shorter by 20% and 6%, respectively, at three days, and 25% and 30% shorter at seven days. Coleoptile development of green foxtail, as in other tests, was stimulated slightly rather than inhibited and showed an average increase of 11% over controls with a reduction of 8% in radicle length at seven days. The sorghum root leachate reduced the germination of

[a] Two germination means in the same line with a letter in common are not significantly ($P < 0.05$) different.

[b] First value in column is average length of hypocotyl (for dicots) or coleoptile (for monocots). Second value is average length of radicle. Standard deviation is indicated by ± value. Seeds that did not germinate were not included in calculations of average length and standard deviation. The number of measurements was equal to the figure given under % germination, since the beginning number of seeds was 100.

[c] Statistically significant difference between control and treatment indicated by † (5% level).

[d] Not a weed, cultivar Curlycress.

TABLE 2. VISIBLE DIFFERENCES BETWEEN GERMINATING WEED SEEDS IN PRESENCE AND ABSENCE OF GERMINATING SORGHUM SEEDS

Weed	Control	Cogerminated with sorghum
Barnyard grass	At 3 days, radicles appeared healthy with no necrosis. At 7 days, plumules were uncurled and seedlings appeared vigorous with strong, branching roots.	At 3 days, necrosis of some radicles was evident. At 7 days, plumules were not uncurled and most roots had no branching with some necrosis.
Curly dock	At 4 days, radicles had abundant root hair development and 48 green, emerging hypocotyls were visible. At 7 days, roots were hairy and branching and 41 sets of cotyledons were developed with 28 fully open. Cotyledons were deep green in color.	At 4 days, only some radicles had root hairs and only 21 green, emerging hypocotyls were visible. At 7 days, roots had little branching and only 14 sets of cotyledons were developed with only four fully open. Cotyledons were much smaller and less green than controls.
Green foxtail	Overall appearance was healthy.	Overall appearance was healthy. Other than size, not visibly different from controls.
Johnson grass	At 7 days, seedlings were healthy in appearance with branching roots and two developed leaves.	At 7 days, roots were thinner than those of the controls and only five seedlings had developed two leaves.
Morning glory	At 3 days, radicles were branched and cotyledons were open. The general appearance was healthy with no necrosis. At 7 days, seedlings had overall healthy appearance with no necrosis.	At 3 days, radicles had fewer and much smaller side branches than the controls and some were necrotic. Only two seedlings had open, fully developed cotyledons. At 7 days, considerably more necrosis than control including both roots and hypocotyls.

Pigweed	At 3 days, all seedlings appeared healthy. At 7 days, lateral root development was apparent. Roots had no necrosis and 76 sets of cotyledons were fully developed and open.	At 3 days, necrosis of some radicles was evident. At 7 days, roots were brown and necrotic with almost no lateral root development. Only 33 sets of cotyledons were opened.
Red sorrel	At 3 days, seeds were just visibly germinated. At 7 days, seedlings had 56 sets of open cotyledons and all roots were healthy with hairs.	At 3 days, not visibly different from controls. At 7 days, seedlings had 50 sets of open cotyledons but their roots were thinner and less vigorous than controls, and only some roots had hairs.
Velvetleaf	At 3 days, radicles were long and healthy in appearance and seven hypocotyls were formed. At 7 days, 48 sets of cotyledons were fully developed and some roots were branched.	At 3 days, there was pronounced necrosis of radicles and no cotyledons were formed. At 7 days, hypocotyls were thinner than controls and only six sets of cotyledons were developed. Roots were necrotic.
Wild mustard	At 3 days, 32 open, developed sets of cotyledons were visible, radicles were sturdy with some side branches and no necrosis. At 7 days, seedlings were sturdy and healthy with only one underdeveloped set of cotyledons; roots were well developed with much branching.	At 3 days, 40 open, developed hypocotyls were visible. Radicles were less healthy in appearance than controls and some were necrotic. At 7 days, many seedlings were pale and underdeveloped with necrosis of roots and necrosis at juncture of radicles and hypocotyls.
Cress	At 3 days, seedlings were healthy in appearance with large, green cotyledons. At 7 days, some necrosis of radicles and cotyledons was visible.	At 3 days, seedlings were less developed than controls. At 7 days, seedlings had much more necrosis than controls and were, in general, unhealthy in appearance.

barnyard grass by 20% and pigweed by 40%, but increased the germination of green foxtail by as much as 17%. The effect on weed germination was more pronounced for the concentrated root exudate than for cogermination with sorghum seed.

Growth of interplanted sorghum and selected weeds in clay pots for periods of up to two months demonstrated that the inhibitory influence of sorghum extends at least into early stages of sorghum growth. The suppression of weed growth by sorghum was clearly more than competition for light and nutrients as demonstrated by the data presented in Figure 1. As the ratio of barnyard grass seeds to sorghum seeds per pot was decreased, the dry weight per plant of the 5-week-old leaves and roots of barnyard grass decreased (white bars of Figure 1). Alone, this could be interpreted as competition, but when identical interplantings were watered not with tap water, but with the leachate collected from pots planted with 25 sorghum seeds, the dry weight per plant of barnyard grass leaves and roots was reduced greatly in all cases (black bars of Figure 1).

The data presented in Figure 2 show that pigweed also was affected adversely in interplantings with sorghum. The harvested leaves and stems of pigweed plants grown in pots with sorghum for two months contained less than 5% of the amount of dry matter in the controls in the most extreme case where five pigweed seeds were interplanted with 20 sorghum seeds. Root development

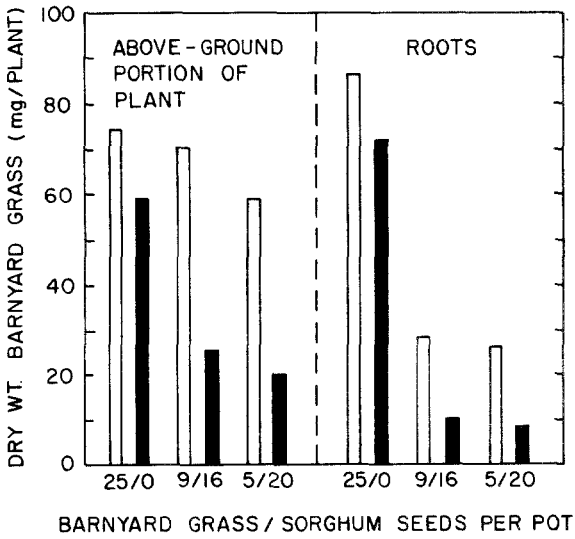

FIG. 1. Dry weights of barnyard grass five weeks after planting in pots by itself or interplanted in two different ratios with sorghum. White bars indicate average weights obtained from pots watered with tap water. Black bars represent average weights from pots watered with leachate obtained from watering pots planted with 25 sorghum seeds.

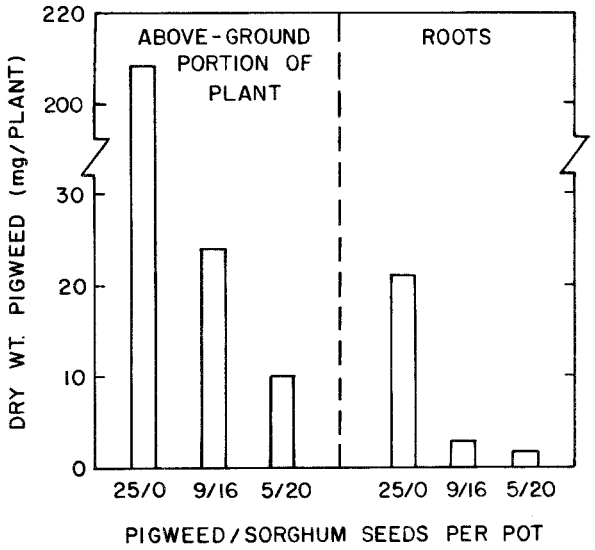

FIG. 2. Average dry weights of pigweed two months after planting in pots by itself or interplanted in two different ratios with sorghum.

of pigweed was suppressed to less than 10% of the growth of controls in the most extreme case.

The growth of red sorrel interplanted with sorghum in pots was inhibited greatly. Two months after planting, the average dry weights of controls (25 red sorrel seeds per pot) was 49.4 and 44.9 mg/plant for the above-ground portion of the red sorrel plants and the roots, respectively. For pots interplanted with 12 red sorrel seeds and 13 sorghum seeds, the harvested average dry weights of the above-ground portions and roots of red sorrel were 23.4 and 15.2 mg/plant (reductions of 53% and 66%), respectively.

In visual observation for periods of up to two months of Jimsonweed and velvetleaf interplanted with sorghum in pots revealed that growth of these weeds also was suppressed greatly by sorghum in comparison to control plantings of the weeds alone. Sorghum had no visible effect on interplanted wild mustard, morning glory, and green foxtail.

DISCUSSION

Our results suggest that young sorghum seedlings produce allelochemicals that can influence the growth and development of a number of weeds. The allelopathic influence of sorghum on some weeds appears to extend from the early stages of germination through at least two months of growth. Other pre-

viously cited investigators have demonstrated that mature sorghum and residues of sorghum plants exert allelopathic effects on other plants, so it is likely that this phenomenon persists throughout the entire growth cycle of sorghum. Under some circumstances, sorghum exerts a pronounced detrimental effect on subsequent planting of sorghum in the same plot (Burgos-Leon et al., 1980), again suggesting the production of allelochemicals that can persist until the next growing season.

In a preliminary experiment, we arranged cress seeds in concentric circles around sorghum seeds germinating on moist filter paper in the center of large, 12-cm Petri dishes. In every trial, the cress seedlings farther removed from sorghum were visibly larger and healthier as they developed. When sorghum was germinated on one side of a divided Petri dish and cress or weeds on the other side, no effect was observed even though the cress or weeds were in close proximity and shared the atmospheric environment of the Petri dish. Taken together, these observations suggested that sorghum produces allelochemicals that are nonvolatile and are water-soluble to the extent that they were able to migrate from sprouting sorghum seeds to nearby locations on a moist filter paper. The reduction in the detrimental effect on cress with increasing distance from the germinating sorghum suggested that the allelochemicals are produced in limited amounts and diffuse slowly from the origin.

Later experiments with root exudates obtained from sorghum potted in sand or grown so that the roots protruded into the water gave further proof that the active allelochemicals are water-soluble. These root exudates suppressed the development of sprouting weed seeds, and the activity could be increased by concentrating the aqueous leachate.

While the allelopathic potential of young sorghum seedlings grown under the laboratory conditions described in this report seems evident, extrapolation of these findings to field conditions is not possible. Our laboratory systems were free of all but a few adventitious microorganisms. In the field, allelochemicals exuded by germinating sorghum seeds or sorghum roots would be subject to possible alteration by soil microorganisms, although the allelopathic effect of mature sorghum residues has been shown to persist from one growing season to the next. Furthermore, our experiments were carried out on moist filter paper, in sand, or with sorghum roots in water while certain soils probably have the capacity to bind and immobilize some allelochemicals. The growth of sorghum following sorghum is markedly decreased in sandy soil, but not at all in soils high in montmorillonite (Burgos-Leon et al., 1980), which supports the contention that allelochemicals may be absorbed on certain types of soil particles, such as clay. Extensive testing would be necessary to document the influence of young sorghum on weeds under various field conditions.

Phenolic compounds, such as *p*-coumaric, *m*-hydroxybenzoic, and protocatechuic acids, have been implicated as the principal allelochemicals produced

by mature sorghum roots (Burgos-Leon et al., 1980). It is likely that these or related phenolics are responsible for the very early allelopathic influence of sorghum on weeds that we have observed. Work is in progress to isolate and identify the active allelochemicals that are produced by sorghum from the time of germination through the first few weeks of growth.

Acknowledgments—The authors thank Dr. John G. Phillips for assistance in organizing the methodology employed in this work and for statistical interpretation of data.

(Received June 17, 1985; accepted October 28, 1985)

Abstract—Three compounds have been identified in the abdominal tip extracts from the female leopard moth, *Zeuzera pyrina L.* Gas–liquid chromatography and mass spectroscopy data showed that (*E*, *Z*)-2, 13-octadecadien-1-ol acetate was the main component and that (*Z*)-13-octadecen-1-ol acetate and octadecan-1-ol acetate were secondary components. The electroantennographic responses of male *Z. pyrina* to nanogram amounts of all four 2, 13-octadecadien-1-ol acetate isomers indicated that the *E*, Z isomer had the maximum activity. A strong EAG response was also recorded for (*Z*)-7-dodecen-1-ol acetate, which was not detected in the female extracts.

Key Words—Sex pheromone, leopard moth, *Zeuzera pyrina*, Lepidoptera, Cossidae, (*E*, *Z*)-2, 13-octadecadien-1-ol acetate, (*Z*)-13-octadecen-1-ol acetate.

INTRODUCTION

The leopard moth *Zeuzera pyrina L.* (Lepidoptera: Cossidae) is a wood borer of worldwide distribution. In Italy the larvae inflict serious damage on pear, apple and olive trees. When newly hatched, the larvae wander for some time and then enter and feed in upper twigs; as they develop, they move to larger branches and increase the damage. Pupation and adult emergence take place one or two years later.

0098-0331/86/0600-1545$05.00/0

The control of this pest is difficult because of the inaccessibility of the older larvae to insecticides. The availability of the *Zeuzera pyrina* sex pheromone would then be very useful for the timing of insecticide applications during the migration of the young larvae.

METHODS AND MATERIALS

The larvae and pupae used were collected from apple trees in the Mantova and Ravenna areas and were fed on an artificial diet (Navon, 1977). Pupae were segregated by sex and kept at a 18–25°C and 75 ± 5% relative humidity on a 9-hr dark–15-hr light regime. Each pupa was rolled up in a wet filter paper tube (ID 1 cm, length 6 cm) to aid emergence. Two weeks after pupation, adults emerged over a period of 20 days. Crude extracts from calling females were obtained as previously described (Capizzi et al., 1983).

Observation of the insects' behavior and gas–liquid chromatography (GLC) analyses of extracts of single female abdominal tips showed that the highest emission of pheromone occurred during the first day and two hours into the scotophase. GLC was done on Carlo Erba gas chromatographs (models HRGC 5300 or HRGC 4160), equipped with an automatic splitless injector system and flame ionization detector. OV-1 glass capillary column (15m, 0.3 mm ID, 0.15 μm coating, H_2 carrier, flow 28 cm/sec), OV-101 glass capillary column (30 m, 0.25 mm ID, 0.2 μm coating, H_2 carrier, flow 32 cm/sec), Carbowax 20 M fused silica capillary column (30 m, 0.25 mm ID, 0.25 μm coating, H_2 carrier, flow 34 cm/sec), or SP-2340 fused silica capillary column (30 m, 0.32 mm ID, 0.25 μm coating, He carrier flow 30 cm/sec) were used.

Mass spectra (MS) were determined on a Varian Mat 112 S instrument with electron impact source, on-column injector, and a Mat 200 data system, that was interfaced with a Varian 3700 capillary GLC. An OV-1 glass capillary column was used (25 m, 0.3 mm ID, 0.15 μm coating, He carrier flow 30 cm/sec).

The technique for recording male moth electroantennographic responses (EAGs) was described elsewhere (Tonini et al., 1982). Antennal responses to GLC fractions of female extracts or to standards were determined and normalized against a reference compound.

Precoated silica gel TLC plates were used to separate active components in the crude extracts. The plates were developed with hexane–ether (98:2, v/v) and detected by UV (254 nm).

Microepoxidation was done on less than 300 ng of purified active component in hexane by adding 20 μg of *m*-chloroperbenzoic acid and allowing the mixture to stand for 3 hr at room temperature. The crude reaction mixture was analyzed by GLC and GLC-MS.

Microozonolysis was done on hexane solutions of the purified active compounds at −78°C as previously described (Capizzi et al., 1983)

Derivatization with dimethyl disulfide (DMDS) was a modification of the method described by Francis and Veland (1981), by Buser et al. (1983), and by Leonhardt and DeVilbiss (1985) for diunsaturated acetates. The results are described elsewhere (Vincenti et al. 1985).

The route used to prepare all the isomers of the natural pheromone is outlined in Figure 6.

Field tests were done in apple orchards of the Ravenna area using Traptest (Farmoplant) traps (Arsura et al., 1977) during the 1983 and 1984 *Zeuzera pyrina* flight seasons. All the traps were suspended from branches 1.5 m above the ground and positioned 300 m apart.

OV-1 GOTC column, 25 m, 0.3 mm ID, He carrier, on-column injection, 80°C, 7°C/min to 300°C, 1 scan/sec (*m/e* 29–500); ion source temperature 260°C, filament current 1.5 mA. (B) MS data for I: *m/e* (relative intensity) [assignment]: 248(4)[M^+-60], 219(0.6)[$M^+-(60+29)$], 205(1)[$M^+-(60+43)$], 192(0.4), 191(1.5), 61(3.5), 55(100), 43(97).

Synthetic chemicals were dissolved in methylene chloride and the appropriate amount of solution soaked into rubber septa (5 × 9-mm rubber stoppers, sleeve type), then used as baits.

RESULTS

Seventy females tips were extracted in hexane. A two-females equivalent was injected into the OV-101 column. Fractions were collected at 2-min intervals up to 60 min and were assayed by EAG. As shown in Figure 1, EAG activity was recorded for the fraction collected at 38–40 min. The main peak I in Figure 1 was followed by two minor peaks, Ia and Ib, and all the retention times corresponded to those of linear 18-carbon acetates (18:Acs).

Samples for GLC-MS analysis and microreactions were purified by TLC and were a mixture of three components (Figure 2A). From the MS data (Figure 2B), the significant ions at *m/e* 248(M^+-60, 4%) and 61 [$(CH_3CO_2H_2)^+$, 3%], diagnostic for diunsaturated 18:acetates, were assigned to peak I. The significant ions at *m/e* 250(M^+-60, 8%) and 61 (15%), diagnostic for monounsaturated 18:acetates, were assigned to peak Ia. The significant ions at *m/e* 252(M^+-60, 0.5%) and 61 (53%), diagnostic for octadecan-1-ol acetate, were assigned to peak Ib. The GLC of standards on OV-1 and Carbowax 20 M columns confirmed these data.

Microepoxidation of I gave only one mono epoxide ($M^+ = 324$; $M^+-60 = 264$ *m/e*). In conjunction with the MS data, this suggested that I had one of the double bonds in a poorly reactive position. Microozonolysis of I produced 1,11-undecanendial which was identified by comparison of the GLC-MS data and of the GLC retention times with those obtained for a standard. These results suggested that there was a nine-carbon-atom interval between the two double bonds. No other oxy compound was identified in the reaction mixture by GLC, probably because the other two products were eluted with the solvent.

The assignment of the position of double bonds was done by preparing the DMDS adducts of I, as outlined in Figure 3. Five hundred nanograms of I were

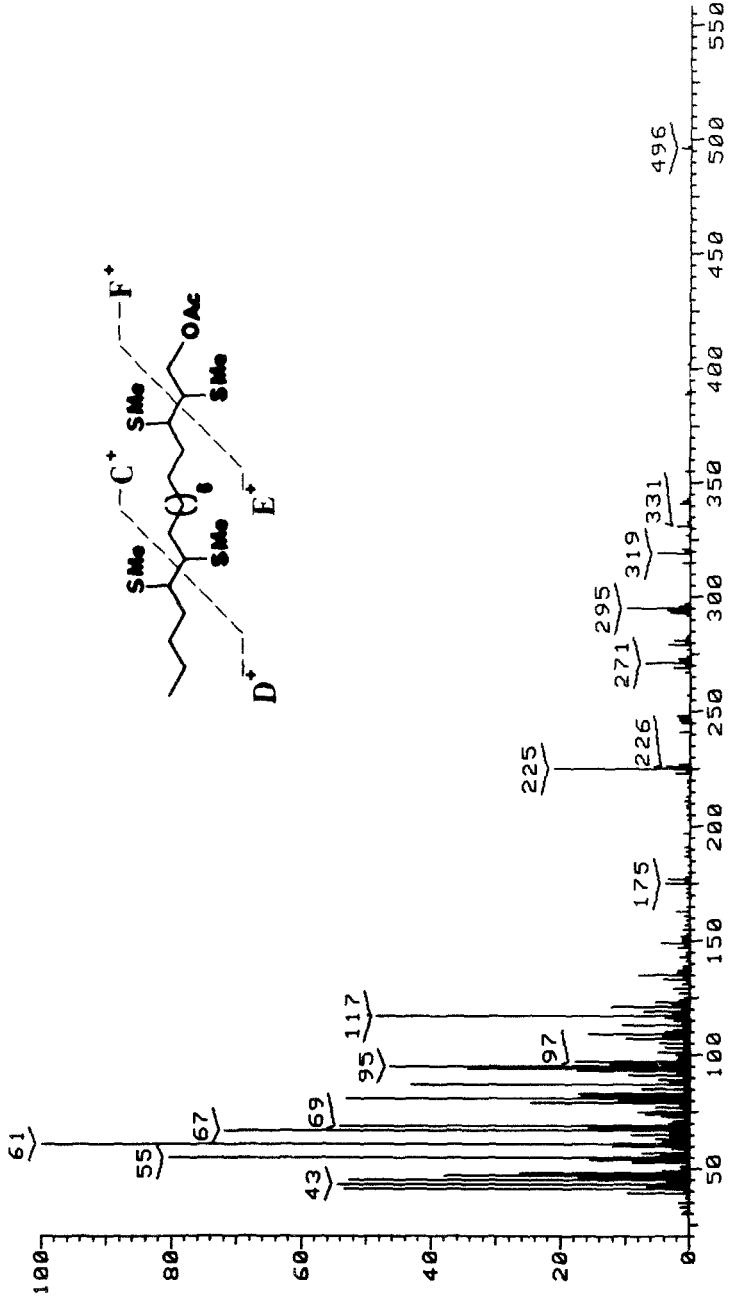

FIG. 4. (A) EI mass spectrum of the mono-DMDS adduct of I: *m/e* (relative intensity) [assignment]: 402(4)[M^+], 285(1)[A^+], 225(53)[$A^+ - 60$], 117(81)[D^+]. (B) EI mass spectrum of the di-DMDS adduct of I: *m/e* (relative intensity) [assignment]: 496(1.5)[M^+], 331(2)[$C^+ - 48$], 319(5)[$C^+ - 60$], 315(1.2)[$E^+ - 48$], 269(2.6)[$E^+ - 47 - 47$], 225(21)[$C^+ - 47 - 47 - 61$], 133(4)[F^+], 117(48)[D^+].

reacted with DMDS for three days and the adducts were analyzed by GLC-MS. The reaction mixture contained only two adducts: the di-DMDS derivative (30%) and one mono-DMDS derivative (70%) (Figure 3). The other possible mono-derivative was not detected. The MS (EI, 70 eV) showed recognizable ions and key fragment ions that indicated the positions of the CH_3S groups. The mono-DMDS adduct (Figure 4A) showed unequivocally that one double bond was in the 13 position. The di-DMDS adduct (Figure 4B) confirmed the same position and showed the 2 position for the other double bond. The spectrum of the di-DMDS adduct of I was identical with that of the corresponding derivative of the synthetic material. Thus I was identified as a 2, 13-octadecadien-1-ol acetate.

A more precise analysis of the DMDS adducts mixture allowed us to find the double bond in Ia (Figure 5). In spite of the very low amount available, we identified the double bond in the 13 position; all the data corresponded to those of a standard sample of *Z*13–18 : Ac.

The preparation of the four isomers of 2, 13–18 : Ac was done by the route reported in Figure 6. All the compounds were analyzed by GLC on the Carbowax 20 M column, and the retention time of the *E*, *Z* isomer coincided with the one of the TLC purified I (Figure 7). This result was confirmed by an independent experiment on the SP-2340 capillary column.

The results of male EAGs to the most active compounds are shown in Figure 8. The four isomers of 2, 13–18 : Ac, *Z*13–18 : Ac, the four isomers of 3, 13–18 : Ac, and *Z*7–12 : Ac were the only standards showing an activity higher than 1 mV. No other active compound was found among most of the known sex attractants and pheromones of Lepidoptera, all available in this laboratory.

*Z*7–12 : Ac was not in the female extracts but its EAG activity (Figure 8) was in agreement with the hypothesis of the relevance of the apolar alkyl end of pheromones (Priesner, 1979; this laboratory, unpublished results). *Z*9–14 : Ac and *Z*11–16 : Ac were slightly active (responses lower than 1 mV).

Preliminary field tests were done in the Ravenna area. The traps were baited with either single compounds or various binary mixtures of all the 2, 13–18 : Ac, 2–18 : Ac, and 13–18 : Ac isomers. *Z*7–12 : Ac was tested as a possible synergist (Table 1). None of the compounds or mixtures was found to be attractive. A trap baited with two virgin females caught five males over a period of two weeks.

DISCUSSION

The data indicated that the ovipositor extracts from *Zeuzera pyrina* females contained at least three compounds that are structurally similar to the known pheromone components of Lepidoptera. The main component of the extracts was characterized as *E*,*Z*2, 13–18 : Ac. This compound is present as a sex at-

tractant in two species of Sesiidae: *Vitacea polistiformis* (Schwarz et al., 1983) and *Synanthedon tipuliformis* (Voerman et al., 1984). A second component we identified as Z13–18 : acetate is also found as main attractant in the *Chilo saccariphagus* sex pheromone (Nesbitt et al., 1980).

Our EAG results have shown that Z7–12 : Ac also had some activity; however, this compound was not detected in the female gland. Among the four isomers of 2,13–18 : acetate, the natural compound *E*, *Z* showed greater activity than the others.

Although the field results were negative, we believe that this cannot be accounted for by a lack in the design of the trap or by inactivity of the products. Our results show that using the virgin female as a bait, the trap is effective. And the EAG activities of the single products were highly positive. It is possible that other components were not detected in the female extracts and that they are essential for the attraction. It is also possible that the release rate of the chemicals was the critical factor in the field tests. Thus we are now working on these two lines with the aim of clarifying these crucial points.

(Received April 15, 1985; accepted September 11, 1985)

Abstract—1,7-Dioxaspiro[5.5]undecane (olean), the major component of the female sex attractant pheromone blend of the olive fruit fly *Dacus oleae* (Gmelin) was shown to be released as a racemate. The response of males and females to pure (*R*)-(−) and (*S*)-(+)- enantiomers was tested under laboratory and field conditions. Males in laboratory and field tests responded only to (*R*)-(−)-olean, which functions as a sex attractant. Females responded only to (*S*)-(+)-olean in laboratory tests but not in the field. There are indications that the latter enantiomer fuctions as a short-range arrestant throughout the day and as an aphrodisiac in the process of mating.

Key Words—*Dacus oleae*, olive fruit fly, Diptera, Tephritidae, pheromones, enantiomers, sex attractants, sex-specific enantiomers.

INTRODUCTION

Female *Dacus oleae* flies release a sex pheromone which functions as a potent long-range male attractant (Haniotakis, 1974; Haniotakis et al., 1977; Delrio et al., 1982). This attractant has been found to be a mixture of the following four substances: 1,7-dioxaspiro[5.5]undecane (I), α-pinene (II), *n*-nonanal (III), and ethyl dodecanoate (IV) (Mazomenos et al., 1981). We suggest "olean" as the name for 1,7-dioxaspiro[5.5]undecane and will use this term in this paper. Baker et al. (1980) identified olean from female *D. oleae* rectal glands. Ma-

zomenos and Haniotakis (1981) found that the natural olean is more attractive than any of the other three alone, but a mixture of all four is more attractive than pure olean. Similar results were obtained with the four synthetic compounds (Mazomenos and Haniotakis, 1984).

The presence of a male sex pheromone has also been reported; De Marzo et al. (1978) observed female attraction by males in laboratory bioassays. Mazomenos and Pomonis (1983) reported the isolation of olean from rectal gland extracts of wild males which is as attractive to males as olean isolated from females. The same authors observed no female attraction to olean of either male or female origin. EAG studies of the racemic mixture of synthetic olean showed similar response of male and female antennae (van der Pers et al., 1984). These findings raised doubts as to the exact function of olean as a sex pheromone. Could the same compound be utilized by both sexes for inter- or intra-sex communication?

The purpose of the present work was to clarify this as well as the following questions: (1) Do the enantiomers of olean show different biological activities against males and females of the olive fly? (2) Which enantiomeric composition does the naturally occurring olean show?

METHODS AND MATERIALS

Test Compounds and Chemical Analysis. Samples of (*R*)-(−)- and (*S*)-(+)-enantiomers of 1,7-dioxaspiro[5.5]undecane (olean) were available through the syntheses of Redlich and Francke (1984) and Mori et al. (1984). Optical purity of the compounds was 96–99% e e as determined by complexation gas chromatography (Weber and Schurig, 1984).

Volatile compounds from female and male olive flies were obtained by pentane extraction of excised rectal glands, cold trap condensation of head space components (Haniotakis et al. 1977), and "closed loop stripping" of living insects with a modified Grob apparatus (Grob and Zurcher, 1976: Boland et al., 1984). Gas chromatographic separation of enantiomers of natural olean was carried out by the complexation method.

Lab Bioassays. The biological activities of (*R*)-(−)- and (*S*)-(+)-olean were tested on both sexes in two types of olfactometers.

Olfactometer type A has been described in detail by Haniotakis (1974). It consisted of a wooden 1.38 × 0.96 × 0.38-m box with a clear Plexiglas top divided into two sections by a partition along its long axis so that two components can be tested simultaneously. A regulated air stream inside each section carried the chemical stimulus, dispensed from 1-ml polyethylene vials loaded with 1 mg of the compounds under test. Responding insects entered a glass cage upwind where they were counted. Insect response was observed for 24 hr and recorded 3 hr before the end and at the end of the photoperiod.

Olfactometer type B, consisting of a 95 × 70 × 40-cm screen cage, has been described by Mazomenos and Haniotakis (1981). A regulated air stream along the long axis of the cage carried the chemical stimulus, evaporated from a triangular 7.5-cm^2 Whatman No. 1 filter paper placed close to the cage ceiling. Concentrations of 1 or 10 g of the compounds under test were used on a different piece of filter paper for each test. The number of insects landing on the paper was counted for 10 min and recorded every 5 min. Tests were conducted during the last 2 hr of the photophase.

Lab-cultured *D. oleae* flies (Tsitsipis, 1977) were used for the tests. Flies 1–2 days old (unmated) were immobilized by chilling at 2–4°C for 1–2 hr and separated according to sex. They were kept in screen cages 270 cm^3 in artificial light (3000 lux intensity) and 10:14 hr dark–light regime. Temperature was 25 ± 2°C and relative humidity 65 ± 5%.

Field Tests. Plywood rectangles 15 × 20 cm coated with sticky substances were used as traps. One-milliliter polyethylene vials loaded with 1 mg of the compound to be tested in 100 μl of pentane containing traces of triethylamine, which served as a stabilizer, were used as dispensers. Traps were checked and rotated once per week.

RESULTS AND DISCUSSION

Chemical Analysis. In a nonacidic medium 1,7-dioxaspiro[5.5]undecane (olean) proved to be rather stable. In contrast to the isomeric bark beetle pheromone, 2-ethyl-1,6-dioxaspiro[4.4]nonane, chalcogran (Francke et al., 1977), pure enantiometers of olean do not tend to racemize easily.

Complexation gas chromatography of gland extracts and cold-trap condensation from both sexes showed the obtained natural olean to be a racemate. A pentane solution of the charcoal absorbed volatiles from a "stripping experiment" with 4000 living females was cooled on Dry Ice and analyzed within 30 hr after collection; the sample contained large amounts of racemic olean.

Tests with Olfactometer Type A. Table 1 shows the response of *D. oleae* males and females to both enantiomers of olean in olfactometer type A. Significantly more males were attracted to (*R*)-(−)-olean (62.2) than to (*R*)-(+)-olean (24.6). Male responses to pentane was 22.5 ± 8.8%. Male response to (*R*)-(−)-olean coincided with the mating period of this insect.

More females on average responded to (*S*)-(+)-olean (9.6) than to the (*R*)-(−)-enantiomer (5.6), but the difference is not significant. Female response to pentane was 4.7 ± 3.3%. Observation of female behavior during testing hours suggested that female response was not the result of a chemical attractant but rather to an arrestant or tranquilizer. Since such pheromones usually have short-range activity, it was decided to repeat the same bioassays but with a shorter distance between dispenser and insect cage. This distance was set at 10 cm,

and the results of these tests are shown on Table 2. The difference in female response between (*R*)-(−)- (13.8) and (*S*)-(+)- (4.0) enantiomers is highly significant. Contrary to that of males, female response was not restricted to the mating period. It was expressed throughout the light period.

Tests with Olfactometer Type B. Table 3 shows male response in olfactometer typr B. Significantly more males responded tp (*R*)-(−)- (47.0 total) than to S-(+)-olean (21.3 total). Response to (*S*)-(+)-olean or to the racemic mixture of the two enantiomers (41.6 total) does not differ from that to the control (30.1 total). The behavior of responding males called to mind typical positive

olfactory attraction, namely zig-zag upwind flying inside the plume toward the source and landing on it. The same tests were repeated with female insects. In this case no response was observed to either enantiomer, while the behavior of females showed no signs of olfactory attraction. The lack of demonstration of female response, such as appeared in tests with olfactometer type A, may be attributed to the restricted time of each test (10 min).

Field Tests. Table 4 shows the number of insects captured by both enantiomers in field tests. Significantly more males were captured by (*R*)-(−)- (5.3) than (*S*)-(+)- (0.4) olean. No females were captured by either enantiomer. It should by pointed out that *D. oleae* populations at the site of these experiments, as is known from many years of observations, decline about mid-May and increase again in late August or early September. The low captures from May 17 to August 23 must therefore be attributed to that reason.

The data presented up to this point show that (*R*)-(−)-olean is a male attractant and male response coincides with the mating period of this species. It is therefore clear that it functions as a sex attractant. In addition, as known from previous work (Haniotakis, 1979), female *D. oleae* flies release this compound throughout the light period at a very low rate, and its release increases greatly during the mating period. It is also known from previous work that olean is a

long-range attractant which does not primarily influence the males' ability to mate after visual contact has been established with receptive females (Delrio et al., 1982, and upublished data).

Furthermore, females respond to (*S*)-(+)-olean, but its exact function is not clear. The mating behavior of this species has not been studied under field conditions, and it is difficult to even make assumptions of its role. Observations of the mating behavior between receptive, nonreceptive , and antennectomized

olive flies in the various combinations of sexes (unpublished data) strongly indicated the requirement of a chemical stimulus on the female for successful mating. This stimulus must play the role of female aphrodisiac or tranquilizer in the absence of which females strongly reject males. It is possible that this role may be undertaken by (*S*)-(+)-olean. In other fruit fly species which form leks during mating, there are indications that, besides visual and olfactory cues emanating from the host, pheromones seem also to be involved in lek formation (Prokopy and Raitberg, 1984, and cited references). A female population increase has indeed been observed in individual trees or orchards in which dispensers of racemic olean were used (Haniotakis et al., 1983, and unpublished data). Further work is required to verify all the above indications.

Acknowledgments—The authors would like to thank Dr. and Mrs. Mazomenos for their help in excising rectal glands, and Miss C. Siaili, agronomist, and E. Kaparos, lab technician, for technical assistance. W.F. and H.R. gratefully acknowledge financial support by the Duetsche Forschungsgemeinschaft.

(Received June 13, 1985; accepted October 29, 1985)

Abstract—Seedlings of North American *Pinus contorta* introduced to Sweden and Finland are severely gnawed by voles, e.g., *Microtus agrestis*. The level of damage varies between provenances. Chemical analyses of various phenolic compounds, monoterpenes, and resin acids of different provenances and of damaged and undamaged stems showed that some phenolic substances in the bark increased after damage without deterring the animals, that monoterpene differences between provenances were not related to vole damage, and that certain resin acids occurred in larger amounts in lightly than in severely damaged provenances. Levopimaric and neoabietic acid, and possibly abietic acid, may be important for a partial resistance to vole browsing.

Key Words—*Pinus contorta*, vole, damage, *microtus agrestis*, defense, phenols, monoterpenes, resin acids.

INTRODUCTION

Pinus contorta has been introduced in Swedish forestry as a fast-growing pine species. However, it has suffered serious damage from bark consumption by voles, chiefly *Microtus agrestis* (Hansson and Lavsund, 1982). Seeds or seedlings have been transferred from several localities in western Canada and north-

0098-0331/86/0700-1569$05.00/0

western United States, constituting distinct provenances. These provenances have been tested for growth and survival in field trials on reforestation areas all over Sweden (Lindgren, 1983). Clear differences in bark attacks by voles have been found between the provenances (Hansson, 1983, 1985).

Genetic differences in resistance to animal consumption are usually related to chemical defense systems, be they constant or induced (Haukioja, 1980), although mechanical defense or nutritional value may also vary. Two different chemical systems seem to be operating (cf. Rhoades and Cates, 1976), one with digestion-reducing substances (quantitative defense) and one with acutely toxic substances (qualitative defense). The former is assumed to be more important for long-lived and common plants such as pines and is suggested to be based on phenolic or terpenoid compounds, while the latter, based on, e.g., alkaloids, is known mainly in the case of rare or fugitive species. Phenolics have played an important role in the discussion of induced defense of deciduous trees and bushes (Bryant and Kuropat, 1980), while terpenes seem more important in conifers (e.g., Sturgeon, 1979, for bark beetles, and Radwan et al., 1982, regarding rodents). Therefore in the present study, bark of *Pinus contorta* was analyzed for various phenolic compounds, monoterpenes, and resin acids (diterpenes) in order to reveal any defense systems related to genotypes or provenances.

METHODS AND MATERIALS

Samples were taken from a field trial at Skalet, Strömsund (64°N), established in 1971 (IUFRO 1970/71), in northern Sweden on September 23, 1983, after vole damage inflicted during the winters of 1980–1981 and 1981–1982. Frost and snow appear usually in early October in this area, where indigenous pines (*Pinus silvestris*) are in the winter physiological state by late September. One square decimeter of bark was cut at 0.5 m height, i.e., at places usually attacked by the voles, from six different provenances. Three of them had been damaged severely by voles in various trials in Sweden (the conditions at Strömsund, with very high level of damage, were not completely representative) and the other three only slightly (Hansson, 1983). From the severely damaged provenances, both damaged and undamaged stems were sampled, but only undamaged stems were taken from the slightly damaged provenances. It was planned to analyze four samples in each series, but in two of the severely damaged provenances only three samples of undamaged stems could be examined.

With the material obtained, differences could be estimated between all the provenances, between severely and slightly damaged provenances, and between damaged and undamaged stems. All these examinations of differences in chemical contents were statistically tested with one-way analysis of variance. In this

way provenance variation independent of vole resistance could be separated from true defense varying between provenances or individuals. An induced defense should be manifested in a higher level of defense chemicals in damaged plants.

The bark was kept deep-frozen until chemical analyses were performed. The methods used for the various substances are described below.

Phenolics. The bark, cut into small pieces, (5 g), was refluxed with 2 × 10 ml acetone for 2 × 30 min. The extract was filtered and evaporated at reduced pressure, and the evaporated residue was fractionated between water (10 ml) and hexane (2 × 10 ml). Glycosides in the water phase were hydrolyzed with pectinase (Sigma, No. P-4625 from *Aspergillus niger*) in the dark at room temperature for 24 hr. The hydrolysate was acidified with one drop of concentrated hydrochloric acid and extracted with 3 × 10 ml ethyl acetate. The organic phase was dried with anhydrous sodium sulfate, filtered, and evaporated. The sample was dissolved in 10 ml methanol and analyzed with a Waters high-performance liquid chromatography system on a Radia-PAK C18, 5 μm column (Waters). The mobile phase consisted of a linear gradient of water–methanol–formic acid 80:20:1 to 30:70:1 for 50 min at a flow rate of 1.5 ml/min. UV absorbance at 280 nm was measured.

Monoterpenes. These were analyzed in *n*-pentane extracts of fresh bark samples by gas chromatography (GC), and absolute amounts of monoterpenes were determined by reference to *p*-cymene (1-isopropyl-4-methyl-benzene), used as an internal standard. Pentane extracts were analyzed using GC on a 50-m × 0.3-mm WCOT column with SP-1000 stationary phase inserted into a glass precolumn of 3% SP-1000 on Chromasorb W, an inlet splitter, flame ionization detector, and chromatographic data system. Operating conditions were: injector 200°C, detector 230°C, carrier gas N_2 at 1.5 ml/min, split ratio 2:55, sample vol 1–2 μl, temperature programmed from 50° to 110° at 4°/min then isothermally at 150°C.

Resin Acids. The bark samples were crushed in a mortar with liquid nitrogen and thereafter freeze-dried for 24 hr. A 100-mg sample of the freeze-dried bark meal was extracted with 2 ml of petroleum ether–diethyl ether (1:1) containing heptadecanoic acid as an internal standard in an ultrasonic bath for 2 hr. The sample was centrifuged and the extractive solution was transferred to a screw cap test tube. The residue was washed twice with 1 ml of diethyl ether, and the combined extracts were evaporated to dryness under a stream of nitrogen. The dried extract was redissolved in 1 ml of diethyl ether methanol (9:1) and methylated with freshly prepared diazomethane prior to the GC analysis. The samples were analyzed on a Varian 2700 GC equipped with a glass wall, coated capillary column with SE-30 as a stationary phase and equipped with a flame ionization detector (FID). The chromatograph was operated isothermally at 240°C. Other operation parameters were as follows; injector and detector temperatures 280°C, carrier gas hydrogen at 2.0 ml/min, and a split ratio of

1:50. Individual resin acids were identified by comparing their relative retention times to published data and with GC–mass spectrometry (Holmbom, 1977; Foster and Zinkel, 1982).

RESULTS

Vole Damage. During 1980–1982, 60% of the still-living *P. contorta* stems were damaged by voles (Table 1). Damaged appeared often repeatedly on the same stems during the two winters. Earlier, almost half the plants had died, many of them due to vole damage. Examinations of provenances with more than 12 still-living seedlings showed also in this trial significant differences between provenances as regards damage with complete stem girdling ($\chi^2 = 40.00$, $df = 22$, $P < 0.05$). This difference was still more pronounced in trials with a lower total frequency of vole damage (Hansson, 1983).

Provenances with IUFRO Nos. 2003, 2019, and 2027 were used as examples of severely damaged provenances; and Nos. 2017, 2022, and 2034 as lightly damaged ones. Differences between these provenances were greater in other less damaged trials.

Phenols. The types of phenolic compounds were generally identified with regard to the retention time in HPLC chromatograms (but see below for specific cases) and the amounts as the height (mm) of the peaks or, in the case of large amounts, in a relative sense as the integrated area below the peaks (Table 2). Analyses of variance showed significant differences for certain compounds in

27.95	0.35	0.14	0.89
33.63	0.15	0.08	0.30

[a] Significant deviations ($P \leq 0.05$) are underlined. The various phenolic substances were distinguished by chromatographic retention times.

at least some of the combinations of damaged/undamaged seedlings and provenances.

Peaks with retention times of 9.62 and 9.93 min showed only differences between the six provenances and were thus not related to the vole damage. Peaks at 5.20, 6.89, 11.61, 18.55, and 19.44 showed a lower probability of being samples from the same population for separate plants than for severely and lightly damaged provenances and thus there was no evidence of a provenance effect in those cases. Only the differences for the peaks at 12.52 and 15.63 min were significant between severely and lightly damaged provenances, and there were no separate stem effects. However, these latter probabilities were just at the border of significance.

The means amounts, as defined above, showed a consistently higher level among vole-damaged stems or provenances than among undamaged stems or lightly damaged provenances (Table 3). This demonstrates that either the voles were attracted by high contents of phenolics or that the vole damage had in-

TABLE 3. AMOUNTS OF VARIOUS PHENOLIC SUBSTANCES, DIFFERING BETWEEN PROVENANCES OR STEMS[a]

Substance (retention time, min)	Measurement	Between provenances		Between stems	
		Severely damaged provenances (N = 22)	Lightly damaged provenances (N = 12)	Damaged stems (N = 12)	Undamaged stems (N = 22)
5.20	h	25 ± 6	21 ± 8	27 ± 6	21 ± 7
6.89	h	18 ± 8	16 ± 6	22 ± 7	15 ± 6
11.61	a	445 ± 174	322 ± 115	491 ± 170	354 ± 142
12.52	h	41 ± 20	28 ± 16	44 ± 23	28 ± 12
15.63	h	38 ± 24	21 ± 8	41 ± 31	27 ± 12
18.55	a	264 ± 110	172 ± 92	318 ± 92	193 ± 93
19.44	a	904 ± 118	745 ± 238	959 ± 118	786 ± 186

[a]The values refer to either chromatographic peak height (h) or integrated areas under peaks (a) and are given as means ± standard deviation.

duced an increase in the amounts of several phenolic compounds. This higher level in damaged stems was especially pronounced at the retention times of 19.44 (identified as *trans-p*-coumaric acid), 11.61, and 18.55 min (the flavonoid taxifolin).

Monoterpenes. There were significant differences in the percentages of certain monoterpenes (retention times 14.14, 15.30, and 18.41 min) between the six provenances but not between severely and lightly damaged provenances nor between damaged and undamaged stems (Table 4). Thus, the provenance variations were not related to any resistance against vole attacks.

Resin Acids. Significant differences appeared between severely and lightly damaged provenances as regards certain resin acids (levopimaric and neoabietic acids, and less clearly so for abietic acid) and for total resin acids (Table 5). No differences appeared when only undamaged and damaged stems were compared, so individual differences were smaller than those between provenances. The amounts of the resin acids mentioned were consistently higher in the slightly damaged provenances (Table 6), which might be of importance in browsing repellence.

Total resin acids	5.65 ± 2.86	7.56 ± 2.06

DISCUSSION

The severely damaged experimental field at Strömsund was chosen for study partly because it would be possible to find induced defense in such an area, if anywhere. The increase observed in several phenolic components in attacked stems demonstrated a metabolic response of the pines, but it is not clear that it is a defense mechanism towards browsers. In spite of this reaction, the vole damage was extremely high during the whole 10-year span of this field trial and, furthermore, stems once attacked were often damaged again, usually at the bark edge of the earlier damage. The alternative, that voles selected stems

high in certain phenolic compounds, is very unlikely; phenolics are considered as generally deterring substances due to their complex formation with proteins (Whittaker and Feeny, 1971). Possibly the increase in phenolics was not directed towards the injurious agent but was just a consequence of tissue damage or repair. Davies et al. (1964) found that a high content of polyphenolic substances was associated with lack of nitrogen (cf. also McKey, 1979).

Rousi and Häggman (1984) measured the total phenol contents both of whole small *P. silvestris* seedlings (excluding roots) and of bark of *P. silvestris* grafts of various provenances and condition in northern Finland. The variation between the grafts of the same clone was so large that it seemed the phenol content in trees was not strictly controlled by genotype. However, grafts and seedlings with high contents of phenol were less damaged by hares (*Lepus timidus*).

Introduced *P. contorta* has also been severely damaged in northern Finland (Rousi, 1983). There, as in Sweden (Hansson, 1983), southern provenances showed higher frequencies of damage from voles than northern ones. Measurements of the total phenol content of *P. contorta* seedlings in Finland (Rousi, personal communication) did not show any significant difference between provenances nor any clear correlation with the frequencies of vole damage.

Rousi and Häggman (unpublished) did not find any seasonal variation of total phenols of *P. silvaticus* (graft) bark but an early autumn peak in whole shoots of one-year seedlings. The Strömsund *P. contorta* samples were taken just before the time for first snowfall and may well represent conditions during winter, when the vole attacks appear. Possibly there are provenance differences, e.g., as observed for phenols at the retention times of 9.62 and 9.93 min, due to the geographical origin as it has been observed that phenols often increase at the time of winter hardening of the trees (Alden and Herman, 1971).

A genetically determined antibrowsing resistance against mammals has been clearly demonstrated in Douglas fir (Dimock et al., 1976). Less is known about effects of plant terpenes than of phenolics on grazing or browsing animals. However, Radwan et al. (1982) demonstrated differences in pocket gopher damage to *Pinus ponderosa* seedlings differing in terpene contents.

There was no completely undamaged provenance at the Strömsund trial. This does not exclude the possibility of finding resistant genotypes, as provenances are still genetically heterogeneous. However, the main impression is that any natural defense will work for this pine species only at fairly low vole browsing pressure.

Acknowledgments—We are grateful to Barbro Harbom for analyses of monoterpenes and to Dag Lindgren for comments. The work was supported by The Foundation for Forestry Research in Sweden.

SEX-SPECIFIC PRODUCTION OF IPSDIENOL AND MYRCENOL BY *Dendroctonus ponderosae* (COLEOPTERA: SCOLYTIDAE) EXPOSED TO MYRCENE VAPORS[1]

(Received August 8, 1985; accepted November 5, 1985)

Abstract—Male mountain pine beetles, *Dendroctonus ponderosae* Hopkins, produced ipsdienol [97.0% ± 0.3 *S*-(+)] and myrcenol (90.3% ± 4.0 *E*) when exposed to myrcene vapors. Females which were exposed to myrcene vapors did not produce any ipsdienol, but did produce low levels of myrcenol (98.0% ± 0.7 *E*). Neither sex produced detectable levels of ipsdienol or myrcenol when fed for 24 hr on lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann. The sex-specific conversion of myrcene to ipsdienol and myrcenol suggests that these compounds may have behavioral significance within the species. In addition, the *S*-(+)-ipsdienol produced by male *D. ponderosae* probably functions as a repellent allomone against *Ips pini* (Say).

Key Words—*Dendroctonus ponderosae*, bark beetle, Coleoptera, Scolytidae, myrcene, aggregation pheromones, ipsdienol, myrcenol.

INTRODUCTION

Although males of *Ips* spp. produce the terpene alcohol pheromones ipsdienol [2-methyl-6-methylene-2,7-octadien-4-ol] and/or ipsenol [2-methyl-6-methylene-7-octen-4-ol] when exposed to the host tree (*Pinus* spp.) monoterpene, myrcene (Hughes, 1974), these compounds have been found only rarely in *Den-*

0098-0331/86/0700-1579$05.00/0

droctonus spp. Hughes (1973) reported that males of *D. brevicomis* LeConte, *D. valens* LeConte, *D. ponderosae* Hopkins, and *D. pseudotsugae* Hopkins produced ipsdienol when exposed to myrcene vapors, but females were apparently not exposed to myrcene, and the behavioral significance of ipsdienol was not investigated. Renwick et al. (1976) and Byers (1982) found that only male *D. brevicomis* produce ipsdienol when exposed to myrcene vapors. Byers (1982) also discovered that this ipsdienol was predominantly the *S*-(+) enantiomer, and that, in the field, racemic ipsdienol significantly reduced the response by *D. brevicomis* of both sexes to a mixture of myrcene, *exo*-brevicomin, and frontalin.

The terpene alcohol myrcenol (2-methyl-6-methylene-octa-2,7-dien-1-ol] was also found in *Dendroctonus* spp. after beetles were exposed to myrcene. *D. brevicomis* of both sexes contained significant amounts of myrcenol after exposure to myrcene vapors (Renwick et al., 1976), and female *D. ponderosae* produced small quantities of myrcenol when fed on pine logs (Conn, 1981); neither study reported whether the compound was *E*- or *Z*-myrcenol or a mixture of both isomers. Conn (1981) found myrcenol to be attractive to *D. ponderosae* of both sexes in laboratory bioassays, but in the field, response to other attractants was slightly inhibited by the presence of *E*-myrcenol (Conn et al., 1983).

Our objectives were to confirm that *D. ponderosae* can produce ipsdienol and myrcenol, to determine which sex(es) produce the compounds, and to identify which geometric isomers of myrcenol or enantiomers of ipsdienol are produced.

METHODS AND MATERIALS

Logs of lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann, infested with the mountain pine beetle were obtained near Princeton in the southwestern interior of British Columbia. The cut ends of the logs were sealed with hot paraffin wax, and the logs were stored at 4°C. To obtain adult *D. ponderosae*, logs containing brood were placed in cages at 27°C. Emergent beetles were collected daily and were stored for a maximum of two weeks on moistened paper toweling at 2–4°C in loosely capped, screw-top jars. When beetles were needed for experiments, the jars were rewarmed to room temperature, and active individuals were selected and their sex determined using the method of Lyon (1958).

D. ponderosae of both sexes were exposed to myrcene by allowing the beetles to bore in fresh lodgepole pine logs for 24 hr or by exposing them to the vapors from a 2-ml vial containing 24 μl of myrcene (>99% pure) in a 500-ml jar for 24 hr. Abdomens from individual insects were excised and extracted in twice distilled pentane. The amounts of ipsdienol and myrcenol pre-

sent in these abdominal extracts were analyzed by gas–liquid chromatography (Hewlett Packard HP5880 A) in the direct injection mode on a glass capillary column (30 m × 0.50 mm ID) coated with SP-1000 (Supelco, Inc., Bellafonte, Pennsylvania). Racemic ipsdienol was obtained from Borregaard, A.S., Sarpsborg, Norway. *E*-Myrcenol was synthesized by the selenium dioxide oxidation of myrcene (Büchi and Wüest, 1967). Analysis of the distilled product (Hewlett Packard 5985B GC-MS) revealed an *E/Z* ratio of 97:3.

The chirality of the ipsdienol produced by individual beetles was determined by the technique developed by Slessor et al. (1986). To a pentane solution (10–30 μl), containing both racemic 3-octanol (4.1 ng/μl) as an internal standard and the insect extract containing >40 ng of ipsdienol, was added a solution of pyridine (50 mg/ml) in ether (15 μl), followed by 25 μl of acetyl-*S*-lactyl chloride reagent (25 mg/ml) in methylene chloride (30 μl) prepared from chirally pure *S*-(+)-lactic acid. The components were mixed, cooled to −20°C, and sealed in a glass ampoule. Ampoules were kept at room temperature overnight. The samples were then diluted with hexane (50 μl), washed by agitation with water (50 μl), and the aqueous phase removed. The organic phase was further washed with aqueous 5% sodium bicarbonate (3 × 50 μl) and once more with water (50 μl). The samples were analyzed by splitless capillary gas chromatography on a Hewlett Packard HP5890 using a 30-m × 0.2-mm ID methyl silicone DB-1 (J&W Scientific, Inc., Rancho Cordova, California) programmed at 60°C for 2 min, 7°C/min to 130°C, 2°C/min to 240°C. Helium carrier gas was used at a flow rate of 1 ml/min, with an injector temperature of 200°C and detector temperature of 250°C. Retention times for the free alcohols, 3-octanol and ipsdienol, were 5.80 and 8.92 min, respectively. The acetyl *S*-(+)-lactic derivatives exhibited retention times of 16.21 and 16.39 min for *R*-(−)- and *S*-(+)-3-octanol, and 19.23 and 19.45 min for *S*-(+)- and *R*-(−)-ipsdienol.

RESULTS

Only male *D. ponderosae* contained detectable levels of ipsdienol (>10 ng/beetle) after exposure to myrcene vapors (Table 1). This ipsdienol was found to be predominantly the *S*-(+) enantiomer (Table 1), with relatively little variation between individuals (Figure 1). However, there was considerable variability in the amount of ipsdienol produced by individual beetles; some produced none at all, while one male contained over 7 μg of the compound (Figure 2). Neither male nor female beetles contained detectable levels of ipsdienol after feeding on *P. contorta*, either alone or with an individual of the other sex. Ipsenol was not produced at any time by either sex.

D. ponderosae of both sexes contained myrcenol, predominantly the *E*-

isomer, after exposure to myrcene vapors, although males contained significantly more than females (Table 1). Neither males nor females contained detectable levels of myrcenol after feeding on *P. contorta*.

DISCUSSION

In most bark beetles, myrcene is converted to ipsdienol more efficiently if the exposure is through feeding, while α-pinene is converted to *cis*- and *trans*-verbenol more efficiently through exposure to vapors. As a result, ipsdienol has been termed a "frass" pheromone, while *cis*- and *trans*-verbenol are termed "contact" pheromones (Vité et al., 1972). Our data, as well as those presented by Byers (1982) and Hughes (1974), indicate that in *Dendroctonus* spp. myrcene is actually oxidized much more efficiently with vapor exposure than with feeding. Apparently this oxidation is not performed in the same way as in *Ips* spp. This conclusion is in agreement with the hypothesis presented by Vité et

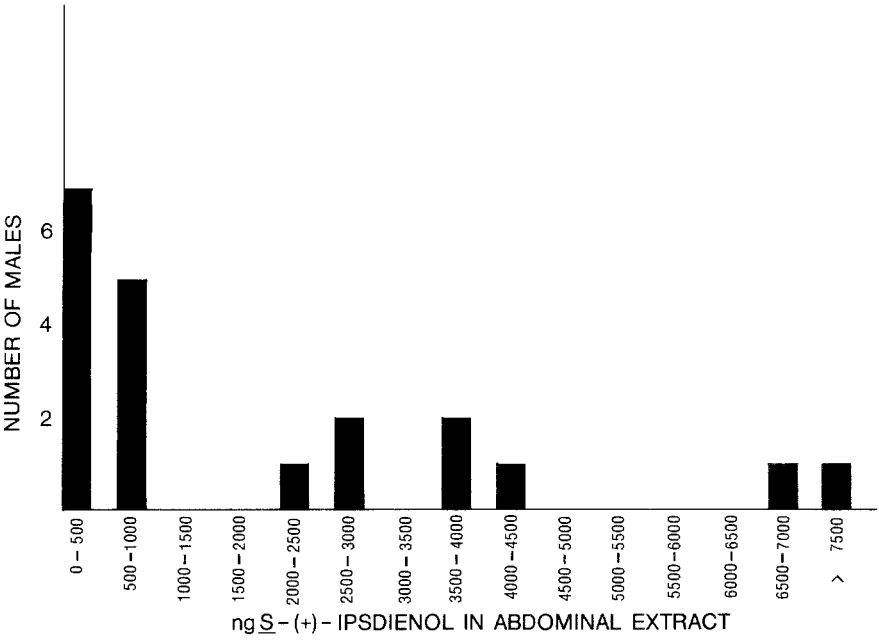

FIG. 2. Variation in *S*-(+)-ipsdienol production by 20 individual male *D. ponderosae*.

al. (1972), suggesting that aggressive bark beetles, such as many *Dendroctonus* spp., begin oxidizing monoterpenes upon initial contact with a new host, while less aggressive species, such as many *Ips* spp., depend on feeding for the conversion of monoterpenes.

The variation in chirality of *S*-(+)-ipsdienol produced by individual male *D. ponderosae* is similar to but not as extensive as the variation in the enantiomeric composition of *R*-(−)-ipsdienol in *Ips pini* (Say) from southeastern British Columbia (Figure 1) (Slessor et al., 1986). Therefore, if ipsdienol proves to be of behavioral significance to *D. ponderosae*, there seems to be less potential than in *I. pini* for natural or artificial selection pressures, such as pheromone-based trapping programs, to select for individuals that utilize different enantiomeric mixtures. The high degree of variation in total ipsdienol content (Figure 2) is in agreement with data on *trans*-verbenol in *D. ponderosae* (Borden et al., 1985), ipsdienol in *I. pini* (Borden et al., 1985) and *cis*-verbenol in *Ips typographus* Linnaeus (Birgersson et al., 1984). Borden et al. (1985) speculated that the few beetles with a capacity for producing very large quantities of terpene alcohol pheromones may be those that are successful pioneer beetles.

There is no overlap in the range of chirality of ipsdienol produced by individual *D. ponderosae* and *I. pini* (Figure 1). Birch et al. (1980) have shown

that *I. pini* from California are attracted to *R*-(−)-ipsdienol, the naturally predominating enantiomer, while *S*-(+)-ipsdienol interrupted the response of *I. pini* to an attractive source in field tests. Therefore, as in the hypothesized interaction between *D. brevicomis* and *I. pini* (Byers, 1982), the *S*-(+)-ipsdienol produced by *D. ponderosae* may function as a repellent allomone, inhibiting the orientation of *I. pini* and thus reducing interspecific competition for the same host. Moreover, the inhibitory effect of racemic ipsdienol on pheromone-positive orientation by *D. brevicomis* (Byers, 1982) suggests that the *R*-(−)-ipsdienol produced by *I. pini* may function reciprocally as a repellent allomone for *D. brevicomis*.

The sex-specific conversion of myrcene vapors to ipsdienol and myrcenol by *D. ponderosae* suggests that either or both products may have behavioral significance within the species. However, with the exception of the work by Byers (1982) on *D. brevicomis*, and Conn (1981) and Conn et al. (1983) on *D. ponderosae*, the oxidation of myrcene by *Dendroctonus* spp., and its possible biological roles, have not been studied. This omission is likely due to the fact that in most pheromone isolation studies beetles are induced to produce pheromones by allowing them to bore in host phloem tissue in cut logs that no longer produce copious amounts of monoterpene-rich resin. Thus, it is not surprising that oxidation products of monoterpene vapors have been largely overlooked. In addition, female *Dendroctonus* spp., which have been studied more intensively than males because they initiate attacks on new host trees, do not appear to oxidize myrcene to the same extent as males. As a result the possible behavioral significance of ipsdienol and myrcenol for *Dendroctonus* spp. has been largely ignored. This topic is presently under study.

(Received July 22, 1985; accepted November 12, 1985)

Abstract—*Pissodes strobi*, *P. approximatus*, and *P. nemorensis* are sibling species of pine weevils that can hybridize in the laboratory but are presumed to be reproductively isolated in nature. Males of all three species produce the terpenoids grandisol and grandisal; these compounds serve as an aggregation pheromone for *P. approximatus* and *P. nemorensis* when deployed with odors from pine bolts. A series of field experiments examined the possibility of cross-attraction among the three species. Tests in New York and Florida found that parapatrically distributed *P. approximatus* and *P. nemorensis* were cross-attractive, but different photoperiodic conditioning was required for pheromone production in males of the two species. Long-day pheromone production (*P. approximatus*-type) was inherited in interspecific hybrids. Other tests showed that *P. strobi* males, or hybrid males from crosses of *P. strobi* with *P. approximatus*, were not attractive to sympatric *P. approximatus*. When the response of *P. strobi* was assessed to males of either *P. strobi* or *P. approximatus* confined on white pine leaders (the breeding site of *P. strobi*), no evidence of cross-attraction or pheromone activity was found; *P. strobi* were caught in equal numbers on *P. strobi*-baited leaders, *P. approximatus*-baited leaders, and unbaited leaders. Tests of interspecific interactions found that male *P. strobi* produce an allelochemical signal that interrupts the response of *P. approximatus* to its natural or synthetic aggregation pheromone. This interspecific response is apparently adaptive for members of both species (classified as an allomone-kairomone or synomone) because it may ultimately serve to prevent interspecific matings that would lower the fitness of the parents.

Key Words—*Pissodes*, Coleoptera, Curculionidae, aggregation pheromone, cross-attraction, synomone, reproductive isolation, grandisol, grandisal.

INTRODUCTION

Aggregation pheromones in *Pissodes* weevils were first reported by Booth and Lanier (1974), who found that males of *P. approximatus* Hopkins, the northern pine weevil, feeding on pine bolts would attract large numbers of conspecific males and females, while females feeding on pine bolts and pine bolts alone were not attractive. They also postulated that *P. strobi* (Peck), the white pine weevil, uses a male-produced aggregation pheromone. Booth et al. (1983) reported that males of *P. approximatus* produce two terpenoid compounds, grandisol (*cis*-2-isopropenyl-1-methylcyclobutaneethanol) and its corresponding aldehyde, grandisal, that, together with odor from cut pine logs, serve as an aggregation pheromone. They also found that males of *P. strobi* produce grandisol and grandisal, but repeated field tests have not convincingly documented attraction of *P. strobi* to these compounds (Booth, 1978; Phillips, 1981; Booth et al., 1983). Phillips and coworkers (1984) reported that male Deodar weevils, *P. nemorensis* Germar, also produce grandisol and grandisal and use them with host odors as an aggregation pheromone (cf. Fontaine and Foltz, 1982). No substantial quantitative differences in the production of these compounds among the three species, either in absolute amounts or relative concentrations, have been found (Silverstein and West,[2] unpublished data). Possible differences in enantiomeric composition of grandisol and grandisal released by these species have not been determined.

We consider *P. strobi*, *P. approximatus*, and *P. nemorensis* to be sibling species because they are very similar morphologically but are presumed to be reproductively isolated in nature. These species are genetically very similar (Phillips, 1984), can hybridize with each other in the laboratory (Godwin and ODell, 1967; Smith, 1973), but differ ecologically and behaviorally. *P. strobi* breeds in one-year-old leaders of vigorous young pines, *Pinus* spp., and spruces, *Picea* spp., across North America (MacAloney, 1930; Smith and Sugden, 1969). *P. approximatus* is sympatric with *P. strobi* in northeastern North America, but breeds in the boles, branches, and root collars of weakened or recently cut pines and spruces (Finnegan, 1958). Breeding site separation between *P. strobi* and *P. approximatus* is strong; artificially produced hybrids display reduced reproductive fitness (Phillps and Lanier, 1983). If *P. strobi* and *P. approximatus* use aggregation pheromones that incorporate grandisol and grandisal, we predict that qualitative differences would prevent cross-attraction between the species.

P. nemorensis also breeds in weakened or cut pines, but is distributed in southeastern North America and is presumed to be parapatric with *P. approximatus* (Baker, 1972; Hopkins, 1911). *P. approximatus* and *P. nemorensis* respond to the same synthetic pheromone (Booth et al., 1983; Phillips et al.,

[2] R.M. Silverstein and J.R. West, Department of Chemistry, State University of New York College of Environmental Science and Forestry, Syracuse, New York 13210.

1984), and it is quite probable that they could be cross-attractive in nature. However, *P. approximatus* and *P. nemorensis* are apparently reproductively active in different seasons (Finnegan, 1958; Fontaine et al., 1983), so cross-attraction in nature may never occur.

Here we report a series of experiments in which we investigated the activity of pheromones and allelochemics among *P. strobi*, *P. approximatus*, and *P. nemorensis*. Using field tests with live weevils, we examined cross-attraction among species, the attractiveness of interspecific hybrids, and the interspecific interruption of pheromone activity. We will assess the importance of pheromones and allelochemics in reproductive isolation and host location, and we will discuss the evolution of semichemicals in these species.

METHODS AND MATERIALS

Field experiments, described in detail below, were conducted in 1982, 1983, and 1985. Traps for assessing the response of either *P. approximatus* or *P. nemorensis* were sticky hardware-cloth cylinders placed directly on the forest floor (design of Booth and Lanier, 1974). Freshly cut pine bolts, about 15 × 25 cm, were enclosed in 30 × 45-cm fiberglass screen bags with or without male weevils and were placed inside the traps. Traps for *P. strobi* (one experiment) were 20 × 91-cm sticky hardware-cloth cylinders with the top ends covered by 20 × 20-cm sticky hardware-cloth squares. These traps were placed on poles supported by metal stakes and suspended over screen-enclosed (15 × 100-cm fiberglass screen sleeves) one-year-old leaders of 3- to 5-m tall eastern white pine trees, *Pinus strobus* L. Male *Pissodes* were then confined on leaders as attractive sources (Phillips, 1981).

Because there are no diagnostic characters for adequately separating specimens of *P. strobi*, *P. approximatus*, and *P. nemorensis*, we initially employed three working hypotheses for the identification of trapped weevils based on geographic locality or ecological qualities of the field site and experiment. Weevils trapped in Florida (experiment 2, see below) were *P. nemorensis* based on distribution. Weevils flying to traps on white pine leaders (experiment 3) in open stands were considered *P. strobi*, while those caught in New York on ground traps containing cut logs (experiments 1, 4–7) were deemed *P. approximatus*. These assumptions are drawn from accumulated information on *Pissodes* behavior, ecology, karyology, and geographic distribution; unfortunately, there is no guarantee that they are true. Therefore, we challenged our designations by performing the discriminant analysis technique of Godwin et al. (1982) on subsamples of the trap-caught specimens (Phillips, 1984). Discriminant analysis corroborated the identification of *P. strobi* and *P. approximatus* by our a priori assumptions, but of weevils that could only be *P. nemorensis* based on geographic definition (experiment 2), a majority were identified

as *P. approximatus*. The utility of the discriminant analysis technique is discussed elsewhere (Phillips, 1984; Phillips et al., 1986).

Weevils used as attractive sources were either laboratory-reared or field-collected; unless otherwise indicated, all were reproductively mature. Females of the three species have certain environmental requirements for reproductive maturity and oviposition (ODell et al., unpublished; Atkinson, 1979; Fontaine et al., 1983). Although males of all three species will produce sperm within a few days of eclosion, Booth et al. (1983) indicated that males of *P. strobi* and *P. approximatus* will not produce pheromone unless they have experienced the same maturation period and conditioning required by females for reproduction. Lab-reared insects were manipulated to ensure reproductive and pheromonal activity (Phillips, 1981), while feral insects were collected on host material during the breeding season and were considered mature and pheromonally active.

RESULTS

Experiment 1. Attraction of wild *P. approximatus* to males of *P. approximatus*, *P. nemorensis*, and *P. strobi* was assessed in a mature red pine, *Pinus resinosa* Ait., stand at Heiberg Memorial Forest (Cortland County, New York) between May 11, and June 18, 1982. This was chosen as the initial test because of the well documented pheromone behavior of *P. approximatus* (Phillips, 1981; Booth et al., 1983). All male weevils were laboratory-reared and conditioned prior to the test. *P. approximatus* and *P. strobi* were fed fresh cuttings of red and white pine, respectively, and held under ambient lighting in an insectary during April and May (increasing from 12 to 15 hr of light per day) at 25–28°C. *P. nemorensis* were fed red pine under 12:12 (light–dark) lighting at 23°C in a growth chamber for at least one month before the test. Experimental treatments consisted of five males of one species confined on a red pine bolt that was then placed in a trap; control traps included a bolt on which no weevils were caged. The four treatments were deployed in five completely randomized blocks of traps, with at least 15 m between traps and 20 m between blocks. Traps were checked weekly and live weevils or fresh bolts were replaced as needed.

Traps baited with *P. approximatus* and *P. nemorensis* males caught significantly more weevils than those baited with *P. strobi* males, which caught no more weevils than uninfested bolts (Figure 1; analysis of variance (ANOVA) followed by Student-Newman-Keuls test, $P < 0.05$). There were no differences in the number of each sex responding to any treatment (t test, $P < 0.05$). There was no marked variation in weekly responses of weevils to *P. approximatus* and *P. nemorensis* traps (Figure 2), which indicates that *P. nemorensis* males continued to produce pheromone after five weeks away from their presumed reproductive photoperiod (12:12, light–dark).

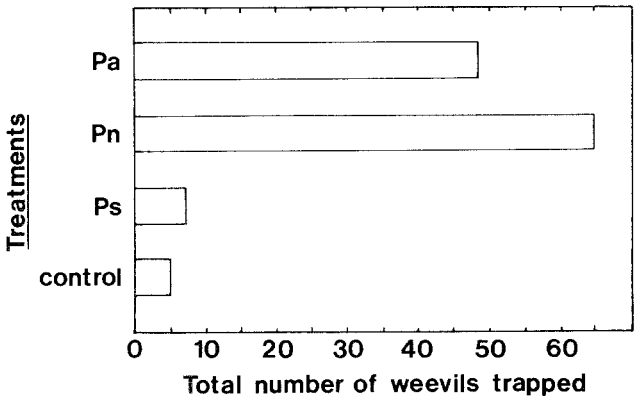

FIG. 1. Total numbers of *P. approximatus* trapped in experiment 1, five traps per treatment. All traps include bolts of red pine. Treatment designations: Pa = five male *P. approximatus*, Pn = five male *P. nemorensis*, Ps = five male *P. strobi*, control = bolt with no weevils.

Experiment 2. A second experiment was conducted in northern Florida from November 12, to December 8, 1982, in which the response of *P. nemorensis* to males of *P. approximatus* and *P. nemorensis* was examined. *P. approximatus* males were laboratory-reared and conditioned under a 16:8 (light–dark) photoperiod at 23°C for one month prior to the test; *P. nemorensis* males were field-collected from split pine billet traps (Fontaine, 1981) and kept in an insectary no more than one week before the test. Five males of each species were caged on freshly cut bolts of slash pine, *Pinus elliottii* Engelm., and bolts

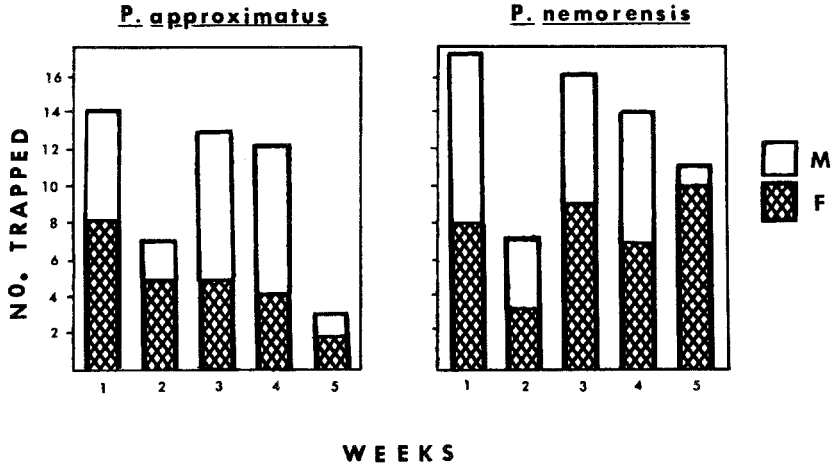

FIG. 2. Total numbers of weevils caught weekly on traps baited with either male *P. approximatus* or male *P. nemorensis* in experiment 1; M = males, F = females.

without weevils served as controls. Five completely randomized blocks, each containing the three treatments, were deployed in a young slash pine plantation west of Newberry, Florida, in Gilchrist County.

The highest responses were to traps baited with males of *P. approximatus* and *P. nemorensis* (ANOVA, $P < 0.10$); only one weevil was caught on a control trap during the three-week period (Figure 3). These results complement those of experiment 1 and lead us to conclude that *P. approximatus* and *P. nemorensis* are cross-attractive and utilize functionally identical aggregation pheromones.

Experiment 3. To further investigate the possibility of cross-attraction between *P. approximatus* and *P. strobi*, sticky traps on eastern white pine leaders were used to determine the attractiveness of males of each species to *P. strobi*. Weevils used as pheromone sources for this test were field-collected from their natural breeding sites in May 1983; *P. strobi* from white pine leaders, and *P. approximatus* from red pine logs. Leaders on randomly selected 3- to 5-m tall white pines at a plantation near Harford, Cortland County, New York, were covered with screen sleeves in April to prevent attacks by native *P. strobi*. Five replicates each of the two male treatments and the blank leader control were distributed in a totally randomized design over the 2-hectare test area; five males per leader were used for the respective baited treatments.

After a three-week period (May 23, to June 13, 1983) all traps had caught weevils, and there were no significant differences among treatments (ANOVA, $P > 0.05$; Figure 4). Although traps baited with males of either *P. approximatus* or *P. strobi* caught equal numbers of weevils, we cannot make any conclusions about cross-attraction. The large number of weevils on control traps

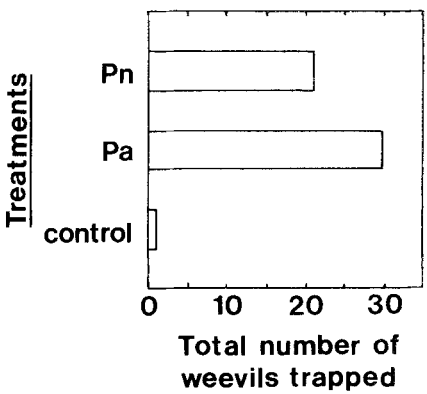

FIG. 3. Total number of *P. nemorensis* trapped in experiment 2, five traps per treatment. All traps included bolts of slash pine. Treatment designations: Pn = five male *P. nemorensis*, Pa = five male *P. approximatus*, control = bolt with no weevils.

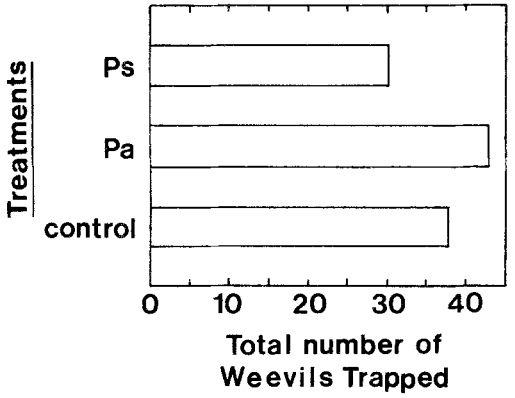

FIG. 4. Total numbers of *P. strobi* trapped in experiment 3, five traps per treatment. All traps included intact leaders of living white pines. Treatment designations: Ps = five male *P. strobi*, Pa = five male *P. approximatus*, control = leader with no weevils.

precludes any discussion of possible pheromone activity for either of the male-baited treatments.

Experiment 4. This test examined the effects of site exposure and host tree species on the attractiveness of male *P. strobi* and *P. approximatus* to feral *P. approximatus*. Bolts of eastern white pine, rather than red pine, were used as host material. Sites were chosen at Heiberg Forest so that traps could be placed in a shaded, closed-canopy stand and at a nearby sunny, open canopy or open field area. Ground traps were deployed at five sun/shade sites as paired randomized blocks in an unbalanced design. Preferred host trees for both weevil species, i.e., red pine, white pine, and Norway spruce, *Picea abies* (Karst), were available at all sites (see Smith and Sugden, 1969). Site exposure was varied because each species is known to prefer certain types of sites: *P. strobi* predominantly attacks trees in sunny, open-growth stands (MacAloney, 1930), and *P. approximatus* oviposits on the undersides of logs, generally in shaded conditions (Finnegan, 1958; Hard, 1962). Weevils used as baits (five males per bolt) were field-collected; limited numbers of male *P. approximatus* prevented equal replication of treatments.

The results after a four-week period (May 25, to June 27, 1983) indicated that the *P. approximatus* males were attractive when feeding on white pine bolts in either sunny or shaded conditions (Figure 5); traps baited with *P. strobi* males or bolts alone caught lower numbers of weevils in both shaded and sunny sites (ANOVA performed separately on sun and shade blocks, $P < 0.05$). These data are similar to those in experiment 1 in which *P. strobi* was on red pine bolts in a shaded site. *T*-test comparisons between the same treatments in sun and shade found no significant differences ($P > 0.05$).

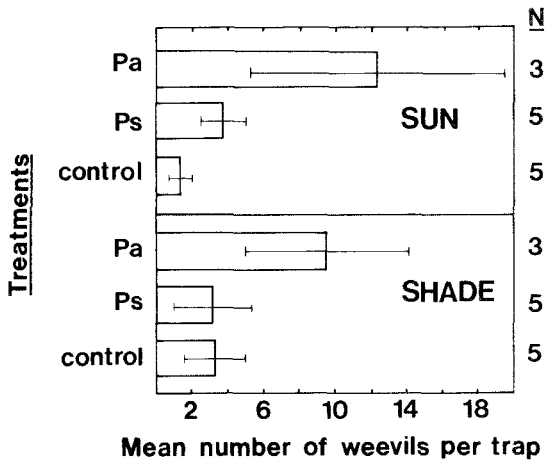

FIG. 5. Mean numbers of *P. approximatus* caught on traps in adjacent sun and shade blocks in experiment 4; N = number of traps per treatment. All traps included bolts of white pine. Treatment designations: Pa = five male *P. approximatus*, Ps = five male *P. strobi*, control = bolt with no weevils. Horizontal lines indicate standard errors of the means.

Experiment 5. The heritability of *P. approximatus* pheromone production in various types of hybrid males was examined in this experiment. Laboratory hybrids were obtained from the reciprocal crosses of *P. approximatus* with *P. nemorensis* and of *P. approximatus* with *P. strobi*. Pure laboratory strains of *P. approximatus* and *P. nemorensis* were also used; lab-reared *P. strobi* were not available for this test. Six different male-baited treatments and a control were deployed in an incomplete randomized block design at Heiberg Forest from June 6 to 28, 1983; red pine bolts were the host material, and five males were caged with each bolt. Limited numbers of progeny from various crosses prevented us from having equal sample sizes. All treatment weevils, including *P. nemorensis* and hybrids, were preconditioned in an insectary at least one month under the naturally occurring increasing spring photoperiod (14–15 hr of light) at 25–28°C. Therefore, *P. nemorensis* males were not exposed to conditions for reproductive maturation, but rather to the conditions for reproductive maturation of *P. approximatus* and *P. strobi*.

The largest catches were on *P. approximatus*-baited traps and the two *P. approximatus* × *P. nemorensis* hybrid treatments (Figure 6). *P. nemorensis*, both *P. approximatus* × *P. strobi* hybrids, and a blank bolt caught lower numbers of weevils. We presume that *P. nemorensis* males were not attractive because they were not conditioned for pheromone production. Like host selection behavior (Phillips and Lanier, 1983), pheromone production apparently breaks down in hybrids of *P. approximatus* and *P. strobi*. Significant differences oc-

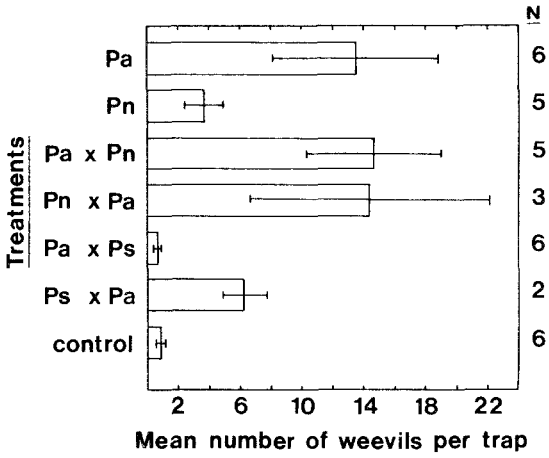

FIG. 6. Mean numbers of *P. approximatus* caught on traps in experiment 5; N = number of traps per treatment. All traps included bolts of red pine. Treatment designations: Pa = five male *P. approximatus*, Pn = five male *P. nemorensis*, Pa × Pn = five male progeny from the cross of female Pa with male Pn, Pn × Pa = five male progeny from the cross of female Pn with male Pa, Pa × Ps = five male progeny from the cross of female Pa with male *P. strobi* (Ps), Ps × Pa = five male progeny from the cross of female Ps with male Pa, control = bolt with no weevils. Horizontal lines indicate standard errors of the means.

curred among treatment means (ANOVA, $P < 0.05$), but any direct comparison of means is unreliable because of the unbalanced design of the experiment.

Experiment 6. In this experiment we investigated the possibility that, in addition to simply being unattractive to *P. approximatus*, *P. strobi* males may actively prohibit the flight of *P. approximatus* to suitable host material. Freshly cut white pine bolts and field-collected male weevils (five per bolt) were used in ground traps in a mature red pine stand at Heiberg Memorial Forest. The response of *P. approximatus* to the following treatments, arranged in five completely randomized blocks, was assessed from May 10 to 22, 1985: five male *P. approximatus* on a bolt, five male *P. strobi* on a bolt, five male *P. approximatus* together with five male *P. strobi* on a bolt, and a bolt alone as a control.

The highest responses were to traps baited with male *P. approximatus*, while the other three treatments caught significantly lower numbers of weevils (ANOVA followed by Student-Newman-Keuls test, $P < 0.05$; Figure 7). As in experiments 1 and 4, male *P. strobi* were not attractive to *P. approximatus*. However, it is quite clear from this experiment that male *P. approximatus* do not attract conspecifics when male *P. strobi* are confined with them on the same pine bolt. It is possible that male *P. strobi* produce a chemical signal that interrupts the response of *P. approximatus* to its natural pheromone, or that the

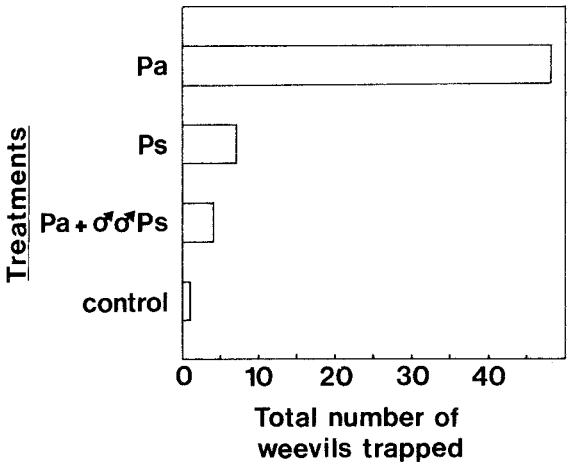

FIG. 7. Total number of *P. approximatus* trapped in experiment 6, five traps per treatment. All traps contained bolts of white pine. Treatment designations: Pa = five male *P. approximatus*, Ps = five male *P. strobi*, Pa + ♂♂ Ps = five male *P. approximatus* with five male *P. strobi*, control = bolt with no weevils.

presence of male *P. strobi* on the same bolt somehow suppresses pheromone production in male *P. approximatus*.

Experiment 7. Our last field experiment examined the possible interruption of synthetic *P. approximatus* pheromone by male *P. strobi*. Ground traps with fresh white pine bolts were used in a mature red pine stand at Heiberg Memorial Forest from May 22 to June 21, 1985. Three treatments, deployed in five completely randomized blocks, were compared for their attractiveness to *P. approximatus*: synthetic racemic grandisol and grandisal with a pine bolt (*P. approximatus* pheromone), grandisol and grandisal with seven field-collected male *P. strobi* feeding on a pine bolt, and an unbaited pine bolt as a control. Racemic grandisol was obtained commercially and grandisal was synthesized from it (method of Booth et al., 1983). Grandisol (5 mg/bait) and grandisal (10 mg/bait) were evaporated from rubber septa at the levels reported by Phillips and coworkers (1984).

The addition of male *P. strobi* to traps baited with the aggregation pheromone of *P. approximatus* depressed the response of *P. approximatus* (Figure 8). The highest response was to traps baited with grandisol and grandisal, but this was reduced by almost half (ANOVA, Student-Newman-Keuls test, $P < 0.10$) in traps containing grandisol, grandisal, and male *P. strobi*; both these treatments caught significantly more weevils ($P < 0.05$) than the control. These data suggest that pheromone production by *P. approximatus* was not suppressed in experiment 6, but confirm that *P. strobi* males produce an allelochemical signal that blocks the pheromone response of *P. approximatus*. We believe that

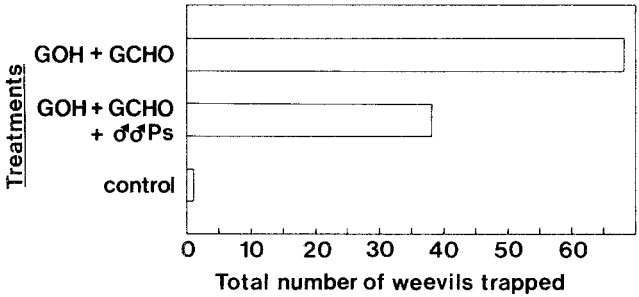

FIG. 8. Total numbers of *P. approximatus* trapped in experiment 7, five traps per treatment. All traps contained bolts of white pine. Treatment designations: GOH + GCHO = pheromone bait of grandisol and grandisal, GOH + GCHO + ♂♂ Ps = pheromone bait of grandisol and grandisal with seven male *P. strobi*, control = bolt with no weevils or bait.

male *P. strobi* could not totally interrupt the response of *P. approximatus* in this experiment because the high levels of synthetic pheromone release (about 1.0 mg/day), compared to natural release rates from male weevils (about 20 ng/day; Booth, et al., 1983), probably overwhelmed the blocking odor produced by *P. strobi*.

DISCUSSION

We can draw four conclusions about weevil-produced semiochemicals in these sibling species: (1) *P. approximatus* and *P. nemorensis* are cross-attractive and apparently use functionally identical aggregation pheromones. (2) Different environmental stimuli (e.g., photoperiod) are prerequisite for pheromone production in *P. approximatus* and *P. nemorensis*; long-day pheromone production (*P. approximatus*-type) is heritable in interspecific hybrids. (3) *P. strobi* males are not attractive to *P. approximatus*, the reciprocal relationship is not clearly supported. (4) *P. strobi* males produce an allelochemical signal that can interrupt the response of *P. approximatus* to its natural or synthetic aggregation pheromone.

If *P. approximatus* and *P. nemorensis* are biologically distinct species (i.e., no gene flow between them) that are geographically contiguous but potentially cross-attractive, there must be some mechanism preventing introgression at the zone of parapatry. The distributions of the two species are not well defined, and their designation as separate species has more of an historical rather than a biological meaning (see species descriptions by Germar, 1824; and Hopkins, 1911). There are no geological barriers that might separate their distributions, and suitable host conifers for both species are continuously distributed from

north to south in the eastern United States. Seasonal isolation between *P. approximatus* and *P. nemorensis* may prevent hybridization in nature, despite the potential for cross-attraction. *P. nemorensis* is flying and reproductively active during the fall and winter months (Atkinson, 1979; Fontaine et al., 1983), while *P. approximatus* is active in the spring and summer. In another study (Phillips et al., 1986), we found that weevils responded to synthetic pheromone in both spring and fall seasons at one site in Virginia, which led us to question the validity of *P. approximatus* and *P. nemorensis* as separate species. As with reproductive development, pheromone activity is apparently dependent on environmental stimuli like photoperiod (experiment 5; Booth et al., 1983). Once the threshold level of conditioning for pheromone production has been crossed (e.g., about 30 days of short-day conditioning for *P. nemorensis*), the phenomenon cannot be reversed by a drastic change in conditions (experiment 1, Figure 2). This threshold phenomenon is similar to that found in studies of diapause with various insect species (Tauber and Tauber, 1976). Our finding that hybrid males of *P. approximatus* and *P. nemorensis* produce pheromone after long-day conditioning (Figure 6) allows for a model of conspecificity that entails successful introgession of southern with northern populations.

P. strobi males or interspecific hybrids are not attractive to *P. approximatus* (experiments 1, 4–6), despite the fact that males of both species produce the pheromone components grandisol and grandisal (Booth et al., 1983). The basis for this lack of cross-attraction lies in the fact that *P. strobi* males apparently produce one or more chemicals that block the response of *P. approximatus* to its pheromone (experiments 6 and 7); the ability to produce this blocking odor is probably inherited in hybrids (experiment 5). Intra- and interspecific interactions in several species of insects are known to be mediated by enantiomeric specificity of semiochemicals (Silverstein, 1979). Since grandisol and grandisal are chiral, we might presume that the blocking phenomenon is imparted by species differences in enantiomeric blends of these compounds. However, we do not believe that the blocking phenomenon results from enantiomers of grandisol and grandisal because *P. approximatus* responds optimally (i.e., greater than or equal to the response to conspecific males) to racemic mixtures of these compounds. Theoretically, *P. approximatus* males may produce and respond to an enantiomeric blend of these compounds, or they may produce just one enantiomer of each (or a blend predominated by one enantiomer) and the other enantiomer is inactive. Even if *P. strobi* produced just one enantiomer each of grandisol and grandisal, it is unlikely that they would act allomonally and block the natural enantiomeric constitution of the *P. approximatus* pheromone. In other cases in which sympatric species display dual activity of enantiomeric semiochemicals, either separate enantiomers serve as a pheromone and an allomone for each species (e.g., ipsdienol for *Ips pini* and *I. paraconfusus*; Birch et al., 1980), or a synergistic blend of enantiomers is required by one species for pheromonal and allomonal activity, while the other species uses just

one enantiomer as a pheromone (e.g., sulcatol for *Gnathotrichus sulcatus* and *G. retusus*; Borden et al., 1980). All possible and probable types of enantiomeric specificity are reviewed by Silverstein (1979).

If our hypothesis above is correct, then male *P. strobi* must produce one or more other chemicals that block the response of *P. approximatus* to grandisol and grandisal. We have no evidence that *P. strobi* males produce an aggregation pheromone when feeding on white pine leaders (experiment 3; Phillips, 1981; Booth, 1978), and grandisol and grandisal, although produced by this species, are no more attractive to it than are white pine leaders (Booth et al., 1983; Phillips, unpublished data). It is possible that host location in *P. strobi*, which results in the finding of mates on suitable host leaders, is mediated primarily by host-related stimuli (e.g., Harris et al., 1983; VanderSar and Borden, 1977a,b). If the grandisol and grandisal produced by male *P. strobi* are qualitatively identical to the same compounds used as a pheromone by *P. approximatus*, then *P. strobi* would attract *P. approximatus* if it did not produce a blocking odor. We hypothesize that the evolution of a novel allelochemical signal in *P. strobi* was adaptive in the divergence and reproductive isolation of these two species. The blocking odor serves to prevent hybrid matings rather than to prevent competition for resources, a phenomenon known to occur in interspecific interactions of some bark beetles attacking the same host (Wood, 1982). *P. strobi* and *P. approximatus* use very different host resources. Any accidental interspecific matings would result in fertile hybrid progeny that would be unsuccessful in colonizing host material of either *P. strobi* or *P. approximatus*, thus reducing the fitness of both parents (Phillips and Lanier, 1983). *P. approximatus* aggregates on suitable host material in response to its aggregation pheronome; *P. strobi* aggregates on suitable host material via mechanisms that are not fully understood, and it produces a blocking odor to keep *P. approximatus* away. Because the blocking odor facilitates reproductive isolation and is adaptively favorable to individuals of both species, it could be referred to as an allomone-kairomone (Borden, 1977) or a synomone (Nordlund and Lewis, 1976).

Acknowledgments—We appreciate the cooperation and assistance of John Foltz, University of Florida, Gainesville, in the execution of test 2. Sheri Rosenblum and Michael Griggs provided valuable technical assistance for these studies. F.X. Webster kindly performed the synthesis of the grandisal needed for experiment 7. We thank Robert Rabaglia and Stephen Teale for their careful reviews of the manuscript. This research was supported by grants from the National Science Foundation, DEB 82-01007 and BSR 84-15879.

ELECTROANTENNOGRAM RESPONSES BY MOUNTAIN PINE BEETLES, *Dendroctonus ponderosae* HOPKINS, EXPOSED TO SELECTED SEMIOCHEMICALS

ARMAND T. WHITEHEAD

Department of Zoology
Brigham Young University
Provo, Utah 84602

(Received July 16, 1985; accepted November 14, 1985)

Abstract—Electroantennograms (EAGs) were obtained for *D. ponderosae* to the bark beetle pheromones *trans*-verbenol, *cis*-verbenol, *exo*-brevicomin, *endo*-brevicomin, frontalin, verbenone; to the kairomones, α-pinene, β-pinene, camphene, Δ-3-carene, limonene, myrcene; to a blend (1 : 1 : 1) of *trans*-verbenol, *exo*-brevicomin, and myrcene; and to diacetone-alcohol. Male and female responses, in general, did not differ significantly over the whole EAG dose–response curves but differed at a few concentrations on many of the curves. There were more differences noted for pheromones than kairomones. The blend yielded among the largest EAGs in both sexes and appeared to show synergism. Responses of females were lower than those for males in most instances. Significant differences in responses by the two sexes were much fewer for the kairomones than the pheromones. EAG recovery rates tested at only one concentration showed significant differences between males and females for three pheromones, *trans*-verbenol, *cis*-verbenol, and verbenone, and two kairomones, camphene and Δ-3-carene. Thresholds were quite low for most of the odorants except *cis*-verbenol, camphene, verbenone, and diacetone-alcohol in females, and *cis*-verbenol, verbenone, α-pinene, and diacetone-alcohol in males. The results, using at least one EAG parameter, support behavioral and field studies involving *exo*-brevicomin, *trans*-verbenol, frontalin, and the blend.

Key Words—Mountain pine beetle, *Dendroctonus ponderosae*, Coleoptera, Scolytidae, electroantennograms, pheromones, kairomones, inhibitors, host selection, aggregation.

INTRODUCTION

The mountain pine beetle (MPB), *Dendroctonus ponderosae* Hopkins, colonizes host trees in response to a complex blend of semiochemicals of both insect

0098-0331/86/0700-1603$05.00/0

and host origin (Vité and Gara, 1962; McCambridge, 1967; Pitman and Vité, 1969). Pitman et al. (1968) identified *trans*-verbenol as the main female-produced pheromone, and Pitman et al. (1969) found large amounts of brevicomin (not identified as *exo*- or *endo*-brevicomin) in the hindguts of feeding males.

Field studies of MPB semiochemicals are extensive. Host colonization by the beetles is dependent upon the interaction of host volatiles and beetle-produced pheromones (Pitman et al., 1968; McKnight, 1979). *trans*-Verbenol, although ineffective by itself (Pitman and Vité, 1969; Billings, 1974), is an effective aggregative pheromone when used in conjunction with the host-tree terpenes α-pinene and especially myrcene (Merrified, 1972; Billings, 1974; Billings et al., 1976; Pitman et al., 1978). Recent studies (Borden et al., 1983a, b; Conn et al., 1983) have shown that a blend of *trans*-verbenol, myrcene, and *exo*-brevicomin is highly effective in attracting beetles of both sexes and mediating mass attack on several hard-pine species in British Columbia.

There is a need to investigate chemicals found to be associated with the MPB and its host, lodgepole pine, on a neurophysiological basis. Until now no studies have been made on the perception of MPB semiochemicals at this level. This paper presents the results of an experiment in which electroantennograms (EAGs) were obtained from beetles of both sexes exposed to selected single semiochemicals (mostly racemic) and a blend similar to the one cited above. An attempt is made to correlate the results to behavioral and field studies by other workers.

METHODS AND MATERIALS

Adult beetles were obtained from laboratory-infested bolts of lodgepole pine, *Pinus contorta* var. *latifolia* Engelmann, cut in Logan Canyon, Utah. After emergence, the beetles were sexed according to a method described by Lyon (1958) and placed on moist strips of filter paper in Petri dishes at 5°C until use within 30 days after emergence.

Electroantennogram (EAG) techniques were modified from those described by Dickens et al. (1983). Ag–AgCl capillary electrodes were filled with insect saline (Yamasaki and Narahashi, 1959). A technique modified from Payne (1970) and Angst and Lanier (1979) was used to secure the beetle. Whole beetles were inserted in an appropriately sized hole drilled in a Plexiglas block. A thin brass plate drilled with a hole just larger than the maximal diameter of the largest beetle's head was attached to the top of the block so that the hole could be swiveled over the test-beetle's head. The plate was then pushed back against the ventral side of the head capsule forcing the head acutely backwards. This action secured the beetle in the block. A narrow strip of double-sticky tape was placed on the plate, and the antenna was pressed lightly onto its surface. The

recording electrode was inserted into the distal end of the antennal club following puncture with a sharpened tungsten needle. The indifferent electrode was inserted into the mouth. The semiochemicals (Table 1) were diluted in *n*-pentane in decade steps. Ten microliters of test solution were applied to a slightly folded 6 × 20-mm filter-paper strip and placed in a glass cartridge (80 mm long, 5 mm ID). After loading, the cartridge was immediately inserted into the dispenser apparatus for application to the insect. The dispenser was constructed to deliver a 1-sec stream of filtered air through the cartridge at 1.7 liter/min. The cartridge tip was placed about 1 cm from the preparation. At least 4 min elapsed between stimulations. Five replicates (different beetles) for each sex were made at each concentration. Most preparations would last 2–3 hr without degradation, thus allowing a full concentration series for one chemical to be tested. Stimulus dilutions were presented in order from the lowest to the highest concentration. *n*-Pentane (10 μl on filter paper) was used as control, and frontalin (10 μg on filter paper) was used as a standard.

Electrical responses were amplified by a Grass P-16 amplifier connected to an oscilloscope and an Apple II computer which digitized the responses via an 8-bit analog to digital converter board (Mountain Hardware), and plotted them [using a modified Waveman™ program (original available from Stolting Co., Chicago, Illinois) supporting an HP-7470A plotter] as regular EAGs on graph paper. EAGs were measured for amplitude and were shown as a percent of the mean of the two standards applied before and after two applications of

test chemicals. Any responses to air or *n*-pentane were subtracted from those of the odorants (Dickens et al., 1983). Threshold was considered as the lowest stimulus concentration at which the lower limit of its standard error did not overlap the upper limit of the standard error for the responses, if any, at lower concentrations (Dickens, 1978). Tests of the responses for significant differences between sexes for each chemical and between chemicals for each sex were made using Duncan's multiple range test at each concentration.

Only 10-μg applications of each chemical were quantified to produce recovery rates which were measured by having the computer calculate the total areas enclosed by the EAG traces and baselines as a percentage compared to those of the 10-μg frontalin standards.

Sample purity (Table 1) was determined using an HP-5880A gas chromatograph fitted with a 20-m $\times$ 0.3-mm ID SE-54 capillary column. The temperature program initial value was set at 40°C for 2 min, increasing at the rate of 4°C/min until 150°C final temperature was reached.

RESULTS AND DISCUSSION

The EAGs recorded in response to the test chemicals were similar to those from other bark beetles (Angst and Lanier, 1979; Grant and Lanier, 1982; Dickens, 1981; Dickens et al., 1983). An increase in stimulus concentration yielded an increase in peak response amplitude (Figures 1–14) and a slower recovery rate. Saturation did not appear to be reached at the highest concentration of any of the chemicals. Shapes of the dosage–response curves were very similar for a given compound for each sex, which may indicate that the receptor mechanisms may be similar for each compound in both sexes (Dickens et al., 1983). The pentane controls produced responses of 10.7 $\pm$ 1.2% of the frontalin standards. Few responses to air were recorded.

In general, EAG amplitude of males versus females did not differ significantly over the entire concentration range of any one compound; however, in several instances a significant difference in response was noted for individual concentrations of most of the pheromones (Figures 1–6) and only one concentration of the kairomone α-pinene (Figure 8). Many of the sexual differences occurred at the higher concentrations, and with the exception of the brevicomins (Figures 1 and 2), female responses at the higher concentrations were lower than the male responses. Females had significantly higher responses to *exo*-brevicomin than males at lower concentrations (Figure 1). This supports findings of Rudinsky et al. (1974) from laboratory-walkway experiments and Conn et al. (1983) from field-trapping studies that females are preferentially attracted over males to lower concentrations of *exo*-brevicomin in combinations with

other semiochemicals; at higher concentrations, females are inhibited. Significant differences between sexes were not noted for the other kairomones.

Dickens (personal communication) suggested that EAG recovery rates (represented as %EAG areas in Figures 15 and 16) may reflect the size of the

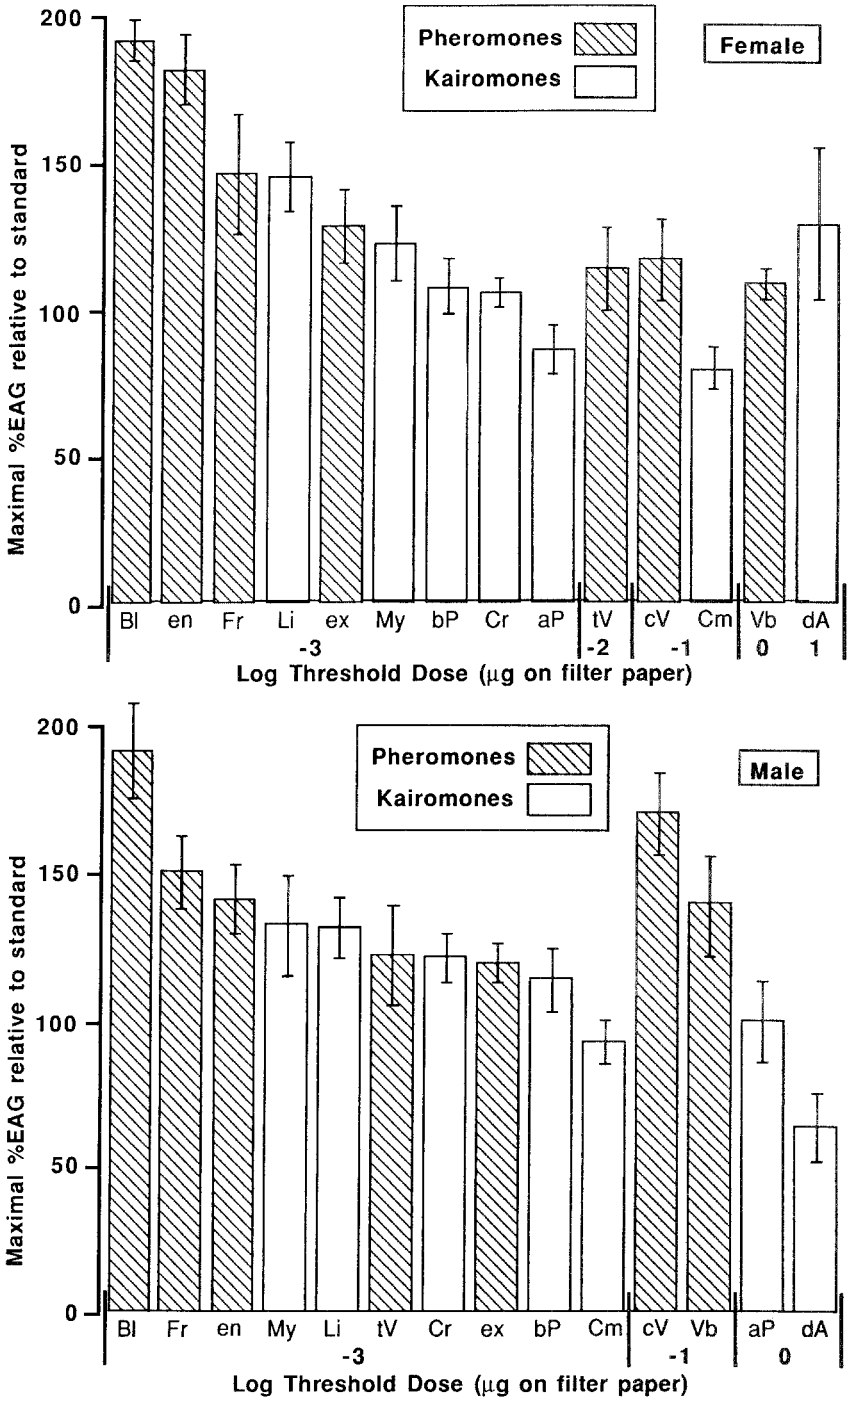
receptor population. Recovery rates may also be related to the amount of time required for the impulse frequency of individual neurons in the population of responding sensilla to return to the nonstimulated state. Roelofs and Comeau (1971) hypothesized that recovery rates are affected by differences in the amount of time that a stimulant molecule spends bound to membrane receptors, and Kaissling (1974) indicated that they may also be affected by intrinsic differences in the time required for deactivation of the molecules. In the MPB, these rates differed significantly between the sexes for three pheromones: *trans*-verbenol, *cis*-verbenol, and verbenone (Figure 15); two kairomones, camphene and Δ-3-carene, also showed differences (Figure 16). Figure 15 also indicated that, of the pheromones, *cis*-verbenol applied to males effected the slowest recovery; and frontalin caused the most rapid recovery in both sexes. The most rapid recovery to all the tested chemicals occurred upon application of diacetone-alcohol (Figure 16). Most of the kairomones had recovery rates only just slightly slower than frontalin.

Figures 17 and 18 show the semiochemical threshold concentration plotted against the maximal EAG amplitude for each odorant. Most of the chemicals having the highest maximal EAGs (usually at the 10 μl dose) also had the lowest thresholds. The most obvious exceptions to this trend were *cis*-verbenol and verbenone in the males. Also, males showed lower thresholds to more of the chemicals than females, including *trans*-verbenol. Conn et al. (1983) captured significantly higher numbers of males than females in traps baited with *trans*-verbenol when combined with other host tree monoterpenes. These data appear to correlate with the need of the males to find the females in the large tracts of trees.

Male response to *cis*-verbenol did not have the lowest threshold but did have the longest recovery rate (Figure 15) and one of the highest maximal EAG amplitudes (Figure 18). It also had a significantly higher male response at higher concentrations than *trans*-verbenol but not at lower concentrations (Figures 3 and 4). Although Pitman et al. (1969) failed to find major quantities of *cis*-verbenol in either sex, it has been identified in female frass (Libbey, Ryker, and Rudinsky, unpublished data as quoted in Ryker and Rudinsky, 1982). In *D. pseudotsugae*, *cis*-verbenol stimulates more generalized synergist cells (Dickens et al., 1984). Thus, the large EAGs elicited by this compound could reflect its interaction with receptors on similar cells in the MPB.

Responses of both sexes to frontalin were almost exactly the same, showing no significant differences (Figures 6, 17 and 18). Frontalin is a major pheromone in several species of *Dendroctonus* (Ryker and Libbey, 1982). Rudinsky et al. (1974) isolated frontalin from pairs of unfed MPB but did not identify the sex producing it. Ryker and Libbey (1982) feel that until males join females, they produce no frontalin. In their laboratory studies, they found that arrestment occurred in males exposed to frontalin in the presence of *trans*-verbenol and other terpenes; furthermore, in their field studies frontalin acted as an antiag-

FIGS. 15 and 16. The larger the %EAG area, the slower the recovery rate. $N = 5$; error bars indicate $\pm$SEM. *Significant difference between male and female response at 0.05 level.



FIGS. 17 and 18. Calculated thresholds for significant EAG responses as related to maximal EAGs (usually at the 100-μg doses) to pheromones (hatched area) in kairomones (clear area) recorded from MPB. $N = 5$; vertical bars represent $\pm$SE.

gregative pheromone for both sexes; however, they were unable to determine the exact role of frontalin in the MPB. On the other hand, Chatelain and Schenk (1984) induced attack of the MPB on frontalin-baited trees. These data lead to the probable conclusion that frontalin is a multifunctional pheromone in the MPB.

Both sexes are sensitive to low levels of *exo*- and *endo*-brevicomin (Figures 17 and 18). These pheromones are reported by Rudinsky et al. (1974) to be male produced and possessing antiaggregative properties; furthermore, supported by results from their bioassays, they found that very low levels of *exo*-brevicomin, when combined with Pondelure™ (*trans*-verbenol and α-pinene blend), would attract large numbers of beetles. They designated *exo*-brevicomin (in various blends of other semiochemicals) as a multifunctional pheromone in both the MPB and *D. frontalis* since it is aggregative at low levels and antiaggregative at high levels. The multifunctionality of *exo*-brevicomin has been supported by more recent research where it was reported to increase attack on lodgepole pine baited with *trans*-verbenol and monoterpenes, but it was antiaggregative on similarly baited white pines (Pitman et al., 1978; McKnight, 1979). Furthermore, Ryker and Rudinsky (1982) suggested that high levels of both racemic *exo*- and *endo*-brevicomin may act as interruptive pheromones preventing aggregation in populations of the MPB infesting lodgepole pine.

Responses of males to the blend composed of *trans*-verbenol, *exo*-brevicomin, and myrcene (1 : 1 : 1 ratio of $\frac{1}{3}$ quantities of each making total concentration equal to those of the single chemicals tested) were significantly greater than those of females at 10-μl doses and lower than females at 10^{-2}-μl doses (Figure 14). Both sexes had low thresholds (Figures 17 and 18) and relatively long recovery rates (Figures 15 and 16). Female responses to the blend were significantly greater than to *trans*-verbenol at all concentrations, whereas male responses were significantly higher at all but the two lowest concentrations. Females showed significantly larger reponses to the blend than to the other pheromones at most doses except *exo*-brevicomin (blend higher at highest dose) and *endo*-brevicomin (blend higher at 10^{-2}-μl and lower at 1-μl doses). Male response to the blend compared to the other pheromones was less marked than that in the female with only verbenone being significantly less for more doses except at the lowest one. Only at the two highest doses did the blend show a significantly greater response in both *exo*-brevicomin and *endo*-brevicomin. However, as a general rule, the blend in both sexes is one of the best EAG stimulants compared to the other odorants tested.

This appears to correlate with field studies which show a blend of the same chemicals to be the best for attracting both sexes and mediating mass attack on trees (Borden et al., 1983a) and in field-trapping studies (Conn et al., 1983). Male responses for the individual components of the blend at 10-μl doses were mathematically extrapolated down to a theoretical mean of 118.6% of the standard at 3.3 μl. The mean for the blend response at 10-μl doses was 173.3% of

the standard or 46% higher than the theoretical mean of 3.3 μl. Computation of a theoretical mean for females at 3.3 μl was 94.5% of the standard compared to 132.6% of the standard for the blend at 10 μl or 40% higher. These large differences between the blend and the theoretical individual responses imply a synergistic relationship between the components of the blend possibly caused by each one stimulating separate sensory cells in the antenna or by occupying multiple receptor sites on single sensory-cell membranes. Recordings from single cells on MPB antennae might be useful in corroborating the occurrence of synergism. Furthermore, since the actual concentrations of odorants reaching the antennae of the beetles tested in both the field experiments and in the present EAG study are unknown, further work needs to be done in adjusting the ratios of the odorants in blends for maximal behavioral and/or electrophysiological responses while monitoring stimulus concentrations.

All of the monoterpenes tested are present in the resin of the lodgepole pine (Smith, 1964). Although not readily apparent from their dose-response curves (Figures 10–13), Figures 17 and 18 show that the lowest thresholds were seen in both sexes to limonene, myrcene, carene, and β-pinene. α-Pinene had a threshold higher in the male than in the female (Figure 17 and 18). In combination with *trans*-verbenol, α-pinene is highly attractive to MPB infesting white pine (Pitman, 1971) but not to MPB infesting lodgepole pine (Borden et al., 1983a; Conn et al., 1983) which may correlate with the fact that lodgepole pine resin has lower concentrations of α-pinene than resins of other species of pines attacked by the MPB (Cole et al., 1981). Camphene had a lower threshold in the male than in the female (Figures 17 and 18).

Diacetone-alcohol has the highest threshold and most rapid recovery time of all the chemicals tested (Figures 16–18). In the female, it tested at the highest concentration with many of the other odorants when compared to that of the male (Figure 7). Since diacetone-alcohol has a much higher evaporation rate than either the pheromones or kairomones, it is likely that much of the odorant at lower concentrations is lost to the atmosphere before a stimulation can be effected. This material has not been reported to be produced by either the beetle or lodgepole pine. However, Ryker (personal communication) indicated that it was effective in attracting beetles to traps in Oregon but not in British Columbia.

Since a gas chromatograph was not available to control the actual concentrations of the stimulants at the antenna (Wadhams, 1982), the assumption was made that all of the odorants (except diacetone-alcohol) have similar vapor pressures and surface-binding characteristics. Since this assumption may not be true, response values and threshold estimates may depend not only upon neuron sensitivity but upon the volatility of the chemicals as well.

The EAG is probably a composite potential resulting from the activity of different populations of sensory neurons. The amplitude and recovery rate of the EAG is likely dependent upon differential responses from these populations

depending on the type of stimulant and its concentration. Furthermore, lack of understanding of the response parameters of each type of neuron in these populations makes interpretation of the EAG difficult. In the long run, behavior of the insect is a result of CNS interpretation of sensory input.

Although it is a valuable tool for investigating insect responses to possible semiochemicals, care must be taken in the interpretation of EAG responses as they relate to behavioral and field studies. Compounds related to or derived from the primary pheromone components may also produce excellent antennal responses as is shown in the *cis*-verbenol response of the MPB in this report; furthermore, it is impossible from the EAG approach to determine if a compound is excitatory (aggregative) or inhibitory (antiaggregative) in terms of insect behavior (Roelofs, 1977). Although good EAG responses can correlate well with effective field odorants (Dickens et al., 1983), this may not always prove to be true. While "the ultimate bioassay is to challenge the natural population with a faithful reproduction of the test material..." (Silverstein, 1984), much can be gained from more subordinate studies such as those involving EAGs if one keeps these problems in mind.

All of the chiral compounds tested were racemic except three kairomones (Table 1). McKnight (1979) found significant differences in the behavior of the MPB to optical isomers of several semiochemicals, especially *trans*-verbenol. Further studies are planned to investigate EAGs of the MPB to the enantiomers of the pheromones tested in this paper.

Acknowledgments—The author wishes to thank Dr. J. C. Dickens for his critical review of the manuscript and for his technical support. This project was supported in part by funds from the USDA-Forest Service, Intermountain Forest and Range Experiment Station, Ogden, Utah 84401, USA; and from a Professional Development Grant, College of Biology and Agriculture, Brigham Young University.

PHEROMONE-MEDIATED COPULATORY RESPONSES OF THE SCREWWORM FLY, *Cochliomyia hominivorax*

L. HAMMACK

Metabolism and Radiation Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture
Fargo, North Dakota 58105

(Received September 11, 1985; accepted November 15, 1985)

Abstract—A bioassay based on male copulatory responses occurring on contact with dead decoy insects was used to confirm the existence of a sex pheromone in the screwworm fly, *Cochliomyia hominivorax*. Males responded to female but not male decoys. Mated and virgin females were equally stimulatory. Activity was abolished when females were washed with hexane but partially restored by treatment with crude hexane extract of females. Responses decreased when extracts were diluted and when the number of females extracted per milliliter of hexane was decreased from 20 to 1 in the preparation of extracts concentrated to 0.4 female/μl. Sexually mature female decoys of the 009 strain, the most laboratory-adapted of three strains examined in intrastrain tests, produced few copulatory attempts compared with those of Aricruz or DE-9 strains. However, newly emerged 009 as well as Aricruz females elicited responses from about 80% of sexually mature males. Those of the DE-9 strain stimulated fewer than 1%. The observation that 009 females were maximally stimulatory before becoming receptive to mating suggests that these strain differences resulted from laboratory colonization.

Key Words—Screwworm fly, *Cochliomyia hominivorax*, Diptera, Calliphoridae, sex pheromone, mating-stimulant pheromone.

INTRODUCTION

Aggregations containing sexually active males of the screwworm fly, *Cochliomyia hominivorax* (Coquerel), have been observed on vegetation (Krafsur, 1978), often in association with flowers of specific types (Guillot et al., 1978; Mackley and Long, 1983). The sexually active males were identified by their position within the vegetation, posture, territoriality, and striking behavior toward screwworms, flies of other species, butterflies, and even small pebbles.

Considering the variety of targets struck, vision appears to be an important stimulus eliciting strikes. However, a contact sex pheromone may play a role in the release of male copulatory behavior (Mackley and Broce, 1981).

In many Diptera, including the housefly, *Musca domestica* L. (Rogoff et al., 1964), and the tsetse fly, *Glossina morsitans morsitans* (Westwood) (Langley et al., 1975), female-produced sex pheromones are located on the cuticle and stimulate male mating behavior either on contact or at close range [see Howard and Blomquist (1982) for additional examples]. Mackley and Broce (1981) suggested that female screwworm flies produce a sex pheromone because dead females elicited fewer male copulatory responses after washing in nonpolar solvent and dead males previously held with females produced more responses than those from all-male groups. However, tests with solvent extracts of females gave inconclusive evidence for a pheromone.

The present study was undertaken to confirm the existence in the screwworm of a female-produced sex pheromone and to examine effects of sex, mating, age, and strain on pheromone-mediated copulatory responses.

METHODS AND MATERIALS

Insects. Screwworms of the DE-9, Aricruz, and 009 strains were reared on a beef-based larval diet and maintained as adults on corn syrup at 25 ± 1°C under a 12:12 light–dark photoperiod (Hammack, 1984). Virgin adults collected within 24 hr of emergence and separated by sex under CO_2 anesthesia were assigned an age of 0 days and tested when 5–8 days old, unless stated otherwise. No anesthetic was administered to males tested before 3 days of age or to either sex after day 0. The three strains had been developed by the former ARS Screwworm Research Laboratory, Mission, Texas, for use in the screwworm sterile-male release program and had been established from multiple collections of egg masses made in the field in 1979 (DE-9, Tamaulipas, Mexico), 1978 (Aricruz, Arizona and Veracruz, Mexico), or 1974–1975 (009, Texas). The DE-9, Aricruz, and 009 strains had been maintained at Fargo, North Dakota, since December 1979, May 1979, and December 1977, respectively. The present tests were conducted with the DE-9 strain between July 1980 and June 1982 and with the Aricruz and 009 strains between February 1980 and February 1981.

Bioassay and Pheromone Extraction. Screwworm mating behavior under laboratory conditions has been described previously (Broce, 1980; Mackley and Broce, 1981). The bioassay used here focused on behavior occurring once the sexes make physical contact and measured the percentage of individually tested males that attempted copulation with decoy insects when males and decoys were paired for a period of 60 sec. The decoys were screwworm flies that had been killed by freezing at −20°C for 30 min on the morning of testing. Dead decoys

were used to eliminate auditory and visual (motion) cues that might contribute to the release of copulatory behavior. Each was pinned through the thorax, dorsal side up, to the base of an inverted paper cup with an insect pin (000). The head of the pin was exposed on the decoy's dorsum. Unwashed decoys were thawed and mounted for testing.

For the other treatments, female decoys warmed to room temperature after freezing were first washed with hexane to prepare the pheromone extracts (as described below) and then washed again in two 0.5-ml streams of hexane dispensed from a pipete. They were air dried for at least 30 min after washing and mounted. Female extract was applied to the dorsal surface of the thorax and abdomen of the mounted washed decoys with a microsyringe at volumes of 5, 10, or 50 μl (air dried for about 60 sec between each of 5 successive 10-μl applications). Washed decoys treated only with hexane served as controls. The decoys were air dried for at least 15 min after the final solvent application. However, they were all generally prepared at the same time and held mounted at 25°C for as much as 5 hr before assay.

Each test male was transferred from its holding cage to a 20-cc glass vial immediately prior to assay. The vial was inverted over the decoy and contact between the male and decoy accomplished by tapping the cup and vial against the substrate. Positive responses were scored when males mounted the decoy dorsally (usually with wing buzzing), flexed their abdomens, and probed the decoy's abdominal tip or occasionally the head with their genitalia. Males were tested once at 25 $\pm$ 1°C within 1–6 hr after the start of a 12-hr photophase and discarded. This interval was used because Crystal (1971) reported high mating rates for screwworm flies throughout the first half of a 12-hr photophase. Light intensity on the test surface was about 700 lux supplied by daylight fluorescent lamps.

In one test, male and female unwashed virgin decoys were assayed to determine their relative effectiveness in eliciting male copulatory attempts. In another, virgin and mated unwashed female decoys were compared. Mated females had been held with males from emergence until the day of testing at eight days postemergence. Insemination was confirmed after assay by detection of sperm in spermathecae of the decoys. These sex and mating status comparisons were done with the Aricruz strain.

Hexane-washed decoys treated with 2 FE of standard female extract in 5 μl of hexane and washed controls treated only with 5 μl of hexane were tested along with unwashed female decoys to confirm that chemical stimuli are involved in eliciting male copulatory responses. The standard extracts were prepared by individually dipping 40 females for 15 sec each in the same 2-ml aliquot of glass-distilled hexane and then reducing the solvent volume in a stream of CO_2 to 0.1 ml [0.4 female equivalent (FE)/μl]. Insects of the DE-9 strain were used here and in all of the following extraction tests.

The pheromone activity in standard extracts was low, and two modified extraction procedures were tried. In one series of tests, the activity recovered when standard hexane extracts were prepared was compared with that recovered when each of 40 females was dipped for 15 sec in a separate 1-ml aliquot of hexane and the 40 aliquots pooled and concentrated to 0.4 FE/μl. Five replicates were tested per treatment in one test done at a dose of 2 FE in 5 μl. Extraction and assay procedures were repeated in a second test, except that decoy pairs were treated with 20 FE in 50 μl and each of two decoys per treatment was tested with 25 males.

Pheromone activity declined with the decrease in the number of females extracted per milliliter of hexane, and dose–response relationships were investigated with extracts prepared by successively dipping 100 females for 15 sec each in the same 4-ml aliquot of hexane and then reducing the solvent volume to 0.1 ml (1 FE/μl). The extract was applied in 10 μl of hexane to washed decoys at five doses ranging from 4.1 to 10 FE. Five decoys (one per dose) were tested simultaneously with matched males, and the process repeated with seven more sets of decoys. The relationship between dose and mean response based on the eight replicates was analyzed by linear regression. The extracts used in the dose–response test were stored at $-20°$C for as much as 20 hr before assay, whereas extracts used in all other tests were assayed immediately after preparation. Storage was minimized because preliminary tests indicated that the pheromone activity of whole females was nearly lost when they were stored at $-20°$C for three to four weeks.

Unwashed female decoys of the DE-9, Aricruz, and 009 strains that ranged in age from 1 to 15 days were assayed to determine their ability to stimulate copulatory attempts in males of the same age and strain. Intrastrain tests were also conducted in which the response of 6- to 8-day-old males to unwashed female decoys of various ages was determined. Zero-day-old females used in the latter tests were frozen within 4 hr after emergence.

Unless stated otherwise, decoys were each assayed with 10 males exposed individually, and at least 10 decoys (replicates) were tested per treatment. Except for the analysis of dose–response relationships, Wilcoxon's signed rank test (T statistic) or the Kruskal and Wallis test (H statistic distributed as χ^2) (Steel and Torrie, 1960) was used to determine whether the null hypothesis of no treatment effects was valid.

RESULTS AND DISCUSSION

Unwashed female decoys elicited copulatory attempts from significantly more test males (73%) than did unwashed male decoys (0%) ($T = 0$, $n = 10$, $P < 0.01$). However, there was no significant difference between the percentages responding to mated and virgin female decoys (48 and 50% respectively,

$T = 25$, $n = 10$, $P > 0.05$). Thus, the sex of decoys significantly affected activity, but the mating status of female decoys did not.

Hexane-washed females treated with 2 FE of standard extract induced significantly more copulatory attempts (32% of test males responding) than controls treated only with hexane (0% responding) ($T = 0$, $n = 10$, $P < 0.01$). Although the extract treatment did not fully restore the activity of unwashed females (64% responding), these results clearly implicated a female-produced chemical stimulus or set of stimuli in the release of male copulatory behavior. This conclusion was strengthened by the demonstration of a significant dose–response relationship (Figure 1). The percentage of males that attempted copulation with extract-treated decoys (Y) varied linearly with the logarithm of the concentration of female extract (X): $Y = 50.3 \log_{10} 100X - 107.8$, $r^2 = 0.80$, $P < 0.05$.

When concentrated to 0.4 FE/μl and tested at 2 FE, an extract prepared by dipping 40 females in 40 1-ml aliquots produced no responses, although a standard extract prepared by dipping 40 females in 2 ml stimulated 38% of test males. An extract prepared by the former method also failed to produce any responses when assayed at 20 FE, although a standard stimulated 50% of males at this dose. The absence of pheromone activity when increased amounts of solvent were blown off suggests that the screwworm pheromone is volatile and thus might have attractant functions. However, the bioassay technique used here was based upon responses elicited on contact because no evidence exists as yet to suggest that female screwworm flies are attractive to males over any distance (Mackley and Broce, 1981; Hammack, unpublished).

Other possible explanations for the observed lack of activity include pheromone lability or, because the tests were done with crude extract, the produc-

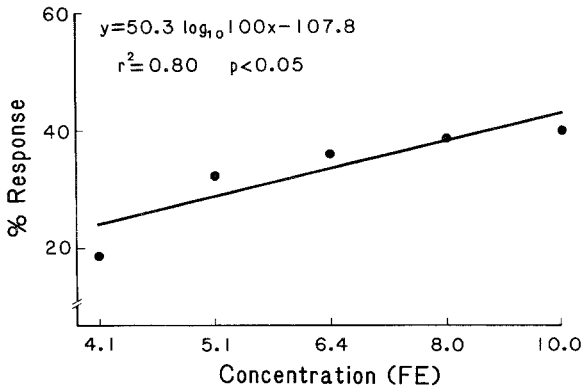

FIG. 1. Percentage of males attempting copulation with dead, hexane-washed, females treated with different concentrations of crude extract of females. Concentrations are plotted on a logarithmic scale and expressed in female equivalents (FE).

tion or more thorough extraction of contaminants interfering with the response to pheromone. When chemical identifications have been achieved in other Diptera, the female-produced sex pheromones that act on contact or at short range have generally proved to be hydrocarbons showing little if any volatility, usually alkenes or methyl branched alkanes with a chain length in the range of 23–37 carbons (Antony and Jallon, 1982; Carlson et al., 1984; see Howard and Blomquist 1982). The possibility of a more thorough extraction of interfering substances with an increase in the solvent volume used to wash screwworms was raised by reports that inactive alkanes that may be present in crude female extracts mask the activity of hydrocarbon sex pheromones in the face fly, *Musca autumnalis* De Geer (Uebel et al., 1975) and in tsetse flies (*Glossina* spp.) (Coates and Langley, 1982; Carlson et al., 1984). More data are clearly needed to explain the loss observed in the screwworm with extraction in the larger solvent volume. It was not prevented by the use of N_2 instead of CO_2 to blow off hexane (Hammack, unpublished data using a screwworm strain designated FC96 from Chiapas, Mexico).

When pairs of males and decoy females of the same age and strain were tested at various intervals after emergence, the maximum response among 009 groups was only 27% of males attempting copulation, a value less than any DE-9 or Aricruz response obtained after 1 day of age (Figure 2). No copulatory attempts occurred in any strain when both sexes were 1 day old, but this could be attributed to immaturity of the male in the Aricruz and 009 strains because newly emerged female decoys of these strains stimulated about 80% of 1-week-old males in intrastrain tests (Figure 3). In contrast, newly emerged females of the DE-9 strain stimulated less than 1%. Interstrain tests are needed to determine whether these differences arose because newly emerged females of differ-

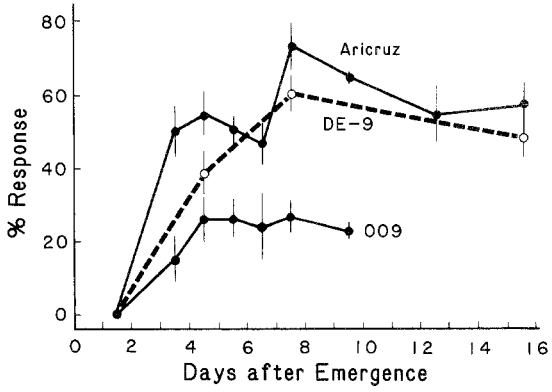

FIG. 2. Percentage ± SE of males attempting copulation with unwashed female decoys in intrastrain tests conducted with dead screwworm flies of the DE-9, Aricruz, and 009 strains. Test males and decoy females were the same age at the time of assay.

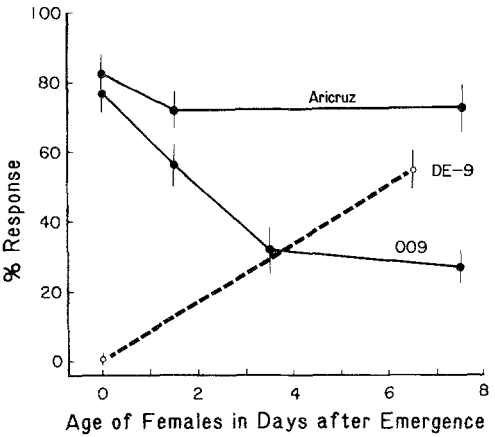

FIG. 3. Percentage ± SE of 6- to 8-day-old males attempting copulation with unwashed female decoys of various ages in intrastrain tests conducted with dead screwworm flies of the DE-9, Aricruz, and 009 strains.

ent strains vary in their ability to stimulate male copulatory attempts and/or whether male responsiveness to a pheromone stimulus varies with strain. Preliminary unpublished data (Hammack) suggest the latter explanation, but the point to be made here, in addition to the low response among 009 pairs of the same age, is that the mating-stimulant activity of females changed differentially with age depending on strain.

Activity increased significantly with age after emergence in the DE-9 strain ($T = 0$, $n = 15$, $P < 0.01$), remained unchanged in the Aricruz strain (corrected $H = 2.4$, $df = 2$, $P > 0.05$), and declined significantly in the 009 strain (corrected $H = 21.6$, $df = 3$, $P < 0.001$). The decline in the 009 strain was evident before 2–3 days of age when female screwworm flies first become receptive to mating (Adams, 1979; Hammack, unpublished data for the 009 strain). For females to be maximally stimulatory when not yet receptive to mating appears wasteful of resources, unless the pattern in the long-colonized 009 strain (and perhaps the Aricruz strain) resulted from adaptation to laboratory conditions. It is of interest in this regard that Pomonis and Mackley (1985) reported changes with colonization in cuticular lipid profiles in female but not male screwworm flies. Thus, colonization seems a likely explanation for the strain differences observed here, although an explanation based on the existence of reproductively isolated field populations, as hypothesized by Richardson et al. (1982), cannot yet be excluded.

A loss or masking of the screwworm pheromone with age might well be adaptive in colonized populations considering the common practice of holding the sexes together in breeding stocks until the time of oviposition. Most insects

in such stocks are the same age within 1.5 days. Mating begins days before females are ready to oviposit, but males, unlike females, are polygamous and continue to court inseminated females (Bushland, 1960). Data from the present study indicating no effect of insemination on female pheromone activity are consistent with Bushland's (1960) observations. Therefore, considering the artificially high density of caged populations, male harassment of females between the times of mating and oviposition could lead to selection for reduced pheromone activity. Indeed, female mortality in mixed-sex laboratory populations has been used as an indicator of the sexual aggressiveness of screwworm males (Crystal and Ramirez, 1975; Crystal and Whitten, 1976).

Additional research is needed to clarify the effects of colonization on the production of and responsiveness to sex pheromone, optimize pheromone extraction and/or its presentation during bioassays, and identify the active chemical(s). Knowledge derived from such research may prove useful for monitoring the quality of screwworms mass-reared for sterile releases and evaluating their mating competitiveness with field populations from different ecological and geographical sources.

Acknowledgments—I thank Mr. F.K. Welch for insect rearing and technical assistance, and Drs. T.S. Adams, P.A. Langley, J.W. Mackley, and C.J. Whitten for helpful comments during preparation of the manuscript.

Editors' Note

This special issue is devoted to the International Conference on Chemical Communication and Regulation of Sexual Reproduction, Growth, and Maturation of Schistosomes held at Johns Hopkins University, Baltimore, Maryland 21205, on May 1–3, 1985. The papers are introduced with a Foreword by Dr. Everett L. Schiller who served also as the conference director and as one of two reviewers for each manuscript. The editors are grateful to several conference participants who also served as second reviewers: Drs. David A. Erasmus, L. K. Eveland, Bernard Fried, Eugene G. Hayunga, Walter M. Kemp, and Irene Popiel.

We acknowledge the cooperation of Plenum Publishing Corporation in producing extra copies of this issue to accommodate registrants of the symposium and others interested.

FOREWORD

The Johns Hopkins University International Conference on Chemical Communication and Regulation of Sexual Reproduction, Growth and Maturation of Schistosomes was a three-day conference organized for the purpose of bringing investigators in the field of schistosome biology together as a specialist group to thoroughly review the subject, provide an update on research findings, critically evaluate ongoing research, and set guidelines for future research. This conference, supported by a grant from the Edna McConnell Clark Foundation, provided an opportunity to learn about a diversity of systems for investigating the complex sequence of events involved in schistosome sexual reproduction and to identify potential targets for interfering with these processes. This publication of the proceedings is expected to focus the attention of other scientists on these important problems.

In the introductory session, reviews are presented of interspecific chemical communication between parasite and host, intraspecific chemical communication between parasites, and internal chemical communication within individual parasites. Chemical communication in parasitic nematodes is reviewed by L.W. Bone. Using *Nippostrongylus* and *Trichostrongylus* as models, he demonstrates an investigative approach which is germane to the study of schistosome chemical communication. Of particular relevance is the emphasis placed on establishing the proper physical system for the in vitro bioassay of responses to pheromonal gradients. Chromatographic partial purification of two pheromones is reported.

G.C. Kearn describes the role of chemical substances from fish hosts in hatching and host finding in monogeneans. The behavioral responses to both host and environmental cues are described. The precise chemical nature of the active host-derived components awaits elucidation.

B. Fried shows that some adult hermaphroditic Digenea tend to pair in vitro and in vivo. Pairing is both intra- and interspecific, suggesting that nonspecific factors are involved. From the considerable evidence presented, lipophilic substances function in aggregation and pairing in these parasites.

The subject of invertebrate internal coordinating mechanisms dependent on "hormonal" regulatory substances is reviewed by P.F. Basch. Attention is drawn to the fact that evidence for these processes occurring in flatworms is observational and few physiological studies have been made. The presence of

0098-0331/86/0800-1635$05.00/0

ecdysteroids in schistosome tissues is demonstrated and their possible role in morphogenetic processes is discussed.

In the session devoted to the subject of chemical regulation of schistosome behavior, L. K. Eveland, M. Haseeb, D. Shirazian, J.E. Childs, and E.L. Schiller present evidence that adult schistosomes attract each other in vitro and that the attraction is chemically mediated. Lipid release from the tegument of adult worms is described by M. Haseeb and its role in chemoattraction is discussed.

J. Gloer reports on a serial stepwise extraction of schistosome tissues using pentane, diethyl ether, ether acetate, methanol, and water and the incorporation of the extracts into a bioassay system for chemoattraction. He shows that the least polar extracts are attractive heterosexually but not homosexually. The major components of this fraction are steroids.

Evidence that a chemoattractant compound(s) in female extracts may serve as a mating pheromone is presented by J.E. Childs. E.L. Schiller describes a time-lapse video tape system for documenting sexual behavior of *S. mansoni* in vitro. Tapes made during various experiments concerned with chemical orientation of these parasites reveal that the opposite sexes are attracted to each other by some means of premating communication that culminates in aggregation and copulation of sexual pairs within 24 hr. He reports that attractivity is significantly greater in heterosexual than in homosexual pairs. Male worms move towards females more rapidly and more vigorously than females move towards males. Clustering and directional preferences of male worms towards test compounds (prepared by J. Gloer) indicate the presence of chemoattractant substances in female extracts that serve as a mating pheromone.

The presentations in this session generated much discussion with the following recommendations: purification and further chemical characterization of the attractant substances should be continued; unisexual adults and sexually immature worms should be cultured in vitro and their excretory-secretory (ES) products and tissue extracts bioassayed for chemoattractant activity; and an in vivo bioassay method should be developed for investigating chemoattraction.

The session on developmental physiology and reproduction is devoted to a detailed consideration of the morphogenetic and biochemical changes which take place in female schistosomes immediately after pairing with males.

Explanations for the nature of male-stimulated female maturation are reviewed by I. Popiel. Attempts to demonstrate direct chemical transfer between members of worm pairs are considered, and the exchange of cholesterol within worm pairs is demonstrated. She reports on differences in the extent of maturation and in responsiveness to male stimulation between unisexual female infections from two different laboratories. Of particular interest to the study of female morphogenesis is the observation that when unisexual females are paired with transected segments of male worms, stimulation of vitellogenesis is local and cannot be propagated internally.

Details of the process of vitellogenesis are provided by D. Erasmus, who also reports on anomalies such as vitelline gland development in unisexual females and in mature males. Some biochemical changes which take place in females after pairing with males are described. Of significance is the demonstration that an increase in thymidine incorporation in unisexual females occurs 24 hr after pairing with mature males derived from bisexual infections. When such females pair with mature males from unisexual infections, the increase in thymidine incorporation is delayed for 24 hr.

M. Shaw reports on changes in the elemental composition of male and female schistosomes in relation to age postinfection and sexual status. An important finding in his investigation is the significant increase in calcium and phosphorus levels in females from bisexual infections which begins about day 28 postinfection, i.e., at the onset of female maturation.

Next, E. Cornford deals with the influence of mating upon surface exchange in schistosomes. He reports that paired males and females take up more glucose than separated individuals, and that glucose is transferred from males to females *in copula.*

G. and C. Wu report that factors present in portal blood, but not in peripheral blood, stimulate egg production in vitro. Sera from nonpermissive hosts were used in these experiments. They show the active fraction of rabbit serum to be between molecular weights 2000 and 50,000 daltons and that of rat serum to be between 2000 and 30,000 daltons. Their results represent the first demonstration of a reproductive response to portal versus peripheral blood. The biochemical nature of the stimulatory factor is not known. They suggest that this factor may be involved in site location during schistosome migration and that it may be a host hormone associated with digestive physiology.

D. Cioli considers the variation in extent to which growth and maturation of schistosomes occur in a spectrum of nonpermissive hosts. In nonpermissive rats, portal worm elimination takes place in the fourth week of infection. The few worms that survive do not develop to full sexual maturity. P. Knopf discusses the effect of host factors in this inhibition of maturation. Thyroidectomy makes rats more permissive; portal worm elimination is delayed for four weeks, maturation of worms proceeds, and miracidia can be hatched from liver eggs. Administration of T3 or T4 to thyroidectomized rats completely restores their nonpermissive status.

In a comparative analysis of schistosome antigenic composition, J. Rotmans demonstrates the detection of a large number of female-specific, but few male-specific, antigens. Unisexual females are antigenically quite different from females derived from bisexual infections. The preparation of monoclonal antibodies to these antigens is described.

W. Kemp describes receptors on the schistosome surface with immunological function. These are identified as hostlike C3 and Fc receptors, and their possible functions are discussed. He raises an important fundamental question

that arises from the fact that schistosomes are totally covered with host components, namely: does the worm surface present effector cells of the immune system with "self" or with idiotype?

The final session is concerned with characterization and mode of action of schistosome metabolic products. E. Hayunga reviews the analytical methods involved in the isolation and characterization of pheromones and other chemicals which may influence schistosome maturation. Special attention is given to the technical problems that arise when investigating parasite molecular biology. He presents data to define the role of an isolated antigen in hepatic egg granuloma attenuation. Evidence of diminished fecundity of female worms in experimental infections supports the theory of a "crowding effect" in murine schistosomiasis and suggests the possibility that toxic or chemotactic secretions by worms may inhibit reproduction.

P. Nirde describes the detection of ecdysteroids by radioimmunoassay of HPLC-separated lipid extracts in schistosomes. He finds higher levels of ecdysone and 20-hydroxyecdysone in juveniles of both sexes than in adults and implicates these compounds as factors in schistosome morphogenesis. Their precise role is yet to be determined.

D. Thompson and J. Bennett report on the effects of steroids and steroid synthesis inhibitors on *S. mansoni* fecundity in vitro. Cholesterol and dianisidine, an inhibitor of cholesterol metabolism to hormonal products, are both ineffective in blocking egg production. The data show that, although various progesterones depress egg production, estrogenic and androgenic hormones have no effect.

P. Morrison and E. VandeWaa show that *S. mansoni* schistosomulae rely on cyanide-sensitive respiratory metabolism for at least 3 hr after transformation from cercariae. After 24 hr, the parasites are metabolically similar to adults and depend on lactate fermentation for most of their energy requirements. The biochemical switches for metabolic transformation are not yet known.

The conferees drew a number of useful conclusions and recommendations from these sessions:

It is not clear whether the male stimulus for female maturation is chemical, physical, or a combination of both. Future investigations should address both possibilities.

Vitellogenesis is the first visible sign of female maturation, and it begins approximately two days after worm pairing. A better understanding of the overall process of male-stimulated female development requires a knowledge of the developmental processes that occur immediately after pairing and before vitellogenesis.

It is important to establish whether or not the variation in extent of maturation in unisexual females observed in different laboratory populations is genetically determined.

These investigations have indicated that sexually mature schistosome pairs are, to some extent, biochemically interdependent. The precise nature and significance of this interdependence is yet to be determined.

Comparative biochemical investigations on males and females should include a consideration of unisexual worms and those from bisexual infections which are not yet sexually mature.

Further information is required on the properties of the schistosome surface membrane with respect to changes which take place during development and especially during the critical period of sexual maturation, i.e., 28–40 days postinfection.

There is a noticeable paucity of characterized chemicals which may function in the regulation of schistosome developmental and reproductive processes. For example, only one class of biochemically characterized ecdysteroids was mentioned in this conference. It was reported that ecdysone and 20-hydroxyecdysone have been extracted from immature and mature worms. These compounds have demonstrated roles in insect morphogenesis. They are now being implicated as factors in the morphogenesis of schistosomes and other helminths, but their specific role has yet to be determined. An overriding recommendation drawn from a consideration of schistosome biochemistry, as related to development and reproduction, was the need to identify associated macromolecules and to establish their precise functions. This presents a formidable task because only small amounts of tissue or worm ES products are available for analysis and biochemical purification often results in only minute quantities of biologically active substances.

New approaches to the control of schistosomiasis are needed. A knowledge of the pheromones that regulate sexual attraction and reproduction in schistosomes could lead to the development of pharmacologic and/or immunologic means of interfering with them. Preventing worms from mating would preclude egg production, thereby eliminating the main cause of pathology in this disease. Interfering with the processes of sexual reproduction also would eliminate the excretion of eggs into the external environment, thereby significantly reducing the transmission potential of the parasite.

NEMATODE REPRODUCTIVE AND INGESTIVE RESPONSES TO HELMINTH AND HOST CHEMICAL STIMULI

LEON W. BONE

Regional Parasite Research Laboratory, ARS, USDA
P.O. Box 952
Auburn, Alabama 36830

(Received October 1, 1985; accepted December 3, 1985)

Abstract—Current knowledge of the involvement of chemical stimuli in the reproductive and ingestive physiology of zooparasitic nematodes is reviewed. The habitat of zooparasitic nematodes, coupled with their sensory reduction, indicates that chemical stimuli may modulate most aspects of their behavioral physiology. Nematodes respond to the feeding status of the host so that the helminth's pharyngeal pumping, site selection, and sexual activity may be altered. Biogenic amines from the host, such as histamine, dopamine, or serotonin, may synchronize host and helminth ingestion. Octopamine, which is released by nematodes, depresses ingestion by male, but not female, worms. Biogenic amines may also regulate ovipositioning by female helminths. Nematodes release pheromones that enable precopulatory location of a mate. The male helminth is activated by both components of the female's pheromone while movement by the female is probably arrested by male-produced chemicals. Continuation of spectral analyses may allow future identification of female pheromone. The male's pheromone receptor binds lectin that is specific for mannose residues. Host immunity also alters the behavior of nematodes. Ingestion by nematodes is depressed by serum, particularly IgG_1, from infected animals. Similar results occur after immunization of noninfected hosts. Immune serum has no effect on pheromone communication between the sexes of helminth, but depresses ovipositional behavior of female worms. Exploitation of these chemical signals and the helminths' responses may allow novel techniques for disease control.

Key Words—Nematode, pheromone, mating attraction, oviposition, reproduction, ingestive activity, host immunity, chemical reception.

INTRODUCTION

The habitat of zooparasitic nematodes, coupled with their sensory reduction, indicates that chemical stimuli from the host or helminth may modulate most

0098-0331/86/0800-1641$05.00/0

aspects of their behavioral physiology. Croll and Sukhdeo (1981) proposed that nematode behavior consisted of only 22 activities; 14 of these patterns were responses predominantly to chemical stimuli. Chemoreception by nematodes may be highly specific since Dusenbery (1975) reported that *Caenorhabditis elegans* showed sterospecificity for D- and L-tryptophan. Adult parasites are characterized by a tremendous fecundity that ensures transmission of the infective stage in the environment and reinfection of another host. The demands of nematode reproduction require significant nutrient acquisition; hence ingestion by helminths may be of primary importance in the maintenance of reproductive status. Accordingly, the host and helminth stimuli that regulate the interrelated functions of feeding and reproduction are reviewed.

SEXUAL COMMUNICATION STIMULI

Pheromones are intraspecific chemical stimuli that regulate diverse physiological or behavioral events in an organism's life history. Pheromones are implicated, commonly for reproductive communication, in over 25 species of nematode from free-living, plant-parasitic, and animal-parasitic habitats (see Bone and Shorey, 1978; or Bone, 1982 for recent reviews).

Chemotaxis by male nematodes to pheromone from their females is affected by various biological and physical factors. Communication between the sexes is disrupted with helminth age, which suggests that host immunity in older infections may impair pheromone production and responsiveness. The age-dependent loss of communication is greater in vitro than in vivo, which indicates that the artificial bioassay systems may have some minor effect on communication (Glassburg et al., 1981). Pheromone reception by males is coupled to the final larval molt. Time-of-day and mating history have little effect on chemical communication. Light, culture sterility, and host food deprivation for 24 hr also have no apparent influence on pheromone production. Anaerobism greatly reduces pheromone production, while optimum chemical production (or less degradation) occurs at pH 7.1. Decreased temperature and osmolarity reduce production of pheromone by females (Ward and Bone, 1983a).

Several in vitro studies have examined the specificity of nematode pheromones. Roberts and Thorson (1977) reported interspecific pairing between *Nippostrongylus brasiliensis*, *Nematospiroides dubius*, and *Trichinella spiralis*. More recently, Belosevic and Dick (1980) have examined three *Trichinella* isolates and reported differential patterns of chemical attraction. However, from the above studies, only *T. spiralis* was tested in a dosage–response format to detect subtle differences.

One pheromone component from *N. brasiliensis* and *Trichostrongylus colubriformis* is similar in HPLC retention. This component is absent in *Toxocara canis*. Hybridization between nematodes occurs in several genera, but the via-

bility of hybrid offspring is low. Thus, closely related species may employ pheromones with similar functional groups so that other mechanisms may control species isolation. Pheromone-based control of helminths would be very appealing if several commonly occurring species of worm were affected by a single synthetic pheromone.

Chemical gradient formation is known to influence male responses to pheromone. In vitro assays have used a 2-hr period for gradient formation with steeper or shallower gradients reducing male responsiveness. In vivo assays revealed that chemical communication via pheromone transmission in the intestine occurs with the direction of peristaltic flow. Adequate male responsiveness was found over a 5- to 11-cm distance in the intestine. Thus, distance influences chemical communication in the aqueous environment of the host (Glassburg et al., 1981).

An unresolved area of research involves the chemical responsiveness of female nematodes to their males. Most investigations have reported a more predictable response of males to females than vice versa. Some available evidence suggests females of *N. brasiliensis* are rapidly arrested by the presence of males (Glassburg et al., 1983). Thus, the stationary females become a pheromone point-source for the approaching male worm. Such a system seems more rational than the collision of two moving organisms and would account for the less consistent reports in the literature regarding attraction of the female. The behavior of males and females differed in the intestine, so that males disperse and females localize. Food deprivation altered female behavior in the intestine, but the female's movement was arrested by males. As discussed in a subsequent section of this review, female nematodes may partition their responses between mating and feeding while males are more driven by their sexual status than by nutrition.

Chemical studies of the pheromone from *N. brasiliensis* have revealed two compounds that account for the biological activity in incubate from females (Ward and Bone, 1983b). One component may be a peptide, based on pronase sensitivity, with an estimated weight of about 600 by gel filtration while the other component is apparently a hydrocarbon (mol wt 375). Isolation of this compound by HPLC has revealed that the chemical is moderately polar and soluble in water and alcohols. Behavioral and chromatographic analyses of pheromone release versus content indicate a rapid biosynthetic mechanism. Elemental analysis suggests the presence of one nitrogen, while spectral analyses seemingly indicate that an amino acid accounts for about 50% of the molecular weight. Mycotoxin inhibitors of amino acid transport in the host intestine yield a 72% increase in pheromone production by female *N. brasiliensis* while depletion of the amino acid in the host's diet causes a 34% reduction in pheromone production. Studies in progress with radiolabeled amino acid may contribute to pheromone identification and ultimately allow insight into pheromone biosyn-

thesis. Pharmaceutical blockage of the biosynthetic pathway may offer new avenues for drug control of helminthiasis.

OVIPOSITIONAL STIMULI

Little information is evident regarding chemical stimuli that govern egg release or oviposition by helminths. Phillipson (1974) proposed that physiological changes in the host's digestive system regulated oviposition by nematodes, but no stimuli were identified. Oviposition by *Haemonchus contortus* was maximal at pH 4–4.5, which suggests that the concentration by hydrogen ion may influence oviposition (Honde and Bueno, 1982). Oviposition by nematodes was stimulated by serotonin, 5-hydroxytryptophan, and epinephrine, while histamine had a moderate effect (Croll, 1975). Serotonin and octopamine had antagonistic effects on oviposition by *Caenorhabditis elegans* and, thus, stimulated and inhibited, respectively, egg release (Horvitz et al., 1982). If these biogenic amines are released by helminths, or used as chemical cues from the host, a regulatory role in oviposition could result. Huang et al. (1982) observed an inverse relation between esophageal and vulvar contractions in *C. elegans*. Thus, oviposition and ingestion may be antagonistic.

Host hormones influence helminth fecundity through an unknown mechanism. Release of larvae by *Trichinella spiralis* was decreased by diethylstilbesterol and increased by testosterone (Reddington et al., 1981). Swanson et al. (1984) found a testosterone-dependent production of eggs by *N. brasiliensis* which was eliminated by ligation of the bile duct. Estrogen decreased egg production by *N. brasiliensis*, while host pregnancy caused greater oviposition which suggests a stimulatory role for progesterone. However, the broad physiological effects of these hormones on the host obscures their direct action as stimuli for reproduction.

Host immunity may also directly affect parasite fecundity by blocking the release of eggs by females. Bosshardt and Damian (personal communication) found that IgG from the baboon host inhibited oviposition in vitro by the blood fluke *Schistosoma mansoni*. Bone and Klesius (unpublished) found that serum from infected animals reduced in vitro oviposition by female *T. colubriformis*. Greater inhibition occurred as the duration of the infection was lengthened. Serum from animals that were immunized with adult worms or their IgG component also reduced oviposition in vitro by 80–90%. Indirect immunofluorescence studies showed that IgG was bound to the cephalic region of the worm, but binding and the inhibition of egg release were eliminated by absorption of serum with whole worms. Vaccination of lambs with irradiated *T. colubriformis* larvae and subsequent infection also decreased fecundity (Wagland et al., 1984).

Charley-Poulain et al. (1984) found a temporal relation between elevated host IgA and depressed oviposition by *Haemonchus contortus*. Host immunity

also reduces fecundity in *Trichinella spiralis* (Kennedy and Bruce, 1981) and *Angiostrongylus cantonensis* (Techasoponmani and Sirisinha, 1980). The lower egg counts typically found in older infections may be the result of these immune influences.

FEEDING STIMULI

Feeding by intestinal nematodes is predominantly by oral ingestion of host tissue or chyme, although a transcuticular uptake of solutes occurs in the filarial nematode *Brugia pahangi* in vitro (Chen and Howells, 1979). *B. pahangi* may also feed orally in vivo (Howells and Chen, 1981). Transcuticular absorption of cholesterol and glucose are reported also for *Ascaris suum* (Fleming and Fetterer, 1984).

Little information is available regarding the stimuli that may regulate pharyngeal pumping, and thus oral ingestion, by nematodes. Several authors (Fernando and Wong, 1964; Roberts and Fairbairn, 1965) have reported that serum stimulated feeding by the hookworm *Ancylostoma caninum*.

Recent studies on *Nippostrongylus brasiliensis* and *Trichostrongylus colubriformis* have used fluorometric analysis of the fluorescent dye rhodamine B to determine in vitro and in vivo ingestion by these worms (Bottjer and Bone, 1984, 1985a,b). Both species increased their feeding as the time of removal from the host was prolonged, which suggests a response to food deprivation. Starvation of the host up to 36 hr reduced in vivo feeding by *N. brasiliensis* which then increased its feeding during subsequent fasting of the host. Feeding by the worms resumed within 15 min after feeding the fasted hosts. Females ingest more and compensate for food deprivation better than do males.

These results indicate that nematodes monitor their nutritional environment and may rapidly adjust their ingestion accordingly. However, the regulatory chemical cues are somewhat elusive. In vitro ingestion by *T. colubriformis* was not stimulated by various sugars, amino acids, enzymes, host chyme or bile, serum from eight mammalian or avian species, seven bacterial species, and nine salt or supplemented culture media (Bone and Bottjer, 1985a; Bottjer and Bone, 1985c).

In contrast, selected biogenic amines altered feeding by *T. colubriformis* in vivo and in vitro, which suggests a synchrony of host and helminth ingestion. Histamine and dopamine elevated nematode feeding, dosage dependently, while serotonin had a less significant effect (Bone and Bottjer, 1985a). Serotonin may coordinate tapeworm movement and host feeding (Mettrick and Cho, 1981). Pharyngeal pumping in the free-living nematode *Caenorhabditis elegans* was stimulated and depressed, respectively, by serotonin and octopamine (Horvitz et al., 1982). Croll (1975) found that histamine elevated pharyngeal activity in several nematodes. The cephalic receptor for histamine-induced feeding may

contain a mannose residue, based on lectin binding and subsequent loss of increased feeding (Bone and Bottjer, 1985b).

In vitro crowding of *T. colubriformis* or *N. brasiliensis* reduced feeding by both helminth sexes (Bottjer and Bone, 1984, 1985a). Ingestion by males was depressed more by the presence of females than by equal numbers of concomitant males. In vitro doses of octopamine decreased ingestion by male, but not female *T. colubriformis*. Horvitz et al. (1982) reported that *C. elegans* contained octopamine. If this biological amine is released by nematodes, females may feed preferentially to males under competitive conditions so that fecundity is maintained.

Host hormones may also affect the feeding status of intestinal nematodes since *N. brasiliensis* ingested more dye in vivo in normal male mice than in female animals (Bone and Bottjer, unpublished). Implantation of gonadectomized mice with testosterone-filled capsules elicited a dose-dependent increase in in vivo ingestion by the nematode. Ligation of the bile duct eliminated the testosterone-mediated feeding and reduced in vivo ingestion to a low level. Thus, the hormone's effect on the worms may be via biliary transport. Implants with estrogen or progesterone increased or decreased, respectively, in vivo ingestion by *N. brasiliensis*. High levels of implanted cholesterol caused some elevation of helminth ingestion.

In vivo feeding by *N. brasiliensis* and *T. colubriformis* declined significantly with helminth age as the duration of infection was increased. Removal of the older helminths from the host showed that in vitro feeding was similar to younger nematodes. Thus, stimuli that are associated with host immunity may become more pronounced with enduring infections and disrupt the ingestive activity of worms (Bottjer and Bone, 1985a). This repression of in vivo feeding was reversible, based on the worm's recovery of expected feeding rates under in vitro conditions.

Additional data also reflect that helminth feeding was deleteriously altered by host immunity (Bottjer et al., 1986). Serum from uninfected goats had no effect on in vitro feeding by *T. colubriformis*. However, serum from infected goats inhibited ingestion by worms. The suppression of feeding increased with the duration of the infection and was dosage dependent. Preexposure of worms to immune serum also decreased subsequent feeding in basal medium, but rigorous washing of the helminths restored normal levels of ingestion.

Fractionation of immune serum and indirect immunofluorescent studies indicated that immunoglobulin G from the host bound to the cephalic region of *T. colubriformis* and was responsible for the inhibition of ingestion. Immunization of goats with adult worms elicited a host response so that serum from these animals reduced in vitro ingestion. In vivo feeding by worms also declined by about 50% in immunized animals. Antiparasite activity by IgG from immune host serum has been shown in vitro in trichostrongylid infections. Pritchard et al. (1983) suggested that *Nematospiroides dubius*-specific IgG from mice me-

diated cell adherence to adult stages. Jones and Ogilvie (1972) found anti-*Nippostrongylus brasiliensis* acetylcholinesterase (AChE) antibody in infected rat serum IgG. Rothwell and Merritt (1974) reported that antibodies in IgG fractions from serum of sheep infected with *T. colubriformis* possessed activity against worm AChE. However, the role of AChE in helminth feeding is unknown.

Oxygenation of a basal medium caused a concentration-dependent elevation of feeding by *N. brasiliensis*, which suggests that a significant quantity of oxygen may be obtained by oral uptake in addition to transcuticular diffusion. Oxygenation of serum also elevated ingestion by the nematode, but oxygen-stimulated feeding was decreased in serum from animals with 14- to 16-day-old infections (Bone et al., 1985). Thus, deleterious effects of host immunity on nematode ingestion may also depress their respiration.

The above alterations of helminth feeding, mediated by host immunity, were consistent with previous reports. Ogilvie and Hockley (1968) and Lee (1969) reported that the intestinal cells of *N. brasiliensis* were damaged severely by host immunity. Older infections of *T. colubriformis* also reveal degenerative changes in the worm's intestinal cells (Rothwell et al., 1980). Ballantyne et al. (1978) proposed that changes in feeding reduced the adenylate energy charge in immune-damaged *N. brasiliensis* and *Nematodirus battus*. Thus, suppression of helminth feeding is apparently one effector mechanism of host immunity.

Phagostimulants may have a potential for control of parasitic helminths. Alphey (1983) found that nematicide was more effective on starved versus fed nematodes. Bottjer and Bone (unpublished) found that *T. colubriformis* ingested four- to five-fold greater quantities of radiolabeled antihelminthic in vitro when stimulated by histamine. In contrast, drug uptake was decreased in immune serum. Discovery of phagostimulants for nematodes with little to no pharmacological effect on the host may permit novel means of improving drug efficacy through enhanced uptake by the parasite.

RECEPTION OF CHEMICAL STIMULI

Most studies of chemical reception by nematodes have been indirect. Wright (1983) noted the resemblance of nematode chemosensilla to vertebrate olfactory sense cells. Samoiloff et al. (1973) used laser microbeam irradiation to determine that the spicules of male *Panagrellus silusiae* contained pheromone receptors. Orientation to females required comparison of pheromone concentrations on both spicules. In contrast, Ward (1973) suggested that *C. elegans* compared chemical concentrations with its cephalic receptors. Croll (1977) proposed that a cephalic nerve in only male *C. elegans* was a likely source of pheromone reception.

Pheromone receptors of *N. brasiliensis* are subject to chemical "swamping" or molecular saturation with subsequent loss of the males' responsiveness,

in vitro and in vivo (Bone and Shorey, 1977; Glassburg, et al., 1981). However, excessive rinsing of *T. colubriformis* males restored their responsiveness to female pheromone at an enhanced level, which suggested that sensory adaptation was the basis of the diminished response. Interestingly, exposure of *T. colubriformis* to immune serum also diminished male responsiveness to female pheromone, which suggests immune-mediated disruption of orientation to chemical stimuli (Bone and Bottjer, 1984).

Bone and Bottjer (1985b) reported that mannose residue was involved in pheromone and histamine-induced feeding reception on *T. colubriformis*, based on lectin binding and behavioral assays. Jansson et al. (1984) reported that enzymatic treatment of *C. elegans* with mannosidase or sialidase inhibited attraction of the worm to a bacterial food source but that subsequent receptor turnover renewed responsiveness. Zuckerman and Jansson (1984) summarized a series of steps in nematode chemoreception that are initiated by the binding of chemoattractants to cephalic surface carbohydrates which were exudates of the amphids or other sensilla. Similarly, binding of immunoglobulins to the surface carbohydrates may account for immune-mediated alterations of nematode behavior and physiology. Continued studies of chemoreception by nematodes may reveal important effector mechanisms of host immunity and means of helminth control by sensory disruption.

ROLE OF CHEMICAL SUBSTANCES FROM FISH HOSTS IN HATCHING AND HOST-FINDING IN MONOGENEANS

G.C. KEARN

School of Biological Sciences
University of East Anglia
Norwich NR4 7TJ, U.K.

(Received October 1, 1985; accepted December 6, 1985)

Abstract—Hatching responses to chemical stimuli appear to have evolved independently in different kinds of monogenean skin and gill parasites of fishes, particularly in those parasites associated with bottom-dwelling hosts. Some monogeneans, such as *Entobdella soleae*, have two hatching strategies, responding readily to host skin mucus but hatching spontaneously in small numbers in the absence of the host. Other monogeneans, such as *Acanthocotyle lobianchi*, have abandoned spontaneous hatching and rely entirely on a "sit-and-wait" strategy, but improvements in the speed of hatching provide opportunities to take advantage of brief periods of contact between the eggs and the host. This has led to the loss of ciliated epidermal cells and to the inability to swim. Comparison of the eggs and hatching responses of two unrelated monogeneans, *Leptocotyle minor* and *Hexabothrium appendiculatum*, which share the same dogfish host, reveals evidence of convergence. Small, stable molecules such as urea, excreted by the host, have been implicated as hatching stimulants in monogeneans. There is evidence that host recognition in *E. soleae* is by chemoperception but, in contrast with the lack of specificity of the chemical hatching stimuli, this appears to be of a specific nature.

Key Words—Monogeneans, fish parasites, chemical hatching factors, host-finding.

Most monogeneans are parasites of the skin and gills of fishes and display strict host specificity. In most monogeneans the eggs leave the host and develop on or in the bottom sediment (Kearn, 1986). The eggs have shells of tanned protein and a ciliated larva or oncomiracidium develops within them over a period of time that usually falls within the range of 10–40 days. It is this ciliated larva that has the task of finding the fish host, there being no intermediate host.

0098-0331/86/0800-1651$05.00/0

The fish hosts of monogeneans have diversified greatly; they occupy many different kinds of habitat and display a variety of behavior patterns. It is perhaps not surprising that the eggs and larvae of monogeneans have responded to this diversity by adaptations that enhance their chances of infecting their specific hosts. Fishes advertize their presence in a variety of ways. As they swim, their movements disturb the surrounding water, and they may cast shadows on the bottom sediment. It has already been established that the eggs of certain monogeneans hatch when mechanically disturbed, e.g., *Microcotyle salpae* (see Ktari, 1969), and larvae emerge when the eggs of *Entobdella diadema* are plunged into darkness (Kearn, 1982). Fishes are also the source of chemical substances in their skin or gill secretions and in their urine or feces, and there is evidence that the eggs of several monogeneans are stimulated to hatch by such chemical cues (Table 1).

The first evidence that monogenean larvae might respond to chemical hatching factors of host origin was presented by Euzet and Raibaut (1960). They collected and incubated eggs of a polyopisthocotylean monogenean, *Squalonchocotyle torpedinis*, from the gills of an electric ray, *Torpedo marmorata*. They observed that eggs kept in seawater, uncontaminated by the host, hatched only in small numbers but, in the presence of either an electric ray or isolated gills from such a ray, a large number of larvae emerged. Similar evidence for a chemical hatching stimulus was reported by Ktari (1969) in the gill-parasitic polyopisthocotylean *Microcotyle salpae*. A significant feature of the freshly hatched larvae of both *S. torpedinis* and *M. salpae* is that these larvae lack ciliated epidermal cells (see below).

More detailed knowledge of the role of hatching factors from the host has emerged from a study of the skin-parasitic capsalid monogenean *Entobdella soleae*. Its bottom-dwelling, flat-fish host, the common sole (*Solea solea*), survives well in aquaria and the life cycle of the parasite continues in these aquaria, providing a supply of adult parasites and eggs for experimental work.

The larva of *E. soleae* is ciliated, and it has been established that hatching occurs in the absence of the host (Kearn, 1973). When eggs are exposed to the natural cycle of illumination or to an artificial light regime, e.g., 12 : 12 light–dark, hatching is rhythmical, most larvae emerging on each successive day during the first few hours after dawn or after the artificial illumination is switched on. However, when sole body mucus is added to fully developed eggs at any time during the illumination cycle, hatching is greatly enhanced, indicating that sole mucus contains a potent hatching stimulant (Kearn, 1974).

It has been shown by Kearn (1975) that hatching is preceded by ciliary activity on the part of the fully developed oncomiracidium; this activity begins spontaneously in the absence of the host or as a result of stimulation by host mucus. The beating cilia produce rotation of the larva about its longitudinal axis, the rotating head of the larva occupying the corner of the tetrahedral egg

Table 1. MONOGENEANS REPORTED TO RESPOND TO CHEMICAL HATCHING FACTORS FROM THE HOST

Species	Relationship	Microhabitat	Host	Oncomiracidium	Author
Squalonchocotyle torpedinis	Hexabothriid polyopisthocotylean	Gills	*Torpedo marmorata*	Unciliated	Euzet and Raibaut, 1960
Hexabothrium appendiculatum	Hexabothriid polyopisthocotylean	Gills	*Scyliorhinus canicula*	Ciliated	Whittington (in progress)
Microcotyle salpae	Mazocraeidean polyopisthocotylean	Gills	*Box salpa*	Unciliated	Ktari, 1969
Leptocotyle minor	Microbothriid	Skin	*Scyliorhinus canicula*	Ciliated	Whittington (in progress)
Acanthocotyle lobianchi	Acanthocotylid dactylogyridean	Skin	*Raja* spp.	Unciliated	Macdonald, 1974
Acanthocotyle greeni	Acanthocotylid dactylogyridean	Skin	*Raja clavata*	Unciliated	Macdonald and Llewellyn, 1980
Entobdella soleae	Capsalid dactylogyridean	Skin	*Solea solea*	Ciliated	Kearn, 1974
Pseudodactylogyrus bini	Uncertain	Gills	*Anguilla japonica*	Ciliated	Chan and Wu, 1984

where the lid or operculum is situated. A considerable body of evidence suggests that erosion of the cement attaching the operculum to the rest of the shell is brought about by secretory material from gland cells in the head region of the larva. The interval between the commencement of rotation and the escape of the larva from the egg may be as short as 4–5 min.

Thus, *E. soleae* appears to have alternative hatching strategies depending on whether or not there are soles in the vicinity of the fully developed eggs of the parasite. If there is no host in the vicinity, hatching takes place soon after dawn, but relatively small numbers of larvae emerge. Natural selection might be expected to favor spontaneous hatching of the parasite during this period of the day because the sole host rests on the bottom during the hours of daylight and slow-moving oncomiracidia seem more likely to successfully locate and attach themselves to an inactive host than to one that is actively swimming. Prolonged close contact is likely to occur between the host and the eggs of the parasite; the host spends long periods of time resting on the sea bottom and the eggs of the parasite are attached to sand grains by adhesive material on a long appendage (Kearn, 1963a,b). In these circumstances, the ability of the larvae to respond at any time of day to chemical hatching factors from the host will enhance the survival of the parasite.

If the response of the larva of *E. soleae* to chemical hatching factors from the host is to be effective in ensuring host invasion, it is important that the larvae are infective immediately after hatching. This has been tested by placing fully developed eggs on the upper surface of a sole. Kearn (1981) observed that some freshly hatched larvae attached themselves by the sticky areas on the head region before the posterior, hook-bearing attachment organ or haptor had been withdrawn from the shell. After emergence, the haptor was then attached to the skin and the sticky areas were released and this was followed, within about 30 sec, by the loss of all the ciliated epidermal cells of the larva. Thus the oncomiracidia of *E. soleae* appear to be infective immediately after hatching, and there is no requirement for an initial period of free-swimming before infection takes place.

There appears to have been a further development in the monogenean *Acanthocotyle lobianchi*, a skin parasite of rays (*Raja* spp.). The eggs of this parasite, like those of *E. soleae*, have adhesive material on their appendages and stick to sand grains. Macdonald (1974) discovered that these eggs fail to hatch spontaneously when kept in seawater free of contamination by host mucus. Nevertheless, the larvae are able to survive within the egg for as long as 80 days at 13°C. When the eggs are treated with ray mucus, hatching occurs but, unlike *E. soleae*, emergence of the larva takes place with great rapidity (within a few seconds). The larva responds by greatly extending its body and in so doing pushes off the operculum; the opercular cement is already weak in

anticipation of the thrust of the larva. Thus, *A. lobianchi* has speeded up the hatching process in response to a chemical hatching stimulus and appears to rely entirely on a "sit-and-wait" strategy, having abandoned the ability to fall back on spontaneous hatching as a "last-ditch" means of locating the host. Because of the adoption of this strategy, there is no longer a requirement for free-swimming and ciliated epidermal cells are absent. The host must virtually make contact with the eggs if infection is to take place, but the speed of hatching ensures that the larva can take advantage of exceedingly brief periods of contact. A similar evolutionary pathway may have led to the absence of ciliated cells in the larvae of *S. torpedinis* and *M. salpae* (see above).

Parasitologists working at the laboratory of the Marine Biological Association of the United Kingdom at Plymouth, England, have encountered the eggs of some other monogeneans that, apparently, fail to hatch spontaneously. Whittington (work in progress) has found that hatching in the skin parasite *Leptocotyle minor* and the gill parasite *Hexabothrium appendiculatum*, both from the dogfish *Scyliorhinus canicula*, resembles hatching in *A. lobianchi*. Eggs of these parasites fail to hatch spontaneously in the absence of the host but survive for at least 80 days; the opercular cement is weakened in readiness for hatching, which is rapid and stimulated by seawater from a tank containing dogfish. Whittington has observed that the eggs of *L. minor* and *H. appendiculatum* are small, with exceptionally long and slender appendages lacking adhesive droplets. These small eggs are readily kept in suspension even by weak convection currents, and the slender appendage makes a contribution to their slow rate of sedimentation because eggs sink faster if the appendage is experimentally removed. Thus the appendages may serve to keep the eggs in suspension, like the silk threads produced by small aerial spiders.

This has led Whittington to suggest that currents produced by dogfish foraging near the bottom may lift resting eggs off the bottom; these eggs may then drift sufficiently close to swimming dogfish for hatching to be stimulated by chemical substances from the host's body. The retention of the ciliated cells and the ability of the larvae of *L. minor* and *H. appendiculatum* to swim, may reflect the fact that drifting eggs are unlikely to make intimate contact with the bodies of moving hosts. Whittington has suggested that the striking similarity between the shapes and sizes of the eggs and the hatching behavior of these unrelated parasites (*L. minor* is a microbothriid and *H. appendiculatum* is a polyopisthocotylean) may be an example of convergent evolution that has arisen because of the exertion of similar selection pressures on the two parasites by the same host.

In contrast with this apparent convergence between dogfish parasites, the skin parasite *A. lobianchi* and the gill parasite *Rajonchocotyle emarginata*, both of which inhabit *Raja* spp., appear to have evolved different strategies for host

invasion. Previous workers had failed to hatch the eggs of *R. emarginata*, but Whittington and Kearn (1986) have found that the ciliated larvae of this parasite do hatch spontaneously but have a relatively long incubation period (44–47 days at 13–14°C). Moreover, these eggs fail to respond when treated with mucus from ray skin or gills.

There are indications that the chemical hatching factors in the skin mucus of soles and rays are small and stable molecules (Kearn, 1974; Kearn and Macdonald, 1976). Exploratory tests with potential hatching stimulants implicated urea, ammonium chloride, and arginine in the hatching of *E. soleae*, but the only substance tested that stimulated hatching in *A. lobianchi* was urea (Kearn and Macdonald, 1976). Incubation with urease was found to be a most effective way of destroying the stimulatory properties of ray mucus for *A. lobianchi* eggs, but similar tests with sole skin washings and eggs of *E. soleae* gave inconsistent results. Recent work by Whittington (in progress) suggests that extrapure urea may be less effective as a hatching stimulant for *E. soleae* eggs than less pure grades, and he has found that lower grade urea rarely proves as effective as sole mucus. This suggests that a trace substance present in commercial urea may stimulate hatching in the eggs of *E. soleae* or, perhaps more likely, that the effectiveness of urea may be enhanced by the presence of one or more other substances. This contrasts with the situation in *A. lobianchi*, the unhatched larvae of which respond equally readily when treated with extrapure urea or lower grade urea. Furthermore, urea appears to be just as effective as ray mucus. Preliminary observations by Whittington (work in progress) indicate that the eggs of *L. minor* and *H. appendiculatum* respond to urea in a similar way.

Kearn and Macdonald (1976) estimated the levels of urea in ray and sole skin mucus. The levels of urea in ray skin mucus are relatively high, providing a strong hatching signal for the eggs of *A. lobianchi*. The levels of urea in sole skin mucus are much lower, and this may have led to the development of sensitivity on the part of unhatched oncomiracidia of *E. soleae* to a combination of substances present in mucus, one component of which may be urea.

Kearn (1974) showed that the chemical hatching stimulus for the eggs of *E. soleae* is nonspecific, the eggs readily hatching if treated with skin washings from a variety of fishes including whiting (*Merlangius merlangus*) and rays. This lack of specificity seems at first sight to be distinctly disadvantageous since hatching might be induced by nonhost fishes or by other bottom-dwelling organisms. However, this nonspecific stimulus may not be disadvantageous if soles are locally abundant, because, in these circumstances, the hatching stimulus is more likely to be provided by a sole than by any other organism. Moreover, even if hatching were stimulated by a nonhost organism, it is most unlikely that the larvae would attach themselves to it. When oncomiracidia are presented experimentally with a choice of skin samples, either in the form of

detached scales or small pieces of skin from more than one fish species, the larvae of *E. soleae* show a strong preference for sole skin, even in total darkness (Kearn, 1967). Larvae also show a preference for agar blocks which have been in contact with sole skin rather than similar blocks soaked in seawater. This indicates that chemoperception may be important in host identification and suggests that the chemical cues provided by the host are specific, in contrast with the nonspecific nature of the hatching stimulus. However, there is not yet any evidence that oncomiracidia are attracted to the sole by chemotaxis, and recognition of the host may rely on contact chemoperception.

The monogeneans that are known to respond to chemical hatching factors from the host are listed in Table 1. Three points are worth stressing. First, the phenomenon appears to have arisen independently several times. Secondly, the hosts that provide the chemical hatching cues may be teleosts or elasmobranchs but are usually flat-fishes or round-bodied hosts that feed on the bottom. This is perhaps not surprising because most monogenean eggs come to rest on the bottom, and the effectiveness of a hatching response to chemical substances of host origin depends on contact or close proximity between the hosts and the fully developed eggs. Thirdly, there is a tendency for the oncomiracidia to dispense with ciliated cells.

Hatching responses to chemical substances from the host of the kind described here have rarely been reported in other flatworm parasites. Shinn (1983) has presented evidence to suggest that in the parasitic turbellarian, *Syndisyrinx franciscanus*, the intestinal fluid of its sea-urchin host stimulates the production of a hatching fluid by the parasite. Host digestive secretions play an important role in hatching of some cestode eggs, perhaps partly by stimulating larval activity, but their main role is concerned with erosion of the egg envelopes (see, for example, Caley, 1975; Holmes and Fairweather, 1982) or the opercular cement (Kennedy, 1965). The molluscan hosts of digeneans are slow-moving, bottom-dwelling organisms, and contact between these hosts and digenean eggs seems likely to be a frequent occurrence. In similar circumstances, several monogeneans have independently acquired a hatching response to chemical substances from the host, and it is rather surprising that there appear to be no reports of a similar phenomenon in those digenean eggs that hatch in water. However, some digeneans have exploited the opportunities offered by accidental ingestion of their eggs by their molluscan hosts, hatching apparently being stimulated by host digestive enzymes and/or physicochemical conditions in the gut (Smyth and Halton, 1983). Smyth and Halton have pointed out that this area has received little attention and further study seems likely to be rewarding.

Host location by digenean miracidia that hatch in water has been studied more intensively than in monogeneans (Smyth and Halton, 1983). Striking changes in the behavior of the free-swimming miracidia have been reported on

the addition of snail-conditioned water, for example in *Schistosoma mansoni* but comparable changes in the behavior of oncomiracidia have not been reported.

CHEMICAL COMMUNICATION IN HERMAPHRODITIC DIGENETIC TREMATODES

BERNARD FRIED

Department of Biology
Lafayette College
Easton, Pennsylvania 18042

(Received October 1, 1985; accepted December 17, 1985)

Abstract—Adult hermaphroditic digenetic trematodes show a tendency to pair or aggregate in vivo, on the chick chorioallantois, and in vitro. Intraspecific pairing studies on *Echinostoma revolutum*, *Leucochloridiomorpha constantiae*, and *Amblosoma suwaense* are reviewed. Lipophilic excretory–secretory products are involved in chemical communication in hermaphroditic digeneans. Free sterols are involved in chemical attraction in *L. constantiae* and *E. revolutum* and sterol esters play a similar role in *A. suwaense*. In vitro pairing between *E. revolutum* and various other digenean species suggest that interspecific pairing occurs in Digenea and that nonspecific factors are involved.

Key Words—Platyhelminths, Trematoda, hermaphroditic digeneans, intraspecific pairing, interspecific pairing, behavior, chemical communication, pheromones, lipids, sterols.

INTRODUCTION

Except for the schistosomes and some didymozoids, digeneans are hermaphroditic. This paper examines studies on chemical communication in adult hermaphroditic digeneans. Some information on this topic has been presented in Nollen's (1983) review on sexual reproduction in parasitic flatworms, and Bone's (1982) review on reproductive chemical communication in platyhelminths.

Digenetic trematodes have complex life cycles and various larval stages. The first intermediate host in the digenean cycle is usually a specific snail, in which intramolluscan stages develop. In monoecious digeneans, cercariae released from sporocysts or rediae encyst on a substratum or in a second inter-

0098-0331/86/0800-1659$05.00/0

mediate invertebrate or vertebrate host. The encysted metacercariae (cysts) are infective to the definitive vertebrate host and are usually acquired by the feeding habits of the host. In the laboratory, cysts are administered per os to experimental definitive hosts and metacercariae usually excyst in the intestine. Excysted metacercariae establish in more or less specific sites in the intestine or its ramifications. How excysted flukes locate specific sites is not well understood, and this subject has been reviewed by Ulmer (1971) and Kemp and Devine (1982).

Laboratory studies on chemical communication have used monoecious digeneans that have little or no economic significance, i.e., *Echinostoma revolutum*, *Zygocotyle lunata*, *Haematoloechus medioplexus*, *Leucochloridiomorpha constantiae*, and *Amblosoma suwaense*. In the future, representative fasciolids may provide interesting models for chemical communication studies. Interference with chemical communication in fasciolids could provide a means for biological control of these important veterinary and medical trematodes.

PHEROMONES

Chemical communication in animals is mediated by pheromones. The parasitology literature indicates that helminthologists use the term essentially as defined by Karlson and Luscher (1959), i.e., pheromones are substances emitted by an organism which can elicit a specific behavioral or developmental reaction in another of the same or closely related species. Both primer and releaser pheromones have been described for behavioral activities associated with digeneans (Bone, 1982). Primers cause physiological changes without immediate accompanying behavioral responses and influence behavior through hormonal changes. Releasers cause an immediate change in the behavior of the recipient and act directly on the recipient's nervous system (Wilson and Bossert, 1962). Other pheromones described for insects and arachnids, i.e., alarm, trail, marking, have not been examined in trematodes.

The term excretory-secretory products or simply ES products has been used in trematode chemoattraction studies (Fried and Shapiro, 1975; Fried et al., 1980a, 1983; Bennett and Fried, 1983). This term refers to excretions and secretions released by trematodes either in vivo or into an in vitro cultivation or maintenance medium (Fried, 1978). Some of these ES products have pheromonal information. Because of the small size of most digeneans, it is difficult to associate the release of ES products with a particular system (von Brand, 1973; see Source of Pheromones, below). ES products have also been described in trematode immunology studies where they serve as a source of antigens (Rotmans et al., 1981; Sandeman and Howell, 1981; Irving and Howell, 1982).

RECEPTORS

Studies on the reception of stimuli in hermaphroditic digeneans are sparse (Kemp and Devine, 1982). Scanning electron microscopy (SEM) and light level argentation studies have shown that larval and adult digeneans have various types of sensory papillae, some of which are probably chemoreceptors (Hoole and Mitchell, 1981; Fried and Fujino, 1984). However, chemoreceptors have not been unequivocally identified in monoecious digeneans, and there are no electrophysiological studies that elucidate their role in chemoreception. In insect physiology, the use of the electroantennogram has allowed for quantitative studies in sensory physiology. Until similar methodology is developed in trematode physiology, sensory studies will remain speculative.

METHODOLOGY

Pairing, i.e., the tendency of two monoecious digeneans to come together, and clustering, i.e., the aggregation of three or more worms have been studied in vivo, on the chick chorioallantois and in vitro (Fried and Roberts, 1972; Fried et al., 1980a, b; Fried and Alenick, 1981; Fried and Robinson, 1981).

For in vivo studies on *Echinostoma revolutum*, experimental hosts were fed metacercarial cysts (Fried and Weaver, 1969); in brachylaimid studies, free (unencysted) metacercariae were inoculated per cloaca into domestic chicks (Fried and Harris, 1971; Fried and Schnier, 1981). At necropsy, observations were made on pairing or clustering of worms in their normal sites (Fried and Roberts, 1972; Fried and Alenick, 1981; Fried and Robinson, 1981).

To eliminate host factors associated with worm migration and establishment in vivo, pairing and clustering have been studied on the chick chorioallantois of domestic chick embryos maintained in ovo or in vitro (Fried and Roberts, 1972; Fried et al., 1980b).

Pairing studies that exclude organisms other than the parasites have been done in vitro in 3.5-, 5.0-, and 8.5-cm-diameter plastic Petri dishes usually maintained in an incubator or on a slide warmer at 35–41°C (Fried and Roberts, 1972; Fried et al., 1980a; Fried and Robinson, 1981; Fried and Pallone, 1984). In this design, a 1% agar substratum is prepared in the dish, since worms move better on the agar than the plastic. A sterile Locke's (Paul, 1975) solution overlay is usually used, and worms migrate at the agar–Locke's interface. In this nonbarrier design, worms show a maximal tendency to pair. However, this design does not exclude worm thigmotaxis, i.e., worm-to-worm contact pairing. In the nonbarrier design worms are usually started 2 cm from each other and the tendency of one worm to attract the other is examined at various intervals up to 24 hr.

Worms in contact with or within 5 mm of each other are considered paired (Fried and Roberts, 1972; Fried et al., 1980a; Fried and Pallone, 1984). This criterion for pairing has also been used by Perkins and Fried (1982) in studies on free-living planarians in the genus *Dugesia*. Both *Dugesia* and the digeneans often show noncontact pairing, i.e., worms come within 1–2 mm of each other, do not make contact, and then retreat to about 5 mm from each other. In nonbarrier studies initial starting distance is a factor in subsequent pairing. *E. revolutum* started more than 8 cm apart did not pair, whereas those started less than 8 cm did (Fried and Pallone, 1984). Other factors involved in *E. revolutum* pairing are temperature and the overlay medium. More pairing occurred at 39°C than 35°C, and an overlay of sterile Locke's was better than the defined medium NCTC 135 (Fried and Pallone, 1984). In our nonbarrier studies with monoecious digeneans and planarians, a single worm did not pair with a dead worm or an inert object.

Attraction of a single worm toward either a filter paper disk or silica gel square containing worm homogenate or ES products has been studied in Petri dish cultures (Fried and Gioscia, 1976; Fried, et al., 1980a; Fried and Robinson, 1981). These studies begin by placing the worm equidistant between the experimentally impregnated disk or square and its control. Migration toward or contact with the experimental disk or square is considered attracted.

In barrier designs, one worm is isolated from the other, thus eliminating the possibility of worm thigmotaxis. Such designs have been used to study heterosexual and homosexual chemical attraction in schistosomes maintained in polycarbonate linear chambers (Imperia et al., 1980; Eveland et al., 1982, 1983). The barrier usually consists of a chimney made of dialysis tubing (Imperia et al., 1980) or a dialysis sac (Fried et al., 1980a). Single *Echinostoma revolutum* adults migrated significantly toward a dialysis sac containing other *E. revolutum* (Fried et al., 1980a). In these designs worms isolated in the sac are designated "releasers" and those outside, "migrators" (Belosevic and Dick, 1980; Fried and Wilson, 1981a). In a recent study, *E. revolutum* pheromonal dosage was examined in a barrier design where either two, four, or six releasers were isolated in a cylindrical stainless steel screen (40-mesh) chimney and a single migrator was allowed to move toward or away from the barrier (Figure 1). The results showed that four and six releasers were better at attracting a single migrator than two releasers (Figure 2) (Fried and Wilson, 1981a).

A recent study has allowed us to track *E. revolutum* adults in an 0.8 agar–Dulbecco's modified Eagle's medium supplemented with 10% fetal calf serum. Worms survived up to 48 hr in the medium and left distinct acetabular tracks in the agar. Some worms showed directed movement toward each other, suggesting that chemotaxis was involved (Fried and Vates, 1984).

In most studies statistical significance of pairing and chemoattraction data at each time period were determined using either the chi-square test or the two-

sample Z-test for proportions (Book, 1977). Based on computer simulations, the probability that two randomly selected points in a 5-cm Petri dish are within 5 mm of each other is less than 0.15 (Wagner, 1975).

SOURCE OF PHEROMONE

An adult hermaphroditic digenetic trematode is a complex metazoan with numerous systems; i.e., tegumentary, nervous, male and female reproductive, digestive, excretory, and others (Smyth and Halton, 1983). Each worm has several pores through which ES products may be released, i.e., mouth, gonopore, excretory. The worm has a complex tegument which may release ES products that play a role in chemical communication. Most adults are less than 1 cm and are not easy to manipulate experimentally. Attempts to collect ES material from the mouth will also yield products from the gonopore (Figure 3) (Bailey and Fried, 1977). Intubation of worms is difficult, although Lutz and Siddiqi (1971) cannulated and expressed fluids from the excretory system of *Fasciola gigantica*. Recently, Gallo and Fried (1984) designed a micropipet apparatus that allowed for the collection of ES products from the excretory system of *E. revolutum*. Ligation experiments have also been used to block certain systems (Fried and Appel, 1977), but the results of ligation experiments

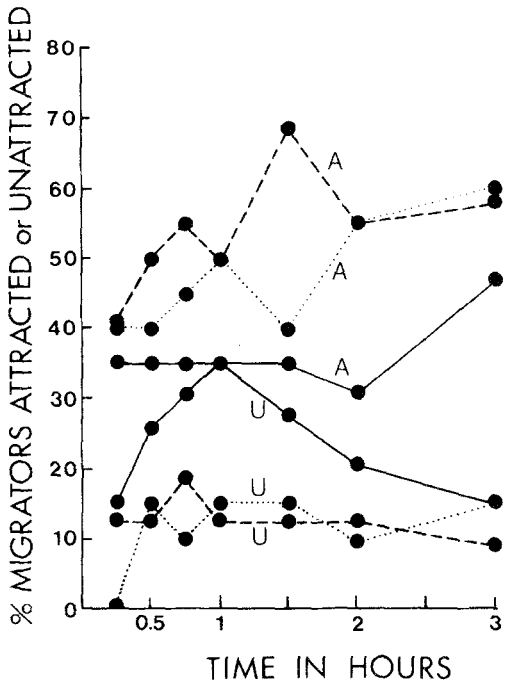

FIG. 2. Summary of migrators attracted (A) or unattracted (U) to releasers in chimney. should be accepted with caution since Halton and Arme (1971) and Nollen and Nadakavukaren (1974) have shown that ligation of adult trematodes may cause tegumentary damage.

PAIRING PHENOMENA—ADVANTAGES OF PAIRING

Observations on adult hermaphroditic digeneans both in the wild and the laboratory indicate that isolated worms are rare. Digeneans are usually found paired or clustered in their natural host site. In 15 of 16 cases, the zoogonid, *Deretrema* sp., was found in pairs in the gallbladder of naturally infected flashlight fish, *Anamalosis katopteron*, and in only one case was a solitary fluke found (Burn, 1980).

In single-worm infections of various digeneans, normal growth and development does not occur (Nollen, 1983). Fried (1962) found that the eyefluke, *Philophthalmus hegeneri*, when maintained singly in experimentally infected domestic chicks, stopped growing after 20 days, and failed to produce fertile

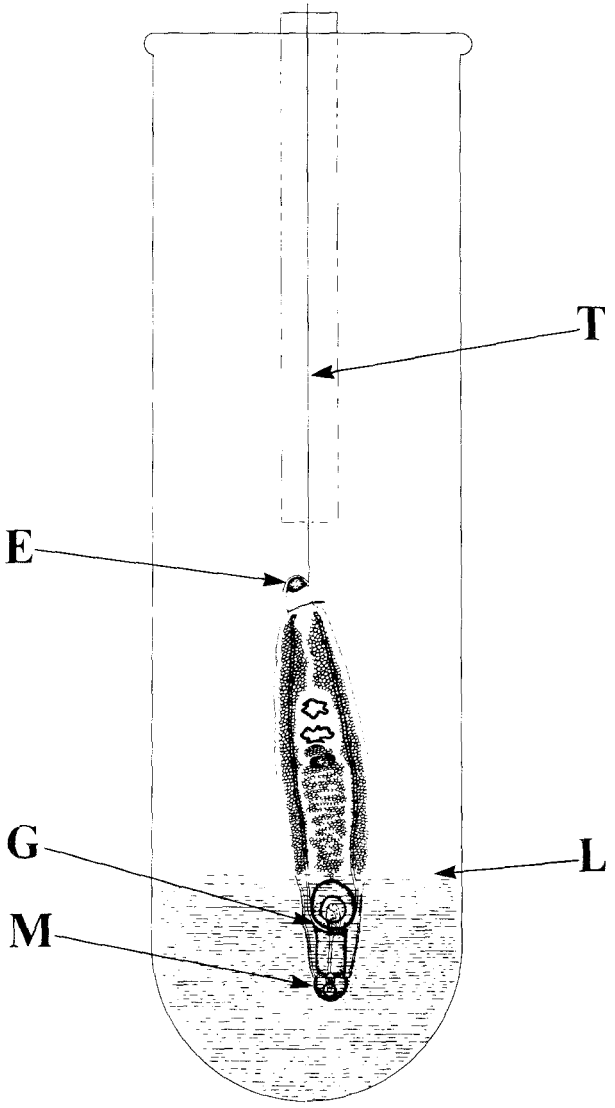

FIG. 3. *Echinostoma revolutum* adult suspended by a thread (T) from its posterior end into Locke's solution to collect excretory–secretory products from the mouth (M) and gonopore (G). The worm can also be suspended from its anterior end to collect ES products from the excretory pore (E).

eggs. An eyefluke of birds, *P. burilli*, described in Australia by Howell and Bearup (1967), showed a pattern similar to *P. hegeneri*. Moseley and Nollen (1973) confirmed Fried's (1962) findings on *P. hegeneri* and Nollen (1983) suggested that contact with another eyefluke of the same species is required for normal growth and sexual maturity of *P. hegeneri*. This may be due to mutual tactile stimulation by worms, or stimulation of growth by the presence of sperm in the seminal receptacle (Nollen, 1983).

Sogandares-Bernal (1966) observed that monometacercarial infections in the domestic cat with *Paragonimus kellicotti* never developed beyond the wandering preadult stage in the abdominal cavity. When these hosts were later infected with other metacercariae, preadults paired and developed to mature worms in the lungs. Sogandares-Bernal postulated that chemotactic factors are involved in both worm attraction and sexual maturation in *P. kellicoti*. Worms do not find each other by chance alone and factors other than "host mediated" are involved in worm chemoattraction.

Foreyt et al. (1977) studied the pairing tendency of *Fascioloides magna* in naturally infected white-tailed deer, *Odocoileus virginianus*. Pairing of worms was important for normal capsule formation in the liver and for worm maturation.

Leucochloridiomorpha constantiae AND *Amblosoma suwaense*

In the early 1970s my students and I became interested in following Sogandares-Bernal's (1966) study, but with a simpler and less expensive model than his *Paragonimus*-cat system. Through the courtesy of Dr. William J. Bacha, Jr., of Rutgers University, Camden, New Jersey, we obtained viviparid snails, *Campeloma decisium*, that were naturally infected with free (unencysted) metacercariae of *Leucochloridiomorpha constantiae* (Brachylaimidae). The metacercaria of *L. constantiae* is precocious and when inoculated per cloaca in the domestic chick achieves sexual maturation within three or four days in the bursa of Fabricius (Harris et al., 1972). In our chick studies we found that this organism invariably paired or clustered in the bursa of Fabricius (Fried and Harris, 1971; Harris et al., 1972). Paired worms produced a significantly greater number of eggs and were larger than singles (Fried and Harris, 1971; Fried et al., 1980b). Single worms were capable of autocopulation, but in situations where worms were paired, we observed cross- but not autocopulation (Fried and Harris, 1971). We concluded that there were genetic and reproductive advantages associated with pairing in *L. constantiae*.

To eliminate definitive host-mediated factors, Fried and Roberts (1972) examined pairing and clustering in the chick chorioallantois of in ovo prepared embryos (Figure 4). In about 50% of the trials, worms were either paired or clustered, suggesting that this reaction could occur in the absence of bursa of

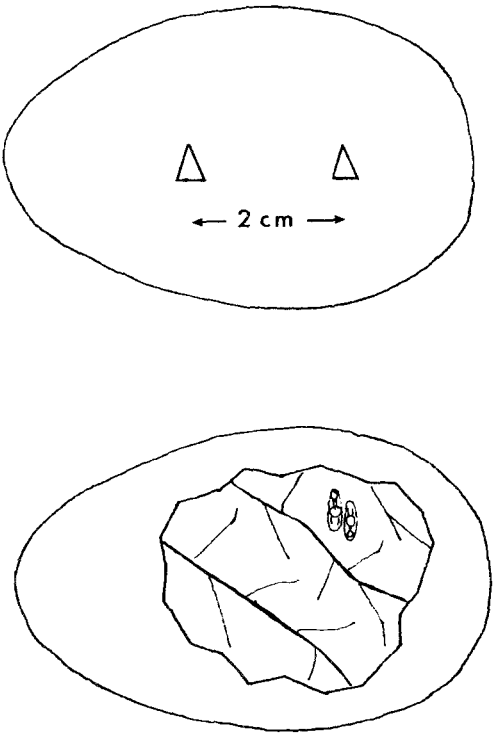

FIG. 4. In ovo chorioallantois technique in which single *L. constantiae* worms were placed in each window, 2 cm from one another (top). Worms often paired on the chorioallantois (bottom). See Fried and Roberts (1972) for details.

Fabricius factors. This study was later confirmed using chick embryos cultivated in vitro (Figure 5) (Fried et al., 1980b).

Fried and Roberts (1972) also examined worm-to-worm attraction in vitro at 37.5°C in 5-cm Petri dishes containing an agar substratum and a Locke's overlay. Metacercariae were started 2 cm from each other and worms in contact or within 5 mm of each other were considered paired (Figure 6). These experiments were maintained up to 24 hr, and we observed overall about 60% pairing. In vitro pairing was very similar to what we had already observed both in the domestic chick and on the chorioallantois.

In unpublished histochemical studies, Tom Roberts found most obvious change in lipids and little change in proteins, carbohydrates, and mucosubstances of *L. constantiae* metacercariae incubated in the Petri dish bioassay. Harris and Cheng (1973) using oil red O histochemical staining procedures reported neutral lipid accumulation in the intestine and release from the mouth in *L. constantiae* metacercariae maintained in Locke's solution. These histochem-

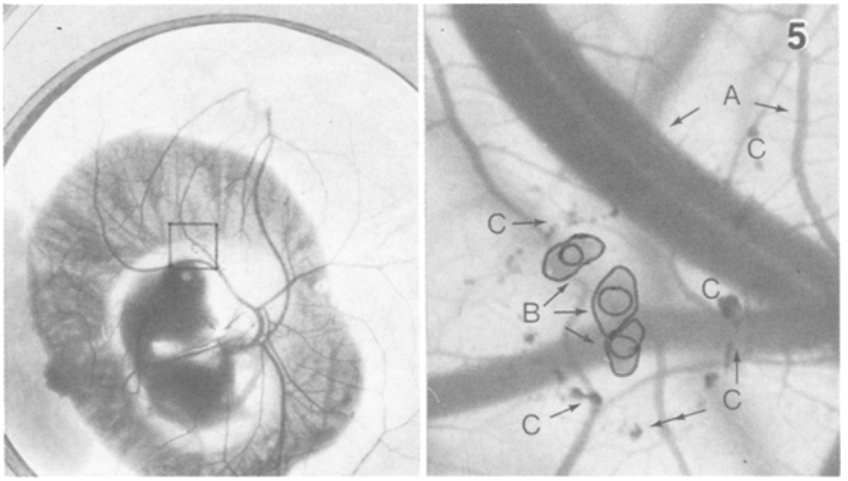

FIG. 5. *L. constantiae* maintained in chick embryos cultivated in vitro. Photo on the left shows a chick embryo cultivated in vitro in a Petri dish. Details of the inset are shown in the photograph on the right. Three *L. constantiae* worms (B) are clustered on the chorioallantois. Worms have been outlined in India ink for clarity. Abbreviations: A = blood vessels; C = hematin-like material associated with worms. See Fried et al. (1980b) for details.

ical findings were confirmed by Fried and Shapiro (1975), who also used thin-layer chromatography (TLC) to show accumulation and release of lipids by this metacercaria. TLC showed that free sterol was the major neutral lipid accumulated and egested by this organism and argentation-TLC of the free sterol fraction showed only cholesterol.

Fried and Gioscia (1976) obtained ES products from *L. constantiae* metacercariae and extracted them in chloroform–methanol (2:1) (Folch et al., 1957). TLC analysis of the material showed only free sterol in 12 of 15 trials. When this material was placed on filter paper disks in the Petri dish bioassay, a significant number of worms were attracted to the disks. Larger amounts of material generally produced greater worm attraction than smaller amounts. We stated that free sterol, presumably cholesterol, was a presumptive chemoattractant for *L. constantiae*. Subsequently, Berger and Fried (1982) used quantitative densitometric TLC to confirm that free sterol was the major ES lipophilic product of *L. constantiae* metacercariae and reported that worms released an average of 3.2 ng of free sterol/metacercaria/hr.

Through the courtesy of Dr. William F. Font, University of Wisconsin, Eau Claire, Wisconsin, we obtained another brachylaimid, *Amblosoma suwaense*, from *C. decisum* snails in Wisconsin. This free metacercaria is larger

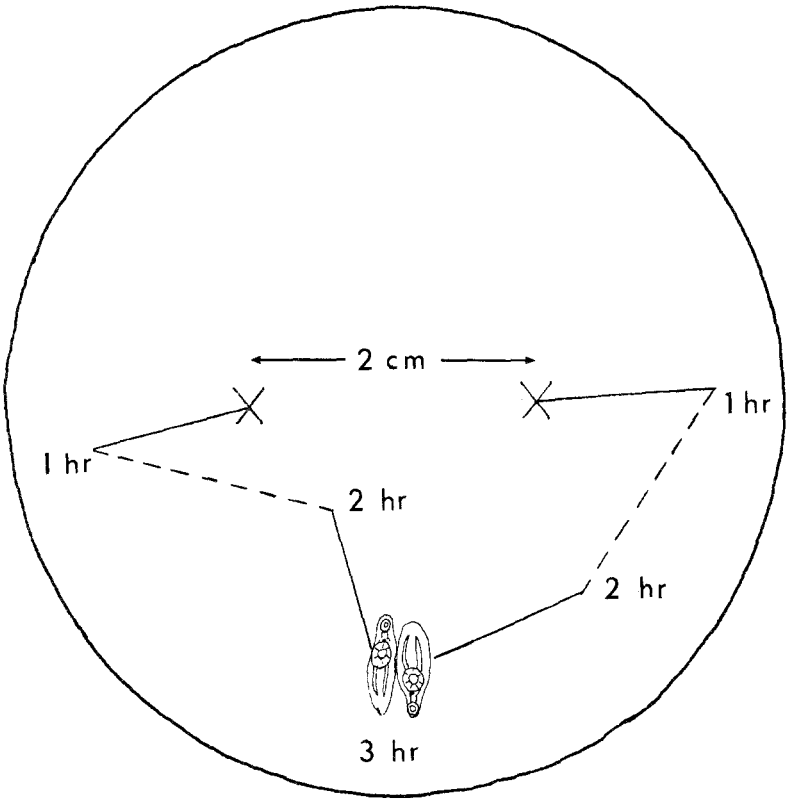

FIG. 6. A diagram showing worm positions of *Leucochloridiomorpha constantiae* metacercariae in the Petri dish culture at the start (X), and at 1, 2, and 3 hr. In this experiment worms paired at 3 hr. See Fried and Roberts (1972) for details.

and more robust than *L. constantiae* and lives between the shell and digestive gland of the snail. This organism also shows a tendency to pair and aggregate in Petri dish bioassays (Fried and Robinson, 1981). Interestingly, its major lipophilic ES product is sterol ester and free sterol is a minor fraction (Figure 7) (Fried and Robinson, 1981; Berger and Fried, 1982). When *A. suwaense* lipids were preparatively isolated and tested in the Petri dish bioassay, *A. suwaense* metacercariae were attracted to sterol esters, but not free sterols (Fried and Robinson, 1981). Berger and Fried (1982) used densitometric TLC to quantify these lipids and found that *A. suwaense* released a mean of 128 ng of sterol ester/metacercaria/hr compared to a mean release of free sterol of 49 ng/metacercaria/hr.

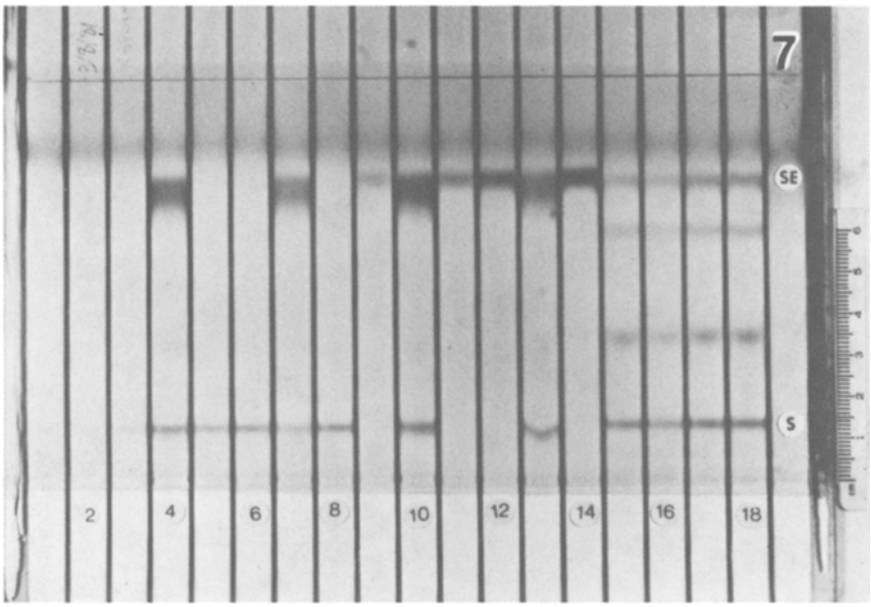

FIG. 7. A thin-layer chromatogram showing sterol ester (SE) and free sterol (S) excretory–secretory products of *Amblosoma suwaense* (lanes 4, 7, and 10). Other lanes contain various neutral lipid standards. See Berger and Fried (1982) for details.

Echinostoma revolutum

Echinostoma revolutum has been maintained in my laboratory since the late 1960s (Fried and Weaver, 1969). This robust fluke reaches 1–2 cm in length and 5–10 mg in experimentally infected domestic chicks. It becomes sexually mature in about nine days and survives for up to six weeks in the domestic chick (Fried, 1984).

Monometacercarial studies of *E. revolutum* in the domestic chick have produced adults with viable eggs, indicating that this species can self-fertilize under conditions that preclude cross-fertilization (Fried and Alenick, 1981). Worms from multiple infections were mainly paired or clustered, and both the number and percentage of hatched eggs were greater in multiple- than single-worm infections. Thus, at least in the domestic chick, reproductive advantages were associated with the tendency to pair or cluster.

Fried et al. (1980a) studied pairing of *E. revolutum* adults in vitro in agar–Locke's Petri dish cultures. Worm-to-worm pairing of adults was highly significant. Chemically excysted metacercariae examined under similar conditions did not pair.

In a modified Petri dish bioassay (cover slips placed in the dish to provide a linear channel), Fried et al. (1980a) observed significant migration of a single

E. revolutum adult to echinostomes in dialysis sacs. TLC analysis of fluids released into the medium from worms in the sac in the absence of another worm outside the sac showed lipids. Oil red O histochemical studies of *E. revolutum* adults have demonstrated neutral lipids in the excretory tubes and bladder and the intestinal ceca were lipid negative (Fried and Morrone, 1970; Fried and Appel, 1977; Butler and Fried, 1977). The *E. revolutum* lipid excretory pattern is different from that of brachylaimids, but is similar to that of *Fasciola hepatica* where lipids are excreted across the epithelial cells of the excretory system (Burren et al., 1967).

To study the activity of ES products released from *E. revolutum*, ES products were collected in Locke's, extracted in chloroform–methanol (2 : 1) (Folch et al., 1957), and separated into hydrophilic and lipophilic fractions. Silica gel squares impregnated with these fractions were tested in modified Petri dish bioassays. The results showed that single adults of *E. revolutum* were very significantly attracted to lipophilic but less significantly attracted to hydrophilic fractions (Fried et al., 1980a).

To further analyze lipophilic fractions, *E. revolutum* adults were extracted in chloroform–methanol (2 : 1) and individual lipophilic fractions were isolated preparatively (Fried and Sherma, 1982) on silica gel sheets developed in the Skipski et al. (1965) dual-solvent system which provides good separation of free sterols from glycerides. When the sterol, triglyceride-free fatty acid, sterol ester, and phospholipid fractions were tested in the bioassay, attraction only occurred with the sterol band. The band that remained at the origin contained phospholipid and other polar compounds and acted as a chemorepellent (Fried et al., 1980a).

Analyses of free sterols in *E. revolutum* by GLC and TLC have shown that the major free sterol is cholesterol (Barrett et al., 1970; Fried and Boddorff, 1978; Fried and Shapiro, 1979). An attempt to use authentic cholesterol as an attractant for *E. revolutum* in the Petri dish bioassay was equivocal (Fried et al., 1980a), a finding similar to that of Roberts and Thorson (1977a) in their heterosexual chemoattraction studies on *Nippostrongylus brasiliensis*.

With the help of Dr. David J. Chitwood and his colleagues in the Insect Physiology Laboratory, United States Department of Agriculture, Beltsville, Maryland, we have begun to examine *E. revolutum* sterols with the goal of determining if individual sterols are pheromones. Using the powerful technique of capillary GLC as well as capillary GLC–mass spectrometry, Chitwood et al. (1985) have identified the relative percentage of sterols in *E. revolutum* adults as follows: cholesterol, 96.73; 24-methylcholesterol, 1.06; 24-ethylcholesterol, 0.87; desmosterol, 0.72; 24-methylenecholesterol, 0.28; 24*Z*-ethylidenecholesterol, 0.13; lathosterol, 0.09; 24-methylcholesta-5,22-dienol, 0.04; 24-ethylcholesta-5,22-dienol, 0.04; cholesta-7,24-dienol, 0.04. Chitwood et al. (1985) concluded that one should not speculate that any of the sterols identified are the lipophilic substance or substances involved in chemoattraction in *E.*

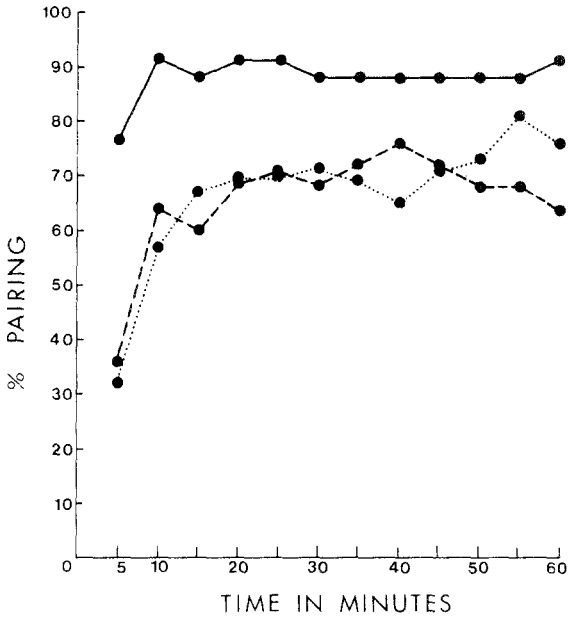

FIG. 8. Summary of interspecific and intraspecific pairing studies with *Echinostoma revolutum* and *Zygocotyle lunata*. Solid line = *E. revolutum* intraspecific studies; broken line = *Z. lunata* intraspecific studies; dotted line = interspecific studies. Reprinted from Fried and Wilson (1981b) with permission of the Helminthogical Society of Washington.

revolutum. Because of the possible occurrence of additional components in column chromatographic or TLC-prepared free sterol fractions other than free sterols, positive identification of the lipophilic chemoattractive substance requires further purification and bioassay.

INTERSPECIFIC PAIRING

Interspecific pairing in vitro has been reported by Fried and Jacobs (1980) for *Echinostoma revolutum* matched against either *Zygocotyle lunata* or *Leucochloridiomorpha constantiae*. Fried and Wilson (1981b) observed that interspecific pairing between *E. revolutum* and *Z. lunata* more closely matched the intraspecific pattern of *Z. lunata* than that of *E. revolutum* (Figure 8). Fried and Leiby (1982) observed significant interspecific pairing of *Haemotoloechus medioplexus* and *E. revolutum* at both 21 and 30°C. Whereas transience of interspecific pairing was noted in nematodes (Roberts and Thorson, 1977b), this was not the case in some trematode interspecific combinations (Fried and Wilson, 1981b; Fried and Leiby, 1982). Both *Z. lunata* and *H. medioplexus* also emit significant amounts of free sterol into a nonutrient medium, indicating that

free sterols may be involved in interspecific as well as intraspecific pairing. Interspecific pairing of trematodes indicates that nonspecific substances are involved in chemoattraction of hermaphroditic digeneans.

CONCLUDING REMARKS

The studies reported herein suggest that monoecious digeneans pair or aggregate both in vivo and in vitro. SEM observations on *E. revolutum* show no damage in the tegument of worms maintained in the agar–Locke's bioassay for 2 hr (Fried and Pallone, 1984). Presumably in vitro observations are indicative of what is happening in the host.

Pairing and aggregation of digeneans may have nutritive, social, developmental, and reproductive advantages for digeneans. In vitro observations on pairing in *L. constantiae* or *E. revolutum* have failed to show copulatory behavior. Perhaps this reflects inadequacies in the in vitro environment, or possibly copulatory phenomena are independent of aggregative behavior in trematodes as reported in nematodes (Bonner and Etges, 1967; Marchant, 1970).

The studies reported herein suggest the importance of worm lipophilic factors in pairing and aggregative behavior in monoecious digeneans. Of particular importance are free sterols which are involved in chemoattraction in *L. constantiae* and *E. revolutum* and sterol esters which play a similar role in *A. suwaense*. Whether lipids are pheromonal in hermaphroditic digeneans or serve as carriers, as described by Sonenshine et al. (1981) for the *Dermacentor* sex pheromone, 2,6-dichlorophenol, is not known.

Lipids also play a role in chemical communication of dioecious trematodes. Extracts of *Schistosoma mansoni* males in organic solvents (presumably lipids) enhance growth and vitellogenesis of unisexual females maintained in vitro (Shaw et al., 1977). Lipids released from the tegument of male *S. mansoni* may be involved in heterosexual chemical attraction (Haseeb et al., 1984, 1985).

Saladin (1979) proposed "behavioral parasitology" as a discipline that would combine ethology, sensory physiology, and parasitology. He also invoked the Timbergen (1963) caveat, which suggests that familiarity with an organism is essential before problems can be attacked by experimentation. This suggestion is important for a better understanding of chemical communication in trematodes. With the aid of videotechnology it should be possible to examine more closely digenean behavior in vitro. Observations on single versus paired worms should elucidate further on migration, locomotion, oviposition, and mating behavior.

(Received October 1, 1985; accepted February 10, 1986)

Abstract—An understanding of reproductive function is important for control of parasitic helminths. In cestodes and trematodes virtually nothing is known about regulatory and coordinating mechanisms that control maturation, gamete formation, egg production, and related processes. Neurosecretory neurons have been reported in various species but specific modes of action of neurohormones have yet to be demonstrated. The role of ecdysone is being investigated.

Key Words—Schistosomes, nerve–hormone interactions, platyhelminths, differentiation reproductive maturation, *Schistosoma mansoni*, ecdysteroids.

In all multicellular animal groups from sponges to vertebrates, hormonal and neural processes play an important role in control and coordination of reproduction and other somatic functions. Reproduction is almost the key to the existence of trematode parasites; maturation and egg production account for much of their metabolic activity. The egg is the basis of transmission and distribution, and in schistosomes is also the agent of pathogenesis, yet little is known about the control or reproduction in these parasites. There is need for a broad understanding of the coordination of sexual development and reproduction in trematodes and cestodes, with comparisons to invertebrates in general. Such knowledge may aid in the development of methods to frustrate egg production and thus to minimize and control trematode diseases. A specific area of interest is the study of relationships between neural and hormonal conditions needed for the attainment and maintenance of reproductive maturity.

Both of the major groups of "hormonal" regulatory substances—steroids and peptides—are almost universally distributed in living organisms. Study of

0098-0331/86/0800-1679$05.00/0

these materials in parasitic helminths has barely begun and has so far been limited to a scattering of reports of their discovery in one or another species. Functional investigations are almost nonexistent. Knowledge of neurotransmitters, while still insufficient, is far more advanced (Hillman, 1983).

In a larger context, the classical distinctions between the nervous and endocrine systems are, as reported by Bloom (1981) "now in disarray." It has been suggested, for example by Le Roith et al. (1982), that there is an early phylogenetic precursor common to both systems so that conventionally conceived neuronal and endocrine functions are manifestations of a single primitive coordinating mechanism. As discussed by Fujita (1983), Krieger (1983), and others, different roles have been assigned to (1) neurons that function through classical neurotransmitters for very local signals; (2) paracrine cells, for short-range transfer of chemical messages; and (3) endocrine cells, which produce chemical substances generally active at a remote site and transmitted through body fluids. Many types of intermediate cells with blended functions are now coming to light. Moreover, it is now clear that insulin and various other polypeptide hormones, generally considered as endocrine substances, may also be products of neural tissues. Both classical brain and classical gut peptides are now known to be widely produced and distributed within vertebrates, so that the distinctions of site origin are largely blurred (Roth et al., 1982; Krieger, 1983). As relatively primitive acoelomate organisms lacking a circulatory system, platyhelminths would have no endocrine functions (as defined above) but may be good candidates for study of paracrine and nerve–hormone interactions.

In their excellent review, Maddrell and Nordmann (1979) provide the following partial list of neurosecretory functions in invertebrates: growth, differentiation, regeneration, body water balance, pigment production, blood sugar levels, heart rate, molting, sexual development, ovulation, and oviposition. The regulatory substances are generally peptides varying from a few amino acid residues to about 10 kd in molecular weight. In starfish, Kanatani (1983) has identified a molecule as small as 1-methyl adenine as a potent regulatory hormone inducing oocyte maturation and spawning in all species so far tested. Recent years have seen an explosion of interest in neurobiology and thousands of papers have dealt with neurohormones and neurotransmitters. Although the parasites in general have not yet shared in this informational wealth, it seems clear that future analyses will deal with basic biological phenomena such as metamorphic phase changes (e.g., from miracidium to sporocyst or cercaria to metacercaria to adult) as well as reproductive maturation. Metamorphosis and maturation are phenomena certainly not peculiar to parasites, but an understanding of their biological and hormonal bases could have practical application through pharmacologic development of specific inhibitors.

An extraordinary phylogenetic conservation of functional peptide configurations is becoming apparent so that many of the peptide hormones once

thought characteristic of mammals are being found in lower organisms. For example, thyrotropin-releasing hormone in gastropods (Grimm-Jorgensen and Connolly, 1983); cholecystokinin/gastrin activity in coelenterates, ectoprocts, crustaceans, insects, and annelids (Larson and Vigna, 1983); and neurophysins, ACTH, and angiotensin in planaria (Remy, 1982). Certain "invertebrate" peptides have also been found in mammalian brain. The phylogeny of neurosecretory functions has been reviewed by Scharrer (1976) and more comprehensively by Remy (1982), who described numerous relationships between vertebrate and invertebrate neuropeptides. Insulin, the subject of concentrated study, has been found in mollusks where it serves in regulation of carbohydrate metabolism (Fritsch et al., 1976; Plisetskaya et al., 1978), and also occurs in insects and annelids (Le Roith et al., 1983).

A great number of papers, which cannot be reviewed here, have described neurohormonal regulation of growth, development, molting, and reproduction in arthropods, particularly insects and crustaceans. Ecdysteroids, best known as molting hormones of arthropods, have recently been reported in schistosomes by Torpier et al. (1982) and Nirde et al. (1983, 1984), and in the cestode *Moniezia expansa* by Mendis et al. (1984). Interrelations between peptide and steroid hormones are seen in such processes as neurosecretory control of production and release of ecdysone by the prothoracic gland, and it is not unlikely that similar functional cascades, feedback loops, and other control mechanisms are to be found in platyhelminths.

In flatworms, work has concentrated on morphological description of neurosecretory cells and granules in planarians and other turbellarians (Grasso and Quaglia, 1970a,b, 1971; MacRae, 1967; Reuter, 1981; Reuter et al., 1980). Experimentally, Sakurai (1981) has demonstrated that feeding of sexually reproducing worms to a normally agamic strain that reproduced only by fission caused the latter to develop gonads. It was proposed by Grasso and Benazzi (1973) that sexualizing factors in planaria are neurosecretory in origin, as nerve plexi containing many neurosecretory cells innervate the gonads. Grasso et al. (1975) reported that sexuality could be induced in agamic planaria by feeding isolated neurosecretory granules concentrated by density gradient centrifugation from homogenized sexual planarians.

In cestodes, Davey and Breckenridge (1967) demonstrated neurosecretory cells in the scolex of *Hymenolepis diminuta* and described a cycle of secretion related to development of the adult and to strobila formation. In *Hymenolepis microstoma*, Webb (1977) showed many neurosecretory cells in the neck region by electron microscopy and followed the release of the electron-dense neurosecretory granules into the intercellular spaces from sites resembling synapses. Gustafsson and Wikgren (1981a,b) and Gustafsson et al. (1983) demonstrated numerous neurosecretory cells in *Diphyllobothrium dendriticum*, showing that both peptidergic and aminergic nerves occur in this species. A rapid activation

of the peptidergic NS system takes place when the plerocercoid larvae are transferred from poikilothermic fish to homeothermic environments in vivo and in vitro. After 1 hr of cultivation, large numbers of granules were evident.

Among trematodes, Ude (1962) first demonstrated neurosecretory granules in the cerebral ganglia of *Dicrocoelium*. Gresson and Threadgold (1964) reported that the beta neurons of adult *Fasciola hepatica* had a NS function, and Dixon and Mercer (1965) showed neurosecretory granules in the nervous system of its cercariae. Grasso and Quaglia (1972, 1974) and Shyamasundari and Rao (1975) suggested, but did not prove, a connection between neurosecretory cells and reproductive maturation in *Fasciola*. A scattering of morphological studies on neurosecretory cells and neurosecretory granules has appeared for other species of trematodes: *Leucochloridiomorpha constantiae* (Harris and Cheng, 1972); *Gastrothylax* sp. (Mehrotra and Bhutia, 1979); *Proalarioides tropidonotus* (Kalyankar and Kankal, 1981); and *Opisthodiscus diplodiscoides* by Matskasi (1970), who described a clear circadian cycle in the increase and reduction of neurosecretory granules within the neurosecretory cells. Sharma and Sharma (1981), studying *Ceylonocotyle scoliocoelium*, stated that "our current investigations indicate that the activities of the neurosecretory cells in a trematode are responsible for initiating growth in juveniles and maturation in adults." An unpublished thesis (Steele, 1971) discussed neurosecretion and development in *Acanthoparyphium spinulosum*. Increased numbers of neurosecretory cells appeared just before large numbers of eggs and sperm were found in the reproductive system. In the author's opinion, neurosecretory cells were responsible for gametogenesis and possible differentiation of the entire reproductive system in this trematode.

In the same year that Ude first described neurosecretory cells in a trematode, Gönnert (1962) reported on the histological structure of the egg-forming region (oogentop) in *Fasciola hepatica*. He discussed the reproductive coordination system as follows (freely translated).

> The oogentop is . . . complicated in structure. Therefore, there must be a coordinating system, whose function it is to regulate the flow and the proper sequence of individual functions. To this question there are as yet no data available. . . . In my investigations I have seen nerve cells in the region of the Mehlis' gland. Precise examination of serial sections revealed the existence of two groups of nerve cells, which are called plexus I and plexus II. Plexus I consists of usually four and at most five nerve cells which lie in the region of the ovovitelline duct and presumably coordinate the functions of the oviduct, vitelline duct, ovovitelline duct, and glands of the upper ootype and Mehlis' gland. . . . Plexus II consists of only two nerve cells. These lie close to the upper uterus. One of these is found very near the ootype valve and appears to be connected to it by a process. The second cell lies further towards the uterus. I presume that plexus II inner-

vates the lower ootype and the ootype valve as well as the upper uterus section, thus the region of eggshell formation.

Specifically regarding schistosomes, much work has been done on neuropharmacology in connection with drug development and assessment (recent reviews by Hillman, 1983; Mellin et al., 1983), but this has little direct application to understanding the neurobiology of reproduction. The influence of host hormones on schistosomes has been reviewed by Knopf (1982), but the current state of knowledge contributes little to the study of schistosome reproductive biology.

Numerous studies have been carried out on the neurobiology of freshwater mollusks, particularly *Lymnaea*, by a large group of Dutch investigators; however, the possible involvement of regulatory peptides in mollusk–trematode interactions does not appear to have been investigated and will most likely prove to be a fertile subject for research. The complexity of studies on trematode neurohormonal regulation should not be minimized: these organisms must function effectively within molluscan and vertebrate milieux at appropriate times, interacting with and perhaps obtaining regulatory chemical cues from each of their hosts, while at the same time retaining their independent internal coordinating systems.

Despite the report and review by Dei-Cas et al. (1980) with diagrams of the neural ganglia and major nerve trunks, surprisingly little information is available on schistosome neuroanatomy. The few detailed studies made with the electron microscope (Silk and Spence, 1969; Reissig, 1970; Dei-Cas et al., 1980) agree in describing a variety of electron-dense granules, some of which were considered to be neurosecretory granules by all authors. However, no function was ascribed to these intraneuronal granules and no study has been made of their association with developmental states or with components of the reproductive system.

We are now studying the presence and distribution of neurosecretory cells in various life history stages of schistosomes. The association between the polypeptide neurohormones and steroid regulatory substances, well established in arthropods, is likely to be found elsewhere. As mentioned above, ecdysteroids have been found by chemical analysis in *S. mansoni*. Accordingly, we have investigated the distribution of immunoreactive ecdysteroids in the life history stages of *S. mansoni*. A rabbit antiserum to beta-ecdysone 2-hemisuccinate (Soumoff et al., 1981) kindly provided by Dr. J.D. O'Connor of UCLA, was used for primary incubation, with fluorescein-conjugated goat anti-rabbit IgG as secondary antiserum. Whole cercariae and paraffin sections of sporocysts, unisexual, paired, and cultured adults were utilized.

Immunoreactivity has been identified in all stages except miracidia. In intramolluscan sporocysts, activity is limited to portions with the maturing cercariae which, when liberated, show strong immunoreactivity in the median re-

gion and postacetabular glands. In adult males and unisexual females activity is concentrated in an assemblage of cell bodies of unknown function within the parenchyma around the intestinal ceca. Interconnections are suggestive of a neuronal network, but this has not been demonstrated. They may also represent ducts of the excretory system. In mature paired females immunoreactive nuclei are found peripherally, just beneath the tegument. An area of strong reactivity in both unisexual and adult females is located in the epithelial lining in the ootype area.

Despite a few tantalizing glimpses, the intricacies of maturational regulation in platyhelminthes remain almost completely unknown. However, the gradually emerging comprehension of generalized neuronal and hormonal control mechanisms in invertebrates will sooner or later be applied to this group. The resulting understanding of trematode and cestode reproductive biology will have profound consequences in new methods of control of these important parasites of animals and man.

Abstract—Schistosome adults attract each other in vitro and the attraction is chemically mediated. In *Schistosoma mansoni* adults, excretory-secretory (ES) products of worms of one sex attract worms of the opposite sex, and at least the lipophilic fraction is attractive. Intra- and interspecific attraction occurs in *Schistosoma mansoni*, *S. japonicum*, and *S. haematobium* adults. Current knowledge of schistosome behavior in vitro is reviewed.

Key Words—Schistosoma mansoni, Schistosoma japonicum, Schistosoma haematobium, trematode, digenetic, chemoattraction, sexual attraction, intraspecific attraction, interspecific attraction; heterosexual behavior, homosexual behavior, premating attraction, pheromonal response, pheromone production, behavior, pheromone, excretory-secretory products, lipophilic, hydrophilic.

Although schistosome chemoattraction has been the subject of many studies during the last two decades, most studies have focused on larval stages (MacInnis, 1965, 1976; Chernin, 1970, 1974; MacInnis et al., 1974; Stibbs et al., 1976; Roberts et al., 1979; Saladin, 1979). Many investigations have been done in vivo on ways that *Schistosoma mansoni* males and females affect each others growth and development. For example, Moore et al. (1954) suggested that substances responsible for female maturation may be transferred from male to female in sperm or through the tegument. However, Armstrong (1965) demonstrated that females paired with males castrated by X-irradiation reached sexual maturity and concluded that materials responsible for female maturation do not originate in the testes and must therefore be transferred through the tegument.

0098-0331/86/0800-1687$05.00/0

Armstrong (1965) first examined the distribution of adult *S. mansoni* in unisexual infections by quick freezing mice in liquid nitrogen and dissecting them after partial thawing to prevent postmortem migration of worms. He found that 97% of the worms of both sexes were located in the liver or in the nearby portal vein, with their anterior ends directed toward the flow of blood. He observed homosexual pairing of males. The homosexual pairs showed a larger male harboring one to several sexually immature males in its gynecophoral canal. He also studied the pairing behavior of X-irradiated schistosome males and females, and observed that badly deformed and sterile males paired less frequently with females than did normal males. He believed that worms find each other because they are attracted to the liver and that both sexes are active in searching for each other, but that tactile attraction is responsible for bringing conspecific members together. In mixed infections of different species, choice initially appeared random, followed by separation into species after two to three months. He suggested that communication between male and female adults is evidenced by the migration of worm pairs from the liver and portal vein to the mesenteric venules and from venule to venule as the blood vessels fill with eggs. By contrast, homosexual pairs did not migrate to the mesenteric veins, and all were found in the liver or portal vein. Awwad and Bell (1978) further reported that human fecal material contains substances which attract paired *S. mansoni*.

Experiments have more recently been designed for direct in vitro observations of adult schistosome behavior. Michaels (1969) showed that when worms were transected into equal halves, and the halves were allowed to pair in vitro, like halves almost always paired normally and unlike halves almost always paired abnormally. Also, whenever an anterior section of a worm of either sex was placed near an intact worm, it resulted in abnormal pairing position, in contrast to the normal position achieved by posterior halves pairing with intact worms. These observations suggested that a posterior linear receptor system exists in schistosomes and that it is probably neurosecretory in nature. She also observed that when worms began to pair it was always posteriorly, and when worms were transected into thirds the middle third showed a pairing efficiency which was intermediate to the anterior and posterior thirds. These observations suggested that pairing involves activity on the part of both sexes. Males rarely paired with dead females, and females never paired with dead males, although both paired with living worms of the opposite sex 90% of the time. Michaels suggested, therefore, that a neurosecretory mechanism combined with tactile behavior is responsible for schistosome pairing.

Shaw (1977) cultivated male and female *S. mansoni* from mixed and unisexual infections and showed that female worms from unisexual infections usually paired with males from mixed or unisexual infections within 24 h.

From the observations of Michaels (1969), and Shaw (1977), it seemed probable that pairing is induced by a chemical mediator transmitted between

males and females. Shaw et al. (1977) further hypothesized the existence of a pheromone in *S. mansoni* associated with the lipid fraction.

Shirazian and Schiller (1978, 1982) reported that when adult *S. mansoni* males and females were separated, then put back together in an oscillating chamber with either their original partners or partners from different pairs, the worms "paired" most frequently with their original partners.

A bioassay system, with Earle's balanced salt solution (EBSS) containing 0.1% glucose and 0.5% lactalbumin hydrolysate (Clegg, 1965), was developed by Imperia et al. (1980) to study the effects of *S. mansoni* excretory-secretory (ES) products in vitro. Although Carlisle et al. (1983), and Weisberg et al. (1983) reported that morphologic changes are induced by maintenance of *S. mansoni* in vitro, Haseeb et al. (1983, 1984, 1985a) demonstrated that EBSS is an appropriate medium for short-term experiments in the bioassay, since it has no deleterious effects on worms and departure from normal morphology is not observed by either scanning electron microscopy (SEM) or transmission electron microscopy (TEM).

Bioassay designs were modifications based on previous models used for nematode behavior studies (Bonner and Etges, 1967; Salm and Fried, 1973). In the nonbarrier design, polycarbonate chambers with 14 linear channels, each channel 3 cm long, 1 cm wide, and 1.5 cm high, were used. The channels were marked into 0.5-cm zones. Each channel was filled to a height of 0.85 cm with 1% agar. The agar was overlaid with EBSS. The chamber was maintained in a controlled environment room at 37°C under subdued light. Worms were pipetted into the chamber 15 mm apart in separate channels. The orientation of worms was initially random, and although it changed within a few seconds, there was no apparent pattern of orientation. This distance allowed each worm to move either toward the other, which was initially 15 mm away, or 7.5 mm in the other direction, toward the end of the channel. Worm movement did not apparently follow any particular orientation, but could only be measured as distance traveled over time. Distances were measured between worm centers at various time intervals. At each time period, the distance between a worm couple was measured, and the percent attraction determined by the formula:

$$\frac{15 - D}{15} \times 100$$

where D is the actual distance between a worm couple at a particular time point. Observations were based on the mean $\pm$ SE values from the summation of individual trials. Thus, by this formula 0% attraction would indicate that worms remained at their original distance, and 100% attraction would indicate that all the worms were in contact.

The obvious advantage of the nonbarrier design is that by allowing both worms to migrate, any chemoattractive effect can be cumulative and therefore

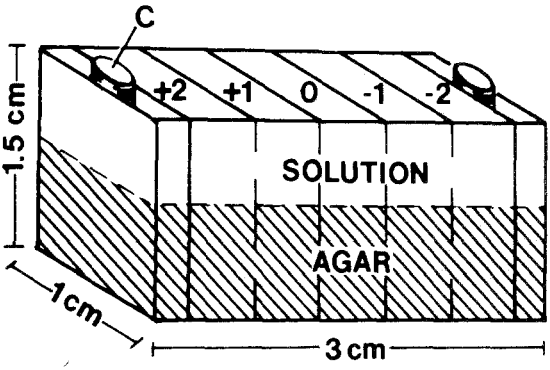

FIG. 1. Linear channel, barrier design of polycarbonate chamber used in pheromonal studies. Reprinted from Imperia et al. (1980) with permission of *The Journal of Parasitology*.

maximized. However, some limitations of this design are: (1) It does not permit determination of whether one or both worms are the emittors or responders; and (2) it cannot rule out the possibility that mating is accomplished by means of thigmotaxis and by trial and error rather than by chemotactic response, as was suggested by Armstrong (1965).

The barrier design, although somewhat less sensitive than the nonbarrier design, permits such distinctions. It also allows testing of excretory–secretory (ES) products, as described below. In this design, shown in Figure 1, channels contained 0.6-cm-diameter dialysis tube chimneys at both ends to restrain worms but allow the passage of ES products. Most experiments employed dialysis tubing with approximately 12,000 M_r exclusion. The chimney tops protruded above the saline. In this design, a worm was placed at the zero (starting) point, equidistant between the chimneys. Worms which moved toward occupied chimneys were considered attracted, whereas those moving toward unoccupied chimneys were scored unattracted. Control experiments have been carried out with single worms placed equidistant between empty chimneys and, at all time points, most of the "migrating" worms remained at the zero (starting) point, and the remaining worms were distributed equally on both sides of the zero point. Thus, a 50% attraction would be expected if migration were random and therefore only those responses greater than 50% are regarded as attraction. Observations were made at regular intervals up to 4 hr. Chi-square and Student's *t*-tests were used to analyze the data.

Initially, Imperia et al. (1980) tested the in vitro attraction of single female *S. mansoni* toward one or three males using the barrier design. Either one, three, or no males were placed in the chimney adjacent to the +2 zone, and one female was placed in the center of the starting zone. Observations on the

migration of the female toward or away from the experimental chimney were made at 0.5, 1, 2, 3, and 4 hr. Females in the +2 and +1 zones were considered attracted, whereas those in −2 and −1 zones were scored unattracted. Chi-square tests indicated that individual females were significantly attracted ($P < 0.025$) to a one-male source at all time periods. Females were not attracted to a three-male source at any time point in this barrier design.

Eveland et al. (1982) then showed heterosexual and homosexual attraction, both in the absence and presence of barriers. Attraction was seen in all cases. No significant differences occurred between male–female, male–male, or female–female combinations in the nonbarrier design. At least during the first hour, attraction was clearly a function of time, with most attraction occurring within 0.5 hr. Also, in no case of heterosexual or homosexual attraction did worms migrate past each other.

Experiments were also done to compare heterosexual attraction in worms from same verses different pairs in the absence of barriers. When males and females were separated, then put into the bioassay with either their original partners or partners from different pairs, there was significantly more heterosexual attraction between same than different pairs.

When heterosexual and homosexual attraction were tested in the presence of barriers, the results were different. Most attraction occurred within 0.5 hr, and the greatest attraction was heterosexual, with males moving toward females. Heterosexual attraction with females moving toward males was approximately equal to homosexual female attraction, and male homosexual attraction was not seen.

It is noteworthy that most of the chemoattraction was demonstrated in this bioassay system, both with and without barriers, within 30 min, in contrast to the "pairing" shown by Shirazian and Schiller (1978, 1982), which took place only after 6 hr. This is not surprising, however, but strongly suggests that chemoattraction and pairing are distinct phenomena.

Eveland et al. (1983) showed heterosexual attraction when one but not two male or female worms were placed behind the barrier. One or two male or female worms, or a male–female in copula were placed in one of the chimneys and either a male or female worm was placed at the zero (starting) point. The results of one vs. two worms in the chimney are shown in Figure 2. Males were significantly attracted to one, but not two females. Beginning at 1 hr, males were significantly repelled when more than one female was in the chimney. Likewise, one male attracted a female, but two males repelled. These results were in agreement with the observations by Imperia et al. (1980) that females are less significantly attracted to a three-male source than to a one-male source at all time periods.

The results comparing a single worm with an in copula pair in the chimneys are shown in Figure 3. Although males and females were significantly attracted

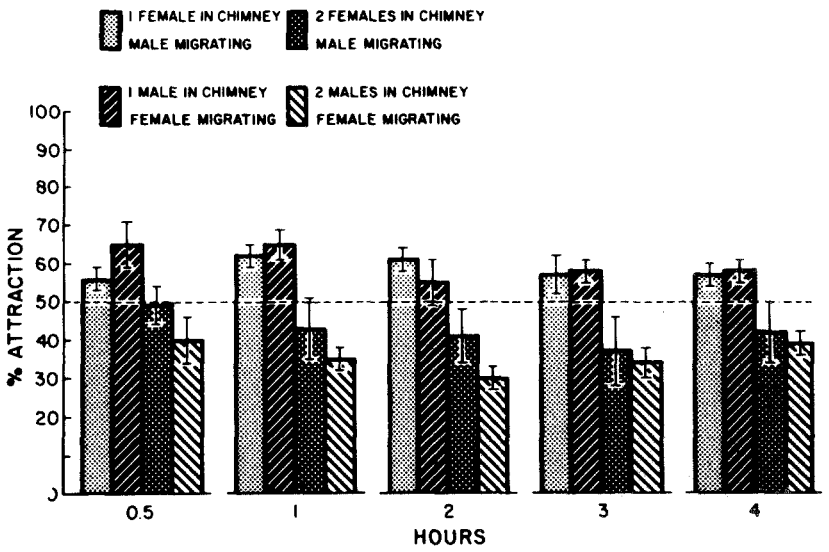

FIG. 2. *Schistosoma mansoni* worms were attracted to one, but not two of the opposite sex. For each time period, 100–110 trials were done with each combination shown. Standard error bars are shown. Reprinted from Eveland et al. (1983) with permission of *Experimental Parasitology*.

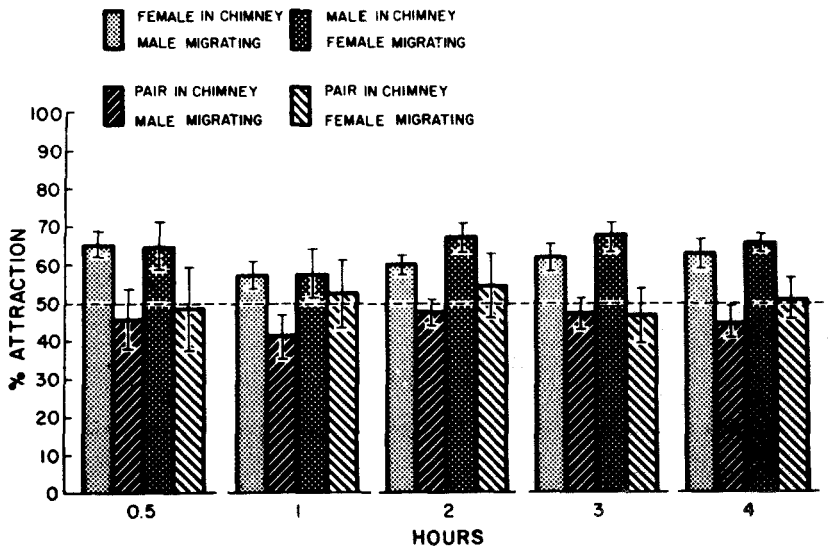

FIG. 3. *Schistosoma mansoni* worms were attracted to single worms but not to worm pairs. For each time period, 100–110 trials were done with each combination shown. Standard error bars are shown. Reprinted from Eveland et al. (1983) with permission of *Experimental Parasitology*.

to single worms in chimneys, they were not attracted to pairs. While no definite explanation can be given for the fact that two or more worms in the chimney were less effective than one in attracting males and females, it is interesting in this regard that Fried et al. (1983) showed that when male worms were incubated singly for 0.5 hr, they released cholesterol, but they did not appear to release cholesterol when incubated in groups of ten. Likewise, Haseeb et al. (1985b) demonstrated that *S. haematobium* males incubated singly released more free sterols than a similar number incubated in groups.

Initially, our studies were done with perforated chimneys to allow free passage of substances of all sizes (Imperia et al., 1980). In the perforated design, barriers were prepared by puncturing dialysis tubing of approximately 12,000 M_r exclusion size with common pins. Unperforated chimneys with approximately 50,000, 12,000, and 1000 M_r exclusions were compared with perforated chimneys. Either a single male or female was placed behind the barrier. No reduction in attraction was seen when unperforated dialysis tubing with a cutoff of approximately 12,000 M_r was used, although a cutoff of 1000 M_r prevented attraction (Eveland et al., 1983).

Similar results were obtained in EBSS containing 10% fetal calf serum, and when 50% fetal calf serum was used, attraction took longer to occur.

Attraction between *S. japonicum* or *S. haematobium* males and females from same or different male–female worm pairs was tested. Also, *S. mansoni* males or females of opposite sex but from different pairs were compared with *S. japonicum* or *S. haematobium* worms of opposite sex for their attraction to *S. mansoni* (Eveland and Fried, 1986).

Experiments were carried out using nonbarrier designs. For each time point, distances between worms were measured in millimeters and the percent attraction was determined by the formula $15 - D/15 \times 100$, as described previously. At 0.5 hr, *S. japonicum* from same pairs were 64% attracted, compared to 45% attraction between worms from different pairs ($P = 0.06$) and at 1.0 hr, *S. japonicum* from same pairs were 71% attracted to each, compared to 53% attraction between worms from different pairs. However, the differences were not significant ($P > 0.05$). Likewise, differences between same and different *S. haematobium* pairs were not significant at any time point. Interspecific attraction was as great as intraspecific attraction. In both interspecific and intraspecific attraction, 10–15% of the males and females were actually in contact at all observed time points.

In nonbarrier design experiments which we reported previously, homosexual attraction was as strong as heterosexual attraction (Eveland et al., 1982), but when barrier designs were used homosexual attraction was much weaker (Eveland et al., 1983), suggesting that more than one type of chemoattractant may be operative. For example, it is possible that homosexual attraction in the absence of chimneys was due to a nonspecific, aggregative chemoattractant, and that expressed in the presence of chimneys was more specific. It is also

possible that the attractants responsible for interspecific and homosexual effects were the same, which differed from those responsible for the more specific effects seen in the presence of barriers. More studies are needed to test interspecific attraction using barrier designs. In any case, the studies reported here show that at least some schistosome chemoattractants cross species lines and suggest that if blocking agents can be developed against schistosome chemoattractants, they may be broadly applied.

Worm ES products, prepared by incubating single males or females for 1 hr in EBSS have also been used in our bioassay, both before and after separation in chloroform–methanol or *n*-hexane into hydrophilic and lipophilic fractions. Initially, 5 μl of one-male incubate was pipetted onto a paper disk prepared by punching holes out of Whatman No. 40 filter paper with a paper punch. A disk was then placed in a channel in lieu of a male worm, and one female was placed in the center of the starting zone. Observations on the migration of the female toward or away from the disks were made up to 0.5 hr. Two additional experiments were carried out in which 200 μl of one-male incubate was applied to paper disks by multiple applications, and observations on the migration of the female were made up to 4 hr. As seen in Table 1, female attraction to the disks was significant at both concentrations and at all time points.

One-male incubates were then extracted with chloroform–methanol, and 10 μl of lipophilic or hydrophilic fractions was pipetted onto paper disks, then the disks were put into channels to test for female attraction. No significant attraction occurred in either case. When female incubates were extracted with chloroform–methanol, and 10 μl of lipophilic fraction was pipetted onto paper disks, males appeared to be attracted, although the attraction was not statistically significant. Hydrophilic fractions did not attract males.

In an attempt to improve the bioassay using ES products, it was modified in the following way: Agar cylinders were prepared by adding 75 μl of 2.5% agar in phosphate buffer (pH 7.0) at 40°C to microtiter round-bottom 250-μl

TABLE 1. ATTRACTION OF *Schistosoma mansoni* FEMALES TO PAPER DISKS CONTAINING ES PRODUCTS FORM ONE MALE

Time (min)	ES products (μL)	Attraction (%)	Probability (*t* test)
30	5	71	<0.01
30	200	60	<0.05
60	200	64	<0.05
90	200	68	<0.01
120	200	68	<0.01
150	200	65	<0.01
180	200	62	<0.05

wells. To this was added 100 μl of male ES products, followed by another 75 μl of agar. When the agar had solidified, the cylinders were removed with a 26-gauge hypodermic needle and placed in one end of the linear channel of the bioassay chamber, and a cylinder without ES products was placed in the other end. A single female was placed equidistant between the two cylinders and was allowed to migrate either toward or away from the ES products. Using videotape methodology in a 37°C environmentally controlled room, the females were scored either attracted or unattracted at 1 min intervals for 30 min. In 40 separate trials, beginning at 3 min, attraction was significant ($P < 0.05$) at every time point. With the agar plug technique, heterosexual attraction sometimes, but not always, occurred with lipophilic fractions and did not occur with hydrophilic fractions.

We then separated lipophilic and hydrophilic fractions with *n*-hexane. As shown in Table 2, when male lipophilic fractions extracted in *n*-hexane were tested in agar cylinders, they attracted females significantly at least through the 4-hr experiment. Interestingly, chloroform–methanol extraction from females did appear to attract males, although the attraction was not statistically significant. Again, hydrophilic fractions were not attractive to females.

Further studies are needed on the effects of distance. The 15-mm distance used in our bioassay was arbitrarily selected, and more studies need to be done to test diffusion rates and concentrations as a function of distance, as well as to establish the maximum distance over which the chemoattractants can be detected.

TABLE 2. ATTRACTION OF *Schistosoma mansoni* FEMALES TO AGAR PLUGS CONTAINING LIPO- OR HYDROPHILIC ES PPRODUCTS FROM ONE MALE (SEPARATED IN *n*-HEXANE)

Time (min)	ES product	Percent Attraction (%)	Probability (*t* test)
30	Lipophilic	66	<0.05

150	Hydrophilic	41	N.S.
180	Hydrophilic	44	N.S.

*Not significant.

We have not yet established the time of onset for the elaboration and detection of chemoattractants. Experiments are planned with 3- to 4-week-old worms which have not yet matured completely and paired in vivo, but for which sex can be determined. The worms will be placed in bioassay chambers in the absence of barriers as described above, and maintained at 37°C. For these 3- to 4-week-old worms, it will be necessary to reestablish optimal bioassay conditions, since smaller worms may not be able to attract each other over the relatively longer distances used for older worms (6 weeks and older). Worm combinations will be placed in separate channels, in a design similar to that of Eveland et al. (1982). One male and one female worm will be positioned in a channel so that each can move in either direction, toward or away from each other, and distances between worms will be measured in millimeters at various time periods. We have found that this nonbarrier design gives maximal worm attraction (Eveland et al., 1982). Worms from unisexual infections, which have never been exposed to the opposite sex will also be tested in the nonbarrier design.

Now that lipids are shown to attract schistosomes in vitro, studies should be done with "shelf lipids" to confirm results of assays using schistosome lipid fractions. If specific lipids are found to be chemoattractive, then efforts can be focused on these putative substances in the appropriate worm fractions. In summary, we have shown that schistosomes attract each other in vitro and that the lipophilic fraction of at least *S. mansoni* males attracts females. Thus, there is a chemical basis for the attraction.

The critical question of whether these events observed in vitro occur normally to worms in the blood vessels is controversial. However, we have demonstrated evidence of in situ lipid transfer from males (Haseeb et al., 1984), and it is possible that such lipids may serve as both primer and releaser pheromones. It is expected that further studies will result in knowledge of schistosome chemoattractants which may lead to the development of convenient, economical, and effective measures against schistosomiasis. For example, it may be possible to specifically block chemoattractants, as has been done in ticks (Sonenshine et al., 1982). The resulting unmated females could not reach maturity and lay eggs, thus preventing the major pathology of schistosomiasis. Alternatively, if the chemoattractants are immunogenic, they may be collected from the in vitro cultivation of schistosomes (Eveland et al., 1979; Basch, 1981a,b) and used as vaccines.

The studies using *S. mansoni*, *S. japonicum*, and *S. haematobium* demonstrate that the attraction is interspecific, and thus if blocking agents can be developed against schistosome chemoattractants, they may be broadly applied.

Abstract—Lipids released by *Schistosoma mansoni* adult males attract females in vitro. Lipid release is modulated by the presence of other worms. Although *S. mansoni* males release lipid when paired with females, the release is enhanced when they are separated. *S. japonicum* adults release more free sterols when incubated individually than when incubated together. Similarly, individually incubated *S. haematobium* males release more free sterols than when incubated in groups. However, *S. haematobium* females incubated in groups release more free fatty acids than do equal numbers of males or pairs incubated in groups. There is evidence that *S. mansoni* adult females concomitantly accumulate and release cholesterol in the absence of an exogenous supply, although de novo synthesis of cholesterol in schistosomes has not yet been demonstrated. Schistosomula and adult schistosomes incorporate exogenous lipids. Lipids are incorporated chiefly through the tegument. Cholesterol is transferred between males and females.

Key Words—Trematoda, Digenea, *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma haematobium*, behavior, chemoattraction, chemical communication, pheromones, lipids, receptors, histochemistry, electron microscopy, thin-layer chromatography.

INTRODUCTION

How male and female schistosomes first locate each other in vivo is still a matter of conjecture, but there is now evidence from in vitro studies that pairing is chemically mediated. Interest in interactions between males and females date back to the 1920s when Severinghaus (1928) and Sagawa et al. (1928) inde-

0098-0331/86/0800-1699$05.00/0

pendently postulated hormonal dependence of females upon males for maturation. Later studies by Vogel (1941, 1942, 1947), Standen (1953), and Moore et al. (1954) provided further evidence for male-induced female maturation.

Several studies have indicated that pairing with males is a prerequisite not only for female maturation but also for migration of paired worms to mesenteric and bladder veins and for continued egg laying (Standen, 1953; Moore et al., 1954; Armstrong, 1965; Michaels, 1969; Shaw, 1977).

MATE LOCATION AND MIGRATION IN THE MAMMALIAN HOST

Because he observed homosexual male pairs, Armstrong (1965) believed that in vivo mating of *Schistosoma mansoni* occurs by trial and error and that pairing results from thigmotaxis rather than chemotaxis. He also concluded that a pheromone from males is responsible for maturation of females in heterosexual pairs and retards the development of one male in homosexual pairs.

We now know that *S. mansoni* females require continuous male contact for reproduction. When mature females from bisexual infections are deprived of males, they are reduced in size and their vitellaria and ovaries degenerate. These regressive changes are reversed if pairing is resumed with males (Clough, 1981; Popiel et al., 1984). Males in the absence of females produce normal sperm and show no degenerative changes (Floyd and Nollen, 1977; Kolzow and Nollen, 1978; see Nollen, 1983, for review).

The route of schistosome migration in the mammalian host following cercarial penetration has been studied by several workers and several hypotheses have been proposed (see Miller and Wilson, 1978, 1980; Wheater and Wilson, 1979, for review). However, none of these studies addresses the issue of initial pairing. Our information is limited to the fact that males are required to escort females to the small veins of mesentery or bladder wall (Standen, 1953).

Recent studies have demonstrated that adult *S. mansoni* attract each other in vitro, and the attraction is chemically mediated (Imperia et al., 1980; Eveland et al., 1982). Imperia et al. (1980) stated that adult males emit pheromone(s) which attract females. The in vitro studies by Eveland et al. (1983) and Shirazian and Schiller (1982) suggest worm-finding and pairing mechanisms which may operate in vivo. Autoradiographic tracking of schistosomula can also elucidate events which occur in vivo prior to, during, and following mating. These techniques have been profitably used in the schistosome–mouse model for purposes other than identified here (Georgi, 1982; Mangold and Dean, 1983).

Several studies have indicated that young schistosomes pair on arrival in the liver. No serious effort has been made to elucidate mechanisms of site selection in the mammalian host except an in vitro study by Awwad and Bell (1978) which indicated that *S. mansoni* pairs were attracted more strongly than

unpaired worms to a dialysate of human feces. Chemical substances providing site-finding cues to schistosomes may originate in the human diet and from metabolic products of normal enteric flora. Whether *S. haematobium* pairs migrate to veins of the urinary bladder because of substances absorbed from the bladder, and whether they would respond to urine in vitro, both remain to be determined.

CHEMICAL INTERACTIONS IN VITRO

Although studies on hermaphroditic trematodes have yielded considerable information on pairing behavior (Fried and Leiby, 1982; Fried and Jacobs, 1980), these digeneans are not suitable models for sex-dependent behavior studies. Schistosomes are ideally suited for studies on both heterosexual and homosexual interactions between worms. Shaw et al. (1977) showed that acetone and ether extracts of male *S. mansoni* induced development of vitelline cells with a corresponding increase in body length of females from unisexual infections. Results of another study also suggest involvement of lipids in the development of females. Unisexually developed females showed increased [^{3}H]tyrosine uptake when they were exposed to males or chloroform extracts of males (Popiel and Erasmus, 1981). These observations suggest that factors produced by males induce maturation in females and that the developmental changes are mediated by lipids. Alternatively, the active substance(s) may be factors for which lipids serve as carriers or solvents. The pheromone of the hard ticks has been shown to be dissolved in neutral lipid (Sonenshine et al., 1981).

LIPID RELEASE IN SCHISTOSOMES

Free sterols and triacylglycerols are the major neutral lipid fractions in extracts of both male and female *S. mansoni* (Smith and Brooks, 1969; Fried et al., 1981), and free sterols constitute the major lipid fraction in male excretory-secretory (ES) products (Fried et al., 1981). Cholesterol is the most abundant lipid and the major free sterol in *S. mansoni* adults (Smith and Brooks, 1969; Meyer et al., 1970). Since free sterol fraction is the major neutral lipid fraction in worm ES products (Fried et al., 1981), Fried et al. (1983) quantitated cholesterol in adult males and females and their ES products to study cholesterol accumulation and release over time (Table 1). They found that males tend to maintain their cholesterol for at least 0.5 hr following removal from the host. At recovery, males contained 1.2–1.5 μg cholesterol/worm and at 0.5 hr they had 0.8–1.5 μg. However, during 0.5 hr incubation, males released 0.012–0.028 μg cholesterol/worm into the incubation medium. Females initially contained 0.13 μg cholesterol/worm and by 0.5 hr their content had risen to 0.42 μg/worm. Females had, however, released 0.008–0.013 μg cholesterol/worm

Worms	Extracts		Incubate
	0 hr	0.5 hr	
Pairs	1.9–2.8	1.2–1.5	0.003–0.013
Males	1.2–1.5	0.8–1.5	0.012–0.028
Females	0.13	0.42	0.008–0.013

[a]Data from Fried et al. (1983).

into the incubation medium during 0.5 hr incubation. Heterosexual worm pairs contained 1.9–2.8 μg cholesterol/worm pair and at 0.5 hr incubation, they contained 1.2–1.5 μg cholesterol/worm pair. Their incubation medium contained 0.003–0.013 μg cholesterol/worm pair at 0.5 hr. These data indicate that the two sexes handle lipid differently and that pairing influences lipid release. However, separate lipid analyses of males and females following incubation of pairs would more clearly delineate the influence of the sexes on each other.

Earlier studies on *S. mansoni* showed that in males lipids are localized in the parenchyma and tubercles (Gönnert, 1955; Smith et al., 1969; Fried et al., 1981) and in females they are found primarily in the vitellaria (Fried et al., 1981). Even though neutral lipid release was reported from *S. mansoni* (Fried et al., 1981, 1983), no specific structure was associated with the release. Recent histochemical and electron microscopic studies indicated that neutral lipids are released from the tegument (Haseeb et al., 1984, 1985b).

These studies confirmed previous observations on lipid distribution in adult schistosomes and demonstrated marked differences between males and females in lipid release. In *S. mansoni* males which were separated from females immediately following their recovery from the host, lipid was usually seen in the parenchyma but rarely in tubercles. However, when incubated in vitro for 0.5–1.0 hr, males accumulated lipid in both the parenchyma and tubercles with release from the latter. These studies demonstrated lipid accumulation and release from the dorsal tegument of unpaired males but not from females. Senft et al. (1978) believed that the gynecophoral canal tegument is a site of active lipid secretion, but our studies do not confirm their observations.

Males which had not been separated from females after recovery from the host contained lipid both in the parenchyma and tubercles with release from the latter. At 0.5 hr incubation in vitro, these males were not observed to release lipid, although their tubercles and parenchyma were lipid-positive. But at 1.0 hr of incubation, they were again releasing lipid and lipid droplet shift from parenchyma to the tubercles was obvious. No prominent differences could be noticed in females which had been incubated with males and those which were

incubated singly. Females contained lipids in the vitellaria and at times in the lumen of intestinal ceca. However, females from unisexual infections were lipid-negative (Haseeb et al., 1984).

Similar studies on *S. japonicum* revealed a similar pattern of lipid distribution as in *S. mansoni* adults, although, patterns of lipid release are different in the two species. Although neutral lipid release was restricted to the dorsal tegument in *S. mansoni* males, in *S. japonicum* males release occurred from both the dorsal and ventral teguments. Haseeb et al. (1984) reported acidic lipid release into the ceca of *S. mansoni* males, but it was not observed in *S. japonicum*. *S. japonicum* males also released neutral lipid from the intestinal ceca. Females released neutral lipid into the intestinal ceca but not from the tegument. Acidic lipid release was not observed from worms of either sex (Haseeb et al., 1986). Results of histochemical lipid studies on *S. japonicum* are summarized in Tables 2–4.

These differences in lipid release patterns between the two schistosome species cannot be explained simply on the basis of absence of tubercles in *S. japonicum*. Although it was conceived earlier that *S. mansoni* males release lipids from their tubercles, electron microscopic studies showed that the whole dorsal tegument is involved in this process (Haseeb et al., 1985b). These studies further indicated differentiation of dorsal and ventral teguments in males of these species. Lipid distribution in *S. haematobium* remains to be determined.

Even though we have demonstrated neutral lipid release in *S. mansoni* and *S. japonicum* by both histochemical and biochemical methods, information on lipid secretion at the cellular level is needed. Further studies are also required to determine if released lipid droplets are membrane bound.

There is some evidence that schistosomes release lipid in vivo. Cryostat

sections of mouse mesenteric veins harboring adult worms revealed neutral lipid droplets in parts of blood vessel walls which were in contact with male worms. These droplets had staining properties similar to those observed in schistosomes. Only parts of the male gynecophoral fold exposed to female contain lipid, suggesting an influence of females on male lipid secretion. Although males of worm pairs released neutral lipid both in vitro and in situ (Haseeb et al., 1984), the release was greater in males after they were separated from females (Haseeb et al., 1985b).

Lipid droplets released from the ventral tegument of *S. japonicum* males were observed in the gynecophoral canal and occasionally in the adjacent female tegument, suggesting possible lipid transfer from male to female. Acetone and ether extracts (presumably lipids) of *S. mansoni* males induce maturation in females (Shaw et al., 1977), and females show vitelline gland differentiation only in regions which contact males (Popiel and Basch, 1984a).

Although *S. japonicum* females released neutral lipid into the intestinal ceca only when paired with males, lipids were detected in worm-free incubates of separated females (Haseeb et al., 1986).

Densitometric thin-layer chromatographic data on neutral lipid release in *S. japonicum* and *S. haematobium* are also available. Pooled worm-free incubates of 10 singly incubated *S. japonicum* males contained 0.30 μg of free sterols, whereas 10 males incubated together failed to release enough to be detected by densitometry. Similarly, females incubated separately released more free sterols than those incubated together (Haseeb et al., 1986). *S. haematobium* males also released more free sterols when incubated singly than a similar number incubated in groups. Ten females incubated together released more free fatty acids than 10 males or 10 pairs incubated in groups (Haseeb et al., 1985c).

Our histochemical and TLC studies clearly indicate that lipid release is affected by the presence of other worms. These observations are in accord with the findings of Eveland et al. (1983), who reported that worms of either sex do not show attraction to worm pairs, two males or two females, although heterosexual attraction to single worms occurred. They proposed that either the "window effect" (Kemp and Devine, 1982) or a "shut-down" mechanism is involved in diminishing attraction. Demonstration of a dose–response relationship would help clarify this issue.

Lipid release and its modulation by the presence of other worms is one aspect of the complex chemical communication system in schistosomes. We do not know how this modulation occurs or what chemical messages are involved. Whether the messages are different from those which mediate attraction is also unknown. We do know that lipids are involved in worm attraction. Excretory–secretory products of worms incubated in vitro and their lipophilic fractions prepared in chloroform–methanol attract worms of the opposite sex (Eveland et al., 1984). Our recent studies indicate that lipophilic fractions of worm-free incubates prepared in *n*-hexane attract worms of the opposite sex better than those prepared in chloroform–methanol (Eveland and Haseeb, 1986). Because all animal pheromones do not belong to a single group of chemical substances (Law and Regnier, 1971; Silverstein, 1981), we must consider that chemicals used in separation procedures may interfere with biologic activities of potential chemoattractants. For example, lipid and protein moieties of most lipoproteins are separated in procedures using chloroform–methanol since methanol precipitates proteins. In separation procedures employing *n*-hexane, such precipitates are not observed.

METABOLIC DEPENDENCE

Metabolic interdependence of male and female schistosomes has been the subject of several studies. Transfer of [^{14}C]glucose from males to females has been demonstrated in *S. mansoni, S. haematobium*, and *S. japonicum* in vitro (Cornford and Huot, 1981). These workers further demonstrated that the rate

TABLE 5. [4-^{14}C]CHOLESTEROL (ng/WORM ± SEM) TRANSFER BETWEEN *Schistosoma mansoni* ADULTS

0 hr	3.0 hr	
Males	Males	Females

Females	Females	Males
0.245 ± 0.020–0.298 ± 0.031	0.167 ± 0.012	0.086 ± 0.004

[a] Data from Haseeb et al. (1985a).

of glucose assimilation by worms was significantly greater in paired than in separated worms and that unpaired males contained more glycogen than did paired males.

Atkinson and Atkinson (1980) reported that "The male worm retains little of the protein it produces in greatest abundance, and this protein is electrophoretically identical to the most abundant protein found in, but not synthesized by, the female." This 66-kd polypeptide occurs naturally in males and females from both unisexual and bisexual infections and, when such worms are exposed to [^{14}C]leucine, it is incorporated into 66-kd bands of mature and unisexually developed females as well as mature males (Popiel and Basch, 1984b).

Our recent studies have shown that cholesterol is transferred in both directions between males and females (Table 5). In these experiments single worms removed from pairs were incubated for 3.0 hr in RPMI 1640 containing 0.16 μCi [4-^{14}C]cholesterol/ml. After initial labeling, these worms were incubated with unlabeled, freshly recovered and separated worms of the opposite sex for another 3.0 hr. Females incorporated 0.090 ± 0.003 ng cholesterol/worm when incubated with males containing 0.722 ± 0.083 ng cholesterol/worm. Males contained 0.346 ± 0.025 ng cholesterol/worm following incubation. Males incorporated 0.086 ± 0.004 ng cholesterol/worm when incubated with females containing 0.245 ± 0.02 ng cholesterol/worm. At the end of the experiment, females contained 0.167 ± 0.012 ng cholesterol/worm (Haseeb et al., 1985a).

Light-level autoradiography revealed the tegument to be the major site of cholesterol uptake. In males, more transtegumental uptake occurred on the dorsal than the ventral surface and label was heavier in the tubercles than the rest of the dorsal surface. The tubercles on the mid-dorsal surface were more heavily tagged than those near the periphery. The cecal walls were tagged in both males and females. Dorsal subtegumental parenchyma was more heavily tagged than the ventral. Vitellaria accumulated most of the label in females and the tegument was not as heavily labeled as in males (Haseeb et al., 1985a).

S. mansoni females accumulate labeled cholesterol in the vitellaria but radioproline is rather sparingly incorporated into the vitellaria (Senft, 1968). *S.*

mansoni adults incorporate proline through the gut and tegument (Senft, 1968), but Fripp (1967) did not detect any radioactivity in *S. haematobium* gut after providing [1-^{14}C]glucose in vitro. In our experiments in which the worms were labeled individually, dense labeling was on the dorsal surface. Therefore, it appears that receptors for different biologically active molecules are located at different sites in schistosomes.

If the worms were incorporating cholesterol through the cecal route, heavier tagging might be expected in the anterior than the posterior half of the gut. Since the tagging in cecal walls was uniform throughout the length of worms of both sexes, it seems unlikely that cholesterol uptake occurs through the ceca, but suggests that excess cholesterol is released into the ceca following transtegumental uptake.

Catabolism of lipids as an alternative source of energy probably does not occur in schistosomes since they do not consume O_2 for their energy-yielding metabolic reactions (Bueding, 1950). Moreover, lipids absorbed by schistosomes are mainly utilized as constituents of parasite membranes (Rumjanek and Simpson, 1980). Cholesterol is incorporated into the outer half of the outer lipid bilayer (Torpier and Capron, 1980). A recent study has shown de novo synthesis of cholesterol in *Fasciola hepatica* (Gerasimova and Leutskaya, 1983). In contrast, schistosomes do not appear to synthesize cholesterol de novo (Smith et al., 1970; Meyer et al., 1970).

Cholesterol metabolism in schistosomes appears to be in a state of dynamic equilibrium. Both the incorporation (Rumjanek and Simpson, 1980; Haseeb et al., 1985a) and release (Fried et al., 1983) of cholesterol are obviously governed by the physiologic state of the worm, but the precise regulatory mechanism is not known. Lipid incorporation in schistosomula is modulated by the amount of lipid present in the incubation medium (Rumjanek and McLaren, 1981). Such data are not available for adult worms in which the presence or absence of worms of the opposite sex may affect lipid uptake. As mentioned above, the presence of worms of the opposite sex affects lipid release (Haseeb et al., 1985c, 1986).

Biologically active ecdysteroids are known to occur in certain helminths, such as *Dirofilaria immitis* (Mendis et al., 1983) and *Moniezia expansa* (Mendis et al., 1984). Ecdysone and 20-hydroxyecdysone have also been detected in *S. mansoni* (Torpier et al., 1982; Nirde et al., 1983). These molecules have been shown to be produced by the worms and have been detected in serum and urine of patients (Nirde et al., 1984). Their role in the biology of the parasite is unclear. The function of ecdysteroids in insects has been reviewed by Loof et al. (1984).

RECEPTORS

From her studies on the mating of transected worms in vitro, Michaels (1969) postulated that the mating position is determined by linear receptors on

S. mansoni males and females. She used several enzymes, including ribonucleases and deoxyribonucleases, and snake venoms in an attempt to determine the nature of postulated receptors, but these attempts remained unsuccessful. Results of her studies are difficult to interpret since normal and abnormal mating positions of transected worms are not clearly defined. She further reported that only one in 10 males mated with frozen and thawed females, which argues against the occurrence of receptors that determine mating position.

Lectin-binding sites have been demonstrated on both schistosomula and adult schistosomes (Stein and Lumsden, 1973; Bennett and Seed, 1977; Murrell et al., 1978). Several oligosaccharide residues, notably alpha-methyl-D-mannoside, D-galactose, D-mannose and/or D-glucose, *N*-acetyl-D-glucosamine, *N*-acetyl-D-galactosamine and sialic acid occur on the schistosome surface (Simpson and Smithers, 1980; Simpson and McLaren, 1982). In these studies, however, distinction between male and female worms was not made. Bennett and Seed (1977) believed that these lectin-binding carbohydrates occur as glycoproteins. Results of other studies did not support this notion (Murrell et al., 1978). A recent study of the interaction of *Salmonella* and schistosomes suggest that at least the mannose-containing receptors are glycolipids (Melhem and Lo-Verde, 1984).

Although these studies have provided information about lectin-binding receptors in schistosomes, there has been no attempt to determine the role of receptors in chemoattraction and/or pairing and mating. Such information is available for other systems, e.g., lectin-mediated functional impairment and inhibition of chemotaxis have been demonstrated in *Caenorhabditis elegans* by Jeyaprakash et al. (1985). Enzyme-mediated inhibition of chemotaxis in this worm has also been demonstrated by Jansson et al. (1984). These workers reported that mannosidase and sialidase caused 100% inhibition and trypsin caused a 50% reduction of chemotactic behavior in *C. elegans*.

Host immunoglobulin binding to schistosomes has been shown to be mediated by Fc receptors present on the worm surface. In addition, receptors for C3 and C1q have also been demonstrated on schistosomula (Smithers and Doenhoff, 1982) but differences between males and females were not examined. At present, there is no evidence of involvement of these receptors in interactions between male and female worms.

Although electron microscopy has revealed structures on schistosome surfaces which may serve as sensory receptors, there is still no information on their function (Hockley, 1973; McLaren, 1980).

ULTRASTRUCTURAL INTEGRITY OF WORMS MAINTAINED IN VITRO

Smith et al. (1969) described degenerative changes in adults following 90 min incubation in either isotonic phosphate-buffered saline, normal human serum, hyperimmune serum, or horseradish peroxidase. Hockley (1970) reported de-

generative changes in worms maintained in hypotonic and hypertonic media (Hockley, 1973). Simpson and McLaren (1982) observed more degenerative changes in worms maintained in RPMI 1640 than in those maintained in Earle's medium supplemented with lactalbumin hydrolysate (LAH). Other studies have reported morphologic changes in worms maintained in vitro in a variety of media (Carlisle et al., 1983; Weisberg et al., 1983). In our laboratory, scanning and transmission electron microscopy following in vitro incubation for 1.0 hr did not reveal any morphologic damage (Haseeb et al., 1984, 1985b). Since Carlisle et al. (1983) and Weisberg et al. (1983) used suction to collect worms, it is possible that they damaged worm surfaces. They also reported that LAH, a constituent of EBSS, appeared to adversely affect the morphology of adult worms. We have not observed damage in the presence of LAH. In other studies LAH has been reported to stimulate egg maturation and production in *S. mansoni* females maintained in vitro over a period of 14 days (Newport and Weller, 1982), which argues against deleterious effects.

(Received October 1, 1985; accepted April 3, 1986)

Abstract—We investigated the suitability of an in vitro culture system for measurement of mating behavior of *Schistosoma mansoni*. The criteria used to evaluate this system were the level of phosphorylated nucleotides, egg production, and mating status of parasites. The level of ATP, ADP, AMP, and G6-P was measured at different time intervals during cultivation of worm pairs and remained essentially the same as that of control worms for up to 6 days. Egg production was observed in this system during 19 days of cultivation. Peak egg production occurred on day 4 with 72% of the total eggs being laid during the first week of cultivation. The variability in the number of eggs produced by different pairs of *S. mansoni* necessitated the selection and matching of tubes with the same number of eggs after 48 hr. This permitted the detection of small changes in egg production by decreasing intertube variation. Mating recognition between male and female *S. mansoni* was evaluated by culturing separated adult worms with their original partner or with a different partner. During the first 24 hr, mating occurred among a greater percentage of worm pairs comprised of their original partner than among worm pairs comprised of different partners ($P < 0.001$). After 48 and 72 hr of cultivation, these differences were not statistically significant. Similar results were obtained with a culture of mixed males and females. Two drugs were studied for their effects on the mating of *S. mansoni* in vitro. Aminoglutethimide (AG) at a concentration of 1×10^{-4} had no effect on the frequency of mating whereas diethyldithiocarbamate (DDC) completely inhibited mating at a concentration of 3×10^{-6} M and reduced the level of ATP in these worms.

Key Words—*Schistosoma mansoni*, in vitro cultivation, mating, egg production, phosphorylated compounds.

INTRODUCTION

One of the distinctive features of the genus *Schistosoma* is the sexual dimorphism exhibited by the parasite. Consequently, the reproduction of the parasite is governed by several important requirements. In the first instance, contact between individuals of separate sexes must be achieved, and, second, this must be followed by successful pairing and insemination. It is also difficult to determine precisely, under in vivo conditions, the spatial relationship between male and female worms and, thus, to assess the relative importance of the various components of the relationship which are essential for the development of the female. The in vitro technique overcomes many of these difficulties, enables more precise observation to be made under relatively defined conditions, and affords an opportunity to isolate or modify aspects of the relationship between the sexes.

In early attempts at in vitro cultivation of schistosomes, Lee and Chu (1935) maintained adult *S. japonicum* for several weeks in horse, sheep, and rabbit sera changed every one to two weeks. Rabbit serum in Carrel flasks gave a maximum survival of $2\frac{1}{2}$ months. Chu (1938) reported egg production and copulation by *S. japonicum* in diluted horse serum. In later studies, successful survival of *S. mansoni* in various sera was reported by several workers. Newsome and Robinson (1962) was able to maintain pairs of *S. japonicum* in an egg-laying state in a medium containing human serum (diluted 3:10 with tyrode solution), glucose, and antibiotics. Eggs produced in this system hatched into miracidia but never successfully established an infection in the intermediate snail host. Michaels and Prata (1968) used a medium consisting of 90% medium 199 plus 10% calf serum to which penicillin and streptomycin were added. In this medium, maximum egg production occurred after two to five days of cultivation and oviposition stopped after 10 days. Senft and Senft (1962) cultured *S. mansoni* in a defined medium which promoted oviposition but the eggs were nonviable. To culture *S. mansoni*, Schiller et al. (1975) used a diphasic medium which had been originally designed for cultivation of the rat tapeworm. *Hymenoplepis diminuta*. In this system under anaerobic conditions egg production was minimal, whereas under aerobic conditions large numbers of eggs were produced with a peak occurring at four to six days cultivation. The average number of eggs laid per day was five times greater than that observed by Michaels and Prata (1968). Schiller et al. (1975) found that adult *S. mansoni* survive under anaerobic as well as when under aerobic conditions. Thus, they suggested that for egg production oxygen is utilized by some non-ATP-yielding reaction such as the oxidative tanning of eggshells or the oxidation of a sterol to a hormone-like compound controlling reproductive physiology.

Short (1952) observed that in *S. douthitti* the males and females may migrate independently from liver to mesenteric venules, and the females proceed to lay eggs without mating. But in *S. mansoni*, mating is considered a prereq-

uisite to this migration, although according to Standen (1953) a proportion of the worms in all-male infections moved toward the mesenteric veins. Vogel (1947) reported that unmated females lack the copious black material that fills the cecae of mated females.. He proposed that the female is too weak to feed normally until held by the stronger male. He also hypothesized a hormone-like substance produced by the male and transferred to the female in copula either with the sex products or through the integument. Michaels (1969) reported that the influence of the male on the female worm was not confined to an initial developmental stimulus but the male also influenced the fecundity of the mature female. He also showed that under in vitro conditions the reassociation of separate males and females takes place rapidly, and within the period of 18–24 hr, 85–100% of the worms become paired. Michaels was unable to determine whether chemical factors were involved, but was able to show that successful pairing was related to features resident in the posterior half of the male worm.

From cross-mating experiments between different species of schistosomes, Armstrong (1965) concluded that the adult members of both sexes are active in the search for mates, and that mating is accomplished by means of thigmotaxis and by trial and error rather than by chemotactic response. Armstrong (1965) and Michaels (1969) both agree that mating is active on the part of both sexes. Armstrong also hypothesized that the male controls the attainment of full body size of the female, and this control is dependent on a pheromone. Voge et al. (1978) reported that the tegumental surface of immature males is indistinguishable from the female, and the differentiation of the adult surface begins several days after copulation. The studies of Shirazian and Schiller (1982) indicated that mating recognition exists between separated pairs of *S. mansoni* in vitro, and there is a preference for mating with original partners at least for 24 hr after separation. Eveland et al. (1982) showed both heterosexual and homosexual attraction with and without perforated dialysis sac chimney barriers. Recently Eveland et al. (1983) demonstrated conclusively that the opposite sexes of *S. mansoni* attract each other in vitro and that dialyzable substances probably are involved in chemoattraction.

The experiments reported below were designed to further investigate aspects of pairing, egg production, and mating behavior of *S. mansoni* maintained in vitro.

METHODS AND MATERIALS

Recovery of Adult Schistosoma mansoni. Female mice (CD_1, Charles River) 4–5 weeks old were infected by tail immersion with 100 cercariae of *S. mansoni* (Puerto Rican strain) which had been obtained from *Biomphalaria glabrata*, as described previously by Bourgeois and Bueding (1971). At 55 days postinfection, *S. mansoni* were removed aseptically with the aid of a dissecting needle

from the mesenteric and portal veins of mice, and placed in a Petri dish containing Hanks' balanced salt solution (HBS) plus 200 units of penicillin and 200 μg of streptomycin (P/S) per milliliter. Worms were observed with a dissecting microscope for their gross morphology, motor activity, and sexual pairing. Worm pairs were placed in 10-cm Petri dishes in an ice bath, and they were separated from their sexual partners after 5 min.

Recovery of Schistosomulae. At 28 days postinfection, each mouse was injected with 0.1 ml of a solution containing 30 μg/ml Na heparin. After 30 min, they were sacrificed by cervical fracture, and the abdomen was painted with 2% iodine in alcohol. The iodine was removed, the abdominal skin deflected, and the hepatic vein, inferior vena cava, and portal vein were tied and cut distal to the ties. After cutting the esophagus and freeing the diaphragm from its insertion, the liver and diaphragm were transferred to a sterile Petri dish. The tie was removed from the portal vein, and a 22-gauge needle was inserted into the hepatic venous sinus. Thirty to 60 ml of HBS and P/S containing 10 μg/ml sodium heparin was forced through the liver at a rate sufficient to keep it slightly distended. The worms were located in the fluid with a dissecting microscope and transferred with the aid of a dissecting needle to the culture media.

In vitro Cultivation. The separated worms were cultured by Schiller's method (Schiller et al., 1975), except that (1) blood agar was dispensed into test tubes (13 × 80 Borosilicate glass, Belco Company) in the amount of 1 ml/tube and stoppered with cotton; and (2) 1 ml of HBS and P/S containing 1 mg glucose was added 24 hr before inoculation of *S. mansoni*. One pair of adult worms was cultured in each test tube, and egg production was recorded.

The eggs were studied to determine the presence of various developmental stages, as well as the type of egg abnormalities recognizable under the microscope as previously described by Belding (1965) and Edungbola (1978). The viability and the development of eggs produced in vitro were further studied by incubating the eggs for seven more days at 37°C in a Dubnoff incubator. The number of viable miracidia obtained after diluting the culture media with dechlorinated water was determined as the criterion for viability and development.

Determination of Phosphorylated Compounds. Commercially prepared hexokinase was used for determination of ATP and G6-P. The method used for the determination of the level of AMP and ADP was similar to the one described by Adam (1963), modified primarily by methods listed as follows: (1) 3% perchloric acid (PCA, Mallinkrodt) was used for extraction instead of potassium carbonate; (2) potassium glycylglycine (Sigma, pH = 7.4, 0.5M) was used as buffer instead of EDTA. Pyruvate kinase (110 mg/10 ml) and myokinase (10 mg/2 ml) were purchased from Boehringer/Mannheim. The levels of phosphorylated compounds were determined by changes in optical density of substrates after the addition of appropriate enzymes, as described by Adam (1963).

Effect of Drugs on Mating Behavior. Prior to cultivation of one male and one female worm, 0.02 ml of drug were added to each culture tube. Control test tubes received 0.02 ml of 8.5% saline. All cultures were incubated in a Dubnoff metabolic incubator under conditions previously described. The drugs utilized were: aminoglutethimide (AG, Aldrich Chemical Co., Milwaukee, Wisconsin) and diethyldithiocarbamate (DDC, sodium salt crystalline, Sigma Chemical Co., St. Louis, Missouri).

RESULTS

The suitability of the in vitro culture system for *S. mansoni* was investigated by measuring the level of some phosphorylated compounds such as ATP, AMP, and G6-P at different time intervals during cultivation beginning with 56-day-old worm pairs in vitro. The level of ATP of paired worms cultured in vitro at day 6 was comparable to freshly recovered parasites. After nine days of cultivation, ATP levels declined 30% and then remained at that level until the end of the 12-day experiment. This decrease in ATP after six days of cultivation was not accompanied by an increase in the level of ADP or AMP, nor was there any significant change in the level of G6-P during the cultivation period (Table 1). Supernatants of culture media did not have any significant amount of phosphorylated compounds. Since a large number of parasites were needed for each determination of phosphorylated compounds, no measurements were made beyond the 12th day in vitro. When ATP was measured six times in parasites freshly obtained from mice and after six days of in vitro cultivation, it was found that the concentration of this compound remained essentially the same.

TABLE 1. LEVELS OF PHOSPHORYLATED COMPOUNDS IN *Schistosoma mansoni* CULTURED IN VITRO
(mg/g OF TISSUE, WET WT)

Sample[a]	Time in culture	G6-P	ATP	ADP	AMP
I	0	0.067	3.29	0.71	
II	2 hours	0.34	3.27	0.87	0.22
III	3 days	0.34	3.11	0.63	0.09
IV	6 days	0.44	3.25	0.64	0.12
V	9 days	0.33	2.31	0.77	0.13
VI	12 days	0.44	2.41		
Control (media without parasite)	3 days		0	0	0.17

[a] Each sample consists of 20 test tubes with a single pair of worms.

Separate pairs of adult worms find each other and mate in this in vitro system. Pairing rarely occurred during the first 6 hr, but thereafter the frequency of mating events increased rapidly. A maximum of pairing was reached on the third day, and then gradually declined until no new matings were observed after the seventh day of cultivation. When separated pairs of worms were cultivated with their original partners, the frequency of mating events was significantly greater than when the worms were cultured with nonoriginal partners. The difference remained statistically significant even after the worms had been separated from their original partners for as long as 72 hr.

In another series of experiments, individual adult worms that had no previous association with each other were cultured in groups. One group consisted of three females and one male, and the other was comprised of three males and one female. After 24 hr of cultivation, the frequency of mating events in both groups was approximately the same as that observed in the preceding experiments among worm pairs comprised of nonoriginal partners. However, when either of these groups contained a male and a female that had been partners originally, the frequency of mating events increased significantly. Pairing between males was not observed in any of the cultures, as previously reported by Shirazian and Schiller (1984).

Egg production was observed daily in 100 test tubes, each containing one pair of parasites, during 19 days of cultivation. Peak egg production occurred on day 4, and 72% of the eggs were laid during the first week of cultivation. Overall, 80% of the parasites produced eggs. Acetocarmine staining of the worms which produced no eggs showed that 60% had no eggs in the reproductive tract, 20% had one abnormal egg, and 20% had only empty eggshells in the uterus.

All stages of egg maturation were observed when eggs were kept for an additional 10 days in the in vitro culture system. Additionally, when the contents of the culture tubes containing mature eggs were diluted with distilled water, the eggs hatched, and living, vigorously active miracidia were released.

In our in vitro system the number of eggs produced per pair of worms is variable. To determine if better reproductive uniformity could be achieved by selecting those pairs that had produced approximately the same number of eggs, 164 worm pairs that had produced 36 $\pm$ 1 ($\bar{X} \pm$ SD) during the first 48 hr in culture were transferred to fresh media and cultivated for an additional six days. At the end of this period, each of the worm pairs had produced eggs ranging in number from 299 to 317 ($\bar{X}$ = 306, SD $\pm$ 7.8). According to these results, it is evident that this selection technique decreases the range of variability in egg production that occurs among worms taken at random, thus providing a means for standardizing samples of *S. mansoni*, (Shirazian and Schiller, 1984).

Attempts were made to inhibit the mating of parasites by adding certain drugs to the in vitro system. Because aminoglutethimide is known to be an inhibitor of all sex hormones in mammals and is nontoxic to living cells at a

concentration of 1×10^{-4} M (Howal, 1967), it was selected for this purpose. In these experiments, separated adult males and females were cultured individually in media containing 1×10^{-4} M of this compound for 48 hr. The parasites then were placed in fresh media, either with a drug-treated or a non-drug-treated worm of the opposite sex. There was no significant difference between the frequency of mating in these experiments.

The copper-containing enzyme, phenoloxidase, plays an important role in egg production by *S. mansoni* (Lees, 1946; Mansour, 1958). Its activity can be inhibited by DDC in vivo (Bennett and Gianutsos, 1977) as well as in vitro (Seed et al., 1978); thus it was of interest to determine if this drug had any effect on the mating behavior of these parasites. Our results indicate that concentration of 3×10^{-6} M of DDC can inhibit mating of *S. mansoni*. However, this effect was accompanied by reduction of the level of ATP. It is thought that inhibition of mating is mainly due to the toxicity of DDC for *S. mansoni* rather than a direct inhibitory effect on mating.

DISCUSSION

Until recently, most of the in vitro systems for *S. mansoni* have involved the use of balanced salt solutions to which various mammalian sera and/or embryonic extracts, amniotic fluids, or ascitic fluids were added (Lee and Chu, 1935; Hoeffli, et al., 1938; Newsome and Robinson, 1954, 1962, 1963; Senft and Weller, 1956). Although such fluid culture media allowed survival of worms and, in some cases, growth of young adults, only limited egg production has been reported (Cheever and Weller, 1958; Robinson, 1960). Several investigators have employed chemically defined media for the in vitro culture of parasites without success, except for that of Ross and Bueding (1950), who found that *S. mansoni* survived for 18 hr in a defined medium. The addition of muscle extract derivatives (largely unidentified substances called protogens) considerably enhanced survival time in the defined medium. Mayo and Lyu (1957) found that *S. japonicum* could survive about 16 days in a Tyrode–glucose–vitamin mixture. Such short-term survival is, however, quite inadequate for growth, regeneration, or egg production studies. Fu et al. (1976) reported that media 199 and NCTC 135 were less than satisfactory for maintenance of adult *S. japonicum*. After a time in these media, body lengths decreased and genitals degenerated. Considering these reports, it appears that a more successful system for the culture of adult *S. mansoni* with production of viable eggs may best be achieved in a diphasic medium prepared with animal blood. Schiller et al. (1975) used a diphasic medium for in vitro cultivation of adult *S. mansoni*. In the current studies, a modified version of this system was used to maintain mated parasites for extended periods of time with the production of viable eggs.

In the present studies, the levels of phosphorylated compounds such as G6-P, ATP, ADP, and AMP were measured during the 12 days of cultivation. These measurements allowed further investigation of the suitability of the in

vitro system for the maintenance of *S. mansoni*. The ATP level in mated parasites slightly decreased for the first three days of culture. This decrease may be interpreted as an adaptation period for the parasite. There is some evidence that can be used to support this hypothesis. As noted earlier, schistosome egg production in vitro is inhibited by physiological changes due to the removal of the worm from its host. Egg production remains suppressed for at least 48 hr. However, when parasites are in the stage of maximum egg production (on day six), the level of ATP reaches its normal control level. After eight days of cultivation, the level of ATP in *S. mansoni* declined 30%. It is interesting to note that this drop in ATP was not accompanied by changes in the levels of ADP or AMP. The reason for this may be due to decreased glucose utilization during this time, as observed by Schiller et al. (1975). The most important finding is that the level of ATP returns to its original level on day six of cultivation. This observation provides additional evidence of the suitability of this system for the in vitro mating and egg production by this parasite.

Edungbola and Schiller (1979) indicated that maximum egg production occurred after three to six days of cultivation. Our observations on 80% of the parasites which produced eggs are in accord with this report and show that the peak of egg production is on day 4 and that more than half of all the eggs are produced between three and six days of cultivation. The reason for the peak of egg production on day 4 may be due to the fact that parasites at this time have adapted themselves to the in vitro system. Since the parasites were transferred every three days, day 4 of cultivation would be the first day in the fresh culture media when there is more nutritional material and fewer waste products in the system.

Eggs which had been produced during the first six days of cultivation were kept for an additional seven days in vitro. These eggs hatched, and active, live miracidia were released when the supernatant of culture media was diluted with distilled water. This result is in agreement with Edungbola and Schiller (1979) that *S. mansoni* eggs from the in vitro system of Schiller (1975) were viable and, since they reached the miracidial stage, induced typical granulomatous response in the livers of recipient mice. Although parasites can survive in this in vitro system for at least two months, egg production was never observed after nineteen days of cultivation.

In the control of schistosomiasis an advantageous development would be an agent which interfered with the reproductive capacity of the worm. Many investigators have reported that the reproductive system of the female worm is a delicately coordinated system which is easily disturbed by a variety of factors, for example, unisexual infection, drugs, host diet, and hormonal imbalances of the host animal. This sensitivity has been utilized by Pellegrino and Katz (1968) to develop the oogram method of assessing the effect of antihelmintics on the parasite. However, *S. mansoni* produce different numbers of eggs in different

in vitro culture systems (Michaels and Prata, 1968; Senft and Senft, 1962; Schiller et al., 1975), and there is a significant variation in the number of eggs produced by individual parasites in the same culture medium. Our methods provide an accurate means of standardizing egg production by these parasites, so that the effect of different drugs on this process can be quantitatively determined.

These results are in agreement with previous work that established that separated pairs of adult worms find each other, mate, and produce eggs in vitro (Eveland et al. 1982, 1983, Shirazian and Schiller, 1982, 1984). Pairing rarely occurred during the first 6 hr, but thereafter the frequency of mating events increased rapidly, reaching a maximum on the third day, and then gradually declined until no new matings were observed after the seventh day of cultivation. As previously reported, when separated pairs of worms were cultured with their original partners, the frequency of mating was significantly greater than when the worms were cultured with nonoriginal partners ($P < 0.001$) (Shirazian and Schiller, 1982). This difference remained statistically significant even after the worms had been separated from their original partners for as long as 72 hr. Even in insect systems in which mating behavior has been studied extensively, the phenomenon of individual recognition seems to be controversial (Shorey, 1976). For this reason and also because the deduction made herein is inferential, it must be regarded with some caution until more direct evidence can be obtained through the use of some technique, not yet available, for marking individual worms.

In an attempt to prevent mating in vitro, we used two different drugs, in this study. Aminoglutethimide, which is known to inhibit the formation of steroids, had no effect on the mating behavior of the parasite. The percentage of mating was not reduced, although the possibility still exists that AG could have been incorporated into the culture medium, thus precluding any effect. It is also possible that the worm's receptors and/or the mediators are not very sensitive to this drug.

DDC was used to inhibit the schistosome copper-containing enzymes which are similar to that described for the phenol oxidase of *F. hepatica* (Mansour, 1958). Exposure to a concentration of 3×10^{-6} M for three days completely inhibited the mating of *S. mansoni*, and significantly reduced the level of phosphorylated compounds of *S. mansoni*.

In general, our results support the conclusion that our in vitro culture system provides the conditions necessary to study the physiology, mating behavior, and egg production of *S. mansoni*. The levels of phosphorylated compounds remain stable for six days, and the number of eggs produced during this time period is comparable to that recorded for the same strain of parasite in vivo. This system is adequate for the short term study of mating behavior and the effects of pharmacological substances on related events.

(Received October 1, 1985; accepted April 15, 1986)

Abstract—Female *Schistosoma mansoni* and their excretory–secretory (ES) products were extracted with a series of solvents to provide fractions of varying polarity. These fractions were assayed for chemoattractivity to males in vitro. One major component of these mixtures was found to be nonattractive and was identified as cholesterol. *n*-Pentane- and ether-soluble fractions derived from ES products exhibited chemoattractive activity comparable to that possessed by whole-worm extracts, but appeared to be simpler mixtures.

Key Words—*Schistosoma mansoni*, intersexual chemoattractivity, cholesterol, excretory–secretory products

INTRODUCTION

Evidence for chemoattraction between the sexes of various species of nematodes and trematodes has been available for some time (Bone et al., 1977; Bone and Shorey, 1977; Fried et al., 1980; Fried and Robinson, 1981). Host reactions to eggs resulting from mating of one such organism, the parasitic trematode *Schistosoma mansoni*, are the primary cause of the debilitating effects of schistosomiasis. Shirazian and Schiller (1982) have shown that each sex of *S. mansoni* shows a tendency to be attracted to the opposite sex in vitro in the

[3]Current address: Department of Chemistry, University of Iowa, Iowa City, Iowa 52242.

0098-0331/86/0800-1725$05.00/0

absence of worm tactile behavior. This observation suggests that sexually specific chemoattractive agents may be produced by each sex of *S. mansoni*. If such agents could be isolated and identified, knowledge of their chemical structures could be used to develop ways of interfering with the mating process. This approach may be useful in combating schistosomiasis. We describe here procedures for obtaining extracts with intersexual chemoattractivity from *S. mansoni*.

METHODS AND MATERIALS

Samples of *S. mansoni* were obtained and prepared for study as described elsewhere in this issue (Shirazian et al., 1986). All solvents employed were distilled in glass. Thin-layer chromatography (TLC) was performed using glass plates which were precoated with a 250-μm layer of silica gel 60 F-254. Chloroform–methanol (9 : 1) was employed as the mobile phase. Compounds were visualized with a vanillin–50% sulfuric acid spray reagent or by exposure to iodine vapor. Gas chromatography (GC) was carried out using a 6-ft glass column of 3% OV-1 on 100–120 Gas-chrom Q, a temperature program from 40 to 280°C at 10 C/min, and a Varian model 2100 gas chromatograph. The mass spectrum was obtained using a Finnigan model 3000 mass spectrometer. The proton NMR spectrum was recorded at 300 MHz on a Bruker WM-300 spectrometer.

Fresh, freeze-dried female *S. mansoni* (150 individuals; 7.5 mg dry weight) were ground with a small mortar and pestle to give a powdery solid. This solid was extracted progressively with solvents of increasing polarity to fractionate the soluble components. Two milliliters of *n*-pentane were added, and the solids were triturated and allowed to soak for 15 min. The solids were centrifuged, and the solution was decanted, filtered, and evaporated under a stream of dry nitrogen to give a colorless oily residue. This procedure was repeated twice more, and all three extracts were combined to afford an *n*-pentane fraction (0.14 mg). This sequence was repeated using diethyl ether in place of *n*-pentane to extract the worm solids. All of the ether-soluble material was combined to give an ether fraction (0.40 mg), and the procedure was repeated consecutively with ethyl acetate, methanol, and water to provide three more fractions (0.75, 1.83, and 2.41 mg, respectively).

Two different types of worm-free incubates were also prepared which contained *S. mansoni* excretory–secretory (ES) products (Shirazian et al., 1986). Groups of 100 female worms were incubated in Hanks' balanced salt solution (HBSS) for 72 hr, or cultured in biphasic medium (Schiller et al., 1975) for 48–72 hr. In each instance, the supernatant solution was collected, freeze-dried, and the resulting residue was subjected to the extraction procedure described above

using only *n*-pentane and ether. The HBSS supernatant gave a 0.38-mg *n*-pentane fraction and a 0.33-mg ether fraction, while the biphasic supernatant gave a 0.14-mg *n*-pentane fraction and a 0.02-mg ether fraction.

Ten percent of each of the fractions described above was set aside for chromatographic analysis, while the remaining material was assayed for chemoattractivity to males using the procedures described elsewhere in this issue (Childs et al., 1986). Extracts of males were prepared in an analogous fashion, but studies were focused on the female extracts because preliminary assays showed that males were more strongly attracted to female extracts than females were to male extracts.

RESULTS

Results of assays for chemoattractivity are reported elsewhere in this issue (Childs et al., 1986). In all cases, attractive activity could be found in the least polar (*n*-pentane- and ether-soluble) fractions. Analysis of the *n*-pentane-soluble whole-female extract by TLC showed that a total of five major components were present (R_f: 0.07, 0.19, 0.75, 0.82, and 0.90), along with an indefinite number of minor constituents. The ether-soluble fraction contained the same five major components, although in different concentrations. Analysis of the *n*-pentane fraction by proton NMR spectroscopy strongly suggested that at least some of the major components of the mixture were steroids. Chromatographic comparison with an authentic sample indicated that the most abundant component of the mixture (R_f 0.75) might be cholesterol. Analysis of the mixture by GC showed a single major peak which coeluted with cholesterol upon coinjection. Analysis by GC–MS showed that this component had a molecular weight of 386 and the expected fragmentation pattern, thus confirming its identity as cholesterol. Comparison with male and ES extracts showed that cholesterol was a major component of each. Cholesterol seems very unlikely to be a sexual chemoattractant for *S. mansoni*. A sample of cholesterol was tested for chemoattractivity in our assays and was found to be unattractive to both sexes (Childs et al., 1986).

The major components of the whole-worm extracts appeared to be identical (by TLC) for males and females even though extracts of each sex were attractive only to the other. This result suggests that the chemoattractants are not major components of these fractions. The *n*-pentane- and ether-soluble fractions obtained from the female worm-free incubates described above exhibited a degree of attractivity comparable to that observed in the whole-worm extracts (Childs, et al., 1986). TLC analysis of these fractions gave results which were very similar to those of the corresponding whole-worm extracts, except that the more polar major components (R_f 0.07, 0.19) were clearly much less abundant in the

worm-free incubate extracts. Since the ES product mixtures are apparently less complex than the whole worm fractions, isolation of the attractive component(s) may be simplified by focusing studies on ES products.

(Received October 1, 1985; accepted February 26, 1986)

Abstract—Chemical orientation of adult male *Schistosoma mansoni* was studied during cultivation in vitro. Directional preference was assessed in culture vessels marked with compass coordinates by the application of circular statistics for determining clustering and orientation to a predicted direction. Organic solvent extracts of fresh female schistosomes and supernatant fluids from 72-hr cultures of female parasites were tested for potential chemotactic activity. Analysis showed significant ($P < 0.05$) directional preference and clustering of male worms towards test compounds at all time periods (24, 48, and 72 hr) with one mixture of female extracts and at one of three time periods with a second female extract. Male worms did not respond to ecdysone, cholesterol, or solvent controls by orienting in predicted direction, although clustering was observed on two of 12 occasions. These results indicate the presence of a chemoattractant compound(s) in female extracts.

Key Words—*Schistosoma mansoni*, chemotaxis, attraction, primer pheromone, releaser pheromone, in vitro maintenance, circular statistics, ecdysone, cholesterol.

INTRODUCTION

Numerous studies have documented the existence of a reproductive stimulus (or stimuli), provided by male schistosomes, that mediates complete development of the reproductive system of females. These stimuli have been attributed to

0098-0331/86/0800-1729$05.00/0

hormones (Moore et al., 1954; Severinghaus, 1928), nutritional influences (Vogel, 1941), tactile contact (Armstrong, 1965), and pheromones (Armstrong, 1965). Substances or stimuli that induce or maintain sexual maturity (e.g., "primer" pheromones) may act independently of chemical substances that act at a distance to aggregate or attract parasites to each other or members of the opposite sex (e.g., "releaser" pheromones).

Chemical orientation of adult schistosomes to substances likely to be significant as mating pheromones is an area of study that has received little attention. Armstrong (1965), in a series of experiments on the mating behavior and development of schistosomes in mice, concluded that both sexes are active in the search for mates and that mating probably occurs via thigmotaxis and trial and error rather than chemotactic response. Imperia et al. (1980) demonstrated in vitro that female *Schistosoma mansoni* were attracted to single males isolated in chambers which allowed release of excretory–secretory (ES) products; however, females failed to respond significantly to chambers containing three males. Eveland et al. (1982) used a linear chamber bioassay to show chemoattraction in adult *S. mansoni* tested in both heterosexual and homosexual combinations. These same investigators implicated a chemoattractant of greater than 1000 molecular weight (M_r) by isolating target worms in dialysis sac barriers with varying molecular exclusions (Eveland et al., 1983). Shirazian and Schiller (1982) inferred the presence of chemical compounds mediating mating recognition on the basis of preferential responses of male and female *S. mansoni* cultivated in vitro for original over nonoriginal partners.

Chemoattractants are known to be released by nematodes, and in vitro demonstration of attractant activity has been reported from several species including *Trichinella spiralis* (Bonner and Etges, 1967) and *Nippostrongylus brasiliensis* (Bone et al., 1977).

This study was designed to use a modified version of an in vitro culture system (Schiller et al., 1975) to investigate the chemoattractant properties of substances derived from extracts of female schistosomes, or culture supernatant fluids, on the behavior of males. Two authentic steroid substances, B-ecdysone and cholesterol, were also tested for chemoattractiveness. Ecdysone, an insect moulting hormone, has been detected in adult *S. mansoni* and their ES products (Nirde et al., 1983), and substances similar to cholesterol, by thin-layer chromatography (TLC), have been implicated as pheromones in other helminths (Fried and Gioscia, 1976; Roberts and Thorson, 1977).

METHODS AND MATERIALS

Adult *S. mansoni* (Puerto Rican strain) were obtained from female CD1 Charles River Mice infected with 100 cercariae 50–60 days prior to dissection as described by Shirazian and Schiller (1982). Paired worms were separated

over crushed ice, sorted by sex, and placed individually in the experimental apparatus for testing of compounds. Single sex groups of 70–150 worms were placed either in saline or in culture for the future collection of supernatant fluids or worms for lyophilization and subsequent extraction of test substances. Each potential chemoattractant compound was tested on 7–10 previously mated, active, male worms, obtained from a single mouse. Replicate experiments were conducted on all test compounds.

Test compounds were prepared from the worms placed in saline and from the supernatant fluids from cultures, maintained for 72 hr, containing the single-sex groups of worms. These materials were lyophilized and lipids were extracted with organic solvents (*n*-pentane, ether, methanol, or ethyl acetate) as described by Gloer et al. (1986). Extracts were dried under nitrogen and reconstituted with solvent prior to analysis by TLC or use in behavioral studies.

Extracted fractions from female parasites were combined into two pools, called female extract pool 1 and female extract pool 2, in order to allow testing for the presence of any chemoattractant activity among the large number of concentrated extracts obtained. An impregnated test agar was made by mixing pooled extracts with 5 ml of 1.6% agar to give total concentrations of 0.14 mg extract/ml agar in female extract pool 1 (five lipid fractions pooled), and 0.19 mg extract/ml agar in female extract pool 2 (same as pool 1, plus three additional nonpolar lipid fractions). Two plugs (0.053 ± 0.004 ml) were cut from this impregnated test agar for use in each experimental vessel. Total amounts of extracts used per individual worm experiment ranged from approximately 15 to 20 μg. This amount of extract was approximately equal to 1.4–3.2 worm equivalents. Ecdysone and cholesterol (Sigma Chemical Company, St. Louis, Missouri) were tested at concentrations similar to those of female extracts. Control substances consisted of appropriate solvents mixed with agar.

A circular culture vessel was used to text experimental compounds. Sterile plastic culture vessels, 5 cm in diameter, were inoculated with 5 ml blood agar (Schiller et al., 1975), and two circular plugs (2–3 mm in diameter; 0.053 ml) were cut and removed by suction from the periphery of the agar sheet approximately 1 mm from the vessel rim. The plugs cut from agar impregnated with worm extracts were placed in the complementary holes cut in the experimental vessels and cemented in place with warm agar. Experimental vessels were left overnight at 4°C to allow some diffusion to test compounds from the plugs to the surrounding agar, although the final concentration gradients were not determined. Culture vessels were then overlayed with the liquid portion of the diphasic medium (Schiller et al., 1975) and placed on clear acetate sheets marked with individual compass coordinates and distance grids corresponding to each test vessel. Single male worms were then placed at the center of test vessels.

Acetate sheets and culture vessels were enclosed in a humidified incubator at 37.5°C under a Plexiglas cover equipped with gas ports and charged with

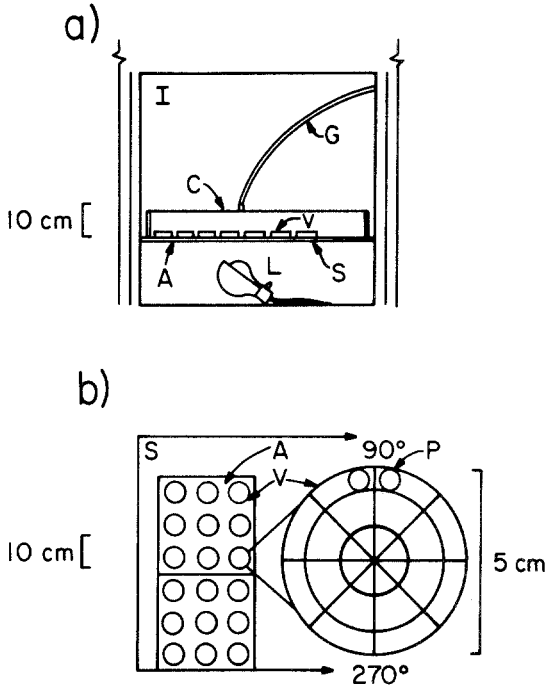

FIG. 1. Experimental apparatus for testing in vitro chemical orientation of *S. mansoni*. (a) Side view; A = acetate sheet marked with grid coordinates; C = Plexiglas cover; G = gas line; I = incubator; L = light; S = Plexiglas shelf; V = vessel; (b) top view showing enlarged view of vessel with grid coordinates; P = agar plug position. Parasites were placed in the center of the vessel.

5% CO_2, 5% O_2, and 90% N_2. The entire testing apparatus rested on a 1.2-cm-thick shelf of Plexigas raised 0.2 m from the bottom of the incubator (Figure 1). Parasite locations were recorded by viewing grid coordinates through the agar, by placing a 50-W light bulb directly below individual culture dishes. Parasites were maintained in the dark, except when location recordings were made at 24-, 48-, and 72-hr intervals. This procedure allowed data collection with minimal disruption of normal parasite activity.

Parasite orientation to each test substance or extract pool was tested by calculation of a mean vector, obtained from summing individual coordinates of parasite locations. Data from replicate tests of compounds were pooled prior to calculation of test statistics. A modified Rayleigh test (MRT) was used to compare mean directions (average of summed sines and cosines) of parasite vectors to the expected preferred direction towards the agar plugs containing the test compounds (Batschelet, 1972). The Rayleigh test (RT) was also applied to test for significant directional preferences (clustering) which could have occurred

independently of any orientation towards test compounds (Batschelet, 1972). In reporting data, two test statistics were used: r = the length of the mean vector and v = the direction of the mean vector. The predicted direction, towards the agar plugs, was standardized to 90° for ease of comparison with experimentally derived mean directions, although during actual tests the location of plugs was randomized with regard to compass bearing.

RESULTS

The results of TLC analyses are presented in detail elsewhere (Gloer et al., 1986). Briefly, the extracts obtained from both female *S. mansoni* and their supernatant fluids contained three nonpolar fractions. The presence of these substances in both whole worms and culture supernatant fluids indicates they were probably ES substances released by worms in culture. One of these nonpolar extracts had a chromatographic mobility similar to cholesterol.

Male *S. mansoni* showed significant clustering and directional preference towards female extract pool 1 at all three time periods (Figure 2). Males showed significant clustering and directional preference at one of three time periods (48

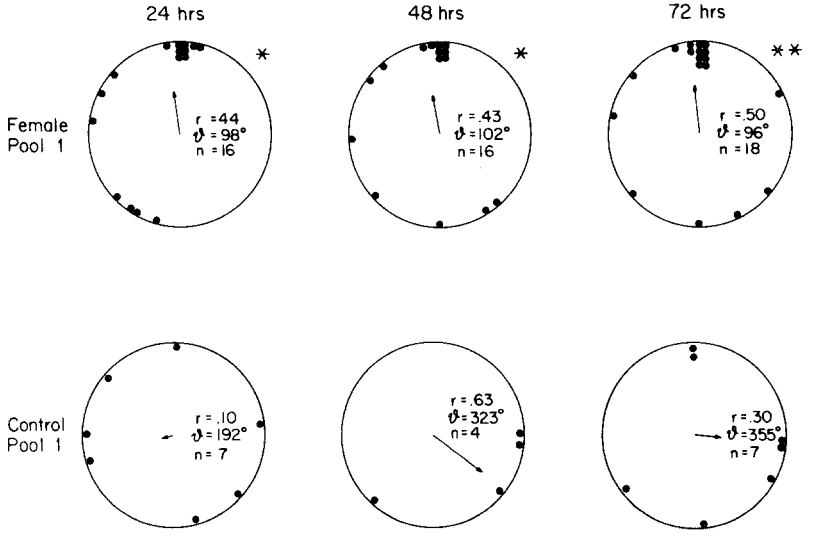

FIG. 2. Individual orientation angles (•), mean vector length (r), and preferred directions of orientation (v) of male *S. mansoni* to agar plugs impregnated with female extract 1. Location of plugs is always 90°, towards the top of the page. Radius of circle = 1. Values shown for p (* = $P < 0.05$; ** = $P < 0.01$) were the least significant obtained by either the Rayleigh test or modified Rayleigh test. Values of P for all time points are shown in Table 1.

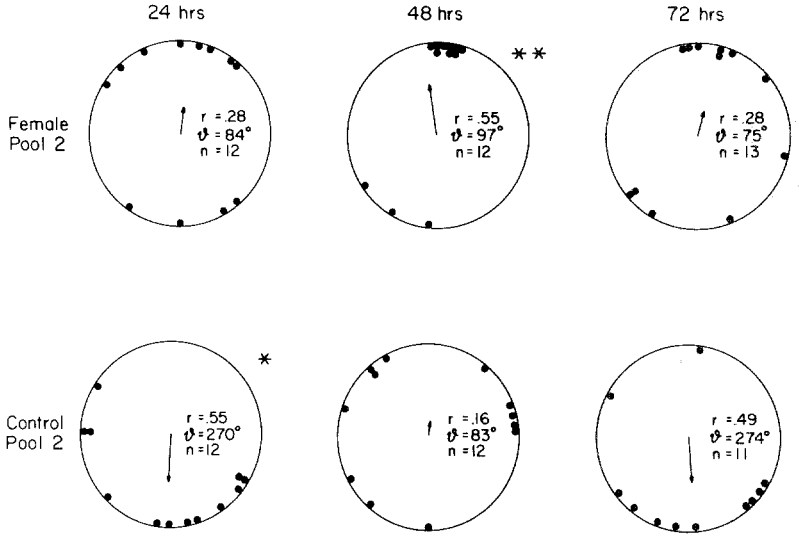

FIG. 3. Individual orientation angles, mean vector length, and preferred directions of orientation of male *S. mansoni* to agar plugs impregnated with female extract 2. Notation as in Figure 2.

hr) for female extract pool 2 (Figure 3). Mean directions in both sets of experiments clustered around the predicted value of 90° even in cases when statistical analyses were insignificant (Table 1). Male schistosomes were significantly clustered in one of six control periods (Figure 3, 24 hr), however, the mean direction was 270°, directly opposite the agar plugs impregnated with control substances. It is possible that solvents used in control plugs are repellent when offered in the absence of female extracts. The number of worms counted per time interval varied (Figures 2 and 3) because occasionally worms would crawl under the agar medium and could not be visualized without disrupting the experiments.

Male schistosomes failed to orient and move in predicted directions when presented with plugs impregnated with ecdysone or cholesterol (Table 1). At one time point, there was significant clustering with ecdysone at a mean direction of 350°.

DISCUSSION

These results, although based on a limited number of experiments, strongly suggest that male *S. mansoni* were responding to a substance(s) in female extracts that was chemoattractive. This substance, presumably a lipid, was present in both whole female schistosomes and in culture supernatant fluids, indicating it may have been an ES product.

TABLE 1. SUMMARY OF CHEMOATTRACTANT EXPERIMENTS WITH DIFFERENT SUBSTANCES ON MALE *S. mansoni*

Test substances	No. replicates (No. worms)	v range (degrees)[a]	r, range[b]	RT[c]	MRT[d]
♀ *S. mansoni* Extract 1	2 (16–18)	96–102°	0.43–0.50	$P < 0.05$[e] all	$P < 0.01$ all
Extract 2	2 (12–13)	75–97°	0.28–0.55	$P < 0.05$ 48 hr	$P < 0.01$ 48 hr
Ecdysone	2 (18)	197–350°	0.15–0.44	$P < 0.05$ 72 hr	N.S.
Cholesterol	1 (8)	258–304°	0.15–0.43	N.S.	N.S.

[b] Length of mean vector, maximum = 1.
[c] Rayleigh test.
[d] Modified Rayleigh test.
[e] P values are for test interval shown (all = 24, 48, 72 hr).

Steroids that can act as chemoattractants have been identified in other in vitro experiments with helminths. Fried and Gioscia (1976) demonstrated that metacercaria of *Leucochlorlidiomorpha constantiae* were attracted to a compound with the identical chromatographic mobility as cholesterol. Roberts and Thorson (1977) reported that adult *Nippostrongylus brasiliensis* were attracted to a lipid fraction of ES products that cochromatographed, by TLC, with colesterol and B-sitosterol; however, neither authentic sterol was attractive when tested in vitro. Our results show that a single nonpolar fraction of *S. mansoni* extract comigrated with cholesterol, but cholesterol alone was not chemoattractive in a single test. The individual substance, or group of substances, that is active as a chemoattractant remains to be identified.

Recent observations on *S. mansoni* (Haseeb et al., 1985a) and *S. haematobium* (Haseeb et al., 1985b) indicate that both species of parasite release lipids when maintained in vitro. Fried et al. (1983) demonstrated that *S. mansoni* release cholesterol in vitro and that male parasites released considerably more than females or pairs.

The potential importance of lipophilic substances in helminthic sexual processes has been stressed (Imperia et al., 1980). Lipids may serve a function as chemoattractants as well as to stimulate sexual development of unmated female *S. mansoni* (Shaw et al., 1977). Shorey (1976) has pointed out that pheromones that elicit aggregation at a distance can stimulate additional close-range behavior. Ecdysone and related hormones, known to stimulate moulting in insects,

have recently been found in *S. mansoni* and are known to be released by these parasites in vivo (Nirde et al., 1983, 1984). The exact function of these hormones in trematodes is still unclear. A suggestion has been made that the predilection of invading miracidia of schistosomes for the ovotestis of snail hosts is due to the presence of morphogenetic substances needed by the worms (Muftic, 1969). Muftic (1969) suggests that these substances may be steroids and reports on the significance of ecdysones in miracidial transformation. The implications of these observations are that this life stage of the worm is capable of locating and aggregating in tissues of a host containing high concentrations of a steroid that may be ecdysone. In our experiments, male adult schistosomes did not respond to ecdysone, but it would be interesting to test miracidia of *S. mansoni* in varying concentrations of ecdysone, as Roberts et al. (1979) have done with snail-conditioned water.

The use of circular statistics has allowed the comparison of experimentally derived measures of response (clustering and orientation to preferred direction) against predicted values. In making these comparisons the magnitude of movement has been intentionally ignored. These measures were chosen because of the nature of the test apparatus and limitations of the sampling procedure (enclosed vessels of limited size, examined at discrete intervals). Ideally, detailed, continuous measurements of the direction and extent of worm movements would have been preferred, but this would have involved greater interruption of culture conditions such as continuous dark lighting and constant temperature. The individual movements of schistosomes has been monitored at shorter time intervals with some success (Schiller et al., 1986).

Increasing evidence now supports the conclusion that chemoattractive substances are present in adult schistosomes and are released in vitro (Imperia et al., 1980; Eveland et al., 1982, 1983). These substances may function as pheromones to help schistosomes become aggregated and mated, although their exact chemical nature and significance in vivo are unclear. Such substances, in other helminths, can be targeted for disruption by chemical, and potentially immunological, means (Bone and Shorey, 1977). Interruption of intraspecific communication would be extremely beneficial in controlling schistosomiasis because the major cause of pathology is due to the production and dissemination of eggs which occurs after mating.

Acknowledgments—This work was supported by grant 284-0017 from The Edna McConnell Clark Foundation and by NIH training grant TO1- AI-0020. Dr. G. Korch first suggested the use of circular statistics, and an anonymous reviewer provided many useful comments.

(Received October 1, 1985; accepted March 17, 1986)

Abstract—In vitro, the opposite sexes of *S. mansoni* are attracted to each other by some means of premating communication which culminates in aggregation and copulation of sexual pairs within 24 hr. The system used for time-lapse video tape documentation of worm sexual behavior in vitro is described and evidence of sexual chemoattraction is presented.

Key Words—*Schistosoma mansoni*, sexual chemoattraction, mating pheromone, videotechnology.

INTRODUCTION

Although the literature suggests that chemical communication by primer and releaser pheromones occurs extensively within the helminths, detailed knowledge of these events is sparse (Bone, 1982; Eveland et al., 1982, 1983; Haseeb et al., 1985). In vitro culture systems that support metabolic and synthetic processes of these parasites for at least 72 hr can be used to bioassay chemically mediated sexual attraction in dioecious species. The basic culture method described by Schiller et al. (1975) has proven useful for such studies of *Schistosoma mansoni* (Childs et al., 1986). Several criteria have been fulfilled in establishing the suitability of this system for investigations of this kind. It supports egg production by *S. mansoni* for at least 96 hr at a rate comparable to that recorded for the same strain in vivo (Schiller et al., 1975). These eggs are viable when laid in culture, complete their development to miracidia after 10 days of cultivation, and are capable of inducing the typical granulomatous response

0098-0331/86/0800-1739$05.00/0

when injected into laboratory rodents (Edungbola and Schiller, 1979). Furthermore, the system provides physiologic conditions under which the ATP level, glucose utilization, and lactate production by these worms are constant for at least six days (Schiller et al., 1975; Shirazian, 1979; Shirazian et al., 1986). When coupled with videotechnology, this system has enabled the documentation and analyses of important reproductive events. The purpose of this report is to describe the time-lapse video system used in our studies of worm sexual behavior and to illustrate some aspects of chemical attraction exhibited by them.

METHODS AND MATERIALS

The source of worms and procedures of in vitro culture were as described by Childs et al. (1986). The system used for recording worm behavior consisted of a Panasonic VHS video camera enclosed in a specially constructed plastic, waterproof housing (Photo-Tech, Baltimore, Maryland). This unit was placed inside the environmental chamber of a Wedco incubator so that it rested on a clear plastic shelf with the camera lens directed downwards, permitting it to be focused on the parasites in a culture vessel underneath. The camera and lighting were operated by remote control through cables leading to the exterior where they were attached to a Panasonic tape recorder connected to a model CT-110 MA color video monitor (Figure 1).

The incubator was maintained at a temperature of 37 C with a gas atmosphere of 90% N2, 5% CO2 and 5% O2. Exposures were made for periods of 15 sec at predetermined intervals of time (usually at 0:15, 0:30, 0:45, 1:00, 2:00, 3:00, 4:00, 5:00, 6:00, and 24 hr). Camera focusing, operation, lighting, and recording were all controlled remotely, thus precluding the need to open the incubator door or to disturb the cultures in any way. A transparent plastic sheet, with circular coordinates drawn upon it, was placed over the video screen of the monitor (Figure 1). Upon completion of a taping sequence, the tape was viewed on the monitor and the location of the worm(s) at each time interval was recorded on work sheets bearing corresponding compass direction and distance grids drawn to scale. Thus, the location of the worms, their direction, and distance traveled in a given period of time could be measured. The resultant data were analyzed statistically as described by Childs et al. (1986).

For heterosexual attraction experiments, adult worms surgically removed from mice were inoculated into culture vessels with four males close together in a group at one side and, similarly, four females at the opposite side. In homosexual experiments, the procedures were the same, except that the two groups of four worms were either all males or all females. Only unpaired worms from the same host animal were used in each test. The experimental design for recording worm response to test compounds was as described by Childs et al. (1986).

Lower photograph: monitor, video tape recorder, and timer.

RESULTS

Videotapes made during each of six experiments were selected as being representative for purposes of illustrating some aspects of worm sexual behavior. The first three experiments were designed to record heterosexual behavior. The significant events revealed by these three video sequences were that: (1) The worms of each sex tended to remain aggregated in groups which moved toward each other, but movement of the male group towards that of the opposite sex was consistently more rapid and more vigorous; (2) Intersexual clustering, with some male to female contact, occurred within 1 hr; (3) Mating, defined herein as being in copula, with the female enclosed within the gynecophoric canal of the male, occurred as early as 5 hr postinoculation; (4) Six of the 12 potential pairs (50%) in these three experiments had mated by the end of the first 12 hr in culture. (5) Paired worms, after mating, tended to disperse at random from the original intersexual cluster.

Experiments 4 and 5 were designed to record homosexual behavior. The video sequences made during these experiments revealed little evidence of sexual attraction, either between males or between females. In both male-to-male and female-to-female situations, worm dispersal was gradual and remained random throughout the 24-hr period of cultivation.

Experiment 6 was designed to record an example of male orientation to chemical fractions of female substances (for details of the experimental design, see Childs et al., 1986). The video sequence made during this experiment revealed considerable randomness of worm directional movement during the first 5 hr, but strong attraction to the test compound (*n*-pentane extract of female worms, see Gloer et al., 1986) was exhibited thereafter. At the end of 24 hr, the worm was located on top of the chemically impregnated agar plug where it remained actively motile throughout the next 24 hr of cultivation.

DISCUSSION

In the system employed in these studies for the in vitro cultivation of *S. mansoni*, the opposite sexes are attracted to each other by some means of premating communication which culminates in intersexual aggregation and copulation of sexual pairs within 24 hr. Male worms respond more vigorously to females than do females to males. As documented by time-lapse video tape photography, the migratory patterns and directional preferences exhibited by male worms in response to female extracts indicate the presence of chemical substances in the latter that serve as a mating pheromone(s). Other studies (Imperia et al., 1980; Eveland et al., 1982, Shirazian and Schiller, 1982) also clearly demonstrate that adult *S. mansoni* attract each other in vitro and that there is a chemical basis for this attraction. Eveland et al. (1982) similarly found the greatest attraction to be heterosexual, with males moving toward females in linear chambers provided with perforated barriers. Male homosexual attraction was not seen in their system but homosexual female attraction was said to be

approximately equal to heterosexual attraction involving female movement towards males.

As demonstrated by this presentation, videotechnology, when coupled with an appropriate method of in vitro cultivation, provides a powerful tool, not only for visualizing worm sexual behavior, but also for generating the analytical data necessary for meaningful bioassays.

New approaches to the control of schistosomiasis are needed. A knowledge of the pheromones that regulate sexual attraction and reproduction in schistosomes could lead to the development of effective pharmacologic and/or immunologic means of interfering with them. Preventing worms from mating would preclude egg production, thereby eliminating the main cause of pathology in this disease. Interference with the processes of sexual reproduction also would eliminate the excretion of eggs into the external environment, thereby significantly reducing the transmission potential of the parasite.

MALE-STIMULATED FEMALE MATURATION IN *Schistosoma:* A Review

IRENE POPIEL

Biosis, 1057 East Meadow Circle
Palo Alto, California 94303

(Received October 1, 1985; accepted December 30, 1985)

Abstract—In *Schistosoma mansoni* and other schistosome species, pairing of the female with a male partner is necessary for the completion of reproductive morphogenesis and growth. Permanent contact with a male is also necessary for the maintenance of reproductivity in the sexually mature female. This phenomenon appears to be unique within the animal kingdom. The mechanism of male-stimulated female reproductive development in schistosomes remains unknown however. In this paper, the theories for the nature of the process are reviewed briefly, recent findings are added, and the biological and technical problems associated with its study are highlighted.

Key Words—*Schistosoma mansoni*, male-derived cholesterol, vitellogenesis, female maturation.

In schistosomes, male stimulation is not species specific, and in a few cases, neither is it genus specific. Interspecific pairing between *S. mansoni, S. haematobium*, and *S. japonicum* results in female maturation and egg production (Vogel, 1941, 1942), as does intergeneric pairing between *S. mansoni* and *Schistosomatium douthitti* (Short, 1948) and between *S. mansoni* and *Heterobilharzia americana* (Armstrong, 1965).

The stimuli for reproductive morphogenesis and growth appear to be different and can act independently of each other. When the female reproductive system is irreversibly damaged by irradiation (Armstrong, 1965) or drug action (Cioli, personal communication), the worms will still grow to normal adult size if paired with males. Conversely, when females of *S. mansoni* pair with males of *Schistosomatium douthitti*, reproductive development occurs but the worms do not grow to normal adult size (Short, 1948; Armstrong, 1965).

Male stimulation is also required for continuous reproductive function in sexually mature females. When mature pairs of *S. mansoni* are separated,

0098-0331/86/0800-1745$05.00/0

regression of the female reproductive system takes place, and the worms become reduced in size (Popiel et al., 1981, 1984; Clough, 1981). If such regressed females are allowed to pair again with males, they can grow back to full size and attain sexual maturity (Clough, 1981). Female *S. mattheei* is exceptional within the genus *Schistosoma* in that reproductive maturation can take place in the absence of males (Taylor et al., 1969; Taylor, 1970).

Explanations for the influence of the male worm on the maturation of the female were reviewed by Michaels (1969); she categorized them into four areas: (1) the presence of sperm or sperm products in the female oviduct; (2) nutritional supplementation; (3) hormonal stimulation; and (4) tactile stimulation. It has been established that sperm is not the stimulus for female maturation (Erasmus, 1973; Shaw, 1977). Investigations within the last ten years have been based on the theory that a chemical factor is involved.

Atkinson and Atkinson (1980) reported that the most abundant female protein of 66 kd is synthesized exclusively by males and is transferred from males to females. They proposed that this is the biochemical basis for continuous copulation in schistosomes, although no evidence for this was provided. More recently, Popiel and Basch (1984a) found no synthetic deficiency in females for a protein of 66 kd. Furthermore, no specific male to female protein transfer was detected.

In a study of glucose uptake in worm pairs, Cornford and Huot (1981) demonstrated a transfer of [^{14}C]glucose from males to females. They suggested that a considerable proportion of the energy requirements of female reproductive activity may be supplied by the male.

The most direct evidence that the male-derived stimulus for female development is of a chemical nature was provided by Shaw et al. (1977). They reported that acetone and ether extracts of male worms stimulated vitellogenesis and growth in unisexual females in vitro and suggested that a male-derived lipophilic factor is responsible. Using identical procedures and the same PR strain of *S. mansoni*, this experiment was repeated in our laboratory at Stanford. A comparison of the results obtained in the two laboratories is given in Table 1. In culture medium plus male extract, vitellogenesis was observed in 56% of the "Cardiff unisexual females" of Shaw et al. Interestingly, 6% of these females, freshly recovered from mice, already exhibited some vitelline cell development, and this percentage increased to 16% and 23% after in vitro maintenance in basic culture medium and NCTC 35, respectively. "Stanford unisexual females" freshly recovered from mice did not show any vitelline cell development, and no maturation took place in either culture medium alone or culture medium plus male extract.

Realizing that the stage of development of the vitelline gland in unisexual females was not as precisely defined as previous studies had suggested, Shaw and Erasmus (1981) performed a systematic study of the reproductive status of females from single sex infections in Tuck strain mice. A similar study has

[a] A comparison of the results of Shaw & Erasmus (1981) using Cardiff females (C) and Popiel and Basch using Stanford females (S).

been performed on Stanford unisexual females in Swiss Webster mice. A comparison of the results is given in Table 2. In the Cardiff females there was an increase in length and in the number of worms exhibiting vitellogenesis with age. In the Stanford females no growth took place after days 30–39 postinfection and no vitellogenesis had taken place in any females as old as 200 days. The clear difference in the extent of maturation attained by these two populations of unisexual females could be the result of a genetic difference or a differential effect of the two strains of mouse host.

From a further comparative experiment, it was found that Stanford unisexual females respond more slowly to stimulation when paired with males in vitro than did Cardiff females. Shaw (1977) demonstrated that in a medium comprising human serum and Earle's balanced salts (50:50), extensive vitellogenesis took place in unisexual females within four days of pairing with males. Stanford females, in the same medium or culture medium 169 of Basch (1981), need to be paired with males for a minimum of six days before even the beginning of vitellogenesis can be detected. It is possible that the reduced respon-

siveness of Stanford females is the basis for their lack of response to male extract.

Despite these conflicting results, the possibility that a male-derived lipophilic compound is responsible for the induction of female maturation cannot be ruled out. Fried et al. (1983) demonstrated that the major neutral lipid component of adult *S. mansoni* excretory–secretory products was cholesterol and that males released considerably more cholesterol in vitro than either females or worm pairs. They implicated cholesterol as a factor influencing growth, development, and behavior of adult worms. We have recently investigated the transfer of [^{3}H]cholesterol in adult *S. mansoni* following labeling of worms in vitro and pairing with unlabeled partners in vitro (Popiel and Basch, 1986). Scintillation counting of thin-layer chromatographic separations of lipid extracts of worm tissues and the culture medium was performed (Figure 1). During the period of time allowed for pairing, labeled worms lost up to 65% of their [^{3}H]cholesterol. In both unlabeled males and females which had paired with labeled partners, levels of [^{3}H]cholesterol were higher than in unpaired controls. We can assume that normal cholesterol transfer in worm pairs is bidirectional, and it is likely that it takes place, at least in part, by a process involving physical contact between adjacent membranes. At this stage we cannot assign a specific function to the process, and it remains to be determined to what extent cholesterol exchange is a by-product of normal tegumental turnover of the molecule.

In Michaels' final category of explanations, she suggested that the male stimulus for female development could be tactile and that a neurosecretory process within the female might convey the message from the tegumentary sense organs to the target organs of the reproductive system. Tactile stimulation was eliminated as a possible mechanism when the results of Shaw et al. (1977) implicated a chemical stimulus. However, even if tactile stimulation per se is not involved, the most efficient pathway for chemical communication would be through direct membrane-to-membrane contact between male and female.

Without knowing the nature of the stimulus, one can only speculate on its localization in the male and on the biochemical and physiological sequellae within the female which result from stimulation and lead to reproductive morphogenesis. The possible regional localization of the stimulatory factor in the male and its target in the female have been investigated (Popiel and Basch, 1984b). Unisexual female and mature male worms were transected into segments and put together in various combinations. Pairing took place between intact worms of each sex and segments of the other, and between segments of both sexes. Vitellogenesis occurred in the majority of female worms and segments so paired. In intact unisexual females paired with small male segments, vitellogenesis was limited to that portion of the worm that had been held by the male. It was concluded that (1) worm pairing, male stimulation, and female developmental response are independent of central nervous control by the ce-

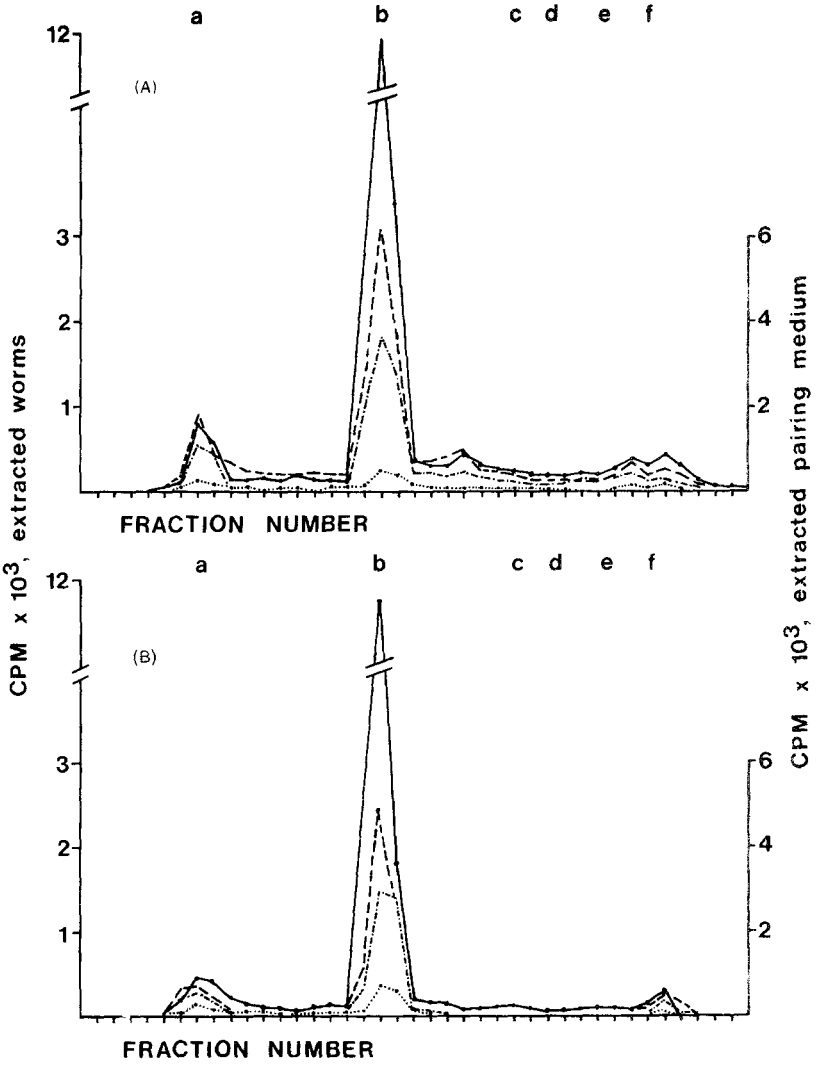

FIG. 1. The distribution of ^{3}H in TLC-separated lipid extracts of [^{3}H]cholesterol-labeled males (•——•) (A) and females (•——•) (B), unlabeled partners (-·--·-), unpaired controls (· · · · · ·), and the pairing medium (---) after a 24-hr period of in vitro pairing. a = origin, b = cholesterol, c = oleic acid, d = triolein, e = methyl oleate, f = cholesterol oleate.

rebral ganglia; (2) males have no centralized location for the female-stimulating factor; (3) vitelline gland differentiation in the female requires local stimulation through male contact, and this is not propagated throughout the worm. Systemic conveyance of the "developmental message" from the tegumental surface of the female to all parts of the reproductive system can, therefore, be ruled out. Neurosecretion, first suggested by Michaels as a mediating process, is still a possibility. However, in higher forms neurosecretory cells are typically morphologically discrete and often operate independently of the nervous system, whereas in schistosomes neurosecretory material has been reported only within nerve cells (Silk and Spence, 1969).

The above review covers results of investigations which have most directly addressed the process of male-stimulated female reproductive morphogenesis in schistosomes. It is useful at this point to highlight a number of factors which, to varying extents, compound progress towards a better understanding of this developmental process.

1. Worm pairing and subsequent female development in vivo is not synchronous (Table 3). Females recovered from mice on a given day will comprise a variable population of worms at different developmental stages. This is especially so on days 30–38 postinfection when reproductive morphogenesis is taking place. Variations in biochemical data obtained from samples of such populations are inevitable. If unisexual females and mature males are transplanted together to recipient hosts, pairing and subsequent female maturation are more synchronized (Table 4). This is a time-consuming and involved method for obtaining females at specific stages of reproductive development.

2. Viable schistosome eggs have yet to be produced by females reared in vitro. The in vitro culture conditions at our disposal are far from satisfactory for the study of reproductive development, a process so dependent on optimal conditions for normal function.

3. The first visible indication that sexually immature females are responding to male stimulation is the appearance of differentiating vitelline cells in the vitelline gland region. Fast red B staining of these cells is the presently used assay for the induction of female maturation. However, it takes three to four days after pairing in vivo and six days in vitro for vitelline cells to appear. Additional knowledge of the biochemical changes which take place in females immediately after pairing would provide a more rapid assay for the stimulation of female maturation and lead to a better understanding of the developmental process.

4. The first step in establishing that the male stimulus for female maturation is chemical in nature is the unequivocal demonstration of the stimulatory effect of whole-male extract or a fraction thereof. The conflicting results in this area are disappointing and require further investigation. The presence of the

insect hormones, ecdysone and 20-hydroxyecdysone (Nirde et al, 1983), lends weight to the idea that hormones are involved in schistosome maturation.

As schistosomes evolved form hermaphroditic ancestors, the phenomenon of male-stimulated female maturation is probably a relic of this ancestry. It was suggested (Popiel et al., 1984; Popiel, 1986) that schistosomes may have evolved from a protandrous ancestor in which maturation of the female reproductive system was dependent on complete development of the male system. Although immature males are unable to stimulate female maturation (Standen, 1953), it has been shown that both mature males lacking testes (Armstrong, 1965) and transected somatic tissue segments of mature males (Popiel and Basch, 1984b) are able to do so. Female development is thus dependent on

stimulation from the somatic tissue of mature males rather than the reproductive system. In most invertebrate species which depend for existence on a very high reproductive output, females are larger than males. Why are schistosomes atypical in that males are larger than females? In the male the testes are anteriorly situated, and the rest of the body, comprising approximately 80% of the worm, is devoid of additional organ systems. It is interesting to speculate that the size of the male schistosome is, for the most part, a reflection of its role in the stimulation and maintenance of female reproductivity and in the conveyance of the female around the portal system.

STRUCTURAL AND METABOLIC CHANGES IN FEMALE *Schistosoma mansoni* FOLLOWING MALE STIMULATION

DAVID A. ERASMUS

Department of Zoology
University College
Cardiff, Wales, U.K.

(Received October 1, 1985; accepted December 17, 1985)

Abstract—Pairing of males and females from single-sex infections results in the multiplication and differentiation of undifferentiated cells of the vitelline lobule culminating in the production of mature vitelline cells involved in egg shell formation. These changes are accompanied by increases in the rate of uptake of tyrosine, thymidine, and an increased accumulation of calcium.

Key Words—*Schistosoma mansoni*, vitelline gland, differentiation, tyrosine, thymidine, calcium, rates of uptake, male stimulation.

INTRODUCTION

It is well established that the sexual maturation of the female schistosome is dependent upon pairing with male worms. The precise nature of this developmental stimulus is still under debate. However, the gross physical changes in the female consequent to male stimulation are easily recognized and consist of an increase in length, maturation of the ovary, and development and maturation of the vitelline gland. As the protection of the fertilized ovum and the results of its differentiation are dependent on an egg shell produced from the synthetic products of the vitelline cell, this paper will largely be concerned with various aspects of vitelline cell development.

METHODS AND MATERIALS

All the experiments conducted in the author's laboratory were based on a Puerto Rican strain of *Schistosoma mansoni* maintained in Tuck Swiss albino

0098-0331/86/0800-1755$05.00/0

mice and *Biomphalaria glabrata*. Details of all procedures, as well as those of other authors, are described in the relevant publications.

OBSERVATIONS AND DISCUSSION

Vitelline Gland of Mature Female. In mixed infections (male and female worms present) sexual dimorphism is not clearly apparent until approximately 25 days postinfection (DPI). The ovary, oviduct, uterus, and ootype are the first structures to appear, followed by the vitelline gland. This begins to differentiate at about 29–31 DPI, and there exists considerable variation in the degree of development until about 40 DPI when presumably most worms have paired and the developmental sequence has stabilized (J.E. Roberts, personal communication).

The vitelline gland consists of a large number of lobules extending on either side of the cecum from the posterior end of the ovary to the terminal portion of the body. The developmental sequence occurring within each lobule was first described by Erasmus (1975b) and later semiquantified by Erasmus and Popiel (1980). (Figures 1 and 2). The continuous developmental sequence was categorized into four stages: S1, representing the undifferentiated cell, proceeding through S2 and S3 to S4, the fully differentiated cell which ultimately is released into the vitelline duct. Mechanisms controlling vitelline cell turnover are unknown, although Nollen et al. (1976) suggested a turnover time of six days. On the basis that a mature female schistosome deposits 300 eggs per day and each egg capsule contains an ovum plus 38 vitelline cells (Gönnert, 1955), then the vitelline gland must produce approximately 11,000 cells in 24 hr. Furthermore, as recent data (Harris *et al.*, 1984) suggests that *S.mansoni* may still be egg-laying after 32 years postinfection, then the productivity of the gland must be enormous. Further analysis of the composition of the lobules did not reveal any differences between the composition of anterior and posterior lobules nor between lobules from worms recovered at 50 and 100 DPI.

A series of experiments to determine the effects of drugs on the vitelline lobule (Erasmus, 1975b; Erasmus and Popiel 1980; Popiel and Erasmus, 1981, 1982, 1984; Popiel et al., 1984) revealed a differing sensitivity between the developmental stages in the lobule to drugs. In the case of Astiban (Erasmus, 1975b; Erasmus and Popiel, 1980) (Figure 3) and Oxamniquine, the undifferentiated cells survived treatment and eventually began to differentiate and repopulate the lobule (Erasmus, 1975b; Erasmus and Popiel 1980; Popiel et al., 1984). The success of in vitro culture methods may be partly dependent on the ability of the S1 vitelline cell to survive and differentiate. It is also likely that it is this cell which, as far as the vitelline gland is concerned, makes the initial response to male stimulation by dividing and differentiating. The complete differentiation, coordination, and functioning of the female reproductive system may, of course, depend on a sequence of other stimuli.

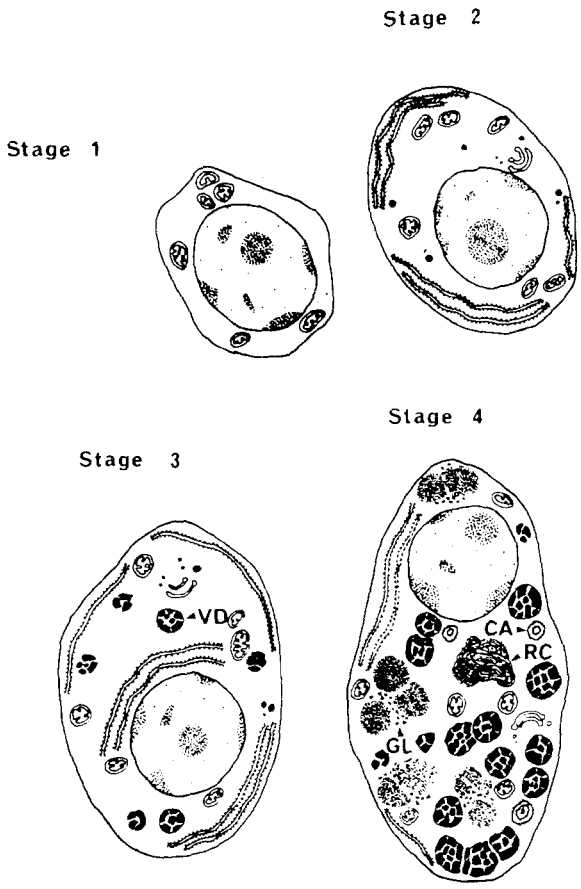

FIG. 1. The four main stages in the differentiation of the vitelline cell in the vitelline lobule of *S. mansoni*. Stage 1 (S1) is the undifferentiated cell; stage 2 (S2) shows a change in nuclear/cytoplasmic ratio together with the appearance of Golgi complexes and granular endoplasmic reticulum; stage 3 (S3) at which the vitelline droplets (VD) begin to appear; and stage 4 (S4), the mature vitelline cell containing vitelline droplets, calcareous concretions (CA), ribosomal complexes (RC), and glycogen (GL) associated with lipid/droplets.

There is some evidence which suggests that the lobules of the gland may develop and function independently. Treatment with Niridazole (Popiel and Erasmus, 1981) results in initial damage occurring at the posterior end of the gland. Exposure in vivo to Oxamniquine results in a patchy disappearance of the lobules (Popiel and Erasmus, 1982). During sexual maturation, the vitelline gland starts to appear as isolated lobules nearest the ovary. The comparison of vitelline lobule composition from anterior and posterior ends of the worm also suggests there is no linear differentiation of development. The most elegant

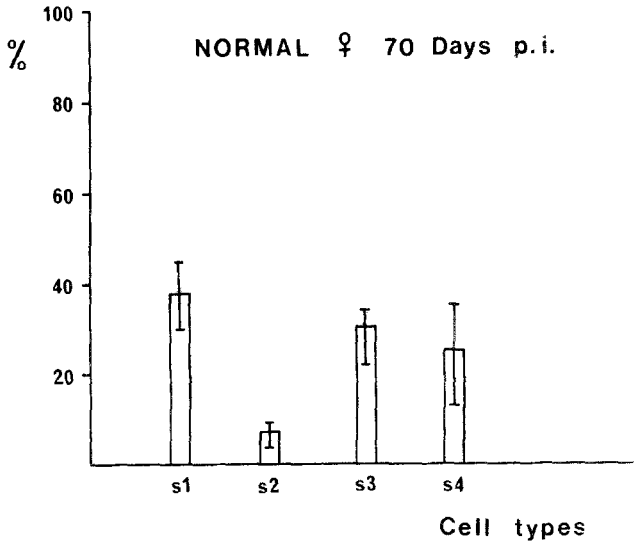

FIG. 2. The relative proportions of the four developmental stages of the vitelline cell in lobules from a normal, 70-day-old worm. Taken from Erasmus and Popiel (1980).

demonstration of isolated lobule development was made by Popiel and Basch (1984) who showed, using unisexual females (with no previous exposure to males) and male worm segments, that differentiation of the vitelline lobules only occurred in those regions enveloped by male segments. This limited evidence suggests that stimulation and activation of S1 cell differentiation and development might occur quite locally.

Unisexual Female. Because of the heterogamety exhibited by schistosomes (Short, 1983), it is possible, using cercariae derived from single miracidial infections, to obtain experimentally a schistosome population consisting of a single sex. Unisexual females are those derived by such techniques and have had no previous exposure to males. The classical picture of such females at 50 DPI and later is a stunted worm (Moore et al., 1954, provide comparative figures) which is sexually immature. An ultrastructural study by Erasmus (1973) revealed that in such worms oviduct, ootype, and uterus were well developed; although the ovary was present, its cells did not produce cortical granules, and the vitelline gland was represented by patches of undifferentiated cells corresponding to the S1 cells of later studies (Erasmus, 1975b).

One of the routine tests used to demonstrate the presence of fully differentiated vitelline cells is the fast red B technique (Johri and Smyth, 1956) which reveals the presence of phenolic substances within the cell. Using this technique Shaw et al. (1977) showed that a small percentage (6%) of unisexual females immediately upon removal from the host showed positively stained cells in the

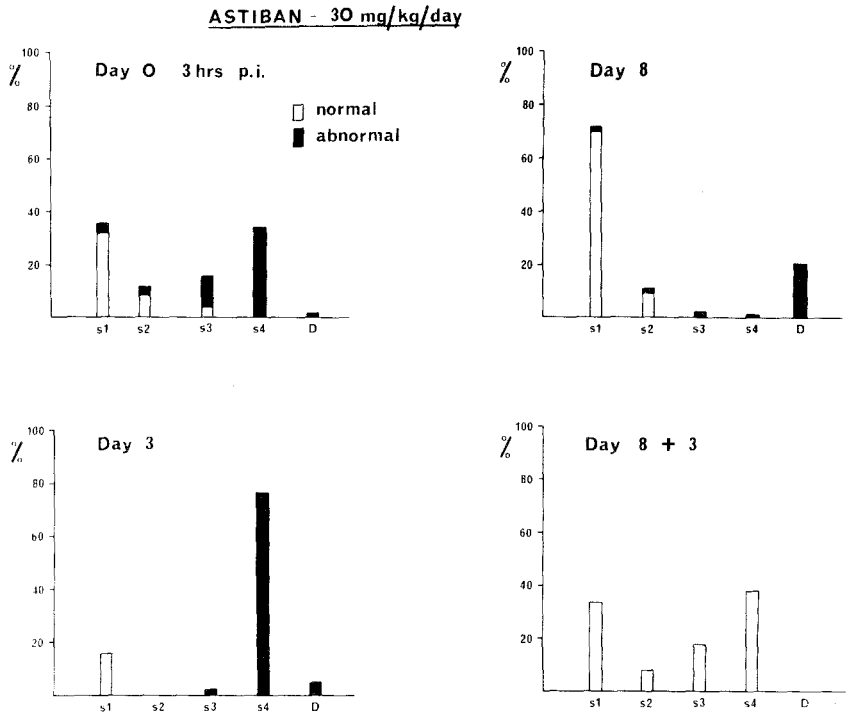

FIG. 3. The effect of Astiban on the cell population of the vitelline lobules of *S. mansoni*. Day 0 = 3 hr after single injection; D 3 = 3 daily injections; Day 8 = after 8 daily injections. Note that 70% of the lobule population consists of S1 cells. Day 8 + 3 = eight daily injections, followed by withdrawal of drug for 3 days and then sampling. D = "dead cells." Taken from Erasmus and Popiel (1980).

region of the vitelline gland. Furthermore, after four days in vitro culture this proportion increased to >16%. In a later study (Shaw and Erasmus, 1981), it was shown that the proportion of a population of unisexual females exhibiting positive fast red B reactions increased with time postinfection. However, the degree of development of the vitelline gland did not increase between worms recovered 30 DPI and those at 200 DPI. At the ultrastructural level the vitelline lobules corresponded to previous descriptions: Mehlis' gland was present in some worms and not in others, but the cells of the ovary remained in a state characteristic of the initial description (Erasmus, 1973). Worm length also increased with time postinfection.

These observations suggest that, in the host/parasite model used, some development of unisexual females occurred in the absence of males. Consequently it may be argued that male stimulation simply accelerates the process of female maturation rather than inducing a de novo response.

Male Worm. It is not anomalous to include the male worm in this consideration of female development as (reviewed by Shaw and Erasmus, 1982), the occurrence of pseudohermaphroditism in the male has been reported by several workers. Using the fast red B technique and ultrastructural studies, it was shown that mature S4 cells, similar in most respects to those in the vitelline lobule from the mature female, occurred in male worms recovered 30–100 DPI. These mature cells were scattered, not incorporated into lobules, nor were prior stages of development observed. A characteristic feature was that they were closely associated with the cecum.

In a study of [^{3}H]thymidine uptake by male and female worms, Den Hollander and Erasmus (1984) showed by autoradiography that undifferentiated cells closely associated with the gut in the male possessed labeled nuclei. It is possible that these cells represented the precursors of the mature cells revealed by histological staining.

These results may indicate that the heterogametic dimorphism associated with the genus may not be absolute but may be influenced by particular host–parasite strain relationships. These anomalies may also influence our consideration of those factors stimulating vitelline cell maturation in the female.

Biochemical Aspects of Vitelline Cell Development. In light of what has been said previously regarding numbers of eggs produced, it is obvious that the vitelline lobule is a highly productive unit. The egg shell or capsule is regarded as consisting of a quinone-tanned protein, and Clegg and Smyth (1968) have identified the presence of proteins rich in $-NH_2$ groups, phenolase, and phenolic materials in the vitelline droplets. Stimulation of the unisexual female by male worms, therefore, not only results in multiplication and differentiation of the S1 cells but also, at the S4 stage, the production of the various precursors of the egg shell components. Both these changes, morphological and synthetic, must involve considerable metabolic changes in the female following stimulation.

As mentioned earlier, one of the standard techniques used to demonstrate vitelline cell differentiation is the fast red B test for the presence of phenolic substances (Johri and Smyth, 1956). The disadvantage of this technique is that it only identifies the final stages of differentiation, i.e., the mature S4 cell. In order to determine the initial events of female development following stimulation by the male, more sensitive methods are required. Erasmus (1975a) demonstrated the uptake of labeled L-tyrosine by mature females of *S. mansoni* and its localization in the mature vitelline cells. Later, Popiel and Erasmus (1981) showed that after unisexual females had paired with males in vitro for five days, tyrosine uptake had risen by 7% on day 5 and by 32% on day 6 over a baseline shown by unpaired unisexual females. These changes must represent the changes in protein synthesis by S4 cells.

Although undetected in an initial study (Erasmus, 1973), further work

revealed the presence of calcareous concretions approximately 0.3 μm in diameter in the cytoplasm of the mature S4 cells of *S. mansoni*. These concretions originated in dilations of the GER, and X-ray probe analysis revealed the presence of calcium, phosphorus, and magnesium (Erasmus and Davies, 1979). In a study of the changes in elemental composition of male, unisexual female, and paired female *S.mansoni* in relation to age and sexual status, Shaw and Erasmus (1983) showed that in paired female worms the calcium content increased significantly over that of males and unisexual females after 30 DPI. This change must reflect the gradual appearance of S4 cells in the vitelline lobules. The possible function of these calcium stores was extensively discussed by Shaw and Erasmus (1983), but no specific conclusion was reached. In a comparative study of vitelline cell structure in *S. mansoni*, *S. japonicum*, *S.haematobium*, and *S.mattheei* (Erasmus et al., 1982), calcareous deposits were found in the vitelline cells of all species with the exception of *S. japonicum*. This anomaly is difficult to explain but may be related to the higher rate of egg production (Moore and Sandground, 1956) and the slightly different chemical composition of the egg capsule (Byram and Senft, 1979).

As has been mentioned, male stimulation results in division and differentiation of the S1 cells of the vitelline gland. This process must involve large-scale DNA synthesis, and Den Hollander and Erasmus (1984) determined the pattern of DNA synthesis in male and female *S. mansoni* from mixed and single-sex infections in mice. [^{3}H]Thymidine was used as a specific marker for DNA synthesis and biochemical tests showed that up to 35 DPI males and females from mixed infections had comparable activity. After this period the activity in males decreased, whereas that of females persisted at a high level, presumably reflecting the continued cell division in the lobules of the vitelline gland.

In females from single-sex infections, the activity was significantly lower than that of single-sex males and females from mixed infection. Thus stimulation of unisexual females by males results in a significant increase in DNA synthesis. Autoradiography at both light and electron microscope levels revealed that in mature females the label localized in the S1 cells of the vitelline lobule and also in small, undifferentiated cells in the parenchyma. In unisexual females after 45 DPI very few labeled cells were observed other than a few cells in the ovary. In mature cells, cells of the testes were labeled as were scattered undifferentiated cells. The general pattern was that in both males and females there was an overall labeling, but as the reproductive systems matured the labeling became concentrated in these organs. The ability of males to stimulate a change in the rate of DNA synthesis of females was also studied by Den Hollander and Erasmus (1986). Under in vitro conditions most unisexual females had paired by 18 hr. By 24 hr after culture, the uptake of labeled thymidine by paired females was significantly different from that of unpaired fe-

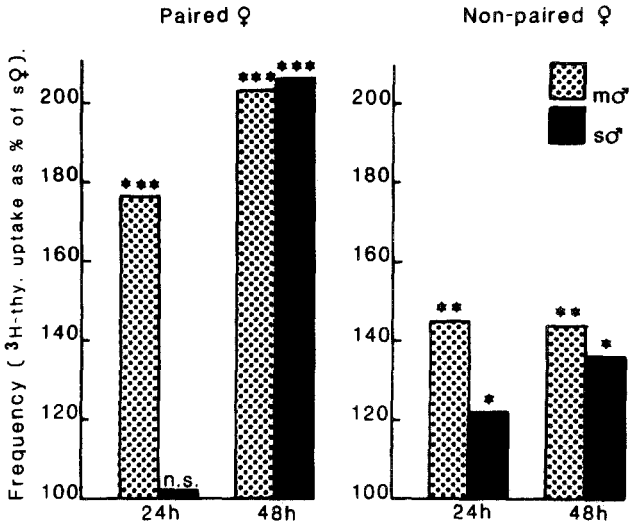

FIG. 4. Mean [^{3}H]thymidine uptake (dpm) by individual unisexual female *S. mansoni* after 24 or 48 hr stimulation with males from either mixed (mσ) or unisexual (sσ) infections expressed as a percentage of the uptake by unstimulated (no males) unisexual females. *** significant, $P < 0.001$; ** significant, $P < 0.01$; * significant, $P < 0.1$; n.s., not significant. Taken from Den Hollander and Erasmus (1986).

males. By 48 hr, the uptake was approximately double that of unpaired females. These experiments therefore indicate a very rapid change in rates of DNA synthesis by the female following male stimulation (Figure 4).

Stimulating Male. It is generally assumed that once males have reached maturity, they possess the ability to stimulate females to develop. However, Den Hollander and Erasmus (1985) showed that females paired with males from mixed infections had a significantly higher rate of uptake of labeled thymidine than females paired with males from unisexual infections (Figure 4). After 48 hr in vitro this difference had disappeared. These observations suggest that some form of maturation of the male is required before efficient stimulation of the female can occur. Popiel and Erasmus (1981) also observed that male extract resulted in a much greater increase in tyrosine uptake by females compared to females paired with males for four days (Figure 5).

Thus the pairing of unisexual females with males results in considerable morphogenesis, changes in the rates of uptake of tyrosine and thymidine, and in the accumulation of calcium. These changes occur rapidly and probably in periods considerably less than the 24 hr demonstrated for thymidine. It is possible that male stimulation produces changes in the physicochemical characteristics of the female tegument which affects the uptake of substances essential to growth and the maturation of the female reproductive system. It seems pos-

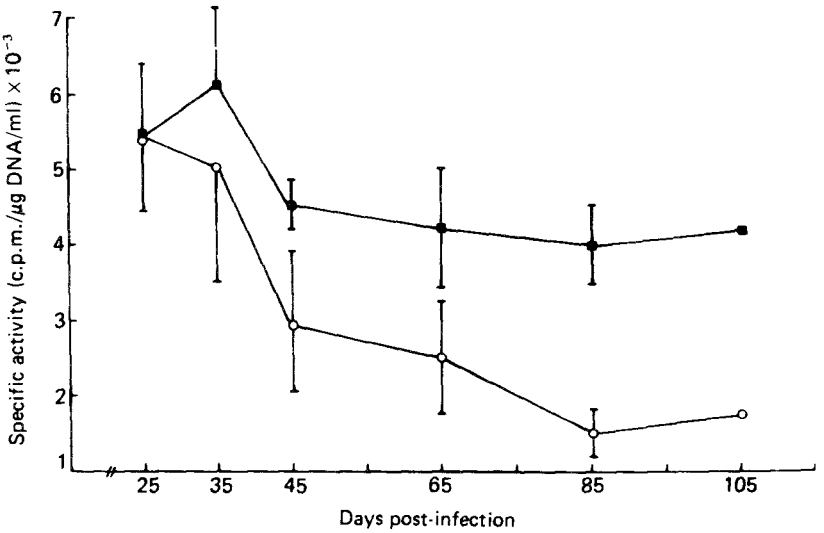

FIG. 5. DNA synthesis in male (○) and female (■) *S. mansoni* from mixed infections. The worms were labeled in vitro with 20 μCi/ml methyl [^{3}H]thymidine, the DNA was extracted, measured, and presented as a specific activity (cpm/μg DNA/ml). Each point is the mean of three experiments with the standard deviation shown. Taken from Den Hollander and Erasmus (1984).

sible that this relationship between stage 1 cell differentiation and changes in tegumental characteristics may provide a suitable target for intervention by drugs.

Acknowledgments—I am indebted to Miss J.E. Roberts for the use of unpublished material on the development of *S. mansoni*. Most of the work described in this paper was supported by grants from the S.E.R.C. and U.N.D.P./World Bank/W.H.O. Special Programme for Research and Training in Tropical Diseases. I wish also to acknowledge the financial support of the Edna McConnell Clarke Foundation for this paper to be presented at the Johns Hopkins University School of Hygiene and Public Health.

ELEMENTAL CHANGES DURING SEXUAL MATURATION IN *Schistosoma mansoni*

MICHAEL K. SHAW

Department of Zoology
University College, P.O. Box 78
Cardiff CF1 1XL, Wales, U.K.

(Received October 1, 1985; accepted February 26, 1986)

Abstract—Changes in the elemental composition of *Schistosoma mansoni* in relation to age and sexual status are described, and studies on the structural localization of calcium in adult worms and the elemental composition of the tegument-subtegumental tissues are reviewed. Some preliminary results on the distribution of Ca^{2+}-dependent ATPase activity in the tegument of worms from both mixed and single-sex infections are also presented.

Key Words—*Schistosoma mansoni*, inorganic metabolism, elemental composition, sexual status, calcium localization, X-ray probe microanalysis, cryosections, tegument, subtegumental tissues, Ca^{2+}-dependent ATPase activity.

INTRODUCTION

Despite significant advances in our understanding of the biology of *Schistosoma mansoni*, information about inorganic metabolism and ionic regulation in both *S. mansoni* and digeneans in general is very limited (see Brand, 1966, 1979; Barrett, 1981; Coles, 1973, 1975, 1984). Until very recently, apart from reports on the influence of salinity on the survival of schistosome cercariae (e.g., Donnelly et al., 1984), our knowledge of the inorganic metabolism of schistosomes has been largely confined to reports of the presence of calcium in the cercarial penetration glands (Dresden and Edlin, 1975; Dorsey and Stirewalt, 1977), and the presence of calcium in the mature vitelline cells of *S. mansoni, S. haematobium*, and *S. mattheei* (Erasmus and Davies, 1979; Erasmus et al., 1982; Shaw and Erasmus, 1982).

For a number of years we have been interested in the biology and metabolism of the male–female relationship of *S. mansoni*. Our aim has been to define

0098-0331/86/0800-1765$05.00/0

more precisely the changes occurring during sexual development and the factors necessary for the maintenance of sexual maturity, particularly in female worms (see review by Erasmus, 1986). Following the initial work of Erasmus and Davies (1979) we have begun to look at various aspects of the inorganic metabolism of *S. mansoni*, particularly in relation to age and sexual status of the worms. The present article reviews our previous work and briefly describes the results from a number of current investigations.

OBSERVATIONS AND DISCUSSION

In our initial study (Shaw and Erasmus, 1983) changes in the elemental contents (Ca, P, K, Mg, and S) of whole male and female *S. mansoni* from both mixed and single-sex infections were measured at various times postinfection, using a quantitative method of X-ray analysis (Davies and Morgan, 1976; Morgan, 1983). From this study the most obvious difference between mixed infection male and female worms and worms from single-sex infections was the significantly higher levels of calcium in females from mixed infections, particularly after 35 days postinfection (DPI) (i.e., after sexual maturation) (Figure 1). Slightly higher levels of phosphorus were also found in female worms from mixed infections as compared to male worms or females from single-sex infections. The levels of the other elements measured (Mg, S, and K) were, in general, similar in male and female worms from both types of infection.

In *S. mansoni*, the main anatomical difference between male and female worms from mixed infections, and between female worms from mixed and single-sex infections, is the presence in sexually mature females of an extensive vitelline gland system (Erasmus, 1973). The mature, stage 4, vitelline cells of *S. mansoni* contain discrete Ca- and P-containing granules (Erasmus and Davies, 1979), and the presence of these granules presumably accounts for the significantly higher levels of calcium found in the sexually mature females. Also, in female worms from mixed infections there is a sharp rise in calcium (Figure 1) and, to a lesser extent, phosphorus levels, between 30 and 35 DPI. This coincides with the rapid development of the vitelline gland and the beginning of egg production. In contrast, females from single-sex infections do not show any dramatic increase in calcium content during the same period. Over the long term (up to 250 DPI) there is a very slight, although variable, increase in calcium content with increased age. This may reflect the low level of differentiation, maturation, and turnover of vitelline cells reported in females from single-sex infections (Shaw and Erasmus, 1981).

From this initial study, it was obvious that there are significant differences in the calcium metabolism of *S. mansoni* particularly in relation to the degree of sexual development of the female worms. This study, however, only provided data on the total calcium content of individual worms and, apart from the

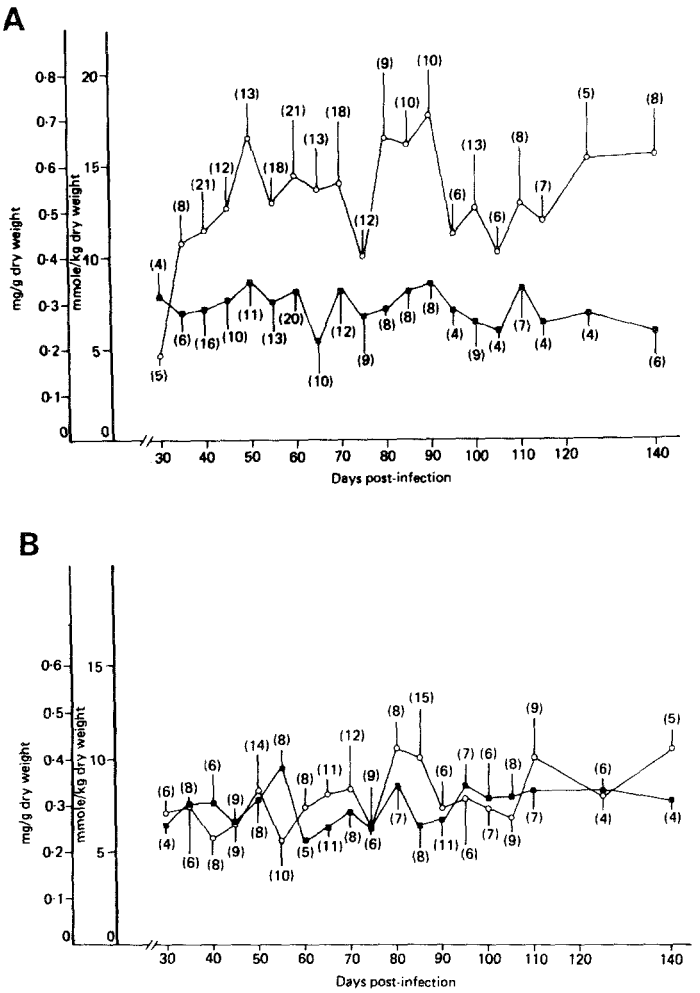

FIG. 1. Changes in the calcium content of male (●) and female (○) *Schistosoma mansoni* from (A) mixed-sex infections and (B) single-sex infections. All values are the mean ± SD. Figures in parentheses are the number of samples analyzed. (From Shaw and Erasmus, 1983.)

study of Erasmus and Davies (1979), little information was available regarding the structural localization of calcium within adult worms.

Initial attempts at localizing calcium within adult worms using either the pyroantimonate or oxalate precipitation methods were not very successful (unpublished observations). These techniques, which involve precipitating reactions and the subsequent analysis of the precipitates have many serious disad-

vantages (Chandler, 1978; Morgan et al., 1978; Morgan, 1980), and the use of freeze-dried cryosections with electron probe X-ray microanalysis has provided a more reliable and accurate method for examining the in vivo distribution of elements within adult *S. mansoni*.

In general, unstained freeze-dried cryosections of the tegument and subtegumental tissues of adult *S. mansoni* have sufficient mass contrast to enable ultrastructural details to be readily correlated with structures recognizable in conventionally fixed and embedded material (see for example Shaw and Erasmus, 1984). We have employed this technique to determine the distribution of calcium within adult *S. mansoni*, and the elemental composition of the tegument and subtegumental tissues of adult worms.

Sites of Calcium Localization in Adult Worms

Males. A conspicuous feature of freeze-dried cryosections of male worms is the presence within the parenchymal tissues of groups of electron-dense granules. These granules, which measure 50–130 nm in diameter, consist of an inner dense core separated from the enclosing membrane by a thin layer of less dense material (Figure 2). X-ray analysis of these granules has shown that they contain, in comparison with the surrounding cytoplasm, significantly larger amounts of calcium and sodium (Figure 2) (Shaw et al., 1982).

These granules have been correlated with the electron-dense, membrane-bounded granules found throughout the peripheral nervous system in sections of glutaraldehyde-fixed material.

Some of the dense granules in *S. mansoni* have been shown to contain the neurotransmitter 5-hydroxytryptamine (5HT) (Dei-Cas et al., 1979), and *S. mansoni* is known, in toto, to contain relatively high levels of 5HT (Bennett et al., 1969). Therefore, a significant proportion of the total calcium in adult male worms may be localized within parts of the nervous system. In comparison with the neuronal granules, the general cytoplasm also contains calcium, albeit at a very much lower level (between 10 and 100 times less), although these low levels of calcium may in total contribute significantly to the total calcium content. What proportion of the total calcium in adult male worms is "parenchymal" as opposed to neuronal is not known. The only other major site(s) of calcium localization in male worms is within the small number of mature vitelline cells present in some worms (Shaw and Erasmus, 1982).

Females. The mature, stage 4 vitelline cells in both *S. mansoni* and *S. haematobium* contain conspicuous inclusions which have been shown to contain calcium, phosphorus, and magnesium (Erasmus and Davies, 1979). Comparison of the calcium contents of female *S. mansoni* from mixed and single-sex infections would suggest that between 50 and 75% of the total calcium in sexually mature, egg-laying female worms is located within the vitelline gland and more specifically within the mature, stage 4 vitelline cells.

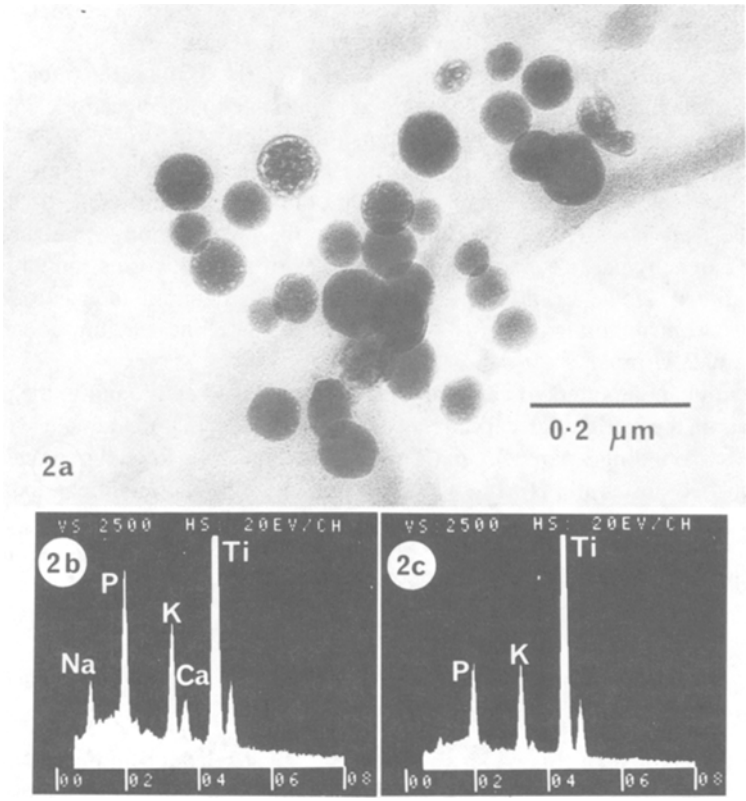

FIG. 2. (a) High-power electron micrograph of the dense granules from the peripheral nervous system of adult male *Schistosoma mansoni*. Freeze-dried cryosection. (b) X-ray spectrum of a group of neuronal granules from a cryosection of *S. mansoni*. Note sodium and calcium peaks. (c) X-ray spectrum of the cytoplasm adjacent to neuronal granules analyzed in b. Note absence of sodium and calcium peaks. (From Shaw et al., 1982).

If it is assumed that each female *S. mansoni* produces between 200–300 eggs per day and that each egg contains, on average, 38 vitelline cells (Gönnert, 1955), then the productivity of the vitelline gland as a whole must be large, producing and releasing up to 11,000 cells/24 hr. Consequently, the total calcium turnover of sexually mature female *S. mansoni* must be relatively large. The physiological significance of relatively large amounts of calcium within the vitelline cells of sexually mature female *S. mansoni* is not known (for a discussion of the possible roles of this calcium, see Erasmus and Davies, 1979; Shaw and Erasmus, 1983), although the presence of calcium-containing corpuscles within the mature vitelline cells present in male worms (Shaw and Erasmus,

1982) would suggest that calcium sequestration was, in itself, a normal part of the developmental biology of the vitelline cells of *S. mansoni*.

Sexually mature female *S. mansoni* feed at nearly 10 times the rate of male worms (Lawrence, 1973), and it was thought possible that the gastrodermis and gut lumen contain relatively large amounts of calcium. Analysis of freeze-dried cryosections of the posterior regions of the gut have shown that, although calcium is present in both the lumen and within the gastrodermis itself, the levels observed were not significantly different from the levels found in the subtegumental/parenchymal (i.e., non-vitelline) tissues of female worms (unpublished observations). However, it is again possible that the calcium in the gastrodermis may also contribute significantly to the total non-vitelline calcium content of adult female worms.

Significant amounts of calcium (and sodium) have been found in the dense granules in the peripheral nervous system of sexually mature female worms, and the surrounding "parenchymal" cytoplasm contains a low level of calcium (unpublished observations). In contrast to male worms, the tegument and, to a lesser extent, the subtegumental tissues of adult female *S. mansoni* contain relatively higher levels of calcium and, in relatively small areas of the tegument, isolated calcium-containing granules have been found (Shaw and Erasmus, 1984; see below).

Elemental Composition of Tegument and Subtegumental Tissues of Adult S. mansoni

In the context of this paper, probably the most relevant finding from this study was that there are statistically significant differences in the elemental composition of the tegument and subtegumental tissues between adult male and female worms, particularly in relation to the levels of calcium (see Shaw and Erasmus, 1984). In general, both the tegument and subtegumental tissues of female worms contain significantly higher elemental levels than the equivalent tissues in male worms. In particular, the female tegumental cytoplasm was found to contain significantly higher levels of both calcium and sodium and, in a number of relatively small areas, discrete calcium-rich granules.

Sexually mature female *S. mansoni* have been shown to contain significantly higher levels of calcium than either male worms or females from single-sex infections (Figure 1) (Shaw and Erasmus, 1983). This higher calcium content is due primarily to discrete calcium deposits within the mature vitelline cells (Erasmus and Davies, 1979). As sexually mature females may produce up to 300 eggs/female/day with each egg containing, on average, 38 vitelline cells (Gönnert, 1955), the demand and turnover of calcium within female worms must be considerable. As yet the physiological significance of this vitelline cell calcium is not known. However, the results of this study, taken in conjunction with the fact that the gut lumen and gastrodermis contain relatively smaller

amounts of calcium (unpublished observations), would suggest that this calcium demand is met, in part at least, by calcium uptake across the tegument.

The schistosome tegument has long been recognized as an important site for nutrient uptake (Pappas and Read, 1975), and there are a number of sex-specific differences in the uptake of certain amino acids (Cornford and Oldendorf, 1979) and glucose (Cornford and Huot, 1981). For a number of amino acids and hexoses in particular, this transtegumental uptake appears to be sodium-dependent (Barrett, 1981; Podesta and Dean, 1982). The presence of significantly higher levels of sodium in the female tegument would therefore be consistent with higher sodium-dependent nutrient uptake in sexually mature female worms.

Tegumental ATPase

The tegument plays a very important role in schistosome biology, and recently there has been a considerable amount of interest in the biochemistry of the tegument (see review by Coles, 1984). In particular, a Ca^{2+}-stimulated ATPase has been found associated with the tegumental membranes in adult *S. mansoni* (Podesta and McDiarmid, 1982), and as adult male worms are able to maintain a lower Ca^{2+} concentration within the tegument than occurs in the surrounding medium (Fetterer et al., 1980), it has been suggested that this enzyme may be involved in moving Ca^{2+} out of the worm (Cesari et al., 1981). In view of the differences in the calcium content of *S. mansoni*, particularly in relation to the sexual status of the female worms, studies are now in progress looking at the distribution of ATPases within the tegument of worms from both mixed and single sex infections.

Both Ca^{2+}-dependent (EC 3.6.1.3) and nonspecific (Na-K-Mg) ATPase activity were localized in whole worms using a modified one-step lead citrate method (Ando et al., 1981).

In female worms from mixed-sex infections Ca^{2+}-dependent ATPase activity was observed primarily in the tegument and in the cytoplasmic processes connecting the tegument with nucleated tegumental cytons (Figure 3a). Some reaction product was occasionally seen within the cytoplasm surrounding the tegumental nuclei. In the tegument the Ca^{2+}-dependent ATPase activity was associated with the cytoplasmic faces of both the outer and inner basal tegumental membranes, although in many regions high concentrations of reaction product also occurred over the tegumental cytoplasm in general. No marked Ca^{2+}-dependent ATPase activity was observed in association with either the tegumental spines or within the tegumental sense organs.

In sexually mature female worms Ca^{2+}-dependent ATPase activity was also localized around/over both the subtegumental muscles and the musculature beneath the gastrodermis. Membrane-associated activity was observed in parts of the excretory system. In comparison, female worms from single-sex infec-

(b) Tegument of a female *Schistosoma mansoni* from a single-sex infection showing the absence of Ca^{2+}-dependent ATPase activity. Note some activity in the subtegumental muscles (arrows). (c) (Na-K-Mg)-dependent ATPase activity in the tegument of female *S. mansoni* from single-sex infection.

tions showed little or no Ca^{2+}-dependent ATPase activity in either the tegument or tegumental connections (Figure 3b), although reaction product was present around/over the subtegumental musculature and in parts of the excretory system. In male worms Ca^{2+}-dependent ATPase activity was localized in the tegument, in the tegumental connections, around/over the subtegumental muscles, and in parts of the excretory system.

In complete contrast to the sexual-status-dependent distribution of Ca^{2+}-dependent ATPase activity in female worms, females from both mixed and single-sex infections showed tegumental staining for (Na-K-Mg)-dependent ATPase (Figure 3c).

In control worms, no marked ATPase activity was observed in specimens incubated in substrate-free medium, although some small areas of the tegument and tegumental connections showed very slight membrane-associated reaction product, suggesting the presence of endogenous substrate. Further control experiments using a number of inhibitors, e.g., bromotetramisole, *p*-hydroxymercuribenzoate, and ouabain, are in progress.

These preliminary results on Ca^{2+}-dependent ATPase activity, taken in association with our initial studies on changes in calcium levels in relation to the sexual status of the worms, suggest that significant and fundamental changes also occur in the physiology of the tegument of female worms concomitant with the previously described morphological and overall biochemical changes that occur during sexual maturation.

Abstract—In schistosomes, the mating process influences male–female transfer and gender-specific exchange of nutrients. The paired male schistosome provides glucose to the female partner. Male-to-female intertegumental transfer of ^{14}C-labeled glucose, ^{14}C-labeled 3-*O*-methylglucose, [^{14}C]2-deoxyglucose and 2-fluorodeoxyglucose has been demonstrated in schistosomes. This phenomenon has been studied extensively in *Schistosoma mansoni*, and confirmed in *Schistosoma japonicum*, as well as *S. haematobium*, using radioactive pulsing methods. Male schistosomes contain significantly greater quantities (nmol/mg worm water) of glucose than do females. The transfer of glucose is apparently not an energy-dependent process, but occurs along this concentration gradient. Most, if not all, of the glucose utilized by the female is transferred from the male partner via tegumentary-facilitated diffusion mechanisms, free diffusion, or some combination of these two components. Unpaired male schistosomes contain greater quantities of glycogen than do comparable paired schistosomes, indicating that the presence of a female in the gynecophoral canal depletes the reserves of the male partner; this is additional indirect evidence for male-to-female transfer of glucose. Tegumentary surface uptake of acidic amino acids has been compared in paired and separated male and female schistosomes. In *S. mansoni*, a saturable carrier-mediated mechanism has been defined which operates only in unpaired male and unpaired female teguments. In contrast, the uptake of aspartate and glutamate is not seen in paired worms of this species. Tegumental uptake of acidic amino acids is not observed in paired or unpaired male or female *S. japonicum*. However, in *S. haematobium*, significant quantities of aspartate are taken up by both paired and unpaired male schistosomes. Measurable aspartate uptake is seen in paired female *S. haematobium*, but in the separated female, there is minimal uptake of this acidic amino acid. Thus the permeability of the teguments of human schistosome species to acidic

0098-0331/86/0800-1777$05.00/0

amino acids is modified in response to the paired state in *S. mansoni* and *S. haematobium*, but these characteristics are not shared by *S. japonicum*.

Key Words—*Schistosoma mansoni, Schistosoma haematobium, Schistosoma japonicum*, glucose transfer, glycogen, glutamate, [^{14}C]aspartate, mating.

INTRODUCTION

It is now well established that many nutrients required by schistosomes can be assimilated across the tegumental surfaces (Fripp, 1967; Rogers and Bueding, 1975; Senft, 1968; Cornford and Oldendorf, 1979) and that a functioning gut is not essential to in vitro survival (Popiel and Basch, 1984b). The present discussion will focus upon male–female exchange of materials between the schistosome pair. A second area of focus will be tegumental exchange between the culture medium and schistosome tissues and specific consideration of the influence of mating upon nutrient uptake in male and female schistosomes.

More than 40 years ago, the possibility of male-to-female transfer of materials was suggested by Vogel (1941). The transfer of nutrients as well as hormones or pheromones was again suggested by Senft (1968, 1969). He suggested that ventralization of nutrients by the male may play a significant role in the nutrition of the female. Lennox and Schiller (1972) noted that fluctuations in glycogen content of male schistosomes were reflected in their female partners. They also indicated that in vitro studies had similarly shown a parallel depletion of histochemically demonstrable glycogen from the tissues of paired male and female schistosomes. It was suggested that the carbohydrate metabolism of the female in vivo was in some way dependent on the male partner. Furthermore, a nutritional relationship was given as the primary mechanism responsible for the growth of female worms subsequent to pairing (Lennox and Schiller, 1972). In a comparative study of glucose uptake by way of either the oral sucker or the tegumental surfaces, Rogers and Bueding (1975) reported that the tegument was probably the only site of glucose absorption by *S. mansoni*. The demonstration of tegumental glucose uptake by female worms was considered to support a hypothesis that, in schistosome pairs, the male provided glucose to the female.

We developed a triple-isotope technique for the study of nutrient transfer across the schistosomal tegument (Cornford and Oldendorf, 1979). This method (Figure 1) involves immersion of the isolated schistosomes (Duvall and DeWitt, 1967) in a buffered saline medium which contains tritiated water, a ^{14}C test substance such as glucose or an amino acid, and indium-113m chelated to EDTA. As the schistosomes are immersed in the isotopic medium, nearly all the tritiated water penetrates rapidly. An unknown quantity of the ^{14}C test substance penetrates, and, because the indium–EDTA chelate is excluded by intact

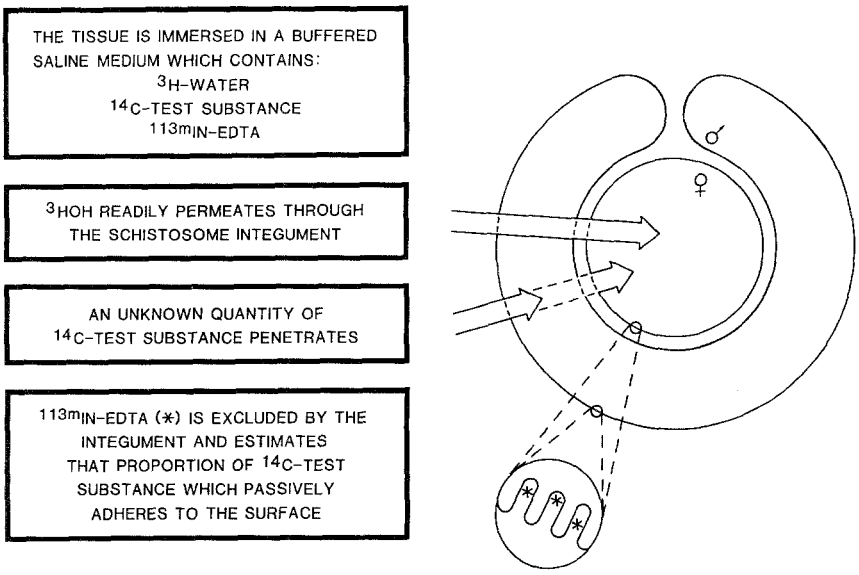

FIG. 1. The triple-isotope method involves immersion of tissue in a buffered saline medium which contains tritiated water, a ^{14}C test substance (e.g., glucose or amino acid), and indium-113m chelated to EDTA. Nearly all the tritiated water rapidly penetrates through the schistosome tegument. An unknown fraction of the ^{14}C test substance penetrates, and the ^{113m}In–EDTA chelate, which is excluded by intact membranes, is used to estimate that proportion of the ^{14}C test substance which passively adheres to the external surfaces of the schistosome. The incubation is halted by removing the schistosomes from the radioactive medium and flooding them with ice-cold silicone oil. This oil rinse not only removes excess surface-adherent isotopes by a sheeting action, but also minimizes evaporative loss of tritiated water. In addition, separation of paired male and female schistosomes is facilitated in this silicone oil environment. Isotopic content of the schistosomes, and of a known volume of the saline medium, is determined routinely in a liquid scintillation counter. The schistosomal tissue uptake index (TUI) equals (^{14}C DV − ^{113m}In DV)/(^{3}H DV) where DV = the distribution volume of each isotope, and the TUI is typically expressed as a percentage. Other studies (Cornford et al., 1982) have demonstrated that the distribution volume of water (= ^{3}H DV) can be correlated with traditional estimators of mass such as wet weight or protein content.

living membranes (such as the schistosome tegument), the third isotope is used to estimate that proportion of the ^{14}C test substance which passively adheres to the schistosomal surfaces. The isotopic content of the schistosomes, and also the isotopic content of the medium, are then measured, and the distribution volume of each isotope defined precisely. The schistosomal tissue uptake index (TUI) is a ratio of the distribution volumes of ^{14}C and ^{3}H, and it has been established that water content in both male and female schistosomes can be correlated with mass measurements (schistosome wet weight and protein con-

tent; Cornford et al., 1982). The distribution volume of water has also been correlated with protein content in *Schistosoma haematobium* and in *Schistosoma japonicum* to establish a broad base for the use of this technique. Estimation of that fraction of test substance which is passively carried on the folded tegumental surfaces of schistosomes is achieved by measuring the distribution volume of ^{113}m In–EDTA chelate. This isotope has a short half-life ($t1/2$ = 100 min), and its emissions are both gamma and beta conversion electrons. Thus the indium content of tissues can be determined without digestion of the schistosome in a gamma counter, or the high-energy beta conversion electrons may be easily distinguished from ^{14}C in a scintillation counter. We typically measure indium emissions immediately upon conclusion of an experiment, and wait two days (when all the indium has decayed away) to measure tritium and carbon contents in the absence of ^{113}m In.

We had just begun to apply this technique to the study of nutrient uptake in schistosomes when we obtained a group of infected mice which had apparently been exposed to an excess number of male cercariae. In addition to the paired schistosomes, we also perfused a large number of unpaired males and proceeded to examine glucose uptake in these unpaired males as well as the paired worms (Figure 2). Over a wide range of hexose concentrations, we observed higher TUIs in the paired males than in comparable unpaired male schistosomes (Figure 2). Thus, the observation that a paired male schistosome had a higher glucose requirement than an unpaired worm seemed to indirectly support the hypothesis that, in paired schistosomes, males supplied glucose to the females.

Further study of this phenomenon utilized an experimental design in which paired schistosomes were separated prior to incubation in isotopic medium and then analyzed. Additional comparisons were made with results obtained where the paired worms were pulsed in isotopic medium and separated immediately after exposure to the isotopes for independent analysis. Consistently, it was observed that paired schistosomes incorporated more glucose than comparable unpaired schistosomes (Figure 3). Thus for both the male and female schistosomes, the paired state is characterized by an increased requirement for hexose. A more interesting trend observed, however, was that when unpaired male and unpaired female schistosomes were compared, the male uptake was generally greater than that of the female. In contrast, when we compared paired schistosomes, the female TUI was higher than that of the comparable paired male (Cornford, 1982; Cornford and Huot, 1981). These data further supported the possibility that the male schistosome could be transferring glucose, or glucose-derived metabolites, to the female partner.

Investigations of male-to-female transfer using isotopic methods are complicated by the fact that, if the male is rapidly pulsed with radiolabeled glucose and removed to a glucose-free medium, the radioactive glucose could equili-

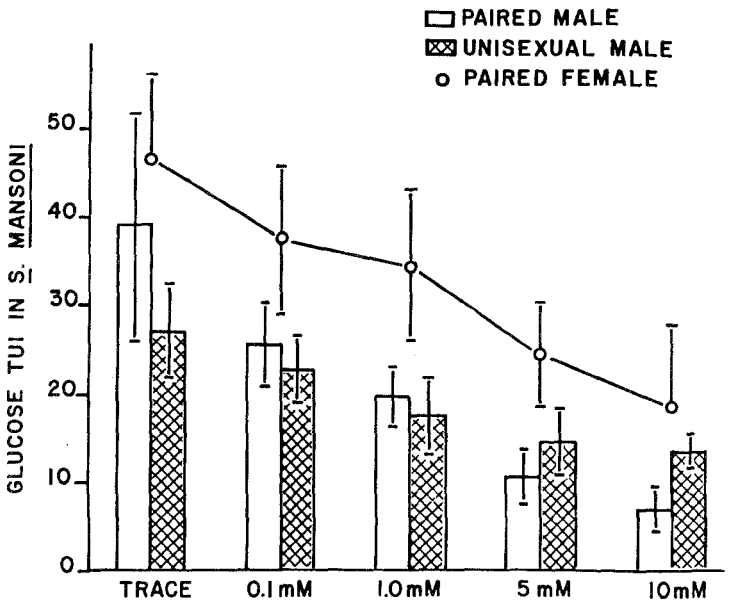

FIG. 2. A comparison of glucose uptake in paired male and female schistosomes as compared with TUIs in male schistosomes which were unpaired at the time of perfusion from mouse hosts. Over a wide range of glucose concentrations, higher glucose uptake was observed in paired males than in comparable unpaired male schistosomes, indicating that paired males apparently have a higher glucose requirement than seen in unpaired worms. The incubation period in isotopic medium was 15 sec, and each vertical bar represents ± 1 SD.

brate either into the female or into the external medium. The triple-isotope technique was consequently modified. Typically, perfused schistosomes are collected and maintained in vitro in culture medium for relatively short time periods. These schistosomes are then pulsed in radioisotopic medium, and the reactions terminated by immediately covering the schistosomes with silicone oil. This oil rinse removes excess adherent isotopic medium by a sheeting action. In addition, the use of ice-cold silicone oil depresses metabolic processes and exchange in the schistosomes. To minimize any possible evaporative loss of tritiated water, schistosome pairs are maintained under ice-cold oil while the male is mechanically separated from the female for subsequent digestion and analysis. To test for transfer of hexose isotopes from the male to the female, schistosome pairs were pulsed in isotopic medium, and then, instead of being covered with cold silicone oil, they were covered with warm (37°C) silicone oil and maintained in the warm oil for varying lengths of time (0.5–4.0 min). In mansonian female schistosomes which have been pulsed for 5 sec in radio-

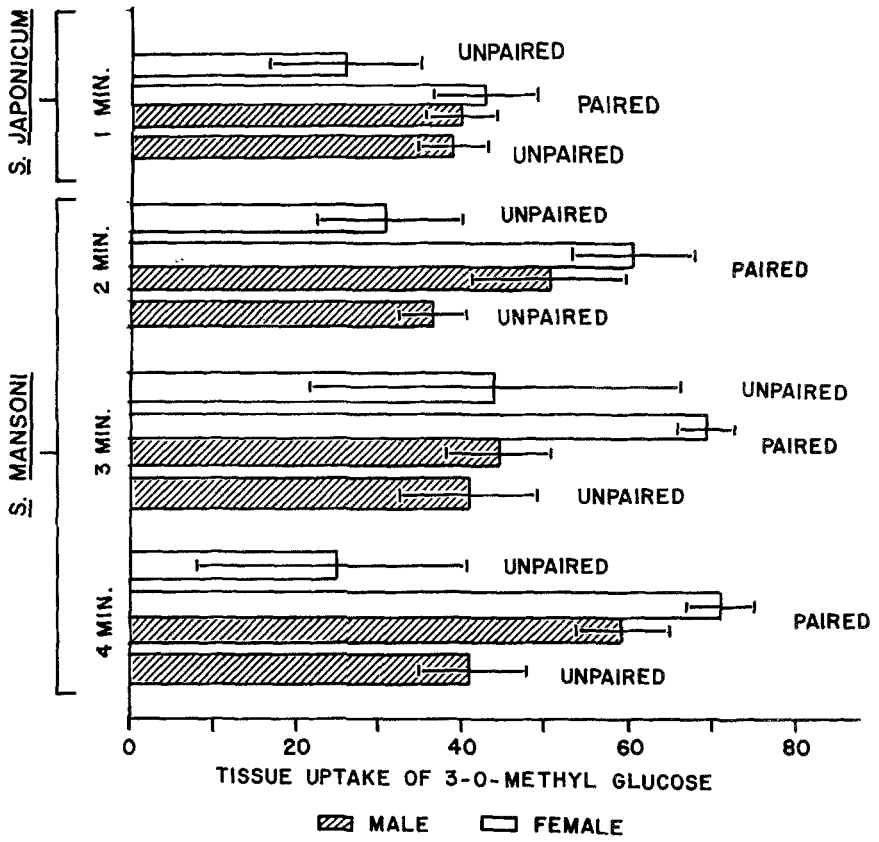

FIG. 3. Comparison of 3-*O*-methylglucose uptake in paired and separated male and female schistosomes. Note that, as in Figure 2, paired schistosomes incorporate more hexose than comparable unpaired schistosomes. Note that for each of the 1- to 4-min incubation periods studied, when schistosomes have been unpaired, the uptake measured in males is typically greater than that seen in females. In contrast, gender comparisons of paired schistosomes indicate that the female uptake is higher than that of the comparable paired male. Since it has been established that 3-*O*-methylglucose is transported, but not further metabolized in schistosomes (Isseroff et al., 1972), these data reflect the distribution of free hexose, rather than some glucose metabolite. Furthermore, the dramatically higher uptakes observed in paired (vs. unpaired) female schistosomes further support the possibility that the paired male schistosome could be transferring glucose to the female partner. Each horizontal bar represents ± 1 SD; $N > 5$ for each mean. (Adapted from Cornford, 1982.)

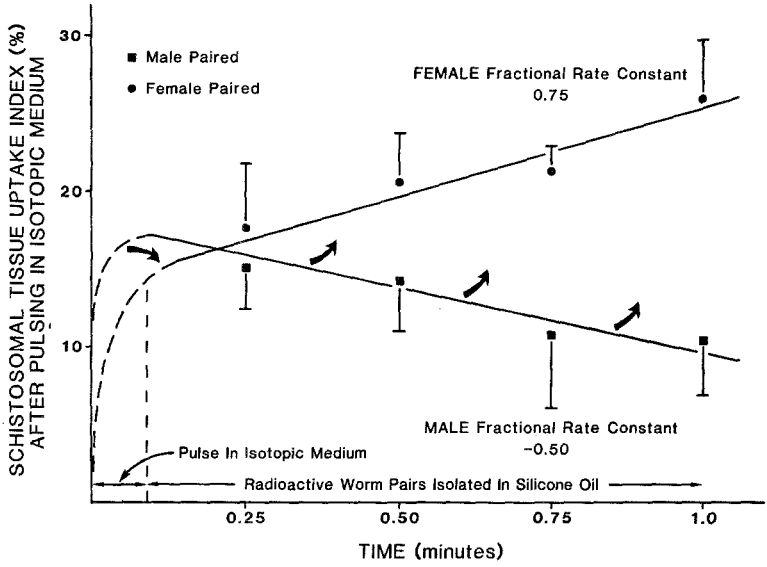

FIG. 4. Transfer of ^{14}C hexoses from the male to the female schistosome partner. (Adapted from Cornford and Huot, 1981; Cornford and Fitzpatrick, 1985.) When paired schistosomes are rapidly pulsed in radioactive glucose medium, and subsequently allowed to equilibrate in a silicone oil environment for varying lengths of time (0.25–4 min), a time-dependent increase in glucose content of the female schistosomes is observed. Concomitantly, a time-dependent decrease in glucose content of the male schistosome partners is observed. Thus, as indicated by the arrows above, [^{14}C]glucose is transferred from the male to the female schistosome partner. In the studies of Cornford and Fitzpatrick (1985), the amount of glucose gained by the female partner each minute was equal to 75% of the total free glucose present in the female. Male schistosomes lose an amount equal to 50% of the total free glucose present, as indicated by the fractional rate constants.

active glucose, chilled with cold oil, and analyzed, we typically observed a mean TUI of about 20%. Females which had been pulsed for 5 sec, and subsequently maintained in warm oil for varying periods of time prior to analysis, consistently showed a time-dependent increase in glucose content (Figure 4). In the male schistosome partners, a concomitant time-dependent decrease in glucose content was typically observed (Figure 4).

To insure that the phenomenon observed was not an artifact of the TUI technique, the distribution volume of tritiated water was measured in both male and female schistosomes. No difference was observed for water content of males pulsed for 5 sec, chilled, and examined, as compared to males which had been pulsed for 5 sec and maintained in warm oil for periods of 2 or 3 min. Similarly, the distribution volumes of water in the comparable female schistosomes showed no significant changes in the experimental time periods employed (Cornford

and Huot, 1981). These studies established that, after pulsing in [^{14}C] glucose, the transfer of ^{14}C from the male to the female schistosome did indeed occur. This phenomenon was observed using D-[^{14}C]glucose and confirmed using [^{14}C]2-deoxy-D-glucose. This hexose analog may be phosphorylated in most biological systems, but it is not further degraded, and the 2-deoxy-D-glucose-6-phosphate thus formed remains trapped intracellularly for extended periods of time (Sokoloff et al., 1977). Furthermore, the transfer of [^{14}C]3-*O*-methylglucose from male to female schistosomes has been established (Cornford and Huot, 1981). 3-*O*-Methylglucose is transported across the schistosome tegument by the glucose transport (facilitated diffusion) system, but not metabolized (Isseroff et al., 1972). Thus the molecular species that is exchanged in the hexose, rather than some glucose metabolite (Cornford and Huot, 1981).

It has also been demonstrated that both [^{14}C]glucose and [^{14}C]3-*O*-methylglucose can be transferred from male to female *S. japonicum*. In addition, transfer of glucose has been established in the Egyptian strain of *S. haematobium*. In the latter species, not only is a time-dependent increase in the glucose content of females seen, but a time-dependent decrease in the glucose content of male schistosomes was concomitantly observed in every instance. The physical appearance of *S. haematobium* pairs is characterized by the fact that the female is most consistently retained within the male gynecophoral canal, and the only portion of the female surface exposed to culture medium is anterior of the acetabulum. Thus this species is particularly suited to the study of male-to-female transfer phenomena, and the most unequivocal demonstrations of transfer are observed in *S. haematobium*. Curiously, it has also been demonstrated that the most striking examples of gender-specific polypeptides were observed in *S. haematobium* (Aronstein and Strand, 1983), and the authors also suggested that because *S. haematobium* males had eight unique polypeptides, this species was the appropriate model for study of gender-specific phenomena. To summarize, male-to-female intertegumental transport of ^{14}C-labeled glucose, ^{14}C-labeled 3-*O*-methylglucose, [^{14}C]2-deoxy-D-glucose (Cornford and Huot, 1981; Cornford, 1982), and 2-fluorodeoxy-D-glucose (Cornford and Fitzpatrick, 1985) has been demonstrated in schistosomes. In addition, this phenomenon has been studied extensively in *S. mansoni* and confirmed in *S. japonicum*, as well as *S. haematobium*.

Once the transfer of glucose had been established, it became necessary to estimate how much glucose was transferred. If the quantity exchanged from the male to the female was comparable to the rate at which glucose was metabolized, this would be presumptive evidence for male-derived glucose as the primary or sole source of hexoses for the female partner. Alternatively, the female gut could be an additional source of glucose, if only a relatively small quantity is transferred from the male to the female in paired worms. Definition of the mechanism by which glucose is transferred also is of importance. It was reasoned that either an active mechanism pumped glucose between the male and

the female, or glucose was transferred along a concentration gradient. If a concentration gradient existed between the male and female schistosome, then the free glucose level in males would be anticipated to be greater than that of female schistosomes. Alternatively, if glucose levels were similar in the paired male and female schistosomes, then presumably an energy-consuming active mechanism must exist and be responsible for the transfer of glucose. Since active transport mechanisms are typically inhibited by ouabain, Cornford and Fitzpatrick (1985) compared glucose transfer in schistosomes exposed to ouabain (preincubated 2 min in 1 mM ouabain) with that of untreated paired worms. Their initial studies demonstrated that the transfer of glucose from males to females was not sensitive to ouabain, and they thus focused their attention on the alternate possibility that a concentration gradient of glucose existed between the male and female schistosomes. Certain problems exist in measuring free glucose levels. Glucose utilization rates are extremely high in schistosomes (Bueding, 1950), and thus schistosomes must be rapidly fixed. In addition, it is important to discriminate between intraworm free glucose and free glucose which may be carried on the amplified external surfaces of the schistosome tegument.

As indicated in Figure 5, it was established that in mansonian male schistosomes, the free glucose level represented 20–30% of the external medium, and levels in the female partners were 40–50% less. Studies of pairs which had been separated and maintained in vitro indicated that unpaired males also had slightly greater free glucose concentrations than paired mansonian males. Cornford and Fitzpatrick (1985) further established that in *S. haematobium* and *S. japonicum*, male schistosomes had significantly higher free glucose contents than seen in females of these two species (Figure 5). Other work demonstrated that, over the range of glucose concentrations anticipated to exceed minimal and maximal portal blood glucose levels (5–20 mM), the free glucose content of mansonian males was always significantly higher than that of female schistosomes. It was concluded that glucose was not actively transported between the paired worms, but exchanged along this concentration gradient. The glucose gradient transfer is accomplished by way of the facilitated diffusion (transport) mechanism, by free diffusion, or by some combination of these two components.

The quantity of glucose transferred between mansonian pairs of schistosomes has also been estimated. In a silicone oil environment, devoid of exogenous glucose, *S. mansoni* females receive 0.1 μmol/mg dry wt/hr (Cornford and Fitzpatrick, 1985). It was conservatively estimated that at least 40% of the glucose utilized by the female schistosome was obtained from the male partner. However, this estimate was based upon a glucose utilization rate of 0.38 μmoles/mg hr of intact worm pairs in a medium containing 8–11 mM glucose (Shapiro and Talalay, 1982). These authors further indicated that the glucose consumption rate was a saturable function of glucose concentration; at a medium con-

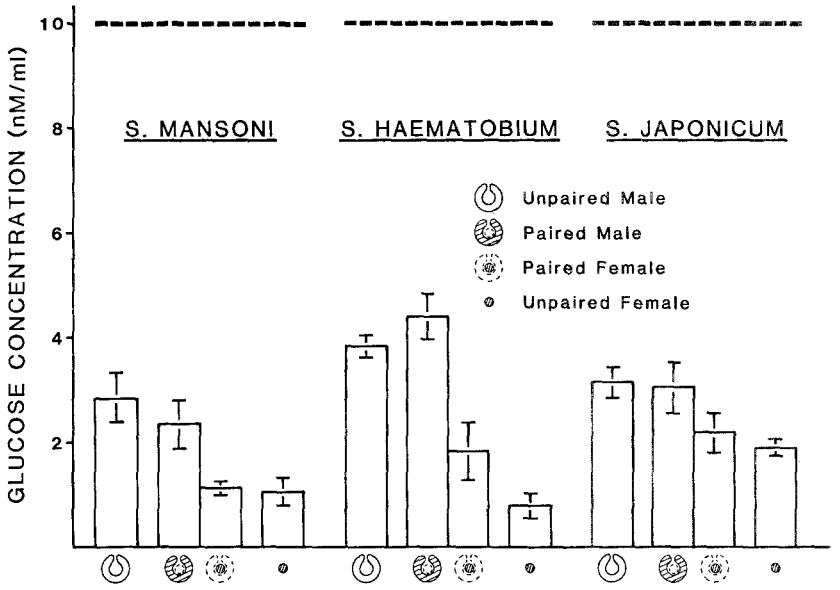

FIG. 5. Free glucose content in separated and paired male and female schistosomes after in vitro incubation in a medium containing 10 mM glucose. Note above that male schistosomes have significantly higher free glucose concentrations (nmol/ml worm water) than seen in females of the same species. In mansonian schistosomes, a gradient exists such that the free glucose content of male schistosomes is 20–25% that of the medium, and females contain only about half the concentrations seen in their male partners. In all three species examined, the presence of a distinct gradient (medium > male > female), together with the observation that male-to-female transfer of glucose was not ouabain-sensitive (Cornford and Fitzpatrick, 1985), indicates that glucose is not actively transported between the paired worms, but rather exchanges along this concentration gradient. Presumably this gradient transfer involves a saturable facilitated diffusion mechanism, free diffusion, or some combination of these two components. (Adapted from Cornford and Fitzpatrick, 1985; each vertical bar = ±1 SD.)

centration of 11 mM glucose, this represented 95% of the calculated maximum rate. Other workers have also reported that glucose utilization rate may be a function of the glucose concentration in the medium. For example, Watts (1978) indicated that when schistosomes were maintained in 0.4 mM glucose, the glucose utilization rate was one fourth to one fifth of that measured for pairs maintained in 5 mM glucose. Since the tegument is believed to be the only site of glucose uptake by *Schistosoma mansoni* (Rogers and Bueding, 1975), it seems reasonable to assume that most, if not all, of the glucose utilized by the paired female schistosome is obtained from the male partner. Any portion of the female surface exposed in vitro to the plasma, as would occur during egg deposition, can directly assimilate glucose.

One other report suggested that male *S. mansoni* synthesize a 66,000-molecular-weight protein which is not synthesized by the female (Atkinson and Atkinson, 1980). It was further suggested that this labeled polypeptide could be transferred from the male to the female over a 20-hr time period. In a subsequent study, some 75 polypeptides were resolved in two-dimensional gels of [^{14}C]leucine-labeled male and female *S. mansoni* (Atkinson and Atkinson, 1982). The extensive studies of Popiel and Basch (1984a) failed to demonstrate transfer of any polypeptides from male to female mansonian schistosomes. Thus the contemporary understanding of intertegumental exchange between the paired male and female schistosome can be succinctly summarized. Transfer of polypeptides does not occur (Popiel and Basch, 1984a). The stimulation of vitelline development in unisexually reared female *S. mansoni* by a lipid-soluble extract obtained from male worms (Shaw et al., 1977) was believed to be indirect evidence for male-to-female transfer of materials. However, this topic is currently under reinvestigation (Popiel, personal communication). Although the transfer of hexoses from male to female schistosomes has been established and confirmed in three different studies (Cornford and Huot, 1981; Cornford, 1982; Cornford and Fitzpatrick, 1985), it has yet to be confirmed outside our laboratory.

Analyses of glycogen contents in unpaired and paired male schistosomes, as well as paired females, indicate that unpaired males are distinctly different from paired males (Figure 6). In three different human species, it has been demonstrated that glycogen content was significantly lower in female than male schistosomes, and significantly higher in unpaired males than in paired males (Cornford and Huot, 1981). This observation has been confirmed in other laboratories (Bueding, personal communication). Thus the presence of a female in the gynecophoral canal of the male has the ability to diminish or deplete glycogen stores in the male partner, and thus represents indirect evidence supporting glucose transfer from male to female schistosomes. When radiolabeled schistosome pairs are transferred into hosts which subsequently receive a second transfer of unlabeled, unpaired male schistosomes, Cioli (personal communication) has observed that a small but significant number of radiolabeled females are recovered two weeks later paired with nonradioactive males. Thus female mansonian schistosomes are apparently able to change male partners in vivo. However, the elevated glycogen content distinctive in unpaired males can be attributed to the fact that schistosomal glycogen levels change rapidly in response to nutritional stress (Cornford et al., 1983), in addition to the low frequency with which female schistosomes change partners.

Most parasitic platyhelminths are hermaphroditic. Sexual dimorphism is a unique characteristic of schistosomes, and complete maturation of female worms is dependent upon a close association with the male partner. Three to six decades ago, the influence of mating upon female somatic development in *S. japonicum* was described (Severinghaus, 1928; Moore et al., 1954). The lack of

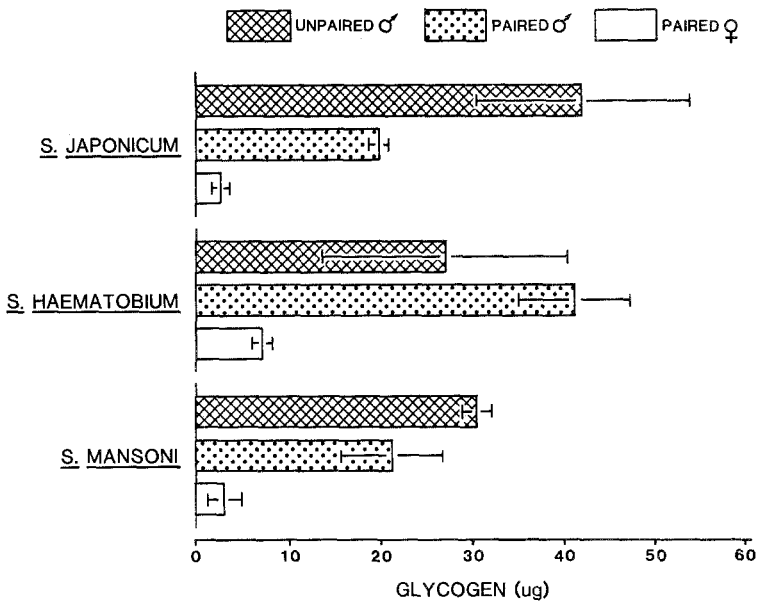

FIG. 6. Comparison of glycogen contents in paired male and female schistosomes, as well as unpaired males perfused from the same infections. In the three human schistosome species, unpaired males have significantly greater quantities of glycogen than do paired male schistosomes (adapted from Cornford and Huot, 1981). These observations suggest that the presence of a female within the gynecophoral canal of the male partner has the ability to diminish or deplete glycogens reserved in the male partner. These observations represent indirect evidence supporting glucose transfer from male to female schistosome partners. (Each vertical bar = ±1 SD; adapted from Cornford and Fitzpatrick, 1985.)

growth of female "mesenchymal cells" was reported to be a consequence of the failure to mate (Severinghaus, 1928). In *S. haematobium* (Brumpt, 1936) and *S. mansoni* (Moore et al., 1954; Armstrong, 1965; Erasmus, 1973), the full growth and sexual maturation of female worms depend upon their physical contact with the male. It was also noted that females derived from unisexual infections were smaller and showed incomplete development of the reproductive system. In contrast, in *Schistosomatium douthitti* (Short, 1952) and *Heterobilharzia americana* (Armstrong, 1965), females will grow, but to a smaller size, in the absence of the male; but parthenogenetic production of eggs which produce viable miracidia has been reported. Vogel (1941) indicated that egg production and full somatic development of the human blood flukes required the stimulation of an enveloping male partner.

In a study where intact female worms were allowed to pair in vitro with male worm segments, Popiel and Basch (1984b) noted that vitelline gland differentiation in the females was restricted to the area of male contact and was

not propagated throughout the worm. They concluded that nutrients absorbed through the tegument were responsible for the survival of worms lacking a functioning gut; secondly, that worm-pairing male stimulation and female developmental response occurred in segments lacking cerebral ganglia; and thirdly, that males had no centralized location for the female-stimulating factor. It has also been demonstrated that when mature females were isolated from the male partners, a significant decrease in worm size was noted, and there was a concomitant regression in the reproductive system (Clough, 1981; Popiel et al., 1984). Autoradiographic studies of proline uptake in *S. mansoni* have demonstrated that the female appears to become more radioactive when an intimate contact with the male is established and that proline uptake in males is concentrated to the female contact zone in the gynecophoral canal (Strunk, 1967; Senft, 1968). Gender-specific responses of schistosomes to drugs have been described in several studies (Senft, 1969; Coles, 1973; Cioli and Knopf, 1980).

The influence of mating upon surface nutrient exchange in schistosomes can be studied by comparing the male and female tegumentary surfaces. Coles (1973) and Cornford (1985) have emphasized need for comparative study of surface phenomena in paired and unpaired male and female schistosomes. Minor differences in glucose uptake by male and female *Schistosomatium douthitti* have been reported (Cornford et al., 1981); in the human schistosomes, the rate of hexose uptake is greater in separated males than separated females, and paired worms always take up hexoses at a greater rate than unpaired schistosomes (Cornford, 1982; Cornford and Huot, 1981). Choline uptake is slightly higher in separated male than separated female *S. mansoni*, and lower in paired than unpaired schistosomes (Young and Podesta, 1984). In a study of nucleic acid precursors, Mattoccia et al. (1982) showed that paired *S. mansoni* take up approximately 13 times more uridine than seen in unpaired males, but this effect was not observed in studies of thymidine uptake. Paired worms reportedly took up two to three times the amount of leucine than did unpaired males. In comparisons of separated male and female schistosomes, these authors suggested the increased radioactive uridine and leucine seen in males was a function of worm size, but isolated females take up approximately four times as much thymidine as do isolated males. It was concluded that male-to-female differences in incorporation of nucleic acid precursors or amino acids should be considered in analyses of schistosome synthesis (Mattoccia et al., 1982). In another study of tyrosine uptake by female *S. mansoni* from unisexual infections, Popiel and Erasmus (1981) observed increased uptake in these females after stimulation by either male schistosomes, or lipid-soluble extracts isolated from male worms.

Other studies from this laboratory suggest that uptake of acidic amino acids in *S. mansoni* is quite different in paired and unpaired male and female schistosomes. We see little or no uptake of glutamate in paired male or female schistosomes. In contrast, the TUI is about 30% for glutamate in unpaired male or

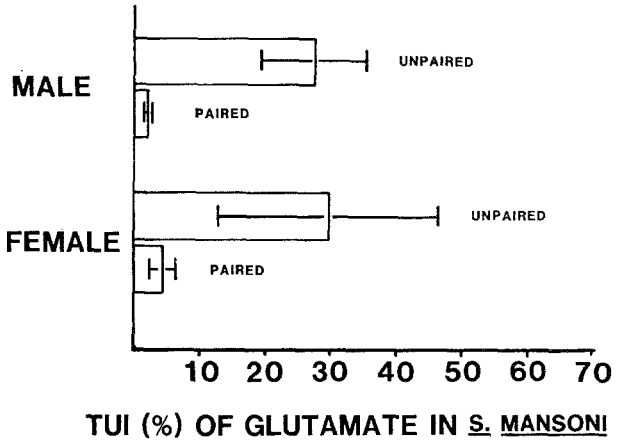

FIG. 7. Comparison of glutamate uptake in unpaired and paired male and female schistosome partners. Note that when the schistosomes are paired, TUIs measured in both males and females are approximately 3%. This approximates the measured TUIs of compounds such as sucrose and polyethylene glycol (Bocash et al., 1981), which are considered to be excluded by the schistosome tegument. (Vertical bars represent ± 1 SD.) In both males and females which were unpaired, however, a marked elevation of uptake of a tracer concentration of glutamate is observed.

unpaired female schistosomes (Figure 7). In paired schistosomes, the TUI is on the order of 3%; this approximates the measured TUIs of compounds such as sucrose and polyethylene glycol (Bocash et al., 1981), which are considered to be excluded by the schistosome tegument. However, a distinctly elevated uptake of glutamate is observed in unpaired males and females. Aspartic acid is the other dicarboxylic amino acid common in mammalian diets. Its uptake is also negligible in paired male and paired female schistosomes, but significant amounts of this amino acid are incorporated in unpaired males and unpaired females (Figure 8). Note also in this figure that the free diffusion of tritiated water in these schistosomes is not significantly different in paired and separated schistosomes; thus the reduced uptake of acidic amino acids is not an artifact of the water-reference technique. Furthermore, since significant amounts of tritiated water freely diffuse into the paired females, we are able to reject the possibility that a reduction in the available surface area of paired (female) schistosomes is responsible for the observed reduced uptake.

To ensure that this was not a time-dependent phenomenon, TUIs of acidic amino acids were examined over a 60-sec period, and similar results were observed. The amounts of aspartate and glutamate incorporated into paired schistosomes were equal to the amount of mannitol incorporated over a 60-sec period. Furthermore, in unpaired male and female schistosomes, the uptake of acidic amino acids was not increased in the presence of physiological concen-

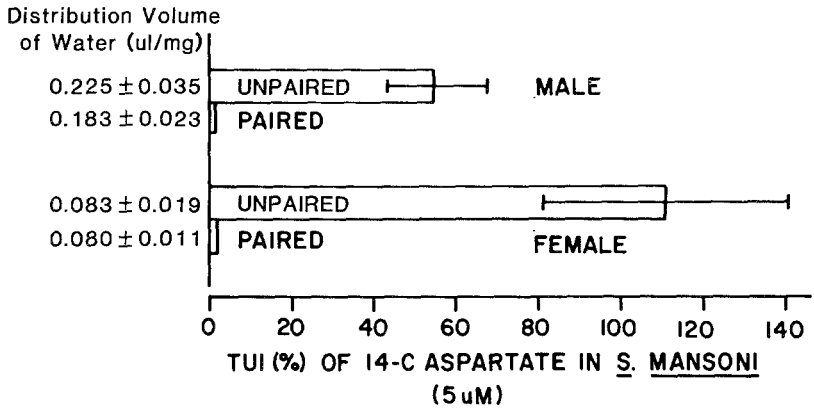

FIG. 8. Comparison of uptake of a trace concentration of aspartate in paired and unpaired male and female *S. mansoni*. Note that in paired males and females, the measured uptake of aspartate, like glutamate, is negligible. However, in separated male and female schistosomes, greatly elevated uptakes for this acidic amino acid are observed. Furthermore, note in the left column that the distribution volume of tritiated water is not significantly different in comparing paired and unpaired male schistosomes, nor is there a difference in the distribution volume of tritiated water in comparing unpaired and paired female schistosomes. Thus the reduced uptake of acidic amino acids, at least by female schistosomes, is not an artifact of the water reference technique, and since significant amounts of tritiated water are taken up by the paired females, the reduced uptake of aspartate, or glutamate (Figure 7), cannot be attributed to a reduction in the available surface area of the paired female schistosomes. (Each horizontal bar = ± 1 SD; $N > 5$ for each mean.)

trations of glucose, suggesting that tegumental incorporation of aspartate and glutamate was not mediated by an energy-dependent mechanism. In other studies, measurements of [^{14}C] glutamate uptake were performed over a wide range of specific activities, and clearly demonstrated the presence of a saturable, carrier-mediated transport mechanism in both unpaired male and unpaired female schistosomes (Cornford, 1985). It was also confirmed that this facilitated diffusion mechanism could not be identified in paired schistosomes. Similarly, when [^{14}C] aspartate uptake was measured over a wide range of substrate concentrations, a carrier-mediated transport mechanism for aspartate was apparent in both male and female schistosomes which were separated. In contrast, the tegument of paired schistosomes excluded aspartic acid over this same broad range of substrate concentrations (Cornford, 1985). These results observed with acidic amino acids contrasted sharply to studies of the uptake of the hexoses, where paired schistosomes were always observed to take up greater quantities of monosaccharides than seen in separated worms (Cornford and Huot, 1981).

Nonlinear regression analysis (Cornford et al., 1981) has subsequently been

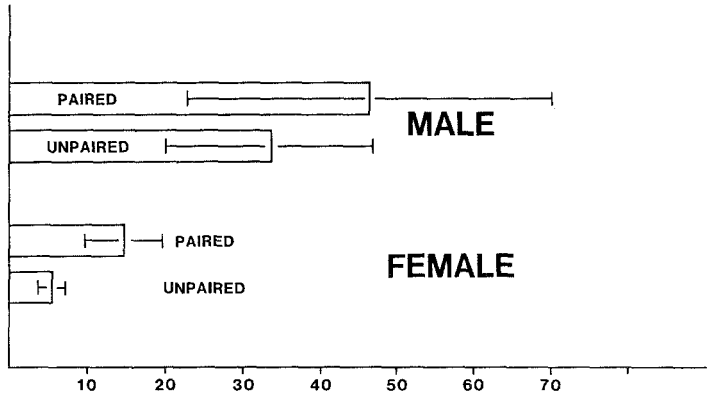

FIG. 9. Comparison of uptake of a trace concentration of [^{14}C]aspartate in paired and separated male and female *Schistosoma haematobium*. Note that in this species, both paired and unpaired male schistosomes take up significant quantities of aspartate. Mated females also incorporate significant quantities of this acidic amino acid, but in separated females, a minimal uptake of aspartate is apparent. Thus this species is unlike either *Schistosoma japonicum* (where no measurable uptake of acidic amino acids is seen in either paired or unpaired males and females; Cornford, 1985), or *S. mansoni*, where measurable uptake of acidic amino acids is seen only in separated males and females (Figures 7 and 8). (Each horizontal bar = ± 1 SD; $N > 5$ for each mean.)

employed to determine the half-saturation constants for uptake of these acidic amino acids. In separated female schistosomes, the half-saturation constant of glutamate was estimated to be 15 $\pm$ 4 μM, and in males, 14 $\pm$ 7 μM. The entry of any glutamate into schistosomes (which were unpaired in vivo) would be regulated by this high-affinity, low-capacity mechanism, since mammalian plasma contains 0.1–0.5 mM glutamate (Diem, 1962; Williamson and Brosnan, 1973). The half-saturation constant for aspartic acid uptake was significantly greater in separated male schistosomes (35 $\pm$ 8 μM) than in females (16 $\pm$ 4 μM), and comparable to plasma aspartate concentrations (about 30 μM; Diem, 1962; Williamson and Brosnan, 1973). The presence of a single acidic amino acid transport mechanism in unpaired *S. mansoni* males and females was suggested by the observation that 0.1 mM [^{14}C] aspartate uptake in male schistosomes could be reduced by a factor of 50% when 1 mM unlabeled glutamate was added to the incubation medium. The saturation of [^{14}C] glutamate uptake by the addition of 25, 100, and 1000 μM concentrations of unlabeled aspartate was observed in both unpaired male and unpaired female schistosomes. Nonlinear regression analyses indicates that the half-saturation constant for aspartate inhibition of glutamate uptake (K_i) was estimated to be 33 $\pm$ 38 μM in unpaired

females and 36 $\pm$ 54 μM in unpaired males. The fact that these K_i values are not significantly different from the estimated half-saturation constants of glutamate (15 and 14 μM in males and females, respectively) indicates that these two acidic amino acids do indeed share a single, facilitated-diffusion transport locus.

Studies utilizing the Japanese strain of *S. japonicum* indicated that no significant uptake of glutamate could be demonstrated over micromolar through millimolar concentrations in unpaired males or in paired males or paired females

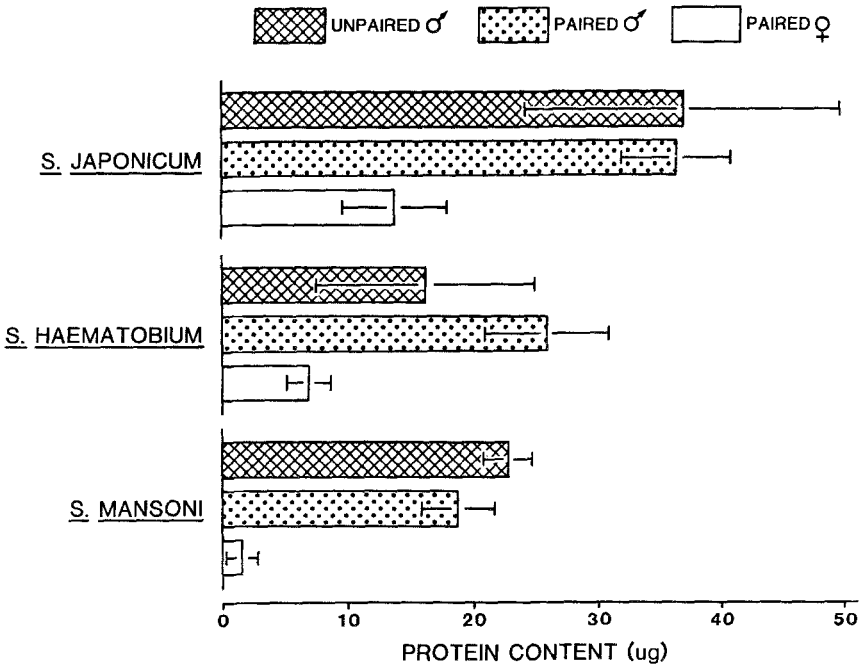

FIG. 10. A comparison of protein content (μg/worm) in unpaired male, paired male, and paired female human schistosomes. Note that in *S. japonicum* and *S. mansoni*, similar protein contents are observed in comparing unpaired and paired male schistosomes. However, in an Egyptian strain of *S. haematobium*, we have observed that males which were perfused unpaired from infected hamsters were significantly smaller than paired male. In this species, a stimulus provided by the paired female is apparently able to enhance the development of the male partner. As indicated in the text, it is typically the male partner which provides the stimulus responsible for full development of the female schistosome (Severinghaus, 1928; Moore et al., 1954; Brumpt, 1936; Armstrong, 1965; Erasmus, 1973; Short, 1952). *S. haematobium* is not only uniquely suited for the study of gender-specific differences (Aronstein and Strand, 1983), but would also represent an appropriate model system to define the nature of the stimulus which the female provides to the male partner.

(Cornford, 1985). However, in another human schistosome, *S. haematobium*, a situation exists which is unlike either *S. japonicum* or *S. mansoni*. Measurable quantities of radiolabeled aspartate are taken up by paired females, paired males, and separated male *S. haematobium*. Only in the separated female did we observe minimal uptake of aspartate (Figure 9). Thus the permeability of the teguments of human schistosome species to acidic amino acids may be modified in response to the copulative state in *S. mansoni* and *S. haematobium*, but these characteristics are not shared by *S. japonicum*.

CONCLUSIONS

The exchange of materials between paired male and female schistosome partners is not easily demonstrated. In the case of glucose, it is a rapid process, and it could be readily confirmed in three different human schistosome species. In these same schistosome species, a female situated in the gynecophoral canal has a negative effect upon glycogen reserves of the male partner; *Schaematobium* is unique in that the mate female affects an increase in tissue mass of the male partner (Figure 10). Most of the transferred glucose is converted to lactic acid by schistosomes, and the mechanism by which female schistosomes excrete lactate has not been defined. Does the paired female transfer lactate to the male partner, which is in turn externalized at the male dorsal surfaces? Alternatively, is lactate efflux accomplished by the osmoregulatory system of male and female schistosomes, and externalized at the excretory pores? Another topic worthy of further study would be to determine whether nutrients other than glucose may be transferred from male to female schistosomes. However, the present studies emphasize that caution should be exercised in analysis and interpretation of data obtained from in vitro investigations of separated male and female schistosomes. Furthermore, these conditions may not resemble in vivo, or paired, function. This caution should perhaps be applied in a wide range of disciplines (immunology, physiology, and pharmacology) involving study of surface phenomena where data are to be obtained in vitro from unpaired male and female schistosomes.

PORTAL SERUM CONSTITUENTS
Possible Determinants for Anatomical Localization of *Schistosoma mansoni* During Maturation and Reproduction

GEORGE Y. WU and CATHERINE H. WU

(Received October 1, 1985; accepted December 30, 1985)

Abstract—Coupled adult pairs of *Schistosoma mansoni* were incubated in medium containing either peripheral or portal serum from rat, rabbit, hamster, or man, and egg production was measured daily. In all cases egg production was significantly increased for pairs in the presence of portal sera compared with that in the presence of peripheral sera. Fractionation of rabbit portal serum according to molecular weight demonstrated that the most active component(s) were in the range of 2000 to 50,000. Similarly, a rat portal serum fraction in the range of 2000 to 30,000 molecular weight was most stimulatory. These fractions were as effective in stimulating oviposition as whole portal serum. Conclusions: (1) portal serum factor(s) exist that stimulate *S. mansoni* oviposition in vitro; (2) they are present in susceptible and nonsusceptible hosts; and (3) the molecular weight range for the active components is larger than would be expected for simple carbohydrates, amino acids, or free fatty acids absorbed from the gastrointestinal tract.

Key Words—*Schistosoma mansoni*, portal serum, maturation, oviposition, reproduction.

INTRODUCTION

In susceptible hosts, the various species of schistosoma bear a remarkable predilection for particular anatomical sites (Cheever, 1965). Because of this phenomenon, the complications of schistosomiasis are generally limited to specific organ systems. In man, the preference of *Schistosoma hematobium* for the veins of the urinary system results in inflammation and ultimately fibrosis of the bladder and/or ureters (Warren, 1978a). Similarly, localization of *Schistosoma man-*

0098-0331/86/0800-1797$05.00/0

soni and *Schistosoma japonicum* in the human portal–mesenteric venous system results in colonic and hepatic granulomatous disease with progressive hepatic fibrosis that becomes manifest as the morbid complications of portal hypertension (Warren, 1978b). From a teleological perspective, the localization phenomenon represents an advantageous evolutionary adaptation in that it simplifies the task of locating mates by bringing both sexes together in a relatively confined vascular region. In addition, deposition of eggs in these areas permits their elimination from the host for completion of the parasitic life cycle. The mechanism by which the parasite determines this site preference, however, is unknown.

In considering this problem, we noted the elegant series of studies by Miller and Wilson (1978, 1980), Wilson et al. (1978), and Knopf et al. (1983), who demonstrated that schistosomules of *S. mansoni* migrate through the venous and arterial vascular systems prior to their arrival in the portal–mesenteric system. In fact, it was determined that immature parasites make several passages through the pulmonary–systemic circulation before chance migration to the preferred site (Miller and Wilson, 1978). This occurs regardless of the site or mode of entry, e.g., percutaneous, subcutaneous, intrapleural, or intracardiac. When schistosomules were injected directly into the portal vein, the majority of the parasites remained at that site (Miller and Wilson, 1978). These data indicate that as a consequence of their migrations, the immature organisms are exposed to various regions of the circulatory system, and yet, they exhibit a definite preference for the portal–mesenteric venous system.

In addition, the work of Taylor et al. (1969), and Taylor (1971) showed that in single-sex infections, schistosomes also migrated to the portal–mesenteric venous system, indicating that each sex is capable of locating the preferred site independent of the other sex. Because blood draining to the portal vein is derived from the gastrointestinal tract, and therefore, different from peripheral blood in many respects (Ishikawa, 1975), we wondered whether the site preference of *S. mansoni* could be dependent on a constituent of portal blood that is not present in the periphery. This might take the form of a substance that the parasite recognizes or requires to develop or maintain a mature state.

We chose to test our hypothesis by measuring *S. mansoni* oviposition since reproductive capacity has been found to reflect the status of maturation in vitro and, furthermore, this feature is highly sensitive to the composition of the incubation media (Clegg, 1965; Newsome, 1962; Robinson, 1960; Senft and Senft, 1982; Michaels and Prata, 1968, Newport and Weller, 1982a,b).

METHODS AND MATERIALS

Animal Portal and Peripheral Serum. In our previous studies, we began by measuring oviposition of coupled pairs of *S. mansoni* incubated in medium

containing serum from different anatomical locations and from different hosts. Adult Sprague-Dawley male rats, adult golden hamsters, male and female, fed ad libitum, were anesthetized with ether. Male New Zealand White rabbits, also fed ad libitum, were anesthetized with a fentanyl and droperidol mixture. Portal blood was obtained by withdrawal into a syringe via a 20-gauge needle by direct puncture facing the mesenteric venous bed. Peripheral blood was obtained from the inferior vena cava. Whole blood was allowed to clot at 25°C for 10 min and then at 4°C for 1 hr. Serum was obtained by centrifugation at 3000 rpm at 4°C for 15 min.

Human Portal and Peripheral Serum. In collaboration with Drs. Michael Dunn and Refaat Kamel, human serum was obtained from an adult Egyptian male suffering from hepatosplenic schistosomiasis. Peripheral blood was drawn from the antecubital fossa and, after preoperative fasting for approximately 12 hr, the patient underwent a procedure for decompression of the portal vein during which portal pressures were measured by direct puncture and portal blood withdrawn through the catheter. The serum obtained was either used immediately or within 2 weeks of collection with storage at −70°C.

Assay for in Vitro Oviposition. Adult *S. mansoni* couples, Egyptian strain, were obtained by sterile perfusion (Duvall and DeWitt, 1967) from golden hamsters after seven weeks of infection with 100 cercariae each. Twelve coupled pairs were incubated, one pair per dish containing 2 ml of medium alone [RPMI 1640 with penicillin 100 units/ml and streptomycin 0.1 mg/ml plus 10% fetal calf serum (FCS)], medium plus 10% portal serum, or medium plus 10% peripheral serum. All media preparations were sterilized by filtration through a 0.20-μm membrane (Millipore Corporation, Bedford, Massachusetts). Incubations were carried out in 35-mm-diameter (35 × 10 mm) polystyrene dishes (Falcon Labware, Oxnard, California) at 37°C under 5% CO_2 in the dark. No microbial contamination occurred in any of the dishes.

Medium was changed and egg production was measured each day for five days by manual counting under a microscope. Repetitive experiments with duplicate dishes were counted for each preparation, and the results are expressed as means ±1 SD with statistical significance determined by two-tailed Student's *t* test. Microscopic examination demonstrated that all worms remained alive and coupled. By five days postdeposition, approximately 50% of the eggs contained motile embryos evaluated microscopically as evidence of viability during the experimental period.

Fractionation of Rabbit Portal Serum. Using a pressure dialysis chamber and filtration membranes (Amicon Corp., Danvers, Massachusetts), rabbit portal serum was fractionated according to molecular weight. Each fraction was washed with distilled water until UV absorption of the effluent as measured at 230 nm and 280 nm was identical to that of distilled water. Each fraction was concentrated by lyophilization and brought back to the original volume and isotonicity by addition of normal saline where necessary. To determine which

fraction contained the active component(s) of the portal serum, medium was prepared supplemented with each fraction to make a 10% solution. Prior to use, all preparations were sterile filtered as described above. Egg production was again measured microscopically with duplicate dishes for each medium preparation, and the results of repetitive experiments are expressed as the average ± 1 SD. Statistical significance was determined by Student's t test.

Recently, we have used a similar technique to separate fractions of rat portal serum and tested these fractions for oviposition stimulatory effect as described for the rabbit portal serum fractions.

RESULTS

Table 1 compares oviposition by coupled pairs of *S. mansoni* in media supplemented with sera from different sources. Regardless of the animal source, medium containing portal serum demonstrated a statistically significant ($P < 0.005$) enhancement of oviposition compared to medium prepared with peripheral serum. The ratio of total egg production of portal medium to peripheral medium was approximately 2.4 : 1 in the rat, 3 : 1 and 3.4 : 1 in man and rabbit respectively, and 11 : 1 for the hamster. Increases in the concentration of portal serum in the medium from 20% to 50% did not significantly increase egg production above that with 10% serum. Addition of rabbit peripheral serum to rabbit portal serum did not significantly change egg production (data not shown), indicating that the observed results are due to portal stimulation and not peripheral inhibition of oviposition.

Table 2 shows the effect of the different molecular weight fractions of rabbit portal serum on egg production: F1 <500; F2 500–2000; F3 2000–10,000; F4 10,000–50,000; F5 >50,000. Oviposition was maximally stimulated by fractions F3 and F4, indicating that the most active components of

TABLE 3. EFFECT OF RAT PORTAL SERUM FRACTIONS ON *S. mansoni* OVIPOSITION IN VITRO[a]

F1	F2	F3	Control (FCS 20%)
77 ± 7	232 ± 13	64 ± 4	55 ± 10

F1 <2000
F2 2000–30,000
F3 >30,000

[a] Egg production per pair (for 10 coupled pairs), mean ± SD after five days of incubation.

rabbit portal serum are of molecular weight greater than 2000 and less than 50,000.

Table 3 shows the effect of different dialysis fractions of rat portal serum on egg production: F1 <2000; F2 2000–30,000; F3 >30,000. Fraction F2 showed the greatest stimulatory effect, three to four times that of the other fractions. This indicates that in the rat the stimulatory constituent(s) have a molecular weight greater than 2000 but less than 30,000.

DISCUSSION

The results of these experiments demonstrate that portal serum from various mammalian sources have components that stimulate *S. mansoni* oviposition in vitro. Significant enhancement of oviposition was seen with portal serum from man and hamster (highly susceptible hosts) (Cheever, 1965) as well as rat and rabbit (poorly susceptible hosts) (Stirewalt et al., 1957), indicating that the

active portal serum components provide the potential for preferential reproductive support regardless of the overall suitability of the animal as a host for *S. mansoni*.

Large differences are seen in egg production in medium containing peripheral serum supplements from various animal sources. In an early study Robinson (1960) also found large differences in egg production with peripheral sera from several animal species.

It has been clearly demonstrated that portal blood contains significantly greater quantities of nutrients (Ishikawa, 1975) compared to peripheral blood because of the drainage of blood from the gastrointestinal tract. Our data suggest that the active principles of portal serum are likely not to be amino acids, carbohydrates, or other simple metabolic substrates based on the effects of the fractions of rabbit portal serum. Our most recent data on rat portal serum fractions confirm the previous rabbit results and suggest that the substances are of similar size. It is possible that the same or similar substance is present in the rat as well as the rabbit. While an intermediate-sized molecule appears to be the most probable, the possibility of a low-molecular-weight substance that exists tightly bound to a macromolecule, as observed by Newport and Weller (1982a), must be considered in the isolation and identification of stimulatory substances.

Our results have not directly demonstrated an effect of portal serum component(s) on *S. mansoni* maturation or localization. We are aware that the observed enhancement of oviposition could be due to effects related to general metabolism and need not necessarily indicate that portal blood has a specific and direct effect on oviposition or on maturation. Nevertheless, we have demonstrated, for the first time, a difference in *S. mansoni* reproductive response in the presence of portal serum versus peripheral serum.

Although these studies are still quite preliminary, we are currently in the process of isolating and identifying the stimulatory substance(s) first from rat portal serum and ultimately from human portal serum. We plan to test the effects of portal serum components to determine if there are specific effects on the growth and maturation of immature *S. mansoni* schistosomula in vitro. In addition, we plan to examine sera from other important anatomical locations for effects on other schistosome species in order to determine if the phenomenon is parasite-species specific.

Abstract—The life cycle of schistosomes is reviewed in its various steps, both in permissive hosts (in which the cycle is completed) and in nonpermissive hosts (which excrete no viable eggs as a result of the infection). A large worm loss occurs at (or after) the lung stage in both types of hosts ("normal attrition") and some nonpermissive hosts (like the rat) have an additional elimination of worms from the portal circulation. Worm growth and reproductive maturation are also impaired in several nonpermissive hosts and the possible host–parasite interactions leading to such limitations are discussed, with special reference to hormonal influences. Attention is also given to peculiar phenomena occurring in some hosts, like the late portal worm elimination in rhesus monkeys, the migration from mesenteric veins to lungs in rats, and the block to egg excretion in guinea pigs. The steps of the schistosome life cycle which appear vulnerable in several hosts are contrasted with the steps which are carried out successfully in the majority of hosts studied.

Key Words—Schistosomes, *Schistosoma mansoni*, permissive and nonpermissive hosts, reproductive maturation, hormones.

INTRODUCTION

The schistosomes which are responsible for human infections can also be infective for a variety of different mammalian hosts. The evidence is derived both from the occasional finding of naturally infected wild mammals and from the observation of schistosome development after controlled laboratory exposures to cercariae. Most of the available information on *Schistosoma mansoni* was

0098-0331/86/0800-1805$05.00/0

obtained in the 1950s and early 1960s through an impressive series of studies designed to explore the suitability of a wide range of mammals as laboratory models for human infections (Moore et al., 1949; Stirewalt et al., 1951; Kuntz and Malakatis, 1955; Bruce et al., 1960; von Lichtenberg et al., 1962). The general picture emerging from these studies is that of a continuum of host behaviors, ranging from refractoriness to susceptibility, with a corresponding spectrum of schistosome stages at which parasite development and reproduction can be blocked. An operational distinction has been suggested for *S. mansoni* between "permissive" hosts, i.e., species in which the parasite can complete its life cycle, and "nonpermissive" hosts, i.e., species where development of worms is incomplete and/or no viable eggs can be isolated from the feces (Cioli et al., 1977; Knopf, 1982). Table 1 presents a list of the major permissive and nonpermissive species for *S. mansoni*. Such a dichotomy can be useful for broad descriptive purposes, but there are clearly borderline species, like the rhesus monkey, where the "self-cure" phenomenon observed under certain conditions may be suggestive of nonpermissiveness (Damian, 1984), whereas the presence of viable eggs in the feces seems to warrant at least the status of "temporarily permissive" to this host.

It would certainly be naive to think of directly applying to the human situation the striking limitations which nonpermissive hosts impose upon schistosome development, reproduction, and pathological effects. It may be fruitful, however, to look at each host–parasite combination as an *experimentum naturae* which can help dissect the schistosome biology by showing the multiple steps at which progression of the infection could be blocked. The subject has been recently reviewed by Knopf (1982), and Figure 1 is largely based on a scheme

proposed in this review. Although reference will be made to a variety of nonpermissive hosts of *S. mansoni*, most of the available information is derived from studies performed in the laboratory rat (*Rattus norvegicus*).

It may be appropriate, at this point, to mention that some instances of successful natural infection of *R. norvegicus* by *S. mansoni* have appeared in the literature. Thus, Martins et al. (1955) found that 46.8% of *R. norvegicus* captured in Belo Horizonte harbored *S. mansoni* and 13.3% of these rats passed viable eggs in the feces. Combes et al. (1975) reported that, out of a total of eight rats (four *R. rattus* and four *R. norvegicus*) captured in Guadeloupe, seven showed the presence of *S. mansoni* adults, of eggs in the intestine, and of eggs in the feces. Günther (1979) reported that, out of 38 *R. norvegicus* trapped in Egypt, six showed the presence of adult *S. mansoni*. He could also document that mature eggs were present in the liver, intestine, and feces; and was able in all six cases to obtain miracidia which were infective to snails. Our attempts to follow up on these observations with the original authors have not been successful, thus far. It would be quite interesting, however, if one could study a combination *R. norvegicus–S. mansoni* where the rat behaves as a permissive host. This might yield either a schistosome strain to compare with the commonly used ones, or a rat strain to cross with laboratory rats and ask whether permissiveness is a dominant or recessive trait (indicating that the presence or the absence of some factor, respectively, is responsible for permissiveness).

QUANTITATIVE ASPECTS OF PREADULT STAGES OF INFECTION

Skin and Lung Stages. The first step of the infection in mammalian hosts, i.e., skin penetration seems to show little selectivity in different species. Even in nonpermissive hosts, a large fraction of cercariae disappear from the infecting suspension (Warren and Peters, 1967), and there is histological evidence for the presence of schistosomula in epidermal and dermal layers of the skin (von Lichtenberg et al., 1962). In the fox, schistosomula have been documented in close proximity to skin blood vessels, but no evidence has been found of their penetration into these structures and no parasites have been found in the lungs (von Lichtenberg et al., 1962). The fox may thus represent an example of hosts in which the infection is effectively blocked at the skin level.

Experiments based on the recovery of schistosomula from minced skin have led to the conclusion that a significant fraction (10–30%) of penetrated cercariae die in the skin of permissive hosts such as the hamster and the mouse, whereas a larger fraction (50%) die in the skin of a nonpermissive host like the rat (Clegg and Smithers, 1968). The use of more recent techniques for the tracking of radioactively labeled schistosomula through the host tissues (Georgi, 1982), on the other hand, has convincingly demonstrated that, in the mouse, virtually all penetrated schistosomula leave the skin and can be quantitatively accounted for in the lungs (Mangold and Dean, 1983). Similar experiments performed in the rat have also shown that virtually no schistosomula remain in the skin of this host and that the number of lung radioactive foci is almost identical with the number of penetrated cercariae (Knopf, Cioli, Mangold, and Dean, manuscript in preparation). These results suggest that the nonpermissive characteristics of the rat are not displayed in the skin but only at later stages of the migration. It cannot be excluded, however, that schistosomula may actually suffer some early damage in the skin, but maintain their capacity to migrate and show only delayed effects when already in different tissues.

Lung-to-Liver Migration. The migration from lung to liver appears to be a critical stage in the *S. mansoni* life cycle. The muskrat may represent an example of nonpermissiveness where the block is exerted mainly at this stage (Figure 1), since von Lichtenberg et al. (1962) could find histological evidence for the presence of schistosomula in the lungs of this host, but not in the liver or in the mesenteric veins. In any event, it is interesting that, with respect to the migration from lung to liver, not even the mouse can be considered 100% permissive. Dean et al. (1984) have shown that, while essentially all penetrated schistosomula appear as radioactive foci in the lungs of mice, only about half of them eventually appear in the liver or in the mesenteric veins. The fate of the missing schistosomes is, as yet, totally unknown, but it would appear that they either disintegrate quite rapidly and/or are lost from the mouse tissue. In the rat, as in the mouse, about half of the parasites which appear in the lungs fail to reach the liver (Knopf et al., manuscript in preparation). Thus, it appears

that the "normal attrition" observed in permissive hosts after the lung stage is present in the rat with substantially similar characteristics (Figure 1).

Portal Worm Elimination ("Self-Cure"). After reaching the liver, the number of parasites will remain essentially constant throughout the rest of the infection in permissive hosts. In the rat, on the contrary, a further worm elimination will occur at the liver stage, beginning on the fourth week after infection ("self-cure"). A dramatic reduction in the number of worms which can be recovered by portal perfusion occurs between the fourth and the sixth week, followed by a slower rate of elimination. From the tenth week onward a very small number of schistosomes—generally corresponding to less than 2% of the infecting cercariae—is left in the rat. These surviving schistosomes are stunted, do not migrate to mesenteric veins, and produce limited numbers of infertile eggs. Their survival, however, can be very long-lasting: a mean of 5.6 worms per rat has been reported one year after infection with 1000 cercariae per rat (Phillips et al., 1978).

One of the possible interpretations of the portal worm elimination in rats is to assume that it is due to an acquired host immune response which becomes effective at the fourth week after infection (Smithers and Terry, 1965). Indeed, thoroughly immunosuppressed rats showed higher numbers of worms than intact controls at all times tested (Cioli and Dennert, 1976). However, portal worm elimination eventually occurred in immunosuppressed rats as well, and worms recovered from these animals were as stunted as those from intact rats, females did not achieve maturation, egg deposition remained abortive, and worm pairs failed to migrate from liver to mesenteric veins. Thus, it is possible that immunological phenomena may be restricted to the final phases of killing and disposing of worms which have been previously affected by some other non-immune mechanism.

Additional evidence against the hypothesis that portal worm elimination is primarily an immune phenomenon comes from a series of experiments designed to determine whether the timing of spontaneous rejection (four weeks) is due to the fact that the rat needs just about four weeks to mount an efficient immune response, or whether this timing is dictated by factors inherent to worm development. Schistosomes obtained from rats which had been infected two, three, or four weeks previously were transferred into the mesenteric veins of normal rats and the timing of worm elimination was determined in the recipients. Two-week-old worms were rejected beginning at two weeks after transfer, 3-week-old worms at one week after transfer, and 4-week-old worms immediately after transfer. It was concluded that the onset of *S. mansoni* rejection in laboratory rats is dependent on the total age of the parasites and independent of the length of contact with the host in which rejection occurs (Cioli et al., 1978). It looks as though around the fourth week schistosomes either have some special requirement which is not fulfilled in the rat, or become sensitive to some inhibitory factor which was not effective at previous stages.

As previously mentioned, a very small number of schistosomes do survive for a long time in the rat, although they never develop into mature adults. The question was raised as to whether the few survivors were genetically different from the rest of the population. Upon transfer of the survivors into permissive hosts, it was possible to obtain progeny of those worms and use them to infect new rats. Although this cycle was repeated eight times, there was no indication that these "selected" schistosomes had a better survival or a better development in the rat (Cioli, to be published). This result makes the genetic hypothesis a very unlikely one and leaves us with two unsolved questions: why are the majority of schistosomes eliminated from the rat, and why are just a few of them capable of long-term survival?

According to a classical hypothesis, schistosomes can survive for long periods of time in permissive hosts because they are disguised under a coat of "host antigens" (Smithers et al., 1969). When rat schistosomes were analyzed with respect to the host antigens, they were found to possess only a very small amount of these antigens, in comparison with the amount present in mouse worms (Cioli, 1976a). However, it is difficult to decide whether the scarcity of host antigens is a primary cause of stunting and death or whether it is a consequence of some other damage to the surface membrane resulting in poor fixation of host antigens. It is indeed shown that the tegument of rat schistosomes undergoes a delayed and incomplete development (Senft et al., 1978).

QUALITATIVE ASPECTS OF PREADULT STAGES OF INFECTION

Up to the fourth week after infection, schistosomes recovered from the rat are indistinguishable from those recovered from mice or hamsters with respect to size distribution, surface morphology, and gross internal appearance (Mackenzie and Clegg, cited by Smithers, 1972; Knopf, 1982). After this point, however, several differences become apparent (Cioli et al., 1977). The majority of rat schistosomes remain at the juvenile stage, fail to grow in size, and are largely eliminated by the mechanism of portal worm elimination. The survivors progress very slowly to the young adult stage and, although the pairing process occurs, worm length lags far behind the values observed in permissive hosts and vitelline gland development in the female is only rudimentary. Paired young adult worms fail to migrate to mesenteric veins and deposit only a moderate number of eggs which are confined to the liver. Only rarely do miracidia emerge from these eggs, but snail infections cannot be obtained from them.

It has been shown that the arrest in development observed in the rat is not an irreversible phenomenon, since complete progression to mature, fertile-egg laying adults can be obtained if rat worms are transplanted—at any stage—into a permissive host (Cioli, 1976b; Cioli et al., 1977). However, the limitation imposed by the rat does not consist only of an arrest in the progression of the

schistosome development from immature to mature stages. The rat will also prevent the maintenance of the adult stage, as shown by the rapid regression of fully developed mouse worms after transfer into rats (Cioli et al., 1977).

Schistosome Reproductive Maturation in Nonpermissive Hosts. It is commonly stated that an essential prerequisite for the reproductive development of female schistosomes consists of their pairing with male worms. The rat situation shows that pairing is essential but not sufficient, since—as previously mentioned—there is no evidence for a deficit in the pairing process in the rat (nor in other nonpermissive hosts), yet paired females possess a largely undeveloped reproductive system. We shall consider three possibilities for the failure of female worms to develop in the rat: (1) The male schistosome is defective in this host, thus failing to supply the stimulus necessary for reproductive female maturation. (2) Migration to mesenteric veins is required for female development. (3) The lack of essential chemical factors or the presence of inhibitory factors make the rat environment unsuitable for female maturation.

Experiments aimed at distinguishing between these possibilities are under way in our Rome laboratory. Our approach consists in exploiting the fact that the rabbit is a permissive host for *S. japonicum*, whereas it is nonpermissive for *S. mansoni* (more or less like the rat, Figure 1). We have performed preliminary experiments showing that in the Nile rat (which is permissive for both *S. mansoni* and *S. japonicum*) immature females of either species are brought to full reproductive development and oviposition by the heterologous male. By performing the hybrid crosses in the rabbit, we should be able to determine whether the *S. mansoni* female will be able to undergo growth, reproductive development, migration, and oviposition in a nonpermissive environment, i.e., we should be able to see whether an efficient male stimulation, possibly coupled with migration to mesenteric veins, is capable of overcoming whatever humoral deficiencies or inhibitions may exist in the rabbit for the *S. mansoni* female.

INFLUENCE OF HOST HORMONES

In the search for host factors which may be responsible for the nonpermissive status of the laboratory rat, a series of experiments on the effect of host endocrine gland removal have been performed (Knopf and Soliman, 1980; Knopf and Linden, 1985). The rationale for this approach was based upon the observation that worm development in rats was significantly retarded at the time when sexual maturation of the parasites occurs (26–28 days postinfection). The potential for an interaction between host hormones and parasites which might either stimulate worm sexual maturation in permissive hosts or interfere with this process in nonpermissive hosts was examined by infecting hypophysectomized (Hypox) mice and rats. Worm survival, development, and oviposition were not significantly altered in Hypox mice. In contrast, Hypox rats showed a two-

week delay in portal worm elimination, worm length was increased by 30%, vitelline gland staining was markedly improved in females, and oviposition was augmented. Further experiments showed that a similar increase in permissiveness could be obtained in thyroidectomized (Thyrox) rats: in these hosts, portal worm elimination was delayed by four weeks, worm length was increased by 80%, and some miracidia could be hatched from the liver eggs (Knopf and Soliman, 1980). These "rat-derived" miracidia from Thyrox rats successfully infect snails and generate cercariae which are capable of completing the parasite life cycle in mice (Knopf and Linden, 1985). Confirmation of the involvement of thyroid hormones in these phenomena has been recently obtained by demonstrating that administration of either T3 or T4 to Thyrox rats restores the portal worm elimination reaction (Knopf and Linden, 1985). Unexpectedly, the low number of worms which survived in hormone-restored Thyrox rats continued to sexually mature and produce increased numbers of eggs. These eggs failed to yield miracidia, however.

Since cell-mediated immune responses are impaired by thyroidectomy (Knopf, 1982), it is possible that the delay in onset of portal worm elimination in Thyrox rats may be due to a reduced activity of the immune mechanisms which, at least in part, contribute to worm elimination in these nonpermissive hosts. A direct inhibitory effect of thyroid hormones T3 and T4 on the maturation of schistosomes seems less likely. T3, incidentally, is included among the constituents of the medium formulated by Basch (1981) to optimize growth of *S. mansoni* in in vitro cultures. Other activities of the thyroid gland must be considered as potential candidates for inhibiting parasite maturation.

MIGRATION FROM LIVER TO MESENTERIC VEINS

This phase of migration is absent in the rat and the rabbit, but is present in other nonpermissive hosts like the skunk and the guinea pig (Figure 1). While most of the previous migration of schistosomes can be imagined to be largely passive (the worms being carried by the bloodstream), this phase represents a displacement in which the schistosome must engage in active movements to negotiate its way against the blood flow down the portal vein and the progressively smaller and smaller branches of mesenteric veins. The migration of paired worms from the liver is even more intriguing in the case of *S. hematobium*, and an interesting way of restating the problem could be to ask: what are the differences between the two schistosome species that guide them to such different final locations? It is in this final portion of the migration, therefore, that it becomes almost compelling to postulate the existence of some cue leading the schistosome to its final location. A concentration gradient of some chemical is usually hypothesized at this point: nutrients from intestinal absorption, oxygen, insulin, serotonin are all factors in which portal blood is particularly rich, but no evidence exists for a special role in worm migration of any of the above. A

fecal extract has been shown to exert some attraction on schistosomes in vitro (Awwad and Bell, 1978), but the possible relevance of this finding to the in vitro situation remains to be determined.

A prerequisite for migration to mesenteric veins seems to be represented by pair formation. In single-sex infections of the mouse, both the single males and the single females are confined almost exclusively to intrahepatic vessels and the main branch of the portal vein (Zanotti et al., 1982). In the rat, however, pairing occurs, but pairs fail to migrate. Sexual maturation, pairing, and onset of oviposition are all important events which roughly coincide with migration to mesenteric veins. Again, the cause–effect relationships (if any) between these phenomena are totally obscure. Thus, it might be that rat worms do not mature because they fail to reach the mesenteric veins, or it might be that they do not migrate because they are not mature (but mature mouse worms do not seem to migrate back to mesenteric veins after surgical transfer into the portal circulation of the rat). In any event, one would like to know which features make the rat different from permissive mammals with respect to the final schistosome migration: lack of chemical cues, presence of inhibitory factors, cumulated defects in worm development?

It may be worth stressing here that the migration from liver to mesenteric veins in permissive hosts is not done once and for all when the newly mature schistosomes first pair around the fourth week of infection. Quite convincing evidence has been derived from oogram studies that each schistosome pair may go up and down the portal system several times a day, depositing eggs in rather distant branches of intestinal vessels (Pellegrino and Coehlo, 1978; Cheever and Duvall, 1982). The same conclusion can be reached by transferring a single mature worm pair into the mesenteric veins of Nile rats (Cioli, unpublished). It is tempting to speculate that the stimulus to continuous migration might come just from the eggs deposited in a given site. Secretions from the eggs (or from the host tissues damaged by eggs) might stimulate schistosomes to move away from that site, a concept which is the reverse of the possible attraction of schistosomes towards a given site. The initial stimulus could come from the first eggs deposited in the liver at the onset of oviposition; if the abnormal, infertile eggs produced in the rat fail to give off the proper stimulus for migration, this might explain the failure of schistosomes to move away from the liver. Whatever the cause for the permanence of worms in the rat liver, this is certainly a dangerous location for a schistosome, since it has been shown that many parasites can be found dead or "trapped" by eosinophil-rich reactions within the blood vessels (Knopf, 1979).

LATE EVENTS IN MESENTERIC VEINS

As outlined in Table 1, while *Rattus norvegicus* (i.e., the laboratory rat) is a nonpermissive host, *Rattus rattus* (black rat or roof rat) is permissive for

S. mansoni. This latter host has been shown to present a peculiar further migration of schistosomes from the mesenteric veins to the lungs (Jourdane, 1978). This migration occurs after the seventh to eighth week of infection, and it has been proposed that adult worms may pass from the portal blood to the caval circulation by directly negotiating their way through the liver sinusoids (Imbert-Establet, 1980). A similar localization of adult *S. japonicum* in the lung of *Rattus rattus mindanensis* has been reported by Oshima et al. (1978), although in this case it has been suggested that this may not represent migration from mesenteric veins but rather a permanent settling in the lungs during the initial period of infection.

Another peculiar phenomenon occurs late in the infection of rhesus monkeys with *S. mansoni*. When this host is infected with a high dose of cercariae, a drastic reduction in the number of worms is apparent around the 16th week (late portal worm elimination), whereas the worm burden seems to remain indefinitely constant after low-dose infections (Cheever and Powers, 1972). It is not known whether the spontaneous worm loss occurring around the 16th week in the rhesus monkey is somehow related to the portal worm elimination occurring at four weeks in the rat, and equally unknown are the mechanisms of this most interesting phenomenon.

Mature adult schistosomes in mesenteric veins are actively engaged in egg production. In permissive hosts, a proportion of the eggs are capable, upon maturation, of passing into the feces. In some nonpermissive hosts (like the guinea pig and the skunk, Figure 1) this last step is blocked. Eggs are deposited in the intestinal tissues of the guinea pig and about half of them are viable, but they are not voided in the feces (Pearce and McLaren, 1983). However, passage of eggs into the feces has been documented in the guinea pig after transfer into this host of hamster-derived 8-day-old worms, an intriguing finding which seems to indicate that the nonpermissive effects of the guinea pig are exerted on worm development rather than against the egg itself (Michaels, 1970).

Apart from the many individual steps of the schistosome life cycle which may receive clarification from the study of single nonpermissive hosts, a very broad generalization may emerge from an overall view of the data available so far. It looks as though the survival mechanisms evolved by the schistosomes have enabled them to overcome certain of the obstacles encountered in their life cycle with remarkably good success in a wide variety of mammalian hosts. Thus, for example, skin penetration and male–female pairing appear to be performed very efficiently in all the hosts studied. Certain other steps of the life cycle, on the contrary, seem to encounter serious problems in several host species. Thus, migration from lung to liver is effected with great losses even in permissive hosts, migration from liver to mesenteric veins often fails, full growth and maturation are achieved only in certain cases, and some hosts are even capable of getting rid of established fertile schistosomes. It is totally up to the ingenuity of the applied biologists whether they prefer to exploit those steps

which appear most vulnerable in natural hosts, or whether they prefer to discover new weak links in the elaborate mechanism of schistosome survival.

(Received October 1, 1985; accepted January 13, 1986)

Abstract—Immunoelectrophoresis and immunoblotting techniques, using sera from hyperimmune rabbits and infected mice, were used to analyze antigens of *Schistosoma mansoni*. A comparison was made between the antigenic composition of adult male and female worms, isolated from monosexually and bisexually infected hamsters. A large number of female-specific and a few male-specific antigens were detected. The antigenic composition of females isolated from monosexually infected hamsters was shown to be very different from that of paired females. The presence of a major female-specific antigen with an apparent molecular weight of 32 kd in paired females only, suggests that synthesis of this antigen by female worms is initiated by the male partner. Analysis of the humoral immune response of mice receiving bisexual or monosexual infections showed that both mono- and bisexually infected mice develop a major humoral immune response to a 36-kd polypeptide antigen. A response to a major polypeptide antigen with an apparent molecular weight of 60 kd was observed in bisexually infected mice only. No antibodies reactive with this 60-kd polypeptide are formed during monosexual infections with either male or female worms. The 60-kd polypeptide was, however, present in monosexually reared females. This presence, and the presence in bisexually reared males, suggests a transfer of this antigen from females to males.

Key Words—*Schistosoma mansoni*, trematode, sex-linked antigens, monosexual and bisexual infections, immunoelectrophoresis, immunoblotting, rabbits, mice.

INTRODUCTION

Granuloma formation around eggs is the major factor in the pathogenesis of schistosomiasis. The granuloma formation is succeeded by fibrosis, which causes obstruction to blood or urine flow. The occurrence of disease following schistosomal infection is related to the number of schistosome eggs in the tissues and the degree of the host's inflammatory response to them (Warren, 1975). The pathology would be minimized if the rate of oviposition could be substantially reduced. This might be accomplished by preventing the females from mating with the males.

There have been numerous investigations on the influence of mating on the sexual maturity of the females (Vogel, 1941; Armstrong, 1965; Erasmus, 1973; Shaw et al., 1977; Popiel and Basch, 1984). In monosexual infections of *Schistosoma mansoni*, female worms fail to develop normally. Growth is inhibited, and the development of the reproductive system is incomplete. Separation of sexually mature females from their male partners leads to a reversible degeneration of the female reproductive tract, and the production of viable eggs is terminated (Clough, 1981).

The mechanism by which the male matures the female is unknown. It has been postulated that female maturation is accomplished nutritionally, hormonally, tactually, and by sperm or components excreted with the sperm (Vogel, 1941; Armstrong, 1965; Moore et al., 1954). However, none of these postulations has been proven. Shaw et al. (1977) have shown that acetone or ether extracts of male worms can stimulate vitelline gland development. These experiments suggest that transfer of male-specific components during residence of the female in the gynecophoral canal of the male is an important factor in the development of the female reproductive system.

If sexual maturation and oviposition are dependent on transtegumental transfer of one or more male components to the female, it might be possible to prevent this transfer by the action of antibodies specific for the transfer component. Sex-linked components might also be part of postulated receptors, which are used to determine mating (Michaels, 1969). Antibodies to these receptor molecules might prevent mating and, as a result, stop egg production.

Comparative analysis of male and female *S. mansoni* proteins has been made mainly by electrophoretic techniques (Ruppel and Cioli, 1977; Cordeiro and Gazzinelli, 1979; Snary et al., 1980). To exclude contaminating host proteins, schistosome proteins have been metabolically labeled in vitro with radioactive amino acids (Atkinson and Atkinson, 1982; Aronstein and Strand, 1983). Atkinson and Atkinson (1982) used isoelectric focusing/SDS-polyacrylamide 2-dimensional gel electrophoresis to separate radiolabeled male and female proteins. Fluorographic analysis of separated peptides revealed the synthesis of 74 major polypeptides, among which were three male- and four female-specific

polypeptides. Atkinson and Atkinson (1980) also showed that a polypeptide with a molecular weight of 66 kd, synthesized by males, is transferred to female worms. However, other investigators were unable to detect transfer of a 66-kd polypeptide (Popiel and Basch, 1984). Aronstein and Strand (1983) showed that females cultured in vitro excrete a 66-kd polypeptide and a number of low-molecular-weight polypeptide antigens.

Only a few studies have been made on the antigenic properties of male- and female-specific components. Capron and Vernes (1968) studied the formation of specific antibodies in mono- and bisexually infected hamsters by immunoelectrophoresis. Precipitation patterns, obtained with male and female antigen preparations, showed no distinct differences. Rotmans et al. (1981) have reported the excretion of a low-molecular-weight female-specific antigen during cultivation of adult female *S. mansoni* in vitro. The presence of this antigen in the culture medium was demonstrated by immunoelectrophoresis using a rabbit antiserum directed against excretory and secretory antigens.

In this paper we report further studies on the analysis of sex-linked *S. mansoni* antigens by immunoelectrophoresis and the use of the immunoblotting technique to select potential target antigens for antibodies interfering with mating or the production of eggs.

METHODS AND MATERIALS

Collection of Parasites. Adult *S. mansoni* were collected from golden hamsters by means of perfusion with a sterile Dulbecco's balanced salt solution (DBSS), 48 days after exposure of the hamsters to 1000–1500 cercariae of mixed sex. Collected worms were washed twice with DBSS. For the most part, worms were used for antigen extraction. A smaller part of the worm pairs were allowed to separate by keeping the worms for 30 min at room temperature in the perfusion medium. Male and female worms were collected separately by manual transfer of individual worms to Petri dishes, using a Pasteur pipet. This procedure allowed the isolation of about 1500 worms of each sex in a 1-hr period. For the isolation of worms of single sex from monosexually infected hamsters, snails (*Biomphalaria glabrata*) were infected with a single miracidium. Each hamster was exposed to cercariae released by one infected snail and, 48 days postexposure, worms were collected by means of perfusion. The sex of the worms obtained from each hamster was determined, and male and female worms were collected separately in perfusion medium.

Antigen Extraction. About 1500 male, female, or mixed worms were homogenized in 15 ml phosphate-buffered saline (PBS) and centrifuged at 30,000*g* for 20 min. Centrifugation at this low *g* value, resulted in a preparation consisting of both water-soluble and membrane-bound antigens. The supernatant was dialyzed for 16 hr against deionized water at 4°C, lyophilized, and stored

at 4°C. For the purpose of immunizing rabbits with an antigen preparation as complete as possible, we extracted membrane-bound antigens from the pellet with a detergent. The pellet was suspended in a 1% solution of octyl-β-D-glucopyranoside (Calbiochem) in 35 mM PBS, pH 7.8. Homogenization was in a glass homogenizer with a Teflon pestle. After centrifugation of the extract at 30,000*g* for 20 min, the supernatant was dialyzed against deionized water and lyophilized.

For immunoblotting experiments, intact whole worms were also extracted in the electrophoresis sample buffer. Extraction was by homogenization in a glass homogenizer with a Teflon pestle. The homogenate was centrifuged (10,000*g*, 1 min) and the supernatant was either immediately subjected to SDS gel electrophoresis or stored at −20°C.

Protein Determinations. Protein was determined by the method of Lowry et al. (1951), using bovine serum albumin as the standard.

Sera. Rabbit antisera directed against male, female, and total worm antigen preparations were prepared as follows: One milliliter of a solution containing 1.0 mg antigen preparation was mixed with an equal volume of Freund's complete adjuvant and injected subcutaneously. After three weeks, booster injections of 1.0 mg antigen preparation in 1.0 ml PBS were given weekly. Serum was obtained five weeks after the first injection and from then on every other week.

Infected mouse sera were obtained from pooled bleeding of mono- or bisexually infected Swiss mice 16 weeks after exposure to 100 cercariae.

Immunoelectrophoresis. Glass slides (7.5 × 2.5 cm) covered with 3 ml of a 0.95% (w/v) agarose gel (Koch-Light) in 0.1 M Veronal buffer, pH 8.2, were used for immunoelectrophoresis. Wells contained 1 mg antigen preparation dissolved in 10 μl Veronal buffer. Electrophoresis was carried out for 3 hr at 55 V and 3.5 mA per slide. After application of 100 μl of a threefold concentrated antiserum, the slides were placed in a moist chamber for 48 hr. At the end of this period, the slides were washed for 48 hr in PBS, and twice for 1 hr with deionized water. The slides were then dried and stained with Amido black 10B.

Polyacrylamide Gel Electrophoresis. One-dimensional gel electrophoresis was conducted essentially as described by Laemmli (1970). Homogeneous slab gels of 12% polyacrylamide or gradient slab gels of 8–15% polyacrylamide, containing 0.1% SDS, were overlaid with a 4.5% polyacrylamide stacking gel containing 0.1% SDS, inset with sample wells. Equal amounts of protein were dissolved in sample buffer at a protein concentration of 2.5 mg/ml. The samples were heated for 2 min at 100°C. The sample buffer contained 63 mM Tris HCl, pH 6.8, 3.3% SDS, 10% glycerol, and 2% 2-mercaptoethanol. Before applying the samples to the wells in the stacking gel, bromophenol blue was added to a final concentration of 0.05%. Electrophoresis was performed in a Pharmacia GE-2/4 LS electrophoresis apparatus at 15–20 mA per slab gel for approximately 15 hr, or until the tracking dye reached the bottom of the gel. Molecular

weight standards were phosphorylase b (M_r 94 kd), Albumin (M_r 67 kd), ovalbumin (M_r 45 kd), carbonic anhydrase (M_r 30 kd), and trypsin inhibitor (M_r 20.1 kd).

Immunoblotting. Separated polypeptides were blotted onto a nitrocellulose membrane (Schleicher und Schuell) essentially according to the procedure described by Towbin et al. (1979). A 25 mM Tris, 192 mM glycine buffer, pH 8.8, containing 20% (v/v) methanol, was used in a commercial blotting apparatus (Bio-Rad). Transfer was at 30 V for 15 hr.

The immunochemical detection of blotted polypeptide antigens was performed as described by Tsang et al. (1983). The blots were first soaked in PBS, containing 0.3% Tween-20 for 1 hr at room temperature. The blots were then washed twice for 30 min with PBS containing 0.05% Tween-20 and incubated with the appropriate antiserum. A mixture of rabbit antisera directed against water-soluble and membrane-bound male and female antigens was used to analyze sex-linked antigens, and mouse antisera from mono- and bisexually infected mice were used to study the immune response in mice. Control blots were incubated with negative rabbit and mouse serum. The rabbit sera were diluted 1:800 and the mouse sera 1:25. Incubation was for 90 min at room temperature. The blots were then washed four times with PBS containing 0.05% Tween-20 and incubated with a peroxidase-conjugated goat anti-rabbit IgG (Nordic Immunological Laboratories) or a peroxidase-conjugated sheep anti-mouse IgG (Institut Pasteur). Conjugates were diluted 1:1000 and incubated for 1 hr at room temperature. Once again the blots were washed with PBS, containing 0.05% Tween-20, and finally rinsed in PBS without Tween 20. Staining was in PBS, containing 1.3 mM 3,3′-diaminobenzidine (Fluka), 1.4 mM 4-chloronaphthol (Merck), and 0.012% hydrogen peroxide (Merck). Color development was stopped by washing with deionized water. The stained blots were dried protected from light.

RESULTS

Analysis of male and female antigen preparations was performed by immunoelectrophoresis. Figure 1 shows the results obtained with an antiserum prepared by immunization of a rabbit with male antigen preparations. The antigen preparations used in the middle electropherograph were prepared from male and female worms isolated from bisexually infected hamsters. Several male-specific or predominantly male antigens gave precipitation lines. These lines are indicated by figures (number 1–5). The major male-specific precipitation line is shown as number 2. Line number 3 represents an antigen, which seems to be more abundant in males than in females, and lines number 1, 4, and 5 are exclusively obtained with the male antigen preparation. The female antigen preparation gave only one female specific precipitation line, which is

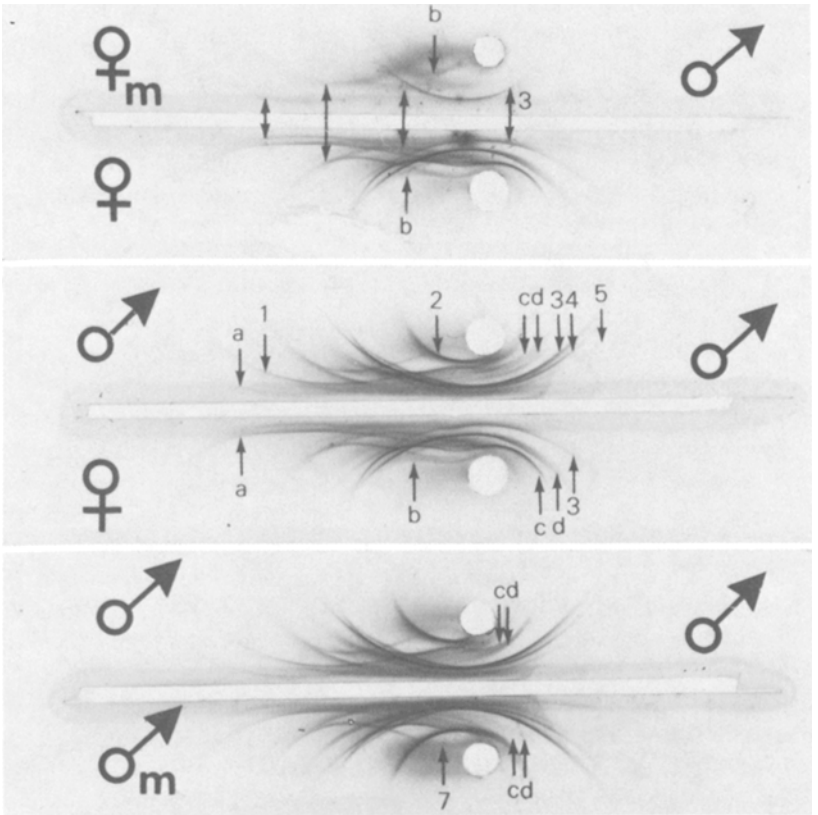

FIG. 1. Immunoelectrophoresis of antigens from bisexually reared males (♂), bisexually reared females (♀), monosexually reared males ($♂_m$), and monosexually reared females ($♀_m$) against serum from a rabbit immunized with antigens from bisexually reared male worms. Male-specific precipitation lines are indicated with numbers, female-specific lines with letters.

indicated by the letter b. Lines indicated by letters a, c, and d represent antigens which are more abundant in females than in males.

We also used antigen preparations obtained from monosexually reared male and female worms (upper and lower immunoelectropherographs of Figure 1). The antigen preparation from monosexually reared males gave a precipitation pattern very similar to that obtained with the preparation from bisexually reared males. A faint additional precipitation line, indicated by number 7, was obtained. The predominantly female antigens c and d, which could be observed in the preparation from bisexually reared males, are nearly absent in the preparation from monosexually reared males. A drastic reduction in the number of

precipitation lines was observed when a preparation from monosexually reared females was used. The presence of precipitation line number 3, which contains antigens predominantly present in the males, was very remarkable.

In a parallel immunoelectrophoresis experiment, we used an antiserum prepared by immunization of a rabbit with the preparation from bisexually reared females. Again, antigens extracted from monosexually and bisexually reared worms were analyzed. Surprisingly, another male-specific antigen was found (Figure 2, line 6). This antigen was present in bisexually reared males only, and not in males from monosexually infected hamsters. Two of the antigens, which with the "anti-male" serum appeared to be male specific, were found

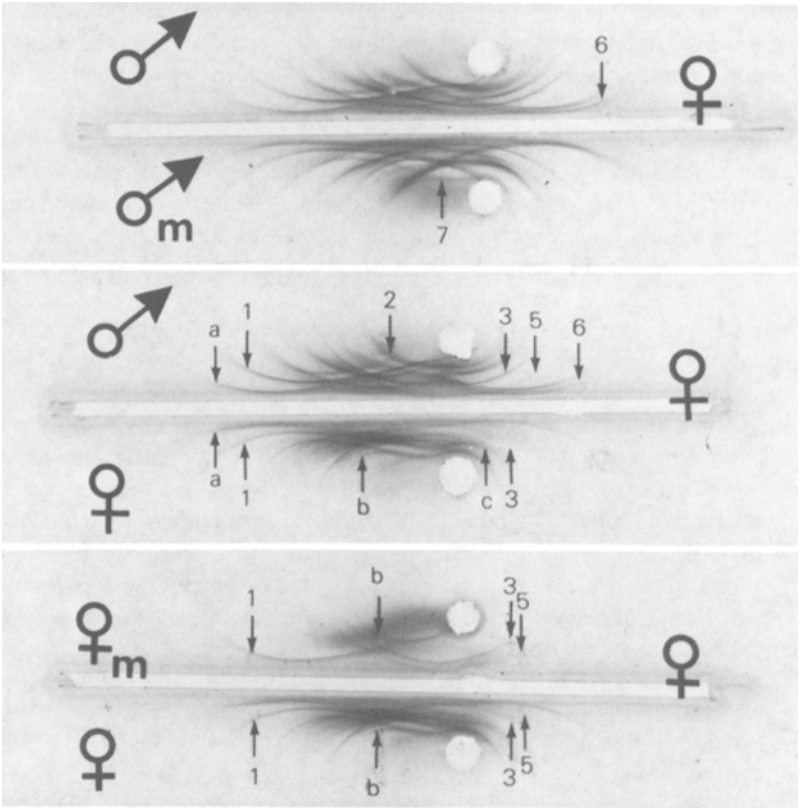

FIG. 2. Immunoelectrophoresis of antigens from bisexually reared males (♂), bisexually reared females (♀), monosexually reared males ($♂_m$), and monosexually reared females ($♀_m$) against serum from a rabbit immunized with antigens from bisexually reared female worms. Male-specific precipitation lines are indicated with numbers, female-specific lines with letters.

both in male and female antigen preparations (numbers 1 and 5). Similarly, an antigen previously found to be female-specific was also found now in both antigen preparations.

We also immunized rabbits with preparations from male and female worms reared in monosexually infected hamsters. The specificities of the antisera obtained after immunization of rabbits with the antigen preparations from the monosexually and bisexually reared males were very similar. However, immunization with a preparation from monosexually reared females gave very different results. None of the rabbits hyperimmunized with this "mono-female" preparation produced antibodies which gave precipitation lines with any of the male or female antigen preparations.

Antigen preparations extracted from males and females from mono- and bisexually infected hamsters were also analyzed by the enzyme-linked immunoelectrotransfer blot technique. Rabbits, used to prepare antisera, gave different humoral immune responses when immunized with male or female antigen preparations. However, considerable differences in response were also observed when different rabbits were immunized with the same antigen preparation. Identification of sex-linked antigens by immunoblotting is obviously only feasible when male and female preparations are compared using a single rabbit antiserum. To obtain a large diversity in reactivity towards male and female antigenic polypeptides in a single antiserum preparation, we mixed several rabbit antisera. These antisera were directed against water-soluble and detergent-extracted male and female antigens. A selection was made of those antisera containing antibodies reactive on blots with the largest number of antigenic polypeptides. Antigen preparations analyzed in the immunoblotting experiment were extracted from separated bisexually reared males and females as well as from monosexually reared males and females. Moreover, whole male and female worms were extracted with sample buffer and directly applied to the polyacrylamide slab gel. In order to subject the same amount of antigen preparation to each sample well, protein determinations were performed on all samples.

Figure 3 shows that a large number of antigenic polypeptides were detected in each of the six preparations. A considerable similarity in patterns was observed. Major antigens with an apparent molecular weight of 20, 24, 40, 45, 51, 92, and 150 kd were observed in all preparations. Many more female- than male-specific polypeptides were observed. Major female-specific polypeptide antigens with an apparent molecular weight of 32, 37, 60, and 66 kd were found. Control blotting experiments with egg antigens showed that the female-specific antigens did not originate from eggs. Only one male-specific polypeptide was detected. This polypeptide (M_r 33 kd) is present in the SDS extract of whole male worms. Two high-molecular-weight polypeptides (M_r 120 and 130 kd) were predominantly present in the male preparations.

The preparation from monosexually reared female worms contained several antigenic polypeptides not present in any of the other preparations (M_r 30,

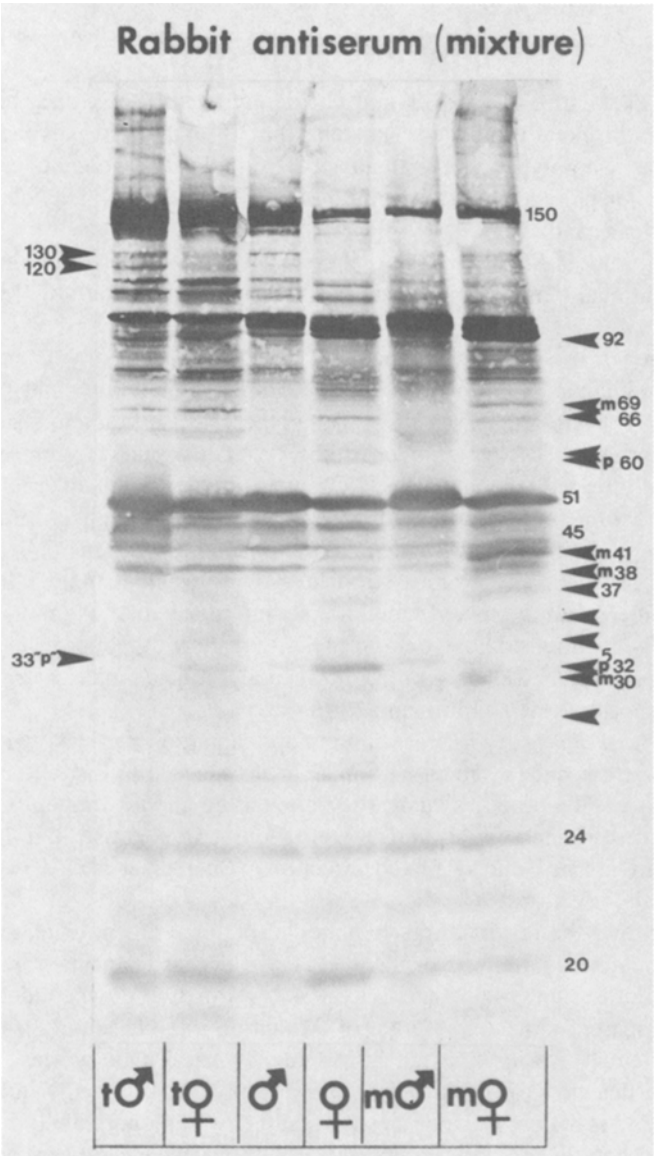

FIG. 3. Immunoblotting of antigens from bisexually reared males (♂), bisexually reared females (♀), monosexually reared males (m♂), and monosexually reared females (m♀). Male and female antigen preparations were also obtained by extraction of whole male and female worms with SDS-sample buffer (t♂ and t♀). A mixture of rabbit antisera against male and female water-soluble and membrane-bound antigens was used for the detection of blotted polypeptide antigens. Arrows on the left indicate male-specific antigens, arrows on the right, female-specific antigens. Antigens, specific for monosexually reared female worms, are indicated by the letter (m), and pair-specific antigens by the letter (p). The apparent molecular weight of major antigens and antigens of special interest, estimated from the position of molecular weight standards, is given in kilodaltons.

38, 41, and 69 kd). Especially the 30- and 41-kd polypeptides gave clear bands. In females from bisexually infected hamsters, the 30- and 41-kd polypeptides were absent, but two polypeptides with an apparent molecular weight of 32 and 60 kd, specific for paired females, were present. The 32-kd polypeptide gave an especially clear band.

Immunoblotting of SDS extracts of whole male and female worms showed only a few additional bands compared to the "standard" preparations (M_r 33, 50 and 67 kd).

The difference in antigenic composition of females from mono- and bisexually infected hamsters is very clear from Figure 4. Smaller amounts of antigen (20 μg/well) were applied to a 8–15% polyacrylamide gradient slab gel. The immunoblot shows a large number of polypeptides exclusively present in the monosexually reared female worms. Moreover, it is shown that the relative concentration of three polypeptides with apparent molecular weights of 92, 94, and 96 kd, is very different in the male and the female preparations.

Sera from infected mice were used to investigate whether the sex-linked antigens, identified with the mixed rabbit antiserum, also evoke a humoral immune response in an infected host. Sera from Swiss mice with monosexual male and female infections, as well as sera from bisexually infected mice, were used for immunoelectrophoresis and immunoblotting.

Figure 5 shows that very different immunoprecipitation patterns were obtained with sera from mice infected with male or female worms only. Remarkable is the absence of antibodies against the circulating anodic antigen (CAA) in serum from mice infected with female worms only. In contrast, high levels of antibodies are formed during mixed infections (Deelder et al., 1976) and monosexual male infections.

Figure 6 shows the results of an immunoblotting experiment using mouse antisera. The obtained pattern of bands was very different from that obtained with the rabbit antiserum. Major reactivity was towards two polypeptide antigens with an apparent molecular weight of 32 and 36 kd. These polypeptides are present in female worms, but not in bisexually reared male worms. Both antigens can be detected with sera from monosexually and bisexually infected mice. Remarkable is the presence of these two antigens in monosexually reared male worms. In conformity with this presence is the occurrence of antibodies against the two antigens in serum from mice infected with male worms only.

A remarkable difference between sera from monosexually and bisexually infected mice was the reactivity of the latter serum towards a 60-kd polypeptide. The presence of the polypeptide antigen in the SDS extract of mixed worms and in monosexually reared female worms was demonstrated.

Control immunoblotting experiments were performed to determine whether the female-specific antigens originated from eggs. However, no cross-reactivity of the female-specific antigens and egg antigens was observed.

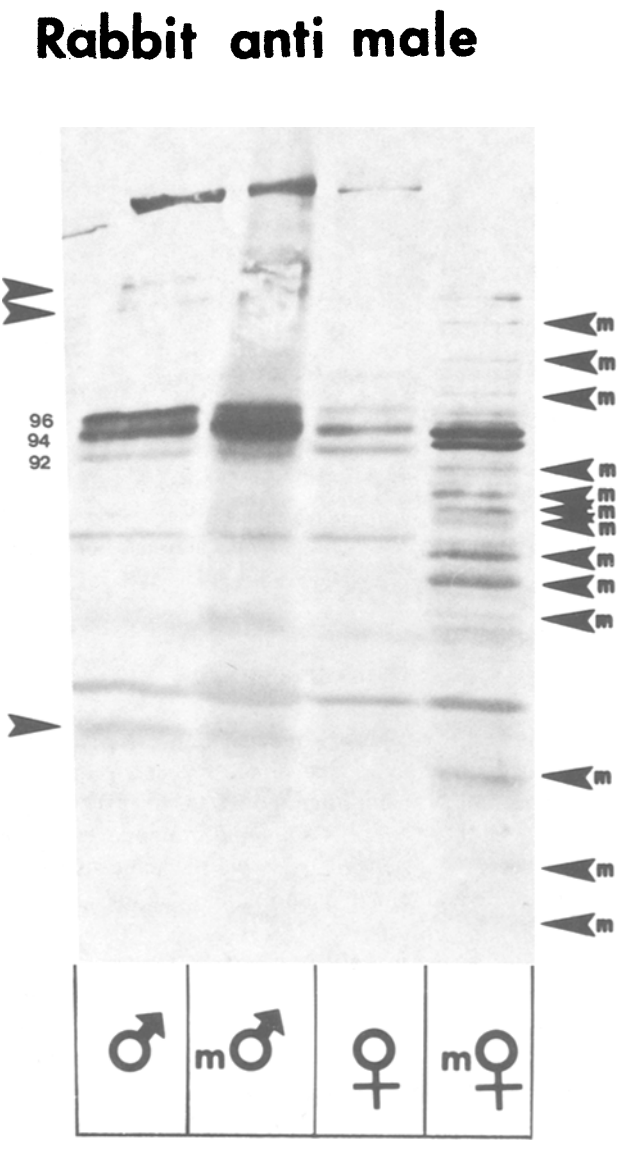

FIG. 4. Immunoblotting on a 8–15% gradient SDS-polyacrylamide slab gel of male and female antigen preparations, isolated from mono- and bisexually infected hamsters. Detection of blotted antigens was by reaction with an antiserum from a rabbit immunized with bisexually reared male worms.

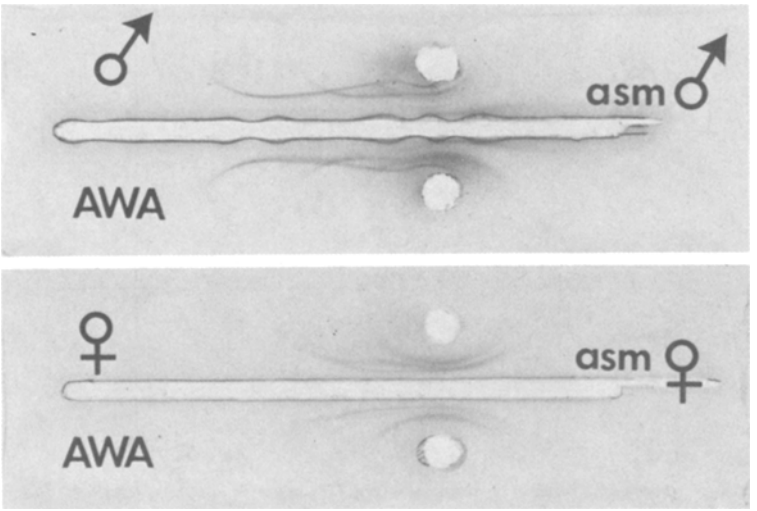

FIG. 5. Immunoelectrophoresis of male and female antigen preparations isolated from bisexually reared worms against antiserum from mice infected monosexually with male or female worms.

DISCUSSION

The aims of our studies on the sex-linked antigens of *Schistosoma mansoni* are to determine whether defined chemical substances are involved in the initiation of mating and female maturation and, if so, to investigate whether antibodies directed against these possibly antigenic components can interfere with the earlier mentioned processes. Moreover, we are interested in the direct or indirect effects of mating and female maturation on the immune response of the host.

Preceding research on the first objective, preliminary investigations on sex-linked antigens were performed. For comparative analysis of male and female antigen preparations, we used a single polyvalent antiserum reactive with a wide range of antigenic determinants. The obvious method for research on the second objective was the analysis of the humoral immune response of experimentally infected hosts. A comparison was made between the humoral immune response of monosexually and bisexually infected mice. Only mice receiving a bisexual infection develop a high degree of resistance to reinfection (Dean et al., 1978). This suggests that egg antigens or antigens which are produced exclusively by worm pairs play an important role in the development of resistance. In this study an antigenic polypeptide of 60 kd was identified which is presented to the immune system of the host by paired worms only.

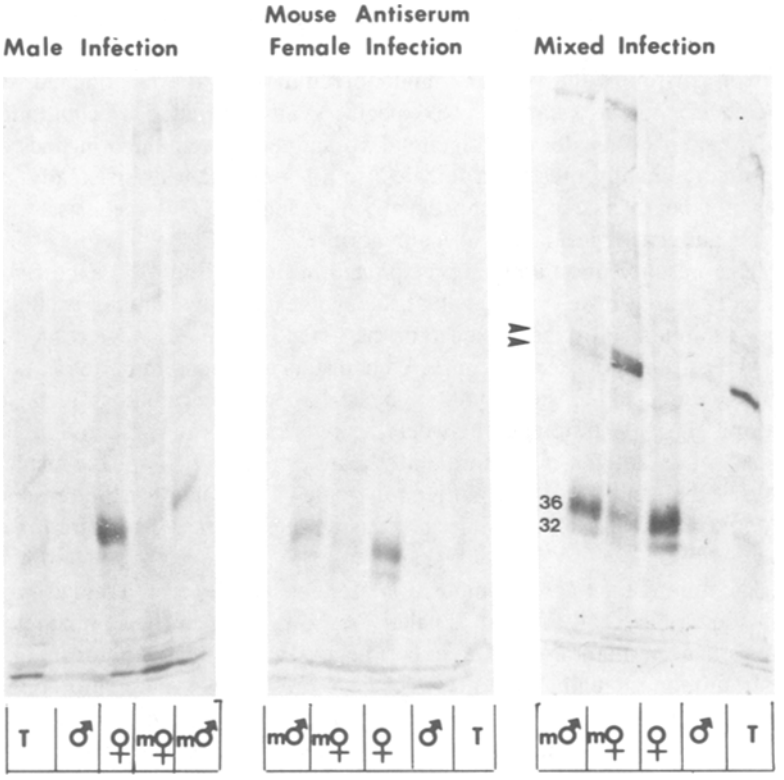

FIG. 6. Immunoblotting of male and female antigen preparations, isolated from mono- and bisexually infected hamsters. Freshly isolated worm pairs were also directly extracted with SDS-sample buffer (T). Electrophoresis was on a 8–15% gradient polyacrylamide gel. Blotted polypeptide antigens were detected with serum from mice monosexually infected with male or female worms or with serum from bisexually infected mice.

In contrast with earlier results obtained by Capron et al. (1965), analysis of sex-linked antigens by immunoelectrophoresis showed the presence of a number of male and female specific antigens. Even with sera raised in rabbits by immunization with a female antigen preparation, male-specific antigens were precipitated. Similarly, sera from rabbits immunized with antigen preparations from male worms can detect female-specific antigens. The same kind of observations were made when sera from monosexually infected mice were used for immunoblotting experiments. Aronstein and Strand (1984) reported a similar phenomenon in their studies on precipitation of antigenic glycoproteins with anti-male and anti-female mouse sera. Possibly, the female- and male-specific antigens are present in minute amounts in the worms of the other sex. This

minute amount might be sufficient or even optimal to evoke an immune response.

Comparison of the various immunoprecipitation patterns obtained by immunoelectrophoresis suggests a sex-specific synthesis, induced or inhibited by the partner, or a transfer of antigens. Two antigens precipitated in lines c and d are predominantly present in females, to a lesser extent in bisexually reared males, and nearly absent in monosexually reared males. This suggests a transfer of these antigens from female to male worms.

The presence of an antigen precipitated in line 6 (Figure 2) exclusively in bisexually reared males suggests that the synthesis of this antigen by the male worm is stimulated by the presence of the female worm.

Males from monosexually infected hamsters are very similar to males from bisexually infected hamsters, both in physical appearance and in antigenic composition. The only difference between the two male worm preparations is the presence of an antigen in monosexually reared males (line 7). This result suggests that the synthesis of this antigen by males is inhibited by the presence of female worms. It is also possible that this antigen is transferred from male to female worms.

The different antigenic composition of monosexually reared female worms, compared to bisexually reared females, is shown both in the immunoelectrophoresis and the immunoblotting experiments. Immunoelectrophoresis of antigens from monosexually reared females gave only a few precipitation lines, all of which were present also in bisexually reared females. In contrast to these results, results from immunoblotting experiments showed the presence of several antigens unique to monosexually infected females. The immunogenicity of the preparation from monosexually reared females is very low. Although several attempts were made, we failed to obtain any humoral immune response in rabbits immunized with this antigen preparation. Capron and Vernes (1968) reported a less marked precipitin formation during monosexual female infections in hamsters, in comparison to bisexual infections.

Immunoblotting experiments showed the presence of several female-specific antigens. The presence of a number of these antigens was limited to either mono- or bisexually reared female worms. Contact with male worms induced a switch in antigen synthesis, an additional processing by the females, or a transfer to and processing by male worms. Of particular interest are the disappearance upon mating of two major female-specific polypeptide antigens with an apparent molecular weight of 30 and 41 kd and the appearance of a major female specific polypeptide with an apparent molecular weight of 32 kd. Preliminary experiments have shown that the latter antigen is identical to one of the major microsomal antigens, as described by Tsang et al. (1984). The antigen, which is found exclusively in the microsomal fraction of a female worm homogenate, could be a surface antigen identical to the major 32-kd surface antigen described by Payares et al. (1985).

Although the use of rabbit antisera in the immunoblotting experiment showed clear differences between male and female preparations, these differences were much better expressed with sera from infected mice. The resemblance of the immunoblotting patterns obtained with sera from mice monosexually infected with male or female worms is striking. Both sera reacted strongly with a female-specific polypeptide antigen with an apparent molecular weight of 36 kd. This antigen was not present in eggs. Compared to the rabbit serum, the mouse serum reacted less strongly with the 32-kd polypeptide antigen. Of particular interest was the reactivity of the serum from bisexually infected mice with a 60-kd polypeptide. The absence of antibodies reactive with this antigen in sera from monosexually infected mice suggests that presentation of the 60-kd antigen by worm pairs is essential for evoking a humoral immune response in mice. The presence in monosexually reared females suggests a transfer of the antigen from females to males when worms are paired.

(Received October 1, 1985; accepted January 13, 1986)

Abstract—Mechanisms by which schistosomes escape host immune responses are reviewed, with particular emphasis regarding the possible contributions of host or host-like Fc and C3 receptors on adult parasites.

Key Words—*Schistosoma mansoni*, Fc receptors, C3 receptors, developmental stage antigen expression, host immunoglobulins, antigenic modulation, immune escape.

INTRODUCTION

Parasites which inhabit the bodies of their hosts are subjected to an awesome panoply of defense mechanisms, some of which are highly specific while others are more general in nature. Successful parasites have evolved mechanisms for accommodating themselves to these defenses and are capable of surviving their onslaught, at least until they can reproduce. One of the most successful parasitic adaptations to murine and primate hosts is the genus *Schistosoma*. This parasite is capable of penetrating the primary barrier to infection, the skin, migrating via the circulatory system to the heart, lungs, and ultimately, the liver, and establishing reproducing adult worms which survive for decades in the definitive host. The adult parasite avoids immune destruction while using the host's immune response to exercise population control by eliciting effector mechanisms which destroy newly invading larvae. Furthermore, the schistosome uses the host's immune response to protect itself from the immune response by a series of biologically sophisticated molecular interactions at the host–parasite interface.

0098-0331/86/0800-1833$05.00/0

The primary research interest of our laboratory at Texas A&M has been, is, and will, at least in part, continue to be the elucidation of those mechanisms by which parasites escape host immune responses. We have been actively involved in pursuing two of the most accepted theoretical mechanisms, namely host antigen mimicry (Damian, 1964) and host antigen adsorption (Smithers et al., 1969). This presentation will focus on one aspect of our work regarding the presence of host or hostlike Fc and C3 receptors on adult parasites, since these molecules may well form a convenient bridge between those two theories.

Research on these receptors began indirectly in the early 1970s with the demonstration by Campbell (1973) that repeatedly frozen and thawed adult worms from mice released host IgG, as detected by immunodiffusion. Direct evidence for the presence of host immunoglobulin associated with the surface of adult parasites was presented for murine worms by Sogandares-Bernal (1976) by immunofluorescence and for baboon worms by Kemp et al. (1976) by immunoperoxidase procedures. The prevailing theory of immune escape at that time was immunological blockade or enhancement, a concept borrowed from tumor immunology which maintained that non-complement-fixing host antibodies of low affinity bound to tumor-specific antigens on tumor cells, thereby denying access to those antigens of more effective host antibodies or effector cells. This hypothesis was made particularly attractive by the observation of Phillips et al. (1975) that passively transferred immunoglobulins in rats from a certain stage of larval parasite migration enhanced the ability of the parasites to survive. Since enhancing or blocking antibody in the tumor systems had been shown to be tumor-antigen-specific IgG_{2b} in the murine model, the next logical step in establishing the schistosome immune escape mechanism to the immunological blockade was to demonstrate that schistosome-specific IgG_{2b}, and only schistosome-specific IgG_{2b}, was bound to the adult worm's surface. As it turned out, however, experiments designed to document these two critical points supported neither.

An immunocytochemical and immunodiffusion survey of tegument associated immunoglobulins on and from mouse worms established that not only was IgG_{2b} present, but also IgG_1, IgG_{2a}, IgG_3, IgA, and IgM (Kemp et al., 1978). The absence of IgD and IgE suggested a certain specificity of uptake by the parasite. It was further demonstrated that worms taken from mice which had been immunized against known antigens such as human red blood cells, bovine serum albumin, or horseradish peroxidase specifically bound those antigens to their surfaces through an antibody-mediated event (Kemp et al., 1977). These data not only established that a considerable amount of the tegument-associated immunoglobulin was specific for antigens other than the parasite but that the antibodies were oriented in such a manner as to be able to present their Fab regions for binding. This suggested an Fc region–parasite tegument linkage.

These observations led our laboratory to consider the possibility that the adult worm was escaping the immune response by masquerading as a host im-

mune effector cell such as a macrophage or a neutrophil. Were this consideration valid, one would predict certain host or hostlike components to be found on the parasite's surface, namely histocompatibility antigens, Fc receptors (FcR), and C3 receptors (C3R). It is of interest to note that histocompatibility antigens have been shown to be bound to both larval (Sher et al., 1978) and adult worms (Gitter and Damian, 1982), although the adult associated H_2 antigens proved incapable of stimulating a mixed lymphocyte reaction (Gitter et al., 1982).

The first direct evidence for FcRs and CRs associated with schistosomes was reported by Torpier et al. (1979) and Santoro et al. (1979). These workers identified receptors for IgG, C1q, and C3 on cercariae and new schistosomula, but not on lung stage schistosomula or adult worms. The negative results regarding adult worms was due to the tegument modulation mechanism (Kemp et al., 1980) which allows adult worms to selectively shed immunologically compromised antigens from their surfaces in less than 20 min at room temperature. The characterization of the modulation process was being conducted in our laboratory at the time of the receptor localization experiments and was not available to the French scientists.

Direct localization of IgG FcRs and C3Rs on adult *S. mansoni* was accomplished by the incubation of adult parasites in intact or modified antigen–antibody or antigen–antibody–complement complexes or in C3-coated bacteria in the presence of tegument modulation inhibitors (Tarleton and Kemp, 1981; McGuinness and Kemp, 1981). It was demonstrated that the receptors were generally distributed on the dorsal tegumental surfaces of adult male worms and that the receptors were probably different since the C3R, but not the FcR, proved to be formalin sensitive.

STUDIES OF RECEPTOR FUNCTION

Recent studies in our laboratory have focused on attempting to ascertain the origin and biological functions of these receptors in the host–parasite relationship.

FcR Studies. The only FcR exhaustively documented as to specificity has shown an affinity for IgG. Our data indicating the presence of other classes and subclasses of immunoglobulins prompted us to ask if there was one receptor which had a broad-spectrum binding range (a general FcR) or if each class and subclass of immunoglobulin had its own specific FcR. We reasoned that if one general receptor were present, preincubation of a worm in one class of immunoglobulin would saturate the available receptors and block the binding of any other class or subclass to the parasite. In performing these experiments, we found that incubation of the parasite in purified IgG prior to incubation in purified IgA did not block the uptake of IgA. Likewise, the binding of IgA did not

onstrated that the binding of either had no effect upon the uptake of the other. These data indicate that there are specific FcRs for IgG_1, IgG_{2b}, and IgA. The other classes and subclasses are being studied at this time to establish their binding specificities. These data also suggest that the receptors are of host rather than parasite origin, since it is difficult to envision a parasite evolving a genome for all murine or primate FcRs, while selectively leaving out those for IgD and IgE (these latter being the only isotypes not previously shown to be associated in any manner with the adult parasite's tegumental surface).

In related studies (Rasmussen and Kemp, 1985) we attempted to ascertain the possible contribution of the FcR to immune escape by defining under what conditions host immunoglobulin specifically binds to the parasite and what conditions or factors are required by the parasite to obviate that binding. Neither normal mouse serum, normal mouse IgG, nor immune mouse serum bound specifically to fresh worms or to worms that had their adsorbed host components removed from their tegumental surfaces by incubation in RPMI-1640 for 2.5–4 hr at 37°C (elution). Immune IgG does not bind to fresh worms, but does bind rather dramatically to eluted parasites. This specific binding was blocked by preincubation of the eluted worms in normal mouse serum or normal mouse serum minus IgG and was partially blocked by preincubation in immune mouse serum or normal mouse IgG. The specificity of this blocking phenomenon is illustrated by the failure of preincubation in mouse albumin, bovine albumin, or fetal bovine serum to contribute to immune IgG binding inhibition. These data suggest that, at least in vitro, adsorbed host components do contribute to the inhibition of specific antibody binding, therefore immune escape, and that the host components involved have yet to be completely identified. It is further apparent that the parasite is selective in what host serum components it adsorbs, host immunoglobulins being only a portion of what the parasite needs to protect itself.

C3R Studies. Although the presence of complement receptors has been firmly established to be associated with the tegumental surfaces of larval and adult parasites, the presence of complement components naturally bound to those surfaces has only recently been unequivocally demonstrated. Kabil (1976) reported the localization of C3 on the surfaces of female, but not male adult worms, while Sogandares-Bernal (1976) found no complement whatsoever on schistosome surfaces. Studies in our laboratory using anti-mouse C3 and fluoresceinated *Staphylococcus aureus* localization procedures (Kemp et al., 1980) confirmed the observations of Sogandares-Bernal (1976) that there was no detectable C3 on the free tegumental surfaces of either sex of adult parasite. However, employing peroxidase labeled anti-mouse C3 at the transmission electron microscope level, we found copious amounts of C3 bound to the membranes of the tegumental infoldings of male worms (Rasmussen and Kemp, in preparation). No C3 was localized on the free tegumental surface, which explains our negative data with the FB assay.

Further studies on the possible functions of C3Rs in the host–parasite relationship led us to observe that adult worms incubated for short periods of time (20–30 min) in normal mouse serum evinced pronounced tegumental damage, while worms incubated for up to 1.5 hr in immune mouse serum displayed no such damage. We also noted that the damage inflicted by normal mouse serum seemed confined to the apical areas of the male doral tubercles. Such observations were reminiscent of the fate of cercariae in normal vs. immune sera (Stirewalt and Evans, 1955; Tavares et al., 1978) and stimulated us to look further into the sources of tegumental damage. Normal mouse serum damage was abrogated by heat inactivation and by EDTA or zymosan treatment. EGTA treatment had no effect, indicating that the alternate rather that the classical complement pathway was responsible. Immune mouse serum which had had the immune IgG removed by protein A affinity chromatography proved as damaging as normal mouse serum, and the addition of immune IgG to the incubation media prior to either normal mouse serum or immune mouse serum minus IgG protected the tegumental surface from damage. It is obvious from these experiments that specific antigen–antibody interaction at the parasite's surface protects the worm in some manner from the destructive effects of alternative complement pathway activation. How these data relate to our previous work suggesting limited specific antibody interaction at the parasite's surface has yet to be determined and appears contradictory (and is always a sure sign that the system being studied is more complex than currently envisioned).

As an extension of these observations, we designed a series of experiments to test if the classical complement pathway could damage a schistosome's surface under conditions which would damage another membrane system. We immunized an infected mouse with rabbit RBCs so that we could obtain an antiserum which contained both anti-schistosome and anti-RBC antibodies. We fractionated this serum to obtain IgG by protein A affinity chromatography, then incubated it with a mixture of adult worms and rabbit RBCs. After 10 min at 30°C, we added normal mouse or guinea pig serum and observed the reactions with phase-contrast microscopy. In certain experiments, we added a solution of acridine orange and ethidium bromide to the media to document membrane disruptions. Intact cells and worms absorb the acridine orange and appear green with fluorescence microscopy, while dead or damaged cells or worms absorb the ethidium bromide and appear orange. The rabbit RBCs either swelled and burst or acquired an orange color, while the parasites appeared totally unaffected by the incubations.

We feel these experiments demonstrate that: (1) factors present in immune serum (perhaps anti-schistosome antibodies) protect the parasite from potential alternative pathway activation by mechanisms as yet not understood. It is possible that the antibodies bind to and disarm those surface molecules which would activate the alternative pathway, thereby sparing the worm one of the host's most effective nonspecific responses: (2) the classical complement pathway,

although active and uninhibited apart from the parasite's surface, is ineffective in dealing with the parasite. These conclusions support the previous observations of Santoro et al. (1979) and Levy-Schaffer et al. (1982).

Studies of Developmental Stage Expression of FcRs and C3Rs. Preliminary observations performed in our laboratory, intended to establish the developmental stage expression and specificity of the FcRs and C3Rs, have confirmed the observations of Torpier et al. (1979) as to the absence of receptors on lung stage worms. We have observed that at day 16 postinfection there is a mixed population of parasites in the liver of the mouse host, some of which are distinctly schistosomular and some of which are adult-like. Those parasites retaining their schistosomular characteristics have no detectable tegument-associated immunoglobulins, no FcRs, no C3Rs, and are unable to modulate their surfaces. The adult-like worms do possess immunoglobulins, FcRs, C3Rs, and can modulate their surfaces. If these observations can be confirmed, they would indicate a dramatic, and potentially critical, developmental shift between days 14 and 20 postinfection and might further suggest the point in the developmental sequence when the schistosome metamorphoses from being at the mercy of the immune response into being its master.

SPECULATIONS

The following comments are speculative in nature, but are based upon our experience in working with the receptors.

1. We feel that the parasite is probably borrowing both FcRs and C3Rs from the host. If this is true, it should also be recognized that the parasite is displaying an impressive degree of control over its interface with the host. The fact that receptor-bound molecules are modulated when immunologically compromised indicates an intimate molecular association between the receptor and the cytoskeleton of the tegumental cytoplasm. If our working hypothesis is correct and the parasite is borrowing the receptors from host cells, the candidate donor host cell or cells should prove to possess histocompatibility antigens, receptors for some fragment of C3, and Fc receptors for all classes and subclasses of host immunoglobulins except IgD and IgE. The elucidation of the mechanism(s) of host membrane antigen acquisition by the parasite is of profound importance in understanding the host–parasite relationship at the molecular level. The future directions of research in this area may already have been suggested by the work of Caulfield et al. (1980a, b) where the apparent transfer of membrane from neutrophils to schistosomula was observed.

2. The adsorption and flagrant display of host immunoglobulins on the parasite's surface may well serve other purposes than simple steric blockade. The removal of significant quantities of antibody from the circulation by the parasite, if only for limited periods of time, may influence the idiotype regu-

lation network resulting in altered immune responses. This idea is particularly attractive when one considers that the FcR-bound immunoglobulins are oriented so that their idiotypes are prominently displayed. The possible function of these antibodies in immunoregulation is not a new idea, given the work of Auriault et al. (1980, 1981), which suggests the proteolytic cleavage of schistosomular FcR-bound antibodies are involved in inhibition of immune responses.

3. The actual role of C3Rs in the host–parasite relationship remains unclear. It is apparent that the parasite is capable of using facets of the immune response to negate the effects of other manifestations of immunity. The specific binding of antibody to the adult parasite's surface is probably an unusual event, but even in experimental situations where antibody binds and complement is activated by the classical pathway, no one has ever reported tegumental damage. Activation of the alternative pathway is extremely damaging to the worm under experimental conditions in normal serum, but we have no evidence that such activation occurs in vivo, where the worm is constantly exposed to immune serum. The presence of C3 in the tegumental infoldings, but not on the free surface, is intriguing and suggests a membrane difference or a differential distribution of membrane characteristics. It is possible that activated C3, from either pathway, is complexed to and inactivated by the C3R, which then moves from the free surface to the infoldings in order to facilitate degradation of that potentially hazardous molecule.

4. The C3R may have nothing whatsoever to do with complement inactivation. Given the well-established biochemical associations between the complement and clotting cascades, perhaps the C3R is involved in some way in aiding the parasite to avoid clot formation. Taking into account the established presence on the parasite of an inhibitor of activated Hageman factor, dubbed bilharzin by its discoverers (Tsang and Damian, 1977), such a suggestion is reasonable.

The purpose of this presentation was to briefly describe the background of the research on immunological receptors associated with *S. mansoni* and to superficially communicate the present status of our work in that area. These studies are consistently suggesting that we have only scratched the surface of an extremely complex series of biological interactions between a well-adapted parasite and its host. We expect to be quite busy sorting out these interactions for some time to come.

(Received October 1, 1985; accepted December 23, 1985)

Abstract—The identification of pheromones and chemicals that may inhibit or stimulate growth and reproduction necessarily leads to the consideration of biochemical methods to isolate and characterize these molecules. Analysis of *Schistosoma mansoni* surface antigens by direct radioiodination, metabolic labeling with tritiated and ^{14}C-tagged hexose precursors, affinity chromatography, isoelectric focusing, hydrophobic chromatography, and competitive inhibition is presented to illustrate methods of immunochemical analysis and antigen purification. Technical problems that may arise when investigating parasite molecular biology are described. Evidence of diminished fecundity of female worms in acutely infected mice supports the theory of a "crowding effect" in murine schistosomiasis and suggests the possibility that worm secretions or metabolites may function as chemical messages to inhibit oviposition. There is also evidence that the immune response of mice to an isolated surface antigen from adult worms results in the attenuation of hepatic granulomata of challenge infections. Several hypotheses are proposed to elucidate the molecular basis for chemical communication between trematodes and analytical approaches to test these hypotheses are outlined.

Key Words—Trematoda, *Schistosoma mansoni*, surface antigens, radiolabeling, affinity chromatography, hydrophobic chromatography, lectins, receptors, pheromones, proteins, glycoproteins, crowding effect.

No. (NIH) 78-23.

INTRODUCTION

There is increasing evidence for communication between parasites with regard to host location (Kearn, 1986), sexual attraction and pairing (Fried, 1986; Childs et al., 1986; Shirazian et al., 1986), and vitellogenesis (Popiel, 1986); and in many instances, the existence of a chemical message is implied. Elucidation of the molecular basis for chemical communication would not only increase our understanding of parasite biology, but would also suggest practical methods to control parasite maturation, egg deposition, and transmission of disease. Chemical communication implies that messages are both sent and received. The transmission of chemical messages may include the active secretion of specific functional molecules, the routine turnover of surface membrane proteins and glycoproteins, or some feedback mechanism involving the release of metabolic by-products. If chemical receptors are present on trematodes, they most likely occur on the tegumental surface. For this reason, an understanding of the molecular composition of the tegument—that active interface between the parasite and its microenvironment (terminology of Dogiel, 1958)—becomes essential.

The identification of pheromones or receptor sites necessarily leads to the consideration of methods to isolate and characterize these molecules. However, the biochemical characterization of trematode secretions or membrane-bound molecules is not a simple task. For several years, our laboratory has been actively engaged in the immunochemical examination of surface antigens on *Schistosoma mansoni* adult worms. Although this work has primarily dealt with large molecular weight, polar antigens rather than small nonpolar or lipophilic pheromones, the basic conceptual approach to molecular analysis is similar for both. Our attempts to isolate and characterize surface antigens are not only particularly relevant to the identification of specific tegumental receptor sites, but also help to illustrate many of the technical problems associated with any investigation of the cell biology of complex metazoan parasites.

PITFALLS IN ANTIGEN ISOLATION AND CHARACTERIZATION

Direct Radioiodination of Surface Proteins. Initial attempts to characterize the surface antigens of *Schistosoma mansoni* sought to apply the well-defined methods of protein radiolabeling that had proven successful in the study of lymphocytes and tumor histocompatibility antigens (Kusel et al., 1975; Ruppel, 1978). It was learned, however, that lactoperoxidase-catalyzed radioiodination of *S. mansoni* adult worms yielded highly inconsistent results (Hayunga and Murrell, 1982). A representative SDS-PAGE profile of detergent-extracted tegumental proteins following lactoperoxidase labeling in phosphate-buffered saline (PBS) is shown in Figure 1; several protein peaks are clearly discernible. In contrast, when worms were labeled under identical conditions in Earle's balanced salt solution (EBSS), no protein peaks were present (Figure 1). It had

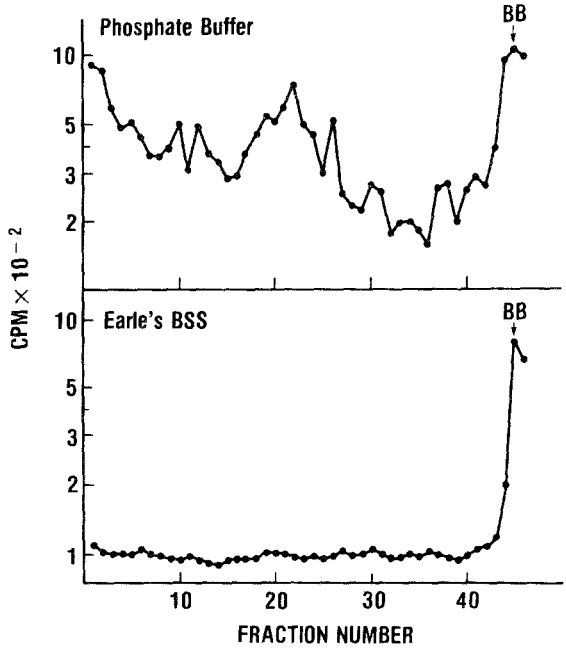

FIG. 1. Comparison of detergent-extracted tegumental proteins from *S. mansoni* adult worms following lactoperoxidase-catalyzed radioiodination in phosphate-buffered saline (upper graph) and Earle's balanced salt solution (lower graph), 10% gels, 2-mm slices.

been found previously by Ruppel (1978) that when worms were incubated in PBS, internal proteins leaked into the media where they became radiolabeled and subsequently adsorbed by the tegument, giving erroneous results. In a balanced salt solution, neither leakage nor labeling took place. Thus, the choice of buffer in radiolabeling experiments was found to be critical.

Metabolic Radiolabeling of Tegumental Glycoproteins. Metabolic labeling has yielded considerable information about membrane turnover by adult schistosomes. We have examined the incorporation of several labeled hexose precursors, as shown in Table 1, and found *S. mansoni* tegumental glycoproteins to have an average biological half-life ranging from 15 min to 2 hr. This is in general agreement with the turnover rates of approximately 2 hr or less determined by Wilson and Barnes (1977), Nash (1979), and Podesta (personal communication), but differs from those reported by Kusel and MacKenzie (1975) and Samuelson and Caulfield (1982), who calculated a longer turnover time. Figure 2A shows the amount of labeled tegumental extract containing tritiated glucosamine that precipitates in 20% trichloroacetic acid (TCA) after varying "chase" incubations in media without the labeled precursor. The points on this graph would be in general agreement with an exponential decay curve, $y = ae^{bx}$, where $a = 10$ and $b = -0.45$. Loss of label is virtually complete by 12

TABLE 1. ESTIMATE OF TURNOVER RATES FOR TEGUMENTAL GLYCOCONJUGATES BASED UPON PULSE-CHASE LABELING WITH HEXOSE AND HEXOSAMINE PRECURSORS

Labeled precursor	Turnover rate (expressed as half-life)
[^{3}H]Galactose	30 min
[^{3}H]Glucose	15 min
[^{3}H]Glucosamine	$1\frac{1}{2}$ hr
[^{3}H]Fucose	1 hr
[^{14}C]Glucose	50 min
[^{14}C]*N*-Acetylglucosamine	45 min
[^{14}C]Mannose	40 min
[^{14}C]Galactosamine	2 hr
[^{14}C]*N*-Acetylgalactosamine	75 min

hr, and by extrapolation, the average half-life of tegumental glycoproteins labeled with this precursor can be estimated to be approximately $1\frac{1}{2}$ hr.

If we assume that all the label lost from the tegument is shed into the media, then we can calculate an "expected" curve for accretion of labeled TCA-ppt material in the media, $y = a(1 - e^{bx})$, as shown in Figure 2B. Although the total cpm recovered from the media corresponded to the total label lost by the tegument, the amount of TCA-ppt material (presumptive glycoprotein) was less than expected. This discrepancy is probably due to breakdown of large molecules incubating in the culture media for several hours, although recycling (ingestion) of labeled glycoprotein by the worms may also occur. The observed values in Figure 2B would be in general agreement with an exponential decay curve superimposed on the "expected" curve, $y - a(1 - e^{bx}) + a'x^{b'}$, where $a = 10$, $b = -0.45$, $a' = -0.01115$, and $b' = 2$.

Ordinarily, a metabolic labeling experiment would require a "pulse" label with a small amount of radioactive precursor followed by a "chase" incubation in media containing an excess (40 mM, for example) of unlabeled precursor. Such was the initial design of our experiments. However, we soon learned that our protocol needed revision because concentrations of glucosamine as low as 1.8 mM (0.4 mg/ml) were shown to be toxic for *S. mansoni* (Bueding et al., 1954). Glucosamine appears to be a normal component of some tegumental glycoproteins (Figure 3). However, it is thought that with high concentrations of this molecule, a build-up of metabolic by-products, such as a phosphate ester of glucosamine, may interfere with chemical reactions essential for the survival of the worms (Bueding et al., 1954). Regardless of the mechanism involved, a "chase" incubation using 40 mM glucosamine would probably have made a serious impact on the normal physiology of the parasite, and thus compromised

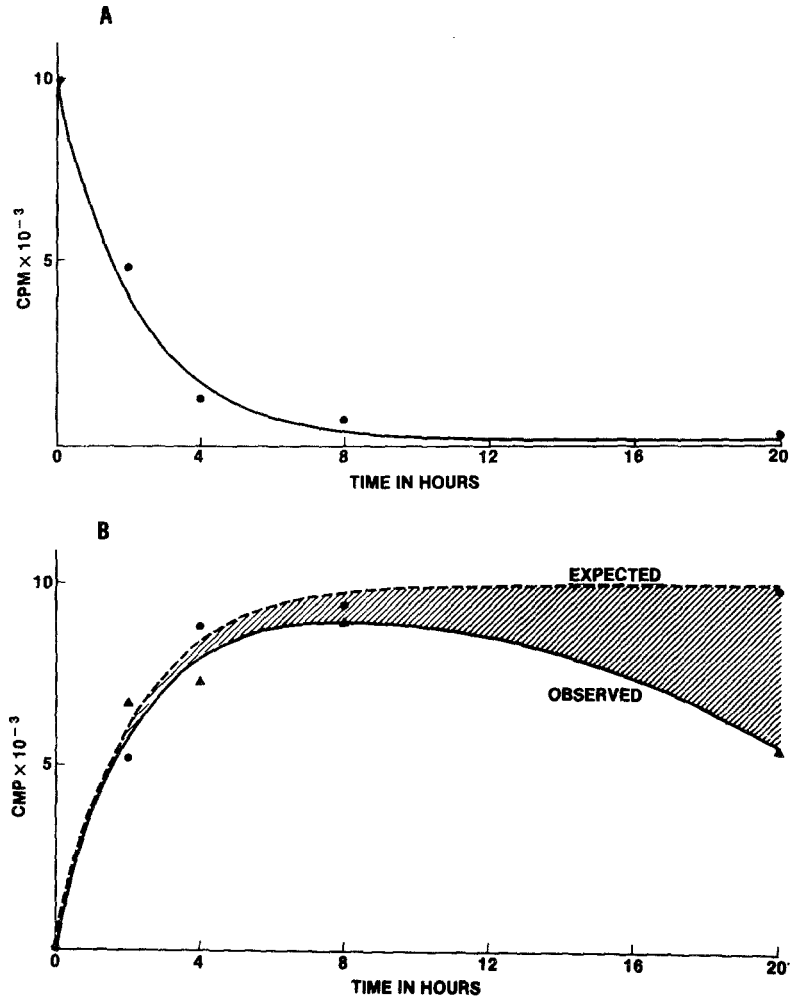

FIG. 2. Amount of TCA-precipitable, detergent-extracted tegumental material (expressed as counts per minute per 100 worms) recovered after a 2-hour incubation with tritiated D-glucosamine. Time refers to the number of hours of incubation in media without label subsequent to radiolabeling. (A) Labeled glycoprotein present in the tegumental extract; (B) labeled glycoprotein present in the culture media; "expected" values are calculated from the previous graph.

the experiment. For this reason, our protocol to examine turnover of glucosamine-containing tegumental glycoconjugates utilized "chase" incubations in unaltered NCTC-135 media which contains only 18 μM glucosamine (Evans et al., 1964). A complication such as this illustrates the importance of a sound knowledge of the experimental animal when designing in vitro studies.

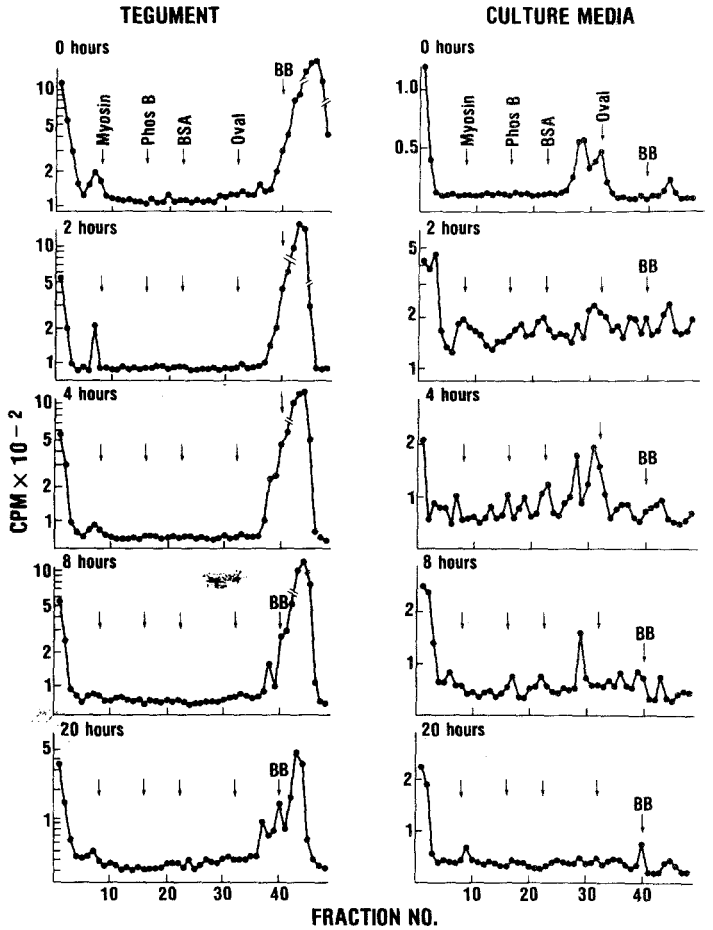

FIG. 3. SDS-PAGE profile of [^{3}H]glucosamine-labeled *S. mansoni* detergent-extracted tegument and culture media following various lengths of "chase" incubation, 7½% gels, 2-mm slices.

Comparison of Tegumental Antigens and Culture Antigens. A qualitative analysis of tegumental glycoproteins and "culture secretory antigens" was performed by running SDS gels on samples taken at varying intervals after a "pulse" incubation in tritiated glucosamine. As shown in Figure 3, two glycoprotein peaks with apparent mol. wt. ≥ 300,000 and 210,000 are distinctly visible immediately after labeling ($t = 0$ hr); however, over 90% of the label migrated ahead of the dye front, which suggests incorporation into glycolipid or low molecular weight glycopeptides. Increasing incubations in unlabeled media result in decreased radioactivity of the tegumental extract, until by 8 hr, the 210,000 mol. wt. peak is barely discernible. At 8 and 20 hr, an additional peak of 30,000 mol. wt. is seen. We believe that this peak was present initially, but

was obscured by the large peak migrating ahead of the dye front; at 4 hr, the 30,000 mol. wt. peak appears as a distinct shoulder on this larger peak.

In contrast, the SDS-PAGE profiles of the culture media are more complex. The profile at $t = 0$ hr represents culture media taken immediately following the "pulse" incubation and contains three distinct glycoprotein peaks with apparent mol. wt. $\geq$ 300,000, 50,000, and 43,000. The 50,000 and 43,000 mol. wt. peaks were not present in the tegumental extracts and may represent nontegumental (gut?) secretions, enzymatic degradation of larger tegumental glycoproteins previously released into the media, or metabolic by-products excreted by the worms. The large ($\geq$300,000 mol. wt.) peak may represent early turnover of a tegumental component, or it may represent a totally different (secreted?) glycoprotein, as resolution of apparent molecular weight is poor in this region of the gel. Turnover of the 210,000 mol. wt. tegumental glycoprotein is not yet detected at $t = 0$ hr.

The profile of the culture media becomes more complex at $t = 2$ hr (i.e., "pulse" labeling followed by a 2-hr "chase" incubation in media without label) and later. The 50,000 and 43,000 mol. wt. peaks found at this time doubtless correspond to similar peaks at $t = 0$ hr, while the $\geq$300,000 and 210,000 mol. wt. peaks are probably tegumental glycoproteins shed into the media. The other peaks may represent additional excretions or secretions, or breakdown of the larger molecules. By 20 hr, few of these peaks can be identified, a finding that is consistent with extensive proteolysis, as very small labeled components would have been lost during the dialysis step that precedes SDS-PAGE.

The presence of the large ($\geq$300,000 mol. wt.) peak in the culture media prior to the appearance of the 210,000 mol. wt. peak suggests a faster rate of turnover for the former glycoprotein. Likewise, pulse-chase experiments using tritiated galactose suggest that a 260,000 mol. wt. component is shed more rapidly than other tegumental glycoproteins (data not shown). Since histochemical localization was not done, we do not know whether such apparent differences in turnover rate reflect gender differences between parasites or regional variation in glycoprotein composition and tegumental turnover as might be expected when comparing dorsal and ventral surfaces of male worms. Results of metabolic labeling with hexose precursors and lectin affinity chromatography (described below) reveal the complexity of the surface membrane glycoproteins and allow for a preliminary characterization of these molecules (Table 2).

Clearly, the surface membrane glycoproteins of *S. mansoni* do appear in time in the media and may constitute a significant portion of the so-called "culture secretory antigens." However, as depicted in Figure 3, the culture media also contains a variety of other worm-derived molecules and breakdown products which only compound the complexity of the preparation. For this reason, the harvesting of secretions or surface antigens from culture media should be approached with caution.

Lectin Affinity Chromatography. Receptor sites for concanavalin A and a variety of other lectins have been demonstrated on the surface of adult worms

[g] Apparent shift in molecular weight in borate eluate.
[h] Detected only in borate eluate; not significantly greater than control.
[i] Detected only in NP40 sample.

and schistosomula (Bennett and Seed, 1977; Murrell et al., 1978; Simpson and Smithers, 1980), and lectin affinity chromatography has been proposed as a method to isolate surface membrane antigens from *S. mansoni* (Bennett and Seed, 1977; Brink et al., 1980; Strand et al., 1982). However, efforts to isolate antigens in quantity were hindered by the heterogeneity of crude antigen preparations, by low yields of the final product, and by the apparent irreversible

on the same line, indicates our opinion that the glycoproteins detected are identical. Data

binding of material by Con A–Sepharose (Hayunga et al., 1983). When preparative columns were used a second time, the yield was markedly diminished. After three or more sample applications, the column took on a permanent yellow-brown color that was not removed by alternate washings to regenerate the column. It was also found that the temperature at which elution is done can have a major effect on antigen recovery (Hayunga, 1986). As shown in Figure

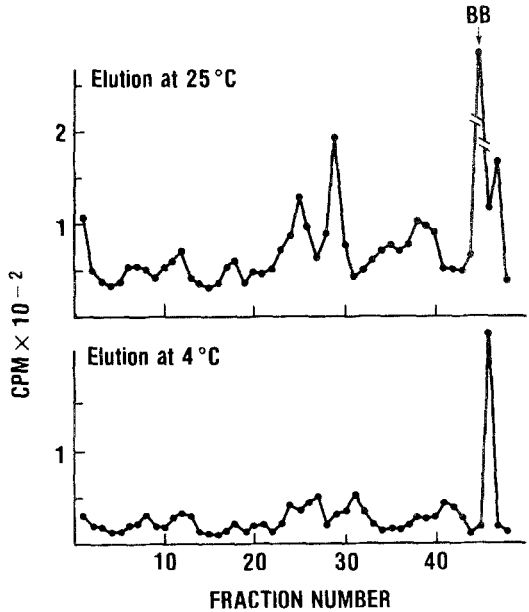

FIG. 4. SDS-PAGE profile of equal aliquots of Bolton-Hunter-labeled tegumental glycoproteins of *S. mansoni* adult worms eluted from identical concanavalin A–Sepharose 4B chromatography columns at different temperatures, $7\frac{1}{2}\%$ gels, 2-mm slices.

4, elution of a Con A–Sepharose column in a cold room results in far less recovery of adsorbed glycoprotein than elution of an identical sample and column at room temperature. Yet temperature can easily be overlooked when attempting to scale up production.

These problems were finally resolved by removing lipid from the crude preparation and by using a sequence of chromatography columns as shown in Figure 5. The purified glycoprotein migrated as a single peak in Ampholine isoelectric focusing. It reacted with sera from humans infected with *S. mansoni*, *S. haematobium*, or *S. japonicum*, and surface binding of fluorescein-labeled Con A by adult worms was inhibited by the purified antigen. Metabolic labeling experiments revealed significant incorporation of galactose into this molecule (Hayunga et al., 1983).

Analytical-scale affinity chromatography was also performed using immobilized *Lens culinaris* (lentil) lectin, wheat germ agglutinin, soybean agglutinin, and the agglutinins from *Ricinus communis* and *Helix pomatia* (Hayunga and Sumner, 1986). It was found that several glycoproteins reacted with more than one lectin. Therefore, to control for nonspecific adsorption of material by the lectin columns, we prepared control columns as follows: CNBr-activated Sepharose 4B or Sepharose 6MB was reacted with ethanolamine to block re-

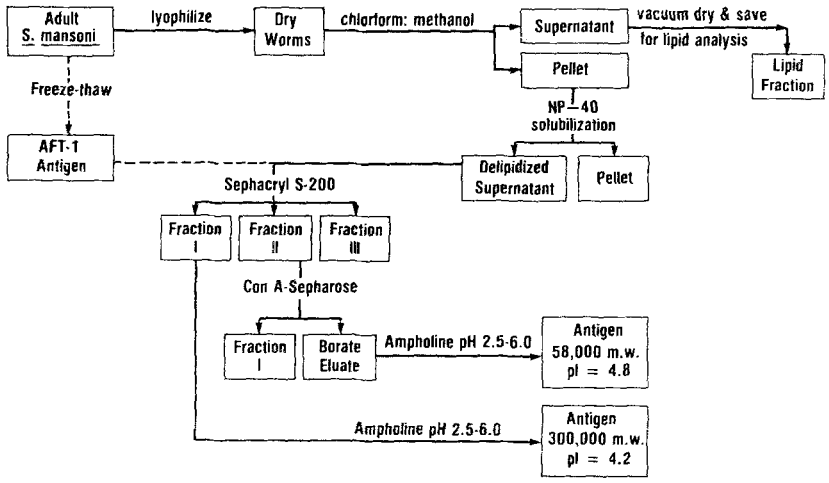

FIG. 5. Flow diagram depicting the fractionation protocol for purifying the Con A-binding surface antigen from *Schistosoma mansoni* adult worms. (Reprinted from Hayunga et al., 1983. Courtesy of Allen Press.)

active groups, followed by alternate washing in 0.1 M $NaHCO_3$, pH 8.3, and 0.1 M sodium acetate, pH 4.0, then final equilibration. In this way, the control columns were identical to the commercially produced lectin columns with the exception that they contained no immobilized ligand.

In Figure 6, it can be seen that the Sepharose 6MB control column yielded two peaks of 45,000 and 30,000 mol. wt. Although these peaks were small, they were identical, both qualitatively and quantitatively, to the sugar eluate from the *Helix pomatia*-Sepharose 6MB column. Thus, without such exhaustive controls, the interpretation of lectin affinity chromatography would have been flawed.

TESTING SOME HYPOTHESES ABOUT CHEMICAL COMMUNICATION

Although many observations of parasite behavior have implied chemical communication, the demonstration of a chemical message requires isolation of an active substance. However, the isolation and subsequent characterization of such substances is often confounded by the complexity of the parasite-host system, by limitations of in vitro models, and by difficulties in distinguishing between parasite and host components in vivo. By way of illustration, several hypotheses are proposed to determine the molecular basis for chemical communication by trematodes. Specific problem areas are addressed and possible solutions suggested. In each instance, the central question posed is, "How does one identify the molecule used as a chemical message?"

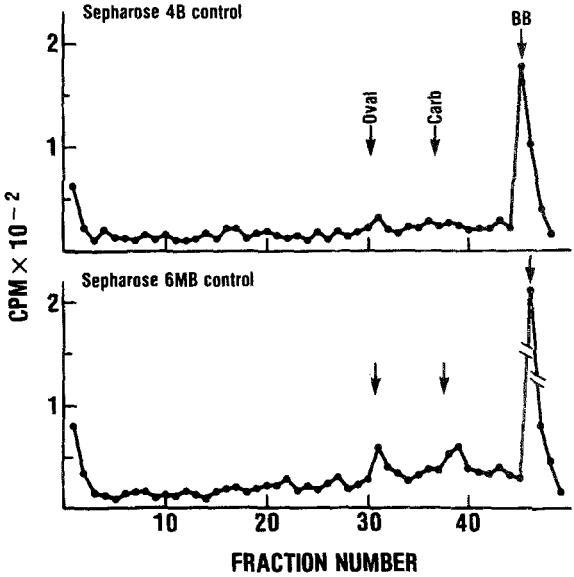

FIG. 6. Borate elutates of Bolton-Hunter radioiodinated *S. mansoni* adult freeze-thaw (AFT) antigen applied to control columns of Sepharose 4B and Sepharose 6MB without ligand, 7½% gels, 2-mm slices. (Reprinted from Hayunga and Sumner, 1986. Courtesy of Allen Press.)

Hypothesis I: Free-Swimming Stages of Trematodes Migrate Directionally in Response to Specific Chemical Signals Produced by the Prospective Host. In the first hypothesis, it is presumed that the behavior of the parasite in proximity to its host has been adequately observed and is well defined. The experimental approach to test such a hypothesis for free-swimming stages would be rather straightforward, involving the use of an environmental chamber (perhaps something as simple as a Petri dish), adding synthetic chemicals or defined fractions derived from the host, and making direct observations. In addition, the experimental design should compare the response between concentration gradients and uniform concentrations of the test material and allow the observer to distinguish between directional movement and nondirectional stimulation of activity.

Such an approach is seen in experiments to determine the behavioral response of *S. mansoni* miracidia to snail-conditioned water by Roberts et al. (1979). Although miracidia did not appear to orient themselves to a gradient of snail-conditioned water, their change in angular velocity while swimming enabled them to remain in regions of higher concentration. Identification of the active component in the water could be done by testing sequential fractions following the kind of protocol described by Gloer et al. (1986) to isolate sexual

chemoattractants. Alternatively, Plorin and Gilbertson (1985) used a more intuitive approach to select glucose as one of the possible stimulants present in snail-conditioned water.

Hypothesis II: Adult Trematodes Produce Secretions that Influence Mating Behavior and Sexual Maturation. The testing of this hypothesis may at first glance also seem rather straightforward. However, identification of chemical signals used by parasitic stages in vivo is inherently more complicated than similar assessments for free-swimming stages. In the first place, the definition of a secretion is problematic. In a preliminary analysis, we may simply designate everything left in the culture dish after incubation under defined conditions as the "culture secretions," but this is a very crude working definition. Eventually, this material will have to be characterized, and it has generally been found that "culture secretions" are very heterogeneous mixtures of proteins, carbohydrates, and lipids (Murrell et al., 1974). It is known that the tegumental surface membrane, and hence its associated proteins and glycoproteins, are continuously shed into the media, as depicted in Figures 2 and 3. How, then, is one to distinguish between true secretions, excretions, and membrane turnover? Furthermore, the heterogeneity of even the best defined preparations is overwhelming. One-dimensional and two-dimensional SDS-PAGE have revealed numerous components in parasite gene products (Ruppel and Cioli, 1977; Atkinson and Atkinson, 1982) and surface membrane extracts (Hayunga et al., 1979; Siddiqui and Podesta, 1985). Even when one selects for molecules with specific carbohydrate moieties by lectin affinity chromatography, the preparations are still rather heterogeneous (Aronstein and Strand, 1984; Hayunga and Sumner, 1986).

Although there is probably no easy solution to the problem of heterogeneity, chemical analyses can nevertheless proceed. In an accompanying paper, Gloer et al. (1986) followed a very rational scheme of chemical fractionation by extracting parasite material with a series of solvents of increasing polarity, and they found an active sexual chemoattractant to be a nonpolar component present in the *n*-pentane extract. Another approach to molecular fractionation might involve affinity chromatography. For example, it seems intuitively obvious that a sexual attractant secretion or its corresponding surface receptor should be unique to one sex. One might therefore consider raising antibodies against male worms and preparing an anti-male affinity column; extracts from female worms could be applied to this column and female gender-specific antigens collected in the "fall-through" fraction. Alternatively, monoclonal antibodies might be used to isolate sex-linked antigens. In this regard, the groundwork for identifying gender-specific antigens has already been laid (Ruppel and Cioli, 1977; Atkinson and Atkinson, 1982; Aronstein and Strand, 1984; Rotmans et al., 1986).

Finally, even when individual components are identified and isolated in relatively homogeneous preparations, yields are low and subsequent biochem-

ical analyses are necessarily limited. For this reason, investigators must rely on highly sensitive analytical probes, such as monoclonal antibodies, or the labeling of parasite molecules with isotopes that can be detected by radiation emission (Hayunga and Murrell, 1982) or by nuclear magnetic resonance (NMR) as described by Mansour et al. (1982) and Thompson and Lee (1985). Molecular structure may also be determined by the analysis of charge differences of glycoproteins following sequential enzymatic degradation by exoglycosidases (Kobata, 1979; Poretz and Pieczenik, 1981), or by competitive inhibition of antibody or lectin binding. Recently, Hayunga et al. (1983) described a "competition ELISA" to infer the structure of antibody binding sites of glycoproteins by competitive inhibition using various sugars and amino sugars; each test required only 1 μg of purified antigen.

Hypothesis III: Adult Female Trematodes Produce a Factor that Suppresses Egg Production in Other Females. The notion of a crowding effect for *S. mansoni* adult worms is somewhat controversial. An inverse relationship between worm length and intensity of infection has been reported in some instances (Radke et al., 1957; Grimaldo and Kershaw, 1961). Yet, in an equally convincing study, Lennox and Schiller (1972) were unable to demonstrate such a crowding effect. With regard to egg production, data from human autopsies (Cheever, 1968; Cheever et al., 1977; Anderson and May, 1982) and from experimental infections of the grivet monkey *Cercopithecus aethiops aethiops* (Cheever and Duvall, 1974) indicate a tendency towards decreased oviposition in heavier infections. However, interpretation of data from these studies is complicated by possible changes in the fecundity of older female worms and by the destruction of tissue eggs in chronic infections.

We have found evidence for reduced fecundity in relation to population density in acutely infected mice (Hayunga et al., 1985). As shown in Figure 7, as the number of female worms increases, the number of eggs produced per female decreases, which is indicative of a crowding effect. Such data also suggest that even when worm burden is reduced, the egg burden in the liver may still be unacceptably high—an important consideration in vaccine development. A similar finding was also reported by Harrison et al. (1982), who concluded that reduced fecundity was related to excess numbers of unpaired female worms.

Clearly, some kind of negative-feedback mechanism is at work. Although reduced egg production by *S. mansoni* suggests a "chemical message," such as the recently reported pheromone that inhibits reproduction in the tick *Argas arboreus* (Khalil, 1984), it is perhaps just as likely that worms may be responding to a build-up of metabolic wastes or to competition for limited resources. The presence of a factor in portal blood that stimulates oviposition (Wu and Wu, 1986), and the observation that tyrosine uptake is increased during vitellogenesis (Erasmus, 1986), both lend support to the notion that egg production by *S. mansoni* may be resource limited. However, there is little evidence to indicate a molecular basis for the crowding effect. With the exception of work

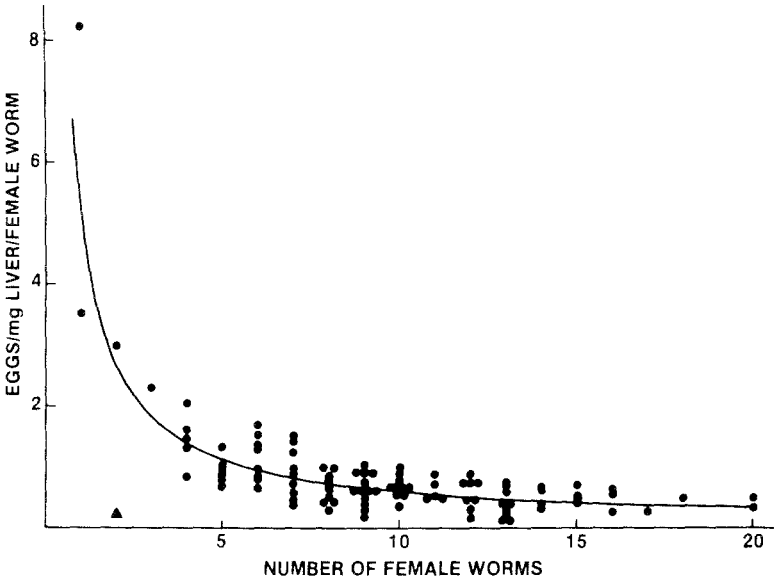

FIG. 7. Number of eggs recovered from the liver per female worm in mice experimentally infected with *Schistosoma mansoni*, eight weeks postinfection. (Reprinted from Hayunga et al., 1985. Courtesy of Allen Press.)

reported in the accompanying papers (Shirazian et al., 1986; Wu and Wu, 1986), in vitro experiments to examine egg production by *S. mansoni* have been sorely lacking and may not always be directly extrapolated to the in vivo situation. We do not know what effects host nutrition and metabolism may have on parasite fecundity, and the effect of infection serum on oviposition in vitro reported by Rotmans et al. (1986) suggests that the immune response of the host may be a major factor in the modulation of egg output. Finally, to further complicate matters, there is even evidence of variation in egg production between individual female worms cultured in uncrowded conditions (Shirazian et al., 1986).

Hypothesis IV: Adult Trematodes Produce a Factor that Stimulates Host Resistance to the Infective Stage of the Parasite. The last hypothesis attempts to establish a molecular basis for concomitant immunity, and implies chemical communication between the parasite and its host in order to limit the establishment of additional parasites. This is by far the most difficult of the hypotheses to test, involving not only the characterization of parasite molecules, with all its inherent problems, but also an assessment of the host's immune response to these molecules and to living parasites. Implicit in this hypothesis, too, is the assumption that concomitant immunity represents an immunological response to infection, and is not simply an ecological phenomenon, as suggested by Warren (1973) and Wilson et al. (1983).

The immunochemical characterization of schistosome antigens is, by itself, a formidable task. Yet testing of the hypothesis also requires manipulation of the host immune system. The complexity of the immune response can be illustrated by contradictory evidence regarding immunization with crude antigen extracts (Murrell et al., 1975) and by the impact that the route of antigen presentation may have on protective immunity (James, 1985). The presence of protective antigens is supported by the observation that specific antibodies bind to cercarial surface membranes and kill parasites in vitro (Harn et al., 1984) and by the reduction of worm burden in challenge infections of mice following inoculation with defined antigen preparations (Hillyer and Sagramoso de Ateca, 1979).

At present, several antigens have been isolated in relatively homogeneous form: the MSA_1 fraction from soluble egg antigen or SEA (Pelley et al., 1976); FhConA, a concanavalin A-binding glycoprotein isolated from the tegument of *Fasciola hepatica* (Hillyer and Sagramoso de Ateca, 1979); SmConA and SmFxI, two glycoproteins isolated from *S. mansoni* adult worms (Hayunga et al., 1983); and a purified protease from *S. mansoni* (Chappell and Dresden, 1984). Of those that have been tested for protection, the results have been equivocal. FhConA, which has been extensively studied, has produced reductions in worm burden as high as 70% (Hillyer and Sagramoso de Ateca, 1979). In our laboratory, FhConA was less effective in reducing worm burden but did appear to reduce the size of egg-induced hepatic granulomata, as did SmConA. SmFxI was ineffective in protecting mice against challenge infection despite high specific antibody titers following inoculation (Hayunga et al., 1985). In general, progress in antigen isolation has been slow, and the matter of establishing a molecular basis for concomitant immunity is far from resolved.

CONCLUSIONS

Attempts to characterize trematode surface antigens and secretions have been complicated by the heterogeneity of even well-defined preparations. Peculiarities of the parasites with regard to radiolabeling and of parasite extracts with regard to nonspecific binding to chromatography columns emphasize the need for meticulous experimental controls. When individual molecules are isolated in homogeneous form, subsequent analysis is often thwarted by low yields of the final product.

In the accompanying papers (Gloer et al., 1986; Eveland and Hajeeb, 1986), low-molecular-weight, nonpolar molecules have been implicated as sexual chemoattractants for *S.mansoni*. This suggests the possible application of hydrophobic chromatography using immobilized alkanes or aminoalkanes to isolate lipophilic molecules on the basis of affinity interactions of their exposed hydrophobic patches, as originally proposed by Shaltiel (1974). We have re-

cently applied this method to the analysis of tegumental extracts from *S. mansoni* adult worms and isolated a stage-specific hydrophobic protein of 40,000 mol. wt. (Hayunga and Sumner, 1983). Hydrophobic chromatography ought to be of value in isolating smaller nonpolar molecules as well.

Although considerable attention has been given to small, lipophilic molecules, the possible role of larger hydrophilic proteins in chemical communication by trematodes should not be overlooked. According to Wilson (1975, p. 235), "proteins, in fact, make up a large fraction of the known waterborne pheromones," while smaller more volatile molecules are usually associated with airborne message transmission. It has been shown that oviposition of *S. mansoni* is stimulated by a large molecular weight protein component in portal serum (Wu and Wu, 1986) and it should not be surprising if other water soluble proteins were used as chemical messages by blood flukes residing in an aqueous environment. Finally, the concept of chemical communication implies not only transmission but also the reception of messages. Yet, except for the descriptions of Fc and complement receptors (Kemp et al., 1986) or benzodiazepine binding sites on the tegument of *S. mansoni* (Bennett, 1980), little attention has been paid to identifying functional surface receptors on trematodes.

Acknowledgments—We wish to acknowledge the collaboration of Drs. K.D. Murrell, W.E. Vannier, M. Stek, Jr., and G.V. Hillyer in various aspects of the research reviewed in this paper. We are also grateful to R.Y. Chestnut, J.F. Duncan, C. DeiSanti, and I. Mollegard for expert technical support; to F. Langely for preparing illustrations; and to B.J. Holland for editorial assistance. Parasite material was provided by Drs. M.A. Stirewalt and F.A. Lewis, Biomedical Research Institute, Rockville, Maryland. This work was supported in part by Grant 18361 from the National Institute of Allergy and Infectious Diseases.

FUNDAMENTAL ASPECTS AND POTENTIAL ROLES OF ECDYSTEROIDS IN SCHISTOSOMES
An Update Overview

(Received October 1, 1985; accepted March 31, 1986)

Abstract—The human digenic trematode *Schistosoma mansoni* produces ecdysteroid hormones. Both ecdysone (22*R*)-2β,3β,14,22,25-pentahydroxycholest-7-en-6-one and 20-hydroxyecdysone (22*R*)-2β,3β,14,20,22,25-hexahydroxycholest-7-en-6-one were detected during the critical development stages of this bisexual parasite: during the exponential growth phase to adult stage (day 11 postinfection) and during the sexual maturation of adult and egg laying (day 40 postinfection). The parasites released their ecdysteroid hormones in the biological fluids of the infected vertebrates as soon as six days postinfection. In addition, the time course of the ecdysteroid titer was correlated with the susceptibility or the innate resistance of the host to schistosome infection. Moreover, we demonstrated that after a schistomicide therapy, ecdysteroids from urine of infected children decreased markedly four days after drug administration. We also have demonstrated that immunization of rodents with an ecdysone-BSA complex led to the reduction of the worm burden. By in vitro studies, we have shown that the ecdysterone antibodies were able to kill the juvenile worms within 24 hr. In addition, we have demonstrated that the enzymes superoxide dismutase (SOD, EC 1.15.1.1) were present in schistosomes and that the total superoxide dismutase activities in both males and females could be correlated with the 20-hydroxyecdysone within parasites.

Key Words—*Schistosoma mansoni*, ecdysteroid, antiecdysteroid, serum/kinetic, urine/diagnosis, superoxide dismutase (EC 1.15.1.1), mass spectrum, chromatography.

INTRODUCTION

The ecdysteroids were first demonstrated in arthropods (Butenandt and Karlson, 1954) where they were associated with their moulting process (for review, see Karlson, 1980). Because the growth of nematodes has involved a series of evident moults (Rogers, 1962), the detection of ecdysteroids in worms was done first in this parasitic species (Rogers, 1973; Horn et al., 1974). Our freeze fracture studies of *Schistosoma mansoni* membrane differentiation allowed the observation of a membrane exuviation during the period of 10–20 days after infection (Figure 1.) (Torpier et al., 1982). Such a phenomenon occurring at a precise period of the worm development is reminiscent of the moulting process of arthropods in which metamorphoses are induced by two specific hormones: namely ecdysone and 20-hydroxyecdysone. Since we demonstrated that the produced ecdysteroids (Nirdé, 1982; Torpier et al., 1982, Nirdé et al., 1983a) were released in the biological fluids of the infected hosts (Nirdé 1982, Nirdé et al., 1983b, 1984), particular interest has been devoted to this topic in platyhelminthic worms. (Whitehead, 1983; Koolmann et al., 1984, 1985; Rees and Merdis, 1984; Rees et al., 1985). The present paper is an update review on the ecdysteroids in the human trematode *Schistosoma mansoni* and on the potential roles of these hormones in schistosomiasis.

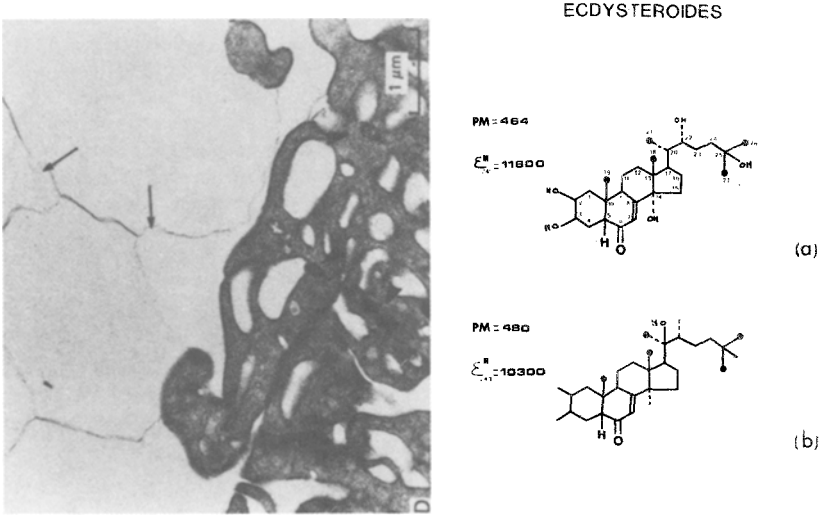

FIG. 1. Illustration of the membrane exuviation (arrow) observed during the 10- to 20-day period after infection (left) and structure of ecdysone (a) and 20-hydroxyecdysone (b). (Modified from Torpier, et al., 1982.)

METHODS AND MATERIALS

Infection of rodents was performed by exposure to cercariae of *Schistosoma mansoni* as initially described by Smithers and Terry (1965). Recovery of parasites of required age was performed by perfusion of the rodents killed by cervical dislocation. Eleven-day-old and 20-day-old worms were collected by perfusion of the liver with MEM. Forty-day-old schistosomes were recovered by total perfusion of the whole blood system with NaCl 0.9% or only from the mesenteric and portal system of hamsters. Eggs were recovered by a 54% Percoll gradient in MEM as described by Nirdé et al. (1983a).

Ecdysteroid extracts of worms were performed by a methanol–water–hexane (10:5:3 by v/v) homogenization as described by De Reggi et al. (1975). For the biological samples such as urine and sera, a methanol–water (3:1 v/v) extraction according to Nirdé et al. (1984) was performed. To 1 ml serum was added 3 ml methanol (Merck). The mixture was then vortexed prior to a 60°C incubation for 15 min and centrifuged (800*g* for 10 min at 4°C). The supernatant was then dried under nitrogen flow and resuspended in 0.1 M citrate buffer, pH 6.1, prior to the RIA assay (De Reggi et al., 1975).

The ^{125}I-labeled hormone was a succinyl ecdysterone coupled to [^{125}I]tyrosine-methyl-ester (Immunotech, Marseille). The binding assays were made in a Plexiglas apparatus containing 10 dialysis compartments, each divided into two 200-μl chambers by a cellulose membrane. One chamber was filled with 150 μl of ecdysteroid antibody (Immunotech) and the other one with 150 μl of a mixture of equal parts of the sample to be analyzed and the ^{125}I-labeled hormone. After 24 hr shaking at 4°C, equilibrium was achieved and 100 μl of each compartment was counted. The sum of the bound (B) and free (F) labeled analog was found on the antibody side, the free (F) alone on the other. The ratio of the binding was computed as $r = B/T$, where $T = B + F$. The standard curve was run with pure 20-OH-ecdysone (Sigma) from 10^{-7} M to 10^{-11} M. Bound fractions were then computed with a WANG 2200 S system, with a linear regression of the standard curve (Nirdé, 1982). The results were expressed as picomoles of 20-OH-ecdysone equivalent per 100 mg of protein or per milliliter of biological fluids (urine or sera).

Mass spectroscopy analysis was done with 600 ml urine of children infected with *Schistosoma haematobium*. A butanol extraction was performed on this material as previously described (Nirdé et al., 1984) The butanol extract was then analyzed by thin-layer chromatography (silicagel plates, 20 × 20 cm, F 254, Merck) with chloroform–methanol as solvent (80:20, v/v). The plates were scraped by 1-cm bands and the products eluted with three washes with 95% ethanol. Only the immunoreactive samples were analyzed by HPLC (Waters, reverse phase) with methanol–water as solvent (40:60 v/v, 1 ml min,

isocratic elution). Gas chromatography was performed on immunoreactive HPLC fractions after derivatization. Fractions to be analyzed were added to 100 μl of trimethylsilylimidazole (TSIM) and heated at 80°C under argon. Separation of derivatized ecdysteroids from reagent was performed through HPLC on silica column with ethanol–hexane as solvent. After evaporation of the solvent under argon, acetone was added to dried extract and 1–2 μl was injected into a gas chromatographic apparatus (Varian 1200, capillary glass column SE/30) at 290°C. A mass spectrometer (LKB 9000S) was coupled to the gas chromatograph. This spectrometer was equipped with an INCOSS computer system which allows the recording of one mass spectrum per second.

The complex ecdysone–BSA was used as immunogenic compound. Hamsters were inoculated by subcutaneous injections by the Vaitukaïtis technique (1971). Each hamster received a primary injection of 200 μg of protein with 1 vol of Freund's complete adjuvent (Bio-mérieux) in a total volume of 500 μl. Boosts of 100 μg were given on day 30 and day 60 after the primary injection. Hamsters were infected 10 days after the last injection with 100 cercariae of *S. mansoni*. Antibody titer was determined by the RIA method.

The in vitro cytotoxicity of sera from hamsters immunized with an ecdysone–BSA complex was performed on skin schistosomula. The skin schistosomula were collected in vitro after penetration of cercariae through isolated pieces of Swiss mice abdominal skin according to the method initially described by Stirewalt and Uy (1969). For the in vitro cytotoxicity assay about 120 schistosomula were incubated in each well of a flat-bottomed microtiter plate (Nunclon, Denmark) with 110 μl of 10% FCS in MEM, 50 μl of heated sample serum to be tested, and 40 μl of fresh guinea pig serum. For studies without complement, the guinea pig serum was heated for 30 min at 56°C. The percentage of mortality was measured by direct visual examination and by scanning microscopy.

For scanning microscopy studies, schistosomula were fixed in 0.1% glutaraldehyde in 0.05 M sodium cacodylate buffer. The samples were then post-fixed with 1% osmium tetroxide solution for 1 hr at 4°C and dehydrated in a ethanol series. A gold–palladium coating (60:40) was then performed before examination.

Superoxide dismutase was assayed by the inhibition of the cytochrome *c* reduction using a xanthine–xanthine oxidase system as originally described by McCord and Fridovich (1969). Batches of 4–10 adult worms or 20,000 schistosomula, or 20,000 day-11 parasites were used. Parasite material was suspended in 2 ml of 50 mM phosphate buffer (pH 7.8), sonicated on ice for 45 sec at 20 kHz (Sonotrode TC 4C, type 20-200 S), and centrifuged for 10 min at 800 *g* (Jouan E96 4°C). Triton X-100 was added to the supernatant to a final concentration of 0.2% (v/v) prior to 30 min incubation at 4°C. Centrifugation was then performed (45,000 *g* for 10 min at 4°C) and the supernatant used in

the SOD assay at pH 10 with or without 1 mM KCN. The final reaction mixture was 2.85 ml and the standard curve was set using bovine erythrocyte SOD (Sigma). Crude extract activities were then computed on a WANG 2200 MVP system by using a polynomial fitting of the standard curve as described by Nirdé (1985). Results were expressed as Sigma SOD units equivalent per milligram of protein.

RESULTS

Figure 2 shows the variation in ecdysone levels during *Schistosoma mansoni* development. Line A indicates that newly derived schistosomula contain 4.3 pmol ecdysone equivalents per 100 mg of protein. Line B corresponds to the day-11 schisotomes. The amount of ecdysteroids at this stage is 25 pmol. Line D represents both males and females collected on day 40 after infection

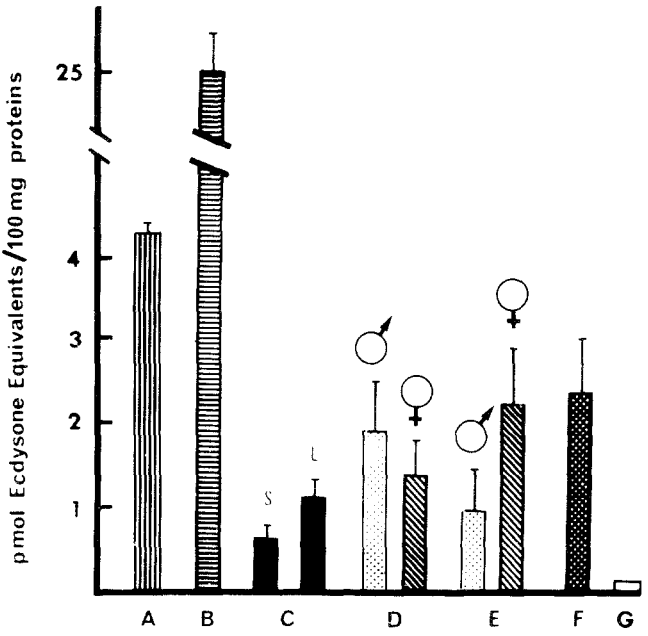

FIG. 2. Ecdysteroid levels during *Schistosoma mansoni* development using the RIA method. (A) Newly derived 3-hr schistosomula ($N = 2$); (B) 11-day-old schistosomes ($N = 4$); (C) 20-day-old schistosomes ($N = 4$); (D) 40-day-old schistosomes (adults) from the total perfusion of hamsters ($N = 6$); (E) 40-day-old schistosomes from mesenteric vessels ($N = 4$); (F) Eggs of *Schistosoma mansoni* ($N = 6$); (G) control performed on uninfected animal tissues ($N = 10$). Bars are standard deviation. (From Nirdé et al, 1983b.)

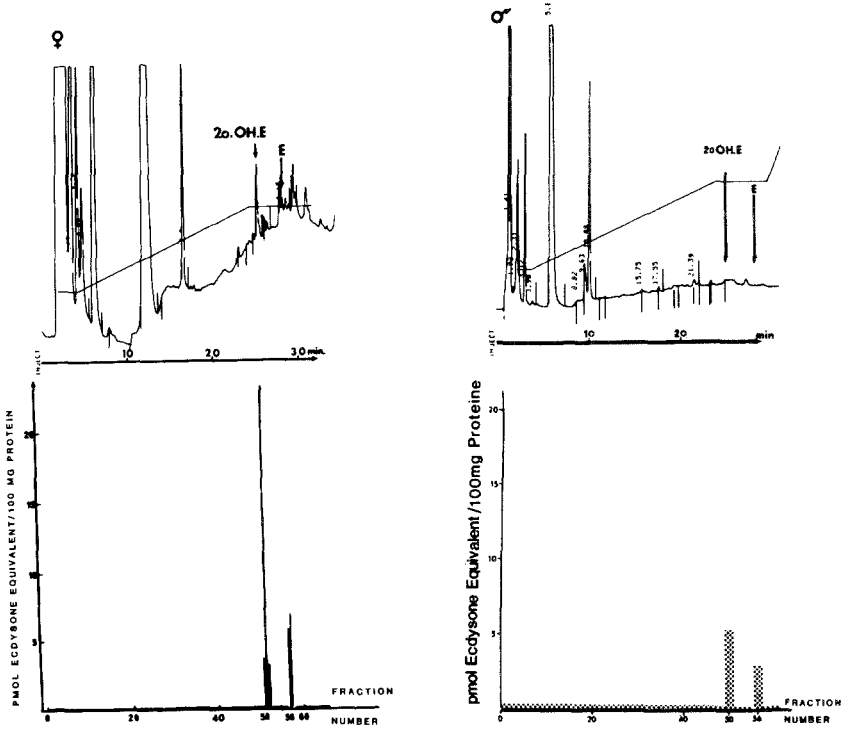

FIG. 3. High-pressure liquid chromatography of the extract of parasite from total perfusion and RIA on collected fractions (♀, females; ♂, males). Column: Whatmann, Partisil 10-25/ODS 3; detection: Waters UV–visible detector M 440, 245 nm; programmer: Waters M 650; flow: 1 ml/min; gradient: 30-min linear gradient of 30% acetonitrile in water was performed; arrows: standard elution of 20-hydroxyecdysone or ecdysone from Sigma run in the same conditions. (Modified from Nirdé et al., 1984a.)

by total perfusion of hamsters exhibiting an ecdysone level at about 2 pmol. No significant sexual differences can be observed by the radioimmunoassay method. In Figure 3, HPLC analyses demonstrate that both ecdysone and 20-hydroxyecdysone are present. The 20-OH-ecdysone is more abundant than ecdysone in both sexes. The ratio, r, of 20-hydroxyecdysone ecdysteroids is $r = 0.62$ for the males and $r = 0.68$ for the females. In contrast, within adults collected exclusively by local puncture of mesenteric vessels (line E), the normal location of these worms for mating and egg laying, sexual differences in ecdysteroid levels were observed: less than 1 pmol for the males and 2.5 pmol for the females.

In addition, HPLC analyses shown in Figure 4 demonstrate that parasites from mesenteric vessels exhibit an inverse ratio of 20-hydroxyecdysone to total

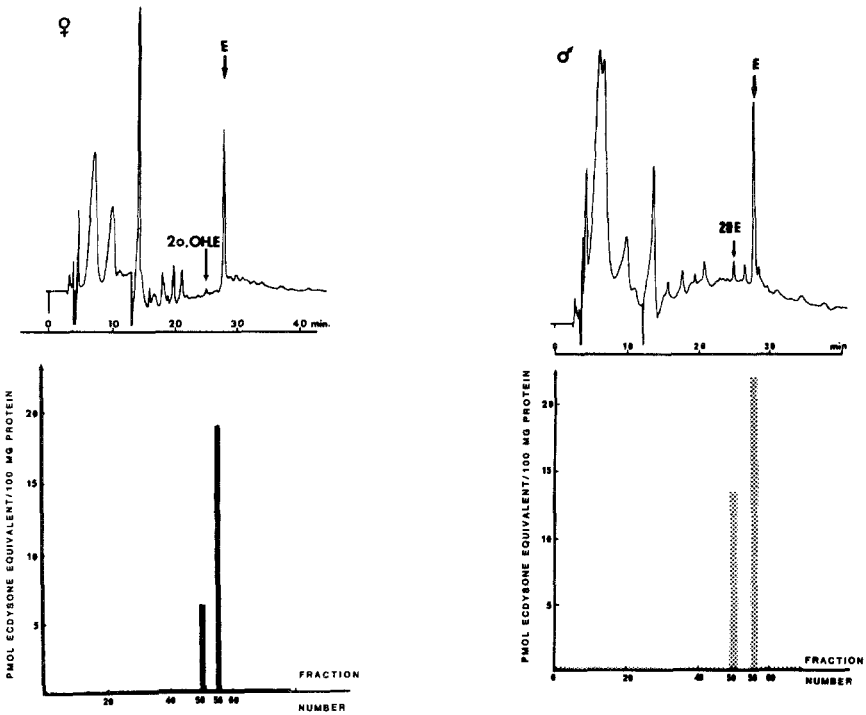

FIG. 4. High-pressure liquid chromatography of the extract of parasite collected exclusively by local puncture of mesenteric vessels and RIA on collected fractions. Column: Waters Microbondapack-phenyl; detection: Waters UV–visible detector M 441; 254 nm; calculator: Waters M 730 and system controler M 720; flow: 1 ml/min with Waters 6000 A pumps; gradient: After 2 min of isocratic conditions with water–acetonitrile (90:10) as solvent, a linear gradient of 30% of acetonitrile:water was performed in 30 min; arrows: standard elution of 20-hydroxyecdysone and ecdysone from Sigma run in the same conditions. (Modified from Nirdé et al., 1984a.)

ecysteroids compared with parasites collected by total perfusion: $r = 0.40$ for the males and 0.24 for the females. In mesenteric vessels, ecdysone is far more abundant than 20-hydroxyecdysone in both sexes. In the eggs, line F, the hormonal content and the ecdysteroid ratio are comparable to those of the females from mesenteric vessels ($r = 0.24$).

As shown in Figure 5, the trematode *Fasciola hepatica* also contains ecdysteroids. The ratio of 20-hydroxyecdysone to ecdysone plus 20-hydroxyecdysone was 0.44. HPLC analyses also indicate that a third ecdysteroid peak was detected. This peak could be specific for this species. Besides the physiological role of these hormones in the parasites, it would be interesting to follow their fate in the biological fluids of the infected hosts. Vertebrates do not pro-

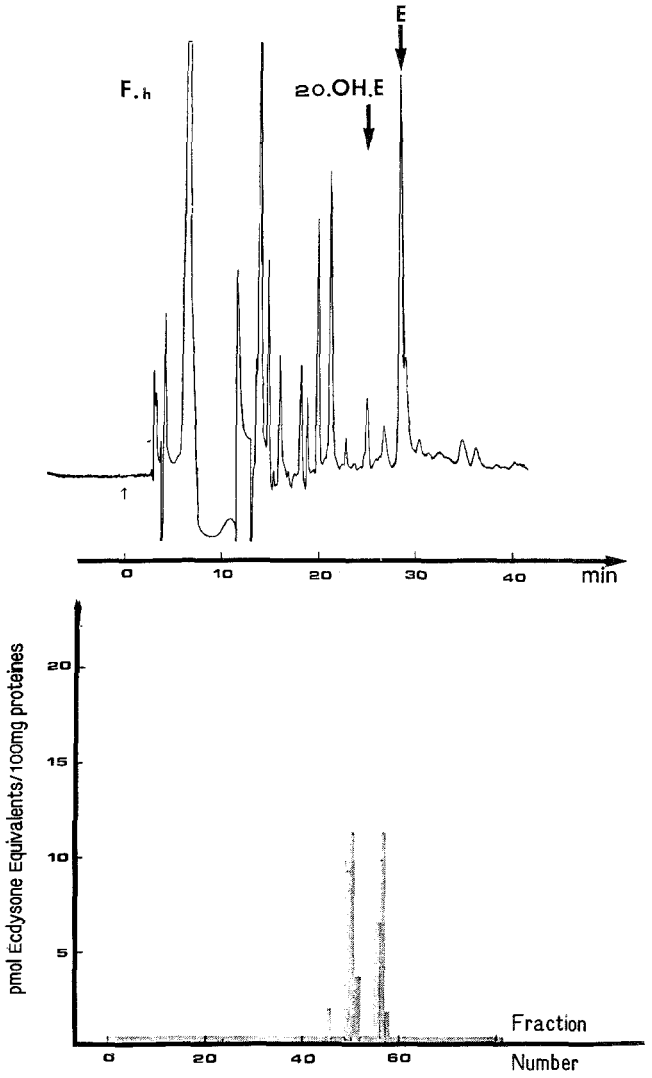

FIG. 5. High-pressure liquid chromatography and RIA analysis in extracts of the trematode parasite *Fasciola hepatica*.

duce insect moulting hormones nor specific enzyme systems to catalyze these hormones and, a priori, the ecdysteroids would not be metabolized by the hosts.

As shown in Figure 6, the serum of infected rodents contains ecdysteroids. As early as six days postinfection, ecdysteroids could be detected in sera of infected rats or hamsters, whereas no detection is possible in uninfected animals, or during the first five days of infection (Nirdé et al., 1984a,b). As shown

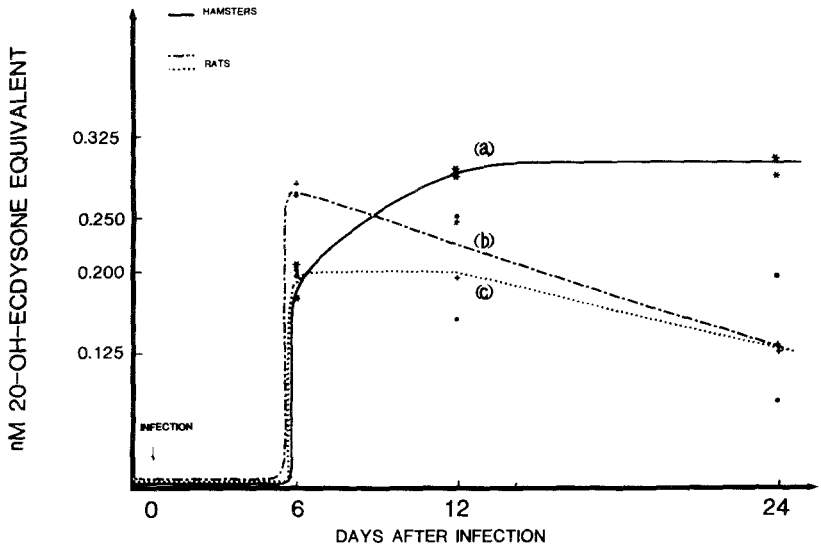

FIG. 6. Changes in ecdysteroid concentration in the serum of permissive and nonpermissive rodent hosts infected with *Schistosoma mansoni*. Hamsters (*M. auratus*, a) and rats (*R. rattus*, b) were infected with 2000 cercariae of *Schistosoma mansoni*, whereas other rats (c) were infected with only 500 cercariae. (From Nirdé et al., 1984a.)

in this figure, the changes in hormone level are different between permissive (curve a) and nonpermissive hosts (curves b and c). In permissive hosts such as hamsters, the RIA activity reaches 0.3 nM on day 12 postinfection, and this value remains unchanged on day 24. In contrast, in the nonpermissive hosts such as rats, the ecdysteroid level reaches 0.3 nM on day 6 postinfection, and, more important, it decreases slowly from day 10–12 onwards. This figure also shows that the rise in ecdysteroid concentration, which occurs on day 6, is significantly lower in rats that received a weaker challenge of 500 cercariae compared to rats challenged with two thousand cercariae. After day 12, the two groups of rats do not differ significantly with regard to the ecdysteroid titer.

Further analyses have shown that ecdysteroids were also present in the blood of infected primates, even in the absence of parasitological markers (Nirdé, 1982, Nirdé et al., 1984a). Based on these data, ecdysteroid titers were determined in the urine of humans infected with *Schistosoma haematobium*.

Figure 7 demonstrates that children have a very high concentration of insect-molting hormones in their urine (Nirdé et al. 1984). Urine of 60 infected children between 10 and 14 years of age were assayed. The average level in hormone before chemotherapy was 4.5 nM. However, in three children, the highest value found was more than 180 nM. As seen in this figure, four days after drug administration, the hormonal concentration decreases markedly to one third and then slowly reaches 6 nM some 100 days after treatment.

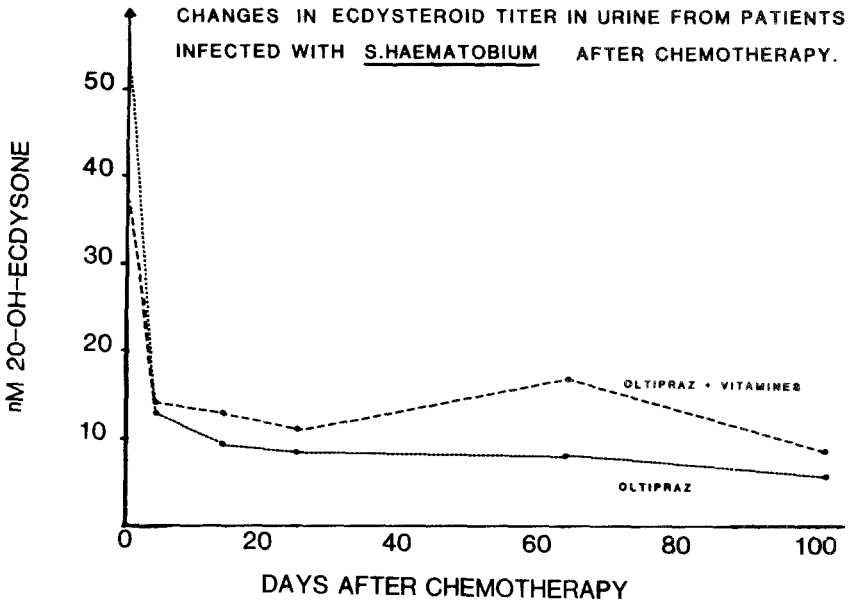

FIG. 7. Changes in ecdysteroid concentration in urine from patients infected with *Schistosoma haematobium* before and after chemotherapy. Day of chemotherapy: D_0, Single dose of Oltipraz (30 mg/kg, $N = 20$) or Oltipraz plus vitamins (30 mg/kg, $N = 20$).

Chemical characterization of ecdysteroids found in urine of infected humans has been achieved by mass spectroscopy as shown in Figure 8. Figure 8A, curve a, is the total ion recording. It indicates that several molecules are present in the urine sample. In curve b, the fragmentograph ion recording allows the detection of four ecdysteroid peaks. Arrow 1, the 20-hydroxyecdysone, and arrow 2, the 5 epi-20-hydroxyecdysone, show the two major peaks. One of the minor peaks is the 3-oxo-20-hydroxyecdysone. The last one has not been identified yet. Figure 8B(a) shows the mass spectrum of the compound yielding peak 1 in the fragmentogram. Spectrum b exhibits the mass spectrum of standard 20-OH-ecdysone run under the same conditions. The differences observed in the molecular weight of these ecdysones compared to crude molecules are caused by the derivatization of the ecdysteroids for the mass spectrum analysis. The fragment at *m/e* 561 corresponds to the nucleus of the ecdysone. The fragments with a larger *m/e* correspond to the fragmentation of the side chain of ecdysone after cleavage between C-20 and C-22 and to the loss of a silanol in the case of fully silylated derivatives.

In Figure 9, we notice that ecdysteroids are also detected in the sera of rodents infected with the nematode *Dipetalonema vitae*. Whereas low levels of ecdysteroids were measured on days 43 and 73 postinfection, high amounts of these hormones could be detected on day 63 postinfection.

FIG. 9. Ecdysteroid levels in the sera of the nematode *Dipetalonema vitae*.

Figure 10 demonstrates that schistosomes contain the enzyme superoxide dismutase. Two isoenzymes have been detected during the development stages of the parasite: cytosolic Cu/Zn SOD and mitochondrial Mn SOD.

Both SOD activities are present in schistosomula and 11-day-old schistosomes. Adults collected on day 40 after infection by total perfusion of hamsters exhibit more SOD than adults recovered by local puncture of mesenteric vessels. Sexual differences in the ratio between mitochondrial and copper-zinc SOD can be observed. The females contain more copper-zinc SOD than the males.

In addition, as shown in Figure 11, total SOD activities in both males and females can be correlated with the ratio of 20-hydroxyecdysone to total ecdysteroids within parasites. When this ratio increases, the total SOD activities also increase. This is true for both sexes. The presence of ecdysteroid hormones around parasites could suggest that these hormones would be necessary for parasite development. As well as the biological role of these ecdysteroids at the parasite level, it seems interesting to investigate the biological activities of antiecdysteroid antibodies against schistosomes.

Figure 12 shows the effects of immunization of rodents on the parasite burden. In hamsters, without any boosts, the reduction of the parasite population is around 38%. However, the females are more sensitive to the ecdysteroid antibodies than the males. In this case the reduction was over 50%. In the same way, in mice the reduction is around 30%. Once again, the females are far more sensitive than the males: the reduction is 60%. For a long time, it was impossible to reduce the parasite burden when rodents were boosted. Thus, another immunogenic compound has been synthesized.

As shown in Figure 13, the immunization of hamsters, followed by two boosts, leads to a significant reduction of the worm population, compared to hamsters which have received no injection (control) or a nonprotective antigen (placebo).

In addition, as shown in Figure 14, the corresponding ecdysteroid anti-

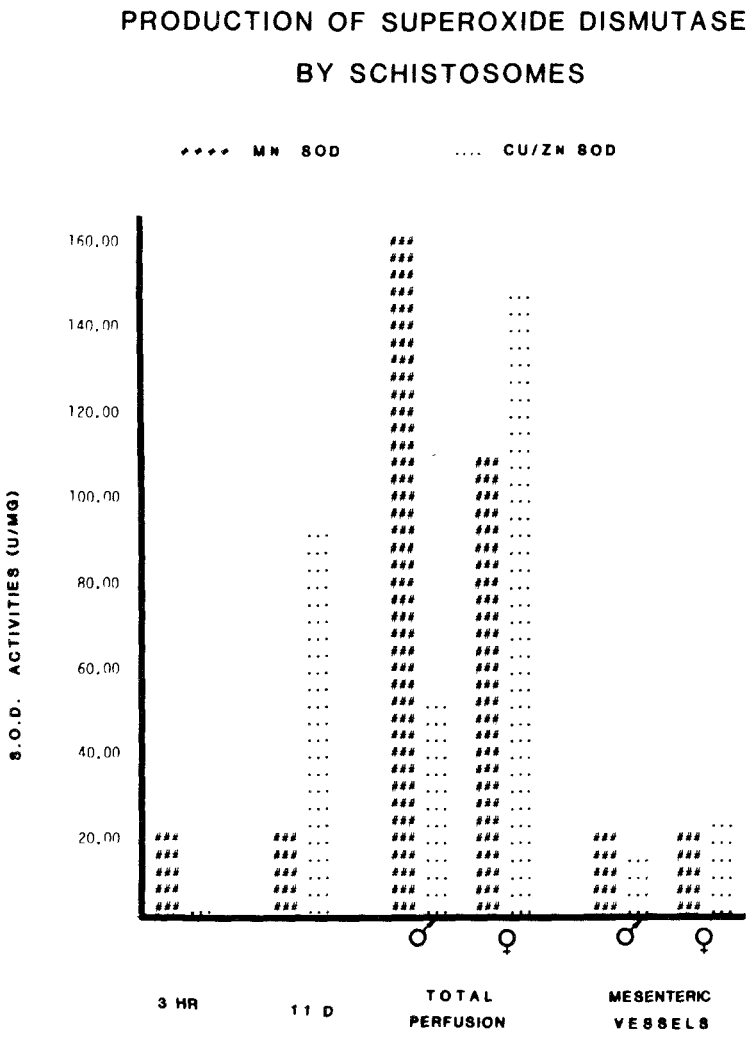

FIG. 10. Variation in superoxide dismutase activities during the development stages of *Schistosoma mansoni*.

bodies thus produced appear to be cytotoxic for schistosomula within 24 hr. For low dilution of the sera (1/4), this cytotoxicity reaches 100% within 24 hr of incubation; otherwise no cytotoxicity occurs. When samples were heated before incubation, the cytotoxicity remained at the same value. As shown in Figure 15, scanning microscopy on the in vitro cultured schistosomula has been investigated. This figure indicates that parasites incubated with the antibodies from immunized hamsters shed their membrane complex. This phenomenon

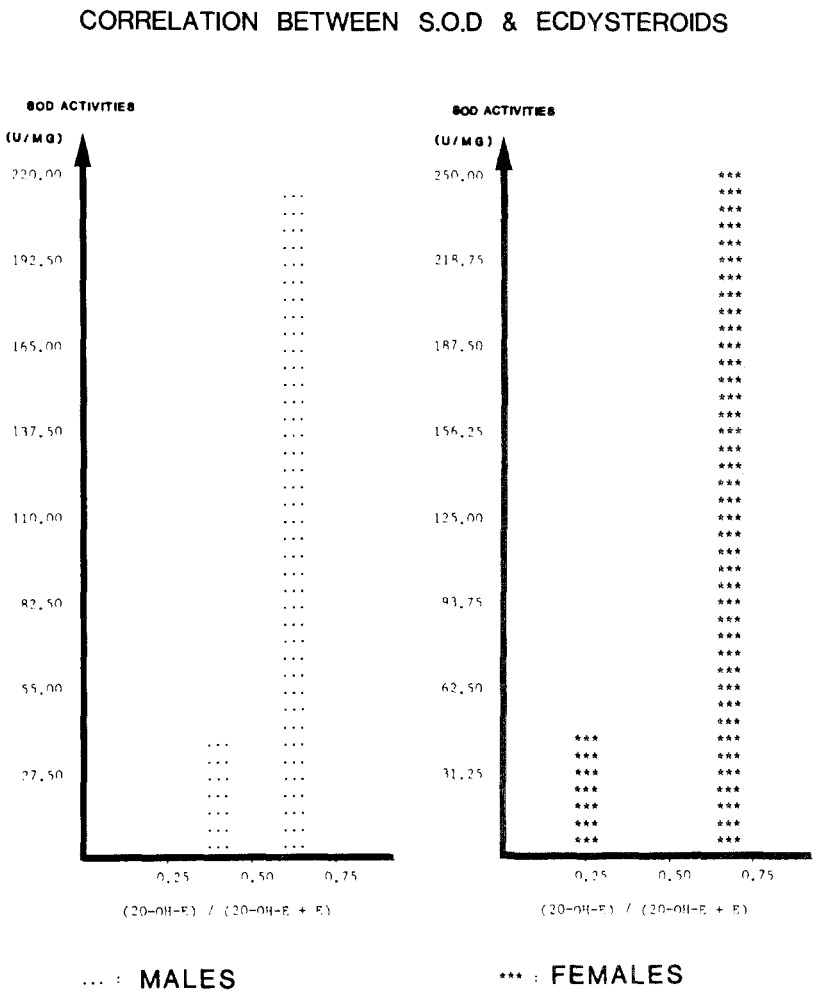

FIG. 11. Correlation between total superoxide dismutase and the ratio of 20-hydroxyecdysone to total ecdysteroids within adult *Schistosoma mansoni*.

leads to the death of the worms. The velvet-like appearance on the surface of the scoured parasites corresponds to the loss of the external tegument of *S. mansoni*.

DISCUSSION

We have demonstrated that the two hormonal activities, ecdysone and 20-hydroxyecdysone, were present at two crucial periods of the development of the bisexual trematode *Schistosoma mansoni*.

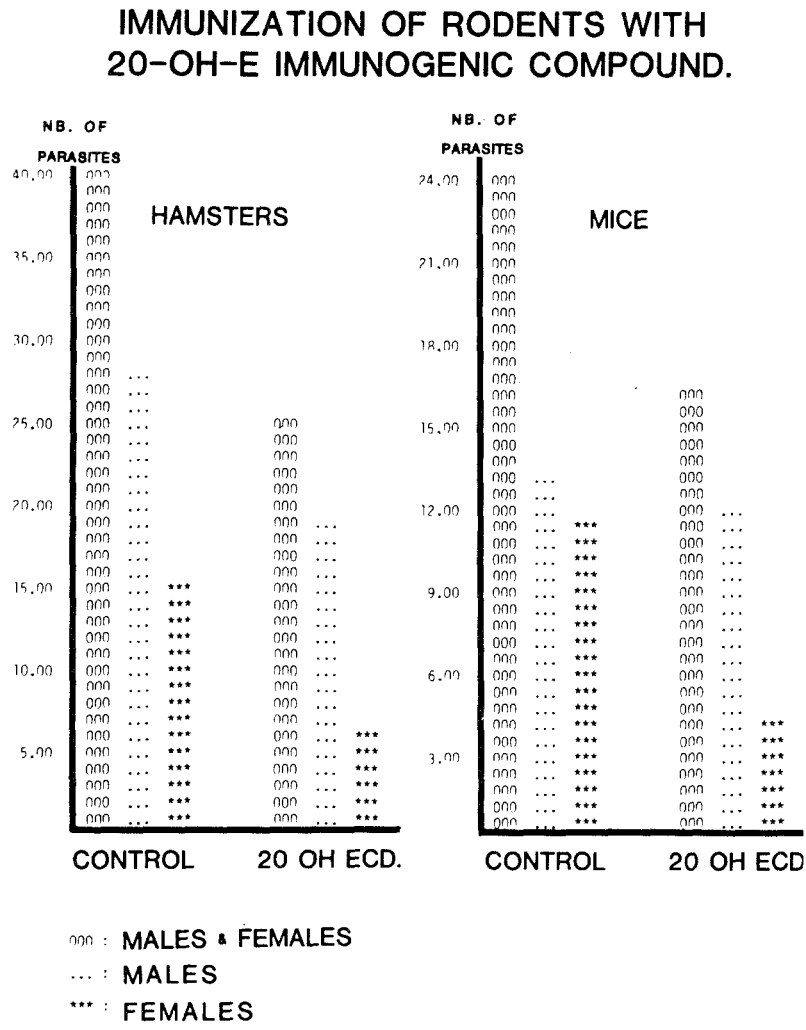

FIG. 12. Effects of a single immunization of an ecdsyone immunogenic compound on the parasite burden.

Firstly, the day 6 to day 11 period after infection is a transition period between the juvenile worm and its exponential growth phase to the bisexual stage. The high amount of ecdysteroids in 11-day-old worms, compared with others, indicates an endogenous synthesis by *S. mansoni*. Because the definitive host does not produce ecdysteroid hormones, passive incorporation of ecdysteroids from the host can be excluded. This rise in ecdysone levels can be correlated to three linked events: (1) The first event is migration and the development of juvenile worms which have left the lungs and just reached the liver.

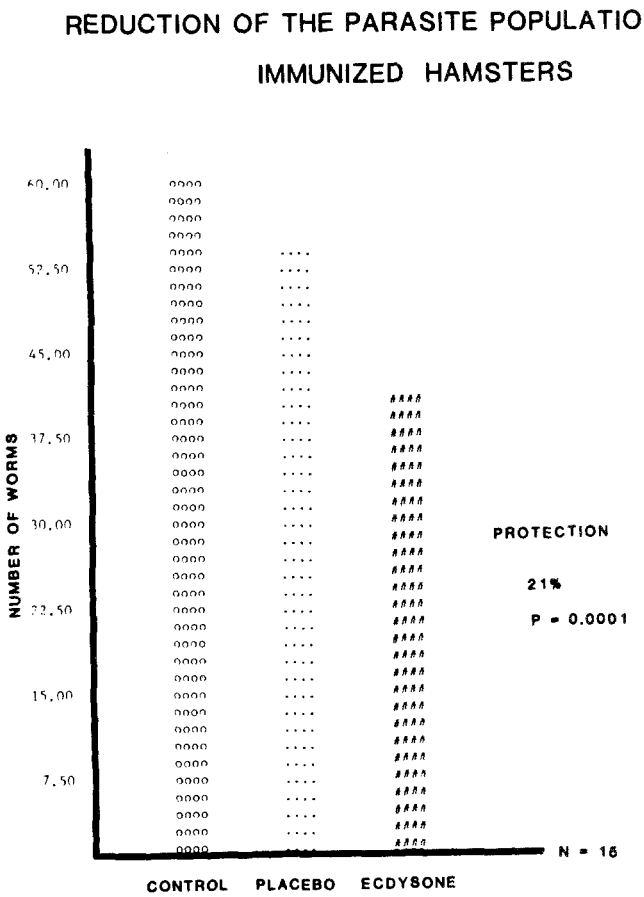

FIG. 13. Effects of immunization with two boosts of an ecdysone immunogenic compound on the parasite burden.

Wilson and coworkers (1978) have demonstrated that the process of transformation from the lung to liver form is characterized by a number of changes in the biological functions of schistosomes. They lose their ability to migrate, and their length and shape are modified. (2) During the same period, metabolic changes occur in the parasite, which leaves a semiquiescent metabolic state. As demonstrated by Lawson and Wilson (1980), an increase in density, nitrogen content, and growth initiation occur. (3) The rise in ecdysteroid is also correlated to membrane modifications of *S. mansoni*, as shown by Torpier et al. (1982).

The second crucial period in adult males and females is the priod of sexual maturation characterized by egg laying. The ratio between ecdysone and 20-hydroxyecdysone appears to be different according to the anatomical localization of the adult worms in mammalian hosts.

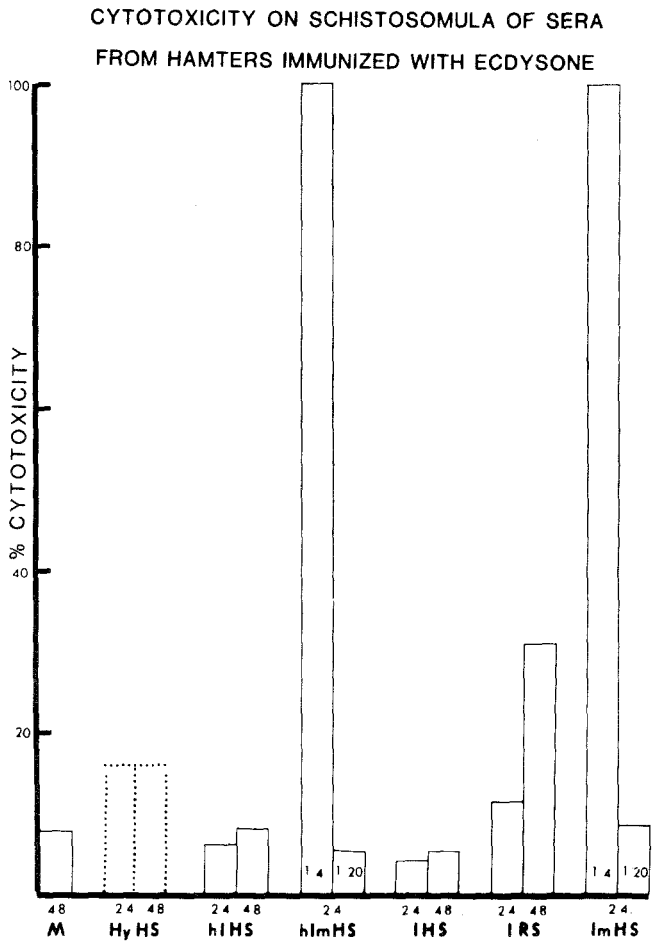

FIG. 14. In vitro cytotoxicity of natural ecdysone antibodies on schistosomules of *Schistosoma mansoni*.

These data indirectly suggest that ecdysteroids would have an important role in inducing the maturation of the female reproductive system. Our work has also demonstrated that the newly derived schistosomula contain ecdysteroids. As our experiments were conducted at 4°C and as the intermediate snail host produced ecdysteroid hormones (Nirdé and Herbert, unpublished), our hypothesis was that this large amount of ecdysteroid hormones found in 3-hr schistosomula might come from the snail host rather than from the parasite itself. In addition, the relatively high level of ecdysteroids during this first larval stage indicates that juvenile schistosomes leave the intermediate snail host with a reserve of ecdysteroids. If the *Schistosoma mansoni* model has allowed some interesting observations in the field of the production of ecdysteroids in para-

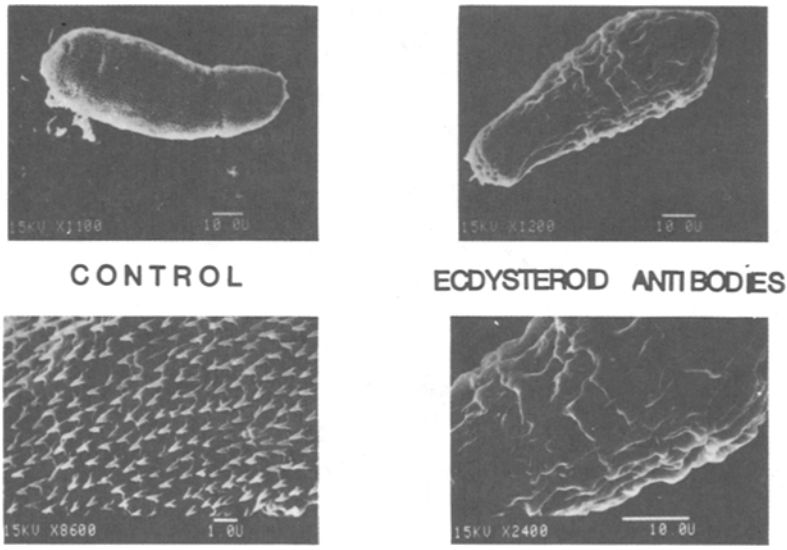

FIG. 15. Scanning microscopy on cultured schistosomula after a 24-hr period of incubation with the natural ecdysone antibodies.

sites, it is obvious that this model is not the most suitable for further investigation in the pathway of ecdysteroid hormones in worms. It must be emphasized that the metabolic pathway of ecdysterone in insects has been studied in ovaries where the hormonal level was more than 10^{-3} M. Therefore, the low hormonal level found in parasites, around 10^{-15} M, has not allowed the chemical characterization of these products by mass spectroscopy.

Our work has demonstrated that the serum of infected rodents contains ecdysteroids as early as six days postinfection. Moreover, the changes in hormone level are different between permissive and nonpermissive hosts. These important observations suggest that the concentration of ecdysteroids could be an early biological parameter of parasite infection and may be correlated with the permissiveness of the host. We also have shown that ecdysteroids were present in the serum of rodents infected with the nematode *Dipetalonema vitae*. In addition, we have demonstrated that ecdysteroids were present in the urine of infected children. It is the first demonstration of excreted ecdysteroids by organisms. These hormones have been characterized by GC and MS as the 20-hydroxyecdysone, the 5-epi-20-hydroxyecdysone and the 3-oxo-20-hydroxyecdysone. Our work also shows that the moulting hormones decrease markedly after an antischistosome chemotherapy. According to these data, we therefore confirmed that the ecdysteroids were correlated with the viability of the parasites. Moreover, the release of ecdysteroids by schistosomes might be a general

feature of parasite infection. This is true for trematodes and nematodes. Our work on this point has been confirmed by other teams (Koolmann et al., 1984). This important observation, that human beings may have insect-molting hormones in their biological fluids, could lead to an early diagnosis of parasite infection.

In arthropods, it is well known that ecdysteroids induce protein synthesis. Two of them appear interesting to study with regards to parasite physiology. The first one is the enzyme superoxide dismutase. This enzyme catalyzes the conversion of oxygen anion to hydrogen peroxide (McCord and Fridovich, 1969). Superoxide dismutase could be involved in escape mechanisms of worms against oxygen anions produced by the immune cells: macrophages and eosinophils.

Our work demonstrated that superoxide dismutase was produced by schistosomes. The two SODs were present during the critical development stages of the parasite. Once again, the ratio of Mn SOD to Cu/Zn SOD was different between males and females. The females contained more cytosolic SOD than the males in both the mesenteric and the total perfusion. However, parasites collected from total perfusion of hamsters exhibited more SOD activities than parasites collected exclusively from the mesenteric vessels. Moreover, the total SOD activities could be correlated with the ratio of 20-hydroxyecdysone to total ecdysteroids within parasites. As 20-hydroxyecdysone is more active than ecdysone, in the physiological sense, our hypothesis is that the 20-hydroxyecdysone, or its conjugates, induces this enzyme in *Schistosoma mansoni*.

The second interesting enzyme is the dopa decarboxylase. Gathering together the publications on ecdysone, serotonin, and dopa decarboxylase, the schema in Figure 16 indicates what the action of ecdysone on egg shell formation may be. Two pathways are possible for the synthesis of melanin. The first one involves the serotonin molecule, the enzymes dopa decarboxylase (EC 4.1.1.28), and hydroxyindole-*O*-methyltransferase. On one hand, the enzyme dopa decarboxylase is known to be under the control of ecdysone (Kraminsky et al., 1981), and, in schistosomes, decarboxylates 5-OH-tryptophan as well as L dopa (Catto, 1981). On the other hand, serotonin is abundant in mesenteric vessels, and *S. mansoni* contains high concentrations of this biogenic amine. In addition, the enzyme hydroxyindole-*O*-methyltransferase is inhibitied by estradiol around 1 mM whereas it is activated by low steroid levels (Cardinali et al, 1981). Thus the amount of circulating estradiol could modulate the production of melanin. This fact must be correlated to the experiments of Barrabes and coworkers (1980), who demonstrated that large amounts of estradiol reduce egg production by schistosomes.

The second pathway involves L-dopa and dopa decarboxylase. At present, no direct experiments have been done to verify this schema, but it must be kept in mind when the induction of the female reproductive system is investigated.

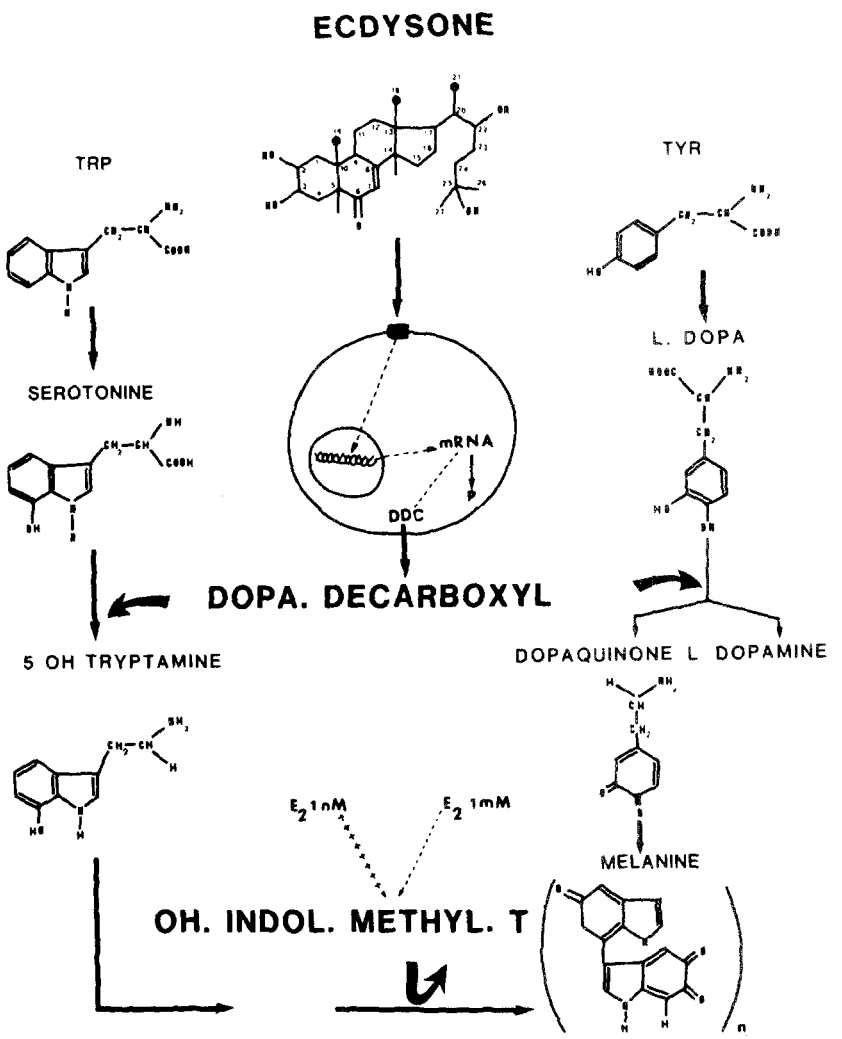

FIG. 16. Action of ecdysone on egg shell formation.

We certainly do not claim that we have achieved a high degree of protection. It is obvious that our experimental protocols have to be optimized. However, this partial result indicates that immunization with ecdysteroids might lead to a reduction of the worm burden. Although no direct evidence has been obtained on the physiological role of ecdysteroids within parasites, close correlations between the presence of significant amounts of hormones and some physiological phenomena are thought provoking. In this regard, the involvement of ecdysteroid hormones seems evident: (1) in parasite morphogenesis,

(2) in sexual maturation of the female reproductive system, and (3) in the induction of enzymes implicated in parasite escape mechanisms. Moreover, because humans do not produce ecdysone, the cytotoxic effect of ecdysteroid antibodies might be a novel strategy for immunoprophylaxis of parasite infections in man.

Acknowledgments—The authors thank Dr. B. Sellin (CERMES, Nigeria) for serum and urine samples of infected children and Dr. G. Prencier for scanning microscopy studies. The authors are indebted to Dr. G. Teller (Strasbourg) for mass spectroscopy analysis and P. Fressancourt for his skillful assistance. These works were carried out with the aid of grant 282-0016 from the Edna McConnell Clark Foundation, New York. This work was also supported by INSERM (U 167) and CNRS (624).

Abstract—The time course of the conversion from a cyanide-sensitive to a cyanide-insensitive energy metabolism in immature *Schistosoma mansoni* was followed by correlating transitions in CO_2 and lactate formation with physiological properties of the parasite. Volume conducted electrical potentials and measurement of CO_2 evolution indicate that 3-hr posttransformational schistosomula are highly sensitive to 1 mM cyanide. By 24 hr after transformation, evolution of CO_2 under control conditions is reduced by 77% from 3-hr levels, while lactate excretion rises by 84%. At the 24-hr stage, neither cyanide nor rotenone affects the frequency or magnitude of endogenous electrical transients, but cyanide does eliminate 83% of the already reduced levels of CO_2 evolved in 24-hr schistosomula. The adult parasite evolves a low level of CO_2 which is reduced by 88% in the presence of 1 mM cyanide. No significant Pasteur effect is detected, however, and endogenous electrical activity as well as mechanical responses of the adult musculature are unaffected by cyanide exposure. Furthermore, adult schistosomes were not adversely affected in terms of the physiological parameters measured by 24-hr incubations in oxygen-free medium. Adults were only marginally affected by 24-hr exposure to several respiratory inhibitors, but responded rapidly to some uncouplers of oxidative phosphorylation, including 2,4-DNP, carbonyl cyanide 3-chlorphenylhydrazone, and closantel. Our results indicate that schistosomula continue to rely on cyanide-sensitive respiratory components for at least 3 hr after transformation; by 24 hr, however, the parasites are metabolically similar to the adult stage, i.e, they depend on lactate fermentation for most of their energy requirements.

INTRODUCTION

Fermentation of glucose to lactate in the adult trematode, *Schistosoma mansoni* occurs both under aerobic and anaerobic conditions. Glycolysis is the principal source of energy, and no Pasteur effect is observed (Bueding, 1950; Schiller et al., 1975; Bueling and Fisher, 1982). During the cercarial stage of the parasite's life cycle, however, most energy is derived by oxidative metabolism (Oliver et al., 1953; Coles, 1972a). Cercariae are killed within 4 hr in the presence of 1 mM cyanide, and addition of glucose (1 mg/ml) does not prolong their lives (Coles, 1972b). However, Coles (1972b) reported that cercariae do exhibit a Pasteur effect under nitrogen and that lactate is excreted under anaerobic conditions only.

Between the aerobic cercariae and anaerobic adult stages of the parasite's life cycle, there is a period of transition during which the recently penetrated schistosomulum undergoes a number of important changes. Morphologically, the parasite loses its tail and develops a heptalaminate outer tegumental membrane (Hockley and McLaren, 1973). Immunologically, the worm undergoes a rapid, nearly linear decline in susceptibility to rejection by passively transferred immune serum (Sher, 1977), possibly due to surface changes which inhibit recognition and/or binding by host immunoglobulins (Dean, 1977). Most evidence suggests that these changes occur rapidly and are, for the most part, completed within 24 hr after the parasite enters the host.

The conversion from the aerobic metabolic state of cercariae to the predominantly anaerobic one of adult schistosomes is important because of its possible functional relationship with changes in immuno- and chemosensitivity. The time course of this metabolic conversion, however, is not well documented. Previous studies have failed to provide quantitative data correlating metabolic conditions with the physiological status of the parasite. Additionally, most of these studies fail to measure evolved CO_2, the major by-product of oxidative metabolism, and rely primarily on enzymatic assays which are less sensitive than readily available chromatographic techniques.

METHODS AND MATERIALS

Parasite Preparations and Incubation Media. A Puerto Rican strain of *S. mansoni* was maintained by passage through Swiss Webster mice and *Biomphalaria glabrata* snails. Cercariae were collected in dechlorinated water by exposing 100–150 infected snails to light for 1–2 hr. Cercarial suspensions were passed through a wire grid to remove snail feces and other debris. Cercariae

were counted under a microscope and maintained in dechlorinated water at 30°C prior to use. Bacterial contamination in all suspensions of organisms was reduced by using sterilized glassware and by adding 100 units/ml penicillin plus 100 μg/ml streptomycin to media prior to sterile filtration.

Schistosomula, the larval or skin stage parasites, were prepared from the same batch of cercariae by two methods. Mechanically transformed schistosomula were obtained by a modification of the method of Ramalho-Pinto et al. (1974). Cercariae were placed in 15 ml conical centrifuge tubes and cooled to 4°C for 10 min to reduce motility. After centrifugation at low speed for 1 min, the supernatant was decanted and replaced by a cold 1 : 1 mixture of filtered horse serum and RPMI-1640 (HS/RPMI; Gibco, Grand Island, New York) buffered to pH of 7.4 with 25 mM HEPES. To remove the parasites' tails and thereby initiate transformation, the packed cercariae were resuspended and stirred for 1 min at a moderate speed on a vortex mixer. After the suspension was centrifuged, the tail-rich supernatant was discarded and the body-rich pellet resuspended in additional HS/RPMI. This process was repeated six times, so that the final suspension of parasites contained fewer than 6% tails or nontransformed cercariae.

Skin-penetrated schistosomula were prepared by a modification of the method of Cousin et al. (1981). Approximately 1000 cercariae in dechlorinated water were pipetted onto the cleaned inner surface of the ears of uninfected, ether-anesthetized Swiss Webster mice and allowed to penetrate for 45 min. The mice were killed by cervical dislocation and nonpenetrating cercariae were removed by cotton swabs. The ears were removed and finely minced in a 20-ml Petri dish containing 5 ml HS/RPMI. After a 1-hr incubation at 37°C with continuous agitation, motile schistosomula were individually transferred by pipet into vials containing HS/RPMI and maintained at 37°C. Schistosomula were transformed from cercariae 3 hr or 24 hr prior to testing, and maintained in HS/RPMI. Transformation was verified by means of the methylene blue dye exclusion test (Clegg and Smithers, 1968).

To determine the effects of protein synthesis inhibition on the metabolic conversion of the schistosomulum, 200 μg/ml puromycin (in distilled water; Sigma Chemical Co., St. Louis, Missouri) was added to cercarial preparations 30 min prior to mechanical and skin transformation. These parasites were maintained in a similar concentration of puromycin during all subsequent incubations and electrophysiological recordings which were conducted 24 hr after transformation. Electrophysiological (but not biochemical) assays were also obtained from schistosomula transformed and maintained in 0.1 mM colchicine or 10 μM cytochalasin B to assess the importance of microtubule and microfilament-mediated processes on the conversion to a physiological cyanide-insensitive state.

Adult parasites were obtained according to the method of Fetterer et al. (1977) by extracting worm pairs from the portal veins of cervically dislocated

mice 55 days after infection. Worm pairs were separated, and the males were placed in vials containing HS/RPMI and maintained at 37°C prior to use.

Electrophysiological and Mechanical Recordings. Endogenous electrical activity was recorded by a modification of the method described by Fetterer et al. (1977). Glass suction electrodes were manufactured from 1.25 mm capillary tubing (W.P. Instruments, New Haven, Connecticut) pulled to a fine tip on a horizontal electrode puller (Narishige, Tokyo, Japan). The electrodes were cut with a diamond pencil to obtain a flat tip, with an outside diameter of 15–30 μm. The tip was then heated on a microforge (Aloe Corp., New York, New York) which melted the glass from the inside, until the flattened tip became smooth, and the aperture was reduced to approximately 2 μm for recording from schistosomula, or 15–20 μm for recording from adults. Electrodes were firmly attached to the parasite's surface during recordings by way of negative pressure created by a 10-ml syringe. Prior to attachment of the parasite, Hanks' balanced salt solution (HBSS) was drawn into the electrode until it made contact with a silver wire connected to an amplifier (model P-15, Grass Instruments, Quincy, Massachusetts). Electrical signals from the parasites were filtered with the low pass set to 0.3 Hz and the high pass to 1 kHz. Signals were displayed on an oscilloscope (model 5113, Tektronix Inc., Beaverton, Oregon) or a chart recorder (Narco Biosystems Inc., Houston, Texas), and passed onto an analog-to-digital converter prior to computer analysis (Alis I-10 Data Acquisition and Control System, Ecotech Inc., Lansing, Michigan).

All recordings of endogenous electrical potentials from parasites exposed to potassium cyanide (CN^-), rotenone (both from Sigma Chemical Co.), or potassium antimony tartrate (KSb tartrate; Fisher Scientific, Fair Lawn, New Jersey) were obtained either 1–2 hr or 24–28 hr after the parasites were preincubated in the presence of the drug. Parasites incubated in the presence of vehicle served as controls.

After electrode attachment, a 2–4 min equilibration period was allowed prior to electrical recording. Electrical activity was quantified by counting all negative field potentials in excess of 20 μV over six 10-sec intervals. Data from these intervals were then averaged. Potentials under 20 μV were not counted as they were within the noise range of the system. Electrical responses were measured in at least eight control parasites and eight parasites exposed to each experimental substance. Statistical analysis for significance of difference between means used Student's nonpaired t test.

The effects of oxygen-free medium, or exposure to respiratory inhibitors or an inhibitor of the TCA cycle on tegumental membrane ionic gradients, were measured as previously described (Thompson et al., 1982). In the present study, all recordings were obtained after 24-hr exposures. Under each condition, recordings were obtained from at least five parasites during each of at least three separate experiments.

Muscle tension recordings were obtained from adult schistosomes using the method described by Fetterer et al. (1977). The effects of inhibitors on the energy-dependent muscle tension changes induced by exposure to elevated potassium (60 mM), which increases muscle tension in schistosomes, or the acetylcholine analog carbachol (0.1 mM), which reduces muscle tension in schistosomes, were assessed by preincubating the parasites for 1–2 hr or 24–28 hr in 1 mM CN^- or 0.1 mM KSb tartrate-containing media prior to exposure to the tension-altering treatments. Mechanical responses were measured in at least five control parasites and five parasites preincubated in drug.

Incubation in [^{14}C]Glucose-Containing Media and Analysis of Metabolites. In biochemical experiments involving immature stages, parasites were concentrated to 12,000/ml in HS/RPMI containing antibiotics. Only mechanically transformed schistosomula were used in biochemical studies, since the skin-transformed parasites were difficult to obtain in sufficient quantities. Aliquots of 400 μl (containing 5000 schistosomula) were pipetted into the center wells of 15 ml Warburg reaction vessels. Drug-treated parasites were concentrated in incubation media containing 1 mM CN^- or 0.1 mM KSb tartrate 1 hr before testing. In experiments involving adult schistosomes, six males were placed into the Warburg vessels along with 400 μl HS/RPMI. Heat-killed controls of immatures and adults were preincubated for 15 min at 56°C immediately prior to testing.

After placement of parasites, uniformly labeled D-[^{14}C]glucose (1.4 μCi, specific activity = 348.2 Ci/mol; New England Nuclear, Boston, Massachusetts) was added to the center well of each vessel. To capture evolved $^{14}CO_2$, 1 ml of 1 N sodium hydroxide, freshly prepared in boiled distilled water, was added to the base of the Warburg vessels. The vessels were then placed on a shaker bath and maintained at 37°C for a period of 4 hr. Following incubation, the vessels were cooled on ice for 15 min prior to sample collection. For measuring evolved $^{14}CO_2$, three 200-μl aliquots of the 1 N NaOH were pipetted from the base of each vessel into scintillation vials containing 50 μl glacial acetic acid and 6 ml aqueous scintillant (Amersham Co., Arlington Heights, Illinois), and counted on a Beckman LS-7,000 liquid scintillation system (Beckman Instruments, Fullerton, California).

Acid-soluble metabolic endproducts were fractionated with a modification of the method of Tielens et al. (1981). A 350-μl sample of incubation medium was recovered from the center well and 20 μl cold 71% perchloric acid was added. The samples were centrifuged at 1000*g* for 15 min and radioactivity was determined in the supernatant by scintillation counting. Samples (50 μl) of the supernatant were loaded onto BioRad AG 1-X10, 100–200 mesh anion-exchange columns (12 × 0.75 cm; BioRad Labs, Los Angeles, California) in chloride form using 25 mM HEPES as the primary solvent. The columns were eluted with 10 ml of 25 mM HEPES (F1), followed by 5 ml of 5 mM HCl

(F2), and 5 ml of 500 mM HCl (F3). Over 99% of the radioactivity applied was recovered. Aliquots (500 μl) of the eluted material were placed into vials containing 10 ml aqueous scintillant for counting. Results were converted from disintegrations per minute (dpm, counts per minute divided by efficiency of counting) to nmol CO_2 or lactate produced. Labeled substrates from the column fractions were identified by descending paper chromatography, with butanol–water–acetic acid (25 : 10 : 4) as developing solvent. In control and CN^- experiments, only 10–12% of the glucose was degraded over the 4 hr incubation periods. Over 90% of the acid-soluble fraction comigrated with and exhibited the expected retention factor of lactate. Total protein was determined by the method of Albro (1975) using bovine serum albumin standards. All tests were run in triplicate on at least three separate occasions ($N \geq 9$), except studies involving KSb tartrate ($N \geq 4$). Variation among triplicate tests was usually less than 15%. Statistical analysis of these results were based on comparison of dpm/mg protein for each sample, using Student's nonpaired t test.

RESULTS

Volume Conducted Electrical Potentials. Endogenous electrical activity recorded from the surface of schistosomula and adult *S. mansoni* consisted of multiphasic potentials ranging from 20 to 200 μV in amplitude and 10 to 300 msec in duration (Figure 1). Under control conditions, these potentials occurred at a rate of 30–40/sec and exhibited rise times of 3–8 μV/msec. There was an exponential decrease in the frequency of potentials with increasing amplitude. Characteristics of electrical activity recorded from all stages of development were essentially identical under control conditions, although the adult parasite showed some regional variation in the frequency of potentials.

After a brief (1–3 min) episode of enhanced activity that normally followed electrode attachment, the frequency of low amplitude potentials was relatively constant over a period of up to 30 min. Large amplitude potentials (>50 μV) occurred more sporadically and appeared to correlate with peristaltic-like contractions of the parasite, suggesting that these transients may originate in underlying muscle bundles. To verify that the electrical activity originated from within the parasite, controls were conducted by recording from worms before and after addition of 0.5 ml 50% ethanol to the recording medium. This treatment immediately immobilized the parasites and eliminated nearly all electrical transients (Figure 1).

Developmental Changes in Glucose Metabolism. The results presented in Figure 2 (open bars) demonstrate that schistosomes undergo a pronounced metabolic alteration during development from the 3-hr schistosomulum to the adult stage. Most of this change appears to be complete by 24 hr after transformation, at which point CO_2 evolution is reduced by 77% from 3 hr levels, while lactate

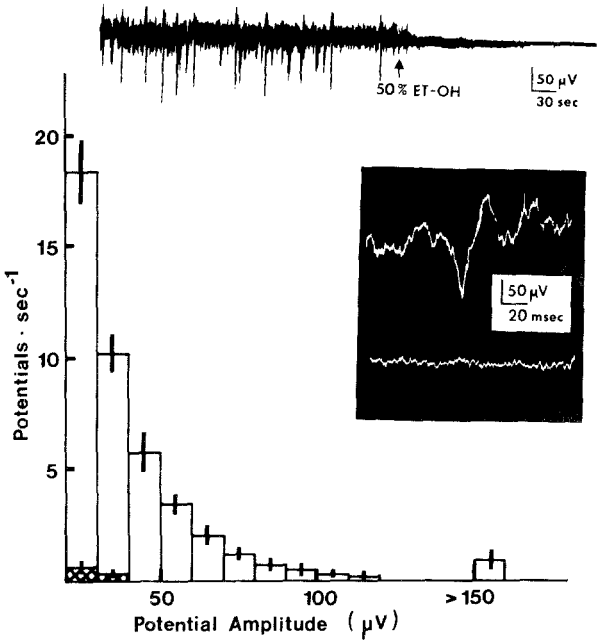

FIG. 1. Electrical activity recorded from the surface of mechanically transformed 3-hr schistosomula under control conditions and after the addition of 50% ethyl alcohol to the recording medium. Upper: slow speed chart recording showing decline in electrical activity after alcohol exposure. Middle right: high speed oscilloscope traces obtained from the same parasite before (upper) and after (lower) exposure to alcohol. Note the elimination of all large amplitude multiphasic potentials. Lower: amplitude–frequency distribution of endogenous electrical transients. Open bars represent electrical activity recorded from schistosomula incubated in HS/RPMI; hatched bars: activity from the same parasites 1 min after the addition of alcohol. Vertical lines are 1 SE; $N = 8$.

excretion nearly doubles, to a level only 18% less than that measured in the adult.

Developmental Changes in Physiological Responses to Metabolic Inhibitors. Electrophysiological recordings indicate that schistosomes undergo a significant developmental alteration in responsiveness to CN^- and rotenone, while their response to KSb tartrate is consistent throughout the course of development (Figure 3). The frequency and mean amplitude of endogenous electrical transients recorded from 3 hr mechanically and skin-derived schistosomula were significantly depressed after a 1 hr incubation in 1 mM CN^-. The degree of CN^--induced depression was essentially identical to that induced by a 1-hr incubation in 0.1 mM KSb tartrate, indicating that the 3-hr posttransformational stage may rely on a CN^--sensitive terminal oxidase for generating some of the energy used to sustain membrane electrical events.

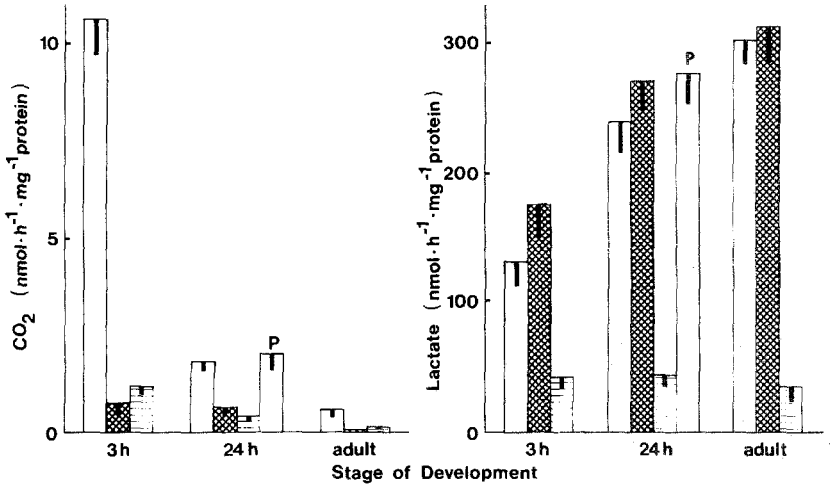

FIG. 2. Developmental changes of *S. mansoni* in the distribution of metabolic endproducts and the effects of metabolic inhibition due to 1 mM CN^- (cross-hatched bars) or 0.1 mM KSb tartrate (lined bars) on CO_2 (left) and lactate (right) produced during 4-hr incubations in D-[^{14}C]glucose-containing media. CO_2 and lactate produced by 24-hr schistosomula incubated in 200 μg/ml puromycin (P) were similar to control levels (open bars). Values for CO_2 based on dpm in NaOH aliquots; those for lactate based on dpm of acid-soluble fractions (F3) obtained from ion-exchange columns. Values presented are means of at least three separate experiments performed in triplicate ($N \geq 9$); vertical lines are 1 SE.

Electrical recordings obtained from 24-hr mechanically and skin-derived schistosomula exposed to 1 mM CN^- indicate that inhibition of the terminal oxidase no longer results in a significant depression of the spontaneous potentials. Since electrical activity in both groups was unaffected by CN^-, it appears that the method of transformation does not significantly alter this conversion process. Based on electrophysiological responses, the expression of CN^--insensitivity by 24 hr is not affected by the presence of 200 μg/ml puromycin, indicating that new protein synthesis is not required for this conversion. The apparent metabolic conversion is similarly unaffected by the presence of the cytoskeletal inhibitors colchicine or cytochalasin B, as 24-hr schistosomula exposed to either of these drugs also became resistant to cyanide-induced depression of the transmembrane electrical transients. Consistent with this finding, the 24-hr schistosomula exhibited a lower level of sensitivity to rotenone than that recorded at the 3-hr stage of development.

The adult parasite, like the 24-hr schistosomulum, exhibited no change in electrical activity in response to 1 mM CN^-, even after 24-hr incubations (Figure 3). Inhibition of glycolysis by 0.1 mM KSb tartrate, however, eliminated 75% of the potentials within 1 hr, and by 24 hr the electrical activity was totally eliminated.

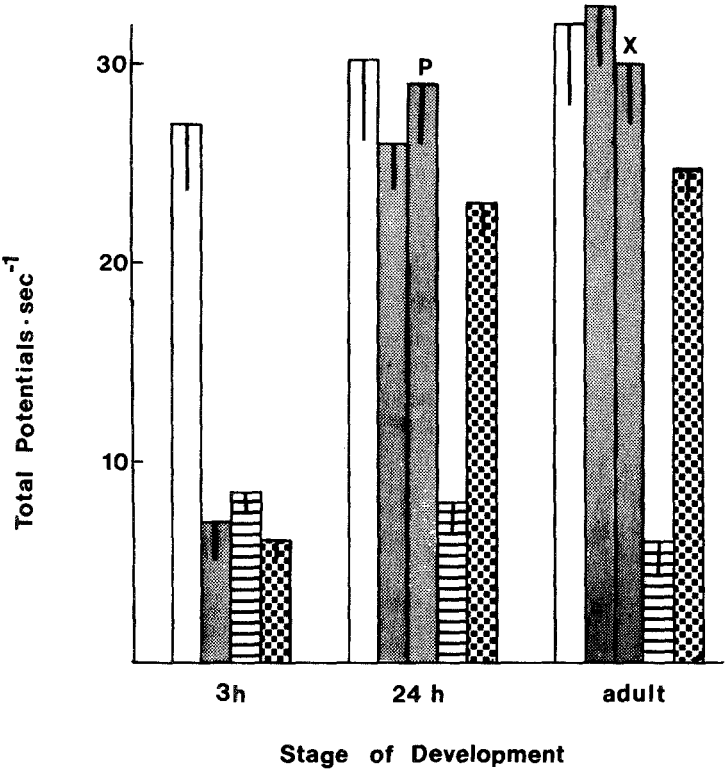

FIG. 3. Frequency of endogenous electrical potentials recorded from developmental stages of *S. mansoni* under control conditions (open bars) or after 1-hr incubations in media containing 1 mM CN^- (cross-hatched bars), 0.1 mM KSb tartrate (lined bars), or 10 μM rotenone (checkered bars). Values obtained from skin- and mechanically transformed (shown here) schistosomula were similar. The frequency of potentials recorded from 24-hr schistosomula preincubated in 200 μg/ml puromycin (P) prior to CN^- exposure was similar to control levels. Similar values were recorded from 24-hr schistosomula preincubated in 0.1 mM colchicine or 10 μM cytochalasin B (not shown). Adult parasites incubated 24 hr in 1 mM CN^- (X) exhibited control levels of electrical activity. Vertical lines are 1 SE; $N \geq 8$.

Intracellular recordings obtained from the adult schistosome revealed that the parasite's response to metabolic inhibition varies significantly with the treatment used (Table 1). In general, depolarization of the parasite's tegument was most pronounced after 24-hr preincubations under glycolytic inhibition (KSb tartrate).

Muscle tension recordings obtained from adult schistosomes indicate that energy obtained from respiration is not essential for muscle function in the mature organism. Introducing a medium containing 60 mM potassium into the recording chamber resulted in a rapid increase in longitudinal muscle tension,

TABLE I. EFFECTS OF METABOLIC INHIBITORS ON TEGUMENT POTENTIAL (E_{Teg}) RECORDED FROM ADULT MALE *S. mansoni*[a]

Control	E_{Teg} (mV)	Experimental	E_{Teg} (mV)
Aerobic medium (under air)	−52.2	Anaerobic medium (< 1% O_2 saturated)	−50.2
	−53.7	1 μM KSb-tartrate	−16.3
	−55.3	0.1 mM KCN	−54.1
	−53.2	0.1 mM FLA[b]	−48.6
	−52.4	10 μM rotenone	−31.7[c]
	−52.7	10 μM oligomycin	−35.2[c]

[a] For all treatments, experimental parasites were preincubated 24 hr in drug prior to microelectrode recordings. Incubation and recording medium consisted of RPMI-1640. All experiments were performed a minimum of three times, with recordings obtained from at least five parasites each time.
[b] FLA = fluoroacetamide.
[c] $P < 0.001$.

which occurred at approximately the same rate and was similarly sustained in parasites preincubated 24 hr in control medium or in anaerobic medium, or medium containing 1 mM CN^- (Figure 4, left). Similarly unaffected by preincubation in 1 mM CN^- was the relaxation of longitudinal muscle induced by exposure to 0.1 mM carbachol (Figure 4, right). These mechanical responses were significantly diminished, however, when adult parasites were preincubated for a period as brief as 1 hr in medium containing 0.1 mM KSb tartrate.

Kymographic recordings obtained after periods of acute exposure (15 min) to several compounds revealed that CN^-, oligomycin, and rotenone are all without effect on the longitudinal muscle tension of the adult parasite (Figure 5, right).

Effects of Metabolic Inhibitors on Substrate Utilization. Results shown in Figure 2 illustrate the effects of metabolic inhibitors on patterns of substrate utilization in various stages of the parasite. CO_2 production (left) was approximately equally inhibited by 1 mM CN^- and 0.1 mM KSb tartrate at all stages tested. Lactate excretion (right), however, was significantly inhibited only by exposure to KSb tartrate, which depressed levels by 80–90% at each stage of development. No significant CN^--induced Pasteur effect was detected in any stages of *S. mansoni* tested.

Consistent with results obtained from electrophysiological recordings, the presence of 200 μg/ml puromycin throughout the transformation process and incubation period of 24-hr schistosomula did not inhibit their conversion to a predominantly anaerobic metabolic state. This is evidenced by the low levels of CO_2 and high levels of lactate produced by these parasites.

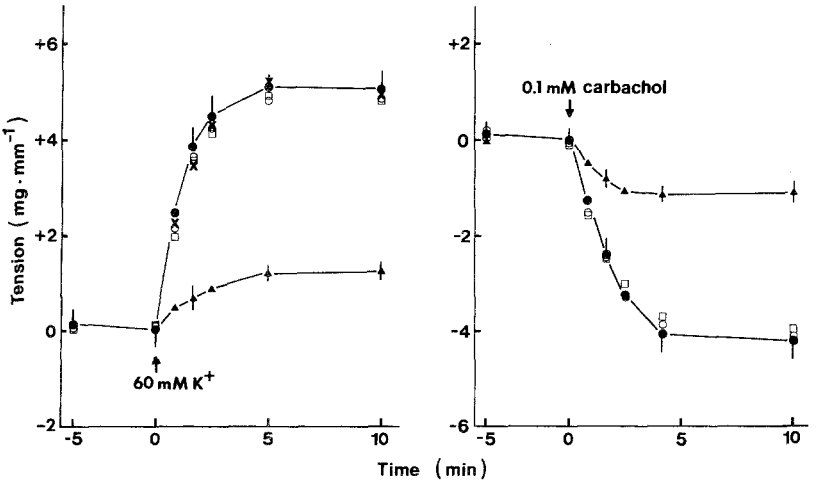

FIG. 4. Effects of incubation for 1 hr (open circles) or 24 hr (open squares) in 1 mM CN^-, 24 hr under nitrogen (Xs), or 1 hr in 0.1 mM KSb tartrate (triangles) on longitudinal muscle tension changes induced by exposure to 60 mM potassium (left) or 0.1 mM carbachol (right) in adult male *S. mansoni*. Closed circles represent muscle tension recorded in control parasites exposed to the same tension-altering treatments. For all treatments, $N \geq 5$; vertical lines are 1 SE.

DISCUSSION

Previous studies have demonstrated that measurement of endogenous electrical potentials provides a sensitive assay for agents affecting the neuromuscular system of immature and adult schistosomes (Fetterer et al., 1977; Semeyn et al., 1982; Mellin et al., 1983; Thompson et al., 1984). By this technique, the inhibitory effects of carbachol and dopamine on the schistosome can be detected at concentrations as low as 10 nM, while the stimulatory effects of serotonin are detectable at 0.1 μM. These drug concentrations are 100× lower than those required to measure detectable changes by previously used techniques. Our results indicate that a high correlation also exists between endogenous electrical activity and the metabolic state of the parasite. That is, metabolic inhibition at any stage of development is associated with a significant depression in endogenous electrical activity. Since the transmembrane electrical gradients which give rise to these potentials in schistosomes are maintained, in part, by energy-dependent processes (Fetterer et al., 1981), it is not surprising that they are sensitive to metabolic inhibition.

Based on electrophysiological recordings, 3-hr schistosomula were depressed equally by 1 mM CN^- and 0.1 mM KSb tartrate. Evolution of CO_2 by the 3-hr schistosomulum was reduced by almost 90% during 4 hr exposures to

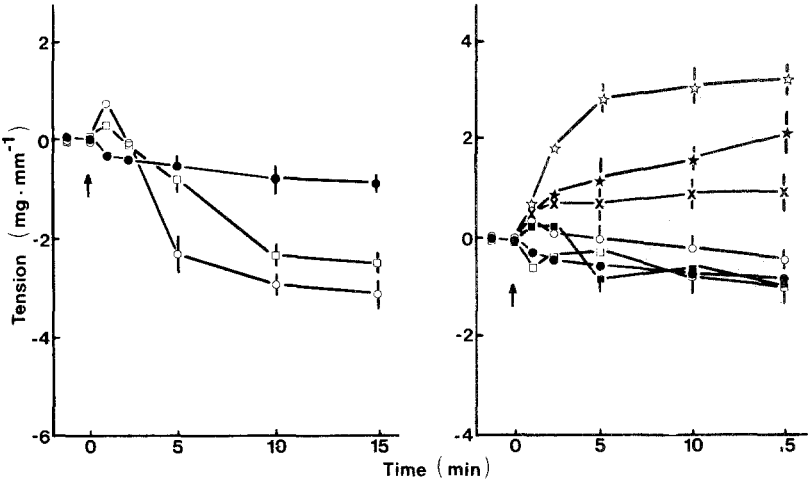

FIG. 5. Effects of acute drug exposure on longitudinal muscle tension in adult male *S. mansoni*. Left: tension-reducing effects of KSb tartrate at 0.1 mM (open circles) and 10 μM (open squares). Right: exposure to oxidative uncouplers, including 1 μM carbonyl cyanide 3-chlorophenylhydrazone (open stars), 10 μM closantel (closed stars), and 0.1 mM 2,4-DNP (Xs), induce significant increases in longitudinal muscle tension. None of the respiratory inhibitors examined, including 10 μM oligomycin (open circles), 10 μM rotenone (open squares), or 1 mM CN^- (closed squares) induced significant changes in longitudinal muscle tension over the periods examined. Closed circles represent muscle tension recorded in control parasites. For all treatments, $N \geq 5$; vertical lines are 1 SE.

these treatments. There is good evidence that the trivalent antimonials, at this concentration, inhibit schistosome phosphofructokinase both in vivo and in vitro (Mansour and Bueding, 1954; Bueding and MacKinnon, 1955; Coles and Chappell, 1979). The high degree of CN^- sensitivity obtained in electrophysiological recordings of 3-hr schistosomula was somewhat surprising, in light of findings that these parasites already excrete nearly 60% as much lactate as 24-hr schistosomula under control conditions. Apparently, the energy requirements of the 3-hr stage cannot be met entirely by lactate fermentation alone.

A number of studies suggest that the in vivo skin penetration process effects changes in schistosomula which render them less susceptible than mechanically derived parasites to the harmful effects of antibody-mediated mechanisms of immunity (McLaren et al., 1978; Van Pijkeren, 1982). During the skin-penetration process, the cercaria's tail is shed and the contents of its preacetabular glands secreted. This loss accounts for 35–50% of the parasite's total nitrogen content (Coles, 1972b). In the present study, 30% of the total protein per 5000 cercariae was lost during the mechanical transformation process. An

additional 17% was lost between the 3-hr and 24-hr stages, presumably due to delayed secretion of preacetabular gland contents and/or sloughing off of residual cercarial surface glycoproteins. It is not presently known what effects residual preacetabular gland enzymes or glycocalyx, both present to a greater extent in mechanically transformed than skin-transformed schistosomula (Cousin et al., 1981), may have on metabolic processes in the parasite. Results of our physiological assays, however, indicate that the time course of the conversion to a CN^--insensitive metabolism is similar for both groups.

In the 24-hr schistosomulum, oxidative phosphorylation appears to play a less significant role in energy production than in the 3 hr schistosomulum, since 1 mM CN^- did not eliminate a significant portion of the endogenous electrical potentials. The absence of a physiological response to CN^- in this case may be explained on the basis of the increase in lactate production which occurs between the 3-hr and 24-hr stages.

Several studies have attempted to elucidate the molecular mechanisms regulating the switch from an aerobic to an anaerobic metabolism in schistosomes. Lactate dehydrogenase was found not to change during this metabolic shift (Von Kruger, 1978). From results obtained in the present study after transforming and incubating schistosomula 24 hr in medium containing 200 μg/ml puromycin, a potent inhibitor of protein synthesis in schistosomes during all stages of development (Kusel, 1972; Nagai et al., 1977; Tavaves et al., 1980), it appears that the conversion to CN^- insensitivity does not depend on synthesis of new proteins. The metabolic changes that occur concomitantly with transformation must therefore depend on a response from enzymes already present in the emerged cercaria.

Results of experiments on the adult schistosome presented in this study are consistent with the findings of Bueding and Fisher (1982), who report that the adult parasite exhibits no Pasteur effect and no dependence on oxygen for energy formation. Although some CN^--sensitive CO_2 was evolved during incubations of the adult parasite, the amount was less than 5% (on a per mg protein basis) of that evolved by the 3-hr schistosomulum. The ratio of lactate excreted to CO_2 evolved under control conditions clearly shows that the adult parasite relies much less on oxidative phosphorylation for its energy production than the 25% reported by Coles (1972a). These findings are consistent with our observations that exposure to CN^- does not depress endogenous electrical activity or muscle responsiveness in the adult and further substantiate the principal role of homolactic fermentation in the energy metabolism of adult *S. mansoni*.

It is important to note, however, that the female parasite does rely on oxygen for egg production (Schiller et al., 1975) and that significant strain differences may exist in the metabolism of carbohydrates by schistosomes. Such differences have already been demonstrated among various strains of cestodes (Ovington and Bryant, 1981) and nematodes (Bryant and Bennett, 1983) and,

if present among *S. mansoni*, they could account for the differences between our data and that of Cole's regarding the role of aerobic energy production in the adult parasite. If there was a tight link between ATP production via this pathway and physiological processes of the parasite, we would have predicted that compounds which inhibit the electron transport chain (i.e., oligomycin, rotenone, or cyanide) would have a rapid effect on the parasite's physiology. Since these compounds did not produce a dramatic effect upon the parasite's musculature, it seems reasonable to assume that oxidative phosphorylation is not vital for the maintenance of muscle function in the parasite. Likewise, since oxygen is the common terminal electron acceptor in the electron transport chain, we should have seen, but did not, an effect on muscle tension when oxygen tension was reduced in the parasite's environment. This is not surprising since Bueding and Fisher (1982) reported that the concentration of ATP was not reduced in parasites incubated under a nitrogen atmosphere for 18 hr.

Lastly, it has been reported that uncouplers of mammalian mitochondrial oxidative phosphorylation will produce a marked decrease in parasite ATP concentration with no associated decrease in parasite lactate production (Van den Bosche, 1985). Since we did observe a clear and rapid effect of these compounds on parasite muscle function, we remain doubtful that this rapid action is due to the uncoupling of parasite mitochondrial oxidative phosphorylation. For example, these uncouplers are all known as protonophores and thus they disrupt many proton gradients, the most important of which is the pH gradient between the parasite's extracellular environment (pH 7.4) and its intracellular environment (pH 7.2). If this gradient followed the resting membrane potential (−60 mV) of the parasite's tegument, the pH should be 6.4 rather than 7.2. Thus, like all cells (except for the red blood cell) the parasite maintains a hydrogen ion concentration considerably above the predicted value (Ross and Boron, 1981). Preliminary results, using various plasma membrane proton pump inhibitors would suggest that protonophores would be highly lethal to this parasite because of their action on nonmitochondrial proton gradients.

(Received October 1, 1985; accepted January 27, 1986)

Abstract—In vitro egg production by *Schistosoma mansoni* was examined following a 72-hr incubation period in the presence of various steroids, steroid precursors, or steroid synthesis inhibitors. Mevinolin, an inhibitor of cholesterol biosynthesis, significantly decreased egg production at 10^{-6} M. However, neither cholesterol (at 10^{-5} M) nor any of its hydroxylated derivatives (at 10^{-4} M) affected *S. mansoni* fecundity. Dianisidine, an inhibitor of cholesterol metabolism to hormonal products, was also ineffective in influencing egg production. The steroid hormones progesterone, 17α-hydroxyprogesterone and medroxyprogesterone acetate, all significantly decreased egg production; however, parasite muscle tension was also significantly reduced by the concentrations of these steroids needed to produce an effect on egg laying. Various androgenic hormones (androsterone, androstenedione, testosterone) and estrogenic hormones (17β-estradiol and estrone) demonstrated no effect on in vitro egg production. Significant elevation in the rate of parasite oviposition was seen in the presence of the corticosteroid prednisolone (at 10^{-4} M), but not by dexamethasone, a corticosteroid analog.

Key Words—*Schistosoma mansoni*, steroids, fecundity, mevinolin, dianisidine.

INTRODUCTION

The effects of hormones on the viability of *Schistosoma mansoni* in vivo have been assessed in studies wherein the host was rendered hormonally imbalanced by gonadectomy and/or steroid injections (for reviews see Schwabe and Kilejian, 1968; Solomon, 1969). Unfortunately, none of the in vivo experiments

0098-0331/86/0800-1901$05.00/0

measured the effects of host hormonal changes on the fecundity of the schistosome. It has long been known that the presence of one sex of schistosome is important for the somatic growth and sexual maturation of the other (Sagawa et al., 1928; Severinghaus, 1928). Stimulation of the development of the female reproductive tract of the parasite is brought about through a close physical relationship with the male. Although the biochemical events which mediate this process are unknown, it may be that the male schistosome secretes a hormone-like substance which triggers vitellogenesis in the female. Therefore, an examination of the effects of hormones and steroidal compounds on in vitro egg production was undertaken.

In the host, *Schistosoma mansoni* oviposits in the mesenteric venules lining the intestinal tract at a rate of over 300 eggs per day (Moore and Sandground, 1956). The pathological consequences of schistosomiasis are due to inflammation and fibrosis in the presinusoidal portal areas of the liver. Unequivocally, it is the host immune response to the schistosome eggs which instigates the pathology (Domingo et al., 1967; Warren, 1978). Hepatosplenic disease does not develop if the onset of egg-laying is prevented, and signs of amelioration of the disease are seen if egg production is halted after the onset of the disease state (Warren, 1970). Therefore, it is critical to elucidate the factors responsible for the fecundity of the female schistosome in an effort to interfere with the process of egg production.

In the present study, various steroidal compounds and steroid metabolic inhibitors were assayed for effectiveness in enhancing or inhibiting the rate of oviposition of *S. mansoni* in vitro. While egg production by the parasite differs in in vivo versus in vitro conditions, the in vitro technique allows for a direct study of these compounds on the schistosome in the absence of effects of host metabolism and host-mediated pharmacokinetic variables which affect distribution and elimination of these compounds.

METHODS AND MATERIALS

Infections. Young female white, outbred (ICR) laboratory mice were infected intraperitoneally with approximately 250 *Schistosoma mansoni* cercariae (Puerto Rican strain). Animals were communally housed with food and water ad libitum. At 50–55 days postinfection, the mice were sacrificed by cervical dislocation, and the mature parasites were removed mechanically by the method of Fetterer et al. (1977). Fifteen pairs of mated worms were transferred to 250-ml Erlenmeyer flasks containing 50 ml of media; flasks were then incubated for 72 hr at 37°C in a shaking water bath at 20 oscillations per minute. The incubation medium was a 1:1 mixture of RPMI 1640 and heat-inactivated horse serum, adjusted to pH 7.4, to which 100 μg/ml penicillin and 100 μg/ml streptomycin were added (media components from Gibco Laboratories). Mercapto-

ethanol was added to a final concentration of 5×10^{-5} M. Steroids (obtained from Sigma or Steraloids), mevinolin (obtained from Merck, Sharp, and Dohme Research Labs), or the appropriate vehicle (DMSO or ethanol) were added to the media in a volume not exceeding 100 μl. Following incubation, the condition of the parasites was noted (i.e., degree of pairing, adherence to the flask bottom), and the eggs in the entire media sample were counted under a compound microscope. Five to seven flasks were run per concentration of each test compound along with the appropriate vehicle control.

Mechanical and Electrical Activity Measurements. Recordings of schistosome longitudinal muscle tension and contractile activity were obtained from male parasites as previously described (Fetterer et al., 1977). Electrical activity recordings from the surface of parasites were determined using suction electrodes as described by Semeyn et al. (1982). Mechanical and electrical activity measurements were made on control and treated worms following the 72-hr incubation period.

RESULTS

Cholesterol or the 20α, 22-(*S*), or 22-(*R*) hydroxylated cholesterol derivatives did not significantly affect schistosome egg production. Dianisidine (3,3-dimethoxybenzidine), a compound which inhibits the metabolism of cholesterol to hormonal products (Sheets et al., 1981), was also ineffective in altering the egg production rate (unpublished observations).

The effects of pregnenolone, progesterone, 17α-hydroxyprogesterone, medroxyprogesterone acetate (MPA), and prednisolone on egg production are shown in Figure 1. Only the progestational hormones exhibited significant inhibition of egg production. However, the degree of pairing of the parasites and adhesion to the bottom of the flask were both adversely affected by these compounds at the concentrations studied. Also, recordings showed marked depression of parasite muscle tension in response to these hormones (Figure 2). These effects were not observed in response to pregnenolone; both fecundity and the physiological parameters remained unchanged in the presence of this hormone.

The corticosteroid prednisolone (10^{-4} M) caused a significant stimulation in egg production (Figure 1), whereas dexamethasone, another corticosteroid, did not. When added along with MPA, prednisolone did not reverse the effects of this compound on fecundity.

Both estrogenic hormones [17β-estradiol (10^{-4} M), estrone (10^{-4} M)] and androgenic hormones [androstenedione (10^{-4} M), testosterone (10^{-4} M), or androsterone (10^{-4} M)] proved ineffective in altering either schistosome fecundity or the physiological parameters studied (data not shown).

The nonsteroidal compound mevinolin significantly depressed egg production at 10^{-6} M (Figure 3). This inhibition was effected without a concomitant

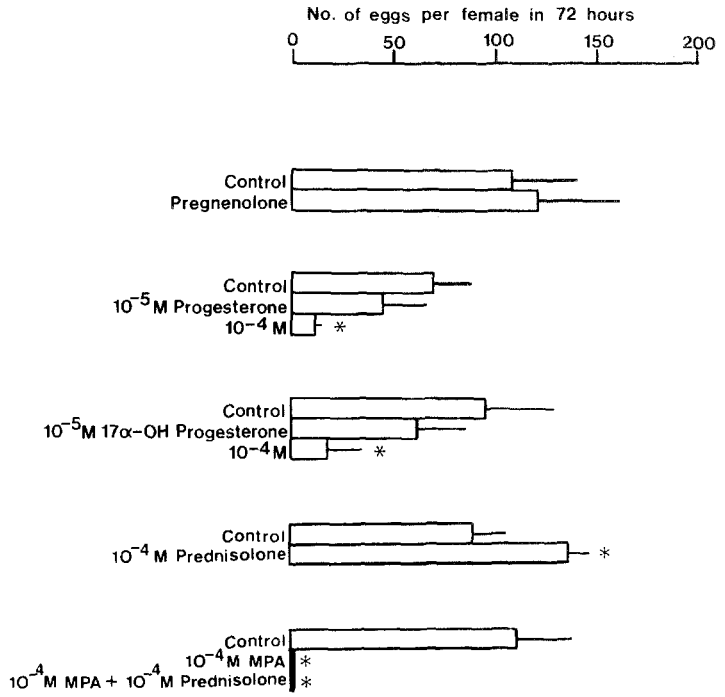

FIG. 1. Effect of various steroids on schistosome fecundity in vitro. Paired schistosomes (15 pair per 50 ml horse serum/RPMI (1:1) in 250-ml Erlenmeyer flasks) were incubated for 72 hr at 37°C in the presence of steroid hormones or their appropriate vehicle at the concentrations indicated. Egg counts were made from the entire media sample following incubation. Values were obtained from the mean egg counts in five to seven flasks run at each concentration for each compound. Asterisk = $P < 0.05$, as determined by the Student's t test; horizontal lines are 1 SE. MPA: medroxyprogesterone acetate.

depression of surface electrical activity or muscle tension. Additionally, parasite pairing and adhesion were unaffected up to concentrations of 10^{-4} M.

DISCUSSION

The factors required for the development of the reproductive tract and subsequent oviposition in the female schistosome remain largely unknown. In light of past in vivo studies wherein the effects of host hormonal imbalance on the viability of the parasite were examined, the present study assessed what effects, if any, the classical steroid hormones, as well as steroid synthesis inhibitors, had on schistosome fecundity in vitro. It could thus be determined whether these steroids played a role in modulating egg production by the schistosome.

The conversion of cholesterol to pregnenolone in *S. mansoni* was reported

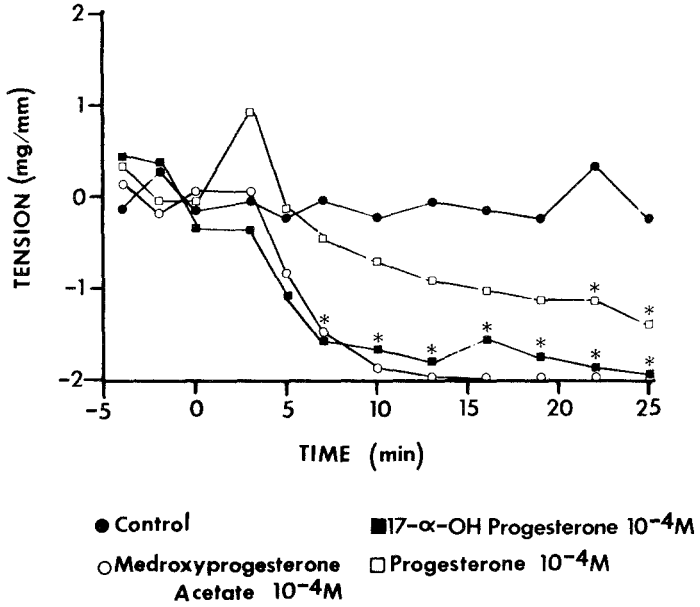

FIG. 2. Effect of progestational hormones on schistosome longitudinal muscle tension. Male schistosomes under tension were treated at time 0 with concentrations of progestational steroid hormones at which a significant effect on egg production was seen. Muscle tension was recorded using the method of Fetterer et al. (1977). Asterisk = $P < 0.05$ (Student's t test); values presented are the means of recordings from eight parasites per steroid examined.

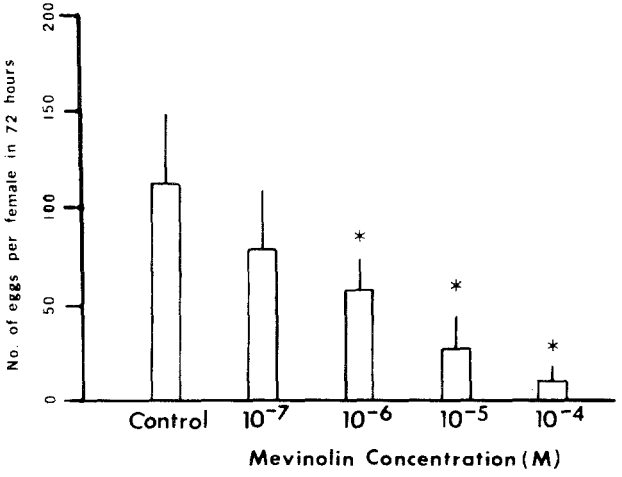

FIG. 3. Effect of mevinolin on schistosome fecundity in vitro. Paired schistosomes were incubated as described in Figure 1. Asterisk = $P < 0.05$ (Student's t test); vertical lines are 1 SE.

by Briggs (1972), although no physiological role was given for this hormone. However, the hydroxylation of cholesterol and subsequent side-chain scission necessary for the formation of pregnenolone is mediated by the cytochrome P-450 complex, which is not known to be present in schistosomes. In the present study, no effect was exhibited by cholesterol, 20α-, 22-(*R*)-, or 22-(*S*)-hydroxycholesterol, or pregnenolone on in vitro oviposition. Furthermore, dianisidine, an inhibitor of the cytochrome P-450-mediated mixed function oxidase system which catalyzes the 20α hydroxylation of cholesterol (Sheets et al., 1981), was also ineffective in altering schistosome egg production, even though the concentration of dianisidine used in this study (10^{-3} M) was in great excess of the IC_{50} for the mammalian enzyme (2.5×10^{-6} M). These data question the ability of the schistosome to form and utilize hormonal precursors under our in vitro culture conditions.

The effects of progestational hormones on the schistosome were evidenced only at concentrations much higher than those reported for most vertebrate hormone–receptor interactions (K_d 10^{-10}–10^{-8} M; Chan and O'Malley, 1978), suggesting a nonspecific physiological effect of these compounds on the parasite. It may be concluded that the decrease in schistosome fecundity caused by the progestational steroids was an effect not specific for the reproductive tract of the parasite, as other parameters of physiological functioning were also depressed.

In the present study, the corticosteroid prednisolone enhanced egg production while dexamethasone, a corticosteroid analog, had no effect. This is of interest, since it was shown that cortisone-treated mice infected with *S. mansoni* generally yield fewer worms than do control infected mice (Coker, 1957; Lewert and Mandlowitz, 1963). Also, both Lagrange (1963) and Newsome (1963) noted effective, long-term antischistosomal activity with dexamethasone and several steroid derivatives of the pregnane series on in vivo treatment. The basis for the stimulation of egg production by prednisolone in vitro is unknown, but it may not be due to a selective effect on the reproductive tract of the parasite. However, at the concentrations tested, prednisolone had no effects on the other physiological parameters examined after incubation. Therefore, the effect of prednisolone on egg production may be the result of a generalized stimulation of the anabolic processes of the parasite.

The inability of either androgenic or estrogenic steroids to alter in vitro fecundity in the present study is interesting considering the results of Bussolati et al. (1967) and Barrabes et al. (1979), who reported a significant reduction in worm burden following dosing of the host with androgenic or estrogenic compounds. The comparison between the in vitro and in vivo data with these hormones suggests that the results obtained in vivo may reflect host-mediated effects on metabolism or distribution of these compounds, rather than direct effects of the hormones on the parasites, since neither group of hormones had an adverse effect on physiological parameters of the parasites.

Finally, the effects of mevinolin on egg production by *S. mansoni* were of great interest. Mevinolin prevents the de novo synthesis of cholesterol by inhibiting hydroxymethylglutaryl-CoA reductase (Alberts et al., 1980), the enzyme which is an important control point in the regulation of cholesterol biosynthesis. Adult schistosomes are incapable of de novo cholesterol formation (Meyer et al., 1970; Smith et al., 1970), and, further, the inhibitory effect of mevinolin on fecundity was not reversed by coincubation with 10^{-4} M cholesterol (unpublished observation), suggesting that the inhibition of egg production caused by this agent is not due to a steroid-mediated effect. The ability of mevinolin to decrease egg production without altering either muscle tension or surface electrical activity of the parasite have warranted our further investigation into the mechanism of action of this agent.

As the data indicate, there are differences between earlier in vivo reports and this in vitro study on the effects of steroid hormones on *Schistosoma mansoni*. Host-mediated processes, such as metabolism and differential distribution of these hormones, could play a role in reducing the worm burden, as was seen in the in vivo studies. Unfortunately, the fecundity of the parasites retrieved after the in vivo studies of Bussolati et al. (1967), Barrabes et al. (1979), and others (Coker, 1957; Lewert and Mandlowitz, 1963) was not examined, making it difficult to compare these in vivo effects of hormones with the present results. However, in the absence of host-mediated processes, as in the in vitro system, the data suggest that the "classical" steroid hormones probably exert little or no effect on the modulation of egg production by *S. mansoni*.

SEX PHEROMONE OF FALL ARMYWORM, *Spodoptera frugiperda* (J.E. SMITH)[1]
Identification of Components Critical to Attraction in the Field

(Received July 30, 1985; accepted November 19, 1985)

Abstract—Analyses of extracts of pheromone glands and of volatiles from calling female fall armyworm moths, *Spodoptera frugiperda* (J.E. Smith), revealed the presence of the following compounds: dodecan-1-ol acetate, (Z)-7-dodecen-1-ol acetate, 11-dodecen-1-ol acetate, (Z)-9-tetradecenal, (Z)-9-tetradecen-1-ol acetate, (Z)-11-hexadecenal, and (Z)-11-hexadecen-1-ol acetate. The volatiles emitted by calling females differed from the gland extract in that the two aldehydes were absent. Field tests were conducted with sticky traps baited with rubber septa formulated to release blends with the same component ratios as those emitted by calling females. These tests demonstrated that both (Z)-7-dodecen-1-ol acetate and (Z)-9-tetradecen-1-ol acetate are required for optimum activity and that this blend is a significantly better lure than either virgin females or 25 mg of (Z)-9-dodecen-1-ol acetate in a polyethylene vial, the previously used standard. Addition of the other three acetates found in the volatiles did not significantly increase the effectiveness of the two-component blend as a bait for Pherocon 1C or International Pheromones moth traps.

Key Words—*Spodoptera frugiperda*, fall armyworm, Lepidoptera, Noctuidae, (Z)-7-dodecen-1-ol acetate, (Z)-9-tetradecen-1-ol acetate, pheromone, attractant, sex pheromone.

INTRODUCTION

The genus *Spodoptera* includes several insect species that cause substantial damage to agricultural crops throughout the world. Three species, *S. exigua* (Hübner), *S. frugiperda* (J.E. Smith), and *S. eridania* (Cramer), are serious pests of many crops in the United States. The fall armyworm (FAW), *S. frugiperda*, is an important pest of corn and other grass crops in the United States and occurs throughout the Caribbean basin, where it is known as the whorlworm, and attacks a variety of crops (Andrews, 1980).

Components of the FAW pheromone have been identified in previous investigations. Sekul and Sparks (1967) used a laboratory bioassay in which a mating response was evoked in FAW males to monitor the isolation and identification of a sex pheromone, (*Z*)-9-tetradecen-1-ol acetate (*Z*9–14 : Ac), from FAW females. Subsequent tests showed this compound to be an ineffective lure for FAW males in the field (Mitchell and Doolittle, 1976; Sparks, 1980). However, this compound did reduce mating by FAWs when it was evaporated into the atmosphere in disruption tests (Mitchell and McLaughlin, 1982). A second compound, (*Z*)-9-dodecen-1-ol acetate (*Z*9–12 : Ac), was isolated and identified from FAW females (Sekul and Sparks, 1976), and this compound either alone or with small quantities of *Z*9–14 : Ac added is a good practical lure for fall armyworm males when used in sticky traps (Mitchell, 1978; Jones and Sparks, 1979). However, fairly large quantities of *Z*9–12 : Ac are required for effectiveness (5–10 mg on a rubber septum), and the baits are effective in the field for only one to two weeks (Mitchell et al., 1983). Sparks (1980) reported that two additional compounds had been identified from washes of FAW female ovipositors, but he did not give their identity and he stated that they did not improve the effectiveness of *Z*9–12 : Ac as a lure.

Descoins and coworkers (personal communication) analyzed the FAW female-produced pheromone and found (*Z*)-11-hexadecen-1-ol acetate (*Z*11–16 : Ac), in addition to the two compounds already reported. However, in field tests conducted in Florida, we could not find a blend of these three compounds that was significantly better than *Z*9–12 : Ac alone in luring FAW males to sticky traps (Mitchell et al., 1983).

Although *Z*9–12 : Ac can be used as a lure for monitoring FAW males, it is obvious that our knowledge of the pheromone system of this insect is incomplete and that the complete pheromone is needed to achieve maximum effectiveness in pheromone monitoring and control programs. Therefore, we decided to reinvestigate the pheromone system of this species to determine the precise blend emitted by calling FAW females and the optimum blend for trapping FAW males in the field.

METHODS AND MATERIALS

Rearing. The majority of the fall armyworm females from which pheromone was obtained were reared in the laboratory on an artificial diet (Burton, 1969). Insects were sexed in the pupal stage and placed in 0.5-liter paper cartons that were then placed in 23 × 23-cm Plexiglas cages for eclosion. Male and female pupae were maintained in separate rooms under a reversed light cycle of 14 hr light and 10 hr dark (65% relative humidity, 26°C). Daily sequential transfers of uneclosed pupae were made to uninhabited cages so each holding cage contained adult insects of a single age and sex.

Additionally, fourth- to sixth-instar fall armyworm larvae were collected in the field from sorghum plants and reared to pupation in the laboratory on artificial diet. Subsequent sexing and handling of these insects were conducted the same as for the laboratory-reared insects.

Pheromone Extraction and Collection. Actively calling 2- to 3-day-old FAW females were used for all pheromone extractions and volatile collections. In the laboratory the calling activity of the female FAW peaked about 4 hr after the beginning of the dark period. Sex pheromone glands from both laboratory-reared and wild females were excised and extracted. Excision of the sex pheromone glands was performed during the dark period by gently squeezing the lateral–posterior abdominal section of the female, causing protrusion of the terminal abdominal segments, which were then clipped as a unit. The excised glands were then placed in 50 μl of isooctane (Fisher Scientific Co., 99 mol % pure) in a microvial. Typically, when 25 glands were accumulated in the solvent (about 15 min), the walls of the microvial were rinsed with an additional 20 μl of isooctane and the solvent was removed from the glands and transferred to a clean vial. The extract was then concentrated by careful evaporation with gentle warming to a final concentration of about five female equivalents (FE) per microliter. The number of glands excised during any collection period varied with availability of calling females within a particular batch. Gland extract was stored at −60°C in microvials with Teflon-lined screwcaps until analysis.

An apparatus similar to the ones described by Cross (1980) and Tumlinson et al. (1982) was used for all volatile collections. Zero-grade nitrogen (99.99% minimum purity, 0.5 ppm maximum hydrocarbons) or, when live females were aerated, "hydrocarbon-free" compressed air, was delivered through a stainless-steel regulator, a gas purifier (Alltech Associates), a methylene chloride-extracted charcoal (6–14 mesh, Fisher Scientific Co.) prefilter (9 cm × 2 cm OD), and then through a glass Y-tube to two aeration chambers simultaneously. Each aeration chamber was constructed from two glass tubes (7 cm × 2.8 cm OD) connected by a ball joint (35/25). A coarse-glass frit was sealed into the upwind

tube to provide a laminar flow of air (or N_2) over the aeration subject. The downwind tube was the aeration chamber, and its exit narrowed to a tube 0.6 cm in outside diameter to which was connected a small charcoal filter similar to the one described by Grob and Zürcher (1976). With this apparatus, volatiles can be collected from any desired subject in one chamber and simultaneously a "system blank" can be collected in the other chamber under identical conditions.

Four or five FAW females were selected during their peak calling activity and placed in an aeration chamber. An airflow of about 1.0 liter/min was maintained over the females for 1.5 hr. When the aeration was complete, the collected volatiles were eluted from the charcoal collection filters with three aliquots (20, 15, and 15 μl) of redistilled dichloromethane (HPLC grade, J.T. Baker), and the eluates from two aerations, representing 9–10 females, were combined.

The initial collections were concentrated by gentle warming to a volume of 2–5 μl. Then 5 μl of isooctane was added to rinse the walls of the microvial and the solution was concentrated to a final volume of 1–2 μl for analysis by capillary gas chromatography. After the initial analyses to establish the location of the peaks of interest on a particular stationary phase, 5 ng of an internal standard in 1 μl of isooctane was added to the CH_2Cl_2 filter eluate before concentration. Pentadecan-1-ol acetate (*S*-15 : Ac) and hexadecan-1-ol acetate (*S*-16 : Ac) were used as internal standards for analyses on OV-1 and cyanosilicone columns, respectively. The system blank filters were extracted and the extract concentrated and analyzed in an identical manner on the same column and on the same day as that of the companion filters containing female volatiles.

Chemical Analyses. Gas chromatographic (GC) analyses were conducted on a Varian model 3700 GC and a Hewlett-Packard model 5710A GC, both equipped with splitless capillary injector systems and flame ionization detectors. A Perkin Elmer chromatographic data system was used for data collection, storage, and subsequent analysis. Either nitrogen (linear flow velocity 9.8 cm/sec) or helium (linear flow velocity 19 cm/sec) was used as a carrier gas. Columns used for initial analyses of gland extracts and volatiles and conditions for each column were: 42-m × 0.25-mm ID glass capillary column coated with SP-2340, operated at 80°C for 2 min, then temperature programmed (TP) at 30°/min to 170°; 60-m × 0.25-mm ID fused silica column coated with 0.20 μm film of SP-2330, initial temp 80°C for 1 min, TP at 30°C/min to 170°C; 29-m × 0.25-mm ID glass column coated with 0.4% OV-1 over 1% Superox, initial temp 80° for 2 min, TP at 32°C/min to 180°C.

Although the three columns initially used for these analyses were adequate for separation of most lepidopteran pheromones, they did not provide the separation and resolution required to unequivocally assign the double bond posi-

tions in the 12-carbon acetates present in volatiles collected from FAW females. Therefore, three columns with superior resolution and with three different, but complementary, separation mechanisms were selected for analysis of the volatiles. They were: 50-m × 0.25-mm ID fused silica CPS-1 (cyanopropyl methyl silicone, Quadrex Corp., New Haven, Connecticut), initial temperature 80°C for 1 min, TP at 10°C/min to 165°C; 50-m × 0.25-mm ID fused silica OV-101, initial temperature 80°C for 1 min, TP at 10°C/min to 180°C; 13.6-m × 0.25-mm ID glass cholesteryl *p*-chlorocinnamate (liquid crystal) (Heath et al., 1979; Heath and Doolittle, 1983) column coupled to 0.46-m × 0.33-m ID fused silica BP-1 (SGE) precolumn, initial temperature 60°C for 1 min, TP at 30°C/min to 150°C. All injections were made in the splitless mode.

Samples also were analyzed by GC–mass spectrometry (MS) with either a Finnigan model 3200 chemical ionization mass spectrometer or a Nermag model R1010 mass spectrometer in the chemical ionization mode. The SP-2340 and OV-101 capillary columns used in previous analyses were used in the GC-MS analyses with He carrier gas. Methane and isobutane were used as the reagent gases in the mass spectrometers. Spectra of the natural products were compared with those of candidate synthetic compounds.

All synthetic standards used in this study were obtained from commercial sources and were purified by high-performance liquid chromatography on a 25 × 2.5-cm (OD) $AgNO_3$-coated silica column eluted with toluene (Heath et al., 1977). These compounds were analyzed on both polar and nonpolar capillary GC columns described previously and determined to be greater than 99% pure.

Formulation. Synthetic blends and individual synthetic compounds were formulated on 5 × 9-mm rubber septa (A.H. Thomas Co.) for all biological tests. Septa were Soxhlet extracted with CH_2Cl_2 for 24 hr and air dried prior to loading. Desired release ratios of the components of blends were obtained by loading the septa with mixtures containing calculated percentages by weight of each component of the blend. The percentage of a component in the loading mixture was calculated on the basis of its relative volatility determined from retention indices on liquid crystal capillary GC columns (Heath and Tumlinson, 1986) and a method developed to predict release ratios of components of a blend from rubber septa (Heath et al., 1986). Each septum was loaded with 200 μl of a hexane solution of the blend pipetted into the well on the large end of the septum. Septa were aired for two days at room temperature before use and were then used for a maximum of 14 days in the field.

In field tests conducted in 1982, the quantity of Z9–14:Ac, the major component, in all blends was 2 mg/septum. In these initial tests, which compared the effectiveness of four-, five-, and six-component blends with live females and Z9–12:Ac in a polyethylene vial, the relative amount of each component was adjusted to keep the release ratio of the blend components as constant

as possible for all blends. In the 1983 and 1984 field tests, each septum was loaded with 2 mg of the total blend dissolved in 200 μl of hexane, and after airing for two days at room temperature, was used for 4–11 days.

To verify that ratios released from the septa were the same as those calculated for a blend, septa loaded with the various blends and aired for two days were aerated in the same apparatus used to collect volatiles from glands and live females, and the volatiles collected on charcoal were eluted and analyzed by capillary GC on SP-2330. Two septa were placed in the aeration chamber of the apparatus, and zero-grade nitrogen was blown over them at flow rates of 100, 200, 400, 600, and 800 cc/min for 1.5 hr. An internal standard, *S*-16:Ac, was added to the eluate from the charcoal filter for quantitative analysis.

Field Tests. Trapping experiments were conducted in Alachua County, Florida, in late summer 1982. The rubber septa containing the test blends were placed in Pherocon 1C sticky traps supported ca. 1 m above the ground on metal poles. Treatments were arranged in three randomized complete blocks in and around corn fields. The traps were set ca. 30 m apart in lines perpendicular to the prevailing wind and were checked every one to two days for captured FAW moths. Trap liners were replaced when more than five moths were captured or on every second visit. Whenever a trap had five or fewer moths, the insects were removed carefully to leave the sticky trapping surface intact; traps were rerandomized after every collection; thus, each collection was considered a separate replicate. For statistical analysis, the data were transformed to $\sqrt{X + 0.5}$ and subjected to analysis of variance (Steel and Torrie, 1960). Mean separations were achieved by Duncan's (1955) multiple-range test.

In 1983, field-trapping experiments were conducted in late September with blends and ratios found in volatiles collected from calling females. The experimental design and data analysis were as described for the 1982 experiment.

In 1984, the field trapping studies were conducted in August and September using International Pheromones moth traps (IPM traps) positioned ca. 1 m above the ground in and around sorghum fields. The IPM traps capture moths using a funnel–bucket system. Moths entering the bucket receptacle through the funnel were killed with a volatile insecticide, Vapona. The switch to the IPM trap was based upon preliminary experiments which indicated that the IPM trap was more effective in capturing large numbers of FAW moths than the Pherocon 1C sticky traps used in 1982 and 1983. The experimental design was as described for the 1982 and 1983 field tests. Due to the large numbers and extreme variations in total numbers of moths captured in different blocks on the same or different dates in the 1984 field tests, the data were converted to percentages using the formula:

$$\frac{\text{Number of moths caught in treatment}}{\text{Total number of moths caught in block}} \times 100$$

The data then were converted to arcsin $\sqrt{X}$ and subjected to analysis of variance (Steel and Torrie, 1960). Means were separated using Duncan's (1955) multiple-range test.

RESULTS AND DISCUSSION

Gland Extracts. Initially the pheromone glands from calling FAW females were excised and extracted to determine what compounds were present, although we realized from previous experience and from literature reports (Cross et al., 1976; Hill et al., 1975) that the components and ratios present in the gland may differ from those released by calling females. Analysis of extracts of pheromone glands excised from laboratory-reared and wild, calling female FAW, by capillary GC on SP-2330 and SP-2340, indicated that there were five peaks consistently present above the background peaks of impurities in the solvent. Four of these peaks coincided in retention times with the following authentic standards: Z7–12 : Ac, Z9–14 : Al, Z9–14 : Ac, and Z11–16 : Ac. The other peak was very close in retention time to that of Z9–12 : Ac. Furthermore, a peak coincidental in retention time with Z11–16 : Al on SP-2330 also appeared, but it was not present consistently in quantities large enough to distinguish it from background impurities. Analysis on OV-1 confirmed the presence of Z9–14 : Ac, the major peak, and Z11–16 : Ac. Additionally, peaks coincidental in retention time with Z7–12 : Ac and Z9–14 : Al were present, but since Z9–12 : Ac coeluted with Z9–14 : Al on this column, confirmation of the presence of the latter two was not possible.

Methane ionization mass spectral analysis of gland extracts from laboratory-reared FAW females confirmed that the major peak, coincidental in retention time with Z9–14 : Ac on SP-2340, SP-2330, and OV-1 capillary columns, was a monounsaturated 14-carbon acetate with diagnostic ions at *m/e* 255 (M + 1), 195 (M + 1 − 60), 89, and 61. Also, the presence of peaks consistent in retention time and mass spectral diagnostic ions with Z7–12 : Ac, Z9–14 : Al, and Z11–16 : Ac was confirmed. Furthermore, small peaks, eluting just prior to and just after Z7–12 : Ac on the SP-2340 column, had mass spectra consistent with dodecan-1-ol acetate (*S*-12 : Ac) and a monounsaturated 12 : Ac, respectively.

Thus the presence of Z7–12 : Ac, Z9–14 : Al, Z9–14 : Ac, and Z11–16 : Ac in pheromone glands of calling FAW females was firmly established by GC-MS and by retention times on OV-1, SP-2340, and SP-2330 capillary GC columns; the cyanosilicone GC phases have previously been demonstrated to separate both geometrical and positional isomers of most olefinic aliphatic primary acetates (Heath et al., 1980; Tumlinson et al., 1982). Additionally, *S*-12 : Ac, Z9–12 : Ac, and Z11–16 : Al appeared to be present in small quantities, but this could not be confirmed.

Gland extracts were prepared from five batches of laboratory-reared FAW females and from two batches of wild FAW females from each of two locations in Alachua County, Florida. There was considerable variability in gland contents, in both ratios and total quantities between laboratory-reared and wild females and also among batches of wild females collected from different locations. The relative amounts of Z9–14 : Al, Z11–16 : Al, and Z11–16 : Ac in particular varied more than those of the other components. Thus, "the most representative ratio" of components found in the glands was 4 : 2 : 13 : 69 : 3 : 9 for Z7–12 : Ac, Z9–12 : Ac (subsequently identified as 11–12 : Ac), Z9–14 : Al, Z9–14 : Ac, Z11–16 : Al, and Z11–16 : Ac, respectively, but the relative amounts of the two aldehydes and Z11–16 : Ac varied from these values by as much as 100%. However, as noted earlier, the actual pheromone blend emitted by the female often differs significantly, both in compounds present and in ratio, from the contents of the gland. Therefore, we proceeded to collect volatiles to more accurately assess the composition of the FAW pheromone.

Volatile Collections. Analysis on the SP-2330 capillary column of the volatiles collected from laboratory-reared, calling FAW females indicated the presence of five peaks not present in the system blank analyzed under identical conditions (Figure 1). Four of these peaks coincided in retention times on this column with peaks representing *S*-12 : Ac, Z7–12 : Ac, Z9–14 : Ac, and Z11–16 : Ac. Again, the third peak in the chromotogram (Figure 1) had a retention

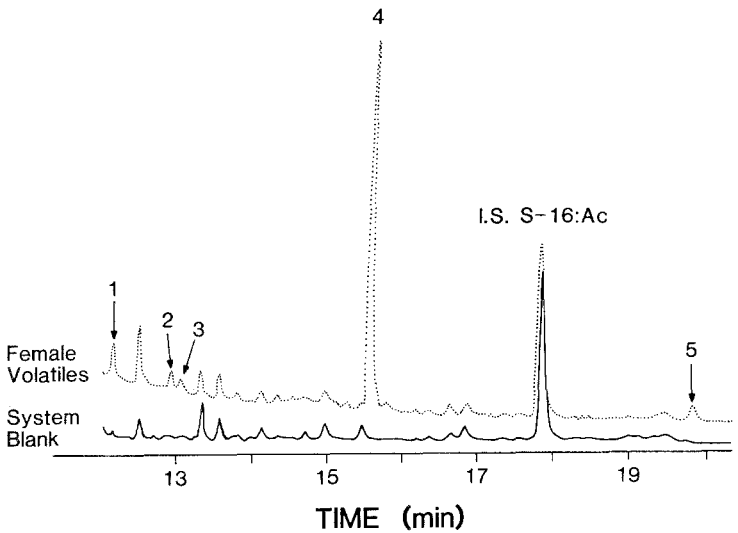

FIG. 1. Analysis of volatiles collected from calling, laboratory-reared fall armyworm female moths on a 60-m fused silica SP-2330 capillary gas chromatographic column. Peaks not present in the blank correspond in retention time to: (1) *S*-12 : Ac, (2) Z7–12 : Ac, (3) 11–12 : Ac, (4) Z9–14 : Ac, and (5) Z11–16 : Ac.

time very close to, but not identical with that of Z9–12 : Ac. The ratio (mean of three replicates, ca. 10 females per replicate) of these compounds present in the volatiles was 4.9 : 3.1 : 1.7 : 86.9 : 3.5, respectively.

Although Z9–12 : Ac was previously reported to be a component of the FAW pheromone, its presence in the volatiles released by calling females could not be confirmed. Additionally, the quantity of *S*-12 : Ac in the volatiles could not be accurately determined because of interference of an impurity in the system. Therefore, an analytical procedure was devised, employing three high-resolution capillary GC columns and mass spectrometry, that was capable of resolving all possible 12-carbon acetate candidate compounds and confirming their identities. The CPS-1 (cyanosilicone) column separated the *S*-12 : Ac from the interfering impurity and resolved the other isomers, although 11–12 : Ac was not completely resolved from Z9–12 : Ac (Figure 2A). However, the OV-101 column completely resolved 11–12 : Ac from Z9–12 : Ac, although *S*-12 : Ac was now incompletely resolved from Z9–12 : Ac (Figure 2B). The liquid crystal column resolved all candidate compounds except 11–12 : Ac and *S*-12 : Ac (Figure 2C).

Volatiles were collected from 44 batches of laboratory-reared, calling FAW females (five females per batch) and pooled for analysis. Aliquots of this sample were analyzed on all three high-resolution capillary columns and by GC-MS. As indicated in Figure 2, the volatile components not present in the system blank were coincidental on all three columns with *S*-12 : Ac, Z7–12 : Ac, and 11–12 : Ac. Z9–12 : Ac did not coincide in retention time with any of the candidate pheromone peaks on any of the these columns. Methane/isobutane ionization mass spectra of the volatile peaks were consistent with these identities. Z9–14 : Ac and Z11–16 : Ac also were present in these volatiles and confirmed by all the data. The ratio of the components in the volatiles was 1.9 : 3.2 : 2.2 : 90.1 : 2.6 for *S*-12 : Ac, Z7–12 : Ac, 11–12 : Ac, Z9–14 : Ac, and Z11–16 : Ac, respectively. The quantity of Z9–14 : Ac collected per hour per female was about 2 ng.

Formulation. Volatiles released from rubber septa formulated for field tests were collected and analyzed by capillary GC to verify that actual release ratios were approximately the same as the calculated release ratios. Examples of release ratios measured in this way for the five-component blend and a four-component blend are given in Table 1. Release rates, but not blend ratios, from the septa varied with the flow rate through the aeration chamber. For example, the mean release rates of Z9–14 : Ac from a septum loaded with 200 μg of the five-component blend at flows of 100, 200, and 400 cc/min were 1.7, 2.5, and 4.3 ng/hr/septum, respectively. Because release rates from septa vary with the velocity of airflow over the septa, as well as temperature, it is very difficult to control release rates in the field. Therefore, it is more practical to compare captures of septa loaded with different doses of pheromone (see later) whose relative release rates can be measured accurately.

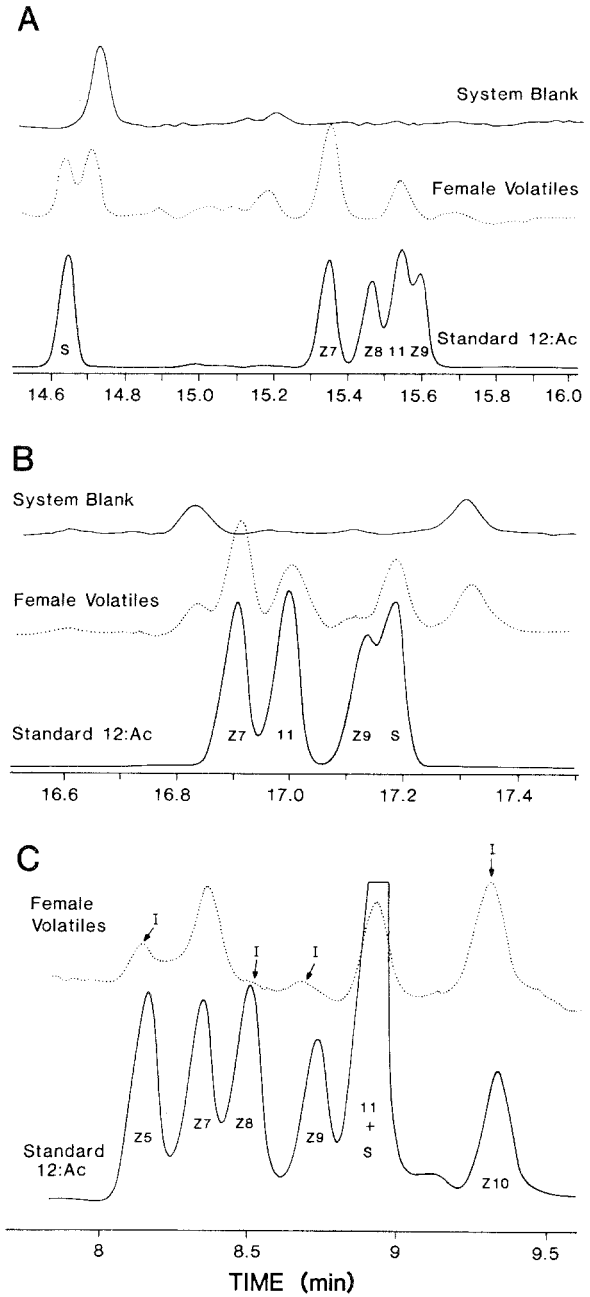

FIG. 2. Sections of chromatograms showing separation of 12-carbon acetates and analysis of volatiles collected from calling, laboratory-reared fall armyworm female moths on three-capillary GC columns (A) CPS-1; (B) OV-101; (C) cholesteryl-*p*-chlorocinnamate (liquid crystal). In (C), the symbol I indicates impurities found in the system blank.

[a] Mean of three replications. Each septum loaded with 2 mg of the total blend.

Field Tests. The field tests conducted in 1982 were designed to evaluate blends of the compounds identified in pheromone gland extracts. All experiments included 25 mg of Z9–12:Ac dispensed from a polyethylene vial, the previously used standard (Mitchell, 1978), and three virgin females for comparison. In the first experiment in which four different ratios of components in the six-component blend (Z7–12:Ac, Z9–12:Ac, Z9–14:Al, Z9–14:Ac, Z11–16:Al, Z11–16:Ac) and two different ratios in a four-component blend (Z9–14:Al, Z9–14:Ac, Z11–16:Al, Z11–16:Ac) were tested (40 replicates/treatment), the ratios of components in these blends were selected to represent ratios found in gland extracts from laboratory-reared and different batches of wild FAW females. All the six-component blends tested were equivalent in luring FAW males to traps (means of 21.5–23.2 males/trap per night), and they were not significantly different from the standard 25 mg of Z9–12:Ac in a polyethylene vial (mean of 26.5). However, it is very unlikely that the attractancy of these blends was due solely to the presence of Z9–12:Ac because the qauntity of Z9–12:Ac loaded on a septum was only 68 μg at the most. Traps baited with both four-component blends tested captured significantly fewer males (mean of 7.4) than either the standard Z9–12:Ac or females (mean of 13.8) (5% level, Duncan's multiple range test). Thus either Z7–12:Ac or Z9–12:Ac or both appeared to be necessary for optimum activity.

In a subsequent experiment, we compared a six-component blend with five-component blends, each of which was missing a different component. The results (Table 2) clearly establish that Z7–12:Ac is necessary for activity and suggested that none of the other components except Z9–14:Ac are required. A separate experiment established that deletion of Z9–14:Ac from the blends resulted in trap captures not significantly different from a hexane blank. It also was interesting to note that deletion of Z9–14:Al increased the trap capture above that of all other blends and of the standard Z9–12:Ac. This suggests that

[a] Numbers under each compound in each row indicate the approximate percentage of that component released in the blend. Numbers in parentheses indicate the percent of each compound loaded to obtain the desired release ratio. The quantity of Z9–14 : Ac loaded onto the septum was 2 mg for all blends.

[b] Forty replicates/treatment; means not followed by the same letters differ significantly at the 1% level, Duncan's multiple-range test.

[c] In a polyethylene vial.

Z9–14 : Al may be an inhibitor and that, although it is present in the pheromone gland, it may not be a pheromone component.

Since the volatiles collected from calling females contained only five acetates and did not contain either of the aldehydes, we designed our 1983 field experiments to evaluate specific blends of the acetates (Table 3). Our primary objective was to determine whether all five compounds were required for optimum trap captures and whether any of the components were critical for biological activity. At this point Z9–12 : Ac was included as a blend component, although we had not yet confirmed whether or not it was released by females.

Blends of two, three, four, and five components were all equally attractive in our 1983 field trapping experiments (Table 3). As demonstrated in our 1982 field tests, both Z7–12 : Ac and Z9–14 : Ac were required for maximum activity. However, in the 1983 tests with blends formulated to release the same ratio emitted by calling females, all the blends were significantly more active than 25 mg of Z9–12 : Ac dispensed from a polyethylene vial. In fact Z9–12 : Ac, formulated in the same manner and quantity as the blends, was not different significantly from the blank.

[a] Numbers under each compound in each row indicate the approximate percentage of the component released in the blend. Numbers in parentheses indicate the percent of each compound loaded to obtain the desired release ratio. Each septum was loaded with 2 mg of the total blend dissolved in 200 μl of hexane.

[b] For analysis of variance, percentages were transformed to arcsin $\sqrt{X}$ and mean separations were achieved using Duncan's (1955) multiple-range test. Treatments were replicated 21 (7 randomizations) and 15 (5 randomizations) times in tests 1 and 2, respectively. Means (reconverted to percentages) followed by different letters differ significantly at the 1% level. Totals of 10,077 and 28,114 moths were captured in tests 1 and 2, respectively.

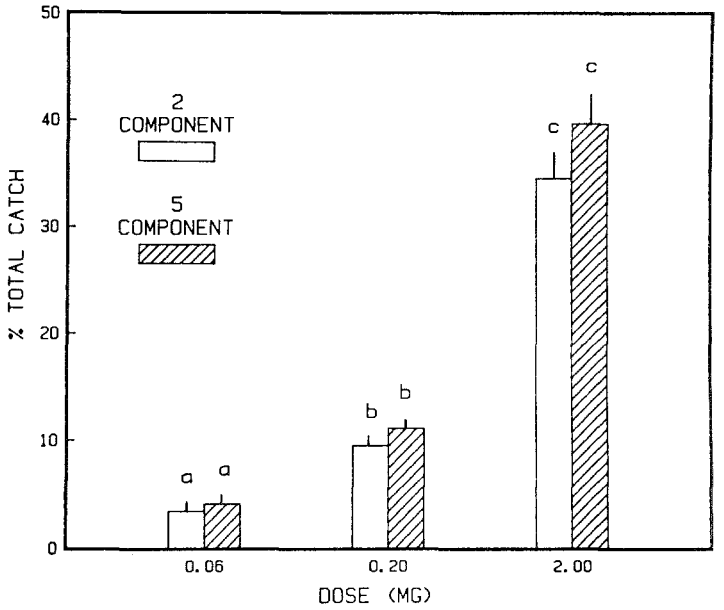

FIG. 3. Capture of male FAW moths in IPM traps baited with different dosages of two blends of synthetic sex pheromone on rubber septa, September 10–17, 1984 (14 replicates per treatment; treatments randomized four times per test period). Two-component blend and approximate release ratios: Z7–12:Ac, 3.4% and Z9–14:Ac, 96.6%. Five-component blend and approximate release ratios: *S*–12:Ac, 1.9%, Z7–12:Ac, 3.2%, 11–12:Ac, 2.2%, Z9–14:Ac, 90.1%, and Z11–16:Ac, 2.6%. Percentages were converted to arcsin $\sqrt{X}$ for statistical analysis. A total of 4668 FAW males were captured. Bars (reconverted to percentages) with different letters differ significantly at the 1% level, Duncan's (1955) multiple-range test. Narrow lines above bars represent SE of the mean.

Our 1984 field trapping tests were designed to evaluate blends containing the compounds and ratios found in our latter analyses and to compare these blends with some of the previously tested blends containing Z9–12:Ac rather than 11–12:Ac. The blends tested and the results are given in Table 4. The numbers of moths captured per trap per night were much greater than in 1983. However, as the data in Table 4 illustrate, it is still difficult to determine which blend, if any, is optimum as a trap bait. There are indications that some blends are better, although they cannot be validated statistically. For example, the five-component blend containing 11–12:Ac, which is identical to the volatile blend collected from calling females, is consistently near the top in percentage of males captured. Also, the two-component blend is always in the middle to low range in percent captured although, statistically, it is always equal to the best blend.

Thus a field trapping test was conducted in 1984 to compare the effectiveness of the two-component and five-component blends. IPM traps, each baited with a rubber septum containing 0.06, 0.2, or 2 mg of either the two-component or the five-component blend, were deployed in randomized complete blocks as previously described (14 replicates). Additionally, volatiles were collected from septa loaded with each of these blends at the doses indicated and analyzed by capillary GC to determine the release rates of the blends. The septa were aerated at flow rates of 1 and 2 liters/m. At any given dose and flow rate, the release rate of the two-component blend from a septum was the same as that of the five-component blend within experimental error. Additionally, the results of the field trapping experiment (Figure 3) indicate that both blends are equivalent as trap baits at each of the three doses tested.

CONCLUSIONS

These data support the conclusion that the sex pheromone of the FAW consists of at least two components, Z7–12 : Ac and Z9–14 : Ac. Three other components also may have a role in the pheromonal communication system of this species, but behavioral studies will be required to define this pheromone system more accurately and precisely.

The reason for the capture of male FAW in traps baited with Z9–12 : Ac is not known. Although we could not detect this compound in gland extracts or volatiles from FAW females, Jones and Sparks (1979) found that traps baited with 500 μg of Z9–12 : Ac on a dental wick captured twice as many FAW males as did FAW females. However, we found that traps baited with 2 mg of Z9–12 : Ac on a rubber septum captured no more FAW males than traps baited with a hexane blank and that much higher doses of Z9–12 : Ac are required for attraction equal to 2 mg of the blends containing both Z7–12 : Ac and Z9–14 : Ac. It is likely that cotton wicks release these compounds at a much higher rate than rubber septa (although we have no data to substantiate this), and that Z9–12 : Ac is active only at concentrations much higher than that of the pheromone produced by a calling female. Thus, we now have identified a pheromone blend that is a more powerful attractant in the field than anything available previously. It is already proving useful in monitoring programs and for studying migration by the fall armyworm (Mitchell et al., 1985).

Acknowledgments—We thank R. Hines and W. Copeland for their assistance in conducting field tests, and V. Bauder for assistance in formulating synthetic pheromone blends for field tests.

(Received December 21, 1984; accepted November 21, 1985)

Abstract—The hypothesis of chemical mimesis in the relationship between *Ophrys* orchids and their pollinators was tested experimentally using preparations of *Ophrys lutea* var. *lutea* odor and the males of the solitary bee *Andrena fuscipes*, a species constellation that does not coexist under natural conditions. Correspondence in odor production was shown to occur. Identification of the compounds in the cephalic secretion of *A. fuscipes*, males and females, and the flower labella extracts, was performed by gas chromatography and mass spectrometry. Geraniol, nerol, citral, *E,E*-farnesol and 6-methyl-5-hepten-2-one were present in the extracts of both the orchid and one or both sexes of the bee. Extracts, TLC fractions of extracts, blends, and separate compounds were tested in the field in the mating flight areas of *A. fuscipes* males. Extracts and blends containing *E,E*-farnesol, geraniol, and geranial showed the highest attractivity to the male bees. These compounds seem to be responsible for the release of the odor-guided mating behavior at the *O. lutea* labellum and can be regarded as general attractants for many species of *Andrena*.

Key Words—Orchidaceae, Andrenidae, Apoidea, Hymenoptera, geraniol, farnesol, chemical mimetism, odor attraction, gas chromatography, mass spectrometry, semiochemical.

INTRODUCTION

Ophrys lutea var. *lutea* Cav. belongs to a group of *Ophrys* L. species that are pollinated by *Andrena* F. male bees (Kullenberg, 1961, 1973a,b). The polli-

0098-0331/86/0900-1927$05.00

nation is a result of the male "pseudocopulatory" behavior on the flower labellum and his subsequent visits to conspecific flowers. The bees are attracted by chemical, visual, and tactile cues. The odor of *Ophrys lutea* attracts members of many, if not all, *Andrena* species and seems not to have a specialized pollinator relationship with one or a few species. Male and female andrenid bees are attracted to one another by their mandibular gland secretion (Tengö, 1979). The composition of this secretion is complex and closely similar between the sexes (Tengö and Bergström, 1976, 1977). For the *Andrena* species that have been tested for their response to *O. lutea* odor, (Kullenberg, 1961; Tengö, 1979), a difference in the intensity of responses between the species has been noted. Also bees of species that are too small to be able to pollinate the *Ophrys* flowers are attracted by the odor (Kullenberg, 1961). It has, therefore, been postulated that *O. lutea* produces a set of substances with properties that attracts a wide array of *Andrena* species. We tested this hypothesis with *Andrena fuscipes* K., a species not coexisting with *O. lutea* under natural conditions, as they are separated both phenologically and geographically. Another purpose of the present study was to identify the substance, or substances, that cause the attraction of a whole set of *Andrena* species to *O. lutea*. These key compounds have so far remained unknown.

METHODS AND MATERIALS

Chemical Analyses. Heads of *Andrena fuscipes* males were extracted in pentane (P) for 24 hr. Three different extracts of *Ophrys lutea* var. *lutea* (Nelson, 1962) flower labella (Montbazin, Hérault, Southern France), were prepared: M, methanol extract of 62 labella/ml solvent (pa. Merck); H, hexane extract of 5 labella/ml solvent (redistilled pa. grade, Merck); MWP, a methanol extract of 800 labella was used for preparation of the TLC (thin-layer chromatography) fractions. The extracts were diluted five times with water. Sodium chloride was added until saturation. The methanol–water–sodium chloride mixture was extracted with pentane (4× 20 ml) and the pentane phase MWP) was carefully concentrated by evaporation at 42°C.

High-performance TLC-plates (Merck, HPTLC plates) were used for the separation. The HPLC plates were rinsed in methanol before use, and 40% diethyl ether in hexane was used as eluent. R_f values were measured between the concentration zone and the solvent front. Seven fractions (1–7) were obtained with the help of a colored standard mixture. The R_f values obtained for the fractions were; 1 = 0.77–1.00; 2 = 0.54–0.77; 3 = 0.42–0.54; 4 = 0.35–0.42; 5 = 0.18–0.35; 6 = 0.09–0.18; 7 = 0.00–0.09. The various fractions were extracted from the TLC plates with methanol (3× 1.5 ml) and treated as described above under MWP, to obtain the odoriferous compounds in a nonpolar volatile solvent.

The concentration of the *O. lutea* extracts was determined in terms of labellum equivalents (LE), which is the number of labella extracted/ml solvent. The calculated concentrations of labella or authentic compounds presented at each test period are listed in Table 1. The identifications were made on an LKB 2091 mass spectrometer (MS) in combination with a PYE gas chromatograph (GC) and/or a Finnigan 4021 GC-MS instrument. A WG11 (FFAP-type) 50-m glass capillary column (ID 0.25 mm) was used for the separation. A typical temperature programming was 50°C in 4 min, followed by 4°C/min to 200°C. Mass spectral data and retention values were compared with authentic compounds, and in a few cases coinjection was performed. Voucher specimens together with gas chromatograms and mass spectra, are deposited at the Ecological Research Station on Öland.

Behavior Tests. The tests took place in the field during the period July 31–August 26, 1980, on Öland, an island in the Baltic sea close to the mainland of southern Sweden. The *A. fuscipes* male mating flight area used was situated at the sandy border to a small *Pinus silvestris* L. forest with heather, *Calluna vulgaris* (L.) Hull, occurring in abundance.

The tested extracts, TLC fractions, blends, and individual compounds (Table 1) were applied to a 5 × 10-mm piece of black velvet (the dummy) that was put out in the mating flight routes patrolled by the *A. fuscipes* males. The dummy was placed either on a food plant bush (heather) or at a branch of a pine. The heights of flight routes above the ground depended on the temperature and varied from 0.1 to 5 m. On days when the temperature was between 20 and 25°C at 1.5 m, the males flew at heights of 3–4 m.

The choice of the test samples was based on the results of the chemical analyses of the mandibular gland secretion of *A. fuscipes* bees (Table 3) and the *O. lutea* flower labella (Table 2). In all, 25 different samples (extracts, TLC fractions of extracts, blends, and single compounds) were tested (Table 1). The proportions of the authentic compounds in the blends were based on the GC-MS chromatograms.

The tests estimated relative attraction and behavior-releasing qualities of the samples for bees passing within 0.1 m of the source. Approach flights were classed into one of four types ranked by increasing attraction and following Kullenberg (1973b), modified by Tengö (1979). Each test lasted for 5 min. The test samples were not presented to the males in a randomized manner but were repeatedly tested during the whole flight period of the males. All approaches towards the scented dummy were counted and classified into behavior types p, 1, 2, and 4 (Figure 1). Assuming homogenity for each test sample {e.g., for each test occasion of a certain test sample, the theoretical frequency [(2 + 4)/all events] should be the same}, the chi-square test for contingency tables was considered to be appropriate for our test data. In addition, Kruskal-Wallis (KW) and Wilcoxon (W) tests were used when comparing pairwise and groups of samples. When using the chi-square test, the frequency of the total number of

[a] For each test 0.1 ml of the solution was used. The percentage of individual compounds in the blends are given in brackets.

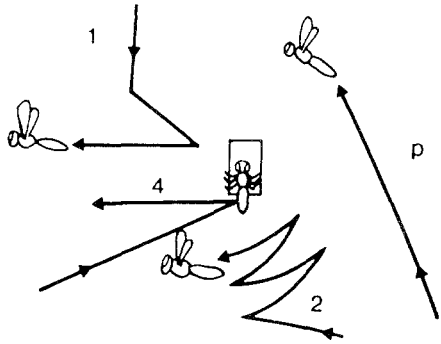

FIG. 1. The four different types of approaching behavior towards the dummy used in the field tests: (1) quick inspection; (2) hovering inspection (short-lasting attraction < 1 sec and long-lasting attraction > 1 sec); (4) Alighting or quick visit with or without an attempted copulation; (p) uninfluenced passage of the dummy.

high attractive behavior (2 + 4) in relation to the total number of low attractive (1 + p) behaviors for each test sample was calculated. When the Kruskal-Wallis or Wilcoxon tests were used, the frequencies [(2 + 4)/all events] for each test occasion were calculated and ranked (Sokal and Rohlf, 1981).

RESULTS

Chemical Analyses. The methanol extracts of *Ophrys lutea* flower labella consisted of a large number of components. It was possible to distinguish about 150 components at a concentration of 5 labellum equivalents (LE). Major compounds were aliphatic alcohols and terpenols with 1-octanol (60% of the total amount), geraniol (5%), 1-nonanol (5%), and 1-decanol (5%) as the most prominent ones. A minor amount of the sesquiterpene alcohol *E,E*-farnesol was also present (2%).

Seven fractions from the preparative TLC of the *O. lutea* MWP extract were analyzed by GC-MS. The results are given in Table 2.

The composition of volatile compounds in pentane extracts of female and male *A. fuscipes* heads is shown in Table 3. *E,E*-Farnesol, large amounts of citral, as well as geranic and nerolic acids, are found in both female and male head extracts.

Behavior Experiments. The test samples 1–25 are ordered in increasing degree of attractivity to the *Andrena fuscipes* males (Figure 2). The numbers in each column are percentage values of the behavior types p, 1, 2, or 4 in relation to all events (N) for a certain sample. Long-lasting behaviors (>1 sec) are calculated in percentage of the behavior type 2. Copulatory attempts to the dummy as well as long-lasting events (>1 sec) are considered to be the most

[a] Main compound = XXX, compound in major amounts = XXX, compound in medium amounts = XX and compounds in minor amounts = X. A = compounds identified also in the mandibular gland secretion of *A. fuscipes*. The R_f values obtained for fractions 1–7 were: 1 = 0.77–1.00; 2 = 0.54–0.77; 3 = 0.42–0.54; 4 = 0.35–0.42; 5 = 0.18–0.35; 6 = 0.09–0.18; 7 = 0.00–0.09.

powerful expression of male behavior and are elicited only by highly excited males.

Extracts. The pentane extract of *A. fuscipes* males heads (No. 24 in Figure 2) was extremely attractive to patrolling conspecific males. Less than one fifth of one head was enough to attract 95% of the males patrolling within a meter of the odor source. The male extract (24), which contained *E,E*-farnesol was comparable in attractivity to the *O. lutea* blend in combination with *E,E*-farnesol (25), the mixture of citral + *E,E*-farnesol (22), and the *E,E*-farnesol (19) itself. The authentic samples of geraniol + nerol (13) and citral + 6-methyl-5-hepten-2-one (6) were less attractive than the male extract ($P < 0.01$), which contained all these compounds.

The three *O. lutea* extracts, M (21), MWP (20), and H (15), showed high levels of attractivity despite large differences in the composition of major compounds (Borg-Karlson et al., 1985). The attraction capacity of M and MWP is as much stronger than 1-octanol 5, $P < 0.01$) and *O. lutea* blend (10, $P < 0.01$), although 1-octanol is the main compound in these extracts (65% of the total amount in the volatile part of the M extract). Because of the scarcity of female bees during the test period, no female extract was tested.

[a]X = small amounts, XX = medium amounts, XXX = major amounts.

Ophrys lutea TLC Fractions. A comparison between all fractions showed that numbers 4 (23) and 5 (18) had the largest attracting capacity. They differed, however, in their chemical composition (Table 2). In fraction 4, 1-octanol, citral, geraniol, and nerol constituted only a few percent, while fraction 5 contained 1-octanol and geraniol in large amounts and, in addition, *E,E*-farnesol. A blend containing these latter compounds has a characteristic smell that closely resembles the fragrance of *O. lutea*.

Fractions 4 (23) differed in attraction capacity from fractions 1 (2), 2(12), and 6 (8, $P < 0.01$). Fraction 6 had only a weak attracting capacity, but the frequency of long-lasting behaviors was high (25% of the approach being of high excitation status). It is probable that only the males in a certain, highly motivated state, reacted.

TLC fractions 1 and 2 showed only weak attracting capacity. Only these fractions contained the sesquiterpenes cyclosativene and γ-cadinene.

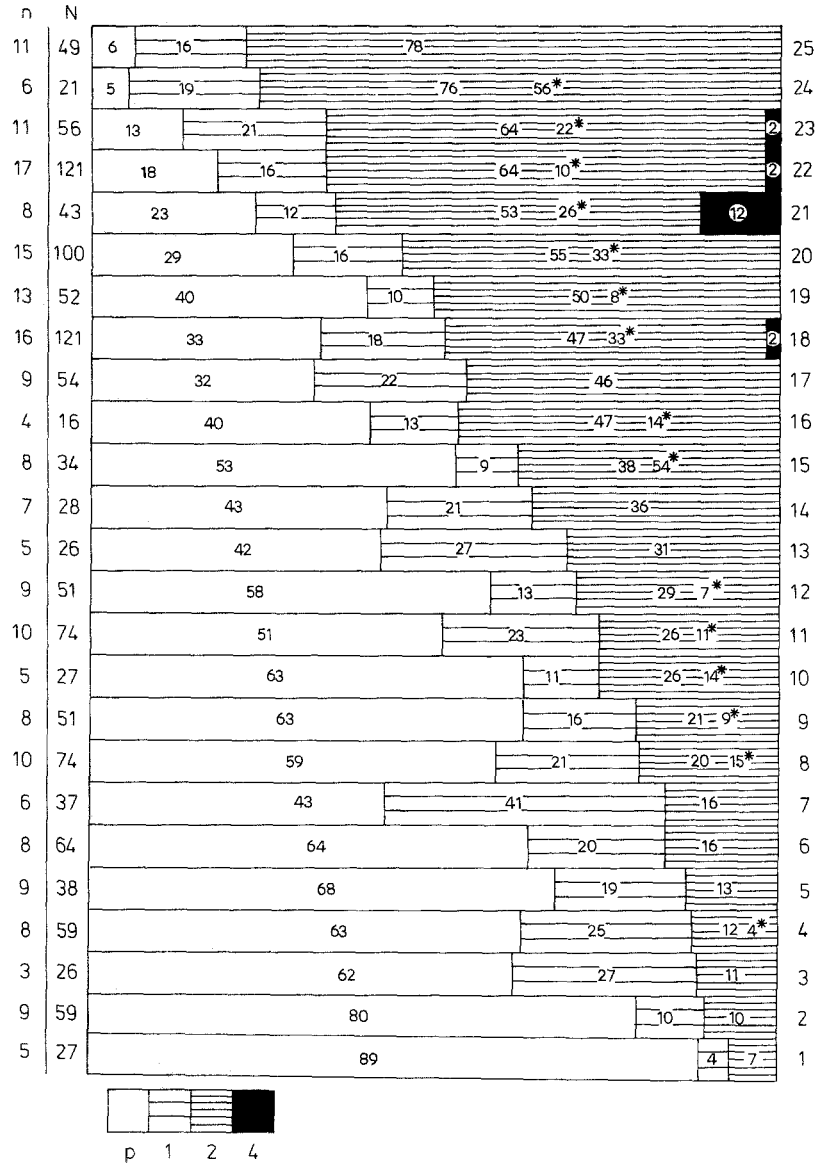

FIG. 2. The figure demonstrates the various types of attraction released by the 25 samples tested. The samples are listed in increasing order of attractivity. The numbers in each column are the percentage values of the behavior type p, 1, 2, or 4 in relation to all events (N) for a certain sample. Long-lasting behavior (>1 sec) is calculated in percentage of behavior type 2 (Figure 1). Sample No.: 1, *O. lutea* fr. 7; 2, *O. lutea* fr. 2; 3, geranic/nerolic acid; 4, *Z,Z*-farnesol; 5, 1-octanol; 6, geranial/neral + 6-methyl-5-hepten-2-one; 7, nerol; 8, *O. lutea* fr. 6, 9, *E,Z*-farnesol; 10, *O lutea* blend; 11, *O. lutea* fr.3; 12, *O. lutea* fr. 2; 13, geraniol/nerol; 14, *Z,E*-farnesol; 15, *O. lutea* H; 16, geranial/neral; 17, geraniol; 18, *O. lutea* fr. 5; 19, *E,E*-farnesol; 20, *O. lutea* MWP; 21, *O. lutea* M; 22, geranial/neral + *E,E*-farnesol; 23, *O. lutea* fr. 4; 24, *A. fuscipes* male; 25, *O. lutea* blend + *E,E*-farnesol.

[a] N = the number of all events for each test sample. n = the number of test occasions for each test sample. The numbers 1–25 in front of the test samples refer to sample No. in Figure 2.

Authentic Samples. Tengö (1979) has shown that *E,E*-farnesol is strongly attractive to the *A. fuscipes* males. Also in this study all samples and extracts containing *E,E*-farnesol had a high behavior-releasing capacity (Table 1, Figure 2). The *O. lutea* blend (12), *E,E*-farnesol (10), and geraniol (17) could not be distinguished as regards their attraction of males. However, when *E,E*-farnesol (19) was tested in combination with the *O. lutea* blend (25: 10 + 19), which also contained geraniol and 1-octanol, a significantly higher attractivity occurred (χ^2, $P < 0.01$; W, $P < 0.05$) in relation to both the blend (10; W, $P < 0.05$; χ^2, $P < 0.01$) and the *E,E*-farnesol (19; W, $P < 0.05$; χ^2, $P < 0.01$).

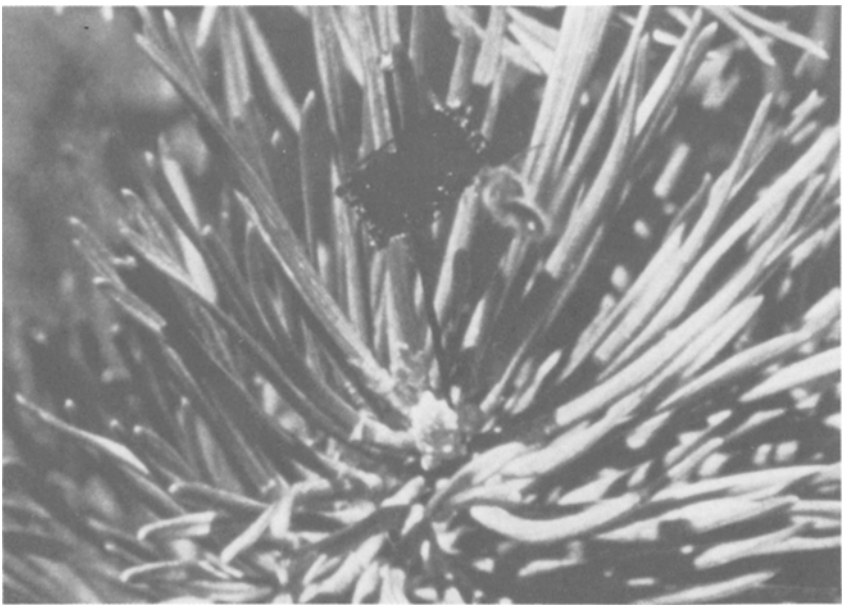

FIG. 3. *Adrena fuscipes* male approaching a dummy scented with *E,E*-farnesol.

When the four isomers of farnesol were compared, significant differences were observed (KW, $P < 0.05$). The *E,E*-farnesol (19) differed significantly from the *E,Z* (9) and *Z,Z* (4) isomers (χ^2, $P < 0.05$). The *Z,E* sample was found to be contaminated with 3% of the *E,E* isomer, which might explain the correspondence observed in attractivity between *E,E* and *Z,E*. Also the behavior-releasing capacity of geraniol (17) was considerably higher than that of the *Z* isomer nerol (7; χ^2, $P < 0.01$; W, $P < 0.05$).

The amounts of geranic and nerolic acids in the extracts of the bees seemed to increase during aging of the extract. Preliminary tests with a mixture (1 : 1) of these acids (3) elicited only weak attraction, which may indicate that these compounds probably are of minor importance in the pollination relationship.

DISCUSSION

Chemical mimesis as a factor in *Ophrys* pollination was proposed by Kullenberg (1961). The compounds hitherto identified and found to be similar for both the *O. lutea* flowers and the cephalic secretion of the *A. fuscipes* bees are, besides the aliphatic hydrocarbons, geraniol, nerol, geranial, neral, 6-methyl-5-hepten-2-one, *E,E*-farnesol, and an isomer of farnesal. These compounds are marked with an A in Table 2. Previously, no single compound or any specific combination of compounds has been reported to be responsible for the attraction

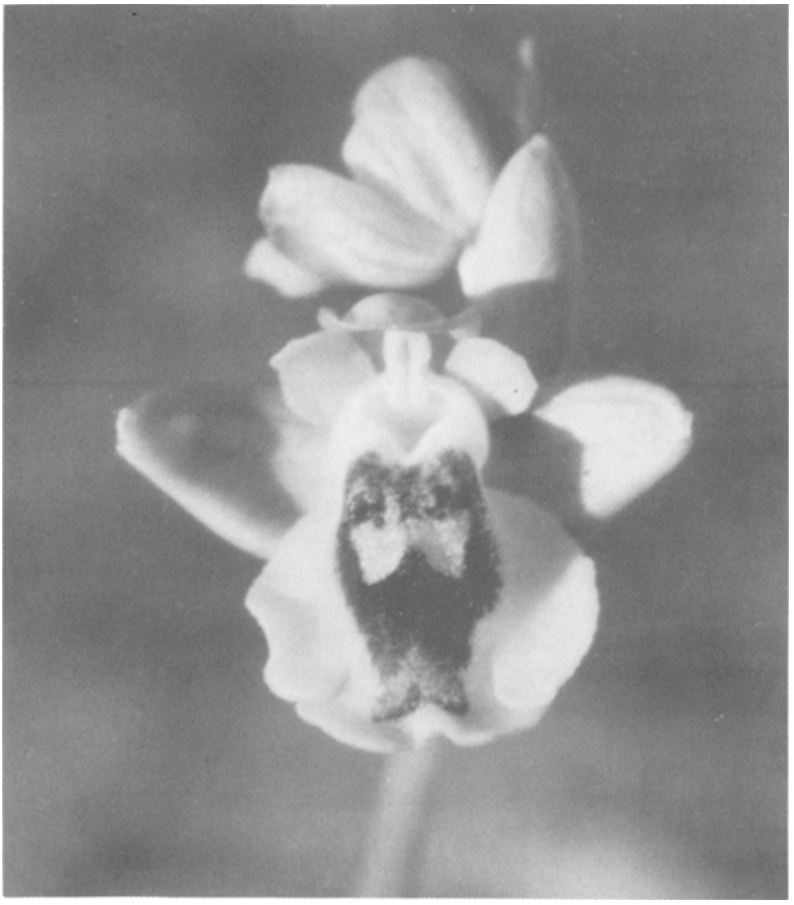

FIG. 4. *Ophrys lutea* flower, Spain.

of the visiting males. However, the strong behavior-triggering effect of the *E,E*-farnesol demonstrated in this study might be interpreted as a hint of such a condition. The females of several *Andrena* species also produce *E,E*-farnesol in their abdominal Dufour's gland (Bergström and Tengö, 1974). Several aliphatic primary and secondary alcohols and a few terpene alcohols present in the *O. lutea* labella extracts also have been found in the gland secretion of other *Andrena* bee species (Tengö and Bergström, 1976, 1977; Francke et al., 1981; Bergström et al., 1982). The odor similarities between the *Ophrys* group *Fusci-Luteae* and their pollinators are further discussed by Borg-Karlson et al. (1985).

The sesquiterpene hydrocarbons found in *O. lutea* have previously been proposed to be responsible for the odor attraction of the pollinator bees to the flowers (Kullenberg and Bergström, 1976). So far these compounds have not

been found in *Andrena* bees. Accepting the condition that the odor of *Ophrys lutea* is generally attractive to many species of *Andrena*, we note that the sesquiterpene hydrocarbons seem to have less influence in the pollination relationship. The large amounts of aliphatic hydrocarbons, aldehydes, and esters in fractions 1, 2, and 3 also seem to be of minor importance in releasing the odor-guided copulatory behavior.

Samples that elicited copulatory attempts on the dummies were the methanol extract (21), the TLC fractions 4 (23) and 5 (18), and the mixture of citral and *E,E*-farnesol (22). No single compound had comparable excitatory capacity. These observations indicate that a complex mixture of odor compounds might have an additive or synergistic function in the behavior chain.

The extracts and the TLC fractions differed from the authentic blends and single substances in their ability to elicit long-lasting approach flights (lasting more than 1 sec) towards the odor source. The *A. fuscipes* male extract (56% of behavior type 2), the *O. lutea* extracts (M = 26%, MWP = 33%, H = 54%), and fractions 4 (22%) and 5 (33%) frequently elicited long-lasting approaches, while the mixture of citral and *E,E*-farnesol as well as the *E,E*-farnesol alone, although being strongly attractive, with many approaches and in some cases copulation attempts, only elicited a few long-lasting behavioral events (10% and 8%, respectively).

A comparison of the *O. lutea* blend (10), the *E,E*-farnesol sample (19), and the combination of these (25) in the behavior experiments may indicate a synergistic effect, but also the importance of a multicomponent secretion to release high-level excitation in the male bees. A comparison of the attractivity of single compounds and blends shows the *E,E*-farnesol is of great importance when a powerful artificial male or female *A. fuscipes*, as well as an *O. lutea*, blend is to be constructed.

The large proportion of citral present in the mandibular gland secretion of *A. fuscipes* (Table 3) (cf. also Tengö and Bergström, 1976) is characteristic for several species of *Andrena* bees (Tengö and Bergström, 1976, 1977; Bergström et al., 1982) The odor marks made by the *A. fuscipes* males during their patrolling flights smell strongly like citral to the human nose. Since the bees continuously odor-mark during their flights, and the gland secretion thus evaporates from all perfume spots within the whole flight area, geranial and neral probably function as a general flight area attractant rather than as an close-range excitant. The occurrence of citral in *O. lutea* (although in relatively small amounts) might attract the pollinators to the orchids' habitats. Geranial and neral may also be formed from the corresponding alcohols during the test period, thus increasing the attractivity of the extract samples.

Tengö (1979) showed that two North American *Andrena* species are attracted to the odor of *O. lutea* hexane extract, thus supporting the concept that *O. lutea* emits a composition of odoriferous compounds that appeals to *Andrena* male bees in general. Our present tests, using a noncoexisting *Ophrys–Andrena*

constellation, confirms this view. It is conceivable that the orchid, by producing a large array of compounds, has evolved and retained the ability to attract males of many or most of the *Andrena* species. It must be advantageous for the *Ophrys* orchids to have an odor that is attractive to *Andrena* species in general. This may facilitate a wider geographical distribution and make the pollination of the flowers less dependent on exact correlation of blossom time and swarming period of the bee.

Acknowledgments—The authors want to thank Professor Bertil Kullenberg who enthusiastically supported the study and took part in the collection of test data. We also want to thank Miss Ingela Johansson, Mr. Thomas Johnsson, and Mrs. Inga Groth for skillful technical assistance. We are grateful to Dr. Erich Klein, Dr. Franz-Josef Hammerschmidt, and Mr. Rojan for a generous gift of the four pure isomers of farnesol. We are grateful to Dr. Staffan Ekblom, Professor Rolf Sundberg, Dr. Christer Solbreck, and Dr. Brian Smith for rewarding discussions concerning the statistical treatment of the test results. For critical reading of earlier versions of the manuscript, we we thank Professors Torbjörn Norin, Gunnar Berström, Wittko Francke, Staffan Ulfstrand, and for the linguistic revision Mr. Nigel Rollison. Grants from the Swedish Natural Science Research The Axel and Margaret Ax:son Johnson Foundation and the Bank of Sweden Tercentenary Foundation made this work possible.

(Received May 9, 1984; accepted November 26, 1985)

Abstract—(*E*)-11-Hexadecen-1-yl acetate and (*E*)-11-hexadecen-1-ol were identified in extracts from the abdominal pheromone gland of female *Sceliodes cordalis* and in a 1:1 ratio acted as a potent field attractant for males. Sustained upwind flight by males to this mixture in a wind tunnel confirmed the identity of these compounds as major components of the natural sex pheromone of this species. The synthetic pheromone was used to define the annual limits of male flight activity. In the presence of 1–10 μg of pheromone per liter of air, the mating rate of laboratory populations was halved. The *Z* isomers of both pheromone components decreased the numbers of males captured in traps baited with virgin females in the field and inhibited upwind flight in the wind tunnel. The attraction of males of *Mnesictena flavidalis* to virgin females of *S. cordalis* and synthetic mixtures was demonstrated to be due to the acetate component alone. Male *Eudonia* sp. nr *linealis* were captured by (*Z*)-11-hexadecen-1-yl acetate.

Key Words—Sex pheromone, *Sceliodes cordalis*, *Mnesictena flavidalis*, Lepidoptera Pyralidae, Pyraustinae, *Eudonia* sp nr *linealis*, Scopariinae, (*E*)-11-hexadecen-1-yl acetate, (*E*)-11-hexadecen-1-ol, (*Z*)-11-hexadecen-1-yl acetate, communication disruption, wind tunnel.

INTRODUCTION

Sceliodes cordalis (Doubleday) (Pyralidae, Pyraustinae) has been recorded as feeding on a variety of solanaceous plants in New Zealand and Australia. Win-

0098-0331/86/0900-1943$05.00

ter crops of eggplant (*Solanum melongena* L.) are seriously affected, but only minor damage to tomatoes and capsicums in Queensland has been recorded (Davis, 1964). New Zealand Ministry of Agriculture and Fisheries records (1980–1981) suggest that *S. cordalis* has the potential to limit the production of pepino (*Solanum muricatum* Aiton) in New Zealand. Large commercial plantings of the New Zealand native host, poroporo (*Solanum aviculare* G. Forster), are relatively little troubled (N. Martin, personal communication).

The adult moth is rarely attracted to light, and no specific baits are known. Our study aimed to identify the sexual pheromone to provide a tool for surveys and possibly as a component of future integrated control programs.

METHODS AND MATERIALS

Insects. Larvae were collected from infested poroporo berries at the Pukekohe Research Station, South Auckland. Adults emerged, mated, and laid eggs on paper towels. The calyx was removed from a poroporo berry, and a freshly emerged first instar larva was placed on the moist surface. The berries were placed on sand-lined trays and held at 25°C in the dark. Pupae were sexed on the basis of their incipient genital apertures and held on paper tissues under ambient conditions until emergence.

Mating Observations. Observations were conducted in the laboratory from dusk till dawn under ambient (moonlit) conditions. Six pairs of virgin moths were placed in a 10-liter plastic observation cage and observed at hourly intervals to establish the time of mating, after which continuous observation commenced. Observations were made on three nights, with three groups of moths.

Field Trapping. Apart from an initial trial with Pherocon IC traps (Zöecon Corporation), metal "triangular" traps (Lewis and Macaulay, 1976) were used for field studies. The bottoms of the triangular traps were lined with 15 × 20-cm acetate sheets smeared with Tangletrap (Tanglefoot Co. Grand Rapids, Michigan).

The traps were baited with moths and/or a 5-mm sleeve-type rubber stopper (Arthur H. Thomas Co. Philadelphia, Cat. No. 1780-B10) loaded with synthetic material. Moth baits included 1–6 virgin females (1 day old), mated females, dead virgin females, a virgin male, or virgin females enclosed in a small plastic bag. Moths were housed in a 5 × 5 × 5-cm wire mesh cage. Control traps were baited with empty mesh cages.

The traps were held on stakes just above the plant canopy or suspended in the top third of the plant in plants more than 2 m high. The trap positions were assigned randomly and rerandomized each time the catch was retrieved; the adhesive liner was replaced each time. When a trap held both a female in a cage and a rubber stopper, the two items were randomized independently when the traps were replaced. Experiments with synthetic chemicals were conducted with stoppers identified solely with a code number.

Although the virgin female first used remained attractive for three weeks

(Figure 3A), in most cases each female was used for one week only. The trap was cleared of males twice a week so each female produced two catches. During the 1981–1982 season, each female was assigned a code letter so that the relative attractiveness of each female could be assessed on the basis of these two catches before the variable under test was examined statistically.

Three areas of poroporo (a total of 360 plants covering 170 m^2) at the Mt. Albert Research Centre, Auckland (MARC), and five areas at the Pukekohe Research Station (a total of 780 plants covering 1800 m^2) were used as trap sites. Either five traps (virgin females 1979–1980) or two traps (synthetic material 1981–1982) were operated at MARC, with up to 22 traps in use at Pukekohe. Apart from a single remote station, the traps at Pukekohe were separated by approximately 9 m. Because of the scarcity of other host plants nearby, it was unlikely that large populations existed outside these areas.

Statistical Analysis. Unless otherwise stated, all quoted significance levels are derived from analysis of contingency tables of counts as log-linear models (McCullagh and Nelder, 1983). Any t statistics used are derived from differences between the parameters of the fitted models.

Preparation of Pheromone Extract. Ovipositors, with attached pheromone glands, were clipped from female moths (2–6 days old) and placed in redistilled pentane or methylene chloride. Collections were made during daylight (1980–1981) or between 2 AM and 4 AM (1982).

Gas Chromatography (GC) and Selected-Ion Mass Spectrometry (SIM). Preparative gas chromatography was performed on a Varian 1700 instrument fitted with a variable-ratio effluent splitter (Scientific Glass Engineering Pty) housed in the detector oven. The eluate was split between a flame ionization detector (FID) (one part) and a heated collection port (nine parts). Samples were collected by attaching the tip of a Pasteur pipet (ca. 10 cm × 1.6 mm OD) to the collection port, using Teflon tubing. During the collection, a section of the Pasteur pipet was cooled in a tray containing powdered solid carbon dioxide. The GC column was stainless-steel tubing (2 m × 2.1 mm ID) packed with 3% OV-1 on Chromosorb W AW-DMCS (80–100 mesh). A nitrogen carrier-gas flow of ca. 15 ml/min and temperature programs of 100–200°C at 4°/min or 140–190°C at 2°/min were used.

Analytical GC was performed using either a OV-101 WCOT (25 m × 0.3 mm ID, fused silica, Hewlett Packard, Avondale, PA, USA) or a Carbowax 20 M SCOT (50 m × 0.5 mm ID, glass, Scientific Glass Engineering, Melbourne, Australia) capillary column. The carrier gas was helium at 1.5 ml/min. The first column was temperature programmed from 150°C to 190°C at 4°/min, while the second column was used isothermally at temperatures between 165°C and 190°C.

GC-MS was carried out on a GC interfaced to an AEI MS30 mass spectrometer via a silicone rubber membrane separator (at 180°C). The mass spectrometer used electron impact ionization (20 eV) and operated in the selective ion monitoring (SIM) mode.

Electroantennogram (EAG) Analysis. The EAG responses of adult male *S. cordalis* to standard samples of acetates and alcohols were determined and standardized according to the procedures of Roelofs and Comeau (1971).

Chemicals. Our original samples of (*E*)-11- and (*Z*)-11-hexadecenyl acetates (*E*11–16:Ac, *Z*11–16:Ac) were kindly provided by Dr. E. W. Underhill (N.R.C., Saskatoon, Saskatchewan, Canada), and Dr. J. Weatherston, Albany International, Needham Heights, Massachusetts). Subsequently we synthesized the (*E*)-11-acetate by conventional means and prepared the corresponding alcohol from it by the method of Schwarz and Waters (1972). Other reference chemicals for EAG tests were from our collection. All samples were >98% pure by GC analysis.

Wind-Tunnel Experiments. A wind tunel was constructed based on the design of Miller and Roelofs (1978). Our wind tunnel lacked their illumination system, observations being made under ambient moonlit conditions supplemented by an incandescent light in a distant room. The motor-driven orange and black belt was replaced by a hand-driven white and black belt. Baffles reduced the speed of the fan-driven air current to 20 cm/sec. Synthetic mixtures on filter paper clipped to a wire fork acted as a pheromone source. Rubber stoppers taken from field traps were also used. For each test two or three males were released from small cages pressed into openings in the downwind wire mesh screen. The experiments were carried out between 1 AM and 4 AM.

Inhibition of Mating with Elevated Background Levels of Normal Pheromone Components. The impact of the identified chemicals on mating was measured with laboratory reared adults in sealed containers. Five unmated 1-day-old moths of each sex were enclosed in 10-liter plastic bowls containing a square of filter paper loaded with either 0, 1, 10, or 100 μg of a 1:1 mixture of *E*11–16:Ac and *E*11–16:OH. The experiment was replicated five times. The bowls were held for three days in darkness in the laboratory at ambient temperatures. Each female was then dissected and scored as mated when a spermatophore was recovered.

RESULTS

Sexual Behavior of S. cordalis. Sexual activity was observed only during the hours preceding daybreak. Very little spontaneous flight was seen until 1 AM (New Zealand summer time) (4 hr into scotophase). The first mating occurred at 1:20 AM, sexual activity peaked at 2 AM, and ceased at 4 AM, approximately an hour before daybreak. The resting posture of both sexes superficially resembled the "calling" posture of other species (Figure 1). The abdomen was tightly curled up over the thorax, the wings were spread with the apices pressed against the ground, the forelegs were outstretched, and the antennae were pressed down on the inner edge of the wing. In this position, prom-

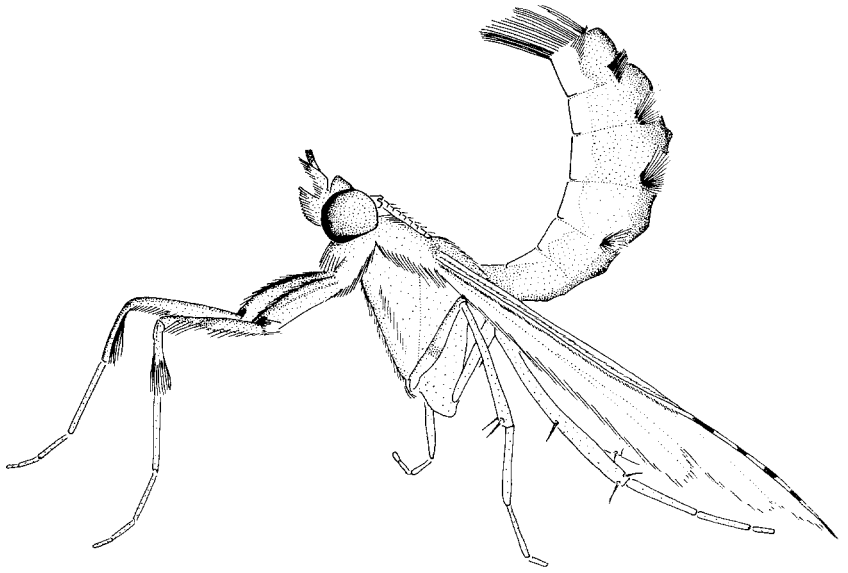

FIG 1. Male *Sceliodes cordalis* at rest (photophase and first half of scotophase), wingspan = 2 cm.

inent scales at the base of the abdomen were spread, exposing well-developed tympanic organs. With the onset of sexual activity, the moths lowered their abdomen. Females with the abdomen touching the substrate were sexually receptive and accordingly were thought to be "calling," although eversion of the sex pheromone gland on the dorsal surface of the ovipositor was not observed.

Low-amplitude antennal movements were the first signal of sexual arousal in the male. The wings were then lifted above the body and vibrated rapidly. The claspers were everted, and the legs were extended to full stretch (Figure 2) for several seconds before take-off. Males hovered below and to one side of the females and then made several short very rapid lunges with the claspers. As soon as coupling was achieved, the male hung head downwards.

Field Trapping with Live Moths. Sticky traps baited with *S. cordalis* females proved an effective means of capturing males. Five hundred sixty-four male *S. cordalis* were taken from five Pherocon IC traps, attracted by single, virgin females (Figure 3A). The traps were operated between December 5, 1979, and March 17, 1980, with the peak catch occurring in late February. Trapped moths were confirmed to be males by extrusion of the claspers with fine forceps. Most of the captured moths were found close to the female's cage and many had everted their claspers. Three individuals had produced a distinct, well-formed spermatophore.

There were no significant differences between the number of males caught

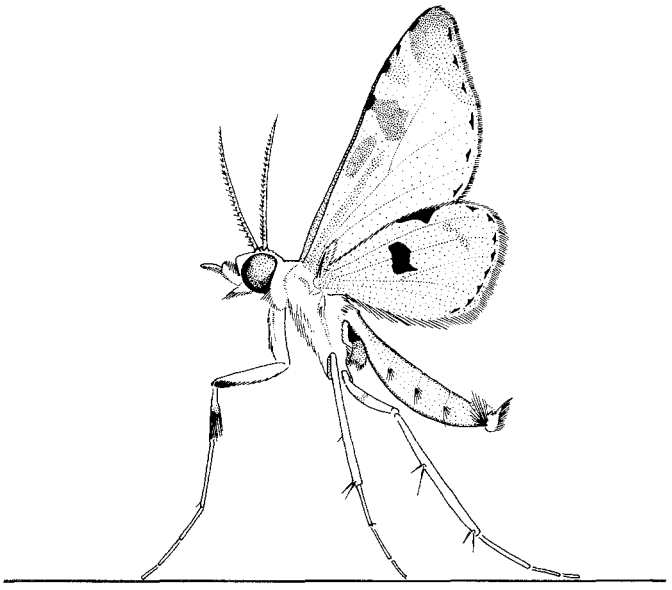

FIG. 2. Sexually stimulated male *s. cordalis* (last half of the scotophase in the presence of virgin females).

by traps containing one, two, or three females ($P > 0.50$), although cages with six females were less attractive, possibly due to physical interference during competition for calling positions on the wire mesh ($P < 0.005$) (Table 1). A single virgin female was used for all subsequent experiments.

Live, unrestricted virgin females were essential for trapping males. All other treatments, namely mated females, dead virgin females, live virgin males, and virgin females inside a small plastic bag, failed to catch a single male. No moths were captured in control traps.

Small numbers (57) of another pyralid moth, *Mnesictena flavidalis* (Doubleday) (Pyralidae; Pyraustinae) were also captured during the 15-week period (Figure 3A). All were males. This species was not captured by the control traps. All other moth species were captured in very small numbers, were of both sexes, and were also captured in the control trap.

Identification of Major Component of Sexual Pheromone of S. cordalis. The electroantennogram offered the first information on the identity of the major component of the pheromone. The strongest response of isolated antennae of male *S. cordalis* presented with a series of monounsaturated hexadecenyl, tetradecenyl, and dodencenyl acetates was observed with *Z*11- and *E*11–16 : Ac followed by the homologous *Z*11- and *E*11–14 : Ac (Figure 4).

The EAG results were supported by chromatographic analysis of the ex-

TABLE 1. *Sceliodes cordalis* MALES ATTRACTED BY ONE, TWO, THREE, OR SIX VIRGIN *Sceliodes cordalis* FEMALES

Trap No.[a]	No. of females	Catch/week	Trap No.[b]	No. of females	Catch/week

[a] Traps with one or three females were compared between December 5 and 20, 1979 at MARC. The traps were sampled on 11 occasions in the course of 16 nights. Eighteen males were caught.
[b] Traps with one, two, three, or six females were compared between January 8 and 14 1980 at MARC. The traps were sampled on five occasions in the course of seven nights. Seventy five males were caught.
[c] Traps with 6 females caught significantly fewer males than traps with one, two, or three females ($P < 0.005$ χ^2 test).

tract from the female pheromone gland. Initially, a crude female abdominal tip extract (from about 10 moths) was fractionated on the 3% OV-1 packed column. The FID trace showed a number of peaks, the major ones being at 18.5 and 20.13 min. Timed, 1-min collections were made of the effluent. The individual collections were then assayed for EAG activity which revealed a distinct maximum in the 17- to 18-min and 18- to 19-min collections. Under the operating conditions (100–200°C at 4°/min), the retention time (R_t) of 12:Ac was 9.65 min, of 14:Ac = 14.45 min, and 16:Ac = 18.08 min. This suggested to us that a C_{16} acetate was a major component of the pheromone. Another extract (from 20 moths) was then fractionated with the 3% OV-1 packed column programmed from 140 to 190°C at 2°/min. Under these conditions, the R_t of 12:Ac was 6.00 min, of 14:Ac = 10.13 min, and 16:Ac = 15.75 min. Three collections were made at 3–7 min (A), at 7–12 min (B), and at 12–17 min (C). Of these fractions, only C was strongly active in the EAG assay.

The Pasteur pipet in which fraction C was collected was rinsed out with ca. 300 μl of methylene chloride, and the washings concentrated to ca. 5 μl under a nitrogen jet. After adding 14:Ac as an internal reference, a 1-μl aliquot of this extract was then analyzed by GC-MS on the Carbowax 20 M SCOT column, at 165°C. The mass spectrometer was operated in the SIM mode (*m/z* 192, 194, 196, and 222). Apart from the 14:Ac reference, R_t = 18.32 min, seen on the *m/z* 194 trace, the only signal seen was an intense one on the *m/z* 222 trace, R_t = 38.20 min. Under the same conditions *Z*7–16:Ac had R_t = 36.89 min. These results suggested that the tip extracts indeed contained a hexadecenyl acetate. Tetradecenyl acetates and alcohols and tetradecadienyl acetates and alcohols were either absent or below detection limits.

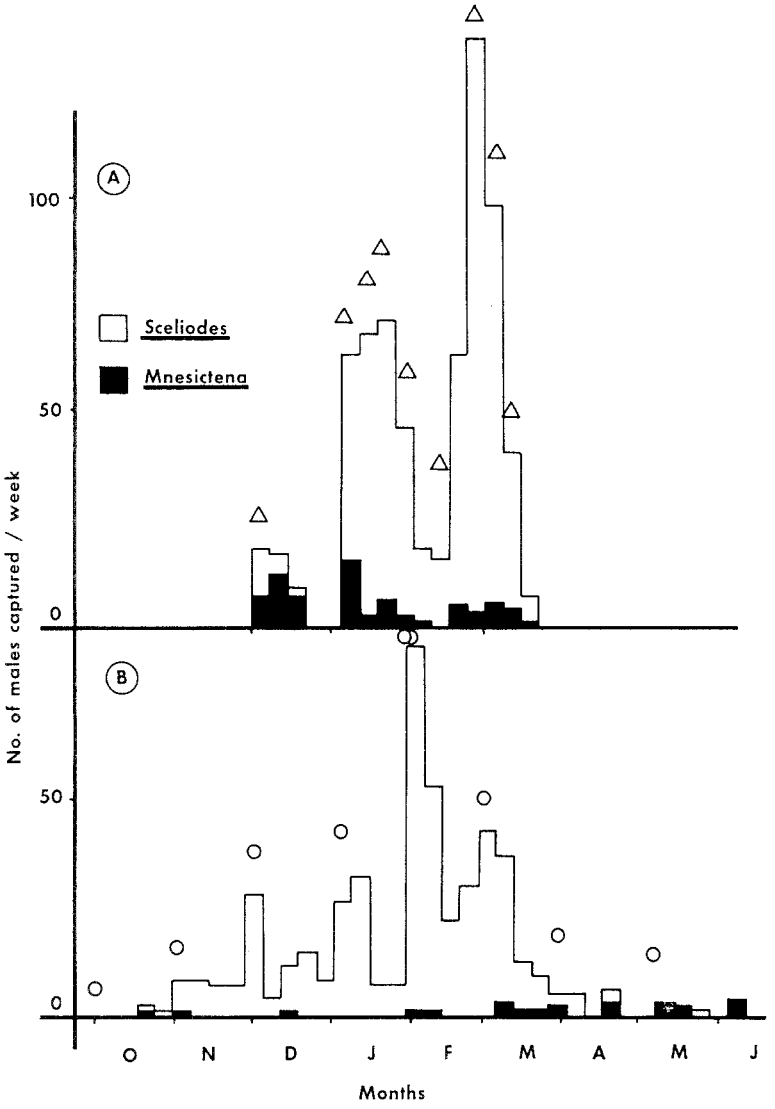

FIG. 3. Male *Sceliodes cordalis* and *Mnesictena flavidalis* captured in sex attractant traps (one-week intervals). (A) Males captured by five Pherocon IC traps baited with virgin females usually replaced (△) every one or two weeks (December 5, 1979, to March 17, 1980). (B) Males captured by two triangular traps baited with synthetic pheromone replaced (○) monthly (October 3, 1981, to June 11, 1982). The new cap replaced on February 1, 1982, was blown away by strong winds and replaced the next day.

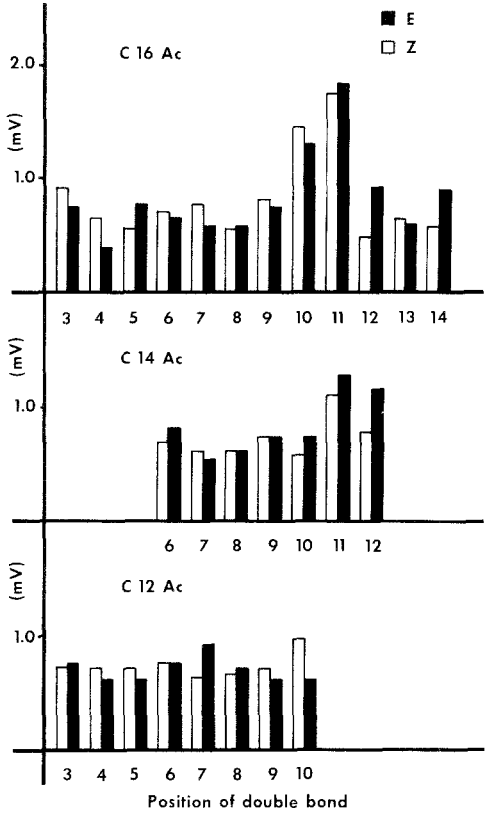

FIG. 4. Electroantennogram responses by antennae of male *Sceliodes cordalis* when stimulated with a series of C_{12}, C_{14}, C_{16} monounsaturated acetates. One microgram of each standard was used, and each point was replicated two or three times.

The presence of the hexadecenyl acetate was indicated by another experiment in which an aliquot of fraction C, to which 16:Ac was added as an internal reference, was analyzed on the Carbowax 20 M column, at 170°C, using SIM (*m/z* 192, 220, 222, and 224 detection). As before, apart from the reference, 16:Ac (R_t = 32.02 min), the only peak seen up to 45 min was on the *m/z* 222 trace (R_t = 35.50 min). The relative retention time (R_t^{rel}) of this component (16:Ac R_t^{rel} = 1.0) was 1.109. Under the same conditions *E*11–16:Ac had the same R_t^{rel} of 1.110 (within experimental error, ±0.004), while the R_t^{rel} of other hexadecenyl acetates were significantly different (e.g., *Z*11–16:Ac R_t^{rel} = 1.123). Hexadecadienyl acetates were not detected [no peaks on the *m/z* 220 trace, (*Z*,*Z*)-7,11-hexadecadienyl acetate had a relative retention time of 1.194]. At this point we considered that *E*11–16:Ac formed a major part of the sex pheromone.

Field Trapping with Synthetic Mixtures. Initial field trials at MARC with *E*11–16:Ac were disappointing. No *S. cordalis* were caught, although 22 *M. flavidalis* were taken. A virgin female caught 13 *S. cordalis* and two *M. flavidalis* during the same period (December 24, 1980, to January 14, 1981). Addition of varying amounts of the *Z* isomer caught more *M. flavidalis* and suggested that a 10:1 mixture of the two acetates might resemble the natural pheromone of this species (Table 2). The *Z* isomer alone or in combination with other chemicals captured large numbers of male *Eudonia* sp. nr *linealis* (Walker) (Pyralidae; Scopariinae). No *S. cordalis* males were captured. Although no additional components had been detected by EAG assay or by initial GC analysis of female pheromone glands, it was clear that at least one further component was required to lure male moths of this species. Three chemicals structurally related to *E*11–16:Ac were selected and tested in the field. (*Z*,*E*)-7,11-Hexadecadien-1-yl acetate and (*E*)-11-hexadecenal were each tested singly or in combination with *E*11–16:Ac and were as unsuccessful as *E*11–16:Ac presented alone. (*E*)-11-Hexadecen-1-ol appeared to be the missing component because traps baited with *E*11–16:Ac supplemented by the free alcohol caught 31 males in four nights (March 5–9, 1981).

A wide range of ratios of these two chemicals attracted males. The first series of traps at MARC caught a diminishing number of males as the proportion of the alcohol was lowered (Figure 5B,C). A third series run at Pukekohe confirmed the 1:1 ratio as the most attractive (Figure 5A). While all stoppers with both components attracted many males, the 1:1 ratio was significantly more attractive and the 9:1 ratio significantly less attractive than the 1:3 and 3:1 ratios ($P < 0.001$ χ^2 test). Three traps, each baited with a virgin female caught an average of 1.46 males/trap/night and were statistically indistinguishable from the 1:3 and 3:1 ratios of synthetic material. Each component offered by itself failed to capture a single male. Unless otherwise specified, a standard pheromone mix of 50 μg *E*11–16:Ac plus 50 μg *E*11–16:OH on a rubber stopper was used for all subsequent experiments.

If the two components were placed on separate stoppers, the catch dropped dramatically. Traps with a stopper loaded with 50 μg of *E*11–16:Ac touching

TABLE 2. *Mnesictena flavidalis* MALES ATTRACTED BY STOPPERS LOADED WITH *E*- AND Z11–16Ac (μg *E*:μg *Z*)[a]

[a] A single example of each of the stoppers was sampled on five occasions in the course of 18 nights (January 14 to February 1, 1980 at MARC). Numbers followed by different letters are significantly different ($P < 0.0001$, χ^2 test). Twenty-six males were captured.

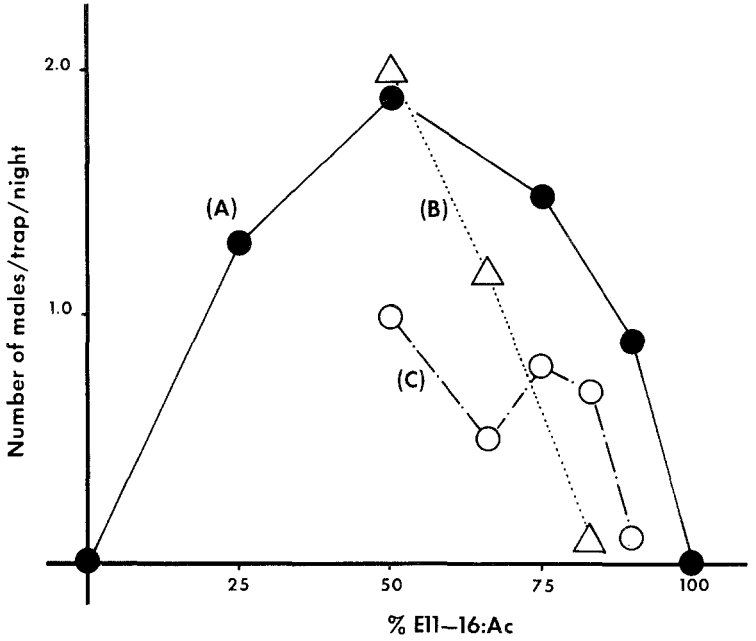

FIG. 5. Comparison between the males captured with stoppers loaded with an increasing percentage of E11-16:Ac. (A) Traps operated at Pukekohe between March 11 and April 1, 1981. Three replicates of each of six types of stopper were sampled on five occasions in the course of 21 nights; 352 males were captured. (B) Traps operated at MARC between March 11 and 21, 1981. A trap of each of three types of stopper was sampled on nine occasions in the course of eleven nights; 36 males were captured. (C) Traps operated at MARC between March 5 and 9, 1981. Two replicates of each of five types of stopper were sampled on three occasions in the course of four nights; 31 males were caught. Stoppers used contained a total of 100 μg synthetic material, in the following ratios. *E*11-16:Ac-*E*11-16:OH 0:1 (0% *E*11-16:Ac), 1:3 (25% *E*11-16:Ac), 1:1 (50% *E*11-16:Ac), 2:1 (66% *E*11-16:Ac), 3:1 (75% *E*11-16:Ac), 5:1 (83% *E*11-16:Ac), 9:1 (90% *E*11-16:Ac), 1:0 (100% *E*11-16:Ac)

a stopper loaded with 50 μg of *E*11-16:OH caught less ($P < 0.001$) than half of the catch of traps with the same amount absorbed on a single stopper (Table 3).

Less than 10% of the expected catch was taken from traps with widely separated stoppers. An acetate-laden stopper was placed near one trap opening and the alcohol-laden stopper placed at the opposite opening (14 cm separation) so that the airflow passing through the trap would produce a well-mixed odor plume. Separate odor plumes were produced by tucking similar stoppers in the sides of the trap (10 cm separation) perpendicular to the airflow. Wide separation of the two components severely reduces the catch ($P < 0.001$), but the

TABLE 3. REDUCTION IN CAPTURE OF *Sceliodes cordalis* MALES WITH INCREASING SEPARATION OF TWO COMPONENTS[a]

	Single stopper	Two stoppers		
		Adjacent	10 cm separation perpendicular to air flow	14 cm separation parallel to air flow
Catch/trapweek	20.8[a]	7.5[b]	0.5[c]	1.8[c]

[a]Single stoppers carried 50 μg *E*11-16:Ac plus 50 μg *E*11-16:OH. Other traps carried two stoppers, one with 50 μg *E*11-16:Ac alone, the second with 50 μg *E*11-16:OH alone. Two replicates of each of four dispositions of stopper were sampled on four occasions in the course of 14 nights (March 1-15, 1982, at Pukekohe). One hundred twenty-two males were caught. Catches followed by different letters are significantly different ($P < 0.001$, t statistic).

distribution pattern of the stoppers in the airflow appears to have had little effect (Table 3).

Four males found in synthetic baited traps had extruded a fully formed spermatophore while held by the adhesive layer.

Confirmation of E11-16:OH as Authentic Component of S. cordalis *Pheromone.* As we had found that this species mated in the hours before dawn, we made our next extracts between 2 and 4 AM. These extracts were analyzed first on the OV-101 capillary column, at 175°C, using SIM (*m/z* 222). Peaks were seen at 12.77 and 19.58 min in the positions expected for hexadecenols and hexadecenyl acetates, respectively. Under the same operating conditions *E*11-16:OH had R_t = 12.67 min, and *E*11-16:Ac 19.58 min. To provide better discrimination among the hexadecenols, the analyses were then repeated on the Carbowax 20-M capillary column at 190°C after adding 16:Ac as an internal standard. The SIM trace (*m/z* 222) showed peaks at 12.62 min, and 15.40 min (16:Ac, SIM *m/z* 224 appeared at 11.68 min). The R_t^{rel} of the two components, 1.080 and 1.318, respectively, corresponded well with those of *E*11-16:Ac (1.081) and *E*11-16:OH (1.324). Other hexadecenyl alcohols tested had different R_t^{rel}. Our successful detection of the hexadecenol only from the early morning extracts suggests that this component is synthesized immediately before release during calling.

The isolated male antennae also responded to this alcohol. There was no significant difference between the EAG response to *E*11-16:Ac and *E*11-16:OH (Wilcoxon's rank-sum test, $P < 0.10$) (Table 4). The saturated hexadecenyl acetate was less stimulatory (Kruskal-Wallis tests for equality of three populations, $P < 0.01$). We therefore concluded that the sex pheromone of *S. cordalis* contains as principal components *E*11-16:Ac and *E*11-16:OH. The relative abundance of the two ions suggested a 2:1 ratio of the two components.

Use of Pheromone Traps to Define Seasonal Distribution of S. cordalis. During the third season, two traps at MARC were baited with the standard pheromone loading and emptied daily from October 3, 1981, to June 11, 1982. Four hundred sixty-two male *S. cordalis* and 15 male *M. flavidalis* were captured. No females of either of these species were caught. The first male *S. cordalis* was captured on October 21 with the first peak in early November. These individuals had probably developed from overwintering prepupae (N. Martin, personal communication). The seasonal peak was reached in early February and male activity had largely ceased by mid-April (Figure 3B). The temporal difference in the seasonal peak populations in 1979–1980 and 1981–1982 (Figure 3A, B) may have been due to climatic differences, while the lower catches of *M. flavidalis* in 1981–1982 were possibly due to the different attractants used. This species is extremely common (Gaskin, 1966), so lack of available males in 1981–1982 was unlikely.

Pheromone Loadings and Male Capture. Trap catches were highly correlated with log pheromone concentration ($P < 0.0001$, $\chi^2 = 166$ with 3 *df*) (Figure 6). Lines A and B intersect the *x* axis between 7 and 9 μg, establishing a minimum effective concentration of pheromone in rubber stoppers in field traps. Only one insect was caught with 1 μg, and then only in a trap placed at the end of the line of poroporo at a distance of 37 m from the other traps. If we assume that the evaporation rates of *Z/E* isomers are similar and use the constants and equations of Butler and McDonough (1979, 1981), a minimally effective stopper would initially release *E*11-16:OH at a rate of 7.4×10^{-8} μg/sec ($t^{1/2} = 432$ days) and *E*11-16:Ac at a rate of 5.0×10^{-8} μg/sec ($t^{1/2} = 635$ days).

Interference between traps was observed. Significantly smaller catches ($P < 0.005$) were taken by all traps neighboring those baited with 1000 μg of pheromone (analysis of data shown in Figure 6A). As traps were only separated by 9 m, interference between traps was not unexpected. When increased loadings of 1000 μg and 10,000 μg were offered, the males exhibited a preference

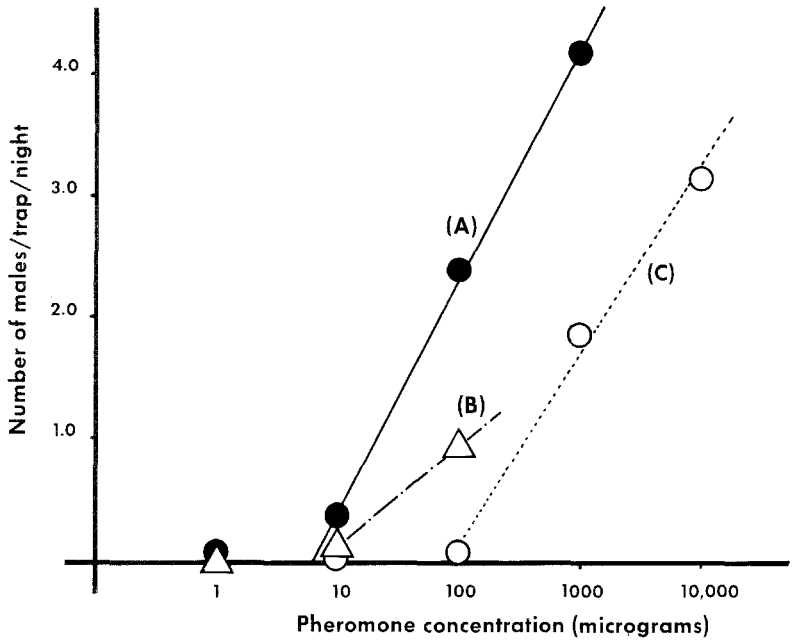

FIG. 6. Relationship between males captured and pheromone concentration in the rubber stopper (Ac to OH ratio = 1:1) (A) Concentrations of 1, 10, 100, and 1000 μg compared between February 8 and March 1, 1982, at Pukekohe. Two replicates of each of four types of stopper were sampled on six occasions in the course of 21 nights; 292 males were captured. (B) Concentrations of 1, 10, and 100 μg compared between April 1 and 15, 1981, at Pukekohe. Three replicates of each of three types of stopper were sampled on three occasions in the course of 14 nights; 43 males were captured. (C) Concentrations of 10, 100, 1000, and 10,000 μg compared between March 15 and 22, 1982, at Pukekohe. Two replicates of each of four types of stopper were sampled on two occasions in the course of seven nights; 72 males were caught.

for the highest loading, almost completely ignoring the usually attractive 100-μg bait (Figure 6C).

Impact of Trapping on Population. The deployment of traps baited with physiologically potent materials and removal of adult males may have a significant effect on the wild population within the catchment area of the traps. At both the MARC and Pukekohe field sites, the first catch markedly exceeded subsequent catches (Figure 7, Table 5). At the MARC site, the 24 moths caught on the first night included older battered individuals as well as apparently freshly emerged males. Later, smaller catches were made up of predominantly newly emerged (i.e., undamaged) insects. At Pukekohe, the first catch of 247 was followed by catches of 64 or less. Both the synthetic attractant and the natural attractant (virgin females) showed initial high catches (Figure 7). The drop in

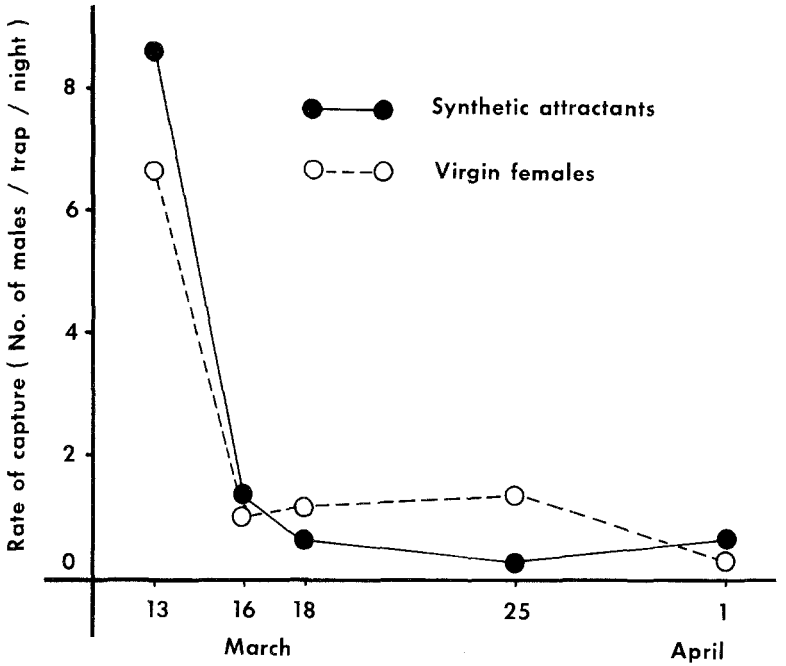

FIG. 7. Catches of male moths at Pukekohe between March 11 and April 1, 1982. Three traps baited with virgin females and 12 traps with stoppers loaded with synthetic material werer sampled on five occasions in the course of 21 nights. Synthetic baited traps caught 352 males and virgin females caught 92 males.

TABLE 5. COMPARISON OF FIRST NIGHTS' CATCH WITH AVERAGE SUBSEQUENT CATCH[a]

	Catch males/trap/night				
	Test A	Test B	Test C	Test D	Test E
First night[b]	2.4	8.6	6.7	8.7	4.5
Av. subsequent nights	0.4	0.6	0.9	1.0	2.5

[a]Test A: ten traps baited with synthetic attractant were smapled on three occasions in the course of five nights (March 5–9, 1981 at MARC). Thirty-one males were captured. Test B: twelve traps baited with synthetic attractant were sampled on five occasions in the course of 21 nights (March 11–April 1, 1981, at Pukekohe). Three hundred fifty-two males were captured. Test C: three traps baited with virgin females were sampled on five occasions in the course of 21 nights (as B). Ninety-two males were captured. Test D: three traps baited with synthetic attractant were sampled on 14 occasions in the course of 14 nights (February 6–20, 1985, at MARC). Sixty-six males were captured. Test E: two traps baited with virgin females were sampled on 14 occasions in the course of 14 nights (as D). Seventy-five males were captured.

[b]The first catches were significantly greater than subsequent catches ($P < 0.05$, χ^2 test).

catch with time was not due to the end of the flight season, as the same result could be obtained during the peak February flight (Table 5, columns D and E).

Inhibition of Male Attraction with Pheromone Geometrical Isomers. Addition of (Z)-11-hexadecen-1-yl acetate (Z11–16:Ac) or (Z)-11-hexadecen-1-ol (Z11–16:OH) to attractive synthetic mixtures and to traps baited with virgin females diminished the daily catch of male moths. Stoppers loaded with 50 μg of E11–16:Ac plus 50 μg of E11–16:OH attracted 37 males to four traps between March 18 and April 15, 1981. No males were captured in four neighboring traps with stoppers loaded with 50 μg of Z11–16:Ac in place of E11–16:Ac. The final group of four traps baited with stoppers containing 50 μg of Z11–16:Ac, 50 μg of E11–16:Ac, and 50 μg of E11–16:OH caught a single male.

The Z isomers diminished the attractiveness of virgin females. A stopper loaded with 100 μg of Z11–16:Ac placed on the trap floor next to the wire cage housing a virgin female reduced catches to 10% of the expected numbers (Table 6). Lesser amounts of this chemical did not significantly reduce catches. A different inhibition pattern was observed with the alcohol, with 30–50% reductions in the expected catch observed across the concentration range tested (Table 6).

Inhibition of Mating with Elevated Background Levels of Normal Pheromone Components. The binary pheromone mixture disrupted normal mating of

TABLE 6. REDUCTION IN NUMBERS OF *Sceliodes cordalis* MALES ATTRACTED TO TRAPS BY VIRGIN FEMALES IN PRESENCE OF INCREASING CONCENTRATIONS OF Z ISOMERS

	Males (catch/trap/week)			
	Virgin female alone	Virgin female +1 μg Z isomer	Virgin female +10 μg Z isomer	Virgin female +100 μg Z isomer
Z11–16:Ac[a]	11.3[a]	12.4[a]	10.8[a]	1.1[b]
Z11–16:OH[b]	7.2[c]	5.0[d]	4.5[d]	3.5[d]

[a] The impact of 0, 1, 10, or 100 μg Z11–16:Ac on the attractiveness of virgin females was measured on (1) January 26–February 8, 1982, and (2) April 1–15, 1981 at Pukekohe. (1) Two replicates of virgin females with no stopper or with one of three types of stopper were sampled on three occasions in the course of 13 days. Two hundred ten males were captured. (2) Three replicates of virgin females with no stopper or with one of three types of stopper were sampled on two occasions in the course of 14 days. Eighty-four males were captured.

[b] The impact of 0, 1, 10, or 100 μg of Z11–16:OH on the attractiveness of virgin females was measured from March 22 to April 8, 1982, at Pukekohe. Two replicates of virgin females with no stopper or with one of three types of stopper were sampled on five occasions in the course of 17 days. Ninety-eight males were captured. In each line, weekly catches followed by different letters were significantly different ($P < 0.001$, ANOVA).

TABLE 7. PERCENTAGE OF *Sceliodes cordalis* FEMALES REMAINING UNMATED IN PRESENCE OF MALES INFLUENCED BY VARYING AMOUNTS OF SYNTHETIC PHEROMONE[a]

	Synthetic pheromone			
	0 μg	1 μg	10 μg	100 μg
Unmated females (%)	4[a]	20[a]	40[b]	44[b]

[a] Five groups of five males and five females held for three days in the presence of 0, 1, 10, or 100 μg pheromone. Percentages with different superscripts are significantly different ($P < 0.05$ ANOVA on arc-sine transformed data).

moths enclosed in a sealed plastic bowl (10 liter volume). After three nights, almost half the females remained unmated when 10 or 100 μg of *E*11–16:Ac plus *E*11–16:OH (1:1) on filter paper was placed in the bowl (Table 7). The possibility of visual mate recognition was eliminated by keeping the bowls in complete darkness for the period of the experiment.

All mated females ($N = 153$) dissected had a single spermatophore. Multiple mating was not encountered in the laboratory or field.

Wind-Tunnel Experiments. On four separate nights, laboratory-reared males flew from a release cage to a pheromone release point. Two or three males in a small mesh cage clipped into a hole in the downwind screen remained inactive until stimulated by the pheromone plume. Sexual arousal began 5–10 sec after the introduction of the pheromone-bearing paper (50 ng of 1:1 *E*11–16:Ac + *E*11–16:OH) into the airstream. The heightened arousal stage lasted a further 5 sec before take-off and flight toward the source. Rubber stoppers from field traps were also adequate stimuli. Males flew at a high angle of incidence (>30°) with antennae raised and claspers partially extruded. The ground speed was low, about 1–3 cm/sec. The line of flight was not completely straight, the moth making short (1 to 2-cm) zig-zags as it flew upwind. When the moth drew near the pheromone paper, it hovered 5–20 cm away from the paper for 4–180 sec ($N = 10$ observations) occasionally darting close ($N = 4$), or immediately landing ($N = 7$). Considerable effort was necessary to dislodge some of the moths from the paper after landing.

When the floor stripes were moved downwind, increasing the apparent ground speed to a moth in midflight, the moth reduced its airspeed and was carried downwind, still facing the plume and zig-zagging slightly ($N = 11$). The moth could be made to retrace its flight path and land again on the downwind screen near to its original point of take-off. Removal of the pheromone source while the moth was still in flight elicited the "casting" behavior observed by Kennedy and Marsh (1974) in *Ephestia* (= *Cadra*) *cautella* (Walker). One to two seconds after removal of the paper, the steady upwind flight pattern

changed to wild swings across the tunnel as the male turned into a rapid crosswind flight with sharp reversals between left and right.

In the middle of one experimental period, the pheromone source was removed, and a group of four males observed for 10 min. During this period, no flight activity of any kind was observed. The moths had been actively following pheromone trails before the break. When the pheromone paper was reintroduced, standard upwind orientation toward the pheromone source was resumed. The two components of the pheromone failed to stimulate upwind flight when presented singly. *E*11–16 : Ac (50 ng) elicited slight antennal movements only ($N = 4$). Strong antennal and wing movements but no upwind flight followed exposure to a similar concentration of *E*11–16 : OH ($N = 4$). Antennal and wing movements and brief undirected flights were stimulated by *Z*11–16 : Ac ($N = 4$). This isomer, presented simultaneously with pheromone-loaded filter papers, inhibited the upwind flight response. A further series of three filter papers were prepared: 25 ng *E*11–16 : Ac + 25 ng *E*11–16 : OH (A), 25 ng *Z*11–16 : Ac (B), and 2.5 ng *Z*11–16 : Ac (C). These papers were presented in the sequence A, A + B, A, A + C. Upwind flight was stimulated by papers A, but addition of either concentration of the *Z* isomer completely inhibited the response. Of the 30 males used in these tests, 22 showed the state of high sexual arousal and 16 individuals flew in reproducible upwind flight patterns. These results confirmed the conclusions based on the field experiments that *E*11–16 : Ac and *E*11–16 : OH are the major, functional components of the pheromone, that both are essential for the full male response, and that the *Z* isomers inhibit the male response.

DISCUSSION

Although the stereoisomers *Z*11–16:Ac and *Z*11–16:OH have been frequently identified as pheromone components, the only species presently known to use *E*11–16:Ac are *Brachmia macroscopa* Meyrick Gelechiidae (Hirano et al., 1976) and *Mamestra brassicae* (L.) Noctuidae (Struble et al., 1980). Six other species respond to empirical mixtures containing this substance (Inscoe, 1982). *E*11–16:OH has not previously been extracted from insect pheromone glands but has been reported as an attractant synergist to two species (Inscoe, 1982).

The male *S. cordalis* does not appear to discriminate greatly between different ratios of the two pheromone components. This may be explained by the fact that, although the two components have a common carbon chain, the different functional groups result in significant differences in vapor pressure. This difference would make it difficult to maintain a sharply defined ratio of the two components at all distances from the emitting female over a range of temperatures (Roelofs & Cardé, 1977). Although the ratio of the two components may vary, complete superposition of the two plumes is important. Reducing the pro-

portion of *E*11-16:OH in the lure to 10–20% of the standard has the same impact on male catch as separating the source of the two components by less than a centimeter (Figure 5, Table 3). Separate sources might adequately attract males from a distance, but confuse short-range orientation.

Roelofs and Comeau (1968) first reported that the geometrical isomer of a pheromone was very effective in inhibiting the approach of males. *S. cordalis* males are deterred to the greatest extent by the opposite geometrical isomer of the major component, in agreement with the observations of Hill et al. (1974, 1975) on *Argyrotaenia citrana* (Fernald), Tortricidae, and *Platynota idaeusalis* (Walker), Tortricidae. The moderate inhibition of male approaches by all tested levels of *Z*11-16:OH contrasts with the almost complete avoidance of traps with 100 μg of *Z*11-16:Ac, suggesting that different behaviors are affected.

Control of *S. cordalis* by mating disruption appears possible. In enclosed bowls 1–10 μg/liter of the natural pheromone in air inhibits mating among half a laboratory population of moths for three nights. Shorey et al. (1967) demonstrated that 50 μg/liter decreased matings of *T. ni* to 10% of the control for one night while 500 μg/liter abolished mating completely. They then went on to demonstrate disruption of male orientation in the field. Cardé (1981), in a discussion of mechanisms by which elevated levels of pheromone disrupt mate finding by male *Grapholita molesta* (Busck), suggested that males remain responsive to pheromone and search actively but fail to find the females because a disruptant pheromone concentration of 2.5×10^{-2} g/hectare/day is well above the maximum production of the female. Unlike most moth species, which respond only to a narrow range of pheromone concentrations (Roelofs and Cardé, 1977), *S. cordalis* can locate traps baited with very high loadings (up to 10,000 μg in our field experiments). In the presence of the latter concentration, the normally effective 100-μg stopper (statistically more attractive than a virgin female) failed to capture males. These results suggest that sexually active male *S. cordalis* would continue to search in the presence of relatively high pheromone levels that effectively camouflage the normal output of their females.

The highest catches of *S. cordalis* are taken when the traps are deployed for the first time of each season. Howell and Quist (1980) ascribed high initial catches of codling moths to the removal of an accumulated pool of older males. Later, smaller catches then reflected the daily recruitment rate into the adult population. An alternative hypothesis suggests that the pattern of daily catches (Figure 7) results from the physical characteristics of the pheromone-laden stopper. Many pheromone formulations rapidly release attractant for the first one to five days before maintaining a steady low release rate (Maitlen et al., 1976; Caro et al., 1981). Because both the synthetic attractant and the virgin females showed initial high catches (Figure 7, Table 5), the differences in release rate with time are likely to make only a small contribution to this effect.

These initial high catches also suggest that the traps are removing a high proportion of the sexually active males. The first nights' trapping of 1981 (March

5, MARC) removed 24 males, leaving a population of approximately 32 males (estimated by mark–release–recapture studies: 28.7 $\times/\div$ 1.87 males on March 9 and 35.9 $\times/\div$ 1.54 males on March 23; Clearwater, unpublished results). Further trapping removed an average of 4.32 males per night (13.4% of the population). Freshly emerged males, with crisp wing patterns, made up most of the later captures. Halving the population initially and preventing population increases by removing newly emerged males suggests that population control by male removal might be possible with *S. cordalis*.

Males captured by pheromone traps (baited with synthetic material or virgin females) were occasionally found with a spermatophore stuck to the adhesive liner close to their claspers. Spermatophores are normally found only within the females reproductive tract, and this is the first report of spermatophore production following flight to a synthetic pheromone source. Preliminary electron microscopy (Clearwater and Hallet, in preparation) confirmed that the ejected capsules are spermatophores. Many elongated bodies inside the capsule were ultrastructurally similar to spermatozoa (Smith, 1968).

The capture of significant numbers of *M. flavidalis* was an unexpected result of our study. Males clearly responded to the acetate component of the *S. cordalis* pheromone. Many species sharing pheromone components are temporally separated by differing circadian rhythms of responsiveness or different seasons of emergence (Roelofs and Cardé, 1974), but our demonstration of attraction of *M. flavidalis* males by *S. cordalis* females indicates overlapping times of responsiveness. We suspect that attraction of *S. cordalis* males to *M. flavidalis* females is unlikely as Z11–16:Ac attracts *M. flavidalis* (Table 2) but inhibits *S. cordalis* (Table 6). Careful dissections failed to reveal any male scent system that might allow close range species recognition (Cardé et al., 1975; Clearwater, 1975).

M. flavidalis is a very variable entity. Color ranges from lemon yellow to light and dark browns. The wingspan and pattern differ greatly within local populations (Dugdale, personal communication). Our traps catch the small light to dark brown segment of the Auckland population. This data might be valuable in future taxonomic investigations of this species.

Our experiments, carried out over four seasons, captured 2573 wild *S. cordalis*. Only three were female, and control traps were consistently empty. The pheromone is highly sex specific, and the trapping of only three females in three years suggests that random captures are extremely low. If populations of *S. cordalis* cause economic losses as plantings of pepinos expand, the female-produced pheromone offers a potentially potent method of control.

Acknowledgments—We thank Dr. N.A. Martin (Entomology Division, D.S.I.R.) for advice on the rearing of *S. cordalis* and access to field plots of poroporo. Dr. C.M. Triggs and Mr. J.H. Maindonald (Applied Mathematics Division, D.S.I.R.) analyzed our results statistically. Mr. J.S. Dugdale (Entomology Division, D.S.I.R.) identified *M. flavidalis* and *E.* sp. nr. *linealis*. NESTMATE RECOGNITION CUES IN LABORATORY AND FIELD COLONIES OF *Solenopsis invicta* BUREN (HYMENOPTERA: FORMICIDAE)
Effect of Environment and Role of Cuticular Hydrocarbons

MARTIN S. OBIN

(Received September 16, 1985; accepted December 2, 1985)

Abstract—Laboratory-reared *Solenopsis invicta* workers were tested for the ability to discriminate nestmates from nonnestmate conspecifics. Postcontact aggressive response to workers from local field colonies was significantly greater than the response to lab-reared workers, even when the latter were selected from colonies originating hundreds of miles away. Behavioral observations support the conclusion that lab-reared ants were less distinctive than field-collected ants with respect to recognition cues detectable on the cuticle. Potential environmental factors affecting colony odor are discussed. In addition, gas–liquid chromatographic and statistical analyses of the major *S. invicta* cuticular hydrocarbons indicate that cuticular hydrocarbon pattern was a poor predictor of laboratory colony response to field colony workers.

Key Words—Ants, Hymenoptera, Myrmicinae, *Solenopsis invicta*, nestmate recognition, colony odor, cuticular hydrocarbons, environmental effects, gas–liquid chromatography, multivariate analysis, Formicidae.

INTRODUCTION

Hamilton's theory of kin selection (1964) argues that individuals act altruistically toward others with whom they share alleles by common descent. One prediction of the theory is that mechanisms should exist that enable individuals to discriminate close relatives from nonrelatives, especially in the social insects (Alexander, 1974; Pfennig et al., 1983). The ability to discriminate colony members or nestmates from nonnestmates (i.e., "nestmate recognition") has been documented in a number of social insects (Wilson, 1971; Hölldobler and

0098-0331/86/0900-1965$05.00

Michener, 1980; Carlin and Hölldobler, 1983; Breed, 1983; Jaffe and Marcuse, 1983). Typically, recognition in social insects is based upon olfactory cues that constitute a "colony odor" (Wilson, 1971) common to all colony members (Bradshaw and Howse, 1984). Elements of an individual's odor profile determine to a large extent whether it is fed, tolerated, or attacked in or near a colony. Chemical recognition cues can be genetically based (Kukuk et al., 1977; Greenberg, 1979; Jutsum et al., 1979; Hölldobler and Michener, 1980; Breed, 1981, 1983; Mintzer and Vinson, 1985), as well as environmentally determined or acquired (Lubbock, 1894; Kalmus and Ribband, 1952; Lange, 1960; Renner, 1960; Free, 1961; Jutsum et al., 1979; Hölldobler and Michener, 1980; Breed, 1983). As a consequence, recognition systems can be complex and dynamic, rendering chemical elucidation difficult.

This paper reports behavioral and chemical data used to investigate nestmate recognition at the colony level in the imported fire ant *Solenopsis invicta* Buren (Myrmicinae). *S. invicta* workers aggressively defend their nest against intruders, including conspecific neighbors. As in other myrmicine ants studied (Jutsum, 1979; Vilela and Howse, 1986), attack is released by close-range or contact chemoreception of surface compounds (see also Wilson, 1971; Bradshaw and Howse, 1984). By rearing colonies under controlled, laboratory conditions, it was possible to assess the effects of environment on nestmate recognition cues. It was also possible to test whether the cuticular hydrocarbon pattern was consistent with aggressive behavior between colonies, as might be predicted if cuticular hydrocarbons provide nestmate recognition cues in this species (Howard and Blomquist, 1982).

METHODS AND MATERIALS

Ant Rearing. Monogynous *S. invicta* colonies were established from newly mated queens collected near Gulfport, Mississippi, and Gainesville, Florida, and established at the USDA/ARS Insects Affecting Man and Animals Research Laboratory, Gainesville, Florida. For details of collection and laboratory rearing, see Banks et al. (1981). Colonies were maintained in plastic Petri dish cells (diameter = 14.0 cm) with Castone® floors at 26–27°C on a diet of honey-water, fly pupae, roaches, and hard-boiled egg. Illumination was provided by fluorescent lamps, and the light–dark cycle was variable. The Petri dish cells were placed in plastic trays (52.0 × 39.0 × 7.5 cm) that served as foraging arenas. The sides of the tray were Fluon®-coated.

Nestmate Recognition Bioassay. Eighteen months after establishment in the laboratory, six of these colonies were tested for their ability to discriminate nonnestmates introduced from (1) each of the five other lab-reared colonies and from (2) *S. invicta* field colonies ($N = 6$) situated in a 24.0 × 55.0-m section of lawn adjacent to the USDA/ARS Fire Ant Project laboratories. Ants intro-

duced into foreign colonies (i.e., "intruders") were collected in groups of 12–15 from either the mound perimeter of field colonies or from the foraging tray of laboratory colonies. Medias, i.e., ants of the intermediate size caste, were selected by visual inspection, and only these were introduced into foreign colonies. Collected ants were maintained in small, glass vials and then introduced individually on the end of forceps into the foraging arena of a laboratory colony. Only ants that walked undisturbed from the forceps into the "resident" colony tray were tested. Intruders were positioned on the tray floor so as to maximize both the initial distance (5–20 cm) between the site of introduction and resident ants as well as the distance from any previous introduction. The forceps were rinsed with acetone and thoroughly dried after each introduction. Controls consisted of lab-reared ants that were removed and subsequently introduced back into their colony of origin (as above).

Tests were conducted on two consecutive days. On day one, control introductions were conducted first, followed by tests of lab-reared intruders and finally by tests of field intruders. This sequence was reversed on the second day. A 90-min period was observed between the three series of introductions. Within each series (other than controls), replicates were randomized with respect to intruder origin and resident colony, and no resident colony was retested before all resident colonies had been equally replicated. Except when they entered the brood chamber, introduced ants (including at times those residents clinging to them) were removed after each introduction.

The recognition bioassay consisted of five behaviors observed following intruder–resident contact (Table 1). The two most aggressive, "hold/sting" and "hold," always resulted in intruder death, whereas the three least aggressive responses, "hold/release," "antennate/follow," and "no follow," resulted in continued intruder mobility throughout the foraging tray. An introduction was

TABLE 1. BEHAVIORS SCORED IN NESTMATE RECOGNITION BIOASSAY

Behavior	Description
Hold/sting	Resident grabs intruder with forelegs and mandibles, curls abdomen and attempts vigorous stinging during first minute of interaction
Hold	Resident holds intruder (usually by the petiole), but does not attempt stinging; intruder is not released, but eventually dismembered by other residents
Hold/release	Resident releases intruder after initial holding (as above); residents may repeatedly hold, release and follow intruder
Antennate/follow	Resident antennates (>5 sec), follows, but does not hold intruder
No follow	Resident antennates intruder, but does not follow

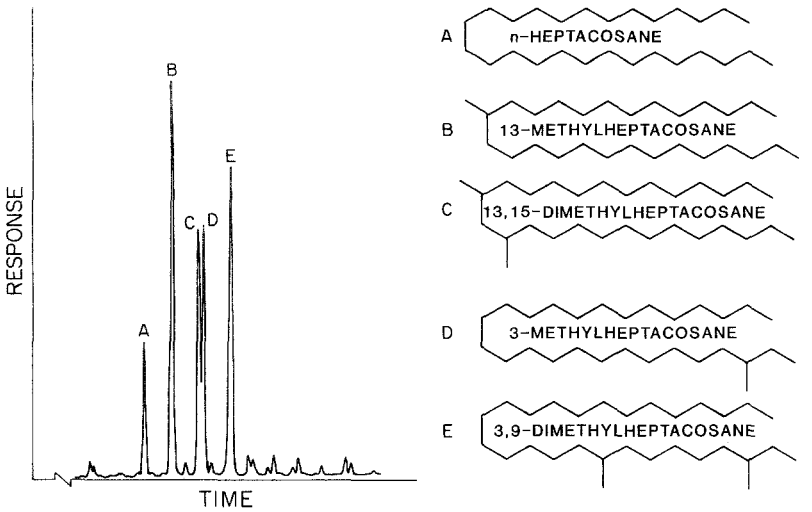

FIG. 1. Chromatographic pattern of *S. invicta* worker cuticular extracts (see Methods and Materials). Structures of the five major hydrocarbons (A–E) are included (after Nelson et al., 1980).

considered completed either when "hold/sting" was observed, or after five resident ants had contacted the intruder. Behavioral data were analyzed according to statistical methods described in Sokal and Rohlf (1981).

Chemical and Statistical Analysis of Cuticular Hydrocarbons. Samples ($N = 3$) consisting of three media workers were collected (as above) from each of the lab and field colonies on the second day of tests. Samples were extracted for 7 min in 150 μl of hexane. Previous studies (Vander Meer, unpublished data) indicate that hydrocarbons extracted by this method are exclusively of cuticular origin. Solvent was removed, reduced under a nitrogen stream to approximately 25 μl and analyzed by capillary gas chromatography: 30 m $\times$ 0.33 mm DB-1 column (J. and W. Scientific, Inc.), splitless; Varian 3700, FID, temperature program = 150 (1 min hold), then 4°C/min to 285°C (Figure 1). Normalized and autoscaled areas (Luc Massart and Kaufman, 1983) of the five major *S. invicta* cuticular hydrocarbons were obtained. These peaks have been chemically identified (Nelson et al., 1980) and are qualitatively invariant in this species. In addition, gas chromatographic comparisons of *S. invicta* cuticular extracts (containing internal standard) with aliquots eluted with hexane from Florisil (60–200 mesh, Applied Science) confirm that these peaks contain only hydrocarbons (Vander Meer, unpublished data). Statistical analysis included *t* tests of individual peak areas in lab and field colonies as well as discriminant function and nearest-neighbor discriminant analyses (SAS, 1982) of cuticular hydrocarbon patterns in the two types of colonies.

RESULTS

Bioassay. Most introduced ants moved immediately about the tray, although some groomed momentarily before doing so. Since the foraging trays contained a minimum of several hundred workers, intruder–resident contact (antennation) occurred within 1 min of introduction in all cases. No introduction took more than 3 min to complete. Forty-eight "control," 120 lab-reared, and 96 field intruders were tested. Eight lab-reared and 14 field intruder replicates were excluded from analysis as a result of either experimenter confusion as to ant identity ($N = 2$), trophallactic appeasement (Bhatkar, 1979) of resident ants by an intruder ($N = 2$), initiation of aggressive behavior by the intruder ($N = 7$), or rapid, erratic movement (escape attempts) following introduction ($N = 11$). Intruders from field colonies (5 of 96 introductions = 5.2%) were no more likely to exhibit initial aggressive responses than were intruders from laboratory colonies (2 of 120 introductions = 1.7%) ($\chi^2 = 2.15$, $DF = 1$, $P = 0.14$), but field intruders were more likely to attempt escape by moving rapidly to one side of the test arena and attempting to climb out (9 of 96 = 9.4% vs. 2 of 120 = 1.7%; $\chi^2 = 6.56$, $DF = 1$, $P = 0.01$).

Data (Table 2) clearly demonstrate that intruders introduced from either lab-reared or field colonies elicit more aggression from resident ants than control intruders. No control ants were killed, whereas 18.8% (21 of 112) of the laboratory intruders were dispatched (test of percentages; $t = 5.17$, $DF = 158$, $P < 0.001$). In addition only 10.4% (5 of 48) of controls were physically detained by residents (i.e., elicited "hold/release," "hold," or "hold/sting"), compared with 54.5% (61 of 112) of lab-reared intruders ($\chi^2 = 26.90$, $DF = 1$, $P < 0.001$). Resident ants responded more aggressively to introductions of field ants than to introductions of lab-reared ants. Both the proportion of intruders killed (61 of 82 = 74.4% vs. 21 of 112 = 18.8%; $\chi^2 = 60.06$, $DF =$

TABLE 2. *S. invicta* NESTMATE RECOGNITION BIOASSAY SUMMARY[a]

Behavior	Observed frequency of resident behaviors		
	Control	Lab/Lab	Field/Lab
Hold/sting	0 (0.0)	1 (0.9)	21 (25.6)
Hold	0 (0.0)	20 (17.9)	40 (48.8)
Hold/release	5 (10.4)	40 (35.7)	15 (18.3)
Antennate/follow	18 (37.5)	28 (25.0)	6 (7.3)
No follow	25 (52.1)	23 (20.5)	0 (0.0)
Total	48 (100)	112 (100)	82 (100)

[a] Scores are frequencies of resident ant responses to (1) nestmates (control), (2) nonnestmates from other lab-reared colonies (lab/lab), and (3) nonnestmates from field colonies (field/lab). Percent total response is included in parentheses.

TABLE 3. RESIDENT RESPONSE (NO. INTRUDERS KILLED AND NO. INTRUDERS RELEASED) WHEN INTRUDER AND RESIDENT COLONIES ORIGINATE FROM SAME POPULATION OR DIFFERENT POPULATIONS (i.e., ALACHUA COUNTY, FLORIDA, VS. GULFPORT, MISSISSIPPI).[a]

Intruder origin	From same population		From different population		χ^2, $1DF$[b]
	Killed	Released	Killed	Released	
Lab	10	41	11	50	0.45
Field	27	11	34	10	0.41

[a] Chi-square values are the result of separate contingency table analyses of resident response to lab-reared intruders and field-collected intruders.
[b] Chi-square$_{(0.05)}$ = 3.84

1, $P < 0.001$) and the proportion of intruders physically detained (76 of 82 = 92.7% vs. 61 of 112 = 54.5%; $\chi^2 = 5.44$, $DF = 1$, $P = 0.02$) were significantly greater among ants introduced from field colonies. These data are homogeneous with respect to the sequence of trials (i.e., day one vs. day two) for both the proportion of intruders killed ($\chi^2 = 3.83$ $DF = 2$, $P = 0.15$) and the proportion detained ($\chi^2 = 2.34$, $DF = 2$, $P = 0.31$). Finally, not significantly different proportions of intruders were killed when intruders and residents were from the same population (i.e., Florida or Mississippi) or from different populations (Table 3).

Analysis of Cuticular Hydrocarbons. A total of 36 samples were analyzed by gas chromatography. Hydrocarbon patterns gave no evidence of hybridization events involving *S. richteri* (Vander Meer et al., 1986), and all colonies tested were therefore included in the analysis. The five major hydrocarbons (Figure 1) constituted 72–77% of the total cuticular extract. Univariate analysis revealed significant differences between laboratory and field colonies in the mean, normalized peak areas of peaks A, B, and E (Table 4). (Variances associated with peak means were not significantly different in the two types of

TABLE 4. MEAN (±SEM) NORMALIZED PEAK AREAS OF FIVE MAJOR *S. invicta* CUTICLE HYDROCARBONS IN LABORATORY ($N = 18$) AND FIELD ($N = 18$) COLONIES[a]

Peak	Lab	Field	T, $DF = 34$	ASL
A	0.209 (0.009)	0.165 (0.012)	2.81	0.008
B	0.268 (0.007)	0.301 (0.009)	2.80	0.008
C	0.170 (0.008)	0.183 (0.008)	1.21	0.235
D	0.194 (0.010)	0.166 (0.011)	1.84	0.074
E	0.164 (0.008)	0.203 (0.011)	2.80	0.008

[a] Univariate test statistics and attained significance levels (ASL) are also presented.

colonies.) When particular laboratory vs. field colony comparisons were made, individual areas of peaks A, B, and E were not always significantly different. However, the absence of a significant univariate peak area difference between individual field and laboratory colonies could not be statistically correlated with significantly reduced resident aggression in the recognition bioassay. For example, it was determined (Newman-Keuls' test; $\alpha = 0.05$) that 19 of the 36 field vs. laboratory bioassay combinations were between colonies with not significantly different normalized, mean peak areas for peak A. Yet, the proportion of intruders killed (36 of 45) was not significantly different from the proportion killed when intruder and resident colonies exhibited significantly different peak A areas (25 of 37 killed; $\chi^2 = 1.65$, $DF = 1$, $P = 0.20$). Similarly, not significantly different proportions of intruders were detained when colony pairs with significant peak B differences were compared with those exhibiting no significant differences (34 of 37 vs. 43 of 45 detained; $\chi^2 = 0.48$, $DF = 1$, $P = 0.49$).

Both parametric (discriminant function) and nonparametric (nearest-neighbor) analysis generated classifications in which the colony "blends" of the five major hydrocarbons were maximally correlated with colony class (i.e., field or lab origin). In the former analysis, a classification criterion based upon the pooled covariance matrix resulted in nine "misclassified" field colony samples, i.e., samples from three colonies that, based upon cuticular hydrocarbon pattern, were more appropriately classified as originating from laboratory-reared colonies. The nearest neighbor discriminant analysis produced identical results utilizing both Euclidean and Mahalanobis distances. In summary, the classification rules developed from the five chemical descriptors (peaks A–E) accurately classified only 50% of the samples. More importantly, of the 21 field intruders not killed by residents (Table 1) only nine originated from these three misclassified ("lab-like") colonies ($\chi^2 = 0.43$, $DF = 1$, $P = 0.51$).

DISCUSSION

Effect of Environment on Nestmate Recognition Cues. S. invicta workers reared under controlled, laboratory conditions respond less aggressively to nonnestmate conspecifics reared under the same conditions than they do to field-collected conspecifics. This phenomenon has been observed in other laboratories as well (Les Greenberg, personal communication). That this effect is not due to reduced aggressiveness overall is indicated by the almost total recognition capability observed when intruders were selected from field colonies (76 of 82 intruders detained). Behavioral differences between lab-reared and field intruders (see above) do not account for these data, although the bioassay is admittedly insensitive to subtle, social interactions such as alarm and recruitment. Overall, however, the data suggest that nestmate recognition cues of laboratory-reared *S. invicta* colonies were less distinctive than those of field col-

onies. These recognition factors or other colony-specific cues may be transferred to the substrate. This is suggested by the significantly greater preencounter escape response of field intruders, although an alternative explanation may be that lab-reared ants had learned that escape was impossible (John Sivinski, personal communication).

The effect of laboratory rearing on detection of nonnestmates supports the hypothesis that nestmate recognition in *S. invicta* is subject to environmental modification. Environmental factors known to affect nestmate recognition in social insects include diet (Lange, 1960; Jutsum, 1979), ambient odors (Renner, 1960; Free, 1961), and nest material (Lange, 1960). The lack of nest soil in lab-reared colonies used in this study removed potentially distinctive odor cues that could conceivably be transferred to the ants' cuticle. In addition, absence of nest soil exposed workers on a continuous basis to a homogeneous rearing-room bouquet that could have become incorporated into the cuticle (see also Shellman-Reeve and Gamboa, 1985). Without knowledge of field colony response to lab-reared intruders, one cannot determine to what extent laboratory rearing homogenizes environmentally determined recognition cues among laboratory colonies or precludes their full expression.

It should be noted that "innate" cues (i.e., those not affected by environment) also contribute to distinctive colony odor in *S. invicta*. Resident response to lab-reared intruders was significantly greater than resident response to controls (Table 1), indicating that detectable differences persisted despite 18 months of laboratory rearing. That locale of intruder origin had no measurable effect on resident aggressive response (Table 3) suggests that variability in genetically based recognition cues is minimal among North American populations. Whether this is a consequence of limited introduction events and genetic drift particular to *S. invicta* (Tschinkel and Nierenberg, 1983), or a more general phenomenon in ants is unclear.

The effect of environment on nestmate recognition in *S. invicta* suggests that colony odor in this species may be, in part, a dynamic phenomenon. If so, it is likely that some form of learning is an underlying mechanism of recognition (Fielde, 1903; Soulié, 1960; Kukuk et al., 1977; Breed, 1981; Carlin and Hölldobler, 1983; Morel, 1983). There are both costs and benefits to a flexible recognition system based on learning. While such a system may increase colony susceptibility to slave-making (i.e., dulotic) species (Wilson, 1971), it may facilitate efficient colony functioning when queens are multiply-inseminated or when, as is sometimes the case for *S. invicta* in North America (Glancey et al., 1973), colonies are polygynous. Dulosis involving *S. invicta* is undocumented.

Role of Cuticular Hydrocarbons. Cuticular hydrocarbons were of interest to this study for several reasons. To begin with, the experiments of Howard et al. (1980, 1982) argued strongly in support of cuticular hydrocarbons as interspecific recognition cues in the termite genus *Reticulitermes*. Second, Howard and Blomquist (1982) demonstrated that cuticular hydrocarbons were both spe-

cies- and caste-specific in *S. invicta*. In addition, Vander Meer and Wojcik (1982) observed that myrmecophilous beetles inquilinous in the nests of *S. invicta*, *S. richteri*, and *S. xyloni* acquired the species-specific hydrocarbon pattern of their host. They suggested that the predaceous beetles reduced the probability of detection by chemically mimicking the host (see also Howard et al., 1980). Finally, hydrocarbons represent 70–75% of all *S. invicta* cuticular lipids (Lok et al., 1975).

However, although differences between the cuticular hydrocarbon patterns of laboratory and field colonies were observed, these differences were inadequate predictors of resident ant response to nonnestmates in the recognition bioassay presented here. Specifically, a negative correlation between similarity of cuticular hydrocarbon pattern and intercolony aggression was not obtained. Rather, intruders from "misclassified" field colonies (i.e., those with hydrocarbon patterns statistically not unlike residents') elicited as much aggression as did intruders from correctly classified field colonies. The same conclusion resulted when individual hydrocarbon peaks were considered separately.

Possible explanations for these results include: (1) Cuticular hydrocarbons are, in fact, not nestmate recognition cues in *S. invicta*. (2) Cuticular hydrocarbons other than or in addition to those addressed in this study provide intraspecific nestmate recognition cues. (3) The major cuticular hydrocarbons do provide nestmate recognition cues, but other, environmentally influenced or acquired surface compounds (perhaps in concert with cuticular hydrocarbons) permit discrimination when hydrocarbons alone do not. Hypotheses 2 and 3 are not mutually exclusive, and each could explain the high levels of aggression directed at intruders from "misclassified" field colonies. It is possible that the major cuticular hydrocarbons represent a part of the more genetically controlled recognition cue profile. If so, it is not surprising that hydrocarbon pattern was such a poor predictor of environmentally based behavioral differences in this study.

Conclusion. Both innate and environmentally based chemical cues appear to affect nestmate recognition in *Solenopsis invicta*. This conclusion supports findings for other Hymenoptera (Wilson, 1971; Jutsum et al., 1979; Hölldobler and Michener, 1980; Discussion in Breed, 1983). It should be possible with the bioassay presented here to elucidate the environmental factors affecting recognition chemistry in this species. In addition, it has been demonstrated that the major *S. invicta* cuticular hydrocarbons cannot account for the dramatically different response of laboratory-reared colonies to field-collected and laboratory-reared workers, respectively. However, it cannot be concluded at this time that these compounds do not constitute a portion of the recognition profile mediating intraspecific interactions.

(Received November 10, 1985; accepted December 2, 1985)

Abstract—Incorporation of certain phytoecdysones (ecdysterone, polypodine B, and ponasterone A) into a semisynthetic artificial diet induces pathophysiological effects in larvae of the leek-moth (*Acrolepiopsis assectella* Zell., Acrolepiidae). The effects include lethality of the newly hatched, first-instar larvae; special ecdysial failures associated with the appearance of larvae with two head capsules; and developmental anomalies during metamorphosis. The effective range of dietary ecdysteroid, as evaluated by larval mortality, varies from 25 to 250 ppm. The EC_{50} value is 100 ppm for polypodine B and 130 ppm for ecdysterone. The dietary effects of the phytoecdysones are similar to the previously observed effects caused by the dried flowers, but not leaves, of the leek plant. However, the active compound of the leek flowers is a saponin.

Key Words—*Allium porrum* L., Liliaceae; *Acrolepiopsis assectella* Zell., leek-moth, Lepidoptera, Acrolepiidae, ecdysone, ecdysteroids, 20-hydroxyecdysone, 5,20-dihydroxyecdysone, 20-hydroxy,25-deoxyecdysone, ecdysial failures

INTRODUCTION

The larvae of the leek-moth are specialist feeders of the leaves of leek (*Allium porrum*). In the laboratory, they can be successfully reared on semisynthetic diets containing small amounts of dried leek leaves. It has been observed that substitution of the dried leaves by an equal amount of dried flowers causes

0098-0331/86/1000-1979$05.00/0

increased mortality of small larvae (Arnault, 1975). This action is occasionally associated with special symptoms of ecdysial failures, i.e., malformed larvae with two head capsules telescoped within the old exuviae (Arnault, 1975, 1979).

Although it is known that certain phytophagous insects became specialized to feed only on some parts of the host plant (Rosenthal and Janzen, 1979), the curious developmental anomaly characterized by larvae with two head capsules is rare. It has been induced experimentally in several other species of Lepidoptera, by rearing the larvae on the diets containing 50–100 ppm of various ecdysteroid compounds (Kubo et al., 1981, 1983; Kubo and Klocke, 1983). We have thus assumed that the flowers, but not the leaves, of the leek may contain some phytoecdysone that is responsible for these effects in larvae of the leek-moth. The assumption has been supported by phytochemical evidence, showing that the flowers of certain plants can contain more than 2% of phytoecdysones on a dry weight basis, while the leaves of the same plant contain only 0.2% or less (Achrem et al., 1973; Sláma, 1979). In this work, we have assayed in the diet of the leek-moth various concentrations of certain common phytoecdysones. The results have been compared with the previously described effects of the dried leek flower (Arnault, 1979).

METHODS AND MATERIALS

The methods of breeding *A. assectella* Zell. and the preparation of the artificial diets have been described previously by Arnault (1979). In the present experiments, we used glass test tubes 25 mm OD, 50 mm long. Each tube contained 5 ml of the artificial medium; the top was sealed by paper wool. After solidification and cooling, the diet in each tube was inoculated with 50–60 3-day-old eggs. The larvae maintained at 26–27°C hatched within 24 hr.

The ecdysteroid compounds tested were 20-hydroxyecdysone (ecdysterone), 5,20-dihydroxyecdysone (polypodine B) and 20-hydroxy,25-deoxyecdysone (ponasterone A). They are natural plant products (see Jizba et al., 1967). After addition of 4.5 ml of the freshly prepared, still-warm diet, the graded doses were supplied to the diet (0.5 ml) in 10% ethanolic solution. The content of each tube was then thoroughly mixed to give the final medium (Arnault, 1979).

Each concentration of ecdysteroid (except for ponasterone A) was assayed in duplicate series and the experiments were duplicated (4 × 50 larvae in each concentration). The results were evaluated at three-day intervals using the criteria of mortality and larval inability to ecdyse. The methanol extracts of leek flowers were assayed for ecdysteroid activity on ligated larvae of *Dermestes* according to the method of Sláma et al. (1974, p. 337).

RESULTS AND DISCUSSION

The addition of exogenous ecdysteroid into the diet of *A. assectella* resulted in an array of pathophysiological disorders. We have divided these syndromes into four categories: (1) death of the newly hatched first-instar larvae; (2) ecdysial failures in the young larval instars, i.e., larvae with two cuticles including two head capsules; (3) prothetelic effects in larvae that survived on ecdysteroid-containing diet until the 4th or 5th instar; and (4) developmental anomalies during metamorphosis.

The combined effects of ecdysteroid present in the diet can be expressed collectively by the rate of larval mortality. Figure 1 shows that the curves for larval mortality exhibit a common pharmacological dose–response pattern. The EC_{50} value is 100 ppm for 5,20-dihydroxyecdysone and 130 ppm for 20-hydroxyecdysone. Leek-moth larvae do not tolerate a dietary concentration of ecdysteroids higher than 250 ppm. With these high concentrations the newly emerged larvae of the first instar are unable to initiate feeding. In most cases these larvae perish without successful ecdysis. This response in the newly emerged larvae is similar to antifeeding or intoxication and apparently is related to the syndrome known as "hyperecdysonism" (see Williams, 1968).

The responses of the second category (ecdysial failures and appearance of larvae with additional head capsules) were responsible for most larval mortality

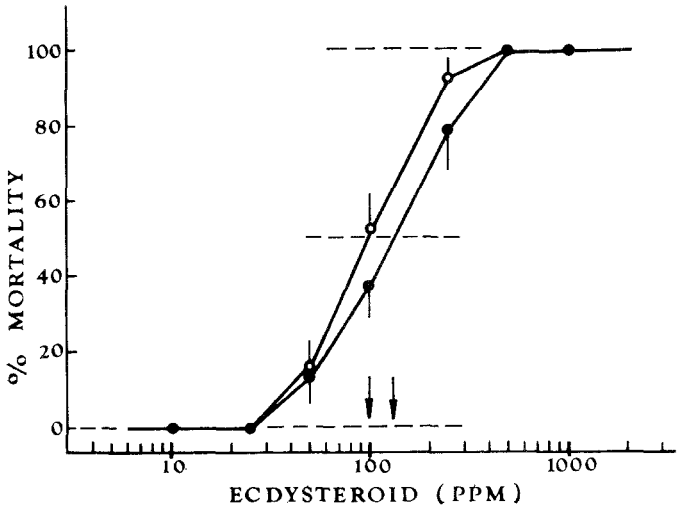

FIG. 1. Mortality of *A. assectella* larvae reared on artificial diet containing 20-hydroxyecdysone (solid circles) and 5,20-dihydroxyecdysone (open circles). Vertical bars are SEM, arrows indicate the respective EC_{50} values.

FIG. 2. Young leek-moth larvae exhibiting two head capsules and incompletely shed exuviae. These effects were induced with 100 ppm dietary 5,20-dihydroxyecdysone.

within a dose range of 100–250 ppm. The affected larvae remained enclosed within their old exuviae. In some cases, as shown in Figure 2, old exuvia was shed from some parts of the thorax or abdomen. However, these treated larvae were unable usually to withdraw the deformed mouth organs from the old head capsule. The latter remained attached permanently to the newly formed head and prevented feeding. The affected larvae had reduced or completely suppressed locomotory activity. The critical developmental stage for these effects to be elicited was the second larval instar. Larvae that succeeded for some unknown reason to ecdyse from a second to a third larval instar were also able to complete larval development.

The prothetelic effects (premature formation of pupal patterns in larvae) occurred occasionally among larvae that survived 50–100 ppm concentrations of ecdysterone or ponasterone A until the fifth larval instar. The characteristic features of prothetelic larvae were everted wing lobes covered with pupal cuticle (see Figure 3). Patches of brown, sclerotized pupal cuticle were also present commonly on the mouth organs, on the distal end of the larval abdomen, and on various parts of the thoracic segments. Prothetelies were not found in 5,20-dihydroxyecdysone-treated animals. By contrast, the largest incidence of the prothetelies (over 15%) occurred in ponasterone A-treated larvae.

The increased mortality of the pupae and pharate adults (effects of the fourth category) has not been included in calculating dose–response relation-

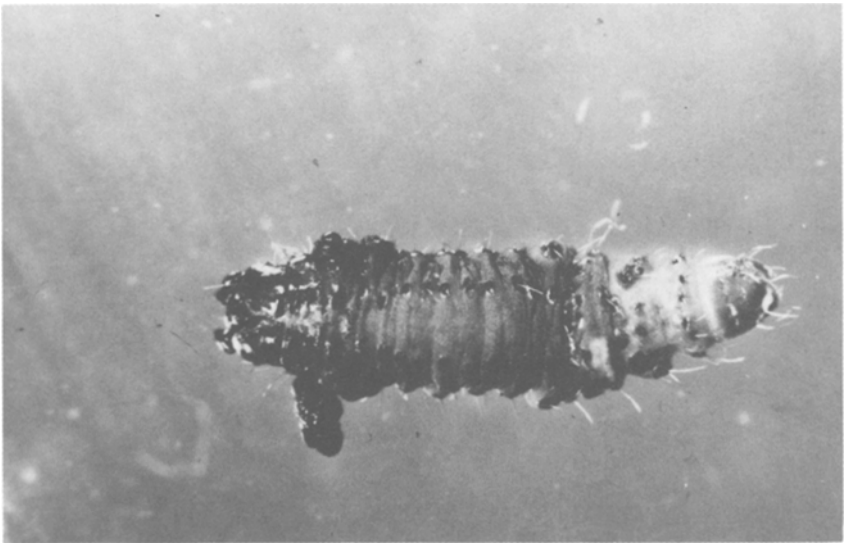

FIG. 3. Typical prothetely of the last-instar larva of the leek-moth. These effects were generated with 100 ppm dietary 20-hydroxy,25-deoxyecdysone. Note the everted and sclerotized wing lobes and deformed mouth parts.

ships in Figure 1. With a 100 ppm concentration of ecdysteroids, we observed that approximately half the pharate adults died enclosed within their pupal cuticular case. Since we have focused our attention mainly on larval effects, these results should be taken as preliminary.

Careful evaluation of our results obtained with ecdysteroids and comparison with the previously described effects of leek flowers (Arnault, 1979), led us to conclude that the dietary action of ecdysteroids in the leek-moth was indeed quite similar, and in certain respects actually identical, with the dietary action of the dried flowers of the leek. This prompted us to assay the ecdysone activity in the methanolic extracts of leek flowers. To this end, we used the assay on ligated terminal instar larvae of *Dermestes maculatus*, which are sensitive to less than 0.01 μg of ecdysterone equivalents and, in addition, respond positively to a number of ecdysone analogs (Sláma et al., 1974). However, the assays revealed an absence of ecdysteroid activity in the flower extracts of leek, although we used 200–300 μg of the dried methanolic extracts. This suggested that the effects of the leek flowers were not due to the presence of an unbound phytoecdysone.

Since the discovery of juvenile hormone activity in balsam fir (Sláma and Williams, 1966), this topic has been frequently discussed and reviewed (Sláma, 1969, 1979; Williams, 1970; Rees, 1971; Beck and Reese, 1976; Harborne,

1977; Bergamasco and Horn, 1984). Experimental evidence that ecdysteroids may cause adverse effects in insects when consumed has been provided by Robbins et al. (1970). The wide distribution of phytoecdysones (ecdysteroids) in plants is now generally known (Bergamasco and Horn, 1984), although some authors still expressed doubts about their real ecological importance (cf. Beck and Reese, 1976).

Our results in *A. assectella* are fully consistent with the observations of Kubo et al. (1981, 1983) on the dietary action of ecdysteroids in larvae of other lepidopteran insects, *Spodoptera*, *Pectinophora*, and *Bombyx*. Our observations are in accord with the reported dietary effects of ecdysteroids in larvae of various dipteran species (Singh and Russell, 1980; Singh et al., 1982; DeClerck and DeLoof, 1983). In all cases, we find the effective dietary range of ecdysteroid between 25 and 100 ppm. This range is comparable to the reported plant ecdysteroid concentration (0.001–0.1% on a dry weight basis; see Sláma, 1979). This supports the supposition that the ecological importance of ecdysteroids in insect–plant interactions cannot be ignored, especially when we consider that dry flowers of certain plants may contain up to 2.9% ecdysteroid (Achrem et al., 1973). These dietary interactions would be likely realized in minute first- and second-instar larvae. However, since these stages are rarely investigated, these effects can be overlooked.

The second larval instar evidently represents the stage most susceptible to the dietary effects of ecdysteroids. The second larval instar has certain unique properties, including the largest relative size increment, shortest duration of the interecdysial period, and the most active metabolic rate (Morohoshi, 1957; Sláma et al., 1974). In *Galleria*, ecdysteroids almost immediately cause cessation of feeding, arrest somatic growth, and reduce drastically respiratory metabolism of young larvae (Sláma, 1982).

Certain developmental effects of insect hormones can be nonspecifically mimicked by various hormonomimetic chemicals. This is mainly true for a number of structurally unrelated, mostly synthetic, bioanalogs of juvenile hormone (cf., Henrick, 1982; Sláma, 1985). By contrast, the action of ecdysone in insects can be simulated only by a limited group of structurally related ecdysteroids, all of which possess the essential steroid nucleus (Bergamasco and Horn, 1984). Our results show, however, that the dietary effects of ecdysteroids can be elicited by a compound from leek flowers that has no ecdysteroid activity in direct bioassays. Recent chemical analysis of leek floral natural products has revealed the active component to be a previously known saponin, aginosid (Harmatha et al., 1986). Experiments performed in the leek-moth with a common saponin, digitonin (Arnault and Mauchamp, 1985) show effects similar to those obtained with leek flowers or ecdysteroids. These data indicate that the described larval effects, such as reduced feeding, inability to ecdyse, or partial ecdysis in small larvae, which result in lethality (formation of larvae with two head capsules), cannot be regarded as the specific effects of the ecdysteroids.

By contrast, induction of the prothetely, produced in our experiments with some ecdysteroids but never with the saponins or flower extracts, could be regarded as a hormonal imbalance specifically caused by the ecdysteroids.

(Received August 2, 1985; accepted December 4, 1985)

Abstract—Food search behavior in Arctic charr (*Salvelinus alpinus*) to extracts of granulated food was quantified and compared with the response to solutions of amino acid mixtures. The concentration of each of 18 amino acids was analyzed in the food extract and similar pure amino acid solutions were prepared. Earlier published electrophysiological data and the data of concentrations in the test area were used to order the amino acids with respect to their presumed contribution to the stimulatory effect of the food extract. The 18 amino acids were tested collectively (18 aa) or were divided into two groups, one group containing 7 amino acids (7 aa) which was presumed to have a high stimulatory effect and the other group containing the remaining 11 amino acids (11 aa). The solutions of 7, 11, and 18 aa were stimulatory at concentrations between 2 and 5×10^{-6} M, but no significant responses were observed at $2\text{–}5 \times 10^{-9}$ M. This can be compared with the food extract which elicited response at all concentrations tested, i.e., the total concentrations of 18 amino acids were 5×10^{-9}, 5×10^{-8}, 5×10^{-7}, and 5×10^{-6} M. The response to the 18 aa solution was compared with the food extract and was shown to be significantly lower at 5×10^{-9} M but not at 5×10^{-6} M. These results show that amino acids induce food search behavior in Arctic charr, but there are other substances which also contribute to the stimulatory effect of the food extract.

Key Words—Amino acids, Arctic charr, fish, food extract, food search behavior, *Salvelinus alpinus*.

INTRODUCTION

Chemical stimuli induce food search behavior in many species of fish (e.g., Bardach and Villars, 1974; Dempsey, 1978; Atema, 1980; Atema et al., 1980;

0098-0331/86/1000-1987$05.00/0

Kamchen and Hara, 1980). Amino acids are important as stimuli, and they are detected both by olfaction and taste. The most important chemical sense in food search behavior varies from one species to the other. Taste is of major significance in food search and orientation in species of fish with taste buds on barbel and body flanks (Bardach et al., 1967; Atema, 1971, 1980; Holland, 1978). In yellow fin tuna (*Thunnus albacares*) food search behavior is induced by prey odor and amino acids with the aid of the olfactory sense. The tuna was most excited by odor from the species of sardine on which it was feeding at the time (Atema et al., 1980). Salmonids also respond with food search behavior to a supply of extract of their normal food (McBride et al., 1962; Kamchen and Hara, 1980) but hitherto no studies have been published which deal with the importance of free amino acids during the search for food.

Kamchen and Hara (1980) found that in white fish (*Coregonus clupeaformis*) food search behavior and attraction to water containing food extract is mediated by olfaction. The distribution of taste buds in salmonids is restricted to the oral cavity (De Kock, 1963; Sutterlin and Sutterlin, 1970; Meyer-Rochow, 1981; Ezeasor, 1982; Marui et al., 1983). Adron and Mackie (1978) found that L-amino acids are important as gustatory feeding stimulants in rainbow trout (*Salmo gairdneri*). The aim of this study was to quantify food search behavior in juvenile Arctic charr (*Salvelinus alpinus*) to extract of their normal food, i.e., granulated food pellets, and compare it with the response to mixtures of amino acids.

METHODS AND MATERIALS

One-year-old hatchery-raised Arctic charr (*Salvelinus alpinus*), deriving from wild fishes in Lake Torrön, Jämtland, Sweden, were used as test fish (2.5–6.0 g, $N = 40$). They were kept in a trough and fed daily at 4 PM with Ewos "Salmon Feed Extra" corresponding to 1% of body weight.

The chemical composition of tap water has been given by Pärt and Svanberg (1981). The water is rich in calcium, 2.8 mM Ca^{2+}. The water temperature in the test area and trough was measured daily. It increased during the experimental period, March 18, 1982, to June 9, 1982, from 7.5 to 9.8° C. The pH in the test area, measured weekly, was 8.0–8.1.

Test Apparatus. In order to quantify food search behavior in Arctic charr, we observed the upstream movement of specimens from their territory while supplied food extracts and amino acid mixtures. Tests were performed in a modified fluviarium with a group of five fish at a time (Höglund, 1961) (Figure 1). Screens of black plastic sheeting were placed in the downstream end of the test area to function as shelters and to decrease the risk that a dominant fish might interact with the others and affect their behavior and therefore their response during the tests. A few tests were omitted as the dominant fish was

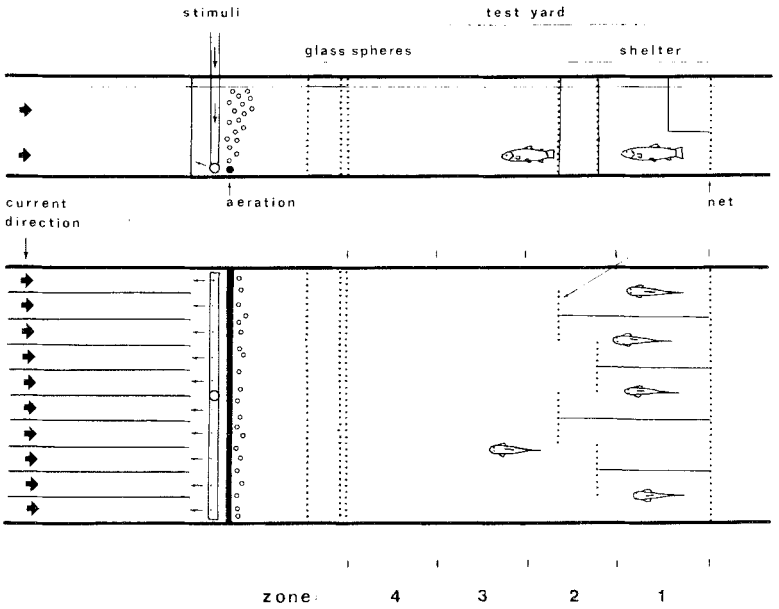

FIG. 1. The modified test area of the fluviarium. The positions of fish were usually noted as shown in the figure except when there was a supply of stimuli inducing the charr to swim upstream. The dominant individual was commonly located in front of screens which functioned as shelters to subordinate fish. Four zones used for analyzing upstream movement of fish were defined by lines on the bottom transverse to the direction of flow.

aggressive and chasing subordinate fish. During chemical stimulation, the test fishes were often observed to seize particles from the bottom. Changes in locomotor activity and direction of body axis were also studied, but these responses were not as distinct as upstream movement. We observed in a pilot test that food extract pumped into a holding tank with three-year-old Arctic charr gave a very strong response; i.e., increased locomotor activity and dispersion of the group.

The bottom of the test area was white. The flow rate of water was 0.8 cm/sec (17.1 liter/min). The light was turned on at 7:00 AM and off at 5:30 PM, both in the test area and in the trough. The light intensity in the test area just above the water surface was 135 $\mu W/cm^2$ (86 lux).

Control and test solutions were evenly distributed over the breadth of the fluviarium with two interchangeable T-tubes (diam. 10 mm) with 10 holes (diam. 0.5 mm) in each. To improve the mixing of solutions in tap water, the water stream passed a curtain of air bubbles and cage of stainless steel containing glass spheres (diam. 5–7 mm) before entering the test area. The admixture of control and test solutions in the test area was analyzed in tests with dye solutions. Samples of 1 ml each were taken every 10 sec during a 5-min period

at six different places both at the up- and downstream ends of the test area. The difference in dye concentration in different parts of the area was smaller than 7% according to absorbance measurements.

Five fishes (size difference < 1 g) were placed in the test area 60 hr before the initial test. After this adaptation period, tests were performed with the fish-group during five days. The fish were fed once a day (1% of the body weight) and food was supplied through a tube after the last test. The tube was located close to the front net of the test area just above the water surface. Food extract was supplied through the T-tubes at the same time as feeding the test fish. The concentration of food extract varied from day to day but corresponded to one of the tested concentrations.

Experiments. Four tests were performed each day, at 9 AM, 11 AM, 1 PM, and 3 PM. Each test lasted for 20 min and was divided into the following four periods of 5 min: (1) Adaptation period (A). No solutions were supplied. (2) Control period (C1). Control solution was supplied (pure water) through a T-tube placed in the fluviarium in the beginning of the period. (3) Test period (T). Control or test solution was supplied through a T-tube in the same way as in C1 but with another T-tube. (4) Control period (C2). Control solution (pure water) was supplied through the same T-tube as in C1.

Each test solution was tested with at least two different groups of fish and the order of experiments with control and test solutions in T was determined by a pseudorandom scheme. The test fish were photographed every 10 sec (started in A) with a film camera connected to a flash filtered through Kodak Wratten gelatin filter No. 89B (no transmittance < 670 nm, cf. Kodak Filters publ. 1978) to reduce visual disturbances (Ali, 1975).

Analysis of Behavioral Response. The test area was divided into four equal zones by lines drawn on the bottom transverse to the stream direction (Figure 1), and numbered from 1 (furthest downstream) to 4 (furthest upstream). The snout position of each fish was recorded, and the behavioral response for the entire group during a test period was calculated by the following formula: Zone value $= Zv = [(n_1 \times 1) + (n_2 \times 2) + (n_3 \times 3) + (n_4 \times 4)]/(n_1 + n_2 + n_3 + n_4)$; where n_i = number of observations in zone "i" ($i = 1$–4) during a period. The initial four photo-recordings, which corresponded to the time (ca. 30 sec) for the frontal line of the solutions to reach the median part of the test area (tested with dye), were excluded from the calculations of the *Zv*s of each period. A mean zone value (*MZv*) was calculated on the basis of the *Zv*s for each of the four periods (A; C1; T; C2) for all tests with the same solutions. All *MZv*s are given in Figure 2.

Statistical treatment was performed in four different ways: (1) *Zv* for C1 was compared with the corresponding value for period T in the same test (*Zv*T − *Zv*C1). The difference between *Zv* for T and C1 is positive if the fish respond to the solution by swimming upstream. (2) *Zv* for C1 was compared with the corresponding value for A in the same test (*Zv*C1 − *Zv*A). All tests performed

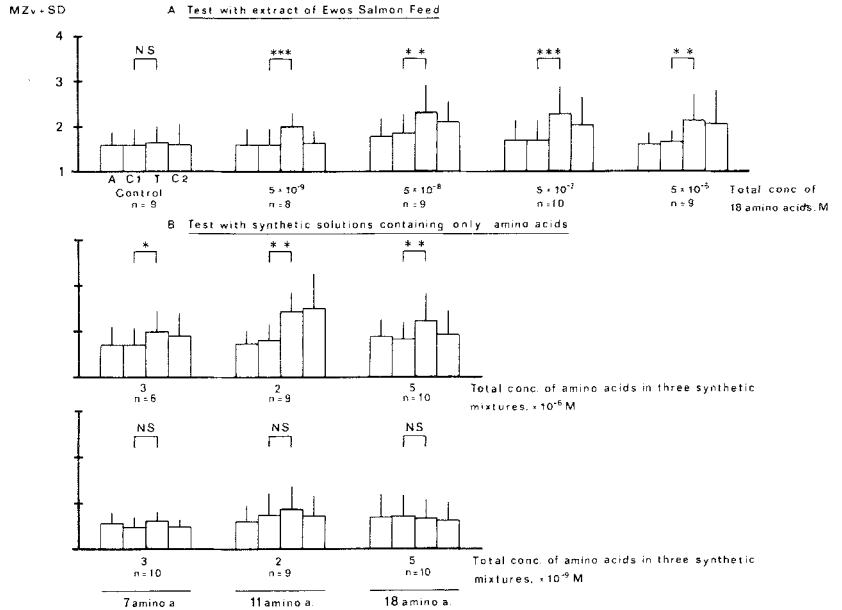

FIG. 2. Mean zone values ($MZv \pm SD$) for separate 5 min. periods in tests with different solutions supplied during the T period. (A) Control tests (pure water) and tests with food extract. The total concentration of 18 amino acids is noted. (B) Experiments with solutions of 7, 11, or 18 amino acids acting as stimuli (see Table 1). A paired t test (one tailed) was used in order to find out whether fish respond to the test solution by swimming upstream. NS = $P > 0.05$; * = $P < 0.05$; ** = $P < 0.01$; *** = $P < 0.001$.

were included in the same analysis ($N = 99$). (3) Zv for C1 and C2 in the same test were compared in order to examine whether the response induced in period T was still significant in C2 ($ZvC2 - ZvC1$). A paired t test (Colquhoun, 1971) was used in the comparisons for 1–3. (4) A one-way ANOVA was performed to examine differences in responses to test solutions (Sokal and Rohlf, 1969). The ($ZvT - ZvC1$) value of each test was used as an observation.

Test Stimuli. The normal fish food, Ewos Salmon Feed Extra, was ground and dried at 40°C. The pulverized food was suspended in distilled water and homogenized (Ultra-Turrax). The suspension was centrifugated at 20,000g during 10 min, and the supernatant was used as crude food extract solution. The solution was divided in small aliquots and kept in a freezer (−20°C). The crude extract was prepared in a total quantity, which was sufficient for all tests performed. The free amino acid content in this extract was analyzed using an amino acid analyzer, Durrum 500 (Eaker, 1970). The mixtures of pure amino acids in distilled water were prepared on the basis of this analysis.

The method used for amino acid analysis cannot discriminate between

serine, asparagine, and glutamine. Instead it resulted in a total concentration for these three amino acids which was divided into three equal parts (69.1×10^{-6} M each) in the preparation of the amino acid solution. The 18 dissolved amino acids were divided into two groups according to their expected significance for inducing food search behavior. The expected significance was based on threshold concentrations of the olfactory sense in Arctic charr for each amino acid observed in an electrophysiological study (Belghaug and Døving, 1977) and the amino acid concentrations in the test area (quotient: conc. in the test area/electrophysiol. threshold) during supply of the highest concentration of food extract, i.e., 5×10^{-6} M of 18 amino acids in the test area. Leucine and valine, due to their high concentration in the crude extract (only alanine had a higher concentration), were included in the group which was expected to have a great effect, although the quotient (conc. test area/electrophysiol. threshold) was less than one for both (0.3 and 0.7, respectively).

Threshold concentrations observed in a corresponding study with rainbow trout (Hara, 1982) were used when results with Arctic charr were lacking (Arg, Gly, Ile, Thr, Tyr, Val). No information on the threshold concentrations of aspartic acid (Asp) and phenylalanine (Phe) was available. These amino acids are relatively weak olfactory stimuli at 10^{-4} M in rainbow trout and, at this concentration, were ranked together with L-amino acids with thresholds between 10^{-6} and 10^{-5} M (Hara, 1973, 1982). The threshold concentration of Asp and Phe was assumed to be 10^{-6} M, the same as for glutamic acid in Arctic charr shown by Belghaug and Døving (1977).

Two different test solutions were prepared: one containing 7 amino acids (7 aa) which were presumed to contribute greatly to the stimulatory effect of the food extract (quotient range: 0.30–3.46; median: 1.50), and the other solution containing the remaining 11 acids (11 aa) (quotient range: 0.002–0.39; median: 0.05). A third solution contained all 18 amino acids (18 aa). The mixture ratios in the different solutions were the same as in the original extract. Amino acid solutions were kept in small aliquots in a freezer (−20°C). The three different amino acid solutions were tested in two different concentrations in the test area, namely, 3×10^{-6} and 3×10^{-9} M with 7 aa; 2×10^{-6} and 2×10^{-9} M with 11 aa; 5×10^{-6} and 5×10^{-9} M with 18 aa.

The food extract was tested at four concentrations, 5×10^{-6}, 5×10^{-7}, 5×10^{-8}, and 5×10^{-9} M, of the 18 amino acids. These concentrations were obtained by calculating the dilution of crude extract, i.e., in a 1000-ml glass beaker (75 ml crude extract + 925 ml pure tap water, 7.5 ml crude extr. + 67.5 ml distilled water + 925 ml tap water, and so forth) and then in the fluviarium (165 ml/min to 17.1 l/min), i.e., approximately 1400 times dilution of the highest crude extract concentration tested (Table 1). Control and amino acid solutions contained the corresponding amount of distilled and tap water as given for food extract.

Control, amino acid, and crude extract solutions were supplied from a

[a] The content of each aa in the test area is given for the highest concentration of crude extract tested. Electrophysiological thresholds are noted. The 18 aa analyzed were divided into two groups, 7 aa and 11 aa, presumed to have a major and a minor contribution, respectively, to the stimulatory effect of the crude extract. For further explanation see Materials and Methods.

[b] B & D = Belghaug and Døving (1977); H = Hara (1982).

[c] Ser + Asn + Gln = 207.3 × 10^{-6} M in crude extract.

1000-ml glass beaker in which the solutions were continuously mixed with a magnetic stirrer. Test and control (dist. water) solutions were pumped into the fluviarium at a rate of 165 ± 5 ml/min.

RESULTS

All concentrations of food extract tested induced upstream movement in the fish (Figure 2). Amino acid solutions with 7, 11, or 18 amino acids (7 aa, 11 aa, or 18 aa) induced a response at the highest concentration level, 10^{-6} M, but none of these solutions gave a significant response when the total amino acid content was reduced to a level of 10^{-9} M.

No significant difference in zone value (Zv) between period A and C1 ($t = 1.12$, $P > 0.05$, $df = 98$) was noted, which indicates that pure tap water

TABLE 2. ONE-WAY ANOVA TO EXAMINE DIFFERENCES IN FOOD SEARCH RESPONSE IN CHARR INDUCED BY DIFFERENT CONCENTRATIONS OF FOOD EXTRACT AND AMINO ACID SOLUTIONS[a]

[a] Tests with control solutions are included in the ANOVA. The difference in *Zv* between T and C1 in one test (*Zv*T - *Zv*C1) was used as an observation. The proportion of each amino acid was the same as in food extract, which is shown in Table 1.
[b] NS = $P > 0.05$; * = $P < 0.05$; ** = $P < 0.01$; *** = $P < 0.001$.

through the T-tube did not influence the fish. Comparisons between *Zv* for C1 and C2 reveal that fish did not return to the positions they occupied in period C1, after the supply of food extract at an amino acid concentration of 5×10^{-7} M in period T ($0.01 < P < 0.02$). Moreover, when testing food extract of 5×10^{-6} and 5×10^{-8} M, respectively, *Zv* for C2 was significantly higher than for C1 ($0.05 < P < 0.1$). *Zv* for C2 was significantly higher than for C1 when using a solution of 11 aa at 2×10^{-6} M ($0.02 < P < 0.05$).

No difference in response to varied concentrations of food extract was found (Table 2). The response to the food extract was significantly stronger than the response to the corresponding 18 aa solution at the lowest concentration (5×10^{-9} M) but not at the higher concentration (5×10^{-6} M). A significant difference in response was observed when comparing all three amino acid solutions at the high concentration level (10^{-6} M) with all amino acid solutions at the low level (10^{-9} M), but there was no difference between amino acid solutions (7aa vs. 11aa vs. 18aa) at the same concentration level. Neither was there any difference between 7aa and 11aa at the same concentration level.

DISCUSSION

The results of this study show that pure amino acid solutions do induce food search behavior in Arctic charr. There are, however, some other substances in addition to the 18 amino acids analyzed which are important in in-

ducing the behavior as the lowest concentration of the 18 aa solution (5×10^{-9} M) did not have any stimulatory effect when compared to food extract at the corresponding amino acid concentration. This is the first study which deals with the significance of mixtures of amino acids, in the same proportions as in food, for the induction of food search in a salmonid species.

Earlier studies with other fishes have shown that a great part of the stimulatory effect of food extract is due to free amino acids, but for many species a complete extract is a more potent stimulus than single or mixed amino acids (Steven, 1959; Hashimoto et al., 1968; Konosu et al., 1968; Carr and Chaney, 1976; Pawson, 1977; Harada and Ikeda, 1984). Ammonia, ornithine, L-cysteine, and L-cystine were not included in the synthetic solutions but may contribute to the strong stimulatory effect of the food extract (Steven, 1959; Hara, 1973, 1977; Harada and Ikeda, 1984). The crude extract contained ammonia (3190.1×10^{-6} M) and ornithine (76.0×10^{-6} M), which resulted in a concentration of 2×10^{-6} M and 5×10^{-8} M, respectively, in the test area when testing the highest extract concentration. L-Cysteine and L-cystine were not analyzed in the crude extract.

In addition, betaine is important as a feeding stimulant and as an attractant in some species of fish (Carr and Chaney, 1976; Mackie et al., 1980; Mackie, 1982). This substance is a weak olfactory stimulus in rainbow trout (Hara, 1976), and Adron and Mackie (1978) found that betaine is of minor importance as a feeding stimulus for rainbow trout.

We did not notice any "dose–response" relationship showing increased response to higher concentrations of food extract. This might be due to the fact that all concentrations tested induced maximum response. There is also the possibility of an "all or nothing" response which means that the fish respond to the stimuli by swimming upstream irrespective of concentration, provided that the threshold concentration is exceeded. It is likely that the specimen in the test group which has the keenest sense of smell and is motivated by hunger initiates the response which is transmitted to the others in the group (cf., Ringler, 1979). An "all or nothing" response to chemical stimuli has been observed in a freshwater catfish (*Ictalurus punctatus*) (Holland and Teeter, 1981).

The presumed low stimulatory solution containing 11 aa was as effective as the high stimulatory solution with 7 aa. The reason may be that the behavioral thresholds are much lower than electrophysiological thresholds and the total amino acid concentrations of the two solutions are the same. But even if each amino acid may not reach its threshold concentration in the 11 aa solution, the mixture may have a stimulatory effect due to additive and synergistic interaction between different amino acids. Studies with radioactively labeled amino acids and with electrophysiological methods have shown that different amino acids may bind to the same receptor site (Cagan and Zeiger, 1978; Brown and Hara, 1981; Caprio, 1982; Hara, 1982). Caprio (1982) studied the electrophysiological response of the olfactory epithelium to amino acid stimulation and distin-

guished by cross-adaptations only a few types of receptor sites, and each site had the highest affinity for a special group of amino acids.

Although salmonids depend a great deal on vision for detection and capture of prey (e.g., Ringler, 1979; Wankowski, 1981), chemical stimulants are of some importance (McBride et al., 1962; Kamchen and Hara, 1980). Their dependence on olfaction should increase in habitats with poor light conditions. Arctic charr populations in deep lakes are often present as shallow and deep living forms or genetically different stocks (Nilsson and Filipsson, 1971; Johnson, 1980; Hammar, 1984). In some Arctic charr populations, different ages are segregated into separate habitats (Klemetsen and Grotnes, 1980; Hammar, 1984). For example the S-charr in Lake Torrön, the charr studied in this experiment, have been shown to make habitat shifts during the life cycle with classes 1+ and 2+ living benthic in deep water (Hammar, 1984). The charr may detect enhanced ammonia and amino acid concentrations and other substances also emitted by their food organisms (Gardner and Miller, 1981; Bengtsson, 1982), giving rise to arousal followed by increased locomotor activity in connection with food search behavior.

FLAVANONE GLYCOSIDES AS OVIPOSITION STIMULANTS IN A PAPILIONID BUTTERFLY, *Papilio protenor*

KEIICHI HONDA

Seishô Biological Laboratory
1-3-11 Naka-cho, Odawara 250, Japan

(Received September 11, 1985; accepted December 6, 1985)

Abstract—Identification of chemical compounds responsible for the oviposition behavior in a Rutaceae feeder, *Papilio protenor demetrius*, was undertaken with the epicarp of sour orange (*Citrus natsudaidai*) which exhibited potent stimulatory activity as did its leaves for egg-laying by the females. The stimulants were present in the hydrosoluble fraction, and the kairomonal activity displayed by the peel was regarded as originating from the synergistic effect of the total chemical complex. One of the active compounds was identified as a flavanone glycoside, naringin (naringenin-7β-neohesperidoside), which, although showing no appreciable effectiveness when bioassayed alone, elicited positive response at the concentration of 0.2% either when admixed with other unidentified components or provided the females had been conditioned with them in advance. Another flavanone glycoside, hesperidin (hesperetin-7β-rutinoside) that was contained in a trace amount in the peel also had a positive effect comparable to that of naringin under similar conditions, while their corresponding aglycones were less active or inactive. In contrast, a flavone glycoside, rhoifolin, coexisting in the peel, and some other flavones and flavonols tested as possible candidates for oviposition stimulants were all found entirely ineffective.

Key Words—Oviposition stimulant, *Papilio protenor*, Lepidoptera, Papilionidae, flavanone glycoside, naringin, hesperidin, synergy, *Citrus natsudaidai*.

INTRODUCTION

A survey of numerous investigations so far conducted on oviposition behavior in many butterfly species covering major families such as Pieridae, Papilionidae, Nymphalidae, and Danaidae reveals that the oviposition sequence in gen-

0098-0331/86/1000-1999$05.00/0

eral consists of the following successive phases: (1) Searching for host plants guided by visual and/or olfactory cues, (2) semirandom or nonrandom (where search image is formed) alighting on plants, (3) drumming on the surface of foliage with foretarsi for the purpose of discrimination and recognition of the host plant, and (4) abdominal curling and probing appropriate ovipositional site with the ovipositor extruded, followed by egg deposition (Chew and Robbins, 1984).

Recent work has documented that in the incipient step of oviposition behavior certain butterflies primarily utilize leaf shape to visually distinguish potential larval food plants from manifold vegetation of which the majority would be unsuitable for larval growth and to enhance the frequency at which they encounter the host plants (Benson, 1978; Rausher, 1978; Stanton, 1982). In selecting the ovipositional sites, females of some species appear to be affected also by the color of leaves of host plants (Ilse, 1937; Vaidya, 1969; Saxena and Goyal, 1978) or by the presence of previously laid conspecific eggs or egg mimics on plants (Rothschild and Schoonhoven, 1977; Rausher, 1979; Shapiro, 1981; Williams and Gilbert, 1981).

Despite the profound involvement in host seeking of visual stimuli and, in some cases, of volatile chemicals emitted by host plants which attract preovipositional females (Saxena and Goyal, 1978; Feeny et al., 1983), it is well established in Pieridae and Papilionidae that dominant stimuli acting in the final stage of host selection at close range as the cues permitting the females to assess the suitability of the plant they landed on are secondary plant metabolites. These are liberated during drumming, are perceived by foretarsal chemoreceptors and induce oviposition (David and Gardiner, 1962; Nishida, 1977; Ichinosé and Honda, 1978; Saxena and Goyal, 1978; Rodman and Chew, 1980; Abe et al., 1981; Feeny et al., 1983). The importance in host recognition of tarsi, especially foretarsi, which are endowed with chemotactile sensory receptors, is fully substantiated in several butterfly families, and their external morphology has been examined microscopically (Myers, 1969; Ma and Schoonhoven, 1973; Calvert, 1974; Ichinosé and Honda, 1978; Stanton, 1979; Feeny et al., 1983).

However, insufficient knowledge of the chemical basis for differential response of ovipositing females to various plants has been accumulated (Nishida, 1977; Ichinosé and Honda, 1978; Abe et al., 1981; Feeny et al., 1983). Only a few compounds have been identified as a trigger for abdominal curling from which egg-laying ensues. Sinigrin (allylglucosinolate) has been reported to stimulate oviposition in *Pieris brassicae* (David and Gardiner, 1962) and *P. rapae* (Renwick and Radke, 1983). Recent study with *Papilio xuthus* (Ohsugi et al., 1985) has revealed that the ovipositional response is elicited by a flavone glycoside, vicenin-2 (6,8-di-C-β-D-glucopyranosylapigenin), which, however, was effective only when admixed with other, as yet unidentified, components.

The present paper reports on the chemical compounds that evoke egg-laying from an oligophagous papilionid butterfly, *Papilio protenor*, which in na-

ture exclusively feeds on specific plants in the limited range of genera, *Citrus* (main), *Poncirus*, *Fagara*, and *Zanthoxylum* belonging to the family Rutaceae.

METHODS AND MATERIALS

Insects. Female butterflies of *Papilio protenor demetrius* were obtained from stock cultures maintained in our laboratory, or collected in the fields in Kanagawa Prefecture. They are of the same population which infests principally *Citrus unshiu* and *C. natsudaidai* in nature.

Extraction and Fractionation of Active Compounds. The epicarp of *C. natsudaidai* was extracted with ca. threefold amount of methanol at room temperature for a month. Female butterflies exhibited positive response to the methanol extract, suggesting that the active substance(s) inducing oviposition is present in the extract. The methanolic extract was concentrated in vacuo below 50°C. The residue (13.3 g), dissolved in 100 ml of water, was extracted with three 50-ml portions of isobutanol. The aqueous layer (fraction 2, 11.7 g) was subjected to ultrafiltration at a level of mol wt 1000 with a membrane filter (UH-1, Tôyô Roshi Co., Ltd.) to give two fractions: one (0.7 g) containing compounds with a molecular weight of more than 1000 (fraction 3) and the other (11.0 g) composed of smaller molecules (fraction 4). An aliquot of fraction 4 (1.5 g) was further fractionated by reverse-phase chromatography on a ODS column (LRP-2, 45 μm, Whatman Inc.; 2 cm ID $\times$ 30 cm) yielding fractions 5 (1.36 g), 6 (0.03 g), 7 (trace), 8 (0.06 g), and 9 (trace). The column was eluted stepwise with methanol–H_2O (20:80), methanol, and acetone, successively. The schematic procedure for separation is shown in Figure 1.

Authentic Chemicals. Commercially available naringin and hesperidin (Tokyo Kasei Kogyo Co., Ltd.) were recrystallized from water and pyridine, respectively. Naringenin, rutin (Tokyo Kasei Kogyo Co., Ltd.), hesperetin, rhoifolin, apigenin, diosmin, and kaempferol-7-neohesperidoside (Sigma Chemical Co.) were all used without further purification.

Bioassay for Ovipositional Activity. Artificial green plastic leaves, shaped like a compound leaf (25 cm long) consisting of 15 fusiform "foliole" (16 mm long $\times$ 11 mm wide), were dipped into aqueous methanol solution of a test sample of a given concentration and air-dried at room temperature to remove methanol. The artificial leaves were remoistened by spraying distilled water on the surface and presented to 3- to 10-day-old fertile females, which, prior to the experiments, had been fed with 10% aqueous sucrose and kept in a transparent plastic cage (25 $\times$ 35 cm; height, 15 cm) that permits them free flight. Appraisal of positive response was based on the following criteria: release of the sequential oviposition behavior usually observed in nature that consists of drumming on a leaf with forelegs and subsequent abdominal curling followed by settling of the ovipositor in contact with the underside of the leaf. The fe-

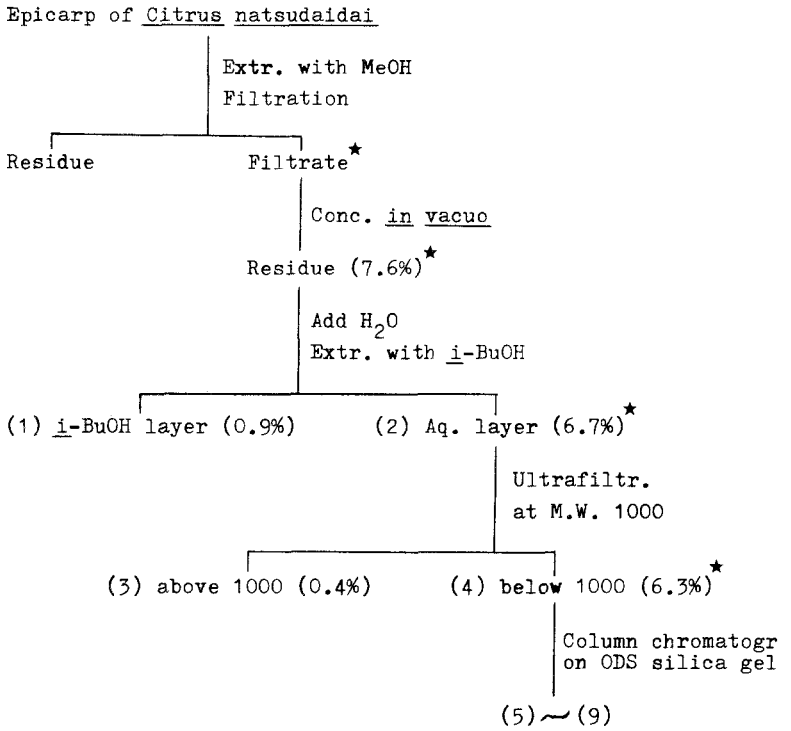

FIG. 1. Schematic procedure for the separation of oviposition stimulants from the epicarp of sour orange (*C. natsudaidai*). Fractions marked with asterisk were consistently active when bioassayed with 0.2–0.5% solution. Relative amount of each fraction to the original fresh weight of the epicarp is given in parentheses.

males screened as available for the behavioral test were only those that showed responses negative to distilled water alone and positive to the leaves of *C. natsudaidai*. Unresponsiveness of the females to the control (water) was carefully confirmed every three trials of sample presentation, for some females appeared to get "hypersensitive" during the experiment, positively responding without any chemical stimuli other than water. The rate of response was expressed by the number of positive responses/number of alighting on the leaves that was accompanied with drumming.

NMR Spectroscopy. [^{13}C]NMR spectra were recorded at 67.8 MHz in CD_3OD on a JEOL JNM-GX 270 FT-NMR spectrometer by proton-decoupled operation with tetramethylsilane as the internal standard. Temperature, flip angle, pulse repetition time, and the number of data points were 25°C, 45°, 5 sec and 64 K, respectively. Chemical shifts were represented by δ unit. Multiplicity of signals determined by means of INEPT technique was abbreviated as follows: singlet (s), doublet (d), triplet (t), quartet (q).

Mass Spectrometry. Fast-atom-bombardment mass spectra (FAB-MS) were measured with a JEOL JMS-DX 300 mass spectrometer. The target was bombarded with 6 KeV Xe atoms employing a mixture of sodium iodide and glycerine as a matrix.

High-Pressure Liquid Chromatography (HPLC). Reverse-phase HPLC analyses were carried out with a Hitachi 635S liquid chromatograph equipped with a wavelength-tunable spectrophotometer using a stainless column (4.6 mm ID $\times$ 15 cm) packed with Hitachi gel 3056 (ODS silica gel, 5 μm). Mixed solvent composed of MeOH–H_2O–AcOH (20 : 80 : 0.1) was used as an eluent, and the column eluate was monitored at 280 nm. The system was operated at an ambient temperature, and the flow rate was regulated at 1 ml/min.

RESULTS

As shown in Figure 1, major active compound(s) was present in the hydrosoluble fraction (fraction 2), and found to be a relatively small molecule whose molecular weight was less than 1000 (fraction 4). Further fractionation by reverse-phase column chromatography on ODS revealed that the active principle is composed of more than two components: the one being contained in fraction 5, and the other in fraction 8 (Figure 2). However, the potency of stimulatory effect on oviposition was quite different between these two fractions. Although 1% solution of fraction 8 was effective to a certain extent, its activity drastically diminished at lower concentrations, and eventually gave out

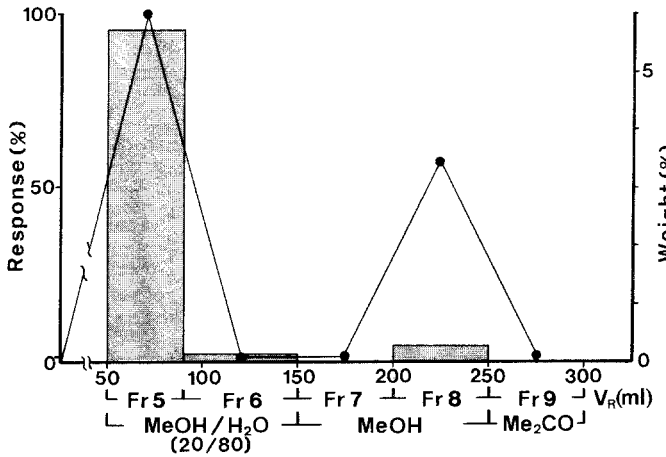

FIG. 2. Ovipositional response of *P. protenor* to fractions 5–9 separated from fraction 4 by reverse-phase (ODS) column chromatography. Three females were tested, and assay concentration of the sample was 1%. The relative weight of each fraction is indicated by a shaded bar, and the response by a closed circle.

almost completely at a level of 0.2%, whereas fraction 5 of the same concentration still provoked strong response at a rate as much as 100%. Therefore, the principal oviposition stimulant in the peel of *C. natsudaidai* was considered to be localized in fraction 5.

Upon further chemical analysis by thin-layer chromatography (TLC) on silicic acid with methanol, fraction 5 was found to be a mixture of a number of compounds, and each of the four fractions separated retained sufficient activity for inducing egg-laying at a level of 0.2%, indicating that at least several compounds combine to evoke oviposition behavior in this species. Since every fraction derived from fraction 5, however, seemed to gradually lose its activity during storage, fraction 5 was not pursued further in this study.

In contrast, fraction 8, although its stimulatory activity was not high, appeared far less labile, and gave a yellow precipitate when stored in a refrigerator for several days. The crude precipitate was recrystallized twice from hot water and dried at 150°C to afford pale yellow crystals (mp: 172–173°C), which, on HPLC analysis, was found to correspond to the major peak (A) in fraction 8 (Figure 3). Compound A was bioassayed for ovipositional response, but showed no appreciable activity at the concentration of 0.2% and was only slightly active at the level of 0.5%. However, the stimulatory effect of this substance, if only the females were "conditioned" beforehand with 0.2% solution of fraction 5, markedly increased to an extent adequate to release egg-laying (Table 1). Although a solid explanation for such remarkable enhancement of activity is hard to find at present (this will be discussed later), compound A should be regarded

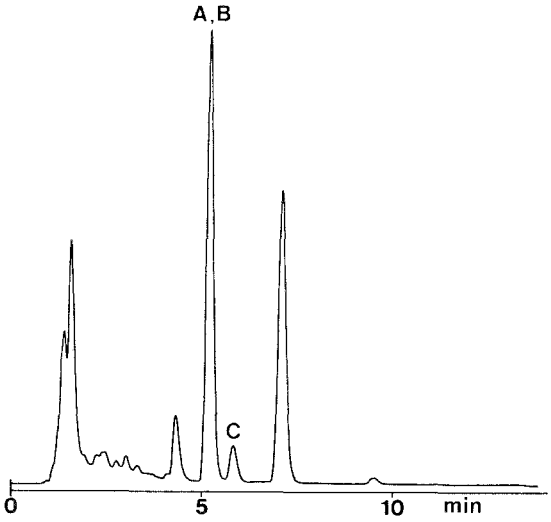

FIG. 3. HPLC chromatogram of fraction 8 on a ODS column. A,B: naringin and rhoifolin; C: hesperidin.

TABLE 1. OVIPOSITION-STIMULATORY ACTIVITY TO *Papilio protenor* OF SAMPLES DERIVED FROM EPICARP OF *Citrus natsudaidai*

Sample	Response (No. of trials)[a]		
	0.1%[b]	0.2%	0.5%

Fraction 5	0.86 (21)	1.00 (21)	1.00 (22)
Compound A	0 (24)	0 (22)	0.12 (26)
Compound A[c]	0 (20)	0.81 (21)	0.92 (26)

[a] Twelve females were tested.
[b] Percent indicates concentration of sample.
[c] The females were conditioned with fraction 5 (0.2%) prior to the experiments. Unresponsiveness to the control (water alone) was carefully confirmed after conditioning to rule out the possibility of a direct effect of fraction 5.

as one of the oviposition stimulants. Therefore, an attempt was made at structural elucidation of compound A.

The aqueous solution of compound A turned reddish-purple when treated with Mg-HCl, thereby adducing the possibility of the compound being a sort of flavonoid. The result of elemental analysis, combined with FAB-MS information [$(M + H)^+$ at *m/z* 581 and $(M + Na)^+$ at *m/z* 603], determined the molecular formula of compound A to be $C_{27}H_{32}O_{14}$. More informative data were obtained by CMR measurement giving the following signals, δ: 197.8(s), 165.9(s), 164.2(s), 164.0(s), 158.4(s), 130.3(s), 130.2(s), 128.7(d), 128.6(d), 116.0(d), 104.5(s), 102.1(d), 99.0(d), 97.5(d), 96.4(d), 80.3(d), 78.9(d), 78.7(d), 78.5(d), 77.7(d), 73.6(d), 71.9(d), 70.9(d), 69.7(d), 62.0(t), 43.9(t), 43.6(t), 18.2(q), which were suggestive of the presence of one carbonyl carbon, no less than 10 aromatic carbons, and at least 10 carbons that may be assigned to the sugar moiety.

Compound A was thus assumed to be a flavonoid glycoside, possibly a flavanone glycoside among others. On the other hand, CMR spectrum of the acid hydrolysis (5% aq. HCl) product (pale yellow crystals soluble in ethyl acetate) of compound A, which was regarded as its aglycone, coincided well with that of authentic naringenin. Furthermore, the resonance at 18.2 ppm assignable to a methyl group was indicative of the presence of rhamnose in the sugar residue. This spectral evidence suggests that compound A is likely to be naringenin-7-rhamnoglucoside, probably either naringin or narirutin. Good agreement in melting point and spectral data of authentic naringin with those of compound A confirmed the identity of the two. Compound A was thus determined to be naringin (naringenin-7β-neohesperidoside, Figure 4).

HPLC analysis and CMR measurement of the crude crystals separated from fraction 8 revealed that fraction 8 also contains a small amount of rhoifolin

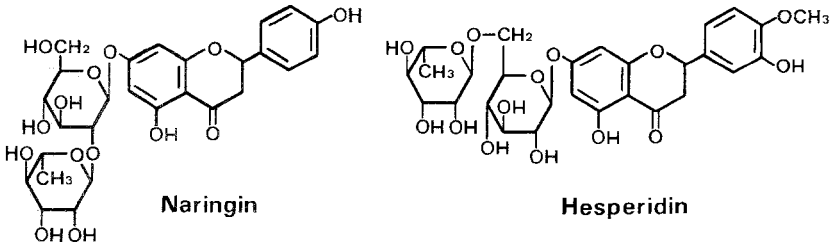

FIG. 4. Chemical structures of flavanone glycosides appraised as active for egg-laying by *P. protenor*. Naringin: naringenin-7β-neohesperidoside; Hesperidin: hesperetin-7β-rutinoside.

(apigenin-7β-neohesperidoside, peak B in Figure 3), which is superimposed on peak A. In addition, the existence of a trace of hesperidin (hesperetin-7β-rutinoside, Figure 4) in fraction 8 was also presumed by HPLC retention data (peak C in Figure 3).

Naringin, hesperidin, rhoifolin (the former two being flavanone glycosides, and the latter, a flavone glycoside), and other several flavonoid compounds available as possible candidates for oviposition stimulants were then bioassayed. The results are summarized in Table 2.

Unless the females were conditioned with fraction 5 prior to the experiment, naringin was virtually inactive when assayed alone, while pretreatment with or coexistence of fraction 5 remarkably promoted its activity, and eventually naringin turned out active. As all the other substances tested exerted little or no stimulatory action by themselves, their activity was evaluated after similar conditioning. Of these compounds, only flavanones such as naringin, hesperidin, and hesperetin, to which females evidently displayed a positive response, were appraised as active. In contrast, flavones and flavonols were entirely inactive, although limited solubility of some compounds precluded examining their dose–response correlation. As for naringin and hesperidin, the minimal concentration necessary for eliciting ovipositional response by females was estimated equally at ca. 0.2%. The latter, however, appears a little more active since the effectiveness of 0.1% solution of hesperidin was somewhat higher as compared with that of naringin, and besides, its aglycone, hesperetin, exhibited unequivocal ovipositional activity despite the inertness of naringenin (aglycone of naringin).

DISCUSSION

The present results are congruent with previous work by Ichinosé and Honda (1978) in that egg-laying of *Papilio protenor* is stimulated by water-soluble substances in *Citrus* plants and further demonstrate definitely that the

[f] Fraction 5 elicited no appreciable response at 0.05%.
[g] Because of the scanty solubility, some portions of crystals remained indissolved.

kairomonal activity for oviposition displayed by the peel of *C. natsudaidai* is the result of synergistic interaction among manifold chemical compounds. Similar synergy of chemicals involved in host selection has been reported for the cabbage butterfly, *Pieris rapae*, where sinigrin, although it stimulates oviposition, does not act alone to mediate discrimination among potential host plants, and combination with other water-soluble compounds evoked more potent ovipositional response (Renwick and Radke, 1983). A recent study with a swallowtail butterfly, *Papilio xuthus*, has also dealt with an analogous topic where vicenin-2 (flavone glycoside), which was inactive alone, proved active when admixed with another water-soluble fraction (Ohsugi et al., 1985).

The stimulatory action of naringin and hesperidin on egg deposition by the females appears to prevail only to a limited extent and to be subsidiary, because they neither exhibited any appreciable activity when assayed alone nor played an essential role in oviposition as evidenced by the fact that fraction 5, devoid of the two compounds, did suffice singly to elicit ovipositional response. Accordingly, such flavanone glycosides are not principal determinants of oviposition; nevertheless, either compound should be regarded as factors conducive to the synergy. Although it is difficult to put an explicit interpretation on the enhanced response by ovipositing females to flavanones caused by pretreatment with fraction 5, a possible reason is that this phenomenon was due to "memory effect" brought about by a trace of residual active substances adsorbed on the tarsal chemoreceptors of forelegs. In fact, repetitive washing of foretarsi with water resulted in much reduced response to flavanones.

Naringin and hesperidin are not specific to *Citrus* plants (although not being widespread in plants); however, most *Citrus* plants have been reported to be excellent producers of these compounds, which are contained not only in fruits but also in leaves (Hattori et al., 1952; Nakabayashi, 1961; Nishiura et al., 1969; Namba et al., 1985). In this respect, it is very likely that *Papilio protenor*, one of *Citrus* feeders, has evolutionarily come to rely not on ubiquitous flavonoids such as rutin (flavonol) but on certain specified flavanones in discriminating more precisely its host plants out of a diversity of unacceptable plants.

Some *Citrus* plants are also known to yield several flavones as minor flavonoid constituents. *P. protenor*, however, made little or no response to such flavone glycosides as rhoifolin and diosmin, the former being frequently encountered in *Citrus* plants (Hattori et al., 1952; Nakabayashi, 1961; Nishiura et al., 1969). Therefore, flavones in general appear essentially inactive to *P. protenor*, whereas a sort of flavone glycoside, vicenin-2, has been reported to be active to a related species, *P. xuthus* (Ohsugi et al., 1985). Feeny et al. (1983) have shown that for *P. polyxenes*, a umbellifer-feeding swallowtail, naringin and hesperidin were ineffective altogether, while chlorogenic acid and apigenin-7-glucoside (flavone) were slightly active. Such disparity may partly reflect interspecific difference in host preference.

In *P. protenor*, all of the components present in active fractions seem not indispensable for inducing oviposition; however, the whole complex of constituents should form the chemical basis for host recognition and preference. To possess a comprehensive response spectrum to or against a variety of compounds, not relying on any single stimulant, may serve to ensure correct and strict discrimination of host plants by mother butterflies.

DYNAMICS OF 6-METHOXYBENZOXAZOLINONE IN WINTER WHEAT
Effects of Photoperiod and Temperature

(Received September 25, 1985; accepted December 9, 1985)

Abstract—6-Methoxybenzoxazolinone (6-MBOA), a compound derivable from some freshly growing plants, is known to stimulate reproduction in some mammals and birds. Winter wheat was studied under controlled laboratory conditions to determine the effects of photoperiod and temperature on derivable 6-MBOA content. Longer photoperiods decrease the amount of derivable 6-MBOA per gram of fresh material in 4-day-old wheat seedlings. Higher temperatures also decrease the amount of derivable 6-MBOA in 4-day-old wheat. 6-MBOA content decreases as the plant ages. Comparisons of only the first centimeter above the seed produced the same age-related result. 6-MBOA is concentrated in the meristematic region with decreasing amounts found in higher portions of the plant. Roots from 9-day-old plants contain 6-MBOA. Unsprouted wheat seeds contain negligible amounts of 6-MBOA. These results demonstrate that environmental variables have a significant effect on derivable 6-MBOA levels, but that under all the regimes studied, 6-MBOA is present in freshly sprouted wheat.

Key Words—6-Methoxybenzoxazolinone, hydroxamic acids, wheat, photoperiod, temperature.

INTRODUCTION

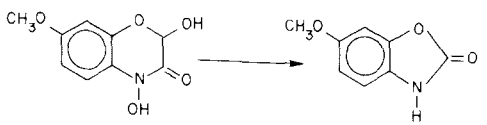
The timing of the onset of breeding of microtine rodents in natural populations can be highly variable. In field populations of *Microtus montanus*, the montane vole, the initiation of reproductive activity is correlated with the beginning of vegetative growth of their plant food resource in the spring, rather than at a

0098-0331/86/1000-2011$05.00/0

specific daylength (Negus et al., 1977). These herbivorous rodents eat primarily grasses and sedges, consuming fresh plant material when available during the growing season. Sanders et al. (1981) identified a factor derived from young winter wheat, 6-methoxybenzoxazolinone (6-MBOA), which increases uterine weight in female *M. montanus* and ovarian weight in *Mus musculus*. Using this compound in field studies, Berger et al. (1981) found that nonbreeding winter populations of *M. montanus* could be stimulated to breed several months before the onset of vegetative growth in the spring. Increases in reproductive function were observed in both sexes. In the laboratory, 6-MBOA increases litter size and frequency in this species (Berger et al., 1986a). This compound has been tested on other vertebrate species and has been found to have stimulatory effects on female reproductive function in rats (Butterstein et al., 1985), kangaroo rats (Rowsemitt, 1984), bobwhite quail (Berger et al., 1986b), rabbits, and mink (Berger and Negus, unpublished).

Prior to the work of Sanders et al. (1981), interest in 6-MBOA and related compounds centered on their role in the defense of young crop grasses against insect predators such as aphids (Argandona et al., 1980, 1981), corn borers (Klun and Brindley, 1966), and other pests. Although 6-MBOA is reported to be absent from intact plants, its precursor, 2,4-dihyroxy-7-methoxy-(2H)-1,4-benzoxazin-3(4H)-one (DIMBOA) has been reported in several species of the family Poaceae (Virtanen and Hietala, 1960; Loomis et al., 1957; Tang et al., 1975). This compound, present as a glucoside in intact tissue, is converted by enzymatic hydrolysis to the aglycone (DIMBOA) after tissue damage. The latter compound is unstable and decomposes to 6-MBOA (Figure 1) (see Virtanen and Hietala, 1960, for review). Therefore, 6-MBOA is formed when the plant's predator masticates the plant tissue. Argandona et al. (1981) examined the distribution of hydroxamic acids in wheat (*Triticum durum*) as an indicator of the major hydroxamic acid present, DIMBOA. On a per gram basis, maximum levels were reached in shoots by the fourth day after germination. Similar results were observed with *Triticum aestivum, Secale cereale,* and *Zea mays*. For *Triticum durum*, hydroxamic acid levels drop in old leaves, and new leaves on 30-day-old plants have lower levels than new leaves on younger plants. The authors did not report the environmental conditions under which the plants were grown.

Microtus montanus and some related species live in habitats with a high



DIMBOA 6-MBOA

FIG. 1. Chemical structure of 6-MBOA and its precursor DIMBOA.

degree of temperature and rainfall variability on a year-to-year basis. The freshly sprouted grasses which they appear to use to cue the onset of reproduction (Negus et al., 1977; Berger et al., 1981) are growing under different temperature and photoperiod conditions in different years. While laboratory studies examining the distribution of derivable 6-MBOA have been performed (Argandona et al., 1981; Klun and Robinson, 1969), no attempts have been made to examine variations in 6-MBOA in young grasses growing under the range of conditions typical of natural habitats. We are currently involved in field studies of available 6-MBOA in wild grasses which are food resources for *M. montanus* and other microtine rodents. In order to more closely examine the effects of environmental variables on 6-MBOA availability in grasses, we have chosen to use winter wheat as a model system to examine the concentrations of derivable 6-MBOA in grasses grown under various photoperiod and temperature regimes.

METHODS AND MATERIALS

General. Winter wheat seeds were soaked in tap water for 1 hr, then planted 24 hr later in Vermiculite and grown in an environmental chamber with high-pressure sodium and metal halide high-intensity discharge lamps. Light intensity was 0.5 mmol photosynthetically active radiation/m^2/sec. Four days after planting, triplicate 1.0-g samples of whole plants were extracted for derivable 6-MBOA. Samples were collected 3 hr after the onset of light. Entire shoots were utilized, cutting at the seed. Plant material was ground with sand to disrupt cell walls, incubated in distilled water for 1 hr at room temperature to allow enzymatic conversion to the aglycone, boiled for 30 min to allow conversion to 6-MBOA, then extracted three times with redistilled reagent-grade dichloromethane and dried under nitrogen. The dried samples redissolved in CH_3OH were analyzed for 6-MBOA by GC-MS. A Dupont model DP102 instrument equipped with an integrator and a SP2250 GC column isothermal at 200°C was used. The peak for the mass ion at *m/z* 165 was the most intense in the fragmentation spectrum and was integrated.

A standard curve was obtained using 0.06, 0.6, and 1.2 μg injections of a pure 6-MBOA in CH_3OH solution and was reproducible to $\pm 5\%$ at the low-weight end of the curve. Statistical comparisons were analyzed by linear regression unless otherwise specified.

Regimen I. 6-MBOA Concentrations under Various Photoperiods. Plants were grown under 8, 10, 14, and 16 hr of light per day with a temperature cycle of 12 hr at 25°C and 12 hr at 15°C such that the warm portion of the day occurred during the light and was symmetrical with the temperature regime.

Regimen II. 6-MBOA Concentrations under Various Temperatures. Plants were grown in 12 hr of light per day under the following temperature regimes

(°C): 35:15, 30:20, 20:10, 15:5, with the higher temperature given during the light portion of the day.

Regimen III. Age and Distribution Profile of 6-MBOA. Plants were grown under 12 hr of light per day with a daytime temperature of 30°C and a nighttime temperature of 20°C. Whole plant samples were taken at days 4, 9, and 16; 1.0-g samples of the first centimeter above the seed were also taken at days 4, 9, and 16. On day 9, the distribution of 6-MBOA within plants was examined by extracting 1.0-g samples of the first, fourth, and tenth centimeter above the seed.

Regimen IV. 6-MBOA Contents of Roots and Seeds. The 6-MBOA contents of roots and seeds were determined. Triplicate 1.0-g samples of roots were extracted from the 20°/10° sample in regimen II. Triplicate 1.0-g samples of unsprouted seeds were ground to a powder and extracted.

RESULTS

Regimen I. Longer daylengths decrease the amount of 6-MBOA present per gram of plant material ($r^2 = 0.852$, $P < 0.001$) (Figure 2). There was no relationship between photoperiod and plant height ($r^2 = 0.077$; $P = 0.68$). Plant height ranged from 2.0 cm in 10 hr of light per day to 5.0 cm in 14 hr of light per day.

Regimen II. Increases in day and night temperatures decrease 6-MBOA content per gram of plant material ($r^2 = 0.867$, $P < 0.001$) (Figure 3). Plant height decreased with increasing temperature ($r^2 = 0.996$; $P = 0.039$). Height ranged from 7 cm in the 35°/25° regime to 0.5 cm in the 15°/5° regime.

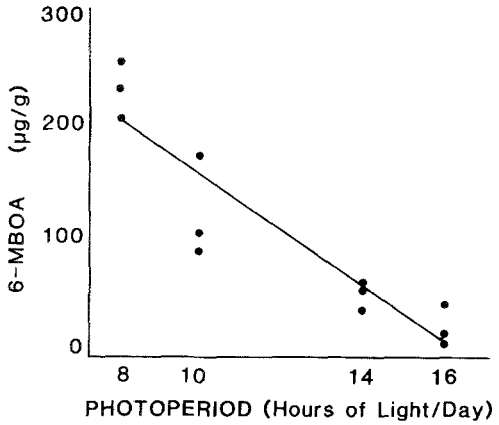


FIG. 2. Effect of photoperiod on derivable 6-MBOA in 4-day-old wheat plants. Regression: $y = -25.82x + 425.31$. $r^2 = 0.852$, $P < 0.001$.

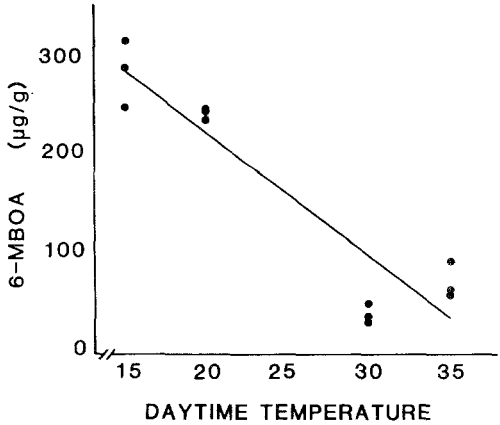

FIG. 3. Effect of temperature on derivable 6-MBOA in 4-day-old wheat plants. (Nighttime temperatures are 10° lower.) Regression: $y = -13.52x + 506.78$. $r^2 = 0.867$, $P < 0.001$.

Regimen III. Age has a highly significant effect on derivable 6-MBOA, with highest levels found in the 4-day sample ($r^2 = 0.650$, $P = 0.0156$) (Figure 4A). Comparisons of only the first centimeter above the seed yielded similar results with the 4-day sample having the highest concentration of derivable 6-MBOA ($r^2 = 0.944$, $P < 0.001$) (Figure 4B). Comparing the concentration of 6-MBOA in the first centimeter with that in the entire plant shows no significant difference at day 4, but significantly higher concentration in the first centimeter than in the whole plant at days 9 and 16 ($P = 0.001$, $P = 0.039$, respectively, Student's t test). This conclusion is supported by the results in Figure 5, showing concentrations in several portions of the plant ($r^2 = 0.976$, $P < 0.001$).

Figure 5 shows the distribution of derivable 6-MBOA within plants at 9 days of age grown under the conditions described above. The highest concentrations are found at the meristematic region at the base of the grass with decreasing concentrations in the higher portions of the plant.

Regimen IV. Root samples from 9-day-old plants as described above averaged 101.3 μg derivable 6-MBOA/g plant material (± 14.0 SD). Unsprouted seeds contained 3.3 μg 6-MBOA/g (± 5.8 SD).

DISCUSSION

To understand the availability of 6-MBOA in natural food resources of microtine rodents such as *Microtus montanus*, we have used one grass (wheat) as a model system. Under controlled environmental conditions in the laboratory, we have studied the effects of altering both photoperiod and temperature

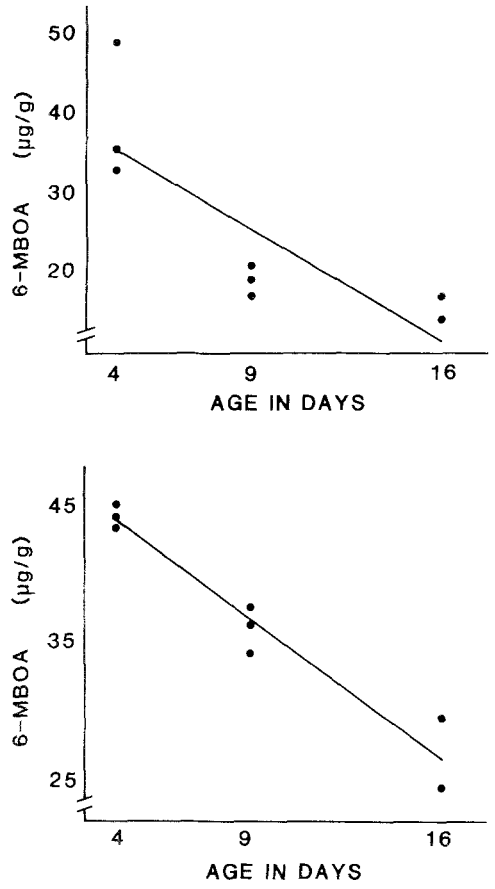

FIG. 4. Effect of age on derivable 6-MBOA in wheat. (A) Whole plant. Regression: $y = -2.05x + 44.78$. $r^2 = 0.650$, $P = 0.016$. (B) First centimeter. Regression: $y = -1.36x + 50.23$. $r^2 = 0.044$, $P < 0.001$.

on derivable 6-MBOA. While we recognize that the absolute values determined here for wheat are not likely to be equivalent to those found in the natural grasses which are food resources for microtine rodents, our purpose is to elucidate how the plants' investment in the production of the precursor to 6-MBOA varies under different growing conditions. Other work in progress examines 6-MBOA content of known food resources of *M. montanus* (Negus, Berger, and Epstein, in preparation).

Our results demonstrate that both photoperiod and temperature affect the concentration of derivable 6-MBOA in 4-day-old plants. Increasing the hours of light per day decreases the concentration of derivable 6-MBOA per gram of

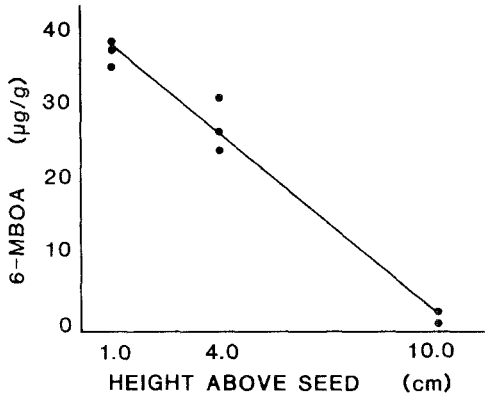

FIG. 5. Distribution of derivable 6-MBOA in the first, fourth, and tenth centimeter above the seed. Regression: $y = -3.73x + 41.86$. $r^2 = 0.976$, $P < 0.001$.

fresh plant material. Increasing the temperature also decreases the amount of derivable 6-MBOA. Since higher temperatures produce more biomass per plant, the temperature effect may be due, in part, to the fact that more individual plants are required to make a gram of material in the wheat grown at lower temperatures than at the higher temperatures. The result is that more meristematic material is present in the samples at lower temperatures. Since 6-MBOA occurs in higher concentration in the first centimeter, a 1.0-g sample of shorter plants will contain more individual plants and thus more first-centimeter portions (the meristematic region in grasses) than a 1.0-g sample of taller plants and will therefore contain more 6-MBOA if plant height is the important factor. The photoperiod effect on 6-MBOA concentrations cannot be explained in this manner because the plant height did not vary in a systematic fashion with photoperiod. Our data demonstrate that, regardless of photoperiod and temperature conditions, freshly sprouted wheat seedlings contain significant amounts of derivable 6-MBOA, with approximately a fivefold range in 6-MBOA on a per gram fresh weight basis under the different treatments.

The results of our examination of the distribution of 6-MBOA within the plant are consistent with those of other workers. Highest concentrations were found at the first centimeter above the seed, with decreasing concentration at greater heights. This is in agreement with the results of Klun and Robinson (1969) for several strains of corn and with those of Argandona et al. (1981) for wheat. Direct comparisons of our results with those of other workers are of limited value for several reasons. The intraspecific differences in 6-MBOA can be very dramatic in inbred strains of crop grasses. Examination of 11 strains of corn in one study revealed almost a 10-fold range in 6-MBOA concentrations (Klun and Brindley, 1966). Furthermore, the growing conditions varied substantially between studies. In spite of high variability in actual 6-MBOA content

in various grasses, interspecific generalities are emerging regarding the distribution of 6-MBOA in those grasses which contain it.

Our age profile, with samples taken at days 4, 9, and 16, showed decreasing levels from day 4, whether the entire grass was sampled or the first centimeter only was used. Other age profile work shows similar results. Argandona et al. (1981) show decreases in hydroxamic acids in wheat after four days of age. Argandona et al. (1980) took their first sample at 10 days of age. For wheat, decreases occurred after day 10; for rye (*Secale cereale*) days 10 and 16 produced similar levels of hydroxamic acids with decreases starting at day 22. Klun and Robinson (1969) reported 6-MBOA concentrations based on plant height in several strains of corn (*Zea mays*). Their first sample, at 6 in., was the highest value for every strain examined. Therefore, highest concentrations are found in the young plants.

The relevance of the root levels of 6-MBOA to microtine food resources is not clear. Behavioral studies of *Microtus breweri* have shown a seasonal shift in preference for various portions of their major food resource, the beach grass, *Ammophila breviligulata*. In late summer, the roots are the preferred portion of the plant (Rothstein and Tamarin, 1977). However, our own and other studies of 6-MBOA in roots have been from young actively growing plants; we know nothing about the availability of 6-MBOA in a perennial grass late in the growing season. Derivable 6-MBOA has been found in the roots of wheat, rye, and Job's tears (Tang et al., 1975). The availability of 6-MBOA in roots may be of importance to reproductive patterns of root-eating subterranean rodents such as pocket gophers (Geomyidae).

Our inability to detect significant amounts of derivable 6-MBOA in wheat seeds is consistent with the results of Argandona et al. (1981). They found no hydroxamic acids in wheat seeds (*Triticum durum*). This fact is of particular interest regarding the breeding patterns of some heteromyid rodents. Certain desert-adapted kangaroo rats, primarily seed-eaters, include fresh vegetation in their diet when it is available after rainfall (Reynolds, 1960; Reichman and Van De Graaff, 1975). Breeding correlates with the availability of the fresh vegetation. In one species of kangaroo rat, *Dipodomys ordii*, 6-MBOA causes uterine hypertrophy (Rowsemitt, 1984). If 6-MBOA is absent from the kangaroo rats' usual diet but is present in the fresh vegetation ingested after rainfall, it may provide a cue for breeding in these animals.

The exact results of this work are not expected to be quantitatively comparable to the values found in field populations of various grasses. The light intensity used was lower than full sunlight. Also the 6-MBOA content of different species of crop grasses, as well as our own unpublished work, show that interspecific differences are substantial. Argandona et al. (1980) demonstrated that hydroxamic acids are present in wheat and rye, but nondetectable in barley. Therefore, not all grasses contain these compounds. The main purpose here has been to examine the range of phenotypic plasticity of this parameter in one

system. The results presented here suggest that 6-MBOA concentrations may be higher per gram of plant tissue in grasses sprouting in the colder temperatures and shorter photoperiods of early spring than in those sprouting later in the season when temperatures are warmer and photoperiods are longer. Therefore, the animals may encounter higher concentrations of 6-MBOA in newly sprouted grass at the beginning of the breeding season than in grasses sprouting later. The dynamic aspects of 6-MBOA concentrations in plants may prove to be an important factor in breeding patterns of many herbivores.

(Received July 23, 1985; accepted December 10, 1985)

Abstract—Results from qualitative and quantitative evaluation of some chemical constituents, particularly phenols and volatile terpenes, from juvenile stages of three primary species belonging to the perennial rain forest are presented. The degree of infection and the time of the year were taken into account. TLC, GC, and simple chemical methods were used to estimate differences among components. Biological assays were conducted to evaluate fungicide potential of the extracts from studied plants. In general terms, the results show significant differences in the chemical composition of the species studied (*Nectandra ambigens, Omphalea oleifera*, and *Licaria alata*) related to the time of the year and the degree of infection. These differences can be related as well to their intrinsic resistance to infection and ability to grow to the adult stage.

Key Words—Secondary metabolites, juvenile stages,. phenols, volatile terpenes, degree of infection, *Nectandra ambigens*, *Omphalea oleifera*, *Licaria alata*.

INTRODUCTION

Seedlings and juvenile stages of primary species from perennial rain forests are kept in latency during long periods of time due primarily to light conditions prevailing in the lower layers of the forest (Richards, 1959; Whitmore, 1975; del Amo, 1978). During this period of growth suppression, plants are subject to constant pressures of many types, and these are a consequence of the inter-

[1]This investigation was sponsored by Project 001077 PCECBNA, Consejo Nacional de Ciencia y Tecnología.

0098-0331/86/1000-2021$05.00/0

action between biotic and abiotic factors. One of the main factors of stress during the first stages of growth is the attack of pathogenic microorganisms.

The importance of chemical mechanisms of defense developed by some plants against pathogenic microorganisms, insects, and other herbivores, through formation and accumulation of secondary metabolites, has been noted by Levin (1976), Whittaker and Feeny (1971), and Seigler (1978), among others. Of the metabolites, those most frequently related to pathogen resistance have been the phenolic compounds and the terpenes (Cobb et al., 1968; Hunter et al., 1978). As for the terpenes, Cobb et al. have suggested that some monoterpenes such as myrcene, phellandrene, limonene, pinene, and carene, produced by *Pinus ponderosa*, play an important part in its resistance to infection by several microorganisms; they also mentioned that their activity can be related to that of phenolic compounds. Monoterpenes and sesquiterpenes are found in the so-called essential oils.

The contents and production of essential oils may vary according to climate, soil conditions, stage of development of the plants, and genetic factors (Swain, 1963; Rice et al. 1978).

The main goal of the present work was to evaluate the qualitative and quantitative variation of chemical components, mainly terpenes and phenolic compounds, in juvenile stages of three primary species from the perennial rain forest, taking into account the degree of infection and the time of the year. At the same time, extracts of each plant were evaluated against phytopathogenic fungi isolated from the same species studied in order to evaluate their fungicidal potential.

METHODS AND MATERIALS

Juvenile stages of plants of three primary species from Ebitrolotu (station for tropical biology at Los Tuxtlas, Veracruz, Mexico, belonging to the National University of Mexico) were used: *Nectandra ambigens*, *Licaria alata* (Lauraceae), and *Omphalea oleifera* (Euphorbiaceae). These species are common in the Tuxtla region, and their seedlings and young plants form a dense mass in the understory of this tropical rain forest (del Amo, 1978; Cordova, 1980).

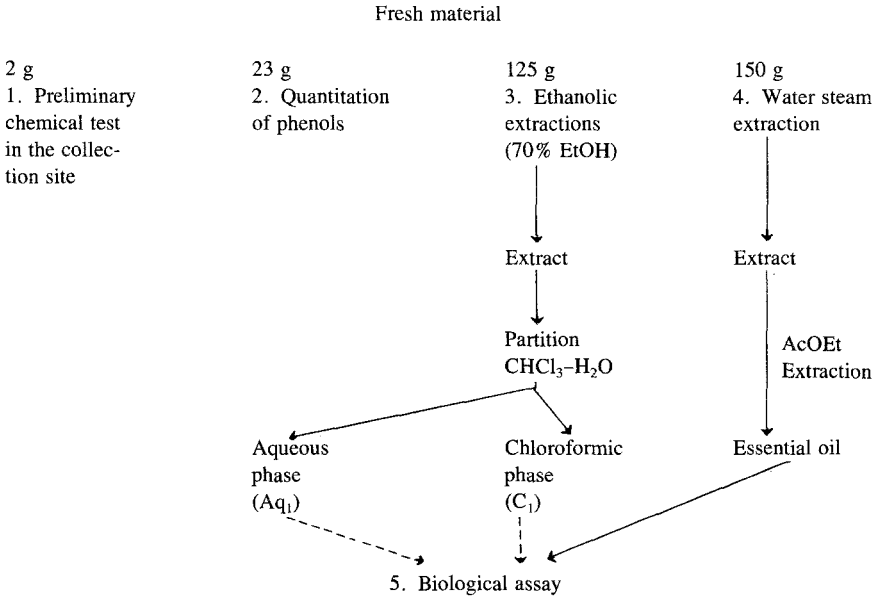
Samples were collected and classified as "damaged" and "healthy" plants, according to the degree of infection. There were no completely undamaged or healthy plants in the case of *Omphalea oleifera* specimens. Even so, the three species were classified in the same manner. It is important to note that the term "damaged" was given to plants with evident signs of infection or insect depredation.

Samples were collected twice during the year: during the dry season in March and the rainy season in July, with the purpose of detecting variations in secondary metabolites according to environmental conditions, specifically plu-

vial precipitation. The samples were processed as soon as possible in order to avoid metabolic transformation due to action of plant enzymes or microorganisms.

Laboratory Methods. Solvents were purified by distillation. Thin-layer chromatography (TLC) was done using silica gel GF 254-60 Merck and microcrystalline cellulose on flexible plates, "Bakerflex," and were made visible with iodine and/or anisaldehyde–H_2SO_4 followed by UV light.

Gas–liquid chromatography (GLC) was carried out in a Varian 3700 apparatus, using a 10% FFAP on Chromosorb WHP column. As an external standard, a mixture of pure terpenes selected according to chemotaxonomic criteria was used (Figure 1). Phenols were measured using a Varian 364 spectrophotometer. Fresh material, 300 g, was processed according to the Scheme 1.



SCHEME 1.

Preliminary Chemical Test (at Site of Collection). One gram of fresh material was triturated in a mortar, extracted with ca. 10 ml of EtOH and filtered; aliquots of this filtrate were used to search for phenols (reaction with ferric chloride), saponins (foam formation), alkaloids (reaction with Mayer, Dragendorff, Wagner, and phosphotungstic acid reagents); and essential oils (characteristic odor).

Evaluation of Phenols. Phenols were quantified by the Price and Butler (1977) method, but using 6 g of fresh material instead of the dry material used by these authors. The material was extracted with 60 ml of distilled water and the extracts filtered. An aliquot of 5 ml of filtrate was diluted to 50 ml with

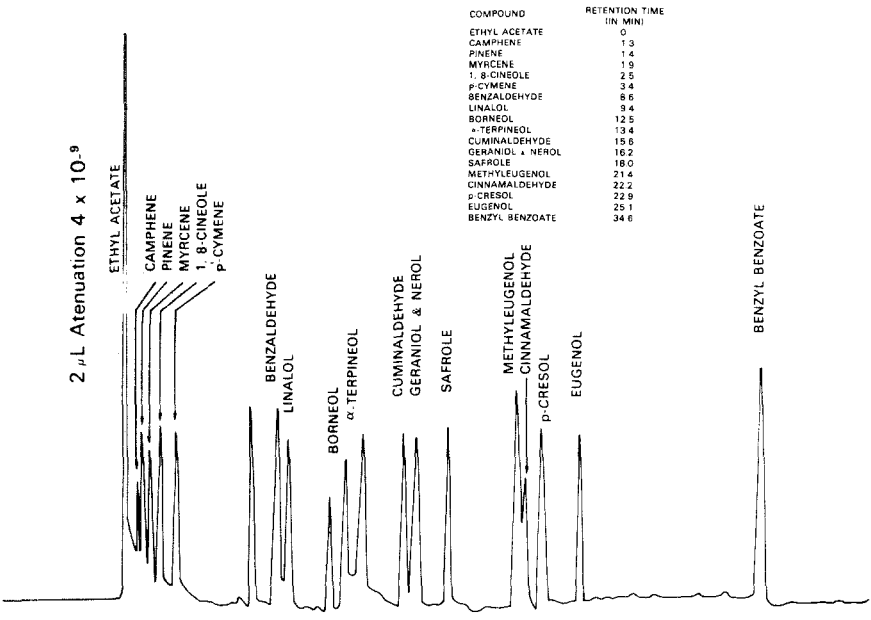


FIG. 1. Standards for GLC (retention time) of essential oils of juvenile plants with different degrees of infection.

water, 0.3 ml of ferric chloride solution was added, and the two were mixed. Afterwards 0.3 ml of potassium ferricyanide was added and the solution stirred. The mixture was allowed to stand for exactly 10 min and read at 720 nm using distilled water as a blank; it is important to read exactly at that time because afterwards absorbance varies and a precipitate may be formed. The test was done in triplicate using a standard of tannic acid, with a curve of concentrations from 1 to 6 μg/ml. Concentrations in micrograms of phenols (as tannic acid) per milliliter of extract are obtained and results are given in milligrams per gram of dry material and in percent of dry material.

Ethanol Extract. Fresh material (125 g) was extracted three times with 70% EtOH at room temperature for 24 h. Extracts were homogenized, filtered and concentrated in a rotary evaporator at a temperature below 60°. The oily aqueous residue was extracted with 100-ml portions of chloroform. Two fractions were obtained: chloroformic (C_1) and aqueous (Aq_1). The chloroformic fraction was evaporated to dryness to obtain a brown powder which was chromatographed by TLC using $CHCl_3$–MeOH (9 : 1) as eluent, made visible with anisaldehyde–H_2SO_4 in UV light. The aqueous phase was lyophilized and the resulting solid treated in the same way and also chromatographed on microcrystalline cellulose with butanol–acetic acid–water (8 : 2 : 3) as eluent.

Essential Oils. Fresh material (150 g) was water-steam extracted for 8 hr.

The suspended oils were further extracted with ethyl acetate and the latter eliminated by distillation. TLC of essential oils was carried out on silica gel using hexane–ethyl acetate (1 : 1) as eluent. As visualizing agents, iodine and anisaldehyde–sulfuric acid were used.

GLC was done under the following conditions: spiral glass column 200 cm in length, 2 mm OD and 0.85 mm ID, filled with 10% FFAP on Chromosorb WHP. Temperature programming: initial 80°C, final 220°C; velocity 4°/min; carrier gas, nitrogen; detector temperature, 250°; injector temperature, 250°.

A mixture of pure terpenes (Figure 1) was used as an external standard. When the retention time of some of the components of the essential oils coincided with one of those of pure compounds, the latter was used as the internal standard, measuring the increment of the corresponding area. Quantification of each component was carried out measuring the area under the curve by the triangle method.

Biological Assay. Pathogenic fungi were isolated from *L. alata* and *N. ambigens*. It was not possible to isolate fungi from *O. oleifera*. To isolate the microorganisms, pieces of infected leaves were scattered in a system of potato–dextrose–agar (PDA) and kept in a humid chamber (Sharvelle, 1969). Depression microscope slides were used, placing one drop of standard suspension of spores (50,000/ml) and one drop of the studied extract in five different dilutions: 25.5, 12.25, 6.12, 3.06, and 1.53 mg/ml.

Extracts of each plant were tested against pathogenic microorganisms isolated from the same plant, but in the case of *O. oleifera*, from which fungi could not be isolated, its extracts were tested against fungi isolated from the other two species of plants.

The extracts were dissolved in an acetone–water (1 : 10) system, adding 0.1% of PDA to facilitate germination. Only extracts available in sufficient amounts to make several dilutions were tested.

Preliminary tests of fungal tolerance to osmotic pressure were conducted, using mannitol in different concentrations: 0, 0.04, 0.08, 0.1, and 1 M.

Incubation time was 20 hr at 20°, after which the number of germinated and nongerminated spores in each scope of the microscope were counted using six scopes for every one of the three repetitions. Spores were considered as germinated whenever the length of the mycelium exceeded the spore diameter.

RESULTS

Preliminary Chemical Test

All the species studied contain, in different amounts, phenolic compounds and essential oils. There were no saponins present, and the amount of alkaloids was negligible. It is important to note that *O. oleifera* contains a lesser amount

of phenolic compounds than essential oils when compared to the other two species studied.

Quantification of Phenolic Compounds

The presence of phenolics is shown in Table 1, expressed as milligrams of tannic acid per gram of dried sample and in percent in dry material. The standard curve used showed a correlation of 0.999; and the standard deviation (SD) of measurements (each was done three times) was always less than 0.1. It can be noted that in the case of *L. alata* there was no significant difference in the phenolic content (rather small) between damaged and healthy plants. In the case of *O. oleifera*, and *N. ambigens*, there were appreciable differences between damaged and healthy populations, specially in the case of *O. oleifera*, where the amount of phenols was always greater in the healthy samples.

Ethanol Extract

Thin-layer chromatography (TLC) of the chloroformic (C_1) and aqueous (Aq_1) fractions of ethanol extracts showed a great number of components (an average of eight for *L. alata* and *O. oleifera* and of 15 for *N. ambigens*). Some of those of phenolic nature were made evident by the characteristic color of the spots after spraying with anisaldehyde–H_2SO_4.

No separation was intended, due to the small amounts of material available; however, it was discerned that the number of components was always greater in the damaged populations than in the healthy ones. For example (Table 2), the chloroform fraction (C_1) of *L. alata* extract shows the presence of three more components (R_f 0.4, 0.43, 0.55) in damaged plants. Similar results were

found in the aqueous fractions (Aq_1) which, in the case of *N. ambigens*, differed in three components (R_f 0.4, 0.56, and 0.83); there was a difference of two in *L. alata* and of only one in *O. oleifera* which, as shown before, was the least damaged species.

Essential Oils

As in ethanol extracts, thin-layer chromatography (TLC) shows qualitative differences between populations from a single species differing in degree of infection; however, due to the nature of the compounds of this extract, the resolution that can be attained is not very good, and better results can be obtained by GLC. For example, the average number of components found by TLC is 9–10, whereas by GLC a minimum of 22 and a maximum of 48 (depending on the extract) is obtained.

Utilizing GLC, differences in composition of essential oils from the three species studied, in damaged and healthy populations and at two different times of the year, are shown in Figures 2 and 3. Main qualitative and quantitative differences in composition of extracts are in Tables 3 and 4. A short account on the average results, shown in Figures 2 and 3, follows.

O. oleifera

Differences Regarding Degree of Infection. In the first crop, there were no substantial differences, either between damaged and undamaged or healthy plants, or between components of their essential oils. The main component was identified as benzyl benzoate, the amount of this component being slightly greater in the healthy plants (Figure 2A).

[a]Symbols as in Table 3.

In the second crop, there were slight differences between damaged and healthy plants; in the latter benzyl benzoate was augmented by ca. 12.5%, and there were two unidentified components (ret. R_t 20.6 and 29.4) that were diminished by 17.2% and 13.7% respectively (Figure 3A).

Differences between Crops. The groups of substances whose retention time indicates they belong to terpenes, such as safrol, cinnamaldehyde, and terpineol, were significantly augmented in extracts belonging to the second crop (rainy season); they were present in both healthy plants as well as in damaged ones.

L. alata

In the first crop, there were marked differences between damaged and healthy or undamaged populations. In the latter, the amount of substances with retention times similar to those of borneol and terpineol increased. Eugenol was identified as one of main constituents (31% in damaged plants and 19.9% in the healthy ones) (Figure 2B).

In the second crop, as happened in the first crop, terpenes found in the first part of the chromatogram were substantially augmented in the case of healthy plants; this fact might be related to plant resistance to disease (Figure 3B).

Differences between Crops. There were few differences in the composition of essential oils from the two crops. Among them, eugenol was found in smaller quantities in plants from the second crop (Tables 3 and 4).

N. ambigens

In the first crop, very slight differences between damaged and healthy populations were found. One of the appreciable differences was the presence of terpineol in the damaged plants and its absence in the healthy ones (Figure 2C).

In the second crop, there were almost no differences between components in the extracts of plants with different degrees of infection, with the important exception of one component which had a retention time (38.5) longer than that of benzoyl benzoate which exists only in undamaged plants (Figure 3C).

As this substance could be responsible for a protective effect in healthy plants, we found it interesting to undertake a further study of such a possibility. Isolation from the original extract was not possible because of the small amount available and because collection of substantial amounts of seedlings would have resulted in ecologic damage. For these reasons, the search of this component in the essential oil from leaves of mature plants was attempted. Unfortunately, composition of the essential oil was somehow different, and the compound in question was not present in the latter material.

Biological Assays

As indicated earlier, no pathogenic fungi were isolated from *O. oleifera*. Antifungal tests were done for species of *Phomopsis*, *Alternaria*, and *Colletotrichum* isolated from *L. alata* and *N. ambigens*. Partial results of these experiments were reported separately (Nava and del Amo, 1985; Nava et al., 1985). Only the inhibitory activity of essential oils studied is reported here; stimulatory activity, when found, was not taken into account.

Following is a brief account of the results obtained, (also shown in Figure 4):

Essential Oil from O. oleifera. Only the essential oil of undamaged plants during the rainy season was tested. This is not a highly inhibitory material for *Phomopsis* sp., isolated from *L. alata*, and for *Alternaria* sp. from *N. ambigens*; only higher concentrations were inhibitory. *Colletotrichum* sp. isolated from *N. ambigens* was more easily affected and was inhibited by the five dilutions used.

Essential Oil from L. alata. Among the three species studied, the essential oil from this plant showed the highest inhibitory activity against all the fungal

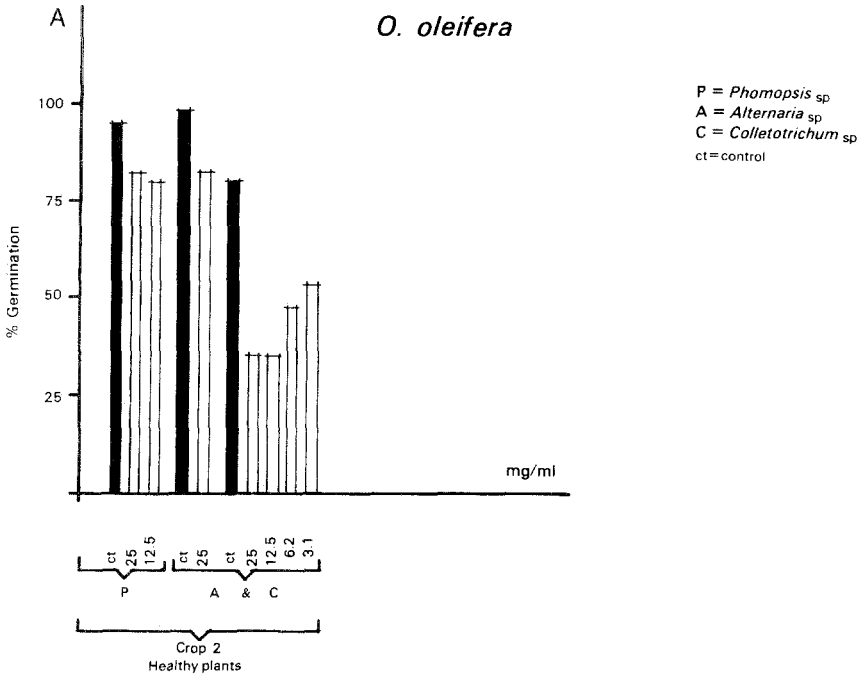

FIG. 4. Effect of the essential oils of *Omphalea oleifera* (A), *Licaria alata* (B), and *Nectandra ambigens* (C) on germination of fungal species from the genera *Phomopsis*, *Alternaria* and *Colletotrichum*.

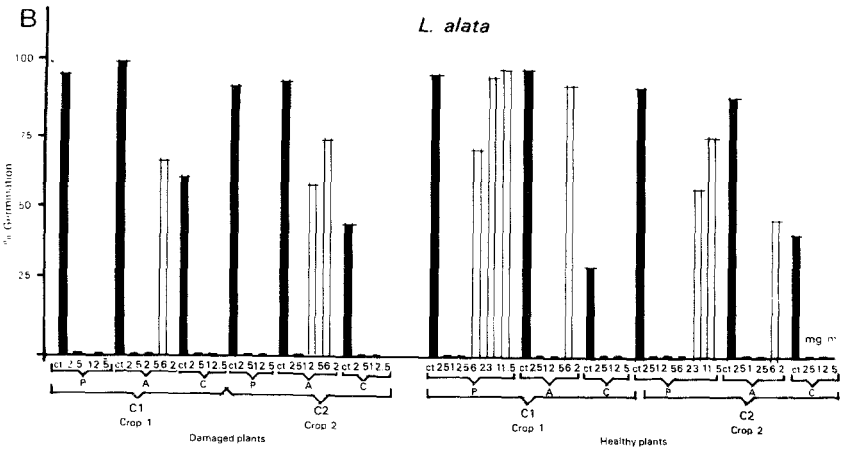

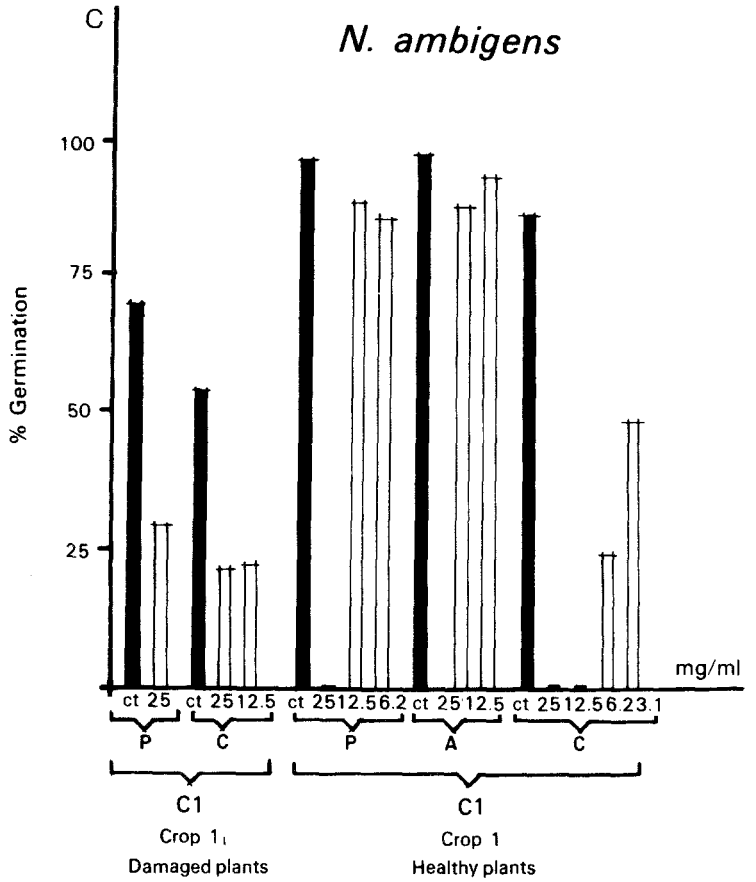

FIG. 4. (Continued)

species used. The minimum inhibitory doses were found to be among the lower concentrations of extract (Figure 4), for both types of populations, damaged and healthy. When higher concentrations were used, they completely inhibited the growth of fungi, with *Phomopsis* being the more affected species, especially by the extracts of healthy plants from the rainy season crop. This material has among its components eugenol and *p*-cresol, the latter being well known for its germicidal activity.

Essential Oil from N. ambigens. Only the extracts from the dry season (damaged and healthy) were tested. Essential oil from undamaged plants showed the highest inhibitory activity, especially against *Colletotrichum* sp. It is interesting to note that the latter differs only in one component from the corresponding extract of the damaged plants. Among its components, borneol, terpineol, and benzyl benzoate were identified.

DISCUSSION

In general terms, experimental results showed significant differences in chemical composition related to the time of year and degree of infection. These differences were also reflected in differences in biological activity against phytopathogenic fungi.

Qualitative and quantitative differences related to the degree of infection in plants corroborated the statement of Stoesl (1970) and Callow (1977). There are compounds that remain constant which would belong to the so-called constitutive components and others that are found present only in damaged populations, a fact that would place them within the groups of phytoalexins or induced metabolites. As evidence, we can note the greater amount of components present in extracts of damaged plants (Table 2).

Regarding the total evaluation of each of the plant species studied, the following can be said: In *O. oleifera* there are quantitative differences between crops, but there are no significant differences related to the degree of infection. The essential oil belonging to healthy plants from the rainy season showed a marked inhibitory effect. It is important to note that quantitative determination of phenolic compounds showed this species to be the one with the greatest amount of these compounds. This could be related to the greater resistance to infection that this species shows, given the known antifungal activity of phenols (Farkas and Kiraly, 1962; Wakimoto and Yoshii, 1958; Piankas and Chorin, 1969).

In *L. alata* the differences in chemical composition due to seasonal effects were less evident than those due to degree of infection. This was reflected in the biological activity of the extracts tested. Inhibition produced by different concentrations of extracts from healthy plants was especially noticeable in the case of *Phomopsis* sp. (Figure 4). This activity could be related to some of the

compounds in the first part of the chromatogram (GLC) that increased in the undamaged populations.

From the other Lauraceae studied, in *N. ambigens* some differences were found, both between crops and between plants with different degrees of infection. The essential oil of this species is scarce, and only the material from the dry season crop was biologically tested. Interestingly, the material from the undamaged plants was more active, especially against *Colletotrichum* sp., and it differed only in one component (R_t 38.2) from the material from damaged populations. Thus, the indicated activity could be related to that single component. Unfortunately, its isolation and identification, although attempted, have not been achieved to date.

In summary, of the plant species studied, the greatest fungicidal potential was found in *L. alata*. The fact that the genera of fungi used to test the plant extracts were some of the more important pathogens for cultivated plants makes it of great interest to extend the bioassays to some crop species.

Seedlings and juvenile stages which are important parts in the life cycle of the primary species are subject to suppression of growth and to attack by phytopathogenic microorganisms for extended periods of time. Thus, the development of chemical mechanisms of defense, such as the ones mentioned in the present study, represents an advantage in adaptation that will allow them to survive until adequate conditions make it possible for them to grow and reach adult stages.

(Received September 12, 1985; accepted December 10, 1985)

Abstract—*Datana ministra* larvae possess a gland situated in the ventral anterior portion of the prothorax. The gland consists of a single sac and is only charged with secretion in the last instar. Its orifice, a simple slit, opens into a transverse invagination of the integument in the cervical margin of the prosternite. The components of the gland have been identified by GC and GCMS and have been shown to be dodecanol, dodecyl acetate, and dodecyl formate. The morphology of the gland and the chemistry of the secretion are discussed in relation to other notodontid larvae which have been investigated. It is conjectured that the secretion is not defensive in nature but may function as a dispersal pheromone.

Key Words—*Datana ministra*, Lepidoptera, Notodontidae, exocrine prothoracic gland, ultrastructure, dispersal pheromone, dodecanol, dodecyl acetate, dodecyl formate.

INTRODUCTION

That larvae of the family Notodontidae possess exocrine prothoracic glands at the cervical margin of the prosternite has been known for more than 200 years.

[5]Present address: Fermone Chemicals Inc., 305 South 2nd Avenue (Suite 101), Phoenix, Arizona, 85003, U.S.A.

The first report was probably that of De Geer (1750) who, working with a species referred to as "la chenile à double queue du Saule" (possibly *Cerura vinula*), accurately described the gland and the irritating secretion produced and ejected when the caterpillar was disturbed. He described the secretion as possessing an "odeure très forte et pénétrante entièrement semblable à celle de liqueur que jettent les grands Fourmis de bois." Among the other early reports are those of Saunders (1881), Poulton (1887), Denham (1888), Packard (1895), and Latter (1897).

Poulton (1887) reported that species of the genus *Cerura*, when disturbed, emitted a fine spray which could be directed to the source of irritation and which was composed of 40% formic acid. Packard (1895) indicated that all *Cerura* species, *Macrurocampa marthesia*, and *Schizura concinna* possess such glands. Although the function of these glands is thought of principally for defense, Latter (1897) presented evidence that the formic acid, in the case of *Dicranura* (*Cerura*) *vinula* is also used for treating the silk of the cocoon, making it very hard, "waterproof and completely closed against aggressors." Studies by Saunders (1881) on *S. concinna* indicated that this species produced a secretion which was incorrectly identified as hydrochloric acid by Denham (1885). Detwiler (1922) noted both the range and direction of the spray, the location of the gland, and correctly identified the active principle of the secretion as formic acid, although he believed there to be other components.

This was confirmed by Weatherston et al. (1979) who showed that the gland consists of two sacs, the anterior and posterior glands joined by an interglandular neck. Both glandular sacs contained formic acid while the anterior sac also contained four minor components, three of which were identified as decyl acetate, dodecyl acetate, and 2-tridecanone, occurring in the ratio 92:9:2, and accounting for about 3.5% of the secretion.

A prothoracic gland complex very similar to that reported for *S. concinna* (Weatherston et al., 1979) was previously described by Eisner et al. (1972) for *Heterocampa manteo*. In this species, the gland contents were identified as formic acid (20–37%) with 2-undecanone and 2-tridecanone in the ratio of 3:1, and accounting for 1.4% of the secretion. *C. vinula* and *Notodonta anceps* have been shown to produce 40% formic acid (Hintze, 1969), the former species also containing DL-threonine, DL-aspartic acid, and L-lysine (Schildknecht and Schmidt, 1963). *Schizura leptinoides* secretes formic acid with no minor ancillary components (Eisner et al., 1961). According to Pavan and Valcurone-Dazzini (1976), nine species of notodontid larvae have been shown to secrete formic acid.

Within the genus *Datana*, Detwiler (1922) found that *D. ministra*, *D. contracta*, *D. intergerrima*, and *D. angusii* all "possessed glands somewhat similar to that of *S. concinna* but evidently very much simpler in structure." He also reported that the gland contents of *D. intergerrima* were acidic. In the present

study, the morphology and ultrastructure of the prothoracic gland of *D. ministra* are described and components of the secretion identified.

METHODS AND MATERIALS

The insects used in this study were collected from service-berry (*Amelanchier saguinea*) as larvae at Big Basswood Lake, Thessalon, Ontario, and maintained on this host in the laboratory.

For morphological observations, whole mounts of dissected glands from insects fixed with ethanol–acetic acid (3 : 1) were stained with Grenacher's borax carmine (Humason, 1967), dehydrated in ethanol, and cleared in xylene.

For ultrastructural studies, insects were injected with cold 5% glutaraldehyde in 0.05 M cacodylate buffer, pH 7.3, containing 2% sucrose and 0.01 M $CaCl_2$. The glands were dissected out of the insects, and placed in fresh glutaraldehyde. A small slit was made in each sac to allow proper fixation and infiltration of the embedding medium. Further processing of tissue was carried out as previously described (Percy and MacDonald, 1979).

For chemical studies insects were killed by freezing, decapitated while frozen, and the glands dissected from the thoracic cavity. The glands were stored at room temperature in N sodium hydroxide or methylene chloride until analyzed.

Gas–liquid chromatography (GLC) analyses were carried out on a Hewlett-Packard 5890 gas chromatograph fitted with flame ionization detectors, a 15-m × 0.25-mm fused silica column coated with Carbowax 20 M, and interfaced to a Hewlett-Packard 3392A integrator; and a Hewlett-Packard 5792 instrument fitted with flame ionization detectors, a 11.5-m × 0.20-mm fused silica column coated with methyl silcone, and interfaced to a Hewlett-Packard 3390A integrator.

The temperature program used in both cases was an initial temperature of 60°C (1 min) rising at 30°/min to 120°C, then at 10°/min to a final temperature of 210°C held for 4 min. With the Carbowax 20 M column, the operating conditions were: injector temperature 160°C, detector temperature 250°C, and a carrier gas (H_2) flow of 30 cm/sec. The operating conditions for the methyl silcone column were: injector temperature 240°C, detector temperature 310°C, and a carrier gas (H_2) flow of 42 cm/sec.

Gas chromatography–mass spectrometry (GC-MS) was carried out on a Kratos MS80 system operated at 70 eV and fitted with a 30-m × 0.32-mm fused silica column coated with DB-1 and programmed from 60°C (3 min) at 20°/min to 140°C, then at 10°/min to 250°C (3 min), then to 270° at 20°/min.

Decyl, lauryl, myristyl, palmityl, and stearyl acetates were obtained from Sigma Chemical Co., St. Louis, Missouri, and 2,4′-dibromoacetophenone from Aldrich Chemical Co. Inc., Milwaukee, Wisconsin. Dodecanol was prepared

by base methanolysis of lauryl acetate, and dodecyl formate by formylation of dodecanol according to standard procedures.

RESULTS

Ultrastructural Studies. When disturbed, *D. ministra* adopts a position typical of notodontid larvae with both the thorax and posterior abdominal segments elevated (Figure 1A). Despite this apparently overt defensive behavior, all attempts to induce the larvae to spray or exude the contents of the exocrine prothoracic gland were unsuccessful.

The gland is located in the ventral anterior portion of the prothorax and consists of a single sac. The gland is small, about 1.7 mm in length in the last instar, and is situated entirely beneath the longitudinal and oblique segmental muscles of the integument. A short duct leads to the orifice located within a transverse invagination in the cervical margin of the prosternite (Figure 1B).

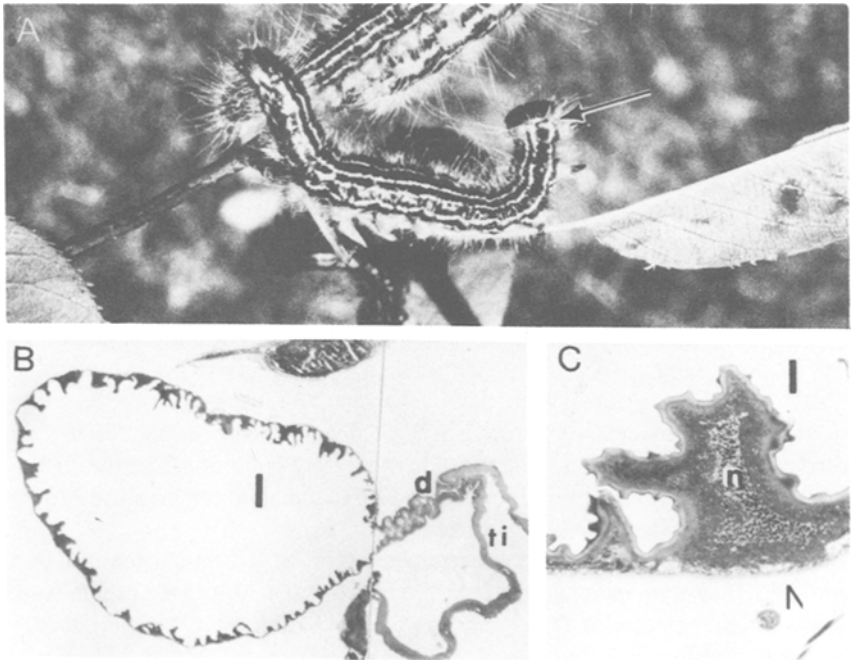

FIG. 1. (A) Late instar *Datana ministra* (Drury) larva in typical warning stance. Arrow indicates the position of the gland. (B) Sagittal section through the prothoracic gland; 38×. Lumen, l; duct, d; transverse invagination, ti. (C) Light micrograph showing irregular shape of gland cell; 720×. Lumen, l, nucleus, n.

The orifice is a simple slit and does not possess the complexity of cuticular structure or musculature seen in *S. concinna* (Weatherston et al., 1979).

The duct between the gland and the orifice has relatively thick cuticle (Figure 1B) and has a corrugated appearance due to annular folds in the cuticular lining. The cuticle is untanned and composed of a thin layer of dense epicuticle and several distinct lamellae of endocuticle. Unlike the analogous structure in *S. concinna*, no mesocuticle is present (Percy and MacDonald, 1979).

The gland lumen is lined with untanned cuticle presenting a surface that is highly convoluted and ridged to accommodate the large irregularly shaped cells (Figure 1C). A thin layer of dense epicuticle overlies an area containing numerous filaments and several lamallae of endocuticle (Figure 2A).

An outstanding feature of the underlying cells is the highly complex configuration of the apical plasma membrane, which is both everted within the cuticle as microvilli and inverted within the cells as folds. At the apices of the folds, there are also finger-like extensions of the plasma membrane which project even further into the cell (Figure 3).

Within the cytoplasm, numerous membranous tubules run parallel to the long axes of the microvilli, folds, and finger-like extensions. Within microvilli, the tubules extend freely in the cytoplasm (Figure 4A). Between the folds, the tubules are sometimes intimately associated with the apical plasma membrane (Figure 4B), and sometimes free within the cytoplasm (Figure 4A). Surrounding the finger-like extensions (fe in Figure 3), are tubules which, when in close association with the plasma membrane and when in cross-section, often present a striking rosette configuration (Figure 4B).

The large, obviously polyploid lobed nuclei, are surrounded by numerous active Golgi complexes and arrays of rough endoplasmic reticulum (Figure 2B). Some smooth tubular endoplasmic reticulum is also present. Numerous mitochondria are found, particularly below the cuticular extensions. Shortly after moulting, glycogen deposits appear peripheral to the nuclei, but quickly disappear. Lipid deposits are rarely present and, although microbodies occur, they are not numerous. Microtubules are observed throughout the cell.

The thick basement membrane is penetrated by numerous tracheoles (Figure 2A) which extend past the area of basal involutions and branch throughout the cells.

Chemical Studies. Absence of significant amounts of formic acid in the insect glands was evidenced by the failure to prepare the *p*-bromophenacyl ester from glands stored in sodium hydroxide by either the methods described by Weatherston et al. (1979) or Durst et al. (1975). The ester could be easily prepared from authentic formic acid. On several occasions the GLC trace of the product derived from insect material contained a trace peak at the retention time of the ester.

Analysis of the gland contents from two glands which had been stored in methylene chloride, by GLC on methyl silicone and Carbowax 20 M revealed

three major components (Figure 5). Their retention times and the ratio in which they occur are given in Table 1.

Base methanolysis of the secretion removed components A and B, indicating that they could be esters. Since component C tailed significantly on methyl silicone, we surmised that it was probably an alcohol. Since acetates have been found in the secretion of *S. concinna* (Weatherston et al., 1979), an homologous series of even-numbered carbon acetates (C_{10}–C_{18}) was chromatographed under the same conditions, and the retention time of authentic dodecyl acetate shown to be 8.34 min and 8.06 min on Carbowax 20 M and methyl silicone, respectively. This suggested that component B was dodecyl acetate.

Dodecanol obtained by base methanolysis of dodecyl acetate was similarly chromatographed, giving retention times of 9.07 min on Carbowax 20 M, and 6.61 min on methyl silicone, indicating that compound C might be dodecanol.

Since base methanolysis of the secretion yielded only one neutral product

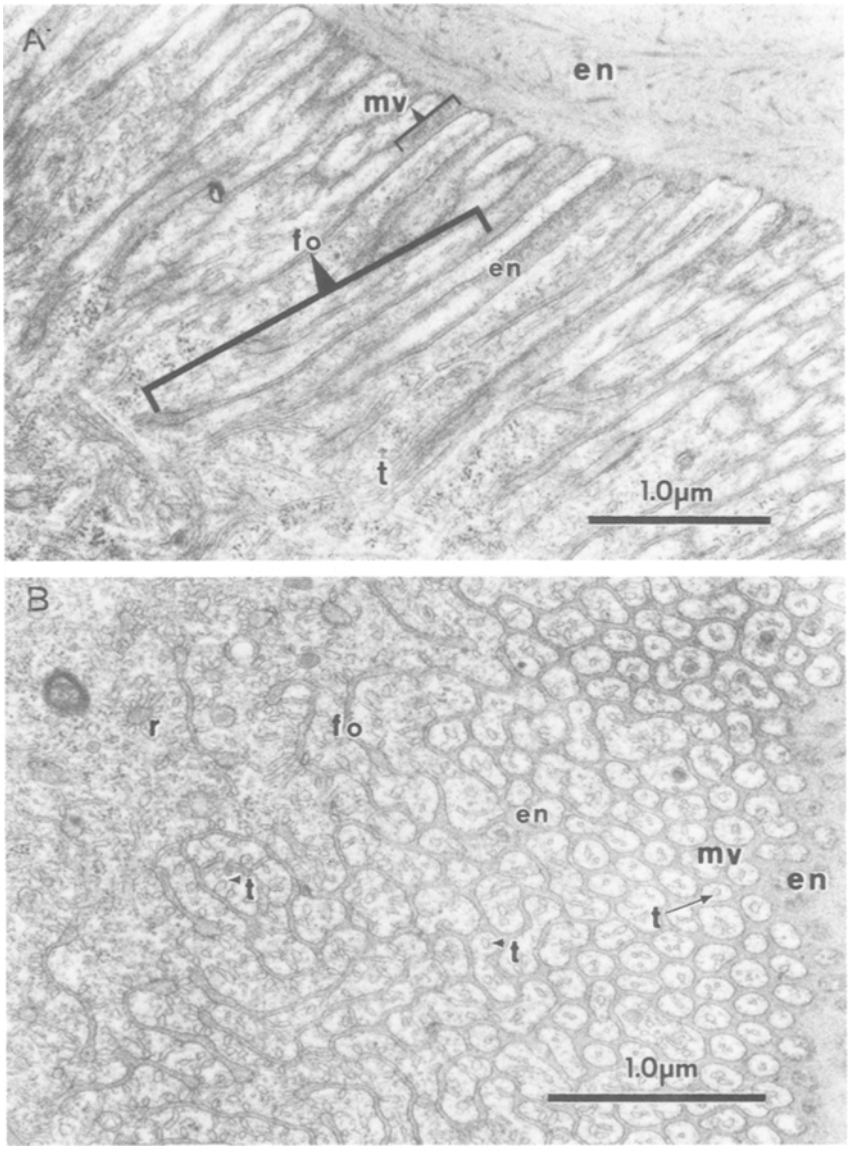

FIG. 4. (A) Longitudinal section through the apex of a gland cell showing microvilli, folds, and tubules free within the cytoplasm; 24000×. Endocuticle, en; microvilli, mv; folds, fo; tubules, t. FIG. 5. GLC traces of the gland contents on Carbowax 20 M (upper) and on methyl silicone (lower).

whose retention time on Carbowax 20 M was 9.09 min, it appeared that compound A was also an ester of dodecanol. This, coupled with the fact that we had only been able to detect an extremely small trace of formic acid as described above, led us to deduce that component A might be dodecyl formate. GLC analysis of authentic dodecyl formate gave retention times of 7.97 min and 7.19 min on Carbowax 20 M and methyl silicone, respectively. The tentative assignments of dodecyl formate, dodecyl acetate, and dodecanol to components A, B, and C, respectively, were confirmed by GC-MS.

DISCUSSION

The prothoracic gland systems of the notodontid larvae examined to date possess either one or two sacs (Table 2). From Table 2 it can be seen that this morphological characteristic is not reflected in the nature of the secretion. Al-

TABLE 1. RETENTION TIMES AND RATIO OF GLAND COMPONENTS OF *D. ministra* CHROMATOGRAPHED ON CARBOWAX 20 M AND METHYL SILICONE

	Carbowax 20 M		Methyl silicone	
	R_t (min)	Ratio	R_t (min)	Ratio
Component A	7.92	2.31	7.21	2.33
Component B	8.35	1.00	8.05	1.00
Component C	9.07	1.46	6.59	1.13
Dodecyl formate	7.97		7.19	
Dodecyl acetate	8.34		8.06	
Dodecanol	9.07		6.61	

TABLE 2. MORPHOLOGY AND CONTENTS OF PROTHORACIC GLANDS IN NOTODONTID LARVAE

Species	Morphology	Secretion	References
Datana ministra	one sac	lipophilics	Detwiler, 1922, this paper.
D. angusii	one sac	?	Detwiler, 1922
D. contracta	one sac	?	Detwiler, 1922
D. integerrima	one sac	acidic	Detwiler, 1922
Notodonta anceps	one sac	formic acid	Hintze, 1969
Cerura vinula	one sac	formic acid + amino acids	Hintze, 1969; Schildknecht and Schmidt, 1963
Litodonta hydromeli	two sacs	?	Percy, unpubl.
Macrurocampa marthesia	one sac	formic acid	Packard, 1895; Poulton, 1887
Heterocampa guttivitta	one sac	formic acid + ?	Percy, unpubl.
H. manteo	two sacs	formic acid + lipophilics	Eisner et al., 1972
Schizura concinna	two sacs	formic acid + lipophilics	Weatherston et al., 1979; Percy and MacDonald, 1979
S. unicornis	two sacs	formic acid	Detwiler, 1922; Percy, unpubl.
S. leptinoides	two sacs	20% formic acid, no additives	Eisner et al., 1961; Percy, unpubl.

though we can only report qualitative analytical data for the gland contents of *D. ministra*, the amounts of materials isolated were much less than from *S. concinna*. This is most probably related to the gland size, which in *D. ministra* is very small (1.7 mm in length) so that it is situated entirely beneath the longitudinal and oblique segmental muscles of the prothorax. By contrast, the gland of *S. concinna* (~ 6 mm in length) extends obliquely to the right posterior dorsal margin of the mesothorax (Weatherston et al., 1979); yet final instar larvae of both species are about the same size.

All the notodontids whose gland ultrastructure have been examined in this laboratory, *Litodonta hydromeli*, *S. unicornis*, *S. concinna*, *S. leptinoides*, and *Heterocampa guttivitta* (Percy and MacDonald, unpublished) possess finger-like inversions of the apical membrane surrounded by membraneous tubules parallel to the long axes of the extensions, and which give a rosette configuration in cross-section. Similar-appearing structures have been observed in midgut cells of the aphid *Hyperomyzus lactucae* (O'Loughlin and Chambers, 1972) and in the wax-producing epidermal gland of a scale insect (Waku and Foldi, 1984). The apical membrane configuration of the *D. ministra* gland cells which possess true microvilli is more complex than those of the cells of insect pheromone-

producing glands and arthropod defensive glands which, in general, are merely highly convoluted (Percy and Weatherston, 1974).

All notodontid larvae examined to date in relation to their chemistry have been shown to produce formic acid (Table 2) (Pavan and Valcurone-Dazzini, 1976). Although Detwiler (1922) reported that the gland contents of *D. integerrima* were acidic, *D. ministra* is the first *Datana* species to have the gland contents analyzed. Our analyses indicate that the glands do not contain formic acid but only a mixture of dodecanol and the two corresponding formate and acetate esters. This is the first report of an alkyl formate in an exocrine secretion of a lepidopteran insect, although synthetic formates have been shown to act as sex attractants, synergists, inhibitors, and disruptants for several lepidopteran species (Henneberry et al., 1981).

No tests were carried out which would have given an insight as to the function of the secretion. Analogy to other notodontid species would seem to indicate that the materials were produced for defense; e.g., Eisner et al. (1961) reported that the lipophilic components isolated from *H. manteo*, although acting as spreading agents and aids to cuticle penetration of the formic acid, also have a defensive function themselves. The following indirect and fragmentary evidence leads us to the conclusion that the secretion from the exocrine prothoracic gland of *D. ministra* does not function as a defensive mechanism: (1) Formic acid is absent in the gland. (2) The glands, although present from the second through the fifth instar, are only replete in the last instar; this differs from *S. concinna* in which the glands from the second instar onwards are charged (Percy and MacDonald, unpublished). (3) On provocation, *D. ministra* adopt the warning posture (Figure 1A); however, even on extreme provocation do not spray, but regurgitate their gut contents. This is in contrast to *S. concinna* which, in common with other notodontids of the genera *Cerura* and *Macrurocampa*, rear up and aim their spray towards the source of the annoyance (Weatherston et al., 1979; Herrick and Detwiler, 1919; Poulton, 1887; Packard, 1895). (4) The difference in the complexity between the gland orifice of *D. ministra* (a single slit) and that of *S. concinna* (containing many folds, spikes, and cuticular projections) would indicate that only the latter possesses a mechanism for ejecting the secretion atomized into a fine spray.

The inability of the insects to spray would not contradict the possibility that the secretion functions as an alarm pheromone. However, there was no evidence in the laboratory of dispersal within a colony when an individual was provoked.

D. ministra are gregarious feeders until during the last instar, at which time they begin to disperse, and since it is only during this instar that the glands are charged with secretion, it can be conjectured that the secretion may act as a "dispersal pheromone."

Acknowledgments—We wish to thank Dr. John Rawlins, University of Texas, Austin, for the gift of specimens of *Litodonta hydromeli*. This study was supported by NSERC grant A2784 to I.W.

Abstract—We report the identification of the southwestern corn borer, *Diatraea grandiosella* Dyar (Lepidoptera: Pyralidae), female sex attractant pheromone as a mixture of (Z)-9-hexadecenal, (Z)-11-hexadecenal, and (Z)-13-octadecenal in the ratio 21.5:70.6:7.9. Initially, six 16- and 18-carbon aldehydes including *n*-hexadecanal, (Z)-9-octadecenal, (Z)-11-octadecenal, and the three above were isolated from female gland rinses and evaluated as potential pheromone components by GLC-MS and laboratory bioassays. By laboratory flight chamber and field tests, the stated mixture of (Z)-9-hexadecenal, (Z)-11-hexadecenal, and (Z)-13-octadecenal was shown to be as effective as the female for male attraction. Electrophysiological studies confirmed the requirement for these three compounds, but not for *n*-hexadecanal, (Z)-9-octadecenal, and (Z)-11-octadecenal.

Key Words—Southwestern corn borer pheromone, *Diatraea grandiosella* Dyar, Lepidoptera, Pyralidae, (Z)-9-hexadecenal, (Z)-11-hexadecenal, (Z)-13-octadecenal, *Zea mays* L.

INTRODUCTION

The southwestern corn borer, *Diatraea grandiosella* Dyar is an important pest of corn in the southwestern and southeastern United States and in Mexico. It is

[1] Lepidoptera: Pyralidae.
[2] Mention of a commercial or proprietary product in this paper does not constitute endorsement of this product by USDA.

0098-0331/86/1100-2051$05.00/0

one of the major insect pests of irrigated corn in certain areas of Kansas, Oklahoma, Texas, and New Mexico. In these areas, the insect regularly causes heavy yield losses if not controlled by insecticides. For insecticides to be effective, they must be applied when eggs and young larvae are present on the plant. Once larvae enter secluded areas on the plant, such as in ears and stalks, insecticide effectiveness is greatly induced. Thus, timing of insecticide applications is critical and relies on the ability to pinpoint the presence of eggs and young larvae on the plant.

In recent years, pheromones have been used more and more as monitoring tools for determining adult insect flights. The presence of a sex attractant pheromone produced by southwestern corn borer (SWCB) females was indicated by field tests (Davis and Henderson, 1967; Langille and Keaster, 1973). The identification of the sex attractant pheromone of the SWCB and its subsequent commercial availability could have considerable value for monitoring adult populations of this pest and for potential behavioral manipulations within an integrated pest management system.

We report the identification of the female sex attractant pheromone of *D. grandiosella* through chemical, laboratory flight chamber, electrophysiological, and field behavioral experiments.

METHODS AND MATERIALS

Insects. Adult *D. grandiosella* used in chemical analyses, electrophysiological experiments, laboratory behavioral bioassays, and some field studies were obtained from a colony maintained on a wheat germ–casein diet (Davis, 1976) in the Crop Science Research Laboratory, Mississippi State, Mississippi, 39762.

Chemical Analyses. Initially, abdominal tips were excised from ca. 24-hr-old virgin females and ground in batches of ca. 1000 in pentane or hexane. The filtrate was concentrated and chromatographed on a 2 × 25-cm Biosil A® (silicic acid) column from which the active components were eluted with hexane-methylene chloride (50:50). Aliquots were employed for a series of functional group tests and were also subjected to ozonolysis (Beroza and Bierl, 1966).

An active fraction was also collected by preparative GLC of tip extracts from a 0.0032 × 1.5-m stainless-steel column packed with 5% Ap L® on 60/80 Gas Chrom Q, 200°C; flow = 30 ml/min. The active fraction was ozonized, cleaved with triphenylphosphine to aldehydes, and then analyzed by GLC-MS employing the previously described Ap L column.

Later, abdominal tips from calling females (ca. 2 hr into scotophase) were rinsed in heptane (5 μl/tip) for 1 min (Klun et al., 1980a,b) to minimize the occurrence of interfering compounds. After concentration under a N_2 stream, an aliquot equivalent to 5 tips/μl was analyzed on a Hewlett-Packard 5792A capillary GLC equipped with a DB-1 fused silica capillary column (60 m ×

0.253 mm ID, film thickness 1 μM, J&W Scientific Co., Cordova, California). The carrier gas was Helium, 40 cm/sec. The oven temperature was programmed from 70 to 250°C at 10°C/min (injection temperature = 200°C, detector temperature = 250°C). Rinses from ca. 2000 abdominal tips were concentrated and fractionated by isocratic high-performance liquid chromatography (HPLC) on a 10-cm Waters μResolve® silica column using 0.75% toluene in isooctane at a flow rate of 1.5 ml/min. Detection was accomplished with a Waters model 450® variable wavelength detector at 295 nm. Peaks were quantitated with a Hewlett Packard 3390A integrator. HPLC fractions were analyzed by GLC on the DB-1 column. Subsequently, a DB-1 (GLC) column (60 m × 0.322 μm) was interfaced to a Hewlett Packard 5985-B® quadrupole mass spectrometer through an open-split interface for acquisition of mass spectra. Aliquots equal to 50 female tips were generally adequate to obtain spectra of major components.

Identification of pheromone components was accomplished by comparing GLC retention volumes and mass spectra with standard compounds acquired commercially or prepared by synthesis. (*Z*)- and (*E*)-9-hexadecenal and (*Z*)- and (*E*)-11-octadecenal were synthesized by oxidation of the related unsaturated *Z*- and *E*-alkenols (Nu-Chek Prep, Inc., Elysian, Minnesota) using chromic anhydride in pyridine (Holum, 1961). Additionally, a number of aldehydes and acetates were acquired by purchase from Shin-Etsu Chemical Co., Ltd., Tokyo, Japan, and Sigma Chemical Co., St. Louis, Missouri. Purity of purchased compounds typically exceeded 98%.

Electrophysiology. Electroantennogram (EAG) techniques used were similar to those described in detail (Schneider, 1957; Dickens, 1979). Briefly stated, Ag–AgCl electrodes filled with insect physiological saline were used. After prepuncture with a sharpened tungsten needle, the recording electrode was placed in either the terminal or penultimate antennal segment, and the indifferent electrode was implanted in the proximal antennal segment.

Single sensillum recording techniques used are described in detail elsewhere (Boeckh, 1962; Dickens, 1979). In general, recordings were made with 50.8-μm-diameter tungsten wire electrolytically sharpened to a tip diameter of ca. 1–2 μm. The recording electrode was positioned under optical control (100×) with a Leitz high-power micromanipulator near the base of a single sensillum trichodeum. The indifferent electrode was implanted in a nearby antennal segment. Records of EAG and single cell reponses were made on Polaroid film.

Two methods of odor delivery were used in these experiments. In one method, candidate odorants were delivered as 1-μg samples placed on filter paper strips (20 × 7 mm) in 20-ml eccentric tip syringes. From a distance of ca. 1 cm, a 10-ml puff of odor-laden air was delivered to the preparation by an air-driven piston device. Stimulus duration was ca. 1 sec. In a second method of odor delivery, potential pheromone compounds were delivered as 10-μl samples of serial dilutions placed on filter paper (8 × 18 mm) inserted into glass

cartridges (5 × 80 mm ID) and oriented toward the preparation from ca. 1 cm. Hydrocarbon-free air (filtered and dried) carried odor molecules evaporating from the filter paper over the antennal preparation. Stimulus duration was 1 sec as regulated by a solenoid valve. Air flow was 1 m/sec as measured by a thermistor. Serial dilutions of potential pheromone compounds were prepared in nanograde pentane.

Flight Chamber Bioassay. The flight chamber was constructed in the general shape of a half cylinder (length 2.4 m, width 0.91 m, height 0.55 m) and is similar in design to the one used by Miller and Roelofs (1978). A large fume hood was located at the downwind end of the flight chamber to eliminate residual pheromone. Wind speed within the chamber was regulated at 1.4 km/hr. A dim source of light was provided by two banks of red-painted, 7.5-W appliance bulbs located at distal ends of the chamber.

Single males (less than 24 hr postemergence) were placed into 5 × 7.6-cm (H × D) wire mesh cages and preconditioned in the dark within the bioassay room (26.7 ± 1.0°C, relative humidity not regulated) for 2–3 hr prior to assay in large plastic containers. Similarly, two virgin females, used as controls, were placed into each wire mesh cage and preconditioned to induce calling.

Rubber septa (A.H. Thomas, No. 8753-D22) that had been exhaustively extracted in a Soxhlet apparatus with CH_2Cl_2, were used as the pheromone-release substrates. Each septum was treated with 100 μg of pheromone in 100 μl of heptane 24 hr prior to testing and sealed in a glass vial. This concentration was based on a preliminary study conducted to determine the most appropriate concentration to use for flight chamber testing. Pheromone component ratios were based upon triplicate GLC measurements of female abdominal tip rinses as previously described (Table 1). Where one or more of the six components was excluded, the ratios of the others were maintained.

The bioassay procedure consisted of: (1) attaching the screen cage containing the male to the screen covering at the downwind end of the chamber at a predetermined location within the pheromone plume; (2) allowing the male 5 min to adapt to wind tunnel conditions; (3) placing the treated septa or the cage containing the virgin females on a metal wire (27.5 cm high) located in the center of the flight chamber 2.3 m upwind from the male; (4) releasing the male from the cage 30 sec after initiation of wing fanning; (5) observing the male's flight behavior for 5 min (Figure 1); (6) removing pheromone source and male from flight chamber; and (7) exhausting flight chamber for 5 min to remove residual pheromone from the flight chamber before testing the next treatment. Males were used only once.

Bioassays were conducted in a random fashion. One male equaled one observation for each treatment. Each group of treatments was randomized and repeated up to 25 times. The percent landing on the source and the time of flight from initiation to landing on the pheromone source were recorded.

Field Studies. Two studies were conducted at Mississippi State, Missis-

TABLE 1. RELATIVE COMPOSITIONS AND QUANTITY PER INSECT OF SOUTHWESTERN CORN BORER PHEROMONE COMPOUND (BASED ON GLC ANALYSES OF TIP RINSES)

Compound	Composition (%)[a]	Quantity per insect (ng)
(Z)-9-Hexadecenal	17.1	2.3
(Z)-11-Hexadecenal	56.3	10.2
n-Hexadecanal	14.9	2.5
(Z)-9-Octadecenal	4.5	0.9
(Z)-11-Octadecenal	0.9	0.05
(Z)-13-Octadecenal	6.3	1.2

[a] These percentages were subsequently used to establish the ratios of blends used in all flight chamber and field tests.

sippi, in May 1985 and in July–August 1985 to compare the attractiveness of synthetic SWCB pheromone blends and virgin females. A third study was conducted in Castro County, Texas, in July–August 1985. The Mississippi studies were conducted in corn fields infested with laboratory-reared SWCB larvae. Responding males were a mixture of wild insects and those from artificial infestation. The Texas studies were conducted in a corn-growing area with high natural infestations of SWCB. The procedures used in the field studies were similar with only minor modifications. In the May 1985 test at Mississippi State,

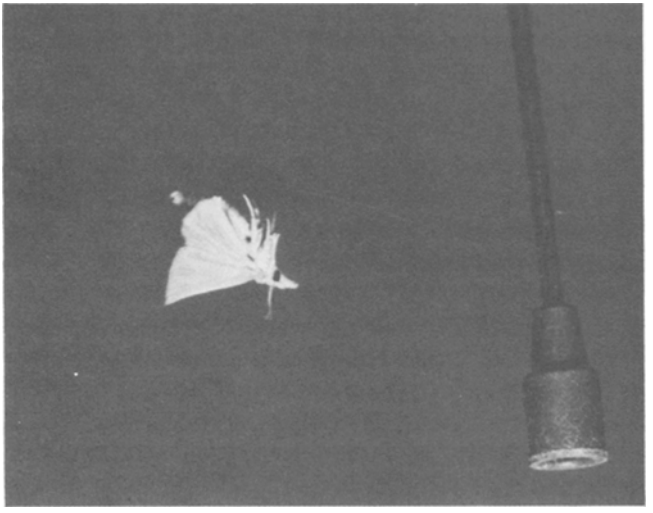

FIG. 1. Male southwestern corn borer moth responding in the flight chamber to a rubber septum impregnated with the synthetic pheromone formulation.

traps were baited with 1500 μg of the three-component formulation found effective in the flight chamber tests: (*Z*)-9-hexadecenal, (*Z*)-11-hexadecenal, and (*Z*)-13-octadecenal (21.5:70.6:7.9); or a four component formulation: (*Z*)-9-octadecenal, (*Z*)-11-hexadecenal, (*Z*)-9-octadecenal, (*Z*)-13-octadecenal (20.4:66.9:5.4:7.5). A solvent control and virgin SWCB females were also included. The treatments were arranged in a 4 $\times$ 4 Latin square within a field of corn that was in the seedling stage of growth. Each treatment was suspended in a small wire cage within Scentry® wing traps held 1 m from the ground by metal stands. The distance between traps was 25 m. A uniform SWCB male population was created around and within the test area by placing 53 SWCB male pupae obtained from our laboratory culture in each of 25 small wire emergence cages suspended 1 m from the ground by metal stands. The experiment was initiated one day after the first adult was observed to have emerged from the field emergence cages.

The number of males captured was recorded, and septa, females, and trap bottoms were replaced daily. The study was conducted for five consecutive nights. Data on the numbers of males captured per night were analyzed using the ANOVA. The Student-Newman-Kuels' test ($P < 0.05$) was employed for separation of means.

In the July–August 1985 tests in Mississippi and Texas, the previously defined three-component formulation only, at 500 and 1500 μg, was employed. In addition to solvent controls, traps holding two Mississippi females (less than 24 hr old) per trap were used in the Mississippi test, and two Mississippi females and two Texas females each were used in the Texas tests. The tests were of RCB design with two replications over a three-week period. The traps were the Pherocon 1C® wing with a metal stand; height, 1 m; distance between traps, 50 m.

The weekly schedule was: Monday, deployment of traps with formulations; Wednesday, remove and record numbers of males and rerandomize treatments; Friday, remove and record numbers of males; remove septa and females; the following Monday, repeat schedule. The statistical analysis was as above.

RESULTS AND DISCUSSION

Chemical Analyses. In the initial work, aliquots of a partially purified, biologically active fraction extracted from the abdominal tip were analyzed to determine the nature of the active substance(s). Silica gel TLC evidence was consistent with a ketone, aldehyde, ester, or similar compound, but not an alcohol or a hydrocarbon. Catalytic hydrogenation (5% palladium on charcoal) destroyed pheromonal activity, suggesting unsaturation. Sodium borohydride and 2,4-dinitrophenylhydrazine destroyed the activity, suggesting a carbonyl function. Because the activity was only slowly decreased by saponification, but

rapidly destroyed by lithium aluminum hydride, an ester was not indicated. Neither prolonged treatment with diazomethane nor reaction with trichloroacetyl isocyanate destroyed the activity; thus an alcohol function was unlikely. Because the activity was slowly destroyed by hydrochloric, sulfuric, and phosphoric acids, the phosphoric acid test for epoxides was inconclusive. GLC retention indices with the Ap L column indicated several components with 16–20 carbon atoms or their equivalents. Thus, the sum of these tests gave presumptive evidence for unsaturated carbonyl compounds.

Ovipositor extracts (100 females, 1 min rinse procedure) were analyzed by GLC and GLC-EI-MS employing the 60-m DB-1 column. The spectra and retention volumes of the major components, (*Z*)-9-hexadecenal, (M^+ 238), (*Z*)-11-hexadecenal (M^+ 238), and *n*-hexadecanal (M^+ 240), were comparable to that of authentic compounds. *n*-Hexadecanal was separated from an obscuring peak of isopropyl myristate (M^+ 270) and identified only after separation by HPLC. Three other peaks in active ovipositor extracts included (*Z*)-9-octadecenal, (M^+ 266), (*Z*)-11-octadecenal (M^+ 266), and (*Z*)-13-octadecenal (M^+ 266), and they accounted for approximately 11% of the total content.

The relative composition of the six candidate pheromone compounds (average of four replicates of 10 insects) was: (*Z*)-9-hexadecenal/(*Z*)-11-hexadecenal–*n*-hexadecanal–(*Z*)-9-octadecenal–(*Z*)-11-octadecenal–(*Z*)-13-octadecenal (17.1 : 56.3 : 14.9 : 4.5 : 0.9 : 6.3 (Table 1). The average recovery of each, respectively, from 1-min heptane tip rinses was 2.3, 10.2, 2.5, 0.9, 0.05, and 1.2 ng/insect. The relative composition of the three (later established) essential pheromone compounds was (*Z*)-9-hexadecenal–(*Z*)-11-hexadecenal–(*Z*)-13-octadecenal: 21.5 : 70.6 : 7.9.

Structural assignments were made for several other compounds using more concentrated ovipositor extracts (approximately 1000 females) by GLC and GLC-EI-MS analysis. These compounds accounted for approximately 9% of the integration count from calling female ovipositor rinses but were present in higher concentrations in less active extracts in which tips were held in solvent for longer periods. Listed in the order of increasing elution times, they are: 2,6-di-tertiary-butyl-4-methyl phenol(probable solvent impurity), isopropyl myristate, (*Z*)-9-hexadecenol, (*Z*)-11-hexadecenol, *n*-hexadecanol, palmitoleic acid, palmitic acid and, perhaps, (*Z*)-9-hexadecen-1-ol acetate.

(*E*)-9-Hexadecenal and (*E*)-11-hexadecenal were prepared by oxidation from their respective *E* alkenols. The *E* aldehydes had slightly longer GLC retention volumes, but there were no apparent differences in the mass spectra of the *E* and *Z* aldehydes. Infrared spectra of the two synthetic *Z* aldehydes did not show the absorption in the 950–1000 cm^{-1} region exhibited by the two synthetic *E* aldehydes, evidence for the isomeric purity and correct assignment of the synthesized aldehydes as *Z* isomers.

Electrophysiology. Electrophysiological studies initially verified the essentiality of (*Z*)-9-hexadecenal and (*Z*)-11-hexadecenal as pheromone compo-

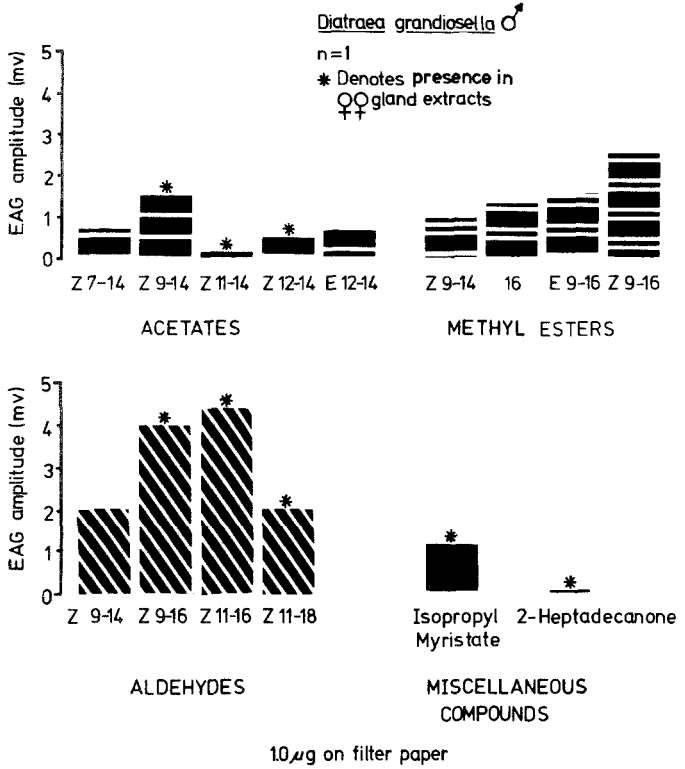

FIG. 2. Electroantennogram (EAG) response of SWCB males to volatiles emanating from 1 μg of several candidate pheromone components (and other compounds) identified in chemical studies from 1976–1983.

nents. Among compounds tested with various functional groups, the antennal receptors were shown to be more responsive to aldehydes than to acetates or methyl esters (Figure 2). This heightened responsiveness was especially clear for the 16-carbon aldehydes with unsaturation at the 9 or 11 position.

Subsequent electrophysiological recordings of cells associated with individual sensilla trichodea revealed the presence of at least two cells with differing spike heights associated with each sensillum (Dickens, unpublished). In each of four recordings made from the sensilla, the cell with the larger amplitude spike responded to the (Z)-11-hexadecenal, while the cell with the smaller amplitude spike was reliably activated by the (Z)-9-hexadecenal.

Further EAG investigations revealed antennal receptors of SWCB males to be highly responsive not only to (Z)-9-hexadecenal and (Z)-11-hexadecenal, but also verified the essentiality of a third compound, (Z)-13-octadecenal (Figure 3). However, *n*-hexadecanal, (Z)-9-octadecenal, and (Z)-11-octadecenal

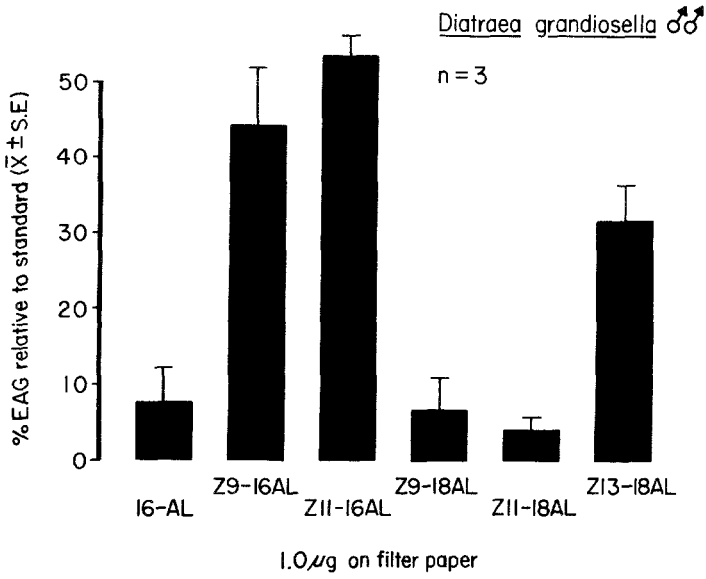

FIG. 3. Mean EAGs of SWCB males to volatiles emanating from 1 μg of six potential pheromone components identified from female abdominal tip extracts in 1983–1984.

also elicited significant EAGs, but only at higher dosages. Thus (Z)-9-hexadecenal, (Z)-11-hexadecenal, and (Z)-13-octadecenal were indicated as the major pheromone components.

Laboratory Flight Chamber Tests. Studies were conducted to determine which pheromone blends were most effective in attracting males. The blends were formulated with each appropriate compound included at the same relative ratios as established by GLC analyses (Table 1). There were at least 16 males/treatment used in testing each formulation. The results are given in Table 2.

Females were effective in attracting males, with 96% landing on the source with an average time of flight of 60 sec. Formulation A containing all six of the candidate components attracted 76% of the males tested in an average time of 60 sec. Failure to include (Z)-9-hexadecenal, (Z)-11-hexadecenal, or (Z)-13-octadecenal (in turn) with the other five components resulted in no attraction (B, C, D). Elimination of *n*-hexadecenal, (Z)-9-octadecenal, and (Z)-11-octadecenal, in turn, from five-component mixtures (E, F, G) did not prevent male performance although the attractiveness was somewhat poorer than that of females. Elimination of *n*-hexadecenal, (Z)-9-octadecenal, and (Z)-11-octadecenal (in pairs) from four-component mixtures also did not prevent male attractiveness (H, I, J). Three two-component mixtures which did not include, in turn, (Z)-9-hexadecenal, (Z)-11-hexadecenal, or (Z)-13-octadecenal were not attractive (K, L, M). Finally, the three-component mixture consisting of (Z)-

TABLE 2. FLIGHT CHAMBER RESPONSES OF SOUTHWESTERN CORN BORER MALES TO 14 SYNTHETIC FORMULATIONS; PERCENT SUCCESSFUL FLIGHTS AND TIME REQUIRED.

Treatment	Formulation[a]

[a] 100 μg of formulations employing the percentage ratios given in Table 1. Where one or more components are excluded, the total of the percentages is less than 100.

9-hexadecenal, (Z)-11-hexadecenal, and (Z)-13-octadecenal (N) was as efficient as the virgin female in attracting males to the pheromone source (96%), and the flight time was somewhat shorter (46 sec).

Field Tests. The May 1985 Mississippi test employed laboratory-reared, released males because the native population was very low at that time. The results of the test showed that the three-component blend was as effective as females in attracting males. A four-component blend that additionally included (Z)-9-octadecenal was equally effective (Table 3, and Figure 4). The four-component blend was evaluated to determine whether an additional component might

[c] 1500 μg of (Z)-9-hexadecenal–(Z)-11-hexadecenal–(Z)-9-octadecenal–(Z)-13-octadecenal (20.4:66.9:5.4:7.5).

either decrease or improve the attractiveness. The possibility of decreased attractiveness had been suggested from the results of the flight chamber bioassays (Table 2).

The results of the July–August 1985 Mississippi and Texas tests which were conducted in corn-growing areas with high natural infestations are summarized in Table 4. The tests show that the defined three-component formulation was as effective as either native Mississippi or Texas females in attracting males from either geographical location. Although not statistically significant, there appeared to be an indication that the 1500-μg formulation is more attractive than the 500-μg formulation and may out perform it over an extended pe-

TABLE 4. SOUTHWESTERN CORN BORER MALES CAPTURED IN MISSISSIPPI AND TEXAS FIELD TESTS, JULY–AUGUST 1985 (MEAN OF CAPTURES PER TRAP PER 2 NIGHTS)

Treatment	Mean[a]	
	Mississippi	Texas
3-Component, 500 μg[b]	8.67a	8.17a
3-Component, 1500 μg[b]	16.92a	10.83a
Virgin Mississippi females	15.92a	10.17a
Virgin Texas females		5.75a
Solvent control	0.08b	

[a] Means followed by the same small letter are not significantly different at the $P < 0.05$ level according to the Student-Newman-Kuels' test.
[b] (Z)-9-Hexadecenal-(Z)-11-hexadecenal-(Z)-13-octadecenal (21.5:70.6:7.9).

riod. There also was no statistically significant difference in the ability of Texas or Mississippi females to attract Texas males.

In subsequent field tests (to be reported in detail later) using a pheromone-baited, nonsaturating *Heliothis* Scentry trap, rather than the sticky trap, much higher captures have been recorded, in fact, as many as 724 males per night. Also evidence has been obtained that the 1500-μg formulation retains a degree of effectiveness for two to four weeks.

In summary, the sex attractant pheromone of the southwestern corn borer has been identified and shown to be very potent and effective for attracting males over its geographical range.

Acknowledgments—The authors thank Thomas Oswalt, Maggie Collier, Betty Yeatman, and Sen-Seong Ng of this laboratory for rearing and handling of insects. They appreciate the valuable suggestions of S.B. Ramaswamy, Department of Entomology, Mississippi State, Mississippi. Additionally, the authors express special appreciation to Pat Morrison of the Texas Agricultural Extension Service and to James White of Funk Seeds International for supply and transportation of female southwestern corn borer pupae with regard to the Texas field tests.

SEX-IDENTIFYING URINE AND MOLT SIGNALS IN LOBSTER (*Homarus americanus*)

JELLE ATEMA and DIANE F. COWAN

Boston University Marine Program
Marine Biological Laboratory
Woods Hole, Massachusetts 02543

(Received June 27, 1985; accepted December 18, 1985)

Abstract—During courtship, premolt female lobsters, *Homarus americanus*, choose a male and initiate a pair bond by repeated approaches to his shelter. The male allows such a female to share his shelter for about one week. This knowledge formed the basis to search for quantitative evidence for lobster sex pheromone(s) used in courtship: male cues to allow premolt females to identify a preferred male, and female cues to allow males to identify a premolt mature female. In each of four 1500-liter naturalistic aquaria, the behavioral responses of one female and two male lobsters to male and female lobster urine (0.5 ml) and body odor (20 ml) stimuli were observed. These stimuli were injected once or twice per day into a continuously flowing delivery tube attached to lobster shelters. Habituation to stimulus introduction—a serious problem in earlier experiments—was apparently avoided in the more natural social and physical environment we employed in these experiments. We demonstrated that male and female molt body odors contain different chemical substances: females responded to male molt body odor and males responded to female molt body odor but not vice versa. In general, male and female intermolt urine caused strong responses; however, females responded only weakly to male urine. This suggests that male and female urine are chemically different. Female urine and molt body odor caused a typically male "high-on-legs" response. These results show that molt body odors and intermolt urine contain sex-specific substances, which may be used in lobster courtship as well as other social interactions.

Key Words—Lobster, *Homarus americanus*, sex pheromone, urine odor, body odor, courtship, chemical communication.

INTRODUCTION

Behavioral evidence for female sex pheromones has been obtained in various Crustacea (Ryan, 1966; Dahl et al., 1970; McLeese, 1970; Atema and Engs-

0098-0331/86/1100-2065$05.00/0

trom, 1971; Teytaud, 1971; Kamiguchi, 1972; Katona, 1973; Kittredge et al., 1971; Eales, 1974; Ameyaw-Akumfi and Hazlett, 1975). In a review of crustacean sex pheromone research, Dunham (1978) argued convincingly that important aspects of experimental design had often been lacking in these studies. However, in many of these studies the possibility of a sex pheromone acting other than as an attractant must be considered, as well as the role of behavioral reinforcement by social interactions, habituation to repeated presentation of unreinforced stimuli, natural biological rhythms, etc. (Atema et al., 1979; Atema and Cobb, 1980; Dunham, 1985). Despite a rather large number of studies by several authors on sex recognition in crayfish, Dunham's recent review (1985) concludes that it remains debatable whether these animals are capable of sex recognition or even species recognition by chemical stimuli, since results are inconsistent and inconclusive.

Early attempts to identify and isolate a female sex pheromone in *Homarus americanus* failed (Atema and Gagosian, 1973; Gagosian and Atema, 1973; McLeese et al., 1977; Atema, unpublished) probably due to the lack of understanding of its biological function and context. It was formerly believed that female lobsters—like moths—were sedentary dispersers of pheromones. Through further behavioral studies in the laboratory (Atema et al., 1979; Cowan and Atema, 1985) and in the field (Karnofsky and Atema, 1979) we have learned that females, not males, are the active partners in sexual selection, seeking mature male lobsters in their shelters. This search and selection takes place in the premolt period and involves courtship and pheromones. Therefore, a bioassay requiring a male to locate the source of release is unnatural and, as experience showed, is doomed to failure. Under conditions where single males were presented with a social odor in the absence of other stimuli, responses often habituated or did not allow discrimination between odors (Atema, unpublished).

Based on new understanding of the role of the female lobster sex pheromone, we designed a naturalistic odor testing situation in which natural context was preserved and habituation was avoided. Similarly, Gleeson (1980) and Gleeson et al. (1984) designed a successful bioassay for blue crab sex pheromone(s) based on the male's natural response to premolt females. We use the term "pheromone" to describe a body odor produced in the context of communication; it may be a mixture of compounds. "Body odor" refers to the entire chemical output which any organism produces as a result of metabolism; body odor may include urine, urine pheromones, and/or other pheromones. Many body odors may be detected and used in predation or social behavior without there being evidence for communication (Atema et al., 1980; Atema and Stenzler, 1977; Bryant and Atema, 1986).

We chose three potential sources of chemical signals that may have social significance: intermolt urine, molt body odor, and intermolt body odor. Urine was shown to be the source of female sex pheromones in crabs (Ryan, 1966; Gleeson, 1980). Crustacean urine, including in lobsters, is stored in bladders,

an indication of the need for controlled release. Control of urine release was implied in a study of female crab pheromones (Christofferson, 1978). Urine is released from a bilateral pair of papillae (nephropores) at the base of the large (second) antennae into the powerful gill current (McPhie and Atema, 1984; Atema 1985), suggesting that the gill current is used—among other functions—as a broadcast system for chemical signals.

Molt body odor is the mixture of metabolites in the water collected from the tank of a molted animal. Mature females molt about one half hour before mating. Molting and mating take place about midway during a cohabitation period of about one week in the male shelter (Atema et al., 1979). Mature female "molt water" contains the female lobster sex pheromone (McLeese, 1970; Atema and Engstrom, 1971) to which males show a typical posture variously described as "mating dance" or "high-on-legs" (Atema and Engstrom, 1971; Atema and Cobb, 1980). Similarly, intermolt body odor is the mixture of metabolites in the water collected from intermolt lobsters. There is no evidence for specific pheromones in intermolt water, but field and laboratory observations (Karnofsky and Atema, 1979; Cowan and Atema, 1985) suggest that lobsters can distinguish between intermolt individuals.

One other aspect of odor signals is important to consider: dispersal and dilution. In mature lobsters, the gill current projects the animal's body odor some seven body lengths forward (McPhie and Atema, 1984; Atema, 1985) with or without the addition of urine. After about seven body lengths, the gill current has lost most of its momentum due to viscous drag (vortices and turbulence) and "dissolves" in a large dilute odor cloud. Ambient currents pick up this cloud and disperse and dilute it further. Reasonable estimates of odor dilution are not known in this or most other cases. Rough estimates can be obtained from measurements of dye diluting away from a stationary source, where dilution of 3–4 orders of magnitude were regularly observed at distances of 3–10 cm away from the source. These figures refer to the relevant parameter, odor peaks, not the commonly used but less significant parameter, average odor dilution. For a discussion of aquatic odor dispersal see Atema (1985).

With our naturalistic bioassay (see Methods and Materials), we provide evidence for special molt substances in male and female molt body odor and for chemical differences between male and female urine. Our focus was on males responding to female cues, since the best evidence thus far was for female pheromones. This focus is reflected in the experimental design using intermolt males in shelter as the primary group of receivers.

METHODS AND MATERIALS

Four groups of three mature lobsters, two males and one female each, were kept in four 1500-liter aquaria under seasonally adjusted artificial light–dark cycles and ambient flow-through seawater conditions (Figure 1). The three lob-

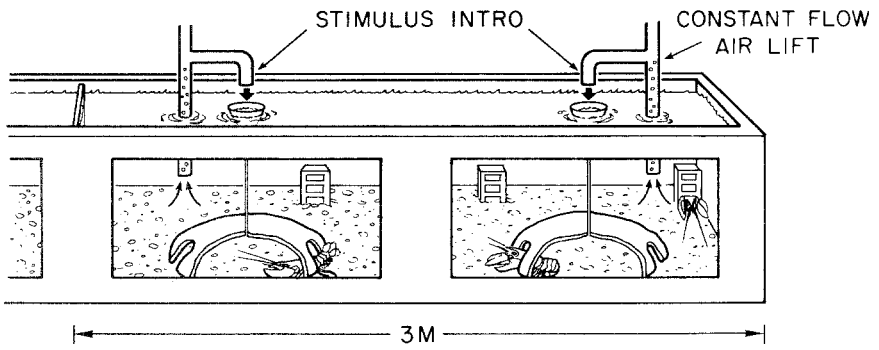

FIG. 1. Diagram of one of four similar naturalistic observation tanks used in these experiments. Observation shelters were placed in front of each window. A constantly flowing air-lift water circulation system with funnel interruption delivered a slow irregular flow of home tank water into these shelters at a mean flow rate of about 320 ml/min. Test and control stimuli were injected into the funnel. Ambient, unfiltered seawater flowed through each of the four tanks at a rate of about 25 liters/min (not drawn in figure). Substrate consisted of sand, gravel, shells, and rocks. The tank sketched here was one half of a 6-m-long tank. The two halves were separated by a solid barrier; each half had its own inflows and drains. Lobsters are drawn in to scale. The lobster in the left shelter is shown fanning his pleopods (FAN) at one of the shelter entrances; the lobster in the right shelter is shown checking one of the shelter entrances (CE). See Table 1 for description of behaviors.

sters per tank interacted normally, allowing each male lobster to recognize the presence of a male and female lobster. Thus, male and female odor stimuli would not be presented in a social vacuum. This feature was designed to prevent habituation to repeated odor introductions. Normal social interactions, including courtship and mating behavior, occurred in the tanks. Odor tests were done only when a lobster was alone in one of the observation shelters. These hand-molded concrete shelters had two entrances and dimensions comparable to those of lobster-made shelters in the field (personal observation). Such shelters were placed against the two observation windows in each tank to record behavior inside the shelter. Cinderblocks provided less preferred shelter space to the rear of each aquarium (Figure 1). The aquaria were supplied with fresh dead fish or squid daily in addition to the constant availability of a variety of live mussels, worms, crabs, fish, and squid. Uneaten dead food was removed the next day. Ample availability of food should keep the lobsters food-satiated to avoid the possibility that hunger motivated responses to social odors. Food-satiated lobsters responded to social odors but not to food odors (McLeese, 1973).

Experiments were begun on May 24, 1984, when the water temperature reached 13°C and terminated on November 13, 1984, at the same temperature. Temperature was recorded daily and reached its summer peak of 23°C in mid-

August. However, no experiments were done at temperatures above 21.5°C (August 2–27).

Each observation shelter was provided with a constant-flow stimulus introduction system (Figure 1). Urine (0.5 ml) or body odor (20 ml) were introduced up to twice a day. We allowed at least 4 hr between tests for an individual lobster to minimize possible interaction between responses. The introduction system caused dilution of the stimuli; dye experiments showed urine to be diluted at least 10,000-fold and body odor at least 1000-fold before reaching the receiving animal. Most likely further dilution due to tank circulation and lobster-generated currents would result in negligible signal-to-noise ratios within minutes. Body odor stimuli were prepared by keeping a donor lobster in a 10-liter aquarium with aeration and flow-through ambient seawater.

After an hour of acclimation, the flow was shut off for 4 hr with the lobster in place. Aliquots were taken to serve as the body odor stimulus within 1 hr after collection. Control stimuli for body odor tests were either 20 ml home tank water (i.e., taken fresh from the tank of the recipient), or 20 ml fresh ambient seawater stored for 4 hr in a 10-liter aquarium with aeration. Home tank water was used as a control for experimental manipulations since, due to habituation, animals should show no novelty response to the water they were inhabiting. Fresh ambient seawater prepared in a manner identical to the test stimulus was the other necessary solvent control. Urine was collected by taking a lobster from a communal holding tank and holding two small vials up to the nephropores. An individual lobster could produce urine from a few drops to a powerful fine jet from both nephropores, occasionally providing as much as 5.0 ml from one nephropore. Often no urine was collected with this method. Urine samples (0.5 ml) were used within 1 hr after collection, usually within 20 min. For urine tests, 0.5-ml samples of home tank water served as controls.

Durations of seven behaviors were recorded to the nearest second (Table 1). These behaviors were chosen from a longer list (Atema and Cobb, 1980; Cowan and Atema, unpublished). Nine different stimuli were tested for both males and females; 0.5 ml male or female intermolt urine; 20 ml male or female intermolt body odor; 20 ml male or female molt body odor (collected in a five-day postmolt period); 0.5 ml and 20 ml home tank water controls; 20 ml fresh seawater control. All experimental lobsters, donors and recipients, were individually marked to follow their molt cycles. All animals were sexually mature (75–90 mm carapace length). Recipient animals never received any one stimulus more than 10 times; molted animals were replaced. The total number of all tests (including controls) done with any individual lobster ranged from 1 to 33, with a median of seven and a mean of eight. A test consisted of two continuous 5-min observation periods: (1) no stimulus and (2) control or test stimulus. A condition for doing a test was that in the no-stimulus observations the lobster was quiet in a shelter and not performing any of the behaviors listed in Table 1. The observer was blind to the type of stimulus being introduced.

TABLE 1. DESCRIPTION OF LOBSTER BEHAVIORS IN STUDY[a]

Behavior	Description	Comments
Locate source (LS)	Reach up the glass at the front of the shelter and probe the stimulus inflow tube with chelae or clasp the tube with the dactyls of the pereiopods	Searching for the source of release; often the basis of experimental designs in other studies of crustacean chemical communication; follows from "check glass"; always accompanied by antennule flicking (an odor sniffing behavior)
Check glass (CG)	Turn to face the front of the shelter and place tips of the chelae at the window below the stimulus inflow tube.	Always precedes "locate source"; sometimes accompanied by antennule flicking and by scanning the shelter from entrance to entrance.
Check entrance (CE)	Walk over to and stand still at one of the two entrances (see Figure 1)	Generally accompanied by antennule flicking; common response to an approaching animal both in nature and in large aquaria (personal observation)
Pleopod fan (FAN)	Slow to rapid beating of the pleopods, almost always with tail extended (see Figure 1)	Creates (strong) current from front to rear of lobster; when standing with tail in shelter entrance, water is drawn into one entrance and blown out the other
Seizer open (SO)	Seizer claw fully opened (half open is the relaxed position)	Aggression (both offense and defense)
Seizer closed (SC)	Seizer claw fully closed	Seen in a variety of social contexts
High-on-legs (HOL)	Stand with all pereiopods (fully) extended	Described as a male response to female molt water (Atema and Engstrom, 1971); resembles male blue crab behavior in response to female sex pheromone (Gleeson, 1980); often accompanied by FAN

[a] For more complete behavioral context see Atema et al. (1979), Atema and Cobb (1980).

After normalizing the raw scores ($\sqrt{x + 0.5}$), data were analyzed with a three-way ANOVA for unequal replicates, comparing two sexes, seven behaviors, and nine stimuli simultaneously. This analysis was followed by Duncan's multiple-range test ($\alpha = 0.05$) to determine differences in duration of individual poststimulus behaviors by comparison with the appropriate control tests and to establish differences between the six test stimuli, and between male and female responses.

RESULTS

The mean durations of all behavioral responses recorded are presented as raw duration scores in Figure 2. Statistical analysis of the results showed a strong three-way interaction between sex, behavior, and stimuli (ANOVA, $P < 0.0005$). Responses to tank water control and fresh seawater control were not different (test for least significant differences, $P > 0.05$). Subsequently all social odor tests were analyzed by comparing the behavioral responses to test stimuli with responses to ambient seawater controls (Duncan's multiple-range test, $\alpha = 0.05$). Based on these comparisons (Table 2), it is evident that some stimuli, such as female urine, elicited the appearance of a number of different behaviors, while other stimuli, such as female molt body odor presented to females, did not. "Locate source" (LS) by itself was rarely a significant response. Since LS is an escalation of "check glass" (CG) (Table 1), we combined the two units into LS/CG for further analysis. The unit "seizer open" (SO) by itself showed no significant differences from control and is not listed in Tables 2–4.

Overall, males responded more than females to each of the stimuli except to male molt body odor (Tables 2 and 3). Males responded to five of the six odors tested, whereas females showed no response to half the stimuli: i.e., both male and female intermolt body odor, and female molt body odor (Table 2). Males responded more strongly than females to female molt body odor and male urine (Table 3).

The strongest response—as indicated by the largest number of different behaviors being significant—was elicited from males responding to female urine (Table 2). This response included the "high-on-legs" (HOL) behavior that turned out to be a unique male response displayed only to this stimulus and perhaps to female molt body odor (Figure 2); females never showed this behavior to a significant degree (Table 2). When compared with controls, female molt body odor elicited the greatest contrast between male and female responses: males showed a number of different behavioral responses to it, whereas females did not respond to it at all (Table 2). Conversely, male molt body odor caused stronger responses in females than in males (Tables 2 and 3). Male urine

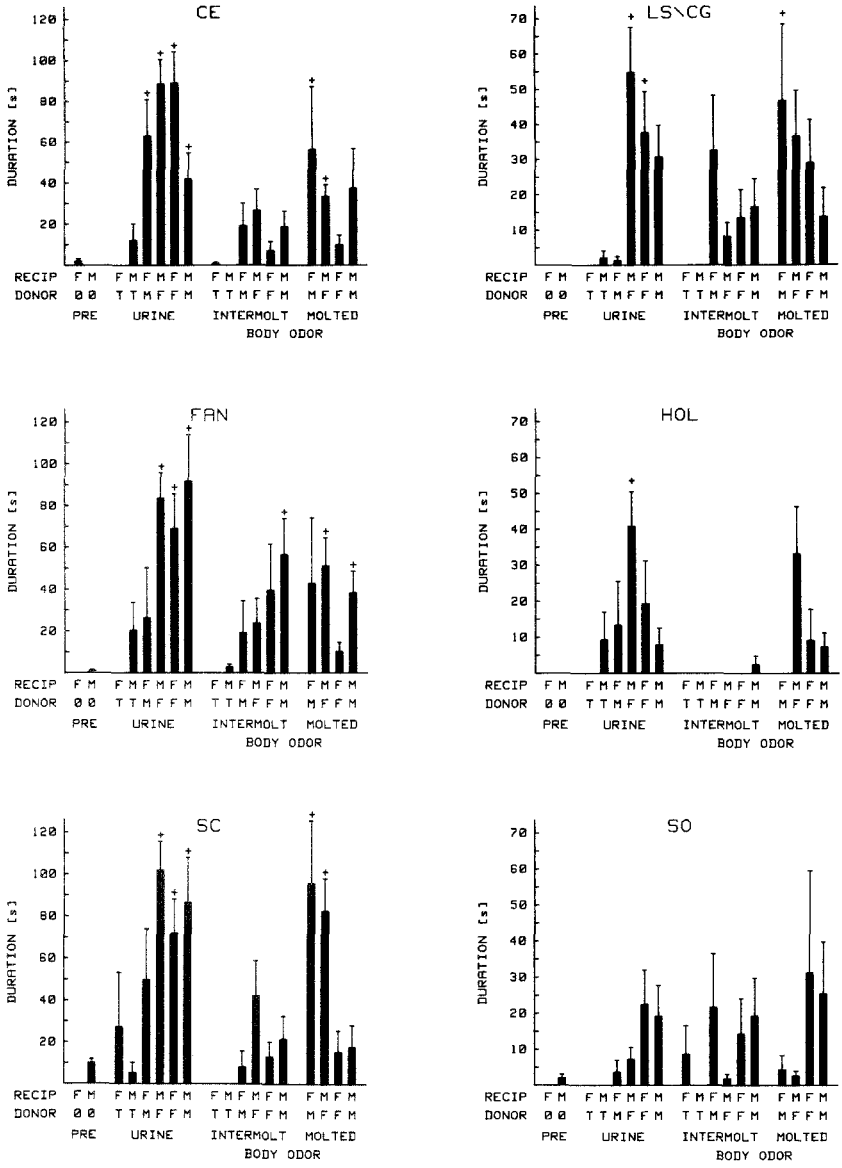

FIG. 2. Mean durations ± SEM of six behaviors (abbreviations and descriptions in Table 1) observed in 5 min following stimulus introduction. Histograms represent raw behavior duration scores approximated to the nearest second. There are two groups of recipients (RECIP): males (M) and females (F); three categories of donors (DONOR): males and females and control tank water (T); and eight stimuli: male and female urine and its 0.5-ml home tank water control, male and female intermolt body odor, male and female molt body odor, and 20-ml ambient seawater control for body odors. Also presented is behavior observed immediately preceding stimulus introduction (PRE). Subsequent data analysis showed behaviors marked (+) to be significantly different from their controls (see Table 2).

[a] The asterisks indicate, for five different behavior units, that the test stimulus caused a stronger response (Duncan's multiple-range test $\alpha = 0.05$) than seawater control stimuli. For behavior units see Table 1. N, sample size; M, male; F, female; Mobo, molt body odor; Ibo, intermolt body odor.

was a strong stimulus for males, but not for females (Tables 2 and 3). Males responded weakly to male molt and intermolt body odor (Table 2). Intermolt body odors did not elicit other significant responses (Table 2).

Because males responded more and generally more strongly than females to the same stimuli, comparisons between the six stimuli can be made only by

[a] The asterisks in this table indicate that the stimulus listed on the left caused longer durations of the particular behavior than the stimulus on the right (Duncan's test $\alpha = 0.05$), except asterisk in parentheses where this is reversed. For example, Mobo F caused significantly more SC in male receivers than Mobo M, but female receivers showed significantly more SC to Mobo M than to Mobo F. See Table 2 legend for abbreviations.

considering male and female responses separately. Stimulus comparison (Table 4) shows that female urine was a stronger stimulus than male urine for males. In addition, for both sexes, female urine was a stronger stimulus than both female molt and intermolt body odor (Table 4). Male urine caused stronger responses than both male molt and intermolt body odor in males. Males and females responded more strongly to the molt body odor of the opposite sex than to molt body odor of their own sex. Male molt body odor was a stronger stimulus than male intermolt body odor for females; males made no distinction between these male stimuli (Table 4) and showed only weak responses to both (Table 2).

While SO did not occur with sufficient consistency to be significantly different from controls, the raw mean scores (Figure 2) show that SO and "seizer closed" (SC), the two independent changes from the relaxed half-open claw

TABLE 5. CONTINGENCY TABLE FOR TESTING DISTRIBUTION OF SO AND SC IN RESPONSE TO MOLT BODY ODORS (MOBO) IN TWO SITUATIONS: INTERSEXUAL AND INTRASEXUAL RESPONSES

Mobo	Intersexual	Intrasexual

SO	2	22	$\chi^2 = 35$
SC	42	8	$P < 0.001$

position (Table 1), are not randomly distributed. In particular, intrasexual responses to molt body odor (i.e., males responding to male molt body odor, and females to female molt body odor) show longer SO than SC, while intersexual responses show the reverse effect. From χ^2 analysis of contingency tables (Tables 5 and 6), we conclude that for both sexes SO is a behavior associated more than expected with introductions of molt body odor and intermolt urine of animals of the same sex, while SC is associated with molt body odor and urine of the opposite sex ($P < 0.001$). This result is partially reflected also in Table 3, showing that males give stronger SC responses to female molt body odor, and vice versa. In contrast, intermolt body odors cause sex differences in claw responses: analysis of Table 7 shows that males are more likely to respond with SC to female intermolt body odor, while females are likely to respond with SO to male intermolt body odor ($P < 0.001$).

DISCUSSION

In interpreting these results, we must consider both the natural biological context of social interactions in lobsters and the experimental design of this study. The study was focused on male responses to female odors and employed two males and one female per tank as odor recipients. In addition, females consistently yielded more urine than males despite our attempts to collect urine from comparable numbers of males and females each day. This resulted in unequal sample sizes. Finally, our experimental design was based on observing responses of males in shelters receiving male and female urine and body odors. This is the natural context in which a male discriminates between lobsters approaching his shelter entrance, and by which he allows premolt females to enter and pair bond (Atema et al., 1979; Karnofsky and Atema, 1979; Atema and Cobb, 1980; Atema, 1986). Courting females, however, do not sit in shelters; they walk around and approach male shelters selecting a mate. For females, the situation of receiving social odors while inside a shelter may not be conducive to producing behavioral responses meaningful to courtship. A bioassay focused on female behavior should be based on her natural courtship behavior; this was not the aim of this study. Nevertheless females showed interesting responses and differentiated well between various stimuli presented.

Our interpretation of the results is based on a statistical comparison between responses to test and control stimuli to avoid being misled by the greatly unequal sample size of the different stimuli presented to males and females. In discriminating between responses, we are not placing great weight on the meaning of the different behaviors measured (see also Rose, 1984). Initially, we focus on the number of behavioral changes. In the interpretation of results, we will not specifically consider the possibility of masking "pheromones" that might suppress responses, although their existence is of theoretical interest.

Overall, males responded more strongly than females when presented with the same stimuli. The six test stimuli caused greatly different responses in both sexes, both qualitatively and quantitatively. But can we conclude that there are qualitative chemical differences in the six stimuli? Body odors may contain various amounts of urine; males and females may produce different amounts of urine; recently molted animals may produce different amounts of urine than intermolt animals. Moreover, the response difference between males and females may be merely a result of a sex difference in response threshold, not the recognition of qualitatively different compounds in the six stimuli. Thus, one extreme hypothesis is that all stimuli are various dilutions of lobster urine, regardless of sex or molt state. On the other extreme one might postulate different chemical compositions of male and female urine and special molt signals for both sexes. We argue that our results contradict the urine dilution hypothesis, and we provide evidence for special male and female molt substances.

Females showed consistently strong responses to male molt body odor (Tables 2, 3, and 4). Whereas in general females were less responsive than males to the same stimuli, in the case of male molt body odor female response was greater than male response (Table 3). Additionally, in contrast to males, females responded more strongly to male molt body odor than to either female molt body odor, or male intermolt body odor or urine (Tables 2 and 4). These results support the hypothesis of a qualitatively different (set of) substance(s) in male molt body odor to which females but not males respond. There may or may not be other compounds in male molt body odor that caused the weak male response.

Female intermolt urine caused similarly strong responses in males and females (Tables 2 and 3), although males showed HOL (Table 2). However, males responded more strongly than females to female molt body odor (Tables 2 and 3). If female molt body odor were merely a dilute female urine, one would expect it to cause weaker but still similar responses in both males and females. However, in reality males responded strongly to female molt body odor and females not at all (Table 2). This result is also evident in the direct stimulus comparisons of Table 4, where female urine and female molt body odor cause greater response differences in females than in males: females responded strongly to female urine but not to female molt body odor. These results support the hypothesis that females produce a (set of) special molt substance(s) to which males but not females respond.

In addition to evidence for special molt substances in male and female molt body odor, the results point to differences between male and female intermolt urine. Female urine caused stronger responses than male urine in both sexes. Thus, according to the dilution hypothesis, female urine may contain a higher concentration of the same active fraction than male urine. However, based on male and female response similarity to female urine (Tables 2 and 3 and Figure 2), the dramatic difference between males and females in their responses to male urine (Tables 2 and 3 and Figure 2) would not be expected, if male urine were merely a dilute form of female urine. While these latter results cannot exclude the dilution hypothesis, it seems more likely to suspect some qualitative rather than merely quantitative sex differences in intermolt urine.

The demonstration of a female-specific molt odor was expected based on previous work (Atema and Engstrom, 1971; Atema et al., 1979). The present experiments provide an indication of how a quantified bioassay might be designed to pursue chemical isolation and identification of the active compound(s). These and the female blue crab sex pheromone(s) (Gleeson et al., 1984) would become the first marine animal sex pheromones to be identified chemically.

In contrast, we did not expect to demonstrate the presence of a male-specific molt odor causing particular excitement for females (Table 2: locate the source of release, check the shelter entrances, and close seizer claw), nor can

we at present provide a natural context for such a response. Females residing in shelters are not likely to ever receive male molt odor and, if they did, we would not know the biological significance of responding to it. The possibility exists that molting in all lobsters is accompanied by a molt-specific odor which might contain, for instance, the arthropod molting hormone, crustecdysone (Atema and Gagosian, 1973) or a metabolite of it. However, the present experiments showed clearly that males and females responded differently to male and female molt odors. One might argue that if intrasexual competition were severe, then both sexes should respond to intrasexual molt odors. This would allow each sex to eliminate a freshly molted and thus vulnerable competitor. Similarly, one might argue that intermolt urine and body odor could act as warning signals announcing the presence of a potentially dangerous competitor, particularly for shelter possession. (It should be remembered that all recipients were tested in their shelters.)

These expectations based on sexual selection theory may find some confirmation in the results of the analysis of SC and SO. Both sexes showed higher than expected durations of wide-open seizer claw (SO) in response to intrasexual molt body odor and intermolt urine. A wide-open seizer claw is seen in defensive and offensive agonistic interactions. Similarly, a higher than expected incidence of closed seizer claw (SC) was observed in response to intersexual molt body odor and intermolt urine. (It should be emphasized that SC and SO are, of course, mutually exclusive, but not dependent, because the relaxed seizer claw position is half open.) Finally, intermolt body odor also caused a sex difference in responses: males tended to close their seizer claw when presented with female body odor, whereas females more often opened their seizer claw toward male body odor. These results seem to indicate that intermolt females are wary of intermolt males, but that males are appeasing to females. Such an interpretation would fit data collected in the field showing that smaller males could successfully defend their shelters against larger females, but not the reverse (E.B. Karnofsky, J. Atema and R.H. Elgin, unpublished observation). To interpret these results properly will require further behavioral-ecological investigation in the field and in naturalistic environments.

The pronounced responses to intermolt urine (0.5 ml diluted several orders of magnitude before reaching the lobster's chemoreceptors) indicate that urine may be used for social communication in general. The fact that male and female intermolt body odors were weak stimuli for males, and caused no response in females, may indicate that body odor contained little urine. Perhaps lobsters do not release urine constantly or under the conditions of confinement in our body odor collecting tank, as argued for crabs (Christofferson, 1978). Together with the presence of a urinary bladder and the positioning of the nephropores just above the gill current, these results argue for controlled urine release and the use of urine as a distinct chemical signal. The urine signal could be injected under the animal's control into the gill current, which would carry it up to seven

animal lengths forward (McPhie and Atema, 1984; Atema, 1985) providing identification of species, sex, and perhaps dominance status, and individual identity. The gill current can also be abruptly reversed by fanning the exopodites of the maxillipeds (McPhie and Atema, 1984; Atema, 1985), thus allowing the animal to not project its body odor with or without urine and instead to sample water chemistry ahead of itself. Such control is required for a communication function. Identifying potential mating partners and competitors appears to be an important aspect of the seemingly loose social structure of a resident lobster population (E.B. Karnofsky, J. Atema and R.H. Elgin, unpublished observation). Under the normally dark, nocturnal conditions of their circadian activity period, chemical identification may well be the best social cue available, and considering the different control mechanisms available to the lobster, urine would be a convenient vehicle for chemical signals.

Acknowledgments—Partial financial support for this study was provided by NSF grant BNS 8413661. We thank Donna McPhie and Mary Wisgirda for help in urine collection and in keeping the stimuli unknown to the observer, and Dr. Rainer Voigt and Gary Banta for help in computer programming and statistical analysis.

CORRELATION OF RETENTION TIMES ON LIQUID CRYSTAL CAPILLARY COLUMN WITH REPORTED VAPOR PRESSURES AND HALF-LIVES OF COMPOUNDS USED IN PHEROMONE FORMULATIONS

R.R. HEATH and J.H. TUMLINSON

Insect Attractants, Behavior, and Basic Biology Research Laboratory
Agricultural Research Service, U.S. Department of Agriculture

(Received May 3, 1985; accepted December 3, 1985)

Abstract—A method has been developed to determine by capillary gas chromatography on liquid crystal stationary phases the relative vapor pressures and half-lives of many compounds used as insect pheromones. This study demonstrated that the retention time of seven acetates on a liquid crystal column (cholesteryl-*p*-chlorocinnamate) could be correlated closely to the reported vapor pressures of the compounds. For 13 additional pheromonal acetates and alcohols, reported half-lives showed a high degree of correlation with their retention times on the liquid crystal column. Thus chromatography on capillary liquid crystal gas chromatographic columns appears to be a useful method for determining the relative volatilities of many pheromones to facilitate the development of more precise formulations.

Key Words—Insect pheromone formulations, liquid crystal capillary columns, half-lives of compounds, vapor pressure.

INTRODUCTION

Considerable effort during the last several years has resulted in the identification of a large number of attractants for economically important insect pests (see for example, Klassen et al., 1982). The utility of these potent chemicals in survey and monitoring traps has been well documented, and rubber septa, which are convenient and proven reliable, have been used extensively to formulate single compounds and pheromone blends. However, most pheromone formulations on rubber septa are developed empirically, and little is known about the release characteristics of these formulations. The only research addressing this problem

0098-0331/86/1100-2081$05.00/0

has been the determination of the half-lives of numerous aliphatic acetates and alcohols impregnated into rubber septa (Butler and McDonough, 1979, 1981; McDonough and Butler, 1983). Both the release rates and, in the case of blends, the release ratios of pheromone components from septa are probably governed, at least partially, by the vapor pressures of the compounds.

In this regard, Olsson et al. (1983) recently reported a method for determining the vapor pressure of selected pheromonal compounds because they were interested in determining the release ratio of multicomponent pheromones volatilized from female glands. Additionally, Olsson et al. suggested that their vapor pressure data were in good agreement with Butler's and McDonough's half-life determinations. However, the degree of correlation was not provided.

In both Butler's and Olsson's methods, considerable effort is required to obtain the necessary measurements for the half-life and vapor pressure data, respectively. Thus, we sought a method that would expeditiously provide both the relative vapor pressures and half-lives of compounds typically encountered in lepidopterous pheromones. Our previous experience with liquid crystal stationary phases in capillary gas chromatography (Heath et al., 1979; Heath and Doolittle, 1983) suggested that the elution order of olefin isomers of aliphatic acetates could be correlated with the relative vapor pressure of the compounds. Based on this premise, we evaluated the degree of correlation between the retention time on a liquid crystal phase such as cholesteryl-*p*-chlorocinnamate with the reported vapor pressure data of seven compounds. Then, by correlation with retention times on the same column, we determined the relative vapor pressure of 13 additional compounds whose half-lives have been reported. Finally, we evaluated the degree to which relative vapor pressure, measured half-lives, and retention time on a liquid crystal column might be correlated.

METHODS AND MATERIALS

The unsaturated decyl acetates (*Z*)-3-decenyl (*Z*3–10 : Ac), (*Z*)-4-decenyl (*Z*4–10 : Ac), (*Z*)-5-decenyl (*Z*5–10 : Ac), (*E*)-5-decenyl (*E*5–10 : Ac), and (*Z*)-6-decenyl (*Z*6–10 : Ac) were obtained from Christer Löfstedt (University of Lund, Lund, Sweden). Other compounds used in this investigation were obtained from Chemical Samples Co. (Columbus, Ohio). In several instances, synthetic modification was required to obtain the desired compound. Authenticity of the compounds was established using mass spectroscopy and infrared and nuclear magnetic resonance analyses when required.

Three different stationary phases coated on capillary columns were used in the analysis of the compounds. A 50-m polar cyano silicone phase CPS-1 (0.25 mm ID, 0.25 μm film) and a 35-m apolar methyl silicone (0.32 mm ID, 0.5 μm film) were purchased from Quadrex Corporation (New Haven, Connecticut). The efficient use of liquid crystal columns is limited to a narrow temper-

ature range (ca. $\pm 10°C$ about the mesophase transition temperature). To provide reasonable retention times for the compounds investigated, we coated four different capillary GC columns with cholesteryl-*p*-chlorocinnamate (a cholesteric liquid crystal phase) by techniques described previously (Heath and Doolittle, 1983). The columns were prepared with varying film thicknesses (0.25, 0.5, 1.5, 2.5 μm), and column lengths, 35, 37, 42, and 27 m, respectively. Less than 1% variation in a compound's retention was noted with the various liquid crystal columns when the retention time was converted to equivalent chain length units (ECLU) (Swoboda, 1962) relative to saturated acetates. Thus, all retention data in this investigation are expressed in ECLUs.

A Hewlett Packard 5792® gas chromatograph equipped with flame ionization detectors and interfaced to a Nelson Analytical Data Station (Nelson Analytical, Cupertine, California) was used for all analyses. A sampling rate of eight data points per second was used. Helium was used as the carrier gas at a linear flow of 18 cm/sec. Samples were chromatographed isothermally at a temperature that resulted in a partition coefficient (k') of 2.9 or greater.

Data were analyzed using a HP-87 (Hewlett Packard, Corvallis, Oregon) desktop computer. Regression analyses using linear and nonlinear curve fitting (logarithmic, exponential and power) were performed routinely on all data.

RESULTS AND DISCUSSION

Correlation of Vapor Pressure with Retention Time of Acetates on Liquid Crystal Column. Previous analysis of an analogous series of tetradecenyl acetates suggested that the elution order on liquid crystal phases is determined by the length-to-breadth ratio of the compounds (Dewar and Schroeder, 1965; Lester, 1978; Heath et al., 1979). A molecule with a decreased length-to-breadth ratio (distortion of linearity) should have a shorter retention time because of its inability to penetrate the crystal lattice of the phase. Thus, for the tetradecenyl acetates, it was found that elution time was shortest for the (*Z*)-4-tetradecenyl acetate (*Z*4–14 : Ac), followed by *Z*5, *Z*6, and *Z*7; with *Z*3–14 : Ac eluting last (Heath et al., 1979). Olsson et al. (1983) showed, with computer-generated models of the compounds they investigated, that the midpoint of the decenyl acetates lies near the 4 position. Thus the smallest length-to-breadth ratio and the smallest molecular size would occur when the double bond is in the 4 position and *Z*4–10 : Ac would have the highest vapor pressure. Although only one isomeric pair was studied, the vapor pressure of the *cis*-5-decenyl acetate was found to be higher than the *trans*-5-decenyl acetate. Again this is in agreement with our findings and those of Lester (1978) in that the distortion of length-to-breadth ratio is greater for the *cis* isomer than for the *trans* isomer.

Using decyl acetate and four of the decenyl acetates used by Olsson et al. (1983) (Table 1), we compared the elution order of these compounds on the

[b] Retention time relative to saturated acetates.
[c] Residual ECLU using ECLU = 1187 − 144.4·ln vapor pressure. Numbers in parenthesis refer to residuals when the seven compounds were used and the equation was ECLU = 1123 − 99.9·ln vapor pressure.

cholesteryl-*p*-chlorocinnamate liquid crystal phase with the reported vapor pressures values. The retention times of the compounds were converted to their equivalent chain length units (ECLU) relative to saturated acetates (Swoboda, 1962). The ECLUs of the 10-carbon acetates were plotted against the natural logarithms of their reported vapor pressures (Figure 1). The equation of the curve was

$$\text{ECLU} = 1187 - 144.4 \cdot \ln \text{ vapor pressure} \quad (1)$$

and had a coefficient of determination (r^2) of 0.988. The difference between actual and curve fit values for each data point (residuals) are reported in Table 1. Because only two points were reported for the vapor pressure determination of the Z4-10:Ac, we did not use this compound in our comparison. It should be noted that in accordance with the findings of Olsson et al. (1983), the Z4-10:Ac, which has the highest vapor pressure, elutes well before (ECLU = 969) the other decenyl acetates on the liquid crystal column.

Attempts to curve fit vapor pressure with retention time on nonpolar and polar isotropic phases were unsuccessful. Previous comparison of retention times on isotropic phases with the retention times on a liquid crystal phase using an analogous series of acetates documents the diverse nature of the mesomorphic phases (Heath et al., 1979). Using the decyl and decenyl acetates, the coefficients of determination (r^2) obtained with the nonpolar (methyl silicon) and polar (90% cyano) phases were found to be 0.724 and 0.446, respectively.

Having obtained a significant correlation of the ECLUs of the positional and configurational isomers of the 10 carbon acetates with their vapor pressures, we extended this study to evaluate the correlation of vapor pressure with the

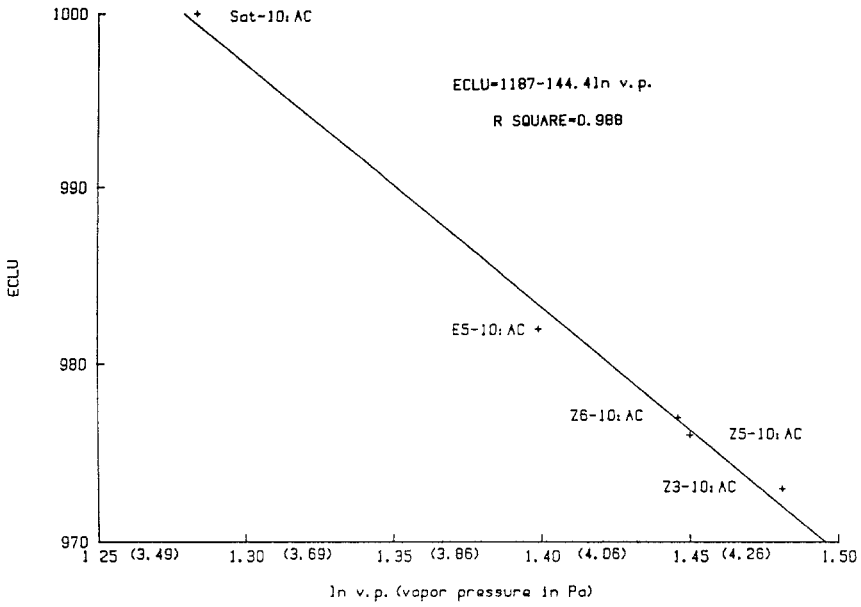

FIG. 1. Plot of retention time (in ECLU) on a 21-m (2.5 μm film) cholesteryl-*p*-chlorocinnamate capillary column of five acetates vs. the natural logarithm of their reported vapor pressures.

retention times of these compounds and (Z)-7-dodecenyl acetate and (Z)-9-tetradecenyl acetate. In this case, while the number of data points between the decenyl acetates and the latter two compounds is limited, we found that using the vapor pressure of seven compounds covering the range of acetates from 10 to 14 carbons still resulted in a high degree of correlation. A curve fit with a coefficient of determination of 0.999 was obtained, and the equation of the curve was determined as

$$\text{ECLU} = 1123 - 99.9 \cdot \ln \text{ vapor pressure} \qquad (2)$$

Residuals from the retention times obtained (in ECLU) are given in Table 1.

Correlation of Vapor Pressure Determined by Retention Time with Half-Life of Compound on Rubber Septa. Using equation 2, which correlates retention time with relative vapor pressure, we determined the vapor pressure of 13 compounds (Table 2) whose half-lives had been determined previously by Butler and McDonough (1979, 1981) and McDonough and Butler (1983). The compounds were chosen because of their availability. They included five saturated acetates (10–14 carbons), four monounsaturated acetates, and four unsaturated alcohols (12–16 carbons). A plot of the curve fit of the reported half-lives vs. the calculated vapor pressure is shown in Figure 2. The coefficient of

[a] Calculated using ln vapor pressure = (ECLU − 1123)/−99.9, equation 2, in text. Vapor pressure units are in P_a.
[b] Half-lives reported by Butler and McDonough (1979, 1981) and McDonough and Butler (1983).
[c] Residual in days. Curve fit equation 3: ln vapor pressure = 2.90 − 1.011 · ln half life.
[d] Residual in days. Curve fit equation 4: ln half life = −8.48 + 0.0101 · ECLU.

determination was 0.995, and the curve was plotted using the natural logarithm of the half-lives and vapor pressures for clarity. The equation of the curve was determined as

$$\ln \text{ vapor pressure} = 2.90 - 1.011 \cdot \ln \text{ half life} \quad (3)$$

The residuals from this curve fit are reported in Table 2.

Since a high degree of correlation of measured half-lives with calculated vapor pressure exists, it is obvious that the same degree of correlation exists between half lives and liquid crystal ECLUs. The residuals (days from the reported half-lives) are given in Table 2, and the equation was determined as

$$\ln \text{ half life} = -8.48 + 0.0101 \cdot \text{ECLU} \quad (4)$$

The coefficient of determination (r^2) for this curve fit was 0.995.

CONCLUSIONS

We found that a high degree of correlation exists between the retention times of seven acetates on a cholesteryl-*p*-chlorocinnamate liquid crystal col-

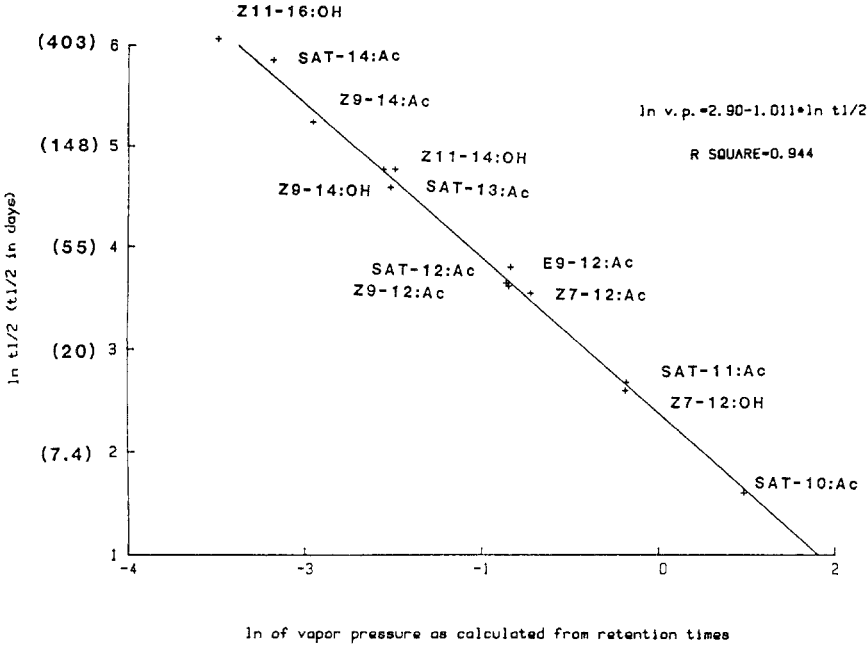

FIG. 2. An ln/ln plot of the reported half-lives of 13 compounds vs. their calculated vapor pressures using ln vapor pressure = (ECLU − 1123)/(−99.9). ECLU were obtained on a 42-m (1.5 μm film) cholesteryl-*p*-chlorocinnamate capillary column.

umn and their reported vapor pressures. The coefficient of determination was 0.999, while the degree of correlation obtained using apolar and polar capillary columns was severely reduced (0.724 and 0.446, respectively). Use of the retention times obtained on the liquid crystal column of 13 compounds (acetates and alcohols) showed a high degree of correlation to their previously reported half-lives. In a subsequent paper, (Heath et al. 1986). The use of the approximate relative vapor pressure of compounds to predict the ratio of components released from rubber septa loaded with multicomponent pheromone blends will be demonstrated. Additionally, investigations are currently in progress using the retention time data obtained on the liquid crystal column to predict release rates of multicomponent blends.

PERSISTENCE OF NONPROTEIN SEED AMINO ACID S-(β-CARBOXYETHYL)-CYSTEINE IN YOUNG LEAVES OF *Calliandra rubescens:* Ecological Implications

JOHN T. ROMEO and LEE A. SWAIN

Department of Biology, University of South Florida
Tampa, Florida 33620

(Received October 10, 1985; accepted December 23, 1985)

Abstract—The insecticidal nonprotein amino acid S-(β-carboxyethyl)-cysteine (S-CEC) is the major free amino acid in the seeds of several *Calliandra* spp. where it accounts for up to 2.9% of dry weight. Lesser amounts of other related S-containing amino acids and an array of nonprotein imino acids derived from pipecolic acid are other constituents. High concentrations of imino acids, which also show insecticidal activity, are maintained in the mature leaves, but sulfur compounds are lacking. In this study the disappearance of S-CEC from the germinating seeds and young seedlings of *C. rubescens* was monitored over time. After 10 weeks, S-CEC continues to be found in high concentrations in the stems and new leaves. As young leaves mature, sulfur compounds quickly decrease in concentration. Traces of S-CEC are found in new leaves of plants up to nine months after germination. Whether high concentration of S-CEC in young leaves is due to transportation from the seed or de novo synthesis is unclear. The ecological implications are discussed.

Key Words—Nonprotein amino acid, sulfur amino acid, S-(β-carboxyethyl)-cysteine, imino acid, seedling metabolism, insecticidal compounds, *Calliandra rubescens*, legumes.

INTRODUCTION

The nonprotein sulfur-containing amino acid S-(β-carboxyethyl)-cysteine (S-CEC) was first isolated from seeds of *Albizzia julibrissin* (Gmelin et al., 1958). Its distribution in the plant kingdom appears to be largely restricted to members of the Mimosoideae (Bell, 1971; Evans and Bell, 1979). In *Calliandra*, it is the major free amino acid accumulated in the seeds of all species except those belonging to Series Laetevirentes (Romeo, unpublished). Insecticidal activity of S-CEC against larvae of the polyphagous herbivore *Prodenia eridania* and

0098-0331/86/1100-2089$05.00/0

the seed beetle *Callosobruchus maculatus* has been demonstrated (Rehr et al., 1973; Janzen et al., 1977). Similar activity was observed in our laboratory against the leaf herbivore *Spodoptera frugiperda* (Shea and Romeo, unpublished). Although it is presumably derived from cysteine, essentially nothing is known of the biogenesis or metabolism of S-CEC in plants (Krauss and Reinbothe, 1970; Mazelis, 1980). The insecticidal nature of the compound against common seed and leaf herbivores and the large amounts accumulated in seeds of *Calliandra* coupled to the fact that S-CEC is virtually absent from mature leaves of *Calliandra* led us to wonder when the compound disappears from the germinating seed or young seedling.

METHODS AND MATERIALS

Plant Material. Mature *Calliandra rubescens* seeds were collected in December 1983 from dehiscing fruits on plants growing along the northeast boundary of Santa Rosa National Park, northwestern Guanacaste Province, Costa Rica (D.H. Janzen Col. No. 12273). Seeds were germinated and grown in pots in a 50:50 mixture of perlite and vermiculite and kept in a growth chamber maintained at constant temperature (27°C), humidity (85%), and light exposure (12 hr/day). Plants were irrigated daily with $\frac{1}{2}$ strength Hoagland's solution and harvested at regular intervals for analysis of amino acids. The experiment ran for 10 weeks. Individual leaves were harvested and numbered. The first nonembryonic leaf was assigned the number 1, and subsequent leaves were numbered according to the order of appearance on the plant (i.e., a leaf assigned the number 10 would be the tenth leaf to emerge on that plant).

Extraction of Amino Acids. Samples were extracted by the method of Singh et al. (1973). Freshly harvested leaves or seeds from which seed coats had been removed were extracted three times with MeOH–$CHCl_3$–H_2O (12:5:1), and the combined supernatant separated into an upper aqueous phase and a lower nonpolar phase by the addition of H_2O and $CHCl_3$. The aqueous phase was removed, evaporated to dryness, and the residue redissolved in 25% EtOH and used for chromatographic and electrophoretic analysis. Samples for quantitative analysis on the amino acid analyzer were prepared by evaporating aliquots of the above solution and redissolving them in 0.2 M Na^+ buffer (Dionex Femto buffer 1A, pH 2.0).

Quantitative Determination of Amino Acids. Amino acids were quantified using a modified Dionex D-300 Amino Acid Analyzer (Bleecker and Romeo, 1982) interfaced via an A/D converter with a Hewlett-Packard desk top computer (model 9825A). Additional amino acid data was obtained by subjecting the 25% EtOH extracts to high-voltage paper electrophoresis (HVE) for 30 min at 5000 V in a pH 1.9 buffer (Romeo et al., 1983). Papers were oven dried and developed with 0.2% ninhydrin in acetone.

Resolution of S-(β-Carboxyethyl)-cysteine. Since S-CEC coeluted with glutamic acid in our HPLC system, additional steps were taken to determine concentrations of S-CEC. Known amounts of the extracts were run on HVE and developed. The intensities of the S-CEC bands were then compared to bands of known amounts of the compound and a range of concentration of S-CEC for each sample was determined.

RESULTS

S-CEC is the major free amino acid of seeds of *C. rubescens*, accounting for as much as 2.9% total seed weight. As the young seedling grows, the total amount of S-CEC remains essentially constant for two weeks and then gradually decreases to day 70 (Table 1). The rapid decrease in percentage of total plant weight is seen very early (Table 1). After the emergence of the cotyledons from the seed coat, S-CEC is found in all parts of the embryo plant and, with the appearance of young leaves, stem, and roots, it continues to be present in all parts. The distribution within the plant, however, changes with development (Tables 2 and 5). Table 2 shows the distribution of S-CEC in leaves up to day 70. Reading down the diagonal, one sees that high levels are consistently found in young emerging leaves. For example, at day 42 new leaf number 5 has a S-CEC content of 2.6–3.3 mg/g fresh weight. The concentration in new leaf 6 at day 54 is similar. Even at day 70 relatively high amounts of S-CEC are still seen in the new leaves 9 and 10. Reading down the vertical columns one observes that these initial high concentrations in new leaves rapidly decrease as the leaves age. Leaf 3 for example has dropped from 0.9–1.9 mg/g fresh weight on day 28 to 0.2 mg/g fresh weight on day 42. All of the compound is gone by day 54. The large amount in new leaf 6 seen on day 54 is completely gone by

day 70. Even more striking is the situation at day 70 where the oldest "new" leaves (those appearing since day 42) 7 and 8 have already lost all or most of their S-CEC, whereas leaves 9 and 10 which appeared later still have relatively large amounts. The only exception to this pattern is in the first leaf where the decrease over time is constant but considerably slower.

Imino acids derived from pipecolic acid also are found at high concentrations in both seeds and leaves. In contrast to S-CEC, total imino acids increase slowly with development. The percentage of total plant weight remains virtually constant, although somewhat less than in seeds (Table 1). The concentration of S-CEC in different leaves relative to various imino acids at day 70 is seen in Table 3. While there is some modest variation between leaves, imino compounds are evenly distributed in the foliage in a 10-week-old seedling. There is no distinct difference between young and old leaves as for S-CEC. The imino

compounds remain essentially unchanged within a particular leaf over time. This is seen in Table 4 where imino acid concentrations are compared within a leaf from its appearance to termination of the experiment at day 70. By the time the fifth leaf has appeared at day 42, imino acid concentrations in the plant are approaching those which are found in mature leaves and seeds. Successive young leaves all produce similar high concentrations and maintain them to maturity.

Concentrations of S-CEC in stems over time generally parallel those found in new leaves, while in the root S-CEC decreases steadily to day 20 at which time it disappears only to reappear in moderate concentrations by day 50 (Table 5). Although the experiment was terminated after 10 weeks, traces of S-CEC continued to persist in very young leaves up to nine months after germination.

DISCUSSION

As Clegg et al. (1979) have pointed out, the developmental fate of defensive secondary compounds present in seeds is an important consideration in the pattern and budget of chemical defense of plants against herbivores. In their study, the cyanogenic glucoside linamarin, which is present in large amounts in seeds of *Phaseolus lunatus*, was shown to be a defensive resource as well for the developing seedling. In our study, the restriction to the stem and young leaves only of large amounts of an insecticidal nonprotein amino acid which is the major soluble nitrogen component of seeds is the interesting finding. Whether S-CEC is simply retained in the young leaves, having been transported from the seeds, or is synthesized de novo in the leaves or roots is uncertain.

One of the most often proposed secondary functions for nonprotein amino acids is that of serving as an additional nitrogen reserve for the germinating seedling. Labeling studies have shown that considerable interconversion and metabolism of amino acid carbon occurs in storage tissue during germination (Lea and Joy, 1983). Particular protein amino acids, usually glutamine or asparagine, accumulate and are involved in transport of nitrogen to the growing seedling for further conversion to supply the full range of amino acids and nitrogenous compounds needed for protein synthesis and growth. Often, however, the amides (ASN and GLN) are supplemented or replaced by other amino acids. For example, ornithine has a transport role in pumpkins, and homoserine in peas (Larson and Beevers, 1965). Since total S-CEC does not drop significantly until two weeks after germination, such a role does not seem likely for S-CEC in *C. rubescens*. While transport remains a viable explanation for the concentration of S-CEC in the stems and emerging leaves, the lengthy persistence (70 days) of significant amounts raises the possibility that S-CEC is being synthesized somewhere in the young seedling. The relatively high and constant concentrations in stems and the varying concentrations in roots permit the hypothesis that S-CEC is synthesized by roots and transported to young leaves or, alternatively, that the leaves are synthesizing the compound and sending the excess into the phloem and downward. Labeling experiments are needed to answer this question.

The possibility that S-CEC is serving a function other than nitrogen storage deserves consideration. Although generally less toxic than alkaloids or cyanogenic glycosides (both of which are absent in *Calliandra* spp.), nonprotein amino acids are widely perceived as being part of the chemical defense of higher plants (Rosenthal and Bell, 1979). *Calliandra* seeds and new young leaves appear to have a double defense in the large quantities of both nonprotein sulfur amino acids and the imino acids they contain. In addition to S-CEC, at least four other nonprotein sulfur amino acids including djenkolic acid and S-(β-carboxyisopropyl)-cysteine are found in lesser but significant concentrations (Romeo and Swain, unpublished). Both S-CEC and djenkolic acid are known to be insecticidal from a number of reports (Rehr et al.,1973; Janzen et al., 1977; Navon and Bernays, 1978; Evans and Bell, 1979; Shea and Romeo, unpublished). Additionally, an array of nine rare imino acids are spread variously throughout members of the genus (Romeo et al., 1983). The imino acids are present in concentrations at which insecticidal activity has been demonstrated (Romeo, 1984a). Unlike the seeds, mature *Calliandra* leaves accumulate only the imino compounds. These high concentrations are a predictable feature, and the genetic basis for this accumulation has been established by populational sampling (Romeo, 1984b). New leaves, however, have not yet developed the additional physical attributes that one associates with chemical protection in mature leaves such as toughness, waxiness, and decreased water content. The presence of both types of defensive amino acids in the young leaves as well as the seeds may be

simply a reflection of the need to protect those parts which are most essential to survival and most vulnerable to herbivory.

DEMONSTRATION OF AN ODOROUS INTRAMALE PRIMER EFFECT IN SHORT-TAILED VOLE, *Microtus agrestis* L.

TASNEEM Y. KHAN[1] and D. MICHAEL STODDART[2]

Department of Zoology, King's College London
Strand, London WC2R 2LS, U.K.

(Received June 27, 1985; accepted December 26, 1985)

Abstract—Anal (proctodeal) glands of male *Microtus agrestis* housed in social isolation undergo severe atrophy. Their weight and volume is significantly lower than those of the stock control males. The atrophied glands can be revived by subjecting deprived voles to various social odors. Atrophied glands of isolated males do not respond to the odors of male and female urine, voided feces of females, and unvoided feces of males. Atrophied anal glands of males exposed to voided male feces (which have passed the orifice of the anal gland) and soiled bedding from adult males show strong recrudescence. The mean weight and volume of the glands and plasma testosterone level are significantly higher than of males maintained in complete social isolation, although they are significantly less than those of stock control males. Atrophied glands of socially deprived males strongly respond to the odor of ethereal extract of gland secretion. In males exposed daily to anal gland secretion extract, the weight and volume of the gland and plasma testosterone level increase and are not significantly different from those of stock controls. They enjoy higher plasma testosterone levels and consequently larger and more active anal glands than complete isolates.

Key Words—Vole, *Microtus agrestis*, anal gland, odor, urine, feces, testosterone, social deprivation.

INTRODUCTION

Although they appear to be widespread among mammals, little attention has been paid to anal (proctodeal) glands. In small rodents of the genus *Microtus*

they occur at the distal end of the rectum, enveloped by the rectal sphincter muscles (Vrtis, 1929; Khan, 1984), but this envelopment is not universal among small mammals (Stoddart, unpublished). In his thorough study of the anal gland complex in the European vole *M. arvalis*, Vrtis (1929) observed that the gland of males was much larger than in females and that it underwent a cycle of development linked with the testicular cycle. Although he presented no behavioral data in substantiation, he suggested that its oily secretion was used as a sexual attractant or stimulant during the voles' breeding season.

More recently, and working with the yellow vole *Lagurus luteus*, Fan (1982) observed that fecal pellets coated in anal gland secretion were deposited densely around the breeding nest and along the colony's territorial boundaries, in such a way that it suggests the function of the glandular secretion is not directly for sexual purposes but for a more broadly based social effect.

This study was undertaken as part of a comprehensive examination of the structure and development of the anal glands of the short-tailed vole, *M. agrestis*, which investigated, in particular, the physiological and anatomical response of the gland to sex hormones (Khan, 1984). Since we knew the anal gland of *M. agrestis* to be highly sensitive to circulating levels of blood testosterone (Khan and Stoddart, in preparation), we designed a series of experiments to examine whether anal gland secretion, which is normally deposited passively on feces, is able to influence anal gland development in other males via a testosterone effect. At the same time we investigated whether urine odor was also able to influence plasma testosterone, and hence anal gland size, as has been shown to occur in rats.

METHODS AND MATERIALS

All experimental and control voles (other than controls taken from stock), were housed individually in shoe-box cages and fed with standard laboratory food and water ad libitum. Stock voles were housed in mixed sex groups of six to eight in rat cages in an animal house where the lighting regime was 16 hr light and 8 hr dark. Sociosexually isolated voles were removed from their mothers at weaning (24 days) and kept individually in shoe-box cages. Each cage was kept under the same light conditions in a separate room of the Zoology Department of King's College for eight weeks. At this time the isolated voles were subjected either to an experimental odor treatment for three weeks or to a further three-week isolation. Voles in the latter category are referred to as "complete isolates."

Urine and feces were separately collected in a glass metabolic chamber, removed daily, and stored in a deep freeze until needed. To prepare anal gland extracts, glands of mature stock males were cleared of any surrounding tissue or fat and macerated in ether until the ether became cloudy and little was left

of the sebaceous parenchyma. Supernatant extract was pipetted off and stored in a deep freeze until needed. For presentation to a test subject, a piece of extract-impregnated filter paper (2 × 1 cm) was laid daily on the sawdust in the subject's cage. Ether alone was used for controls. To expose a subject to the odor of urine, a small vial was filled with glass wool soaked in urine and attached to the side of the cage holding the experimental male. In the case of the controls, urine was replaced by distilled water.

Anal gland weight was obtained by weighing with a microgram balance following dissection and removal of the rectal sphincter musculature and adhering mesentery. Gland volume was measured by volumetric displacement, using a modified microvolumeter (Khan and Stoddart, in preparation). In control males, a linear relationship between body weight and gland weight and volume was observed. Accordingly, these parameters have been scaled up or down, as appropriate, to what their value would have been had they been taken from a vole of standard weight of 20 g (Khan, 1984). Plasma testosterone was established by radioimmunoassay (Collins et al., 1972). The number of subjects in each test is shown in the tables, but was never more than 10.

RESULTS

The results shown in Table 1 indicated that very substantial differences with standard parameters occur between the stock males and those subjected to complete sociosexual isolation. Isolated males exposed to female urine, male urine, female feces odor, and unvoided male feces show no significant differences in the standard parameters when compared to the complete isolates, but all show a substantial difference when compared to the stock males. Males exposed to the odor of voided male feces, in contrast, show considerable similarity with the stock males, and substantial differences from the complete isolates. It is noticeable, however, that anal gland weight and volume are significantly lower than those of stock males, but they are noticeably higher than those of subjects exposed to the other odorants. Table 2 examines the effect of voided and unvoided feces odor on isolated males in more detail. It is apparent that there is no difference in testes weight between classes of subjects but substantial differences in the other parameters. In Table 3 a comparison is made between males exposed to voided feces odor and soiled bedding odor taken from stock cages. This table indicates that there is no difference in the standard parameters between these groups with the exception of testes weight, which is significantly higher in the soiled bedding exposure trials than in the male voided feces trials.

As the only perceptible difference between voided and unvoided feces is the presence of or absence of the coating of anal gland secretion, experiments were designed in which isolated males were exposed to anal gland secretion. The results are shown in Table 4. It is evident that, when compared to complete

isolates, extract-exposed voles experience a development of the gland and a rise in blood testosterone, such that there is no difference between the experimental group and stock males. In Table 5 this group is compared with those exposed to voided male feces odor and soiled sawdust from stock cages. The most significant observation is that the plasma testosterone level of this group is significantly lower than that of either groups with which it is compared.

DISCUSSION

We have demonstrated elsewhere that sociosexual isolation of newly weaned males *M. agrestis* for between 8 and 11 weeks results in severe atrophy of the anal gland. Testes and seminal vesicle weights are significantly lower than in controls of the same age and body weight, as are plasma testosterone levels (Khan and Stoddart, in preparation). The present experiments reveal that the odor of male or female urine, unvoided male feces and voided female feces have no effect on atrophied anal glands of deprived males. With respect to the effect of female urine odor, these data are contrary to those obtained by Purvis and Haynes (1978) on rats.

It was assumed from anatomical investigation that voided feces would be coated with anal gland secretion. Sociosexually deprived males showed a significant increase in the standard parameters when exposed to the odor of voided feces of stock males, although the glands fail to reach the weight and volume of the glands of stock males. Males exposed to voided feces odor also have significantly heavier bodies than complete isolates. Soiled sawdust from the stock cages, and presumably impregnated with odors other than just those of urine and feces, brought about a similar increase in gland size. An ethereal extract of anal gland secretion similarly returned anal gland size to that of the stock controls, but it is significant to note that, with the exception of testes weight, all the standard parameters of this group were lower than those of the stock controls used in other experiments. It would appear that ether odor has an inhibitory effect on the anal glands and plasma testosterone level in stock males.

Our observation that exposure of isolated males to voided male feces which are coated with anal gland secretion, or to soiled bedding from control cages of normal healthy animals, or to the extract of anal gland secretion itself for three weeks causes enlargement of the weight and volume of anal glands. A concomitant increase in plasma testosterone level suggests that the odor of anal gland secretion of *M. agrestis* modulates the endocrine status of males and may be regarded as an important component of the social environment. Our data refer only to exposure periods of three weeks' duration; we know nothing of any chronic effect of prolonged exposure or habituation arising therefrom.

We can tentatively conclude that anal gland secretion exerts an odorous effect on the anal gland of other males via its effect on plasma testosterone. It appears that odors of female urine, male urine, female feces, and unvoided male feces have no effect on male plasma testosterone levels and the anal gland. The biological significance of this intramale primer effect remains unclear.

Acknowledgments—We are deeply indebted to the government of Pakistan for providing finances to Tasneem Y. Khan for this study.

(Received October 10, 1985; accepted December 30, 1985)

Abstract—A 6,9-nonadecadiene, (Z)-9-nonadecene, and *n*-nonadecane were identified in extracts of sex pheromone glands of female *Sabulodes caberata* Guenée. Potential pheromonal activity of gland components was assessed by electroantennogram measurements of gas-chromatographic fractions of abdominal tip extracts. Chemical identification was based on gas chromatography and mass spectrometry of parent compounds, hydrogenation products, ozonolysis products, dimethyl disulfide adducts, and synthesis. The monoene was synthesized via coupling of alkyl and acetylenic intermediates. (Z,Z)-6,9-Nonadecadiene (Z6,Z9-19 : H) was synthesized from methyl linoleate via chain lengthening. Synthetic Z6,Z9-19 : H had the same retention times on polar and nonpolar capillary gas-chromatographic columns as the 6,9-nonadecadiene from the sex pheromone glands. In field tests Z6,Z9-19 : H alone produced trap catch of male *S. caberata* and addition of (Z)-9-nonadecene or *n*-nonadecane had no effect on trap catch.

Key Words—*Sabulodes caberata* Guenée, *Sabulodes aegrotata* Guenée, omnivorous looper, Lepidoptera, Geometridae, sex pheromone, (Z,Z)-6,9-nonadecadiene, (Z)-9-nonadecene, *n*-nonadecane

INTRODUCTION

Sabulodes caberata Guenée, the omnivorous looper, is a general feeder which is primarily an economic pest on avocados in California. It feeds on both foliage and fruit. As with other foliage feeders, higher populations can be tolerated before an economic threshold is reached than with pests that feed exclusively on the fruit. The identification of the sex pheromone of *S. caberata* was undertaken along with that of another fruit and foliage feeder of avocados, *Amorbia cuneana* (Walsingham) (McDonough et al., 1982; Hoffmann et al., 1983; Bailey et al., 1986), as part of a study to develop an integrated management program for these two insect species based on the use of *Trichogramma platneri* Nagarkatti parasites and pheromone monitoring traps.

Preliminary tests (Hoffmann et al., unpublished) with virgin female *S. caberata*-baited traps resulted in large captures of males, indicating the potential for using synthetic pheromone-baited traps to monitor this pest. Also *S. caberata* was shown to have an external sex pheromone gland (Smithhisler et al., 1985) in contrast to the internal gland reported for another species of Geometridae (Werner, 1977). The sex pheromone of *S. caberata* is chemically similar to the pheromones of other members of the geometrid family which have recently been reported.

METHODS AND MATERIALS

Insects

Pupae or larvae were collected from avocado groves in Ventura County, California, and the larvae were reared in a bioclimatic chamber at the University of California South Coast Field Station, Santa Ana, on artificial diet (Johnson and Federici, 1982). The pupae were sexed and sent to Yakima, Washington, where they were placed in a bed of moist vermiculite at 21 $\pm$ 1°C, relative humidity 68 $\pm$ 2%, and 14 hr light–10 hr dark. Emerging moths were collected daily. Males and virgin females were maintained separately on a diet of beer, sucrose, and ascorbic acid (Calkins and Sutter, 1976).

Collection of Pheromone

Female moths (2–4 days old) were collected 2–6 hr after the beginning of scotophase and placed in a refrigerator 10–60 min prior to dissection. Abdominal tips were excised at the 7th intersegmental membrane and extracted with dichloromethane for about 15 min. The sex pheromone gland (SPG) is epidermal tissue between the 8th and 9th abdominal segments (Smithhisler et al., 1985).

Gas Chromatography (GC)

The following analytical gas chromatography columns were used: (1) 60 m × 0.25 mm ID fused silica capillary column with methyl silicone bonded phase (DB-1, J and W Scientific, Inc., Rancho Cordova, California); and (2) 60 m × 0.25 mm ID glass capillary column with polyethylene glycol liquid phase (Carbowax 20 M®, Hewlett-Packard Corp., Bellevue, Washington). Both columns were operated in the splitless mode with the following program: 40 sec delay on inlet purge; 2 min at 80°C; 32°/min to various isothermal temperatures of 160–190°C for various runs; samples were used as heptane solutions.

Purification of SPG Components

Purification of SPG components from extracts was effected by collection from a gas chromatograph (Hewlett-Packard, model 5711, Avondale, Pennsylvania) equipped with a flame ionization detector and a metal, glass-lined, column-effluent splitter (Scientific Glass Engineering, Inc., Austin, Texas) (one part of effluent to detector and nine parts to collection trap). The column was 1.8 m × 2.3 mm OD silanized glass containing 3% methyl silicone (SE-30®) on 80–100 mesh Gas Chrom Q®. Eluting materials were collected with an efficiency of 70–90% in glass tubes cooled in Dry Ice–acetone.

Electroantennogram Measurements (EAG)

Natural and synthetic samples were bioassayed by the EAG procedure as previously described (Kamm and McDonough, 1980).

Ozonolysis

Ozonolysis of EAG active material, which had been purified by gas chromatography, was conducted in a mixture of dichloromethane and heptane at −70°C with an ultraviolet ozonizer (Orec Co., model 03VI, Phoenix, Arizona), and the ozonide was reduced with triply recrystallized triphenyl phosphine (Beroza and Bierl, 1967). The ozonized sample was injected on an analytical gas chromatographic column (1) at 35° for 6 min, programmed at 10°/min to 200°C and then held at that temperature. The retention times of eluting peaks were compared with *n*-alkanal standards.

Hydrogenation of Diene–Monoene Fraction

The purified EAG-active material was allowed to react with lithium aluminum hydride plus platinum catalyst by the procedure of Bierl-Leonhardt and DeVilbiss (1981). The hydrogenated material was then analyzed by gas chro-

matography–mass spectrometry (GC-MS) and compared with authentic hydrocarbons.

Dimethyl Disulfide (DMDS) Derivative of Monoene

The DMDS derivative was prepared by the procedure of Buser et al. (1983). A dichloromethane solution containing 30 ng of monoene and 570 ng of diene which had been isolated from SPG extract by gas chromatography was transferred to a 1-ml Reacti-vial® (Pierce Chemical Co., Rockford, Illinois) and evaporated just to dryness in a stream of nitrogen. The residue was dissolved in 50 μl heptane and 50 μl of DMDS, and 10 μl of a saturated solution of I_2 in diethyl ether were added. The vial was sealed and the mixture was heated overnight at 40°C in a convection oven. Then the solution was diluted with 200 μl heptane and excess I_2 was removed by adding 100 μl of 5% $Na_2S_2O_3$ solution and shaking. The heptane layer was removed with a syringe and concentrated to 20 μl; 2 μl was used for mass spectral analysis.

Gas Chromatography–Mass Spectrometry

Two different GC-MS instruments were used: (1) Finnegan Corp. (Sunnyvale, California) model 4000, quadrupole mass spectrometer with computerized data collection and a GC inlet consisting of a methyl silicone (SP-2100®) capillary column (30 m × 0.25 mm ID) with splitless injector; and (2) Hewlett-Packard (Avondale, Pennsylvania) model 5970 quadrupole mass selective detector with computerized data collection and a model 5790 gas chromatograph inlet equipped with fused silica capillary column (60 m × 0.25 mm ID) with splitless injection. The liquid phase was methyl silicone (DB-1®). Instrument 1 was used to characterize SPG components and their hydrogenation products. Instrument 2 was used to characterize SPG components, the DMDS derivative of the monoene, and the synthetic intermediates and products.

Synthesis

9-Nonadecyne. 1-Decyne (1.70 g, 12.3 mM) and lithium amide (1.1 g, 48 mM) in 50 ml dry dioxane were refluxed under nitrogen for 3.5 hr and cooled to room temperature. Then 1-bromononane (5.6 g, 27 mM) was added dropwise over a period of 30 min. The mixture was refluxed for 18 hr, cooled, and extracted with water–hexane. The hexane layer was washed successively with 2 N HCl and water and then dried with Na_2SO_4. The yield after liquid chromatographic purification (silica gel and hexane) by gas chromatographic analysis was 1.27 g (39%).

(Z)-9-Nonadecene (Z9-19H) and (E)-9-Nonadecene (E9-19:H). 9-Nonadecyne (0.2 g) in 40 ml ethanol containing four drops of quinoline and 0.4 g palladium (5%)–calcium carbonate catalyst was reduced with hydrogen for 5

min. The solution was filtered and partitioned into hexane and water, and the hexane layer was dried with sodium sulfate. Gas chromatographic analysis showed 86.1% *Z*9-, 13.9% *E*9–19:H, 3.0% *n*-nonadecane, and no unreacted 9-nonadecyne. GC-MS confirmed these products.

9-Nonadecyne (50 mg) was also reduced with "P-2 nickel" (Brown and Ahuja, 1973a,b) to give a product of 98% *Z*9- and 2% *E*9–19:H.

Linoleyl Alcohol. Methyl linoleate (25 g) was added dropwise to a stirred solution of 5 g lithium aluminum hydride in 300 ml ether. Excess hydride was destroyed with ethyl acetate, and the ether solution was extracted successively with ammonium chloride solution and water. The yield of linoleyl alcohol after liquid chromatography (silica gel, hexane–ether, 3:1) was 17.5 g (77%).

Linoleyl Bromide. Phosphorous tribromide (18.0 g) in 100 ml of dry dichloromethane was added dropwise over 1.5 hr to a stirred solution of 17.5 g of linoleyl alcohol in 100 ml dry dichloromethane cooled with an ice bath. Then water was added dropwise until the fuming stopped. The solution was washed with water and dried with sodium sulfate. The yield of product after liquid chromatography (silica gel, hexane) was 7.3 g (34%).

Linoleyl Iodide. A solution of linoleyl bromide (7.3 g, 22 mM) and sodium iodide (6.6 g, 44 mM) in 66 ml of acetone was stirred for 2.5 hr. Hexane (300 ml) was added, and the solution was filtered and washed with water. The yield after liquid chromatography (silica gel, hexane) was 6.6 g (80%).

(Z,Z)-6,9-Nonadecadiene (Z6,Z9–19:H). Methyl magnesium iodide (25 mM) from 3.5 g of methyl iodide and 0.66 g of magnesium in 30 ml of ether was added dropwise to a cooled (0–10°C) and stirred solution of 6.6 g (17.5 mM) linoleyl iodide, 0.074 g (1.75 mM) lithium chloride, and 0.12 g (0.88 mM) cupric chloride in 150 ml tetrahydrofuran (Fouquet and Schlosser, 1974). When the addition of methyl magnesium iodide was completed, the solution was allowed to warm to room temperature over an hour, and then partitioned into hexane–water. After work-up and liquid chromatography (silica gel, hexane), the yield was 4.5 g (98%).

Field Tests

Field tests were conducted in commercial avocado groves located in Ventura and Orange counties. Synthetic pheromone was tested after impregnation of dichloromethane solutions into rubber septa (West Co., Phoenixville, Pennsylvania) which were placed in Pherocon® 1C traps (Zoecon Corp., Palo Alto, California). Traps were hung from peripheral branches on mature avocado trees, 1–3 m above the ground, at a distance between traps of no less than 40 m. Each treatment was replicated four times and arranged in a randomized block design. Traps were rotated one position each time they were checked to minimize bias of location.

Traps were checked a number of times equal to an even multiple of the

number of treatments in the test. The Ventura county test was checked four times at three-day intervals. The Orange county test was checked 12 times at two-day intervals.

RESULTS

Structure. Figure 1 shows a GC trace (capillary, methyl silicone column) of the extract of the female SPG (0.4 female equivalent). When the extract from four females was injected into a GC with a methyl silicone-packed column and fractions corresponding to the volatility range encompassing zero time to the retention time of tetracosane were collected and their EAG activity determined, only the fraction containing peaks A and B of Figure 1 (which were not separated on the packed column) possessed strong EAG activity (3 mV vs. 1–1.5 mV for the other fractions). The retention times of peaks A and B relative to *n*-nonadecane on the methyl silicone column were 0.90 and 0.93, respectively,

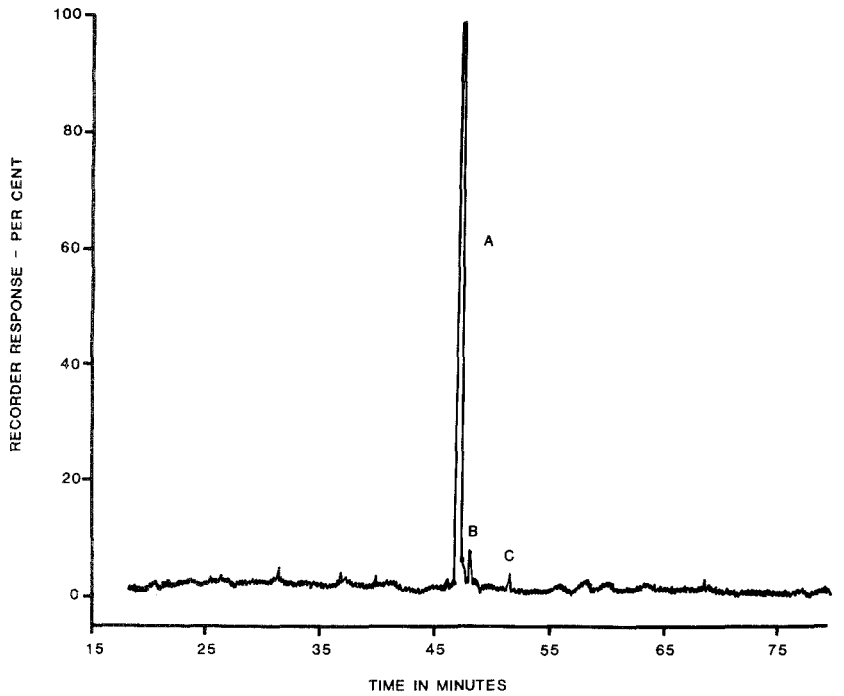

FIG. 1. Gas chromatogram of the extract of the female sex pheromone gland (0.4 female equivalent) of *S. caberata*. Components A and B were both in the EAG active fraction collected from the packed GC column. C is *n*-nonadecane. The amount of peak A represented by the GC trace was about 15 ng.

and on the Carbowax 20 M column were 1.11 and 1.04, respectively. The retention times suggest hydrocarbons with 19 or more carbon atoms and unsaturation. Mass spectra showed A to be a doubly unsaturated 19 carbon hydrocarbon (M+, m/z = 264) and B to be a singly unsaturated 19 carbon hydrocarbon (M+, m/z = 266). Peak C (Figure 1) was *n*-nonadecane. When the GC collected fraction containing A and B was hydrogenated, the only product was *n*-nonadecane based on retention time and mass spectrum. The only products detected from ozonolysis were hexanal and decanal, indicating a 6,9-nonadecadiene.

The addition of dimethyl disulfide (DMDS) to a monoene increases the GC retention index by about 600 units. Thus, when the EAG active fraction of 30 ng of nonadecene and 570 ng of 6,9-nonadecadiene was converted to the dimethyl disulfide derivative, only one GC peak was expected corresponding to mono addition. However, two peaks were found in that region. The second eluting peak was narrow and had the molecular weight (M+, m/z = 360, 30%) and principal peaks (m/z = 187, 100%; m/z = 173, 92%) corresponding to the DMDS adduct of 9-nonadecene. The first eluting peak was broad and had a molecular weight (M+, m/z = 358, 7%) and strong peaks (m/z = 131, 31%; m/z = 227, 16%; m/z = 171, 17%; m/z = 187, 38%) corresponding to a mixture of mono adducts to 6,9-nonadecadiene. The first eluting broad peak was of about the same intensity as the monoene adduct. Thus, the percent of mono adduct formation by the diene was about 5%.

Synthesis. 9-Nonadecene was synthesized using a catalyst which produces mainly *Z* but also a significant quantity of the *E* isomer. The 9-nonadecene from the SPG had the same retention time as the synthetic *Z* isomer. Synthesis with the more modern catalyst, P-2 nickel, gave a product of 98% *Z* isomer which was used for the field tests.

*Z*6,*Z*9–19 : H was conveniently synthesized from methyl linoleate. It had the same mass spectrum and the same retention times as 6,9-nonadecadiene from the SPG on both methyl silicone and Carbowax 20 M capillary columns.

Field Tests. Field tests were conducted during a period of low moth flight activity. The first field test was conducted to determine what combination of components was important for trap catch (Table 1). *Z*6,*Z*9–19 : H effected trap catch by itself and addition of *Z*9–19 : H or *n*-nonadecane in proportions in which they occurred in the SPG had no effect on trap catch. The second field test was conducted to determine the effect of dosage on trap catch (Table 2). Trap catch was constant for dosages of 3–30 mg; 1 mg was not quite as effective.

DISCUSSION

Although the configuration of 6,9–19 : H from the SPG has not been rigorously established, it is probably the *ZZ* isomer. Capillary columns separate *Z*

TABLE 1. TEST OF IDENTIFIED COMPONENTS FROM SPG OF FEMALE *S. caberata*[a]

[b] Duncan's new multiple-range test ($P = 0.05$).

and *E* isomers; retention times of *ZE* and *EZ* isomers might overlap, but *EE* and *ZZ* should have distinctive retention times. Thus, the coincidence of the Z6,Z9-19:H retention times on polar and nonpolar capillary columns with the SPG component and the demonstrated attractancy of Z6,Z9-19:H in field tests strongly suggests that the main active component of the SPG is Z6,Z9-19:H.

Z6,Z9-19:H has been previously reported as a sex pheromone component of another geometrid, *Bupalus piniarius* L. (Bestmann and Vostrowsky, 1982). Also, in combination with Z3,Z6,Z9-19:H, Z6,Z9-19:H has been found in field screening tests to be attractive to *Alsophila quadripunctata* Esp. (Szöcs et al., 1984).

The first reports of the structures of sex pheromones of species of Geometridae were made relatively recently. The sex pheromone of the winter moth, *Operophtera brumata* (L.), is (1,3Z,6Z,9Z)-1,3,6,9-nonadecatetraene (Roelofs et al., 1982; Bestmann et al., 1982). Becker et al. (1983) reported (Z,Z,Z)-3,6,9-nonadecatriene to be a component of the giant looper, *Boarmia* (*Ascotis*) *selenaria* Schiffermüller, and Wong et al. (1984) found the sex pheromone of

TABLE 2. EFFECT OF DOSAGE OF (Z,Z)-6,9-NONADECADIENE ON TRAP CATCH OF MALE *S. caberata*[a]

the fall cankerworm moth *Alsophila pometaria* (Harris) to be a ternary mixture of (*Z*,*Z*,*Z*)-3,6,9-nonadecatriene, (*Z*,*Z*,*Z*,*E*)- and (*Z*,*Z*,*Z*,*Z*)-3,6,9,11-nonadecatetraene. Thus far the common theme of all sex pheromone components of the Geometridae is a 19-carbon straight chain with 6*Z* and 9*Z* double bonds. In other studies (Wong et al., 1985), a variety of C_{18}–C_{22} unsaturated hydrocarbons and unsaturated epoxides have been found attractive to other species of Geometridae in field trapping tests.

*Z*6,*Z*9–19:H is conveniently synthesized from methyl linoleate, methyl (9*Z*,12*Z*)-9,12-octadecadienoate, by functional group modification and chain lengthening. Methyl linoleate is commercially available and inexpensive. This type of synthesis has been used previously by Underhill et al. (1983) and Heath et al. (1983) to synthesize noctuid sex pheromones of similar structure. Thus (3*Z*,6*Z*,9*Z*)-3,6,9-eicosatriene and (3*Z*,6*Z*,9*Z*)-3,6,9-heneicosatriene were synthesized from methyl linolenate, i.e., methyl (*Z*9,*Z*12,*Z*15)-9,12,15-octadecatrienoate. These syntheses may mimic the methods used by the insects. Recent biosynthetic studies have shown that sex pheromone components are synthesized from fatty acid moieties (Wolf et al., 1981; Bjostad and Roelofs, 1984, and references cited therein) and that lepidopteran insects possess enzymes for both chain lengthening and shortening of 18-carbon acids.

Abstract—Snowshoe hare (*Lepus americanus*) feeding preferences for Alaskan green alder (*Alnus crispa*) are governed by the concentrations of two deterrent secondary metabolites, pinosylvin and pinosylvin methyl ether. For instance, the preference of mature internodes over juvenile internodes was correlated with about a threefold increase in the levels of these compounds in the juvenile form. During the last year of the study, however, the levels of these compounds dropped below the threshold of avoidance in both types of internodes, resulting in nondiscriminatory use by hares even though the relative levels of these metabolites remained the same between the juvenile and mature form internodes. These conclusions are strongly supported with feeding bioassays using pure pinosylvin, pinosylvin methyl ether, and other less active secondary metabolites found in alder.

Key Words—Pinosylvin, pinosylvin methyl ether, *Alnus crispa*, snowshoe hare, herbivore, plant defense, feeding deterrence, alder.

INTRODUCTION

Crowns of adult Alaskan green alder (*A. crispa*) are readily available to snowshoe hares in winter because snow bends them to the ground in late fall. Even though snowshoe hares frequently reside within the subnivean space created by snowbent adult *A. crispa*, twigs and bark of *A. crispa* are relatively lightly used as winter food by free-ranging hares as compared to highly palatable early successional woody plants such as *Salix alaxensis* (Wolf and Zasada, 1979; Bryant and Kuropat, 1980). When winter-dormant twigs of adult *A. crispa* are used, hares reject essentially all buds and catkins and eat internodes pri-

0098-0331/86/1200-2117$05.00/0

marily less than 4 mm diameter (Bryant et al., 1983a). Very little use of juvenile form *A. crispa* has been observed. These observations are interesting in that green alder is an abundant shrub which contains relatively high levels of protein (Chapin and Kedrowski, 1983), a nutrient traditionally associated with high palatability of browse to snowshoe hares (e.g., Sinclair et al., 1982).

Several years ago we reported that the low palatabilities of *A. crispa* buds and catkins to the snowshoe hare are the result of the concentrations of pinosylvin methyl ether found in these plant parts (Bryant et al., 1983a). However, it was also clear that the low palatability of *A. crispa* internodes could not be attributed to the effects of this substance since pinosylvin methyl ether was present in internodes only in very low concentrations relative to those found deterrent in bioassays. Consequently we initiated a more detailed study of the chemistry of *A. crispa*.

This study had three objectives. The first objective was to gain a more complete understanding of the chemical basis of snowshoe hare use of *A. crispa* parts and growth stages. Our strategy for realizing this goal was: (1) determine what phytochemicals influence hare use of *A. crispa*, (2) quantify the levels of these substances in winter-dormant *A. crispa* growth stages and parts, and (3) correlate concentrations of biologically active substances with snowshoe hare use of winter-dormant *A. crispa*. The second objective was to determine if subtle differences in the structures of active components could affect food choice by snowshoe hares. The ramifications of realizing this objective would be the need for future work to place more emphasis on specific compounds and less on "total phenolics," "percent resins," "vanillin reactives," etc. Finally, we wished to determine the cause of the overall unpalatability of *A. crispa* as compared to *S. alaxensis*, a highly preferred species that frequently precedes *A. crispa* during plant succession in Alaska.

METHODS AND MATERIALS

Sample Collection and Storage. Winter-dormant, small diameter (up to 4 mm) twigs of both physiologically adult and juvenile (Kozlowski, 1971; Kramer and Kozlowski, 1979) *A. crispa* plants were collected at five locations near Fairbanks, Alaska, over three consecutive winters (1982–1984). Collection sites were old fields where *A. crispa* and Alaska feltleaf willow (*S. alaxensis*) were dominant species in primary succession. Each collection of adult material or juvenile material from each of the five locations contained five individual twigs sampled at random from each of five randomly selected adult or juvenile plants. When juvenile and adult *A. crispa* were directly compared, the juvenile and adult plants sampled were nearest neighbors (less than 3 m separation). This sampling procedure minimized chemical variation caused by site differences. All collections were stored in tightly sealed plastic bags at $-40°C$ prior to use in feeding trials or chemical analysis.

Isolation of Secondary Metabolites. Because chemical analyses of resins from different alder parts (buds, catkins, and internodes) demonstrated them to be qualitatively similar and because catkins were the most convenient source of resin, secondary metabolites were isolated from catkin extracts. Alder catkins (200 g; fresh wt) were soaked in 2.0 liters of acetone overnight. The acetone was decanted and flash evaporated to yield a viscous oil which was dissolved in 300 ml of ether and washed with two 100-ml portions of a saturated sodium chloride solution. After drying the ether ($MgSO_4$) and subsequent removal of solvent, 12.0 g (6.0% of catkin mass) of oil remained.

A chromatographic column was prepared by the addition of 1.2 kg of silica gel (60–200 mesh) in a methylene chloride slurry to a column (7.6 × 70 cm). After loading the column with the above extract, the sample was eluted with methylene chloride. The progress of the separation was monitored by thin-layer chromatography (silica gel; methylene chloride). Four major components (pinosylvin, pinosylvin monomethyl ether, pinostrobin, and 2-phenethyl cinnamate; Figure 1) were identified by their melting points as well as proton nuclear magnetic resonance, infrared, and mass spectra.

The first 2.8 liters of eluant yielded 1.06 g (8.8% of extract) of unidentified fats (R_f = 0.72). Bioassays of this fraction demonstrated negligible deterrence and hence additional investigations of this fraction were abandoned.

2-Phenethyl cinnamate (0.76 g, 6.3% of extract; R_f = 0.48) was obtained in relatively pure form (as shown by [^{1}H]NMR) as an oil in the 2.8- to 3.5-liter fraction. Because additional purification was difficult, pure material (mp = 57–58°C; lit. 56–57°C, Asakawa, 1970) was obtained by standard synthetic methods from cinnamic acid and benzyl alcohol.

Pinostrobin (2.81 g, 23.4% of extract; R_f = 0.33) was isolated as yellowish crystals in the 3.5- to 7.8-liter fraction. Pure pinostrobin (mp = 96–97°C; lit. 99–100°C, Asakawa, 1970) was readily obtained by flash chromatography (Still et al., 1978) (silica gel; methylene chloride) followed by recrystallization from petroleum ether (30–60°C).

Pinosylvin monomethyl ether (2.79 g, 23.3% of extract; R_f = 0.17), contaminated with pinostrobin (TLC), was isolated as brownish crystals in the 7.8- to 12.2-liter fraction. Pure colorless crystals (mp = 120–121°C; lit. 119–120°C, Asakawa, 1971) were readily obtained by recrystallization from petroleum ether–methylene chloride (1 : 1) followed by sublimation (140°C; 0.05 mm Hg).

After all of the pinosylvin monomethyl ether had eluted, the solvent composition was gradually changed to 20% ether (ca. 2%/liter). Pinosylvin (2.49 g, 20.8% of extract; R_f = 0.03) was obtained after an additional 12 liters of solvent was eluted. It is important that the solvent composition is changed gradually, otherwise the pinosylvin is obtained as a tar that is very difficult to recrystallize. Given patience in the elution, however, slightly discolored crystals were obtained that easily provided pure pinosylvin (mp = 156–157°C; lit. 156–158°C, Asakawa, 1971) by recrystallization from petroleum ether–methylene chloride (1 : 1).

Quantification of Secondary Metabolites. Plant parts (1–4 g) to be analyzed for secondary plant metabolite concentrations were extracted overnight in ether (10 ml/g plant). After filtration and drying ($MgSO_4$), the ether was removed and the residue weighed. Dry wt/fresh wt ratios were used to calculate the dry mass concentrations. The ratios used were 0.50 for internodes and 0.65 for buds and catkins.

High-pressure liquid chromatography (HPLC) was the method best suited for most of the quantifications except that of pinostrobin. Because pinostrobin was determined to be essentially inactive as an herbivore deterrent, a routine quantification of it was not required. When quantification of pinostrobin was required, gas–liquid chromatography (GLC) was used. The advantage of HPLC was the ability to analyze for pinosylvin, a strongly deterrent substance which could not be directly analyzed by GLC. Both methods of analysis are described below.

The plant residue described above was dissolved in a carefully measured volume of acetonitrile (ca. 20 ml) containing an accurately weighed amount of resorcinol (ca. 2 mg/g plant part). Twenty microliters of the solution was injected onto a C-18 reverse phase analytical column (25 cm × 4 mm) and was eluted with 70% aqueous acetonitrile (flow rate = 1.0 ml/min). Individual components were detected with an ultraviolet detector (Hitachi, model 100-10) set at 285 nm. As mentioned previously, pinostrobin was not detected using those conditions. The retention times for resorcinol, pinosylvin, pinosylvin monomethyl ether, and 2-phenethyl cinnamate were 3.0, 3.7, 5.6, and 12 min, respectively. Peak areas were obtained by interfacing an automatic digital integrator to the detector. In a separate experiment using a standard mixture, the relative sensitivities of pinosylvin, pinosylvin monomethyl ether, and 2-phenethyl cinnamate were 6.19, 6.28, and 7.62 g/g resorcinol, respectively. Reproducibility was within 2%.

In order to determine pinostrobin levels, GLC was utilized. The residue described earlier was dissolved in ether and spiked with a measured quantity of pinosylvin dimethyl ether as an internal standard. Quantitative analysis was carried out on a 1.8-m × 2-mm OV-101 (2%) column using a temperature program (T_1 = 100°C 4 min, 8°C/min; T_2 = 200°C) and a flame ionization detector. Flow rate was 55 ml/min. The retention times of pinostrobin and pinosylvin dimethyl ether were 5.8 and 9.1 min, respectively.

Test for Alkaloids. Three parts of *A. crispa* (buds, juvenile internodes, and mature internodes) were individually tested for alkaloids using Dragendorff's reagent (Gordon and Ford, 1972). Plant parts (ca. 20 g) were extracted for about 30 min with boiling ethanol (10 ml), and the resulting solution was filtered. Five drops of the filtrate were placed on a clean filter paper followed by one drop of Dragendorff's reagent. An orange spot is a positive test for the presence of organic bases (i.e., alkaloids).

Free-Choice Feeding Trials. Captive hares were offered a choice of physiologically mature *S. alaxensis*, mature *A. crispa*, and juvenile *A. crispa* browse in ca. 75-, 50-, and 50-g bundles, respectively, in addition to chow (Quality Texture; Fisher Mills, Seattle, Washington) ad libitum. At the end of the 24-hr feeding period, the weight of each browse eaten was determined. The experiments were performed in April of 1982 and 1984 using 10 and 5 hares respectively.

Bioassay of A. crispa *Extracts.* Four feeding trials were performed to elucidate what substances deter snowshoe hare use of green alder. Captive hares maintained upon a combination of chow (Quality Texture), oatmeal, adult *S. alaxensis* browse, and adult and juvenile *A. crispa* browse were used in bioassays. In all experiments solvent-treated oatmeal was used as a control. Treated oatmeal and controls were offered in 5- to 20-g quantities in a random array of muffin pans. During all experiments except experiment 4, hares had access to chow and adult and juvenile *A. crispa* browse ad libitum. At the end of each feeding trial, all remaining oatmeal was removed and weighed. The number of hares used in each feeding trial ranged from 5 to 10. Hare preferences are expressed as a preference index (PI = % treated oatmeal eaten/% control oatmeal eaten). Probabilities that the PI values differ significantly from unity are reported as P values and are calculated according to a paired t test.

In the first experiment crude diethyl ether extracts were bioassayed for feeding deterrence at both 2% and 4% dry mass concentrations which were the approximate levels found in alder internodes (Table 1). Diethyl ether was allowed to evaporate from the oatmeal in a fume hood over 24 hr, and diethyl ether-treated oatmeal served as the control for resin-treated oatmeal. Additionally, β-sitosterol-treated oatmeal (4% dry mass) was offered to hares during these experiments. This experiment allowed the deterrence of crude *A. crispa* fractions to be compared with that of a secondary metabolite that is not deterrent to snowshoe hare feeding (Bryant et al., 1983a) and thus helped ensure the reliability of our bioassay.

In experiment 2, pinostrobin, pinosylvin, pinosylvin monomethyl ether, and pinosylvin dimethyl ether (synthesized from 3,5-dimethoxy benzaldehyde and benzyldiphenylphosphine oxide) were simultaneously bioassayed at the same concentration, 1.5% dry weight oatmeal. In addition to these substances, 2-phenethyl cinnamate was offered at 1.0 and 2.0% dry weight concentrations. All five compounds were applied as a diethyl ether solution. Diethyl ether-treated oatmeal served as the control for this experiment.

In experiment 3, secondary metabolites that were strongly deterrent in experiment 2 (pinosylvin and pinosylvin monomethyl ether) were offered to hares at decreased concentrations (0.5% and 0.1% dry mass). Conversely, secondary metabolites that proved moderately deterrent (pinostrobin and pinosylvin dimethyl ether) or nondeterrent (2-phenethyl cinnamate) were offered at a higher

concentration (4% dry mass). In this experiment, each metabolite was offered singly with its respective control (diethyl ether treated oatmeal).

In experiment 4, hares were offered only pinosylvin-treated and pinosylvin monomethyl ether-treated oatmeal (10 g each) for 24 hr. Both substances were applied to oatmeal at a concentration of 1.5% dry mass. The hares had no access to alternative foods, e.g., chow, oatmeal, or browse, in this experiment.

RESULTS

Free-Choice Feeding Trials with Fresh Browse. Figure 1 presents data for two winters of snowshoe hare use of fresh browse. When offered fresh mature *S. alaxensis*, mature *A. crispa* and juvenile *A. crispa* twigs during the winter of 1981–1982 captive snowshoe hares preferred twigs of adult *A. crispa* over twigs of juvenile *A. crispa* ($P < 0.001$; t test). During the winter of 1983–1984, however, hares no longer differentiated between juvenile and adult *A. crispa* ($P > 0.25$; t test). Throughout both years, a large preference for *S. alaxensis* over alder was evident ($P < 0.001$; t test).

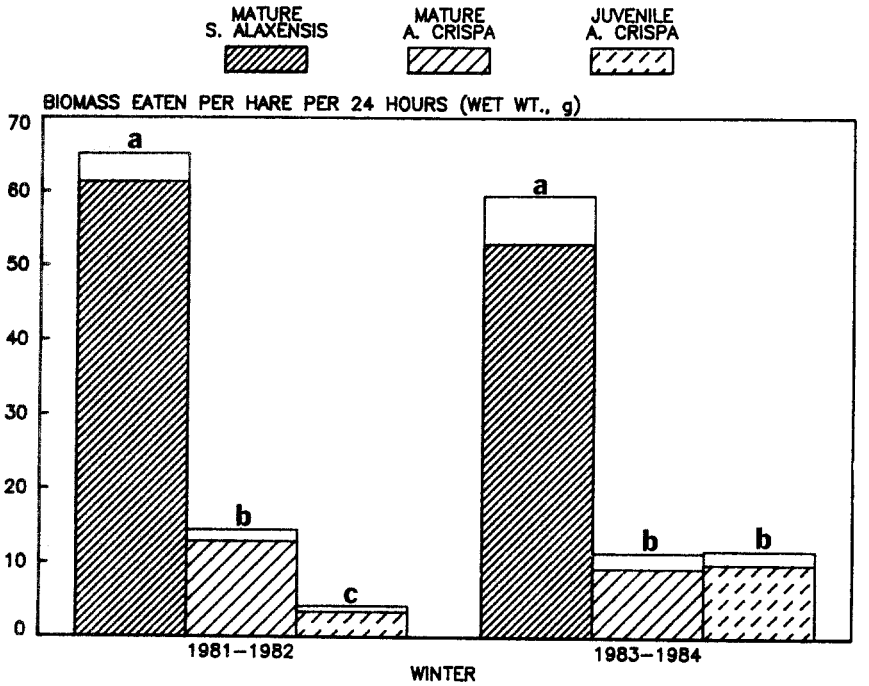

FIG. 1. Use of mature *S. alaxensis* and *A. crispa* growth stages by captive snowshoe hares. Bars with same superscripts do not differ at $P \leq 0.05$. Unshaded region represents mean plus one standard error.

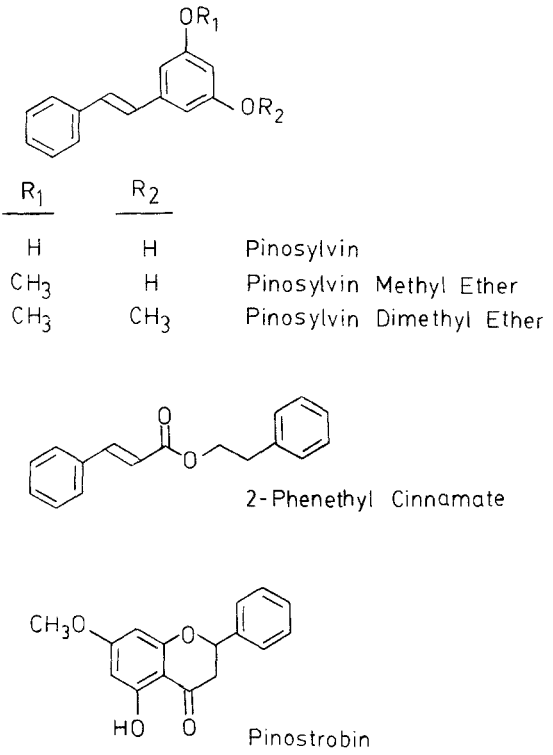

FIG. 2. Structures of the major secondary metabolites of green alder and of pinosylvin dimethyl ether.

Bioassay of A. crispa *Extracts.* Fractionation of the ether extract by column chromatography gave four principle components: pinosylvin, pinosylvin methyl ether, 2-phenethyl cinnamate, and pinostrobin (Figure 2). When offered simultaneously at 1.5% dry mass concentration (experiment 2), pinosylvin and pinosylvin monomethyl ether were very deterrent ($P < 0.0001$); pinostrobin and pinosylvin dimethyl ether were moderately deterrent ($P < 0.001$). 2-Phenethyl cinnamate demonstrated a slight deterrence at 2% concentration ($P < 0.05$). Decreasing the concentrations of pinosylvin and pinosylvin monomethyl ether decreased deterrence. At 0.10% dry mass pinosylvin was still deterrent ($P < 0.001$), but pinosylvin monomethyl ether was not ($P > 0.10$). Increasing the concentrations of pinostrobin, pinosylvin dimethyl ether, or 2-phenethyl cinnamate to 4% did not significantly increase deterrence. These results are summarized in Figure 3.

When hares only had access to pinosylvin and pinosylvin methyl ether-treated oatmeal (1.5% dry wt; experiment 4) they ate only 2.4 $\pm$ 0.6 g/hare/24 hr. Normal consumption over a 24-hr period is 50–100 g/hare.

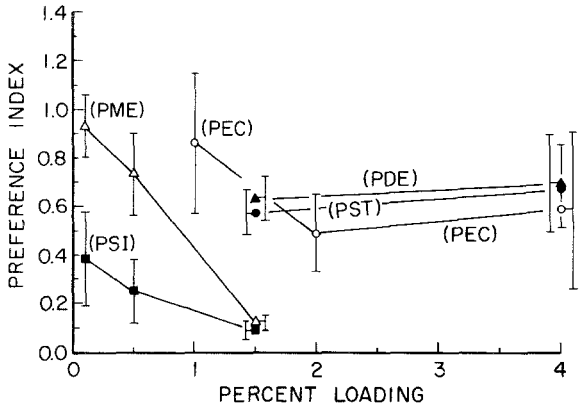

FIG. 3. Effects of alder metabolites on snowshoe hare feeding (experiments 2 and 3). Error bars represent plus and minus one standard error. PI = % treatment eaten ÷ % control eaten.

Chemical Analysis of A. crispa. All plant parts tested had less pinosylvin and pinosylvin methyl ether during the winter of 1983–1984 than in previous winters (Table 1; $P < 0.001$; t test). For convenience, the plant parts are listed in Table 1 in order of increasing palatability to hares (Bryant et al., 1983a). The levels of pinostrobin and 2-phenethyl cinnamate are presented only for the first winter because they are not important as feeding deterrents at levels present in alder (compare the data of Table 1 with those of Figure 3). No detectable (0.0001%) levels of pinosylvin dimethyl ether, a secondary metabolite found in another alder, *A. sieboldiana* (Asakawa, 1971), could be found in any sample nor was any alkaloid detected by Dragendorff's test.

DISCUSSION

From the bioassay data in Figure 3, it is apparent that hares are sensitive to specific compounds. For example, at typical concentrations found in *A. crispa* buds (1.5%), both pinosylvin and pinosylvin monomethyl ether are highly repellent (PI = ca. 0.1) while the corresponding dimethyl ether is only marginally active (PI = 0.63). Even though it can be argued that the latter compound does not occur in *A. crispa* (and hence is not recognized by hares) or has no phenolic functionality, pinostrobin similarly is essentially inactive (PI = 0.57; 1.5%) and is a phenol found in green alder. While the data presented here for *A. crispa* generally support the hypothesis (Bryant and Kuropat, 1980) that resinous plants or plant parts are unpalatable to herbivores (buds and catkins versus internodes), it is also clear that the hares' discrimination between (relatively nonresinous) juvenile and mature stages of internodes is based upon levels of specific com-

pounds rather than total resins. Hence it is important that correlations of "total phenolics" or "percent resins" with palatability be treated with skepticism.

The levels of pinosylvin methyl ether in the buds and catkins are sufficient to account for their rejection by snowshoe hares (Bryant et al., 1983a). The addition of similar levels of pinosylvin provides additional support for our earlier thesis that use of green alder by snowshoe hares is governed in part by its secondary chemistry. It is notable that the slight preference of catkins over buds (Bryant, personal observation) is also reflected by lower levels of these two active chemicals in catkins. Although we have not tested whether hares can detect such variation in concentrations of pinosylvin and its monomethyl ether at these high levels, the circumstantial evidence is compelling.

The internodes of alder, however, contain much lower levels of all the secondary metabolites measured; and, in order to correlate plant chemistry with hare use, levels of both pinosylvin and pinosylvin methyl ether must be considered. For simplicity, other compounds will not be discussed here due to their negligible repellency at concentrations typically found in internodes.

Several major considerations emerge when attempting to predict palatability of internodes based on our bioassay data. First, synergistic relationships have not been tested. The possibility exists that while it is apparent that hares readily detect and avoid pinosylvin and pinosylvin monomethyl ether, certain mixtures of all four major secondary metabolites (and other minor substances) might be more recognizable by hares and more repellent to them. The possibility of a synergism becomes appealing upon realizing that the repellency of resin in Table 2 cannot be totally accounted for by the repellency of its individual components at their respective concentrations. For example, although resin demonstrates similar deterrency at 2% loading (Table 2) as both pinosylvin and pinosylvin methyl ether do at 1.5% loading (Figure 3), the maximum levels of pinosylvin and pinosylvin methyl ether in the internode resins are only 2.3% and 11.8%, respectively (Table 1; winter 1981–1982). Thus the bioassay using 2.0% resin involves as an upper estimate, about 0.04% and 0.24% loading of pinosylvin and pinosylvin methyl ether, respectively. To justify the observed repellency of resin, a small but significant synergistic relationship seems reasonable.

A second problem is that our bioassays are based on treated oatmeal. Because the food value of oatmeal is much higher than alder internodes, hares may respond differently to secondary metabolites present in internodes versus those placed on oatmeal. Indeed, in the case of retarding wood decay, Hart and Shrimpton (1979) have shown that the activities of pinosylvin and its methyl ether are greater in agar solutions than in the heartwood of several evergreens. Presumably the cause of this decline in activity results from a portion of the pinosylvins being chemically bound in the heartwood. Since the pinosylvin and pinosylvin methyl ether levels measured in our study were unbound, a similar decline in activity in alder is unlikely. Still, caution must be exercised when

attempting to predict the absolute palatabilities of alder parts based upon the palatabilities of alder's secondary metabolites placed on oatmeal.

Regardless, we feel that our bioassays suggest that as long as the combined levels of pinosylvin and pinosylvin monomethyl ether in internodes are not below the "threshold of avoidance" by hares, internodes that contain the lower inclusive amounts will be the preferred food choice. That Table 1 confirms the predicted inverse relationship between palatability of internodes and chemical composition is adamantine evidence that hare use of *A. crispa* parts is governed by variable levels of both pinosylvin and its methyl ether. For example, the threefold preference of mature over juvenile growth in the winter of 1981–1982 (Figure 1) correlates with a significant decrease (Table 1) in the amounts of both of these deterrent phytochemicals in the preferred mature browse. It is also apparent from the bioassay data in Figure 3 that the amount of pinosylvin present in the juvenile internodes (0.10%; winter 1981–1982) is above the threshold of detection by hares (PI = 0.38; 0.1%; $P < 0.01$, t test). Thus the "two-level" defense we suggested earlier (Bryant et al., 1983a) merely reflects a chemical defense of internodes based upon the levels of two substances while the unpalatability of buds and catkins compared to internodes can be explained by levels of either of the two substances.

During the winter of 1983–1984, however, hares no longer discriminated between juvenile and mature green alder internodes (Figure 1). While there still remains about a threefold increase in the levels of both stilbenes in the juvenile internodes, we maintain that the overall drop in these levels from those of previous years (Table 1) has been sufficient to pass below the threshold of avoidance by hares. The resultant increase in juvenile green alder palatability during the winter of 1983–1984 suggests that environmental factors may have a subtle but real effect on hare use of woody plants. The specific factors that can have such impacts on *A. crispa* chemistry have not been ascertained, but we believe one possibility is drought, which was experienced during the spring of 1983 in the Fairbanks area.

These results indicate that allocation of secondary metabolites among plant parts by species such as *A. crispa* strongly influences hare use of woody plant parts and growth stages. This conclusion has precedent in several other recent studies of the woody plant–hare interaction in winter (e.g., Barikmo, 1976; Klein, 1977; Bryant, 1981a,b; Pehrson, 1980, 1981, 1983, 1984; Bryant et al., 1983a,b; Sulkinoja, 1983; Reichardt et al., 1984; Tahvanainen et al., 1985). At this point the accumulated evidence on the effects of secondary plant metabolites on palatability is sufficient to suggest that optimal foraging hypotheses must include allocation of plant resources to toxic and/or digestion-inhibiting chemical defense in order to explain the foraging behavior of boreal forest vertebrate herbivores such as snowshoe hares.

Finally we point out an unexpected result of this study that is germane to

theories of plant–herbivore interactions that attempt to provide a chemical rationale for selective use of plant species by generalist herbivores such as snowshoe hares (e.g., Feeny, 1976; Rhoades and Cates, 1976; Bryant and Kuropat, 1980; Bryant et al., 1983a, 1984; Coley, 1983). If snowshoe hares were not deterred by the combined levels of pinosylvin and pinosylvin methyl ether in the juvenile internodes of the last year of study (0.074% ± 0.014%), then it is extremely unlikely that they were repelled by the combined levels of these compounds present in the mature internodes during the winter of 1981–1982 (0.076% ± 0.026). This prediction is confirmed by the data in Figure 1 that demonstrate hares' use of mature alder internodes did not change significantly between the winters of 1981–1982 and 1983–1984 even though threefold and sixfold decreases in the levels of pinosylvin and pinosylvin methyl ether, respectively, were recorded (Table 1). Consequently snowshoe hare preference for *A. crispa* parts and growth stages can be adequately explained by varying concentrations of two specific secondary metabolites, but these same compounds cannot explain the low palatability of mature *A. crispa* relative to *S. alaxensis* (Figure 1).

This result indicates that the "gestalt" that hares use to distinguish between parts and growth stages within a woody plant species differs from that which enables hares to distinguish between different plant species. Although we have not determined why *A. crispa* is less palatable than *S. alaxensis* (Bryant et al., 1985), Bryant et al. (1983a,b) indicate it is not caused by a lack of nutritional chemicals, e.g., protein or soluble carbohydrate, in *A. crispa* as compared to *S. alaxensis*. Disregarding the possibility of a dominant synergistic interaction, low-molecular-weight, ether-soluble secondary metabolites are unlikely explanations of the low palatability of *A. crispa* as compared to *S. alaxensis*. Only fractions of *A. crispa* containing pinosylvin or pinosylvin methyl ether demonstrated any large activity, and a negative Dragendorff's test precludes the possibility of significant amounts of alkaloids. Similarly, there is no large difference in the levels of structural carbohydrate or lignin in *A. crispa* and *S. alaxensis* winter dormant twigs (Bryant et al., 1983a,b; 1985). We also cannot detect any obvious physical difference between winter dormant twigs of these species.

In short, there is now substantial evidence that levels of specific secondary metabolites strongly influence (if not determine) hares' selective use of woody plant parts and growth stages within a browse species (e.g., Bryant, 1981a,b; Bryant et al., 1983a,b, 1984, 1985; Tahvanainen et al., 1985). The basis for hare selective use of woody plant species as winter food is, however, still an open question.

(Received October 18, 1985; accepted December 31, 1985)

Abstract—A method has been developed to predict the release ratio of the components of blends of alcohols, acetates, and/or aldehydes from rubber septa. The calculations of predicted release ratios are based on the relative vapor pressures of the components. The relative vapor pressures of the compounds were calculated from their retention indices on a liquid crystal capillary gas chromatographic column. The correlation between the theoretically predicted and experimentally determined ratios was very good. Thus, formulations can be prepared that will release a desired ratio of the components of a multicomponent pheromone blend.

Key Words—Pheromone blends, formulation on rubber septa, relative vapor pressure, liquid crystals.

INTRODUCTION

The sex pheromones of many lepidopteran insect species have been identified, and the practical value of several of these has been demonstrated in programs designed to monitor or suppress pest insect populations. Additionally, extensive studies have been conducted to analyze and evaluate insect behavior in the laboratory and in the field. Several materials have been adapted or developed to release pheromones at controlled rates to increase the effectiveness of these chemicals in monitoring or control programs. Chemical analyses of pheromone gland constituents and volatiles collected from calling females, in addition to

behavioral studies and field trapping experiments, have established that most lepidopteran pheromones consist of blends of two or more compounds. Usually a precise ratio of the components of a blend is required to elicit optimum response. However, thus far there has been very little research to develop an accurate method to predict and control the precise ratio and rate at which a pheromone blend is released from a formulation.

There have been several investigations in which the ratio of components in a pheromone blend loaded onto a controlled release substrate was empirically adjusted to give optimum trap captures. Additionally, the release rate of individual pheromonal compounds from different substrates has been measured. Butler and McDonough (1979, 1981) and McDonough and Butler (1983) determined the half-lives of several n-alkyl and alkenyl acetates and alcohols loaded individually on rubber septa by quantitating the amount of a compound remaining on a septum after various periods of time. Similarly, Leonhardt and Moreno (1982) measured release rates of several pheromones and pheromone blends from laminated Hercon® dispensers by gas–liquid chromatographic (GLC) analysis of quantities of the materials remaining in the dispensers after they were aged varying amounts of time in a greenhouse and in the field. Baker et al. (1980) collected and quantified Oriental fruit moth pheromone deposited on the wall of a glass flask and determined that (*Z*)-8-dodecen-1-ol (*Z*8–12 : OH) was emitted three times faster than (*Z*)-8-dodecenyl acetate (*Z*8–12 : Ac) from rubber septa.

Using an improved version of Regnault's (1845) gas saturation technique, Hiroka and Suwanai (1978) measured the vapor pressures of 12 alkyl compounds including alkanes, acetates, and an alcohol. Their investigation of a binary mixture of lauryl and myristyl acetate demonstrated that a binary sex pheromone system behaves approximately according to Raoult's Law, i.e., the mole fraction of a compound in the vapor above a binary liquid mixture correlated closely with the mole fraction of the compound in the liquid mixture and the relative vapor pressures of the two compounds. Thus, two compounds with equal vapor pressure would occur in the same ratio in the vapor as in the liquid. Other references pertaining to pheromone release rates from various substrates include the work of Weatherston et al. (1982) and several chapters in books edited by Mitchell (1981) and Kydonieus and Beroza (1982).

The information developed so far allows the determination of the average release rate of a pheromone over a period of days and, in some cases, may allow the approximate average ratio to be determined and controlled. Unfortunately, there is as yet no information that will allow one to predict and control with a reasonable degree of accuracy the precise ratio and rate at which the components of a pheromone blend will be released during a period of 1 hr or less under a given set of conditions. Our interest in analyzing the behavioral responses of males of several species of *Heliothis*, *Spodoptera*, and other Lep-

idoptera to their respective pheromone blends requires a method to predict and control release rates and ratios for blends of compounds that might vary considerably in chain length and functionality.

In a previous paper, we demonstrated that the retention time of a compound on a liquid crystal capillary column could be correlated with the compound's reported vapor pressure and/or reported half-life (Heath and Tumlinson, 1986). The correlation of the retention time expressed in equivalent chain length units (ECLU) of seven acetates and the natural logarithm of their reported vapor pressures (Olsson et al., 1983), resulted in a coefficient of determination (r^2) of 0.999. Attempts to correlate the retention times of the seven acetates on capillary columns coated with isotropic phases (apolar OV-101® and polar CW-20) with their vapor pressures resulted in drastically reduced coefficients of determination of 0.724 and 0.446, respectively. Correlation of the retention time (in ECLU) on the liquid crystal column with the reported half-lives (Butler and McDonough, 1979, 1981; McDonough and Butler, 1983) of five saturated acetates (10–14 carbons), four monounsaturated acetates, and four monounsaturated alcohols (12–16 carbons), resulted in a high degree of correlation (r^2 of 0.995). Based on these findings, we proceeded on the hypothesis that relative vapor pressure and evaporation rates of many compounds could be approximated based on the compounds' retention times on a liquid crystal column. This information could then be used to predict the release ratios of components in pheromone blends.

We report in this paper the results of our investigation into the prediction of the release ratios of various combinations of acetates, aldehydes, and alcohols from rubber septa based on retention indices of the compounds on a liquid crystal column.

METHODS AND MATERIALS

Chemicals used for this investigation (Table 1) were obtained from Chemical Samples Co. (Columbus, Ohio). In several instances synthetic modification of the functional group was required to give the desired compound. All compounds were purified by $AgNO_3$ liquid chromatography or recrystallized from pentane, distilled in a short-path distillation apparatus, and analyzed on three different capillary columns to ensure a high degree of purity. Capillary columns were drawn and coated in our laboratory by previously described techniques (Heath et al., 1980, 1981). The three columns used were: 46 m × 0.25 mm ID cholesteryl-*p*-chlorocinnamate (a cholesteric liquid crystal phase); 46 m × 0.25 mm ID OV-101; and 42 m × 0.25 mm ID SP-2340®. Columns were operated in either the split or splitless mode with helium as the carrier gas at a linear flow of 18 cm/sec. The columns were installed in a Varian® 3700 gas

chromatograph equipped with flame ionization detectors with a lower limit of detection of ca. 0.2 ng for hexadecane.

Rubber septa (Cat. No. 8753-D22, A.H. Thomas Co., Philadelphia, Pennsylvania) were exhaustively extracted with CH_2Cl_2 for 24 hr and air dried a minimum of three days before use. A septum was loaded by depositing the desired blend, dissolved in 100 μl of hexane, into the cup of the large end. The quantity of pheromone loaded varied somewhat, depending on the number of blend components but was maintained between the limits of 400 μg and 600 μg per septum.

The collection apparatus is an adaptation of a Grob and Zücher (1976) design and includes modifications by P.S. Beevor and coworkers (Tropical Products Institute, London, England) to collect pheromones from insects. We have adapted and further modified this method (Tumlinson et al., 1982). Briefly, it consists of a small charcoal trap prepared by sealing 3–5 mg of charcoal (Bender and Hobein AG, Zurich, Switzerland) between two 325-mesh stainless-steel frits in a 6-mm OD, 3.7-mm ID Pyrex® tube. Air is delivered through the silanized glass aeration apparatus at a flow rate of 0.5–1 liter/min. The septa are placed ca. 2 cm upwind from the charcoal trap and aerated for 1–2 hr. When

aeration is complete, the filter is rinsed with six aliquots (15–20 μl each) of distilled dichloromethane, the aliquots are combined, an internal standard is added, and the solution is concentrated to about 5–10 μl by gently warming. Isooctane or another solvent of choice is added for analysis by capillary GLC with splitless injection.

In a preliminary experiment, a backup charcoal trap was connected to the outlet of the primary trap. Extraction and analysis of the secondary trap resulted in no detectable amount of material. Additionally, recoverability of compounds from the charcoal trap was determined by depositing a known amount of the compound (usually as a blend with three other compounds) onto the charcoal directly in 20- to 50-ng amounts. The compounds were extracted after solvent evaporation and analyzed as previously described. Before each experiment, the aeration chamber was cleaned by rinsing with hexane, acetone, water, acetone, and hexane. The chambers were dried overnight at ca. 100°C. The charcoal traps were cleaned by rinsing with ca. 4 ml CH_2Cl_2 and CS_2. The traps were then dried using a flow of nitrogen.

Determination of relative vapor pressure and half-lives of compounds used in this investigation are based on the previously determined equations (Heath and Tumlinson, 1986). The equation for the relative vapor pressure of a compound is

$$(\ln)\ \text{vapor pressure} = (\text{ECLU} - 1123)/-99.9 \tag{1}$$

and the equation for a compound's half-life is

$$(\ln)\ \text{half-life} = -8.48 + 0.0101 \cdot \text{ECLU} \tag{2}$$

where ECLU is equal to the retention time of a compound on a cholesteryl-*p*-chlorocinnamate capillary column relative to saturated acetates (Swoboda, 1962).

To derive a formula for determining the release ratio from rubber septa of components in pheromone blends, several assumptions were made. We assumed that the relative vapor pressure of the solute in rubber septa could be approximated by using ECLU values obtained by chromatography on a liquid crystal stationary phase (isotopic phases showed no correlation) (Heath and Tumlinson, 1986). Thus in this assumption, the proportionality constant as required by Henry's Law is empirically determined, and the rate of evaporation of a compound from rubber septa is also correlated with the retention time of the compound in the liquid crystal phase. The ratio of a component in the vapor from a multicomponent blend is the percent of the compound in the liquid times its evaporation rate, divided by the sum of each of the components (in %) in the liquid multiplied by their respective evaporation rates. It is well documented that the evaporation rates of pheromones from rubber septa can be determined by measuring their half-lives and is a first-order equation (Butler and McDonough, 1979, 1981; McDonough and Butler, 1983). If we assume that the

evaporation of one component will not affect the evaporation rate of another component, our formula for release ratio is the same as that using relative vapor pressure. However, in this case evaporation rate is in days, and we must convert all half-lives to their reciprocals for calculation of release ratios using equation (3).

The calculation of the percent release of a compound when formulated in a blend on rubber septa is based on use of the calculated relative vapor pressure of the compound or calculated half-life of the compound. The equation for calculating percent release of a compound is

$$R_1 = \frac{L_1 P_1^r}{L_1 P_1^r + L_2 P_2^r + L_n P_n^r} \tag{3}$$

where L is the percent load of the compound and P^r is the reciprocal of the relative half-life (evaporation rate) or the relative vapor pressure of the compound.

RESULTS AND DISCUSSION

The equivalent chain length, calculated relative vapor pressures, and calculated relative half-lives for all compounds included in this study are presented in Table 1. Various blends were prepared and the theoretical release ratio of each component was determined using equation 3. The volatiles released by the blend when formulated on rubber septa were trapped and analyzed.

Prior to analysis of charcoal-trapped volatile blends, the aeration apparatus and charcoal traps were evaluated to determine the amount of material lost due to adsorption on glass surfaces or irreversible adsorption on the trap. The percent of each compound recovered when blends containing ca. 50 ng of each component were deposited directly on the trap and then reextracted without aeration is given in Table 2. The recoveries ranged from 74 to 94%, and data obtained in subsequent experiments were corrected to account for the losses on the trap. Analysis of the solvent rinses of the internal glass surfaces of the apparatus after experiments indicated that no measurable material was adsorbed on the silanized glass surfaces. This is probably because the septa were placed within 2 cm of the trap, and thus there was very little glass surface downwind of the septum for the volatiles to contact. Analysis of backup traps connected in series to the primary traps indicated no significant breakthrough of compounds from the first trap occurred.

The various blends of compounds that were formulated and aerated are listed in Table 3. Different ratios of the same blend of compounds were analyzed to test the hypothesis that this method would be valid over a wide range of ratios. Volatiles from the septa were analyzed over a seven-day interval. Analyses were obtained on 1- to 2-, 3- to 4-, and 5- to 7-day-old septa (after

[a] Example, (Z)-9-tetradecenal = Z9-14:Al, (Z)-9-tetradecen-1-ol = Z9-14:OH, (Z)-9-tetradecenyl acetate = Z9-14:Ac), (Z)-11-hexadecenal = Z11-16:Al, and (Z)-11-hexadecenyl acetate = Z11-16:Ac.

the three-day aging process). The analysis of each blend at a given time interval was replicated at least three times. Because there was no significant change in the measured ratio during the seven-day interval, the data from all analyses were averaged and compared to the calculated theoretical release ratio. For blends that contained compounds for which the half-lives had been reported by Butler and McDonough (1979, 1981) and McDonough and Butler (1983), we calculated the predicted release ratio based on reported half-lives and compared the data with the predicted release ratios based on relative vapor pressure and with the measured release ratios (Table 3).

An attempt was made to analyze a representative number of different combinations of molecular weights and/or functional groups to correlate as closely as possible with actual pheromone blends found in a variety of insects.

The results obtained when C_{12}–C_{14} saturated acetates were formulated as three-component blends in approximately equal amounts showed that the release ratio of the acetates could be predicted with less than 4% error (Table 3). When the 16-carbon acetate was formulated with other saturated acetates, a large difference was found between percent recovered and percent theoretical. McDonough and Butler (1979) found similar discrepancies with the half-life of the 16-carbon acetate when compared to shorter chain length acetates and suggested that the deviation was due to the inability of the larger acetate molecules to penetrate the rubber matrix. Another possible explanation is that the 16-

[a] Example: (Z)-9-tetradecenal = Z9-14:Al, (Z)-9-tetradecen-1-ol = Z9-14:OH, (Z)-9-tetradecenyl acetate = Z9-14:Ac, (Z)-11-hexedecenal = Z11-16:Al, and (Z)-11-hexadecenyl acetate = Z11-16:Ac.

[b] Calculated from reported half-lives (Butler and McDonough, 1979, 1981; McDonough and Butler, 1983).

[c] Mean is calculated from the average obtained from the 1- to 2-, 3- to 4-, and 5- to 6-day-old samples. Each mean represents a minimum of nine analysis.

[d] Analysis obtained on samples left in the field in parentheses.

carbon acetate is a solid at room temperature, and our inability to predict the release rate may be due to the establishment of a solid–liquid phase equilibrium.

The relative vapor pressure data obtained for the aldehydes using the retention time data obtained on the liquid crystal column enables us to predict relative release rates for the aldehyde blends with less than 6% error for any given component in the three blends investigated (Table 3). Greater variability occurred between calculated and measured released ratios when blends were composed of acetates and alcohols or acetates and aldehydes (Table 3). There are at least two possible explanations for this. The aldehydes and the alcohols are adsorbed more strongly by the charcoal and glass surfaces, and thus small but immeasurable differences could contribute to greater error when analyzing blends composed of compounds with two or more types of functional groups. Also, solutions of compounds with more than one type of functional group may differ more in physical chemical properties than do compounds with one type of functionality. Further investigation of this phenomenon is required to determine the actual reason for these discrepancies. Nonetheless, as a first approximation, the experimental results are very close to the calculated values, and this

is the most accurate method developed thus far for predicting release ratios of components in pheromone blends.

A greater disparity between the predicted release ratio and measured release ratio was obtained when reported half-lives (Butler and McDonough, 1979, 1981; McDonough and Butler, 1983) were used in the calculations (Table 3). It should be noted that the error is significantly reduced (equal to that observed using relative vapor pressure values) if the values for the half-lives are determined using equation 2.

As an example of the practical application of this study, we formulated blends containing two aldehydes and two acetates (Z)-9-tetradecenal (Z9–14:Al), (Z)-9-tetradecenyl acetate (Z9–14:Ac), (Z)-11-hexedecenal (Z11–16:Al), and (Z)-11-hexadecenyl acetate (Z11–16:Ac) in two different ratios. All septa were analyzed in the laboratory on the first or second day after loading. Then one batch was placed in traps in the field for four days while an identical batch was aged in the laboratory during the same period and analyzed again at the end of three to four days. At five to seven days after loading, release ratios of the blends were again measured from both lab- and field-aged septa. The result of this study (Table 3) indicated that the placement of septa in the field for a five-day period did not increase significantly the variation of the release ratio of the compounds when compared to the lab septa.

CONCLUSIONS

The purpose of this investigation was to explore the hypothesis that relative release rates (half-lives) and relative vapor pressure of individual compounds could be used to calculate the approximate release ratios of the compounds formulated as a blend in rubber septa. Our results indicate that, at least to a first approximation, our hypotheses enabled us to determine release ratios. Certain refinements in measurement techniques or more accurate correction factors for recoveries of alcohols and aldehydes may yield more accurate data. Additionally, our investigation was based on an empirical approach and does not provide fundamental reasons for the existence of the correlation of the retention time of a compound on a liquid crystal column and its predicted release ratio when formulated in a blend on rubber septa. Thus there exists a need to further define the mechanism of evaporation of pheromones from rubber septa. However, the use of the method described should greatly facilitate the determination of the percent load required to provide the desired release ratio of components in pheromone blends.
